Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

PREFACE

The first edition of this textbook was published well over 30 years ago, when Peter Callen was a young faculty member, we were in medical school, and obstetric sonography was an emerging subspecialty. Whereas the book has grown and evolved through the subsequent editions, it has remained one of the most highly regarded texts in obstetric and gynecologic ultrasound. The three of us grew up reading and learning from Callen's *Ultrasonography in Obstetrics and Gynecology*. Therefore, when we were invited to edit the sixth edition, it was an opportunity that we were eager to embrace, daunting though it was to follow in Peter's footsteps.

Over the years, many aspects of obstetric and gynecologic ultrasound have changed. Ultrasound technology and equipment continue to improve. The anatomic detail that can be visualized and the physiologic parameters that can be assessed have expanded the utility, as well as the complexity, of ultrasound imaging. As in other areas of medicine, care of the obstetric and gynecologic patient in today's practice has advanced to involve much more collaboration across disciplines. This sixth edition reflects this change and was truly a multidisciplinary effort reflecting contributions from experts in obstetrics and gynecology, maternal-fetal medicine, and diagnostic radiology and biomedical imaging. Mary recruited authors from the fields of obstetrics and maternal-fetal medicine and edited chapters on obstetric and fetal sonography. Leslie served as the gynecology editor, managing the recruitment of authors and editing of chapters focused on gynecologic imaging. Vickie helped ensure that the ultrasound images, diagrams, and medical illustrations were of the highest quality. The three of us have been fortunate to have been trained by, and subsequently worked alongside, some renowned leaders in the field of obstetric and gynecologic imaging. Many of these colleagues and friends, names well known to those in this arena, have contributed to this textbook. The updated information highlights the clinical context and impact of imaging findings. We believe this approach has added to the richness, breadth, and depth of the content of this new edition.

The prior editions of this textbook were edited by Peter with meticulous care and attention. He was always mindful of including authors who are respected experts in their fields and whose writing is authoritative and clear. He ensured that each edition was a substantial update from the previous version and that each chapter was well and liberally illustrated with high-quality sonographic images, drawings, and diagrams to help clarify concepts and illustrate ideas. We aimed to follow his lead and have greatly benefited from his experience, advice, and help throughout this process.

In addition to Peter, who taught us so much and had faith that we could successfully carry on this tradition, there are many others to whom thanks is due. First and foremost, we want to acknowledge and thank all the authors who contributed such outstanding chapters, representing many hours of dedication and effort. The staff at Elsevier, including Taylor Ball in particular, was very helpful and patient as we moved through the production process. Many sonographers and sonologist colleagues helped us collect high-quality images. Finally and importantly, we must thank our families who tolerated so many late nights, early mornings, and weekends spent writing, editing, and tending to this text.

Obstetric Ultrasound Examination

Peter W. Callen, Mary E. Norton

SUMMARY OF KEY POINTS

- Recent years have seen dramatic advances in ultrasound technology, including improved spatial and contrast resolution, routine use of three-dimensional (3D) and four-dimensional (4D) imaging, volumetric scanning, expanded indications for color and spectral Doppler, new and improved ultrasound scanning probes, and improved digital review workstations.
- With improved imaging comes the complicating corollary as to what minor findings should be reported to the patient and which merely lead to unnecessary anxiety.
- Although there is high-quality evidence that ultrasound is safe for the fetus when used appropriately, consensus statements conclude that Doppler examination of fetal vessels in early pregnancy should not be performed without a clinical indication.
- The nonmedical use of ultrasound for psychosocial or entertainment purposes is strongly discouraged by professional organizations such as the American Institute of Ultrasound in Medicine (AIUM).
- Only those with adequate training in a conventional training program should be performing and interpreting ultrasound examinations.
- Consensus guidelines and criteria for transvaginal sonographic diagnosis of pregnancy failure in a woman with an intrauterine pregnancy of uncertain viability have been established and should be followed.
- Although early detection of a morphologic abnormality is useful, the confident unequivocal detection of an abnormality is even more important. Unless one is extremely confident of the existence of an abnormality in the first trimester, a follow-up examination should be performed.
- Measurements made early in pregnancy, for the most part, are more accurate than those made near term.
- Although a diagnosis of oligohydramnios and polyhydramnios can be made subjectively, the extremes of amniotic fluid volume should also be assessed objectively using either the deepest vertical pocket (DVP) or amniotic fluid index (AFI).
- It is preferable to report the distance from the inferior edge of the placenta to the internal cervical os rather than relying on terms that may have differing meanings (e.g., marginal placenta).
- If a single obstetric ultrasound or a targeted examination is performed, it should be done at a gestational age of 18 to 20 weeks.
- Obstetric ultrasound examinations represented the majority of medical malpractice cases involving ultrasound.
- Ultrasound examination is a noninvasive, safe procedure that has a high degree of patient acceptance and can yield a wealth of information.

OUTLINE

It has now been over 4 decades since sonography was first used to evaluate the obstetric patient. At first, the questions this modality sought to answer were very basic: Is there a pregnancy? Is the fetus alive? Is there a singleton or a twin gestation? What is the location of the placenta? What is the gestational age? Probably, few envisioned the day when ultrasonography would be used to identify subtle anatomic defects such as cleft lip or palate, to predict obstetric complications such as placenta accreta, or to accurately detect the presence of fetal anemia. It is hard to believe that, at its inception, it was difficult to convince clinicians as to the usefulness of this new diagnostic modality in obstetric management. Now, it is routine for a patient to have at least one, and often several, ultrasound examinations during her pregnancy. The technologic advances in ultrasound imaging, including 3D/4D and volumetric measurements, the use of high-frequency transvaginal probes, and the utility for chromosomal screening in early pregnancy (e.g., nuchal translucency) have only expanded the indications for sonographic imaging in the obstetric patient.

Since the last edition of this textbook, there have been dramatic advances in ultrasound technology, including improved spatial and contrast resolution, routine use of 3D and 4D imaging, volumetric scanning, expanded indications for color and spectral Doppler, new and improved ultrasound scanning probes, and improved digital review workstations, to name a few. Likewise, our knowledge of normal fetal anatomy and pathology, and the pathophysiology of disease in general, has increased substantially. The Internet has made communication among and between researchers and clinicians easier. In addition, there have been many collaborative studies and refinements of the guidelines for the performance of the obstetric ultrasound examination. However, there are still differences in the approach to the obstetric ultrasound examination from one group to the next. Although guidelines have improved consistency in the conduct and reporting of obstetric examinations, several issues are often hotly debated: for example, what constitutes a basic ultrasound examination, what structures should be evaluated, what is the ideal timing of the examination, what is the appropriate role of the first trimester anatomic survey, who should perform and interpret the examination, how safe is ultrasound, how should it be recorded and documented, how should it be reported, and last, how should the patient be told the results of the examination? With improved images comes the complicating corollary as to what minor findings should be reported to the patient and which merely lead to unnecessary anxiety. These issues are addressed later in the text and some of them are discussed here.

SAFETY OF ULTRASOUND EXAMINATION

It was not long after the inception of ultrasound imaging that questions were raised as to the safety of this new modality. Despite numerous claims for the safety of ultrasound to the mother and fetus, a number of studies have noted possible adverse effects of diagnostic ultrasound to the developing fetus. These studies have focused primarily on thermal and cavitation mechanisms leading to possible injuries to the developing fetus.[1-5]

Absorption of the ultrasound wave's energy by soft tissue and bone, and its conversion to heat, are measured by the thermal index (TI). A TI of 1 means an increase of 1° C. Several studies have suggested a general threshold of temperature elevation of 1.5° to 2° C above maternal core temperature before any evidence of a developmental effect occurs. With modern ultrasound machines, there is only a negligible rise in temperature, usually less than 1° C. The World Federation for Ultrasound in Medicine and Biology has stated that "a diagnostic exposure that produces a maximum in situ temperature rise of not more than 1.5° C above normal physiological levels may be used without reservation on thermal grounds."[6] However, this organization further stated that "a diagnostic exposure that elevates embryonic and fetal in situ temperature above 41° C for 5 minutes should be considered potentially hazardous."[6] The conclusion overall is that it is unlikely that there is a deleterious effect of ultrasound in the first trimester during embryogenesis with routine gray-scale ultrasound.

However, when Doppler ultrasound is used during the first trimester, it is likely that temperature increases of over 1.5° C may occur.[1] Studies of the effect of Doppler on soft tissues adjacent to bone and nerve conductance demonstrated a significant rise in temperature when the ultrasound Doppler beam was held for more than 30 seconds.[1,7] The European Federation for Societies in Medicine and Biology in 1998 concluded that "until further scientific information is available, investigations using pulsed or color Doppler should be carried out with careful control for output levels."[1,8] It is recommended that when performing Doppler imaging in early pregnancy, the displayed TI should be 1.0 or less and exposure time should be kept as short as possible, usually no longer than 5 to 10 minutes and not exceeding 60 minutes.[9] A thermal index for soft tissue (TIs) should be used at earlier than 10 weeks' gestation, and a thermal index for bone (TIb) should be used at 10 weeks' gestation or later when bone ossification is evident. In keeping with the ALARA (As Low As Reasonably Achievable) principle of prudent scanning, M-mode imaging should be used instead of spectral Doppler imaging to document embryonic/fetal heart rate.[10] Transvaginal ultrasound is not more harmful than transabdominal scanning; again, the risk is dependent on the TI.

Although the potential for embryonic effects from Doppler imaging exists, there is little evidence that ultrasound is teratogenic. As stated in one editorial on the subject, "Many of the studies to date have shown the embryo to be remarkably resilient to ultrasound exposure. Logic would suggest that Doppler techniques should not affect the embryo if the pulses are applied at a low level."[11] In one study, Zhu and associates[12] insonated pregnant rats with diagnostic levels of color Doppler ultrasound energy and studied the cell cycles of newborn rats by flow cytometry and factorial analysis. They found that the deoxyribonucleic acid content was not affected in any phase of the cell cycle in newborn rats by any of the different insonation times and frequencies. In another animal study, Pellicer and colleagues examined cellular damage in rats following exposure to low-intensity ultrasound for as long as 10 minutes. These investigators found that the longer the exposure time, the greater the liver cell damage that was observed.[13] Other animal studies have likewise demonstrated a relationship between the length of exposure to Doppler ultrasound and potential effects on the developing brain.[14,15] Although such studies support caution and minimizing unnecessary exposure, it is unclear whether such animal models can be extrapolated to humans and if such findings are important. However, at the present time, consensus statements conclude that Doppler examination of fetal vessels in early pregnancy should not be performed without a clinical indication.[16]

Cavitation involves the occurrence of gaseous bubble formation in an air-water interface.[1] One concern is that stress from the fluid adjacent to the gaseous body during the process of cavitation may disrupt cell membranes.[1,17] Cavitation has been difficult to document in mammalian fetuses, because, for the most part, there is not an air-water interface, which is needed for the cavitation mechanism.[1] The mechanical index (MI) is an onscreen indicator that provides a rough guide to the likelihood that ultrasound will induce an adverse biologic effect by a nonthermal mechanism, including cavitation. For all practical purposes, this index is probably not relevant for obstetric scanning owing to the relative absence of gas bubbles (air) in the fetus.[18]

A number of studies have evaluated the effect of prenatal ultrasound on neonatal and infant outcome in animal models. Although some studies have documented lower birth weights, shorter heights, and lowered white blood cell counts in neonates who were scanned in utero compared with control subjects, the size differences disappeared when studied after 3 months. In addition, hematologic parameters normalized by this time.[19] Neurodevelopmental studies revealed no significant differences in motor or cognitive tasks, or in learning skills.[1,19] Studies evaluating the human fetus and neonate have reached similar conclusions. Studies have found either no difference in birth weights between exposed and nonexposed fetuses, or a difference that, although present at birth, was not present at 6 to 7 years of age.[20,21]

The information on an association between ultrasound and congenital malformations is limited. Studies evaluating chromosomal aberration and ultrasound exposure have demonstrated little or no change.[1,12,22]

The major difficulties with the studies investigating a possible deleterious effect of diagnostic ultrasound evaluation are threefold: (1) experimental ultrasound exposure levels or time of exposure often far exceeded those that are normally used diagnostically; (2) the systems used to show ultrasound effect (plants, cell culture, laboratory animals) may not be applicable to humans; and (3) many studies that have demonstrated adverse effects in vitro have not been reproducible.[23]

One study evaluating the effect of diagnostic ultrasound on neuronal migration in mice raised much attention in the media.[15] Although this is an interesting study in mice, for the reasons stated earlier, it has little to no applicability in humans. There are two major criticisms of this study. Although the study did use commercially available equipment in which only slightly greater ultrasound frequency than normal was used (6.7 MHz vs. 3.5-5.0 MHz), the fixed duration of exposure far exceeded what would normally be used in humans. The study did not demonstrate statistically significant abnormal results until 30 minutes of exposure. More than 10 years ago, when a sonologist wished to determine whether an embryo was nonviable, the recommended evaluation of the embryo was 3 minutes of observation, demonstrating no evidence of embryonic or cardiac activity. Two minutes of evaluation, let alone 3 minutes, seemed like an eternity, and most examiners, in our experience, stopped after 1 minute. In the slightly older embryo and early fetus, greater than 5 to 10 minutes of sustained evaluation of the fetal brain would be excessive. In most cases, the transducer would be moving around the brain rather than being in a fixed position during the examination.

The second criticism relates to the timing of embryology and the relative sizes of the mouse and human brains. As stated by the authors of this study: "The duration of neuronal production and the migratory phase of cortical neurons in the human fetus lasts approximately 18 times longer than in mice (between 6 and 24 weeks of gestation in humans, with the peak occurring between 11 and 15 weeks, compared with the duration of only approximately 1 week (between E11 and E18) in a mouse).[15,24,25] Thus an exposure of 30 minutes represents a much smaller time dedicated to the development of the cerebral cortex in the human than in the mouse, and thus could have a lesser overall effect, making human corticogenesis less vulnerable to ultrasound waves."

The AIUM statement on the clinical safety of diagnostic ultrasound reiterates previous findings that no confirmed bioeffects caused by exposure at intensities typical of present diagnostic instruments have ever been reported in patients or instrument operators.[26] This statement acknowledges the possibility that bioeffects may be identified in the future but emphasizes the current data indicating that the benefits of the prudent use of diagnostic sonography outweigh the risks, if any.[26,27] At a recent consensus conference on fetal imaging, it was concluded that there is high-quality evidence that ultrasound is safe for the fetus when used appropriately.[28] However, as stated by Kremkau,[29] "even if this risk is so minimal that it is difficult to identify, prudent practice dictates that routine measures be implemented to minimize the risk while obtaining the necessary information to achieve the diagnostic benefit. This is the ALARA (as low as reasonably achievable) principle of prudent scanning" (Fig. 1-1).

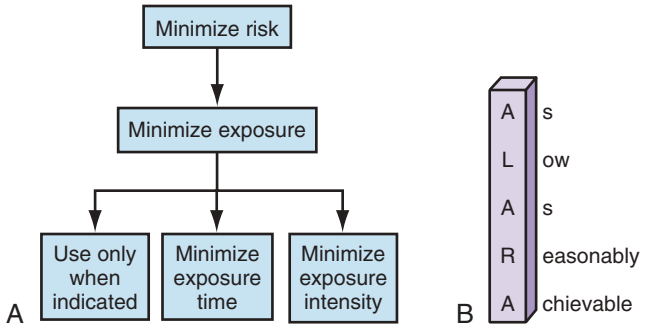

FIG 1-1 Minimizing risk by minimizing exposure (**A**) is the cornerstone of the ALARA principle (**B**). (From Kremkau FW [ed]: Diagnostic Ultrasound: Principles and Instruments, 7th ed. Philadelphia, WB Saunders, 2006.)

The sonographer's knowledge of ultrasound and its safety is crucial to the safe implementation of this modality. Merritt, in an editorial, summarized it best: "In view of the rapid growth of sonography and its proliferation into the hands of minimally trained clinicians, it is likely that more patients are harmed each day by misdiagnosis resulting from improper indications, poor examination technique, and errors in interpretation than from all bioeffects."[27]

INDICATIONS FOR OBSTETRIC ULTRASOUND EXAMINATION

National guidelines from many organizations in the United States and elsewhere, including the American College of Obstetricians and Gynecologists (ACOG), the Royal College of Obstetricians and Gynaecologists, and the Society of Obstetricians and Gynaecologists of Canada, highlight the benefits of obstetric ultrasound examination, including accurate determination of gestational age, fetal number, cardiac activity, placental localization, and diagnosis of major fetal anomalies. Because of these benefits, and because most congenital anomalies occur in patients with no known risk factors, these organizations agree that second trimester ultrasonography should be offered routinely to all pregnant women and should follow specific guidelines.[30-32] In addition, ACOG recommends that all pregnant women should be offered first trimester screening for aneuploidy, which may include nuchal translucency sonography.[33]

The benefit of routine sonography in the detection of fetal anomalies has been debated. Large studies and systematic reviews report detection rates of 16% to 44% of anomalies prior to 24 weeks of gestation.[31,34,35] Higher detection rates of major and lethal anomalies, as high as 84%, have been reported.[31] The sensitivity of anomaly detection has been noted to vary with respect to the type of abnormality, patient factors, gestational age, and expertise of the imager.[28] Possible explanations for the variance in the detection rate of anomalous fetuses may include (1) differences in neonatal assessment, (2) differences in the definition of a major anomaly, (3) a differing risk status of the population, (4) differences in what is considered a routine or standard sonogram, and (5) the expertise of the examiner.[36]

Who Should Perform the Ultrasound Examination and How Should It Be Performed?

Theoretically, the answer to who should perform the ultrasound examination should be extremely easy. In fact, it is one of the most controversial issues relating to the ultrasound examination. The answer should be that only those persons who have had adequate training (including didactic as well as supervised "hands-on" experience) should perform and interpret an ultrasound examination.

More than 30 years ago, the Joint Task Group on Training for Diagnosis in Obstetrical and Gynecologic Ultrasound developed guidelines for the post-resident physician who had completed residency programs in either radiology or obstetrics and gynecology that did not provide formal training in obstetric and gynecologic ultrasound evaluation.[37] These guidelines have been continuously updated, most recently in 2014, and include a recommendation of a minimum experience in obstetric and gynecologic ultrasound evaluation as well as training that includes basic physics, technique, performance, and interpretation. In addition, the physician should obtain practical and supervised experience (at least 300 examinations) before offering services as a physician competent in diagnostic ultrasound examination. Ongoing experience with at least 170 examinations per year is also recommended.[38]

The "turf" battles between radiologists and obstetricians as to who should perform the examination are unfortunate. As long as the examining physician is adequately trained and performs the minimum standard obstetric ultrasound examination, as per the guidelines of the American College of Radiology (ACR), AIUM, and ACOG, the specialty of the examiner does not matter.[39,40] However, we do not believe in the practice of self-referral. Self-referral examinations tend to be performed more and more frequently[41] and are often less "complete" and of a lower quality than when they are performed by a dedicated ultrasound practitioner. Except in localities where there are no diagnostic ultrasound specialists, patients should be referred to practitioners whose major practice is ultrasonography.

Guidelines for the performance of obstetric ultrasound examinations have been published by ACR, ACOG, and AIUM, and components of the standard fetal examination at 18 to 20 weeks of gestation were published in a consensus report by National Institute of Child Health and Human Development (NICHD), Society for Maternal-Fetal Medicine (SMFM), ACOG, ACR, AIUM, Society of Pediatric Radiology (SPR), and Society of Radiologists in Ultrasound (SRU) in 2014.[28] AIUM has likewise published guidelines for performance of a detailed fetal anatomic survey, referred to by the billing code 76811.[42] Although there may be sonologists who exceed these guidelines, the guidelines serve as a minimum standard for practitioners of basic and detailed obstetric ultrasonography.

Nonmedical Use of Ultrasonography

The AIUM has published a "prudent use" statement, which was also endorsed by ACOG. The AIUM advocates the responsible use of diagnostic ultrasonography and strongly discourages its nonmedical use for psychosocial or entertainment purposes. The use of either 2D or 3D ultrasound imaging only to view the fetus, obtain a picture of the fetus, or determine the fetal sex without a medical indication is inappropriate and contrary to responsible medical practice. Although there are no confirmed biologic effects on patients caused by exposures from present diagnostic ultrasound instruments, the possibility exists that such biologic effects may be identified in the future. Thus, ultrasound imaging should be used in a prudent manner to provide medical benefit to the patient.[43] This position has been ethically defended.[44]

Terminology

The latest classification[45] of fetal sonographic examinations by the AIUM, ACR, and ACOG groups the examinations into four major categories: (A) the first trimester ultrasound examination, (B) the standard second or third trimester examination, (C) the limited examination, and (D) specialized examinations. The standard second and third trimester obstetric examination is often referred to as a routine examination, basic examination, Level 1 examination, or complete ultrasound examination. Specialized examinations might include a detailed anatomic examination, as well as fetal Doppler ultrasound, a biophysical profile, a fetal echocardiogram, and additional biometric measurements. A detailed anatomic examination is generally performed when a patient is at high risk for a fetal anomaly, or when an anomaly is suspected on the basis of the history, biochemical abnormalities or abnormal results on other screening tests, or the results of either the limited or standard scan.

It is important to note that although those individuals performing detailed anatomic examinations must be proficient in evaluating patients for congenital anomalies, it is not acceptable for the Level 1 examiner to be unskilled. In an excellent editorial on the subject, Filly[46] notes that unfortunately some examiners have chosen to use the term "Level 1" as a shield for incompetency. As he states, the Level 1 sonogram is not defined by the technical capability of the examiner, nor by the cost of the sonographic instrumentation employed. In fact, the Level 1 examination "requires a high degree of competency" and should follow the standard second or third trimester obstetric sonographic examination as described in the AIUM/ACR/ACOG guidelines.[10]

The specialized examination (CPT 76811) has been referred to as the Level 2 examination, survey examination, or targeted examination. As the AIUM/ACR/ACOG guidelines state, this is a detailed anatomic examination that is performed when an anomaly is suspected on the basis of history, abnormalities detected on prenatal screening tests, or the results of either a limited or standard examination previously performed.[45]

The individuals performing the sonographic examination are referred to as either sonographers or sonologists. Traditionally, the technical component and initial production of images has been the responsibility of the sonographer (nonphysician), and the professional component and interpretation of images has been the responsibility of the sonologist (physician). The degree of collaboration between the two and their degree of involvement in the ultrasound examination vary from locality to locality. In many parts of the world, examinations are performed predominantly by physicians. Although the contribution of sonographers to the ultrasound examination is invaluable, it should be remembered, as stated by the AIUM, that "Ultrasound studies shall be supervised and interpreted by a physician with training and experience in the specific area of sonography. Findings must be recorded and results communicated in a timely fashion to the health care provider responsible for care. Although a sonographer may play a critical role in extracting the information essential to deriving a diagnosis, the rendering of the final diagnosis of ultrasound studies represents the practice of medicine, and, therefore, is the responsibility of the supervising physician."[47]

Perhaps the least controversial aspect of this discussion should be who should interpret the ultrasound examination. This, we believe, is straightforward. Only those with adequate training in a conventional training programs (e.g., residency) in which there are didactic lectures, hands-on scanning, and physician supervision in the performance and interpretation of cases should be performing and interpreting ultrasound findings. Training by manufacturer's training specialists or 1- to 2-week mini-courses do not constitute adequate training in ultrasound.

Ultrasound Lexicon

Undoubtedly, hundreds of terms are used in obstetrics and ultrasonography that are either incorrect or confusing. Many of these terms are addressed later in this chapter and in other chapters in this text. Two areas in which terminology is often either misused or misunderstood in obstetric ultrasonography are fetal life and age. The term *viability* is defined as the ability to survive in the extrauterine environment. Even in cases of very late third trimester examinations, this statement cannot be used with complete certainty. We prefer to state that the embryo or fetus is living, if that is the case, and use the term *nonviable* for those embryos or fetuses that either are dead or are not capable of living in the extrauterine environment. Early pregnancy failure is another, perhaps even better, way of communicating this information.

The second often-confused term is gestational age. Taken as it sounds, this term would seem to imply the actual age of the fetus from conception to the present. In fact, this term, which is widely used by obstetricians and sonologists, is most often meant to be synonymous with menstrual age. Menstrual age refers to the length of time calculated from the first day of the last normal menstrual period to the point at which the pregnancy is being assessed. The true age of the embryo or fetus, *fetal age*, is rarely known accurately unless the patient has had assisted fertilization or has extremely regular menstrual periods and the day of conception is known. In general, the fetal age is 2 weeks less than the menstrual age.

In this text, the terms gestational age and menstrual age are used interchangeably. The important point for any examiner to remember is not which term is necessarily preferable but rather that the person interpreting the examination and the physician who ordered the examination both use the same terminology.

Another often-misused term is *fetal pole*. This term should be abandoned. It is most often used to describe the presence of the embryo in the early first trimester sonogram. The embryonic period lasts until the end of the 10th menstrual week; during this time the developing conceptus should be referred to as the embryo. Thereafter, the conceptus should be referred to as a fetus.

THE AMERICAN INSTITUTE OF ULTRASOUND IN MEDICINE GUIDELINES

In 2013 the Practice Guideline for the Performance of an Antepartum Obstetric Ultrasound Examination was updated by the AIUM in collaboration with the ACR, the SRU, and ACOG.[45] It is a modification of previously developed guidelines that were first published in 1986. The actual ACR/AIUM/ACOG guidelines are presented in Table 1-1. What follows is our own bias as to what constitutes an appropriate ultrasound examination. In some respects, this discussion is an expansion of the guidelines previously mentioned. Because this multiauthor text is essentially a detailed review of the obstetric ultrasound examination, we recognize that our viewpoint in this chapter and those of the authors of the subsequent chapters may differ.

ULTRASOUND EQUIPMENT AND DOCUMENTATION

It seems that there will always be differences of opinion as to which ultrasound machines produce the best images. With the present state of ultrasound technology, these differences are often subjective, particularly when discussing state-of-the-art machines. Most ultrasound machines use phased-array real-time technology and include 3D/4D ultrasound technology and color and pulsed Doppler flow capabilities and cine recording.

An often-debated issue is which transducer should be used for the ultrasound examination. The answer is as many transducers as are necessary should be used to answer the question for which the patient is referred. There is a misconception that the newest transducer introduced by a manufacturer may be the only one that is needed. When sector and, ultimately, transvaginal probes were first introduced, many practitioners believed that these transducers alone could be used for the entire examination. Many learned that using only a single transducer restricts the field of view or visualization of detail, making diagnosis more difficult.

The most common transducers, which are the workhorses of the ultrasound laboratory, are a convex linear array, a sector transducer (3 to 5 MHz), and a transvaginal probe (5 to 10 MHz). The higher frequency transducers are most useful in achieving high-resolution scans, particularly in the near-field, and the lower frequency transducers are useful in those circumstances in which increased penetration of the sound beam is necessary. Variations of transducer technology include convex linear transducers and multifrequency probes as well as probes allowing harmonic and 3D imaging and Doppler flow imaging.[48]

Whatever technology is used, images from the examination should be documented and stored. The purpose of documentation is twofold. First, the identification of normal structures is important so they can be viewed retrospectively and compared with later images if pathologic processes are ultimately demonstrated. Second, if a pathologic problem is identified, it can be shown to referring examiners, who will be doing further examinations.

Most imaging centers utilize picture archiving and communication systems (PACS). These systems allow for the storage of digital ultrasound images on computers and transmission of complete studies to computer workstations for viewing and interpretation. The quality of the images is excellent with these systems. Digital images can be also transmitted to remote locations (telemedicine) for review and consultation.[49]

In addition to digitally stored images, a written report of the ultrasound examination should be included in the patient's medical record. When significant pathologic processes are present, the referring physician should be notified immediately. This immediate communication should occur not only in cases of fetal malformations but also in cases of serious obstetric complications, such as oligohydramnios, diminished fetal movement, macrosomia, and fetal growth restriction. Physician notification should be documented.

THE FIRST TRIMESTER ULTRASOUND EXAMINATION

Identification of an Intrauterine Pregnancy

Patients referred for first trimester ultrasound evaluation often have vaginal bleeding, which raises the question of an ectopic pregnancy or a threatened abortion. The primary goal of ultrasound evaluation in the first trimester is to determine whether the pregnancy is intrauterine and whether the embryo is living. With present-day equipment, particularly transvaginal transducers, both of these tasks should be readily accomplished at very early stages of gestation. The same care taken in concluding that a pregnancy in the second or third trimester has a lethal malformation should be applied in deciding that an early pregnancy is nonviable. If there is reasonable doubt about embryonic life, a repeat examination in as few as 7 to 10 days will invariably make the conclusion unequivocal. In 2012 a consensus conference from the SRU established guidelines and criteria for transvaginal ultrasonographic

Text continued on p. 12

TABLE 1-1 Guidelines for Performance of the Antepartum Obstetric Ultrasound Examination

I. Introduction

The clinical aspects contained in specific sections of this guideline (Introduction, Classification of Fetal Sonographic Examinations, Specifications of the Examination, Equipment Specifications, and Fetal Safety) were revised collaboratively by the American Institute of Ultrasound in Medicine (AIUM), the American College of Radiology (ACR), the American College of Obstetricians and Gynecologists (ACOG), and the Society of Radiologists in Ultrasound (SRU). Recommendations for personnel qualifications, written request for the examination, procedure documentation, and quality control vary among the organizations and are addressed by each separately.

This guideline has been developed for use by practitioners performing obstetric sonographic studies. Fetal ultrasound should be performed only when there is a valid medical reason, and the lowest possible ultrasonic exposure settings should be used to gain the necessary diagnostic information. A limited examination may be performed in clinical emergencies or for a limited purpose such as evaluation of fetal or embryonic cardiac activity, fetal position, or amniotic fluid volume. A limited follow-up examination may be appropriate for reevaluation of fetal size or interval growth or to reevaluate abnormalities previously noted if a complete prior examination is on record.

While this guideline describes the key elements of standard sonographic examinations in the first trimester and second and third trimesters, a more detailed anatomic examination of the fetus may be necessary in some cases, such as when an abnormality is found or suspected on the standard examination or in pregnancies at high risk for fetal anomalies. In some cases, other specialized examinations may be necessary as well.

While it is not possible to detect all structural congenital anomalies with diagnostic ultrasound, adherence to the following guidelines will maximize the possibility of detecting many fetal abnormalities.

II. Classification of Fetal Sonographic Examinations

A. First-Trimester Examination

A standard obstetric sonogram in the first trimester includes evaluation of the presence, size, location, and number of gestational sac(s). The gestational sac is examined for the presence of a yolk sac and embryo/fetus. When an embryo/fetus is detected, it should be measured and cardiac activity recorded by a 2-dimensional video clip or M-mode imaging. Use of spectral Doppler imaging is discouraged. The uterus, cervix, adnexa, and cul-de-sac region should be examined.

B. Standard Second- or Third-Trimester Examination

A standard obstetric sonogram in the second or third trimester includes an evaluation of fetal presentation, amniotic fluid volume, cardiac activity, placental position, fetal biometry, and fetal number, plus an anatomic survey. The maternal cervix and adnexa should be examined as clinically appropriate when technically feasible.

C. Limited Examination

A limited examination is performed when a specific question requires investigation. For example, in most routine nonemergency cases, a limited examination could be performed to confirm fetal heart activity in a bleeding patient or to verify fetal presentation in a laboring patient. In most cases, limited sonographic examinations are appropriate only when a prior complete examination is on record.

D. Specialized Examinations

A detailed anatomic examination is performed when an anomaly is suspected on the basis of the history, biochemical abnormalities, or the results of either the limited or standard scan. Other specialized examinations might include fetal Doppler ultrasound, a biophysical profile, a fetal echocardiogram, and additional biometric measurements.

III. Qualifications and Responsibilities of Personnel

See the AIUM Official Statement *Training Guidelines for Physicians Who Evaluate and Interpret Diagnostic Abdominal, Obstetric, and/or Gynecologic Ultrasound Examinations* and the *AIUM Standards and Guidelines for the Accreditation of Ultrasound Practices*.

IV. Written Request for the Examination

The written or electronic request for an ultrasound examination should provide sufficient information to allow for the appropriate performance and interpretation of the examination. The request for the examination must be originated by a physician or other appropriately licensed health care provider or under the provider's direction. The accompanying clinical information should be provided by a physician or other appropriate health care provider familiar with the patient's clinical situation and should be consistent with relevant legal and local health care facility requirements.

V. Specifications of the Examination

A. First-Trimester Ultrasound Examination

1. Indications

   Indications for first-trimester sonography include but are not limited to:

   a. Confirmation of the presence of an intrauterine pregnancy;
   b. Evaluation of a suspected ectopic pregnancy;
   c. Defining the cause of vaginal bleeding;
   d. Evaluation of pelvic pain;
   e. Estimation of gestational (menstrual) age;
   f. Diagnosis or evaluation of multiple gestations;
   g. Confirmation of cardiac activity;
   h. Imaging as an adjunct to chorionic villus sampling, embryo transfer, and localization and removal of an intrauterine device;
   i. Assessing for certain fetal anomalies, such as anencephaly, in high-risk patients;
   j. Evaluation of maternal pelvic masses and/or uterine abnormalities;
   k. Measuring the nuchal translucency (NT) when part of a screening program for fetal aneuploidy; and
   l. Evaluation of a suspected hydatidiform mole.

   Comment

   A limited examination may be performed to evaluate interval growth, estimate amniotic fluid volume, evaluate the cervix, and assess the presence of cardiac activity.

Continued

TABLE 1-1 Guidelines for Performance of the Antepartum Obstetric Ultrasound Examination—cont'd

2. Imaging Parameters

Comment

Scanning in the first trimester may be performed either transabdominally or transvaginally. If a transabdominal examination is not definitive, a transvaginal scan or transperineal scan should be performed whenever possible.

a. The uterus (including the cervix) and adnexa should be evaluated for the presence of a gestational sac. If a gestational sac is seen, its location should be documented. The gestational sac should be evaluated for the presence or absence of a yolk sac or embryo, and the crown-rump length should be recorded when possible.

Comment

A definitive diagnosis of intrauterine pregnancy can be made when an intrauterine gestational sac containing a yolk sac or embryo/fetus with cardiac activity is visualized. A small, eccentric intrauterine fluid collection with an echogenic rim can be seen before the yolk sac and embryo are detectable in a very early intrauterine pregnancy. In the absence of sonographic signs of ectopic pregnancy, the fluid collection is highly likely to represent an intrauterine gestational sac. In this circumstance, the intradecidual sign may be helpful. Follow-up sonography and/or serial determination of maternal serum human chorionic gonadotropin levels are/is appropriate in pregnancies of undetermined location to avoid inappropriate intervention in a potentially viable early pregnancy.

The crown-rump length is a more accurate indicator of gestational (menstrual) age than is the mean gestational sac diameter. However, the mean gestational sac diameter may be recorded when an embryo is not identified.

Caution should be used in making the presumptive diagnosis of a gestational sac in the absence of a definitive embryo or yolk sac. Without these findings, an intrauterine fluid collection could represent a pseudo-gestational sac associated with an ectopic pregnancy.

b. The presence or absence of cardiac activity should be documented with a 2-dimensional video clip or M-mode imaging.

Comment

With transvaginal scans, while cardiac motion is usually observed when the embryo is 2 mm or greater in length, if an embryo less than 7 mm in length is seen without cardiac activity, a subsequent scan in 1 week is recommended to ensure that the pregnancy is nonviable.

c. Fetal number should be documented.

Comment

Amnionicity and chorionicity should be documented for all multiple gestations when possible.

d. Embryonic/fetal anatomy appropriate for the first trimester should be assessed.

e. The nuchal region should be imaged, and abnormalities such as cystic hygroma should be documented.

Comment

For those patients desiring to assess their individual risk of fetal aneuploidy, a very specific measurement of the NT during a specific age interval is necessary (as determined by the laboratory used). See the guidelines for this measurement below.

NT measurements should be used (in conjunction with serum biochemistry) to determine the risk of having a fetus with aneuploidy or other anatomic abnormalities such as heart defects. In this setting, it is important that the practitioner measure the NT according to established guidelines for measurement. A quality assessment program is recommended to ensure that false-positive and false-negative results are kept to a minimum.

Guidelines for NT Measurement:

i. The margins of the NT edges must be clear enough for proper placement of the calipers.
ii. The fetus must be in the midsagittal plane.
iii. The image must be magnified so that it is filled by the fetal head, neck, and upper thorax.
iv. The fetal neck must be in a neutral position, not flexed and not hyperextended.
v. The amnion must be seen as separate from the NT line.
vi. The + calipers on the ultrasound must be used to perform the NT measurement.
vii. Electronic calipers must be placed on the inner borders of the nuchal line space with none of the horizontal crossbar itself protruding into the space.
viii. The calipers must be placed perpendicular to the long axis of the fetus.
ix. The measurement must be obtained at the widest space of the NT.

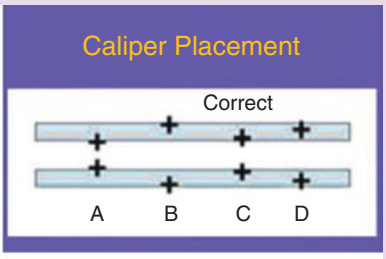

TABLE 1-1 Guidelines for Performance of the Antepartum Obstetric Ultrasound Examination—cont'd

f. The uterus including the cervix, adnexal structures, and cul-de-sac should be evaluated. Abnormalities should be imaged and documented.
Comment
The presence, location, appearance, and size of adnexal masses should be documented. The presence and number of leiomyomata should be documented. The measurements of the largest or any potentially clinically significant leiomyomata should be documented. The cul-de-sac should be evaluated for the presence or absence of fluid. Uterine anomalies should be documented.

B. Second- and Third-Trimester Ultrasound Examination

1. Indications

Indications for second- and third-trimester sonography include but are not limited to:

a. Screening for fetal anomalies;
b. Evaluation of fetal anatomy;
c. Estimation of gestational (menstrual) age;
d. Evaluation of fetal growth;
e. Evaluation of vaginal bleeding;
f. Evaluation of abdominal or pelvic pain;
g. Evaluation of cervical insufficiency;
h. Determination of fetal presentation;
i. Evaluation of suspected multiple gestation;
j. Adjunct to amniocentesis or other procedure;
k. Evaluation of a significant discrepancy between uterine size and clinical dates;
l. Evaluation of a pelvic mass;
m. Evaluation of a suspected hydatidiform mole;
n. Adjunct to cervical cerclage placement;
o. Suspected ectopic pregnancy;
p. Suspected fetal death;
q. Suspected uterine abnormalities;
r. Evaluation of fetal well-being;
s. Suspected amniotic fluid abnormalities;
t. Suspected placental abruption;
u. Adjunct to external cephalic version;
v. Evaluation of premature rupture of membranes and/or premature labor;
w. Evaluation of abnormal biochemical markers;
x. Follow-up evaluation of a fetal anomaly;
y. Follow-up evaluation of placental location for suspected placenta previa;
z. History of previous congenital anomaly;
aa. Evaluation of the fetal condition in late registrants for prenatal care; and
bb. Assessment for findings that may increase the risk for aneuploidy.
Comment
In certain clinical circumstances, a more detailed examination of fetal anatomy may be indicated.

2. Imaging Parameters for a Standard Fetal Examination

a. Fetal cardiac activity, fetal number, and presentation should be documented.
Comment
An abnormal heart rate and/or rhythm should be documented. Multiple gestations require the documentation of additional information: chorionicity, amnionicity, comparison of fetal sizes, estimation of amniotic fluid volume (increased, decreased, or normal) in each gestational sac, and fetal genitalia (when visualized).

b. A qualitative or semiquantitative estimate of amniotic fluid volume should be documented.
Comment
Although it is acceptable for experienced examiners to qualitatively estimate amniotic fluid volume, semiquantitative methods have also been described for this purpose (eg, amniotic fluid index, single deepest pocket, and 2-diameter pocket).

c. The placental location, appearance, and relationship to the internal cervical os should be documented. The umbilical cord should be imaged and the number of vessels in the cord documented. The placental cord insertion site should be documented when technically possible.
Comment
It is recognized that the apparent placental position early in pregnancy may not correlate well with its location at the time of delivery. Transabdominal, transperineal, or transvaginal views may be helpful in visualizing the internal cervical os and its relationship to the placenta. Transvaginal or transperineal ultrasound may be considered if the cervix appears shortened or cannot be adequately visualized during the transabdominal sonogram.
A velamentous (also called membranous) placental cord insertion that crosses the internal os of the cervix is vasa previa, a condition that has a high risk of fetal mortality if not diagnosed before labor.

Continued

TABLE 1-1 Guidelines for Performance of the Antepartum Obstetric Ultrasound Examination—cont'd

d. Gestational (menstrual) age assessment.
First-trimester crown-rump measurement is the most accurate means for sonographic dating of pregnancy. Beyond this period, a variety of sonographic parameters such as biparietal diameter, abdominal circumference, and femoral diaphysis length can be used to estimate gestational (menstrual) age. The variability of gestational (menstrual) age estimation, however, increases with advancing pregnancy. Significant discrepancies between gestational (menstrual) age and fetal measurements may suggest the possibility of a fetal growth abnormality, intrauterine growth restriction, or macrosomia.
Comment
The pregnancy should not be redated after an accurate earlier scan has been performed and is available for comparison.
i. The biparietal diameter is measured at the level of the thalami and cavum septi pellucidi or columns of the fornix. The cerebellar hemispheres should not be visible in this scanning plane. The measurement is taken from the outer edge of the proximal skull to the inner edge of the distal skull.
Comment
The head shape may be flattened (dolichocephaly) or rounded (brachycephaly) as a normal variant. Under these circumstances, certain variants of normal fetal head development may make measurement of the head circumference more reliable than biparietal diameter for estimating gestational (menstrual) age.
ii. The head circumference is measured at the same level as the biparietal diameter, around the outer perimeter of the calvarium. This measurement is not affected by head shape.
iii. The femoral diaphysis length can be reliably used after 14 weeks' gestational (menstrual) age. The long axis of the femoral shaft is most accurately measured with the beam of insonation being perpendicular to the shaft, excluding the distal femoral epiphysis.
iv. The abdominal circumference or average abdominal diameter should be determined at the skin line on a true transverse view at the level of the junction of the umbilical vein, portal sinus, and fetal stomach when visible.
Comment
The abdominal circumference or average abdominal diameter measurement is used with other biometric parameters to estimate fetal weight and may allow detection of intrauterine growth restriction or macrosomia.

e. Fetal weight estimation.
Fetal weight can be estimated by obtaining measurements such as the biparietal diameter, head circumference, abdominal circumference or average abdominal diameter, and femoral diaphysis length. Results from various prediction models can be compared to fetal weight percentiles from published nomograms.
Comment
If previous studies have been performed, appropriateness of growth should also be documented. Scans for growth evaluation can typically be performed at least 2 to 4 weeks apart. A shorter scan interval may result in confusion as to whether measurement changes are truly due to growth as opposed to variations in the technique itself.
Currently, even the best fetal weight prediction methods can yield errors as high as ±15%. This variability can be influenced by factors such as the nature of the patient population, the number and types of anatomic parameters being measured, technical factors that affect the resolution of ultrasound images, and the weight range being studied.

f. Maternal anatomy.
Evaluation of the uterus, adnexal structures, and cervix should be performed when appropriate. If the cervix cannot be visualized, a transperineal or transvaginal scan may be considered when evaluation of the cervix is needed.
Comment
This will allow recognition of incidental findings of potential clinical significance. The presence, location, and size of adnexal masses and the presence of at least the largest and potentially clinically significant leiomyomata should be documented. It is not always possible to image the normal maternal ovaries during the second and third trimesters.

g. Fetal anatomic survey.
Fetal anatomy, as described in this document, may be adequately assessed by ultrasound after approximately 18 weeks' gestational (menstrual) age. It may be possible to document normal structures before this time, although some structures can be difficult to visualize due to fetal size, position, movement, abdominal scars, and increased maternal abdominal wall thickness. A second- or third-trimester scan may pose technical limitations for an anatomic evaluation due to imaging artifacts from acoustic shadowing. When this occurs, the report of the sonographic examination should document the nature of this technical limitation. A follow-up examination may be helpful. The following areas of assessment represent the minimal elements of a standard examination of fetal anatomy. A more detailed fetal anatomic examination may be necessary if an abnormality or suspected abnormality is found on the standard examination.
i. Head, face, and neck:
Lateral cerebral ventricles;
Choroid plexus;
Midline falx;
Cavum septi pellucidi;
Cerebellum;
Cistern magna; and
Upper lip.
Comment
A measurement of the nuchal fold may be helpful during a specific age interval to assess the risk of aneuploidy.

TABLE 1-1 Guidelines for Performance of the Antepartum Obstetric Ultrasound Examination—cont'd

ii. Chest:
Heart:
Four-chamber view;
Left ventricular outflow tract; and
Right ventricular outflow tract.
iii. Abdomen:
Stomach (presence, size, and situs);
Kidneys;
Urinary bladder;
Umbilical cord insertion site into the fetal abdomen; and
Umbilical cord vessel number.
iv. Spine:
Cervical, thoracic, lumbar, and sacral spine.
v. Extremities:
Legs and arms.
vi. Sex:
In multiple gestations and when medically indicated.

VI. Documentation

Adequate documentation is essential for high-quality patient care. There should be a permanent record of the ultrasound examination and its interpretation. Images of all appropriate areas, both normal and abnormal, should be recorded. Variations from normal size should be accompanied by measurements. Images should be labeled with the patient identification, facility identification, examination date, and side (right or left) of the anatomic site imaged. An official interpretation (final report) of the ultrasound findings should be included in the patient's medical record. Retention of the ultrasound examination should be consistent both with clinical needs and with relevant legal and local health care facility requirements.

Reporting should be in accordance with the *AIUM Practice Guideline for Documentation of an Ultrasound Examination*.

VII. Equipment Specifications

These studies should be conducted with real-time scanners, using a transabdominal and/or transvaginal approach. A transducer of appropriate frequency should be used. Real-time sonography is necessary to confirm the presence of fetal life through observation of cardiac activity and active movement.

The choice of transducer frequency is a trade-off between beam penetration and resolution. With modern equipment, 3- to 5-MHz abdominal transducers allow sufficient penetration in most patients while providing adequate resolution. A lower-frequency transducer may be needed to provide adequate penetration for abdominal imaging in an obese patient. During early pregnancy, a 5-MHz abdominal transducer or a 5- to 10-MHz or greater vaginal transducer may provide superior resolution while still allowing adequate penetration.

VIII. Fetal Safety

Diagnostic ultrasound studies of the fetus are generally considered safe during pregnancy. This diagnostic procedure should be performed only when there is a valid medical indication, and the lowest possible ultrasonic exposure setting should be used to gain the necessary diagnostic information under the ALARA (as low as reasonably achievable) principle.

A thermal index for soft tissue (Tis) should be used at earlier than 10 weeks' gestation, and a thermal index for bone (Tib) should be used at 10 weeks' gestation or later when bone ossification is evident. In keeping with the ALARA principle, M-mode imaging should be used instead of spectral Doppler imaging to document embryonic/fetal heart rate.

The promotion, selling, or leasing of ultrasound equipment for making "keepsake fetal videos" is considered by the US Food and Drug Administration to be an unapproved use of a medical device. Use of a diagnostic ultrasound system for these purposes, without a physician's order, may be in violation of state laws or regulations.

IX. Quality Control and Improvement, Safety, Infection Control, and Patient Education

Policies and procedures related to quality control, patient education, infection control, and safety should be developed and implemented in accordance with the *AIUM Standards and Guidelines for the Accreditation of Ultrasound Practices*.

Equipment performance monitoring should be in accordance with the *AIUM Standards and Guidelines for the Accreditation of Ultrasound Practices*.

X. ALARA Principle

The potential benefits and risks of each examination should be considered. The ALARA principle should be observed when adjusting controls that affect the acoustic output and by considering transducer dwell times. Further details on ALARA may be found in the AIUM publication *Medical Ultrasound Safety*, Second Edition.

TABLE 1-2 Guidelines for Transvaginal Ultrasonographic Diagnosis of Pregnancy Failure in a Woman With an Intrauterine Pregnancy of Uncertain Viability*

Findings Diagnostic of Pregnancy Failure	Findings Suspicious for, But Not Diagnostic of, Pregnancy Failure†
Crown-rump length of ≥7 mm and no heartbeat	Crown-rump length of <7 mm and no heartbeat
Mean sac diameter of ≥25 mm and no embryo	Mean sac diameter of 16-24 mm and no embryo
Absence of embryo with heartbeat ≥2 wk after a scan that showed a gestational sac without a yolk sac	Absence of embryo with heartbeat 7-13 days after a scan that showed a gestational sac without a yolk sac
Absence of embryo with heartbeat ≥11 days after a scan that showed a gestational sac with a yolk sac	Absence of embryo with heartbeat 7-10 days after a scan that showed a gestational sac with a yolk sac
	Absence of embryo ≥6 wk after last menstrual period
	Empty amnion (amnion seen adjacent to yolk sac, with no visible embryo)
	Enlarged yolk sac (>7 mm)
	Small gestational sac in relation to the size of the embryo (<5 mm difference between mean sac diameter and crown-rump length)

*Criteria are from the Society of Radiologists in Ultrasound Multispecialty Consensus Conference on Early First Trimester Diagnosis of Miscarriage and Exclusion of a Viable Intrauterine Pregnancy, October 2012.
†When there are findings suspicious for pregnancy failure, follow-up ultrasonography at 7 to 10 days to assess the pregnancy for viability is generally appropriate.

diagnosis of pregnancy failure in a woman with an intrauterine pregnancy of uncertain viability (see Table 1-2 and Chapter 4).

Embryonic/Fetal Number

With a careful examination, the true number of embryos can be accurately determined even early in the first trimester. The literature has emphasized that it is important not to overestimate the number of developing gestations by misinterpreting findings such as a double sac sign, fluid in the uterine cavity, the yolk sac, or the presence of the amnion as evidence of multiple sacs or embryos and thus multiple gestations. However, the examiner may be just as likely to underestimate the number of developing gestations and embryos if a thorough evaluation of the gestational sac is not made for all embryos.[50] It is our experience that when multiple gestations are missed using ultrasound assessment, it is usually from a less than optimal first trimester examination. The head (crown) of one embryo may be added to the body (rump) of an adjacent embryo and measured as a singleton. This misdiagnosis, of course, occurs only in monochorionic gestations. For these reasons some investigators prefer that if one ultrasound examination is to be done concentrating on fetal number, it should be done in the early to middle second trimester of pregnancy.

Estimating Gestational Age

The subject of estimating gestational age is covered in detail in Chapter 6. An estimate of gestational age should be made when an ultrasound examination is performed in the first trimester, as this is the most accurate time to determine gestational age. The two most common methods of gestational age estimation are mean gestational sac diameter and crown-rump length. For many years, the crown-rump length has been acclaimed as the most reliable method of estimating gestational age in utero. The crown-rump length is a highly accurate method of estimating gestational age using ultrasound evaluation (accuracy within 3 to 7 days). Other measurements, such as the head circumference or femur length, performed in the second trimester, are nearly as accurate and have the added benefit of allowing one to assess fetal morphologic features to a better advantage in a larger fetus. We believe that the first trimester ultrasound examination should not be done for the sole purpose of obtaining more accurate measurements if there is not a clinical reason why it cannot be done in the second trimester, and this approach was also affirmed in the NICHD Fetal Imaging Workshop consensus.[28]

Morphologic Abnormalities

Recent years have seen continuous improvement in the resolution of ultrasound and many reports documenting morphologic abnormalities detected in the first trimester. Abnormalities involving virtually every organ system have been reported. In light of these reports, we are frequently asked when is the earliest time that a particular abnormality can be detected. Our reply is often that although early detection of a morphologic abnormality is useful, the confident unequivocal detection of an abnormality is even more important. Unless one is extremely confident of the existence of an abnormality in the first trimester, a follow-up examination should be performed.

One should be aware of four potential pitfalls in diagnosis in the first trimester: (1) the normal extra-abdominal position of the embryonic intestine simulating an abdominal wall defect, (2) the prominence of the developing cerebral vesicles (rhombencephalon), (3) the potential false negative diagnosis of anencephaly, and (4) the false positive diagnosis of cerebellar vermian and callosal abnormalities because of these structures not being fully developed at an early gestational age.[51-53]

Placenta

In early pregnancies, it may be difficult to ascertain the site of the developing placenta. If, however, the examiner can confidently identify the site of placentation, either anterior or posterior, this information should be documented. It should be noted that the placenta either overlies the cervix or just reaches the cervix in up to 2% of pregnancies imaged transvaginally in the early second trimester.[54,55] Placental "migration," or resolution of placenta previa as pregnancy progresses, occurs in most cases, probably as a result of the faster growth of the placenta-free uterine wall relative to the uterine wall covered by the placenta.[54] Factors such as prior cesarean delivery and the degree to which the placenta overlies the cervix affect whether placenta previa in the second trimester will resolve prior to delivery. In general, the placenta commonly extends to the cervix before 16 weeks, and a placenta previa should not be reported. At 16 weeks and beyond, if the placental edge is within 2 cm of the internal os, a diagnosis of "low-lying placenta" is made and follow-up at 32 weeks of gestation is recommended.[28] If one is uncertain as to the location of the inferior edge of the placenta, a transvaginal scan will help clear up any confusion and prevent a patient being labeled as having a placenta previa.

Uterus and Adnexa

The maternal uterus should be examined carefully for evidence of uterine abnormalities, particularly in high-risk patients. Late in pregnancy, these anomalies may be more difficult to detect. If uterine myomas are detected, their size, site, and relationship to the cervix should be recorded. It should be remembered that transient myometrial contractions may simulate myomas.

The adnexa should be carefully searched for the presence of cysts as well as ovarian neoplasms, both benign and malignant. Again, later in pregnancy, as the adnexal areas are displaced superiorly, they may be more difficult to evaluate adequately.

THE SECOND AND THIRD TRIMESTER ULTRASOUND EXAMINATIONS

Fetal Number and Fetal Life

Evaluating the number of fetuses should be extremely easy and accurate in the second and third trimesters. The increased perinatal morbidity and mortality risks of multiple gestations make it mandatory that a "surprise twin" at delivery be a rare event in any patient who has had a second or third trimester ultrasound examination. The major potential error in determining the number of fetuses is one of underestimation. This mistake, when made, is likely due to either not evaluating the fundal region or not making sure that the fetal head is associated with its body rather than that of a twin. When a multiple gestation is identified, it is important to determine the number of placentas and the number of amniotic sacs (the chorionicity and amnionicity).

In the ultrasound report, a statement should be made that the fetus was living, if this was the case, by virtue of cardiac motion being identified. If there is any doubt about fetal life, a confirmatory examination by another examiner should take place. The lack of fetal movement should not be interpreted as representing fetal death. Slow fetal heart rates often portend a poor prognosis; however, this observation alone should not be considered evidence of a nonviable pregnancy. Many cases of fetal heart rates less than 80 beats per minute result in normal outcomes.

Fetal Position

Once fetal life and number have been identified, then the fetal lie and presenting part should be determined in patients beyond 20 weeks of gestation. Fetal lie refers to the relationship of the long axis of the fetus to the long axis of the uterus. Presentation defines the presenting fetal part closest to the cervix. The most common fetal lie is longitudinal, and the most common presenting part is the fetal head. Fetal lie or presentations other than these are referred to as malpresentations. Their significance lies in increased perinatal morbidity during delivery.

The advent of real-time ultrasound evaluation has placed an additional demand on the sonographer. If the sonologist interpreting the scans has not performed the examination, he or she must be able to deduce the lie and presentation from the sonographer's images. This may be done only by understanding the normal fetal anatomy and applying it to the scanning position (Figs. 1-2 and 1-3). Likewise, some congenital anomalies (e.g., dextrocardia, abnormal right-sided abdominal cystic mass) are recognized only fortuitously if a structure is identified as abnormal by virtue of its abnormal position related to the lie and presentation of the fetus.

As mentioned previously, the most common presenting part is the fetal head (cephalic presentation). (We prefer the term *cephalic* rather than vertex because the latter term may also be used to describe a location on the fetal head.) When the head is adjacent to the lower uterine segment, it is likely that the fetus is in cephalic presentation; however, one must see all images before coming to that conclusion. The fetal body may also be low in the uterus with the fetal head, and, thus, the fetus would be in a transverse lie rather than in a cephalic presentation.

Fetal malpresentation requires that the sonographer extend the examination to answer two additional questions important to the referring obstetrician. First, what specifically is the presenting part (i.e., foot, buttocks in the case of a breech presentation, or shoulder in the case of a fetus in transverse lie) (Figs. 1-4 and 1-5)? Second, if a malpresentation persists into the latter third trimester, is there an associated fetal malformation or placental abnormality that may be causally related to the abnormal lie?[56]

Assigning Gestational Age and Weight

The assignment of gestational age and weight is covered in detail in Chapter 6. It is important to remember several concepts when assigning gestational age using ultrasonography. First, measurements made early in pregnancy, for the most part, are more accurate than those made near term. In most cases, the measurements of the fetal head, body, and femur will be concordant with one another, within a week in the early to mid-second trimester. This is often not true in the late third trimester, when the femur may lag behind the other measurements and more variation is common and normal. In the early to mid-second trimester, if the femur or the head measurements are greater than 1 week less than the other measurements, this should raise a red flag and alert one to the possibility of either short-limbed bone dysplasia, trisomy 21, or microcephaly. Follow-up in these cases may be indicated. Second, pathologic states should be taken into consideration when deciding which body parts to use in assigning gestational age or weight. Most ultrasound machines allow the user to eliminate from the gestational age calculation those body parts that are abnormal. The abdominal circumference measurement is likely to be inaccurate in the presence of fetal ascites, and the femur length measurement is unreliable in fetuses with short-limbed dwarfism. Third, every obstetric ultrasound report should relate the calculated sonographic age to the patient's menstrual age or clinical gestational age. Because menstrual histories are frequently inaccurate, there is often a tendency to not believe a woman's menstrual history in deference to the calculated sonographic age. In doing so, however, one runs the risk of assigning an earlier gestational age to a fetus that is in fact older but growth restricted. Likewise, there is the possibility of assigning an earlier gestational age to a pregnancy that is post term, placing the fetus at risk for fetal postmaturity syndrome or in utero death. Fourth, the calculated fetal weight should be stated not only in grams but also as a percentile based on the patient's clinical gestational age or best obstetric estimate. Again, if the patient's menstrual dates are inaccurate, the obstetrician can make the decision not to become alarmed at a reported low-weight percentile. This is far better than misinterpreting a growth-restricted fetus as normal by relating the estimated weight only to the ultrasound-determined age. (Remember that although the formulas are different for the calculations of fetal age and weight, they are based upon the same biometric measurements and when compared to one another will often be near the 50% percentile.) Fifth, if there has been a previous ultrasound examination, there should be some statement in the report as to whether interval fetal growth has been normal or abnormal. Finally, sonograms attempting to assess normal or abnormal interval growth should have an interval of no less than 2 weeks. It may be difficult to determine whether there has been a growth abnormality versus a measurement error if scans are done with a shorter interval.

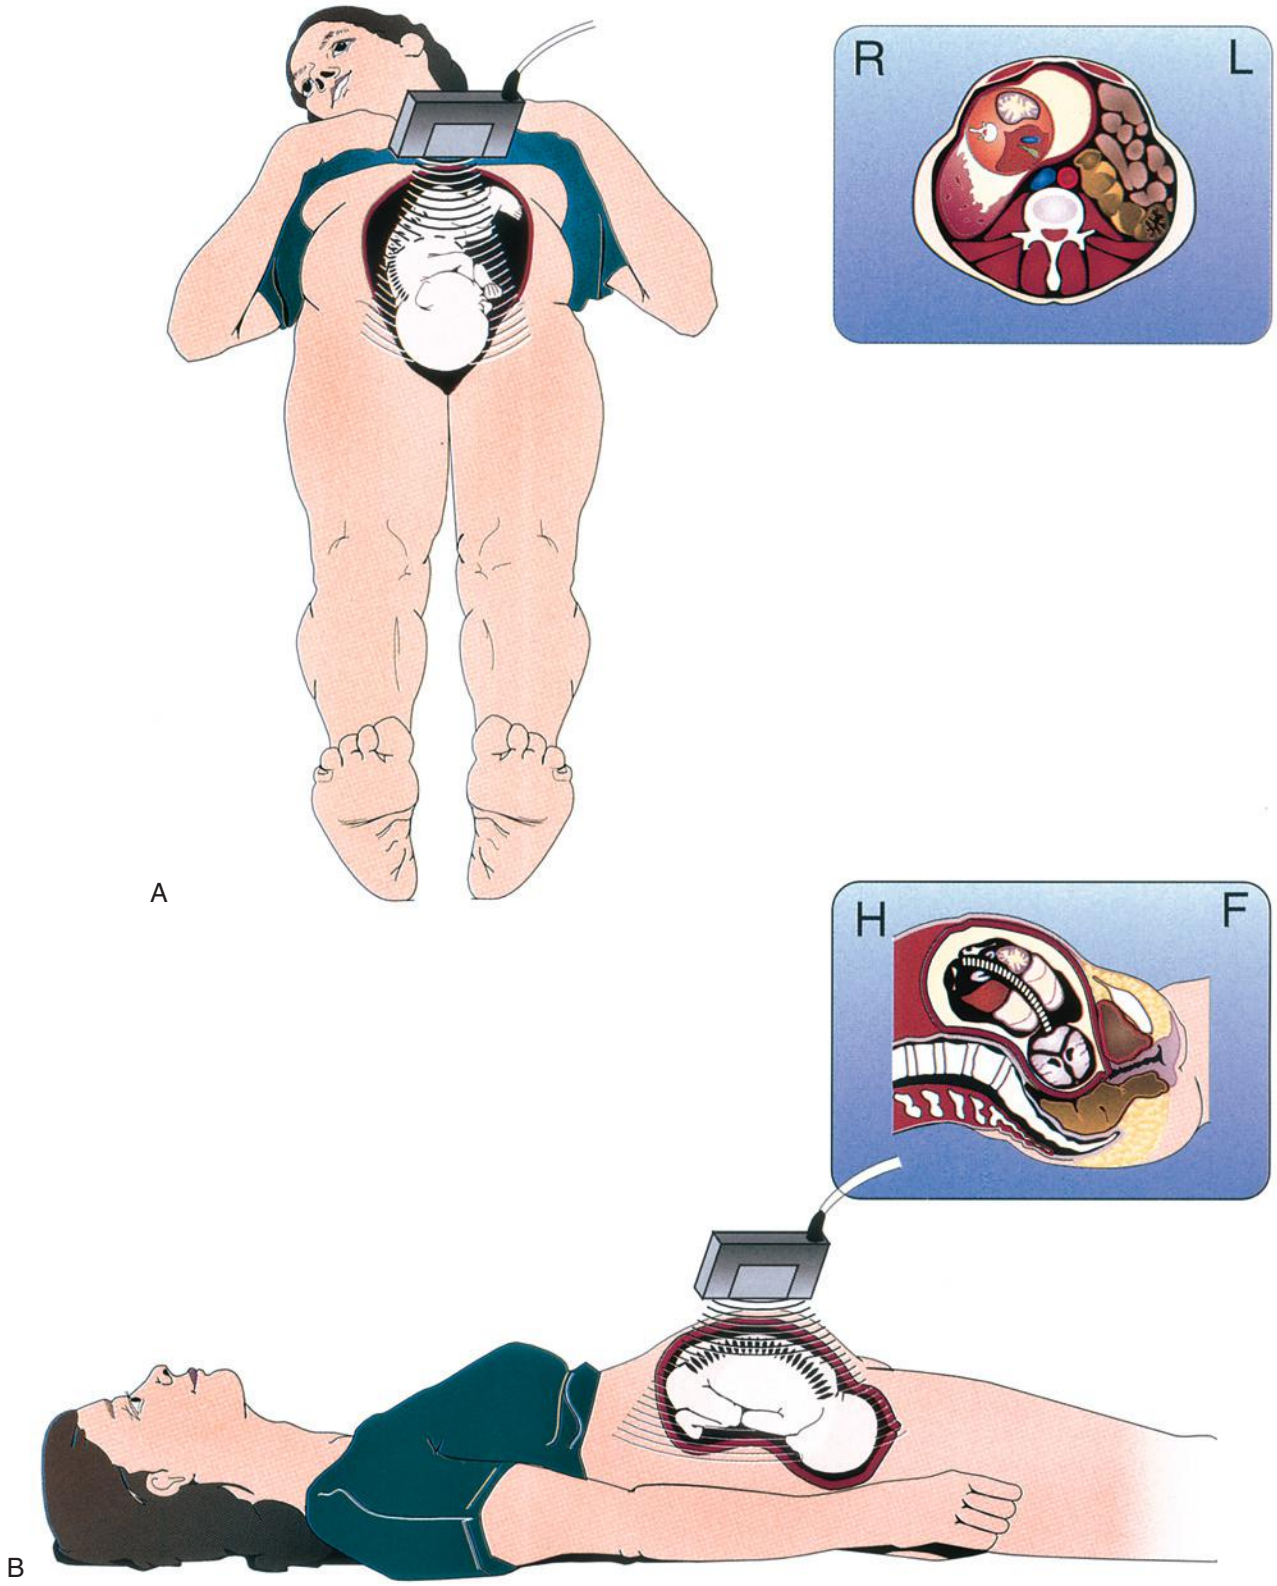

FIG 1-2 **A,** Illustration of a transverse plane of section of the gravid uterus. The fetus is in cephalic presentation, so this scan transects the fetal abdomen transversely. **B,** Longitudinal plane of section of the same fetus. These images are viewed with the maternal head to the left of the recorded image. F, foot; H, head; L, left; R, right.

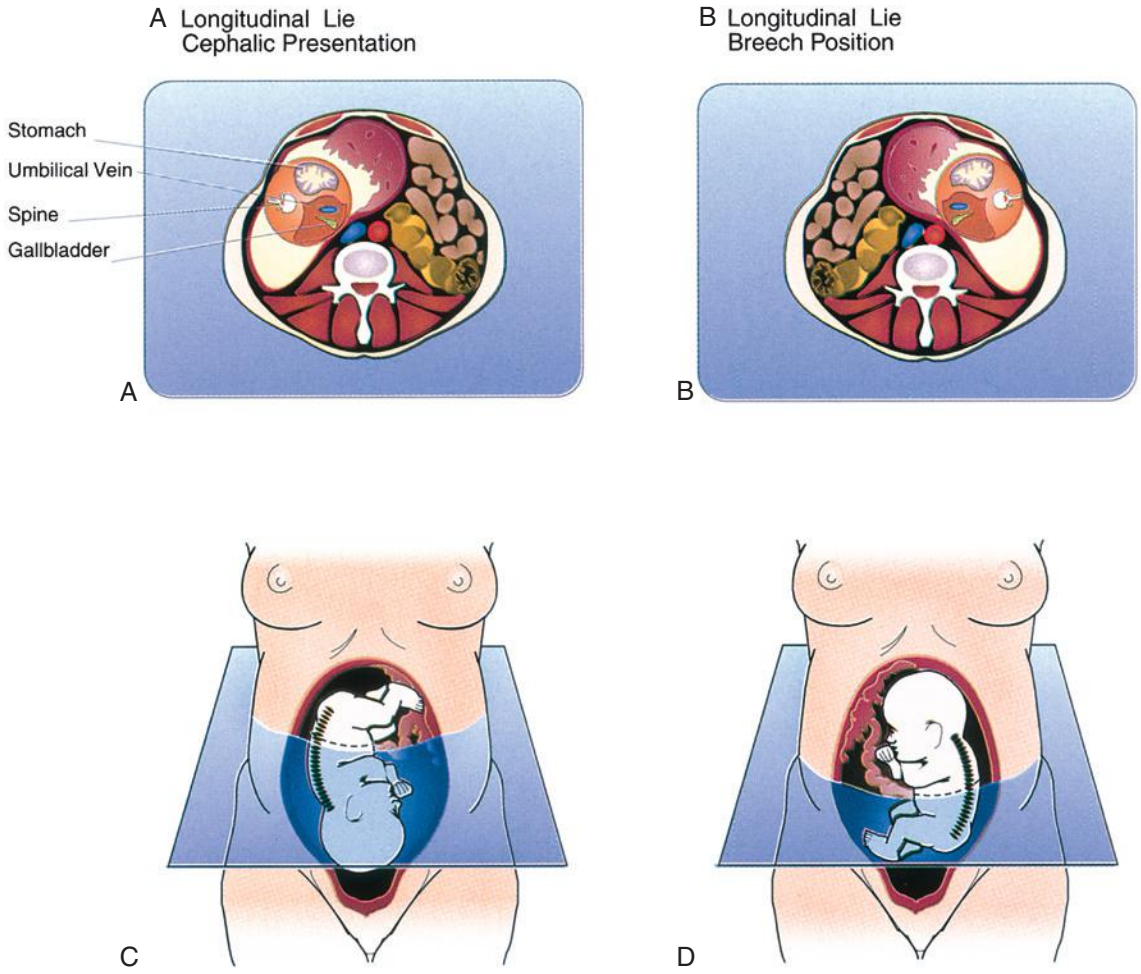

FIG 1-3 Knowledge of the plane of section across the maternal abdomen (longitudinal or transverse) as well as the position of the fetal spine and left-sided (stomach) and right-sided (gallbladder) structures can be used to determine the fetal lie and presenting part. **A,** This transverse scan of the gravid uterus demonstrates the fetal spine on the maternal right with the fetus lying with its right side down (stomach anterior, gallbladder posterior). Because these images are viewed looking up from the patient's feet, the fetus must be in a longitudinal lie and cephalic presentation. **B,** When the gravid uterus is scanned transversely and the fetal spine is on the maternal left, with the right side down, the fetus is in a longitudinal lie and breech presentation. **C,** When a longitudinal plane of section demonstrates the fetal body to be transected transversely and the fetal spine is nearest the lower uterine segment with the fetal right side down, the fetus is in a transverse lie with the fetal head on the maternal left. **D,** When a longitudinal plane of section demonstrates the fetal body to be transected transversely and the fetal spine is nearest the uterine fundus with the fetal right side down, the fetus is in a transverse lie with the fetal head on the maternal right. Although real-time scanning of the gravid uterus quickly allows the observer to determine fetal lie and presentation, this maneuver of identifying specific right- and left-sided structures within the fetal body forces one to determine fetal position accurately and identify normal and pathologic fetal anatomy.

Amniotic Fluid Volume

Amniotic fluid is an important consideration in assessing fetal development and well-being. Although there is relatively good agreement on the significance of extremes of amniotic fluid volume, there remains some controversy over the methodology used to make the diagnosis of either too much or too little amniotic fluid. Amniotic fluid volume should be assessed subjectively at all ultrasound examinations. Although a diagnosis of oligohydramnios and polyhydramnios can be made subjectively, the extremes of amniotic fluid volume should also be assessed objectively using either the DVP or AFI. The ability to assess amniotic fluid volume subjectively at different stages of gestation is readily learned and should not be difficult for most examiners. Two points should be remembered when assessing amniotic fluid volume. First, amniotic fluid volume is large compared with fetal volume at early stages of gestation and should not be misinterpreted as polyhydramnios. Conversely, in term patients, the normal volume of amniotic fluid is quite small so that only small pockets may be seen. Second, patients who are obese often appear to have less than normal volumes of amniotic fluid. This may be due in part to scattering of sound with resultant artifactual echoes within the amniotic fluid.

In making the diagnosis of oligohydramnios, one should remember two points. First, because in many cases, it will imply the likelihood of a fetal renal malformation or severe growth restriction in the absence of ruptured membranes, this diagnosis should be made only when there is almost no amniotic fluid. An exception to this is when there is

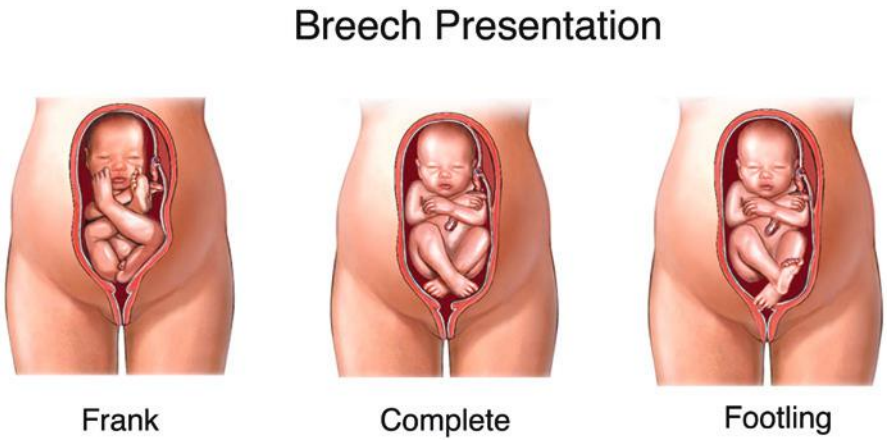

FIG 1-4 Illustration of the types of breech presentation. In a frank breech presentation (the most common), the thighs are flexed at the hips with the legs and knees extended. In complete breech (the least common), the thighs are flexed at the hips, and there is flexion of the knees as well. One or both hips and knees are extended in the footling breech. The risk of cord prolapse is greatest with a footling breech and least with a frank breech. (Illustration copyright © 2006 Nucleus Medical Art, www.nucleusinc.com. All rights reserved.)

FIG 1-5 Longitudinal scan of a footling breech presentation. In this scan, the leg (*arrow*) and foot extend into the lower uterine segment and cervix.

a small amount of fluid in an early or mid-second trimester examination (when normally large amounts of amniotic fluid would be anticipated). Second, because of the association of severe diminution of amniotic fluid in a compromised fetus with ultimate fetal demise, the obstetrician should be alerted immediately if this diagnosis is made, before the patient leaves the ultrasound evaluation area.

The diagnosis of polyhydramnios, although seeming to be less serious, in many cases may in fact be associated with significant complications to the mother and fetus. In the mother, preterm labor and ruptured membranes may occur as a result of polyhydramnios, and in the fetus, fetal anomalies may be present. Although many cases of polyhydramnios ultimately result in a normal fetus, the high number of anomalous fetuses with this condition reported in the literature should alert the sonographer to perform a thorough evaluation when this diagnosis is suggested.[56-58]

Amniotic Fluid Volume in Multiple Gestations

If one looks at a list of causes of polyhydramnios in many obstetric texts, multiple gestations will most likely appear. Although increased amniotic fluid volume may appear in twin gestations, in most cases the cause is some abnormality of pregnancy.[59] Many of these cases are due to twin-twin transfusion syndrome.[60]

Placenta

As mentioned earlier, whenever the placenta is identified in pregnancy, its position and relationship to the cervix should be noted in the interpretation. The literature has emphasized the large number of false positive diagnoses of placenta previa that are made either early in pregnancy or in the presence of an overdistended urinary bladder.[61,62] Although this is true, one must not be lulled into a sense of security in thinking that all low-lying placentas will "go away" and be clinically unimportant. If the placenta is low lying during a second trimester examination, every effort should be made to answer the question as to whether there is or is not a placenta previa; this may require a transvaginal examination. However, if after a variety of maneuvers and transducers (Trendelenburg position, emptying the bladder, translabial or transvaginal scanning) one is still unsure about the relationship of the edge of the placenta to the cervical os, the placenta should be interpreted as low lying, and a placenta previa cannot be excluded. Therefore, these patients should have follow-up examination at 32 weeks of gestation. We prefer to report the distance from the inferior edge of the placenta to the internal cervical os rather than relying on terms that may have differing meanings (e.g., marginal placenta). In patients with a prior cesarean delivery and a placenta previa, the placenta should further be assessed for evidence of placenta accreta, as described in Chapter 19.

Abruptio placentae is a diagnosis that is often difficult to make using ultrasonography. One should remember that the myometrium and its vessels, as well as a transient myometrial contraction, may simulate a hematoma and that these potential false positive diagnoses should be avoided. Because most clinicians are aware that abruptio placentae is a difficult diagnosis, they often refer patients for ultrasound evaluation to exclude a placenta previa rather than to specifically view the abruption. Patients with a true placental abruption may not ever be seen in the ultrasound laboratory and go straight to labor and delivery.

Vasa previa, which is a variation of umbilical cord anatomy rather than a placental abnormality, is a serious and often overlooked condition. It occurs when fetal vessels cross the internal cervical os in an

attempt to reach the main substance of the placenta. Vasa previa can result in fetal exsanguination during delivery and should be suspected in cases of a velamentous cord insertion or a succenturiate lobe of the placenta, as well as in cases of "resolved" placenta previa.

Fetal Malformations

The subject of fetal malformations is among the most emotionally charged issues that either the parents or a diagnostician may have to face. Over time, ultrasound evaluation has undergone a transformation that has allowed us to answer not only the basic question as to whether the patient is pregnant but also whether a fetal anomaly is present. As smaller and smaller abnormalities are identified, the question now becomes what degree of assurance should a patient expect from a report that no anomaly was seen during a routine ultrasound examination. This is a complex issue. To examine every patient for all anomalies would be highly impractical. Fortunately, most major anomalies can be detected as part of a routine evaluation.

Major genetic or structural birth defects affect approximately 3% of infants born in the United States.[63] Congenital malformations are the single leading cause of infant death in the United States, accounting for more than 21% of all infant deaths.[64] In the United States, it has been estimated that 100,000 to 150,000 children are born each year with major congenital malformations, and approximately 8000 of these babies die before completing their first year of life.[64] Children with congenital malformations account for approximately 30% of pediatric admissions, and the total cost of health care is estimated at more than $1.4 billion annually.[64-66]

As was mentioned in the discussion of the first trimester ultrasound examination, fetal anomalies have been described in virtually every organ system at almost every gestational age. There is much controversy as to when a comprehensive scan of a pregnancy should occur. There has been a desire from many to accomplish this task at a time just before an amniocentesis (14 to 16 weeks) or even earlier, at the time of nuchal translucency measurement.[67] In particular, three advantages to earlier anatomic evaluation have been cited: (1) transient abnormalities such as an increased nuchal translucency and echogenic bowel (which may serve as markers for chromosomal and structural abnormalities) may disappear if scanning first occurs after 16 weeks[68]; (2) structures such as the fetal hands may be more readily seen, particularly with fingers extended, earlier than later in pregnancy[68]; and (3) if necessary, termination may be easier to accomplish and safer earlier than later in gestation.[68] Although it is true that many morphologic abnormalities will be detected particularly when using a transvaginal probe, certain abnormalities of the face, heart, and skeleton will not be detected at early gestational ages. Likewise, certain embryologic developmental stages, such as the development of the cerebellar vermis and corpus callosum, are not complete until the mid to late second trimester. If one has the economic luxury of performing several sonographic examinations during pregnancy, a scan at 11 to 14 weeks' gestation followed by a scan at 22 to 24 weeks' gestation might be ideal. It is certainly not unreasonable to exclude gross and potentially lethal abnormalities during the time of the nuchal translucency scan. This would obviously affect the timing of the next scan. However, it is our recommendation, and that of professional organizations (Reddy and coworkers[28]), that if a single ultrasound or a targeted (Level 2) examination is performed, it should be done at a gestational age of 18 to 20 weeks. The reason for this is that the fetus will be of a sufficient size to exclude most abnormalities and still allow time for a follow-up examination, if necessary. The slight loss of accuracy in assigning gestational age at this time is typically of limited clinical significance and is well worth the gain in visibility of fetal anatomy and pathologic malformation.

The patient and the referring obstetrician should be made aware that during the standard ultrasound examination, although many abnormalities may be detected fortuitously, more subtle lesions are likely to be detected only when the fetus is known to be at risk for a specific malformation. Anatomic malformations are likely to grow during pregnancy just as the fetus does; a defect seen at birth may have been too small to be detected earlier in pregnancy. Some lesions, such as duodenal atresia and achondroplasia, may not manifest until late in the second trimester. Finally, it is important for sonologists to know the limits of their expertise. If a malformation is suspected and the examiner has had little experience with the abnormality in question, the case should be referred to a more experienced examiner. Only in this way will patients be served best.

Uterus and Adnexa

Evaluation of the uterus and adnexa becomes more difficult the later in gestation the examination occurs. The most common abnormalities that are likely to be detected are uterine myomas. As stated earlier, it is important to measure the size of the myoma, record the location of the myoma, and define the relationship of the myoma to the cervix. If ovarian abnormalities are suspected, patients should have a postpartum examination.

VERBIAGE USED IN THE AIUM/ACR/ACOG GUIDELINES

The committees and individual members of the AIUM, ACR, and ACOG who helped develop the guidelines described earlier did a remarkable job. It is not easy producing a document such as this that will be widely applicable to ultrasound practitioners. In a few areas in which the words chosen were not clear we would like to give our own suggestions for interpretation.

It is understandable that the guidelines attempted to give the practitioner latitude in requirements for the obstetric ultrasound examination. They attempted to take into account the differences in maternal and fetal anatomy from one patient to the next as well as technical limitations at times. There are a number of instances in which the guidelines state that a structure or structures should be imaged. Unfortunately, additional wording is added that states "when possible" or "can also be attempted" or "when technically feasible." As stated in the editorial mentioned earlier, "One could reasonably state that any of the views defined in the guidelines can only be obtained 'if technically feasible.'" Indeed, the introduction to "Fetal Anatomic Survey" states that one may anticipate technical limitations: "some structures can be difficult to visualize due to fetal size, position, movement, abdominal scars, and increased maternal wall thickness."[28] Adding these additional words, mentioned earlier, gives the examiner a "way out" to not examine important fetal or maternal anatomy. This issue occurs in discussion of the first trimester, when these modifiying statements are made with respect to the cervix and amnionicity and chorionicity in multiple gestations. We do not know of a reason why the cervix cannot be assessed in the first trimester in any patient using a variety of methods available. Chorionicity and amnionicity can best be assessed in the first trimester of pregnancy; although the differentiation of monoamniotic from diamniotic twins may be difficult later in gestation, there is no reason chorionicity cannot be determined at this time. In the extremities section, the legs and arms are mentioned. Medically, this would mean only the tibia/fibula and the humerus. We believe the intent was for the femur, humerus, tibia, fibula, radius, and ulna to be evaluated.

The fetal sex was stated as, "Medically indicated in low-risk pregnancies only for evaluation of multiple gestations." Although we

appreciate the intent, we suggest that it should be noted that fetal sex should also be demonstrated in singleton gestations when medically indicated for diagnosis and counseling. Examples of this type of indication would include hemophilia or distal urinary obstruction, attempting to differentiate posterior urethra valves (predominantly male disorder) from a cloacal abnormality (predominantly female disorder). As for multiple gestations, there are many who would take issue with saying that any multiple pregnancy is low risk. It perhaps would have been better stated that "when chorionicity is difficult to determine in multiple gestation pregnancies, fetal sex determination, when different between the twins, will be helpful in excluding monochorionicity."

For weight determination, a statement is made that "Currently, even the best fetal weight prediction methods can yield errors as high as ±15%." Although we agree with this in concept, we would not have put what appears to be an upper limit on errors in weight estimation. This seems to imply that errors greater than this would be below the standard of care. Particularly in macrosomic fetuses, errors as high as 25% to 30% can be seen from what seemed to be reasonable biometry.

A statement regarding technical difficulties reads: "A second- or third-trimester scan may pose technical limitations for an anatomic evaluation due to imaging artifacts from acoustic shadowing. When this occurs, the report of the sonographic examination should document the nature of this technical limitation. A follow-up examination may be helpful." Although we fully understand this limitation, which all of us have encountered, the recommendation is problematic. There are certain anatomic structures or situations in which the anatomy has to be imaged or an abnormality reported. The statement "follow-up examination may be helpful" is too vague. In far too many cases, failure to visualize normal anatomy was judged to be due to fetal position, when in fact the structure was abnormal. If the brain, heart, or kidneys and bladder (in the presence of oligohydramnios) are not seen, a short-interval follow-up examination should be performed. If failure to adequately visualize the anatomy is a result of maternal body habitus, follow-up in 2 to 4 weeks may be useful. If the structure is still not seen, the referring obstetrician should be notified and the conversation documented. Further follow-up should be recommended as clinically indicated.

INTERPRETATION OF THE ULTRASOUND EXAMINATION

This is, of course, the focus of the remainder of this book; however, we would like to make several comments. Although the subspecialty of obstetric ultrasound seems to attract new biometric applications daily, we have never been much of advocates of the sole use of measurements to achieve a diagnosis. It seems that every day, someone has developed and published a new chart for the measurement of a fetal anatomic structure. We fully recognize that there are many measurements that are necessary for accurate ultrasound interpretation, fetal biometry for size and weight, cervical length, and fetal ventricular size, to name a few. For many of the abnormalities that can be recognized sonographically, we would prefer that the sonologist give more credence to his or her subjective eye than to a measurement when images or individual structures "just don't seem right." Although a measurement may appear to be within normal limits, with experience, there are times when subjectivity, in our opinion, wins out. It is acceptable to say that despite an AFI of 6, there is oligohydramnios or that the fetal bowel appears dilated without an objective measurement of the bowel lumen.

Another pitfall is making a measurement of an anatomic structure and not interpreting the significance of the measurement. For example, some ultrasound laboratories believe that adding numerous measurements, for example, transcerebellar, renal, or intraorbital measurements, in addition to standard biometry (biparietal diameter [BPD], head circumference [HC], abdominal circumference [AC], femur length [FL]), will make the examination more complete. Although we will not argue the necessity of doing these additional measurements in some select cases, what is puzzling is that often the interpreter of the examination will not check these measurements against standard tables or nomograms to determine if they are normal or abnormal. In our opinion, this is a serious mistake.

Without launching into a discussion of statistics, suffice it to say that no measurement will likely be 100% accurate without false positive or false negative results. There are some situations in which false positive results may be acceptable (e.g., screening examinations for a serious abnormality). Every practitioner abhors the notion of being labeled an "over-reader" of examinations. The sonologist needs to consider whether the goal is to not miss any patients with a condition (thus, resulting in more potential false positive results), which may mean additional testing or intervention, or whether they wish fewer false positive results and thus risk missing the detection of an abnormality in some patients. With this in mind, one can set the threshold level for the test, either lower or higher. If the sonologist is calling a referring clinician or scheduling follow-up examinations four to six times a week with a suspected abnormality (pelviectasis, echogenic bowel, and so on), one should perhaps reevaluate the criteria for defining something as abnormal. However, if one calls a referring physician once every 2 to 4 weeks when one is "bothered" by a finding and wishes to call attention to it, one should not feel as if he or she is "over-calling" an abnormality. Likewise, one should not be embarrassed about calling the referring physician about a concern that something might be abnormal even if it ultimately proves to be normal. Only in this way will patients be best served.

Reporting of Ultrasound Results

One would anticipate that this might be the least contentious topic when discussing the obstetric ultrasound examination. However, it is controversial. In concert with recommendations by various organizations (e.g., AIUM, ACR, ACOG) a written report should be produced at the completion of the ultrasound examination and should be placed in the patient's medical records. With widespread implementation of electronic medical records, this report typically uses one of a number of available reporting packages. Such reporting packages have been developed to make reporting easier: they include but are not limited to obstetric worksheets or checklists, computer templates or canned reports, computer voice recognition, digital transcription systems accessed by telephone or computer, and traditional voice dictation that is typed by transcriptionists (on site or remotely). All of these methods have the potential for producing an accurate and readable report. However, in our experience, the easier the reporting method, the more likely that observations made during the examination will not be conveyed accurately. Too often, sonographers and sonologists finish an examination and quickly enter checks into boxes on a worksheet indicating that a particular structure was observed or was normal. It is inconceivable, watching the speed with which the worksheet is completed, that they ever asked themselves the question, Did I really see those structures? Although it is becoming antiquated, conventional dictation systems that require the examiner to pick up the recording device and say "the following structures were seen …" or some similar device or mechanism probably had a better chance of succeeding in conveying accurate information.

There are mixed benefits to templates that contain standard paragraphs such as the following structures were seen: lateral ventricles,

cerebellum, and so on. Although this information may be necessary for reimbursement purposes, it is likely that sonologists or referring physicians rarely read these paragraphs. They also have the potential to be confusing when abnormalities are detected, particularly if the paragraph ends with "and these structures were normal." If one does not alter the paragraph, the referring physician will read in this standard paragraph a sentence that says: "the fetal kidneys were normal" and in the next paragraph a sentence that reads "bilateral fetal hydronephrosis was seen."

It is our practice and recommendation that when fetal abnormalities are detected, the referring physician should be contacted in person or by telephone and the discussion should be documented in the report.

A question often raised concerns what to do when a structure normally seen on routine (basic) sonograms (and listed in the guidelines) is not seen. Or what to do when one identifies a structure that has an unusual appearance but that one suspects is probably normal. Often, it is assumed that failure to see a structure or structures are secondary to technical limitations, such as shadowing or poor fetal position or fetal physiology (the fetus just urinated or fluid in the stomach passed into the duodenum). If the examination is performed in the early second trimester, the patient should return within 2 to 4 weeks for another evaluation. As was mentioned earlier, if a structure in question relates to the heart or brain or kidneys and bladder (when oligohydramnios is present), the study should be considered incomplete. If a follow-up examination is warranted, the referring physician should be contacted and the conversation documented. The rationale for these recommendations is the concern that adequate follow-up and evaluation will not occur, or if they do occur, they will not be performed in a timely fashion. Statements indicating "clinical correlation recommended" are appropriate when the abnormality seen needs to be correlated with patient's medical condition, laboratory tests, family history, and the patient's age, but not when an isolated abnormality is seen (dilated bowel loop).

Discussing the Examination With the Patient

This topic is also controversial. The patient obviously wants to know that the fetus is healthy and to know the results at the time of the examination. As a general rule, the referring obstetrician knows the patient best and also often has important information about the patient's menstrual history, family history, laboratory values, and emotional state. However, the performing sonologist may be more knowledgeable about the significance of a given finding and may be better able to explain the results to the patient and to counsel her effectively. In cases of suspected morphologic or genetic abnormalities, the advice of a reproductive geneticist may prove invaluable. As is discussed later, often the first words that are said to the patient are the things that she remembers. Despite what is said later, it may be difficult to undo what was said initially. It is appropriate to say that the diagnosing physician needs to evaluate all of the images together and possibly compare them with previous studies. At that time, the final report will be generated.

Counseling is often straightforward if the case is normal or when the diagnosis is unequivocally lethal (anencephaly). It becomes more complex in cases in which the outcome is less than 100% certain (e.g., mild isolated ventriculomegaly). It is important not to insert our own bias and values about raising children with disabilities. One cannot assume that if a serious malformation is detected that a patient will desire an abortion rather than to deliver a baby with disabilities. In some cases, the person informing the patient of the results is uncertain of the significance of the findings,[69-71] and the first information the patient hears may be unclear or misleading. This confusion may color how patients perceive later information and may result in dissatisfaction with the bearer of the news.[69,71]

It is often assumed that women weigh equally the risk of delivering a baby with a congenital abnormality versus a procedure-related pregnancy loss (amniocentesis). In fact, studies have demonstrated that most women see the long-term consequences of raising a disabled child as worse than a miscarriage, although women vary widely in this regard.[70] It is important to remember that we do not know better than our patients what is best for them. Our challenge is to help them reach a decision that is best for them given their particular background, experience, and values.

Even when precise and correct information is transmitted in a counseling session, it may not be interpreted with the same intended meaning by the patient. Certain words tend to have more serious and worse connotations to the patient than alternative words.[71] The words "rare abnormality" are often interpreted as serious (even if it is a mild abnormality). The word "abnormality" is often interpreted as worse than a variation of normal. Likewise, technical genetic words often have a worse connotation. "Trisomy" sounds worse to most patients than "an extra chromosome."[71] Choroid plexus cysts (CPCs) and echogenic intracardiac foci (EIF) are discussed in Chapter 3. One should be aware that even if the sonologist firmly believes that the finding of an isolated CPC or an EIF is likely a normal variant and of no consequence, for a patient, the fact that these structures are in the brain and heart is no small matter. The fact that there may not be a significant increased risk in that individual patient based on other findings or that the abnormality is of small size may not alleviate the patient's anxiety once she is told of these findings.

There has been much debate regarding whether physicians should disclose that an isolated sonographic "soft marker" for a chromosomal abnormality has been detected in a fetus in the absence of other risk factors for aneuploidy.[72-74] A 2007 study by Lee and associates[75] found that the detection and communication of isolated aneuploidy markers (CPCs, EIF, renal pyelectasis, echogenic bowel) is associated with increased maternal anxiety and perhaps unnecessary amniocenteses. Their conclusion: "given the amount of maternal anxiety generated with detection of aneuploidy markers, serious consideration should be given to offering pre- and post-ultrasound genetic counseling or otherwise, nothing should be mentioned about ultrasound markers that may be normal variants in patients who have no other risk factors for aneuploidy."[75]

The likelihood of having a normal child when an abnormality is suspected or a patient found to be at increased risk based on screening is almost always received more favorably by the family than being told of the small percentage of having an abnormal child. That is, a 99% chance of normal sounds less worrying than 1% chance of abnormal. When risk is given as a proportion, it often sounds worse than when it is given as a rate; in other words, 1/X sounds worse than X%.[71] One should be aware that a large portion of the public lacks functional knowledge of fractions, large numbers, or percentages.[76,77] In one study,[78] a third of adult women with less than a college education did not recognize that 1/1000 is less than 1%. It is interesting that although in most medical specialties, risk or prognosis is given as a percentage, for example, 10% chance of a cure or bad outcome, in prenatal genetic counseling, risk is often given as a proportion, which most patients do not fully understand. In a study by Grimes and Snively,[76] women of varying ages, education levels, and languages were asked to identify which proportion of bladder infection was higher: 1 in 384 or 1 in 112 persons. The same women were then asked to identify which rate of infection was higher: 2.6 per 1000 women or 8.9 per 1000 women. Overall, 73% correctly identified the higher risk in rate format (X/1000), in contrast with 56% who correctly answered the same

question framed as proportions (1/X).[76] Clearly, women understood rates better than proportions.

Perhaps the most important point of this discussion is what to do when a slight variation of normal or an unusual finding is seen. The first answer would be to consult your colleagues. If that does not answer the question, then one should discuss the case further with more experienced experts or refer the patient to a university or specialty center. In some cases, one will simply need to report that there is a finding and that you are uncertain of the significance. When the physician feels pressure to always give a black and white, or normal versus abnormal, answer without honest indecisiveness, this approach does a disservice to the patient.

Evaluating the Obstetric-Gynecologic Ultrasound Literature

Whereas this text serves as a reference to many, as an aid to ongoing clinical problems, new and useful clinical information is reported constantly in the medical literature. It is appropriate that the reader keep current with new advances. It is also important to be vigilant for poorly constructed studies and conclusions. Although virtually every report will have some mention of the sensitivity and specificity of a new test, this is only a small part of an adequate analysis of the utility of a new technique. There are a number of areas that should be considered when evaluating a new report in the literature; these areas are outlined in Table 1-3.[79] Perhaps the most common error is that authors do not state the prevalence of "disease or abnormality" in their population or that readers do not take this into account when applying the report to their own practice. This also holds true for both equipment and techniques used for analysis.

When the authors discuss a new technique or potentially helpful finding, it is invariably depicted in their first figure (i.e., Fig. 1-1). If after looking at Figure 1-1 in the new publication, as well as its legend and text description, the reader does not understand what is being demonstrated, the publication is likely to be of little value in clinical practice.

TABLE 1-3 Evaluating the Literature

Abstract
What are the objectives, findings, and conclusions of the study?

Introduction
What is the purpose of the diagnostic test?

Materials and Methods
How are the patients selected?
Are they representative of those who are ordinarily tested?
How is the test(s) performed and interpreted?
Are the interpretation criteria well defined and reproducible?
What is the gold standard for diagnosis? Is it appropriate?
Are the sonologists blinded from the final diagnosis and is the final diagnostician (pathologist) blinded from sonographic interpretation?
Is the gold standard applied uniformly?
In a comparison study, are the tests evaluated fairly?

Results
How is the accuracy reported?
Are the spectrum of disease and important covariates, such as comorbidity, age, sex, and body habitus, accounted for in tabular presentation of data?
Is the statistical analysis clearly described and appropriate?

Discussion
Are the deficiencies in the methodology of accuracy assessment acknowledged and discussed?
Are other relevant factors, such as disease prevalence, therapeutic effectiveness, and cost, adequately accounted for in the clinical recommendations?

Malpractice and the Obstetric Ultrasound Examination

It is likely that each person reading this text has been touched in some way by the ongoing malpractice crisis. For most of us, this crisis has resulted in increased costs of goods and services, and for some, it has meant being the defendant in a malpractice suit.

Medical malpractice actions typically arise from a patient's allegation of negligent diagnosis or treatment. In order to prevail, the patient must show that the physician fell below the applicable standard of care. Standard of care is established most commonly by the testimony of an expert witness. Although guidelines promulgated by various organizations (AIUM, ACR, ACOG) alone do not establish the standard of care introduced at trial, they do describe the general practice of obstetric ultrasound in many communities and are often referred to by medical experts.[80] The definition of standard of care varies slightly from state to state. California's instruction to juries regarding standard of care in medical malpractice cases is listed here:

CALIFORNIA CIVIL JURY INSTRUCTIONS (CACI)

501. Standard of Care for Health Care Professionals

[A/An] [*insert type of medical practitioner*] is negligent if [he/she] fails to use the level of skill, knowledge, and care in diagnosis and treatment that other reasonably careful [*insert type of medical practitioners*] would use in the same or similar circumstances. This level of skill, knowledge, and care is sometimes referred to as "the standard of care."

[You must determine the level of skill, knowledge, and care that other reasonably careful [*insert type of medical practitioners*] would use in the same or similar circumstances, based only on the testimony of the expert witnesses [including [*name of defendant*]] who have testified in this case.]

Data on the number of claims of malpractice and their settlements are difficult to obtain. In one report, Sanders[78] reported malpractice claims in diagnostic ultrasonography in 228 cases. Obstetric ultrasound examinations represented the majority (78%) of the cases.

Some of the more common reasons for the initiation of malpractice suits (whether legitimate or not) include the following:

- Unreasonable expectations of the ultrasound examination on the part of the patient and the referring physician
- Physician performing the examination having inadequate training or equipment
- Failure to seek consultation in difficult cases
- Inadequate or incomplete study
- Misinterpretation of the ultrasound examination (resulting in the inability to terminate before the legal state limit, a wrongful termination, or preterm or postterm delivery)
- Poor communication with referring clinicians (improper wording, lack of timely communication)
- Failure to maintain ultrasound equipment
- Failure to supervise personnel adequately

It is our desire that this text, through the education process of the sonographer and sonologist, will help alleviate errors in diagnosis

and thus reduce the number of these cases. Unfortunately, despite the best medical care, some malpractice suits are brought against physicians.

CONCLUSION

The appeal of the ultrasound examination is that it is a noninvasive, safe procedure that has a high degree of patient acceptance and can yield a wealth of information. It is always a delight to examine the obstetric patient and reassure her about her pregnancy, when appropriate.

When a pathologic process is first identified, the role of the sonologist is that of a detective who attempts to piece together all of the information to arrive at the correct diagnosis (Fig. 1-6). Although discovering a pathologic process is always disconcerting, the sonologist can be a counselor to the patient and the clinician and can help guide them to appropriate management decisions. However, there are times when an abnormality is strongly suspected but it may be equivocal or may not fit into a specific category. Under these circumstances, the best pathway for the sonologist to follow may be to do a follow-up examination and seek consultation. If time does not allow a follow-up examination, then the sonologist should communicate to the referring physician and the patient that a definitive answer is not possible and that decisions will have to be made with less-than-perfect information.

We are hopeful that this text will serve two purposes: to educate and to excite. If those reading this text maintain the same enthusiasm

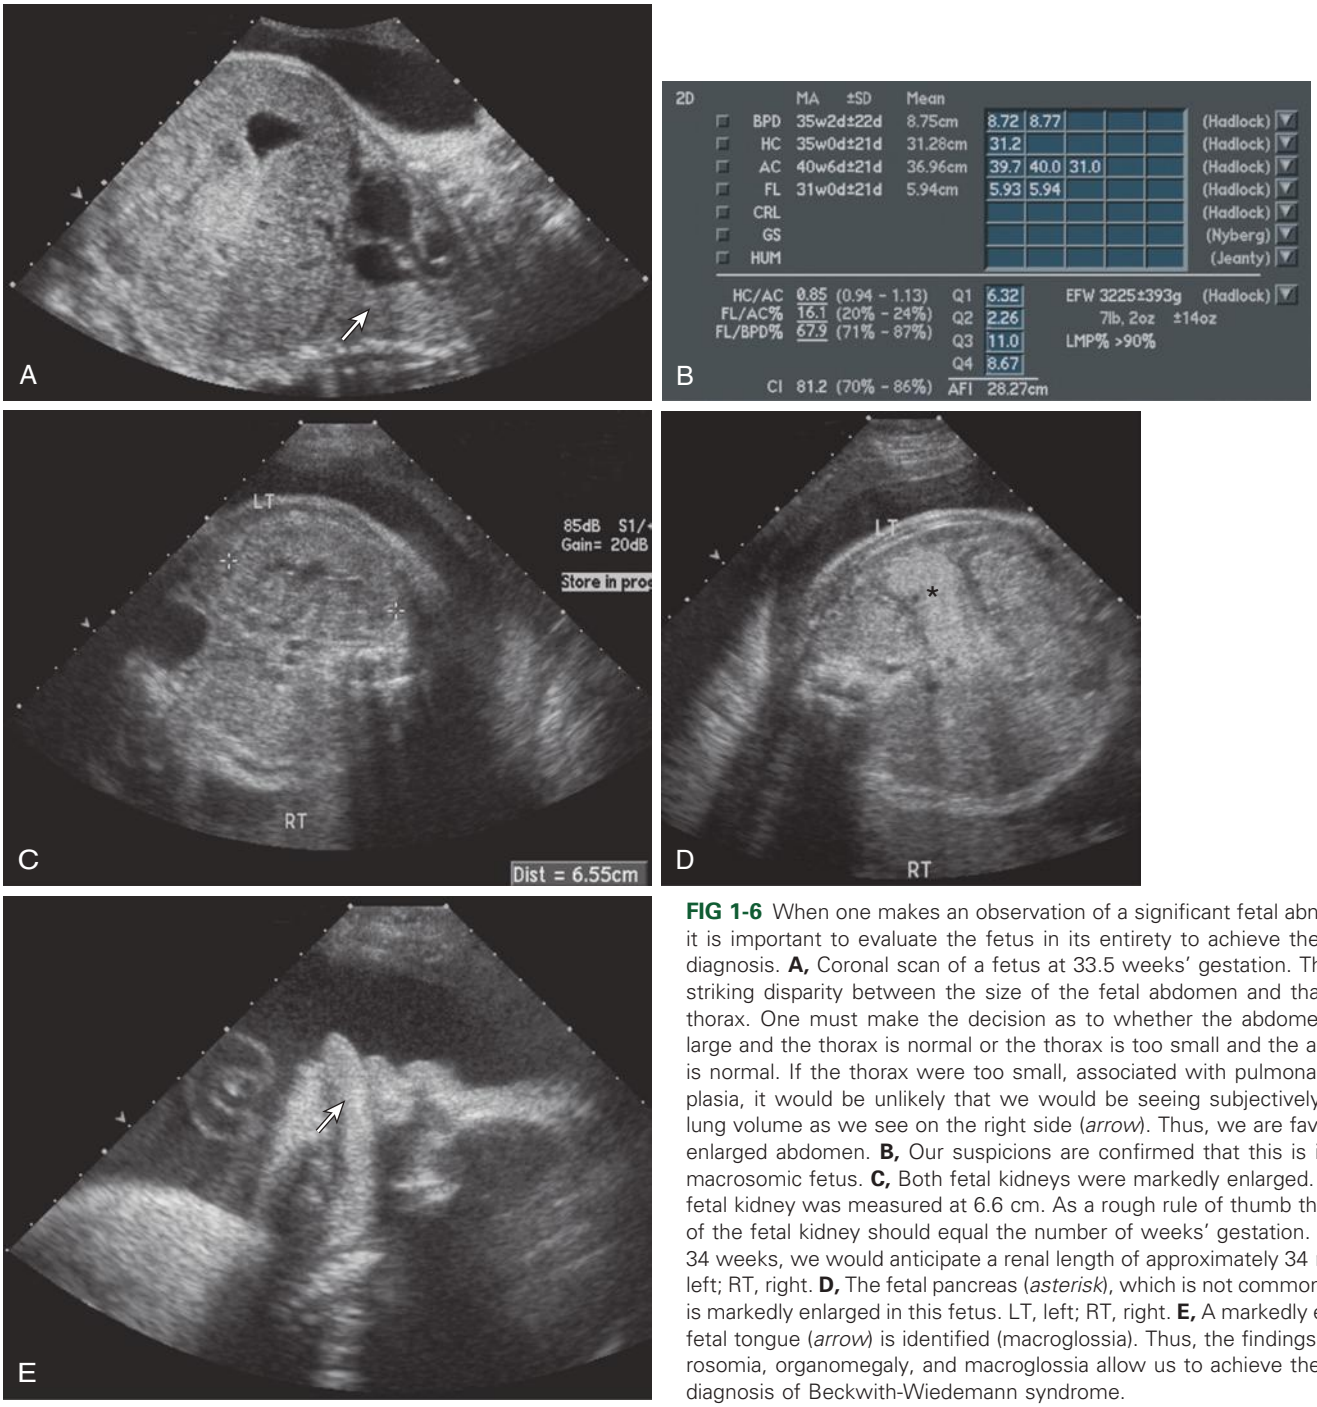

FIG 1-6 When one makes an observation of a significant fetal abnormality it is important to evaluate the fetus in its entirety to achieve the correct diagnosis. **A,** Coronal scan of a fetus at 33.5 weeks' gestation. There is a striking disparity between the size of the fetal abdomen and that of the thorax. One must make the decision as to whether the abdomen is too large and the thorax is normal or the thorax is too small and the abdomen is normal. If the thorax were too small, associated with pulmonary hypoplasia, it would be unlikely that we would be seeing subjectively normal lung volume as we see on the right side (*arrow*). Thus, we are favoring an enlarged abdomen. **B,** Our suspicions are confirmed that this is in fact a macrosomic fetus. **C,** Both fetal kidneys were markedly enlarged. The left fetal kidney was measured at 6.6 cm. As a rough rule of thumb the length of the fetal kidney should equal the number of weeks' gestation. Thus, at 34 weeks, we would anticipate a renal length of approximately 34 mm. LT, left; RT, right. **D,** The fetal pancreas (*asterisk*), which is not commonly seen, is markedly enlarged in this fetus. LT, left; RT, right. **E,** A markedly enlarged fetal tongue (*arrow*) is identified (macroglossia). Thus, the findings of macrosomia, organomegaly, and macroglossia allow us to achieve the correct diagnosis of Beckwith-Wiedemann syndrome.

for obstetric and gynecologic sonography that we have, we will have fulfilled our goal.

Genetics and Prenatal Genetic Testing

Mary E. Norton, Britton D. Rink

SUMMARY OF KEY POINTS

- In the population, 2% to 3% of newborns have a congenital malformation or genetic disease identified at birth.
- Despite advances in genetics, the cause of more than half of human congenital abnormalities remains unknown.
- Chromosomal abnormalities are present in about 0.9% of newborns and include abnormalities of chromosome number as well as abnormalities of chromosome structure.
- The embryo is most sensitive to teratogenic effects between 3 and 8 weeks of development.
- Current available tools for fetal aneuploidy screening include cell-free DNA screening, various forms of multiple marker screening with first and second trimester maternal serum analytes, and ultrasound measurements, including nuchal translucency.
- The prevalence of many single gene disorders varies with race and ethnicity, and testing is often recommended based on an individual patient's background.
- Expanded carrier screening, including panels to simultaneously test for a large number of genetic conditions, is increasingly utilized for prenatal genetic screening.
- Chorionic villus sampling (CVS) and amniocentesis are both routinely used for prenatal diagnostic testing and can provide tissue for such tests as fluorescence in situ hybridization (FISH), karyotyping, chromosomal microarray analysis (CMA), and DNA-based tests.
- The loss rate attributable to CVS and amniocentesis is estimated to be between 1/500 and 1/1000 and decreases with provider experience.
- Many structural fetal abnormalities are associated with an increased risk of aneuploidy as well as copy number variants detectable with chromosomal microarray.

OUTLINE

Genetic diseases are often perceived to be so rare that the average practitioner will seldom encounter them. However, increasing knowledge and technologic advances in genetic testing have demonstrated that this is far from the case. The availability of prenatal diagnosis for a wide range of disorders continues to increase with advances in genetics. In addition, progress has been made in population screening tests to identify couples who carry a genetic disorder. New techniques, such as cell-free DNA screening, have also changed the field of prenatal diagnosis significantly. These improvements in prenatal screening and diagnosis mean that many more at-risk couples are able to have unaffected children. In addition to reproductive choice, carrier screening and fetal diagnostic testing afford the important opportunity for preparation of the family and the delivery site for the birth of a fetus with a known genetic disorder.

Ultrasound plays a central role in the provision of prenatal screening and diagnosis. Not only is ultrasound key to guiding prenatal diagnostic procedures, but also integration of a genetics-based prenatal diagnosis program has been shown to increase the accuracy of diagnosis when compared to ultrasound alone.[1] This chapter includes a discussion of genetics, with an emphasis on recent advances relevant to prenatal diagnosis and a description of current strategies for genetic testing with a focus on how genetic screening and sonography together contribute to the provision of accurate and precise prenatal diagnosis.

Genetics and Birth Defects

According to most studies, 2% to 3% of living newborns have a congenital malformation.[2] When considering birth defects noted in the first years of life, this incidence is nearly doubled. With the decline in infant mortality in the United States from infection and malnutrition, congenital malformations are now a leading cause of infant death (>20%) and are responsible for greater than 30% of intensive care nursery admissions.[3] Congenital defects range from enzyme deficiencies caused by single gene mutations to complex associations of structural defects. The continuum between purely biochemical abnormalities and structural birth defects includes disorders of structure, function, metabolism, and behavior.

Birth defects result from the interaction between the genetic makeup of the embryo and the environment in which it develops. The basic developmental information is encoded in genes, but the genotype is subjected to environmental influences that can impact the observed phenotype. In some cases, the genetic information is expressed regardless of environment, whereas in others, environmental causes interfere with normal development despite a normal genotype. Although some processes are primarily environmental and others mainly genetic, the distinctions between the two are not perfect.

Despite considerable advances and research over past several decades, the cause of more than half of human congenital abnormalities remains unknown. Of those with a recognized cause, approximately 15% to 20% are autosomal genetic diseases and 20% are cytogenetic in origin. Fewer than 1% of anomalies are thought to result from teratogenic medications. Some of the remaining defects are associated with other environmental exposures during pregnancy, including infectious agents (3%), maternal disease states (4%), mechanical problems (1% to 2%), irradiation, and unknown environmental causes. The remainder are of unknown or complex causes (multifactorial, polygenic, spontaneous errors of development, and synergistic interactions of teratogens) (Fig. 2-1).[3,4]

Developmental Disorders: Causes, Mechanisms, and Patterns

Errors in morphogenesis are often classified by dysmorphologists according to the underlying pathogenesis (Fig. 2-2). *Malformations* are defects in the structure of an organ resulting from a specific primary abnormality of development, such as a congenital heart or neural tube defect (NTD). *Deformations* are abnormalities of form, shape, or position caused by mechanical forces such as intrauterine molding or constraint. Factors leading to deformations may be extrinsic (e.g., oligohydramnios owing to ruptured membranes) or intrinsic (e.g., oligohydramnios owing to renal agenesis). Deformations may also occur postnatally; for example, an infant may develop a flat head from sleeping in one position. A *disruption* is a morphologic defect that results from breakdown of previously normal tissue. Disruptions can be due to extrinsic forces, internal interferences with a developmental process, or vascular insults. Examples of disruptions include amputations owing to amniotic bands, and gastroschisis and porencephaly, both thought to result from in utero vascular insults.

A *sequence* is a pattern of multiple abnormalities resulting from a single primary anomaly or mechanical factor; it may be a malformation, deformation, or disruption. An example is Potter sequence, in which oligohydramnios from any cause leads to similar features of fetal compression: characteristic facial features and abnormal positioning of the hands and feet. A *syndrome* is a pattern of multiple abnormalities known to have a common, specific cause. An example is Down

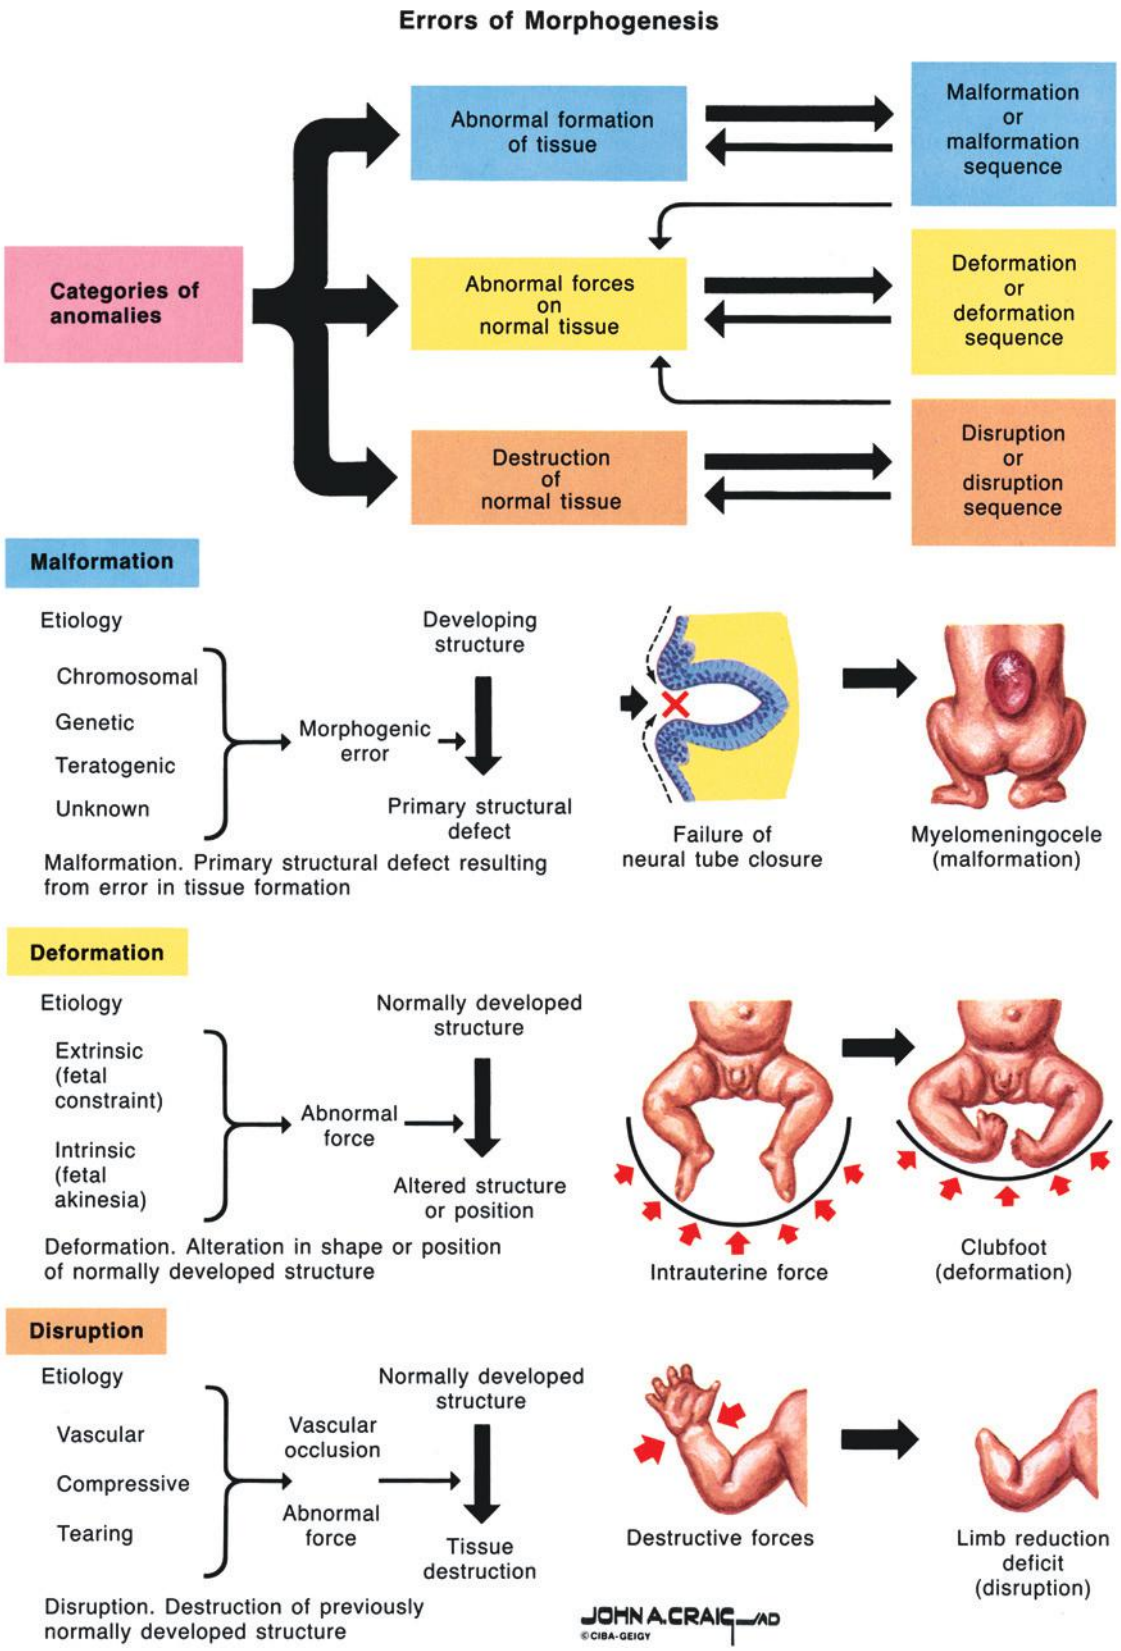

FIG 2-2 Errors of morphogenesis. For further explanation, see text. (From Nyhan WL: Structural Abnormalities: Clinical Symposia. CIBA-GEIGY, Vol. 42, No. 2, 1990, Plate 1, used with permission.)

syndrome (DS), which is caused by the presence of an extra copy of chromosome 21. Finally, the term *association* is used when two or more features occur together more commonly than expected by chance alone but for which no cause has been demonstrated. A common example is VACTERL association (Vertebral defects, Anal atresia, Cardiac defects, Tracheoesophageal fistula with Esophageal atresia, Renal anomalies, and Limb anomalies). This term does not imply a specific underlying cause but rather prompts the search for specific other defects when one component of the association is identified.

CHROMOSOMAL DEFECTS

Chromosomal abnormalities occur in approximately 0.9% of newborns, and it is estimated that at least 10% to 15% of conceptions are chromosomally abnormal. Chromosome abnormalities are the leading cause of pregnancy loss, and at least 95% of chromosomally abnormal conceptions are lost before term. Abnormalities seen in abortuses differ from those seen in liveborn infants because the most severe chromosome abnormalities result in early arrest of development, whereas less severe abnormalities yield milder phenotypes that allow survival until later in pregnancy or even live birth. The most common abnormalities seen in first trimester spontaneous abortions are 45,X and 47,+16 (trisomy 16). Full or complete trisomy 16 is never seen in live births, whereas fewer than 1% of conceptions with 45,X survive until term.

Chromosome abnormalities can be either numeric or structural. They can involve one or more autosomes (chromosomes numbered 1-22), sex chromosomes, or both simultaneously. *Aneuploidy* refers to the presence of an abnormal number of chromosomes and is almost always associated with abnormalities of physical and cognitive development. *Translocations*, the exchange of segments between nonhomologous chromosomes, are relatively common and can be balanced, in which the appropriate amount of chromosomal material is present but rearranged, or unbalanced, in which some chromosomal material is gained or lost. Individuals with a balanced translocation are most often phenotypically normal unless the break for the rearrangement occurs in a critical gene and disrupts its function. Those with an unbalanced rearrangement most often have some phenotypic consequence including intellectual disability and structural birth defects as a result of being trisomic for one segment and monosomic for another. Many autosome translocations are unique, with some variation in expression of the additional or missing genetic material. A *Robertsonian translocation* is a rearrangement that involves any of the five acrocentric chromosomes, namely, 13, 14, 15, 21, and 22. The incidence of balanced Robertsonian translocations in the general population is 1/1000 and confers a higher risk for the relevant trisomies (most commonly trisomy 21 and 13) in offspring of balanced carriers. Balanced carriers are phenotypically normal and often only become aware of the rearrangement when they experience pregnancy with an abnormal karyotype, recurrent miscarriages, or male infertility.[5]

Abnormalities of Chromosome Number

Aneuploidy is the most common clinically significant type of human chromosomal abnormality and occurs in 3% to 4% of recognized pregnancies. Nondisjunction in mitosis or meiosis is the cause of most aneuploidies. Maternal meiotic nondisjunction is known to increase with maternal age, and therefore the risk for aneuploid offspring also increases with advancing maternal age (Table 2-1). Both trisomy, the presence of three copies of an individual chromosome, and monosomy, the presence of a single copy of a chromosome, typically have significant phenotypic consequences. Monosomy is seen less frequently than trisomy because this situation is generally not compatible with life. Trisomy or monosomy for any chromosome can occur theoretically, but in practice, some are seen much more frequently than others (Table 2-2). This is because most aneuploidies are incompatible with life, and aneuploid embryos spontaneously abort very early in gestation. Some chromosome abnormalities, for example, trisomy 8, are seen at birth only in mosaic form, and the full trisomy is likely lethal. *Mosaicism* is defined as the presence of two different cell lines with different genotypes in the same individual. Mosaicism is not always deleterious but can result in an abnormal phenotype depending on the degree and type of affected tissue. An entire extra set or sets of chromosomes, polyploidy, is also possible but is not compatible with long-term survival.

TABLE 2-1 Risk of Chromosomal Abnormalities in Liveborn Infants

Maternal Age (Years)	Risk for Down Syndrome	Total Risk for Chromosomal Abnormalities*
20	1/1667	1/526

Trisomy 21

The most common aneuploidy detected at birth is trisomy 21, which occurs in approximately 1/700 live births (Fig. 2-3). Trisomy 21 occurs as a result of maternal nondisjunction during meiosis in 95% of cases of DS; the remainder of cases is due to translocations involving

TABLE 2-2 Population Frequency of Specific Chromosomal Disorders

Disorder	Frequency per 1000 Live Births*
Trisomy 21	1.5
Trisomy 18	0.12

chromosome 21. Karyotype analysis from the affected individual can differentiate between nondisjunction and translocation causes. Individuals with DS from either cause have a characteristic phenotype that includes distinctive facial features including midface hypoplasia and upslanting palpebral fissures, short stature, brachycephaly, a short neck with redundant skin on the nape, short broad hands with a single transverse palmar crease, and hypotonia. Other findings include intellectual disability, an increased risk for acute myeloid leukemia in the first 3 years of life, and thyroid dysfunction. Congenital heart defects (CHDs) are reported in 44% to 58% of affected newborns and are important contributors to morbidity and fatality.[6,7] Other structural birth defects associated with this diagnosis include hydronephrosis and duodenal atresia.

The recurrence risk of trisomy 21 (or other autosomal trisomies) is approximately 1% after one such child with nondisjunction-related aneuploidy is born to a couple. Although often requested, there is no indication for parental chromosomal evaluation after the birth of a child with trisomy 21 unless it is due to a translocation. A history of DS elsewhere in the family does not increase the risk of having a child with a chromosome abnormality, provided there is no familial translocation.

Trisomy 18

Trisomy 18 occurs in about 1/8000 live births but is much more common at conception, with about 95% of such cases resulting in spontaneous abortion or stillbirth. Postnatal survival is poor, and the majority of liveborn neonates dies in early infancy. Characteristic findings include cardiac malformations, severe intellectual disability, growth restriction, a prominent occiput, dolicocephaly, small mandible, short sternum, clenched hands with overlapping digits, and rocker-bottom feet. Choroid plexus cysts are identified more frequently in this population, although most fetuses that demonstrate choroid plexus cysts are not aneuploid.

Trisomy 13

Trisomy 13 occurs in about 1/20,000 live births. There is a high stillbirth rate among pregnancies with this diagnosis, and those who are liveborn typically die in early infancy. The phenotype includes midline defects including severe central nervous system (CNS) malformations such as holoprosencephaly, severe intellectual disability, growth restriction, cleft lip and palate, microphthalmia, omphalocele, polydactyly, clenched hands with overlapping digits, CHDs, and renal abnormalities such as polycystic kidneys.

Turner Syndrome (45,X)

Although monosomy for an entire chromosome is almost always lethal, an important exception is monosomy X (45,X), which results in Turner syndrome. Turner syndrome is estimated to occur in 1% to 2% of all conceptions, but most end in miscarriage, resulting in a frequency of 1/2000 to 1/3000 live births. Females with Turner syndrome have a characteristic phenotype, which includes short stature, webbed neck, peripheral lymphedema at birth, CHDs, and renal abnormalities. Other features include ovarian dysgenesis with failure to develop secondary sexual characteristics and associated infertility. Prenatally, fetuses with Turner syndrome often have an increased nuchal translucency or cystic hygroma, lymphangiectasia, structural renal abnormalities, and CHDs, particularly left-sided obstructive lesions such as coarctation of the aorta. Females with Turner syndrome usually have normal intelligence, although they may have specific learning disabilities.

The chromosomal abnormalities that cause Turner syndrome vary. Only about 50% of patients have a nonmosaic 45,X karyotype. Approximately 30% to 40% of cases involve mosaicism, most commonly 45,X/46,XX or 45,X/46,XY. Patients with a Y chromosome may have ambiguous genitalia and are at risk for development of gonadoblastoma in their dysgenetic gonads. Structural abnormalities of the X chromosome are seen in 10% to 20% of cases and often involve mosaicism. The fact that these patients have more than one cell line can account for the variability in phenotype of individuals affected with Turner syndrome. Unlike the other diagnoses discussed, the nondisjunction that most often results in Turner syndrome is paternal in origin and is not associated with the age of either parent. There is no increased risk in subsequent pregnancies for another fetus with a chromosome abnormality.

Klinefelter Syndrome (47,XXY)

Klinefelter syndrome (47,XXY) occurs in about 1/1000 male births and is a common cause of primary hypogonadism. Men with Klinefelter syndrome tend to be tall, with long arms and legs. They have small testes and are sterile owing to atrophy of the seminiferous tubules. Gynecomastia occurs in about 30%. There is an increased risk for learning disabilities, with intelligence quotient (IQ) about 10 to 15 points below that of unaffected siblings, although men with Klinefelter syndrome do not usually have significant intellectual disability. Because

the disorder is often subtle, men are often first diagnosed in infertility clinics. This condition is typically not identified by prenatal ultrasound findings because it is not associated with structural birth defects. In the prenatal setting, Klinefelter syndrome is most commonly incidentally identified by diagnostic testing done during pregnancy for another indication.

Triploidy

Triploidy is a type of polyploidy and is defined as an entire extra set of chromosomes (69 chromosomes per cell). Triploidy is generally a lethal condition and is rarely reported in live births. Of those fetuses with triploidy who are liveborn, the longest reported survivors have lived to less than 1 year of age.[8] Congenital abnormalities seen in triploidy include micrognathia, prominent forehead, relative macrocephaly, low-set malformed ears, microphthalmia, hypertelorism, cleft lip and palate, omphalocele, syndactyly, and asymmetric development.

The extra chromosome set in triploid pregnancies can be of either maternal or paternal origin. Maternally derived triploidy results from fertilization of a diploid ovum by a haploid sperm and can involve either an XXX or XXY karyotype. Paternally derived triploidy can result from fertilization of a haploid ovum by either a diploid sperm or by two haploid sperm and can have either an XXX, XXY, or XYY karyotype.

The phenotype of triploid pregnancies depends on the parental source of the extra chromosome set. Triploids with an extra set of paternal chromosomes have a well-formed fetus with an abnormal placenta and may result in partial hydatidiform moles. By definition, all partial molar pregnancies are triploid but not all triploid fetuses have a molar placenta. Those with an extra set of maternal chromosomes usually have a small, growth-restricted fetus and a small, noncystic placenta.[9-11]

Abnormalities of Chromosome Structure

There are many types of abnormalities of chromosome structure, but all generally result from chromosome breakage, followed by recombination in an abnormal configuration. Overall, structural chromosome abnormalities occur in about 1/375 newborns. Reciprocal translocations involve an exchange of segments between nonhomologous chromosomes. These rearrangements are relatively common and can be balanced (that is, the appropriate amount of chromosomal material is present), typically resulting in a normal outcome, or unbalanced, in which some chromosomal material is gained or lost, therefore resulting in an abnormal outcome. There is an increased risk of unbalanced rearrangements in the offspring of people who carry balanced translocations, thereby leading to decreased fertility and an increased risk of offspring with structural malformations or intellectual disability.

A robertsonian translocation occurs when the long arms of two acrocentric chromosomes (chromosomes 13, 14, 15, 21, and 22) are fused and the corresponding two short arms are lost. Because the short arms of these chromosomes do not contain essential genetic material (they are made up of multiple copies of ribosomal RNA genes), the loss of this material does not result in an abnormal phenotype in a balanced robertsonian translocation carrier. The phenotype of an unbalanced robertsonian translocation is either miscarriage or a child with a trisomic condition such as trisomy 21 or trisomy 13 from the additional material. The most common robertsonian translocation involves chromosomes 14 and 21 and is responsible for about 5% of cases of DS. The recurrence of translocation DS depends on whether the translocation was inherited from a carrier parent. In 75% of cases, the translocation is de novo, and the recurrence risk is very low (<1%). If the translocation was inherited from a parent who carries a 14;21 balanced translocation, there is a 10% chance of recurrence if the mother is the carrier and about a 2% chance if the father is the carrier.

When a balanced translocation or other rearrangement is identified in a fetus at the time of prenatal diagnosis, testing of the parents is recommended. If the translocation was inherited from a phenotypically normal parent, the fetus would be predicted to be normal. If a reciprocal translocation occurs as a de novo event, there is approximately a doubling of the background risk of phenotypic abnormality. This is thought to be due to subtle, undetected chromosomal imbalance or disruption of genes at the breakpoint(s).

TABLE 2-3 Common Microdeletion Syndromes

Syndrome	Location	Frequency
Prader-Willi	15q11-13	1/10,000-1/30,000

Retinoblastoma	13q14.2	1/15,000-1/20,000

*Wilms tumor, aniridia, genitourinary anomalies, retardation.

Other Types of Chromosomal Rearrangements

In addition to translocations, there are several other types of unbalanced chromosomal rearrangements. These types include *deletions*, which occur with the loss of a chromosome segment, resulting in partial monosomy. Such deletions can involve one or many genes and are responsible for a number of clinically distinct microdeletion syndromes (Table 2-3). One of the most common is the 22q deletion syndrome, which occurs in about 1/4000 live births. The 22q deletion is a relatively common cause of CHDs, particularly conotruncal abnormalities, such as truncus arteriosus and tetralogy of Fallot. Other features include cleft palate, velopharyngeal incompetence, renal malformations, characteristic facial features, immune deficiency, hypocalcemia, and learning difficulties. The majority of individuals (93%) has a de novo deletion identified by microarray or FISH. When an individual is diagnosed with this condition, parental testing is recommended because of the variable expressivity within a family and the small chance that one of the parents is a more mildly affected carrier.

Duplications of a chromosome segment also occur, resulting in partial trisomy. The size and region of the duplication confer risk for abnormal phenotype ranging from normal to significant structural defects and intellectual disability.

SINGLE GENE DISORDERS

Many important genetic diseases occur as the result of a mutation at a single gene. Gregor Mendel first described the principles of segregation and independent assortment of genes in his well-known experiments with garden peas. This work led to the classic descriptions of autosomal-dominant (AD) and autosomal-recessive (AR) inheritance. X-linked inheritance occurs with conditions encoded on the X chromosome, and it may be either recessive or dominant. Figure 2-4 shows

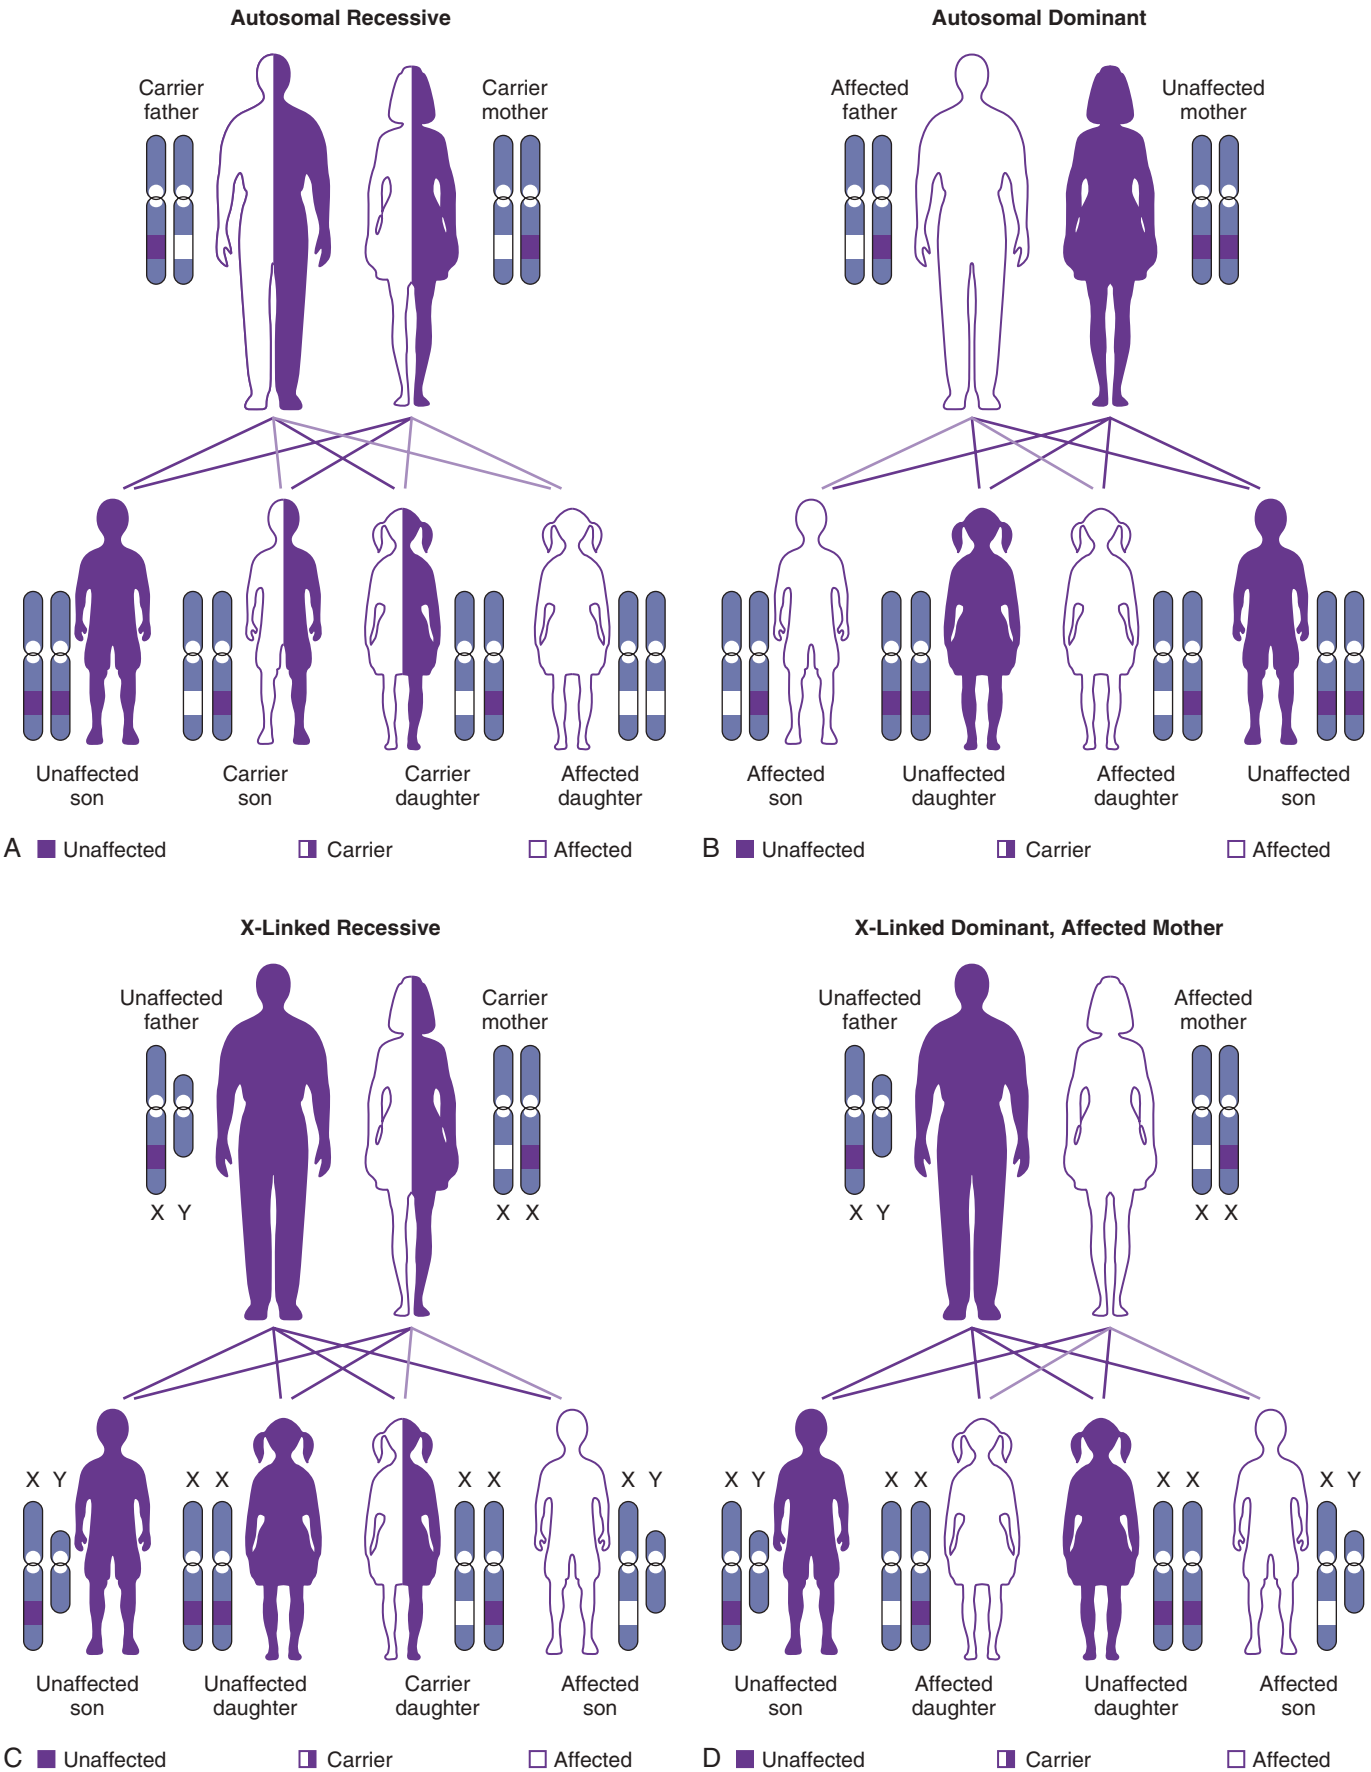

FIG 2-4 Modes of inheritance: **A,** autosomal-recessive; **B,** autosomal-dominant; **C,** X-linked recessive; and **D,** X-linked dominant inheritance patterns. See text for explanation.

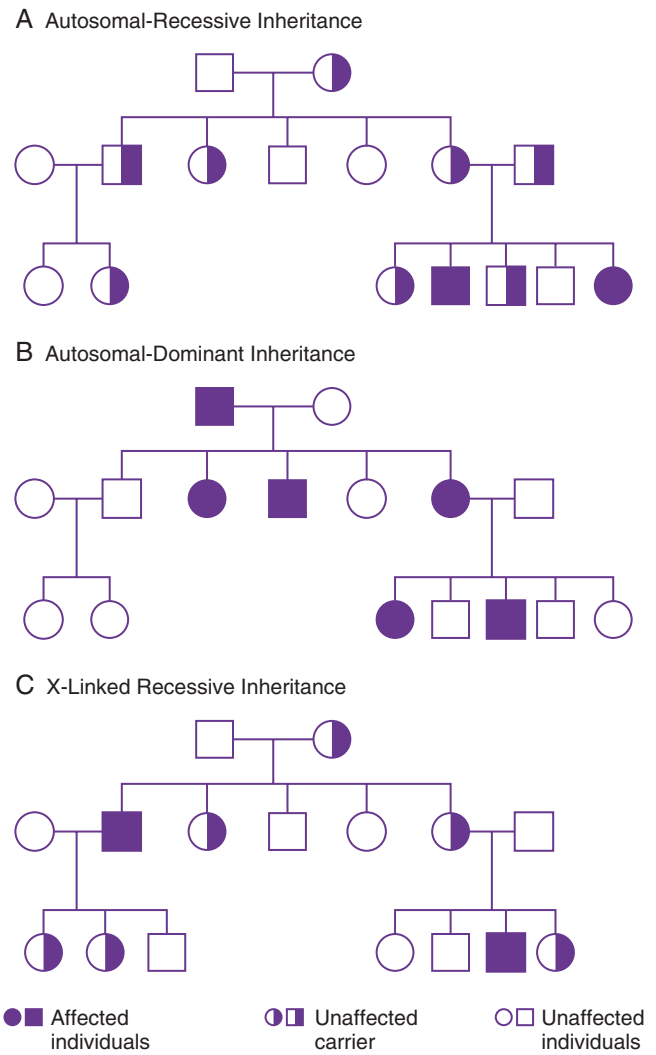

FIG 2-5 Pedigrees diagraming modes of inheritance. **A,** Autosomal-recessive inheritance. **B,** Autosomal-dominant inheritance. **C,** X-linked recessive inheritance. See text for further detail.

modes of inheritance; Figure 2-5 shows pedigrees demonstrating modes of inheritance.

The completion of the human genome project in 2003 was an epic chapter in laying the foundation for the study of human genes and the diagnosis and treatment of genetic disease. Although the human genome has now been sequenced, we still do not know how most genes work in either health or disease. We have gained an increased appreciation, however, for the complexity of human genetics. Relevant to clinical genetics, we have greatly increased our understanding of genetic heterogeneity, and the less than clear-cut association of one gene with one disorder. We now understand that mutations at more than one gene locus can lead to the same phenotype and that multiple different phenotypes can result from mutations in the same gene. Phenotypes also result from the interaction of genotype with the environment (including other genes), and there are numerous phenomena that advances in genetic technology have uncovered that make genetics far more fascinating, if far more complex.

Autosomal-Dominant Inheritance

In AD inheritance, affected individuals are heterozygous for an abnormal allele that they transmit to 50% of their offspring, independent of

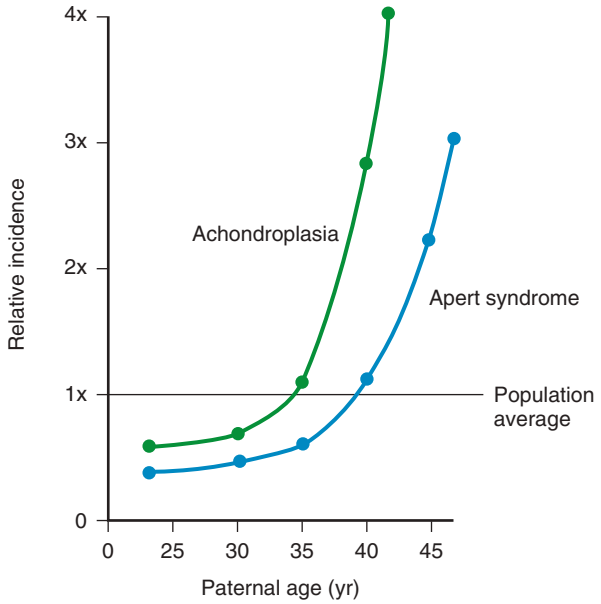

FIG 2-6 Paternal age and risk of autosomal-dominant disorders. (Modified from Carlson BM: Human Embryology and Developmental Biology, 3rd ed. Philadelphia, Mosby/Elsevier, 2004.)

gender. Overall, approximately 1/200 individuals is affected with an AD condition, although individual conditions are generally rare.

In theory, AD inheritance is straightforward, but in actuality, there are numerous factors affecting gene expression that can make evaluation of such cases extremely complex. Counseling of families regarding AD disorders requires consideration of mechanisms such as the rate of new mutation, mosaicism, conditions with late or variable age of onset, incomplete penetrance, and variation in expressivity. AD disorders may be inherited from an affected parent or may result from a new mutation, with the risk varying with each specific condition. Paternal age has a demonstrable effect on the rate of such new mutations (Fig. 2-6) and is associated with an increased risk for AD disorders, including achondroplasia and neurofibromatosis (NF). No current screening or diagnostic testing is recommended for men who are aged 45 years or more, but genetic counseling, routine ultrasound, and discussion of this phenomena are indicated.

If a disorder occurs as a result of a new mutation, the risk of recurrence in a sibling is generally low. However, an individual may be mosaic for an AD mutation, meaning that there are cells of more than one genetic constitution present. If germline mosaicism is present, an apparently unaffected individual will have an increased risk of having affected offspring. Germline mosaicism is thought to occur in approximately 16% of cases of the perinatal lethal disorder osteogenesis imperfecta type II and can also occur in X-linked disorders such as Duchenne muscular dystrophy and hemophilia A. This means that the rate of recurrence is increased and is about 1.3% to 4% with osteogenesis imperfecta.[12]

Penetrance and Expression

Further complicating recurrence risk counseling and clinical evaluation of AD disorders are the phenomena of penetrance and variable expression. A given individual may have a disease genotype but may not express the phenotype if a disorder is not 100% penetrant, as is the case with retinoblastoma, which affects only about 90% of individuals who inherit the causative mutation. Age is also an important consideration because a disorder such as polycystic kidney disease is about 80% to 90% penetrant by 20 years of age and nearly 100%

penetrant by 30 years of age, although only with careful imaging of the kidneys.[13] A disorder may also demonstrate variable expression among affected individuals, even within a family. Targeted physical examinations, radiologic investigation, and other studies may be required to identify features of a disorder in at-risk family members; NF is a notable example. Essentially all individuals inheriting a mutation in the NF gene have some clinical symptoms, although they may range from only mild skin manifestations to multiple debilitating neurofibromas. Referral to a geneticist is indicated for those families identified with risk for heritable disorders.

Autosomal-Recessive Disorders

AR disorders are classically described as those for which two gene mutations must be present for the disorder to manifest. Such disorders occur most commonly in persons whose healthy parents each carry a mutation in the same recessive gene. The recurrence risk to such carrier parents is 25% in each pregnancy. Because the carrier frequency of a given condition is usually low, these disorders most commonly occur with no prior family history. Multiple affected individuals may be identified in a sibship but not typically in multiple generations unless there is consanguinity or the disorder is particularly common. Consanguinity increases the risk of having offspring with AR disorders because of the shared genetic material within a family. The increased risk to parents who are first cousins to have a child with a major genetic or congenital abnormality is about 6%, or twice the background rate.

Again, with advances in genetics, the exceptions to the traditional rules of AR inheritance are increasingly evident. It is now appreciated that carriers of many of these conditions may have subtle symptoms. Examples of this are cystic fibrosis (CF), in which male carriers have increased susceptibility to chronic pancreatitis and congenital bilateral absence of the vas deferens.[14,15] Similarly, sickle cell carriers may suffer splenic infarct at high altitudes and are at increased risk for urinary tract infection in pregnancy.

AR disorders demonstrate much less variation in expression, and lack of penetrance is rarely encountered, so counseling is more straightforward with these conditions. Genetic heterogeneity due to more than one causative locus, or multiple alleles at a single locus, is the major cause of variation in severity of a single disorder.

X-Linked Inheritance

X-linked disorders can be dominant or recessive. Most X-linked conditions are recessive and are traditionally thought of as affecting only men, who have unaffected carrier mothers. Because women carry two X chromosomes whereas men carry only one, one X chromosome is randomly inactivated early in embryonic development, thereby allowing women to produce X-linked gene products in the same quantities as men (Lyon hypothesis). As X inactivation is random, some female heterozygote carriers of X-linked disorders will inactivate primarily their X chromosomes carrying the normal allele and therefore be symptomatic due to skewed X inactivation. This occurs in hemophilia A, in which some carriers can have a mild bleeding disorder because of reduced levels of factor VIII. Such affected women have symptoms that are usually, but not always, milder than their male counterparts. With isolated X-linked recessive disorders, it is helpful when possible to determine if an isolated case represents a new mutation or if the mother is a carrier. When molecular diagnosis or other methods of carrier detection are available, the situation can be clarified. However, such tests are not available for all conditions, and risks must often be empirically determined based on pedigree analysis and consideration of other factors such as the number of unaffected men in the pedigree. Increasingly, genomic sequencing is available to identify genetic mutations in individuals in whom a genetic disorder is suspected.

X-linked dominant disorders are less common than X-linked recessive diseases, and some such conditions are lethal in men. Examples include Rett syndrome, incontinenti pigmenti, and Aicardi syndrome. Aicardi syndrome is a rare disorder primarily of the CNS, including agenesis of the corpus callosum, microphthalmia, and infantile spasms. When an affected child with such a condition is born to healthy parents, it is likely due to a new mutation and the recurrence risk is low, although consideration must be given to germline mosaicism.

Fragile X syndrome, the most common inherited form of mental retardation, is an important disorder that demonstrates X-linked inheritance. Fragile X syndrome is characterized not only by mental retardation but also by behavioral difficulties including autism, and specific dysmorphic features. The condition affects males (approximately 1/4000) more commonly and more severely than females. Fragile X syndrome is a trinucleotide repeat disorder, characterized by expansion of DNA triplets beyond the normal, stable threshold, which may occur in certain genes and result in a condition or disease. Trinucleotide repeat disorders are typically neuromuscular diseases and include Huntington disease, myotonic dystrophy, Friedreich ataxia, and spinocerebellar ataxia. The number of repeats can expand due to chromosomal instability during meiosis, which can cause the phenotype of the condition to change and become more severe. Because of this, trinucleotide repeat disorders generally show genetic anticipation, in which the severity increases with each successive generation that inherits them. Individuals are considered to be carriers for fragile X syndrome when they have an intermediate number of trinucleotide (CGG) repeats in the *FMR1* gene (also called a premutation) that can expand during oogenesis to a larger number of repeats (full mutation) (see Fig. 2-5). Full-mutation men have moderate to severe mental retardation and behavioral problems such as autism, whereas women are affected by a more variable phenotype, ranging from normal to as severe as affected men. Premutation female carriers have a relatively high rate of premature menopause (15% to 25%), whereas male premutation carriers can have a tremor ataxia condition with an onset later in life.[16,17] For any patient with a family history of mental retardation, early menopause, or autism without an attributable diagnosis, or adults with parkinsonian features, carrier testing for fragile X syndrome is indicated.[18]

Other Novel Genetic Mechanisms

Some genetic mutations have been noted to have a very different effect depending on the parent of origin, a phenomenon known as *genetic imprinting*. Imprinting is an epigenetic phenomenon by which certain genes are expressed or not expressed depending on the parent of origin (Fig. 2-7). As depicted in Figure 2-8, the imprinting cycle takes places in primordial germ cells early in development. A number of genetic disorders, including Prader-Willi syndrome (PWS) and Beckwith-Wiedemann syndrome (BWS), occur because of abnormalities of imprinted genes. Prader-Willi syndrome is characterized by neonatal and infantile hypotonia, hypogonadism, typical facial features, and feeding problems; these are followed in early childhood by excessive caloric intake resulting in morbid obesity and intellectual disability. The disorder occurs when there is no functional paternal copy of the *SNRPN* gene on chromosome 15. This can happen when both copies of chromosome 15 are maternally inherited, and no paternal copy is present, or when there is a deletion on the paternally inherited copy of chromosome 15. Several recent reports have indicated an association between imprinting disorders and in vitro fertilization (IVF) with intracytoplasmic sperm injection.[19]

Mitochondria, which produce adenosine triphosphate (ATP), have their own unique DNA in addition to nuclear DNA. Mitochondria are all maternally inherited and have a high mutation rate. Many

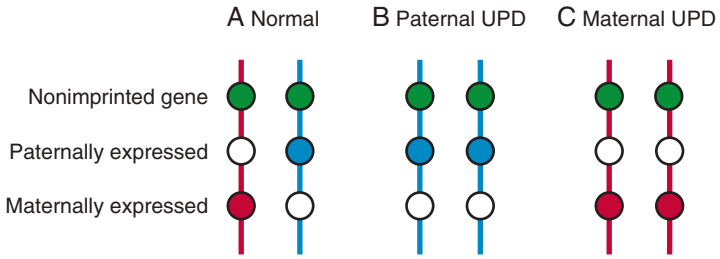

FIG 2-7 Genomic imprinting and uniparental disomy (UPD). Schematic of a hypothetical chromosome pair representing genomic imprinting. The maternal chromosome is indicated by the red line, and the paternal copy by the blue line. Genes are represented by circles: colored circles indicate genes that are expressed, and the white circles represent genes that are inactive. The green circles are genes that are not imprinted, whereas red circles indicate genes in which only the maternal copy is active and the blue circles genes in which only the paternal copy is active. **A,** Normal state, with one chromosome inherited from each parent. The nonimprinted gene is expressed from both parents, whereas only one copy of the red or blue (imprinted) gene is expressed. **B,** Paternal UPD. With two copies of the paternal chromosome present, there is a double dose of the paternally expressed (blue) gene, and absence of expression of the maternally expressed gene. **C,** Maternal UPD. There is an absence of paternally expressed gene product (blue) and a double dose of the maternally expressed products (red).

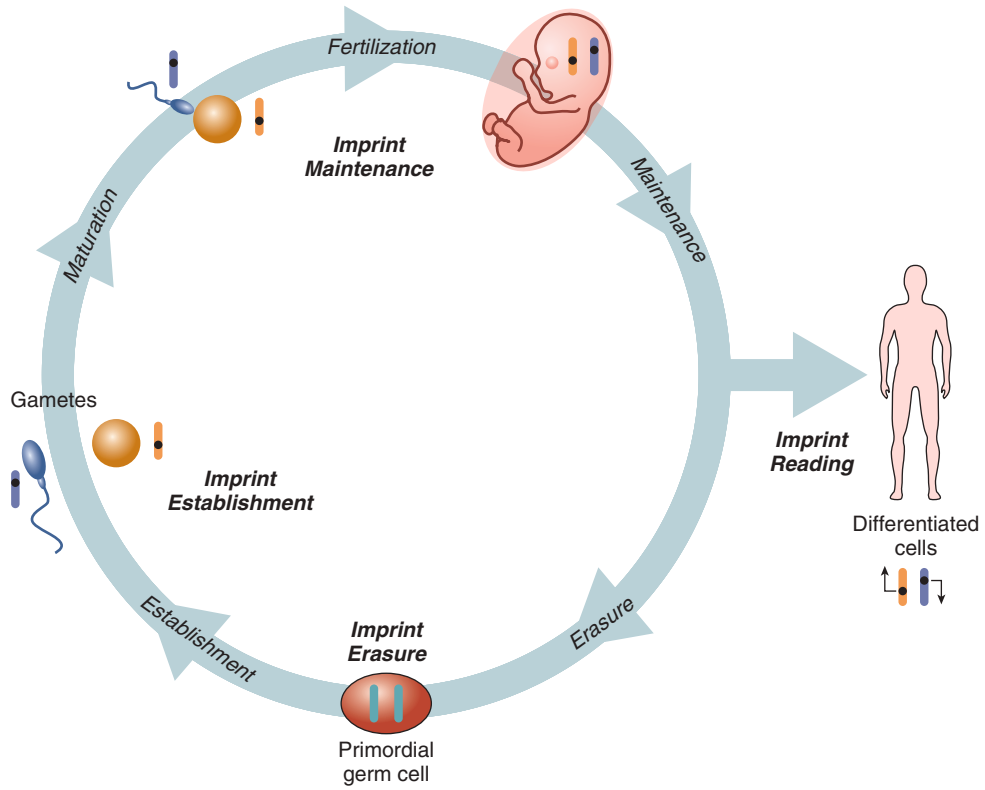

FIG 2-8 Imprinting cycle. Imprinting occurs in primordial germ cells, early in development.

mitochondrial diseases have now been identified, and they are most commonly maternally inherited such that affected women pass the condition to all of their offspring and affected men do not pass the condition to any of their offspring. Mitochondrial disorders demonstrate variable expressivity within a family. Typical symptoms include neuromuscular abnormalities (such as loss of motor control, muscle weakness, and pain), gastrointestinal disorders and swallowing difficulties, poor growth, cardiac disease, liver disease, diabetes, respiratory complications, seizures, visual/hearing problems, lactic acidosis, developmental delays, and susceptibility to infection.

Multifactorial Inheritance

Many common congenital malformations, including NTDs, cleft lip and palate, and CHDs, have an increased risk of recurrence in families above the baseline population risk. A small percentage of such defects have a specific cause, such as single gene disorders, chromosomal abnormalities, or teratogens. Most, however, are isolated defects that result from complex interactions among a number of factors, including genotype at one or more loci, and a variety of environmental exposures that trigger, accelerate, or exacerbate the disorder. Therefore, occurrence does not match simple mendelian inheritance but is complex and

multifactorial. Recurrence risk of such disorders is increased by the presence of more than one affected relative, a severe or early-onset form of disease, an affected person of less common sex (in disorders in which persons of one sex are more likely to be affected), high heritability of the disorder, and consanguineous parentage.

NTDs have long been thought to follow a typical complex inheritance pattern determined by multiple genetic and environmental factors. Known environmental risk factors include maternal obesity, diabetes, and medications such as valproic acid. The association between lower socioeconomic status and NTD led investigators to consider nutritional deficiencies as risk factors. Therefore, it was a remarkable discovery that folate supplementation reduced the risk for NTD by approximately 80%, although most women with a fetal NTD diagnosed during pregnancy have normal range folate levels.[20] Public health initiatives to educate reproductive age women about the importance of folate and fortification of the food supply (cereals and breads) with folic acid have been instituted in the United States for the purpose of decreasing the incidence of NTDs. The mechanism for the protective action of folic acid in prevention of NTDs is not well understood.[21] Recent data suggest folate deficiency is not problematic unless present in combination with a mutated gene or genes; together these risk factors result in the embryologic malformation.[22]

TERATOLOGY

A milestone in human teratology occurred in 1941, when an Australian named Norman Gregg noted the association between first trimester maternal rubella infection and serious birth defects.[23] Twenty years later, the thalidomide disaster sensitized the medical community to the risks of medications in pregnancy. Thalidomide, a very effective sedative, was widely used for several years in West Germany, Australia, and other countries until the association of prenatal exposure with phocomelia and amelia was recognized. Following the recognition of the potent teratogenicity of this drug, intense investigations into the safety of various medications in pregnancy heralded the modern age of teratology.

Embryos are more susceptible to teratogenic agents at specific critical periods of development (Fig. 2-9). The preorganogenetic phase, from conception until somite formation, is known as the all-or-none period, when insults to the embryo are likely to result in either death of the conceptus and miscarriage or in intact survival without sequelae.[24] At this stage, the embryo is undifferentiated, and repair and recovery are possible through multiplication of the still totipotential cells to replace those that have been lost. Exposure of embryos to teratogens during the presomitic stage usually does not cause

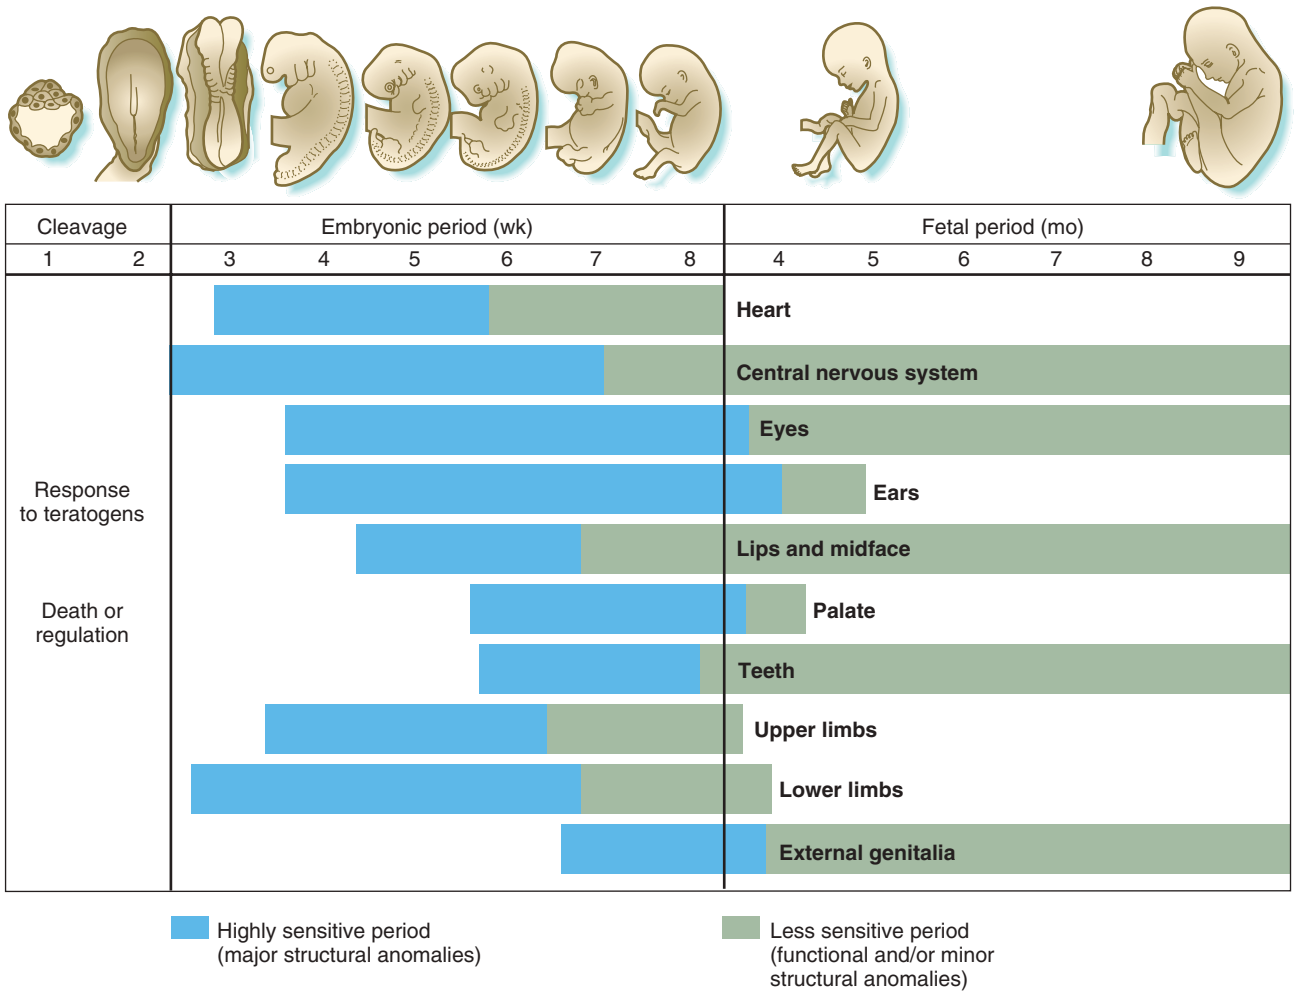

FIG 2-9 Periods and degrees of susceptibility of embryonic organs to teratogens. (From Carlson BM: Human Embryology and Developmental Biology, 3rd ed. Philadelphia, Mosby/Elsevier, 2004, used with permission.)

congenital malformations[25] unless the agent persists in the body beyond this period.

The embryonic period, between weeks 3 and 8 after conception, is when the basic steps of organogenesis occur. This is the period of maximum sensitivity to teratogenicity because tissues are differentiating rapidly and damage to them becomes irreparable. Exposure to teratogenic agents during this period has the greatest likelihood of causing a structural anomaly. Because teratogens are capable of affecting many organ systems, the pattern of anomalies produced depends upon which systems are differentiating at the time of teratogenic exposure. In general, organs that form first tend to be sensitive earlier, and very complex organs tend to have prolonged periods of high susceptibility to disruption.

The fetal phase, from the end of the embryonic stage to term, is the period when growth and functional maturation of organs and formed systems occur. Exposure to teratogens in this period will mainly affect fetal growth or the size or function of a specific organ. The brain in particular may be functionally affected almost throughout the entire pregnancy. Teratogens rarely cause gross structural anomalies during this time.[26]

Recognized Teratogenic Agents

A large number of environmental factors have been reported to be associated with birth defects. They include chemical teratogens such as medications and hormones, maternal infections, and physical agents such as radiation. Although the list of medications suspected of teratogenicity is long, relatively few agents have been demonstrated to unquestionably cause birth defects in humans (Table 2-4). In some cases these medications must still be used during pregnancy, as the benefit outweighs the risk they impose. Patients must be made aware of the risks and benefits of use in pregnancy to treat the maternal condition versus the potential for harmful fetal effects and maternal morbidity and mortality risks if untreated. Often, maternal uncontrolled diseases are more harmful to the fetus than the administered drug.

Maternal Infections

The incidence of intrauterine infections ranges between 3% and 15%. Rubella was one of the first infectious agents recognized to cause birth defects in humans and previously was one of the most common. Today, because of effective immunization programs against rubella, the number of affected fetuses has significantly decreased. Currently, the most common intrauterine infection with deleterious fetal effects is cytomegalovirus (CMV). Approximately 1 in 750 children born in the United States is born with or develops permanent problems as a result of this intrauterine infection.[27] Features include hearing and vision loss, seizures, intellectual disability, and rarely death.

Intrauterine infections with long-term fetal sequelae may be viral, parasitic, or bacterial (see Table 2-4). The timing of maternal infection can influence both the severity and likelihood of fetal infection. For example, rubella causes a high percentage of malformations in the first trimester, whereas toxoplasmosis causes fetal infection more commonly in the third trimester but with more severe consequences if contracted earlier. Infection of the fetus may occur owing to hematogenous spread through the placental barrier or via ascending infection through the fetal membranes with direct contamination of the amniotic fluid.

Fetal CMV infection may be suspected by ultrasound features identified during routine surveillance or in the course of evaluation for a known maternal exposure. Ultrasound findings may include fetal ascites or nonimmune hydrops, ventricular dilation and periventricular calcifications, echogenic bowel (EB), calcifications within the fetal liver, fetal growth restriction (FGR), and placental thickening.[28] Cases of suspected intrauterine CMV infections can be evaluated by measuring serum levels of maternal specific antibodies, but the significance of antibody levels is often uncertain. Moreover, a rise in levels of maternal antibodies is diagnostic for maternal, but not necessarily for fetal, infection. To diagnose fetal infection, the infective agent should be identified in the amniotic fluid by culture or polymerase chain reaction (PCR) or by specific immunoglobulin M (IgM) in fetal blood. At birth, viral culture of the neonatal urine or saliva is the gold standard.

Medications

Although many medications have been suspected of being human teratogens, there are a relatively small number for which there is convincing evidence linking the substance directly to congenital malformations in humans. Testing drugs to determine teratogenicity is difficult because agents may cause a high incidence of severe defects in animals but may not cause malformations in other species or in humans (e.g., cortisone causes cleft palate in mice but not humans). Conversely, thalidomide is a tragic example of an agent that is highly teratogenic in humans but not in animals. Antiepileptic drugs (AEDs) are classic examples of medications associated with structural birth defects as well as neurocognitive impairment. Risk for NTDs is increased with exposure to valproic acid (1-5% of exposed offspring) and carbamazepine (0.5-1.0%), but NTDs have not been reported with other AEDs.[29,30] Valproate monotherapy in utero exposure has also been associated with significantly lower IQ scores at the age of 3 when compared to use of other AEDs.[30] Therapy with more than one agent seems to compound the risk for not only structural changes but intellectual disability as well.

Radiation

Ionizing radiation is a potent teratogen, with the response dependent on the dose as well as the gestational age at which the embryo/fetus is irradiated. Experience with the Japanese atomic bomb survivors as well as women treated with therapeutic radiation in pregnancy provides evidence of the damaging effects of large doses of ionizing radiation in humans. In contrast, there is no evidence that radiation exposure at typical diagnostic levels (e.g., a chest radiograph with two views and fetal exposure of 0.02-0.07 mrad) poses a significant threat to the embryo, and noncancerous health effects are not evident for fetal doses of less than 5 rads. Estimates indicate a slight increase in leukemia (approximately 1.5-2 times over baseline risk) with exposures of 1 to 2 rads (risk increases from 1 in 3000 background to 1 in 2000 with exposure to 1-2 rads).[31] Ionizing radiation at high doses (>5 rads) can cause a variety of anomalies in various organ systems. The most prominent radiation-associated abnormalities are defects in the CNS, ranging from NTD to neurocognitive impairment.[22] For fetuses exposed between 8 and 15 weeks' gestation, atomic bomb survivor data indicate that the decline in IQ score is approximately 25 to 31 points per 100 rads, at doses above 10 rads. At 16 to 25 weeks' gestation, the average IQ loss is approximately 13 to 21 points per 100 rads, at doses above 70 rads. After 26 weeks, at doses above 100 rads, the risks for stillbirth and neonatal death increase.[32,33] When evaluating the need for imaging or therapeutic radiation in pregnancy, the indication and both maternal and fetal health consequences should the exposure be rendered or withheld should be discussed with the woman.

Maternal Illnesses

A number of maternal illnesses and metabolic disorders have been implicated in the genesis of congenital malformations. Maternal diabetes is strongly associated with congenital malformations, with the

TABLE 2-4 Proven Teratogenic Agents in Humans

Agent	Effects
ACE inhibitors	CNS defects, congenital heart defects (first trimester exposure) Renal failure, skull hypoplasia (second trimester exposure)
Alcohol	Fetal alcohol syndrome: intrauterine growth retardation, microcephaly, developmental delay, characteristic facies, CHD, cleft palate
Carbamazepine	Neural tube defects, similar features to fetal hydantoin syndrome
Chemotherapeutic agents	Miscarriage, various malformations
Cocaine	Abruptio placentae, prematurity, fetal loss, decreased birth weight, microcephaly, limb defects, urinary tract anomalies, and poor neurodevelopmental performance
Coumarin anticoagulants	Fetal warfarin syndrome: hypoplasia and calcific stippling of the epiphyses, intrauterine growth retardation, developmental delay, CNS damage, eye defects, hearing loss
Diethylstilbestrol	Clear cell adenocarcinoma, benign adenosis of the vagina, female genital structural changes (cervix/uterus)
Folic acid antagonists	Fetal aminopterin syndrome: CNS defects (hydrocephalus, meningomyelocele), facial anomalies (cleft palate, high-arched palate, micrognathia, ocular hypertelorism, external ear anomalies), abnormal cranial ossification, abnormalities of first branchial arch derivatives, intrauterine growth retardation, mental retardation
Hydantoin	Fetal hydantoin syndrome: craniofacial dysmorphology (wide anterior fontanel, ocular hypertelorism, metopic ridge, broad depressed nasal bridge, short anteverted nose, bowed upper lip, cleft lip, cleft palate), hypoplasia of the distal phalanges, nail hypoplasia, growth retardation, mental deficiency, cardiac defects
Isotretinoin	Retinoic acid embryopathy: craniofacial anomalies (microtia or anotia, accessory parietal sutures, narrow sloping forehead, micrognathia, flat nasal bridge, cleft lip and palate, and ocular hypertelorism), cardiac defects (primarily conotruncal malformations), abnormalities in thymic development, and alterations in CNS development
Lithium	Cardiac defects, especially Ebstein anomaly
Misoprostol	Limb defects, Moebius sequence
Organic mercury	Mental retardation, cerebral atrophy, spasticity, blindness
Sodium iodide (I-131)	Ablation of fetal thyroid gland
Thalidomide	Limb defects, including phocomelia, polydactyly, syndactyly, and oligodactyly; defects of the external ears; facial capillary hemangiomas; palsies of cranial nerve VI or VII; cardiovascular defects; agenesis of kidneys, spleen, gallbladder, and appendix; atresia or stenosis of esophagus, duodenum, and anus
Trimethadione	Fetal trimethadione syndrome: characteristic craniofacial anomalies, growth retardation, delayed psychomotor development, clefting, and congenital heart defects
Valproate	Neural tube defects, fetal valproate syndrome: narrow bifrontal diameter, high forehead, epicanthal folds, infraorbital creases, telecanthus, low nasal bridge, short nose with anteverted nares, midfacial hypoplasia, long philtrum, thin vermilion border, small mouth, cardiovascular defects, long fingers and toes, hyperconvex fingernails, and cleft lip
INTRAUTERINE INFECTIONS	
Cytomegalovirus	Cytomegalic inclusion disease: intrauterine growth retardation, microcephaly, chorioretinitis, seizures, blindness, optic atrophy Neonatal hepatosplenomegaly, jaundice, and thrombocytopenia
Rubella virus	Spontaneous abortion, congenital rubella syndrome: heart disease, deafness, cataracts, intrauterine growth retardation, encephalitis, abnormal long bones Neonatal hepatosplenomegaly, obstructive jaundice, thrombocytopenic purpura, mental retardation, neurologic deficits, and behavioral abnormalities
Treponema pallidum (causing syphilis)	Congenital malformations, prematurity, stillbirth, hepatosplenomegaly, osteochondritis or periostitis, jaundice, petechiae or purpuric skin lesions, lymphadenopathy, hydrops, edema, ascites, rhinitis, pneumonia, myocarditis, nephrosis, and bulbar pseudoparalysis
Toxoplasma (causing toxoplasmosis)	Encephalitis, hydrocephalus, intracranial calcifications, chorioretinitis, erythroblastosis, anemia, jaundice, hepatosplenomegaly, glomerulitis, myocarditis, myositis, CNS damage, seizures, mental retardation, cerebral palsy, deafness, and blindness
Varicella-zoster virus	Skin lesions, fetal growth retardation, limb hypoplasia, brain and eye defects, cerebral and cerebellar atrophy, seizures, developmental delay, and nerve palsies

CHD, congestive heart disease; CNS, central nervous system.

This table represents selected medications and their possible associations with fetal structural abnormalities. Many of the listed associations are based on isolated case reports that have appeared in the medical literature for which the association is unproved or on animal studies in which the dosage of medication far exceeded the normal clinical amount normally used. It is likely that in many cases the reported association was coincidental to, rather than resultant from, the medication. This table is not intended for patient counseling regarding the likelihood of fetal malformations or abnormalities. This table should be used by the sonologist/sonographer as a guide to evaluate specific organ systems in addition to a thorough sonographic examination. In all cases of suspected teratogenic effects a reproductive geneticist or teratologist and the drug manufacturer should be consulted.

From Diav-Citrin O, Ornoy A: Adverse environment and prevention of early pregnancy disorders. Early Pregnancy 4:5, 2000, used with permission. Modified from Brigs GG, Freeman RK, Yaffe SJ: Drugs in Pregnancy and Lactation, 5th ed. Philadelphia, Lippincott Williams & Wilkins, 1998.

risk to the embryo directly related to the degree of maternal glucose control.[34,35] The most common abnormalities include CHDs and NTDs, whereas caudal regression is rare but of greatly increased frequency in infants of diabetic mothers. The phenotype of the infants of diabetic mothers also includes macrosomia, polyhydramnios, and stillbirth, with hypoglycemia and erythroblastosis (increased fetal nucleated red blood cells) common neonatal complications. Maternal prepregnancy obesity is independently associated with fetal malformations including cleft palate, CHDs, NTDs, and congenital diaphragmatic hernias.[36] Untreated maternal phenylketonuria is also a potent teratogen and results in microcephaly, mental retardation, CHDs, and low birth weight. Risks to the fetus are related to the level of maternal phenylalanine and almost entirely eliminated with maternal dietary management and avoidance of phenylalanine in the diet of affected women during pregnancy.[37]

Mechanical Factors

Mechanical disruption can result in a number of recognizable and characteristic sequence disorders. Mechanical forces may include multiple gestations, uterine myomas that distort the uterine cavity, or amniotic bands. Often, the underlying cause is less important than the common disruption pathway. Potter sequence, for example, results from early, longstanding oligohydramnios of any cause and consists of pulmonary hypoplasia, clubfeet, congenital hip dislocation, low-set ears, micrognathia, and flattened faces. This same phenotype can result from different causes of absent amniotic fluid, including bilateral renal agenesis and early rupture of the amniotic membrane.

GENETIC COUNSELING

Clinical genetics is the discipline that is concerned with the diagnosis and management of the medical, social, and psychological aspects of hereditary disease. Often, people seeking genetic counseling are parents of a child with a potential or known genetic condition. Others who seek genetic counseling include adults with an abnormality or a family history of a condition such as cancer or neurodegenerative diseases. Genetic counseling is an integral part of genetic testing and screening programs, including prenatal testing.

The process of genetic evaluation involves several components: validation of the diagnosis, obtaining the family history, estimation of the risk of recurrence, helping the family to reach decisions and take appropriate action (i.e., genetic testing), and follow-up. An important part of genetic counseling involves understanding the family history. Health care providers in any field of medicine should include a three-generation pedigree as part of the patient history. Couples referred for prenatal testing for one specific indication will frequently have other risk factors identified when the family history is reviewed. Genetic counseling is based on the concept of nondirective counseling. Patients are not told what decisions to make with regard to testing and management options but, instead, are provided information and support.

A family may be referred to a medical genetics physician for evaluation and discussion of the diagnosis in question. The purpose could be to evaluate features in a parent or sibling suggestive of an underlying disorder or features of a fetus identified through ultrasound or testing that indicate a condition. The precise diagnosis must be certain in order to provide accurate prenatal diagnostic testing. The inheritance pattern must be known to provide correct risk assessment, as some disorders may have different patterns of inheritance in different families.

Making a precise diagnosis may have enormous implications for counseling a family. For example, if a prior male fetus was diagnosed with hydrocephalus and the pregnancy terminated, a recurrence risk of 5% in future pregnancies would generally be quoted. Ultrasound would be offered for prenatal diagnosis, although in some cases of recurrence, ventriculomegaly may not manifest until late in pregnancy. On the other hand, more thorough evaluation of the prior fetus may have resulted in a diagnosis of X-linked aqueductal stenosis with identification of a mutation in the *L1CAM* (cell-adhesion molecule) gene. In such cases, testing of the mother is indicated to determine if she is a carrier. The chance that a woman who has one affected son (and no family history) is a carrier of the mutated *L1CAM* gene (or any X-linked male lethal condition) is approximately 2:3, or 67%, which is why genetic counseling and testing are important to consider. If she is a carrier, the recurrence risk is 50% for male offspring and very small for female offspring (although 50% of her daughters would also be carriers). Carrier females may manifest minor features such as adducted thumbs and intellectual disability. Rarely do females manifest the complete L1 syndrome phenotype. CVS at 10 weeks would be possible for prenatal diagnosis if a molecular mutation has been identified. The spectrum of the disorder includes boys with mental retardation but without hydrocephalus, so ultrasound would not be adequate for ruling out a recurrence of this condition.

Patients who undergo genetic testing are also educated on the options of screening and diagnostic testing in pregnancy. The concept of screening as risk assessment for specific conditions in pregnancy must be clearly distinguished from the definitive nature of diagnostic procedures. It is currently recommended that both screening and diagnostic testing options should be offered to all women in pregnancy regardless of maternal age or perceived risk. Important counseling points to convey include the optional nature of all prenatal testing and the fact that a low-risk screening test result does not guarantee a healthy child and a high-risk screening test result does not mean the fetus has the disorder. Educational and counseling components must be provided both before and after all prenatal genetic tests. Issues of privacy and confidentiality of test results must be addressed.

GENETIC SCREENING IN PREGNANCY

Screening is currently available and should be offered in pregnancy for a number of genetic (single gene or mendelian) disorders, chromosomal aneuploidy, and structural birth defects in the fetus regardless of maternal age or family history. A variety of tests provide risk assessment for genetic conditions and may be performed in the preconception period or in pregnancy. Screening for single gene defects such as CF or Tay-Sachs disease (TSD) has historically been targeted to the specific ethnic background of the patient, although this approach is changing and universal carrier screening for many disorders simultaneously is now available.[38,39] Screening for chromosomal abnormalities, traditionally associated with maternal age, is now recommended for all patients, with an overwhelming array of sonographic and maternal serum-based options available for carrying out risk assessment. Screening for structural birth defects, such as NTD, may involve maternal biochemical screening as well as ultrasound. Additionally, ultrasound should be considered a screening tool for genetic disorders and chromosomal aneuploidy, as many diagnoses have associated structural birth defects that are ascertained during a routine anatomic survey. As with any screening test, the patient should be made aware that a negative test result does not guarantee a healthy baby and a positive test result does not mean the fetus has the condition. In this scenario, the woman should undergo genetic counseling to understand the results, limitations of the test, and options for additional screening and diagnostic tests.

Carrier (Heterozygote) Screening for Single Gene Disorders

The main purpose of carrier screening in pregnancy is to identify individuals who are themselves healthy but are at risk of having children with a genetic disorder. The majority of disorders in this category are AR diseases, in which both parents must be carriers of the gene but typically are unaffected. In the majority of cases, there is no family history of the disorder. Should a family history of a particular disorder be identified, that patient should undergo genetic counseling and be offered targeted genetic testing if indicated.

It has historically been agreed that the following criteria should be met for heterozygote screening programs to be effective: (1) disorder of sufficient severity to warrant screening, (2) high frequency of carriers in the screened population, (3) availability of an inexpensive and dependable test with low false negative and false positive results, (4) access to genetic counseling for couples identified as heterozygotes, (5) availability of prenatal diagnosis, and (6) acceptance and voluntary participation by the population targeted for screening. Testing directed at specific ethnic groups is increasingly criticized as our society becomes more multiethnic and it is recognized that genetic conditions do not occur uniquely in specific populations, as ethnicity-based screening limits accessibility of genetic information for individuals based on their reported ancestry. In addition, as genetic and genomic testing evolves, broad-based testing is available for many disorders, some very rare, simultaneously. This is rapidly changing the paradigm of genetic testing.

Because DNA-based screening tests generally look only at a set of the most common genetic mutations, not all carriers will be detected by a given screening test. Individuals with other mutations not included in the screening panel will not be detected. In some disorders, screening is more effective in a particular ethnic group in which a limited number of disease-causing gene mutations are seen. For example, DNA screening for CF is sensitive in the Ashkenazi Jewish population, in which greater than 95% of carriers can be detected because the majority of disease-causing mutations in this population is known. However, in Asian or African populations, fewer disease-causing mutations are known; therefore, fewer carriers of Asian or African descent will be identified by the current CF DNA test. It is important to remember that although a negative carrier test lowers the chance that an individual is a carrier, it does not rule it out (Table 2-5).

Table 2-6 lists the inherited disorders for which carrier screening is currently recommended. There are many other disorders for which screening is available and frequently performed. These disorders include fragile X syndrome, as well as extensive panels of diseases more common in the Ashkenazi Jewish population, and spinal muscular atrophy (SMA).[18,40-42] As genetic testing becomes more efficient and less expensive, clinicians and professional societies that establish practice guidelines and policies are faced with the challenge of deciding which tests should be offered for general screening. Expanded, or universal, carrier screening is increasingly being offered as high-throughput genotyping and gene sequencing are able to rapidly provide information on many conditions, beyond those traditionally recommended in screening guidelines.[39] Many of the conditions have a variable phenotype and variable age of onset with a clinical course that is not well defined given the rarity of some of the included disorders. Pretest and posttest counseling is strongly recommended for patients undergoing expanded carrier screening to discuss the potential for unanticipated information and an inability to calculate a residual risk given the rare nature of many disorders included on panels.

TABLE 2-5 Cystic Fibrosis Carrier Frequency and Detection Rates by Ethnic Group

Group	Incidence	Carrier Risk	Detection Rate
Ashkenazi Jews	1/3300	1/24	94%
Europeans	1/3300	1/25	88%
Hispanics	1/8464	1/58	72%
African Americans	1/17,000	1/61	64%
Asian Americans	1/32,400	1/94	49%

Tay-Sachs Disease

Carrier screening for TSD in the Ashkenazi Jewish population has been done on a large scale since 1969. Screening, followed by prenatal diagnosis when indicated, has resulted in a dramatic decrease in the incidence of TSD in the Jewish population.[37] A number of practical, social, and ethical complexities have also been identified in this prototypic population-based effort.[43] More than 100 mutations in the hexosaminidase A gene have been identified to date. Some are associated with later onset or more chronic forms of neuronal storage disease. In part because of this history of success with TSD screening, and in part because of cultural isolation, an increased number of tests for genetic disorders have been proposed for testing of the Ashkenazi Jewish population. Some of these tests have become routine, whereas others are provided through commercial laboratories that offer an extensive Ashkenazi Jewish panel.

Cystic Fibrosis

CF is the most common severe AR disease to affect individuals with European ancestry, with an incidence of 1/2500 to 1/5000 corresponding to a carrier frequency of 1/25 to 1/35. The disease is characterized by chronic pulmonary obstruction and infection and by digestive disorders such as pancreatic insufficiency. It is caused by mutations in the gene that encodes the CF transmembrane receptor protein, or *CFTR*, on chromosome 7. Since the gene was cloned in 1989, more than 1800 mutations have been identified. The mutations have ethnic and geographic variation, as well as a wide range of phenotypic variation, from those causing classical, severe CF (such as the common delta F508 mutation) to those that may have subtle or no clinical manifestations.

Since 2001, the AGOC and the ACMG have recommended that screening for CF should be offered to women in pregnancy; the most recent guidelines recommend that testing be offered regardless of ancestry.[38] Implementing this recommendation is complex and therefore somewhat controversial. The complexity arises in part because the incidence of CF varies in people of different ethnic groups. It is most common in Ashkenazi Jewish and Northern European populations, in which 1/25 is a carrier, but is far less common in Hispanic, Black, and Asian-American persons. Furthermore, as mentioned earlier, the detection rate varies greatly among ethnic groups because not all alleles are known for each population. Most laboratories test for the most common mutations present in the population; in the United States this typically involves screening for the 23 to 32 mutations most common in the European population. Genetic counseling is particularly important in order to explain the limitations of testing (that is, not all carriers will be detected), especially for couples in which one or both partners is a carrier or has a positive family history or is of nonwhite ancestry. It is also imperative that individuals are made aware of the residual risk to be a carrier or have an affected child depending on the number of mutations analyzed and partner status.

TABLE 2-6 Genetic Screening Tests Currently Recommended by Ethnic Group

Condition	ACOG	ACMG	NSGC	Comment
Hemoglobinopathies[a]	African ancestry: hemoglobin electrophoresis	No current guideline	No current guideline	Sickledex and other solubility tests do not identify variant hemoglobins other than hemoglobin S
	Mediterranean or Southeast Asian ancestry: If anemia and MCV less than 80 fL, evaluate for iron deficiency; if iron study results are normal, perform hemoglobin electrophoresis; if hemoglobin electrophoresis result is normal, molecular testing for α-thalassemia is indicated			
Conditions prevalent among Ashkenazi Jewish population[b,c]	Offer screening for Tay-Sachs disease, cystic fibrosis (CF), Canavan disease, and familial dysautonomia to those with Ashkenazi Jewish ancestry; provide education materials and genetic counseling as requested for additional conditions	Offer screening for Tay-Sachs disease, CF, Canavan disease, and familial dysautonomia; also offer screening for Niemann-Pick disease (type A), Bloom syndrome, Fanconi anemia group C, mucolipidosis IV, and Gaucher disease	No current guideline	Biomedical screening of hexosaminidase; this enzyme is the most sensitive screening test for Tay-Sachs disease in all populations
Cystic fibrosis[d,e,f]	Offer CF carrier screening to all women of reproductive age; complete sequencing of the CF gene is not appropriate for carrier screening	Offer population screening using a panel of 23 pathogenic variants in the *CFTR* gene associated with classic CF and present in at least 0.1% of patients with CF	Carrier testing for CF should be offered to all women of reproductive age, regardless of ancestry, preferably before pregnancy	
Spinal muscular atrophy[g,h]	Testing recommended only when a family history of spinal muscular atrophy is present	Offer screening regardless of ancestry or family history	No current guideline	
Fragile X syndrome[h,i,j]	Screening should be limited to individuals with family history of intellectual disability suggestive of fragile X syndrome, unexplained intellectual disability, or developmental delay, autism, or primary ovarian insufficiency	Screening should be limited to individuals with family history of intellectual disability suggestive of fragile X syndrome	Screening should be limited to individuals with family history of intellectual disability suggestive of fragile X syndrome	ACOG, ACMG, and NSGC do not recommend population carrier screening

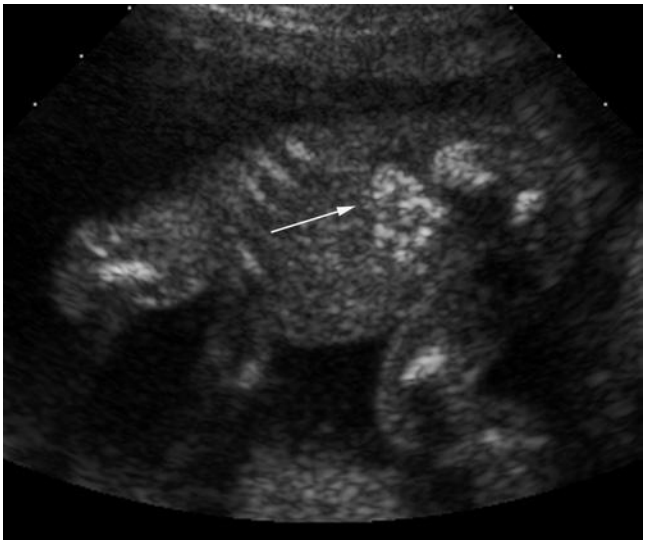

FIG 2-10 Hyperechogenic bowel (*arrow*) in a fetus with cystic fibrosis.

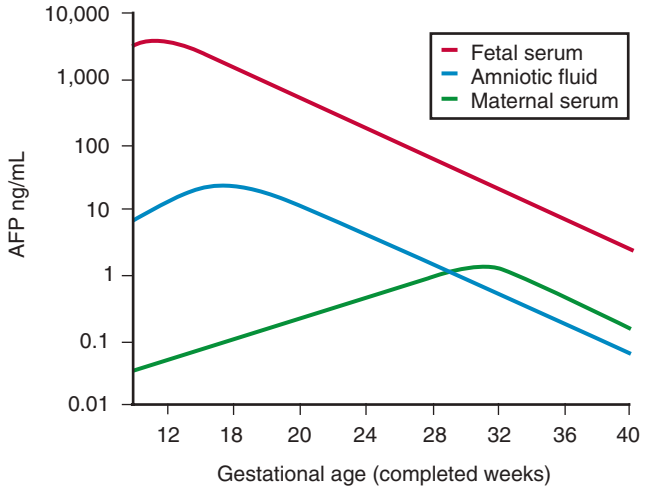

FIG 2-11 Mean concentrations of alpha-fetoprotein (AFP) in maternal serum, amniotic fluid, and fetal serum. (Redrawn from Haddow JE: Prenatal screening for open neural tube defects, Down's syndrome, and other major fetal disorders. Semin Perinatol 14:488, 1990.)

CF may be suspected in a fetus by the specific ultrasound finding of EB. Fetal EB, defined as bowel with sonographic density equal to or greater than that of surrounding bone, is diagnosed in 0.2% to 1.8% of fetuses during routine ultrasound examination in the second trimester of pregnancy. This increased echogenicity has been associated with chromosomal abnormalities, congenital infections, intestinal obstruction, and CF (Fig. 2-10).[44] In the case of CF, it is hypothesized that the malfunctioning CFTR protein leads to dehydration of mucous secretions, which become viscous and obstruct the bowel lumen, leading to meconium ileus. The risk for CF with EB has been extensively studied and reported to have a wide range, from 0% to 33%.[45] This range could result from differences in ascertainment, CF prevalence, and mutation detection rates.

Screening for Structural Birth Defects

Alpha-Fetoprotein and Open Neural Tube Defects

Population-based prenatal screening began in the late 1970s with the use of maternal serum alpha-fetoprotein (AFP) measurements to identify women at increased risk of carrying a fetus with an open NTD. AFP is the major serum protein early in fetal life.[46] This oncofetal protein is produced initially by the yolk sac and, after involution of this structure in early pregnancy, by the fetal liver. Relatively few data have been published on the biologic activities of AFP during fetal development. AFP is present in amniotic fluid initially through diffusion across immature skin, and later through the kidneys and fetal urination. The fetus recirculates swallowed amniotic fluid AFP (AFAFP), with eventual degradation by the fetal liver. Minute amounts of AFP are present in maternal serum through diffusion across the placenta and amnion. Nonpregnant, healthy women have levels of AFP that are barely detectable (1 µg/L), whereas normal median levels at 16 to 18 weeks of gestation range from 18 to 40 µg/L. When the fetal serum level is 2 million µg/L, the corresponding AFAFP is 20,000 µg/L, and the maternal serum level is 20 µg/L.[3] Fetal plasma and amniotic fluid levels of AFP peak in the midtrimester of pregnancy, whereas maternal serum AFP (MSAFP) continues to increase until 28 to 32 weeks of gestation (Fig. 2-11). The discrepancy between amniotic fluid and maternal serum levels of AFP is not completely understood but may be due to the rapidly expanding placental and amniotic interfaces.

In the fetus with a defect such as anencephaly or spina bifida, AFP enters the amniotic fluid in increased amounts, leading to higher levels in the maternal serum as well. Levels of AFP are elevated in amniotic fluid and maternal serum only when such lesions are open, that is, when the neural tissue is exposed or covered by only a thin membrane. When NTDs are skin covered, AFP does not escape from the fetal circulation, and such defects are generally not detected by MSAFP. Whereas essentially 100% of anencephaly lesions are open, approximately 20% of spina bifida cases are skin covered, as are 82% of encephaloceles.[47] Discussions of the sensitivity and specificity of AFP testing are generally restricted to open lesions, because it is assumed that closed lesions will not be detected. Elevated MSAFP is not uniquely associated with open NTDs. It may also be elevated in fetuses with abdominal wall defects, oligohydramnios, or renal abnormalities as well as in cases of placental dysfunction leading to later obstetric complications such as preterm birth, preeclampsia, and fetal growth restriction.[48,49]

Because more than 80% of infants with NTD are born into families with no prior history of the disorder, MSAFP screening is an important public health program. In laboratories providing AFP screening, results are expressed as multiples of the median (MoM). This provides less interlaboratory variation, which can be considerable, as well as a way to report results across a range of gestational ages. Encephaloceles are a less frequent cause of an elevated MSAFP, owing to both a lower incidence and a higher frequency of closed lesions. Given the extent of overlap between affected and unaffected pregnancies, it is not possible to detect all cases of open spina bifida with MSAFP screening, and likewise, most cases reported to be in need of further evaluation will ultimately be determined to be normal.

As discussed previously, AFP levels vary with gestational age. The optimal time for serum NTD screening is 16 to 18 weeks of gestation. Before 16 weeks, there is more overlap between affected and unaffected pregnancies. Whereas last menstrual period (LMP) dating is sufficiently accurate for NTD screening, sonographic dating is more accurate and its use improves sensitivity and specificity of screening. In addition, because second trimester biparietal diameter (BPD) measurements are usually smaller in fetuses with spina bifida, the MSAFP will appear higher, and this artifact improves the detection rate for this lesion. Other sonographic measurements (e.g., crown-rump length or composite biometry) can reliably date the pregnancy but do not have

this unique advantage of BPD dating. Therefore, in the second trimester, ultrasound dating based on BPD alone is recommended for pregnancies at 14 weeks of gestation or later for the purposes of AFP screening. Most laboratories have separate sets of distribution parameters for ultrasound versus LMP-dated pregnancies.

Several factors other than gestational age affect MSAFP levels, including maternal weight,[50] race,[51,52] insulin-dependent diabetes mellitus (IDDM),[53,54] and the number of fetuses. Studies have also suggested that second trimester MSAFP is consistently elevated after first trimester transabdominal multifetal pregnancy reduction (MFPR) and should not be performed in this setting.[55] Because larger maternal size results in greater dilution of AFP derived from the fetus, obese women have lower levels of MSAFP. Black and Asian women have levels that are 10% to 15% higher than nonblack women, and insulin-dependent diabetic women have levels that are lower than the general population. The physiologic basis for this lower value is unclear. Each of these factors is usually taken into account in the calculation of risk. Although other factors, such as maternal smoking[56,57] and IVF,[58,59] have a small impact on levels of MSAFP and other biochemical markers, these differences are not generally of sufficient magnitude to warrant correction.

Elevated Maternal Serum Alpha-Fetoprotein

When the MSAFP level is above the cutoff (either 2.0 or 2.5 MoM), the accuracy of dating should be assessed. If dating based on LMP was used for the original calculation, an ultrasound is indicated to confirm dating and rule out multiple gestations and fetal demise, both of which can cause an elevated MSAFP. An anatomic survey should be performed as well to assess any identifiable structural birth defect to explain the elevation.

If the screening ultrasound does not identify a cause for the increased MSAFP, further assessment with more sophisticated sonography and potentially amniocentesis is indicated. The sensitivity of ultrasound for the detection of NTD and other significant structural abnormalities associated with increased MSAFP has been reported to be as high as 94% to 100%.[60] Ultrasound alone is reported to be more sensitive than MSAFP for the initial detection of NTD, although this varies with the experience and expertise of the ultrasound examiner.[61] Ultrasound is less expensive than amniocentesis and does not carry the risk of pregnancy loss.

Amniocentesis allows for measurement of both AFP and acetylcholinesterase (AChE) in the amniotic fluid. Measurement of AFAFP and AChE has a 97% detection rate for NTDs, with a false positive rate of 0.5%.[62] Although many disorders can result in an elevated AFAFP, AChE is more specific to neural tissue. Detection of AChE in the amniotic fluid generally indicates that an open NTD is present, although a positive AChE has also been reported with omphalocele, gastroschisis, cystic hygroma, fetal skin lesions, and fetal hydrops.[63,64]

A major cause of borderline AFAFP elevations and false positive AChE results is contamination of the sample with fetal blood. Fetal blood AFP levels are more than 100 times higher than AFAFP levels. False positive AChE results occur in about 2% of visibly bloodstained samples and 0.2% of samples that are not visibly bloodstained. Testing for the presence of fetal hemoglobin is indicated for samples with elevated AFAFP, visible red blood cell contamination, and certain other indications (e.g., unexplained elevated MSAFP, reddish AFAFP).

Several investigators have reported an association between elevated MSAFP and an increased risk of fetal aneuploidy, an additional argument for amniocentesis. These studies have estimated the prevalence of clinically significant aneuploidy in this setting at 1%, with approximately 55% of these being autosomal aneuploidies and 45% sex chromosomal abnormalities.[65,66]

Other Abnormalities and Elevated Alpha-Fetoprotein

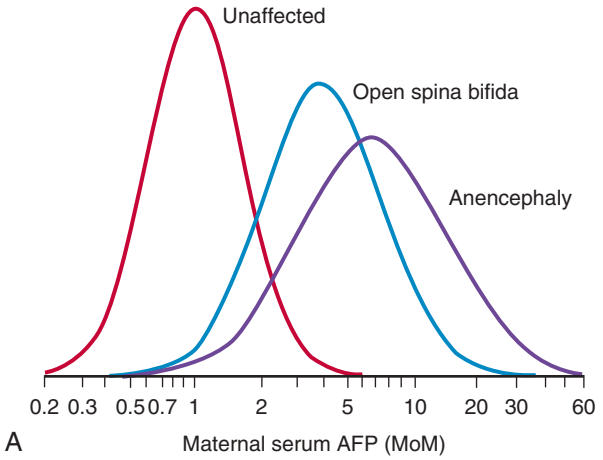
An elevated MSAFP can be associated with fetal defects other than NTDs (Fig. 2-12, Table 2-7), including omphalocele and gastroschisis. In addition, some fetal skin disorders allow increased diffusion of AFP into the amniotic fluid, resulting in an elevated MSAFP. Congenital nephrosis can cause extremely high levels of AFP owing to fetal proteinuria and is suspected with a normal ultrasound and markedly elevated MSAFP (often >10 MoM). This AR disorder results in renal failure early in life, and children often die in infancy or early childhood. It is relatively rare except in Finland, where the reported incidence of 1/2600 live births makes the disease a primary focus of an AFP screening program. DNA testing for Finnish nephrosis is now available, although it is of low yield in families not of Finnish descent.[47,67,68] Rarely, the source of an unexplained MSAFP can be maternal in nature and not reflective of the pregnancy. This includes maternal hepatic tumors or ovarian tumors that secrete AFP and confound the screening results. An unexplained MSAFP and AFAFP have been associated with adverse obstetric outcomes including preeclampsia and preterm delivery.[69]

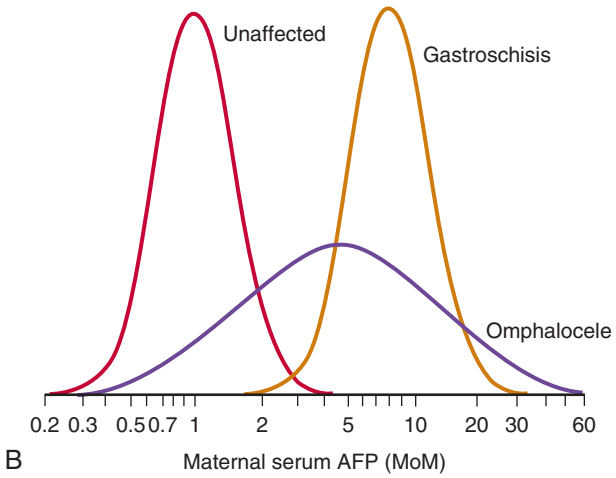
Fetal Chromosomal Aneuploidy

Maternal age has historically been the most frequent method for identifying women at increased risk for fetal chromosome abnormalities and determining who should be offered prenatal diagnostic testing. As maternal age increases, the chance of delivering a child with DS increases from about 1/1000 at 30 years of age, to almost 1/400 at 35 years of age, and 1/100 at 40 years of age (see Table 2-1).[70] Paternal age does not affect aneuploidy risk. This clinical observation is consistent with studies demonstrating that greater than 90% of trisomy 21 results from nondisjunction in the oocyte, most commonly during meiosis I.[71] The mechanism of the nondisjunction event related to maternal age is not known. Because of the association of advancing maternal age with nondisjunction predisposing to aneuploidy, prenatal diagnosis has been offered to women 35 years of age or older for many years. At 35 years of age, the chance of identifying a fetus with DS approximates the chance of miscarriage due to the amniocentesis procedure. It is in part for this reason that testing has traditionally been offered at this point. For many women, however, the decision to undergo amniocentesis is difficult, because not all women weigh the risks equally. For some, the possibility of miscarriage is far more of a concern than the possibility of having a child with DS. For others, concerns over caring for a child with disabilities may be more serious.[72] All patients considering prenatal diagnosis should undergo genetic counseling to discuss the options available and the risks, benefits, and limitations of each testing choice.

FIRST TRIMESTER RISK ASSESSMENT

First trimester risk assessment typically occurs between 9 and 14 weeks' gestation, depending on which markers are used, and provides risk assessment for trisomy 21 and 18 primarily, as well as for trisomy 13 in some laboratories. First trimester screening generally includes ultrasound measurement of the nuchal translucency, done at a crown-rump length of approximately 38 to 84 mm, and biochemical measurements of free β- or total human chorionic gonadotropin (hCG) and pregnancy-associated plasma protein A (PAPP-A). These markers are combined with maternal age and the number of fetuses to provide a patient-specific risk with a sensitivity of 85% for DS with a 5% false positive rate.[73-78] hCG level is typically elevated in pregnancies affected with fetal DS, whereas PAPP-A is lower. The nuchal translucency is often increased in fetuses with DS as well as a variety of other genetic conditions, including trisomy 13, trisomy 18, Turner syndrome, triploidy, and structural birth defects, particularly CHDs.[77] The nuchal





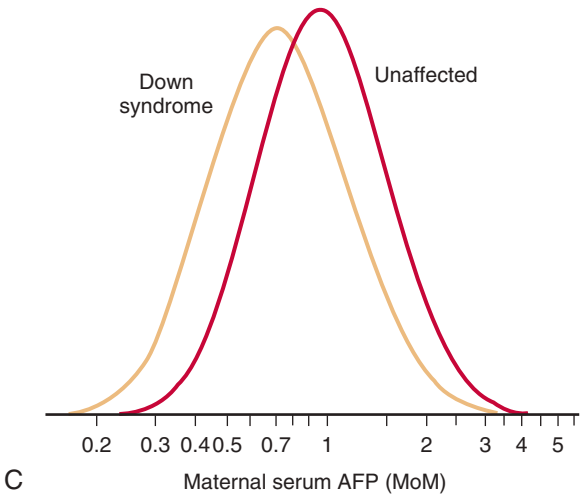


FIG 2-12 A, Distribution of second trimester maternal serum alpha-fetoprotein levels (MSAFP) in unaffected pregnancies and those affected by open spina bifida and anencephaly. The median for open spina bifida is 3.8 multiples of the median (MoM) and for anencephaly is 6.5 MoM. **B,** Distribution of second trimester MSAFP levels in unaffected pregnancies and those affected by gastroschisis and omphalocele. The median for gastroschisis pregnancies is 7.0 MoM and for omphalocele is 4.1 MoM. **C,** Distribution of second trimester MSAFP levels in unaffected pregnancies and those affected by Down syndrome. The median alpha-fetoprotein value is 0.75 MoM, and extensive overlap occurs between the affected and unaffected populations. MSAFP, maternal serum alpha-fetoprotein.

measurement must be very precise and can be challenging to obtain accurately. It is also known to be dependent on the sonographer's experience and the quality of equipment, and therefore, proper training and quality management are important components of screening programs that include this ultrasound measurement in chromosomal aneuploidy risk assessment. The risk for aneuploidy increases as the nuchal translucency thickness increases (see Chapter 3). Cystic hygroma is a single or septated fluid-filled cavity usually involving the nuchal region that is the result of a lymphatic malformation and subsequent lymph accumulation. Approximately 50% of cystic hygromas identified in the first trimester are associated with chromosomal aneuploidy, and the majority of these are fetuses affected with DS.[79]

Women with a positive screening test in the first trimester should be counseled regarding the results and options for further testing including CVS as the most immediate diagnostic test available in the late first and early second trimester. Options for further screening include contingent and stepwise sequential screening as well as cell-free DNA testing. The benefit of identifying aneuploidy in the first trimester is that it affords patients information earlier in pregnancy so that decisions regarding pregnancy termination may be made at a time when services are more readily available and represent less maternal risk. The risk with early screening for chromosomal aneuploidy is the inherent loss rate in this population and the identification of a pregnancy that would go on to be spontaneously miscarried. Screening for NTDs by MSAFP or detailed ultrasound in the second trimester is recommended for those women who have first trimester genetic risk assessment.

SECOND TRIMESTER RISK ASSESSMENT

Shortly after the introduction of MSAFP screening for NTD, it was recognized that fetuses with DS had a lower mean MSAFP in the second trimester.[80,81] Subsequent investigations have reported that maternal serum, amniotic fluid,[81] and fetal cord serum[82] levels of AFP

TABLE 2-8 Pattern of Results Seen with Expanded AFP Screening in Fetal Disorders

	AFP	uE_3	hCG	Inhibin A
Open NTDs	↑	No change	No change	No change
Down syndrome	↓	↓	↑	↑
Trisomy 18	↑	↓	↓	No change

AFP, alpha-fetoprotein; hCG, human chorionic gonadotropin; NTDs, neural tube disorders; uE_3, unconjugated estriol.

are all lower in pregnancies in which the fetus has DS. A number of other biochemical markers have also been studied for use in aneuploidy screening. Unconjugated estriol (uE_3),[83] hCG,[84] and dimeric inhibin A[76,77,85] all add sensitivity and specificity to second trimester biochemical screening for DS and are included in a test routinely referred to as the *quad screen.*[77,86] Like AFP, uE_3 is 25% to 30% lower in DS pregnancy, whereas hCG and inhibin A are both increased with a median value about twice that of normal control subjects (Table 2-8).[72] With the use of quad screening, the detection rate for DS is 80% with a false positive rate of 5%.[87] In pregnancies in which the fetus is affected with trisomy 18, the levels of AFP, uE_3, and hCG are all decreased, with median values of 0.6, 0.5, and 0.3 MoM, respectively. Inhibin A does not contribute to the detection of trisomy 18 and is not included in the screening algorithm. Use of a protocol evaluating this characteristic pattern is associated with an 80% detection rate for trisomy 18, but it identifies only 0.5% of women as high risk.[88] The second trimester maternal serum quad screen reports risk results for DS, trisomy 18, and NTDs. The quad screen does not reliably report risk assessment for trisomy 13 and is therefore not reported by most laboratories.

Sonographic "Soft Markers" for Aneuploidy

A fetal anatomic survey in the second trimester has also been used as a screening tool for chromosomal aneuploidy (see Chapter 3). Approximately one third of fetuses with DS have an identifiable sonographic finding of either a major or minor structural variation. This includes CHDs (most commonly ventricular septal defects or endocardial cushion defects), ventriculomegaly, duodenal atresia, or a variety of "soft markers." Soft markers include thickened nuchal skin fold, EB, renal pyelectasis, shortened femur and humerus, and hypoplastic or absent nasal bone. There are contrasting opinions on the utility of ultrasound to modify risk for DS. Most providers use the information to adjust prior risk from maternal age or standard screening results by applying likelihood ratios. In one large study of 7800 women to determine the effectiveness of ultrasound in genetic risk assessment, when performed by experienced providers, a genetic ultrasound alone had a detection rate for DS of 69% with a 5% false positive rate and enhanced the sensitivity of all other screening modalities.[89] A meta-analysis pooling data from 48 studies of low- and high-risk women indicate hypoplastic or absent nasal bone to be associated with the greatest risk for DS[90] (see Chapter 3).

COMBINED FIRST AND SECOND TRIMESTER RISK ASSESSMENT

There are several ways to combine ultrasound and serum testing in the first trimester with second trimester serum analytes. Integrated testing has the highest DS detection rate (90%) with the lowest false positive rate (2%) compared to other blood and ultrasound test strategies in the first or second trimester.[91] This test includes blood and nuchal translucency ultrasound in the first trimester in addition to blood in the second trimester to produce a single risk calculation for DS. The advantage of this test is the superior sensitivity and low false positive rate, whereas a disadvantage is that the information is not available until the second trimester. Stepwise sequential screening utilizes the same combination of nuchal translucency and first and second trimester serum analytes, but preliminary results are provided in the first trimester. For patients at high risk for aneuploidy, diagnostic testing is offered. Those whose risk is not increased can then have serum done in the second trimester and integrated with the first trimester results for a final risk calculation. The serum-integrated test (blood only) includes biochemical analytes from the first and second trimesters and is offered in locations where expertise in nuchal translucency ultrasound is limited or not available.[92]

Cell Free DNA Screening

The quest to identify fetal genetic material in maternal blood began decades ago and was first described in 1969.[93] Efforts to isolate and purify intact fetal cells for prenatal testing ultimately proved to be unsuccessful, in part because of the scarcity of tissue and persistence of cells from antecedent pregnancies. The concept of cell-free DNA as a source of fetal genetic material was reported by Lo and colleagues in 1997.[93] Both maternal and fetal DNA are found circulating in plasma, and measurement of relative chromosomal content can be used to identify fetal trisomy[94] (Fig. 2-13). Fetal cell-free DNA is identifiable in maternal blood as early as 5 to 7 weeks' gestation, is found in relatively larger quantities than intact fetal cells, and is cleared from maternal circulation within hours of delivery, making this a better source of genetic material than intact cells. Approximately 10% of circulating DNA found in maternal plasma during pregnancy is fetal in origin, and this fetal fraction is almost entirely made up of trophoblast-derived DNA. This is important to understand, as there is potential for placental mosaicism, in which the placental and fetal genotypes differ, presenting the possibility of false positive or false negative results.

Cell-free fetal DNA testing was reported for the determination of fetal rhesus D genotype and early fetal sex identification for those at risk for X-linked male lethal disorders several years prior to the application for chromosomal aneuploidy risk assessment.[95,96] In October 2011, the first commercial laboratory began offering cell-free DNA (cfDNA) screening, also referred to as noninvasive prenatal testing or NIPT, for common aneuploidy conditions. Since that time, the utilization of this technique has markedly increased owing to the very high reported detection rate and low false positive rate, particularly for DS screening. Although highly accurate, cell-free DNA is considered a screening test and initial recommendations were that this test be reserved for high-risk women.[97] Most commercial laboratories report risk results for chromosomes 21, 13, 18, X, and Y. Laboratories that offer the technology use either massively parallel shotgun sequencing, which sequences DNA fragments from the whole genome, or targeted sequencing that looks only at regions of interest. In either scenario, high-throughput DNA sequencing undergoes extensive data analysis to detect abnormal amounts of genetic material specific to a chromosome or region of interest from the fetus. The sensitivity and specificity of cell-free DNA screening for the detection of DS has been reported to be between 96% and 100%, although this figure does not account for the subset of patients in which the testing is unsuccessful because of the low fraction of fetal DNA or high sequencing variance leading to difficulty in interpreting the results.[98] It is recommended that patients undergo pretest counseling to understand the screening nature of the test, that the test only detects common aneuploidies, the potential for unanticipated results or failure to obtain test results, and the options for diagnostic testing. Patients with a low-risk test should be aware that this does not guarantee an unaffected pregnancy. Because aneuploidy is relatively

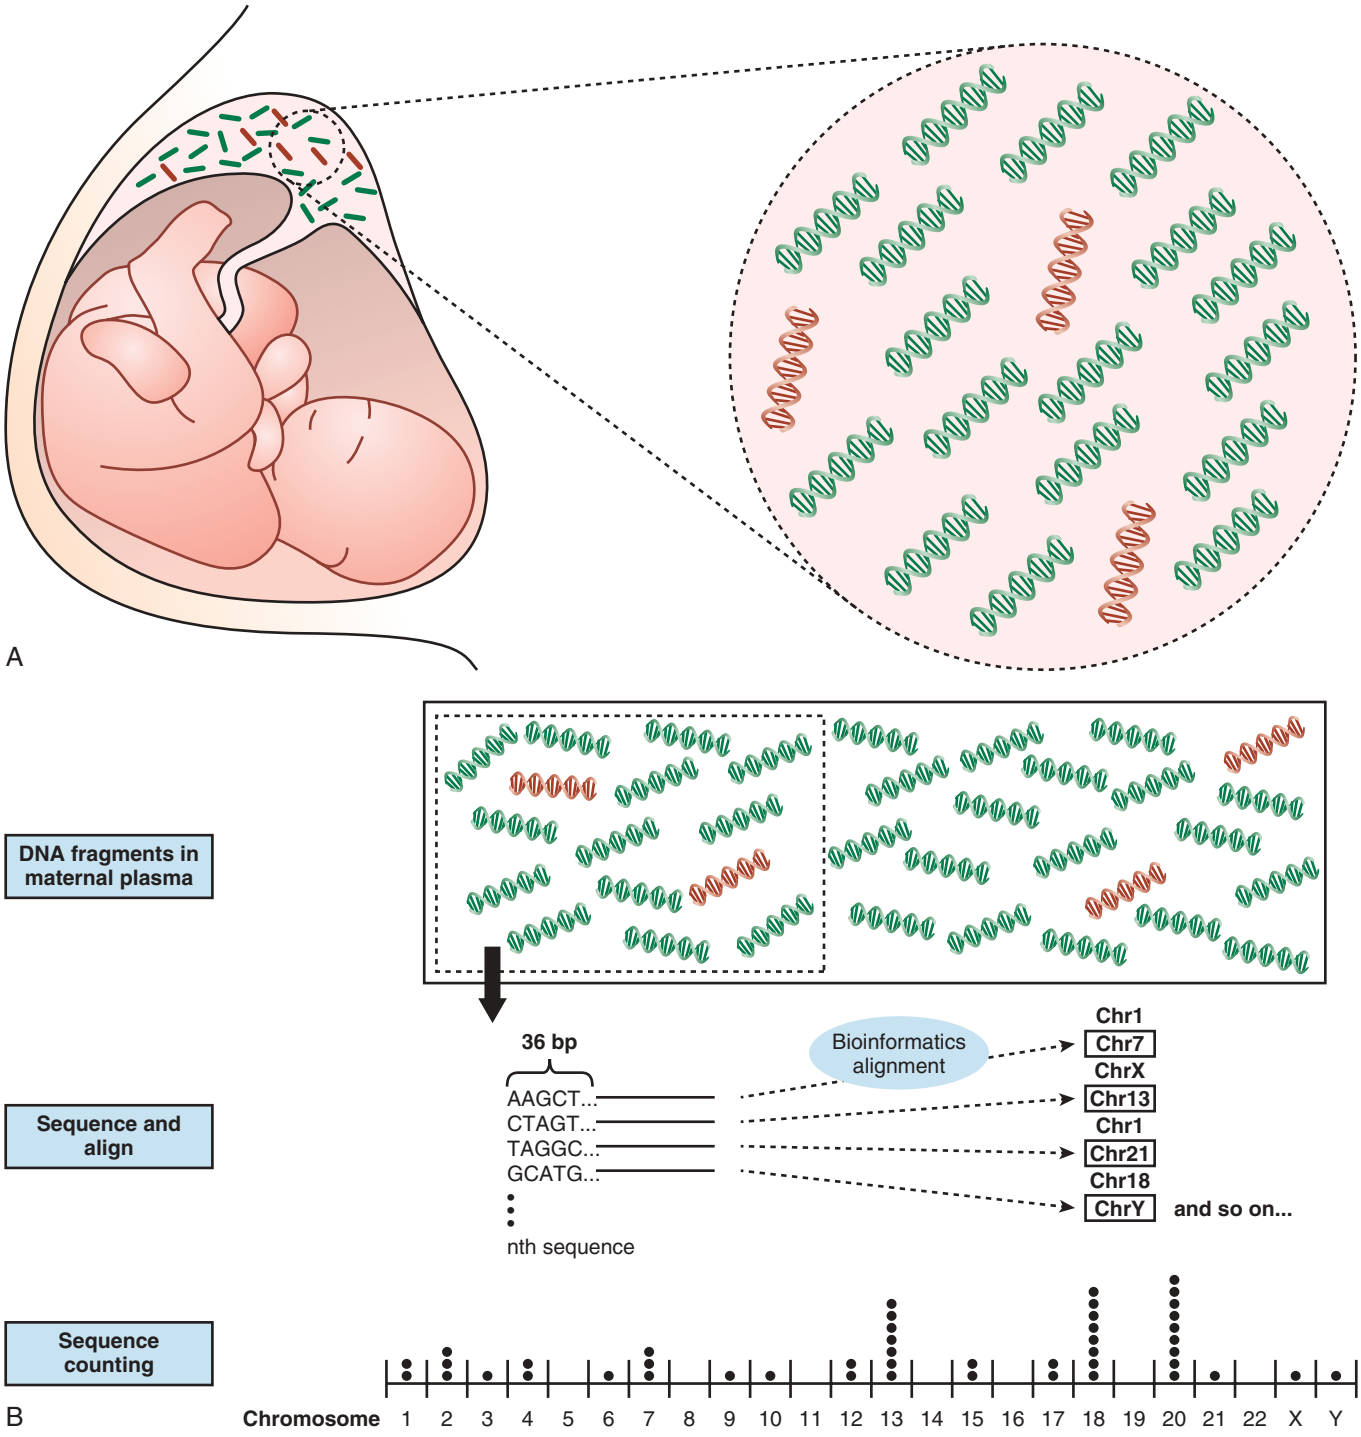

FIG 2-13 **A,** Cell-free DNA from the placenta contributes approximately 10% to 12% of the total cell-free DNA in the maternal circulation. **B,** The approach to detecting trisomy through measurement of relative chromosomal contribution to the cell-free DNA in the maternal plasma. Alignment of each chromosomal fragment to the chromosome of origin, followed by a bioinformatics calculation of the relative contribution, can be used to calculate the likelihood of fetal trisomy. (With permission from Circulating Cell-Free DNA in Women's Medicine by Dr. Xiao Yan Zhong and Dr. Wolfgang Holgreve. The Global Library of Women's Medicine.)

uncommon, the positive predictive value or chance of an affected fetus given a positive result by cell-free DNA screening is likely 50% or less, depending on other risk factors and the particular aneuploidy.[99] Therefore, a patient with a high-risk test result should be referred for genetic counseling to discuss options for further testing.

In this evolving field of perinatal medicine, the technology is rapidly expanding to offer more and more clinical data. For example, some companies offer screening for 4 to 5 microdeletion conditions, such as 22q deletion and 1p36 deletion. Although most are individually rare, the 22q microdeletion is reported to occur in about 1/3000

newborns. These conditions are not associated with advanced maternal age, and some may lack structural birth defects on ultrasound evaluation.[100] The importance of pretest counseling and discussing possible results and implications for prenatally ascertained information should be reviewed.

Although cell-free DNA screening has changed the landscape of prenatal screening, further research to reduce cost and improve efficiency of the testing is ongoing. The concept of "precision medicine for the fetus" is evolving with work on the fetal transcriptome, metabolome, and proteome using epigenetic information, RNA, and microRNA. The entire fetal genome has been sequenced from DNA in maternal blood with important implications for future prenatal testing.[101] Many ethical issues have been raised regarding prenatal testing, including fetal autonomy in genetic testing, identification of adult-onset disorders in the prenatal setting, unanticipated or uncertain results, lack of appropriate resources and trained providers for counseling and interpretation of complex genetic information, and the role of industry in promoting research.

PRENATAL SCREENING IN MULTIPLE GESTATIONS

A number of complexities arise in the screening of twin pregnancies. First, the incidence of DS appears to be lower than expected in twin pregnancies, making risk calculation more challenging.[102] Second, serum markers are approximately, but not exactly, twice those found in singleton pregnancies. Third, a single maternal serum value is used to provide information about multiple fetuses. In discordant cases, the normal co-twin will mask the abnormal marker production associated with the affected twin. Finally, with monozygotic twins, both are most commonly either affected or unaffected, whereas with dizygous twins, the risk of DS is independent. Although ultrasound determination of monochorionicity is diagnostic of monozygosity, with same-gender dichorionic pregnancies, zygosity is uncertain. Although rare, monozygous twins can have discordant karyotypes that most frequently involve sex chromosomes. Because nuchal translucency screening in the first trimester is able to evaluate each fetus individually, it may be the most useful screen for multiple pregnancies. In high-order multiple gestations, biochemical screening is generally not possible, and again, nuchal translucency is the most useful and often the only option in such cases. Large studies are needed to determine the optimal screening method in multiple pregnancies.

THIRD-TRIMESTER PREGNANCY COMPLICATIONS AFTER ABNORMAL SERUM SCREENING

Extreme marker levels, both low and high, have been associated with third trimester pregnancy complications such as hypertensive disorders, FGR, and preterm birth. Most cases, however, are not due to fetal or maternal disease and ultimately result in a normal outcome. Numerous studies have demonstrated that women with elevated levels of MSAFP have an increased risk of complications, such as spontaneous abortion, small-for-gestational-age infants, pregnancy-associated hypertensive disorders, and preterm delivery. The magnitude of risk for any adverse outcome increases with increasing maternal serum levels, from a risk of 19% with levels of 2.5 to 2.9 MoM, to 67% with an MSAFP of greater than 6.0 MoM.[103] In cases of unexplained increased MSAFP, increased transplacental transfer is responsible for the elevated value. Such increased transfer occurs with various placental abnormalities, and these same placental abnormalities later result in perinatal complications. Abnormalities such as placenta accreta, increta, and percreta have also been reported with an elevated AFP,[104,105] and uterine anomalies have been reported to be 22 times more common in these patients as well.[106] Because of the very large concentration gradient between fetal and maternal serum levels of AFP, even a slight compromise in uteroplacental integrity will allow detectably increased transport of AFP across the placenta.

Other biochemical markers and combinations of markers have also been studied with respect to adverse outcome in late pregnancy. Elevated hCG has been associated with an increased risk of FGR, hypertension/preeclampsia, fetal malformations, chromosomal abnormalities, and adverse perinatal outcome.[48] As with MSAFP, the highest levels of hCG are associated with the highest risk of poor outcome.[107] The risk of having an adverse outcome is most significantly increased if a patient has two or more abnormal markers.[108] Both singleton and twin pregnancies with elevated hCG and AFP have been associated with adverse obstetric outcomes.[109-111]

Women with low estriol (<0.75 MoM) have also been found to have an increased risk of adverse outcome, including FGR, oligohydramnios, and delivery of small-for-gestational-age infants, a risk that seems independent of elevated hCG or AFP.[112] About 0.27% of women will have a very low uE_3 (<0.15 MoM), a finding that has been associated with a number of metabolic and genetic disorders including Smith-Lemli-Opitz syndrome, steroid sulfatase deficiency, Kallmann syndrome, congenital adrenal hyperplasia, and other disorders associated with adrenal dysfunction. Smith-Lemli-Opitz syndrome is an AR disorder that results in multiple malformations, including CHDs, mental retardation, and ambiguous genitalia. Because the primary abnormality involves cholesterol biosynthesis, a lack of cholesterol precursors from the fetus renders the placenta unable to produce uE_3.[113] Prenatal diagnosis is possible through detection of elevated levels of 7-OH-dehydrocholesterol in amniotic fluid or maternal urine.[114] The other, more common cause of very low estriol is the presence of X-linked steroid sulfatase in the fetus. Lack of this enzyme in the placenta also results in the inability to produce uE_3. This disorder is an X-linked condition leading to ichthyosis as the primary symptom in offspring, and a careful family history will often reveal symptoms in a previously undiagnosed male relative (grandfather or brother). The diagnosis can be confirmed through molecular testing for the causative microdeletion on amniotic fluid. Although the disorder is relatively mild, prenatal diagnosis can reassure the family and physician that another, more serious condition is not present.[115-117]

Optimal management of pregnancies with unexplained abnormal biochemical screening, however, remains controversial.[49] Although many of the associations between adverse obstetric outcomes and abnormal serum markers are statistically significant, the low sensitivity and low predictive value of these tests precludes their use as a screening tool for complications. Various strategies of antenatal surveillance have been proposed using ultrasound for growth, Doppler studies, and other forms of fetal testing. For example, uterine artery Doppler may indicate pregnancies at risk for uteroplacental insufficiency in those with abnormal serum analytes, and some recommend that it be performed in the second trimester.[49] Ideally, further research will better define a model of care for patients with abnormal serum analytes in the absence of fetal aneuploidy and structural birth defects.

GENETIC DIAGNOSIS IN PREGNANCY

For many families seeking genetic counseling, a major goal is learning the risk for heritable disease in their children and the options that are available for avoiding having an affected child. The principal goal of prenatal diagnosis is to provide at-risk families with definitive information so they can make informed choices during pregnancy. The potential benefits of prenatal diagnosis include (1) providing reassurance to at-risk families when the results are normal, (2) providing risk

information to couples who would not have a child without such reassurance, (3) allowing couples to prepare for the birth of an affected child, (4) allowing medical providers to plan for the delivery and postnatal care of an affected infant, and (5) providing risk information to couples for whom termination of an affected pregnancy is an option. Other considerations include the potential impact of the information for other family members and the possibility of unanticipated information or information of uncertain significance. As genetic testing has advanced, these latter considerations are increasingly important and relevant.

Prenatal diagnosis is typically performed early in pregnancy, at a time when termination of an affected fetus can be performed safely. Although prenatal diagnosis with termination of affected fetuses is one option for preventing the recurrence of a genetic disorder in a family, it is by no means a universal solution. There are still disorders for which prenatal diagnosis is not possible, and for many parents termination is not an acceptable option, even if prenatal diagnosis is available. Other measures for avoiding recurrence of a genetic disorder include avoiding childbirth through contraception or sterilization; adoption; sperm or ovum donation; or preimplantation genetic diagnosis (PGD) on embryos obtained through IVF (see later). For many families, even if termination of pregnancy is not an acceptable option, prenatal diagnosis can help them prepare mentally, emotionally, and financially and to seek support systems and arrange for appropriate neonatal care before the baby is born.

Genetic Counseling Before Prenatal Diagnostic Procedures

Parents considering prenatal diagnosis need information that will allow them to understand their personal and clinical circumstances and to give (or withhold) consent for the prenatal diagnostic procedures. Genetic counseling before such procedures usually addresses the following: (1) the chance that the fetus will be affected, (2) the nature and consequences of the testable disorder(s), (3) the risks and limitations of the procedures being performed, (4) the time required before a report of the test results can be issued, and (5) the possibility of complications of the procedures such as a failed attempt to obtain a sufficient, testable sample, or inconclusive results. Options for dealing with abnormal results are usually discussed, and it is emphasized that undertaking prenatal diagnosis in no way obligates the parents to terminate a pregnancy if an abnormality is discovered.

Techniques for Prenatal Diagnosis

Amniocentesis

In amniocentesis, a sample of amniotic fluid (20-30 mL) is removed by inserting a 20- or 22-G spinal needle through the maternal abdomen and uterine wall into the amniotic cavity under ultrasound guidance (Fig. 2-14). Amniotic fluid contains desquamated fetal cells that can be cultured and karyotyped or used for metabolic assays or DNA extraction if a specific indication is present. AFAFP levels are also usually routinely measured.

Amniocentesis is typically performed at 15 to 20 weeks' gestation. The volume of amniotic fluid at 15 menstrual weeks is 125 mL, and it increases 50 mL/week for the next 13 weeks.[118] In an attempt to provide earlier results, the feasibility and safety of amniocentesis as early as 11 weeks' gestation have been investigated. Results of a large, multicenter randomized trial of early (11 to 13⁄7 weeks) versus midtrimester (15 to 16⁄7 weeks) amniocentesis revealed a significantly increased loss rate in the early aminocentesis group (7.6% vs. 5.9%). In addition, there was a significantly increased incidence of talipes equinovarus in the early amniocentesis group (1.3% vs. 0.1%). Thus, it appears that early amniocentesis does carry an increased risk compared with midtrimester amniocentesis, and for this reason this procedure is not recommended prior to 15 weeks' gestation.[119]

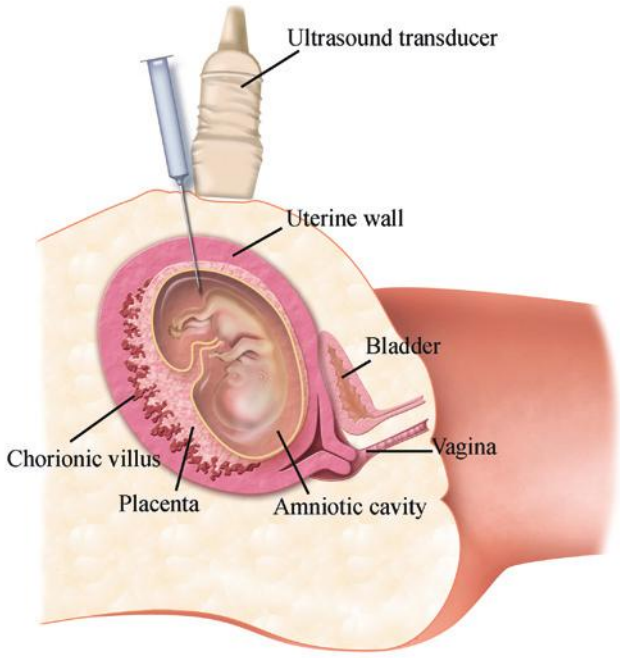

FIG 2-14 Amniocentesis needle is positioned in the amniotic cavity under ultrasound guidance. (Illustration by James A. Cooper, MD, San Diego, CA.)

The major complication of amniocentesis is the risk of miscarriage (above the 2% to 3% risk for any pregnancy at this gestational age unrelated to the procedure). The miscarriage risk of midtrimester amniocentesis at 15 to 20 weeks' gestation is typically quoted at 0.2% to 0.3% (1/300 to 1/500),[120] although risks as low as 1/1600 have been reported in some studies.[121,122] The only randomized trial that has been performed in low-risk patients was in the United Kingdom in 1986; this study demonstrated a 1% procedure-related loss rate.[123] Leakage of amniotic fluid following amniocentesis is not uncommon but typically resolves without long-term sequelae. Needle-associated injury to the fetus is rare, as is the incidence of maternal infection or intrauterine infection.

Chorionic Villus Sampling

In CVS, a biopsy of the developing placenta is performed at 10 to 13 weeks' gestation (Fig. 2-15). The primary advantage of CVS is that it can be performed earlier in gestation, which allows a decreased period of anxiety for patients at risk. Early results also permit first trimester termination, a safer and more readily available procedure than abortion in the second trimester. Indications for CVS are generally the same as those for amniocentesis, although AFP levels cannot be assessed on chorionic villi. Therefore, women who undergo CVS should be offered NTD screening with either MSAFP measurement or ultrasound later in pregnancy.

The two commonly used approaches to CVS are transcervical and transabdominal. Both are performed under ultrasound guidance, which is used to document fetal viability, gestational age, fetal number, localization of the placenta, and determination of the best approach and sampling path. With transcervical CVS, the patient is placed in the dorsal lithotomy position, a speculum inserted, and the vagina and cervix prepared with iodine antiseptic. A 16-G polyethylene catheter

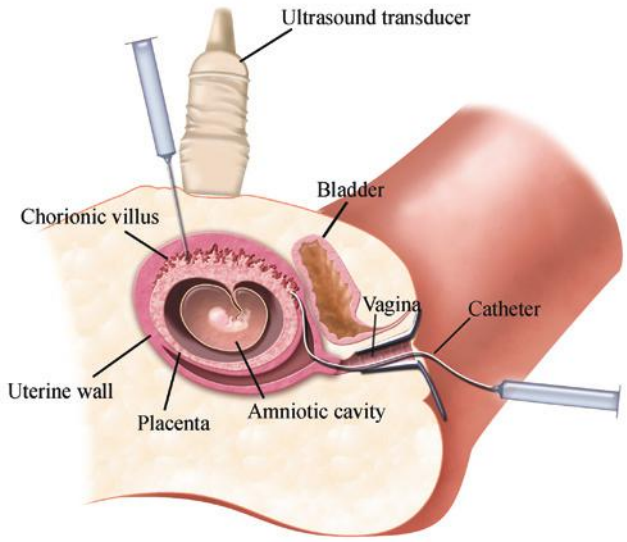

FIG 2-15 Chorionic villus sampling. Either chorionic villus catheter or sampling needle is placed into the developing placenta under continuous ultrasound guidance. (Illustration by James A. Cooper, MD, San Diego, CA.)

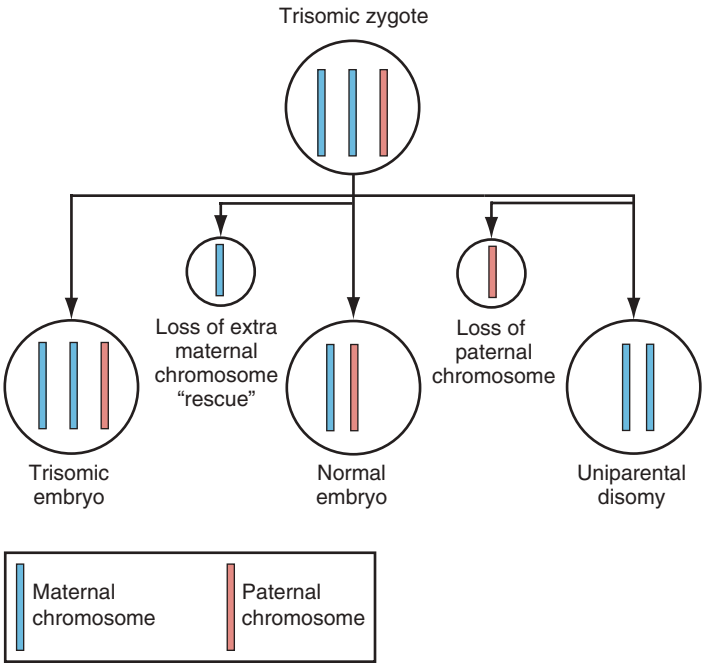

FIG 2-16 Trisomy rescue and uniparental disomy. Diploid ovum is fertilized by a normal, haploid sperm, resulting in a trisomic zygote. The cells multiply and divide, and one cell reverts to a diploid state owing to anaphase lag. This may happen owing to loss of either of the maternal chromsomes, or of the paternal chromosome. If one of the maternal chromosomes is lost, the resulting cell or cells will be normal. If the paternal chromosome is lost, the cells will be diploid but uniparental disomy will result.

with a flexible, stainless steel obturator is inserted through the cervix and into the developing placenta. With a transabdominal approach, a 20-G needle is inserted into the placenta in a fashion similar to that used for amniocentesis. In either approach, a 20-mL syringe is used to apply negative pressure and obtain a sample.

The risks of CVS were compared with those of amniocentesis in several trials performed shortly after introduction of the technique in the 1980s. A U.S. collaborative study demonstrated a loss rate 0.8% higher than that of midtrimester amniocentesis, a difference that was not statistically significant.[124] A Canadian trial also demonstrated a nonsignificant increase in losses of 0.6% above amniocentesis.[125] CVS does have a long learning curve, and the risks are very provider dependent; therefore, this equivalent loss rate may not be generalizable to all centers and providers.[126]

One important characteristic of CVS, different from amniocentesis, is the risk of confined placental mosaicism (CPM), which occurs in 1% to 2% of cases. CPM represents a discrepancy between the chromosomal makeup of the placenta and the fetus and is diagnosed when a mixture of aneuploid and normal cells are detected by CVS, whereas only normal cells are found on a subsequent amniocentesis or in the infant at birth. Most commonly, CPM represents a trisomic cell line present only in the placenta with a normal diploid chromosome complement in the fetus.[127] However, the fetus is truly mosaic in about 10% of cases,[128] although the risk is somewhat dependent on the specific trisomy identified.[129] Although some cases of CPM are associated with poor placental function and perinatal complications such as FGR and maternal hypertension, most commonly the outcome is normal. Such discordance between fetus and placenta can also confound results of cell-free DNA screening, which is based on placental trophoblast cells.

CPM can be associated with so-called trisomy rescue of an originally trisomic conception (Fig. 2-16). When this occurs, the fetus may be disomic but have uniparental disomy (UPD), a condition in which both chromosomes were inherited from the same parent. For example, if an embryo has trisomy 15 due to maternal nondisjunction, one or more cells in the inner cell mass, destined to become the fetus, may be "rescued" by loss of one chromosome 15. The mechanism is not well understood and the chromosome lost is thought to be random. If by chance the paternal copy is lost, there will be a normal chromosome number in the fetus, but maternal UPD 15. Trisomy rescue and UPD can potentially involve any chromosome, but if imprinted genes are present on the particular chromosome involved, this may have consequences for the fetus. Maternal UPD 15 is a cause of Prader-Willi syndrome (see earlier). In this scenario, there is no paternal contribution of chromosome 15. Therefore, testing for UPD is indicated as a follow-up to CPM detected by CVS when a chromosome containing known imprinted genes is involved (e.g., chromosomes 6, 7, 11, 14, and 15). If the chromosome involved in the original trisomy does not contain imprinted genes, no phenotypic consequences for the fetus would be predicted.

In the early 1990s, there were a number of reports of fetal limb reduction defects following CVS.[130,131] The procedures in the affected infants were largely performed between 55 and 66 days of gestation, and subsequent studies indicated that early gestational age (<10 completed weeks) at sampling increased the risk for this complication. After much investigation, including a large study of more than 140,000 cases of CVS submitted to the World Health Organization registry, it was concluded that there is no increased risk of limb reduction defects following CVS performed at greater than 10 weeks' gestation.[132] With both CVS and amniocentesis, the miscarriage rates are correlated with experience of the clinician and ongoing procedure volume.[133,134]

Multiple Gestations

If a twin gestation is present, the risk of a chromosome abnormality has been thought to be increased as compared with a singleton pregnancy, and mathematically derived formulas have been used to estimate age-related risks of chromosomal abnormalities in twin

gestations.[135] However, the incidence of DS actually appears to be significantly lower than expected in twin pregnancies, particularly in older women and in monochorionic twins.[102] The chance that one or both fetuses will have a chromosome abnormality is dependent on the zygosity. There are three possibilities that would result in either one or both twins being affected: (1) dizygotic twins with one fetus affected, (2) dizygotic twins with both fetuses affected, and (3) monozygotic twins with both fetuses affected. Postzygotic errors can also result in discordant karyotypes in monozygotic twins, although this is rare.

Knowledge of chorionicity is critical when performing invasive procedures in multiple gestations. This is best determined by ultrasound in the first trimester, at which time the determination of chorionicity is highly accurate[136] (see Chapter 7). Prenatal diagnosis in monochorionic pregnancies theoretically requires only one sample, because the fetuses should be chromosomally identical. However, there is a small chance of postzygotic mutations leading to discordant karyotype or of incorrect assignment of chorionicity. For this reason, both twins are typically sampled.

Both CVS and amniocentesis can be used for prenatal diagnosis in multiple gestations. The technique for amniocentesis involves visualizing the dividing membrane and identifying an amniotic fluid pocket in each sac. In order to be certain that each amniotic sac is sampled, 0.5 mL of indigo carmine dye is often instilled after removal of fluid from the first sac. Aspiration of clear fluid from the second sac ensures proper placement. Indigo carmine has not been associated with risks to the fetus, whereas methylene blue dye should not be used owing to reports of fetal hemolysis, bowel atresia, and fetal demise when injected intra-amniotically.[137-139] A single-needle insertion technique for amniocentesis has also been reported, with puncture of the dividing membrane to access the second sac.[140] This raises the potential for admixture of samples with mosaic results, as well as disruption of the intertwin membrane. Reports of fetal abnormalities in twin gestations following rupture of the membrane,[141] and the possibility of creating an iatrogenic monoamniotic twin pregnancy with potential for umbilical cord entanglement, are also concerns.

With CVS, the procedure requires careful sonographic determination of placentation, because dye studies to mark the sample are not possible. Placing the tip of the aspiration device (catheter or needle) near the cord insertion can minimize the possibility of sampling the same fetus twice. A risk of less than 2% of sampling error has been reported with CVS in multiple gestations.[142] With either CVS or amniocentesis, detailed description of the relative locations of the fetuses and placentas is important, particularly if discordant karyotypes are present and selective termination is to be considered. Noting any structural abnormalities or other findings that can differentiate the fetuses is also helpful.

Postprocedural Loss Rates in Multiple Gestations

Although genetic amniocentesis is frequently performed in multiple gestations, smaller numbers limit the availability of data regarding postprocedural losses in multiple gestations following either amniocentesis or CVS. A number of studies have been performed to assess fetal loss rate following amniocentesis in twins. The quoted rate of loss ranges from 2.7% to 8.1%, with a recent systematic review reporting an overall pregnancy loss rate of 3.07%.[142-144] Whereas some studies do suggest a higher postprocedural loss rate in twin pregnancies when compared with singletons, not all account for the higher background loss rate of twins.

With CVS, even more limited data are available to determine the safety and accuracy of this procedure in multiple gestations. Reported pregnancy loss rates in the largest recent trials reported in the literature range from 0.6% to 4.0%, again comparing favorably with the 6% background loss rate reported for twin pregnancies.[136,142-147] Current data indicate that the excess risk following invasive diagnostic testing with either amniocentesis or CVS is approximately 1% to 2%.[144,147]

The choice as to whether to perform amniocentesis or CVS in a multiple pregnancy depends on many factors, such as the likelihood of proceeding to multifetal pregnancy reduction, the gestational age at presentation, the experience of the operator, and the technical difficulties of the specific case, including maternal body habitus and relative positions of the gestational sacs and placentas. Several studies have shown that CVS, in the hands of experienced operators, is at least as safe as second trimester amniocentesis for prenatal diagnosis in multiple pregnancies, with loss rates comparable to control twins.[136,142-147]

Selective Termination of Multifetal Pregnancies

The finding of a single affected fetus in a multiple gestation can present a complex counseling situation. Management options include termination of the entire pregnancy, continuation of the pregnancy, or selective termination. Selective termination in a dichorionic twin pregnancy can be performed with fetal intracardiac injection of potassium chloride. Such an approach is effective, but it carries a loss rate of 4% to 12% for the remaining fetus or fetuses, depending on the gestational age of the pregnancy, starting number of fetuses, and location of the affected fetus.[148,149] If the pregnancy is monochorionic, but discordant for a chromosomal or structural abnormality, the ubiquitous presence of intertwin anastomoses makes intracardiac injection unsafe for the normal twin. If selective termination is desired in this situation, umbilical cord occlusion using laser, ligation, or bipolar coagulation is the only option. Few data exist as to risks to the pregnancy and the remaining twin if this approach is chosen, although there is an increased risk of pregnancy loss and preterm delivery of 15% to 25%.[150,151]

Fetal Blood Sampling and Other Fetal Tissue Biopsy

Although there are theoretically many indications for accessing the fetal circulation directly, advances in molecular genetic technology have greatly decreased the need for percutaneous umbilical blood sampling (PUBS) as well as for performing biopsy of tissues such as fetal muscle, skin, or liver. PUBS has frequently been used to obtain fetal blood for rapid karyotyping, but again, the availability of FISH to detect the most common trisomies has decreased the need for this technique. Disorders such as hemophilia, hemoglobinopathies, immunodeficiencies, and diseases expressed in muscle, skin, and liver that have, in the past, required direct biochemical evaluation of fetal tissue can now commonly be detected through DNA analysis on amniocytes or chorionic villi. At present, PUBS is most commonly used in the evaluation and treatment of fetal alloimmunization when a need for in utero transfusion is suspected. When this procedure is performed, it is done under continuous ultrasound guidance. The umbilical cord insertion into the placenta is identified; this site is commonly used for sampling because the cord is fixed at this location. The cord insertion into the fetus or a free loop of cord can also be accessed; however, this may be more difficult owing to movement of the cord and fetus. The mother may be given parenteral sedation both for her comfort and to decrease fetal movement. Intramuscular or intravascular injection of a short-acting paralytic medication is also occasionally used to eliminate fetal movement, although the long-term effects of fetal paralysis are unknown.[152,153] Once the optimal site for accessing the cord has been identified, the maternal abdomen is prepped and draped, and the insertion site is infiltrated with a local anesthetic. Under ultrasound guidance, a 20- or 22-G spinal needle is advanced into the umbilical vein. Samples of fetal blood are aspirated into heparinized syringes.[154]

Preimplantation Genetic Diagnosis

PGD is a prenatal testing technique in which early embryos, conceived through IVF, undergo genetic testing while being cultured in vitro, before reimplantation in the uterus (Fig. 2-17). *Preimplantation genetic screening* (PGS) is a term used to specifically describe cases in which aneuploidy testing is performed to screen for chromosomal abnormalities in the embryo. In either case, only those embryos with normal results are transferred. PGD can be used to test for most genetic disorders in which a mutation has been identified and can be helpful for couples at high risk of having a fetus affected by a genetic disease for whom pregnancy termination after CVS or amniocentesis is not an option. Because the genetic testing done in cases of PGD must be performed using just one or two cells from these early embryos, with a very rapid turnaround time (generally less than 24 hours), the technique is complex and errors can occur. The rate of error is generally quoted as less than 5%,[155] and it is recommended that CVS or amniocentesis be used to confirm results from PGD. Again, large studies to determine the accuracy and efficacy of PGD are clearly needed.[156] PGD is also used to select euploid embryos in couples who are carriers of balanced translocations. Although the use of IVF with PGS and selection of only euploid embryos is appealing for couples with unexplained recurrent pregnancy loss, the prognosis for live birth in a subsequent pregnancy without any intervention is approximately 75%.[157] Whether the outcome of IVF with PGS for common aneuploidies in women of advanced reproductive age is of benefit remains controversial.[158-160]

PRENATAL TESTING FOR CONGENITAL MALFORMATIONS

Anomalies such as NTD, cleft lip and palate, and CHDs usually occur as multifactorial traits, caused by an interaction of multiple genes with environmental factors. Because these disorders have an elevated risk of recurrence in families, prenatal testing is often requested. Owing to their complex genetic causes, congenital malformations cannot be identified by amniocentesis or CVS. In most cases, prenatal testing consists of detailed ultrasound evaluation aimed at the detection or elucidation of specific fetal birth defects.

As in all other areas of medicine, providing appropriate information and treatment relies on a correct diagnosis. In the prenatal diagnosis of congenital disorders, providing prognostic information or evaluating a possible recurrence in a future pregnancy relies first and foremost on ensuring the correct diagnosis of the original affected child (or other relative). Increasingly, prenatal intervention is offered for such disorders, and again, the prognosis and outcome with such intervention also are dependent on accurate diagnosis of the abnormality and associated findings. Whereas many congenital malformations are isolated traits, they can also occur as part of a syndrome in which a pattern of malformations and features results from a single cause. The cause of a syndrome can involve an entire chromosome (that is, trisomy), deletion of a small chromosome region, or a single gene mutation. Often the other features of the syndrome cannot be detected by ultrasound, and therefore, careful counseling of the family, as well as consideration of other testing, is important.

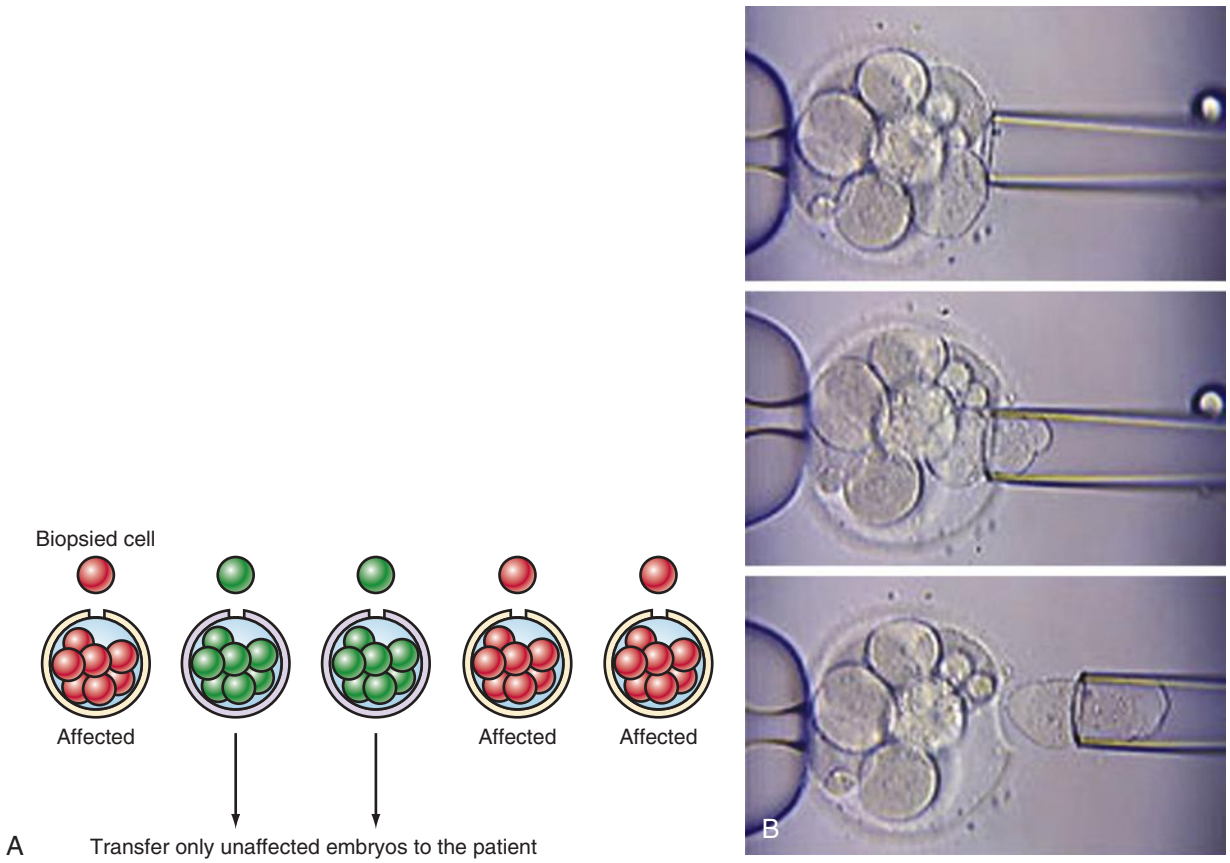

FIG 2-17 **A** and **B,** Technique of preimplantation genetic diagnosis. In vitro fertilization is used to create embryos. One or two cells are removed for genetic analysis, and unaffected embryos are transferred to the uterus.

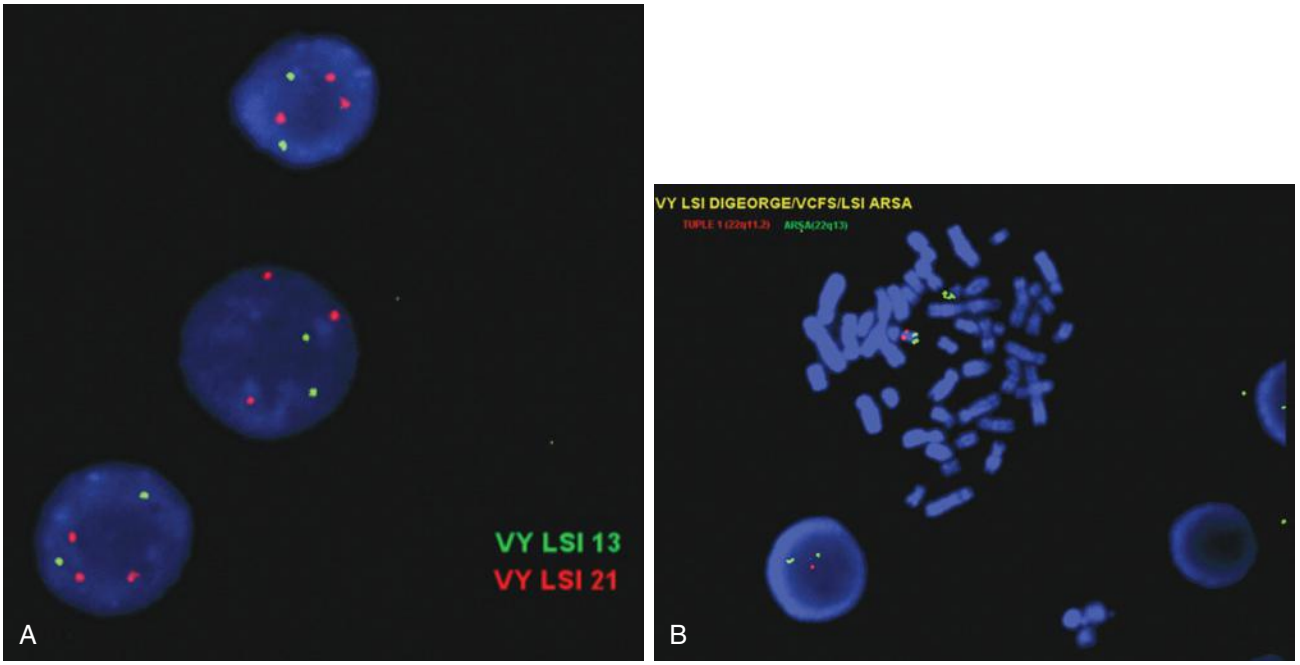

FIG 2-18 **A,** Fluorescence in situ hybridization in interphase cells. Probes to chromosome 21 (test) are red and to chromosome 13 (control) are green. Presence of three red signals indicates the presence of trisomy 21. **B,** Fluorescence in situ hybridization in metaphase cell. Probes to chromosome 22q11 (test) are red, and to 22q13 (control) are green. Presence of a single red signal indicates a 22q11.2 deletion and the presence of 22q11.2 deletion syndrome.

