Acute appendicitis is one of the most common nongynecologic causes of acute pelvic pain and the most common gastrointestinal cause of right lower quadrant pain. Classically, patients present with initial periumbilical pain that migrates to the right lower quadrant, rebound tenderness, nausea, vomiting, and leukocytosis. In the adult patient,

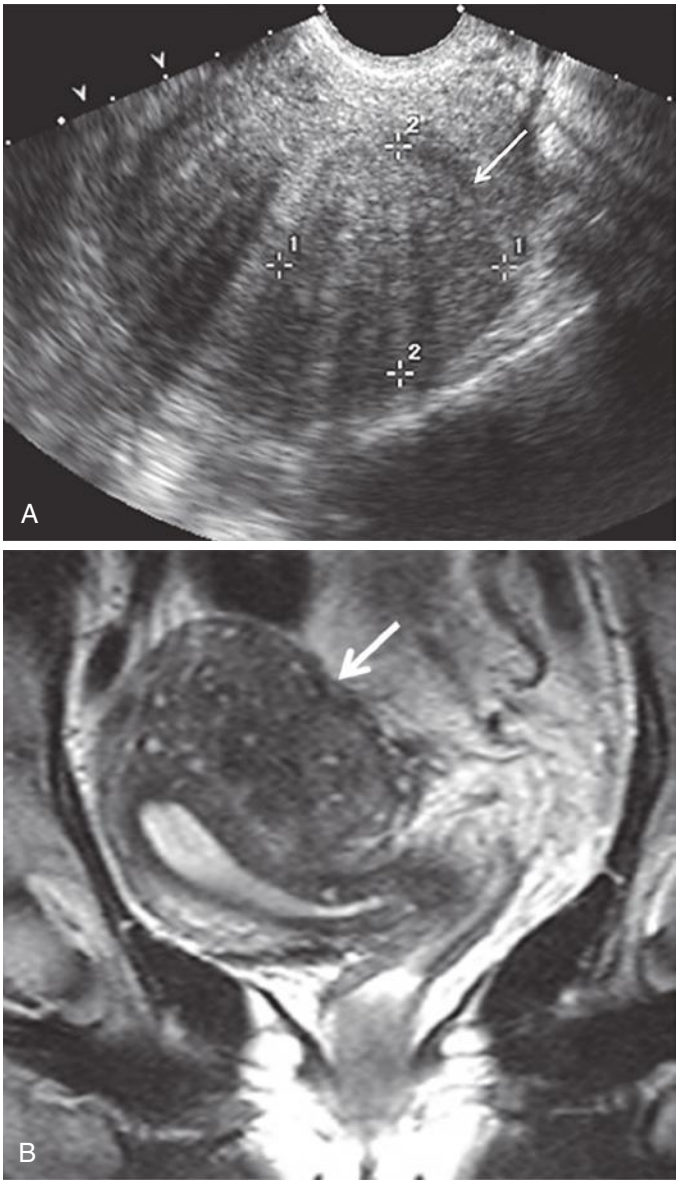

FIG 29-40 Focal adenomyosis mimicking leiomyoma. **A,** Transvaginal sonogram suggests an ill-defined hypoechoic lesion in the posterior myometrium (*arrow* and *calipers*) without associated mass effect. Note "comb-like" shadowing posterior to this area as well as in the adjacent myometrium, which can be seen with adenomyosis as well as leiomyomas. **B,** Sagittal T2-weighted magnetic resonance image reveals focal adenomyosis (*arrow*) posteriorly. No myoma present.

CT is generally the gold standard for diagnosis and receives the highest ACR Appropriateness Criteria score for evaluation of suspected appendicitis.[221] In a meta-analysis of six prospective studies performed through 2006, CT demonstrated superior sensitivity (91%; 95% confidence interval [CI], 84-95%) and specificity (90%; 95% CI, 85-94%) compared to ultrasound imaging (sensitivity 78%; 95% CI, 67-86%; specificity 83%; 95% CI, 76-88%).[222] A significant decrease in negative appendectomy rates has been shown in reproductive age women who undergo preoperative CT.[223] However, in children, young women, and pregnant women, sonography is often the initial recommended imaging modality in order to reduce radiation exposure. If ultrasound imaging is inconclusive in the nonpregnant patient, CT will generally then be performed; in the pregnant patient, MRI is the next test of choice. A meta-analysis of five case series evaluating MRI for diagnosis of suspected appendicitis in the pregnant patient yielded a sensitivity of 90.5%, specificity of 98.6%, PPV of 90.4%, and NPV of 99.5%[224] (Fig. 29-44).

At ultrasound examination, the inflamed appendix is best visualized using a high-frequency linear array transducer, typically 7 to 13 MHz, utilizing a graded compression technique at the point of maximal tenderness. The left lateral decubitus position may help visualize a retrocecal appendix. The inflamed appendix appears as a distended, noncompressible, nonperistalsing blind-ending tubular structure with outer wall to outer wall diameter greater than 6 mm[225] (Fig. 29-45). A diameter greater than 6 mm has a reported sensitivity, specificity, NPV, and PPV of 98% for acute appendicitis.[226] If 7 mm is used as the upper limit of normal, there is increased specificity but slightly decreased sensitivity.[218] On cross section, the classic target sign with concentric rings, the multilayered "gut" signature, will be observed. Appendicoliths appear as round, intraluminal echogenic shadowing foci. Mural hyperemia is variable but can be a useful secondary sign. Increased echogenicity and vascularity in the surrounding mesoappendiceal fat suggest inflammation. A periappendiceal abscess will appear as a focal fluid collection and may indicate associated perforation.

The inflamed appendix may occasionally be visualized during a transvaginal pelvic sonogram[227] (Fig. 29-46). Imaging features are similar to those observed on transabdominal scanning, although compression maneuvers cannot be performed. The inflamed appendix must be differentiated from an inflamed fallopian tube, which may at times pose a challenge. However, the appendix will be a blind-ending structure with multilayered gut signature composed of echogenic submucosa and hypoechoic muscularis layers. The inflamed fallopian tube will not be blind-ending and will demonstrate thickened endosalpingeal folds ("cogwheel" morphologic appearance), incomplete septations, and serpentine shape (see Fig. 29-18).

A mucocele of the appendix is an extremely rare condition and refers to dilatation of the appendix with abnormal intraluminal accumulation of mucus.[228,229] There are several subtypes including retention (simple) mucocele, obstruction of the appendix by a benign process such as an endometriotic implant, or other process associated with fibrosis and retention of mucin. Increased mucin production is more commonly due to mucosal hyperplasia than either benign or malignant appendiceal neoplasms (mucinous cystadenomas, adenocarcinomas, or carcinoid tumors). Preoperative diagnosis is essential to prevent rupture and spillage of the contents, which may result in pseudomyxoma peritonei.

A mucocele may be identified sonographically as a blind-ending tubular or oblong structure that is fluid-filled[230,231] (Fig. 29-47). The echogenicity is variable. The onion skin sign has been described, representing layering of the mucin-forming concentric rings.[232] Mural calcification may occasionally be observed. A mucocele could potentially be confused with a dilated fallopian tube or a cystic adnexal mass. Cross-sectional imaging with CT or MRI may be helpful by demonstrating the origin of the mass from the cecum and absence of a normal appendix (Fig. 29-47B). The clinical setting often differs from acute appendicitis with more chronic symptoms of pelvic pain and possibly a palpable mass. However, occasionally a mucocele may become acutely inflamed and present with features similar to acute appendicitis. A greater degree of cystic dilatation of the appendix and mural calcifications may suggest the diagnosis.[233]

Acute Diverticulitis

Diverticulosis results from either acquired herniations of the submucosa and mucosa into the muscular layer (pseudodiverticula) of the bowel wall or true diverticula containing all bowel layers, which are usually congenital. The incidence of diverticulosis increases with

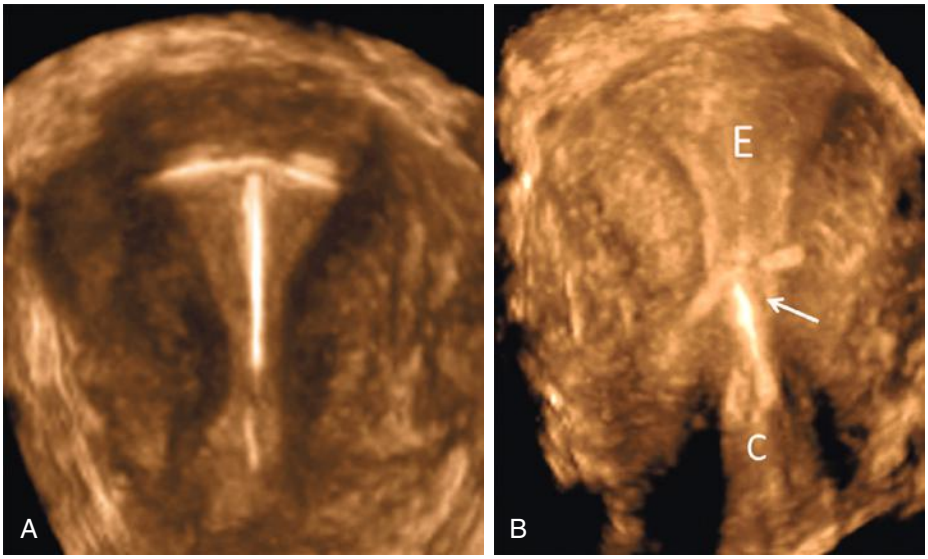

FIG 29-41 Intrauterine device (IUD) evaluation with three-dimensional (3D) sonography. **A,** The 3D coronal view demonstrates appropriately positioned, intact Copper T IUD within the endometrial cavity. **B,** 3D coronal view demonstrates malpositioned Copper T IUD (*arrow*) located abnormally low in the uterus with side arms embedded in the myometrium. C, cervical canal; E, endometrial canal.

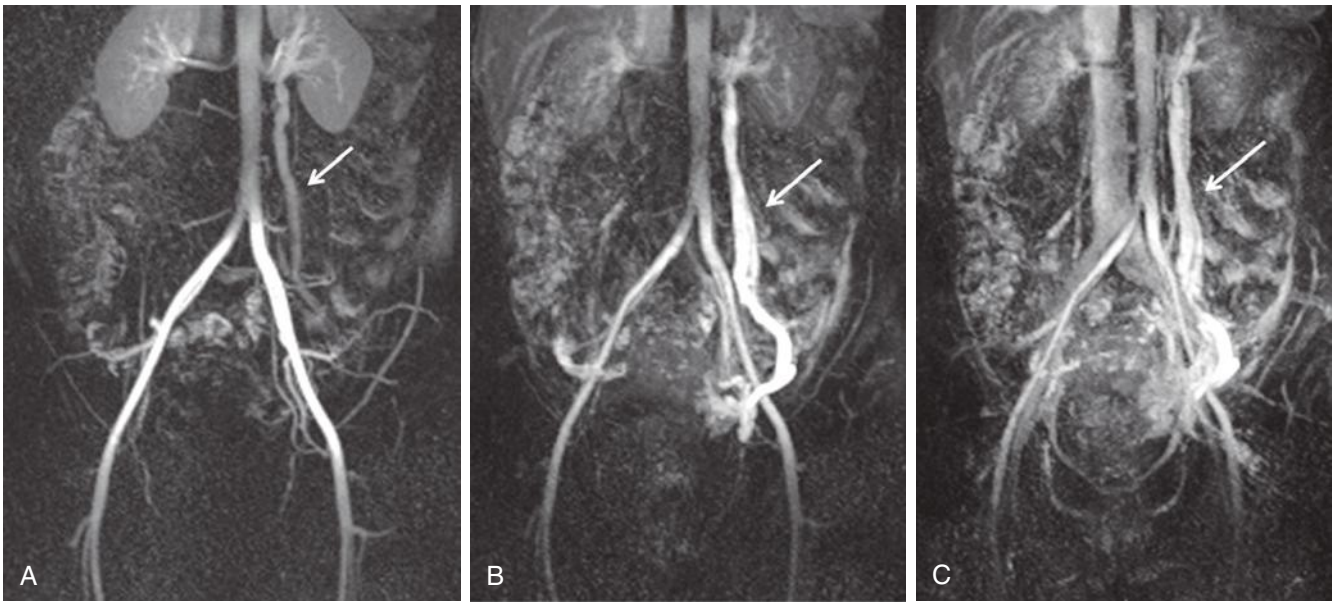

FIG 29-42 Pelvic congestion syndrome: time-resolved magnetic resonance venography. **A** through **C,** Sequential images demonstrate reflux of contrast agent into the left gonadal vein (*arrow*), which is distended, with associated prominent pelvic varicosities.

advancing age, and it is estimated that diverticulosis is present in 60% of patients older than 80 years.[234] Diverticulitis occurs in 10% to 20% of patients with diverticulosis when a diverticulum becomes obstructed, leading to focal inflammation, diverticular distention, localized ischemia, and ultimately perforation.[235,236] Acute diverticulitis most commonly affects the sigmoid colon. Patients typically present with left lower quadrant pain, fever, and leukocytosis. However, the clinical presentation of acute diverticulitis may mimic that of various pelvic disorders, in particular PID. CT is generally the imaging modality of choice for suspected diverticulitis as it not only establishes the diagnosis but can also reliably identify associated complications such as perforation, abscess and fistula formation, and bowel obstruction.[237] However, acute diverticulitis may also be reliably diagnosed at sonography with comparable accuracy to CT, and sonography is advocated by some as an alternate first-line imaging modality.[238,239]

To evaluate for diverticulitis, the ultrasound examination is generally performed with a 3.5- to 5.0-MHz probe, which can be supplemented with a high-frequency linear 5- to 12-MHz transducer, using the graded compression technique. Occasionally, the inflamed colonic segment may be visible on transvaginal examination. Ultrasound findings of diverticulitis vary with the degree of inflammation.[240,241] The most common finding is hypoechoic thickening of the colonic wall with a hyperechoic center and variable degrees of hyperemia (Fig. 29-48). An inflamed diverticulum may sometimes be identified

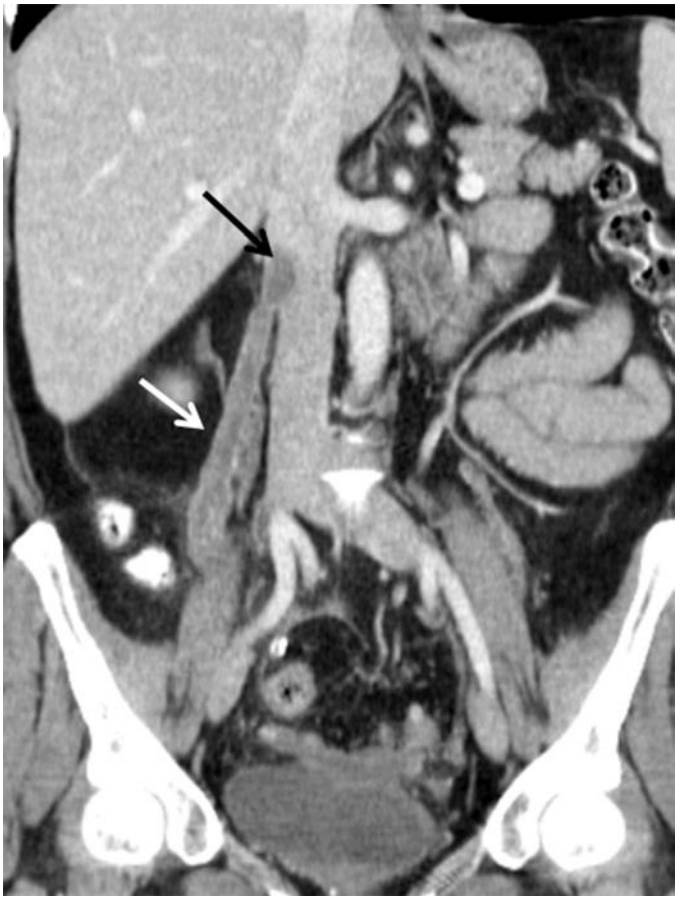

FIG 29-43 Gonadal vein thrombosis. Coronal reformatted image from contrast-enhanced computed tomography demonstrates distended thrombosed right gonadal vein (*white arrow*) with thrombus extending into the inferior vena cava (*black arrow*).

FIG 29-44 Magnetic resonance image of acute appendicitis in a pregnant patient. Coronal T2-weighted single shot fast spin echo (SSFSE) image demonstrates distended fluid-filled appendix (*white arrows*) located superior to the gravid uterus (*black arrow*) with multiple hypointense filling defects compatible with appendicoliths. Ultrasound examination was indeterminate.

at the site of maximum tenderness and can contain air, fluid, or occasionally a fecolith. Increased echogenicity and vascularity of the adjacent mesentery and omentum suggest inflammation. An abscess appears as a focal pericolonic fluid collection and may contain echogenic foci with dirty shadowing indicating extraluminal air. Diverticulitis in the pelvis may lead to inflammation of the adnexa, mimicking PID (see Fig. 29-17). CT may help confirm the diagnosis and identify complications, in particular perforation and abscess formation, which may require immediate surgical or percutaneous intervention.

Other Inflammatory Conditions of the Bowel and Mesentery

Epiploic appendagitis is a benign inflammatory process involving the epiploic appendages, which are small finger-like projections of fat covered by serosa on the surface of the large bowel, most numerous in the sigmoid and transverse colon. The cause is believed to be ischemic infarction from torsion or spontaneous thrombosis of the epiploic central draining vein with development of focal inflammation. The patient typically presents with acute-onset pelvic pain and localized tenderness without leukocytosis or fever. This self-limited nonsurgical condition is treated with anti-inflammatory medications and usually resolves in 5 to 7 days.[242] However, the clinical presentation may mimic diverticulitis, appendicitis, or gynecologic disorders, and misdiagnosis may lead to unnecessary intervention, including surgery. The features at CT have been well described and include an oval pericolonic lesion of fat density surrounded by inflammatory changes.[242-245] A central ill-defined round area (central dot sign) corresponds to engorged or thrombosed central vessels or central areas of hemorrhage or fibrosis. There is minimal, if any, thickening of the adjacent colonic wall, which helps to distinguish this entity from primary bowel-related processes. At sonography, a noncompressible hyperechoic ovoid or round solid mass of fatty tissue is identified between the colon and the abdominal wall at the site of maximal tenderness[244-247] (Fig. 29-49). A thin hypoechoic wall may be observed around the mass. Changes to the colonic wall are generally not observed.

Segmental omental infarction can also occur as a result of torsion or spontaneous thrombosis of omental vessels and may present in a similar fashion. Although there are predisposing factors, most cases are idiopathic. These infarctions are usually localized to the right upper and right lower quadrants and may mimic cholecystitis or appendicitis. This is also a benign self-limiting condition. Hazy increased soft tissue density of the omentum or a more discrete fat-density mass is observed on CT, and inflammation in the omentum is disproportionate to any reactive inflammatory changes in the bowel. At ultrasound examination, a hyperechoic mass is identified centered in the omentum in the area of patient discomfort and localized tenderness.[244]

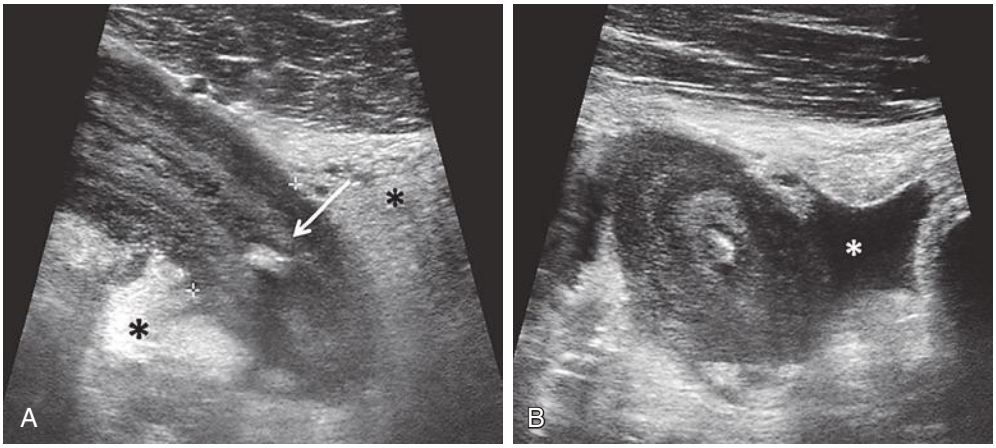

FIG 29-45 Acute appendicitis. **A,** Targeted ultrasound examination of the right lower quadrant performed with a linear high-resolution transducer shows distended thick-walled appendix (*calipers*) with echogenic, shadowing intraluminal appendicolith (*arrow*). The surrounding periappendiceal fat demonstrates increased echogenicity (*asterisks*) compatible with inflammation. **B,** Transverse image demonstrates periappendiceal fluid (*asterisk*).

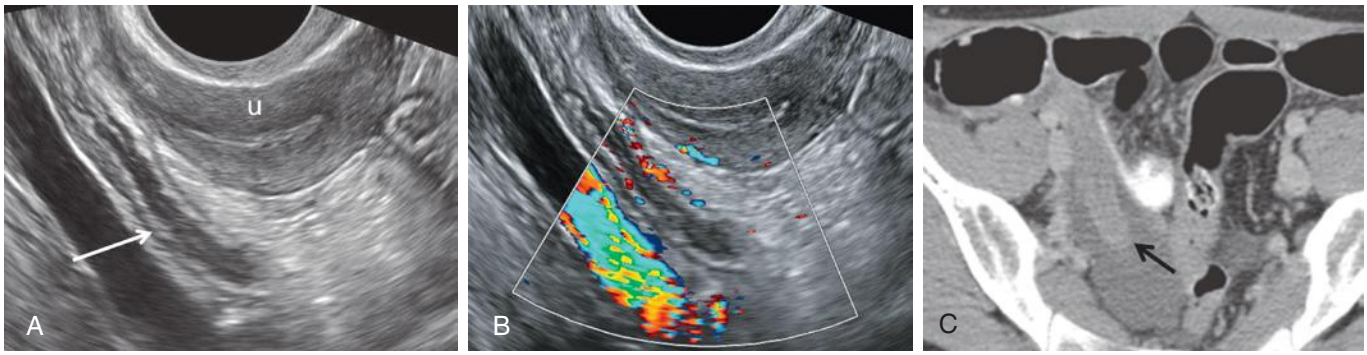

FIG 29-46 Acute appendicitis detected on transvaginal sonogram. **A,** Patient presented with right pelvic pain and clinically suspected adnexal disease. The tubular, blind-ending appendix is dilated and fluid-filled (*arrow*), located to the right of the uterus (u). **B,** Color Doppler sonographic image demonstrates hyperemia in the wall of the inflamed appendix. **C,** Acute appendicitis (*arrow*) was confirmed at computed tomography scan.

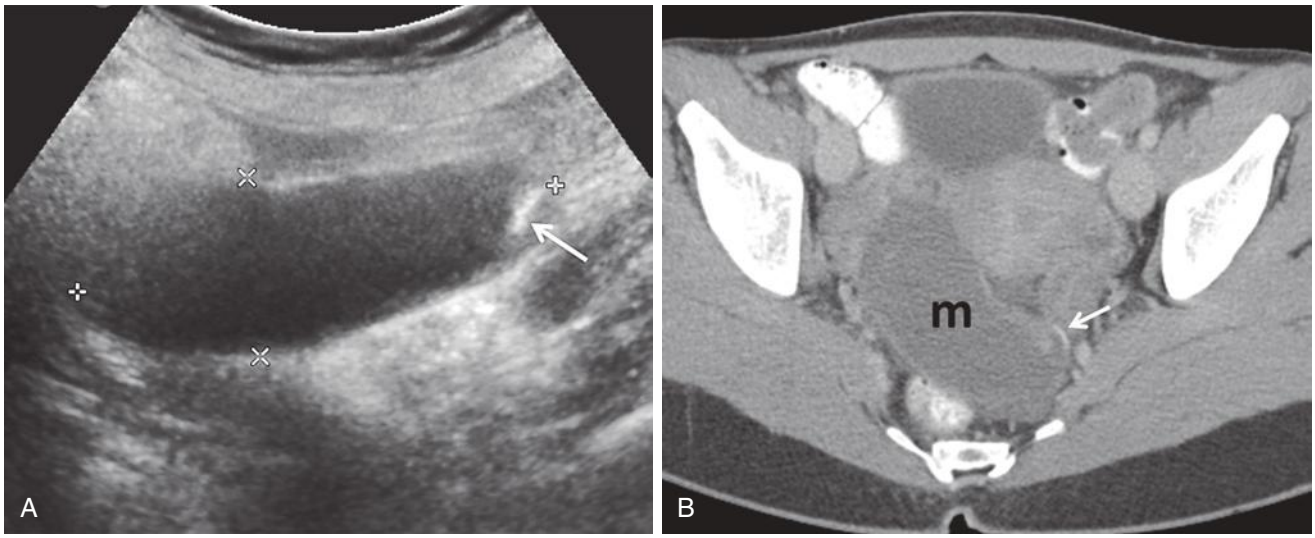

FIG 29-47 Mucocele of the appendix. **A,** Transabdominal ultrasound image of right lower quadrant demonstrates a markedly dilated, blind-ending tubular structure (*calipers*) with mural calcification at the tip (*arrow*). **B,** Contrast-enhanced axial computed tomography confirms that the mucocele (m) originates from the base of the cecum and has mural calcification (*arrow*).

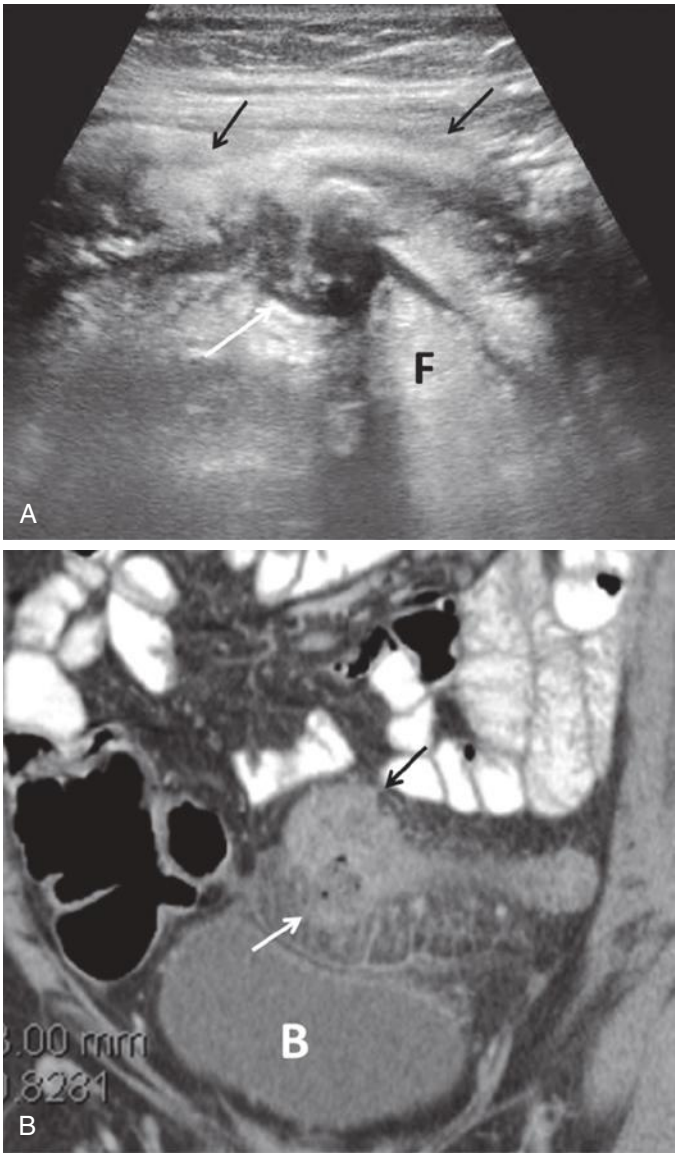

FIG 29-48 Acute sigmoid diverticulitis in a patient with left pelvic pain. **A,** Evaluation of the left lower quadrant with a linear ultrasound transducer shows thickened sigmoid colon (*black arrows*). There is a focal outpouching with fluid and debris (*white arrow*) representing the inflamed diverticulum. The adjacent inflamed pericolonic fat (F) is hyperechoic. **B,** Coronal reformatted image from contrast-enhanced computed tomography demonstrates inflamed diverticulum (*white arrow*), with bowel wall thickening (*black arrow*) and stranding in the adjacent pelvic fat consistent with inflammation. B, urinary bladder.

Clinical features of enteritis or colitis may overlap with other pelvic conditions. Inflamed bowel in the setting of enteritis or colitis will demonstrate wall thickening with variable degrees of echogenicity and hyperemia. Decreased peristalsis and increased echogenicity of the mesenteric fat may also be observed. A Meckel diverticulum may appear as a blind-ending pouch-like structure arising from the small bowel, allowing it to be differentiated from the appendix.[248,249]

Obstructive Uropathy

In general, patients with renal colic present with acute onset of severe colicky flank pain and nausea; 50% of patients will have hematuria on urinalysis. Although the diagnosis can often be made based on clinical presentation, imaging may be required for confirmation or to exclude other causes of pain and to guide appropriate management (conservative management versus intervention). Intervention is more likely to be required if there is significant hydronephrosis or if the stone is larger than 5 mm.[250,251] In adults, low-dose non-contrast-enhanced renal stone protocol CT is the initial imaging study of choice given the high accuracy for identification and characterization of obstructing ureteral stones as well as associated complications, and this protocol is given the highest score in the ACR Appropriateness Criteria for evaluation of flank pain and suspected kidney stone.[252] The sensitivity and specificity of CT for the diagnosis of kidney stones range from 95% to 96% and 98% to 100% with overall accuracy of 100%.[253,254]

Because the clinical presentation of renal colic may overlap with emergent gynecologic conditions including ovarian torsion or ruptured ovarian cyst, pelvic ultrasound protocols for evaluation of pelvic pain at many institutions include at least limited assessment of the kidneys to evaluate for hydronephrosis, particularly if no cause for the patient's symptoms is identified in the uterus or adnexa. A dilated ureter should be followed as far distal as possible to identify the cause and level of obstruction (Fig. 29-50). A dilated ureter may also be identified as an incidental finding at transvaginal sonography.

The sensitivity of ultrasound for detecting ureteral calculi depends on the size and location of the stone. Proximal stones, near the ureteropelvic junction, and stones in the distal ureter, at a level where the bladder can be used as an acoustic window, are more readily visualized. Detection of distal ureteral stones, close to the level of the ureterovesical junction, can be facilitated by using a transvaginal sonographic approach.[255] However, midureteral stones are often obscured by bowel gas. The reported sensitivity of sonography for obstruction of the collecting system is 73% to 100%.[256] Signs of obstruction include hydronephrosis, hydroureter, and absence of the ureteral jet in the urinary bladder. However, obstructive uropathy cannot be confirmed unless a ureteral stone is visualized, as there are many nonobstructive causes of dilatation of the collecting system.

Sonography is the preferred imaging modality in this evaluation in pregnant patients and children to avoid ionizing radiation.[256] A 2014 analysis of over 2700 patients with flank pain randomized to point-of-care sonography in the emergency department, sonography performed in the radiology department, or CT scan as initial evaluation demonstrated that initial sonography was associated with lower cumulative radiation exposure than initial CT, without significant differences in high-risk diagnoses with complications, serious adverse events, pain scores, return emergency department visits, or hospitalizations.[257] In light of these data, it is likely that sonography will play an even larger role in evaluation of suspected urolithiasis in the nonpregnant patient.

CONCLUSIONS

Pelvic sonography is the first-line imaging method of choice for evaluation of pelvic pain in the reproductive age patient when a gynecologic disorder is suspected. Sonography often conclusively establishes the diagnosis of ovarian torsion, hemorrhagic ovarian cyst, endometriosis, PID, adenomyosis, complications of leiomyomas, and vascular abnormalities. Furthermore, many nongynecologic causes of pelvic pain including gastrointestinal and genitourinary disorders may be identified at ultrasound examination performed for suspected pelvic abnormalities, and recognition of these disorders may enable prompt diagnosis and eliminate the need for further imaging. When ultrasound findings are equivocal, CT and MRI can be helpful complementary techniques.