As an example, a CHD identified on prenatal ultrasound is commonly an isolated finding. However, it may occur as part of a syndrome in which other abnormalities, such as mental retardation, are present. CHDs are heterogeneous in etiology, caused in some cases by a single gene or chromosomal mechanism, and in others by teratogens such as rubella infection or poorly controlled maternal diabetes. The cause in most cases is unknown, and the majority is believed to be multifactorial in origin. First-degree relatives have an increased recurrence risk of 2% to 4%. Prenatal ultrasound (echocardiography) is typically offered to couples with a strong family history or a previous fetus with CHD. In cases in which a CHD is unexpectedly detected by ultrasound, amniocentesis is offered to test for chromosome abnormalities, which underlie 10% to 15% of fetal CHD. Amniocentesis can also test for genetic abnormalities that increase the risk of CHD. For example, CHD is often associated with chromosomal microdeletions, which can be detected through the use of FISH (Fig. 2-18) or chromosomal microarray on fetal tissue obtained by amniocentesis (Fig. 2-19).

Techniques of Genetic Analysis

Over the past 2 decades, advances in genetics have included increases in our understanding of novel genetic mechanisms. Much of this increased understanding has come about from improvements in genetic technology, allowing more detailed investigation of genes, mechanisms of mutation, and genetic variation in the population. As these techniques are used and investigated, an increasing number of clinically available tests are offered, with more and more being applicable to and useful for evaluation of the fetus.

Chromosome Identification

Standard prenatal diagnosis involves evaluation of the individual chromosomes making up the fetal karyotype. Giemsa staining, which produces a specific banding pattern called G banding, is the technique that has been most widely used in clinical cytogenetics laboratories for chromosome analysis, although chromosomal microarrays are becoming increasingly routine (see later). Each chromosome stains in a characteristic pattern of light and dark bands (Fig. 2-20). In an internationally accepted system of chromosome classification, the dark and light bands on each chromosome are numbered. This numbering system allows the location of any particular band and its involvement

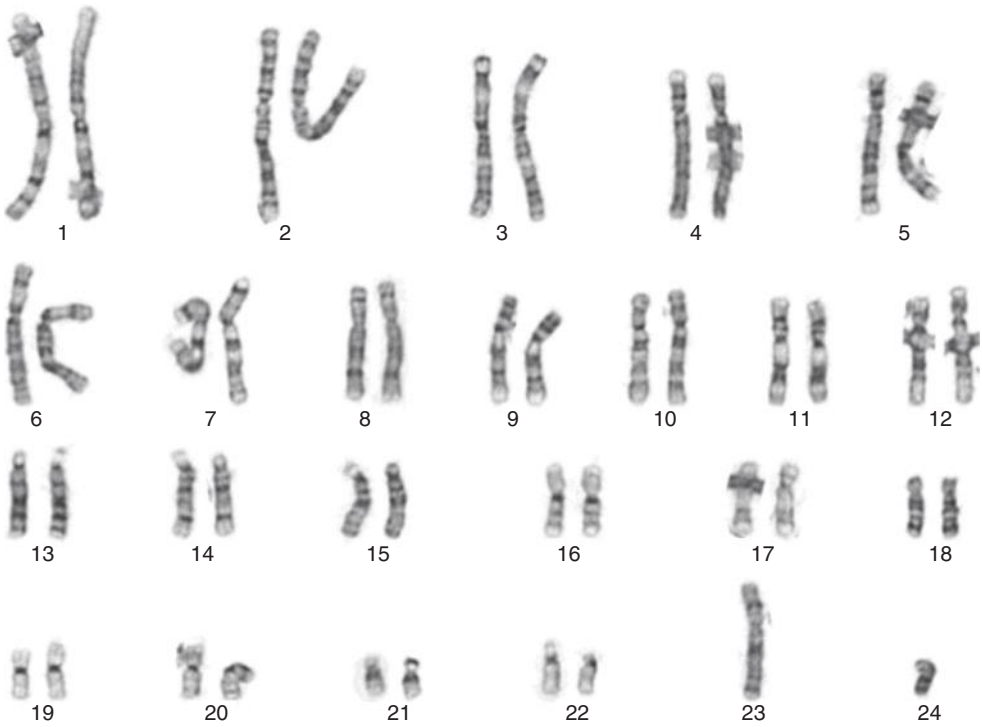

FIG 2-20 G-banded male karyotype.

in any chromosome abnormality to be described unambiguously and precisely.

Fluorescence in Situ Hybridization

FISH is a technique that allows visualization of a small chromosomal region, generally too small to be seen with karyotyping. FISH can also be used for rapid chromosome identification because it can be performed on interphase cells and, therefore, culturing is not required for analysis. FISH is carried out by using a small fragment of DNA (called a DNA probe) with the same nucleotide sequence as the stretch of chromosomal DNA of interest. The DNA probe is covalently attached to a fluorescent label; hybridized with metaphase, prophase, or interphase chromosomes; and then visualized under a fluorescence microscope. FISH is used to determine whether a small portion of a chromosome (too small to be seen on the karyotype) is deleted and to identify translocations and marker chromosomes. It is also used to identify pieces of chromosomal material that are too small or too ambiguous to be localized by banding techniques. Normally, a probe will hybridize in two places, reflecting the presence of two homologous chromosomes. If a probe from the chromosome segment in question hybridizes to only one of the patient's chromosomes, then the patient is likely to have a deletion on the other. Excess chromosomal material can also be detected with FISH, in which case the probe will hybridize in more than two places. As a rapid assessment for trisomy (or other aneuploidy), interphase cells can be analyzed with FISH probes that hybridize to centromeric regions of specific chromosomes, thereby allowing a fast count of the copy number of a specific chromosome (e.g., 21 to rule out DS) (see Fig. 2-18). In the prenatal setting, this is typically targeted to chromosomes 13, 18, 21, X, and Y with results from analysis of interphase nuclei available in 24 to 48 hours. The sensitivity and specificity for the detection of aneuploidy are greater than 99.6% and greater than 99.9%, respectively. Because only specific chromosomes are queried, the technique is not comprehensive. It cannot detect balanced rearrangements, inversions, or robertsonian translocations.

Molecular Techniques for DNA Analysis

It is surprisingly easy to isolate pure DNA, which is generally very stable when compared with enzymes and other molecules. DNA can be extracted from any cell type that has a nucleus, including white blood cells, buccal cells, amniocytes, chorionic villi, and skin fibroblasts. PCR can be used to amplify very small quantities of DNA, allowing small samples to be used for the detection of specific mutations.

Genetic mutations generally occur as a result of point mutations, deletions, or duplications. PCR and Southern blotting are commonly used techniques for the identification of genetic mutations in DNA samples. Automated techniques of DNA sequencing are also available; such sequencing was used to complete the human genome project in 2003. Use of sequencing in clinical practice is increasingly common but is complicated by the potential for identification of previously undescribed mutations of uncertain clinical significance.

When a molecular cause of a disorder is identified, this allows a specific test to be applied to at-risk relatives or for prenatal diagnosis. Although gene sequencing is a powerful tool for the identification of genetic mutation, it is critical that firm proof of the diagnosis exists and that the gene mutation identified is known to be causative. In addition, detection of a mutation in a person (or fetus) at risk does not make a diagnosis of a clinical disorder and all the previously described caveats are critical to accurate diagnosis and management of genetic disorders, particularly in the prenatal setting.

Chromosomal Microarray

Other techniques for molecular evaluation of the genome, such as chromosomal microarray analysis (CMA), have been relatively recently developed and introduced into clinical use. CMA is increasingly used for prenatal evaluation of chromosomes and chromosome abnormalities in the fetus. Currently, CMA is recommended by the ACMG as a first-tier test in the evaluation of children with intellectual disabilities, autism spectrum disorders, and birth defects of undetermined origin,

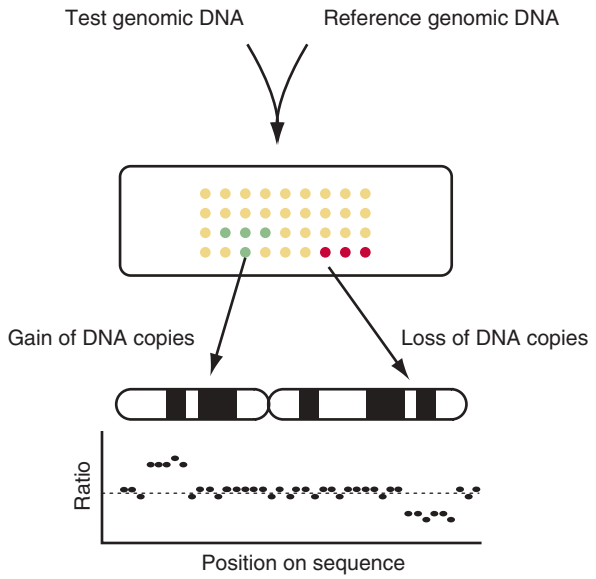

FIG 2-21 Array comparative genomic hybridization (CGH) technique. DNA to be tested is labeled green, and control reference DNA is red. Labeled DNA is hybridized to a microarray containing hundreds to thousands of DNA clones, and copy number is analyzed for each clone. The ratio of test to reference DNA at each clone is indicated on the graph. Increase in ratio of test DNA indicates duplication or trisomy, and decrease in ratio indicates deletion or monosomy for each clone.

and this technique is now also recommended by the ACOG for the evaluation of fetuses with structural abnormalities.[161] CMA can be performed by two techniques: comparative genomic hybridization (CGH) and single nucleotide polymorphism (SNP) array. CGH is a technique whereby DNA from a test subject is hybridized together with control DNA. Differential labeling of the test versus control DNA allows comparative analysis of copy number, thus screening for decrease or increase in copy number across the genome. This method of testing cannot identify triploidy. Deletions or duplications in a particular region are identified by computer analysis of signal intensity. CMA by single nucleotide polymorphism array is a technique whereby only the fetal DNA is affixed to the slide where labeled control DNA has been applied. This modality of testing can identify regions of homozygosity, suggesting consanguinity or UPD (see earlier) as well as triploidy. Originally developed primarily for use in cancer, CMA has great utility in pediatric and prenatal cases, in which features suggest a chromosomal abnormality but are not specific enough to indicate a single FISH analysis (Figs. 2-20 and 2-21).[162]

The benefit of CMA in the prenatal setting is the ability to perform the test from nearly any tissue including archived tissue or tissue that cannot be cultured. The test may be customized to focus on known disease-causing regions in the genome commonly identified in prenatal testing and has a higher yield than standard karyotype analysis. In 2012, a multicenter trial was published comparing prenatal CMA with standard karyotype analysis. CMA identified all of the clinically significant aneuploidies identified by conventional karyotype. In addition, the array CGH technique identified additional clinically significant abnormalities in approximately 6% of pregnancies in which there were structural abnormalities identified by ultrasound that were not detected by karyotype. CMA also detected an abnormality in 1.7% of structurally normal fetuses that had a normal karyotype.[100]

Limitations of CMA include an inability to identify a balanced rearrangement (although this is not typically disease causing unless there is disruption of a critical gene by the chromosome break) and an inability to detect low levels of mosaicism. The time to results is not as rapid as FISH, which is often important in the prenatal setting. Although CMA can detect whole chromosomal aneuploidy, when common aneuploidy is suspected (trisomy 21, trisomy 18, or sex chromosome), conventional karyotype analysis may be more appropriate because of cost. The interpretation of microarray results can be challenging with variations of unknown significance or alterations in regions of unknown clinical significance. In the prenatal setting, clinically uncertain variants, variants associated with adult-onset disorders, and complex results may cause significant parental anxiety. Therefore, pretest and posttest genetic counseling is recommended.[161]

Ultrasound Evaluation of Fetal Aneuploidy in the First and Second Trimesters

Katherine R. Goetzinger, Anthony O. Odibo

SUMMARY OF KEY POINTS

- Major fetal malformations are highly associated with fetal chromosomal abnormalities, particularly central nervous system anomalies, facial abnormalities, cystic hygroma, diaphragmatic hernia, cardiac defects, gastrointestinal abnormalities, genitourinary anomalies, nonimmune hydrops fetalis (NIHF), and abnormalities involving the extremities.
- The combination of nuchal translucency (NT) measurement and maternal serum analytes, pregnancy-associated plasma protein-A (PAPP-A) and free β-hCG (human chorionic gonadotropin), is the most common aneuploidy screening paradigm in the first trimester of pregnancy.
- Incorporation of first trimester nasal bone documentation into NT and serum screening can increase the detection rate of trisomy 21 without significantly altering the false positive rate.
- The genetic sonogram is a targeted second trimester ultrasound examination that is performed at the time of the anatomic survey and assesses for major fetal malformations as well as minor markers of aneuploidy. The presence or absence of these markers, either alone or in combination, can adjust a patient's aneuploidy risk, specifically for trisomy 21.
- Likelihood ratios (LRs) have been established for each individual sonographic marker of aneuploidy; they can be multiplied by the patient's *a priori* risk to determine the patient's posttest odds for aneuploidy.
- Thickened nuchal skinfold and absent/hypoplastic nasal bone are the sonographic markers most specifically associated with trisomy 21 in the second trimester.
- In a low-risk population, pyelectasis, echogenic intracardiac foci, and choroid plexus cysts are not associated with an increased risk for aneuploidy when observed in isolation.
- The finding of one sonographic marker of aneuploidy should prompt a more targeted ultrasound examination to evaluate for additional signs of aneuploidy.

OUTLINE

In addition to biochemical screening, sonography is a noninvasive method used to perform risk assessment for fetal aneuploidy. In addition to the major congenital anomalies discussed later and listed in Table 3-1, multiple other first and second trimester ultrasound findings are associated with aneuploidy. Such findings, commonly referred to as *minor markers* or *soft markers,* typically are not structural anomalies per se and usually have no clinical significance to the fetus except for their association with aneuploidy. The presence or absence of these minor markers can be used to adjust a patient's a priori risk for aneuploidy based on biochemical screening results or maternal age. This becomes particularly important in screening for trisomy 21, as approximately 75% of fetuses affected by trisomy 21 will not have ultrasound-detectable major congenital anomalies at the time of the second trimester anatomic survey.[1] This is in contrast to fetuses affected by trisomies 18 and 13, of which greater than 90% will have major structural malformations detectable by sonography in the second trimester of pregnancy.[2-4]

This chapter will review the most common first and second trimester ultrasound findings associated with fetal aneuploidy. We will discuss major malformations, as well as soft markers and their

TABLE 3-1 Major Congenital Anomalies Associated With Fetal Aneuploidy

Trisomy 21	Trisomy 13	Trisomy 18
AV canal defect	Cardiac defects	Cardiac defects
Duodenal atresia	CNS abnormalities	Spina bifida
Ventriculomegaly	Cleft lip/palate	Micrognathia
Other cardiac defects	Omphalocele	Omphalocele
Cystic hygroma	Midline facial anomalies	Clenched hands/wrists
Nonimmune hydrops	Echogenic kidneys	Radial aplasia
	Urogenital anomalies	Clubfeet
	Polydactyly	Cerebellar dysgenesis
	Rocker bottom feet	Cystic hygroma
	Cystic hygroma	Nonimmune hydrops
	Nonimmune hydrops	
	Congenital diaphragmatic hernia	Congenital diaphragmatic hernia

screening efficiency as well as their current role in aneuploidy risk calculation in the era of first trimester biochemical screening and prenatal screening using cell-free DNA (cfDNA).

STRUCTURAL ABNORMALITIES

Structural abnormalities are more common in aneuploid fetuses, particularly central nervous system anomalies, facial abnormalities, cystic hygroma, diaphragmatic hernia, cardiac defects, gastrointestinal abnormalities, genitourinary anomalies, NIHF, and abnormalities involving the extremities. The large majority of fetuses with trisomies 13 and 18 have multiple major structural anomalies. Fetuses with Down syndrome, in contrast, are less likely to have structural abnormalities identified by second trimester sonography; it is reported that just 25% of second trimester fetuses with Down syndrome have sonographically detectable major congenital anomalies.[5] In two prenatal series before 20 weeks, structural anomalies were detected by sonography in only 16% to 17% of trisomy 21 fetuses.[6,7]

Identification of *cardiac malformations* on prenatal sonography substantially increases the risk for chromosomal abnormalities, with a frequency of aneuploidy reported to be as high as 22% to 32%.[8,9] The frequency of aneuploidy varies with the type of cardiac defect present and is higher with hypoplastic heart (Fig. 3-1), atrioventricular canal defects, tetralogy of Fallot, and double-outlet right ventricle as compared with isolated ventricular septal defects or valvular stenosis.[10] Atrioventricular canal defects have a very high risk of aneuploidy, particularly Down syndrome. In one series of 38 atrioventricular septal defects, aneuploidy was present in 22 (58%), with Down syndrome (n = 19), trisomy 18 (n = 1), trisomy 13 (n = 1), and mosaicism (n = 1) all identified.[11]

Approximately 50% of infants with Down syndrome have cardiac defects. However, most of these are ventricular septal defects (Fig. 3-2) and common atrioventricular canal defects (Fig. 3-3), and their detection by prenatal sonography is quite variable. One study reported that heart defects were detected in just over one half of fetuses with Down syndrome.[12] DeVore reported that nonspecific cardiac findings (such as tricuspid regurgitation, pericardial effusion, and right-left disproportion) were present in 76% of fetuses with Down syndrome, whereas just 9% had a characteristic atrioventricular septal defect.[13] In contrast, cardiac malformations are present in more than 90% of fetuses with trisomy 18 and 13. Studies have reported that major congenital heart defects can be identified sonographically in over 80% of fetuses with trisomy 18.[4,14]

Duodenal atresia (Fig. 3-4) is rarely recognized until after 20 to 24 weeks of pregnancy, when the characteristic double bubble sign (dilated fluid-filled stomach and proximal duodenum) and polyhydramnios become apparent. Duodenal atresia is the leading cause of intestinal obstruction among newborns and is highly associated with Down syndrome. Among cases of duodenal atresia detected prenatally, trisomy 21 is present in approximately one third of cases.[10]

The differential diagnosis of NIHF is extensive (Fig. 3-5); this disorder can result from a variety of both maternal and fetal causes. NIHF is recognized sonographically by ascites, pericardial effusions, pleural effusions, polyhydramnios, thickened placenta, and skin edema (see

FIG 3-3 Transverse axial view of the fetal chest, showing a complete atrioventricular canal defect of the heart in a Down syndrome fetus. Note the primum atrial septal defect and inlet ventricular septal defect at the crux of the heart, along with a single atrioventricular valve.

Chapter 17). Aneuploidy is a common cause of NIHF, accounting for up to 16% of cases.[15,16] The most common karyotype abnormalities associated with hydrops include Turner syndrome (45,X); trisomies 21, 18, and 13; and triploidy. NIHF is most highly associated with aneuploidy when diagnosed earlier in pregnancy; a higher incidence of aneuploidy is identified in the second trimester as compared with the latter half of pregnancy.[17] The combination of generalized hydrops and cystic hygroma is often referred to as lymphangiectasia, which has a very poor prognosis. Lymphangiectasia is associated with aneuploidy, especially Turner syndrome, in approximately two thirds of cases (Fig. 3-6).

Hydrothorax (pleural effusion, chylothorax) has been linked to aneuploidy, especially Turner syndrome, Down syndrome, and trisomy 13. Among 82 cases of isolated fetal pleural effusion (Fig. 3-7) reported in the literature, Down syndrome was present in 4.9%.[18] Ascites (see Fig. 3-5) may also occur in isolation without other signs of hydrops. This finding has also been associated with aneuploidy; in one report of 18 fetuses with ascites, 5.6% ($n = 1$) had Down syndrome.[19]

Diaphragmatic hernia (Fig. 3-8) results from a congenital defect in the fetal diaphragm, with herniation of abdominal viscera into the fetal chest (see Chapter 12). This abnormality carries an increased risk for aneuploidy, particularly trisomy 18 (most common), trisomy 13,

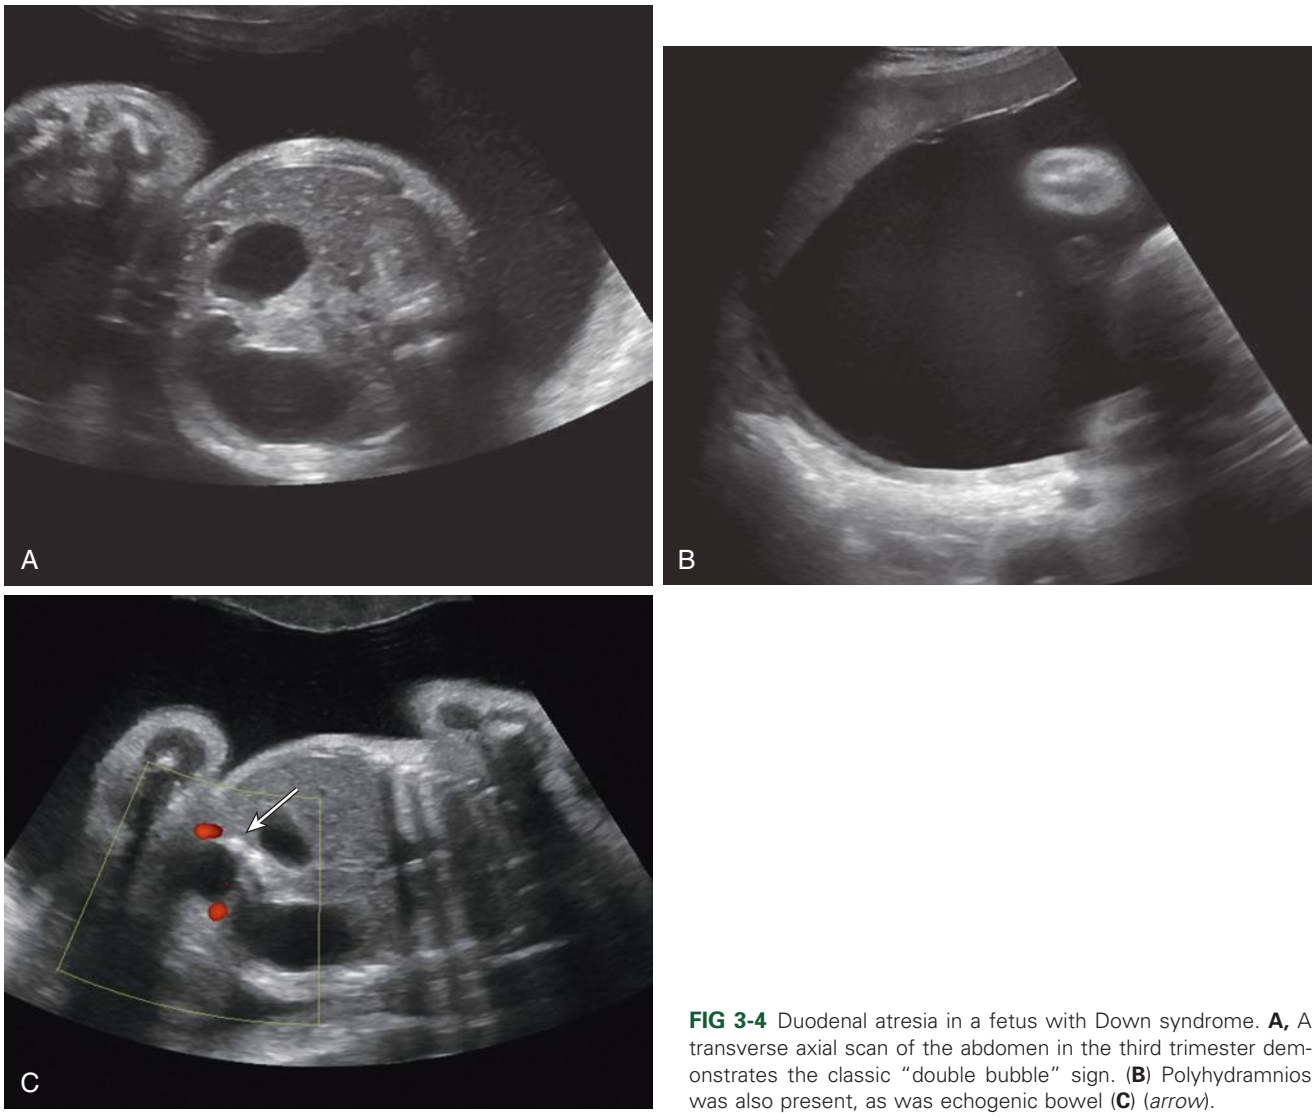

FIG 3-4 Duodenal atresia in a fetus with Down syndrome. **A,** A transverse axial scan of the abdomen in the third trimester demonstrates the classic "double bubble" sign. (**B**) Polyhydramnios was also present, as was echogenic bowel (**C**) (*arrow*).

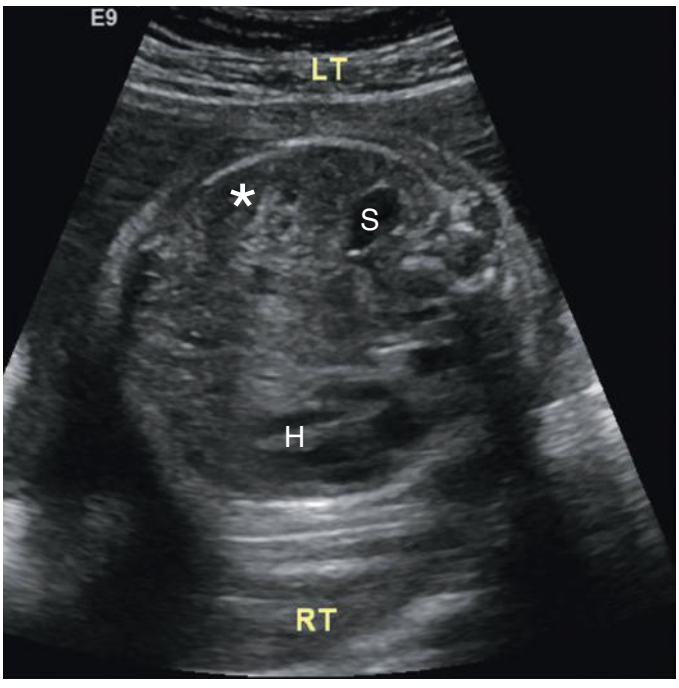

FIG 3-8 Transverse axial view of the fetal chest, demonstrating a left-sided congenital diaphragmatic hernia (*asterisk*). The stomach (S) is herniated into the chest, and the heart (H) is displaced to the right. LT, left thorax; RT, right thorax.

Down syndrome, Turner syndrome, and other chromosomal abnormalities. The frequency of aneuploidy is reported to be as high as 34%, although it generally ranges from 10% to 20% in reported series.[20-22]

An *omphalocele* (Figs. 3-9 and 3-10) occurs when there is a central abdominal wall defect that results in herniation of intra-abdominal structures into the base of the umbilical cord, which is covered by a membrane. Omphaloceles are associated with other fetal anomalies and aneuploidy, which complicates more than half of prenatally diagnosed cases. Associated aneuploidies include trisomies 18 and 13 (which are most frequent), Down syndrome, Turner syndrome, and triploidy. Similarly to other fetal malformations, there appears to be a higher frequency of aneuploidy in prenatal (30-40%) as compared with neonatal studies (which have a combined rate of 12%) owing to in utero lethality.[10] In one study of 35 cases of prenatally diagnosed omphalocele, 54% had aneuploidy: trisomy 18 (n = 17), triploidy (n = 1), and Klinefelter syndrome (n = 1).[23] Small omphaloceles containing only bowel (see Fig. 3-10) have a higher aneuploidy risk than those containing liver, with one series reporting an aneuploidy rate of

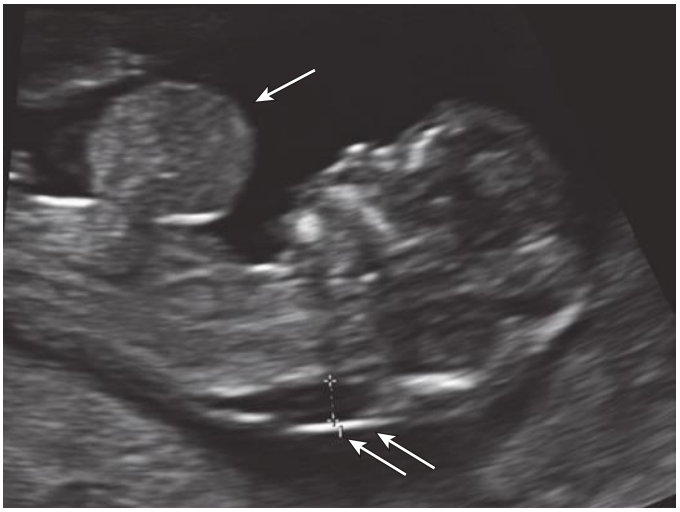

FIG 3-9 Sagittal view of a fetus with an omphalocele (*arrow*) at 13 weeks' gestation. Fetus also has an enlarged nuchal translucency (*double arrows*).

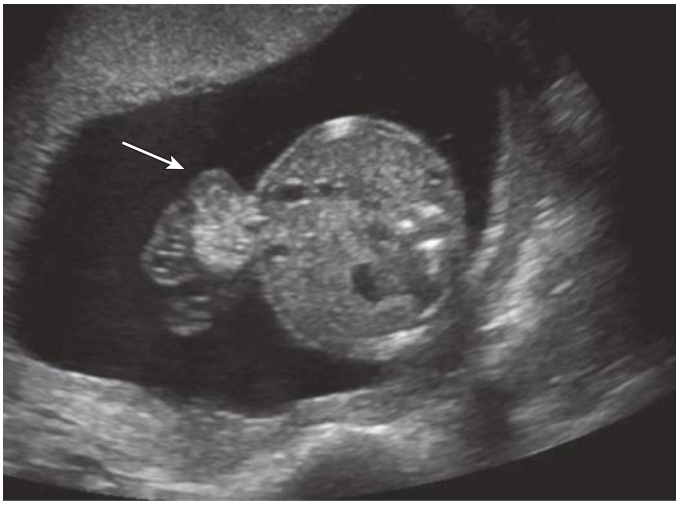

FIG 3-10 Transverse scan of abdomen in a second trimester fetus demonstrating a small omphalocele (*arrow*) containing only small bowel.

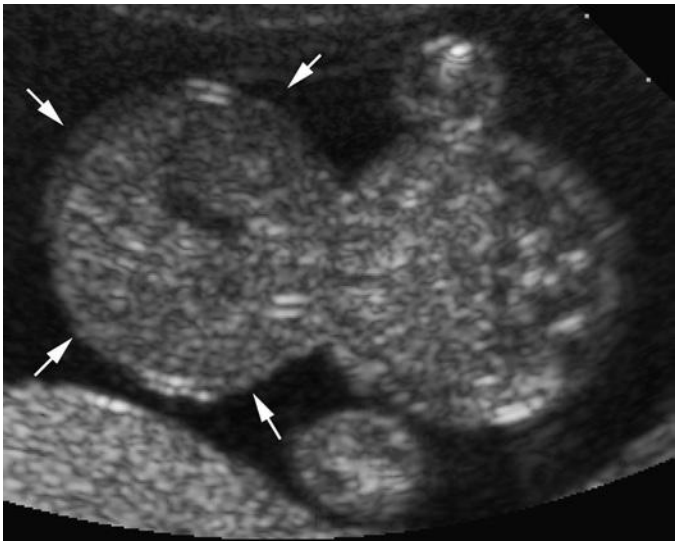

FIG 3-11 Large liver containing omphalocele (*arrows*) in a second trimester patient. The omphalocele is larger than the native fetal abdomen.

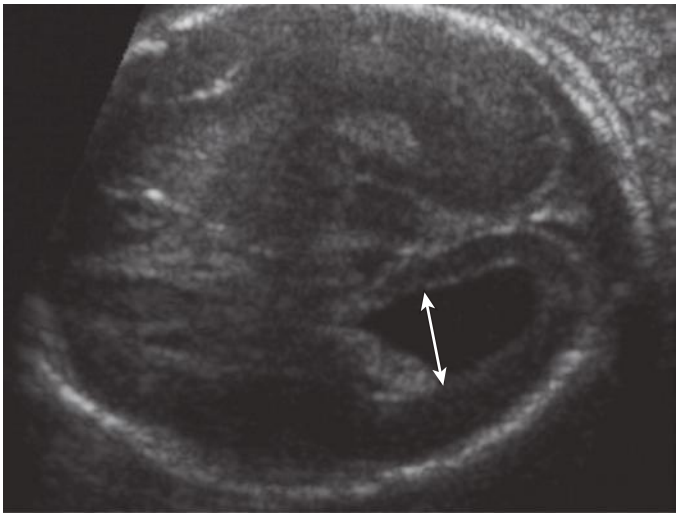

FIG 3-12 Transverse axial scan at midgestation demonstrates mild ventriculomegaly associated with trisomy 21 (*arrow*).

87% in bowel only omphaloceles versus 9% in those containing liver (Fig. 3-11).[24]

Many central nervous system abnormalities carry an increased risk for fetal aneuploidy. Cerebral *ventriculomegaly* (Fig. 3-12), which is diagnosed when the atrial diameter of the cranial lateral ventricle reaches 10 mm or more, is relatively common finding on prenatal sonography. Ventriculomegaly (even mild) is associated with an increased risk for aneuploidy, particularly Down syndrome. However, mild ventriculomegaly may also be seen as a normal variant in the second trimester (after 20 weeks' gestation) and in male fetuses.[10] In one study of 31 fetuses with isolated borderline ventriculomegaly (10-15 mm), 9.7% ($n = 3$) were found to have aneuploidy (Down syndrome [$n = 2$] and trisomy 13 [$n = 1$]).[25] In large series, 3.8% of fetuses with mild ventriculomegaly are karyotypically abnormal, with Down syndrome the most common aneuploidy.[6] In chromosomally normal, aneuploid, and Down syndrome fetuses, mild ventriculomegaly is observed in 0.5%, 6.8%, and 5.5%, respectively.[6]

Hydrocephalus (Fig. 3-13) and *spina bifida* (Fig. 3-14) are both associated with chromosomal abnormalities, primarily trisomy 18, trisomy 13, and triploidy.[26] In a review of 107 fetuses with central nervous system abnormalities, aneuploidy was found in 3%, 8%, and 33% of fetuses with hydrocephalus, hydrocephalus and spina bifida, and spina bifida alone, respectively.[26] In one study of 38 fetuses with trisomy 18, 19% had neural tube defects and 8% had ventriculomegaly or hydrocephalus.[4]

Cerebellar abnormalities, such as Dandy-Walker malformation (DWM) or cerebellar hypoplasia, are associated with an increased risk for aneuploidy[27] (Figs. 3-15 to 3-17). Trisomy 18 is the most common aneuploidy seen with these anomalies, but other chromosomal abnormalities may also be observed. *Agenesis of the corpus callosum* (Fig. 3-18) can be complete or partial. The diagnosis is made by showing absence of the complex formed by the corpus callosum and cavum septum pellucidum, along with various other sonographic findings such as colpocephaly (disproportionate enlargement of the occipital horns) (Fig. 3-19). Aneuploidy is reported in approximately 20% of prenatally diagnosed cases, primarily trisomies 18, 8, and 13,[28] although a variety of other chromosomal abnormalities are also reported. A study reported in 2009 examined cases of agenesis of the corpus callosum diagnosed prenatally and postnatally.[29] Among the prenatally

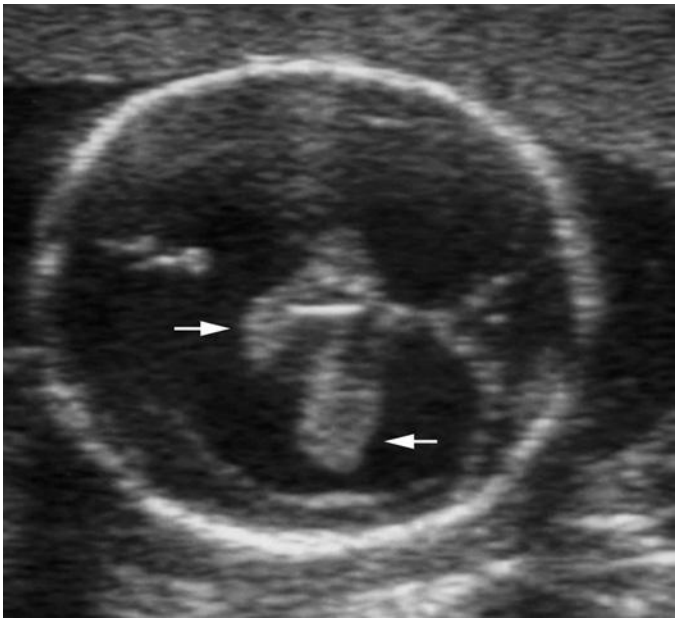

FIG 3-13 Marked dilation of both lateral ventricles with dangling choroid plexuses (*arrows*) in a fetus with hydrocephalus.

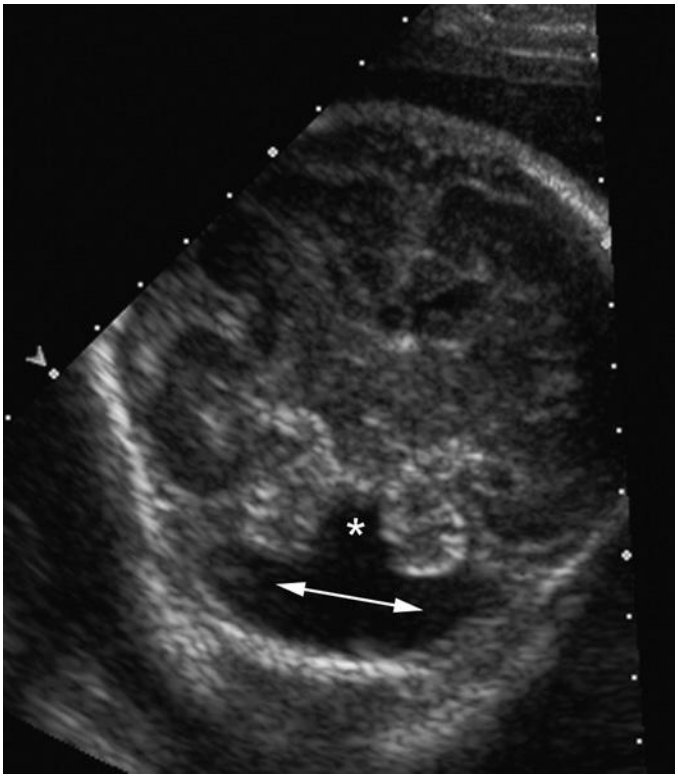

FIG 3-15 Dandy-Walker malformation in a trisomy 13 fetus. In a transverse axial plane, an enlarged fourth ventricle (*arrow*) is seen along with a defect in the cerebellar vermis. Note that the cerebellar hemispheres are splayed (*asterisk*).

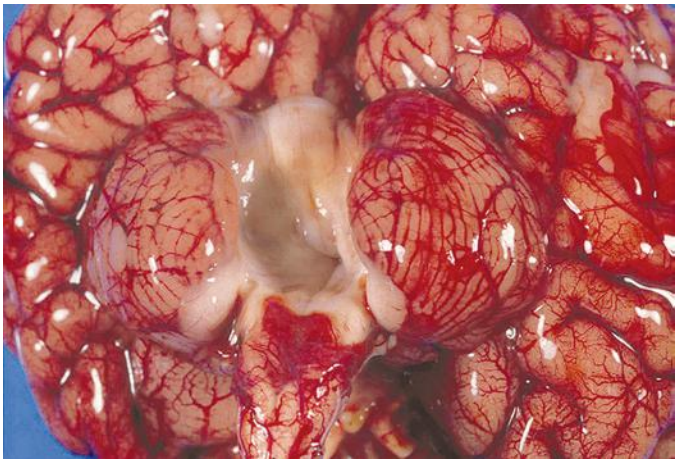

FIG 3-16 Pathologic specimen of brain shows cerebellar hemispheres bilaterally, but with complete absence of the vermis, consistent with Dandy-Walker malformation.

diagnosed cases, aneuploidy was present in 8%, as compared with 4% in postnatal cases.

Holoprosencephaly (Figs. 3-20 and 3-21) is a midline abnormality of the brain, resulting from absent or incomplete division of the prosencephalon (embryonic forebrain) and formation of the midline structures. It is embryologically related to development of the midface, hence the common association with median facial anomalies (Fig. 3-22). There are three major types of holoprosencephalies, depending on the degree of anatomic abnormality: alobar, semilobar, and lobar. Aneuploidy is present in 50% to 60% of fetuses with alobar or semilobar holoprosencephaly. Of the various types of chromosomal abnormalities, trisomy 13 or a variant of trisomy 13 is the most common (found in 50-75% of those with abnormal karyotype). However, a wide variety of other aneuploidies has been reported. In fetuses with trisomy 13, holoprosencephaly was reported in 39%.[30] When other abnormalities are present, in addition to holoprosencephaly, the risk for aneuploidy is increased.

Abnormalities of the facial profile are common in fetuses or neonates with chromosomal abnormalities. Some chromosomally abnormal fetuses or neonates demonstrate *micrognathia* (Figs. 3-23 and 3-24), a sloping forehead (see Fig. 3-24), flattened profile (Fig. 3-25), or *retrognathia*. In one study examining the sonographic features of 38 fetuses with trisomy 18, approximately one half (53%) had facial anomalies identified.[4] Twenty-nine percent had an abnormal profile

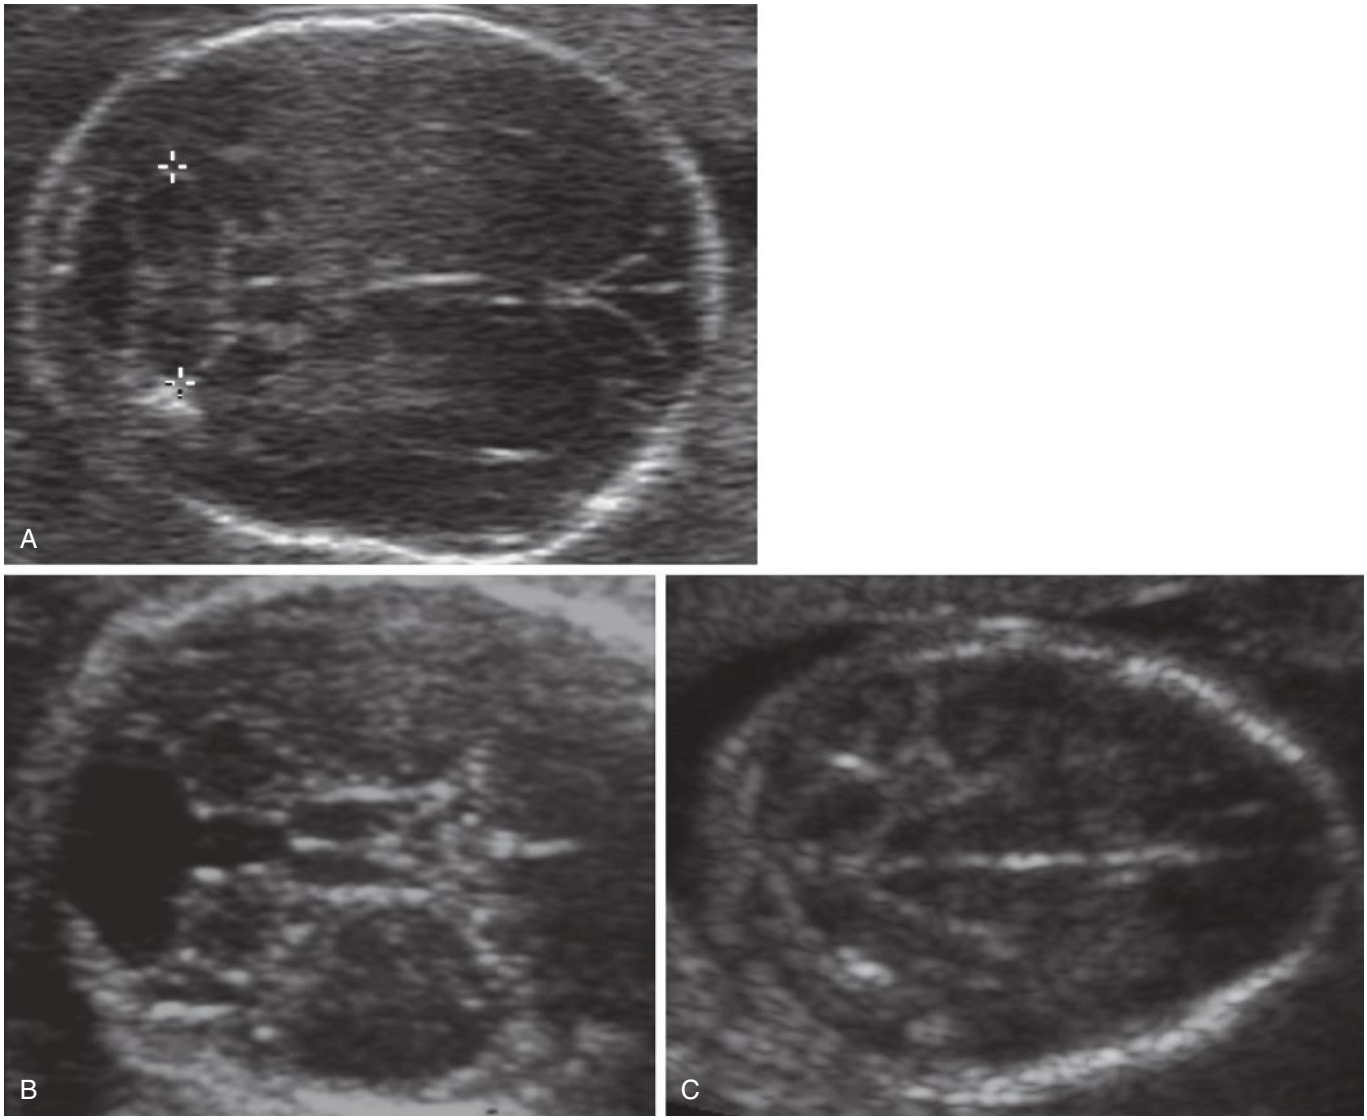

FIG 3-17 **A,** Normal posterior fossa. **B,** Vermian agenesis. **C,** Chiari II malformation.

(excluding micrognathia), 21% had micrognathia, and 18% had hypotelorism.

The presence of *cleft lip/palate* (Figs. 3-26 and 3-27) is associated with aneuploidy such as trisomies 13 and 18, especially when other anomalies are also present. One study of fetuses with cleft lip and palate reported aneuploidy in 0%, 32%, 59%, and 82% in unilateral cleft lip, unilateral cleft lip and palate, bilateral cleft lip and palate, and median cleft lip and palate, respectively.[10]

Ocular anomalies, such as *hypotelorism* (Fig. 3-28), *hypertelorism, microphthalmia, anophthalmia,* and *cyclopia* (see Fig. 3-22), can be associated with fetal chromosomal abnormalities. Most importantly, when they are seen along with other malformations (especially holoprosencephaly), the risk of aneuploidy is particularly increased.

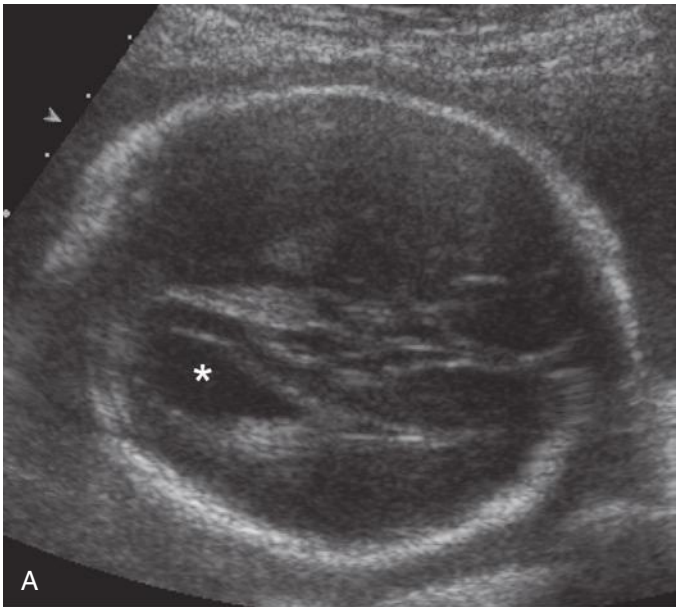
Genitourinary abnormalities can be associated with fetal chromosomal abnormalities. The highest frequency of aneuploidy has been reported in those fetuses with *urethrovesical obstruction* (bladder outlet obstruction), most commonly trisomy 18 or 13.[10] In one cohort of 39 fetuses with obstruction at or distal to the urethrovesical junction, chromosomal abnormalities were reported in 23%.[31] With urinary tract abnormalities that are more proximal, aneuploidy is reported with less frequency. In unilateral renal abnormalities such as ureteropelvic junction obstruction and multicystic dysplastic kidneys, the risk of aneuploidy is low.[32]

Although the presence of most congenital malformations significantly increases the risk for fetal aneuploidy, there are some notable exceptions. They generally involve disorders that are thought to result from tissue or vascular disruption, such as *gastroschisis, tumors, limb-body wall complex, hydranencephaly,* and *amniotic band syndrome.*

FIRST TRIMESTER MARKERS OF ANEUPLOIDY

Nuchal Translucency

The term *nuchal translucency* (NT) was first coined by Nicolaides and colleagues in 1992 to describe the finding of an increased translucent region behind the neck of fetuses who were diagnosed with aneuploidy at the time of chorionic villus sampling.[33] This group published the first large cohort study on the association between NT and aneuploidy in 1995.[34] This sonographic marker for aneuploidy was subsequently validated by several investigators and is now an integral component of most first trimester screening tests for chromosomal disorders.[35-45] Despite widespread use of the NT measurement, the pathologic basis for enlargement of the NT in fetuses with aneuploidy is not known.



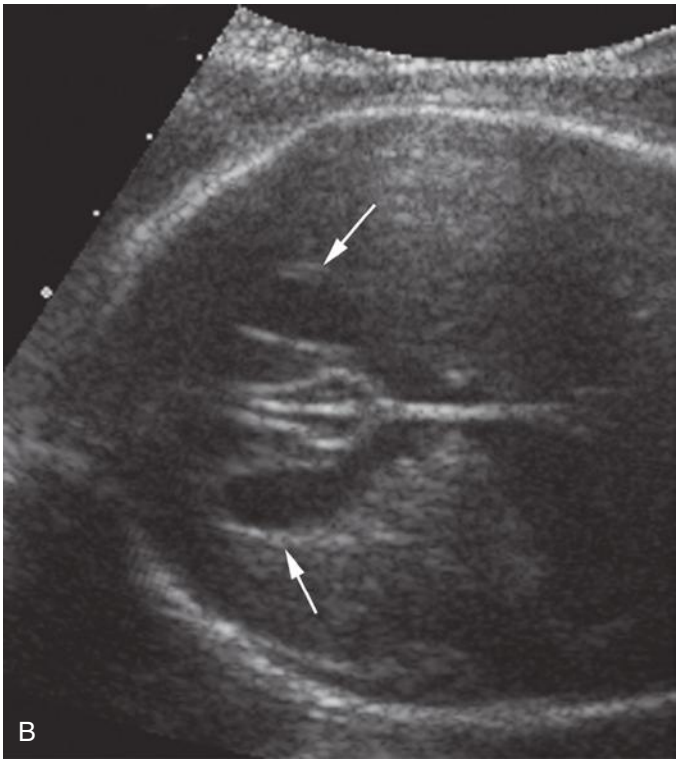


FIG 3-18 Fetus with agenesis of corpus callosum. **A,** Transverse axial scan through the lateral ventricle shows the characteristic teardrop shape of lateral ventricles or disproportionate enlargement of the occipital horns (colpocephaly) (*asterisk*), which is indicative of agenesis of corpus callosum. **B,** Widely separated frontal horns (*arrows*) are seen with absence of the cavum septum pellucidum.

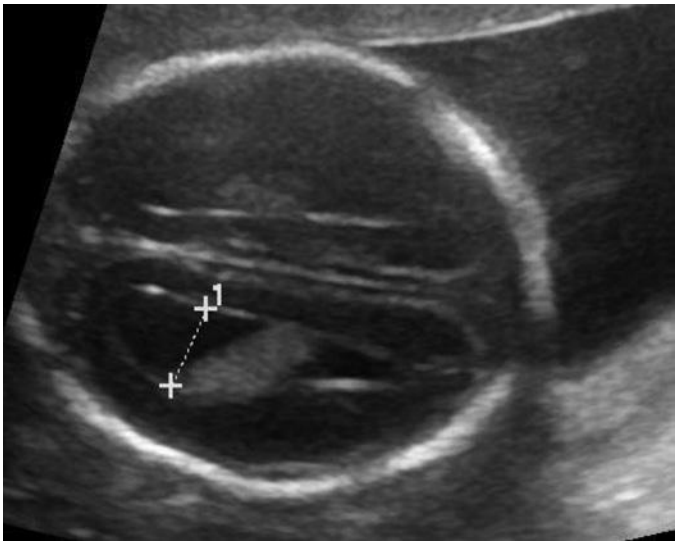

FIG 3-19 Agenesis of the corpus callosum. Transverse scan of the fetal head demonstrates mild ventriculomegaly, a characteristic teardrop shape of the lateral ventricle, and absence of the cavum septum pellucidum.

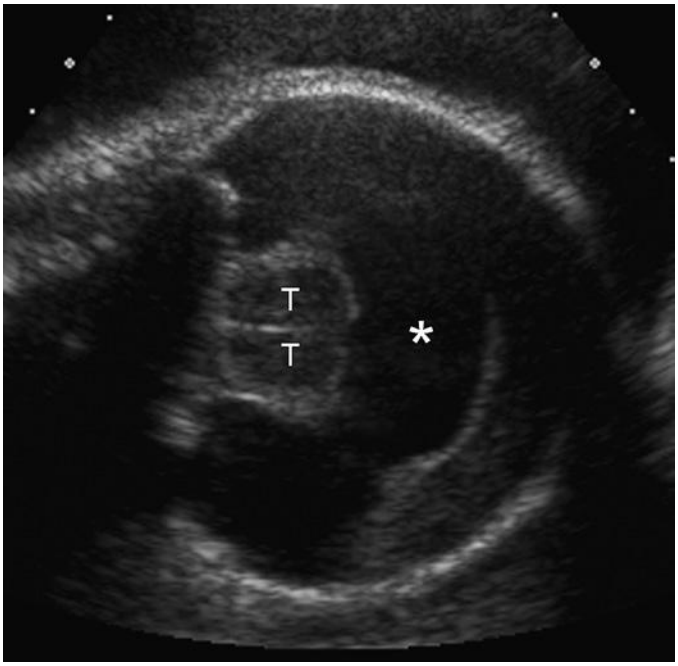

FIG 3-20 Transaxial view through the head of a trisomy 13 fetus, showing alobar holoprosencephaly. Note the fused thalami (T) surrounded by a single monoventricle (*asterisk*).

Suggested mechanisms include a decrease in cardiac function and impaired circulation, increased collagen and hyaluronan content within fetal skin, dysfunction within the jugular-lymphatic drainage system, and increased intrathoracic pressure.[46-50]

The most common first trimester screening paradigm combines the measurement of the NT with serum markers including PAPP-A and hCG to modify a woman's a priori risk for aneuploidy based on her age. The reported sensitivity for trisomy 21 detection using the combined first trimester approach alone ranges from 80% to 91%, with a specificity of 91% to 96%.[33,35,38,43-45] When the first trimester approach is combined with second trimester serum markers including unconjugated estriol, alpha-fetoprotein, and inhibin A in a modified sequential or integrated protocol, the sensitivity approaches 95% with specificity ranging from 95% to 98%.[36,45,51]

Detection rates for aneuploidies other than trisomy 21 are lower, but the NT is similarly enlarged, with many different chromosomal abnormalities. The combined first trimester screening test or the presence of cystic hygroma detected 78% of all non–Down syndrome aneuploidies with a 6% false positive rate in the FASTER (First and

Second Trimester Evaluation of Risk) trial, a large multicenter trial of aneuploidy screening in over 30,000 pregnant women.[51]

It is important to emphasize the need for meticulous technique in evaluating the NT, which must be measured accurately to achieve the previously described screening efficiency. An important observation since the introduction of NT-based aneuploidy screening is the importance of maintaining good quality measurements to achieve optimal screening effectiveness. Unlike biochemical markers that display low interrater variability, NT measurement can be subject to large interobserver variation if not performed under a strict protocol.

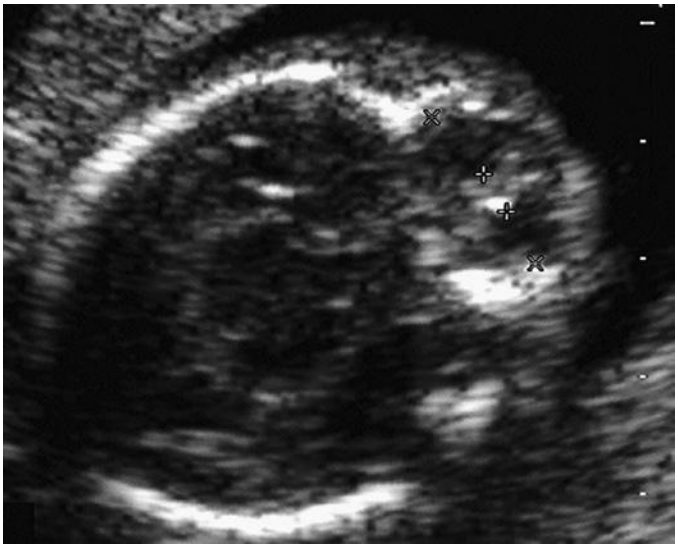

FIG 3-28 Marked hypotelorism in a fetus with trisomy 13.

Measurements should be performed when the crown-rump length measurement is between 36 and 84 mm, depending on the laboratory used. In addition, some important criteria must be fulfilled for a good quality measurement (Fig. 3-29):

- The image should be magnified to occupy 75% of the screen and should show only the fetal head, neck, and upper thorax.
- The fetus must be in the midsagittal plane.
- The fetal neck must be in a neutral position—not hyperextended or hyperflexed.
- Three echogenic lines indicating the inner and outer borders of the fetal skin and the amnion must be displayed.
- The ultrasound calipers must be placed with the horizontal cross on the inner borders of the echolucent space and perpendicular to the fetal axis.
- The measurement of the NT must be taken at the widest space.

The impact of poor quality measurements of the NT on aneuploidy detection can be twofold. Undermeasurement can result in lower detection rates, whereas exaggerated measurement can increase the false positive rate. A modeling study by Cuckle suggested that a 10% undermeasurement may result in a 6% reduction in the trisomy 21 detection rate.[53] In a multicenter study published shortly after the introduction of NT-based screening, the importance of adequate training and monitoring of sonographers was highlighted by a reported low detection rate for Down syndrome of 31%.[54] The Nuchal Translucency Quality Review (NTQR) program and the Fetal Medicine Foundation are two organizations that provide NT training, certification, and oversight and have helped ensure maintenance of high-quality programs offering first trimester screening. Despite the institution of these quality assurance steps, a 2015 review of approximately 1.5 million ultrasound images performed for NT measurement still revealed wide variability among providers, with the more experienced providers demonstrating measurements closer to the expected norms.[55]

When NT-based screening was first introduced, absolute or categoric NT cutoffs were suggested to define an abnormal screening result. It was soon realized that the NT increases with gestational age even in the short-term window between the 10th and 14th weeks when these tests are performed.[56,57] Therefore, NT measurements must be adjusted for gestational age. The approach to adjusting involves converting the NT to multiples of the median (MoM) for gestational age and using either the 95th percentile for the MoM or the delta value of the observed NT from that expected for the gestational age or crown-rump length.

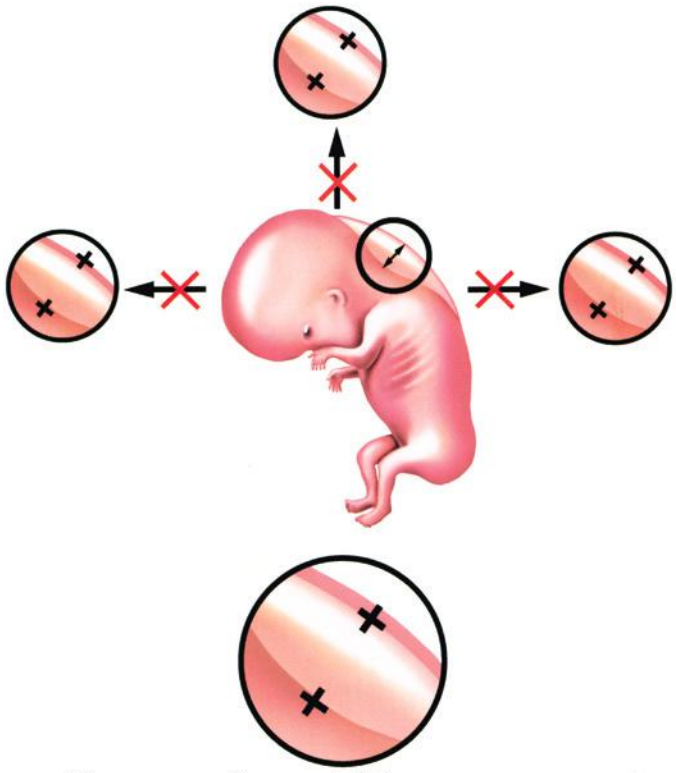

FIG 3-29 Technique for obtaining accurate first trimester nuchal translucency (NT) measurement. **A,** Demonstration of appropriate caliper placement. **B,** Demonstration of appropriate magnification, fetal neck position, and visualization of the amnion. Illustration by James A. Cooper, MD, San Diego, CA.

Sophisticated software is used to perform such calculations, and these measurements are now considered the gold standard. However, it is also important to note that an enlarged NT (greater than 3.0 mm) may be considered an indication for diagnostic testing, regardless of gestational age correction, given that the risk for aneuploidy exceeds 1 in 6 at this threshold. Further adjustment using first trimester serum analytes will not significantly alter the risk for aneuploidy in most cases.[58]

Cystic Hygroma

Cystic hygromas represent an abnormality of the fetal lymphatic system and occur in approximately 1 in 285 first trimester pregnancies.[59] This diagnosis is made when the nuchal space is enlarged with large posterior or posterolateral fluid-filled cavities noted within the fetal neck, with or without the presence of septations. This edema can extend caudally along the upper back of the fetus (Fig. 3-30). The presence of a cystic hygroma in the first trimester confers a 50% risk for fetal aneuploidy, with the most common chromosomal abnormalities being Turner syndrome (45,X), trisomy 21, and trisomy 18. In euploid fetuses with cystic hygomas, 50% to 60% will be diagnosed with major fetal structural abnormalities later in pregnancy.[59] Debate continues as to whether cystic hygromas represent a continuum of thickened NT and if the presence or absence of septations alters the aneuploidy risk. Based on the available data, it would appear that in the presence of either a thickened NT or cystic hygroma with or without septations, the aneuploidy risk remains comparably very high, and this distinction is clinically relatively unimportant. In either case, invasive diagnostic testing should be offered.[60]

Absent Nasal Bone

The appearance of a small nose with a low nasal bridge in children and adults with Down syndrome initially led to the investigation of the fetal nasal bone as a marker for this condition. In 2002, Sonek and Nicolaides reported on three unselected first trimester fetuses with Down syndrome. Two of those fetuses had sonographically undetectable nasal bones, and the third had a nasal bone that was below the 2.5th percentile in length for gestational age.[61] A 2003 study performed NT screening on 5532 fetuses from 5425 pregnancies and found that the nasal bone was absent in 70% of fetuses with Down syndrome versus in 0.2% of euploid fetuses. Not only did the authors show an association of absent nasal bone with Down syndrome, but they also demonstrated that appropriate imaging of the nasal bone was attainable in a large percentage of the study population, with a 99.8% visualization rate.[62]

Additional studies have confirmed the association of absent nasal bone and Down syndrome. One study demonstrated that a successful view of the fetal profile could be obtained in 1752 of 1906 consecutive fetuses undergoing NT scanning (91.9%).[63] In this study, the nasal bone was absent or hypoplastic in 12 of 19 fetuses with chromosomal abnormalities and in 8 of 10 with trisomy 21. Absence of the nasal bone was recorded in only 24 of 1733 chromosomally normal fetuses (1.4%). In an additional study, investigators successfully assessed the nasal bone in 1027 of 1089 (94.3%) fetuses and found that the nasal bone was absent in 10 of 1000 (1.0%) unaffected cases and in 10 of 15 (66.7%) Down syndrome cases.[64]

To assess the nasal bone sonographically, the fetal profile is first viewed in the midsagittal plane. The transducer can then be rocked sideways to maintain the angle of insonation at 45 or 135 degrees.[65] The nasal bone is visualized as an echogenic line below and parallel to the overlying skin. When present, the nasal bone and skin appear similar to an equal sign[66] (Fig. 3-31). Although obtaining sonographic images of the fetal nasal bone is straightforward, there is a learning curve associated with developing proficiency. In 2003, Cicero and colleagues determined that it took sonographers with NT imaging expertise an average of 80 nasal bone images, with a range of 40 to 120, to become competent in examining the fetal nasal bone.[67]

Recent research has attempted to incorporate nasal bone evaluation into current first trimester screening protocols in order to improve the accuracy of aneuploidy diagnosis. In 2005, a prospective cohort study assessing the utility of incorporating nasal bone assessment into screening with standard first trimester markers (NT, free β-hCG, PAPP-A) was performed. Incorporating nasal bone measurement improved the detection rate of Down syndrome to 90% and reduced the false positive rate to 2.5%.[68] Cicero and colleagues observed similar results with the incorporation of fetal nasal bone into first trimester screening.[69]

It has been noted that race and ethnicity are associated with an absent nasal bone. In a study reported in 2003, in 3358 karyotypically normal fetuses, absent nasal bone was identified in 2.8% of Caucasians, 10.4% of African Caribbeans, and 6.8% of Asians.[70] The finding of racial variation and absent nasal bone was reinforced by another large series of patients. In that study, the fetal profile was successfully examined in 5851 cases (98.9%), and absent nasal bone in chromosomally normal fetuses was seen in 2.2% of Caucasians, 9.0% of African Caribbeans, and 5.0% of Asians.[71] These findings have led investigators to question whether the simple presence or absence of the nasal bone is applicable when evaluating the nasal bone in the first trimester, given that race and ethnicity may not be known or easily incorporated into risk adjustment.

Ductus Venosus Doppler Studies

The ductus venosus is a unique fetal blood vessel that shunts highly oxygenated blood from the umbilical vein to the right atrium, after

which it is shunted through the foramen ovale to provide oxygenated blood to the fetal circulation. Doppler study of the ductus venosus normally will show triphasic, pulsatile forward flow. However, an absent or reversed a wave during atrial systole has been observed in cases of fetal cardiac malformations and aneuploidy. In 1998, Matias and colleagues demonstrated the feasibility of first trimester ductus venosus Doppler sonography to screen for aneuploidy, showing that 57 of 63 (90.5%) chromosomally abnormal fetuses had either an absent or reversed a wave.[72] A subsequent study by Prefumo and colleagues demonstrated a positive LR of 7.05 for Down syndrome in the setting of abnormal ductus venosus flow in a high-risk population undergoing chorionic villus sampling.[73] Using ductus venosus Doppler studies as an adjunct to NT screening appears to be more discriminatory than using either test alone.[74,75]

In chromosomally normal fetuses with a normal NT, abnormal ductus venosus blood flow in the first trimester has been associated with adverse fetal outcome such as congenital heart disease and fetal growth restriction.[76,77] Despite these reports, the technical feasibility of successfully interrogating such a small fetal vessel (~2 mm) with Doppler sonography in the first trimester of pregnancy may preclude its practical use in screening for fetal abnormalities.

Tricuspid Regurgitation

Tricuspid regurgitation has also been proposed as an adjunct to first trimester aneuploidy screening. This measurement is obtained by using pulse-wave Doppler imaging of the tricuspid valve in the apical four-chamber view with insonation parallel to the ventricular septum, A regurgitant jet must be present over at least half of systole with a velocity over 60 to 80 cm/second for a diagnosis of tricuspid regurgitation.[78] Falcon and colleagues demonstrated significant tricuspid regurgitation in 74% of Down syndrome fetuses compared to 6.9% of normal fetuses.[78] The addition of tricuspid regurgitation to first trimester serum screening and NT measurement has been shown to increase the detection rate of Down syndrome from 91% to 96% at a 3% fixed false positive rate.[79] Similar to first trimester ductus venosus Doppler screening, the technical difficulties and need for experienced sonographers with training in fetal echocardiography limit the utility of this measurement for screening in the general population.

Frontomaxillary Facial Angle

In 2007, Sonek and colleagues proposed the use of first trimester fetal frontomaxillary facial (FMF) angle as a sonographic screening tool for aneuploidy based on the characteristic flat facial profile observed in children and adults with Down syndrome.[80] This measurement is taken by first obtaining a midsagittal view of the fetal profile. The FMF angle is defined as the angle between a line along the upper surface of the upper palate and a line that traverses the upper corner of the anterior aspect of the maxilla and extends to the external surface of the frontal bone at the point of its greatest anterior excursion.[80] This angle measurement has been demonstrated to be significantly larger in Down syndrome fetuses compared to euploid fetuses.[80,81] Incorporation of this measurement into first trimester screening increases the Down syndrome detection rate from 90% to 94% at a 5% false positive rate.[82]

THE SECOND TRIMESTER GENETIC SONOGRAM

The sonographic detection of a major structural abnormality significantly increases the risk that a fetal chromosome abnormality is present. Some structural abnormalities are particularly associated with a specific aneuploidy (see Table 3-1). However, many aneuploid fetuses, particularly those with Down syndrome, do not have major structural abnormalities that are readily detected in the first or second trimester. Because Down syndrome is the most common clinically significant chromosome abnormality, identification of minor features of Down syndrome, or so-called sonographic soft signs, is often employed as a screening tool.

Prior to the introduction of the genetic sonogram, the only additional option available for patients with elevated aneuploidy risks obtained by second trimester serum screening was to undergo amniocentesis. As the association between ultrasound markers and Down syndrome became more apparent, the genetic sonogram was introduced as an alternative noninvasive method to further refine aneuploidy risk, most specifically for Down syndrome.

The genetic sonogram is a targeted second trimester ultrasound study performed at the time of the anatomic survey, which assesses for major fetal malformations as well as minor markers of aneuploidy, including increased nuchal skinfold, shortened long bones, pyelectasis, absent/hypoplastic nasal bone, hyperechoic bowel, and echogenic intracardiac focus (EIF) as well as a number of other, less common markers. The presence or absence of these markers, either alone or in combination, can adjust a patient's aneuploidy risk obtained by second trimester screening results, potentially aiding in the decision as to whether or not to pursue invasive testing with amniocentesis. The components of the genetic sonogram have been revised over the years with markers such as widened pelvic angle and sandal gap toe deformity falling out of favor and newer sonographic findings such as aberrant right subclavian artery (ARSA), prenasal thickness, and FMF angle gaining more popularity.[83,84]

In isolation, each sonographic marker typically carries low to moderate sensitivity and specificity for the detection of Down syndrome. However, the presence of multiple markers can substantially improve the detection rate while also lowering the false positive rate. Studies have demonstrated Down syndrome detection rates ranging from 50% to 93% in the presence of one or more minor aneuploidy markers on genetic sonogram.[85-88] In addition, LRs have been established for each individual marker; these ratios can be multiplied by the patient's a priori risk for aneuploidy calculated by serum screening results or age alone to provide an age-adjusted ultrasound risk assessment [AAURA] of the patient's posttest odds for aneuploidy. These LRs weight the influence of each individual marker by their strength of association with Down syndrome. Bromley and colleagues demonstrated an exponential increase in the chance of Down syndrome based on the number of markers observed on ultrasound imaging, ranging from 1.9 in the presence of one marker to 80 in the presence of three or more markers.[89] Table 3-2 presents individual LRs as reported in several studies.[89-92] The differences between studies likely stem from the heterogeneity of the populations studied, thereby making interpretation difficult. In the setting of multiple markers, it has been proposed that it is appropriate to multiply the LR of each individual marker by the patient's a priori aneuploidy risk. However, caution must be taken with this approach, as the independence of the various markers has not been proved.

In addition to the utility of these calculated positive LRs, the absence of any of these markers on second trimester sonography can decrease a patient's aneuploidy risk. It has been demonstrated that a normal genetic sonogram can decrease the risk of Down syndrome by 60% to 80%, correlating to a negative LR of 0.2 to 0.4.[89,90] This result may provide additional reassurance to patients with a positive second trimester serum screen, although it is important that patients understand the nature and limitations of this screening test and that these findings cannot diagnose or rule out Down syndrome with certainty.

The genetic sonogram originally was targeted toward a high-risk population (i.e., advanced maternal age, positive second trimester serum screening) and was found to significantly decrease the rate of invasive testing with amniocentesis.[93,94] The application of the genetic

sonogram to low-risk populations has been more controversial. Given the low prevalence of aneuploidy in this population, positive findings on a genetic sonogram carry low predictive values and high false positive rates, resulting in increased patient anxiety. The presence of isolated minor markers such as echogenic intracardiac foci, pyelectasis, and femoral/humeral shortening confers only a small effect on the pretest odds for Down syndrome in this population.[91,92] However, the finding of one minor marker of aneuploidy should prompt a more thorough search for other associated markers or structural abnormalities as well as a review of the patient's aneuploidy risk based on age or other screening tests.

In the current era of first trimester biochemical and cfDNA screening, the utility of the second trimester genetic sonogram has been questioned. The FASTER trial attempted to answer this question in a subset of patients and found a modest increase in the Down syndrome detection rate with application of the genetic sonogram after normal screening. When the genetic sonogram was added to the quadruple screen in an integrated, stepwise, or contingent manner, the detection rate of Down syndrome increased from 93%, 97%, and 95% to 98%, 98%, and 97%, respectively. However, substituting the genetic sonogram for second trimester serum screening did not appear to be useful, yielding only a 90% Down syndrome detection rate.[95] Kranz and colleagues performed a simulation study to determine the effectiveness of the genetic sonogram following negative first trimester combined screening results. Using individual marker LRs, the genetic sonogram identified an additional 6.1% of Down syndrome cases, resulting in a total detection rate of 94.6% with a false positive rate of 5.4%.[96]

Given the recent introduction of cfDNA screening into clinical practice, studies specifically addressing the performance of the genetic sonogram following cfDNA screening are not yet available. With the increased ability to diagnose aneuploidy early in pregnancy, the prevalence of Down syndrome at the time of the second genetic sonogram has decreased, therefore decreasing the positive predictive value of these sonographic markers. Despite this fact, the genetic sonogram likely still can play a role in aneuploidy screening in populations with limited access to cfDNA, in twins and higher-order multiple gestations, and in patients with borderline or failed cfDNA results.[97]

Thickened Nuchal Fold

The association between a thickened nuchal skinfold (NF) and Down syndrome was first described by Benacerraf and colleagues in 1985 and remains one of the most specific second trimester markers for Down syndrome.[98] This sonographic finding phenotypically correlates to the redundant soft tissue in the posterior neck that is characteristic of newborns affected by Down syndrome.[99] Although it initially was thought, and seems logical, that a second trimester thickened NF measurement results from a first trimester thickened NT, these markers do not appear to be correlated and, therefore, can be used independently to assess aneuploidy risk.[100,101]

The NF is typically measured between 15 and 21 weeks by obtaining a transverse plane of the fetal head at the level of the biparietal diameter. The transducer is then angled caudally to include the cerebellum and occipital bone. The NF is measured by placing calipers on the outer skull and outer skin edge[98] (Fig. 3-32). Significant fetal neck extension or excessive abdominal pressure with the ultrasound probe may falsely increase this measurement.[102] Thresholds of 5 mm or greater and 6 mm or more have been proposed; however, 6 mm or greater seems to be the most accepted standard value to define abnormal.[98,103,104] Using this threshold, positive LRs as high as 94.7 have been reported; however, more recent meta-analyses indicate a more modest association, with LRs ranging between 11 and 17.[89,91,92] Importantly, the false positive rate for this sonographic marker is exceedingly low (0.1-1.3%), making this one of the most specific second trimester sonographic markers for Down syndrome.[3,98,103] Nuchal skinfold thickness has been found to increase with advancing gestational age, leading many investigators to evaluate gestational age–specific nomograms to extend the utility of this measurement up to 24 weeks' gestation.[105,106] Alternatively, some fetuses with Down syndrome may experience complete resolution of nuchal thickness as gestation advances, suggesting that following serial sonograms for resolution is unwarranted and may even provide false reassurance.[107]

Absent/Hypoplastic Nasal Bone

As discussed earlier in this chapter, studies utilizing the absence of the nasal bone in the first trimester have clearly shown an association with Down syndrome. However, concerns exist regarding maternal ethnic variability as well as the potential for late ossification of the nasal bone in select populations. To minimize false positive results and to offer screening options to the patient who presents for later prenatal care, attention shifted to nasal bone screening in the second trimester. The addition of absent nasal bone to the second trimester genetic sonogram as a marker of Down syndrome has been shown to significantly increase the sensitivity of the examination (Fig. 3-33).

When evaluating the facial profile for the nasal bone, the correct technique and angle of insonation should be used. The profile should be viewed in the midsagittal plane, with care taken to keep the angle of insonation close to 45 degrees or 135 degrees. With angles less than 45 degrees or greater than 135 degrees, the nasal bone may artificially appear to be absent. On the other hand, as the angle approaches 90 degrees, edges of the bone may become difficult to delineate precisely because of echo scatter, and the measurement may be artificially large. The nasal bone should be visualized as a linear echogenic structure if the correct technique is used (Figs. 3-34 and 3-35).

The definition of nasal bone hypoplasia is important because its inclusion into screening strategies that utilize other sonographic markers can significantly improve Down syndrome detection rates while minimizing false positive rates—much in the same manner as first trimester screening strategies. In 2006, Odibo and colleagues evaluated second trimester nasal bone hypoplasia as a marker for fetal aneuploidy and demonstrated that its incorporation into risk assessment with other markers of fetal aneuploidy significantly improved the sensitivity and specificity for karyotype abnormalities. When used

FIG 3-35 Hypoplastic nasal bone. Facial profile of another fetus showing a small nasal bone (*arrow*).

alone, nasal bone hypoplasia had a sensitivity of 23% to 64% and a specificity of 57% to 99% for detecting Down syndrome. The ranges depended on the definition of nasal bone hypoplasia that was used. When combined with other markers (nuchal fold, femur and humeral lengths, choroid plexus cysts, echogenic bowel), the sensitivity increased from 59% to 82%, and the specificity improved from 74% to 87%.[108] Interestingly, a recent study comparing nasal bone with NF thickness found absent nasal bone to be a more efficient marker for Down syndrome. This study also evaluated a cohort that had not been well studied—the low-risk patient population. The authors found that nasal bone and NF thickness were equally efficient Down syndrome markers in both high- and low-risk populations.[109] Finally, a recent meta-analysis demonstrated a positive LR of 23.27 for absent or hypoplastic nasal bone; this LR is high enough that it would categorize essentially all patients with this finding as "screening positive" regardless of maternal age.[92]

Although absent nasal bone as a dichotomous marker for Down syndrome has been shown to have superior screening efficiency, other measures to assess nasal bone hypoplasia have been proposed. One such measure is the use of fetal biometry ratios. A commonly reported ratio is the fetal biparietal diameter/nasal bone length (BPD/NBL). By utilizing a ratio, the influence of gestational age is potentially offset. In 2002, Bromley and colleagues used a BPD/NBL ratio and compared Down syndrome and euploid infants. They reported 100% sensitivity for the detection of affected fetuses using a BPD/NBL ratio of 9 or greater. However, this high sensitivity was associated with a false positive rate of 22%.[110] Subsequent studies have tried to balance the rate of detection with a more acceptable false positive rate. In 2004, Odibo and colleagues reported that a ratio of BPD/NBL greater than 11 identified 50% of Down syndrome fetuses and had a false positive rate of 7%.[111] More recent studies have shown that using MoM values of the nasal bone could improve specificity for detecting Down syndrome. Results from a prospective cohort study reported that nasal bone MoM less than 0.75 was the best definition of NB hypoplasia, with a sensitivity of 49% and a specificity of 92%, as compared to a sensitivity of 61% and a specificity of 84% for BPD/NBL ratio greater than 11.[65] Although the optimal threshold to define nasal bone hypoplasia is uncertain, this marker is one of the best sonographic predictors of Down syndrome in both the first and second trimesters.

Hyperechoic Bowel

Hyperechoic bowel, also referred to as echogenic bowel or bright bowel, is a nonspecific finding that is observed in 0.2% to 1.8% of routine second trimester ultrasound examinations. This sonographic finding is somewhat subjective and is diagnosed when the fetal bowel appears as bright as surrounding bone, typically as compared to the iliac wing (see Fig. 3-36). The echogenicity of fetal bowel can be affected by the frequency of the transducer used; therefore, the diagnosis of hyperechoic bowel should always be confirmed with a low-frequency transducer, less than 5 Mz, and without utilizing harmonics. Although grading systems to classify the degree of bowel echogenicity have been proposed, they have not been routinely accepted into clinical practice.[112]

After thickened NF and absent nasal bone, hyperechoic bowel is the next most sensitive sonographic marker for the detection of Down syndrome. The association between hyperechoic bowel and aneuploidy was first reported by Nyberg in 1990, when he observed a 7% prevalence of hyperechoic bowel in 94 fetuses with Down syndrome.[7] This finding has been duplicated in subsequent studies, with LRs ranging from 6 to 14.[90-92,112-114] Decreased bowel motility and increased water absorption leading to subsequent dehydration of meconium is the proposed mechanism that results in this finding in aneuploid fetuses.[115]

Although Down syndrome is the most common chromosome abnormality associated with hyperechoic bowel, it has also been reported with trisomy 18, trisomy 13, triploidy, and monosomy X.[112] As with other sonographic markers, the predictive value of hyperechoic bowel for aneuploidy is greatly increased in the presence of other sonographic findings.

Once aneuploidy is excluded, the differential diagnosis for hyperechoic bowel includes fetal swallowing of intra-amniotic blood, cystic fibrosis, congenital infection, and primary gastrointestinal disease.[116-119] In addition, isolated hyperechoic bowel has been associated with adverse pregnancy outcomes such as fetal growth restriction and intrauterine fetal demise.[114,120]

Femoral/Humeral Shortening

Given that the majority of individuals with Down syndrome are short in stature, it was theorized that affected fetuses may also demonstrate shortening of their long bones. Multiple definitions to classify a shortened femur and humerus in the second trimester have been proposed, including biparietal diameter/femur length (BPD/FL) and BPD/humerus length (HL) greater than 1.5 MoM for gestational age; observed to expected (O/E) ratios of FL and HL measuring 0.91 or less

and 0.89 or less, respectively; and FL and HL measurements below the 5th percentile for gestational age.[121-124] Regardless of which definition is used, it is imperative that femur and humerus diaphysis lengths be measured with the long bone positioned horizontally in the image, in order not to falsely truncate the measurement.

Benacerraf and colleagues first reported that 68% of fetuses with Down syndrome had a shortened FL as measured by O/E ratio.[123] Using BPD/FL ratios, Lockwood and colleagues demonstrated a 50% sensitivity for the detection of Down syndrome at a 7% false positive rate.[125] However, as an isolated marker, short femur lacks discriminatory effectiveness, with positive LRs of only 1.2 to 1.5.[89,90] Shortened humeral length appears to be a superior marker, with reported Down syndrome detection rates of approximately 50%.[124,126] In 2009, Gray and colleagues revisited the optimal definition of short humeral length and demonstrated that an HL below the 5th percentile for gestational age was the most discriminatory definition, with a positive LR as high as 25.[122] Combining short femur and short humeral length yields an 11-fold increase in Down syndrome risk and has a lower false positive rate compared to using either marker alone.[127] Given the probable ethnic and gender variation in long bone measurements, race- and gender-specific nomograms have been proposed. However, such nomograms have not been found to substantially improve Down syndrome detection rates.[128-130]

Pyelectasis

Pyelectasis (also referred to as pelviectasis) is observed in 1% to 3% of normal fetuses during second trimester anatomic survey.[131] This diagnosis is made when the anteroposterior dimension of the fluid-filled renal pelvis exceeds 4 mm prior to 32 weeks' gestation. Measurements of the renal pelves should be taken with the fetal spine at either the 12 o'clock or 6 o'clock position to ensure greatest accuracy (see Fig. 3-37). Pyelectasis is often seen as a normal variant or may be an early sign of genitourinary obstruction (see Chapter 15). In 1990, Benacerraf and colleagues demonstrated an association between fetal pyelectasis and Down syndrome, with 25% of Down syndrome fetuses in their cohort having pyelectasis, as compared to only 2.8% of euploid control subjects.[132] Subsequent studies confirmed this association, although the sensitivities remain low, ranging from 17% to 25%, with false positive rates of 2% to 3%.[131,132] Although this finding is more common in male fetuses, gender does not appear to alter the risk of aneuploidy.[133]

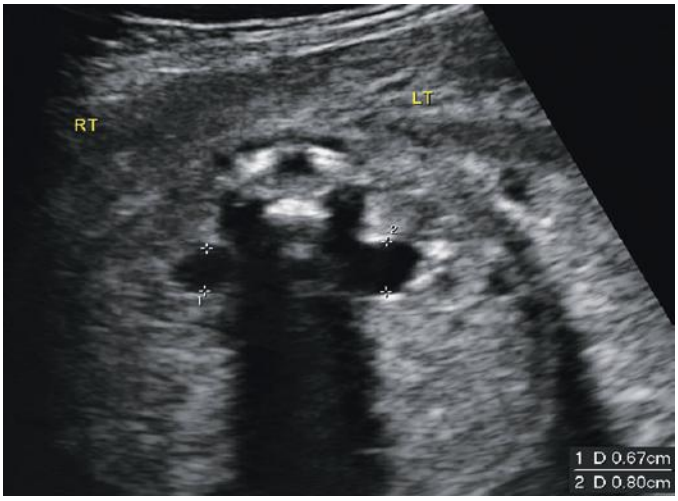

FIG 3-37 Transverse view of the fetal kidneys at the midtrimester; ultrasound image demonstrates mild bilateral pyelectasis. The anteroposterior diameters of the renal pelves measure 0.67 and 0.80 cm on the right (RT) and left (LT), respectively.

When combined with other sonographic markers, the finding of pyelectasis in the detection of Down syndrome can make a modest contribution, with LRs ranging from 5.5 to 8.8.[89,90,92] In a 2007 retrospective review of a large amniocentesis database, Bornstein and colleagues demonstrated an eightfold increased risk of major fetal trisomy when pyelectasis was identified with another single sonographic marker and a 62-fold increase when pyelectasis was identified in combination with multiple other markers.[134] Conversely, the performance of pyelectasis as an isolated marker remains more controversial. Prior studies reported very low LRs (1.5-1.9) in the setting of isolated fetal pyelectasis, suggesting that this isolated finding would not significantly alter the a priori risk of aneuploidy in low-risk women with normal serum screening results.[89,90] More recent studies have attempted to further refine these risk estimates. In 2010, Carbone and colleagues demonstrated a greater than twofold increased risk for Down syndrome with isolated pyelectasis. This increased risk remained significant when stratified by maternal age.[135] A recent meta-analysis evaluating the risk of Down syndrome in the setting of isolated pyelectasis revealed similar results, calculating a pooled positive LR of 2.78. Interestingly, this study also calculated a negative LR of 0.99, suggesting that the absence of this sonographic finding does not *decrease* the likelihood of Down syndrome.[136] Although these results suggest that the presence of isolated pyelectasis may impact the risk of Down syndrome in a high-risk population (advanced maternal age, abnormal serum screening results), it remains a dilemma how to handle this finding in a low-risk population. However, based on the preceding data, it seems unlikely that isolated pyelectasis substantially impacts aneuploidy risk in an otherwise low-risk population and should not be a sole indication for invasive diagnostic testing.

Echogenic Intracardiac Focus

An EIF is the most common sonographic soft marker observed at the time of second trimester anatomic survey, occurring in 3% to 5% of normal fetuses.[137] This finding is thought to represent microcalcification and fibrosis of the papillary muscle and chordae tendineae and is diagnosed when an echogenic area, as bright as bone, is visualized in the fetal heart, most commonly within the left ventricle. An EIF is best appreciated in the apical four-chamber view but must be identified in two distinct cardiac planes to make the diagnosis (Fig. 3-38). An isolated EIF is not associated with structural cardiac abnormalities or myocardial dysfunction based on pathologic correlation and long-term childhood follow-up studies.[138,139]

The association between microcalcifications of the fetal papillary muscle and chromosome abnormalities was first made in the early 1990s when Roberts and Genest noted that this finding was present on pathologic examination in 16% of Down syndrome fetuses as compared to only 2% of normal fetuses.[140] Subsequent ultrasound studies were able to identify this finding sonographically and demonstrated a greater than fourfold increased risk for Down syndrome in the presence of an EIF.[141,142] Similar to pyelectasis, EIF tends to perform best for the detection of Down syndrome in the presence of other sonographic markers, with positive LRs ranging from 2.8 to 8.0.[89-92] Performance of EIF as an isolated marker remains more controversial. In 2009, Shanks and colleagues demonstrated that an EIF was not significantly associated with an increased risk for Down syndrome in patients not otherwise at an increased risk for aneuploidy.[143] Other studies have drawn similar conclusions, stating that EIF should not be considered a marker for aneuploidy in patients without an elevated a priori risk, specifically in those under the age of 35 with negative first or second trimester screening results.[144-147] In contrast, a 2003 meta-analysis reported a relatively high pooled LR estimate of 5.4 for fetal Down syndrome in the presence of an isolated EIF. However, heterogeneity

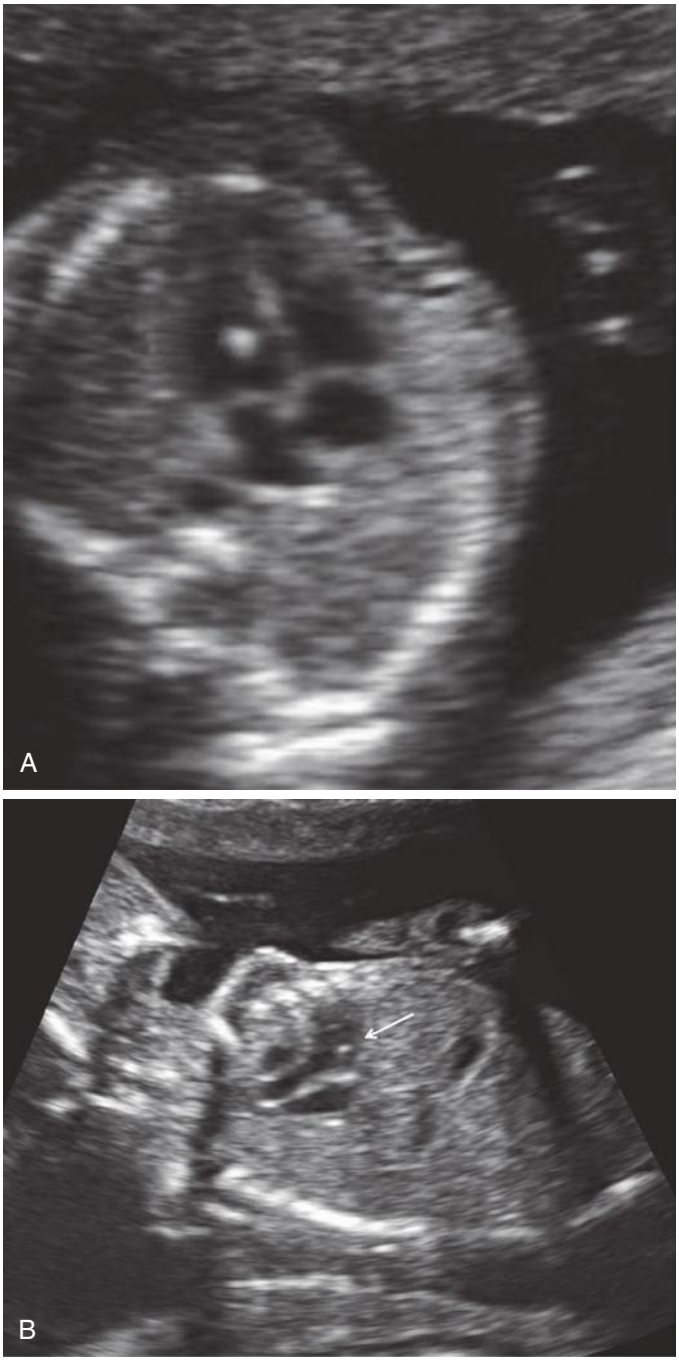

FIG 3-38 **A,** Apical four-chamber cardiac view demonstrating the presence of an echogenic intracardiac focus in the right ventricle. **B,** View of the left ventricular cardiac outflow tract demonstrating the presence of an echogenic intracardiac focus (*arrow*) in the left ventricle.

of the included studies must be taken into consideration and limited the strength of the conclusions to some degree.[148]

Given these conflicting results, obstetricians have struggled with the dilemma of whether or not to disclose the finding of an isolated EIF and offer diagnostic genetic testing to low-risk patients, especially given how commonly this finding is identified on routine sonography. Supporters of full disclosure cite an ethical responsibility of physicians to fully inform and counsel patients. Others have argued that disclosure of this finding, which is common and only weakly associated with Down syndrome, creates unnecessary parental anxiety and leads to an increased rate of invasive diagnostic testing with the potential for fetal loss without significantly improving detection of aneuploidy.[149,150] Caughey and colleagues published a decision analysis evaluating the impact of offering routine amniocentesis to all patients younger than 35 years old with an isolated EIF on second trimester sonogram. This study estimated that more than 100,000 additional amniocenteses would be performed per year to identify 244 additional cases of Down syndrome. This would correlate to 2.4 procedure-related losses per Down syndrome fetus identified.[151] More recently, Chasen and Razavi reported that rates of amniocentesis were significantly higher in low-risk patients following disclosure of an isolated EIF compared to patients without an EIF at a similar level of risk.[152] The issue of disclosure remains an ethical dilemma for obstetric providers. With improvements in prenatal aneuploidy screening, including introduction of cfDNA, this option may allow follow-up testing and alleviation of patient anxiety without concern over unnecessary fetal loss from amniocentesis.

Other Minor Markers for Down Syndrome

Based on the phenotypic features of children with Down syndrome, investigators have suggested that ultrasound findings such as widened iliac wing angle, shortened ear length, clinodactyly, and sandal gap toe deformity be included as part of the second trimester genetic sonogram. However, over the years, these findings have fallen out of favor given their lack of specificity and reproducibility. Instead, other novel markers have been introduced, some of which have demonstrated promise.

An aberrant right subclavian artery (ARSA) has been reported to occur in up to 35% of individuals with Down syndrome.[153] Typically, the right subclavian artery arises as the first branch of the brachiocephalic artery as it originates as the first vessel from the aortic arch. With ARSA, the right subclavian artery arises anomalously as a fourth branch of the aortic arch. This is best visualized in the trachea and three-vessel view of the fetal heart, in which color Doppler demonstrates a fourth vessel coursing from the aorta to the right side of the fetus. In 2005, Chaoui and colleagues noted that an ARSA could be identified in 35.7% of fetuses with Down syndrome.[154] This finding has been confirmed in subsequent studies, with positive LRs as high as 23.27 to 45 in the setting of other sonographic markers.[83,155,156] A recent 2013 meta-analysis demonstrated a positive LR of 3.94 when ARSA was evaluated as an isolated marker. However, few studies were available for the analysis, given that this is a relatively recently reported finding.[92]

In 2005, Maymon and colleagues proposed measurement of prenasal thickness as a second trimester marker of Down syndrome, extrapolating from the physical finding of poor skin elasticity in children with this disorder.[157] To acquire this measurement, the fetal facial profile view is obtained, and a measurement between the frontonasal angle and outer skin edge is taken. In the original study, the prenasal thickness was significantly increased in Down syndrome compared to euploid fetuses. Using both nasal bone and prenasal thickness, the detection rate for Down syndrome was 70%, compared to 43% using nasal bone alone.[157] A subsequent study evaluated prenasal thickness/nasal bone length ratio and demonstrated that a ratio above the 95th percentile resulted in a 100% detection rate for Down syndrome, with a 5% false positive rate and a positive LR of 21.2.[158] Using receiver operator curve analysis, another study found that a prenasal thickness/nasal bone length ratio of 0.76 or greater resulted in an 80% detection rate for Down syndrome at a 5% false positive rate.[159] The optimal threshold for use of prenasal thickness in clinical practice remains to be determined.

As with first trimester imaging, the FMF angle measurement has also been proposed as a second trimester marker for Down syndrome.[160,161] Sonek and colleagues demonstrated an 85% detection rate of Down syndrome when the FMF angle measured above the 95th percentile.[160] Odibo and colleagues demonstrated less promising results, with the FMF angle identifying only 9.5% of Down syndrome fetuses. When used together with nasal bone, the FMF angle identified only one additional case of Down syndrome.[162] It remains unclear whether this angle measurement is dependent on gestational age and ethnicity. Future large prospective studies are needed to determine the true association between this finding and Down syndrome and to standardize measurement technique and optimal threshold values.

SECOND TRIMESTER SONOGRAPHIC MARKERS FOR OTHER ANEUPLOIDIES

Choroid Plexus Cysts

Choroid plexus cysts occur in 1% to 2% of normal fetuses.[163,164] The normal choroid plexus fills the atrium of the lateral cerebral ventricles prior to 16 weeks and can be best visualized in the transventricular view just superior to the plane of the biparietal diameter. Choroid plexus cysts are typically identified between 16 and 23 weeks and are seen as round hypoechoic structures within the choroid plexus (Fig. 3-39). They can vary greatly in size and can be unilateral or bilateral, single or multiple. These cysts tend to be transient, typically resolving by 26 weeks, and have no effect on structure or neurodevelopment of the fetus.[165]

The incidence of choroid plexus cysts in fetuses with Down syndrome appears to approximate the incidence in the general population; therefore, this finding is not thought to be a sonographic marker for that condition.[166,167] Several studies have demonstrated positive LRs that approximate 1.0 for the association between choroid plexus cysts and Down syndrome, indicating no increased risk over the background risk.[91,168]

In contrast, choroid plexus cysts have been associated with a significantly increased risk for trisomy 18. Snijders and colleagues demonstrated that choroid plexus cysts are found in approximately 50% of fetuses with trisomy 18 in the midtrimester. As isolated findings, these cysts only marginally increase the risk of aneuploidy. However, when identified in combination with other markers of aneuploidy, the risk for trisomy 18 may be increased by 20-fold.[169] Gupta and colleagues reported a risk for trisomy 18 of 1 in 3 when choroid plexus cysts were identified in conjunction with other anatomic abnormalities. That study also found that the risk for aneuploidy was not related to cyst size, laterality, or regression over the course of gestation.[170]

Debate in the literature remains regarding the significance of choroid plexus cysts as isolated sonographic findings. In a meta-analysis by Ghidini and colleagues, the finding of an isolated choroid plexus cyst increased the risk of trisomy 18 by a factor of 7.[171] More recent data suggest that the presence of an isolated choroid plexus cyst in an otherwise low-risk patient does not increase the risk of trisomy 18.[172-174] These studies support the role of targeted sonography to evaluate for other features of trisomy 18 when a choroid plexus cyst is identified (Figs. 3-40 through 3-42). Similar to EIF, disclosure of this isolated finding remains controversial.[149,150]

Single Umbilical Artery

The normal umbilical cord contains three vessels, one vein and two arteries, surrounded by Wharton jelly. The finding of a single umbilical artery (SUA) is common, occurring in approximately 1% of all live singleton births.[175] Primary agenesis or thrombotic atrophy of one of the umbilical arteries versus persistence of a single allantoic artery are potential explanations for this finding.[176] On prenatal ultrasound imaging, the umbilical arteries are best viewed as they course around either side of the fetal bladder in a transverse view of the fetal pelvis. Using color or power Doppler, demonstration of an absent intra-abdominal segment of one umbilical artery can make the diagnosis of SUA (Fig. 3-43A). Alternatively, a cross-sectional view of a free-floating loop of cord demonstrating only two vessels can also aid in diagnosis (Fig. 3-43B). Some investigators have noted that SUA can be diagnosed as early as 11 to 14 weeks' gestation; however, this finding more typically is diagnosed at the time of the midtrimester anatomic survey.[177]

The association between SUA and major aneuploidies is well established, with trisomy 18 being the most common aneuploidy in affected fetuses. Trisomy 13, monosomy X, and triploidy have also been observed in the setting of SUA.[177-181] Although there have been reports of trisomy 21 in the setting of SUA, there appears to be no significant association or increased risk.[179] Granese and colleagues demonstrated

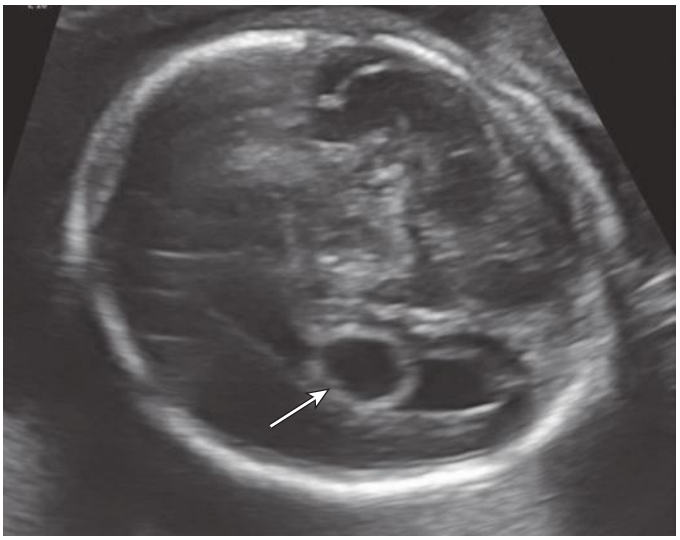

FIG 3-39 Transverse view of the fetal head at the level of the choroid plexus demonstrating the presence of a single choroid plexus cyst (*arrow*).

FIG 3-40 Sonogram of fetus with trisomy 18 shows bilateral clenched hands, which persisted throughout the sonographic examination.

FIG 3-41 Three-dimensional image of fetus with trisomy 18 shows persistently bilateral clenched hands in front of the face. These hand findings are characteristic of this aneuploidy.

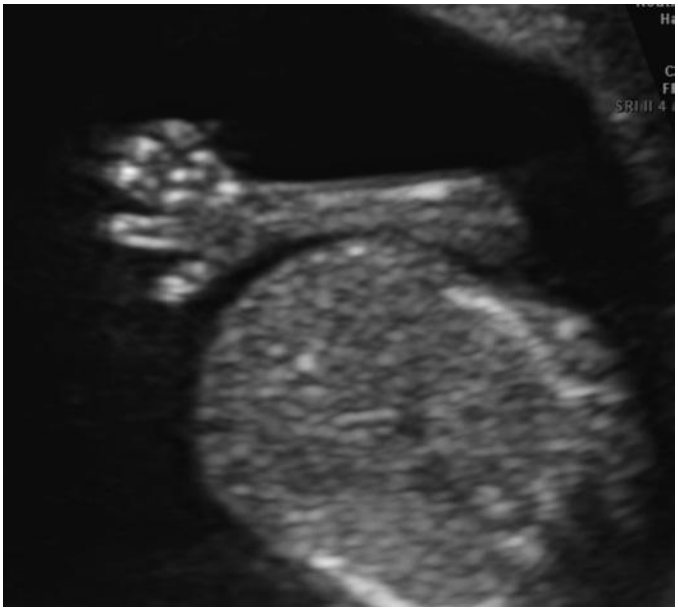

FIG 3-42 Normal open fetal hand. The absence of the characteristic clenched hands seen in trisomy 18 is an important component of a fetal evaluation when choroid plexus cysts are identified.

a 41.6% incidence of chromosomal malformations in fetuses with SUA and a concomitant major anomaly compared to a 2.56% incidence when SUA was an isolated finding.[179] In a 2010 population-based retrospective cohort study of greater than 200,000 fetuses and neonates, SUA conferred a 15.35 times greater risk of chromosomal

abnormalities overall.[182] Another recent study demonstrated no cases of aneuploidy in the setting of isolated SUA, a 3.7% risk in fetuses with one additional defect, and a 50.7% risk in fetuses with multiple defects.[181] Finally, a recent meta-analysis demonstrated no increased risk for aneuploidy in fetuses with isolated SUA.[183] Based on these data, it would appear that the association between SUA and aneuploidy is strongest in the setting of other major anomalies, and there is little evidence to support an increased risk of aneuploidy in the setting of an isolated SUA. However, this sonographic finding should prompt more detailed targeted examination to evaluate for other markers of aneuploidy. In the absence of aneuploidy, SUA has also been associated with other major anomalies, specifically cardiac and renal abnormalities, as well as fetal growth restriction[182,184] (see Chapter 19).

Abnormalities of the Extremities

Malformations of the fetal extremities are commonly observed in fetuses with autosomal trisomies. Abnormal positioning of the fetal hands, including clenched fists and overlapping digits, is one of the most common findings seen in fetuses with trisomy 18. These findings may be subtle sonographically and are best observed during real-time imaging. Shields and colleagues found that 89% of fetuses with trisomy 18 demonstrated persistent abnormal positioning of the fetal fingers during ultrasound examinations between 14 and 22 weeks.[185] These

FIG 3-44 Left-sided clubfoot identified at 20 weeks' gestation. LT, left.

investigators suggested that sonographic documentation of an open hand should significantly decrease trisomy 18 risk (see Fig. 3-42). Similarly, Watson and colleagues demonstrated that abnormalities of the position of the fetal hands were the second most common sonographic finding in trisomy 18 (43%), following cardiac defects (62%).[186] These fetal hand abnormalities may be one of the earliest sonographic findings in trisomy 18 fetuses, identifiable as early as 12 to 13 weeks' gestation.[187,188]

"Rocker-bottom feet" are pathognomonic for trisomy 18, with the fetal feet having the sonographic appearance of a rocking chair bottom instead of the typical inward arch of the plantar surface of the foot. This finding has been reported in 10% to 52% of fetuses with trisomy 18.[3,189,190] Other reported extremity malformations in trisomy 18 include hypoplastic/absent thumb, syndactyly of the fingers and toes, and radial/ulnar deviation of the hands.[190]

Talipes equinovarus (clubfoot) has also been associated with trisomy 18, trisomy 13, and sex chromosome abnormalities.[191] This abnormality is diagnosed when the foot is rotated inward and fixed in a plantar-flexed position (Fig. 3-44). Clubfeet are identified in approximately 20% to 40% of all fetuses with trisomy 18. However, as reported previously, the vast majority of these fetuses will also have additional associated abnormalities.[3,189] As an isolated finding, the incidence of aneuploidy associated with clubfoot ranges from 1.7% to 3.6% and is generally not thought to be an indication for invasive genetic testing in a low-risk patient.[192,193]

Polydactyly is diagnosed when more than five digits are located on either the hand or foot. Postaxial polydactyly is diagnosed when the digit is located on the ulnar or fibular side of the hand or foot and has been associated with trisomy 13.[4,194,195] Recent studies demonstrate a 7% to 10% incidence of postaxial polydactyly in trisomy 13 fetuses.[194,195] Because this extra digit is often a simple skintag without the presence of ossified bone, it can be difficult to detect sonographically.

CONCLUSIONS

A large number of major and minor sonographic findings have been associated with fetal aneuploidy in the first and second trimesters of pregnancy. Although structural anomalies are strongly associated with chromosome abnormalities, a search for major malformations will identify relatively few cases of Down syndrome. For this reason, so-called soft markers are often used to identify fetuses at risk. The presence of an isolated soft marker usually does not represent a markedly elevated risk for Down syndrome, the exception being an absent nasal bone or a thickened nuchal fold. The identification of one soft marker should result in a careful assessment for other markers and structural abnormalities, as well as a determination of the patient's baseline aneuploidy risk.

Ultrasound of the Early First Trimester

Peter M. Doubilet, Carol B. Benson

SUMMARY OF KEY POINTS

- The progression of transvaginal sonographic findings in normal early first trimester pregnancies follows a highly predictable pattern, with a gestational age variability of approximately ±0.5 week: gestational sac at 5.0 weeks, yolk sac at 5.5 weeks, embryo with heartbeat at 6.0 weeks, and amnion at 7.0 weeks.
- In a woman with a positive pregnancy test and no evidence of an intrauterine or ectopic pregnancy on ultrasound (pregnancy of unknown location [PUL]), a single hCG measurement does not reliably distinguish a normal intrauterine pregnancy from a failed intrauterine pregnancy or an ectopic pregnancy.
- In a woman with a positive pregnancy test, any round or oval intrauterine fluid collection should be interpreted as highly likely to be a gestational sac, not a pseudogestational sac or decidual cyst, and treatments that could damage an intrauterine pregnancy should be avoided.
- An extraovarian mass can be distinguished from an intraovarian lesion, such as a corpus luteum, by observing its motion relative to the ovary when pressure is applied by the transvaginal transducer.
- Sonographic findings definitive for failed intrauterine pregnancy include crown-rump length (CRL) of at least 7 mm without cardiac activity, mean sac diameter (MSD) of at least 25 mm without an embryo, and no embryo with a heartbeat on a follow-up scan at specific time intervals after the initial scan.
- Sonographic findings suspicious, but not definitive, for failed intrauterine pregnancy include CRL of less than 7 mm without cardiac activity, MSD of 16 to 24 mm without an embryo, no embryo with a heartbeat 6 weeks or more after the first day of the last menstrual period (LMP), empty amnion sign, expanded amnion sign, and a large yolk sac.
- Risk factors for pregnancy failure when embryonic heartbeat is seen include slow heart rate, large subchorionic hematoma, and small gestational sac size.
- Pregnancy number (singleton, twin, triplet, and higher order multiples) assessed prior to 6 weeks of gestation may subsequently decrease owing to the vanishing twin phenomenon or may increase by one or more additional embryos that appear on a follow-up scan.

OUTLINE

A developing pregnancy generally becomes visible on transvaginal ultrasound at 5 weeks' gestational age, which corresponds to 3 weeks after conception and 5 weeks after the first day of the LMP in a woman with regular 28-day cycles. This chapter will address sonographic evaluation of pregnancies during the gestational age range of 5.0 to 8.0 weeks. Since the 1970s, this age range has been a major focus of ultrasound research.[1] Improvements in ultrasound technology over the past 3 decades, especially the introduction and dissemination of transvaginal sonography, have made ultrasound an increasingly valuable tool.

During the early part of the first trimester, very careful sonographic technique and interpretation are critical because of the small size of the pregnancy-related structures in the uterus and adnexa, including the intrauterine or ectopic gestational sac and corpus luteum. If done well, ultrasound can confirm the presence and location of pregnancy and accurately determine the gestational age. If done poorly, an intrauterine pregnancy can be mistaken for an ectopic pregnancy,[2,3] or a normal pregnancy in the uterus can be mistaken for a failed pregnancy (also termed *miscarriage*), mistakes that can have serious consequences.

NORMAL TRANSVAGINAL SONOGRAPHIC FINDINGS IN THE EARLY FIRST TRIMESTER

Approximately 1 week after fertilization, the pregnancy implants in the decidua on one side of the uterine cavity[4] (Fig. 4-1), but it is not yet visible on ultrasound for about 2 more weeks. The progression of findings on transvaginal sonography in normal early first trimester pregnancies follows a highly predictable pattern,[5-8] with a gestational age variability of approximately ±0.5 week. The gestational sac is first seen on transvaginal sonography at 5.0 weeks of gestation as a fluid collection 2 to 3 mm in diameter normally located in the central echogenic region of the uterus, which corresponds to the decidua (Figs. 4-2 and 4-3). It grows at the rate of 1 mm/day over the course of the next week.[8]

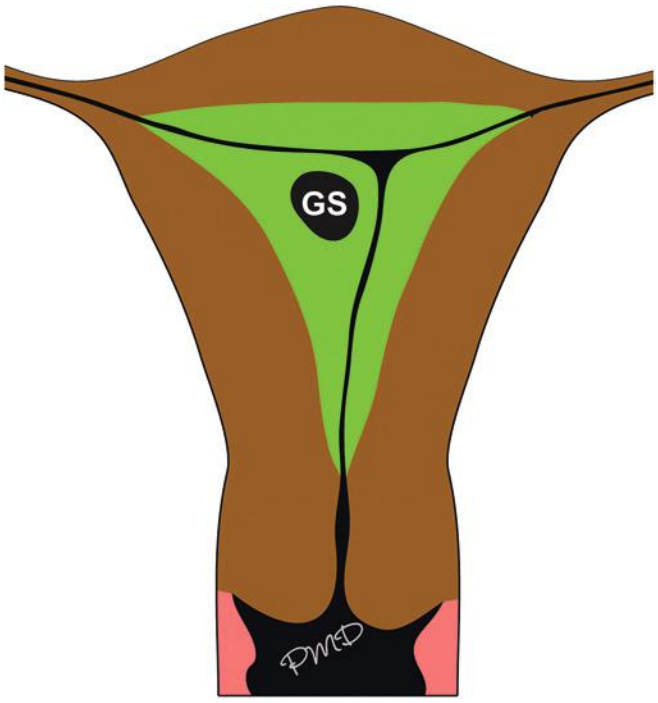

FIG 4-1 Diagram of the early gestational sac (GS) at approximately 5.0 weeks of gestation. The sac is implanted within the decidua (depicted in *green*). The uterine cavity (*thin black lines*) is collapsed.

The first structure that is identifiable within the gestational sac is the yolk sac, which appears as a circular structure up to 6 mm in diameter (Fig. 4-4). It can be seen beginning at 5.5 weeks and remains visible for most of the first trimester. The embryo is first visible at 6.0 weeks, initially appearing as a 1- to 4-mm echogenic structure adjacent to the yolk sac with a flickering motion inside it, representing the beating heart (Fig. 4-5, Video 4-1, Table 4-1).

By 7.0 weeks, the embryo is approximately 1 cm in length[9-11] and is still fairly featureless. At that point, the amnion first becomes visible around the embryo, as the amniotic cavity enlarges with fluid between the embryo and the amnion (Figs. 4-6 and 4-7).[12] By 8.0 weeks' gestation, the embryo is 16 mm in length, and individual body parts can be identified on ultrasound. The embryonic head can be distinguished from the trunk, and limb buds are visible (Fig. 4-8).

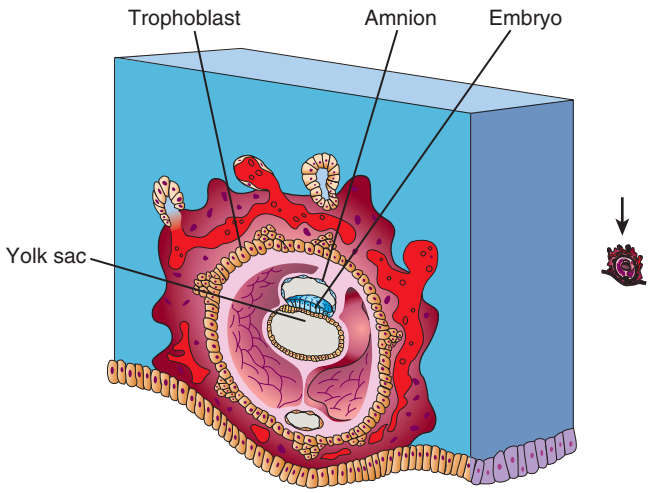

FIG 4-2 Diagram of the blastocyst at the end of the conceptus stage of development. The gestational sac, which is now visible by sonography, measures approximately 5 mm in diameter and contains the secondary yolk sac lying opposite the amniotic cavity. A developing embryo is interposed between these two fluid-filled cavities. Sonography variably identifies the secondary yolk sac, although the embryo cannot yet be seen. (From Moore KL, Persaud TVN: The Developing Human: Clinically Oriented Embryology, 7th ed. Philadelphia, WB Saunders, 2003.)

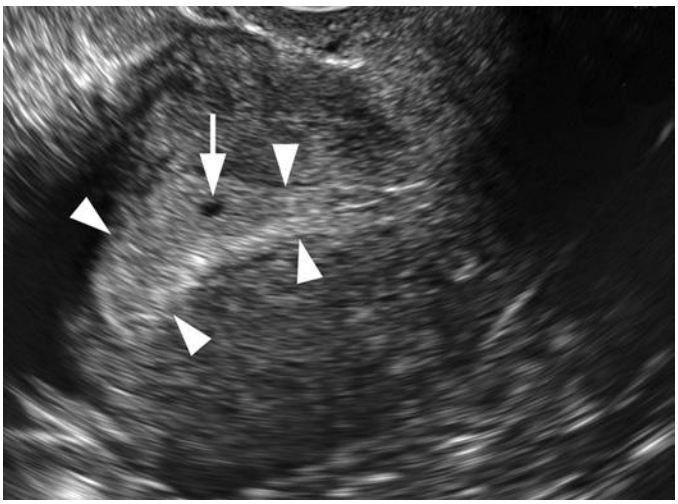

FIG 4-3 5.0-week pregnancy. The gestational sac (*arrow*), with no identifiable internal structures, lies within the decidua (*arrowheads*).

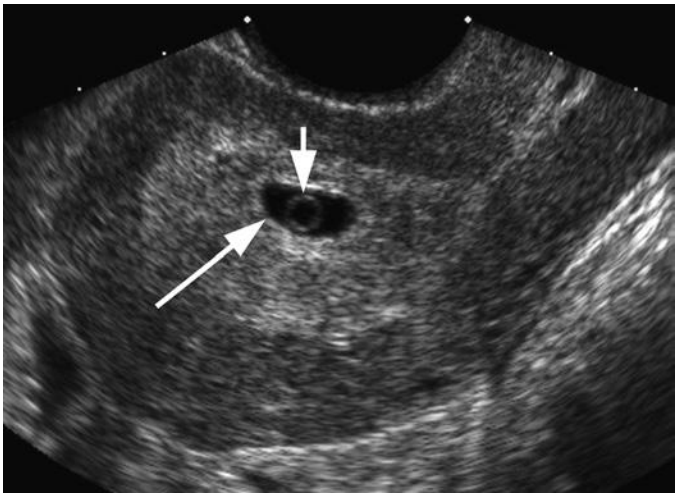

FIG 4-4 5.5-week pregnancy. The gestational sac (*long arrow*) contains a yolk sac (*short arrow*). No embryo is seen.

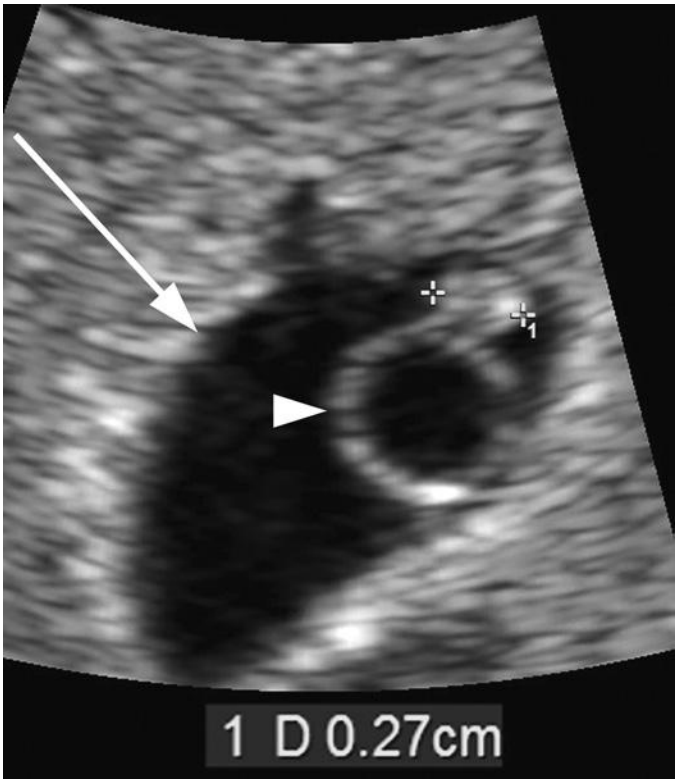

FIG 4-5 6.0-week pregnancy. The gestational sac (*arrow*) contains an embryo (*calipers*) lying beside the yolk sac (*arrowhead*). The embryo is 2.7 mm in length, and a heartbeat was perceived within it on real-time sonography. (See Video 4-1, which shows the heartbeat.)

CONFIRMATION OR EXCLUSION OF INTRAUTERINE PREGNANCY WHEN NO YOLK SAC OR EMBRYO IS SEEN

When a sonogram is performed on a woman with a positive pregnancy test, a fundamental question concerns where the pregnancy is located: intrauterine or ectopic. The question is answered based on the sonographic findings in the uterus and adnexa. The sonographic finding that is definitive for a gestational sac in either location is a fluid collection containing a yolk sac or an embryo with cardiac activity. In the absence of such a fluid collection, the diagnosis is less straightforward. We will consider a number of scenarios involving various potential sonographic appearances of the uterus and adnexa.

TABLE 4-1 Normal Transvaginal Sonographic Findings in the Early First Trimester

Gestational Age (Weeks)	Structure First Appears on Ultrasound*	Mean Sac Diameter (mm)[8]	Crown-Rump Length (mm)[10]
5.0	Gestational sac	2	—
5.5	Yolk sac	6	—
6.0	Embryo with heartbeat	10	3
6.5		14	6
7.0	Amnion	18	10
7.5		22	13
8.0		26	16

*±0.5-week age range for first visibility of each structure.

Ultrasound Demonstrates No Intrauterine Fluid Collection and No Adnexal Abnormality (No Extraovarian Adnexal Mass or Significant Free Fluid)

When the human chorionic gonadotropin (hCG) test is positive but ultrasound demonstrates neither an intrauterine nor ectopic pregnancy, the woman is said to have a pregnancy of unknown location (PUL). The diagnostic possibilities in this setting are a normal intrauterine pregnancy that is too early to be visualized, a failed intrauterine pregnancy (miscarriage), and an ectopic pregnancy. The quantitative hCG is of some value in distinguishing among these possibilities, but care must be taken not to rely on a single hCG level.[13]

The concept of the hCG *discriminatory zone* was introduced by a study published in 1981.[14] That study demonstrated that, in women with normal intrauterine pregnancies, a gestational sac was not generally identifiable on transabdominal ultrasound (the ultrasound technique in general use at that time) when the hCG was below 6000 mIU/mL, and a gestational sac was consistently seen when the hCG was above 6500 mIU/mL. Since that time, the latter of these values—the hCG measurement above which a gestational sac is consistently visible on ultrasound, or the discriminatory level—has been the focus of considerable attention. The rationale is that nonvisualization of an intrauterine fluid collection when the hCG measurement is above the discriminatory level largely excludes a normal intrauterine pregnancy, so it may be safe to undertake treatment for possible ectopic pregnancy without fear of causing harm to a pregnancy that might have a good outcome. As ultrasound technology improved, especially with the introduction of transvaginal sonography, gestational sacs could be identified earlier in pregnancy. This led to a progressive decrease in the recommended hCG discriminatory level. By the mid-1980s it dropped to 1000 to 2000 mIU/mL.[5,15-17]

Management algorithms based on the hCG discriminatory level were put forth for women with bleeding and pain in early pregnancy, when the hCG measurement is above the discriminatory level and no intrauterine or ectopic pregnancy is identified on ultrasound. One algorithm advocates administering systemic methotrexate for suspected ectopic pregnancy in this setting.[18] Another algorithm

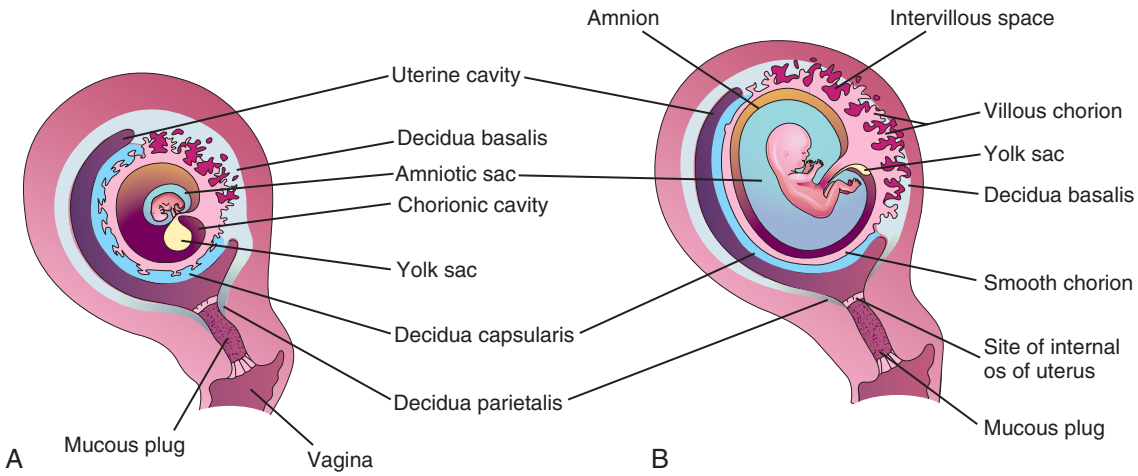

FIG 4-6 **A,** At 7 weeks' gestational age, chorionic villi completely surround the gestational sac and are relatively thick where they contact underlying endometrial tissue (decidua basalis). As the sac enlarges, the chorion and overlying decidual tissue (decidua capsularis) protrude into the compressed uterine cavity and come into contact with the decidua parietalis. This anatomic configuration gives rise to the double decidual sac sign. **B,** The compressed and avascular chorionic tissue becomes smooth and is defined by sonologists as the chorionic "membrane." Because of its fixed anatomic relationship to the developing placenta, in the event of placental bleeding, blood can dissect between the chorionic membrane and overlying decidual tissue, giving rise to a subchorionic hematoma. (From Moore KL, Persaud TVN: The Developing Human: Clinically Oriented Embryology, 7th ed. Philadelphia, WB Saunders, 2003.)

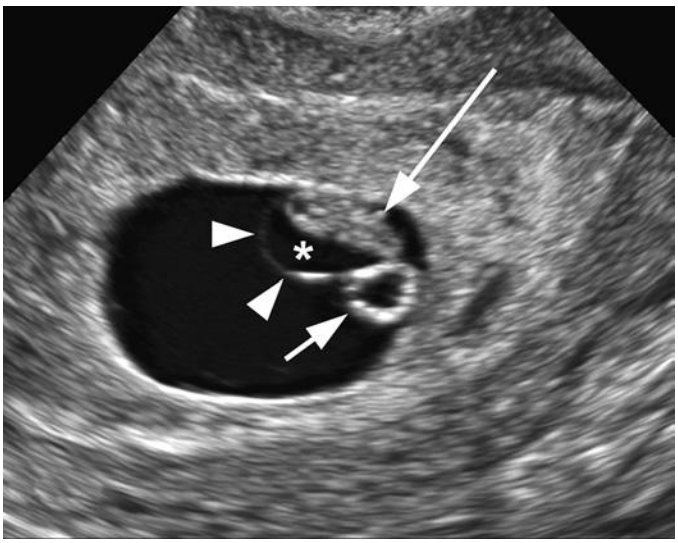

FIG 4-7 7.0-week pregnancy. The embryo (*long arrow*) is surrounded by a thin membrane, the amnion (*arrowheads*), adjacent to the yolk sac (*short arrow*). Fluid (*) is present within the amniotic cavity, separating the amnion from the embryo.

recommends performing a dilatation and curettage procedure (D&C) and then administering systemic methotrexate if no chorionic villi are retrieved.[19]

Over the past several years, however, it has become clear that these management algorithms are overly simplistic and can result in serious errors. As our knowledge of PUL has increased, a number of important points have been learned:

- The discriminatory level does not reliably exclude a normal intrauterine pregnancy. In particular, an hCG value above 2000 mIU/mL, or even above 3000 mIU/mL, in conjunction with a sonogram demonstrating no intrauterine saclike structure, does not fully exclude a normal intrauterine pregnancy.[20]
- A single hCG measurement in a woman with PUL does not reliably distinguish a normal intrauterine pregnancy from a failed intrauterine pregnancy or an ectopic pregnancy.[21]
- Delaying treatment by a few days in a woman with ectopic pregnancy and no adnexal mass on ultrasound carries little risk if she is hemodynamically stable.[22]

Thus, treatment of a woman with a PUL based on a single hCG measurement runs the risk of inadvertently harming a normal intrauterine pregnancy or unnecessarily administering methotrexate to a woman with a failed intrauterine pregnancy. Instead, proper management entails sequential testing with hCG or sonography over a period of 2 or more days.[13] The hCG ratio—ratio of hCG value at 48 hours to initial hCG value—provides more diagnostic information than does a single hCG measurement.[23] A number of management algorithms based on sequential testing have been put forth.[24-26] Regardless of which management approach a facility chooses to follow, the key message is as follows: if ultrasound shows no evidence of intrauterine or ectopic pregnancy and the woman is hemodynamically stable, one should not intervene based on a single hCG measurement but instead do follow-up testing with at least one additional sonogram and hCG measurement.[13]

Ultrasound Demonstrates an Intrauterine Fluid Collection and No Adnexal Abnormality

In a woman with a positive pregnancy test, an intrauterine fluid collection without a yolk sac or embryo can represent a gestational sac, fluid (blood or secretions) in the uterine cavity, or a cyst in the decidua. Around 1980, ultrasound practitioners observed that some women with an ectopic pregnancy have fluid in the uterine cavity.[27,28] Despite the fact that the location of this fluid is different from that of a gestational sac—the former is situated in the uterine cavity and the latter within the decidua—the limited resolution of ultrasound equipment at that time often made it difficult to distinguish between them. As a result, intrauterine fluid in women with ectopic pregnancy was termed a *pseudogestational sac*.[28] Subsequently, it was noted that decidual cysts can also be seen in some women with ectopic pregnancy.[29]

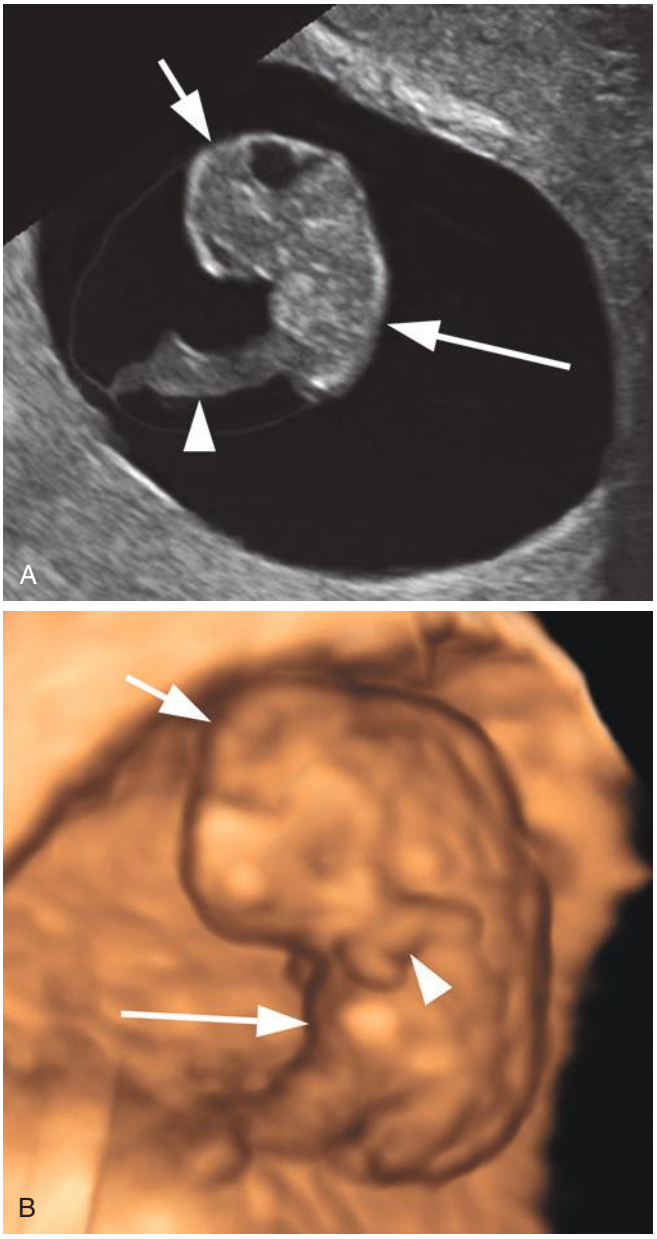

FIG 4-8 8.0-week pregnancies. **A,** The head (*short arrow*) and trunk (*long arrow*) are identifiable. The umbilical cord (*arrowhead*) connects to the anterior abdominal wall. **B,** On a three-dimensional sonogram of another embryo, the head (*short arrow*), trunk (*long arrow*), and an upper extremity (*arrowhead*) are identifiable.

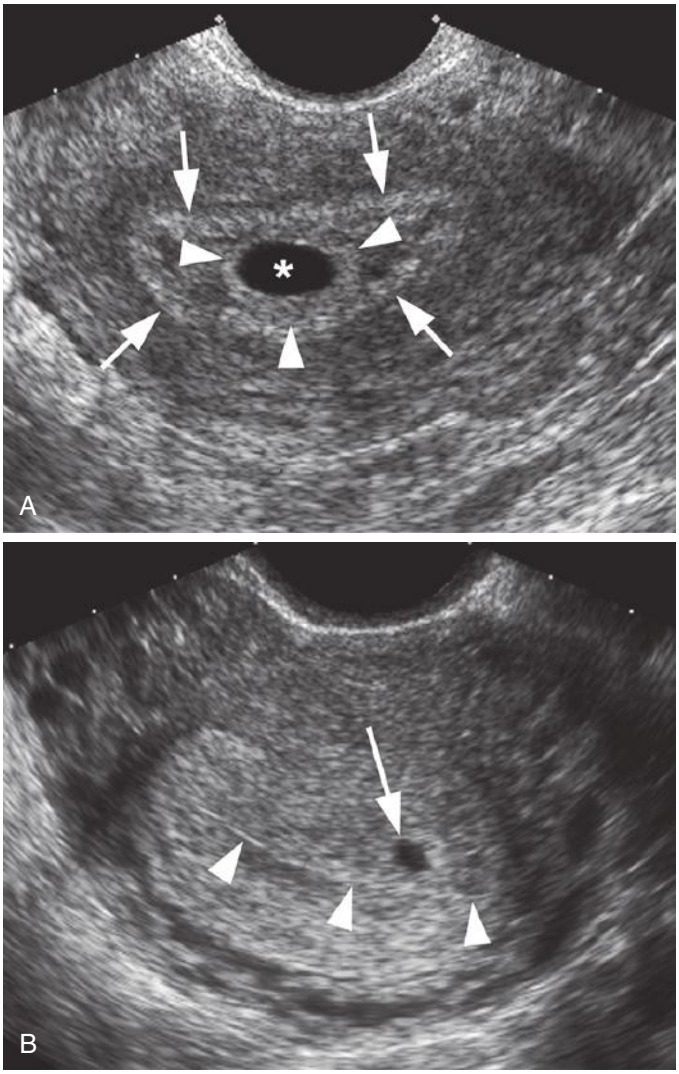

FIG 4-9 Double sac and intradecidual signs. **A,** The gestational sac (*) is surrounded by an inner echogenic ring (*arrowheads*) and an outer echogenic ring (*arrows*). The presence of two surrounding rings constitutes the double sac sign of early intrauterine pregnancy. **B,** The gestational sac (*arrow*) is eccentrically located in the echogenic decidua, anterior to a thin white line (*arrowheads*) representing the collapsed uterine cavity. This appearance constitutes the intradecidual sign of early intrauterine pregnancy.

Because of the importance of diagnosing intrauterine pregnancies and distinguishing them from ectopic pregnancies, early practitioners sought criteria that would permit them to conclude that a fluid collection in the uterus was a gestational sac. Two signs of intrauterine pregnancy were put forth: the *double sac sign*[30] and the *intradecidual sign*[31] (Fig. 4-9). The double sac sign refers to the presence of two concentric echogenic rings surrounding at least part of the fluid collection, hypothesized to represent the decidua capsularis and parietalis. The intradecidual sign refers to an intrauterine fluid collection eccentrically located in the decidua, anterior or posterior to a thin white line representing the collapsed uterine cavity.

The development and wide dissemination of transvaginal ultrasound in the mid- to late 1980s revolutionized early pregnancy sonography. With this technique, gestational sacs can be seen earlier in pregnancy and with different sonographic characteristics than via transabdominal sonography. In particular, normal early gestational sacs frequently display neither the double sac sign nor the intradecidual sign on transvaginal sonography[32] (Fig. 4-3). Furthermore, intrauterine fluid in women with ectopic pregnancy can often be distinguished from gestational sacs when scanning transvaginally, in that the fluid with ectopic pregnancy often conforms to the shape and location of the uterine cavity, has an irregular shape, and is filled with debris[33] (Fig. 4-10).

Despite the far greater resolution of transvaginal sonography, some practitioners continue to rely on the concepts of pseudogestational sac, double sac sign, and intradecidual sign that were defined using transabdominal sonography, even when interpreting transvaginal scans in early pregnancy. Furthermore, a misconception about these signs appears to be fairly common: "the presence of a double sac sign or

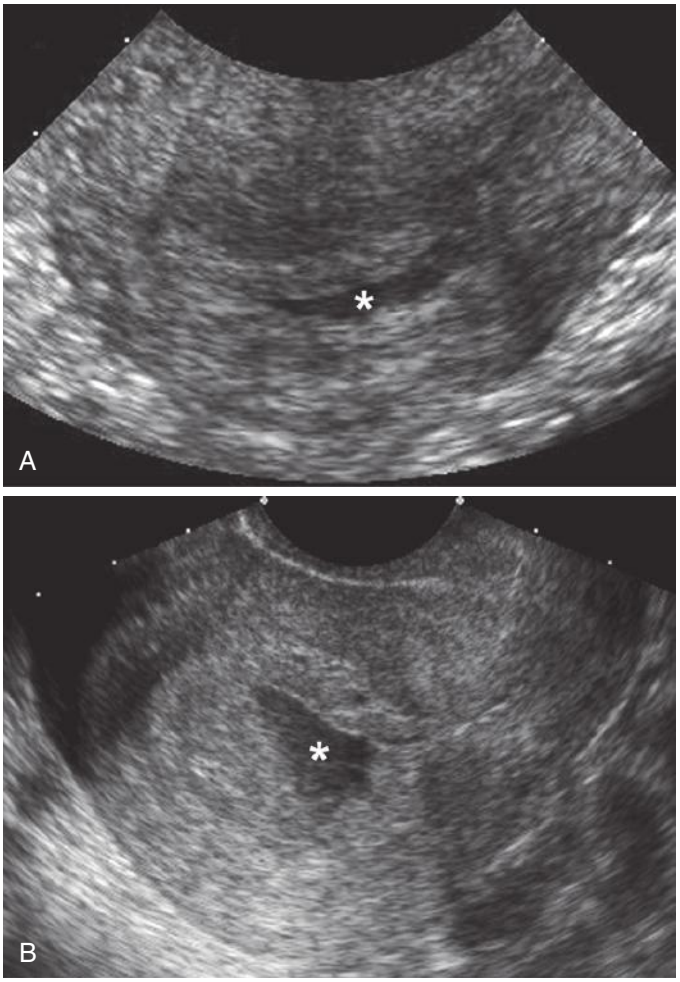

FIG 4-10 Intrauterine fluid in women with ectopic pregnancy. **A,** There is a fluid collection (*), with internal debris, conforming to the shape and location of the uterine cavity. **B,** In another woman with ectopic pregnancy, an irregularly shaped fluid collection (*) with internal debris is seen within the uterine cavity.

intradecidual sign indicates intrauterine pregnancy" (correct interpretation) is sometimes assumed to mean "the absence of a double sac sign or intradecidual sign excludes intrauterine pregnancy" (incorrect interpretation). Such misinterpretation may lead to management errors in early pregnancy: small intrauterine fluid collections in early pregnancy, representing gestational sacs, are incorrectly diagnosed as pseudogestational sacs associated with ectopic pregnancy, leading to treatments (systemic methotrexate or D&C) that damage the intrauterine pregnancy. Reports of malpractice lawsuits for this error[3] and the existence of online support groups for women mismanaged in this way[34] are evidence that this is not a rare occurrence.

A straightforward calculation based on recent data is informative. Approximately half (range: 35-70%) of early intrauterine gestational sacs have a nonspecific saclike appearance: they are oval or round with no double sac sign or intradecidual sign.[32] About 3% of women with ectopic pregnancies have an intrauterine fluid collection with a similar cystic appearance.[33] Two percent of all pregnancies in the United States are ectopic, and 98% are intrauterine.[35] Combining these values, it follows that, when an intrauterine saclike fluid collection without a double sac sign or intradecidual sign is seen on ultrasound in the absence of an adnexal mass or significant free pelvic fluid, the likelihood is at least 99% that it is a gestational sac and at most 1% that the diagnosis is ectopic pregnancy.[32,33]

The takeaway message is that any round or oval intrauterine fluid collection in early pregnancy should be interpreted as highly likely to be a gestational sac and that treatments that would damage a desired intrauterine pregnancy should be avoided unless a potentially normal intrauterine pregnancy is subsequently ruled out.

Ultrasound Demonstrates a Complex or Solid Adnexal Mass

When an adnexal mass is seen in a woman with a positive hCG test, the crucial distinction is whether it is intraovarian or extraovarian. An intraovarian mass is almost certainly a corpus luteum (unless the flicker of a heartbeat is seen within it), whereas an extraovarian mass is highly likely to represent an ectopic pregnancy. An extraovarian mass with a "tubal ring" appearance—anechoic center surrounded by an echogenic ring—has the highest probability of representing an ectopic pregnancy, but even in the absence of such characteristics, a complex or solid adnexal mass outside the ovary in a woman with a positive pregnancy and no intrauterine pregnancy has a high probability of indicating ectopic pregnancy.[36]

In most cases, the sonographic distinction between intraovarian and extraovarian mass is straightforward. In some cases, however, it is uncertain whether a mass is abutting the ovary or is within the ovary. A number of sonographic features of the mass have been suggested for making this important distinction, including its grayscale appearance, its Doppler characteristics, and its movement when pressure is applied by a transvaginal transducer.

One study found that a tubal ring of ectopic pregnancy is usually more echogenic than the ovarian parenchyma, whereas the echogenicity of a corpus luteum is generally less than or equal to that of the ovarian parenchyma.[37] However, the comparison of these echogenicities is not definitive for distinguishing a tubal ring from a corpus luteum: in this series, 6 of 39 (15%) tubal rings were equal or lower in echogenicity than the ovary, whereas 3 of 45 (7%) corpora lutea were more echogenic than the ovary.

When assessed by Doppler, an adnexal mass of ectopic pregnancy typically has prominent flow on color Doppler and a low impedance pattern on spectral Doppler.[38,39] When there is an adnexal mass indeterminate for being within, as opposed to abutting, the ovary, however, the presence of these Doppler characteristics in the mass does not reliably establish the diagnosis of ectopic pregnancy because a corpus luteum can have similar Doppler findings.[38]

The most definite way to demonstrate that a mass abutting the ovary is extraovarian is to observe its motion relative to the ovary when pressure is applied by the transvaginal transducer.[40] If the mass slides along the ovary, then it is extraovarian and the probable diagnosis is ectopic pregnancy (see Fig. 4-11, Video 4-2). If the mass and ovary move together, the mass is likely to be a corpus luteum within the ovary, and the probable diagnosis is intrauterine pregnancy. In an ultrasound facility that has the capability of storing video clips, it is good practice to store a clip of the adnexa while transducer pressure is applied.

ASSIGNMENT OF GESTATIONAL AGE BY EARLY FIRST TRIMESTER ULTRASOUND

Prior to visualization of an embryo, gestational age can be assigned based either on the contents or the size of the gestational sac. The former approach assigns a gestational age of 5.0 weeks if the sonogram demonstrates a gestational sac with no visible internal structures and 5.5 weeks if a yolk sac is seen. Alternatively, the gestational age can be assigned based on the MSD (average of the anteroposterior, transverse,

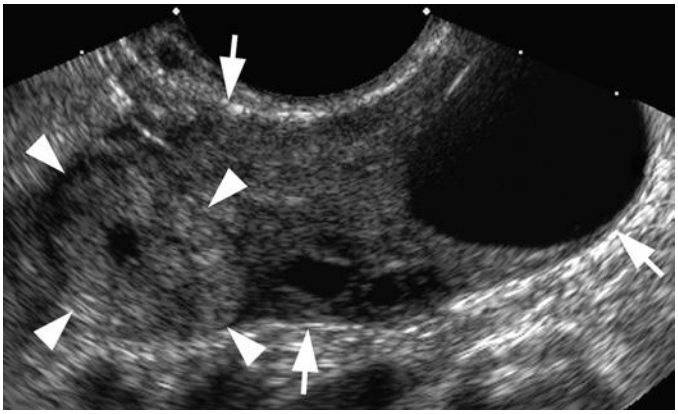

FIG 4-11 Movement with transducer pressure distinguishing ectopic pregnancy from corpus luteum. Note the structure with an echogenic rim and anechoic center (*arrowheads*) lying in or adjacent to the ovary (*arrows*). When pressure was applied with the transvaginal ultrasound transducer, the structure was seen to move separately from the ovary, confirming it as being extraovarian and thus representing an ectopic pregnancy. (Video 4-2 shows the movement when transducer pressure is applied.)

and sagittal measurements of the gestational sac) via a table that correlates MSD and age (see Table 4-1).[8]

Once the embryo is visible, the most accurate way to assign gestational age is via the CRL. A number of formulas and tables have been devised for this purpose.[9,10] Using the gold standard of gestational age in pregnancies achieved via in vitro fertilization, a variety of published CRL formulas and tables have been shown to have minimal bias in estimating gestational age.[11,41]

All of these approaches, whether based on sac contents, MSD, or CRL, provide a highly accurate age estimate in normal early pregnancies. Each has a 95% confidence range of approximately ±0.5 week.[41]

DIAGNOSIS OF FAILED INTRAUTERINE PREGNANCY (MISCARRIAGE)

A previous section presented the normal progression of sonographic findings in early pregnancy. Failure to meet one or more of the expected early milestones raises concern for pregnancy failure, but it is important to distinguish between those that are definitive for pregnancy failure and those that are merely suspicious for that diagnosis. A suspicious finding should prompt a follow-up sonogram, generally 7 to 10 days later. If, on the other hand, there is a finding that is definitive for pregnancy failure, there is no need for a follow-up scan and it would be safe to undertake an intervention such as uterine evacuation.

Because erroneous diagnosis of early pregnancy failure can have serious consequences, such as uterine evacuation in a woman with a normal, desired pregnancy, criteria for definite pregnancy failure should be strict. That is, these criteria should virtually eliminate false positive diagnoses, which means that they should have specificities of very close to 100%. Furthermore, they should apply to a broad range of ultrasound facilities that meet at least minimum quality criteria, not solely to experts in early obstetric ultrasound.

Criteria for definite pregnancy failure fall into three categories[13]: (1) embryo above a certain size (measured by the CRL) with no visible heartbeat, (2) gestational sac above a certain size (measured by the MSD) with no visible embryo, and (3) no embryo with heartbeat visible after a certain time interval since an initial scan. Less stringent variants of these criteria, as well as a number of other sonographic findings, are suspicious for pregnancy failure.

TABLE 4-2 Sonographic Findings Definitive for Failed Intrauterine Pregnancy

Category	Criterion for Definite Pregnancy Failure
Embryo with no cardiac activity	CRL ≥ 7 mm
Gestational sac containing no embryo with heartbeat	MSD ≥ 25 mm
Time-based findings	No embryo with heartbeat on a follow-up scan at least 2 weeks after an initial scan that showed a gestational sac without a yolk sac No embryo with heartbeat on a follow-up scan at least 11 days after an initial scan that showed a gestational sac with a yolk sac

CRL, crown-rump length; MSD, mean sac diameter.

Sonographic Findings Definitive for Failed Intrauterine Pregnancy

Crown-Rump Length With No Embryonic Heartbeat

In a normal intrauterine pregnancy, the flickering motion of cardiac activity is generally seen once the embryo is identifiable, regardless of embryonic size. A number of researchers over the past 3 decades have sought to answer the following question: at what CRL is cardiac activity always (not merely generally) seen in a normal intrauterine pregnancy? Studies reported in the 1990s concluded that cardiac activity is consistently visible by a CRL of 4 mm[42,43] or 5 mm.[44,45] Based on that research, the transvaginal sonographic finding of an embryo with CRL of at least 5 mm and no cardiac activity became widely accepted as a criterion for definite pregnancy failure (Table 4-2).[46-50]

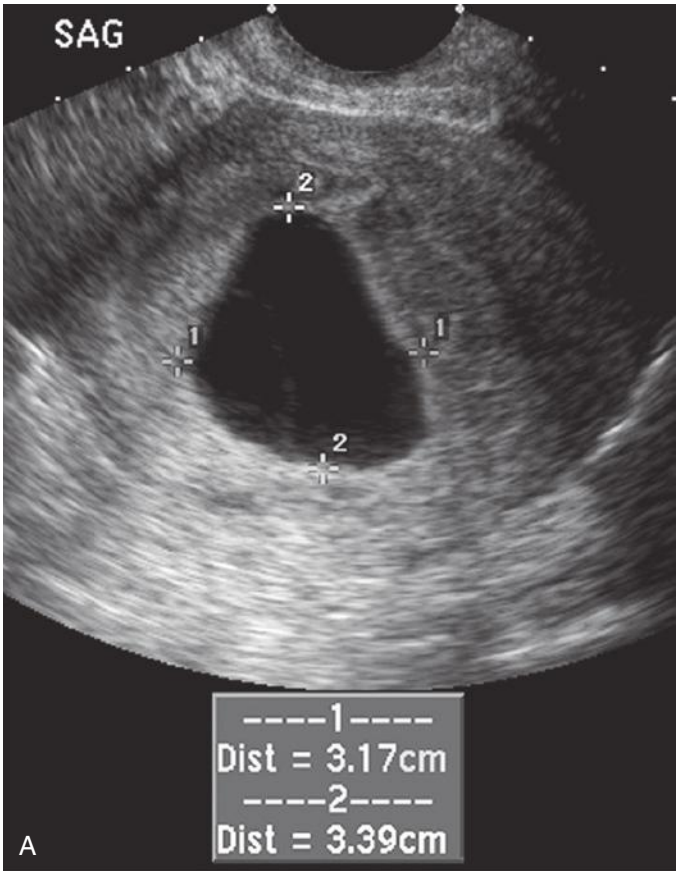
In recent years, serious doubts have arisen regarding the 5-mm CRL cutoff, for a number of reasons. First, despite the importance of avoiding false positive diagnoses of pregnancy failure, the studies on which the 5-mm CRL had been based had small study populations. A meta-analysis concluded that, because of the small study sizes, the 5-mm criterion may have a specificity as low as 90%,[51] undercutting its value for definitively diagnosing pregnancy failure. Second, there were reported cases of embryos measuring 5 to 6 mm without cardiac activity on an initial scan, in which a heartbeat was apparent on a follow-up scan.[52,53] Third, a study found an interobserver variability of ±15% (95% confidence range) in CRL measurements at 6 to 9 weeks of gestation,[54] so that an embryo measuring 6 mm by one observer may be measured as high as 6.9 mm by a second observer. On the basis of these factors, 7 mm has become the generally accepted CRL cutoff for diagnosing pregnancy failure in the absence of cardiac activity[13,55] (Fig. 4-12, Video 4-3).

Mean Sac Diameter With No Embryo

The criterion for diagnosing pregnancy failure based on nonvisualization of an embryo by a certain gestational sac size has followed a progression of events similar to that described previously for CRL with no heartbeat. Around 1990, a number of studies found that an embryo with a heartbeat is consistently visible on ultrasound when the MSD is 16 mm[56] or 17 mm.[57] Based on these studies, nonvisualization of an embryo with a heartbeat with an MSD of at least 16 mm became a generally accepted criterion as definitive for pregnancy failure.[48,49]

In more recent years, a number of doubts about the reliability of this criterion arose, similar to those discussed earlier for the CRL with

FIG 4-12 Failed intrauterine pregnancy. An embryo (*calipers*) 9 mm in length is seen within the uterus. No heartbeat was detected within it. (Video 4-3 shows the absence of cardiac activity.)



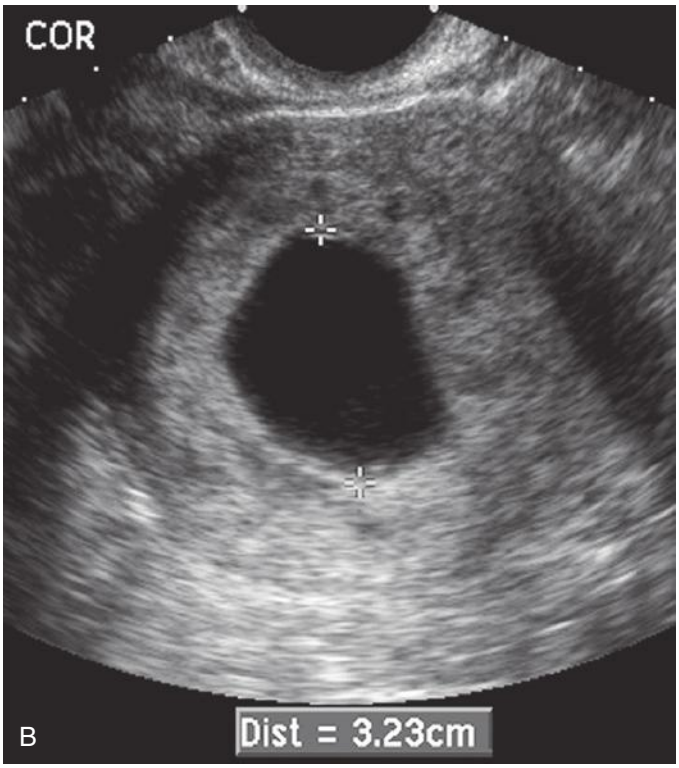


FIG 4-13 Failed intrauterine pregnancy. **A** and **B,** The mean sac diameter is 32.6 mm, the average of the anteroposterior, transverse, and sagittal measurements of the gestational sac on sagittal (SAG) and coronal (COR) images of the gestational sac. No embryo is seen.

no visible heartbeat. First, the initial studies that led to the MSD criterion of 16 mm with no embryo involved small patient populations, so that subsequent reanalysis demonstrated that the specificity had a wide 95% confidence range of 0.88 to 1.00.[51] Second, there were a number of reported cases in which the MSD was 17 to 20 mm and no embryo was seen, and then a subsequent scan demonstrated an embryo with cardiac activity.[52,58] Third, the measurement of the MSD has an interobserver confidence range of ±19% (95% confidence interval),[54] so that a measurement of 20 mm may be 19% higher, or 24 mm, when measured by another examiner.

Thus, the generally accepted criterion for early pregnancy failure based on an MSD with no visible embryo has become more stringent: one should diagnose failed pregnancy only if the MSD is at least 25 mm and no embryo is seen on transvaginal sonography[13,55] (Fig. 4-13).

Time-Based Criteria for Pregnancy Failure

The CRL and MSD criteria described earlier permit pregnancy failure to be diagnosed on a single scan in early pregnancy. The diagnosis can also be established when there is abnormal progression of findings on sequential scans. These time-based criteria for pregnancy failure are needed because, in many cases of early pregnancy failure, the CRL and MSD never reach a size of 7 mm and 25 mm, respectively.

As noted previously, the gestational sac, yolk sac, and embryo are first visible at 5, 5.5, and 6 weeks, respectively, with a variability of ±0.5 week. Based on these values, pregnancy failure can be diagnosed with certainty in either of the following situations: (1) an initial scan shows a gestational sac without yolk sac or embryo, followed by a scan at least 2 weeks later in which no embryo with a heartbeat is seen, or (2) an initial scan demonstrates a gestational sac with a yolk sac but no embryo, followed by a scan at least 11 days later in which no embryo with a heartbeat is seen.[13]

Sonographic Findings Suspicious (but Not Definitive) for Failed Intrauterine Pregnancy

Crown-Rump Length With No Embryonic Heartbeat

Because cardiac activity is usually identifiable in any embryo seen on transvaginal ultrasound, the presence of an embryo without a heartbeat is always a worrisome (if not definitively abnormal) finding. Although not definitive, absence of cardiac activity when the CRL is below the cutoff of 7 mm is suspicious for pregnancy failure (Fig. 4-14, Video 4-4, Table 4-3).

Mean Sac Diameter With No Embryo

Pregnancy outcome may, in rare cases, be normal when no embryo is seen in a gestational sac whose MSD is at least 16 mm (the previously accepted cutoff for definite pregnancy failure) but less than 24 mm (the currently accepted cutoff). The fact that this happens infrequently means that the finding of an MSD of 16 to 24 mm without identifiable embryo is suspicious for pregnancy failure (Fig. 4-15).

Time-Based Criteria Suspicious for Pregnancy Failure

When an initial scan shows a gestational sac and a follow-up scan shows no embryo with a heartbeat, this is worrisome if the time interval between scans is only slightly less than that required for diagnosis of definite pregnancy failure. In particular, the following sequences are suspicious for pregnancy failure: (1) an initial scan shows a gestational sac without yolk sac or embryo, and there is no visible embryo with a heartbeat on a subsequent scan 7 to 13 days later, and (2) an initial scan shows a gestational sac with yolk sac but no embryo, and there is still no visible embryo with a heartbeat on a subsequent scan 7 to 10 days later.[13]

Another time-based finding that is suspicious for pregnancy failure is nonvisualization of an embryo with a heartbeat 6 weeks or more after the first day of the LMP. In view of variable cycle lengths[59] and often unreliable recollection of LMP,[60,61] failure to identify an embryo with a heartbeat at any point after the LMP reported by the mother should not be taken as definitive proof of pregnancy failure.

Empty Amnion Sign

The normal order of visibility of structures within the early gestational sac is yolk sac, then embryo, then amnion. Thus, it can be normal to see an embryo and no amnion[62] but not to see an amnion and no embryo. The latter combination has been termed the *empty amnion sign*.[62,63] This sign is present when the gestational sac contains two adjacent circular structures, representing the yolk sac and amnion, but no embryo (Fig. 4-16).

The empty amnion sign carries a poor prognosis. In two studies that included 15 patients[62] and 68 patients[63] with this sign, pregnancy failure was confirmed in all 83 cases. Because both of these studies were done at the same institution, and because two yolk sacs in a case of early monochorionic diamniotic twins could potentially be mistaken for the empty amnion sign, this sign should be considered a suspicious, but not definitive, indicator of pregnancy failure.

Expanded Amnion Sign

Embryonic cardiac activity is normally seen before the amnion is first identifiable around the embryo.[64,65] The term *expanded amnion sign* has been coined to describe the following combination of findings on an early pregnancy sonogram: visualization of an embryo that is surrounded by an amnion and has no cardiac activity (Fig. 4-17, Video 4-5). Among 108 patients with this finding who had a CRL at or below

FIG 4-14 Suspected pregnancy failure. An embryo (*calipers*) 3.09 mm in length is seen within the uterus. No heartbeat was seen within it. (Video 4-4 shows the absence of cardiac activity.)

TABLE 4-3 Sonographic Findings Suspicious (but Not Definitive) for Failed Intrauterine Pregnancy

Category	Finding Suspicious for Pregnancy Failure*
Embryo with no cardiac activity	CRL < 7 mm
Gestational sac containing no embryo with heartbeat	MSD 16-24 mm
Time-based findings	No embryo with heartbeat on a follow-up scan 7-13 days after an initial scan that showed a gestational sac without a yolk sac No embryo with heartbeat on a follow-up scan 7-10 days after an initial scan that showed a gestational sac with a yolk sac No embryo with heartbeat at least 6 weeks after LMP
Empty amnion	Amnion seen adjacent to yolk sac, with no visible embryo
Expanded amnion	Embryo with no cardiac activity, with amnion visible around it
Enlarged yolk sac	>7 mm

*When findings are suspicious for pregnancy failure, follow-up ultrasound in 7 to 10 days is generally appropriate.
CRL, crown-rump length; LMP, last menstrual period; MSD, mean sac diameter.

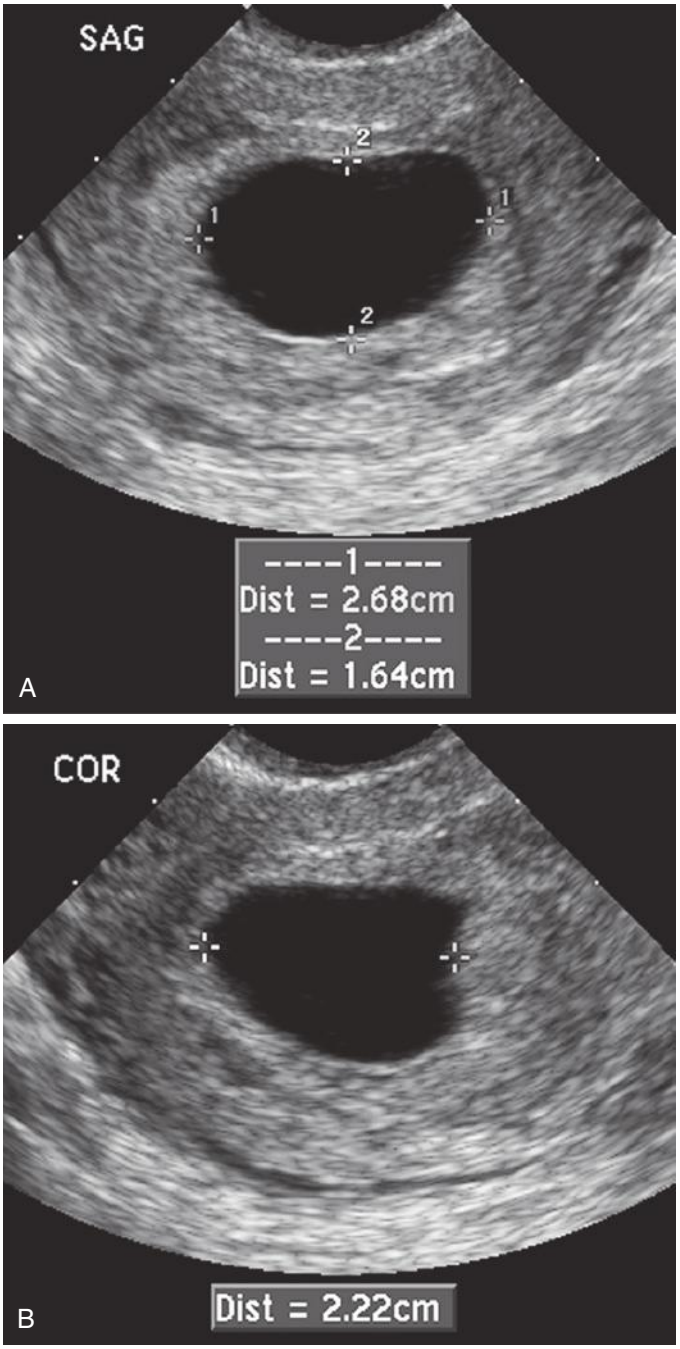

FIG 4-15 Suspected pregnancy failure. **A** and **B,** The mean sac diameter is 21.8 mm, the average of the anteroposterior, transverse, and sagittal measurements of the gestational sac on sagittal (SAG) and coronal (COR) images of the gestational sac. No embryo is seen.

5.4 mm and known outcome, pregnancy failure was confirmed in all 108.[65]

Large Yolk Sac

The upper limit of normal yolk sac diameter in the early first trimester is approximately 4.5 mm when measured inner-to-inner[66] and 6 mm when measured outer-to-outer.[67] A large yolk sac is an indicator of poor prognosis. Although the causal relationship between a large yolk sac and pregnancy prognosis is unclear, a number of studies have documented a high rate of pregnancy failure when the diameter of the yolk sac is more than 7 mm[66,68] (Fig. 4-18).

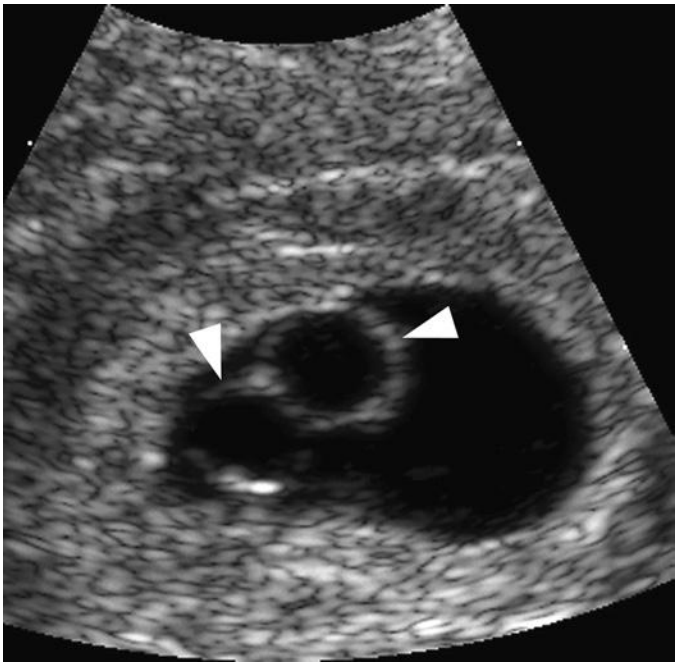

FIG 4-16 Suspected pregnancy failure based on empty amnion sign. Two circular structures (*arrowheads*) are within the gestational sac, representing the yolk sac and amnion. No embryo is visible.

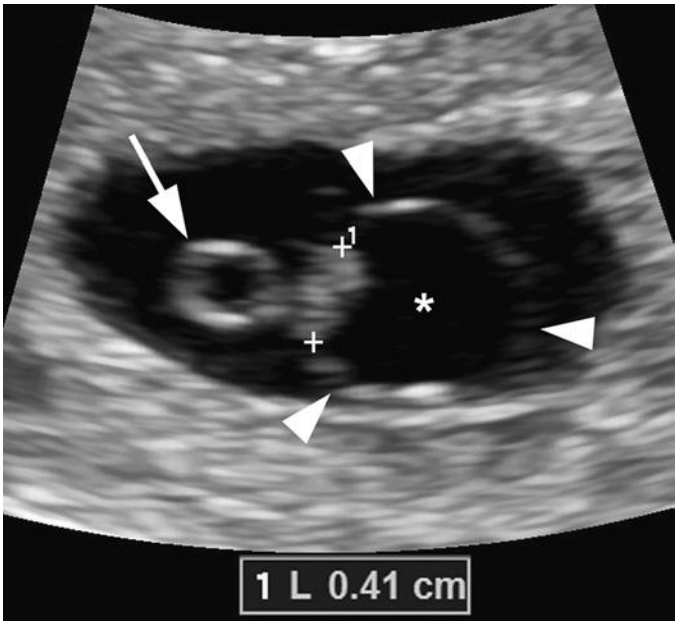

FIG 4-17 Suspected pregnancy failure based on expanded amnion sign. There is an embryo (*calipers*), 4.1 mm in length, surround by the amnion (*arrowheads*), lying adjacent to the yolk sac (*arrow*). No heartbeat was detected within the embryo. (Video 4-5 shows the absence of cardiac activity.)

RISK FACTORS FOR IMPENDING PREGNANCY FAILURE WHEN EMBRYONIC HEARTBEAT IS SEEN

Visualization of an embryonic heartbeat is a reassuring finding on an early first trimester sonogram, but it does not guarantee a good pregnancy outcome. Subsequent pregnancy failure is always a potential occurrence, but the chance of this untoward event is higher if the heart

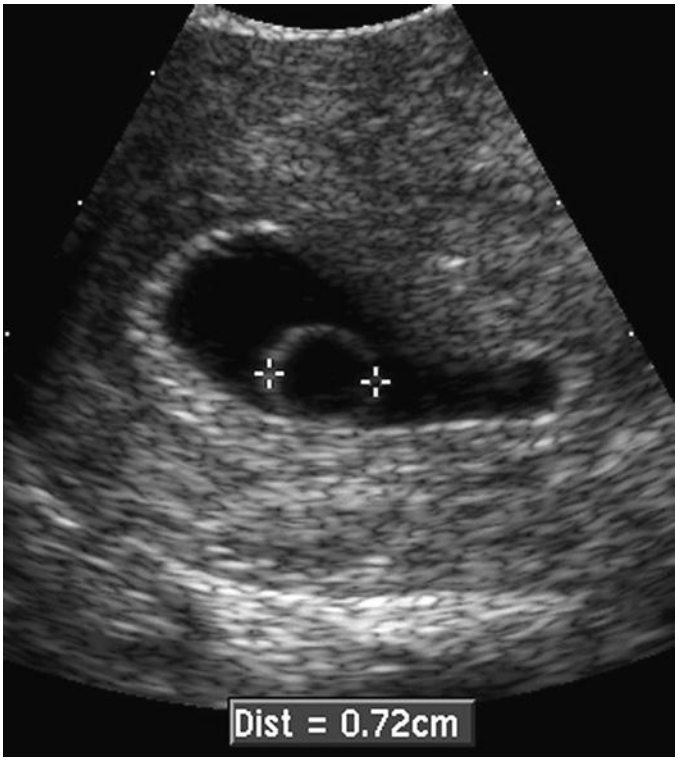

FIG 4-18 Suspected pregnancy failure based on enlarged yolk sac. The yolk sac (*calipers*) measures 7.2 mm in diameter.

TABLE 4-4 Risk Factors for Impending Pregnancy Failure When Embryonic Heartbeat Is Seen

Category	Finding Suspicious for Impending Pregnancy Failure
Slow embryonic heart rate	GA 6.0-6.2 weeks or CRL 1-4 mm: • Slow: <90 bpm • Borderline: 90-99 bpm GA 6.3-7 weeks or CRL 5-9 mm: • Slow: <110 bpm • Borderline: 110-119 bpm
Large subchorionic hematoma	Variously diagnosed as large by the following: • Subjective assessment • Hematoma surrounds at least two thirds of the gestational sac • Volume of hematoma ≥ 60 mL
Small gestational sac size in relation to the embryo	MSD − CRL < 5 mm (or subjective assessment)

bpm, beats per minute; CRL, crown-rump length; GA, gestational age; LMP, last menstrual period; MSD, mean sac diameter.

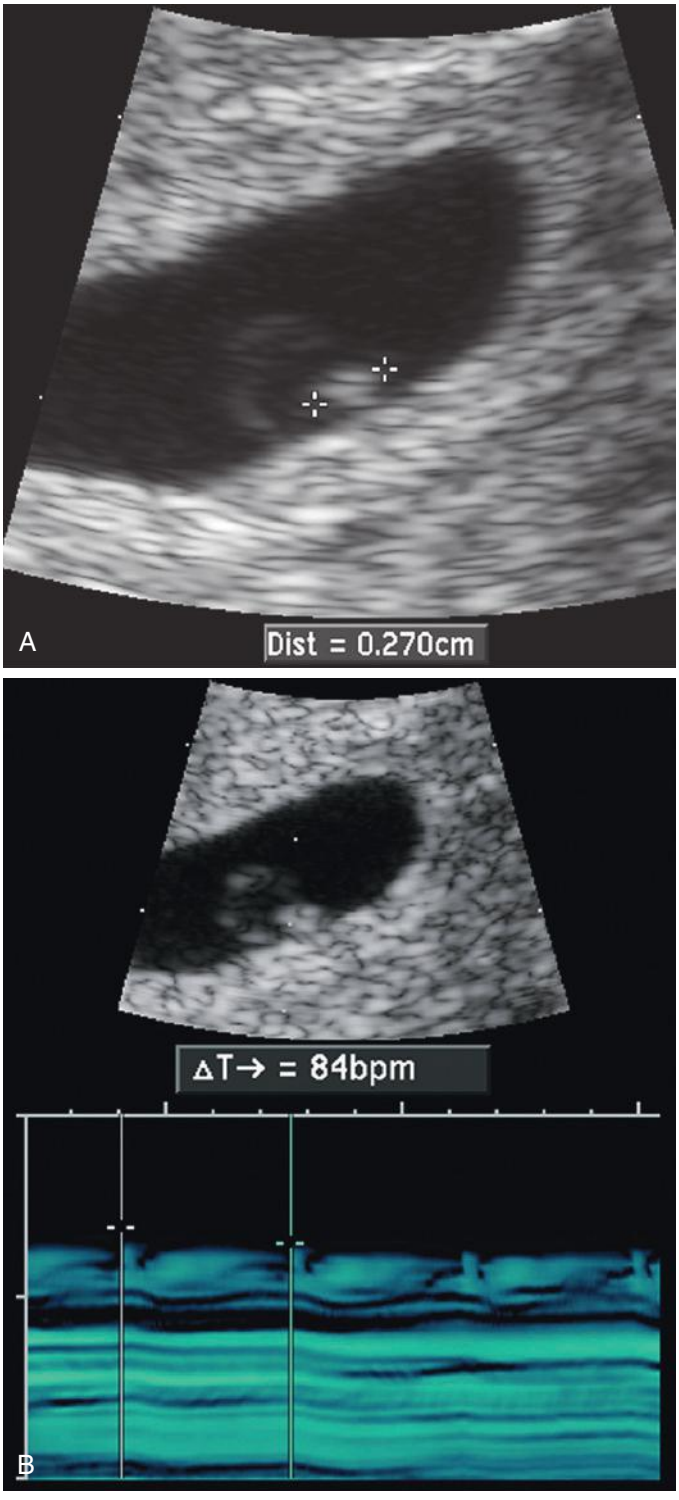

FIG 4-19 Slow embryonic heartbeat. **A,** There is a 2.7-mm embryo in the uterus. **B,** The heart rate, measured via M-mode, is 84 beats per minute. There was no cardiac activity on a follow-up scan 2 weeks later.

rate is slow, a large subchorionic hematoma is present, or the gestational sac is abnormally small (Table 4-4).

Slow Embryonic Heart Rate

The mean embryonic heart rate increases from 100 to 110 beats per minute (bpm) at 6 weeks to approximately 150 bpm at 8 to 9 weeks, and then plateaus for the rest of pregnancy.[69-71] A slow heart rate in the early first trimester carries a high risk that the pregnancy will fail by the end of the first trimester.[69-73] The slower the rate, the worse the prognosis. At 6.0 to 6.2 weeks, when the CRL is up to 4 mm, almost all pregnancies will subsequently miscarry if the heart rate is less than 80 bpm and a majority will fail if the rate is 80 to 89 bpm, so any rate below 90 bpm should be considered abnormal (Fig. 4-19). The prognosis is better for heart rates of 90 to 99 bpm and plateaus for heart

rates of 100 bpm or above, so a rate of 90 to 99 bpm should be considered borderline and one of 100 bpm or above is normal. At 6.3 to 7.0 weeks, corresponding to a CRL of 5 to 9 mm, the corresponding heart rates are 20 bpm higher: a heart rate of less than 110 bpm is abnormal, a rate of 110 to 119 bpm is borderline, and one of 120 bpm and above is normal.[73]

It is appropriate to perform a follow-up sonogram in 1 to 2 weeks when a scan at 6.0 to 6.2 weeks reveals a heart rate less than 90 bpm or a 6.3- to 7.0-week scan demonstrates a heart rate less than 110 bpm. In most cases, the cardiac activity will have ceased by the time of the follow-up scan. In a minority of cases, cardiac activity will still be present, occasionally with a normal heart rate. When this occurs, the prognosis is better but still not normal, as 25% will go on to miscarry by the end of the first trimester.[74] If the fetus is still alive at the end of the first trimester, the likelihood of pregnancy loss then reverts to normal, but the risk of fetal anomalies may be somewhat elevated.[73]

Subchorionic Hematoma

A subchorionic hematoma appears on ultrasound as an irregular hypoechoic space, sometimes crescent-shaped, around part of the gestational sac. The hematoma usually has internal echoes and is separated from the fluid inside the gestational sac by a thick band of tissue (Fig. 4-20). It must be differentiated from separation of the amnion from the chorion, a normal finding in the first trimester, in which the very thin, smooth amnion lies between the inner amniotic fluid and the outer chorionic fluid.

Several studies have assessed the prognostic significance of subchorionic hematomas in pregnancies with a live embryo. These studies have differed considerably in design, both with respect to the gestational age range of the study population and the way that the size of the hematoma is determined. Studies variously classify the hematoma as small, moderate, or large based on subjective assessment[75] or on the fraction of the gestational sac surrounded by the hematoma.[76] Still others use a quantitative estimate of the hematoma's volume, despite the fact that determining the volume of an irregular space is prone to error. Even among these latter studies there is considerable variability, with one study comparing outcomes with hematoma volume greater versus less than 60 mL[77] and another comparing those greater or less than 15 mL.[78]

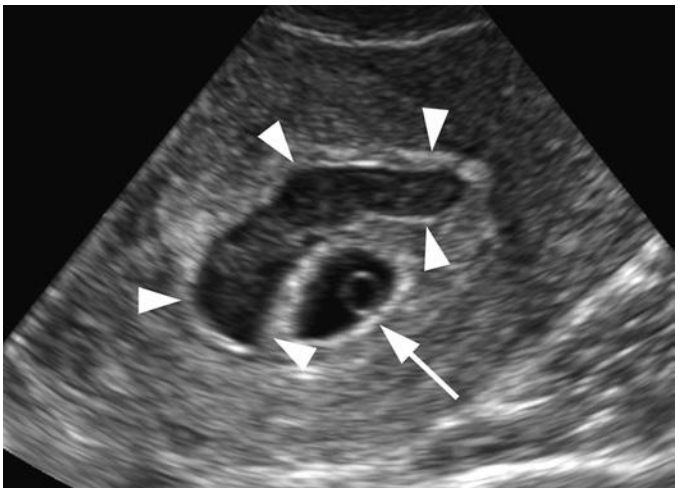

FIG 4-20 Subchorionic hematoma. An irregular, somewhat crescent-shaped, fluid collection with internal debris (*arrowheads*) lies adjacent to the gestational sac (*arrow*). A thick band of tissue separates the hematoma from the fluid in the gestational sac.

Despite these differences, there is general consensus that a small subchorionic hematoma carries little or no risk.[75-79] Most studies,[75-78] though not all,[80] have found that a large subchorionic hematoma carries an elevated risk of subsequent pregnancy loss. In one study that provides separate data for early first trimester cases up to 8 weeks of gestation, 5 of 22 cases (22.7%) with a large hematoma went on to pregnancy loss, compared to 12 of 88 (13.6%) with a moderate and 14 of 116 (12.1%) with a small hematoma.[76]

Small Gestational Sac Size in Relation to the Embryo

The gestational sac is normally considerably larger than the embryo. One group of authors has proposed using the metric of MSD minus CRL to distinguish gestational sacs that are abnormally small in relation to the embryo from those that are normal. In particular, they diagnose the sac as being abnormally small if MSD – CRL is less than 5 mm and normal if 5 mm or greater.[81] In their case series of 16 early first trimester pregnancies with normal embryonic heart rates and small sac size, 15 (94%) ended in pregnancy loss. Although most practitioners do not use objective criteria to assess the size of the gestational sac in relation to the embryo, relying instead on subjective assessment, the results of this study confirm that small size of the gestational sac in relation to the embryo is an indicator of poor prognosis (Fig. 4-21).

ASSESSMENT OF PREGNANCY NUMBER

One of the basic elements of obstetric ultrasound is to assess pregnancy number: singleton, twin, triplet, or higher order multiples. It is important to recognize that the number determined on an early first trimester scan may subsequently increase or decrease, owing to the "vanishing" and "appearing" twin phenomena.

FIG 4-21 Small gestational sac size in relation to the embryo. Very little fluid is seen around the embryo (*calipers*).

Vanishing Twin

It was reported as early as the 1970s that a woman diagnosed as having twins on a first trimester scan may go on to have a singleton on subsequent scans or at delivery.[82-84] Because the ultrasound scanners in use at that time had low resolution and did not display images in real time, their cases likely fell into two categories: (1) pregnancies that began as twins, with one of the gestations failing to progress beyond an early stage, or (2) singleton pregnancies with a second fluid collection (e.g., subchorionic hematoma) misinterpreted as a second gestational sac.

After real-time sonography was introduced, a published report documented a series of twin pregnancies with two heartbeats on an initial scan followed by a single live fetus on subsequent scans.[85] In this series, the incidence of first trimester twinning was 3.3%, and 21% of early twins had loss of one. When there is loss of one twin in the early first trimester, the remaining singleton has a good prognosis, and in most cases, the second sac is no longer seen later in pregnancy or at birth, leading to the term *vanishing twin* (Fig. 4-22).

Loss of one twin can occur at any time during pregnancy but is most common during the early first trimester. Among early first trimester twins with two heartbeats, 70% to 80% result in live twins, and most of the remaining 20% to 30% deliver a live singleton.[86-88] The likelihood of loss of one twin is greatest if the twins are monochorionic[86,87] or the woman has symptoms of vaginal bleeding at the time of the initial scan.[88]

Appearing Twin

From 6 weeks onward, pregnancy number is determined by counting embryos or fetuses with heartbeats. Prior to 6 weeks, when the embryo may not be visible, the assessment of number is less straightforward and more prone to error. At that stage, it is done by counting gestational sacs and yolk sacs. Undercounting of twins or higher order multiples can occur in a number of ways. When more than one gestation implants in the uterus, one or more of them might not be visible at the time of the initial scan because of its small size or location. This is especially true when image quality is suboptimal due to patient body habitus, uterine myomas, or uterine orientation. Monochorionic twins scanned prior to visualization of yolk sacs (i.e., before about 5.5 weeks) will always be mistaken for a singleton gestation, as will monochorionic monoamniotic twins scanned prior to visualization of embryos (i.e., before about 6.0 weeks), because monoamniotic twin gestations typically have only a single yolk sac.

One case series assessed the frequency of undercounting. Using a database of ultrasound reports, all reports with findings of at least two heartbeats were retrieved, and then the subset of these cases that had been scanned prior to 6 weeks' gestation was identified. Of the 325 cases in this subset, 47 cases (14%) had undercounted pregnancy number on the ultrasound performed before 6 weeks' gestation (Figs. 4-23 and 4-24). Undercounting occurred more frequently at 5 to 5.4 weeks than at 5.5 to 5.9 weeks (19% vs. 9%), in higher order multiples than in twin gestations (16% vs. 14%), and in monochorionic twin gestations than in dichorionic twins (86% vs. 11%). There was no difference in pregnancy outcome in undercounted cases as compared to correctly counted cases.[89]

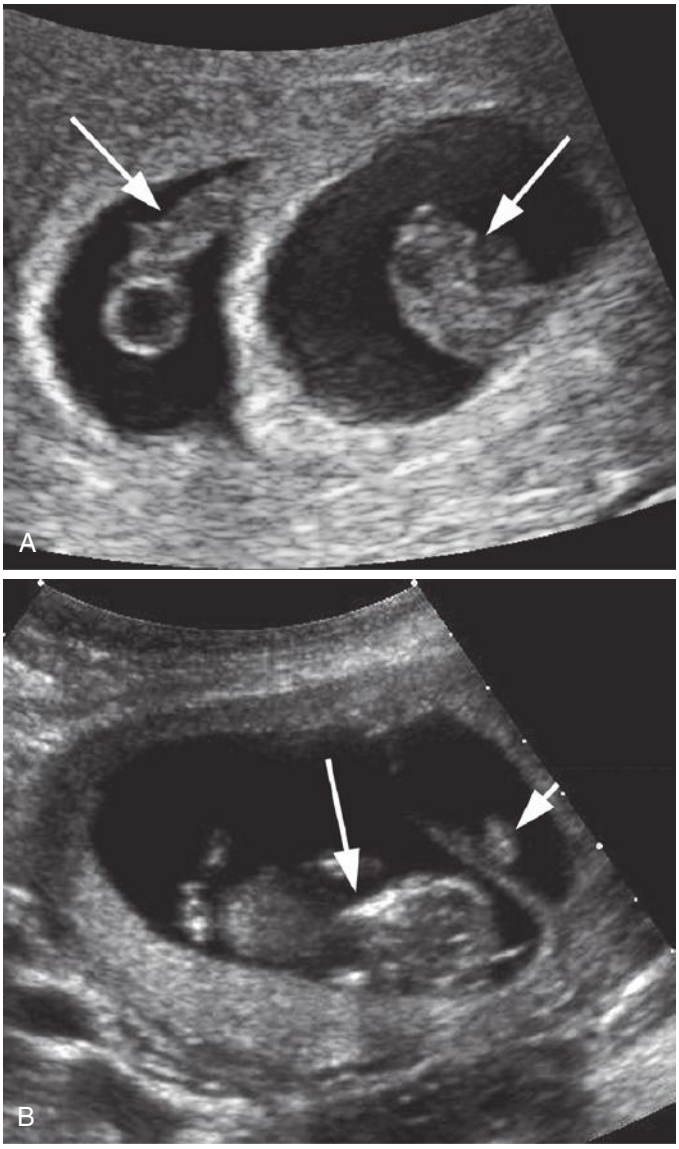

FIG 4-22 "Vanishing" twin. **A,** Sonogram at 7.9 weeks' gestation demonstrates two gestational sacs, each containing an embryo with heartbeat (*arrows*). **B,** Follow-up scan 4 weeks later demonstrates a normal fetus that had cardiac activity (*long arrow*) and a second, much smaller, fetus (*short arrow*) that had no cardiac activity. Subsequent second and third trimester scans showed no evidence of the demised twin or its gestational sac.

Thus, although pregnancy number should be assessed on any obstetric ultrasound, it should be understood that, for ultrasound scans performed in early pregnancy, the count is preliminary. The number may subsequently decrease because of the vanishing twin phenomenon, and the number may increase by one or more embryos that appear on a follow-up scan.

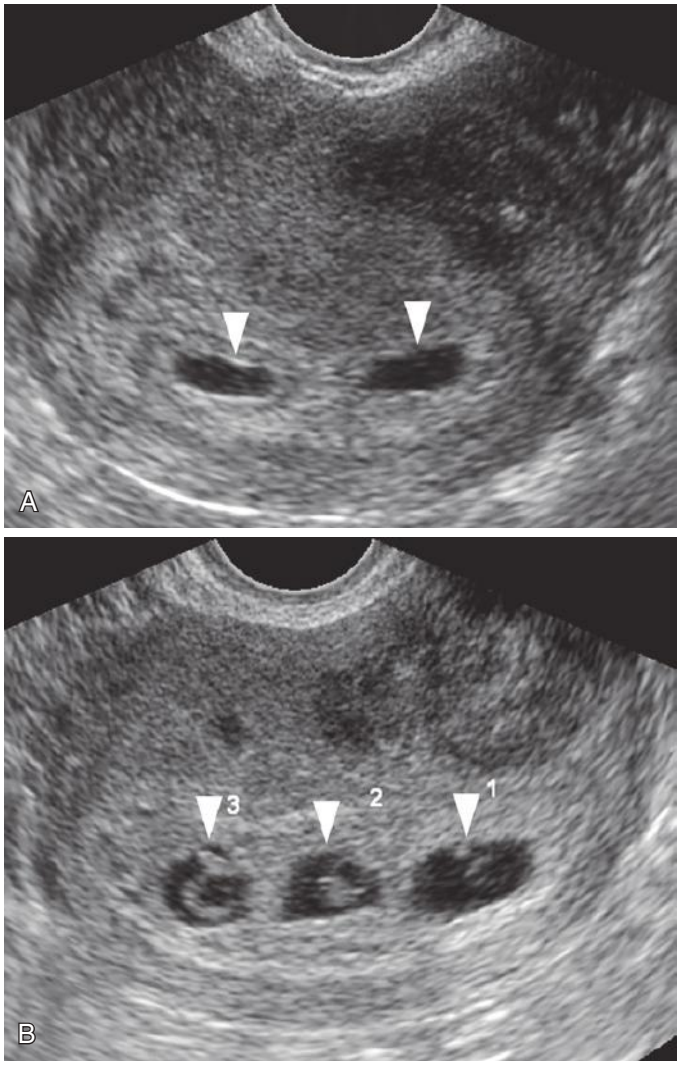

FIG 4-23 "Appearing" triplet. **A,** Sonogram at 5.3 weeks' gestation demonstrates two gestational sacs (*arrowheads*). **B,** Follow-up scan 1 week later demonstrates three gestational sacs (*arrowheads*), each of which contains an embryo with cardiac activity.

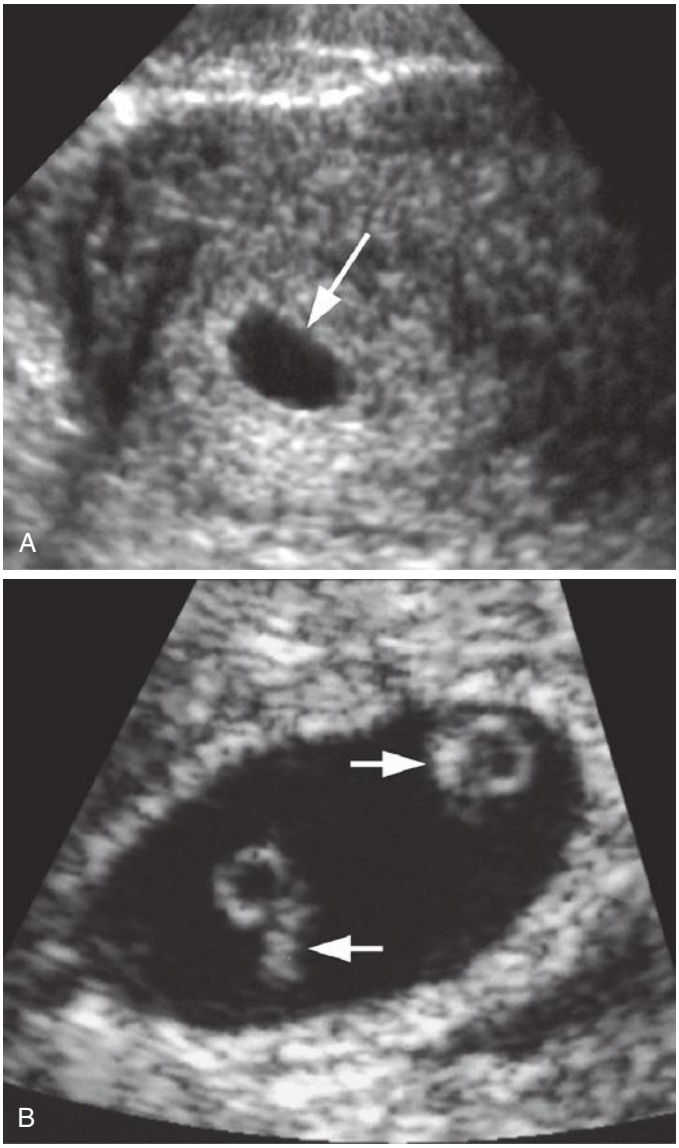

FIG 4-24 "Appearing" twin. **A,** Sonogram at 5.0 weeks' gestation demonstrates a gestational sac (*arrow*). **B,** Follow-up scan 1 week later demonstrates two embryos (*arrows*) with heartbeats. They are located within a single gestational sac, indicating that they are monochorionic twins.

Evaluation of Fetal Anatomy in the First Trimester

Amanda S. Trudell, Anthony O. Odibo

SUMMARY OF KEY POINTS

- Evaluation of fetal anatomy, including a detailed fetal cardiac examination, is possible in the late first trimester.
- Many anatomic abnormalities can be detected in the first trimester, giving families time to make important decisions regarding pregnancy management and the opportunity for early termination of pregnancy to reduce maternal morbidity risks.
- Doppler techniques and four-dimensional spatiotemporal image correlation (4D STIC) are modalities used to help examine the fetal heart in detail during the first trimester, although detection rates using STIC technology are reported to be slightly lower than with two-dimensional (2D) sonography.
- In experienced centers, or when educational programs are instituted, the reliability and detection rates of first trimester anatomic evaluation have been demonstrated to parallel those of second trimester anatomic evaluation.
- The cost effectiveness of first trimester anatomic screening in the general population remains unknown at this time.
- It is important to keep the ALARA (as low as reasonably achievable) principle in mind when performing detailed anatomic evaluation in the first trimester. This point becomes particularly important when using modalities that employ higher frequencies, such as power Doppler sonography.
- The thermal index for soft tissue (TIS) and thermal index for bone (TIB) should be kept below 1.0.

OUTLINE

First trimester fetal anatomy evaluation has developed over the past several decades. As a result of advances in technology, the resolution of sonography has improved, and subsequently, our ability to image the fetus with increasing detail. Initially, first trimester sonography was limited to use as a means of measuring crown-rump length for pregnancy dating. As the utilization of high-frequency transvaginal sonography evolved through the 1980s, sonographic investigation of the anatomic development of the embryo and early fetus became possible.[1] With the boom in first trimester aneuploidy screening in the 1990s came the discovery of increased nuchal translucency as a marker of aneuploidy, propelling further investigation into the potential for first trimester anatomy evaluation.[2] As reports of normal and abnormal first trimester fetal anatomy continued to surface in the literature and detection rates and technical aspects began to be published, our ability to image the fetus in the first trimester became more refined. Today, the possibility of performing a detailed anatomic assessment, including fetal echocardiography, between 12 and 14 weeks is a reality.

FETAL DEVELOPMENT IN THE FIRST TRIMESTER

The first trimester marks a period of rapid fetal growth and development (Fig. 5-1, Table 5-1). Prior to embarking on a detailed description of the use of sonography to assess fetal anatomy in the first trimester, it is important to understand the structure and development of the embryo and fetus, as this directly impacts the potential of ultrasound to detect abnormal structures. Note that embryonic development is typically described by weeks post conception, whereas sonographic findings are described using clinical menstrual age dating. Menstrual age dating is typically 2 weeks greater than conceptional age (see Chapter 6).

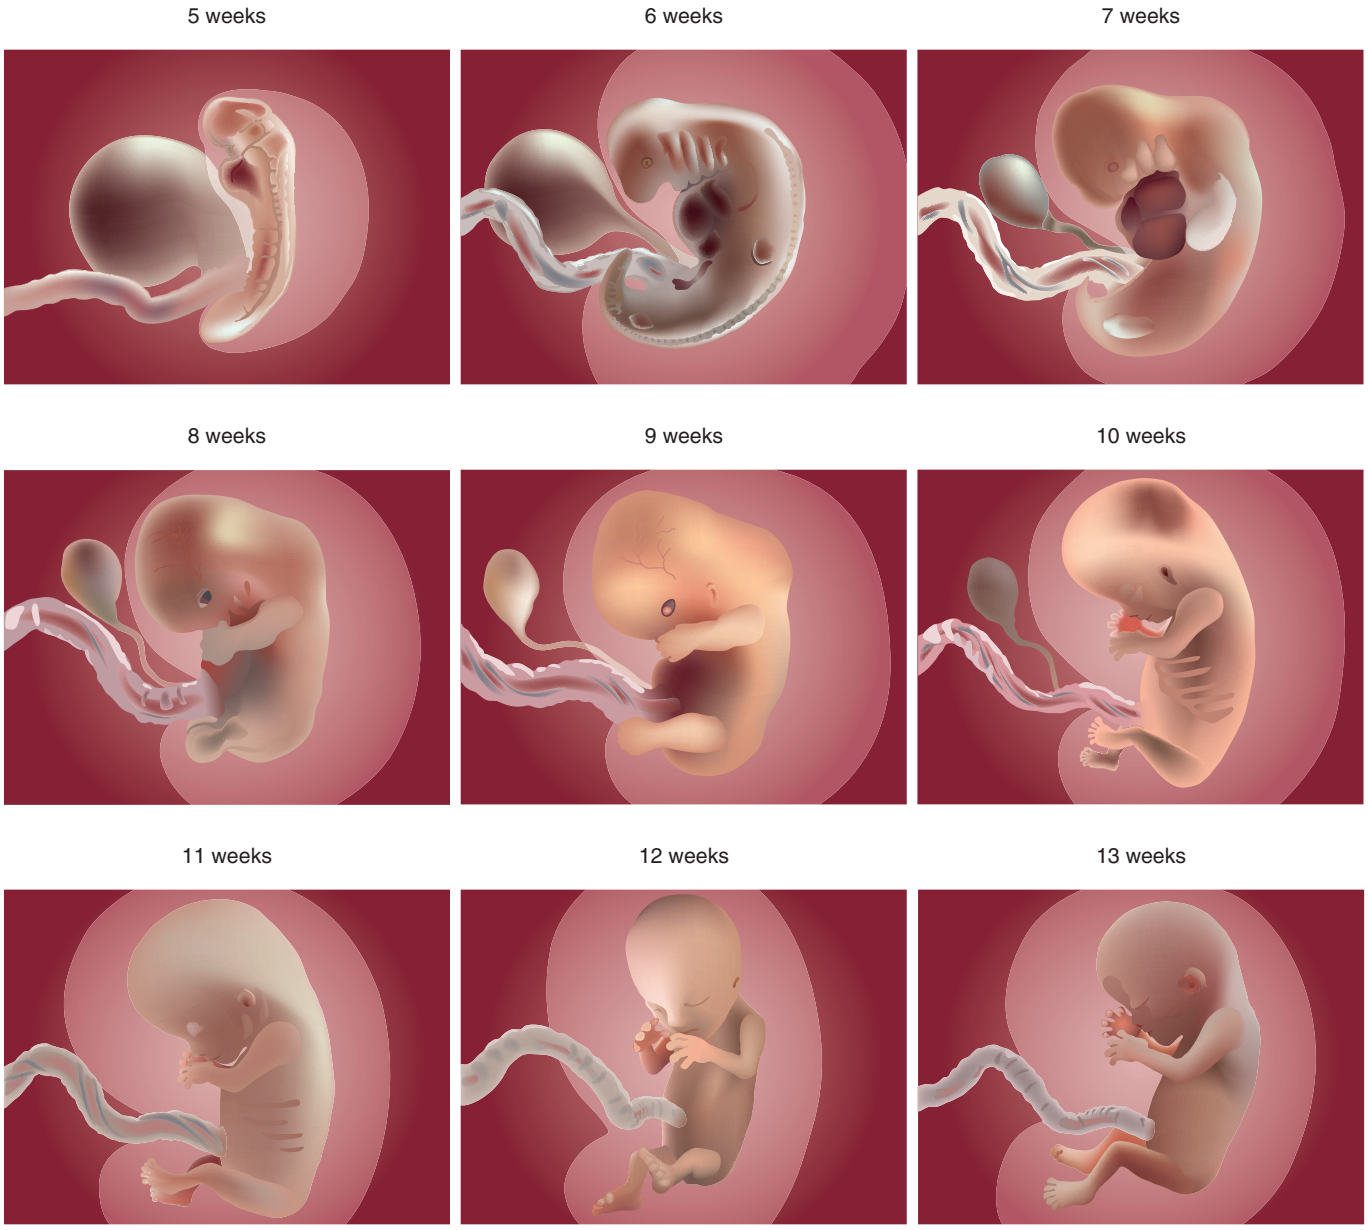

FIG 5-1 Development of the early embryo/fetus from 5 through 13 weeks of gestation (menstrual weeks). See text for details.

Embryonic Period (Weeks 4-9 Post Conception)[3]

Week 4: The 4th week marks significant development of the embryonic body, with formation of the primordium of the brain from the previously formed neural tube, the oropharyngeal membrane, and the foregut (primordium of the pharynx, esophagus, and lower respiratory tract). Primitive erythroblasts enter the embryo proper at 4 weeks' gestation, and the primordial heart begins to develop and contract. During the 4th week, hematopoietic cells begin to colonize the newly forming liver, which serves as the major site of hematopoiesis.[4] As the embryo folds in both the cephalocaudal and lateral directions, the intraembryonic coelom is divided by the septum transversum (future diaphragm), located just caudal to the heart. The septum transversum divides the primordial body cavities into the cranial pericardial cavity and the caudal peritoneal cavity. The maxilla and mandible begin to take form. The prominence of the forebrain results in the classic C-shaped curve of the embryo. Caudal folding results in the caudal eminence, a tail-like structure, with lower limb buds visible by the end of the 4th week.

Week 5: The 5th week is marked by accelerated growth, with head growth outpacing the other embryonic structures. The face begins to take form, and the mesonephric ridges develop to mark the site of the future kidneys. The embryonic heart develops into a four-chambered structure.

Week 6: By the 6th week, the limb buds begin to differentiate into upper and lower limbs with large hand plates, which develop primordial digits. The lower extremities lag behind the upper limbs by approximately 4 to 5 days. The primordial ear develops and the eyes become obvious as the retina becomes pigmented. The fetal liver occupies the majority of the abdominal cavity at the 6th week. As the rapid growth of the intestines exceeds the growth of the abdominal cavity

Modified from Timor-Tritsch IE, Farine D, Rosen MG: A close look at early embryonic development with the high-frequency transvaginal transducer. Am J Obstet Gynecol 159(3):676-681, 1988; and Timor-Tritsch IE, Bashiri A, Monteagudo A, Arslan AA: Qualified and trained sonographers in the US can perform early fetal anatomy scans between 11 and 14 weeks. Am J Obstet Gynecol 191(4):1247-1252, 2004.

the physiologic herniation of the intestines into the umbilical cord occurs. Spontaneous twitching movements and reflex responses to touch begin to take place.

Week 7: The most notable change in structure at 7 weeks is limb development as the digits become distinct and ossification begins. The plantar surfaces of the feet face each other. The developing central nervous system (CNS) is divided into the prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain); however, the midline falx cerebri has not formed, and what will become the lateral ventricles is a single ventricle at this point.

Week 8: The 8th week marks the final week of the embryonic period. By then, the heart has developed all of its adult components, pulmonary veins, tricuspid and mitral valves, coronary arteries, inferior and superior vena cava, interventricular septum, and aortic and pulmonary valves. Near the end of the 8th week, the choroid plexus begins to fold inward and the falx cerebri develops, thus dividing the single ventricle into two lateral ventricles.[5] The face takes form over the course of weeks 5 through 8. By the end of the 8th week, the mandibular, maxillary, and nasal processes have merged in the midline, and the primary and secondary palates have fully fused to produce the two palatal shelves of the definitive palate.[6]

Fetal Period (Weeks 9-14)

Weeks 9 to 12: At 9 weeks, 50% of the fetus is composed of the head, and the 9th through 12th weeks are marked by acceleration in body growth. At 10 weeks, the knees begin to rotate ventrally and the soles of the feet become reoriented with the plantar surface on the ventral aspect.[7] In the 10th week, the hindbrain develops and the cerebellum takes form. It is not until 12 weeks that the corpus callosum begins the first stages of development that will continue through the second trimester.[5,8,9] From 10 to 12 weeks, the male and female genitalia differentiate. The intestines begin to return to the abdominal cavity in the 10th week with full return by the end of the 11th week. Between weeks 10 through 12, the two shelves of the definitive palate fuse in the midline. Primary ossification centers appear by 12 weeks; the lower limbs have reached their final relative length, and the upper limbs are nearly at their relative length. Between 9 and 12 weeks the fetal kidneys begin urine production and excretion into the amniotic fluid.

Weeks 13 to 14: Weeks 13 through 14 are marked by more fetal growth. Limb movements become coordinated by 14 weeks. The eyes begin to rotate from anterolateral to anterior.

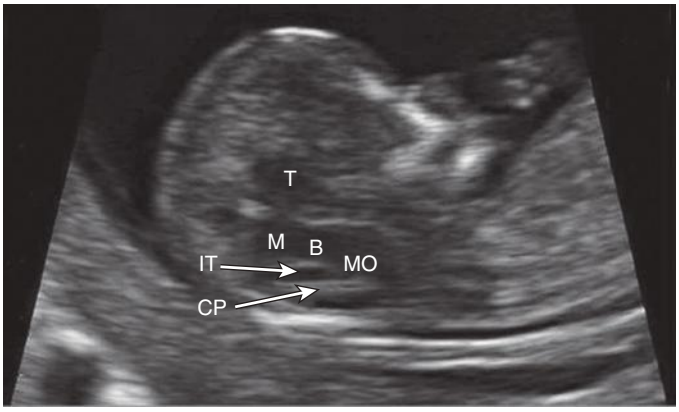

FIG 5-2 Ultrasound image of a normal fetal central nervous system in the midsagittal plane at 12 weeks' gestation. The thalamus (T), midbrain (M), brainstem (B), medulla oblongata (MO), and choroid plexus (CP) of the fourth ventricle are noted. The normal intracranial translucency (IT) of the fourth ventricle is present.

FIG 5-3 Coronal view demonstrating normal choroid plexus (CP), falx cerebri (F), and lateral ventricles (LV) at 12 weeks.

NORMAL ULTRASOUND FINDINGS IN THE FIRST TRIMESTER

Head and Neck

Central Nervous System

In the embryonic period, the brain is hypoechoic and characterized in the sagittal plane by the presence of three echogenic structures: prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain). The rhombencephalon can be visualized as early as 7 weeks and is the most prominent cavity owing to its relatively larger size compared to the other two cavities.[10] These fluid-filled cavities are positioned in a triangular fashion, laid out as to predict their future site of structure and function. The base of the triangle is formed by the forebrain in the anterior position and the hindbrain in the posterior position with the midbrain forming the apex of the triangle in between[10] (Fig. 5-2).

Forebrain and Midbrain. The cerebral hemispheres are only tiny buds at 7 weeks, but by 9 weeks Blaas and associates demonstrated the appearance of measureable hemispheres in 79% of embryos with visualization in all fetuses by 10 weeks. As the hemispheres grow, they conceal the diencephalon and meet in the midline at 11 to 12 weeks. At 12 weeks the mean measurements of the cerebral hemisphere in the sagittal view are length 16.4 mm (12.4-20.9 mm); width 6.1 mm (4.2-8.4 mm); and height 2.0 mm (1.4-2.5 mm).[11] As the first trimester progresses from the 8th week onward, the mesencephalon gradually moves toward a more central location, and the third and fourth ventricles become more organized with a distinct isthmus visible between the cavities of the prosencephalon and mesencephalon by the 9th week.

Lateral Ventricles. At 7 weeks, a single ventricle is visible, as the midline falx cerebri has not yet developed. Timor-Tritsch and colleagues demonstrated variability in the development of the falx. Although the falx was visible in the majority (75%) of embryos by 9 weeks, in a small proportion the division of the ventricles was not visible until the 10th week, when the falx was clearly visualized dividing the two lateral ventricles in all embryos.[7] The choroid plexus can be visualized routinely within each of the lateral ventricles by the middle of the 9th week, and by the 12th week it fills most of the space of the lateral ventricles[11] (Fig. 5-3).

At 12 weeks, the corpus callosum is not visible, but the trunk from which it will continue to develop may be seen. The cavum septi pellucidi (CSP), an important marker of normal CNS development, can be seen in 40% of pregnancies at 15 weeks and in 82% at 16 to 17 weeks.[12]

Cerebellum and Posterior Fossa. The rhombencephalon is the most obvious structure of the early embryonic CNS. As the cerebellar hemispheres grow, they become measurable by the middle of the 10th week and appear to meet in the midline by 11 to 12 weeks.[10] The choroid plexuses of the fourth ventricle are visible by the middle of the 10th week as echogenic areas that traverse the roof of the fourth ventricle.[5,10]

Spine. The spine will be detectable as two parallel lines as early as the 8th week in a majority of embryos.[7] The cervical, thoracic, and lumbar spine can be visualized in 80%, 81%, and 72% of fetuses between 11 and 12 weeks and 89%, 87%, and 72% of fetuses between 13 and 14 weeks.[13] The sacral spine is more difficult to visualize in the first trimester, with visualization rates of 35% between 11 and 12 weeks and 48% between 13 and 14 weeks[13] (Fig. 5-4A and B).

Skeletal Structures/Face

Skull. The bony cranium begins to ossify at 9 weeks and can be precisely measured after 9 weeks using high-frequency transvaginal sonography.[1] Using a combination of transvaginal and transabdominal sonography, Souka and colleagues were able to visualize the fetal head, including the complete cranium and the presence of the falx in all cases between 11 and 14 weeks' gestation[14] (Fig. 5-5A).

Face. The structure of the face changes dramatically throughout the first trimester and therefore is not reliably imaged until the 11th or 12th week.[7] Souka and colleagues were able to visualize the fetal face, including the orbits, lenses, and profile 99.7% of the time using a combination of transabdominal and transvaginal sonography from 11 to 14 weeks.[14] In addition, there does not seem to be a significant difference in the ability to detect the structures of the face, including the lenses, profile, nose, and lips between 11 and 12 weeks compared to 13 and 14 weeks.[13] In the embryonic and early fetal periods, the forehead is the dominant feature of the developing human face. After 11 weeks, the fetal profile takes on the expected contour with balance between the mandible, the maxilla, and the forehead. At 12 weeks a coronal section of the face can reliably be obtained and allows assessment for symmetry through imaging of the orbits, mandible, and maxilla[7] (Fig. 5-6). In the coronal section of the face, the fetal lenses can be visualized as an echogenic ring with a sonolucent center in 91% of fetuses at 11 to 12 weeks' gestation.[7]

By 11 weeks, imaging of the palate and lips can be reliably performed[7] (Fig. 5-7). The nose also becomes fully formed by 11 weeks, and the presence or absence of the nasal bone can be evaluated at this time. The frontomaxillary facial angle measured using three-dimensional (3D) volumes of the fetal face has been investigated as a screening tool for trisomy 21, which is associated with significant flattening of the face. The frontomaxillary angle decreases with increasing crown-rump length. Nomograms for chromosomally normal fetuses have been reported.[15]

The international 3D focus group has published recommendations regarding imaging of the fetal face in the first trimester. These recommendations include imaging specifications that are unique to the developing first trimester face and are particularly useful for correct visualization of the nasal bone and excluding face malformations.[16]

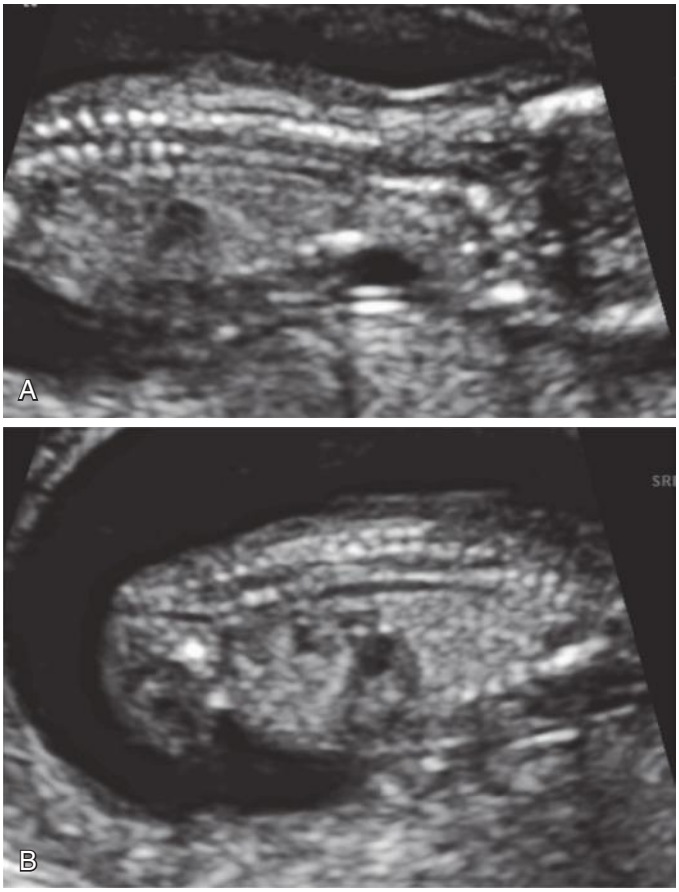

FIG 5-4 Normal fetal spine at 12 weeks' gestation. **A.** Cervical and thoracic spine. **B.** Thoracic and lumbar spine.

Neck

Evaluation of the nuchal anatomy in the first trimester has been a stepping stone that has led to the development of fetal anatomic assessment in the first trimester. The measurement of the nuchal translucency (NT) is now a widely accepted tool used for first trimester aneuploidy screening.[2,17] The nuchal translucency is gestational age dependent and can be reliably measured from 11 to 14 weeks' gestation[18,19] (Fig. 5-8).

Chest

The fetal chest, imaged between 11 and 14 weeks' gestation, demonstrates improved visualization of the pulmonary and cardiac structures occurring over the course of time. Using a combination of transvaginal and transabdominal sonography, Timor-Tritsch and colleagues demonstrated a significant difference in the ability to visualize the fetal lungs between 13 and 14 weeks compared with 11 to 12 weeks (77% vs. 64%, $P = 0.02$). The fetal diaphragm was visualized by the same group in 87% of fetuses from 11 to 12 weeks[7] (Fig. 5-9).

Cardiac Features

Using high-frequency transvaginal sonography, the fetal heart motion is first visualized from 5 weeks and 4 days to 5 weeks and 6 days, with an average rate at 6 weeks of 104 bpm.[1,7,20] In a longitudinal study of cardiac development in the first trimester, Blaas and colleagues demonstrated that the fetal heart rate follows an inverted-U curve from 7 weeks to 12 weeks. The fetal heart rate was noted to be at 138 bpm at 7 weeks, peaks at 175 bpm at 9 weeks, and then decreases to 166 bpm at 12 weeks.[21]

Although it has been demonstrated that the major structures of the heart can be visualized as early as 10 weeks, the success rate of visualizing these structures has been shown by several authors to improve with each advancing week.[21-24] In addition, Gembruch and colleagues

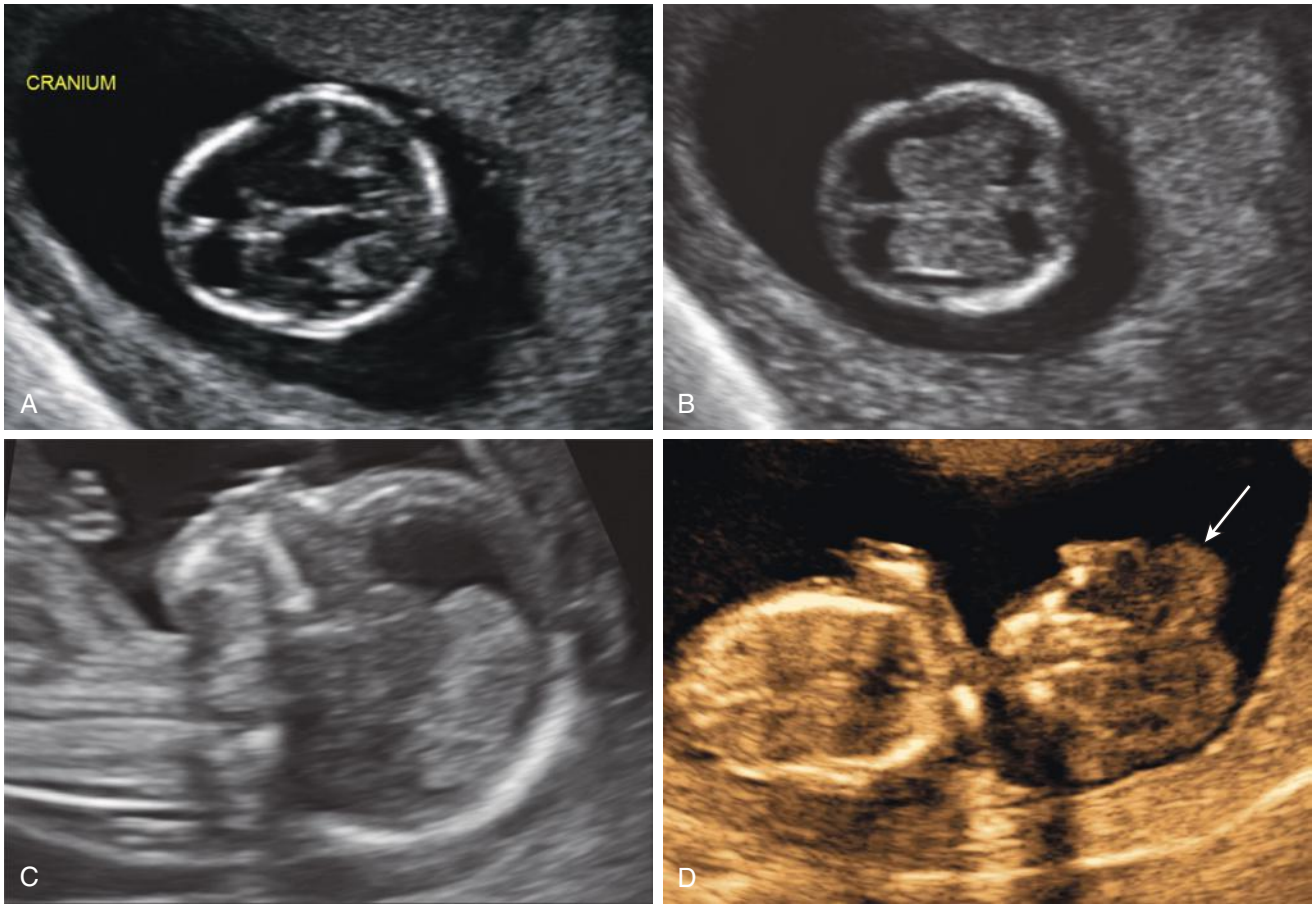

FIG 5-5 Fetal head at 12 weeks' gestation demonstrating a normal cranial vault (**A**) and normal choroid plexus (**B**). The midline falx is also demonstrated. **C,** The large echolucent area anterior to the choroid plexus is normal at this gestational age. **D,** This 13-week fetus has acrania or exencephaly, with absence of the cranial vault and irregular brain tissue floating in the amniotic fluid (*arrow*). have demonstrated better visualization using transvaginal sonography compared to transabdominal sonography from 10 to 13 weeks, equivalent visualization of the two approaches at 14 weeks, and after 14 weeks superiority of the abdominal approach.[24]

Situs can be confirmed by documenting appropriate orientation with the aorta to the right of the spine, inferior vena cava anterior and right of the spine, and the heart lying on the left side of the chest with the appropriate axis.[25] Compared to the 45 ± 10 degree cardiac axis in the mid-second and third trimesters, the cardiac axis in the first trimester begins much more midline and gradually rotates to the 45-degree position by about the 12th week.[26] From the 8th through the 9th weeks the heart sits at approximately 25 ± 12 degrees, from the 10th through the 11th week the axis rotates to 40 ± 9 degrees, and between the 12th and 15th weeks it reaches the final cardiac axis at 49 ± 7 degrees[26] (Fig. 5-10).

At 12 weeks the four-chamber view can be obtained reliably in 90% of fetuses using transvaginal sonography.[23] Two equally sized ventricles and atria with an intact ventricular septum up to the cardiac crux are seen in the normal four-chamber view[23] (Fig. 5-11A and C). The atrial appendages are more pronounced in the first trimester fetal heart compared to later in gestation, and the ventricles are in a spiral arrangement; however, the resolution of 2D sonography limits our ability to appreciate these differences, which have been demonstrated using 4D high-resolution transvaginal sonography (4D HREVS).[27] The right and left ventricles can be difficult to distinguish because of their spiral orientation, but they can be distinguished by identification of the offset of the atrioventricular valves with the tricuspid valve on the right side positioned slightly lower than the mitral valve on the left. The atrioventricular septum grows relatively late in the first trimester, and as such, the offset of the mitral and tricuspid valves may not be apparent until after 12 weeks.[25] Doppler sonography can be used to help identify the morphologic features of the right and left ventricles. Lombardi and colleagues described the "banana-shaped" right ventricle and

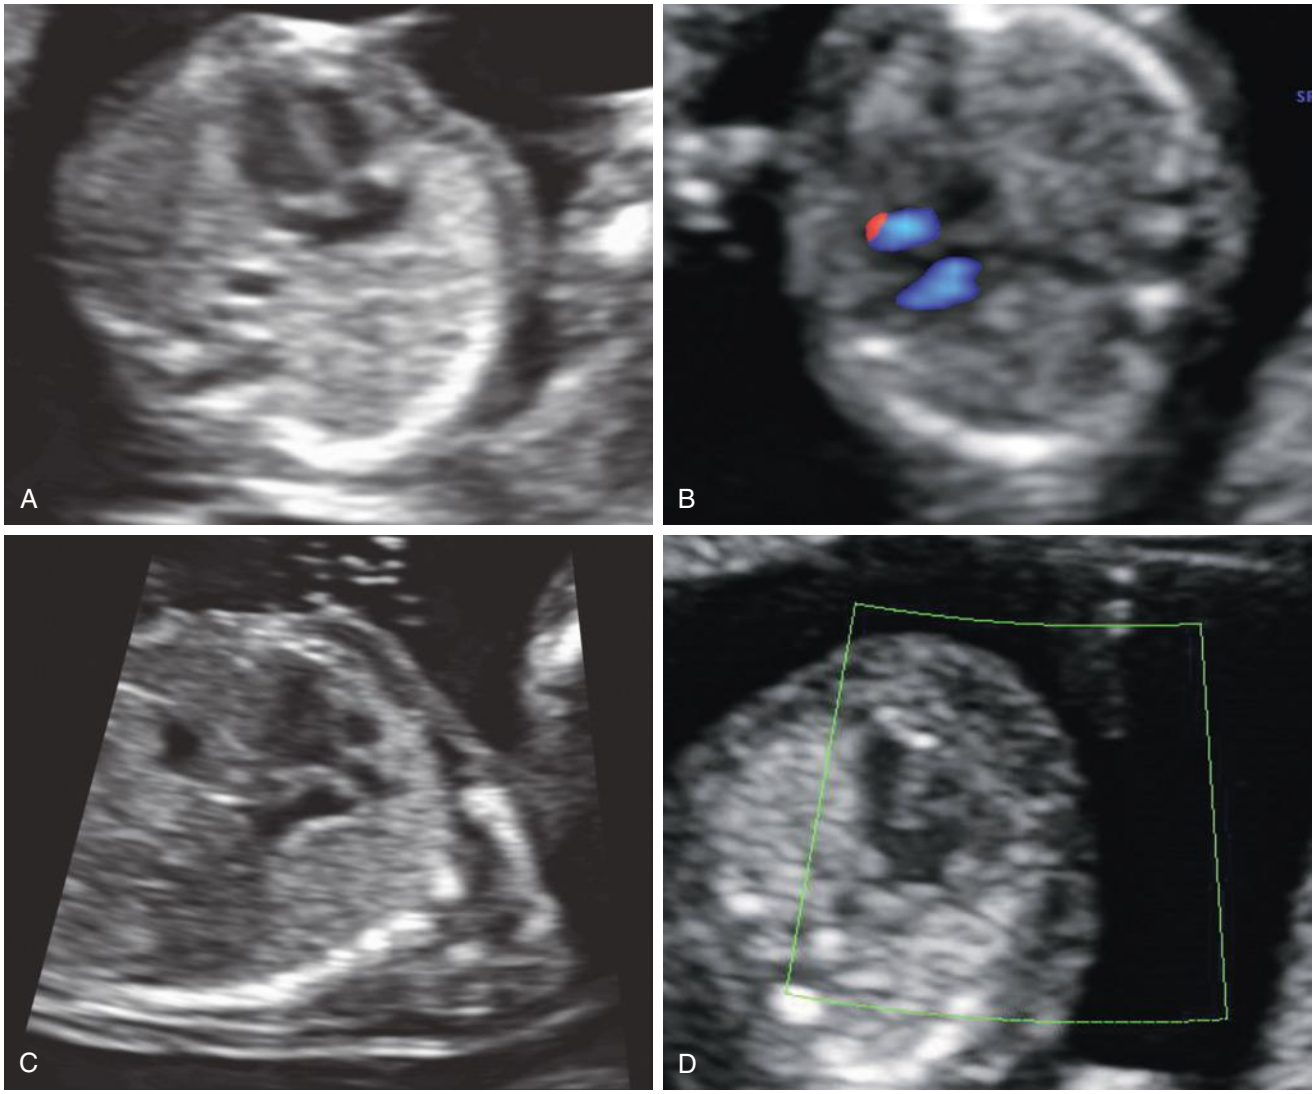

FIG 5-11 Fetal heart in the late first trimester. **A,** Four-chamber view of the heart at 14 weeks' gestation. **B,** Four-chamber view visualized with color Doppler. **C,** Left ventricular outflow tract. **D,** Atrioventricular canal defect at 12 weeks' gestation.

"ballerina shoe–shaped" left ventricle with its less severe curvature.[25] In addition, a combination of color Doppler and power Doppler is also recommended to help define the septal aortic continuity, evaluate normal valvular flow, and show pulmonary vein flow into the left atrium. The short axis view of the great vessels, which demonstrates the wrapping of the pulmonary artery from the right ventricle continuous with the branching of the ductus arteriosus, also demonstrates the tricuspid and pulmonary valves and is therefore useful for measuring flow across these valves.[25,28] It should be noted that in the first trimester it is particularly important to apply the ALARA principle and keep the thermal index below 1, which can become an issue when Doppler is used.[29]

Demonstration of the outflow tracts can be achieved in many fetuses by the 12th week, with improved visualization in the 13th week.[25] The long-axis view of the aorta with the aorta arising from the left ventricle adequately demonstrates the left ventricular outflow tract (LVOT) in 68% of fetuses in the 12th week, increasing to 92% in the 13th week[22] (Fig. 5-11B). In the long-axis view of the aorta, the continuity of the ventricular septum with the anterior wall of the aorta and the anterior mitral leaflet with the posterior wall of the aorta can be visualized. By angling the transducer toward the fetal right side, if the aorta and pulmonary artery are oriented in their normal crossover configuration, the long-axis view of the pulmonary artery can be obtained, which demonstrates the right ventricular outflow tract as the pulmonary artery branches off the right ventricle cephalad toward the fetal left side.

The aorta is seen arising centrally from the left ventricle and the pulmonary trunk from the anterior right ventricle with the pulmonary trunk crossing over the ascending aorta to the left side of the fetus (Fig. 5-12). The ductal arch is anterior to the transverse section of the aortic arch and heads almost directly posterior toward the spine where it converges with the descending aorta to the left of the spine (Fig. 5-13). The three-vessel view with the pulmonary trunk originating from the right ventricle, the aorta, and the superior vena cava is useful for identifying and comparing the sizes of the great vessels. The use of color Doppler can confirm forward flow through the outflow tracts. Using power Doppler, the normal orientation of the great vessels can be demonstrated using the X sign, which identifies the normal crossover

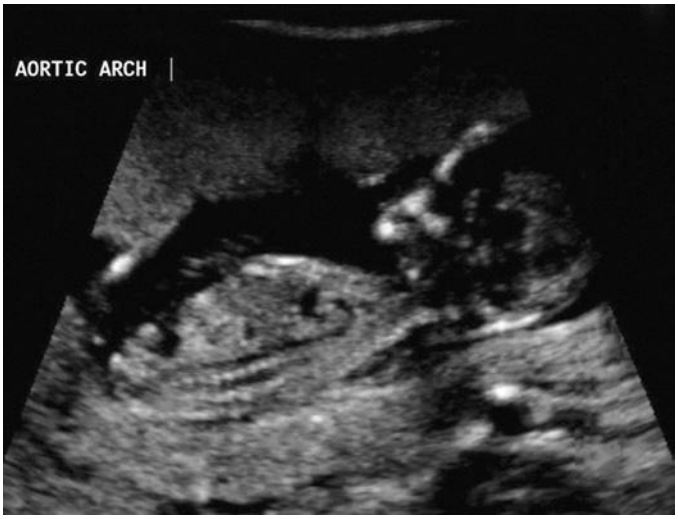

FIG 5-12 Normal aortic arch at 12 weeks.

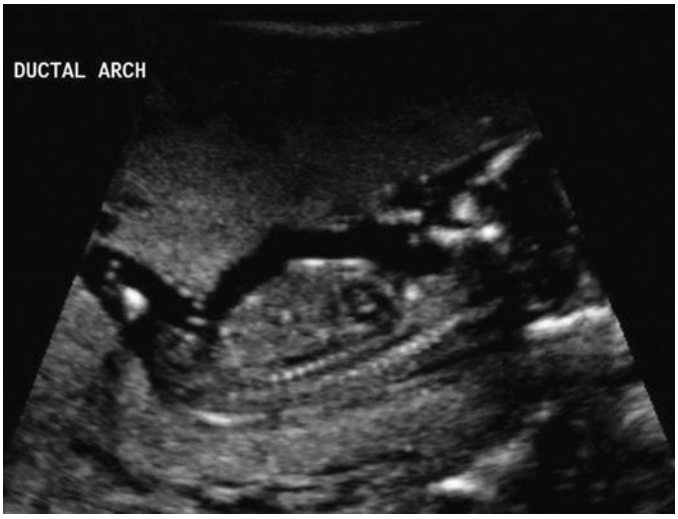

FIG 5-13 Normal ductal arch at 12 weeks.

of the pulmonary trunk over the aorta, and the b sign, which demonstrates a transverse plane at the level of the sweeping arch of the aorta and near linear path of the pulmonary artery.[25]

Nomograms for cardiac biometry between the 10 and 15 weeks have been published by Smrcek and coworkers.[28]

Abdomen

Examination of the abdomen in the first trimester begins with evaluation of the ventral wall (Fig. 5-14). The physiologic herniation of the midgut can be seen as early as 7 weeks and becomes most identifiable from 9 to 10 weeks with retraction back into the abdominal cavity from the middle of the 10th week through the 11th week[21] (Fig. 5-15). By 12 weeks the thickening of the umbilical cord associated with midgut herniation has resolved, and the umbilical cord insertion into the abdominal cavity is able to be evaluated.[7,30]

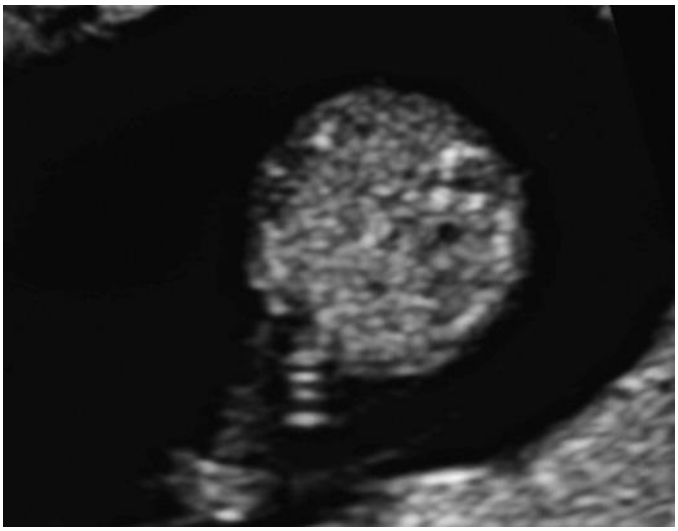

FIG 5-14 Axial view through the fetal abdomen at 13 weeks of gestation, demonstrating an intact abdominal wall and normal fetal cord insertion.

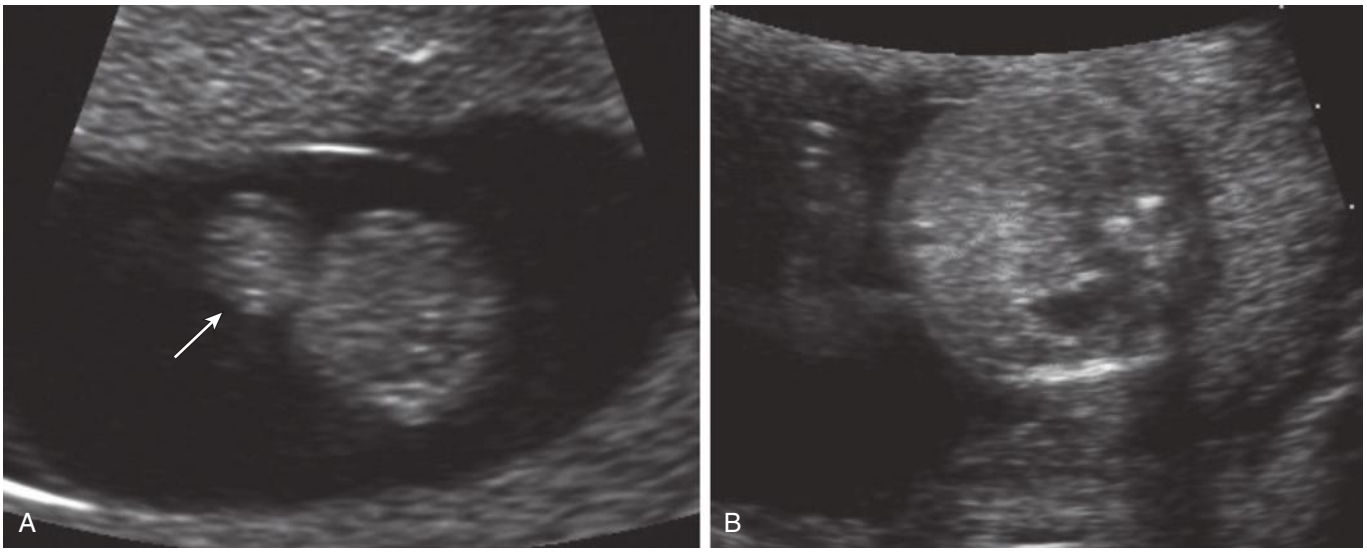

FIG 5-15 Physiologic bowel herniation. **A,** At 11 weeks' gestation, bowel can be seen in the base of the umbilical cord (*arrow*). **B,** At 18 weeks' gestation, the ventral wall and umbilical cord insertion site are now normal.

Gastrointestinal Tract

Stomach. As early as 8 weeks, the stomach can be visualized as a left-sided hypoechoic cavity in the upper abdomen.[21,30] By 11 to 14 weeks the stomach is visible in 99% of fetuses[14] (Fig. 5-16).

Bowel. After 12 weeks the entire bowel is intra-abdominal, with visualization more successful between 13 and 14 weeks compared to 11 to 12 weeks (88% vs. 77%, $P = 0.02$)[13] (Fig. 5-17).

Genitourinary Tract

Kidneys. The fetal kidneys appear as hyperechoic structures with hypoechoic centers lateral to the spine. Using a combination of transvaginal and transabdominal sonography between 11 and 14 weeks, the visualization rate for the kidneys in the first trimester ranges from 80% to 95%.[13,14] Timor-Tritsch and associates demonstrated improved visualization rates for the kidneys later in the first trimester with 80% visualization between 11 and 12 weeks compared to 91% visualization between 13 and 14 weeks ($P = .02$)[13] (Fig. 5-18).

Bladder. The normal first trimester fetal bladder is identified as a hypoechoic structure in the fetal pelvis visualized in 93% to 100% of fetuses between 11 and 14 weeks.[13,14,31,32] Using color Doppler, the umbilical arteries can be seen coursing from the umbilical cord insertion around the bladder in 84% of fetuses from 11 to 12 weeks[13] (Fig. 5-19). Normal measurements of the fetal kidney from 12 to 14 weeks have been published by Bronshtein and coworkers.[32]

Genitalia. Early accurate determination of fetal gender has been reported as early 11 weeks with an accuracy rate ranging from 46% to 70%.[33,34] The male and female genitalia are best distinguished in the first trimester by the direction of the genital tubercle (future phallus or clitoris) seen in the sagittal plane. The male genital tubercle points in the cephalad direction, whereas the female genital tubercle is directed caudally or on the horizontal. Subjective assessment of the first trimester gender has been described and quantified for accuracy using a combination of the sagittal view and the transverse view. In the transverse view identification of a round structure at the base of the genital tubercle representing the scrotal swelling, or a midline echo at the base of the genital tubercle, representing the median penile raphe, aid in identifying the male fetus. Two, or four, parallel lines, representing the labia minora and majora, help to identify the female fetus. When the subjective two-view assessment is used 67% of male fetuses are correctly identified at 11 weeks with improvement in identification of male fetuses at 12 weeks to 89% without further significant improvement beyond 12 weeks. This is in contrast to the female fetus in which correct gender identification occurs 83% of the time but does not improve until 14 weeks when it is correct 95% of the time.[33] Using an objective cutoff of 30 degrees from the horizontal for the direction of the genital tubercle in the sagittal view appears to have improved accuracy over the subjective two-view method, although there is no study directly comparing the two methods. Using a cutoff of 30 degrees, the gender is accurately determined in 70% of fetuses at 11 weeks, 99% at 12 weeks, and 100% at 13 weeks. Male fetuses are incorrectly assigned as female 56% of the time at 11 weeks, but only 3% of the time at 12 weeks, and 0% at 13 weeks. In contrast, female fetuses will be incorrectly assigned only 5% of the time at 11 weeks and 0% at 12 and 13 weeks.[34]

Extremities

Using high-frequency transvaginal sonography, the upper and lower limb buds can be imaged from 7 weeks onward. At this early gestational

age, the tail of the embryo is longer than the lower limb buds and will be prominent. By the 10th week, the full length of the limbs are able to be fully imaged.[7] Using a combination of high-frequency transvaginal and transabdominal sonography, full examination of the extremities including biometry of the short and long bones, the fingers, toes, and the movement and posture of the joints is possible in 100% of fetuses by 11 weeks[14] (Fig. 5-20).

ABNORMAL ULTRASOUND FINDINGS IN THE FIRST TRIMESTER

Head and Neck

Central Nervous System

CNS anomalies account for approximately 11% of abnormalities detected in the first trimester.[35]

Neural Tube Defects. Closure of the neural tube occurs early in embryogenesis, from 4 to 6 weeks' conceptional age. When there is disruption in this closure, the result is a neural tube defect (NTD). Open spina bifida (myelomeningocele) is a specific type of NTD that occurs when the caudal portion of the neural tube fails to close at 4 weeks. Myelomeningocele is distinct from anencephaly, which results when the cranial portion of the neural tube fails to close. Exencephaly is the finding that precedes anencephaly when the floating brain tissue is still present (Fig. 5-5D).

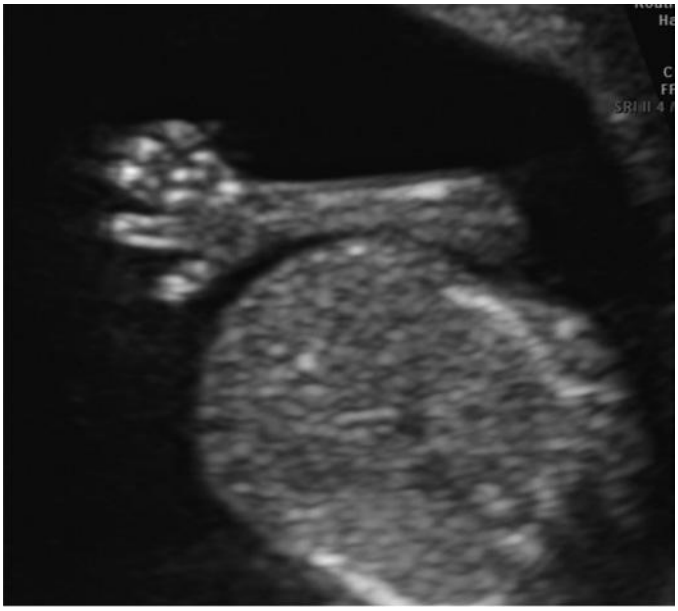

FIG 5-20 Normal fetal hand demonstrating five normal digits.

Anencephaly (Exencephaly). Imaging of the cranial vault is reliable at 11 weeks, making the diagnosis of anencephaly possible at this early gestational age. In the first trimester, the cerebral hemispheres have not yet eroded away, but with absence of the cranium, in the sagittal view the "Mickey Mouse sign" has been shown to be 100% sensitive and specific for lethal anomalies associated with a missing cranium including anencephaly and acrania.[36]

Myelomeningocele. The diagnosis and management of myelomeningocele have evolved dramatically over the past century.[37] Lesion level has been closely correlated to short- and long-term outcomes, and advances in open fetal surgery available in select cases at specialty centers has made early diagnosis and characterization of the defect important for patient counseling.[38-40]

In addition to the visualization of an obvious myelomeningocele, which may be present as early as 9 weeks, there are several signs unique to the first trimester that have been described in association with open NTDs. Small biparietal diameter (BPD) in the first trimester has been associated with myelomeningocele, with nearly 50% of cases having a BPD below the 5th percentile between 11 and 14 weeks.[41-43] Bernard and associates demonstrated that the combination of first trimester BPD below the 5th percentile with maternal serum markers, maternal serum alpha-fetoprotein, and free β-hCG (human chorionic gonadotropin), improves the first trimester detection rate for myelomeningocele to 70% with a fixed false positive rate of 10%.[42]

Imaging of the posterior fossa can be helpful for ruling out and diagnosing NTDs in the first trimester. Intracranial translucency, which was first noted during nuchal translucency screening, is the normal fluid-filled area of the fourth ventricle seen in the midsagittal view (see Fig. 5-2). Chaoui and coworkers retrospectively evaluated 191 fetuses and found that myelomeningocele was successfully ruled out in 100% of fetuses with a normal intracranial translucency.[44] Larger prospective studies are still needed before widespread search for this sign can be proposed. In addition, using 3D sonography, cisterna magna width and measurements of the brainstem in comparison to the brainstem-occipital bone distance have been identified as potential first trimester screening signs for open spina bifida.[45]

Beyond the posterior fossa, an overall reduction in cerebrospinal fluid with corresponding reduction in the area of the cerebral ventricular system has also been associated with myelomeningocele.[46]

Encephalocele. Encephalocele is a herniation of neural tissue through a cranial defect, which can be located either in the occipital or, less commonly, frontal locations. Occipital encephaloceles are considered on the spectrum of NTDs. Several autosomal recessive conditions are associated with encephalocele, the most common of which is Meckel-Gruber syndrome. When high-frequency transvaginal sonography was used to screen women with a previous pregnancy complicated by Meckel-Gruber syndrome, encephalocele was able to be diagnosed as early as 11 weeks and as early as 12 weeks in low-risk populations undergoing first trimester anatomic screening.[47-49]

Holoprosencephaly. Incomplete cleavage of the forebrain results in holoprosencephaly, which can range from complete fusion (alobar), partial fusion with separation of the posterior cerebral hemispheres (semilobar), and partial fusion with separation of both the anterior and posterior cerebral hemispheres (lobar). Chervenak and coworkers described the diagnostic findings of holoprosencephaly to include absence of a midline echo with hypotelorism; however, the authors acknowledge that hypotelorism may be absent in cases with normal facial structure. Ventriculomegaly with either microcephaly or macrocephaly is also often present in cases of holoprosencephaly.[50] Beyond the CNS findings, there is a range of midface abnormalities that can result from incomplete facial development including cyclopia, proboscis, bilateral or unilateral cleft lip, single nostril or blind ended nose, flat nose, iris coloboma, single maxillary incisor, or simply absent philtrum.[51] Transverse views of the normal fetal head in the first trimester reveal the symmetric shape of a butterfly including clear demarcation of the midline. Systematic imaging of the choroid plexus from 11 to 14 weeks by Sepulveda and colleagues demonstrated absence of the butterfly sign in cases of holoprosencephaly.[52]

Skeletal/Face

Clefts. Oral clefts are one of the most prevalent fetal anomalies, occurring at a rate of 1.05/1000 live births and fetal deaths with cleft lip alone occurring at a lower rate, 0.66/1000 in live births and fetal deaths combined. In the majority (73.8%) of cases of cleft lip with or without cleft palate the anomaly is isolated; however, when the palate is involved it is less likely to be an isolated anomaly (48.3%).[53] Using 2D sonography in the second trimester, the RADIUS (Routine Antenatal Diagnostic Imaging with Ultrasound) trial demonstrated relatively low detection rates for oral clefts (30%).[54] However, with the ability to systematically manipulate multiplanar images using 3D sonography, detection rates of 90% have been reported.[55] In the first trimester, using 2D sonography, Sepulveda and colleagues described the systematic examination of the natural triangle formed between the frontal processes of the maxilla and the palate, termed *retronasal triangle*, as a screening tool for oral clefting. The authors used 2D sonography to identify abnormalities of the alveolar ridge and nasal bone using the view of the retronasal triangle; these abnormalities were then further evaluated using manipulation of 3D datasets, which demonstrated accurate detection in 100% of primary palate clefts and 86% of secondary palate clefts, with a false positive rate of less than 1%.[56,57]

Micrognathia. Micrognathia is associated with many chromosomal and genetic syndromes. During their investigation of the retronasal angle, Sepulveda and colleagues recognized normal fetuses to have a gap between the mandibular bodies and have since published the finding of an absent mandibular gap as found in 100% of fetuses with micrognathia (77.8%) or severe retrognathia (22.2%).[58]

Absent Nasal Bone. The sagittal view allows imaging of the fetal nasal bone and the frontomaxillary angle, abnormalities of which have been associated with trisomy 21 (Fig. 5-8B). The likelihood ratio for trisomy 21 when the nasal bone is absent was reported to be 146 (95% confidence interval [CI] 50-434) by Cicero and colleagues. This group also demonstrated a trisomy 21 detection rate of 90% with a false positive rate of 5% when first trimester examination of the nasal bone was incorporated into a screening strategy that included nuchal translucency, serum free β-hCG, and pregnancy-associated plasma protein A (PAPP-A).[59,60]

Increased Frontomaxillary Angle. The frontomaxillary angle can be measured in the sagittal view and when combined with maternal age, nuchal translucency, and serum free β-hCG and PAPP-A gives a detection rate for trisomy 21 of 94.3% with a false positive rate of 5%, which was increased over the detection rate of 89.5% when the frontomaxillary angle was not included.[61]

Neck

Increased nuchal translucency has been well established as a risk factor for aneuploidy (see Chapter 3). Nuchal translucency screening alone identifies 75% to 80% of trisomy 21 fetuses with a false positive rate of 5%[62] and when combined with measurement of serum levels of free β-hCG and PAPP-A identifies 82% to 87% of trisomy 21 fetuses (fixed false positive rate of 5%) and 78% of non–trisomy 21 aneuploid fetuses (false positive rate of 6%).[63,64] One third of fetuses with a nuchal translucency greater than the 95th percentile will be aneuploid and the remaining two thirds will be euploid.[65] Among euploid fetuses with increased nuchal translucency, there is an increased risk of structural malformations, syndromes, and perinatal death[65-67] (Fig. 5-21B). Nicolaides and associates first described a nuchal translucency cutoff of 3.0 mm as a useful screening tool for aneuploidy screening.[2] Since that time, several cutoffs have been studied including 2.5 mm, 3.0 mm, 3.5 mm, 95th and 99th percentiles, and multiples of the median (MoM) of 2 or delta value 1.5.[68,69] In a large trial of 96,127 women across 22 centers in the United Kingdom, 95th percentile for nuchal translucency measurement was noted to change significantly with crown-rump length, but the 99th percentile remained relatively constant at 3.5 mm.[19,67] Although 92% of euploid fetuses with a nuchal translucency of less than 3.5 mm will result in a healthy infant, this number decreases to 20% for a nuchal translucency greater than 6.5 mm.[65] The prevalence of cardiac anomalies has been shown to increase exponentially with increasing nuchal translucency thickness (Table 5-2).[67,70] The American Institute of Ultrasound in Medicine recommends fetal echocardiogram when there is a first-degree relative with a congenital heart defect.[71] The baseline prevalence of congenital heart disease in the general population is approximately 8/1000 (0.8%),[72] and the risk of congenital heart disease among siblings increases from this baseline to

TABLE 5-2 Prevalence of Major Cardiac Defects by Nuchal Translucency Thickness

Nuchal Translucency Thickness	Prevalence of Major Cardiac Defect
<95th percentile	1.6/10,000*
95th percentile to 3.4 mm	10/1000†
3.5-4.4 mm	27/1000†
4.5-5.4 mm	43/1000†
5.5-6.4 mm	63/1000†
≥6.5 mm	169/1000†

TABLE 5-3 Chromosomal and Structural Abnormalities of 132 Cases of Septated Cystic Hygroma

Outcome	N (%)
Chromosomal Abnormality	67/132
Trisomy 21	25/67 (37.3)
Monosomy X	19/67 (28.3)
Trisomy 18	13/67 (19.4)
Trisomy 13	6/67 (9.0)
Triploidy	3/67 (4.5)
Mosaic deletion of chromosome 9	1/67 (1.5)
Structural Malformation	22/65
Cardiac	16/22
Skeletal	6/22

Modified from Malone FD, Ball RH, Nyberg DA, et al: First-trimester septated cystic hygroma: prevalence, natural history, and pediatric outcome. Obstet Gynecol 106(2):288-294, 2005.

approximately 30/1000 (3%).[73] Therefore, it is reasonable to use a nuchal translucency of greater than or equal to 3.5 mm, associated with a prevalence of 2.7% (see Table 5-1), as the cutoff for referral to specialized fetal echocardiogram.[70,74,75]

Cystic Hygroma. Cystic hygroma is a malformation of the lymphatic system that causes collection of edema at the fetal neck and may encompass the entire fetus (Fig. 5-22). Early cystic hygromas are associated with congenital syndromes and other malformations and should be distinguished from cystic hygromas developing later in pregnancy that are generally isolated lymphangiomas. Using data from the FASTER trial,[63] Malone and colleagues reported on the short- and long-term outcomes of a total of 134 septated cystic hygromas compared to the general population of 38,033 fetuses. The authors defined cystic hygroma as a septated hypoechoic area behind the fetal neck extending along the fetal back to make the distinction from simple increased nuchal translucency thickness. Chromosomal abnormalities were diagnosed in 51% (67/132) of cases (Table 5-3). Among the chromosomally normal cases, 33.8% were complicated by a major structural anomaly, with cardiac malformations being the most common (72.7%) followed by skeletal abnormalities (27.3%). The most common cardiac defect was a single ventricle, that is, hypoplastic left-sided or right-sided heart syndrome (25%). Termination of pregnancy was chosen by 60% of patients, and stillbirth occurred in an additional 15% (25% chromosomally normal). In all, there were 23 structurally and chromosomally normal liveborn infants followed for a mean of 25 months, 22 of whom remained developmentally normal and one who developed spastic diplegia for which no cause of cerebral palsy could be identified. In addition, the authors demonstrated a significant increase in the odds for aneuploidy (odds ratio [OR] 5.2, 95% CI 2.9-9.6), cardiac malformation (OR 12.4, 95% CI 3.2-56.3), and fetal or neonatal death (6.0, 95% CI 1.4-26.2) among cases of septated cystic hygroma compared to simple increased nuchal translucency thickness (≥3.0 MoM).[76]

Chest

Most of the literature regarding identification of chest abnormalities in the first trimester focuses on congenital heart disease; however, a general overview of the chest in the first trimester can identify other malformations.

Extracardiac Masses/Congenital Diaphragmatic Hernia

First trimester detection of pulmonary sequestration, cystic adenomatoid malformation, and congenital diaphragmatic hernia has been reported.[67,77,78] Although these malformations may be detected in the first trimester, visualization will depend on size, and continued growth may aid detection in the second trimester. In a randomized trial of routine 12-week anatomic survey versus routine 18-week anatomic survey, Saltvedt and colleagues detected 0% of the three diaphragmatic hernias in the 12-week group but 50% of four diaphragmatic hernias in the 18-week group, but this difference was not statistically significant because of the overall low prevalence of congenital diaphragmatic hernia in the cohort (7/36,108).[78]

Cardiac Disease

Congenital heart disease is one of the most common severe congenital abnormalities, with a prevalence of 8/1000 live births.[22,72,79,80] Over the past 2 decades, imaging of the fetal heart in the first trimester has evolved considerably to include full echocardiographic studies, with several authors reporting diagnosis of congenital heart disease in the first trimester[22,30,79-81] (Fig. 5-23). In a retrospective study of 2165 singleton pregnancies that underwent fetal echocardiogram from 1997 to 2003 Smrcek and colleagues reported the frequency of congenital heart malformations diagnosed between 11 and 13 weeks, with atrioventricular septal defects being the most frequent by about 4.5-fold (18/29), followed by ventricular septal defect (4/29), and tetralogy of Fallot (3/29).[28] Additionally, ectopia cordis, hypoplastic left-sided and right-sided heart syndrome, double outlet right ventricle, transposition of the great arteries, absence of the pulmonary valves, aortic stenosis, aortic coarctation, left and right atrial isomerism, pulmonary stenosis, truncus arteriosus, tricuspid atresia, and total anomalous pulmonary venous return have all been reported as either isolated findings or in combination as complex congenital heart disease.[22,28,81-83] The majority of studies evaluating first trimester fetal cardiac evaluation have included a selected population referred for specialized fetal echocardiogram in which the indication most commonly was increased nuchal translucency but may also include risk factors such as cardiac findings on a nonspecialized routine first trimester sonogram, multiple gestation, or family history. Detection rates for cardiac malformations in a high-risk population have been reported to range from 70% to 84.2%.[81,83] Orlandi and colleagues prospectively evaluated a systematic approach at first trimester fetal cardiac imaging, which did not include a full fetal echocardiogram but evaluated the four-chamber view and outflow tracts. The overall detection rate for cardiac abnormalities was 66%, 80% for major defects and 42% for minor defects with no false positive major congenital heart defects.[84]

FIG 5-23 Atrioventricular canal defect detected at 10 weeks' gestation in a fetus with a cystic hygroma. Cell-free fetal DNA test is positive for trisomy 13. Patient opted for termination of pregnancy.

Advances in technology have led to developments in 4D sonography with STIC, which allows the offline manipulation and evaluation of images.[85] First trimester use of 4D STIC for the detection of cardiac malformations has demonstrated detection rates in the range of 90% to 95% in high-risk populations attending specialty centers.[86,87] The benefit of 4D STIC over traditional 2D sonography for the detection of cardiac anomalies has not been demonstrated, as Bennasar and colleagues identified 2D modalities to be slightly better than STIC, with a detection rate of 98% with no false positive results.[86] Even so, the value in 4D STIC may go beyond detection rates and likely lies in the ability to manipulate and evaluate images offline, which could aid in efficiency by enabling cardiac evaluation via a small number of specialists trained in this modality.[85] However, the acquisition of high-quality images is technically difficult, which limits the application of this technology.[87] Therefore, the role of 4D STIC at this time continues to be in the investigational arena.

Abdomen

Abnormalities of the fetal abdomen that are detectable by ultrasound can be divided into gastrointestinal malformations, which primarily include abdominal wall defects, and the genitourinary system abnormalities of the kidneys and bladder.

Gastrointestinal Malformations

First trimester diagnosis of esophageal atresia and duodenal atresia have been described, but abdominal wall defects are more frequent and as such have received the most attention in the literature on first trimester anatomic evaluation.[77,88-90]

Abdominal Wall Defects. Omphalocele has been reported to affect 1.4 to 2.5/10,000 live births.[91-94] Compared to omphalocele, the prevalence of gastroschisis is greater at 4.4/10,000 live births and has increased in prevalence over time. There has been significant epidemiologic variation in the prevalence of gastroschisis over time. In a large U.S. study of over 14,000 cases of gastroschisis occurring across 15 states, the prevalence of gastroschisis rose from 2.32/10,000 in 1995 to 4.42/10,000 in 2005, with the majority of the increased prevalence occurring among mothers younger than 20 years of age (11.45/10,000).[95]

The midgut herniation resolves by 12 weeks' gestation; therefore, unless it is equal to or greater than the size of the abdomen, any midgut herniation should be considered physiologic prior to this time[96] (see Figs. 5-15 and 5-21). In theory, gastroschisis should be able to be distinguished from the physiologic herniation and omphalocele in the first trimester by its location lateral to the umbilicus (typically right-sided) (Fig. 5-24); however, image resolution or fetal position and movement may limit the ability to adequately characterize any bowel herniation prior to 12 weeks and requires confirmation after 12 weeks.

When gastroschisis or omphalocele is detected in the first trimester, the next step is ruling out additional anomalies. Although gastroschisis is typically an isolated anomaly, it can be associated with abnormalities of the brain (4.5%), heart (2.5%), limbs (2.2%), and kidneys (1.9%) and with chromosomal syndromes (1.2%) and nonchromosomal syndromes (0.7%).[97] In contrast to gastroschisis, omphaloceles are much more commonly associated with other major structural anomalies or chromosomal syndromes. In a study of 98 fetuses diagnosed with omphalocele prior to 14 weeks' gestation, 45.9% of fetuses had an additional major structural malformation and

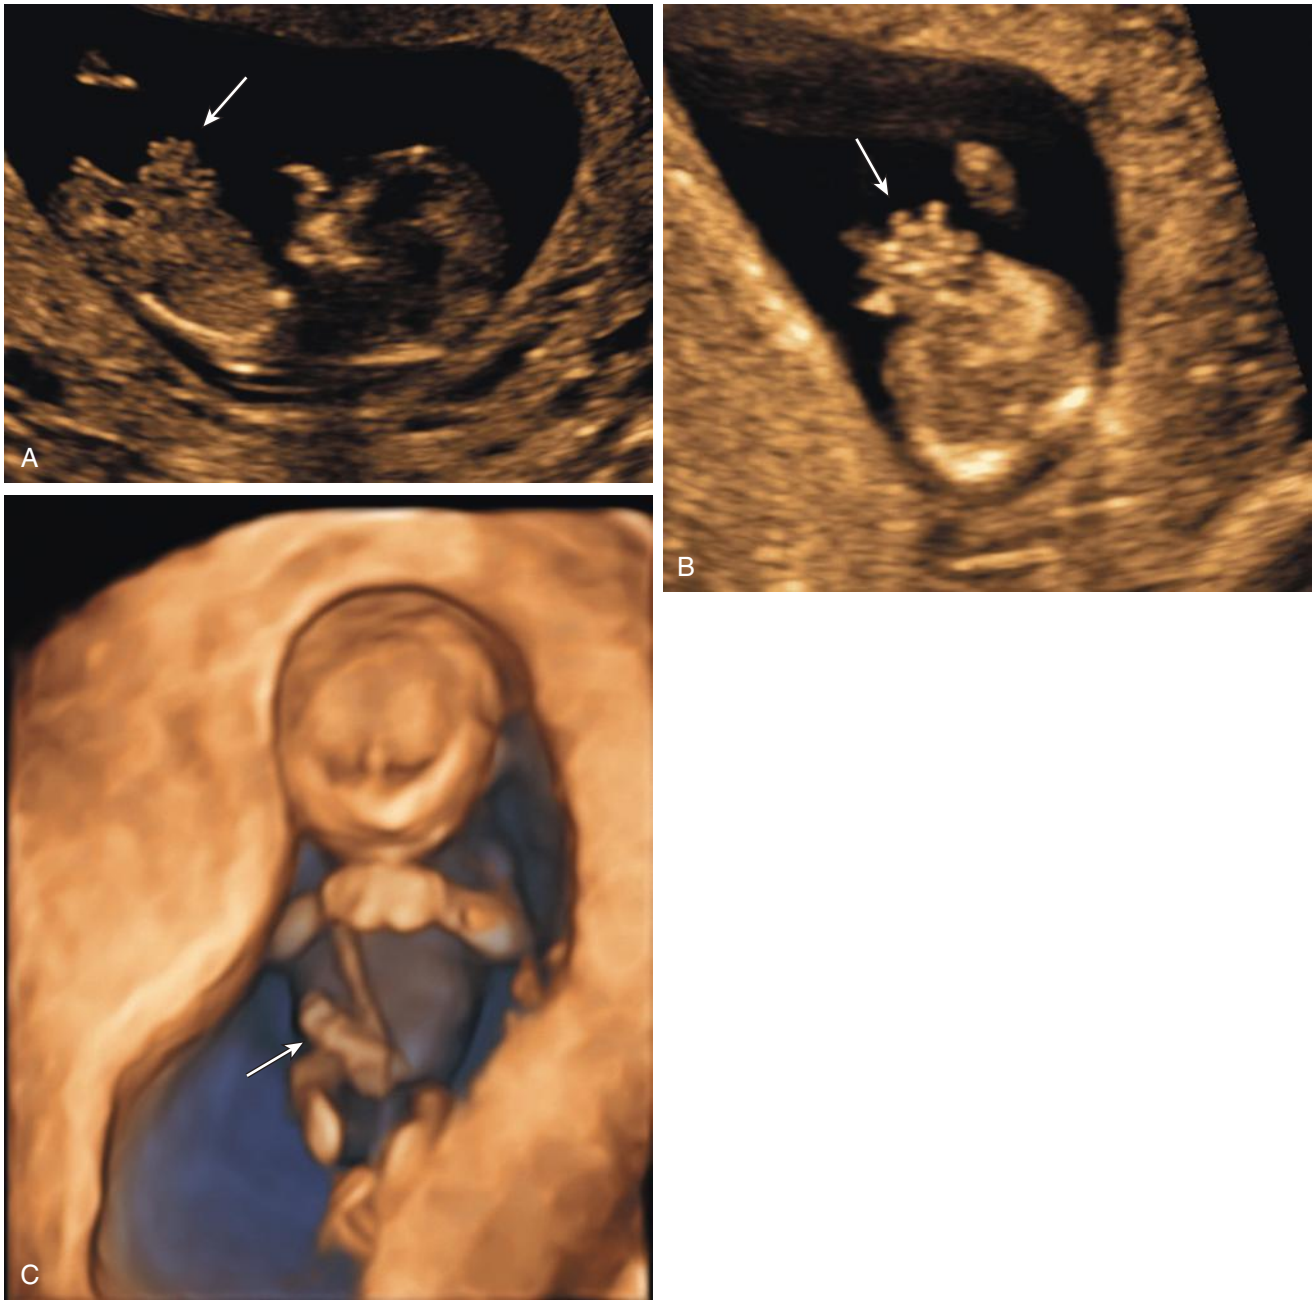

FIG 5-24 Fetal gastroschisis (*arrows*) at 12 weeks' gestation in sagittal (**A**), axial (**B**), and three-dimensional (3D) (**C**) images. The 3D image clearly demonstrates the typical defect with extruded bowel to the right of the umbilical cord insertion. (Courtesy of Barbora Mrazek-Pugh.)

53.8% of 80 fetuses karyotyped were affected by a chromosomal abnormality, most frequently trisomy 18 (72.1%). In addition, the authors reported on 33 fetuses with an apparently isolated omphalocele seen prior to 14 weeks that underwent an additional anatomic survey at 16 weeks, and 6 of these cases (18.2%) were found to have an additional malformation and 21 (63.6%) had an intact abdominal wall, stressing the importance of follow-up ultrasound assessment when omphalocele is suspected in the first trimester. Outcomes for fetuses with omphalocele are largely dependent on whether the abdominal wall defect is isolated or complicated by additional anomalies or aneuploidy. Tassin and colleagues reported the outcomes of isolated omphalocele diagnosed prior to 14 weeks.[90] Of 79 cases there were 15 (19%) medically indicated terminations, 4 (5%) elective terminations, 6 (8%) stillbirths, and 54 (68%) live births. The authors investigated the omphalocele/transabdominal diameter ratio and suggest a ratio of greater than or equal to 0.8 for a threshold to discriminate increased neonatal morbidity. Although the sensitivity of this threshold in the study was shown to be 86.7%, the specificity remained low at 50% ($P = .017$), and neither this measure nor this threshold has been externally validated to date.[90]

Genitourinary Abnormalities

The most commonly detected genitourinary abnormality seen on ultrasound images in the first trimester is megacystis; however,

hydronephrosis and cystic kidneys have also been reported. The detection of renal agenesis in the first trimester is technically difficult because of confusion with the adrenal glands.[98]

Megacystis. Megacystis is a sign of lower urinary tract obstruction (LUTO), which may have several causes. When megacystis is diagnosed in the first trimester, because the fetus is young and the obstructive cause may resolve or progress throughout the pregnancy, a spectrum of outcomes are possible, ranging from complete resolution without sequelae to dysplastic nonfunctioning kidneys with resulting anhydramnios, accompanying pulmonary disease, and death. In a retrospective investigation of pregnancies in the United Kingdom enrolled in a protocol to evaluate screening nuchal translucency in the general population from 10 to 14 weeks, megacystis was found in 0.06% of 24,492 fetuses screened.[99,100] Among the cases of megacystis the authors found the minimum longitudinal bladder diameter to be 8 mm with a minimum bladder/crown-rump length ratio of 13%. When a control group of 3000 normal fetuses were selected for comparison, the maximum bladder diameter was 6 mm and the median bladder/crown-rump length ratio was 5.4% (0-10.4%). Chromosomal abnormalities were found in 20% of the cases of megacystis, trisomy 21, trisomy 13, and a balanced translocation of chromosomes 14 and 20, and nuchal translucency was found to be greater than the 95th percentile in 40% of cases, the two trisomy cases, and four additional euploid cases. Spontaneous abortion occurred in one chromosomally normal fetus. Megacystis was found to resolve spontaneously by 20 weeks' gestation in 7 of the 11 chromosomally normal surviving cases (63%), of which 4 cases were found to have pyelectasis at 20 weeks persisting to the postnatal period in only 1 case. Of the remaining four chromosomally normal pregnancies repeat ultrasound examinations demonstrated progression, with two of the parents opting for termination, one after vesicocentesis indicated elevated urine calcium. Of the remaining two progressive cases, vesicoamniotic shunt was performed followed by spontaneous abortion within 1 week of the procedure in both cases.[99]

There has been some evidence showing that the cause of megacystis diagnosed in the first half of pregnancy may be more likely to be due to a functional obstruction from banding of the wolffian ducts as opposed to posterior urethral valves (the most common cause of LUTO diagnosed in the second half of pregnancy).[101] It has been hypothesized that sudden decompression with vesicocentesis may successfully relieve a functional obstruction of the urethra in these cases and should be the first line of therapy in progressing megacystis diagnosed in the first trimester; however, the evidence to support this theory is limited, and therefore, serial vesicocentesis for the resolution of megacystis remains investigative at this time. Additionally, urine biochemistry has been used to prognosticate which fetuses may benefit from vesicoamniotic shunting. However, current evidence suggests first trimester urine biochemistry does not correlate with prognosis which may, in part, be due to physiologic differences in first trimester fetal renal function and preclude the use of currently published urine biochemistry cutoff values in fetuses younger than 16 weeks. Further, vesicoamniotic shunts have been shown to be associated with a high rate of fetal loss when performed in the first trimester, and the benefit is questionable at this time.[99,102-104] The Prenatal Treatment of Lower Urinary Tract Obstruction (PLUTO) trial of LUTO, which was stopped early because of poor recruitment, did not show a significant benefit of vesicoamniotic shunting, but the trial was not focused on first trimester cases of LUTO.[105]

Extremities

Skeletal anomalies detected in the first trimester can vary greatly, ranging from osteochondrodysplasias to minor abnormalities such as polydactyly. Grande and colleagues found that the most common skeletal abnormalities detected in the first trimester among low-risk women were osteochondrodysplasias followed by limb-reduction defects and arthrogryposis, with detection rates of 86%, 57%, and 50%, respectively (Fig. 5-25). The authors also reported detection of minor skeletal abnormalities such as clubfoot, syndactyly, and polydactyly but with a much lower overall detection rate of 9%.[98]

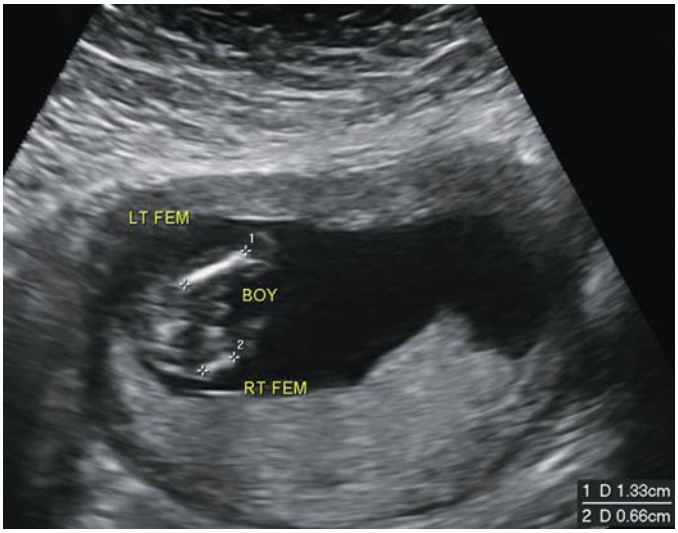

FIG 5-25 Right focal femoral (RT FEM) deficiency detected at 13 weeks' gestation. LT FEM, left femoral.

LIMITATIONS OF FIRST TRIMESTER FETAL ANATOMIC SURVEY

Despite great progress in the ability to perform a comprehensive fetal anatomic survey in the first trimester, several limitations must be mentioned. First, at the present time, most sonographers and physicians have only limited experience with complete anatomic evaluation in the first trimester. Second, even in experienced hands, several abnormalities develop and change throughout pregnancy and may not be appreciated in the first trimester. Major examples include congenital diaphragmatic hernia, skeletal dysplasias, and congenital heart defects such as cardiomyopathy and abnormalities of single ventricle physiology (i.e., hypoplastic left-sided heart syndrome), which may evolve from stenotic valves that can be difficult to appreciate in the first trimester.[106]

Also, several limitations are specific to first trimester fetal echocardiography. High termination rates have been reported in pregnancies with cardiac abnormalities identified in the first trimester; therefore, follow-up and confirmation rates remain low, at 20%, which makes true detection rates difficult to determine.[107] Even with recent advances in technology, the resolution of 4D STIC imaging remains in the range of 50 to 100 μm, and therefore, subtle differences that may be visible later in pregnancy, such as offset of the atrioventricular valves, may not be perceived in the first trimester. Additionally, Votino and colleagues demonstrated that 4D sonography is no better than 2D sonography for the detection of cardiac malformations in the first trimester.[87] The normal fetal heart is a developing organ that has demonstrable physiologic differences in the first trimester that could be falsely interpreted as normal or abnormal if we assume that baseline parameters for fetal cardiac structure and function developed in the second and third trimesters apply in the first trimester. For example, tricuspid regurgitation was present in the first trimester in 27% of fetuses that were later confirmed to have a normal heart.[82] Concerns regarding resource

utilization secondary to the time-intensive and technically challenging nature of fetal echocardiography have also been raised.[108] To counter this argument, Lombardi and colleagues demonstrated that with an initial investment of a 1-week intensive course, sonographers were able to reliably perform first trimester fetal echocardiogram in 10 minutes on average. However, the cost effectiveness of this strategy remains to be determined.[25]

DETECTION RATES

The overall detection rate of first trimester fetal anatomic survey for structural abnormalities reported in the literature varies greatly, from 17% to 90%.[109] Aside from the technical limitations including education and skill development, much of this heterogeneity exists because of study selection criteria.

There is no doubt that sonography is a valuable tool to assess first trimester fetal anatomy, but with the preceding limitations in mind, the controversial question to address is whether first trimester anatomic survey should be applied as a screening tool offered to all pregnancies or reserved for a selected group of high-risk patients. To answer this question, the Swedish Nuchal Translucency (NUPP) trial randomized patients to one routine ultrasound examination either at 12 to 14 weeks or at 18 weeks. The authors found no statistically significant difference in overall detection rates for fetal anomalies among pregnancies with normal chromosomes in the first trimester compared to the second trimester (20% vs. 25%, $P = 0.11$). These detection rates were noted to be low in contrast to the U.S. RADIUS trial (35%).[54] RADIUS randomized women to receive two ultrasound screening examinations at 18 to 20 weeks and at 31 to 33 weeks, which may account for the improved detection rates. The NUPP trial did demonstrate that detection rates for lethal or severe anomalies improved, but again, they did not differ between the first versus the second trimester groups (38% vs. 47%, $P = 0.06$). Of note, lethal anomalies were detected at the initial 12- to 14-week ultrasound examination in 69% of fetuses in the early ultrasound examination group.[78] This study was not powered to find significant differences in detection rates of specific anomalies, but the group published an additional analysis of the NUPP trial to examine detection rates of major congenital heart malformations.[80] Overall, detection rates for cardiac abnormalities were low and did not differ between the 12- to 14-week group and the 18-week group (11% vs. 15%, $P = 0.60$). Only a limited cardiac examination was performed in which the four-chamber view was the only obligatory view and evaluation of the outflow tracts was not required, which may account for the low detection rates compared to cardiac evaluation that includes the outflow tracts.[84] Referral for echocardiogram was made if the four-chamber view was difficult to interpret or abnormal, if the nuchal translucency was 3.5 mm or greater, or first trimester trisomy 21 risk was 1:250 or greater and the chromosomes were normal or karyotype was declined.

To date, two systematic reviews with diagnostic meta-analyses have been published which report similar pooled detection rates for first trimester ultrasound examination to detect anatomic abnormalities of about 50% (45.2% and 51%).[109,110] Rossi and Prefumo demonstrated varying detection rates depending on the location of the anomaly[110] (Table 5-4). The detection of cardiac abnormalities was higher in fetuses that underwent focused fetal echocardiogram compared to those that underwent anatomic survey alone (53% vs. 43%, $P = 0.040$). In addition, the authors found that the use of Doppler did not seem to imrove detection rates (52% vs. 44%, $P = 0.11$). Heterogeneity due to population differences was also explored, and as expected, detection in a high-risk population was significantly better than detection in a low-risk population (65% vs. 50%, $P < 0.001$).

TABLE 5-4 First Trimester Detection Rate by Location of Fetal Anomaly

Location of Anomaly	Detection Rate*
Neck	92%
Abdomen	88%
Brain and spine	51%

*Modified from Rossi AC, Prefumo F: Accuracy of ultrasonography at 11-14 weeks of gestation for detection of fetal structural anomalies: a systematic review. Obstet Gynecol 122(6):1160-1167, 2013.

COST EFFECTIVENESS

Overall, there is limited quality evidence on the cost effectiveness of ultrasound surveillance for the detection of fetal anomalies.[111] It should be kept in mind that a majority of studies evaluating first trimester fetal anatomy go on to offer additional ultrasound screening in the second trimester. In a prospective cross-sectional study of unselected women undergoing first trimester sonographic screening of fetal anatomy, Roberts and associates[111] estimated the cost of such screening in their unit in 1999 was £7470 (USD $9268.22) per case for detecting fetal aneuploidy and £6258 (USD $7764.46) per case for detecting structural abnormalities. In our experience these estimates are low; the cost of first trimester sonography in our perinatal laboratory in the midwestern United States in 2014 is $170 compared to £33 (USD $40.94) used by the authors to generate their cost estimates (based on 2014 exchange rates).

At this time, the current evidence does not support routine anatomic screening with ultrasound in the first trimester, and first trimester fetal anatomic evaluation should be reserved for a selected population of high-risk patients, such as those with a significant family or genetic history or prior child with a structural anomaly, poorly controlled diabetes, teratogen exposure, or increased nuchal translucency thickness. Additionally, there is evidence that second trimester anatomic evaluation is difficult in women with a body mass index higher than 40 kg/m^2.[112-114] First trimester anatomic evaluation may be improved while the uterus remains low in the pelvis, which facilitates abdominal imaging below the pannus and may be additionally aided with the use of transvaginal imaging.

SAFETY

Ultrasound is generally considered to be safe in pregnancy, but as a source of energy, it does have the potential for biological harm.[115] Unfortunately, human data on the safety of ultrasound are limited. In a World Health Organization (WHO) systematic review on the safety of ultrasound, the authors reviewed clinical trials, case control studies, and cohort studies reporting any long-term or short-term effects of ultrasound exposure.[116] Of over 6000 citations identified, 61 studies were reviewed, and not a single study included evaluation of ultrasound safety as a specific objective.[116] In general, the thermal index should be kept below 1, and the ALARA principle should be respected, reserving ultrasound use to clinically indicated situations, for the shortest duration with the lowest amount of acoustic energy to achieve an accurate diagnosis.[29] The thermal index is the amount of energy required to raise tissue temperature by 1° C, and the American Institute of Ultrasound in Medicine recommends the use of a thermal index for

soft tissue (TIS) prior to 8 weeks and a thermal index for bone (TIB) at 8 weeks or greater when bone ossification is identified.[117] The first trimester fetus is particularly vulnerable to teratogenicity, and the use of color Doppler ultrasound increases the acoustic energy exposure such that safe levels can easily be exceeded if one is not cautious. Therefore, when fetal anatomic survey is performed in the first trimester it is particularly important to be mindful of ultrasound safety and respect the ALARA principle.

CONCLUSIONS

As ultrasound technology has continued to advance, our ability to reliably assess the fetal anatomy in the first trimester has come to parallel that of the second trimester in experienced hands. Complete, detailed, fetal anatomic assessment including fetal echocardiography is possible in the first trimester, but at the current time, controversy exists surrounding the application of this tool. Although routine first trimester anatomic screening has not been shown to improve detection rates compared to second trimester anatomic screening, the cost effectiveness of such a screening strategy also remains unproved.[78]

Fetal Biometry and Growth

Carol B. Benson, Peter M. Doubilet

SUMMARY OF KEY POINTS

- In the first trimester, gestational age should be assigned to the pregnancy based on sonographic findings or mean sac diameter prior to the visualization of the embryo and by embryonic or fetal crown-rump length (CRL) thereafter.
- In the second trimester, gestational age should be assigned based on head measurements that take into account head shape—namely, the corrected biparietal diameter or head circumference (HC)—or a composite age formula.
- By the latter part of the third trimester, neither dating by ultrasound nor dating by last menstrual period (LMP) is very accurate.
- Once gestational age has been assigned by an accurate method, such as sonography, the pregnancy should not be redated nor should the estimated due date be changed, because the earlier the gestational age is determined, the more accurate the dating of the pregnancy.
- Estimating fetal growth is best performed through estimating fetal weight and weight percentile, starting in the latter part of the second trimester and during the third trimester.
- The diagnosis of fetal growth restriction (FGR) should be suspected if the estimated weight falls below the 10th percentile for gestational age.
- The diagnosis of fetal macrosomia is suspected when the estimated fetal weight (EFW) is greater than 4000 g in a diabetic patient and above 4500 g in a nondiabetic patient.
- The diagnosis of a large for gestational age fetus is suspected when the EFW is above the 90th percentile for gestational age.
- In addition to its role in assessing gestational age and monitoring growth, fetal biometry is also important for identifying fetal abnormalities that are characterized by abnormal size of specific body parts, such as long bones with skeletal dysplasias.

OUTLINE

Sonographic measurements of fetal structures provide an accurate means of determining the age of a pregnancy, estimating fetal weight, and assessing the normality of a number of fetal body parts. This chapter will discuss various fetal measurements and how they are used to date pregnancy, monitor fetal growth, diagnose fetal growth disturbances, and diagnose fetal abnormalities that are characterized by abnormal size of specific fetal structures.

Gestational age is the term most commonly used for specifying the age of a pregnancy. Prior to the advent of sonography, gestational age referred to the time elapsed since the first day of the woman's last menstrual period (LMP). This is also termed *menstrual age*. With the development of means of dating pregnancies that are often more accurate than LMP, the term *gestational age* is no longer tied to the LMP. Instead, it refers to the time since the estimated conception date plus 2 weeks. Because women typically conceive at or close to 2 weeks after their LMP, gestational age and menstrual age are generally the same, but gestational age is a more accurate measure of the age of the pregnancy than is menstrual age in a woman with irregular cycle length. Full term is 40 weeks' gestational age. The *estimated due date* (EDD) or *estimated date of confinement* (EDC) is calculated as the date at which the gestational age of a pregnancy will reach 40 weeks.

Another term sometimes used to date pregnancy is *conceptional age*, defined as the time since the date of conception. In some situations, such as in patients conceiving through *assisted reproductive techniques* (ART), conceptional age can be determined very accurately. In these cases, gestational age is equally accurate, because it is equal to the precisely known conceptional age plus 2 weeks. To avoid using different terms for dating pregnancies in ART patients, the term *gestational age* is the preferred term for dating all pregnancies, regardless of the mode of conception.[1]

Accurate dating of pregnancy is extremely important for managing the obstetric patient, as many clinical decisions during pregnancy are dependent on gestational age. In the first trimester, the timing of prenatal testing for fetal chromosomal abnormalities is gestational age

dependent. For assessment of some fetal structures, gestational age must be taken into account when distinguishing some normal from abnormal findings. For example, protrusion of intra-abdominal contents into the base of the umbilical cord can be a normal finding prior to 12 weeks' gestation (physiologic bowel herniation) but is abnormal in the second trimester, when it represents an omphalocele.[2] In the second trimester, selecting the best time to perform the sonographic fetal survey to assess for anomalies requires knowledge of the gestational age.[3] Accurate dating is also important to determine if a fetal structure is abnormal in size. For example, if the femur is small for gestational age, concern for Down syndrome or a skeletal dysplasia should be raised.[4,5] In the third trimester, accurate dating is needed to diagnose and manage preterm labor and to diagnose postterm pregnancies and determine when intervention is required.

Accurate assignment of gestational age is also essential for assessing fetal growth, because a key method for assessing growth is determining whether the EFW is within the normal range for gestational age or abnormally low or abnormally high. Abnormally small fetuses may require increased prenatal surveillance[6,7] and possibly early delivery. Cesarean delivery may be appropriate for fetuses measuring abnormally large for gestational age.[8,9]

ASSIGNMENT OF GESTATIONAL AGE

The gestational age of a pregnancy can be assigned based on either clinical factors or sonographic findings. In general, clinical factors, such as LMP or uterine size estimation, are less accurate than ultrasound for dating pregnancies. Dating based on LMP is fraught with inaccuracies, including incorrect recall, irregular menstrual cycles, menstrual cycles longer or shorter than 28 days,[10-12] and variable timing of ovulation during the cycle.[13] Dating based on physical examination assessment of uterine size is even less accurate than LMP, because the assessment of uterine size is affected by body habitus as well as myomas and other uterine abnormalities.

Dating by ultrasound, particularly before the third trimester, is generally more accurate than clinical dating by LMP or physical examination.[10,11,14,15] One exception in which clinical information is more accurate than ultrasound for dating is in pregnancies conceived by ART. Such pregnancies can be dated very accurately because the exact date of conception is known. Based on that date of conception, gestational age is assigned as the number of weeks since known conception plus 2 weeks.[1]

Once gestational age has been assigned by sonography or by clinical information in an ART patient, the pregnancy should not be redated nor should the EDD be changed. This is because the earlier in pregnancy the gestational age is determined, the more accurate the dating of the pregnancy.[11,16,17] Selecting the appropriate sonographic method for dating pregnancy depends on how far along the pregnancy is, and therefore, dating for each trimester will be discussed separately.

FIRST TRIMESTER DATING

Early in the first trimester, before the embryo is visible, gestational age can be assigned based on transvaginal sonographic findings. The earliest sonographic finding of pregnancy is a small rounded intrauterine fluid collection in the central portion of the uterus.[18-23] The fluid collection may or may not demonstrate the intradecidual sign[18,19] or the double sac sign.[24] When ultrasound demonstrates an intrauterine fluid collection with no visible yolk sac or embryo, the pregnancy can be accurately assigned a gestational age of 5.0 weeks. When the fluid collection contains a yolk sac but no embryo, the pregnancy can be accurately assigned a gestational age of 5.5 weeks. The presence of a small embryo, less than 2 mm in size, with the embryonic heartbeat visible adjacent to the yolk sac, can be accurately dated as 6.0 weeks' gestation (Fig. 6-1). The accuracy of these early sonographic milestones for dating pregnancy is ±0.5 week.[22-24]

An alternate method for dating early pregnancy is to measure the mean sac diameter of the gestational sac. This is done by averaging the sagittal, coronal, and anteroposterior measurements of the fluid component of the gestational sac (Fig. 6-2) and assigning gestational age based on published tables (Table 6-1) or formulas.[25-27] Dating by mean sac diameter very early in pregnancy has similar accuracy to dating by sonographic milestones.[21,23,25,26,28] However, once the embryo is large enough to measure, dating based on the size of the embryo is more accurate than using the mean sac diameter.[11,29]

From the time the embryo is visible until the end of the first trimester, dating is based on the length of the embryo or fetus, measured from the top of the head to the bottom of the rump, the CRL. Gestational age is assigned based on CRL by using published formulas or tables (Table 6-2).[27,29-32] Dating by CRL is more accurate in the early first trimester, when accuracy is ±0.5 week, than toward the end of the first trimester, when accuracy approaches ±1.0 week.[27-33] Care must be taken to measure the CRL correctly, particularly toward the end of the first trimester. The fetus should be in neutral position, neither hyperextended nor hyperflexed with the chin tucked against the chest. The calipers should be placed at the top of the fetal head and the bottom of the rump, making sure not to include the yolk sac or lower extremities in the measurement (Fig. 6-3).[28-32]

When dating a pregnancy during the first trimester, sonography is more accurate than LMP.[14,15] However, it is acceptable to use the LMP to date a pregnancy if the LMP is certain and the difference between gestational age by LMP and gestational age by first trimester sonography is less than 7 days.[11]

SECOND AND THIRD TRIMESTER DATING

Measurements

During the second and third trimesters of pregnancy, measurements of specified fetal parts can be used individually or in combination to estimate gestational age of the pregnancy. The most commonly used measurements for gestational age assignment are the biparietal diameter (BPD), occipitofrontal diameter (OFD), head circumference (HC), abdominal diameter (AD), abdominal circumference (AC), and femur length (FL).

The BPD, OFD, and HC are measured on an axial image of the fetal head at the level of the paired thalami, third ventricle, and cavum septum pellucidum (Figs. 6-4 and 6-5).[34,35] With a true axial view, the calvarium and intracranial contents appear symmetric on either side of the falx and paired thalami. The BPD is measured by placing the caliper closer to the transducer (i.e., at the top of the image) at the outer edge of the bony calvarium, while the caliper farther from the transducer should be placed on the inner edge of the bony calvarium. That is, the BPD is measured from leading edge to leading edge of the calvarium.[34,36] Improper measurements, either from using an image at an incorrect plane of section through the fetal head or from misplacement of the sonographic calipers, will lead to errors in estimating gestational age and fetal weight.

The OFD and HC can be measured on the same view of the fetal head as the BPD, provided the image is a true axial view that includes the entire head from the frontal bone to the occipital bone. For the OFD measurement, one caliper is placed in the anterior midline in the middle of the echogenic line of the frontal bone, and the second is placed posteriorly in the middle of the echogenic line of the occipital bone.[34,36] The HC is measured by using elliptical calipers to outline the

outer edge of the skull (see Figs. 6-4 and 6-5A). The HC can also be calculated from the BPD and OFD:

$$HC = 1.62 \times (BPD + OFD)$$

This formula is based on the circumference of an ellipse with diameters BPD and OFD with a correction factor because these diameters are not outer-to-outer.[36-38]

The OFD is also used in conjunction with the BPD to take into account the shape of the fetal head. A standard-shaped fetal head has an OFD:BPD ratio of 1.265. When the OFD:BPD ratio is higher or lower than 1.265, a corrected BPD can be calculated with the formula:

$$\text{Corrected BPD} = \text{square root of } [(BPD \times OFD)/1.265]$$

The corrected BPD represents the BPD of a standard-shaped fetal head with the same cross-sectional area.[38]

The AD and AC are measured on an axial image of the fetal abdomen at the level of the stomach and intrahepatic portion of the umbilical vein.[36,39,40] The abdomen should be as round as possible, and the outer skin surface should be visible all the way around. For the AD, two perpendicular measurements are taken with the calipers placed on the outer surface of the skin. The anteroposterior AD is measured from the anterior midline to the posterior midline, the latter behind the spine. The transverse AD is measured perpendicular to the anteroposterior AD, with calipers placed on the skin surface on both sides of the fetal abdomen (Fig. 6-6). The AC is measured via elliptical calipers outlining the outer surface of the skin around the abdomen (Figs. 6-6 and 6-7). The AC can also be calculated from the two orthogonal AD measurements as:

$$AC = 1.57 \times (\text{anteroposterior AD} + \text{transverse AD})$$

When measuring the fetal abdomen, care must be taken to make sure the image is at the correct level, the entire abdomen is included on the image, the outer skin surface is visible, and the calipers are placed appropriately. Images showing part of a kidney are too low in the abdomen and will yield inaccurate estimations of fetal age and weight. Misplacement of the calipers inside the fetal skin layer or the abdomen will lead to underestimation of the gestational age and weight.[41,42]

The measurement of the fetal femur is actually a measurement of the femoral diaphysis, because, for most of pregnancy, only the diaphysis of the bone is ossified. For most accurate femur measurements, an attempt should be made to image the femur as perpendicular to the ultrasound beam as possible. On the image, the femur is measured by placing the calipers at either end of the ossified diaphysis (Figs. 6-8 and 6-9). It is important not to include any of the femoral epiphysis, which can appear as a linear projection from the proximal or distal end of the diaphysis.[36,43]

Assigning Gestational Age in the Second and Third Trimesters

In the second and third trimesters, gestational age can be assigned based on a single measurement, such as the BPD, corrected BPD, HC, or FL (Tables 6-3 through 6-5), or on a combination of measurements, such as with composite age formulas. Head measurements that take into account the shape of the fetal head—namely, the corrected BPD

FIG 6-3 Crown-rump length measurement. Sonogram of fetus in gestation sac with crown-rump length measured (*calipers*). The yolk sac (*arrow*) is visible adjacent to the fetus, not included in the crown-rump length measurement

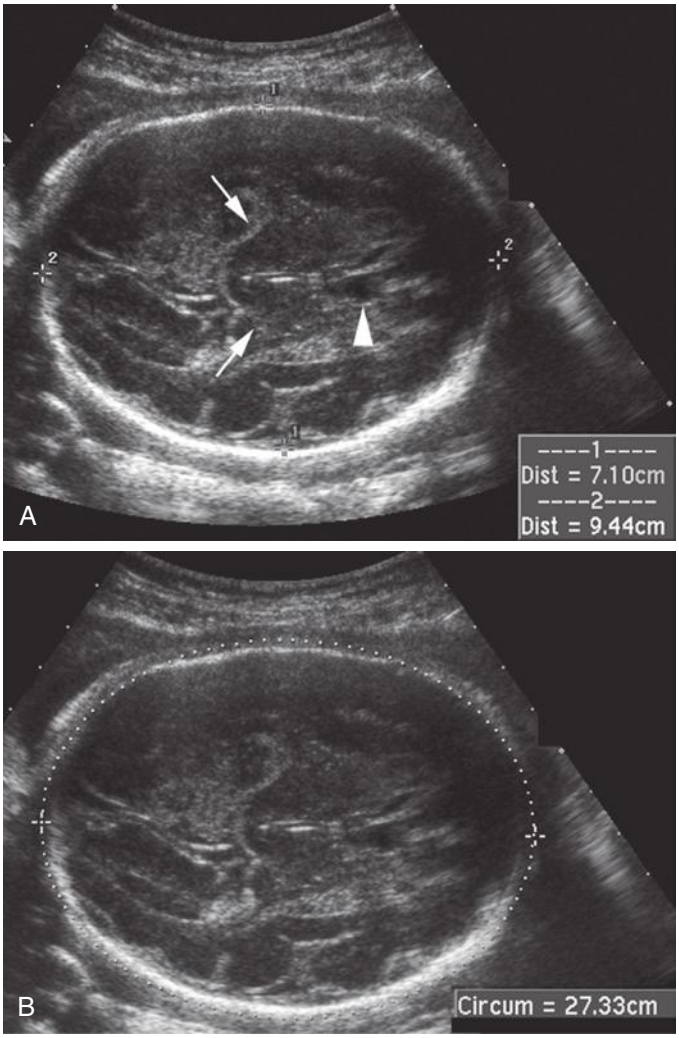

FIG 6-4 Head measurements. **A,** Axial image of fetal head at the level of the paired thalami (*arrows*), third ventricle, and cavum septum pellucidum (*arrowhead*), with biparietal diameter (*calipers 1*) and occipitofrontal diameter (*calipers 2*) measured. **B,** Head circumference measured with elliptical caliper tracing (*dotted line*) on the same image used to measure the biparietal and occipitofrontal diameters.

and the HC—are more accurate than the BPD alone or FL alone in the second trimester. Accuracy of the corrected BPD and the HC before 20 weeks is approximately ±1.2 weeks.[44-46] As pregnancy progresses, the accuracy of all measurements decreases, such that, by the end of the third trimester, the accuracy of gestational age estimation by head measurements is about ±3.5 weeks (Table 6-6).[44-46] Although head measurements are more accurate than FL in the second trimester, by the third trimester, the accuracy of the FL is similar to that of head measurements. The AC is a poor predictor of gestational age, particularly later in pregnancy, and should not be used on its own to assign gestational age.

Composite age formulas estimate gestational age via two or more fetal measurements,[47-49] such as the BPD, HC, FL, and AC. The accuracy of gestational age estimation using these composite age formulas is similar to the accuracy of the corrected BPD and HC and is more accurate than age estimation using the FL.[44,46,50] One drawback of using the composite gestational age formulas is the potential to miss an abnormal measurement or anomaly. For example, if the fetal head is abnormally small and the FL and AC are normal for gestational age, the composite age formula that incorporates measurements of the BPD, HC, FL, and AC will be an underestimation of the true age. In such cases, the interpreter of the sonogram might not recognize that the head is abnormally small, because its size might be within the normal range for the calculated gestational age, an underestimate.

Therefore, when the first ultrasound examination during pregnancy is in the second trimester, the best approach to assigning gestational age at that time is either to use a head measurement that takes into account head shape—namely, the corrected BPD or HC—or to use a composite age formula. Both have similar accuracy during the second trimester of about ±1.2 weeks early in this trimester and approximately ±2.0 weeks by the end of the trimester.[44-46] When the first ultrasound examination is not until the third trimester, any of the corrected BPD, HC, or FL can be used to assign gestational age, or a composite age formula can be used. However, caution must be used when assigning gestational age this late in pregnancy because of the broad error range of more than ±3.0 weeks.[11,44-46]

An acceptable alternative to sonographic dating in the second trimester is to use the LMP to date the pregnancy when the difference in gestational age by LMP and gestational age by ultrasound is less than 10 days. Similarly, for dating in the early third trimester, up until 28 weeks' gestation, it is acceptable to date by the LMP if the age difference between dating by LMP and dating by ultrasound is less than 14 days.[11] By the latter part of the third trimester, neither dating by ultrasound nor dating by LMP is very accurate.[11]

As mentioned previously, once the gestational age has been assigned based on sonographic findings or measurements, the dating should not be changed based on measurements of the fetus on subsequent examinations. Rather, measurements on subsequent sonograms should be assessed to ensure that the fetus is growing appropriately and that all measurements are within normal limits for gestational age.

FETAL WEIGHT ESTIMATION AND WEIGHT PERCENTILES

Fetal weight is estimated using a formula based on fetal measurements. Each formula was developed using a population of fetuses scanned close to the time of delivery by assessing the sonographic measurements in relation to birth weight. Numerous weight estimation formulas have been developed[51-57] and tested.[58-61] From these studies testing various formulas, several conclusions can be drawn.

- Formulas that use measurements of the fetal head, abdomen, and femur have a mean error of 15% (±2 standard deviations [SDs]).[62] Formulas that use fewer than three measurements of fetal body parts perform less well (i.e., have larger standard deviations).
- Adding other measurements to the head, abdomen, and femur, such as the thigh circumference or thickness of thigh soft tissue[63,64] or three-dimensional volume calculations,[61,65-67] does not improve accuracy of weight estimation.
- Despite considerable improvements in sonographic equipment, the accuracy of estimating fetal weight has not changed since the development of formulas 3 decades ago.[58-61,68,69]

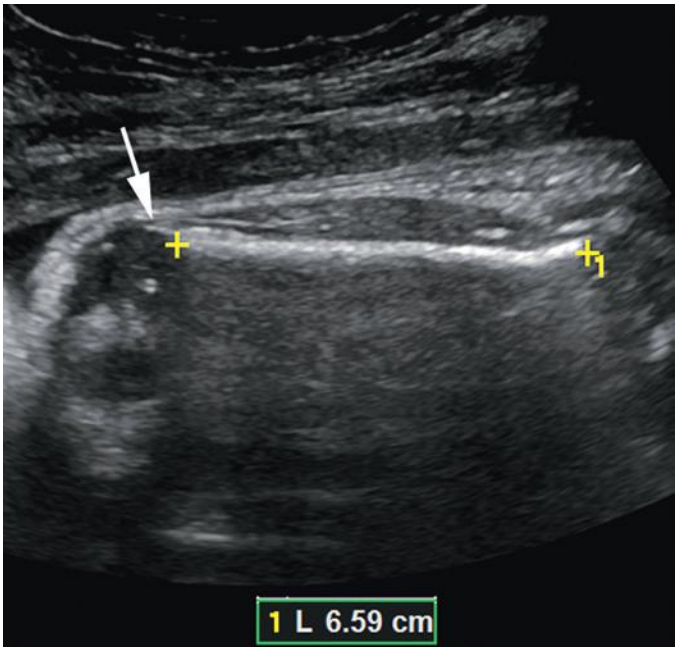

FIG 6-8 Femur length measurement. Sonogram of femur with ossified diaphysis measured (*calipers*). The linear projection from the diaphysis of the femoral epiphysis (*arrow*) is not included in the measurement.

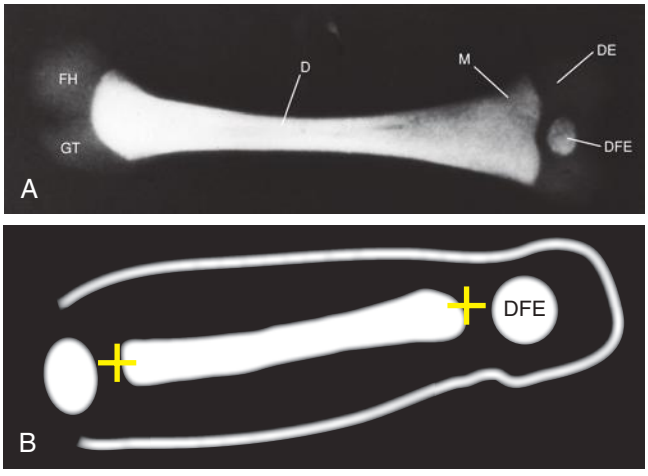

FIG 6-9 Radiograph (**A**) from a term neonatal autopsy specimen and illustration (**B**) of the femur. Sonographic measurements of the "femur" include only the ossified portion of the diaphysis (D) and metaphysis (M). The cartilaginous femoral head (FH), greater trochanter (GT), and distal epiphysis (DE) are not included in the measurement. When it ossifies, the distal femoral epiphyseal (DFE) secondary ossification center is also not included in the measurement.

- Formulas designed for singletons can also be used for estimating weight in twin gestations, because formulas developed specifically for twins are no more accurate than those developed for singletons.[61,70]
- The accuracy of fetal weight estimates is not affected by maternal body mass index or fetal sex,[61] nor is it affected by oligohydramnios or polyhydramnios.[41,53,71,72]
- Fetal weight estimation is less accurate in diabetic mothers than in nondiabetic mothers[73] and less accurate in very small fetuses (i.e., those weighing less than 1000 g).[41]
- The intraobserver and interobserver variability is high for fetal weight estimation. Higher quality scans result in more accurate weight estimation.[41,42] Thus, attempts should be made to minimize this variability by averaging several measurements of each body part, using careful measurement techniques and optimizing image quality such that anatomic landmarks are clearly visible.[61]

Among the most widely used formulas for estimating fetal weight are those published in 1985 by Hadlock and colleagues (Table 6-7).[56] These formulas have been tested by multiple authors. Although attempts have been made to improve fetal weight prediction with other

formulas, none has been developed that outperforms the Hadlock formulas consistently and across all types of patient populations.[58-62,68-73]

Fetal size in proportion to that expected for age is assessed by comparing the EFW to norms for gestational age. The metric used for this purpose is the weight percentile. Determining the weight percentile, once the gestational age has been established and the fetal weight estimated, is accomplished using published formulas or tables (Table 6-8).[74-77] Selecting the most appropriate table is important for making sure the weight percentiles apply to the population being scanned. Because babies are born larger than they were several decades ago, newer tables, such as that published by Alexander and associates in 1991,[75] are likely better than older ones.[76,77] Those based on more accurate sonographic dating are likely to be even better[74,78] than those in which dating may be less precise. However, even weight tables based on known birth weights and gestational age have an important drawback. Prior to term, the weight percentiles do not reflect those of normal fetuses but rather reflect those of preterm neonates. Because neonates born premature are smaller than fetuses of the same gestational age who will remain in utero until term, the weight tables based on neonatal birth weights contain lower weights at each percentile than what is likely the norm.[79-81]

Estimating fetal size for gestational age via weight percentile is best performed in the latter part of the second trimester and during the third trimester. Prior to this time, weight estimation is less accurate.[41,61-68] The fetal weight percentile is used to assess whether or not the fetus is growing appropriately. Appropriate weight percentiles are those between the 10th and 90th percentiles for gestational age. An EFW below the 10th percentile is concerning for an abnormally small fetus, which may be due to FGR. An infant with a birth weight below the 10th percentile is termed *small for gestational age* (SGA), and one above the 90th percentile is termed *large for gestational age* (LGA).[82]

Fetal interval growth from one ultrasound scan to the next can be estimated to make sure the fetus is gaining weight at an appropriate rate. Because of the wide 95% confidence interval of fetal weight estimation of ±15% (2 SDs), assessment of fetal growth between two sonograms should be performed after an interval of at least 7 days. Normal fetuses grow fairly steadily from 30 to 40 weeks' gestation at a rate of approximately 220 g per week. After 40 weeks, the growth rate declines.[74,76] The fetal growth rate from one examination to the

next can be calculated by taking the difference between the two estimated weights and dividing by the number of weeks that have elapsed.

Another way to assess fetal interval growth is to compare the weight percentiles from one sonogram to the next. If the weight percentiles for gestational age are similar from one examination to the next, the fetal growth is likely to be normal. If, however, the weight percentile falls considerably between two examinations, concern should be raised that the fetus is not growing appropriately.

ABNORMAL FETAL GROWTH

Fetal Growth Restriction and Small for Gestational Age Fetuses

The term *fetal growth restriction* is used to describe a fetus that is abnormally small for gestational age, often due to complications of placental insufficiency. The term *small for gestational age* (SGA) is used to describe a neonate whose weight falls below the 10th percentile for gestational age. FGR fetuses are at increased risk of perinatal morbidity and mortality, including in utero demise,[83,84] brain injury, fetal distress,[85] neonatal hypothermia, hypoglycemia, hyperbilirubinemia, and decreased immune function.[86-93] When FGR is diagnosed prenatally and close fetal monitoring is instituted, including nonstress tests, biophysical profiles, and umbilical artery Doppler, the neonatal outcome is better than that of neonates born with FGR that were not diagnosed prenatally.[6,7,83,94-96]

The terms FGR and SGA are often used interchangeably because the most common definition of FGR is a neonate with birth weight below the 10th percentile for gestational age, the same as the definition of SGA.[6,84,94,95] In utero, SGA and FGR are diagnosed when the EFW is below the 10th percentile for gestational age. Although some have tried to differentiate SGA fetuses who are constitutionally small but are achieving their expected growth potential from FGR fetuses whose

growth is compromised, in practice it is often difficult to make this distinction.[97] It has been shown that the smaller the fetal size for gestational age, the greater the likelihood that fetal growth is compromised.[83] SGA neonates have significantly higher postnatal mortality rates in the first week of life, the first month of life, and the first year as compared to neonates who are appropriate or LGA.[98] Thus, identification of a small fetus (i.e., one whose weight is below the 10th percentile for gestational age) will identify fetuses at risk of being FGR neonates and prompt close surveillance in an attempt to improve outcome.[6,85,96-98]

Although the diagnosis of FGR in utero is most often made based on an EFW below the 10th percentile,[94,95,97,98] not all such fetuses truly have FGR. Because of this, a number of other sonographic criteria have been proposed to improve the accuracy of diagnosing FGR prenatally. However, none of these criteria, including the EFW percentile, has both a high sensitivity and high positive predictive value. The EFW, for example, has a fairly high sensitivity of 89% for FGR, but its positive predictive value is only 45%.[99] Using multiple parameters can improve the sensitivity and positive predictive value of sonographic diagnosis of FGR.[100-102] One method for predicting FGR using multiple parameters is the FGR score, which incorporates EFW, amniotic fluid volume, and maternal blood pressure status (normal vs. hypertensive) to diagnosis or exclude FGR with high sensitivity and positive predictive value.[100,101] For each week of data on gestation, amniotic fluid volume classification, and maternal blood pressure status, the table presents an EFW range. For a particular fetus, if the EFW is below the lower end of the EFW range, then the fetus can be confidently diagnosed with FGR. If the EFW is above the upper end of the range, FGR can be excluded with confidence. If the EFW falls within the range, the likelihood of FGR is elevated but indeterminate, because FGR cannot be diagnosed or excluded with confidence. These combined criteria perform even better if the pregnancy has accurate early dating with first trimester ultrasound than if dating was assigned later in pregnancy. In those pregnancies with first trimester dating, only the lower value in the EFW range is used, with a diagnosis of FGR made with confidence if the EFW is below the lower EFW number and excluded with confidence if the EFW is above the lower EFW number.[100,101]

Doppler criteria, including umbilical and uterine artery Doppler measurements, have previously been suggested for diagnosing FGR. However, all proposed Doppler criteria have low sensitivities and positive predictive values and, therefore, are not reliable for diagnosing FGR.[6,97,103,104] In a fetus already suspected of being growth restricted, however, umbilical artery Doppler is useful for fetal monitoring and for guiding management decisions[6,83,94,95,97] (see Chapter 22).

When a fetus is diagnosed with FGR, attempts should be made to determine the cause. Maternal factors should be considered, including genetic and nutritional factors, as well as medical diseases, such as hypertension, vasculitis, and renal disease.[97,105] Fetal abnormalities should be investigated, including fetal anomalies and aneuploidy.[107] Lastly, placental abnormalities, such as circumvallate placenta or velamentous cord insertion, or an abnormally invasive placenta with accreta, can be the cause of FGR.[105]

Macrosomic and Large for Gestational Age Fetuses

The term *macrosomia* is defined as a large neonate with a birth weight above a defined value such as 4000 g or 4500 g, independent of gestational age. The term *large for gestational age* is used to describe a neonate with birth weight above the 90th percentile for gestational age.[74,106-111] Macrosomic fetuses are at increased risk of shoulder dystocia, birth injury, and neonatal hypoglycemia and have a lifelong increased risk of obesity.[82,109,110] Accompanying the fetal and neonatal risks are maternal risks, including anal sphincter tears and postpartum hemorrhage.[109] The higher the birth weight, the greater the risks. Identifying a fetus as macrosomic prior to delivery can direct management decisions regarding delivery, often prompting cesarean delivery when appropriate.[80,109,111-115]

Infants of diabetic mothers have different body proportions than those of nondiabetic mothers, such that their shoulders and trunk tend to be bigger compared to their head size, because of overgrowth of internal organs and increased subcutaneous fat. Thus, fetuses of diabetic mothers have a higher rate of perinatal complications, including shoulder dystocia, for the same birth weight.[112,116-118] As a result, some advocate defining macrosomia in diabetic mothers as greater than 4000 g, whereas they may define macrosomia in nondiabetic mothers as greater than 4500 g.[109,112-114] LGA fetuses are at increased risk of the same fetal and maternal complications as macrosomic fetuses, particularly when they are carried to term.[106,112,116,119]

The prenatal diagnosis of macrosomia relies on the EFW. A weight above 4500 g in a nondiabetic mother or a weight above 4000 g in a diabetic mother suggests macrosomia.[82,109,112-114] The prenatal diagnosis of LGA, like macrosomia, relies on the EFW as well as reliable dating. An EFW above the 90th percentile for gestational age suggests an LGA fetus.

Although sonographically EFWs are somewhat imprecise, using the EFW is still the best way to predict macrosomia and LGA, and better than physical examination or maternal estimates of fetal size.[82,109,110] This holds true despite the fact that EFWs are less precise in diabetic mothers than nondiabetic mothers and less accurate in large fetuses than in those who are average size.[73,82,120-123]

In addition to EFW and fetal weight percentile, a number of other criteria have been proposed to predict LGA and macrosomia. However, none of these proposed criteria has both a higher sensitivity and higher positive predictive value than the EFW.[106,120,121,124-129]

FETAL ANOMALIES ASSOCIATED WITH ABNORMAL BIOMETRY

In addition to its role in determining gestational age and evaluating fetal size and growth, fetal biometry is important for identifying a number of abnormalities that are characterized by abnormal size of individual fetal structures. Examples include skeletal dysplasias, many of which are associated with abnormally small bones, and microcephaly, in which the head size is small. Furthermore, fetal biometry can assist in the diagnosis of trisomy 21 and other forms of aneuploidy.

When interpreting an obstetric ultrasound image, it is important to assess the normality of all individual body parts that are measured. In addition, a number of measurement ratios, including the HC : AC ratio,[130,131] the FL : AC ratio,[132-134] the BPD : FL ratio,[4,135] and the BPD : HL ratio,[136-138] can be helpful for detecting fetal abnormalities. Once calculated, these ratios can be compared to the norm for gestational age to help identify abnormal measurements within the fetal biometry.

If fetal head measurements are small, such that the HC falls more than 2 SDs below the mean for gestational age, concern for microcephaly should be raised. The smaller the head is for gestational age, the more likely it is that the neonate will be microcephalic at birth and have associated neurologic deficits.[139-141]

Each time the FL is measured, its size should be compared to norms for gestational age. In the second trimester, an FL below the 10th percentile for gestational age has been associated with Down syndrome[136,142] and should prompt further investigation into the likelihood of Down syndrome in the fetus. A very short femur, one falling more than 2 SDs below the mean for gestational age, raises concern for a skeletal dysplasia or FGR, with the latter much more often the

cause than the former.[143,144] An extremely short femur, one falling more than 4 SDs below the mean for gestational age, is usually the result of a skeletal dysplasia.[145-147] In such cases, the other long bones should be assessed for size by comparing their measurements to norms for gestational age,[148,149] and all long bones should be examined for fractures or bowing.[145-147]

The humeral length can also be used as a marker for Down syndrome. In particular, a humeral length that is small compared to the BPD is associated with an increased risk of Down syndrome.[136-138] The fetus should be examined for other markers, such as an absent or small nasal bone.[150,151]

Abnormalities of a single long bone or several bones in one limb can be diagnosed with ultrasound. Such abnormalities may be isolated or may represent one characteristic of a broader syndrome. For example, a very short or hypoplastic radius is associated with a variety of syndromes, including Holt-Oram, Nager, and vertebral defects, anal atresia, cardiac defects, tracheo-esophageal fistula, renal anomalies, and limb abnormalities (VACTERL).[152,153]

Tables and formulas listing normal measurements for gestational age of a variety of other fetal structures beyond the head, abdomen, and femur have been developed, including other long bones in the extremities,[148,149] the clavicle,[154,155] the foot,[156,157] and binocular distance,[158,159] as well as nonbony structures, such as the cerebellum,[160,161] and others.[162,163] (see Appendices). These tables and formulas can be used when evaluating a fetus for anomalies. For example, a binocular distance abnormally small for gestational age is called *hypotelorism*, an anomaly often associated with holoprosencephaly.

CONCLUSION

In summary, pregnancy dating is important for optimal obstetric care, and sonography is the most accurate method for assigning gestational age. The earlier in pregnancy that gestational age is assigned with ultrasound, the more accurate is the dating of the pregnancy. Once assigned, the pregnancy should not be redated and the EDD should not be changed. Beginning in the late second trimester and thereafter, fetal biometry should be used to estimate fetal weight and calculate the fetal weight percentile. An EFW between the 10th and 90th percentiles for gestational age is normal. EFW below the 10th percentile should raise concern for FGR, whereas EFW above the 90th percentile should raise concern for an LGA fetus. An EFW above 4500 g in a nondiabetic mother suggests fetal macrosomia, as does an EFW above 4000 g in a diabetic mother. Fetal measurements are also used to diagnose fetal abnormalities involving abnormal size of one or more fetal structures.[164] For all of the reasons mentioned here and others discussed in this chapter, fetal measurements are an important component of obstetric ultrasound evaluation throughout gestation.

Ultrasound Evaluation in Multiple Gestations

Lynn L. Simpson

SUMMARY OF KEY POINTS

- Early diagnosis and determination of chorionicity in the first trimester are critical for the optimal management of multiple gestations.
- Dichorionic twins may be either monozygotic or dizygotic, whereas essentially all monochorionic twins are monozygotic.
- In addition to risks for aneuploidy and malformations, increased nuchal translucency (NT) in monochorionic twins reflects the potential for complications related to inter-twin anastomoses within a shared placenta.
- Pregnancy risk for fetal structural anomalies is increased in multiple gestations, being highest in those with monochorionic placentation.
- Even with monozygotic twins, most structural anomalies are discordant and uncommonly affect both fetuses.
- Transvaginal sonography may be useful to assess for placenta previa, vasa previa, and cervical shortening, which are all increased in multiple pregnancies.
- Because of limitations of the physical examination and risks associated with abnormal fetal growth and amniotic fluid volume, monthly ultrasound examinations are recommended in multiple gestations.
- Multiples with monochorionic placentation require increased scrutiny and serial surveillance for a variety of unique complications such as twin-twin transfusion syndrome (TTTS), unequal placental sharing with discordant twin growth or selective fetal growth restriction (FGR), and twin anemia-polycythemia sequence (TAPS).

OUTLINE

Ultrasound technology plays a critical role in the management of multiple gestations, which now compose over 3% of all live births in the United States[1] (Figs. 7-1 and 7-2). Advances in reproductive technologies have contributed to this increase, and, fortunately, these cases are detected early owing to the routine use of sonography in practices that provide these services. In contrast, half of all of twin pregnancies were undiagnosed until delivery in the years before sonography was integrated into obstetric practice.[2] Today, with wide availability of sonography, most multiple gestations are identified in the first trimester, providing the opportunity to individualize and optimize the care of these complicated pregnancies.

Multiple gestations pose special considerations as well as unique conditions that may necessitate additional imaging studies. Standard indications for sonography in multiple gestations include pregnancy dating, determination of chorionicity, nuchal translucency (NT) assessment, anatomic survey, placental evaluation, cervical length assessment, routine fetal growth studies, and serial surveillance of pregnancies complicated by anomalies, fetal growth disturbances, and amniotic fluid abnormalities. Multiples with monochorionic placentation require increased scrutiny for monoamnionicity, conjoined twins, twin reversed arterial perfusion (TRAP) syndrome, twin-twin transfusion syndrome (TTTS), unequal placental sharing with discordant twin growth or selective fetal growth restriction (FGR), twin anemia-polycythemia sequence (TAPS), and single fetal demise. Undoubtedly, ultrasound evaluation is essential for the supervision of multiple gestations in modern obstetrics.

EMBRYOLOGY OF TWINS

The embryology of twin gestations includes the added complexity of the development of two embryos and either one or two placentas. Twins may be monozygotic or dizygotic, depending on the number of

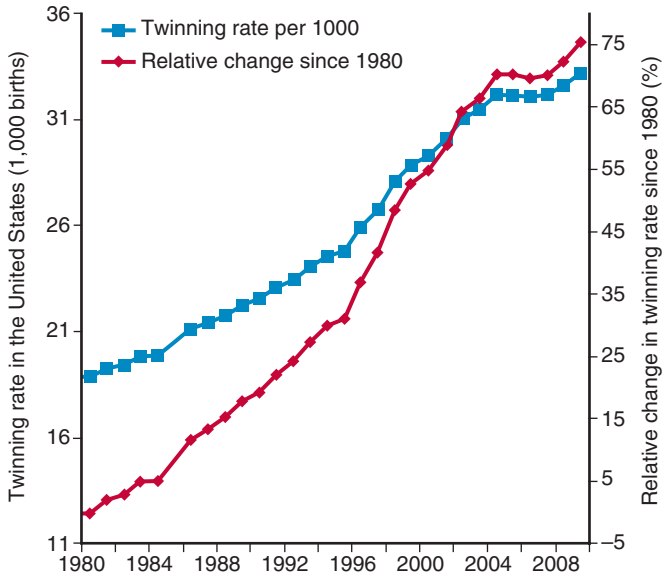

FIG 7-1 Temporal trends in the rate of twinning (per 1000 births), and the change in twinning rates in the United States, 1980 to 2009. (From Ananth CV, Chauhan SP: Epidemiology of twinning in developed countries. Semin Perinatol 36(3):156-161, 2012.)

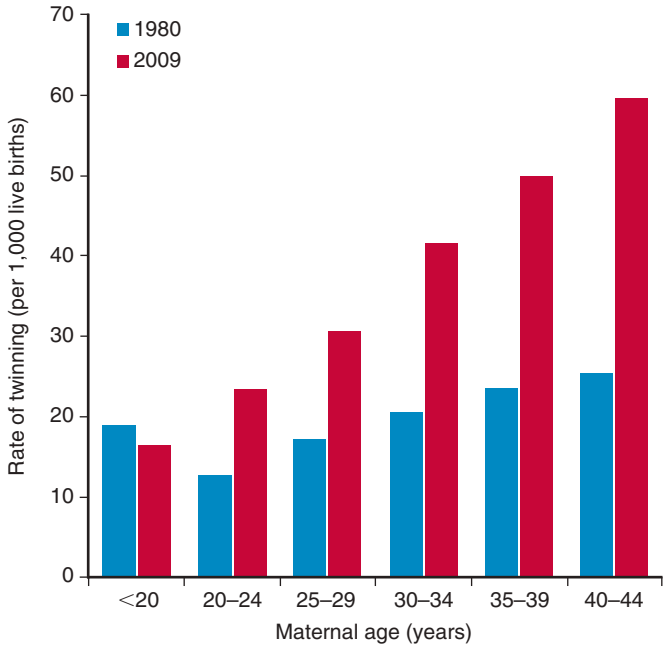

FIG 7-2 Changes in the rate of twinning (per 1000 births) in relation to maternal age in the United States, 1980 and 2009. (From Ananth CV, Chauhan SP: Epidemiology of twinning in developed countries. Semin Perinatol 36(3):156-161, 2012.)

ova that are fertilized at conception (Fig. 7-3). Monozygotic twins result from fertilization of one ovum by one sperm with subsequent division into two embryos. Because they have the same genome, they are often referred to as "identical" twins, although influences on development after conception mean that monozygotic twins are not truly identical. Dizygotic twins result from fertilization of two ova by two sperm (Figs. 7-3 and 7-4). These fetuses are no more closely related than other siblings and are therefore sometimes referred to as "fraternal twins."

Unlike dizygotic twinning, the rate of monozygotic twinning is constant worldwide and occurs in approximately 1/250 pregnancies (Table 7-1). The timing of cleavage in monozygotic twins determines the type of placentation and the likelihood of additional complications. This effect is depicted in Figure 7-5 and Table 7-2, which demonstrate the timing and types of placentation. Dichorionic placentation is present in approximately 1/3 of monozygotic twins and results from cleavage very early, in the first 3 days after conception. Monochorionic placentation occurs in 2/3 of monozygotic twins and results from cleavage between days 4 and 8 after conception. Monoamniotic pregnancies are much less common, reported in fewer than 1% of monozygotic gestations, and result from splitting on days 9 to 12. Finally, conjoined twins result from very late attempts at cleavage on day 13 or later. With very rare exceptions, dizygotic twins always have dichorionic-diamniotic placentation.

Although the rate of monozygotic twinning is relatively constant in spontaneous twin gestations, it is increased by assisted reproductive technologies (ARTs), particularly those that involve embryo manipulation or later embryo transfer.[3,4] The rate of monozygotic twinning with ART is increased approximately 2- to 12-fold. The frequency of dizygotic twinning, in contrast, varies and is associated with maternal age, race, geography, and use of fertility treatment.[5,6] Prior to the widespread use of assisted reproduction, the highest rates of dizygotic twinning were in Nigeria, where 49/1000 live births were twin pregnancies, and lowest in Japan at 1.3/1000 live births (see Table 7-1). It is thought that the high rate in Nigerian women results from higher baseline levels of follicle-stimulating hormone.[5] The peak maternal age for spontaneous multiple gestations is 37 years old.[6]

With greater use of fertility treatments, including ovulation induction as well as ARTs, the geographic differences in rates of twinning have changed over time. In one survey in the United Kingdom in 2003, it was reported that 1.4% of deliveries were twins and 0.01% were triplets. ARTs were used in 1.9% of all pregnancies, with 13.5% of ART pregnancies associated with multiple gestations versus 1.2% in spontaneous conceptions.[7] Recognition of the higher perinatal morbidity and mortality risks in multifetal pregnancies has resulted in efforts to decrease the rate of this complication by judicious use of ovulation induction as well as an emphasis on single embryo transfer in ART pregnancies.[8]

PREGNANCY DATING

Accurate pregnancy dating is important for the timing of screening and diagnostic testing as well as the correct interpretation of fetal growth in multiple gestations. Experts now recommend that uncomplicated dichorionic twins be delivered at 38 weeks, monochorionic twins at 36 weeks, and monoamniotic twins at 34 weeks.[9] Early confirmation of gestational age, with establishment of a fixed due date, is necessary for delivery planning in multiple pregnancies.

As in singletons, determining gestational age is best accomplished in the first trimester using the crown-rump length (CRL)[10] (Fig. 7-6). Accuracy of the CRL, obtained prior to 14 weeks, to predict the due date is ± 5 to 7 days.[11] After the first trimester, multiple biometric measurements should be used to date the pregnancy but this approach is less precise. For multiples conceived by in vitro fertilization (IVF), dating by embryo transfer is comparable to dating by CRL in the first trimester. In both spontaneous and IVF conceived multiple gestations, dating can be uncertain if there is a significant discrepancy in size between the fetuses. In these cases, dating based on the size of the larger fetus decreases the risk of overlooking early FGR, although the smaller CRL has been shown to be more accurate in the estimation of gestational age.[12,13]

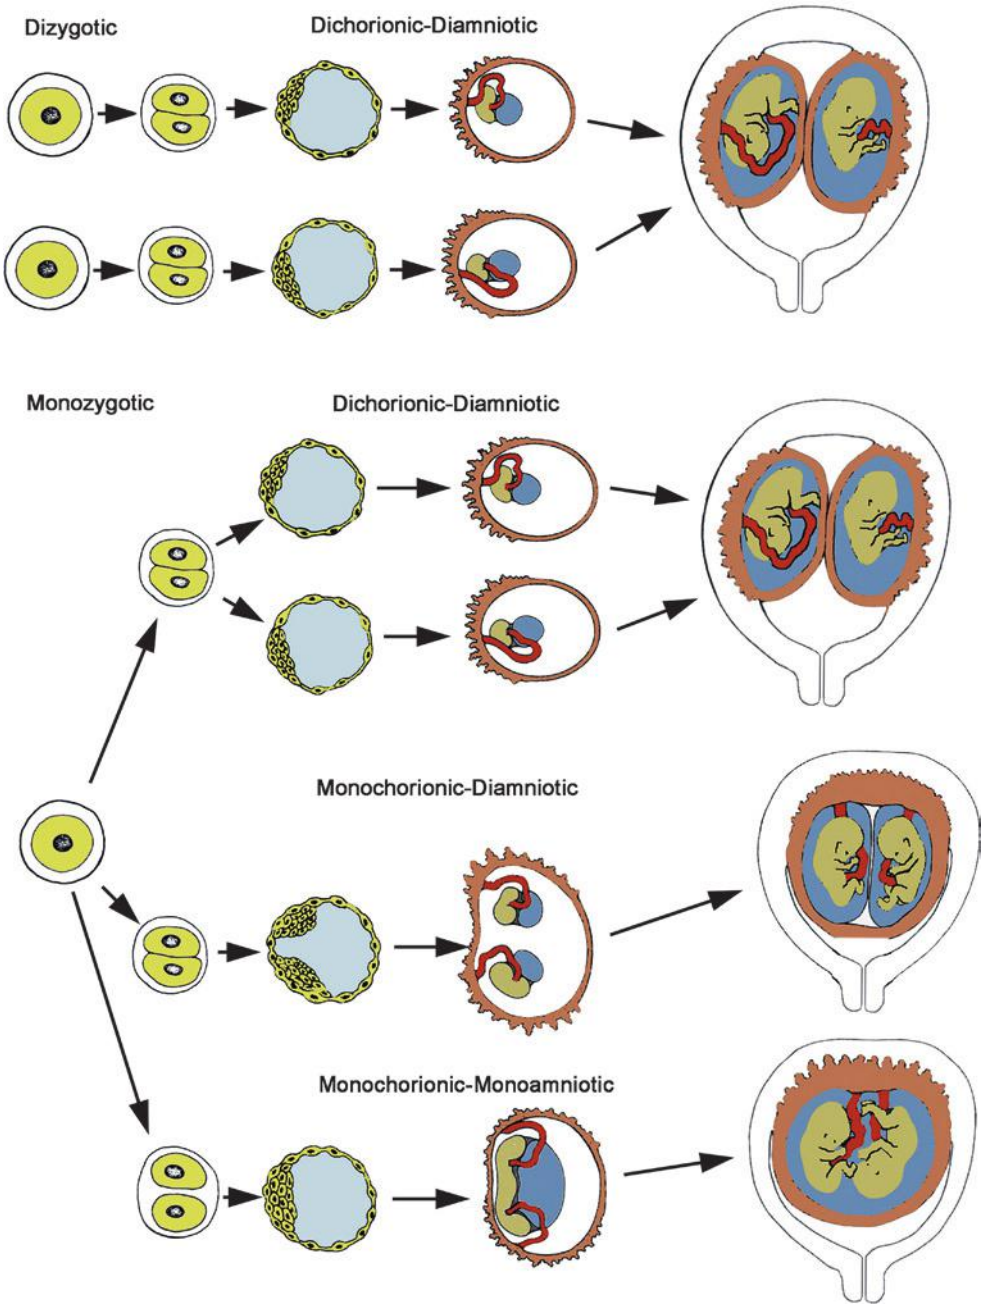

FIG 7-3 Diagram of the development and placentation of dizygotic and monozygotic twins. The degree to which monozygotic twins share placentas, chorions, and amnions depends on the stage of development at which splitting occurs. (Modified from Larsen WJ: Human Embryology, 2nd ed. New York, Churchill Livingstone, 1997.)

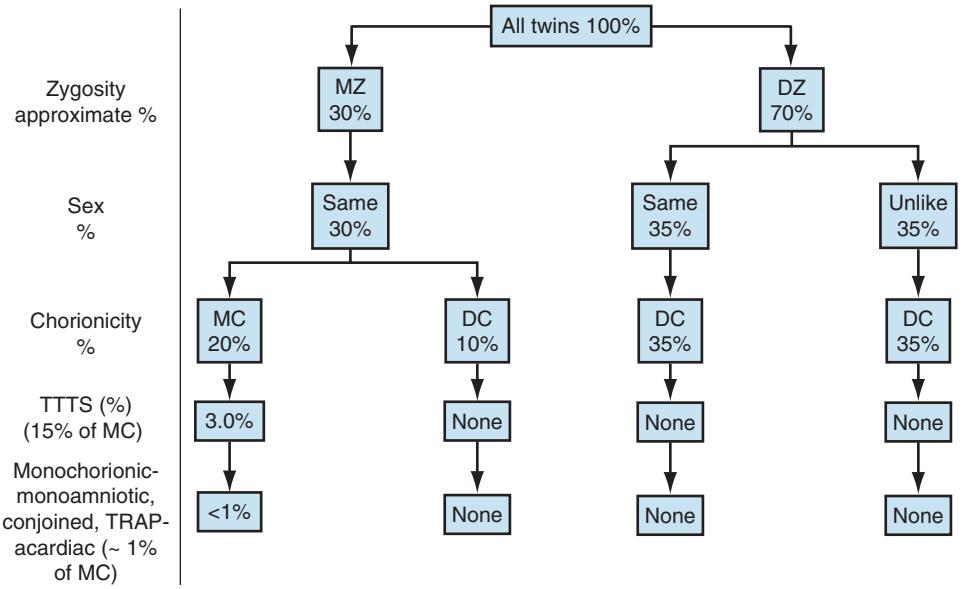

MZ monozygous, DZ dizygous, MC monochorionic, DC dichorionic, TTTS twin to twin transfusion syndrome, TRAP twin reversed arterial perfusion.

FIG 7-4 Approximate distribution of monozygous (MZ) and dizygous (DZ) twinning with chorionicity and complications of monozygous twins as a percentage of all twins. This represents the approximate distribution of twin gestations in the United States by zygosity and chorionicity. Both monochorionic (MC) and dichorionic (DC) twin gestations are at greater risk for maternal and fetal/neonatal complications (such as preeclampsia, diabetes, structural fetal abnormalities, aneuploidy, growth restriction) when compared with singleton gestations. Complications found only in monochorionic twin gestations include twin-twin transfusion syndrome (TTTS), monochorionic-monoamniotic twins, twin reversed arterial perfusion (TRAP) acardiac twins, conjoined twins, and fetus in fetu.

CHORIONICITY

Chorionicity impacts obstetric management as well as the risk of possible complications and adverse perinatal outcomes in multiple pregnancies. Selective reduction of an abnormal fetus or multifetal reduction in higher-order multiple pregnancies relies on accurate determination of chorionicity to inform procedural decisions. Correct assignment of chorionicity using sonography is nearly 100% when done in the first trimester compared to an approximate 10% likelihood of error in the second trimester.[14,15] A 2014 study found that before 20 weeks, sonography incorrectly assigned chorionicity in 6.4% of twins overall, with 4% of dichorionic twins and 19% of monochorionic twins misclassified.[16] Although dizygotic twins are always dichorionic, placentation in monozygotic twins varies, depending on the timing of embryo division after fertilization, and is more difficult to assess with advancing gestational age[17] (Table 7-3). Therefore, chorionicity should be established at the time of the initial sonogram, optimally in the first trimester.

The approach to assigning chorionicity depends on gestational age. Early in the first trimester, the number of gestational sacs equals the number of chorions (Fig. 7-7 and Table 7-4). Late in the first trimester, the visualization of two separate placentas can be used to diagnose dichorionicity (Fig. 7-8). In cases with a single placenta or adjacent apparently "fused" placentas, evaluation of the intervening membrane can help distinguish between monochorionic and dichorionic placentation. Membrane thickness, number of membrane layers, and presence of either the lambda sign or T-sign at the base on the intervening membrane can be evaluated using ultrasound imaging. In dichorionic twins, the separating membrane tends to be thicker, as it is composed of two layers of amnion and two layers of chorion, compared to only two layers of amnion in monochorionic twins. Although a membrane thickness of 2 mm has been used as a threshold to distinguish between dichorionic and monochorionic twins, it does not perform reliably as a diagnostic test.[18] The lambda sign, consisting of a small triangular wedge of echogenic chorionic tissue observed between layers of the intervening membrane at its base, where it meets the fetal surface of the placenta, is diagnostic of dichorionicity[19] (Figs. 7-9 and 7-10). The lambda sign is best visualized in the late first and early second trimesters of pregnancy. It is important to remember that this sign does not necessarily persist on follow-up scans later in pregnancy, but when seen, it helps confirm dichorionicity. The T-sign, which appears as a thin linear structure, composed of two opposing layers of amnion, forming a perpendicular angle where it intersects the fetal surface of the shared placenta, is characteristic of monochorionic placentation

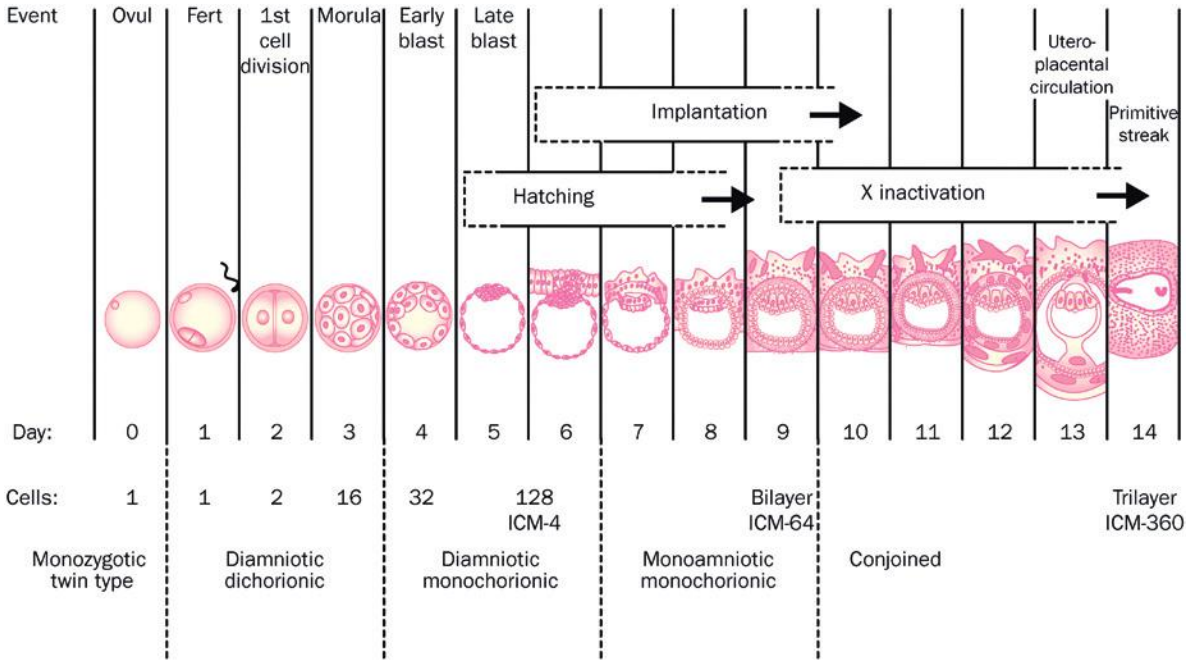

FIG 7-5 The timing of monozygotic twinning demonstrating the impact of the day cleavage occurs on placentation and complications, that is, monochorionic monoamniotic placenta or conjoined twins. (Figs. 7-10 and 7-11). Toward the end of the first trimester and beyond, fetal sex can also be assessed to aid in determination of chorionicity. Although this finding is not useful if both twins appear to be the same sex, different phenotypic findings (one with male and one with female external genitalia) imply dichorionicity except in very rare cases. These principles also apply when evaluating higher-order multiple gestations.

Establishing amnionicity is also important in the evaluation of multiples with monochorionic placentation because fetuses that share a single amniotic sac face increased risks and are managed differently. This is particularly true when caring for higher-order multiple

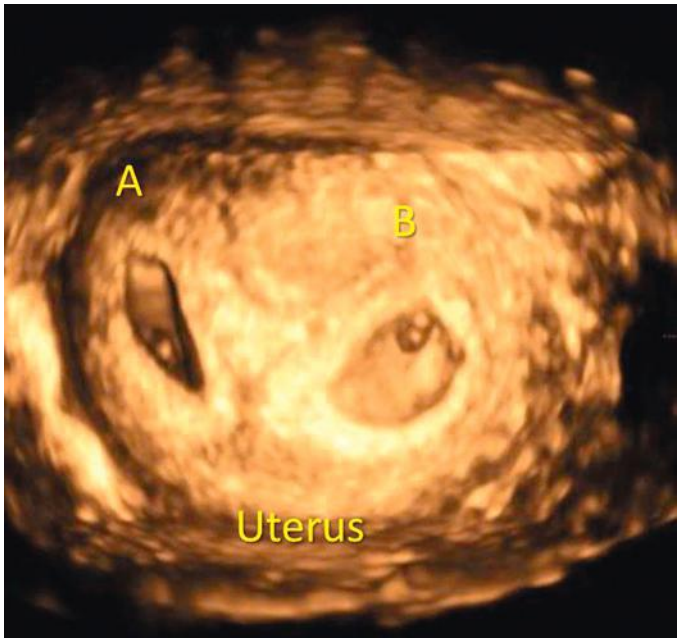

FIG 7-7 Three-dimensional image of two distinct gestational sacs (A and B) indicating a dichorionic twin pregnancy.

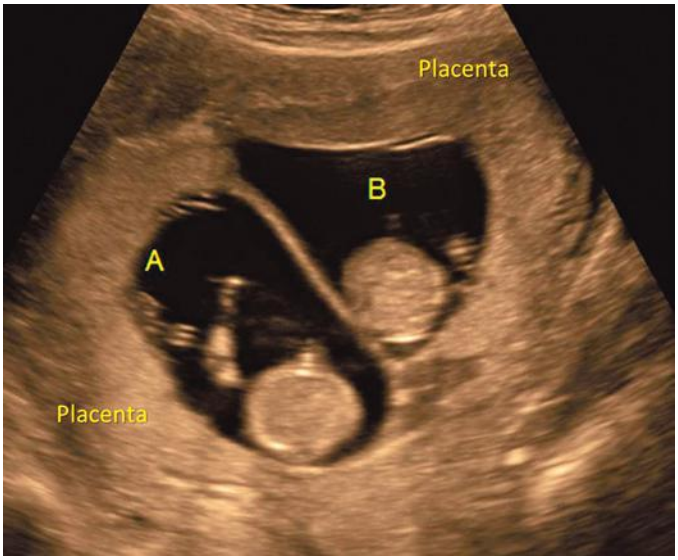

FIG 7-8 Visualization of two separate placentas confirms dichorionicity.

TABLE 7-4 Sonographic Determination of Chorionicity and Amnionicity in First Trimester Twin Gestations

Placentation	Gestational Sacs	Yolk Sacs	Embryos/ Sac	Amniotic Cavities
DC, DA	2	2	1	2
MC, DA	1*	2	2*	2
MC, MA	1*	1 or partially divided*	2*	1

*Amnionicity cannot be determined by this finding.

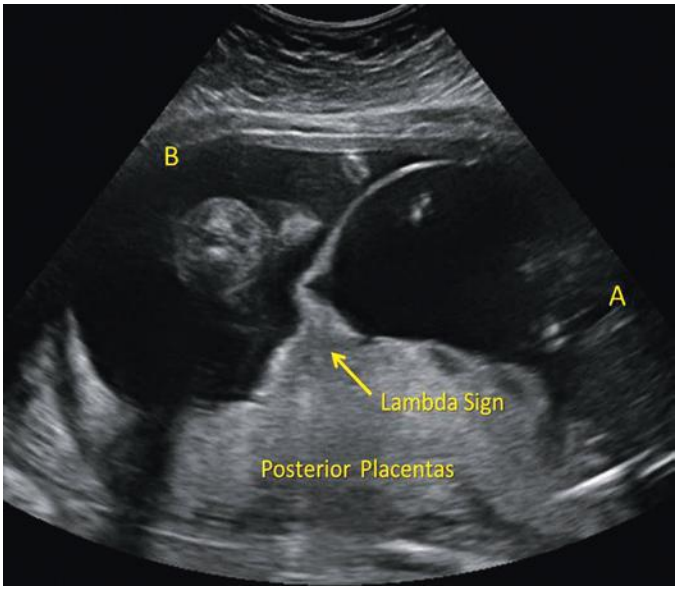

FIG 7-9 The lambda sign (*arrow*) represents chorionic tissue wedged between layers of the intervening membrane (separating the gestational sacs of twins A and B) where it meets the fetal surface of the abutting placentas. This finding is not always present, but when seen, it is a useful indicator of dichorionicity.

gestations that include a monochorionic twin pair. Although the number of yolk sacs seen early in gestation tends to equal the number of amnions, this is not a reliable diagnostic criterion. A transvaginal sonogram early in gestation can often demonstrate the two amnions of a monochorionic twin pregnancy (Fig. 7-12). Visualization of a separating inter-twin membrane ensures the presence of two amnions in both dichorionic and monochorionic gestations. In monochorionic twins, the intervening membrane can be very thin and difficult to identify, possibly leading to an incorrect diagnosis of monoamnionicity (Fig. 7-13). A transvaginal sonogram and repeat imaging in the first trimester may be required to distinguish between monochorionic diamniotic and monochorionic monoamniotic twin gestations (Fig. 7-14).

NUCHAL TRANSLUCENCY

In both singleton and multiple gestations, NT measurements have been used in the evaluation of risk for aneuploidy and fetal anomalies. Overall, the sensitivity of NT combined with maternal age for detection of trisomy 21 in twins is comparable to that in singletons at over 70%, but the screen positive rate is higher, particularly in monochorionic twins.[20] Monochorionic twins have been observed to have increased NT measurements compared to dichorionic twins[21] (Fig. 7-15). This difference may reflect the higher likelihood of structural malformations in monozygotic twins as well as the potential for complications related to inter-twin vascular anastomoses within a shared placenta. The detection rate for Down syndrome in twin pregnancies can be increased by combining maternal age and NT with maternal serum analytes, although it is important that chorionicity be taken into consideration.[22] Because maternal serum screening has not been adequately studied in higher-order multiples and there are likewise limited data regarding the utility of cell-free DNA screening in multiple pregnancies, NT screening is still worthwhile for identifying

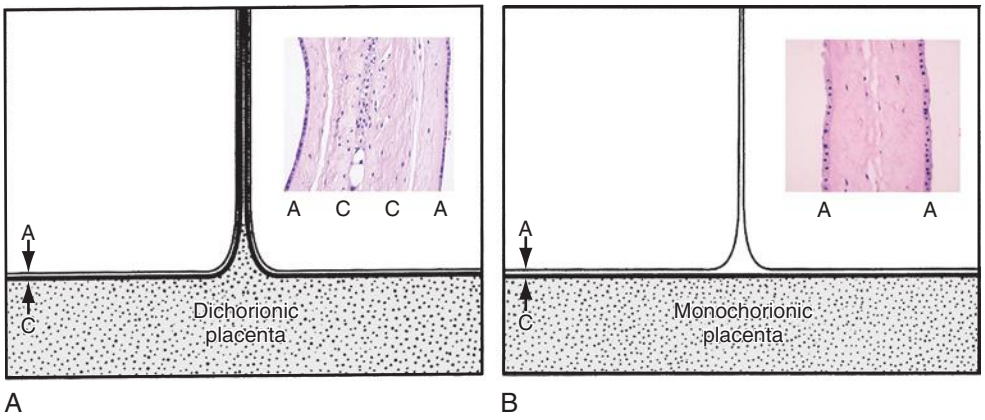

FIG 7-10 Twin peak sign with placental pathologic images of fetal membranes. **A,** Diagram of the twin peak sign in dichorionic twin gestations. The chorion (C) and amnion (A) of each twin reflect away from the fused placenta to form the inter-twin membrane. A potential space exists between the membranes, which are filled with the amniotic and chorionic mesoderm as seen in the pathologic images of dichorionic membranes (see *inset*). **B,** In monochorionic-diamniotic twins the inter-twin membrane is composed of only two amnions. A single chorion does not allow the chorionic mesoderm to access the potential space between the diamniotic membranes as seen in the pathologic sample of monochorionic fetal membranes (see *inset*). (From Finberg HJ: The "twin peak" sign: reliable evidence of dichorionic twinning. J Ultrasound Med 11:571, 1992; pathologic images courtesy Melinda Sanders, MD, and Erika Walz, PA, University of Connecticut Health Center, Farmington, CT.)

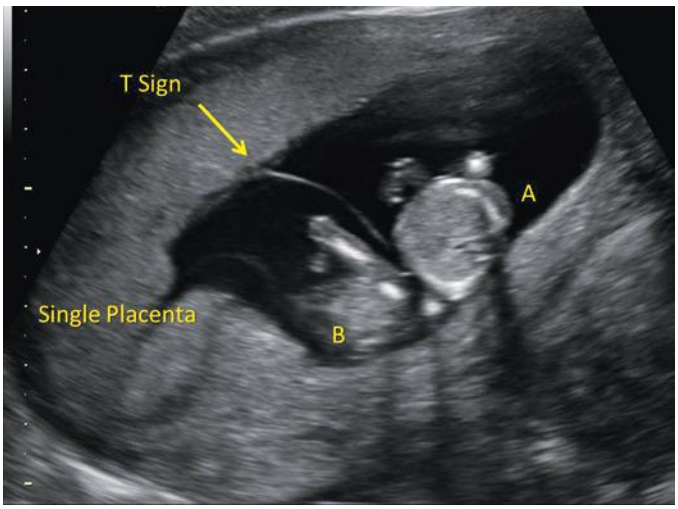

FIG 7-11 The T-sign (*arrow*) formed by the thin inter-twin membrane (composed of two layers of amnion, separating the sacs of A and B) where it meets perpendicular to the fetal surface of the single shared placenta—indicating a monochorionic diamniotic twin pregnancy.

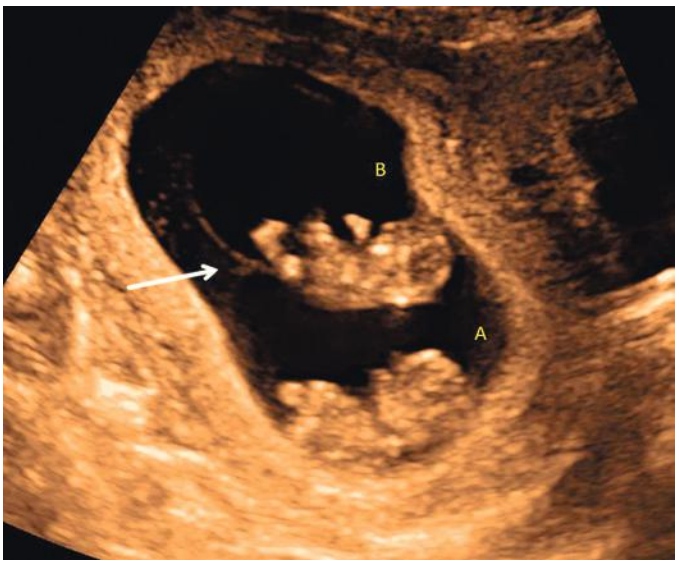

FIG 7-12 Two amniotic sacs, each containing one twin (A and B), can be seen on this transvaginal ultrasound image. The thin separating membrane of this monochorionic diamniotic pregnancy will be formed by the two opposing layers of amnion (*arrow*).

a potentially abnormal fetus in a multiple gestation warranting further investigation.[23]

Cystic hygroma or hydrops identified at the time of NT assessment may reflect chromosomal or structural abnormalities in both singletons and multiples (Fig. 7-16). Although many different malformations have been associated with enlarged NT and first trimester cystic hygroma, both are recognized risk factors for major cardiac anomalies.[24,25] Furthermore, both structural and functional types of heart disease are more common in monochorionic twins, and an increased NT may identify those cases most at risk. An added benefit of assessing NT in monochorionic twins is that a 20% inter-twin difference in NT measurement is associated with a greater than 30% risk of fetal death or subsequent development of severe TTTS, thereby identifying those cases that warrant increased scrutiny during follow-up sonographic surveillance.[26] Observation of enlarged NT, cystic hygroma, or early hydrops in a monochorionic pair of a higher-order multiple gestation may also influence recommendations and clinical decisions.

ANATOMIC SURVEY

The main objective of the anatomic sonographic survey in multiples is the same as that in singletons: to provide reassurance that the fetuses are developing normally with no evidence of structural abnormalities. Overall, twin and triplet pregnancies have a higher background risk of major malformations, greater than the 2% reported in singletons.[27] Although the rate per fetus remains roughly the same in dizygotic

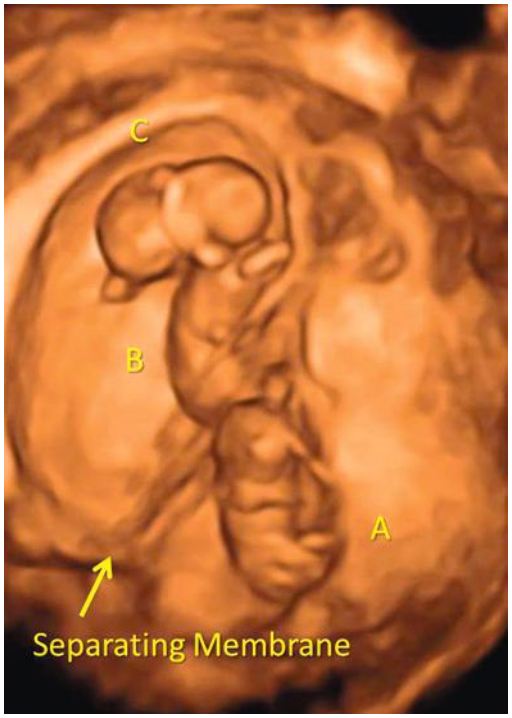

FIG 7-13 Dichorionic triplet gestation with a monochorionic pair (B and C) in which amnionicity could not be firmly established early in the pregnancy. A membrane (*arrow*) was seen separating triplet A from B and C.

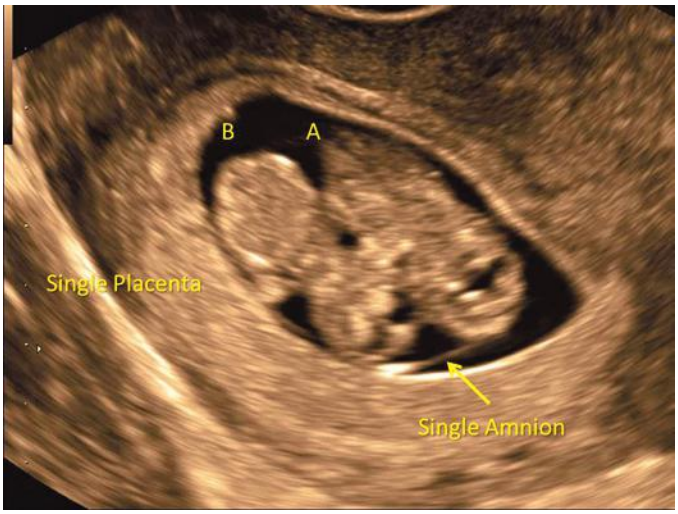

FIG 7-14 Lack of an intervening membrane and visualization of a single amnion (*arrow*) confirms monochorionic monoamnionic twin pregnancy.

twins or trizygotic triplets, this amounts to an overall rate of 4% and 6% for such pregnancies, respectively (Fig. 7-17). The prevalence of birth defects in monochorionic twins is even higher, nearly twice that observed in dichorionic twins.[28] Interestingly, when both twins are found to have a structural malformation, only 10% of dichorionic and 20% of monochorionic twin pairs have the same defect.[27] Of twin pregnancies with congenital anomalies, only one twin is affected in about 90% of cases.[27] Heightened awareness with careful inspection for malformations is warranted whenever scanning twins and higher-order multiples.

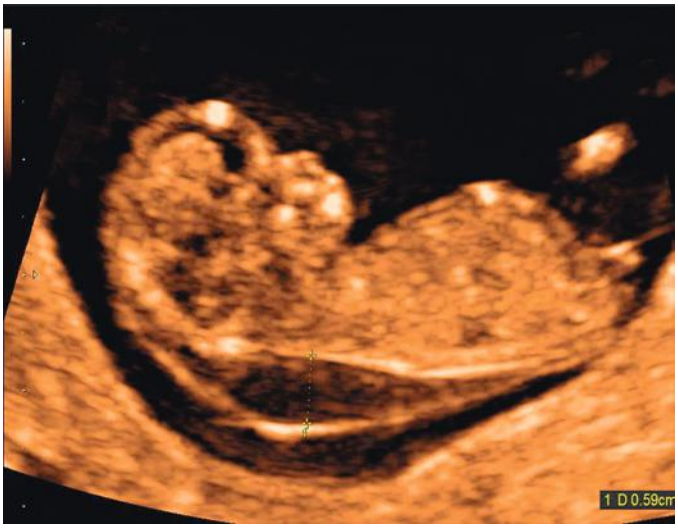

FIG 7-15 Monochorionic diamniotic twin pregnancy in which twin A was noted to have an enlarged nuchal translucency (NT) measuring 0.59 cm.

Approximately one third to one half of all birth defects are identified prenatally in singleton pregnancies, and the detection rate in twins and triplets is expected to be even lower.[29] Certain anomalies, such as those involving the central nervous system, are often recognized prenatally, whereas major cardiac abnormalities are frequently missed in twins[29] (Fig. 7-18). This difference is of clinical importance because congenital heart disease is more common in monochorionic twins, in which the prevalence is reported to be about 7.5%.[30] Although controversial, there are some data to suggest that fetuses conceived by IVF are also at increased risk for cardiac defects.[31,32] The standard cardiac screening examination, consisting of the four-chamber view of the heart and views of the great vessels and outflow tracts, identifies about one third of major heart defects prenatally.[33,34] Today, IVF, monochorionicity, and increased NT are all accepted indications for fetal echocardiography, which when done in experienced centers can detect close to 100% of major cardiac anomalies.[35] Given the challenge of imaging multiple fetuses in variable positions at midgestation, repeat ultrasound examinations may be necessary to complete the anatomic sonographic surveys in these pregnancies. The management of discordant anomalies in multiples depends upon the gestational age at diagnosis, placentation, type of defect, and potential for associated pregnancy complications. Prenatal diagnosis in twin pregnancies is discussed in Chapter 2.

PLACENTAL EVALUATION

The ultrasound evaluation of each placenta is essential in the assessment of multiple pregnancies. Placenta previa is 40% more common in twin and triplet gestations than in singletons, related in part to the greater placental mass and larger implantation site.[36] Vasa previa is also more common, secondary to the higher proportion of velamentous placental cord insertions (PCIs) noted in multiples, particularly those with monochorionic placentation.[37] Color flow Doppler ultrasound imaging during transvaginal sonography can help identify the presence of placental tissue or a fetal vessel overlying the cervix (Fig. 7-19).

Color flow Doppler sonography can also be used to identify and evaluate the PCI of each fetus, an important component of the ultrasound examination (Fig. 7-20). Both sonographic and pathologic studies have reported that marginal and velamentous cord insertions are more frequent in monochorionic diamniotic twins and that

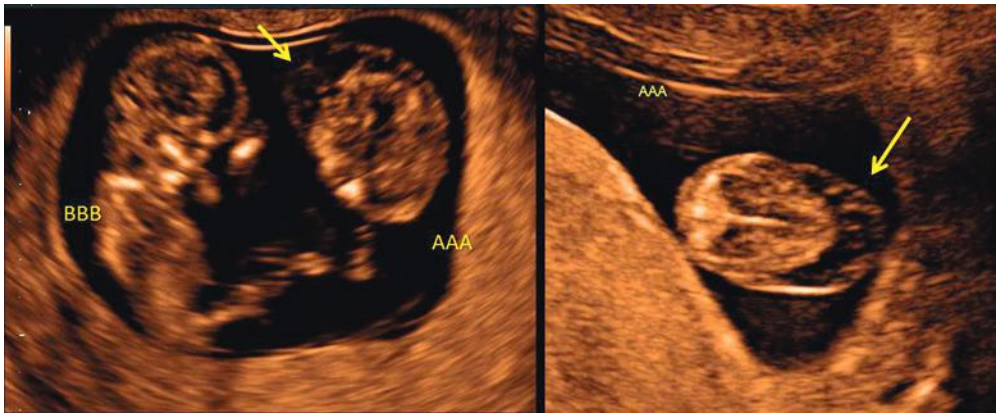

FIG 7-16 Monochorionic monoamniotic twin pregnancy with cystic hygroma (*arrows*) shown affecting the twin labeled AAA. The twin labeled BBB appeared normal.

FIG 7-17 Three-dimensional ultrasound image of trichorionic triamniotic triplets (labeled A, B, and C), each with a 2% risk of structural anomalies amounting to a total pregnancy risk of 6%.

FIG 7-18 Absence of the calvarium (*arrow*) suggesting acrania in twin A of a monochorionic diamniotic pregnancy.

velamentous cord insertion, in particular, is associated with an increased likelihood of TTTS, unequal placental sharing with discordant twin growth, and selective FGR[38,39] (Fig. 7-21). With velamentous insertion, fetal vessels are devoid of protective Wharton jelly as they traverse the membranes; this lack may contribute to the threefold increase in perinatal mortality rate observed in pregnancies with monochorionic placentation and velamentous PCI[38] (Fig. 7-22). PCI determination early in gestation can help identify those monochorionic diamniotic twins or higher-order multiples with a monochorionic twin pair that merit increased sonographic surveillance for TTTS and disturbances in twin growth.[40] Early detection of these complications should trigger adjustments in clinical management that may help decrease the risk of perinatal morbidity and mortality.

CERVICAL LENGTH

Although universal screening of cervical length is controversial, its assessment can be useful in the management of patients with preexisting risk factors for preterm delivery. Over half of all twins deliver prior to term, as do almost all higher-order multiples, and thus, an awareness of cervical length can influence patient counseling and management of multiple gestations[41] (Fig. 7-23). Transvaginal sonography is optimal for visualization of the cervix and measurement of its length and its response to the Valsalva maneuver or fundal pressure. In the second trimester, a cervical length of 20 to 25 mm or less is observed in 5% to 10% of twins and increases the likelihood of preterm delivery threefold to fivefold.[42] The negative predictive value of a midtrimester cervical length measuring greater than 35 mm is over 90%, which provides reassurance to patients carrying twins.[43] Although the optimal cervical length threshold and the appropriate frequency of follow-up evaluation are uncertain, a baseline measurement in the midtrimester with serial assessment at the time of subsequent growth studies in the second and early third trimesters can identify those at highest risk for spontaneous preterm delivery. Despite a lack of data, this is a reasonable approach when caring for higher-order multiple pregnancies as well.

FETAL GROWTH STUDIES

Ongoing sonographic assessment of fetal growth is necessary when managing multiple gestations. Abnormal growth may be evident as

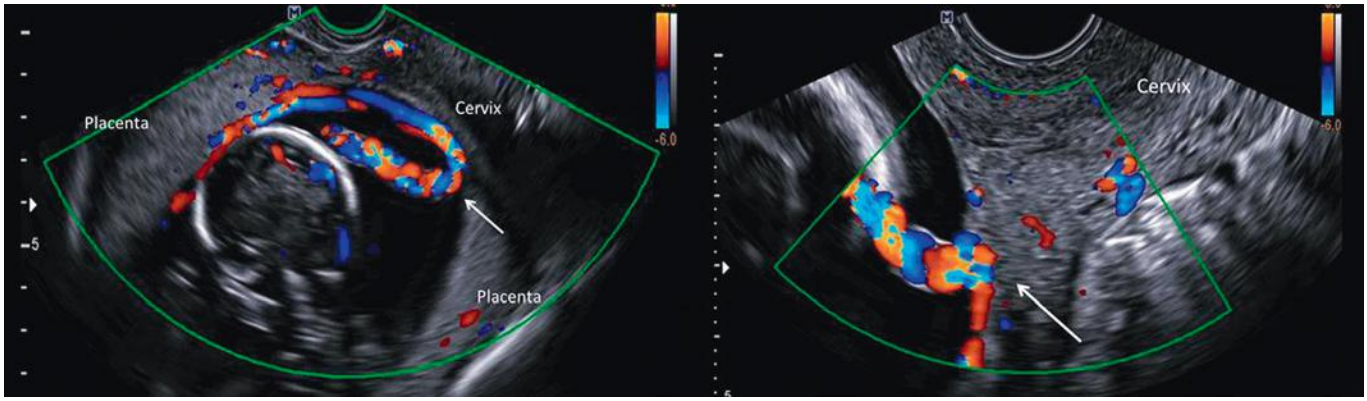

FIG 7-19 Transvaginal sonography with color Doppler flow imaging demonstrates vasa previa, with fetal vessels crossing the cervix. The cord insertion is velamentous (*arrow*), in close proximity to the internal cervical os.

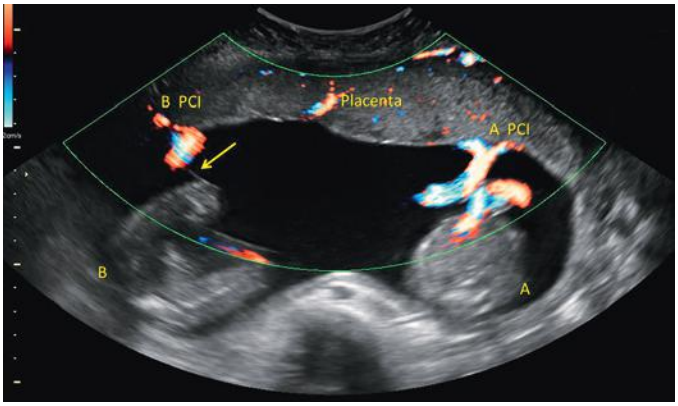

FIG 7-20 Color flow Doppler ultrasound imaging is used to identify each placental cord insertion (PCI) of the monochorionic diamniotic twin pair (A and B). The thin inter-twin membrane is in close proximity to twin B (*arrow*).

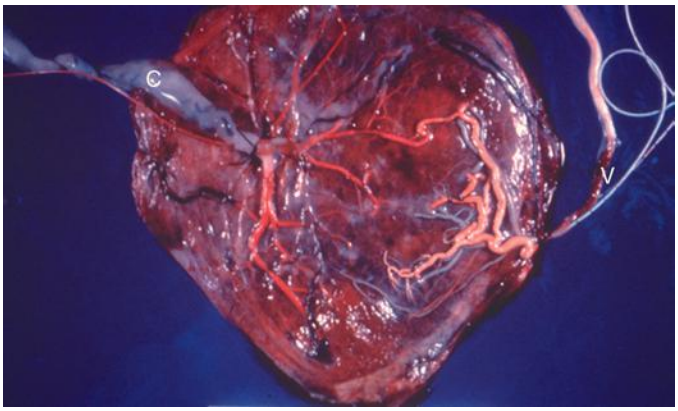

FIG 7-21 Photograph of a monochorionic placenta. The cord insertion sites are shown to be central (C) for one twin and velamentous (V) for the other. (Courtesy Geoffrey A. Machin, MD, PhD.)

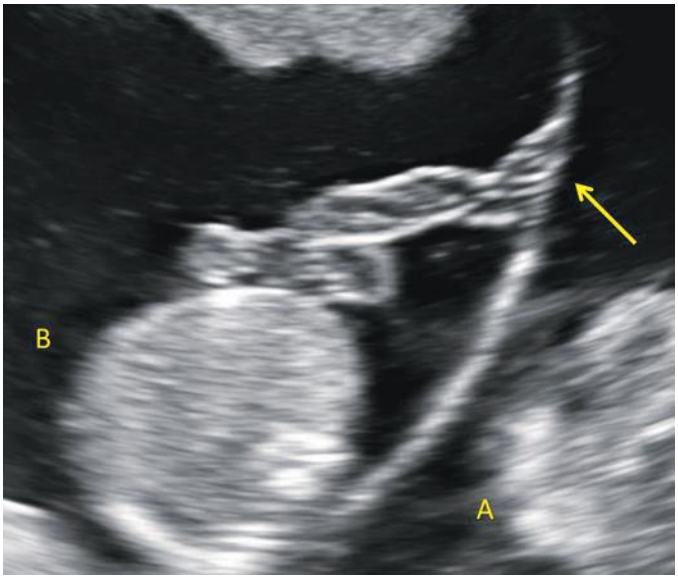

FIG 7-22 Two-dimensional ultrasound image demonstrates a velamentous cord insertion (*arrow*) of twin B, directly into the separating inter-twin membrane.

early as the first trimester (Fig. 7-24). Physical examination with abdominal palpation and symphysis-fundal height measurements are unreliable in predicting fetal sizes in multiple pregnancies, so sonographic estimation of twin or triplet growth is justified.[44] Serial sonographic estimations of fetal weight can detect early growth restriction or discordance that might otherwise be missed and can identify those cases that might benefit from increased antenatal surveillance.

Healthy singletons and twins tend to follow similar growth patterns until the third trimester, at which time twin growth begins to lag behind that of singletons.[45] FGR, defined as estimated fetal weight corresponding to less than the 10th percentile for gestational age, can be determined using singleton growth curves. Following twin or triplet growth using singleton curves assures that cases of suboptimal growth are not overlooked, as physiologic growth potential is best estimated with singleton growth curves. The downside of this approach is that many healthy fetuses of higher-order multiple pregnancies will be labeled as having FGR. The most commonly used definition of growth discordance between fetuses in a multiple gestation is variance of 20% or more, which is calculated as the difference between the estimated fetal weights of two fetuses, divided by the estimated fetal weight of the larger fetus. An early sonographic clue of impending discordant growth is disparate abdominal circumferences (Fig. 7-25). An inter-twin abdominal circumference difference of 20 mm or greater and a ratio of less than 0.93 are predictive of discordant birth weights.[46] Both

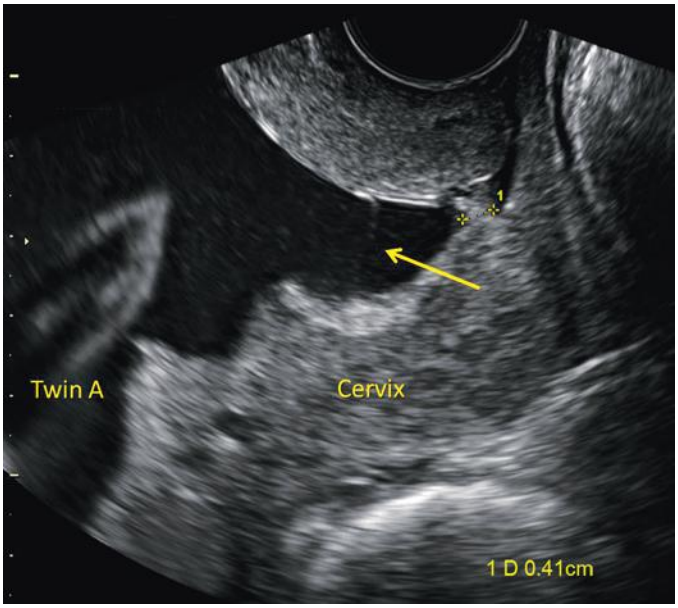

FIG 7-23 Transvaginal ultrasound image showing a funneled short cervix, measuring 0.41 cm in length, in a monochorionic diamniotic twin gestation with oligohydramnios-polyhydramnios sequence. A portion of the amniotic membrane of the presenting twin A (*arrow*) is seen within the dilated cervical canal.

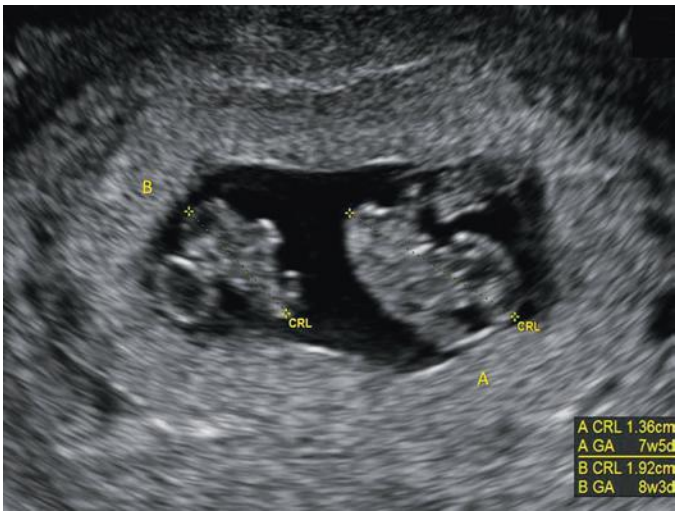

FIG 7-24 Early discrepancy in crown-rump lengths (CRL) shown between a monochorionic diamniotic twin pair, labeled A and B. GA, gestational age.

FGR and twin discordance are associated with higher likelihood of fetal and perinatal death compared to normally grown and concordant twins.[47,48] The use of sonography to assess fetal size and growth every 4 weeks in multiple gestations is recommended for the early detection of growth abnormalities and timely initiation of antenatal fetal testing.

Amniotic fluid abnormalities may also be identified during routine sonographic examinations in multiple gestations, forewarning of potential complications (Fig. 7-26). Folding of the intervening membrane upon itself can sometimes be seen and may suggest early discrepancies in amniotic fluid volume between the two sacs (Fig. 7-27). Different methods to assess amniotic fluid volume in multiple gestations may be used, but a common approach is to measure the maximal vertical pocket (MVP) in each sac (Fig. 7-28). Using this method,

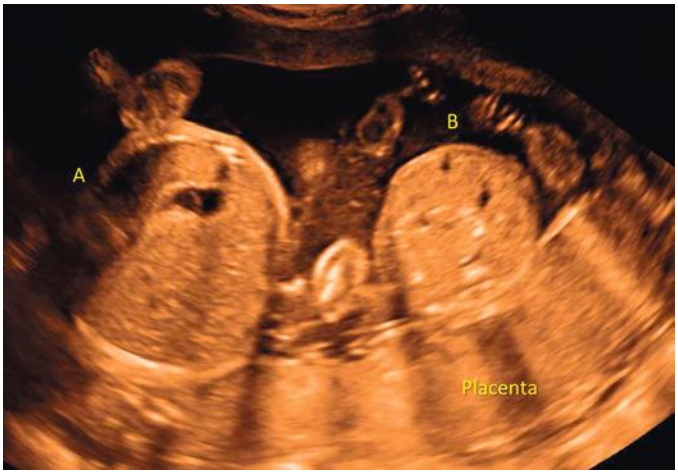

FIG 7-25 Significant discordance in abdominal circumferences noted in this monochorionic diamniotic pregnancy, with lagging growth of twin B compared to twin A.

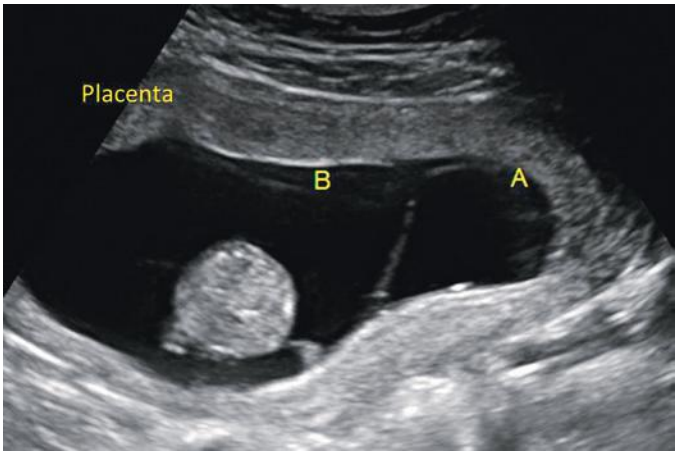

FIG 7-26 Monochorionic diamniotic pregnancy with less amniotic fluid in the sac of twin A compared to the sac of twin B.

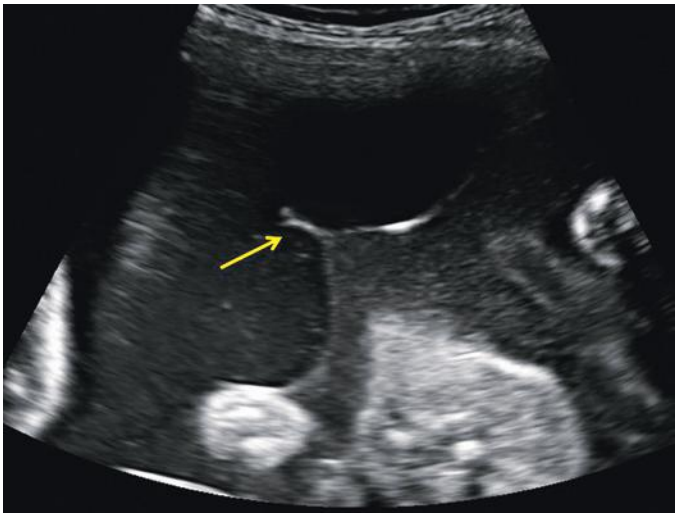

FIG 7-27 Slight redundancy and focal fold of the thin separating membrane (*arrow*) of this monochorionic diamniotic twin pregnancy. Although this may be a normal observation, it can be seen in cases of evolving oligohydramnios-polyhydramnios sequence.

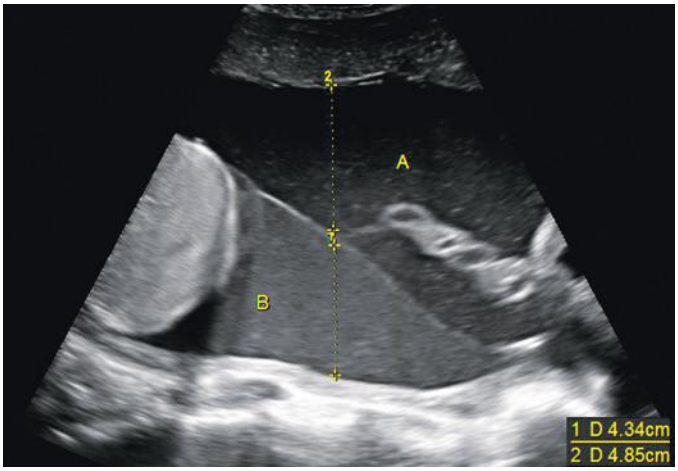

FIG 7-28 Normal pocket of amniotic fluid shown and measured for each twin (A and B) in a monochorionic diamniotic pair.

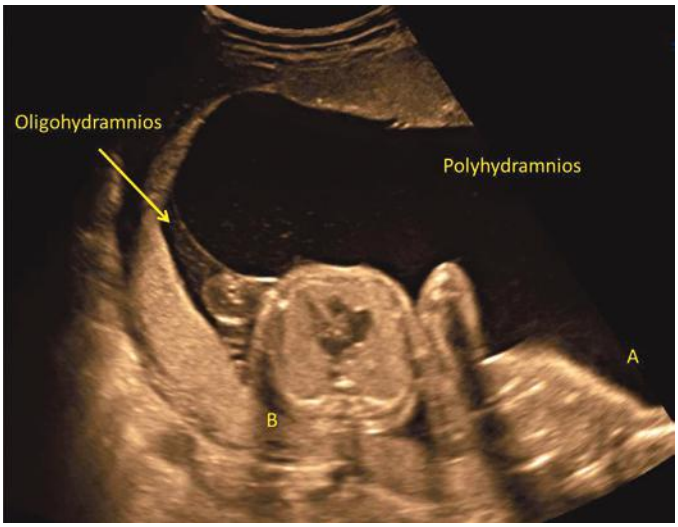

FIG 7-29 Twin-twin transfusion syndrome with polyhydramnios in the sac of twin A and oligohydramnios in the sac of twin B.

oligohydramnios is defined as an MVP smaller than 2 cm and polyhydramnios as an MVP larger than 8 cm.[19,40] As with singletons, pregnancies with oligohydramnios or polyhydramnios require additional investigation to determine the underlying cause, as well as serial antenatal testing to ensure fetal well-being. TTTS should be considered and addressed when both oligohydramnios and polyhydramnios are detected in pregnancies with monochorionic diamniotic placentation[40] (Fig. 7-29). In the third trimester, the position and presentation of the fetuses should be determined by sonography and reported, to aid in delivery planning. Sonography plays a key role in assessing potential candidates for vaginal delivery of a nonpresenting nonvertex twin. As experience and skills with breech delivery decline, planned cesarean delivery is increasing for all twin pregnancies to avoid combined vaginal-cesarean births. Although higher-order multiples are routinely delivered by cesarean, presentation as well as placental location of each fetus may inform intraoperative decision making.

SERIAL SURVEILLANCE

Although serial surveillance by sonography is indicated in multiple pregnancies diagnosed with anomalies, fetal growth disturbances, and

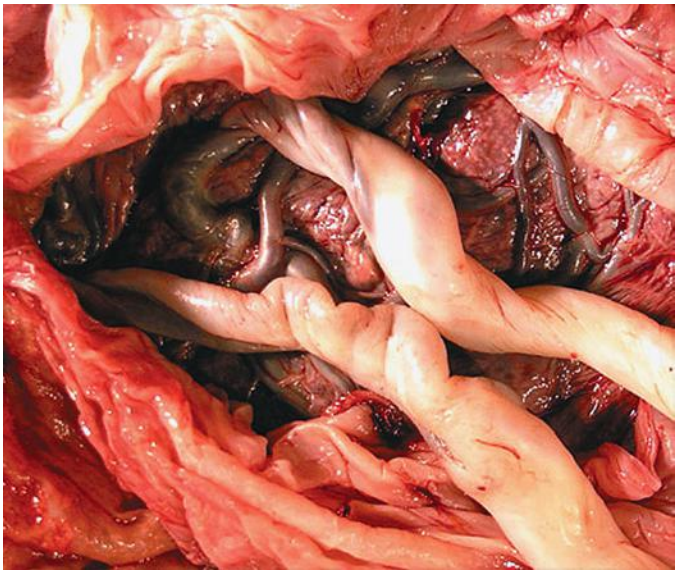

FIG 7-30 Placenta showing both umbilical cords close to one another with no intervening membranes. (Pathologic image courtesy Melinda Sanders, MD, and Erika Walz, PA, University of Connecticut Health Center, Farmington, CT.)

amniotic fluid abnormalities, seemingly uncomplicated monochorionic twins require extra scrutiny as they are at risk for developing a number of unique conditions. These disorders are overrepresented in IVF-conceived pregnancies, as IVF appears to increase the risk of embryo splitting.[49] Nevertheless, all twin or higher-order multiple gestations with a monochorionic pair should be carefully evaluated for the following possible complications.

Monoamniotic Twins

Overall, about 1% of monozygotic twins are monoamniotic, which should be suspected when a separating membrane cannot be visualized on serial sonograms.[50] The number of yolk sacs does not reliably reflect the number of amnions and therefore should not be used to determine amnionicity.[51] The thin intervening membrane associated with monochorionic diamniotic placentation can be difficult to visualize and is frequently missed in early pregnancy, leading to an incorrect diagnosis of monoamnionicity. Monoamniotic gestation can also be incorrectly diagnosed later in pregnancy when the separating membrane encasing a "stuck" twin is closely apposed to the fetus with oligohydramnios and therefore is thought to be absent. This error can be avoided by repositioning the patient during the sonogram and reassessing fetal location, looking for monoamniotic twin fetuses to move freely within the shared amniotic sac. Possible errors in diagnosis must be taken into consideration when counseling patients with suspected monoamniotic twins in the first trimester. Twins sharing a single placenta within a single sac confirmed on repeat ultrasound imaging establishes the diagnosis of monoamnionicity (Fig. 7-30). Entanglement of the umbilical cords also confirms that the twins share a common amniotic sac (Figs. 7-31 and 7-32). Color flow imaging has demonstrated entwined cords in virtually all monochorionic monoamniotic twins.[52]

The confirmation of monoamnionicity affects patient counseling and alters pregnancy management. In women carrying higher-order multiple pregnancies, selective termination of a monoamniotic twin pair may be considered in order to decrease difficult management decisions and optimize healthy outcome of the remaining fetus(es). Congenital structural anomalies are found in up to 10% and cardiac defects in 4% of monoamniotic twins, with additional risks related to

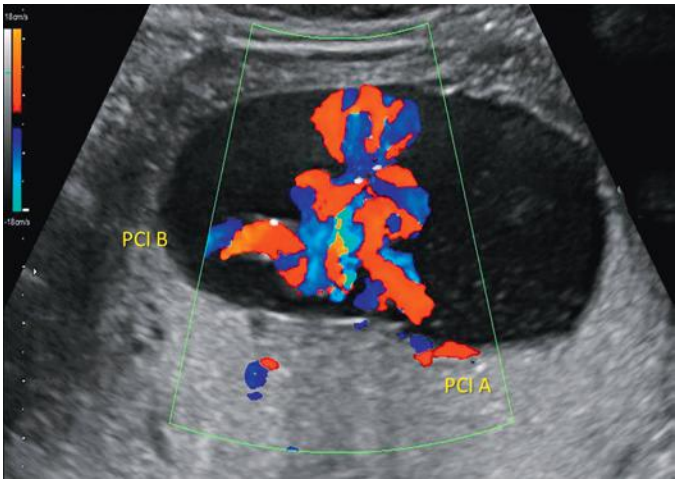

FIG 7-31 Color Doppler ultrasound image demonstrating entangled umbilical cords of monochorionic monoamniotic twins. PCI, placental cord insertion of twins A and B.

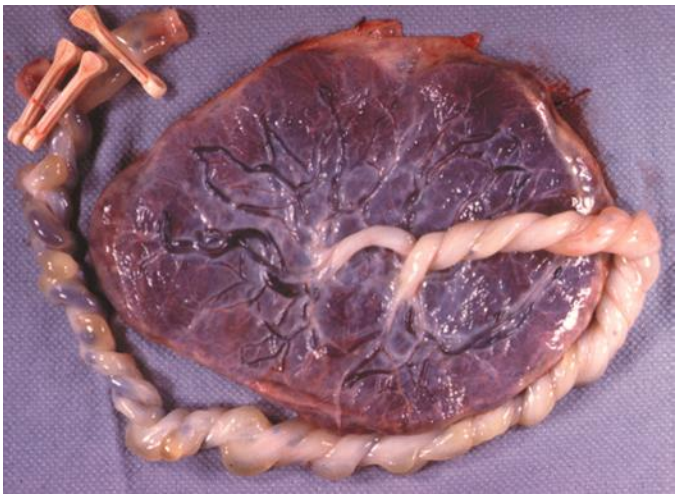

FIG 7-32 The placenta of a monochorionic monoamniotic twin pregnancy with entanglement and twisting of the umbilical cords. (Courtesy Geoffrey A. Machin, MD, PhD.)

the single shared placenta.[53] Single or dual intrauterine fetal demise may result from cord entanglement, so increased antenatal testing of these high-risk twins is appropriate.[53] After careful detailed patient counseling, daily fetal monitoring and serial growth scans for monoamniotic pregnancies are initiated at approximately the age of fetal viability; management usually involves hospitalization for close surveillance at 24 to 28 weeks' gestation. This careful rigorous approach has resulted in decreased perinatal mortality rate from 30% to 50% to 10% to 20% in recent series.[53,54]

Conjoined Twins

Conjoined twins are rare, affecting less than 1% of monozygotic twin pairs.[55] The diagnosis should be suspected when monozygotic fetuses are shown to consistently hold the same fixed position relative to each other. The location and extent of fusion between the twins determine the potential for surgical separation and postnatal survival. Conjoined twins are classified based upon the location of attachment, with thoracopagus twins representing over 40% of reported cases[55] (Table 7-5 and Figs. 7-33 and 7-34). All types of conjoined twins are at risk for

TABLE 7-5 Common Types of Conjoined Twins (*N* = 383 cases)

Type	Description	Frequency
Thoracopagus	Ventrally joined; thorax to upper abdomen, involves heart	42%
Parapagus dicephalus	Laterally joined; one trunk, two heads	11.6%
Cephalopagus	Laterally joined; top of head to umbilicus, two faces	5.5%
Omphalopagus	Ventrally joined; abdomen to lower thorax, never the heart	5.5%
Parasitic	Asymmetric, fetus in fetus	3.9%
Craniopagus	Skulls joined; shared meninges, not face or trunk	3.4%
Parapagus diprosopus	Laterally joined; one trunk, one head, two faces	2.9%
Ischiopagus	Lower abdomen and pelvic bones joined	1.8%
Rachipagus	Dorsally fused; dorsolumbar vertebrae area	1.0%
Pygopagus	Dorsally fused; perineal and sacrococcygeal area	1.0%
Unspecified	Rare types	21.4%

Data from Mutchinick OM, Luna-Munoz L, Amar E, et al: Conjoined twins: a worldwide collaborative epidemiological study of the International Clearinghouse for Birth Defects Surveillance and Research. Am J Med Genet 157:274-287, 2011.

associated structural malformations, which impact prognosis (Fig. 7-35). Although shared organs can be visualized on gray-scale sonography, color flow mapping with Doppler can delineate vascular communications between the circulations. If significant, these vascular connections can lead to cardiovascular compromise and twin death.

Early diagnosis of conjoined twins is important, as many patients will opt for termination because of the grave prognosis. When this condition is identified in higher-order multiple gestations, selective reduction of the conjoined pair is usually recommended to optimize outcome for the remaining fetus(es). Beyond the first trimester, termination of conjoined twins can be technically very difficult and in the third trimester, cesarean delivery is often necessary for patient safety. Overall, intrauterine fetal demise complicates over 10% of affected pregnancies and fewer than half of liveborn conjoined twins survive.[56] Sonographic surveillance in ongoing pregnancies should be individualized based on the condition of the conjoined twins, recommendations from the multidisciplinary team of providers, and input from the patient.

Twin Reversed Arterial Perfusion Syndrome

TRAP syndrome complicates approximately 1% of monochorionic twins, with 75% occurring in diamniotic and 25% in monoamniotic twin pairs.[57] TRAP is characterized by a pump twin perfusing a dysmorphic acardiac fetus through aberrant arterioarterial anastomoses within the shared single placenta (Figs. 7-36 and 7-37). The sonographic diagnosis requires monochorionic placentation, a normal-appearing pump twin, an abnormal-appearing co-twin without discernible cardiac activity, and reversed arterial flow directed toward, rather than away from, the anomalous acardiac fetus (Fig. 7-38).[57] The use of color and spectral duplex Doppler interrogation, which indicate direction and character of flow, is particularly helpful in this setting, to confirm the diagnosis of TRAP (see Fig. 7-38). It is theorized that

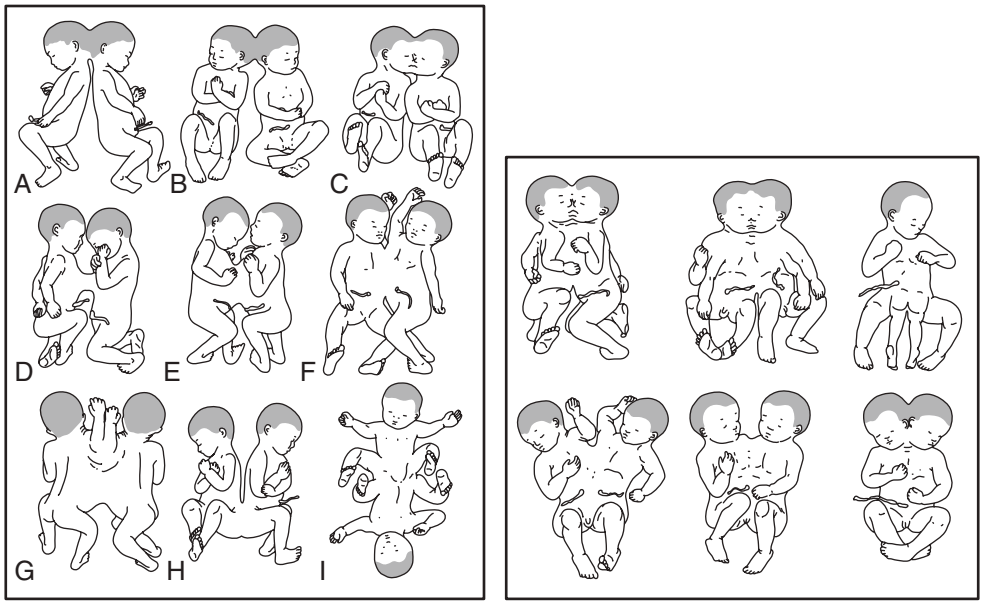

FIG 7-33 Different types of conjoined twins. *Left,* Examples of limited fusions in which heads and limbs are separate and retain their identity: **A** to **C,** craniopagus; **D** to **G,** thoracopagus; **H** and **I,** pyopagus. *Right,* Examples of more extensive fusion. (From Patten BM: Human Embryology, 4th ed. New York, McGraw Hill, 1976, Figs. VIII-5, VIII-6, pp 128-129.)

FIG 7-34 Newborn conjoined thoraco-omphalopagus twins.

the relatively deoxygenated arterial blood flowing away from the pump twin perfusing its co-twin contributes to the abnormal development of the acardiac fetus. The acardiac twin often lacks a recognizable head, trunk, and upper extremities but has lower extremity development and demonstrable internal flow on Doppler ultrasound imaging (Fig. 7-39). Up to 10% of cases have karyotype abnormalities, and 5% to 10% of pump twins have structural malformations, including cardiac anomalies, so genetic counseling and comprehensive evaluation of the pump twin are recommended in ongoing pregnancies.[58] In addition to evaluating for possible structural defects, fetal echocardiography is indicated to assess the cardiac function of the pump twin owing to the risk of hemodynamic compromise from the additional burden and high-output state related to perfusion of the acardiac co-twin.

The risk of developing cardiac failure in the pump twin influences the possible need for in utero intervention; this threat is greatest when the estimated size of the acardiac twin measures 50% or larger than the pump twin.[59,60] Various methods are used to estimate the size of the acardiac twin. One approach is to estimate its weight using the equation for volume of a prolate ellipsoid by multiplying length × width × height (in centimeters) × 0.52 (this factor is used to generate a volume in cubic centimeters and convert this figure into estimated weight, in grams), or to simply compare the abdominal circumferences of the twins.[59,60] In ongoing pregnancies with TRAP, serial sonographic surveillance and fetal echocardiography are warranted to monitor cardiac function of the pump twin and assess for hydrops, as deterioration may be an indication for intervention such as cord occlusion of the acardiac twin, in utero medical therapy, or early delivery depending on gestational age. High-output cardiac failure in the pump twin may also be accompanied by polyhydramnios, placing the patient at increased risk for cervical shortening, premature rupture of membranes, or preterm labor and delivery. Historically, the perinatal mortality rate in TRAP pregnancies was over 50%, but recent series have reported 85% to 90% survival rate of the pump twin with judicious use of umbilical cord occlusion techniques, such as radiofrequency ablation of flow to the acardiac twin.[59-62]

Twin-Twin Transfusion Syndrome

TTTS affects approximately 10% of monochorionic twins, occurring almost exclusively in monochorionic diamniotic twin pairs.[40] Although the exact pathophysiologic mechanism of TTTS is not completely understood, placental anastomoses linking the circulations of the twins are critical for its development. Inter-twin vascular anastomoses are present in virtually all monochorionic placentas, and net flow between the twins is "balanced" in the majority of cases. However, in pregnancies affected by TTTS, blood flow becomes unbalanced with one twin, the donor, transferring a net volume (with unidirectional flow through arteriovenous connections) to its co-twin, the recipient (Figs. 7-40 and 7-41). Differences between twins in CRL, NT, abdominal circumference, and amniotic fluid volume identify a subset of monochorionic diamniotic pairs more likely to be diagnosed with TTTS.[40] The risk of

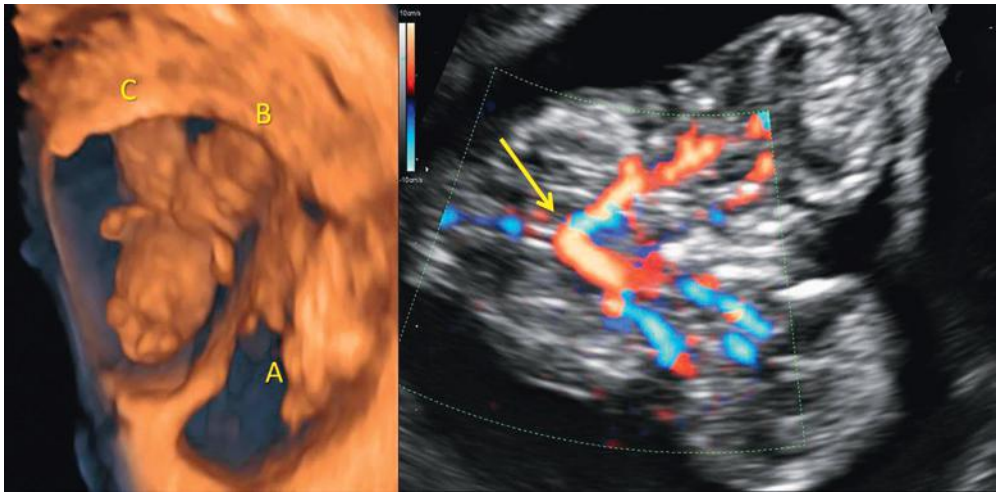

FIG 7-35 Dichorionic diamniotic triplet pregnancy with parapagus dicephalus conjoined pair (B and C). Color Doppler flow imaging (*right*) demonstrates the head and neck vessels of B and C arising from a single heart (*arrow*).

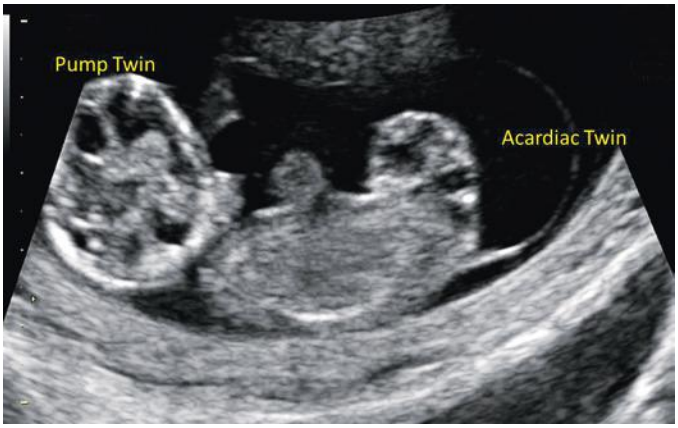

FIG 7-36 Longitudinal ultrasound image shows abnormal upper body development of the anomalous acardiac twin, which lacked demonstrable cardiac activity despite continued growth. The image includes an axial view through the brain of the morphologically normal pump twin.

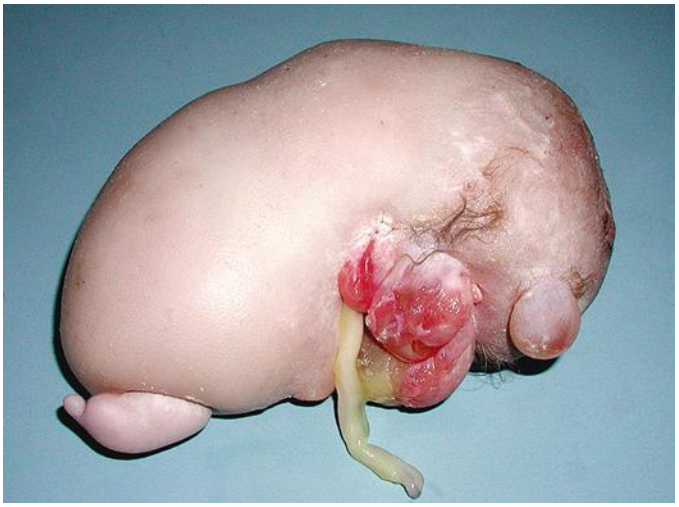

FIG 7-37 Acardiac twin demonstrating the amorphous, vestigial structures cephalad and caudad as the distance from the umbilical cord arterial circulation increases. (Pathologic image courtesy Melinda Sanders, MD, and Erika Walz, PA, University of Connecticut Health Center, Farmington, CT.)

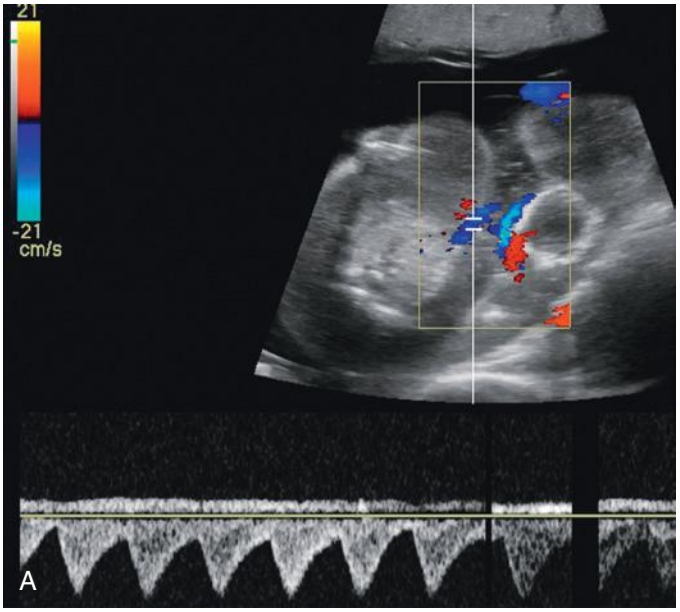
TTTS also appears to be increased when velamentous cord insertions, for one or both fetuses, into the shared placenta are seen.[63]

Sonography is used to categorize TTTS into stages, with less favorable outcomes observed with advanced stages of the disorder[64] (Table 7-6). Serial sonographic surveillance of monochorionic twins is recommended, aiming to detect TTTS in its earliest stages. The finding of monochorionic twins with concomitant oligohydramnios (low fluid in one amniotic sac) and polyhydramnios (high fluid in the other) is essential for the diagnosis of TTTS[40] (see Fig. 7-29). The "donor" twin with oligohydramnios may appear "stuck" in its sac, plastered against the placenta or uterine wall with membrane closely draped over its body (Figs. 7-42 and 7-43). With advanced stages of TTTS, the bladder of the donor twin is not visualized (stage II) and abnormal arterial or venous Doppler waveforms may be seen in the donor or recipient (stage III) (Fig. 7-44). Doppler velocimetry of the middle cerebral artery (MCA) may demonstrate elevated peak systolic velocity in the donor twin, suggesting fetal anemia and reduced peak systolic velocity in the recipient twin implying polycythemia—consistent with coexisting TAPS (see later).[65] Fetal echocardiography and fetal magnetic resonance imaging (MRI), targeting the developing brains, are ancillary studies that may provide additional information about the impact of TTTS and the status of the twins. The imbalance of blood flow from the donor to the recipient twin increases preload, resulting in adaptive responses within the recipient's cardiovascular system (Fig. 7-45). Cardiac dysfunction, biventricular hypertrophy, and functional or structural right ventricular outflow obstruction may develop in the recipient twin over time[40] (Fig. 7-46). Central nervous system abnormalities such as hemorrhagic and ischemic white matter changes, which carry a poor prognosis, have been detected in both donors and recipients in cases with TTTS.[66]

Given the risk of developing TTTS, ultrasound evaluation of monochorionic twin pregnancies is recommended every 2 weeks beginning in the second trimester.[40] Management options for TTTS vary depending on gestational age and stage at time of diagnosis. These options may include pregnancy termination, selective reduction of an anomalous growth-restricted or hydropic co-twin, fetoscopic laser photocoagulation of inter-twin placental vascular anastomoses,



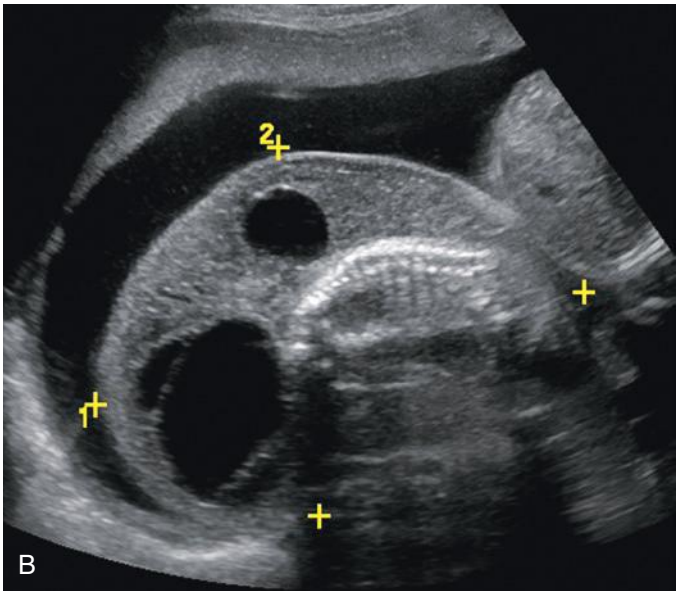


FIG 7-38 Twin reversed arterial perfusion (TRAP). **A,** Color and spectral duplex Doppler interrogation demonstrates reversed arterial flow directed into the acardiac fetus at the level of the umbilical cord insertion at the anterior abdominal wall. **B,** Electronic calipers placed to measure a large anencephalic acardiac parabiotic twin. Diffuse integumentary edema and large cystic hygromas are noted.

amnioreduction, expectant observation, or delivery. The options are similar for complicated triplet pregnancies, but with early detection, some patients may opt for selective reduction of the TTTS pair. Most cases of TTTS are diagnosed in the second trimester and in ongoing pregnancies with advanced stages of TTTS (stage II-IV), fetoscopic laser photocoagulation of vascular anastomoses within the shared placenta is currently considered the best therapeutic intervention to improve perinatal survival[40] (see Chapter 24). This procedure is typically performed between 16 and 26 weeks' gestation and is done in conjunction with post-laser amnioreduction, with aspiration of excess amniotic fluid from the recipient's sac. The management of stage I TTTS is controversial, as only 10% to 30% of cases progress, whereas

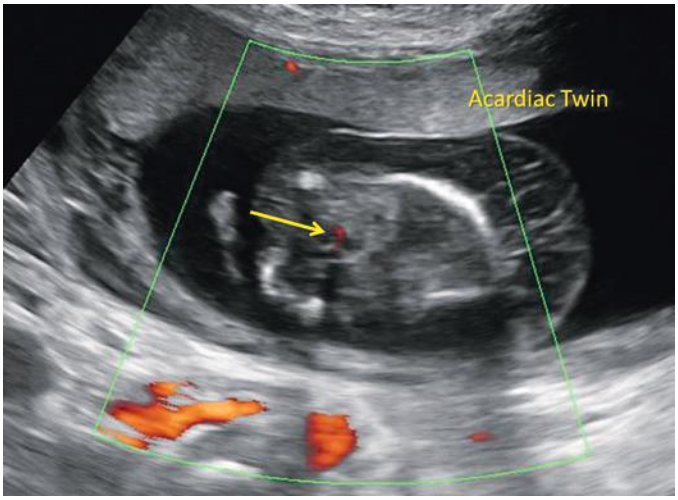

FIG 7-39 Power Doppler ultrasound image demonstrating signal, indicating flow, at the level of the umbilical cord insertion (*arrow*), but no flow was seen within the chest of this acardiac twin.

most remain stable, resolve spontaneously, or do not recur after a single amnioreduction.[67,68]

Following fetoscopic laser photocoagulation for advanced TTTS, serial sonographic surveillance is recommended to assess the twins' response to treatment. In the majority of cases, TTTS resolves with normalization of amniotic fluid volume in each sac, visualization of the donor twin's bladder, and improvement in the recipient twin's cardiac function.[69] Umbilical artery Doppler ultrasound findings may remain abnormal in the presence of coexistent unequal placental sharing with discordant twin growth and in these cases, antenatal fetal testing should be incorporated into third trimester management. Serial assessment by sonography is also used to evaluate for recurrent TTTS, reversed TTTS, TAPS, and unequal placental sharing until delivery.[40]

The outcome of pregnancies with TTTS is dependent on the gestational age at diagnosis, clinical stage, and progression of disease. Mild, early stage TTTS that presents after 26 weeks and does not progress tends to have a favorable outcome for both twins. However, most cases of severe advanced TTTS present in the second trimester. Without treatment, perinatal mortality rate in cases with advanced stages of TTTS is 70% to 100%.[40,70] Following intervention with laser to treat TTTS, perinatal survival rate is reported to be 50% to 70%.[40] In general, two twins survive in 50% of cases, a single twin survives in 30% of cases, and there are no survivors in 20% of cases treated with fetoscopic laser photocoagulation.[40] Procedure-related twin loss is a recognized complication of fetoscopic intervention. In addition, survival with neurologic impairment is a potential serious long-term sequela of TTTS, with or without treatment. Intracranial abnormalities, including intraventricular hemorrhage and cystic periventricular leukomalacia, and subsequent diagnosis of neurodevelopmental delay and cerebral palsy remain risks for survivors of TTTS. Long-term neurologic sequelae are observed in 5% to 20% of survivors of TTTS treated with fetoscopic laser.[40] Additional risks related to preterm delivery and prematurity of these complicated monochorionic diamniotic pregnancies likely impact the long-term outcomes of surviving twins.

Twin Anemia-Polycythemia Sequence

Spontaneous TAPS complicates 5% of monochorionic diamniotic twins and is usually diagnosed after birth when one twin is pale and the other plethoric and the twins are found to have discordant

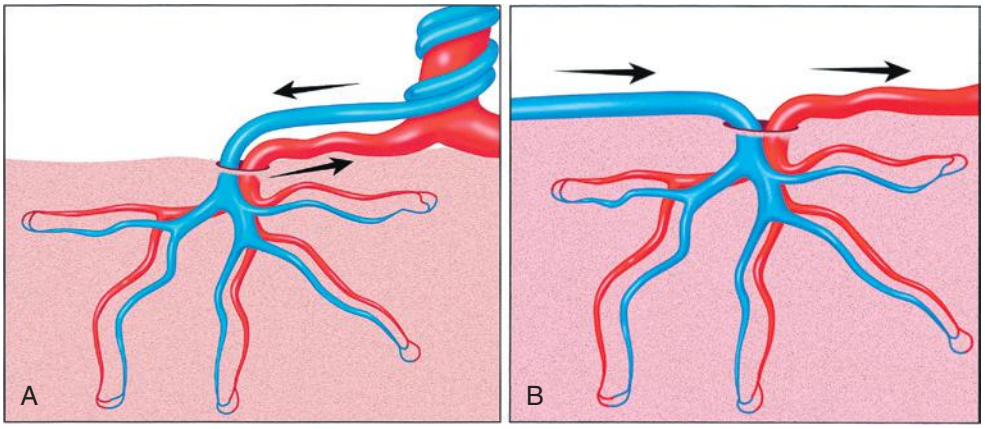

FIG 7-40 Illustrations of normal-paired branch vessels from the umbilical cord (A) and arteriovenous anastomosis in monochorionic twin placenta (B). **A,** Normal paired branches of the umbilical artery (*blue*) and umbilical vein (*red*) are seen coursing together on the fetal surface of the placenta. Blood flows from the umbilical cord toward the placenta by way of the umbilical artery and returns by way of the umbilical vein. **B,** Unpaired vessels course on the fetal surface of the placenta. A branch of the donor umbilical artery (*blue*) meets a branch of the recipient umbilical vein (*red*) where they enter and exit the placental cotyledon by way of a common foramen. Note that the arteriovenous communication occurs deep within the placenta. (Courtesy Vickie Feldstein, MD, University of California, San Francisco, School of Medicine, San Francisco, CA.)

hemoglobin values (Fig. 7-47).[65] As in cases of TTTS, it is theorized that inter-twin vascular anastomoses in the single shared placenta result in a chronic imbalance of blood flow from donor to recipient. However, in TAPS the flow is presumably low volume and slow, such that significant amniotic fluid abnormalities do not develop. Iatrogenic TAPS, observed in up to 10% of TTTS cases treated with fetoscopic laser photocoagulation, is more likely to be recognized in utero because of increased sonographic surveillance following laser treatment.[65] It has been reported that incomplete photocoagulation of inter-twin vascular anastomoses, particularly small unidirectional connections, contributes to the development of postprocedure TAPS.[71]

Serial sonographic surveillance for iatrogenic TAPS is often recommended after laser photocoagulation. The diagnosis is confirmed when peak systolic velocity in the MCA is more than 1.5 multiples of median (MoM) in one twin and less than 0.8 MoM in the co-twin[65] (Fig. 7-48). Screening for spontaneous TAPS in otherwise uncomplicated monochorionic twins is not routine but is performed in some centers when minor variance in amniotic fluid volumes is detected. MCA Doppler velocimetry may be the only sonographic marker of TAPS complicating a monochorionic diamniotic twin pregnancy. Although TAPS and TTTS can occur concomitantly, the observation of both oligohydramnios in one twin and polyhydramnios in the other is not seen in cases of pure "isolated" TAPS. The management of TAPS is controversial, but options include termination, observation, repeat laser intervention, intrauterine fetal transfusion, or delivery, depending on gestational age. The perinatal outcome of TAPS is also variable, ranging from double twin demise to liveborn twins with no obvious long-term sequelae.[65]

Unequal Placental Sharing With Discordant Twin Growth or Selective Fetal Growth Restriction

Although discordant growth and FGR may complicate any multiple gestation, the cause and implications are more wide-ranging with monochorionic placentation. Overall, significant discordance in growth occurs in 15% to 25% of monochorionic twins.[72,73] When compared to monochorionic twins concordant in size, velamentous PCIs and unequally shared placentas are more common in cases with growth disturbance.[74,75] Selective FGR of one twin in a monochorionic pair has been classified into three groups based upon findings on Doppler interrogation of the umbilical artery: type I has normal Doppler waveforms with diastolic flow; type II has persistent absent or reversed end-diastolic flow; and type III has intermittent absent or reversed end-diastolic flow[73] (Fig. 7-49).

As in all multiple pregnancies, growth disorders in twins that share a common placenta may present at any time in gestation. Early disturbances in twin growth, particularly when associated with abnormal diastolic flow in the umbilical artery, have the poorest prognosis with reported 15% to 20% risk of intrauterine fetal demise.[73] TTTS often occurs in conjunction with unequal placental sharing, thereby complicating the diagnosis and management of the pregnancy. For instance, abnormal umbilical artery Doppler waveforms in monochorionic twins may represent uteroplacental insufficiency but may also be related to inter-twin anastomoses and changes in vascular reactivity. Close sonographic surveillance is recommended for all multiple gestations complicated by discordant growth but is of increased importance in monochorionic pregnancies as death of one monochorionic twin increases the likelihood of death or neurologic injury in the co-twin. In general, the latency between development of abnormal diastolic flow in the umbilical artery and fetal deterioration necessitating delivery tends to be longer in monochorionic twins compared to singletons with FGR, but frequent surveillance is still warranted once fetal viability is reached.[76]

Single Twin Demise

Similar to singleton pregnancies, spontaneous loss in the first trimester occurs in 15% to 20% of dichorionic twin gestations and may be recognized as an empty sac or absent cardiac activity in one embryo.[77] Overall, it is expected that only 50% of spontaneous twin pregnancies identified in the first trimester will result in two liveborn infants.[77] Fortunately, the finding of a "vanishing twin" early in gestation is associated with a favorable prognosis for the surviving twin, similar to that of a singleton pregnancy. However, cases with neurologic injury following in utero demise of a monochorionic co-twin have been reported as early as 14 weeks' gestation.[78]

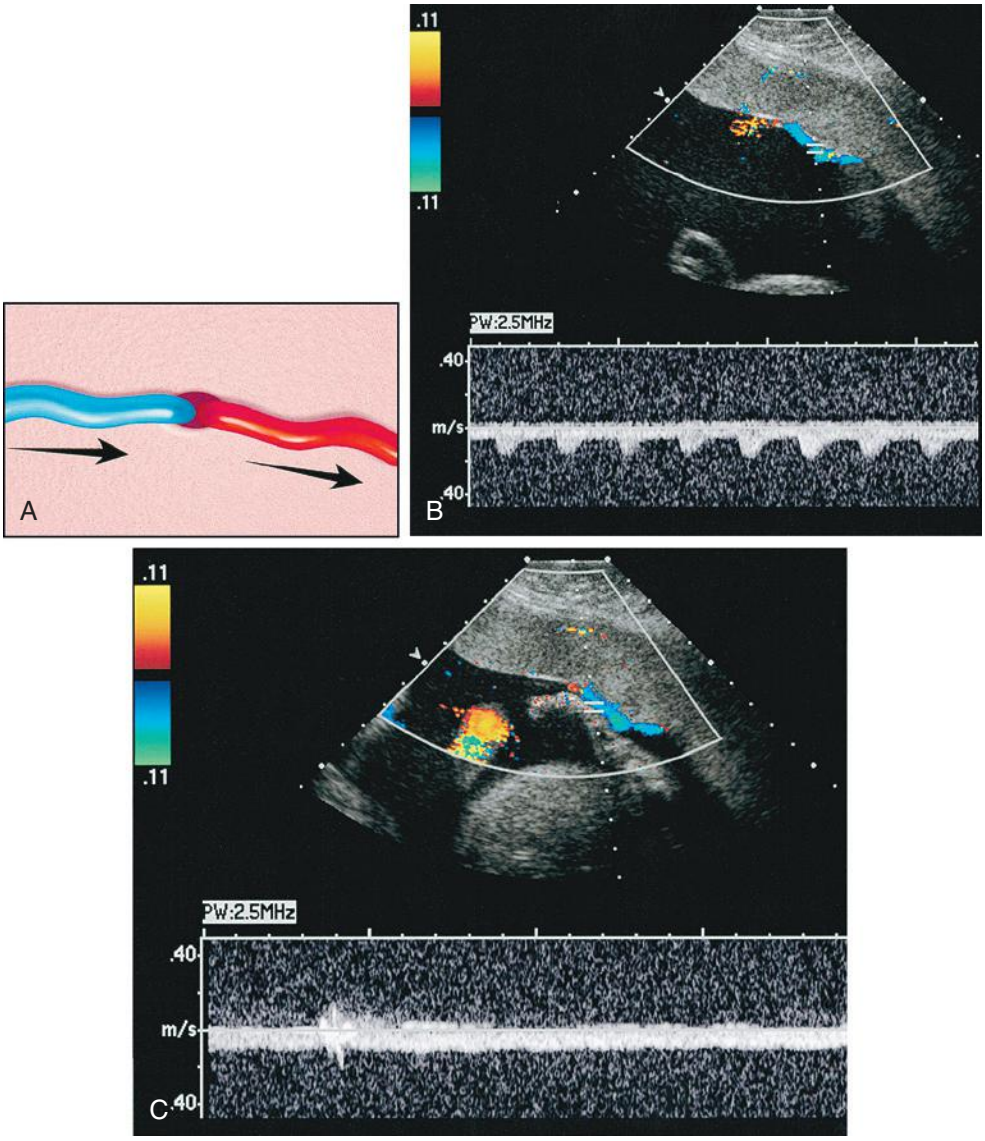

FIG 7-41 Color and pulsed Doppler of the surface-communicating vessels in monochorionic twins. **A,** Arteriovenous anastomosis in a monochorionic placenta. Overview from the fetal surface of the placenta shows feeding branch of umbilical artery from donor (*blue*) and draining branch of umbilical vein of recipient (*red*) entering the placenta via a common foramen. **B** and **C,** Color Doppler ultrasound study demonstrates an unpaired vascular structure on the placental surface. Spectral Doppler waveforms reveal a feeding arterial branch (in B) and draining venous branch (in C), with flow directed from the donor toward the recipient. **D,** Placental pathologic injection study showing an arteriovenous anastomosis (*arrow*) with donor-feeding arterial branch blue and recipient-draining venous branch red. **E,** Pulsed-wave color Doppler insonation of placental surface vessel showing the characteristic periodic bidirectional interference pattern of an arterio-arterial anastomosis. TABLE 7-6 Quintero Staging of Twin-Twin Transfusion Syndrome

TTTS Stage	Ultrasound Features
I	MVP fluid <2 cm in the donor sac and >8 cm in the recipient sac
II	Nonvisualization of the fetal bladder in donor twin for >60 minutes
III	Absent or reversed umbilical artery diastolic flow, reversed ductus venosus a wave flow, or pulsatile umbilical vein flow
IV	Fetal hydrops in one or both twins
V	Fetal demise of one or both twins

MVP, maximal vertical pocket; TTTS, twin-twin transfusion syndrome. Data from Quintero RA, Morales WJ, Allen MH, et al: Staging of twin-twin transfusion syndrome. J Perinatol 19:550-555, 1999.

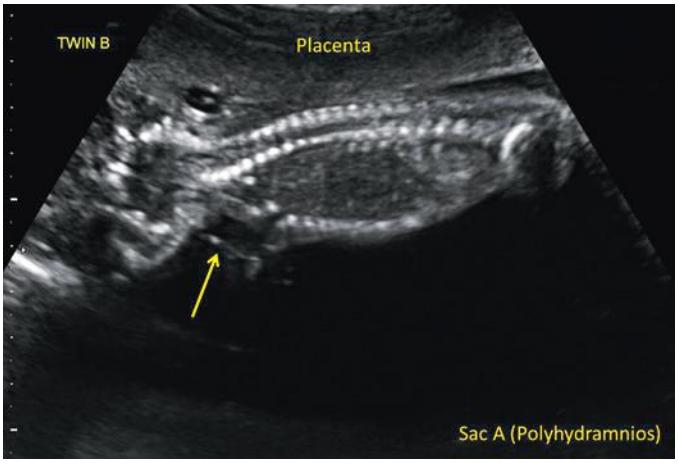

FIG 7-42 Monochorionic diamniotic pregnancy complicated by twin-twin transfusion syndrome with oligohydramnios and polyhydramnios. Twin B, the donor, appears plastered against the anterior placenta with marked oligohydramnios. Polyhydramnios is noted in the sac of the recipient twin A. The thin separating inter-twin membrane is barely visible (*arrow*) as it is adjacent and closely apposed to the "stuck" twin B.

The majority of cases with subsequent in utero demise of a twin will be diagnosed at the time of routine sonographic surveillance for fetal growth and well-being. Beyond the first trimester, intrauterine demise of one fetus occurs in about 5% of twin gestations.[79] Twins with structural malformations are more likely to die in utero than their morphologically normal co-twins. The smaller twin of a discordant pair or a twin with early-onset FGR is also at greater risk of in utero demise.[73] As with singletons, the cause of fetal death in a multiple gestation is often unknown, although there is a threefold to fourfold increase in the rate of intrauterine death in monochorionic compared to dichorionic twins.[80] Complications unique to monochorionic twin pregnancies that contribute to a higher likelihood of single twin demise include cord entanglement in monoamniotic twins, conjoined twins, TRAP, TTTS, unequal placental sharing, and TAPS. Unlike the loss of one twin in a dichorionic gestation, intrauterine demise of one twin in a monochorionic pair increases the risk of specific adverse events, including 10% risk of dual fetal demise and 10% to 30% risk of neurologic injury in the surviving co-twin.[80] Immediate delivery of a monochorionic twin following demise of its co-twin does not eliminate the risk of neurologic compromise. The intracranial insult that a fetus may sustain following demise of a monochorionic co-twin is best assessed by means of in utero MRI, as it is more sensitive than sonography for the detection of hypoxic-ischemic brain injury. Clinical management of these pregnancies depends on gestational age and evidence of fetal or maternal complications. Figure 7-50 shows an ultrasound image of a 21-week twin gestation with in utero demise of one fetus. The head circumference and abdominal circumference of the deceased twin are much smaller than those of the surviving fetus. Figure 7-51 is a photograph of a fetus papyraceus, mummified remains of the lost twin found in the folds of the membranes of the placenta after delivery of the surviving twin at 38 weeks.

CONCLUSION

Despite the expanding literature on twins and higher-order multiples, recommendations about the use of obstetric sonography in multiple gestations are based primarily on level II and III evidence with few randomized controlled trials[81] (Table 7-7). Many of the indications for sonography in multiple pregnancies parallel those for sonographic evaluation in singletons. Pregnancy dating, NT assessment, structural anatomic survey, and placental evaluation should be standard practice. Multiple pregnancies warrant careful sonographic determination of chorionicity early in gestation. Cervical length assessment and sonograms with biometry to evaluate fetal growth are recommended in multiple gestations, but the optimal timing and frequency of these measurements remain uncertain. However, it is evident that multiple gestations with a monochorionic pair require careful serial sonographic surveillance searching for a multitude of potential complications unique to twins that share a single placenta.

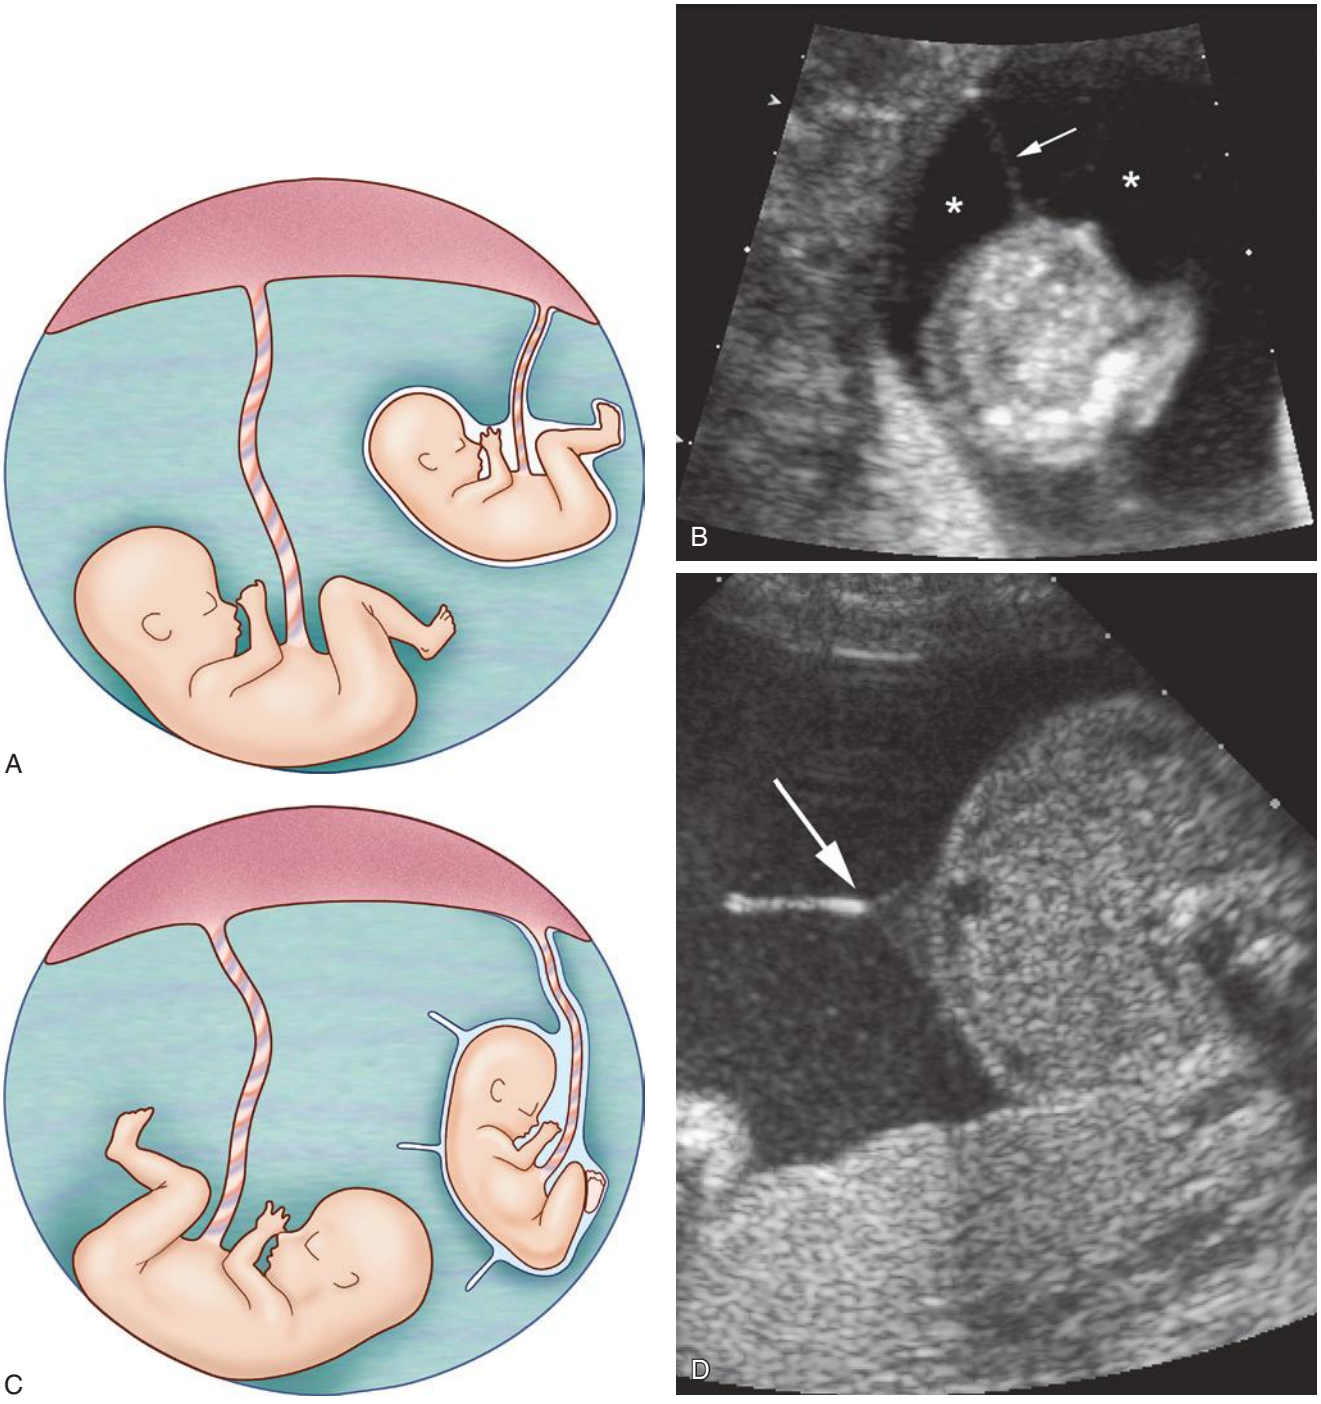

FIG 7-43 Twin-twin transfusion syndrome (TTTS) with a "sling" around the "stuck" twin. When there is little to no amniotic fluid in the amniotic sac of the donor "stuck" twin, the membrane appears as a sling around the fetus. In the absence of amniotic fluid in this sac, the fluid surrounding this twin may wrongly be assumed to be in its sac, when in fact it is the fluid in the adjacent recipient twin's sac with polyhydramnios. **A,** A pregnancy with TTTS in which the fetus on the right is enshrouded by its membrane in an oligohydramniotic sac. **B,** In this case of TTTS, the donor twin is in an anhydramniotic sac. The apposed membranes appear as a single membrane (*arrow*). The surrounding amniotic fluid (*asterisks*) is in the other twin's amniotic sac. **C,** A pregnancy with TTTS in which the fetus on the right is enshrouded by its membrane in an oligohydramniotic sac. Redundant amnion is seen projecting from the fetus and at times presents a confusing appearance. **D,** Scan of a donor fetus with severe oligohydramnios and redundant amnion (*arrow*) seen projecting into the amniotic fluid of the other fetus. (A and C courtesy Vickie A. Feldstein, MD, University of California School of Medicine, San Francisco, CA.)

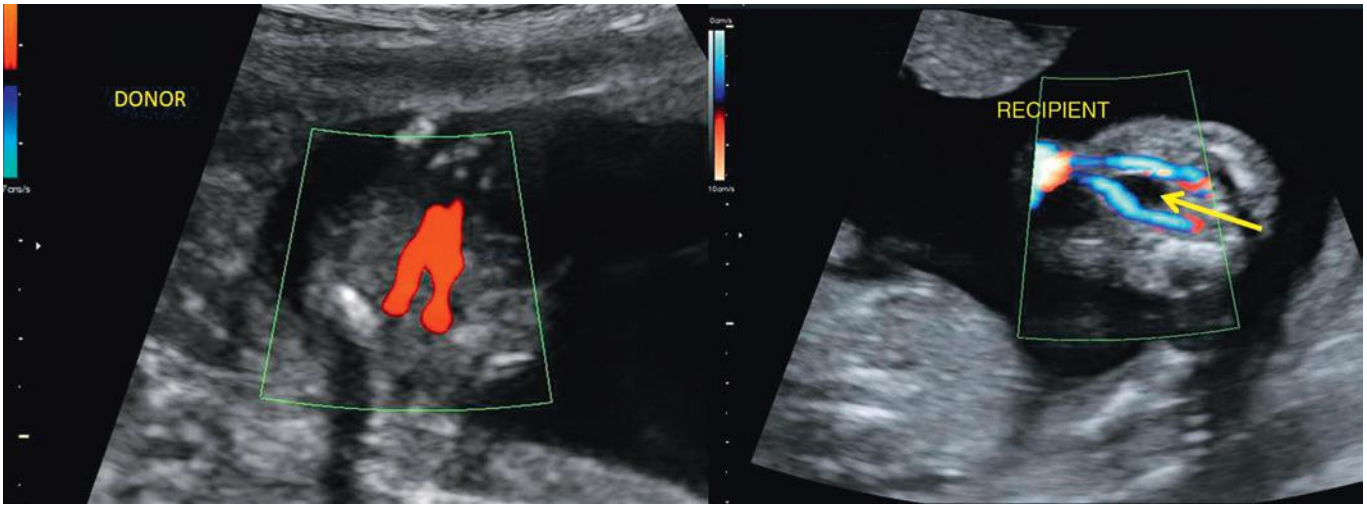

FIG 7-44 Twin-twin transfusion syndrome, stage II. Monochorionic diamniotic twin pregnancy with oligohydramnios and polyhydramnios (not shown). Nonvisualization of the empty bladder in the donor. Fluid shown within the normal-appearing bladder (*arrow*) of the recipient. Color Doppler demonstrates flow within the umbilical arteries, which flank the bladder, of each twin.

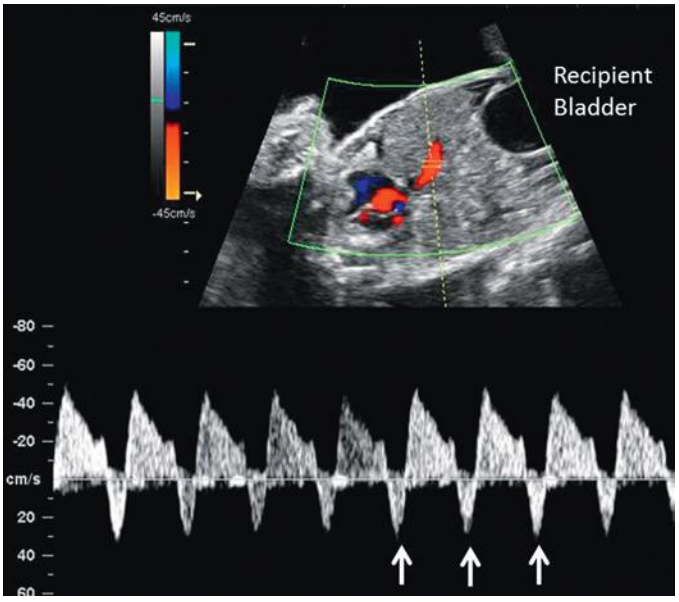

FIG 7-45 Twin-twin transfusion syndrome. Recipient twin with distended urinary bladder. Spectral Doppler waveform of the ductus venosus demonstrates reversed a-wave flow (*arrows*), indicative of cardiac diastolic dysfunction associated with overload.

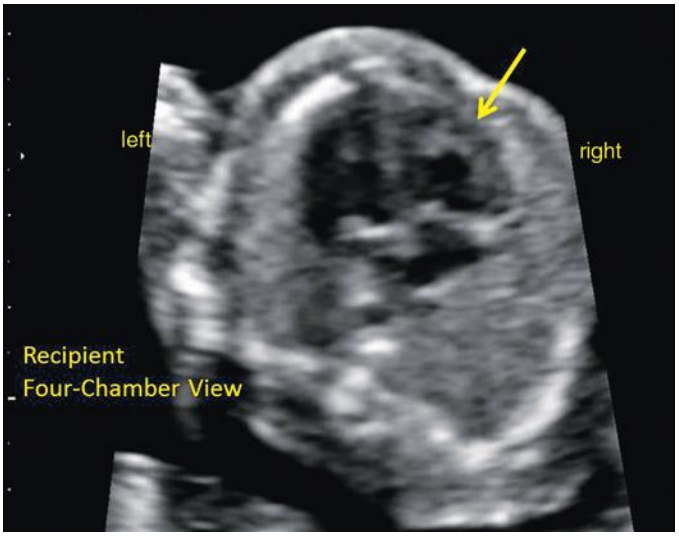

FIG 7-46 Twin-twin transfusion syndrome. Biventricular hypertrophy in the recipient twin is noted early in the second trimester. The thick-walled right cardiac ventricle (*arrow*) was noted to be more affected than the left.

FIG 7-47 Placenta in a case of twin-twin transfusion syndrome. The donor's placental disc is paler, suggesting fetal anemia, whereas the recipient's placental disc is darker, suggesting polycythemia. The donor's hematocrit was 22% and the recipient's was 54%. (Courtesy Melinda Sanders, MD, and Erika Walz, PA, University of Connecticut Health Center, Farmington, CT.)

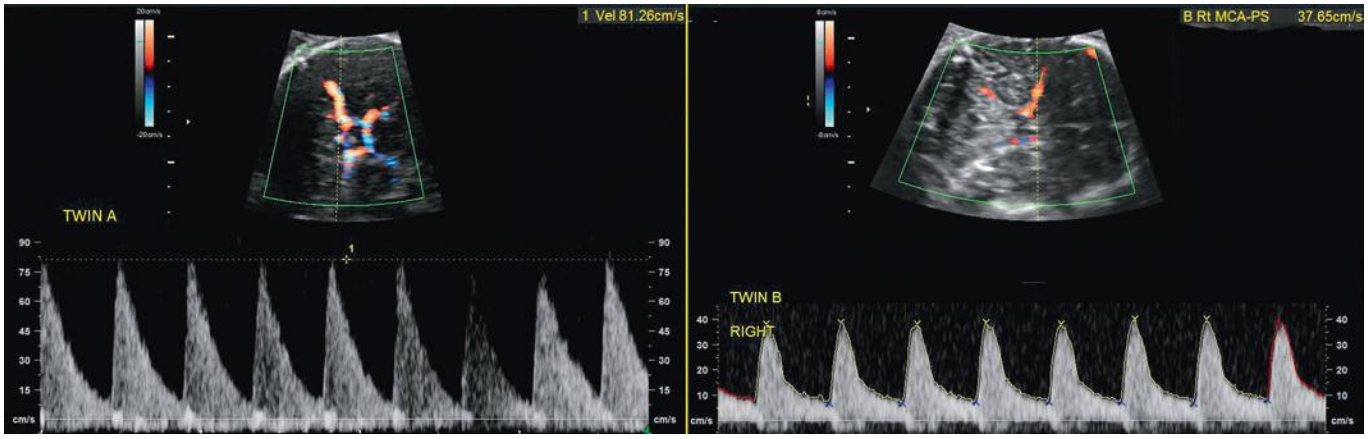

FIG 7-48 Twin anemia-polycythemia sequence (TAPS). Elevated peak systolic (PS) velocity in the middle cerebral artery (MCA) in twin A (measuring 81.26 cm/second) and decreased in twin B (measuring 37.65 cm/second) characteristic of TAPS.

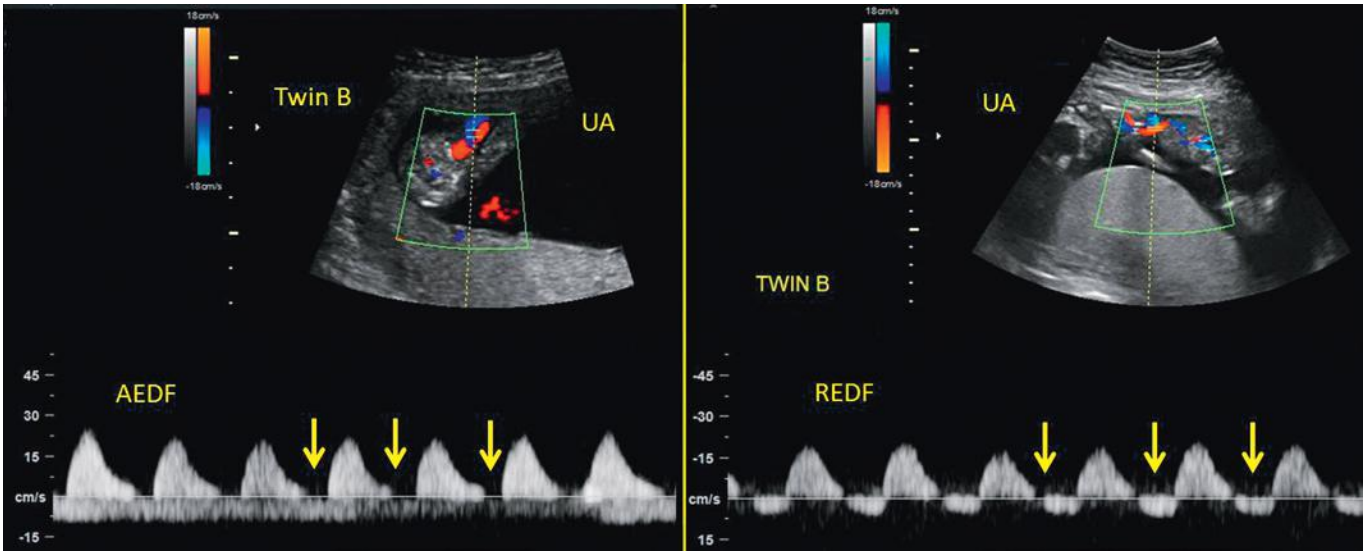

FIG 7-49 Abnormal umbilical artery (UA) Doppler waveforms in growth-restricted twin B of a monochorionic diamniotic pair. At left, initially, absent end-diastolic flow (AEDF) was observed (*arrows*). On right, follow-up sonogram revealed progression (*arrows*) with reversed end-diastolic flow (REDF) in this case with suspected unequal placental sharing.

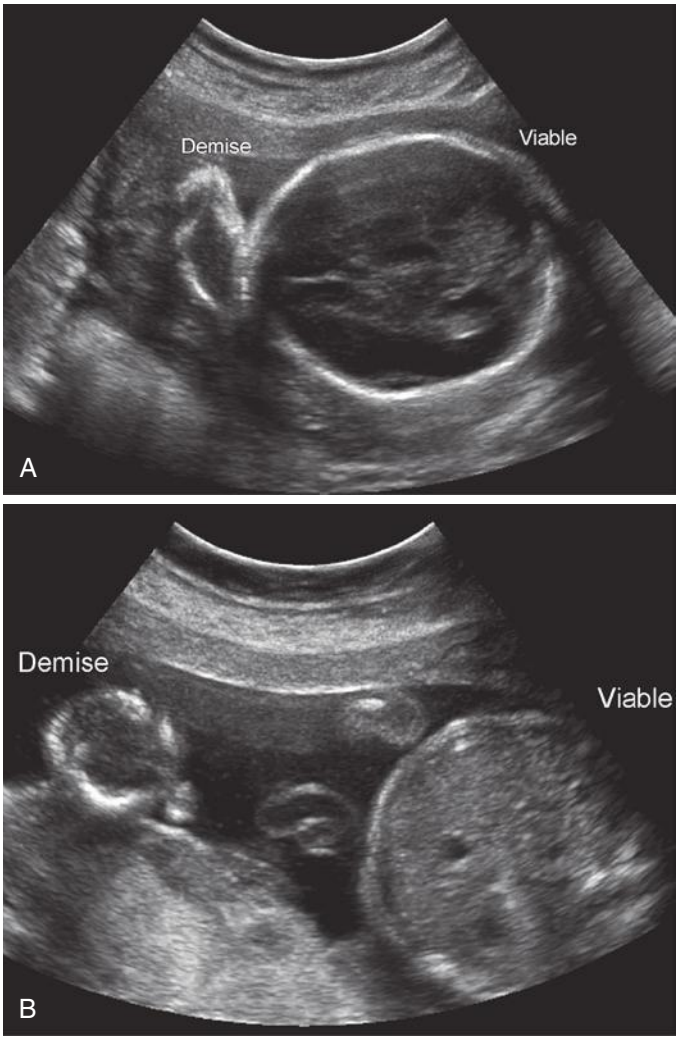

FIG 7-50 Fetal demise of one twin with a surviving co-twin at 21 weeks' gestation. **A,** The collapsed cranium of the twin with the fetal demise compared with the surviving twin's cranium. **B,** The abdominal circumference of the fetal demise is compared with that of the surviving twin.

FIG 7-51 Fetus papyraceus resulting from a midtrimester fetal demise of a co-twin. This fetus was noted on inspection of the placenta and membranes following a term delivery of the surviving twin. TABLE 7-7 Ultrasound Evaluation in Multiple Gestations

Reason for Evaluation	Timing	Points
Pregnancy dating	1st trimester	Optimal at 7-10 weeks using CRL
Determination of chorionicity	1st trimester	Close to 100% accuracy if done prior to 2nd trimester
Nuchal translucency assessment	10-13 weeks	Increased with aneuploidy, malformations, TTTS
Anatomic survey	2nd trimester	Optimal at 18-22 weeks; consider fetal echocardiography for IVF and presence of monochorionic twin pair
Placental evaluation	2nd trimester	Transvaginal imaging to exclude placenta previa and vasa previa; color imaging for PCI localization
Cervical length	2nd trimester	Transvaginal imaging optimal
Interval fetal growth	2nd and 3rd trimesters	Every 4 weeks for uncomplicated multiple gestations
Serial surveillance	2nd and 3rd trimesters	Every 2 weeks for uncomplicated monochorionic twins; daily testing for viability for monoamniotic twins; frequency and type of testing of twins and higher-order multiples depends on chorionicity, risk, and complications

CRL, crown-rump length; IVF, in vitro fertilization; PCI, placental cord insertion; TTTS, twin-twin transfusion syndrome.

Ultrasound Evaluation of Normal Fetal Anatomy

Tara A. Morgan, Vickie A. Feldstein, Roy A. Filly

SUMMARY OF KEY POINTS

- Continued advancement of ultrasound technology including increase in frequency and choice of focal position have improved visualization of fetal anatomy and therefore have also increased the required anatomic knowledge of these structures for those performing and interpreting fetal sonograms.
- Superficial anatomy of the fetus can be delineated with either two-dimensional or three-dimensional sonography and can be useful in confirming normal formation of facial structures and genitalia.
- Fetal skeletal structures are the earliest recognizable fetal features, and their sonographic evaluation is highly dependent on the position of the fetus.
- Identification of a normal three-vessel umbilical cord and normal portal venous anatomy is useful in determining whether cardiovascular development is normal.
- The liver is the largest gastrointestinal organ and is the largest contributor to the size of the abdominal circumference.
- The lungs become more echogenic later in pregnancy; however, the change is not related to lung maturity.
- Kidneys grow throughout pregnancy, with a ratio of kidney circumference to abdominal circumference of 0.27 to 0.30.
- The calvaria can obscure the portion of the brain nearest the transducer. Bone-free windows through the fontanelles can be used to increase visualization, and when one hemisphere is not well seen, symmetry is assumed unless images prove otherwise.

OUTLINE

Our understanding of normal fetal anatomy as seen on sonograms continues to evolve. Instrumentation has improved steadily, yielding both improved and more consistent image quality. Among the most significant advances in fetal imaging has been the ability to choose the depth of the zone of best focus of the ultrasonic beam and to select frequency without changing transducers. With these capabilities, the area of anatomy being observed can be consistently inspected with the focused portion of the beam at an optimal frequency, both highly significant advantages. Recent technologic advances allow imaging at higher frequencies than a mere decade ago.

In addition to these technologic advances, sonologists have gradually improved their understanding of the anatomy portrayed on in utero sonograms. Unquestionably, clearer images have led the way to our improved understanding, but other factors have been involved; not the least of these has been the surge in ultrasonic imaging of premature neonates.[1,2] These tiny neonates are the equivalent of second trimester fetuses as early, at times, as 24 weeks' gestation. Visualization of their brains[1,2] (Fig. 8-1) and abdominal (Fig. 8-2) anatomy in the ex utero environment, which permits the use of higher frequency transducers, a greater selection of planes of section, and comparison with other imaging modalities, has done much to improve our understanding of fetal anatomy. This information can be, to a large extent, extrapolated to younger fetuses. As well, as magnetic resonance imaging (MRI) continues to be a growth area in fetal imaging, our ability to compare sonographic anatomy of the fetus with that portrayed on MR imaging further enhances our understanding of fetal sonographic anatomy[3-7] (Fig. 8-3).

The ability of sonography to detect intrafetal structures is a balance between spatial resolution and contrast.[8] This balance, however, strongly favors contrast as the more important aspect of perception. For example, a large white dot on a white wall is difficult or impossible to see because no contrast differential exists even though the eye can spatially resolve easily a tiny black dot (high contrast) on the same wall. Structures possessing high levels of subject contrast can be consistently detected at a smaller size (often equating to an earlier age) than those displaying poor contrast. Although sonographic contrast agents are available for imaging in adults and children, current agents do not cross the placenta in sufficient concentration to affect fetal organs.[9] Therefore, sonologists possess no agents to alter contrast of fetal organs and thus are totally dependent on subject contrast (inherent contrast) for visualization of internal fetal morphologic details. Clearly, spatial resolution is also a critical feature in defining morphologic structure but has not been the limiting factor in demonstrating fetal anatomy. Fortunately, sophisticated modern sonographic imaging systems have

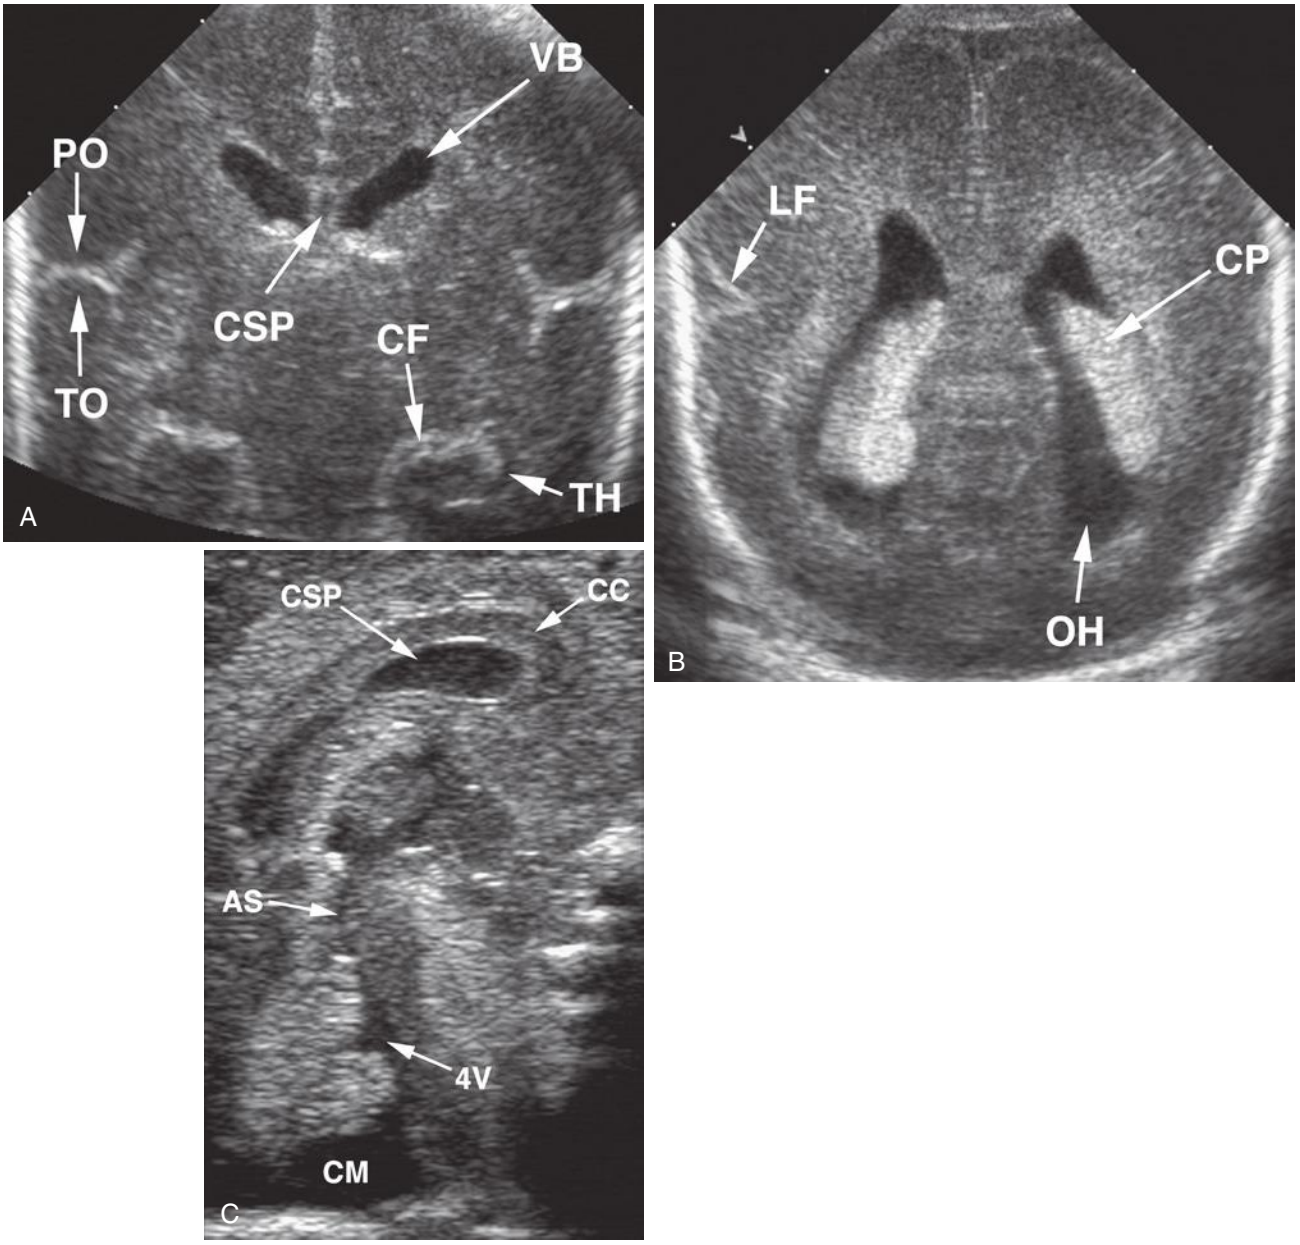

FIG 8-1 Neonatal head sonograms. Coronal (**A**), axial (**B**), and midsagittal (**C**) images enable correlation with fetal examinations. AS, sylvian aqueduct; CC, corpus callosum; CF, choroidal fissure; CM, cisterna magna; CP, choroid plexus; CSP, cavum septi pellucidi; LF, lateral fissure; OH, occipital horn; PO, parietal operculum; TH, temporal horn; TO, temporal operculum; VB, lateral ventricular body; 4V, fourth ventricle.

the ability to choose varying contrast settings, which enhance inherent tissue differences. An important aspect of the technical advancements allowing ever higher frequency imaging is that at higher frequencies, contrast differences between organs change, which can have diagnostic impact.

Another technology that has improved fetal imaging, particularly for earlier gestations, is the intracavitary (transvaginal) transducer.[10-12] Certain aspects of fetal and even embryonic, anatomy can be seen with amazing detail (Fig. 8-4). Although this methodology is crucial to modern imaging, we intend to concentrate our discussion on anatomy visualized by transabdominal transducers in fetuses beyond the 14th week. When examining later pregnancies, in the context of fetal anatomic imaging, we use transvaginal transducers predominantly to visualize the presenting part when transabdominal transducers fail to adequately image this region of the fetal anatomy (e.g., distal sacrum in a breech fetus).

Other parameters, important in fetal imaging, also cannot be controlled. Sonography is a tomographic technique. Appropriate positioning for obtaining the best tomographic plane is always desirable. However, we are unable to control fetal position to attain this end. We also cannot control maternal body habitus or the amount of amniotic fluid, both of which may dramatically alter our ability to discern fetal anatomy. Despite these problems, a large number of fetal structures are consistently visible sonographically.

High-resolution, real-time scanners with their flexible approach to imaging are mandatory for modern fetal sonography.[13-15] In the following sections, various aspects of fetal anatomy are detailed as seen on such instrumentation. An estimate is made of the ability of

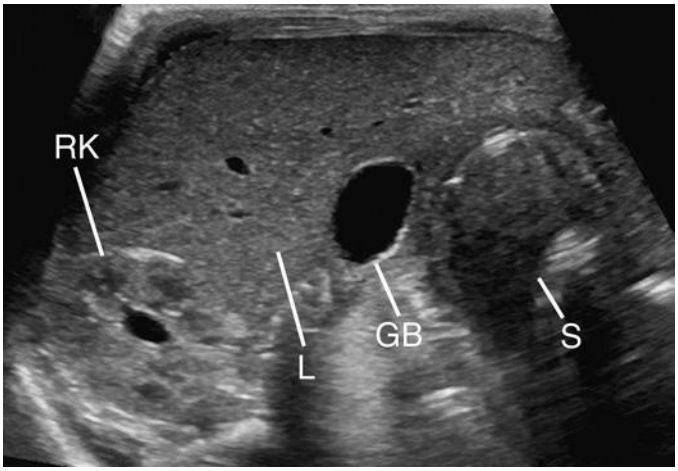

FIG 8-2 Neonatal abdominal sonogram. Transverse axial image in a 1-month-old infant born premature at 24 weeks' gestation demonstrates the right kidney (RK), liver (L), gallbladder (GB), and stomach (S).

FIG 8-3 T2-weighted fetal magnetic resonance imaging in a 21-week fetus demonstrates normal anatomy of the liver (L), cerebral lateral ventricle (LV), stomach (S), heart (H), right lung (RL), small bowel (SB), and bladder (B).

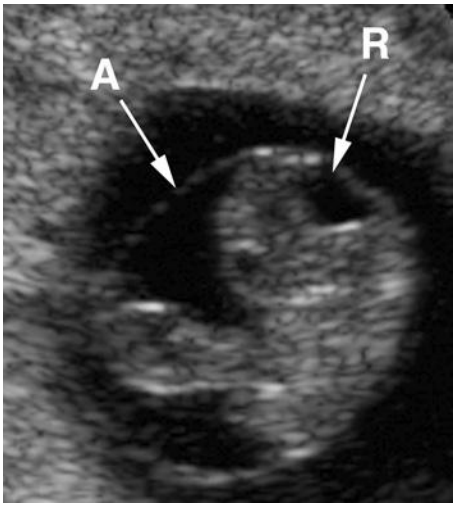

FIG 8-4 Transvaginal sonogram of a 17-mm embryo. This midsagittal view demonstrates the large early fourth ventricle formed by the folding of the rhombencephalon (R). A, amnion.

ultrasound instrumentation to consistently demonstrate the anatomic part under consideration as well as an attempt to estimate when the fetus has attained sufficient size such that the anatomic structure is large enough to be detected. It is important to recall that size and visualization may be relative at any given stage of development. For example, in a small fetus with a well-distended urinary bladder, identification of the bladder is relatively easy. Alternatively, identification of the bladder will be difficult in a term fetus that has recently voided. The urine, in this instance, provides the "contrast" that ordinarily makes the urinary bladder an easy structure to perceive. If this contrast agent drains away, the size of the fetus (and thus its bladder) will not rescue one from the loss of contrast. Also important is the concept that the human eye sees best in the "relative" rather than the "absolute" sense of size. Thus, in a young fetus, the cerebral ventricle is much more readily seen than in an older fetus because the relative size of the ventricle compared with overall brain size is larger early (even though the absolute size is larger later).

If the sonographer begins with a specific intent to image a particular fetal part, it is frequently possible to succeed.[8,16] To accomplish this end, the sonographer must (1) assess the precise fetal position; (2) consider whether the anatomic part of interest is best visualized in planes perpendicular to the fetal long axis or parallel to the fetal long axis; and (3) adjust acoustic imaging parameters, particularly time-gain compensation, and transducer angulation to visualize the area to best advantage. Obviously, such rules are the same throughout all of sonography. The challenge of imaging intrafetal structures is to apply these rules when fetal position is changing such that the current scanning plane is no longer applicable for the part one wishes to visualize.

The flexibility offered by real-time sonographic systems enables one to survey the fetus quickly to determine precise position. Second, the sonographic tomograms, which are rapidly generated (virtually "real-time" imaging), enable one to view a large volume of the fetus with closely spaced sections. Such a rapid look at many contiguous tomograms eliminates one of the basic flaws of tomographic imaging of a moving target. Finally, fetal movements are viewed directly, which enables one to quickly reorient the transducer to the optimal plane of section to image the structure of interest. As digital image storage and viewing continues to expand, cine clip technology has greatly improved the capture and viewing of many fetal parts, especially those that are

in motion, like the heart. Surprisingly, many imaging groups fail to take advantage of cine technology when recording fetal examinations. This immensely powerful technology should not be left on the sidelines by imaging specialists.

Currently, three-dimensional imaging systems have reached a clinically relevant stage of development.[17-19] These instruments depend on *volume imaging*. That is, a volume of tissue within the fetus is insonated and the data are gathered in the processing computer. From this volume, three-dimensional images are generated. Of perhaps greater importance in the future, individual planes of section in virtually any orientation can be computed. When and if it becomes possible to generate equivalent planar images to those obtained with a hand-held transducer, the current method of "fluoroscopic" sonography, the entire nature of sonography will change. The technical challenges of sonography will be greatly reduced (Fig. 8-5).

Fetal parts of interest to the sonologist fall into three major categories of subject contrast that subsequently determine the relative ease with which the structure is sonographically visible: (1) structures that generate high-amplitude reflections (e.g., ossified bones, submucosa of fetal bowel, leptomeninges); (2) structures that generate no internal echoes (e.g., fluid-containing viscera); and (3) structures that generate midrange gray echoes (e.g., the parenchymal organs such as the lungs, brain, spleen, liver, kidneys, and muscles). The categories are listed from most visible to least visible. Within the last category, one may anticipate seeing a spectrum of gray shades that will enable distinction between parenchymal organs and intraorgan components. For example, the medullary portions of the fetal renal parenchyma generate lower amplitude internal echoes than do the surrounding cortical tissues and Bertin septa, thus enabling recognition of this separate component of renal tissue (Fig. 8-6).[20] Modern imaging systems enable distinctions previously not possible. An example from a relatively common pathologic circumstance is the apposition of the herniated spleen against the lung in left congenital diaphragmatic hernia. Previously these organs "blended" together, but currently they are readily discriminated, resulting in better estimations of residual lung volume in affected fetuses (Fig. 8-7).

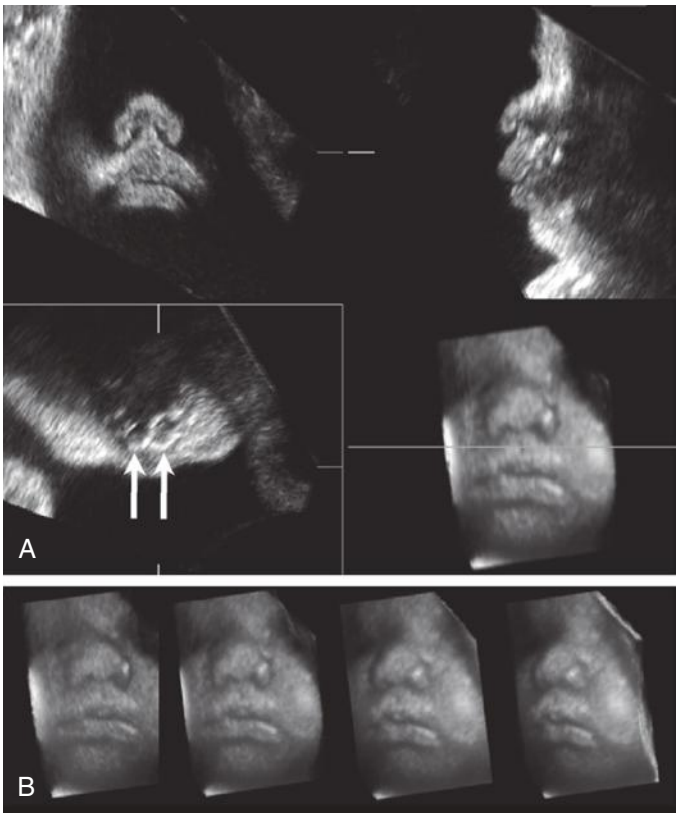

FIG 8-5 Normal fetal face at 35 menstrual weeks. **A,** Multiplanar and volume-rendered images of the fetal face are displayed. *Upper left,* a coronal view through the nose and lips is seen. *Upper right,* a sagittal or profile view of the face is seen. *Lower left,* an axial plane through the anterior alveolar ridge of the primary palate is shown. *Lower right,* a volume-rendered image of the face using surface and light techniques is shown. A line is visible crossing the upper lip of the fetus, which identifies the level of the axial plane in the lower left box. Note two tooth buds in the anterior alveolar ridge (*arrows*). **B,** Images from multiple rotations of the fetal face are shown. Generally, a volume is rotated with a knob on the work panel to provide the impression of three-dimensionality. (From Pretorius DH, Nelson TR: Three-dimensional ultrasound in gynecology and obstetrics. Ultrasound Q 14:218-233, 1998.)

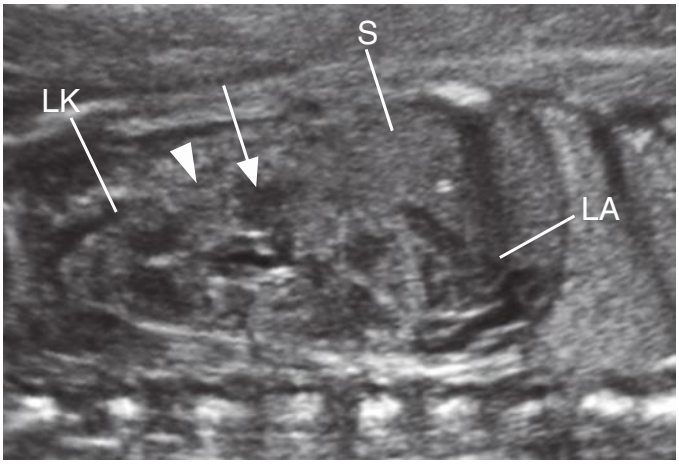

FIG 8-6 Sonogram of a fetal left kidney (LK) in longitudinal axis. The medullary pyramids (*arrow*) are darker, triangular areas distinguishable from the surrounding cortical tissues and septa of Bertin (*arrowhead*). LA, left adrenal gland; S, spleen.

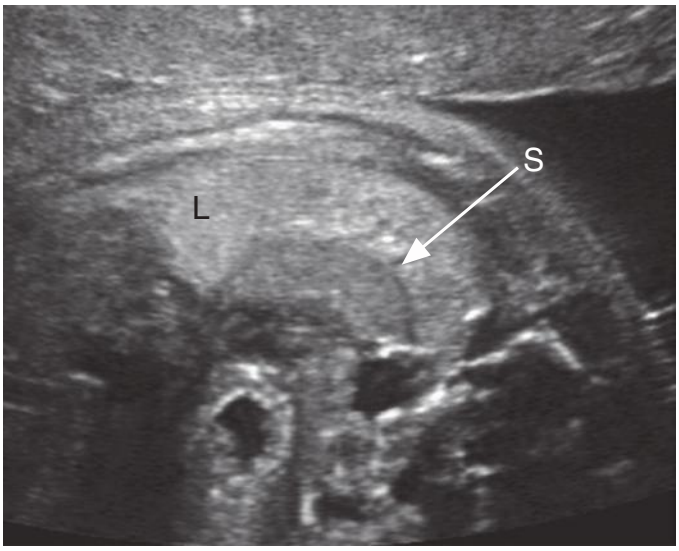

FIG 8-7 Transverse sonogram of the left fetal hemithorax with congenital diaphragmatic hernia demonstrates that the spleen (S) within the chest is well differentiated from and less echogenic than the adjacent fetal lung (L).

A feature of critical importance for organ imaging is the fetal position. A prone fetus is in an optimal position for imaging the kidneys, ordinarily difficult to perceive, but in a poor position to demonstrate the urinary bladder, which is usually easy to image. Determination of fetal position should be accomplished in all obstetric sonographic examinations from the second trimester onward. The fetal position should be determined as precisely as possible before an interpretation of fetal anatomy is begun, because the position of a structure will often influence our interpretation. The general fetal orientation is first assessed (e.g., cephalic, breech, oblique, or transverse). Once this is determined, the location of the fetal spine is noted. If, for example, the fetal spine is on the maternal left side and the fetus is in a cephalic presentation, one can judge that the fetus is lying on its left side (Fig. 8-8). Conversely, if the fetus is breech, then it must be lying on its right side. The reverse is the case for breech and cephalic fetuses when the fetal spine lies on the maternal right side. In the transverse or oblique fetal positions the same rules apply but with a different orientation.

Such an analysis of fetal position is vital for proper interpretation of abdominal and thoracic situs (now a requirement of the AIUM/ACR/ACOG [American Institute of Ultrasound in Medicine/American College of Radiology/American College of Obstetricians and Gynecologists] practice guidelines for second and third trimester obstetric sonograms) and for identification of abnormal fetal structures. For instance, a rounded, fluid-filled structure in the left posterior portion of the upper fetal abdomen may be assumed to represent the fundus of the fetal stomach. However, a structure of identical appearance but located on the right side of the upper fetal abdomen must be interpreted as a pathologic lesion or an abnormality of situs.

It is important to recall that pathologic structures are frequently more visible than their normal counterparts (e.g., dilated small bowel loops are easier to detect than normal small bowel loops). However, it is even more important to keep in mind that the most difficult pathologic observation is to recognize the absence of a structure that ordinarily could be visualized (i.e., a missing portion of an extremity or the inability to see the stomach when esophageal atresia without tracheoesophageal fistula is present).

SUPERFICIAL ANATOMY OF THE FETUS

Routine sonography for obstetric indications in many cases does not require a survey of superficial fetal structures. However, when an anomaly is suspected, a careful look at superficial features of the fetus becomes important or even mandatory. Superficial anatomy considered in this section includes the face, ears, hair, and external genitalia. Importantly, technologic advancements in three-dimensional renderings of fetal sonograms have had a dramatic impact on visualization of superficial fetal anatomy.[21-23]

The fetal face can be viewed with considerable clarity with two-dimensional sonography. Expectant mothers are often surprised to see their fetus so clearly (Figs. 8-9 to 8-11). The brow, cheeks, eyelids (and occasionally even eyelashes), nose, lips, and chin can be seen with consistency. The nose and lips are the more important to image in detail (to exclude clefting). The alae, column, and nares can be clearly depicted (Figs. 8-12 and 8-13). The upper lip is more important diagnostically than the lower lip and fortunately easier to see. Visualization is usually good enough to identify the philtrum. The cheeks are prominent, as expected, and the subcutaneous tissues of the cheek, because of the presence of a large fat pad, are brightly echogenic (Fig. 8-14). The profile is also readily demonstrated (see Fig. 8-11) and provides useful information about the brow (e.g., frontal bossing), chin (e.g., hypognathia), and nose (e.g., midface hypoplasia and Down syndrome).

The ears can be visualized quite well and their progressive maturation noted.[24] The external auditory canal, helix (and antihelix in older fetuses), lobule, and tragus can be depicted (Fig. 8-15), but the relative position of the ear (e.g., as in low-set ears) is difficult to judge—a task more readily accomplished with three-dimensional imaging. The ear may be protuberant and can be mistaken for an abnormality, especially an encephalocele.[25]

When present, scalp hair is readily perceived in late fetuses. The bright linear echoes protruding from or paralleling the scalp and neck are quite conspicuous. The only benefit of recognizing hair is not to be misled into mistaking long hair for a pathologic process—namely, an encephalocele or cystic hygroma—because longer hair, wet and matted by the amniotic fluid, may trap some of the fluid between it and the skin of the occiput or neck, creating the false impression of a cystic mass in this location (Fig. 8-16).

The external genitalia can be appreciated from early second trimester onward. Fetal sex can be quite accurately assigned.[26-28] Ordinarily, this is not of clinical consequence. However, in certain circumstances, fetal sex should always be determined. These situations include all living twins in which a single placental site is seen or when monozygotic twinning, other than for reasons of placentation, would be considered detrimental to pregnancy outcome.[29] All fetuses with suspected lower urinary tract obstruction should have fetal sex determined because the differential diagnosis is different in males and females. Certain other circumstances would require determination of sex if karyotyping were refused or impractical to perform and cell-free DNA screening were not possible or inconclusive. These indications include, but are not limited to, risk for X-linked disorders or when Turner syndrome is suspected because of a dysmorphic feature (e.g., cystic hygroma).

Female sex should be assigned only by identification of the major and minor labia (Fig. 8-17). Assigning female sex based solely on an inability to see a penis will result in many diagnostic errors. Male genitalia are readily seen (Fig. 8-18). The penis and scrotum are most obvious. Testes may be seen in the scrotal sac, sometimes as early as the beginning of the third trimester (the testes are intra-abdominal during most of gestation but are only visualized in the presence of ascites). Care should be taken to image the entirety of the phallus to avoid false foreshortening. Details of the penis, including the glans, urethra, and corpora cavernosa, may be appreciated (Fig. 8-19). Even the foreskin is visible in some cases.

MUSCULOSKELETAL SYSTEM

Real-time ultrasonography provides the most appropriate format for imaging fetal bones. The resolution and flexibility offered by such systems enable one to survey the fetal skeleton rapidly. Of all structures within the fetus, the ossified portions of the skeleton possess the highest level of subject contrast and thus are seen earlier and more consistently than any other organ system.[13,30-33] Sonography surpasses all other imaging modalities in fetal skeletal imaging. Although radiographs of abortuses demonstrate bony morphologic appearance more advantageously than would a sonogram,[34,35] the reverse is true of fetuses in the womb, where overlying maternal soft tissues and bones, fetal movement, and inappropriate fetal position degrade radiographic images of the early fetal skeleton. With volumetric imaging (three-dimensional sonography), special processing can give a more global view of fetal skeletal structures than can be achieved with two-dimensional sonography.[36-38] This enhances the image and diagnostic process for assessment of both normal and pathologic findings (Fig. 8-20).

Fetal position dramatically affects visualization of the bony structures. The posterior elements of the fetal spine may be clearly imaged

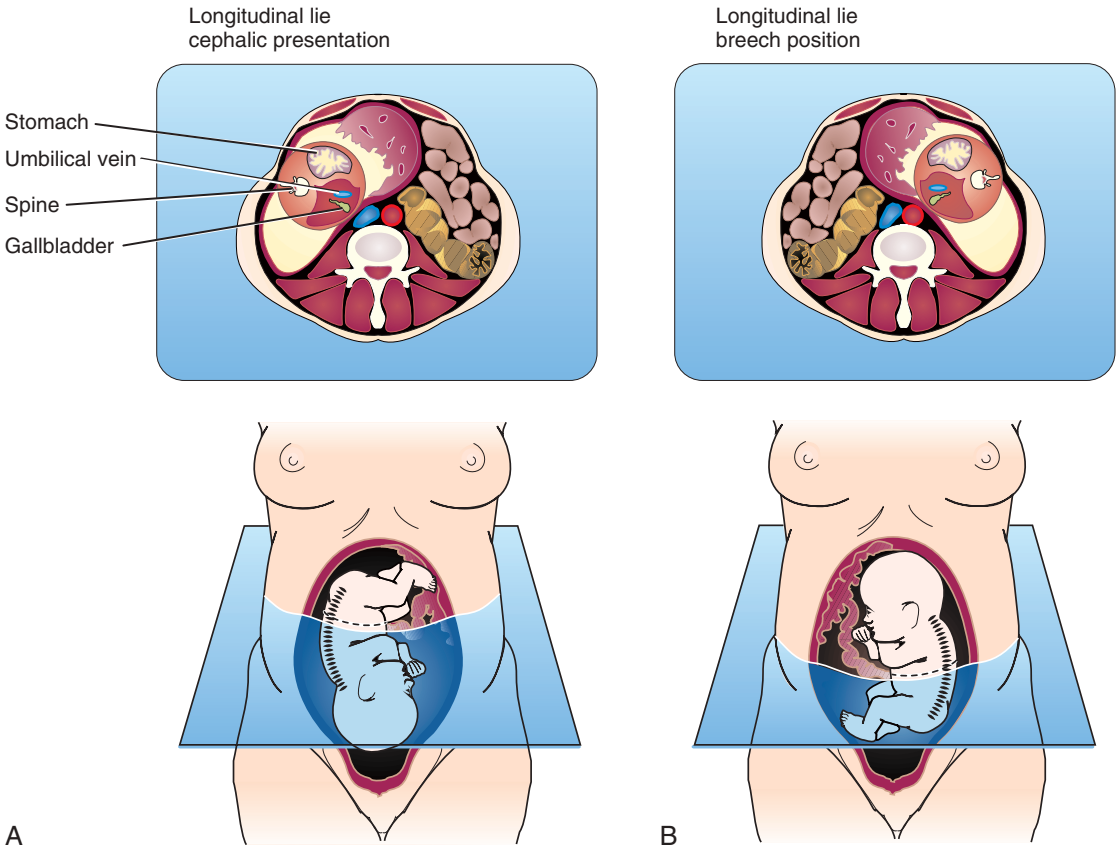

FIG 8-8 Knowledge of the plane of section across the maternal abdomen (longitudinal or transverse) as well as the position of the fetal spine and left-sided (stomach) and right-sided (gallbladder) structures can be used to determine fetal lie and presenting part. **A,** This transverse scan of the gravid uterus demonstrates the fetal spine on the maternal right with the fetus lying with its right side down (stomach anterior, gallbladder posterior). Because these images are viewed looking up from the patient's feet, the fetus must be in a longitudinal lie and in cephalic presentation. **B,** When the gravid uterus is scanned transversely and the fetal spine is on the maternal left, with the right side down, the fetus is in a longitudinal lie and in breech presentation. **C,** When a longitudinal plane of section demonstrates the fetal body to be transected transversely and the fetal spine is nearest the lower uterine segment, with the fetal right side down, the fetus is in a transverse lie with the fetal head on the maternal left. **D,** When a longitudinal plane of section demonstrates the fetal body to be transected transversely and the fetal spine is nearest the uterine fundus with the fetal right side down, the fetus is in a transverse lie with the fetal head on the maternal right. Although real-time scanning of the gravid uterus quickly allows the observer to determine fetal lie and presentation, this maneuver of identifying specific right- and left-sided structures within the fetal body forces one to determine fetal position accurately and identify normal and pathologic fetal anatomy.

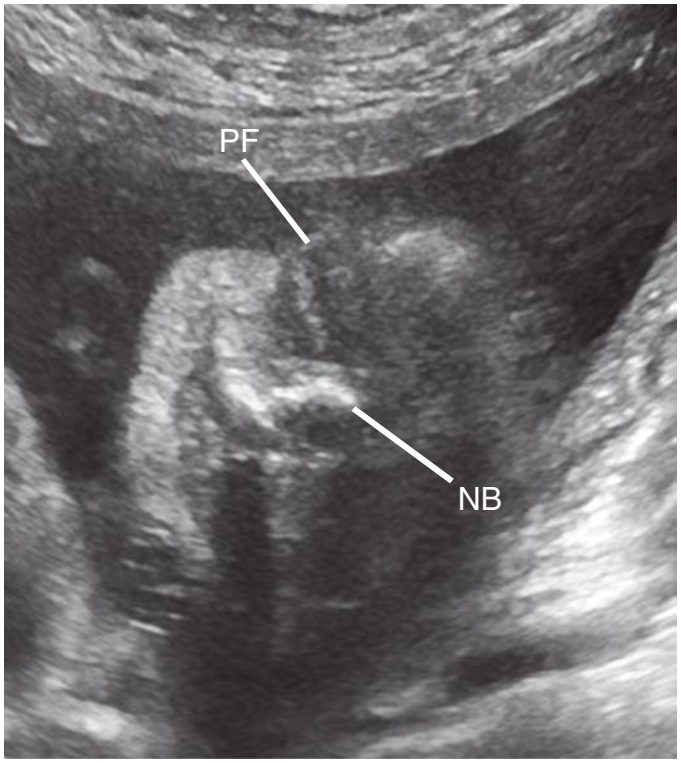

FIG 8-9 Coronal section of the fetal face that demonstrates the palpebral fissures (PF) particularly well. NB, nasal bone.

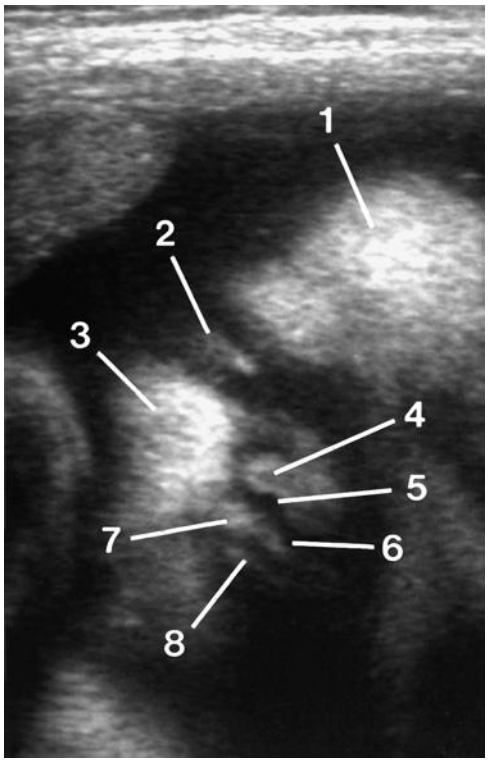

FIG 8-10 Sonogram of the fetal face. Even though this image is a tomogram with relatively little depth, facial features are seen well. Amniotic fluid surrounding the face provides the "contrast" for visualization. 1, brow; 2, eyelid; 3, cheek; 4, ala of nose; 5, nostril; 6, philtrum; 7, upper lip; 8, lower lip.

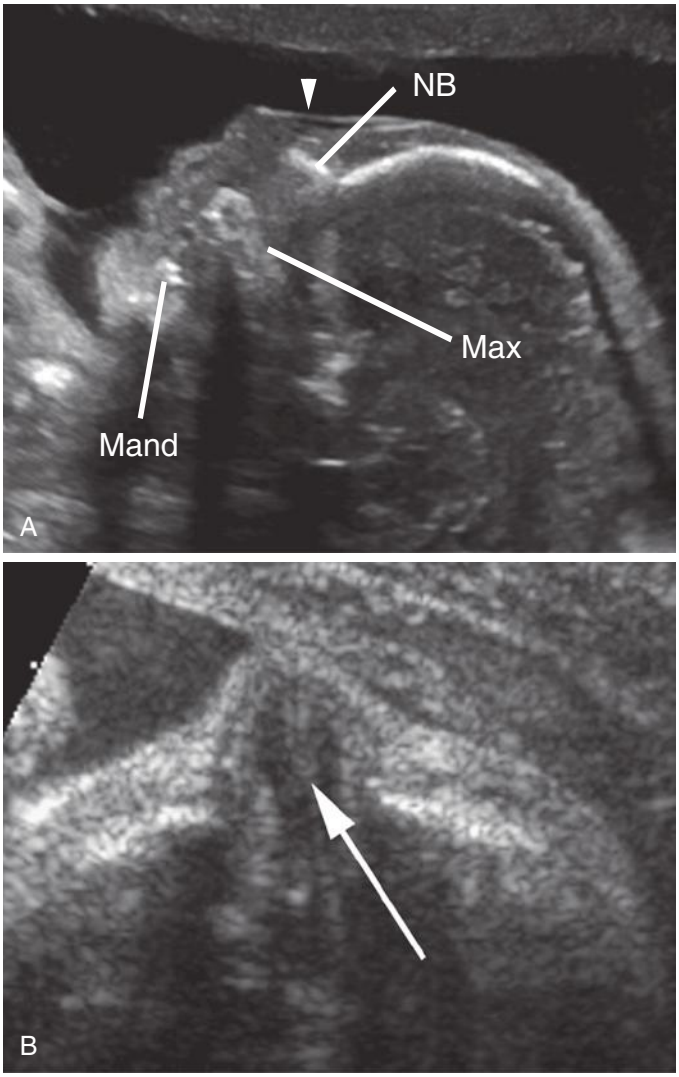

FIG 8-11 **A,** Midsagittal view of the fetal face (profile view). **B,** Axial sonogram through the nose. Note that the cartilaginous nasal septum (*arrow*) is well seen. Mand, mandible; Max, maxilla; amniotic membrane *(arrowhead)*; NB, nasal bone.

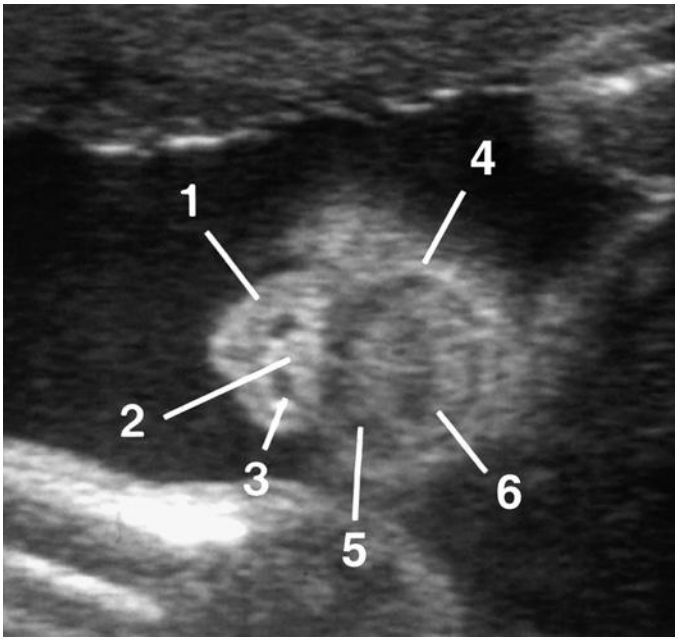

FIG 8-12 "Coronal" sonogram of the nose and mouth. Nasal structure is particularly well seen: 1, ala; 2, column; 3, nostril. The mouth displays less detail, although consistent and characteristic layering of echoes is seen. These layers are (presumably) the subcutaneous fat (4) and muscular tissue (5), the orbicularis oris muscle, and (6) the mucosal tissue.

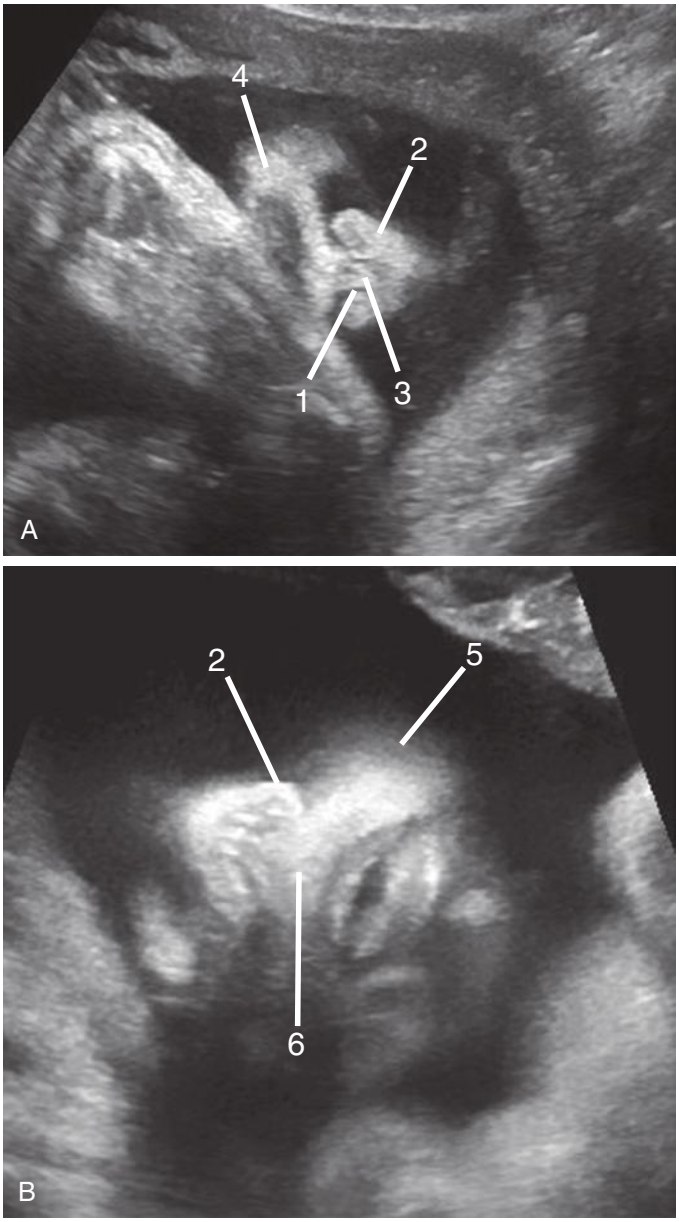

FIG 8-13 **A,** True coronal image of the nose and upper lip. **B,** Inclined coronal image demonstrates a slightly different perspective. 1, nostril; 2, ala; 3, column; 4, upper lip; 5, cheek; 6, philtrum.

with the fetus in a prone or decubitus position but are difficult to image when the fetus is supine.[39] Similarly, the extremities are imaged to excellent advantage when floating freely in the amniotic fluid, yet when tucked under the fetus an extremity will be quite difficult to adequately assess.

Despite these potential problems, fetal skeletal structures remain the earliest and most readily recognized fetal anatomic structures. The earliest structures seen with consistency are the ossification centers of the maxilla, mandible, and clavicle, the first bones of the human body to ossify.[13] The calvaria can be imaged from the late first trimester onward. The same is true of the long bones of the upper and lower extremities (Fig. 8-21). Visibility of bony detail rapidly increases, and by 15 to 16 menstrual weeks (sometimes earlier) even phalanges can be visualized. Bones as small as 2 to 3 mm can be consistently imaged by sonography, provided that no unusual impediments to the scanning procedure exist (Fig. 8-22). Many specific bony structures can be depicted. Bones in both the appendicular and axial skeleton are well imaged.

Sonography has the capacity to visualize not only the ossified portions of the fetal skeleton but also the cartilaginous portions.[13] Bones entirely in cartilage can be seen sonographically (Fig. 8-23). Cartilaginous ends of the long bones may be seen by the early second trimester. It is also important to recognize that the full thickness of the ossified diaphysis of long bones is not seen sonographically.[40] This is due to acoustic shadowing. The cartilaginous ends of long bones help us to recognize this aberration. By matching up the width of the epiphysis, the full thickness of which can be seen, with the apparent width of the bony diaphysis, it is clear that they are unequal (Figs. 8-24 and 8-25). This observation helps to eliminate perceptual errors that can lead to erroneous diagnoses. For example, the inability to see the full thickness of the femoral diaphysis creates the impression that the fetal femur farther from the transducer is bowed (Fig. 8-26).[40] This error is caused by visualization of only the medial cortex of the femoral diaphysis (which is normally curved) (Fig. 8-27). However, the inability to visually correct this normal curvature by simultaneous observation of the straight lateral cortex may cause a perceptual error.

The majority of the bones of the appendicular skeleton can be seen in the early to mid–second trimester, although phalanges may be difficult to perceive in some instances. It is a general rule of appendicular skeletal imaging that the more proximal a bone, the more readily it is identified. This rule in one sense is untrue of the hands and feet, where the metacarpals and metatarsals are seen more readily and earlier than either the carpal or tarsal bones (Figs. 8-22 and 8-28). This is because the metacarpals and metatarsals are well ossified at 4 months, whereas the carpals and tarsals (except for the tarsal calcaneus and talus) remain cartilaginous throughout pregnancy. The tarsal calcaneus and talus ossify between the 5th and 6th months, whereas the remaining tarsals and carpals do not ossify until after birth (Figs. 8-29 and 8-30).

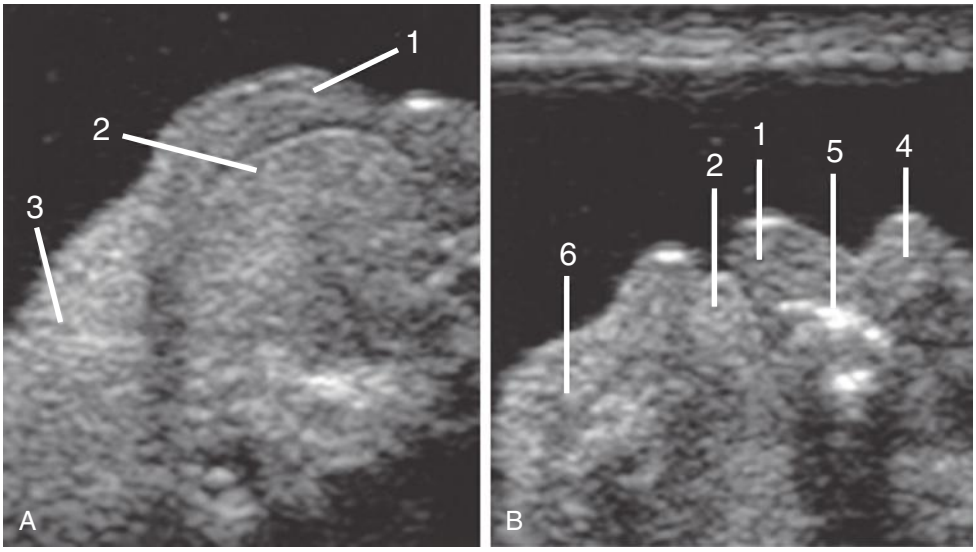

FIG 8-14 **A,** Axial section of the fetal face demonstrating the tongue. **B,** Midsagittal section of the fetal face demonstrating the tongue. 1, lip; 2, tongue; 3, fat pad of cheek; 4, nose; 5, maxilla; 6, chin.

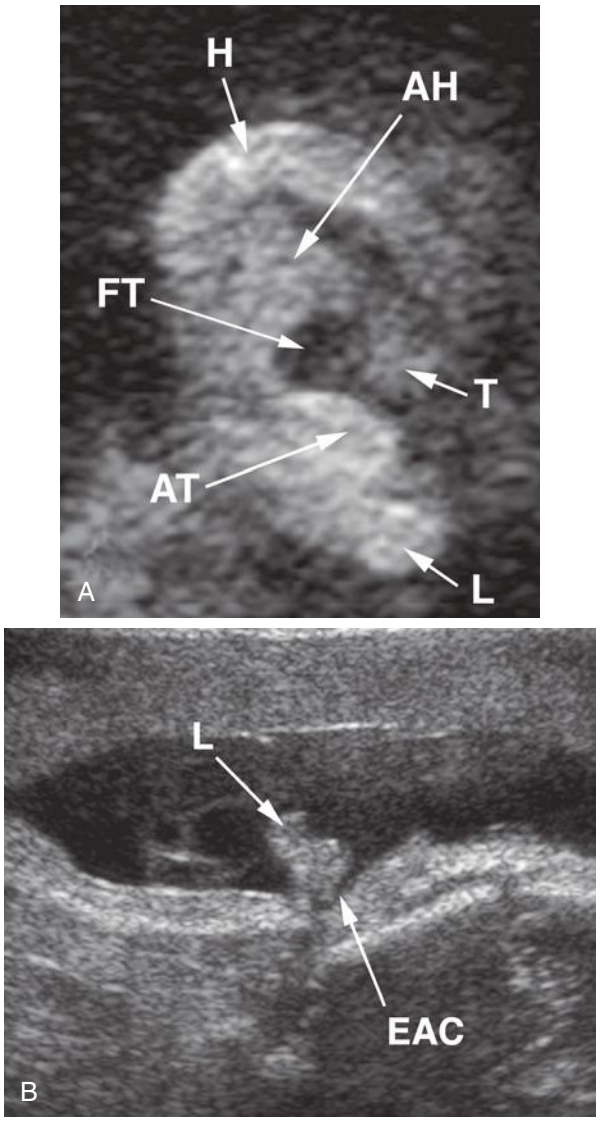

FIG 8-15 Parasagittal (**A**) and coronal (**B**) sonograms of the fetal ear. AH, antihelix; AT, antitragus; EAC, external auditory canal; FT, fossa triangularis; H, helix; L, lobule; T, tragus.

The scapula (Figs. 8-31 and 8-32), clavicle (Fig. 8-33), humerus (Figs. 8-31 and 8-34), radius (Fig. 8-35), ulna (see Figs. 8-34 and 8-35), metacarpals (see Figs. 8-22 and 8-35), and phalanges (Fig. 8-36) can be imaged in most cases. Interestingly, the clavicle may be difficult to see, presumably because of the flexed position of the fetal neck, which draws the calvaria into an obscuring position. Nonetheless, if one desires to see the clavicle, this can nearly always be accomplished. Measurements exist for normal clavicular length at various gestational ages.[41] Similarly, the femur (Figs. 8-37 to 8-40), tibia (Figs. 8-41 and 8-42), fibula (see Fig. 8-41), metatarsals (see Figs. 8-28 and 8-29), and phalanges (see Fig. 8-28) of the lower extremity can be appreciated well sonographically. The figures demonstrating the hip joint, femur, and knee (see Figs. 8-37 to 8-41) demonstrate the remarkably detailed anatomy that can be achieved with high-resolution sonography.

The simplest way to identify the types of long bones of the extremity viewed on the sonogram is to obtain planes of section that traverse the short axis of the limb. Sonograms obtained in such a plane through the forearm and lower leg will demonstrate two bones. In the lower leg, the more lateral bone is the fibula, and the medial bone is the tibia (see Fig. 8-41). This method works as well in the forearm but is less precise because pronation may cause the radius and ulna to "cross." In the normal fetus, the tibia and fibula and radius and ulna end at the same level distally (see Fig. 8-35). Proximally, the ulna is longer than the radius (see Fig. 8-34) and the tibia is longer than the fibula. This allows both ready differentiation of the tibia and fibula in the lower extremity and of the radius from the ulna in the upper extremity. Knowledge that both paired long bones of the upper and lower extremity end at the same level distally is important in assessing possible limb reduction abnormalities.

The hand can be assessed more critically than the foot.[42-44] With patience one can usually discern all four fingers and the thumb. The hand is frequently clenched in a fist-like fashion, which can complicate the counting of fingers. However, even under this circumstance, one can frequently make the necessary observations. The toes, although smaller than the fingers, can be seen relatively well with modern equipment (see Figs. 8-28 and 8-30). If difficulty arises, it is usually the functionally less important fourth and fifth toes that are not seen.

It is possible in the late third trimester fetus to identify the distal femoral (Figs. 8-25 and 8-43) and proximal tibial (see Fig. 8-43)

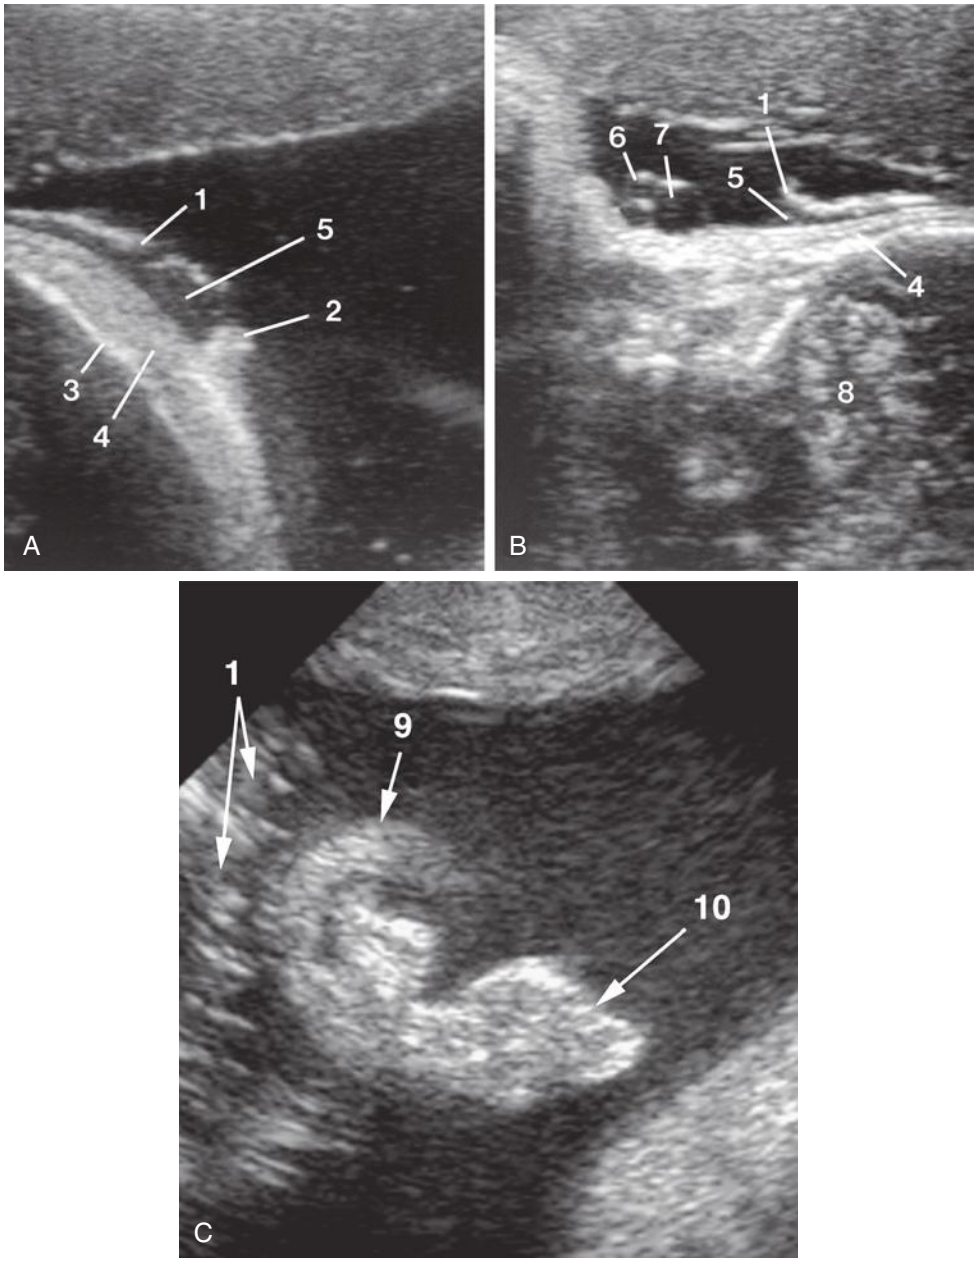

FIG 8-16 **A,** Hair may be mistaken for the outer membrane of a cystic mass in an older fetus. **B,** Scan at 90 degrees to A. This image clarifies that the fetus is normal. **C,** Parasagittal plane through a different fetus demonstrates hair above the ear. 1, hair; 2, portion of ear; 3, occipital bone; 4, subcutaneous tissues and muscles in the occipital region; 5, "trapped" amniotic fluid; 6, umbilical artery; 7, umbilical vein; 8, cerebellum; 9, helix; 10, lobule.

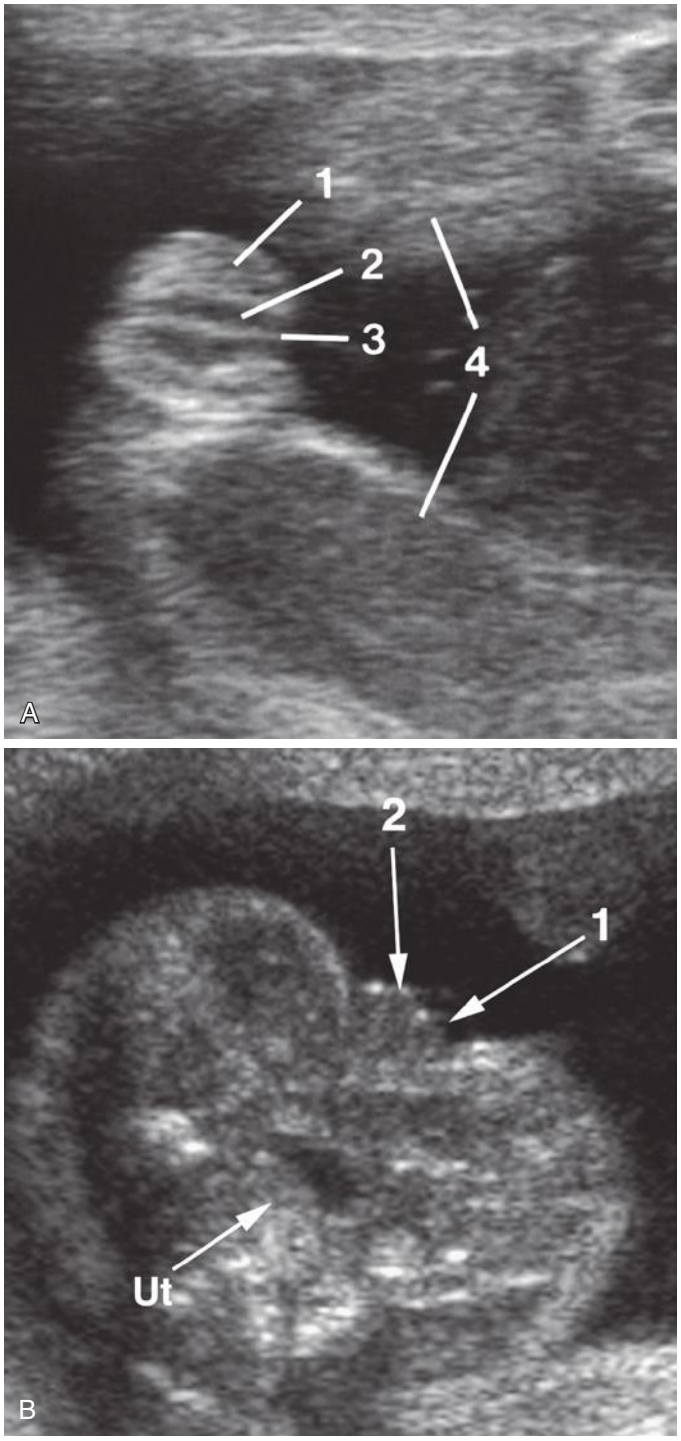

FIG 8-17 Coronal (**A**) and axial (**B**) views. External (and "internal") female genitalia. Of interest, the uterus (Ut) can be seen to asymmetrically indent the bladder of female fetuses (Ants Toi, MD, personal communication). 1, major labium; 2, minor labium; 3, vaginal cleft; 4, thighs.

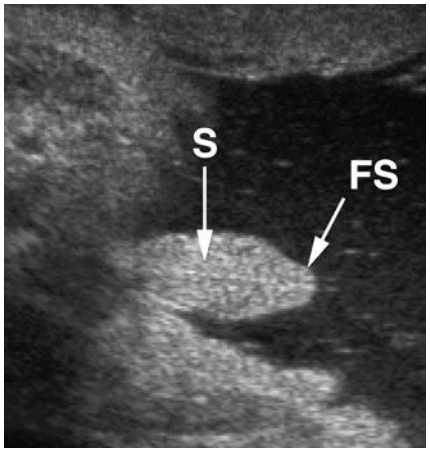

FIG 8-18 Nonerect fetal penis seen sonographically. FS, foreskin; S, shaft.

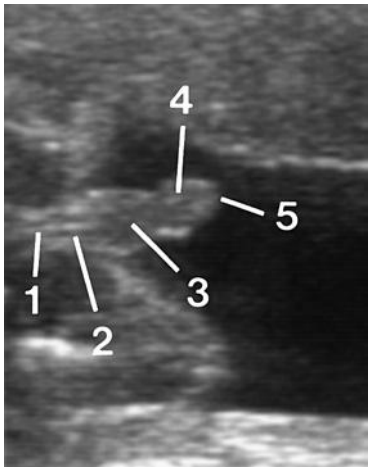

FIG 8-19 Details in an erect fetal penis. 1, urethra; 2, corpus cavernosum; 3, shaft; 4, glans; 5, foreskin.

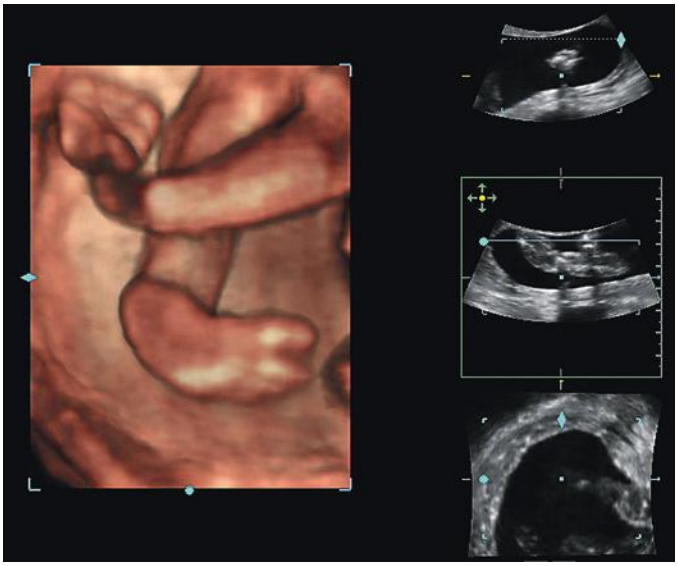

FIG 8-20 Three-dimensional image (*left*) reconstructed from the multiplanar two-dimensional images (*right*) demonstrates bilateral clubbed feet in a 20-week fetus.

FIG 8-21 Sonogram of a 10.5-week embryo demonstrates the tiny (approximately 1 mm) primary ossification center of the femur (*arrow*). (From Mahony BS, Filly RA: High-resolution sonographic assessment of the fetal extremities. J Ultrasound Med 3:489, 1984.)

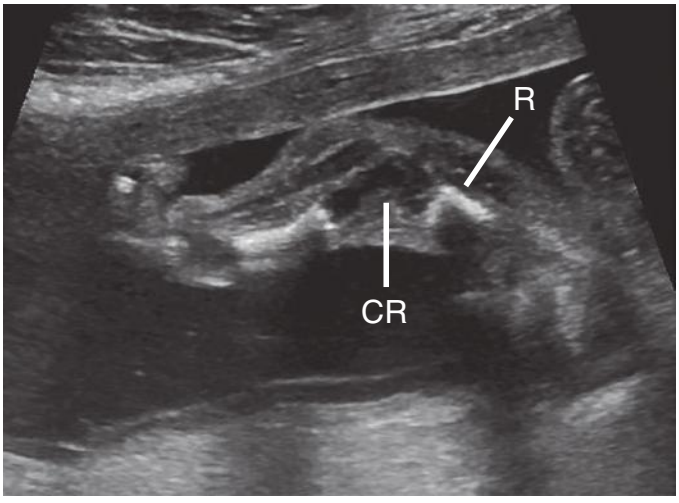

FIG 8-22 Sonogram of a 25-week fetal wrist. CR, cartilaginous carpal bones; R, radial diaphysis (distal radial epiphysis is also cartilaginous).

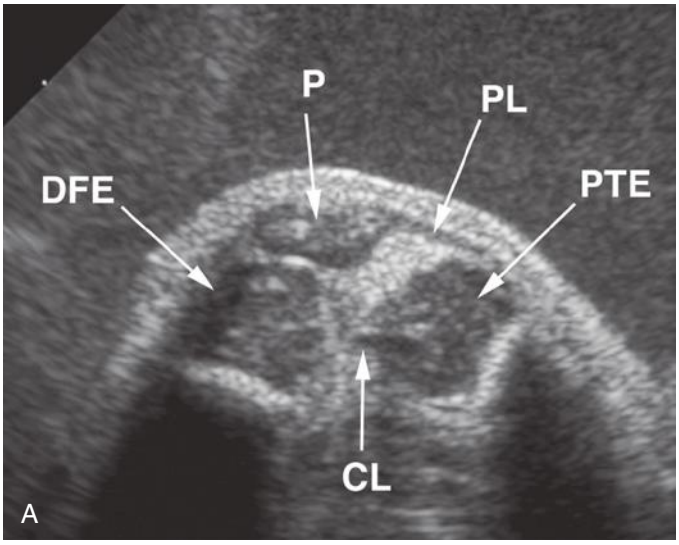

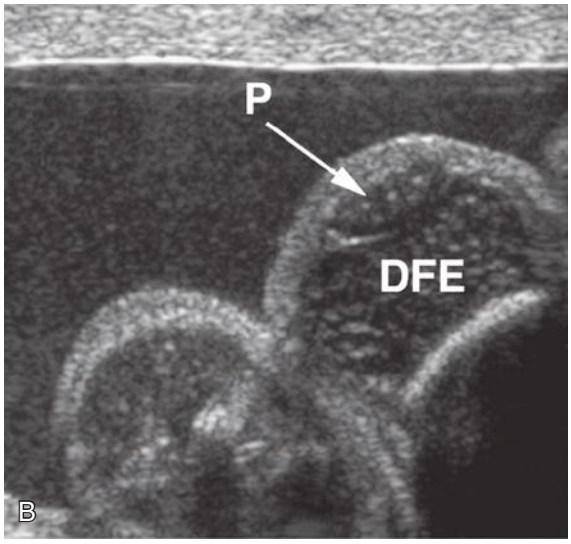

FIG 8-23 **A,** Midsagittal sonogram of the fetal knee. **B,** Axial sonogram (similar to the knee radiograph called the *sunrise view*). Note the echogenic synovium located between the patella, patellar ligament, and epiphyses. P, patella (a bone that is entirely cartilaginous); DFE, distal femoral epiphysis; CL, posterior cruciate ligament; PL, patellar ligament; PTE, proximal tibial epiphysis.

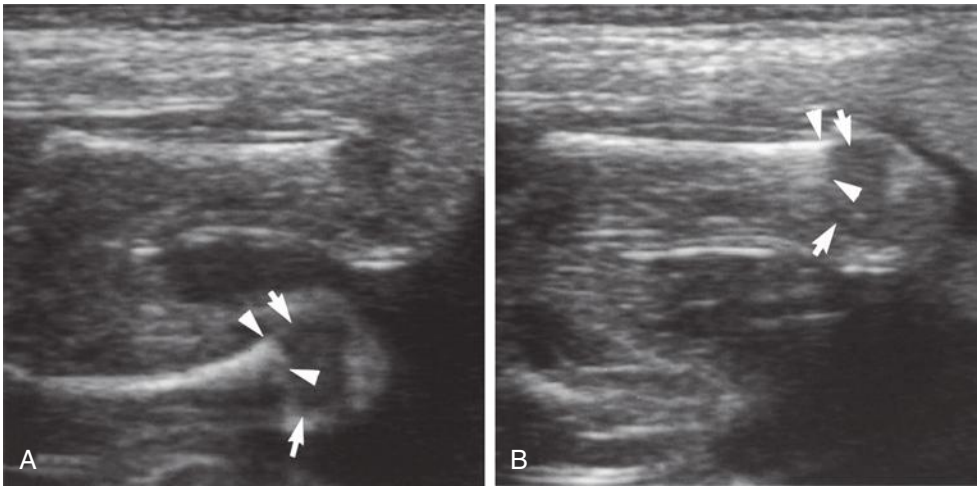

FIG 8-24 **A,** Sonogram best demonstrating the femur farther from the transducer. Arrows mark the edges of the distal epiphysis. Arrowheads mark the apparent "edges" of the distal femoral diaphysis. The more medial edge of the diaphysis matches the edge of the medial condyle, but the lateral edges of "diaphysis" and lateral condyle are widely disparate. **B,** The same exercise can be performed on the nearer femur. Again, arrows mark the edges of the distal epiphysis, and arrowheads mark the "edges" of the femoral diaphysis. Shadowing by the bone but not the cartilage causes this deceptive appearance.

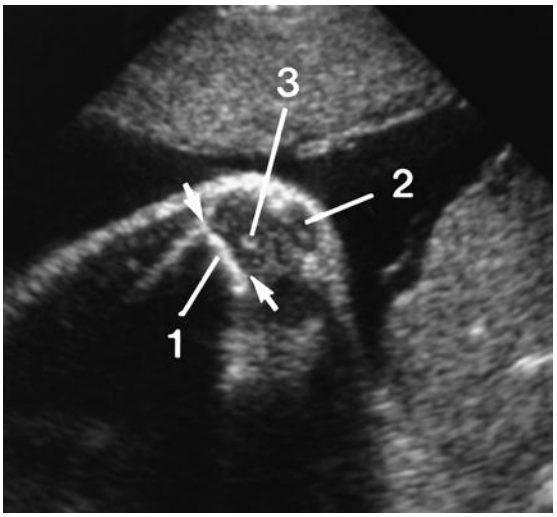

FIG 8-25 Sector sonogram of the distal femur taken such that the lines of sight from the transducer intersect the inferior end of the femoral metaphysis at the epiphyseal plate (1). By this maneuver, the full thickness of the distal ossified femur is seen sonographically (compare with Fig. 8-24). Now, the thickness of the epiphysis (*arrows*) and ossified femoral shaft match perfectly. 2, patella; 3, secondary ossification center of the distal femoral epiphysis.