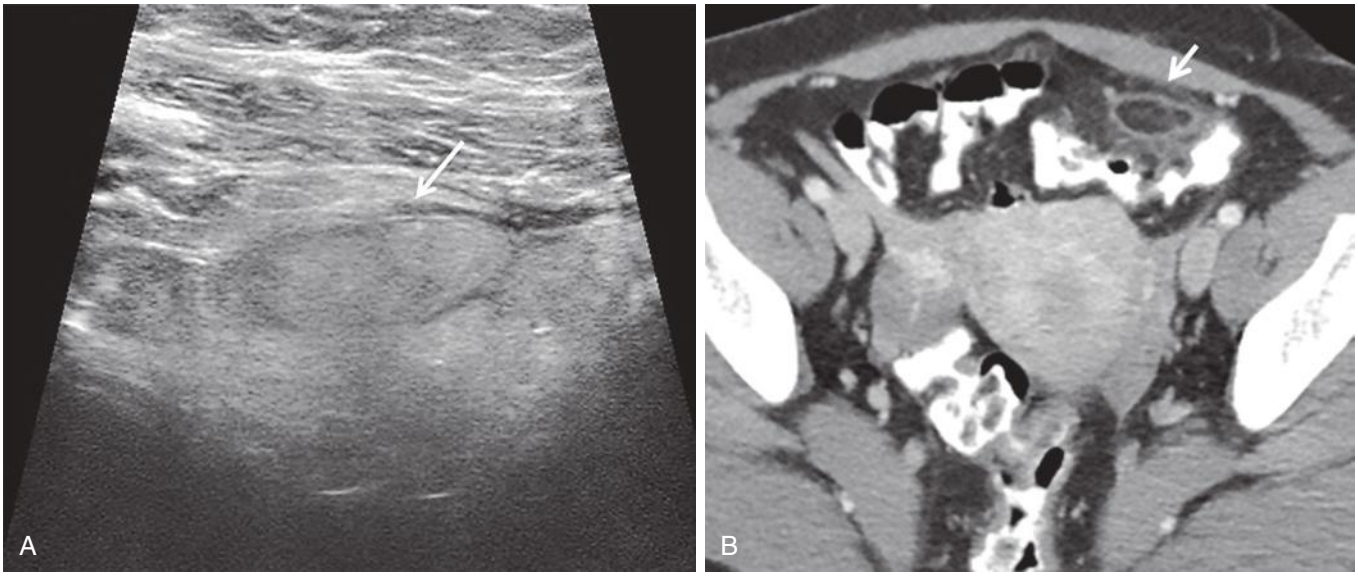

FIG 29-49 Epiploic appendagitis in patient with left pelvic pain. **A,** High-resolution linear transducer demonstrates an oval hyperechoic mass-like area (*arrow*) with hypoechoic rim at the point of maximal tenderness. The uterus and adnexa were normal (not shown). **B,** Contrast-enhanced axial computed tomography confirms the diagnosis of epiploic appendagitis. Note rim-enhancing fat-attenuation abnormality at the left lower quadrant (*arrow*).

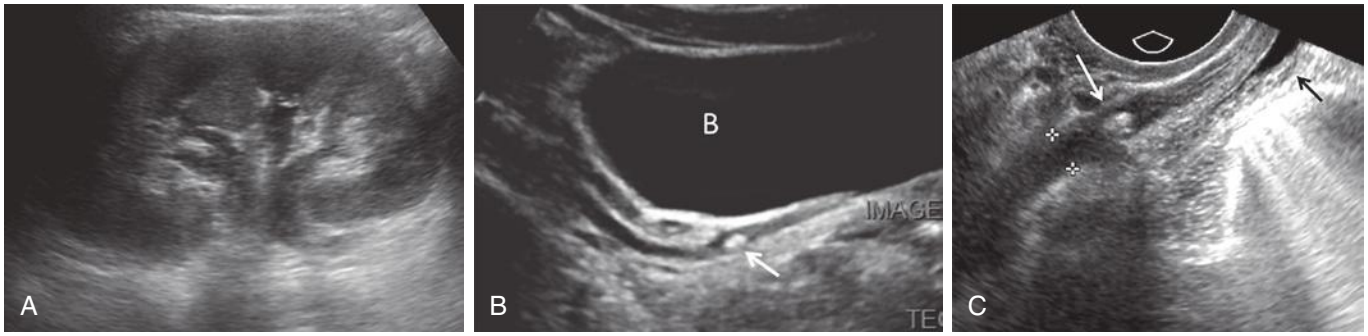

FIG 29-50 Urolithiasis in patient with right pelvic pain. **A,** Sagittal gray-scale ultrasound image of the right kidney demonstrates mild dilatation of the intrarenal collecting system. The uterus and adnexa were normal (not shown). **B,** Transabdominal scan, using the distended urinary bladder (B) as an acoustic window, demonstrates an echogenic calculus (*arrow*) in the mildly distended, fluid-filled distal right ureter. **C,** Transvaginal scan demonstrates an echogenic calculus (*white arrow*) in the dilated distal ureter (*calipers*) just proximal to the ureterovesical junction. The bladder (*black arrow*) is decompressed.

Ultrasound Evaluation of the Ovaries

Douglas L. Brown, Darci J. Wall

SUMMARY OF KEY POINTS

- A simple cyst less than 3 cm in the ovary of a premenopausal patient is best termed a follicle and is a normal finding.
- A simple cyst less than 1 cm in the ovary of a postmenopausal patient is considered inconsequential.
- Most ovarian masses are benign and have a typical sonographic appearance that allows accurate diagnosis.
- Many simple and hemorrhagic cysts do not need sonographic follow-up in asymptomatic patients.
- Before diagnosing a simple ovarian cyst, it is important to search carefully for small nodules along the wall.
- A solid area with flow on Doppler imaging is the most important morphologic characteristic of an ovarian mass that raises concern for malignancy.
- The occasional indeterminate appearing ovarian mass can be managed variably by repeat sonography, magnetic resonance imaging (MRI), or surgical evaluation.

OUTLINE

Pelvic sonography, including transvaginal scanning, is the preferred initial imaging modality for evaluation of a suspected ovarian or other adnexal mass.[1] Its high sensitivity and specificity for ovarian malignancy, lack of ionizing radiation, relatively low cost, and wide availability make it an ideal method for evaluation of the ovary. In most patients, sonography is adequate to evaluate an ovarian mass. Scoring systems have been used to characterize ovarian and other adnexal masses sonographically, and they perform reasonably well. However, subjective assessment has been shown to perform as well or better than mathematical scoring systems.[2] Although accurate and timely identification of ovarian malignancy is extremely important, most adnexal masses are benign and most have a typical sonographic appearance. Thus, it is essential to recognize these common benign ovarian masses as frequently as possible and not mistake them for ovarian malignancy. Appropriate sonographic characterization of adnexal masses may help prevent unnecessary follow-up imaging along with its attendant patient anxiety and unnecessary surgery as well as its attendant risks. Detailed sonographic evaluation can prompt referral to gynecologic oncologists for management of adnexal masses that are likely to be malignant. When an adnexal mass has one of the classic benign appearances (to be discussed in this chapter), characterization is complete, although some may warrant sonographic follow-up. If a mass has characteristic malignant findings, imaging for characterization or diagnosis is also typically complete, though further evaluation for staging may be needed. For masses with indeterminate sonographic findings, management will vary depending upon the clinical circumstances, but options would typically include follow-up sonography, MRI, or surgical evaluation. Standardized terminology[3] and reporting[4] have been suggested for ovarian masses; neither has been widely adopted at this time, but both may be further developed in the future.

In a small minority of patients, additional pelvic imaging with MRI may be helpful when ultrasound fails to clarify the origin of an adnexal mass, when the sonographic features are indeterminate, or when an adnexal mass is inadequately imaged with ultrasound (such as in an obese patient or in one who cannot undergo or declines transvaginal scanning).[1] Although computed tomography (CT) is helpful in staging of patients with known or suspected ovarian malignancy, it does not usually have a significant role in the characterization of adnexal masses.[1] CT may occasionally be helpful if a gastrointestinal origin of an adnexal mass is suspected or to search for a primary neoplasm when ovarian metastases are suspected. Positron emission tomography/CT has little, if any, role at this time in the primary evaluation of ovarian masses,[1] although it too may be helpful to search for a primary neoplasm if ovarian metastases are suspected.

In this chapter, we will review a few normal findings specific to the ovary, discuss sonographic features of benign and malignant ovarian masses, present an approach to assessing indeterminate ovarian masses, and review pitfalls in evaluation of the ovary. When appropriate, the

findings and recommendations of the Society of Radiologists in Ultrasound consensus conference on ovarian and other adnexal cysts have been included in this chapter.[5] Some aspects of ovarian disease will not be discussed or will be mentioned only briefly, as they are covered elsewhere in this text. Ovarian torsion is discussed in Chapter 29, nonovarian adnexal masses including tubo-ovarian abscess in Chapter 31, and polycystic ovary syndrome and ovarian hyperstimulation syndrome in Chapter 32.

NORMAL AND INCONSEQUENTIAL FINDINGS

Although normal ovarian findings and ultrasound technique is more thoroughly discussed in Chapter 26, a few observations unique to the ovary bear additional mention here (Fig. 30-1). Ovarian follicles typically achieve a size of 2 to 3 cm before ovulation. Hence, simple (unilocular, thin-walled, anechoic) ovarian cysts less than 3 cm in greatest diameter in premenopausal women should generally be considered normal findings.[5] In order to prevent confusion with pathologic findings, it is best not to use the term "cyst" for normal ovarian structures and better to describe them as follicles or to simply report the ovary as normal.[6,7] Simple ovarian cysts less than 1 cm in greatest diameter may be present in postmenopausal women and have been reported in approximately 20% of women 5 or more years following menopause.[8] Hence, simple ovarian cysts less than 1 cm in maximal diameter in a postmenopausal woman generally require no follow-up and are considered inconsequential.[5] The corpus luteum, which typically appears as a thick-walled cystic lesion less than 3 cm in diameter with internal echoes and crenulated wall, should also be recognized as a normal finding in premenopausal women.[5] The wall of the corpus luteum may be quite vascular on Doppler interrogation.

Echogenic foci are a normal finding in many ovaries (Fig. 30-2). Tiny echogenic foci, measuring 1 to 3 mm in width, have no posterior shadowing (although comet-tail artifact may be seen) and may be due to psammomatous calcifications associated with epithelial inclusion cysts, hemosiderin deposition, or bright specular reflections off the back walls of tiny follicles.[9-11] These ovarian echogenic foci are found both in premenopausal and postmenopausal women.[8] They are generally of no significance and may occasionally be helpful in identifying an ovary. Larger echogenic foci in the ovary, usually from isolated calcifications, are also typically benign findings (Fig. 30-3). Echogenic foci 5 mm and larger, some of which may demonstrate posterior acoustic shadowing, seen in otherwise normal ovaries have been attributed to corpus albicans.[12,13] Some association between these foci and adenofibromas has been reported.[14] The pattern of calcifications within the ovary should be examined, as a more extensive peripheral rind of calcifications has been reported in a patient with endosalpingiosis and serous borderline ovarian neoplasms.[15] Larger coarse ovarian calcifications, in the absence of a mass, are generally benign and can be followed sonographically.[12] Anecdotal evidence suggests that patients with larger or more extensive calcifications in an otherwise normal-appearing ovary should receive additional evaluation or closer follow-up.

OVARIAN CYSTS WITH TYPICAL BENIGN FEATURES

Ovarian lesions with classic features of simple cysts, hemorrhagic cysts, endometriomas, or dermoids are highly likely to be benign. It is important to recognize the characteristic sonographic features that, when seen, are highly predictive of these benign entities. Reliable characterization of ovarian masses using these sonographic features

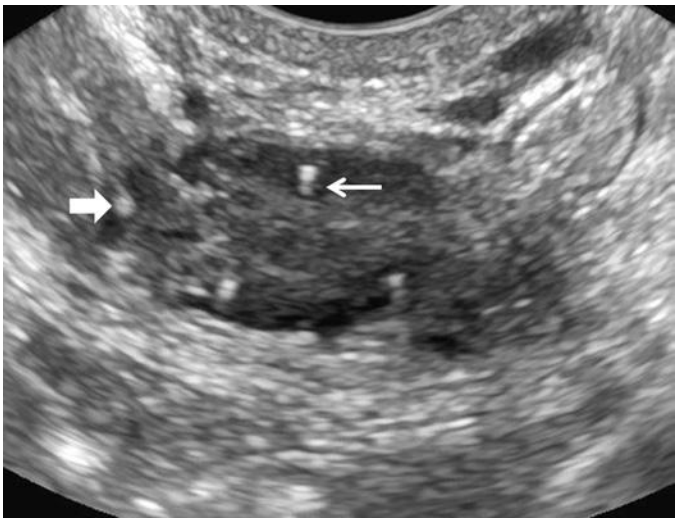

FIG 30-2 Tiny echogenic foci in the ovary. A 53-year-old postmenopausal patient with several tiny peripheral echogenic foci in each ovary, some with associated comet-tail artifact (*thin arrow*) and some with no distal artifact (*thick arrow*).

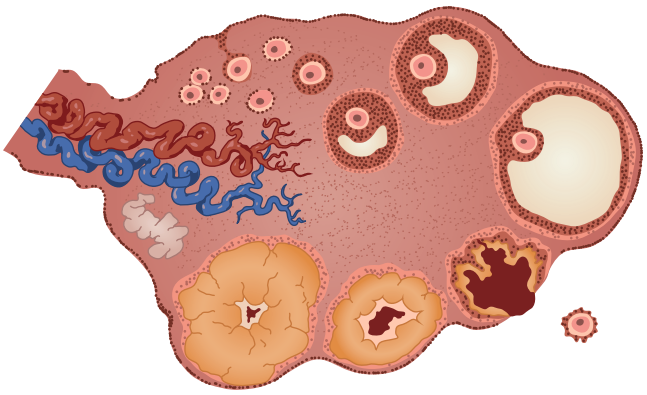

FIG 30-1 Diagram demonstrating a normal ovary with follicles in various stages of development, from early follicles in the follicular phase of development, through ovulation and subsequent development of the corpus luteum.

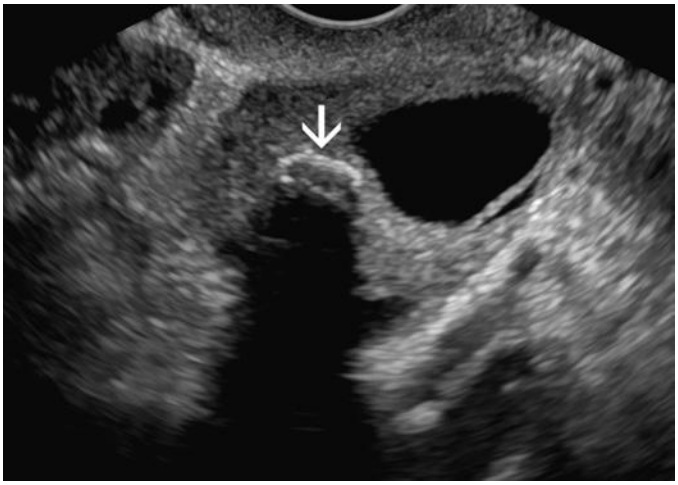

FIG 30-3 Ovarian calcification. A 9-mm calcification (*arrow*), with posterior acoustic shadowing, is shown within an otherwise normal-appearing ovary. Such calcifications are generally of no clinical significance, but may be followed sonographically.

requires that the mass be fully and adequately visualized by ultrasound. Occasionally, in a patient with a suboptimal ultrasound examination, the interpreting physician will need to decide how to proceed based on available imaging findings and degree of clinical concern. When reporting on adnexal masses seen on pelvic sonograms, it is important to describe specific sonographic features (detailed later) that allow one to determine the likely diagnosis. Use of the word "complex" as a descriptor, with no additional explanation, is problematic as the "catch-all" term is often used for any cystic mass that is not a simple cyst. There are many features that may result in a "complex" sonographic appearance, including a typical reticular pattern suggesting benign hemorrhagic cyst and typical solid nodule worrisome for malignant ovarian carcinoma. Thus, if an ovarian cyst is reported as "complex," further descriptors detailing those features making it complex should also be provided.[6,7]

Simple Cysts

As with cysts elsewhere in the body, ovarian cysts with thin walls, anechoic internal contents, posterior acoustic enhancement, and no septations or solid components meet sonographic criteria for simple cysts (Fig. 30-4). Follicular or corpus luteal cysts and serous cystadenomas may appear as simple cysts by sonographic criteria. Simple ovarian cysts occur in 4% to 17% of postmenopausal women and the majority resolve or remain stable on follow-up ultrasound evaluation.[16-21] However, annual follow-up sonography for simple ovarian cysts larger than 1 cm (though some practices may choose to raise this threshold to 3 cm) is recommended in postmenopausal women.[5] In premenopausal women, it is recommended that cysts between 5 and 7 cm in largest diameter be followed yearly by ultrasound examination. The vast majority of simple ovarian cysts are benign.[22-24] With increasing cyst size, however, there is a risk of inadequate assessment of the cyst wall for detection of small solid nodules or papillary formations,[22] which, if present, increase the likelihood of malignancy. The rare occurrence of malignancy in an apparent simple ovarian cyst is more likely in larger cysts, in which small mural nodules may be overlooked.[22] Hence, when evaluating what appears to be a simple cyst, it is important to confirm that the cyst is adequately imaged in its entirety and to carefully assess for small nodules before concluding that it is indeed a simple cyst. Simple cysts measuring larger than 7 cm are still likely benign, though one should consider further imaging evaluation with MRI to confirm that there is no solid component overlooked by sonography.[5]

Hemorrhagic Cysts

Fibrin strands and retracting clot are highly specific features of hemorrhagic ovarian cysts (Fig. 30-5).[5,25,26] The fibrin strands are often described as lacy, reticular, fishnet, cobweb, spider web, or sponge-like in appearance.[26,27] Although retractile clot might be confused with a solid mural nodule, it will have no detectable flow by Doppler imaging and typically has scalloped, concave, or straight margins. These features can help differentiate retracting subacute clot from malignant solid tissue, which is usually more round or lobular in configuration and often has demonstrable flow on targeted Doppler imaging.[26,28] Cystic ovarian lesions without detectable internal flow on Doppler imaging and with either the fibrin strand or retractile clot pattern of internal echoes very likely represent hemorrhagic cysts, and typically

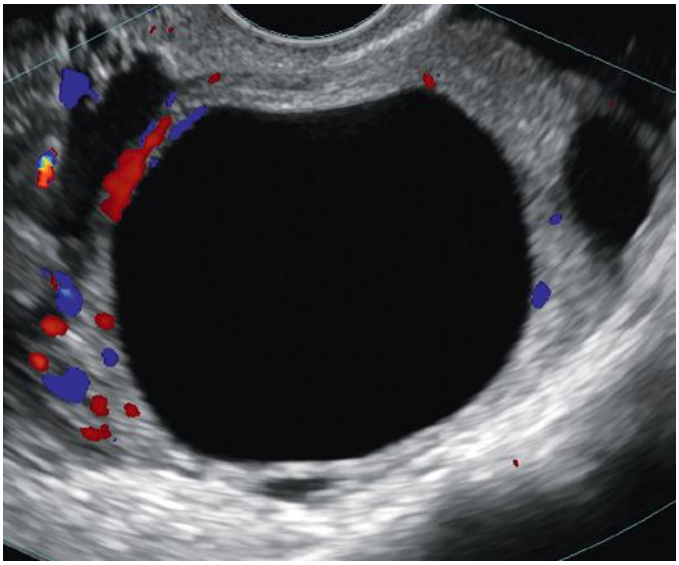

FIG 30-4 Simple ovarian cyst. Color Doppler ultrasound image of a simple ovarian cyst demonstrates the characteristic findings of anechoic contents, smooth thin wall, no internal vascularity, and posterior acoustic enhancement.

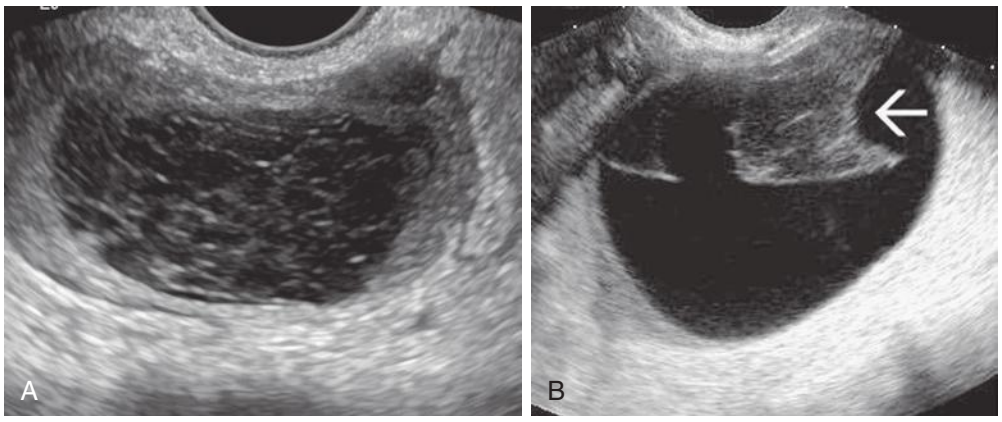

FIG 30-5 Hemorrhagic ovarian cysts. **A,** This hemorrhagic cyst has a "fishnet" or reticular lace-like pattern of internal echoes due to fibrin strands. Fibrin strands typically appear as thin linear or curvilinear echoes that do not extend across the span of the cyst but appear discontinuous. True internal septations usually course from wall to wall across the cyst. **B,** A hemorrhagic cyst from another patient has a solid-appearing area with a concave margin (*arrow*) due to retractile clot. Color Doppler imaging (not shown) demonstrated no flow in the clot.

resolve within 8 weeks.[27] Such sonographically typical hemorrhagic cysts less than 5 cm in maximal diameter do not generally need follow-up sonography in asymptomatic premenopausal patients.[5] However, sonographically typical hemorrhagic cysts larger than 5 cm, suspected hemorrhagic cysts with atypical morphologic features, and hemorrhagic cysts in perimenopausal or early postmenopausal (1 to 5 years after final menstrual period) women should be reevaluated by follow-up ultrasound evaluation in 6 to 12 weeks to ensure resolution or decrease in size.[5] Women in late postmenopause (greater than 5 years since final menstrual period) would not be expected to develop hemorrhagic ovarian cysts. It is unlikely that one would suspect a hemorrhagic ovarian cyst based on ultrasound criteria in late postmenopause, but if this were to occur, one should consider the possibility of neoplasm and recommend further evaluation with MRI or surgical consultation.[5]

Hemorrhagic ovarian cysts may contain solid-appearing areas due to clot with concave or straight margins and lack of detectable flow by careful Doppler interrogation. There are occasional problematic cases in which apparently solid areas without detectable flow have outwardly convex margins and thus may simulate solid mural neoplastic nodules. Gentle pressure on the cyst with the transvaginal transducer is sometimes helpful, as an intracyst clot may show jiggling or jelly-like motion with this maneuver.[26] If the diagnosis remains uncertain, follow-up ultrasound imaging is often helpful in distinguishing a hemorrhagic cyst (with interval resolution of clot) from an ovarian neoplasm (with persistence, enlargement, or apparent development of internal blood flow). Occasionally a hemorrhagic cyst may simulate a solid lesion with a sonographic appearance of diffuse heterogeneous internal echoes (Fig. 30-6), typically encountered in an acute or subacute stage, before fibrin strands develop.[6,29] Lack of detectable flow by Doppler imaging (using settings optimized to detect low-volume, low-velocity flow) within the apparently solid component, posterior acoustic enhancement, and awareness of this entity in premenopausal women can suggest this possibility. Resolution on follow-up ultrasound examination would confirm the diagnosis of self-limiting hemorrhagic cyst.

The most significant potential complication of a hemorrhagic ovarian cyst is rupture with hemoperitoneum. A ruptured hemorrhagic cyst may be difficult to distinguish from a ruptured ectopic pregnancy, thus necessitating correlation with serum human chorionic gonadotropin (hCG) level.[30,31] A ruptured ectopic pregnancy typically requires operative management, whereas a ruptured hemorrhagic ovarian cyst can usually be managed expectantly in hemodynamically stable patients.[32-34]

Endometriomas

Endometriosis occurs when there is endometrial tissue outside the uterus. Most cases are reported in women of childbearing age and a 10-fold increase in prevalence has been reported in patients with an affected first-degree relative.[35] Although some may be asymptomatic, patients most commonly present with pain, which may be cyclic, correlating with their menstrual cycle, or infertility. Some patients with endometriosis will form cysts, termed endometriomas, which are found in up to 44% of women with endometriosis.[36] Most endometriomas are located within the ovary.[37-39] The pathogenesis of intraovarian endometriomas may be different than that of endometriosis that occurs as superficial peritoneal implants.[40] Endometriomas are usually readily detectable by ultrasound. Cystic lesions with diffuse low-level internal echoes, sometimes described as "ground glass," are characteristic, with 95% of endometriomas having this appearance (Fig. 30-7).[26,35,41] Multilocularity and echogenic foci in the wall have been reported to increase the likelihood that a lesion represents an endometrioma[35]; however, neither is required for the diagnosis. In our experience, it is uncommon for endometriomas to be multilocular though there may be multiple adjacent endometriomas that could be difficult to distinguish from multilocularity. Lack of acoustic streaming (movement of echoes inside the cyst during gray-scale or Doppler ultrasound imaging) was initially thought to be predictive of an endometrioma, but subsequent studies have not found absence of acoustic streaming to be reliable for this diagnosis.[42]

Surgical removal is considered for symptomatic endometriomas, for those causing pain and infertility, as well as for those in which malignancy is suspected. Fertility does not always improve following cystectomy, however, as surgery can reduce the number of viable ovarian follicles.[43] Malignancy, typically clear cell carcinoma and less often endometrioid adenocarcinoma, should be suspected in endometriomas that develop solid mural nodules or that rapidly increase in size.[44] MRI can be helpful in assessing endometriomas for enhancing mural nodules and for restricted diffusion in those suspected of

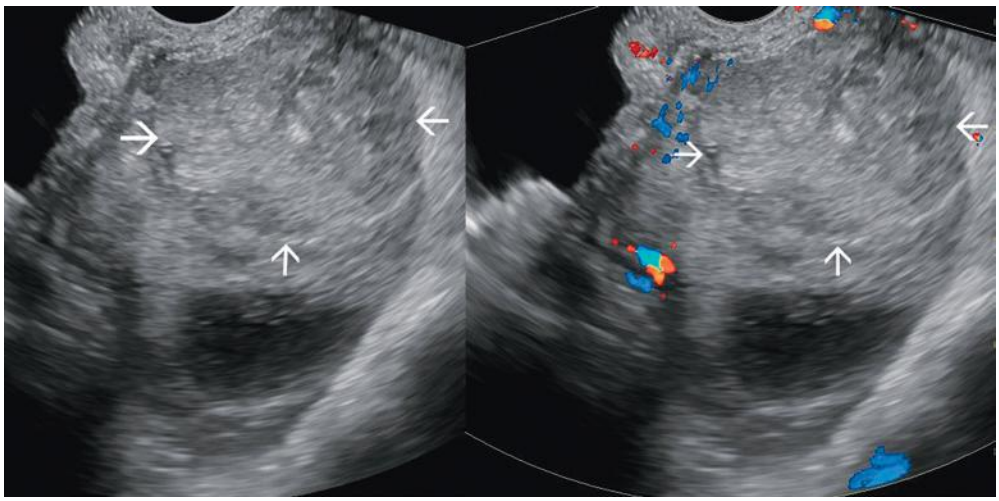

FIG 30-6 Subacute hemorrhagic ovarian cyst simulating a solid ovarian mass. Dual screen image without and with color Doppler interrogation shows a heterogeneous, predominantly isoechoic, solid-appearing mass (between *arrows*) within the left ovary of a 41-year-old woman who presented with pelvic pain. Color Doppler imaging (*right*) shows flow around the periphery of the mass but no flow within it. This lesion resolved on follow-up ultrasound examination.

undergoing malignant transformation.[45] Asymptomatic lesions with typical sonographic appearance of endometriomas can be followed annually with ultrasound.[5]

Given that the sonographic appearance of endometriomas and hemorrhagic cysts occasionally overlap, follow-up sonogram, typically in 6 to 12 weeks, is suggested, particularly if surgical removal of a presumed endometrioma is planned.[5] If the lesion is a hemorrhagic cyst, it will resolve or change on follow-up study. Endometriomas in postmenopausal women may differ in appearance from the typical homogeneous echotexture seen in premenopausal women and may be more heterogeneous with echogenic foci centrally.[46] A small number of endometriomas may contain a small solid-appearing area on ultrasound imaging, and, therefore, it can be difficult to distinguish these endometriomas from malignant lesions.[6,40,41,46,47] Doppler sonographic imaging is suggested, although it may not resolve the diagnosis as the solid area may be due to focal endometrial tissue with internal blood flow. In such cases, additional evaluation with MRI should be considered.

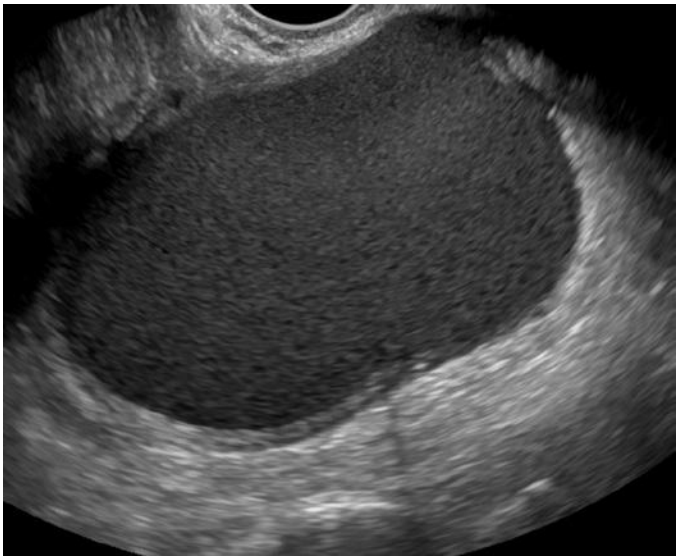

FIG 30-7 Endometrioma. This endometrioma has the classic appearance of a cystic mass with homogeneous low-level internal echoes, sometimes referred to as a "ground glass" appearance. Note posterior acoustic enhancement, suggesting that this is a cystic rather than a solid lesion. There was no internal flow demonstrated by color Doppler imaging (not shown).

Mature Cystic Teratomas

Mature cystic teratomas of the ovary, also termed dermoids, account for up to 20% of ovarian neoplasms. These benign germ cell tumors are composed of at least two of the three germ cell layers (ectoderm, mesoderm, and endoderm). Dermoids are estimated to account for up to 20% of all ovarian tumors found in adult women and are bilateral in 15% to 25% of cases. Most dermoids are asymptomatic and are incidentally detected. However, dermoids may present with symptoms related to large size resulting in compression of adjacent structures. Torsion or rupture of a dermoid may cause significant pain. Several characteristic sonographic appearances have been described, including focal or diffuse hyperechoic component; areas of acoustic shadowing, also known as the "tip of the iceberg" sign; and echogenic lines and dots, also referred to as dermoid "mesh" or "dot-dash" sign. Any combination of these classic sonographic features allows a confident diagnosis of a dermoid (Fig. 30-8).[5,48-54] The hyperechoic component, termed a Rokitansky nodule, typically corresponds to mixed hair and sebaceous material or occasionally to calcification, sometimes related to a bone or tooth.[48,54] The echogenic lines and dots represent hair in fluid.[48,54] Fluid-fluid levels may occur in dermoids but are seen infrequently.[49,53] A dermoid can be confidently suggested if the nondependent fluid is hyperechoic (indicating fat). However, teratomas can display nondependent hypoechoic fluid and thus be difficult to distinguish from other cystic lesions with fluid-fluid levels.[55,56] In such cases, it is important to look for other sonographic features suggesting a dermoid. Floating echogenic globules within a large mass is an uncommon appearance but is reported to be highly predictive of a dermoid.[54,57] Calcifications can occur in dermoids, but calcification alone is not enough to make the definitive diagnosis.[6]

Dermoids can increase in size but tend to do so slowly, with a mean growth rate of 1.8 mm per year in premenopausal women.[58] A serious potential complication of mature cystic teratomas is malignancy—occurring in up to 2% of teratomas, 80% of which are squamous cell carcinoma.[59-63] Additional potential complications include hyperthyroidism resulting from teratomas containing a large amount of thyroid tissue[64]; chemical peritonitis following spontaneous or iatrogenic

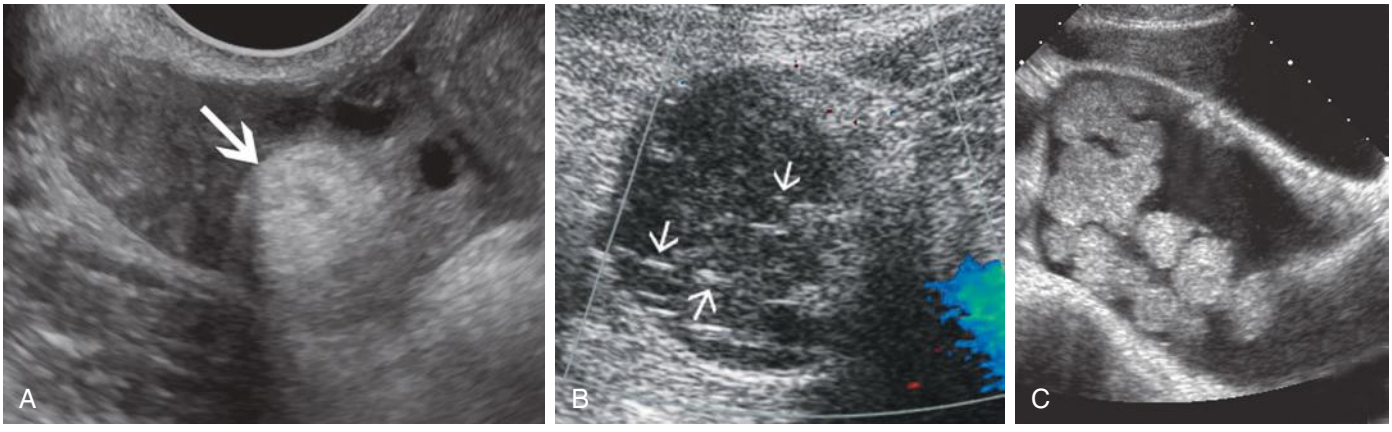

FIG 30-8 Ovarian dermoids. **A,** This dermoid *(arrow)* is diffusely hyperechoic. There is adjacent hypoechoic ovarian parenchyma. **B,** Dermoid with hyperechoic lines and dots (some indicated by *arrows*), also known as dermoid mesh appearance. This morphologic appearance is usually due to the presence of hair within the lesion. This dermoid also has a hyperechoic peripheral component. **C,** Uncommon but pathognomonic appearance of a dermoid containing several spherical structures, some of which are nondependent, thought to represent floating fat balls. These spherical structures contain fat, which allows them to float.

dermoid rupture[65]; and ovarian torsion. Torsion has been reported in 3.5% of dermoids and is more common with larger lesions.[60] Given the possibility of malignant transformation and of interval growth, which could increase the risk of ovarian torsion, annual sonographic follow-up of dermoids should be considered.[5] The reliability of ultrasound in identifying malignant transformation of dermoids is not well established. Features suggestive of malignant transformation include isoechoic branching structures,[66] demonstration of central flow within the mass by Doppler imaging,[67,68] or findings of metastatic disease.