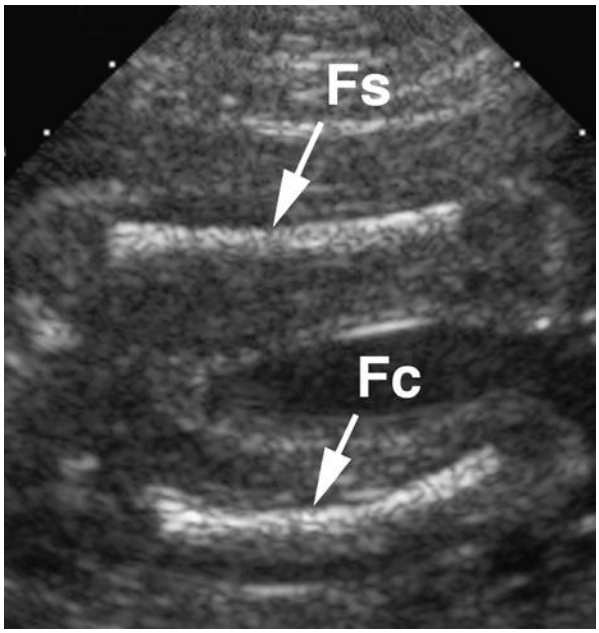

FIG 8-26 In this sonogram the diaphysis of the femur nearer to the transducer appears straight (Fs). The full thickness of the diaphysis is not seen. The diaphysis of the femur farther from the transducer appears curved (Fc). Compare with Figure 8-27. This is a normal shape of the medial aspect of the bone. However, the straight lateral cortex seen in the radiograph but not the sonogram visually compensates the curvature because the full thickness of bone is not perceived.

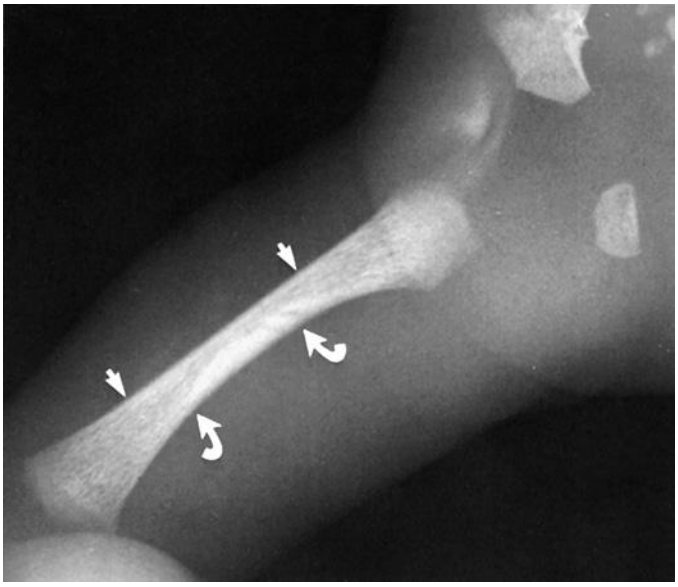

FIG 8-27 Radiograph of a midtrimester fetal femur. Note that our eye compensates for the curvature of the medial diaphyseal cortex (*curved arrows*) by noting the straight lateral diaphyseal cortex (*straight arrows*). Compare with Figure 8-26.

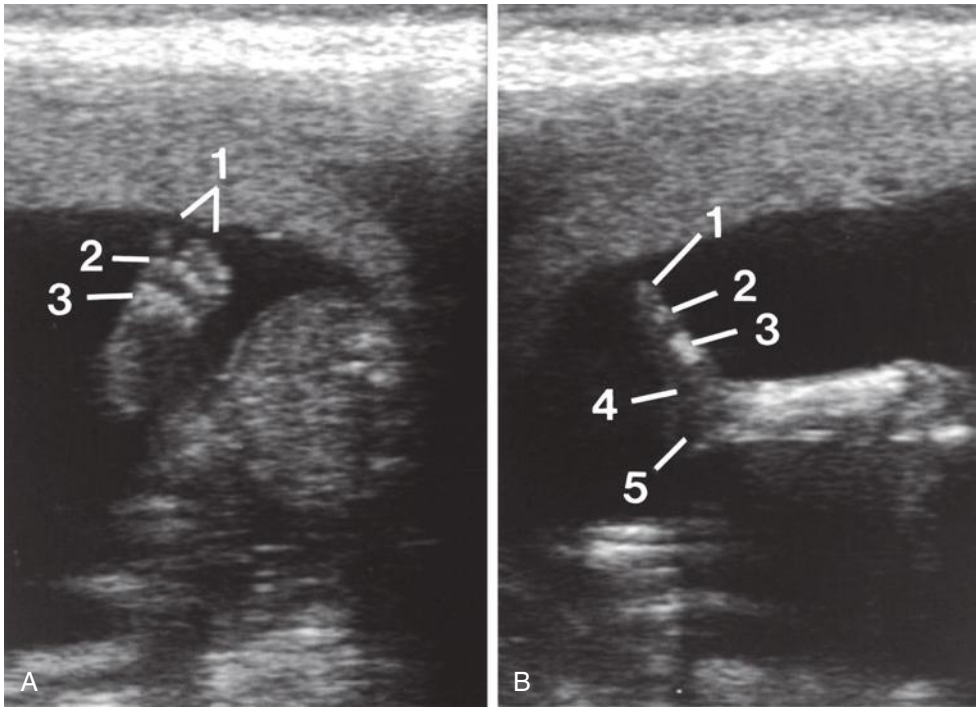

FIG 8-28 Fetal foot at 16 weeks' gestation in transverse axial (**A**) and parasagittal (**B**) planes. 1, toes; 2, proximal phalangeal ossification centers; 3, metatarsal ossification centers; 4, tarsal cuboid in cartilage; 5, tarsal calcaneus in cartilage.

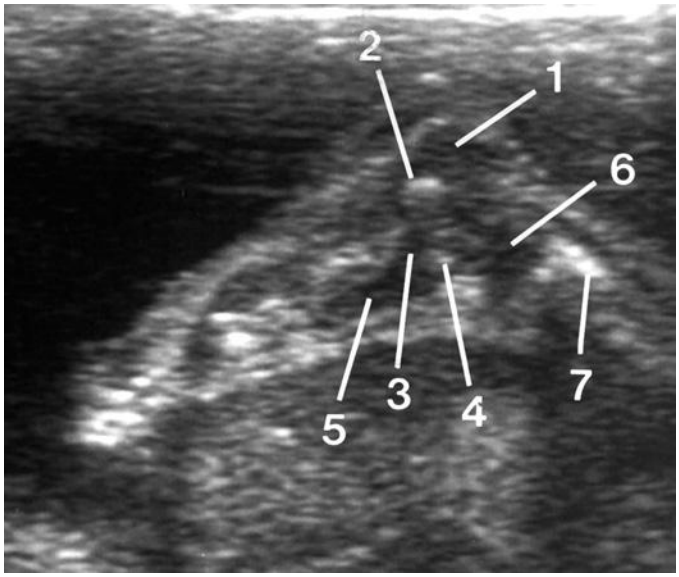

FIG 8-29 Midsagittal sonogram of the fetal foot in late second trimester. 1, cartilaginous calcaneus; 2, primary ossification center of calcaneus; 3, cartilaginous talus; 4, primary ossification center of talus; 5, tarsal navicular in cartilage; 6, distal tibial epiphysis; 7, distal tibial diaphysis.

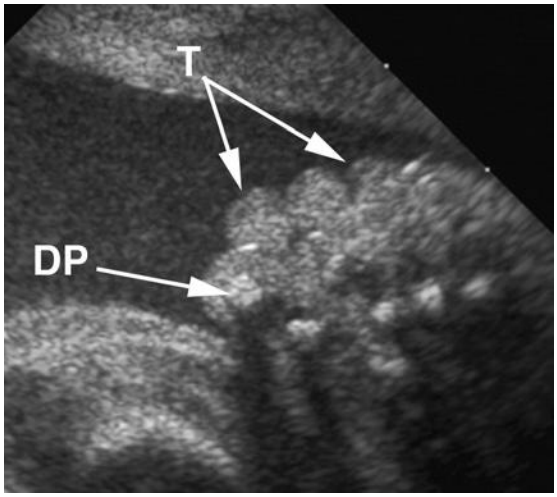

FIG 8-30 Axial sonogram of the fetal toes (T) demonstrating the soft tissues. Little bony structure is seen, although the distal phalanx (DP) of the great toe is visible.

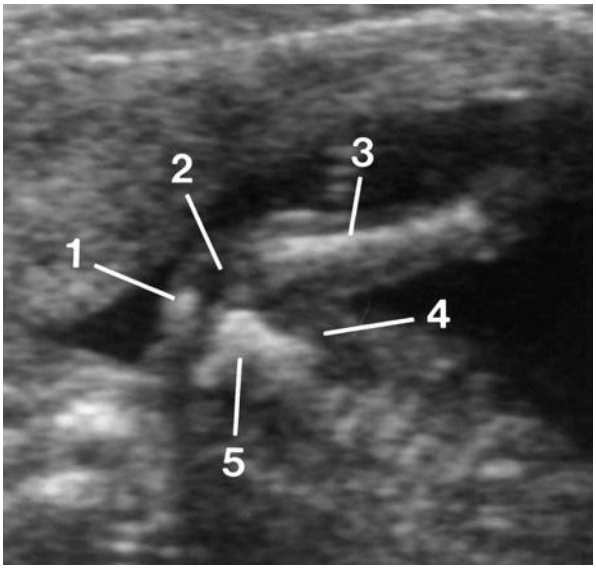

FIG 8-31 Coronal sonogram of the shoulder and upper arm. 1, distal clavicle; 2, cartilaginous humeral head; 3, ossified humeral diaphysis; 4, latissimus dorsi muscle; 5, scapula.

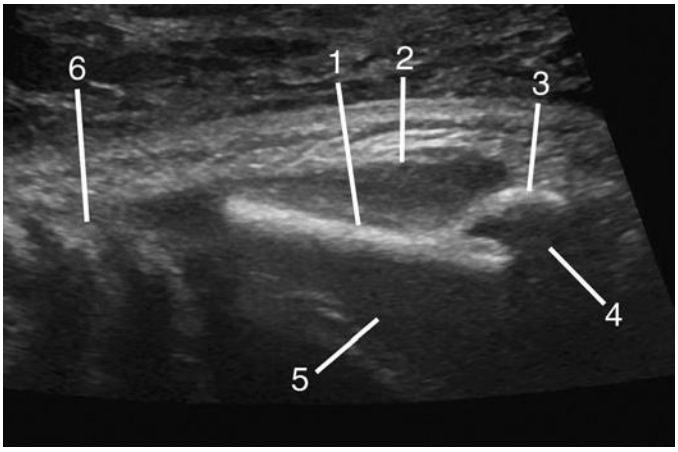

FIG 8-32 Parasagittal sonogram of the scapula. 1, infraspinous fossa; 2, infraspinatus muscle; 3, scapular spine; 4, supraspinatus muscle; 5, subscapularis muscle; 6, ribs in short axis.

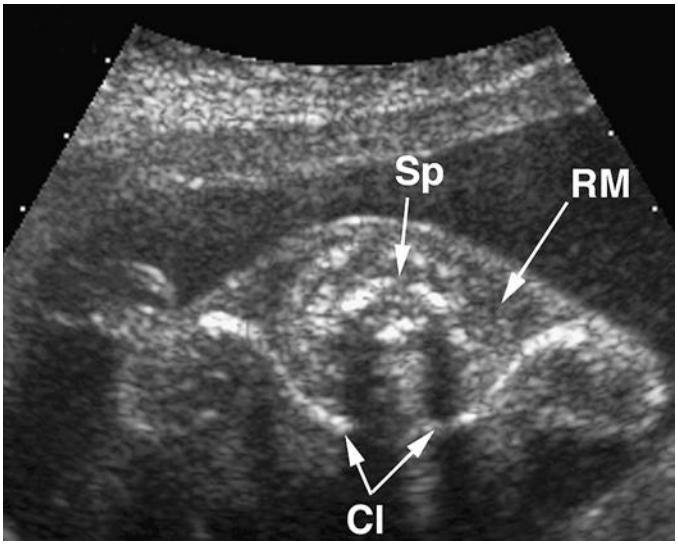

FIG 8-33 Axial sonogram of the clavicles (Cl). RM, rhomboid muscle; Sp, spine.

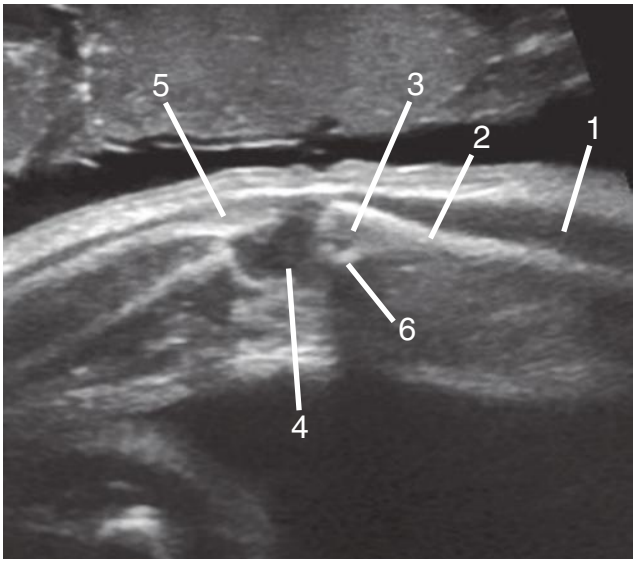

FIG 8-34 Fetal elbow, hand pronated, coronal sonogram. 1, triceps muscle; 2, ossified humeral diaphysis; 3, cartilaginous olecranon fossa; 4, conglomerate cartilages about the elbow joint; 5, proximal ulnar diaphysis; 6, medial humeral epicondyle.

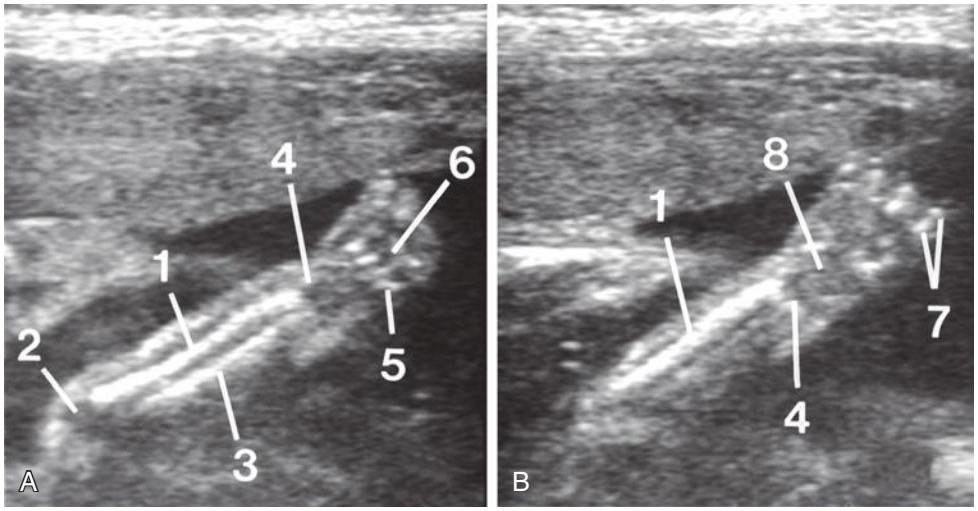

FIG 8-35 **A** and **B,** Coronal sonograms of the forearm and wrist. 1, ulnar diaphysis; 2, olecranon in cartilage; 3, radial diaphysis; 4, distal ulnar epiphysis; 5, metacarpal diaphysis; 6, distal metacarpal epiphysis; 7, phalangeal ossification centers; 8, carpal arch seen as a conglomerate cartilage.

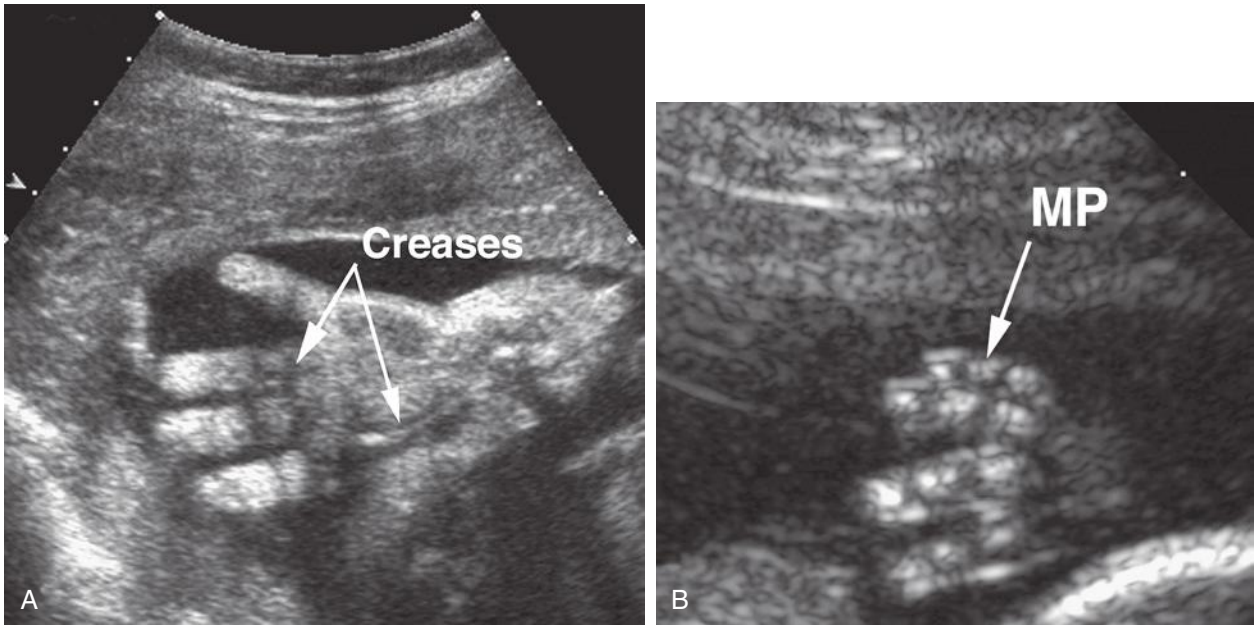

FIG 8-36 **A,** Coronal sonogram of the fetal hand demonstrating the soft tissues of the fingers and palm. Creases at the interphalangeal joints and palmar creases are seen. **B,** Coronal sonogram of the hand demonstrating some of the bony detail of the developing phalanges. MP, middle phalanx.

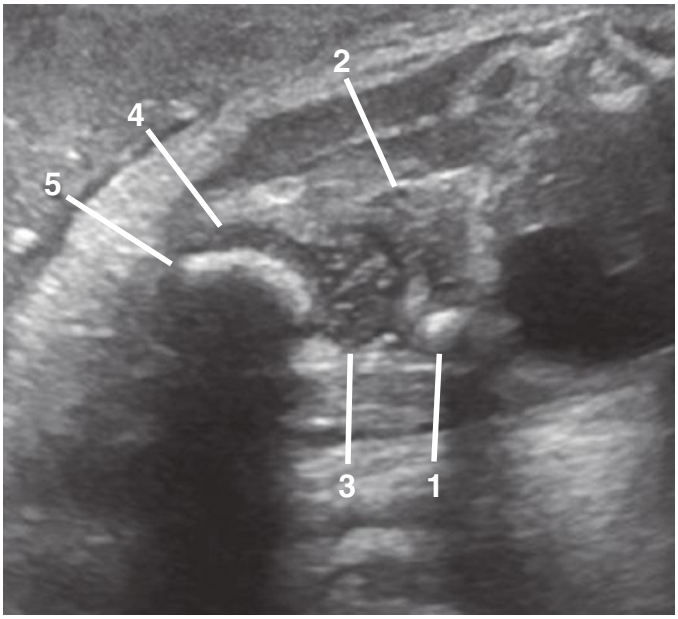

FIG 8-37 Coronal oblique image of the fetal hip. 1, ischial ossification center; 2, cartilaginous acetabulum; 3, femoral head in cartilage; 4, greater trochanter in cartilage; 5, femoral metaphysis.

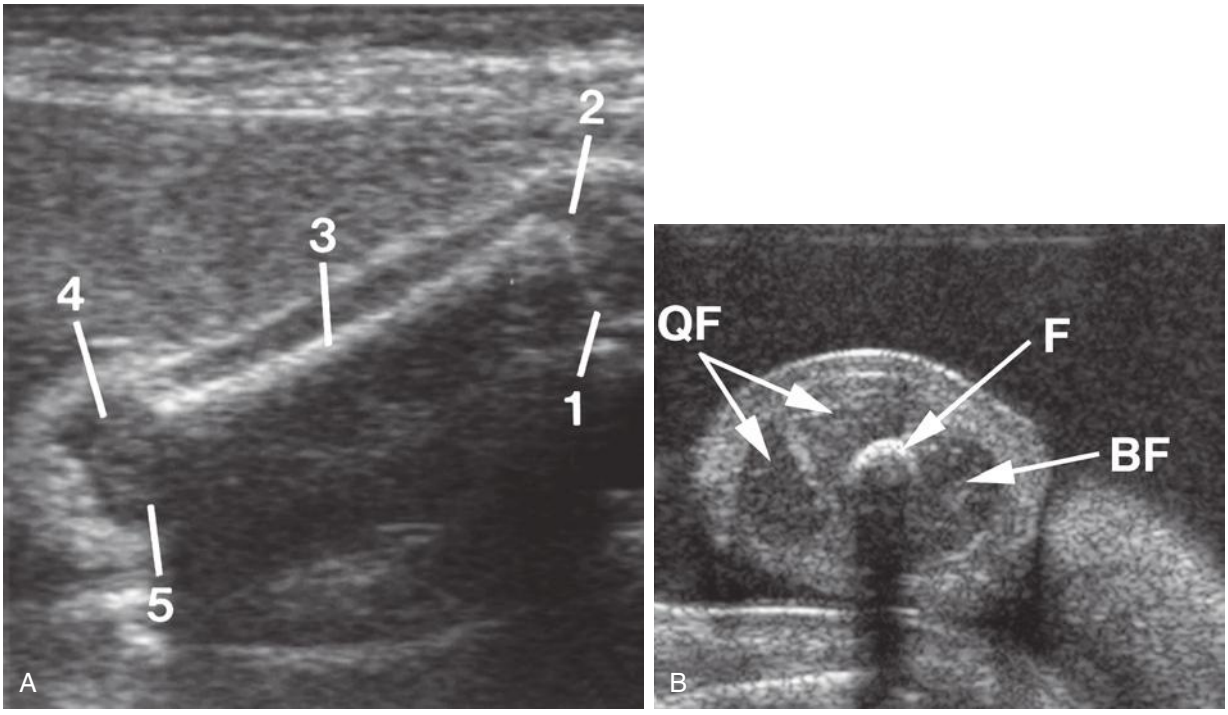

FIG 8-38 Longitudinal (**A**) and transverse axial (**B**) sonograms of the fetal thigh. 1, posterior hip joint capsule; 2, greater trochanter; 3, femoral diaphysis; 4, lateral condyle; 5, medial condyle; BF, biceps femoris muscle; F, femoral diaphysis; QF, quadriceps femoris muscle.

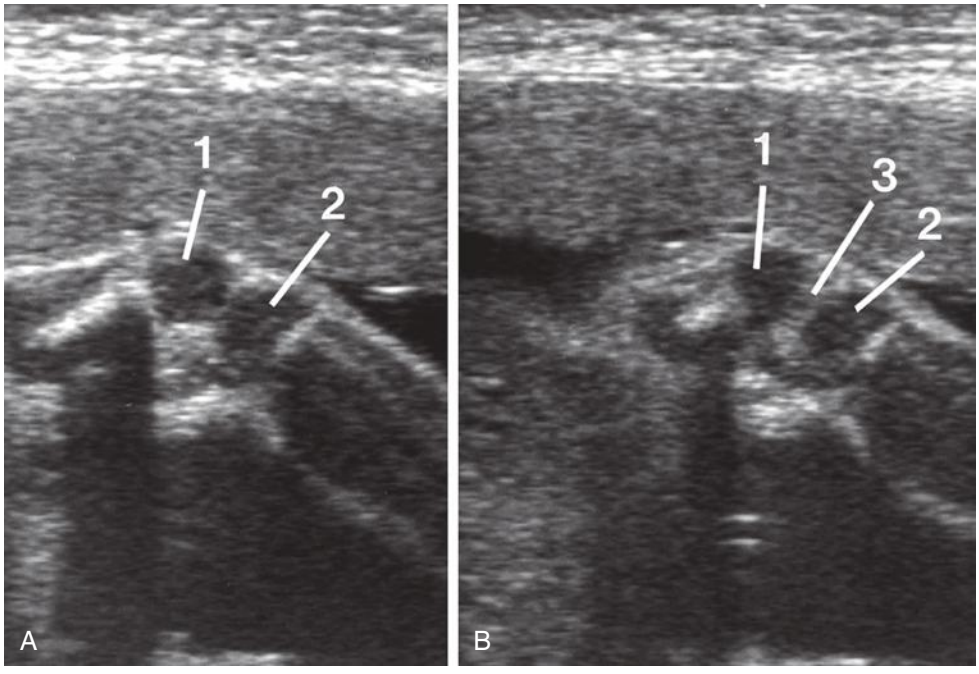

FIG 8-39 **A,** Parasagittal sonogram of the fetal knee. The femoral condyle (1) articulates with the tibial plateau (proximal tibial epiphysis). **B,** Midsagittal sonogram of the fetal knee. The gap (3) between the distal femoral epiphysis (1) and the proximal tibial epiphysis (2) is due to the intercondylar notch (see Fig. 8-40).

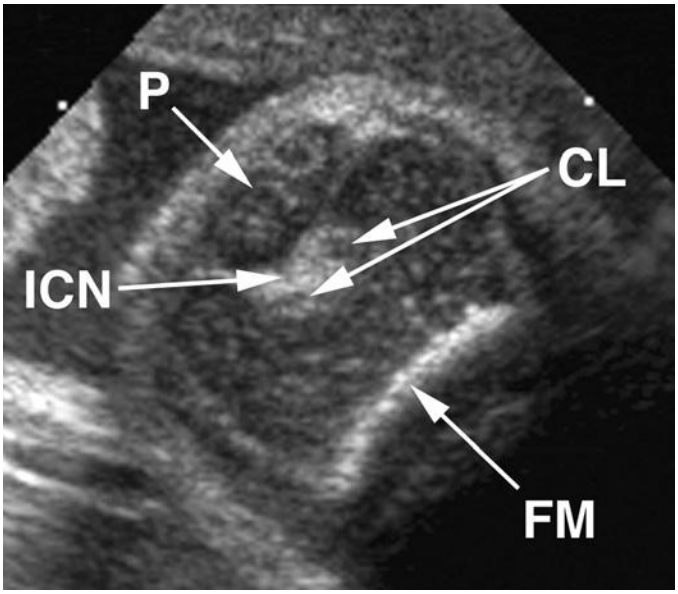

FIG 8-40 Axial sonogram of the knee in flexion. CL, cruciate ligaments; FM, femoral metaphysis; ICN, intercondylar notch (note the brightly echogenic synovium within the joint); P, patella.

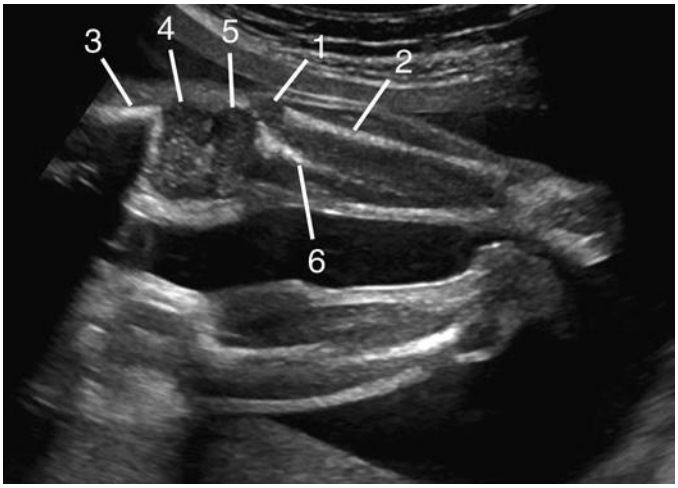

FIG 8-41 Coronal sonograms of the knee. 1, proximal fibular epiphysis; 2, fibular diaphysis; 3, femoral metaphysis; 4, lateral femoral condyle; 5, proximal tibial epiphysis; 6, tibial diaphysis.

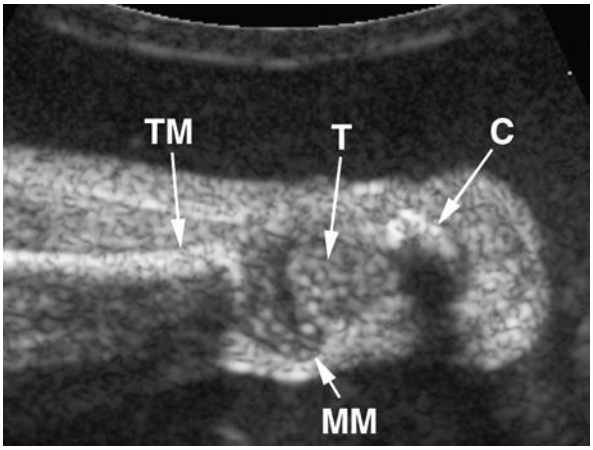

FIG 8-42 Axial sonogram of the distal tibia and a portion of the ankle joint. C, calcaneus; MM, medial malleolus; T, talus (a bone that is entirely cartilaginous); TM, tibial metaphysis.

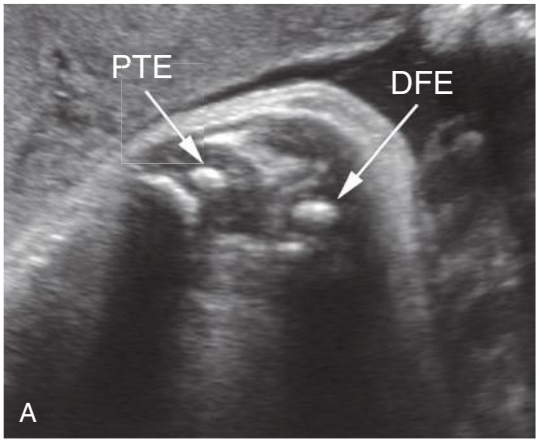

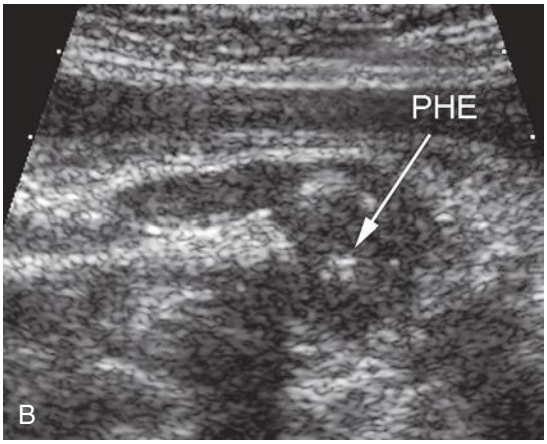

FIG 8-43 **A,** Coronal sonogram of the distal thigh in a term fetus. Note the large and similar sizes of the ossification centers, a virtually certain sign of a near-term fetus. **B,** Coronal sonogram through the proximal humerus shows an early secondary ossification center in the humeral head, another finding indicating a later gestation. DFE, ossification center of distal femoral epiphysis; PHE, ossification center of proximal humeral epiphysis; PTE, ossification center of proximal tibial epiphysis.

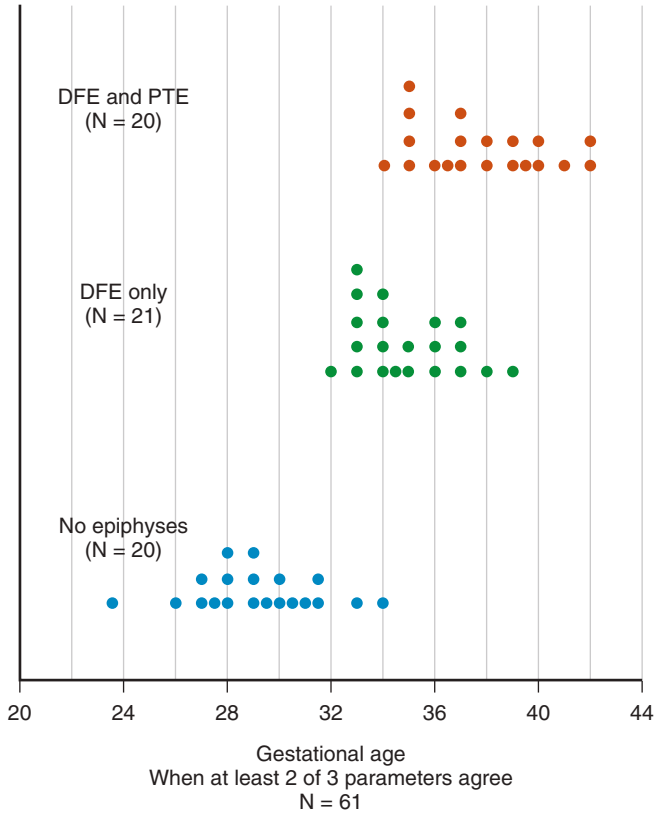

FIG 8-44 Appearance time of the distal femoral epiphysis (DFE) and proximal tibial epiphysis (PTE) in a mixed group of 61 fetuses when two of the following three dating parameters agreed: last menstrual period, early sonogram, and Dubowitz scores. (From Chinn DH, Bolding DB, Callen PW, et al: Ultrasonographic identification of fetal lower extremity epiphyseal ossification centers. Radiology 147:815-818, 1983.)

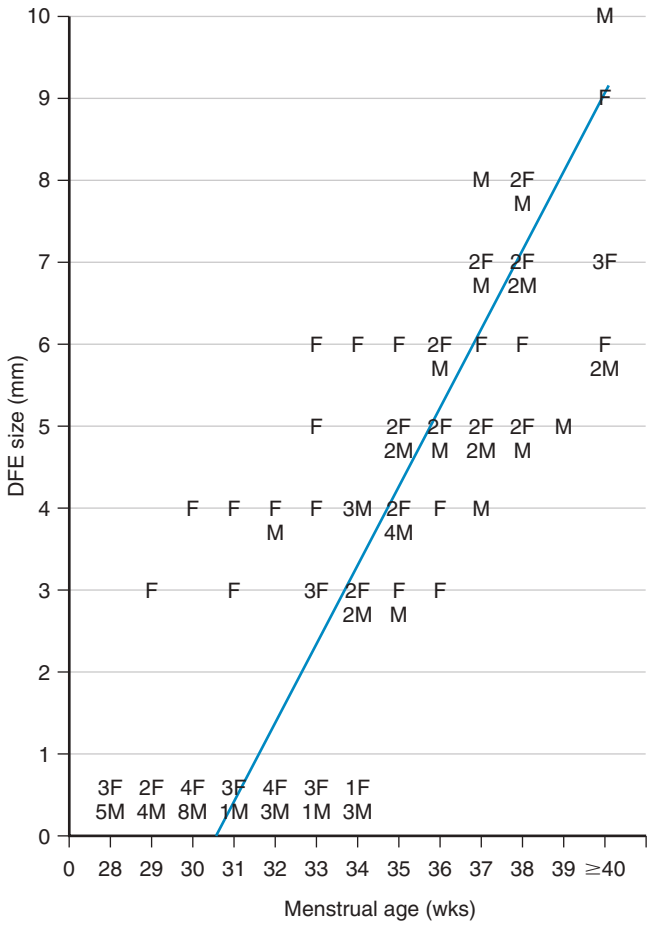

FIG 8-45 Variation in the distal femoral epiphysis (DFE) appearance time and size in male (M) and female (F) fetuses. (From Mahony SB, Callen PW, Filly RA: The distal femoral epiphyseal ossification center in the assessment of third trimester menstrual age: sonographic identification and measurement. Radiology 155:201-204, 1985.)

epiphyseal ossification centers.[45,46] Ossification of these epiphyses, as seen on radiographs, is known to be an indicator of fetal maturity. Identification of the epiphyseal ossification centers about the knee provides a different type of parameter that sonologists can use in the assessment of gestational age in the third trimester of pregnancy. In general, visualization of a distal femoral epiphyseal ossification center indicates a gestational age of at least 33 weeks (Figs. 8-44 to 8-46). Similarly, the same data suggest that demonstration of the proximal tibial epiphysis indicates a gestational age of at least 35 weeks. These ossification centers appear earlier, on average, in female fetuses (see Fig. 8-45).[46] The size of the distal femoral ossification center correlates with late gestational age (see Fig. 8-46).[46] The proximal humeral epiphyseal ossification center is usually the last of the secondary ossification centers to ossify and generally can be seen at a gestational age of 38 weeks or later.

As stated earlier, many bones of the fetal appendicular skeleton are entirely cartilaginous. Some of these still can be imaged sonographically. For example, the patella, which does not begin to ossify until after birth, can be seen rather commonly (see Figs. 8-23 and 8-25). All of the carpal and most of the tarsal bones are entirely cartilaginous (see Figs. 8-22, 8-28, 8-29, and 8-35). The carpal bones cannot be seen discretely. Rather, they are perceived as a conglomerate hypoechoic band spanning the gap from the distal radius and ulna to the proximal metacarpal ossification centers (see Fig. 8-35). This gap includes the cartilaginous epiphyses of the long bones as well. Conversely, some of the tarsal bones can be discretely identified from time to time (see Figs. 8-28 and 8-29). These include, most notably, the early calcaneus and talus (before 24 weeks) and the tarsal navicular and cuboid throughout gestation.

Visualization of the cartilaginous ends of the long bones assists in their measurement in two ways. The measurement of fetal long bones is confined to the ossified portion. A potential error is to foreshorten the bone by failing to obtain the plane of section through the true long axis of the bone. To avoid underestimating length, this shortcoming is often compensated for by assuming the "longest" measurement obtained in several attempts to be the most accurate, an assumption that can lead to serious overestimates, as is discussed shortly. However, if both cartilaginous ends of the desired bone to be measured are seen, this guarantees that the plane of section has passed through the longest axis of the bone (Fig. 8-47). The only remaining task to minimize error is to accurately position measurement cursors at the ends of the bone.

Another common misconception in measurement of the femur is that no other tissue in proximity to the bony termination will yield an echo of equal brightness to the bone. Thus, one should always place measurement cursors from the edge of the distal brightest reflection to the edge of the proximal brightest reflection. This longstanding belief is unfortunately untrue, especially in older fetuses, although younger fetuses are not exempt from this potentially significant error in femur length estimation.[47] Figure 8-48 demonstrates that a

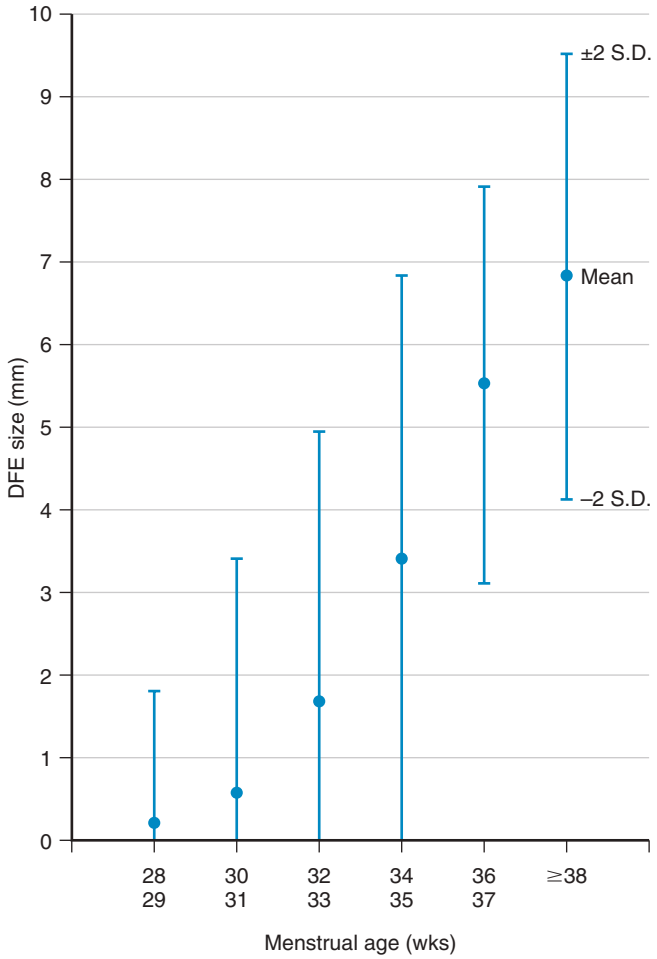

FIG 8-46 Mean diameter of the distal femoral epiphysis (DFE) with increasing age. S.D., standard deviation. (From Mahony SB, Callen PW, Filly RA: The distal femoral epiphyseal ossification center in the assessment of third trimester menstrual age: sonographic identification and measurement. Radiology 155:201-204, 1985.)

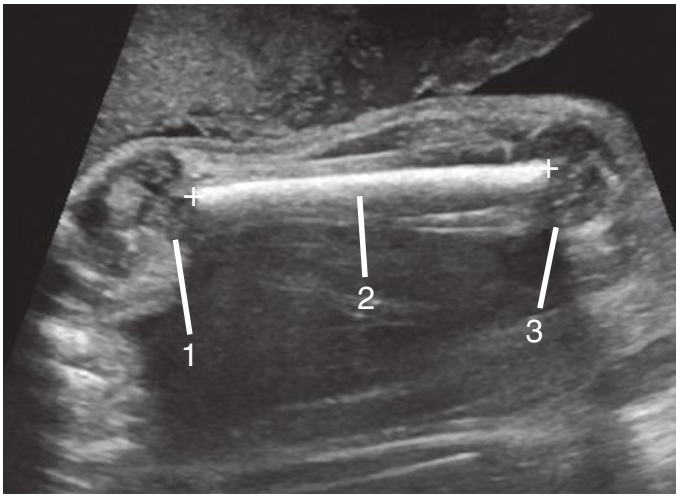

FIG 8-47 Longitudinal view of femur for measurement. Visualization of the proximal (3) and distal (1) cartilaginous bone ensures that the plane of section is through the long axis of the diaphysis (2). Only proper positioning of the cursors (+) remains to ensure an accurate measurement.

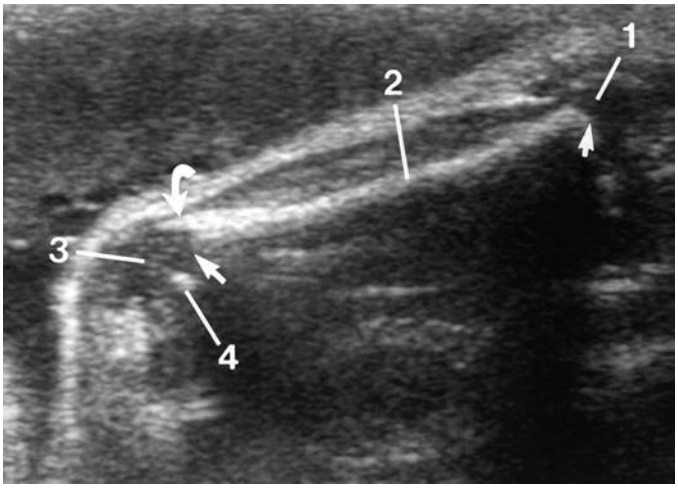

FIG 8-48 View of the fetal femur, third trimester. A bright reflector (*curved arrow*) is seen in continuity with the lateral femoral metaphysis. This structure is not part of the ossified femur. End points of femur measurement are marked by straight arrows. 1, greater trochanter; 2, femoral diaphysis; 3, lateral condyle; 4, ossification center of the distal epiphysis.

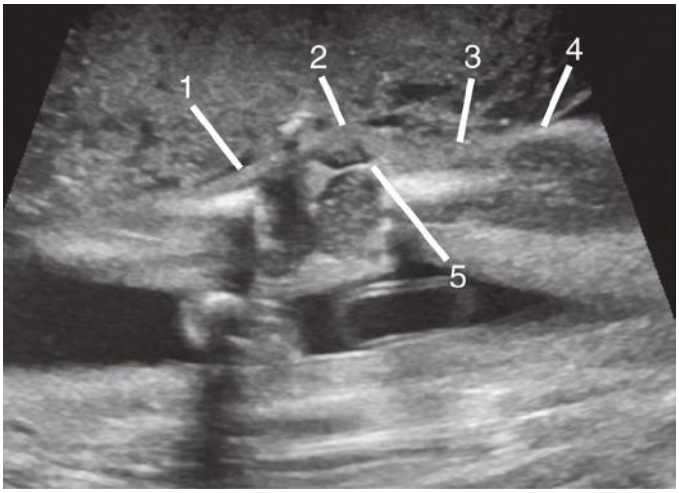

FIG 8-49 Midsagittal sonogram of the extended knee. In addition to structures pointed out in earlier figures, note the patellar ligament (1), patella (2), quadriceps tendon (3), quadriceps muscle (4), and synovium (5) contained by the knee joint.

nonosseous, but nonetheless equally bright, reflection is returned from tissues distal to the epiphyseal plate but in immediate contiguity with the distal femoral metaphysis. This is called the distal femoral point for lack of a more precise anatomic term.[47] That this "point" is not part of the ossified femur can be determined by noting its relationship to the cartilaginous lateral condyle. The femoral metaphysis ends at the beginning of the distal femoral epiphysis and does not overlap the edge of the epiphysis. Compare the radiograph of the fetal femur in Figure 8-27 with the sonogram of the fetal femur in Figure 8-48. No such *ossified* femoral point exists.

Sonography, from time to time, demonstrates rather extraordinarily detailed anatomy of the musculoskeletal system of the extremities such as indivudal tendons and ligaments. At present, no known diagnostic usefulness for this information has been established, nor is it possible to demonstrate such structures with the consistency necessary to use their visualization in diagnostic pursuits. However, several of these remarkable features are demonstrated in Figures 8-49 to 8-51.

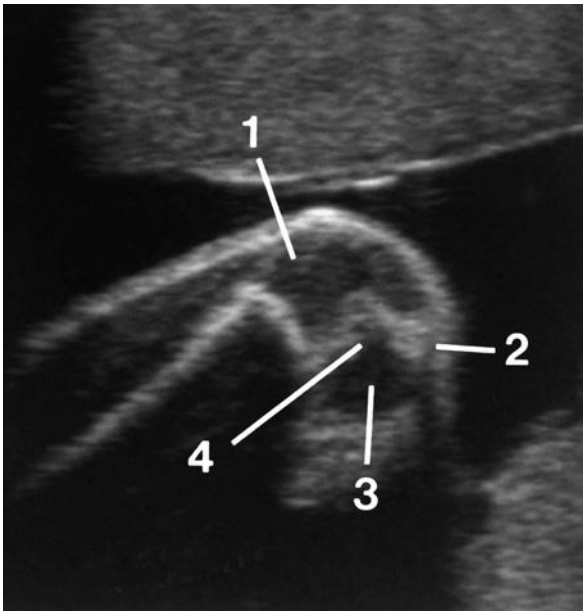

FIG 8-50 Midsagittal sonogram of the fetal knee in flexion shows the distal femoral epiphysis (1), patellar ligament (2), and proximal tibial epiphysis (3). These three structures marginate the knee joint. Within the knee joint is a large quantity of highly echogenic tissue, presumably synovium. Clearly outlined by the bright "synovium" is the cruciate ligament (4).

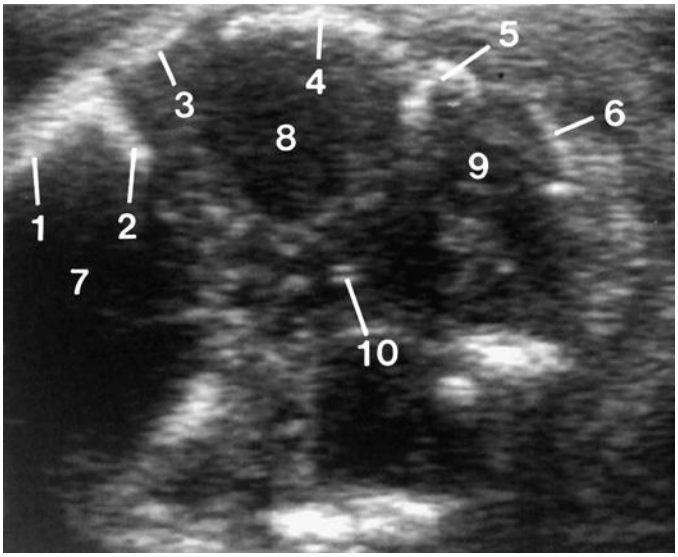

FIG 8-52 Transverse axial sonogram near the skull base. 1, frontal bone; 2, greater wing of sphenoid bone; 3, parietal bone; 4, temporal bone; 5, petrous ridge; 6, occipital bone; 7, anterior cranial fossa; 8, middle cranial fossa; 9, posterior cranial fossa; 10, basilar artery.

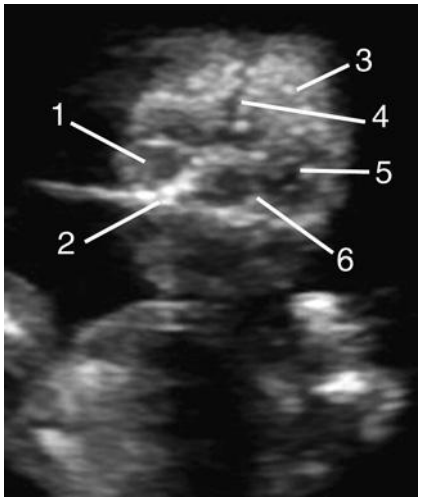

FIG 8-53 Fetal orbits, early second trimester. 1, orbit; 2, maxilla; 3, frontal bone; 4, metopic suture; 5, lens; 6, nasal bone.

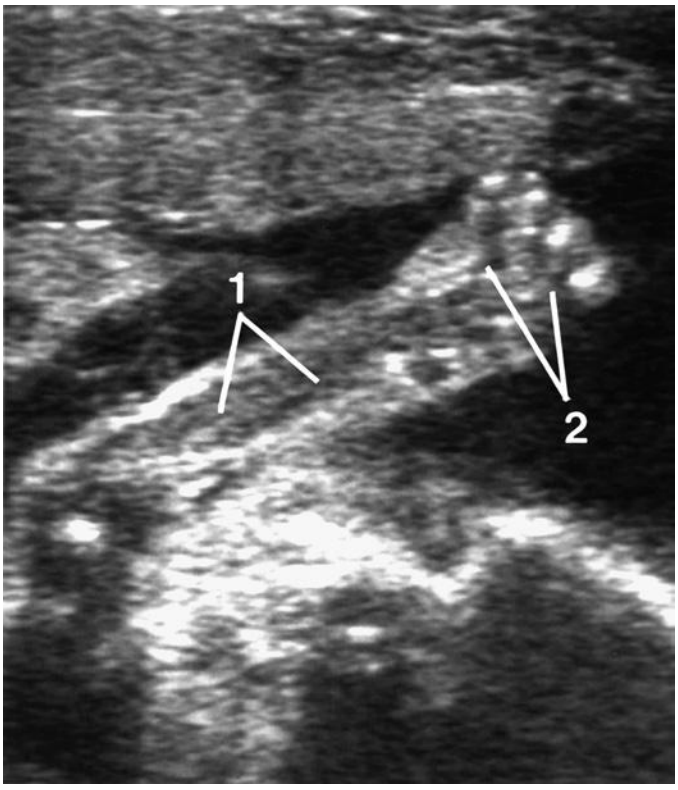

FIG 8-51 Coronal sonogram through the dorsal soft tissues of the forearm and hand. 1, extensor muscle group; 2, extensor tendons.

Many bones or components of bones of the axial skeleton are also routinely visualized. In the skull region, one can perceive a number of bones individually or as a conglomerate. The greater wings of the sphenoid and petrous ridge are easily identified and define the anterior, middle, and posterior cranial fossae (Fig. 8-52). Both orbits can be visualized without difficulty unless the more anteriorly positioned orbit severely shadows the more posteriorly positioned orbit (Fig. 8-53). Standards have been established for fetal interorbital distances to evaluate hypotelorism and hypertelorism.[48] In older fetuses, surprising detail of the intraorbital contents can be appreciated, including the wall of the globe, lens, retrobulbar fat, optic nerve, and rectus muscles (Fig. 8-54). Portions of the maxilla and nearly the entire mandible can be identified, as can the bony nasal ridge (see Fig. 8-53). Similarly, the frontal, parietal, and squama of the temporal and occipital bones, the bones making up the calvaria, can be seen clearly. The cartilaginous zones of articulation of these bones, the coronal, sagittal, and lambdoid sutures, are commonly visible (Fig. 8-55). The fontanelles may be seen

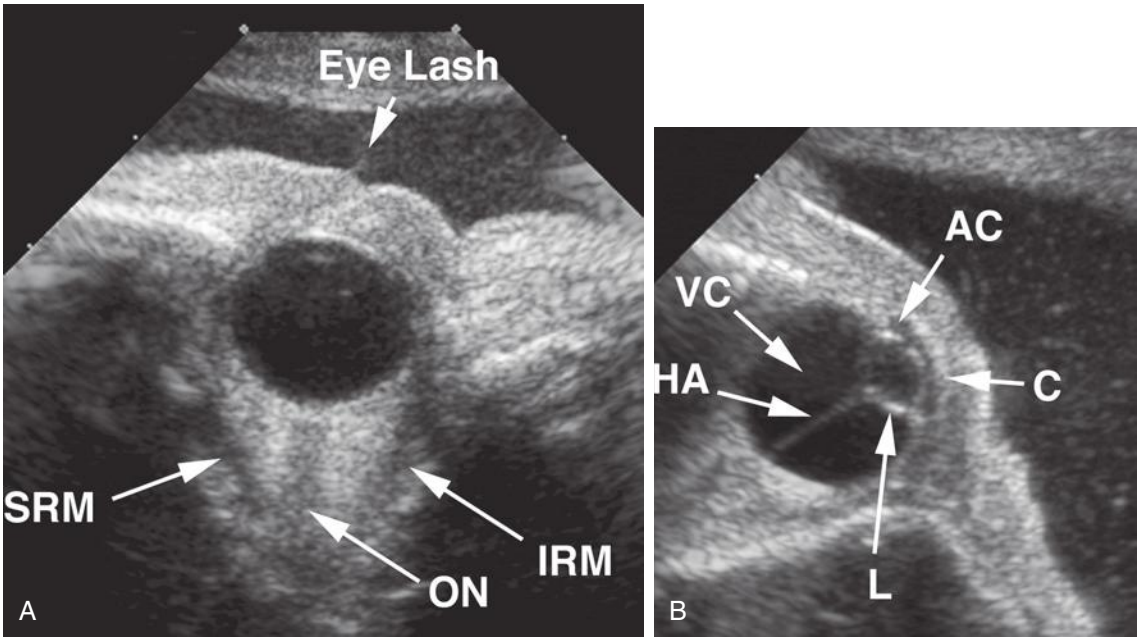

FIG 8-54 Fetal orbits and contents seen on parasagittal sonograms (**A** and **B**). AC, anterior chamber; C, cornea; HA, hyaloid artery; IRM, inferior rectus muscle; L, lens; ON, optic nerve (traversing the retrobulbar fat); SRM, superior rectus muscle; VC, primary vitreous. Note the eyelash extending from the closed eyelids (also visible in B).

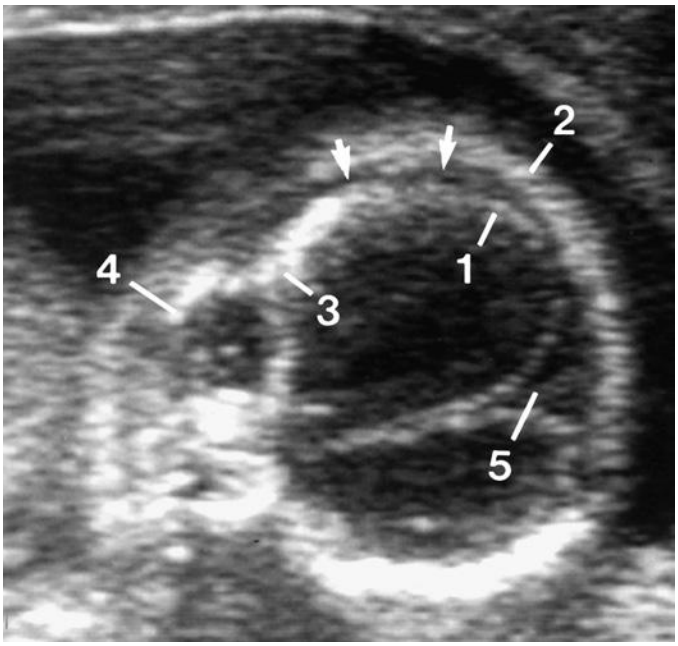

FIG 8-55 Oblique view demonstrating the coronal suture (*arrows*). 1, frontal bone; 2, parietal bone; 3, greater wing of sphenoid bone; 4, maxilla; 5, interhemispheric fissure with brain edges showing brightly reflective covering of pia-arachnoid.

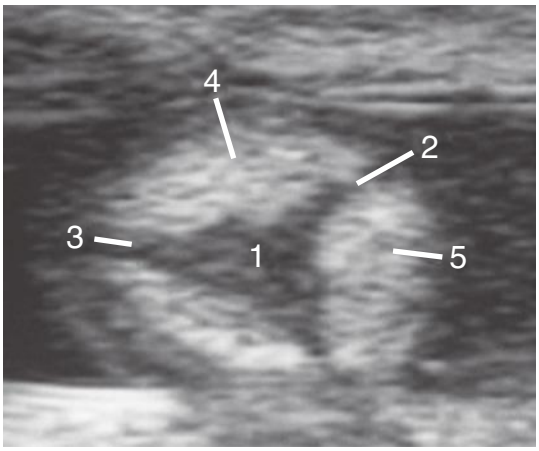

FIG 8-56 Transverse axial sonogram of the posterior fontanelle (1). 2, lambdoid suture; 3, sagittal suture; 4, parietal bone; 5, occipital bone.

as well (Fig. 8-56). These anatomic features are particularly well seen in three-dimensional reconstructions of the calvaria, as demonstrated in Chapter 11. Sutures and fontanelles function as windows for brain imaging (Fig. 8-57). Although many individuals who perform sonography do not realize that they are employing sutures and fontanelles to image the fetal brain, they visually ascertain that, as they move the transducer, "fuzzy" brain images suddenly become clearer. The reason, of course, is that as they move the transducer the beam inevitably passes through a suture or fontanelle, enabling even the unsophisticated imager to take advantage of these gaps between the calvarial plates.

The ribs, spine, and pelvis are easily imaged and serve as excellent anatomic landmarks. In the pelvis, the iliac ossification centers are easily observed from the early second trimester onward (ossified at 2.5 to 3 fetal months). Ischial ossification (see Fig. 8-37) is present at 4 months, whereas pubic ossification is not present until 6 months.

The spine is an extremely important structure in fetal diagnosis.[39,49-51] With the advent of maternal serum α-fetoprotein screening, as well as the concurrent development of sophisticated high-resolution ultrasound imaging technology, the potential exists to diagnose nearly all lesions of spina bifida before the 20th week of pregnancy.[52] These changes in obstetric care mandate that the morphologic appearance of the fetal spine be well understood by sonologists. The sequence of development of ossification centers in the fetal vertebral column has

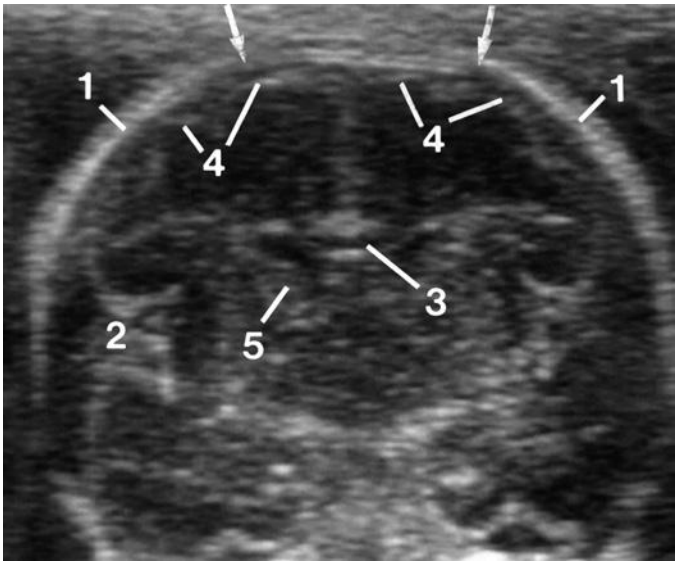

FIG 8-57 The sonographic beam was directed through the anterior fontanelle (*arrows*) in a midtrimester fetus, enabling recognition of striking detail in the fetal brain because of the "bone-free window." 1, parietal bone; 2, lateral fissure; 3, corpus callosum; 4, brain edges over the most cephalic portions of the parietal lobes; 5, head of caudate nucleus.

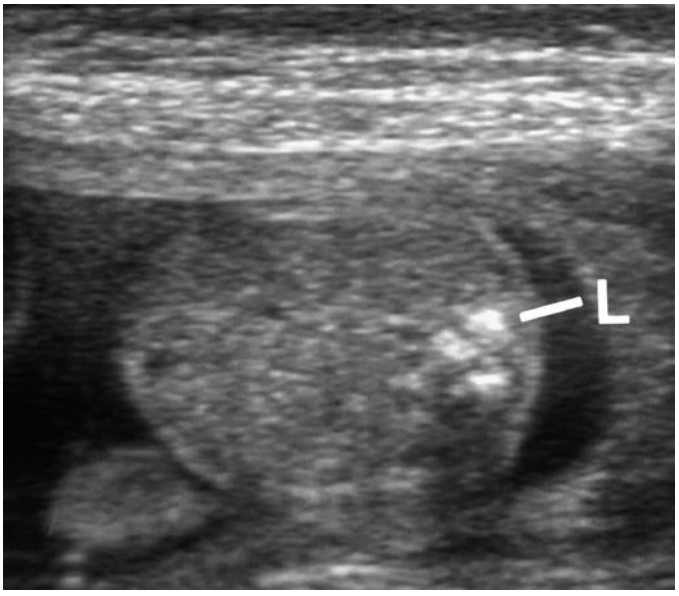

FIG 8-59 Lumbar vertebra, transverse axial sonogram. The laminae (L) demonstrate early ossification, causing the appearance of "inward angulation" of the posterior arch. (From Filly RA, Simpson GF, Linkowski G: Fetal spine morphology and maturation during the second trimester: sonographic evaluation. J Ultrasound Med 6:631, 1987.)

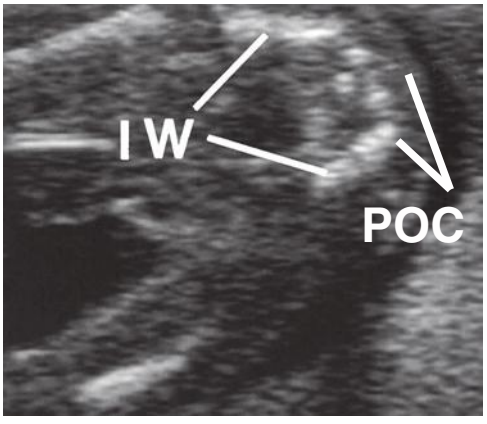

FIG 8-58 Early ossification centers in the sacral spine. Anteriorly is the centrum, and posteriorly (POC) the ossifications of the posterior arch appear near the base of the transverse processes. IW, iliac wings. (From Filly RA, Simpson GF, Linkowski G: Fetal spine morphology and maturation during the second trimester: sonographic evaluation. J Ultrasound Med 6:631, 1987.)

been extensively studied in the past with radiologic and histologic methods.[34,35] Each vertebra usually has three primary ossification centers, one for the body (centrum) and one on each side of the posterior neural arch. The centra are ossified first in the lower thoracic and upper lumbar regions followed by progressive ossification in both the cephalic and caudal directions. By contrast, and in general, the ossification centers for the posterior neural arch appear in a more standard cephalocaudal direction. The posterior neural arch first begins to ossify (sonographically recognizable high-amplitude reflections) at the base of the transverse process (Fig. 8-58). Ossification proceeds from this center to progressively include the laminae and pedicles. The progression of ossification of the laminae is more important for the diagnosis of neural tube defects because spina bifida is the most consistently demonstrable dysmorphic lesion in open spinal defects. This abnormality is recognized sonographically by an abnormal outward flaring of the posterior neural arch ossification centers.

Varying degrees of maturation of spinal ossification are present at differing levels of the spine when we are most frequently called on to assess normality of the fetal spine.[39] Although there are some exceptions as noted previously, ossification in the neural arch first appears at the base of the transverse process. Early posterior neural arch ossification then progresses anteriorly into the pedicles, also contributing a portion of the vertebral body, and posteriorly into the laminae. Additionally, craniocaudal extension into the articular processes and lateral extension into the transverse processes occur. Because the critical observation in the diagnosis of open spinal neural tube defects is the demonstration of spina bifida (seen as an outward flaring of the posterior arch ossification centers), the ideal situation to confirm normality is to observe the antithesis of this pathologic state (i.e., inward angulation of the laminae). This is readily acheived when visible ossification is present in the normal laminae (Fig. 8-59). Unfortunately, there is insufficient ossification of the laminae to perceive inward angulation of the posterior neural arch ossification centers in the lower spine to confirm normality of the fetal spine during the crucial stage of gestation when this sonographic diagnosis must be made (18 to 22 menstrual weeks) (see Fig. 8-58).[49,52] This is particularly important when considering the most common location of such lesions (i.e., lumbar and sacral regions).[49] Easily identifiable ossification of the laminae is visible in the cervical region in all fetuses by 18 to 19 menstrual weeks, whereas thoracic ossification of the laminae is only partially visible during 18 to 19 menstrual weeks.[39] There is no ossification of the laminae in the lumbar or sacral regions of fetuses examined before 19 menstrual weeks (see Fig. 8-58). The thoracic vertebrae consistently demonstrate partial ossification of the laminae in the range of 20 to 22 weeks; the lumbar region does not demonstrate a similar degree of ossification until 22 to 24 weeks (Fig. 8-60). The sacral spine reveals no evidence of ossification in the laminae before 22 weeks. Only after 25 weeks is there consistently recognizable ossification of the arch

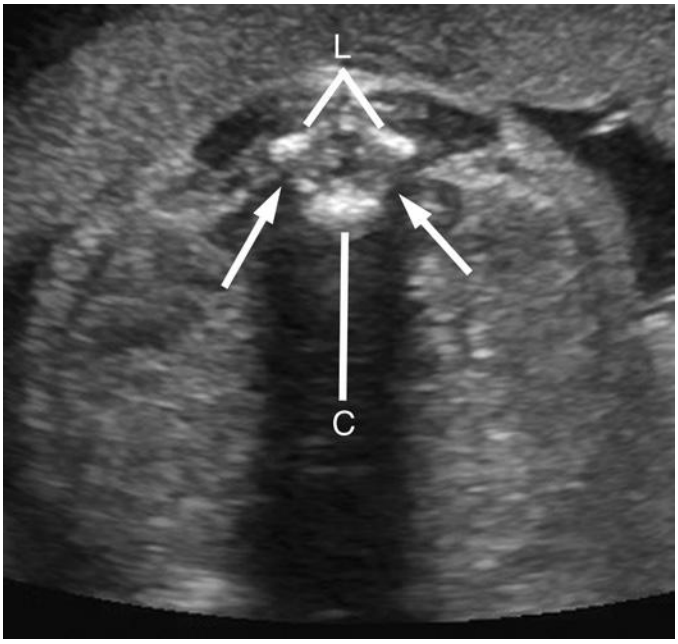

FIG 8-60 Lumbar spine, transverse axial sonogram, 23 weeks, showing well-defined ossification of the laminae (L) and neurocentral synchondroses (*arrows*). C, centrum.

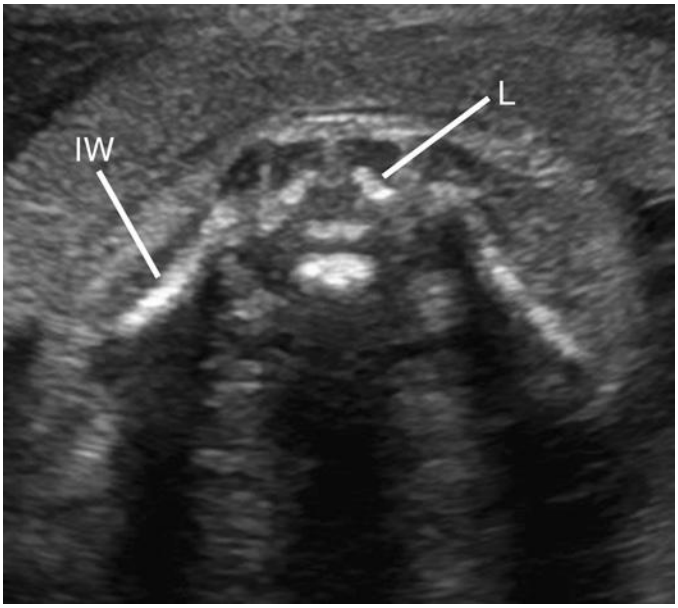

FIG 8-61 Sacral spine, transverse axial sonogram, 26 weeks. L, laminae; IW, iliac wing.

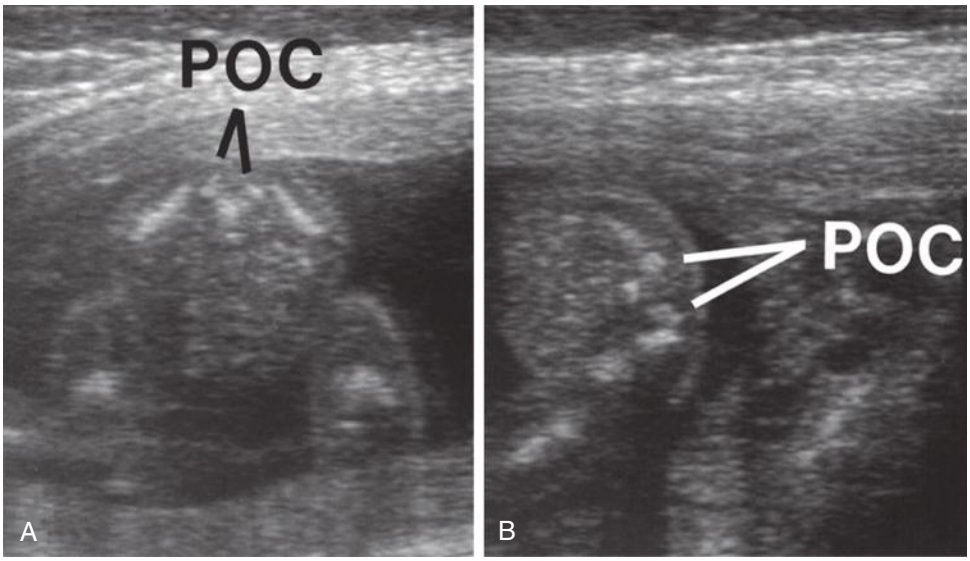

FIG 8-62 Transverse axial sonograms, sacral spine, in prone (**A**) and decubitus (**B**) positions. The posterior arch (POC) anatomy is seen well in either position. (From Filly RA, Simpson GF, Linkowski G: Fetal spine morphology and maturation during the second trimester: sonographic evaluation. J Ultrasound Med 6:631, 1987.)

in the sacral region (Fig. 8-61). Fetal position (either prone or decubitus) does not appear to affect appreciably the ability to discern the degree of neural arch ossification, although the prone position usually results in the clearest images (Fig. 8-62). If the fetus is supine, a critical examination of the posterior neural arch cannot be accomplished (Fig. 8-63).[39]

The spine may be seen in both longitudinal and transverse axial planes. Although both planes are important, the transverse axial plane demonstrates the anatomy to best advantage. On longitudinal planes of section the posterior elements are seen as "parallel" bands of echoes. In fact, they are not precisely parallel because they flare in the upper cervical region and converge in the sacrum. In addition, careful scanning usually discloses a slight widening of the lumbar area. It is important not to mistake this slight lumbar widening as a pathologic event. Because the fetal spine is normally kyphotic, usually one cannot visualize the entire spine in a single longitudinal coronal plane. For this reason, transverse axial planes of section are necessary to be certain that the entire spine has been imaged on a segment-by-segment basis. Caution must be exercised as well to ensure that the spine has been examined in its entirety on transverse planes. At the cephalic end, no problem arises because one encounters the calvaria. However, the caudal end is more difficult. The ischial ossification centers can be successfully used as landmarks to ensure that the caudal end of the spine has been reached (Fig. 8-64). In older fetuses, both vertebral and spinal canal anatomy can often be quite dramatically depicted (Figs. 8-65 and 8-66).

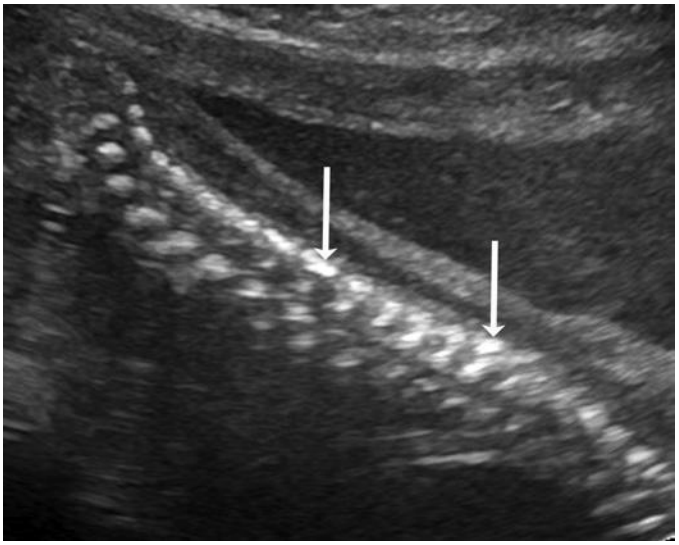

FIG 8-63 Supine fetus, second trimester. The vertebral bodies, lying between the arrows, are clearly seen, but the posterior arch cannot be well appreciated. Note that the vertebral body ossification centers smoothly align along their anterior surfaces.

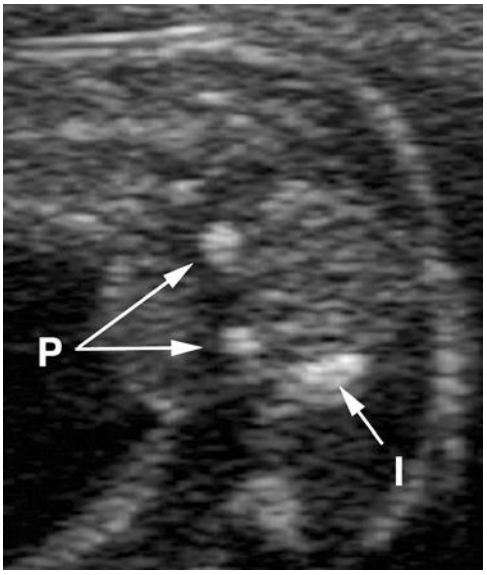

FIG 8-64 Axial sonogram of the pelvis demonstrating the early ossification centers of the pubis (P). Also seen is an ischial ossification (I).

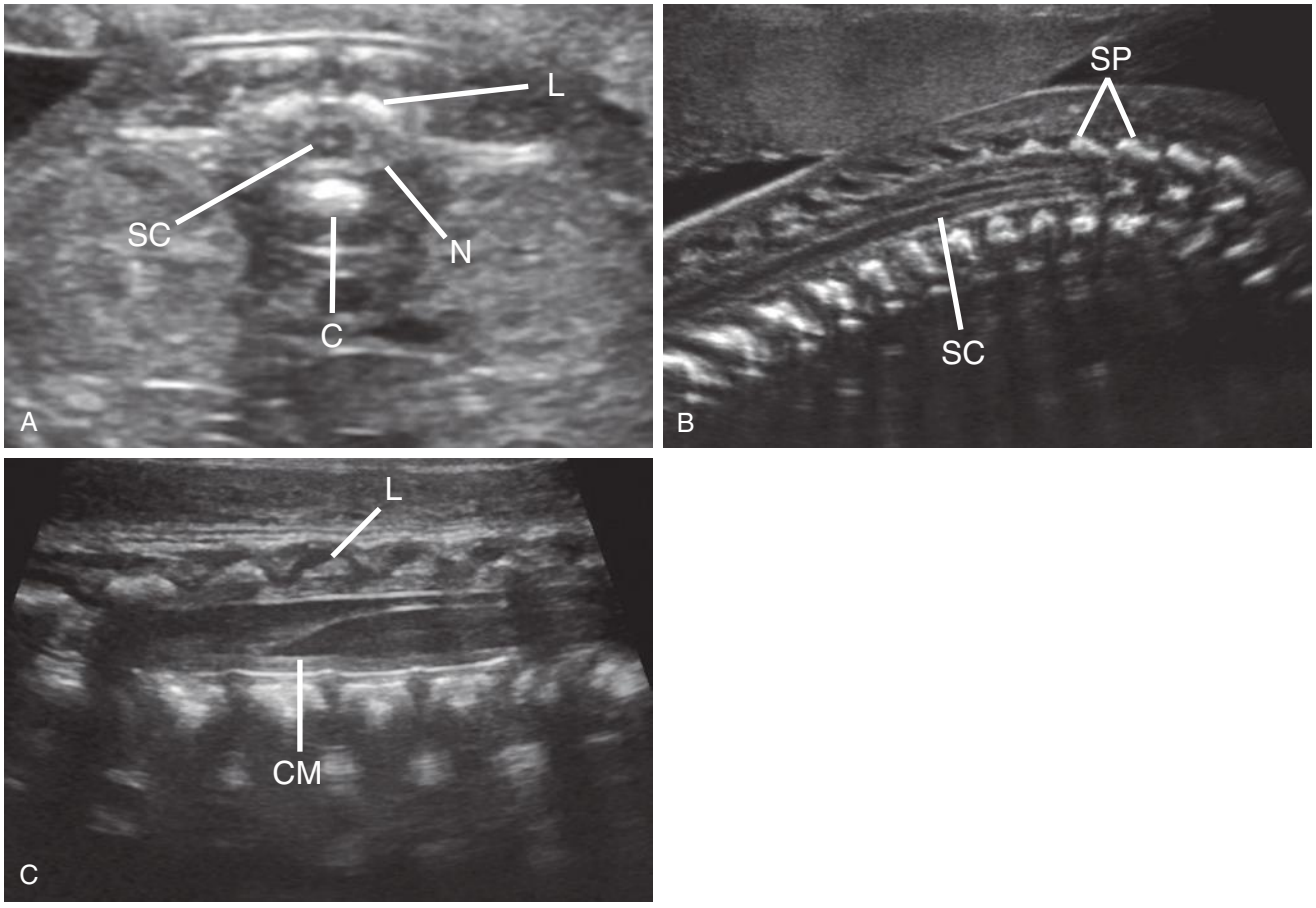

FIG 8-65 **A,** Lumbar spine of 20-week fetus, axial section. Longitudinal scans of the thoracolumbar (**B**) and lumbosacral (**C**) spine. C, centrum; CM, conus medullaris; L, laminae; N, neurocentral synchondrosis; SC, spinal cord (note bright linear echo from central canal); SP, spinous process (in cartilage).

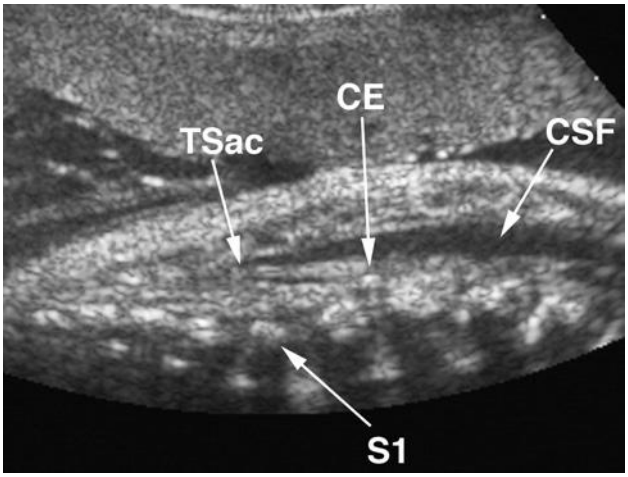

FIG 8-66 Midsagittal sonogram of the fetal spine demonstrating the termination of the thecal sac (TSac). The S1 vertebral body is marked. Overlying the echogenic cauda equina (CE) (echogenic owing to the leptomeninges that cover the nerve roots) is lucent cerebrospinal fluid (CSF).

Cartilaginous structures in the axial skeleton are less conspicuous than in the appendicular skeleton but nonetheless are visible in virtually all fetuses. The sutures of the calvarial vault already have been noted. The cartilaginous neurocentral synchondrosis of the spine (the junction of the centrum and the posterior ossification centers) is visible in all fetuses from the end of the first trimester onward (see Figs. 8-58 to 8-62).[39] Similarly, the gaps between the vertebral body ossification centers are a composite of the nonossified margin of the adjoining vertebral bodies plus the intervertebral disk (see Fig. 8-63). The margin of cartilage in the vertebral body is best appreciated posteriorly, lying between the ossification center and the dura of the spinal canal (Fig. 8-65A and C). The spinous processes of the posterior neural arch are also occasionally seen and again are composed entirely of cartilage in fetal life (Fig. 8-65B).

A feature of the fetal musculoskeletal system that is poorly judged sonographically is the degree of bony ossification. Increased ossification, as in osteopetrosis, is completely unrecognized on sonograms. Similarly, diminished ossification is difficult to recognize. Only in the most extremely osteopenic bone can one appreciate diminished ossification on sonograms. Examples are the nearly nonossified calvaria in fetuses with osteogenesis imperfecta lethalis or recessive hypophosphatasia[53-55] or the spine in fetuses with achondrogenesis.[56]

Little attention is typically devoted to the fetal muscular system, even though many muscles and muscle groups can be very well visualized (see Fig. 8-32). In general, normal muscles are quite hypoechoic, at times so much so that they simulate fluid collections. This is most notable of the abdominal wall musculature, which may simulate ascites (pseudoascites) (Fig. 8-67).[57] Currently, high-resolution sonographic equipment decreases the propensity to "overcall" ascites caused by this artifactual situation because the layers of the abdominal wall can be individually discerned.[58]

The abdominal wall muscles, the internal and external oblique and the transversus abdominis, at times, are so clearly visible that the individual layers can be detected. More commonly seen as a single layer of muscles, this tissue is easily recognized as lying within the abdominal wall by noting its position between the subcutaneous and properitoneal fat (Fig. 8-67B). The latter is traced from the paranephric fat as it curves along the lateroconal fascia. Furthermore, the abdominal wall

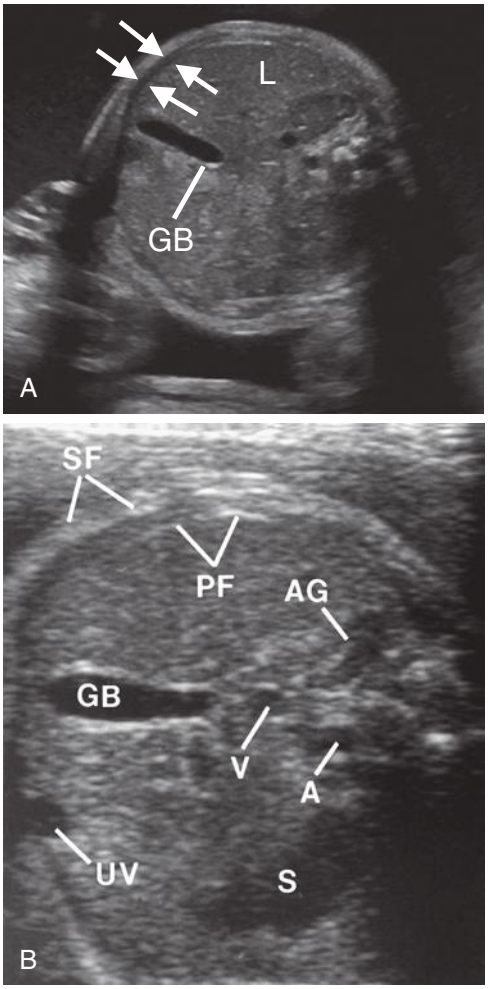

FIG 8-67 Transverse axial sonograms, fetal abdomen. **A,** Lucent abdominal wall musculature (*arrows*) may erroneously give the impression that ascites is present. **B,** Abdominal wall musculature lies between the subcutaneous fat (SF) and the properitoneal fat (PF). Individual layers can be appreciated. A, aorta; AG, adrenal gland; GB, gallbladder; L, liver; S, stomach; UV, umbilical vein; V, inferior vena cava.

muscles "meet" the ends of the lower thoracic ribs, whereas ascites would pass "between" the ribs and the abdominal viscera.[58]

CARDIOVASCULAR SYSTEM

The anatomy of the heart and great vessels is discussed in detail in Chapter 13. Here, the focus is on those fetal vessels visible within the uterus and fetal corpus that are not covered elsewhere. A surprisingly large number of individual fetal blood vessels can be seen. Color Doppler sonography has greatly added to our ability to consistently demonstrate fetal vessels.

The fetal circulation begins in the placenta. In virtually all second and third trimester fetuses, surface (fetal) vessels of the placenta can be detected, and with color Doppler sonography these vessels are seen penetrating the placental substance. The surface vessels coalesce at the cord "insertion." The identification of the cord insertion is important in the performance of percutaneous umbilical (fetal) blood sampling (PUBS) and intrauterine fetal transfusion for diagnosis and management of a number of fetal disorders (Chapter 24).[59] As well, velamentous and peripheral cord insertions can have obstetric implications.

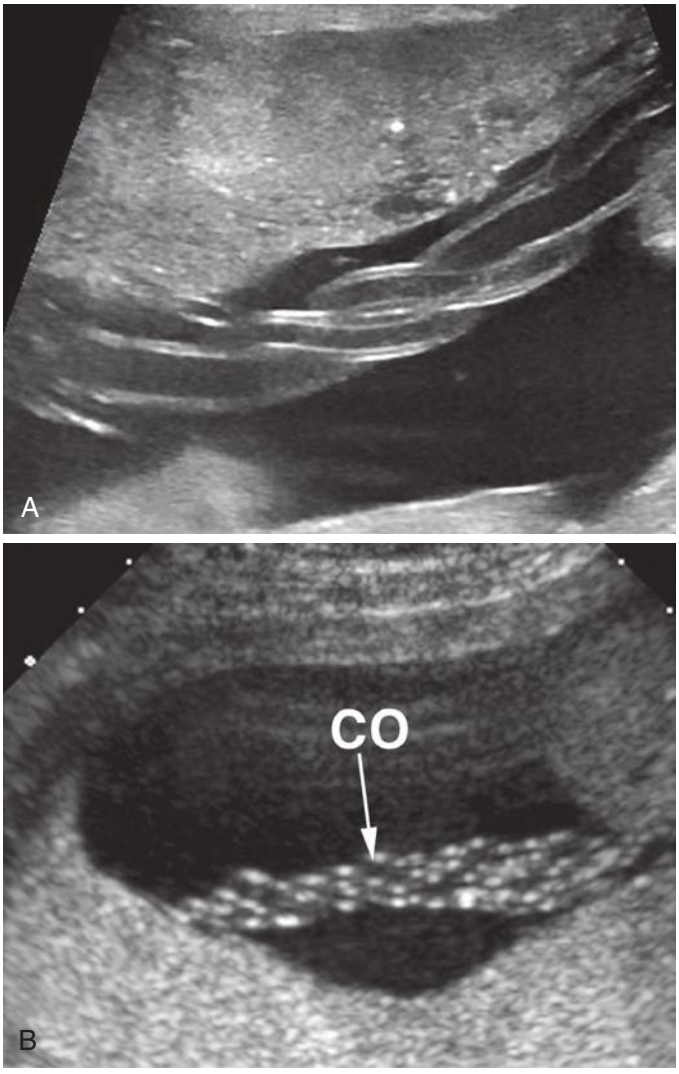

FIG 8-68 A, Longitudinal sonogram of a three-vessel umbilical cord with a typical amount of coiling. **B,** Longitudinal sonogram of a three-vessel umbilical cord (CO) with a greater than usual amount of coiling (there is an issue as to whether this is a variant or an abnormal circumstance).

The cord "insertion" is often easily seen, but if not, it is worthwhile to search for large placental surface vessels using color Doppler and trace these vessels to where they collalesce with the cord.

The normal umbilical cord is composed of two arteries and a vein (Fig. 8-68). The cord is virtually always coiled and sometimes extremely so, or "hypercoiled." This arrangement leads to a variety of appearances of the cord when viewed with tomographic sections as generated by sonography (Fig. 8-69). The seemingly "simple" task of counting cord vessels can be made quite frustrating by numerous coils. To obtain the correct count of cord vessels consistently, one must rely on a true transverse axial section. Longitudinal or oblique views can be misleading and result in error.

Umbilical vessels enter the fetus, by definition, at the umbilicus and there immediately diverge.[60] The umbilical vein proceeds cephalically (Fig. 8-70); the umbilical arteries egress from a caudal direction. The umbilical arteries proceed along the margin of the urinary bladder from their origin at the iliac arteries in their course toward the umbilicus (Fig. 8-71). As they course along the bladder margin, they should not be mistaken for dilated ureters, a distinction easily made by interrogating them with color Doppler sonography. Regardless of the degree of bladder distention, normal umbilical arteries *always* flank the bladder wall. Thus, this relationship can be employed both to detect the umbilical arteries or the urinary bladder, particularly when some defect or disease has altered the expected appearance of the bladder. Although not representing certain evidence of a three-vessel cord, the identification of two umbilical arteries flanking the bladder lumen represents excellent evidence for a three-vessel cord and, employing color Doppler sonography, constitutes the easiest method of "confirming" a three-vessel cord. If using the technique of color Doppler identification of umbilical arteries flanking the bladder to determine "cord vessel number"—a common practice—caution should be exercised to avoid mistaking an iliac artery for an umbilical artery. The iliac artery will also "light up" on color Doppler and is sufficiently close to the umbilical artery to create confusion from time to time.

The umbilical vein joins the fetal portal circulation, which is seen with a high degree of consistency on sonograms. Obviously, the larger the fetus, the more readily one will see the smaller elements of this system. Many of the illustrations in the literature incorrectly interpret the fetal umbilical and portal venous anatomy. Confusion has led not only to improper nomenclature but also to use of inappropriate landmarks for obtaining important fetal measurements. With a clear understanding of fetal portal vein anatomy, these pitfalls can be avoided and similarity of the fetal and adult segmental hepatic anatomy better appreciated.

The dynamics of fetal circulation determine the details of fetal hepatic portal venous and segmental anatomy.[61] Because there are no blood-diverting branches of the umbilical vein, the volume of placental blood entering the left portal venous system equals that in the umbilical vein. Thus, the umbilical vein and the portion (umbilical segment) of the left portal vein that it joins have the same diameter (see Fig. 8-70). Therefore, the left portal vein of the fetus is larger than the right, the reverse of the situation seen in the child and adult. From this point, blood may reach the right atrium through several pathways. A common misconception of the fetal circulation is that the bulk of umbilical venous blood bypasses the liver capillary bed through a large patent ductus venosus. In utero, the ductus venosus averages only one seventh the diameter of the umbilical vein[62] and even may be closed (see Fig. 8-70).[63] It should be remembered, however, that the peripheral resistance of the hepatic vascular bed is not present in the ductus venosus, enabling this smaller caliber vessel to carry a larger quantity of blood than might be expected. A significant portion of umbilical venous blood, which carries the highest concentration of nutrients and oxygen in the fetus, circulates through the left lobe of the fetal liver through branches supplying the medial and lateral segments before entering the systemic venous system through the left and middle hepatic veins (Fig. 8-72). Although the right lobe of the liver receives a small amount of umbilical venous blood from the left portal vein, the bulk of blood entering the right portal vein is derived from the main portal vein, which, in the fetus, contains low concentrations of both nutrients and oxygen.[63] The unequal distribution of nutrients to the fetal liver partially accounts for the relatively large size of the left lobe of the fetal liver. After closure of the umbilical vein at birth, the nutrient supply to the entire liver equalizes and the relative size of the left lobe decreases.

In the fetus, the umbilical vein courses cephalically in the free margin of the falciform ligament (see Fig. 8-70). As noted earlier, it joins the umbilical portion of the left portal vein near the caudal margin of the left intersegmental fissure of the liver.[64] After birth, the umbilical vein thromboses, collapses, and ultimately becomes the ligamentum teres hepatis, a classical marker of the left intersegmental fissure (for a very long time this structure was considered the line of division of the left and right hepatic lobes). The precise line of division

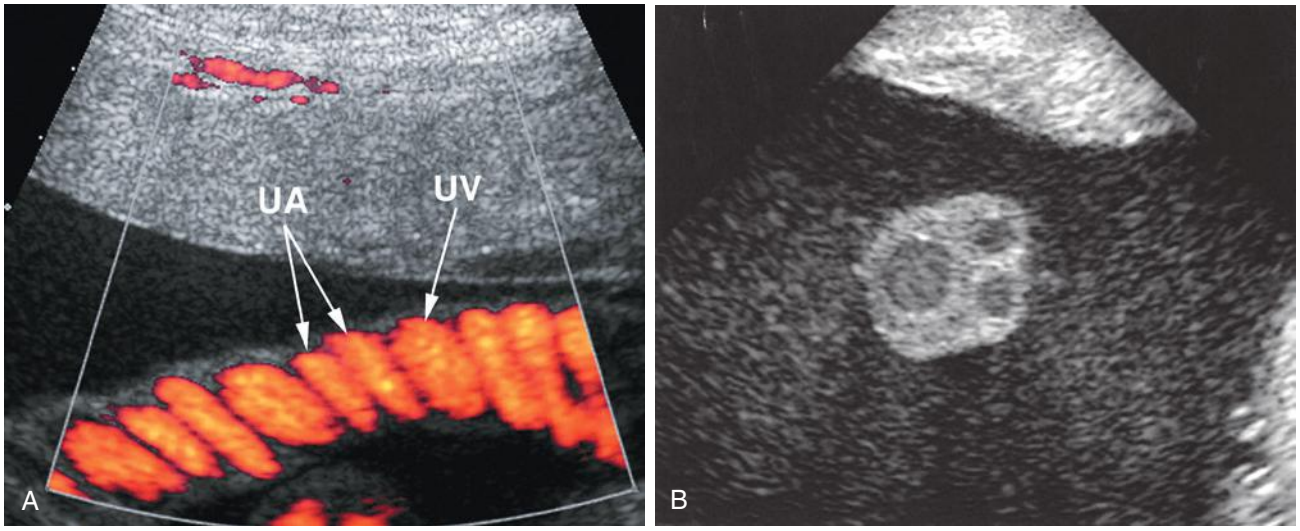

FIG 8-69 **A,** Longitudinal nondirectional color Doppler sonogram of the umbilical cord. The umbilical vein (UV) is interlaced by the two umbilical arteries (UA). **B,** Transverse axial sonogram of the umbilical cord.

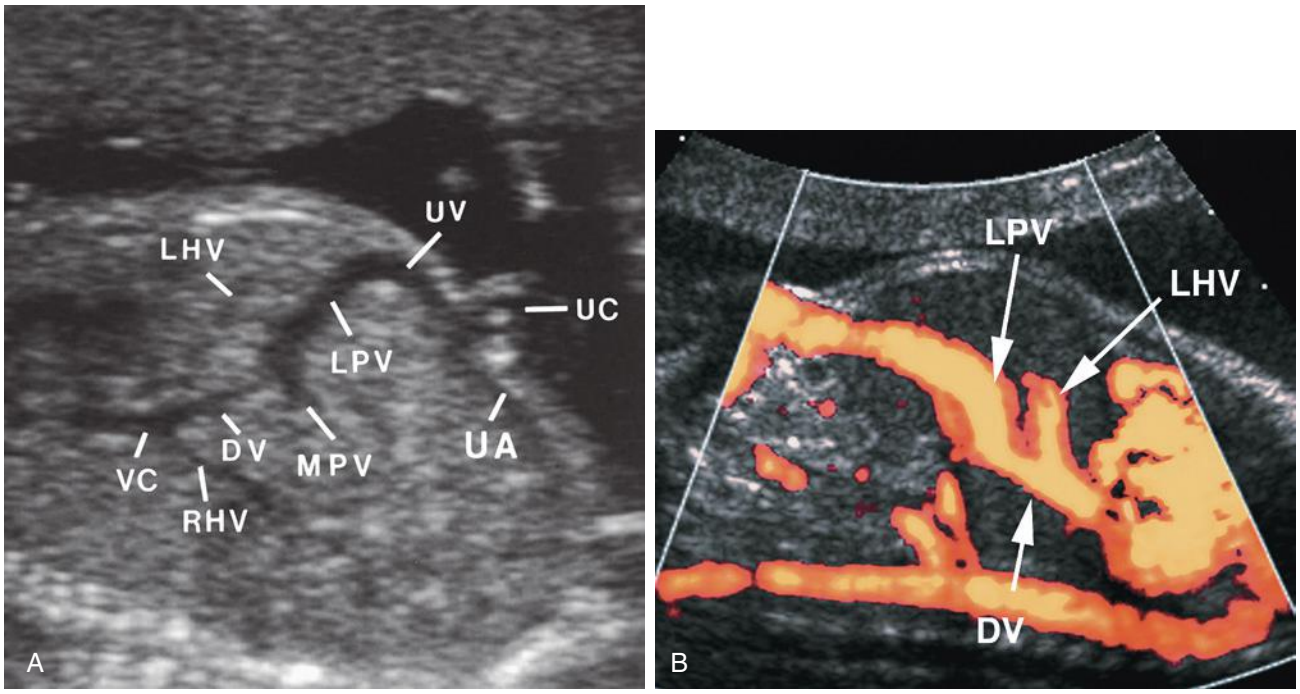

FIG 8-70 Midsagittal sonograms of the umbilical circulation in gray scale (**A**) and nondirectional color Doppler (**B**). between the umbilical vein and the umbilical segment of the left portal vein is the point at which the most anterior of the medial and lateral segmental branches to the left hepatic lobe egress the left portal vein (the branches to segments 3 and 4). Remember, the umbilical vein has no blood diverting branches. Therefore, these two hepatic intraparenchymal vessels had to originate from the umbilical segment of the left portal vein.

The umbilical portion of the left portal vein has a predominantly posterior course but also courses superiorly in the left intersegmental fissure (see Fig. 8-70). As noted, its branches supply the medial and lateral segments of the left lobe of the liver.[65] The left portal vein then courses abruptly to the right, exits the left intersegmental fissure, and forms the transverse portion (pars transversa) of the left portal vein (Figs. 8-72 and 8-73). The pars transversa joins imperceptibly with the right portal vein at the main lobar fissure. The ductus venosus originates from the pars transversa (but occasionally more rightward).[66] The ductus continues posteriorly but assumes a more cephalad course than the umbilical portion of the left portal vein (see Fig. 8-73). It continues as an unbranched structure to join the left or, less commonly, the middle hepatic vein (this distinction is somewhat artificial as the left hepatic vein, the middle hepatic vein, and the ductus venosus most commonly form a confluence before entering the inferior vena cava). In this position the ductus venosus lies in the superior extension of the gastrohepatic ligament, which separates the developing caudate lobe

posteriorly from the lateral segment of the left hepatic lobe anteriorly (the gastrohepatic ligament, the dominant ligament of the lesser omentum, also separates the greater and lesser peritoneal cavities). After birth, the ductus venosus closes and becomes the fibrous ligamentum venosum.[64]

Sonograms of the upper portion of the fetal abdomen clearly demonstrate the anatomy described previously (see Figs. 8-70 to 8-73).

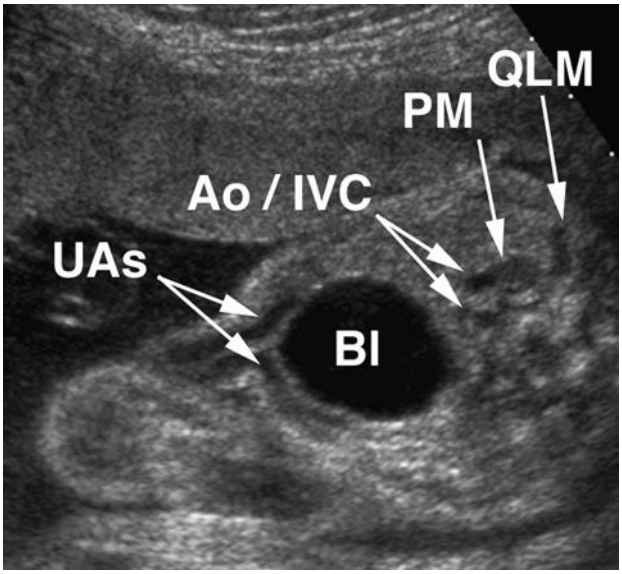

FIG 8-71 Umbilical cord insertion into the fetus. The umbilical arteries (UAs) egress from a caudal direction, coursing along the margin of the urinary bladder (Bl). Ao/IVC, aorta and inferior vena cava; PM, psoas muscle; QLM, quadratus lumborum muscle.

Because the umbilical vein courses cephalically, transversely oriented planes of section intersect this vessel's short axis (see Fig. 8-67). Slight cephalad movement of the transducer demonstrates a position at which this venous structure abruptly courses posteriorly (see Figs. 8-72 and 8-73). This posteriorly coursing vein represents the umbilical portion of the left portal vein rather than the cephalic portion of the umbilical vein, as it is commonly mislabeled in the literature. Confirmation that this vessel is the left portal vein is easily made by observation of branches arising from this vein to the medial and lateral segments of the left hepatic lobe (see Figs. 8-72 and 8-73). When the umbilical portion of the left portal vein is seen throughout its entire course, one can be certain that some angulation has been introduced into the scan plane because this venous structure courses not only posterior but slightly cephalad (see Fig. 8-70). A variety of branches of the umbilical segment of the left portal vein are occasionally imaged; they include the medial, superolateral, and inferolateral branches (see Fig. 8-72).

The right portal vein divides into anterior and posterior segmental branches, the same as in the adult (see Fig. 8-73). Each supplies a respective segment of the right hepatic lobe. The hepatic veins can be recognized by their relationship to portal veins[64] and can be seen to radiate toward the inferior vena cava, coalescing with this venous channel immediately before it enters the right atrium (Fig. 8-74). These veins divide the liver into lobes and segments. The hepatic veins are most easily sought near the level of the diaphragm where their caliber is the largest.[67] Nonetheless, the middle and right hepatic veins are commonly seen in more inferior planes of section by noting their relative position compared with the right portal vein divisions (see Fig. 8-73). The right hepatic vein passes between as well as bisecting the distance between the anterior and posterior divisions of the right portal vein, whereas the middle hepatic vein always crosses anterior to the right portal vein (in the main lobar fissure) and bisects the distance

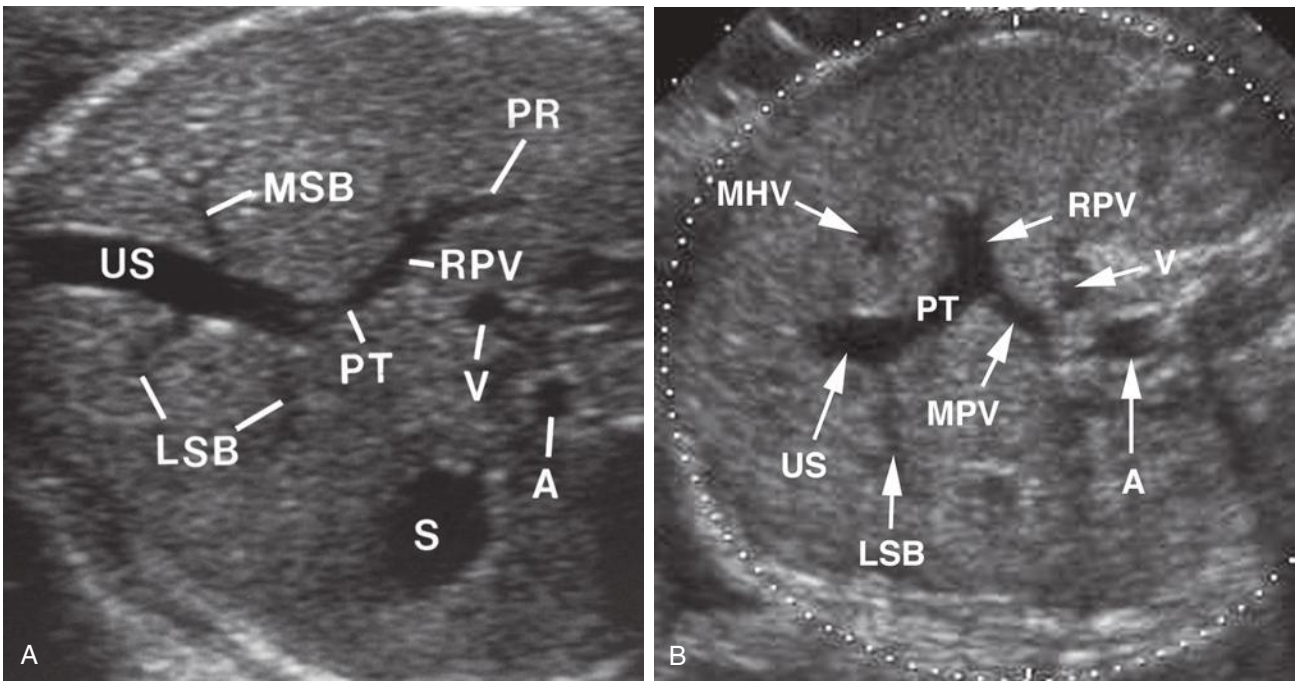

FIG 8-72 **A,** Fetal portal circulation. Umbilical segment (US) of the left portal vein begins at the point where the medial (MSB) and the distal lateral (LSB) segmental branches originate (proximal to that point the vessel is the umbilical vein). **B,** Note that the main portal vein (MPV) is the appropriate line of division between the right portal vein (RPV) and the first portion of the left portal vein, the pars transversa (PT). A, aorta; MHV, middle hepatic vein; PR, posterior division of right portal vein; S, stomach; V, vena cava.

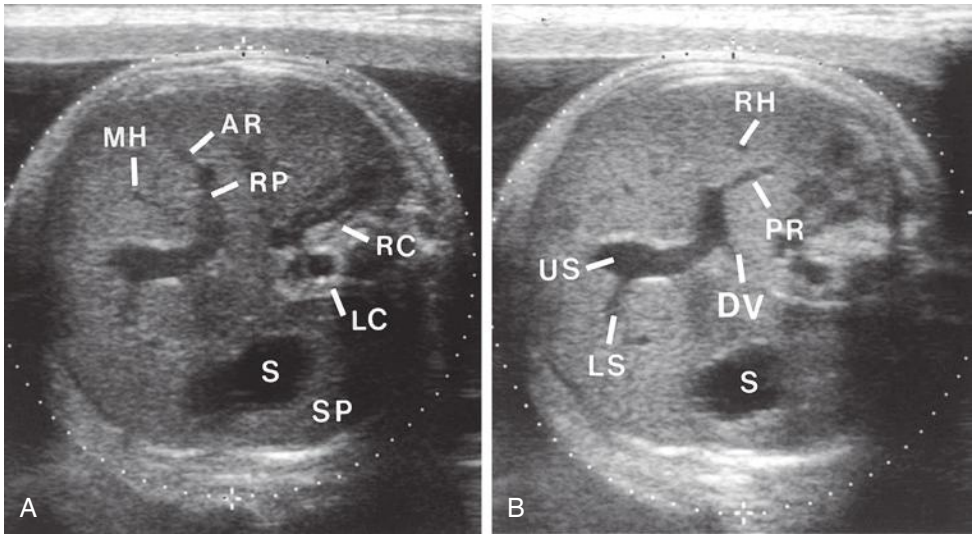

FIG 8-73 **A** and **B,** Transverse axial sonograms of fetal liver. FIG 8-74 Sonogram through the long axis of the proximal fetal hepatic veins: IVC, inferior vena cava; LHV, left hepatic vein; MHV, middle hepatic vein; RHV, right hepatic vein. These veins divide the liver into lobes and segments: AS and PS, anterior and posterior segments of the right hepatic lobe; MS and LS, medial and lateral segments of the left hepatic lobe.

between the anterior branch of the right portal vein and the umbilical segment of the left portal vein. The aorta and inferior vena cava have a similar course in the lower abdomen but diverge in the upper abdomen, where the aorta penetrates the diaphragm posteriorly (in contact with the spine), whereas the inferior vena cava turns anteriorly to join the right atrium (Fig. 8-75).

The great vessels and heart are described in detail in Chapter 13. Briefly, a second or third trimester sonogram of all pregnancies should include a four-chamber heart view (Fig. 8-76). Outflow tract views of the left and right cardiac ventricles also are required in the most recent guidelines.[68] Useful information about the position and size of the great vessels can be quickly gleaned from a transverse axial view of the upper mediastinum by simply moving the transducer cephalically from the four-chamber heart view. This section traverses the superior vena cava, the ascending and descending thoracic aorta, and the pulmonary artery. As well, one or more branches of the pulmonary artery will be seen. These may be one or the other or both the right or left pulmonary arteries or the ductus arteriosus (coursing from the pulmonary artery to the descending thoracic aorta) (Fig. 8-77).

The vessels arising from the transverse aorta are frequently visible and normally comprise the brachiocephalic, left common carotid, and left subclavian arteries (Fig. 8-78A). The common carotid arteries and jugular veins are also commonly seen in the neck of an older fetus. The brachial artery and vein are less frequently seen adjacent to the humerus but again can be found using color Doppler sonography.

Intracranial arterial structures are easily perceived using color Doppler sonography (Fig. 8-79). These include the vessels of the circle of Willis located in the basal cistern and surrounding the inferior portion of the third ventricle. The middle cerebral artery can be identified coursing in the sylvian cistern, the posterior cerebral artery in the ambient cistern, and the anterior cerebral arteries in the interhemispheric cistern (near the genu of the corpus callosum). The basilar artery lies ventral to the pons in the prepontine space and upon reaching the interpeduncular cistern it bifurcates. The basilar artery is most often seen on sonograms depicting the interpeduncular cistern where it is part of the circle of Willis. Also commonly seen after the formation of the corpus callosum commences is the pericollosal artery coursing along its body.

The abdominal aorta and inferior vena cava are easily identified, as are the common iliac arteries and veins (Fig. 8-78B and C). Other branches of the abdominal aorta can be consistently visualized using color Doppler sonography. They include the celiac axis, the superior mesenteric artery, and the renal arteries. Similarly, the renal veins can be consistently seen.

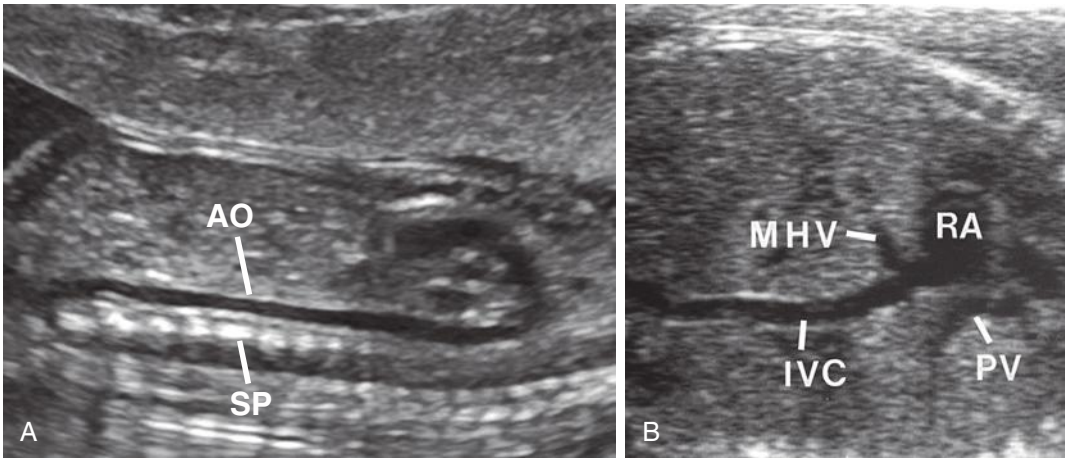

FIG 8-75 **A,** Longitudinal view of the aorta (AO). **B,** Longitudinal view of the inferior vena cava (IVC). MHV, middle hepatic vein; PV, pulmonary vein; RA, right atrium; SP, spine.

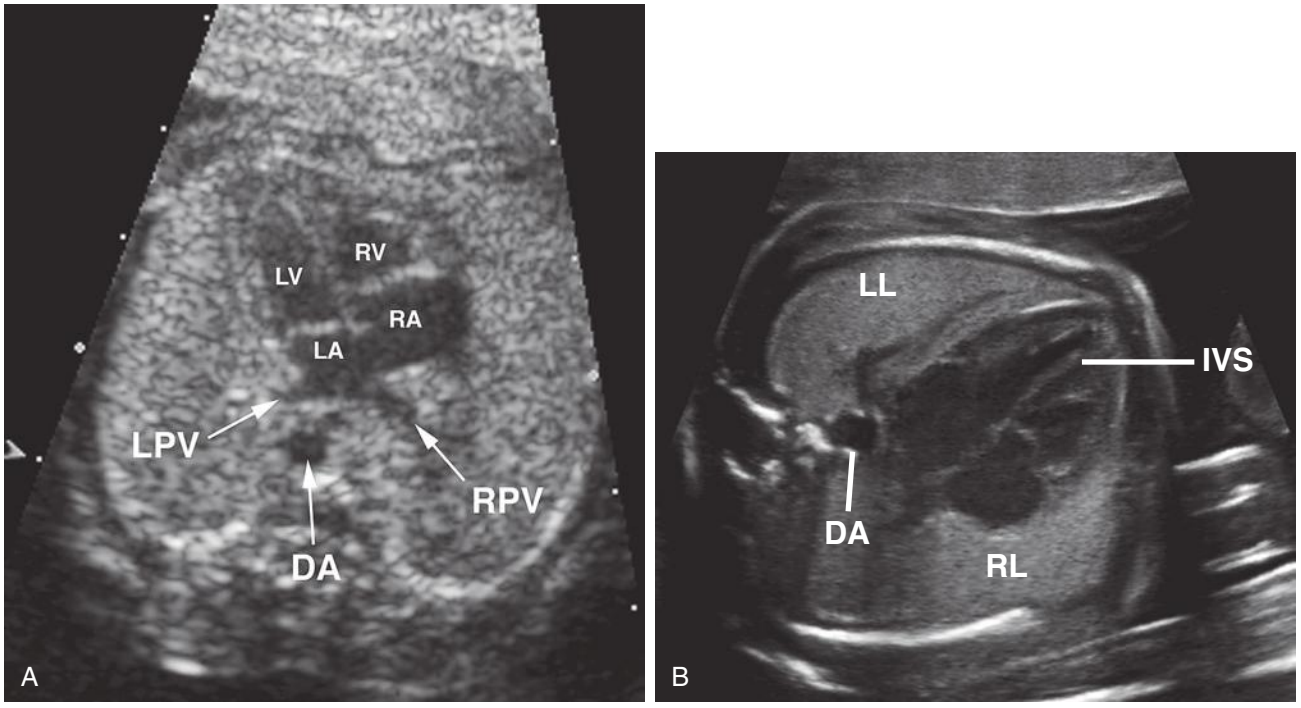

FIG 8-76 Transverse axial sonograms through the fetal thorax, the "four-chamber view." In **A,** the fetus is supine. In **B,** the fetus is in right decubitus position. DA, descending thoracic aorta; IVS, interventricular septum; LA, left atrium; LL, left lung; LPV, left pulmonary vein; LV, left ventricle; RA, right atrium; RL, right lung; RPV, right pulmonary vein; RV, right ventricle.

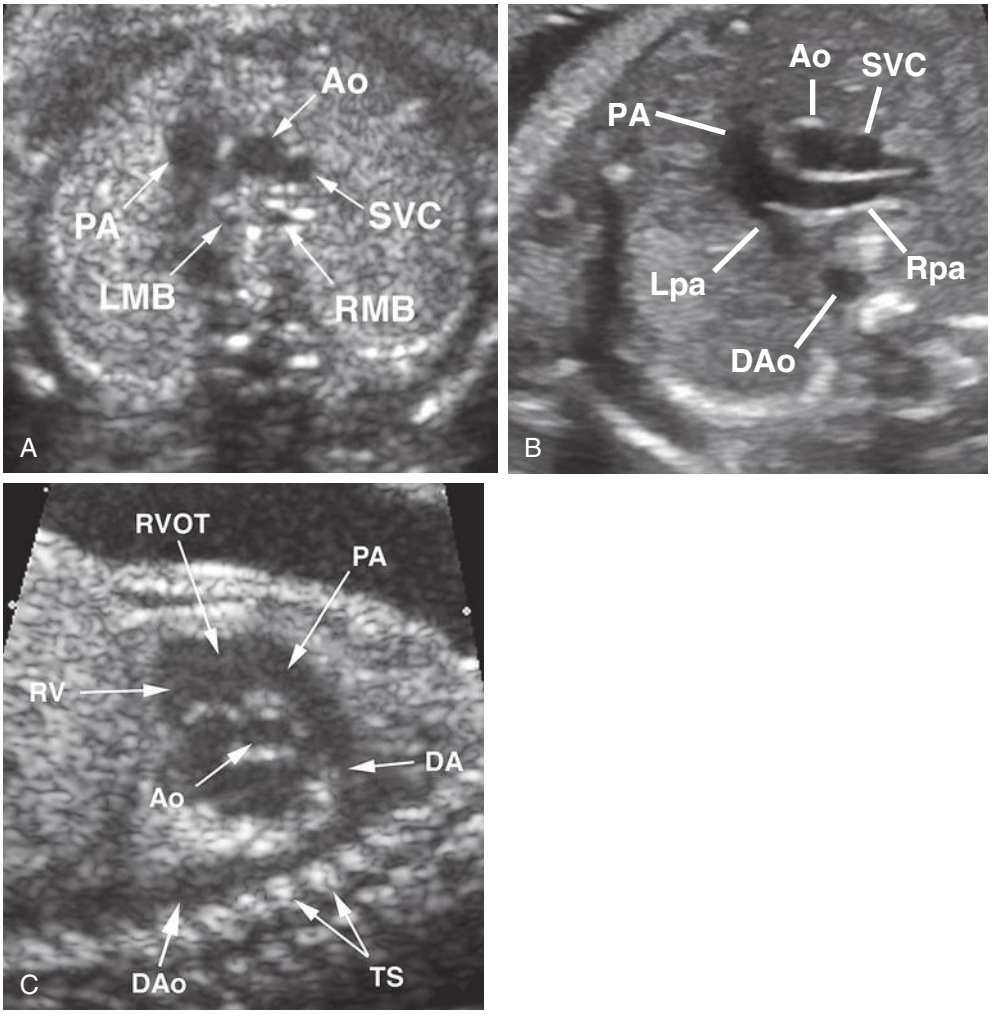

FIG 8-77 **A** and **B,** Transverse axial sonograms through the fetal chest. **C,** Midsagittal sonogram of the fetal chest. In transaxial sonograms (**A** and **B**) the great vessels lie sequentially from right to left and posterior to anterior as follows: superior vena cava (SVC), aorta (Ao), and pulmonary artery (PA). The descending aorta (DAo) lies immediately anterior to the thoracic spine (TS). The right pulmonary artery (Rpa) passes directly posterior to the aorta and superior vena cava. The right (RMB) and left (LMB) mainstem bronchi lie posterior to the great vessels. DA, ductus arteriosus; Lpa, left pulmonary artery; RV, right ventricle; RVOT, right ventricular outflow tract.

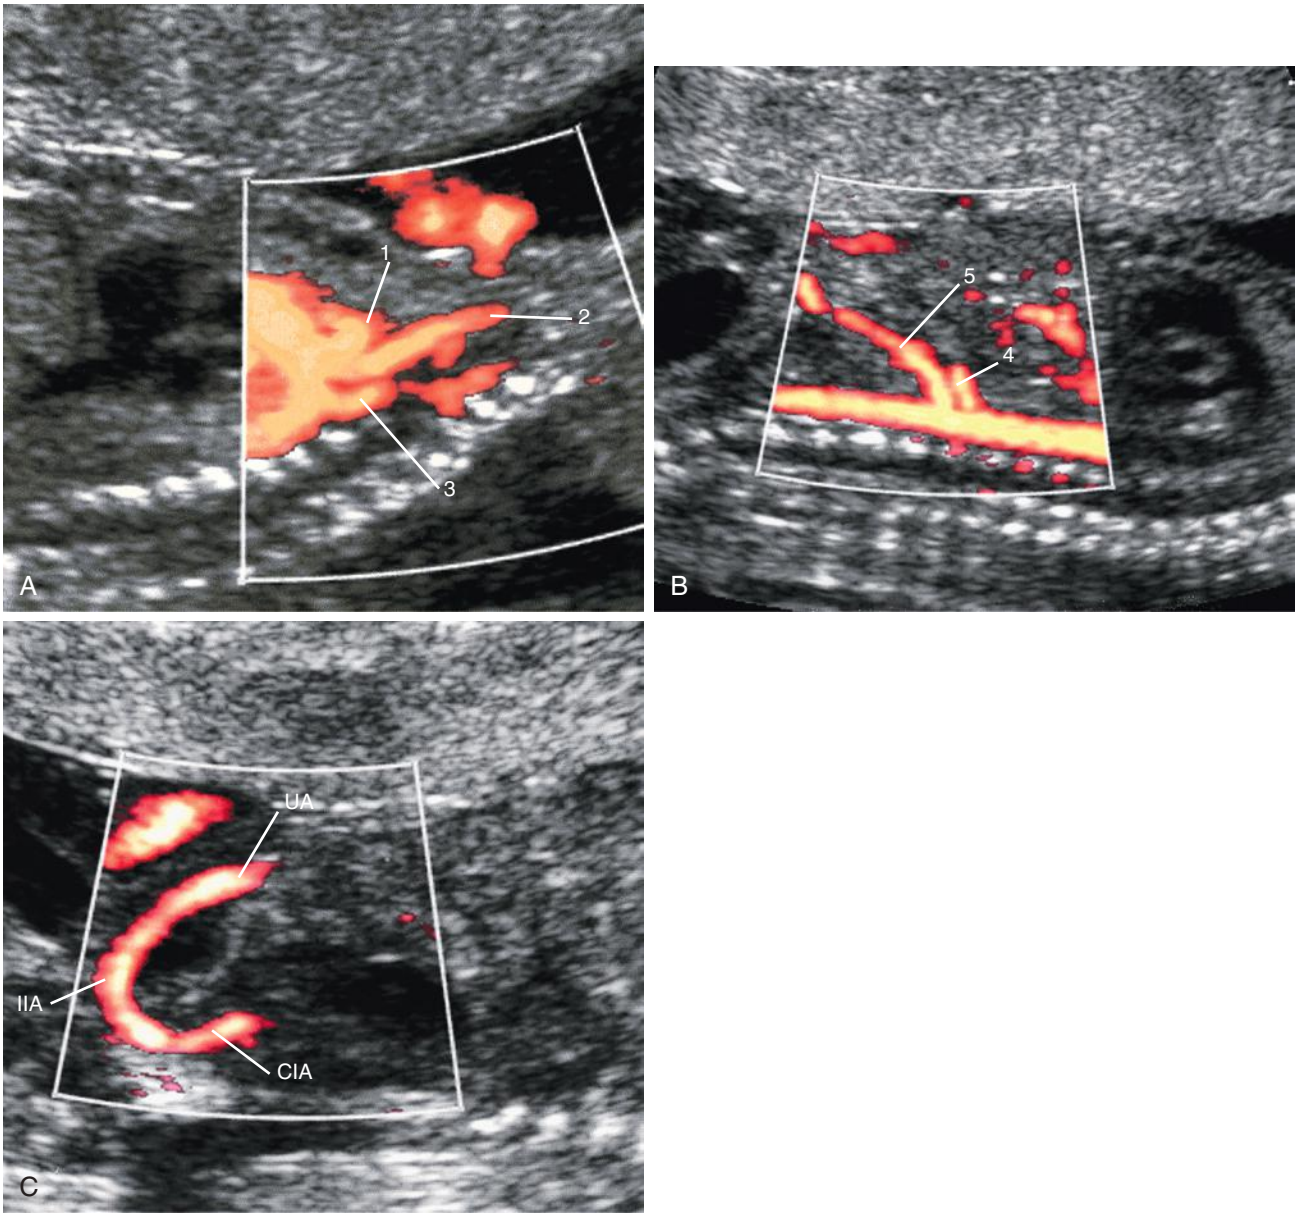

FIG 8-78 Series of nondirectional color Doppler sonograms of the fetal torso. **A,** The aortic arch is seen to good advantage. 1, brachiocephalic artery; 2, left common carotid artery; 3, left subclavian artery. **B,** Midsagittal sonogram of the abdominal aorta. 4, celiac axis; 5, superior mesenteric artery. **C,** Oblique sonogram through the fetal pelvis demonstrating the umbilical artery (UA) joining the internal iliac artery (IIA) and continuing into the common iliac artery (CIA).

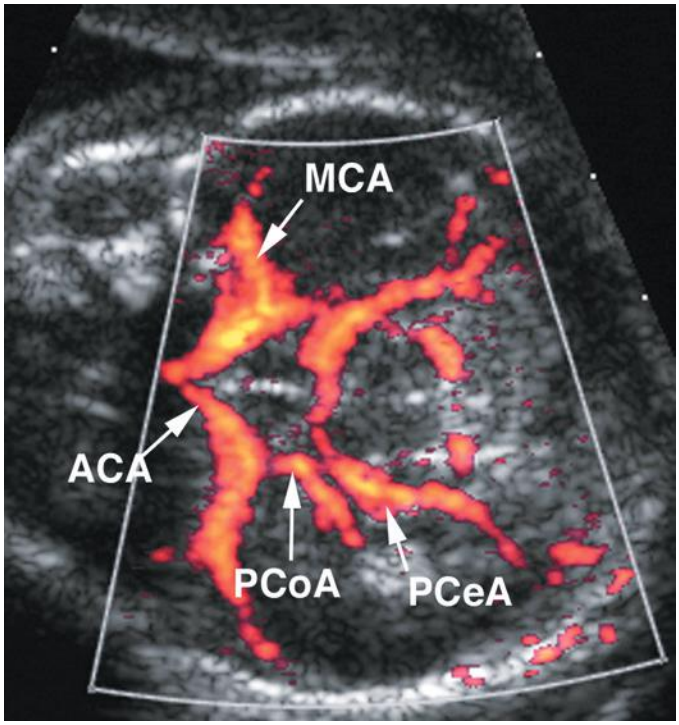

FIG 8-79 The circle of Willis is well seen on this nondirectional color Doppler image. ACA, anterior cerebral artery; MCA, middle cerebral artery; PCeA, posterior cerebral artery; PCoA, posterior communicating artery.

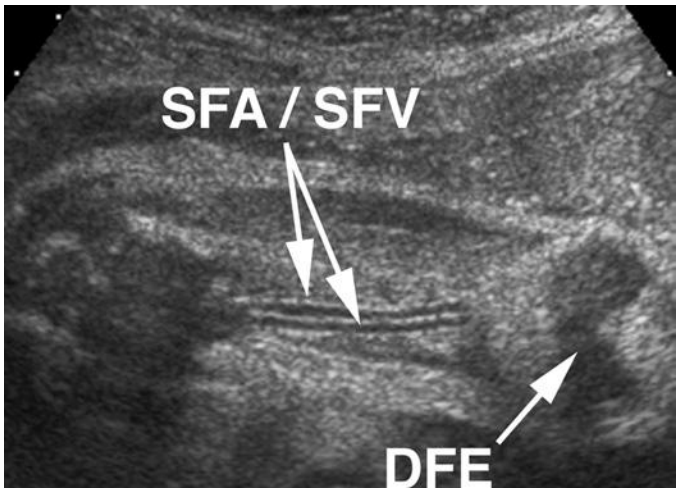

FIG 8-80 Superficial femoral artery and vein (SFA/SFV) seen side by side in the mid- and distal thigh. DFE, distal femoral epiphysis.

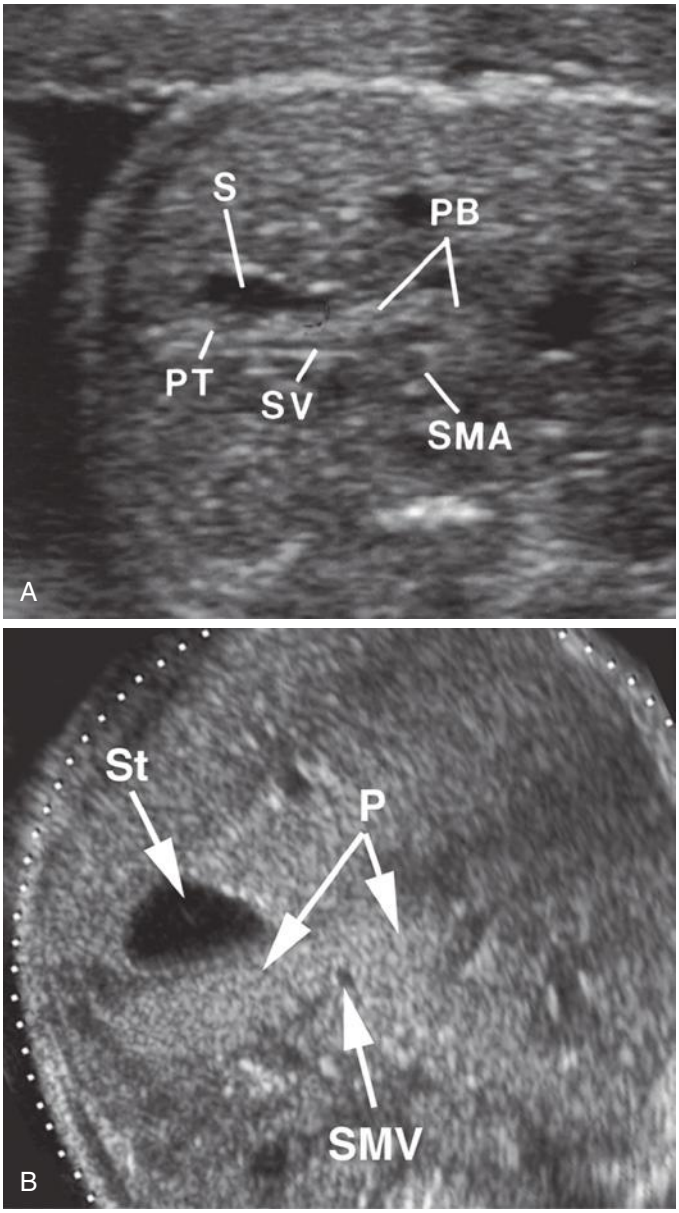

FIG 8-81 **A** and **B,** The fetal pancreas is not commonly seen discretely but is well depicted in these sonograms. When sought, it can often be detected. Those who perform abdominal sonograms in adults and children will recognize the familiar landmarks. In **B** the pancreas (P) is enlarged (Beckwith-Wiedemann syndrome). The pancreas lies between the splenic vein (SV) and the posterior stomach wall (St). PB, pancreatic body; PT, pancreatic tail; S, stomach; SMA, superior mesenteric artery; SMV, superior mesenteric vein.

In the leg, the superficial femoral artery and vein (Fig. 8-80) may be visualized in older fetuses. When the knee is extended, it is not difficult to trace these vessels to the level of the popliteal artery and vein, a virtually impossible task when the knee is flexed.

GASTROINTESTINAL SYSTEM

Many components of the gastrointestinal system can be seen sonographically, some as early as the end of the first trimester.[69] The liver, the largest parenchymal organ of the system and of the torso, is seen consistently from the second trimester onward, although its margins are often indistinct in earlier gestations. With the latest equipment the liver is usually easily discriminated from surrounding structures. Conversely, the other major parenchymal organ of the gastrointestinal system, the pancreas, is much less commonly seen, even in third trimester fetuses (Fig. 8-81). The spleen, more appropriately a part of the reticuloendothelial system and not the gastrointestinal system although considered here, is also visible consistently in the second trimester, but similar to the liver in early pregnancy, its margins are frequently indistinct (Figs. 8-73 and 8-82). Conversely, those portions of the fetal gastrointestinal system that consistently contain fluid, the stomach (see Figs. 8-67, 8-72, and 8-73) and gallbladder

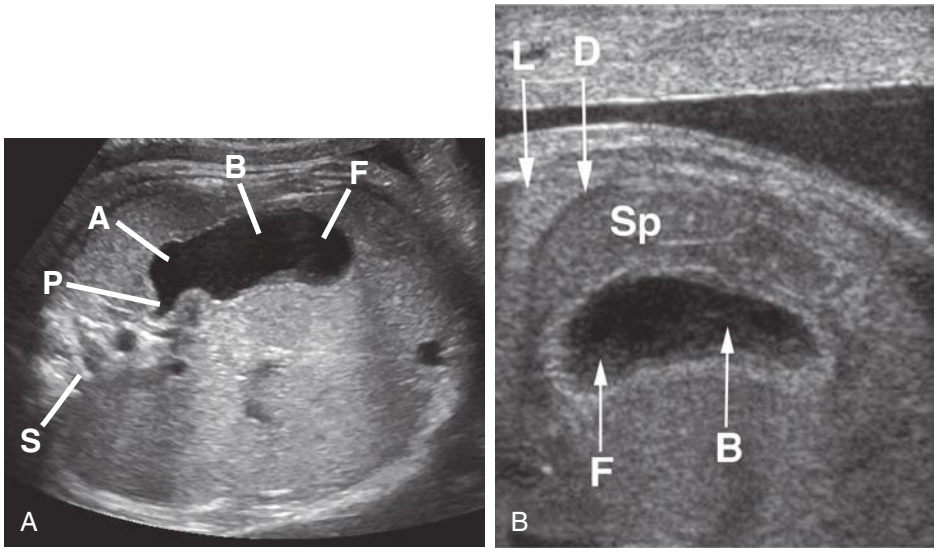

FIG 8-82 **A,** Coronal image of the stomach demonstrating all portions of the stomach including the fundus (F), body (B), antrum (A), and pylorus (P). S, spine. **B,** Axial sonogram of the fetal stomach showing the fundus (F) and body (B). A portion of the left lung (L) and spleen (Sp) are included. D, diaphragm.

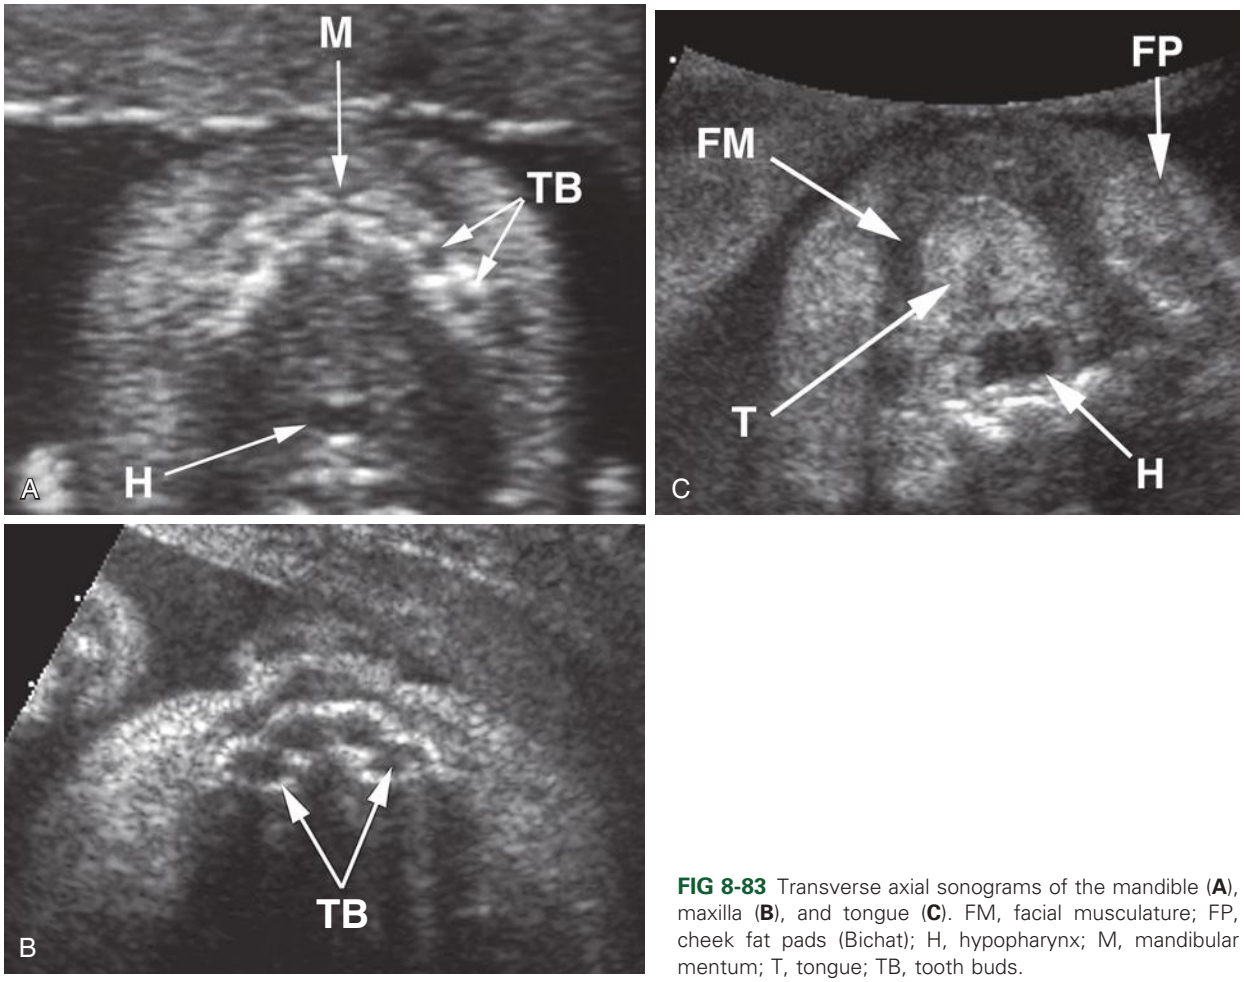

FIG 8-83 Transverse axial sonograms of the mandible (**A**), maxilla (**B**), and tongue (**C**). FM, facial musculature; FP, cheek fat pads (Bichat); H, hypopharynx; M, mandibular mentum; T, tongue; TB, tooth buds.

(see Fig. 8-67), are among the earliest and most consistently seen of fetal structures.

The components within and about the oral cavity are seen relatively well sonographically.[70] The lips and cheeks have been described in the section on superficial anatomy (see Figs. 8-12 and 8-13). The tongue (Fig. 8-83) is also consistently seen and to best advantage during swallowing movements. The gingival ridge with tooth buds is seen commonly in fetuses of 20 weeks or more (Fig. 8-83A). The hard palate is difficult to define consistently but with practice can be detected. For this reason, cleft palate is more difficult to detect than cleft lip. Clefting

of the soft palate is difficult to diagnosis sonographically because the soft palate cannot be discretely recognized. The oropharynx and laryngeal pharynx frequently contain fluid and thus are seen relatively often when sought (Figs. 8-83 and 8-84). Transverse axial scans through the upper neck are quite successful for visualization of the pharynx, but longitudinal coronal images, although more difficult to obtain, display the anatomy to greater advantage. In longitudinal coronal planes, the continuity of the pharyngeal zones can be appreciated as well as the larynx protruding into the pharynx (see Fig. 8-84). The piriform sinuses, valleculae, and glottis may also be appreciated.

The mid- and distal esophagus may be seen surprisingly often when sought (Fig. 8-85).[70] The proximal esophagus is extraordinarily difficult, if not impossible, to visualize in the normal fetus. The mid- and distal esophagus may be seen, although inconsistently, in both longitudinal coronal and transverse axial images. The key to identification of this structure is its relationship to the descending thoracic aorta, a structure easily seen. The mid- and distal portions of the esophagus lie immediately anterior to the descending thoracic aorta. The aorta is first visualized in a longitudinal coronal plane. The transducer is then slowly moved anteriorly. As the aorta disappears from view, the esophagus comes into view but is much more difficult to recognize. It is seen as five parallel linear echoes. The hyperechoic serosa, submucosa, and lumen and the hypoechoic muscular wall (Fig. 8-86) create these. Conceptually, one could apply a similar strategy to visualization of the upper third of the esophagus. In this instance, one would image the trachea (see following section) in a longitudinal coronal plane and then slowly move the transducer posteriorly. As the trachea disappears, the esophagus should again come into view. Unfortunately, this concept, although anatomically correct, is practically less successful.

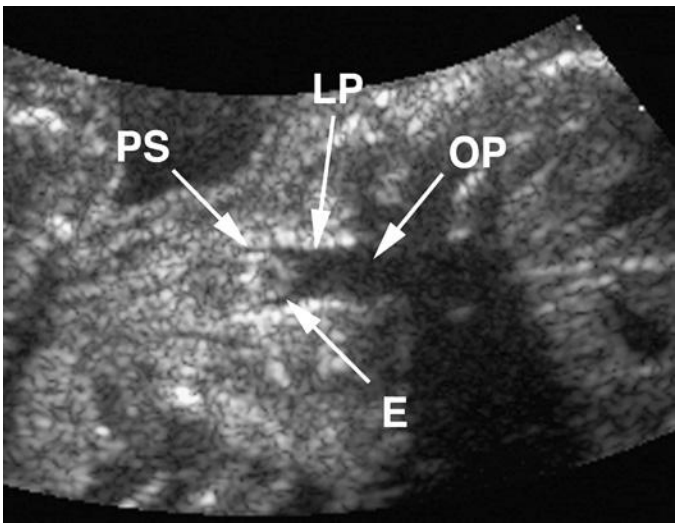

FIG 8-84 Coronal sonogram of the fetal hypopharynx. The fluid-filled oropharynx (OP) and laryngopharynx (LP) are well seen. Fluid slightly distends the piriform sinuses (PS). E, epiglottis.

The stomach and gallbladder are the only portions of the subdiaphragmatic fetal gastrointestinal system that consistently contain fluid (Figs. 8-67, 8-72, and 8-73).[69,71,72] Thus, any fluid-containing small bowel should be viewed with suspicion, although in late fetuses one not infrequently sees very small amounts of normal succus entericus in the small bowel lumen, usually made more obvious by accompanying peristalsis. In particular, fluid in the duodenum should be viewed with suspicion. However, the normal duodenum can be seen and can contain very small amounts of succus entericus. If one wishes to interrogate the duodenum, it is most easily found by its anatomic relationship to the gallbladder. These two organs always touch in the absence of an intervening pathologic structure (Fig. 8-87). Fluid contained within the normal fetal stomach is almost entirely imbibed. The fetus begins to swallow amniotic fluid at approximately 16 weeks.[71,72] The volume that the fetus swallows increases dramatically throughout pregnancy and reaches 400 to 500 mL by term. There is a relative proportionality between the volume of urine produced and the amount of amniotic fluid imbibed by the fetus. This proportionality (production versus absorption) maintains the equilibrium of the amniotic fluid volume. In the absence of a patent esophagus, the stomach will be empty (invisible) except in two circumstances. First, and most common, is the concomitant presence of a tracheoesophageal fistula, enabling the lung fluid that is produced by the fetus to enter the esophagus via the fistula and thence to the stomach.[73] This malformation is commonly associated with polyhydramnios in late pregnancy but not always before 24 weeks. Second, the association of esophageal atresia without tracheoesophageal fistula but with a second proximal gastrointestinal tract atresia or obstruction will allow secretions from the stomach to accumulate within the gastric lumen.

The stomach varies considerably in size depending, presumably, on how much amniotic fluid has been recently imbibed by the fetus.[71,72] A prominent stomach never should be taken as sole evidence of obstruction. When the stomach is well distended, its various parts (i.e., the fundus, body, and antrum) can be identified (see Fig. 8-82). The fundus is most posterior, whereas the antrum is most anterior. The incisura angularis can be noted when the stomach is well distended.

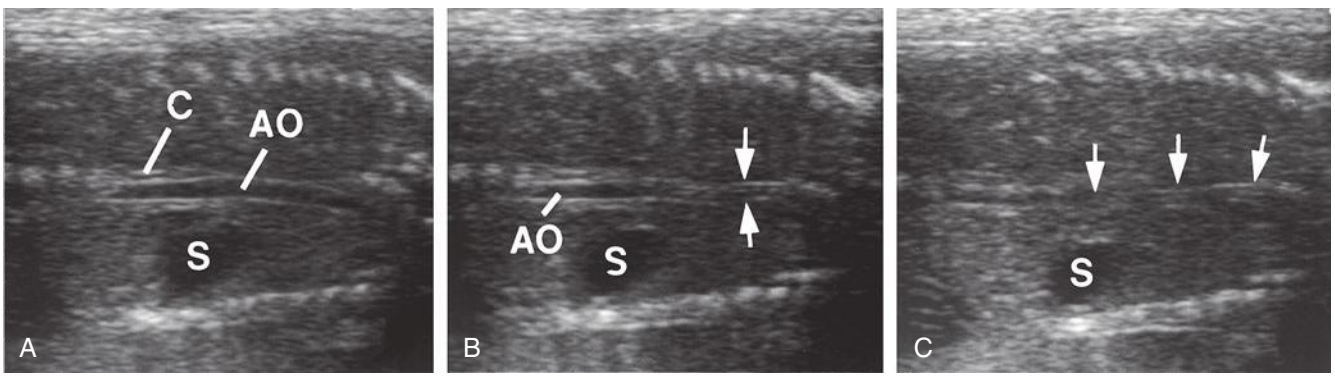

FIG 8-85 Coronal sonograms depicting the mid- and distal esophagus. First (**A**), the descending aorta (AO) is localized. **B** and **C,** As the transducer is moved anteriorly, the esophagus (*arrows*) comes into view. C, diaphragmatic crura; S, stomach.

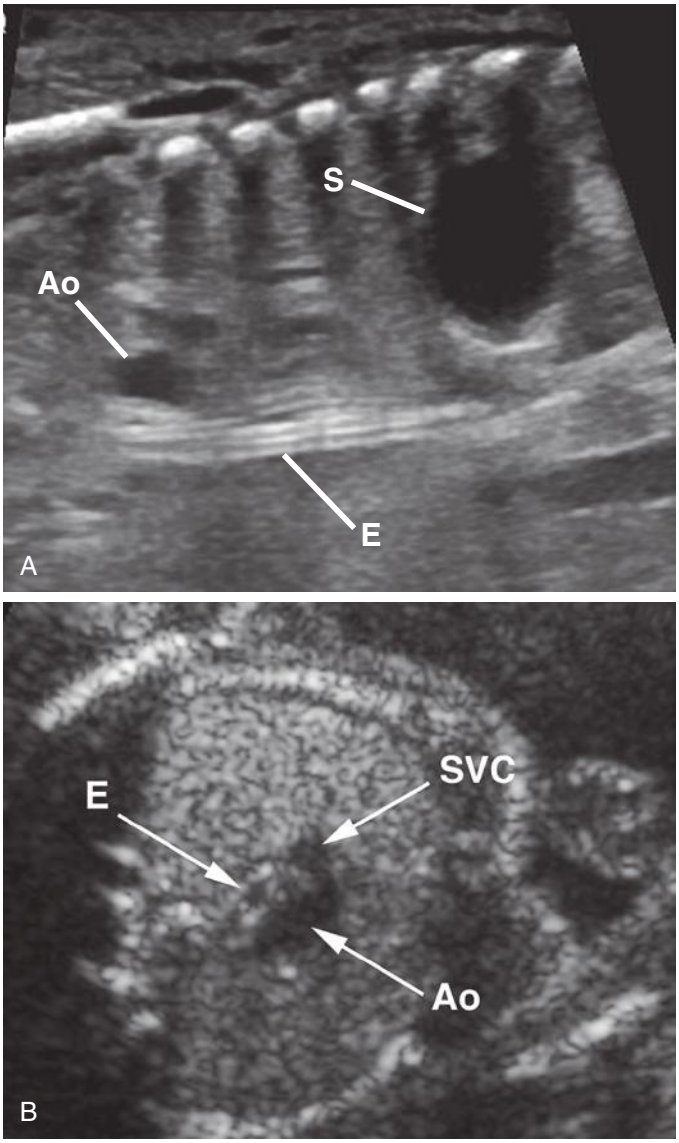

FIG 8-86 Coronal (**A**) and transverse axial (**B**) sonograms demonstrating the esophagus (E). The serosa and lumen appear hyperechoic, and the muscular wall is hypoechoic. Distally, the esophagus lies anterior to the descending aorta (compare Fig. 8-83). Proximally, it lies posterior to the transverse aorta (in B) and medial to the ascending aorta (in A). Ao, aorta; S, stomach; SVC, superior vena cava.

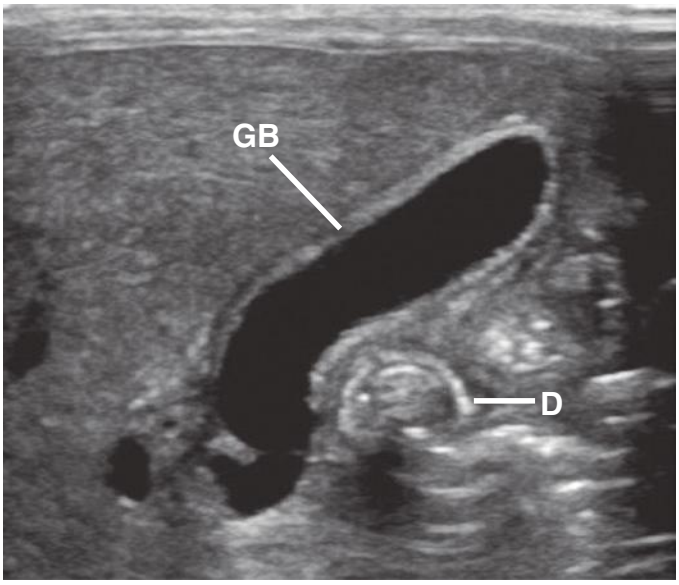

FIG 8-87 Longitudinal image through the gallbladder in a 1-month-old infant born premature at 24 weeks' gestation demonstrates the normal relationship of the gallbladder (GB) with the duodenum (D), closely opposed without any intervening structure.

The incisura angularis is a notch of variable depth that is usually found along the lesser curvature between the body and antrum of the stomach. If the incisura angularis is deep enough it is possible to generate a sonographic plane of section, which simulates a "double bubble."[74]

Small bowel becomes progressively more visible through the second and third trimesters. This is particularly true of the echogenically bright submucosa of the small bowel. This may impart the appearance of a "conglomerate" zone of increased echogenicity in the mid- and lower abdomen of the fetus. This should not be mistaken either for an abnormal mass (pseudomass of bowel)[75-77] or for a bowel abnormality (so-called echogenic bowel). With passage of time, and somewhat dependent on ease of imaging, discrete small bowel loops become visible (Fig. 8-88). With modern equipment, the bowel wall is seen to good advantage. The submucosa and serosa display greater

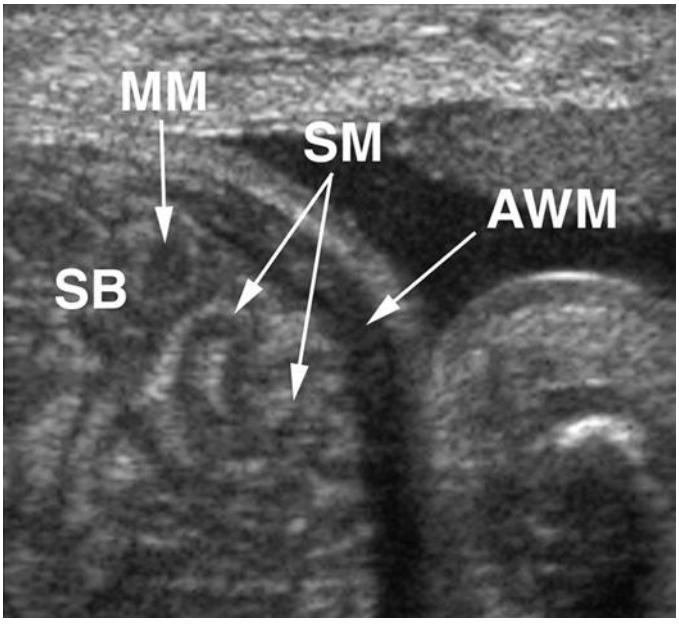

FIG 8-88 Discrete small bowel (SB) loops are clearly visible on images through the fetal abdomen. The morphology of the bowel wall is well shown. The dominant feature of the small bowel wall is the submucosa (SM), which demonstrates bright echoes (not to be mistaken for "echogenic bowel"). The muscularis mucosa (MM) lies "inside" the submucosa and is hypoechoic. Note that the anterior abdominal wall musculature (AWM), like all musculature, demonstrates darker gray echoes. If one looks closely, one can appreciate the more echogenic small bowel mucosa "sandwiched" between the layers of muscularis mucosa.

echogenicity than the muscular layers, the thinner muscularis mucosa and thicker muscularis propria. Later in pregnancy, deposition of fat in the mesentery probably accentuates the separation of individual bowel loops and increases echogenicity in the region of the abdomen where the small bowel resides.

Importantly, "increased echogenicity" of the bowel has been implicated as a harbinger of several serious abnormalities of the fetus.[78,79] It is therefore important to discriminate increased echogenicity of the bowel content (potentially indicating a problem) from echogenicity caused by normal bowel structure, but perceived in conglomerate to represent "increased bowel echogenicity" (unlikely to indicate a problem). Examining to see if the echogenicity is due to well-visualized submucosa or mesenteric fat will avoid these issues. Generally, high-frequency transducers demonstrate the submucosa of the small bowel to much greater advantage, thus giving the examiner the impression that the bowel is "echogenic."[80] When transducers with frequencies greater than 5 MHz are being employed, the probability that fetal bowel wall structure has resulted in an impression of "increased echogenicity" is great. Confirmation with lower frequent transducers should be performed. By late pregnancy, almost regardless of equipment quality, discrete small bowel containing small amounts of fluid (succus entericus) can be visualized in nearly all fetuses.[81]

The colon tends to become visible near the beginning of the third trimester and, again, is seen progressively better with increasing gestational age.[81,82] The colon tends to be relatively hypoechoic (Figs. 8-89 and 8-90). As such, colon should not be mistaken for dilated small bowel. It is the characteristic course of the colon that most readily permits distinction from pathologically dilated small bowel. The ascending colon courses along the right flank (see Fig. 8-86A) in relation to the right kidney. As it approaches the liver, it bends leftward, in the hepatic flexure (see Fig. 8-89A). The transverse colon courses along the free edge of the liver (see Fig. 8-89B) and passes inferior to the stomach. At the splenic flexure, the colon turns posteriorly and again comes into intimate relationship with the kidney; of course, in this instance it is the left kidney. Frequently, when imaging the kidneys, the colon is detected. If one kidney is absent, the colon occupies the renal fossa and should not be misinterpreted as a normal or abnormal kidney. Finally, the sigmoid colon arcs over the urinary bladder to join the rectum (see Figs. 8-89C and 8-90B). Occasionally, haustral markings can be noted in the colon wall. A redundant sigmoid colon should not be mistaken for dilated small bowel. The anus can be visualized at the base of the gluteal cleft (see Fig. 8-90C). A normal appearance of the anus is helpful to exclude anal atresia when dilated colon is suspected.

The liver, as noted earlier, is proportionately larger in the fetus than in the child or adult.[83] Similarly, in the early second trimester, the liver constitutes 10% of the total fetal weight but only 5% of the total weight at term. The fetal liver, in addition, has a substantially larger left lobe. Blood with a high degree of nutrients and oxygen enters the umbilical segment of the left portal vein. Thus, the left hepatic lobe is nourished with the highest levels of nutrients. Conversely, the blood going to the right hepatic lobe comes almost exclusively from the main portal vein, which has the lowest levels of nutrients (it has already passed through a capillary network). The fetal liver spans the entire width of the abdomen throughout pregnancy, the left lobe always contacting the left abdominal wall. This would be unusual but possible in an adult. The

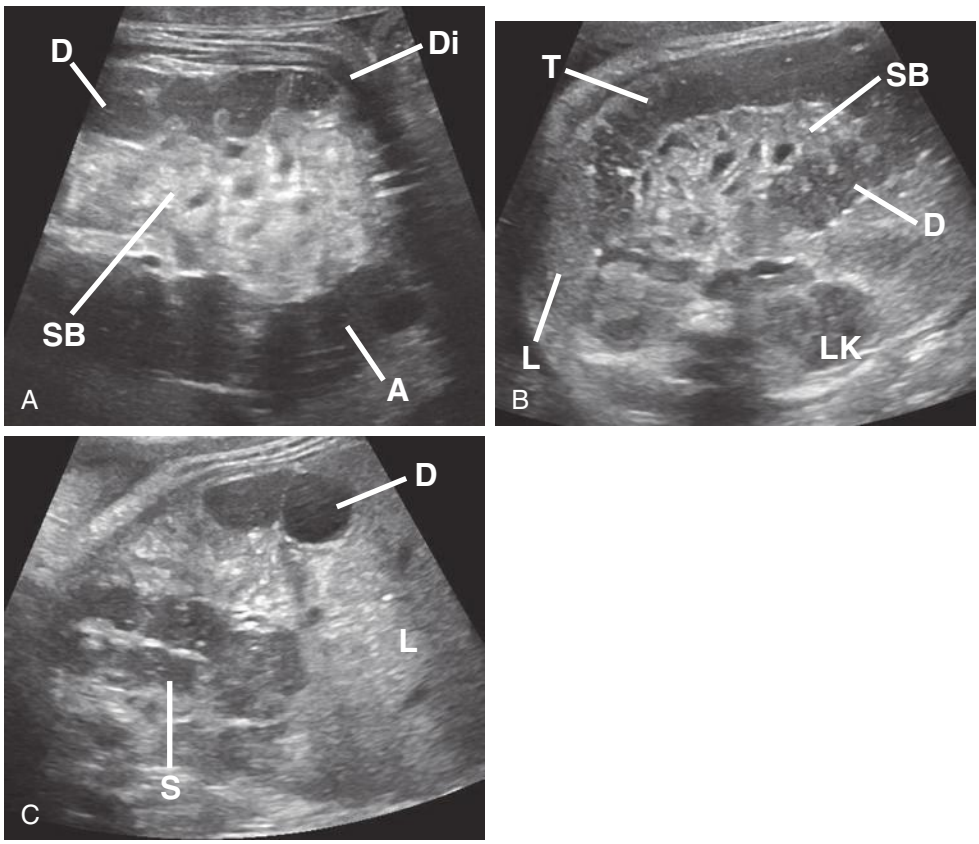

FIG 8-89 Coronal (**A** and **C**) and transverse (**B**) sonograms of the fetal abdomen demonstrating, by position, the ascending (A), transverse (T), descending (D), and sigmoid (S) colon. Di, diaphragm; L, liver; LK, left kidney; SB, small bowel.

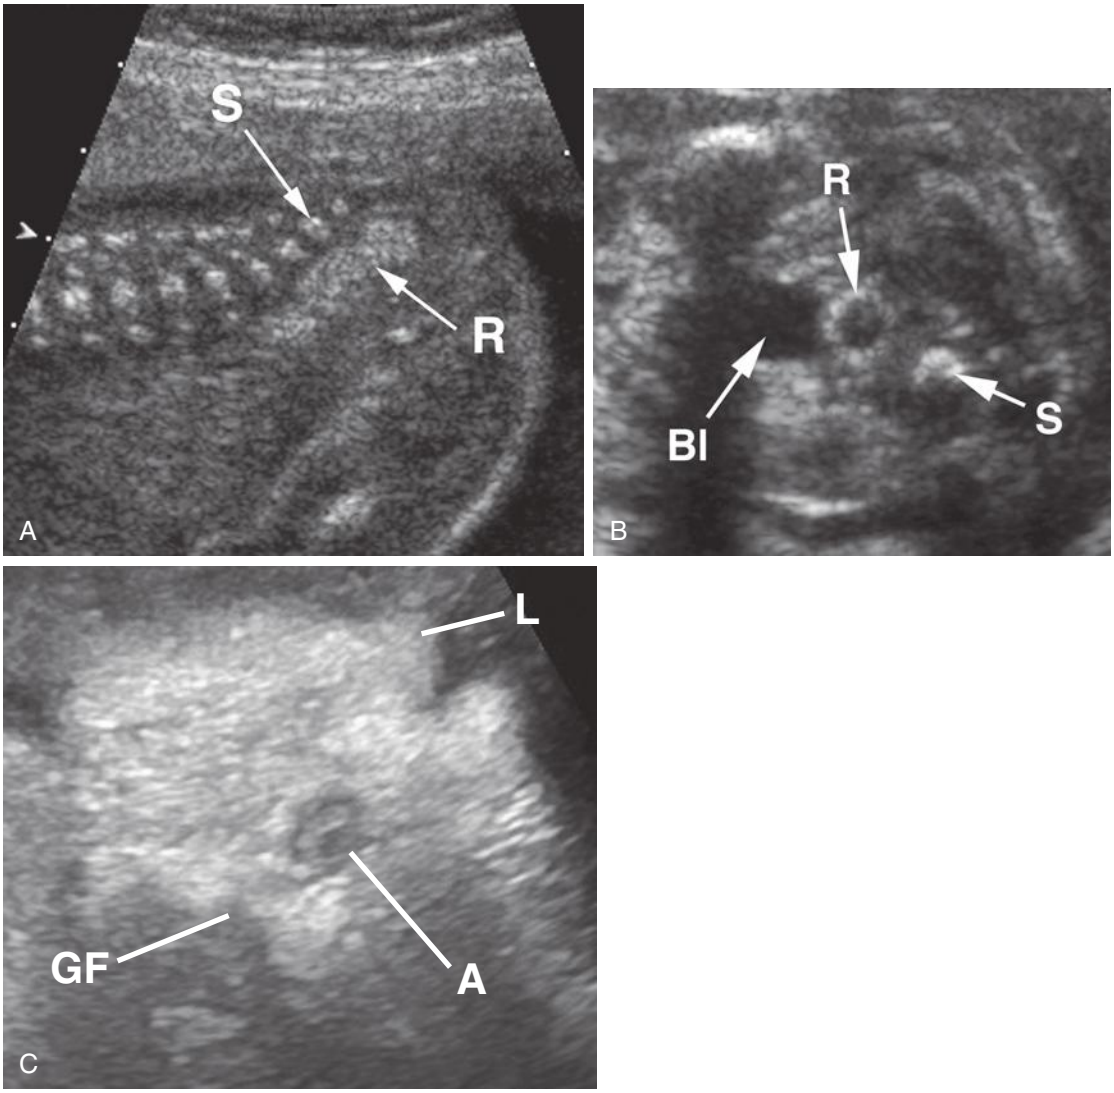

FIG 8-90 **A,** Midsagittal sonogram demonstrates the rectum (R) anterior to the sacrum (S). **B,** A transverse axial sonogram demonstrates the rectum (R) lying between the bladder (Bl) and sacrum (S). **C,** Transverse axial sonogram demonstrates the anus (A). GF, gluteal fold, L, labia majora.

two major segments of each hepatic lobe can be seen in older fetuses (see Fig. 8-74) and to some extent even in early second trimester fetuses.[61,64] The lateral segment of the left lobe extends to the left of the umbilical segment of the left portal vein (see Figs. 8-72 and 8-73). The medial segment of the left lobe is the tissue lying between the gallbladder (or middle hepatic vein more superiorly) and the umbilical segment of the left portal vein or the intersegmental fissure more caudally (Fig. 8-91). The right lobe is all of the hepatic tissue lying to the right of the gallbladder, middle hepatic vein, and inferior vena cava (see Figs. 8-67 and 8-73). These latter three structures all reside in the main lobar fissure. The left portal vein and left hepatic vein mark the left intersegmental fissure. Finally, the right intersegmental fissure is marked by the right hepatic vein cephalically and its anterior branch inferiorly.

As equipment has improved, the pancreas is more readily perceived from the midtrimester onward. The pancreatic tissue lies posterior to the stomach, an area that can be visualized consistently in the fetus. The pancreatic tissue is more echogenic than the liver or the left kidney, making its visualization somewhat easier. One should not presume that acoustic enhancement from fluid in the stomach is the cause of the greater intensity echoes from the pancreas (although acoustic enhancement increases the brightness of all echoes in its path). Definitive recognition of the pancreas requires demonstration of the splenic vein and origin of the superior mesenteric artery in a transverse axial plane of section (see Fig. 8-81). The pancreas then is the band of tissue between these vessels and the posterior gastric wall.

The spleen is not truly a gastrointestinal organ (see Figs. 8-73 and 8-82B). It is part of the reticuloendothelial system. However, as an upper abdominal organ it fits most appropriately in this section. The spleen is bounded by the diaphragm superiorly, the lower ribs laterally, the stomach medially, and the diaphragm and kidney posteriorly. It is only the inferior margin that is difficult to delimit. In the fetus, spleen echogenicity is similar to that of the liver. In the adult, the liver is slightly less echogenic than the spleen.[84-87] The spleen grows progressively through fetal life, and nomograms of splenic size are available in the literature.[84]

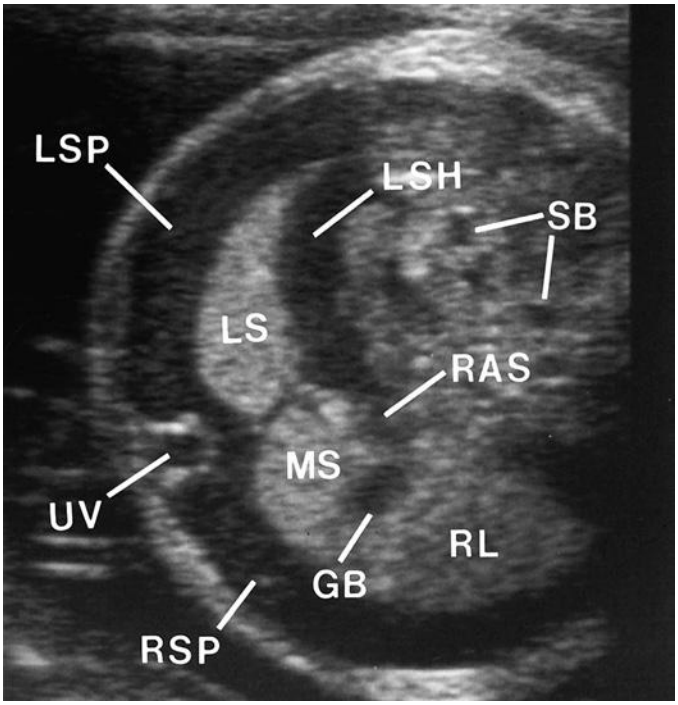

FIG 8-91 Transverse axial sonogram of the fetal abdomen after an intraperitoneal transfusion for Rh isoimmunization enables recognition of many peritoneal spaces, including the right (RSP) and left (LSP) subphrenic spaces and the right anterior (RAS) and left subhepatic (LSH) spaces. Segmental anatomy of the fetal liver is also well seen, including the medial (MS) and lateral (LS) segments of the left hepatic lobe. GB, gallbladder; RL, right hepatic lobe; SB, small bowel; UV, umbilical vein.

RESPIRATORY SYSTEM

The upper respiratory tract system is seen partially. The nose has been previously illustrated (see Figs. 8-12 and 8-13). The nasal cavity, septum, and palate can be detected with practice. As noted earlier, portions of the pharynx and hypopharynx are commonly visible because of the presence of fluid.[70] The piriform sinuses are seen when fluid filled (see Fig. 8-84). When relatively large amounts of fluid are present in the pharynx of an older fetus, the epiglottis may be seen protruding into the fluid (Fig. 8-92). The epiglottis is particularly visible during swallowing.

The larynx is virtually always visible when the hypopharynx is fluid filled (see Figs. 8-84 and 8-92). Details of laryngeal anatomy are not particularly evident, but the larynx itself is easily recognized as a superior constriction of the tracheal fluid column protruding into the hypopharynx and flanked by the piriform sinuses. If the head is markedly flexed, the overlying mandible frequently defeats efforts to visualize the larynx and hypopharynx. The larger thyroid cartilage of the larynx is hypoechoic as are virtually all cartilaginous structures in the fetus. Thus, it is commonly seen as two thin hypoechoic bands paralleling the upper tracheal fluid column of the fetus on longitudinal sections of the trachea (Fig. 8-93).

As noted earlier, the trachea is a relatively easy structure to visualize (Figs. 8-92 to 8-95).[70] Again, this is predominantly because it is consistently fluid filled. Not only do the lungs produce fluid that is expelled into the trachea, but additionally, the trachea, along much of its length, is flanked by the conspicuous pulsations of the common carotid arteries. The trachea can usually be traced to its distal end, coursing posterior to the aortic arch (Fig. 8-94A), but the carina and bronchi are quite difficult to perceive. Because mainstem bronchi are usually invisible, smaller ramifications of the bronchi are, for all intents and purposes, universally invisible at this time in the development of fetal sonography.

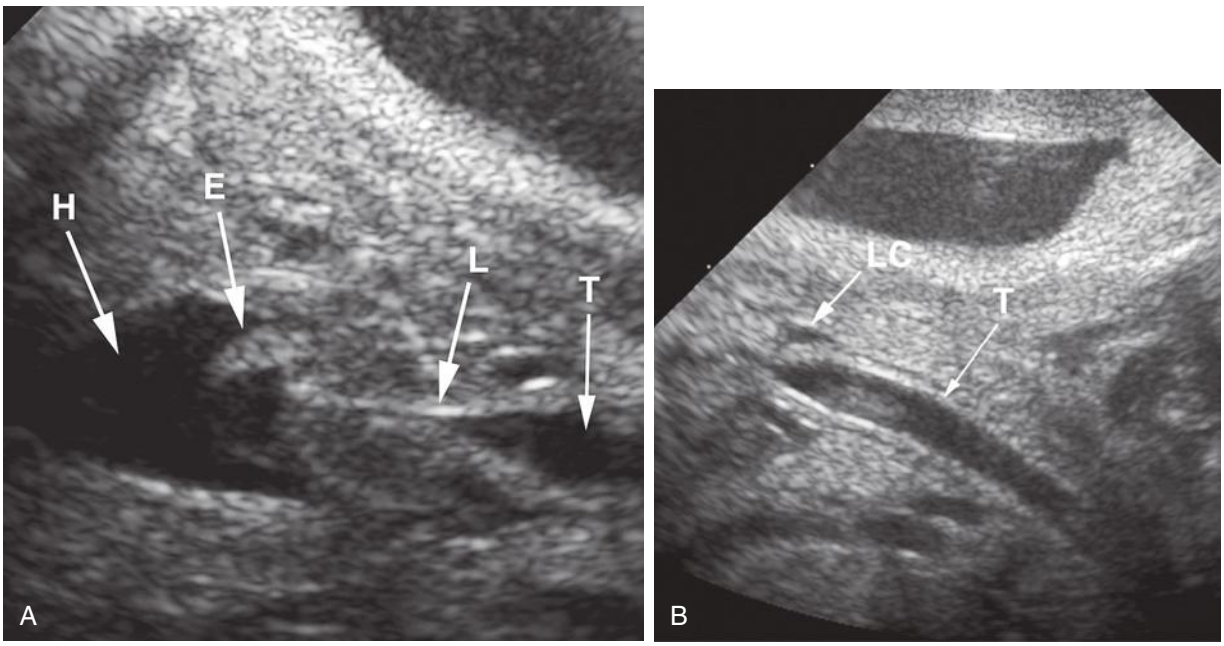

FIG 8-92 **A** and **B,** Coronal sections through the hypopharynx (H), larynx (L), and trachea (T). E, epiglottis; LC, laryngeal cartilage.

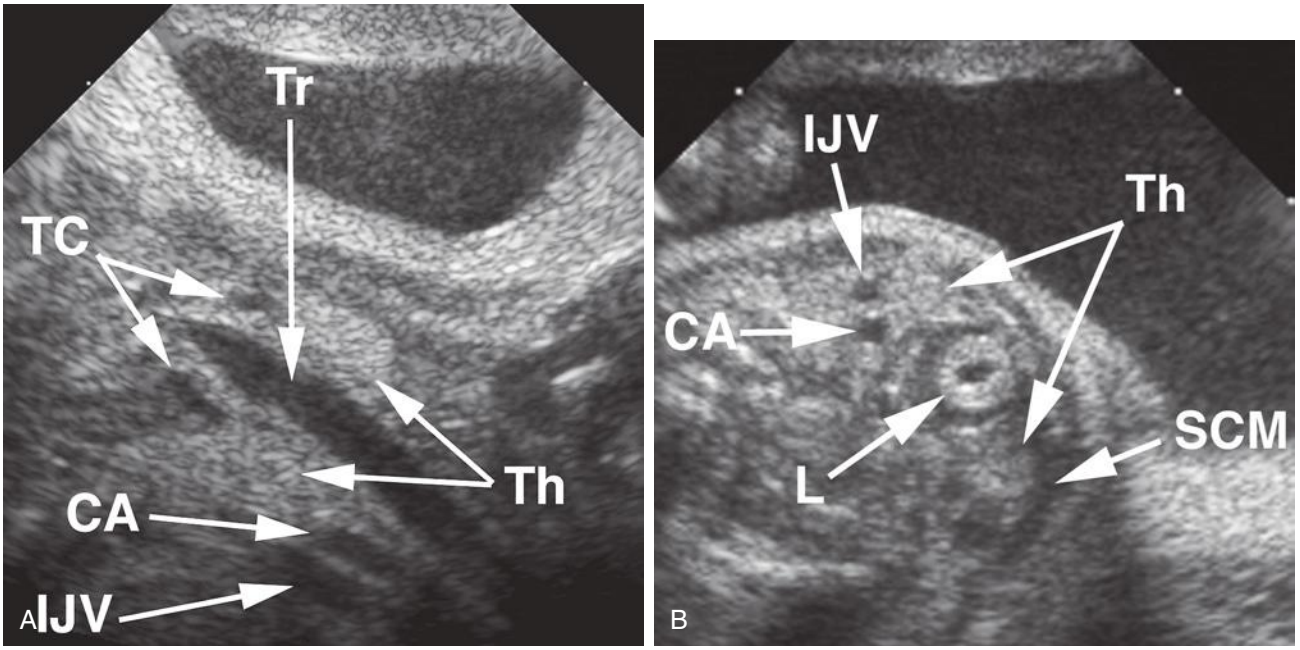

FIG 8-93 Longitudinal (**A**) and axial (**B**) sonograms of the fetal neck. CA, carotid artery; IJV, internal jugular veins; L, larynx; SCM, sternocleidomastoid muscle; TC, thyroid cartilages; Th, thyroid lobes; Tr, trachea.

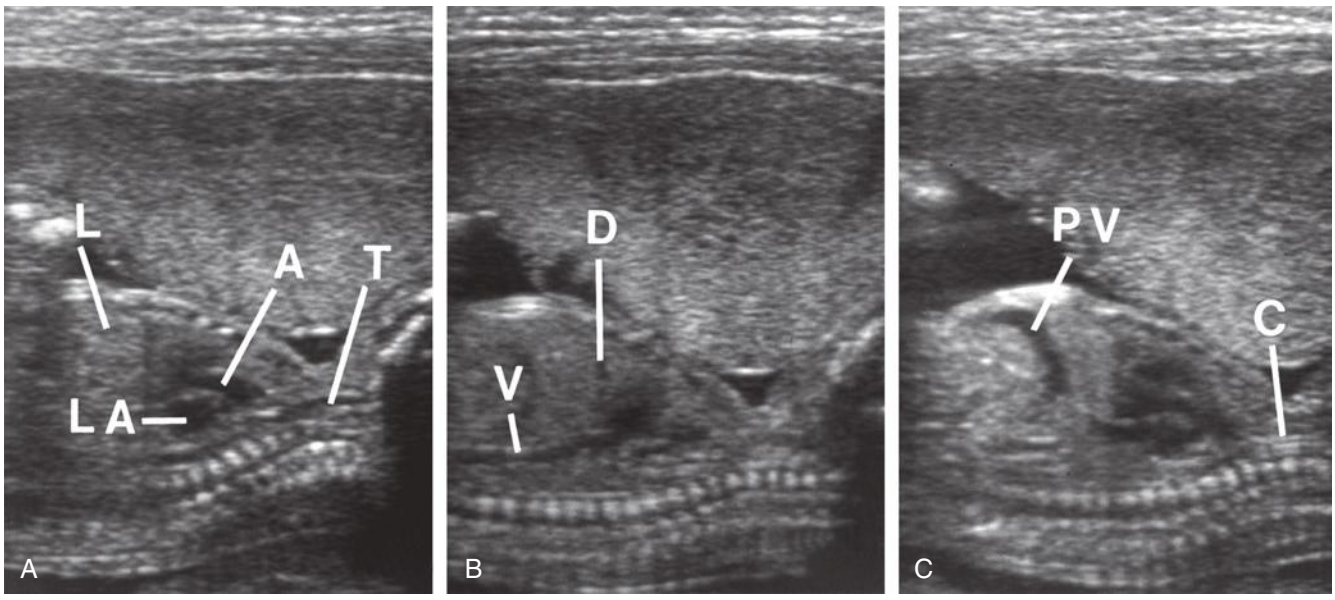

FIG 8-94 Relationships of mediastinal and neck structures. Midsagittal (**A**) and parasagittal (**B** and **C**) sonograms demonstrate the trachea (T) down to the level of the aortic arch (A). The cervical esophagus (C) lies posterior to the trachea in the neck (note again the muscular and mucosal layering). D, diaphragm; L, liver; LA, left atrium; PV, left portal vein; V, inferior vena cava.

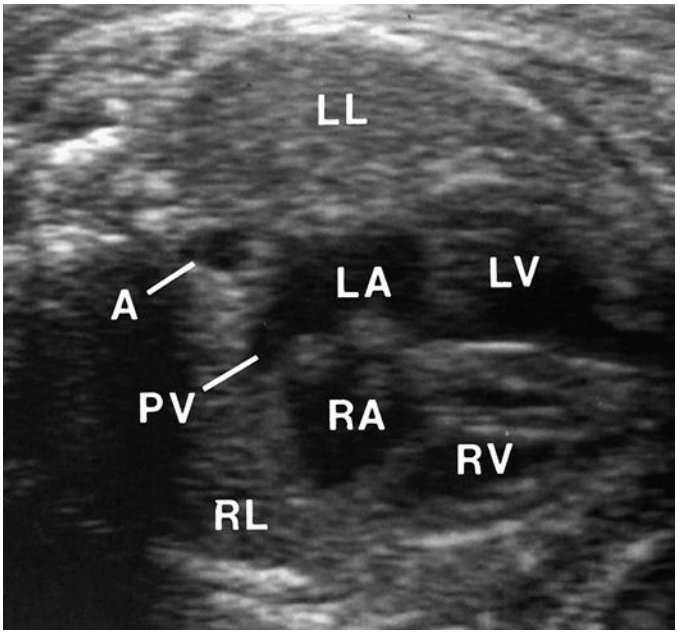

FIG 8-95 Transverse axial sonogram of the fetal thorax. A, descending aorta; LA, left atrium; LL, left lung; LV, left ventricle; PV, pulmonary vein; RA, right atrium; RL, right lung; RV, right ventricle.

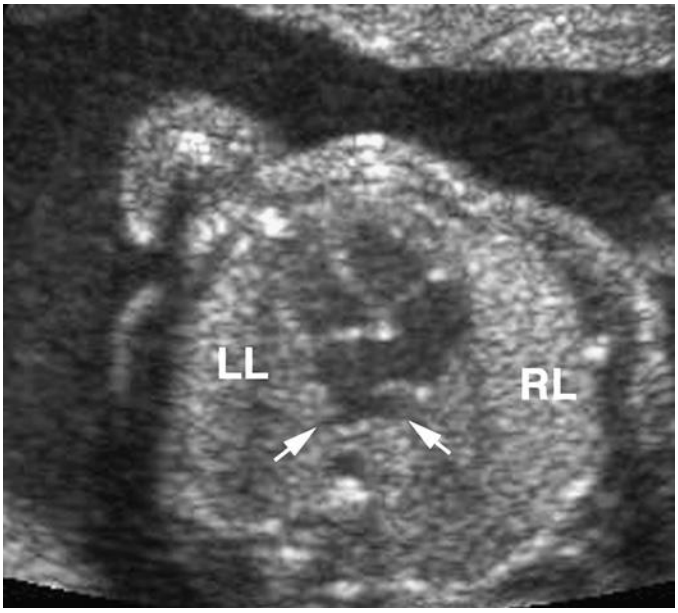

FIG 8-96 Axial section through the fetal thorax. *(Arrows),* pulmonary veins; LL, left lung; RL, right lung.

The right and left pulmonary arteries and pulmonary veins (Figs. 8-95 and 8-96) are visible in a large percentage of second and third trimester fetuses. However, one generally pursues visualization of these major vessels during examination of the heart rather than of the lungs. Details of the pulmonary arterial and venous anatomy are found in Chapter 13.

The lung (at least lung tissue) can be seen from late first trimester onward. Early in pregnancy, definition of the lung is drawn more from the structures that surround it. These include, predominantly, the ribs superolaterally and the heart (and to a lesser extent other mediastinal structures) medially. Inferiorly, the early lung blends imperceptibly with the liver. These two organs are equal in echogenicity throughout some of the second trimester. As pregnancy progresses, the lung becomes more echogenic than the liver (Fig. 8-97). The reason for this is unknown. It was speculated that this difference may signal pulmonary maturity, a notion that is certainly erroneous because a lung of greater echogenicity than the liver can be seen earlier in pregnancy than lung maturity can possibly develop.[88,89] Furthermore, the muscular portion of the diaphragm becomes progressively more visible with fetal growth and the hypertrophy of the diaphragmatic muscle that occurs as the fetus "breathes" against atelectatic, fluid-filled lungs (Fig. 8-98). These markers of the inferior extent of the lung improve pulmonary tissue visibility with advancing gestational age. Discrete pulmonary lobes are not visible in the normal fetus, but when a pleural effusion is present, insinuation of fluid into the major fissures (and the minor fissure on the right) marks lobar boundaries.

GENITOURINARY SYSTEM

Although the extreme variability of fetal positioning and the lack of subject contrast between kidney and the surrounding tissues do not permit consistent identification of both fetal kidneys, normal fetal kidneys are commonly identified in their paraspinous location after the early second trimester. In longitudinal section, fetal kidneys appear as bilateral elliptical structures, and in transverse section they have an ovoid to circular appearance adjacent to the lumbar spinal ossification centers bilaterally (Fig. 8-99). Later in pregnancy, echogenic retroperitoneal fat, which surrounds the kidneys, assists in their sonographic visualization (Fig. 8-100). The fetal renal pyramids can be discriminated from the surrounding cortex and columns of Bertin in most fetuses and are arranged in an anterior and posterior row (see Fig. 8-99A) in a configuration corresponding to the calices that contact the apices of the pyramids (the papillae).[20] The echogenicity of the normal fetal renal cortex, which usually approximates or may even be slightly greater than that of the surrounding tissues, highlights the relatively hypoechoic pyramids. The characteristic position of the pyramids avoids any potential confusion with renal parenchymal cysts. Confusion with dilated calices is avoided by noting the interspaced columns of Bertin and the lack of communication with dilated infundibula and pelvis. Within the renal sinus of fetuses, there is a paucity, or more commonly a frank absence, of fat. Intrarenal collecting structures, the pelvis and infundibula, are commonly seen in fetuses because they frequently contain fluid,[91,92] a topic that is addressed in Chapter 15. The normal fetal ureter is, for all intents and purposes, not identifiable in fetuses. Visualization of a fetal ureter should always suggest pathologic dilatation.

The fetal kidneys grow throughout gestation. Standards for renal length, width, thickness, volume, and circumference have been established as a function of menstrual age and correspond with measurements of renal size obtained on stillborn fetuses postnatally.[93-95] Throughout pregnancy, the ratio of kidney circumference to abdominal circumference remains relatively constant at 0.27 to 0.30. Such measurements are more efficient for detecting enlarged kidneys than small kidneys. Diminution in renal size is more difficult to detect because the exact renal border, especially of small kidneys, may be partially obscured, because the plane of section may not be through the longest renal axis, and because of the wide standard deviation in renal size.[93-95]

As early as 15 menstrual weeks the normal fetal urinary bladder can be identified (see Fig. 8-71). Less than a milliliter of bladder urine is needed to allow ready visualization in a young fetus. Because the fetus

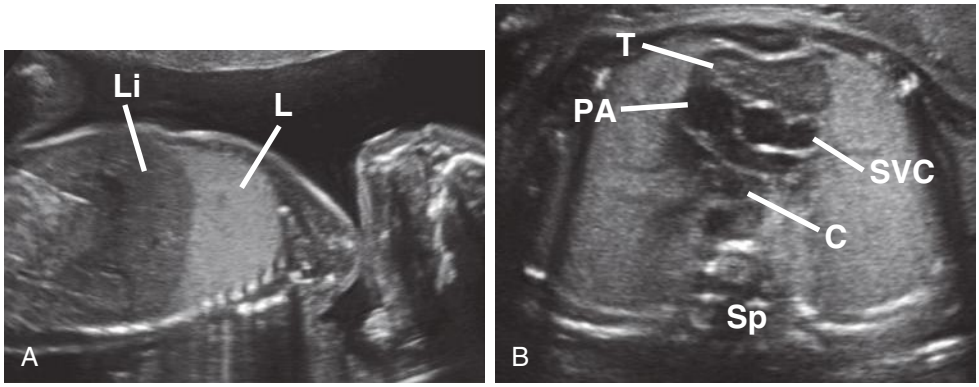

FIG 8-97 **A,** Sagittal sonogram through the fetal chest. Echogenicity differences between lung (L) and liver (Li) are easily seen in this older fetus. **B,** Axial sonogram through the fetal chest. Again, the echogenicity differences between the lung and thymus (T) are easily seen. C, carina; PA, pulmonary artery; Sp, spine; SVC, superior vena cava.

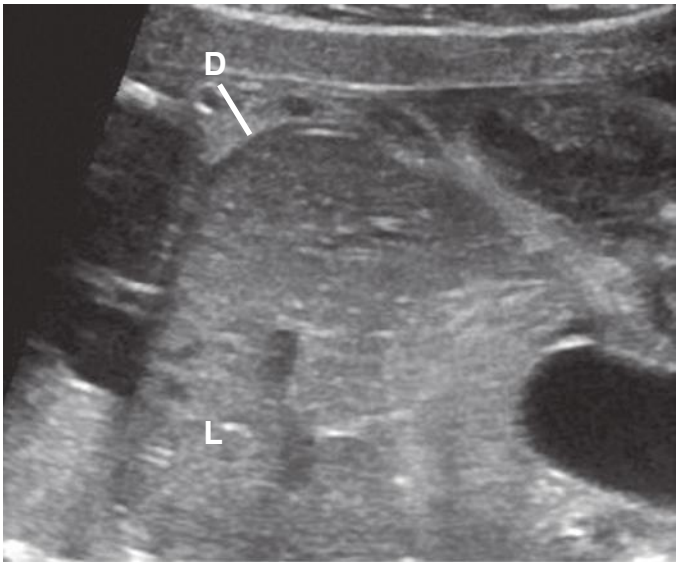

FIG 8-98 The muscular diaphragm (D) is relatively hypoechoic. L, liver.

normally fills and empties the urinary bladder every 30 to 45 minutes, the bladder will frequently be seen to increase in size and to empty during the course of a sonographic examination.[96-98] Similarly, fetuses in whom the urinary bladder is not visualized can be examined at intervals for bladder filling. If the bladder cannot be seen in the presence of oligohydramnios, sequential imaging to test for bladder filling is mandatory.

At 32 weeks of gestation, the maximum fetal bladder volume measures 10 mL. By term, the normal fetal bladder volume quadruples. Similarly, fetal urine production, as calculated by determination of change in bladder volume with time, increases from 9.6 mL/hour at 30 weeks to 27.3 mL/hour at 40 weeks menstrual age.[96,97] Of course, term fetuses void; thus, the bladder may be empty.[98] Filling and emptying of the fetal urinary bladder confirm that the fetus produces urine but does not indicate the "quality" of urine produced. The normal fetal urinary bladder, the wall of which is very thin and virtually invisible when the bladder is well distended, occupies a midline position within the fetal pelvis (Fig. 8-101). Changes in volume of the urinary bladder with time differentiate it from cystic pathologic pelvic structures. Recall that the umbilical arteries, regardless of the degree of bladder distention, always flank the urinary bladder. This anatomic relationship is extremely useful for identification of a persistently empty urinary bladder or the confirmation of a massively overdistended bladder.

The normal fetal urethra may be identified, from time to time, as an echogenic line extending the length of an erect penis (see Fig. 8-19). In females and in males examined when the penis is flaccid, the normal urethra is difficult or impossible to identify. The uterus and ovaries cannot be visualized in normal female fetuses. The testes can be visualized in male fetuses only after they have descended into the scrotum under normal circumstances. The prostate cannot be visualized. The external genitalia were discussed previously in the section entitled "Superficial Anatomy of the Fetus."

The fetal adrenal gland, although not part of the genitourinary system, is seen quite routinely when searching for the kidneys (Figs. 8-100 and 8-102).[99,100] Even in the presence of agenesis of one or both kidneys, the adrenal glands can be appreciated in their expected paraspinous locations. The fetal adrenal glands may often be imaged after 20 menstrual weeks. The adrenal glands have a specific size, shape, and echogenicity. The echo pattern is so characteristic that the cortex and medulla can be appreciated separately (see Figs. 8-6, 8-67, and 8-102). In the fetus, both adrenal glands cap the upper renal poles (in the adult the left adrenal gland most often lies anterior to the upper pole).[100] The right adrenal is seen more consistently. Its upper portion lies immediately posterior to the proximal inferior vena cava (see Fig. 8-102).

CENTRAL NERVOUS SYSTEM

The fetal brain was one of the first areas of investigational interest in the diagnosis of fetal anomalies.[101] This was a result of two factors: (1) the fetal head was imaged routinely to obtain a biparietal diameter for the determination of gestational age, and (2) central nervous system anomalies are among the most common birth defects. At first, only gross morphologic aberrations such as anencephaly or advanced hydrocephalus were discovered prenatally. As instrumentation has improved to the present day, many more malformations of the brain can be diagnosed with accuracy.[102-107]

The path to the diagnosis of anomalous development, as always, begins with a firm grasp of normal developmental anatomy. Initially, many errors were made when interpreting normal fetal intracranial anatomy as seen by sonography.[108-110] This was due to the unusual circumstance that "fluid" and "solid" areas of the brain did not behave in an anticipated manner. It was initially expected that the sonographic

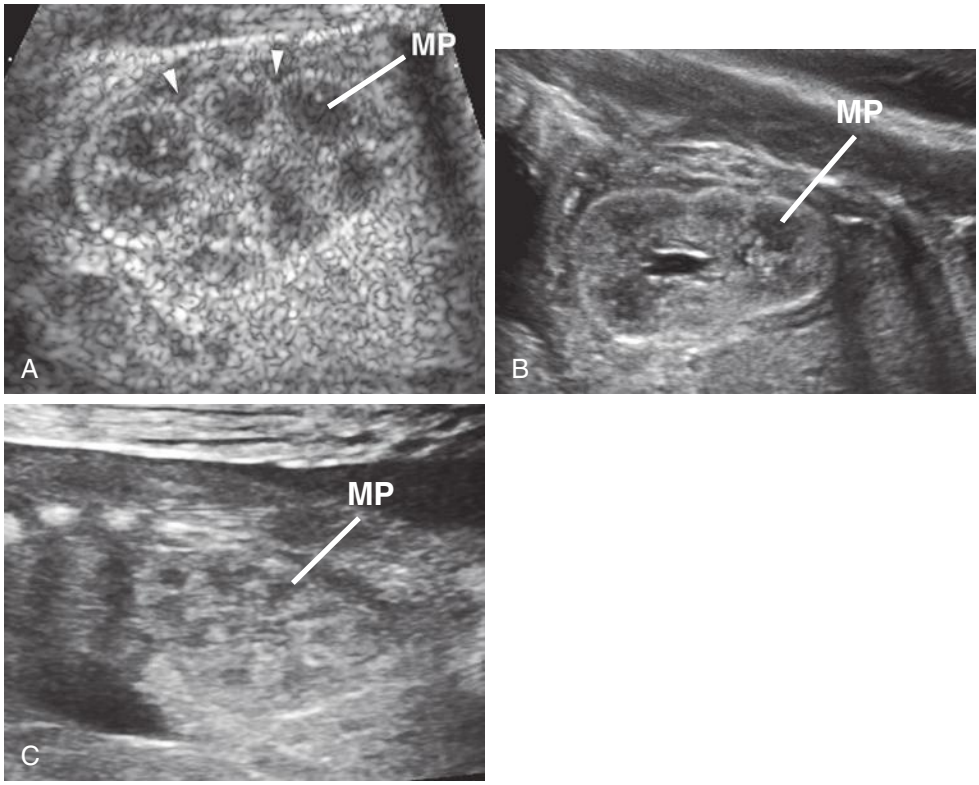

FIG 8-99 **A,** Longitudinal sonogram through the early second trimester fetal kidney *(arrowheads)*. **B,** Longitudinal sonogram through a late second trimester fetal kidney. Note that the medullae (MP) appear more prominent earlier. This is because cortical growth is greater than that of medullary growth, and thus the relative size of the medullae decreases. **C,** Longitudinal sonogram through a third trimester fetal kidney. Among the normal variations of fetal renal appearances, note that the renal echogenicity can be relatively increased because the cortical tissue is echogenic, thus better outlining the more echolucent medullary pyramids (MP).

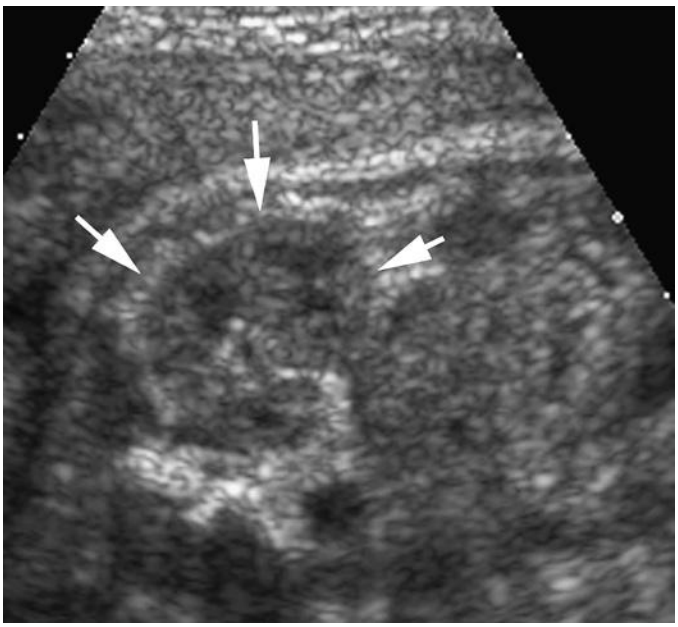

FIG 8-100 Transverse axial sonogram of a fetal kidney marginated by perirenal fat (*arrows*). The brightly echogenic perirenal fat helps to sonographically outline the less echogenic renal parenchyma.

appearance of the lateral ventricles would be dominated by cerebrospinal fluid, which would render them echolucent. Instead, their appearance was dominated by highly echogenic choroid plexus (Figs. 8-103 to 8-106).[111,112] Conversely, the bulk of neural tissue, the telencephalon, diencephalon, and mesencephalon, is quite hypoechoic compared with other solid tissues in the human body (see Fig. 8-103).[111,113] The more recent entrant into the area of diagnostic sonography can well imagine the potential for misinterpretation among early researchers when the largest fluid-containing areas of the brain yielded the greatest amplitude echoes whereas the solid tissue yielded the lowest. To further complicate matters, dramatic changes occur as brain development progresses, resulting in ever-changing positions of certain "landmarks." These changes had never been observed in vivo, and postmortem examination of the brain can be at variance with its appearance during life.

A series of key observations led to the clear delineation of normal developmental neuroanatomy as viewed sonographically. These observations included recognition of the fetal third ventricle, the brightly echogenic choroid plexus,[111] and pulsating vasculature in several cisterns.[113] The first two identified the supratentorial ventricular system. The last enabled identification of the sylvian cistern (middle cerebral artery pulsation), interpeduncular cisterns (basilar artery pulsation), and ambient cisterns (posterior cerebral artery pulsations) (see Fig. 8-79). The landmarks established by these observations provided a

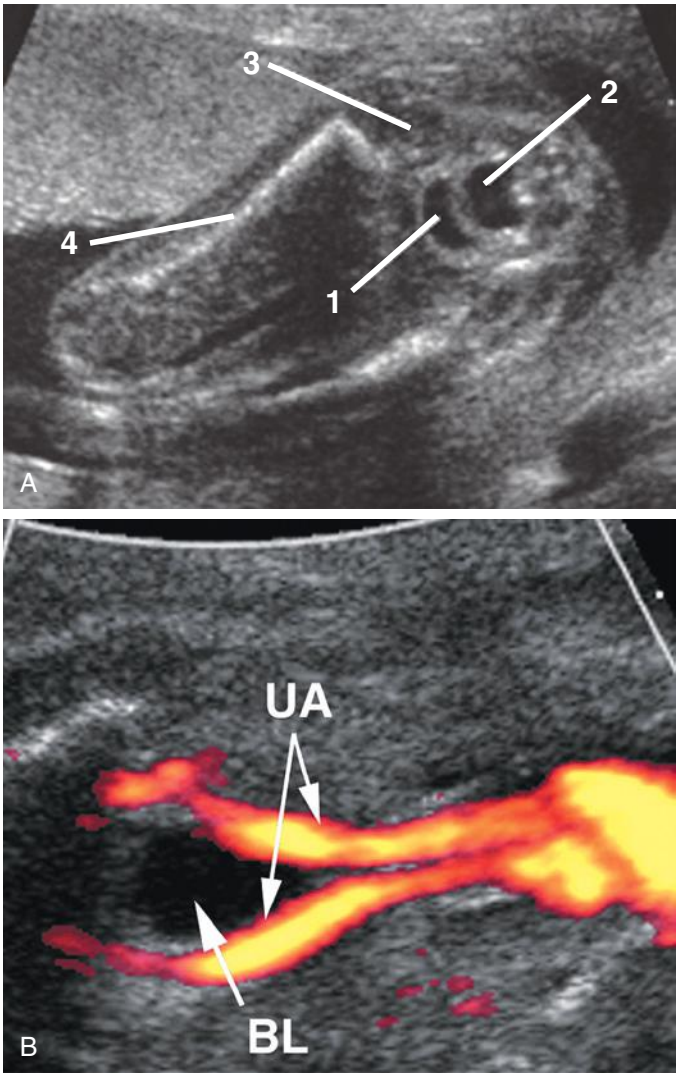

FIG 8-101 A, Transverse axial sonogram through the fetal pelvis. 1, urinary bladder; 2, rectum; 3, femoral head; 4, femoral diaphysis. **B,** Oblique axial sonogram through the fetal pelvis with nondirectional color Doppler. The umbilical arteries (UA) mark the lateral margins of the bladder (BL).

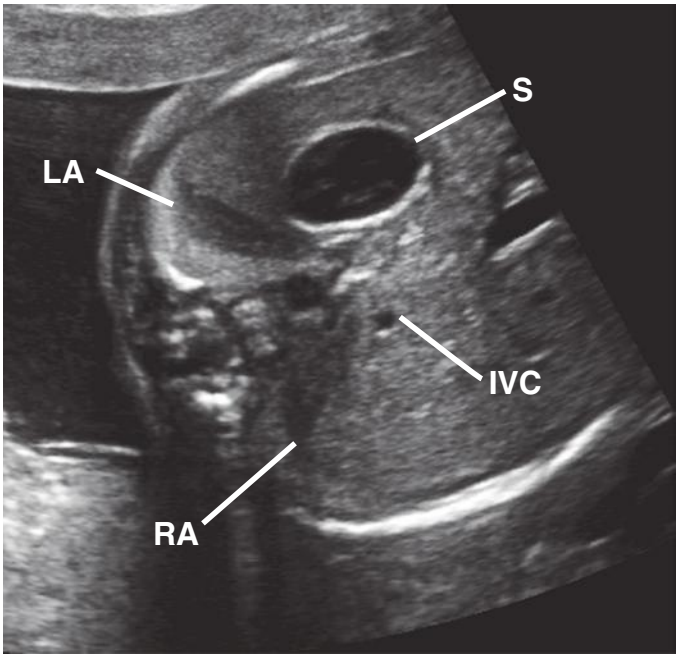

FIG 8-102 Transverse axial sonogram of the adrenal glands; much anatomy can be seen on this image of the upper fetal abdomen. Note both limbs of the right adrenal gland (RA) immediately posterior to the inferior vena cava (IVC), and the left adrenal gland (LA) is to the left of the aorta and posterior to the stomach (S). See also Figure 8-6 for the typical triangular appearance of the adrenal gland in the coronal plane superior to the kidney.

framework for subsequent identification of other specific neural structures.[114-118]

Later in the course of the development of sonography, the neonatal brain came under study (Figs. 8-1 and 8-107).[1,2,112] Interestingly, this resulted in much greater understanding of the appearance of the *fetal* brain because examination of "newborn children" now begins commonly at 24 to 25 weeks of development (essentially a second trimester fetus) (see Fig. 8-1). Investigators then began to apply neuroanatomy as learned from the neonatal brain, which was imaged with great clarity through the anterior fontanelle, to the developing fetal brain. The following analysis of fetal intracranial anatomy is presented on the basis of these observations.

The fetal head can be clearly discriminated from the fetal torso when an embryo reaches a crown-rump length of 10 to 15 mm. By the 10th to 11th week after the last normal menstrual period (see Fig. 8-4), one can already begin to appreciate anatomy inside the developing fetal head. At this point, the intracranial tissue components consist almost entirely of the thalamus and corpus striatum, which yield the symmetric appearance of the brain as these structures narrow the developing third ventricle into a midline specular reflector.[119-122]

By the end of the first trimester, the thalamus, third ventricle, midbrain, brainstem, and cerebellar hemispheres have achieved an appearance that will remain largely unchanged, other than progressive enlargement, throughout the remaining period of sonographic observation of the fetus (see Fig. 8-103). Therefore, the vast majority of the changes that are observed—and they are substantial—relate to the growth and development of the telencephalon. As mentioned, by the end of the first and beginning of the second trimesters, the lateral ventricles (see Figs. 8-103 and 8-104) dominate the sonographic appearance of the telencephalon. The brightly echogenic choroid plexus dominates these in turn. By 12 to 13 weeks, the lateral ventricles can be clearly seen, appear ovoid, and are largely filled with choroid plexus. Only the frontal horns are devoid of choroid plexus, as they are throughout life (see Figs. 8-103B, 8-104, and 8-105). At this stage of development, only the rudiment of a temporal horn (see Fig. 8-104B) is seen, and an occipital horn has yet to develop. The frontal horn, body of the ventricle, and atrium of the ventricle are large and easily detected. The choroid is the easiest structure to recognize because of its size and high-amplitude echogenicity. Conversely, the mantle of developing cerebral cortex surrounding the lateral ventricle is more difficult to delineate because of its low-amplitude echogenicity (see Fig. 8-103A), but a demarcation between the lateral ventricle and the cerebral mantle can be appreciated from specular reflections arising from the walls of the lateral ventricle (see Figs. 8-103B and 8-104B). These are seen where the acoustic beam intersects the ventricular wall perpendicularly. By 16 to 18 weeks the mantle of developing cortical tissue has thickened appreciably (compare Figs. 8-104 and 8-106). As the occipital lobe has increased in volume, an occipital horn of the lateral ventricle has gradually appeared (see Figs. 8-104 through 8-106).

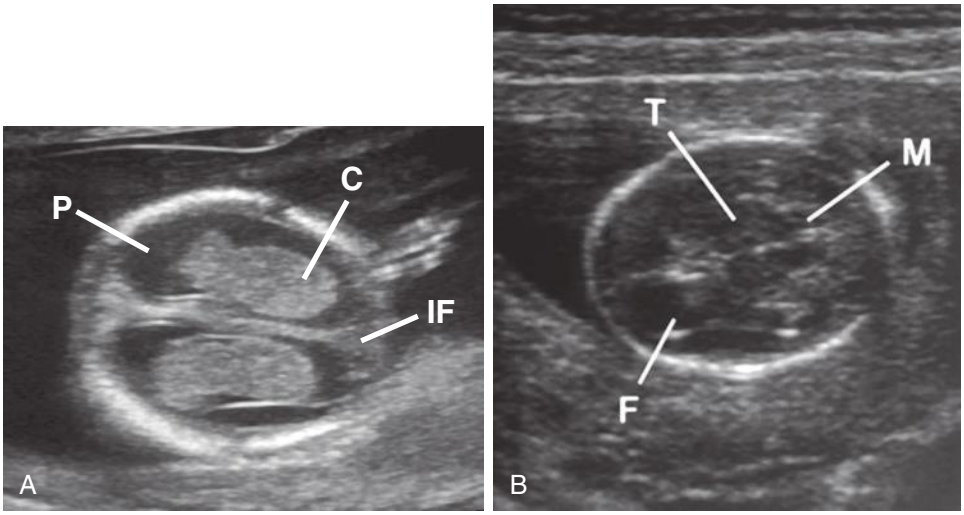

FIG 8-103 **A,** Transverse axial scan at the level of the lateral ventricular atria in a 14-week fetus. The brain parenchyma (P) is very lucent. C, choroid plexus; IF, interhemispheric fissure. **B,** Slightly caudal scan demonstrates well-developed thalami (T) and midbrain (M). The frontal horns (F) are large and filled with cerebrospinal fluid.

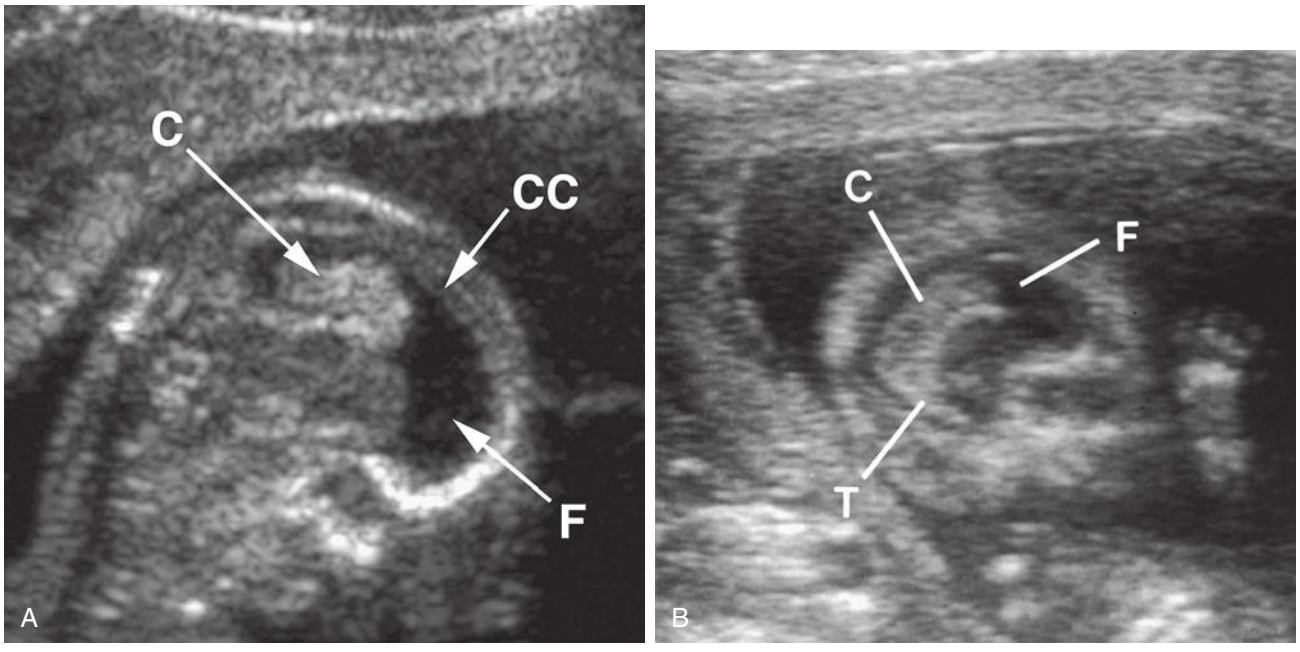

FIG 8-104 **A** and **B,** Parasagittal sonograms in late first trimester demonstrate that, even this early in development, choroid plexus (C) fills the posterior and inferior portions of the ventricle. Specular reflectors demarcate the frontal horn (F), which is devoid of choroid plexus and thus seen as a "fluid-containing" portion of the ventricular system. The early temporal horn is seen (T). Note absence of an occipital horn. Choroid plexus fills the body, atrium, and early temporal horn. Note as well how remarkably thin the cerebral cortical (CC) tissue is.

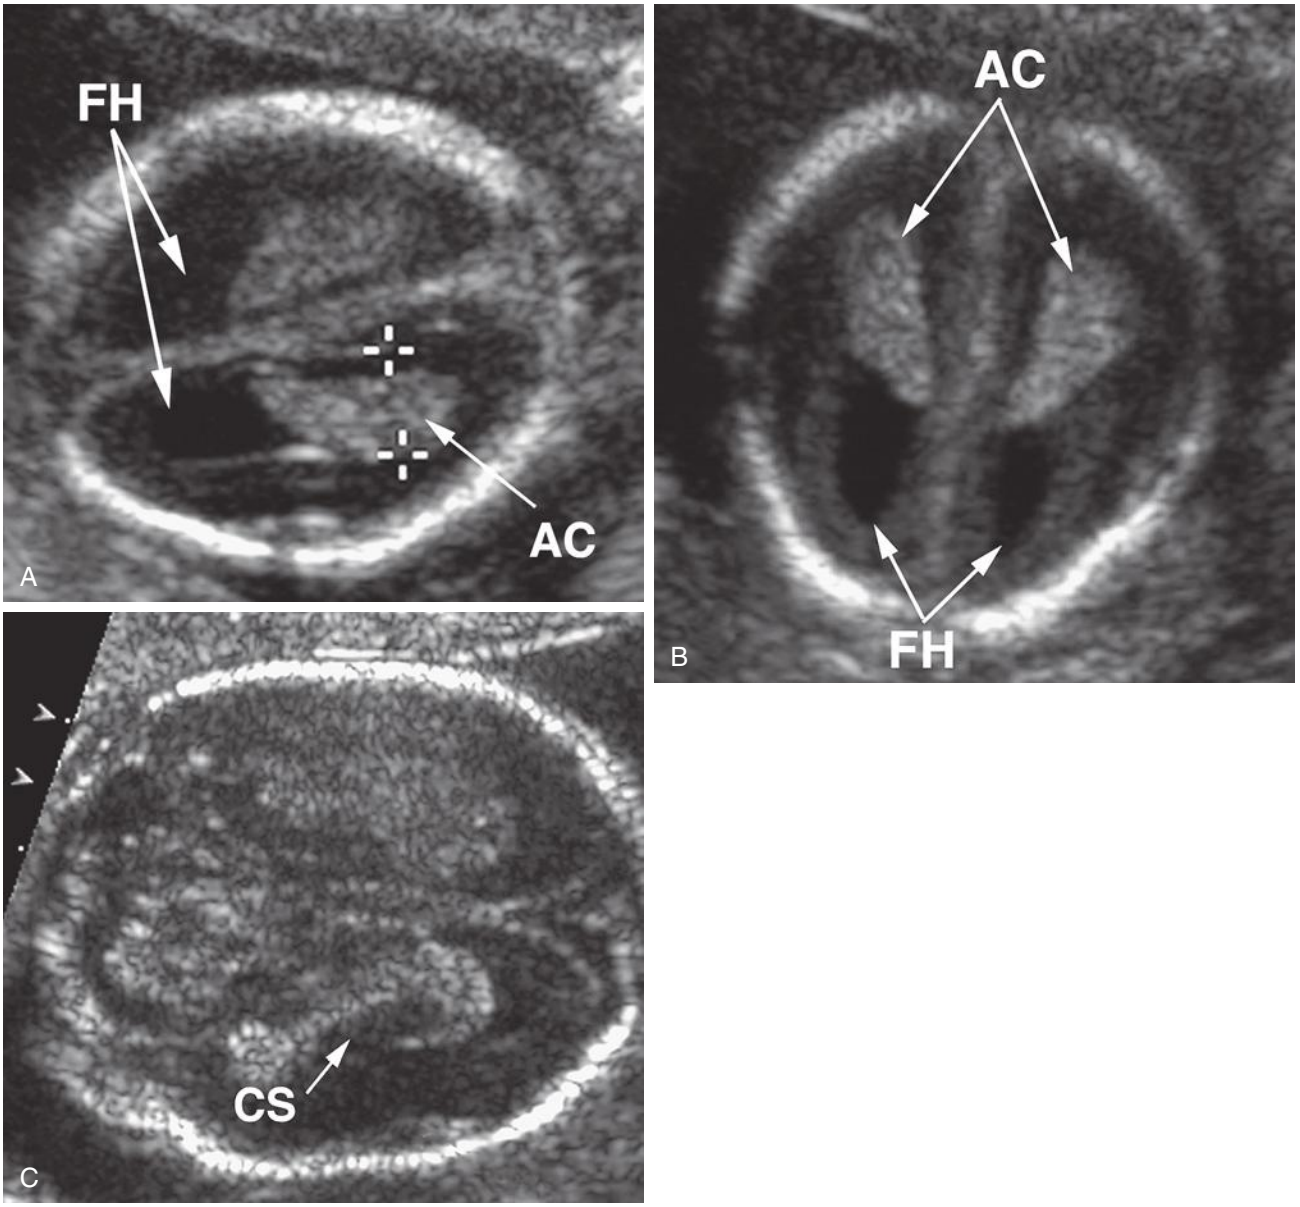

FIG 8-105 Three axial sonograms through the lateral ventricles of early second trimester fetuses. **A,** Axial sonogram demonstrates degradation of visualization of the near ventricle due to calvarial reverberation artifact. Note the difference in clarity of the frontal horns (FH). AC, atrial choroid. **B,** By imaging through the posterior fontanelle, calvarial reverberation is nearly eliminated, and the frontal horns are now seen with equal clarity. **C,** At this early stage of development the corpus striatum (CS) is prominent and indents the ventricular choroid. This should not be mistaken for an abnormality (sometimes, when more lucent, it masquerades as a choroid plexus cyst).

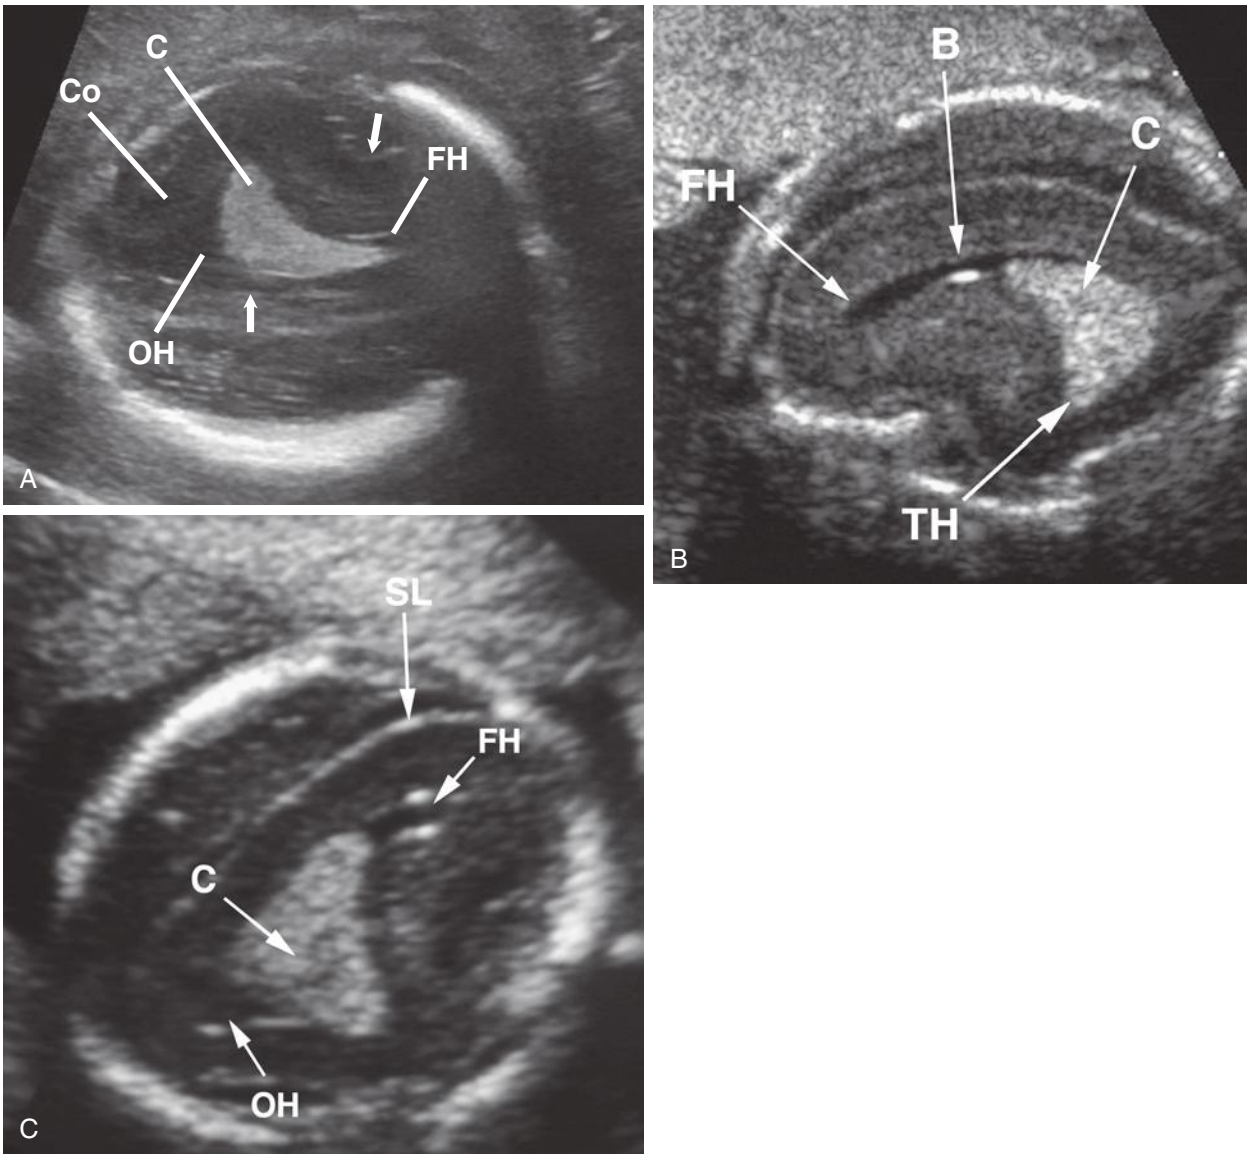

FIG 8-106 **A** through **C,** Parasagittal sonograms through the ventricle of 16- to 18-week fetuses. The choroid (C) defines the ventricular size and the position of the ventricular atrium. Note the substantial increase in cortical brain (Co) thickness compared with fetuses only a few weeks younger (see Fig. 8-104). Bright echoes marginate the edge of the telencephalon (*straight arrows*). The bright reflector represents surface leptomeninges (SL). Note the beginnings of an occipital horn (OH) in **A,** and compare with the more developed occipital horn in **C.** Note, as well, that the frontal horn (FH) is much narrower in craniocaudal diameter because growth of the head of the caudate nucleus has reshaped this portion of the ventricle. B, ventricular body; TH, developing temporal horn.

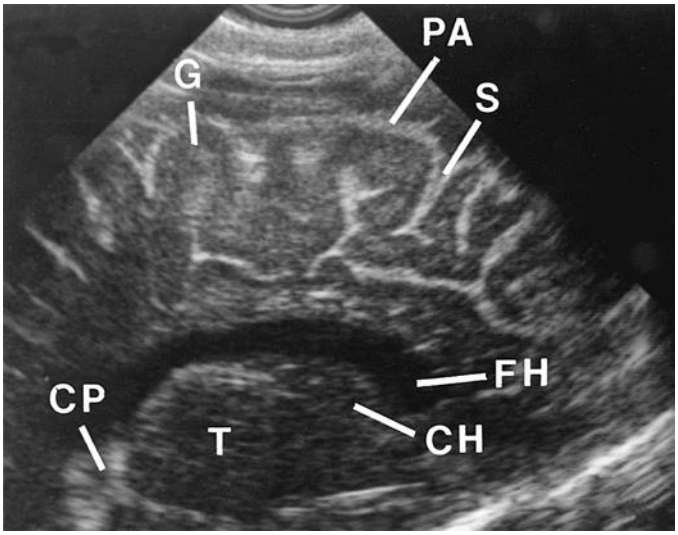

FIG 8-107 Parasagittal sonogram of the brain of a 6-month-old child. Gyri (G) are well developed. Pia-arachnoid (PA) tissues cover the surface of the brain and make the sulci (S) highly conspicuous. Careful inspection of gyri shows that cortical "gray matter" is less echogenic than the "white matter" (this is almost certainly not a difference due to gray and white matter distinction but to the vessels coursing through the central gyrus). CH, caudate head; CP, choroid plexus; FH, frontal horn; T, thalamus.

The relative echogenicity of structures, which will be viewed throughout the remainder of gestation, is largely established at this time. Two types of tissues are brightly echogenic and, therefore, most easily seen during the examination of the fetal brain. These tissues are the choroid plexus, as noted earlier, and the brain coverings: the dura (pachymeninx) and pia-arachnoid (leptomeninx). Interestingly, the choroid develops from the vascular pia. The leptomeninges demarcate the edges of the brain with a brightly reflective margin of echoes (Figs. 8-106 through 8-108). Peripheral to this echogenic margin are the subarachnoid spaces that contain cerebrospinal fluid (Figs. 8-107 through 8-109). A characteristic feature is the relative lack of change in echogenicity between the peripheral (i.e., cortical brain) tissue and the cerebrospinal fluid space as seen across the brightly reflecting marginal echo from the pia-arachnoid (the cerebrospinal fluid–containing space may be more echogenic) (see Figs. 8-108 and 8-109). This perceptual problem originates from the anticipation that the subarachnoid spaces should be anechoic whereas the brain parenchyma should be echogenic. This reasonable assumption is untrue in many instances. These spaces have both cerebrospinal fluid and pia-arachnoid tissue within them, and it is the relative amount of these two components that determines the sonographic appearance of the subarachnoid spaces. Small subarachnoid cisterns (such as the basal and perimesencephalic cisterns) have an appearance dominated by pia-arachnoid and thus are seen as brightly echogenic spaces (Fig. 8-110). This is not to say that these cisterns are devoid of cerebrospinal fluid, but the fluid does not significantly influence their sonographic appearance.

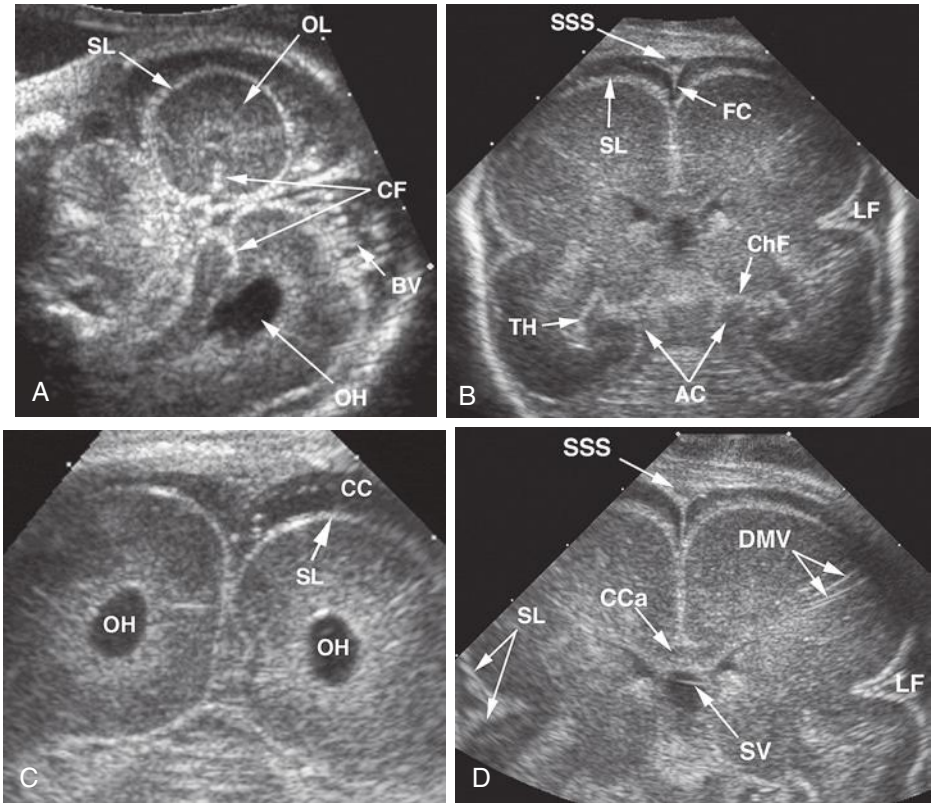

FIG 8-108 **A** through **D,** Sequence of sonograms obtained through fontanelles and sutures. This technique enables one to see symmetric brain anatomy. The surface leptomeninges (SL) are crucial to discriminating the edge of the brain tissue and the adjacent cisterns. AC, ambient cistern; BV, bridging veins; CC, convexity cistern; CCa, corpus callosum; CF, calcarine fissure; ChF, choroidal fissure; DMV, deep medullary veins; FC, falx cerebri; LF, lateral fissure; OH, occipital horn; OL, occipital lobe; SSS, superior sagittal sinus; SV, septal vein; TH, temporal horn.

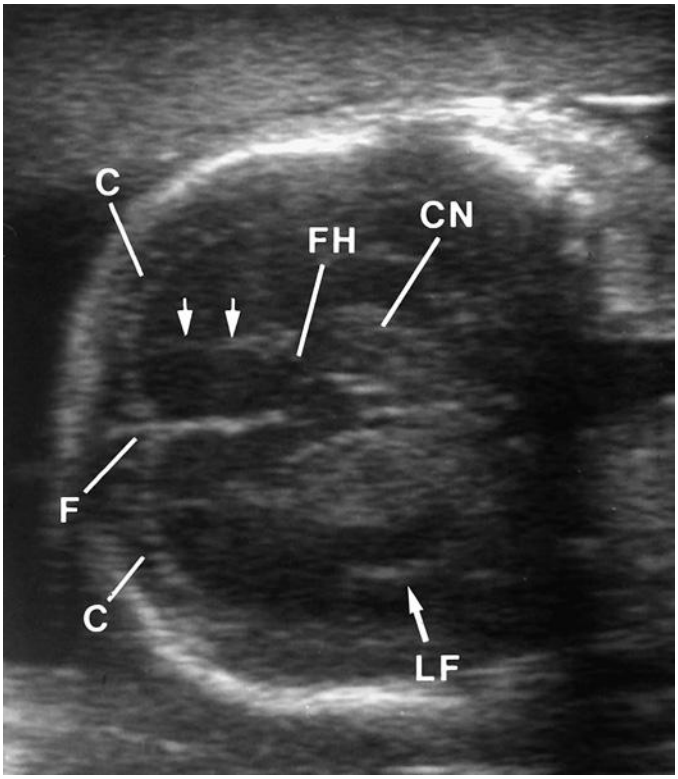

FIG 8-109 Coronal section through the heads of the caudate nuclei (CN). The frontal horn (FH), which is not well seen, drapes over the caudate. Extending between the ventricular margin and the edge of the brain are linear echogenic structures previously mistaken for ventricles (*arrows*). Also seen are bridging strands of pia-arachnoid through the cistern (C) over the convexities (probably bridging veins covered with pia-arachnoid). F, falx; LF, lateral fissure.

Conversely, larger subarachnoid spaces, such as those over the convexities of the hemispheres (see Fig. 8-107 and 8-108) and the cisterna magna (Fig. 8-111), have an appearance dominated by cerebrospinal fluid. Thus, they behave, in the sonographic sense, as one would anticipate for a fluid-containing cavity. Intermediate-sized subarachnoid spaces will have both anechoic zones from visible cerebrospinal fluid and brightly echogenic zones from visible pia-arachnoid tissues (see Figs. 8-108 through 8-110). The bright margination provided by the leptomeninges enables one to visualize, for example, the midbrain quite elegantly (see Fig. 8-110). Without these margin echoes our perception of the midbrain would be greatly hindered.

As noted earlier, brightly reflecting structures dominate the sonographic appearance of the fetal brain. The choroid plexus and brain coverings (pia-arachnoid and dura) are the two major components within the developing calvaria that produce bright reflections. The important dural structures from the perspective of sonographic fetal brain anatomy are the falx cerebri and the tentorium (Figs. 8-108 through 8-112). Some neural structures generate high-amplitude reflections. This is particularly true of the basal ganglia, especially the lenticular nuclei (see Fig. 8-111). The cerebellar vermis and the surface tissues of the cerebellar hemispheres also appear very bright (Figs. 8-113 and 8-114), but this appearance is again secondary to leptomeninges. The cerebellar folia "drag" meninges below the "surface" of the hemisphere, making the surface tissues appear bright (see Fig. 8-113B). The cerebellar vermis has the greatest number of folia and intertwined meninges. Thus, it often appears strikingly echogenic (see Fig. 8-114B).

Also important as high-amplitude echoing structures are specular reflections from the walls of the ventricular system (see Figs. 8-103B, 8-104B, 8-105A, and 8-106C). Such reflections occur when the ultrasonic beam strikes the smooth ventricular wall perpendicularly or nearly so. Thus, one would assume that points and lines of brightness so produced might vary from moment to moment depending on the direction in which the transducer was pointed. This, however, is not the case for two reasons. First, fetal brain images are predominantly

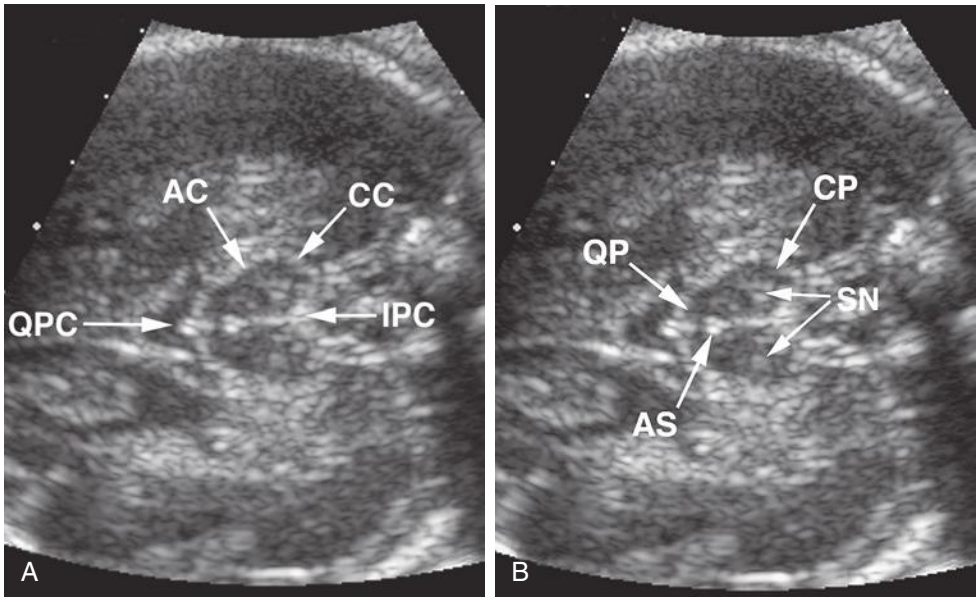

FIG 8-110 **A** and **B,** Sonograms demonstrating the midbrain. The midbrain is seen well because of the sharp outline provided by the brightly echogenic perimesencephalic cisterns (the leptomeninges provide the bright line of demarcation). These cisterns marginate the cerebral peduncles (CP) and the quadrigeminal plate (QP). AC, ambient cistern; AS, aqueduct of Sylvius; CC, crural cistern; IPC, interpeduncular cistern; QPC, quadrigeminal plate cistern. SN, substantia nigra.

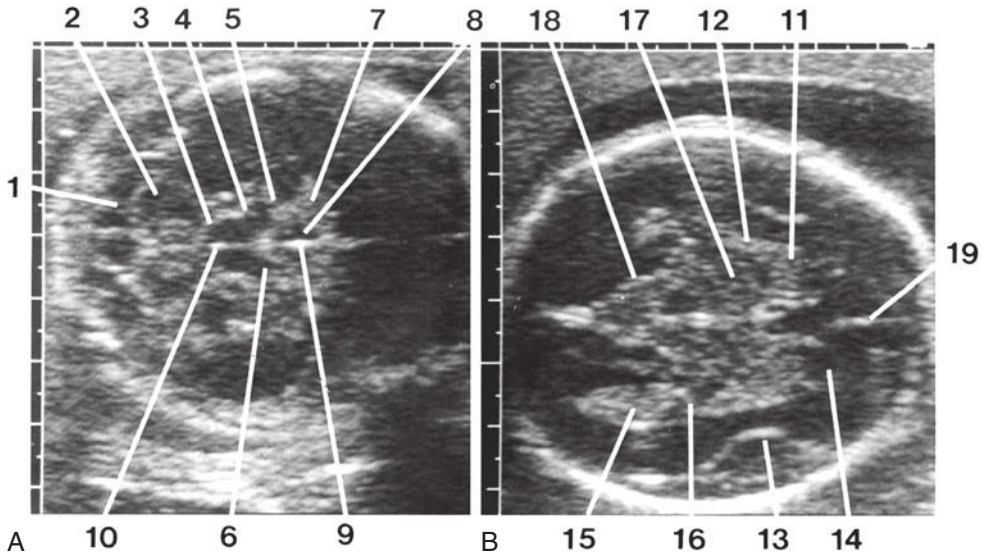

FIG 8-111 **A** and **B,** Transverse axial sonograms demonstrating many discrete neural structures. Note the varying echogenicities of the cisterns. Large cisterns (1, cisterna magna) have an appearance dominated by cerebrospinal fluid. Small cisterns (7, basal cisterns) are dominated by pia-arachnoid. 2, cerebellar hemisphere; 3, quadrigeminal cistern; 4, ambient cistern; 5, crural cistern; 6, interpeduncular cistern (note walls of basilar artery centrally in this cistern); 8, hypothalamus; 9, inferior recess of third ventricle; 10, sylvian aqueduct; 11, head of caudate; 12, lentiform nuclei, 13, lateral fissure; 14, frontal horn; 15, atrial choroid; 16, posterior limb of internal capsule; 17, thalamus; 18, tentorial hiatus; 19, falx cerebri.

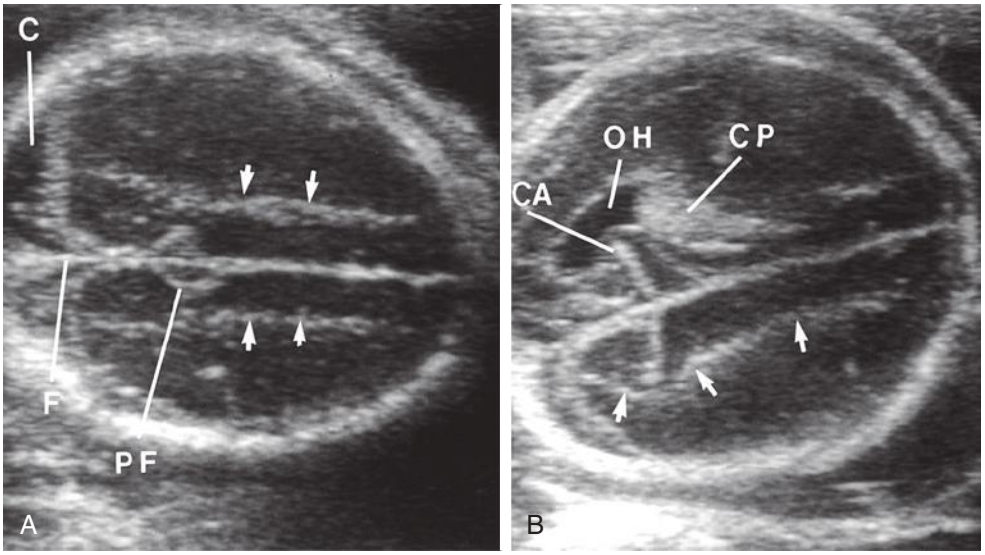

FIG 8-112 **A,** Transverse axial sonogram near the vertex. Bright linear echoes (*arrows*) often mistaken for lateral ventricles are clearly seen. Note that these echoes extend to the brain edge. C, convexity cistern with cerebrospinal fluid and hair-like bridging veins covered by brightly echogenic pia-arachnoid; F, falx; PF, parieto-occipital fissure. **B,** Off-axis scan through both the lateral ventricle and the linear echo (*arrows*) seen in **A.** The occipital horn (OH) is now well seen. Note again that the linear echo extends to the brain edge, whereas the occipital horn is entirely marginated by brain tissue. CA, calcar avis; CP, choroid.

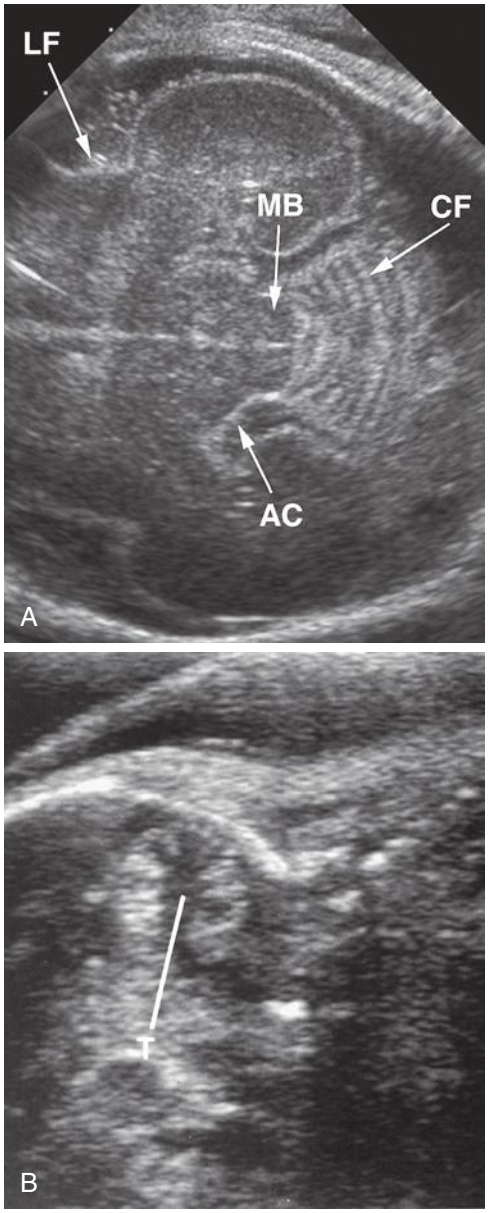

FIG 8-113 A, Posterior fossa view (transverse axial) demonstrating cerebellar folia (CF). AC, ambient cistern; LF, lateral fissure; MB, midbrain. **B,** Parasagittal sonogram of the posterior fossa. Cerebellar white matter tracts (T) are well seen. The bright margin of the cerebellum is "artifactual" in that it is due to reflections from leptomeninges drawn into the cerebellum by folia formation (gray matter is hypoechoic).

produced in transverse axial planes (appropriate for both biparietal diameter and head circumference measurements) (see Fig. 8-103B) and less commonly coronal or parasagittal (see Fig. 8-106C) planes. In these planes, the beam tends to intersect the ventricular system perpendicularly at the same interfaces. Second, the curvature of the bony calvaria limits the number of axial, coronal, and parasagittal planes that can be achieved as a result of significant beam divergence when the beam intersects curved portions of calvaria. Thus, the specular reflections from the ventricular walls tend to be seen in stable locations and can be used as important and reproducible anatomic landmarks.

Additionally, within the substance of the brain, most notably in the region of the cerebral white matter tracks, other bright reflections are noted (Figs. 8-108 to 8-110 and 8-115). Although these reflectors might be mistaken for the lateral ventricular walls, with which they are contiguous (see Figs. 8-109 and 8-112),[110,113,119] origins of these reflections are blood vessels draining the deeper white matter regions (see Figs. 8-108D, 8-109, 8-112, and 8-115).[120] Interestingly, pia accompanies these vessels as they course through the brain substance. Therefore, again it is the leptomeninges that account for bright echoes in the fetal brain. Thus, the brightly echoing structures of the fetal brain, including the surface echoes, cisterns, draining veins of the deep white matter, and choroid plexus, are all tied to the pia mater. As Dr. James Bowie observed regarding the grand unifying theory of bright echoes in the brain, "it's all pia" (personal communication, 1991).

The sonographic "skeleton" of the developing fetal brain originates from the brightly reflective structures just considered. Using these structures as the framework, numerous discrete neural tissue areas are discernible sonographically (Figs. 8-110, 8-111, and 8-116).[1,2] As the brain develops, multiple areas of the telencephalon, diencephalon, midbrain, pons, and cerebellum become anatomically identifiable. They are recognized by variations in the echogenicity of specific nuclei and tracts that pass through these zones (see Figs. 8-109, 8-111, 8-113B, 8-114, 8-115A, and 8-116). Several brain nuclei, as well as some other areas of neural tissue, demonstrate a moderate increase in echo amplitude compared with surrounding brain elements (Figs. 8-109, 8-111, 8-116, and 8-117A). These nuclei demonstrate lower amplitude signals than choroid or leptomeninges. Among these structures are the caudate and lenticular nuclei, separated by the internal capsule. Less commonly, the claustrum, marginated by the extreme and external capsules, is visible. Similarly, the substantia nigra (see Fig. 8-110B) in the midbrain and dentate nuclei of the cerebellum (Fig. 8-111A, not labeled) are discernible. Also the pars ventralis (belly) of the pons is seen as a zone of moderate echogenicity as opposed to the pars dorsalis (tegmentum), which returns low-amplitude echoes (Fig. 8-118A).[1]

The appearance of the lateral ventricles undergoes characteristic changes throughout growth and development of the fetal brain. By 18 weeks, easily recognizable occipital horns and temporal horns are visible (see Fig. 8-106). The lateral ventricles have achieved their adult components. From this point onward, the lateral ventricles change in shape and proportion as influenced by neural tissues growing adjacent to their walls. For example, the growth of the caudate nucleus markedly reshapes the frontal horn of the lateral ventricles (see Fig. 8-106).[121] However, throughout the period of observation of fetal lateral ventricles (from 13 to 40 weeks), the size of the atria remains largely unchanged. The transverse diameter of the ventricular atrium at the level of the glomus of the choroid plexus shows an average dimension of approximately 7 mm and an upper limit of 10 mm throughout the second and third trimesters.[122] This is the most convenient area to recognize fetal ventricular enlargement, as is discussed in detail in the section on ventriculomegaly in Chapter 9.[111,112,122] The developing fetus is the most dynamic structure an imager will ever confront. Within this dynamic organism, there is only one structure that remains stable in size throughout the second and third trimesters. That structure is the ventricular atrium, and this stability is nature's gift to the prenatal diagnostician.

It is important to note that the frontal (anterior) and occipital (posterior) horns of the lateral ventricles do not possess choroid plexus (see Figs. 8-104 through 8-106). Between 24 weeks and term, the telencephalon undergoes little structural change other than increased cortical growth and the consequent increase in convolutions (and thus sulcal markings), which can be recognized adjacent to the convexities (Fig. 8-119A and 8-120B).[123] The increase in brain volume causes the lateral ventricles, which are growing more slowly, to become progressively less conspicuous.

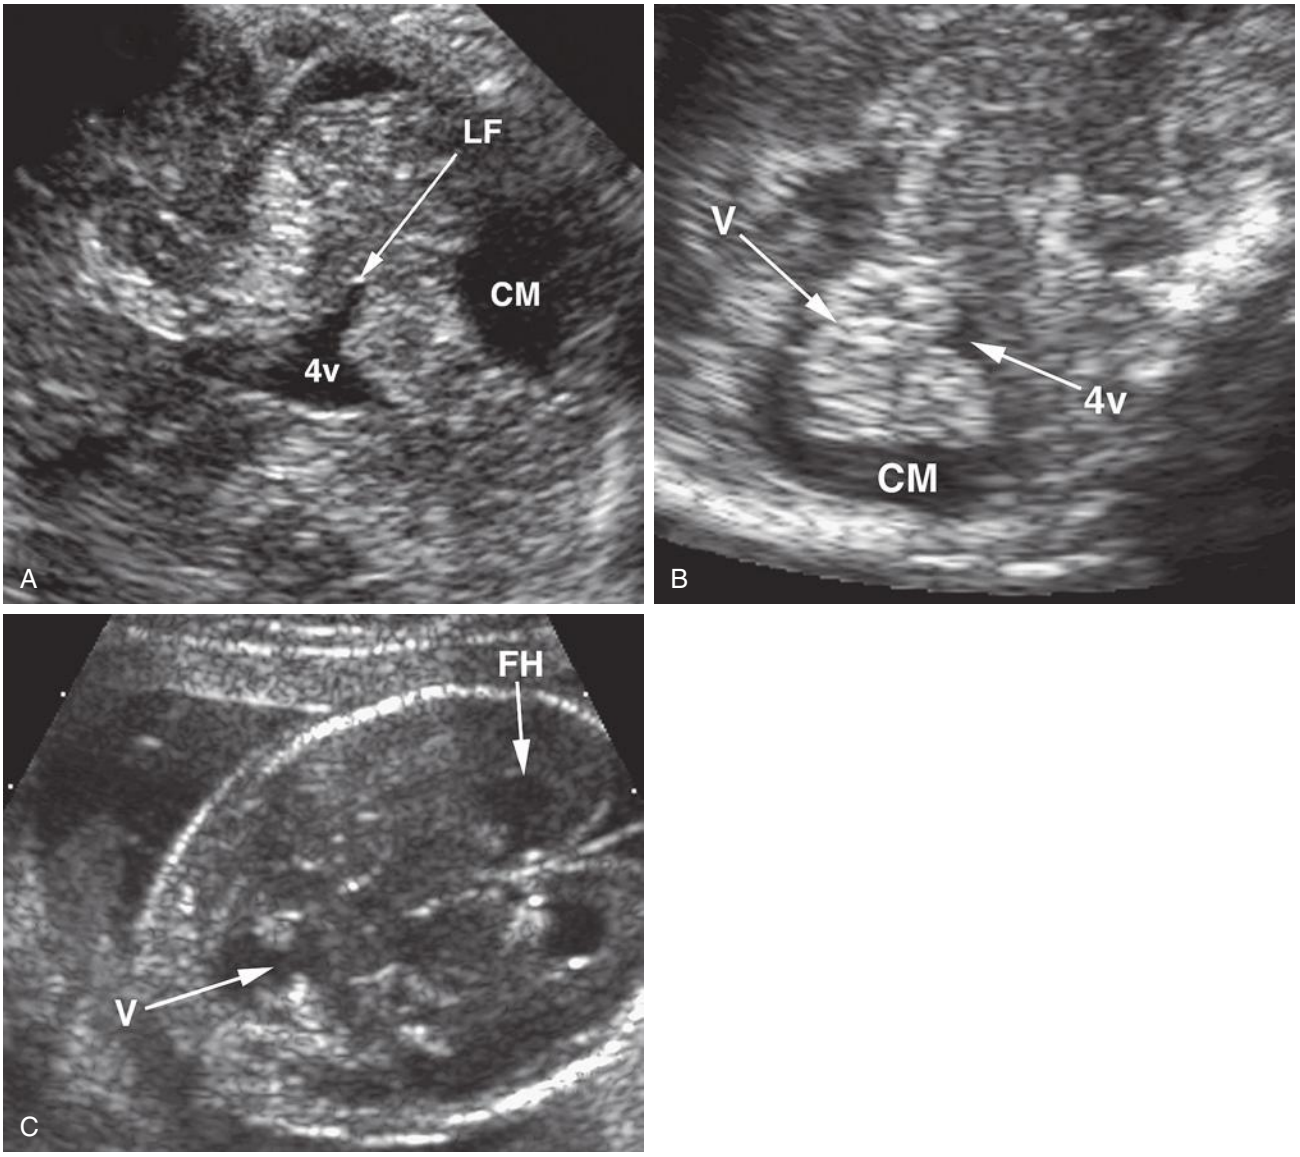

FIG 8-114 Three images of the posterior fossa at different stages of cerebellar development. **A** and **B** are images of later fetuses whereas **C** is obtained in the early second trimester. **A,** Transverse axial sonogram of the posterior fossa demonstrating the fourth ventricle (4v) and the Luschka foramen (LF). Lying between the fourth ventricle and the cisterna magna (CM) is the fully developed inferior vermis. **B,** Parasagittal sonogram of the posterior fossa. The fully developed vermis (V) is seen. The fourth ventricle is outlined by the superior peduncle and ala lobula centralis superiorly and the nodule and tonsil inferiorly. The inferior vermis is well depicted between the fourth ventricle and cisterna magna (CM). Note that the vermis appears very brightly echogenic because of the large number of folia and, most importantly, the intervening leptomeninges covering the surfaces of the folia. **C,** Transverse axial sonogram of the posterior fossa demonstrating the fourth ventricle communicating freely with the cisterna magna across an incompletely formed inferior vermis (V). This is a normal finding at this early stage of pregnancy. FH, frontal horn.

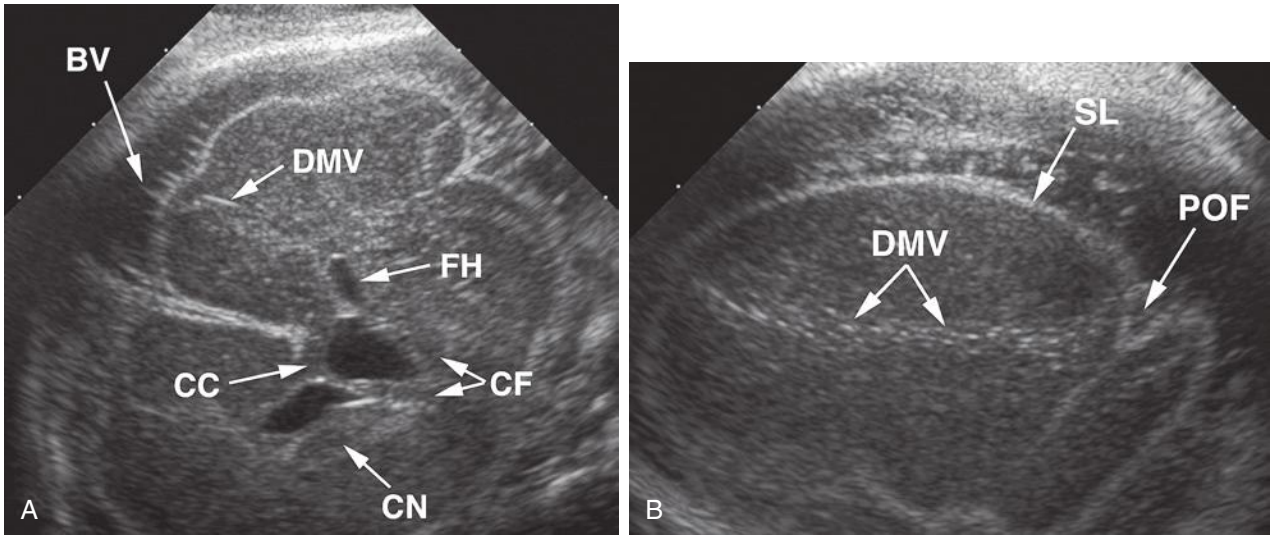

FIG 8-115 **A,** Coronal plane. **B,** Parasagittal plane. The deep medullary veins (DMV) and the bridging veins (BV) are invested with pia mater and thus are brightly reflective. Brightly reflective surface leptomeninges (SL) demarcate the brain surface and help to delineate fissures and sulci such as the parieto-occipital fissure (POF). CC, corpus callosum; CF, columns of the fornix; CN, caudate nucleus; FH, frontal horn.

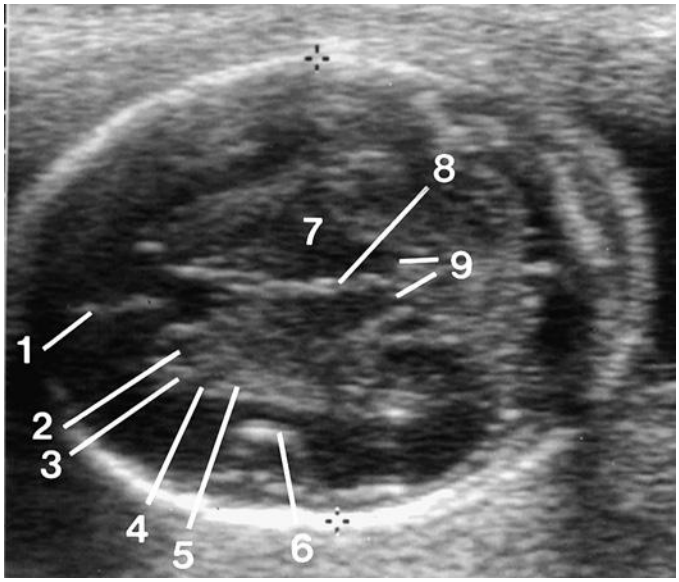

FIG 8-116 Transverse axial sonogram. 1, falx; 2, frontal horn; 3, caudate head; 4, anterior limb of internal capsule; 5, lentiform nuclei; 6, lateral sulcus; 7, thalamus; 8, third ventricle; 9, quadrigeminal bodies.

As opposed to sulci, which are narrow and develop later as gyri form, fissures are broader, present earlier in development, and can be seen before 20 weeks.[116] Of the two that are commonly seen, the parieto-occipital fissure, an indentation medially adjacent to the interhemispheric cistern, is smaller (see Figs. 8-112A, 8-115B, and 8-119A). The lateral fissure (insula and sylvian fossa/fissure) is a deep groove in the lateral margin of the developing telencephalon.[122,124,125] The groove is seen as a smooth depression as early as 14 weeks (see Fig. 8-105C).[116] Subsequently, its appearance gradually changes as the frontoparietal and temporal opercula develop (see Figs. 8-109, 8-111, 8-113, 8-116, and 8-120).[116] This important fissure results in frequent confusion because it causes a portion of the brain surface to be invaginated deeply into the hemisphere (see Figs. 8-109, 8-111, 8-113, and 8-116). The pia-arachnoid on the surface of the insula, the tissue at the base of the lateral fissure, generates a curvilinear reflection that appears to lie within the brain substance rather than at its "edge." This echo is often mistaken for a specular reflection from the lateral wall of the lateral ventricle, an error leading to misdiagnoses of hydrocephalus. With progressive growth of the temporal and parietal lobes, this fissure progressively closes, burying the previously exposed insular cortex behind the developing temporal and parietal opercula (Figs. 8-120 and 8-121). By term (38 to 42 weeks), the lateral fissure closes and ultimately becomes the sylvian cistern complex.

Other fissures and sulci become visible at predictable times during fetal brain development. This developmental sequence, or the failure thereof, enables one to diagnose or exclude certain brain malformations associated with migrational abnormalities. Among these are either the absence of formation of fissures and sulci (lissencephalic anomalies) or the appearance of fissures and sulci in aberrant locations (dysplastic brain).[116,126] The calcarine fissure (sulcus) (see Fig. 8-108A) is associated with the parieto-occipital fissure. The calcarine fissure angles caudally from the midportion of the parieto-occipital fissure, creating a prominent fold in the medial occipital lobe (the two fissures form a "Y" lying on its side). The calcarine fissure's greatest importance is that, as it grows, it indents the medial aspect of the occipital horn, thereby actually changing the shape of the ventricle at the junction of the atrium and occipital horn (the other piece of developing brain that greatly reshapes ventricular configuration is the caudate nucleus). The folded tissue is called the *calcar avis* (translated, the "bird's heel," which it somewhat resembles [at least to the anatomist who described it—I would have called it the "bird's beak"]) (see Figs. 8-112B and 8-120B). The calcarine fissure is easily seen on coronal sections of the posterior brain (see Fig. 8-108A). In the coronal plane one would think that it is the parieto-occipital fissure except that the coronal plan favors visualization of the calcarine fissure whereas the axial plane favors visualization of the parieto-occipital fissure (see Fig. 8-119B). The calcarine fissure (sulcus) becomes visible by the 24th week.[116] The cingulate sulcus, the sulcus that parallels the superior surface of the corpus callosum (see Fig. 8-118), also becomes visible at approximately the same time as the calcarine sulcus.[116] The cingulate sulcus is important in that

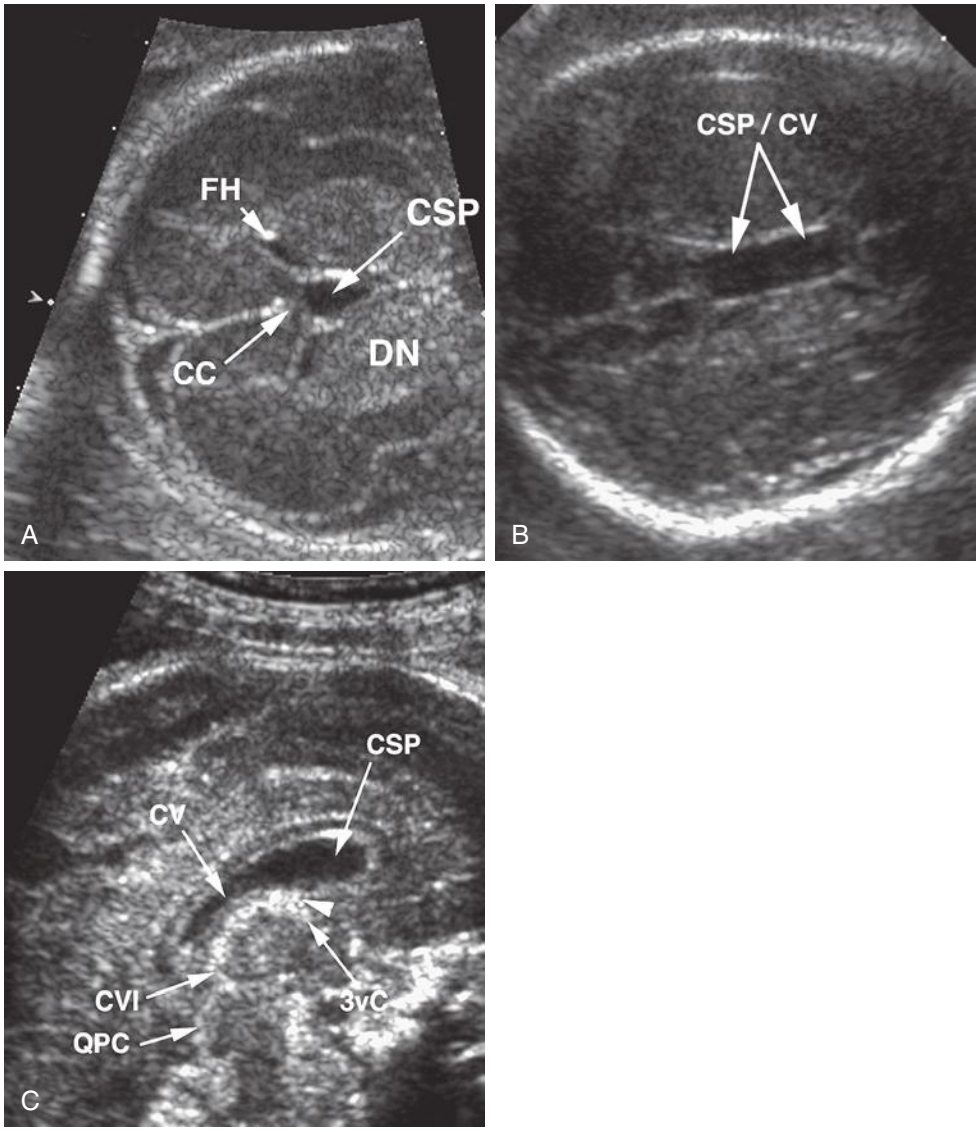

FIG 8-117 Coronal (**A**), transverse axial (**B**), and midsagittal (**C**) sonograms of the cavum septi pellucidi/cavum vergae complex. **A,** In the coronal plane the cavum septi pellucidi (CSP) lies between the frontal horns of the lateral ventricle (FH). The genu of the corpus callosum (CC) marks its roof. DN, deep gray matter nuclei. **B,** An axial sonogram demonstrates a relatively large cavum septi pellucidi complex (CSP/CV). A line of division between these entities cannot be adequately drawn in this plane of section. **C,** In the midsagittal plane the line of division between the cavum septi pellucidi and cavum vergae is more readily determined. First, the cavae lie between the brightly echogenic choroid in the roof of the third ventricle (3vC) and the corpus callosum (not labeled). The cavum septi pellucidi (CSP) "ends" where the third ventricular choroid begins (*arrowhead*). Posterior to that point it is most appropriately called the *cavum vergae* (CV). The third ventricular choroid blends imperceptibly with the brightly echogenic leptomeninges in the cistern of the velum interpositum (CVI) and the quadrigeminal plate cistern (QPC). Occasionally there is also a "cavum of the velum interpositum" that can produce a cyst-like small mass inferior to the splenium of the corpus callosum. This is a normal variant.

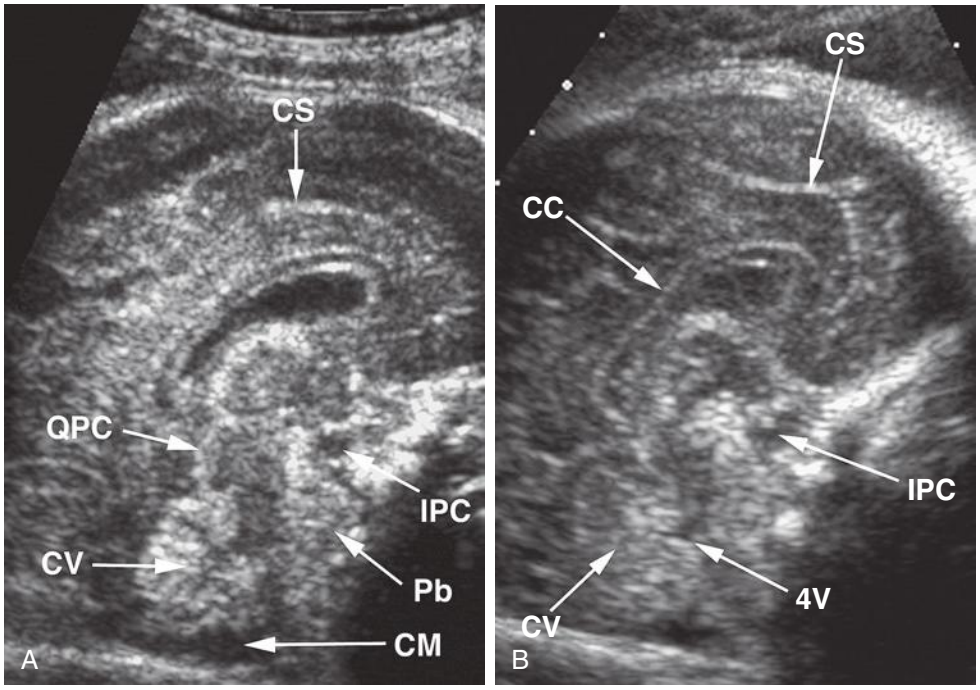

FIG 8-118 Midsagittal sonograms of a younger (**A**) and older (**B**) fetus. The cingulate sulcus (CS) is readily seen. The cingulate gyrus (not labeled) lies between the cingulate sulcus and the corpus callosum (CC). In the older fetus more visible sulci along the medial frontal and parietal lobes are visible. CM cisterna magna; CV, cerebellar vermis; IPC, interpeduncular cistern; Pb, belly of pons; QPC, quadrigeminal plate cistern; 4V, fourth ventricle.

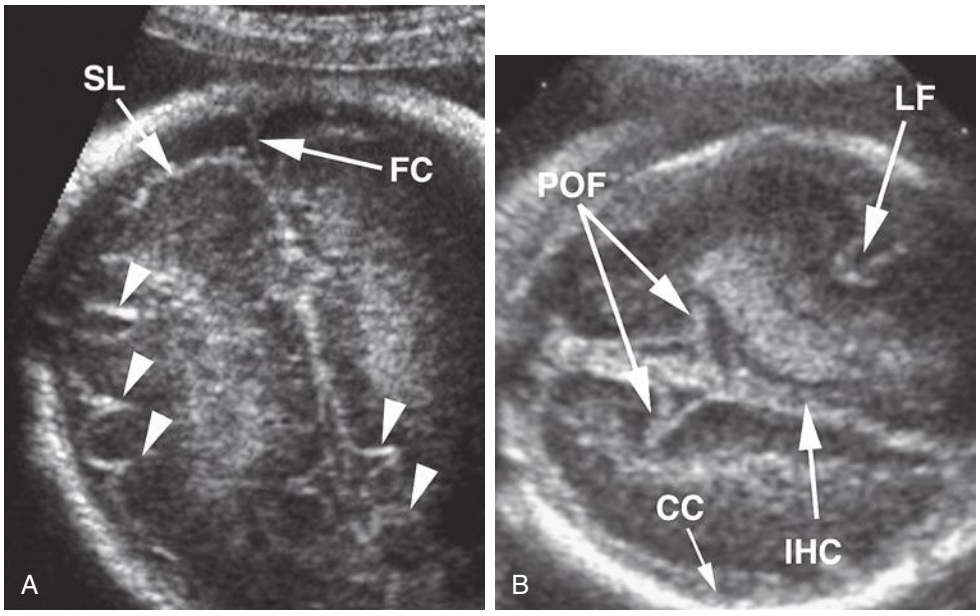

FIG 8-119 **A,** Older fetus. **B,** Younger fetus. Sonograms concentrating on the brain surface. In the younger fetus the brain surface is relatively smooth, although some of the major developing fissures are visible. In the older fetus, numerous sulci and gyri are visible (*arrowheads*). CC, convexity cistern; FC, falx cerebri; IHC, interhemispheric cistern; LF, lateral fissure; POF, parieto-occipital fissure; SL, surface leptomeninges.

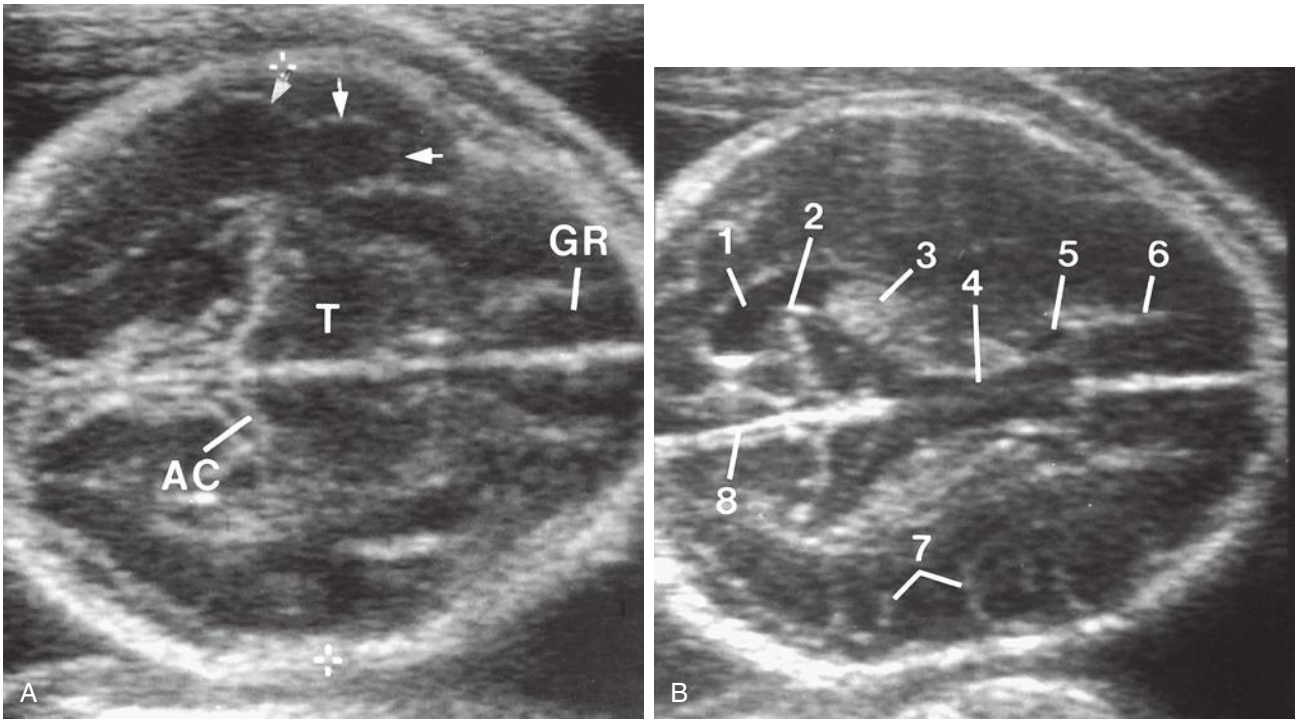

FIG 8-120 Transverse axial sonograms of a fetus with little calcification of the calvaria (recessive osteogenesis imperfecta). **A,** Note the lack of near calvarial reverberation artifact enabling visualization of the near temporal lobe (*short arrows*) with greater clarity than the far temporal lobe. AC, ambient cistern; GR, gyrus rectus; T, thalamus. **B,** Note the clarity which with the near ventricle is visualized. 1, occipital horn; 2, calcar avis; 3, atrial choroid; 4, corpus callosum (it is very unusual to see so much of the corpus callosum in an axial plane); 5, frontal horn; 6, deep medullary veins; 7, sulci; 8, falx cerebri.

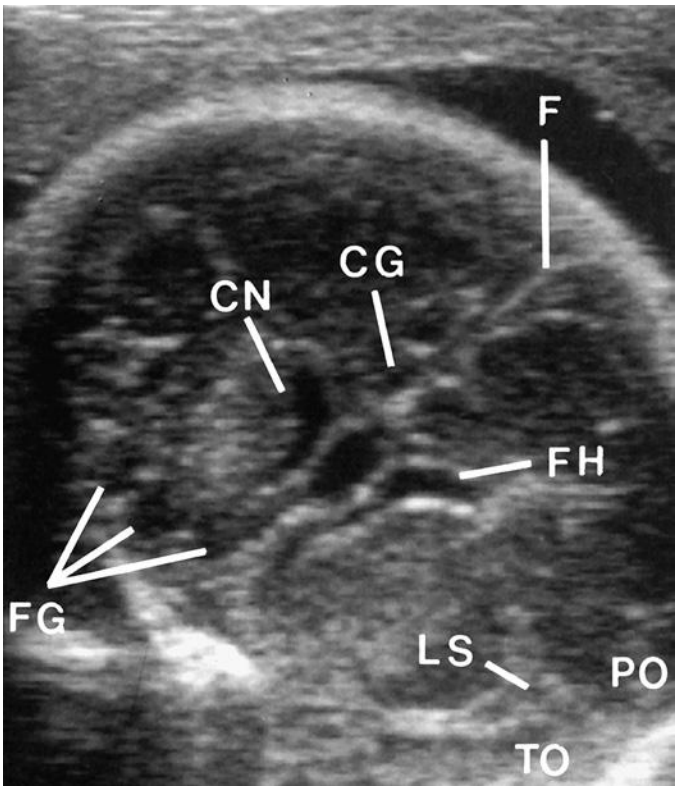

FIG 8-121 Coronal sonogram, anterior. CG, cingulate gyrus; CN, caudate nucleus; F, falx; FG, frontal gyri; FH, frontal horn; LS, lateral sulcus; PO, parietal operculum; TO, temporal operculum.

it does not form when there is complete agenesis of the corpus callosum. Thus, the formation of the corpus callosum is the "causative" element determining sulcation of the medial frontoparietal cortex. As the cingulate sulcus is the first of the medial sulci to develop, its presence is helpful in excluding complete callosal agenesis. Finally, the sulci over the convexities gradually become increasingly visible from the beginning of the third trimester onward.[116] Other recognizable sulci include those on the inferior frontal lobe that help define the gyrus rectus (see Figs. 8-120 and 8-121).

A structure of great importance in fetal neuroanatony is the corpus callosum (Fig. 8-122). The corpus callosum begins its development between the 10th and 11th weeks of gestation. It has achieved its adult configuration by the end of the 17th week. The development starts at the genu and proceeds posteriorly to the splenium. However, the rostrum (the most anterior part of the corpus callosum) forms last. The rostrum is not usually seen on prenatal sonograms. Sonographic imaging of the corpus callosum for the detection of abnormal formation should not be attempted in earnest until after 17 weeks (see Fig. 8-122D). The best views of the corpus callosum are obtained in the midsagittal plane (see Figs. 8-118B and 8-122B). However, information about the corpus callosum can be obtained in other planes of section. The body and genu can be seen in coronal and axial planes (see Figs. 8-115A, 8-117A, and 8-122A). Unfortunately, when partial agenesis (dysgenesis) of the corpus callosum is present, typically the splenium and distal body are missing. Importantly, the splenium can be imaged in axial planes of section, although with some difficulty, because the plane of section must approach from the occipital region (see Fig. 8-122C). Occipital ossification and the smaller posterior fontanelle make this approach difficult at times.

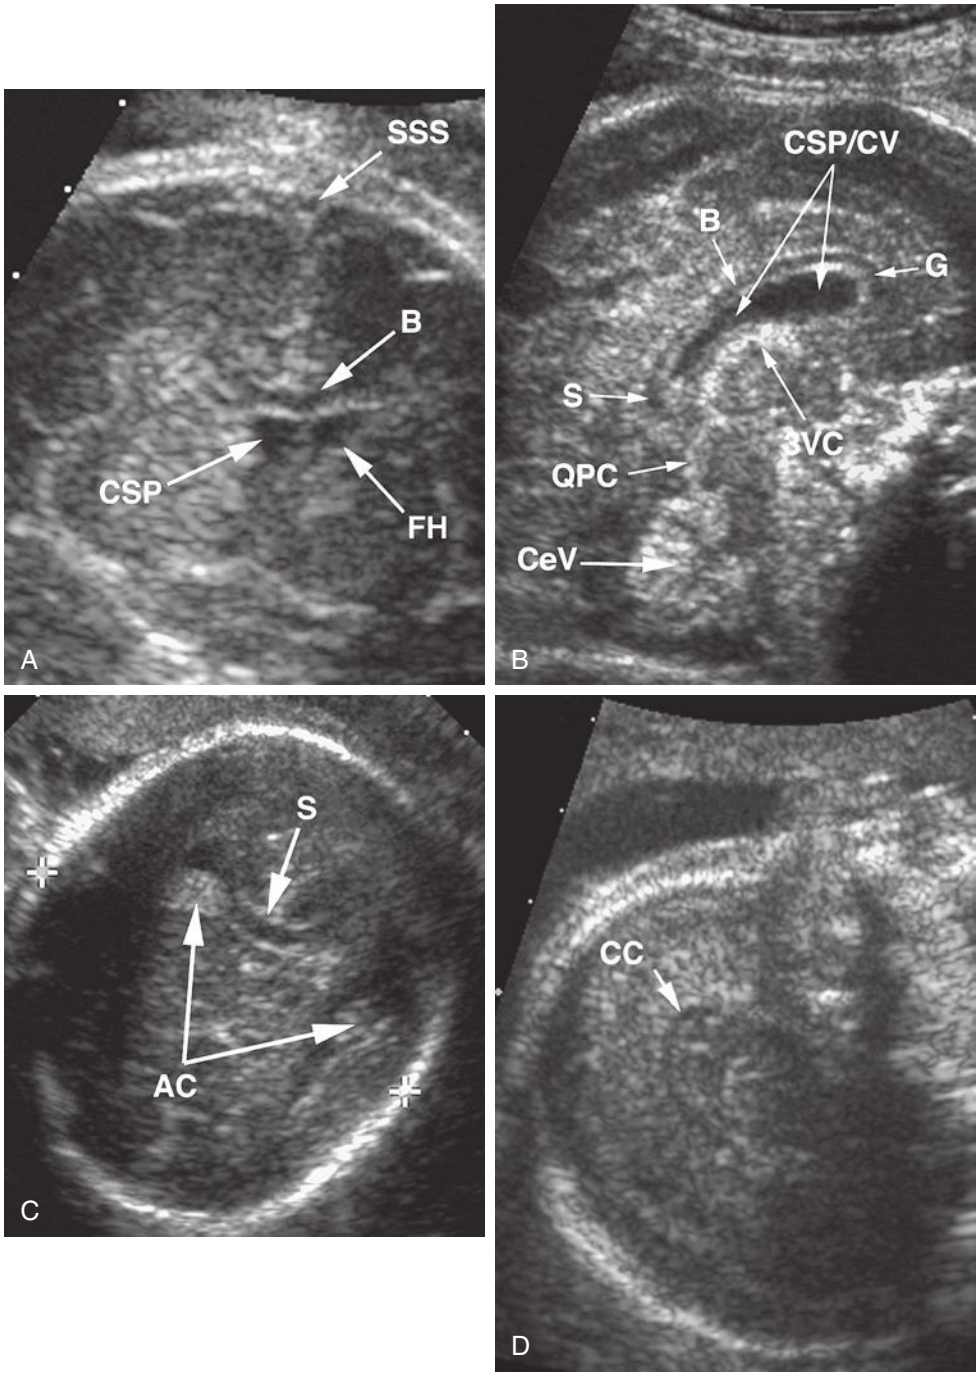

FIG 8-122 **A,** Coronal section through the body (B) of the corpus callosum. **B,** Midsagittal sonogram shows the corpus callosum to best advantage. **C,** Axial view "aimed" at the occiput demonstrates the splenium (S), the most crucial portion of the corpus callosum to visualize. In an "occiput up" fetus, a midsagittal sonogram of the corpus callosum would be nearly impossible to obtain. **D,** A 19-week fetus with corpus callosum well demonstrated. AC, atrial choroid; B, body; CC, corpus callosum; CeV, vermis of the cerebellum; CSP, cavum septi pellucidi; CV, cavum vergae; FH, frontal horn; G, genu; QPC, quadrigeminal plate cistern; S, splenium; SSS, superior sagittal sinus; 3VC, choroid plexus in the roof of the third ventricle.

An extremely helpful structure, both in terms of visualization of the corpus callosum and for excluding complete agenesis of the corpus callosum, is the cavum septi pellucidi/cavum vergae complex (see Fig. 8-117). The cavum septi pellucidi is the median cleft between the two laminae of the septum pellucidum. Sometimes called the fifth ventricle, it is not. It is not lined by ependyma. The cavum vergae (described by the Italian anatomist, Andrea Verga) is the posterior extension of the cavum septi pellucidi (see Fig. 8-117C). The actual line of division is the fornix, but as the fornix is not visible in a midsagittal plane, the Monroe foramen can be used to demarcate the end of one cavum and the beginning of the other (see Fig. 8-117C). The corpus callosum is the roof of the cava, and the roof of the third ventricle is the floor of the cava. Fortunately, we have an excellent marker of the roof of the third ventricle. This is because the third ventricular choroid recurves along the roof (see Figs. 8-117C and 8-122B). The most anterior extent of the third ventricular choroid (see Fig. 8-117C) marks the position of the Monro foramen and thus is a very reasonable dividing line between the cavum septi pellucidi and the cavum vergae. In axial planes of section, a reasonable line of division cannot be drawn (see Fig. 8-117B). A final aspect of callosal development is that formation of the cingulate gyrus (and thus the cingulate sulcus) is dependent on the formation of the corpus callosum (see Fig. 8-118).

The cerebellar vermis, like the corpus callosum, is also a late structure to develop (see Fig. 8-114). Of the major parts of the fetal brain to develop, the cerebellar vermis is last in line. The cerebellum is well imaged throughout the second and third trimesters (except near term when occipital ossification is sufficiently great to thwart passage of the acoustic beam) (see Figs. 8-113, 8-114, 8-118, and 8-122B). Like the corpus callosum, the cerebellar vermis develops from "front to back." Thus, the inferior portion of the vermis does not complete its formation until relatively late (in the range of the 18th gestational week). Sonographically, one detects the inferior vermis lying between the fourth ventricle and the cisterna magna, or Blake pouch (see Figs. 8-114A, 8-114B, and 8-118A). In midsagittal planes the fourth ventricle is outlined by the superior peduncle and ala lobula centralis superiorly and the nodule and tonsil inferiorly. The inferior vermis is well depicted between the fourth ventricle and cisterna magna. Note that the vermis appears very brightly echogenic because of its large number of folia (see Fig. 8-114B) and, most importantly, the intervening leptomeninges covering the surfaces of the folia. By contrast, in a fetus 16 to 17 weeks old, a transverse axial sonogram of the posterior fossa typically demonstrates the fourth ventricle communicating freely with the cisterna magna across an incompletely formed inferior vermis (see Fig. 8-114C). This is a normal finding at this early stage of pregnancy. The cerebellar hemispheres are outlined by the fluid in the cisterna magma (see Fig. 8-114). The fourth ventricle can be depicted throughout the second and third trimesters unless technical imaging problems confound its visualization (the "fourth ventricle" is even seen in the first trimester [see Fig. 8-4]).

Blake pouch is clearly seen in the majority of fetuses during the second trimester. One sees two septa extending posteriorly from the midcerebellum and crossing the cisterna magna. At one point, these septa were thought to represent separated dural leaves. However, when dural leaves separate they do so to house a venous sinus. This is not the origin of these septa. Robinson and Goldstein showed these septa to represent Blake pouch.[127] Blake pouch is an early embryologic structure that persists. It is a posteriorly positioned membranous structure protruding from the region of the developing fourth ventricle. Details of the formation of this structure are discussed in the orginal article. Other landmarks in the posterior fossa (like the torcular herophili) become important when addressing the differential diagnosis of posterior fossa cysts. These landmarks are seen to better advantage with MRI. All posterior fossa cysts should be imaged with MRI before a diagnosis is offered, in the opinion of these authors.

One of the difficulties in mastering the sonographic anatomy of intracranial structures is the usual inability to see both hemispheres of the brain symmetrically.[128] The hemisphere nearest to the transducer is virtually always "clouded" over by reverberation artifacts generated as the acoustic beam passes through the near calvarial wall. Calvarial ossification appears to be at the root of this artifact because the artifact is markedly reduced in fetuses with the most severe form of osteogenesis imperfecta or other bone dysplasias wherein calvarial ossification is nearly absent (see Fig. 8-120). Unfortunately, essentially all other fetuses possess calvarial ossification. The following rule should always be applied: the sonologist must assume that the intracranial anatomy of the fetus is symmetric, whether normal or abnormal, unless images document an asymmetry. Visualization of the near hemisphere requires that we use bone-free windows in the near calvaria. The "windows" are the anterolateral and posterolateral fontanelles in axial approach or the anterior and posterior fontanelles in coronal imaging. Because the anterolateral and posterolateral fontanelles are nearer to the base of the brain than to the vertex, using the anterolateral and posterolateral fontanelles results in images of the near hemisphere that are off axis to the axial plane (at least in most images). Therefore, caution must be exercised in the interpretation of the off-axis planes, particularly when judging the size of the near ventricular atrium.

As noted earlier, the fetal spine is seen well from 15 to 16 weeks onward. However, we often delay evaluation for suspected myelomeningocele until 18 to 20 weeks of gestation because of the significant and favorable maturational changes in the spine that occur during this period. The posterior ossification centers begin at the base of the transverse processes (see Figs. 8-58 to 8-63). As ossification progresses, the laminae become visible (see Figs. 8-59 to 8-61 and 8-65). The inward angulation of the normal laminae is the opposite of the outward splaying of the laminae seen in spina bifida, an optimal situation for detecting this anomaly. Spina bifida is the bony anomaly seen in all myelomeningoceles. The spinal cord neural tissue, like that of most brain tissue, is echopenic (see Fig. 8-65). The conus medullaris (see Fig. 8-65C) and the craniocervical junction (Fig. 8-123) can be seen,

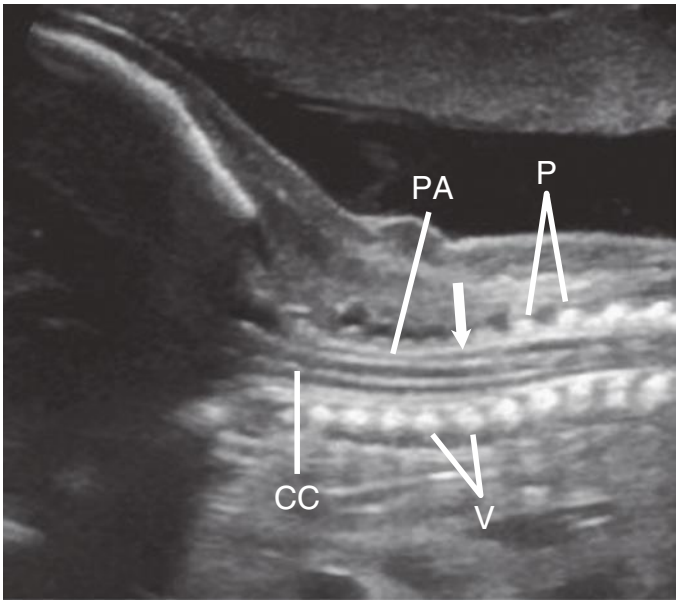

FIG 8-123 Longitudinal sonogram at the craniocervical junction demonstrating the cervical cord (CC). *(Arrow)*, dura; P, posterior arch ossification centers; PA, pia-arachnoid; V, vertebral body ossification centers.

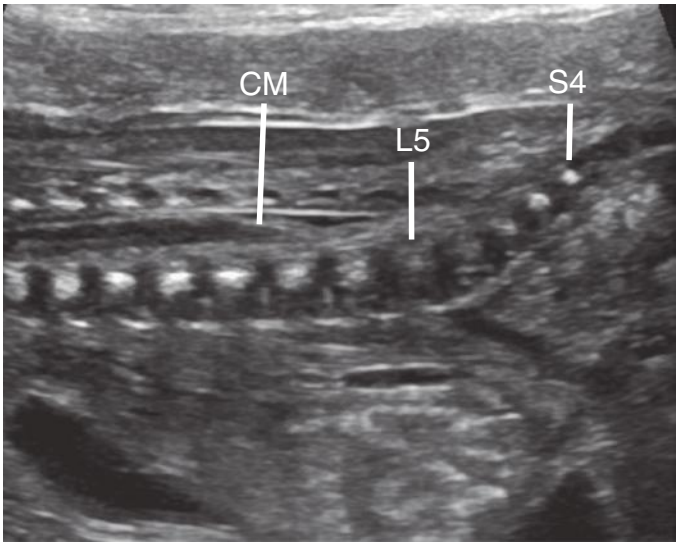

FIG 8-124 Sagittal plane of section of the spine in a 20 weeks' gestation fetus. The spinal level can be determined by counting up from the last ossified vertebral segment (assumed to be S4 in the second trimester and S5 in the third trimester). In this case the S4 ossification center is the most distal segment present and is used to count cephalad to identify L5. Note the conus medullaris (CM) at the L2-L3 level.

albeit inconsistently, in nearly all fetuses by 18 to 20 menstrual weeks. The tissues surrounding the cord (leptomeninges) are brightly echogenic, as are those that surround the brain, and the dura is usually also seen discretely as a linear bright reflector (see Fig. 8-65 and 8-66). In fetuses with myelomeningoceles, determination of the most cephalic spinal level of the lesion is an important factor in prognosis. This level can be determined by counting up from the last ossified vertebral segment (assumed to be S4 in the second trimester and S5 in the third trimester) (Fig. 8-124).

Ultrasound Evaluation of the Fetal Central Nervous System

Gianluigi Pilu

SUMMARY OF KEY POINTS

- Central nervous system (CNS) anomalies are among the most frequent malformations encountered by antenatal sonography.
- Ultrasound allows detection of a large proportion of all CNS malformations in early gestation. However, in some cases the findings may be subtle, whereas in others the anomaly may be progressive and manifest only in late gestation or after birth. Ultrasound will also frequently demonstrate normal anatomic variations difficult to differentiate from true malformations.
- Magnetic resonance imaging (MRI) is often useful with CNS anomalies to improve diagnostic accuracy.
- One of the most common antenatal diagnoses, enlargement of the lateral cerebral ventricles or ventriculomegaly, may be associated with other CNS malformations and requires a detailed workup.
- Neural tube defects, such as anencephaly and open spina bifida, are often recognized in early gestation. Demonstration of the spinal defect in spina bifida may be difficult, but the diagnosis is facilitated by frequently associated abnormalities of intracranial anatomy.
- Alobar and semilobar holoprosencephaly may be recognized in early gestation; more subtle varieties, such as the lobar type, are more difficult to identify.
- Complete agenesis of the corpus callosum (ACC) can be recognized by midgestation. Counseling regarding prognosis is difficult because the prognosis is variable and studies suggest that many infants diagnosed in utero may have normal intelligence. Partial agenesis is much more difficult to identify by prenatal sonography.
- Cystic and cyst-like anomalies of the posterior fossa are often difficult to diagnose with certainty. Although the increased fluid is easily recognized, a specific diagnosis is often difficult because many different entities exist and there is much overlap with normal variants.

OUTLINE

CNS malformations are among the most common congenital abnormalities encountered at birth. The true incidence of these anomalies, however, is probably underestimated; most epidemiologic surveys are based upon clinical examinations performed in the neonatal period, and many cerebral malformations will only be discovered later in life. Long-term follow-up studies suggest that the true incidence may be as high as 1 in 100.[1]

Detection of CNS anomalies was one of the early goals of sonography in pregnancy. Although there has been much debate regarding the value of ultrasound screening, it is now clear that open neural tube defects, including anencephaly, open spina bifida, and large cephaloceles, as well as other severe malformations such as holoprosencephaly, are easily identified in early gestation. Improvements in image quality have led to increased detection of relatively minor malformations, such that the challenge sonologists now face is not sensitivity, but rather specificity. Many CNS anomalies that are poorly understood (ACC and posterior fossa cysts are representative examples) are now detected antenatally and for many such abnormalities, the postnatal consequences are difficult to predict. Furthermore, there is often significant overlap between normal variation and pathologic changes, as with enlargement of the ventricular system and small dimensions of the fetal head. Fetal sonography can precisely diagnose some lethal or severe malformations. But in a significant proportion of patients (e.g., enlargement of the lateral ventricles alone has an in utero prevalence of 1%), CNS findings carry uncertain prognostic significance that can provoke much anxiety in expectant couples, require difficult decisions, and may eventually result in the loss of normal fetuses. It has been suggested that MRI may add important diagnostic and prognostic information, although the precise impact of this technique continues to be debated.

EMBRYOLOGY

The nervous system develops from the neural plate, a thickened area of embryonic ectoderm. It is the notochord and paraxial mesoderm that induce the overlying ectoderm to differentiate into the neural plate. The neural plate folds along its central axis to form a neural groove lined on each side by a neural fold. The two neural folds fuse together and pinch off to become the neural tube. Fusion of the neural folds begins in the middle of the embryo and moves cranially and caudally. The cranial open end of the tube is the anterior (rostral) neuropore, and the caudal open end of the tube is the posterior (caudal) neuropore (Figs. 9-1 and 9-2). The rostral neuropore closes on or before day 26 and the caudal neuropore closes 2 days later. The walls of the neural tube thicken to form the brain and spinal cord. The neural canal of the neural tube is converted into the ventricular system of the brain and the central canal of the spinal cord.

At about 8 to 10 weeks' gestation, a focal dilatation of the neural tube is seen in the dorsal aspect of the developing hindbrain; it is the rhombencephalic vesicle, the predecessor to the fourth ventricle. This structure may appear quite prominent and should not be misinterpreted as representing ventriculomegaly or another CNS anomaly (Figs. 9-3 and 9-4).

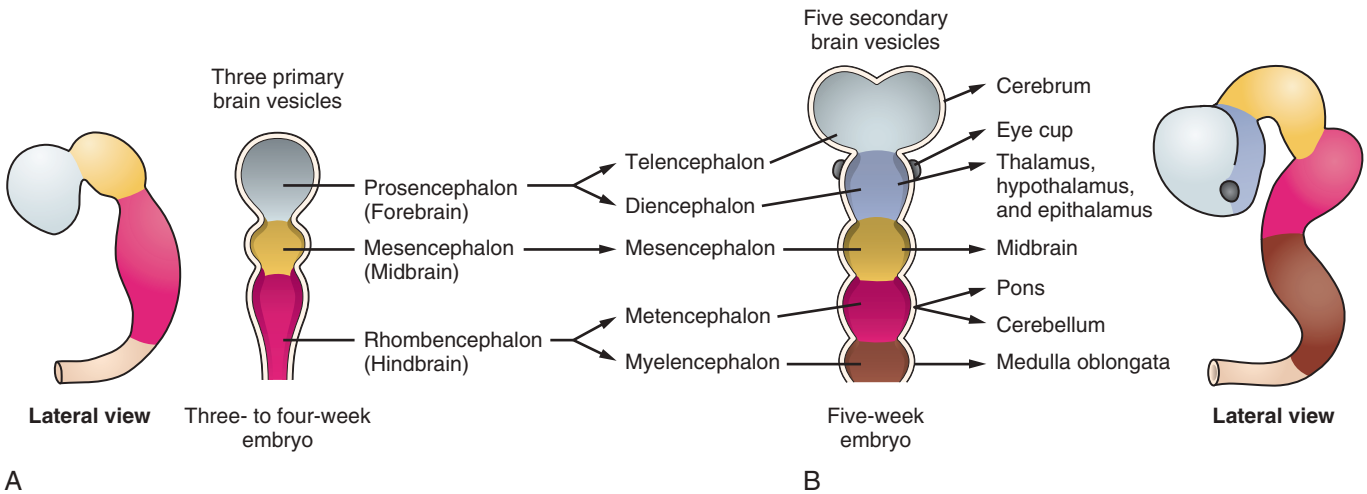

FIG 9-1 The embryonic brain develops complexity through enlargements of the neural tube called *vesicles*. **A,** The primary vesicle stage has three regions. **B,** The secondary vesicle stage has five regions. (From OpenStax College: Anatomy & Physiology, CNX Web site. June 19, 2013. Available at http://cnx.org/content/col11496/1.6/.)

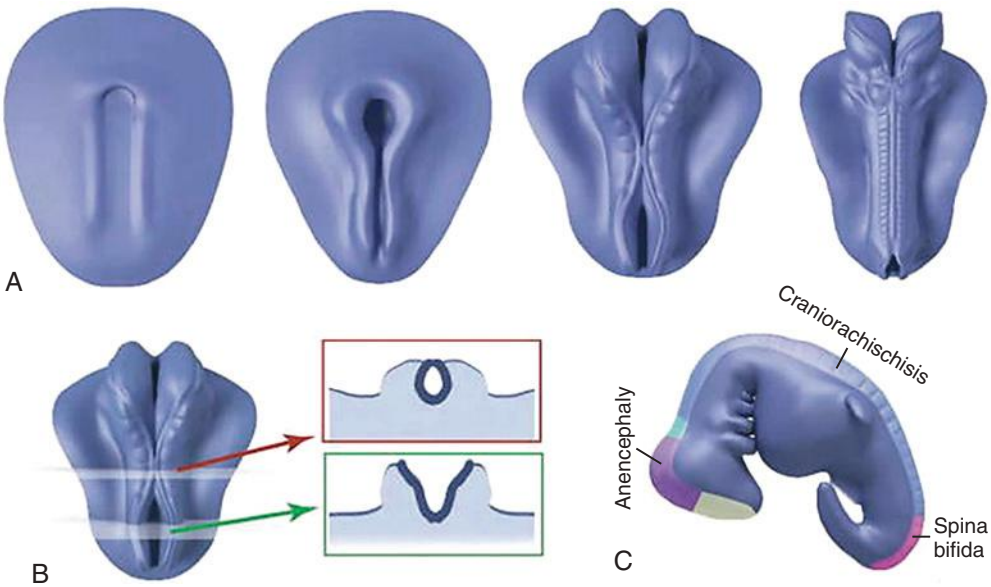

FIG 9-2 **A,** Successive images showing the time course of neural tube closure in a stylized vertebrate embryo (rostral = up). Initially, the central nervous system is a flat sheet; paired neural folds elevate along the rostrocaudal axis and move medially, eventually fusing to enclose the neural tube. **B,** Cross sections illustrate closed (*red arrow*) and open (*green arrow*) regions of the neural tube. **C,** Region-specific neural tube defects. (From Wallingford JB, Niswander LA, Shaw GM, Finnell RH: The continuing challenge of understanding, preventing, and treating neural tube defects. Science 339(6123):1222002, 2013.)

FIG 9-3 Sonogram of the fetal brain in an embryo (8 weeks 5 days of gestation). The prominent fourth ventricle precursor (rhombencephalon) (*arrow*) should not be mistaken for ventriculomegaly or another central nervous system anomaly.

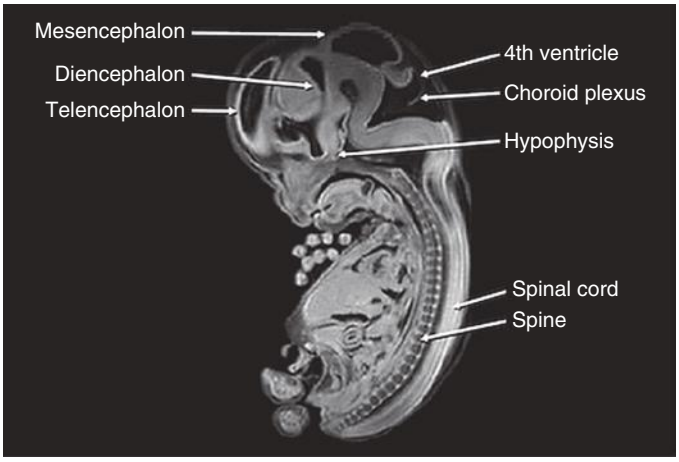

FIG 9-4 Sectional magnetic resonance image of Carnegie stage 23 (10 weeks' gestational age) human embryo. (From Pooh RK, Shiota K, Kurjak A: Imaging of the human embryo with magnetic resonance imaging microscopy and high-resolution transvaginal 3-dimensional sonography: human embryology in the 21st century. Am J Obstet Gynecol 204(1):77.e1–16, 2011.)

Ventriculomegaly

Enlargement of the lateral cerebral ventricles, commonly referred to as *ventriculomegaly* (Fig. 9-5), is a nonspecific marker of abnormal brain development. The presence of normal fetal lateral ventricles on ultrasound examination decreases the risk of a CNS anomaly, whereas detection of ventriculomegaly increases the risk that a significant malformation is present. Although many different approaches to the evaluation of the lateral ventricles have been proposed, measurement of the width of the atrium (or posterior horn) of the lateral ventricle is currently favored. In a normal fetus, the measurement of the lateral ventricle should be less than 10 mm between 15 and 40 weeks' gestation. In most fetuses with significant ventricular enlargement, the ventricles are symmetrically affected whereas cases with milder degrees of ventriculomegaly are more commonly unilateral. Male fetuses have a slightly larger atrial size than female fetuses. A study by Patel and associates[2] demonstrated that atrial size demonstrated a near-normal distribution, with mean size for all subjects 6.1 mm ± 1.3 (standard deviation [SD]). When separated by sex, the mean atrial diameter of 122 female fetuses was 5.8 mm ± 1.3, and the mean atrial diameter of 97 male fetuses was 6.4 mm ± 1.3. The difference in mean size was statistically significant ($P < 0.005$).[2] Thus, a ventricular atrial measurement of 10 to 11 mm will have more significance in a female fetus than in a male fetus.

A ventricular atrial width of more than 15 mm indicates *severe ventriculomegaly*. This is almost always associated with an intracranial malformation, although the outcome is variable and depends largely upon the underlying cause. The available studies suggest that fetuses with isolated severe ventriculomegaly have an increased risk of perinatal death and a probability of severe long-term neurologic sequelae in at least 50% of survivors.[2]

An intermediate value of the atrial width, 10 to 15 mm, is commonly referred to as *mild ventriculomegaly* and is less frequently associated with significant CNS anomalies, although it can be seen with ACC and open neural tube defects.[3,4] Mild ventriculomegaly is also associated with chromosomal aberrations: the risk of trisomy 21 is increased 3.8 times when ventricular enlargement is an isolated finding.[5] Fetal infections, such as cytomegalovirus (CMV), may result in ventricular enlargement, although usually other sonographic abnormalities are also present (areas of focal cerebral increased echogenicity, microcephaly, and porencephaly). When mild ventriculomegaly is isolated, and associated anomalies are absent, most infants are asymptomatic after birth. However, several reports have indicated that some fetuses are found to have severe CNS anomalies in advanced gestation or after birth (hydrocephalus, white matter injury, and cortical plate abnormalities), and some studies have reported an increased risk of neurologic compromise. Studies reporting on the prognosis of mild ventriculomegaly have been limited by the lack of standardized follow-up protocols and difficulty in defining "normal" neurologic outcome. However, most fetuses with mild ventriculomegaly will have a normal outcome, whereas about 10% demonstrate neurodevelopmental abnormalities of variable types and magnitude.[4]

When mild ventriculomegaly is encountered, it is important to rule out associated anomalies. A targeted sonographic survey of fetal anatomy should be performed, with particular attention to details of the CNS. Fetal diagnostic testing for aneuploidy should be offered, and chromosomal microarray should be considered. Detailed ultrasound assessment of the CNS may be enhanced by transvaginal scanning, particularly if the fetus is in cephalic presentation. There is some debate as to whether fetal MRI is indicated in all cases of apparently isolated ventriculomegaly.[4] This technique may provide significant diagnostic information, as it allows more detailed assessment of the developing fetal brain and detection of disorders of sulcation, cortical malformations, and migrational abnormalities. In continuing pregnancies in which mild ventriculomegaly has been identified, standard obstetric management is recommended.

Neural Tube Defects

The incidence, cause, and recurrence risk of neural tube defects are reported in Tables 9-1 through 9-3. There are several different forms of neural tube defects.

Anencephaly is characterized by the absence of the cranial vault and telencephalon. The diagnosis is made by ultrasound in the second and third trimesters and relies upon demonstration of the absence of the cranial vault. In addition, most cases can be confidently identified by 11 to 13 weeks' gestation. At this time, the fetal head can be recognized as overtly abnormal owing to lack of an ossified calvarium (Fig. 9-6).[6]

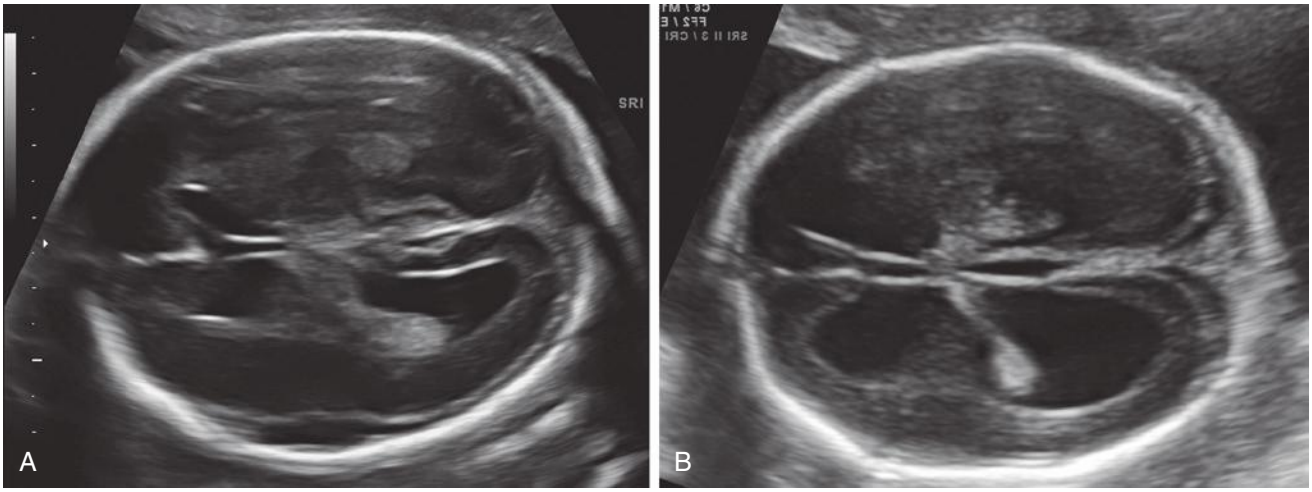

FIG 9-5 Fetal lateral cerebral ventriculomegaly. **A,** Mild ventriculomegaly (atrial width 11 mm); **B,** severe ventriculomegaly (atrial width 16 mm) with "dangling choroid."

Modified from Brocklehurst G: Spina bifida. In Vinken PJ, Bruyn GW (eds): Handbook of Clinical Neurology. Amsterdam, Elsevier/North Holland Biomedical Press, 1978, vol. 32, pp 519–578.

The terms *acrania* and *exencephaly* have also been used to describe this appearance; these represent early stages in the development of anencephaly. The outcome of anencephaly is uniformly fatal.

Spina bifida can occur in open as well as closed forms. Open spina bifida is characterized by a full-thickness defect of the skin, underlying soft tissues, and vertebral arches, with exposure of the neural canal. These defects may vary considerably in size, with the lumbar and sacral areas most frequently affected. Leakage of cerebrospinal fluid through the defect results in an increased concentration of alpha-fetoprotein (AFP) and acetylcholinesterase in the amniotic fluid and maternal serum, and measurement of maternal serum and amniotic fluid AFP can be used to screen for neural tube defects.

Open spina bifida can be identified sonographically by demonstrating the opening of the neural tube and the defect in the vertebrae (splaying outward of the posterior elements) as well as the overlying soft tissues (Fig. 9-7). A cyst formed by the fusion of the malformed cord and meninges (myelomeningocele) is usually found. In a minority of cases, there is no covering membrane (myelocele). The diagnosis of a neural tube defect may be difficult and requires meticulous scanning. Examination of the fetal head is of great utility, as open spina bifida is consistently associated with characteristic and readily recognizable intracranial lesions. Leakage of cerebrospinal fluid leads to displacement of the cerebellum and medulla oblongata through the foramen magnum inside the upper cervical canal (Chiari type II or Arnold-Chiari malformation). Sonographically, this results in small head measurements in the midtrimester, as well as obliteration of the cisterna magna; small size and abnormal shape of the cerebellum (banana sign), which is located deep in the posterior fossa; scalloping of the frontal bones (lemon sign); and ventriculomegaly. Another characteristic abnormality is a "pointed" appearance of the occipital horns of the lateral ventricle. The occipital point is a common supratentorial feature of the Chiari II malformation. It is seen more commonly in fetuses younger than 24 weeks and in those with normal-sized ventricles. Interestingly, it is seen as commonly among fetuses with mild posterior fossa deformations as in those with more severe distortions[7] (see Fig. 9-7). Overall, the detection rate of open spina bifida at the midtrimester obstetric sonogram has been reported to be at least 90%.[8-10] Abnormalities of the posterior fossa and lateral ventricles have also been described at 11 to 13 weeks' gestation, but the diagnostic accuracy of these findings to screen for spina bifida is still being assessed.

Several other neural axis abnormalities are frequently associated with myelomeningocele and Chiari II malformation, both intracranial and extracranial. These abnormalities are known to exist in the presence of myelomeningocele, and thus, when observed, the fetus should not be considered to have "multiple anomalies" (Table 9-4).

There is a correlation between the location (vertebral level) and extension of the spinal lesion and the neurologic outcome. In general, lower and smaller defects result in less severe neurologic compromise. The level of the bony spinal lesion can be determined by counting the affected vertebrae either from the most distal vertebra (in the second trimester fetus, the lowest ossified vertebra is S4) or from the rib cage (which ends at T12). Antenatal ultrasound assessment correlates reasonably well with postnatal assessment (75%), and MRI has been found to add little to determination of the bony level of the defect. However, it is not possible to precisely predict motor function, morbidity, or developmental milestones.[11] Of note, the degree of ventricular enlargement does correlate with the need for postnatal shunting.[12]

Antenatal counseling after detection of fetal spina bifida is complex and should involve a multidisciplinary team. Postnatal hydrocephalus requiring shunting, causing incontinence, and resulting in motor

TABLE 9-2 Recognized Causes of Neural Tube Defects

Multifactorial Inheritance
Anencephaly, myelomeningocele, meningocele, and encephalocele

Mendelian Syndromes
Pallister-Hall syndrome
Meckel-Gruber syndrome, autosomal recessive (phenotype includes occipital encephalocele and rarely anencephaly)
Median-cleft face syndrome, possibly autosomal dominant (phenotype includes anterior encephalocele)
Robert syndrome, autosomal recessive (phenotype includes anterior encephalocele)
Syndrome of anterior sacral meningomyelocele and anal stenosis (dominant, either autosomal or X-linked)
Jarcho-Levin syndrome, autosomal recessive (phenotype includes meningomyelocele)
HARD(E) syndrome (hydrocephalus, agyria, retinal dysplasia, ± encephalocele), autosomal recessive (phenotype includes encephalocele)

Chromosome Abnormalities
Trisomy 13
Trisomy 18
Triploidy
Other abnormalities, such as unbalanced translocations and ring chromosome

Probably Hereditary but Mode of Transmission Not Established
Syndrome of occipital encephalocele, myopia, and retinal dysplasia
Anterior encephalocele among Bantus and Thais

Teratogens
Valproic acid (spina bifida)
Phenytoin
Carbamazepine
Aminopterin/amethopterin (anencephaly and encephalocele)
Exposure to high heat caused by fever
Monozygotic twinning

Maternal Predisposing Factors
Diabetes mellitus (anencephaly more frequently than spina bifida)
Obesity
Methyltetrahydrofolate reductase (*MTHFR*) gene carrier

Specific Phenotypes, Without Known Cause
Syndrome of craniofacial and limb defects secondary to amniotic bands (phenotype includes multiple encephaloceles)
Cloacal exstrophy (phenotype includes myelocystocele)
Sacrococcygeal teratoma (phenotype includes myelomeningocele)

Modified from Main DM, Mennuti MT: Neural tube defects: issues in prenatal diagnosis and counselling. Obstet Gynecol 67(1):1–16, 1986.

TABLE 9-3 Estimated Incidence of Neural Tube Defects (NTDs) Based on Specific Risk Factors in the United States

Population	Incidence per 1000 Live Births
Mother as Reference	
General incidence	1.4-1.6
Women undergoing amniocentesis for advanced maternal age	1.3-3.0
Women with diabetes mellitus	20
Women on valproic acid in first trimester	10-20
Fetus as Reference	
One sibling with NTD	15-30
Two siblings with NTD*	57
Parent with NTD	11
Half sibling with NTD	8
First cousin (mother's sister's child)	10
Other first cousins	3
Sibling with severe scoliosis secondary to multiple vertebral defects	15-30
Sibling with occult spinal dysraphism	15-30
Sibling with sacrococcygeal teratoma or hemartoma	~15-30

*Risk is higher in British studies. Risk increases further for three or more siblings or combinations of other close relatives.
Modified from Main DM, Mennuti MT: Neural tube defects: issues in prenatal diagnosis and counselling. Obstet Gynecol 67(1):1–16, 1986.

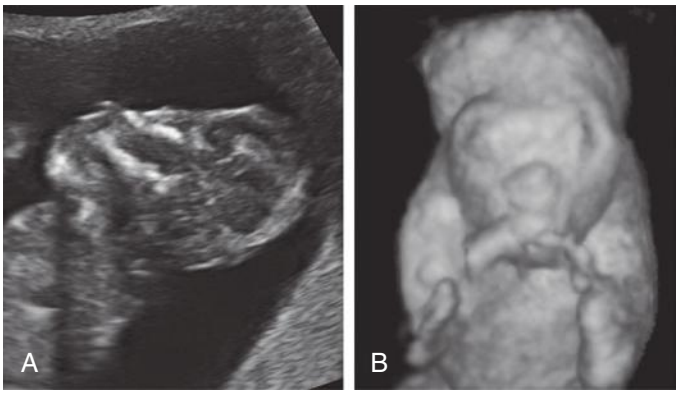

FIG 9-6 Anencephaly at 13 weeks' gestation. **A,** Two-dimensional midline sagittal sonographic image; **B,** three-dimensional sonogram.

weakness requiring wheelchair use is common. Options for management of an affected pregnancy include termination, expectant management with postnatal repair, and in utero surgical repair[13-15] (see Chapter 24). The benefit of cesarean delivery to improve neurologic outcome of infants with open spina bifida is uncertain.[16,17]

Closed spina bifida is characterized by a vertebral defect (schisis) covered by skin. Most defects are small, involving only a few vertebral segments, and the classic intracranial signs (lemon-shaped calvarium, banana-shaped cerebellum, ventriculomegaly) are absent (Fig. 9-8). As a consequence, the sonographic diagnosis of closed spina bifida is difficult and in practice is only possible in those cases that are associated with a subcutaneous mass, such as a meningocele or lipoma overlying the bony defect.[8] The outcome of closed spina bifida is difficult to predict. These infants do not develop Arnold-Chiari malformation or hydrocephalus. However, those with subcutaneous masses may suffer from neurologic sequelae, including weakness or paralysis of the lower extremities and incontinence, usually as a consequence of tethering or compression of the spinal cord.

The term *cephalocele* is used to describe a protrusion of intracranial contents through a bony defect of the skull.[18-20] Most commonly, these lesions arise from the midline, in the occipital area; they arise less commonly from the parietal or frontal bones. *Encephaloceles* are

FIG 9-7 Open spina bifida (myelomeningocele). **A,** Typical associated intracranial findings including scalloping of the bilateral frontal bones and small posterior fossa with obliteration of the cisterna magna. **B,** Large vertebral defect with overlying septated cyst. **C,** Axial sonographic image of a fetus with Chiari II malformation and normal-size ventricle showing pointed configuration (*arrow*) of the occipital horn. TABLE 9-4 Frequency of Brain and Spine Anomalies in Patients With Chiari II Malformations

Anomaly	Frequency
Myelomeningocele	Always
Hydrocephalus	Almost always
Dysplastic tentorium	Almost always
Small posterior fossa	Almost always
Luckenschädel	Almost always
Caudal displacement of brainstem	Usually
Cervicomedullary kink	Usually
Upward cerebellar herniation	Usually
Large massa intermedia	Usually
Elongated cranial nerves	Usually
Tectal beak	Usually
Callosal hypogenesis	Usually
Syringohydromyelia	~50%
Malformations of cortical development	Occasionally
Aqueductal stenosis	Occasionally

From Barkovich AJ, Raybaud C (eds): Pediatric Neuroimaging, 5th ed. Philadelphia, Lippincott Williams & Wilkins, 2012.

characterized by the presence of brain tissue in the lesion. When only meninges protrude, the term *cranial meningocele* is used. Cephaloceles often cause impaired cerebrospinal fluid circulation and hydrocephalus, and massive encephaloceles may be associated with microcephaly. Associated anomalies are frequent (Table 9-5). Fetal cephaloceles are suspected when a paracranial mass is seen on sonography (Fig. 9-9). The diagnosis of encephalocele is typically straightforward, as the presence of brain tissue inside the sac is striking on ultrasound images, although distinguishing a cranial meningocele from soft tissue edema or a cystic hygroma of the neck may be difficult. The diagnosis of cephalocele is favored when it is possible to demonstrate a bony defect in the cranial vault or associated cerebral abnormalities, such as ventriculomegaly. The pediatric literature suggests that the outcome of cephaloceles is primarily related to the presence or absence of brain tissue inside the lesion. The largest available antenatal series reports a dismal prognosis for both varieties,[21] with the possible exception of small lesions associated with normal intracranial anatomy.

Midline Anomalies

Midline cerebral anomalies include a group of brain defects that encompass a wide spectrum of severity and are often associated with craniofacial malformations.

The *holoprosencephalies* are complex abnormalities of the forebrain characterized by incomplete separation of the cerebral hemispheres and formation of diencephalic structures. They are rarely seen at birth owing to a high intrauterine mortality rate, although these disorders are relatively common in series of antenatally detected CNS anomalies. The cause of holoprosencephaly is heterogeneous, and in most cases, the anomaly is isolated and sporadic. However, holoprosencephaly may also be associated with chromosomal abnormalities (trisomy 13 and polyploidy), a number of single gene disorders, and other anatomic abnormalities.

The most widely accepted classification of these disorders recognizes three major varieties: the alobar, semilobar, and lobar types. In addition, a middle interhemispheric variant is described (Fig. 9-10).

The alobar, semilobar, and middle interhemispheric variant types have a similar appearance on antenatal ultrasound imaging: there is no midline echo anteriorly (absent septum pellucidum), and a single ventricular cavity is present (Fig. 9-11). In the *alobar* form, which is the most severe, the interhemispheric fissure, falx cerebri, and corpus callosum are absent; there is a single primitive ventricle; the thalami are fused in the midline; and there is absence of the third ventricle, neurohypophysis, and the olfactory bulbs and tracts. In *semilobar* holoprosencephaly, the two cerebral hemispheres are partially separated posteriorly but there is still a single ventricular cavity. The splenium of the corpus callosum is present without the genu or body of the corpus callosum.[18,22,23] In both alobar and semilobar holoprosencephaly, the roof of the ventricular cavity, the *tela choroidea* (which is normally enfolded within the brain), may balloon out between the cerebral convexity and the skull to form a cyst of variable size called the *dorsal sac.* Both of these forms are often associated with microcephaly, though they can sometimes be associated with macrocephaly because of a dorsal cyst or obstructive hydrocephalus.

In *lobar holoprosencephaly,* the interhemispheric fissure is well developed posteriorly and anteriorly, but there is a variable degree of fusion of the cingulate gyrus and the lateral ventricles, and the septum pellucidum is absent. In the *middle hemispheric* variant, fusion occurs primarily at the level of the bodies of the lateral ventricles, whereas the frontal horns and posterior horns are relatively well developed.[24]

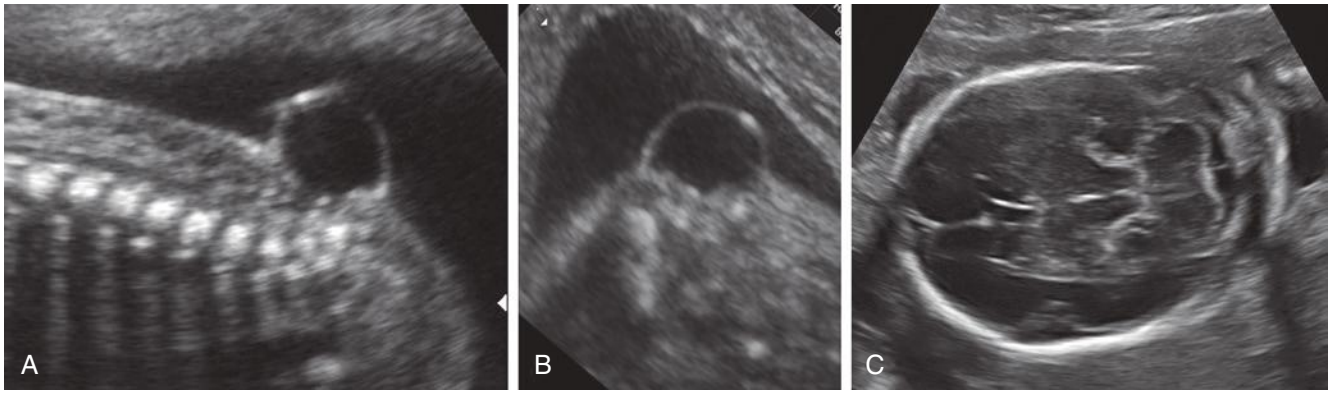

FIG 9-8 Closed, or skin-covered, cystic spina bifida (meningocele). **A** and **B,** Small vertebral defect with an overlying nonseptated cyst; **C,** normal intracranial anatomy.

TABLE 9-5 Conditions Associated With Cephaloceles

Amniotic band syndrome (sporadic)
Multiple cephaloceles, predominantly anterior
Amputations of digits or limbs
Bizarre oral clefts
Chemke syndrome (AR)
Hydrocephaly
Agyria
Cerebellar dysgenesis
Cryptophthalmos syndrome (AR)
Forehead skin covers one or both eyes
Ear abnormalities
Soft tissue syndactyly
Dyssegmental dysplasia (AR)
Short limb skeletal dysplasia
Metaphyseal widening
Small thorax
Micrognathia
Frontonasal dysplasia (sporadic, some cases are familial)
Frontal cephalocele
Ocular hypertelorism
Meckel-Gruber syndrome (AR)
Polycystic kidneys
Polydactyly
Microphthalmia
Orofacial clefting
Ambiguous genitalia
von Voss–Cherstvoy syndrome
Agenesis of the corpus callosum
Phocomelia
Urogenital anomalies
Thrombocytopenia
Warfarin syndrome
Nasal hypoplasia
Bone stippling
Limb shortening
Hydrocephaly

Modified from Cohen MM Jr, Lemire RJ: Syndromes with cephaloceles. Teratology 25(2):161–172, 1982.

Gross facial abnormalities (cyclopia, hypotelorism, and absence of the nose) are frequently associated with alobar and semilobar holoprosencephaly (Fig. 9-12). Facial malformations include cyclopia and severe hypotelorism with median cleft lip/palate. The nose may be absent, replaced by a proboscis, or flattened.[25] Facial anomalies are rarely associated with lobar holoprosencephaly or the middle interhemispheric variant.

Prenatal diagnosis of alobar or semilobar holoprosencephaly depends on the demonstration of a single rudimentary cerebral ventricle, which may protrude posteriorly through the incompletely enfolded cortex to form a dorsal sac. Additional findings of typical facial anomalies can assist in confirming the diagnosis. In most cases, the diagnosis is possible at 11 to 13 weeks' gestation. The lobar variety is associated with more subtle findings (absence of the septum pellucidum with central fusion of the frontal horns), and this diagnosis is rarely made prior to 20 weeks' gestation (Fig. 9-13).[25]

Infants affected by alobar and semilobar holoprosencephaly have an invariably poor prognosis. Antenatally diagnosed lobar holoprosencephaly is also associated with poor postnatal neurodevelopmental outcomes.[26]

ACC is an anomaly of uncertain prevalence and variable clinical significance. The best estimates suggest a prevalence of approximately 1.4 per 10,000 live births in the general population and 2% to 3% in the developmentally disabled.[27,28] The cause of ACC is heterogeneous. Genetic causes are common, and the anomaly is associated with a number of different genetic syndromes. The high frequency of associated malformations and chromosomal aberrations suggests that ACC is often part of a widespread developmental disturbance. ACC may be either complete or partial. In the latter case, also referred to as dysgenesis or partial agenesis, the caudad or posterior portion is missing to varying degrees. *Hypoplasia* refers to a corpus callosum of normal length but with much decreased thickness; this is rarely identified by prenatal sonography.

The diagnosis of ACC is possible from midgestation onward[29] but can be challenging even for expert sonologists.[30] The anatomic elements useful for reaching this diagnosis are summarized in Figure 9-14.

Characteristic changes of the ventricular system and cerebral hemispheres were first described by Davidoff and Dyke in 1934 based upon observations made by pneumoencephalography.[31] They noticed:

- Lateral separation of the frontal horns and bodies of the lateral ventricles
- Angled lateral peaks of the frontal horns and bodies of the lateral ventricles

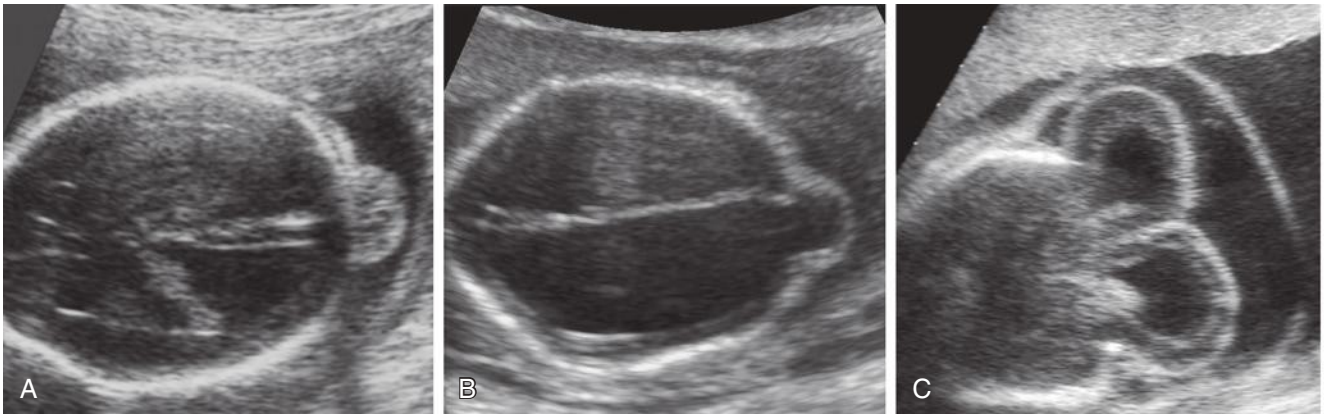

FIG 9-9 Cephalocele. **A,** Small occipital cephalocele; **B,** small occipital cephalocele with severe ventriculomegaly; **C,** large occipital cephalocele with large cranial defect and marked extracranial displacement of the brain.

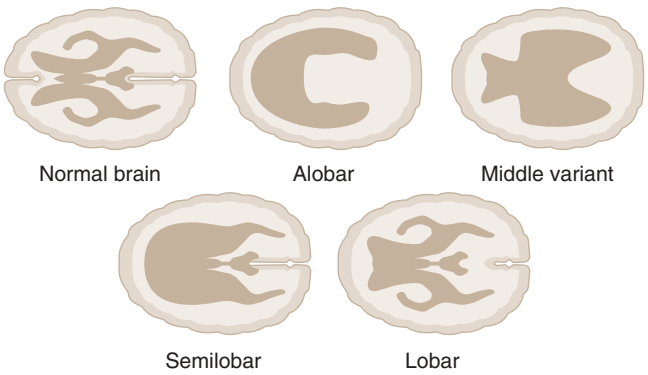

FIG 9-10 Categorization of holoprosencephaly.

- Elevation and variable dilatation of the third ventricle
- Dilatation of the occipital horns
- Concave medial wall of the lateral ventricles related to the bundles of Probst
- Abnormal radial orientation of medial cerebral gyri extending from the roof of the third ventricle

In a series of fetuses with ACC, Bertino and colleagues[32] reported that a minority demonstrated a characteristic midline cyst. They described three findings that might lead one to suspect ACC on routine transverse views of the fetal brain:

1. Disproportionate enlargement of the occipital horn (colpocephaly)
2. Demonstration of both medial and lateral ventricular walls at a level where the single periventricular line is normally demonstrated
3. A more parallel course of both ventricular walls than normal

Complete ACC is usually suspected on midgestation obstetric sonograms based on absence of the cavum septi pellucidi (CSP) and characteristic configuration of the lateral ventricles with increased separation of the frontal horns and mild enlargement of the posterior horns with "teardrop" shape, frequently associated with mild ventriculomegaly. The two hemispheres tend to appear more separated than usual in the central portion of the brain. In coronal section, the frontal horns appear more widely spaced than usual and have a comma-like shape. In the transverse axial plane, the lateral ventricles have a teardrop shape with posterior enlargement of the atria and occipital horns, referred to as *colpocephaly.*

Once suspected, definitive diagnosis of ACC may be made by demonstrating absence of the corpus callosum in the coronal and sagittal planes (Fig. 9-15).[20] Diagnosis of partial agenesis is also possible, although the sonographic findings are subtler than those seen in complete ACC. With partial agenesis, the CSP is usually present and the axial images may be unremarkable. The diagnosis requires a midline sagittal view demonstrating that the corpus callosum is shorter than normal and does not form a complete arch over the third ventricle (Fig. 9-16). Visualization of the pericallosal artery with color Doppler sonography may be useful if complete or partial ACC is suspected (Fig. 9-17). Charts listing normal size of the corpus callosum are available for reference but should be used with caution as partial agenesis is relatively rare, and a clear threshold defining pathologic appearance has not been established. Most cases diagnosed antenatally have had a reduction in size of 50% or more. We have detected many cases with measurements of the corpus callosum below the 5th centile, and most have resulted in the birth of normal children.

Complete or partial ACC is frequently associated with a genetic syndrome (Table 9-6) or other malformations. One syndrome that may be associated with ACC is Aicardi syndrome, an X-linked dominant syndrome that consists of infantile spasms, callosal agenesis or hypogenesis, chorioretinopathy, severe global developmental delay, and medical refractory epilepsy.[33,34] Imaging findings include ACC, heterotopias, cortical dysplasia, posterior fossa cysts, cerebellar hypoplasia, choroid plexus papillomas, and microphthalmia. Assessment of fetal sex can be helpful if this disorder is suspected, as it is seen at birth only in female infants.

A recent systematic review of 16 studies assessed neurodevelopmental outcome in 132 fetuses with isolated ACC.[35] With complete ACC, the outcome was normal in 74.3%, borderline or with moderate disability in 14.3%, and associated with severe disability in 11.4%. The outcome was slightly less favorable, although not significantly different, with partial ACC (65.5%, 6.9%, and 27.6%, respectively). When considering only those studies using MRI confirmation and standardized tools of neurodevelopmental assessment, in cases with complete ACC, the rates were 83.7%, 8.2%, and 8.2% for normal, borderline/moderate, and severe disability, respectively. The corresponding rates for partial ACC were not reported because of the small number of cases. The authors of the review highlighted many limitations in existing studies, including limited and inconsistent data that prevented subgroup analyses. Providing a precise estimate of the risk of neurodevelopmental delay is difficult, and one important limitation of the available studies is the length of time of follow-up. In most cases, assessment was made in the preschool period. This may represent an important shortcoming, as in one series a progressive decline of

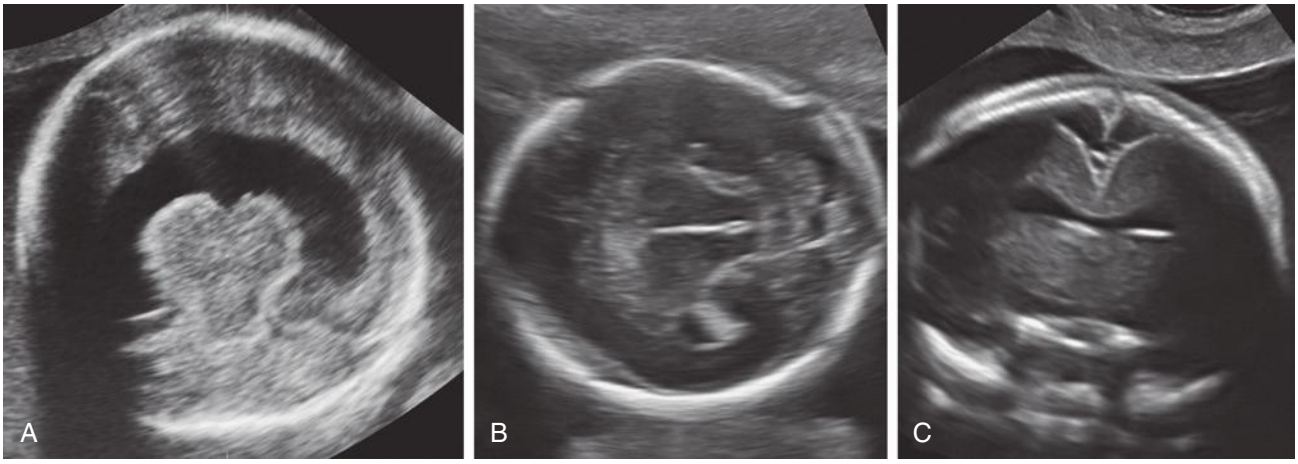

FIG 9-11 Holoprosencephaly. **A,** Alobar holoprosencephaly with a large single ventricular cavity (monoventricle) and fused thalami; **B,** milder case with subtle findings—the anterior midline structures are absent. The single ventricular cavity and absent septum were best demonstrated by means of transvaginal sonographic image in the coronal plane (**C**).

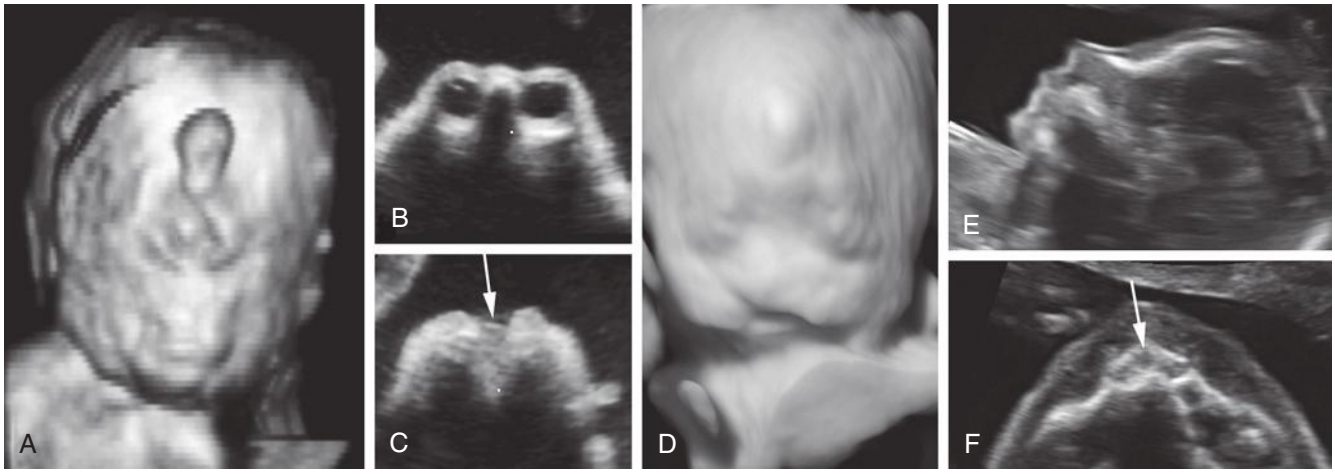

FIG 9-12 Facial anomalies associated with holoprosencephaly. **A,** Three-dimensional ultrasound image of cyclopia, with proboscis protruding above the single orbit; **B** through **D,** marked hypotelorism and median cleft lip (*arrow*); **E** and **F,** subtle facial features of holoprosencephaly—although the midline sagittal profile view appears normal, meticulous scanning reveals a single median incisor tooth (*arrow*).

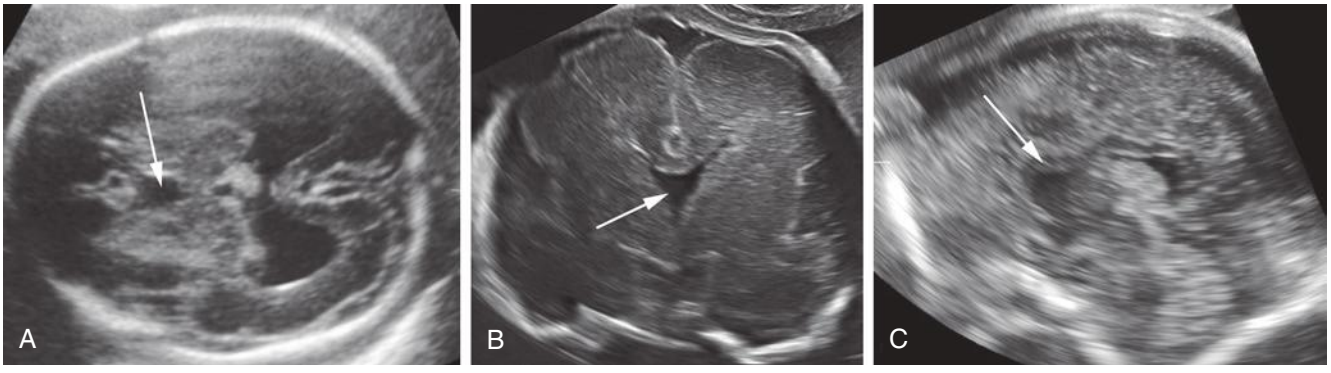

FIG 9-13 Lobar holoprosencephaly. **A** and **B,** The predominant finding on axial and coronal ultrasound images is the absence of the septum pellucidum (*arrows*) and the diminutive frontal horns. **C,** The typical configuration of the corpus callosum is absent and has been replaced by irregular fibers connecting the two hemispheres in the midline (*arrow*).

intellect was noted, with a considerable number of children demonstrating learning difficulties in school.

The *septum pellucidum*, with the inferior fornix, forms the medial border of the lateral ventricles. It contains two leaves that in fetal life are separated by a fluid-filled cavity, the *CSP*. The leaves fuse in late gestation or immediately after birth, and the cavity is seen only in a minority of adults. *Absence of the septum pellucidum* in fetuses can be associated with a number of CNS anomalies including ACC, holoprosencephaly, destruction secondary to raised intraventricular pressure, schizencephaly, and septo-optic dysplasia (de Morsier syndrome). Isolated absence of the septal leaves with central fusion of the frontal horns is possible and is usually of no consequence (Fig. 9-18). The greatest challenge is to differentiate isolated absence of the CSP from septo-optic dysplasia. Visualization of the optic chiasma by either MRI or three-dimensional ultrasound is useful but does not always provide a definitive diagnosis. Although data are limited, two thirds of fetuses with absent CSP have been reported to be normal at birth. If a normal optic chiasma can be demonstrated, the probability of a normal outcome increases to 90%.[36]

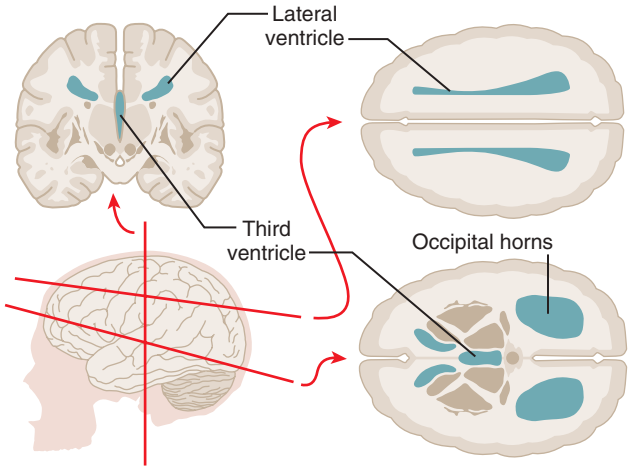

FIG 9-14 Schematic diagram of agenesis of the corpus callosum without interhemispheric cyst. On a coronal view (*top left*), the widely spaced lateral ventricles are shown pointing cephalad. On an axial view superiorly (*top right*), both medial and lateral walls of the lateral ventricles are identified. A more inferior axial view (*bottom right*) reveals dilatation of the occipital horns (colpocephaly) and separation of the frontal horns. The third ventricle may or may not be dilated.

Cystic and Cyst-like Abnormalities of the Posterior Fossa

Fluid collections in the fetal posterior fossa encompass a wide spectrum of entities, ranging from normal variants to severe anomalies (Table 9-7).

In the late first trimester, the fourth ventricle is large and the cerebellum is relatively small. In the following weeks, the cerebellum grows to completely enfold the fourth ventricle. However, a small finger-like appendage of the fourth ventricle, the Blake pouch, is frequently seen protruding into the cisterna magna, caudal to the cerebellum. It has been suggested that there is a continuum of anatomic anomalies involving the fourth ventricle–Blake pouch complex (Fig. 9-19).[37-40] The mildest of these anomalies is the *Blake pouch cyst*, an isolated persistence of the Blake pouch. This term was originally introduced in the pediatric neuroradiology literature to indicate a compressive cyst of the posterior fossa that displaced the cerebellar vermis superiorly and caused obstructive hydrocephalus. Recently, the same term has been used more frequently in fetal imaging to describe cases in which a posterior fossa cyst was seen to superiorly displace an intact cerebellar vermis, typically in association with a normal ventricular system and normal size of the posterior fossa. The entities described in the original neonatal literature and later described in fetal reports are likely different, as the latter typically has a normal outcome and is rarely associated with ventriculomegaly. *Mega-cisterna magna* may be a variation of the Blake pouch cyst that does not result in superior displacement of the vermis.

In the largest available series, Blake pouch cyst and mega-cisterna magna were the two most common entities described antenatally, representing about 50% of all cystic anomalies of the fetal posterior fossa.[39] These two conditions share many clinical similarities. Although they may be associated with other anomalies, when isolated, they undergo spontaneous resolution during gestation in one third of cases, and regardless of resolution, they result in normal postnatal neurodevelopment in about 90% of cases.[39]

Dandy-Walker malformation (DWM) is relatively rare, with an estimated prevalence of approximately 1 in 30,000 births, and is associated

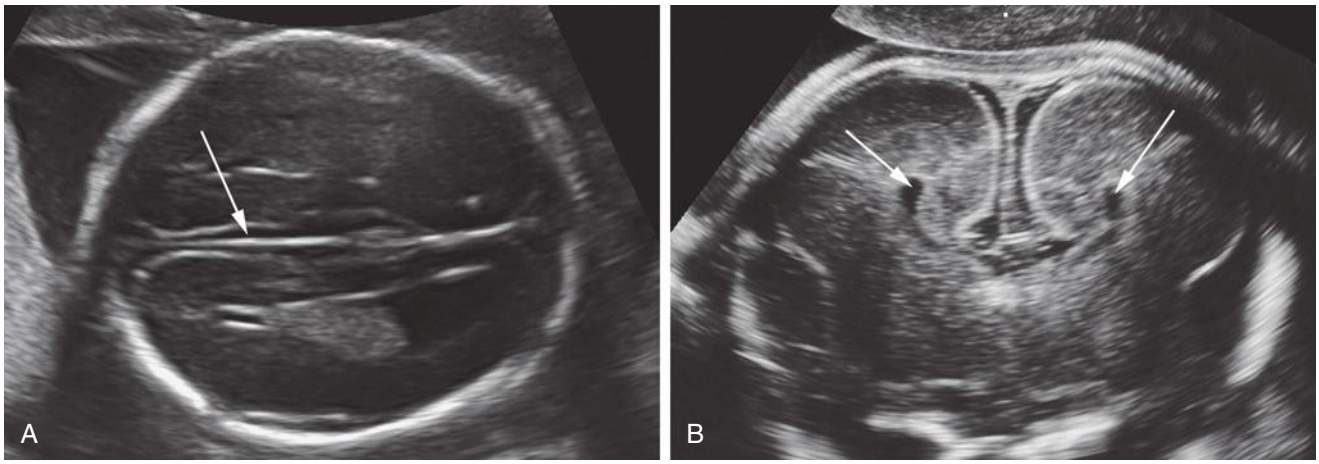

FIG 9-15 Complete agenesis of the corpus callosum. **A,** The axial plane reveals mild enlargement of the lateral ventricles, which have a typical teardrop shape, absence of the cavum septi pellucidi and distention of the interhemispheric fissure, which is centrally partitioned by the falx cerebri (*arrow*). **B,** The coronal plane demonstrates the large interhemispheric fissure, the absence of any bridging structure connecting the two hemispheres, and the lateral separation of the frontal horns that appear medially concave (*arrows*).

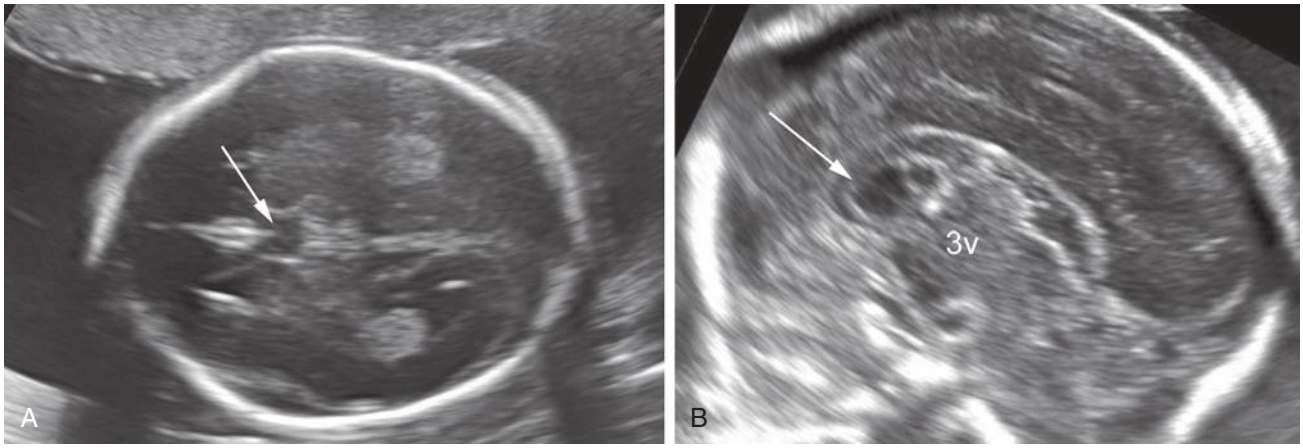

FIG 9-16 Partial agenesis of the corpus callosum. **A,** This axial image shows a relatively normal appearance of the cavum septi pellucidi (*arrow*). **B,** The midline sagittal view demonstrates a corpus callosum (*arrow*) that is short (the arch does not completely cover the area of the third ventricle [3v] and the measurement is about 50% the expected length at this gestational age) and irregular in shape.

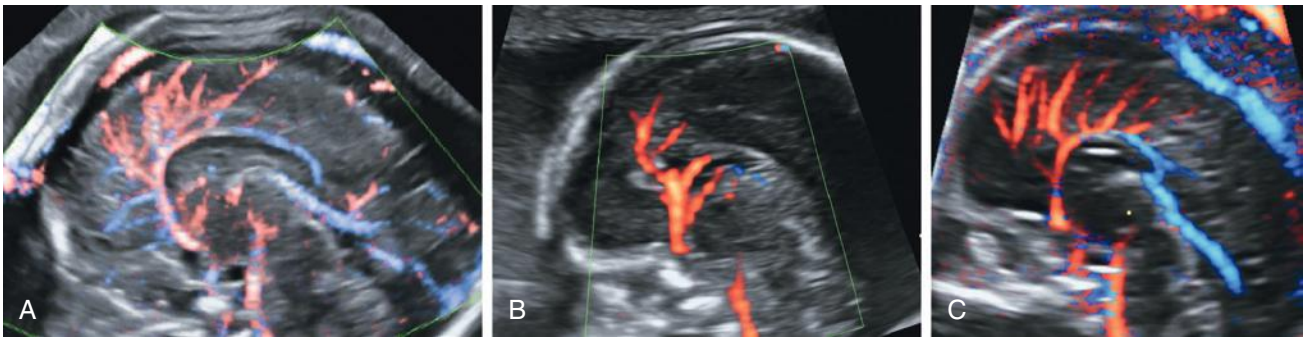

FIG 9-17 Pericallosal artery. **A,** In a normal fetus, color Doppler sonography demonstrates the pericallosal artery, which courses adjacent to and highlights the corpus callosum. **B,** In complete agenesis of the corpus callosum, the loop of the pericallosal artery is lost. The anterior cerebral artery ascends vertically and branches with a tree-like configuration. **C,** In partial agenesis of the corpus callosum, the pericallosal artery forms an unusually short loop.

with 4% to 12% of infantile hydrocephalus. The main features of DWM are enlargement of the cisterna magna and superior displacement of the cerebellar vermis, which may be intact or incompletely formed. Historically, hydrocephalus was considered an essential diagnostic element of DWM, but more recent evidence suggests that it is not present at birth in most patients, though it may develop later in life. DWM is frequently associated with other CNS (ACC, holoprosencephaly, or encephalocele) and non-CNS anomalies (polycystic kidneys, cardiovascular defects, and facial clefts) and genetic conditions (Table 9-8). When isolated, the outcome is variable. In antenatal studies, approximately 50% of surviving infants are reported to have normal intelligence, and 50% have variable degrees of neurodevelopmental disability.[39]

Vermian agenesis/hypoplasia is characterized by an absent or small cerebellar vermis with a normal cisterna magna. This condition was originally labeled *Dandy-Walker variant*, a term that has fallen out of favor. Follow-up studies of children with antenatally diagnosed vermian agenesis or hypoplasia have reported widely variable outcomes, ranging from largely normal in some series, to a high prevalence of neurologic compromise in others.[39,41]

Joubert syndrome and related disorders are a group of conditions characterized by hypoplasia of the cerebellar vermis with a characteristic neuroradiologic finding described as the *molar tooth sign*, which refers to elongation of the superior cerebellar peduncles that gives an appearance reminiscent of a molar or wisdom tooth (Fig. 9-20). These CNS findings can be associated with a variety of non-CNS anomalies and therefore may constitute different syndromes, although all generally share an unfavorable neurologic outcome.[42]

Arachnoid cysts of the posterior fossa are rare and most frequently result in a mass effect on the cerebellar structures. They may be difficult to differentiate from mega-cisterna magna or DWM and should be considered in the differential diagnosis of cystic lesions of the posterior fossa (see later section for further discussion).

With the exception of mega-cisterna magna, in which the diagnostic criteria are clear-cut (the widely accepted definition is a cisterna magna with anteroposterior diameter measuring >10 mm with normal-appearing cerebellum and cerebellar vermis), the other cystic anomalies of the fetal posterior fossa can appear quite similar to each other and thus the differential diagnosis is often difficult. Blake pouch cyst, DWM, vermian hypoplasia/agenesis, and Joubert syndrome share a similar finding: the impression, on an axial image, of communication between the fourth ventricle and the cisterna magna (open fourth ventricle sign). This communication is created by the presence of a cystic structure extending from the roof of the fourth ventricle into the cisterna magna beneath the cerebellar vermis. This observation is frequent in early gestation and becomes significant only when it is demonstrated after 20 weeks' gestation. After this time, the most valuable diagnostic information is obtained from a midsagittal view of the

TABLE 9-6 Syndromes Featuring Agenesis of the Corpus Callosum

Frequent in:
Acrocallosal syndrome (AR)
Aicardi syndrome (X-linked dominant)
Andermann syndrome (AR)
Cerebro-oculo-facio-skeletal (COFS) syndrome (AR)
Fryns syndrome (AR)
Marden-Walker syndrome (AR)
Meckel-Gruber syndrome (AR)
Microphthalmia-linear skin defects syndrome (X-linked dominant)
Miller-Dieker syndrome (lissencephaly syndrome)
Neu-Laxova syndrome (AR)
Septo-optic dysplasia sequence
Walker-Warburg syndrome (X-linked dominant)
Zellweger syndrome (AR)

Occasional in:
Apert syndrome (AR)
Baller-Gerold syndrome (AR)
Calloso-genital dysplasia syndrome (AR)
Coffin-Siris syndrome (?AR)
Congenital microgastria–limb reduction complex (unknown)
Crouzon syndrome (AD)
Duplication 4p syndrome
Fetal alcohol syndrome
Fetal warfarin syndrome
FG syndrome (X-linked recessive)
Frontonasal dysplasia sequence (sporadic/AD)
Gorlin syndrome (AD)
Greig cephalopolysyndactyly syndrome (AD)
Hydrolethalus syndrome (AR, X-linked dominant)
Lens dysplasia (X-linked recessive)
Marshall-Smith syndrome (unknown)
Oculo-auricolo-vertebral spectrum (unknown)
Oculo-cerebro-cutaneous syndrome (Delleman syndrome) (unknown)
Opitz syndrome (AD, X-linked recessive)
Oral-facial-digital syndrome type 1 (X-linked dominant)
Peters-plus syndrome (AR)
Radial aplasia-thrombocytopenia syndrome (AR)
Rubinstein-Taybi syndrome (sporadic)
Shapiro syndrome (X-linked recessive)
Simpson-Golabi-Behmel syndrome (X-linked recessive)
Trisomy 8 syndrome
Trisomy 13 syndrome
Trisomy 18 syndrome
X-linked hydrocephalus spectrum (X-linked recessive)
Turner syndrome (45,X)
49,XXXXY syndrome (hypoplastic)
Yunis-Varon syndrome
Metabolic disorders

AD, autosomal dominant; AR, autosomal recessive.
Modified from Blum A, André M, Droullé P, et al: Prenatal echographic diagnosis of corpus callosum agenesis. The Nancy experience 1982-1989.

brain. Antenatal studies combining the use of sonography and MRI report diagnoses consistent with postnatal confirmation in approximately 90% of cases. Differentiating a Blake pouch cyst from a DWM and diagnosing vermian hypoplasia in early gestation remain diagnostic challenges.[38,39,41]

Intrauterine Cerebral Injuries

Many congenital anomalies of the brain are not the consequence of an embryogenetic malformative process but are due to destructive injury. The pathophysiology is frequently unclear and most of these conditions are idiopathic. An association with obstetric complications may be found in some cases.

Intracranial hemorrhage (ICH) is a frequent complication in premature infants. Rarely, it may occur antenatally, as a consequence of fetal thromobocytopenia or other coagulopathies, trauma, or other unrecognized factors. The sonographic appearance is extremely variable depending upon the type (Table 9-9), location, severity, and chronicity of the bleed (Fig. 9-21). Blood initially appears as a hyperechoic collection; with time, the blood clot retracts and demonstrates hypoechoic components. Antenatal ICH is frequently associated with ventricular dilatation. Large intraventricular hemorrhages may be complicated by infarction and destruction of the surrounding white matter.

As with neonates, there is a correlation between the grade of the in utero fetal hemorrhage and the neurologic outcome. The prognosis is typically favorable with grade 1 and 2 hemorrhage (involving the germinal matrix only, or extending into the ventricle but without ventriculomegaly), which may resolve in utero. More significant degrees of ICH, including grade 3 and 4 lesions (intraventricular hemorrhage with ventriculomegaly, or intraparenchymal involvement), are associated with a higher likelihood of abnormal neurologic development. Most cases identified prenatally are grade 3 or 4; in one review of the literature, 50% of these fetuses died in the perinatal period and 50% of survivors were neurologically impaired.[43] If ICH is suspected, the possibility of fetal alloimmune thrombocytopenia should be addressed. Fetal MRI is particularly helpful in confirming ICH, assessing extent of associated injury, and distinguishing hemorrhage from other intracranial injuries.

Fetal stroke has been documented antenatally.[44] The cause is heterogeneous, but most reported cases have been identified in monochorionic twin gestations, usually as a consequence of in utero co-twin demise or severe hemodynamic compromise associated with twin-to-twin transfusion syndrome. The appearance is variable (Fig. 9-22). Following the initial insult, focal areas of increased cerebral echogenicity may be seen. With evolution, microcephaly, cystic intraparenchymal cavities (porencephaly, schizencephaly, periventricular leukomalacia), and cortical malformations may develop. The outcome is determined by the size and location of the lesion. Microcephaly and extensive porencephaly have a guarded prognosis.

Intrauterine infection is an important cause of congenital brain lesions. Fetuses with CMV infection affecting the brain may present with a wide range of intracranial abnormalities, including periventricular and intraparenchymal echogenic foci, ventriculomegaly, cerebellar hypoplasia, microcephaly, and cortical abnormalities. The most characteristic findings include hyperechoic periventricular halo and septations within the occipital horns of the lateral ventricles (Fig. 9-23). Patients with recent CMV infection and characteristic cerebral findings have symptomatic infection at birth in virtually all cases. The negative predictive value of ultrasound in the setting of maternal CMV infection is more limited, as sonography does not reliably detect intracranial fetal findings in all cases. Recent series suggest that a normal obstetric ultrasound image in the setting of fetal CMV infection is more common in the second trimester than in the third.[45]

Microcephaly

Microcephaly refers to the association of abnormal neurologic development and a small head. The association between both brain mass and total cell number in *microcephalic infants* is well established. The

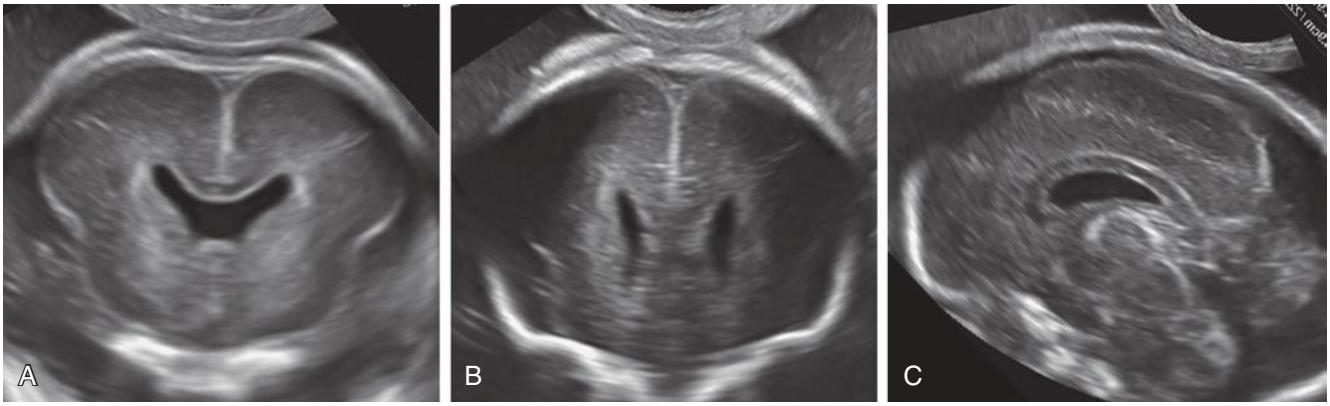

FIG 9-18 Absence of the septum pellucidum. **A,** The frontal horns of the lateral ventricles communicate centrally, and no intervening leaves of the septum pellucidum are seen. **B** and **C,** The anterior coronal and sagittal views appear within normal limits.

TABLE 9-7 Sonographic Findings of Posterior Fossa Cyst and Cyst-like Anomalies

Anomaly	Findings
Mega-cisterna magna	Intact cerebellum; cisterna magna >10 mm
Blake pouch cyst	Cerebellum of normal size, intact vermis with mild rotation (usually <30 degrees)
Dandy-Walker malformation	Cerebellum of normal or diminished size, normal to small vermis with significant rotation (usually >45 degrees), large cisterna magna
Vermian hypoplasia	Cerebellum of normal or diminished size, small dysmorphic vermis with or without moderate rotation (usually <45 degrees), normal cisterna magna
Joubert syndrome	Cerebellum and cisterna magna of normal size, extremely small or absent vermis, typical configuration of fourth ventricle and cerebellar peduncles
Posterior fossa arachnoid cyst and other extra-axial cysts	Cystic asymmetric enlargement of the cisterna magna with a mass effect on the cerebellum

smaller the head dimensions, the greater the probability of microcephaly, although there is not an absolute quantitative cutoff point. The prevalence of microcephaly is estimated to be 1.6 per 1000 live births, but a minority of microcephalic infants diagnosed in the first year of life are detected at birth.

Microcephaly is not a single clinical entity but rather can result from primary cerebral malformations or exposure to teratogens or as part of a variety of syndromes. Microcephaly can also be transmitted with mendelian inheritance, usually as an autosomal recessive trait (Table 9-10). Association with abnormal intracranial anatomy is common, including abnormal convolutional patterns, such as macrogyria, microgyria, and agyria. The ventricles may be enlarged. Microcephaly is frequently found in cases of porencephaly, lissencephaly, and holoprosencephaly.

Microcephaly is a progressive condition, and therefore, definitive prenatal diagnosis is not possible in most cases. The natural history of fetal microcephaly is largely unknown. About 80% of infants affected with microcephaly have a normal head circumference at birth, and about 90% of those diagnosed at birth had normal cranial measurements in the second trimester. Cases diagnosed in utero represent the exception and typically include fetuses with extreme reduction of head dimensions, usually with multiple anomalies.

Traditionally, microcephaly is suspected if the head circumference is 2 SDs or more below the mean for gestational age. However, only when the measurement is 5 SD or more below the mean is the diagnosis certain.[46] In those cases in which the head measurements are small and of concern, a detailed neurosonographic examination or MRI scan may be useful, as two thirds of microcephalic infants have abnormal CNS anatomy, including holoprosencephaly, anomalies of the corpus callosum, or cortical malformations. The forehead is often sloping, and demonstration of this feature should increase the index of suspicion.

The outcome of microcephaly varies, in part depending on the presence of associated anomalies. For infants without associated malformations, the prognosis is related to head size. The pediatric literature suggests that the risk of intellectual disability with head circumference between 2 and 3 SDs below the mean is in the range of 10% and 30%, rising to 50% to 60% for measurements of 3 SDs below the mean. Prenatal data, however, are more limited. In the largest available series, of the 20 infants found in utero to have head circumference between −2 and −3 SD below the mean, none had intellectual disability or neurocognitive abnormalities on long-term follow-up.[47]

Megalencephaly, or an abnormally large brain, usually results in normal neurologic outcome, although it can be associated with intellectual impairment.[48] Megalencephaly is part of some congenital syndromes, including Beckwith-Wiedemann syndrome, achondroplasia, neurofibromatosis, and tuberous sclerosis. Obstetric and pediatric sonologists are often challenged by the problem of possible megalencephaly, a condition that should be suspected with abnormally large head measurements but normal intracranial anatomy. In such cases, examination of the parents can be helpful, as a large head size can be familial.

INTRACRANIAL CYSTS AND TUMORS

Intracranial *arachnoid cysts* are accumulations of clear cerebrospinal-like fluid between the dura and the brain substance. The histologic diagnosis is not always available, and the term is frequently used to indicate any intracranial cyst located in the subarachnoid space.

Arachnoid cysts may occur anywhere in the CNS, including the spinal canal. Most cases diagnosed antenatally involve supratentorial

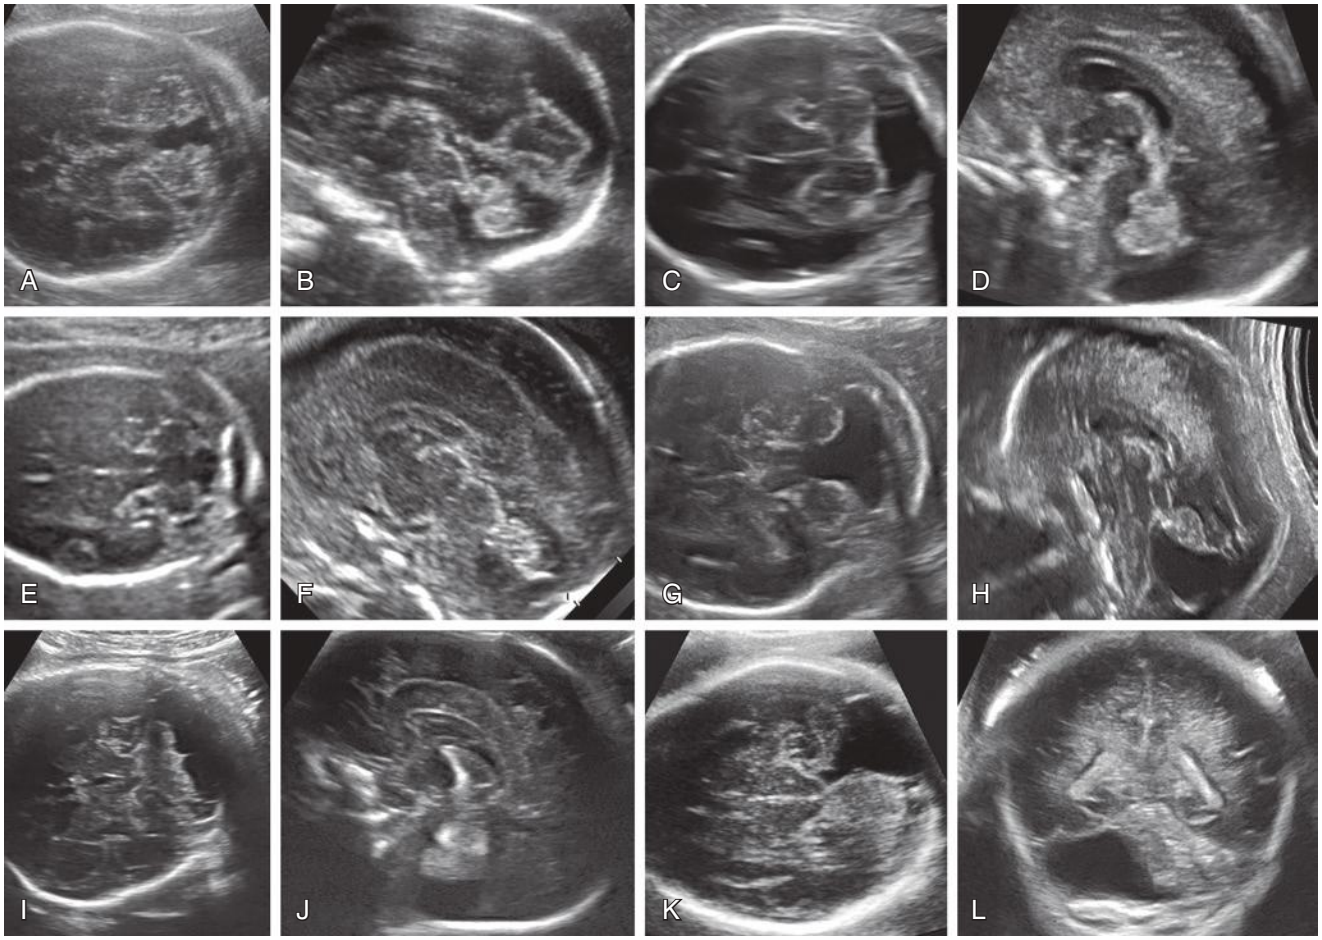

FIG 9-19 Posterior fossa fluid collections (see Table 9-7). **A** and **B,** Blake pouch cyst; **C** and **D,** megacisterna magna; **E** and **F,** vermian hypoplasia; **G** and **H,** Dandy-Walker malformation; **I** and **J,** cerebellar hypoplasia; **K** and **L,** arachnoid cyst of the posterior fossa. (From Gandolfi Colleoni G, Contro E, Carletti A, et al: Prenatal diagnosis and outcome of fetal posterior fossa fluid collections. Ultrasound Obstet Gynecol 39(6):625–631, 2012, used with permission.)

cysts in the midline, or between the skull and the hemispheres. They appear as well-defined anechoic lesions, occasionally associated with ventriculomegaly, that usually develop in late gestation (Fig. 9-24). Arachnoid cysts should be differentiated from other cystic lesions with different prognostic implications; the most important feature is that they are external to the hemispheres and do not involve the brain parenchyma. Porencephalic cysts occur within the brain substance and frequently communicate with the ventricular system (see Fig. 9-22). Arachnoid cysts may be asymptomatic, although in some cases they may be associated with seizures, mild motor or sensory abnormalities, or hydrocephalus. Neurosurgical series generally suggest a good prognosis with absence of symptoms in more than 70% of cases.

Choroid plexus cysts (CPCs) appear as round sonolucent structures within the choroid plexus of the lateral ventricles and are found in 1% to 3% of midtrimester fetuses (Fig. 9-25). They may be unilateral or bilateral and are sometimes multiple. They are typically found in the atria of the lateral ventricles. CPCs are benign findings, although they have been associated with an increased likelihood of trisomy 18. The available data do not indicate an association with other chromosomal aberrations, including trisomy 21. As fetuses with trisomy 18 typically have severe malformations readily detectable with in utero ultrasound, there is general consensus that isolated CPCs do not present a significantly increased risk for trisomy 18 in the absence of other risk factors or findings. The identification of isolated CPCs should not modify standard obstetric management, and as no deleterious effects on the fetus have been reported, there is no need for follow-up sonography. A handful of cases of very large cysts of the choroid plexus leading to increased intracranial pressure have been described in the neurosurgical literature, but these cysts likely represent a separate clinical entity.

Fetal *intracranial tumors* are rare, present in about 3 to 4 cases per 1 million live births. Teratomas account for most cases. The remaining minority include neuroepithelial tumors, lipomas, and craniopharyngiomas (Table 9-11). Ultrasound will rarely allow a specific diagnosis, as teratomas, astrocytomas, and craniopharyngiomas have a similar appearance, all presenting as a complex mass distorting the brain architecture, possibly associated with macrocephaly, ventriculomegaly, and intracranial calcifications (Fig. 9-26).[49] Only intracranial lipomas and choroid plexus papillomas have distinct sonographic appearances. Lipomas appear as well-defined echogenic areas, usually located in the midline, in the position normally occupied by the corpus callosum, and within the bodies of the lateral ventricles. Choroid plexus papillomas appear as large choroid plexuses, most frequently in association with ventriculomegaly and subarachnoid space enlargement. Cerebral tumors typically develop rapidly in late gestation, and many cases have been reported in which the midtrimester sonogram was unremarkable. The differential diagnosis of intracranial tumors includes other

space-occupying intracranial lesions, and it may be challenging in some cases to distinguish between a tumor and an acute intraparenchymal hemorrhage.

The prognosis of congenital CNS tumors is generally poor, with overall mortality rates in the range of 75%.[40] No clear data are available with regard to degree of neurologic impairment in survivors, but this is likely to be high as well. Large complex masses distorting intracranial anatomy (usually teratomas, astrocytomas, or craniopharyngiomas) have particularly dismal prognoses, with an overall survival rate of only 14%.[49] Intracranial lipomas represent an exception in that the reported survival rate is 100% and developmental handicap is rare.

Tuberous sclerosis is a syndrome characterized by multiorgan involvement, including the CNS, heart, and kidneys. Although transmitted as an autosomal dominant trait, the syndrome frequently arises from a spontaneous new mutation. Intellectual disability is present in 50% to 80% of cases and appears to be more frequent when the diagnosis is made antenatally or in early infancy. The most typical brain lesions are tubers, which are nodules of variable size composed of poorly differentiated neurons and glial cells disseminated in the neural plate or periventricular area. The CNS lesions are difficult to identify by antenatal sonography, although they can be seen more readily by MRI. The condition is usually suspected antenatally when cardiac tumors are identified (see Chapters 13 and 16). About 90% of such tumors are rhabdomyomas, and about 75% of fetuses with sonographic rhabdomyomas will be affected by tuberous sclerosis.[50] The risk appears to be higher when multiple cardiac tumors are present. Therefore, whenever cardiac tumors are identified, a search for cerebral lesions is warranted. Sonographic diagnosis is possible, although MRI is generally considered to be more sensitive.

TABLE 9-8 Abnormalities Associated With Dandy-Walker Malformation

Malformations
- Holoprosencephaly
- Agenesis of the corpus callosum
- Neural tube defects
- Cleft lip
- Congenital heart disease
- Cornelia de Lange syndrome
- Goldenhar syndrome
- Kidney abnormalities
- Facial hemangiomas
- Klippel-Feil syndrome
- Polysyndactyly

Mendelian Syndromes
- Walker-Warburg syndrome (AR)
- Aase-Smith syndrome (AD)
- Ruvalcaba syndrome (AD/X-linked)
- Coffin-Siris syndrome (AR)
- Oral-facial-digital syndrome, type II (AR)
- Meckel-Gruber syndrome (AR)
- Aicardi syndrome (X-linked dominant)
- Ellis–van Creveld syndrome (AR)
- Fraser cryptophthalmos syndrome (AR)

Chromosomal Abnormalities
- 6p-
- Dup 5p
- Dup 8p
- Dup 8q
- Trisomy 9
- Triploidy
- Dup 17q

Environmental Causes
- Rubella
- Coumadin
- Alcohol
- Cytomegalovirus
- Diabetes
- Isotretinoin

AD, autosomal dominant; AR, autosomal recessive.

Vascular Abnormalities

Vascular abnormalities of the fetal brain are relatively rare, and only a limited number of cases have been described. The majority of reports refer to vein of Galen vascular malformations.

The term *aneurysm of the vein of Galen* refers to a spectrum of arteriovenous malformations, ranging from a single large aneurysmal dilatation of the vein of Galen to multiple communications between the vein and the carotid and vertebrobasilar systems. The typical finding is an elongated anechoic area at the level of the cistern of the vein of Galen, with color and spectral Doppler evidence of turbulent venous or arterial intraluminal blood flow (Fig. 9-27). The cerebral architecture may be intact or may be distorted owing to associated ventriculomegaly, porencephaly, and cerebral edema suggested by increased echogenicity of the cortex. A large arteriovenous shunt may lead to increased cardiac work and result in high-output heart failure and hydrops. The available experience with prenatal diagnosis suggests a mortality rate of about 50%, and normal neurodevelopment in about 50% of survivors.[51] The outcome is strongly dependent on antenatal evidence of other intracranial abnormalities (hydrocephalus, brain edema, porencephaly) and hydrops. When any of these is identified, the prognosis is poor. In general, cases with normal postnatal development had isolated vascular lesions, without cerebral or cardiovascular compromise in utero, and were treated after birth with angiographic embolization.

It may be difficult to distinguish an aneurysm of the vein of Galen from a pial arteriovenous malformation.[52] The latter is a vascular malformation within the brain parenchyma that results in enlargement of the cerebral venous system in general and the vein of Galen in particular. The outcome is similar to that of vein of Galen aneurysm, and the prognosis is poor when there are associated abnormal cerebral findings or evidence of cardiac overload.

Several cases of in utero *thrombosis of the dural sinuses* have been described. The sonographic findings include identification of a posterior, fluid-filled structure displacing the fetal brain anteriorly and usually containing an echogenic core likely representing thrombus (Fig. 9-28). The cause of antenatal cases is uncertain. Thrombophilias may be found, but usually the condition is idiopathic. Although the intrauterine appearance may be quite dramatic, complete remission occurs frequently,[53] and if there are no signs of cerebral compromise, the outcome is good in most cases.

Cortical Malformations and Anomalies of Neuronal Migration

The neuronal cells that form the gray matter of the CNS originate from the surface of the lateral ventricles and later migrate along radially aligned glial cells to reach the outer surface of the brain. The migration occurs in different waves that last for several weeks. Most of the process takes place between 8 and 16 weeks' gestation, but this migration continues until 25 weeks. Once the neuronal cells have reached their destination on the surface of the brain, they undergo a process of maturation and differentiation, grow axons and dendrites, and develop synapses with other neurons, giving rise to a well-ordered, six-layer cortex. Cortical malformations are characterized by the incomplete formation of the cortical layers, with abnormal locations of neurons that have failed to reach their intended final destination. The migrational process may be arrested by environmental factors (ischemia,

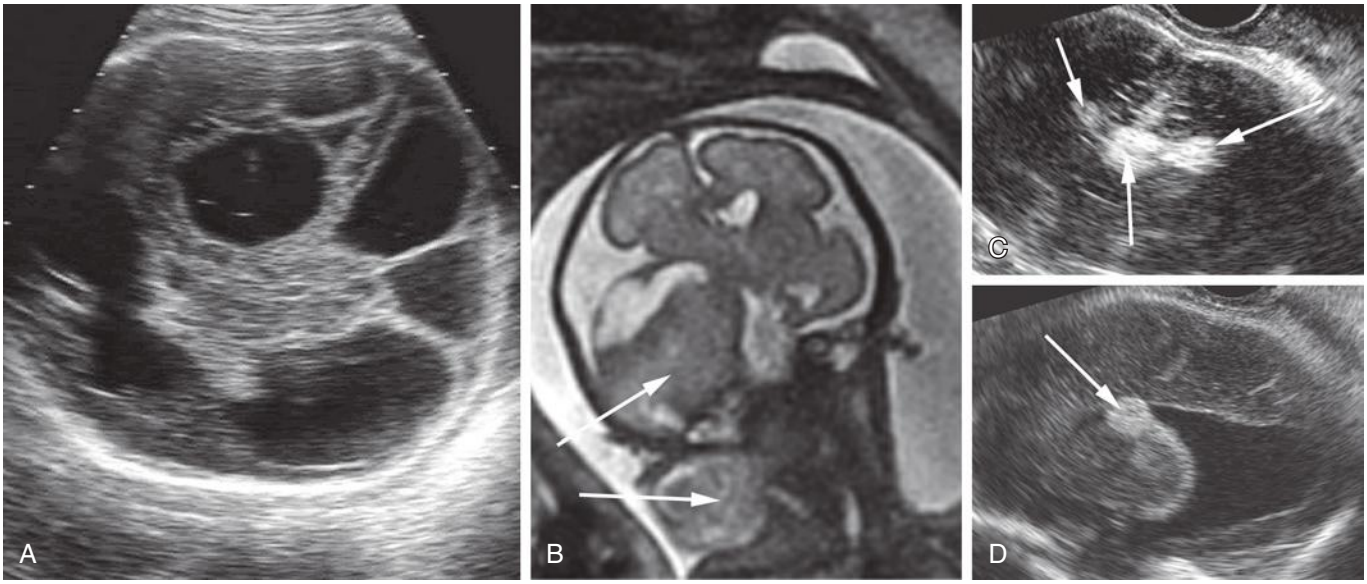

FIG 9-26 Fetal intracranial tumors: intracranial teratoma as visualized by ultrasound (**A**) and magnetic resonance imaging (**B**) (*arrows*). Multiple lipomas appear as echogenic round masses (*arrows*) in a fetus with associated agenesis of the corpus callosum (**C** and **D**).

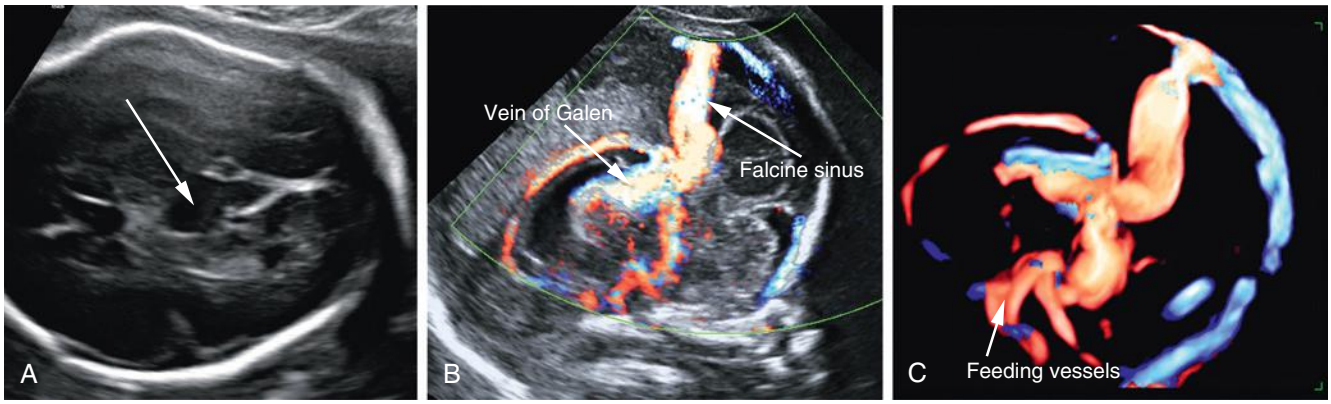

FIG 9-27 Aneurysm of the vein of Galen: **A,** The aneurysm appears as a hypoechoic tubular midline structure; **B,** with prominent turbulent intraluminal flow on color Doppler sonography, draining into a large falcine sinus; and **C,** 3D color Doppler sonogram delineating the vascular anatomy with abnormal arterial feeding vessels supplying the large vein of Galen.

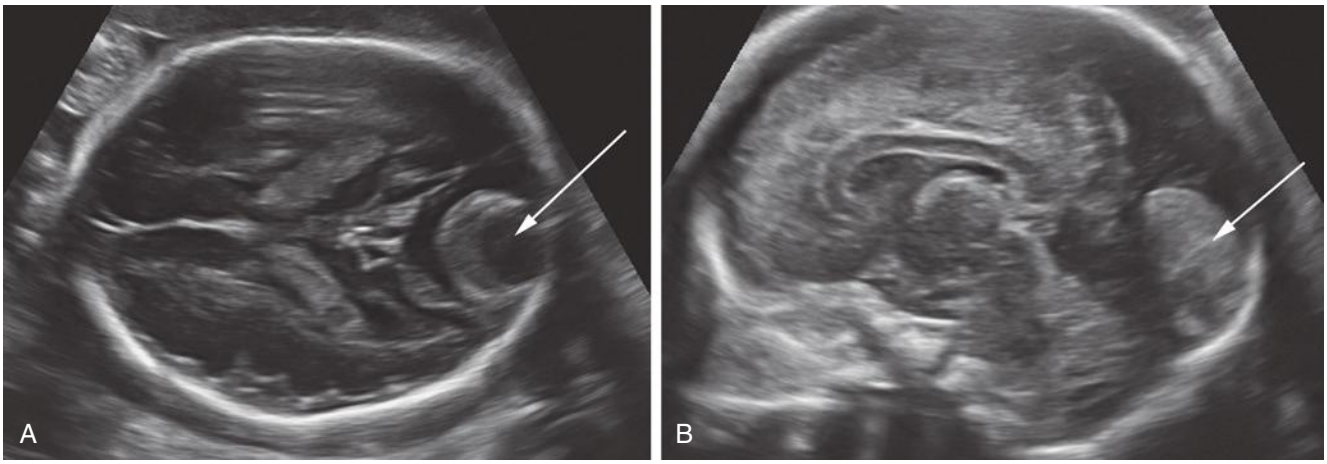

FIG 9-28 Thrombosis of the sinus confluence: a large hypoechoic collection containing an echogenic core suggestive of thrombus is seen in the occipital region, posterior to the brain on axial (**A**) and midline sagittal (**B**) images (*arrows*).

teratogens) but for some anomalies, a genetic predisposition is present. Although the anatomy may be variable, with many cortical malformations the cortex is abnormally thickened by a large, disorganized layer of neurons, whereas the underlying white matter is thin. Macroscopically, the primary finding is an alteration in the convolutional pattern of the brain, which may be associated with modifications in brain mass and ventricle size.

Cortical malformations should be considered in the differential diagnosis of ventriculomegaly, microcephaly, and macrocephaly and are suspected when an anomalous pattern of cerebral convolutions is present.[54] These disorders include a broad spectrum of anomalies, including *lissencephaly*, in which there is absence or reduction of convolutions; *polymicrogyria*, an increased number of small convolutions; *unilateral megalencephaly*; *schizencephaly*; and *gray matter heterotopias.*

The entities most frequently described in antenatal studies are summarized in Table 9-12 and Figure 9-29. The optimal imaging technique for the diagnosis and evaluation of these anomalies postnatally is MRI, as this allows clear discrimination between white and gray matter. Antenatally, faster sequences are used because of fetal movement, and these have more limited resolution. In addition, the neural plate is incompletely formed antenatally, and this also limits diagnosis of many CNS anomalies. In utero MRI can, however, provide a panoramic view of the fetus and improved visualization of the cerebral surface and is therefore an important complementary imaging modality (see Chapter 23). With improvements in imaging quality and resolution, detection of typical macroscopic abnormalities of the brain, such as cortical clefts and gyral anomalies, is sometimes possible prenatally, although usually only in late gestation (Figs. 9-30 and 9-31). Studies have documented the

TABLE 9-12 Sonographic Findings Associated With Cortical Malformations

Anomaly	Sonographic Findings
Lissencephaly	Smooth brain contour without recognizable convolutions/gyri; ventriculomegaly and microcephaly may be present
Unilateral megalencephaly	Macrocephaly; shift of the midline with overgrowth of one hemisphere; abnormal thick gyri and ventriculomegaly frequently present in the larger hemisphere
Schizencephaly	Cleft of the brain resulting in connection between the subarachnoid space and the ventricular ependyma; may be unilateral or bilateral
Periventricular nodular heterotopia	Irregular margin of the lateral ventricle due to small subependymal nodules of heterotopic gray matter; may be focal or diffuse
Polymicrogyria	Excessive number of small gyri; may be generalized or focal
Pachygyria	Large thick convolutions/gyri of the cerebral cortex

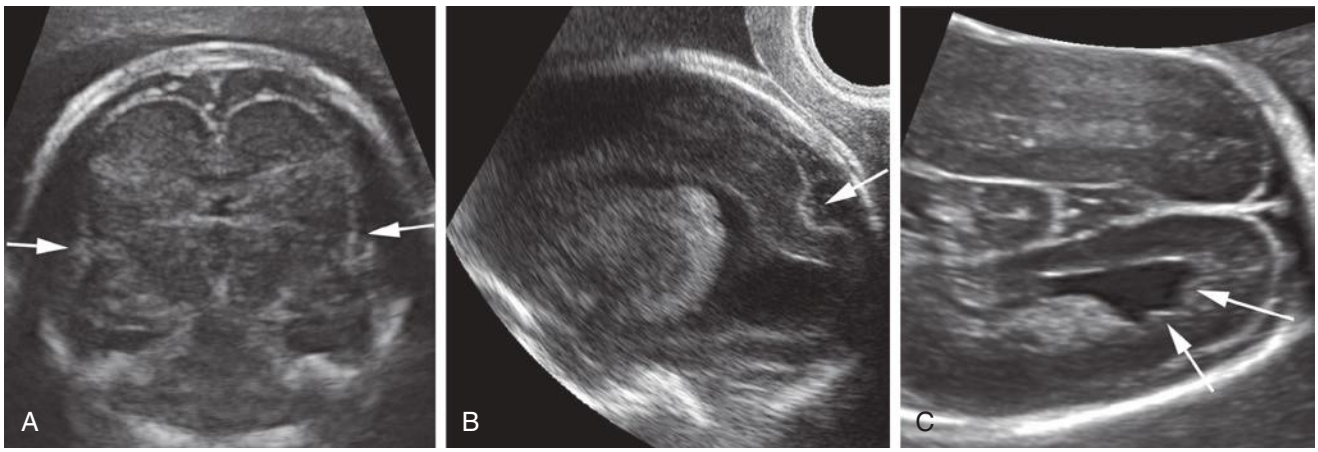

FIG 9-29 Cortical malformations (see Table 9-12). **A**, Lissencephaly; in this third trimester fetus, the brain contour appears abnormally smooth on this coronal ultrasound image, without evidence of convolutions or development of the sylvian fissures (*arrows*). **B,** An irregular sulcus/infolding (*arrow*) is noted in this fetus, diagnosed after birth with polymicrogyria. **C,** Irregular contour of the posterior aspect of the dependent lateral ventricle (*arrows*) suggests periventricular nodular heterotopia.

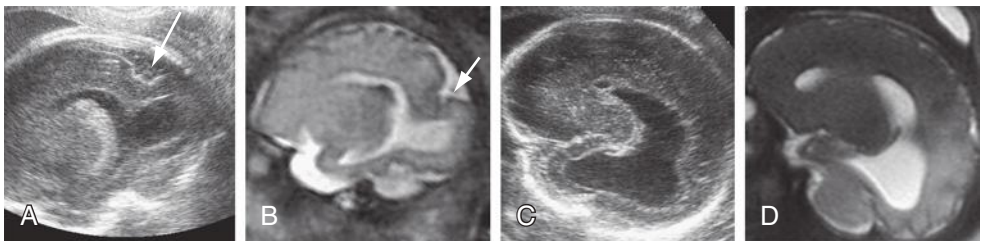

FIG 9-30 Fetal cortical abnormalities demonstrated by sonography and magnetic resonance imaging. **A** and **B,** Abnormal convolution associated with unusual shape of the cortex (*arrows*) and underlying lateral ventricle. **C** and **D,** This fetus at 34 weeks' gestation has a very smooth brain and an unusual echogenicity of the cortex.

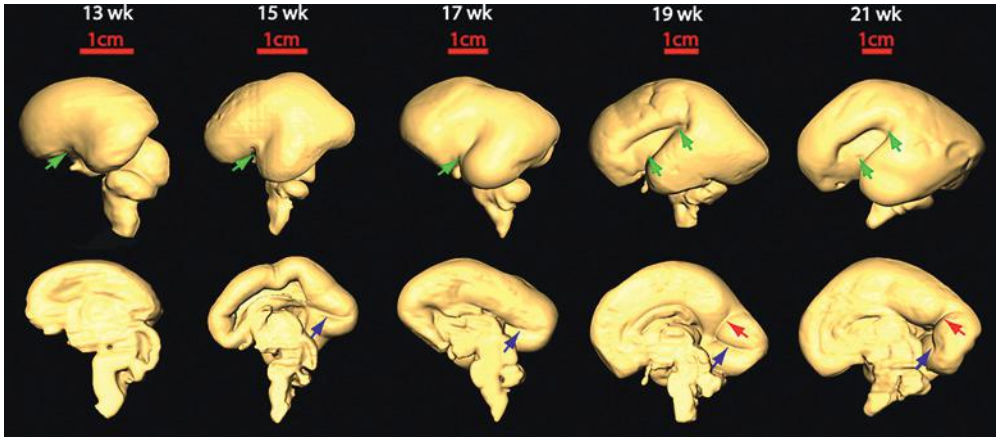

FIG 9-31 Three-dimensional reconstruction of the lateral (*top row*) and medial (*bottom row*) surface of 13- to 21-week fetal brains to reveal the development of the sylvian fissure (*green arrows*), the calcarine fissure (*blue arrows*), and the parieto-occipital sulcus (*red arrows*). sonographic appearance of developing brain structures such as the parieto-occipital fissure, calcarine fissure, cingulate sulcus, and other convexity sulci. In a study by Toi and coworkers,[55] the authors reported the youngest age at which a specific sulcus was first visible in a fetus and the age after which the sulcus was visible in all fetuses (Table 9-13). Sulci could be seen by transabdominal sonography as early as 18.5 weeks. The medial hemispheric sulcus and the insula were visible earlier and more confidently than convexity sulci. The earliest gestational ages at which specific sulci could be seen in any fetus were as follows: parieto-occipital fissure, 18.5 weeks; calcarine fissure, 18.5 weeks; cingulate sulcus, 23.2 weeks; and convexity sulci, 23.2 weeks. In this series, the gestational ages at which these sulci were always visible were the parieto-occipital fissure, after 20.5 weeks; calcarine fissure, after 21.9 weeks; cingulate sulcus, after 24.3 weeks; and convexity sulci, after 27.9 weeks.[55] Failure of identification of sulcation beyond these gestational ages would prompt one to suspect lissencephaly.

CONCLUSIONS

Modern ultrasound equipment affords unique potential for the visualization and evaluation of normal and abnormal fetal CNS development. A large number of congenital anomalies can be consistently recognized. Transvaginal sonography can extend antenatal diagnosis to very early gestation, and MRI can be used to improve the accuracy of the diagnosis in many cases.

Nevertheless, there are many limitations to the prenatal diagnosis of CNS anomalies. Some studies of low-risk patients undergoing basic sonographic examinations have reported sensitivities in excess of 80%.[56,57] However, these results probably overestimate the diagnostic performance of the technique. These surveys typically had very short postnatal follow-up, and almost all included cases of open neural tube defects, with recognition of these lesions facilitated by systematic screening with maternal serum AFP. Pitfalls of prenatal sonography are well documented. One of the most important limitations is related to the continuation of brain development in the second half of gestation and into early childhood, limiting the detection of some anomalies such as microcephaly and cortical malformations. Furthermore, some cerebral lesions do not result from abnormal embryologic development but represent the consequence of acquired prenatal, perinatal, and postnatal insults. Even in expert hands, some fetal CNS anomalies may be difficult or impossible to diagnose in utero.[58]

When abnormal intracranial anatomy is identified, accurate and compassionate counseling of the parents is critically important but frequently difficult. Some cerebral anomalies have outcomes that are

relatively predictable, as with catastrophic lesions such as anencephaly and severe holoprosencephaly. Others are more variable, although a relatively predictable range of outcomes can be provided such as with spina bifida. There are, however, a large number of conditions that can be correctly identified in utero and yet have uncertain progression and prognosis. Representative examples of such conditions include mild ventriculomegaly, ACC, intracranial cysts, and posterior fossa anomalies. When the sonographic findings are uncertain, MRI can often be helpful. However, the available literature reports some conflicting results, and the precise role of this technique is yet to be defined.

Ultrasound Evaluation of the Fetal Face and Neck

Kate E. Pettit, Nga V. Tran, Dolores H. Pretorius

SUMMARY OF KEY POINTS

- The diagnosis of a typical orofacial cleft involving the palate can be suspected as early as the first trimester by the presence of an anechoic space or discontinuity in the retronasal triangle (RNT) view.
- Using two-dimensional (2D) ultrasound, identifying typical clefts in the second trimester is best done by utilizing the coronal view of the nose and lips and the axial view of the fetal palate.
- Three-dimensional (3D) ultrasound, particularly the rendering function, can be helpful in the diagnosis of clefts of the hard and soft palate as well as in showing the surface rendered images to the family.
- Hypertelorism and hypotelorism, which can be defined by standard tables, are associated with a range of genetic syndromes.
- Micro- and retrognathia are identified in the sagittal profile view, and the diagnosis can be made subjectively or objectively with the use of facial angles.
- Craniosynostosis, the premature closure of cranial sutures, should be suspected in the presence of significant dolichocephaly or brachycephaly and may be associated with other anomalies or syndromes.
- Nuchal cystic hygromas are often associated with aneuploidy, with a higher frequency of trisomy 21 in the first trimester and Turner syndrome in the second trimester.
- Facial tumors and neck masses can compromise the fetal airway at birth and may require the use of an ex utero intrapartum treatment (EXIT) procedure at the time of delivery.

OUTLINE

NORMAL SONOGRAPHIC ANATOMY OF THE FETAL FACE

The fetal face can be evaluated in three different planes using 2D ultrasound—sagittal, axial or transverse, and coronal (Fig. 10-1). Each plane has a unique contribution to the evaluation of fetal craniofacial anatomy. The sagittal plane allows for assessment of the fetal profile and can illustrate any dysmorphism of the forehead or nose and the presence of the nasal bone as well as the positioning of the fetal chin to evaluate for micrognathia or retrognathia (Table 10-1). The axial or transverse plane is integral at two different levels (Table 10-2). The first key image is that of the orbits and eyes, which can be obtained caudad to the image displaying the biparietal diameter. Romero and associates have published nomograms for the various ocular parameters including binocular distance, interocular distance, and ocular diameter (Table 10-3).[1] Moving the transducer further caudad on the fetal head, one arrives at the level of the superior lip and palate followed by the fetal mandible.

3D ultrasound has an integral role in the evaluation and diagnosis of craniofacial anomalies. Though not yet validated for routine use in low-risk pregnancies, its use in the context of a detected or suspected craniofacial anomaly is quite apparent. A single midsagittal volume obtained with 3D ultrasound can allow for the evaluation of the sagittal, axial, and coronal views using multiplanar reconstruction. The rendering mode can create a realistic image of the exterior facial features as well as a 3D image of the fetal palate. In order to obtain a volume, a pocket of amniotic fluid needs to be present in front of the fetal face. These techniques can be applied to the routine anatomic survey in the midtrimester as well as the late first trimester. In addition to being used as a diagnostic modality, 3D ultrasound can also help to illustrate the appearance of a particular anomaly and to display the location and severity of the anomaly to consulting surgical specialists as well as families.

As discussed previously, there are multiple displays of 3D ultrasound that can be used to explore a craniofacial anomaly. The multiplanar display allows the simultaneous display of three perpendicular

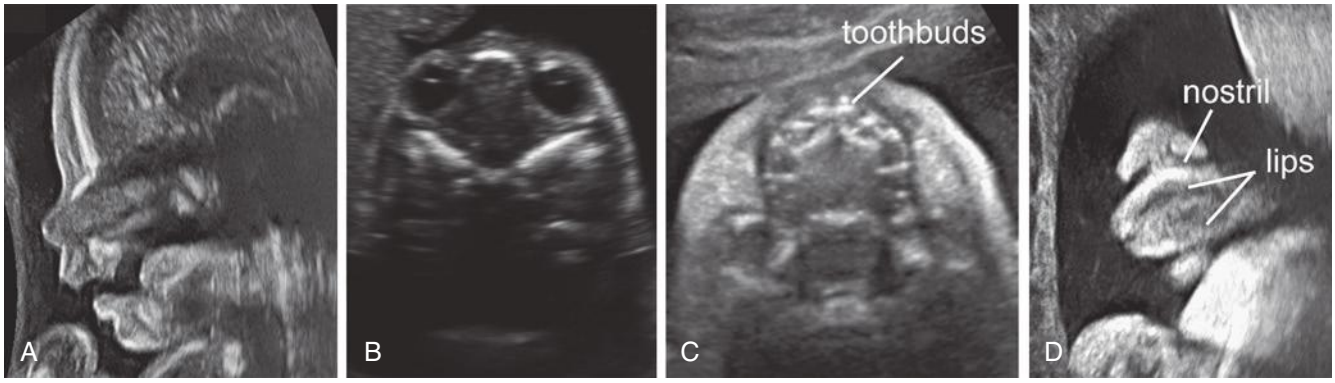

FIG 10-1 Normal images of fetal face. **A,** Sagittal image showing profile. **B,** Axial image through orbits. **C,** Axial image through palate showing toothbuds. **D,** Coronal image showing lips and nostrils.

TABLE 10-1 Normal Appearance of Fetal Facial Features on Ultrasound Image in the Midsagittal Section Plane

Structure	Normal Appearance
Forehead	Almost linear immediately above the articulation between the nasal bones and the frontal bone, followed by a smooth backward bend. This view allows measurement of the thickness of the frontal skin (at the level of the middle of the frontal bend).
Nasal bones	Oblique along a frontocaudal direction. This view allows measurement of the length of the nasal bones and of the superior facial angle (angle between the vertical section of the frontal bone and the nasal bones).
Nasal soft tissues	The columella is oblique or horizontal but should not be vertical.
Upper lip	The philtrum is linear and should present no bulging. This view allows measurement of the length of the philtrum.
Secondary palate	Thick echoic line, beginning at the alveolar level, and extending horizontally backward. Its middle is marked by a notch, present on both the superior and inferior edges, and corresponds to the transverse palatal suture. The notch is mostly visible on the superior edge.
Oral cavity	The tongue is slightly oblique upward (10-15 degrees). Its tip lies immediately behind the alveolar ridge.
Inferior lip	Rests edge to edge with the upper lip. Both lips are arranged along the same axis; there should be no anteroposterior shift between them.
Chin	At the level of the vertical line traced on the prefrontal skin (esthetic vertical line of the face).

From Rotten D, Levaillant JM: Two- and three-dimensional sonographic assessment of the fetal face. 1. A systematic analysis of the normal face. Ultrasound Obstet Gynecol 23:224, 2004.

TABLE 10-2 Normal Appearance of Fetal Facial Features on Ultrasound Image in the Axial Section Planes

Structure	Normal Appearance
Orbits	The interorbital axis is perpendicular to the strict sagittal axis. This view allows measurement of the inner and outer interorbital lengths.
Nasal septum, molar	The nasal septum is perpendicular to the axial plane. The two malar arches are symmetric with regard to arches to the nasal septum.
Upper lip, maxilla	There is no lack of continuity of the upper lip. The maxilla appears as a regular, U-shaped echoic bend. The alveolus and tooth buds appear as hypoechoic spots regularly distributed along the alveolar ridge. There is no shift between adjacent alveoli. The hard palate appears as an echoic structure, with a complex shape. The anterior part is semicircular and lies immediately posterior to the alveolar ridge. The posterior part presents as a rectangular figure, with a notch on its distal side. This view allows measurement of the size of the maxilla.
Oral cavity	The tongue occupies the totality of the oral cavity and is glued to the alveolar ridge. Posteriorly, the tongue ends at the oropharynx level. This view allows measurement of the width and length of the tongue.
Mandible	Appears as a regular V-shaped echoic image. Both hemimandibles are almost rectilinear. The symphysis menti is clearly visible. The alveoli appear as regularly distributed hypoechoic spots. This view allows measurement of the size of the mandible (e.g., mandible width and computation of mandible width/maxilla width ratio).

From Rotten D, Levaillant JM: Two- and three-dimensional sonographic assessment of the fetal face. 1. A systematic analysis of the normal face. Ultrasound Obstet Gynecol 23:224, 2004.

planes—namely, sagittal, axial, and coronal—of the fetal head and face (Fig. 10-2). These planes can be manipulated by the sonographer to highlight the region of interest. The surface rendering mode can be used to create a model of a frontal view of the fetal face (Fig. 10-3). The maximum and transparent modes can be mixed to evaluate the hyperechoic bony structures including the fetal sutures, which can be useful in the diagnosis of craniosynostosis (Fig. 10-4). The same volume may be viewed with both surface rendering and skeletal displays.

Abnormalities of the fetal hard palate, particularly the secondary palate, can be challenging to evaluate with 2D ultrasonography. Acquiring a volume in the axial plane and then rendering the hard palate from a viewing plane inferior to the palate in an axial plane can be helpful (Fig. 10-5); this approach is a modification of the "flipped face" reported by Platt and colleagues and by Faure and coworkers.[2-4] Other techniques that have been used include the "reverse face" view using a coronal plane through the hard palate and oblique face views (Fig. 10-6).[5,6] Parallel slice imaging can use a single 3D volume to create

multiple parallel slices, similar to a computed tomography (CT) scan, which can be useful in diagnosing abnormalities of the fetal hard palate (Fig. 10-7). Magnetic resonance imaging (MRI) can be helpful in selected cases to better elucidate fetal craniofacial clefts, particularly when there is a concern for associated neurologic abnormalities.[7]

CRANIOFACIAL ANOMALIES

Craniofacial anomalies are relatively common findings, both in prenatal diagnosis as well as in liveborn infants. The basic ultrasonographic survey of the fetal face should include the upper lip, and a more detailed examination could potentially include the profile, nose, orbits and lenses, palate, maxilla, mandible, tongue, and ear position and size.[8] The prenatal sonographic diagnosis of a craniofacial anomaly should indicate the need for a more detailed full anatomic examination to evaluate for concomitant anomalies. In addition, patients should be offered prenatal diagnostic testing to evaluate for associated genetic syndromes.

The accuracy of ultrasonographic diagnoses of craniofacial anomalies varies by the patient population as well as the expertise and experience of the institution and examiner. A systematic review of 21 studies cited a large range in the prenatal detection rates for orofacial clefts, from 0% to 73%, in low-risk women with 2D ultrasound.[9] In a more contemporary study of a population of more than 30,000 women, both low and high risk, the sensitivity for cleft lip with or without cleft palate reached 88%.[10] In high-risk women, in whom 3D ultrasound was used as an adjunct to 2D imaging, the detection rate in specialized centers has been quoted as high as 100%.[9] 3D ultrasound has much to offer in the elucidation of the detailed anatomy and extent of craniofacial anomalies.

Typical Facial Clefts

Orofacial clefts are relatively common and occur in 1 in 700 live births.[11] The rate varies by ethnicity, with higher rates seen in Asian and Native American populations and significantly lower rates in African populations.[12] Typical facial clefts can occur as isolated cleft lip (CL), isolated cleft palate (CP), or as a combination of both cleft lip and cleft palate (CL+CP). They are often further subdivided into the categories of CL±CP and isolated CP. Clefts most often run from one or both of the nostrils to the central part of the posterior palate. An in-depth anatomic classification system was proposed by Tessier in 1976.[13]

Of all orofacial clefts, CL with CP represents 50% of cases, isolated CL 25% of cases, and isolated CP 25% of cases.[14,15] Clefts involving the lip are more common in males, with a ratio of 2:1, and isolated CP clefts are more common in females, also with a ratio of 2:1.[12] A large

study of almost 50,000 deliveries in Norway with 77 fetuses with CL±CP revealed that among cases of CL±CP, 64% were unilateral and 34% were bilateral, with only 3% being midline.[15] The same study demonstrated that in unilateral clefts, 69% were left-sided and 31% were right-sided, with a ratio of 2.3:1. The left-sided predominance has also been shown in other studies; however, there is no definitive anatomic explanation for this finding. Median clefts have unique causes and associations and are detailed in the next section ("Atypical Facial Clefts").

An appreciation for the embryologic development of the face can help in the understanding of the development of orofacial clefts. The face arises from five prominences that surround the mouth—the central frontonasal prominence and the paired maxillary and mandibular prominences. These prominences are composed of neural crest cells and are present by the fourth week of embryogenesis (Fig. 10-8). By the fifth week, the nasal placodes have formed, separating each side of the inferior portion of the frontonasal prominence into lateral and medial nasal processes. The upper lip and primary palate are formed by the end of the sixth week, when the medial nasal processes fuse with each other and the paired maxillary processes. This sixth week is a sensitive time for development, and teratogenic exposures at this time can result in orofacial clefts. The purpose of the secondary palate is to separate the oral and nasal cavities. The development of the secondary palate begins in the sixth week and is completed by the tenth week. The secondary palate is formed from paired palatal shelves that are outgrowths of the maxillary processes. These shelves fuse during the seventh week and differentiate into the hard and soft palate. By the tenth week, the primary palate and nasal septum have fused with the secondary palate (Fig. 10-9).[16-18] Clefting can occur during multiple stages of the embryogenesis process and results in different anatomic variations depending on the timing and which prominences are affected (Fig. 10-10).

Orofacial clefts are often divided into the categories of syndromic and nonsyndromic clefts. In CL±CP, 70% to 90% of clefts are nonsyndromic, and in isolated CP, 60% to 80% of clefts are nonsyndromic.[19] Isolated CL should be counseled similarly to CL+CP because it has a similar developmental pattern. Table 10-4 reviews some of the more common syndromic associations with orofacial clefts. It is essential that parents with fetuses with the prenatal diagnosis of orofacial clefts be offered further genetic workup with chorionic villus sampling or amniocentesis and evaluation of chromosomal abnormalities with karyotyping and chromosomal microarray.

All types of orofacial clefts can potentially be associated with other structural anomalies. In one study, 43% of those with CL±CP and 58% of those with isolated CP had associated structural anomalies.[15] Rates of associated anomalies vary, with another study reporting 35% of patients with CL±CP as having an associated anomaly or suspected genetic syndrome.[20] A third study suggested a lower level of association with anomalies, reporting that those with unilateral CL±CP had a rate of associated structural anomalies of 9.8%, whereas bilateral CL+CP had associated anomalies in 25%.[21] Most of these studies are biased by tertiary care subselection; in our practice, we counsel a risk of associated anomalies of approximately 10% when an isolated CL±CP is identified on prenatal ultrasound images.

In addition to genetic causes, orofacial clefts have been linked to several environmental factors and medications. Organic solvent and agricultural chemical exposure may contribute to the risk for cleft anomalies.[22,23] Antiepileptic medications, including the older generation drugs such as diazepam, phenytoin, and phenobarbital as well as some of the newer generation drugs such as topiramate and lamotrigine have been associated with an increased risk of orofacial clefts in some studies.[17,24-26] Early exposure to retinoid medications and corticosteroids has also been linked to fetal craniofacial anomalies.[27,28] Maternal smoking has been consistently associated with CL±CP with

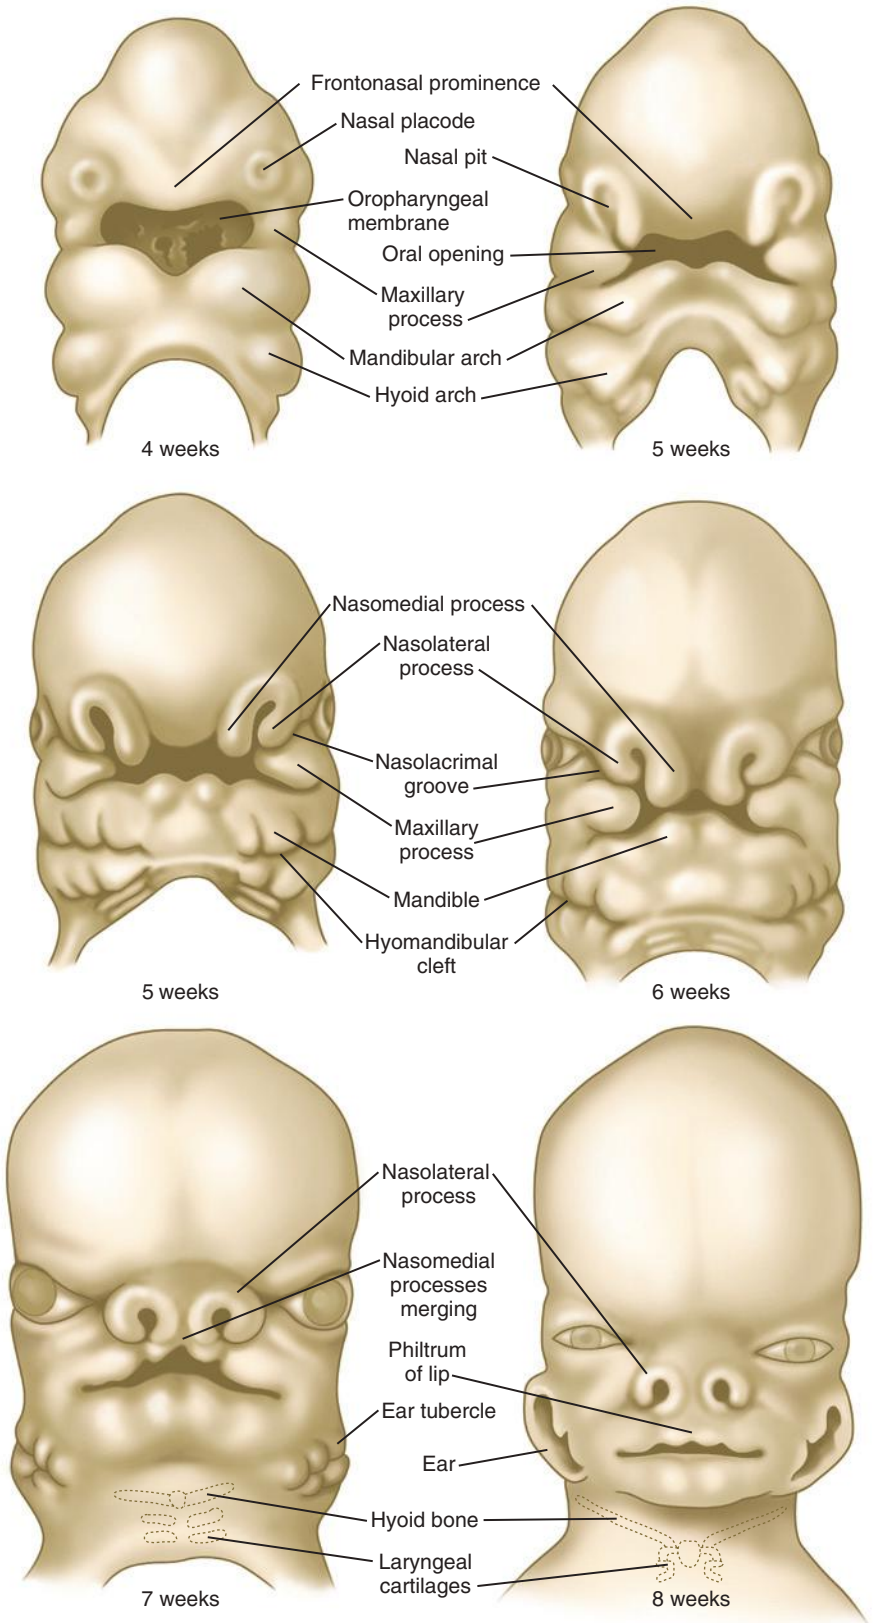

FIG 10-8 Frontal views of the heads of human embryos from 4 to 8 weeks of age. (From Carlson BM [ed]: Human Embryology and Developmental Biology, 3rd ed. Philadelphia, Mosby/Elsevier, 2004, p 322.)

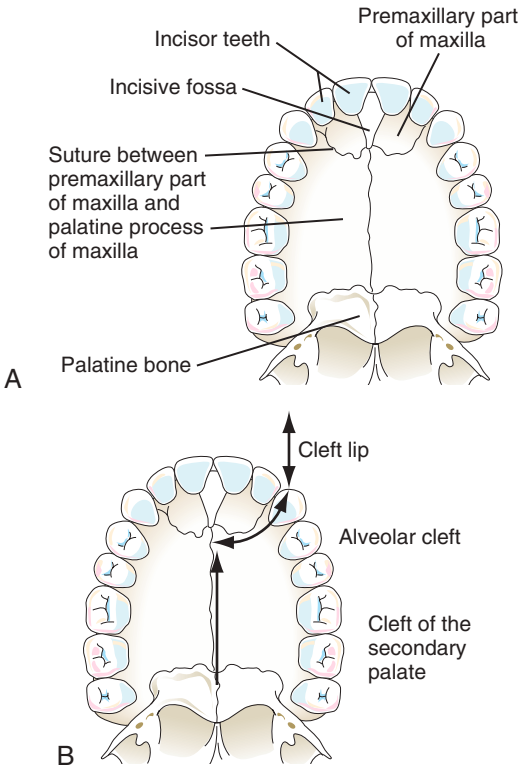

FIG 10-9 A, Drawing of the human palate in the axial plane highlights the anatomy of the premaxillary part of the maxilla and the lateral palatine processes of the secondary palate. Their points of fusion are indicated by the black lines between them. The four incisor teeth arise from the premaxillary portion of the primary palate, and the remaining teeth, from the canines posteriorly, arise from the lateral palatine processes of the secondary palate. **B,** Schematic representation of the various cleft constituents of the palate. (A adapted from Moore KL: The Developing Human: Clinically Oriented Embryology, 6th ed. Philadelphia, WB Saunders, 1998, p 245; B from Rotten D, Levaillant JM: Two- and three-dimensional sonographic assessment of the fetal face. 2. Analysis of cleft lip, alveolus and palate. Ultrasound Obstet Gynecol 24:402, 2004.)

a relative risk of 1.34 and CP alone with a relative risk of 1.22 in a large meta-analysis.[29] There is inconsistent evidence suggesting that folic acid deficiency may yield an increased risk for orofacial clefts and thus that supplementation could potentially decrease the risk of recurrence in a subsequent pregnancy, but this relationship has not been definitively established.[30,31] The early prenatal use of multivitamins has been associated with a 25% reduction in the risk for CL±CP and a nonsignificant 12% reduction in the risk for CP.[30]

Prenatal diagnosis of clefts can allow parents to choose options for further genetic testing and can also prepare them for the child's medical course if they continue the pregnancy. In 1981, Christ and Meininger reported the first prenatal ultrasonographic diagnosis of an orofacial cleft.[32] Research has demonstrated that the detection of clefts has improved over time, with one study citing a detection rate of 34% in the period of 1987-1995 and 58% in the period of 1996-2004.[9,15] A systematic review of 21 studies reported a broad range in prenatal detection rates for low-risk women, from 9% to 100% for CL±CP and 0% to 22% for CP only. Detection of isolated CP in particular continues to be poor, with some large contemporary studies showing a detection rate of 0%.[15,21]

In the second trimester, CL±CP and CP can be best visualized by utilizing both coronal and axial planes. In the anterior coronal plane, with a view of both the nose and lips, a CL is identified as a defect extending from one nostril to the oral rim (Table 10-5). These defects can cause distortion of the upper lip and nose, which can be seen well with a 3D rendered image (Fig. 10-11). To determine whether the defect extends into the alveolus or the primary palate, the axial plane is the best approach (Table 10-6). This view can demonstrate the extent of the cleft and determine if it also involves the secondary or hard palate (Fig. 10-12, Table 10-7). As discussed, identifying an isolated CP is quite challenging, and these defects are often missed, even with thorough 2D or 3D ultrasonography. In the case of bilateral CL+CP, the sagittal plane with the fetal profile can be helpful. This view can demonstrate the protrusion of the central palate and lip, often termed the *premaxillary mass* (Fig. 10-13). The sagittal plane will likely be normal in cases of unilateral CL+CP or with bilateral CL. When any type of orofacial cleft is suspected, 3D ultrasound can often offer a more accurate portrayal of the facial anatomy and specifically the hard and soft palate (Figs. 10-14 and 10-15).[3,33,34] As previously reviewed, the "flipped face" and the "reversed face" view allow the examiner to evaluate the posterior hard and soft palates.[2,3,34] MRI may better illustrate the extent of orofacial clefting, as it allows for improved visualization of the palate, particularly the hard or secondary palate.[7]

Prenatal diagnosis of orofacial clefts in the first trimester has been reported by Sepulveda and associates.[35] It has been proposed that the RNT view may be a useful diagnostic tool. This view is a coronal image of the fetal face posterior to the nose that includes the three echogenic lines formed by the two frontal processes of the maxilla and the palate (Fig. 10-16).[35] A hypoechoic defect in the palate region can be indicative of an orofacial cleft.

The prognosis of orofacial clefts depends first and foremost on the presence of associated anomalies or genetic syndromes. Feeding, respiratory function, and speech attainment may be compromised with all clefts, particularly those involving the palate. The cosmetic appearance can also be debilitating to a child's psychological and social development. A multidisciplinary approach is a necessity with the involvement of nursing, plastic surgery, maxillofacial surgery, otolaryngology, speech therapy, audiology, counseling, genetics, orthodontics, and dentistry. The American Cleft Palate–Craniofacial Association 2009 guidelines recommend surgical repair of a CL in the first 12 months of life and surgical palate repair by 18 months, or earlier if possible.[36] Most children with CL and CP will undergo approximately 10 surgeries (related to the cleft and tubes for ears) by the age of 10 years.

Recurrence of orofacial clefts tends to be type-specific, with either a history of CL±CP or isolated CP within the same familial line. In a large study of over 54,000 relatives from 1952 to 2005, the recurrence risk in those with first-degree relatives with orofacial clefts was 3.5% (95% confidence interval 3.1-4.0%).[19] Table 10-8 details the approximate recurrence risks for various degrees of familial relationships. Despite the hereditary risk factors, the majority of orofacial clefts are sporadic.

Atypical Facial Clefts

Median and lateral facial clefts are far less common than the typical clefts reviewed earlier. Only about 3% of clefts are located at the midline.[15] Median or midline clefts are associated with two distinct phenotypes: (1) the median cleft, which is often associated with holoprosencephaly, and (2) frontonasal dysplasia or median cleft face syndrome.

The processes of midline and facial defects and brain development are closely linked. Inadequate development of the frontonasal prominence can result in a midline facial defect. This is often correlated with holoprosencephaly, a process in which the embryonic forebrain has incomplete cleavage.[37] In 1964, DeMyer and coworkers described the

spectrum of facial phenotypes that can accompany holoprosencephaly, which can range from a median quadrangular CL±CP with orbital hypotelorism and a flattened nose to cyclopia with arhinia and a proboscis (Figs. 10-17 through 10-19).[38] The degree of facial dysmorphism is often reflective of the degree of holoprosencephaly.

The prognosis of median clefts associated with holoprosencephaly is universally poor. The majority of the time, the condition will be lethal and the few survivors are affected by significant neurodevelopmental disability.[39] Holoprosencephaly occurs in 1 in 8000 live births,[40] with chromosomal abnormalities, most commonly trisomy 13, present in 37% to 67% of cases.[37,39]

The second phenotype associated with median facial clefts is frontonasal dysplasia or the median cleft face syndrome. In contrast to the hypotelorism and midline clefts associated with holoprosencephaly, this condition instead presents with hypertelorism and the unique features of median clefting affecting the nose or both the nose and lip or palate, broadening of the nasal root, with unilateral or bilateral colobomas of the nasal alae, lack of formation of the nasal tip, anterior cranium bifidum occultum, and a widow's peak hair distribution.[41] The identification of hypertelorism on ultrasound image in the axial scan differentiates this condition from the median cleft associated with holoprosencephaly. Prenatal ultrasonographic diagnosis has been reported as early as the first trimester, utilizing 3D ultrasonography.[42]

The prognosis for patients with median cleft face syndrome depends on the severity of the defects and also on the presence of any central nervous system malformations. Patients with median cleft face syndrome usually do not typically present with developmental disability, though one small series of 21 patients cited a prevalence of neurodevelopmental abnormalities in approximately 50% of cases, associated with a high frequency of agenesis of the corpus callosum.[43] The surgical correction of these multiple facial malformations, including the midline defect as well as the hypertelorism, can be a significant undertaking.

Lateral facial clefts are another form of atypical facial cleft. They often begin at the corners of the mouth and extend outward, with the most severe forms reaching the ear. These anomalies occur in 1 in 50,000 to 1 in 175,000 live births.[44] Such clefts, like the typical clefts, may develop as errors of early embryogenesis, although they may also be due to the disruptive effects of amniotic band syndrome and occur later in development.[45,46]

The clinical finding when a lateral cleft is present is termed *macrostomia,* or widening of the oral commissure. These clefts can be associated with skeletal malformations of the lateral face and external ear including the maxilla, zygomatic bone, and ascending branch of the mandible.[47] This type of cleft is challenging to diagnose on prenatal ultrasound examination, particularly with 2D ultrasound. The widening of the mouth and facial asymmetry are best seen in the coronal view (Fig. 10-20).[44] If such a cleft is suspected, 3D ultrasound in surface mode may be helpful to further elucidate the location and extent of the cleft. Given the frequent involvement of nearby skeletal structures, surgical repair of these types of clefts is a difficult and multistep process.

Orbital and Ocular Defects

Approximately 22 days after conception, the development of the eye begins, and formation of the globe structure is complete by 42 days. Differentiation of the lens and eye structures occurs following these initial steps.[48] The orbit itself is complex and made up of seven different bones—the frontal, zygomatic, sphenoid, ethmoidal, maxillary, lacrimal, and palatine.[49] The eyes grow in size and move medially with advancing gestation, with the eventual goal to allow stereoscopic vision. The angle between the optic nerves is initially 180 degrees and at birth is only 70 degrees.[49] Sonographically, the vitreous and lens of the eye are normally hypoechoic, whereas the lens outline and orbit are hyperechoic.

Hypotelorism is defined prenatally as an interocular distance below the 5th percentile (see Table 10-3).[1,50] Burns and associates have published tables of normal values of orbital distances based on gestational age.[50] In our experience, hypotelorism should be suspected if the space between the orbits is not equivalent to at least the size of one orbit. Hypotelorism is associated with holoprosencephaly and is also found

TABLE 10-5 Sonographic Characteristics of Unilateral or Bilateral Cleft Lip

Section Plane	Unilateral Cleft	Bilateral Cleft
Sagittal and parasagittal	The midsagittal view is usually normal. The parasagittal views show the cleft of the upper lip as a defect between two thickened zones, with visible asymmetry between both sides of the defect. The narinal bridge is always complete, but there is a flattened narinal bend.	The normal image of the lip is replaced by the protruding premaxillary prolabium. The prolabium is stuck to the nose and consequently flattened. The columella cannot be analyzed.
Axial premaxillary	The loss of continuity of the labial arc is clearly apparent. The nostrils are asymmetric and distorted, but the nasal aisles are always present, constituting a bridge over the cleft.	On each side, the protruding prolabium is separated from the remaining upper lip extremities by the clefts. Both nostrils are flattened but complete.
Coronal	The loss of lip continuity is clearly apparent.	The defects in lip continuity are clearly apparent.

From Rotten D, Levaillant JM: Two- and three-dimensional sonographic assessment of the fetal face. 2. Analysis of cleft lip, alveolus and palate. Ultrasound Obstet Gynecol 24:402, 2004.

TABLE 10-6 Sonographic Characteristics of Unilateral or Bilateral Cleft Alveolus

Section Plane	Unilateral Cleft	Bilateral Cleft
Axial	The alveolar defect ranges from a simple slant to a cleft involving the alveolus and premaxilla. Clefts involving the alveolus present as a defect in alveolar continuity. A simple irregularity in the alveolar lining signals an alveolar slant. A defect in alveolar regularity with anteroposterior shift between the two hemimaxillas signals a cleft involving the alveolus and premaxilla.	The premaxilla is protruded together with the prolabium. The premaxillary mass is analyzed (size, soft tissue, and bone content). The external parts of both alveoli are symmetric.
Coronal	There is a defect in alveolar continuity, with missing buds.	There is a median defect in alveolar continuity. This defect contrasts with an intact hard palate.

From Rotten D, Levaillant JM: Two- and three-dimensional sonographic assessment of the fetal face. 2. Analysis of cleft lip, alveolus and palate. Ultrasound Obstet Gynecol 24:402, 2004.

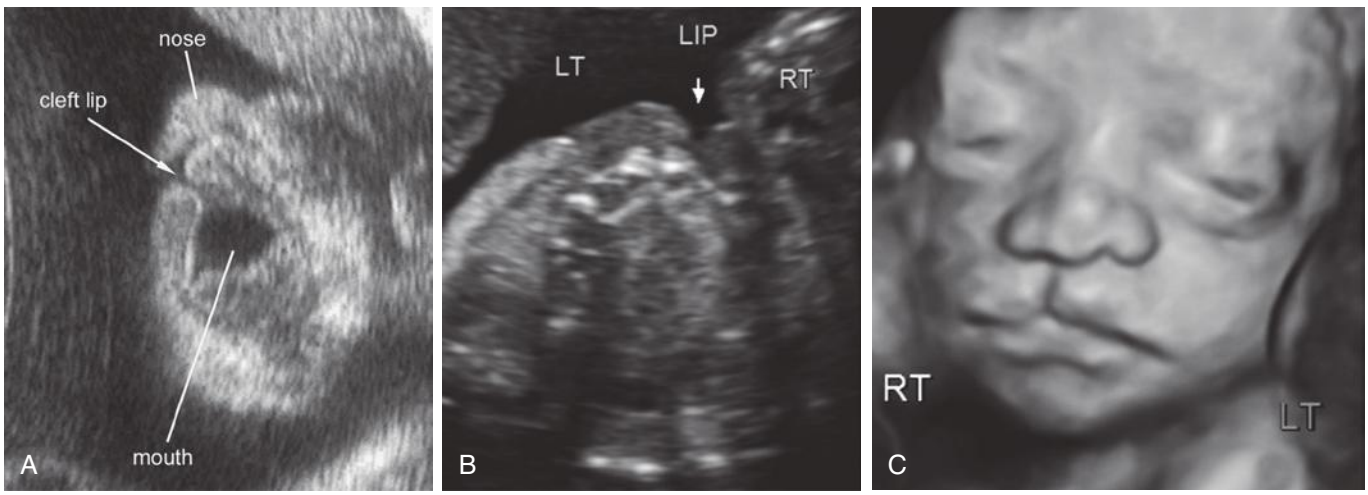

FIG 10-11 Unilateral right cleft lip in fetus at 27 weeks: **A,** Frontal two-dimensional ultrasound image of lip and nose showing cleft lip (*arrow*). **B,** Axial two-dimensional image of palate showing intact primary and secondary palate with unilateral right cleft lip (*arrow*). **C,** Frontal three-dimensional surface rendered image of right unilateral cleft lip.

in OMIM (Online Mendelian Inheritance in Man) to be associated with over 80 syndromes. The same mechanisms that result in the excessive central migration of the orbits also contribute to the formation of the forebrain.[50] The prognosis of hypotelorism depends largely on the associated anomalies and the presence or absence of holoprosencephaly.[51]

Hypertelorism is defined prenatally as an interocular distance above the 95th percentile (see Table 10-3)[1,50] and is found in OMIM to be associated with over 500 syndromes. It can be associated with the median cleft face syndrome or frontonasal dysplasia, as previously discussed under "Atypical Facial Clefts."[52] Hypertelorism can be seen with typical CL and CP as well. Isolated mild hypertelorism can also be seen as a normal variant. As with hypotelorism, the prognosis depends on whether the fetus is affected with other anomalies or a genetic syndrome. Surgical procedures that have been proposed for correction of hypertelorism include canthoplasty, orbitoplasty, surgical positioning of the eyebrows, and rhinoplasty.[53]

Microphthalmia is defined as decreased size of the eye as reflected by a decreased ocular diameter, and anophthalmia is the absence of the eye structures on pathologic examination (Table 10-3, Figs. 10-21 and 10-22). Prenatal sonographic diagnosis of microphthalmia was first reported by Feldman and coworkers in 1985.[54] This finding can be

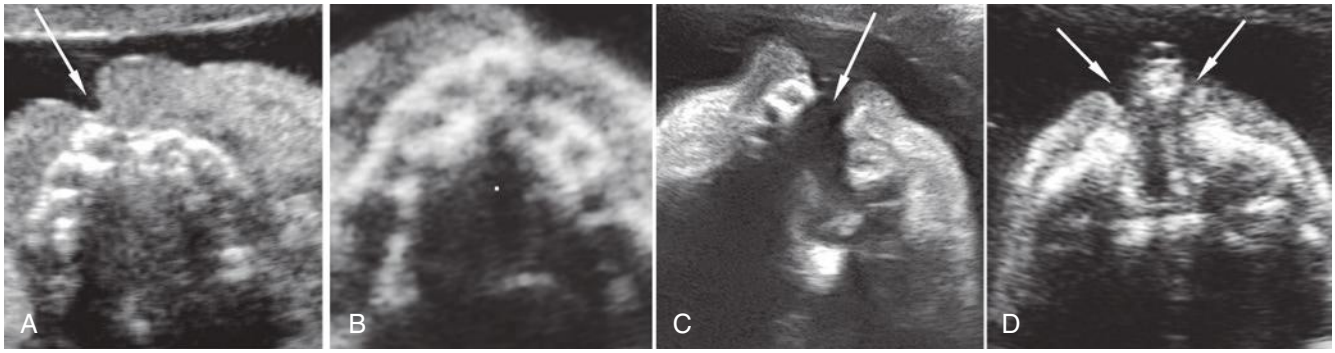

FIG 10-12 Axial planes of the maxilla in fetuses with facial clefts: **A,** Isolated cleft lip (*arrow*): the alveolar ridge is intact albeit irregular in shape as frequently happens in these cases. **B,** Unilateral cleft lip and palate: the defect extends only to the alveolar ridge; note that one toothbud is missing but that the secondary palate does look intact; this defect is frequently referred to as *cleft alveolus*. **C,** Unilateral cleft lip and palate; the defect is seen extending to the secondary palate (*arrow*). **D,** Bilateral cleft lip and palate (*arrows*); the anterior protrusion of the central portion of the maxilla (or premaxilla) indicates that the defect extends posteriorly to the secondary palate.

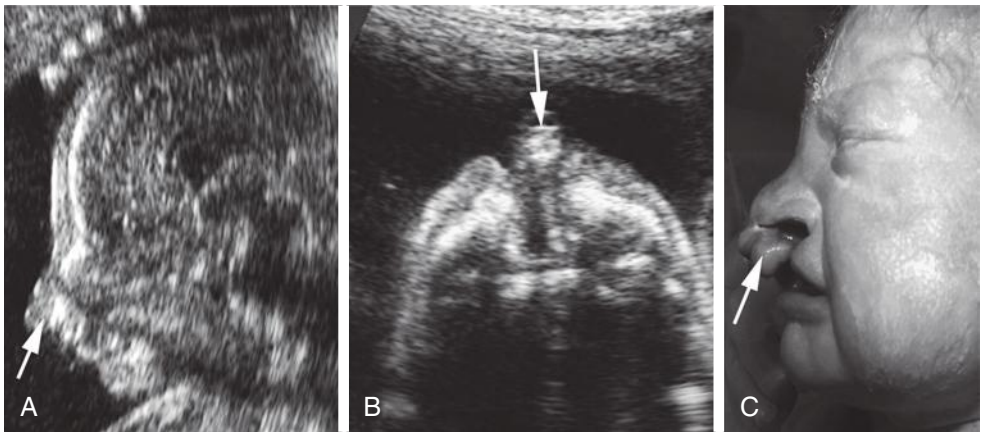

FIG 10-13 Protrusion of the premaxilla (*arrows*) in a fetus with bilateral cleft lip and palate: **A,** Sagittal view; **B,** axial view; **C,** postnatal image for comparison.

TABLE 10-7 Sonographic Characteristics of Unilateral or Bilateral Secondary Palate Cleft

Section Plane	Secondary Palate Cleft With a Unilateral CLA	Secondary Palate Cleft With a Bilateral CLA
Midsagittal and parasagittal	The successive views show a defect in hard palate continuity. This defect is asymmetric. It is not strictly median but lateralized, usually toward the same side as the CLA.	A hyperechoic midline image is present in the midsagittal view. Care must be taken: although a median line is present, it is not the palate but the vomer bone. On each side of the sagittal view, the parasagittal views show the hard palate defects.
Axial	When looking for the palate caudally to the alveolus (remember that the alveoli are separated by a defect and a shift), one does not find it. The only apparent image is that of an oblique vomer bone.	The anteroposterior hyperechoic line corresponding to the vomer bone is present. Anteriorly, it extends onto the premaxillary prolabium. On each side of this median structure, the cleft is readily apparent.
Coronal	Medially, the palatal arch is interrupted by a defect. Actually, this defect is not symmetric but lateralized on the same side as the CLA. Thus, the two half arches are not symmetric. The wider half is on the nonpathologic side. The vomer bone is deflected toward the half arch situated on the pathologic side and rests on it.	The hard palate cannot be imaged. The vomer appears as a suspended midline line, with no supportive structure to rest on. The palatal arch is reduced to two small lateral structures.

CLA, cleft lip and alveolus.

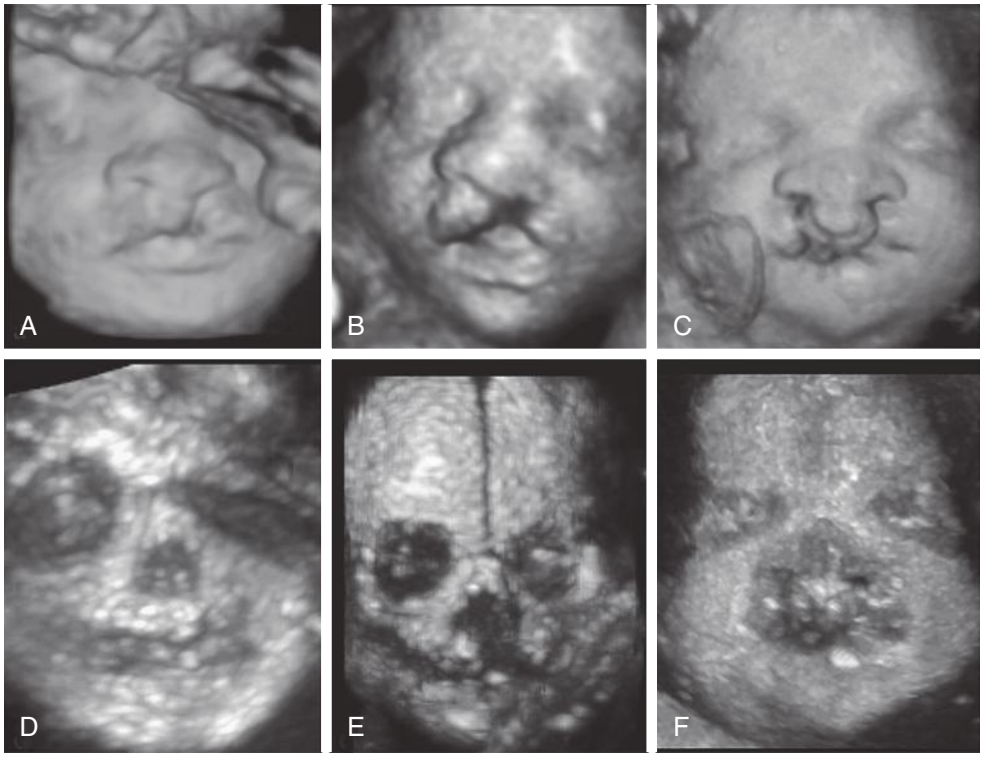

FIG 10-14 Three-dimensional ultrasound imaging of cleft lip in surface mode (**A** through **C**) and maximum mode (**D** through **F**). **A** and **D,** Unilateral cleft lip. **B** and **E,** Unilateral cleft lip and palate. **C** and **F,** Bilateral cleft lip and palate.

unilateral or bilateral and may be associated with many genetic syndromes including Goldenhar syndrome, a condition of hemifacial microsomia thought to occur secondary to a vascular event involving the first and second branchial arches.[55] It can also be a result of infection or exposure to a teratogen.[56] It is possible to detect microphthalmia in the early second trimester fetal survey; however, it can also develop over time, as there are cases of microphthalmia in the third trimester with normal ocular diameters documented in the second trimester.[56] Infants and children with microphthalmia are often affected by vision impairment and blindness; 3.2% to 11.2% of all blind children have microphthalmia.[57]

Congenital cataracts are rare, occurring in 1 to 6 per 10,000 live births.[58] They can be detected on prenatal ultrasound image, as the lens will be very echogenic (see Fig. 10-21).[59] The cause of congenital cataracts can be genetic (either autosomal dominant, recessive, or X-linked) or related to aneuploidy or other syndromes, infections, and metabolic conditions.[59,60] Unilateral cataracts are genetic in 30% of cases, and bilateral cataracts are genetic in 50% of cases.[59] Surgery via lens removal for infants is recommended prior to 6 weeks for unilateral cataracts, and prior to 10 weeks for bilateral cataracts, in order to optimize visual outcome.[60]

Dacrocystoceles can present prenatally as anechoic masses medial and inferior to the eye and can be imaged well with tomographic ultrasound imaging (TUI) (Fig. 10-23). They are caused by obstruction of the lacrimal drainage system that then results in dilation of the nasolacrimal sac.[61] The differential diagnosis for this finding includes an encephalocele, hemangioma, and dermoid cyst. Some dacrocystoceles will resolve in utero, and the majority will resolve postnatally without intervention.[61,62] For those that do not resolve spontaneously, initial therapy can include warm compresses, massage, and antibiotics, with surgery for unresolved cases in the form of nasolacrimal duct probing or marsupialization.[63]

Micrognathia and Retrognathia

In the 4th week of gestation, neural crest cells travel to the head and neck area and stimulate pharyngeal arch formation. The mandibular and maxillary prominences form from the first pharyngeal arch. The mandible or jaw is derived from the mandibular prominence.[64] It is likely that defects in mandibular development begin at this early stage.

Micrognathia refers to a small chin secondary to an underdeveloped mandible, whereas retrognathia refers to the posterior displacement of the chin. These two findings can be difficult to differentiate sonographically and may also occur simultaneously; the terms are often used interchangeably. It is possible to mimic micrognathia if a suboptimal image of the fetal profile is taken obliquely, rather than in a true midsagittal plane. With true micrognathia, a normal fetal profile image cannot be obtained.

Micrognathia is often associated with syndromes and other abnormalities. In one series of 58 cases identified prenatally, Luedders and colleagues found that 43% had musculoskeletal disorders, 15% had nonskeletal anomalies, and only 7% were isolated; only 15% were alive postnatally.[65] Micrognathia is commonly associated with the Pierre Robin sequence, a condition that includes a U-shaped palatal cleft and glossoptosis.[66] Pierre Robin sequence can be isolated or may be associated with other anomalies, aneuploidy, or other syndromes, such as Treacher Collins, Stickler syndrome, and the 22q11.2 deletion syndrome. It occurs in 1 in 8500 to 1 in 14,000 live births and is isolated in approximately 40% of cases.[67] The original triad as published by Robin in 1923 did not include the palatal cleft but rather included respiratory compromise with airway complications.[68] However, 90%

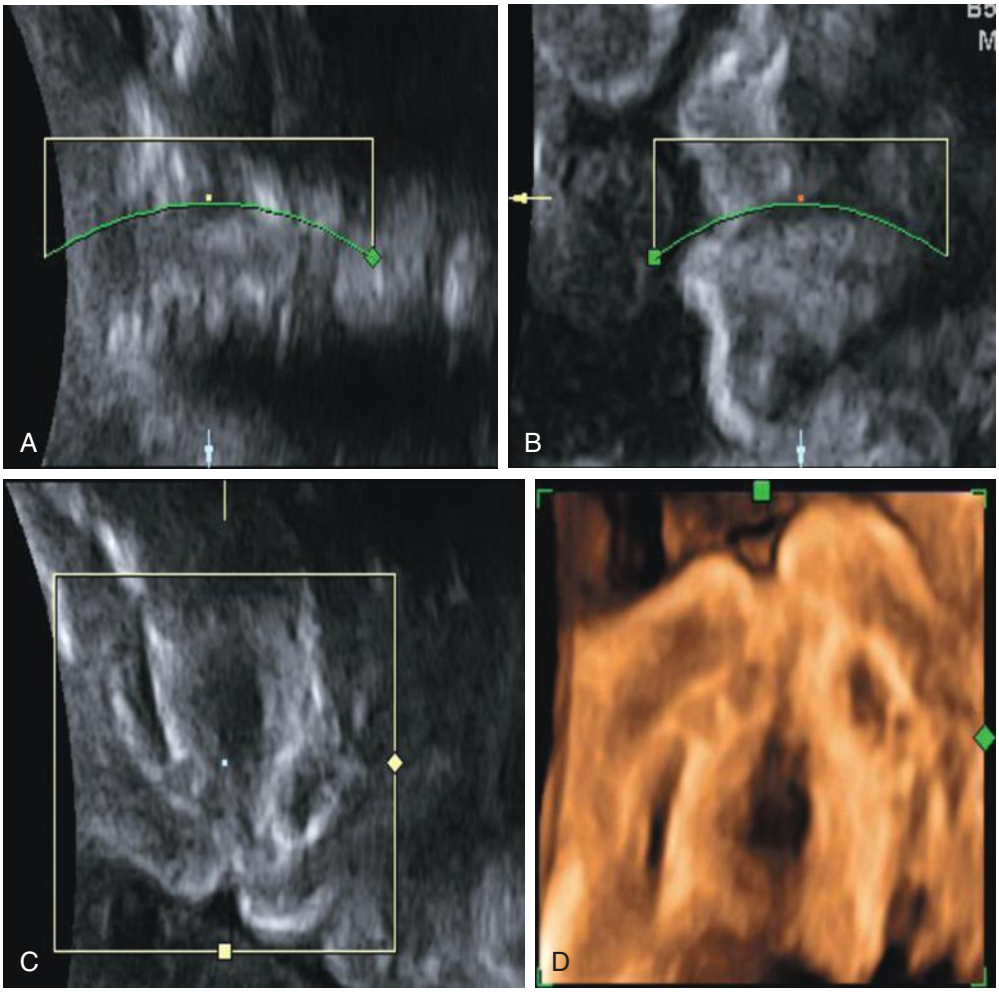

FIG 10-15 Multiplanar display of cleft lip and palate: **A,** Frontal view of palate. **B,** Sagittal view of palate. **C,** Axial view of palate. **D,** Rendered image of cleft palate including alveolar ridge and hard palate. Notice that the green rendering line is curved and viewed from the inferior direction of the palate/maxilla in images A and B.

of children with Pierre Robin sequence have an accompanying CP.[69] The initial mandibular malformation likely causes the upward and posterior displacement of the tongue, which prevents palatal closure, leading to the cleft.

The first approach to sonographic assessment of mandibular size and position is the sagittal profile view. This view allows determination as to whether the midportion of the mandible is aligned with the maxilla. Subjective estimation of the presence of micrognathia or retrognathia is generally done on the sagittal image; however, quantitative methods have also been explored. Multiple quantitative methods have been proposed for the diagnosis of micrognathia with both 2D and 3D ultrasound imaging.[70-73] For the diagnosis of retrognathia, measurement of the inferior facial angle (IFA) has been suggested. This angle is represented by the angle between a line orthogonal to the vertical part of the forehead at the level of the synostosis of the nasal bones (reference line) and a line joining the tip of the mentum and the anterior border of the more protrusive lip (profile line) (Fig. 10-24). In a study by Rotten and coworkers, an IFA less than 50 degrees at 18 to 28 weeks was consistent with retrognathia.[73] Despite advances in the manipulation of sonographic images, the prenatal diagnosis of micrognathia and retrognathia remains challenging. This is particularly true of retrognathia, which can be a normal variant early in the second trimester, with mandibular growth occurring after 20 weeks' gestation and postnatally.[69] 3D rendered images can be created to better demonstrate the realistic appearance of retrognathia (see Fig. 10-24).

First trimester identification of micrognathia or retrognathia has also been reported. Sepulveda and colleagues proposed the use of the RNT view to identify mandibular abnormalities. The RNT view, also used for the identification of clefts, is an image in the coronal plane of the face in which the primary palate and the frontal processes of the maxilla are simultaneously visualized.[74] In their study, the presence of a gap in the mandible was seen in 204 normal fetuses, and an absence of a mandibular gap was seen in nine fetuses with micrognathia (see Fig. 10-16).

The essential issues for neonates with these mandibular abnormalities, particularly Pierre Robin sequence, are airway obstruction and feeding difficulties.[66,69] At birth, the neonatal team should be prepared for difficult airway management and possible intubation. In addition, 38% to 62% of neonates with Pierre Robin sequence will have challenges with feeding. This can be addressed with nasogastric tube feeding.

Depending on the severity of the micrognathia or retrognathia, multiple treatment modalities are available after birth. Nonsurgical approaches include prone positioning and the use of a nasopharyngeal

airway.[69] In a study by Meyer and associates, 68% of infants with isolated Pierre Robin sequence responded to one of these interventions.[75] Surgical procedures include tongue-lip adhesion, mandibular distraction osteogenesis, and tracheotomy.[69] Many infants with Pierre Robin sequence have accompanying anomalies or concomitant genetic syndromes, and their postnatal prognosis is based on these factors as well as their response to treatment for the mandibular abnormality.[66]

Macroglossia

Macroglossia is subjectively defined as a protruding tongue that extends beyond the teeth and lips. This finding is characteristic of Beckwith-Wiedemann syndrome, an overgrowth syndrome that has been detected successfully on antenatal ultrasound image (Fig. 10-25).[76] Trisomy 21, an absent thyroid, triploidy, metabolic storage disorders, and multiple other genetic syndromes may also present with macroglossia either prenatally or, more often, after birth. Protrusion of the tongue is best seen on the sagittal profile view but is often not detected until the late second or third trimester.

Tumors of the Face

The differential diagnosis of congenital tumors of the oropharyngeal region includes teratoma, hemangioma, lymphangioma, neurofibroma, and granular cell tumor.[77] Hemangiomas may appear as cystic or solid lesions and arise from subcutaneous tissues. Lymphangiomas are largely cystic masses that typically originate from the nuchal region, although sublingual lymphangiomas have been reported.[78] Epignathus is a rare benign oral cavity tumor that occurs in 1 in 35,000 to 1 in 200,000 live births.[79] These tumors occur more often in females than males, with a ratio of 3:1.[80] The tumor is a teratoma with derivatives of foreign tissue from any or all of the three germinal layers.[81] Patients often present with elevated maternal serum alpha-fetoprotein. The tumor most commonly grows from the hard palate or the mandible but can also arise from other oral cavity tissues and structures[80] and will appear as a large solid or cystic mass protruding from the mouth (Figs. 10-26 and 10-27). Tumors may develop through gestation, as cases have been documented with normal sonograms in the second trimester and with the epignathus identified only later in the pregnancy.[80] The tumors can be unidirectional, growing only outward through the mouth, or bidirectional and extend intracranially.[81] The latter portends a poor prognosis with no reported surviving infants.[80,81] For cases with unidirectional spread, delivery and survival may be

possible with an EXIT procedure, in which a cesarean delivery is performed and the placenta is left in the uterus and attached to the fetus via the umbilical cord, allowing continued oxygen supply while the fetal airway is addressed via intubation or tracheotomy. These procedures are performed only in specialized centers with appropriate multidisciplinary support. The size and location of the lesion are features predictive of postnatal prognosis. Intracranial tumors such as teratomas can also present as facial tumors if they are extensive (Fig. 10-28).

Ears

Embryologically, the ears are derived from the first and second branchial arches. Development of the ears begins as early as week 3 after conception and is usually fully completed by week 20.[82] Beyond 20 weeks, only progressive growth of the inner, middle, and external ear structures occurs. At the time of birth, the inner and middle ear structures have reached adult size, whereas the external ear continues to grow throughout childhood (Fig. 10-29). Ear abnormalities can include anotia (absent ear), microtia (small ear), large ears, and abnormal shape and position.

Conditions associated with ear abnormalities include the trisomies (13, 18, and 21), Turner syndrome, first and second pharyngeal arch syndromes, holoprosencephaly, anencephaly, Crouzon syndrome, Treacher Collins syndrome, the CHARGE association (*c*oloboma of the eye, *h*eart anomaly, choanal *a*tresia, *r*etardation, and *g*enital and *e*ar anomalies), and VACTERL syndrome (abnormalities of *v*ertebrae, *a*nus, *c*ardiovascular tree, *t*rachea, *e*sophagus, *r*enal system, and *l*imb buds).[83] In 1955, it was first suggested that small ear size or microtia may be associated with aneuploidy, particularly Down syndrome or trisomy 21.[84] Hall noted that 60% of newborns with Down syndrome had abnormal ears.[85]

Prenatal diagnosis of ear abnormalities is possible, particularly with 3D ultrasound (Fig. 10-30). Shih and colleagues obtained adequate images of the fetal ears in 84% of cases utilizing 3D ultrasound.[83] Chang and coworkers determined that 3D ultrasound was superior to 2D ultrasound given that 3D ultrasound allowed for the evaluation of ear shape in 93% of cases versus only 40% with 2D ultrasound.[86] Ear length, width, and area have been shown to correlate with increasing gestational age,[86] and various nomograms have been established. In one study, the sensitivity and specificity for aneuploidy in fetuses with structural malformations if fetal ear length was below the 5th percentile were 80% and 84%, respectively.[87] The authors suggested that fetal ear length may be as useful for aneuploidy risk assessment as other commonly used soft signs, such as a thickened nuchal fold. Dysmorphic ear shape can also be a sign of an underlying syndrome, and attention should be paid to assessing for associated anomalies if abnormal ears are identified (see Fig. 10-30).

Beyond ultrasound technology, fetal MRI, when obtained to evaluate cranial or brain abnormalities, may also be useful in the diagnosis of ear abnormalities, particularly when obtained after 25 weeks' gestation. This can apply to external as well as internal ear abnormalities.[88]

CRANIOSYNOSTOSIS

Craniosynostosis is defined as premature closure of single or multiple cranial sutures.[89] The overall prevalence of craniosynostosis is approximately 4.3 per 10,000 births.[90] Isolated craniosynostosis represents approximately 85% of cases, whereas craniosynostosis associated with syndromes or other anomalies accounts for the remainder (Fig. 10-31).[91]

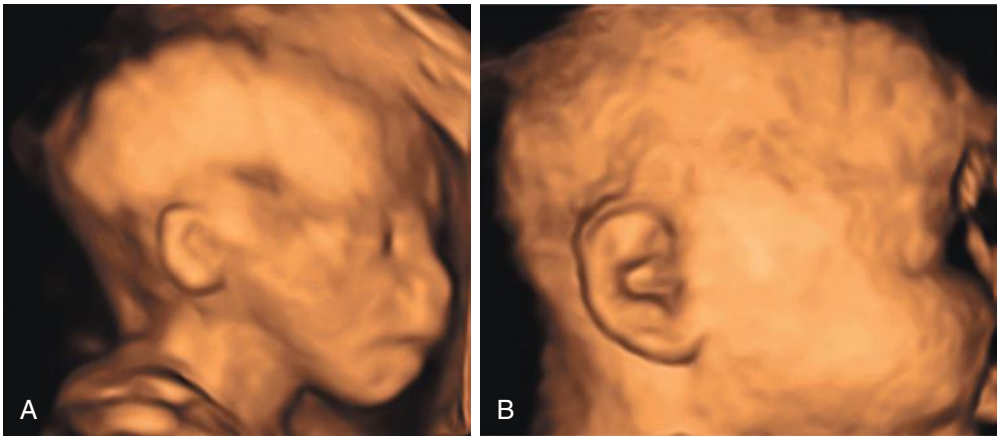

FIG 10-29 Three-dimensional ultrasound imaging of normal ear. **A,** Rendered profile with normal ear at 19 weeks. **B,** Rendered profile with normal ear at 31 weeks.

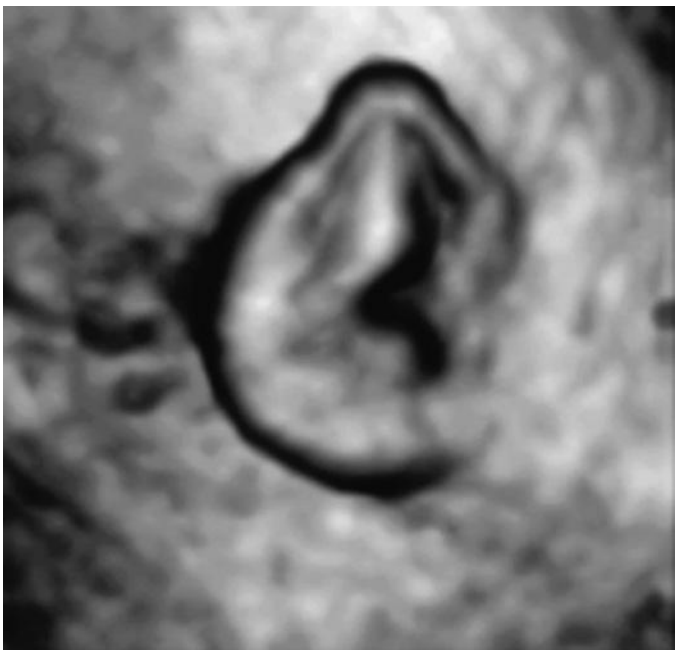

FIG 10-30 Three-dimensional ultrasound image of abnormal ear. Unfurled ear at 33 weeks; fetus had tetralogy of Fallot and mother had coarctation of aorta. Both mother and neonate had unilateral abnormal ears.

In single suture synostosis, the most commonly affected suture is the sagittal suture, followed by the coronal, metopic, and lambdoid sutures.[92] Skull shape is dependent on the sutures involved: sagittal suture synostosis results in scaphocephaly (also called dolichocephaly), and coronal synostosis results in brachycephaly.[91] A rarer form of craniosynostosis, Kleeblattschädel, which usually involves fusion of the majority of the sutures, results in a cloverleaf-shaped skull (Fig. 10-32).[93]

Isolated and syndromic craniosynostosis have multiple causes. In one study of a prospective cohort of craniosynostosis cases over 10 years, 21% of the cases were given a genetic diagnosis.[92] Of these, 86% were single gene disorders and 15% were chromosome abnormalities (one patient had both findings). In addition, Kleeblattschädel synostosis specifically is associated with thanatophoric dysplasia type 2 and Pfeiffer syndrome type 2.[93,94]

Syndromic craniosynostosis is often more severe and tends to be associated with other anomalies. Some syndromes involving craniosynostosis include Crouzon, Apert, Pfeiffer, Saethre-Chotzen, Jackson-Weiss, Antley-Bixler, and Carpenter syndromes.[91] These conditions differ both in the types of sutures involved (Fig. 10-33) and the accompanying anomalies.

Apert syndrome was originally described in 1906 by Eugène Apert in a sentinel report describing nine patients with similar characteristics.[95] It usually involves the fusion of the coronal, sagittal, and lambdoid sutures (Fig. 10-34).[91] Rare, the incidence is approximately 6 to 15 per 1 million live births.[96-98] This is an autosomal dominant condition, and it is recognized that advanced paternal age is a risk factor for the development of de novo autosomal dominant mutations.[99] Unique clinical features include maxillary hypoplasia, proptosis, and syndactyly of the hands and feet (Figs. 10-31 and 10-35).[100] The hands are often called mitten hands, as there is fusion of all of the fingers aside from the thumb. Up to 75% of patients can have CP or a bifid uvula.[101] Intelligence levels range from significant developmental disability to normal intelligence.[102]

Crouzon syndrome is slightly more common than Apert syndrome, with an estimated incidence of 16 per 1 million live births.[97] It is also an autosomal dominant condition. In this syndrome, the coronal and sagittal sutures are both fused.[91] However, the facial and cranial features tend to be less severe than those in Apert syndrome. In addition, there is no evidence of syndactyly with Crouzon syndrome, and the children usually have normal intelligence.

Pfeiffer syndrome is less common than either Apert or Crouzon syndrome, and the condition is also autosomal dominant.[103] Pfeiffer syndrome is divided into three types, with type 2 and 3 having more severe features and poorer prognoses given that multiple sutures are frequently involved (see Fig. 10-31).[94] A variable extent of syndactyly is seen in this syndrome, which is not usually as significant as that seen in Apert syndrome.

Another unique craniosynostosis condition is trigonocephaly, which results from the closure of an isolated suture, the metopic suture, and is not usually syndromic. Closure of the metopic suture creates the appearance of a triangular forehead (see Fig. 10-31).

Prenatal detection of craniosynostosis can be challenging, and often only the severe cases are identified by prenatal ultrasound examination.[94,104] The hyperechogenic bones of the skull have been visualized as early as 9 weeks of gestation.[94] The hypoechoic sutures become thinner as gestation advances. Abnormal fetal head shape or growth parameters (biparietal and occipitofrontal diameters) or the inability

to visualize the intervening sutures should raise concern for craniosynostosis. However, the abnormal skull shape may appear later, 4 to 16 weeks prior to the full closure of the sutures.[91] Widening of the nonfused sutures can also be noted and is best visualized with 3D ultrasound. The volumes need to be acquired by targeting each specific suture; otherwise, refractive shadows may simulate sutures. For example, the coronal suture should be acquired from an axial scan of the head, whereas the metopic suture should be acquired from a frontal view of the face, whether axial or sagittal. It is important to place the region of interest rendering boundaries along one suture at a time so that there is no overlapping of bones (see Fig. 10-34). Fetal MRI has been reported to be an excellent adjunct to ultrasound technology for the detection of craniosynostosis and the associated anomalies in small series.[99,105]

Treatment for craniosynostosis is surgical and involves several stages in those with multiple suture synostosis. The goals of care are to correct skull deformities and reduce the risk of raised intracranial pressure and subsequent neurologic damage.[92] The procedures can

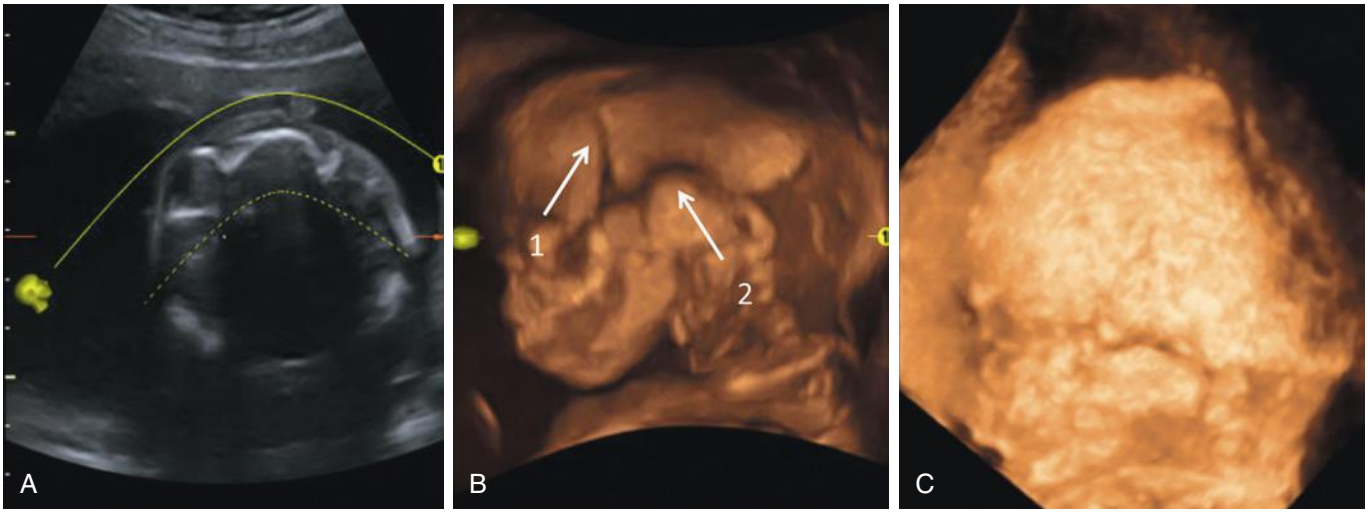

FIG 10-34 Normal and abnormal cranial sutures. **A,** Normal four-dimensional OmniView reference image of sutures at 26 weeks showing curved line over skull. **B,** Rendered image of normal sutures obtained using OmniView. 1, coronal suture; 2, squamosal suture. **C,** Craniosynostosis of coronal suture in Apert syndrome at 21 weeks.

include craniosynostosis release with fronto-orbital advancement at age 6 to 8 months followed by midface advancement later in childhood and possibly again in adolescence.[106,107] Airway management during these procedures can be difficult.[108]

The recurrence risks for craniosynostosis are likely less than 5% in those with nonsyndromic sagittal, metopic, or unicoronal synostosis but up to 30% to 50% in bicoronal and multisuture synostosis.[92] The autosomal dominant conditions can recur if there is germline mosaicism.

ANOMALIES OF THE NECK

Using a combination of 2D and 3D ultrasound imaging, a detailed assessment of the fetal neck can be made. In a study by Liberty and coworkers of 582 fetuses undergoing routine screening ultrasonography, the fetal neck structures were adequately visualized in 23% of fetuses at 10 to 13 weeks, 29% at 14 to 16 weeks, 35% at 17 to 19 weeks, and 88% at 20 to 24 weeks.[109] The success of imaging was therefore gestational age dependent. Structures that can be appreciated included multiple components of the fetal pharynx and larynx as well as the esophagus. Assessment of five standardized planes was proposed to evaluate the larynx and pharynx, including a posterior coronal plane, anterior coronal plane, and three axial planes (high, mid, low) (Fig. 10-36).[109] Standardized tables were established for the larynx and pharynx based on the study by Liberty and coworkers. These images are best accomplished by 3D multiplanar reconstruction; however, 2D real-time ultrasound is useful in detecting flow of amniotic fluid by color Doppler via both the pharynx and larynx into the fetal lungs and via the esophagus to the fetal stomach. The fetal esophagus, when decompressed, appears as two echogenic lines representing the serosa and mucosa with surrounding hypoechogenic muscular walls. Potential anomalies that can be detected via imaging of these basic structures of the fetal neck include laryngeal or esophageal atresia or a tracheoesophageal fistula (see Chapter 14).

Nuchal Cystic Hygroma

A cystic hygroma is a cystic lymphatic structure, usually occurring predominantly in the occipitocervical region, though it can extend

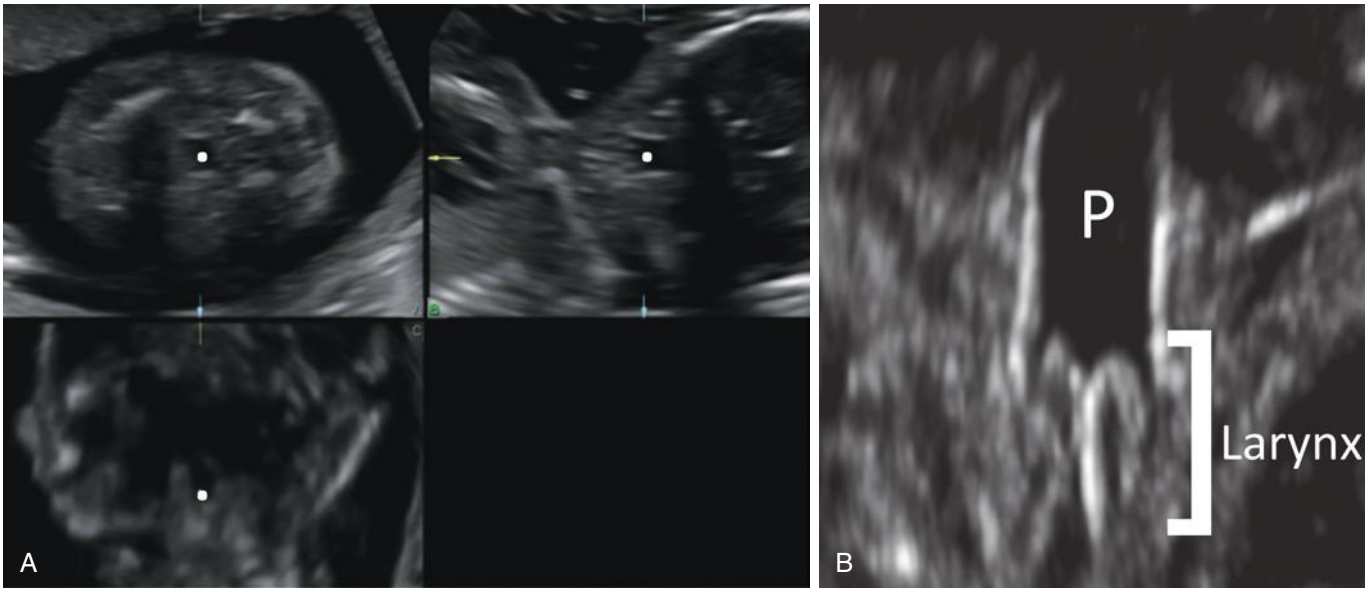

FIG 10-36 Normal ultrasound images of the fetal neck: **A,** Three-dimensional multiplanar display of the fetal neck acquired in the axial plane. The white cursor dot is centered in the pharynx in all three planes; upper left is axial, upper right is coronal, and lower left is sagittal. **B,** Coronal image of the fetal neck showing the pharynx (P) and larynx.

along the entire length of the fetus.[110,111] The proposed physiology of the formation of cystic hygromas was termed the *jugular lymphatic-obstruction sequence* by Smith and Graham.[112] In theory, the lymph fluid in a fetus first flows into the jugular lymphatic sacs, and the jugular sacs then develop connections to the venous system. They ultimately become the terminal portions of the right lymphatic duct and thoracic duct.[112,113] Distention of the jugular sacs and cystic hygromas occurs when this sequence is unsuccessful and the venous connections are not made. This can eventually result in global lymphedema and fetal hydrops (often called *congenital lymphangiectasia*) and fetal death (Fig. 10-37). Cystic hygromas may resolve in some cases as gestation progresses, with the theory that in these fetuses, recanalization of the lymph vessels occurs and collaterals develop.[110] For continuing pregnancies, isolated cystic hygromas identified in the first trimester, in otherwise normal fetuses, have been shown to resolve 78% of the time.[111]

In a large contemporary study of almost 40,000 patients screened in the first trimester, the frequency of cystic hygromas was found to be 1 in 285, whereas other studies report a frequency of 1.7%.[110,111] Some consider cystic hygroma to be the extreme of an enlarged nuchal translucency.

On ultrasound imaging, cystic hygromas and bilateral distention of the jugular sacs appear as hypoechoic structures in the fetal nuchal space. They may be septated or nonseptated. Multiple fibrous septa can give the hygroma a honeycomb appearance (Fig. 10-38). The hygromas vary in size and may be associated with sonographic findings of hydrops, including skin edema, pleural and pericardial effusions, and ascites.[53]

Cystic hygromas are concerning sonographic findings, as they are associated with aneuploidy, fetal anomalies, and fetal death. In a study of 134 cases, 51% were associated with confirmed aneuploidy whereas 34% of the remaining cases were affected with a major structural malformation.[111] Hygromas in the first trimester have been shown to be associated more often with trisomy 21 and in the second trimester with 45,X (Turner syndrome), although they can be seen with other aneuploidies as well.[111,113] Septa and larger cystic hygromas have been shown to be particularly concerning in terms of the association with aneuploidy and anomalies.[110,111] A cystic hygroma in a euploid fetus

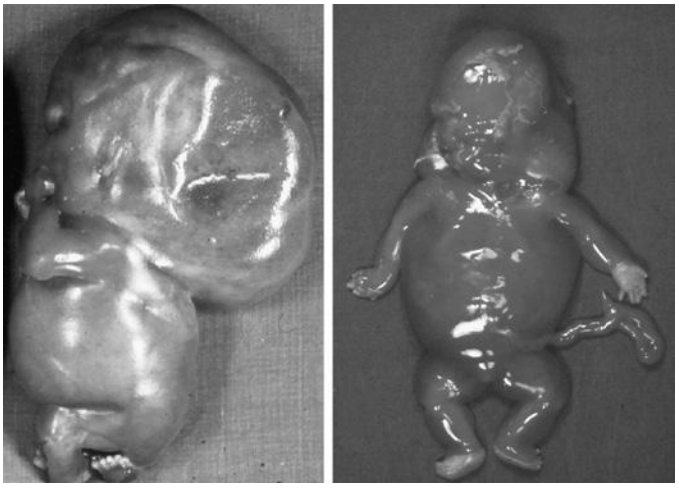

FIG 10-37 Nuchal cystic hygroma with lymphatic obstruction sequence.

can also result in pterygium colli (webbed neck) after birth. Anterior hygromas or lymphangiomas, rather than posterior, do not have the same association with aneuploidy.

The finding of a cystic hygroma warrants a thorough evaluation, including consideration of an invasive diagnostic procedure (chorionic villous sampling or amniocentesis) for genetic diagnosis and a detailed anatomic survey and fetal echocardiogram for those with continuing pregnancies. Only 17% of fetuses with the finding of a cystic hygroma in the first trimester will have normal pediatric outcomes.[111]

Other Neck Masses

The differential diagnosis for a fetal neck mass includes cystic hygroma, lymphangioma, hemangioma, cervical teratoma, goiter, branchial cleft cyst, and thyroglossal duct cyst.[114] All of these neck masses can be associated with polyhydramnios secondary to fetal esophageal compression and can potentially result in compromise of the neonatal airway at birth. Evaluating these masses to assess for potential involvement of vital neck structures such as the trachea and esophagus with

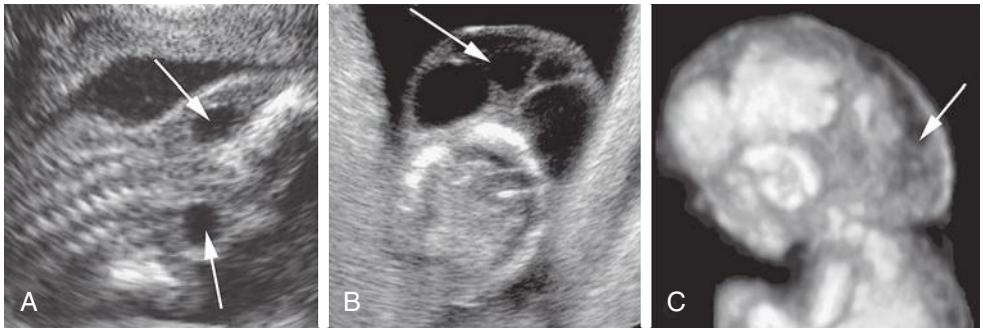

FIG 10-38 Nuchal cystic hygroma: **A,** Small hygroma in a second trimester fetus: two separate fluid accumulations (jugular sacs) are seen on each side of the neck (*arrows*). **B,** Large cystic hygroma (*arrow*) with septations in a fetus at 14 weeks' gestation. **C,** Three-dimensional ultrasound in surface mode in a fetus with a cystic hygroma (*arrow*).

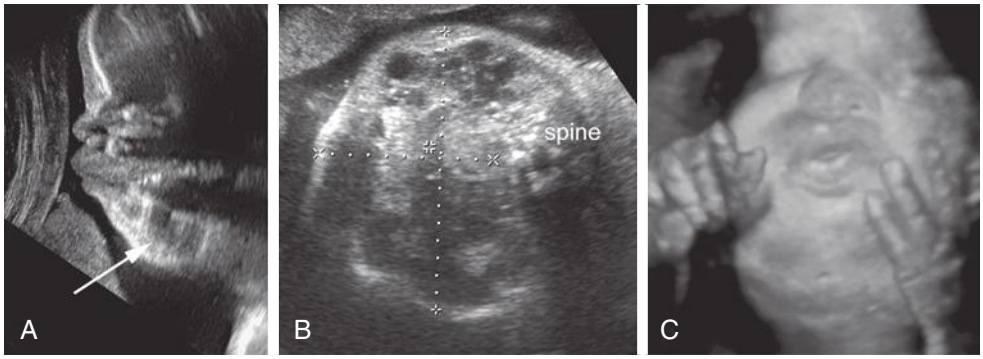

FIG 10-39 Although the antenatal diagnosis was cervical teratoma, this fetus was found at birth to have a cavernous lymphangioma infiltrating the neck tissues. **A** and **B,** Two-dimensional sonograms demonstrating the large neck mass. **C,** Surface rendered 3D sonogram demonstrating the mass.

the use of 3D and 4D ultrasound, as well as MRI, can be helpful.[115-117] If tracheal occlusion is suspected with any of these masses, an EXIT procedure may be required.[118]

Lymphangiomas are lymphatic malformations similar to cystic hygromas that infiltrate the subcutaneous space and muscular septa.[115] They can be seen by prenatal ultrasound as fetal neck masses of varied sizes with cystic components infiltrating the surrounding tissues (Fig. 10-39). They can require immediate surgical treatment either at the time of birth in the event of airway compromise or surgery in early neonatal life. Spontaneous resolution is less likely.

Hemangiomas are benign vascular malformations that can be located in the area of the fetal head and neck and have an appearance similar to lymphangiomas on prenatal ultrasound images. They are found in the dermis and subcutaneous tissues. There are three types—capillary, cavernous, and nevus flammeus.[119] Cavernous hemangiomas are found in 2% of infants and can be detected on prenatal ultrasound images as echogenic soft tissue masses.[119] The borders of these benign tumors are often hard to differentiate from surrounding tissues.[120] Color power Doppler examination has been used to demonstrate significant vascularity of the lesions, which is a distinctive finding differentiating them from lymphangiomas.[119] High-output cardiac failure can occur with cavernous hemangiomas, which can lead to fetal hydrops, and they therefore require close monitoring, particularly if they are large. Depending on the location and size of the hemangioma, some can be managed expectantly postnatally, whereas others will require surgical intervention.

Teratomas are rare tumors, occurring in 1 in 20,000 to 1 in 40,000 live births, and about 5% of them are located in the cervical region.[121-123] They are most often benign, though malignant transformation has been reported.[124] Like epignathus tumors of the mouth,

FIG 10-40 Parasagittal sonographic image showing large exophytic solid and cystic cervical teratoma.

these tumors can be derived from all three germ cell layers. On ultrasound imaging, the tumors appear as pharyngeal masses usually crossing the midline with solid and cystic components (Figs. 10-40 and 10-41). Approximately 50% of teratomas display calcifications.[121] Thirty percent of these tumors are associated with polyhydramnios.[114,121] Treatment is via surgical excision, and fetuses with airway

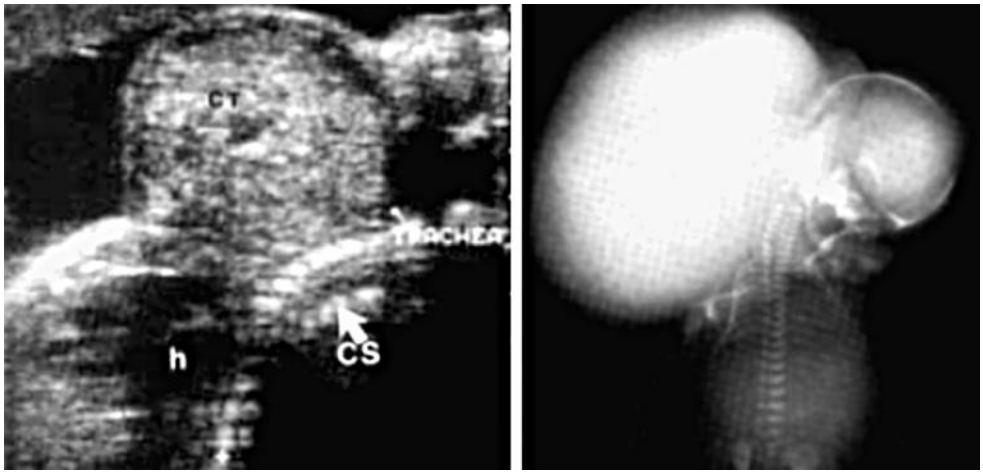

FIG 10-41 Large cervical teratoma (CT). CS, cervical spine; h, heart.

compression may require delivery by means of the EXIT procedure, like several of the other neck masses, depending on the size and the structures involved.

Fetal goiter can also manifest as an anterior neck mass that may lead to tracheal compression and neonatal airway concerns at birth. On ultrasound imaging, it is a homogeneous, uniform well-demarcated central neck mass that may result in hyperextension/retroflexion of the fetal neck (Fig. 10-42).[125] Iodine deficiency, overtreatment of maternal Graves disease or other causes of hyperthyroidism, excessive thyroid replacement, and congenital hypothyroidism can lead to the development of a fetal goiter.[125,126] If the cause is a maternal medical issue, it can be addressed appropriately; however, if there is concern for congenital hypothyroidism, percutaneous umbilical blood sampling may be necessary to assess the fetal thyroid status and determine if treatment is warranted. If significant fetal hypothyroidism is identified, it has been successfully treated with intra-amniotic levothyroxine; this treatment can result in reduction of the size of the goiter and decrease the risk of tracheal compression at birth.[126,127] If tracheal patency is highly suspected on prenatal sonography and MRI, and the mass is not expected to pose an airway problem at the time of birth, fetal goiter has also been managed conservatively with treatment of the congenital hypothyroidism initiated after birth.[125]

Establishing a definitive diagnosis of a fetal neck mass on prenatal imaging can be challenging, even with the use of advanced ultrasound technology and MRI.[114,120] Attention must be paid to the presence of solid or calcified components, which are more common in teratomas, whereas hemangiomas and lymphangiomas are more often fluid-filled structures.[114,121] One of the essential goals of prenatal imaging is to identify whether the trachea appears patent as this finding can alter delivery planning and the need for an EXIT procedure.[118] It is highly recommended that infants with large neck masses be delivered in a tertiary care center to allow for involvement of a multispecialty team and avoid any delay in necessary immediate treatment.

FIG 10-42 Fetal goiter (*arrow*) that was found to be associated with hypothyroidism as a consequence of excessive maternal propylthiouracil intake.

CONCLUSIONS

Orofacial clefts are among the most common fetal and neonatal anomalies. With improved access to and expertise in both 2D and 3D sonography, the frequency and accuracy of prenatal diagnosis are improving. Particularly with clefts that involve the palate only, 3D ultrasound imaging can be essential. Other abnormalities of the fetal face and head amenable to potential prenatal detection include ocular defects, micrognathia and retrognathia, and craniosynostosis. Identifying a facial anomaly should always signal the need for a complete detailed fetal anatomic survey, particularly the brain, to evaluate for any associated anomalies that could represent a known chromosomal abnormality or syndrome. The same is true of the finding of fetal neck abnormalities, particularly the cystic hygroma. The prognosis for fetal facial anomalies depends on the severity of the finding, the presence of an underlying syndrome, and any associated neurologic abnormalities. The outcome for fetal facial tumors and neck masses relies on the ability to treat and resect such lesions. Advances in prenatal ultrasound imaging of the fetal face and neck assist in preparing the patient and the surgical teams for the optimal care of the neonate.

Fetal Musculoskeletal System

Edgar Hernandez-Andrade, Lami Yeo, Luís F. Gonçalves, Suchaya Luewan, Maynor Garcia, Roberto Romero

SUMMARY OF KEY POINTS

- The prevalence of skeletal dysplasias is about 2.4/10,000 births, and 9.1/1000 among perinatal deaths; the most common anomalies are thanatophoric dysplasia, achondroplasia, osteogenesis imperfecta, and achondrogenesis.
- The new edition of Nosology and Classification of Genetic Skeletal Disorders includes 436 clinical conditions classified into 42 groups involving 364 affected genes; therefore, molecular diagnosis is possible in about 75% of skeletal disorders.
- Molecular diagnosis can be offered to couples with a family history of skeletal dysplasia to estimate the risk in a future pregnancy, or to pregnant women with ultrasound signs suggestive of fetal skeletal dysplasia.
- Two-dimensional (2D) and three-dimensional (3D) sonography and 3D helical computed tomography (3D-HCT) are the main imaging modalities used to evaluate a fetus with suspected skeletal dysplasia.
- Thanatophoric dysplasia and achondrogenesis account for 60% of all lethal skeletal dysplasias and are characterized by extremely reduced thoracic dimensions and very short long bones.
- A complete fetal ultrasound evaluation, including assessment of fetal movements, should be performed if a skeletal disorder is suspected.
- Ultrasound signs suggestive of a skeletal dysplasia include bones with reduced length, abnormal shape, reduced mineralization, and fractures; abnormal fetal facial profile; polyhydramnios; and abnormal pattern of fetal movements.
- The diagnosis of a possible skeletal dysplasia during pregnancy should be corroborated by molecular diagnosis and neonatal or pathologic evaluation.

OUTLINE

DEVELOPMENT OF THE FETAL SKELETON

The skeleton is formed by 206 skeletal elements constituted by two tissues (bone and cartilage) and three cell types (osteoblasts, osteoclasts, and chondrocytes).[1,2] Skeletal tissues derive from three embryonic cell lineages: (1) cranial neural crest cells, from which the craniofacial skeleton originates; (2) paraxial mesoderm cells or somites, which are the embryologic precursors of the axial skeleton; and (3) the lateral plate mesoderm, which is responsible for limb formation.[1,3-6] Limb buds begin to develop during the 4th week of embryonic life (6th menstrual week) as clusters of mesenchymal cells covered by a layer of ectoderm.[1-3] Mesenchymal models of bone (anlagen: templates for future bones) form around the 5th week of embryonic life (7th menstrual week) (Fig. 11-1).[3] Development of the upper limbs precedes the lower limbs in bud appearance, differentiation, and final relative limb size. Limbs develop in a proximodistal sequence, with the anlagen of the humerus and femur forming first, followed by the radius and ulna, the tibia and fibula, the metacarpal and metatarsal bones, and phalanges.[1,2,7]

Skeletogenesis (Genetics and Embryology)

Skeletogenesis involves four steps: patterning, organogenesis, growth, and homeostasis.[4] Patterning is the process by which the final size, shape, number, and arrangement of bones are determined.[2,4] This process takes place long before skeletogenesis, and three signaling regions have been identified: (1) an apical ectodermal ridge; (2) an area consisting of ectoderm covering the sides of the bud; and (3) a zone of polarizing activity.[5] The apical ectodermal ridge consists of densely packed ectodermal cells located at the tip of the limb bud, which express several fibroblast growth factors (FGFs) that initiate and control limb outgrowth.[5,8,9] The ectoderm covering the sides of the bud regulates dorsoventral patterning.[5] The zone of polarizing activity is located on the posterior limb bud margin. It is responsible for anteroposterior patterning and, thus, the formation of digits.[9,10] Besides FGFs, other genes are involved in the control of limb patterning, including Sonic hedgehog (Shh), GLI-Kruppel family member GLI3 (Gli3), sal-like 1 (Sall1), Hoxd13, Hoxa13, bone morphogenetic/cartilage-derived morphogenetic protein (CDMP), growth differentiation factors (GDFs), Noggin (Nog), Wn7-a, engrailed (en), and LIM homeobox transcription factor 1 beta (Lmx1b).[1,11-16]

Bone and cartilage are formed during the organogenesis period, which consists of three phases: condensation, cell differentiation, and histogenesis. Condensation is of great importance in skeletal development, because the templates for future bones are defined at this stage.[6] Condensation initiation, boundary set, proliferation, adhesion, and growth are regulated by complex interactions between extracellular matrix molecules, cell surface receptors, cell adhesion molecules (e.g., fibronectin, tenascin, Noggin, syndecan, and neural cell adhesion molecule [N-CAM]), homeobox genes (e.g., Hoxa-2, Hoxa-13, Hoxd-11, and Hoxd-11-13), transcription factors (e.g., runt-related transcription factor 2 [RUNX2], winged-helix transcription factor [CFKH-1], mesenchyme forkhead 1 [MFH-1], paired box transcription factors 1 and 9 [PAX-1, PAX-9], periaxin 1 and 2 [PRX-1 and PRX-2], scleraxis, and mammalian SRY box 9 [SOX-9]), and growth factors (e.g., bone morphogenetic proteins, fibroblast growth factor 2 [FGF-2], transforming growth factor beta [TGF-β]).[17,18] Osteogenesis initiates during the 7th week of embryonic development (9th menstrual week), with bones developing by either endochondral or membranous ossification.[4]

Endochondral Ossification

The axial and appendicular skeletons are formed by endochondral ossification (Fig. 11-2). The axial skeleton (e.g., vertebrae and the dorsal part of the ribs) originates from the somites. Cartilaginous

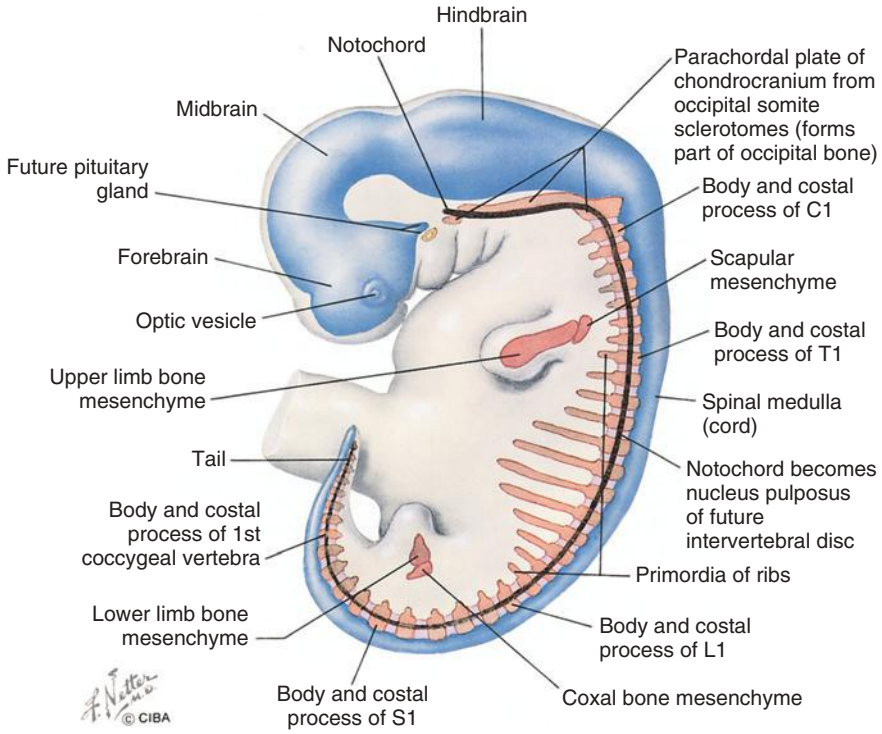

FIG 11-1 Diagram of the mesenchymal precartilage primordia of the axial and appendicular skeletons at 5 weeks' embryologic age (7 weeks' menstrual age). These primordia develop further and eventually ossify to form skeletal structures. (Illustration by Netter FH; from Crelin ES: Development of the musculoskeletal system. CIBA Clin Symp 33:6, 1981. Used with permission from CIBA-GEIGY Corporation, Summit, NJ.)

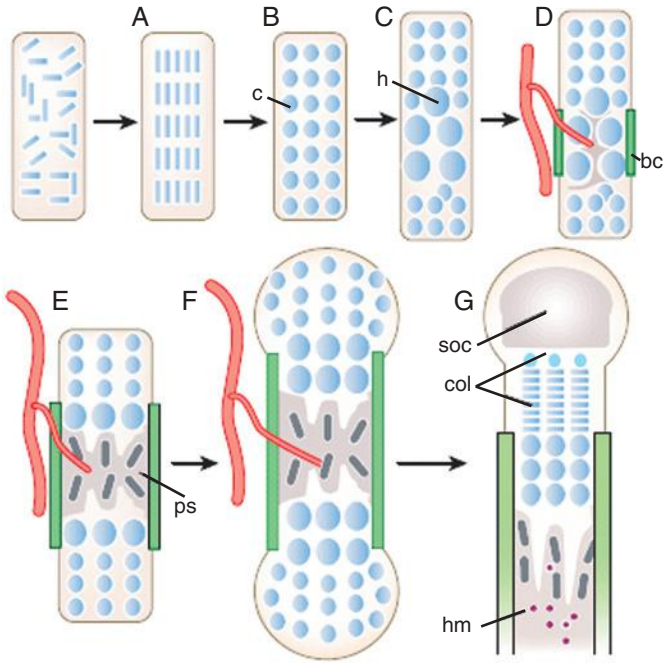

FIG 11-2 Endochondral bone formation. **A,** Mesenchymal cells condense. **B,** Cells of condensations become chondrocytes (c). **C,** Chondrocytes at the center of condensation stop proliferating and become hypertrophic (h). **D,** Perichondrial cells adjacent to hypertrophic chondrocytes become osteoblasts forming bone collar (bc). Hypertrophic chondrocytes direct the formation of mineralized matrix, attract blood vessels, and undergo apoptosis. **E,** Osteoblasts of primary spongiosa accompany vascular invasion forming the primary spongiosa (ps). **F,** Chondrocytes continue to proliferate, lengthening the bone. Osteoblasts of primary spongiosa are precursors of eventual trabecular bone; osteoblasts of bone collar become cortical bone. **G,** At the edge of the bone, the secondary ossification center (soc) forms through cycles of chondrocyte hypertrophy, vascular invasion, and osteoblast activity. The growth plate below the secondary center of ossification forms orderly columns of proliferating chondrocytes (col). Hematopoietic marrow (hm) expands in marrow space along with stromal cells. (From Kronenberg HM: Developmental regulation of the growth plate. Nature 423:332-336, 2003.)

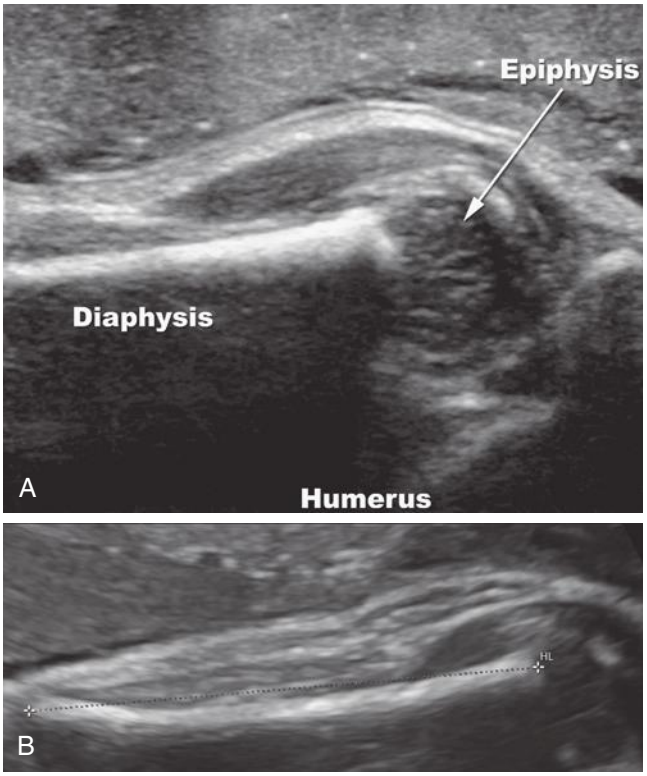

FIG 11-3 **A,** Proximal humeral epiphysis imaged with a high-frequency linear transducer (10 MHz) in a fetus at 29 weeks' gestation. **B,** Measurement of the femur in a third trimester. The femur should be measured along the ossified bone (between the electronic calipers).

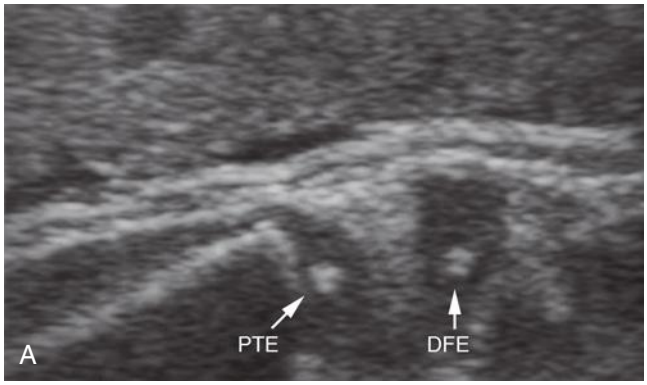
models of the future bones differentiate within mesenchymal condensations during the 6th week of development (8th menstrual week), with primary ossification centers developing in the middle of the anlagen between the 7th and 12th weeks of development (9th to 14th menstrual weeks).[3] *SOX9* plays an important role in chondrogenesis. Mutations in this gene cause campomelic dysplasia, a severe skeletal disorder characterized by congenital bowing and angulation of the long bones (especially of the tibia), hypoplastic scapulae, sex reversal in male fetuses, and a high lethality rate due to respiratory insufficiency.[9] Another gene involved in chondrogenesis is procollagen type II alpha 1 (*COL2A1*), which encodes collagen type II.[1,19]

Within primary ossification centers, hypertrophic cartilage matrix is degraded, chondrocytes undergo apoptosis, osteoblasts replace the disappearing cartilage with trabecular bone, and bone marrow is formed.[1] Simultaneously, osteoblasts in the perichondrium begin to deposit a collar of compact bone matrix along the diaphysis.[1,19] Osteoblast differentiation is controlled by RUNX2[20] and Osterix,[21] whereas proliferation is controlled by the low-density lipoprotein receptor–related protein 5 (LPR5) signaling pathway.[2] Eventually, cartilage in the center of the anlagen degrades, mineralizes, and is removed by osteoclasts.[3,6] Vascular ingrowth is stimulated by vascular endothelial growth factor, with the influx of osteoprogenitor cells occurring at the same time that the bone matrix is deposited along the periosteum of the midshaft.[3,6,22] Some of these invading cells differentiate into hematopoietic stem cells, whereas others differentiate into osteoclasts or osteoblasts.[4]

Secondary ossification centers begin to appear at the extremities of bones (epiphyses) later in pregnancy.[3] The portion of cartilage trapped between the expanding primary and secondary ossification centers is known as the growth plate or physis.[3,9] This structure is formed by a cartilaginous component (epiphyseal plate), a bony component (metaphysis), and fibrous tissue surrounding the periphery of the plate.[23,24] The growth plate is responsible for the longitudinal growth of long bones until definitive fusion of epiphyses and diaphyses occurs at the end of puberty.[3,6,19] Longitudinal growth is coordinated by Indian hedgehog (Ihh), a stimulator of chondrocyte proliferation at the growth plate.[1] Bone mass, shape, and strength are maintained throughout development and adult life by balancing bone destruction and formation. Homeostasis is the process that controls the continuing remodeling of bones.[4]

It is noteworthy that when a long bone is imaged by ultrasound, only the diaphyses are measured, because the epiphyses are hypoechoic and are not always clearly visualized. Under favorable conditions, good sonographic images of the epiphysis can be obtained, especially when high-frequency transducers are used (Fig. 11-3). Secondary ossification centers may often be visualized by ultrasound in the third trimester. The distal femoral ossification center may be seen at approximately 32 to 33 weeks of gestation, the proximal tibial epiphyseal center at 34 to 35 weeks, and the proximal humeral epiphyseal ossification center at 37 to 38 weeks of gestation (Fig. 11-4). When all three centers are identified, it is likely that the fetus is at least 37 weeks' gestational age.



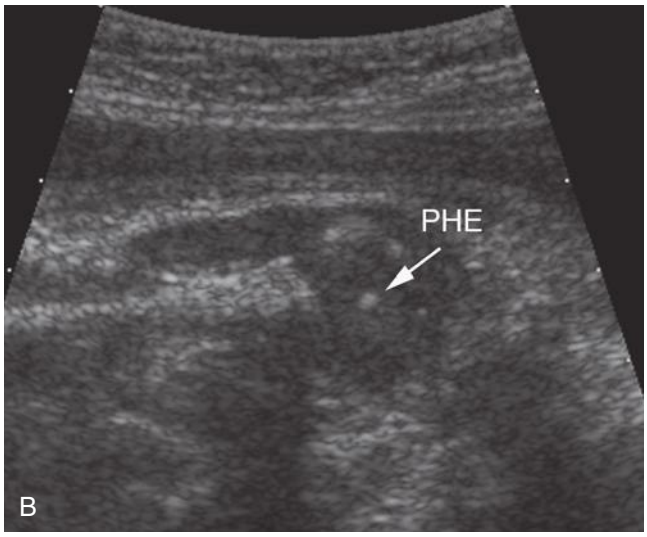


FIG 11-4 A, Sonogram of the knee in a fetus at 35 weeks' gestation. Increased echogenicity from the secondary ossification centers of distal femoral (DFE) and proximal tibial (PTE) epiphyses are seen. **B,** Sonogram of the proximal humerus in a fetus at 38 weeks' gestation. Ossification of the proximal humeral epiphyseal ossification center (PHE) is noted.

These ossification centers may be seen slightly earlier in female fetuses than in male fetuses. The timeline for radiographic and histologic appearance of primary and secondary ossification centers is illustrated in Figure 11-5.

Formation and detachment of new somites in the axial skeleton from the paraxial mesoderm occur in craniocaudal direction following a molecular clock produced by oscillations of cycling genes (e.g., c-hairy-1, lunatic fringe [l-fng], and naked cuticle 1 [nkd1]) that stimulate Notch receptor signaling waves that sweep through the paraxial mesoderm.[25-28] Spatial coordination is provided by a decreasing gradient of FGF8 from the posterior to the anterior pole of the embryo.[5,28,29] Differential expression of delta-like (Dll) proteins determines the size and polarity of the somites,[5] which mature as they move rostrally and differentiate into dermatomyotomes and sclerotomes.[5,28] Dermatomyotomes give rise to the appendicular and axial musculatures, as well as the dorsal epithelium. The sclerotome is the precursor of the axial skeleton, and its formation is initiated and controlled by the Sonic hedgehog gene (*SHH*).[5,30,31]

Intramembranous Ossification

The craniofacial skeleton and clavicles develop by intramembranous ossification.[1] This process differs from endochondral ossification by the direct differentiation of mesenchymal cells into osteoblasts, which produce a bone matrix rich in type I collagen.[1-3,19,22] Bone remodeling is accomplished by continuous and concerted action of osteoblasts (cells that produce bone matrix) and osteoclasts (cells that remove bone).

SKELETAL DYSPLASIAS

Abnormal development, growth, or maintenance of cartilage and bone tissues results in skeletal dysplasias. Skeletal dysplasias are a heterogeneous group of disorders affecting the development of chondro-osseous tissues leading to abnormalities in the size, mineralization, and shape of various segments of the skeleton. Despite recent advances in imaging and molecular genetics,[32-34] accurate prenatal diagnosis of skeletal dysplasias remains a clinical challenge.[35] In the most recent revision of the International Nosology and Classification of Constitutional Disorders of Bone[36] it is mentioned that in approximately 25% of all bone disorders the mutated gene has not been yet identified. It is important to acknowledge the contribution of the International Skeletal Dysplasia Registry[37] in the identification and study of skeletal anomalies, assisting providers and patients in the diagnosis and clinical management of skeletal disorders.

In subsequent sections of this chapter, we will review the birth prevalence, classification, and molecular genetics of skeletal dysplasias that are identifiable at birth.

Birth Prevalence and Contribution to Perinatal Mortality

In a large multicenter study conducted by Camera and Mastroiacovo[38] the birth prevalence of skeletal dysplasias (excluding limb amputations) was estimated as 2.4/10,000 births. Twenty-three percent of the affected infants were stillborn, whereas 32% died during the first week of life. The overall frequency of skeletal dysplasias among perinatal deaths was 9.1/1000. This study also reported on the birth prevalence of the different skeletal dysplasias and their relative frequency among perinatal deaths. The four most common skeletal dysplasias were thanatophoric dysplasia, achondroplasia, osteogenesis imperfecta (OI), and achondrogenesis. Thanatophoric dysplasia and achondrogenesis accounted for 62% of all lethal skeletal dysplasias, and the most common nonlethal skeletal dysplasia was achondroplasia.[38] In another large series from western Scotland, the prevalence of skeletal dysplasias at birth was 1.1/10,000 births. The most frequent conditions were thanatophoric dysplasia (1/42,000), OI (1/56,000), chondrodysplasia punctata (1/84,000), campomelic syndrome (1/112,000), and achondrogenesis (1/112,000).[39] Rasmussen and associates[40] reported a prevalence of 2.1/10,000 deliveries in a longitudinal study, which included elective pregnancy termination, stillborn infants at more than 20 weeks of gestation, and liveborn infants diagnosed by the 5th day of life. The rate of lethal cases in this study was 0.95/10,000 deliveries.[40] Of interest, the study reporting the highest prevalence of skeletal dysplasias at birth (9.5/10,000 births) was conducted in a population with a high rate of consanguineous unions.[41] An overview of the prevalence of skeletal dysplasias in different populations is presented in Table 11-1.

Classification of Skeletal Dysplasias

Molecular-Pathogenetic Classification of Skeletal Dysplasias

The first classification of skeletal anomalies was proposed more than 40 years ago and was mainly based on clinical and radiographic findings.[50] Since that time, the classification has continuously evolved owing to the contribution of imaging and molecular biology techniques.[33,34,51-55] This classification is currently known as Nosology and

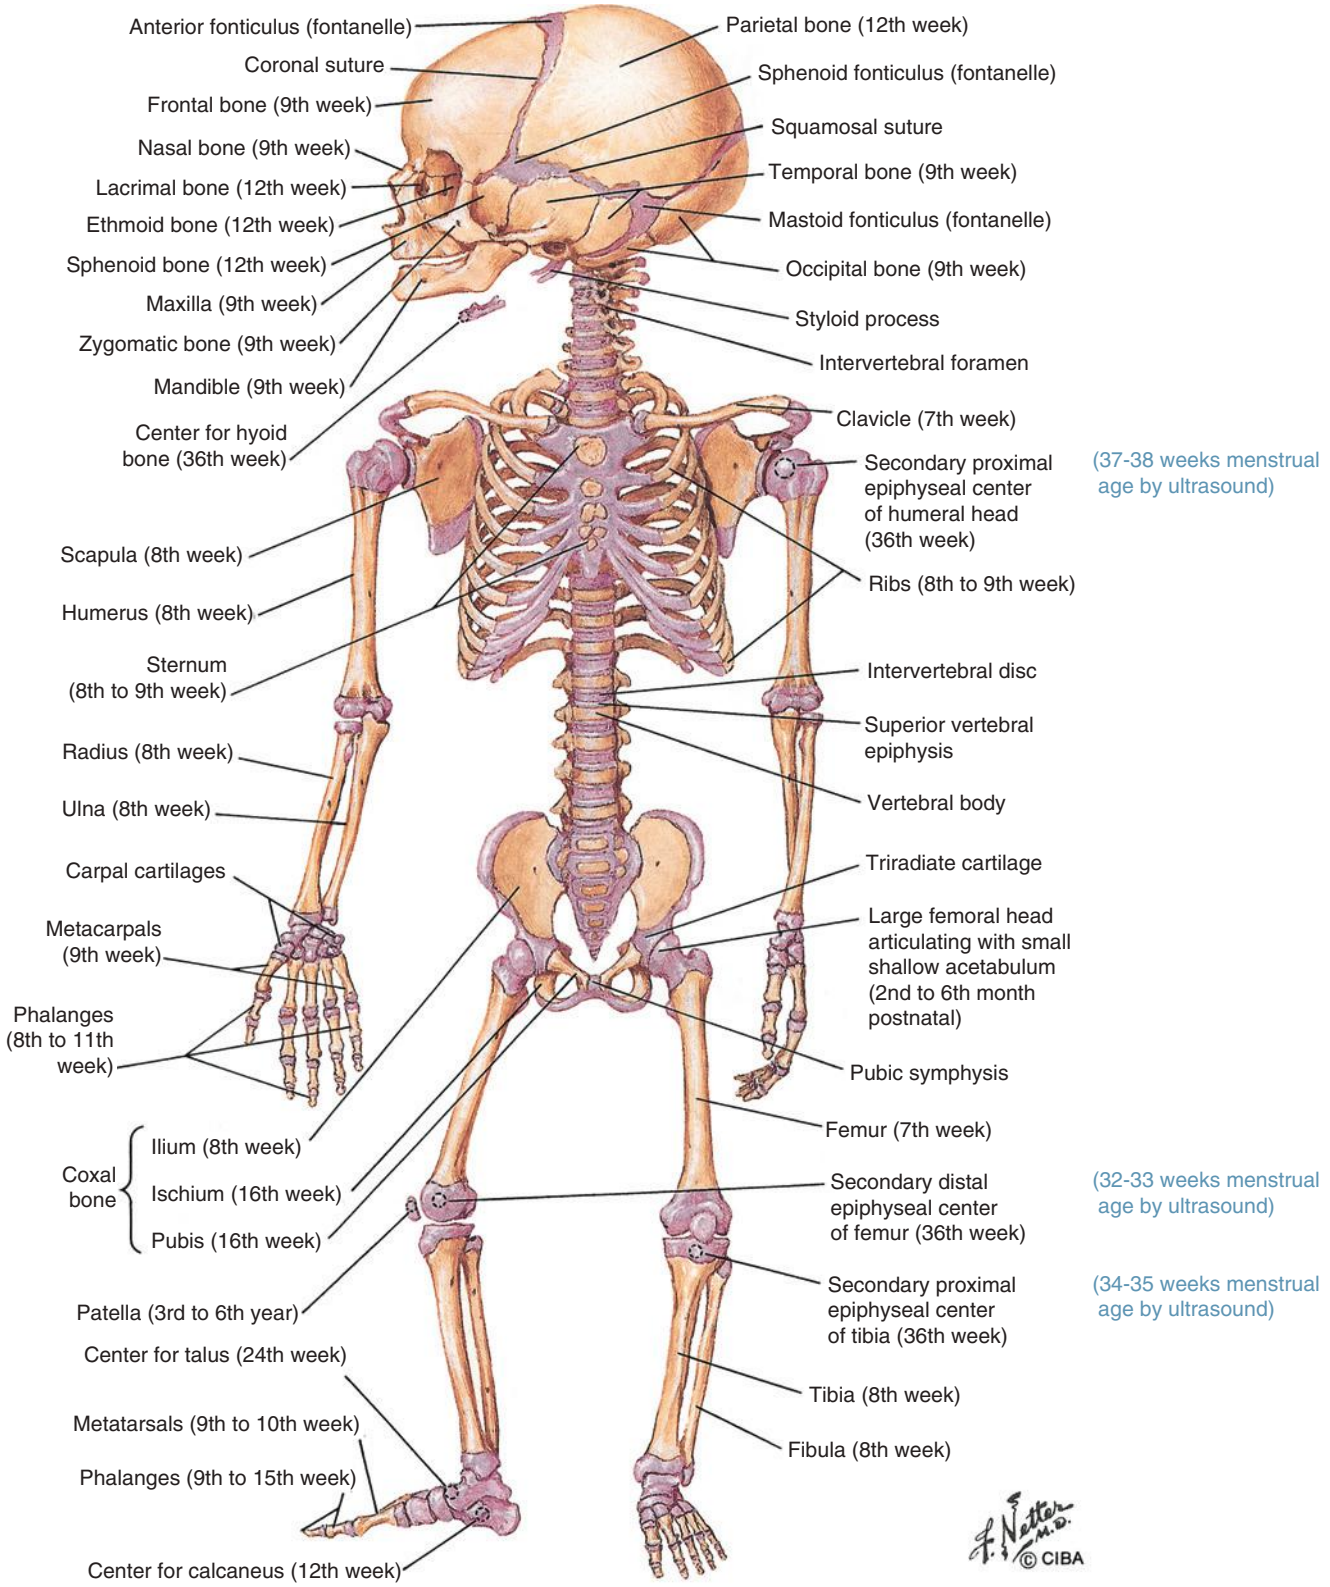

FIG 11-5 Diagram of the skeleton of a full-term newborn. The times that the ossification centers appear are designated in embryologic weeks (add 2 weeks for menstrual age). These times are somewhat different from those using ultrasound because ultrasound is more sensitive for detection of ossification than radiographic methods. All refer to the primary ossification centers unless otherwise designated. Only at birth do the lower extremities have the same length as the upper extremities; subsequently, the lower extremities become longer than the upper extremties. TABLE 11-1 Prevalence of Skeletal Dysplasias

Study*	Prevalence	Comment
Gustavson and Jorulf[42]	1/2117	Newborns
Camera and Mastroiacovo[38]	1/4600	Neonates
Connor et al[39]	1/8900	Neonates
Weldner et al[95]	1/1333	Achondroplasia
Orioli et al[43]	1/4347	First 3 days of life
Stoll et al[44]	1/3125	First 8 days of life
Andersen[45]	1/6667	At birth
Kallen et al[46]	1/6250	Multicenter study
Rasmussen et al[40]	1/4166	First 5 days of life
Barbosa-Buck et al[47]	1/21,276	Thanatophoric dysplasia
Donnelly et al[48]	1/8000	Thanatophoric dysplasia
Stevenson et al[49]	1/7900	Osteogenesis imperfecta

*Studies are listed in the references at the end of the chapter.

Classification of Genetic Skeletal Disorders.[36] Most skeletal anomalies are a phenotypic manifestation of a mutation in a gene and altered protein expression; therefore, they can be grouped according to the affected genes as they share similar clinical characteristics. The International Skeletal Dysplasia Society (ISDS) periodically reviews this classification, and the last version corresponding to the 9th edition was published in 2015.[36] In this document, the authors acknowledge the contribution of next-generation sequencing technologies and the increasing availability of whole exome sequencing, allowing the discovery of more gene-related skeletal anomalies. For this review, 436 clinical conditions were classified into 42 groups involving 364 affected genes (Table 11-2). The classification provides (1) the group/name of the skeletal disorder; (2) type of inheritance; (3) MIM (Mendelian Inheritance in Man) number; (4) locus of the mutation in the gene; (5) affected protein; and (6) associations/difference with other skeletal anomalies. Skeletal dysplasias, metabolic bone disorders, dysostosis, skeletal malformations, and reduction syndromes are included in this classification. However, the authors also clarify that in approximately 25% of skeletal disorders, the mutated gene has not yet been identified. The genetic basis for classification of very rare diseases was done by family pedigree, or was based on homogeneity or phenotype in unrelated families. The classification aims to provide more complete information for prenatal counseling and clinical management. The full document can be consulted at the ISDS website.[56]

Skeletal Dysplasias Seen at Birth

The molecular pathogenic classification of genetic disorders of the skeleton is very extensive and includes many conditions that may not be apparent at birth and therefore are not amenable to prenatal diagnosis by imaging methods.[33] A more clinically relevant list of skeletal dysplasias that may be recognizable during pregnancy along with their mode of inheritance and causative genes has been published by Krakow[57] (Table 11-3). The authors acknowledge that for a full classification of skeletal anomalies the Nosology and Classification of Genetic Skeletal Disorders should be consulted.[36]

Clinically Oriented Classification

A skeletal anomaly is suspected prenatally either by family history or by ultrasound findings, while after birth, the diagnosis is suspected based on family history and on clinical and radiographic findings. When a previous family member is affected, a gene panel can be offered to the mother (and if necessary to the father) to evaluate the risk to the fetus. Direct testing can also be performed and genetic panels evaluated on amniotic fluid or chorionic villus samples when sonographic findings suggestive of a skeletal anomaly are identified. Krakow and colleagues[58] compiled a practical list of abnormal ultrasonographic findings seen in skeletal dysplasias along with a list of differential diagnoses for each finding (Table 11-4). Once the differential diagnoses have been narrowed down to the most likely disorder(s), definitive genetic testing can be offered. Limitations of genetic panels include study cost, time to obtain the results, and that the genetic basis of all skeletal anomalies are not known. A benefit of molecular testing is that identification of the gene mutation can provide information on the severity of the disease.

Terminology Frequently Used to Describe Bone Dysplasias

Shortening of the extremities can involve the entire limb (micromelia), the proximal segment (rhizomelia), the intermediate segment (mesomelia), or the distal segment (acromelia) (Fig. 11-6). The diagnosis of rhizomelia or mesomelia requires comparing the bony dimensions of the lower legs and forearms with those of the thighs and arms. Figures 11-7 and 11-8 display the relationships between the humerus and ulna, as well as the femur and tibia, which can be used for the objective assessment of rhizomelia and mesomelia. Table 11-5 presents a list of skeletal dysplasias characterized by rhizomelia, mesomelia, and micromelia.

Several skeletal dysplasias feature alterations of the hands and feet. The term *polydactyly* refers to the presence of more than five digits. It is classified as postaxial if the extra digits are on the ulnar or fibular side, and preaxial if they are located on the radial or tibial side. *Syndactyly* refers to soft tissue or bony fusion of adjacent digits. *Clinodactyly* consists of deviation of a finger or fingers.