OVARIAN CYSTS WITH TYPICAL MALIGNANT FEATURES

Ovarian neoplasms, both benign and malignant, are usually classified into one of four general histologic groups: epithelial, sex cord–stromal, germ cell, or metastatic neoplasms.[16,69] There are also borderline epithelial neoplasms that are usually considered malignant, though they confer a better prognosis than frankly malignant lesions, even if peritoneal spread is noted at the time of diagnosis.[16] Borderline tumors tend to occur in younger women. Most ovarian malignancies are epithelial neoplasms and demonstrate a mixture of cystic and solid components. Epithelial neoplasms include several histologic types, including serous, mucinous, endometrioid, and clear cell cystadenocarcinomas. The serous and mucinous forms also have benign counterparts, namely serous and mucinous cystadenomas. There is recent evidence that some epithelial ovarian carcinomas actually arise from the fallopian tube.[70-73] Most ovarian cystadenomas do not undergo malignant degeneration into carcinoma or, if transformation does occur, it is usually into a borderline neoplasm or low-grade malignancy and the rate of transformation is exceedingly slow.[5] Recent studies suggest there may be two types of epithelial ovarian carcinomas. Type I tumors are low-grade neoplasms that present at an early stage with an indolent course and are believed to arise from precursor lesions in the ovary, such as cortical inclusion cysts lined by tubal epithelia (perhaps incorporated into the cyst during ovulation), serous cystadenomas, borderline neoplasms, or endometriosis. Type II tumors are highly aggressive malignancies that present with advanced stage at diagnosis and likely originate from precursors arising in the fimbriated segment of the fallopian tube epithelium.[73-75] Current molecular and genetic research suggests that inactivating mutations of the tumor suppressor gene *TP53* give rise to "p53 signatures" (short segments of fallopian tube epithelium that overexpress p53, a tumor suppressor protein) in the fimbriated portion of the fallopian tube, which may ultimately transform into serous tubal intraepithelial cancers (STICs). It is now believed that STICs are the likely precursors of all pelvic extrauterine high-grade serous carcinomas either in the fallopian tube or following implantation onto the ovary or peritoneal surfaces.[70-75] *TP53* mutations have been reported in over 90% of high-grade serous carcinomas and *BRCA1/BRCA2* mutations (also tumor suppressor genes that help repair DNA damage) have been found in up to 50% of high-grade serous carcinomas.[75]

Sex cord–stromal neoplasms tend to present as solid ovarian masses[69] but can sometimes have a mixed cystic and solid appearance, especially when large. Germ cell neoplasms and metastatic neoplasms vary in sonographic appearance, some being solid and some mixed cystic and solid. Some specific ovarian neoplasms such as fibromas (the most common sex cord–stromal neoplasm),[76] dysgerminomas (the most common malignant germ cell neoplasm),[77] and many metastases, such as from breast carcinoma,[78] are typically solid masses.

The presence of a solid component, with detectable flow by Doppler imaging, within a cystic ovarian mass is the most important sonographic feature for predicting ovarian malignancy.[5,79] There is also evidence that the larger the solid component within a cystic mass, the higher the risk of malignancy.[80] A small soft tissue component is more typical of borderline or stage I ovarian carcinoma than of advanced ovarian carcinoma.[81] Apart from the characteristic hyperechoic tissue typical of dermoids, the presence of solid nodules (sometimes referred to as papillary projections, excrescences, or vegetations) or more confluent solid tissue with blood flow detected by Doppler imaging is highly likely to indicate malignancy (Figs. 30-9 through 30-11). However, solid components are not a specific finding for ovarian malignancy, as solid mural nodules can be seen in benign cystadenomas and cystadenofibromas. The absence of a solid component makes ovarian malignancy unlikely.[5,6,79] Focal wall thickening in a cystic mass is another sonographic feature worrisome for malignancy.[5]

Irregular or thick (generally defined as >3 mm) septations are also concerning for malignancy, though they are less predictive than solid components.[5] A cystic mass with thin septations and no solid component or a cystic mass with a solid component that has no detectable flow by Doppler imaging (Figs. 30-12 and 30-13) is likely to be a benign ovarian neoplasm, such as a cystadenoma or cystadenofibroma.[5,82] Additional findings of ascites (more than the trace physiologic amount common in premenopausal women), peritoneal implants (Fig. 30-14), or evidence of metastasis are all worrisome findings suggesting malignancy[79] but are not required to prompt suspicion of ovarian cancer.

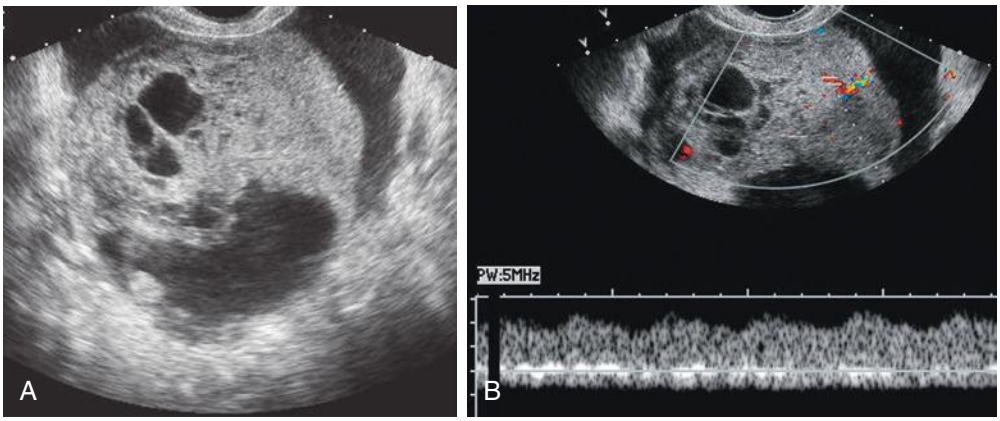

FIG 30-9 Clear cell cystadenocarcinoma of the ovary. **A,** Mixed cystic and solid mass with a relatively large solid component. **B,** Color and spectral Doppler imaging confirm flow within the solid component of the mass.

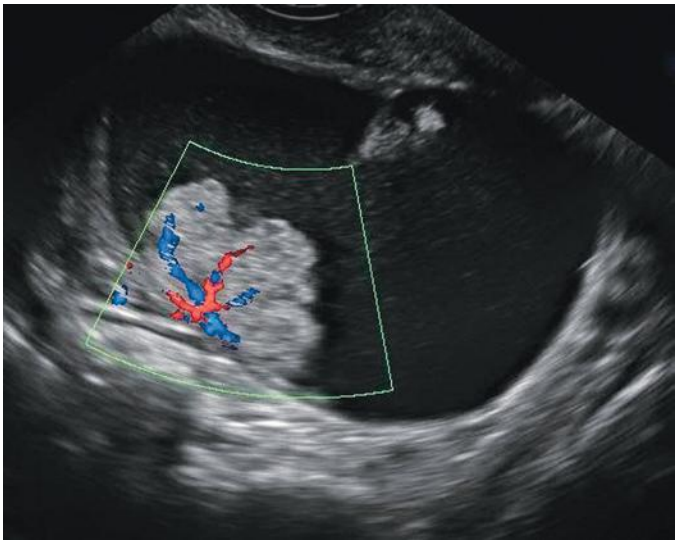

FIG 30-10 Borderline mucinous neoplasm. The predominantly cystic ovarian mass contains an irregular solid mural nodule that demonstrates internal flow on color Doppler interrogation.

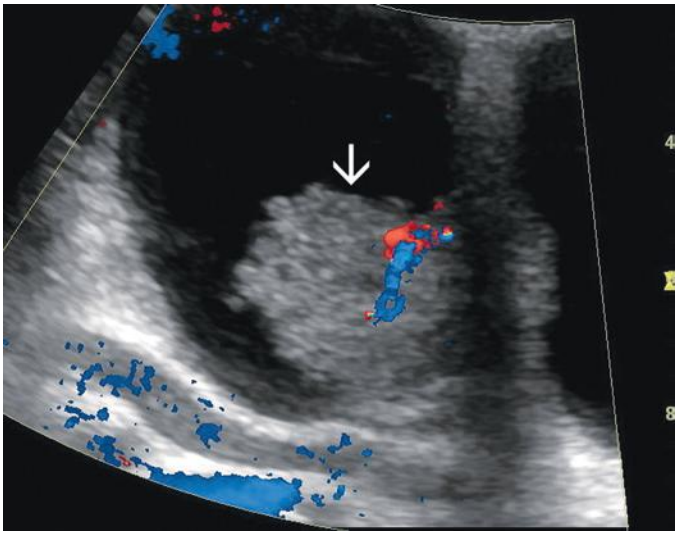

FIG 30-11 Serous cystadenocarcinoma of the ovary. This predominantly cystic mass contains a solid nodular area (*arrow*) with irregular margins and flow shown by color Doppler sonography. (Courtesy of Kika Dudiak, MD, Rochester, MN.)

OVARIAN CYSTS WITH INDETERMINATE FEATURES

The majority of ovarian masses found by sonography are benign, and most demonstrate one of the typical reassuring sonographic patterns discussed earlier. A minority of ovarian masses will be malignant and display characteristic worrisome features. Infrequently, one may encounter an ovarian mass with sonographic morphologic features not characteristic of either a benign or malignant lesion, and, thus, it cannot be definitively diagnosed by ultrasound (i.e., an indeterminate mass). In surgical series, such indeterminate masses have been reported in fewer than 10% of patients.[80,81] The frequency of persistent indeterminate masses in clinical practice is likely less, given that many cystic ovarian lesions resolve spontaneously. The histologic diagnoses of ovarian lesions that tend to be classified as indeterminate masses by sonographic criteria include borderline neoplasms, serous and mucinous cystadenomas/cystadenofibromas, fibromas, and pedunculated uterine leiomyomas.[80,81] There are rare ovarian neoplasms, such as struma ovarii, yolk sac tumors, and others that do not demonstrate characteristic, easily categorized sonographic features.[77,81] At times, laboratory findings such as elevated alpha-fetoprotein level associated with yolk sac tumor or elevated hCG level associated with nongestational ovarian choriocarcinoma may be helpful.[78] The sonographic features more frequently encountered in indeterminate lesions include large mass size, multiple septations, and solid nodules that are small or few in number.[80] For such indeterminate masses, one needs to decide between sonographic follow-up, further assessment with MRI, or surgical evaluation, influenced by the degree of concern based on imaging and clinical findings.[5]

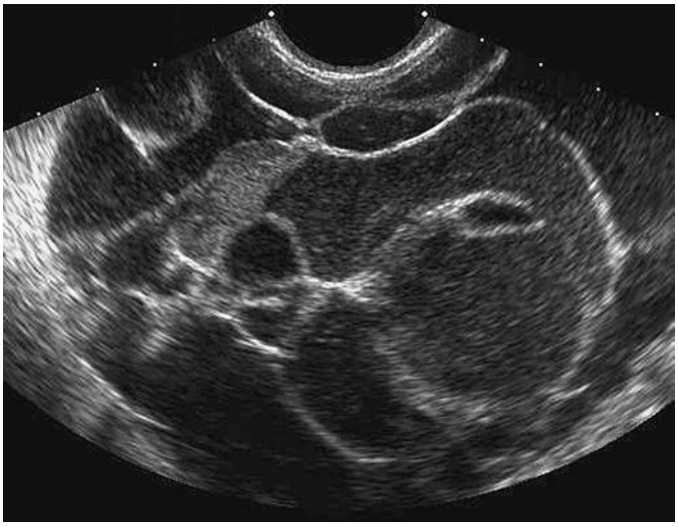

FIG 30-12 Mucinous cystadenoma. This multiloculated cystic mass contains multiple septations with fluid of varying degrees of echogenicity in the locules. This appearance, although not diagnostic, is typical of mucinous cystadenoma.

Ovarian cysts that appear unilocular, thin-walled, and anechoic except for a single thin septation or a small calcification in the wall are probably benign and can be followed in a manner similar to that for simple cysts.[5] Cysts that have features suggestive of, but not quite classic for, hemorrhagic cyst, endometrioma, or dermoid can be followed sonographically in 6 to 12 weeks in premenopausal patients.[5] Resolution within this time frame on follow-up ultrasound usually confirms hemorrhagic cyst, whereas lack of change generally excludes a self-limiting lesion such as hemorrhagic cyst.[5] Patients with persistence of such a cyst may benefit from additional imaging with MRI or surgical evaluation.[5]

Ovarian cysts with multiple thin (<3 mm) septations or seemingly solid components, but without detectable flow by color Doppler imaging, are also considered indeterminate masses.[5] Many of them represent benign neoplasms such as serous or mucinous cystadenomas/cystadenofibromas (see Fig. 30-12). Clot within a hemorrhagic cyst can occasionally simulate a solid component in a neoplasm, and, therefore, one should consider a follow-up sonogram in premenopausal patients with this finding, particularly when no flow is detected in the solid-appearing area by targeted Doppler interrogation. Otherwise, patients with such lesions should generally undergo additional imaging with MRI or surgical evaluation.[5] Collision tumors (two adjacent but histologically distinct tumors in the same ovary) can be problematic to recognize and diagnose by ultrasound, but are uncommon. Dermoid and cystadenoma are reported to be the most frequent combination of ovarian collision tumors.[83,84]

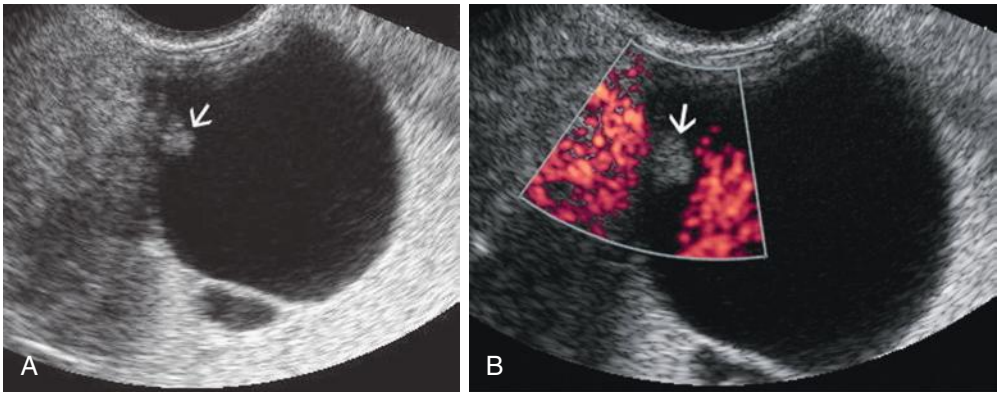

FIG 30-13 Serous cystadenofibroma. **A,** This predominantly cystic mass contains a small peripheral solid nodule (*arrow*). **B,** Power Doppler imaging shows no detectable flow in the small solid nodule (*arrow*). Color pixels in the anechoic fluid of the cystic mass are due to motion artifact.

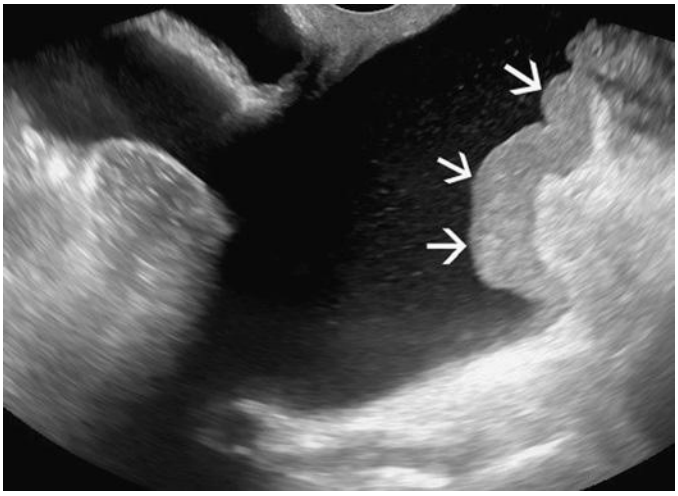

FIG 30-14 Peritoneal implants. Sagittal transvaginal ultrasound image demonstrates ascites and confluent solid peritoneal nodules (*arrows*) in the posterior cul-de-sac. This patient had metastatic serous cystadenocarcinoma of the ovary.

SOLID OVARIAN MASSES

Solid ovarian masses may be problematic to interpret. Some studies reporting that solid ovarian masses are associated with malignancy have included predominantly solid lesions, defining "solid" as those with up to 20% cystic component.[3,85] The reproducibility of classifying a mass with up to 20% cystic component is not clear, as the authors used a subjective assessment based on two-dimensional images.[3] Other investigators report that the majority of solid adnexal masses are benign, particularly if one considers ovarian lesions that are completely solid and includes the common occurrence of pedunculated uterine leiomyomas simulating solid ovarian masses (in those cases when the ipsilateral ovary is not identified).[6,86,87] Use of color or power Doppler imaging to demonstrate a vascular connection to the uterus can help prevent mistaking a pedunculated leiomyoma for a solid ovarian mass.[88,89] If that is not helpful, MRI is often useful for evaluating a solid adnexal mass of unclear origin.[90] Patients with solid adnexal masses that cannot be confirmed to be pedunculated uterine leiomyomas by means of sonography or MRI will generally need surgical consultation.

When a solid ovarian mass is seen, a sex cord–stromal tumor should be considered. Fibromas or fibrothecomas are the most commonly encountered type and usually occur in women aged 40 to 50 years old.[76] Ovarian fibromas or fibrothecomas typically appear as hypoechoic solid masses,[76] sometimes homogeneous and sometimes heterogeneous (Fig. 30-15). On occasion, they may demonstrate marked posterior acoustic shadowing, which is strongly suggestive of this diagnosis.[91] Other sex cord–stromal tumors, such as granulosa cell tumors and Sertoli-Leydig cell tumors, vary in appearance, some being completely solid and some with variable cystic components.[90,92-94] Of all ovarian masses, sex cord–stromal tumors are most commonly associated with hormone secretion. Granulosa cell tumors most commonly secrete estrogen, and Sertoli-Leydig cell tumors most commonly secrete androgens. Inhibin B levels are often elevated in patients with granulosa cell tumors and may be useful for reaching the diagnosis and for follow-up surveillance after surgery.[95] Patients with estrogen-secreting granulosa cell (or other) neoplasms may demonstrate associated findings due to hormonal effect, such as endometrial thickening or other endometrial abnormalities. Several published reports provide more detailed review of sex cord–stromal tumors.[76,90,92-94]

Most tumors in the surface epithelial group demonstrate cystic components, with variable amounts of solid tissue. Malignant epithelial tumors are infrequently completely solid.[96] Brenner tumors (also known as transitional cell tumors)[97] are uncommon surface epithelial tumors that often differ in appearance from other epithelial tumors; most are solid, and internal calcifications have been described.[98,99] The vast majority of Brenner tumors are benign.[97]

Of the germ cell neoplasms, dermoids are by far the most common type and have been discussed previously. Dermoids may infrequently be mistaken for solid ovarian tumors, but the majority demonstrate a cystic component. Malignant teratomas are rare and usually have a mixed cystic and solid appearance.[90] Most malignant teratomas are primary tumors occurring in young patients, usually younger than 20 years of age.[77] Malignant transformation (most commonly to squamous cell carcinoma) of a mature cystic teratoma is rare, usually occurring in patients older than 45 years of age, in masses larger than 10 cm, and often associated with elevated squamous carcinoma antigen levels.[68,77] It is unclear which sonographic features best predict malignant transformation of a teratoma. Isoechoic branching structures within the mass,[66] evidence of adjacent extension, and Doppler depiction of flow centrally[67] have been reported as features concerning for malignancy.[5] If one encounters a lobulated solid ovarian mass in a 20- to 30-year-old woman (Fig. 30-16), dysgerminoma should be

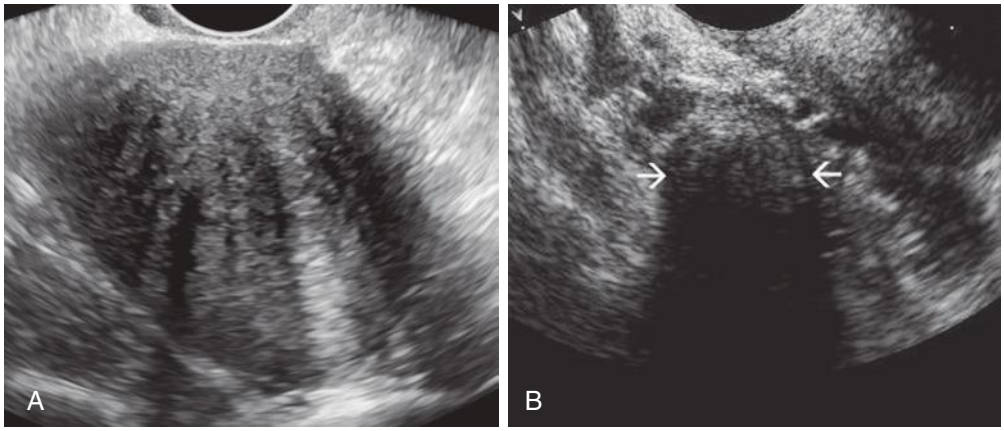

FIG 30-15 Ovarian fibroma. **A,** This fibroma appears as a slightly heterogeneous, completely solid mass. **B,** This fibroma, from a different patient, appears as a hypoechoic markedly attenuating solid mass (*arrows*). The marked sound attenuation strongly suggests the diagnosis of fibroma. Unlike acoustic shadowing posterior to a calcification or dermoid, there is no echogenic focus or bright reflector at the leading edge of a fibroma.

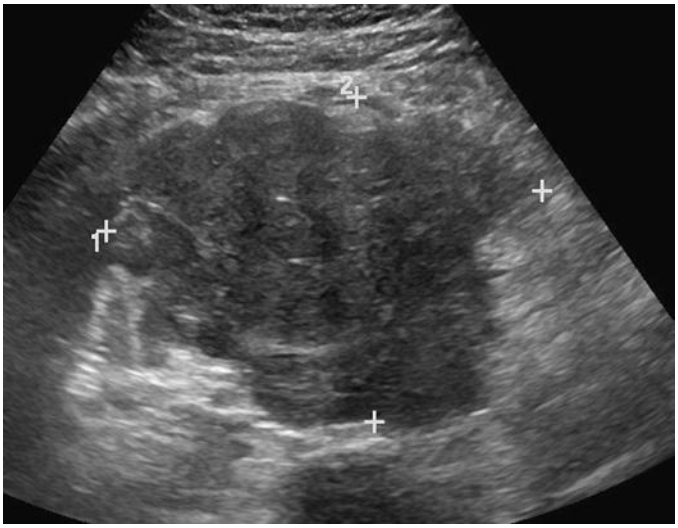

FIG 30-16 Ovarian dysgerminoma. Completely solid ovarian mass (*calipers*), with an irregular lobulated external contour, seen in a 20-year-old woman. The combination of sonographic appearance and patient age is suggestive of this diagnosis.

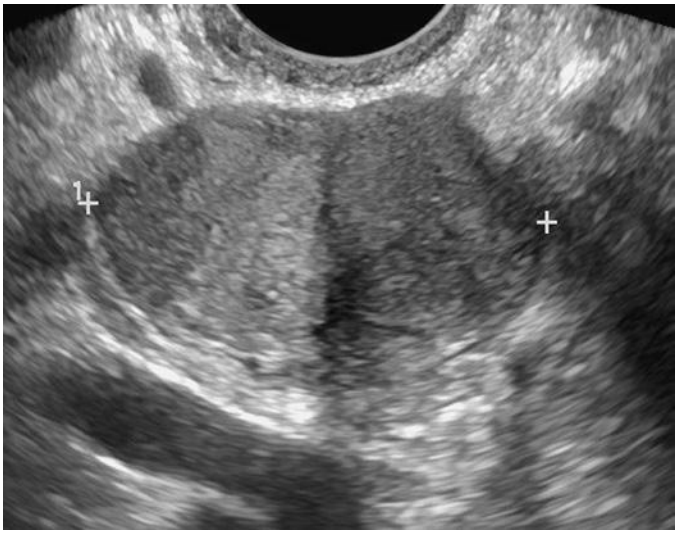

FIG 30-17 Metastasis to the ovary. This completely solid heterogeneous ovarian mass (*calipers*) was found to be metastasis from a pancreatic neuroendocrine tumor.

strongly considered.[100] It is the most common malignant germ cell neoplasm.[77]

Metastases to the ovary (Fig. 30-17) may occur with various primary malignancies but most commonly are related to breast, colon, or gastric carcinomas.[78,101,102] The finding of bilateral solid ovarian masses is worrisome, though not definitive, for metastases. It is often difficult to distinguish primary ovarian malignancy from metastasis to the ovary.[101] Metastases from breast carcinoma are usually solid masses[78,102] and typically occur only with advanced stage disease.[16] Some authors have found metastases from gastric carcinoma also to be predominantly solid, but this has not been observed by others.[78,102] Metastases from colorectal carcinoma tend to be multiseptated and larger than metastases from other primary tumors.[102] Bilateral ovarian masses are reported to occur most commonly with metastases from gastric carcinoma, compared with other primary tumors.[78]

When evaluating a solid adnexal mass, one needs to consider several possibilities, particularly given that a patient with a solid mass of ovarian origin usually needs surgical evaluation.[86] Many solid masses of ovarian origin, particularly those occurring in 40- to 50-year-old women, are fibromas or fibrothecomas. These benign ovarian neoplasms are typically treated surgically, in part to confirm the diagnosis. The differential diagnosis for a solid-appearing adnexal mass would include pedunculated uterine leiomyoma, acute or subacute hemorrhagic ovarian cyst (see Fig. 30-6) in which echogenic blood simulates solid tissue (considering this possibility in a premenopausal patient and prompting a short interval follow-up sonogram will usually confirm the diagnosis), and chronic endometrioma in which the degree of internal echogenicity simulates a solid mass (MRI may help confirm the diagnosis of endometrioma in this instance). A pedunculated uterine leiomyoma is the lesion most likely to simulate a solid ovarian mass, and this distinction is most problematic when the ipsilateral ovary is not identified. In such cases, color or power Doppler sonographic evaluation should be used to search for bridging vessels arising from the uterus; if seen, this finding can help confirm pedunculated leiomyomas.[88,89] If the diagnosis of pedunculated uterine leiomyomas cannot be reliably determined by ultrasound, then MRI is

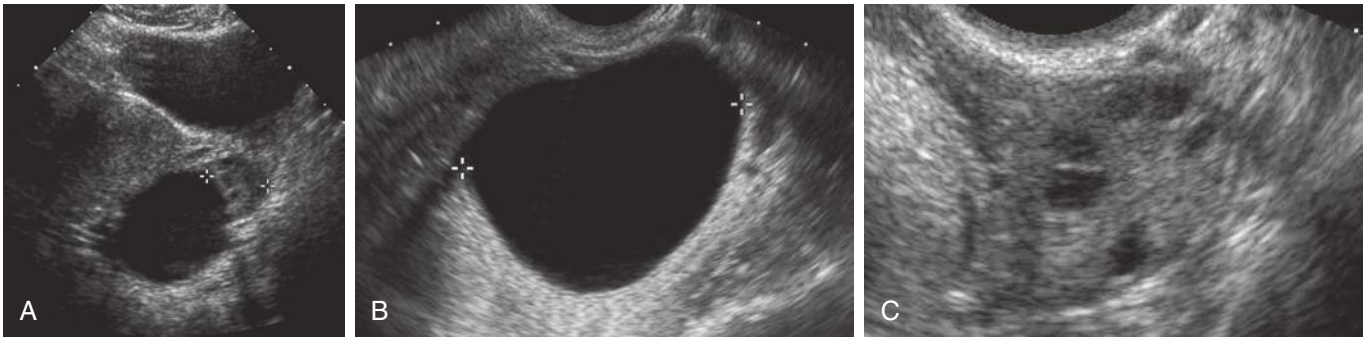

FIG 30-18 **A,** Transabdominal image of a paraovarian cyst that could be mistaken as arising from the ovary. **B,** Paraovarian cyst. **C,** Normal ovary. On transvaginal imaging (**B** and **C**), the cyst is seen as distinct from the normal ipsilateral ovary.

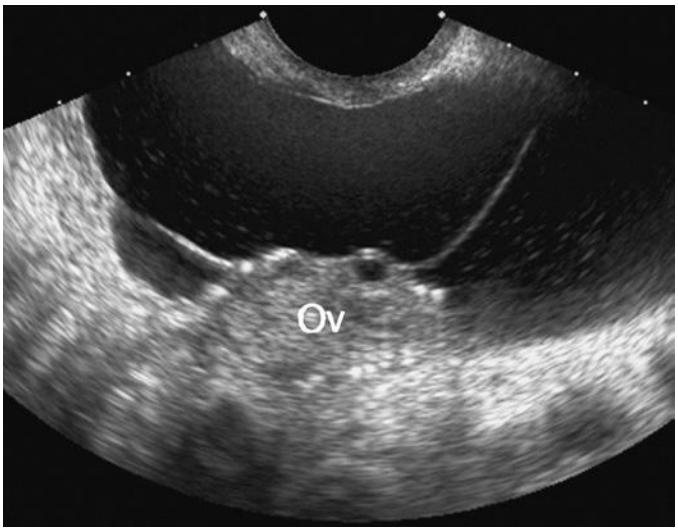

FIG 30-19 Peritoneal inclusion peritoneal inclusion cyst. Note the ovary (Ov) suspended among adhesions in the periphery of the pseudocyst.

often helpful. In the setting of bilateral solid ovarian masses, metastases should be considered if there is a known primary malignancy. The remainder of completely solid ovarian masses will likely represent one of various other uncommon neoplasms.

PITFALLS IN EVALUATING THE OVARY

A few potential pitfalls have been described herein. The possibility of an extraovarian origin of an observed adnexal mass, whether predominantly cystic or solid, should always be considered.[28,103] For example, a paraovarian cyst, which usually appears as a simple unilocular cyst, might be mistaken for an ovarian cyst but can be correctly recognized if seen separate from the ipsilateral ovary (Fig. 30-18). A peritoneal inclusion cyst often has internal septations and can mimic an ovarian neoplasm. Peritoneal inclusion cysts are thought to develop secondary to adhesions around the ovary, resulting in trapping of fluid originating from the ovary during ovulation. They often are irregular in configuration with acute angles and conform to the shape of adjacent structures. The ovary is typically found at the edge of the inclusion cyst (Fig. 30-19) or may appear suspended by septations within the cyst.[104,105] Risk factors for peritoneal inclusion cysts include prior pelvic surgery, endometriosis, trauma, and pelvic inflammatory disease. The possibility of a pedunculated uterine leiomyoma simulating a solid ovarian mass has been discussed.

Another potential pitfall relates to the use of Doppler imaging of the ovary to assess for flow in suspected solid tissue. Optimal Doppler technique (using low-volume, low-velocity settings) is important so that true intrinsic blood flow is detected (Fig. 30-20). However, there is also potential for false positive depiction of flow using Doppler imaging as a result of motion or noise, with possible resultant erroneous diagnosis of suspected malignancy. Distinct linear or curvilinear vessels within tissue shown by color or power Doppler imaging generally represent actual blood flow. However, if only a few isolated pixels of color are shown, this may represent noise/artifact. Therefore, confirmation of an arterial or venous waveform using spectral Doppler interrogation is important before concluding that blood flow is present.[6]

Other potential pitfalls include superior or lateral location of the ovary, such that it is not identified or is poorly visualized on transvaginal scanning.[106] Although transvaginal sonography is most often the optimal approach for imaging an ovarian mass, transabdominal scanning can be helpful and may be necessary in some cases. For example, transabdominal evaluation would be suggested when the ovary is not visualized, when there is high clinical suspicion for an adnexal mass but one is not identified with transvaginal scanning, or when an ovarian mass is so large it cannot be completely evaluated on the small field of view available with the transvaginal approach.[106]

Ovarian tissue situated between two adjacent simple cysts or follicles can simulate a septation and thus falsely raise concern for neoplasm.[28] It might be difficult to differentiate this pseudoseptation from a true intracyst septation, and Doppler depiction of flow is not reliable in making this distinction.[28] Occasionally, a small follicle or cyst may protrude into a larger follicle or cyst, producing a "cyst within a cyst" appearance, which may also simulate a septation. Awareness of these pitfalls/potential mimics and use of short interval follow-up ultrasound evaluation may be helpful and may avert misdiagnosis of ovarian neoplasm.