The most common spinal abnormality seen in skeletal dysplasias is platyspondyly, which consists of flattening of the vertebrae (Fig. 11-9).[59-65] Xyphosis, scoliosis[66-70] (Figs. 11-10 and 11-11), hemivertebra (Fig. 11-12),[66,71,72] and coronal clefting of vertebral bodies have been also reported.[68]

Long bone biometry has been used extensively for the prediction of gestational age. Nomograms for this purpose display the distribution of bone lengths in relation to gestational weeks. For the proper use of these nomograms, the clinician must know the accurate gestational age of the fetus. Therefore, patients at risk for skeletal dysplasias are advised to seek prenatal care at an early gestational age in order to assess all clinical estimators of gestational age. Tables 11-6 and 11-7 present nomograms of the measurement of limb biometry for the upper and lower extremities, respectively. Comparisons between the limb dimensions and head circumference can be used for patients presenting with uncertain gestational age (Figs. 11-13 and 11-14).

The nomograms and figures in this chapter provide the mean, 3rd, and the 97th percentiles of limb biometric parameters. The reader should be aware that approximately 6% of the general population will fall outside these boundaries. Ideally, a more stringent criterion, such as the 1st percentile of limb growth for gestational age, should be used for diagnosis. Unfortunately, none of the currently available nomograms has been based on a sufficient number of patients to provide an accurate discrimination between the 3rd and the 1st percentiles. However, most skeletal dysplasias diagnosed in utero or at birth are associated with dramatic long bone shortening, and under these circumstances, the precise boundary used (i.e., 1st or 3rd percentile) is not critical. An exception to this is achondroplasia, in which limb biometry is only mildly affected until the third trimester, when abnormal growth can be detected by examining the slope of growth of the

TABLE 11-2 Nosology and Classification of Genetic Skeletal Disorders

GROUPS/NAME OF DISORDER

1. FGFR3 chondrodysplasia group
   a. Thanatophoric dysplasia type 1 (TD1), type 2 (TD2)
   b. Severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN)
   c. Achondroplasia
   d. Hypochondroplasia
   e. Camptodactyly, tall stature, and hearing loss syndrome (CATSHL)
   f. Hypochondroplasia-like dysplasia(s)
2. Type 2 collagen group
   a. Achondrogenesis type 2 (ACG2; Langer-Saldino)
   b. Platyspondylic dysplasia, Torrance type
   c. Hypochondrogenesis
   d. Spondyloepiphyseal dysplasia congenita (SEDC)
   e. Spondyloepimetaphyseal dysplasia (SEMD), Strudwick type
   f. Kniest dysplasia
   g. Spondyloperipheral dysplasia
   h. Mild SED with premature onset arthrosis
   i. SED with metatarsal shortening (formerly Czech dysplasia)
   j. Stickler syndrome type 1
3. Type 11 collagen group
   a. Stickler syndrome type 2
   b. Marshall syndrome
   c. Stickler syndrome type 3 (nonocular)
   d. Fibrochondrogenesis
   e. Oto-spondylo-mega-epiphyseal dysplasia (OSMED), recessive type
   f. Oto-spondylo-mega-epiphyseal dysplasia (OSMED), dominant type (Weissenbacher-Zweymüller syndrome, Stickler syndrome type 3)
4. Sulfation disorders group
   a. Achondrogenesis type 1B (ACG1B)
   b. Atelosteogenesis type 2 (AO2)
   c. Diastrophic dysplasia (DTD)
   d. MED, autosomal recessive type (rMED; EDM4)
   e. SEMD, PAPSS2 type
   f. Brachyolmia, recessive type
   g. Chondrodysplasia gPAPP type (includes Catel-Manzke-like syndrome
   h. Chondrodysplasia with congenital joint dislocations, CHST3 type (recessive Larsen syndrome)
   i. Ehlers-Danlos syndrome, CHST14 type ("musculoskeletal variant")
5. Perlecan group
   a. Dyssegmental dysplasia, Silverman-Handmaker type
   b. Dyssegmental dysplasia, Rolland-Desbuquois type
   c. Schwartz-Jampel syndrome (myotonic chondrodystrophy)
6. Aggrecan group
   a. SED, Kimberley type
   b. SEMD, Aggrecan type
   c. Familial osteochondritis dissecans
7. Filamin group and related disorders
   a. Frontometaphyseal dysplasia
   b. Osteodysplasty Melnick-Needles
   c. Otopalatodigital syndrome type 1 (OPD1)
   d. Otopalatodigital syndrome type 2 (OPD2)
   e. Terminal osseous dysplasia with pigmentary defects (TODPD)
   f. Atelosteogenesis type 1 (AO1)
   g. Atelosteogenesis type 3 (AO3)
   h. Larsen syndrome (dominant)
   i. Spondylo-carpal-tarsal dysplasia
   j. Frank-ter Haar syndrome

GROUPS/NAME OF DISORDER

8. TRPV4 group
   a. Metatropic dysplasia
   b. Spondyloepimetaphyseal dysplasia, Maroteaux type (pseudo-Morquio syndrome type 2)
   c. Spondylometaphyseal dysplasia, Kozlowski type
   d. Brachyolmia, autosomal dominant type
   e. Familial digital arthropathy with brachydactyly
9. Ciliopathies with major skeletal involvement
   a. Chondroectodermal dysplasia (Ellis–van Creveld)
   b. Short rib–polydactyly syndrome (SRPS) type 1/3 (Saldino-Noonan/Verma-Naumoff)
   c. Asphyxiating thoracic dysplasia (ATD; Jeune)
   d. SRPS type 2 (Majewski)
   e. SRPS type 4 (Beemer)
   f. SRPS type 5
   g. Oral-facial-digital syndrome type 4 (Mohr-Majewski)
   h. Cranioectodermal dysplasia (Levin-Sensenbrenner) types 1, 2
   i. Thoracolaryngopelvic dysplasia (Barnes)
10. Multiple epiphyseal dysplasia and pseudoachondroplasia group
   a. Pseudoachondroplasia (PSACH)
   b. Multiple epiphyseal dysplasia (MED) type 1 (EDM1)
   c. Multiple epiphyseal dysplasia (MED) type 2 (EDM2)
   d. Multiple epiphyseal dysplasia (MED) type 3 (EDM3)
   e. Multiple epiphyseal dysplasia (MED) type 5 (EDM5)
   f. Multiple epiphyseal dysplasia (MED) type 6 (EDM6)
   g. Multiple epiphyseal dysplasia (MED), other types
   h. Stickler syndrome, recessive type
   i. Familial hip dysplasia (Beukes)
   j. Multiple epiphyseal dysplasia with microcephaly and nystagmus (Lowry-Wood)
11. Metaphyseal dysplasias
   a. Metaphyseal dysplasia, Schmid type (MCS)
   b. Cartilage-hair hypoplasia (CHH; metaphyseal dysplasia, McKusick type)
   c. Metaphyseal dysplasia, CHH-like, POP1 type
   d. Metaphyseal dysplasia, Jansen type
   e. Eiken dysplasia
   f. Metaphyseal dysplasia with pancreatic insufficiency and cyclic neutropenia (Shwachman-Bodian-Diamond syndrome, SBDS)
   g. Metaphyseal anadysplasia types 1, 2
   h. Metaphyseal dysplasia, Spahr type
   i. Metaphyseal dysplasia with maxillary hypoplasia
12. Spondylometaphyseal dysplasias (SMD)
   a. Spondyloenchondrodysplasia (SPENCD)
   b. Odontochondrodysplasia (ODCD)
   c. SMD, Sutcliffe type or corner fractures type
   d. SMD with cone-rod dystrophy
   e. SMD with retinal degeneration, axial type
13. Spondylo-epi-(meta-)physeal dysplasias (SE(M)D)
   a. Dyggve-Melchior-Clausen dysplasia (DMC)
   b. Immuno-osseous dysplasia (Schimke)
   c. SED, Wolcott–Rallison type
   d. SEMD, Matrilin type
   e. SEMD, short limb–abnormal calcification type
   f. SED tarda, X-linked (SED-XL)
   g. Spondylodysplastic Ehlers-Danlos syndrome
   h. SPONASTRIME dysplasia
   i. Platyspondyly (brachyolmia) with amelogenesis imperfecta
   j. CODAS syndrome

TABLE 11-2 Nosology and Classification of Genetic Skeletal Disorders—cont'd

GROUPS/NAME OF DISORDER

14. Severe spondylodysplastic dysplasias
    a. Achondrogenesis type 1A (ACG1A)
    b. Schneckenbecken dysplasia
    c. Spondylometaphyseal dysplasia, Sedaghatian type
    d. Severe spondylometaphyseal dysplasia (SMD Sedaghatian-like)
    e. Opsismodysplasia
    f. Mitochondria-associated granulocyte macrophage colony stimulating factor-signaling gene (MAGMAS) related skeletal dysplasia
15. Acromelic dysplasias
    a. Tricho-rhino-phalangeal dysplasia types 1/3
    b. Tricho-rhino-phalangeal dysplasia type 2 (Langer-Giedion)
    c. Acrocapitofemoral dysplasia
    d. Geleophysic dysplasia
    e. Acromicric dysplasia
    f. Weill-Marchesani
    g. Myhre dysplasia
    h. Acrodysostosis
    i. Angel-shaped phalango-epiphyseal dysplasia (ASPED)
    j. Albright hereditary osteodystrophy
16. Acromesomelic dysplasias
    a. Acromesomelic dysplasia type Maroteaux (AMDM)
    b. Grebe dysplasia
    c. Fibular hypoplasia and complex brachydactyly (Du Pan)
    d. Acromesomelic dysplasia with genital anomalies
    e. Acromesomelic dysplasia, Osebold-Remondini type
17. Mesomelic and rhizomesomelic dysplasias
    a. Dyschondrosteosis (Leri-Weill)
    b. Langer type (homozygous dyschondrosteosis)
    c. Omodysplasia
    d. Omodysplasia, dominant
    e. Robinow syndrome, recessive type and dominant type
    f. Mesomelic dysplasia, Kantaputra type
    g. Mesomelic dysplasia, Nievergelt type
    h. Mesomelic dysplasia, Kozlowski-Reardon type
    i. Mesomelic dysplasia with acral synostoses (Verloes-David-Pfeiffer type)
    j. Mesomelic dysplasia, Savarirayan type (triangular tibia–fibular aplasia)
18. Campomelic dysplasia and related disorders
    a. Campomelic dysplasia (CD)
    b. Stuve-Wiedemann dysplasia
    c. Kyphomelic dysplasia, several forms
19. Slender bone dysplasia group
    a. 33-M syndrome
    b. Kenny-Caffey dysplasia
    c. Osteocraniostenosis
    d. Microcephalic osteodysplastic primordial dwarfism types 1/3 (MOPD1)
    e. Microcephalic osteodysplastic primordial dwarfism type 2 (MOPD2; Majewski type)
    f. IMAGE syndrome (intrauterine growth retardation, metaphyseal dysplasia, adrenal hypoplasia, and genital anomalies)
    g. Hallermann-Streiff syndrome

GROUPS/NAME OF DISORDER

20. Dysplasias with multiple joint dislocations
    a. Desbuquois dysplasia (with accessory ossification center in digit 2)
    b. Desbuquois dysplasia with short metacarpals and elongated phalanges (Kim type)
    c. Desbuquois dysplasia type 2
    d. Pseudodiastrophic dysplasia
    e. SEMD with joint laxity (SEMD-JL) leptodactylic or Hall type
    f. SEMD with joint laxity (SEMD-JL) Beighton type
21. Chondrodysplasia punctata (CDP) group
    a. CDP, X-linked dominant, Conradi-Hünermann type (CDPX2)
    b. CDP, X-linked recessive, brachytelephalangic type (CDPX1)
    c. CHILD (congenital hemidysplasia, ichthyosis, limb defects)
    d. Keutel syndrome
    e. Greenberg dysplasia
    f. Rhizomelic CDP types 1, 2, 3
    g. CDP tibial-metacarpal type
    h. Astley-Kendall dysplasia
22. Neonatal osteosclerotic dysplasias
    a. Blomstrand dysplasia
    b. Desmosterolosis
    c. Caffey disease (including prenatal, infantile, and attenuated)
    d. Caffey dysplasia (severe variants with prenatal onset)
    e. Raine dysplasia (lethal and nonlethal forms)
23. Osteopetrosis and related disorders
    a. Osteopetrosis, severe neonatal or infantile forms (OPTB1)
    b. Osteopetrosis, severe neonatal or infantile forms (OPTB4)
    c. Osteopetrosis, severe neonatal or infantile forms (OPTB8)
    d. Osteopetrosis, infantile form, with nervous system involvement (OPTB5)
    e. Osteopetrosis, intermediate form, osteoclast-poor (OPTB2)
    f. Osteopetrosis, infantile form, osteoclast-poor with immunoglobulin deficiency (OPTB7)
    g. Osteopetrosis, intermediate form (OPTB6)
    h. Osteopetrosis, intermediate form (OPTA2)
    i. Osteopetrosis with renal tubular acidosis (OPTB3)
    j. Osteopetrosis, late-onset form type 1 (OPTA1)
    k. Osteopetrosis, late-onset form type 2 (OPTA2)
    l. Osteopetrosis with ectodermal dysplasia and immune defect (OLEDAID)
    m. Osteopetrosis, moderate form with defective leukocyte adhesion (LAD3)
    n. Osteopetrosis, moderate form with defective leukocyte adhesion
    o. Pyknodysostosis
    p. Osteopoikilosis
    q. Melorheostosis with osteopoikilosis
    r. Osteopathia striata with cranial sclerosis (OSCS)
    s. Melorheostosis
    t. Dysosteosclerosis

TABLE 11-2 Nosology and Classification of Genetic Skeletal Disorders—cont'd

GROUPS/NAME OF DISORDER

24. Other sclerosing bone disorders
    a. Craniometaphyseal dysplasia, autosomal dominant type
    b. Diaphyseal dysplasia Camurati-Engelmann
    c. Hematodiaphyseal dysplasia Ghosal
    d. Hypertrophic osteoarthropathy
    e. Pachydermoperiostosis (hypertrophic osteoarthropathy, primary, autosomal dominant)
    f. Oculo-dento-osseous dysplasia (ODOD) mild type
    g. Oculo-dento-osseous dysplasia (ODOD) severe type
    h. Osteoectasia with hyperphosphatasia (juvenile Paget disease)
    i. Sclerosteosis
    j. Endosteal hyperostosis, van Buchem type
    k. Trichodento-osseous dysplasia
    l. Craniometaphyseal dysplasia,
    m. Diaphyseal medullary stenosis with malignant fibrous histiocytoma
    n. Craniodiaphyseal dysplasia
    o. Craniometadiaphyseal dysplasia, Wormian bone type
    p. Endosteal sclerosis with cerebellar hypoplasia
    q. Lenz-Majewski hyperostotic dysplasia
    r. Metaphyseal dysplasia, Braun-Tinschert type
    s. Pyle disease
25. Osteogenesis imperfecta and decreased bone density group
    a. Osteogenesis imperfecta, nondeforming form (OI type 1)
    b. Osteogenesis imperfecta, perinatal lethal form (OI type 2)
    c. Osteogenesis imperfecta, progressively deforming type (OI type 3)
    d. Osteogenesis imperfecta, moderate form (OI type 4)
    e. Osteogenesis imperfecta with calcification of the interosseous membranes and/or hypertrophic callus (OI type 5)
    f. X-linked osteoporosis
    g. Bruck syndrome type 1 (BS1)
    h. Bruck syndrome type 2 (BS2)
    i. Osteoporosis-pseudoglioma syndrome
    j. LRP5 primary osteoporosis
    k. Calvarial doughnut lesions with bone fragility
    l. Idiopathic juvenile osteoporosis
    m. Cole-Carpenter dysplasia (bone fragility with craniosynostosis)
    n. Spondylo-ocular dysplasia
    o. Osteopenia with radiolucent lesions of the mandible
    p. Ehlers-Danlos syndrome, progeroid form
    q. Geroderma osteodysplasticum
    r. Cutis laxa, autosomal recessive form, type 2B (ARCL2B)
    s. Cutis laxa, autosomal recessive form, type 2A (ARCL2A) (Wrinkly skin syndrome)
    t. Singleton–Merten dysplasia
26. Abnormal mineralization group
    a. Hypophosphatasia, perinatal lethal, infantile and juvenile forms
    b. Hypophosphatasia, juvenile and adult forms
    c. Hypophosphatemic rickets, X-linked dominant
    d. Hypophosphatemic rickets, autosomal dominant
    e. Hypophosphatemic rickets, autosomal recessive, type 1 (ARHR1)
    f. Hypophosphatemic rickets, autosomal recessive, type 2 (ARHR2)
    g. Hypophosphatemic rickets with hypercalciuria, X-linked recessive
    h. Hypophosphatemic rickets with hypercalciuria, autosomal recessive (HHRH)
    i. Neonatal hyperparathyroidism, severe form
    j. Familial hypocalciuric hypercalcemia with transient neonatal hyperparathyroidism
    k. Calcium pyrophosphate deposition disease (familial chondrocalcisnosis) type 2

GROUPS/NAME OF DISORDER

27. Lysosomal storage diseases with skeletal involvement (dysostosis multiplex group)
    a. Mucopolysaccharidosis type 1H/1S (Hurler, Hurler-Scheie, Scheie)
    b. Mucopolysaccharidosis type 2 (Hunter)
    c. Mucopolysaccharidosis type 3A (Sanfilippo A)
    d. Mucopolysaccharidosis type 3B (Sanfilippo B)
    e. Mucopolysaccharidosis type 3C (Sanfilippo C)
    f. Mucopolysaccharidosis type 3D (Sanfilippo D)
    g. Mucopolysaccharidosis type 4A (Morquio A)
    h. Mucopolysaccharidosis type 4B (Morquio B)
    i. Mucopolysaccharidosis type 6 (Maroteaux-Lamy)
    j. Mucopolysaccharidosis type 7 (Sly)
    k. Fucosidosis
    l. Alpha-mannosidosis
    m. Beta-mannosidosis
    n. Aspartylglucosaminuria
    o. GMI gangliosidosis, several forms
    p. Sialidosis, several forms
    q. Sialic acid storage disease (SIASD)
    r. Galactosialidosis, several forms
    s. Multiple sulfatase deficiency
    t. Mucolipidosis II (I-cell disease), alpha/beta type
    u. Mucolipidosis III (pseudo–Hurler polydystrophy), alpha/beta type
    v. Mucolipidosis III (pseudo–Hurler polydystrophy), gamma type
28. Osteolysis group
    a. Familial expansile osteolysis
    b. Mandibuloacral dysplasia type A, B
    c. Progeria, Hutchinson-Gilford type
    d. Torg-Winchester syndrome
    e. Hajdu-Cheney syndrome
    f. Multicentric carpal-tarsal osteolysis with and without nephropathy
29. Disorganized development of skeletal components group
    a. Multiple cartilaginous exostoses 1, 2 , 3
    b. Cherubism
    c. Fibrous dysplasia, polyostotic form (McCune-Albright)
    d. Progressive osseous heteroplasia
    e. Gnathodiaphyseal dysplasia
    f. Metachondromatosis
    g. Osteoglophonic dysplasia
    h. Fibrodysplasia ossificans progressiva (FOP)
    i. Neurofibromatosis type 1 (NF1)
    j. Carpotarsal osteochondromatosis
    k. Cherubism with gingival fibromatosis (Ramon syndrome)
    l. Dysplasia epiphysealis hemimelica (Trevor)
    m. Lipomembranous osteodystrophy with leukoencephalopathy (presenile dementia with bone cysts; Nasu-Hakola)
    n. Enchondromatosis (Ollier) and enchondromatosis with hemangiomata (Maffucci)
    o. Metaphyseal chondromatosis with D-2-hydroxyglutaric aciduria
    p. Genochondromatosis
    q. Gorham-Stout

TABLE 11-2 Nosology and Classification of Genetic Skeletal Disorders—cont'd

GROUPS/NAME OF DISORDER

30. Overgrowth (tall stature) syndromes with skeletal involvement
    - a. Weaver syndrome
    - b. Sotos syndrome
    - c. Sotos-like syndrome
    - d. Marshall-Smith syndrome
    - e. Proteus syndrome
    - f. CLOVES
    - g. Marfan syndrome
    - h. Congenital contractural arachnodactyly
    - i. Loeys-Dietz syndrome types 1A,1B, 2A, 2B, 3, 4
    - j. Overgrowth syndrome with 2q37 translocations
    - k. Overgrowth with macrodactyly and NPR2 gain of function
    - l. Overgrowth syndrome with skeletal dysplasia (Nishimura-Schmidt, endochondral gigantism)
31. Genetic inflammatory/rheumatoid-like osteoarthropathies
    - a. Progressive pseudorheumatoid dysplasia (PPRD; SED with progressive arthropathy)
    - b. Chronic infantile neurologic cutaneous articular syndrome (CINCA)/ neonatal onset multisystem inflammatory disease (NOMID)
    - c. Sterile multifocal osteomyelitis, periostitis, and pustulosis (CINCA/ NOMID-like)
    - d. Chronic recurrent multifocal osteomyelitis with congenital dyserythropoietic anemia (CRMO with CDA; Majeed syndrome)
    - e. Hyperostosis/hyperphosphatemia syndrome
    - f. Hyaline fibromatosis syndrome
32. Cleidocranial dysplasia and related disorders
    - a. Cleidocranial dysplasia
    - b. CDAGS syndrome (craniosynostosis, delayed fontanelle closure, parietal foramina, imperforate anus, genital anomalies, skin eruption)
    - c. Yunis-Varon dysplasia
    - d. Parietal foramina (isolated)
33. Craniosynostosis syndromes
    - a. Pfeiffer syndrome (FGFR1-related)
    - b. Apert syndrome
    - c. Craniosynostosis with cutis gyrata (Beare-Stevenson)
    - d. Crouzon syndrome
    - e. Bent bone dysplasia
    - f. Crouzon-like craniosynostosis with acanthosis nigricans (Crouzonodermoskeletal syndrome)
    - g. Craniosynostosis, Muenke type
    - h. Antley-Bixler syndrome
    - i. Craniosynostosis Boston type
    - j. Saethre-Chotzen syndrome
    - k. Shprintzen-Goldberg syndrome
    - l. Baller-Gerold syndrome
    - m. Carpenter syndrome
    - n. Coronal craniosynostosis
    - o. Complex craniosynostosis
34. Dysostoses with predominant craniofacial involvement
    - a. Mandibulofacial dysostosis (Treacher-Collins, Franceschetti–Klein)
    - b. Oral-facial-digital syndrome type I (OFD1)
    - c. Weyers acrofacial (acrodental) dysostosis
    - d. Endocrine-cerebro-osteodysplasia (ECO)
    - e. Craniofrontonasal syndrome
    - f. Frontonasal dysplasia, types 1, 2, 3
    - g. Hemifacial microsomia
    - h. Miller syndrome (postaxial acrofacial dysostosis)
    - i. Acrofacial dysostosis, Nager type
    - j. Acrofacial dysostosis, Rodriguez type
    - k. Mandibulofacial dysostosis with microcephaly

GROUPS/NAME OF DISORDER

35. Dysostoses with predominant vertebral with and without costal involvement
    - a. Currarino triad
    - b. Spondylocostal dysostosis type 1 (SCDO1), type 2 (SCDO2), type 3(SCDO3), type 4 (SCDO4), type 5 (SCDO5)
    - c. Spondylothoracic dyostosis (STD)
    - d. Vertebral segmentation defect (congenital scoliosis) with variable penetrance
    - e. Klippel-Feil anomaly with laryngeal malformation
    - f. Cerebro-costo-mandibular syndrome (rib gap syndrome)
    - g. Cerebro-costo-mandibular-like syndrome with vertebral defects
    - h. Diaphanospondylodysostosis
    - i. Spondylo-megaepiphyseal-metaphyseal dysplasia (SMMD)
36. Patellar dysostoses
    - a. Ischiopatellar dysplasia (small patella syndrome)
    - b. Nail-patella syndrome
    - c. Genitopatellar syndrome
    - d. Ear-patella-short stature syndrome (Meier-Gorlin)
37. Brachydactylies (without extraskeletal manifestations)
    - a. Brachydactyly types A1, A2, B, B2, C, D, E
    - b. Brachydactyly with anonychia (Cooks syndrome)
38. Brachydactylies (with extraskeletal manifestations)
    - a. Brachydactyly-mental retardation syndrome
    - b. Hyperphosphatasia with mental retardation, brachytelephalangy, and distinct face
    - c. Brachydactyly-hypertension syndrome (Bilginturan)
    - d. Microcephaly-oculo-digito-esophageal-duodenal syndrome (Feingold syndrome)
    - e. Hand-foot-genital syndrome
    - f. Rubinstein-Taybi syndrome
    - g. Brachydactyly, Temtamy type
    - h. Christian type brachydactyly
    - i. Coffin-Siris syndrome1
    - j. Adams-Oliver
    - k. Catel-Manzke syndrome
39. Limb hypoplasia–reduction defects group
    - a. Ulnar-mammary syndrome
    - b. de Lange syndrome
    - c. Fanconi anemia
    - d. Thrombocytopenia–absent radius (TAR)
    - e. Thrombocythemia with distal limb defects
    - f. Holt-Oram syndrome
    - g. Okihiro syndrome (Duane–radial ray anomaly)
    - h. Cousin syndrome
    - i. Roberts syndrome
    - j. Split-hand-foot malformation with long bone deficiency (SHFLD3)
    - k. Tibial hemimelia
    - l. Tibial hemimelia-polysyndactyly-triphalangeal thumb
    - m. Acheiropodia
    - n. Tetra-amelia
    - o. Terminal transverse defect
    - p. Al-Awadi Raas-Rothschild limb-pelvis hypoplasia-aplasia
    - q. Fuhrmann syndrome
    - r. RAPADILINO syndrome
    - s. Femoral hypoplasia-unusual face syndrome (FHUFS)
    - t. Femur-fibula-ulna syndrome (FFU)
    - u. Hanhart syndrome (hypoglossia-hypodactylia)
    - v. Gollop-Wolfgang
    - w. Scapulo-iliac dysplasia (Kosenow)

Continued

TABLE 11-2 Nosology and Classification of Genetic Skeletal Disorders—cont'd

GROUPS/NAME OF DISORDER

40. Ectrodactyly with and without other manifestations
    - a. Ectrodactyly with and without other manifestations
    - b. Ankyloblepharon-ectodermal dysplasia-cleft lip/palate (AEC)
    - c. Ectrodactyly-ectodermal dysplasia cleft-palate syndrome type 3 (EEC3)
    - d. Ectrodactyly-ectodermal dysplasia cleft-palate syndrome type 1 (EEC1)
    - e. Ectrodactyly-ectodermal dysplasia-macular dystrophy syndrome (EEM)
    - f. Limb-mammary syndrome (including ADULT syndrome)
    - g. Split hand-foot malformation, isolated form, type 4 (SHFM4)
    - h. Split hand-foot malformation, isolated form, type 1 (SHFM1)
    - i. Split hand-foot malformation, isolated form, type 3 (SHFM3)
    - j. Split hand-foot malformation, isolated form, type 5 (SHFM5)
    - k. Hartsfield syndrome
41. Polydactyly-syndactyly-triphalangism group
    - a. Preaxial polydactyly type 1 (PPD1)
    - b. Postaxial polydactyly type A
    - c. Postaxial polydactyly type B
    - d. Triphalangeal thumb (TPT)-polydactyly syndrome
    - e. Preaxial polydactyly type 3 (PPD3)
    - f. Preaxial polydactyly type 4 (PPD4)
    - g. Greig cephalopolysyndactyly syndrome
    - h. Pallister-Hall syndrome
    - i. Synpolydactyly (complex, fibulin 1-associated)
    - j. Synpolydactyly
    - k. Townes-Brocks syndrome (renal-ear-anal-radial syndrome)
    - l. Lacrimo-auriculo-dento-digital syndrome (LADD Gene FGFR2)
    - m. Lacrimo-auriculo-dento-digital syndrome (LADD Gene FGFR3)
    - n. Lacrimo-auriculo-dento-digital syndrome (LADD Gene FGF10)
    - o. Acrocallosal syndrome
    - p. Acro-pectoral syndrome
    - q. Acro-pectoro-vertebral dysplasia (F-syndrome)
    - r. Mirror-image polydactyly of hands and feet (Laurin-Sandrow syndrome)
    - s. Cenani-Lenz syndactyly
    - t. Cenani-Lenz-like syndactyly
    - u. Syndactyly, Malik-Percin type
    - v. STAR syndrome (syndactyly of toes, telecanthus, ano- and renal malformations)
    - w. Syndactyly type Lueken
    - x. Oculodentodigital dysplasia, syndactyly type 3 (IV-V)
    - y. Syndactyly Haas type
    - z. Syndactyly with metacarpal and metatarsal fusion
    - aa. Metacarpal 4-5 fusion syndrome
    - bb. Syndactyly with craniosynostosis (Philadelphia type)
    - cc. Syndactyly with microcephaly and mental retardation (Filippi syndrome)
    - dd. Meckel syndrome types 1, 2, 3, 4, 5, 6
42. Defects in joint formation and synostoses
    - a. Multiple synostoses syndrome type 3
    - b. Proximal symphalangism type 1
    - c. Proximal symphalangism type 2
    - d. Radioulnar synostosis with amegakaryocytic thrombocytopenia
    - e. Liebenberg syndrome
    - f. Congenital clubfoot

TABLE 11-3 Well-Defined Skeletal Disorders Seen During the Neonatal Period

Group or Name of the Disorder	Mode of Inheritance	Gene Symbol
Fibroblast Growth Factor Receptor 3 (FGFR3) Disorders		
Thanatophoric dysplasia	AD	*FGFR3*
Achonodroplasia	AD	*FGFR3*
Hypochondroplasia	AD	*FGFR3*
Severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN)	AD	*FGFR3*
Type II Collagen Disorders		
Achondrogenesis II	AD	*COL2A1*
Hypochondrogenesis	AD	*COL2A1*
Spondyloepiphyseal dysplasia congenita (SEDC)	AD	*COL2A1*
Kniest dysplasia	AD	*COL2A1*
Type XI Collagen Disorders		
Fibrochondrogenesis	AR	*COL11A1*
Fibrochondrogenesis	AD	*COL11A1, COL11A2*
Otospondylomegaepiphyseal dysplasia (OSMED)	AR	*COL11A2*
Sulfation Disorders		
Achondrogenesis IB	AR	*SLC26A2*
Atelosteogenesis II	AR	*SLC26A2*
Diastrophic dysplasia	AR	*SLC26A2*
Chondrodysplasia with congenital joint dislocations	AR	*CHST3*
Perlecan Disorders		
Dyssegmental dysplasia	AR	*PLC*
Dyssegmental dysplasia, Silverman-Handmaker type	AR	*PLC*
Dyssegmental dysplasia, Rolland-Desbuquois type	AR	*PLC*
Filamin Disorders and Similar Disorders		
Otopalatodigital syndrome I and II	XLD	*FLNA*
Osteodysplasty, Melnick-Needles	XLD	*FLNA*
Atelosteogenesis types I and III	AD	*FLNB*
Larsen syndrome	AD	*FLNB*
Spondylo-carpal-tarsal dysplasia	AR	*FLNB*
Serpentine fibula–polycystic kidney syndrome	AD	*NOTCH2*

TABLE 11-3 Well-Defined Skeletal Disorders Seen During the Neonatal Period—cont'd

Group or Name of the Disorder	Mode of Inheritance	Gene Symbol
TRPV4 Disorders		
Metatropic dysplasia	AD	*TRPV4*
Short Rib Dysplasias (With and Without Polydactyly)		
Chondroectodermal dysplasia (Ellis–van Creveld)	AR	*DYNC2H1*
Short rib–polydactyly syndrome I, II, III, and IV including asphyxiating thoracic dystrophy	AR	*IFT80 NEK WDR35*
Thoracolaryngeal dysplasia	AD	Unknown
Metaphyseal Dysplasias		
Cartilage-hair hypoplasia	AR	*RMRP*
Metaphyseal dysplasia, Jansen type	AD	*PTHR1*
Spondylo-Epi-(Meta)-Physeal Dysplasia (SEMD)		
SEMD, short limb abnormal calcification type	AR	*DDR2*
Severe Spondylodysplastic Dysplasias		
Achondrogenesis 1A	AR	*GMAP210*
Schneckenbecken dysplasia	AR	*SLC35D1*
Opsismodysplasia	AR	*INPPL1*
Acromesomelic Disorders		
Acromesomelic dysplasia, type Maroteaux	AR	*NPR2*
Mesomelic and Rhizomesomelic Dysplasias		
Langer type (homozygous dyschondrosteosis)	Pseudo-AR/XLD	*SHOX*
Omodysplasia	AR	*GPC6*
Robinow syndrome, recessive	AR	*ROR2*
Robinow syndrome, dominant	AD	*WNT5*
Bent Bone Dysplasias		
Campomelic dysplasia	AD	*SOX9*
Stuve-Wiedemann dysplasia	AR	*LIFR*
Bent bone dysplasia FGFR2 type	AD	*FGFR2*
Slender Bone Dysplasias		
Microcephalic osteodysplastic primordial dwarfism (MOPD1)	AR	*RNU4ATAC*
Microcephalic osteodysplastic primordial dwarfism (MOPD2)	AR	*PCNT*
Dysplasias With Multiple Joint Dislocations		
Desbuquois dysplasia	AR	*CANT1, XYLT1*
Pseudodiatrophic dysplasia	AR	Unknown
Chondrodysplasia Punctata Group (CDP)		
CDP, X-linked dominant	XLD	*EBP*
Conradi-Hunermann type (CDPX2)	XLR	*ARSE*
Brachytelephalangic type (CDPX1)	XLD	*NSDHL*
Congenital hemidysplasia with ichthyosiform erythroderma and limb defects (CHILD) syndrome	XLD	*EBP*
Greenberg dysplasia	AR	*LBR*
Rhizomelic CDP type 1	AR	*PEX7*
Rhizomelic CDP type 2	AR	*DHPAT*
Rhizomelic CDP type 3	AR	*AGPS*
Neonatal Osteosclerotic Dysplasias		
Bloomstrand dysplasia	AR	*PTHR1*
Desmosterolosis	AR	*DHCR24*
Caffey disease (infantile)	AD	*COL1A1*
Raine dysplasia	AR	*FAM20C*
Increased Bone Density Group		
Osteopetrosis (severe neonatal or infantile forms)	AR	*TCIRG1*
Osteopetrosis (severe neonatal or infantile forms)	AR	*CLCN7*
Dysosteosclerosis	AR	*SLC29A3*
Lenz-Majewski hyperostotic dysplasia	SP	*PTDSS1*
Osteogenesis Imperfecta and Decreased Bone Density Group		
Osteogenesis imperfecta (OI), moderate, severe, and perinatal lethal	AD	*COL1A1, COL1A2, IFITM5,*
OI, moderate, severe, and perinatal lethal	AR	*CRTAP, P3H1, PPBI, FKBP10, HSP47, SP7, WNT1, TMEM33B,*
Bruck syndrome		*PLOD2, FKBP10,*
Osteoporosis-pseudoglioma syndrome	AR	*LRP5*
Cole-Carpenter dysplasia	SP	*LRP5, SEC24D, P4HB, CRTAP*
Abnormal Mineralization Group		
Hypophosphatasia, perinatal and infantile forms	AR	*ALPL*

From Krakow D: Skeletal dysplasias. Clin Perinatol 42:301-319, 2015.

TABLE 11-4 Common Abnormal Ultrasound Findings and Differential Diagnosis of Skeletal Disorders

Disorders	MIM No.	Gene Defect
Poor Mineralization of the Calvarium		
Achondrogenesis IA	200600	Unknown
Cleidocranial dysplasia	119600	*RUNX2*
Hypophosphatasia	241500	*ALPL*
Osteogenesis imperfecta type II	166210	*COL1A1*
	166210	*COLIA2*
	610854	*CRTAP*
Fractures of Long Bones (Particular Femora)		
Hypophosphatasia	241500	*ALPL*
Neurofibromatosis	162200	*NF1*
Osteogenesis imperfecta types II and III	166210	*COL1A1*
	166210	*COLIA2*
	610854	*CRTAP*
	259440	*P3H1*
Bent/Bowed Bones by Ultrasound		
Achondrogenesis IA	200600	Unknown
Achondrogenesis IB	600972	*SLC26A2*
Antley-Bixler syndrome	207410	*FGFR2*
Atelosteogenesis I	108720	*FLNB*
Atelosteogenesis II	256050	*SLC26A2*
Atelosteogenesis III	108721	*FLNB*
Campomelic dysplasia	114290	*SOX9*
Diastrophic dyplasia	222600	*SLC26A2*
Hypophosphatasia	241500	*ALPL*
Osteogenesis types II and III	166210	*COL1A1*
	166210	*COLIA2*
	610854	*CRTAP*
	259440	*P3H1*
Short-rib polydactyly syndromes	263530	Unknown
(types I-IV)	263520	Unknown
	263510	Unknown
	269860	Unknown
Stuve-Wiedemann syndrome	601559	*LIFR*
Thanatophoric dysplasia types I and II	187600	*FGFR3*
	187601	*FGFR3*

Disorders	MIM No.	Gene Defect
Poor Mineralization of the Vertebrae		
Achondrogenesis IA	200600	Unknown
Achondrogenesis IB	600972	*SLC26A2*
Achondrogenesis II	200610	*COL2A1*
Atelosteogenesis I	108720	*FLNB*
Atelosteogenesis II	256050	*SLC26A2*
Atelosteogenesis III	108721	*FLNB*
Opsismodysplasia	258480	Unknown
SMD—sedaghatian type	250220	Unknown
Thanatophoric dysplasia types I and II	187600	*FGFR3*
	187601	*FGFR3*
Absent/Hypoplastic Scapula		
Campomelic dysplasia	114290	*SOX9*
Equinovarus		
Achondrogenesis IA	200600	Unknown
Achondrogenesis IB	600972	*SLC26A2*
Achondrogenesis II	200610	*COL2A1*
Atelosteogenesis I	108720	*FLNB*
Atelosteogenesis II	256050	*SLC26A2*
Atelosteogenesis III	108721	*FLNB*
Campomelic dysplasia	114290	*SOX9*
Desbuquois dysplasia	251450	Unknown
Diastrophic dyplasia	222600	*SLC26A2*
Ehler-Danlos syndrome types VIIA and B	130060	*COL1A1, COL1A2*
Hypophosphatasia	241500	*ALPL*
Larsen syndrome	150250	*FLNB*
Osteogenesis imperfecta types II and III	166210	*COL1A1*
	166210	*COLIA2*
	610854	*CRTAP*
	259440	*P3H1*
Pseudodiastrophic dysplasia	264180	Unknown
Short-rib polydactyly syndromes (types	263530	Unknown
I-IV)	263520	Unknown
	263510	Unknown
	269860	Unknown
Thanatophoric dysplasia types I and II	187600	*FGFR3*

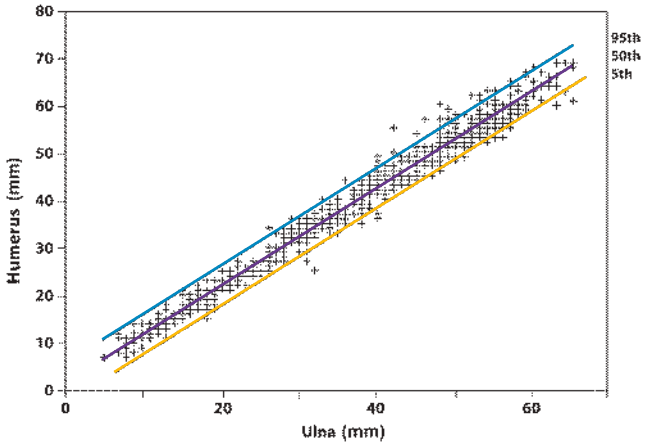

FIG 11-7 Relationship between the lengths of the ulna (mm) and the humerus (mm).

TABLE 11-5 Skeletal Dysplasias Characterized by Rhizomelia, Mesomelia, and Micromelia

Rhizomelia
- Thanatophoric dysplasia
- Atelosteogenesis
- Chondrodysplasia punctata (rhizomelic type)
- Congenital short femur
- Achondroplasia
- Hypochondroplasia

Mesomelia
- Mesomelic dysplasia (Langer, Reinhardt, and Robinow types)
- Ellis–van Creveld syndrome (chondroectodermal dysplasia)

Acromesomelia
- Ellis–van Creveld syndrome (chondroectodermal dysplasia)

Micromelia
- Achondrogenesis
- Atelosteogenesis
- Short rib–polydactyly syndrome
- Diastrophic dysplasia
- Fibrochondrogenesis
- Osteogenesis imperfecta (type II)
- Kniest dysplasia
- Dyssegmental dysplasia
- Roberts syndrome

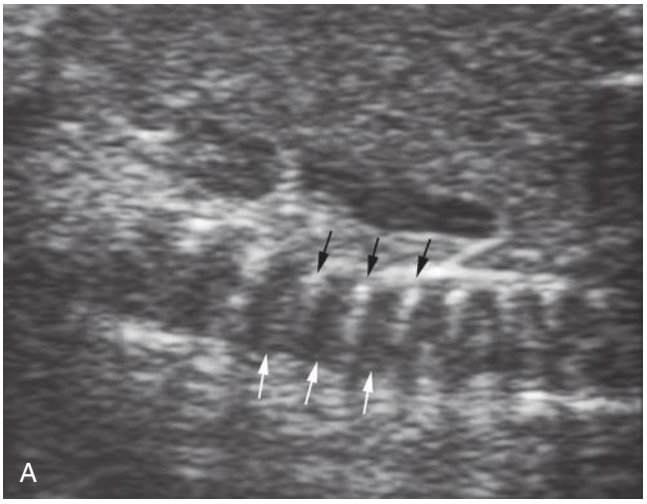

FIG 11-9 A, Longitudinal scan of the spine in a fetus with thanatophoric dysplasia and platyspondyly. The intervertebral disks (*white arrows*) are greater in height than the vertebrae (*black arrows*), which are flat. **B,** Lateral spine radiograph from a fetus with platyspondyly and thanatophoric dysplasia. Note the markedly flattened vertebrae.

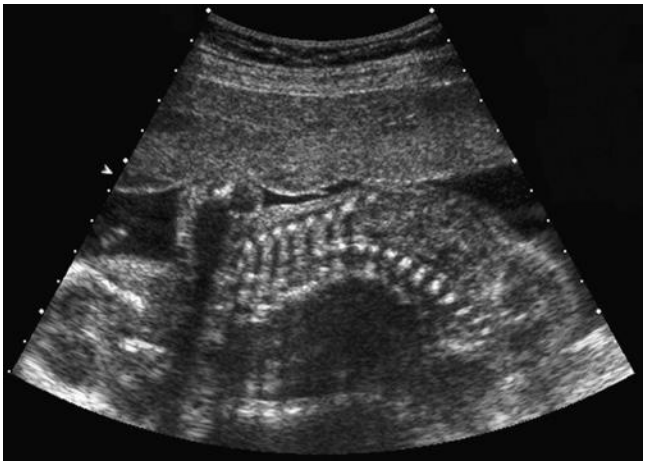

FIG 11-10 Coronal scan of the fetal spine by two-dimensional sonography showing scoliosis.

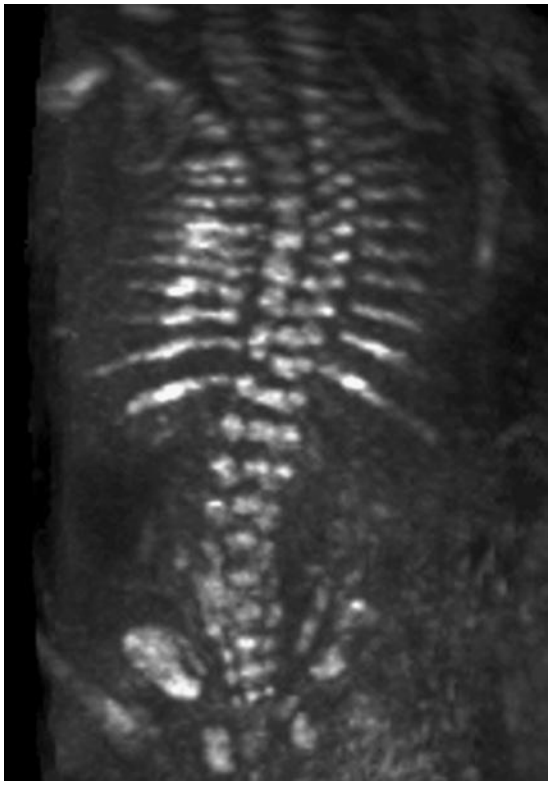

FIG 11-11 Three-dimensional ultrasound image of the fetal spine showing scoliosis.

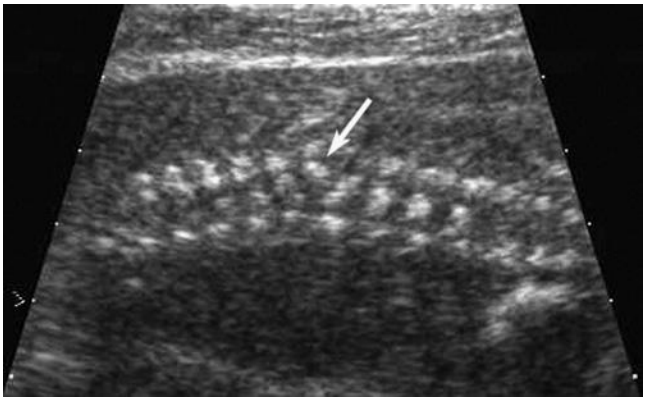

FIG 11-12 Coronal scan of the fetal spine showing lateral hemivertebra (*arrow*) in the thoracic segment.

femur length.[73] In a study including 127 cases of 17 skeletal dysplasias, Gonçalves and Jeanty[74] concluded, with the use of discriminant analysis, that the degree of femur length shortening can be used as the initial step in distinguishing among the five most common disorders: thanatophoric dysplasia, OI type II, achondrogenesis, achondroplasia, and hypochondroplasia. Gabrielli and coworkers[75] reported the early diagnosis of skeletal dysplasias in eight women with previous pregnancies affected with skeletal dysplasias. Five recurrent cases were identified during the first trimester by the femur length/crown rump length ratio and the femur length/biparietal diameter ratio. The results of this study suggest that early evaluation of fetal structures might be helpful in the diagnosis of severe skeletal dysplasias. Nomograms for long bone measurements according to crown rump length in a large population of normal fetuses examined between 11 and 14 weeks of gestation have been published, but still their role in the early assessment of pregnancies at risk for skeletal dysplasias remains to be determined.[76]

Clinical Presentation

In general, the challenges of the prenatal diagnosis of skeletal dysplasias presents in one of two ways: (1) a patient who has delivered an infant with a skeletal dysplasia and desires antenatal assessment in a subsequent pregnancy or (2) the incidental finding of a shortened, bowed, or anomalous extremity during a routine sonographic examination. In patients at risk, the examination is easier when the particular phenotype of the skeletal dysplasia is known. The inability to obtain reliable information about skeletal mineralization and the effect of depth on sonography is a limiting factor in establishing an accurate diagnosis after identification of an incidental finding. Another limitation is the paucity of information about the in utero natural history of these disorders. Yet, despite these difficulties and limitations, good medical reasons justify attempting an accurate prenatal diagnosis of skeletal dysplasias. A number of these disorders are uniformly lethal, whereas others are associated with severe physical handicap and neurodevelopmental disabilities.[77] In addition, there is a group of disorders associated with thrombocytopenia for which vaginal delivery may expose the infant to an increased risk of intracranial hemorrhage. Therefore, accurate diagnosis of skeletal dysplasias is important for prenatal counseling.

Diagnostic Imaging and Prenatal Diagnosis of Skeletal Dysplasias

Despite increasing availability of molecular testing, in about one third of skeletal dysplasias their molecular basis has not been defined.[34] The role of diagnostic imaging in the prenatal investigation of skeletal

dysplasias is (1) to narrow the differential diagnosis of skeletal dysplasias, so that appropriate confirmatory molecular tests can be done; (2) to predict lethality; and (3) to identify the fetus with a skeletal dysplasia early enough in gestation so that the diagnostic workup can be completed before the limit of fetal viability.[78-82]

Sonography is the primary imaging modality used for detection of an affected fetus.[59,73,83-94] The prevalence of skeletal dysplasias identified by ultrasound examination during the second and third trimesters of pregnancy is about 7.5/10,000 pregnancies.[95] In early pregnancy (11-14 weeks) the most frequently diagnosed skeletal dysplasias are thanatophoric dysplasia and achondrogenesis. However, despite ultrasound findings highly suggestive of skeletal dysplasia, the definitive diagnosis should only be determined by molecular testing and confirmation of the ultrasound findings later in pregnancy.[96] Table 11-8 summarizes the sensitivity of 2D sonography for the prenatal diagnosis of skeletal dysplasias.[35,93,99-102] Schramm and associates[103] reported a 67.9% (110/162) correct diagnosis and a 30.9% (50/162) partially correct diagnosis of skeletal dysplasia by evaluating the following sonographic parameters: (1) measurements of all segments of the long bones; (2) examination of the hands, spine, and head; (3) assessment of mineralization and shape of the bones; and (4) a full anatomic survey. For lethal skeletal dysplasias, the accuracy of sonographic findings was 99% (113/114). The authors reported that an accurate diagnosis of skeletal dysplasias before 24 weeks of gestation was possible in 62% of cases, although achondroplasia was the only skeletal dysplasia that could not be diagnosed before 24 weeks of gestation. When there is a family history of skeletal dysplasias, the following should be carefully evaluated on ultrasound imaging: complete biometry including the biparietal diameter, head and abdominal circumferences, lengths of all long bones, femur-foot ratio, and measurements of the mandible, clavicle, scapula, skull, chest, and spine. Other ultrasound parameters that might also be helpful in differentiating skeletal dysplasias include the fetal facial profile (e.g., flattened nasal bridge), presence and shape of vertebral bodies, appearance of the hands and feet (e.g., extra, missing, or malformed digits), and fetal thorax to assess the risk for lethality.[58] More recently, Nelson and colleagues[104] reported an overall prevalence of skeletal dysplasias of 2/10,000 pregnancies. In their series, 60% of skeletal dysplasias survived to hospital discharge, although 20% died in the neonatal period, 4% were stillbirths, and 16% were terminated. The authors reported that a femur/abdominal circumference ratio less than 0.16 was the main discriminator among fetuses with lethal skeletal dysplasias, and that this measurement had better performance than femur shortening, thoracic circumference, and thoracic circumference/abdominal circumference ratio.

Several investigators have also proposed that 3D ultrasonography may improve the prenatal diagnostic accuracy for skeletal dysplasias and arthrogryposis.[105-119] It allows observation of phenotypic features that can be difficult to detect by 2D sonography such as detailed evaluation of the face, scapular anomalies, and abnormal calcification patterns.[108,116] As an example, Moeglin and Benoit[112] applied the multiplanar view to demonstrate the pointed appearance of the upper femoral diaphysis in achondroplasia. 3D reconstruction of the fetal bones is best performed using the maximum intensity projection or skeletal mode, a rendering algorithm that prioritizes the display of the brightest voxels contained within a region of interest selected by the operator[108,112] (Fig. 11-15). It is noteworthy that if a fetus is examined early enough in pregnancy, the entire skeleton can be included within the region of interest, and therefore, panoramic imaging can be obtained.[108] However, in some skeletal dysplasias the abnormal features may not be detectable until later in fetal development. Case reports and small series of skeletal dysplasias have described phenotypic characteristics or skeletal features for which 3D sonography may provide additional information (Table 11-9).[106,108-112,114-116,118,120]

3D-HCT has been proposed as an adjunctive imaging modality for improving the prenatal diagnosis and clinical management of skeletal dysplasias (Fig. 11-16).[121-129] 3D-HCT overcomes the main limitation of 2D and 3D ultrasonography for assessment of bones (i.e., acoustic shadowing), allowing easy and exquisite 3D rendering of mineralized bones at the expense of a mild radiation exposure to the fetus.[130,131] Long bone measurements in fetuses with suspected skeletal dysplasias obtained using ultrasound show a good correlation with measurements obtained by postmortem 3D-HCT within 24 hours of delivery.[132] Measurements obtained from 3D-HCT are not distance dependent and therefore are more accurate.[128] Excellent panoramic images of the fetal skeleton can be obtained without superimposition of the maternal skeleton (which occurs with radiography).[123] Yet, because of the low radiation dose currently used in pregnancy, 3D-HCT provides limited visualization of bone density, of fetal metaphyseal deformities, and of the feet and hands at early gestational ages.[133,134]

The contribution of 3D-HCT, 3D sonography, and 2D sonography in the evaluation of skeletal dysplasias was analyzed by Ruano and coworkers,[121] who compared the phenotypic characteristics of fetuses with skeletal dysplasias (achondroplasia [$n = 3$], OI [$n = 2$], and chondrodysplasia punctata [$n = 1$]) using these three imaging modalities. Deformation of the fetal pelvis and an increase in the intervertebral space of the lumbar vertebrae were diagnosed more often using 3D-HCT. In contrast, some phenotypic characteristics of fetuses with skeletal dysplasias were demonstrated only by ultrasound such as phalangeal hypoplasia, point-calcified epiphysis (by both 2D and 3D sonography), and facial dysmorphism (by 3D sonography only). Although the overall count of correct phenotypic characteristics detected prenatally favored 3D-HCT over 3D sonography (94.3% [33/35] vs. 77.1% [27/35]; $P = 0.03$), the diagnostic performance of 3D-HCT was not superior to that of 3D sonography, as the correct prenatal diagnosis was established by both modalities in all cases. However, 3D sonography has two important advantages over 3D-HCT, namely the lack of radiation exposure and wider availability in the clinical setting. It is also noteworthy that the overall experience with 3D sonography for the diagnosis of skeletal dysplasias is still limited.[105-108,111-118,120,135-141] Nevertheless, even in the study of Ruano and coworkers[121] 3D sonography performed better than 2D sonography in the identification of phenotypic characteristics (77.1% [27/35]

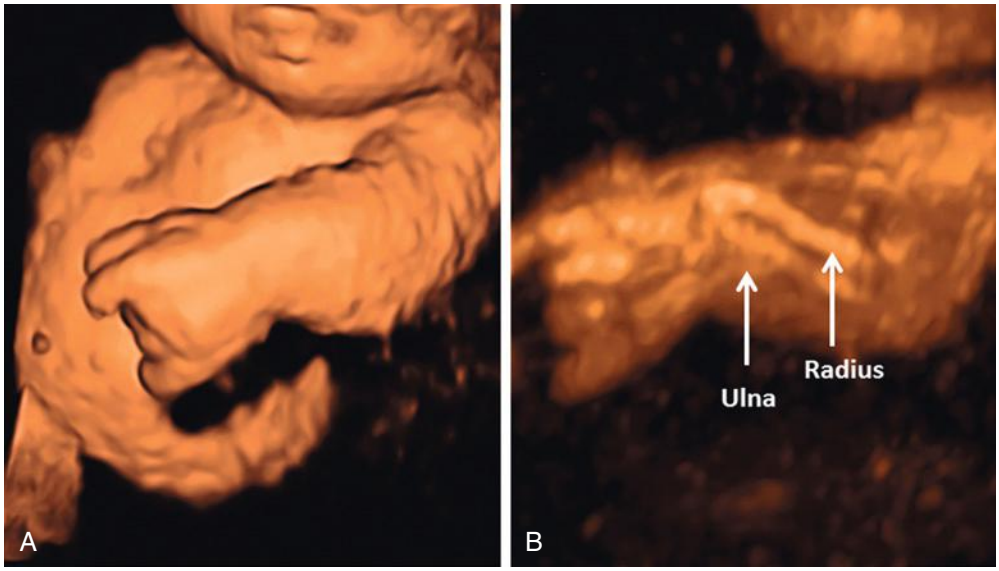

FIG 11-15 Comparison between the surface rendering mode (**A**) and the maximum intensity projection mode (**B**) for visualization of the fetal arm in a fetus with mesomelic shortening of the long bones. Using the maximum intensity projection mode, only voxels with the highest intensity are displayed, thus allowing a clear representation of the mesomelic shortening of the radius and ulna.

TABLE 11-9 Additional Phenotypic Findings and Improved Visualization in Skeletal Dysplasias Imaged by Prenatal Three-Dimensional Ultrasound (3DUS) as Compared to Two-Dimensional Ultrasound (2DUS)

Skeletal Dysplasia	Phenotypic Characteristics Identified Better by 3DUS than 2DUS
Platyspondylic lethal chondrodysplasia[106]	Enhanced visualization of femoral and tibial bowing; Better characterization of the facial soft tissues with surface rendering
Campomelic dysplasia[118,141]	Micrognathia, flat face, hypoplastic scapulae, bifid foot, fan-like position of the toes
Thanatophoric dysplasia[109,110]	Improved characterization of frontal bossing and depressed nasal bridge; Demonstration of redundant skinfolds; Low-set dysmorphic ears
Achondroplasia[116]	Improved characterization of frontal bossing and depressed nasal bridge; Superior evaluation of the epiphyses and metaphyses of the long bones, with demonstration of a vertical metaphyseal slope; Caudal narrowing of the interpedicular distance; Clear visualization of trident hand; Better visualization of disproportion between limb segments
Chondrodysplasia punctata, rhizomelic form[116]	Improved characterization of the Binder facies (depressed nasal bridge, midface hypoplasia, small nose with upturned alae); Identification of laryngeal stippling
Achondrogenesis[116]	Panoramic demonstration of short neck and severe shortening of all segments of the limbs
Jarcho-Levin syndrome[115]	Vertebral defects with absence of ribs and transverse process
Spondylocostal dysostosis[138]	Fan-like rib cage with rib fusion
Larsen syndrome[120]	Genu recurvatum, midface hypoplasia, low-set ears
Cleidocranial dysplasia[140]	Widened cranial sutures, poor mineralization of the occipital bones, pseudoarthrosis of the clavicle
Apert syndrome[137]	Coronal craniosynostosis

Phenotypic characteristics of osteogenesis imperfecta,[108] and short rib–polydactyly (SRP) syndrome,[114] have also been described using 3DUS, although no additional findings to 2DUS were observed.
Superscript numbers indicate references listed at the end of the chapter.

vs. 51.4% [18/35]; $P = 0.004$) and in establishing an accurate diagnosis.

Fetal magnetic resonance imaging (MRI) is useful when the ultrasound examination is inconclusive because of oligohydramnios, maternal obesity, late gestational age, or fetal position. Both skeleton and muscle can be assessed by MRI using echoplanar imaging,[142] with thick slab T2-weighted and dynamic sequences.[143-149] Echoplanar imaging can demonstrate epimetaphyseal characteristics used in measurement of fetal long bones,[150] increasing the accuracy of diagnosing short long bones.[148,151] MRI can also be useful in differentiating between normal bone development and bone dysplasia caused by a disruption of endochondral ossification.[152] Moreover, MRI can be applied to measure fetal thoracic and lung volumes, which are used to predict lethality in skeletal dysplasias.[153]

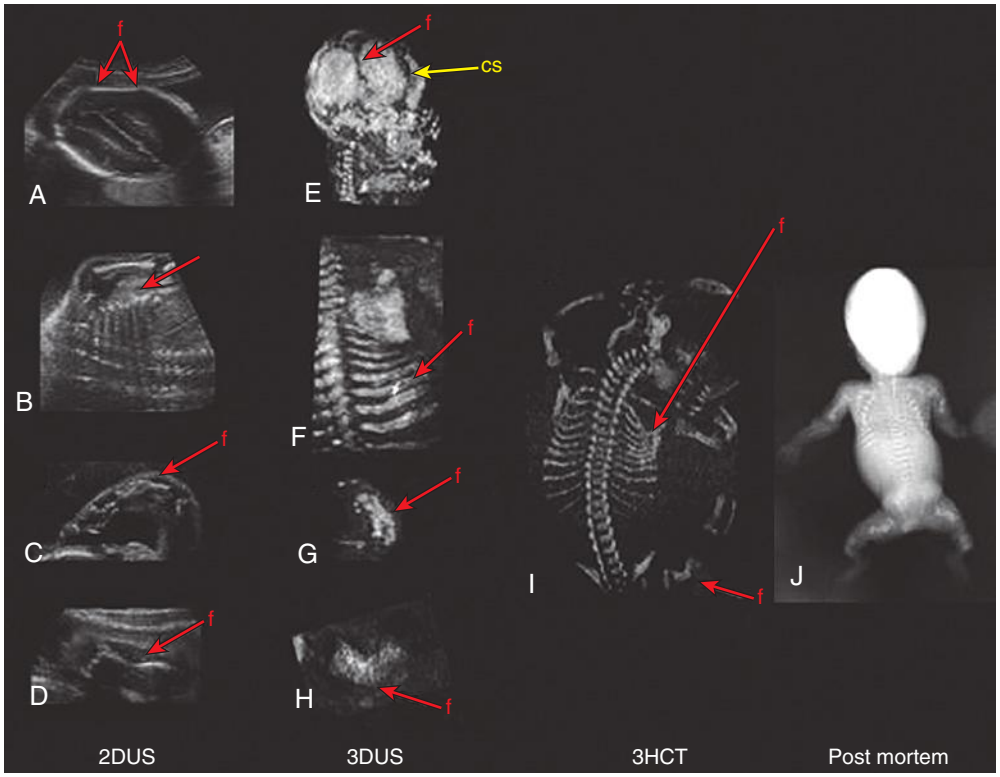

FIG 11-16 Comparison of phenotypic features of osteogenesis imperfecta by three-dimensional helical computed tomography (3HCT), three-dimensional ultrasound (3DUS) images, two-dimensional ultrasound (2DUS) images, and postmortem radiographs. **A,** 2DUS: transverse section of fetal head with a skull fracture (f) deformed by the transducer pressure. **B,** 2DUS: coronal section of fetal thorax showing irregular ribs (*arrow*). **C,** 2DUS: sagittal section of the right superior limb showing a short and bowed arm. **D,** 2DUS: sagittal section of fetal femur with a fracture (f). **E,** 3DUS image showing lateral view of fetal skull with a fracture (f) that could be differentiated from a normal coronal suture (CS) by the location and the abnormal shape depending on the transducer pressure; this was confirmed by postmortem examination. **F,** 3DUS-rendered bone mode demonstrating posterior view of fetal thorax showing fractured and irregular ribs (f). **G,** 3DUS-rendered bone mode image showing short and bowed radius and ulna. **H,** 3DUS-rendered bone mode image showing a fractured femur (f). **I,** 3HCT: posterior view of entire fetus confirming fractures (f) of ribs and femur as well as decreased mineralization of the skull. **J,** Postmortem radiologic examination, confirming shortening, bowing, and fracture of long bones. (From Ruano R, Molho M, Roume J, et al: Prenatal diagnosis of fetal skeletal dysplasias by combining two-dimensional and three-dimensional ultrasound and intrauterine three-dimensional helical computer tomography. Ultrasound Obstet Gynecol 24:134, 2004.)

Approach to the Diagnosis of Skeletal Dysplasias

A proposed systematic approach to the prenatal diagnosis of skeletal dysplasias is summarized in Table 11-10 and described in greater detail in the following section.

Evaluation of the Long Bones

Measurements. All long bones must be measured in all extremities. Comparisons with other segments should be performed to establish whether the limb shortening is predominantly rhizomelic, mesomelic, or acromelic, or whether it involves all segments (see Figs. 11-6 to 11-8). A detailed examination of each bone is necessary to exclude absence or hypoplasia of individual bones (fibula, tibia, ulna, radius, clavicles, and scapulae).[90,154-157] From a group of fetuses less than 24 weeks of gestation with a short femur length, Papageorghiou and associates[158] reported that 35% presented with skeletal dysplasias; all affected fetuses had associated anomalies. The authors suggested that in the presence of a short femur, a complete fetal anatomic evaluation is necessary. The most frequently associated skeletal dysplasias were asphyxiating thoracic dystrophy, osteogenesis imperfecta, thanatophoric dysplasia, and campomelic dysplasia.

Degree of Mineralization. An attempt should be made to characterize the degree of mineralization, which can be assessed by examining the acoustic shadow behind the bone as well as the echogenicity of the bone itself. Signs of demineralization include visualization of an unusually prominent falx in the fetal brain and the absence of or decreased echogenicity of the spine. It should be emphasized that there are limitations to the sonographic evaluation of long bone mineralization and that other structures, such as the fetal skull, may be better suited for such assessment (Fig. 11-17).

Degree of Long Bone Curvature. At present, there is no objective means to assess long bone curvature, and experience is necessary to assist the operator in discerning the boundary between normality and abnormality. Bowed or angulated femora (campomelia) (Fig. 11-18) is characteristic of campomelic dysplasia, thanatophoric dysplasia, osteogenesis imperfecta, short rib dysplasia, and hypophosphatasia.[159]

Metaphyseal Flaring. Metaphyseal flaring denotes widening at the level of the metaphyseal growth plate. It can be observed in many

conditions, including achondroplasia, hypochondroplasia, hypochondrogenesis, asphyxiating thoracic dysplasia, chondrodysplasia punctata, diastrophic dysplasia, hypophosphatasia, Kniest dysplasia, kyphomelic dysplasia, metatropic dysplasia, and OI.[18]

Femoral Angle. Khalil and colleagues[160] reported an increased diaphysis-metaphysis femoral angle measured at 20 weeks to 23 weeks and 6 days of gestation in fetuses later diagnosed with achondroplasia. The femoral angle in affected fetuses was 125 degrees as compared to 95 degrees in normal fetuses. The authors conclude that estimation of the femoral angle might improve the early detection of fetuses with achondroplasia.

Fractures. Fractures can be found in certain skeletal dysplasias such as OI and hypophosphatasia (Fig. 11-19). The fractures may be extremely subtle or may lead to angulation and separation of segments of the affected bone (Fig. 11-20).

TABLE 11-10 Checklist for Ultrasound Evaluation of a Fetus With Suspected Skeletal Dysplasia

1. Long bones
   - Presence/absence
   - Length/shape
   - Mineralization/fractures
2. Hands and feet
   - Presence/absence
   - Position/movements
   - Fingers and toes: number/position/movements
3. Spine
   - Shape/curvatures
   - Mineralization
   - Clefts
   - Size and number of vertebral bodies
4. Skull
   - Shape/mineralization/size
5. Face
   - Profile
   - Hypertelorism/hypotelorism
   - Clefts
6. Thorax
   - Shape
   - Lung and thoracic areas/volumes
   - Ribs: shape/fractures/number
   - Scapula/clavicle
7. Fetal movements
8. Complete anatomic evaluation
9. Echocardiography
10. Amniotic fluid

Prediction of Pulmonary Hypoplasia

Skeletal dysplasias associated with a hypoplastic thorax frequently have lung hypoplasia, which is the most frequent cause of death for these conditions. When a severe skeletal dysplasia is diagnosed, the presence

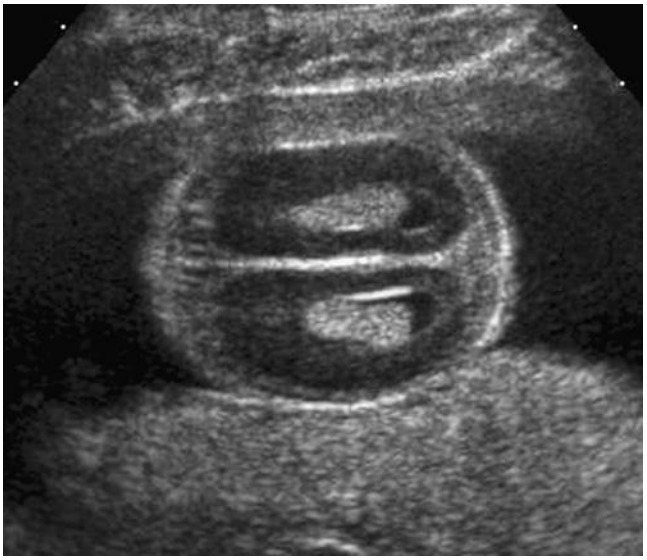

FIG 11-17 Demineralization of the skull in a case of osteogenesis imperfecta. The lateral ventricle and choroid plexus in the near field are well visualized because of lack of normal mineralization of the calvarium. In normal fetuses, reverberation artifact from the calvarium would obscure the ultrasound image of these structures.

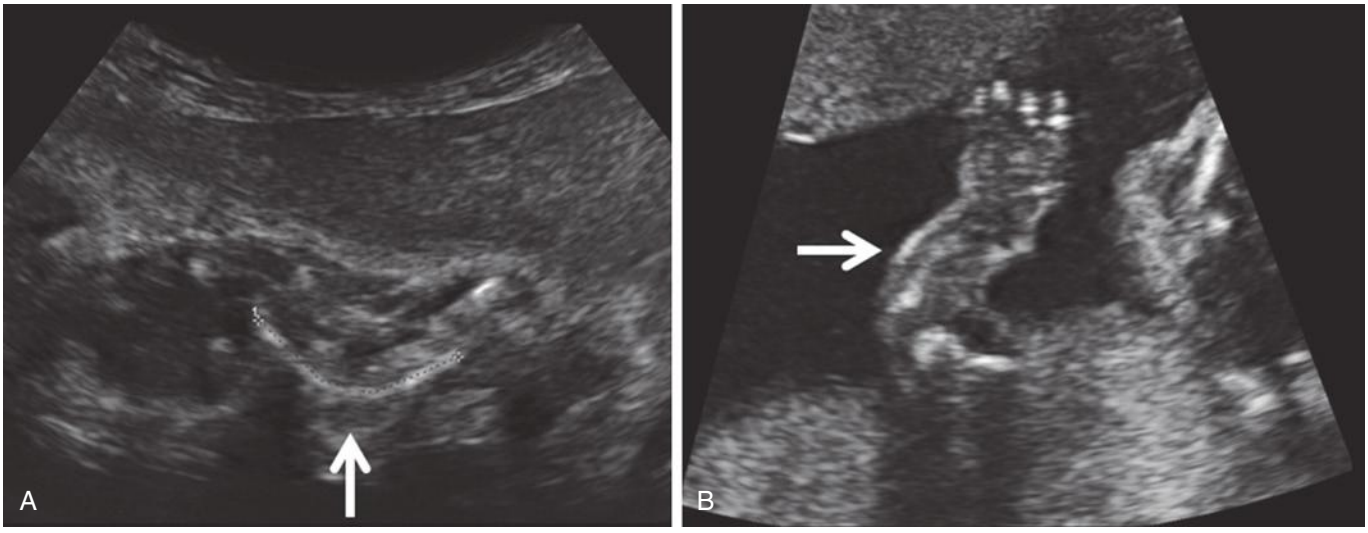

FIG 11-18 Bowing of long bones of the limbs (*arrows*) in fetuses with campomelic dysplasia (**A**) and with thanatophoric dysplasia (**B**).

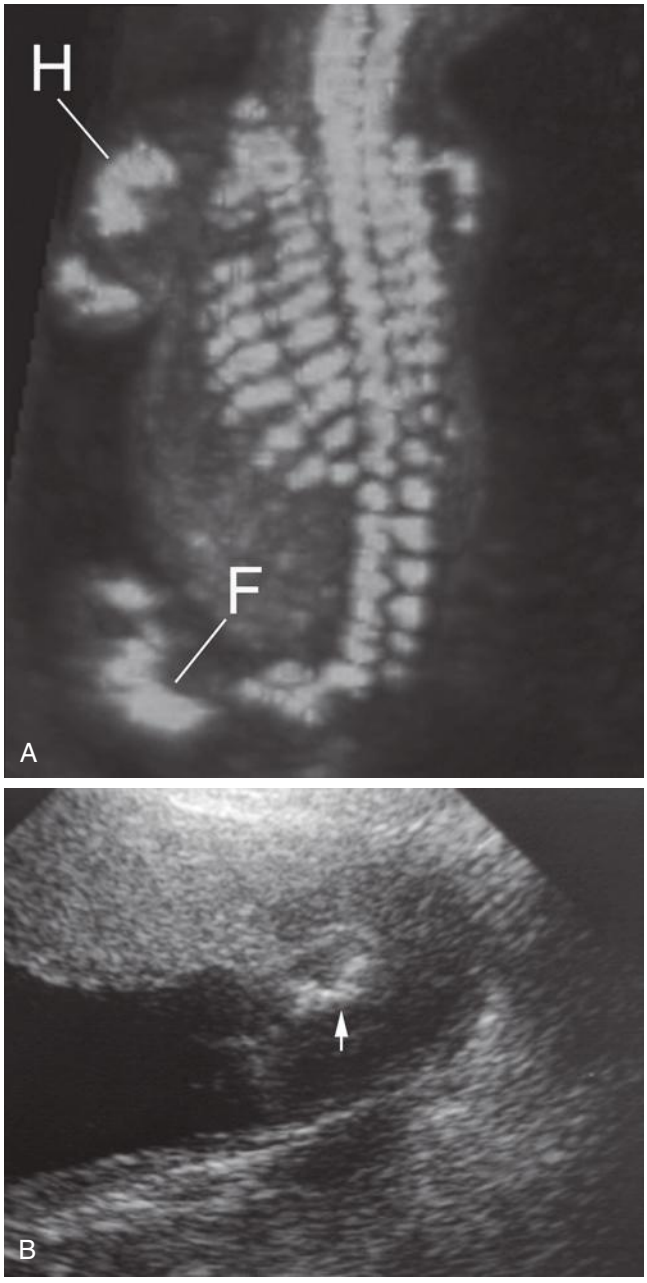

FIG 11-19 A, Three-dimensional sonogram in a fetus with osteogenesis imperfecta type II. The volume dataset was rendered using the maximum intensity mode. Multiple fractures in the ribs are present. Note the severe bowing and shortening of the femur (F) and humerus (H). **B,** Sonogram of a fetus with osteogenesis imperfecta type II. The femur is markedly shortened (*arrow*) with multiple fractures.

of marked thoracic involvement and pulmonary hypoplasia will allow the clinician to counsel the parents regarding prognosis, even though the specific type of skeletal dysplasia may be unknown. A number of sonographic parameters have been investigated for the prediction of pulmonary hypoplasia. They include measurements of the thorax and lungs, ratios between thoracic measurements and other biometric parameters, Doppler velocimetry of the pulmonary arteries, Doppler evaluation of tracheal fluid flow, and more recently, three-dimensional volumetric measurements of the fetal lungs by either sonography or MRI.

A detailed evaluation of the thorax in order to answer the following questions can assist in the diagnosis of the particular skeletal dysplasia[161]:

- Is the thorax extremely small? (thanatophoric dysplasia)
- Is the thorax long and narrow? (Jeune syndrome)
- Are the ribs extremely short? (short rib–polydactyly syndromes)
- Are there rib fractures? (osteogenesis imperfecta type II)
- Are there gaps within the ribs? (cerebra-costo-mandibular syndrome)
- Are there fused ribs? (spondylocostal dysplasia)
- Is there clavicular aplasia, hypoplasia, or pseudoarthrosis? (cleidocranial dysplasia)
- Are the scapulae abnormal? (hypoplasia or absence in campomelic dysplasia)

Evaluation of Thoracic and Lung Dimensions by Two-Dimensional Ultrasound. Thoracic and lung biometry has been extensively studied to identify fetuses at high risk for pulmonary hypoplasia.[162-173] Table 11-11 lists the skeletal dysplasias associated with altered thoracic dimensions, and Figures 11-21 and 11-22 illustrate features associated with a hypoplastic thorax. Methods used to measure the thorax, lungs, and heart by 2D sonography are illustrated in Figure 11-23. Thoracic areas and volumes in fetuses with a known gestational age can be evaluated using the nomograms reproduced in Tables 11-12 and 11-13. When gestational age is uncertain, age-independent ratios, such as the thoracic/abdominal circumference ratio (normal value: 0.77 to 1.01) and the thoracic/head circumference ratio (normal value: 0.56 to 1.04) can be used.[164]

A summary of the diagnostic accuracy of biometric parameters for the diagnosis of pulmonary hypoplasia is presented in Table 11-14.[153,163,165-170,173-182] Of particular interest are measurements of the right lung diameter, or the ratio between right lung diameter and the bony thoracic circumference proposed by Merz and associates,[171] who reported that fetuses with pulmonary hypoplasia all had a right lung diameter below the 5th percentile for gestational age, regardless of the primary disorder (skeletal dysplasias [$n = 7$], renal agenesis [$n = 11$], diaphragmatic hernia [$n = 7$], and hydrothorax [$n = 2$]).[177] In another study of 19 fetuses with congenital diaphragmatic hernia, Bahlmann and colleagues[178] demonstrated that the ratio of right lung diameter/bony thoracic circumference detected all fetuses with pulmonary hypoplasia with 100% sensitivity and 100% specificity.

Short Femur Length and Prediction of Lethality in Skeletal Dysplasias. Rahemtullah and coworkers[183] studied 18 fetuses with skeletal dysplasias in which all lethal cases were associated with a femur length/abdominal circumference ratio of 0.16. Although the test detected lethal cases with 100% sensitivity, two cases of achondroplasia were erroneously identified as lethal using this method. A different approach has been proposed by Hersh and associates,[101] who predicted lethality in 23 out of 25 cases of skeletal dysplasias with a femur length below the 1st percentile for gestational age and presence of bell-shaped thorax or decreased bone echogenicity.

Lung Volumetry by Three-Dimensional Sonography. Fetal lung volumetry by 3D sonography has been performed using two techniques: multiplanar[184-190] (Fig. 11-24) and VOCAL (Virtual Organ Computer-Aided AnaLysis, GE Medical Systems, Milwaukee, WI) (Fig. 11-25).[191-198] Nomograms for lung volumetry using 3D sonography are available in the literature (see Table 11-12).[198] Kalache and colleagues[191] demonstrated that both the 3D multiplanar and 3D VOCAL modes can be used to measure fetal lung volumes, an observation that was subsequently confirmed by Moeglin and associates.[196] A potential advantage of the VOCAL technique is the possibility of obtaining fine contours of the lungs, which may be particularly valuable when

2D, two-dimensional; 3D, three-dimensional; AC, abdominal circumference; APTD, anteroposterior thoracic diameter; CC, cardiac circumference; FL, femur length; HA, heart area; LD, lung diameter; LL, lung length; LV, lung volume; O/E TLV, observed-to-expected total lung volume; PROM, premature rupture of membranes; TA, thoracic area; TC, thoracic circumference; TTD, transverse thoracic diameter; US, ultrasonography.

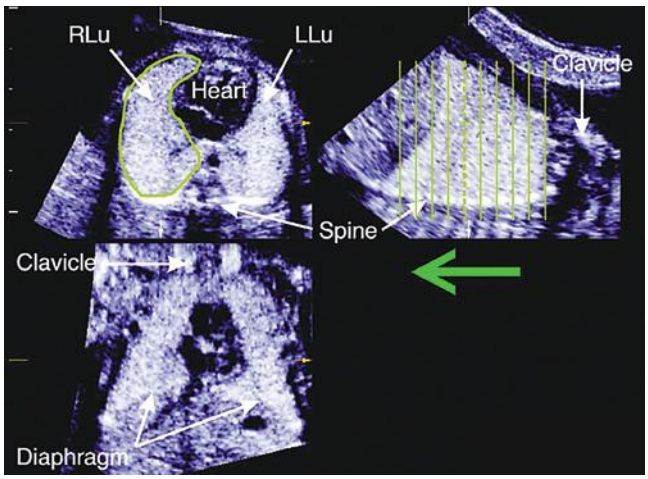

FIG 11-24 Three-dimensional ultrasound fetal lung measurements using the multiplanar technique. Note the image sequences (*green vertical lines*) used to obtain transverse views of the lung. The right lung (RLu) is outlined. Fetal lung volume is obtained by scrolling through the transverse plane (*green arrow*). LLu, left lung. (From Kalache KD, Espinoza J, Chaiworapongsa T, et al: Three-dimensional ultrasound fetal lung volume measurement: a systematic study comparing the multiplanar method with the rotational (VOCAL) technique. Ultrasound Obstet Gynecol 21;111, 2003.)

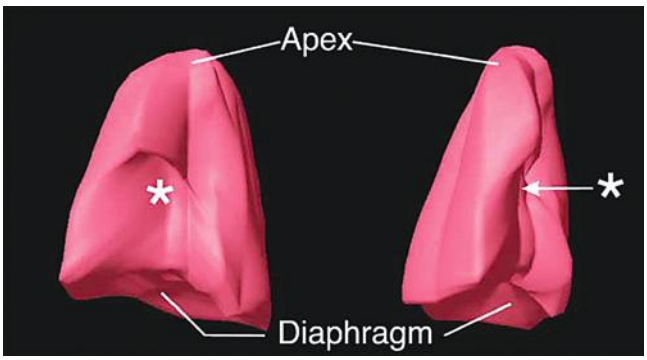

FIG 11-25 Three-dimensional ultrasound model of the right lung volume obtained using VOCAL. Note the indentation of the fetal heart (*asterisk*). The frontal view is shown on the left and the lateral view on the right. (From Kalache KD, Espinoza J, Chaiworapongsa T, et al: Three-dimensional ultrasound fetal lung volume measurement: a systematic study comparing the multiplanar method with the rotational (VOCAL) technique. Ultrasound Obstet Gynecol 21;111, 2003.)

the outline of the organ is irregular, such as in cases of congenital diaphragmatic hernia. In contrast, obtaining lung volume measurements using the 3D multiplanar technique is faster, taking usually less than 5 minutes to perform.[196] Volumes are best estimated when datasets are acquired using a transverse view of the fetal thorax.[186,198] Ruano and coworkers[197] compared volumetric measurements of the fetal lungs obtained using the VOCAL method with lung volumes calculated at the time of autopsy in 8 cases of congenital diaphragmatic hernia and in 25 control fetuses without pulmonary malformations. The mean relative error of 3D sonography to estimate the actual lung volume was −7.19% (range: −42.70% to +18.11%) in cases of congenital diaphragmatic hernia and −0.72% (range: −30.25% to +19.22%) in normal fetuses. Barros and colleagues[190] studied 24 fetuses with skeletal dysplasia and measured the total lung volume using VOCAL. An abnormally reduced lung volume was defined as below the 5th percentile for gestational age. From 18 fetuses diagnosed at birth with lethal pulmonary hypoplasia, 83% had a total lung volume below the 5th percentile for gestational age. Lung volume more accurately predicted pulmonary hypoplasia than thoracic circumference, thoracic circumference/abdominal circumference ratio, and thoracic area/cardiac area ratio.

Estimation of Pulmonary Hypoplasia by Magnetic Resonance Imaging. Parameters proposed to evaluate lung volume by MRI include the relative lung volume (observed/expected lung volume ratio), lung volume/estimated fetal weight (LV/EFW) ratio, and the lung/spinal fluid signal intensity (L/SF) ratio.[199-206] Fetal lung volume shows a linear increase across gestational age with the right lung volume accounting for 56% of the total fetal lung volume.[200] Lung volume evaluated by MRI is significantly reduced in fetuses at risk of pulmonary hypoplasia,[203] and MRI might perform better than sonography.[204] In addition, reduced signal intensity and altered L/SF ratio on T2-weighted imaging have been reported in fetuses with pulmonary hypoplasia.[202,205,206]

Doppler Assessment of Tracheal Fluid Flow. Kalache and coworkers[207] proposed that the volume of lung fluid displaced in the trachea could be useful for the analysis of fetal lung function. The investigators tested this hypothesis in a case-control study that included six cases of congenital diaphragmatic hernia and in a control group of five healthy fetuses matched for gestational age. Parameters that were analyzed included the (1) length of the inspiratory phase; (2) length of the expiratory phase; (3) peak velocities during inspiration and expiration; and (4) volume estimation of the displaced fluid in the trachea during breathing, calculated as

$$\text{Volume} = \text{VTI} \times \pi \times (d \times 0.5)^2$$

where VTI = velocity time interval and d = distance. The estimated breathing-related tracheal volume flow in uncomplicated pregnancies increased with gestational age (from 0.21 ± 0.10 mL/breath at 26 weeks, to 1.37 ± 0.48 mL/breath at 36 weeks of gestation) and was significantly lower in fetuses with diaphragmatic hernia who died of pulmonary hypoplasia. Tracheal volume flow in survivors was comparable to that in control subjects.

Doppler Velocimetry of the Pulmonary Arteries. Underdevelopment and structural changes of the pulmonary vascular bed in cases of pulmonary hypoplasia may result in increased pulmonary vascular resistance and reduced pulmonary arterial compliance.[208] Therefore, several investigators have attempted to use Doppler measurements of the pulmonary arteries and its branches in an attempt to identify fetuses at risk for pulmonary hypoplasia.[180,209-213] However the observed increment in the resistance or pulsatilty indices in fetuses at risk of pulmonary hypoplasia[209,211] has not been consistently documented,[210] and when present it has not been found superior to thoracic measurements.[180] Other Doppler parameters, such as acceleration time, have been also proposed for identification of fetuses at risk of pulmonary hypoplasia.[214]

Evaluation of Hands and Feet

The fetal hands and feet should be examined to exclude polydactyly (Fig. 11-26), brachydactyly, and extreme postural deformities, such as those seen in diastrophic dysplasia. Table 11-15 shows a nomogram of fetal foot size throughout gestation. Table 11-16 displays disorders associated with hand and foot deformities. Disproportion between the hands and feet and other parts of the extremity may also be a sign of skeletal dysplasias. Figure 11-27 illustrates the relationship between femur length and foot length. The femur length/foot length ratio is nearly constant from 14 to 40 weeks of gestation, with a mean value of 0.99 (standard deviation ±0.06). A ratio below 0.87 is considered abnormal.[215] Although fetuses with skeletal dysplasias have been reported to have abnormally low ratios, more experience is required to establish the diagnostic value of this method.[216] It is expected that

a small proportion of normal fetuses may have an abnormal ratio. As in the case of other limb biometric parameters, large deviations from the lower limit of normal are likely to be significant.

Evaluation of the Fetal Cranium

Several skeletal dysplasias are associated with defects of membranous ossification, and, therefore, skull bones are affected. Examination of the skull bones may reveal poor ossification (see Fig. 11-17), frontal bossing (Fig. 11-28), or cloverleaf deformity (Fig. 11-29). Table 11-17 presents abnormalities of the skull and face in various skeletal dysplasias.

Evaluation of the Fetal Face

Sonographic examination of the fetal face is of major importance in the assessment and diagnosis of skeletal dysplasias, because many of these disorders are associated with characteristic abnormalities.[217] Sonographic evaluation of the fetal face is easily performed in a high percentage of patients from 16 to 20 weeks of gestation onward. The single most reliable view in detecting facial abnormalities is the sagittal plane. This view permits determination of midface hypoplasia, which occurs in several skeletal dysplasias, such as thanatophoric dysplasia, achondroplasia, campomelic dysplasia, osteogenesis imperfecta, and spondyloepiphyseal dysplasia congenita.[86,217]

In cases of median cleft lip, the central portion of the upper lip is absent, and on the midline sagittal view, no upper lip will be demonstrated. In bilateral cleft lip, the midline view will have a variable appearance, depending upon the amount of residual premaxillary tissue present in the midline. In unilateral cleft lip, the midline sagittal scan may be relatively normal but the parasagittal view will reveal

the cleft. Clefts should be confirmed by imaging the lips in the coronal plane.

Cleft palate occurs in 66% of patients with cleft lip. Isolated cleft palate is more difficult to diagnose with ultrasound due to the shadowing from the facial bones. 3D sonography has been shown to be superior to 2D sonography for prenatal diagnosis of cleft lip and palate.[135,218,219] Potential advantages of 3D sonography over 2D sonography include the following: (1) a true coronal view of the lips can be displayed, even when the original scanning plane was obtained from a different orientation; (2) 3D standardized multiplanar imaging makes it easier to successfully demonstrate the maxillary tooth-bearing alveolar ridge in suspected cases; and (3) the maxillary tooth-bearing alveolar ridge can be more accurately localized by the multiplanar technique because this region can easily be mistaken for the mandibular ridge.[220,221] Rendered views of the cleft lip/palate have also been particularly useful for patient counseling.[220,222,223] A novel technique for visualization of the fetal palate, called the 3D reverse face view, has been proposed for the antenatal characterization of facial clefting; specifically, clefting of the hard palate.[224] This technique consists of rotating the volume dataset 180 degrees around the vertical axis in order to examine the secondary palate. Campbell and associates[225] reported that a cleft in the soft palate was missed in only one of eight cases of suspected orofacial clefting with the use of this rendering technique. Recent studies recommend the use of MRI in the evaluation of fetal cleft lip and palate identified by sonography. MRI appears to provide a better assessment of the degree of involvement of the secondary palate and of cleft extent since shadowing artifacts from adjacent osseous structures do not affect fetal MR images.[226-230]

FIG 11-28 Frontal bossing (*arrow*) in a sagittal plane of a fetus with achondroplasia.

Micrognathia is frequently observed in cases of skeletal dysplasia (Table 11-18).[231-233] In an attempt to provide an objective tool to diagnose micrognathia prenatally, Paladini and colleagues[234] proposed the jaw index, which is computed as the ratio between the anteroposterior mandibular diameter and the biparietal diameter. In a population of 198 fetuses with congenital anomalies (11 of which had micrognathia at necropsy or at birth), a jaw index below 23 correctly identified all cases of micrognathia with a false positive rate of 2%. Rotten and coworkers[235] proposed two parameters to differentiate between retrognathia and micrognathia: the inferior facial angle (Fig. 11-30) and the mandible width/maxilla width (MD/MX) ratio (Fig. 11-31). The inferior facial angle is defined as the angle between two lines traced on a sagittal profile view of the fetal face: (1) a reference line, orthogonal to the vertical part of the forehead, at the level of the synostosis of the nasal bones, and (2) the profile line, joining the tip of the mentum to the anterior border of the more protruding lip. In a population of fetuses at high risk for facial anomalies, an inferior facial angle less than 50 degrees identified retrognathia with a sensitivity of 100% and specificity of 98.9%. The MD/MX ratio was computed using transverse sections of the mandible and maxilla, with the actual measurements performed 10 mm posteriorly to the anterior osseous border; an MD/MX ratio less than 0.8 (between 18 and 28 weeks of gestation) correctly identified micrognathia in three cases of Treacher Collins syndrome.

Intraorbital and interorbital diameters should also be measured, because hypertelorism may occur in cases of skeletal dysplasia (Table 11-19).

Evaluation of the Fetal Spine

Sonographic assessment of the fetal spine must be performed in all fetuses with suspected skeletal dysplasias. The following parameters should be assessed:

Vertebral Bodies. Fetal vertebral bodies are composed of three ossification centers representing the vertebral body and two laminae.[236-239] Abnormalities of the ossification centers of the fetal vertebral bodies may result in hemivertebra (see Fig. 11-12), butterfly vertebrae, spinal dysgenesis (Fig. 11-32), or block vertebrae causing congenital scoliosis (see Figs. 11-10 and 11-11). A study of the associated anomalies in 27 cases of prenatally detected hemivertebra noted that 16 (59%) have additional associated anomalies, including gastrointestinal, renal, facial, limb, and cranial anomalies; only five of the fetuses with additional anomalies survived.[236] Usually these anomalies are not a risk factor for aneuploidy. Rib defects are often associated with thoracic vertebral body anomalies.

Platyspondyly can be diagnosed using high-resolution sonography (see Fig. 11-9).[240] An objective evaluation of platyspondyly is obtained by estimating the ratio between measurements of the vertebral interspace and of vertebral body height.[59]

Clefting of the vertebrae may be longitudinal or transverse and complete or incomplete.[68] Coronal vertebral clefts are a result of missed fusion between the anterior and posterior primary ossification centers

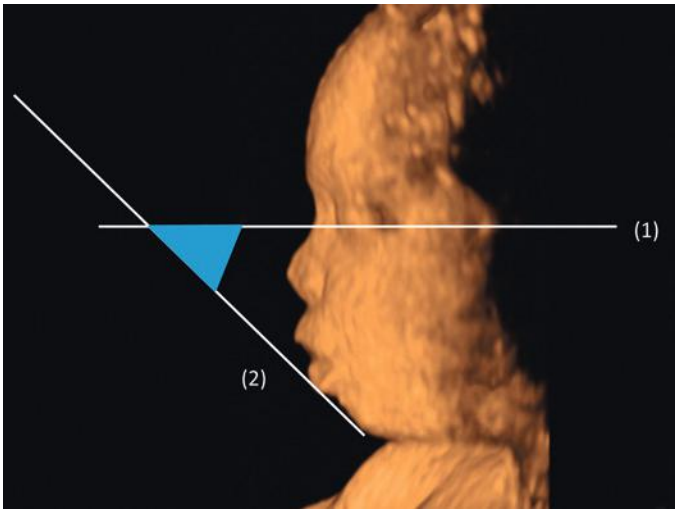

FIG 11-30 Inferior facial angle obtained from a sagittal view of the fetal face. The angle is formed by a reference line (1), orthogonal to the vertical part of the forehead at the level of the synostosis of the nasal bones, and the profile line (2), joining the tip of the mentum to the anterior border of the more protruding lip. beyond 16 weeks of gestation and can be observed by prenatal sonography.[241,242] Sagittal clefts in the vertebral bodies are believed to represent localized splitting of the notochord due to adhesions between ectoderm and endoderm during the embryonic period. The role of vertebral clefting in the diagnosis of skeletal dysplasias was assessed by Westvik and Lachman[242] based on the International Skeletal Dysplasia Registry. The authors reported coronal and sagittal clefts in 40 different skeletal anomalies. Coronal clefts were more common than sagittal clefts and were mainly located in the thoracolumbar region. Clefts were most frequently observed in atelosteogenesis (88%), followed by chondrodysplasia punctata (79%), dyssegmental dysplasia (73%), Kniest dysplasia (63%), and short rib–polydactyly syndrome (SRPS) (53%).[242] The authors concluded that vertebral clefts are of major diagnostic value in these groups of skeletal dysplasias.

Spinal Curvature. The most common osseous anomaly causing scoliosis is unilateral unsegmented bar with contralateral hemivertebra.[236,243-246] Spinal dysraphism may also occur with congenital scoliosis. An apparent etiologic relationship exists between neural tube defects and other vertebral anomalies. Siblings of infants with congenital scoliosis have a 4% risk of neural tube defects.[247] This increased risk is present in siblings of children with a single hemivertebra, as well as multiple vertebral anomalies (with or without neural arch defects). The differential diagnosis of fetal scoliosis includes neural tube defects, large abdominal wall defects, amniotic band syndrome, caudal regression, and hemivertebra. Nonossification of the lumbar vertebral bodies has been detected in achondrogenesis and other diseases.[248-250]

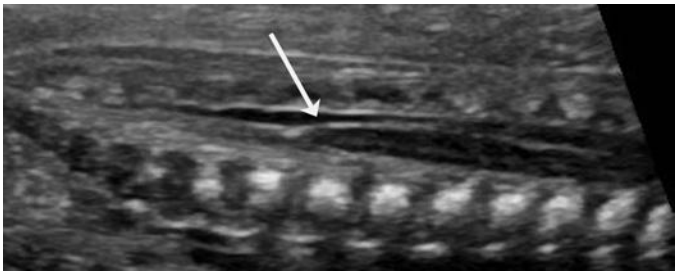

FIG 11-33 Conus medullaris (*arrow*) in a fetus at 21 weeks of gestation.

Conus Medullaris. Hoopmann and associates[251] performed detailed sonographic evaluation of the fetal spine and reported that the distance from the tip of the conus medullaris to the sacrum was useful in identifying fetuses with skeletal dysplasias with a shortened trunk (Fig. 11-33). In their study, all fetuses with a shortened trunk at birth had a considerably shorter distance from the tip of the conus medullaris to the sacrum as compared with normal fetuses. The authors suggest that evaluation of the conus medullaris might be useful in the evaluation of skeletal dysplasias.

Evaluation of the Internal Organs

A detailed examination of the cardiovascular, genitourinary, gastrointestinal, and central nervous system (CNS) organs should be performed for differential diagnosis among syndromes presenting with fetal skeletal anomalies. For example, congenital heart disease is a prominent feature of Ellis–van Creveld and Holt-Oram syndromes.[252,253]

Fetal Movements

The normal pattern of fetal movements can be identified as early as 11 weeks of gestation through a detailed anatomic evaluation.[254-257] Abnormal fetal movements can be observed in skeletal disorders involving joint contractures, neural muscular connective tissue disorders, amyoplasia (lack of muscle growth), vascular compromise, and anomalies of the spinal cord. The most frequent conditions associated with abnormal or absent fetal movements are fetal akinesia deformation sequence (FADS) or Pena-Shokeir syndrome, and arthrogryposis.[258] In FADS there is a significant reduction in the amplitude, velocity, and complexity of fetal movements.[259,260] In arthrogryposis, there is fixed position of the distal parts of the limbs and reduced amplitude in limb movements. Abdulkadir and colleagues[261] reported a characteristic pattern of movements in a fetus with thanatophoric dysplasia at 32 weeks of gestation including rigid abduction of the limbs, flexed elbows and knees, lack of synchronous movements, hyperextended neck, and rhythmic segmentation of trunk movements.

Newborn Evaluation

Even when all efforts have been made to establish an accurate prenatal diagnosis, a careful study of the newborn is always required.[92] The evaluation should include radiographs of the skeleton and a detailed physical examination performed by a geneticist or by a professional with experience in the field of skeletal dysplasias. The radiographs should include anteroposterior (AP), lateral, and Towne views of the skull, as well as AP views of the spine, extremities, and scapula,[262] with separate films of the hands and feet. Veeramani and coworkers[263] reported that a full skeletal x-ray survey helped to establish the correct

diagnosis in 69% of all skeletal dysplasias. In lethal skeletal dysplasias, histologic examination of the chondro-osseous tissue should be performed as this information may help the physician reach a specific diagnosis. Chromosomal studies should also be included, as there is a specific group of constitutional bone disorders associated with cytogenetic abnormalities. Biochemical studies are helpful in some cases (e.g., hypophosphatasia). Enzymatic activity assays may be considered if the phenotype suggests a metabolic disorder (e.g., mucopolysaccharidosis). Molecular diagnosis can be performed for disorders in which a specific genetic mutation has been identified or if a specific diagnosis is suspected, and it is recommended that DNA should be saved in all cases.[33,34,264] Increasingly, whole exome sequencing is helpful in the diagnosis of suspected genetic disorders.

Increased Nuchal Translucency and Skeletal Dysplasias

In chromosomally normal pregnancies, increased nuchal translucency (NT) thickness is associated with a higher risk of major anomalies,[265-268] including skeletal dysplasias.[115,268-272] In one multicenter screening project for trisomy 21 performed in 100,000 pregnancies by the combination of maternal age and NT, a significant association between increased NT and a wide range of skeletal dysplasias was found.[265] In addition, several case reports and small series have confirmed that in chromosomally normal fetuses, an association may exist between increased NT thickness and skeletal anomalies. The skeletal dysplasias associated with increased thickness of NT are listed in Table 11-20.

OSTEOCHONDRODYSPLASIAS

A growing number of skeletal dysplasias have been recognized in utero, and a complete account of each disorder is beyond the scope of this chapter. For detailed information on classification and molecular diagnosis of skeletal disorders, the interested reader should consult the International Nosology and Classification of Constitutional Disorders of Bone.[36] For detailed information on prenatal and postnatal imaging methods applied to evaluate skeletal dysplasias, we highly recommend the book *Fetal and Perinatal Skeletal Dysplasias; An Atlas of Multimodality Imaging* by Christine Hall, Amaka Offiah, Francesca Forzano, Mario Lituania, Michelle Fink, and Deborah Krakow.[161] The following discussion presents a few of the most common disorders relevant to prenatal diagnosis.

Achondroplasia, Thanatophoric Dysplasia, and Hypochondroplasia

Achondroplasia, thanatophoric dysplasia, and hypochondroplasia are discussed in the same section because these disorders are caused by different mutations in the fibroblast growth factor receptor-3 gene (*FGFR3*).[290-297] Mutations in *FGFR3* are gain-of-function mutations that produce a constitutively active protein capable of initiating intracellular signal pathways in the absence of ligand binding.[298,299] This activation leads to premature maturation of the bone.[299] The critical clinical difference between thanatophoric dysplasia and achondroplasia/hypochondroplasia is severe shortening of the ribs in thanatophoric dysplasia, resulting in restricted lung volumes, respiratory insufficiency, and death within hours or days after birth.[300]

Achondroplasia

The most common nonlethal skeletal dysplasia is achondroplasia, an autosomal dominant condition with complete penetrance and an estimated prevalence ranging from 1:10,000 to 1:50,000 births.[301-303] It is clinically characterized by rhizomelic shortening of the limbs and mild limb bowing, exaggerated lumbar lordosis, and an enlarged head.[304] The bones of the hands and feet are short (brachydactyly). The head is large (macrocephaly), with frontal bossing, midface hypoplasia, a flattened nasal bridge, and a broad mandible. Achondroplasia is frequently misdiagnosed during pregnancy.[305] Modaff and associates[306] retrospectively collected data from 37 consecutive referrals of infants with achondroplasia in whom prenatal sonography was performed. Nine of the 37 (24%) infants had a positive family history of achondroplasia; all 9 were correctly diagnosed prenatally. Of the 28 infants with no family history of achondroplasia, 16 (57%) were recognized to have abnormalities on ultrasound imaging, although none was diagnosed with certainty. Five received an appropriate diagnosis of "most likely" achondroplasia, and four others were given a nonspecific (but appropriate) diagnosis of some skeletal dysplasia, not otherwise specified. In seven instances (25%), an incorrect diagnosis of a lethal or very severe disorder was provided.

The major difficulty in the prenatal diagnosis of this condition is that abnormal long bone growth is not recognized in most cases until the third trimester of pregnancy.[74,304] However, prenatal diagnosis of achondroplasia is possible and has been reported.[307-310] For example, the "trident hand" (an increased interspace between the third and fourth digit) is a specific finding for achondroplasia[311,312] (Fig. 11-34). A distinct difference in the femoral length growth curves of homozygous, heterozygous, and unaffected children of achondroplastic parents was described by Patel and Filly.[313] Fetuses with homozygous achondroplasia demonstrated early shortening of the femora less than the 3rd percentile at 14.0 to 16.5 weeks of gestation (mean 15.6 weeks), but fetuses with heterozygous achondroplasia showed femoral

FIG 11-34 **A,** Drawing demonstrating separation between the third and fourth digit. **B,** Photograph of a child with achondroplasia and trident hand. **C,** In utero sonogram of a fetus with achondroplasia and trident hand with separation between the third and fourth digits (*arrow*).

shortening less than the 3rd percentile at 18.2 to 26.2 weeks of gestation (mean 21.5 weeks).[313] Recently, Tonni and colleagues[303] reported the association of first trimester increased NT in a fetus with achondroplasia, and Karadimas and associates[314] reported a fetus with achondroplasia and multiple craniosynostoses. Khalil and colleagues suggested that widening of the proximal femoral angle at 20 to 23 weeks of gestation can identify fetuses with achondroplasia.[160]

More than 99% of individuals with achondroplasia have one of two mutations in the *FGFR3* gene, which is located on the short arm of chromosome 4.[315-317] The most common mutation is a guanine-to-adenine (G-to-A) transition, at nucleotide 1138 in the amino acid 380, and about 1% of affected individuals have a guanine-to-cytosine (G-to-C) transversion at the same nucleotide.[290,317] A transversion occurs when a pyrimidine replaces a purine or vice versa, and a point mutation occurs when a pyrimidine replaces a pyrimidine or a purine replaces a purine.[264] The G380R mutation has been shown to result in constitutive activation of the *FGFR3* gene, which inhibits chondrocyte proliferation and differentiation and is responsible for the shortness of long bones. It is noteworthy that all new mutations occur on the paternal allele, suggesting an increased mutability of *FGFR3* during spermatogenesis is associated with increased paternal age.[318] Molecular diagnosis is possible in pregnancies in which one or both parents have

achondroplasia, either in placental tissue obtained by chorionic villus sampling (CVS) or in fetal cells obtained by amniocentesis.[308,319,320] Molecular analysis can also identify mutations in fetuses suspected to have achondroplasia based on ultrasound findings.

Heterozygous achondroplasia is compatible with normal life and intellectual development. However, cervicomedullary junction abnormalities, which may lead to spinal cord compression, put the infant with achondroplasia at risk for lethal sequelae.[321] Cervicomedullary decompressive surgery can be lifesaving by decreasing neurologic complications associated with damage of the spinal cord and may eliminate the risk of central apnea that can cause sudden death.[322] In the homozygous state (which occurs in 25% of the offspring of two parents with achondroplasia), the disease is usually lethal during the first 2 years of life.[301] However, a case of survival until 37 months has been reported.[323] The radiologic characteristics of homozygous achondroplasia lie between those of thanatophoric dysplasia and those of heterozygous achondroplasia.

Administration of growth hormone (GH) has been proposed for the treatment of achondroplasia.[324] Children treated with GH for 2 years showed an increment in annual height (6.5 ± 1.8 cm in the first year, and 4.6 ± 1.6 cm in the second year) significantly greater than before treatment (3.9 ± 1.0 cm).[325] However, individual variability in response to GH treatment has been reported.[326] Other innovative therapeutic approaches include downregulation of the tyrosine kinase activity of the *FGFR3* by selective chemical inhibitors,[302] blocking antibodies to interfere with the binding of FGF ligands to *FGFR3*,[302] and targeted overexpression of C-type natriuretic peptide.[327]

Severe Achondroplasia With Developmental Delay and Acanthosis Nigricans. Tavormina and associates[328] identified a *FGFR3* missense mutation in four unrelated individuals with skeletal dysplasias approaching the severity observed in thanatophoric dysplasia type I. Three of the four individuals developed extensive areas of acanthosis nigricans beginning in early childhood, suffered from severe neurologic impairments, and survived past infancy without prolonged life support measures. The *FGFR3* mutation associated with this phenotype (A1949T:Lys650Met) occurs at the nucleotide adjacent to the thanatophoric dysplasia type II mutation (A1948G:Lys650Glu) and results in a different amino acid substitution. The authors of the study referred to the phenotype caused by the Lys650Met mutation as "severe achondroplasia with developmental delay and acanthosis nigricans" (SADDAN) because it differs significantly from the phenotypes of other known *FGFR3* mutations. SADDAN is also associated with unusual bone deformities, such as femoral bowing with reverse (i.e., posterior apex) tibial and fibular bowing, and so-called ram's horn bowing of the clavicle. This condition has not been associated with cloverleaf skull or craniosynostosis.[329]

Thanatophoric Dysplasia

Thanatophoric dysplasia is the most common lethal skeletal dysplasia,[38] and it is characterized by severe rhizomelia, normal trunk length with a narrow thorax, and a large head with prominent forehead. It occurs in 0.24 to 0.69 of 10,000 births.[39,40,293,330] Two subtypes (I and II) have been identified, which are phenotypically differentiated by the skull shape and femur morphology. Type I typically presents with bowed "telephone receiver" femora[331] (Fig. 11-35) and no or mild cloverleaf skull, whereas the type II phenotype is characterized by a severe cloverleaf skull (see Fig. 11-29) and short but straight long bones.[331-335] Cloverleaf skull results from premature closure of the coronal and lambdoid sutures, defective development of the cranial base with secondary synostosis, or a primary developmental disorder of the brain with secondary deformation of the skull. The differential diagnosis between the two types depends on the radiographic findings

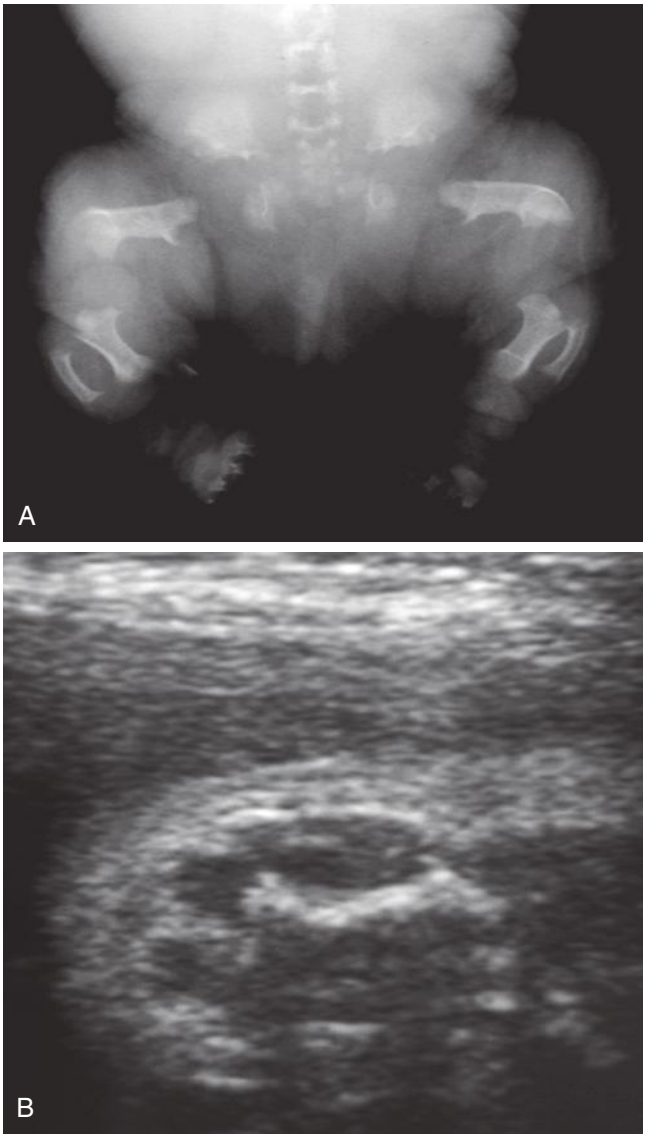

FIG 11-35 A, Radiograph of a patient with thanatophoric dysplasia. Marked limb shortening and characteristic bowed "telephone receiver" femora. **B,** Sonogram of a fetus with thanatophoric dysplasia with marked femoral shortening and bowing.

and histologic characteristics. Both types of thanatophoric dysplasia are inherited in an autosomal dominant manner. The majority of cases of thanatophoric dysplasia (all type I and most cases of type II) are sporadic. Some familial cases of type II have been reported.[336-339] Distinct mutations in the *FGFR3* gene cause each one of the two types of thanatophoric dysplasia.[301,336,338,340] Three common mutations (R248C, Y373C, and S249C) are found in approximately 90% of the patients with thanatophoric dysplasia type I.[298,341,342] Importantly, up to 99% of the mutations causing type I and more than 99% of mutations causing type II thanatophoric dysplasia can be identified through molecular genetic testing of *FGFR3*. The *FGFR3* mutation p.Lys650Glu has been identified in all individuals with type II thanatophoric dysplasia,[343] and one mutation (K650E) is found in almost all cases of type II thanatophoric dysplasia.[343-345] Camera and colleagues[346] described an individual with the common thanatophoric dysplasia type I mutation and the clinical phenotype of achondroplasia. Although mosaicism was considered as a possible explanation for the milder phenotype, no trace of mosaicism was found in buccal mucosal cells or blood.

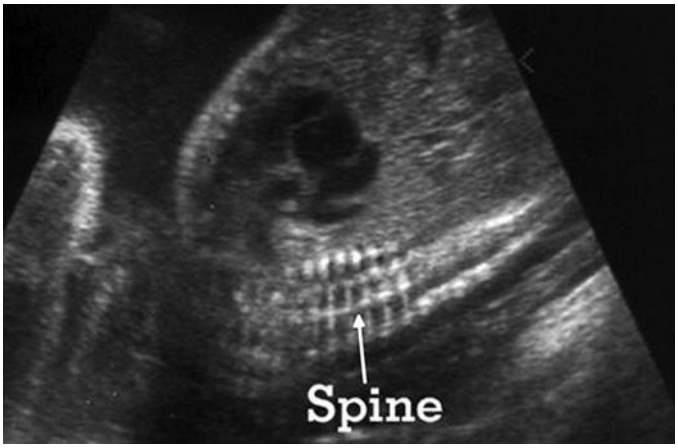

FIG 11-36 Platyspondyly in a fetus with thanatophoric dysplasia. (Courtesy of Theera Tongsong, MD, and Suchaya Luewan, MD.)

The prenatal sonographic findings depend on the specific type of thanatophoric dysplasia.[241] The association of cloverleaf skull with micromelia is specific to thanatophoric dysplasia type II. Although campomelic syndrome may also be associated with cloverleaf skull, micromelia is not a feature of that condition. Ventriculomegaly, macrocranium, and polyhydramnios are frequently seen in thanatophoric dysplasia. Cerebellar hypoplasia is observed in approximately 37% of cases in postnatal series.[300] There is a relatively large calvarium with a prominent forehead, a saddle nose, and hypertelorism. Additional findings include short ribs, platyspondyly (see Fig. 11-9 and Fig. 11-36), and short and broad tubular bones in the hands and feet.

Thanatophoric dysplasia is associated with a specific pattern of brain malformations, characterized by megalencephaly (100%), hippocampal dysplasia (100%), rudimentary dentate gyrus (100%), polymicrogyria (97%), enlarged temporal lobes (93%), abnormal deep transverse sulci across the inferomedial temporal lobe (88%), subependymal neuronal heterotopia (81%), and subarachnoid neuroglial heterotopia (79%).[300] This pattern of brain anomalies has been extensively described in the neuropathology literature and has been observed with similar frequency in the two types of thanatophoric dysplasia.[300] Research conducted in mouse models for thanatophoric dysplasia suggests that the cortical malformations result from compound disturbances in cortical patterning, proliferation, and apoptosis. The result is gyral pattern abnormalities, regional dysplasia, and altered surface area (especially temporal lobe hyperplasia and premature sulcation).[300,347] Macroscopic gyral abnormalities and enlargement of the temporal lobes are specific for the disease, and are already present at midgestation by the time ultrasonography is performed.[300,348]

The differential diagnoses for thanatophoric dysplasia include SRPS, homozygous achondroplasia (in which both parents are typically affected), and asphyxiating thoracic dysplasia (differentiated by slight shortening of the long bones and normal vertebrae). On a review of radiologic findings of several cases of thanatophoric dysplasia, Horton and colleagues[349] were able to discern a group of distinct entities characterized by severe platyspondyly. These disorders include Torrance, San Diego, Lutton, and Shiraz types of platyspondylic lethal osteochondrodysplasias. The differential diagnosis among these entities is based on histologic and radiologic characteristics. Individuals with platyspondylic lethal skeletal dysplasia-San Diego type, have *FGFR3* mutations that have been previously reported in association with thanatophoric dysplasia type I.[350]

Thanatophoric dysplasia is a uniformly lethal disorder, although survival for several months has been reported.[339,349,351-354] Diagnosis by prenatal sonography has been documented,[111,249,355-372] including a case in a triplet pregnancy.[237] Prenatal diagnosis by CVS or amniocentesis is available.[135,373-375]

Hypochondroplasia

Hypochondroplasia is an autosomal dominant disorder that resembles achondroplasia,[376] although the clinical symptoms and radiologic features in hypochondroplasia are generally milder than those seen in achondroplasia. Hypochondroplasia can result from a mutation in the *FGFR3* gene,[377,378] even though genetic heterogeneity has been suspected.[379,380] The incidence and prevalence of this disorder have not been determined, in part because of lack of agreement on a definitive set of diagnostic criteria, which makes it difficult to review data from many studies reported in the literature. Most cases occur sporadically as a result of a new mutation.[381]

Two *FGFR3* mutations (C1620A and C1620G) result in a lysine for asparagine substitution at codon 540 (N540K) and have been shown to cause hypochondroplasia.[291,382] Several other *FGFR3* mutations have been proposed to cause a small number of cases of hypochondroplasia. In addition, the *IGF1* gene has been proposed to be associated with hypochondroplasia although no pathogenetic mutations have been identified.[379]

The differential diagnosis between this condition and achondroplasia is based on sparing of the head and lack of tibial bowing in hypochondroplasia.[376,383-387] However, it is noteworthy that medial temporal lobe dysgenesis, similar to that observed in patients with thanatophoric dysplasia, has been described in three patients with a C1620A mutation in the *FGFR3* gene.[388,389] Thus, brain abnormalities that are commonly seen in hypochondroplasia and thanatophoric dysplasia can be used to distinguish them from achondroplasia.[388-390] In contrast to achondroplasia, the skull, pelvis, and hands are essentially normal.

Although hypochondroplasia is generally first detected during childhood, prenatal diagnosis has been reported in fetuses at risk.[309,384] A reduced femur length and a normal growth of the skull have been suggested as a potential sonographic marker for the prenatal diagnosis of hypochondroplasia.[391] DNA-based diagnosis through CVS or amniocentesis may be possible. It has been recommended that molecular analysis should include both achondroplasia and hypochondroplasia mutations.[392] Wang and coworkers[393] reported the molecular diagnosis in a Chinese family with a history of hypochondroplasia, using microarray-based next-generation sequencing (NGS) to evaluate disease-related genes *FGFR3* and cartilage oligomeric matrix protein (COMP). Similarly, Chen and associates[394] reported a mutation in *FGFR3* in a fetus presenting with very short limbs. The initial diagnosis was achondroplasia; however, study of *FGFR3* showed a de novo mutation for hypochondroplasia. The most common mutations are N540K in the tyrosine kinase 1 domain, G342C, and Y278C.[394,395] Hypochondroplasia has also been reported in Léri-Weill dyschondrosteosis[396] and shares similar clinical characteristics with Turner syndrome.[397]

Fibrochondrogenesis and Atelosteogenesis

These two conditions have a clinical presentation similar to that of thanatophoric dysplasia. The differential diagnosis between these disorders in utero is difficult. Fibrochondrogenesis and atelosteogenesis are extremely rare, and only a few cases of each have been reported.[68,398-405]

Fibrochondrogenesis

This skeletal disorder is a very rare lethal chondrodysplasia.[406] The first case was described in 1978 by Lazzaroni-Fossati and colleagues.[407] This disorder is inherited in an autosomal recessive fashion and is

characterized by micromelia with significant metaphyseal flaring, normal head size, flat face, flattened nasal bridge with anteverted nostrils, prominent eyes, undermineralized skull, platyspondyly, clefting of the vertebral bodies, and a narrow and bell-shaped thorax.[404,408-411] Metaphyseal flaring is not a feature of thanatophoric dysplasia.[399,407,412,413] This condition has been described in four consanguineous families.[400,407,410,414] Other conditions to be considered in the differential diagnosis include metatropic dysplasia and Kniest dysplasia. Histologic examination is characterized by chondrocytes with fibroblastic appearance and poor endochondral ossification.[404,410] The prenatal diagnosis of fibrochondrogenesis by ultrasound has been reported as early as 17 weeks of gestation.[399,400,404] The recurrence risk for fibrochondrogenesis is 25%, which emphasizes the importance of genetic counseling.[404] At present, the molecular defect involved in fibrochondrogenesis is not known.[415] However, Bekdache and coworkers[416] studied 20 cases in which fibrochondrogenesis was identified prenatally. Among them, 6 pregnancies were terminated, 13 were delivered, and 11 died within 3 months after birth. In the two surviving children, a mutation in the gene *COL11A1* was observed. The authors suggested that molecular diagnosis might be possible for fibrochondrogenesis.

Atelosteogenesis

This condition includes a heterogeneous group of disorders with overlapping phenotypic features. It is a lethal chondrodysplasia characterized by severe micromelia (with hypoplasia of the distal segments of the humerus and femur), bowing of long bones, flat nasal bridge, cleft palate, micrognathia, narrow thorax with short ribs, coronal and sagittal vertebral clefts,[68] and dislocation at the level of the elbow and knee. Clubfoot deformities may also be present.[417] Three subtypes of atelosteogenesis (I, II, and III) have been described based on radiologic and pathologic findings.[418-421] Sillence and associates[421] retrospectively collected data from 17 referrals of fetuses and newborns with atelosteogenesis during a 20-year period. Clinically, all cases had marked limb shortening, and micrognathia, flattened nasal bridge, cleft palate, and pulmonary hypoplasia were more common in atelosteogenesis type II. Talipes was present in 80% of the cases of atelosteogenesis type I. Radiographic findings of atelosteogenesis type I (5 cases) showed distal hypoplasia of the femur; the humerus was absent or segment shaped; the radius, ulna, and tibia were bowed; there was absence of the fibula; and all cases had coronal clefts in the lumbar vertebrae. In atelosteogenesis type II (11 cases), the femora were shortened with expanded club-like ends and not distally tapered, and the humeri presented with distal hypoplasia and pointing. The forearm was shorter due to distal hypoplasia of the ulnae and proximal hypoplasia of the radii. In the lower limbs, the tibiae were short and bowed, and the fibulae had proximal or distal hypoplasia and pointing. The sacrum was horizontal. All cases had an S-shaped cervical spine. Only one case of atelosteogenesis type III was reported, with distal tapering of the femur and humerus, absence of ossification of the fibula, and an S-shaped cervical spine.[421]

Atelosteogenesis types I and III are sporadic and caused by missense mutations in the gene encoding filamin B, a protein that has a role in vertebral segmentation, joint formation, and endochondral ossification.[422] Atelosteogenesis type I shows giant cells in the growth plate cartilage and a mutation in the filamin B gene (*BLNB*).[423] Atelosteogenesis type II is inherited in an autosomal recessive pattern and is caused by a mutation in the diastrophic dysplasia sulfate transporter (DTDST) gene (*SLC26A2*).[375–378] It overlaps phenotypically and genetically with diastrophic dysplasia and achondrogenesis type IB.[421,424,425]

Differential diagnoses include diastrophic dysplasia and de la Chapelle dysplasia.[426,427] Three cases of a lethal dysplasia termed boomerang dysplasia (so-called boomerang-like tibia) may actually represent the same disorder as atelosteogenesis type I.[428]

Achondrogenesis

This skeletal dysplasia, also known as anosteogenesis, is a lethal chondrodystrophy characterized by extreme micromelia, a short trunk, and macrocrania. Prevalence at birth varies from 0.09 to 0.23 in 10,000 births.[39,40,89,93,100] Traditionally, this disorder has been classified into two types: the more severe form or type I achondrogenesis (Parenti-Fraccaro) and the less severe form or type II achondrogenesis (Langer-Saldino). In 1998, type I was subdivided into two types: type IA (Houston-Harris) and type IB (Fraccaro).[429,430] Although hypochondrogenesis had been considered a separate disorder from achondrogenesis, evidence now suggests that hypochondrogenesis and achondrogenesis type II are phenotypic variants of the same disorder.[330,431,432] Indeed, clinically and radiologically, achondrogenesis type II, hypochondrogenesis, and neonatal spondyloepiphyseal dysplasia congenita form a continuous spectrum of disease.[433] The fundamental biochemical disorder seems to be allelic mutations of the gene coding for type II procollagen.[434]

Type IA achondrogenesis (Houston-Harris) is characterized by micromelia, lack of ossification of vertebral bodies (but ossification of the pedicles in the cervical and upper thoracic region), and short ribs with multiple fractures. The calvarium is demineralized. Type IB (Fraccaro), which is a recessively inherited chondrodysplasia, is caused by a mutation in the DTDS gene[435-437] and is similar to type IA achondrogenesis. The calvarium, however, is ossified, and fractured ribs cannot be seen; the pedicles of the vertebral bodies show some degree of ossification. Type II achondrogenesis is characterized by micromelia; lack of mineralization of all or many of the vertebral bodies, sacrum, and ischium; an enlarged calvarium with normal ossification; variable shortening of the ribs; and absence of fractures (Fig. 11-37).[438] Table 11-21 illustrates the characteristics of the different types of achondrogenesis.[439,440]

Prenatal diagnosis should be suspected on the basis of micromelia, lack of vertebral ossification, and a large head with various degrees of ossification of the calvarium.[248,438-451] Polyhydramnios and hydrops have been associated with achondrogenesis. An association between cystic hygromas and achondrogenesis has been reported in a fetus with normal karyotype.[438,441,452]

Achondrogenesis types IA and IB are inherited in an autosomal recessive pattern, whereas most cases of achondrogenesis type II and hypochondrogenesis have been sporadic (new autosomal dominant mutations). Some severe cases of type II achondrogenesis follow an autosomal recessive pattern.[453] The distinction between achondrogenesis type IB (which has a recurrence risk of 25%), and the more frequent autosomal dominant achondrogenesis type II, which has a lower recurrence risk, is important for genetic counseling. A couple at risk of having a child with achondrogenesis type IB may take advantage of the possibility of molecular prenatal diagnosis by CVS or amniocentesis, or preimplantation genetic diagnosis.[324,454,455]

Achondrogenesis type IA is caused by a homozygous or compound heterozygous mutation in the thyroid receptor-interacting protein 11 gene (*TRIP11*) on chromosome 14q32. *TRIP11* encodes the Golgi microtubule-associated protein (GMAP) 210, which is associated with development of the skeletal system.[456] Achondrogenesis type IB is caused by a homozygous or compound heterozygous mutation in the diastrophic dysplasia sulfate transporter (DTDST) gene (*SLC26A2*) located in chromosome 5q32.[455,457] This gene is required for synthesis of sulfated proteoglycans in cartilage. It is also affected in atelosteogenesis type II (AO2), diastrophic dysplasia (DTD), diastrophic dysplasia variant (DTDv), and recessively inherited multiple epiphyseal

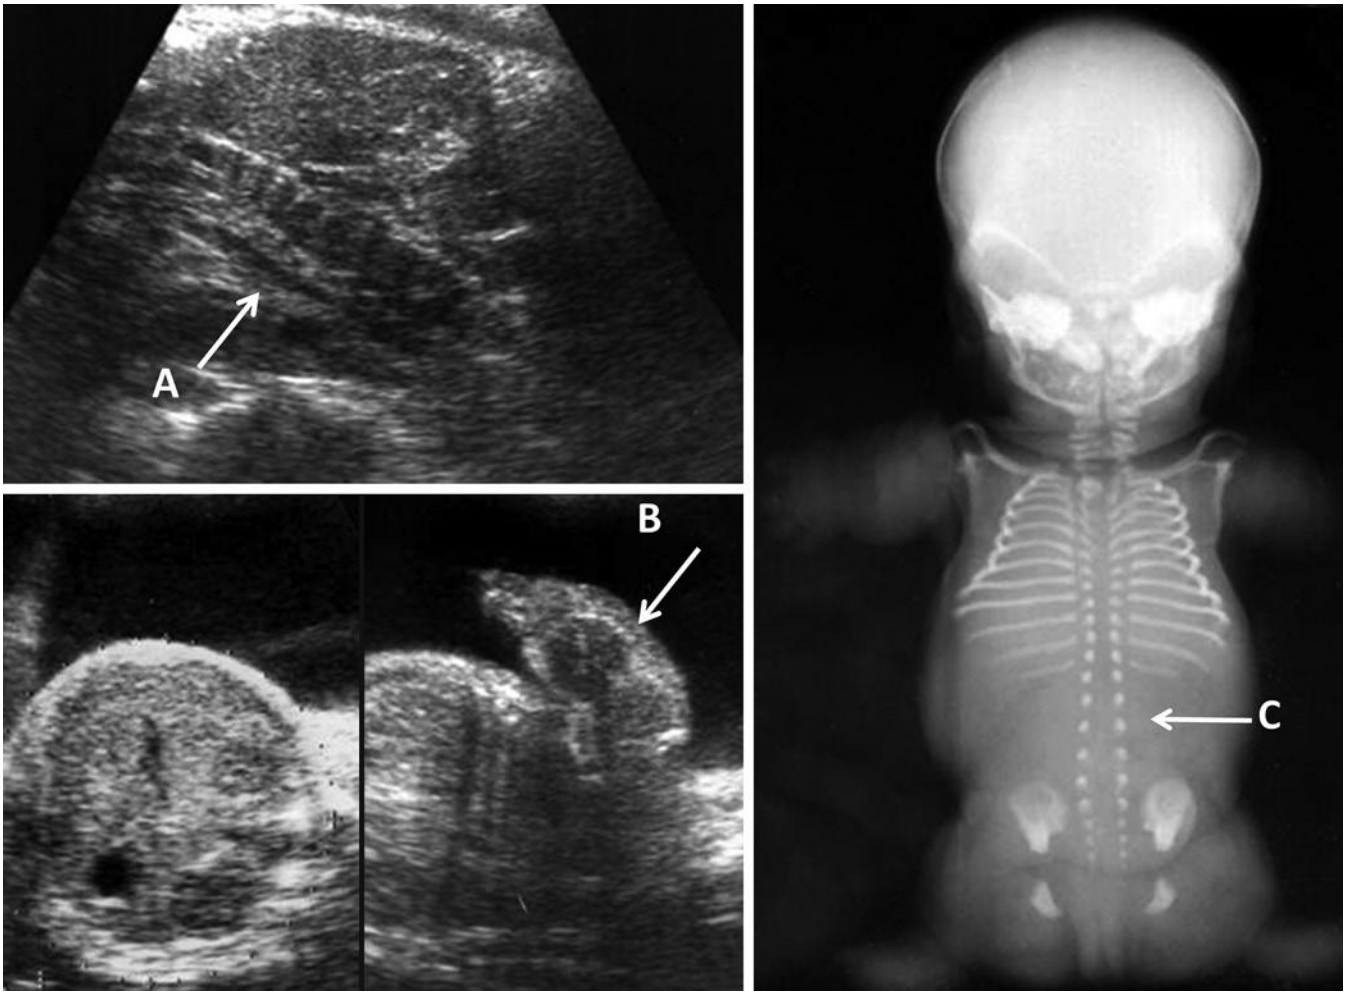

FIG 11-37 Frontal and lateral views of a fetus with achondrogenesis type II. Hypomineralization of the spine ischial bones and vertebral bodies (A). The long bones are extremely short with metaphyseal flaring and cupping (B). The thorax is bell-shaped, with short and straight ribs and no fractures (C). (Courtesy of Theera Tongsong, MD, and Suchaya Luewan, MD.)

TABLE 11-21 Radiologic Differences Between Achondrogenesis Type I (A-B), Type II, and Hypochondrogenesis

	Type IA (Houston-Harris)	Type IB (Fraccaro)	Type II (Langer-Saldino)	Hypochondrogenesis
Skull	Membranous calvarium	All parts of ossified skull well seen	Normal ossification	Normal ossification
Long bones	Extremely shortened with metaphyseal cupping and spurs Rectangular bones	Arms and legs shorter than with type IA with minimal ossification; abundant metaphyseal spiking or spurring on lower leg bones Square or stellate bones	Short and bowed with metaphyseal flaring and cupping Mushroom stem bones	Less bowed and shortened with irregular or smooth metaphyses
Thorax	Short and barrel-shaped Short ribs with cupped metaphyses and multiple fractures	Same as in type IA with unfractured ribs	Short and barrel- or bell-shaped with short unfractured ribs	Near normal but shallow cage with short unfractured ribs
Spine	Vertebral bodies unossified, with partly ossified pedicles	Vertebral bodies minimally or not ossified, pedicles ossified	Variable pattern of ossified or unossified vertebral bodies and pedicles	Thoracic and upper lumbar vertebral bodies ossified but still platyspondylic Cervical and lower lumbar bodies unossified
Pelvis	Poorly formed and ossified, with iliac bones and ischial bones poorly ossified, pubic bones unossified	Iliac bones same aspect as in type IA Ischial and pubic bones unossified	Halberd-like iliac bones with unossified ischial and pubic bones	Near normally developed iliac bones with partial ossification of ischial bones and unossified pubic bones

From Spranger J: Pattern recognition in bone dysplasias. In Papadatos CJ, Bartsocas CS (eds): Endocrine Genetics and Genetics of Growth. New York, Alan R. Liss, 1985, p 315.

dysplasia (rMED).[436,454,455,458] Achondrogenesis type II is caused by a heterozygous mutation in the collagen, type II, alpha 1 gene (*COL2A1*) located in chromosome 12q13.[459,460] Prenatal diagnosis by molecular analysis of the *COL2A1* gene is available.

Osteogenesis Imperfecta and Hypophosphatasia

Osteogenesis imperfecta (OI) and hypophosphatasia are discussed together because they are characterized by skeletal demineralization.

Osteogenesis Imperfecta

The term OI was introduced over a century ago to describe a newborn with extremely brittle bones (see Figs. 11-17, 11-19, and 11-20). At present, the term refers to a heterogeneous group of disorders caused (in most cases) by mutations in one or two structural genes for type I procollagen.[461-467] Extraskeletal malformations are variably associated with the disorder and include blue sclerae, dentinogenesis imperfecta, hyperlaxity of ligaments and skin, hearing impairment, and presence of wormian bones on skull radiographs.[467] Advanced paternal age is considered a risk factor for OI.[468] The prevalence of OI is 0.18 per 10,000 births.[39,40]

The most popular classification is that proposed by Sillence and colleagues.[469] Further modifications of this classification included four additional types (V, VI, VII, and VIII)[467,470] [Table 11-22]). Clinically, the most relevant characteristic of OI is bone fragility, with severity increasing in the following order: (1) type I (less severe); (2) types IV, V, VI, and VII; (3) type VIII; (4) type III, and (5) type II (more severe).[467]

In OI type I (autosomal dominant), there are no prenatal deformities. After birth, patients are affected by bone fragility, blue sclerae (all ages), and hearing loss. Other findings include osteoporosis, a normal calvarium, and no dentinogenesis imperfecta. Fractures may range from none to multiple, especially vertebral fractures that can lead to mild scoliosis.[467] Mutations resulting in OI type I cause premature termination codons that lead to decreased production of type I procollagen.[464]

OI type II is an autosomal dominant condition.[471] It is also known as the perinatal variety and is uniformly lethal. Other features include almost no ossification of the skull; beaded ribs; shortened, crumpled long bones; and multiple fractures in utero (see Fig. 11-19). The thorax is short, but not narrow. Type II is subclassified into three subtypes (IIA, IIB, and IIC) according to radiologic criteria: (1) subtype A has short, broad, crumpled long bones, angulation of tibiae, and continuously beaded ribs; (2) subtype B has short, broad, crumpled femora, angulation of tibiae, but normal ribs, or ribs with incomplete beading; and (3) subtype C has long, thin, inadequately modeled long bones with multiple fractures and thin beaded ribs.[472]

OI type III (autosomal recessive/rare) is a nonlethal variety characterized by blue sclerae and multiple fractures present at birth. The sclerae become white with time. The membranous skull is severely deossified, and the long bones are mildly shortened but with marked angulation. Type IIB and type III OI are difficult to distinguish and may represent different degrees of severity of the same disorder.[473]

In OI type IV (autosomal dominant), the long bones and sclerae are normal. There is mild to moderate osseous fragility, and 25% of the newborns have fractures. There is significant heterogeneity in disease expression, even within the same family.[474] From this heterogeneous group, Rauch and Glorieux[467] have identified three separate clinical entities based on distinct clinical and bone histologic features. These disorders have been classified as OI types V, VI, and VII.[467,474-476]

OI types V and VI have in common primary defects in endochondral bone ossification or mineralization. Type V is associated with a heterozygous mutation in IFITM5 (interferon-induced transmembrane protein 5).[477] It is characterized by moderate to severe bone fragility, calcification of the interosseous membrane at the forearm that severely limits movements of the hand, radial head dislocation, and predisposition for developing hyperplastic calluses during fracture healing. The color of the sclerae is variable, and no teeth anomalies are seen.[478] The characterization of OI type VI is based on bone histologic findings showing an increased amount of osteoid and an abnormal pattern of lamellation. Individuals with type VI have mutations of the gene *SERPINF1*.[479] Type VI has also been associated with a defect in the gene encoding for pigment epithelium-derived factor (PEDF).[475,480] These patients are usually asymptomatic during the first year of life; however, afterward, they develop deformed bones, fractures, vertebral compression, and reduced bone mineral density.

OI type VII is a recessive disorder with bone fragility, rhizomelia, and coxa vara. This type has been described in a community of Native Americans in northern Quebec.[467]

TABLE 11-22 Expanded Classification of Osteogenesis Imperfecta

Type	Clinical Severity	Typical Features	Typically Associated Mutations
I	Mild nondeforming	Normal height or mild short stature; blue sclera; no dentinogenesis imperfecta	Premature stop codon in *COLIAI*
II	Perinatal lethal	Multiple rib and long bone fractures at birth; pronounced deformities; broad long bones; low density of skull bones on radiographs; dark sclerae	Glycine substitutions in *COLIAI* or *COLIA2*
III	Severely deforming	Very short stature; triangular face; severe scoliosis; grayish sclerae; dentinogenesis imperfecta	Glycine substitutions in *COLIAI* or *COLIA2*
IV	Moderately deforming	Moderately short stature; mild to moderate scoliosis; grayish or white sclerae; dentinogenesis imperfecta	Glycine substitutions in *COLIAI* or *COLIA2*
V	Moderately deforming	Mild to moderate short stature; dislocation of radial head; mineralized interosseous membrane; hyperplastic callus; white sclerae; no dentinogenesis imperfecta	*IFITM5*
VI	Moderately to severely deforming	Moderately short stature; scoliosis; accumulation of osteoid in bone tissue, fish-scale pattern of bone lamellation; white sclerae; no dentinogenesis imperfecta	*IFITM5, SERPINF1*
VII	Moderately deforming	Mild short stature; short humeri and femora; coxa vara; white sclerae; no dentinogenesis imperfecta	*CRTAP*
VIII	Moderately to severely deforming	Growth deficiency and extreme undermineralization of the skeleton, white sclerae	*LEPRE1*

OI type VIII is similar to OI types II and III in appearance and symptoms, except for white sclerae, and is characterized by severe growth deficiency and extreme undermineralization of the skeleton. It is caused by absence or severe deficiency of prolyl 3-hydroxylase activity due to mutations in the *LEPRE1* gene.[481]

Types I to IV and VII are caused by a collagen defect. OI type I is caused by a premature stop codon in *COL1A1*.[463] Types II, III, and IV typically result from mutations that lead to substitutions for glycine within the triple helical domain of the pro-alpha chain, disrupting the normal folding of the molecule and initiating the production of abnormal collagen.[482,483] Approximately 90% of patients with a clinical diagnosis of OI have a mutation in either the *COL1A1* or *COL1A2* gene, resulting in an abnormal molecular constitution of procollagen type I.[467,483-485]

The natural history of OI in utero is variable. Prenatal diagnosis of OI type II has been reported numerous times,[108,486-507] in some cases as early as 12 weeks of gestation by either 2D or 3D sonography.[508-511] It is noteworthy, however, that fractures and limb shortening may not be observed until the second or even the third trimester.[512-514] A typical sonographic finding associated with OI type II is the improved visualization of intracranial structures. Prenatal diagnosis of OI types I, III, and IV has also been reported using ultrasound, biochemistry, or molecular techniques.[515-519] The differential diagnosis should include other skeletal disorders such as hypophosphatasia, achondrogenesis, and campomelic dysplasia.

Hypophosphatasia

This rare autosomal recessive disorder has an estimated incidence of 1 in 100,000 births.[520] It is characterized by demineralization of bones and low alkaline phosphatase (ALP) in serum and other tissues.[521,522] The severity of the disease is inversely related to serum levels of ALP activity.[523] ALP acts on pyrophosphate and other phosphate esters, leading to the accumulation of inorganic phosphates, altering the formation of bone crystals, and increasing bone fragility.[524]

Hypophosphatasia has been subdivided into six clinical types according to the age of onset: (1) perinatal (lethal); (2) infantile; (3) childhood; (4) adult; (5) odontohypophosphatasia; and (6) pseudohypophosphatasia.[525] The perinatal form is associated with stillbirth or early neonatal death due to intracranial hemorrhage or respiratory insufficiency secondary to poorly developed ribs and reduced thoracic volume.[526,527] The infantile variant may cause craniosynostosis and nephrocalcinosis from hypercalcemia and hypercalciuria during the first year of life and is often lethal. Premature loss of deciduous teeth and rickets are the cardinal clinical features of hypophosphatasia during childhood. In the adult form, recurrent metatarsal stress fractures and pseudofractures in long bones can be the hallmark. Odontohypophosphatasia refers to especially mildly affected individuals who have dental, but no skeletal, manifestations. The teeth are predisposed to cavities and may be lost prematurely. Pseudohypophosphatasia is an extremely rare variant characterized by typical clinical, radiologic, and biochemical findings of infantile hypophosphatasia with the exception that the total serum ALP concentrations are normal or increased.[525] The perinatal and infantile varieties have an autosomal recessive pattern of inheritance, and the childhood, adult, and odontohypophosphatasia forms can be transmitted as either an autosomal dominant or autosomal recessive trait.[528]

Fetuses with congenital hypophosphatasia have generalized demineralization of the skeleton with shortening and bowing of tubular bones with multiple fractures.[529] The generalized and marked demineralization of the cranial vault results in deformation of the skull after external compression. This sonographic sign is also present in OI type II and achondrogenesis type IA. Prenatal diagnosis of this condition has been reported using ultrasound as early as 18 weeks of gestation.[451,530-539] Other sonographic findings include short and beaded ribs, markedly reduced mineralization of the spine (mainly in the thoracic region), and a small chest.[529,540] Identification of bone spurs projecting perpendicular from the limbs can be considered pathognomonic for lethal hypophosphatasia.[540,541] Bone spurs have been identified using 3D sonography as early as 18 weeks of gestation.[541]

ALP can be measured from tissue obtained by CVS[521,542,543] or amniotic fluid culture. However, ALP measurement in amniotic fluid is not a reliable method to make the diagnosis of hypophosphatasia because most of the ALP in amniotic fluid is of intestinal origin.[544,545] Involved isoenzymes in hypophosphatasia are bone and liver ALPs, and these isoenzymes contribute only 16% of the total amniotic fluid enzymatic activity.[546] Therefore, although prenatal diagnosis by DNA analysis is possible,[547] it requires sequencing the entire gene, which increases the complexity of the process.

Hypophosphatasia has been shown to be caused by mutations in the ALP liver gene (*ALPL*), also called the tissue nonspecific alkaline phosphatase gene (*TNSALP*), located on chromosome 1p36.1-p34.[548-551] A large spectrum of mutations is observed in the Caucasian population.[549,552,553] All reported gene mutations are continuously updated,[554] and about 80% of all mutations are missense.[523] Missense mutations in the gene lead to variable residual enzymatic activity and the extremely high phenotypic heterogeneity observed in hypophosphatasia.[292,555]

Diastrophic Dysplasia

Diastrophic dysplasia is an autosomal recessive disease with low frequency in most populations, but highly prevalent in Finland, with a carrier frequency of 1% to 2% of a mutation in the dystrophy sulfate transporter (DTDST) gene or *SLC26A2*.[457,556] The condition is characterized by micromelia, clubfoot, hand deformities, multiple joint flexion contractures, and scoliosis.[557] The diagnosis may be difficult at birth because of phenotypic variability, and milder cases are often diagnosed at a later age.[558] The clinical features include rhizomelic-type micromelia, joint contractures, hand deformities with an abducted position of the thumbs (so-called "hitchhiker thumb" [Figs. 11-38 and 11-39]), spine disorders (e.g., scoliosis, kyphosis, spina bifida oculta, spinal stenosis, lumbar lordosis), and severe talipes equinovarus. The head is normal, but micrognathia and cleft palate may be seen.[559] Diastrophic dysplasia is a generalized disorder of cartilage leading to destruction of the cartilage matrix, formation of fibrous scar tissue and subsequent ossification. The latter process is responsible for the contractures. The mutations in the DTDST gene (*SLC26A2*), located on chromosome 5q32-q33.1,[560,561] are associated with reduced sulfate transport in chondrocytes, resulting in undersulfation of proteoglycans, leading to abnormal cartilage formation.[454,561-563] Five common *SLC26A2* mutations (R279W, IVS1 + 2T>C, delV340, R178X, and C653S) account for approximately 65% of disease alleles.[561] Sequence analysis of the coding region can detect mutations in greater than 90% of alleles in individuals with typical clinical, radiologic, and histologic features.[561]

The prenatal diagnosis of diastrophic dysplasia has been made in patients at risk based on severe shortening and bowing of all long bones.[67,70,558,564-567] Sepulveda and coworkers[568] suggested that 3D sonography can improve the visualization of limbs and face deformities. Prenatal diagnosis in at-risk pregnancies in which the familial mutations have been identified can be accomplished by DNA analysis of fetal cells obtained by CVS or amniocentesis.[569] Biochemical studies of fibroblasts and chondrocytes are available and may be useful for cases in which molecular genetic tests fail to identify *SLC26A2*

mutations. This disorder has a wide spectrum, and some cases may not be diagnosable in utero.

Diastrophic dysplasia is not universally lethal. Intelligence and sexual development are unaffected. However, joint contractures and painful osteoarthroses are associated with severe physical handicaps that require corrective orthopedic surgery.[457] An increased mortality rate in the neonatal period and infancy is due to upper airway obstruction secondary to tracheobronchomalacia and medullary compression caused by severe cervical kyphosis.[457,570]

The differential diagnoses include arthrogryposis multiplex congenita, atelosteogenesis type II, and pseudodiastrophic dysplasia. Pseudodiastrophic dysplasia has a similar presentation as diastrophic dysplasia[571] and is inherited in an autosomal recessive pattern.[40] Histologic examination is required for differential diagnosis, because the distinctive morphologic abnormalities of the growth plate noted in diastrophic dysplasia have not been observed in pseudodiastrophic dysplasia. Cetta and associates[572] demonstrated that a patient with pseudodiastrophic dysplasia had no defect in the DTDST gene and that both sulfate uptake by skin fibroblasts as well as sulfation of proteoglycans were normal.

Kniest-like Disorders

The term Kniest-like disorders is used in reference to a group of conditions that share histologic and radiologic characteristics with Kniest syndrome but differ in terms of clinical presentation and inheritance.

Kniest Syndrome

In 1952, Dr. Wilhelm Kniest[573] published the case of a 3.5-year-old girl with "skeletal changes showing a certain relationship to classical chondrodystrophy but differing in many of its manifestations." His publication clarified the phenotypic differences between this condition and other forms of chondrodystrophies. Kniest syndrome is one of the type II collagenopathies, which are disorders that not only impair fetal growth but are also characterized by ocular and otolaryngologic abnormalities.[574-577] The pattern of inheritance is autosomal dominant,[337] and these diseases are usually caused by de novo mutations in the *COL2A1* gene.[575,577,578] Other type II collagenopathies include spondyloepiphyseal dysplasia and Stickler dysplasia type I.[579]

Phenotypic features of Kniest syndrome include rhizomelic shortening of the long bones with widened metaphyses and prominent joints. Spinal involvement is common and characterized by platyspondyly and coronal clefts. The thorax is broad and short. Other manifestations, which may be detected during prenatal life, include micrognathia and cleft palate. However, Kniest syndrome may be difficult to recognize at midgestation because long bone biometry does not become remarkably abnormal until the third trimester of pregnancy.[580] Prenatal diagnosis has been reported using 3D helical computed tomography showing abnormal shape in the femora, platysplondyly, and clefts in the lumbar vertebral body,[580] and by MRI demonstrating enlarged hyaline cartilage structures, abnormal T2 signal intensity, delayed ossification of the pubic and ischiatic bones, and platysplondyly.[581] The prognosis varies widely, ranging from long-term survival with short stature, kyphoscoliosis, and craniofacial anomalies to lethality in the neonatal period secondary to tracheomalacia and respiratory insufficiency.[582] Other long-term disabilities include feeding difficulties, hearing impairment, and blindness.

Dyssegmental Dysplasia

Dyssegmental dysplasia is a disorder characterized by anarchic ossification of the vertebral bodies (anisospondyly), metaphyseal flaring, and severe bowing of the long bones.[583,584] Two distinct types have been recognized: the mild Rolland-Desbuquois, and the lethal Silverman-Handmaker.[583,585-587] Encephaloceles are frequently present in the Silverman-Handmaker type,[588] and prenatal diagnosis has been established in patients at risk.[585,589-591] The Silverman-Handmaker type is caused by a functional null mutation in the gene encoding perlecan (*HSPG2*).[592-594] The Rolland-Desbuquois type has milder radiographic features resembling Kniest dysplasia. Although long-term survival is possible, a substantial proportion of affected individuals die during the first year of life.[336,582] Decreased levels of matrix metalloproteinase-2 and the tissue inhibitor of metalloproteinase-1 have been reported in cases of the Rolland-Desbuquois type of dyssegmental dysplasia.[595] The inheritance of both conditions is autosomal recessive.[584] Other disorders associated with vertebral disorganization include Jarcho-Levin syndrome and mesomelic dysplasia.

Campomelic Dysplasia

First described by Maroteaux in 1971, campomelic dysplasia (CMD) is a rare lethal disorder.[596] The prevalence varies between 0.05 and 1.6/10,000.[596,597] The disorder is characterized by bowing of the long bones of the lower extremities, an enlarged and elongated skull with a peculiarly small face, hypoplastic scapulae, and several associated anomalies such as micrognathia, cleft palate, talipes equinovarus, congenital dislocation of the hip, macrocephaly, hydrocephalus, hydronephrosis, and congenital heart defects[596,597] (Fig. 11-40). The most important and significant features are bowing of the femur and tibia;

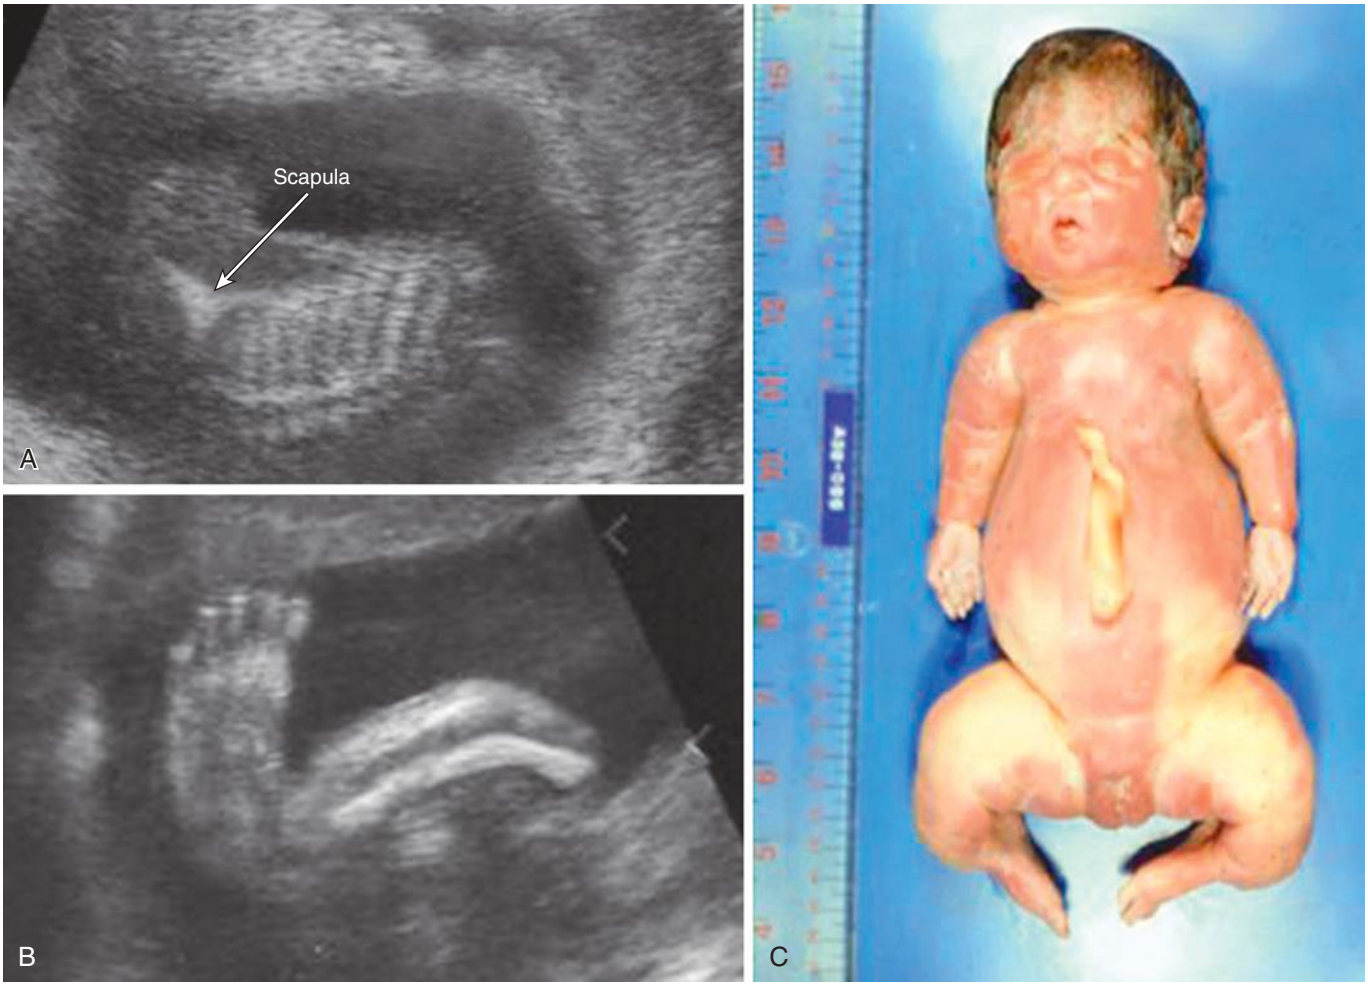

FIG 11-40 Fetus with campomelic dysplasia showing hypoplasia of the scapula (**A**) and bowing of the tibia and clubfoot with normal ossification (**B**). **C,** Postnatal appearance. (Courtesy of Theera Tongsong, MD, and Suchaya Luewan, MD.)

other tubular bones are normal in length (see Fig. 11-18A). The thorax is narrow, can be bell-shaped, and 11 pairs of ribs are usually present. Cervical vertebrae are hypoplastic and poorly ossified.[598] Campomelic dysplasia is considered a sporadic autosomal dominant condition.[596]

There are two short-bone varieties of campomelic dysplasia, representing distinct syndromes: (1) the normocephalic form, known as kyphomelic dysplasia, and (2) the craniostenotic type, which appears to be identical to Antley-Bixler syndrome. The antenatal diagnosis of campomelic dysplasia has been reported several times and the differential diagnosis includes OI, thanatophoric dysplasia, and hypophosphatasia.[100,141,241,599-602]

A unique aspect of campomelic dysplasia is that 75% of affected infants with a male karyotype present with sex reversal syndrome and have female or ambiguous genitalia.[353,596,603] The histologic features of the gonads vary, from gonads with testicular differentiation to dysgenetic gonads with primary follicles. Indeed, mutations in the *SOX9* gene, which is also a fundamental testis-differentiation gene common to all vertebrates,[604] have been reported in several patients with this disorder.[353,603,605-608] These mutations interfere with DNA binding by *SOX9* or truncate the carboxy-terminal transactivation domain, thereby impeding the ability of *SOX9* to activate target genes during organ development.[607] Molecular genetic testing of *SOX9* detects mutations or chromosome rearrangements in approximately 95% of affected individuals.[596] In approximately 5% of cases with campomelic dysplasia, routine karyotype analysis may identify de novo reciprocal translocations and a de novo interstitial deletion of 17q.[609-614] In rare cases, the translocation may be familial; thus, parental karyotypes should be analyzed when an abnormality is identified in the proband. Campomelic dysplasia is an autosomal dominant condition; however, most cases are de novo mutations in *SOX9*; thus, parents are not typically affected. Recurrence in siblings has occurred, and somatic and germline mosaicism have been also reported. Campomelic dysplasia is frequently lethal in infancy, although some cases of survivors have been reported.[599,615-619] The cause of death is respiratory insufficiency due to tracheomalacia.

Skeletal Dysplasias Characterized by a Hypoplastic Thorax

A dysplastic process involving the ribs and other bones of the thorax occurs in many skeletal dysplasias. A reduction in thoracic dimensions leads to restriction of lung growth and, consequently, pulmonary hypoplasia, which is the main cause of death in lethal skeletal dysplasias. Dysplasias in which thoracic hypoplasia is a cardinal feature include: asphyxiating thoracic dysplasia, Ellis–van Creveld syndrome, SRPS, and campomelic dysplasia. Table 11-23 illustrates criteria for the differential diagnoses of some of these conditions. Other disorders presenting with altered thoracic dimensions include thanatophoric dysplasia, atelosteogenesis, fibrochondrogenesis, achondrogenesis, and Jarcho-Levin syndrome (Fig. 11-41).[620]

Asphyxiating Thoracic Dysplasia (Jeune Syndrome)

Jeune syndrome is a rare autosomal recessive condition, with an estimated prevalence of 0.14/10,000 births.[621-624] Asphyxiating thoracic dysplasia is characterized by a combination of a small thorax, varying degrees of brachymelia, polydactyly, pelvic abnormalities, and renal involvement.[625,626] Phenotypic expression is wide and includes lethal,[627] mild,[624,628] and latent[622] forms. In severe cases, thoracic narrowing is responsible for pulmonary hypoplasia, respiratory failure, and death in early infancy.[629] In the milder forms, the presence and degree of renal

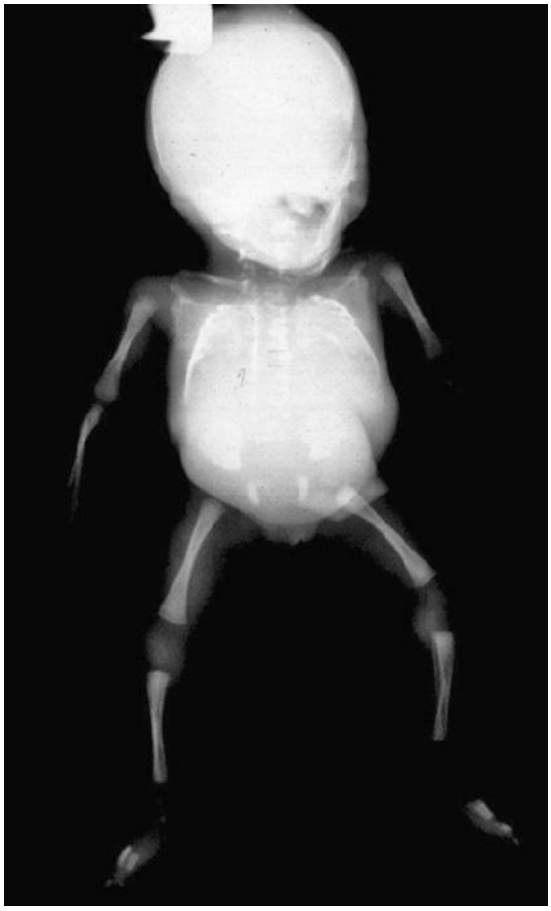

FIG 11-41 Jarcho-Levin syndrome. There is dramatic spinal shortening with disorganization of the vertebral bodies, a characteristic chest deformity (crab-like appearance with posterior fusion and anterior flaring of the ribs), and unaffected long bones.

involvement[630-641] constitute the main prognostic factor.[628,632,642] Individuals surviving childhood are likely to have a clinical course complicated by respiratory insufficiency, recurrent pulmonary infections,[641] hepatic involvement,[630,638,642-649] and pancreatic involvement.[650,651] Ocular/retinal manifestations have been sporadically described in association with Jeune syndrome.[638,652-654]

Skeletal Findings. The thorax is described as narrow and bell-shaped, and the ribs are short, broad, and horizontally oriented.[640,655] Brachymelia (if present) is predominantly of the rhizomelic type.[654,656,657] Long bones may be bowed[655,657] and have visible proximal ossification centers at birth in two thirds of cases.[657] Postaxial polydactyly can be present, with both the upper and lower limbs variably affected.[642,655,656,658,659] Pelvic findings include small-squared iliac wings, a trident pelvis (shortened ilia with a downward hook of the greater sciatic notches), and horizontal acetabular roofs with spur-shaped projections.[656,658] A handlebar-like conformation of clavicles has been reported.[657] Cleft lip and palate can also occur.

Renal Findings. The degree of renal involvement is the main prognostic factor for individuals surviving the neonatal period.[628,634,638,640,642] Renal failure can occur during childhood[632,635,638,640] and may require renal transplantation.[637,639,641] Cystic or scleroatrophic changes, partly indistinguishable from those associated with juvenile nephronophthisis, are the two characteristic histologic patterns of renal involvement.[634,640,660] Cystinuria has also been described in patients with Jeune syndrome.[636,661]

Hepatic Findings. Liver involvement ranges from subclinical to biliary cirrhosis and progressive portal hypertension,[647,649,662] requiring transplantation during childhood.[649] Intralobular bile ducts loss, portal tract periphery bile duct proliferation, and fibrosis are the most frequent histologic findings.[630,638,649] Because liver involvement at early stages can be subclinical and manifest as early as in the neonatal period,[644,646] early diagnostic workup and close follow-up of hepatic function has been proposed.[647]

Other Findings. Ophthalmologic evaluation of long-term survivors has revealed a wide spectrum of retinal anomalies such as pigmentation, dystrophy, degeneration, and aplasia.[652,653,663] Visual loss and night blindness have been sporadically reported as the initial manifestation of mild forms of Jeune syndrome.[652] Other associated anomalies include Dandy-Walker malformation,[646,664] agenesis of the corpus callosum,[665] situs inversus,[666] neuroectodermal tumor in the soft tissue of the chest wall,[637] Hirschsprung disease,[667] and asplenia.[666]

Prenatal Diagnosis. The prenatal sonographic diagnosis of Jeune syndrome has been reported in the literature.[625,642,655-657,659,668-674] A positive family history contributes to second trimester recognition of recurrent forms,[359,656,657,669] while diagnosis in low-risk pregnancies is more challenging and has been reported in the third trimester of pregnancy.[625]

Although the locus for asphyxiating thoracic dystrophy maps to chromosome 15q13, mutation analysis of two candidate genes (*GREMLIN* and *FORMIN*) did not reveal pathogenic mutations.[675] In 2013 Baujau and colleagues[676] studied 39 families in which one of the members presented with asphyxiating thoracic dysplasia and reported in 23 families (59% of cases) with mutations in the *DYNC2H1* gene (dynein cytoplasmic 2 heavy chain 1). The authors concluded that *DYNC2H1* is a major gene responsible for asphyxiating thoracic dysplasia.

Surgical Management for Respiratory Insufficiency. Lateral thoracic expansion, a surgical procedure that attempts to enlarge the thoracic cage by separating ribs from their periosteum and plating them together with titanium struts, has been performed in a handful of patients with asphyxiating thoracic dysplasia, resulting in improvement in respiratory function or eliminating the need for external ventilators.

Short Rib–Polydactyly Syndromes

SRPSs are a heterogeneous group of disorders inherited as autosomal recessive conditions.[677] Traditionally, four major types of short rib–polydactyly syndromes have been described: type I (Saldino-Noonan),[678] type II (Majewski),[679,680] type III (Verma-Naumoff),[681] and type IV (Beemer-Langer).[682] These conditions are classified within the family *short rib dysplasia with or without polydactyly*, which also includes asphyxiating thoracic dysplasia (Jeune syndrome) and chondroectodermal dysplasia (Ellis–van Creveld dysplasia). Because SRPSs I to IV are lethal in the newborn period (due to severe pulmonary hypoplasia and associated anomalies) and, conversely, Ellis–van Creveld and Jeune syndromes are not uniformly lethal, accurate prenatal diagnosis is important in order to provide adequate counseling.

SRPSs I to IV are characterized by short limbs/micromelic dwarfism, constricted thorax, usually polydactyly, and multiple anomalies of major organs (Fig. 11-42).[683,684] Scarano and coworkers[685] indicated that the absence of polydactyly does not exclude the diagnosis of this condition. In fact, although polydactyly is a constant feature in SRPS type II (Majewski) and is commonly found in types I and III (Saldino-Noonan and Verma-Naumoff),[686] patients with SRPS type IV (Beemer) seldom have polydactyly. Type IV is also characterized by ambiguous genitalia, anophthalmia, cleft lip and palate, pulmonary hypoplasia, renal dysplasia, and occasionally hydrops.[687]

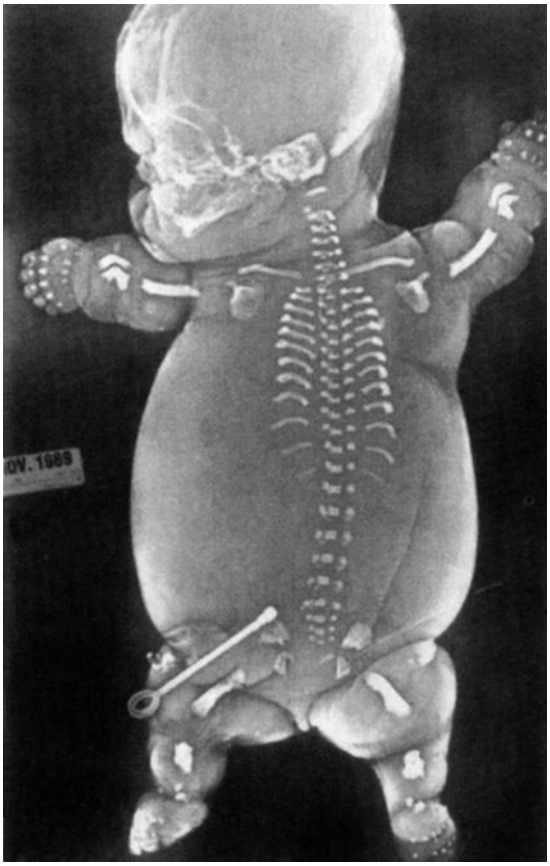

FIG 11-42 Short rib–polydactyly syndrome. There is severe shortening of all long bones, very short and horizontal ribs, and postaxial polydactyly in all four extremities. Note the angulation of the bones in the forearm.

Differential Diagnosis. SRPSs have been identified prenatally by 2D and 3D sonography.[688-690] Table 11-23 illustrates the differential diagnosis and features of the disorders characterized by polydactyly and a narrow thorax. The differential diagnosis is often challenging, especially before birth, because a high degree of overlap exists in clinical and radiologic features. Indeed, there is debate as to whether the various forms of SRPSs are related to different genes, to different mutations on the same gene, or to variability of expression of the same mutant gene.[633,691] Chen and associates[692,693] reported a mutation in the *NEK1* gene, which encodes NIMA (never in mitosis gene A-related kinase 1), in fetuses with type II and type III SRPS.

Molecular Diagnosis. Mutations have been identified in several intraflagellar transport (IFT) genes responsible for SRPS III, including *DYNC2H1, IFT80, WDR34, WDR35*, and *WDR60*.[694-697] IFT proteins are involved in chondrocyte maturation through bone morphogenetic protein signaling. Recently, Mei and colleagues[698] reported the identification of novel compound heterozygous mutations of *DYNC2H1* in a fetus with SRPS III, using targeted next-generation sequencing.

Chondroectodermal Dysplasia (Ellis–van Creveld Syndrome)

Ellis–van Creveld syndrome is a rare autosomal recessive condition with an estimated birth prevalence of 1/60,000 in the general population and 5/1000 among the Amish community.[699] Ellis–van Creveld syndrome is defined by the tetrad of chondrodysplasia, ectodermal dysplasia, polydactyly, and congenital heart disease.[700] The combination and severity of each of these features are extremely variable, and, as a consequence, the clinical course and prognosis range from death in the neonatal period due to cardiopulmonary complications to long-term survival.[701,702]

Skeletal Findings. In Ellis–van Creveld syndrome, the long bones most commonly present as mesomelic[703] or acromesomelic shortening.[700] The presence and severity of rib cage dysplasia are important factors in determining prognosis. A narrow thorax with short and horizontal ribs is frequently associated with pulmonary hypoplasia, early respiratory failure, and recurrent pulmonary infections.[702,704]

Postaxial polydactyly (Fig. 11-43) can involve the hands and feet in several combinations: only hands bilaterally,[705] both hands and both feet,[706] or both hands and one foot.[707] Clinodactly[701] and syndactly[708] have also been reported. Bowing of the long bones, genu valgum, and pelvic radiologic anomalies (including broad, squared, and vertically short ilia; trident configuration of the acetabula; spur-like projections at the acetabular roof) are additional phenotypic features.[700,703] The vertebrae and skull have a normal appearance.[673]

Cardiac Defects. Congenital heart disease occurs in up to 60% of affected individuals, and its presence and severity are strongly correlated to mortality rate.[703,709] The most common cardiac anomalies are those characterized by defects of endocardial cushion closure, such as atrial septal defects, ventricular septal defects, atrioventricular canal, and single atrium[710-712]; however, complex cardiac malformations have also been reported.[713]

Ectodermal Dysplasia. Clinical manifestations of ectodermal dysplasia are present in 70% of cases.[714] The most frequent are dystrophic changes of the fingernails, thin and sparse hair, and oral and dental abnormalities.[715] A short upper lip, multiple and hyperplastic frenula, and fusion of the upper lip to the gingival margin are common.[716] Dental anomalies include dysmorphic cone-shaped and microdontic teeth, taurodontism, delay in eruption or anodontia,[717] and natal and neonatal teeth.[716] Sporadic cases of micrognathia and mandibular malocclusion have also been reported.[718] This variety of oral manifestations requires multidisciplinary dental treatment, with special attention to the high incidence of cardiac defects in these patients.[716]

Other Manifestations. Central nervous system anomalies can occasionally occur in association with Ellis–van Creveld syndrome, including ventriculomegaly[719] and Dandy-Walker anomaly.[720] The kidneys are rarely involved, although there are sporadic reports of renal agenesis, congenital megaureter,[721] renal medullary dysplasia,[722] and nephronophthisis.[723] An association between Ellis–van Creveld syndrome and bile duct dysplasia requiring liver transplantation has been reported.[722] Thymic hypoplasia,[724] Hodgkin disease, nodular sclerosing at young age,[725] and retinal dystrophy[726] are other less common associations. Prenatal diagnosis by ultrasound has been reported during the second[727,728] and third trimesters,[729] as well as in the first trimester.[730]

Differential Diagnosis. Differentiating between Ellis–van Creveld and Jeune syndrome can be challenging because there is a great degree of overlap in the phenotypic features of these two conditions. McKusick-Kaufman syndrome shares with Ellis–van Creveld postaxial polydactyly and heart defects,[731] but differentiating characteristics include absence of chondrodysplasia and ectodermodysplasia as well as hydrometrocolpos.[732] Weyers acrofacial dysostosis, an autosomal dominant condition, shares with Ellis–van Creveld syndrome the mild short stature and postaxial polydactyly, as well as dental and nail dystrophy, but thoracic dysplasia and congenital heart disease are not typical features in Weyers acrofacial dysostosis. Linkage and haplotype analysis have raised the possibility that Weyers acrofacial dysostosis is the heterozygous expression of a mutation that, in the homozygous form, causes Ellis–van Creveld syndrome.[733]

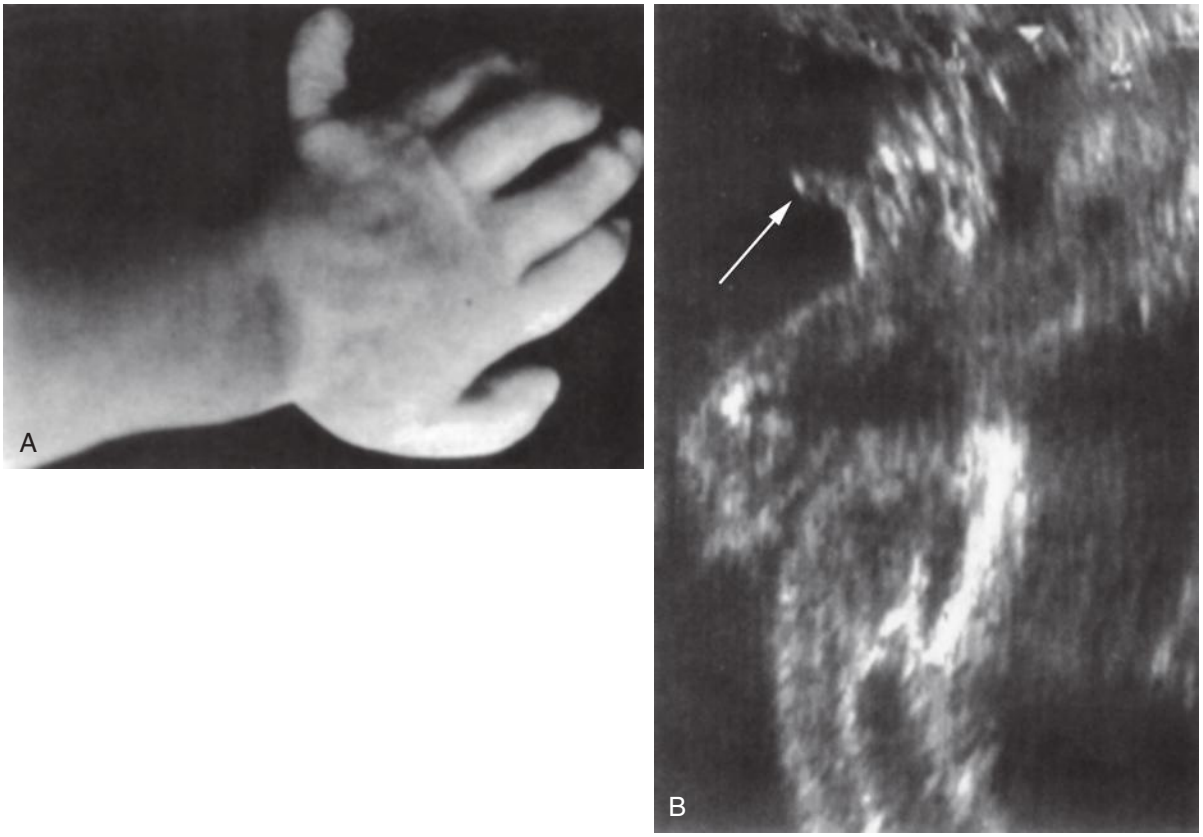

FIG 11-43 **A,** Postaxial polydactyly in a fetus with Ellis–van Creveld syndrome. **B,** Sonographic image of the hand shown in A. Note the abnormal angulation of the extra digit on the ulnar side of the forearm (*arrow*).

Genetics and Molecular Diagnosis. Mutations on the two nonhomologous genes *EVC1* and *EVC2* located in the short arm of chromosome 4 (4p16) have been related to Ellis–van Creveld syndrome[734,735]; however, not all affected subjects present with these mutations.[736] Typing of microsatellite markers flanking the *EVC* locus has been reported for the first trimester diagnosis of Ellis–van Creveld syndrome in a family with a previously affected child.[737] There is debate about the possibility of partial manifestations in heterozygous carriers.[738]

Skeletal Dysplasias With Predominant Membranous Bone Involvement

This group of skeletal dysplasias is characterized by disruption in the process of intramembranous bone ossification. They include cleidocranial dysplasia, Yunis-Varon syndrome, and isolated parietal foramina. Among these disorders, cleidocranial dysplasia is the one more often diagnosed prenatally.

Cleidocranial Dysplasia

Cleidocranial dysplasia is an autosomal dominant condition characterized by clavicular aplasia or hypoplasia, brachycephaly, midface hypoplasia, patent or delayed closure of fontanelles (Fig. 11-44), delayed eruption of permanent teeth, and relatively short stature with an estimated incidence of 0.5/100,000 live births.[739] Cleidocranial dysplasia is caused by mutations in the human osteoblast-specific transcription factor gene (*RUNX2*) located in chromosome 6p21.[740,741] The *RUNX2* gene is essential for osteoblast differentiation and affects membranous and endochondral bone formation. *RUNX2* induces and regulates the expression of genes involved in bone matrix formation and remodeling by modification of chromatin or interaction with co-regulatory proteins.[742,743]

The sonographic prenatal diagnosis of cleidocranial dysplasia has been reported as early as 13 weeks of gestation.[744,745] The most common finding is unilateral and bilateral hypoplastic and hypomineralized clavicles, although pseudoarthrosis (fracture) of the clavicle (Fig. 11-45) has also been reported.[140] Other features include hypomineralization/poor ossification of the spine, cranial bones, and pelvis; large fontanelles with wide sutures; obvious corpus callosum; brachycephaly; frontoparieto-occipital bossing; low nasal bridge; and long bones below the 5th percentile[744,746,747] Molecular prenatal diagnosis for *RUNX2* mutations can be accomplished by CVS or amniocentesis, or through analysis of fetal tissue.[748]

The differential diagnosis includes disorders characterized by poor mineralization of the calvarium (such as hypophosphatasia) as well as disorders that have fracture/pseudoarthrosis of the clavicle (e.g., congenital pseudoarthrosis of the clavicle and Yunis-Varon syndrome). Congenital pseudoarthrosis defines a spontaneous fracture that progresses to nonunion, and it is associated with abnormal movement at the site. The mechanisms proposed for this clavicular defect include an abnormal elevation of the first rib and right subclavian artery, or a failure of fusion of the two ossification centers (congenital pseudoarthrosis).[749]

Yunis-Varon Syndrome

This severe autosomal recessive disorder is characterized by skeletal defects and severe neurologic involvement. It shares characteristics with cleidocranial dysplasia but additionally includes micrognathia, bilateral absence of the thumbs and of the distal phalanges of the fingers, as well as hypoplasia of the great toes.[750] The skeletal defects include wide fontanelles with calvarial dysostosis, and aplasia or hypoplasia of the clavicles. Pelvic bone dysplasia, absent sternal ossification

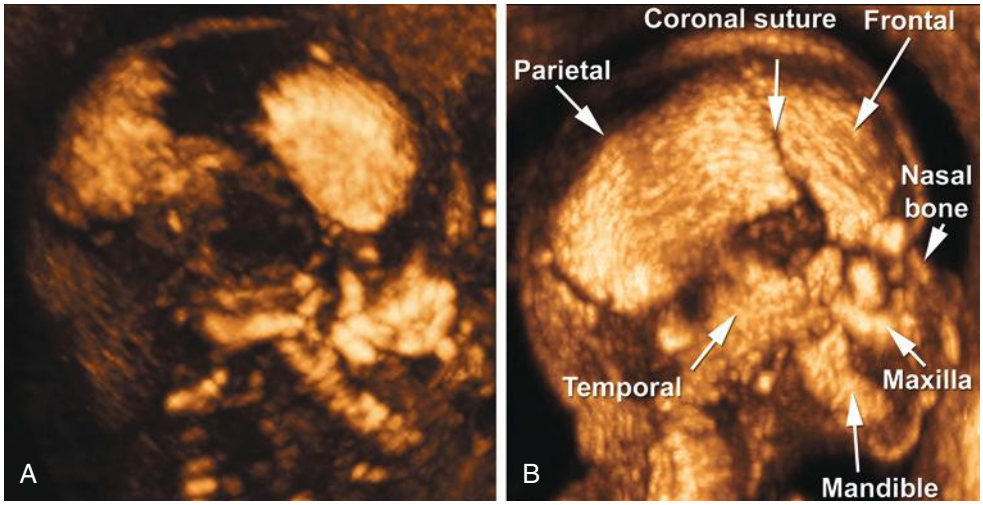

FIG 11-44 A, Three-dimensional ultrasound image of the fetal skull at 18⅔ weeks of gestation using the maximum intensity projection mode demonstrates widening of the coronal suture, absence of the squamous portion of the temporal bone, and absence of the nasal bones in a fetus with cleidocranial dysplasia. **B,** Labeled three-dimensional ultrasound image of a normal fetal skull at 18⅔ weeks (control). (From Soto E, Richani K, Goncalves LF, et al: Three-dimensional ultrasound in the prenatal diagnosis of cleidocranial dysplasia associated with B-cell immunodeficiency. Ultrasound Obstet Gynecol 27:574, 2006.)

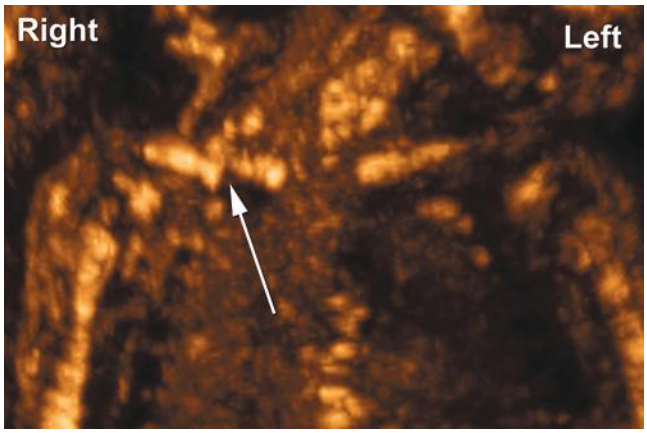

FIG 11-45 Three-dimensional ultrasound-rendered image of the fetal shoulders using the maximum intensity projection mode in a fetus with cleidocranial dysplasia. The arrow points to a site of pseudoarthrosis (fracture) of the clavicle (From Soto E, Richani K, Goncalves LF, et al: Three-dimensional ultrasound in the prenatal diagnosis of cleidocranial dysplasia associated with B-cell immunodeficiency. Ultrasound Obstet Gynecol 27:574, 2006.)

centers, and bony fractures are also frequent. Neurologic findings include diffuse atrophy of the cerebellar vermis, corpus callosum, basal ganglia, and frontal lobes.[751] Prenatal ultrasound imaging can demonstrate limb abnormalities, polyhydramnios, and hydrops fetalis.[752] Recently, mutations of the *FIG4* gene on chromosome 6q21 (also known as *SAC3*), a 5′-phosphoinositide phosphatase which is essential for endosome/lysosome function, have been identified as a cause of Yunis-Varon syndrome.[753,754]

Limb Deficiency or Congenital Amputations

Occasionally, the only identifiable anomaly is the absence of an extremity (limb deficiency) or a segment of an extremity (congenital amputation) (Table 11-24). These disorders differ from osteochondrodysplasias,

TABLE 11-24 Congenital Amputations

- Absent limbs only
  - Single absent limb
  - Multiple absent limbs
- Absent limbs with rings
  - Congenital ring constriction syndrome
- Absent limbs and face anomaly
  - Aglossia-adactylia syndromes
  - Moebius syndrome
- Absent limbs with other anomalies
  - Ichthyosiform skin (CHILD syndrome)
  - Fibula agenesis-complex brachydactyly (Du Pan syndrome)
  - Splenogonadal fusion
  - Skull and scalp defects (Adams-Oliver syndrome)
- Phocomelia
  - Thalidomide syndrome
  - Thrombocytopenia with absent radius (TAR) syndrome
  - Roberts pseudothalidomide-SC syndrome
  - Grebe syndrome
- Proximal femoral focal deficiency
  - Femoral hypoplasia–unusual facies syndrome
  - Femur-fibula-ulna complex
  - Femur-tibia-radius complex
- Split hand/split foot (SH/SF) syndromes
  - Only SH/SF
  - SH/SF and absent long bones
  - Ectrodactyly, ectodermal dysplasia, cleft lip and palate syndrome
- Others
  - SF and triphalangeal thumb, autosomal dominant
  - SF, or SH and central polydactyly (see central polydactyly)
  - SH/SF and congenital nystagmus (Karsch-Neugebauer syndrome)
  - SH/SF and renal malformations (Acrorenal syndrome)
  - SF and mandibulofacial dysostosis (Fontaine syndrome), autosomal dominant

From Goldberg MD: The Dysmorphic Child: An Orthopedic Perspective. New York, Raven Press, 1987, reproduced with permission.

and the terms used to refer to limb reduction abnormalities include the following[755]:

- Amelia: absence of a limb or limbs
- Hemimelia: absence of a longitudinal segment of a limb (e.g., radial aplasia, radial hypoplasia)
- Phocomelia: hypoplasia of the limbs, with hands and feet attached to the shoulder and hips
- Acheira: absence of the hands
- Apodia: absence of a foot or feet
- Acheiropodia: absence of hands and feet

The overall incidence of congenital limb reduction deformities ranges from 0.49 to 3.5 per 10,000 births.[756] It has been estimated that approximately 50% of these limb reduction defects are simple transverse reduction deficiencies of one forearm or hand without associated anomalies.[757] The remainder consist of multiple reduction deficiencies, with an approximate 23% incidence of additional anomalies of the internal organs or craniofacial structures.[758]

Limb deficiencies can present alone or as part of a specific syndrome. An isolated limb deficiency of the upper extremity (e.g., distal segment of an arm) is generally an isolated anomaly. The hand often deviates in the direction of the absent bone (Fig. 11-46). In contrast, congenital amputation of the leg generally occurs within the context of a syndrome, as do bilateral amputations or reduction of all limbs.[759]

Isolated amputation of an extremity can be due to amniotic band syndrome, to a vascular accident, or to exposure to a teratogen. In most cases, the anomaly is sporadic, and the risk of recurrence is negligible. Sonographic findings related to these conditions have been reviewed in depth by Bromley and Benacerraf.[760]

In a large European study including 709,030 births from 20 malformation registries in 12 European countries, the overall prenatal detection rate for limb reduction defects was 35.6% (89/250), with a higher detection rate observed among cases with associated malformations (49.1% [55/112]).[756] The frequency of chromosomal anomalies in the presence of associated malformations was 14.3% (16/112), with eight cases of trisomy 18, two cases of trisomy 21, and one case each of triple X, Klinefelter syndrome, deletion 7q, isochromosome 12p, deletion 3q, and an unbalanced translocation: t(5;14)(p13;q13). Among fetuses with a normal karyotype and associated anomalies, 33.9% (38/112) have been related with the following syndromes: Poland, Hanhart B, Brachmann–De Lange, thrombocytopenia–radial aplasia (TAR), ulnar mammary, Holt-Oram, Roberts, femur-fibula-ulna, Aarskog, Adams-Oliver, Otofaciodigital type 2, Robinow, and Carey-Fineman-Ziter; and with the following sequences or associations: amniotic bands, VATER/VACTER (*v*ertebral, *a*nal atresia, *c*ardiac defects, *t*racheo*e*sophageal fistula, *r*enal anomalies) limb body wall complex, caudal regression, Fanconi anemia, and twin-reversed arterial perfusion sequence.

The following section reviews syndromes in which a limb amputation or deficiency is associated with other anomalies. We follow the classification proposed by Goldberg (see Table 11-24).[758]

Syndromes With Absent Limbs and Facial Anomalies

Aglossia-Adactylia Syndrome

This syndrome consists of transverse amputations of the limbs and malformations of the mouth, including micrognathia, vestigial tongue (hypoglossia), dental abnormalities, and ankylosis of the tongue to the hard palate, the floor of the mouth, or the lips (glossopalatine ankylosis). The spectrum of limb anomalies is variable, ranging from absent digits to severe deficiencies of all four extremities. Intelligence is generally normal; however, associations between aglossia-adactylia syndrome and mental retardation have been reported.[761] As the defects are usually asymmetric and distal, this condition has been attributed to a vascular accident or to an interruption of the blood supply to different regions of the embryo.[762] It includes the Moebius sequence, Hanhart syndrome, glossopalatine ankylosis syndrome, and limb deficiency–splenogonadal fusion syndrome.[763-765] There is confusion in the classification of these patients because of the associated anomalies and the frequency of overlapping features. Although some authors have considered Hanhart syndrome and glossopalatine ankylosis syndrome as distinct entities, the differential diagnosis is extremely difficult.

Moebius Sequence

This condition consists of a number of facial anomalies attributed to paralysis of the sixth and seventh cranial nerves.[766] Limited jaw mobility and micrognathia are present, and ptosis is a common feature.[767] The Moebius sequence is generally sporadic, but autosomal dominant, autosomal recessive, and X-linked recessive forms have been described.[768] An association between prenatal exposure to misoprostol and Moebius sequence has been reported by several authors.[769-771] The associated limb reduction anomalies (25% of cases) are generally

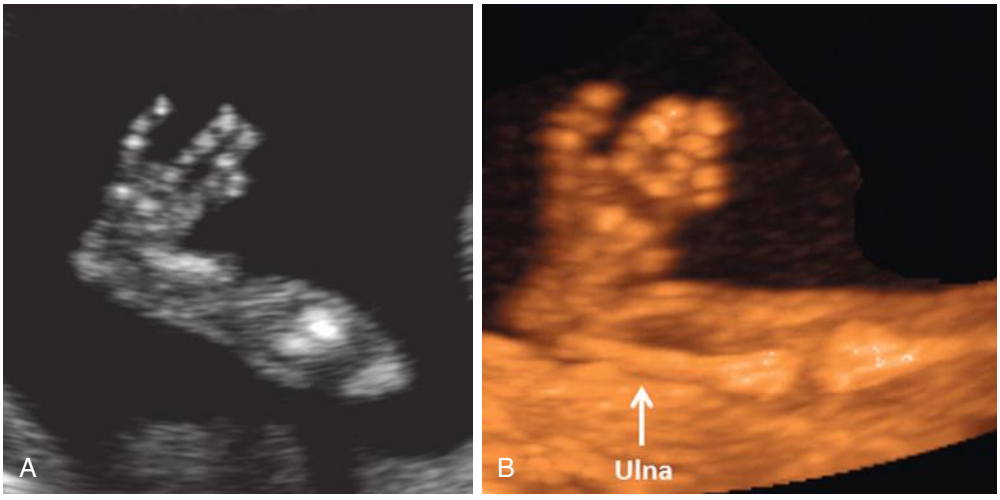

FIG 11-46 Sonogram of a fetus with radial aplasia using two-dimensional ultrasound (**A**) and three-dimensional maximum intensity projection mode (**B**). The hand deviates toward the side of the absent bone (radius).

present in the upper extremities and range from transverse deficiencies to absent digits. The Moebius, Poland, and Klippel-Feil syndromes have been considered as subclavian artery supply disruption sequences, and it is hypothesized that interruption of the early embryonic blood supply to the subclavian and vertebral arteries and their branches may lead to these conditions.[772,773]

Limb Reduction Defects Associated With Other Anomalies

Congenital Hemidysplasia With Ichthyosiform Erythroderma and Limb Defects Syndrome

Congenital hemidysplasia with ichthyosiform erythroderma and limb defects (CHILD) syndrome is characterized by strict demarcation of the lesions to one side of the midline.[774,775] The presence of unilateral defects of long bones is an important feature of the syndrome.[776] Limb deficiencies vary from hypoplasia of phalanges or metacarpals to complete absence of an extremity. The calvarium, scapulae, or ribs may also be involved. Zellweger syndrome, chondrodysplasia punctata, and warfarin embryopathy may present with similar findings. Visceral anomalies include congenital heart disease, unilateral hydronephrosis, hydroureter, and unilateral absence of the kidney, fallopian tube, ovaries, adrenal gland, and thyroid.[776,777] CHILD syndrome predominantly affects females (by a ratio of 19:1)[774,778] and is caused by mutations in the *NSDHL* gene (NAD[P]H steroid dehydrogenase-like protein), located at Xq28 and encoding a beta-hydroxysteroid dehydrogenase involved in the cholesterol biosynthetic pathway.[778-781] The detection of 4-carboxylsterols in affected skin flakes may be a marker for diagnosis.[782-784] Genetic testing from CVS is available. Raychaudhury and coworkers[785] reported an unusual phenotype of CHILD syndrome, most likely resulting from a novel X-chromosomal microdeletion encompassing the promoter region and exon 1 of the nicotinamide adenine dinucleotide phosphate steroid dehydrogenase-like protein gene, the neighboring gene *CETN2*, and more than 10 kb of noncoding DNA.[785] The prognosis is highly variable and mainly based upon skeletal or cardiac anomalies. Cases of minimal involvement can carry a risk of severe disease in the offspring.

Fibula Aplasia Complex Brachydactyly (Du Pan Syndrome)

Du Pan syndrome is an extremely rare condition characterized by bilateral agenesis of the fibula with abnormalities of the metacarpals and proximal phalanges. Limb reduction defects can involve the lower extremities.[786,787] An autosomal recessive pattern of inheritance has been suggested.[786] Faiyaz-Ul-Haque and associates[788] have examined genomic DNA from a family with Du Pan syndrome for mutations in the *CDMP1* gene. Affected individuals were homozygous for a missense mutation, T1322C, in the coding region of the *CDMP1* gene. Homozygous *CDMP1* mutations also cause Hunter-Thompson and Grebe syndromes.[789] Douzgou and colleagues[790] identified compound heterozygosity for two mutations (P436T and R378Q) in the growth differentiation factor 5 (*GDF5*) gene in mild forms of Du Pan type chondrodysplasia.

Splenogonadal Fusion Syndrome

Splenogonadal fusion (SGF) syndrome is characterized by limb reduction defects and splenogonadal fusion.[791] When associated with terminal limb defects, it is called splenogonadal fusion limb defect syndrome (SGLDS).[792] Mandibular hypoplasia, micrognathia, spina bifida, cleft palate, and complex cardiac malformations have been reported in cases of SGLDS. Most reported cases of SGF have occurred in boys.[793] Typically, there is a mass in the scrotum and an ectopic spleen can be identified during surgery. There is a variant in which the normally located spleen is connected to the gonad by bands or cords of splenic tissue.[794] A review of 14 reported cases indicates that there is some overlap between this syndrome and the aglossia-adactylia syndrome or Hanhart syndrome.[795]

Adams-Oliver Syndrome

This group of disorders is characterized by the association of limb reduction defects and scalp anomalies (aplasia cutis and deficiency of bony calvarium).[796-798] Other organ systems may be involved, and there are reports of associated cardiovascular, brain, pulmonary, hepatic, and renal anomalies.[799-801] Congenital heart defects include ventricular septal defects, anomalies of the great arteries and their valves, and tetralogy of Fallot.[802]

Becker and coworkers[803] reported the sonographic prenatal diagnosis of two cases of Adams-Oliver syndrome in the same family, the first at 13 weeks, and the second at 23 weeks of gestation. Both cases showed limb reduction defects, and in the second case, the scalp defect was diagnosed as an echo-free space between the scalp and bone. Papadopolou and associates[804] reported bilateral dilatation of lateral ventricles and periventricular cysts at 26 weeks of gestation by MRI in a fetus that was diagnosed after birth with Adams-Oliver syndrome. At 14 months of age the child presented with aplasia cutis congenita, distal limb traverse defects, growth retardation, a wide atrial septal defect, periventricular leukomalacia, and enlarged ventricles.

Eye anomalies have been also described in an autosomal recessive variant of Adams-Oliver syndrome,[805-807] and retinal hypervascularization is a recurrent finding.[802] Facial features include hypertelorism, epicanthal folds, blue sclerae, and micrognathia.[808,809] Vandersteen and colleagues[810] described an autosomal dominant form of Adams-Oliver syndrome involving characteristic scalp defects and terminal limb defects, but without congenital heart defects or immune defects. An association between mutations in *DOCK6* and the autosomal recessive form of Adamas-Oliver syndrome has been reported.[811]

Phocomelia

In phocomelia, the hands and feet are present, but the intervening arms and legs are absent. Hands and feet may be normal or abnormal.[812] Three syndromes should be considered in the differential diagnosis of phocomelia: Roberts syndrome, some varieties of the TAR syndrome, and Grebe syndrome. Phocomelia also can be caused by exposure to thalidomide.[813] Prenatal diagnosis of phocomelia has been reported using 3D sonography.[814]

Roberts Syndrome

This autosomal recessive disorder is characterized by the association of tetraphocomelia and craniofacial dysmorphism, including macrocephaly, hypertelorism, shallow orbits, facial clefting defects, and hypoplastic nasal alae. The upper extremities are generally more severely affected than the lower extremities. Polyhydramnios has been noted, and other anomalies associated with the syndrome include horseshoe kidney, ventriculomegaly, cephalocele, and spina bifida.[815] 3D sonography might provide clearer visualization of the short bones, contracted legs, and additional anomalies.[816] Roberts syndrome is caused by mutations in the *ESCO2* gene (establishment of cohesion 1 homolog 2) similar to SC phocomelia syndrome[817] (named after the first descriptions in two families with surnames beginning with S and C, respectively).[818] SC phocomelia is considered a mild variant of Roberts syndrome and is characterized by (1) nearly symmetric reductive malformations of the limbs, resembling phocomelia; (2) flexion contractures of various joints; (3) minor anomalies, including capillary hemangioma of the face, forehead, and ears, hypoplastic cartilages of the ears and nose, micrognathia, scanty silvery blond hair, and cloudy

corneas; (4) growth restriction; and (5) mental retardation. Mental retardation may be mild, and survival into adulthood is common.[819]

Grebe Syndrome (Grebe-Quelce-Salgado Chondrodystrophy)

This autosomal recessive nonlethal acromesomelic skeletal disorder was first described in two girls by Grebe,[820] and subsequently in 47 Brazilian individuals by Quelce-Salgado.[821] Affected individuals have a normal head, neck, and trunk skeleton, relatively normal humeri and femora, short and deformed radii, ulnae, tibiae, and fibulae, and severe abnormalities of hands and feet. Polydactyly is frequent. Digits are very small and have been variously described as bulbous,[822] bud-like,[823] mere knobs, globular appendages,[824] or stubby toe-like fingers. The proximal and middle phalanges of the fingers and toes are invariably absent, and the distal phalanges are present. Radiographic and computed tomography imaging provide information on subtle clinical characteristics for obligate heterozygotes such as polydactyly, brachydactyly, hallux valgus, and metatarsus adductus.[825-827] The disease is caused by a missense mutation in the gene encoding cartilage-derived morphogenetic protein-1 (*CDMP1*).[828,829] Survivors have normal intelligence and develop normal secondary sexual characteristics. Prenatal diagnosis of Grebe syndrome has been made based on the phenotypic features of the disease (acromesomelic dysplasia and dysmorphic distal appendages with normal craniofacial and axial skeletal development)[822,830,831] and by the identification of mutations in the *CDMP1* gene.[831]

Congenital Short Femur (Proximal Femoral Focal Deficiency)

Congenital short femur refers to a group of disorders encompassing a wide range of congenital developmental anomalies of the femur. The disorder has been classified into five groups, types I through V: (I) simple hypoplasia of the femur; (II) short femur with angulated shaft; (III) short femur with coxa vara (most common); (IV) absent or defective proximal femur; and (V), absent or rudimentary femur[832,833] (Fig. 11-47). One or both femora can be affected, although the right femur is more frequently involved. Anomalies of the upper limbs can also be present and do not exclude the diagnosis.[39] Proximal femoral focal deficiency syndrome may be associated with umbilical or inguinal hernias. If both femora are affected, it is important to examine the face carefully, because the disorder may be *bilateral femoral hypoplasia and unusual facies syndrome*,[834,835] which consists of bilateral femoral hypoplasia and facial anomalies, including short nose with broad tip, long philtrum, micrognathia, and cleft palate. Long bone abnormalities can extend to other segments of the lower extremities (absent fibula) and to the upper extremities. Femoral focal deficiency syndrome is considered a sporadic condition, but a familial form has been described. Except in bilateral proximal focal deficiency, the diagnosis is usually suspected when there is unilateral short femur, in the absence of other anomalies.[835-841] If the defect is unilateral, it may correspond to the femur-fibula-ulnar or femur-tibia-radius complex. These two syndromes have different implications for genetic counseling: the former is nonfamilial, whereas the second has a strong genetic component.[840]

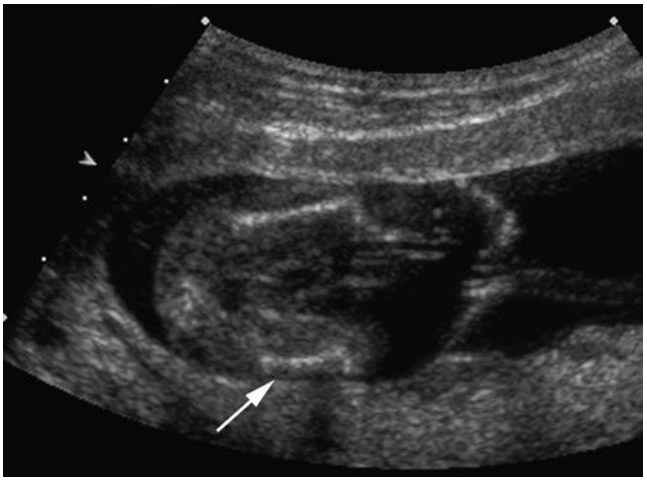

FIG 11-47 Second trimester sonogram in a fetus with proximal femoral focal deficiency. The right femur (*arrow*) is significantly shorter than the left femur.

Thrombocytopenia With Absent Radius Syndrome

TAR syndrome is discussed in detail later in the section titled "Radial Clubhand and Hematologic Disorders."

SPLIT HAND AND FOOT DEFORMITIES

The term split-hand-and-foot syndrome is used to refer to a group of disorders characterized by splitting of the hand and foot into two parts. Other terms include lobster-claw deformity, ectrodactyly, and aborted fingers.[841] The conditions are classified into typical and atypical varieties.[842] The typical form consists of absence of both the finger and the metacarpal bone, resulting in a deep V-shaped central defect that clearly divides the hand into an ulnar and radial part. It occurs in 1 per 90,000 live births and has a familial tendency (usually inherited in an autosomal dominant fashion).[843] The atypical variety is characterized by a much wider cleft formed by a defect of the metacarpals and the middle fingers. As a consequence, the cleft is U-shaped and wide, with only thumb and small finger remaining. The atypical variety occurs in 1 per 150,000 live births.[844]

Although a complex system for the classification of these disorders (based on the distribution of remaining fingers) has been proposed,[845] it is not helpful in differential diagnosis and syndrome classification. Split-hand-and-foot deformities can occur as isolated anomalies or as part of a more complex syndrome. The syndromic types are more frequently encountered.

The split-hand-and-foot and absent-long-bones syndromes include two conditions in which there is split hand and aplasia of the tibia, or split foot with aplasia of the ulna. However, skeletal anomalies are not limited to these bones; the clavicle, femur, and fibula can also be affected. The pattern of inheritance of these disorders has not been clearly determined. Autosomal dominant, recessive, and X-linked recessive patterns have been proposed.[846]

ECTRODACTYLY ECTODERMAL DYSPLASIA–CLEFT LIP/PALATE SYNDROME

Ectrodactyly ectodermal dysplasia–cleft lip/palate syndrome is an autosomal dominant condition characterized by the triad of ectrodactyly, ectodermal dysplasia, and facial clefting.[847] Ectrodactyly generally involves the four extremities, with more severe deformities of the hands.[848,849] The spectrum of ectodermal defects is wide and includes hypopigmentation, dry skin, sparse hair, and dental defects.[850-852] Tear duct anomalies and decreased lacrimal secretions lead to chronic keratoconjunctivitis and severe loss of visual acuity.[853,854] Cleft lip is generally bilateral, obstructive uropathy often occurs in this condition,[855] and intelligence is generally normal.[856] There is a marked phenotypic variability even within members of the same family showing isolated or combined limb defects as split hand/foot and mesoaxial polydactyly, cleft lip/palate, and ectodermal manifestations such as blond sparse hair with slow growth, thin nails, periorbital hyperpigmentation, dental caries, hypodontia, edentulism, and micturition and defecation

difficulties.[857] Mutations in the P63 gene account for most cases of ectodermal dysplasia–cleft lip/palate syndrome,[858] and some individuals are mosaic for the mutation.[859] Differential diagnosis includes a group of syndromes with associations of the split-hand-and-foot deformity with other anomalies such as Karsch-Neugebauer syndrome (split hand and foot with congenital nystagmus) and mandibulofacial dysostosis (Fontaine syndrome).[856]

CLUBHAND DEFORMITIES

Clubhand deformities are classified into two main categories: radial and ulnar. Radial clubhand includes a wide spectrum of disorders that encompass absent thumb, thumb hypoplasia, thin first metacarpal, and absent radius (Table 11-25). Ulnar clubhand is much less frequent than radial clubhand and ranges from mild deviations of the hand on the ulnar side of the forearm to complete absence of the ulna. Although radial clubhand is frequently syndromic, ulnar clubhand is usually an isolated anomaly.[860,861] Table 11-26 displays conditions that present with ulnar ray defects.

Whenever a clubhand is identified, it is important to conduct a thorough examination of the fetus and newborn to delineate associated anomalies that may suggest a syndrome. Fetal blood sampling can be helpful, and fetal echocardiography is recommended. A complete blood cell count, including platelets, is important for the diagnosis of Fanconi pancytopenia, TAR syndrome, and Diamond-Blackfan anemia. A fetal karyotype is indicated because several chromosomal abnormalities (e.g., trisomy 18 and trisomy 21) have been reported in association with clubhand deformities. Congenital heart disease is an important feature of the Holt-Oram syndrome, the Lewis upper limb–cardiovascular syndrome, and in some cases of TAR syndrome.

Radial Clubhand

An isolated radial clubhand is usually a sporadic nonsyndromic disorder[861-863]; however, other structural anomalies may be present (e.g., scoliosis and congenital heart disease). A detailed list of conditions associated with radial clubhands is presented in Table 11-25.

Radial Clubhand and Hematologic Disorders

Radial clubhand may be part of the three syndromes characterized by hematologic abnormalities: Fanconi pancytopenia, TAR syndrome, and Diamond-Blackfan anemia.

Fanconi Anemia

Fanconi anemia (pancytopenia) is an autosomal recessive disease characterized by the association of bone marrow failure (anemia, leukopenia, and thrombocytopenia) and skeletal anomalies, including radial clubhand with absent thumbs, radial hypoplasia, and a high frequency of chromosomal instability (demonstrated in amniotic fluid cells or fetal lymphocytes as a high rate of chromosomal breakage after incubation with diepoxybutane).[864-866] Approximately 25% of affected individuals do not have limb reduction anomalies. Other associated findings include microcephaly, congenital dislocation of the hips, scoliosis, cardiac, pulmonary, and gastrointestinal anomalies, and fetal growth restriction.[867]

It is assumed that the basic defect is related to the inability to repair DNA damage, in particular that of so-called DNA cross-links. At least 11 complementation groups (A, B, C, D1/BRCA2, D2, E, F, G, I, J, and L)[868] and 8 associated genes have been identified: *FANCA, FANCC, FANCD2, FANCE, FANCF, FANCG/XRCC9, FANCL*, and *FANCD1* (*BRCA2*).[869-871] About 200 mutations have been described, and among these, mutations in the gene for complementation group FA-A (*FANCA*) account for approximately 65% of the cases.[868] Prenatal

TABLE 11-25 Radial Ray Defects: A Differential Diagnosis of Congenital Deficiency of the Radius and Radial Ray

- I. Isolated: nonsyndromatic
- II. Syndromes with blood dyscrasias
  - A. Fanconi anemia
  - B. Thrombocytopenia with absent radii syndrome
  - C. Diamond-Blackfan syndrome: congenital anemia, non-opposable triphalangeal thumb, scaphoid and distal radius hypoplasia, radioulnar synostosis, short stature with narrow shoulders, autosomal recessive
- III. Syndromes with congenital heart disease
  - A. Holt-Oram syndrome
  - B. Lewis upper limb–cardiovascular syndrome: more extensive arm malformations and more complex heart anomalies than with Holt-Oram but probably not a separate syndrome, autosomal dominant
- IV. Syndromes with craniofacial abnormalities
  - A. Nager acrofacial dysostosis
  - B. Radial clubhand and cleft lip and/or cleft palate: sporadic
  - C. Juberg-Hayward syndrome: cleft lip and palate, hypoplastic thumbs, short radius, radial head subluxation, autosomal recessive
  - D. Baller-Gerold syndrome: craniosynostosis, bilateral radial clubhand, absent/hypoplastic thumb, autosomal recessive
  - E. Rothmund-Thomson syndrome: prematurely aged skin changes, juvenile cataract, sparse gray hair, absent thumbs, radial clubhands, occasional knee dysplasia (see progeria syndromes)
  - F. Duane-radial dysplasia syndrome: abnormal ocular movements: inability to abduct and eyeball retraction with adduction, radius and radial ray hypoplasia, vertebral anomalies, renal malformation, autosomal dominant (see Klippel-Feil variants)
  - G. The IVIC syndrome (Instituto Venezolano de Investigaciones Cientificas): radial ray deficiency, hypoplastic or absent thumbs and radial clubhands, impaired hearing, abnormal movements of extraocular muscles with strabismus, autosomal dominant
  - H. LARD syndrome (lacrimo-auriculo-radial-dental; Levy-Hollister): absent lacrimal structures, protuberant ears, thumb and radial hypoplasia, abnormal teeth, autosomal dominant
  - I. Radial defects with ear anomalies and cranial nerve dysfunction
  - J. Radial hypoplasia, triphalangeal thumb, hypospadias, diastema or maxillary central incisors, autosomal dominant
- V. Syndromes with congenital scoliosis
  - A. VATER/VACTER association
  - B. Goldenhar syndrome (oculo-auriculo-vertebral dysplasia)
  - C. Klippel-Feil syndrome
- VI. Radial aplasia and chromosome aberrations
- VII. Syndromes with mental retardation
  - A. Seckel's syndrome (bird-headed dwarfism): microcephaly, beaklike protrusion of nose, mental retardation, absent/hypoplastic thumbs, bilateral dislocated hips
- VIII. Thalidomide embryopathy (of historical interest, but some 60% had radial clubhand)

VACTER, vertebral, anal atresia, cardiac defects, tracheoesophageal fistula, renal anomalies.
From Goldberg MD: The Dysmorphic Child: An Orthopedic Perspective. New York, Raven Press, 1987, reproduced with permission.

TABLE 11-26 Ulnar Ray Defects: A Differential Diagnosis of Congenital Deficiency of the Ulna and Ulnar Ray

I. Isolated: nonsyndromatic absent ulna
II. Ulna hypoplasia and skeletal deficiency elsewhere
  A. Ulna aplasia with lobster claw deformity of hand and/or foot, autosomal dominant
  B. Femur-fibula-ulna complex
III. Syndromes with ulna deficiency
  A. Cornelia de Lange syndrome
  B. Miller syndrome (postaxial acrofacial dysostosis): absent ulna and ulnar rays and absent fourth and fifth toes; Treacher Collins mandibulofacial hypoplasia, autosomal recessive; distinguish from Nagar preaxial acrofacial dysostosis
  C. Pallister ulnar-mammary syndrome (autosomal dominant): hypoplasia of ulna and ulnar rays; hypoplasia of the breast and absence of apocrine sweat glands
  D. Pillay syndrome (ophthalmomandibulomelic dysplasia; autosomal dominant): absent distal third of ulna, absent olecranon, hypoplastic trochlea and proximal radius, fusion of interphalangeal joints in ulnar fingers, knee dysplasia; corneal opacities, fusion of temporomandibular joint
  E. Weyers oligodactyly syndrome (sporadic): deficiency of ulna and ulnar rays, antecubital webbing, short sternum, malformed kidney and spleen, cleft lip and palate
  F. Schnizel syndrome (autosomal dominant): absent/hypoplastic fourth, fifth metacarpals and phalanges, hypogenitalism, anal atresia
  G. Mesomelic dwarfism, Reinhardt-Pfeiffer type (ulno-fibula dysplasia; autosomal dominant): a generalized bone dysplasia but with a disproportionate hypoplasia of the ulna and fibula
  H. Mesomelic dwarfism, Langer type: a generalized bone dysplasia, but with aplasia of the distal ulna and proximal fibula and hypoplasia of the mandible

From Goldberg MD: The Dysmorphic Child: An Orthopedic Perspective. New York, Raven Press, 1987, reproduced with permission.

diagnosis is possible with DNA testing for the most common mutations.[872,873] For those cases in which the affected gene and parental mutations are not known (e.g., in case of radial ray abnormalities identified by sonography but negative family history), chromosome breakage studies after exposure to DNA cross-linking agents,[874] single-cell parameter flow cytometry of amniotic fluid cell cultures, or bivariate flow cytometry of umbilical cord cell cultures have been used for prenatal diagnosis. The rationale for using flow cytometry to test for Fanconi anemia is the hypersensitivity of Fanconi anemia cells to alkylating agents leading to elevated G2-phase cell fractions in positive cases.[875]

Thrombocytopenia With Absent Radius Syndrome

TAR syndrome is an autosomal recessive disorder characterized by thrombocytopenia (platelet count of less than 100,000/mm^3) and bilateral absence of the radius.[876,877] Thumbs and metacarpals are always present. The ulna and humerus may be absent, and clubfoot deformities may occur. Congenital heart disease is present in 33% of cases (e.g., tetralogy of Fallot and septal defects). Delivery by cesarean section is recommended, because these fetuses are at risk for intracranial hemorrhage.[878] TAR has been successfully diagnosed in utero.[879,880] Houeijeh and coworkers[881] reported that the presence of 1q21.1 deletion can be associated with TAR syndrome.

Diamond-Blackfan Syndrome/Aase Syndrome

Diamond-Blackfan syndrome is an autosomal recessive condition characterized by congenital hypoplastic anemia and a radial clubhand with bilateral triphalangeal thumb and a hypoplastic distal radius.[882,883] Triphalangeal thumbs are a feature of several bone dysostoses and malformation syndromes. They may also occur in random association with other defects and as isolated, often familial, anomalies.[884] The differential diagnosis of this condition includes Holt-Oram syndrome, chromosomal abnormalities, and fetal hydantoin syndrome.[885] Diamond-Blackfan syndrome has been associated with mutations and deletions of different ribosomal protein (RP) genes.[886-889]

Holt-Oram Syndrome

Holt-Oram syndrome is an autosomal dominant disorder characterized by congenital heart disease (mainly atrial and ventricular septal defects and interrupted aortic arch), aplasia or hypoplasia of the radius, and triphalangeal or absent thumbs.[890-892] Limb defects are often asymmetric, with the left side being more affected than the right side. There is no correlation between the severity of the limb defects and cardiac anomalies.[893] Indeed, some individuals have only a skeletal anomaly. Other findings include hypertelorism and chest wall and vertebral anomalies. This condition has been diagnosed prenatally by 2D and 3D sonography.[891,894] Holt-Oram syndrome is caused by mutations in the *TBX5* gene,[895,896] and preimplantation diagnosis of this condition has been reported.[897]

Radial Clubhand and Scoliosis

Radial clubhand may also be associated with congenital scoliosis. Three conditions should be considered in the differential diagnosis: VATER/VACTER association, some cases of the Goldenhar syndrome, and Klippel-Feil syndrome.

VATER/VACTER Association

VATER/VACTER association is the result of a defective mesodermal development during embryogenesis before the 35th day of gestation.[898] The typical findings are vertebral segmentation defects, anal atresia, tracheoesophageal fistula, cardiac defects, esophageal atresia, single umbilical artery, and radial and renal defects.[899-901] VATER/VACTER association occurs sporadically, although recurrence within a sibship may occur.[902] The features of VATER/VACTER can be detected by prenatal sonography.[903,904]

Goldenhar Syndrome

Goldenhar syndrome is characterized by hemifacial microsomia, vertebral anomalies, and radial defects.[905] Alterations in the morphogenesis of the first and second brachial arches result in hypoplasia of the malar, maxillary, or mandibular region; microtia; and ocular and oropharyngeal anomalies.[906,907] Prenatal diagnosis based on ultrasound findings has been reported.[907-909]

Klippel-Feil Syndrome

Klippel-Feil syndrome is characterized by fusion of two cervical vertebrae, resulting in short neck, low posterior hairline, and restricted mobility of the upper spine. Several associated anomalies may be present, including spina bifida, encephalocele, cleft palate, rib abnormalities, lung disorders, congenital heart disease, and limb anomalies.[910,911] Herman and associates[911] reported a large occipital encephalocele, abnormal kidney, and marked dilatation of the duodenum on fetal MRI at 31 weeks of gestation. Postnatally, segmentation

anomalies of the cervical spine and cervical vertebral body fusion are consistent findings in Klippel-Feil syndrome.

Other Conditions Associated With Radial Clubhand

Radial clubhand has also been reported in association with chromosomal anomalies, including trisomy 18, and deletion of the long arm of chromosome 13.[912,913]

Some disorders present with craniofacial abnormalities and radial clubhand deformities. These conditions are sporadic and have common features that make a prenatal differential diagnosis difficult. The most common craniofacial anomaly is cleft lip and palate.[914]

Ulnar Clubhand

Ulnar clubhand usually occurs as an isolated, nonsyndromic anomaly. Syndromes that may have ulnar clubhand as part of their phenotype (e.g., Poland syndrome) are described in Table 11-26.[915]

Polydactyly

Polydactyly is the presence of an additional digit, and it is the most common hereditary limb deformation.[916] The extra digit may range from a fleshy nubbin to a complete digit with controlled flexion and extension (see Figs. 11-42 and 11-43). Polydactyly can be classified as postaxial (the most common form), preaxial, and central (see Table 11-16). Postaxial polydactyly occurs on the ulnar side of the hand and on the fibular side of the foot. Preaxial polydactyly is present on the radial side of the hand and on the tibial side of the foot (Fig. 11-48).[917] Central polydactyly consists of an extra digit that is usually hidden between the long and the ring finger.[918]

Evidence from mouse models suggests that several types of polydactyly involve the hedgehog pathway, either directly or indirectly.[919,920] Specifically, mutations in the downstream effector of Shh, *GLI3*, give rise to different polydactyly phenotypes, the mildest of which are postaxial polydactyly type I and preaxial polydactyly type IV (or Greig cephalopolysyndactyly).[921] Postaxial polydactyly type I is about 10 times more frequent in blacks than in whites and is characterized by a well-developed extra digit that articulates with the fifth digit. Greig cephalopolysyndactyly is characterized by pre- or postaxial polysyndactyly of variable degrees, frontal bossing, and hypertelorism.[921] The most severe malformations are found in Pallister-Hall syndrome, which is characterized by hypothalamic hamartomas, craniofacial anomalies, polysyndactyly, and anal defects.[922]

Although the majority of cases of polydactyly are isolated and inherited as an autosomal dominant trait, polydactyly is a phenotypic trait in 119 disorders (97 syndromic and 22 nonsyndromic), 39 of which are caused by mutations in known genes and 16 are mapped to a locus in the genome.[923] Central polydactyly is often bilateral and may be associated with other hand and foot malformations. Preaxial polydactyly, however, especially when a triphalangeal thumb is present, is more likely to be part of a syndrome.

Arthrogryposis

The term arthrogryposis multiplex congenita (AMC) refers to multiple joint contractures present at birth with an intact skeleton.[924] The prevalence of AMC has been estimated as 8.5/100,000 births in a population-based study including 8.9 million births from 1980 to 2006.[925] The inheritance pattern of AMC was analyzed in 320 cases and reported as follows: 46% were part of syndromes with no recurrence risk; 23% were inherited with a mendelian pattern (autosomal dominant, autosomal recessive, or X-linked); and 3% were associated with chromosomal anomalies. In 28% of AMC cases no direct cause or associations were observed.[926] Table 11-27 shows a list of motor disorders that can lead to AMC.

FIG 11-48 Femoral hypoplasia–unusual facies syndrome. Note the absence of the left femur and only a tiny portion of ossified bone on the right side. There is partial fusion of the tibia and fibula. Of interest is the presence of preaxial polydactyly (*arrows*) in both feet.

Normal fetal movement between 7 and 8 weeks of gestation onward is important for development of the joints; limitation of fetal joint motion leads to development of contractures and AMC.[927] This has been confirmed in experimental rats exposed to a viral myopathy induced by coxsackie A viruses.[928,929] AMC is therefore a syndrome, not a specific disorder, associated to neurologic, muscular, connective, and skeletal abnormalities and, with reduced intrauterine space, that can lead to impaired fetal motion and development of AMC.[930-932] In most cases of AMC, deformities are symmetric and involve the four limbs (Figs. 11-49 and 11-50). Anomalies of the lower extremities only, or bimelic involvement, can also occur. The severity of deformities increases distally with the hands and feet typically being the most affected.[933]

Cardinal findings on prenatal ultrasonography include absence of fetal movement on real-time examination and severe flexion deformities.[924,934] Zelop and Benacerraf[935] evaluated the clinical significance and outcome of postural deformities and contractures of the upper extremities detected prenatally. Among 52 fetuses with sonographically detected abnormalities of the upper extremities, 59% (n = 26) had aneuploidies, mostly trisomy 18 (88% [23/26]). Fetuses with a normal karyotype presented with a variety of syndromic conditions, including three cases of AMC and one case each of Pierre-Robin sequence, Freeman-Sheldon syndrome, and Whistler syndrome, and bilateral syndactyly requiring multiple corrective surgical procedures. The

TABLE 11-27 Disorders of the Developing Motor System Leading to Immobilization

Disorders of the developing neuromuscular system
Loss of anterior horn cells
Radicular disease with collagen proliferation
Peripheral neuropathy with neurofibromatosis
Congenital myasthenia
Neonatal myasthenia (maternal myasthenia gravis)
Amyoplasia congenita
Congenital muscular dystrophy
Central core disease
Congenital myotonic dystrophy
Glycogen accumulation myopathy
Disorders of developing connective tissue or connective tissue disease
Muscular and articular connective tissue dystrophy
Articular defects by mesenchymal dysplasia
Increased collagen synthesis
Disorders of developing medulla or medullar disease
Congenital spinal epidural hemorrhage
Congenital duplication of the spinal canal
Disorders of brain development (e.g., porencephaly or brain disease)
Congenital encephalopathy

FIG 11-49 Arthrogryposis multiplex congenita; note flexion of the upper limbs with hyperextension of the lower limbs.

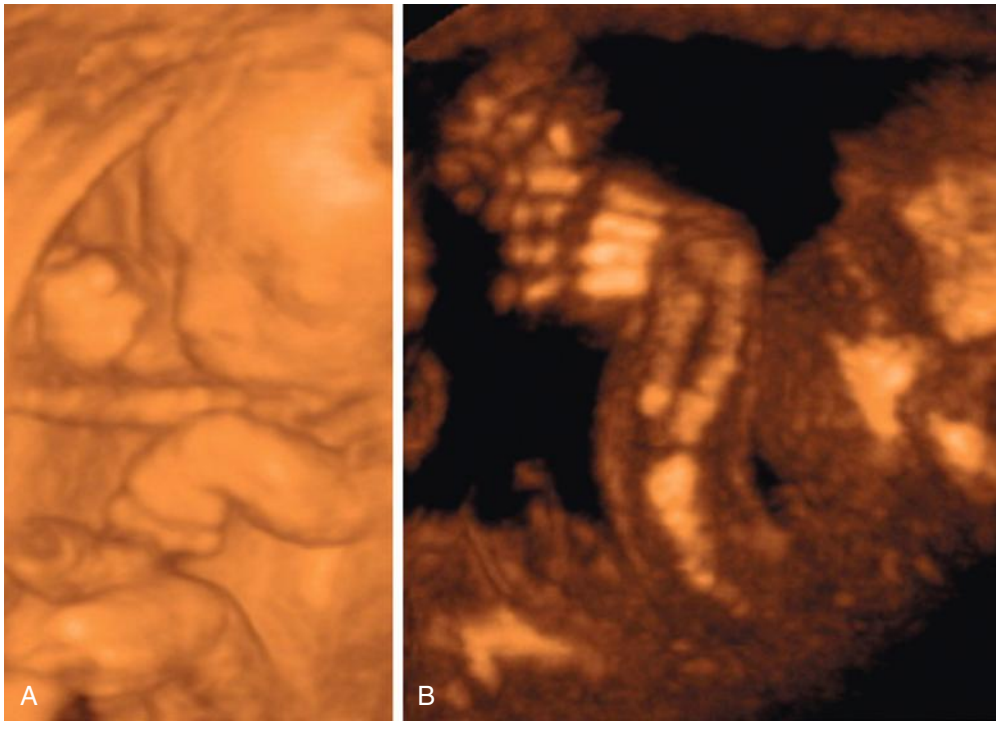

FIG 11-50 Bilateral hyperflexed wrists in a fetus at 23 weeks of gestation with arthrogryposis multiplex congenita. Three-dimensional ultrasound rendered images using surface mode (**A**) and maximum intensity projection mode (**B**). (Courtesy of Maynor Garcia, MD.)

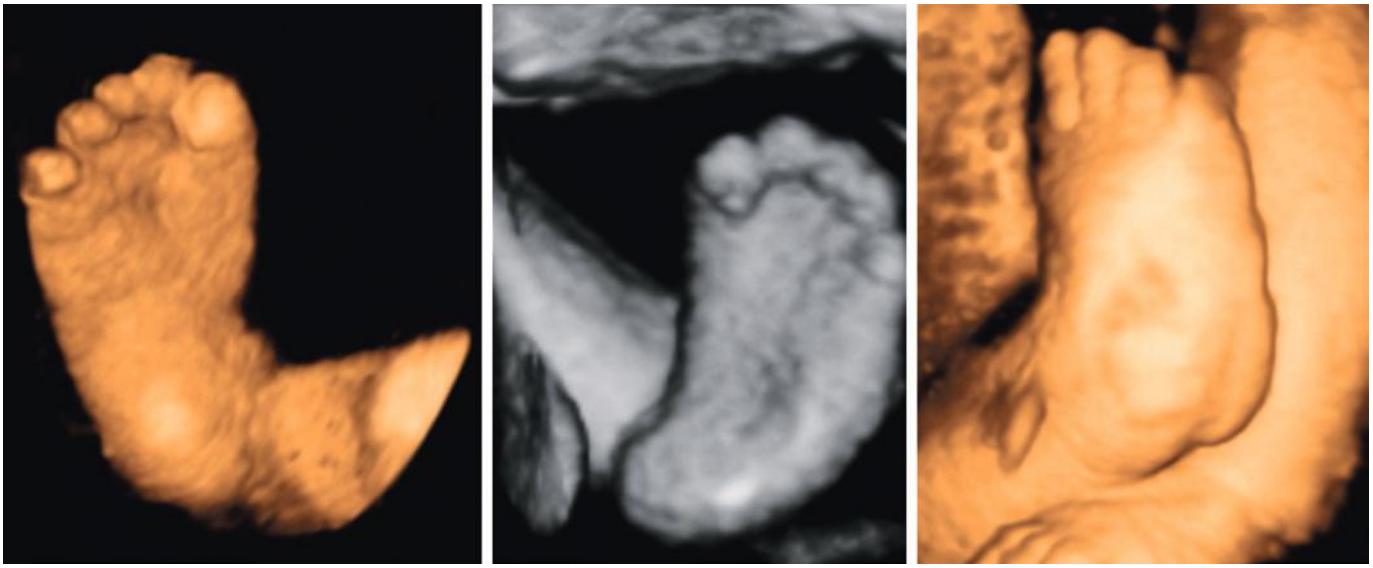

FIG 11-51 Two-dimensional ultrasound images using surface mode in a fetus with unilateral clubfoot showing internal rotation and hyperflexed toes.

survival rate was 5% (8/52), and only one of the survivors was phenotypically normal after birth. Dicke and colleagues[936] reported that ultrasound can detect up to 81% of cases of AMC before 22 weeks of gestation.

The prognosis of AMC depends on the specific cause. Although some cases are uniformly lethal, others are associated with mild to moderate handicap. Polyhydramnios is considered a poor prognostic sign.[937]

CLUBFOOT

Clubfoot (talipes equinovarus) is a congenital malformation of the bones of the ankle and foot, resulting in adduction of the forefoot, inversion of the heel, and plantar flexion of the forefoot and ankle.[938] There is subluxation of the talocalcaneonavicular joint. As a result of this malformation, the dorsal aspect of the foot is often rotated medially, which assumes a clublike appearance. The sonographic diagnosis is made when the metatarsals and phalanges of the foot are seen in the same plane as the tibia and fibula[939,940] (Fig. 11-51).

The severity of the clubfoot deformity varies from (1) a postural deformity often requiring no treatment; (2) an isolated clubfoot deformity needing casting and possible surgery, often with a favorable outcome; or (3) a complex clubfoot abnormality associated with other chromosomal, neuromuscular, or structural abnormalities. Clubfoot may also result from restriction of movement in utero, as in severe oligohydramnios.[941] The prevalence is often reported as 1 per 1000 live births with a 2:1 male-to-female predisposition.[942] Several series reported that an initially diagnosed isolated clubfoot is usually associated with other abnormalities, appearing either later in pregnancy or in the neonatal period.[943] The association of an isolated clubfoot with aneuploidy is controversial. Shipp and Benacerraf found that 5.9% of 87 fetuses with isolated clubfoot had an abnormal karyotype and concluded that amniocentesis is indicated after such diagnosis.[944] Other investigators do not suggest invasive testing for chromosomal anomalies in fetuses with isolated unilateral clubfoot.[945]

Ultrasound Evaluation of the Fetal Thorax

Deborah Rose Berman, Marjorie C. Treadwell

SUMMARY OF KEY POINTS

- The most common chest masses are congenital pulmonary airway malformations (CPAMs) and congenital diaphragmatic hernias (CDHs). For both, the displacement of the heart from its normal position is the most commonly recognized ultrasound finding.
- CPAMs are unilateral 98% of the time and appear as echogenic areas of the lung, with or without identified cysts. The CPAM volume ratio (CVR) can be used to subdivide these malformations into high- and low-risk categories for development of fetal hydrops.
- Fluid-filled dilated airways should raise suspicion for bronchial or laryngeal atresia. Bilateral hyperechogenic lungs with fluid-filled airways are characteristic of congenital high airway obstruction syndrome (CHAOS), whereas a unilateral hyperechogenic lung with fluid-filled airways suggests bronchial atresia or congenital lobar emphysema (CLE).
- Hydrothorax may be primary or secondary. Primary hydrothorax is usually chylous in origin and may progress to hydrops, usually associated with significant skin edema. A large unilateral hydrothorax, even if associated with significant hydrops, may respond to prenatal drainage and shunting.
- CDHs are left-sided and posterior in 85% of cases. They are associated with other anomalies (structural and chromosomal) in 40% to 50% of cases.
- Prognosis for CDHs depends on the presence of associated abnormalities, the gestational age at delivery, and the degree of pulmonary hypoplasia.
- Estimation of lung volume by two-dimensional ultrasound lung-head ratios or volumes obtained through magnetic resonance imaging (MRI) or three-dimensional ultrasound may help guide counseling.

OUTLINE

The neonatal identification of chest lesions frequently relies on decompensation of the newborn. Prenatal identification allows for appropriate triaging for site of delivery as well as early and appropriate treatment. Better definition and prenatal identification of chest lesions along with enhanced understanding of the natural history of these lesions has resulted in improvements in counseling. In addition, prenatal therapies are now available for many different types of chest abnormalities. The appropriate use of these therapies depends on accurate identification and assessment of the lesion and the associated pathologic changes. Identifying prognostic factors facilitates continued improvement in the understanding of the natural course of the disease.

This chapter will explore the range of chest lesions that can be identified prenatally and will discuss factors associated with a thorough sonographic diagnosis to facilitate complete and accurate counseling for patients.

EMBRYOLOGY

Although an intact pulmonary system is not required for intrauterine viability, the prenatal development of the respiratory system is integral to ex utero life and survival. To allow successful transition to neonatal life, fetal lungs must proceed through both structural and functional maturation processes, which occur from the early embryonic period and continue after birth. During structural development, there is branching of the airways and development of alveolar spaces, allowing gas exchange to occur once the first breath is taken at delivery. Functional development results in the creation of a surfactant system. This system is composed of phospholipids that decrease alveolar surface tension, inhibiting alveolar collapse during exhalation. The surfactant system develops in the third trimester and is typically mature at 36 weeks' gestation. Birth prior to the development of the surfactant

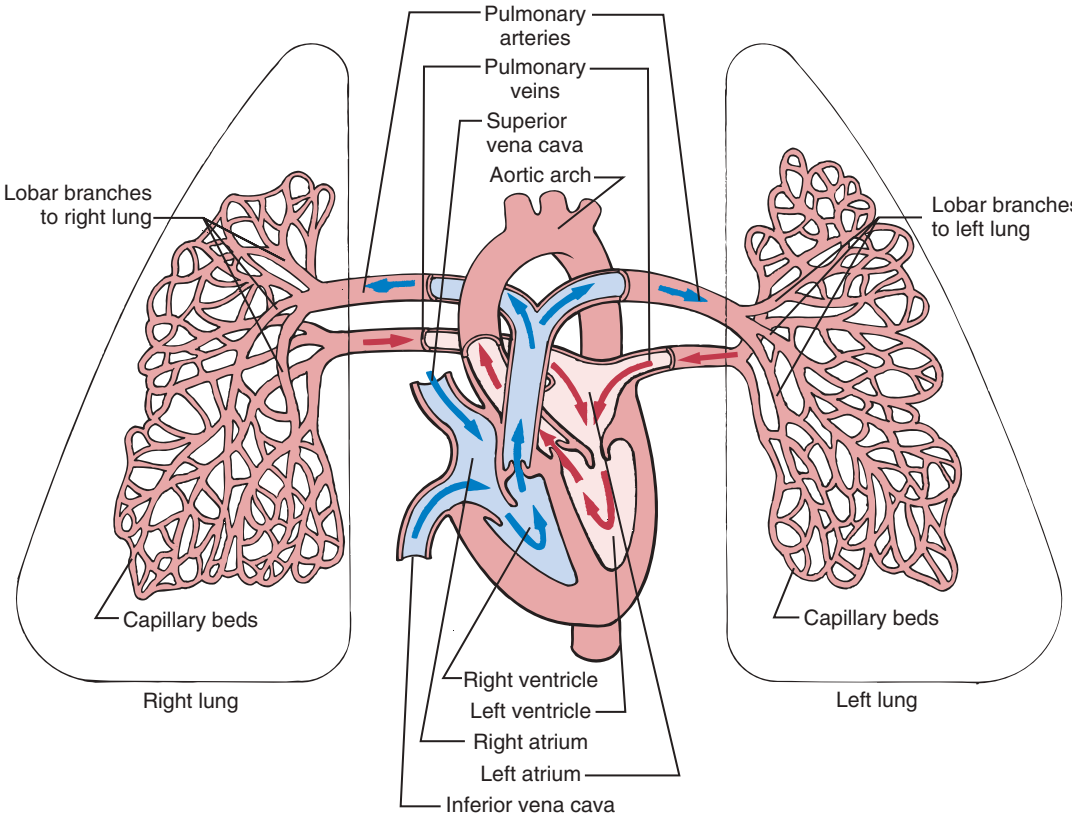

FIG 12-1 The pulmonary circulation. The right and left pulmonary veins and arteries and the branching capillaries are illustrated. (From Brashers VL: Structure and function of the pulmonary system. In McCance KL, Huether SE [eds]: Pathophysiology: The Biologic Basis for Disease in Adults and Children. St. Louis, Elsevier, Mosby, 2006.)

system or completed pulmonary development results in neonatal respiratory compromise.

The respiratory diverticulum (lung bud) appears as an outgrowth of the ventral wall of the foregut. The epithelium of the internal lining of the larynx, trachea, bronchi, and lungs is entirely of endodermal origin. The cartilaginous, smooth muscle, and connective tissues of the trachea and lungs are derived from splanchnic mesoderm that surrounds the tubular framework. The lung bud is in open communication with the foregut. The diverticulum develops in a craniocaudal direction, leading to development of the upper respiratory structures (nose and pharynx) prior to the lower structures. Two tracheoesophageal ridges separate the diverticulum from the foregut. The dorsal portion of the foregut divides into the esophagus and the ventral portion into the trachea and lung buds.[1]

The pulmonary circulation is a highly specialized vascular network, connecting the interdependent heart and lungs (Fig. 12-1). The vascular bed parallels the airways and links the arterial and venous poles of the heart. The pulmonary vasculature has been described as appearing de novo within the mesoderm ventral and lateral to the foregut endoderm, suggesting that this mesoderm pool gives rise to the future pulmonary vasculature as lung develops from the foregut.[2] The lungs have two sets of lymphatic vessels, a superficial set located beneath the pleura and a deep set which follows the blood vessels and extends along the bronchi. Both sets end within the bronchial glands. Efferent lymphatic vessels travel up the trachea, ending at the left-sided thoracic duct or the right-sided lymphatic duct. The fetal lungs play a key role in amniotic fluid volume maintenance: 15 mL/kg of body weight in fluid is produced by the lungs and flows out via the trachea and mouth, circulating and contributing to the amniotic fluid that is swallowed.[3]

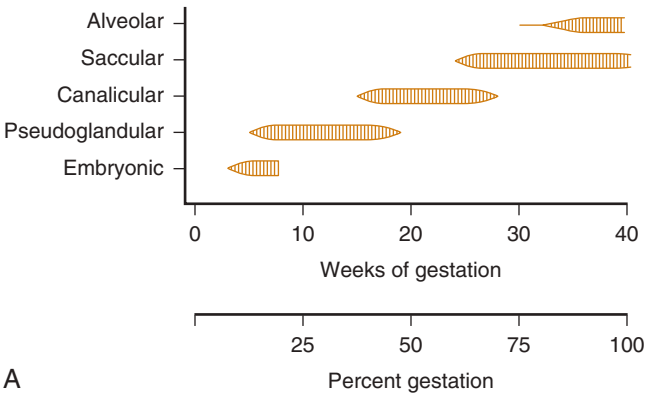

FIG 12-2 A, The five stages of normal fetal lung development.

The basic structure of the diaphragm is also established early in gestation. Initially, the septum transversum develops, lying caudal to the heart and rostral to the umbilicus, in a position that eventually divides the intraembryonic cavity into the pleuropericardial cavity and the peritoneal cavity.[4] The diaphragm subsequently undergoes programmed muscularization; this represents the final stage in the formation of the basic foundation of the diaphragm and is completed by 14 weeks' gestation.

Fetal lung development occurs in five stages: embryonic, pseudoglandular, canalicular, saccular, and alveolar (Fig. 12-2). The timing of these phases is approximate. Transitions between stages are gradual, with overlap from one stage to the next.

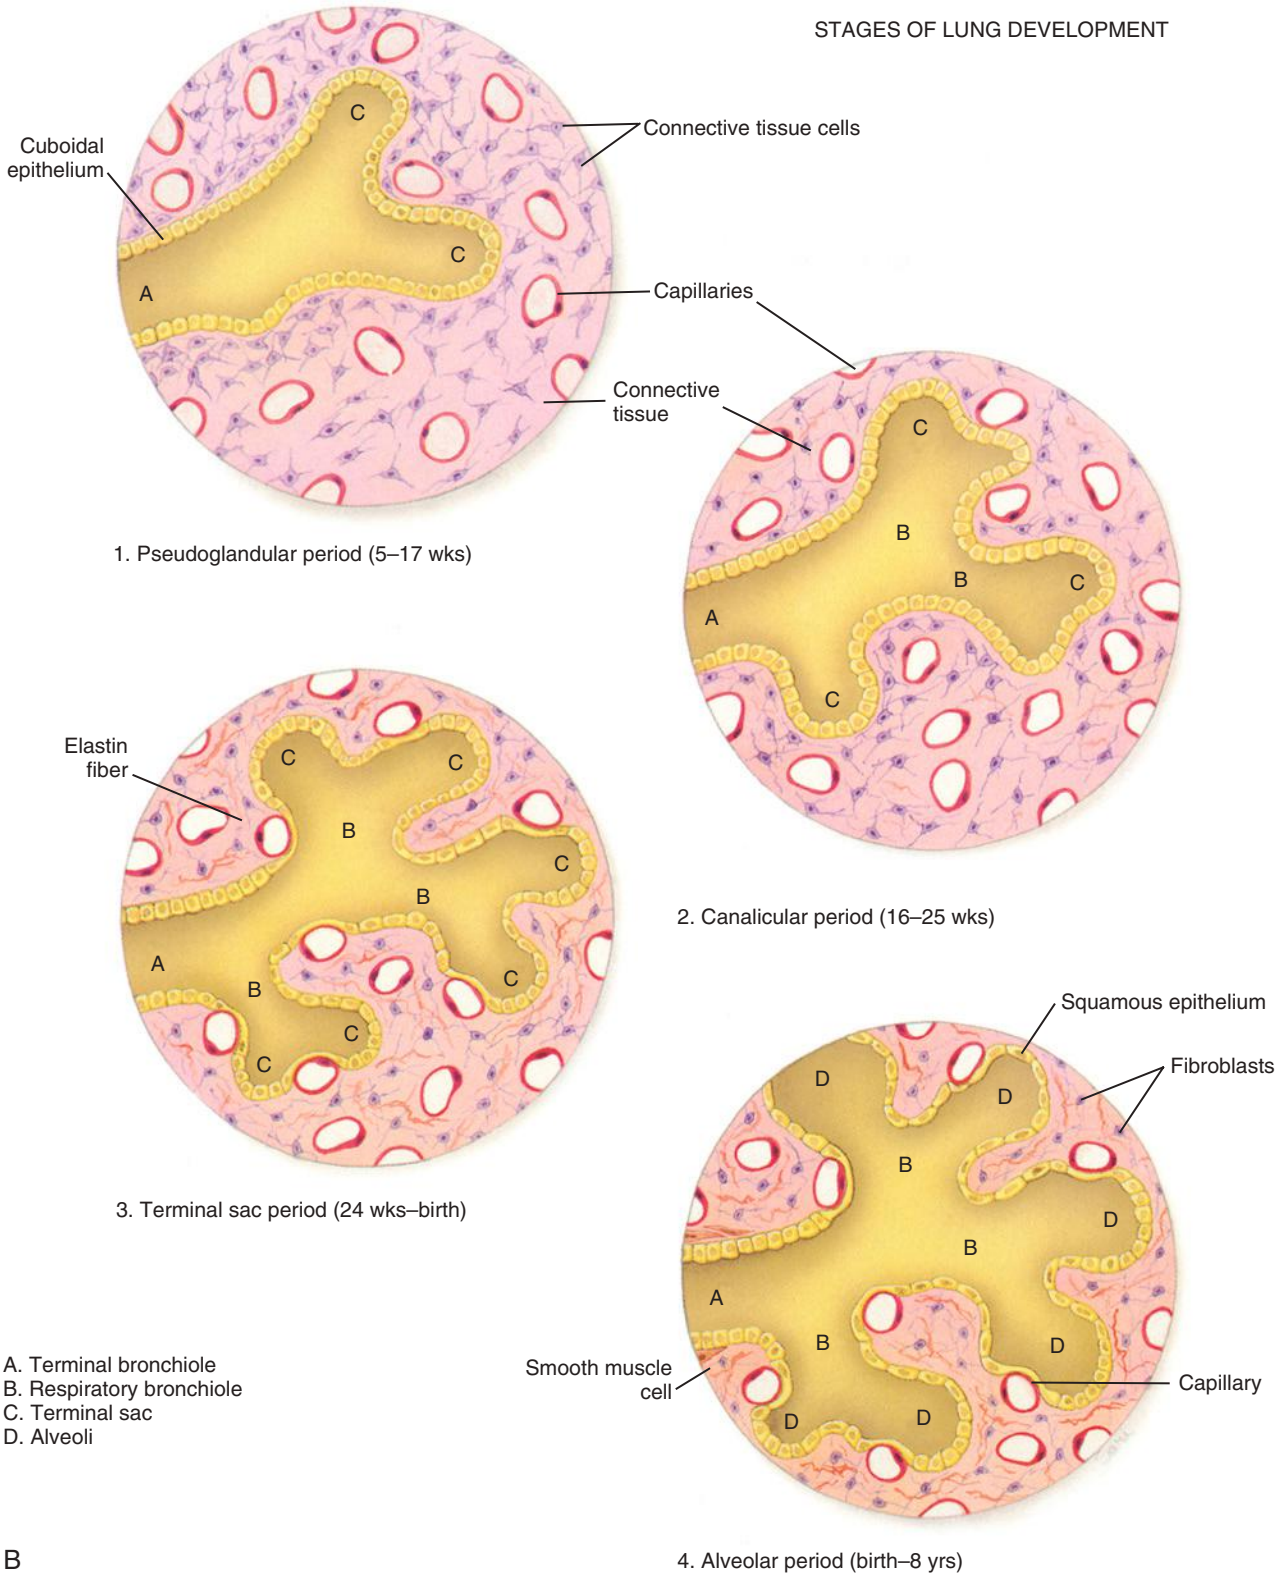

FIG 12-2, cont'd B, Histologic sections illustrating progressive stages of lung development. 1. Pseudoglandular period (about 8 weeks). 2. Late canalicular period (about 24 weeks). 3. Early terminal sac period (about 26 weeks). 4. Early alveolar period (newborn infant). Note that the alveolocapillary membrane is thin and that some of the capillaries have begun to bulge into the primordial alveoli. (A from Pringle KC: Human fetal lung development and related animal models. Clin Obstet Gynecol 3:502, 1986; B from Moore KL, Persaud TVN, Shiota K [eds]: Color Atlas of Clinical Embryology, 2nd ed. Philadelphia, WB Saunders, 2000.)

Embryonic Phase

The embryonic phase of lung development takes place during the first 4 to 5 weeks of gestation. During this phase, the larynx, trachea, and lung bud form from the foregut. The embryonic phase of lung development begins at about day 28 with the formation of a groove in the ventral lower pharynx, the sulcus laryngotrachealis. A few days later, at about day 30, a bud forms from the lower part, creating the true lung primordium.[5] Development progresses in the 8-week-old embryo as the lobar buds subdivide and form the bronchopulmonary segments. Early on, the asymmetry of the main bronchi is established, with the smaller bud on the left directed more laterally than the larger one on the right, which is parallel to the esophagus and directed more caudally. The embryonic phase proceeds with the unequal dividing of the endodermal branches followed by further division. At the end of the embryonic period, the five lobes of the lungs (three right and two left) are present.

Pseudoglandular Phase

The pseudoglandular stage takes place between the 7th and 16th weeks of embryonic development. Conducting airways are formed by progressive branching of the original lung buds into smaller and more numerous areas. Each bud eventually becomes an independent respiratory unit, served by a bronchiole surrounded by capillary vessels that will bring blood to the lungs for oxygen. During this stage, the first differentiation of lung epithelium occurs. By 13 weeks' gestation, cilia appear in the proximal airways.

Canalicular Phase

Lasting until approximately 25 weeks' gestational age, the canalicular phase is crucial for the development of the gas-exchanging portion of the lung. By 20 weeks, there is differentiation into type I pneumocytes, the primary structural cell of the alveolus. Capillaries grow in close proximity to the distal surface of the alveolar cells. Lamellar bodies develop in type II alveolar cells and are the site of surfactant storage prior to release into the alveoli. A sufficient differentiation of the type II pneumocytes into the type I pneumocytes and the proliferation of the capillaries into the mesenchyme marks an important step toward the fetus being able to survive outside the uterus. By the end of this stage, structural development has progressed sufficiently such that gas exchange is possible and neonatal survival can occur. Amniotic fluid is required for the canalicular stage to occur. Fetal lung growth is stimulated in part by the distending force of lung fluid in the airways, which occurs during fetal breathing and is inhibited by anhydramnios.[6]

Saccular Phase

The saccular phase encompasses the period from 26 weeks until term, when the last generation of airspaces of the bronchial tree evolve. During this stage, there is a decrease in interstitial tissue, and a thinning of the airspace, resulting in a smaller population of collagen and elastic fibers. Surfactant production begins in the lungs. At the end of each respiratory tract passage, smooth-walled sacculi form, coated with type I and type II pneumocytes. Lamellar bodies of the type II cells store surfactant, which is rich in phosphatidylinositol, a necessary component for alveolar stability. Neonatal lung stability correlates with the number of lamellar bodies present. In the absence of surfactant, the lung alveoli are prone to collapse.

Alveolar Phase

The last phase of lung development spans the period from approximately 32 weeks' gestation into early childhood. In addition to further surfactant production, lung development during this period is characterized by growth of more bronchioles and alveoli. This allows the gas-exchange tissues of the lungs to expand and makes them capable of moving more air as the neonate grows. This final stage of lung development primarily occurs during postnatal life, building on the several million alveoli already present.[5]

Understanding these processes provides important insight into the aberrations in development associated with pulmonary lesions. The failure of normal physical development of the lung at any phase can result in pathologic lesions and potential respiratory compromise.

KEY FEATURES FOR ASSESSMENT

Complete assessment of the thoracic structures includes evaluation of lung structure and appearance. The lung fields should appear homogeneous with no fluid collections present (Fig. 12-3). The size of the thorax relative to the fetal abdomen and the overall chest size relative to the size of the heart structures are nonspecific but are important components of evaluation. The cardiac circumference should be approximately 50% of the thoracic circumference. When the heart is large relative to thoracic size, further evaluation will determine if the chest is too small (potential pulmonary hypoplasia) or whether cardiomegaly is present. Abnormal cardiac axis or abnormal position within the chest may be a marker for displacement by a chest mass or a missing portion of the lung. Any abnormal cardiac position should prompt thorough evaluation of the lung fields. In addition to the homogeneous appearance of lung fields, the echogenicity of the lungs should also be assessed, with normal echogenicity being slightly greater than that of the fetal liver.

Adequate evaluation of the diaphragm requires sweeping side to side to assess continuity of the structure. The diaphragm will appear echolucent on ultrasound images (Fig. 12-4). Shadowing from the ribs may present a challenge to visualization of the entire diaphragm. Particular care should be taken to examine the posterolateral portions, where most defects will occur. It is important that diaphragm

FIG 12-3 Normal transaxial image of the fetal chest with four-chamber view of the heart. Normal cardiac position and axis. The bilateral lung tissue appears homogeneous.

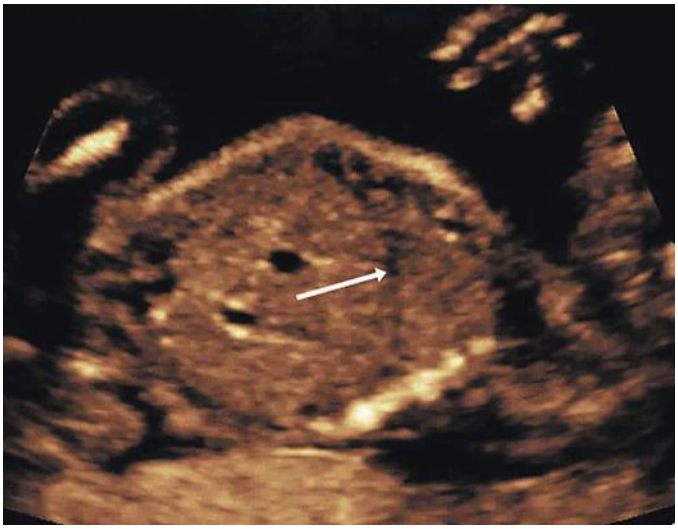

FIG 12-4 Sagittal section through the fetal chest showing the echolucent diaphragm (*arrow*). Note the convex shape of the diaphragm.

continuity is confirmed and not just assumed based on other organs that are not appreciated in the chest. The contour of the diaphragm should also be assessed, as some abnormalities may be associated with eversion of the diaphragm downward.

PULMONARY HYPOPLASIA

Pulmonary hypoplasia occurs as a spectrum characterized by incomplete development of unilateral or bilateral lung tissue. Clinically, it presents as respiratory compromise, with the severity reflecting the degree of reduction in lung size or in the number of lung cells, alveoli, or degree of bronchial branching.[7] The severity is related to the timing of the insult in relation to the stage of embryologic development.[8,9] Normal lung development requires adequate thoracic space as well as sufficient distention of the lungs through fluid exchange. Hypoplasia may therefore be caused by restriction or compression of developing fetal lung as well as by lack of amniotic fluid. Space-occupying lesions within the hemithorax, such as CDH, CPAM, massive cardiomegaly, and pleural effusion, can all cause pulmonary hypoplasia through mass effect, inhibiting normal formation of the pulmonary airways and alveoli. Thoracic musculoskeletal abnormalities, such as skeletal dysplasias and neuromuscular disorders, prohibit full expansion of the thoracic cage, with the restriction of chest size leading to hypoplasia.[10] Additionally, oligohydramnios associated with renal or urinary tract abnormalities or preterm premature rupture of membranes during crucial embryologic stages reduces the development of normal pulmonary components. The mechanism by which lack of amniotic fluid inhibits lung growth is unknown. However, inhibition of fetal breathing movements or increased loss of fetal lung fluid into the amniotic space have been suggested as two possible mechanisms for pulmonary hypoplasia in the setting of oligohydramnios. The incidence of neonatal pulmonary hypoplasia with premature rupture of membranes between 18 and 26 weeks' gestation ranges from 9% to 28%.[11,12]

Although it is relatively uncommon, the high mortality rate associated with pulmonary hypoplasia makes prenatal prediction critical for appropriate counseling. Subjective ultrasound assessment of relative chest size is helpful only in extreme cases (Fig. 12-5). Two-dimensional ultrasound measurements of fetal thoracic circumference, thoracic length, and the thoracic circumference to abdominal circumference (TC/AC) ratio have all been established (Table 12-1) but also have

FIG 12-5 Axial view through the chest in a fetus with pulmonary hypoplasia. Note the heart occupying nearly the entire thorax.

limited predictive value except at the extremes. The use of the lung-to-head ratio (LHR) and lung volume measurements has been described more frequently with CDH[10] (see later discussion under "Congenital Diaphragmatic Hernia"). Other methods, such as the quantitative lung index (QLI), have been employed in attempts to mathematically quantify lung volumes.[13,14] This index, which is obtained by calculating lung area/(head circumference/10)^2, has been described as a calculation that is fetal age independent. It has been reported to have minimal variation throughout pregnancy, with near constant parameters. Recent studies have provided reference ranges for normal 20- to 36-week fetal lung areas and LHRs (using the longest diameter and area tracing methods).[15] Unfortunately, these indirect measurements of lung volumes do not reliably and uniformly predict pulmonary hypoplasia, lung function, or likelihood of survival. The use of three-dimensional ultrasound to obtain volume measurements either directly or through the VOCAL technique (Virtual Organ Computer-Aided Analysis, General Electric Medical Systems) would seem more promising but have not been shown to be superior. MRI has also been used to calculate lung volumes (Fig. 12-6). The risk for pulmonary hypoplasia is assessed by comparing lung volumes measured by MRI with normal reference values based on the gestational age.[16] MRI has the advantage of more clearly delineating lung tissue from mediastinal structures and is not compromised by some of the limitations of ultrasound in the presence of oligohydramnios or high maternal body mass index (BMI). However, the ability of MRI to predict prognosis and survival has also been inconsistent, and the superiority of MRI in this regard remains controversial.[13,17]

Pulmonary hypoplasia is associated with a need for prolonged respiratory support and can even result in infant death despite aggressive postnatal management. It is important to understand that neither sonography nor MRI uniformly predicts hypoplasia except in extreme cases. Despite the limitations, measurements obtained from both

CONGENITAL PULMONARY AIRWAY MALFORMATION

Fetal chest masses include CPAM (formerly referred to as *congenital cystic adenomatoid malformation* [CCAM]) and bronchopulmonary sequestration (BPS). CPAMs are the most common lung lesions identified by fetal ultrasound imaging. On occasion, hybrid lesions are found, with imaging and pathologic features of both CPAM and BPS. Historically, CPAMs were thought to be infrequent, with reported incidence between 1 in 25,000 and 1 in 35,000 live births. With ongoing improvements in ultrasound resolution, smaller CPAMs are now being diagnosed with increasing frequency, and the incidence of CPAM is now reported to be as high as 1 in 12,000 live births,[18,19] accounting for 30% to 47% of fetal thoracic lung lesions.[20] These lesions are most often unilateral (95%) and are rarely bilateral. The right and left lungs are involved with equal frequency, with the lower lobes more commonly affected.[21,22] Current theories of pathogenesis suggest maturational arrest in bronchopulmonary development, resulting in dysplastic tissue distal to this segment.[23,24]

CPAMs have best been described as hamartomatous malformations of the lung characterized by abnormal branching of immature bronchioles. They communicate with the normal tracheobronchial tree and derive their blood supply from normal pulmonary circulation. These lesions develop during the pseudoglandular period, at 7 to 16 weeks.[25] Stocker and associates initially classified the most common types of CPAMs into three categories.[25] Type 1 is described as a lesion with a dominant cyst (3-10 cm in diameter); type 2 comprises multiple small cysts (0.5-2.0 cm diameter) that are distributed evenly and blend in with adjacent normal tissue; and type 3 is the small microcyst or what appears to be solid type of cyst on sonographic images (Fig. 12-7). Recently, Stocker added two subtypes: type 0 (acinar dysplasia) and type 4 (large peripheral cyst of the distal acinus lined with alveolar cells), expanding the classification of CPAMs into five subtypes.[26] However, this categorization was intended to be applied to resected lung specimens, rather than sonographic diagnoses. As the various types of CPAMs have little clinical significance, and the size and presence of larger cysts have more prognostic importance, the most common current practice is to describe the CPAM lesion as microcystic or macrocystic and to report its size.[27]

BPS describes a mass of nonfunctioning lung tissue that does not communicate with the bronchial tree. These lesions have aberrant systemic arterial blood supply (which is how they can be differentiated from CPAM), commonly arising from the descending thoracic aorta[28,29] (Fig. 12-8). BPS may be intralobar, with the same pleural covering as normal lung tissue, or extralobar, with a distinct and separate pleural covering. Almost all prenatally diagnosed cases of BPS are extralobar, above the diaphragm, and most frequently in the lower left side of the chest.[30] Extralobar lesions may occur within the abdomen, appearing as echogenic masses below the diaphragm[31,32] (Fig. 12-9).

The identification of CPAM is often aided by shift in the location or axis of the fetal heart. The affected lung tissue will appear to have

increased echogenicity with possible presence of discrete cysts (see Fig. 12-7). Sometimes the increased echogenicity is confined to a single lobe of the lung, most often a lower lung field (Fig. 12-10). Polyhydramnios may be seen in the later stages of pregnancy and might be a consequence of decreased swallowing of amniotic fluid owing to mass effect by the lesion resulting in esophageal compression or increased fluid production by the abnormal lung (Fig. 12-11).[33] With larger masses, there is a risk of fetal hydrops.

FIG 12-6 Magnetic resonance imaging (MRI) obtained in a 29-year-old pregnant woman at 30 weeks' gestation in whom detailed prenatal ultrasound depicted a normal fetal chest and fetal abdomen; MRI was performed because placenta accreta was suspected. Coronal single-shot rapid acquisition with relaxation enhancement (T2-weighted MR image 8/90, 4-mm section) of the fetal chest and fetal abdomen shows lungs (*arrows*) with high signal intensity. Use of this sequence facilitated easy identification of the lungs and planimetry. (From Williams G, Coakley FV, Qayyum A, et al: Fetal relative lung volume: quantification by using prenatal MR imaging lung volumetry. Radiology 233:457, 2004.)

The overall prognosis for CPAM lesions has improved considerably, in part owing to the diagnosis of smaller lesions but also because of prenatal therapy for larger masses. For the individual patient, the natural history and prognosis depend primarily on the size of the lesion, the presence of mediastinal shift, and fetal hemodynamic alterations.[34] The presence of hydrops without therapy is associated with a poor outcome and is generally an indication for fetal intervention.

Because the outcome of CPAM is most closely related to the size of the mass, attempts have been made to quantify lesion size to provide prognosis. The CVR is one approach used for risk assessment and patient counseling.[35] The volume of the chest mass is calculated by multiplying the maximal length, width, and depth dimensions (in cm) of the lesion: craniocaudal × anteroposterior × mediolateral dimensions). This product (in cm^3) is then multiplied by a correction factor of 0.52, resulting in a calculated lesion volume (formula for determining volume of a prolate ellipsoid). Then, to control for gestational age, this estimated volume is divided by the fetal head circumference (in cm) (Fig. 12-12):

$$\text{CVR} = (\text{length} \times \text{width} \times \text{depth} \times 0.52)/\text{head circumference}$$

In calculating CVR, it is important to include the margins of the lesion and to measure its maximal dimensions (Fig. 12-13).

CPAMs tend to stabilize in size in the late second/early third trimester, at a mean gestational age of 26 weeks. However, in some cases these lesions may continue to grow late into the third trimester. The size of the lesions, the variable growth behavior, the presence of a dominant cyst, and possible systemic venous obstruction all play a role in prognosis and in potential development of hydrops.

For an individual patient, the volume of the lesion relative to the size of the fetus, as measured by the CVR, is the best predictor of both prenatal development of hydrops and the presence of respiratory symptoms at birth. A CVR greater than 1.6 is associated with risk for fetal hydrops. A maximum CVR greater than 1.0 at any point in gestation is associated with respiratory symptoms at birth and an increased risk of requiring neonatal surgical intervention (positive predictive value 75%; negative predictive value 98%).[36] Hydrops is associated with close to 100% mortality rate and is considered an indication for prenatal therapy.[37] Open fetal surgery has been offered to patients with

FIG 12-7 **A,** Macrocystic congenital pulmonary airway malformation, type 1, with several sizable cysts in the left-sided chest mass. **B,** Echogenic congenital pulmonary airway malformation, type 2, within the chest, displacing the heart. Small peripheral cysts are seen. **C,** Displacement of the fetal heart toward the right facilitates identification of homogeneous left-sided mass. The solid-appearing mass is consistent with congenital pulmonary airway malformation, type 3. No discrete cysts are seen. Small amount of normal-appearing lung is present on the right. LT, left thorax; RT, right thorax.

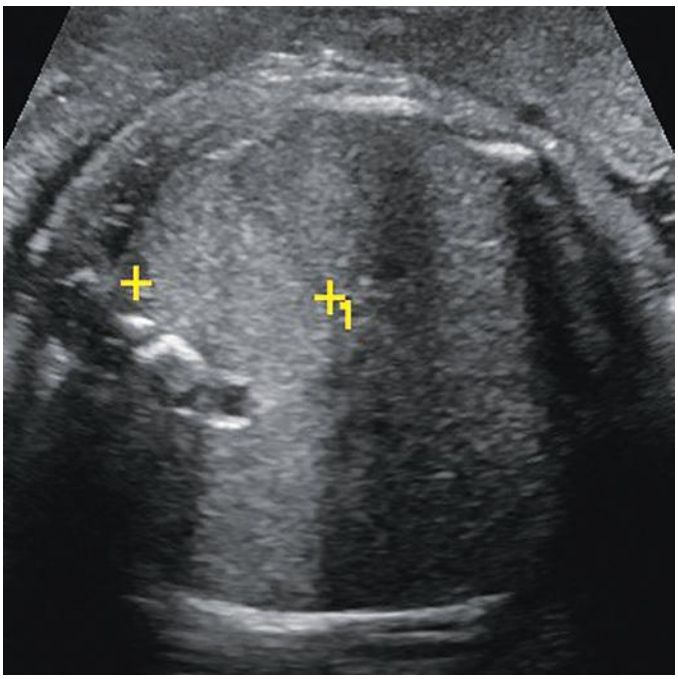

FIG 12-9 Axial sonographic image through the fetal upper abdomen demonstrating a subdiaphragmatic sequestration.

large microcystic CPAM lesions in the setting of hydrops or early decompensation of the fetus.[38] Survival rates of 52% have been reported, with mean gestational age at delivery of 31.3 weeks.[39] The associated risks including preterm labor, preterm rupture of membranes, fetal demise, and potential maternal complications have to be balanced against high risk of mortality for the fetus. Less invasive approaches including cyst aspiration have been performed as temporizing measures to slow disease progression and to determine if thoracoamniotic shunting will be effective. Placement of thoracoamniotic shunts in hydropic fetuses results in an overall survival rate approaching 60%.[39]

Prenatal administration of corticosteroids has been shown to be an effective alternative to the more invasive surgical approach.[40,41] When administered in the setting of CPAM and fetal hydrops, reversal of hydrops is reported in 78% of cases, with 83% survival rate to neonatal discharge.[41-43] Additionally, when corticosteroids were administered in the setting of CPAM with CVR greater than 1.6, hydrops did not develop.[43] Ongoing research is focused on ideal timing, dosing, and selection of candidates for steroid therapy.

Management of CPAM includes observation for signs of lesion growth or development of hydrops with serial scans every 2 weeks (Fig. 12-14). For patients at highest risk of hydrops (i.e., CVR > 1.6), weekly assessment may be appropriate. Frequent observation is recommended until there is evidence of a plateau in growth and stabilization in size of the lesion based on CVR measurements. Corticosteroid

administration may be considered if CVR is more than 1.6 and should be offered if signs of hydrops are present, without a single dominant cyst. If a single dominant cyst is noted within the lesion, in the setting of hydrops or decompensation, percutaneous ultrasound-guided drainage of the cystic lesion can be considered. In the absence of contraindications, term delivery is recommended. If the maximum CVR measures more than 1.0 at any point during the pregnancy, delivery at a tertiary care center should be considered because of the possible need for neonatal respiratory support.[36]

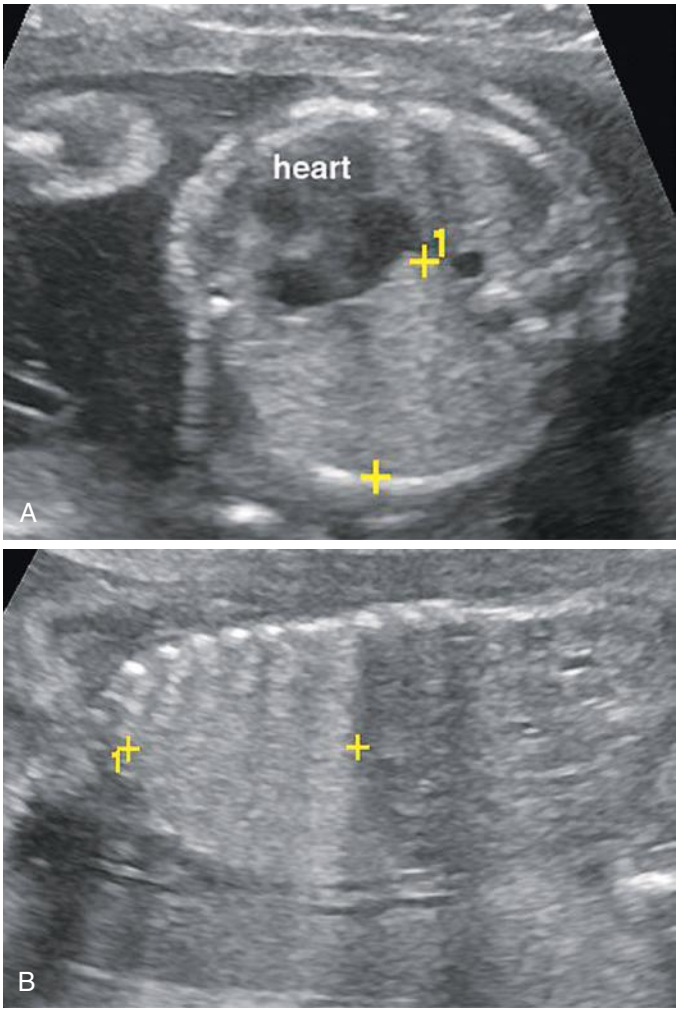

FIG 12-10 Homogeneous, echogenic chest mass shown in axial (**A**) and sagittal (**B**) views, consistent with type 3 congenital pulmonary airway malformation.

BRONCHOGENIC CYST

Bronchogenic cysts result from abnormal budding of the primitive esophagus and tracheobronchial tree during embryogenesis. Because they form between 4 and 8 weeks' gestation, prior to the development of distal airways, they rarely connect to a normal bronchus. Lesions arising before or during the separation of the embryonic foregut are located in the mediastinum (30%). The more common location is within the lung parenchyma, where the lesion arises after separation of the airway and the esophagus (70%).[44] The cyst wall is lined with ciliated epithelium and contains structural elements of the airway, including cartilage, smooth muscle, mucous glands, and respiratory epithelium.[45]

Bronchogenic cysts usually appear as a single anechoic unilocular cyst located in the central area of the lung parenchyma[45] (Fig. 12-15); they may also present as multiple cysts. Most are right-sided, near the midline, and in close proximity to the tracheobronchial tree. On rare

occasions, they migrate to the perihilar area or even subdiaphragmatic regions.[46] Cyst size is variable, ranging from 2 to 10 cm in diameter.[47] Bronchogenic cysts may be difficult to distinguish from macrocystic CPAM with a single dominant cyst, but the location and the absence of surrounding echogenic lung tissue characteristic of CPAM will aid in reaching the correct diagnosis.

Bronchogenic cysts can enlarge with advancing gestation and cause compression of surrounding normal lung parenchyma. The compression of the mediastinum and the surrounding lung tissue may be associated with hydrops as well as pulmonary hypoplasia.[48] In utero aspiration of the cyst can be performed if there is evidence of hydrops or compromise of cardiac function; thoracoamniotic shunting will decompress enlarging cysts and may reverse the mediastinal compression and hydrops. Most often these lesions are closely followed and managed in the neonatal period with thoracotomy and cyst excision. Wedge resection, segmental resection, and lobectomy have been described to improve neonatal respiratory status.[49]

The differential diagnosis of a sizeable cystic lesion within the fetal chest also includes neurenteric cyst. Neurenteric cysts are posterior enteric remnants that result from incomplete separation of the notochord from the foregut in the 3rd to 4th weeks of embryogenesis.[50-53] Approximately 90% of neurenteric cysts occur in the right posterior mediastinum, superior to the carina, and about 50% are associated with vertebral abnormalities such as scoliosis, segmentation abnormalities with hemivertebrae, and butterfly vertebrae. The cysts may be unilocular, though often they have an internal septation. Neurenteric cysts can be distinguished from the other cystic lesions discussed based on their association with vertebral anomalies.

BRONCHIAL ATRESIA

Bronchial atresia is on the spectrum of developmental disorders related to the variable timing of airway obstruction. Congenital bronchial atresia is a relatively rare lesion characterized by localized atresia or stenosis of a segmental bronchus. It results from focal obliteration of a proximal segmental or subsegmental bronchus, with normal development of the distal structures. Bronchial atresia can involve lobar, segmental, or mainstem bronchi, more often affecting segmental or subsegmental bronchi. Prenatally diagnosed CLE can be caused by lobar bronchial atresia.[44] The short atretic segment leads to mucous accumulation within the distal bronchi, resulting in a bronchocele.[45]

Prenatal ultrasound findings of bronchial atresia demonstrate an extremely large, massively overexpanded unilateral lung or lung segment. The mass will typically result in mediastinal shift from mass effect, with compression of chest structures and often with eversion of the ipsilateral hemidiaphragm[54] (Fig. 12-16). Contralateral lung volumes may appear small. Branching fluid-filled structures may be seen within the enlarged echogenic lung, representing dilated airways peripheral to the central obstructed bronchus.[45,46] Serial sonograms should be performed to delineate anatomy, assess for enlargement of the lesion and development of hydrops, and search for possible concomitant anomalies. MRI may be helpful to identify the atretic airway and to distinguish this lesion from a large CPAM (Fig. 12-17). When these lesions are suspected, MRI acts as an adjunctive imaging tool, assisting with tissue characterization, determining level and location of atresia, and delineating complex anatomy. As lesions enlarge and change, they may affect the development of surrounding lung, obstruct venous return, and result in lung hypoplasia.[49]

Ultrasound differentiation between bronchial atresia and CPAM may be challenging, as the large echogenic lung appears very similar to microcystic (type 3) CPAM. The central versus peripheral location of cystic components and the involvement of multiple lobes of the lung should raise suspicion for bronchial atresia and may prompt further imaging. Serial sonograms are recommended, as these lesions typically enlarge during pregnancy. In this way, they differ from CPAMs, which typically plateau in size during gestation. The risk of hydrops is increased with larger lesions, but the ability to prognosticate based on lesion size at the time of initial diagnosis or based on CVR measurements is not very reliable with bronchial atresia.[48]

Bronchial atresia more commonly affects segmental or subsegmental bronchi, and therefore, it is often asymptomatic or may not present until adolescence.[55,56] Prenatally diagnosed segmental CLE caused by bronchial atresia has been reported and is managed surgically in the newborn period.[57] Although segmental and lobar bronchial atresias may be compatible with ex utero survival, the outcome for mainstem

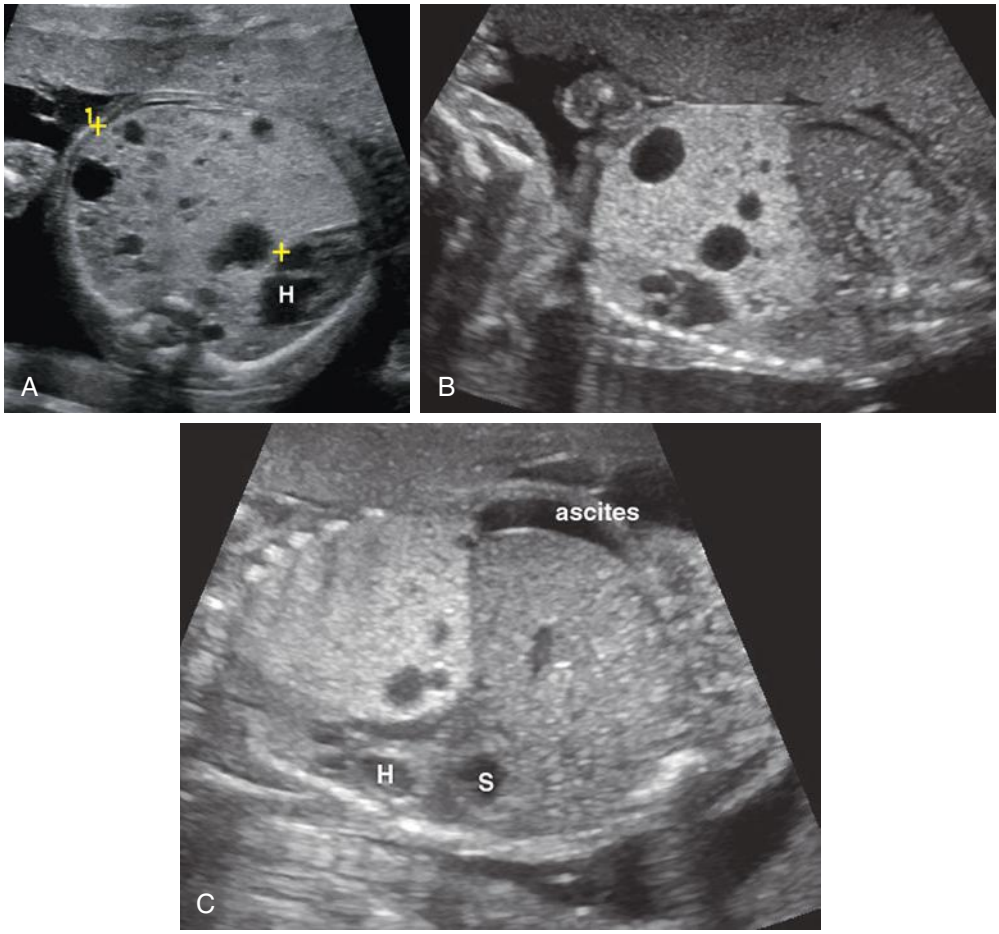

FIG 12-14 Large solid and cystic type 2 congenital pulmonary airway malformation shown on axial (**A**) and coronal (**B** and **C**) views. Note the small amount of ascites present at the upper abdomen. There is marked leftward displacement of the heart (H). S, stomach.

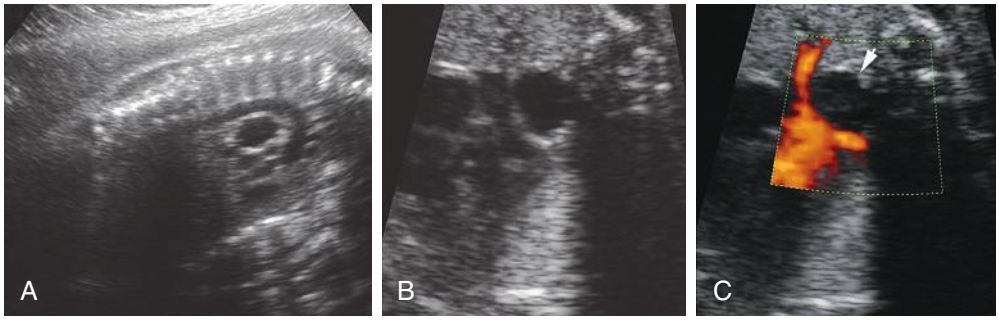

FIG 12-15 Bronchogenic cyst (*arrow*) in fetus at 28 weeks' gestation, shown in longitudinal (**A**) and transverse (**B**) planes and transverse image with power Doppler sonographic evaluation (**C**).

bronchial atresia is grim.[47] Optimal management for a fetus with mainstem bronchial atresia remains uncertain. It is possible that fetal surgical resection may provide the best opportunity for survival, although benefits have not been clearly documented. Prenatal intervention to remove the enlarged lung segment has been attempted; reported outcomes have been poor to date, with prematurity remaining a significant complication.[58] In one reported case, maternal betamethasone administration was thought to explain the lack of fetal hydrops. However, the lung lesion was smaller (CVR 2.6) and may have represented only partial bronchial obstruction.[48]

It is recommended that a fetus with bronchial atresia be delivered in a tertiary care center because of possible pulmonary hypoplasia and potential for air trapping in the alveoli supplied by the affected bronchi. There is a wide spectrum of involvement and severity with this lesion. When a larger lesion is noted, ex utero intrapartum treatment (EXIT) and a primed extracorporeal membrane oxygenation (ECMO) circuit may be considered for delivery.[59] Overall prognosis remains poor for the larger lesions identified by massive unilateral hyperplasia, marked distention of the obstructed bronchi, bronchiectasis, as well as fluid-filled airspaces seen at the time of postnatal surgery.

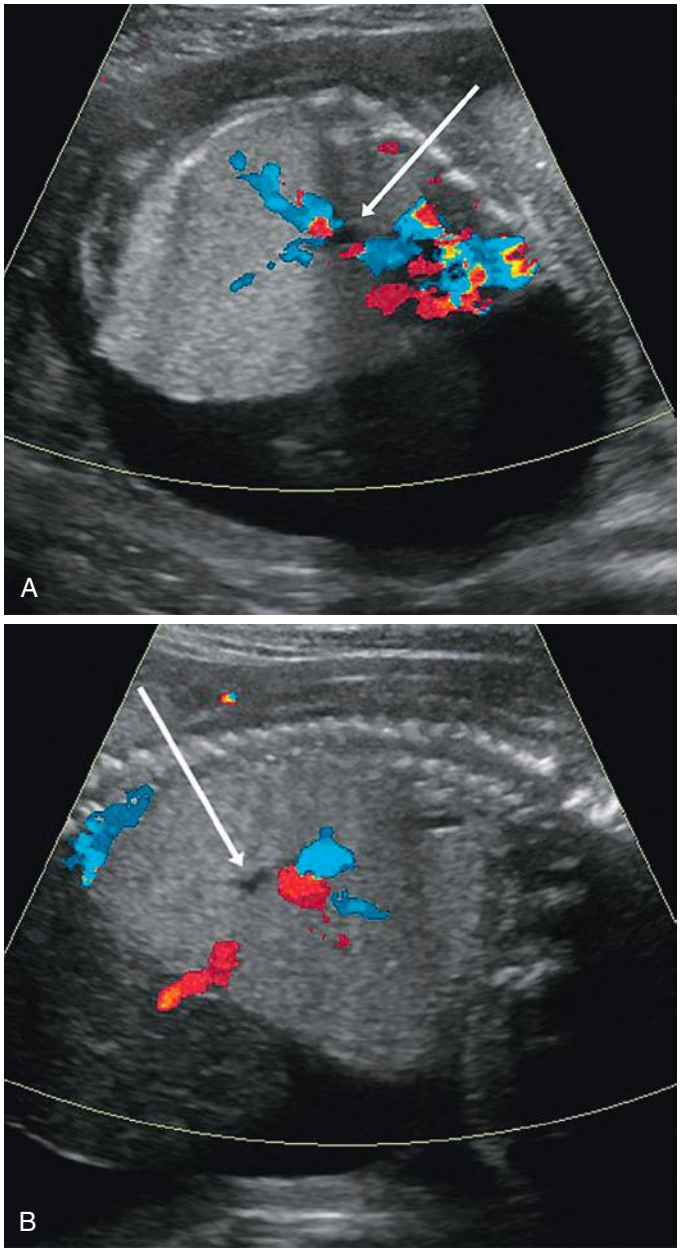

FIG 12-16 Color Doppler images through fetal chest. Axial (**A**) and sagittal (**B**) images demonstrate markedly enlarged echogenic lung, with eversion of the hemidiaphram, consistent with bronchial atresia. Note fluid-filled airway (*arrow*).

CONGENITAL LOBAR EMPHYSEMA

CLE is a developmental abnormality of the lower respiratory tract that is characterized by entrapment of fluid in the lungs, resulting in hyperinflation of one or more of the pulmonary lobes. Bronchial atresia, with an atretic portion of the bronchus, is one of many causes of CLE. The prevalence prenatally is not certain, but it is reported to affect approximately 1 in 20,000 to 1 in 30,000 newborns.[60] It has been postulated that CLE may result from intrinsic obstruction caused by defects in the bronchial wall, such as deficient or dysplastic bronchial cartilage leading to obstruction of the lower airway. Extrinsic compression causing obstruction may also result from aberrant cardiopulmonary vasculature or other intrathoracic lesions, including anomalous pulmonary venous return, duplication cysts, teratomas, or bronchogenic cysts.[61,62] This results in altered distal development and diffuse bronchial abnormalities. Approximately 25% of the time, CLE is caused by an intrinsic obstruction.[63] Whether the bronchi are underdeveloped or obstructed, collapsed distal lung prohibits normal lung fluid homeostasis. This, in turn, leads to progressive lobar hyperinflation. Postnatally, airway obstruction leads to a "ball-valve" mechanism in which a greater volume of air enters the affected lobe during inspiration than leaves during expiration. This air trapping in distal areas of the lung results in emphysema.[64]

Sonographic appearance of the fetal thorax with CLE demonstrates a homogeneous echogenic lung mass, usually without cystic components. This mass appears as a unilateral lesion because of the inflated lung distal to the obstruction. The mass often crosses the midline and results in displacement and compression of the heart.[65] Mediastinal shift, polyhydramnios, and fetal hydrops can also be seen and are predictors of severe respiratory distress and increased risk of death. Ninety-five percent of lesions occur in the upper and middle lobes and are unilateral.[66] The lower pulmonary tissue is typically normal in appearance. Mass effect may result in downward displacement of the diaphragm. Blood supply is derived from the normal pulmonary artery and vein. CLE is most often diagnosed in the neonatal period secondary to respiratory symptoms.

The differential diagnosis of an echogenic lung mass is diverse and includes CPAM, BPS, and unilateral bronchial atresia. BPS may be recognized if anomalous arterial supply arising from the aorta is observed. Dilated fluid-filled airways will not be seen in CPAM and when they are noted, the differential diagnosis is limited to CLE or bronchial atresia. Because CLE occurs secondary to obstruction, it may resolve during the course of the pregnancy. CPAM typically demonstrates a plateau or gradual decrease in lesion size after 26 weeks' gestation. CLE should be considered if a striking reduction in size of a chest mass is observed over a short interval, as relief of the obstruction may result in resolution of hyperinflated echogenic lung. Unfortunately, resolution of in utero findings with CLE does not always confer normalization of lung function after birth. As with bronchial atresia, fetal MRI may help confirm and delineate the underlying pathologic process.

The appropriate treatment of CLE in neonates with respiratory distress is surgical resection of the affected lobe.[67] Historically, open thoracotomy was performed. Recent advances in minimally invasive thoracoscopic surgery have resulted in decreased morbidity associated with neonatal resection.[68]

CONGENITAL HIGH AIRWAY OBSTRUCTION SYNDROME

Congenital high airway obstruction syndrome (CHAOS) results from obstruction of the fetal upper airway. This obstruction, whether partial or complete, is most often secondary to atresia or stenosis of the larynx or trachea. Laryngeal agenesis, subglottic stenosis or atresia, and laryngeal webs or cysts are also reported causes of this condition.[69] When complete atresia is seen, tracheoesophageal fistula is often present.[70] Although rare, with an uncertain incidence,[71,72] it is understood that tracheal atresia occurs secondary to deficient recanalization of the upper airway at about the 10th week of gestation.[71] The prenatal diagnosis of CHAOS was first described in the late 1980s.[73] The increasing frequency of CHAOS diagnosis and reporting has allowed for a better understanding of the pathophysiologic mechanisms (Fig. 12-18).

Although some fluid secreted by the fetal lung is absorbed through the tracheobronchial tree, the bulk of secreted fluid is released into the amniotic sac. When an obstruction is present in the tracheobronchial

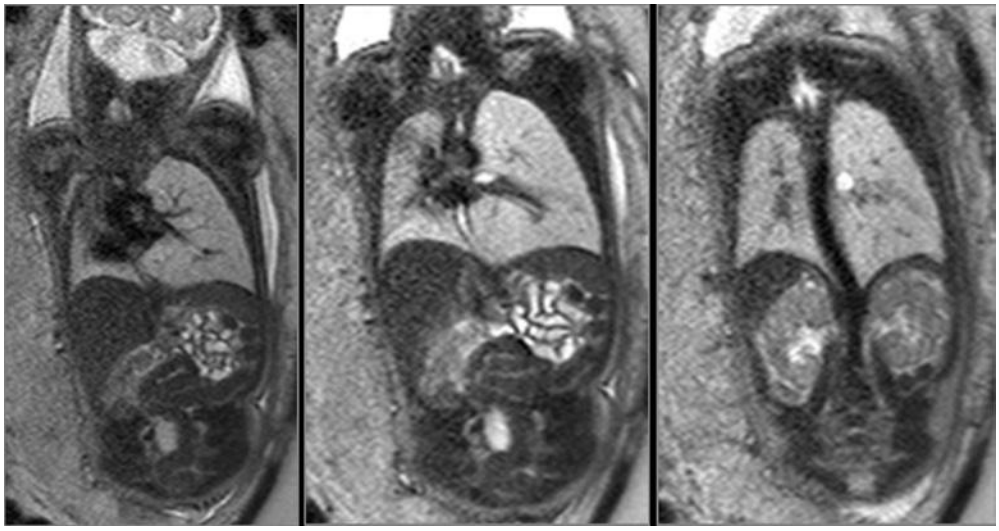

FIG 12-17 Coronal fetal magnetic resonance images showing unilateral hyperexpanded left lung. Note the left perihilar T2-weighted hyperintense structure consistent with a dilated, fluid-filled airway.

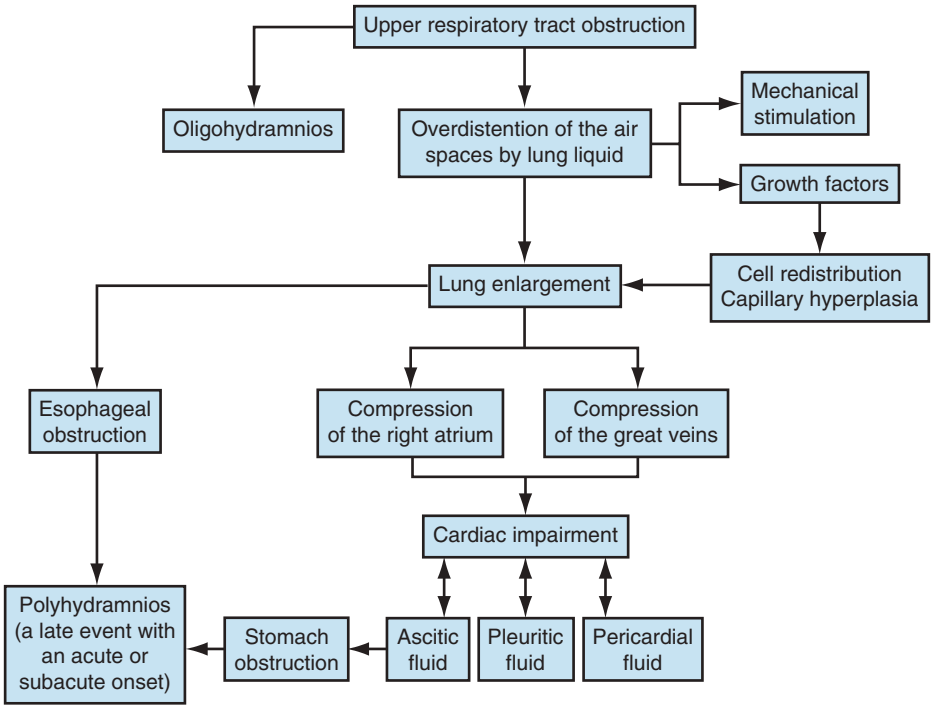

FIG 12-18 The pathophysiologic mechanisms and sonographic findings of upper respiratory atresia sequence in congenital high airway obstruction syndrome. (From Kassanos D, Christodoulou CN, Agapitos E, et al: Prenatal ultrasonographic detection of the tracheal atresia sequence. Ultrasound Obstet Gynecol 10:133, 1997.)

tree and prevents fluid egress into the amniotic sac, the accumulated fetal lung fluid causes increased intratracheal pressure and distention of the lungs. The enlarged fetal lungs compress the heart, resulting in central deviation of the cardiac structures (Fig. 12-19). The classic sonographic findings of high upper airway obstruction, which may be more readily appreciated on coronal or sagittal views, include bilateral symmetric enlarged hyperechoic fetal lungs, flattened or everted hemidiaphragms, and dilated, fluid-filled trachea.

Increased intrathoracic pressure, decreased venous return to the heart, and impaired cardiac contractility can lead to the development of ascites, placentomegaly, and nonimmune hydrops with effusions and polyhydramnios.[74] Compression of the esophagus by dilated lungs may result in impaired swallowing, a potential additional contributing factor to the later development of polyhydramnios seen in some, but not all, cases of CHAOS.[75]

Spontaneous resolution of the ultrasound findings of CHAOS has been reported.[70,76] This may result from spontaneous perforation of an obstructing web with decompression of the lungs as the fluid is released into the amniotic cavity. Recurrent obstruction is possible and patients should be followed with serial sonograms even after apparent resolution. Unfortunately, resolution of the ultrasound findings is not always associated with improvement in lung function, and there may be

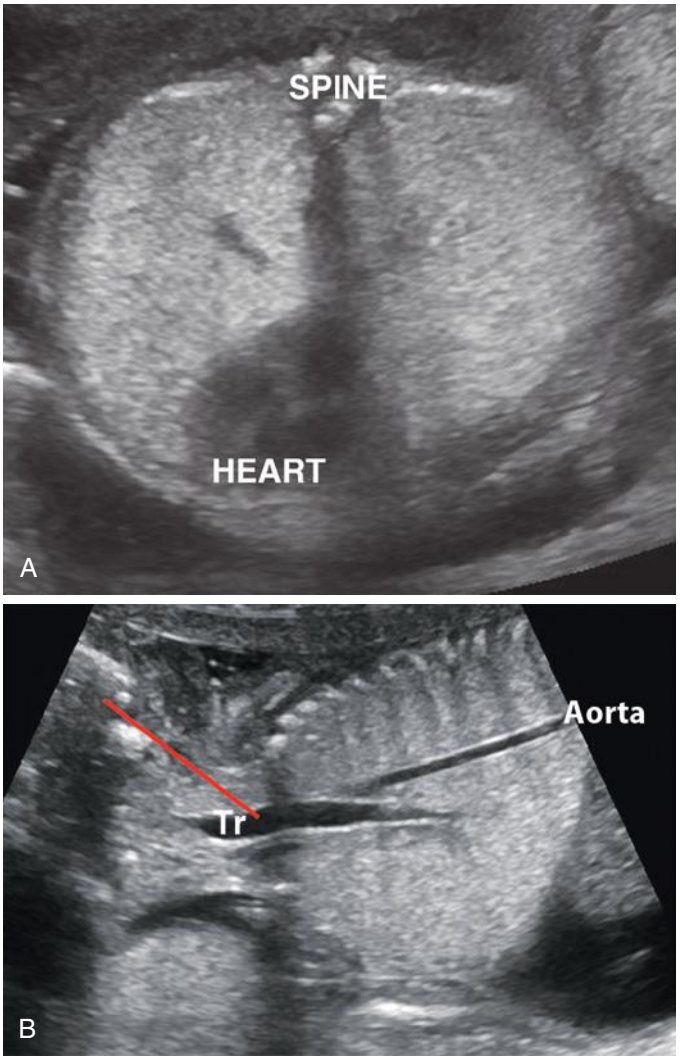

FIG 12-19 Congenital high airway obstruction syndrome (CHAOS). Two views, axial (**A**) and coronal (**B**), showing markedly enlarged hyperechoic bilateral fetal lungs. The heart is in the midline, displaced anteriorly, and the fluid-filled trachea (Tr) is visualized (*red line*).

significant pulmonary compromise at birth even after apparent prenatal resolution.

Because of the lack of a patent airway, CHAOS is frequently lethal. There are also high reported rates of intrauterine fetal demise.[74] Prenatal sonographic diagnosis allows improved neonatal survival, and antenatal recognition of CHAOS allows for a multidisciplinary delivery management plan. MRI may allow for improved visualization of dilated airways with detection of the level and structure of the obstruction,[77] and these findings may assist with counseling and delivery planning[69,78] (Fig. 12-20). EXIT may be offered if the location of the obstruction is compatible with establishment of an airway and CHAOS is an isolated finding.[70,79] By improving identification of the level of obstruction, sonography and MRI have allowed appropriate delivery planning. Postnatally, diaphragmatic dysfunction is commonly due to diaphragmatic stretching, and survivors may require extended ventilator support.[74]

Although CHAOS is most often an isolated finding, it may be seen with syndromes or isolated unilateral lung agenesis (Figs. 12-21 and 12-22). Fraser syndrome, an autosomal recessive genetic disorder, includes microphthalmia, cryptophthalmos, polydactyly, and syndactyly in association with upper airway obstruction.[80] Other syndromes that have been reported in association with CHAOS are cri du chat syndrome, short-rib polydactyly syndrome, and 22q11.2 deletion syndrome.[81] A thorough anatomic survey identifying additional findings allows for optimal counseling regarding anticipated prognosis and inheritance implications for future pregnancies.[74]

The differential diagnosis of CHAOS includes bilateral CLE, bronchial atresia, or bilateral CPAM. CHAOS must be distinguished from extrinsic causes of tracheolaryngeal obstruction such as lymphatic malformation, cervical teratoma, and vascular rings, as accurate distinction is crucial for management planning.[70]

CONGENITAL HYDROTHORAX

Congenital fetal hydrothorax, also known as primary pleural effusion, is the abnormal accumulation of fluid in the pleural space. The estimated incidence of hydrothorax has been reported as 1:10,000 to 1:15,000 pregnancies[82] and may initially be either unilateral or bilateral. As the fluid increases, mass effect may result in compression of adjacent thoracic structures, compromising heart function as well as lung development. It is worth remembering that fetal pleural effusions can be associated with nonimmune hydrops—either as a primary cause or as a consequence. Unilateral hydrothorax in particular can lead to nonimmune hydrops if the effusion is large and asymmetric, as these effusions can cause a mass effect with cardiomediastinal shift and eversion of the ipsilateral hemidiaphragm. Primary hydrothorax as a cause of nonimmune hydrops should be suspected with a very large, unilateral effusion or markedly asymmetric bilateral effusions; this cause of nonimmune hydrops is important to recognize, as it can be effectively treated with in utero percutaneous aspiration or thoracoamniotic shunting. Such treatment may be lifesaving for an otherwise normal fetus.

Isolated pleural effusions present as echolucent fluid collections between the lungs and chest wall. They are differentiated from pericardial effusions by the extension of fluid around the lung structures (Fig. 12-23). Sonographic findings range from small amounts of fluid adjacent to the normal-appearing lung (typically more prominent in the anterior chest) to larger effusions causing mediastinal shift and downward displacement of the diaphragm (Fig. 12-24). Polyhydramnios is often seen with larger pleural effusions.

The natural history of hydrothoraces varies from spontaneous prenatal resolution (22%) to generalized hydrops fetalis or even death. The mortality rate for isolated effusions has been reported to be between 15% and 36%.[83,84] A worse prognosis is associated with bilateral effusions, the presence of hydrops, persistence of effusions, or premature delivery.[85] When generalized hydrops fetalis is present, mortality rate may approach 95% without treatment (Fig. 12-25).[86,87] Prenatal therapy including drainage and shunting of the pleural effusion is reported to improve the survival rate to over 70%.[88-91] The presence of polyhydramnios tends to be associated with a poorer prognosis,[85] in part because of the association with larger effusions and presence of hydrops.

The most common cause of isolated pleural effusion is chylothorax. Prenatal confirmation is made by ultrasound-guided thoracentesis and identification of high lymphocyte count (>80%) in the aspirated fluid.[92] Aspiration of the fluid and drainage of the chest allows for diagnosis, in addition to potential therapeutic benefits.[89] Drainage also allows for pulmonary reexpansion and evaluation of lung tissue to ensure that no underlying abnormalities are present. It also may facilitate evaluation of the heart and mediastinal structures to assess for possible associated structural abnormalities. Impaired venous return

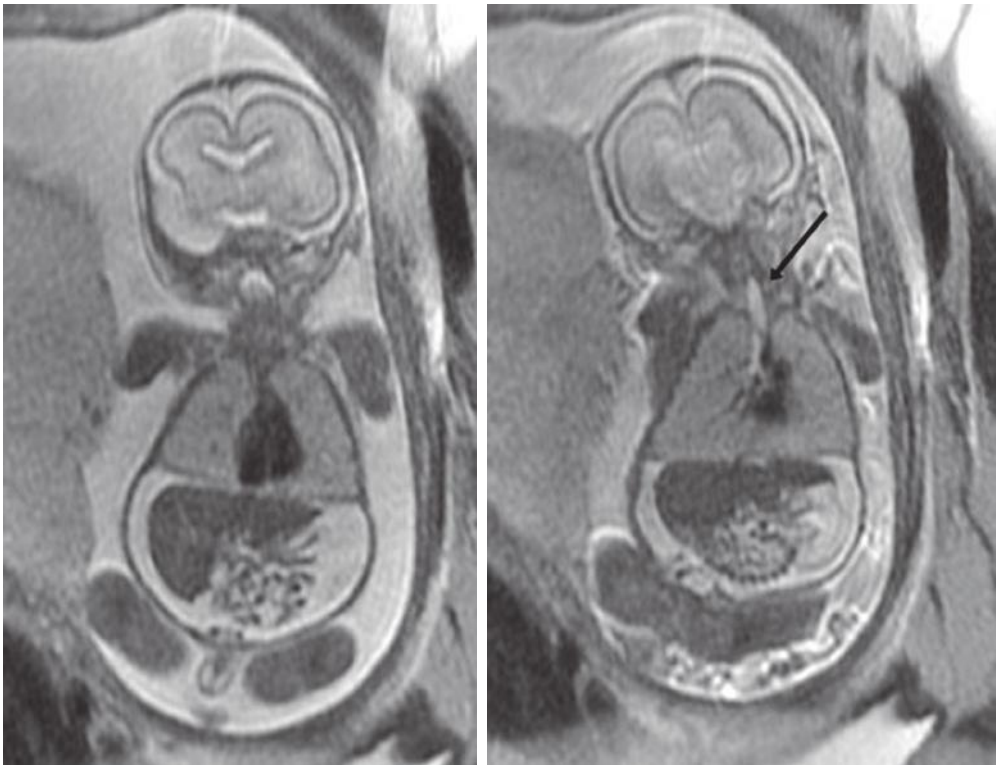

FIG 12-20 Coronal T2-weighted fetal MR images showing enlarged bilateral lungs with eversion of the diaphragm and fluid-filled trachea (*arrow*) consistent with congenital high airway obstruction syndrome, owing to laryngeal atresia. Associated hydrops with moderate volume of fetal ascites is evident.

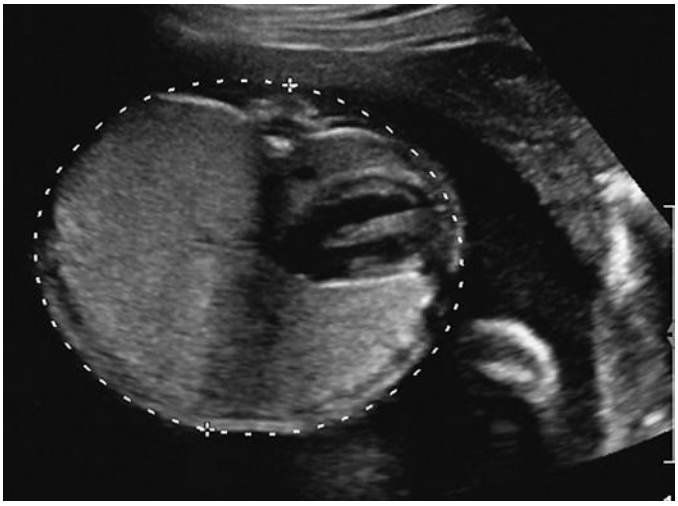

FIG 12-21 Transverse ultrasound image shows marked deviation of the fetal heart toward the left. The right lung appears enlarged and echogenic, suggesting unilateral bronchial atresia.

secondary to compression and tamponade-like effects on the heart may result in the development of hydrops. When pleural effusions are first seen in a fetus with hydrops, it can be challenging to identify the underlying cause. Hydrops secondary to primary pleural effusion is usually associated with significant skin edema and with volume of pleural fluid significantly larger than the volume of ascites. In addition, hydrops most commonly results from unilateral effusion with associated mass effect, and less commonly it is the consequence of bilateral effusions. In the setting of fetal hydrops with bilateral effusions, attention should be paid to the relative size of the effusions and the presence

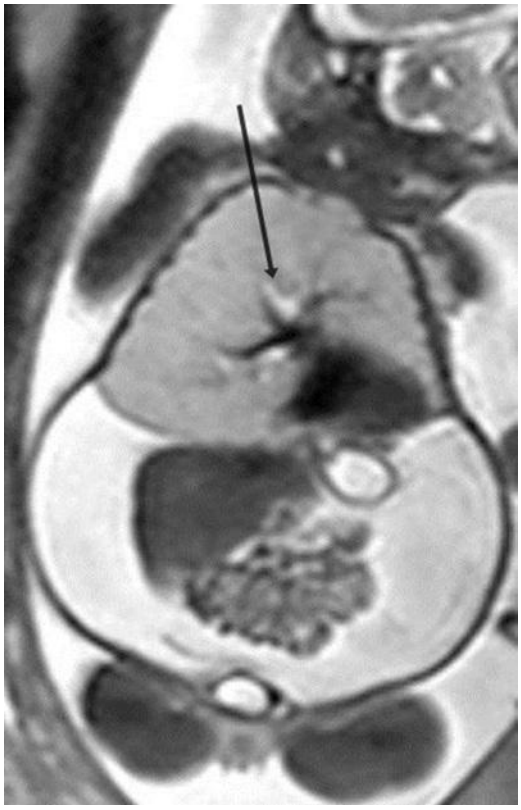

FIG 12-22 Coronal T2-weighted fetal magnetic resonance image of unilateral bronchial atresia with markedly enlarged right lung. Distended fluid-filled airway seen centrally (*arrow*). Associated hydrops with marked fetal ascites. The contralateral left lung was not visualized.

FIG 12-24 Large unilateral right pleural effusion causing significant mass effect with leftward cardiomediastinal shift.

FIG 12-25 Significant integumentary edema associated with large pleural effusion at 24 weeks' gestation. Patient underwent ultrasound-guided thoracoamniotic shunt placement and subsequently delivered a healthy infant at 38 weeks' gestation.

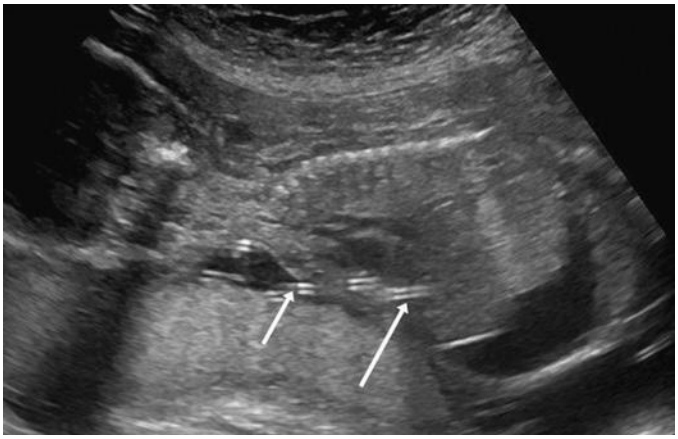

FIG 12-26 Thoracoamniotic shunt adjacent to and within the fetal chest (*arrows*). Though ascites is still present, there is no residual pleural fluid in the chest.

or absence of mass effect. Large primary hydrothorax can result in hydrops with development of contralateral pleural fluid, though typically there is significant discrepancy in volume and marked cardiomediastinal shift.

Fetuses whose effusions rapidly reaccumulate after aspiration may benefit from ultrasound-guided percutaneous placement of a thoracoamniotic shunt[93] (Fig. 12-26). Thoracoamniotic shunt placement allows for lung reexpansion, permitting normal development of compressed pulmonary tissue and resolution of mediastinal shift with improved cardiovascular function.[87] Resolution of significant hydrops occurs gradually after successful shunt placement. Preterm delivery prior to 32 weeks is more likely to result in neonatal demise of the fetus with significant pleural effusions; pulmonary hypoplasia remains a major complication for some neonates despite prenatal shunting. The most common complication of prenatal shunting is the need for shunt replacement because of obstruction or dislodgment (37%).[94]

Neonates with pleural effusions may be symptomatic with respiratory distress at birth from compression of otherwise normal lung by the fluid or from residual pulmonary hypoplasia.[95] Delivery in a tertiary care center is recommended owing to uncertainty regarding pulmonary function and need for resuscitation. For a newborn with a catheter in place at delivery, it is important to occlude the bidirectional shunt at the time of birth to prevent pneumothorax. Long term, there is increased risk of childhood asthma when prenatal pleural effusions were identified.[96]

Causes for congenital pleural effusions, in addition to primary chylothorax, include infection, congenital heart disease, genetic or chromosomal abnormalities, pulmonary lesions including CPAM, or other lesions such as CDH or tracheoesophageal fistula.[92] The two most commonly associated abnormalities are CDH and trisomy 21.[97,98] Alternatively, the fluid collection may be one of several findings seen in hydrops fetalis due to other causes.

Cystic or fluid-filled structures within the thorax such as CDH, cystic CPAM, bronchogenic cyst, and pericardial fluid may simulate pleural fluid collections or may be associated with pleural effusions. It is important to clearly delineate the anatomy to allow for appropriate diagnosis and therapy.

CONGENITAL DIAPHRAGMATIC HERNIA

CDH results from absence or deficiency of a portion of the diaphragm owing to incomplete formation of the structure, with subsequent herniation of abdominal contents into the fetal chest (Fig. 12-27). The incidence of CDH in the United States is estimated at 1088 cases per year, or 1 in 3836 live births.[99] The reported incidence may be lower than the actual incidence because of a higher rate of intrauterine demise and early (undiagnosed) neonatal death in infants with CDH.

CDH is most often a sporadic condition, and 85% of the defects are posterolateral and on the fetal left side (Fig. 12-28). Right-sided defects are seen in approximately 10% to 15% of cases, and 2% of defects occur bilaterally or centrally[102] (Fig. 12-29). Females and males are equally affected. The normal primitive diaphragm is formed by the end of the 8th week of gestation with development of the muscular diaphragm completed by the 14th week. Although the failure of fusion of the pleuroperitoneal canal occurs early in gestation, the herniation of intra-abdominal contents may not occur until later in fetal life, making small defects difficult to identify early in pregnancy. Most CDHs are detected at the time of the 18- to 20-week fetal anatomy sonogram, with a median gestational age at diagnosis of 19 weeks. An eventration of the diaphragm may appear as herniation of intra-abdominal contents into the fetal chest and can be mistaken for CDH. Eventration results from failure of muscularization of the otherwise intact primitive diaphragm and has a better prognosis.

It is frequently the abnormal position of the fetal heart that provides the first clue to the presence of a diaphragmatic defect. On a transaxial image through the thorax, a shift of the mediastinum and heart toward the right will be seen in most left-sided lesions. With a right-sided lesion, it is possible for the heart to appear in the usual location. Therefore, in every examination, care must be taken to assess the echogenicity and morphologic appearance of the intrathoracic contents, to assure that herniated bowel or liver is not misinterpreted as lung tissue. The presence of the fluid-filled stomach in the chest is easily recognized. A bowel-containing CDH with normal-appearing, normally located stomach at the left upper quadrant of the abdomen, which may occur with small left-sided lesions, is more challenging to detect. Review of real-time images may demonstrate peristalsis, allowing for recognition of herniated bowel, but it is often the echotexture of the intrathoracic tissue that raises suspicion (Fig. 12-30). The inability to visualize the fluid-filled fetal stomach is often associated with esophageal atresia but may also occur in some cases of CDH, and this

FIG 12-27 Pathologic specimen of intrauterine fetal demise associated with left-sided congenital diaphragmatic hernia. Failure of closure of the diaphragm allowed herniation of the bowel and stomach into the fetal chest. (Image courtesy of Mason Barr, MD.)

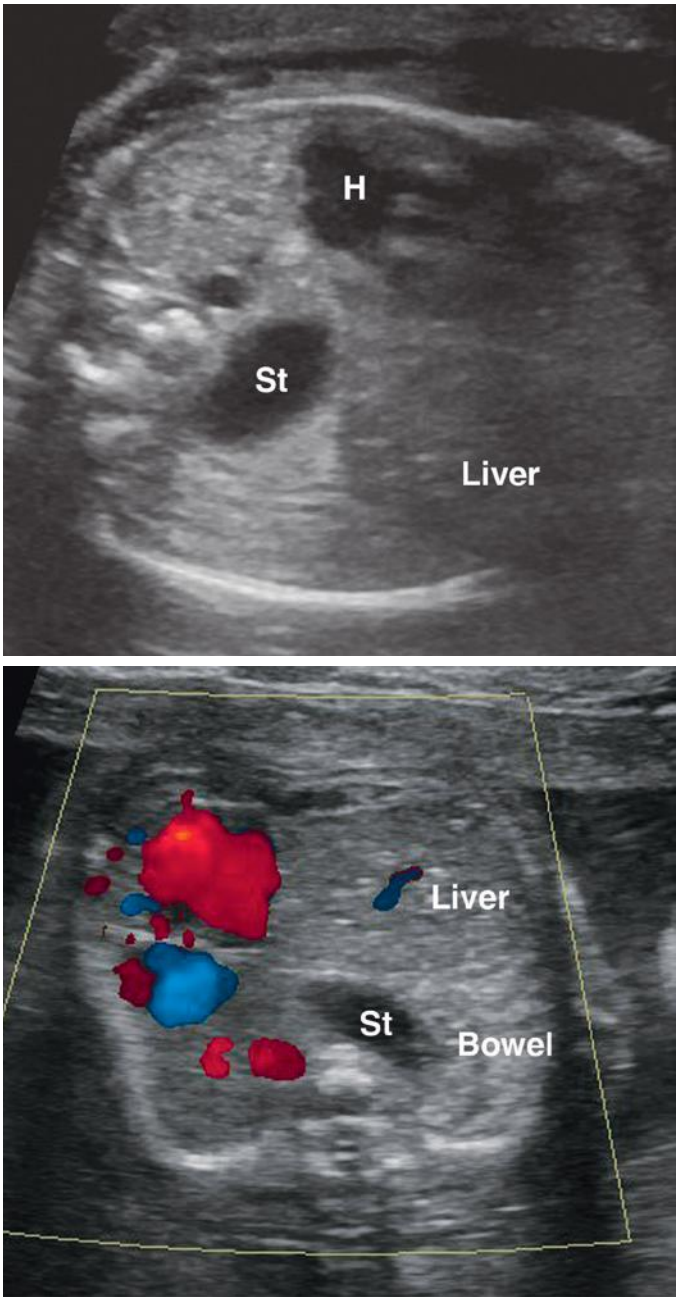

FIG 12-28 Two axial sonographic views through the chest in a fetus with a left congenital diaphragmatic hernia. Stomach (St), bowel, and portion of liver are herniated into the left hemithorax. Rightward shift of the heart (H) is also evident.

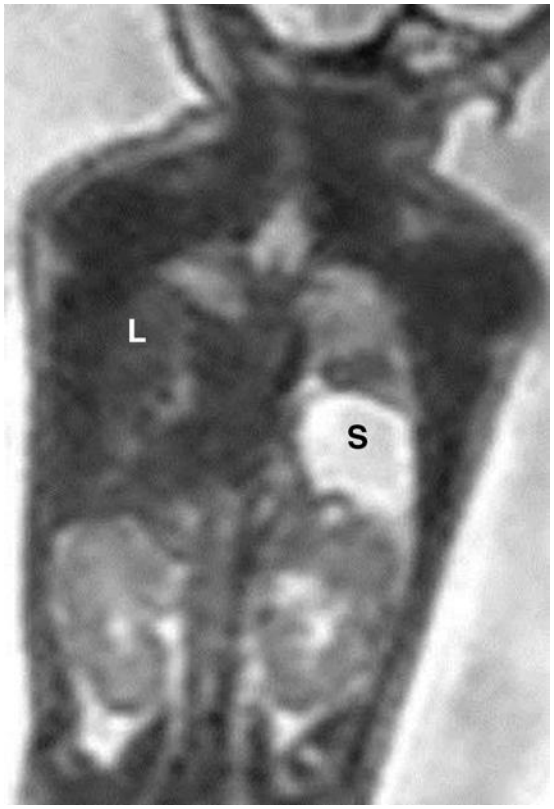

FIG 12-29 Coronal fetal magnetic resonance imaging showing bilateral congenital diaphragmatic hernia with liver (L) and stomach (S) herniated into the right and left hemithorax, respectively.

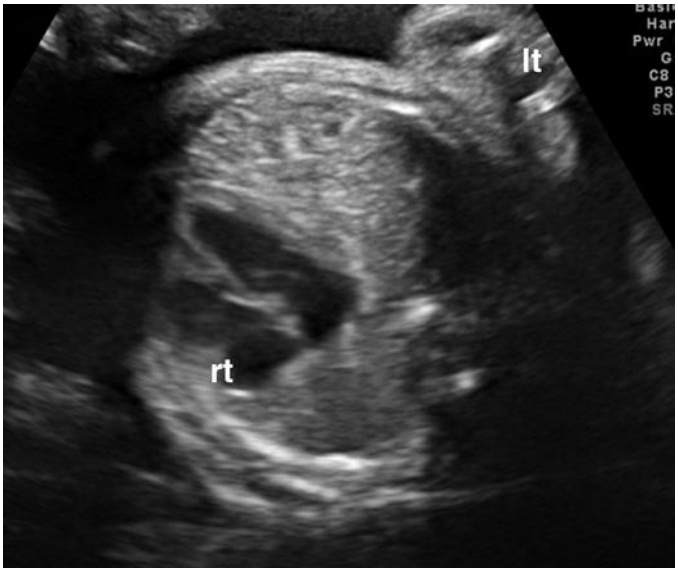

FIG 12-30 Transverse image through the fetal chest demonstrates mild rightward shift of the heart. The fluid-filled stomach (not shown on this view) was identified in the expected location at the left upper quadrant, within the abdomen. Heterogeneous echogenic material within the left hemithorax represents herniated, nondilated small bowel segments. lt, left thorax; rt, right thorax.

FIG 12-31 Parasagittal sonographic image with discontinuity and defect at the posterior aspect of the left hemidiaphragm. Herniation of the fluid-filled stomach and bowel into the left hemithorax.

FIG 12-32 Transverse plane through the fetal chest with left-sided congenital diaphragmatic hernia and associated rightward cardiomediastinal shift.

possibility should be considered in the differential diagnosis when no stomach is identified. A fluid-filled stomach noted at the expected level of the diaphragm (Fig. 12-31) or within the fetal chest facilitates the diagnosis of CDH (Fig. 12-32). The location of the stomach is also helpful in assessing the severity and the presence of other herniated abdominal contents, in particular the left lobe of the liver. With left CDH, liver herniation is more likely if the stomach is located in the mid- or posterior left chest. Polyhydramnios frequently accompanies CDH but is usually a late finding, seen most often in the third trimester.

Paradoxic motion of the hemidiaphragm with fetal breathing movements is diagnostic of a diaphragmatic abnormality. This observation is manifest by descent of one hemidiaphragm with ascent of the other, observed on coronal imaging during fetal inspiration.[100] This sign can be useful, particularly in patients in whom heart deviation is noted, but suboptimal sonographic resolution makes the diagnosis difficult.

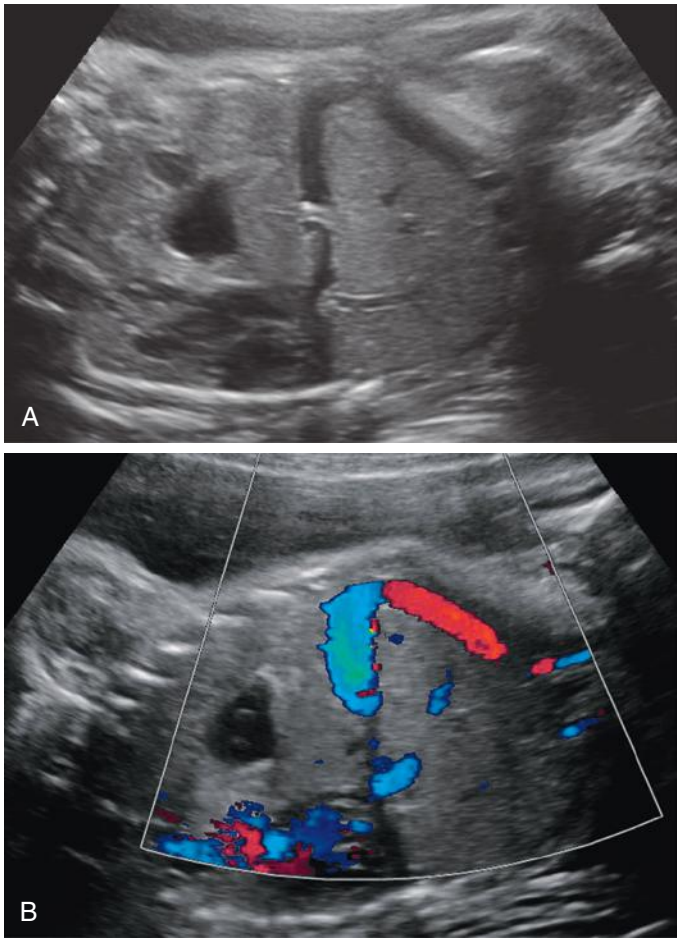

FIG 12-33 Left congenital diaphragmatic hernia (CDH). Coronal sonographic image (**A**) with liver herniation confirmed by color Doppler (**B**) showing flow in deviated umbilical/left portal vein.

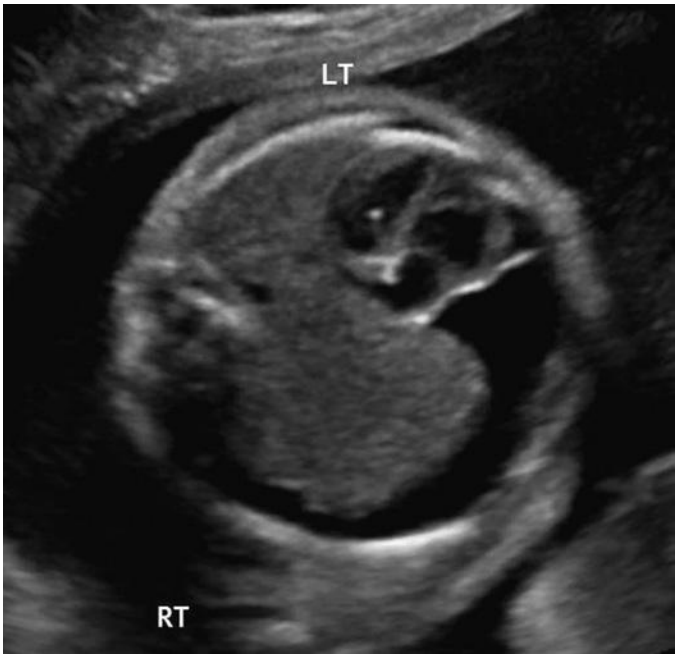

FIG 12-34 Right congenital diaphragmatic hernia with liver and fluid shown in the right hemithorax. Note associated leftward shift of the heart. LT, left thorax; RT, right thorax.

In cases of left CDH, assessment of the location of the fetal liver is necessary for providing prognosis and patient counseling. Liver herniation is consistently associated with higher rate of postnatal mortality as well as morbidity, and increased liver herniation appears to predict outcome.[101] As mentioned, a portion of the left hepatic lobe is likely herniated into the thorax (liver "up") if the fetal stomach is located posteriorly within the chest. This can also be suggested by deviation/distortion of the midhepatic portion of the umbilical vein toward the left[102] (Fig. 12-33). This altered hepatic venous anatomy can be differentiated from an intrahepatic persistent right umbilical vein by assessing the location of the gallbladder. Color Doppler sonography to identify hepatic vessels and demonstrate crossing at the expected level of the diaphragm can be used to recognize liver herniation. The observation of a horizontal stomach in the abdomen has been described as early as 13 weeks' gestation as a marker for liver herniation with right-sided CDH.[103]

Pleural effusions are not uncommon with CDH and are seen much more often with right-sided (29.2%) than with left-sided hernias (5.2%)[104] (Fig. 12-34). Interestingly, if pleural effusions are noted in a fetus with suspected left-sided CDH, the possibility of diaphragmatic eventration should be raised, as over half of fetuses with eventration will have pleural and pericardial effusions.[105] Diaphragmatic hernia and eventration may be difficult to distinguish on ultrasound images, and in these cases additional evaluation by MRI may be helpful.

The presence of effusions with CDH does not confer the same poor prognosis as generalized hydrops or effusions caused by other conditions. The cause of pleural fluid with CDH is not certain but may be secondary to liver congestion related to hepatic venous kinking, especially with right-sided lesions. It is possible that pleural fluid is associated with bowel irritation. Pleural effusions communicate with the peritoneal cavity through the diaphragmatic defect, and in half of the cases of CDH with pleural effusion, peritoneal fluid is also seen. In addition, there is a high incidence of chylothorax following postnatal CDH repair. It is not known whether this is due to surgical insult or thoracic duct dysfunction. In general, the observation of ascites and pleural effusions in association with "isolated" CDH does not significantly alter the prognosis.[104]

The differential diagnosis of CDH includes any intrathoracic lesion that displaces the fetal heart or lungs, including masses in the spectrum of CPAMs. Bronchogenic cysts, cystic teratomas in the anterior mediastinum, and neurogenic tumors in the posterior mediastinum may also be considered. Dextrocardia and unilateral lung hypoplasia or agenesis can be manifest as abnormal position of the heart and should be considered if no specific chest mass or abnormal intrathoracic tissue is identified.

The prognosis of CDH depends on the presence of associated anomalies and the degree of pulmonary hypoplasia. The severity of pulmonary hypoplasia is related to gestational age at diagnosis (as earlier detection is associated with larger lesions and more herniated contents) and to the presence and degree of liver herniation. Survival is influenced by gestational age at delivery.

Risk factors for CDH include maternal pregestational diabetes and alcohol use.[106] Previous studies have also suggested an association with low maternal BMI.[107] The presence of associated anomalies greatly influences survival in neonates with CDH. From 40% to 50% of fetuses will have associated anomalies including chromosomal abnormalities, single gene disorders and genetic syndromes, and other structural

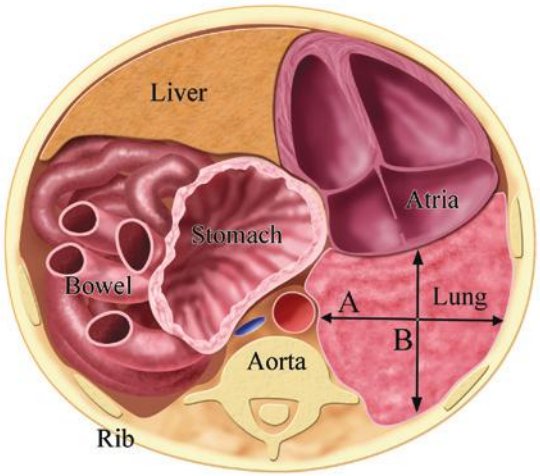
lesions. The incidence of karyotype abnormality is 34%, the majority being deletions, translocations, marker chromosomes, and other unusual chromosomal abnormalities.[108] Multiple syndromes have been described in association with CDHs including Fryns, Cornelia de Lange, Perlman, Beckwith-Wiedemann, and others. Identification and differentiation of various syndromes are not always possible, but suspicion should be raised, particularly if growth abnormalities are noted. In addition, identification of subtle dysmorphic features, including hand and ear anomalies, may facilitate reaching a complete, correct diagnosis.

Fetuses affected with both major cardiac anomalies and CDH face much worse prognosis. Overall survival rate appears more closely related to the severity of the cardiovascular malformation than the CDH.[109] It is important to recognize that mild heart defects are common with left-sided CDH. In a series of 125 left-sided CDH patients, 111 had small left-sided cardiac structures based on aortic valve and mitral valve diameters, with the left ventricle contributing only 33% of prenatal cardiac output as compared to the expected 40% to 50%. Z-scores of left-sided cardiac structures increased to normal in postnatal life. The small size is likely secondary to reduced flow and to mass effect with increased external pressure on the heart.[110] The presence of concomitant major congenital heart disease, intrathoracic herniation of a portion of the liver, and premature birth all significantly impact survival of infants with CDH. However, minor left side of the heart dimension and reduced left-sided heart flow on prenatal echo are not associated with postnatal outcome independent of other cardiac findings.

In the absence of associated anomalies, the degree of lung hypoplasia determines the ultimate outcome for a fetus with CDH. The degree of pulmonary hypoplasia correlates with gestational age at herniation and with herniated structures present in the fetal chest. Liver herniation is associated with a greater degree of pulmonary hypoplasia. In general, right-sided hernias (which typically contain liver) are associated with worse prognosis than left-sided lesions. For left-sided CDH, the presence and degree of liver herniation impact outcome.[111] Although the presence of a hernia sac has been associated with less pulmonary hypoplasia, this is often difficult to discern on prenatal ultrasound.[112]

Multiple attempts have been made to prenatally identify those fetuses at highest risk of demise or other poor outcome, including requirement for ECMO due to respiratory compromise. This prognostic information is helpful for counseling families, for selecting the most appropriate location for delivery, and for identifying those who might benefit from referral to specialized centers offering fetal intervention. The use of the LHR was first described in 1996 in a retrospective cohort.[113] The authors found that in fetuses with left-sided CDH, the LHR measurement correlated with survival and inversely with the need for ECMO. Since that time, additional retrospective and prospective studies have shown the value of LHR in predicting outcome for fetuses with left-sided CDH, and it has been widely incorporated into this assessment.[114] A higher LHR is associated with improved neonatal outcomes and with lower risk of pulmonary hypertension.[115]

Three main methods of determining LHR in the setting of left-sided CDH have been described. LHR is calculated by measuring the size of the right lung, as seen on a transaxial image of the fetal chest at the level of the four-chamber view of the heart, and dividing that by the head circumference—to control for gestational age and fetal size (Fig. 12-35). In a fetus with a small left-sided hernia and minimal cardiomediastinal shift, there is more right lung visible, greater right lung size to measure, larger numerator in the formula, and higher calculated LHR. The three main approaches to calculating the numerator (right lung size) include the anteroposterior diameter method, the longest diameter method, and the tracing method. The measurement is best done on a technically optimized, transaxial sonographic image at the appropriate level. Avoiding acoustic shadowing by the ribs and enlarging the image so the chest fills the screen allow for more accurate assessment[116] (Figs. 12-36 and 12-37). The tracing method has been shown to be the most reliable and the longest diameter method the least.[116] There is a learning curve associated with reliability and



$$\text{LHR} = \frac{\text{A} \times \text{B (mm)}}{\text{HC (mm)}}$$

A Head Circumference

FIG 12-35 A, Diagrammatic illustration of the method for measuring the lung-to-head ratio (LHR) in a fetus with congenital diaphragmatic hernia. The measurement of the right lung (in the typical left congenital diaphragmatic hernia) uses a transverse axial plane of section of the fetal thorax at the level of the four-chamber view of the fetal heart. The plane of section should be symmetric so that a single rib is seen on each side. A measurement in millimeters (mm) is made from the thoracic aorta to the lateral inner chest wall (A). Another measurement, also in mm, is made in a plane perpendicular to the first measurement from the outer wall of the atrium to the inner aspect of the posterior chest wall (B). These two measurements are multiplied and their product is divided by the measurement of the head circumference (HC), also in mm.

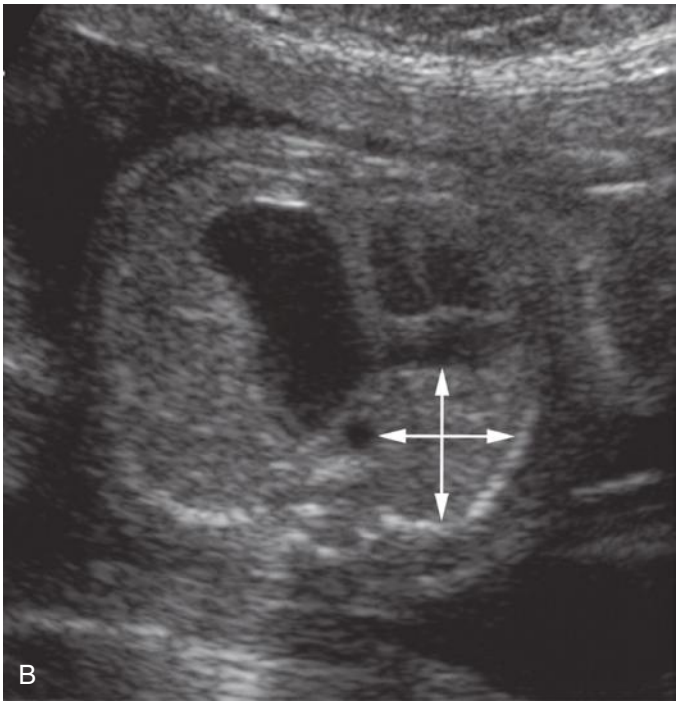


FIG 12-35, cont'd B, Transverse axial sonogram of a fetus with a left congenital diaphragmatic hernia. The two diameters (*arrows*) used in measuring the remaining area of the right lung are shown. (In A, sonogram courtesy of Roy A. Filly, MD, San Francisco, CA. Illustration by James A Cooper, MD, San Diego, CA.)

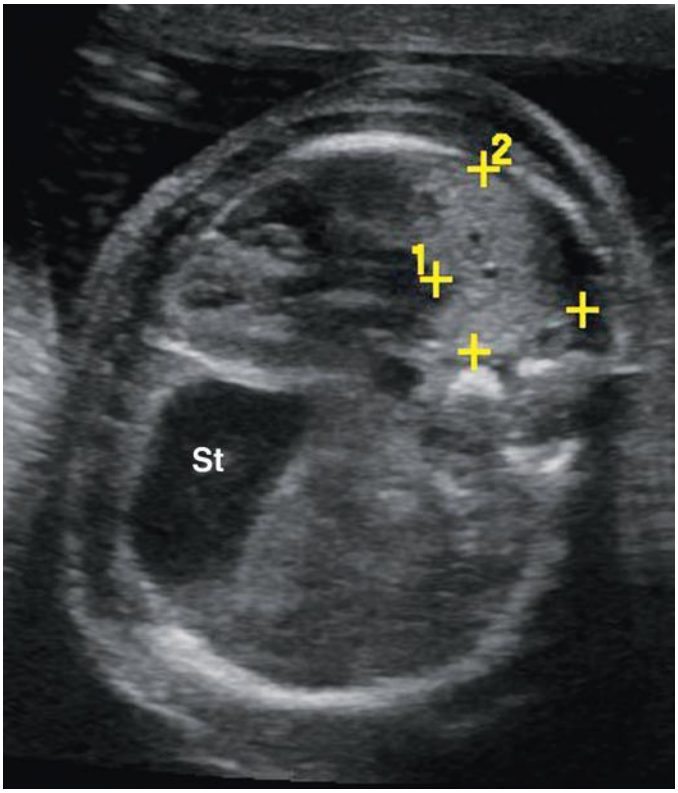

FIG 12-36 Axial view of fetus with left congenital diaphragmatic hernia (CDH). Herniated fluid-filled stomach (St) is shown in the left side of the chest. Electronic calipers are measuring dimensions of the right lung (used to calculate the numerator in LHR [lung-to-head ratio]).

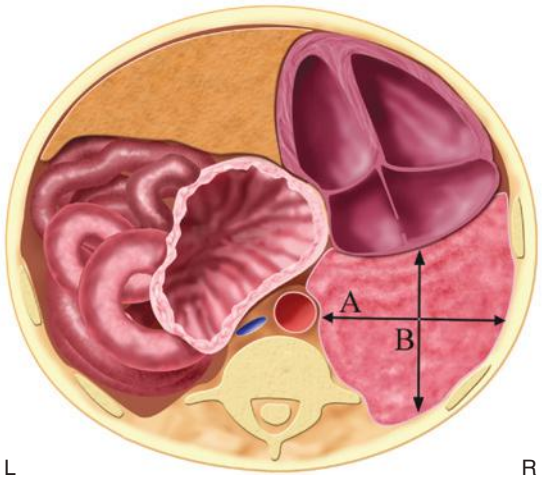
reproducibility of LHR measurements. The technique can be practiced on images of normal fetuses, with approximately 70 to 80 measurements needed to reach consistency among examiners.[117]

Variable cutoffs for LHR have been reported in the literature for prediction of poor postnatal outcome in fetuses with CDH. Some of this variation results from difference in gestational age at time of measurement, alternate techniques in caliper placement, range in operator experience, and application in fetuses with and without liver herniation. There is an 18-fold increase in lung area between 12 and 32 weeks' gestation with a fourfold increase in head circumference during that same time period.[118] Utilizing observed-to-expected LHRs rather than LHR alone may thus result in improved outcome prediction across gestational ages.[113,119] Still, the reported positive predictive value for survival is only 46% with a false positive rate of 10%.[119] The possibility of in utero intervention with tracheal occlusion in the treatment of severe CDH relies on accurate diagnosis and prognosis. The most severe lesions—those with herniated liver, significant mass effect, low LHR measurements, and predicted poor outcome—are considered for in utero intervention as they are most likely to benefit.

Fetal endoscopic tracheal occlusion has been used prenatally in the treatment of CDH. In utero, the fetal lungs secrete fluid into the airways that is eventually drained into the amniotic fluid through fetal breathing movements. With in utero intervention, occlusion of the trachea prevents this drainage of secretions, resulting in growth and stretching of the fetal lung parenchyma. This technique has been shown to stimulate fetal lung growth in a variety of animal models.[120] In this procedure, usually done between 22 and 26 weeks' gestation, an



$$\text{LHR} = \frac{\text{A} \times \text{B (in mm)}}{\text{Head circumference (in mm)}}$$

FIG 12-37 Diagram illustrating caliper placement for measurement of numerator in lung-to-head ratio.

endoscope is passed through the fetal mouth, and a balloon is deployed just above the carina (Fig. 12-38). Following balloon placement, ultrasound surveillance ensures the balloon's structural integrity and measures the fetal pulmonary response. At approximately 34 weeks' gestation, the balloon is deflated and removed. Ultimately, the goal of fetal endoscopic tracheal occlusion is to minimize pulmonary hypoplasia and pulmonary arterial hypertension. Following delivery, neonates still require diaphragm repair. Although results of one randomized trial of tracheal occlusion did not show improved outcomes over standard postnatal repair, better selection of the most severe cases and prenatal removal of the balloon are advances that appear to result in better outcomes. However, the ultimate utility of this intervention remains uncertain.[121,122]

Although measurement of the LHR is helpful in predicting outcome and selecting cases most likely to benefit from in utero therapy, it does not successfully identify fetuses at highest risk for pulmonary hypertension, another major cause of postnatal morbidity. Measurement of the pulmonary artery Doppler waveform has been studied, but further research is needed to identify prenatal factors that predict pulmonary hypertension in the neonate. Other areas of investigation to better evaluate and predict outcome in fetuses with CDH include prenatal MRI and three-dimensional ultrasound measurement of lung volumes[123,124] (Fig. 12-39). As with other conditions, the extremes may have higher predictive value than lung volumes in the middle of the spectrum. The best way to assess and predict outcome in these cases is continuing to evolve.

FIG 12-38 Coronal T2-weighted magnetic resonance imaging of fetus with large left congenital diaphragmatic hernia. Stomach (S) and bowel are shown within the left hemithorax. Fetoscopic intervention had been performed with placement of fluid-filled balloon (*arrow*) within the fetal trachea. Lu, right lung.

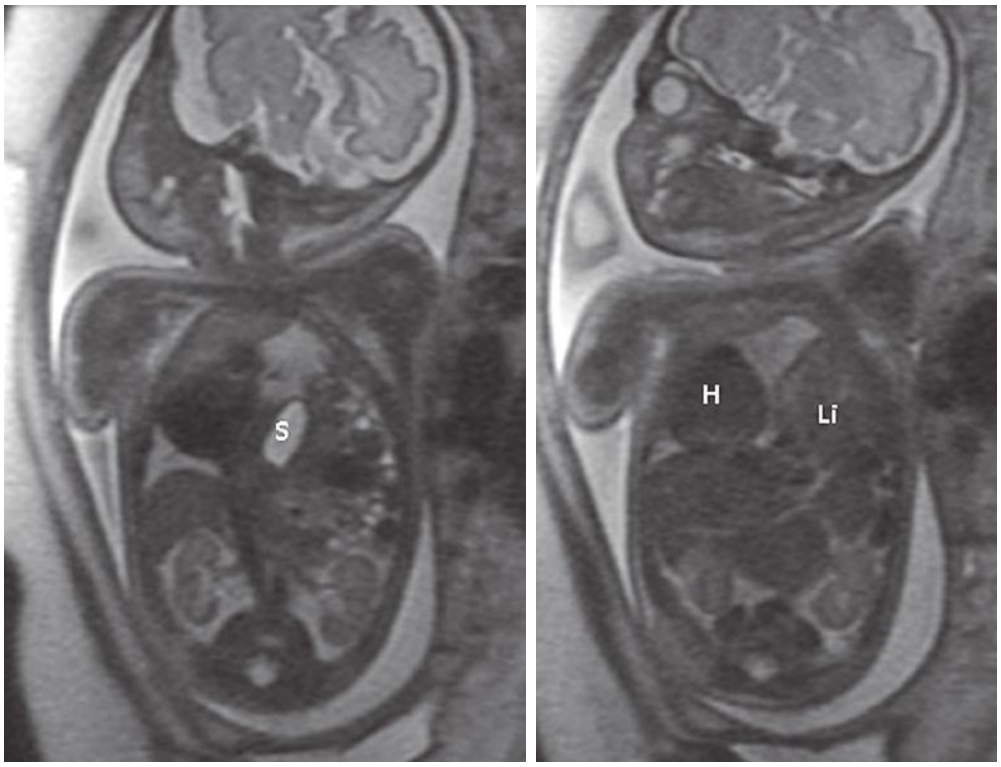


FIG 12-39 Fetal left congenital diaphragmatic hernia shown on coronal T2-weighted images. Fluid-filled stomach (S) is noted within the left hemithorax with rightward shift of the heart (H). High signal intensity lung tissue can be visualized and distinguished from herniated contents including portion of left lobe of the liver (Li).

Sonographic Evaluation of the Fetal Heart

Shaine A. Morris, Nancy A. Ayres, Jimmy Espinoza, Shiraz A. Maskatia, Wesley Lee

SUMMARY OF KEY POINTS

- Prenatal diagnosis of congenital heart disease (CHD) can reduce morbidity and mortality rates by means of delivery and intervention planning.
- With the proper technology and skill, some forms of fetal cardiac disease can be detected using first trimester and early second trimester sonography.
- The addition of outflow tracts to the four-chamber view in the standard midtrimester screening examination greatly improves the detection of fetal cardiac disease and is recommended.
- Use of standard scan planes and systematic assessment of the fetal cardiovascular system is useful in evaluating for cardiac disease.
- Ventricular septal defects (VSDs) are the most common CHD, and their size and location determine the clinical course and management.
- Conotruncal defects may be difficult to differentiate and are associated with widely variable outcomes, so accurate diagnosis is important. For these lesions, the key to diagnosis is determining the source of pulmonary blood flow.
- There are varying patterns of left-sided heart hypoplasia. In evolving hypoplastic left heart syndrome (HLHS) due to aortic stenosis, the four-chamber view may initially appear normal in early gestation; the key to early detection is to assess for left-sided heart growth as pregnancy advances and for the development of left ventricular dysfunction and endocardial fibroelastosis.
- Fetal heart failure is a common pathway for both primary and secondary cardiovascular disorders. Careful assessment of signs of cardiac failure can help determine prognosis and possible need for intervention.

OUTLINE

A major purpose of fetal sonographic evaluation is detection of cardiovascular disease to optimize counseling and care of the fetus. This noninvasive approach has been used to evaluate the fetal heart since the 1970s,[1] and in the current era, with advances in imaging technology, up to 95% of major CHD can be prenatally detected by detailed fetal echocardiography.[2-4] However, in population studies, the rate of prenatal diagnosis of major congenital heart lesions by screening methodology is much lower and highly variable by practice and region.[5-10] This lower rate is likely due to a combination of factors, including limitations in access to prenatal care, equipment, and experience of the sonographer or medical care provider; time constraints; and certain patient factors, such as poor acoustic windows.

A large portion of fetal cardiovascular disease is composed of CHD. CHD is associated with significant morbidity and mortality risks; in fact, CHD is the primary contributor to birth defect–related infant fatality, accounting for nearly one quarter of infant deaths from birth defects.[11,12] Approximately 18 per 10,000 live births have critical congenital heart defects, defined as defects requiring surgery or catheter intervention in the first year of life.[13,14] Outcomes are highly variable by lesion and coexisting conditions. For example, isolated VSD has

nearly 100% infant survival rate, HLHS has 70% to 80% infant survival rate, but HLHS with Turner syndrome has less than 10% survival rate.[15-20] Fetal cardiovascular disease also consists of fetal arrhythmia, cardiac dysfunction and high output heart failure, pericardial effusions, and cardiac and extracardiac thoracic masses.

Prenatal diagnosis of CHD or arrhythmia allows for many potential benefits for the family and fetus. These benefits include emotional preparation for the parents, fetal therapy when indicated, and parental choice of the hospital that will provide postnatal care and intervention. Parents can plan delivery at an institution with considerable expertise and experience to provide the best postnatal care for the infant. Prenatal diagnosis, by conferring these benefits to families, is associated with improved presurgical status of the infant with CHD, as well as lower morbidity and mortality rates in infants with complex CHD.[21-24] Prenatal detection of CHD also allows time for families to accept and understand the diagnosis prior to the birth of the infant. Although prenatal diagnosis has been shown to increase stress during pregnancy, families overwhelmingly state they would prefer to have this knowledge sooner than to learn of CHD after birth.[25-27]

In this chapter, we review normal fetal cardiovascular anatomy and physiology, recommended approaches for prenatal cardiac screening and detailed evaluation, ultrasound findings associated with common types of CHD, and specific imaging tools for common fetal heart diseases.

FETAL CARDIOVASCULAR PHYSIOLOGY

Our fundamental understanding of the human fetal circulation and changes attributable to CHD was originally extrapolated from early work with fetal lambs.[28-30] The introduction of fetal ultrasound imaging and more recently the use of fetal cardiac magnetic resonance imaging (MRI) have refined our understanding of fetal cardiac physiology.[31,32] Unlike the postnatal heart, in which blood flow is in series, the right and left fetal ventricular outputs are parallel circuits (Fig. 13-1A). Starting from the placenta, maternal oxygenated blood courses through the umbilical vein and enters the inferior vena cava via the ductus venosus (DV). This oxygenated blood accounts for approximately 50% of blood returning to the right atrium (RA) (Fig. 13-2). Oxygenated blood enters the RA, but instead of predominantly then flowing to the right ventricle (RV), oxygen-rich blood is directed across the fetal foramen ovale to the left atrium (LA) by the eustachian valve. Most fetal left-sided blood flow is provided in this manner (~63% per MRI estimates[32]). Blood then courses from the LA across the mitral valve to the left ventricle (LV) and is ejected across the aortic valve into the ascending aorta. Blood flow is then directed to the brain and upper extremities (73% of aortic outflow) while the rest is ejected to the inferior portion of the fetal body (28% of aortic output, 11% of combined cardiac output [CCO]) and joins blood from the ductus arteriosus (72% of pulmonary output, 41% of CCO) in the descending aorta.

Some of the blood that was delivered to the head, arms, and lower extremity organs and muscles eventually returns deoxygenated to the heart via the superior vena cava and inferior vena cava (52% of CCO), while some is returned to the placenta via the umbilical artery (approximately 29% of CCO). Deoxygenated blood with lower glucose levels returning through the fetal systemic veins courses through the RA, RV, and across the pulmonary valve into the pulmonary artery, and primarily traverses the ductus arteriosus into the descending aorta. A small proportion of blood in fetal life is directed into the branch pulmonary arteries into the lungs (approximately 28% of pulmonary flow, 16% of CCO) and returns to the LA via the pulmonary veins. Three percent of cardiac output supplies the coronary artery system. This normal fetal circulation essentially allows the most oxygen-rich, glucose-rich blood to reach the fetal brain, and may be significantly altered when CHD is present.

At the time of birth, when placental blood flow ceases, oxygen-rich umbilical venous blood is no longer directed into the fetal heart (see Fig. 13-1B). However, at the same time, the newborn infant has started to breathe, and much of the blood flow from the pulmonary artery that was directed across the ductus arteriosus in fetal life is now redirected to the pulmonary arteries to perfuse the newly expanded lungs. This blood becomes oxygenated and returns to the LA via the pulmonary veins. During this transition, the ductus arteriosus closes[33] and in most infants the foramen ovale also closes. Blood flow to the left side of the heart transitions from being supplied via the foramen ovale to being supplied by the pulmonary veins. Failure of the foramen ovale or the ductus arteriosus to close results in patency of these structures; these defects are considered CHD (patent foramen ovale [PFO] and patent ductus arteriosus [PDA]).

ULTRASOUND EQUIPMENT

Contemporary two-dimensional (2D) ultrasound systems for fetal cardiac screening provide gray-scale and Doppler ultrasound capabilities. Broadband ultrasound transducers are designed to minimize ergonomic stress with a small scanning footprint that can be angled or maneuvered between fetal ribs for satisfactory views of the heart. Higher frequency transducers provide greater resolution, but at the expense of decreased penetration. Harmonic imaging, speckle reduction, and write priority for balancing color Doppler with gray-scale ultrasound images are commonly available. Optimal cardiac studies will be achieved while using high frame rates because temporal resolution should adequately capture movement of anatomic structures throughout the cardiac cycle. Digital video clips are recommended to document fetal cardiac findings.[34]

FIRST AND EARLY SECOND TRIMESTER FETAL CARDIAC EVALUATION

Our ability to identify heart defects in the prenatal period is limited by the following factors: (1) early or late gestational age; (2) structural complexity of the fetal heart, particularly in the abnormal heart; (3) the extensive training required to become proficient in, and maintain expertise in, fetal cardiac sonography; (4) frequent fetal and maternal motion; (5) maternal obesity; (6) limited or excessive amniotic fluid volume; (7) fetal position; and (8) maternal abdominal scar tissue. Limitations are especially present in early pregnancy, when small fetal structures are most difficult to image.

Cardiac Examination

The American Institute of Ultrasound in Medicine (AIUM) recommends routine documentation for the presence or absence of cardiac activity with a 2D video clip or M-mode imaging when a standard viability first trimester ultrasound examination is performed.[35] However, additional cardiac evaluation may be performed when indicated, as discussed later.

High-frequency, high-resolution transvaginal and transabdominal probes, with improvements in magnification imaging and signal processing, have increased the visualization of the fetal heart during the first and early second trimesters of pregnancy. The standard fetal cardiac screening 2D views (details in next section) typically performed in second and third trimester cardiac screening can also be performed in the first trimester and early second trimester, usually no earlier than 11 weeks' gestation. Visualization of these sonographic planes can be facilitated by using color Doppler imaging.[36-52]

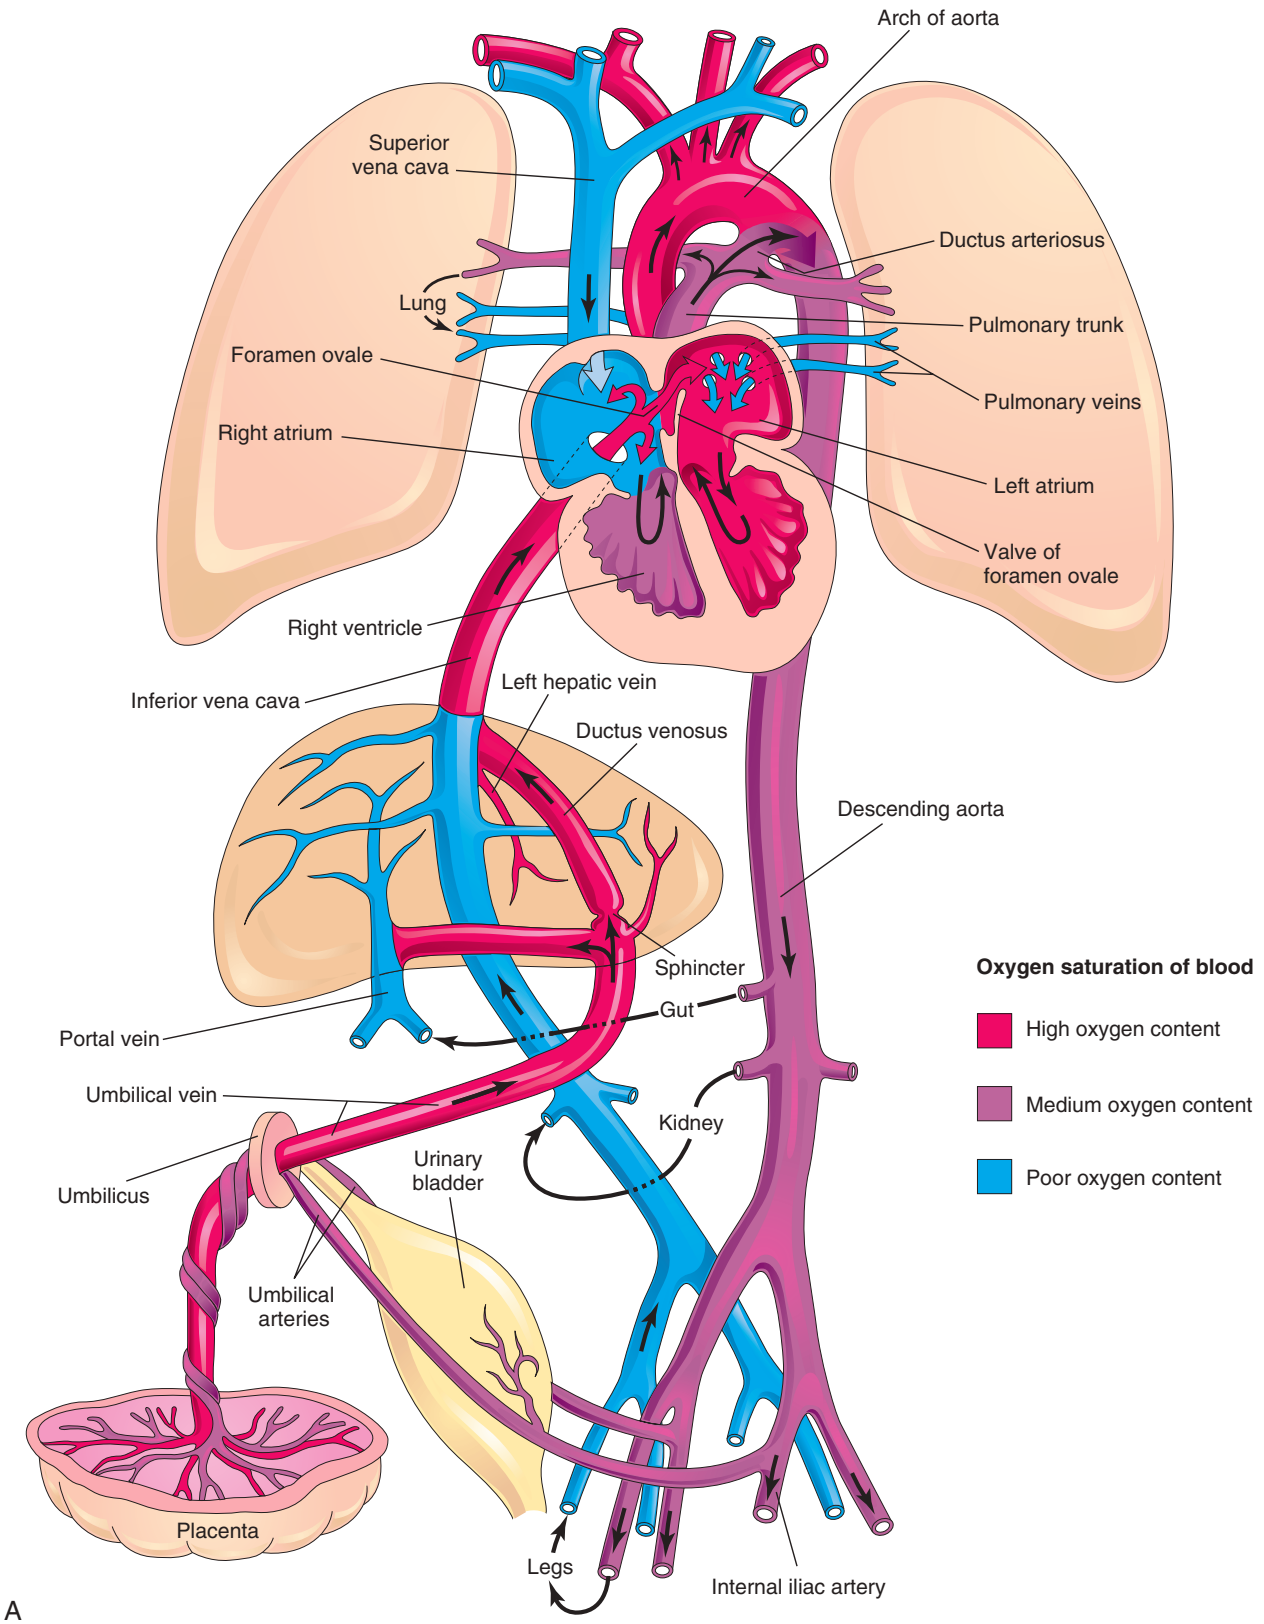

FIG 13-1 Cardiovascular circulation before and after birth. **A,** Prenatal cardiovascular circulation.

Continued

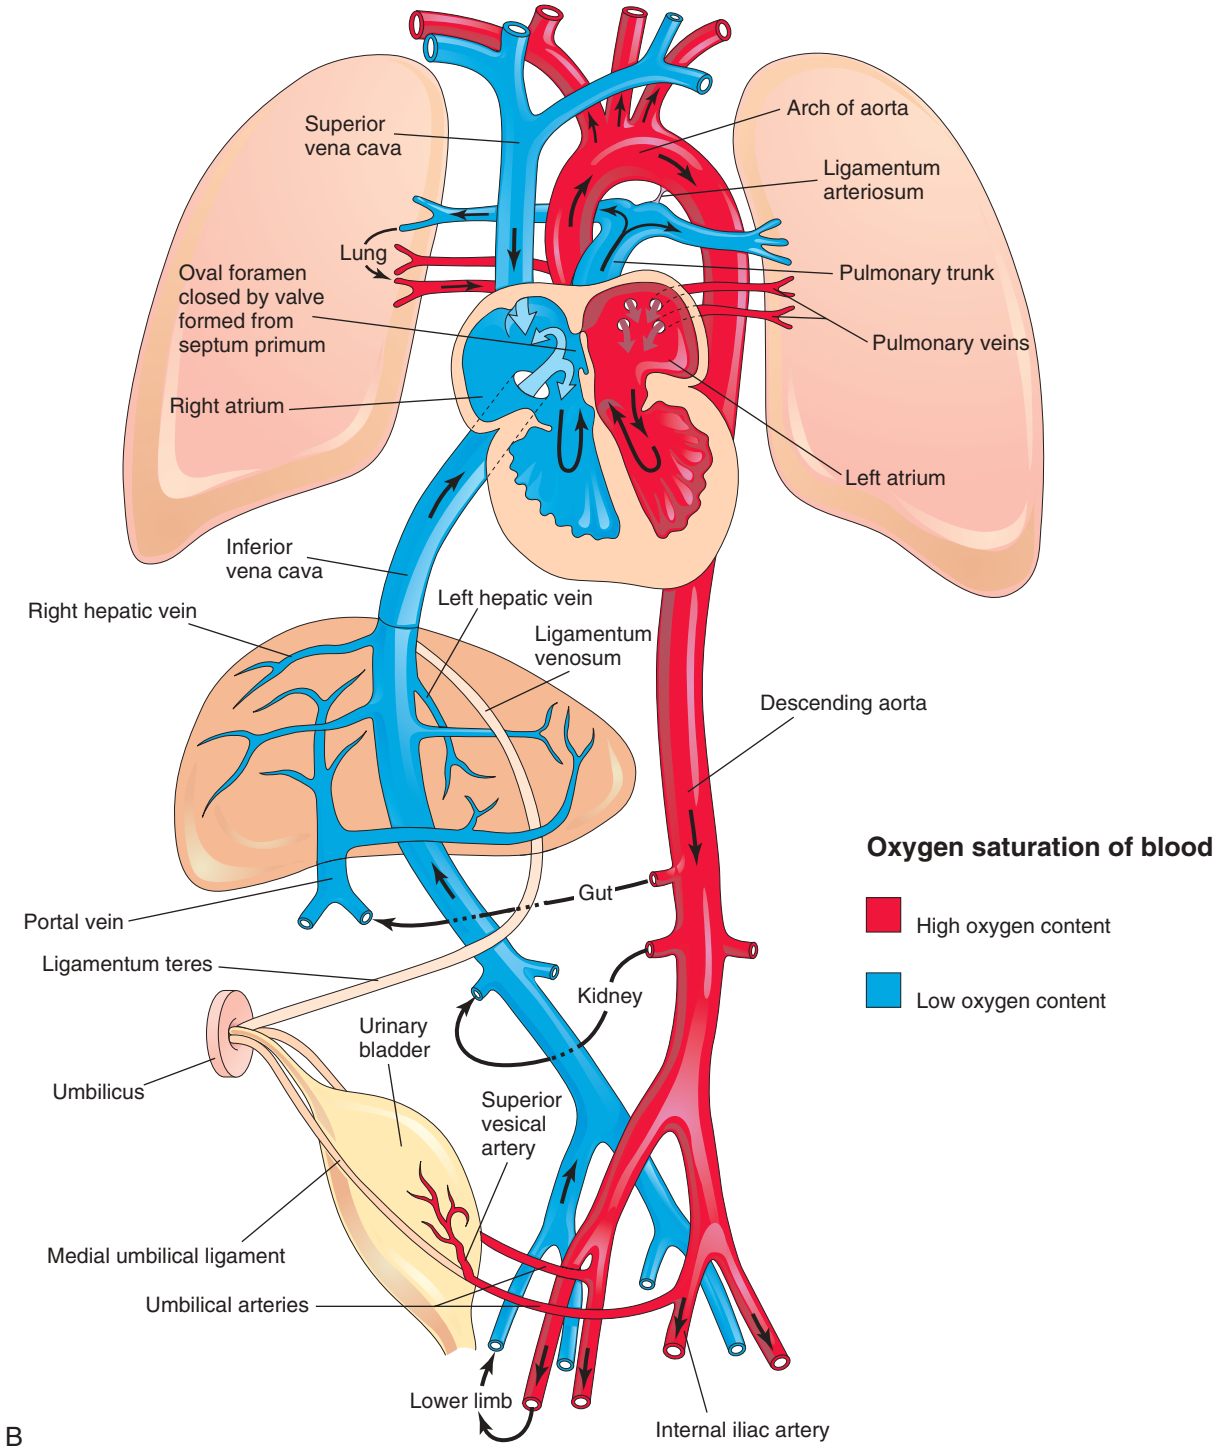

FIG 13-1, cont'd B, Postnatal cardiovascular circulation. The colors indicate the oxygen saturation of the blood, and the arrows demonstrate the direction of flow. (From Moore K, Persaud TVN: Before We Are Born: Essentials of Embryology and Birth Defects, 9th ed. Philadelphia, Elsevier, 2015, Figs. 14-32, 14-33.)

Early gestation views in the four-chamber plane are depicted in Figure 13-3A. Color flow mapping helps in the evaluation of the four-chamber view to delineate the flow into both ventricles and gives an approximate estimation of the ventricular size (Fig. 13-3B).

Early gestation imaging in the left ventricular outflow tract (LVOT) view can be performed and may be better visualized with color Doppler early in pregnancy (Fig. 13-4). In the three-vessel and trachea (3VT) view (Fig. 13-5A), color flow mapping is useful in delineating the great arteries and the confluence of the ductus arteriosus and the aortic arch (V sign) (Fig. 13-5B). Color and spectral Doppler evaluation can also help in the identification of valvar regurgitation. For the spectral Doppler evaluation of tricuspid regurgitation, a sample gate of 2 mm to 3 mm is recommended, which should be positioned above the tricuspid valve in an apical four-chamber view with an angle of insonation of less than 20 degrees. The diagnosis of tricuspid regurgitation can be made with the demonstration of a spectral Doppler

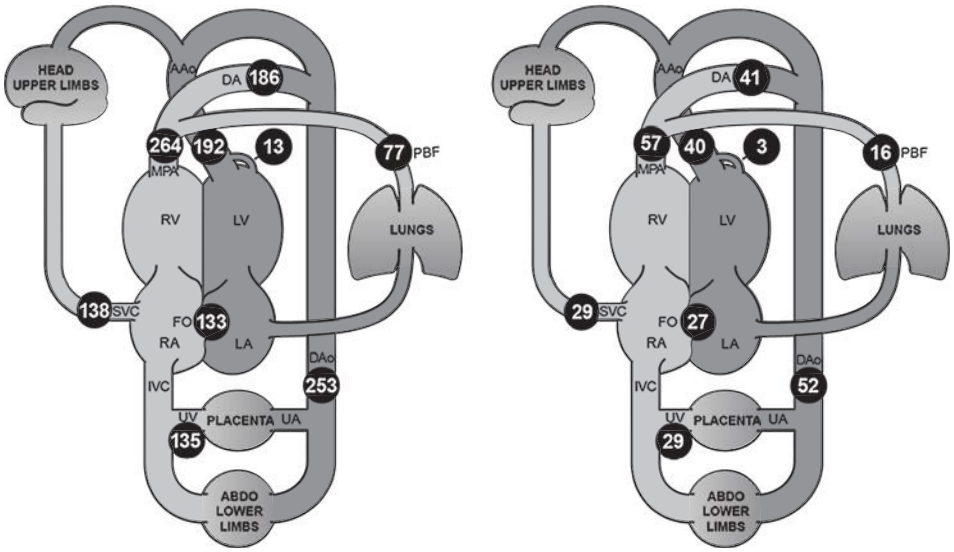

FIG 13-2 Distribution of the normal human fetal circulation measured by phase-contrast MRI in 40 late-gestation fetuses expressed as mean flows (mL/minute per kg) (numbers in black circles, *left*) and converted to modeled mean percentages of the combined ventricular output (numbers in black circles, *right*). FO flow calculated as the difference between left ventricular output and PBF. AAo, ascending aorta; ABDO, abdomen; DA, ductus arteriosus; Dao, descending aorta; FO, foramen ovale; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; MPA, main pulmonary artery; PBF, pulmonary blood flow; RA, right atrium; RV, right ventricle; SVC, superior vena cava; UA, umbilical artery; UV, umbilical vein. (From Prsa M, Sun L, van Amerom J, et al: Reference ranges of blood flow in the major vessels of the normal human fetal circulation at term by phase-contrast magnetic resonance imaging. Circ Cardiovasc Imaging 7:663-670, 2014, used with permission. Courtesy of Luke Itani, The Hospital for Sick Children, Toronto, Canada.)

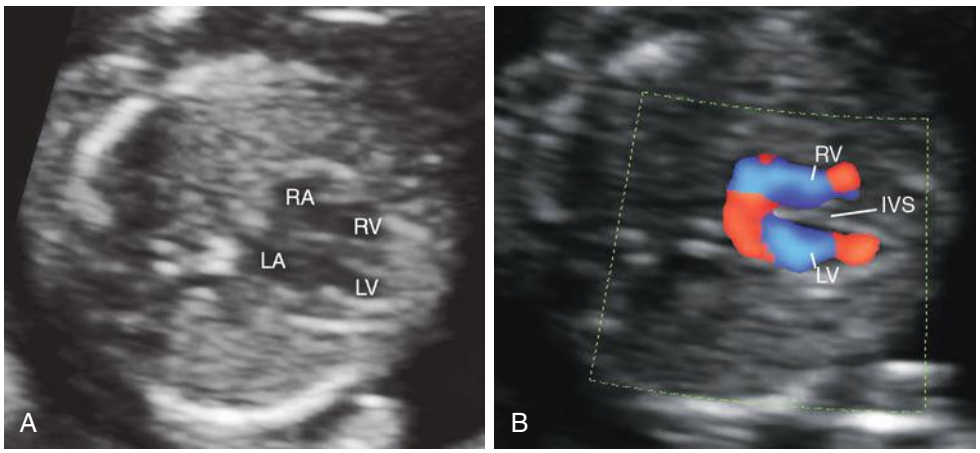

FIG 13-3 Early gestation four-chamber view. **A,** Four-chamber view in a fetus at 13⅙ weeks of gestation. **B,** Four-chamber view with high definition color Doppler in a fetus at 13⅙ weeks of gestation. Note that color Doppler allows for a better delineation of the interventricular septum. IVS, interventricular septum; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

waveform that involves at least half of systole and a velocity of more than 80 cm/second (Fig. 13-6).[53] In cases of severe tricuspid regurgitation such as in Ebstein anomaly this can be visualized by color Doppler in the first trimester of pregnancy (Fig. 13-7).

If normality of situs and cardiac connections, atrioventricular (AV) connections, right- and left-sided symmetry, and ventriculoarterial connections can confidently be demonstrated, most major structural malformations can be excluded.[15] However, septal defects and developmental lesions may be overlooked; thus, there is a need for follow-up in the second trimester of pregnancy. The additional use of color flow mapping to assess intracardiac flow velocities will enhance detection of valvar lesions, such as aortic and pulmonary stenosis, which may progress to critical stenosis during the third trimester. Methods have been described to optimize prenatal detection of CHD using adjunctive evaluation of the fetus in early pregnancy, including assessment of nuchal translucency (NT), fetal Doppler waveforms, aberrant right subclavian artery, and cardiac axis.[54-61]

Mounting evidence supports the association of increased NT between 11 and 14 weeks of gestation and an increased risk for CHDs in both high-risk[54-57] and low-risk populations.[62] Among fetuses with increased NT measurements, the higher the NT measurement, the higher the prevalence of CHDs.[54,57] However, increased NT measurement is only modestly predictive of CHD. In a large meta-analysis involving more than 58,000 fetuses, the detection rate of an increased

NT measurement was only 31%, for a false positive rate of 1%.[63] Thus, other approaches had been used to evaluate the risk for CDH in the first trimester of pregnancy, including a combination of increased NT measurement, tricuspid regurgitation, and abnormal spectral flow waveforms in the DV (Fig. 13-8).[58,59]

Abnormal DV waveforms, including negative/reversed a wave and increased pulsatility index for the veins (PIV), have been associated with structural cardiac abnormalities in euploid first trimester fetuses.[59] The sensitivity and specificity of abnormal DV waveforms in the identification of CHDs are 80% and 83% in fetuses with increased NT, whereas the respective values in fetuses regardless of their NT measurement are 50% and 93%.[64]

Other findings during the first trimester scan associated with CHD include abnormal cardiac axis (Fig. 13-9)[65] and aberrant subclavian artery.[60,61] Sinkovskaya and associates[65] measured the cardiac axis on the four-chamber view in a prospective study between 11 and 14 weeks' gestation. The authors reported that the mean value for the cardiac axis in fetuses without cardiac anomalies was 47 degrees with limits of normality between 35 degrees and 60 degrees. An abnormal axis was seen in four of the six cases with CHD (of which three showed a structurally abnormal four-chamber view): one with HLHS, two with atrioventricular septal defects (AVSDs, one unbalanced, one associated with isomerism), and one with tetralogy of Fallot (TOF). The authors concluded that this approach may help to identify pregnancies at risk of CHD.[65] Of note, women with a body mass index (BMI) of 30 or higher were excluded from the study, and nearly one in five cases required a combined transabdominal and transvaginal approach. Thus, for CHD screening purposes, this strategy may be applicable only in facilities with availability and expertise in transvaginal sonography.

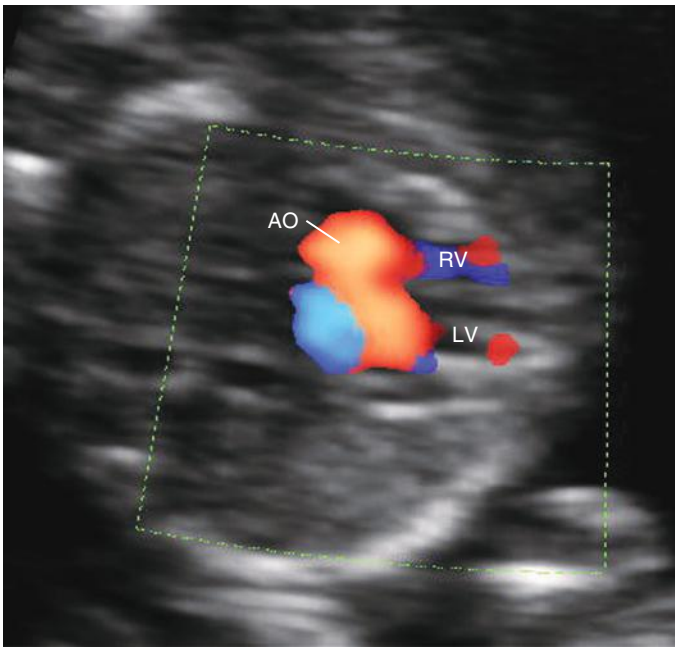

FIG 13-4 Color Doppler imaging demonstrates a five-chamber view in the first trimester of pregnancy; the aortic root is visualized arising from the left ventricle. AO, aorta; LV, left ventricle; RV, right ventricle.

Effectiveness of Early Gestation Cardiovascular Evaluation

A study using transvaginal sonography reported that the success rate of visualization of the four-chamber view, LVOT view, pulmonary trunk with three-vessel view (3VV) and crossover of the great arteries increased with gestational age, from 20% in week 11 to 92% in week 13.[41] In a study among women undergoing chorionic villus sampling between 11 and 13 weeks of gestation, the authors reported a 93.1% accuracy in the identification of CHDs using a high-frequency linear transducer.[52] In another study in high-risk women, using a combination of transabdominal and transvaginal sonography, the authors reported a 70% sensitivity and a 98% specificity in the identification of CHDs before 16 weeks' gestation.[47] In a large low-risk population, the authors reported that in 29 of the 39 cases of CHDs the heart defect was suspected in the first trimester.[66] Of note, in the latter study all examinations were performed using transabdominal sonography; however, in 7.3% of the cases a transvaginal scan was also required.

In a more recent study, Zidere and coworkers[67] performed a comparison of fetal echocardiography findings at less than 15 weeks of gestation in 1200 patients and a follow-up scan at least 6 weeks later.[67] The authors reported a high degree of accuracy in the identification of CHD by early fetal echocardiography (sensitivity 84.8%, 95% confidence interval [CI] 75.0-91.9; specificity 95.3%, 95% CI 93.9-96.4). Discordance between the two scans was found in 85 patients. In 50 of

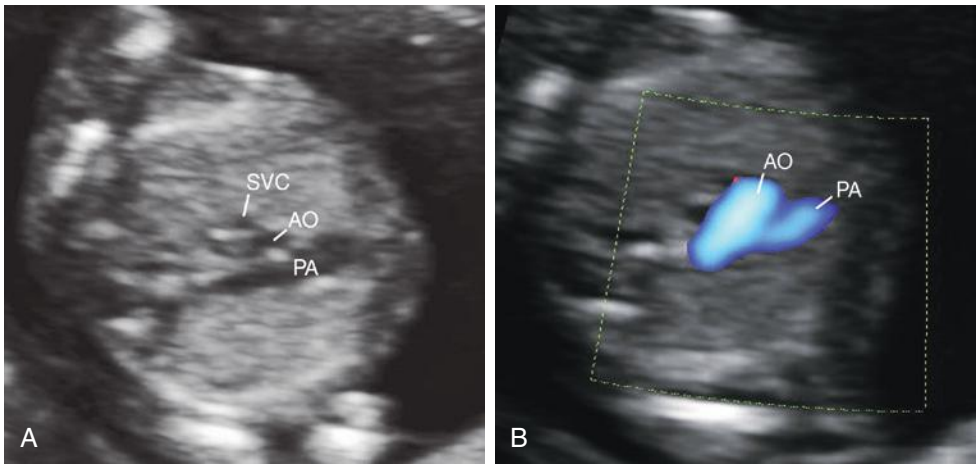

FIG 13-5 The three-vessel and trachea view demonstrates the main pulmonary artery in communication with the ductus arteriosus (**A**). Color flow mapping is useful in the delineating the great arteries and the confluence of the ductus arteriosus and the aortic arch (V sign) (**B**). AO, aorta; PA, pulmonary artery; SVC, superior vena cava.

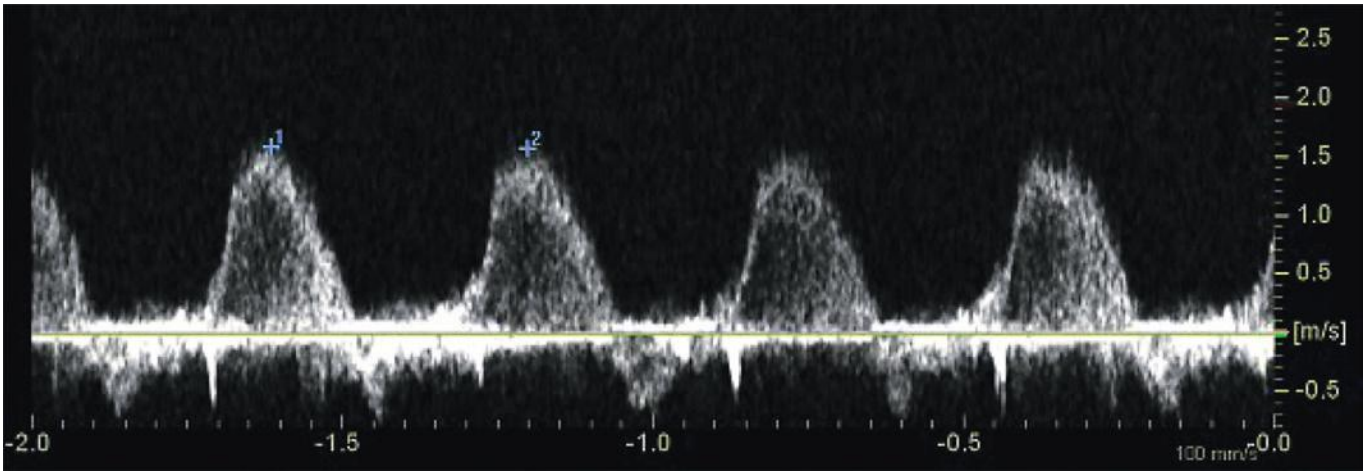

FIG 13-6 Spectral Doppler in a first trimester fetus with severe tricuspid valve regurgitation. Note that the duration of regurgitation extends for over half of systole.

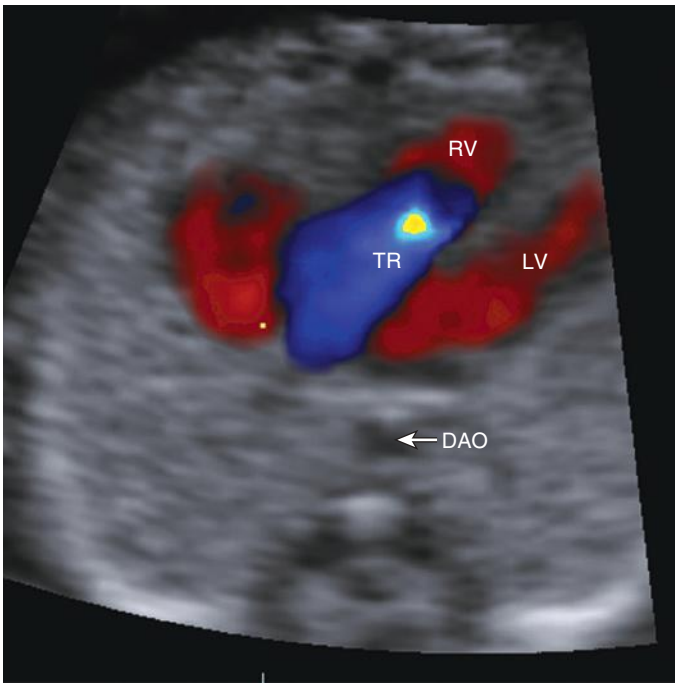

FIG 13-7 Color Doppler imaging demonstrates severe tricuspid regurgitation in a fetus with Ebstein anomaly at 13⅔ weeks of gestation. DAO, descending aorta; LV, left ventricle; RV, right ventricle; TR, tricuspid regurgitation.

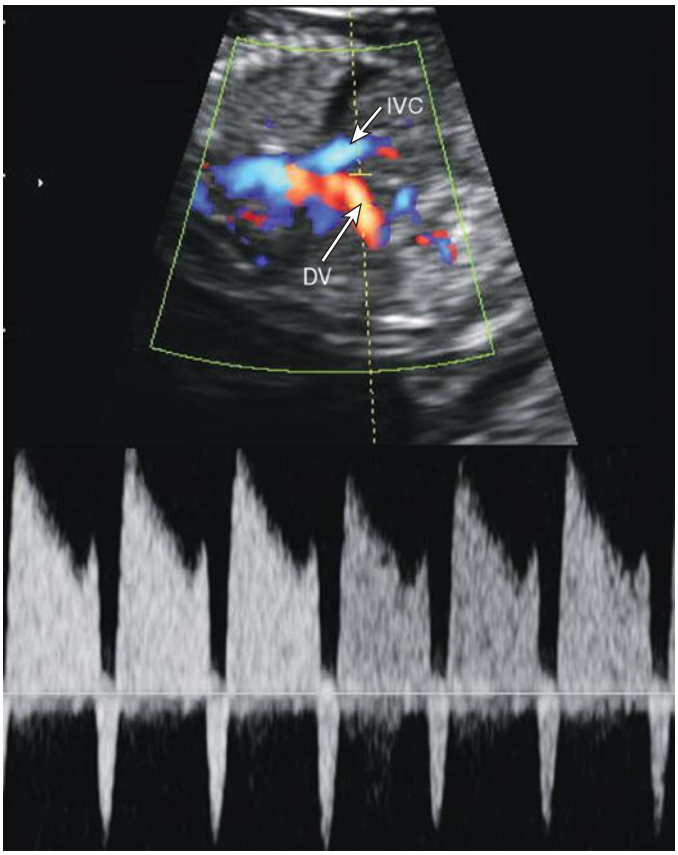

FIG 13-8 Reversed a wave in the ductus venosus in a fetus with trisomy 18 and tricuspid atresia. DV, ductus venosus; IVC, inferior vena cava.

them, there was mild tricuspid regurgitation (n = 44), mild mitral regurgitation (n = 3), or both (n = 3) at the early scan and no abnormal findings at the second scan. In three cases, CHD was suspected at the first scan but was not confirmed at the second scan (false positive diagnoses), and in four cases, less complex CHD than originally suspected at the first scan was found at the second scan. In 29 fetuses, an abnormality was found at the second scan that had not been detected at, or that had changed in severity since, the early study. The discordance was considered significant in 15 of the 29 cases. The authors suggested that in 10 cases of the latter group the significant differences between the early and later scans represented true progression of findings between the early and later scans, rather than missed or incorrect diagnoses. The authors concluded that early fetal echocardiography between 12 and 14 completed weeks' gestation is highly specific for the detection of CHD. However, the identification of every case of TOF and mild AV canal variants presents particular diagnostic challenges in early fetal echocardiography. Changes in severity appear to occur particularly in obstructive lesions at the aortic and pulmonary valves and in the aortic arch, and there are limitations on accuracy with more subtle malformations. In an accompanying editorial the author cautioned that in the study of Zidere and coworkers,[67] if fetuses with resolving mild functional abnormality are removed from the denominator, 7/81 (9%) had a false positive diagnosis of CHD. A further 15/81

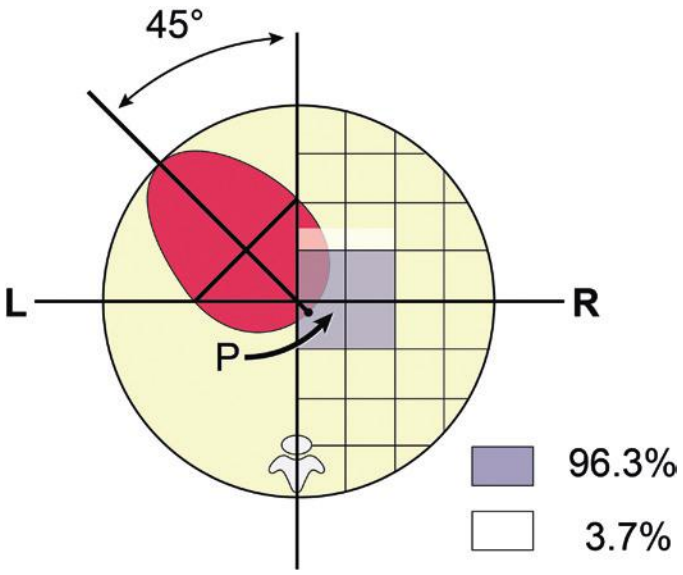

FIG 13-9 Fetal cardiac axis and position. The mean cardiac axis is 45 degrees (2 SD = 20 degrees, range 22-75 degrees). A line through the interventricular axis is extended to the posterior border of the heart to produce point P, the location of which can be used to define cardiac position. The percentages represent the proportion of time point "P" is in the indicated location. L, left; R, right; SD, standard deviation. (Modified from Comstock CH: Normal fetal heart axis and position. Obstet Gynecol 70:255-259, 1987.)

(18.5%) had important discordant findings at the second trimester scan, with 10/15 thought to be due to progression of disease that led to an alteration in counseling. Thus, even in expert hands, over 27% of important fetal structural CHD were missed or the parents were counseled inappropriately for the eventual outcome. The author proposed that concerns about the quality of information that can be obtained from the early human heart in euploid fetuses should make us pause to reconsider echocardiography in the first trimester and perhaps defer it until later in pregnancy.

SECOND TRIMESTER FETAL CARDIAC EVALUATION

Rationale and Effectiveness

Given that CHD is the most common birth defect, one of the major goals of the standard second trimester ultrasound examination is to evaluate for cardiac disease. Of highest priority is the identification of fetuses at risk for ductal dependency and hypoxemia after birth (Table 13-1). The examination is typically performed at 18 to 22 weeks' gestation. Of note, a prospective randomized study of second trimester fetal cardiac screening suggests that unselected pregnant women are less likely to require an additional scan at 20 to 22 weeks' gestation than at 18 weeks' gestation.[68]

Earlier practice guidelines for fetal cardiac screening encouraged visualization of the four-chamber view or "basic scan" with inclusion of the cardiac outflow tracts as part of an "extended basic scan" only if technically feasible.[34,69] However, additional assessment of both ventricular outflow tracts can improve the cardiac anomaly detection rate to approximately 80%.[70-72] A large retrospective review of over 18,000 midtrimester screening examinations with normal four-chamber views were examined at a single institution to determine how often outflow tracts could be obtained during a routine scan.[73] In 7.0% of 1308 scans, the main pulmonary artery, aortic outflow tract, or both were poorly visualized. In 778 scans (4.2%), poor visualization of the aorta only was noted. In 297 scans (1.6%), poor visualization of the pulmonary artery only was noted. In 233 scans (1.3%), neither ventricular outflow tract could be visualized. Given the significantly improved detection of CHD, and the low rate of poor visualization of the outflow tracts, recent guidelines now consider visualization of both arterial outflow tracts to be an integral part of the midtrimester fetal cardiac screening examination.[34,74]

The effectiveness of routine midtrimester fetal cardiac evaluation was reported in a large screening study of over 30,000 pregnancies in a nonselected Norwegian population.[75] This study was performed at a single institution where 98% of pregnancies received routine midtrimester screening scans at approximately 18 weeks' gestation that included a four-chamber view with visualization of the great arteries. Over one half (57%) of the 97 CHD cases with major cardiac defects were detected prenatally. Their findings underscored the importance of examiner experience for the effective detection of major CHD.[75]

TABLE 13-1 Critical Congenital Heart Disease Lesions and Associated Clinical Characteristics

Lesion	Prevalence*	Hypoxemia	Ductus Arteriosus Dependent
Outflow Tract Defects			
Tetralogy of Fallot	6.1	Most	Uncommon
D-transposition of the great arteries	4.0	All	Uncomon
Double-outlet right ventricle	1.7	Some	Some
Truncus arteriosus	1.0	All	None
TAPVC	1.2	All	None
Ebstein anomaly	0.6	Some	Some
Right Obstructive Defects			
Tricuspid atresia	0.5	All	Some
Pulmonary atresia, intact septum	0.8	All	All
Pulmonary stenosis, atresia	6.3	Some	Some
Left Obstructive Defects			
Hypoplastic left heart	3.3	All	All
Coarctation of the aorta	4.7	Some	Some
Aortic arch atresia or hypoplasia	1.0	Some	All
Aortic valve stenosis (critical)	1.6	Uncommon	Some
Other major heart defects	12.4	Some	Some

Cardiac Screening

The cardiac screening examination is optimally performed between 18 and 22 weeks' gestation, typically as part of a routine fetal anatomic survey.[34] Standardized transverse scanning planes are used to screen

fetuses for CHD using basic principles that have been based on a sequential segmental approach to describing sonographic findings.[34,76,77] Cardiac ultrasound images are typically optimized by adjusting image display depth, modifying acoustic focus for the heart, and maintaining low frame persistence. A relatively narrow scan angle will permit satisfactory temporal resolution.

Standardized Scan Planes. Because the relatively enlarged fetal liver displaces the fetal heart into a more horizontal position, the examiner can use standardized transverse planes to systematically evaluate fetal cardiac anatomy (Figs. 13-10 through 13-12).

The four-chamber view permits assessment of major anatomic landmarks with particular emphasis on the AV junctions. Further examination of the size and relationship of the aortic and pulmonary outflow tracts, 3VV, and 3VT view (Figs. 13-13 and 13-14) provides a means to evaluate the size, number, alignment, and appearance of the great arteries in relation to their ventriculoarterial junctions and surrounding anatomy. The same views used in cardiac screening are used

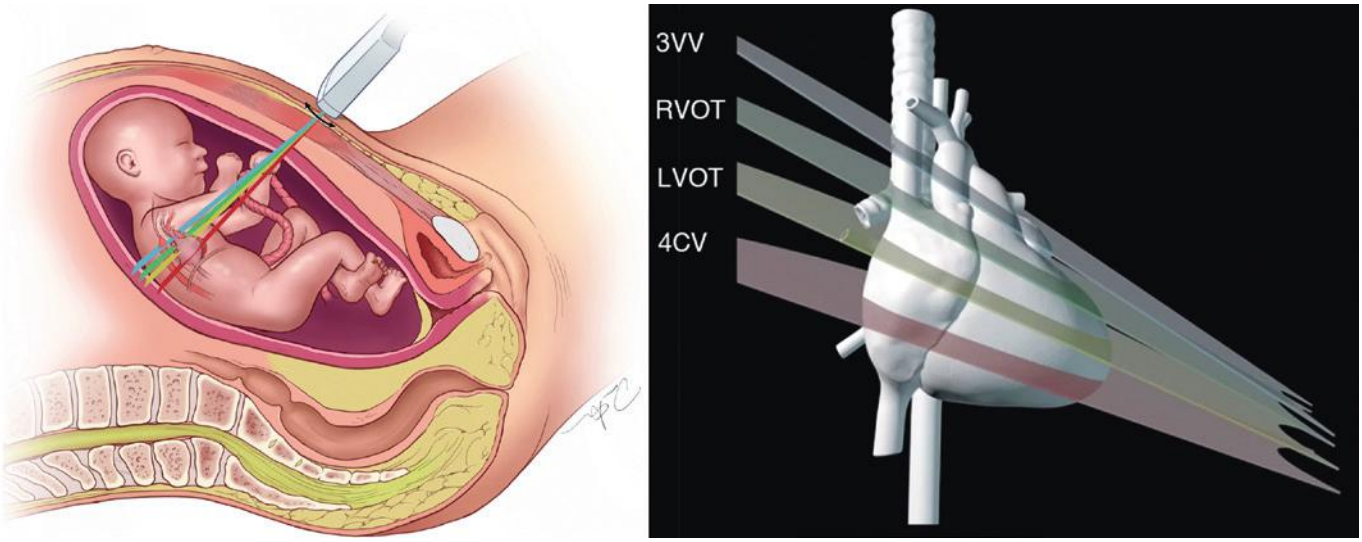

FIG 13-10 Basic sonographic approach for the midtrimester fetal cardiac screening examination. Cephalad sweep of an ultrasound transducer toward the fetal head is used to visualize a four-chamber view (4CV), left ventricular outflow tract (LVOT), right ventricular outflow tract (RVOT), and three-vessel view (3VV), respectively.

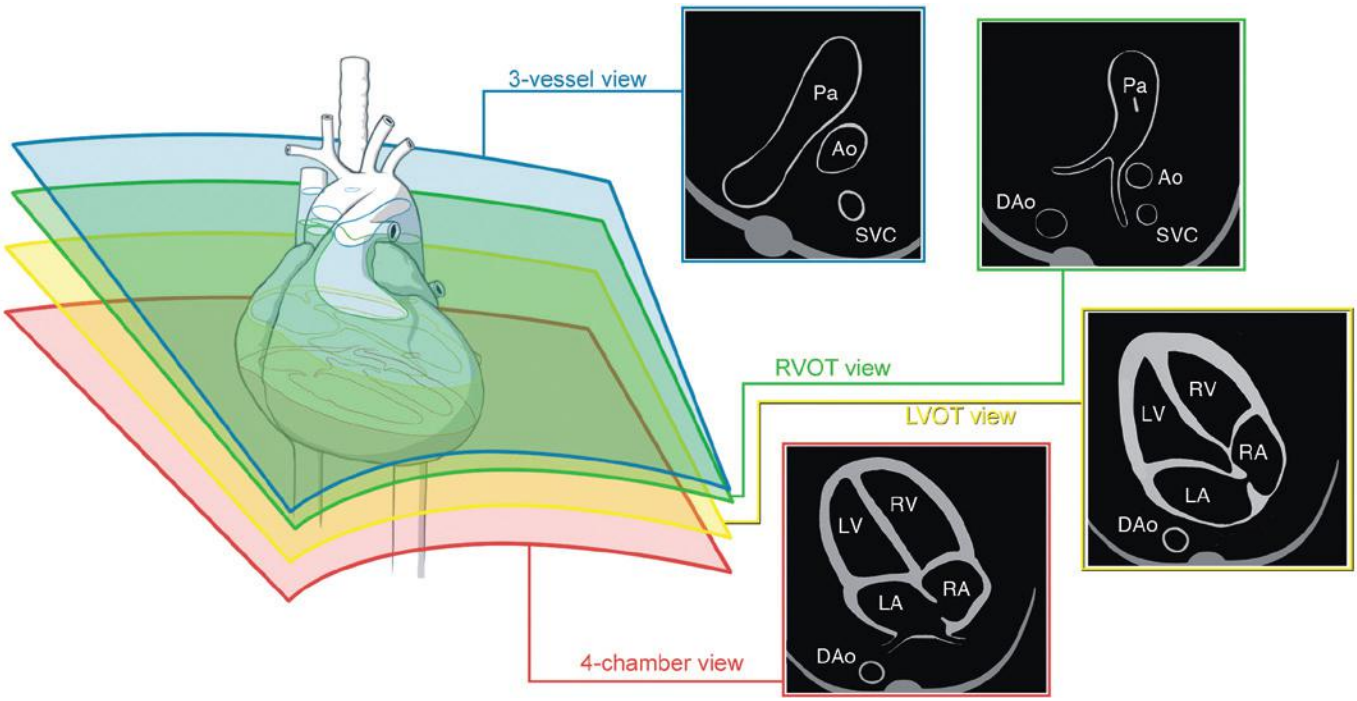

FIG 13-11 Sonographic scanning planes for fetal cardiac screening. The most inferior transverse plane is used to confirm that the stomach and heart are both on the left side of the fetus (not shown). A cephalad sweep of an ultrasound transducer toward the fetal head is used to visualize (1) four-chamber view; (2) left ventricular outflow tract (LVOT); (3) right ventricular outflow tract (RVOT); (4) and three-vessel view. Ao, ascending aorta; DAo, descending aorta; LA, left atrium; LV, left ventricle; Pa, pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

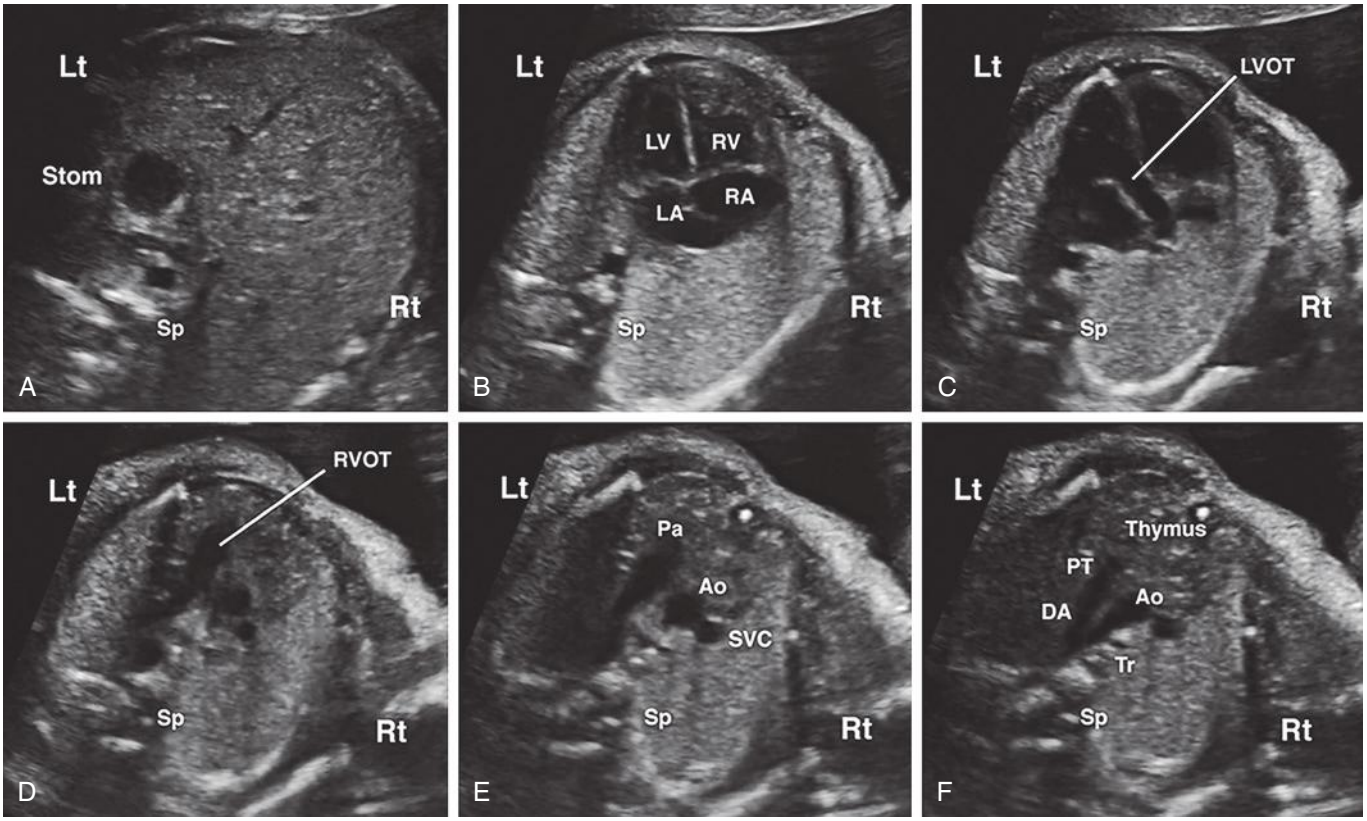

FIG 13-12 Standard ultrasound scanning planes are used to evaluate the fetal heart by evaluating the following: **A,** abdominal situs; **B,** four-chamber view; **C,** left ventricular outflow tract; **D,** right ventricular outflow tract; **E,** three-vessel view; and **F,** three-vessel and trachea view. Ao, ascending aorta; DA, ductus arteriosus; LA, left atrium; Lt, left; LV, left ventricle; LVOT, left ventricular outflow tract; Pa, pulmonary artery; PT, pulmonary artery trunk; RA, right atrium; Rt, right; RV, right ventricle; RVOT, right ventricular outflow tract; Sp, spine; Stom, stomach; SVC, right superior vena cava; Tr, trachea.

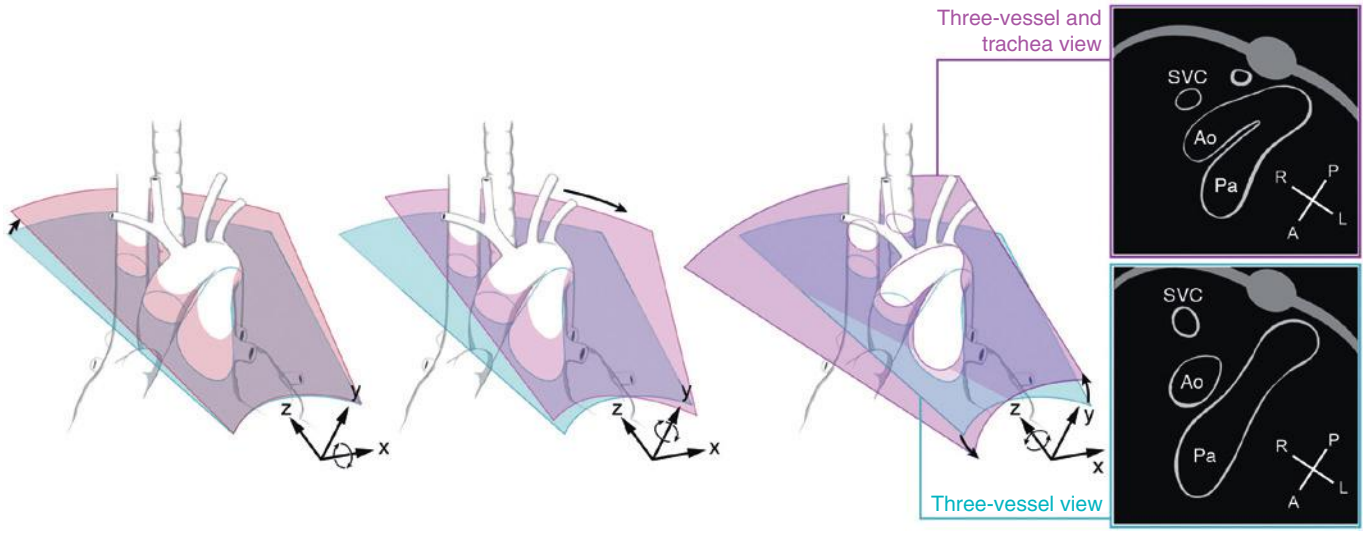

FIG 13-13 Subtle transition between a three-vessel view (3VV) and three-vessel and trachea view (3VTV). A final transverse scan plane (purple plane, far left figure) completes the cephalad transducer sweep. Next, this plane is slightly rotated clockwise (purple plane with *curved arrow*, middle figure) and followed by a counterclockwise roll that allows the plane to intersect the ductus arteriosus as part of a "V-connection" between the aorta (Ao) and pulmonary artery (Pa) (purple plane, far right figure). Some investigators place more emphasis on the 3VTV because it captures similar diagnostic information as the 3VV and permits identification of anomalies such as a right aortic arch or vascular ring. A, anterior; L, left; P, posterior; R, right; SVC, right superior vena cava.

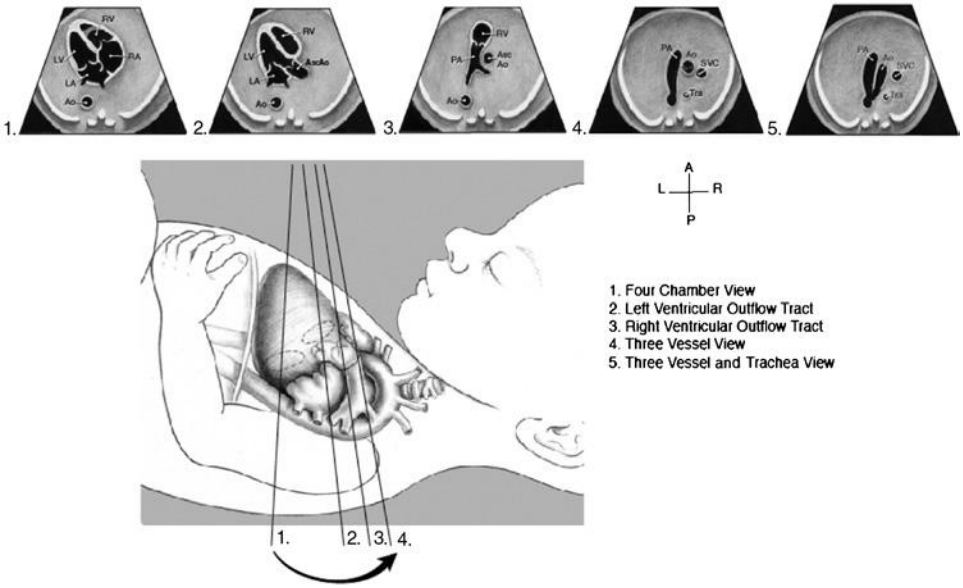

FIG 13-14 Standardized transverse scanning planes for fetal echocardiography include an evaluation of the four-chamber view (1), arterial outflow tracts (2 and 3), and the three-vessel and three-vessel and trachea views (4 and 5). A, anterior; Ao, descending aorta; Asc Ao, ascending aorta; L, left; LA, left atrium; LV, left ventricle; P, posterior; PA, pulmonary artery; R, right; RA, right atrium; RV, right ventricle; and Tra, trachea. (From American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013, used with permission.)

in formal fetal echocardiography, in addition to a series of other views obtained in different planes (Figs. 13-14 and 13-15). The additional views are discussed further later in this section ("Standard Views").

Describing the Heart. Evaluation of cardiovascular structures includes a description of the anatomy using sequential segmental analysis. Two main historical schools of nomenclature are typically used: the Van Praagh/Boston school and the Anderson/European school, as well as consensus-based nomenclature for CHD surgery that is typically used for databases.[78] Regardless of the names used, description of the heart typically includes evaluation of (1) atrial anatomy, (2) AV connections, (3) ventricular looping/topology, (4) ventriculoarterial connections, and (5) description of the great arteries (Fig. 13-16). Abnormalities of these normal relationships are present in many types of heart disease, as detailed in the following sections. Some examples of abnormal atrial anatomy, AV connections, ventricular looping, ventriculoarterial connections, and great artery arrangement are illustrated in Figure 13-17.

Standard Views

Plane 1: Transabdominal View. A transverse view of the upper fetal abdomen is first evaluated to confirm normal situs (Fig. 13-18). The most caudal transabdominal scanning plane typically reveals a left-sided fetal stomach with a main hepatic lobe and gallbladder on the right side. This view is useful in heterotaxy syndromes such as left atrial isomerism (polysplenia) and right atrial isomerism (asplenia)[79,80] that may be associated with complex cyanotic heart disease and cardiac rhythm disturbances.

Plane 2: Four-Chamber View. After one verifies the stomach on the left side and liver on the right, the transducer is swept cephalad across the fetal thorax toward the head to obtain a four-chamber view and to assess cardiac position and direction of the apex (Figs. 13-11, 13-12B, 13-14, and 13-19, Video 13-1). The four-chamber view is defined by a specific set of diagnostic imaging criteria that have been well summarized by the International Society of Ultrasound in Obstetrics and Gynecology[34] (Table 13-2).

Plane 3: Left Ventricular Outflow Tract View. Continuation of a transducer sweep toward the fetal head will reveal an aortic outflow tract that originates from the LV (Figs. 13-11, 13-12C, 13-14, and 13-20, Video 13-2). Although not required for screening, it may be possible to visualize neck vessels of the transverse aortic arch as one follows the distal end of the LVOT. The medial aortic wall should be continuous with the ventricular septum. Membranous or conoseptal VSDs will be seen in this plane and will not be visualized on a four-chamber view. Use of color or spectral Doppler imaging is not a mandatory part of the LVOT evaluation, although familiarity in its use and adding it to routine screening is encouraged,[34] as they can aid in the identification of aortic stenosis or aortic regurgitation.

Plane 4: Right Ventricular Outflow Tract View. The next scanning plane demonstrates a pulmonary artery that originates from a morphologic RV that is identified by a moderator band (Figs. 13-11, 13-12D, 13-14, and 13-21). A pulmonary artery bifurcation may be visualized (Fig. 13-21C), although this finding is not a required element for a technically satisfactory cardiac screening examination. An example of a right ventricular outflow tract (RVOT) abnormality is narrowing of part of the RVOT in TOF, although narrowing may not be apparent until later stages of pregnancy.[81,82] Familiarity of using color Doppler sonography for routine assessment of the RVOT is encouraged, although it is not considered a mandatory component for cardiac screening.[34] Color and spectral Doppler evaluation of the RVOT can aid in the identification of pulmonary stenosis or pulmonary regurgitation.

Plane 5: Three-Vessel View. A 3VV provides a transverse view of the upper fetal mediastinum. In this plane, the main pulmonary artery, ascending aorta, and superior vena cava are arranged in a straight line that extends from the left anterior to right posterior aspect of the

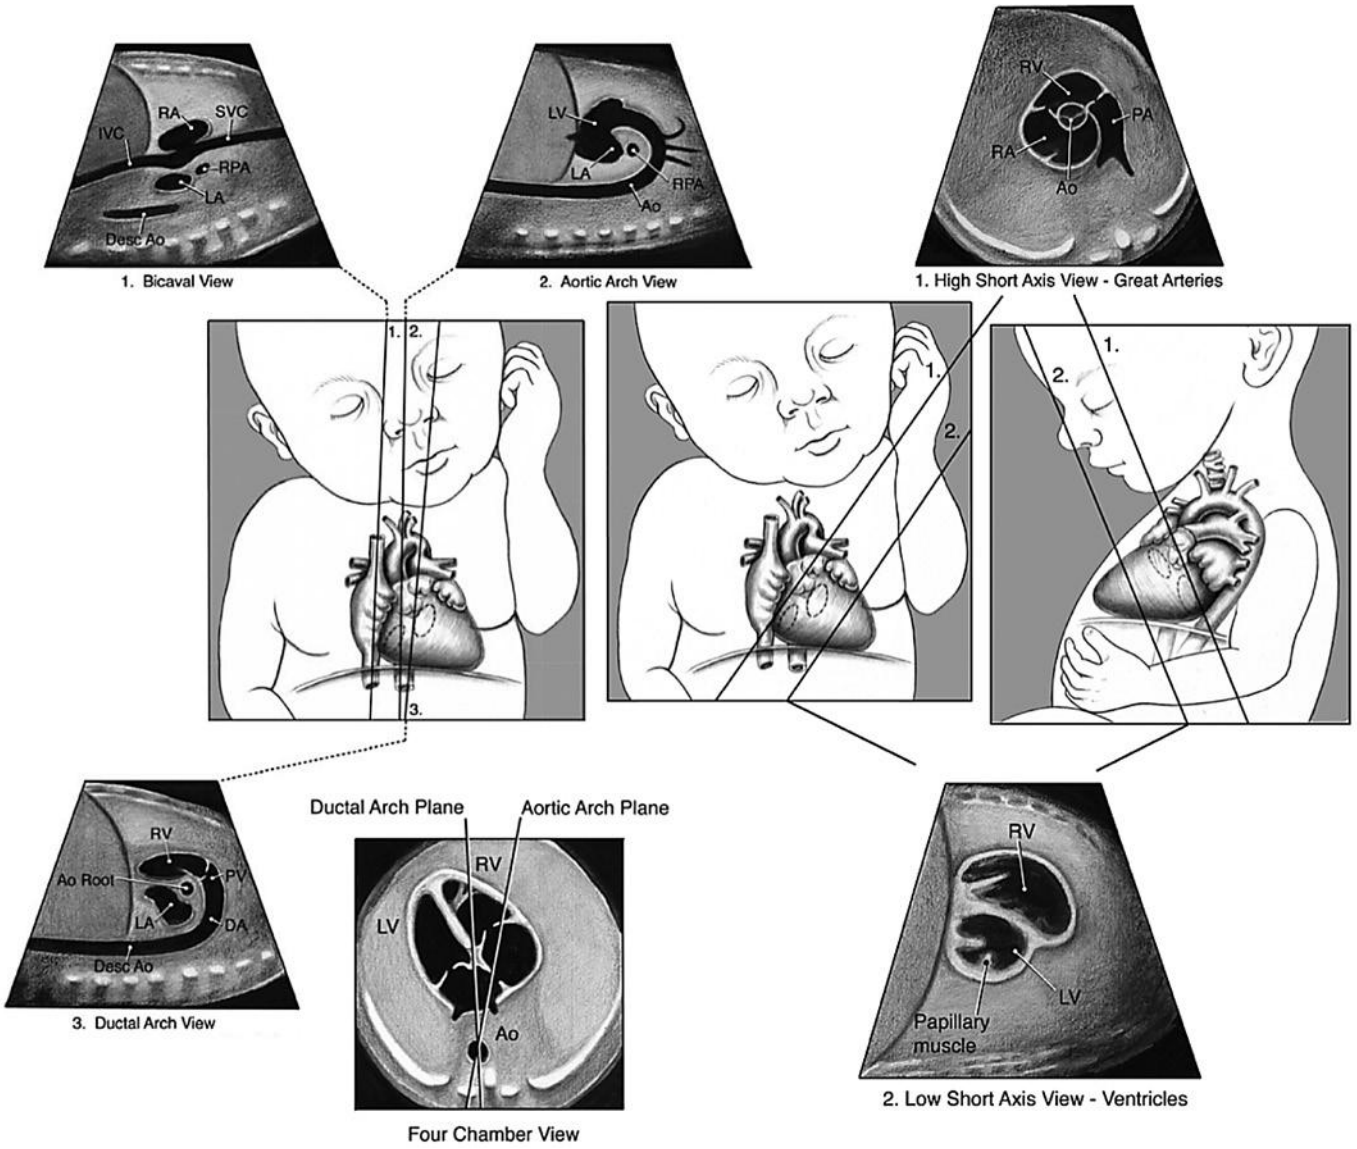

FIG 13-15 Sagittal views of the superior and inferior venae cavae, aortic arch, and ductal arch, as well as low and high short-axis views of the fetal heart. Ao, aorta; Ao Root, aortic root; DA, ductus arteriosus; Desc Ao, descending aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA: main pulmonary artery; PV, pulmonary valve; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; SVC, superior vena cava. (From American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013, used with permission.)

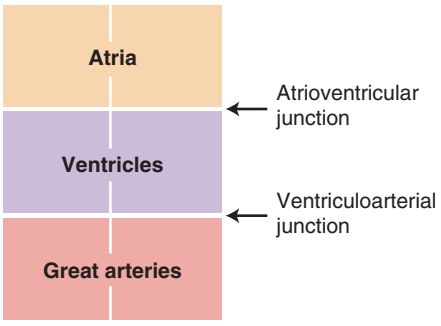

FIG 13-16 Basic cardiac segments and junctions.

mediastinum with decreasing magnitude of their vessel diameters[83] (Figs. 13-11, 13-12E, 13-13, 13-14, and 13-22). If technically feasible, the 3VVshould be attempted as a routine part of a midtrimester screening examination.[34] Color Doppler sonography is not a mandatory part of the 3VV, although familiarity in its use and adding it to routine screening is encouraged.[34]

Normal and abnormal examples for using color Doppler sonography with the 3VV have also been reported.[84] Abnormalities in vessel number, size, alignment, and arrangements may provide clues for anomalies of the great vessel such as right aortic arch or a persistent left superior vena cava. Paladini[85] has also described how the internal mammary arteries can be used to outline the fetal thymus from a 3VT view for fetuses at risk for chromosome 22q11.2 microdeletion.

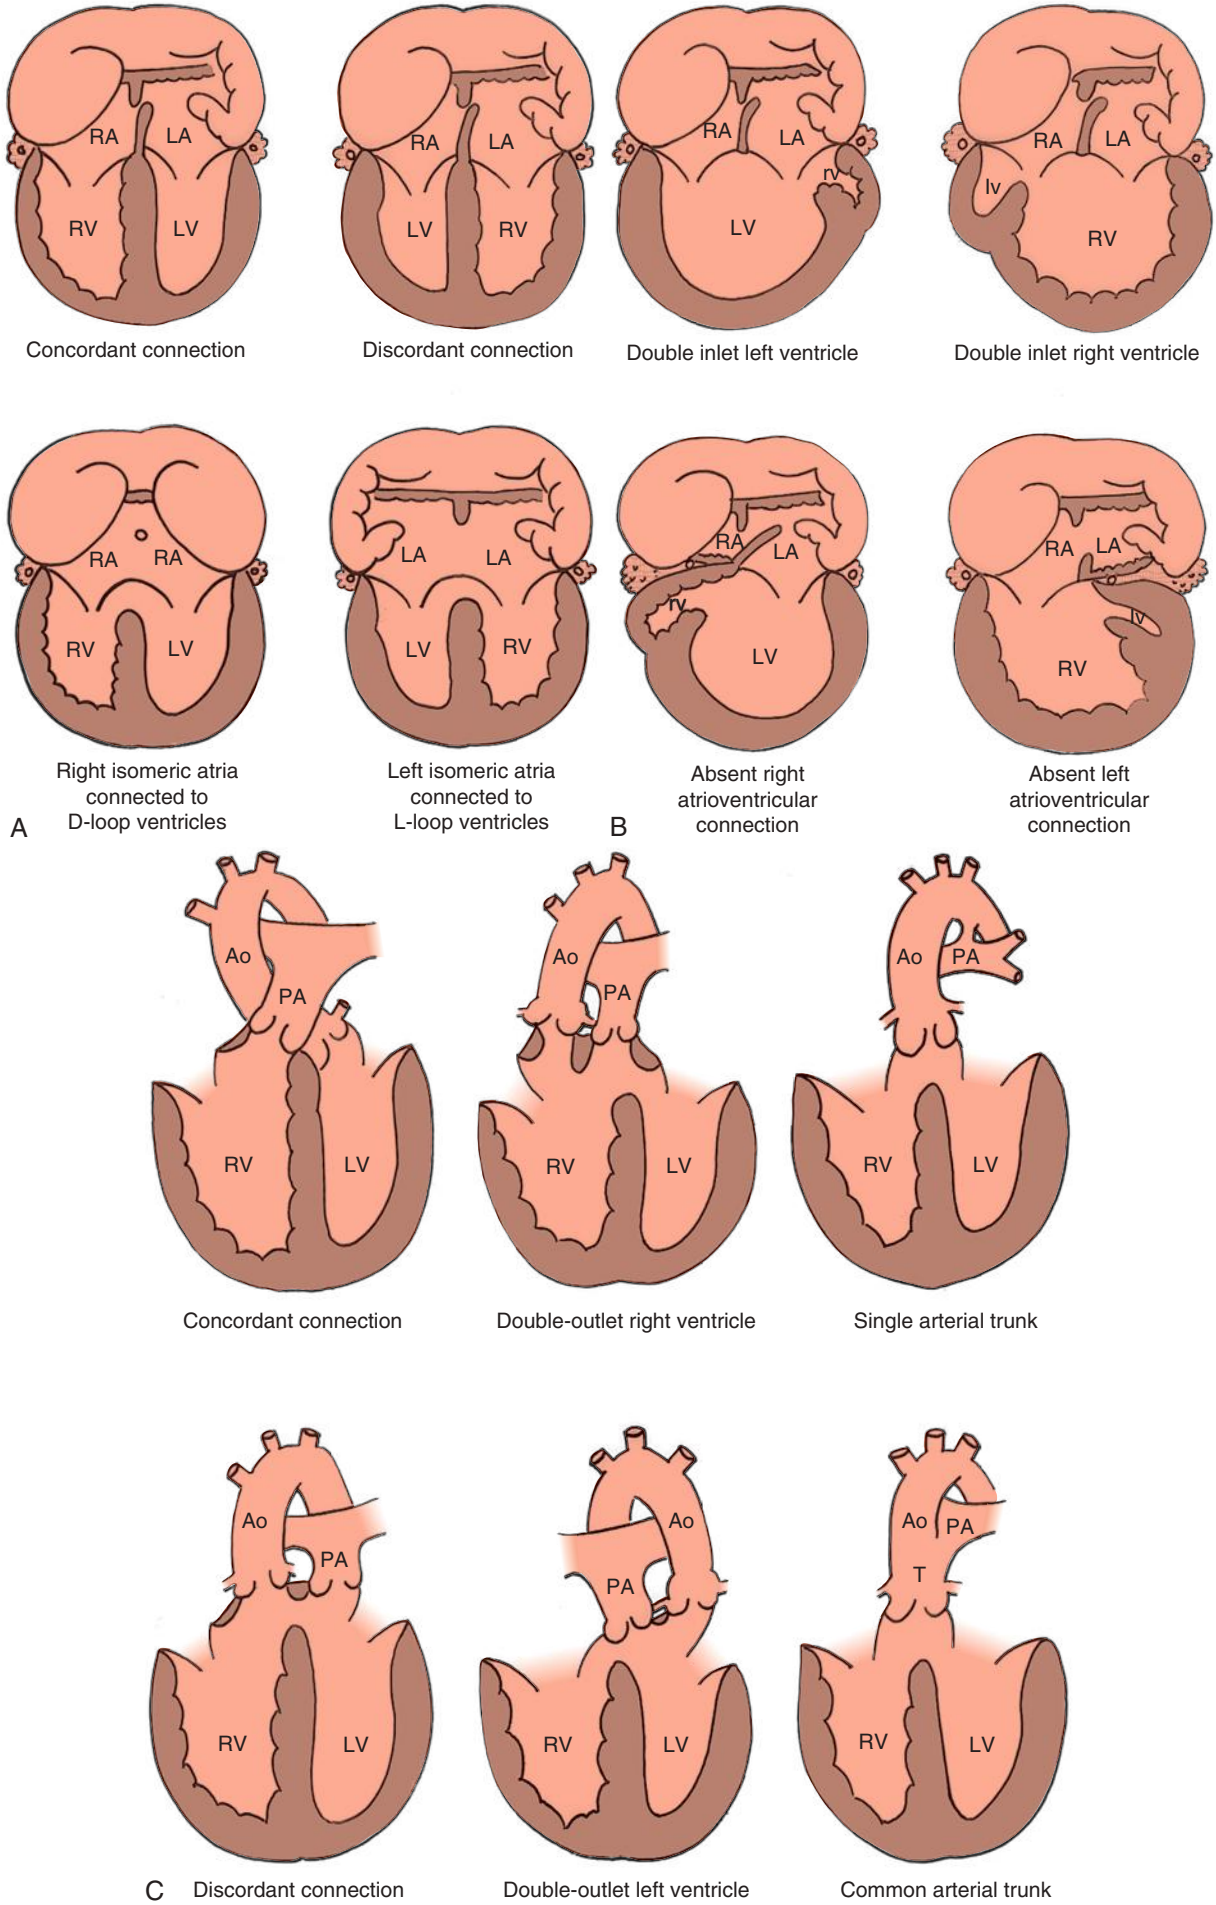

FIG 13-17 Biventricular atrioventricular connections (**A**), univentricular atrioventricular connections (**B**), and types of ventriculoarterial connections (**C**). Ao, ascending aorta; LA, left atrium; LV (lv), left ventricle; PA, main pulmonary artery; RA, right atrium; RV (rv), right ventricle; T, truncus.

Plane 6: Three-Vessel and Trachea View. Finally, a 3VT view is obtained just a few millimeters above the 3VV after slight counterclockwise angulation toward the left from an axial plane[86] (Figs. 13-12F, 13-13, 13-14, 13-22, and 13-23). This plane is used to evaluate major vessels in the fetal mediastinum. The transverse aortic arch and isthmus merge into the descending aorta, as does the pulmonary trunk and ductus arteriosus, creating a V-shaped configuration. Note the presence of an anterior fetal thymus gland in this view as well and how the V-shaped landmark lies just to the left of the trachea.

A 3VT view is very similar to the 3VV except that the aortic and ductal arches are both visualized just superior to the carina (see Fig. 13-13). Both arches are normally visualized to the left of the spine and trachea. Much like the 3VV, the 3VT view can be used to assess the number, size, and alignment of the main pulmonary artery, aorta, and right superior vena cava. However, the 3VT view will likely allow the detection of life-threatening ductus-dependent cardiac malformations.[87] In this regard, color Doppler sonography can be very useful for identifying ductus-dependent lesions in this scanning plane. The 3VT view has also been used for the detection of aortic arch anomalies and aberrant right subclavian artery (ARSA).[88,89] In a study of 106 second trimester Down syndrome fetuses, the incidence of aberrant right subclavian artery was 25%.[90]

Key Components of Screening

General Assessment

Heart Rate. Fetal heart rate (FHR) reference ranges during the second and third trimesters typically fall between 120 and 160 beats/minute (bpm) with occasional and limited decelerations or accelerations beyond these limits.[91] Benign episodes of fetal bradycardia can occur during a second trimester screening scan, but they quickly recover to normal values, especially if maternal abdominal pressure of the ultrasound transducer is reduced. Although fetal bradycardia has been broadly accepted as a heart rate less than 100 bpm, the American College of Obstetricians and Gynecologists (ACOG) has defined bradycardia as a heart rate less than 110 bpm.[92,93] Sustained bradycardia below this threshold may be caused by heart block. Mild tachycardia (>160 bpm) can transiently occur in normal fetuses, although persistent tachycardia (≥180 bpm) should be further investigated for problems such as supraventricular tachycardia (SVT), chorioamnionitis, fetal distress, or hyperthyroidism.

Heart Size. Cardiac circumference measurements provide quantitative verification when cardiomegaly is suspected.[94,95] Enlarged hearts can be associated with cardiac dysfunction, especially in the presence of pericardial effusion. Cardiomegaly is generally defined as

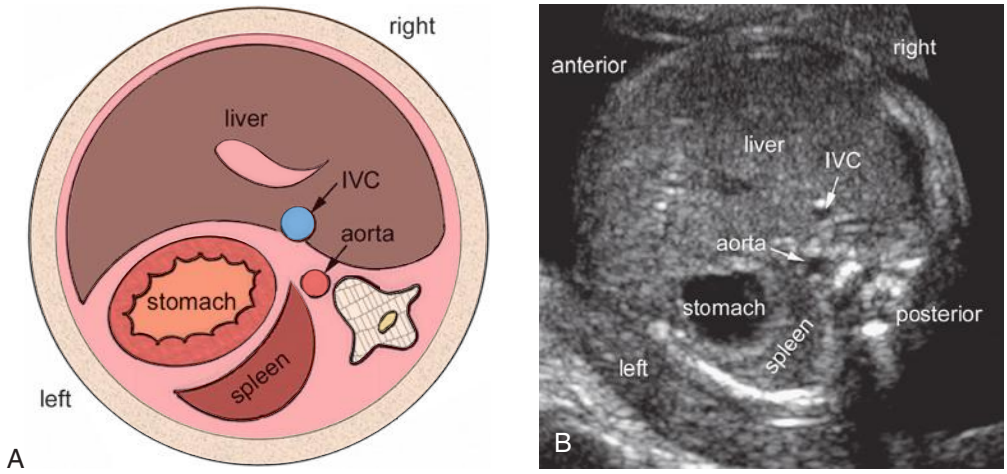

FIG 13-18 Transverse view of the upper abdomen, diagram (**A**) and sonographic image (**B**). The larger lobe of the liver is on the right, and the stomach on the left. The descending aorta is at the left anterior aspect of the spine. The inferior vena cava (IVC) is on the right side of the midline. Note that the IVC is located anteriorly at some distance from the spine as it courses forward to connect to the right atrium above this level.

FIG 13-19 Diagram (**A**) and sonographic images (**B** through **F**) in the four-chamber view. The right- and left-sided chambers are symmetric in size. The atrioventricular valves have offset attachments (*dots* in B-D) to the septum, with the tricuspid valve having more apical attachment than the mitral valve. The apex of the right ventricle (RV) is obliterated in B and C by the moderator band (*asterisk*). The moderator band can also be seen as a distinct muscle bundle as shown in D. Right and left lower pulmonary veins (RLPV and LLPV) course obliquely forward as they connect to the left atrium (LA). The central part of the atrial septum is the septum primum (*arrows* in C). It is thin and mobile and bulges into the LA. The descending aorta (ao) is seen at the left anterior corner of the spine. E shows a slice just inferior to the four-chamber view. The coronary sinus (CS) is seen as a tubular structure between the left ventricle (LV) and the inferior vena cava (IVC) orifice. Note that the proximal part of the coronary sinus can be seen as a small circle at the left atrioventricular junction in a regular four-chamber view. The color Doppler image (F) shows both lower pulmonary veins and the right upper pulmonary vein (RUPV). Both lower pulmonary veins course obliquely forward, whereas the RUPV courses obliquely backward as it connects to the LA. RA, right atrium. (A from American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013.)

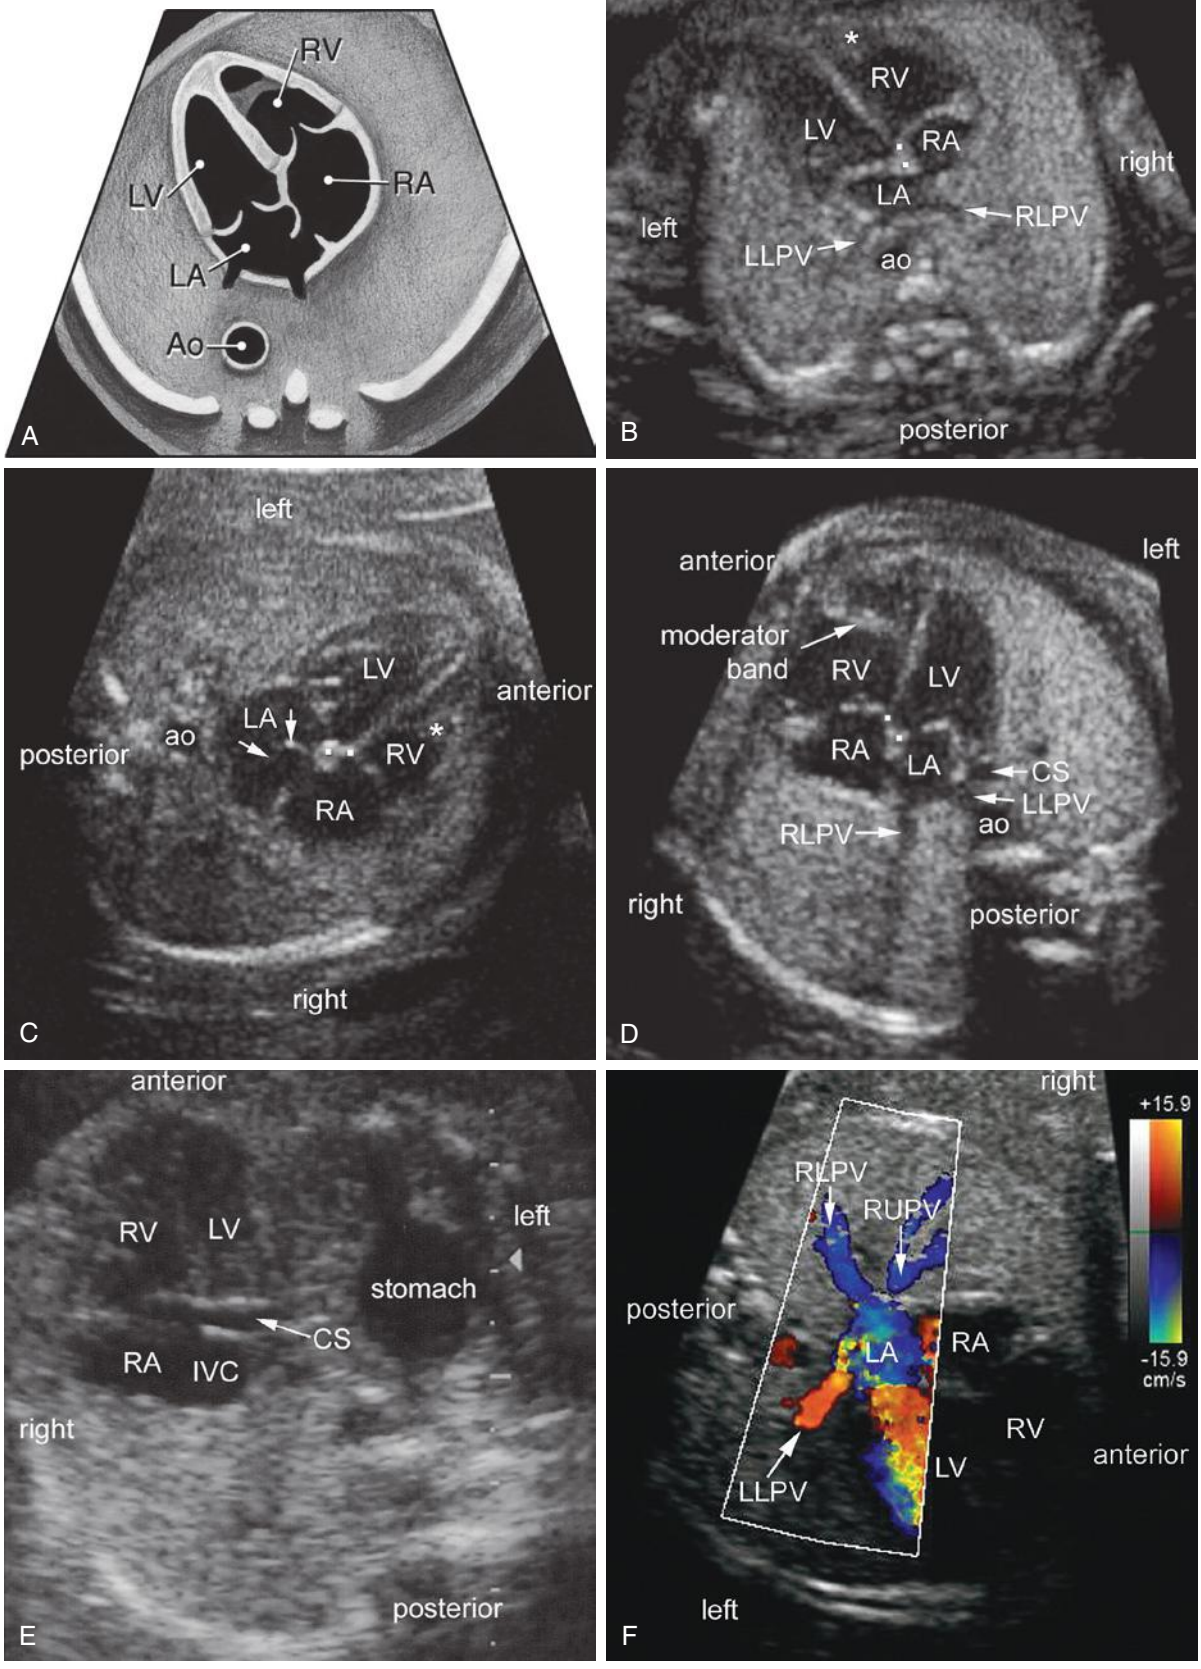

TABLE 13-2 Fetal Situs/Laterality and Four-Chamber View of the Fetal Heart

General Assessment
1. Fetal laterality (identify right and left sides of fetus)
2. Stomach and heart on left
3. Normal cardiac rate and rhythm
4. Heart occupies no more than a third of thoracic area
5. Majority of heart in left side of chest
6. Normal cardiac axis and position
7. Four cardiac chambers present
8. No pericardial effusion or hypertrophy

Atrial Chambers
1. Two atria, approximately equal in size
2. Foramen ovale flap in left atrium
3. Atrium septum primum present (near to crux)
4. Pulmonary vein enters left atrium

Ventricular Chambers
1. Two ventricles, approximately equal in size
2. No ventricular wall hypertrophy
3. Moderator band at right ventricular apex
4. Ventricular septum intact (apex to crux)

Atrioventricular Junction and Valves
1. Intact cardiac crux
2. Two atrioventricular valves open and move freely
3. Differential offsetting: tricuspid valve leaflet inserts on ventricular septum closer to cardiac apex than does mitral valve

Adapted from International Society of Ultrasound in Obstetrics and Gynecology; Carvalho JS, Allan LD, Chaoui R, et al: ISUOG Practice Guidelines (updated): sonographic screening examination of the fetal heart. Ultrasound Obstet Gynecol 41(3):348-359, 2013.

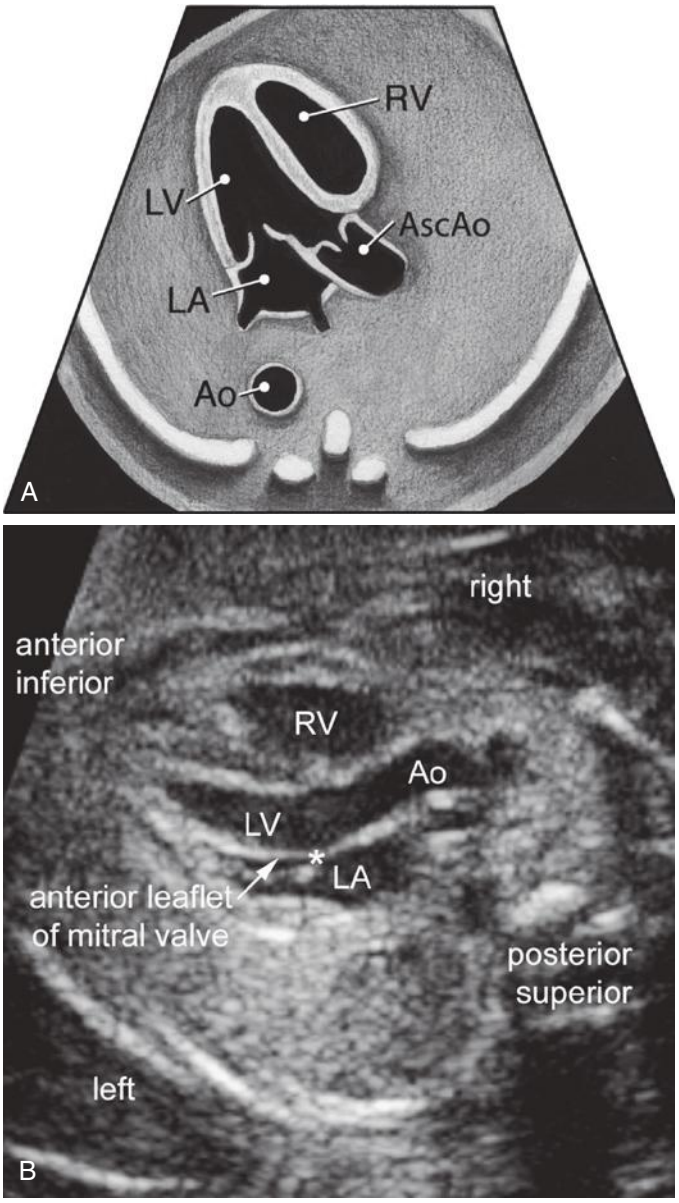

FIG 13-20 Diagram (**A**) and sonographic image (**B**) in the left ventricular outflow tract view. Ao, aorta; AscAo, ascending aorta; LA, left atrium; LV, left ventricle; RV, right ventricle. (A from American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013.)

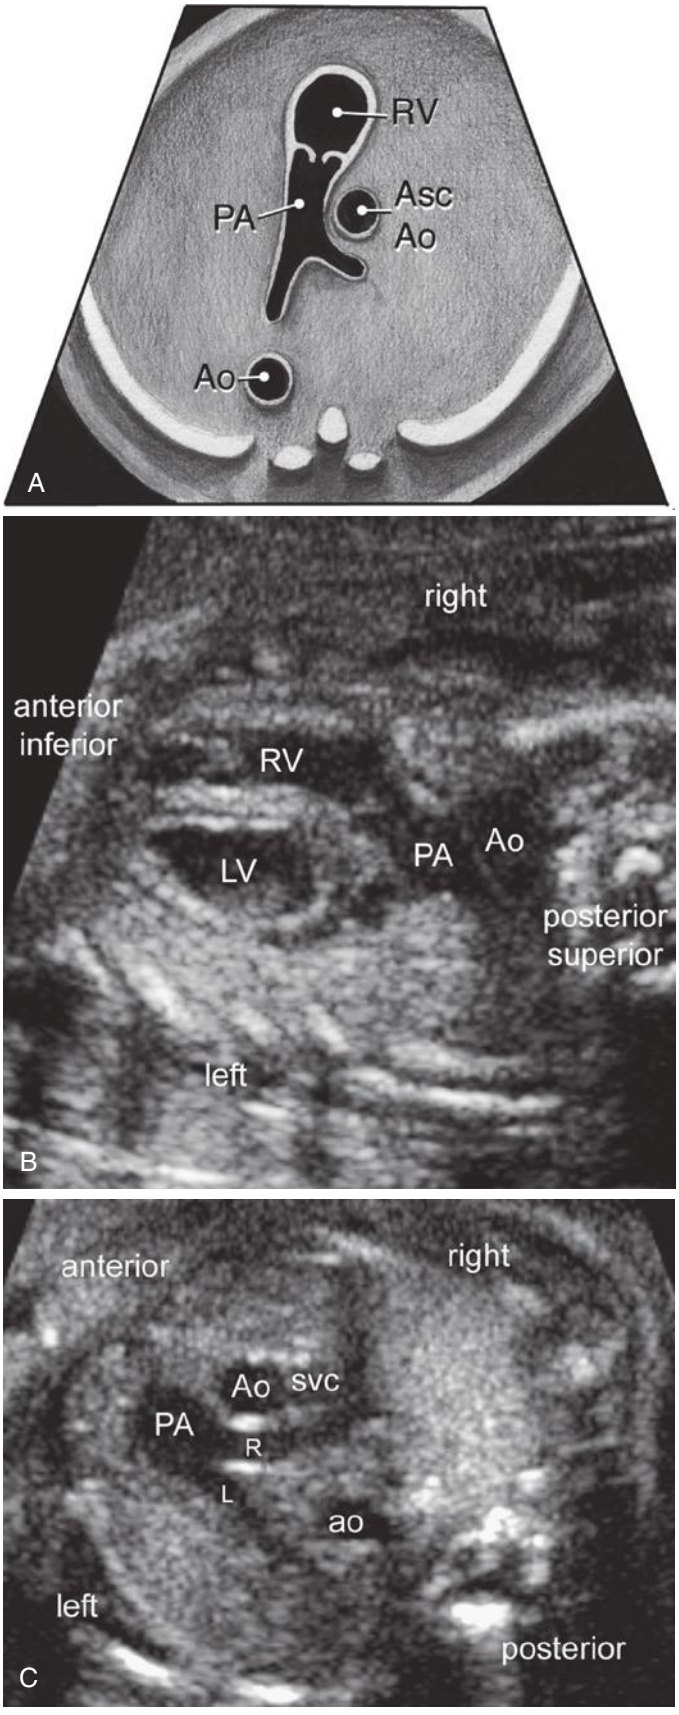
a cardiothoracic circumference ratio greater than 0.50 or a cardiothoracic area ratio greater than 0.25.[96,97]

Cardiac Axis and Position. Cardiac axis is determined from a line that is drawn from the spine to the anterior chest wall.[98] This line divides the fetal chest into equal halves with an angle that the interventricular septum makes with this line as the cardiac axis. The fetal heart is located in the left hemithorax with a cardiac axis of 45 ± 20 degrees (see Fig. 13-9). The heart can point toward the midline (mesocardia) or be deviated toward the right side of the chest (dextrocardia) as a normal variant. The same line can be extended to the most posterior cardiac border where it intersects the posterior wall as a "P point." Point P is located within a specific area of the thorax in 96.3% of fetuses.

Both cardiac axis and position are constant throughout pregnancy. Although left cardiac axis deviation (>75 degrees to left) can occur as a normal variant, most cases will be associated with structural malformations, particularly conotruncal anomalies and coarctation, which may not otherwise be detectable from a four-chamber view.[99] Right cardiac deviation (heart axis from 25 degrees to the left of midline to anywhere in the midline or right side of the chest) has been associated with polysplenia/asplenia, situs inversus, AVSD, double-outlet right ventricle (DORV), or common atria.[100] Abnormal cardiac position deviated into the right chest (dextroposition) warrants a further search for either a left-sided congenital diaphragmatic hernia or space-occupying mass such as a cystic adenomatoid malformation.

Four Cardiac Chambers Present. The presence of four cardiac chambers is an essential component of a normal four-chamber view. However, a simple count of four chambers alone should not be mistaken as being sufficient to fulfill diagnostic criteria for a technically acceptable four-chamber view. In a normal four-chamber view the two atria and the two ventricles will be symmetric in size (see Fig. 13-19A through D).

No Pericardial Effusion or Hypertrophy. Pericardial effusions are occasionally identified at the time of a routine cardiac screening examination (Fig. 13-24). A pericardial fluid collection of more than 2 mm in thickness is considered abnormal.[101,102] Isolated effusions can spontaneously resolve with good postnatal outcomes, although this finding can also be associated with a genetic syndrome such as trisomy 21.



Age-specific reference values for left and right ventricular wall thickness have been reported in fetuses.[103]

Atrial Chambers. A normal fetal cardiac screening examination identifies two atrial chambers of approximately the same size with a normal-appearing foramen ovale flap in the LA (see Fig. 13-19A through D). The primum atrial septum is intact and pulmonary veins enter the left atrial chamber. The coronary sinus can be visualized in the left AV groove when sweeping inferiorly (see Fig. 13-19E).

One of the primary reasons for investigating atrial morphologic appearance is to rule out heterotaxy (also known as isomerism), in which the heart has inappropriate symmetry. Berg and colleagues reviewed 30 prenatally diagnosed cases of heterotaxy and have described two types of atrial morphologic features[104]: (1) sickle shape with tip pointing laterally and apically and (2) blunt shape resembling the usual atrial appearance in the four-chamber view (see Fig. 13-17A). Their results suggest that prenatally diagnosed heterotaxy most often presents with an isomeric morphologic appearance in the four-chamber view, and that differentiation between bilateral left (sickle-shaped) and bilateral right (blunt and pyramidal) isomerism can be determined. This differentiation is particularly significant because the greatest attrition in left atrial isomerism occurs during fetal life, whereas neonates with right atrial isomerism are more likely to experience postnatal problems associated with complex CHD. However, caution should be exercised when applying these findings to a screening population. More information regarding evaluating heterotaxy in the fetal echocardiogram is given in the discussion of congenital heart lesions ("Situs Abnormalities").

Atrial septal aneurysm may also be visualized from the four-chamber view. A retrospective study of 1302 fetal echocardiograms found a 7.6% incidence of atrial septal aneurysm that was defined as redundant tissue extending at least halfway across the LA. They observed that 36% of fetuses with atrial septal aneurysm had premature atrial beats that appeared to be related to the degree of septal bulging. Their results suggest that such aneurysms almost always resolve after birth and are not typically associated with major cardiac dysrhythmias.[105] Severe atrial septal aneurysms that extend over the mitral valve apparatus have been reported with left-right asymmetry on fetal evaluation, and occasionally with coarctation of the aorta.[106]

Routine screening should also include assessment of the pulmonary veins. A normal four-chamber screening examination usually demonstrates at least two of the four pulmonary veins entering the LA (see Fig. 13-19B through D and F). Total anomalous pulmonary venous return (TAPVC) should be suspected when the connection between the pulmonary veins and the LA is not evident. The diagnosis of TAPVC should always be considered in cases of heterotaxy, especially in fetuses suspected to have right isomerism.[107] Ganesan and colleagues described sonographic findings for 26 fetuses with a prenatal diagnosis of TAPVC.[108] They concluded that the diagnosis of TAPVC can be suspected on standard axial views during the cardiac screening examination and confirmed on fetal echocardiography based on pulsed-Doppler studies. More detailed information on anomalies of pulmonary

venous return is provided later in this chapter under "Anomalous Pulmonary Venous Connection."

Ventricular Chambers. A normal four-chamber view requires confirmation of two cardiac ventricles that are approximately the same size, although the RV is usually slightly larger, particularly in late gestation. The normal RV/LV size ratio increases with progressing gestational age (90% CIs ranging from 0.79 to 1.24).[109] Ventricular size discrepancy may be an initial clue for cardiac anomalies during the screening examination despite the presence of normal ventricular diameter measurements.

Left Ventricle. A cone-shaped LV lies posterior to and leftward of the RV (see Fig. 13-19A through E). The LV has two distinct papillary muscles, the anterolateral and posteromedial. Both papillary muscles have chordae tendineae, which connect to the mitral valve. The LV septal surface is smooth with fine apical trabeculations and no septal connection to the mitral valve.

Right Ventricle. The morphologic anterior right ventricular chamber has a moderator band near the cardiac apex (see Fig. 13-19A through D). Chordae tendineae extend from the septal tricuspid valve leaflet and insert into papillary muscles that arise from the right ventricular septal surface. Unlike the LV, the inlet and apical portions of the RV are heavily trabeculated.

Atrioventricular Junction and Valves

Mitral and Tricuspid Valves. The AV valves prevent ventricular blood from backing up into the atrial chambers. On the screening examination, valve leaflets do not appear thickened and should move freely throughout the cardiac cycle. Although not required, color Doppler imaging of the AV valves is the most useful way to assess for AV valve regurgitation, which is commonly seen in fetal heart disease, especially in atrioventricular canal defects (AVCDs), Ebstein anomaly and other tricuspid valve disorders (Video 13-3), and fetal primary or secondary cardiac dysfunction (Fig. 13-25). AV valves should also be assessed for appropriate connections to the ventricles, as conditions such as tricuspid atresia and mitral atresia can have absent connections to the ventricles, and double-inlet LV can have both AV valves entering the LV (Fig. 13-26 and Video 13-4).

Offset Atrioventricular Valves. In the normal heart, the tricuspid valve annulus is slightly offset from the center crux of the heart and more apically positioned than the mitral valve annulus (see Fig. 13-18). Absence of this normal offsetting suggests an abnormality. For example, in Ebstein anomaly, there is excessive apical displacement of the septal tricuspid valve leaflet (Fig. 13-27).[110] In AVCDs and variants, the normal valve offsetting is not present as there is either a common AV valve or separate AV valves at the same level.[111] The normal valve offsetting may not be apparent in fetuses with a dilated coronary sinus,[112] or may be challenging to recognize due to technical factors.

Offset AV valves can usually be visually confirmed in fetuses, although occasionally it may be helpful to measure the distance between insertions of the medial leaflets of the mitral and tricuspid valves (MTD). Calipers are placed parallel to the ventricular septum

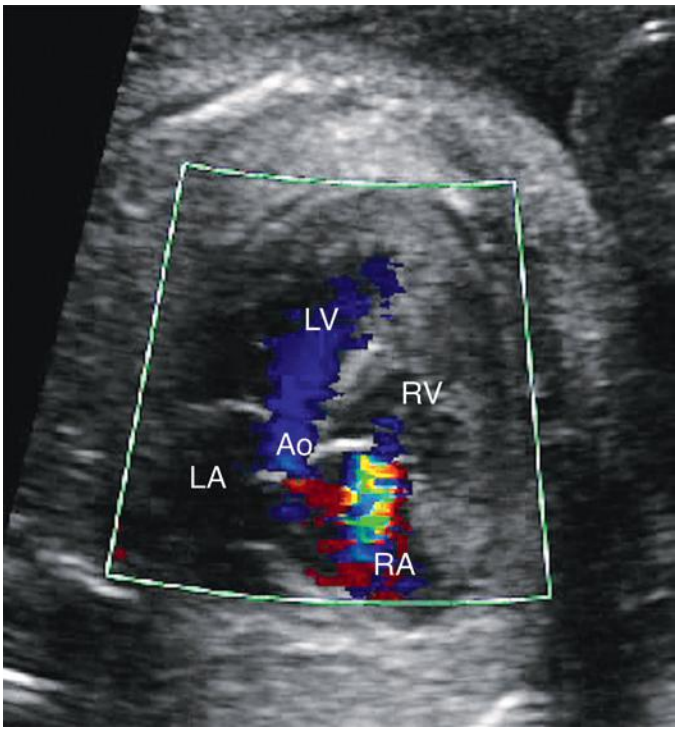

FIG 13-25 Moderate to severe tricuspid valve regurgitation. Ao, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

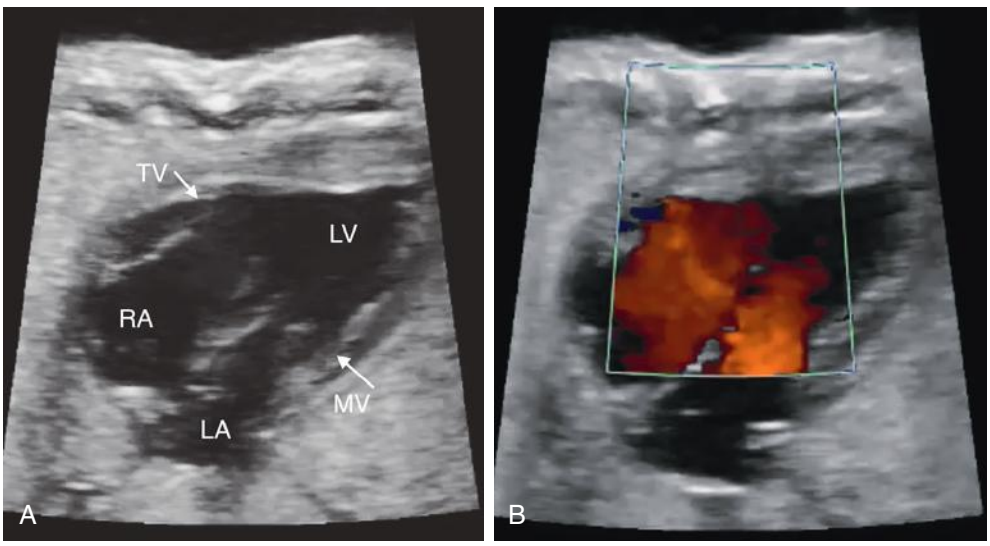

FIG 13-26 Double-inlet left ventricle (LV) by two-dimensional imaging (**A**) and color Doppler imaging (**B**). Both the tricuspid valve (TV) and the mitral valve (MV) open into the LV. The right ventricle is severely hypoplastic and not visible from this view. LA, left atrium; RA, right atrium.

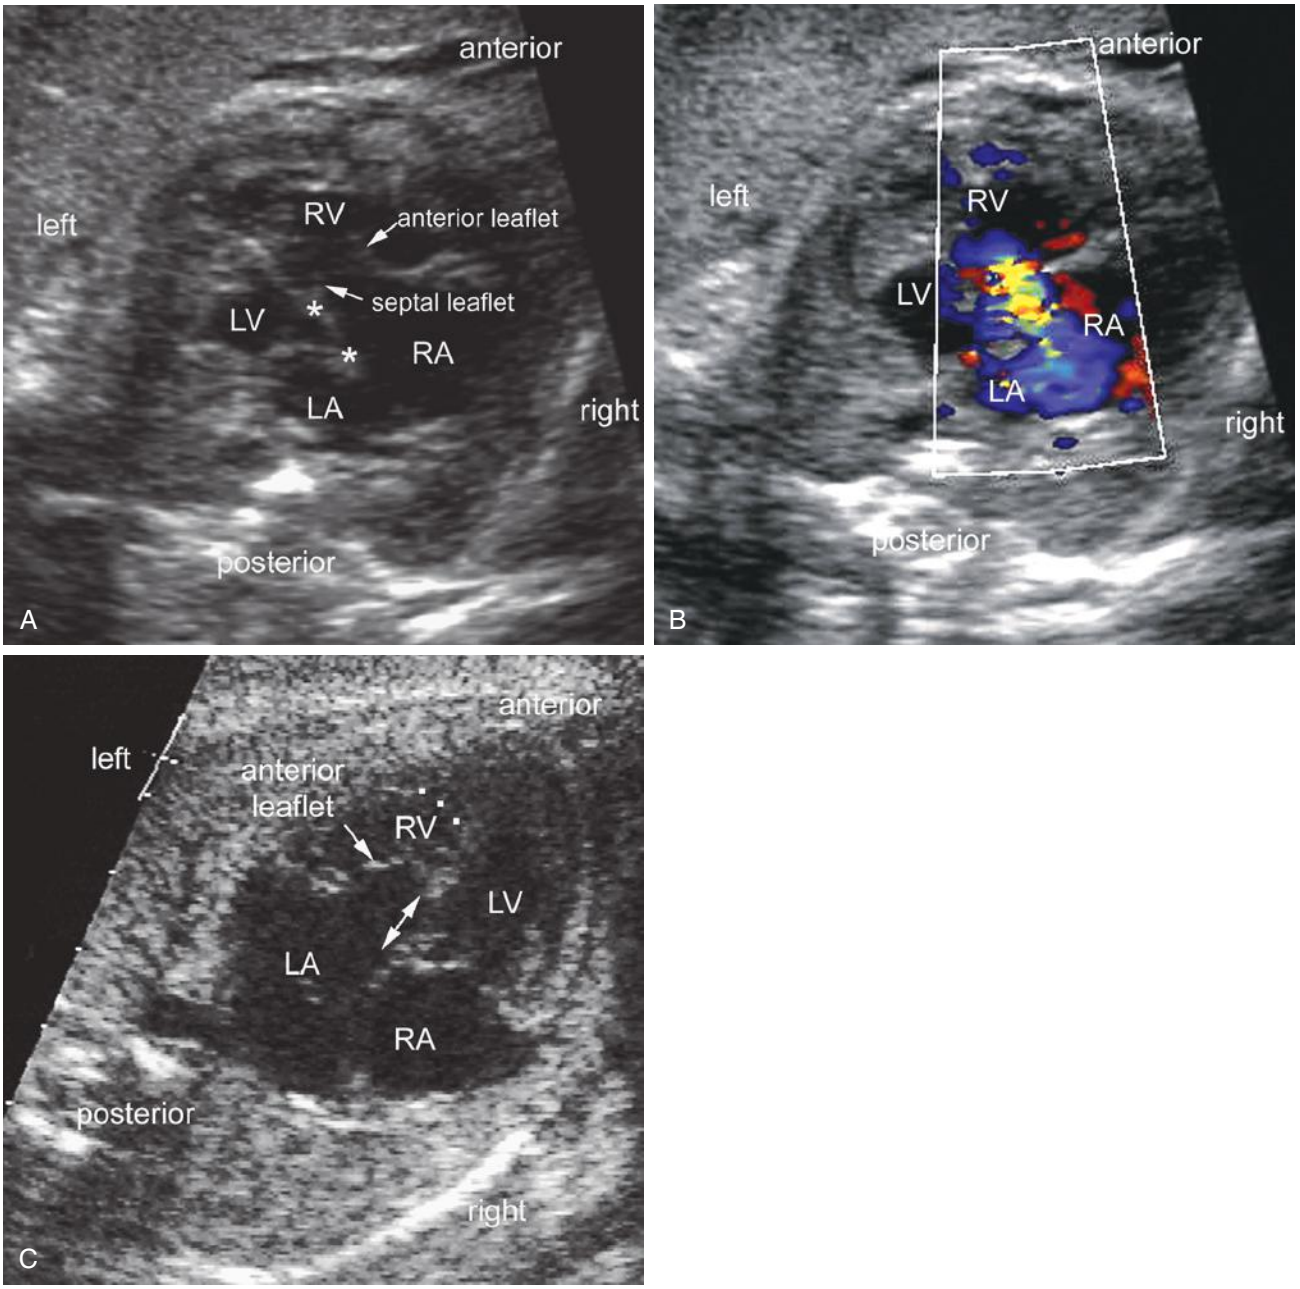

FIG 13-27 Ebstein malformation of the tricuspid valve. **A,** Four-chamber view shows a big heart with dilatation of the right atrium (RA) and right ventricle (RV). Note the displaced attachment of the septal leaflet of the tricuspid valve (*upper asterisk*). The anterior leaflet of the mitral valve has a normal insertion to the septum (*lower asterisk*). The anterior leaflet of the tricuspid valve is large, whereas the septal leaflet is small. **B,** Color Doppler image in the same view as A shows moderate tricuspid regurgitation. **C,** Ebstein malformation in a patient with congenitally corrected transposition of the great arteries (atrioventricular discordance with ventriculoarterial discordance). LA, left atrium; LV, left ventricle. (From Yoo SJ, Jaeggi ET: Ultrasound evaluation of the fetal heart. In Callen PW [ed]: Ultrasonography in Obstetrics and Gynecology. London, Elsevier Health Sciences, 2011, pp 511-586, used with permission.)

using a standard four-chamber view. The first caliper is placed at the junction of the insertion point of the atrial surface of the tricuspid valve and ventricular septum, and the second caliper is placed at the level of insertion of the atrial surface of the mitral valve and the ventricular septum. In the second trimester, the mean MTD is 2.8 ± 0.9 mm, and in the third trimester the mean MTD is 4.6 ± 1.1 mm.[113]

Ventriculoarterial Junction and Valves

Aortic and Pulmonary Valves. The aortic and pulmonary valves prevent blood from backing up into the ventricular chambers during diastole. On the screening examination, normal valve leaflets appear thin and mobile throughout the cardiac cycle.

Arterial Outflow Tracts. The aorta normally arises from the LV and the pulmonary artery arises from the RV. Conotruncal

abnormalities involve a spectrum of anatomic defects such as DORV, TOF, transposition of the great arteries (TGA), and truncus arteriosus that are not usually evident in a four-chamber view. Identification of conotruncal anomalies remains a challenging task for those who routinely screen fetuses for CHD.

The great vessels should appear approximately equal in size and cross over each other at approximately 80 degrees from their respective ventricular chambers.[114] The addition of color and spectral Doppler to outflow tracts is not mandatory, but may facilitate making the diagnosis of valvar regurgitation or stenosis.

Fetal Echocardiography

Guidelines. Fetuses at risk for CHD should be further examined using a detailed echocardiogram. A practice guideline consensus was recently developed on behalf of several organizations that included the AIUM, ACOG, Society for Maternal-Fetal Medicine (SMFM), American Society of Echocardiography (ASE), and American College of Radiology (ACR).[74] In brief, this collaborative document outlined common maternal and fetal indications for fetal echocardiography but emphasized that most referrals are not associated with known risk factors. Further details on the rationale for fetal cardiac diagnosis and treatment, including a more detailed list of indications for prenatal echocardiography, can be found in a multidisciplinary Scientific Statement from the American Heart Association[115] (Table 13-3).

Timing of Fetal Echocardiogram. The timing of the first fetal echocardiogram depends on the study indication. For most practitioners and programs, fetal echocardiography is easily performed after 18 weeks' gestation. There are many reports, however, of fetal echocardiography performed at 13 to 18 weeks with accurate results, although this option is not offered in all programs.[4,47,67] When there is a structural anomaly suspected on screening ultrasound images, fetal echocardiography should be performed shortly after to provide early counseling. When fetal echocardiography is indicated because of increased risk secondary to another condition (e.g., family history, maternal diabetes mellitus), recommendations are generally for fetal echocardiography to be performed at 18 to 22 weeks.[115] It still should be kept in mind that some lesions progress over the course of the pregnancy, and the abnormality may be more evident later in gestation.

Fetal Echocardiography Views. Specific components of the fetal echocardiogram as recommended by the American Heart Association 2014 guidelines are listed in Table 13-4. Evaluation in standard planes can be useful, including those listed earlier for cardiac screening (see Fig. 13-14), along with the following additional views (see Fig. 13-15): (1) the bicaval view, (2) long-axis view of the aortic arch, (3) long-axis view of the ductal arch, (4) high short-axis view—great arteries, and (5) low short-axis view—ventricles. Details of these views are listed next. In addition to gray-scale imaging in all views, color and spectral Doppler are performed. Sweeps of the heart allow anatomic definition of the fetal heart. Measuring cardiac structures is optional, although this step should be considered for suspected structural or functional anomalies. Reference values have been published for most fetal cardiac structures, and free gestational age–based or size-based Z-score

TABLE 13-3 Common Indications for Referral for Fetal Echocardiogram

Indications With Higher Risk Profile (estimated >2% absolute risk)	Indications With Lower Risk Profile (estimated >1% but <2% absolute risk)	Not Indicated (≤1% risk)
Maternal pregestational diabetes mellitus	Maternal medications	Maternal gestational diabetes mellitus with HbA_{1c} <6%
Diabetes mellitus diagnosed in the first trimester	Anticonvulsants	Maternal medications
Maternal phenylketonuria (uncontrolled)	Lithium	SSRIs (other than paroxetine)
Maternal autoantibodies (SSA/SSB^+)	Vitamin A	Vitamin K agonists (Coumadin), although fetal survey is recommended
Maternal medications	SSRIs (only paroxetine)	Maternal infection other than rubella with seroconversion only
ACE inhibitors	NSAIDs in 1st/2nd trimester	Isolated CHD in other than first- or second-degree relative
Retinoic acid	CHD in second-degree relative of fetus	
NSAIDs in third trimester	Fetal abnormality of the umbilical cord or placenta	
Maternal first trimester rubella infection	Fetal intra-abdominal venous anomaly	
Maternal infection with suspicion of fetal myocarditis		
Assisted reproductive technology		
CHD in first-degree relative of fetus (maternal, paternal, or sibling with CHD)		
First- or second-degree relative with disorder with mendelian inheritance with CHD association		
Fetal cardiac abnormality suspected on obstetric ultrasound		
Fetal extracardiac abnormality suspected on obstetric ultrasound		
Fetal karyotype abnormality		
Fetal tachycardia or bradycardia, or frequent or persistent irregular heart rhythm		
Fetal increased NT >95% (≥3 mm)		
Monochorionic twinning		
Fetal hydrops or effusions		

ACE, angiotensin-converting enzyme; CHD, congenital heart disease; HbA_{1c}, hemoglobin A_{1c}; NSAIDs, nonsteroidal anti-inflammatory drugs; NT, nuchal translucency; SSRI, selective serotonin reuptake inhibitor.

TABLE 13-4 Components of the Fetal Echocardiogram

Two-Dimensional Imaging	Rhythm Assessment	Color Flow Map Imaging	Pulsed Doppler Interrogation	Continuous Wave Doppler	Ventricular Function
Cardiac size (qualitative)	Heart rate	Tricuspid and mitral valves/ventricular inflows	Tricuspid and mitral inflows	*Valvar insufficiency (if present)*	Exclusion of hydrops
Cardiac axis	AV relationship/ rhythm	Pulmonary and aortic outflows/ ventricular outflows	Pulmonary and aortic outflows	*Ventricular outflows (if pulse Doppler abnormal)*	Exclusion of cardiomegaly
Cardiac position	*Mechanical PR (AV) interval‡*	Aortic/ductal arches	Ductus venosus	*Ductus arteriosus (if pulse Doppler abnormal)*	Qualitative assessment of ventricular contractility
Visceral and atrial situs	*Description of AV relation including arrhythmia onset/ offset, duration‡*	Ventricular and atrial septal flow	*Pulmonary veins*		*Systemic venous Doppler examination**
Systemic venous anatomy		Superior and inferior venae cavae	*Umbilical vein*		*Pulmonary venous Doppler examination**
Pulmonary venous anatomy		Pulmonary veins	*Umbilical artery*		*Ventricular Doppler inflow examination**
Qualitative atrial size		Ductus venosus	*Aortic and ductal arches*		*Right and left ventricular cardiac output**
Atrial septal morphology/localization of defect if present		*Proximal branch pulmonary arteries*	*Superior/inferior venae cavae*		*Ventricular shortening fraction**
AV connections		*Umbilical vein*	*Branch pulmonary arteries†*		*Isovolumetric contraction and relaxation time**
Tricuspid/mitral valve morphology and size		*Umbilical artery*	*Middle cerebral artery Doppler†*		*Myocardial performance index**
Ventricular morphology, looping, size					*Cardiovascular profile score**
Ventricular septal morphology with description of defect if present					
Ventricular-arterial connections					
Pulmonary/aortic valve morphology and size					
Great artery relationship/size					
Aortic/ductal arch morphology					
Aortic/ductal relationship relative to the trachea					
Proximal right and left branch pulmonary arteries					
Pericardial or pleural effusions					
Tricuspid/mitral annulus diameters					
Atrial dimensions					
Ventricular length and width					
Pulmonary and aortic valve annulus diameters					
Main pulmonary artery and ascending aorta diameters					
Ductus arteriosus diameter					
Aortic transverse arch diameter					
*Cardiothoracic ratio measurement**					
Branch pulmonary artery diameters†					

Required (class I) elements for fetal echocardiography are in plain text; elements that are reasonable to include (class IIa) are indicated in italics.
Note: In specific clinical situations, italicized elements may be recommended and therefore mandatory to perform.
AV, atrioventricular.
*Elements that can be used for assessment of a known/suspected cardiac function abnormality.
†Additional elements for which usefulness is not well established but which may be considered (class IIb).
‡Required elements (class I) for a known/suspected rhythm abnormality or if indication for examination relates to potential for rhythm abnormality.
From Donofrio MT, Moon-Grady AJ, Hornberger LK, et al: Diagnosis and treatment of fetal cardiac disease: a scientific statement from the American Heart Association. Circulation 129(21):2183-2242, 2014.

calculators are available[116,117] using published reference values.[97,118-121] This detailed assessment may include an advanced assessment of cardiac function such as ventricular strain and myocardial performance index (MPI) measurements.

Plane 7: Bicaval View. The bicaval view is obtained by sagittal imaging of the fetal chest, just to the left of midline (Fig. 13-28 and Video 13-5). This view confirms that the suprahepatic portion of the inferior vena cava is intact (may be interrupted in heterotaxy) and that a right superior vena cava is present. This view is also the best view to visualize the foramen ovale. Color Doppler should be used to assess the direction of flow across the foramen ovale, which is normally from the RA to the LA, but may be left to right in cases of HLHS.

Plane 8: Long-Axis View of the Aortic Arch. The long-axis view of the aortic arch, or "candy-cane" view, is obtained by sagittal imaging of the fetal thorax and angling slightly leftward (Fig. 13-29 and Video 13-6). It can also be obtained by aligning the transverse arch with the ultrasound beam in the 3VT view and turning the probe 90 degrees. The arch should be assessed for hypoplasia or coarctation, and measurements can be performed and compared with the normal range for age.[122] Flow should be toward the descending aorta. Reversal of flow in the arch indicates that the ductus arteriosus is supplying some of the flow to the head and upper extremities circulation and may be seen when there are hypoplastic left-sided structures or an atrial septal aneurysm obstructing mitral valve inflow.[106]

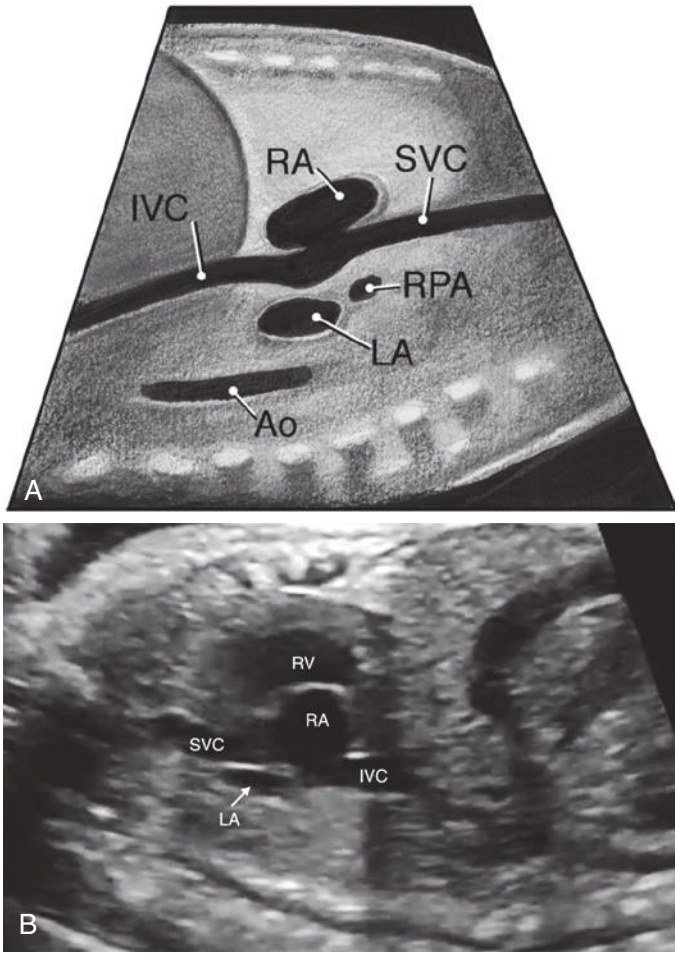

FIG 13-28 Diagram (**A**) and sonographic image (**B**) in the bicaval view. The atrial septum and foramen ovale are best seen from this view as well between the left atrium (LA) and right atrium (RA). Ao, descending aorta; IVC, inferior vena cava; RPA, right pulmonary artery; RV, right ventricle; SVC, superior vena cava. (A from American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013.)

Plane 9: Long-Axis View of the Ductal Arch. The long-axis view of the ductal arch, or "hockey stick" view, is usually accomplished by obtaining a direct sagittal view of the fetal thorax, just left of center (Fig. 13-30). The ductus should be assessed for restriction and direction of flow. By spectral Doppler, a restrictive ductus arteriosus typically has a peak velocity greater than 2.0 m/second and an abnormal flow pattern with continuous flow. Continuous high-velocity flow is also usually evident by color Doppler imaging. Flow reversal in the ductus arteriosus is present with severe right-sided obstructive lesions, such as severe pulmonary stenosis or pulmonary atresia.

Plane 10: High Short-Axis View—Great Arteries. Imaging in cross section of the heart can be very useful in assessing the outflow tracts, the ventricular septum, function, and AV valve anatomy. The first short-axis view is the high short-axis view, which demonstrates the aortic valve en face, surrounded by the pulmonary artery wrapping around the aorta (Fig. 13-31 and Video 13-7). The proximal branch pulmonary arteries can also be seen bifurcating, and the tricuspid valve is well seen in this view. The high short-axis view is best for demonstrating RVOT obstruction and for differentiating types of VSDs that involve the outlet portion of the ventricular septum. Tricuspid regurgitation can also be assessed from this view.

Plane 11: Low Short-Axis View—Ventricles. The low short-axis view is the best view to assess ventricular function and to evaluate for muscular VSDs (Fig. 13-32 and Video 13-8). As muscular VSDs are often very small, the use of color Doppler to show flow across the septum is usually necessary to detect or confirm these defects. The AV valve morphologic appearance can be assessed as well, including detection of a common AV valve or mitral valve cleft.

Assessment of Cardiovascular Function. Detailed functional assessment should be performed if cardiac function appears impaired. The assessment of cardiac function in the fetus can be complex. In an effort to standardize the assessment of cardiovascular function, Huhta and colleagues developed the Cardiovascular Profile Score (CPS), a scoring system that incorporates cardiac and extracardiac aspects of fetal cardiovascular function.[123] Figure 13-33 details the five categories of the CPS (hydrops, umbilical venous Doppler, heart size, abnormal myocardial function, and arterial Doppler), each worth 2 points, for a total score of 10. A lower value signifies worsened cardiovascular

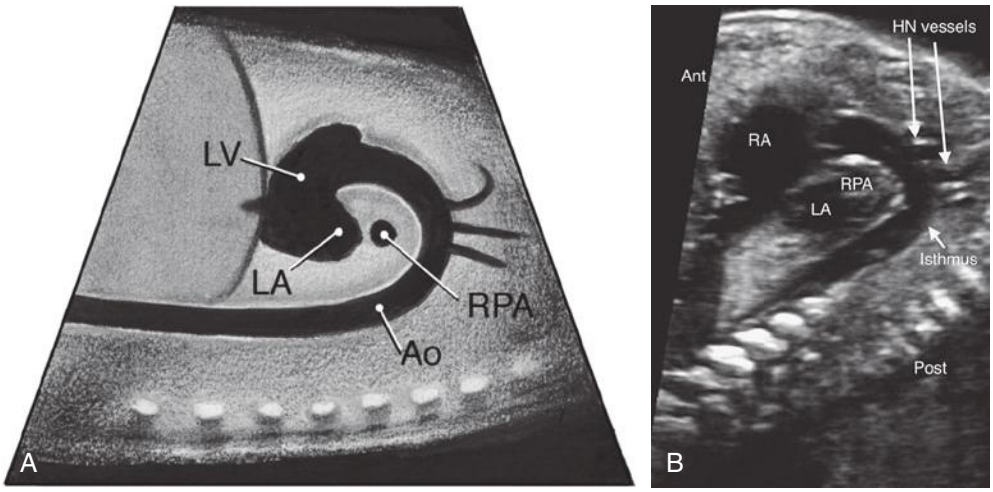

FIG 13-29 Diagram (**A**) and sonographic image (**B**) in the long axis of the aortic arch. In addition to the arch and the head and neck (HN) vessels, the right atrium (RA), left atrium (LA), and atrial septum can often be seen in this view. Ant, anterior; Ao, aorta; LV, left ventricle; Post, posterior; RPA, right pulmonary artery. (A from American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013.)

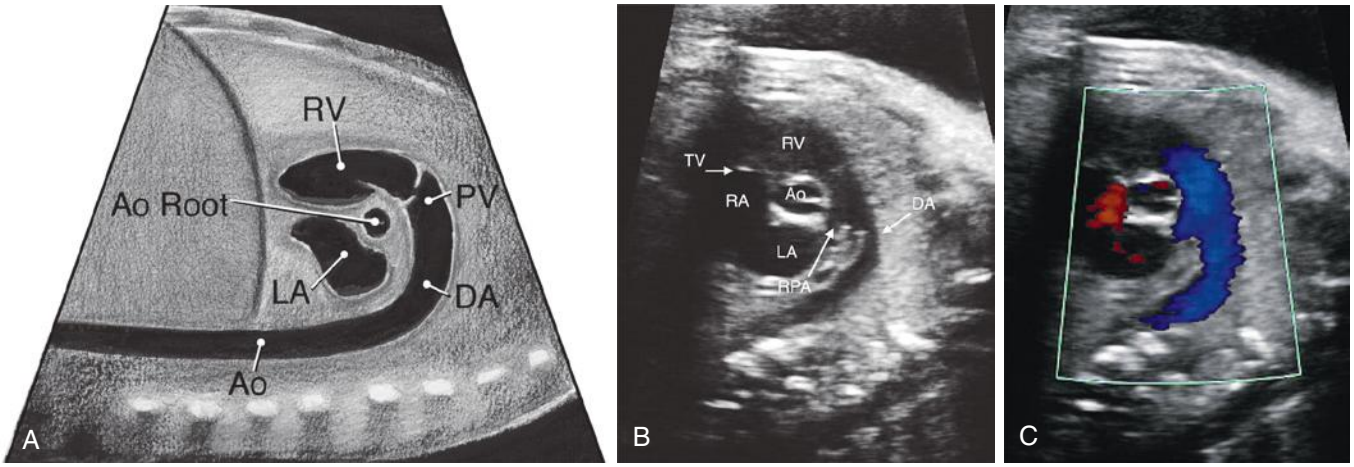

FIG 13-30 Diagram (**A**) and sonographic images (**B** and **C**) in the long axis of the ductal arch by two-dimensional and color Doppler imaging. Ao, aorta; Ao Root, aortic root; DA, ductal arch; LA, left atrium; PV, pulmonary valve; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; TV, tricuspid valve. (A from American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013.)

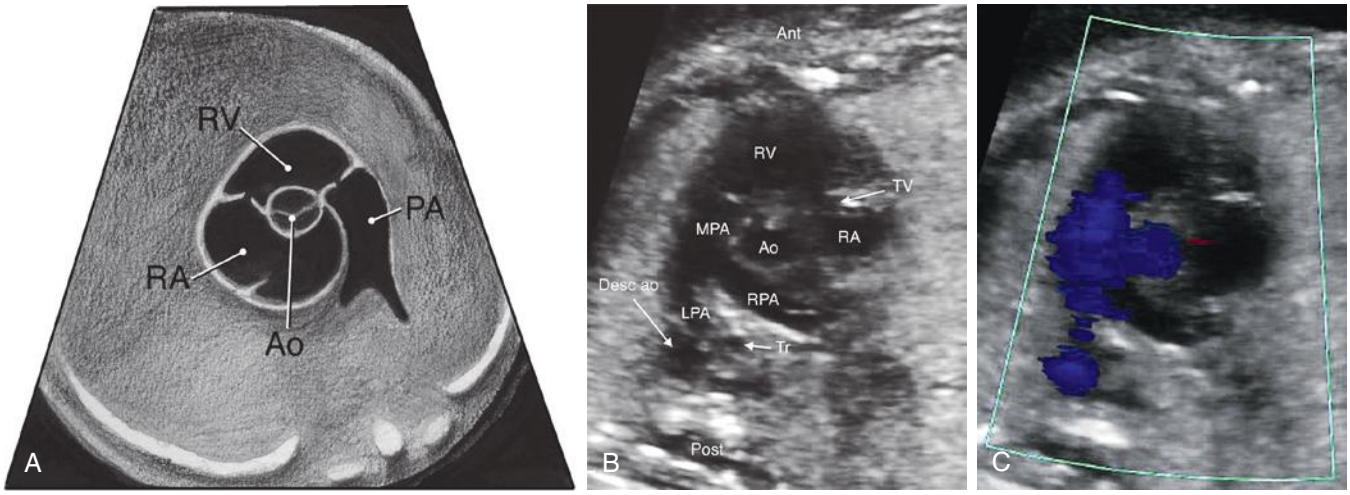

FIG 13-31 Diagram (**A**) and sonographic images (**B** and **C**) in the high short-axis view of the great arteries by two-dimensional and color Doppler imaging. Ant, anterior; Ao: aortic root; Desc ao, descending aorta; LPA, left pulmonary artery; MPA, main pulmonary artery; PA, main pulmonary artery; Post, posterior; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; Tr, trachea; TV, tricuspid valve. (A from American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013.)

function, although a discrete cutoff point for predicting poor fetal outcome has varied between studies, from lower than 6 to lower than 10.[124-132]

Cardiac output (CO) can be estimated by echocardiography using the following formula:

$$CO = VTI \times \pi \times (D2/4) \times HR$$

where VTI = velocity time integral of flow across that semilunar valve, D = diameter of the semilunar valve, and HR = heart rate. In the fetus, because of the parallel circulation physiology, aortic cardiac output can be added to pulmonary cardiac output to arrive at an estimated combined cardiac output (CCO).[133,134] Fetal estimates of CCO have correlated with cardiovascular profile score in high cardiac output lesions such as sacrococcygeal teratoma[126] and with worse outcomes in twin-twin transfusion syndrome.[135]

The MPI, or Tei index, is a commonly used and extensively studied measure of fetal cardiac function. The MPI is obtained by measuring the AV valve closure to opening time (systole) and the semilunar valve ejection time. The ejection time is then subtracted from the AV valve closure to opening time in order to arrive at the sum of isovolumetric contraction and isovolumetric relaxation times. This sum is then divided by the ejection time (Fig. 13-34). Normal values of the MPI change slightly throughout gestation. Generally, values less than 0.43 to 0.45 are considered to be normal.[136] Elevations of MPI values reflect alternations in both systolic and diastolic function.

Myocardial deformation imaging is a relatively new technique, which has begun to be applied to fetal echocardiography. Deformation refers to the degree to which myocardial tissue fibers shorten over the cardiac cycle. Discrete layers of ventricular muscle fibers oriented in longitudinal, circumferential, and radial dimensions play specific roles

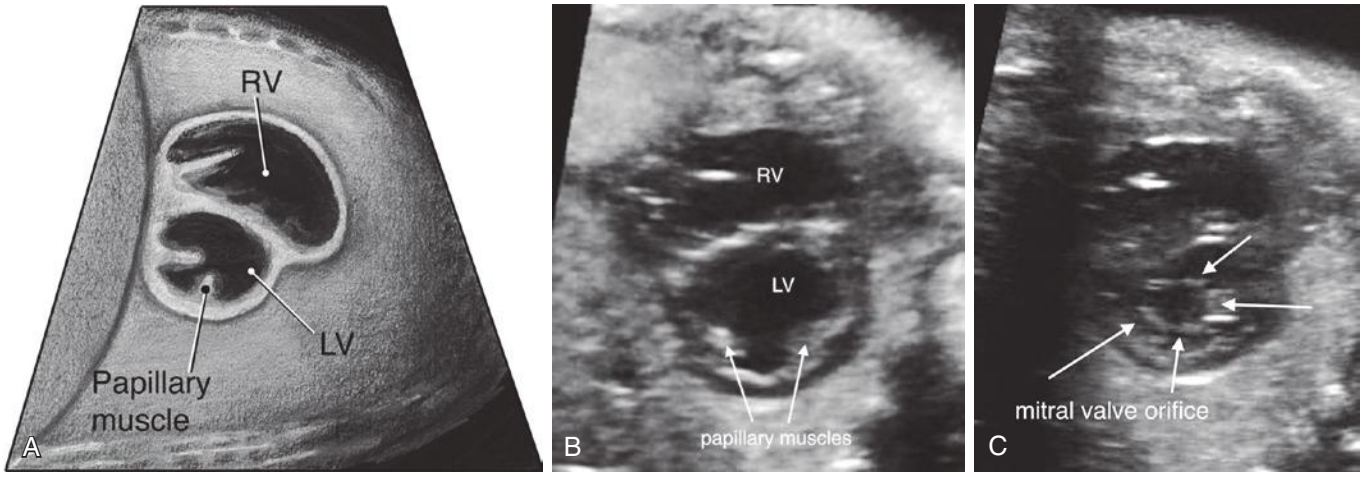

FIG 13-32 Diagram **(A)** and sonographic images **(B** and **C)** in the low short-axis view of the ventricles. At the midventricular level two papillary muscles are seen in the left ventricle. Just basal to this (closer to the atria), the mitral valve can be visualized en face to ensure there is not a cleft and that there is not a common atrioventricular valve. LV, left ventricle; RV, right ventricle. (A from American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013.)

	Normal	–1 point	–2 points
Hydrops	None	Ascites or pleural effusion or pericardial effusion	Skin edema
Venous Doppler (umbilical vein) (ductus venosus)	 UV  DV	 UV  DV	 UV pulsations
Heart size (Heart area/chest area)	>0.20 and ≤0.35	0.35–0.50	>0.50 or <0.20
Cardiac function	Normal TV and MV RV/LV SF >0.28 Biphasic diastolic filling	Holosystolic TR or RV/LV SF <0.28	Holosystolic MR or TR dP/dt <400 or monophasic filling
Arterial Doppler (umbilical artery)	 UA	 UA (AEDV)	 UA (REDV)

FIG 13-33 Components of the Cardiovascular Profile Score. The score is 10 if there are no abnormal signs and reflects 2 points for each of 5 categories: hydrops, venous Doppler, heart size, cardiac function, and arterial Doppler. AEDV, absent end-diastolic velocity; dP/dt, change in pressure over time of TR jet; DV, ductus venosus; LV, left ventricle; MR, mitral valve regurgitation; MV, mitral valve; REDV, reversed end-diastolic velocity; RV, right ventricle; SF, ventricular shortening fraction; TR, tricuspid valve regurgitation; TV, tricuspid valve; UA, umbilical artery; UV, umbilical vein. FIG 13-34 Calculation of the myocardial performance index (MPI, or Tei index). AV, atrioventricular; ET, ejection time; ICT, isovolumetric contraction time; IRT, isovolumetric relaxation time. (From Sugiura T, Suzuki S, Hussein MH, et al: Usefulness of a new Doppler index for assessing both ventricular functions and pulmonary circulation in newborn piglet with hypoxic pulmonary hypertension. Pediatr Res 53:927-932, 2003, used with permission.)

in the cardiac cycle. The most commonly reported measures of deformation are strain and strain rate. Strain (ε) represents the fractional change in length (L) of a myocardial segment caused by an applied force.[137]

$$\varepsilon = \frac{L - L_0}{L_0} = \frac{\Delta L}{L_0}$$

Strain rate represents the rate of myocardial deformation (strain per unit time). Speckle tracking echocardiography is an imaging technique that involves tracking the motion of natural acoustic markers throughout the cardiac cycle in order to calculate strain and strain rate.[138,139] Deviations of the angle of interrogation are overcome by this method, which makes it very attractive for fetal cardiac imaging. Furthermore, standard measures of systolic dysfunction are ominous, late findings in fetal cardiovascular disease, thus making a more sensitive measure of diminished contractility appealing. However, the small fetal heart mass and fast heart rate pose significant challenges to applying existing myocardial deformation technology. In order to reduce undersampling throughout the cardiac cycle, optimal temporal resolution (high frame rate) and optimal spatial resolution are required.[140,141] Despite these concerns, multiple studies have reported successfully tracking the fetal heart and have reported normal strain and strain rate values at various gestational ages.[142-148]

Within the past few years, there have been studies of differences in myocardial deformation values between normal fetuses and those with CHD,[149-153] those exposed to maternal diabetes,[154,155] those with growth restriction,[156] and those with twin-twin transfusion syndrome.[157] Although concerns for reproducibility and uncertainty about the actual added clinical benefit of myocardial deformation imaging currently limit its clinical use, it is a promising technique for the assessment of fetal cardiac function.

3D AND 4D FETAL CARDIAC EVALUATION

3D sonography can be used evaluate the anatomy of the heart, but does not incorporate time. 4D technology has been developed that allows 3D evaluation of the fetal heart plus the aspect of time as the fourth dimension. Spatiotemporal image correlation (STIC) is a feature of 4D sonography that allows the acquisition of volume datasets akin to blocks of pathologic specimens, in which all the anatomic information is contained in the block and the information displayed depends on the level at which the block is cut. STIC has the additional advantages that these planes can be assessed in a virtual beating heart, that fetal electrocardiographic triggering is not needed, and that rendering techniques can be used to gain additional insight into the structure and function of the fetal heart.[40,50,158,159]

With the use of STIC, volume datasets from fetal heart are acquired with a single automated sweep of the transducer, and spatial and temporal information is combined to display images that can be extracted from volume datasets. Thus, standardized planes for fetal echocardiography can be obtained from the volume datasets at the time of the sonographic examination or afterward; moreover, novel planes to examine the fetal heart can also be obtained including coronal views. In addition to this anatomic information, functional information of the fetal heart can be obtained including the direction of blood flow if the volume dataset was obtained with color Doppler or high definition (HD) power Doppler.

Several studies suggest that 4D sonography facilitates examination of the fetal heart.[158-169] Thus, 4D fetal echocardiography has the potential to reduce the operator dependency of 2D sonography. Prenatal diagnosis of CHDs is challenging because of the complexity of the fetal heart and the expertise required in performing fetal echocardiography. In addition, fetal and maternal motion, maternal body mass index, gestational age, adequacy of the amniotic fluid volume, and fetal position are important factors that can affect image quality. This section of the chapter reviews some technical aspects of 4D sonography including volume acquisition and rendering, displays modalities in 4D sonography, and summarizes the evidence evaluating the accuracy and reproducibility of 4D sonography in the prenatal diagnosis of CHDs.

Acquisition of Volume Datasets With 4D Sonography and STIC

Volume Acquisition With Mechanical Transducers. Volume acquisition is performed with an automated sweep of the transducer, acquiring sequential frames at a rapid rate. Acquisition time ranges from 5 to 15 seconds; the longer the acquisition time, the better the spatial resolution. During acquisition, on the basis of changes in the cardiac motion, the STIC algorithm detects the FHR and synchronizes 2D images. Frames acquired during the same phase in the cardiac cycle are merged into one volume dataset representing approximately 40 volumes. After analysis and rearrangement the dynamic images are displayed on the screen in three planes that are orthogonal to each other.[158]

The image quality contained in a STIC cardiac volume dataset can be improved by optimizing the settings before acquisition by adjusting the 2D gray-scale and color Doppler parameters. Our preference is to use low persistence, high contrast, and high frame rate settings. Typical acquisition time ranges from 5 to 15 seconds. Shorter acquisition times can be used to minimize motion artifacts but this reduces the image spatial resolution.

Volume Acquisition With Matrix Array Technology. Matrix array transducers utilize several thousand elements and have eliminated the need for internal moving parts. Each element fires an ultrasound beam that is used to create a pyramidal group of ultrasound voxels, with an opening angle between 6 and 100 degrees. This allows real-time 4D imaging that does not require mechanical translation of the ultrasound transducer. Additionally, the large aperture in the elevation plane provides for superior resolution. Volume dataset acquisition with mechanical transducers relies on approximately 40 volume datasets to reconstruct a virtual volume. In contrast, the 4D volume dataset

obtained with matrix transducers divides the volume into four subvolumes. Acquisition of a spatially and temporally correlated volume takes approximately 25% of the time that is required using a mechanical transducer. Typically, STIC acquisitions take about 5 to 15 seconds, during which time the fetus may move and affect the quality of volume acquired. With matrix array technology, the volume acquisition takes about 3 seconds with less motion artifact in addition to increased spatial and temporal resolution. Hence, the real-time data acquisition is less prone to artifact from fetal movement and maternal respiratory motion.

Display Modalities in 4D Sonography and STIC

2D sonography relies on standard anatomic views of the fetal heart, as described previously.[71,170-172] Acquisition of these views can be facilitated using different display modalities of 4D sonography.[168,173-183]

Dynamic Multiplanar Display. This modality in 3D and 4D sonography allows for the simultaneous display of three anatomic planes that are orthogonal to each other: the transverse, sagittal, and coronal planes. Moreover, an imaging tool referred to as the reference dot allows for the identification of anatomic structures in these three orthogonal planes (Fig. 13-35). This display modality can also be used to scroll through the volume dataset to visualize the transverse view of the upper abdomen, four-chamber view, five-chamber view, and the 3VV. For example, in cardiac rhabdomyomas, the transverse plane allows visualization of the cardiac tumor in the four-chamber-view, whereas the sagittal and coronal planes reveal additional smaller tumors that are not seen in the axial plane (Fig. 13-36). One approach is to display the standard transverse view used in fetal cardiac evaluation in panel A, to place the dot in the abnormal vascular structure, and to identify the structure in the sagittal and coronal planes in panels B and C (Fig. 13-37).

Novel algorithms using the multiplanar display have been proposed for simultaneous display of both outflow tracts,[158] to visualize the aortic and ductal arches,[184] and to determine the nature of vascular connections to the fetal heart using the spin technique.[185] The latter technique involves positioning the reference dot in the center of the structure and "spinning" the volume dataset around the y-axis to determine its spatial relationship with the heart and other vascular structures.

The sagittal view of the ductal arch can be easily obtained using 4D volume datasets of the fetal heart acquired with STIC (Fig. 13-38).[186] A retrospective study using this approach[186] reported that the visualization rate of the sagittal view of the ductal arch was significantly lower in fetuses with conotruncal anomalies than among normal fetuses and those with other CHDs. The authors concluded that the inability to visualize the ductal arch using the proposed algorithm should raise the possibility of conotruncal anomalies.

Automated Display of Multiple Slices. This modality allows for the simultaneous display of up to eight parallel planes whose distance can be adjusted for better visualization of anatomic planes. Tomographic ultrasound imaging (TUI) (GE Healthcare, Milwaukee, WI) allows the visualization of multiple sections of a beating heart at the same time.[187-190] An overview image, which is shown on the upper left corner, shows a plane orthogonal to the slices, and parallel lines demarcate the position of the slices within the volume dataset (Fig. 13-39). However, the simple use of planes parallel to the four-chamber view of the heart does not allow for the visualization of the long-axis view of the left outflow tract and the short-axis view of the aorta, which are considered part of an integral examination of the fetal heart.[71,171,172,191] An algorithm using TUI with STIC was developed that allows for the simultaneous visualization of the standard planes for fetal cardiac screening including the four-chamber view, 3VV, long-axis view of the

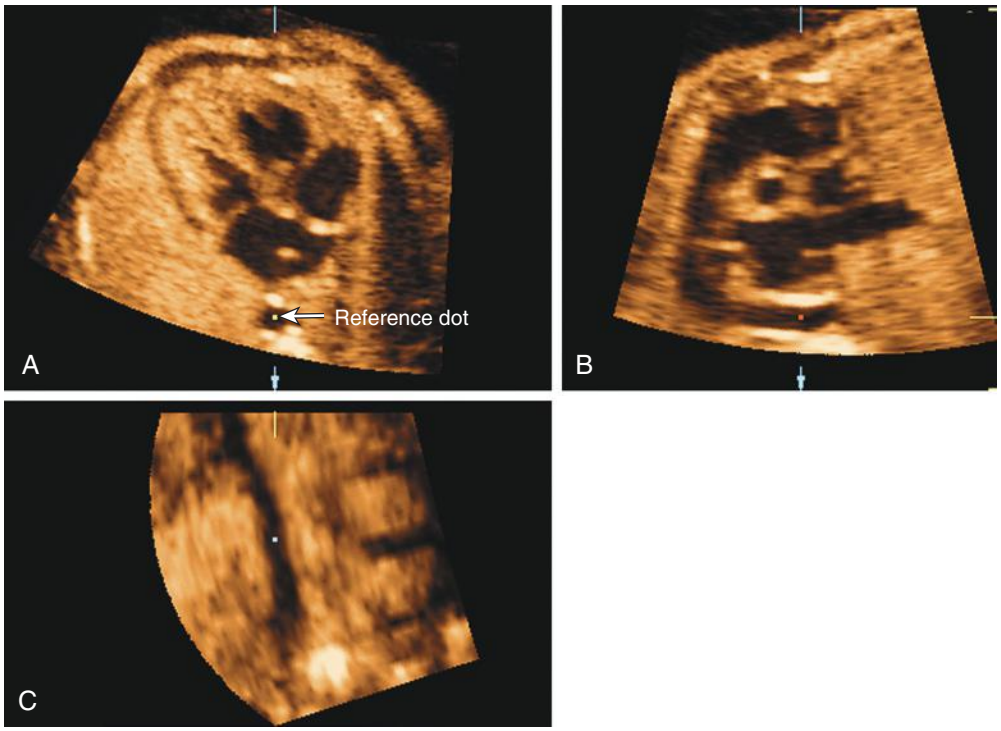

FIG 13-35 Multiplanar display in three- and four-dimensional sonography allows for the simultaneous display of three anatomic planes that are orthogonal to each other: the transverse (**A**), sagittal (**B**), and coronal (**C**) planes. An imaging tool referred to as the reference dot allows for the identification of anatomic structures in these three orthogonal planes.

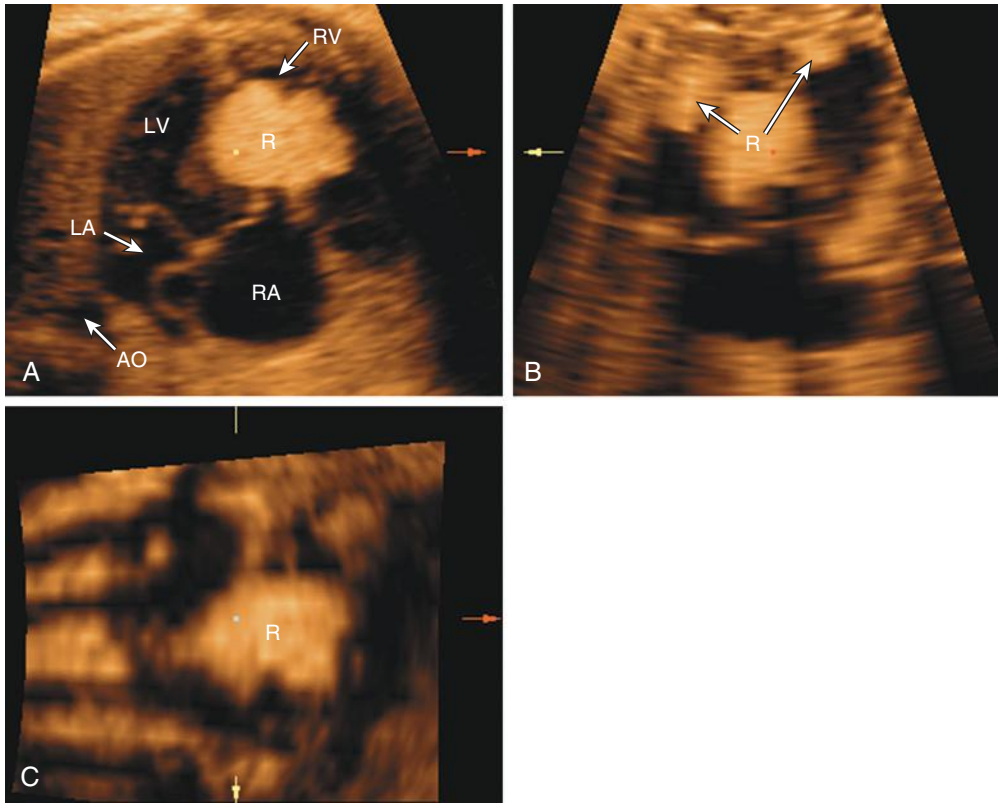

FIG 13-36 Multiplanar display of a fetus with cardiac rhabdomyomas allowing the simultaneous visualization of a large cardiac tumor in the four-chamber view (**A**) filling most of the right ventricle (RV), whereas the sagittal (**B**) and coronal (**C**) planes reveal additional smaller tumors that are not seen in the axial plane. AO, aorta; LA, left atrium; LV, left ventricle; R, rhabdomyoma; RA, right atrium.

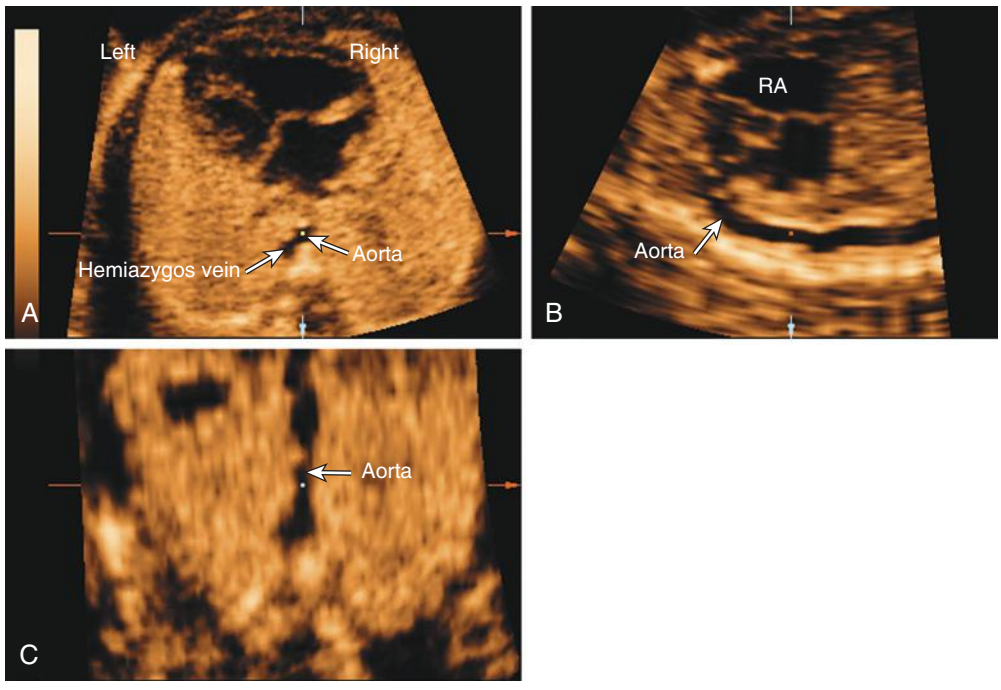

FIG 13-37 Multiplanar display of a dilated hemiazygous vein in a fetus with interrupted inferior vena cava. The reference dot was placed on the aorta in the four-chamber view (**A**). The corresponding orthogonal images are displayed in the sagittal (**B**) and coronal (**C**) views. RA, right atrium.

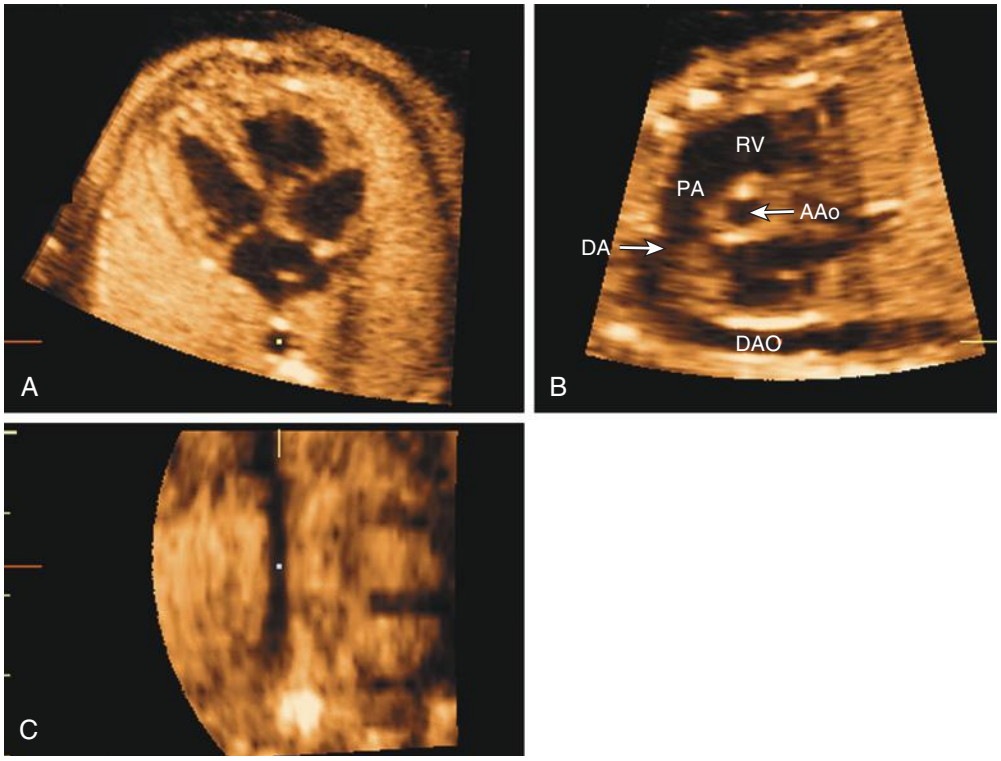

FIG 13-38 Multiplanar display of a normal fetal heart in the second trimester of pregnancy. **A,** The four-chamber view. **B,** The components of the sagittal view of the ductal arch including the right ventricular (RV) outlet, main pulmonary artery (PA), ductus arteriosus (DA), descending aorta (DAO), and a cross section of the ascending aorta (AAo). **C,** The coronal view of the DAO.

left outflow tract, and short-axis view (right outflow tract) in most fetuses without CHDs.[192] With the use of this algorithm a normal four-chamber view, five-chamber view, longitudinal view of the ductal arch, 3VT view, view of the left outflow tract, and short-axis view were visualized in 99%, 96.9%, 98.5%, 88.2%, 93.3%, and 87.2% of the volume datasets, respectively. Similar results were recently reported by Rizzo and associates[193] using STIC and a simplified method referred to as the "three-step technique." Other algorithms designed to evaluate the fetal heart using multiplanar display includes the Four-chamber view And Swing Technique (FAST) echo[194] and Fetal Intelligent Navigation Echocardiography (FINE)[195] techniques.

Rendering Techniques in 4D Sonography and STIC

Several rendering algorithms have been described for visualization of the fetal cardiovascular structures.

Inversion Mode. This mode transforms echolucent structures into solid structures. Thus, anechoic structures such as the heart chambers, lumen of the great vessels, stomach, and bladder appear echogenic on the rendered image, whereas structures that are normally echogenic become anechoic. Postprocessing adjustments are performed as necessary, including adjustments of the gamma curve, threshold, and transparency to improve image quality. The technique allows examiners to obtain 4D rendered images of cardiovascular structures from volume datasets acquired with gray-scale only. For example, the value of this display modality can be observed in the visualization of a dilated azygous vein in a case of interrupted IVC in heterotaxy complex (Fig. 13-40).

Transparency Modes. The minimum projection mode (MPM) is another volume-rendering tool that allows preferential display of minimum gray-scale values within a volume dataset. This algorithm can be useful for displaying vascular structures and fluid-filled organs.[196,197] The MPM can provide important insight into the spatial relationships of abnormal vascular connections to the fetal heart in the upper mediastinum and could potentially be useful in the determination of atrial morphologic features in cases of left and right isomerism.[168]

B-Flow Rendering. This 4D display modality enhances signals from weak blood reflectors from vessels and, at the same time, suppresses strong signals from surrounding tissues.[198-200] Because this technology does not rely on Doppler methods to display blood flow, it is angle-independent and does not interfere with the frame rate. This modality is potentially advantageous over color or power Doppler imaging when used in conjunction with STIC for the evaluation of the fetal vasculature. In B-flow imaging, the echoes from the tissue and the blood flow can be displayed with high resolution and without the overlay that characterizes color Doppler imaging. Moreover, B-flow may have less signal dropout when the ultrasound beam is perpendicular to the vessel. B-flow imaging can provide important insight into abnormal vascular connections to the fetal heart including TAPVC[201] (Fig. 13-41) and tortuous aorta in cases of coarctation[202] (Fig. 13-42).

Accuracy and Reproducibility of 4D Sonography in the Prenatal Diagnosis of Congenital Heart Disease

The accuracy and reproducibility of 4D sonography with STIC in the diagnosis of CHDs were recently evaluated in two multicenter studies in the second trimester of pregnancy.[203,204] One cross-sectional study included seven international centers with expertise in 4D sonography where fetuses with and without confirmed heart defects were scanned between 18 to 26 weeks' gestation and their volume datasets were uploaded onto a centralized FTP (file transfer protocol) server.[204] The authors reported that the median (range) sensitivity, specificity, and positive and negative predictive values as well as false positive and false negative results for the identification of fetuses with CHDs were as follows: 93% (77%-100%), 96% (84%-100%), 96% (83%-100%), 93% (79%-100%), 4.8% (2.7%-25%), and 6.8% (5%-22%), respectively. Moreover, there was excellent intercenter agreement (kappa statistic = 0.97) in the identification of CHDs. The authors concluded that 4D volume datasets can be remotely acquired and accurately interpreted by different centers and that among centers with technical expertise 4D sonography is an accurate and reliable method for fetal echocardiography. However, 10% of volume datasets have limited clinical value because the image quality was not adequate, the volume dataset

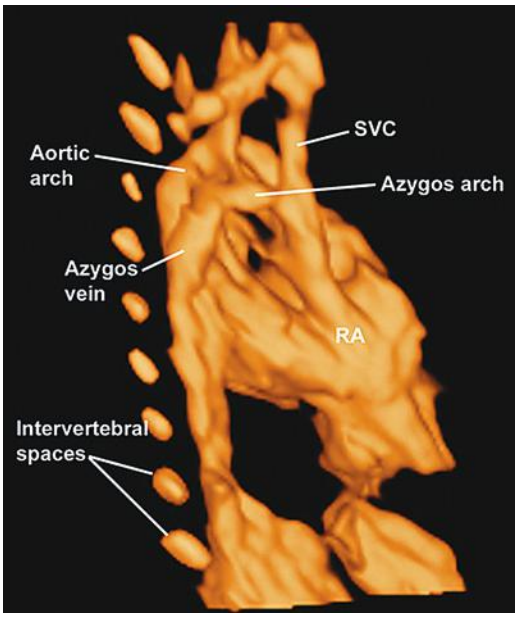

FIG 13-40 Three-dimensional reconstruction of a fetal heart rendered with the inversion mode in a case of interrupted inferior vena cava with azygous vein continuation. RA, right atrium; SVC, superior vena cava.

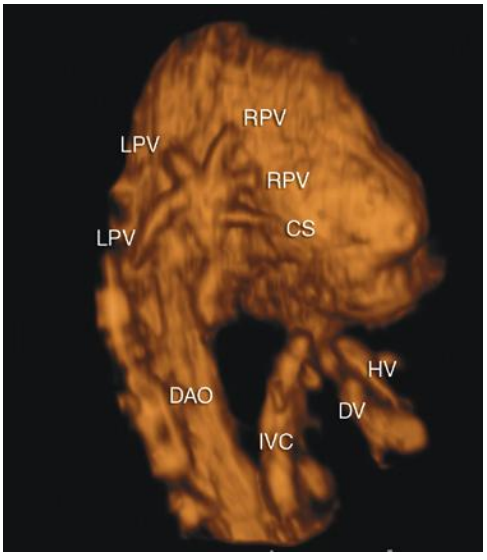

FIG 13-41 B-flow imaging of a fetus with total anomalous pulmonary venous return. did not include sufficient anatomic information, or image artifacts limited the visualization of the anatomic structures. Of note, the median time required to upload or download each volume dataset into the centralized FTP server was 2 minutes (range: 1-3 minutes), and the median time required to analyze each volume dataset was 6 minutes (range: 2-15 minutes). Similarly, in another study involving 167 normal fetuses and 175 fetuses with CHDs the authors reported that the sensitivity, specificity, and positive and negative predictive values of 4D sonography with STIC in the identification of CHDs were 91.6%, 94.9%, 88.1%, 89.7%, and 94.0%, respectively. Two different sonographers with expertise in 4D sonography read the volume datasets in a blinded fashion and agreed in the final diagnosis in 74% of the cases.[203] However, in a different report the same authors reported good or excellent intraobserver and interobserver agreement in the identification of fetal cardiac structures using 4D sonography and STIC in all trimesters of pregnancy.[205]

One study evaluated if 3D and 4D sonography can improve the ability of 2D sonography in the identification of CHDs. The authors compared 2D cine loops and 4D volume datasets from 181 fetuses with CHDs. The authors reported that with different 4D rendering modalities 12 CHDs were identified by 3D/4D sonography but not by 2D cine loops. These cases included one case of right aortic arch with anomalous branching, one case of TGA with pulmonary atresia, one case of segmental interrupted aortic arch, one case of RV aneurysm, two cases of total anomalous pulmonary venous connections (TAPVCs), and four cases of VSDs.[206]

First and Early Second Trimester 4D Fetal Echocardiography

A 2014 study evaluated the role of 4D sonography in the identification of CHDs between 11 and 15 weeks of gestation.[207] The study included 48 volume datasets from fetuses with normal ($n = 17$) and abnormal ($n = 16$) hearts. Overall, the median (range) accuracy, sensitivity, and specificity, as well as the positive and negative likelihood ratios, for the identification of fetuses with CHDs were 79% (77-83%), 90% (70-96%), 59% (58-93%), 2.35% (2.05-9.8%), and 0.18% (0.08-0.32%), respectively. Of note, there was only a moderate intercenter agreement (kappa = 0.6); and between 15% and 23% of volume datasets were considered to have limited clinical value because the image quality was not adequate, the volume dataset did not include sufficient anatomic information, or image artifacts limited the visualization of the anatomic structures. Moreover, participating centers with lower diagnostic indices reviewed a higher proportion of suboptimal volume datasets than those with higher diagnostic indices. The authors concluded that 4D sonography can be performed in the first trimester and early second trimester of pregnancy and that 4D volume datasets obtained from fetuses between 11 and 15 weeks can be remotely acquired and accurately interpreted by different centers. These results are in keeping with a 2008 report indicating that standardized planes for fetal echocardiography can be obtained from 4D volume datasets obtained in the first trimester of pregnancy in a reproducible manner[50] and with a 2009 report indicating that 4D fetal echocardiography in the first trimester can identify CHDs with 95.3% accuracy.[208]

The median sensitivity (90%) of 4D first trimester fetal echocardiography for the identification of CHDs reported in the multicenter study is comparable with the results of a study done at a single institution.[208] However, the median specificity (59%) is lower than previously reported. This may be a reflection of moderate intercenter agreement. The observation that in almost one fifth of the cases 4D volume datasets had limited clinical value appears to be a reflection of the challenges of 4D first trimester fetal echocardiography due to frequent fetal motion, the size of the cardiac structures, and the frequent need to rely on color Doppler imaging to evaluate these structures. However, in many instances the anatomic information contained in these volume datasets was sufficient to differentiate normal from abnormal cases and to diagnose the specific CHD.