Sonography of ovarian dermoids can be difficult and problematic.[28,106] They can be overlooked if they consist predominantly of hyperechoic (fatty) tissue as this appearance might be mistaken for gas-filled bowel. Dermoids that are predominantly cystic with only a small peripheral hyperechoic component may be erroneously characterized if only the cystic component is seen and the small hyperechoic component is mistaken for adjacent bowel. Alternatively, a dermoid might be falsely diagnosed if an area of hyperechoic bowel or mesentery is misconstrued as an adnexal mass. Identification of a separate ipsilateral ovary can help avoid this error. Manipulation with the transducer might also prove useful, as bowel may change in shape or peristalse with extrinsic compression. In some challenging cases, further imaging with MRI or CT might be useful for clarification.

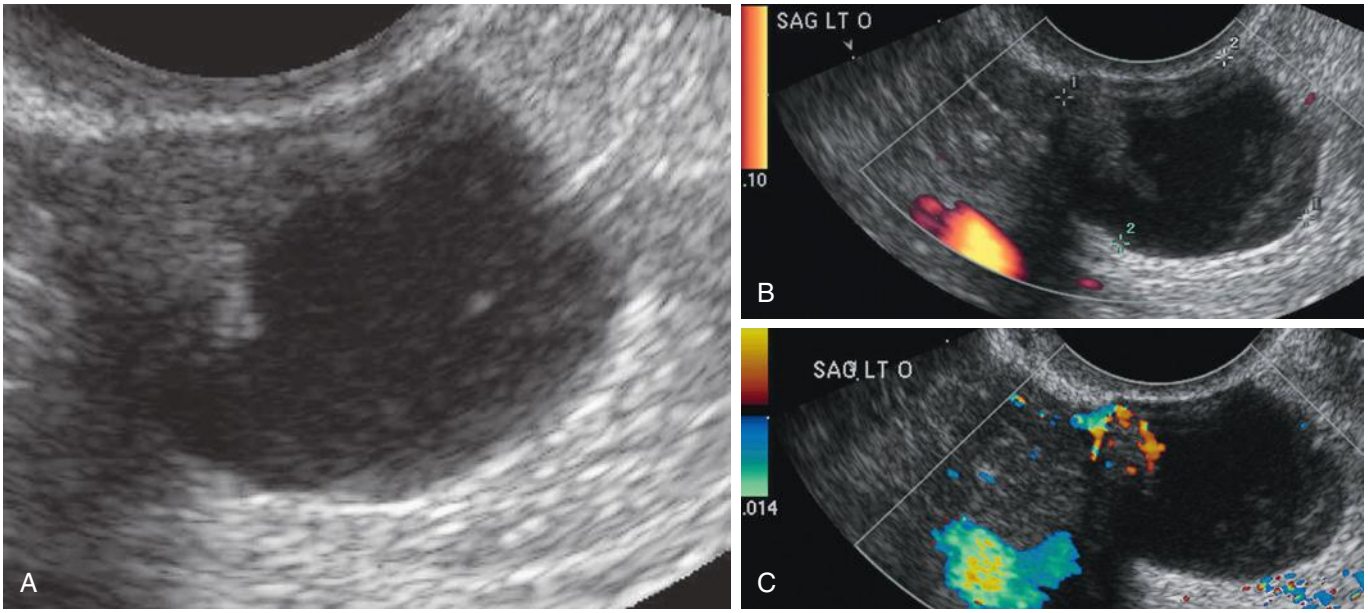

FIG 30-20 A, Cystic ovarian lesion with moderately echogenic, possibly solid mural component. **B,** No convincing blood flow is shown within cystic ovarian lesion on initial power Doppler sonographic images. **C,** Blood flow is shown within solid mural nodule using color Doppler sonography with adjusted settings (including low-scale pulse repetition frequency) optimized to detect low flow.

OVARIAN MASSES IN PREGNANCY

Many of the same principles discussed earlier regarding sonographic evaluation of ovarian masses also apply during pregnancy. For ovarian masses identified during pregnancy, the risk of malignancy is low and most patients can be managed conservatively with observation and surveillance with follow-up sonograms.[107] Recognition of a few ovarian lesions unique to pregnancy is important to help prevent misdiagnosis.

Theca lutein cysts are most frequently associated with gestational trophoblastic disease, but can also occur with normal singleton or multiple pregnancies and with pregnancies complicated by fetal hydrops. The term *hyperreactio luteinalis* has been used variably, often referring to theca lutein cysts in the absence of ovulation induction[108] and sometimes in the absence of gestational trophoblastic disease. Theca lutein cysts may simulate ovarian neoplasms because they usually appear as a multiseptated cystic mass or multiple adjacent cysts (Fig. 30-21). The bilateral nature of these masses and their known clinical associations usually help suggest the diagnosis.

Decidualized endometriomas are rare but are worth recognizing as they may simulate ovarian malignancy. These lesions are often cystic with small solid components with internal flow detectable by Doppler imaging (Fig. 30-22).[109-111] The endometrial changes that occur in response to progesterone in pregnancy (i.e., decidualization) can also affect ectopic endometrial tissue, resulting in growth of vascularized solid areas within in preexisting endometriomas.[110,112,113] Unfortunately, color Doppler imaging does not reliably distinguish decidualized endometriomas from ovarian malignancy, as both may have detectable flow by Doppler sonography.[113] Awareness of this entity and recommendation for follow-up sonogram, particularly when there is a known history of endometrioma, no other features of malignancy,[109] decrease in size of the mass on follow-up imaging,[110] or MRI showing that the solid tissue has signal characteristics similar to the endometrium[112] can help one suggest the correct diagnosis and possibly obviate the need for surgical evaluation.

FIG 30-21 Theca lutein cysts. This condition (*calipers*) is likely due to multiple adjacent cysts but can simulate a multiseptated cystic mass. This patient had gestational trophoblastic disease.

Luteoma of pregnancy is a rare benign disorder that has a nonspecific sonographic appearance, though most frequently appears solid.[108,114,115] It may be associated with maternal virilization; thus, the presence of hirsutism and elevated serum androgens can help suggest the diagnosis.[108,116]

SYNDROMES AND DISEASES ASSOCIATED WITH OVARIAN NEOPLASMS

There are a few uncommon syndromes associated with ovarian neoplasms. Some that occur in the setting of an ovarian abnormality

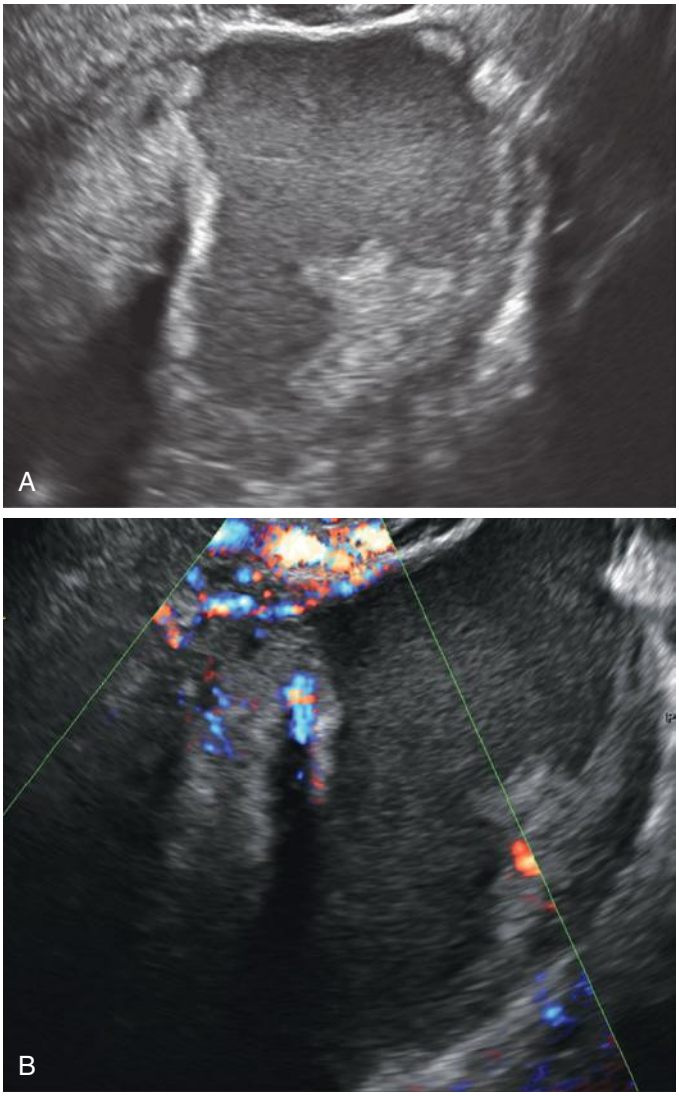

FIG 30-22 Decidualized endometrioma. **A,** Cystic ovarian mass in a pregnant patient contains diffuse homogeneous low-level internal echoes with an irregular solid-appearing peripheral component. **B,** Color Doppler imaging shows blood flow within the solid area, a finding that is often considered worrisome for malignancy. At surgery, this mass proved to be a decidualized endometrioma. (From Benacerraf BR, Goldstein SR, Groszmann YS: Endometriosis. In Benacerraf BR, Goldstein SR, Groszmann YS [eds]: Gynecologic Ultrasound: A Problem-Based Approach. Philadelphia, Elsevier, 2014, Fig. E4-5.)

include Meigs syndrome and ovarian remnant syndrome. Meigs syndrome refers to the rare association of a benign ovarian neoplasm (most frequently a fibroma) with ascites and sometimes with pleural effusion.[117] The presence of ascites may result in increased concern for possible malignancy. Ovarian remnant syndrome refers to the incomplete removal of ovarian tissue following oophorectomy, in association with a pelvic mass and pain.[69] Conditions that result in development of pelvic adhesions are risk factors for this syndrome and one should consider this diagnosis in a patient with the appropriate clinical history and a cystic adnexal mass.[69,118,119]

Other syndromes and diseases may place patients at increased risk for developing ovarian neoplasms. Patients with basal cell nevus (Gorlin syndrome) are at increased risk for ovarian fibromas, which may be bilateral and calcified.[117] Patients with Peutz-Jeghers syndrome may develop a rare neoplasm known as sex cord tumor with annular tubules (SCTAT).[120] Sonographically, SCTAT may appear as multiple small hyperechoic, possibly calcified masses.[121] There is a reported association with ovarian dermoids in patients with anti-*N*-methyl-D-aspartate receptor encephalitis, a serious and potentially fatal neurologic disease that has been underrecognized.[122] Awareness of the condition and this association should prompt a careful sonographic search, as detection and surgical removal of an ovarian dermoid improve outcomes.

Lynch syndrome and genetic mutations, such as *BRCA1* and *BRCA2*, are associated with increased risk of ovarian carcinoma, though currently there is no convincing evidence supporting the effectiveness of ovarian cancer screening even in these high-risk populations.[123] It is hoped that ongoing studies will provide additional information on the utility and impact of ovarian cancer screening for these patients. Several paraneoplastic syndromes are also associated with ovarian neoplasms.[124] Patients with dermatomyositis are at an increased risk of malignancy, and ovarian carcinoma is one of the most frequently associated cancers.[125] Sonography is used to evaluate these patients for possible ovarian neoplasms.

In women with clinical evidence of hyperandrogenism, sonography is often performed to evaluate for morphologic features of polycystic ovaries, the most common ovarian cause of this condition (discussed in Chapters 32 and 34). Less frequently, ovarian stromal hyperthecosis or androgen-secreting tumors may result in hyperandrogenism. Androgen-secreting lesions such as Sertoli-Leydig cell tumors should be considered in patients with markedly elevated androgen levels or rapid onset or progression of virilizing symptoms.[126] These tumors may be small and difficult to detect by any imaging method. Ovarian stromal hyperthecosis can occur with sonographically normal ovaries but should be considered in patients with suggestive clinical findings and mildly enlarged ovaries.[127]

SUMMARY

Recognition of normal ovarian sonographic features, such as a dominant follicle and corpus luteum, is important so as not to mistake them for pathologic findings. Most ovarian masses are benign, and the majority demonstrates sufficiently typical sonographic appearances such that they can be reliably characterized by ultrasound. The infrequent ovarian malignancy can also usually be recognized and diagnosed based on typical ultrasound features. A small minority of ovarian masses have indeterminate sonographic findings and generally need to undergo further evaluation by means of follow-up sonography, MRI scan, or surgical evaluation.

Ultrasound Evaluation of the Fallopian Tube

Mindy M. Horrow

SUMMARY OF KEY POINTS

- Normal fallopian tubes are difficult to visualize with ultrasound unless surrounded by small amounts of free peritoneal fluid.
- Classic sonographic signs that help distinguish a dilated fallopian tube from other cystic adnexal masses include waist, incomplete septation, cogwheel, and beads on a string signs.
- Acute pyosalpinx is diagnosed on ultrasound examination by the finding of a dilated, tubular adnexal structure filled with complex fluid and a thick, hyperemic wall.
- A tubo-ovarian abscess (TOA) typically presents as a complex adnexal mass with solid and cystic components, thick walls, hyperemia, and an indistinguishable ovary.
- Hematosalpinx secondary to endometriosis appears on ultrasound images as a dilated tubular adnexal structure filled with fine low level echoes.
- Isolated tube torsion is a rare event, often presenting as a dilated fluid-filled tubular structure with a V-shaped configuration or beak-like pointed narrowing at the twisted edge of the tube and is often found in an unusual location.
- The classic clinical presentation of primary fallopian tube malignancy consists of intermittent bloody vaginal discharge, colicky pain relieved by discharge, and a pelvic mass.
- Tube patency can be evaluated sonographically using agitated saline or ultrasound contrast agents.

OUTLINE

Unlike the uterus and ovaries, the normal fallopian tube is usually not visible on ultrasound images, and, therefore, documentation of the fallopian tube is not a standard requirement for pelvic sonography. Indeed, when visualized, the fallopian tube is usually dilated or thickened and hence abnormal. Further confounding the evaluation of the fallopian tubes is the relative difficulty in distinguishing an abnormal fallopian tube from a complex cystic ovarian mass. The goals of this chapter are to describe the appearance of the normal fallopian tube; review the pathologic processes that result in abnormalities of the tube, both benign and malignant and either acute or chronic; and demonstrate a variety of sonographic findings that can aid the sonographer in correctly distinguishing tube versus ovarian origin of an adnexal mass.

EMBRYOLOGY AND NORMAL ANATOMY

The fallopian tube serves to connect the ovary to the uterus, allowing passage of the fertilized oocyte into the endometrial cavity. Embryologically, the paired paramesonephric ducts develop from coelomic epithelium during the 5th to 6th weeks of gestation. As the caudal portions fuse to form the uterus, the cranial aspects become the fallopian tubes with the funnel-shaped end remaining open to the peritoneum. The normal fallopian tubes are 10 to 12 cm long and between 1 to 4 mm in diameter and are located in the mesosalpinx, a fold of the peritoneum within the broad ligament.[1]

The fallopian tube is divided into four anatomic components (Fig. 31-1). The interstitial segment is intramural and found within the uterine cornua near the fundus. The interstitial segment courses from the serosal surface of the uterus through the myometrial wall to open into the endometrial cavity. It is the shortest (2 cm) and narrowest (1 mm) portion of the fallopian tube. The isthmic segment is closest to the uterus with a length of approximately 3.5 cm and a diameter of 2 mm. The ampulla of the tube is the most lateral portion of the fallopian tube as well as the widest and longest section measuring 6 to 7.5 cm in length. The ampulla terminates at the funnel-shaped infundibulum, which has a fimbriated end that drapes over the ovary. Histologically, the plicae or folds of the fallopian tube are more numerous and complex in the ampulla and infundibulum where the ciliated columnar epithelial cells are also more numerous. Peg cells located between the ciliated cells produce the tubular fluid, which provides nutrients for the spermatozoa and oocyte. This fluid progresses toward the lateral end of the fallopian tube near the ovary in the opposite direction of the motion of the cilia and is excreted into the peritoneal cavity, accounting for the frequent finding of a small

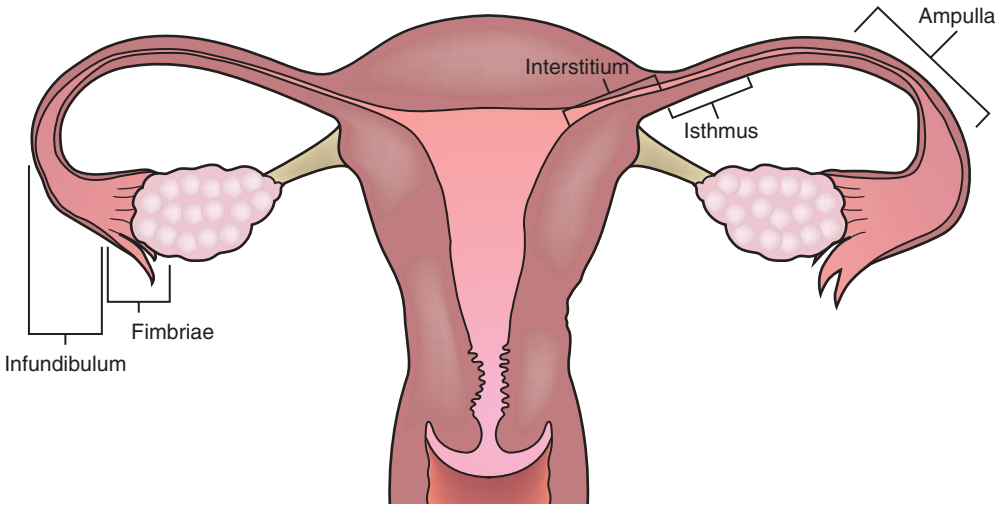

FIG 31-1 Schematic diagram demonstrating the anatomy of the normal fallopian tube.

amount of simple free fluid in the female pelvis at all stages of the menstrual cycle.[2] The fallopian tube functions to capture the released ovum from the ruptured ovarian follicle and provides a hospitable environment for fertilization and subsequent transfer of the fertilized ovum to the uterus as it grows and differentiates into the blastocyte. The ovum is propelled through the tube toward the uterus by the ciliated epithelium and mucosal plicae as well as muscular contractions in the wall of the tube.

Normal fallopian tubes can occasionally be visualized with transvaginal sonography, especially when there is some fluid in the adnexal regions and minimal pressure is exerted on the probe. The normal fallopian tube appears solid, separate from the ovary and isoechoic to the uterus (Fig. 31-2). The presence of a paratubal cyst, also known as a hydatid of Morgagni, may help localize the tube. These paratubal cysts are usually müllerian remnants of the paramesonephric duct. Most often, they are small, unilocular, simple cysts located at the fimbriated end of the fallopian tube between the tube and the ovary (Video 31-1). An echogenic fat plane between the cyst and the ovary as well as absence of a surrounding rim of ovarian parenchyma serve to differentiate a paratubal cyst from an exophytic ovarian cyst (Fig. 31-3). Simple paratubal cysts are considered a benign finding, and the vast majority of paratubal cysts are of no clinical significance. However, a large paratubal cyst can rupture or serve as a lead point for isolated tube torsion.[3] Rarely, papillary projections in a large (>5 cm) paratubal cyst will indicate malignancy, usually a borderline tumor. Other congenital anomalies of the fallopian tube include hypoplasia, aplasia, ectopic location, and herniation (with the ovary) and are much less common.[4]

SONOGRAPHIC SIGNS OF ABNORMAL FALLOPIAN TUBES

A variety of sonographic characteristics and signs have been described to help distinguish a dilated fallopian tube from an ovarian mass or other tubular structures in the pelvis such as bowel loops, hydroureter, and varices. Peristalsis, connection to other loops of bowel, as well as the classic striated echopattern or "gut signature" of the bowel wall will serve to distinguish a fluid-filled loop of bowel from a dilated fallopian tube. A dilated ureter can often be traced to the ureterovesicular junction (UVJ) on transabdominal or transvaginal sonography, and color Doppler should always be used to evaluate any apparent fluid-filled or cystic structure to exclude vascular pathology such as ateriovenous malformations or pelvic varices (Fig. 31-4). Asking the patient to perform a Valsalva maneuver may increase flow in a pelvic varix, making it easier to confirm on color Doppler imaging. Identification of the ovary that is clearly separate from an adnexal mass is the single most helpful finding in distinguishing an abnormal or dilated fallopian tube from a complex cystic ovarian lesion. As the fallopian tube dilates, it often develops an S, U, V, C, or serpiginous shape (Fig. 31-5A and B). The ampullary segment is often wider than the isthmus, and an abrupt transition in diameter between the two segments is often observed (Fig. 31-5C). A waist sign, consisting of diametrically opposed indentations in the wall[5] (Fig. 31-5D), may be observed, usually at the junction of the ampullary portion of the tube with the much wider fimbria. If the dilated tube folds back on itself, the juxtaposition of the two inner walls will create the incomplete septation sign (Fig. 31-5A, E, F, and G), consisting of a linear echogenic protrusion arising from one wall but not reaching the opposite wall. Both cine clips and two-dimensional and three-dimensional reformats can help display the serpiginous nature of the dilated tube (Video 31-2). When the thickened plicae or endosalpingeal folds are visible projecting into the lumen, one may observe numerous 2- to 3-mm echogenic mural-based masses projecting into the lumen of the dilated tube, creating the cogwheel sign (Fig. 31-5H and I) or the beads on a string sign (Fig. 31-5J) as tube markers.[6] These signs are more frequently identified when the tube is only mildly dilated. The wall of the tube is thicker with the cogwheel sign and thinner with the beads on a string sign, with the latter more likely to be seen with chronic inflammation. As the tube becomes increasingly dilated, the thickened plicae are effaced and the hydrosalpinx assumes a more nonspecific cystic appearance with a thin, regular wall. The combination of a tubular shape, waist sign, and visualization of the ovary separate from an adnexal mass has been reported to be the most specific constellation of ultrasound findings to differentiate a dilated fallopian tube from a complex cystic mass of ovarian origin.[5,7] It should be appreciated that visualization of a hydrosalpinx indicates that the tube is blocked, most often secondary to adhesions.

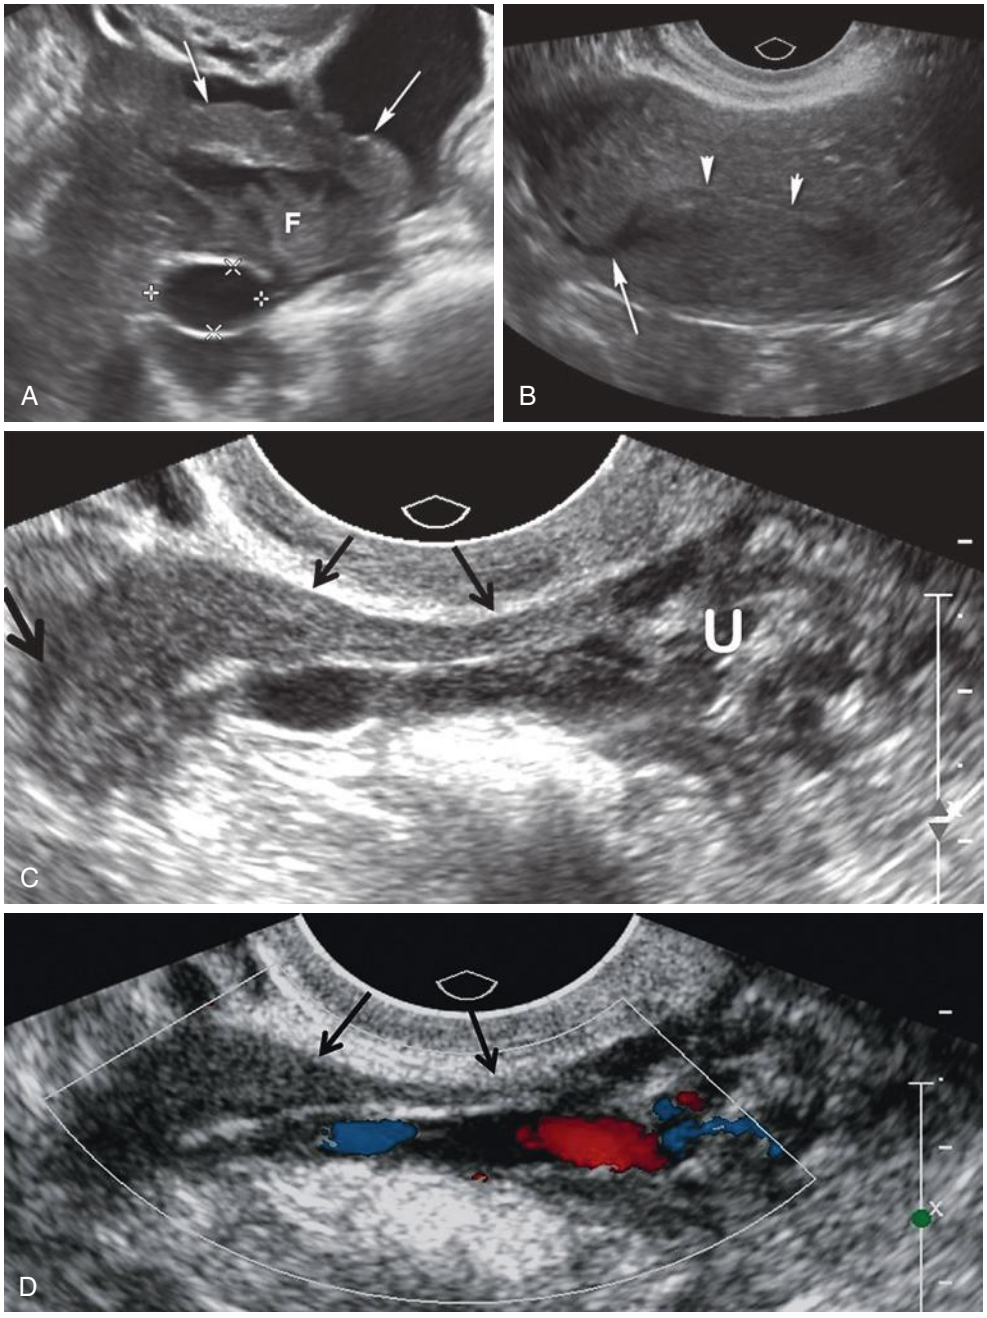

FIG 31-2 Normal fallopian tubes. **A,** A small amount of anechoic free fluid surrounds the fallopian tube (*arrows*). Note anechoic paratubal cyst (*calipers*) adjacent to the fimbriated end (F). **B,** A partial coronal view of the uterine fundus demonstrating a trace amount of fluid (*arrow*) in the interstitial portion of the right fallopian tube; endometrium is indicated by *arrowheads*. **C,** Normal fallopian tube (*arrows*) coursing from the cornua of the uterus (U) above the anechoic uterine vessels to the right adnexa. Note that the more medial isthmic portion (*thin arrows*) of the tube is the thinnest segment, whereas the fimbriated end (*thick arrow*), which usually sits above or "caps" the ovary, is the thickest segment. **D,** Color Doppler image of the same patient in C demonstrating the fallopian tube (*arrows*) above the uterine vessels (*blue/red*).

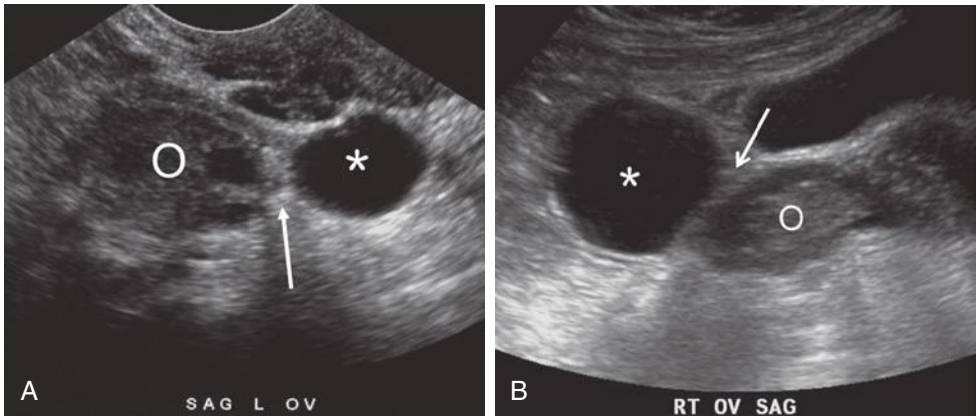

FIG 31-3 Paratubal cysts. **A** and **B,** Two different patients with paratubal cysts (*asterisks*). Note echogenic fat plane (*arrows*) clearly separating the paratubal cysts from the adjacent ovary (O).

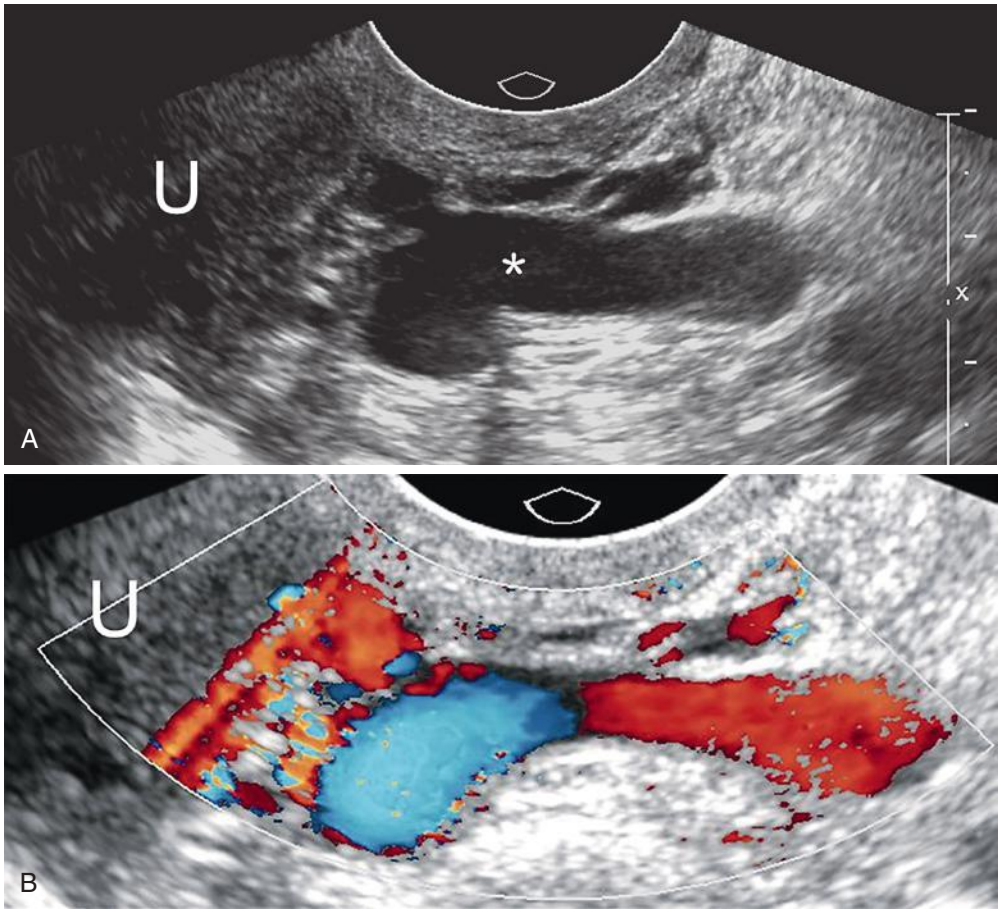

FIG 31-4 Pelvic varix mimicking hydrosalpinx. **A,** Gray-scale image demonstrating an anechoic serpiginous tubular structure (*asterisk*) adjacent to the left uterine cornua (U) that could easily be mistaken for a hydrosalpinx. However, color Doppler imaging (**B**) demonstrates that the structure fills in with color, consistent with a pelvic varix. Uterine cornua (U). (From Baltarowich OH, Scoutt LM: Avoiding pitfalls in transvaginal sonography of the female pelvis. Ultrasound Clin 5:177-193, 2010, used with permission.)

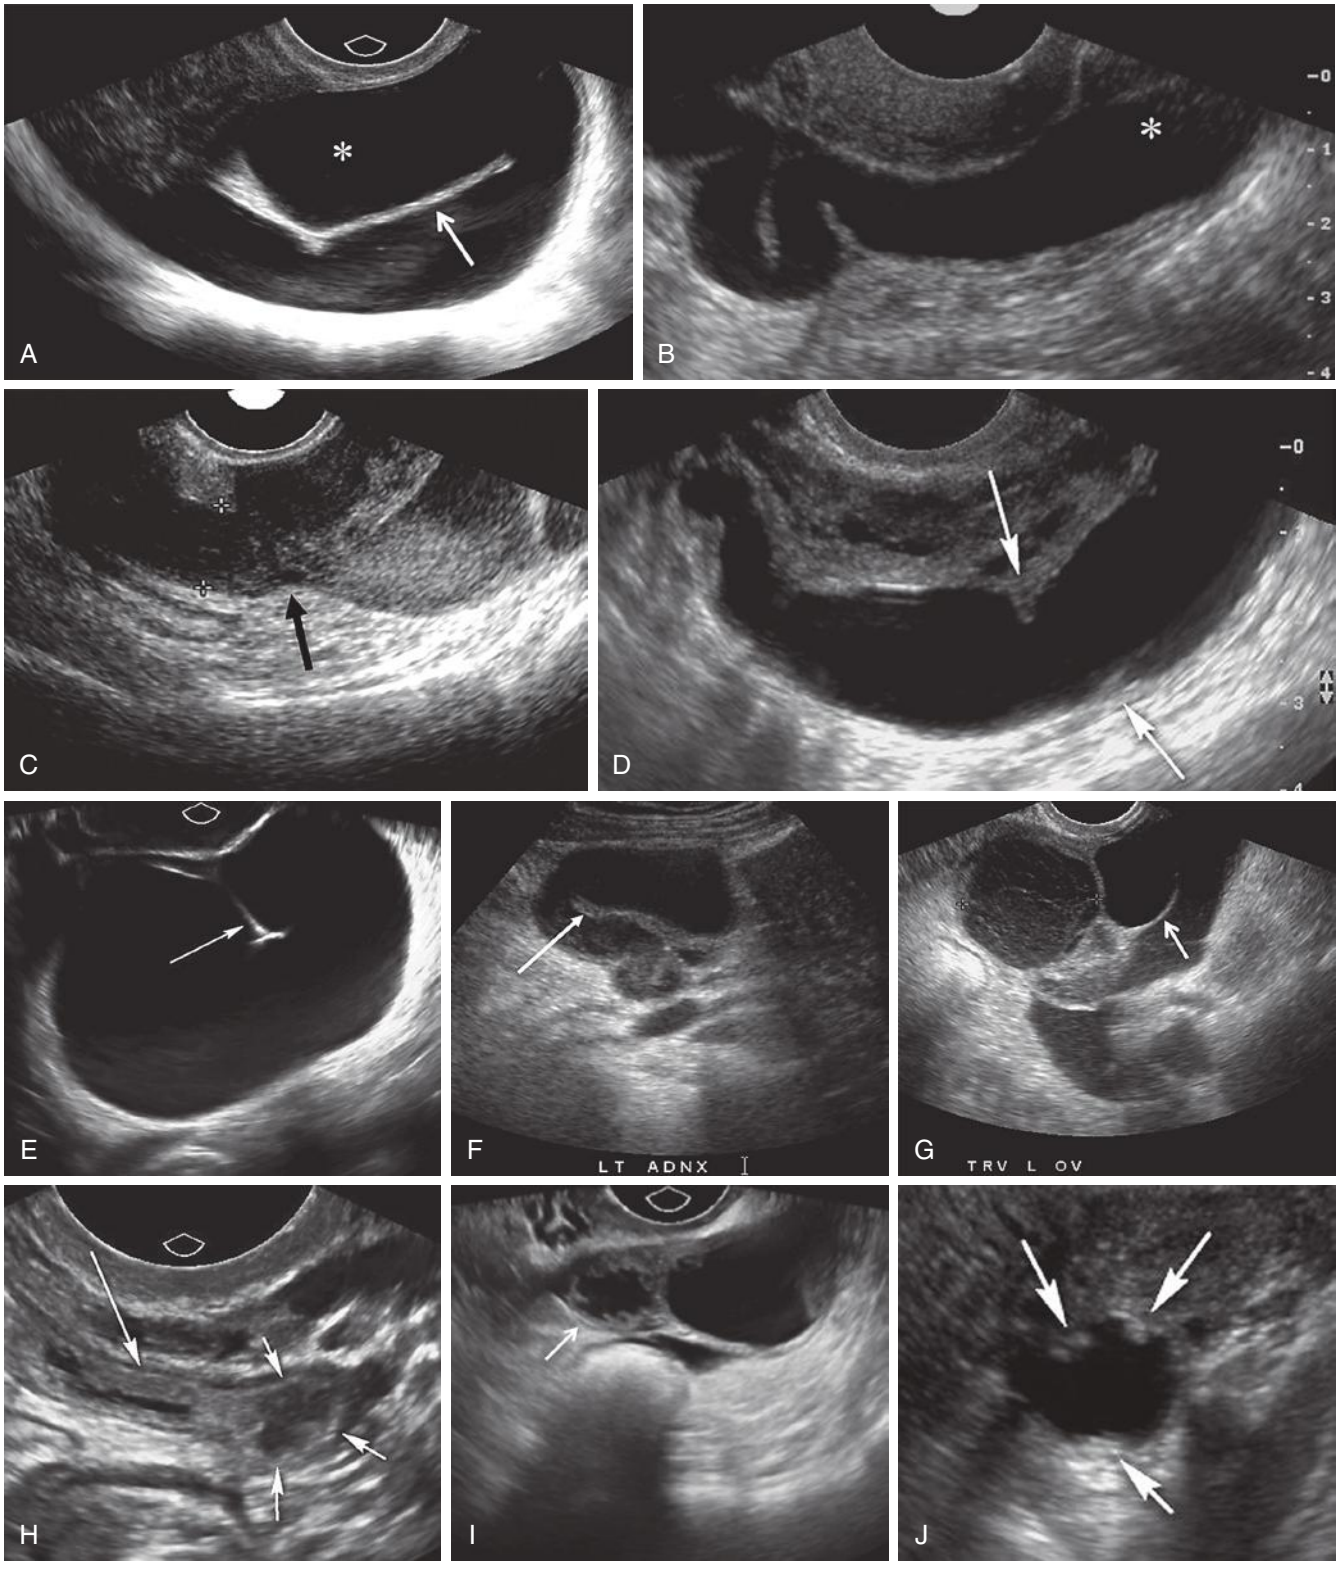

FIG 31-5 The varied ultrasound image appearance of hydrosalpinx. **A,** Dilated anechoic tubular left adnexal structure in a U shape is consistent with hydrosalpinx. Note that the ampullary end (*asterisk*) anteriorly is wider than the isthmic portion of the tube, which is more posterior on this image. The linear echogenic structure (*arrow*) between the ampullary and isthmic segments represents the two juxtaposed inner walls of the tube as it folds on itself and has been described as the "incomplete septation sign." Unlike a true septation, the incomplete septation of a folded tube will not extend from wall to wall and the lumen of the tube will remain open around the free edge. This sign helps to differentiate a folded hydrosalpinx from a complex, cystic adnexal mass. **B,** Serpiginous or S-shaped hydrosalpinx. The more lateral ampullary end

FIG 31-5, cont'd (*asterisk*) is wider than the isthmus. **C,** Often there is an abrupt transition in diameter (*arrow*) between the wider ampullary portion of the tube and the isthmus (*calipers*) as in this patient with a dilated left fallopian tube containing internal echoes consistent with pyosalpinx. **D,** Waist sign: Note indentations (*arrows*) on opposing sides of the dilated fallopian tube believed to be due to thickening of the endosalpingeal folds. **E,** Incomplete septation sign: Note the thin linear echogenic structure (*arrow*) appearing to protrude into the dilated fallopian tube. This represents the apposition of two segments of the inner wall of the fallopian tube as it folds on itself and, therefore, does not extend across the entire diameter of the dilated fallopian tube. This appearance serves to differentiate a folded fallopian tube from a complex cystic adnexal mass with a true septation that would extend from wall to wall. **F,** Incomplete septation sign (*arrow*) in a second patient with a serpiginous dilated fallopian tube containing low level internal echoes consistent with pyosalpinx. The more dilated ampullary segment is located anteriorly. **G,** Incomplete septation sign (*arrow*) in another patient with pyosalpinx. Note the left ovarian cyst (*calipers*) with fine reticular pattern of internal echoes, likely representing hemorrhage or possibly infection. **H,** Cogwheel sign: Note the slightly dilated, thick-walled tortuous fallopian tube visualized on this image in both long axis (*long arrow*) and in cross section (*short arrows*). Note several mural-based small nodules on cross section representing thickened endosalpingeal folds. This appearance has been termed the cogwheel sign. **I,** Cogwheel sign: Note numerous echogenic, thickened, endosalpingeal folds regularly spaced around the periphery of the dilated fallopian tube in this patient with chronic salpingitis. In cross section (*arrow*), these thickened folds may appear nodular, mimicking cystic ovarian malignancy except that these folds are so regularly spaced and symmetric. **J,** Beads on a string sign: Note the slightly dilated thin-walled fallopian tube in cross section with multiple mural-based echogenic nodules (*arrows*) due to thickening of the endosalpingeal folds, resulting in the appearance of "beads on a string." (J courtesy of Dr. Margarita Revzin, Yale University School of Medicine, New Haven, CT.)

PELVIC INFLAMMATORY DISEASE

Pelvic inflammatory disease (PID) is usually caused by sexually transmitted organisms that ascend from the vagina and cervix to the upper female genital tract. Approximately 770,000 acute cases are reported yearly in the United States. The number of subacute and chronic cases is unknown. Risk factors for PID include young age, multiple sexual partners, lack of barrier contraception, low socioeconomic class, and smoking.[8-10] The inciting organisms are usually *Chlamydia trachomatis* and *Neisseria gonorrhoeae*, which cause epithelial damage to the tubes, allowing superinfection with polymicrobial opportunistic organisms. The infection initially ascends from the cervix to involve the endometrium causing endometritis and progresses to involve the fallopian tubes resulting in tube inflammation. Tube adhesions may form causing obstruction leading to hydrosalpinx, hematosalpinx, or pyosalpinx. Eventually the infection will spread to the ovary and peritoneum causing uterine serositis, peritonitis, inflammation of the pelvic fat, tubo-ovarian complex (TOC), and finally tubo-ovarian abscess (TOA). Symptoms include pelvic pain, cervical motion tenderness, purulent vaginal discharge (which may be foul smelling), fever, leukocytosis, and elevated erythrocyte sedimentation rate or C-reactive protein level.[11] The degree of pelvic pain is highly variable. Inflammation around the liver can result in right upper quadrant (RUQ) pain, termed Fitz-Hugh–Curtis syndrome. Complications following PID include pelvic abscess, infertility (20%), ectopic pregnancy (9%), and chronic pelvic pain (18%).[12-14]

Because symptoms are insufficient for diagnosis in up to 50% of cases and often overlap with other pelvic conditions such as appendicitis, ruptured or hemorrhagic ovarian cysts, and diverticulitis, imaging is frequently performed. In addition, imaging may be required if the patient is not responding appropriately to antibiotic therapy, particularly if an abscess is suspected. Sonography should be the first imaging study obtained, although occasionally computed tomography (CT) or magnetic resonance imaging (MRI) may be required to assess the full extent of an abscess, especially when rupture is considered likely. Despite the frequent use of ultrasound to assess patients with PID, there are no large trials evaluating the sensitivity and specificity of sonography for the diagnosis of PID. However, sonography likely has relatively low sensitivity for detecting mild abnormalities and is nonspecific for many others. When the fallopian tubes become involved, the specificity of sonography improves.[15,16] Transvaginal sonographic imaging is considered most useful for detecting tube abnormalities and to identify the ovaries, with transabdominal imaging most often used to evaluate large pelvic abnormalities and to assess the full extent of ascites.

Cervicitis is typically occult on ultrasound examination and is diagnosed by direct visualization and culture. Endometritis will appear on ultrasound imaging as indistinct thickening of the endometrium, which is often extremely vascular. The endometrial cavity may be distended with fluid, hemorrhage, and even air, which is characterized on sonography by the presence of echogenic foci with dirty posterior shadowing. However, there is overlap in the sonographic appearance as well as the clinical presentation of endometritis with normal postpartum changes and retained products of conception. In addition, endometritis may develop postpartum or in patients with retained products of conception.

Involvement of the fallopian tube or ovary is the hallmark of PID and results in a variety of sonographic findings. Salpingitis manifests as mild thickening and hyperemia of the tube (Fig. 31-6) and peritubal inflammation. Sonographically, these changes result in a prominent or thick tube that is thus more easily visualized, and hyperemia is typically observed on color Doppler imaging. Increased echogenicity and vascularity in the surrounding pelvic fat is common as a result of inflammation or infection (Fig. 31-7).[17] Small amounts of adjacent complex free fluid may be present and the ovaries may appear enlarged and edematous with an appearance simulating polycystic ovary disease.[18]

Pyosalpinx occurs when adhesions obstruct the fimbriated end of the tube allowing pus to accumulate within the lumen (Fig. 31-8). Fluid debris levels are common, although intraluminal gas is rare. The wall of the tube becomes thick and vascular. Thickening of the endosalpingeal folds may cause the tube wall to appear nodular with numerous 2- to 3-mm nodules projecting into the lumen, the previously described cogwheel sign (see Fig. 31-5J). As the infection progresses, the ovary may become adherent to and surrounded by the

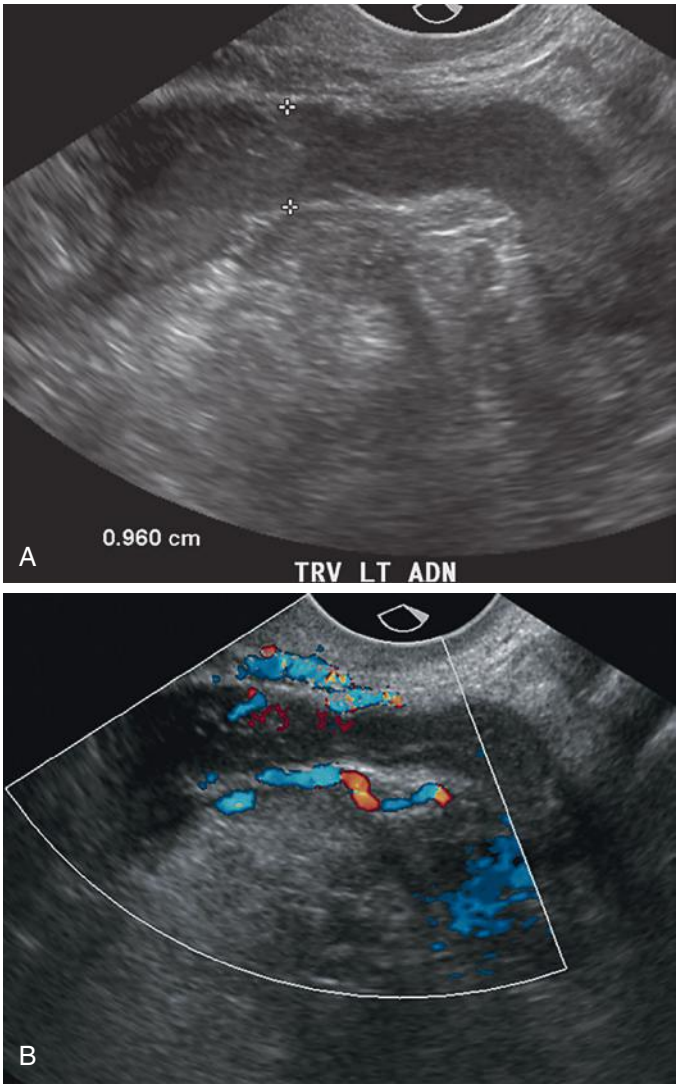

FIG 31-6 Salpingitis. Note thickened (0.96 cm) left fallopian tube (*calipers*) on gray-scale image (**A**) in a patient presenting with pelvic pain, fever, and vaginal discharge. Color Doppler image (**B**) demonstrates increased vascularity in the wall of the tube and in the surrounding inflamed peritubal fat. There is no discernible fluid in the lumen of the tube.

inflamed tube, and eventually pus will pour out of the tube and engulf the ovary. The ovary is initially protected from infection by its thick fibrous capsule. If the ovary (with or without the tube) is clearly distinguishable from the surrounding inflamed and infected tissues, the mass is termed a TOC (Fig. 31-9). Eventually the fibrous capsule will break down and the ovarian parenchyma itself will become infected and necrotic resulting in formation of a TOA and loss of the normal sonographic ovarian architecture. The resulting complex mass is usually multilocular with solid and cystic components, increased vascularity, thickened septa, and sometimes mural nodularity (Figs. 31-10 and 31-11). An acute TOA is usually quite tender on examination. The ovary will not be identifiable within the mass, although the dilated fallopian tube may be at least partially visible (Fig. 31-12). Distinguishing between a TOC and a TOA is clinically important because a TOC will respond better to antibiotic therapy. Clinical findings may not always correlate with the degree of sonographic abnormality. Women with only peritoneal inflammation but without sonographic evidence of pyosalpinx or TOA may be extremely symptomatic owing to inflammation of the peritoneal surface, whereas patients with recurrent PID and previously damaged tubes may have a very abnormal sonogram but only mild symptoms. Sonographic findings of a TOA are somewhat nonspecific, and endometriomas, ovarian malignancy, and periappendiceal and diverticular abscess may have a very similar appearance[19] (Fig. 31-13). Occasionally acute appendicitis may mimic the clinical presentation of PID and can be diagnosed on transvaginal ultrasound examination. Unilaterality of the right-sided dilated tubular structure, clear separation from the normal ovary, the presence of an appendicolith, and absence of the incomplete septation, waist, or cogwheel signs can be helpful in differentiating acute appendicitis from a pyosalpinx (Fig. 31-14).

Little is known about the sonographic response to medical therapy for PID, particularly how long it may take for acute abnormalities to resolve.[20] In this author's experience, complex fluid, inflammation and minimally dilated tubes can resolve in several days, whereas a large pyosalpinx or TOA may require weeks to months to resolve. Some reports indicate that patients with a normal sonogram initially may, over time, develop a hydrosalpinx as a result of development of adhesions. Persistent inflammatory masses most likely signify an incompletely treated infection, especially if vascular. Although hydrosalpinx most commonly develops secondary to PID, tube ligation, ovulation induction, tumors, and endometriosis may all lead to hydrosalpinx formation. Occasionally hydrosalpinx occurs after hysterectomy if the fallopian tubes have not been removed.[21]

UNCOMMON TUBE INFECTIONS

A variety of tube infections occur by routes other than those of ascending sexually transmitted diseases. Tuberculosis reaches and infects the fallopian tubes most commonly via hematogenous or lymphatic routes and occasionally via direct contiguous peritoneal spread. Clinical manifestations include acute and chronic pain, unexplained infertility, and vaginal bleeding. Most commonly the tubes become thick and hyperemic rather than markedly dilated and may progress to a TOA or pelvic abscess (Fig. 31-15).[22]

Tube actinomycosis is most commonly caused by infection of the female genital tract by *Actinomyces israelii*, an opportunistic gram-positive bacterium typically introduced by foreign bodies (such as intrauterine devices [IUDs]), surgery, bowel perforation, and trauma. It is estimated that 25% of IUDs become colonized with *Actinomyces* and that 2% to 4% may develop an infection requiring treatment.[23] The presence of an IUD and pelvic abscess should suggest this diagnosis.[24] Actinomycosis is an aggressive and infiltrative infection, likely due to the proteolytic enzymes produced by the bacteria. The hallmark of this infection is extensive inflammatory infiltration with spread across tissue planes often with fistula and abscess formation (Fig. 31-16). Thus, CT is the modality of choice to determine extent of disease. Treatment involves removal of the IUD, administration of penicillin, and abscess drainage. If the infection is severe, hysterectomy or salpingo-oophorectomy may be required.

Xanthogranulomatous inflammation, which occurs in many organs, most notably in the kidney and gallbladder, has rarely been reported in the female genital tract. It may affect the endometrium, ovary, or fallopian tube.[25] The likely cause is subacute infection with obstruction of the fallopian tube. The characteristic histologic finding of all xanthogranulomatous infections is the presence of lipid-laden macrophages and multinucleated giant cells that replace the destroyed parenchyma of the involved organ. The sonographic and CT appearance of xanthogranulomatous TOA has been reported as a mixed solid and cystic adnexal mass, typically unilateral, with a fairly nonspecific

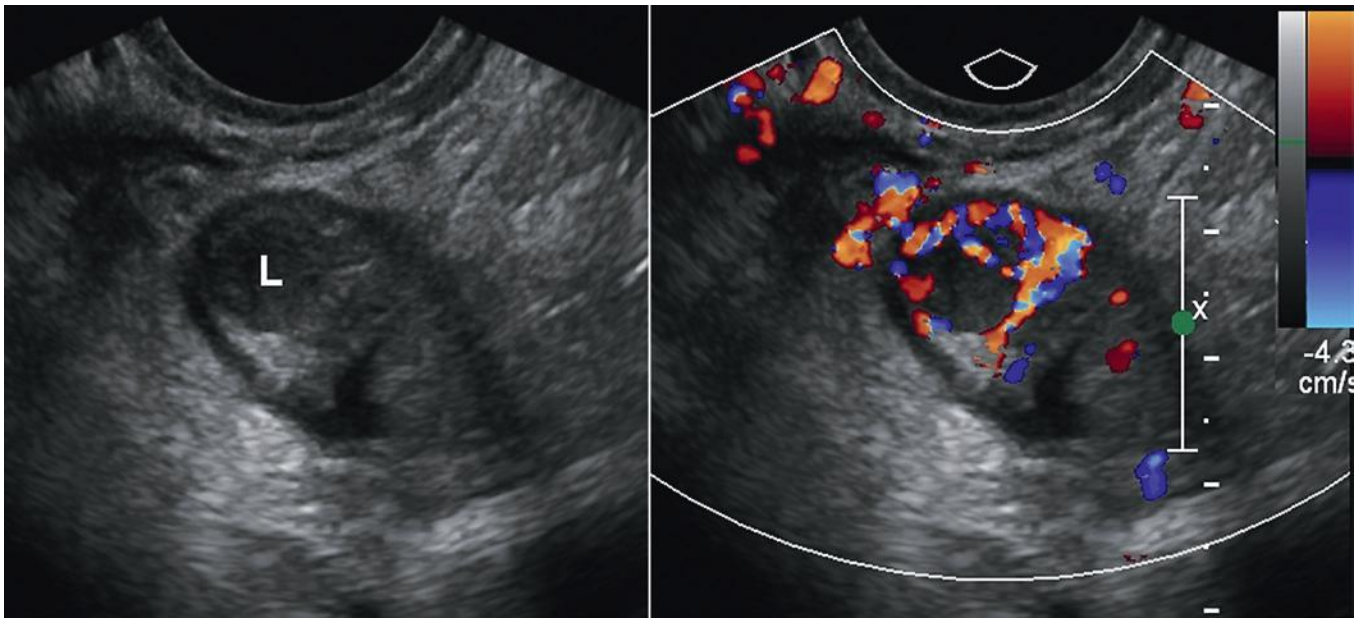

FIG 31-7 Acute salpingitis: Split screen image of the fallopian tube in cross section on gray-scale (*left*) and color Doppler (*right*). The wall of the fallopian tube is thick and hyperemic with a small amount of complex fluid in the lumen (L). The surrounding fat is echogenic and vascular consistent with inflammation.

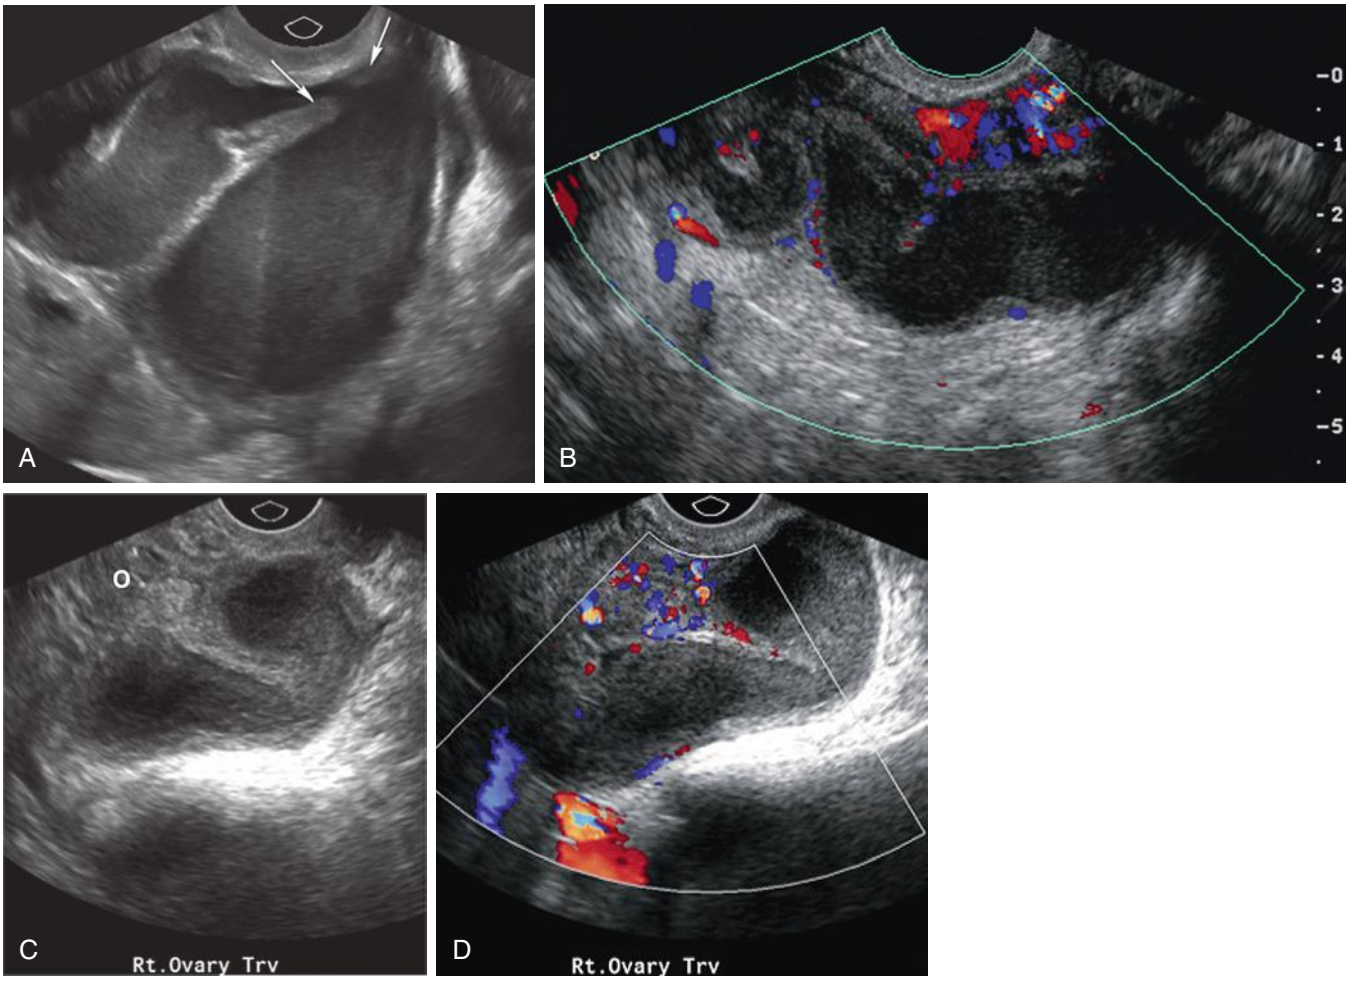

FIG 31-8 Pyosalpinx. **A,** The left fallopian tube in a patient with pyosalpinx is markedly dilated and filled with echogenic material, consistent with pus, hemorrhage, or debris. Note fluid/fluid level and thick echogenic wall. The tube is curled back upon itself demonstrating the incomplete septation sign and is also focally symmetrically indented, the "waist sign" (*arrows*). **B,** Color Doppler image of the left adnexa in a second patient with pyosalpinx demonstrating a dilated serpiginous tubular structure containing low level intraluminal echoes and increased mural vascularity. Gray-scale (**C**) and color Doppler (**D**) ultrasound images from a third patient with pyosalpinx demonstrating a dilated fallopian tube adherent to the enlarged, edematous right ovary (O). The wall of the tube is thick and hyperemic and the lumen contains internal echoes. Findings are most consistent with pyosalpinx, although hematosalpinx could also result in layering or conglomerate intraluminal echoes within a dilated fallopian tube. (C and D courtesy of Dr. Margarita Revzin, Yale University School of Medicine, New Haven, CT.)

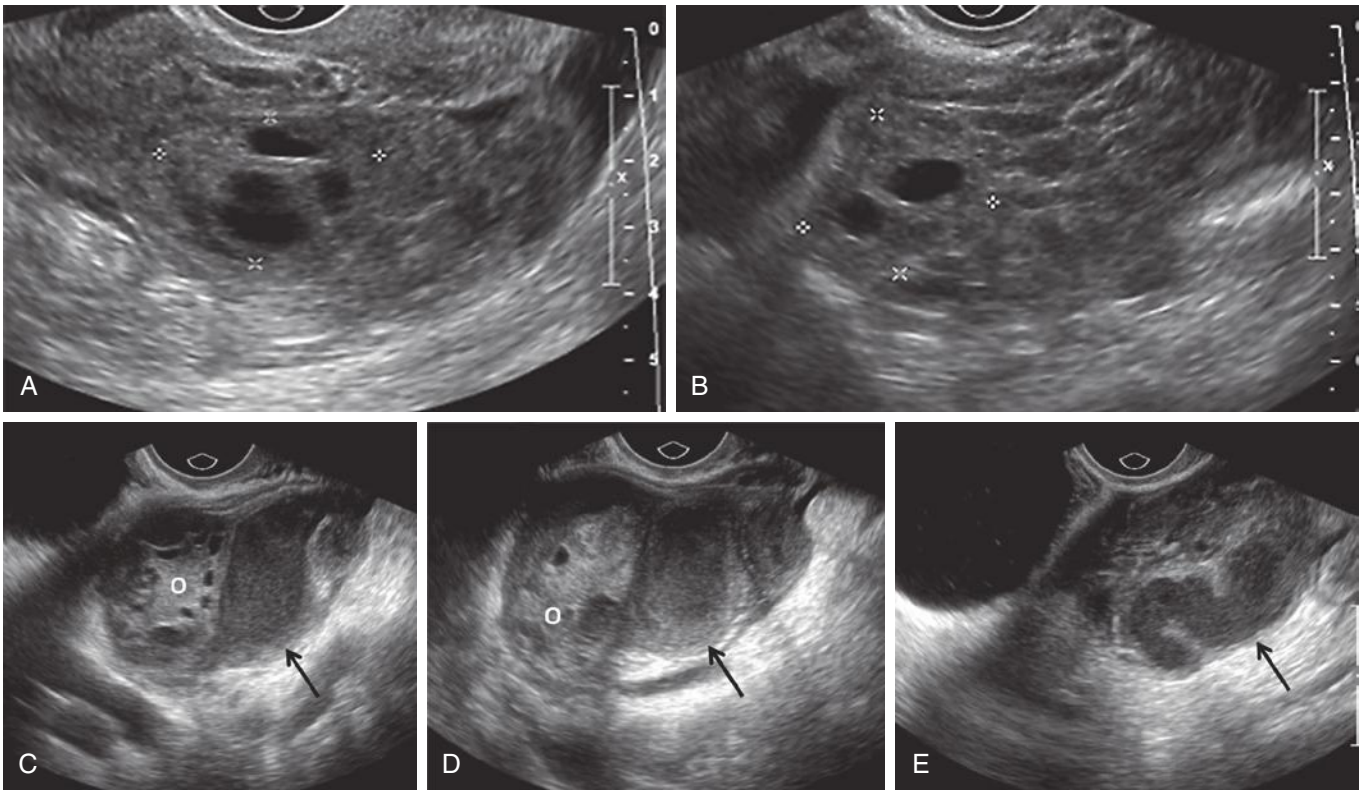

FIG 31-9 Tubo-ovarian complex. Transverse (**A**) and sagittal (**B**) images demonstrating a complex adnexal mass in a patient presenting with pelvic pain and fever. Note that the ovary (*calipers*) is recognizable and is surrounded by complex inflammatory material suggesting tubo-ovarian complex (TOC) rather than tubo-ovarian abscess (TOA). Sagittal (**C** and **D**) and transverse (**E**) gray-scale images in another patient presenting with pelvic pain and leukocytosis. The ovary (O) is recognizable with its small follicles but is surrounded by the dilated, pus-filled fallopian tube (pyosalpinx) (*arrows*) and complex fluid consistent with TOC. Note increased echogenicity of the adjacent pelvic fat, suggestive of inflammation or infection. (C, D, and E courtesy of Dr. Margarita Revzin, Yale University School of Medicine, New Haven, CT.)