The evidence reviewed in this section indicates that 4D fetal echocardiography with STIC can facilitate the examination of the fetal heart with the use of multiple display and rendering modalities. Moreover, 4D sonography appears to be an accurate and reproducible technique for the identification of CHDs in the second trimester of pregnancy. The initial reports on the value of 4D sonography in the first trimester and early second trimester of pregnancy are promising. However, larger studies are required to confirm these results. Another important area for research is the evaluation of 4D sonography in the screening of CHDs as well as the use of automated or semiautomated algorithms using 4D sonography and STIC in the screening and diagnosis of CHDs. The practical application of STIC for fetal cardiac screening, versus a role better suited to a specialized echocardiographic procedure, requires further investigation in the context of emerging technologies.

FETAL CARDIOVASCULAR DISEASE

Overview

Epidemiology. Fetal cardiovascular disease most commonly consists of structural heart disease, fetal arrhythmias, or secondary heart disease, but also includes fetal myocarditis and cardiomyopathy, pericardial effusions, and cardiac tumors. The prevalence of fetal cardiovascular disease is unknown and difficult to ascertain. Given that some fetuses with CHD do not survive to term, it is suspected that the prevalence of CHD in the fetus is significantly higher than the liveborn estimate of 6 to 10/1000, although this topic has not been extensively studied.[209,210]

Etiology. The cause of CHD is unknown in most cases, but is clearly multifactorial. Maternal exposures that have been associated with CHD include environmental (dioxins, polychlorinated biphenyls, pesticides),[211,212] ingested (alcohol, isotretinoin, thalidomide),[213] and infectious (rubella).[214] Maternal fever alone, regardless of the cause, has also been implicated in CHD,[215,216] as has the increasingly prevalent health conditions of obesity and diabetes.[217-219]

There are genetic influences on development of CHD, both inherited and sporadic. A large number of syndromic disorders are associated with CHD, and genetic disorders have also been shown to be associated with isolated CHD (Table 13-5).[212] Genetic disease with CHD may be due to aneuploidies, such as Down syndrome or Turner syndrome; may result from chromosomal deletions, such as chromosome 22q11.2 deletion; or may be secondary to a single DNA base mutation that causes abnormal protein transcription, such as Alagille syndrome due to a *JAG1* mutation. Given the frequent associations between CHD and genetic disorders, many advocate that genetic evaluation should be performed in any fetus or child with CHD.

Of note, however, at this time only a minority of CHDs can be attributed to a recognized genetic condition. The majority of infants born with CHD are born to parents with no identifiable risk factors. Therefore, despite discovered risk factors, the most important tool for detection of prenatal CHD is a high-quality second trimester ultrasound examination.

TABLE 13-5 Commonly Diagnosed Genetic Disorders in the Fetus and Cardiovascular Associations

Condition	Cardiovascular Findings
Turner syndrome (monosomy X)	Left-sided disease: hypoplastic left heart syndrome, bicuspid aortic valves, coarctation of the aorta
	Systemic venous anomalies: absence of the ductus venosus, left superior vena cava
	Pulmonary venous anomalies: partial anomalous pulmonary venous return
Down syndrome (trisomy 21)	Atrioventricular canal defect
	Atrioventricular canal defect with tetralogy of Fallot
	Isolated ventricular septal defect
22q11.2 deletion	Tetralogy of Fallot
	Truncus arteriosus
	Double-outlet right ventricle
	Pulmonary atresia with ventricular septal defect
	Right aortic arch
	Aberrant right or left subclavian artery
	Double aortic arch
Edwards syndrome (trisomy 18)	Atrial septal defect
	Ventricular septal defect
	Polyvalvar disease
Patau syndrome (trisomy 13)	Atrial septal defect
	Ventricular septal defect
	Polyvalvar disease
Williams syndrome (*ELN* mutation)	Supravalvar aortic stenosis, branch pulmonary artery stenosis, mitral valve and aortic valve disorders
Alagille syndrome (*JAG1* mutation)	Tetralogy of Fallot
	Branch pulmonary artery stenosis
CHARGE syndrome	Atrial septal defect
	Ventricular septal defect
	Tetralogy of Fallot

CHARGE, coloboma, heart defects, choanal atresia, retarded growth and development, genital abnormalities, and ear anomalies.

Neurodevelopmental Outcomes. Over the last 30 years, there have been significant advances in understanding neurodevelopment sequelae in children with CHD. Although the vast majority of nonsyndromic children with CHD do not have severe neurodevelopmental impairments, children who have undergone cardiac surgery are more likely to have neurodevelopmental abnormalities than children without cardiac disease.[220] A 23% incidence of structural brain abnormalities has been identified by fetal MRI in children with complex forms of CHD as compared to normal control subjects (<2%).[221] Owen and colleagues[222] have also reported impaired brain volume growth before cardiac surgery in infants with CHD. Given that prenatal diagnosis has been shown to improve the preoperative status of newborns with critical CHD, prenatal coordinated multidisciplinary care and possibly early interventions may result in improved neurodevelopmental outcomes.[223]

Congenital Heart Lesions

This section highlights the anatomy and imaging pearls of the most common CHDs. Detection of these lesions can most easily be accomplished by use of sweeps through the heart that are centered on the key views listed earlier.

Ventricular Septal Defect

Definition. A VSD is a communication between the RVs and LVs. There are several types of VSDs and multiple names for the same lesion, depending on nomenclature used (Table 13-6).[224-226] The Congenital Heart Surgery Nomenclature and Database Project addressed this topic, simply classifying VSD types as types 1 through 4.[227] For the purposes of this chapter, the Van Praagh classification will be used.

Epidemiology. When excluding the residual fetal structures PFO and PDA, VSDs represent the most common type of CHD. The birth prevalence of VSD has been increasing over the last several decades,

TABLE 13-6 Ventricular Septal Defect Nomenclature

Congenital Heart Surgery Nomenclature and Database Project	Van Praagh	Anderson	Other
Type I	Conalseptal	Doubly committed juxtarterial or Muscular—outlet or infundibular	Supracristal Infundibular Juxtarterial Conal Right ventricular outlet Subarterial
Type II	Conoventricular—membranous type or Conoventricular—malalignment type	Perimembranous—outlet	
Type III	Atrioventricular canal type	Perimembranous—inlet*	Inlet
Type IV	Muscular	Muscular—trabecular or Muscular—inlet	

*Unless defect is associated with an endocardial cushion defect, in which case it would not be included in VSD classifications.

and in recent series it is approximately 300/100,000.[9,228] The increase over time appears to be primarily due to nonsurgical perimembranous and muscular defects.[14] Given this, there has been speculation that the increase in VSDs is at least in part due to improved cardiovascular imaging.[229,230]

Anatomy. The various potential locations of VSDs as seen from the right ventricular side of the ventricular septum are displayed in Figure 13-43. Membranous types of conoventricular VSDs (more commonly referred to simply as membranous VSDs, Fig. 13-44) are bordered by the aortic valve and the tricuspid valve and are one of the most common types of VSD. Malalignment type of conoventricular VSDs (commonly referred to as conoventricular VSDs) are also bordered by the tricuspid and aortic valves, but the conal septum is either anteriorly or posteriorly deviated, resulting in overriding of the aorta or of the pulmonary artery, respectively (Fig. 13-45). Anteriorly malalignment defects are the type most commonly seen in TOF, and posterior malalignment defects are most commonly seen with interrupted aortic arch.

Defects that are in the trabecular septum are termed muscular VSDs (Fig. 13-46 and Video 13-9), which may be further described as apical, midmuscular, posterior, and anterior. Muscular VSDs are the most common type of VSD. Defects in the inlet septum that borders both AV valves are called AV canal type VSDs (perimembranous inlet type by Anderson terminology, Fig. 13-47).

Conalseptal defects (Fig. 13-48) are the least common and are present when the septum between the RVOT and the LV is incomplete. These defects often are bordered by both the pulmonary valve annulus and the aortic annulus, hence the name given in the Anderson nomenclature is *doubly committed juxtarterial*. If a defect is in this region, but completely surrounded by muscular tissue (instead or bordered by a valve), it would be classified using Anderson terminology as muscular outlet VSD.

Genetic Considerations. Genetic disorders must be considered when a VSD is noted. One study reported that among fetuses noted to have a VSD, 46% had a genetic abnormality.[231] Of note, however, all patients except one with genetic abnormalities had an abnormal NT, were high risk for aneuploidy, or had known extracardiac defects. When broken down into those with and without risk factors, 2.5% of those with none of the previous factors had a genetic abnormality, whereas 58% of those with risk factors had a genetic disorder. Another paper showed similar findings, with only 1.2% of patients with a VSD but no extracardiac anomalies having a genetic disorder.[229]

Particular VSD types significantly increase the risk of a genetic disorder. For example, if an AV canal type VSD is seen, one must be sure this is not a complete AVCD, which would confer an almost 50% risk of Down syndrome. If a malalignment type VSD is associated with pulmonary stenosis or a right aortic arch, the risk of 22q11.2 deletion syndrome increases substantially to as high as 25%. If polyvalvar disease is present with a VSD, the risk of trisomy 13 or 18 is very high.

Interventions and Prognosis. A VSD typically has one of three fates. It can close spontaneously, can be closed with surgery, or can be left alone without intervention if it is not hemodynamically significant. Both muscular and membranous VSDs may close spontaneously, and this may occur in utero.[229,231-233] Studies suggest that muscular defects close in fetal life 2% to 31% of the time, with another 19% to 75% closing in the next 12 months.[229,232-234] An estimated 0% to 15% of muscular defects discovered in utero will require surgery.[229,233] For membranous defects, studies suggest 4% to 35% of them close in fetal life, and another 1% to 23% in first 12 months, with an estimated 42% needing surgery.[229,231,234] AV canal type VSDs, malalignment VSDs, and conalseptal defects rarely close spontaneously and will require surgical repair.

For VSDs that require intervention, in the absence of other congenital heart lesions, the procedure can usually be deferred to several months of age, although diuretic therapy may be used in the interim to improve symptoms. At present, surgical repair for pediatric VSD is the preferred therapy in most centers, although catheter-based techniques are demonstrating an improved safety profile compared to prior decades.[235-238] Pulmonary artery banding is largely reserved for critically ill infants with multiple VSDs or for those with associated anomalies.

In isolation, prognosis of children with VSDs is excellent. Even if surgical repair is necessary, most pediatric cardiac surgical programs have mortality rates for VSD closure below 1%.[236] There are potential complications of postoperative arrhythmia (~4%, usually temporary) and postoperative AV block (~1%). Patients with conalseptal defects and membranous or malalignment defects may develop aortic regurgitation or aortic dilation far beyond the surgery, so lifetime follow-up is recommended.

Diagnostic Imaging Features. VSDs are some of the most commonly missed CHD lesions by prenatal imaging, likely because of wide variation in size and equal ventricular pressures in the fetus precluding easy observation of shunting.[239] Medium to large VSDs can be detected in the fetus with careful imaging. Smaller defects are able to be visualized, but it can be challenging to distinguish them from artifact. In some cases, the "T-sign" may be helpful in distinguishing a true VSD from artifact, although it is not completely reliable. The T-sign refers to an area of dropout bordered by an echobright, sharp structure that represents the blunted end of the intact portion of the septum (Fig. 13-50C).[239a] In both early and later gestation, a combination of 2D sonography and Doppler color imaging can help identify VSDs, to optimize detection and minimize false positive diagnoses.[232] Although large defects may be easily seen by 2D imaging, VSDs should always be confirmed by color Doppler imaging, which usually demonstrates bidirectional flow across the large defects.

Diagnostic Imaging Tips

Membranous Ventricular Septal Defect (See Fig. 13-44)

- Defects are seen from many views.
- Aortic valve or tricuspid valve will always be in the picture as a border of the defect.
- If one starts from a four-chamber view, and sweeps superiorly, the defect will be seen just as the aortic valve comes into view.

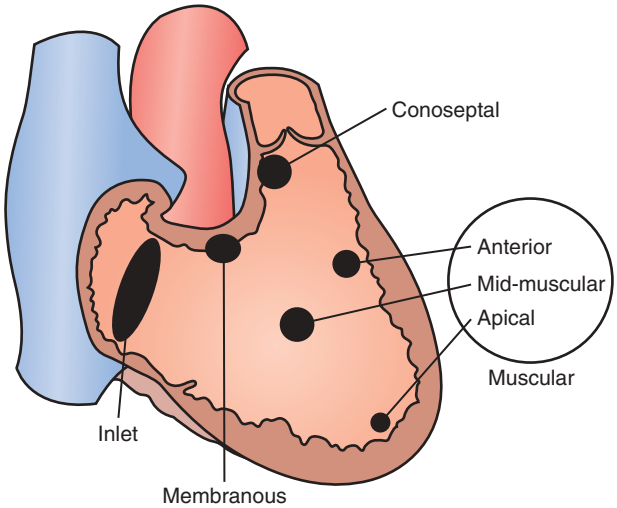

FIG 13-43 Diagram of location of ventricular septal defects from the view of the right ventricular septum.

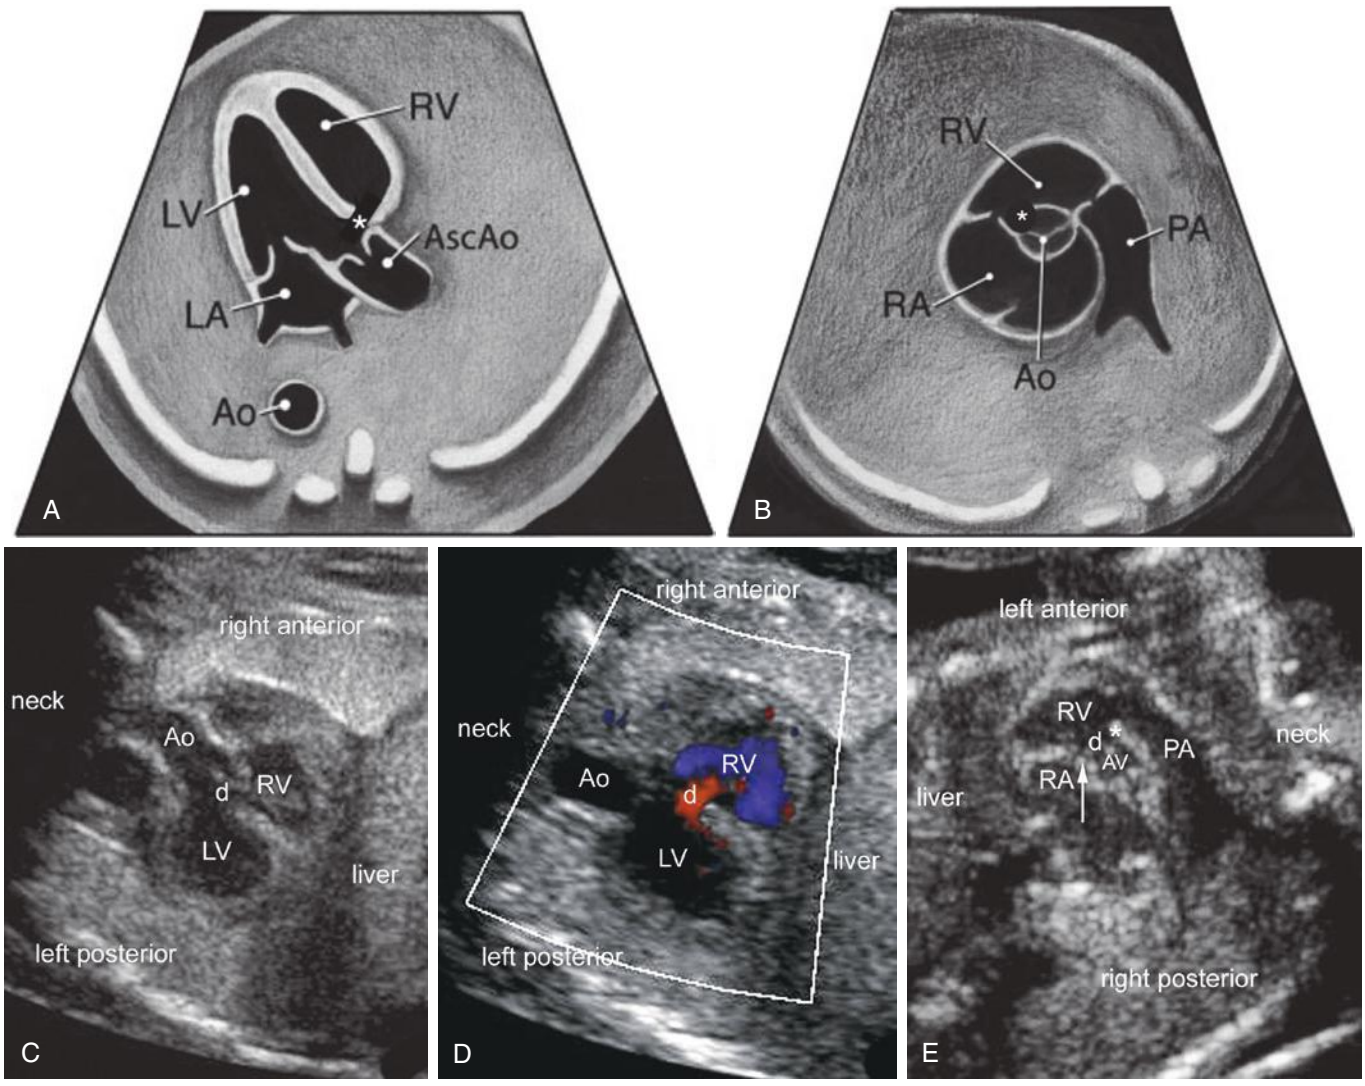

FIG 13-44 Diagrams and sonograms of membranous (also known as perimembranous) ventricular septal defects by two-dimensional and color Doppler imaging. A membranous defect is typically bordered by the tricuspid valve and the aortic valve and is best seen in a left ventricular outflow tract view or a high short-axis view, as shown by the asterisks in **A** and **B,** and the letter "d" in **C** through **E**. There is remnant outlet septum seen in **E** (*asterisk*) anterosuperior to the defect. By color Doppler **(D)**, shunting across the defect is typically bidirectional; in this image there is left-to-right shunting in a systole frame. Ao, aorta; AscAo, ascending aorta; AV, aortic valve; d, ventricular septal defect; LA, left atrium; LV, left ventricle; PA, main pulmonary artery; RA, right atrium; RV, right ventricle.

- False positive findings are common, as the membranous septum is the thinnest part of the septum and can appear to be missing even when present. Findings should always be confirmed by color Doppler.

Conoventricular Ventricular Septal Defect (See Fig. 13-45)

- Defects can exist in isolation, but are most frequently associated with other defects, specifically TOF (anterior malalignment) and interrupted aortic arch (posterior malalignment).
- Conoventricular VSDs frequently are associated with outflow tract obstruction and therefore warrant close evaluation of great artery size discrepancy and obstruction.
- There is a higher association with right aortic arch.
- Classically, the aorta appears to be overriding (anterior malalignment). The pulmonary artery can also appear to be overriding (posterior malalignment), which is usually associated with aortic arch hypoplasia or interrupted aortic arch.

Muscular Ventricular Septal Defects (See Fig. 13-46 and Video 13-9)

- Muscular VSDs do not border any valves.
- They may appear fenestrated on imaging, as some defects have a single opening on the left ventricular side and multiple openings on the right ventricular side.

Atrioventricular Canal Type Ventricular Septal Defect (See Fig. 13-47)

- If the aortic valve is seen at the same time as the VSD, the defect is probably not an AV canal type VSD, or it occurs in combination with a membranous VSD.
- It is best diagnosed in the four-chamber view (see Fig. 13-47B).
- Carefully inspect for primum ASD (four-chamber view) and common AV valve (en face imaging in the short-axis view).
- Defect must be seen when the AV valves are in view because they serve as borders of this defect.

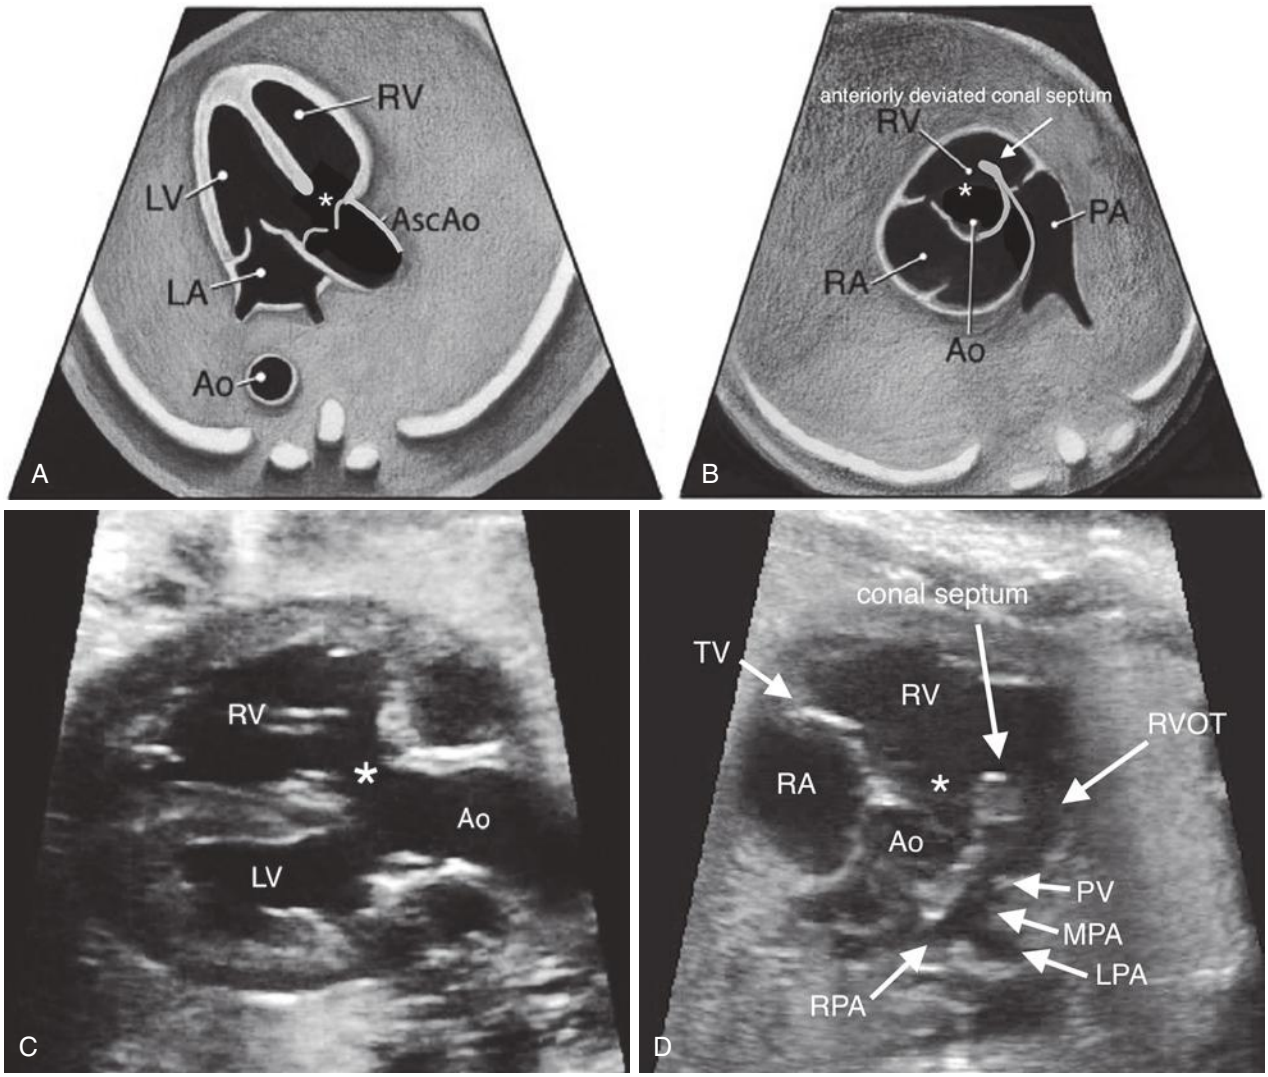

FIG 13-45 Diagrams and sonographic images of conoventricular (also known as anterior malalignment or perimembranous outlet) ventricular septal defects in tetralogy of Fallot. Conoventricular septal defects are most often associated with anterior deviation of the conal septum, as is seen in tetralogy of Fallot. The defect is indicated by an asterisk in the images. The defect typically borders the tricuspid valve (TV) and the aortic valve, but is differentiated from a nonmalalignment membranous ventricular septal defect (VSD) by the abnormal conal septum. **A** and **C,** Left ventricular outflow tract view shows a large conoventricular septal defect and overriding aorta. **B** and **D,** The high short-axis view shows narrowing of the right ventricular outflow tract (RVOT) due to deviation of the conal septum. The VSD (*asterisk*) is seen bordering the TV and aorta. The pulmonary valve annulus is also mildly hypoplastic. Ao, aorta; AscAo, ascending aorta; LA, left atrium; LPA, left pulmonary artery; LV, left ventricle; MPA, main pulmonary artery; PA, main pulmonary artery; PV, pulmonary valve; RA, right atrium; RPA; right pulmonary artery; RV, right ventricle. (**D** from Morris SA, Maskatia SA, Altman CA, Ayres NA: Fetal and perinatal cardiology. In Allen HD, Shaddy RE, Penny DJ et al [eds]: Moss and Adams' Heart Disease in Infants, Children, and Adolescents Including the Fetus and Young Adult, 9th ed. Philadelphia, Wolters Kluwer, 2016, used with permission.)

Conalseptal Ventricular Septal Defect (See Fig. 13-48)

- This least common VSD may be confused with a membranous VSD in some views.
- With this diagnosis, VSD cannot be bordered by the tricuspid valve.
- The defect lies close to the pulmonary valve.
- Short-axis imaging is best to distinguish membranous defects from conalseptal defects.

Atrioventricular Canal Defects

Definition. An atrioventricular canal defect (AVCD) is also known as an atrioventricular septal defect (AVSD) or an endocardial cushion defect. For this section, AVCD terminology will be used. This cardiac malformation has a septum primum atrial septal defect (ASD), an AV canal type VSD, and an abnormal common AV valve, usually composed of five leaflets (Fig. 13-49 and Video 13-10). The defect is an anomaly of the crux of the heart resulting in an ASD in the atrial septum near the AV valves and a VSD in the inlet ventricular septum. There is failure of the common AV valve to be septated by the endocardial cushions. The common AV valve has a single annulus that connects both atria and ventricles. The common AV valve crosses both ventricles at the same level at the crux of the heart resulting in the absence of the normal AV valve offsetting.

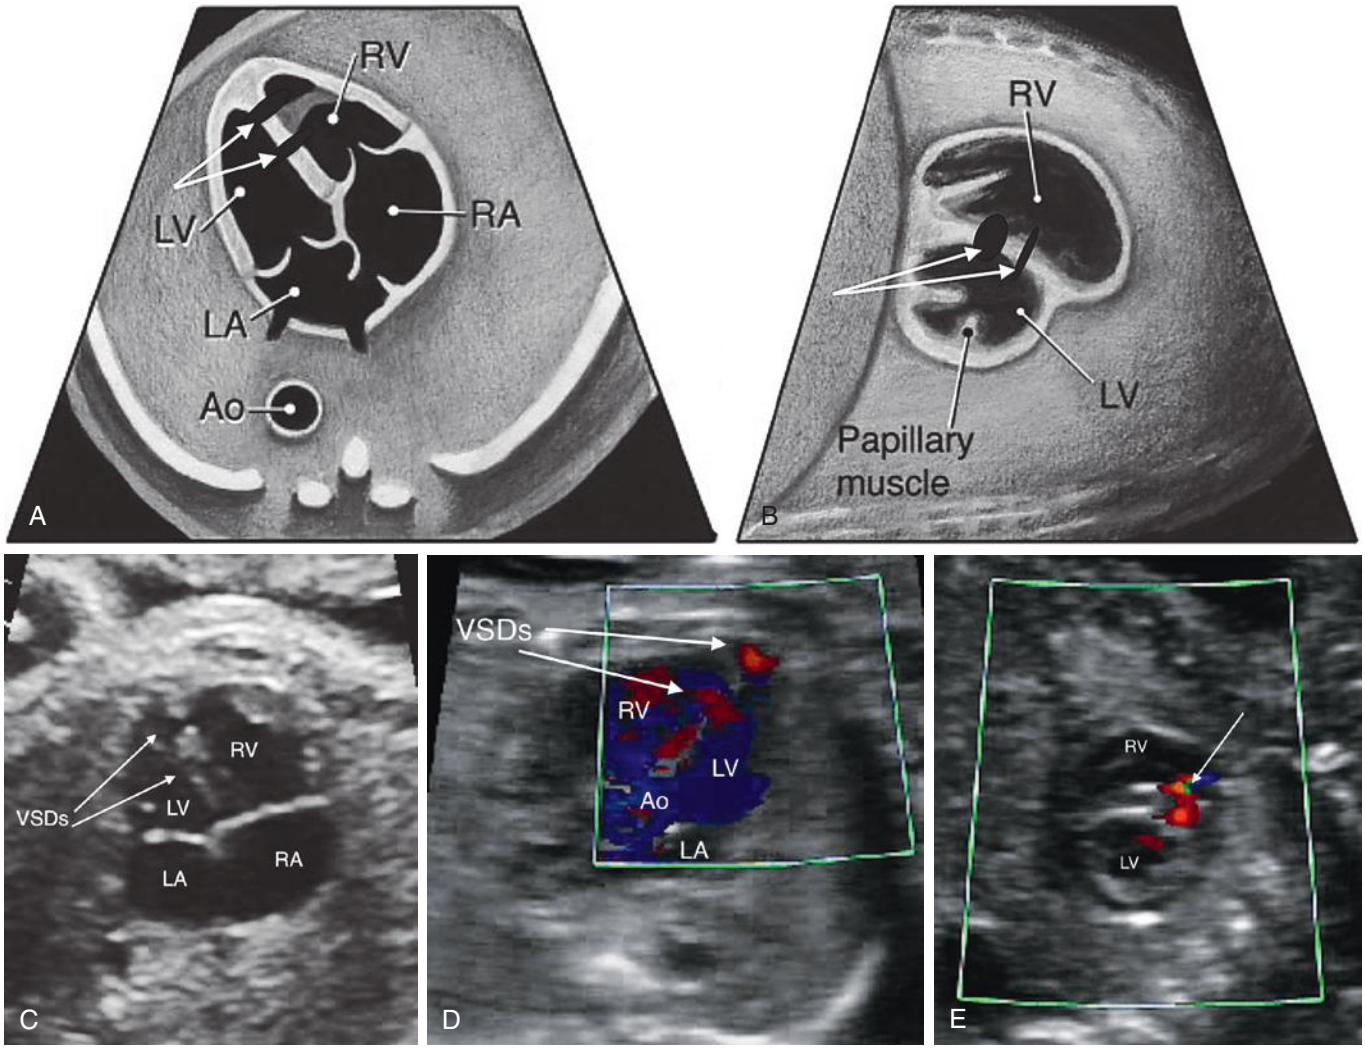

FIG 13-46 Diagrams and sonographic images of muscular ventricular septal defects (VSDs). The VSDs are indicated by the arrows. The first diagram (**A**) and the images in **C** and **D** show a midmuscular and apical muscular VSD. The second diagram (**B**) shows two midmuscular defects, and **E** shows an anterior muscular defect. Ao, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (**A,** Adapted with permission from American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013.)

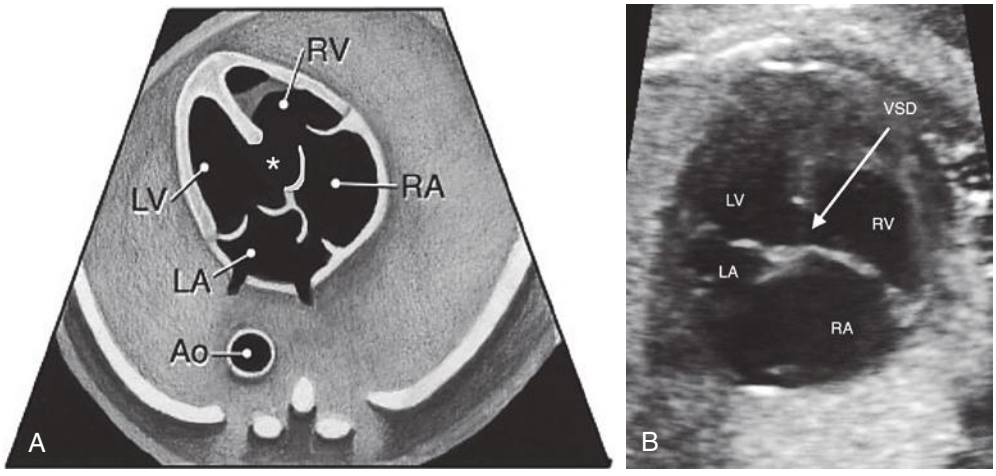

FIG 13-47 Diagram **(A)** and sonographic image **(B)** of atrioventricular canal type (also known as perimembranous inlet) ventricular septal defects (VSDs). VSDs are indicated by an asterisk in A, and the arrow in B. Note that there are two atrioventricular valves, and there is no primum atrial septal defect in this defect. Ao, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (**A,** Adapted with permission from American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013.)

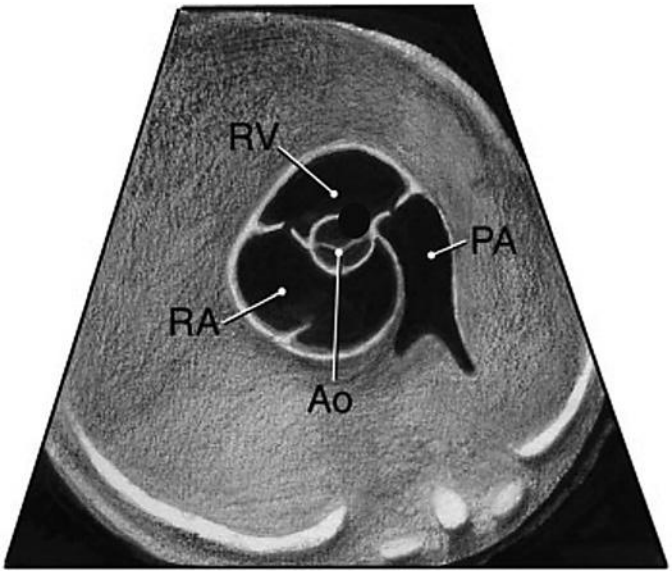

FIG 13-48 Diagram of a conoseptal type ventricular septal defect. Ao, aorta; PA, main pulmonary artery; RA, right atrium; RV, right ventricle. (Adapted with permission from American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013.)

Epidemiology. AVCD accounts for 4% to 5% of infants with CHD and occurs in 0.19 to 0.35 per 1000 live births.[209,240,241] In a large prospective study of fetal CHD, AVCD was the most common cardiac diagnosis and was found in 18% of abnormal fetal hearts.[242] In AVCD, the four-chamber view is diagnostic given that the ASD, VSD, and common AV valve are evident (Fig. 13-50).

Because the dextrodorsal conus cushion contributes to the right AV valve development and the outflow tracts, AVCD may be associated with conotruncal anomalies such as TOF and DORV. Complete AVCD and variations of AVCDs with TOF can be seen in trisomy 21 patients. Unbalanced AVCD occurs when the AV valve connection is shifted primarily toward one ventricle and the contralateral ventricle has hypoplasia. AVCD also occurs in heterotaxy syndrome and is more common in asplenia (bilateral right atrial isomerism) than in polysplenia (bilateral left atrial isomerism).

Anatomy. AVCD defines a group of cardiac defects resulting from an abnormal development of the endocardial cushions during cardiogenesis. Failure of the endocardial superior and inferior cushions to fuse results in a defect in the inferior atrial septum and the inlet ventricular septum. There is a common AV valve with the left and right components of the common AV valve attaching at the same septal insertion level. The inferior displacement of the left component of the common valve results in the absence of the normal offsetting of the AV valves. The distance from the crux of the heart to the apex is foreshortened and the distance from the apex to the aorta is increased and results in an elongated LVOT with the aorta anteriorly displaced. The aorta is "sprung" and is not normally wedged between the two AV valves. The elongated, narrowed LVOT has the appearance of a "goose neck." The narrowed LVOT and abnormal attachment of the anterior bridging leaflet to the ventricular septum can result in subaortic stenosis and LVOT obstruction after surgical repair.

A complete AVCD is characterized by a large primum ASD and AV canal type VSD, with the common AV valve positioned between both defects. The ostium primum ASD is located anterior and inferior to the fossa ovalis and adjacent to the AV valves. An AVCD is classified by the morphologic features of the anterior (sometimes called superior) bridging leaflet as described by Giancarlo Rastelli. In type A, which is the most common, the anterior bridging leaflet inserts entirely on the anterosuperior rim of the ventricular septum. Type B is the least common, and the anterior bridging leaflet is larger and straddles the ventricular septum with chordal attachments along the right ventricular septum or moderator band. Type C has an anterior bridging leaflet that is not attached to the ventricular septum and has chordal attachments to the right anterior papillary muscle. The type C anterior bridging leaflet is described as a "free-floating" leaflet with no septal chordal attachments and it "floats" over the VSD.[243] The papillary muscles in AVCD are rotated counterclockwise. The papillary muscles may be closely positioned or fused as a single papillary muscle.

An incomplete or partial form of AVCD occurs when both the anterior and posterior (sometimes called inferior) bridging leaflets have dense septal attachments to the crest of the ventricular septum, which results in no VSD. There is a large primum ASD but no VSD (Fig. 13-49B and C, Fig. 13-51, and Video 13-11). The AV valves are at the same level with a common, single AV valve annulus, but there are two separate orifices due to a tongue of AV valve tissue centrally connecting the superior and inferior bridging leaflets. The left AV valve component has a cleft in the anterior leaflet, which is directed toward the middle portion of the ventricular septum. A "transitional" AVCD is similar to the incomplete AVCD but the chordae are less dense and there is a restrictive VSD or multiple small VSDs.

When the AV valve is equally connected to both ventricles, the AVCD is balanced. An unbalanced AVCD occurs when the AV inlet is primarily committed to one ventricle (Video 13-12). Unbalanced AVCDs account for about 10% of all AVCDs. Approximately two thirds of unbalanced AVSDs are RV dominant with more than half of the common AV valve committed to the RV. In RV-dominant AVCD, the LV is hypoplastic, and there are frequently LVOT obstruction, aortic valve hypoplasia, and aortic arch anomalies such as coarctation of the aorta. In LV-dominant AVCD, the RV is hypoplastic, and there are associated RVOT obstruction and pulmonary stenosis or atresia. In trisomy 21 patients with an unbalanced AVCD, the LV-dominant type is common.[244]

Genetic Considerations. Approximately 40% to 45% of children with trisomy 21 have congenital cardiac anomalies. Of children with trisomy 21 and heart disease, about 45% have an AVCD. Of the patients with AVCD, more than 75% have trisomy 21.[245] Thus, in the prenatal diagnosis of AVCD, trisomy 21 should be high in the differential diagnosis. A common atrium with an absent atrial septum and common AV valve and no VSD is associated with Ellis–van Creveld syndrome, an inherited condition with an autosomal recessive pattern of inheritance.[246]

Interventions and Prognosis. Incomplete or partial AVCD has the physiology of a large ASD and because there is no ventricular component, these patients undergo surgical repair in the first 2 years of life to patch the ASD and repair the cleft in the left anterior AV valve leaflet. The morbidity and mortality rates are very low in this lesion. Left residual AV valve regurgitation may be a chronic problem and is more commonly seen in children repaired after 4 years of age.[247,248]

Over the last several decades AVCD has become one of the most successfully repaired congenital heart anomalies. The Pediatric Heart Network recently reported an overall 1-month mortality rate of 2.5% and a 6-month mortality rate of 4%. In complete AVCD, a residual ASD or VSD was common at 1 month but at 6 months only 1% had a residual VSD of significance.[247,249] Late operations occurred in approximately 20% of complete AVCD patients and include repair of residual AV valve regurgitation (most often the left AV valve), AV valve stenosis, LVOT obstruction, and residual VSD. The most common reason for a subsequent surgery is moderate to severe residual left AV valve regurgitation, which may be repaired but in some cases requires replacement.[244,249-253]

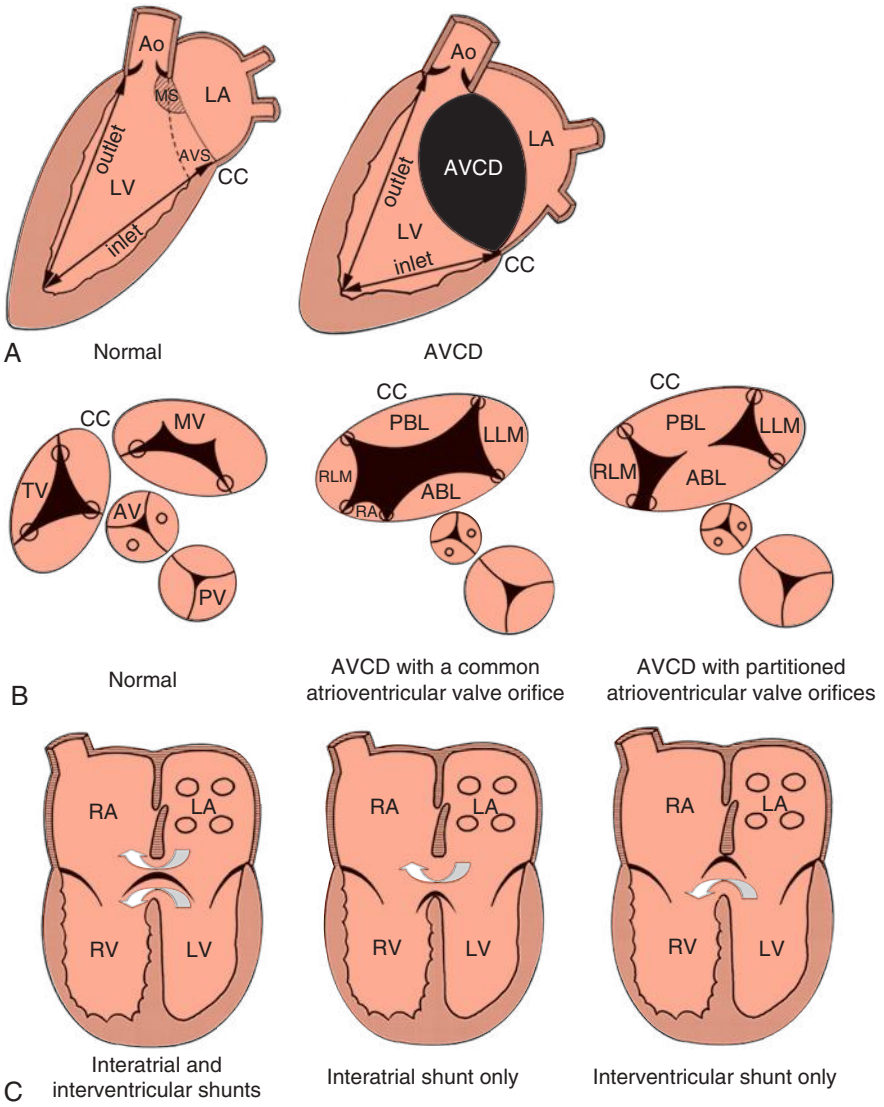

FIG 13-49 Diagrams showing characteristic features of atrioventricular septal defect (AVSD). **A,** Left ventricle (LV) seen from the left side showing inlet-outlet disproportion and increased distance between the aorta (Ao) and crux cordis (CC) in AVSD. **B,** Atrioventricular valves seen from above. Note the wedged position of the aortic valve (AV) between the tricuspid (TV) and mitral (MV) valves in the normal heart. The aortic valve has an unwedged position in AVSD with an increased distance between the AV and CC because of a common atrioventricular annulus. The five leaflets of AVSD are the anterior and posterior bridging leaflets (ABL and PBL), the left and right lateral mural leaflets (LLM and RLM), and the right anterior leaflet (RA). **C,** Level of shunts. The level of shunt across the AVSD is determined by the relationship of the bridging leaflets to the septal margins of the defect. LA, left atrium; MS, membranous septum; PV, pulmonary valve; RA, right atrium; RV, right ventricle.

Diagnostic Imaging Features. All types of AVSD (see Figs. 13-50 and 13-51 and Video 13-10) have the following features:

- AV valve leaflets insert at the same level at the cardiac crux.
- Cleft in the left AV valve component is directed toward the ventricular septum.
- Aorta is unwedged and anteriorly displaced.
- LVOT is elongated.
- Primum ASD is located anteroinferior to the margin of the fossa ovalis.
- LV papillary muscles are rotated counterclockwise.

Complete AVCDs (see Fig. 13-50 and Video 13-10) have all the previous findings as well as the following:

- Large AV canal type VSD.
- Common AV valve crossing between the large ASD and large VSD.
- Unbalanced AVC when the common AV is committed primarily to one ventricle. Given this possibility, examination should include evaluation of the contralateral hypoplastic ventricle for outflow tract and distal semilunar valve obstruction. In RV-dominant AVC, evaluation for aortic arch obstruction is required.

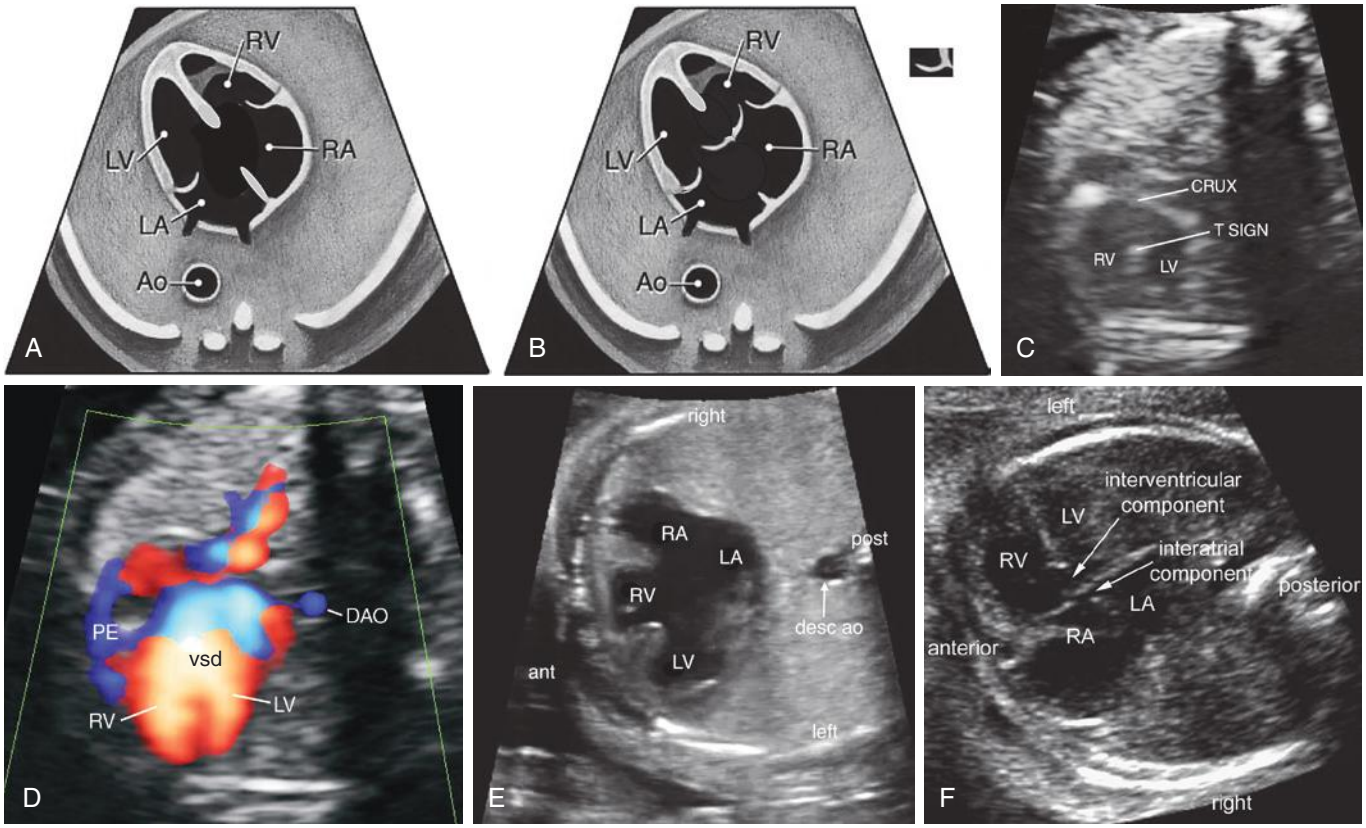

FIG 13-50 Diagrams (**A** and **B**) and sonographic images (**C** through **F**) of a complete atrioventricular canal defect (atrioventricular septal defect). Depending on the angle of the transducer and point in the cardiac cycle, more or less of the common atrioventricular valve may be seen. The four-chamber view in a fetus with trisomy 13 and a complete atrioventricular canal at 13⅔ weeks of gestation is shown by two-dimensional (**C**) and color Doppler (**D**) imaging. ant, anterior; Ao, aorta; DAO, descending aorta; desc ao, descending aorta; LA, left atrium; LV, left ventricle; PE, pericardial effusion; post, posterior; RA, right atrium; RV, right ventricle; vsd, ventricular septal defect. (**A** and **B,** Adapted with permission from American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013.)

Features of an incomplete or partial AVC (see Fig. 13-51):

- No VSD.
- Common AV valve with a connecting tongue of AV valve tissue creates two separate orifices in the single AV valve annulus.
- The left AV valve component has a cleft in the anterior leaflet, which is directed toward the middle portion of the ventricular septum (Fig. 13-51C).

Features of the transitional AVC:

- Small, restrictive VSD.
- Common AV valve with a connecting tongue of AV valve tissue creates two separate orifices in the single AV valve annulus.

Tetralogy of Fallot and Pulmonary Atresia With Ventricular Septal Defect

Definition. In 1671, Niels Stensen initially described a constellation of findings now known to represent TOF.[254,255] Over 200 years later, Etienne Fallot described a "blue malady" linked to four distinct structural anomalies of the heart: a large VSD, aortic override, right ventricular hypertrophy, and stenosis of the pulmonary artery (Figs. 13-45 and 13-52, Videos 13-13and 13-14).[256] It is now well understood that TOF is the result of four unrelated structural cardiac lesions. In fact, underdevelopment and anterosuperior deviation of the infundibular septum is the pathognomonic feature.[257] This deviation of the infundibular septum is crucial to the echocardiographic diagnosis of TOF (Fig. 13-45B and D). Pulmonary atresia with a ventricular septal defect (PA-VSD) represents the most severe form of TOF, with complete obliteration of the RVOT (see Fig. 13-46).

Epidemiology. TOF is the most common cyanotic heart defect, with a prevalence of approximately 0.5 per 1000 live births.[209,258] In the absence of a genetic syndrome, a mother who has had a child with TOF has a 3% to 4% risk of having a second child with CHD.[259-261]

Anatomy. Although the presence of a conotruncal defect may be readily identified, distinguishing between conotruncal diagnoses can be challenging.[262,263] In the long-axis view of the LV, the appearance of a VSD and an overriding semilunar valve can signal the presence of any of a variety of lesions, including TOF, PA-VSD, truncus arteriosus, some forms of DORV, or aortic atresia with large VSD (Figs. 13-45A and C and 13-53A through C). Distinguishing these lesions and searching for known associated abnormalities is of the utmost importance.

TOF represents a wide spectrum of disease. In contrast to infants with very little obstruction to pulmonary blood flow and VSD physiology ("pink tet"), infants with severe outflow tract obstruction require prostaglandin administration at delivery to assure sufficient pulmonary blood flow ("blue tet"). Evaluation of the RVOT is crucial. Color and spectral Doppler interrogation at the pulmonary valve and of the ductus arteriosus, as well as 2D measurements of the pulmonary valve and main pulmonary artery, can aid in predicting the need for prostaglandin infusion after delivery, for early intervention, and for a transannular patch during the initial repair.[264-267] Specifically, severe pulmonary valve annular hypoplasia, significantly elevated flow

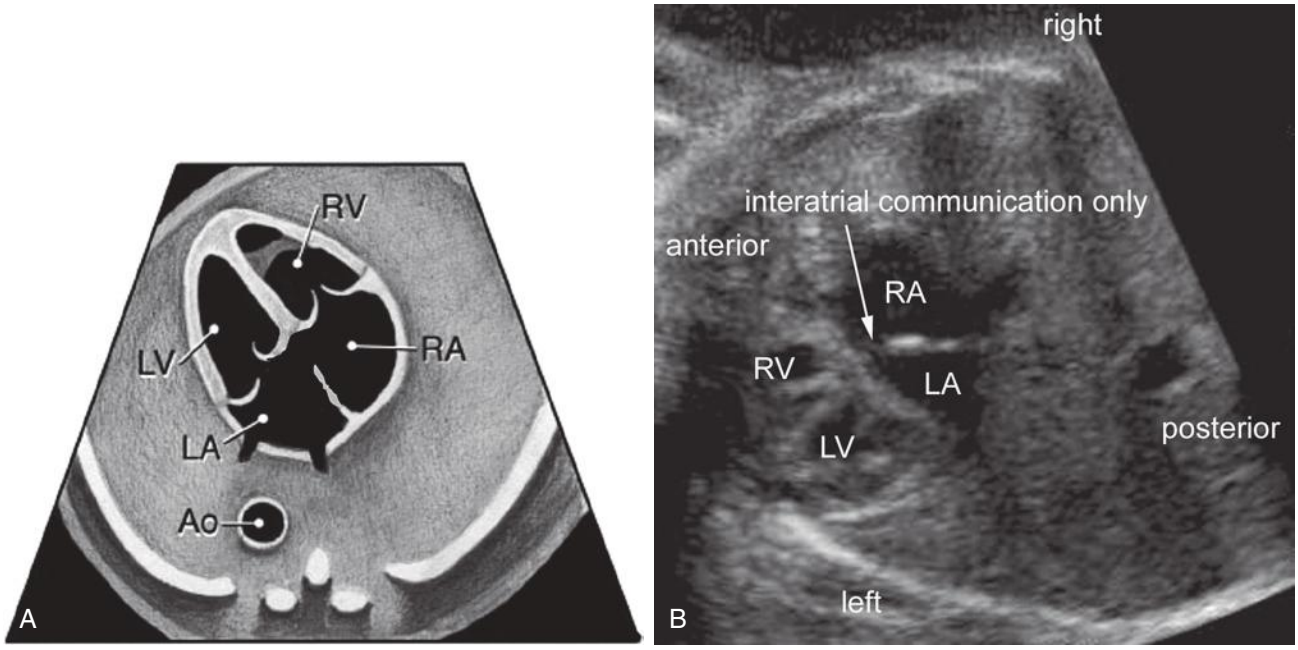

FIG 13-51 **A** and **B,** Diagram and sonographic images of a partial atrioventricular canal (atrioventricular septal) defect, with a primum atrial septal defect and cleft left atrioventricular valve. **A** shows the low short-axis view, with en face imaging of the left atrioventricular valve showing abnormal attachment to the ventricular septum and a cleft in the anterior leaflet. No ventricular septal component of the defect is seen. AL, anterior leaflet of the mitral valve; LA, left atrium; LV, left ventricle; PL, posterior leaflet of the mitral valve; RA, right atrium; RV, right ventricle. (**A,** Adapted with permission from American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013.)

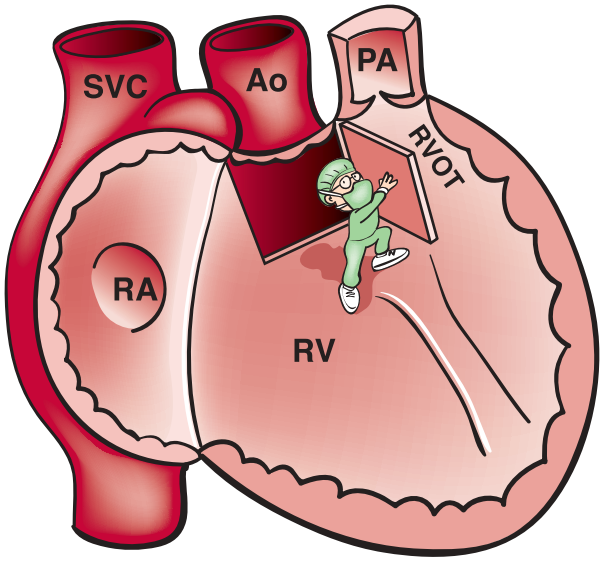

FIG 13-52 Cartoon showing pathogenic mechanism of tetralogy of Fallot. The essential feature of tetralogy is leftward, anterior, and superior deviation of the outlet septum, causing right ventricular outflow tract (RVOT) narrowing and malalignment type of ventricular septal defect. Ao, aorta; PA, pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava. (From Yoo SJ, Jaeggi ET, used with permission.)

velocity at the level of the pulmonary valve, and flow reversal in the ductus arteriosus are all signs of more severe obstruction, requiring prostaglandin administration at delivery. Additionally, the presence of associated cardiac anomalies, such as additional VSDs, a right-sided aortic arch (Fig. 13-53D), and branch pulmonary artery hypoplasia should be investigated.

Determining the source of pulmonary blood flow in pulmonary atresia is crucial. In the case of pulmonary blood flow fed by a ductus arteriosus (see Fig. 13-53A through D), prostaglandin initiation would be necessary at birth, as would neonatal surgery to establish a stable source of pulmonary blood flow. When the pulmonary blood flow is supplied by multiple aortopulmonary collateral arteries (MAPCAs) (Fig. 13-53E and F), pulmonary blood flow is stable at birth. In the case of pulmonary blood flow supplied by a ductus arteriosus, the ductus is tortuous and elongated (Fig. 13-53A and B and Video 13-15).

Genetic Considerations. The common features among conotruncal defects are further highlighted by their association with 22q11.2 deletion syndrome (i.e., DiGeorge syndrome, but this describes only a subset of findings in 22q11.2 deletion syndrome). CHD of some form is present in approximately 80% of liveborn patients with 22q11.2 deletion syndrome. Cardiac anomalies most closely linked to 22q11.2 deletion include absent pulmonary valve syndrome, pulmonary atresia and MAPCAs, truncus arteriosus, and type B interrupted aortic arch (Table 13-7). In addition, the presence of a right aortic arch, anomalous subclavian artery, and crossing pulmonary arteries further increase the risk of 22q11.2 in these populations.[268] A fetal study published in

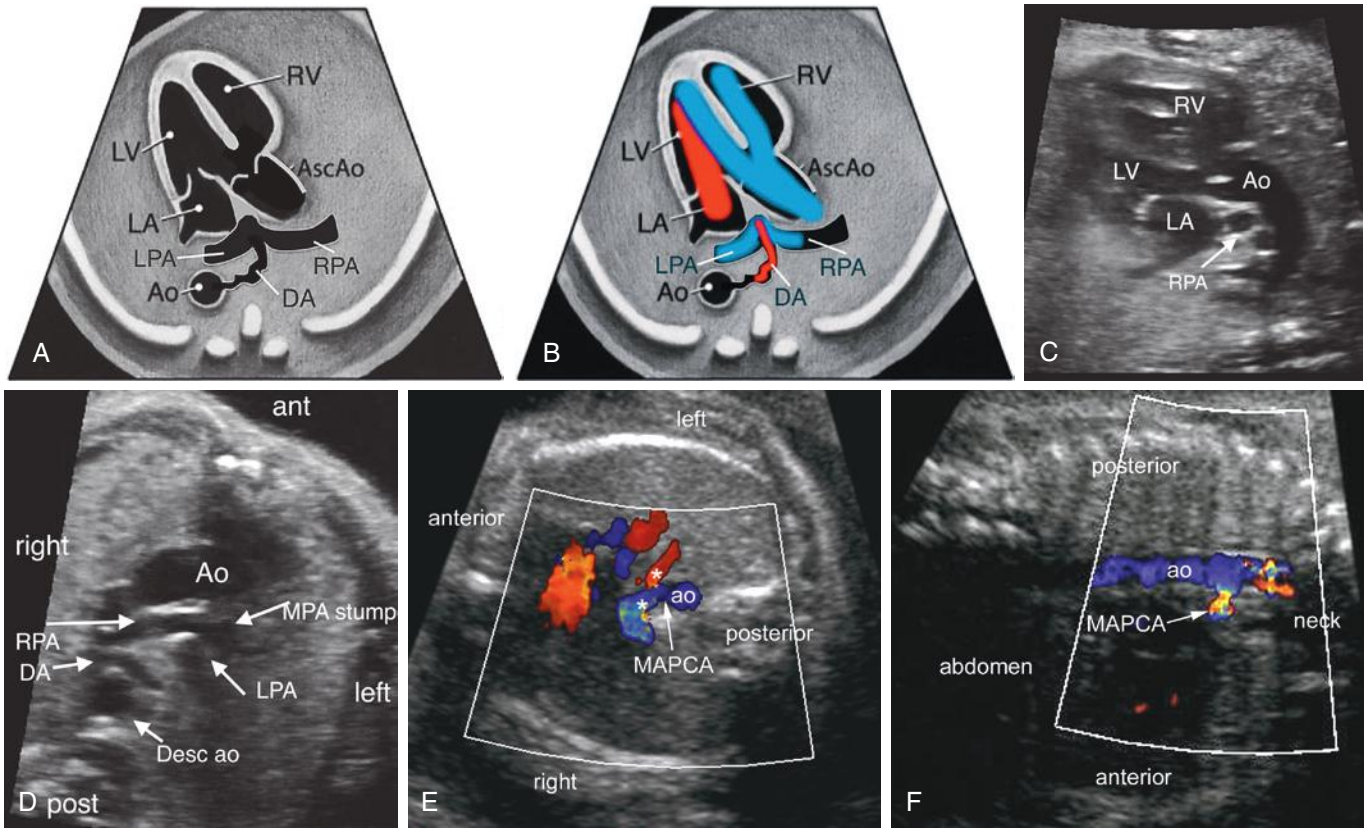

FIG 13-53 Diagrams (**A** and **B**) and sonographic images (**C** through **F**) of pulmonary atresia with ventricular septal defect (PA-VSD). PA-VSD with confluent branch pulmonary arteries are shown in **A** through **D,** and PA-VSD with multiple aortopulmonary collateral arteries (MAPCAs) are shown in **E** and **F.** In **A** and **B** the schematic shows how outflows look with subtle superior sweeping with and without color Doppler. From the left ventricular outflow tract view (**A** through **C**), a large conoventricular VSD is seen with an overriding aorta. From this view, it is difficult to distinguish tetralogy of Fallot (TOF) with pulmonary stenosis, pulmonary atresia with VSD, truncus arteriosus, and TOF-type double-outlet right ventricle from looking at intracardiac anatomy alone. To distinguish these, pulmonary blood flow must be determined. With anterosuperior sweeps, no right ventricular outflow tract is seen; a main pulmonary artery (MPA) stump is seen in **D.** In **A** and **B,** the tortuous ductus arteriosus (DA) arises in the typical fashion from the descending aorta in a left-sided arch. In **D,** the aortic arch is right-sided, and the ductus arises from the origin of the left innominate artery; the ductus is only partially seen in the image. In **E,** a MAPCA (*asterisks*) is seen arising from the anterior wall of the descending aorta (desc ao). **F,** Axial view shows a MAPCA bifurcating into branches to both lungs. Ant, anterior; Ao, aorta; AscAo, ascending aorta; DA, ductus arteriosus; Desc ao, descending aorta; LA, left atrium; LPA, left pulmonary artery; LV, left ventricle; MPA, main pulmonary artery; post, posterior; RPA; right pulmonary artery; RV, right ventricle. (**A,** Adapted with permission from American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013.)

2001 demonstrated a 45% prevalence of 22q11.2 deletion in patients with an interrupted aortic arch compared to 38% in absent pulmonary valve syndrome, 31% in truncus arteriosus, 18% in PA-VSD, 14% in TOF, and 12% in complex TGA.[269] Interestingly, the association between TGA and 22q11.2 is not consistently observed postnatally, indicating that this transposition with 22q11.2 deletion may represent a group at risk for fetal demise.[268]

Interventions and Prognosis. TOF requires surgical repair to eliminate shunting across the VSD and to prevent cyanosis. For most children, the initial repair is performed within the first 6 months of life (but not as a neonate) and involves closing the VSD and establishing unobstructed pulmonary blood flow. For neonates with pulmonary atresia or severe pulmonary obstruction, complete repair may be performed in the neonatal period, or a systemic to pulmonary artery shunt may be placed to provide pulmonary blood flow until a few months of age, when the complete repair is performed. After repair, patients typically have some degree of pulmonary insufficiency. If severe, patients may require repeat pulmonary valve replacement later in life. Those with pulmonary atresia will require serial replacement of a prosthetic conduit from the RV to the pulmonary artery, necessitating repeat surgery over a lifetime.

Fetal demise in TOF is rare.[269] The long-term outcomes of patients with TOF with or without pulmonary atresia hinge upon the health of the RV.[270-272] Overall, survival is excellent, with survival rate in those undergoing surgery since 2000 over 98%.[272] Children and adults with TOF and PA-VSD do need to be followed throughout their lifetime for complications of the heart conditions and repairs, including arrhythmias, exercise intolerance, and impairment of the right side of the heart.

Diagnostic Imaging Features. Features of TOF (see Fig. 13-45 and Videos 13-13 and 13-14):

TABLE 13-7 Likelihood of Chromosome 22q11.2 Deletion Syndrome With Different Lesions

Lesion	% With 22q11.2 Deletion	Lesion	% With 22q11.2 Deletion
Isolated right aortic arch	6-30%	D-transposition of the great arteries	0-0.4%
Right aortic arch, mirror image branching	0-22%	L-transposition of the great arteries	0%
Right aortic arch, aberrant left subclavian artery	12-32%	Double-outlet right ventricle	0-5%
Isolated double aortic arch	14%	VSD with coarctation	26%
Tetralogy of Fallot, all	9-21%	Posterior malalignment type VSD with coarctation	33-67%
TOF with left arch, normal branching	6-11%	Truncus arteriosus	30-41%
TOF with any arch anomaly	21%	Type A1	25-42%
TOF with left arch, aberrant left subclavian artery	0-31%	Type A2	17-33%
TOF with right arch, mirror image branching	10-24%	Type A3	63-100%
TOF with right arch, aberrant right subclavian artery	0-40%	Type A4	25-50%
Pulmonary atresia with VSD	21-47%	Absent pulmonary valve syndrome	14-40%
PA-VSD and RAA	70%	Interrupted aortic arch with VSD	45-89%
PA-VSD with PDA	0-22%	Type A	0%
PA-VSD with MAPCAs	43-77%	Type B	56-57%
PA-VSD with MAPCAs and RAA	100%		

MAPCAs, multiple aortopulmonary collateral arteries; PA-VSD, pulmonary atresia with a ventricular septal defect; PDA, patent ductus arteriosus; RAA, right aortic arch; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

- The four-chamber view may appear normal. The lesion is commonly detected by a sweep from the four chambers to the outflow tracts, which demonstrates the VSD and aortic override (Fig. 13-45A and C). TOF may be confused with truncus arteriosus, DORV, and aortic atresia with VSD. Look carefully at the outflow tracts and arch morphologic features to distinguish them from each other.
- The distinction between TOF and PA-VSD is that in TOF, there is still forward flow across the pulmonary valve, which is best seen by color Doppler imaging.
- The VSD is typically of the conoventricular type (see earlier). Rarely it is of the conoseptal type.
- Zooming in on the RVOT and branch pulmonary arteries can help determine the location of the obstruction by 2D imaging. Any of the following may be present: subvalvar stenosis, pulmonary annular hypoplasia, valvar stenosis, supravalvar stenosis, branch pulmonary artery stenosis.
- In the fetus, the velocity is rarely elevated across the RVOT by spectral Doppler, even in cases of moderate to severe obstruction. 2D imaging and Z-scores are better able to determine the degree of hypoplasia.

Features of PA-VSD (see Fig. 13-53 and Video 13-15):

- In PA-VSD, all pulmonary blood flow is from another source, either retrograde from the ductus arteriosus or via MAPCAs, which usually arise from the descending aorta.
- MAPCAs are best seen by putting a color Doppler box at a low Nyquist limit over the descending aorta and looking for small vessels with anteriorly directed continuous flow.
- Fetuses may have a combination of hypoplastic branch pulmonary arteries and MAPCAs.

Truncus Arteriosus

Definition. Truncus arteriosus is a complex lesion that is defined as a congenital cardiovascular malformation in which a single great artery arises from the base of the heart and gives origin to the coronary, pulmonary, and systemic arteries.[273] It may easily be confused with PA-VSD or aortic atresia with VSD on fetal cardiac evaluation, because one of the great arteries in those conditions is severely hypoplastic.

Epidemiology. Truncus arteriosus has an estimated birth incidence of approximately 7 to 21 per 100,000 live births.[274-276] There is some suggestion that the prevalence of truncus arteriosus in both the United States and Europe is decreasing, perhaps associated with improved prenatal diagnosis and subsequent termination.[228,274]

Anatomy. There are various subtypes of truncus arteriosus (Figs. 13-54 and 13-55), typically categorized by one of two classifications: The Van Praagh Classification[273]:

- Type A1: The branch pulmonary arteries arise from a common pulmonary trunk (most common type) (Video 13-16).
- Type A2: The branch pulmonary arteries arise separately from the truncal artery (second most common). Of note, types A1 and A2 may be difficult to distinguish, even in the initial case series, in which 9% were unclear.[273]
- Type A3: Either the right or left pulmonary artery branch is absent. Collateral arteries supply the lung that does not receive a pulmonary artery branch from the truncus arteriosus (rare).
- Type A4: Underdevelopment of the aortic arch results in preductal hypoplasia, coarctation, atresia, or aortic arch interruption (Video 13-17).

The Collet-Edwards Classification[277]:

- Type I: same as Van Praagh type A1.
- Type II: same as Van Praagh type A2.
- Type III: similar to type II, but pulmonary arteries arise separately from the lateral walls of the truncus (as opposed to posterior truncus); this type is included in Van Praagh type A2.
- Type IV: Previously called truncus arteriosus, this type is now more correctly labeled pulmonary atresia with aortopulmonary collaterals (discussed earlier).

Genetic Considerations. Approximately 50% of newborns with truncus arteriosus are found to have a genetic disorder,[275] most commonly the chromosome 22q11.2 deletion syndrome.[278] However, truncus arteriosus has also been described in trisomy 18,[279] trisomy 21,[280] 14q deletion,[281] *GATA6* mutations,[282] and chromosome 3q22.3 deletions.[283]

Interventions and Prognosis. Truncus arteriosus is typically repaired in the newborn period by creating a baffle that closes the VSD and connects the LV to the aorta and by placing an RV to pulmonary artery conduit. The conduit does not grow with the child and therefore usually needs replacing, often multiple times over the course of a lifetime. Other possible complications include the development of carotid obstruction, conduit regurgitation, branch pulmonary artery obstruction, and aortic dilation/regurgitation. Many of these complications can be treated with catheter-based techniques. If they do need to be surgically addressed, the procedure may be performed at the time of a conduit replacement.

In the current era, outcomes of truncus repair surgery are quite good, with operative mortality rate less than 10% in most centers.[284-286] Despite this, overall mortality rate in truncus arteriosus is still relatively high, estimated at 10% to 20% in infancy, primarily because of additional cardiac lesions, such as interrupted aortic arch, as well as noncardiac problems including necrotizing enterocolitis, extracardiac birth defects, and immunodeficiency associated with DiGeorge syndrome.[278,284,286]

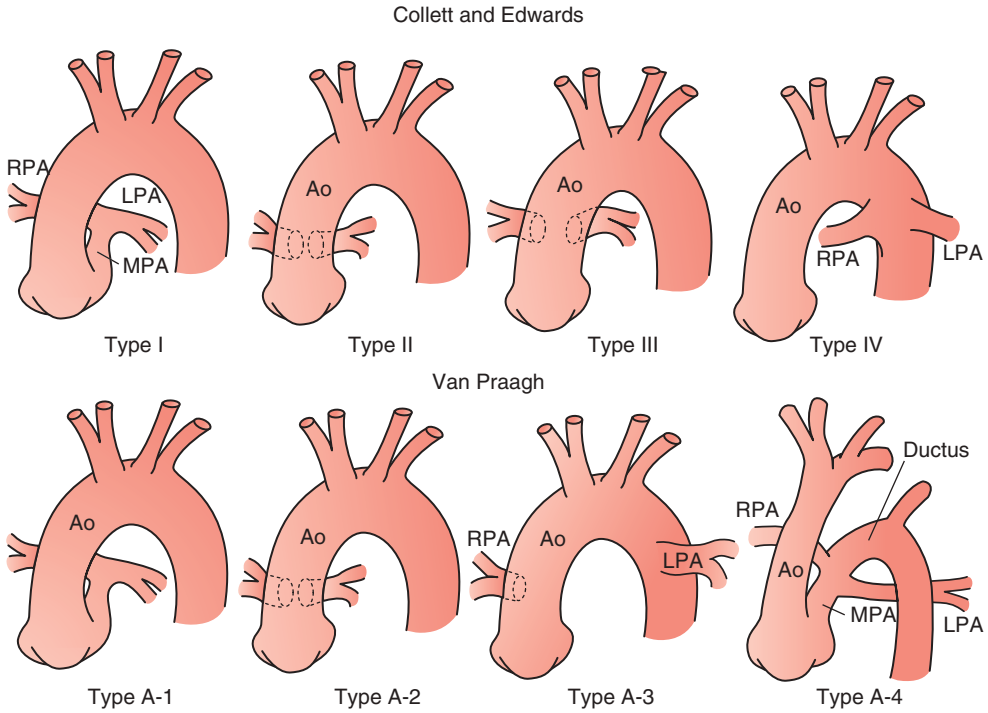

FIG 13-54 Classifications of truncus arteriosus. Ao, ascending aorta; LPA, left pulmonary artery; MPA, main pulmonary artery; RPA, right pulmonary artery. (Adapted from St Louis JD: Persistent truncus arteriosus. In Nichols DG, Ungerleider RM, Spevak PJ, et al [eds]: Critical Heart Disease in Infants and Children. Philadelphia, Mosby, 2006, p 690.)

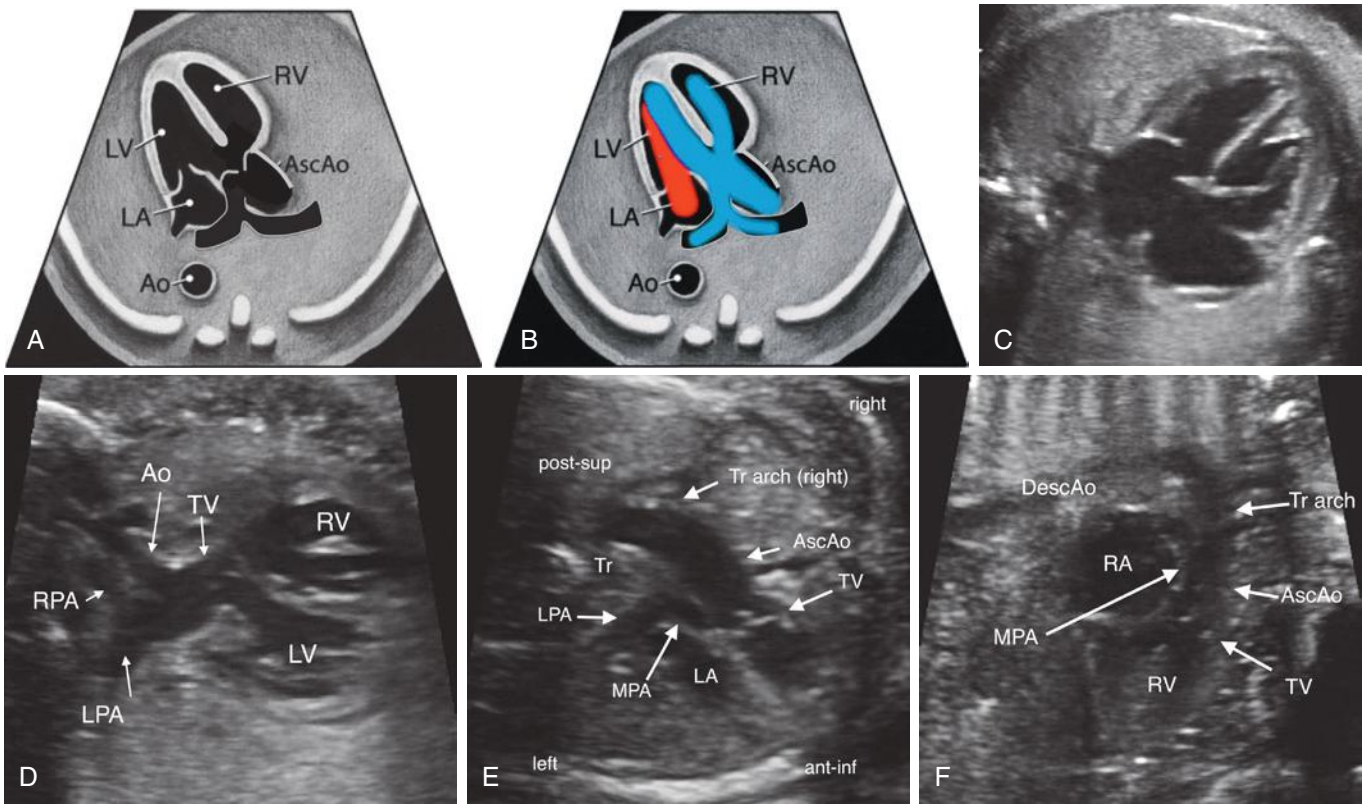

FIG 13-55 Diagrams and sonographic images of truncus arteriosus. **A** and **B,** These schematics show how outflows look with subtle superior sweeping with and without color Doppler. **C,** The deceivingly normal four-chamber view. **D,** The left ventricular outflow tract view shows a large VSD and overriding aorta. In **D** and **E,** evaluation of the great arteries shows a main pulmonary artery arising from the aorta (Van Praagh type A1, Collet-Edwards type I). **D** shows a hypoplastic ascending aorta and interrupted aortic arch (arch anatomy not visible in image). E shows a right-sided aortic arch. In **F,** the main pulmonary artery and ascending aorta arise from the same truncal valve in this patient with a right aortic arch. No ductus arteriosus is present. ant-inf, anterior-inferior; Ao, aorta; AscAo, ascending aorta; DescAo, descending aorta; LA, left atrium; LPA, left pulmonary artery; LV left ventricle; MPA, main pulmonary artery; post-sup, posterior-superior; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; Tr, trachea; Tr arch, transverse arch; TV, truncal valve. (**A,** Adapted with permission from American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013.)

Diagnostic Imaging Features

- The four-chamber view appears normal (see Fig. 13-55C).
- This malformation can be detected on the outflow tract views when only one arterial trunk is identified overriding a large VSD (see Fig. 13-55A, B, and D and Videos 13-16 and 13-17).
- Truncus arteriosus can be easily confused with TOF, PA-VSD, DORV, or aortic atresia with VSD, as in these situations the pulmonary artery or aorta may be hypoplastic and difficult to visualize. Making this distinction is important because both pulmonary atresia and aortic atresia are ductus-dependent lesions and truncus arteriosus is not.
- The ductus arteriosus is typically absent (see Fig. 13-55E and F and Video 13-16). Therefore, only one great artery and *one* arch should be evident. If two arches are present, other diagnoses must be considered, including aortic atresia, pulmonary atresia, and DORV.
- To distinguish truncus arteriosus from pulmonary atresia, one should identify the blood source of the branch pulmonary arteries. In truncus arteriosus, the branch arteries arise from the single great artery, but in pulmonary atresia either the branch pulmonary arteries arise from the ductus arteriosus, which will have retrograde flow, or the branch pulmonary arteries are hypoplastic and the lungs are supplied via MAPCAs.
- To distinguish truncus arteriosus from aortic atresia with VSD, one should evaluate the arch anatomy. In aortic atresia, there will be a severely hypoplastic ascending aorta and arch, and flow in the arch will be retrograde.
- In approximately 1% of cases, truncus arteriosus is associated with severe coarctation of the aorta or interrupted aortic arch (Van Praagh type A4) (Fig. 13-55D and Video 13-17). In these cases, the ductus arteriosus is present and is the primary source of blood flow to the lower half of the body. In cases of coarctation, two arches may be present, with the aortic arch being hypoplastic. Much more common is interrupted aortic arch with truncus arteriosus, and in this situation the ductus arteriosus is usually the only arch present.

Double-Outlet Right Ventricle

Definition. DORV comprises a group of complex lesions, and various definitions of DORV are used. Some define DORV as greater than 50% override of the posterior great artery over the VSD, others define the condition as a lack of continuity between the mitral and

aortic valves, and still others diagnose DORV only when both great vessels completely arise from the RV.[287] The Congenital Heart Surgery Nomenclature and Database Project considered DORV in 2000, and their consensus definition of DORV was made deliberately broad by stating, "DORV is a type of ventriculoarterial connection in which both great vessels arise either entirely or predominantly from the right ventricle."[287]

Epidemiology. DORV is thought to occur in approximately 6 to 15 infants per 100,000 live births.[288,289] There appears to be a larger proportion of males with DORV than females, with estimates of approximately 1.6 males to every female.[289]

Anatomy. Nearly all patients with DORV also have a VSD. Rare exceptions include mitral valve atresia and DORV in which no VSD is apparent. VSDs in DORV are traditionally classified as subpulmonary, subaortic, doubly committed, and remote (Fig. 13-56). Subpulmonary and subaortic VSDs are most similar to the membranous (perimembranous outlet) VSD described earlier and are bordered by an AV valve and the posterior semilunar valve (or semilunar valve closest to the ventricular septum if the great arteries are side by side). Therefore, if the aorta is the posterior/leftward vessel, this defect would be subaortic (Fig. 13-57A through C). If the pulmonary artery is posterior and leftward, the defect is called subpulmonary (Fig. 13-57D). The great artery closest to the ventricular septum may appear to override the VSD (see Fig. 13-57D). The doubly committed VSD is most closely related to conalseptal hypoplasia (doubly committed subarterial), described previously. A doubly committed VSD is bordered by both the aortic and pulmonary valves and occurs when the conal septum is hypoplastic or absent. Remote VSDs include other VSDs that are not bordered by a semilunar valve, and often include AV canal type VSDs.

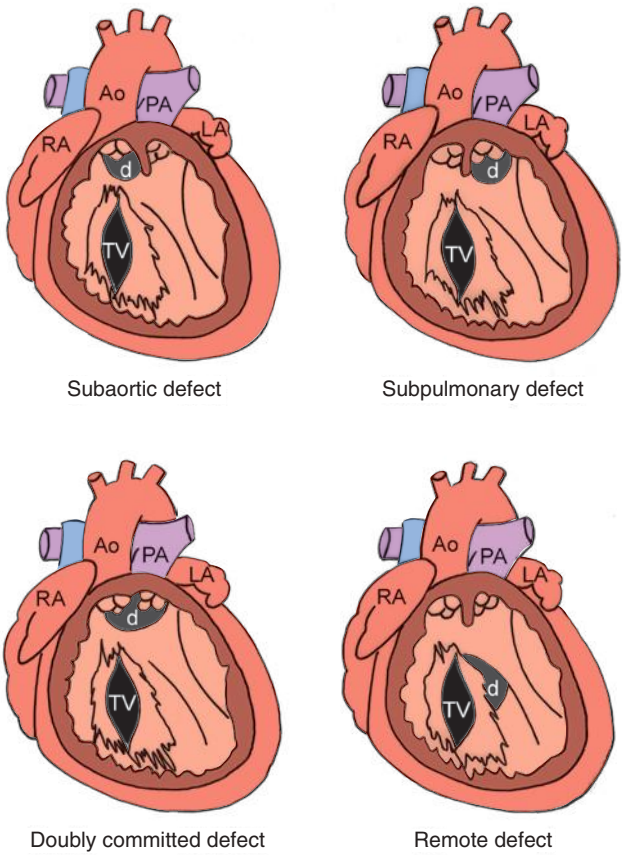

FIG 13-56 Types of ventricular septal defects in double-outlet right ventricle. Ao, ascending aorta; d, ventricular septal defect; LA, left atrium; PA, main pulmonary artery; RA, right atrium; TV, tricuspid valve.

Because many variations of DORV are possible, the cardiac hemodynamics will ultimately determine the child's prognosis and required interventions. Apart from DORV associated with single ventricle lesions (such as mitral atresia with DORV), there are three major physiologic types: TOF type, TGA type, and VSD type. In TOF type DORV, the pulmonary artery is usually anterior, there is a subaortic VSD, and a degree of pulmonary stenosis is present.[290] The infant has decreased pulmonary blood flow in accordance with the relative degree of pulmonary stenosis. In TGA type DORV, the aorta is typically anterior and the VSD is subpulmonary (see Fig. 13-57D). The physiology will mimic that of TGA, with systemic desaturation at birth. This type is also referred to a Taussig-Bing anomaly. The third type, VSD type DORV, typically is associated with a large subaortic VSD, an anterior pulmonary artery, and no outflow tract obstruction. This type of DORV presents with VSD physiology and pulmonary overcirculation with normal or near-normal oxygen systemic saturation. In a recent study, VSD type DORV was the most common subtype among the prenatal group (64%), with TOF type making up 26%, and TGA type DORV composing 10%.[290] The postnatal group consisted of 52% with VSD type DORV, 35% with TGA type, and only 13% with TOF type (see Fig. 13-2 and Table 13-2).[290]

Genetic Considerations. All mothers carrying a fetus with DORV should be offered genetic counseling and testing, given that up to 43% of patients with DORV have a genetic disorder.[291] The most commonly associated chromosomal abnormalities are trisomy 13 and trisomy 18. DORV has also been associated with 22q11.2 microdeletion, trisomy 21, and Klinefelter syndrome.[278,292]

Interventions and Prognosis. Surgery for DORV usually depends on the physiologic nature of the lesion and can vary greatly. For TOF type DORV with severe pulmonary stenosis, an aortopulmonary shunt may be required in the neonatal period to augment pulmonary blood flow, followed by complete repair later in infancy, although some institutions will perform a complete neonatal repair.[290,293,294] A complete repair would include VSD closure, eliminating of obstruction of the RVOT, and shunt takedown.

For TGA type VSD, an arterial switch and VSD closure can often be performed. However, if associated with significant subpulmonary or pulmonary stenosis, an RV to pulmonary artery conduit may be placed with the VSD baffled to the anterior aorta instead of an arterial switch. This procedure is known as a Rastelli repair.[295] In VSD type DORV, VSD closure including a baffle to direct left ventricular flow to the aorta is typically performed. Occasionally in this lesion the pulmonary overcirculation becomes significant at a very young age, and a pulmonary artery band may be placed prior to other surgeries to limit pulmonary blood flow temporarily. In any type of DORV, when there is a remote VSD or significant straddling of the AV valves, a single ventricle palliation may be the only option.[296]

Many coexisting lesions can occur with DORV, and they may also need to be addressed with intervention, including ASDs, coarctation of the aorta, and pulmonary vein anomalies. Sometimes DORV is associated with mitral or tricuspid atresia, and these patients will require single ventricle palliation.[290,293-296]

DORV is associated with a high risk of early demise and complex postnatal care.[290] Factors associated with fetal demise include hydrops, chromosomal abnormalities, and tricuspid regurgitation,[290] which occur in approximately 8% of DORV.[290] The primary factor associated with infant death prior to surgery is the presence of extracardiac malformations. Heterotaxy complex and single ventricle physiology are associated with worse surgical outcomes. For children able to undergo

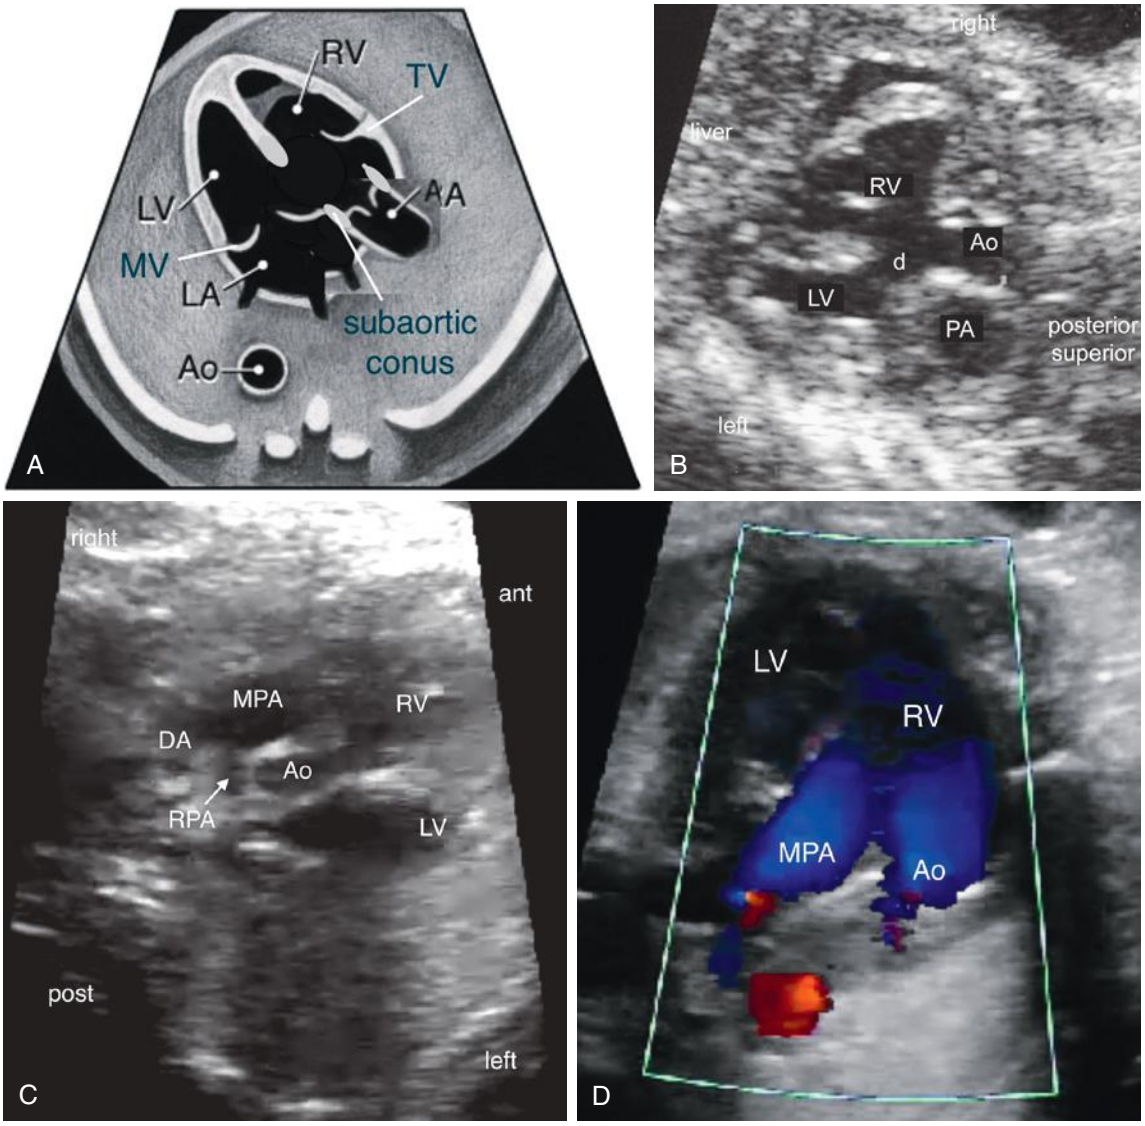

FIG 13-57 Diagram and sonographic images of double-outlet right ventricle (DORV). The diagram (**A**) shows that the great artery closest to the ventricular septum (which typically arises from the left ventricle) arises from the right ventricle in DORV, as does the anterior great artery (not shown). In **A** through **C,** the aorta is closest to the ventricular septal defect (VSD), and there is a subaortic conus. In **D** the pulmonary artery is closest to the VSD. For all, the ventricular septal defect (d in **B**) is below the aortic valve and is the only outlet of the left ventricle. **B** shows subaortic narrowing. In **D** both outflow tracts are unobstructed and the great vessels are malposed, with the aorta rightward and anterior. AA, ascending aorta; ant, anterior; Ao, aorta; d, ventricular septal defect; DA, ductus arteriosus; LA, left atrium; LV, left ventricle; MPA, main pulmonary artery; MV, mitral valve; PA, main pulmonary artery; post, posterior; RPA, right pulmonary artery; RV, right ventricle; TV, tricuspid valve. biventricular repair, chance of survival is much better, with survival rate to discharge 93% to 95%[293] and approximately 85% to 91% survival rate at 5 years. Reinterventions among those with biventricular repair are common but are associated with low morbidity and mortality rates.[297]

Diagnostic Imaging Features. General features (Fig. 13-57 and Video 13-18):

- DORV is associated with other cardiac anomalies. Common associations include venous anomalies such as TAPVC, partial anomalous pulmonary venous return (PAPVC), and left superior vena cava; endocardial cushion defects including complete AVCDs; pulmonary stenosis; aortic hypoplasia; and coarctation of the aorta.
- Secundum ASDs are also common in DORV but may be difficult to assess in the fetus, given the widely patent foramen ovale.
- DORV is common in heterotaxy conditions. If DORV is seen in combination with an AVCD or any venous anomalies, heterotaxy must be considered, and careful imaging should be performed of all cardiovascular, thoracic, and abdominal structures.
- A sweep toward the fetal head starting in a four-chamber view is often helpful to delineate which great artery is more inferior and posterior and to delineate left-right relationships.

Features of TOF physiology DORV:
- Aorta is closest to the VSD (therefore VSD is subaortic) and may appear to override the VSD, but to a greater degree than that in TOF.
- Subpulmonary or pulmonary valve stenosis is present.

Features of TGA physiology DORV (see Fig. 13-57D):
- Pulmonary artery is closest to the VSD (thus subpulmonary VSD) and may appear to override the VSD.
- The great arteries are malpositioned with the aorta, usually either anterior and rightward or adjacent but rightward of the pulmonary artery.
- Pulmonary stenosis or aortic and arch hypoplasia may be present.
- Coarcation and aortic arch hypoplasia are more common in TGA type DORV.

Features of VSD physiology DORV:
- Neither great artery is obstructed.
- The pulmonary artery is usually anterior.

Transposition of the Great Arteries

Definition. D-transposition of the great arteries (DTGA), also known as complete transposition of the great arteries, is a congenital heart defect in which there is atrial situs solitus (usual atrial arrangement) and AV concordance but ventricular arterial discordance, with the RV connection to the aorta, and the LV connection to the pulmonary artery (Fig. 13-58). The aorta is rightward and anterior to the pulmonary artery, which is leftward and posterior. The great artery relationship is designated as D-transposed in which "D" indicates *dexter*, the Latin word meaning "right."

Epidemiology. DTGA is a relatively common congenital cardiac anomaly, occurring in 5% to 7% of all congenital cardiac defects, with an incidence of 0.33 cases per 1000 live births and a 2:1 male-female predominance.[298,299] Extracardiac anomalies are extremely rare in patients with DTGA when no other cardiac lesions are present.

Anatomy. DTGA is seen in isolation with no additional cardiac anomalies other than a persistent PFO or PDA in approximately 50% of cases. The most commonly associated cardiac anomaly is a VSD, occurring in about 40% to 45% of DTGA patients; one third of the VSDs are small and of no hemodynamic significance. LVOT obstruction occurs in 20% to 30% of DTGA. LVOT obstruction is associated with a VSD in approximately 30% of DTGA. However, the combination of a VSD with significant LVOT obstruction occurs in nearly 10%. The LVOT obstruction can be a dynamic obstruction related to septal deviation into the LVOT, which is most common with an intact interventricular septum (IVS) because the right ventricular systolic pressure exceeds that in the LV. Fixed LVOT obstruction can be secondary to a subpulmonary fibromuscular membrane and tunnel-like fibromuscular narrowing. Subpulmonary obstruction can also be noted secondary to redundant mitral valve tissue or abnormal anterior mitral valve chordae in the LVOT. Redundant tricuspid valve tissue or aneurysm of the membranous septum bulging across the VSD during systole can also cause LVOT obstruction. Pulmonary valve stenosis and hypoplasia of the pulmonary valve annulus are rarely seen with DTGA with an intact IVS but are seen in approximately 30% of DTGA/VSD, which often have complex LVOT obstruction.[300,301]

Taussig-Bing anatomy is a term used for DORV with malposition of the great arteries, and the physiology closely resembles that of DTGA. In this anatomy, there is a large subpulmonary VSD. As the pulmonary artery may override the aorta, sometimes this is referred to as Taussig-Bing type of TGA instead of DORV. In Taussig-Bing anatomy, there is a subaortic conus or infundibulum, which may be malaligned anteriorly and often results in subaortic obstruction. This is associated with aortic valve hypoplasia, aortic arch hypoplasia, and coarctation of the aorta. The pulmonary valve annulus overrides the VSD and the pulmonary artery is significantly larger than the aorta.[300]

Genetic Considerations. There is a low incidence of extracardiac or chromosomal anomalies with isolated DTGA. DTGA may occur in association with heterotaxy (most commonly asplenia syndrome/right atrial isomerism), most commonly when DORV or complete AVCDs are also present. In some patients with DTGA and heterotaxy (and rare cases of isolated DTGA), mutations of *ZIC3*, *CFC1*, and *NODAL* genes (laterality genes) have been observed.

DTGA occurs in pregnant mice treated with retinoic acid or with retinoic acid inhibitors. In humans, some families have recurrence of DTGA or congenitally corrected transposition of the great arteries (CCTGA) cases in first-degree relatives.[302,303] These data suggest that monogenic inheritance with a variable phenotypic expression could explain the familial aggregation of DTGA and CCTGA. The prevalence of DTGA is also higher in infants of diabetic mothers, following maternal infection (i.e., flu with fever) during critical cardiogenesis, with intake of ibuprofen, and in cases of in vitro fertilization.[302-306]

Interventions and Prognosis. DTGA is well tolerated in utero. Following delivery, there are parallel systemic and pulmonary cardiac circuits. The deoxygenated systemic venous return is to the RA-RV-aorta, and the oxygenated pulmonary venous return is to the LA-LV-PA. To survive, the newborn requires either intracardiac mixing at either the atrial (ASD) or ventricular (VSD) level or at the level of the great arties via a PDA. A newborn with DTGA with an intact ventricular septum and a restrictive atrial septum or PDA may present with profound hypoxemia and acidosis after delivery. Some studies suggest that prenatal diagnosis can lower the mortality rate in infants with DTGA, given the ability to rapidly diagnose and intervene at birth.[21,22]

Surgical repair in DTGA involves an arterial switch operation. The native pulmonary valve becomes the neoaorta and the coronary arteries are reimplanted into the sinuses of the neoaorta. The native aortic valve and root become the neopulmonary valve. If there is a VSD or ASD, the septal defects are closed. If there is complex LVOT obstruction or significant pulmonary valve stenosis, an arterial switch is not an option for repair. DTGA and VSD with significant LVOT obstruction are best palliated by baffling the VSD patch to the anteriorly positioned aorta. This requires placing a valved conduit from the RV to the branch pulmonary arteries (Rastelli operation). DTGA and DTGA with a VSD have excellent results in major congenital cardiovascular surgical centers.[307] In the current era, the mortality rate for an arterial switch ranges from 0% to 2.8% in experienced congenital cardiovascular centers. Patients with complex DTGA with LVOT obstruction have increased risk of recurrence of LVOT obstruction and higher morbidity and mortality rates.[308-311]

Diagnostic Imaging Features. Isolated DTGA with an intact ventricular septum, which is seen in up to 50% of patients, will have a normal-appearing four-chamber view (see Fig. 13-58C). Thus, DTGA is commonly missed on a prenatal anatomic scan; a large national series gathering data over 21 years of fetal cardiac screening noted a detection rate of DTGA of only about 26%.[298] Improved detection of DTGA is expected with the inclusion of a detailed evaluation of the outflow tracks in addition to the four-chamber view.[70]

Two very important structures to define in the DTGA fetus are the PFO and the PDA, which, if restrictive, suggest the newborn is at risk of developing severe hypoxemia at birth.[312-314] Fetuses with DTGA who are at risk for severe neonatal hypoxemia have abnormal flow in the fetal PDA, in which there is retrograde diastolic flow in the PDA and low-velocity systolic prograde PDA flow. In the fetus with DTGA and no atrial septal restriction, the atrial septum bows into the LA with continuous right-to-left flow. A fetus with DTGA and either a restrictive foramen ovale or a hypermobile, redundant atrial septum

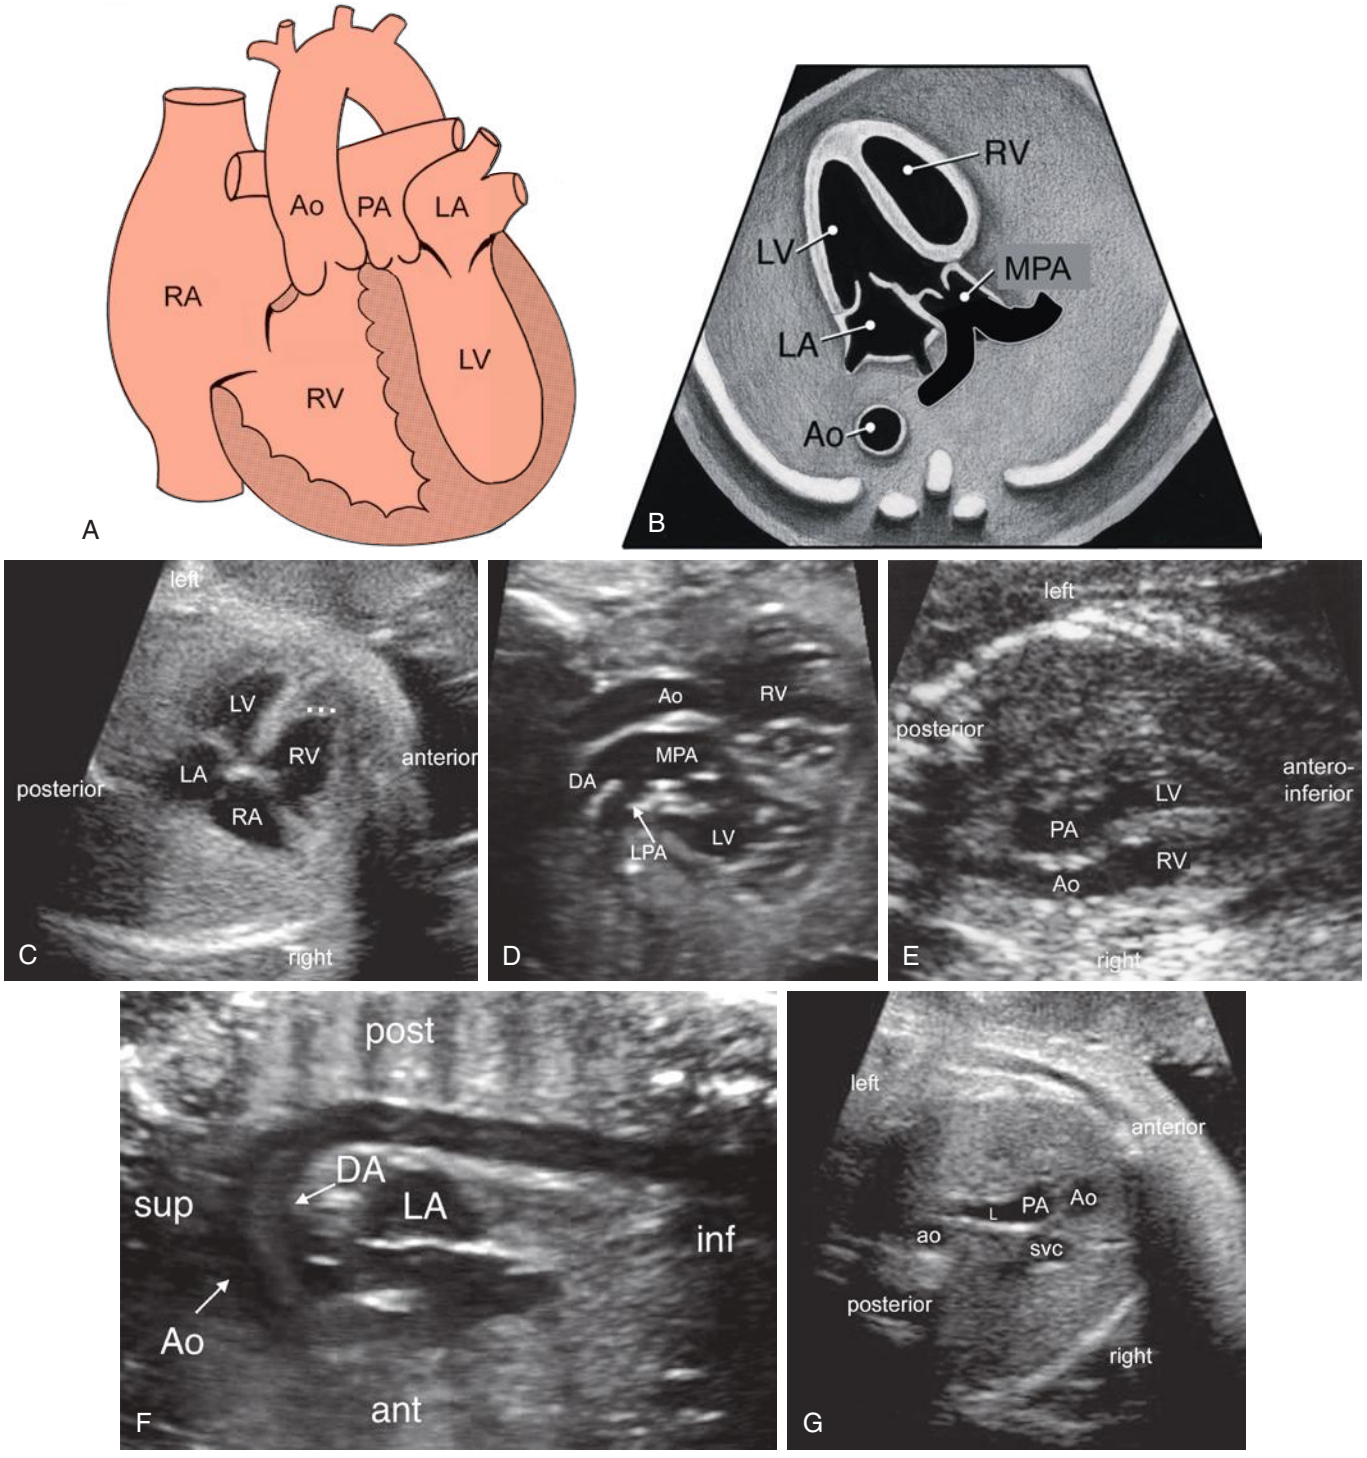

FIG 13-58 Diagrams and sonographic images of D-transposition of the great arteries (DTGA, also known as complete transposition of the great arteries). **A,** Anatomy of DTGA. **B,** Fetal echocardiographic diagram of the left ventricular outflow tract view; small sweeps show the bifurcation of the branch pulmonary arteries. **C,** The four-chamber view shows normal cardiac anatomy. The apex of the right ventricle (RV) is obliterated by the moderator band (*asterisks*). **D,** A view obtained between the short-axis views and the arch views. The parallel great arteries are easily visualized, and the left pulmonary artery and ductus arteriosus can be seen arising from the posterior great artery, that helps identify it as the pulmonary artery. **E,** Ventricular outflow tract view shows discordant ventriculoarterial connections with parallel courses. **F,** View of the arches shows that the aortic arch has a more anterior origin and is more "hockey-stick-shaped" in DTGA, and the ductal arch originates more posteriorly and is more "candy-cane-shaped." **G,** Three-vessel view shows triangular arrangement of the three vessels. The aorta (Ao) is located right and anterior to the main pulmonary artery (PA). ant, anterior; ao, aorta; DA, ductus arteriosus; inf, inferior; L, left pulmonary artery; LA, left atrium; LV, left ventricle; post, posterior; RA, right atrium; sup, superior; svc, superior vena cava. Philadelphia: Lippincott Wolters Kluwer, 2016, used with permission.)

that undulated between the left and right atria is at risk for neonatal hypoxemia.[312-315]

Imaging Tips

- The outflow tracts will be parallel (Fig. 13-58D through F).
- The main pulmonary artery is typically short, arises posteriorly from the LV, and bifurcates (Fig. 13-58B and D).
- 3VV will demonstrate the aorta as the anterior great artery, and the pulmonary artery as posterior (Fig. 13-58G). At times, the vessels cannot be seen in the same view, as the aorta ascends more superiorly than the pulmonary artery (Fig. 13-58F).
- The aorta is superior or cephalad to the pulmonary artery and this elongates the transverse arch and has a more "hockey stick" appearance (Fig. 13-58F). Note the head and neck vessels arising from the superior and anterior aorta. Color Doppler can assist in the differentiation of the two great arteries.
- If TGA is suspected, inspect the PDA for retrograde flow. Note ductal pulsatility index (PI) because a PI of 1.8 or less is associated with ductal restriction and may be a harbinger of neonatal hypoxemia.
- Inspect the atrial septal status for any restriction or bidirectional shunting at the atrial level. Determine if the atrial septum is hypermobile or excessively redundant because this too may indicate a high risk of neonatal hypoxemia and need for urgent intervention.
- Inspect the ventricular septum for a VSD.
- Evaluate the mitral valve and tricuspid valve for any abnormalities or evidence of LVOT obstruction.
- Evaluate the LVOT and pulmonary valve for obstruction, which is more frequently noted with VSD; more severe and complex LVOT obstruction has increased the morbidity rate due to the complex surgical repair.
- Compare the size of the aorta and pulmonary artery. If the pulmonary artery is abnormally large, evaluate the subaortic region for obstruction due to a malaligned conus. This defect is associated with arch hypoplasia and obstruction as seen in Taussig-Bing type of DTGA.

Congenitally Corrected Transposition of the Great Arteries

Definition. CCTGA occurs when there is both AV and ventriculoarterial discordance. In other words, the great arteries are transposed, as are the morphologic LVs and RVs (Fig. 13-59A).

Epidemiology. CCTGA is relatively rare and occurs in approximately 0.03 per 1000 live births and accounts for 0.05% of CHD.[316]

Anatomy. In CCTGA (see Fig. 13-59), systemic venous return is to the RA, which is connected to the morphologic LV via the mitral valve. The LV gives rise to the pulmonary artery that is positioned rightward and posterior to the aorta. Pulmonary venous return is to the morphologic LA, which connects to the morphologic RV via the tricuspid valve. The RV gives rise to the aorta, which is anterior and to the left of the pulmonary artery. In this defect, the unoxygenated systemic venous return is to the lungs via the morphologic LV and pulmonary artery, and the oxygenated pulmonary venous return is directed to the aorta via the morphologic RV. Thus, there is physiologic correction in terms of blood oxygen saturation due to the discordance of both the AV and ventriculoarterial connections. In CCTGA, abnormal leftward looping/topology of the ventricles results in the ventricular septum being in a more sagittal or horizontal plane.

Only 1% to 2% of CCTGA patients have no additional cardiac anomaly.[317] VSD is the most commonly associated defect with CCTGA and is present in approximately 80% of CCTGA cases (Fig. 13-59D). Other coexisting anomalies are subpulmonary valve stenosis, pulmonary valve stenosis, tricuspid valve anomalies, ASD, and congenital complete heart block. Approximately 5% of patients with CCTGA have an abnormality of atrial situs.[317,318]

The most common type of VSD is a membranous defect, and they are often large and have anterior extension. The location of the perimembranous VSD is in close proximity to the tricuspid valve septal leaflet and the posterior mitral valve leaflet. Less frequently seen are conoseptal and muscular VSDs.

The right AV valve is a morphologic mitral valve with two papillary muscles. In majority of CCTGA, the mitral valve has chordal attachments only to the morphologic left ventricular free wall. However, mitral valve abnormalities occur in up to 10% of CCTGA patients and may account for subpulmonary obstruction due to abnormal or accessory chordae attached to the crest of the ventricular septum or redundant or accessory mitral valve tissue in the LVOT.[319,320] The pulmonary vein is wedged between the two AV valves, and with the absence of the subpulmonary infundibulum or conus, the mitral valve is in close proximity to the pulmonary vein. This creates a substrate for LVOT obstruction.

The left AV valve is the morphologic tricuspid valve connected to the morphologic RV that is left in position. The tricuspid valve has an approximately 90% incidence of valve abnormalities of varying degrees, with Ebstein anomaly the most common (Fig. 13-27C).[317,321] A subaortic infundibulum or conus positions the aorta superiorly and anteriorly. Thus, the aorta is to the left of the pulmonary artery. The subaortic conus causes the lack of fibrous continuity between the tricuspid valve and the aortic valve. The subaortic conus elevates the aortic valve more superior than the left AV valve, and thus the tricuspid valve, which is the left AV valve, is not seen in the same plane as the aortic valve.[316] Both AV valves can contribute to LVOT obstruction secondary to the anatomic proximity to the LVOT, resulting in straddling of either AV valve into the VSD.[317]

Rhythm Abnormalities. Congenital complete heart block is associated with CCTGA. In utero, the fetus with complete AV block has a better prognosis when associated with normal cardiac chamber dimensions.[322] CCTGA has also been associated with atrial ectopy, reentry tachycardia, accessory bypass track, and ventricular tachycardia.[322]

Genetic Considerations. Familial recurrence of CCTGA is uncommon; however, in a large clinical case series from four Italian centers the authors noted a 5.2% risk for a sibling to have a cardiac anomaly. The most common congenital cardiac defect seen in siblings of CCTGA patients was DTGA. Recurrence risk of DTGA for relatives of CCTGA patients was 2.6%. Five families with nonaffected parents had two children each with one child with CCTGA and the other child with DTGA. Vertical transmission was seen in one mother with CCTGA, who had a son with DTGA.[303] The recurrence risks were significantly higher than prior published epidemiologic studies, which have reported a recurrence risk of 1% to 3% for parents with a child with CHD.[323] The study suggests single gene involvement in some cases, and possibly autosomal recessive inheritance. Environmental factors have also been shown to be associated with CCTGA.[303,324,325]

Another study reported six twin sets in which one twin had CCTGA and the other twin had no cardiac anomalies. This study and others have documented an increased incidence of CHD in twin pregnancies, suggesting that the twinning process itself increases the risk of one twin having a cardiac defect due to epigenetic or environmental effects on monozygotic twins with identical genetic makeup.[326,327]

In all vertebrates, the linear heart tube undergoes rightward looping, which is essential for proper orientation of the pulmonary (right) and systemic (left) ventricles, and for alignment of the heart chambers with the vasculature. The molecular mechanisms governing cardiac looping remain unknown, but identification of genes differentially expressed along the outer and inner curvatures of the looped heart tube suggests that intrinsic properties of the two surfaces may underlie this critical morphogenetic event. The direction of cardiac looping is determined

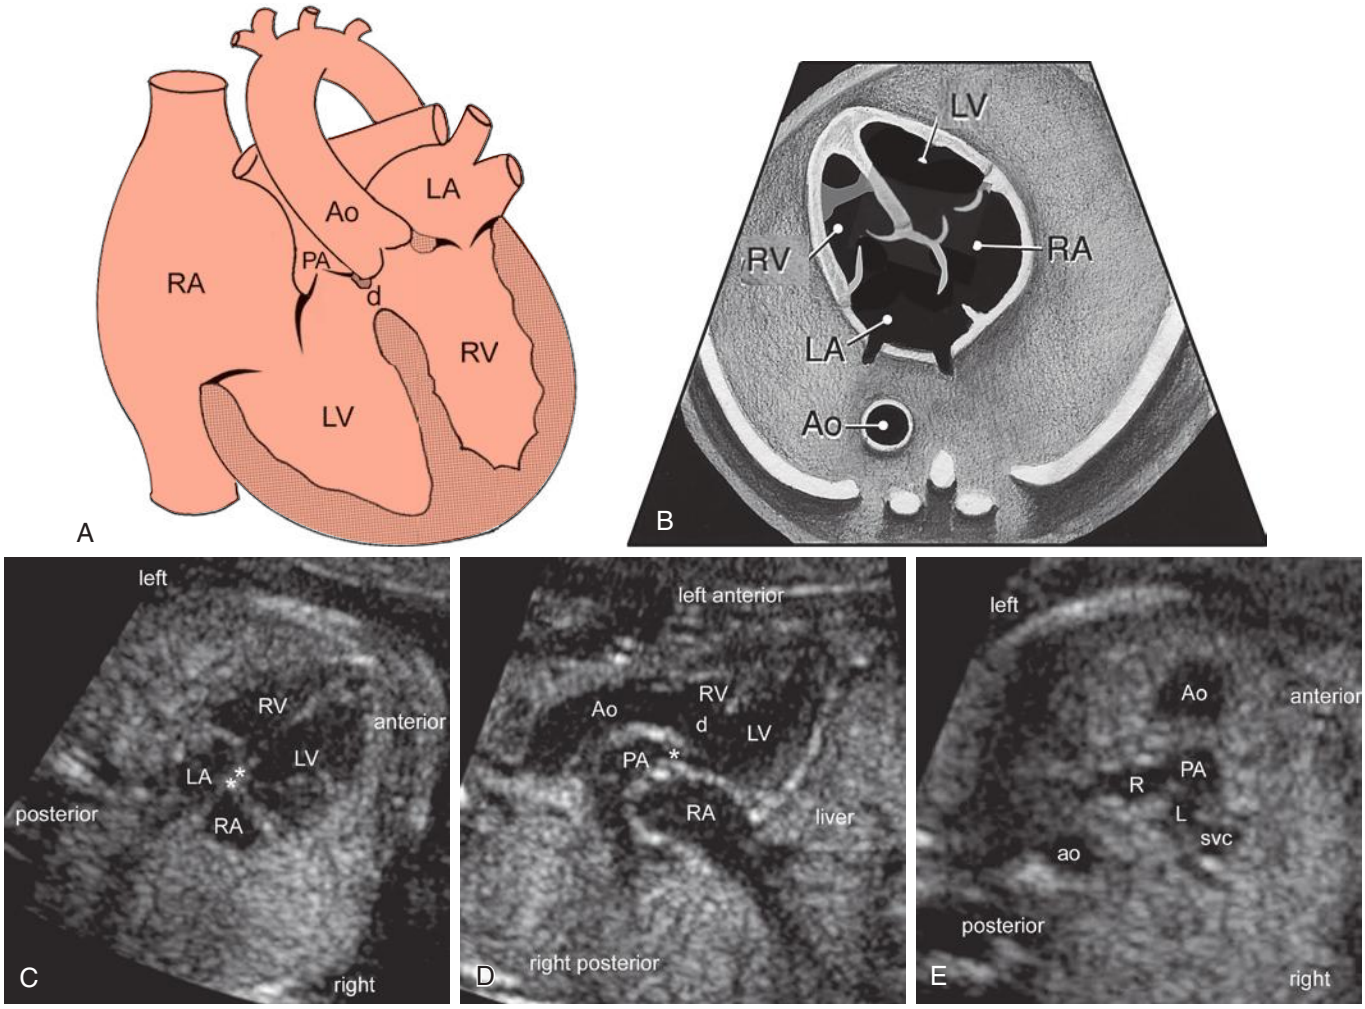

FIG 13-59 Diagrams and sonographic images of congenitally corrected transposition of the great arteries (CCTGA, also known as discordant atrioventricular and ventriculoarterial connections). **A,** Anatomy of CCTGA. **B** and **C,** Diagram and sonographic image in the four-chamber view, with left ventricular looping (left-handed topology), with the morphologically right ventricle (RV) on the left and the morphologically left ventricle (LV) on the right, and discordant atrioventricular connections. Note the more apical attachment of the left-sided atrioventricular valve to the septum (*asterisks*). **D,** Right anterior oblique view shows a superoinferior relationship of the parts of the ventricles and discordant ventriculoarterial connection. The subpulmonary outflow tract (*asterisk*) shows narrowing. **E,** The three-vessel view shows a grossly abnormal great artery relationship with the ascending aorta (Ao) on the left anterior aspect of the main pulmonary artery (PA). This position is most commonly seen in and is highly suggestive of corrected transposition of the great arteries in situs solitus. Ao, aorta; d, ventricular septal defect; L, left pulmonary artery; LA, left atrium; R, right pulmonary artery; RA, right atrium; SVC, superior vena cava. (**B,** Adapted with permission from American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013.)

by an asymmetric axial signaling system that also affects the location of the lungs, liver, spleen, and gut. Before organ formation begins, this signaling cascade directs the asymmetric expression of sonic hedgehog and Nodal, members of the transforming growth factor (TGF) family, in the lateral mesoderm. Interpretation of left-right signals is mediated in part by the transcription factor Ptx2, which is expressed along the left side of developing organs, including the early heart tube. Mouse models of left-right defects demonstrate absent, bilaterally symmetric, or reversed Nodal and Ptx2 expression. In humans, mirror-image reversal of left-right asymmetry is often associated with normal organogenesis. But a discordance of cardiac, pulmonary, and visceral asymmetry (heterotaxy syndrome) reflects a lack of coordinated left-right signaling and is universally associated with defects in organogenesis. The common association of human cardiac alignment defects with abnormalities in left-right asymmetry points to intersecting pathways that regulate the direction and process of cardiac looping, and highlights the clinical significance of this area of study.[305,328] Pregnant mice receiving retinoic acid and retinoic acid inhibitors have fetuses with CCTGA.[304] Thus, the cause of CCTGA is heterogeneous and multifactoral.

Interventions and Prognosis. A classic or physiologic complete repair of CCTGA is VSD closure and addressing any LVOT obstruction or pulmonary valve stenosis. The classic repair leaves the morphologic RV as the systemic ventricle and the tricuspid valve is the systemic AV valve. The morphologic RV supports systemic circulation, which leads to progressive RV dilation and subsequently increasing tricuspid valve

insufficiency and chronic heart failure. Long-term outcomes include increased morbidity and mortality risks due to significant the tricuspid valve insufficiency, AV block and secondary heart failure due to RV dysfunction. The systemic RV has single coronary supply, which can also contribute to RV dysfunction. The classic repair does not address the ventricular arterial discordance.[329] Survival rate at 1 year is approximately 84% with a decline to 60% at 15 years.[330-332]

More recently, CCTGA has been repaired via double switch. The systemic venous return is baffled to the tricuspid valve via a Mustard or Senning atrial switch. The great arteries are switched and coronary arteries reimplanted into the neoaorta. The LV must be "prepared" and have systemic or near systemic pressures prior to the double switch. In the presence of significant pulmonary valve or subvalvular stenosis, the LV is accustomed to high systolic pressures. A pulmonary artery band is placed when there is no significant pulmonary or subpulmonary valve stenosis. In CCTGA cases with a large VSD, the VSD closure baffles the LV to the anterior aorta and there is an RV to pulmonary artery conduit placed (Rastelli procedure) in addition to the atrial switch for an anatomic repair. The anatomic repair commits the morphologic LV and mitral valve to systemic pressures. An anatomic repair is preferred when there is significant tricuspid valve regurgitation. The double switch has about 7% early death risk, but at 10-year follow-up in one study, the patients were heart failure free and had a 10-year survival rate of 77% to 84%.[333-336] Late LV dysfunction has been noted in CCTGA patients with an anatomic repair and complete heart block.[337,338] Overall, an anatomic repair to commit the LV to the systemic ventricle has a better long-term outcome than the classic repair.

Diagnostic Imaging Features

- Left AV valve is inferiorly displaced and lower in position than the right AV valve (Fig. 13-59C).
- Left AV valve has chordal attachments to the ventricular septum.
- The ventricle on the right has two papillary muscles and the right AV valve most frequently has no septal attachments.
- A moderator band is noted in the posterior leftward positioned morphologic RV (Fig. 13-59B).
- Aorta is anterior and leftward and is often just posterior to the sternum (Fig. 13-59E).
- VSDs are present in 80% of CCTGA so careful inspection of the ventricular septum is important.
- Pulmonary valve and subpulmonary valve are coexisting anomalies.
- CCTGA can present with complete heart block, bradycardia, or atrial tachycardia, so evaluation of the rhythm is critical.
- In the 3VV, the aorta is to the left of the pulmonary artery and more superior and anteriorly positioned (see Fig. 13-59E).
- The pulmonary artery is wedged between the two AV valves.

Hypoplastic Left Heart Syndrome

Definition. HLHS is one of the most severe heart conditions and is a spectrum of cardiac malformations, characterized by a severe underdevelopment of the left heart-aorta complex, consisting of aortic or mitral valve atresia, stenosis, or hypoplasia with marked hypoplasia or absence of the LV, and hypoplasia of the ascending aorta and of the aortic arch (Fig. 13-60 and Video 13-19).[339]

As discussed later, hypoplasia of the left-sided cardiac structures, including the mitral valve, the LV, aorta, and aortic arch, can occur without meeting criteria for HLHS.

Birth Prevalence/Epidemiology. HLHS occurs in approximately 1 in 5000 to 6000 live births.[24,230] Without surgery, this condition is lethal, and comfort care previously was the only option. However, major changes over the last 30 years in diagnosis, surgical intervention, and medical management of HLHS have now allowed survival into adulthood for the majority of patients.[15]

Anatomy. Although HLHS is used collectively to describe the collection of features described previously, there are likely several mechanisms of developing left-sided hypoplasia,[15] and HLHS defines the most severe form. Understanding of this process has been improved with modern fetal imaging.[340] Most mechanisms appear to be related to the "no flow, no grow" phenomenon: when blood flow is impaired, growth of the affected fetal heart structures halts.

Classic HLHS is severe mitral stenosis or atresia with severe aortic stenosis or atresia and a severely hypoplastic slit-like LV cavity and severely hypoplastic aortic arch (see Fig. 13-60 and Video 13-19). Although sometimes the LV is severely hypoplastic on the first fetal evaluation and a diagnosis of HLHS is clear, it is not uncommon to see moderate left ventricular hypoplasia in the fetus that progresses to HLHS later in pregnancy.

There are two general patterns to left ventricular hypoplasia when classic HLHS is not already present—a long thin LV or a short fat LV. When the left-sided structures are not clearly small enough to meet criteria for HLHS, it may be referred to as a "borderline LV."[296] The pattern of a long, thin hypoplastic LV is most commonly seen when arch hypoplasia is present and is often first recognized as left-right ventricular asymmetry (Fig. 13-61).[341] The presence of left-right asymmetry (with left side smaller) on fetal echocardiography should trigger concern for developing coarctation of the aorta (Fig. 13-61A). When there is asymmetry in addition to moderate to severe hypoplasia of multiple small left-sided structures, this pattern is also often referred to as Shone complex, although Shone and colleagues described a very specific set of anatomic features that are not always present in this pattern of findings.[296,342] Others have referred to this as "hypoplastic left heart complex."[339,343] In this pattern of hypoplasia, the mitral valve and aortic valve are often hypoplastic and subaortic obstruction may be present (Fig. 13-62 and Video 13-20). Endocardial fibroelastosis is typically not present. For many of these patients, the LV may actually expand with improved filling after birth, and single ventricle palliation may not be necessary. Many children with the long thin LV pattern will require aortic arch repair, and possible mitral valve surgery and subaortic or aortic surgery, and sometimes in severe cases may require single ventricle palliation.[341]

For those with a long thin LV, a main cause is postulated to be obstruction of inflow into the LV, as this pattern of hypoplasia has been described with various associations, including abnormal or small PFO,[344] left superior vena cava to coronary sinus (Fig. 13-63),[345,346] aneurysmal atrial septum obstructing mitral valve flow,[106] and leftward malattachment of the atrial septum.[344,347]

The second pattern of left ventricular hypoplasia when frank HLHS is not present is a short LV, which is almost universally associated with severe fetal aortic stenosis (Fig. 13-64).[348,349] In fetal aortic stenosis, the LV first becomes dilated and severely dysfunctional (Video 13-21). Endocardial fibroelastosis develops, and the pressure generated by the LV decreases. Left ventricular growth halts, and right-sided structures grow around the left side of the heart, resulting in HLHS (Videos 13-22 and 13-23).[348,350,351] Endocardial fibroelastosis and ventricular dysfunction are nearly universal in late fetal aortic stenosis. Mitral valve abnormalities and arch obstruction are also common. Fetal aortic stenosis is particularly easy to miss on cardiac screening, as the LV may appear normal on the four-chamber view (see Video 13-21) and only later develop dilation and ongoing left ventricular growth arrest and left ventricular dysfunction.[352] Clues for development of HLHS in the fetus in the absence of a severely small LV are severe left ventricular dysfunction, endocardial fibrosis (Fig. 13-64A and B), monophasic mitral

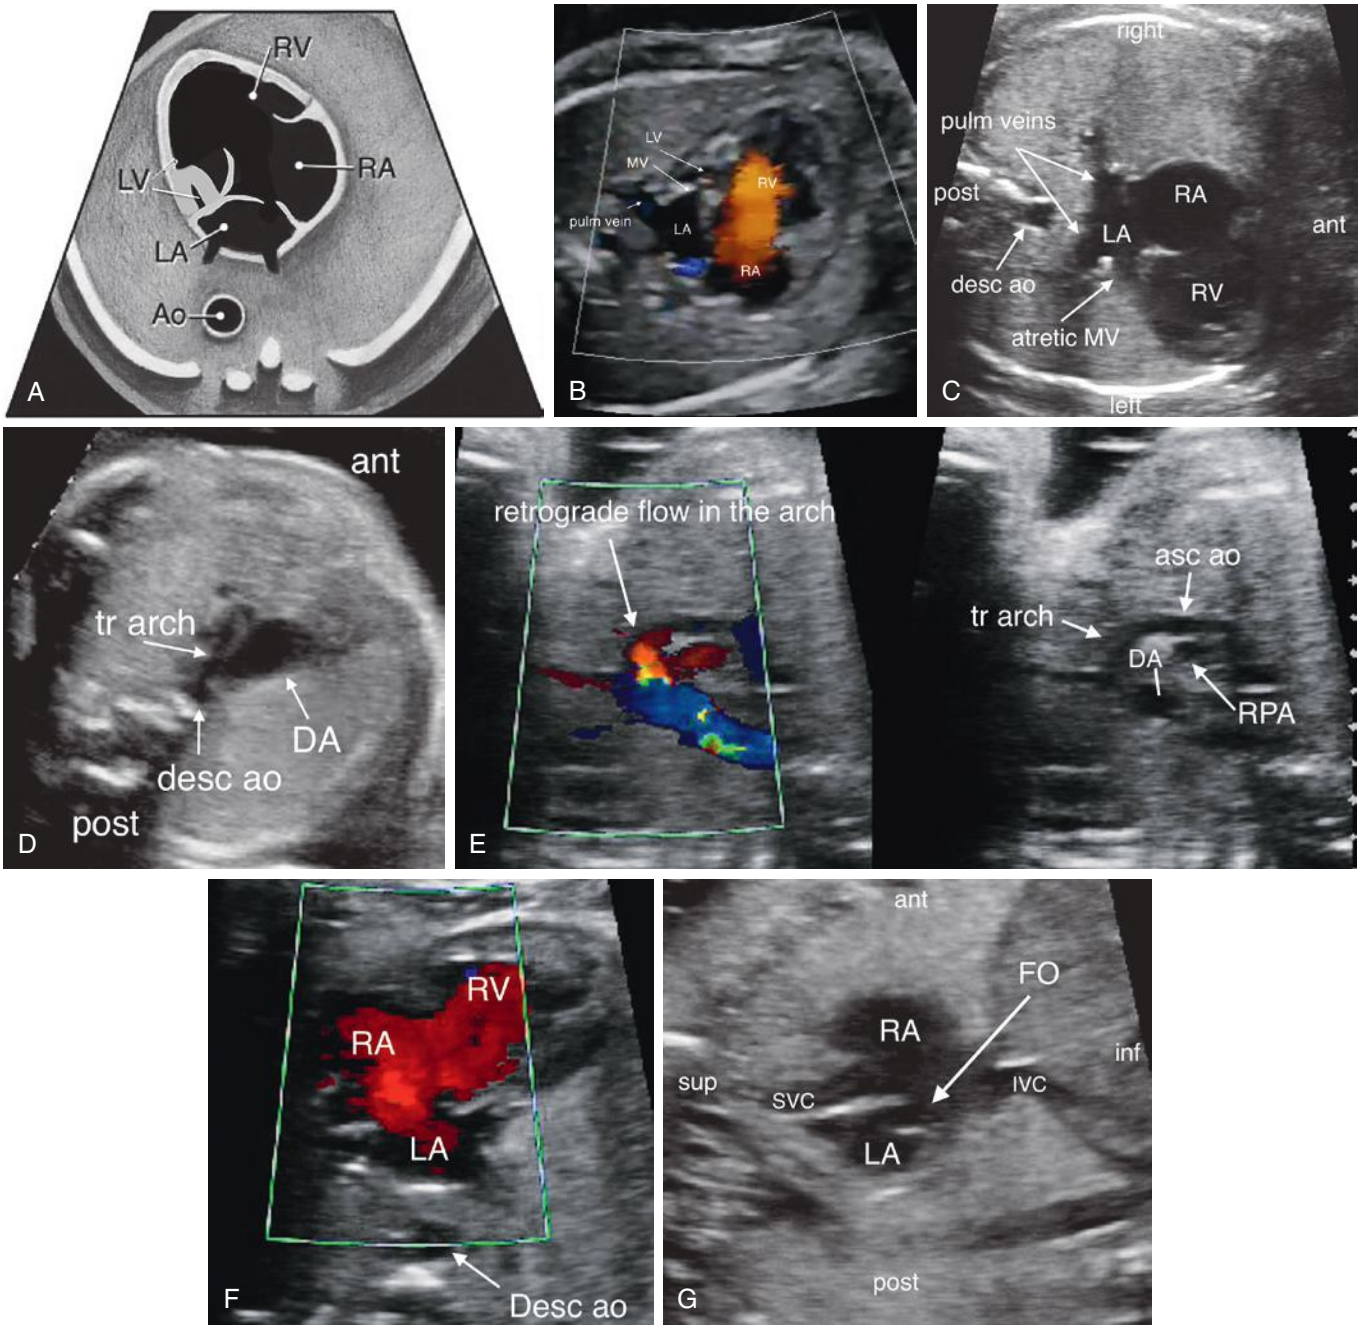

FIG 13-60 Diagram and sonographic images of hypoplastic left heart syndrome (HLHS). **A** through **C,** Diagram and color Doppler images of HLHS in the four-chamber view. B shows HLHS with severe mitral stenosis and aortic atresia (not in image), with a severely hypoplastic left ventricle. In **C,** the fetus has mitral and aortic atresia, and there is no discernible left ventricle. **D,** Three-vessel and trachea view shows a severely hypoplastic transverse aortic arch. **E,** A long-axis view of the aortic with two-dimensional and color Doppler imaging shows a severely hypoplastic ascending aorta and transverse arch. **F,** Unrestrictive atrial septum with left-to-right flow across the foramen ovale. **G,** The bicaval view is often the best way to evaluate the atrial septum in HLHS. ant, anterior; Ao, aorta; asc ao, ascending aorta; DA, ductal arch; desc ao, descending aorta; FO, foramen ovale; inf, inferior; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; MV, mitral valve; post, posterior; pulm vein(s), pulmonary vein; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; sup, superior; SVC, superior vena cava; tr arch, transverse arch. inflow (Fig. 13-64D), retrograde flow in the aortic arch (Fig. 13-64E), and left-to-right flow across the atrial septum.

A portion of patients with HLHS will develop severe restriction at the atrial septum or closure of the foramen ovale, which confers a much worse prognosis because there is no exit of pulmonary blood flow.[340,353,354] For this reason, fetal intervention or emergent postnatal intervention are often offered.[353,355-357] Interrogation of the pulmonary venous Doppler pattern may help determine the severity of atrial level restriction (Fig. 13-65).

Genetic Considerations. From 10% to 19% of patients with HLHS are ultimately found to have either extracardiac birth defects or a genetic abnormality.[24,291,340,358,359] The most common of these is Turner syndrome, occurring in approximately 6% of liveborn females with HLHS.[20] Given that survival is poor in patients with Turner syndrome and HLHS,[360,361] counseling regarding the prognostic utility of diagnostic testing is particularly important in female fetuses with HLHS. Other genetic disorders that have been associated with HLHS include trisomy 13, trisomy 18, Noonan syndrome, chromosome 7 deletions, Holt-Oram syndrome, Smith-Lemli-Opitz syndrome, partial trisomy 9, Jacobsen syndrome, and others.[39,291,349,358,362] Extracardiac anomalies associated with HLHS include agenesis of the corpus callosum, diaphragmatic hernia, duodenal atresia, tracheoesophageal fistula, and omphalocele, among others (see Video 13-21).[361,363] The large majority of fetuses with HLHS and genetic disorders also have extracardiac birth defects.[39]

Interventions and Prognosis. Two fetal interventions are available for fetuses with evolving complete HLHS, depending on the anatomy. In cases of fetal aortic stenosis where the LV is not yet hypoplastic, in utero aortic valvuloplasty has been offered to promote forward flow.[364,365] Early results suggest that fetal aortic valvuloplasty may be associated with an increased chance of a biventricular repair, but this intervention is associated with fetal fatality and the effects on overall mortality rate and outcomes are unclear.[365-368]

For fetuses with a highly restrictive or intact atrial septum, atrial septal perforation and stenting have been performed.[354,356] The purpose of this procedure is to open the atrial septum early in order to allow the pulmonary vasculature to improve over the rest of the pregnancy and to perform the intervention under "maternal bypass," as opposed to after birth, when the infant will be in extremis because of the profound hypoxemia and subsequent acidosis. After birth, the highly restrictive or intact atrial septum results in the oxygenated blood returning from the newborn's lungs being trapped in the LA, and

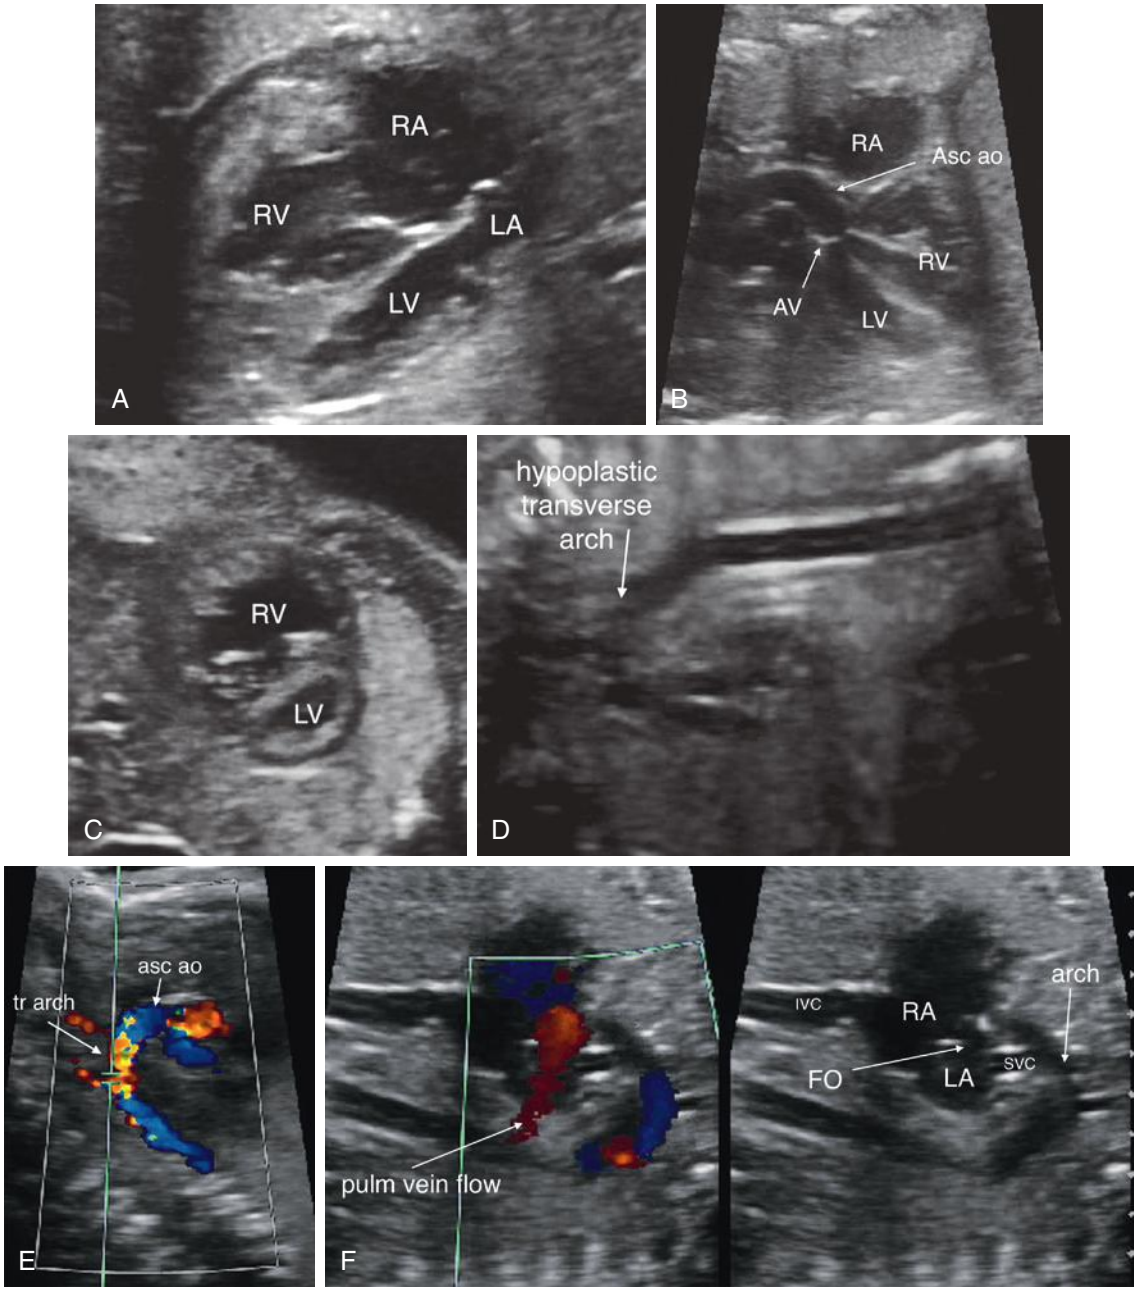

FIG 13-62 Left-sided heart hypoplasia/hypoplastic left heart complex/Shone complex. This form of left ventricular hypoplasia is almost universally associated with arch hypoplasia/coarctation of the aorta, mitral annular hypoplasia, aortic annular hypoplasia, and an apex-forming, but narrow left ventricle (LV). **A,** Four-chamber view of a long, thin LV with a hypoplastic mitral valve annulus. **B,** Left ventricular outflow tract view shows a hypoplastic aortic valve annulus. **C,** Low short-axis view shows that the LV is much narrower than the right ventricle (RV). **D** and **E,** Hypoplastic aortic arch that has retrograde flow by color Doppler, secondary to inadequate prograde flow across the left side of the heart. **F,** Atrial level shunting is typically bidirectional or left to right. Asc ao, ascending aorta; AV, aortic valve; FO, foramen ovale; IVC, inferior vena cava; LA, left atrium; pulm vein, pulmonary vein; RA, right atrium; SVC, superior vena cava; tr arch, transverse arch.

therefore this condition requires an emergent atrial intervention. Although technical success of in utero intervention has been reported, complications are common.[354,369]

For infants born with HLHS, surgery can be anticipated within the first week of life, and a minimum of three palliative surgeries are typically required in the first 5 years of life. For those with an intact or highly restrictive atrial septum, emergent postnatal intervention is necessary for survival, although this may not be sufficient.[354,361] The Norwood operation includes aortic arch reconstruction, atrial septectomy, and anastomosis of the main pulmonary artery to the aorta, creating a neoaorta. Pulmonary blood flow is supplied by either an aortopulmonary (Blalock-Taussig) shunt or Sano conduit (RV to pulmonary artery conduit).[15] Less commonly a hybrid operation is offered as the first stage, which includes an atrial septostomy, PDA stent, and bilateral pulmonary artery banding. Although this strategy may be an option for the most critically ill newborns, in most centers

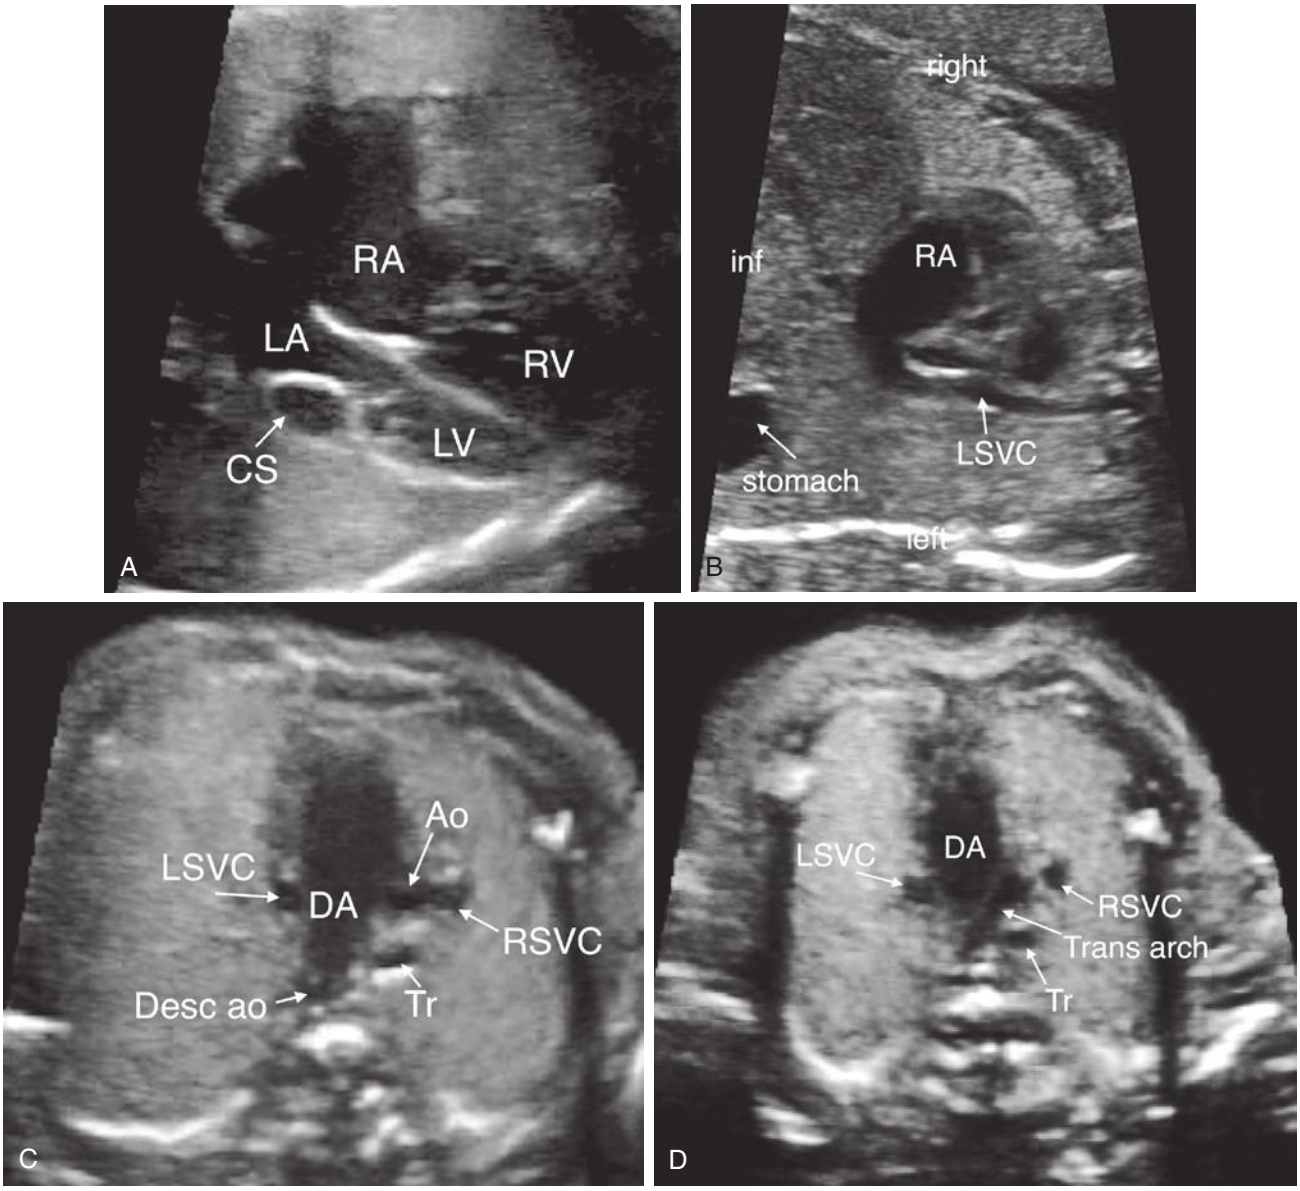

FIG 13-63 Left superior vena cava (LSVC) to coronary sinus and left-sided heart hypoplasia. **A,** Four-chamber view shows a long, thin left ventricle, a dilated coronary sinus (CS), and hypoplastic mitral valve annulus. **B,** A coronal view of the fetal chest shows the LSVC draining to a CS and emptying into the right atrium (RA). **C,** A three-vessel view shows an extra vessel on the left that is the LSVC. **D,** The three-vessel and trachea view shows the LSVC on the left mirroring the right superior vena cava (RSVC). The transverse arch also appears hypoplastic and the ductal arch is larger than usual. Ao, ascending aorta; DA, ductal arch; inf, inferior; LA, left atrium; LV, left ventricle; RV, right ventricle; Tr, trachea; trans arch, transverse arch.

it is not the standard surgery offered for HLHS.[355,370] The Glenn procedure (anastomosis of the superior vena cava to the pulmonary artery) is typically performed at approximately 3 to 6 months of age. The Fontan procedure to create a conduit from the inferior vena cava to the pulmonary arteries is then typically performed between 2 and 4 years of age. In most cases, after the Fontan procedure, the patient is no longer cyanotic, as all of the systemic blood flow is passively directed to the lung.[15]

Termination rates for HLHS vary widely throughout the world and have been reported to range from 16% to 79% in countries that allow termination.[340,358,359,371] Although fetal demise may occur in HLHS, it is rare unless there is severe AV valve regurgitation or intact atrial septum.[15,339] Fatality in the neonatal period, however, is common and occurs both before and after surgery. Presurgical mortality rate is estimated to be as high as 10% in epidemiologic studies, although it is only about 3% in patients born in or surviving transfer to a cardiac surgical center.[24,371] Presurgical fatality is associated with delivery far from a surgical center, major extracardiac congenital anomalies, and obstructed pulmonary venous return. Mortality rate following the Norwood operation is high compared to that for other CHDs, but has significantly improved since the introduction of this procedure. Recent estimates suggest that hospital mortality rate in patients undergoing a Norwood procedure is 7% to 26%.[372-375] Mortality rate of 2% to 16% may occur between the first and second stages,[23,376-379] and death may

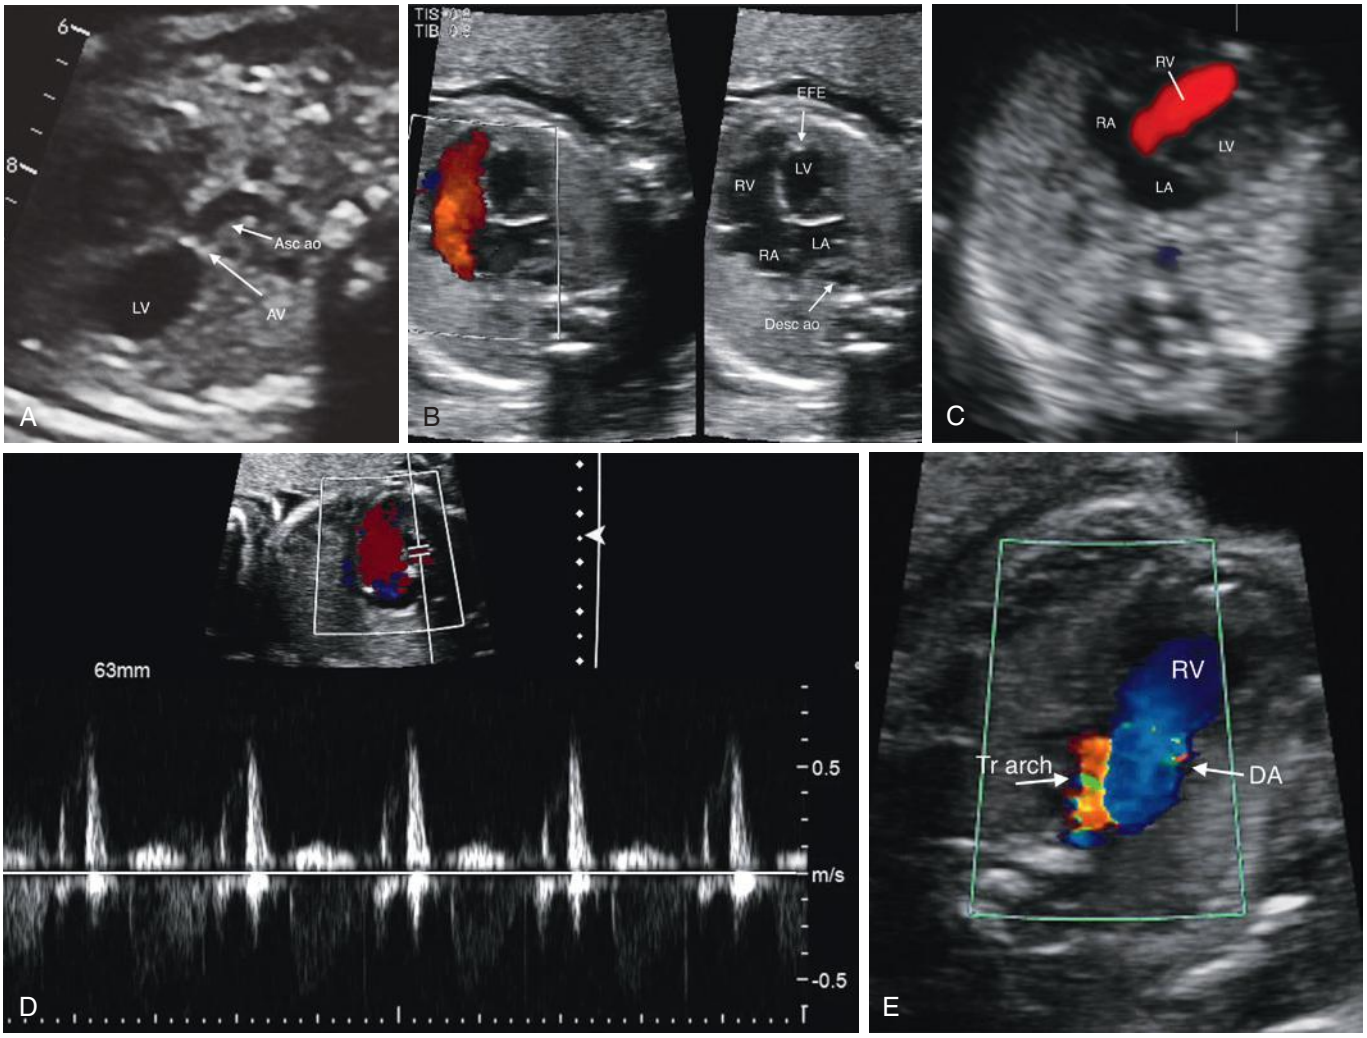

FIG 13-64 Severe aortic stenosis (AS). **A,** Left ventricular outflow tract view shows a hypoplastic aortic valve and ascending aorta. The aortic valve leaflets are echobright. The left ventricle (LV) is globular. Echobright lining of the endocardium is consistent with endocardial fibroelastosis (EFE). **B,** Two-dimensional (2D) and color Doppler imaging in the four-chamber view. By 2D imaging, the LV appears globular and is lined with EFE. Although color Doppler imaging shows inflow into the right ventricle, no inflow is seen into the LV due to severe mitral stenosis. **C,** Four-chamber view in a fetus with aortic stenosis evolving into hypoplastic left heart syndrome (HLHS) at 12⅞ weeks of gestation; note a thickened myocardium, a small LV, and no flow into the LV. **D,** Spectral Doppler pattern of inflow across the mitral valve shows monophasic inflow, suggesting progression to HLHS. **E,** Retrograde flow in the aortic arch in a three-vessel and trachea view. Asc ao, ascending aorta; AV, aortic valve; DA, ductal arch; Desc ao, descending aorta; EFE, endocardial fibroelastosis; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; Tr arch, transverse arch. (A and D from Morris SA, Maskatia SA, Altman CA, Ayres NA: Fetal and perinatal cardiology. In Allen HD, Shaddy RE, Penny DJ, et al [eds]: Moss and Adams' Heart Disease in Infants, Children, and Adolescents Including the Fetus and Young Adult, 9th ed. Philadelphia, Lippincott Wolters Kluwer, 2016, used with permission.)

occur with later procedures as well. In the current era, 50% to 70% of newborns will survive the three surgeries to age 5, and the survival rate continues to improve over time.[374,380,381]

Aside from fatality, long-term complications associated with HLHS include learning disabilities, attention-deficit/hyperactivity disorder, arrhythmias, and heart failure, among others. Many patients with a Fontan circulation develop hepatic impairment with age, and the ultimate therapeutic option is heart transplant for the adult population with HLHS, although much work is being done to develop alternative solutions.[15]

Diagnostic Imaging Features. Features of HLHS (see Fig. 13-60):

- The LV is severely hypoplastic.
- The mitral valve annulus is severely hypoplastic (atresia) with minimal or no flow.
- The aortic valve annulus is severely hypoplastic (atresia) with minimal or no flow.
- Aortic arch flow is completely retrograde.
- Foramen ovale flow is completely left to right. In some cases the foramen ovale may be severely restrictive or the atrial septum may be intact. In these cases, the pulmonary veins often appear dilated,

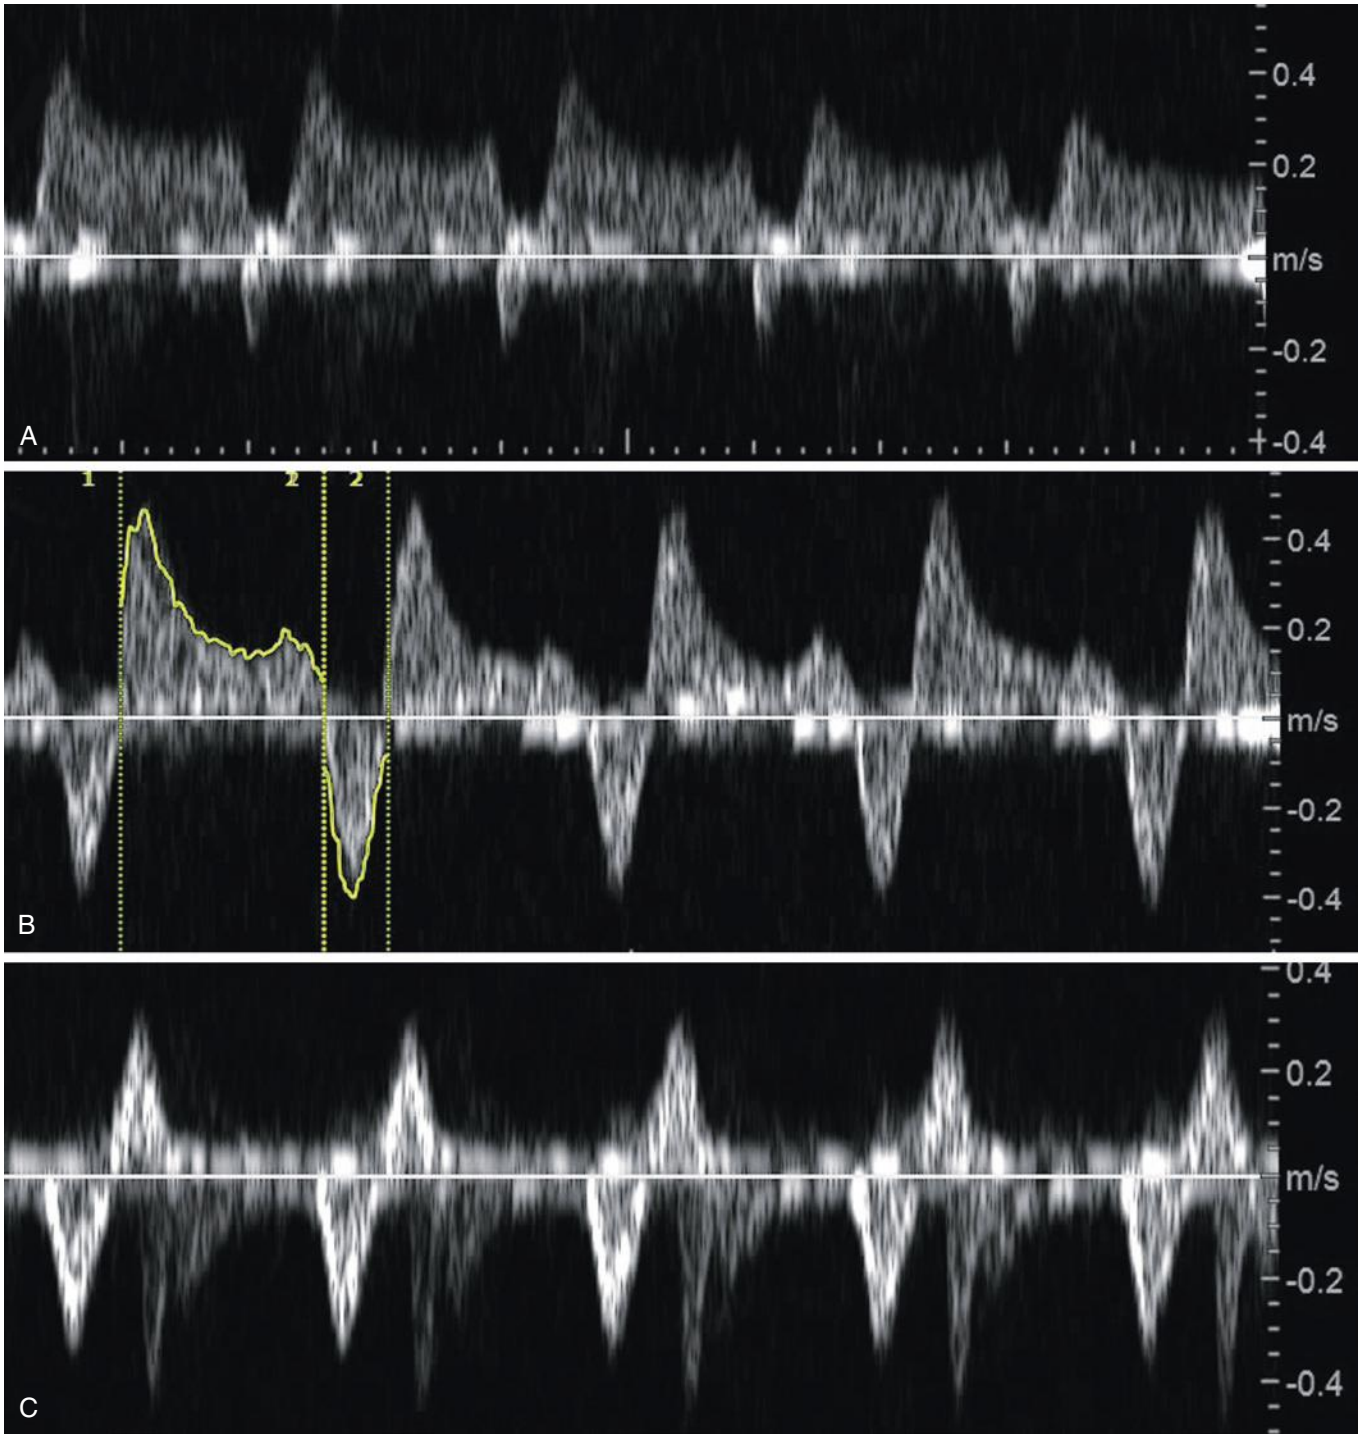

FIG 13-65 Pulmonary venous Doppler patterns with increasing degrees of atrial level restriction. **A,** Pulmonary venous Doppler pattern seen with no atrial septal restriction, with a very short period of a-wave reversal. **B,** Pulmonary venous Doppler pattern seen with mild to moderate obstruction at the atrial septal level. Both a systolic wave and a diastolic wave are seen, but there is more prolonged a-wave reversal. Measurement of the ratio of prograde-retrograde velocity time integral (VTI) is greater than 3 and suggests there will likely not be decompensation at birth. **C,** Pattern of pulmonary venous flow seen with severe atrial level restriction in HLHS. The VTI of the antegrade flow (below line) is just slightly larger than the VTI of retrograde flow (above line) and suggests acute decompensation postnatally. (From Morris SA, Maskatia SA, Altman CA, Ayres NA: Fetal and perinatal cardiology. In Allen HD, Shaddy RE, Penny DJ, et al [eds]: Moss and Adams' Heart Disease in Infants, Children, and Adolescents Including the Fetus and Young Adult, 9th ed. Philadelphia, Lippincott Wolters Kluwer, 2016, used with permission. Information from Divanović A, Hor K, Cnota J, et al: Prediction and perinatal management of severely restrictive atrial septum in fetuses with critical left heart obstruction: clinical experience using pulmonary venous Doppler analysis. J Thorac Cardiovasc Surg 141(4):988-994, 2011.)

and pulmonary venous flow is both prograde and retrograde (see Fig. 13-65). Fetuses with severe restriction have a much worse prognosis at birth, and fetuses with this physiology may therefore be candidates for fetal cardiac intervention.

Features of the coarctation complex/Shone complex with a long thin LV (Figs. 13-61 and 13-62):

- The LV is usually long and narrow and forms an apex.
- Endocardial fibrosis is usually not present.
- The mitral valve and aortic valve annuli are usually hypoplastic.
- The mitral valve apparatus is often abnormal with short chordae, closely spaced papillary muscles, or a single papillary muscle.
- Mitral valve inflow is typically biphasic.
- Subaortic narrowing may be present.
- Aortic arch hypoplasia is typically present.
- Flow reversal and arch may be present.
- It may be associated with atrial septal aneurysm or left superior vena cava (Fig. 13-63).

Features of severe aortic stenosis (Fig. 13-64):

- The LV appears globular (more round than long) and may be dilated and dysfunctional.
- Endocardioal fibroelastosis is often present; this condition appears as an echobright lining of the LV.
- Spectral Doppler across the mitral valve demonstrates monophasic inflow.
- Flow across the atrial septum is usually left to right.
- Aortic arch flow is often bidirectional or completely retrograde.
- Flow across the aortic valve may be high velocity, but in severe cases with near atresia, a small amount of low-velocity flow may be visible and the velocity of the mitral regurgitation jet may be helpful in determining whether the fetus is a good candidate for in utero aortic valvuloplasty, as higher velocities portend better response to fetal intervention.

Tricuspid Valve Atresia

Definition. Tricuspid valve atresia (TVA) is complete absence of the tricuspid valve with no direct communication of the RA to the RV (Fig. 13-66). The lack of right ventricular inflow results in hypoplasia of the RV, which is variable in severity due to the frequent association of a VSD with this condition.

Birth Prevalence/Epidemiology. TVA is an uncommon congenital cardiac anomaly and accounts for 1% to 3% of congenital cardiac lesions. One study reported a prevalence of TVA of 0.056/1000 live births.[239]

Anatomy. TVA results in an obligatory right-to-left atrial level shunt. The four morphologic types of TVA are muscular (62%),

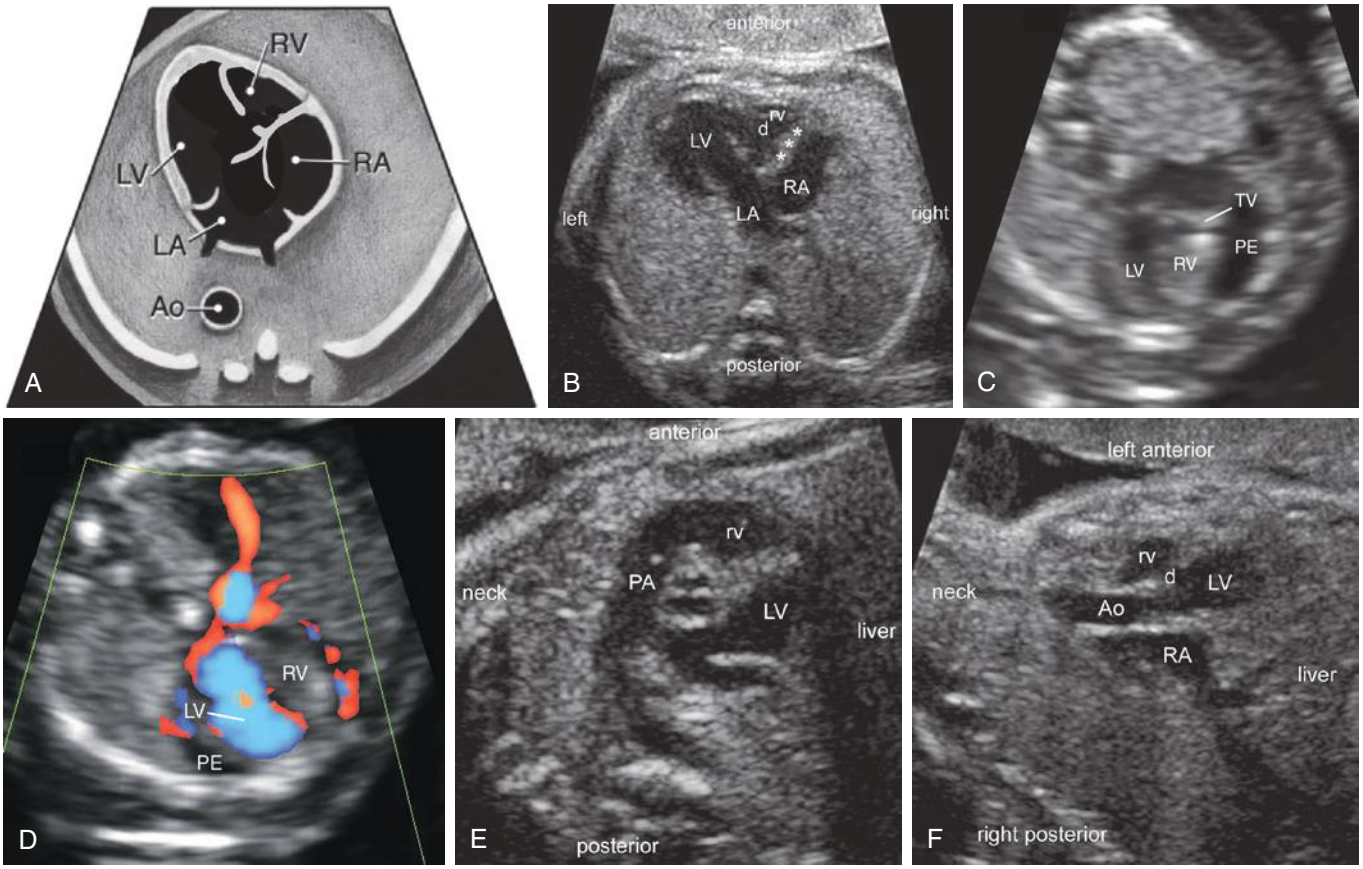

FIG 13-66 Tricuspid atresia with normally related great arteries. **A** and **B,** Fetal echocardiographic diagram and sonographic image of tricuspid atresia in the four-chamber view. This view shows that the muscular floor (*asterisks*) separates the right atrium (RA) from the underlying small right ventricle (rv). There is an unrestrictive ventricular septal defect (d) between the large left ventricle (LV) and the small right ventricle. **C** and **D,** Four-chamber view in a fetus with tricuspid atresia at 13⅐ weeks of gestation; note the lack of blood flow to the right ventricle (RV) by both 2D sonography **(C)** and color Doppler imaging **(D). E,** Oblique sagittal view through the right ventricle shows the pulmonary artery (PA) arising from the right ventricle. **F,** Oblique sagittal view through the left ventricular outflow tract shows the aorta (Ao) arising from the left ventricle. ao, descending aorta; LA, left atrium; PE, pericardial effusion; TV, tricuspid valve. (**A,** Adapted with permission from American Institute of Ultrasound in Medicine: AIUM practice guideline for the performance of fetal echocardiography. J Ultrasound Med 32:1067-1082, 2013.)

membranous (29%), Ebstein-like (6%), and valvar (3%). Muscular TVA has a muscular floor to the RA and no valve tissue. With membranous TVA, the floor of the RA is the membranous AV septum. The Ebstein-like TVA is seen with the imperforate tricuspid valve leaflets plastered to the inferiorly displaced tricuspid valve tissue, resulting in sealed off "atrialized" RV resulting in no connection of the RA to the RV. In valvar TVA tricuspid valve tissue and chordae are visualized but the valve is completely imperforate. In all forms, the inlet RV is absent. Thus, the RV is composed of only the trabecular and infundibular segments of the RV.[382] The overall size of the RV is directly related to the presence and size of an accompanying VSD. If there is no VSD, the RV is diminutive or absent, whereas a larger VSD is typically associated with a larger RV. The sizes of the VSD and RV are also directly related to the sizes of the RVOT and pulmonary valve annulus. When the VSD is restrictive, there is often pulmonary valve stenosis and hypoplasia.

TVA has been classified according to the relationship of the great arteries. Type I TVA is the most common, accounting for approximately 70% to 80% of the patients. Type I TVA has normally related great arteries and, using the Van Praagh segment notation, is designated as {S, D, S}, which describes normal atrial situs (S), normally D-looped ventricles (D), and normally related great arteries (S). Type I TVA with no VSD has pulmonary valve atresia and is a ductus-dependent lesion with the pulmonary arteries being supplied by the ductus arteriosus. Type I TVA with a VSD is more frequently found. In type I TVA with a VSD, the size of the VSD determines the amount of pulmonary blood flow. A recent study of 150 type I TVA infants noted absent antegrade pulmonary blood flow in 19%, restricted pulmonary blood flow in 54%, and unrestricted blood flow in 28%.[383]

Type II comprises approximately 12% to 25% of TVA cases and is associated with TGA. The segmental Van Praagh definition is {S, D, D}, indicating that the RV gives rise to the aorta secondary to transposed great arteries. Thus, the systemic blood flow is dependent upon the sizes of the VSD and RV. Type II TVA has an increased incidence of RV and aortic hypoplasia, aortic valve stenosis, aortic arch hypoplasia, and coarctation of the aorta. Only about 8% of type II TVA have an associated coarctation of the aorta. Type III TVA is uncommon and accounts for approximately 3% to 6% of TVA patients. Type III comprises a complex form of TVA associated with L-transposition of the great arteries. The Van Praagh segments are {S, L, L} with L-looped ventricles or ventricular inversion and an atretic, leftward-positioned tricuspid valve, which is connected to the systemic RV. In addition, the morphologic RV is connected to the L-transposed anteriorly positioned aorta. The systemic AV valve is an atretic tricuspid valve and flow to the aorta is via a VSD into the morphologic RV that is leftward in orientation.

In TVA, the PFO is usually large and unrestrictive, which is critical in this defect because all the systemic venous return and hence the right cardiac output must cross right to left through the PFO. The PFO in the type III TVA may become restrictive, as the pulmonary venous return is limited in the fetus and with the atretic left tricuspid valve, the only egress from the LA is left to right across the atrial septum.

TVA is generally an isolated defect. A small percentage (<20%) of associated defects are seen in TVA patients. Associated cardiac anomalies include left juxtaposed atrial appendages, left superior vena cava, and a right aortic arch.

Genetic Considerations. To date, the genetic mechanism responsible for the development of TVA remains obscure.[384,385] There are isolated case reports of chromosome 22q11.2 deletion with TVA but they appear sporadic.[386,387]

Interventions and Prognosis. TVA is an obligatory single ventricle repair, and all TVA patients are ultimately managed as a single ventricle palliation with a Glenn shunt in the first year of life and a Fontan operation as a toddler. Management of type I TVA with normally related great arteries is dependent upon the degree of pulmonary blood flow. If the neonate has inadequate pulmonary blood flow, then an arterial to pulmonary shunt is placed. Later, TVA is managed via a single ventricular pathway. When an infant with an aortopulmonary shunt develops desaturation in the first year, the pulmonary blood flow is augmented with a Glenn shunt (superior vena cava [SVC] to right pulmonary artery shunt) and takedown of the arterial shunt. Later a Fontan baffle is performed to baffle the systemic venous return (inferior vena cava [IVC]) to the pulmonary artery.

In type I TVA with a large VSD and unrestricted pulmonary blood flow, a pulmonary artery band is placed to prevent pulmonary overcirculation and pulmonary hypertension. The later management is the Glenn shunt followed by a Fontan procedure.

In type II TVA with TGA, the size of the VSD impacts the size of the RV and the degree of aortic valve and arch hypoplasia. If there is type II TVA with aortic arch obstruction or coarctation of the aorta, the aortic arch obstruction is repaired. In cases of aortic arch obstruction and RV hypoplasia, an arterial switch operation results in the LV being the systemic ventricle and resolving the RV outflow tract obstruction. The neopulmonary artery is connected to the hypoplastic RV, which subsequently restricts the pulmonary arterial blood flow. In TVA, the long-term goal is a Glenn shunt and Fontan baffle, which connects the systemic venous return directly to the pulmonary arteries. A Damus-Kaye-Stansel procedure (anastomosis of the pulmonary valve and main pulmonary artery to the proximal aorta) with an aortic arch repair or a type I Norwood procedure has also been a surgical repair used in type II TVA with significant aortic valve and arch obstruction as the first palliative procedure.

Outcomes of TVA reflect the severity of these lesions. A large multicenter series of prenatally diagnosed TVA reported four in utero demises. Survival rate of the liveborn neonates was 91% at 1 month, 87% at 6 months, and 83% at 1 year with no subsequent deaths for 13 years.[388] A more recent series of 54 prenatally diagnosed TVA cases reported two in utero demises. Fifty-two percent ($n = 28$) had normally related great arteries and 14 of those 28 had pulmonary outflow obstruction. Forty-six percent ($n = 25$) had transposed great arteries of which 14 of the 25 had aortic outflow obstruction. The overall survival rate of the continued pregnancies was 89% at 2 years with the greatest loss occurring in the first year of life.[389] A study of 150 type I TVA neonates reported an 86% 5-year survival rate and improved outcomes when a smaller aortopulmonary shunt was placed in neonates with confounding mitral regurgitation.[383]

Overall long-term Fontan survival rate in TVA patients ranges from 79% to 82% in 25-year and 10-year follow-up respective series.[390,391] The more complicated type II TVA-TGA with systemic outflow tract obstruction has a survival rate of 68% at 6 years.[392] The independent risk factors for fatality are low birth weight, premature birth, aortic arch obstruction, and RV hypoplasia.[391]

Diagnostic Imaging Features

- Both 2D sonography and Doppler color imaging in the four-chamber view can aid in recognition of the ventricular disproportion that is seen in TVA (Figs. 13-66A to D and 13-67).
- When TVA is suspected, the following steps are important in evaluation:
  - Assess the great artery relationship. With normally related great arteries, assess for degrees of pulmonary blood flow obstruction.
  - When the great arteries are normally related, the size of the VSD determines the amount of pulmonary blood flow. Assess the direction of flow in the ductus arteriosus. Normal forward antegrade flow in the ductus arteriosus implies adequate blood flow

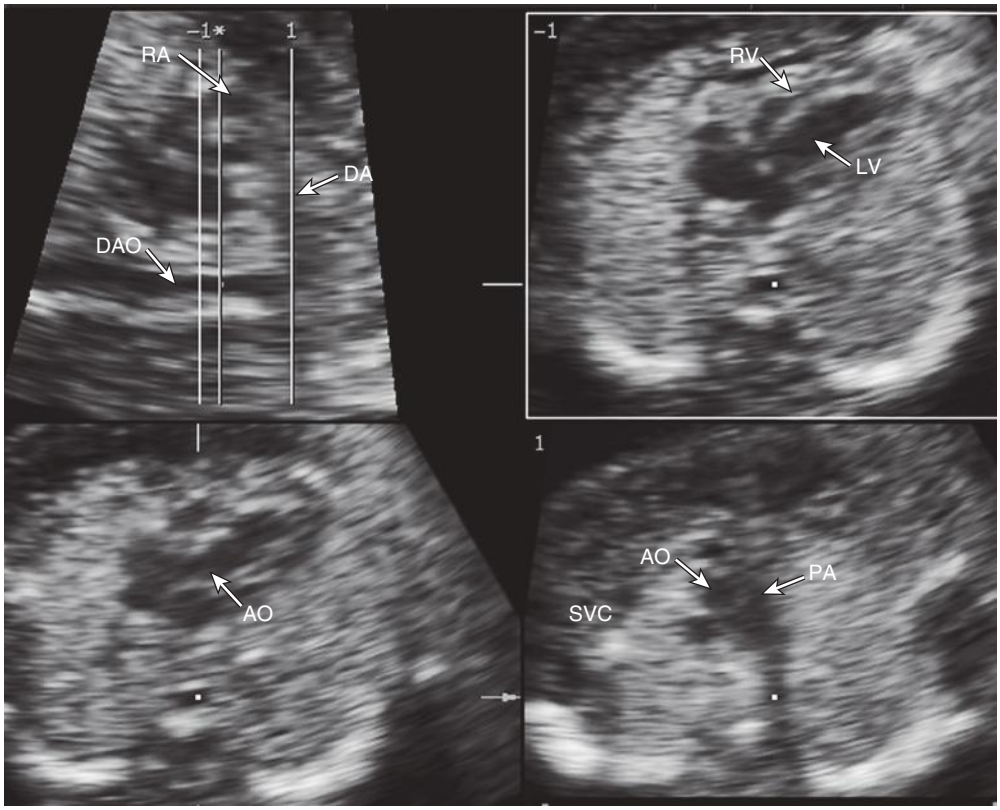

FIG 13-67 Early gestation imaging of tricuspid atresia. Tomographic ultrasound imaging in a fetus with tricuspid atresia and normally related great arteries at 12⅖ weeks of gestation. The image on the upper left corner corresponds to the ductal arch plane. The four-chamber view is displayed on upper right corner, which demonstrates a small right ventricle (RV); the five-chamber view is displayed in lower left corner. A very small pulmonary artery (PA) is seen on the three-vessel view. AO, aorta; DA, ductus arteriosus; DAO, descending aorta; LV, left ventricle; RA, right atrium; SVC, superior vena cava.

after delivery. Retrograde ductus arteriosus implies significant RVOT obstruction or pulmonary obstuction and a ductus-dependent pulmonary blood flow.

- In type II TVA with transposed great arteries, assess for aortic outflow tract and aortic arch obstruction. Note if retrograde flow in the proximal or transverse arch indicates significant systemic outflow track obstruction and ductus-dependent postnatal systemic circulation.
- Most type I and type II TVA fetuses have a wide PFO, but the atretic tricuspid valve will cause a reduction in the DV flow with atrial contraction. Venous pulsations in the umbilical vein suggest atrial septal restriction.
- Type III TVA with ventricular inversion and an atretic left AV connection between the LA and RV presents a risk of atrial level restriction and requires thorough evaluation of the atrial septum. Most fetuses tolerate mild to moderate atrial level restriction, but after birth with increased cardiac output any significant atrial level restriction may require an urgent neonatal balloon atrial septostomy.
- Although both TVA and severe pulmonary stenosis or pulmonary atresia with an intact ventricular septum (PA-IVS) may have a hypoplastic RV and flow reversal in the ductus arteriosus (Fig. 13-68), three features help to distinguish the two: (1) At least a small amount of tricuspid inflow and regurgitation will usually be present in PA-IVS. (2) A VSD is typically associated with TVA, but not with PA-IVS. (3) RV-coronary fistulas are commonly present in PA-IVS, but not in TVA.

Anomalous Pulmonary Venous Connection

Definition. Normally there are two pulmonary veins from the right lung and two pulmonary veins from the left lung with all the veins connected to the LA. When anomalous pulmonary venous connection is present, the pulmonary veins connect directly with a systemic vein or drain directly into the RA. With TAPVC, there is no connection of the pulmonary veins to the LA (Fig. 13-69). In PAPVC at least one pulmonary vein returns normally to the LA, and at least one returns anomalously.

Birth Prevalence/Epidemiology. TAPVC occurs in approximately 0.9/10,000 live births and accounts for approximately 2% of CHD.[324] One of the most common coexisting conditions is heterotaxy syndrome; TAPVC is common in right atrial isomerism/asplenia, whereas PAPVC is more common in left atrial isomerism/polysplenia. Disruption of the left-right asymmetry pathways has been shown in mice to affect alignment of cardiac and visceral structures and to be associated with anomalous pulmonary venous return and heterotaxy syndrome.[305]

Anatomy. The classification of pulmonary venous anomalies is based upon embryologic origins of the pulmonary veins. Thus, a brief review of the embryologic development of the pulmonary veins follows. The primordia of the lungs, larynx, and tracheobronchial tree are derived from divisions of the human embryo foregut. The lungs are enmeshed by the splanchnic vascular plexus of the foregut. During pulmonary differentiation, part of the splanchnic plexus forms the pulmonary vascular bed. Early in development, there is no direct connection with the fetal heart. At this stage, the pulmonary vascular bed

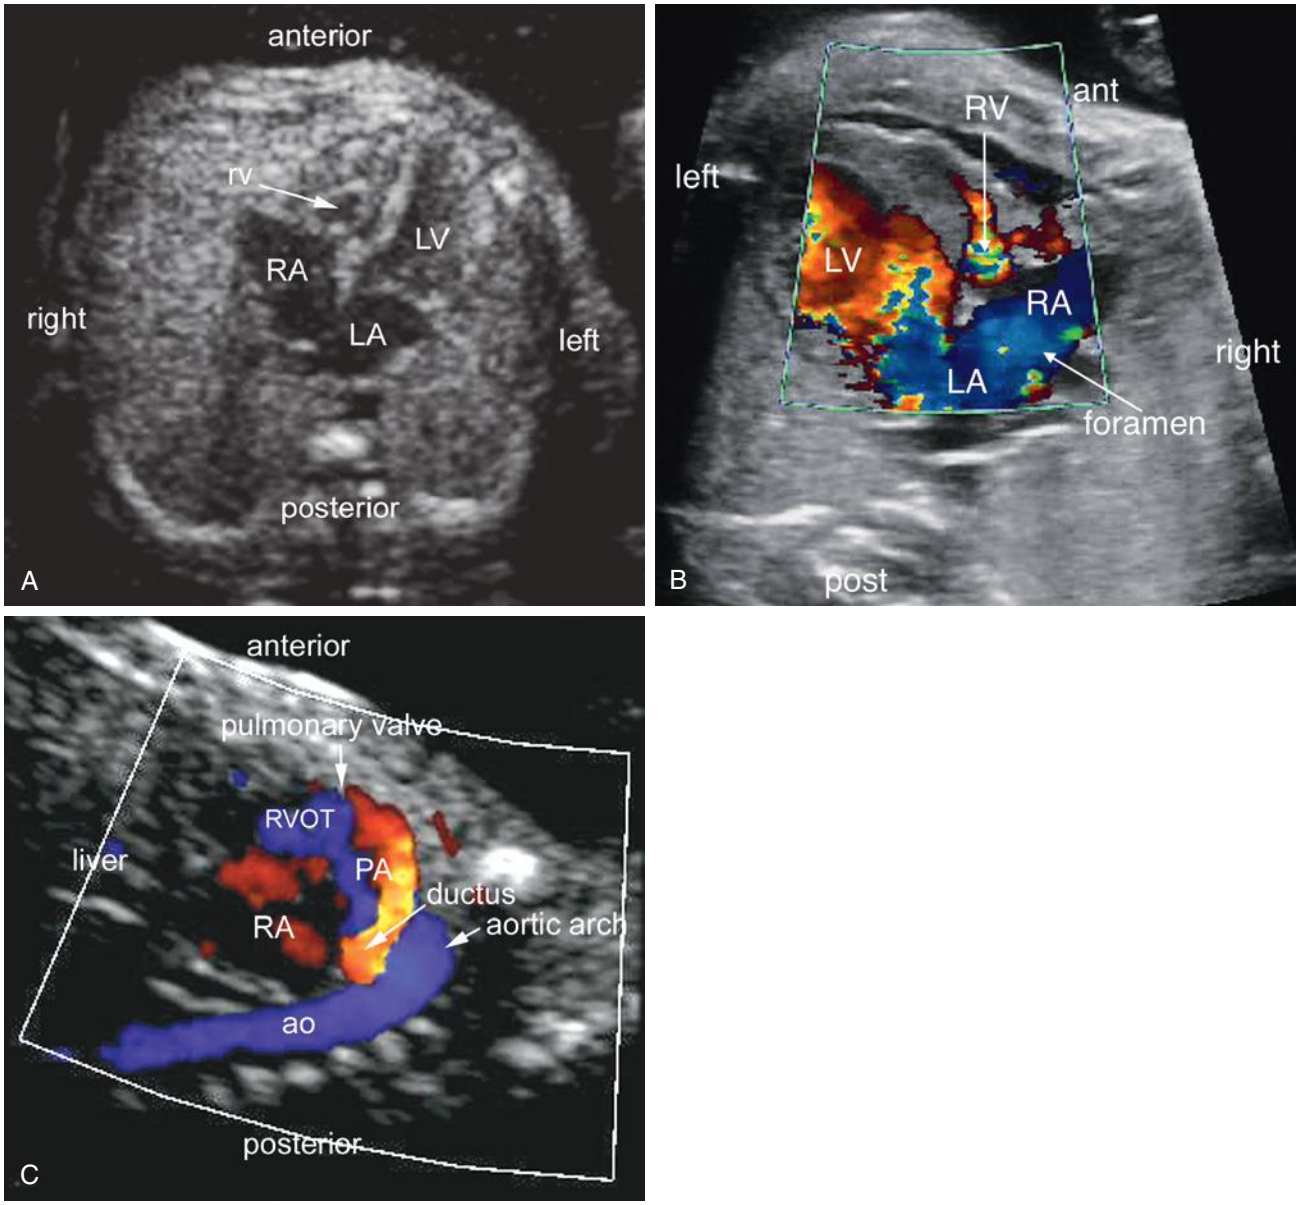

FIG 13-68 Pulmonary atresia with intact ventricular septum. **A,** Four-chamber view shows severe hypoplasia of the right ventricular cavity (rv) and markedly thickened right ventricular free wall. **B,** A four-chamber view using color Doppler shows minimal inflow into the right ventricle (RV). **C,** Ductal arch view with color Doppler shows left-to-right shunt across the ductus. The blood flow from the right ventricle (*blue* signal in right ventricular outflow tract [RVOT]) and the retrograde flow in the main pulmonary artery (*red* signal) collide at the atretic pulmonary valve. ant, anterior; ao, aorta; LA, left atrium; LV, left ventricle; PA, main pulmonary artery; post, posterior; RA, right atrium.

has drainage via the veins of the umbilicovitelline and cardinal systems from the splanchnic plexus. By the end of the first month of gestation, the intraparenchymal pulmonary veins become connected with a common pulmonary vein that evaginates into the LA. The common pulmonary evagination is positioned cephalad to the right and left horns of the sinus venosus and to the left of the developing septum primum.[393] Failure of the normal development of the common pulmonary vein to develop or failure of evagination of the common pulmonary into the LA results in TAPVC of drainage. The abnormal pulmonary venous connections or drainage is via the veins of the primitive umbilicovitelline and cardinal systems from the splanchnic plexus. Thus, abnormal pulmonary venous connections can be total, with all the pulmonary veins draining anomalously, or partial, in which one, two, or three veins have failed to connect to the common pulmonary vein and thus the LA, with the anomalous vein(s) connecting back to the heart via a residual connection to one of the primitive umbilicovitelline and cardinal veins from the splanchnic plexus.

Supracardiac TAPVC. There are several types of TAPVC with the supracardiac being the most common. The pulmonary veins form a confluence posterior to the LA, and a venous channel originates from the confluence and ascends anterior to the left pulmonary artery and bronchus. The vertical venous channel is a derivative of the left cardinal venous system. This vertical venous channel often ascends anterior to the aorta and into the superior mediastinum where the vertical vein

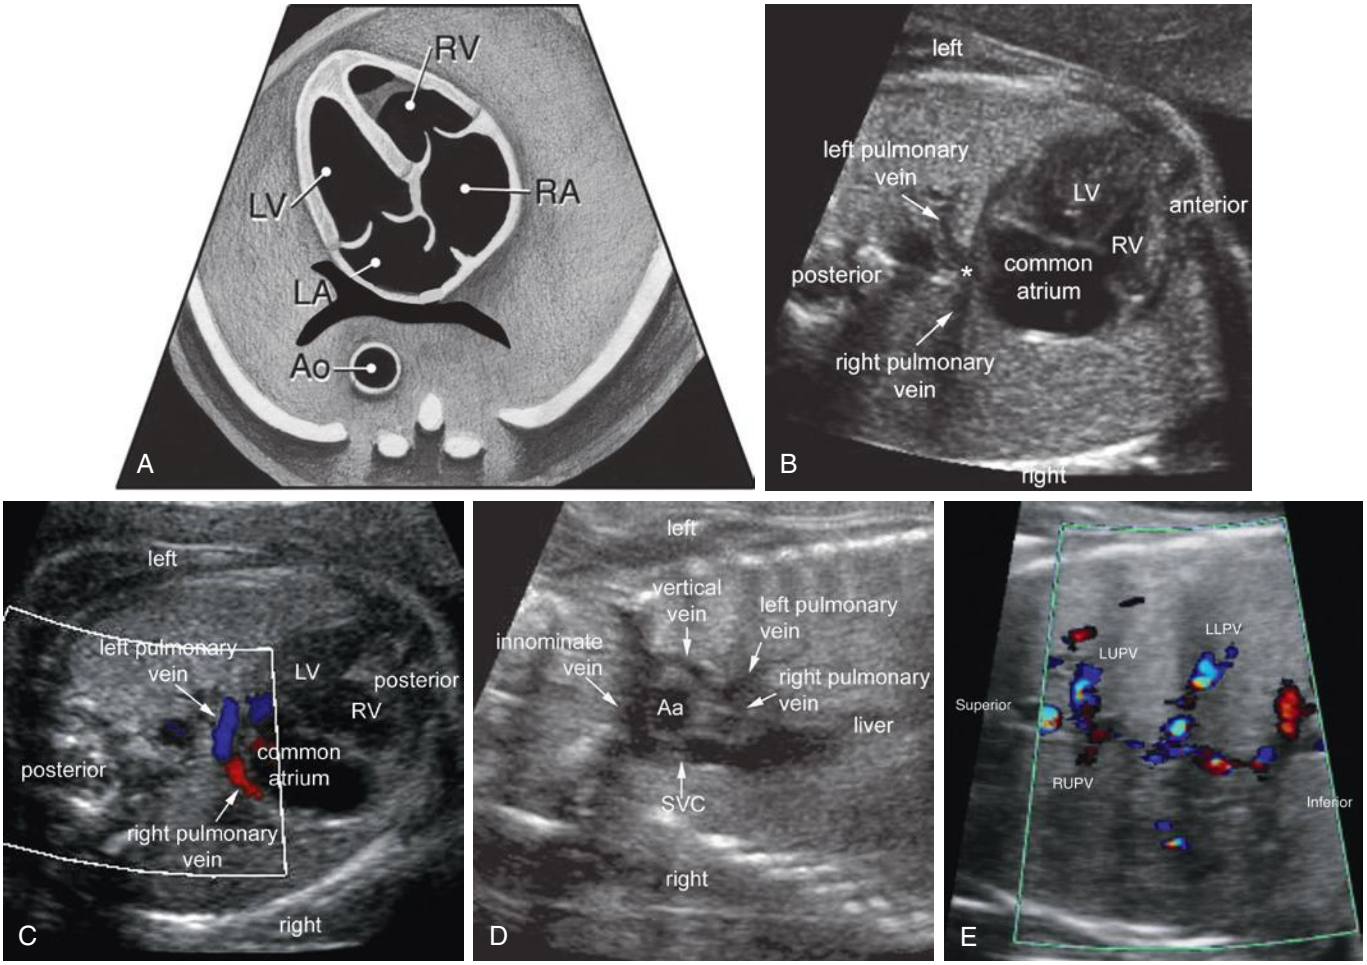

FIG 13-69 Total anomalous pulmonary venous return (TAPVC). **A** through **C,** Diagram and images in the four-chamber view show that the pulmonary venous confluence (*asterisk* in **B**) is in close proximity to but does not connect to the left atrium. **B** and **C** show a fetus with right atrial isomerism. **D,** Coronal view in supracardiac TAPVC shows that the right and left pulmonary veins make a confluence to the vertical vein that connects to the innominate vein. The superior vena cava (SVC) is dilated. **E,** Coronal view in infracardiac TAPVC shows two left and one right pulmonary veins returning to a long descending vein. Aa, aortic arch; Ao, descending aorta; LA, left atrium; LLPV, left lower pulmonary vein; LUPV, left upper pulmonary vein; LV, left ventricle; RA, right atrium; RUPV, right upper pulmonary vein; RV, right ventricle. (**E** from Morris SA, Maskatia SA, Altman CA, Ayres NA: Fetal and perinatal cardiology. In Moss and Adams' Heart Disease in Infants, Children, and Adolescents Including the Fetus and Young Adult, 9th ed. Allen HD, Shaddy RE, Penny DJ, et al [eds]: Philadelphia, Lippincott Wolters Kluwer, 2016, used with permission.)

joins the left innominate vein proximal the insertions of the left subclavian and left jugular veins. When the left vertical vein passes between the left pulmonary artery and left bronchus, the extrinsic compression of the bronchus frequently causes pulmonary venous obstruction. The pulmonary venous return traverses to the left innominate vein and proceeds into the SVC, joining the RA. The embryologic splanchnic venous plexus is a midline structure and this explains why pulmonary venous return may cross the midline with left veins draining to the right cardinal venous system and right veins crossing to the left cardinal venous system. TAPVC to the left innominate vein is seen in approximately 36% of all TAPVC cases, whereas TAPVC to the right SVC is seen less frequently, in about 10% of cases.

TAPVC to the Heart. TAPVC to the coronary sinus occurs in approximately 16% of cases of TAPVC. The posterior venous confluence connects to the coronary sinus in the region of the left AV groove. The coronary sinus follows the normal course entering the RA. TAPVC to the coronary sinus is unobstructed because the course of the anomalous drainage is all within the pericardium.

Infracardiac TAPVC. In this form of TAPVC, the umbilicovitelline venous system allows anomalous pulmonary venous drainage to return below the diaphragm. This form occurs in approximately 13% of cases of TAPVC. The venous confluence is posterior to the LA, and a common vessel descends from the confluence anterior to the esophagus and passes through the esophageal hiatus into the abdomen. Most often the descending vein connects with the portal system via the confluence of the splenic and superior mesenteric veins. When the descending vein connects with the umbilicovitelline venous system, pulmonary venous obstruction is seen in the fetus, which is exacerbated after delivery with increased pulmonary venous return. The descending vein can also connect with the IVC, hepatic vein, or via the DV.[394]

TAPVC to the Right Atrium. In cases of heterotaxy syndrome with an absent septum secundum (often with polysplenia), the septum

primum is displaced superiorly and leftward, which results in the pulmonary veins being incorporated into the RA. The pulmonary veins are connected normally to the posterior atrial wall between the right and left SVCs but drain abnormally into the RA as a result of the abnormal atrial septal displacement.[395]

Mixed TAPVC. Mixed type of TAPVC occurs in approximately 7% and occurs when the pulmonary veins connect to different venous structures and not all connect or drain via the same systemic vein.[394]

Partial Anomalous Pulmonary Venous Connection. Partial anomalous pulmonary venous connection or drainage (PAPVC) occurs when one or more, but not all, of the pulmonary veins are connected to a systemic vein. PAPVC exhibits a wide spectrum of variable venous connections. Left pulmonary veins frequently connect anomalously with the derivatives of the left cardinal system—either the left innominate vein or the coronary sinus, whereas the right pulmonary veins connect to the derivatives of the right cardinal system—the SVC or IVC. In the most common type of PAPVC the left pulmonary veins connect to the left innominate vein. In the second most common type, the right pulmonary veins connect to the IVC.

Scimitar syndrome is seen in the fetus with anomalous right pulmonary venous drainage to the junction of the IVC with the RA. There is also hypolasia of the right lung and the right pulmonary artery along with anomalous arterial pulmonary blood flow from the aorta. This results in pulmonary sequestration. The right lung hypoplasia results in subsequent shift of the heart into the right side of the chest.[396,397]

PAPVC to the right SVC or into the RA occurs in association with a sinus venosus ASD, which is a superiorly positioned ASD at the junction of the SVC with the superior atrial septum. This defect has not been reported to be detected in utero.

Genetic Considerations. Isolated case reports of siblings with recurrence of TAPVC has suggested a possible autosomal-recessive cause.[398-401] There are also case reports of TAPVC and heterotaxy syndrome in patients with a frameshift in *NKX2.5* gene.[402] Cat eye syndrome, a duplication of chromosome 22q11.2, has been associated with TAPVC.[403] PAPVC is also seen in Turner and Noonan syndromes.

Interventions and Prognosis. Infants with infradiaphragmatic TAPVC almost always have obstruction and present in the first 12 hours of life with cyanosis, acidosis, and pulmonary venous congestion. Obstructed TAPVC below the diaphragm commonly requires emergent surgical repair. About 50% or more of supracardiac TAPVC infants also have obstruction and have similar symptoms as the subdiaphragmatic TAPVC and require early surgical repair. The systemic cardiac output is dependent upon the size of the ASD or PFO. Any restriction of the atrial septum will contribute to symptoms and can result in decreased systemic cardiac output if the atrial septum is restrictive.

Surgical repair connects the pulmonary venous confluence to the posterior LA wall and patch-closes the ASD or PFO. The vertical ascending or descending vein is ligated. If there is an additional defect such as a VSD or PDA, the additional defect is closed at the time of surgery. Unobstructed pulmonary veins present with the physiology of a large ASD with right-sided heart volume loading and enlargement due to pulmonary overcirculation and are electively repaired.

TAPVC to the coronary sinus has the physiology of a large ASD. Repair is to excise the common wall of the coronary sinus and LA and close the ASD.

An international, multicenter study of 422 TAPVC patients noted a 3-year mortality rate of 15%. Independent risk factors for death were hypoplastic or stenotic pulmonary veins, earlier age at surgery, associated complex cardiac defects, postoperative pulmonary hypertension, and postoperative pulmonary venous obstruction. Following TAPVC repair, 60 neonates (15%) developed pulmonary venous obstruction and had a 3-year mortality rate of 41%.[404]

A 2014 report of surgical outcomes after TAPVC repair compared patients with isolated TAPVC to those with additional congenital heart disease lesions.[405] Supracardiac TAPVC comprised 48%, intracardiac 20%, infracardiac 20%, and mixed 12% of all TAPVC patients. Obstructed pulmonary venous connection was seen in 33% of all TAPVC, with infradiaphragmatic type demonstrating the most frequent type with obstruction at the level of the diaphragm or in the liver. Overall operative mortality rate in isolated TAPVC was 6.9%, whereas it was 41.2% in TAPVC with more complex heart disease. The risk factors for higher operative fatality were weight less than 3 kg, single ventricle physiology, and aortic cross-clamp time of longer than 1 hour. The late mortality rate combined with the surgical mortality rate was 17% in isolated TAPVC and was 77% in complex TAPVC.[405]

Surgical series note that intrinsic pulmonary venous obstruction and pulmonary vein stenosis have increased morbidity and mortality rates. A 2015 study evaluated 46 isolated TAPVC cases. Those presenting hours after delivery in shock with hypoxemia, hypotension, and severe pulmonary venous congestion were deemed to have intrinsic pulmonary vein obstruction. This group had a 10-year survival rate of 69%. These neonates required prolonged nitric oxide and ventilation along with higher reoperation risk than the other TAPVC neonates without immediate symptoms after birth. Neonates who developed obstruction during the first day of life owing to obstruction of a vertical vein and descending vein because of increasing pulmonary blood flow had a 10-year survival rate of 88%. Neonates presenting with unobstructed TAPVC and pulmonary overcirculation had a 96% 10-year survival rate. Intrinsic pulmonary venous obstruction has a worse prognosis than the nonobstructed TAPVC infants.[406]

Repair of scimitar syndrome involves redirecting the anomalous right pulmonary veins to the LA. Because 70% of scimitar patients have an ASD, the anomalously draining right pulmonary veins are often baffled through the ASD to the LA. Reimplantation of the anomalous right pulmonary vein is also a technique used to reimplant the anomalous veins to the LA. The anomalous aortopulmonary vessels from the descending aorta are either occluded with coils in a preoperative cardiac catheterization or occluded at the time of surgery. The highest risk patients are those with pulmonary hypertension and symptomatic infants requiring surgery prior to 1 year of age. The most successful repairs are performed in older children, of whom many are asymptomatic over a long term.[407,408]

Diagnostic Imaging Features. Series have described TAPVC detected in fetal life, although it is one of the hardest lesions to detect prenatally when isolated.[108] Ganesan and colleagues described sonographic findings for 26 fetuses with a prenatal diagnosis of TAPVC.[108] Lack of visible pulmonary venous connections back to the atrium (100%) and the presence of a visible venous confluence on axial four-chamber views (96%) were the most consistent findings (see Fig. 13-69). The presence of additional vertical venous channels on 3VV or axial abdominal views were also sometimes noted.

There may be a size discrepancy with the RA and RV appearing larger than the LA and LV, although in the Ganesan study, cardiac asymmetry was observed but not consistently in the fetus. When asymmetry is present, it is usually present later in pregnancy as the pulmonary blood flow in the fetus increases. During the last 10 weeks of pregnancy, the pulmonary venous return increases from 20% to 25% of the combined cardiac output. When the pulmonary venous return is abnormal and diverted away from the left side of the heart, a relative left-sided heart hypoplasia can develop. The location of the abnormal pulmonary connection impacts the degree of left-sided heart hypoplasia. Supracardiac TAPVC and TAPVC to the RA and coronary sinus increase the RA and RV volume and thus the right-sided heart enlargement is often more evident, whereas infradiaphragmatic TAPVC

returns via the umbilicovitelline venous system and the IVC, and the blood is directed across the atrial septum. In some infradiaphragmatic TAPVC cases, the left side of the heart can be normal in size and is less likely to have significant hypoplasia.[401]

More rarely, TAPVC is associated with intrinsic pulmonary vein stenosis and hypoplasia, which may also result in decreased pulmonary flow and some degree of left-sided heart hypoplasia due to intrinsic pulmonary venous obstruction. Severe intrinsic pulmonary venous hypoplasia and stenosis are associated with severe hypoxemia, acidosis, and shock in the first several hours of life. Thus, if pulmonary veins are not seen or abnormal flow within the pulmonary veins is noted, the fetus may have the most critical type of TAPVC.

Normal pulmonary venous flow velocity and volume increases during the third trimester.[409] Abnormal spectral Doppler with turbulence by color Doppler may be seen at the site of obstruction in a vertical or descending vein. At the site of obstruction, there is an abnormally high velocity (0.6-1.4 m/second in late gestation) for a pulmonary vein and continuous flow. This is a similar spectral Doppler pattern seen after delivery. Proximal to the pulmonary venous obstruction, the flow in the pulmonary venous channel is low velocity and monophasic. In TAPVC, there is no direct connection of a pulmonary vein to the LA. There is also a separation between the posterior LA wall and the descending aorta, as well as a posterior venous confluence that may be star-shaped or oval between the posterior LA wall and the descending aorta. The aorta is the only normal vessel in the retrocardiac space, and any additional structure or vessel requires interrogation for possible TAPVC and a vertical or descending venous channel.[108,397] A disproportional size in the SVC and IVC is seen when either the IVC or SVC is connected to the anomalous pulmonary venous connection. The systemic vein draining the TAPVC will be larger than the systemic vein with normal venous return.

Imaging Tips for TAPVC

- Size discrepancy may be present, with the right heart chambers and pulmonary artery being larger than the left heart chambers and aorta.
- The LA may appear small, with no venous connections.
- Posterior pulmonary venous confluence is posterior to the LA and anterior to the descending aorta. The posterior confluence may be twig-like star-shaped or ellipsoid.
- An additional vertical structure in the thorax may be seen, with low-velocity venous monophasic flow directed either superiorly or inferiorly. Turbulence is seen in the vertical structure with obstructed flow pattern of increased velocity of 0.6 to 1.4 m/second, and monophasic flow is seen with pulmonary venous obstruction.
- A dilated IVC or SVC should be interrogated for possible TAPVC connection.
- A markedly dilated SVC and innominate vein along with a vertical vein with venous flow superiorly directed into the innominate vein is seen with supracardiac TAPVC. The size of the SVC is dilated in the 3VV and along with the pulmonary artery appears larger than the aorta.
- Abnormal, additional venous structure crossing from the thorax inferiorly through the diaphragm entering the IVC, portal veins, DV, or hepatic veins with increased turbulent flow in the liver is seen with infradiaphragmatic TAPVC.
- Small LA with moderate or greater enlargement of the coronary sinus and lack of pulmonary veins to the LA may be seen with TAPVC to the coronary sinus.
- Small right pulmonary artery, dextroposition of the heart, relative hypoplasia of the right lung, and increased venous return to the IVC are seen with scimitar syndrome and anomalous right pulmonary venous drainage to the IVC.
- Pulmonary veins require spectral and color Doppler analysis and attention to anatomic connection with the LA. In TAPVC the four pulmonary veins may enter a confluence just posterior to the LA, but there will be a horizontal membrane (the posterior LA wall) separating the pulmonary venous confluence from the LA.
- PAPVC in the absence of scimitar syndrome is a more difficult diagnosis in the fetus and may not be detected.

Situs Abnormalities

Definition. Abnormalities of situs are complex and will be discussed only briefly. These conditions refer to abnormalities of laterality in the thorax and abdomen and are discussed because they frequently involve cardiac anomalies. Laterality defects are typically divided into two major forms: situs inversus totalis and heterotaxy (also known as heterotaxy syndrome or isomerism, Fig. 13-70).

Birth Prevalence/Epidemiology. The estimated birth prevalence of nonsyndromic laterality defects is approximately 0.9 to 1.4 per 10,000 live births, with 73% representing heterotaxy and 27% representing situs inversus totalis.[14,240,324,410-412]

Situs defects have been shown to be more prevalent among nonwhite mothers under 20 years of age.[410] Approximately 17% of patients with heterotaxy are born small for gestational age, which is approximately twice the prevalence in the normal population. Although situs inversus totalis has an associated CHD presence of approximately 40%, about a third of these are simple defects. In contrast, heterotaxy is associated with CHD in over 90% of cases, with over 83% of cases having complex heart disease.[410]

Anatomy. In situs inversus totalis, the position of all thoracic and abdominal organs is entirely reversed, which includes dextrocardia, a rightward stomach, a leftward liver, and inverted cardiac anatomy (see Fig. 13-70). This form includes pulmonary venous return to a right-sided atrium and systemic venous return to a left-sided atrium, left-handed cardiac ventricular looping, and leftward malposed arteries (aorta anterior and leftward). Situs inversus totalis is not typically associated with major cardiac defects, but it is commonly associated with minor cardiac defects.[410,413]

Heterotaxy is much more complicated and typically involves abnormal thoracic status, abdominal visceral situs, and cardiovascular anatomy (Figs. 13-70 and 13-71). Traditionally two overall forms of heterotaxy are described, although many variations can occur.[414] The two historical forms of heterotaxy are (1) polysplenia complex (Van Praagh nomenclature), also known as left atrial isomerism (Anderson nomenclature), and (2) asplenia complex (Van Praagh nomenclature), also known as right atrial isomerism (Anderson nomenclature). As the Anderson nomenclature is more descriptive of this lesion, that terminology will be used for this section. Left atrial isomerism is associated with "duplication" or mirror image of the left-sided structures with the classic involvement of absence of the IVC with azygous continuation, ipsilateral pulmonary venous return with right pulmonary veins to the RA and left pulmonary veins to the LA, and frequent absence of the sinoatrial node with associated sinus node dysfunction. Right atrial isomerism is associated with an intact IVC, TAPVC, right or bilateral SVC, and secondary sinoatrial nodes. Both conditions are associated with AVCDs, although they are more common in right atrial isomerism; they are present in approximately 55% of cases of right atrial isomerism compared to 26% of left atrial isomerism cases. Bilateral SVC, broad-based midline liver, DORV, and pulmonary stenosis are seen in similar frequency in right and left forms.[410]

Genetic Considerations. Over 100 genes have been identified as important in left-right asymmetry in animal models,[413] and disruption of these pathways is implicated in human laterality defects. Primary

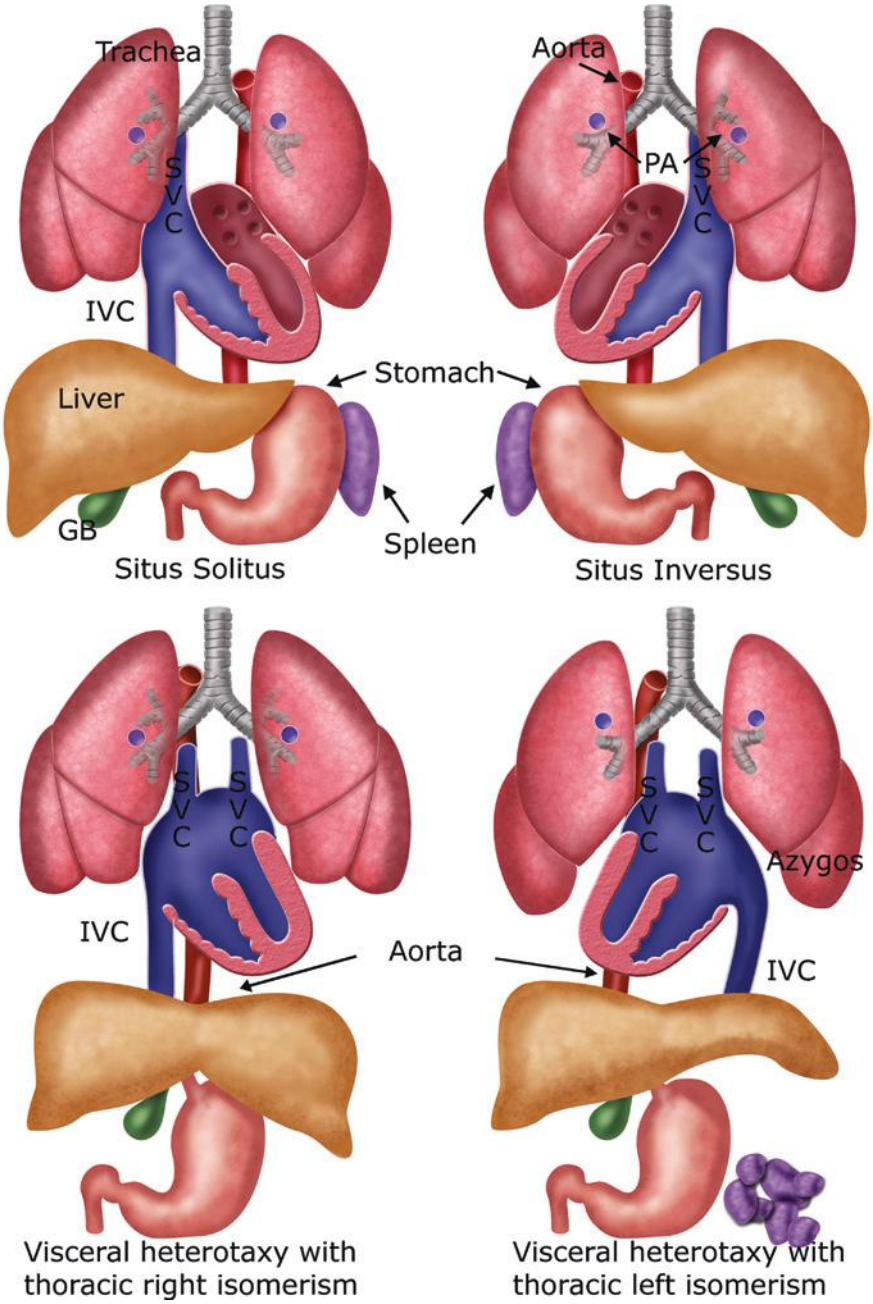

FIG 13-70 Types of visceral situs. GB, gallbladder; IVC, inferior vena cava; PA, branch pulmonary artery; SVC, superior vena cava. (Illustration by Shi-Joon Yoo, MD.)

ciliary dyskinesia (PCD), previously known as immotile cilia syndrome, is one of the most widely recognized ciliopathies and is associated with situs inversus approximately 20% of the time.[413] PCD may be caused by a variety of gene defects, but is almost always an autosomal recessive condition.[413] Studies indicate that heterotaxy can also be caused by single gene mutations, although it is most often sporadic, and there is probably extensive locus heterogeneity.[415] Autosomal dominant, autosomal recessive, and X-linked inheritance have all been shown. Some of the genes implicated in heterotaxy include *NODAL, ZIC3, CFC1, CRELD1, SHROOM3*, and *ACVR2B*.[413,415,416] As these mutations will not typically be detected on karyotype or chromosomal microarray, a heterotaxy gene panel or whole exome sequencing may be considered for patients with laterality defects.[416]

Interventions and Prognosis. Surgical therapies are widely varied for heterotaxy complex and are based on the lesions that are present. These procedures are broad and can include repair of anomalous pulmonary veins, AVCD repairs, VSD repairs, and single ventricle palliations when a biventricular repair cannot be achieved. It is not uncommon for pacemaker placement to be indicated for either sinus node dysfunction or AV block. Ablation may also be needed for SVT secondary to dual AV node physiology.

Fetal demise and stillbirth may occur in the presence of heterotaxy syndrome with reports ranging from 7% to 31%.[79,80] When fetal demise occurs it is most often in association with significant AV valve regurgitation or bradyarrhythmia, at median ages in studies ranging from 24 to 26 weeks' gestation.[80,417] Termination rates are relatively high in

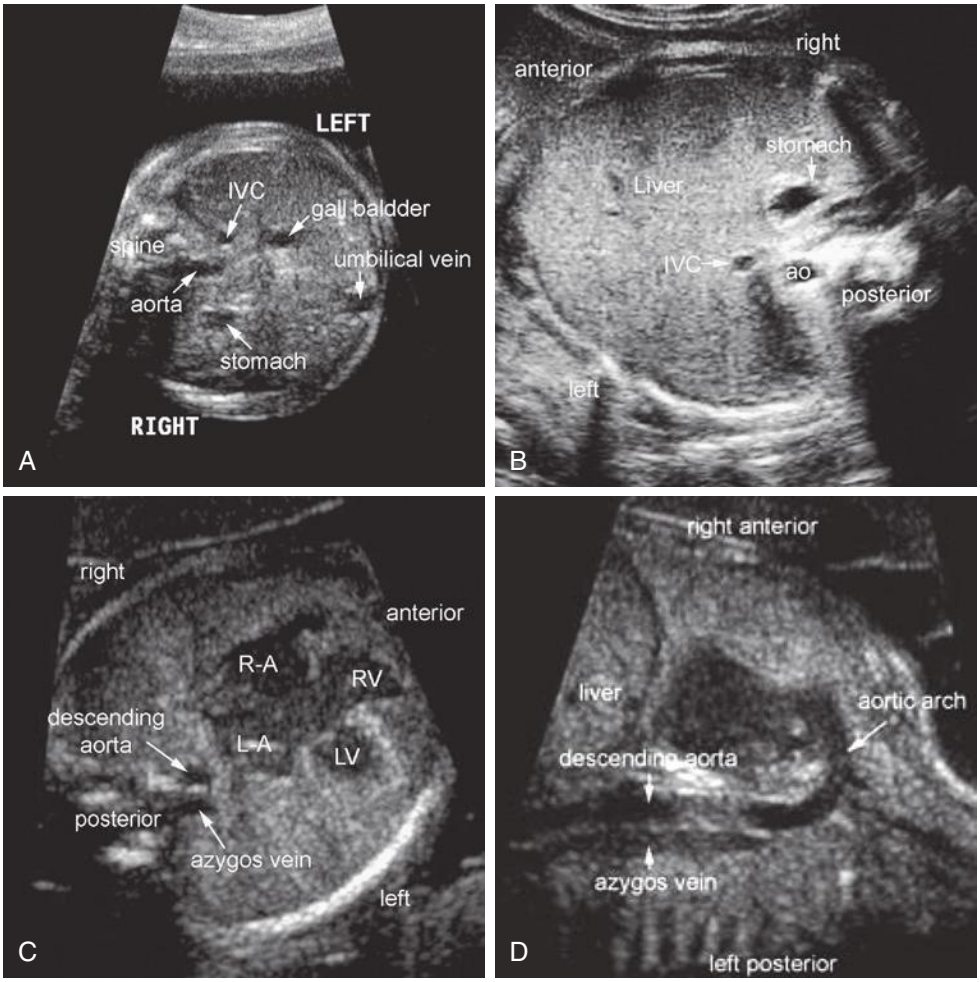

FIG 13-71 Situs abnormalities. Transverse view of the upper abdomen in situs inversus (A), and heterotaxy with asplenia/right atrial isomerism **(B)**. **A,** Situs inversus is characterized by mirror-image arrangement of the abdominal organs. **B,** The abdominal aorta is piggybacked behind the inferior vena cava (IVC) on the same side of the spine. This juxtaposed position of the IVC and abdominal aorta is seen in more than 90% of right isomerism. The liver extends from one side of the abdomen to the other. **C** and **D,** Left isomerism with interruption of the IVC. Two parallel large vessels are seen in front of the spine in both four-chamber (A) and oblique coronal (B) views. This is the characteristic feature of interrupted IVC with azygous or hemiazygous venous connection. ao, aorta; L-A, left-sided atrium; LV, left ventricle; R-A, right-sided atrium; RV, right ventricle.

published series, especially among those with single ventricle physiology, and have been reported to vary from 22% to 55%.[79,80,417]

Of those who are liveborn, the mortality rate is higher with right atrial isomerism, and death is often due to pulmonary vein stenosis and noncardiac anomalies.[79,80,418] Estimated 5-year survival rate in a recent report was 83% in left atrial isomerism and 55% in right atrial isomerism.[80]

Diagnostic Imaging Features

- Abdominal situs abnormalities may be the first sign of abnormal cardiac situs (Fig. 13-71A and B).
- The presence of an AVCD or dextrocardia should trigger a careful evaluation of systemic and pulmonary venous anatomy to evaluate for possible heterotaxy (Fig. 13-71C).
- Although both left and right ventricular hypoplasias are common in heterotaxy, they are rarely secondary to lesions such as HLHS or pulmonary atresia with intact ventricular septum. Rather, they are most frequently representative of an unbalanced AVCD.
- Look for the SVC anatomy using the 3VV or 3VT view; determine if there are bilateral SVCs or only a left SVC (Fig. 13-63C and D).
- To determine the location of IVC and hepatic venous drainage, a coronal view of the fetus is often helpful.
- Both 2D and color imaging to carefully evaluate systemic and pulmonary veins should be performed when heterotaxy is suspected (Fig. 13-71D).
- Pulmonary stenosis and atresia are commonly present in heterotaxy. In the case of severe pulmonary stenosis or pulmonary atresia there is usually a tortuous ductus arteriosus with retrograde flow.
- A right aortic arch is very common in heterotaxy and can be best diagnosed sweeping through the 3VT view to determine the relationship of the trachea and the arch. When the arch is right-sided, the duct often arises from the innominate artery and not the underside of the aortic arch.

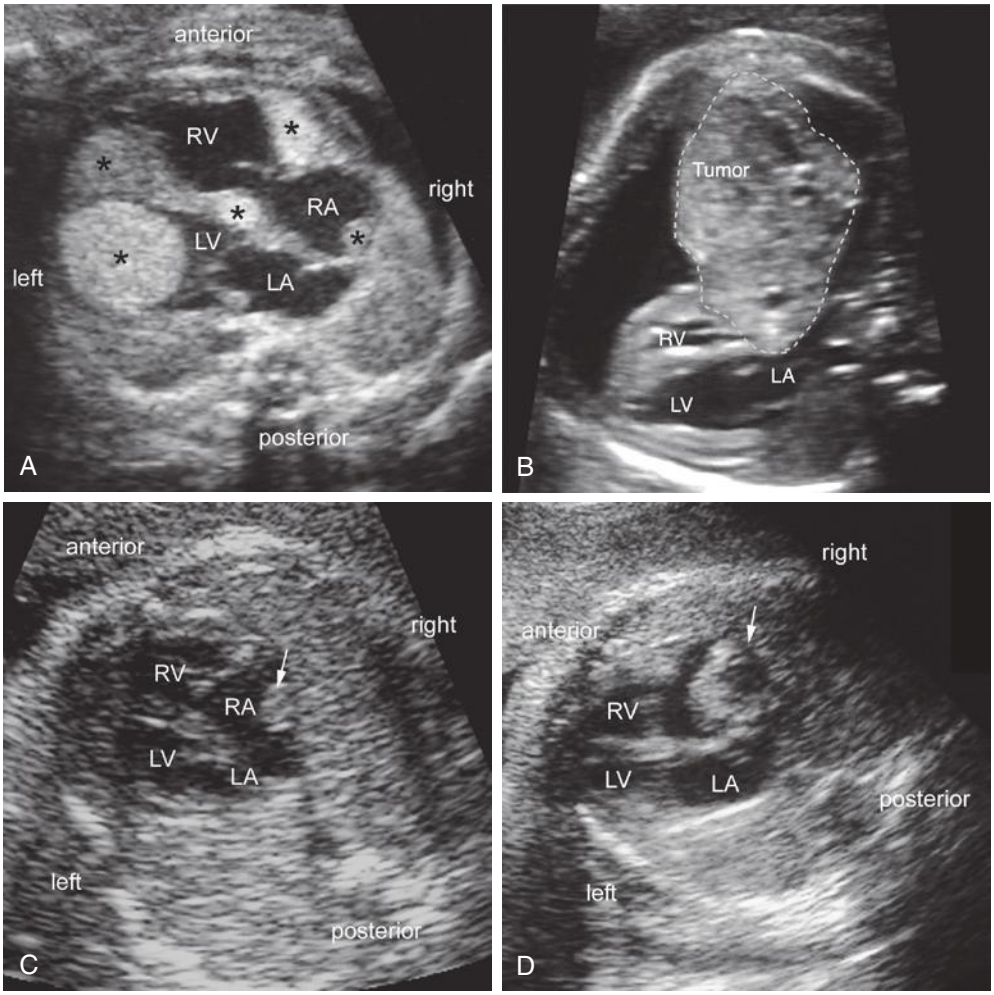

FIG 13-72 Cardiac tumors. **A,** Rhabdomyomas. Four-chamber view shows multiple tumors (*asterisks*) involving both ventricles, interventricular septum, and right atrium (RA). **B,** Hemangioma. Large pericardial teratoma in a four-chamber view. The tumor is heterogeneous and appears adherent to the RA, which is compressed. The heart is displaced leftward in the chest, and there is a large pericardial effusion taking up most of the chest. **C** and **D,** These four-chamber views show a hemangioma at 32 weeks and 35 weeks of gestation. In **C,** at 32 weeks, there is a round protruding mass (*arrow*) arising from the posterior wall of the RA. **D** shows growth of the mass and development of an echolucent cystic area. The removed mass showed histologic features of hemangioma with central hemorrhage. LA, left atrium; LV, left ventricle; RV, right ventricle.

Cardiac Masses and Tumors

General Features

Definition. A cardiac tumor is an abnormal mass or structure in the heart, myocardium, or pericardial space (Fig. 13-72). The mass may be single or multiple. Most pediatric primary cardiac tumors are benign. The natural history of a cardiac tumor is dependent upon the histologic composition and anatomic location. Fetal tumors that are large may result in hemodynamic obstruction of normal intracardiac flow patterns and hemodynamic compromise. Large tumors may present with myocardial dysfunction and hydrops fetalis. Fetal arrhythmias, such as atrial tachycardia, ventricular tachycardia, and bradycardia, may be the presenting findings of a fetal cardiac tumor. Fetal cardiac tumors have been noted in fetal demise cases.[419]

Epidemiology. An autopsy series in children reported an incidence of fetal cardiac tumors of 0.027% to 0.08%.[420] A large multicenter study evaluated 14,000 fetal echoes to document the frequency of fetal cardiac tumors, which were present in 19 pregnancies, or approximately 0.14%. Single tumors were found in 10 fetuses and multiple tumors in 9. Tumor size ranged from 0.4×0.4 cm to 3.5×4 cm. There were 17 rhabdomyomas, 1 fibroma, and 1 atrial hemagioma. Tuberous sclerosis complex (TSC) was diagnosed in 10 of the 17 (54%) fetuses with rhabdomyomas. Rhabdomyomas in 8 patients had partial or complete regression in size and in 5 fetuses there was no change. Three had cardiac hemodynamic obstruction and required tumor resection after birth.[421] The most common reason for a fetal echocardiogram was cardiac mass on routine obstetric ultrasound.

A study evaluating 224 patients (89 fetuses and 135 neonates) with cardiac tumors reported that rhabdomyoma was the most common, followed by teratoma, fibromas, and hemangiomas. In this study, rhabdomyoma accounted for 64% of the fetal tumors detected, teratoma accounted for 23%, fibroma approximately 6% to 7%, and vascular tumors such as hemangioma approximately 6% to 7%.[419] Toronto investigators reported on a series of 40 fetuses with cardiac tumors.[422] Hydrops fetalis was seen in 18%, ventricular obstruction in 30%, arrhythmias in 13%, and ventricular dysfunction in 5%. Rhabdomyomas were seen in 33 fetuses; 3 had elective termination. Four fetuses with rhabdomyomas died at birth. TSC was found in 88% of

the 26 fetuses with rhabdomyomas who survived. Three intrapericardial teratomas were found with pericardial effusions, and all had a fetal demise.[422]

A cardiac tumor may be the initial presentation of a genetic disorder such as tuberous sclerosis, neurofibromatosis, familial myxoma syndrome (cardiac myxoma, skin and mucous membrane lesions, and endocrine gland lesions in pituitary, adrenal gland, and testis), Gorlin syndrome (basal cell nevoid carcinoma syndrome), and rarely Beckwith-Wiedemann syndrome (macroglossia, macrosomia, and omphalocele).[419]

Anatomy

Rhabdomyoma. Rhabdomyomas are the most frequently detected fetal cardiac tumor (Fig. 13-72 and Video 13-24). Rhabdomyomas are found within the ventricular wall and septum in the subepicardial region and within the atria. Rhabdomyomas are frequently multiple, well-circumscribed, nonencapsulated white or gray-white intramural or intracavitary nodules. On fetal echo, rhabdomyomas appear as rounded, homogeneous, and hyperechogenic masses. Less often, rhabdomyomas are single lesions.[419] When large, these intramural tumors may encroach on the intracavitary ventricular space or the outflow tract. The large tumors can also impinge upon the function of the AV and semilunar valves.

Rhabdomyomas have a biphasic growth pattern in the fetus. The tumor size typically increases between 20 and 32 weeks' gestation and subsequently either begins to regress or remains the same size in the fetus. During the first year of life, rhabdomyomas exhibit partial to complete regression in approximately 50% of cases.[421]

Multiple large rhabdomyomas may result in primary myocardial dysfunction. Depending on location, large tumors can also severely compromise blood flow in the outflow tracts and lead to hydrops fetalis. Fetal arrhythmias can be associated with rhabdomyomas and include atrial ectopy, SVT, bradycardia, and ventricular tachycardia, any of which can also precipitate hydrops fetalis and potentially in utero fetal demise. Tumor size 20 mm or larger and fetal arrhythmia are associated with poor fetal and neonatal outcomes.[421-428]

Rhabdomyomas are generally not associated with CHD, although there are sporadic case reports of rhabdomyomas seen with endocardial fibroelastosis, TOF, Ebstein anomaly, hypoplastic tricuspid valve, and HLHS.[421,429,430]

Fibroma. Fibromas are the second most common pediatric intracardiac tumor, but they are much less frequently seen in the fetus.[421] Fibromas are predominantly single, white, nonencapsulated intramural tumors located in the free wall, apex or IVS of the LV. Less frequently, fibromas can be in the right ventricular free wall, atrial septum, or atrial free wall. These lesions may demonstrate calcifications and cystic degeneration, which assist in differentiating them from a single rhabdomyoma, which is more homogeneous in character. Fibromas have been noted to increase in size prenatally and typically do not regress.[431] Again, this feature can help differentiate these lesions from rhabdomyomas.

Intrapericardial Teratoma. Intrapericardial teratomas are rare tumors that often present in the fetus with a large pericardial effusion (Fig. 13-72B and Video 13-25), and detection of a large pericardial effusion should lead to investigation for an intrapericardial teratoma. These lesions are single, encapsulated, bosselated tumors containing multiple cysts and attached at the base of the heart either by a broad-based stalk or pedicle to the aortic root and wedged between the SVC and the base of the aorta. The tumor most frequently is right-sided, arising from the aorta, and infrequently arises from the pulmonary artery. Intrapericardial teratomas can be three to four times the size of the fetal or newborn heart, and the solid tumor mass is contained within the restrictive fibrous pericardium. The large mass has a propensity to obstruct and compress the heart. The development of a pericardial effusion may be related to obstructed or impaired lymphatics and SVC venous obstruction. These lesions are associated with fetal demise and a high mortality rate.

Cardiac Hemangiomas. Cardiac hemangiomas are single, highly vascular tumors, which may be epicardial, intramural, or intracavitary (Fig. 13-72C and D). They may be polypoid or sessile with central areas of necrosis and calcification.[432] Hemagioendotheliomas are commonly located in the RA with vascular flow from the coronary arteries.

Myxoma. Myxomas are rare fetal cardiac tumors and form exophytic intracavitary masses in the endocardium. A left atrial origin via a pedicle or a broad base off the fossa ovalis is seen in 75% of myxomas. Single right atrial tumors account for approximately 25% of myxomas. Rarely, myxomas originate in the ventricle, from valves or valve chordae. Calcification and cystic regions can develop. They are friable tumors with regions of thrombosis, which may result in peripheral emboli. Myxoma is the most common tumor in adults but is uncommon in the pediatric and prenatal populations.[431]

Genetic Considerations. Cardiac rhabdomyomas are associated with TSC. Fetal studies report that between 59% and 79% of fetuses with cardiac rhabdomyomas have TSC.[421,433-435] Mutations of the *TSC1* and *TSC2* genes cause TSC, and this disorder can be diagnosed in many cases by DNA analysis of *TSC1* (hamartin gene on chromosome 9q34) and *TSC2* (tuberin gene on chromosome 16p13.3). Both of these genes are tumor suppressor genes.[436] The clinical manifestations of TSC include mental retardation, seizures, and tumor-like malformations in the brain, kidney, retina, pancreas, and skin. TSC has an autosomal dominant mode of inheritance, although approximately 50% of TSC cases occur because of spontaneous mutations with no family history.[432]

Approximately 7% of myxomas are familial. Cardiac myxomas are seen in the pediatric age group as part of multiple lentigines syndrome and may be associated with non-neoplastic endocrine disorders.[432]

Outcomes. Some large *rhabdomyomas* may obstruct tricuspid valve inflow or cause RVOT obstruction and present with cyanosis due to right-to-left shunting at the atrial level. LVOT obstruction can be severe and cause low cardiac output symptoms and right-to-left shunting at the PDA. Severe RVOT or LVOT obstruction may be ductus-dependent at birth and require surgical resection. Rhabdomyomas 20 mm or greater and fetal arrhythmias increase the risk for hydops fetalis and in utero demise and are associated with poorer outcomes.

Depending on size, a *fibroma* may encroach upon the intracavitary space, obstruct the LVOT or RVOT, and present with symptoms of low cardiac output when obstructing the LVOT and cyanosis with significant RVOT obstruction. In severe outflow tract obstruction, surgical resection is necessary. Ventricular tachycardia is an arrhythmia associated with fibromas and may be the cause for sudden death in fibroma patients.[427] Prenatal diagnosis of an *intrapericardial teratoma* can allow for fetal intervention with pericardial fluid drainage or tumor resection. With prenatal pericardial fluid drainage, reaccumulation is typical. Delivery at a tertiary medical center with planned neonatal intrapericardial tumor resection allows for an excellent outcome because these tumors are seldom malignant or recurrent. Thus, surgical resection is considered curative with an excellent long-term outcome.[437-441] Large *hemangiomas* in the RA have been associated with hydrops fetalis and fetal demise.[442,443] *Myxoma* is rare, but prenatal diagnosis has been reported, and this condition has also been reported in a stillbirth.[444]

Diagnostic Imaging Features

Rhabdomyoma

- Multiple rounded, homogeneous, hyperechoic lesions are seen in the ventricular, septal, and atrial myocardium; rarely is rhabdomyoma a single tumor.

- Associated arrhythmias include both tachycardia and bradycardia.

Fibroma

- This single, often large intramural tumor may be found in the free wall, apex, or septum of the LV.
- It is nonhomogeneous due to regions of calcification and cystic degeneration.
- Fibroma is associated with ventricular tachycardia.

Intrapericardial Teratoma

- This tumor is a large single, nonhomogeneous, lobular mass arising from the base of the heart.
- Echolucent cystic regions and calcifications are echogenic foci.
- Attachments to the base of the aorta or less frequently the pulmonary artery are seen.
- It is associated with large pericardial effusions.

Cardiac Hemangioma

- This nonhomogeneous hemangioma may include calcifications or regions of cystic necrosis.
- It is highly vascular, with vascular flow often from coronary arteries.
- The cardiac hemangioma is frequently found in the RA; large tumors in the RA can obstruct the tricuspid valve.

Myxoma

- Myomas are nonhomogeneous and friable.
- A single LA > RA tumor is attached to the fossa ovalis by a broad base or pedicle.
- It can be mobile and cross to and from either atrium.
- In diastole, it protrudes across the AV valve. In systole, it moves into the atria.

Ectopia Cordis/Pentalogy of Cantrell

Definition. Ectopia cordis is a form of a pericardial defect and is marked by displacement of the heart outside the thorax (Fig. 13-73 and Video 13-26). There can be partial or complete displacement of the heart, and this condition is further classified by the location of the heart: cervical (3%), thoracic (60%), thoracoabdominal (7%), or abdominal (30%).[410,445,446] Pentalogy of Cantrell consists of an anterior diaphragmatic deficiency, midline abdominal wall defect, a diaphragmatic pericardial defect, and a lower sternal defect.[447]

Epidemiology. Ectopia cordis accounts for less than 0.1% of all congenital heart defects. The failure of the fetal embryonic sternum to fuse inferiorly results in a sternal cleft, which allows the heart to protrude outside the thorax. The incidence ranges from 5.5 to 7.9 per 1 million live births.[448] However, the true incidence may be higher, but unknown because of in utero demise. Ectopia cordis is a complex field defect, which involves a deficiency in the sternum, the diaphragm, and the anterior body wall. The development of the sternum begins during the 6th week of gestation when a pair of parallel mesenchymal bands of condensed mesenchyme migrate medially from two lateral plates on either side of the anterior chest wall. Fusion of the midline sternum occurs in a ventrolateral and craniocaudal fashion by the 10th week of gestation.[445,449]

Anatomy. Regardless of the subtype, coincident CHD is common in the setting of ectopia cordis, and outcomes are almost universally poor.[448,450,451] Although various cardiac structural defects have been reported, conotruncal abnormalities such as DORV and TOF predominate.[448,451] Coincident abdominal wall defects should prompt careful inspection of the position of the heart.

Most often, pentalogy of Cantrell presents in an incomplete form, with one or more of the previously mentioned diagnoses absent. Associated intracardiac defects are common, and various defects have been reported, including ASD, VSD, TOF, and Ebstein anomaly.[452] Demise is common in pentalogy of Cantrell, and the mortality rate is higher in complete forms and in cases with coincident extracardiac anomalies.[453]

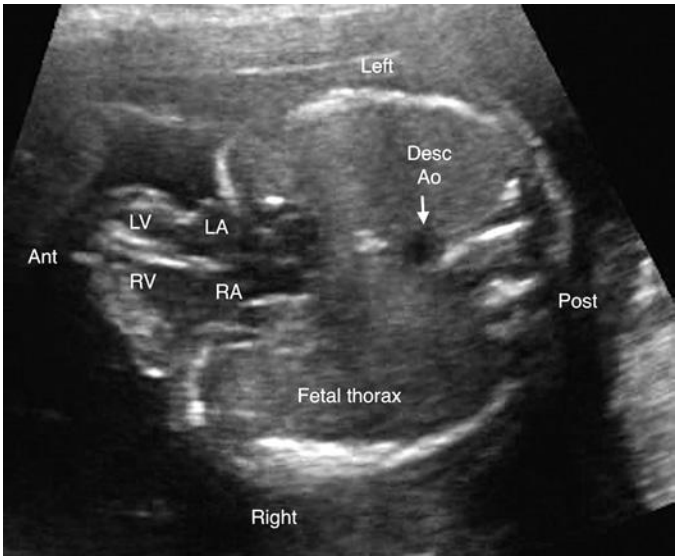

FIG 13-73 Ectopia cordis. This transverse view of the chest shows the heart protruding out of the thorax through a sternal cleft. The ribs are impinging on the atria, and the ventricles are outside the chest. Ant, anterior; Desc Ao, descending aorta; LA, left atrium; LV, left ventricle; Post, posterior; RA, right atrium; RV, right ventricle.

Ectopia cordis is commonly associated with other anomalies, including a variety of intracardiac defects and midline body wall defects. Pentalogy of Cantrell was originally described as five associated anomalies, including a midline supraumbilical abdominal wall defect, a cleft in the inferior sternum, a deficiency of the anterior diaphragm, a pericardial diaphragmatic defect, and an intracardiac malformation. The hallmark of this syndrome is an omphalocele associated with ectopia cordis. Cantrell's series of ectopia cordis reported the following intracardiac defects: VSD (100%), ASD (53%), TOF (20%), and ventricular diverticulum (20%).[447] Other conotruncal anomalies such as DORV, pulmonary stenosis/atresia, aortic valve stenosis, TGA, and truncus arteriosus have been reported, as have many other cardiac defects. A small thorax can occur with ectopia cordis and be associated with lung hypoplasia and pulmonary artery hypoplasia, which has a very poor outcome. This disorder often presents as an incomplete form of pentalogy of Cantrell and exhibits a wide spectrum of other congenital anomalies, including omphalocele, diastasis recti, gastroschisis, craniofacial defects (such as cleft lip and palate), neural tube defects (such as encephalocele, hydrocephalus, and craniorachischisis), and skeletal anomalies[448,453-455]

In thoracic ectopia cordis, the heart either partially or completely protrudes through the sternal cleft with the apex of the ventricles pointing cephalad. In thoracoabdominal ectopia cordis, there is a partial absence or a cleft in the inferior sternum, a midline anterior diaphragmatic defect, and a defect in the diaphragmatic pericardium, which allows the ventricular portion of the heart to enter the epigastrium. The heart may also protrude ventrally into an omphalocele or supraumbilical abdominal wall defect such as a gastroschisis. Often the heart appears to be sitting on top of the liver. Cervical ectopia cordis is very rare and is seen with either an intact sternum or partial cleft in the superior sternum. Abdominal ectopia cordis results from an anterior pericardial defect and diaphragmatic hernia, with the heart positioned in the abdomen.

Genetic Considerations. Familial cases have been reported, and some suggest a possible X-linked inheritance.[456] Trisomy 21, trisomy

18, trisomy 13, and Turner syndrome have also been reported with ectopia cordis, although the majority of ectopia cordis patients have a normal karyotype.[457] Ectopia cordis has been associated with maternal teratogens and viral infections and has been induced in animal models.[458,459]

Outcomes. In utero and postnatal demise is common in the setting of ectopia cordis, although survival following repair of the thoracic defect has been reported.[448,451,460,461]

Interventions and Prognosis. Treatment strategy for ectopia cordis consists of corrective or palliative cardiovascular surgery, correction of the ventral hernia diaphragmatic defects, and correction of associated anomalies. The overall outcome is dependent upon the size of the abdominal wall defect, the associated intracardiac abnormality, and the location of the ectopia cordis. A multistage repair is recommended, with the initial stage used to cover the heart with skin. Untreated, death occurs as a result of desiccation, trauma, or kinking of the heart and vessels, in addition to hypoxemia, sepsis, and arrhythmias. High morbidity and mortality rates are associated with attempted repair of pentalogy of Cantrell. Overall, surgical repair carries a survival rate of 40% to 50% and often is associated with prolonged ventilatory support and poor quality long-term outcomes.[453,462] Management is multidisciplinary, involving neonatology, congenital heart surgery, pediatric surgery, plastic surgery, obstetrics, and pediatric cardiology. If attempted repair is planned, delivery should be cesarean and neonatal resuscitation is required along with sterile coverage of the heart. Temporary coverage of the heart and abdominal defects is followed by repair of the diaphragmatic hernia and palliative or complete repair of the cardiac defect. The intracardiac repairs are based on the type of cardiac lesion. A multistaged approach has been the most successful. The best outcomes are related to ectopia cordis with no associated intracardiac defect. However, there are case reports of single ventricles undergoing successful repair and repair of ectopia cordis in staged surgeries.[448,463-466]

Cervical ectopia cordis has an extremely poor prognosis due to kinking of the great arteries and cardiac constriction, which occurs with attempts to reposition the heart. Abdominal ectopia cordis involves migration of the heart into the upper abdomen, and the outcomes are dependent upon the intracardiac anomalies, size of thorax, and degree of pulmonary hypoplasia.

Diagnostic Imaging Features

- Location of the heart must be carefully evaluated, as it may be partially or completely outside of the thorax (see Fig. 13-73).
- Cardiac anatomy should be carefully assessed, as VSDs and other associated anomalies are common.
- The degree of thoracic and pulmonary hypoplasia should be assessed.
- A careful evaluation for extracardiac anomalies is warranted, as they are common and significantly affect prognosis.

Fetal Cardiac Arrhythmias

General Features. The cardiac conduction systemic consists of highly specialized tissue that rhythmically generates electrical signals from the sinoatrial node. This electrical signal is propagated through the atria to the AV node and into the His-Purkinje system in the ventricles. Synchronized depolarization and repolarization of the atrial and ventricular myocardial tissues corresponds to the rhythmic contraction and relaxation of the cardiac chambers, which allows synchronized filling and emptying. Derangements in the normal rhythm sequence of contraction or an abnormal rate result in abnormal filling and emptying. Therefore, persistent tachycardia or bradycardia result in myocardial dysfunction, low cardiac output, and congestive heart failure. In the fetus, congestive heart failure typically manifests as hydrops fetalis.

Fetal arrhythmias are detected in 1% to 2% of pregnancies and are a common obstetric reason for a referral for fetal echocardiogram. The normal FHR ranges between 120 and 180 bpm with limited beat-to-beat variability. Fetal bradycardia is defined as FHR less than 100 bpm and fetal tachycardia as FHR greater than 180 bpm. An irregular rhythm is frequently due to atrial premature beats and infrequently due to ventricular extrasystoles. In the fetus, atrial ectopy is often encountered and ventricular ectopy is uncommon.

Echocardiographic Assessment of the Fetal Cardiac Rhythm. Arrhythmias are traditionally diagnosed by electrocardiography, which measures the rate and morphologic and chronologic features of the atrial and ventricular electrical events. This assessment is challenging in the fetus because there is no conventional electrocardiography for the fetus. Current research tools use fetal magnetocardiography and fetal electrocardiography, but these tools are available at only a few centers.[467-469] Echocardiography is therefore used to measure the fetal chronology and temporal relationship of the atrial and ventricular myocardial sequence of contractions. For reference, normal Doppler signals of various cardiovascular structures are pictured in Figure 13-74. The fetal rhythm is determined by timing the atrial and ventricular mechanical contractions, which occur after depolarization. Both M-mode and Doppler imaging can be used to time the atrial and ventricular rates and the relationship of mechanical chamber contractions.

From the four-chamber view, positioning the M-mode beam through an atrial free wall and the opposite ventricular free wall near the AV groove, is preferred because these regions exhibit the greatest lateral excursion during the cardiac cycle (Fig. 13-75). An alternative view, placing the M-mode curser across an atrial wall and the aortic valve in cross section, also allows timing of atrial systole and ventricular systolic ejection. By M-mode, the atrial contraction is the inward motion of the atrial wall, whereas the aortic valve opening represents the ventricular systolic ejection period. Mechanical events are not precisely recorded by M-mode measurements; rather, a more precise timing of cardiac events is defined using spectral Doppler sonography. The SVC and aorta are anatomically adjacent to each other, allowing a wide spectral Doppler sample volume to be positioned within both the aorta and the SVC. In the SVC, there is a larger S wave followed by a D wave directed toward the heart during ventricular systole (S) and in early diastole (D), and with atrial systole there is a brief retrograde a wave (A) that occurs following atrial depolarization and correlates with the P wave. The aortic ejection occurs after ventricular depolarization, which correlates with the QRS complex. The onset of the a wave to the onset of ventricular systole (onset of aortic flow) or AV interval correlates with the electrical PR interval and can be measured in the fetus. Doppler sonography can also be used to measure the timing of pulmonary vein and artery flow; with atrial systole there is a brief cessation of pulmonary venous flow, whereas pulmonary artery flow represents ventricular systole. These features again represent the AV duration and correlate to the PR interval.[470]

In normal sinus rhythm, the FHR most often ranges between 120 and 160 bpm and there is a 1:1 relationship between an atrial contraction followed by a ventricular contraction. The AV chronology and AV conduction ratio are also determined when evaluating the fetal cardiac rhythm. Analysis of the regularity of the atrial to atrial events and ventricular to ventricular events is important along with the relationship of the atrial and ventricular events.

Irregular Fetal Rhythm. The most common reason for an irregular fetal cardiac rhythm is premature atrial contractions (PACs), which

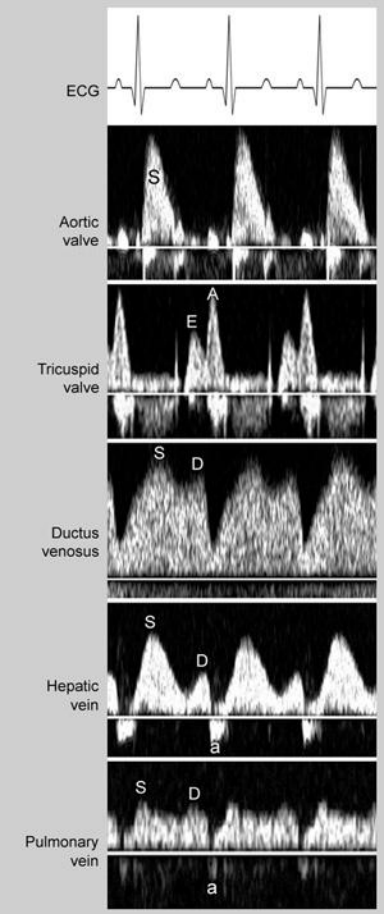

FIG 13-74 Normal fetal cardiovascular Doppler tracings and correlation with an electrocardiogram (ECG). The aortic valve (and pulmonary valve) Doppler waveforms show a systolic ejection pattern, with no significant flow in diastole. The tricuspid valve (and mitral valve) waveforms are diastolic and biphasic: the shorter peak (E) occurs in early diastole, and the second peak (A) occurs with atrial contraction. For normal atrioventricular valves, there is no flow in systole. In the case of significant atrioventricular valve regurgitation, Doppler interrogation demonstrates a long, high-velocity systolic waveform (Fig. 13-6). The ductus venosus, hepatic veins, and pulmonary veins have a venous waveform, with systolic (S) and diastolic (D) waves. The normal hepatic vein and pulmonary vein Doppler waveforms may also have short a-wave reversal. A-wave reversal in the ductus venosus, however, is a sign of fetal heart failure.

occur in 1% to 3% of pregnancies. An atrial cell that electrically fires prior to the sinoatrial node results in a premature atrial beat or contraction. The PAC is either conducted to the ventricle or may be blocked, with no ventricular contraction (Fig. 13-76). With a blocked PAC, there is an increased V-V interval and a pause in the rhythm as the sinus node resets. Blocked atrial PAC followed by a sinus beat results in atrial bigeminy, with every other beat alternating between a sinoatrial beat and a blocked PAC, and two atrial events for each ventricular event. There is a short A-A interval between the sinus atrial beat and the blocked PAC, followed by a longer A-A interval between the blocked PAC and next sinoatrial beat. This short A-A interval followed by a longer A-A interval results in a consistent and repetitive pattern in persistent blocked atrial bigeminy and is characterized by a ventricular rate that ranges between 70 and 100 bpm but is never less than 65 bpm.[471] Approximately 10% to 14% of fetuses with blocked

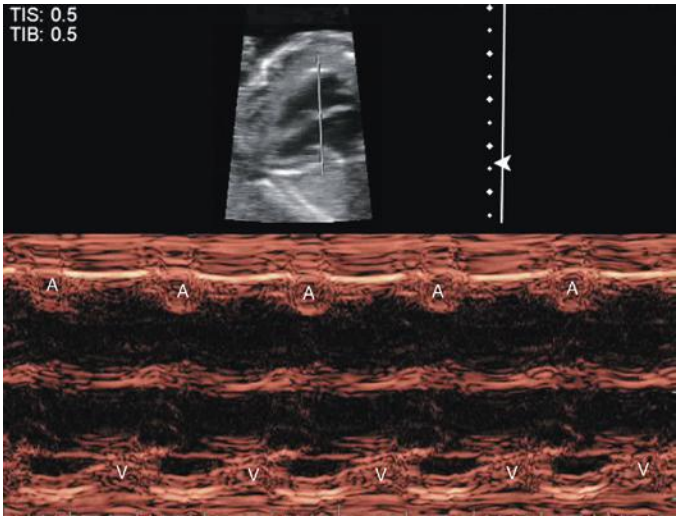

FIG 13-75 Normal M-mode tracing for cardiac rhythm assessment using a four-chamber view. The M-mode beam is directed through the atrial and ventricular wall, and timing of contractions is observed. In normal sinus rhythm, every atrial contraction (A) is followed by one ventricular contraction (V).

atrial bigeminy develop SVT later in the pregnancy or after delivery, but most cases spontaneously resolve.

Frequent atrial couplets, two conducted PACs in a row, or frequent PACs present a risk for the development of SVT and should be monitored every 1 to 2 weeks. Atrial ectopy can be seen with intracardiac rhabdomyomas and with very redundant, aneurysmal atrial septum.

Premature ventricular beats or contractions are uncommon in the fetus and are most often benign. They can be seen in fetuses with rhabdomyomas and ventricular fibromas. Fetal premature ventricular contractions have also been associated with myocarditis in the fetal heart and with long QT syndrome.

Fetal Bradycardia. Fetal bradycardia is defined as an FHR of 110 bpm or less. FHRs in the 100 to 110 bpm range remain hemodynamically stable and there is no progressive cardiac dysfunction.