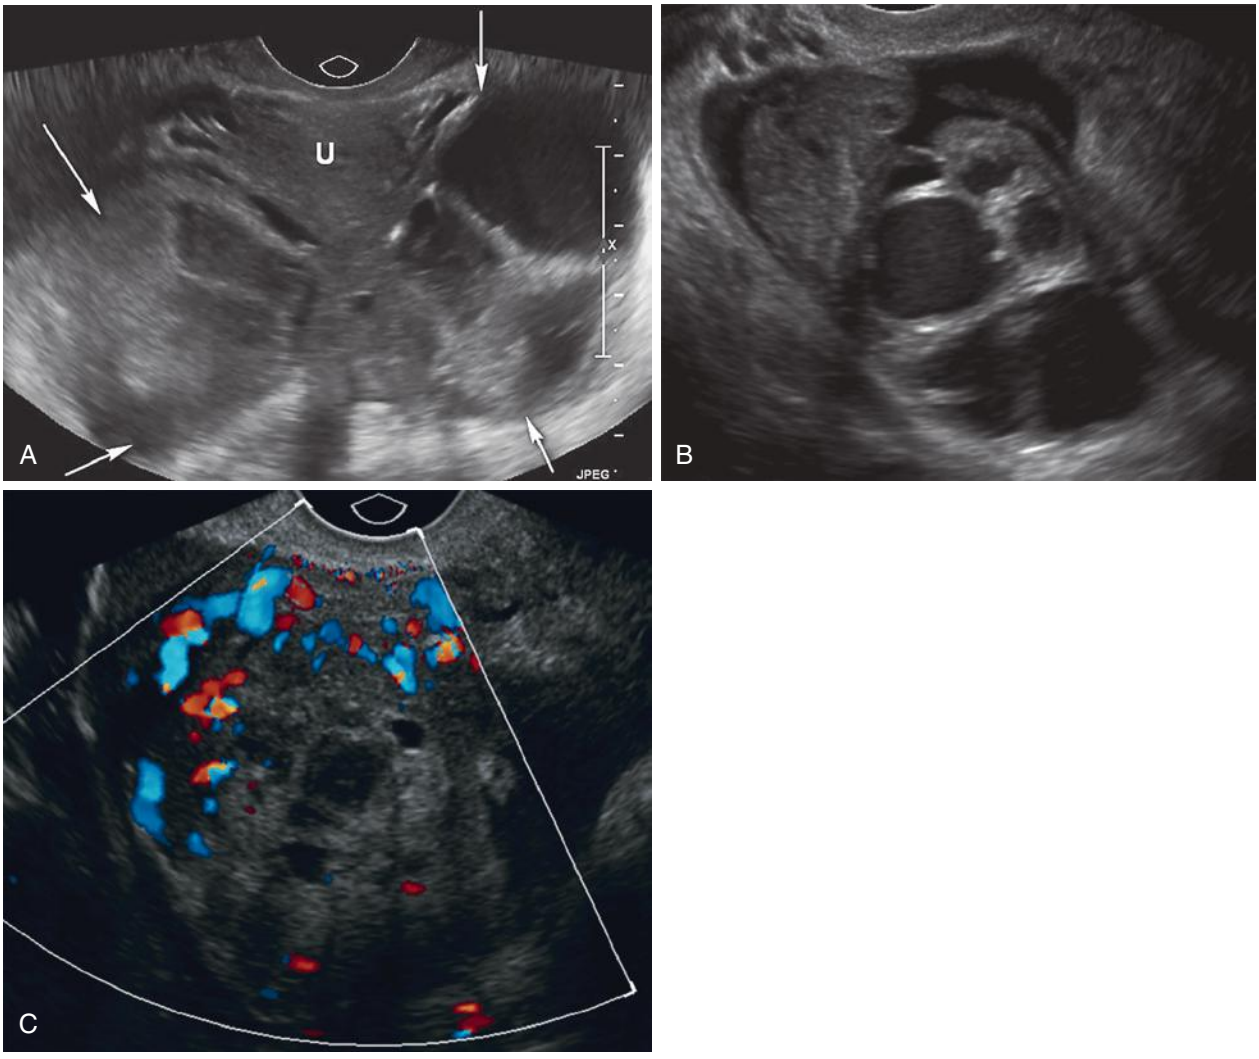

FIG 31-10 Tubo-ovarian abscess (TOA). **A,** Transverse gray-scale view of the uterus (U) with bilateral TOAs (*arrows*) demonstrating solid and complex cystic components with ill-defined borders. No normal-appearing ovary could be identified on either side. **B,** Another patient with TOA. Note the complex, multilocular adnexal mass with surrounding free fluid. The ovary and tube are not discretely recognizable. **C,** In a third patient with a TOA, note increased vascularity on color Doppler image of more solid appearing, markedly tender adnexal mass.

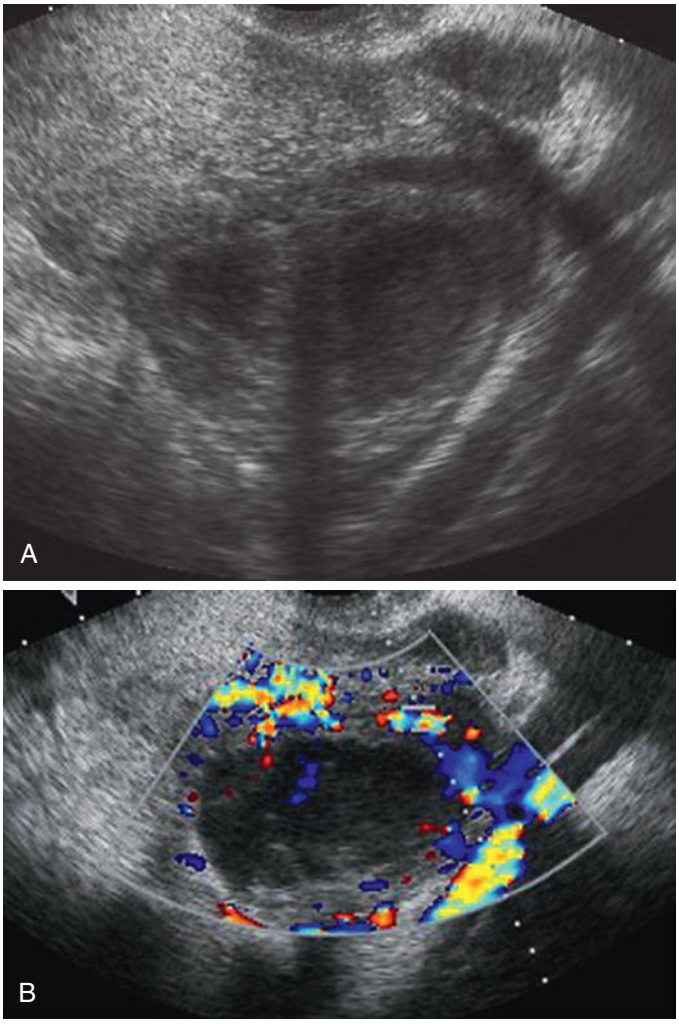

FIG 31-11 Tubo-ovarian abscess. Gray-scale (**A**) and color Doppler (**B**) transvaginal sonographic images of left adnexal cystic mass with internal echoes and marked peripheral vascularity.

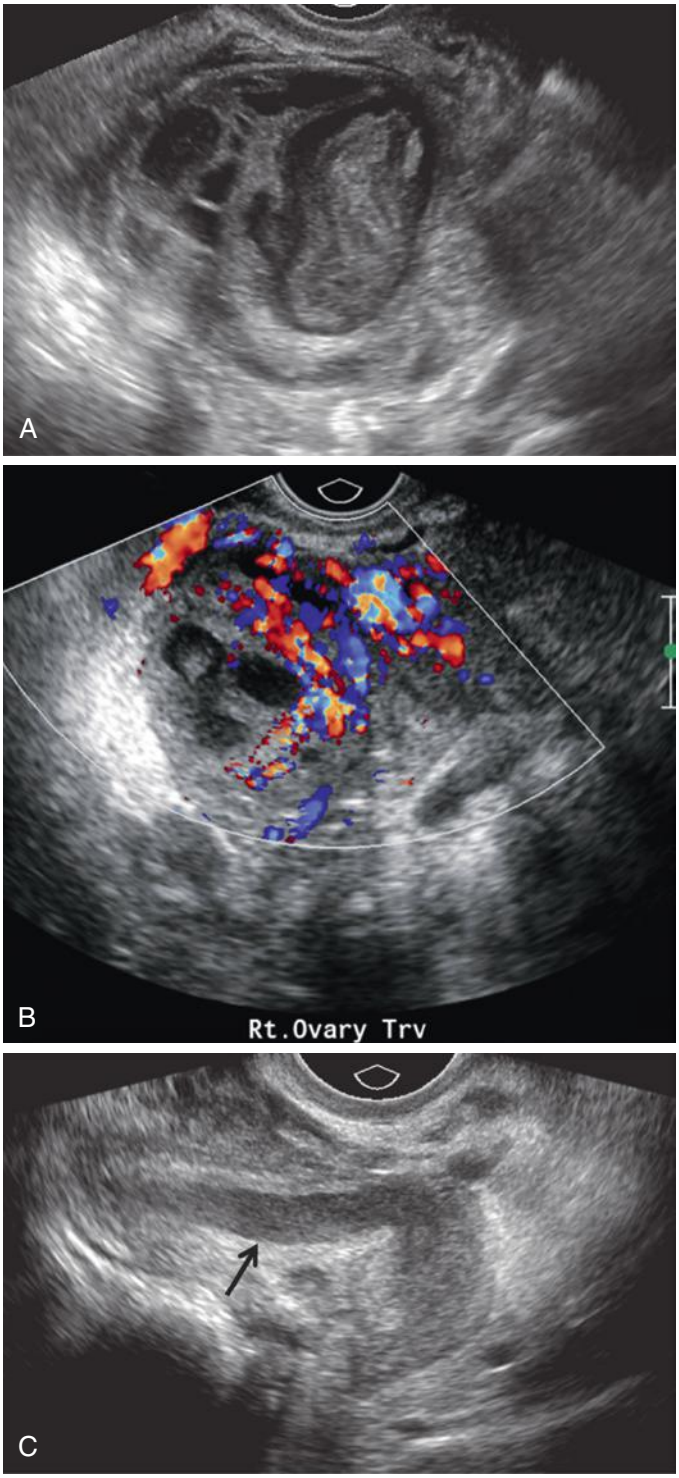

FIG 31-12 Tubo-ovarian abscess. A 27-year-old woman presented with bilateral pelvic pain and purulent vaginal discharge. **A,** Gray-scale image of the right adnexa demonstrating a complex, tender adnexal mass that was markedly vascular on color Doppler imaging (**B**). **C,** Note mildly dilated thick-walled adjacent pyosalpinx (*arrow*) and increased echogenicity of the adjacent pelvic fat. (Images courtesy of Dr. Margarita Revzin, Yale University School of Medicine, New Haven, CT.)

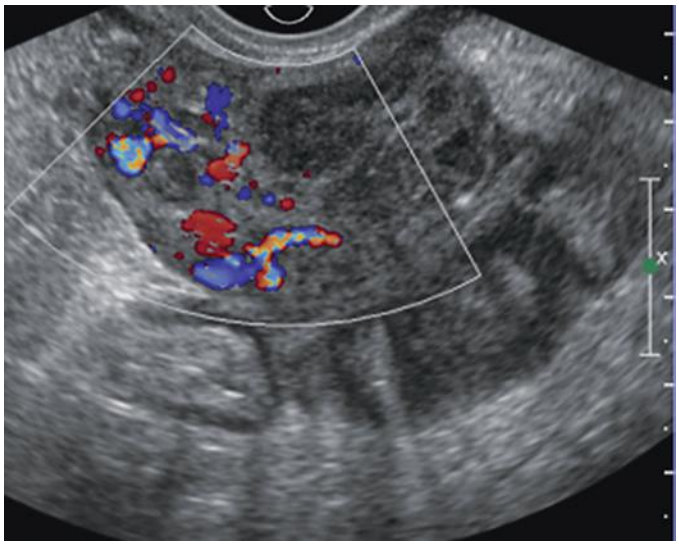

FIG 31-13 Diverticular abscess. Complex, hypervascular left adnexal mass adjacent to thick-walled bowel loop in a 62-year-old woman who presented with left-sided pelvic pain and fever. At surgery this mass was found to be a diverticular abscess. Diverticular abscess is more likely to occur in older women, be unilateral and left-sided, contain air, and be associated with abnormal loops of bowel. (From Baltarowich OH, Scoutt LM, Hamper UM: Nongynecologic findings on pelvic ultrasound: focus on gastrointestinal diseases. Ultrasound Q 28:65-85, 2012, used with permission.)

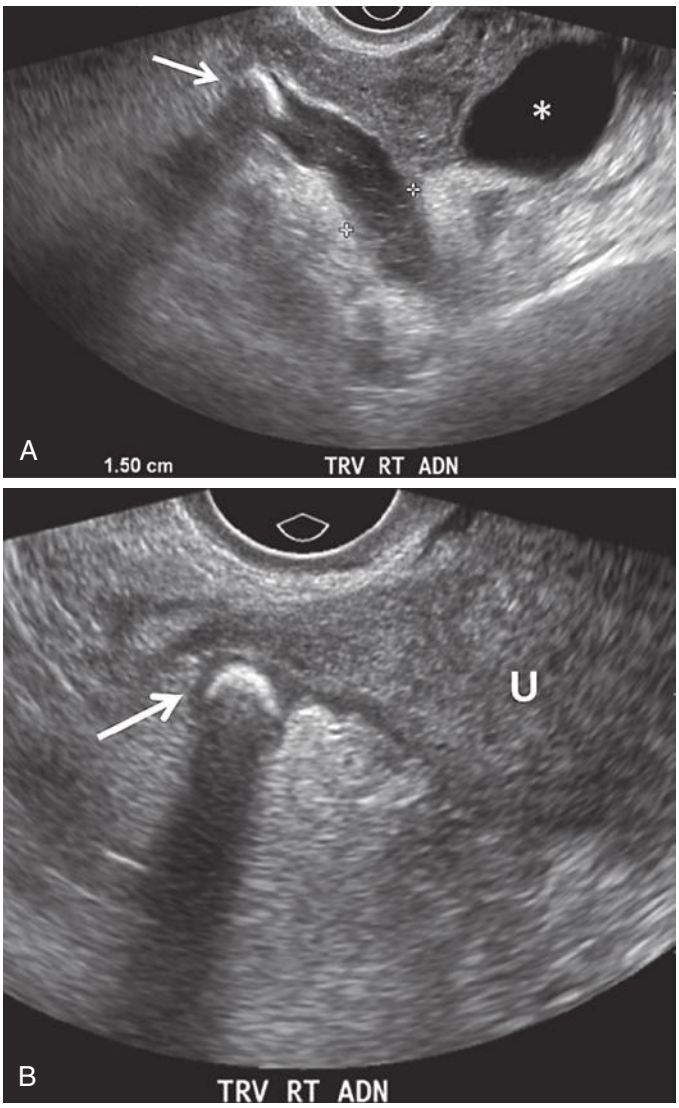

FIG 31-14 Acute appendicitis. A 37-year-old woman presented with pelvic pain and chills for 2 days. Transvaginal sonographic images of right adnexa (**A** and **B**) revealed a tender, fluid-filled tubular structure (*calipers*) measuring 1.5 cm in diameter lateral to the right ovary. Also shown is a sharply marginated echogenic round structure (*arrow*) with dense acoustic shadowing, consistent with appendicolith. Also note increased echogenicity of the adjacent pelvic fat, a nonspecific finding indicative of inflammation or infection. *Asterisk*, right ovarian cyst; U, uterus.

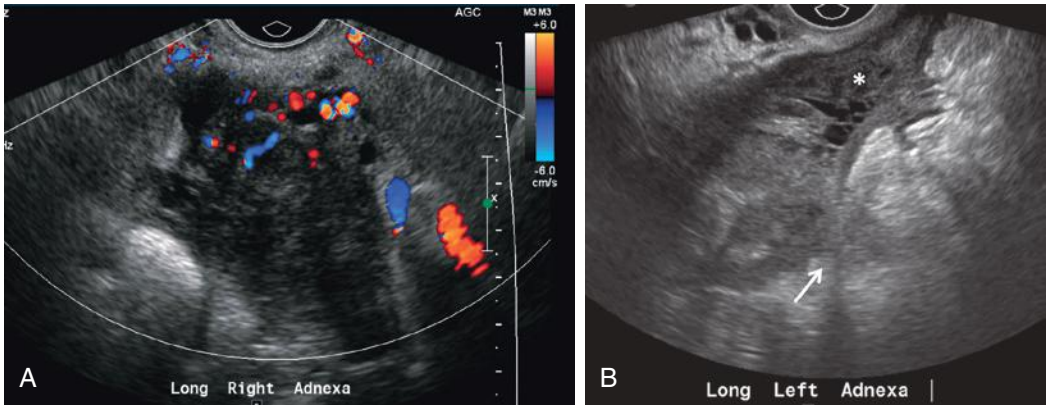

FIG 31-15 Thirty-year-old woman from southeast Asia presenting with 9 months of unexplained weight loss and pelvic pain. Color Doppler image of the right adnexa **(A)** and gray-scale image of the left adnexa **(B)** demonstrate bilateral hyperemic complex adnexal masses. Note surrounding complex free fluid, best seen in **B** (*) and infiltration of adjacent pelvic fat *(arrow* in **B***)*. Neither fallopian tube or ovary could be discretely identified. Whereas findings are nonspecific and consistent with bilateral tubo-ovarian abscesses, the clinical presentation is atypical for pelvic inflammatory disease because the patient was afebrile and there was no vaginal discharge. CT scan (not shown) demonstrated omental thickening, and biopsy was positive for tuberculosis. CXR (not shown) also demonstrated findings suspicious for tuberculosis. The adnexal masses slowly resolved with anti-TB therapy. (Images courtesy Dr. Manjiri Dighe, University of Washington Medical Center, Seattle, Washington.)

appearance (Fig. 31-17). The differential diagnosis includes endometriosis, PID-related inflammatory mass, and malignancy.[26]

Lastly, a gastrointestinal process that has spread beyond the bowel such as perforated appendicitis or diverticulitis may secondarily infect the fallopian tubes.

HEMATOSALPINX

In the nonpregnant patient, hematosalpinx is most commonly due to endometriosis but can also occur secondary to PID, adnexal torsion, malignancy, trauma, and uterine anomalies with retrograde menstruation.[19] The sonographic appearance of a hematosalpinx is similar to a pyosalpinx with variable degrees of wall thickening and internal echoes. Echogenicity will be variable depending upon the length of time since the hemorrhage occurred. Layering of the intraluminal echoes may be observed. Endometrial implants on the surface of the tube may cause hydrosalpinx from scarring and fibrosis, whereas luminal implants are more likely to result in hematosalpinx.[27] A hematosalpinx secondary to endometriosis often demonstrates the fine, homogeneous low level internal echoes typical of an endometrioma (Fig. 31-18, Video 31-3). Unlike an acute pyosalpinx, the walls of the tube will be sharply delineated without hyperemia or surrounding inflammation. The presence of blood in the fallopian tube may be easily confirmed on MRI if the sonographic findings are nonspecific.

TUBE TORSION

Torsion of the fallopian tube without associated ovarian torsion is a rare event and is reported most frequently in adolescent girls. Patients present with nonspecific acute pelvic pain. The diagnosis can be suggested when a painful dilated fallopian tube with a normal ipsilateral ovary is observed.[4] In this author's experience, the tube will often have a tense appearance and be in an unusual location high in the adnexal region or in the midline (Video 31-4). A beaked or pointed appearance of the ends of the twisted dilated tube, which is often in a V- or U-shaped configuration, may be observed (Fig. 31-19). As in ovarian torsion, detection of color flow in the wall of the tube does not exclude the diagnosis of tube torsion. A whirlpool sign may be demonstrated with coiling of the proximal tube and tube vessels.[28] Tube torsion is usually managed with salpingectomy, though some have suggested a more conservative approach of detorsion and drainage to preserve fertility in girls and young women.[29]

MALIGNANCY

Previously, primary fallopian tube carcinoma (PFTC) was thought to be the rarest gynecologic malignancy, with an incidence of less than 2%. Risk factors include the *BRCA* mutations as well as nulliparity. PFTC is most common in postmenopausal women. The diagnosis previously required the following characteristics: (a) main tumor arising from endosalpinx, (b) papillary pattern on histologic examination, (c) visible transition between benign and malignant epithelium within the tube, and (d) normal or minimally involved ovary and endometrium (i.e., the tube tumor was required to be larger than any tumor in the ovary or endometrium).[30] However, a recently proposed theory now accepted by many pathologists suggests that most serous ovarian carcinomas actually arise from malignant tube epithelial cells that implant on the ovary.[31] This concept is supported by data from women with *BRCA1* or *BRCA2* mutations who underwent prophylactic salpingo-oophorectomy and were found to have carcinoma in situ or invasive carcinoma of the fallopian tube without ovarian malignancy. Furthermore, the ovary does not intrinsically harbor an epithelial cell of origin as does the fallopian tube. Thus, the true incidence of PFTC may have been significantly underestimated. See Chapter 30, "Ultrasound Evaluation of the Ovaries," for further detail.

Latzko's triad—namely, intermittent bloody vaginal discharge, colicky pain relieved by the discharge, and a pelvic mass—has been described as the classic clinical presentation of PFTC but only occurs in a minority of patients, less than 10%. These symptoms occur as the tumor secretes serous fluid into an obstructed fallopian tube resulting in painful distention of the tube, which intermittently decompresses by discharging fluid into the endometrial cavity or the peritoneum. However, many patients are asymptomatic and the tumor is found incidentally. Approximately 50% of patients present with postmenopausal vaginal bleeding. The imaging findings overlap with primary ovarian carcinoma and depend upon whether the tube is primarily

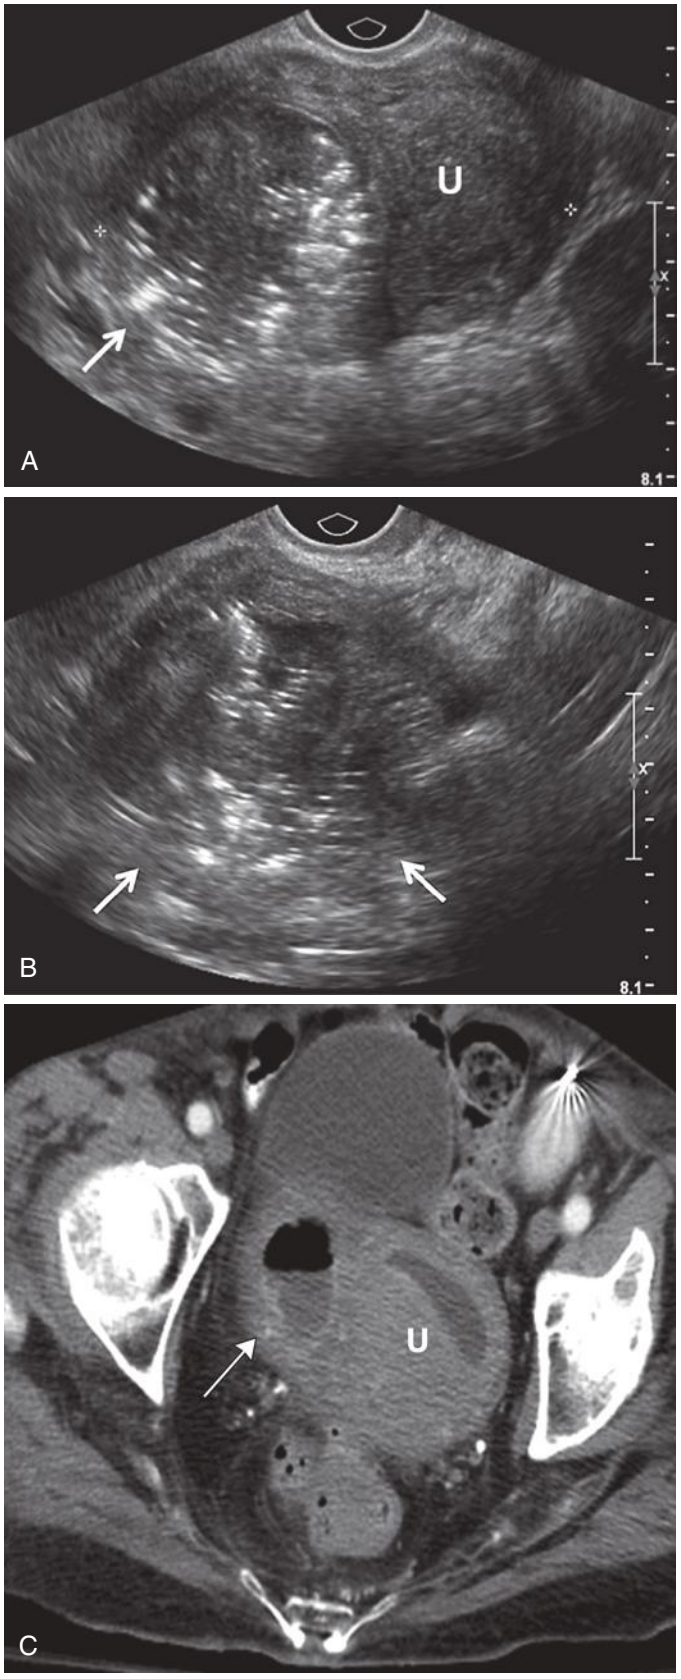

FIG 31-16 Actinomycosis. Transvaginal sonographic images of the right adnexa (**A** and **B**) in an 82-year-old woman presenting with abdominal discomfort. Note a large mass (*arrows*) adjacent to the uterus (U) containing numerous brightly echogenic foci suggesting microbubbles of gas. Contrast-enhanced axial computed tomographic scan (**C**) confirms the presence of a large gas-containing abscess (*arrow*) in the right adnexa adjacent to the uterus (U). A fistula to the bowel was found at surgery and cultures grew *Actinomyces*. (Images courtesy of Dr. Margarita Revzin, Yale University School of Medicine, New Haven, CT.)

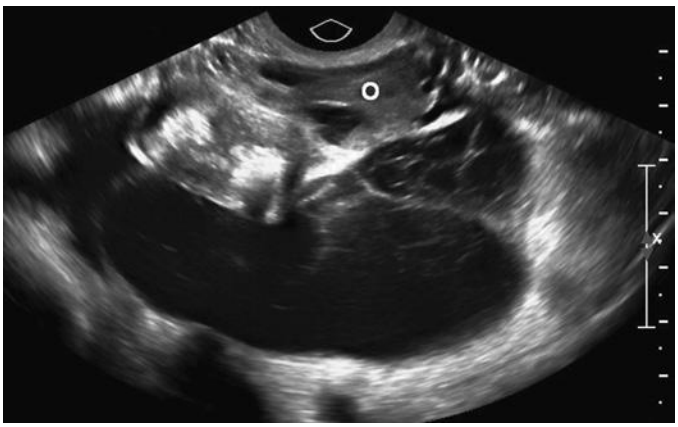

FIG 31-17 Xanthogranulomatous salpingitis: Note large complex mass with a tubular cystic component posteriorly and a solid component with shadowing echogenic foci adjacent to the normal ovary (O).

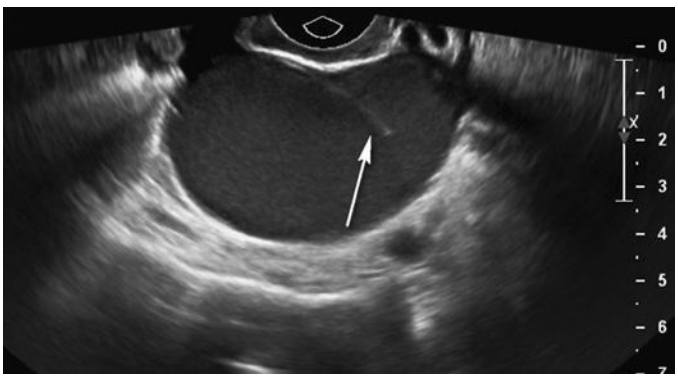

FIG 31-18 Hematosalpinx. Dilated, thin-walled fallopian tube contains fine, homogeneous low level echoes consistent with blood. Posterior enhancement confirms the cystic nature of the lesion. Incomplete septation sign (*arrow*) indicates where the tube has folded on itself.

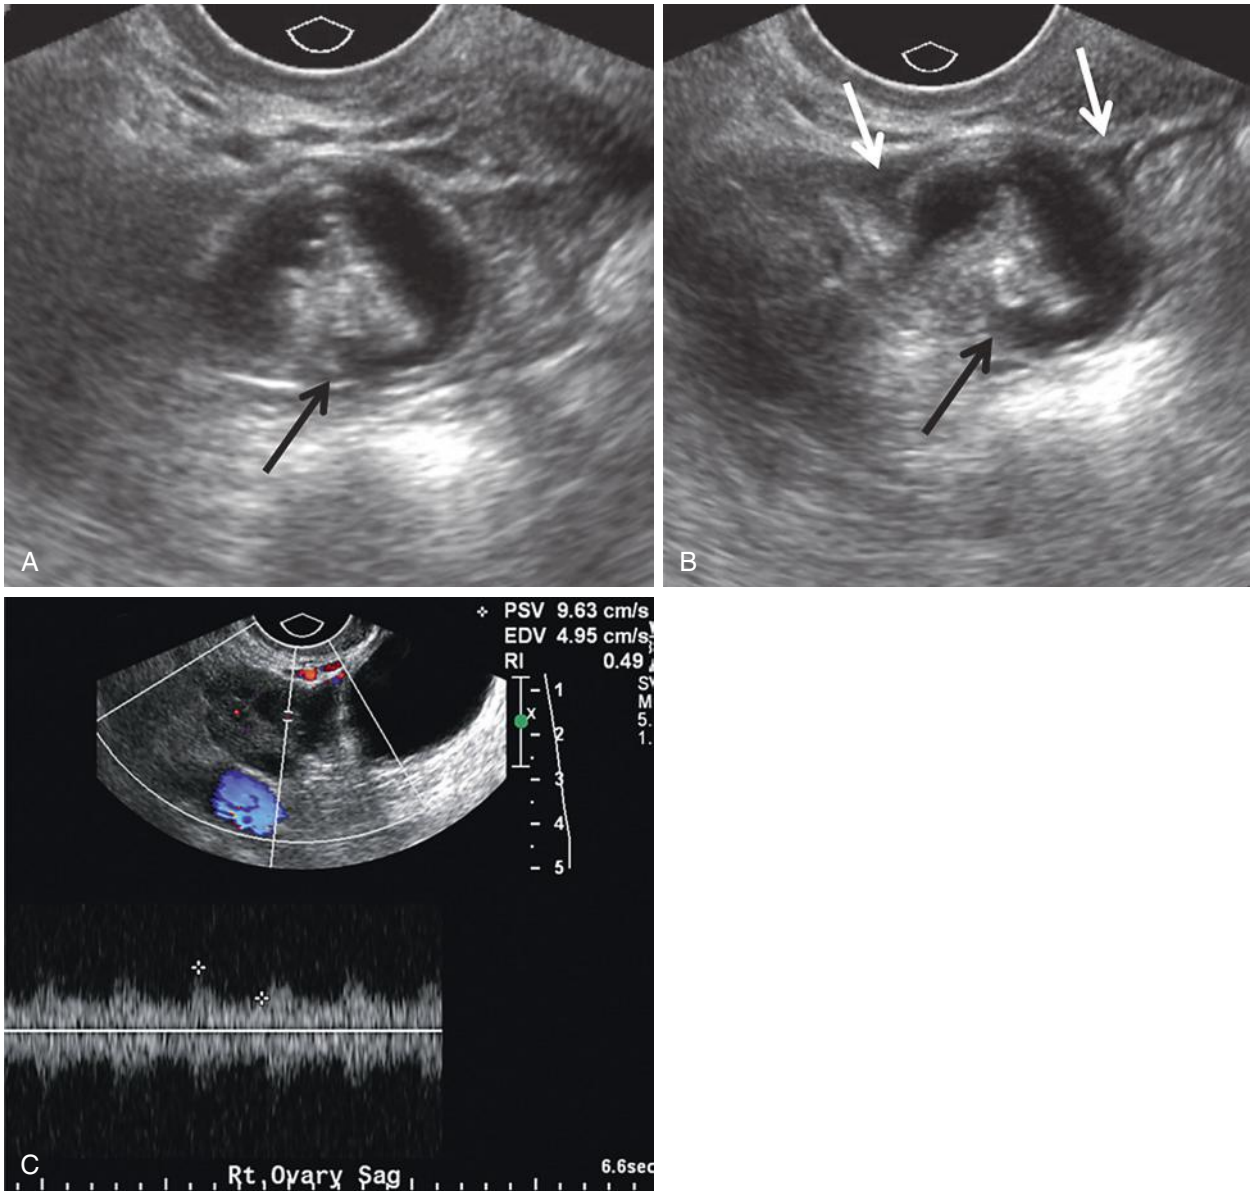

FIG 31-19 Isolated torsion of the fallopian tube. A 15-year-old girl with acute onset, severe right lower quadrant to midline pelvic pain. **A** and **B,** Note dilated tubular fluid-filled structure in an upside-down U-shaped configuration with a pointed or "beaked" appearance at the medial end (*black arrow*), as a result of twisting or torquing. The twisted fallopian tube was in an abnormal location, situated above the uterus toward the midline. There is a small volume of adjacent free fluid (*white arrows*). **C,** The right ovary appears normal in size and morphologic appearance with normal flow on color and spectral Doppler interrogation.

dilated and fluid-filled, or predominantly thick-walled and solid in appearance (Fig. 31-20).[32] A characteristic observation is a change in sonographic appearance on serial studies as the degree of tube distention varies. Doppler imaging may be useful to differentiate tumor from debris and to detect low resistance flow.[33] CT and MRI should be used for staging.

EVALUATION OF TUBE PATENCY

Though hysterosalpingography (HSG) has been the traditional imaging modality of choice to evaluate tube patency, newer techniques involving agitated saline and ultrasound contrast agents injected during sonohysterography (SIS) have shown promise as an alternate imaging technique. Although the injection of saline agitated with air bubbles when performing SIS can confirm tube patency, the bubbles are fairly evanescent. Ultrasound contrast "microbubbles" last longer and can be imaged with real-time cine clips and reconstructed two-dimensional and three-dimensional images to confirm tube patency. Reported correlations with HSG are excellent in several small series.[34] Adding targeted color Doppler interrogation of each tube during directed contrast agent injection can increase the accuracy of SIS for tube patency.[35] It is also generally accepted that accumulation of free fluid in the peritoneal cavity during routine SIS implies patency of at least one fallopian tube.[36] Sonography can also be useful in evaluating patients with mechanical tube occlusion devices, such as Essure, used for contraception. When normally positioned, the portion of the Essure placed in the intramural or interstitial segment of the fallopian tube is easily visualized sonographically (Fig. 31-21). A malpositioned Essure device

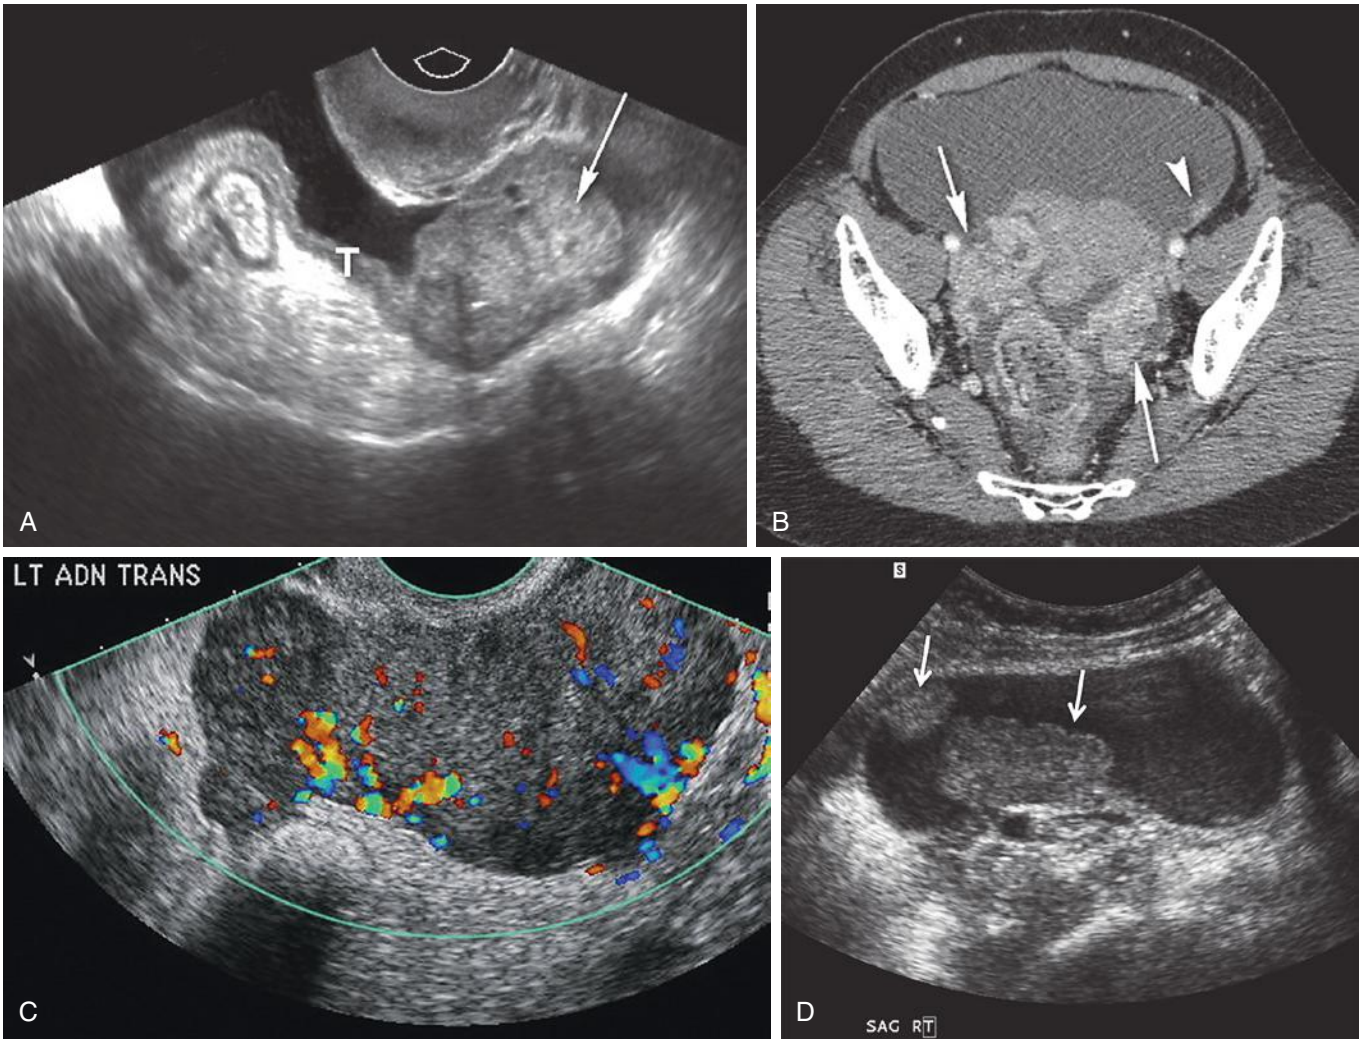

FIG 31-20 Fallopian tube carcinoma. **A,** Anechoic ascites partially surrounds the hypoechoic left fallopian tube (T), which has an abnormally thick, slightly heterogeneous solid mass-like appearance at the distal end (*arrow*). **B,** Corresponding axial contrast-enhanced computed tomographic scan demonstrates bilateral abnormal fallopian tubes (*arrows*), which are thickened, nodular, and enhancing. There is a large amount of surrounding ascites. Note enhancing peritoneal implant (*arrowhead*). **C,** Color Doppler image demonstrating a solid, vascular left adnexal tubular structure in another patient with primary fallopian tube cancer. **D,** A 43-year-old woman with fallopian tube cancer presented with vaginal bleeding. Transvaginal sonographic image demonstrates right hydrosalpinx containing two solid mural nodules (*arrows*) highly suggestive of malignancy rather than chronic inflammation as the wall of the fallopian tube is otherwise thin and smooth. (C courtesy of Dr. Douglas Brown, Department of Radiology, Mayo Clinic, Rochester, MN; D courtesy of Dr. Anna Lev-Toaff, Hospital of the University of Pennsylvania, Philadelphia, PA.)

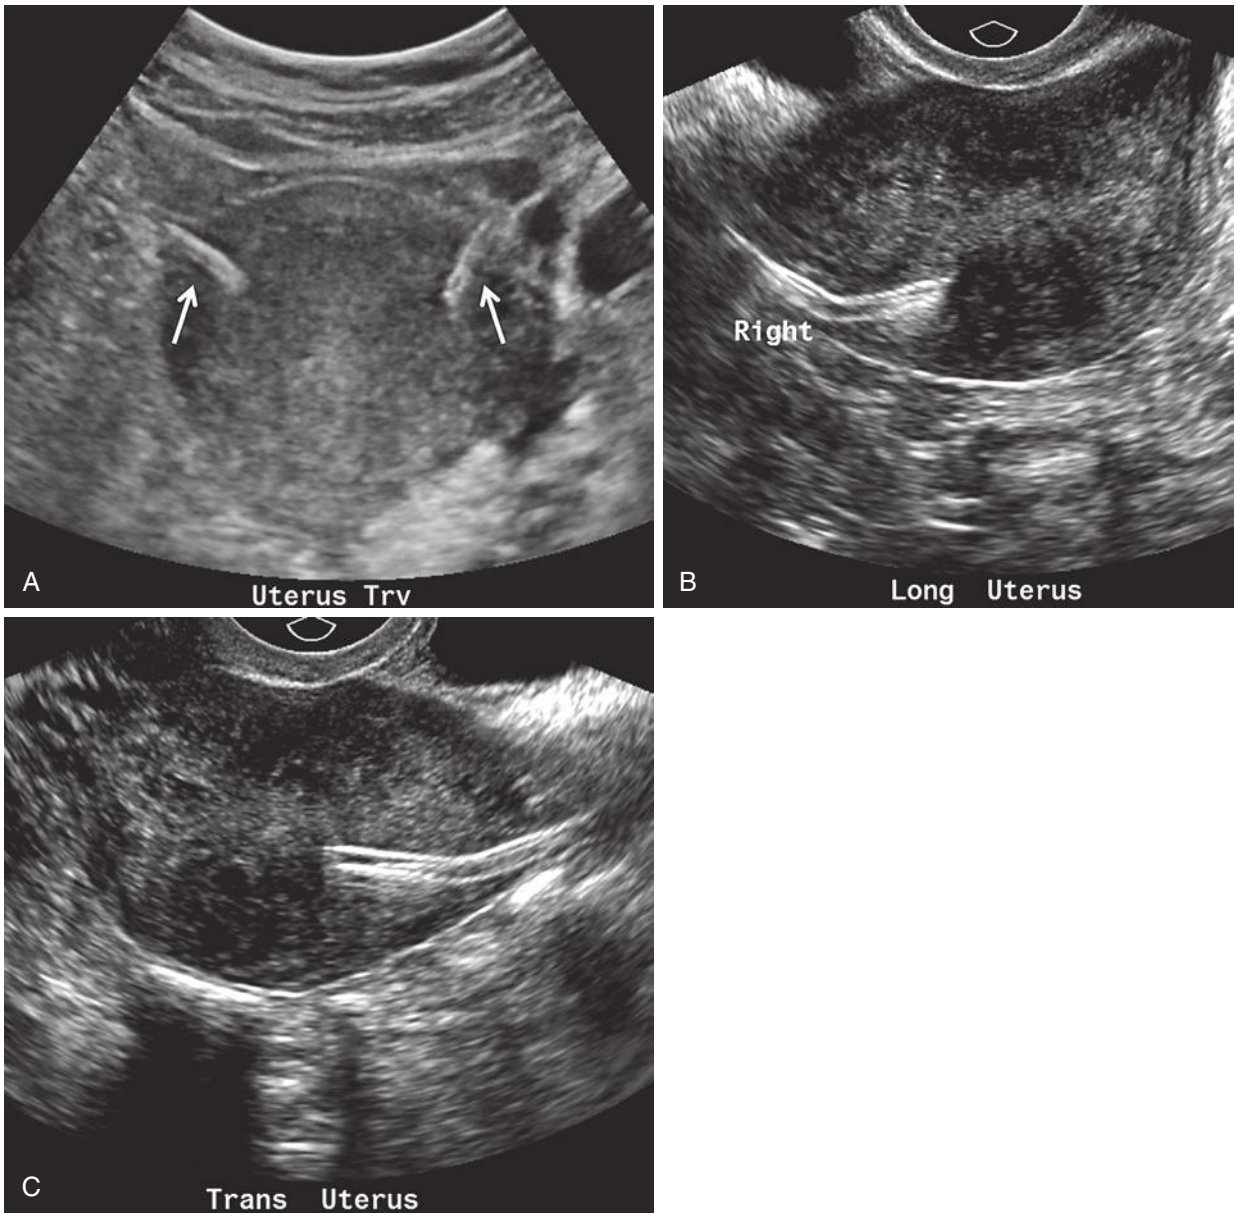

FIG 31-21 Normal ultrasound appearance of Essure device. **A,** Transabdominal image of the uterus demonstrates Essure microinsert birth control devices. On this coronal view through the uterine fundus, bilateral, slightly curved linear echogenic foci are seen (*arrows*), indicating normal device placement within the interstitial segment of the fallopian tube on each side. On transvaginal sonographic images, the right (**B**) and left (**C**) Essure devices can be seen extending from the interstitial portion of the fallopian tube into the isthmic segment. (Courtesy Department of Obstetrics and Gynecology, Yale University School of Medicine, New Haven, CT.)

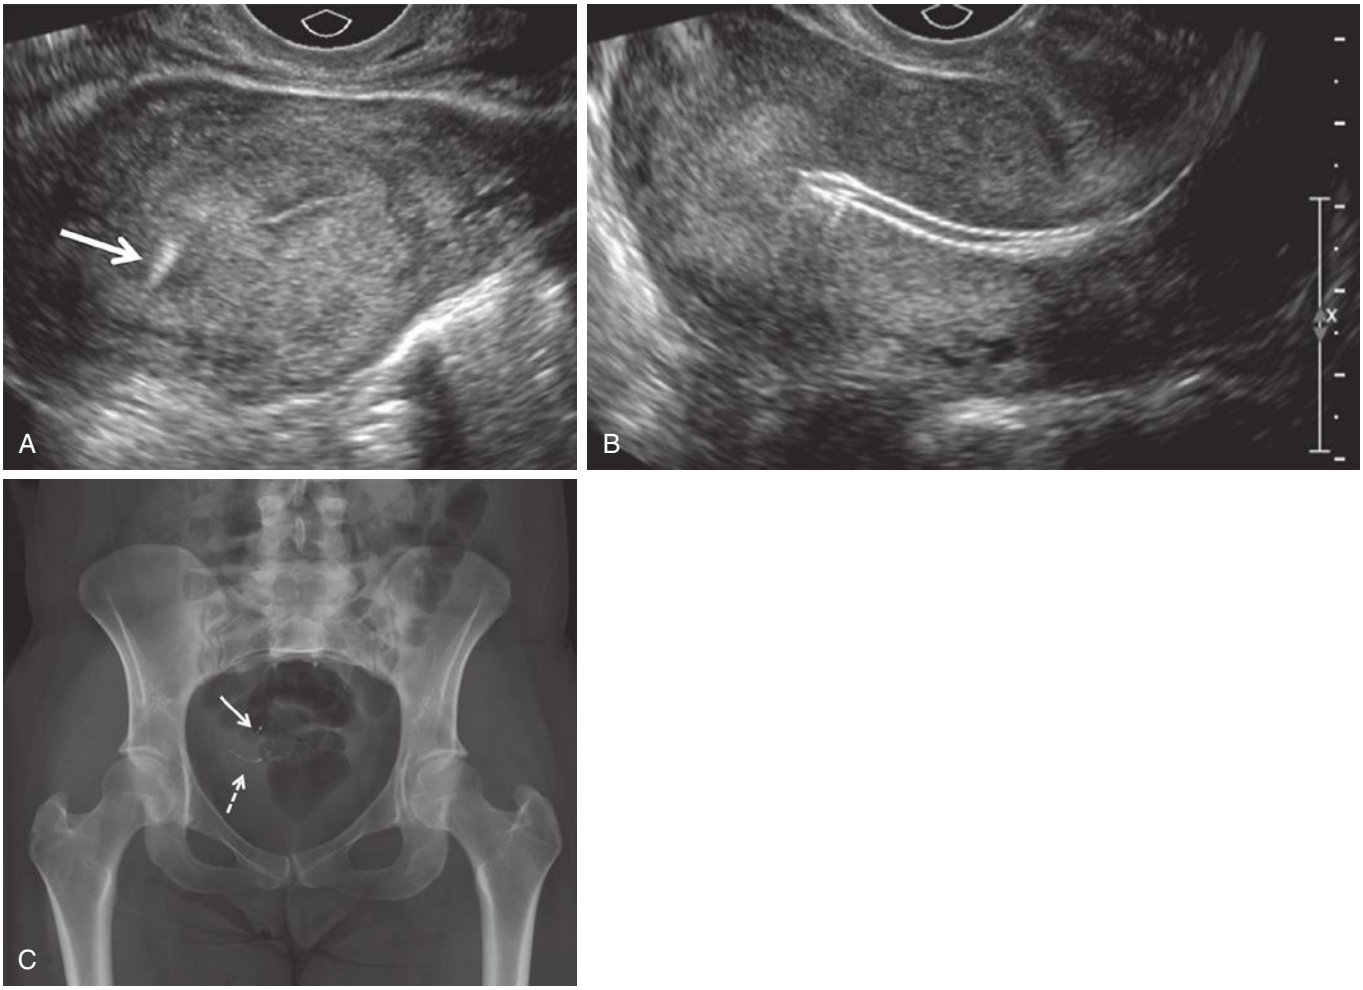

FIG 31-22 Essure device in abnormal location. **A,** Transverse transvaginal sonographic image of the uterine fundus demonstrating the right Essure device (*arrow*) in the appropriate location in the interstitial portion of the right fallopian tube. The left device is not visualized on this image. **B,** Midline sagittal transvaginal sonographic image of the uterus demonstrating the left Essure device centrally located within the endometrial cavity. **C,** Radiograph confirms abnormal location of the left Essure device (*dotted arrow*). *Solid arrow*, right Essure device. (Courtesy Department of Obstetrics and Gynecology, Yale University School of Medicine, New Haven, CT.)

may also be recognized on sonography (Fig. 31-22).[37] See Chapter 37, "The Role of Ultrasound in Gynecologic Interventions," for more detail.

SUMMARY

Both normal and abnormal fallopian tubes can be identified using ultrasound. A dilated fallopian tube, whether a hydrosalpinx, pyosalpinx, or hematosalpinx, will demonstrate a variety of classic sonographic signs that can be used to differentiate a cystic mass of tube origin from ovarian and other pelvic causes. These signs include the waist sign, incomplete septation sign, cogwheel sign, and beads on a string sign and can also be used in other pelvic imaging modalities. However, sonography has the advantage of allowing for more direct correlation with the patient's pain. In addition, dynamic scanning using compression can help differentiate fallopian tube from ovary. Visualization of subtle tube abnormalities such as mild salpingitis and tube carcinoma can be accomplished using high frequency transvaginal sonography transducers, and evaluation of tube patency using SIS may become more common with the more widespread use of ultrasound contrast agents.

Sonographic Imaging in Infertility and Assisted Reproduction

Mary C. Frates

SUMMARY OF KEY POINTS

- Transvaginal sonography (TVS) provides valuable information as part of the initial evaluation of an infertile patient.
- EVS has an essential role in monitoring endometrial thickness and morphology as well as follicular development during hormonal stimulation.
- EVS or transabdominal sonography provides guidance for oocyte retrieval.
- Postretrieval complications such as ovarian hyperstimulation, hemorrhage, and infection are optimally imaged with sonography.

OUTLINE

Infertility can be defined as the inability to conceive a pregnancy after 1 year of unprotected intercourse or after 6 months in a woman over 35 years old. It affects between 6% and 10% of couples in the United States.[1] Because fertility peaks in the third decade and subsequently declines, the age of the female partner is an important variable in the treatment of infertility. The use of sonography, in particular EVS, has become an integral component of the evaluation and treatment of infertility. The transvaginal approach allows high-resolution assessment of the uterus, ovaries, and fallopian tubes. EVS plays a critical role in the diagnosis and treatment of infertile women in combination with serologic testing, physical examination, and careful assessment of medical and surgical history, as well as evaluation of the male partner. Initial baseline ultrasound examination is used primarily to identify structural abnormalities that might affect fertility such as uterine anomalies, endometrial polyps or submucosal leiomyomas, endometrial adhesions/synechiae, or hydrosalpinges. Sonography is also used to assess for possible underlying pathologic processes associated with infertility such as adenomyosis, endometriosis, polycystic ovary syndrome (PCOS), and low antral follicular count. If the baseline pelvic sonogram is inconclusive or noncontributory, further anatomic evaluation can be obtained by means of pelvic magnetic resonance imaging (MRI), hysterography, sonohysterography, or even hysteroscopy and laparoscopy, as indicated. It is estimated that ovulatory defects are the primary cause of infertility in 20% to 40% of infertile women. Structural abnormalities of the female reproductive tract account for approximately 30% of cases; male factors up to 35%; and cervical mucosal, peritoneal, or unexplained abnormalities account for approximately 10% to 15%.[2] Once a treatment plan has been established, sonography plays an important role in monitoring response, particularly in assessing folliculogenesis and endometrial receptivity. In addition, ultrasound imaging is crucial for guiding infertility treatment such as oocyte retrieval and in assessing posttreatment complications. This chapter will review the role of sonographic imaging in the diagnosis and treatment of women presenting with infertility.

INITIAL EVALUATION

Part of the initial evaluation of all women with infertility is an assessment of pelvic anatomy. Although high-resolution EVS is the preferred method for imaging the pelvic organs, an initial overview using a transabdominal approach should be performed to evaluate for the possible presence of an enlarged uterus or other pelvic mass. Transvaginal probes are higher frequency than transabdominal transducers and, thus, provide high-resolution images of the uterus, ovaries, and fallopian tubes, but with the tradeoff of reduced penetration and smaller field of view. Masses that extend out of the pelvis cannot be fully imaged or characterized with the transvaginal approach, as they extend beyond the field of view of the transducer. A formal transabdominal sonogram, performed with a distended urinary bladder, or a combination of both transabdominal and transvaginal imaging may be required in some patients. A baseline transvaginal sonographic examination consists of images of the uterus, endometrium, and ovaries, with additional targeted evaluation of any identified abnormality. The reader is referred to individual chapters elsewhere in this textbook about the uterus (Chapter 28), ovaries (Chapter 30), and fallopian tubes (Chapter 31) for additional detail.

BASELINE EVALUATION

Uterus

Imaging of a patient with infertility often begins with hysterosalpingography (HSG) to assess for uterine anomalies and determine tubal patency. Sonography, including three-dimensional (3D) coronal views, is also a highly accurate initial imaging modality to evaluate for possible structural abnormalities such as congenital uterine anomalies, masses, or adenomyosis[3,4] and is an integral part of the baseline evaluation. At real-time sonography, the uterus should be imaged in both longitudinal (sagittal) and coronal (or transverse) orthogonal planes, with some views including the full length of the cervix. In patients with an enlarged or elongated uterus, it is important to ensure that the entire fundus as well as any exophytic lesion is included. The normal uterus is oval in shape with a curved, slightly convex fundal contour. Uterine malformations are reported to occur in 1% to 7% of infertile patients.[5,6] These malformations are often initially identified at HSG but can be appreciated on the baseline ultrasound image in most affected patients.

A uterine anomaly may be suspected at real-time sonography when, in the transverse plane, the endometrium appears to separate toward the fundus. In this instance, the addition of a 3D coronal view, which provides direct visualization of the fundal contour, the shape of the endometrial cavity, and characterization of any septum between the two uterine horns, can be extremely helpful in categorizing the type of uterine anomaly, which can range from an arcuate configuration (considered by most to be within the range of normal) to uterine didelphys[7-10] (Fig. 32-1A and B). If a uterine anomaly is suspected but cannot be confirmed, repeating the 2D and 3D sonography during the secretory phase of the menstrual cycle, when the endometrium is thick and hyperechoic and thus more visible, may be beneficial. If concern for a uterine anomaly and need for characterization persists, further imaging with pelvic MRI may be helpful. In addition, MRI may provide additional important structural information in patients with complex anomalies (Chapter 36).

Another major component of the baseline sonogram is evaluation of the endometrial pattern and thickness, typically assessed on the midline sagittal long-axis view. The endometrial morphologic appearance and thickness change through the menstrual cycle in response to rising serum estrogen concentrations. During the menstrual phase, the endometrium appears thin, linear, regular, and homogeneously echogenic, typically measuring less than 5 mm in thickness (Fig. 32-2), although in some patients, a more heterogeneous pattern can be seen. Occasionally a small amount of fluid is present in the uterine cavity. This fluid is not included in the reported measurement. Rather, the two endometrial layers (anterior and posterior) are measured separately and added together for reporting purposes (Fig. 32-3). At the baseline study, careful evaluation of the endometrium is necessary to search for intracavitary lesions such as submucosal leiomyomas or endometrial polyps (Fig. 32-4A and B). Focal lesions in the endometrial cavity are typically removed prior to fertility treatment, as resection has been reported to be associated with increased pregnancy rates.[11,12] In a retrospective study of infertility patients with endometriosis published in 2011, Shen and associates reported a clinical pregnancy rate of 49.5% in patients following hysteroscopic polypectomy compared to a pregnancy rate of 29.8% in those without polyps.[11] Medina and colleagues reported in a randomized, prospective study that infertility patients with endometrial polyps undergoing intrauterine insemination were twice as likely to become pregnant if hysteroscopic polypectomy was performed prior to insemination, with a relative risk of 2.1 and a pregnancy rate of 59% in the study group versus 25.4% in the control group.[12] Rarely, other more unusual types of endometrial diseases, such as unsuspected retained products of conception or osseous metaplasia (Fig. 32-5), are found on baseline imaging; these lesions should also be addressed prior to initiation of fertility treatment.[13] In some patients, sonohysterography may provide further information regarding endometrial disease and is particularly useful in identifying adhesions within the endometrial cavity (Asherman syndrome). Asherman syndrome most commonly occurs following instrumentation such as dilatation and curettage (D&C) but can also occur following intrauterine device placement, uterine artery embolization, radiation therapy, pregnancy, or endometritis. Up to 43% of women with Asherman syndrome will have difficulty

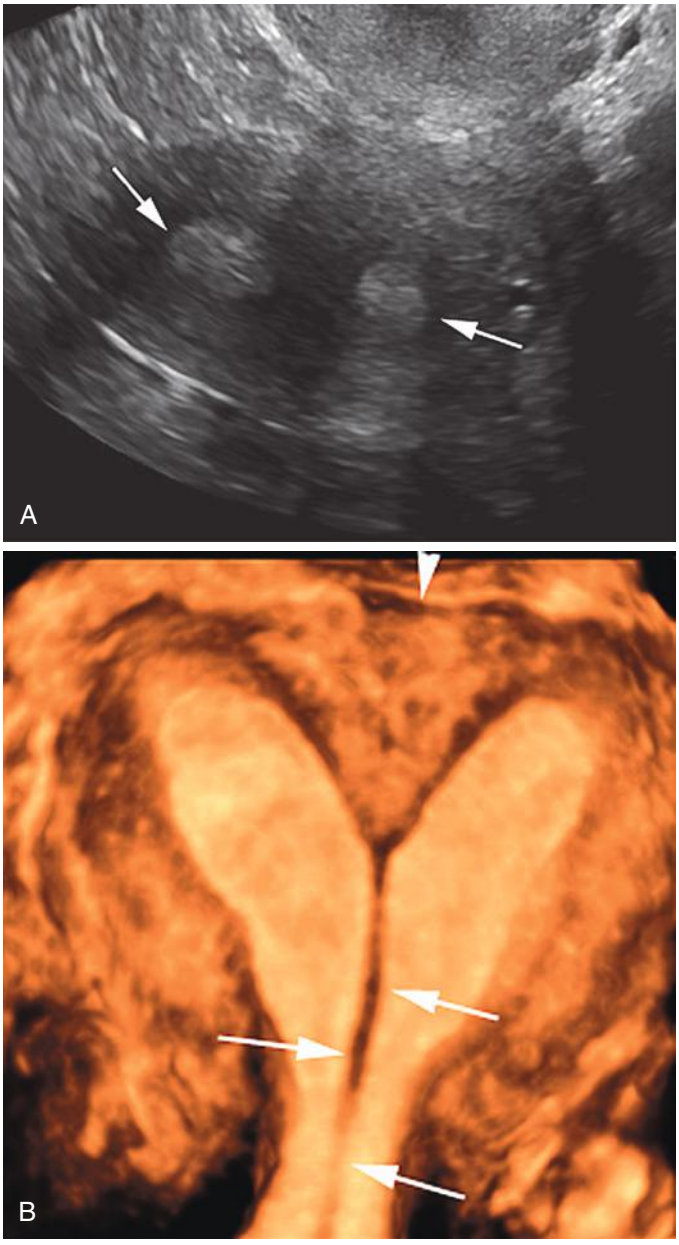

FIG 32-1 Septate uterus. **A,** Gray-scale axial transvaginal sonogram of the uterus shows a divided echogenic endometrial cavity (*arrows*). **B,** Three-dimensional rendered coronal image clearly demonstrates a complete thin uterine septum (*arrows*) dividing the endometrial cavity, extending from the fundus inferiorly into the cervix, below the level of the internal os. Note that the outer serosal contour of the uterine fundus remains smooth, without indentation (*arrowhead*).

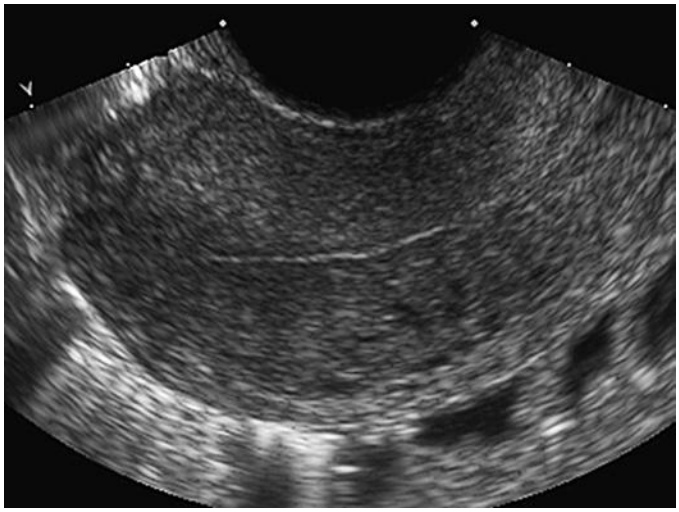

FIG 32-2 Normal ultrasound appearance of the endometrium during the menstrual phase. Gray-scale transvaginal sagittal image of the uterus demonstrates a thin, linear echogenic endometrium.

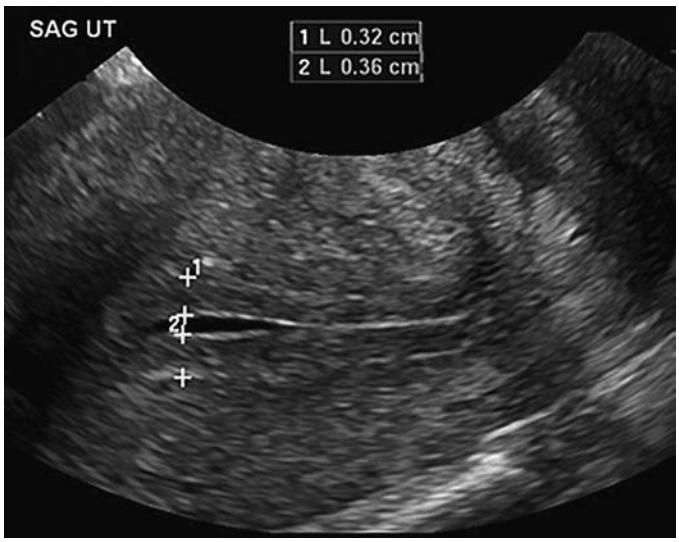

FIG 32-3 Normal ultrasound appearance of the endometrium during the periovulatory phase. Gray-scale transvaginal sagittal image of the uterus demonstrates the multilayered endometrium, with trace anechoic intrauterine fluid. The measurements of the anterior (*1 calipers*) and posterior (*2 calipers*) endometrial layers are summed, resulting in an endometrial thickness of 6.8 mm. The intracavitary fluid is not included in the measurement.

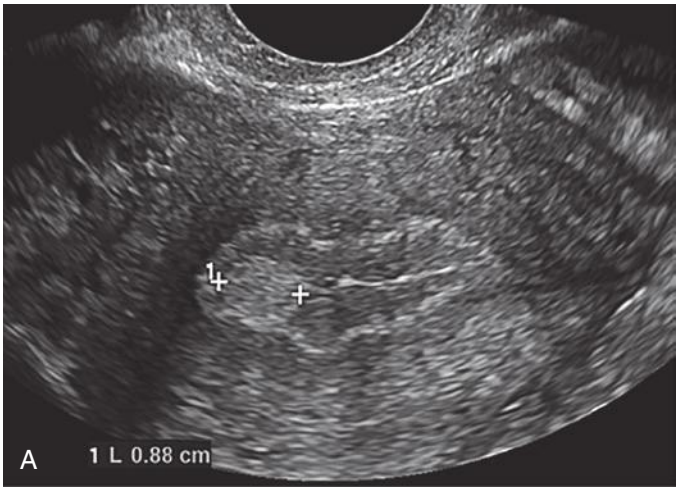

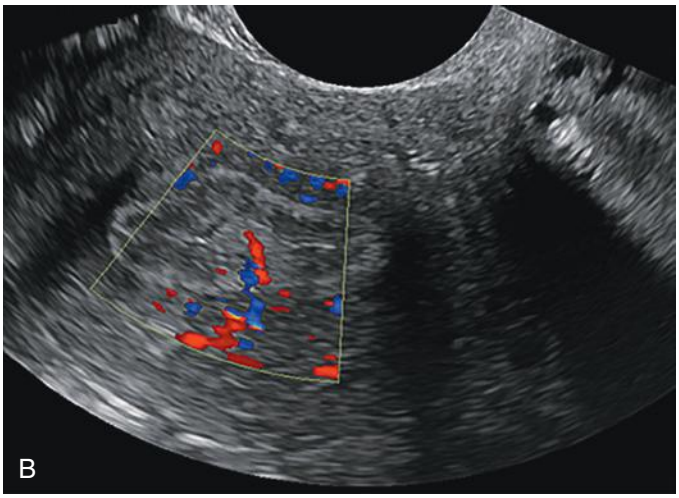

FIG 32-4 Endometrial polyp. **A,** Coronal gray-scale image of the uterus demonstrates a multilayered appearance of the endometrium (typical of the periovulatory phase of the menstrual cycle) and a focal echogenic lesion (*calipers*) representing an endometrial polyp. **B,** Sagittal color Doppler image shows a small feeding vessel supplying the polyp.

conceiving or will present with recurrent early pregnancy loss. Sonohysterography may also be helpful in identifying and delineating submucosal leiomyomas and polyps (Fig. 32-6).[14]

The myometrium is also evaluated on the baseline sonogram. Abnormalities of the myometrium that may affect fertility include adenomyosis and leiomyomas (also called *fibroids*). Adenomyosis occurs when endometrial glands and stroma burrow into the subjacent myometrium. The classic appearance on EVS is a globular, smooth-contoured, enlarged uterus with asymmetric wall thickening, heterogeneity of the myometrium, thickening of the subendometrial halo, subendometrial myometrial cysts or echogenic nodules or striations, and pencil-thin dark linear radiating striations through the myometrium (Fig. 32-7).[15-17] The presence of adenomyosis is associated with a significantly lower clinical pregnancy rate,[18-20] with *clinical pregnancy* defined as a pregnancy documented by visualization of a gestational sac or embryo, whereas *chemical pregnancy* indicates a pregnancy diagnosed by documentation of a positive human chorionic gonadotropin (hCG) level. The cause of infertility in patients with adenomyosis is not fully understood but may be related to decreased myometrial contractility, which is necessary to transport the sperm and zygote through the uterus. In addition, adenomyosis has a strong association with endometriosis, particularly in patients less than 36 years of age. Patients with adenomyosis also have an increased risk of early pregnancy loss as compared to patients without adenomyosis.[18-20]

Myomas are found in approximately 20% to 40% of women, with the rate increasing with patient age.[21] The percentage of infertile patients with myomas will likewise vary with age. The classic sonographic appearance of a myoma is a solid mass with well-defined borders. Echogenicity is variable, with most being hypoechoic. Larger myomas are often heterogeneous and may demonstrate a typical swirling pattern, edge refraction, posterior shadowing, and focal areas of calcification on EVS. Identifying and documenting the location of all myomas, particularly in relation to the endometrial cavity and lower uterine segment, are important components of the baseline ultrasound

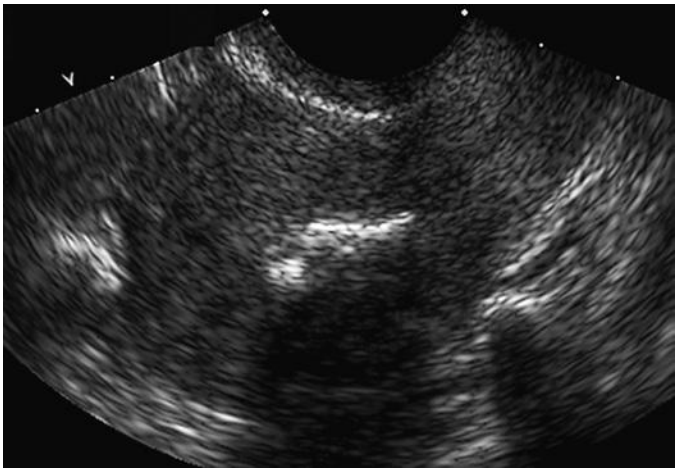

FIG 32-5 Calcified intrauterine material shown on sagittal gray-scale image of the uterus, incidentally noted on baseline infertility examination. There is angular, echogenic, densely shadowing material, indicating calcification within the endometrial cavity. This does not demonstrate characteristics of submucosal myoma or endometrial polyp. At hysteroscopy, fragments of bone were found and removed, retained since a remote prior pregnancy termination.

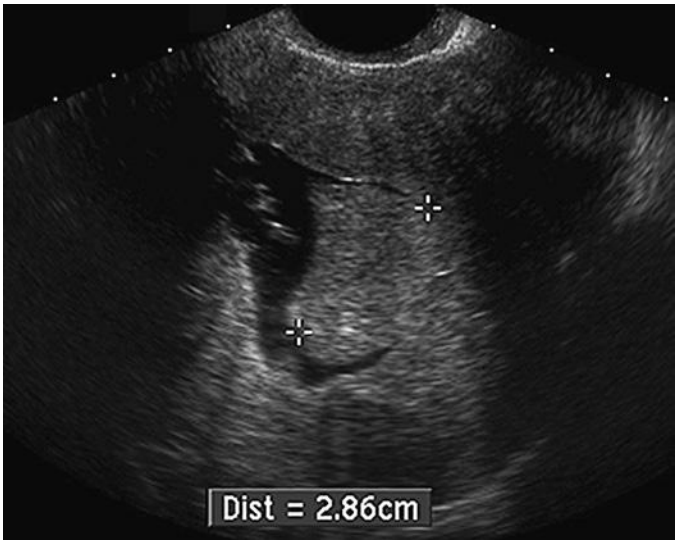

FIG 32-6 Sonohysterogram with endometrial polyp. Sagittal gray-scale transvaginal ultrsound image from a sonohysterogram. The uterus is retroflexed. Instilled anechoic intracavitary sterile saline distends the endometrial cavity and partially outlines a large (2.86 cm) echogenic polyp (*calipers*).

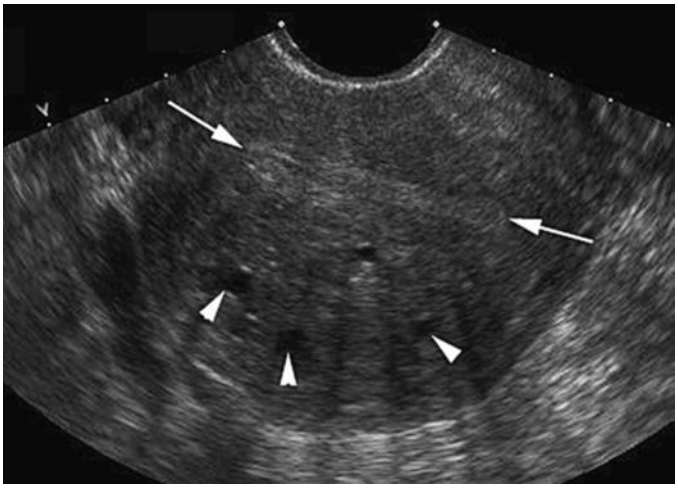

FIG 32-7 Adenomyosis. Coronal transvaginal gray-scale image demonstrating an enlarged, globular uterus, without focal mass or lobulated contour. The echogenic endometrium is asymmetrically located (*arrows*), indicating thickening of the posterior myometrium. Myometrial heterogeneity with "pencil-thin" radiating dark striations and several small cysts (*arrowheads*) is also noted.

examination. Myomas that deviate or protrude into the endometrial cavity (submucosal) (Fig. 32-8A and B) appear to have a deleterious effect on fertility because of interference with implantation, possibly secondary to pressure effect on the endometrium, which decreases receptivity, and may cause mechanical blockage of the endocervical canal or fallopian tubes. Hence, the possible presence of submucosal myomas should be carefully assessed during the preliminary workup of the infertile patient.[22-25] An increased rate of first trimester pregnancy loss is also found in patients with submucosal myomas,[22,24] and resection of submucosal myomas appears to enhance fertility.[22,23,25] Although the presence of subserosal myomas does not appear to adversely affect conception rates, the effect of intramural myomas on fertility remains unclear.[22,23,26,27] It has been proposed that the presence of intramural myomas adversely affects uterine peristalsis, with more frequent peristalsis associated with poor pregnancy rates.[28] Patients with intramural myomas also appear to have higher miscarriage rates.[24] However, it is not clear whether resection of intramural myomas is beneficial.[22,29,30] Because of all this, careful documentation with precise localization of all uterine myomas in the infertile woman is extremely important. Three-dimensional sonography can be helpful in delineation of centrally positioned myomas (Fig. 32-9A and B). If myoma location remains indeterminate, MRI, saline infusion sonohysterography (SIS), HSG, or hysteroscopy should be considered, as these techniques provide the most accurate evaluation of the endometrial cavity and demonstration of possible submucosal myomas.[7] Although myomectomy is the typical treatment option, for some patients with multiple large myomas for whom myomectomy is not an option, uterine artery embolization may have a role (see Chapter 37).[31]

Ovary

On baseline imaging, the ovaries are routinely evaluated to assess for normal expected findings and to screen for any abnormality. In the first portion of the menstrual cycle, a normal ovary will demonstrate multiple antral follicles, which measure between 2 and 9 mm in maximum diameter (Fig. 32-10). The antral follicle count (AFC) can be correlated with fertility status, response to ovarian stimulation, and success of conception.[32] A low AFC of 4 to 10 follicles between days 2 and 4 of a regular menstrual cycle suggests poor ovarian reserve, which assists in predicting outcome for fertility treatments. Infertile patients over 35 years of age, patients with a single ovary, a prior history of pelvic radiation therapy or chemotherapy, and patients with a family history of early menopause are at increased risk of decreased ovarian reserve. The potential role of 3D sonography in assessing the AFC, aiming to allow for remote evaluation of the ovary via stored 3D imaging, is under investigation.[33,34] Focal ovarian lesions are frequently found at the baseline ultrasound examination. The most common is the residual corpus luteum, a complex thick-walled cyst related to ovulation during the prior menstrual cycle (Fig. 32-11A and B). This is a normal physiologic process, and this "cyst" will spontaneously involute. Additional lesions that might be identified at baseline EVS include endometriomas (Fig. 32-12) and benign ovarian tumors such

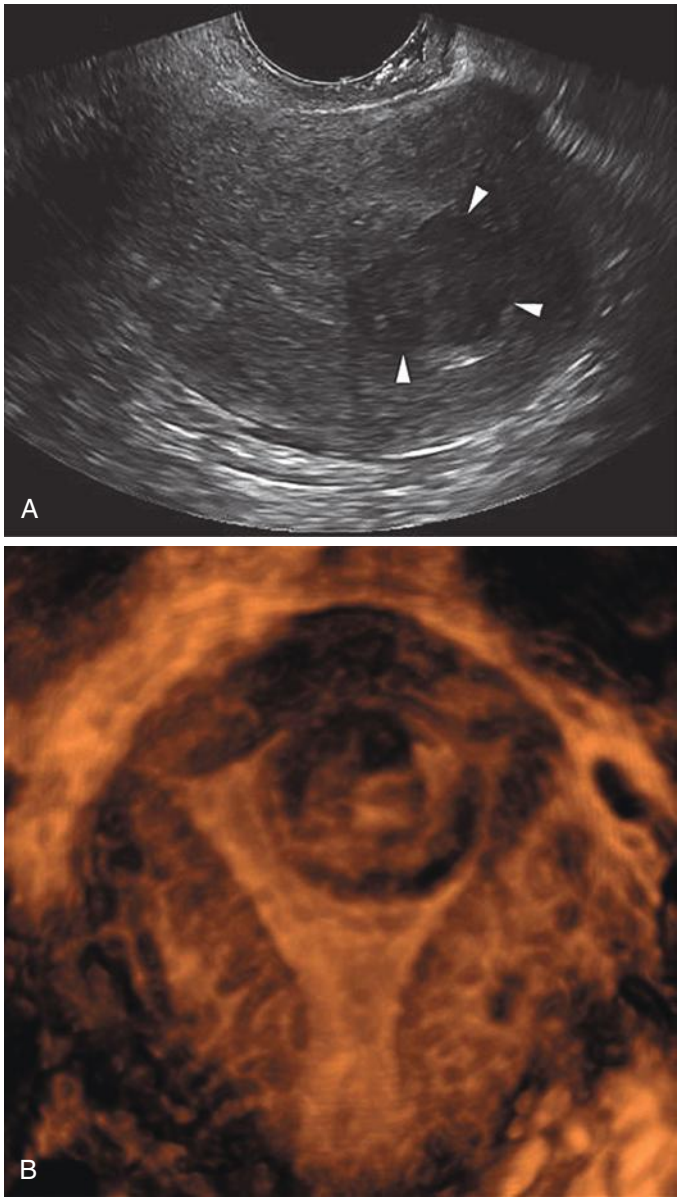

FIG 32-8 Submucosal leiomyomas. **A,** Sagittal gray-scale transvaginal image of a retroverted uterus shows a hypoechoic round solid mass (*arrowheads*), consistent with a leiomyoma, centrally positioned toward the uterine fundus. Note edge refraction at the inferior surface. **B,** Three-dimensional coronal reconstruction confirms the intracavitary location of this submucosal leiomyoma. Determining the percentage of a submucosal leiomyoma that is intracavitary is important in guiding clinical management. This leiomyoma is amenable to hysteroscopic resection because it is >50% intracavitary.

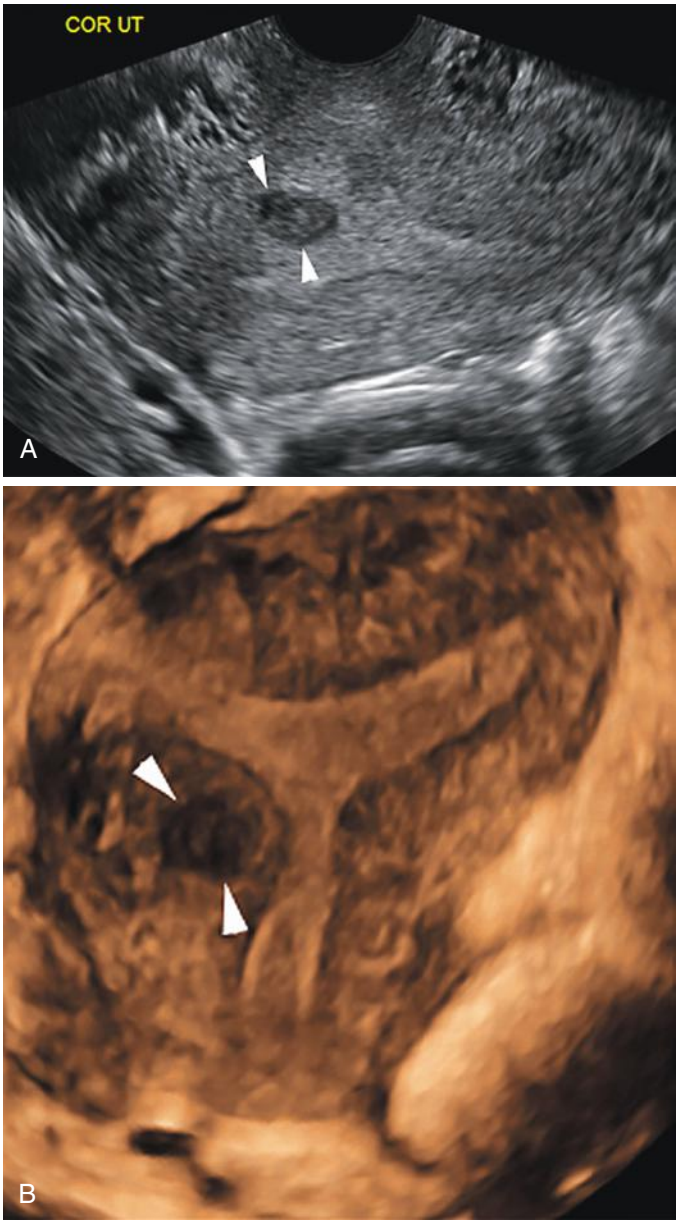

FIG 32-9 Localization of uterine leiomyoma with three-dimensional sonography. **A,** Coronal gray-scale transvaginal sonographic image of the uterus shows a small hypoechoic leiomyoma (*arrowheads*) in the central portion of the image. On this projection, the leiomyoma appears to be located within the echogenic endometrial cavity. **B,** Three-dimensional coronal reconstruction demonstrates that the small leiomyoma (*arrowheads*) is actually located within the right lateral uterine wall completely surrounded by myometrium and therefore is intramural rather than submucosal.

as dermoid cysts. The ovaries should be assessed for sonographic findings suggestive of PCOS. Patients with PCOS often present with the clinical triad of amenorrhea, hirsutism, and obesity, although clinical presentation is variable. Patients with PCOS are at increased risk of anovulation and thus infertility.[35] In 2003, the Rotterdam Consensus workshop published what was considered the standard sonographic diagnostic criteria for PCOS: 12 or more 2- to 9-mm follicles in each ovary and/or increased ovarian volume measuring more than 10 mL (Fig. 32-13).[36] More recently, it has been noted that with improved image quality and resolution resulting from rapid technologic advancements in sonographic equipment, more than 12 tiny follicles are often seen in healthy women with normal ovaries. Therefore, adhering to the Rotterdam criteria could potentially lead to an overdiagnosis of PCOS.[37,38] A modification of the Rotterdam criteria has been suggested with a threshold of over 25 small follicles necessary for the diagnosis of PCOS in patients imaged with state-of-the-art, high-resolution sonographic equipment.[37,38] At present, this issue has not been settled. The imager is reminded that PCOS is a clinical diagnosis and the sonographic findings should not be used in isolation, as they are neither entirely sensitive nor specific.

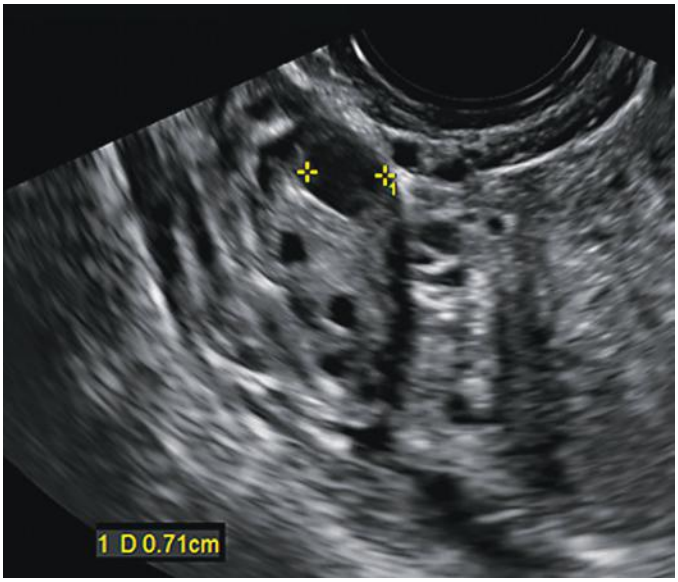

FIG 32-10 Normal ultrasound appearance of the ovary. Coronal gray-scale image of the right ovary on a baseline examination in an infertility patient. There are several antral follicles noted, the largest measuring 7 mm (*calipers*).

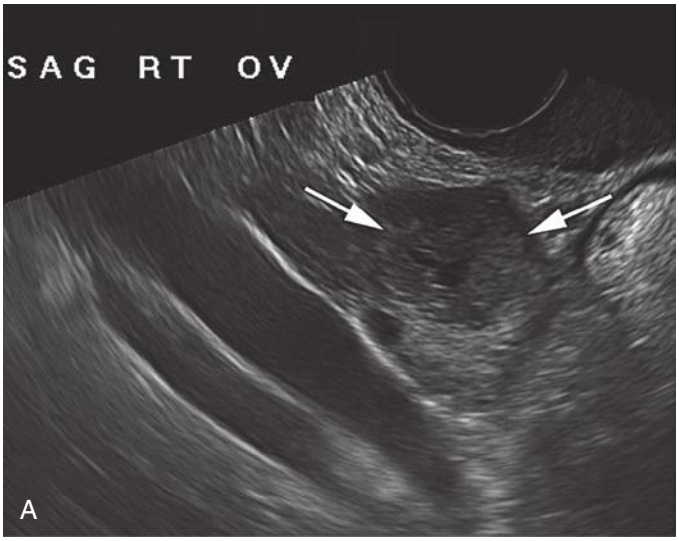
A potential additional role of EVS is to assess mobility of the ovaries. A normal ovary is freely mobile, and pressure on the ovary, either directly with the transvaginal probe or from an anterior approach with the examiner's hand or a transabdominal transducer, will often result in movement of the ovary detectable on real-time imaging. If the ovary remains fixed in position, the presence of adhesions in the pelvis is suggested, possibly related to endometriosis, prior surgery, or prior infection. Such adhesions may affect fertility by potentially preventing "pickup" of the ovum by the open fimbriated end of the fallopian tube.

Fallopian Tube

The normal fallopian tube is typically not visualized at EVS, although occasionally a collapsed normal tube can be identified (Fig. 32-14), particularly in patients with small amounts of free intraperitoneal fluid. Obstructed fallopian tubes become distended with intraluminal secretions, resulting in hydrosalpinges, which are readily visualized by sonography. A classic hydrosalpinx appears as a tubular, fluid-filled structure with an S, V, or U shape and often a folded configuration (Fig. 32-15) demonstrating the "incomplete septation sign" as the tube folds upon itself. Occasionally small spokes (<3 mm) of similar size or cogwheel-like indentations mimicking small mural nodules can be seen along the wall. The uniformity and regular spacing of these nodules, in addition to the tubal configuration, are critical features in differentiating chronic salpingitis with dilated tube and redundant or inflamed mucosa from a complex, cystic ovarian mass. Tubal patency is most commonly established by means of HSG, where free spillage of contrast material into the peritoneal cavity provides confirmation that the fallopian tube is patent. However, if a hydrosalpinx is visualized at sonography, it can be assumed that the tube is obstructed. The use of intraluminal sonographic contrast material or normal saline agitated with air during sonohysterography, termed *hysterosalpingo-contrast-sonography,* or more commonly abbreviated as HyCoSy, has been proposed as a method of determining tubal patency. Visualization of the brightly echogenic sonographic contrast material or air as it moves through unobstructed tubes and subsequently accumulates in the peritoneal cavity indicates tubal patency.[39-42] The addition of



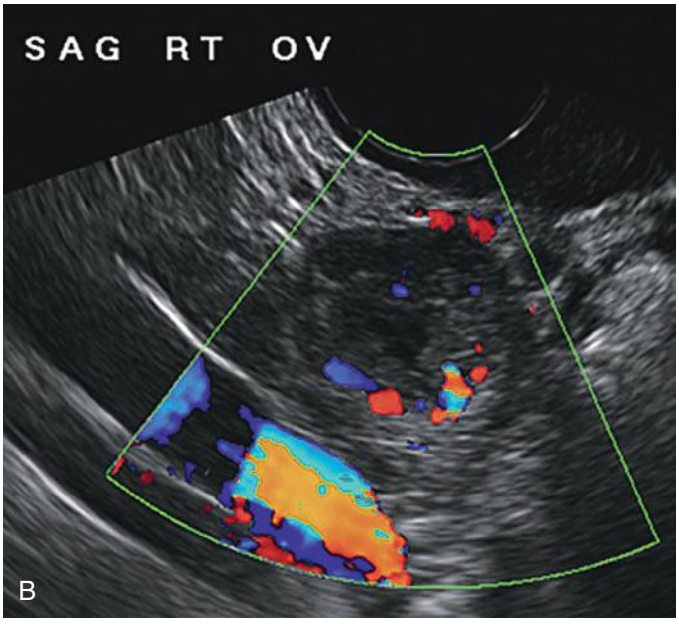


FIG 32-11 Corpus luteum. **A,** Sagittal gray-scale image of the right ovary, adjacent to the iliac artery and vein, shows a complex, hypoechoic thick-walled cyst (*arrows*) with the characteristic sonographic appearance of a corpus luteum. There is an adjacent small anechoic follicle posteriorly. **B,** Color Doppler sonographic image shows a prominent ring of peripheral vascularity at the outer edge of the thick-walled cyst, compatible with a corpus luteum.

contrast material (air bubbles) to sonohysterography (i.e., HyCoSy) does appear to provide improved assessment of tubal patency.[42] The further addition of 3D imaging to sonography with contrast injection may be useful.[43] However, all of these techniques are limited by the inability to distinguish unilateral from bilateral tubal patency (as accumulation of contrast material in the peritoneal cavity only indicates that at least one fallopian tube is patent), difficulty in completely visualizing the tube owing to tortuosity, and interference or confusion created by peristalsing bowel. Hence, unless there are comorbid conditions such as endometriosis or pelvic infection, HSG remains the reference standard to screen for fallopian tube patency,[44] as it continues to offer the unique advantage of improved pregnancy rates following the procedure, possibly due to flushing of tubal plugs and luminal debris.[45] Other proposed hypotheses for this phenomenon of improved

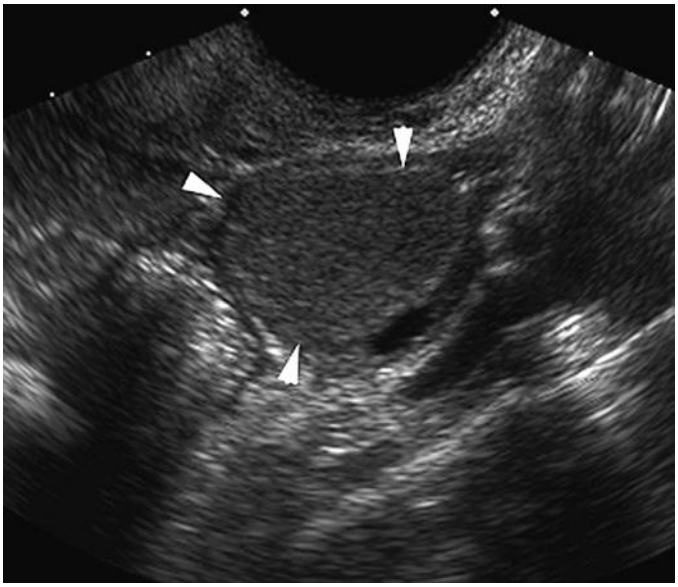

FIG 32-12 Endometrioma. Coronal gray-scale transvaginal sonographic image of the left ovary demonstrates a complex cyst (*arrowheads*), containing diffuse homogeneous low-level internal echoes, consistent with an endometrioma.

FIG 32-13 Polycystic ovary syndrome (PCOS). Gray-scale transvaginal sonographic image demonstrating an enlarged right ovary with over 12 small (2- to 9-mm) follicles, located peripherally. The central portion of the ovary has a more solid, echogenic appearance. Similar ovarian morphologic pattern was noted on the left (not shown).

pregnancy rates following HSG include stimulation of tubal ciliary action or alteration of interleukin and prostaglandin production by peritoneal macrophages, which modulate phagocytosis of sperm.[45] Whether oil-soluble media is more effective than water-soluble media remains a matter of debate and ongoing research.[45] If endometriosis or pelvic infection is suspected, then laparoscopy with intraoperative dye test might be considered to assess tubal patency, as full assessment of the pelvis with concomitant treatment could be offered.[44]

When a hydrosalpinx is identified, occlusion of the fallopian tube, which blocks the oocyte from reaching the endometrial cavity, is established. This critical piece of information will impact decision making regarding the type of fertility treatment offered, typically leading to a

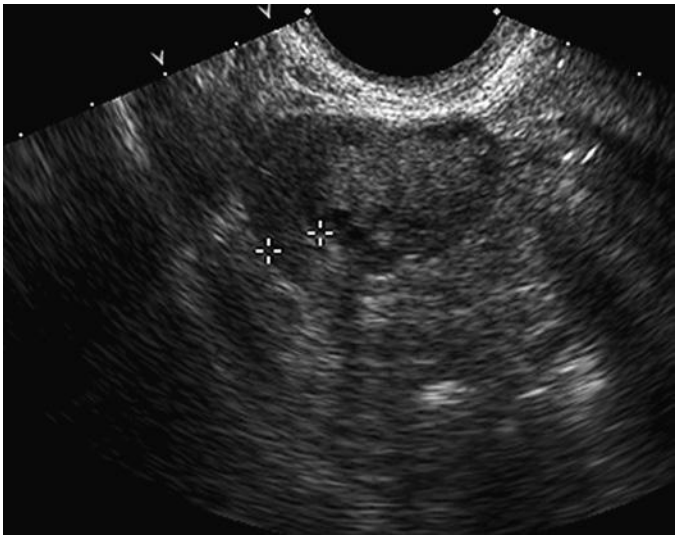

FIG 32-14 Normal fallopian tube. Coronal gray-scale image of the right ovary shows a small, hypoechoic solid structure (*calipers*) adjacent to the lateral aspect of the ovary, representing a collapsed fallopian tube.

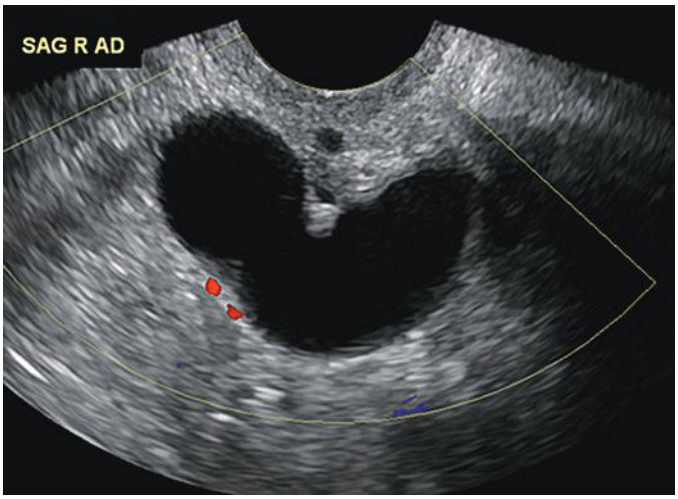

FIG 32-15 Hydrosalpinx. Sagittal gray-scale image of the right adnexa shows an anechoic, fluid-filled, elongated structure with a waist-like central narrowing consistent with a dilated fallopian tube.

recommendation for in vitro fertilization (IVF). Of note, the presence of hydrosalpinx adversely impacts fertility success rates, not only decreasing the success rate of IVF but also increasing the risk of ectopic pregnancy. Furthermore, components of the fluid within a hydrosalpinx have been shown to be toxic to the developing embryo.[46] Therefore, aspiration or resection of the abnormal tube is sometimes considered in patients with known hydrosalpinx at the time of egg retrieval, with reported increase in subsequent pregnancy rates.[47-49] If internal echoes/debris is identified within a hydrosalpinx, infection must be considered in the appropriate clinical setting.

TREATMENT MONITORING

Once fertility treatment has been initiated, transvaginal sonographic monitoring of both the endometrium and follicular development begins. Unlike the baseline study, which consists of a complete evaluation of the pelvis in all patients, a sonogram performed for

monitoring purposes is targeted to the endometrium and ovaries or occasionally to the endometrium alone.

The endometrium is evaluated for both thickness and morphologic pattern. Under the influence of hormones given for ovulation induction, the endometrium evolves from a thin (<5 mm) echogenic linear appearance early in the menstrual cycle to a trilaminar or multilayered striated appearance, measuring up to 12 or 14 mm in double-layer thickness during the periovulatory stage (Fig. 32-16). The endometrial thickness typically increases on each subsequent sonogram during the first half of the cycle. Clinical pregnancy rates are reported to be highest when the endometrium measures more than 9 to 10 mm in anteroposterior diameter, whereas an endometrium of under 6 mm correlates with a decreased likelihood of full-term pregnancy[50,51]—although the reason for this difference is unclear. Another study suggests that the combination of both the multilayered pattern and appropriate thickness (7-14 mm) is associated with the best clinical outcomes.[52] Patients undergoing transfer of embryos frozen during a prior stimulated cycle only require targeted endometrial evaluation with attention to morphologic appearance and thickness to determine optimal timing of the transfer procedure. In general, it is preferred to transfer embryos when the endometrium demonstrates a trilaminar appearance and is 7 mm or more in diameter.

Ultrasound plays a critical role in the monitoring of folliculogenesis that occurs during ovulation induction and of controlled ovarian stimulation from parenterally administered gonadotropins or orally administered clomiphene citrate. The choice of treatment is made by a reproductive endocrinology specialist, based upon the most likely cause of the infertility. In general, patients with anovulatory cycles, such as those with PCOS, are treated with clomiphene citrate, whereas patients with hypothalamic pituitary failure, diminished ovarian reserve, or failing ovaries, as well as women with unexplained infertility, might be treated with gonadotropins. Ovarian stimulation is initiated during the first few days of a normal menstrual cycle. Under the influence of stimulating hormones, multiple enlarging follicles can be seen, rather than the typical single dominant follicle created during a natural menstrual cycle. These follicles are monitored intermittently using EVS, thus providing feedback confirming appropriate treatment. Early in the menstrual cycle, patients are typically monitored with blood work and EVS every 3 to 4 days. However, when the follicles are closer to maturation and ovulation, patients are monitored more frequently, every 1 to 2 days. The reproductive endocrinologist uses the sonographic appearance of the follicles during days 7 through 10 of the menstrual cycle in combination with serum estradiol measurements to predict the most likely time of ovulation. At present, 2D real-time sonography is used for follicular monitoring, but there is increased interest in the possible future role of 3D sonography, which might improve sonographer efficiency as well as decrease measurement error.[53] Once the follicles have reached the optimal size and number (≥2 follicles over 18 mm for IVF or a dominant follicle measuring approximately 25 mm following ovulation induction with clomiphene citrate), the patient is given intramuscular hCG, as a substitute for luteinizing hormone, to trigger ovulation (Fig. 32-17A and B).

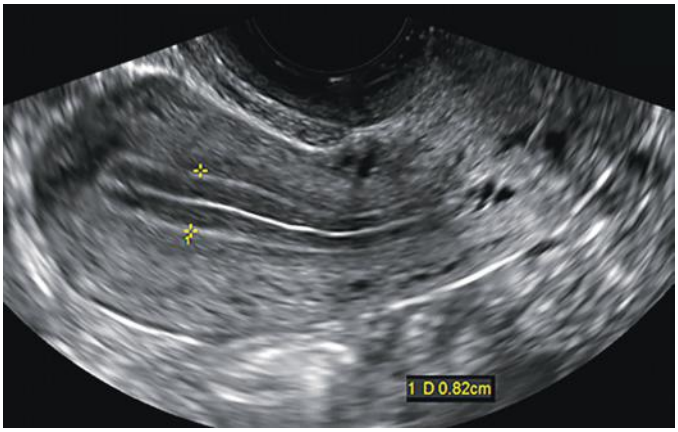

FIG 32-16 Role of ultrasound in monitoring endometrial changes. Sagittal gray-scale image of the endometrium was obtained during a follicular monitoring examination. The endometrial pattern is multilayered or trilaminar, with an anteroposterior diameter thickness measuring 8 mm (*calipers*), consistent with the periovulatory phase.

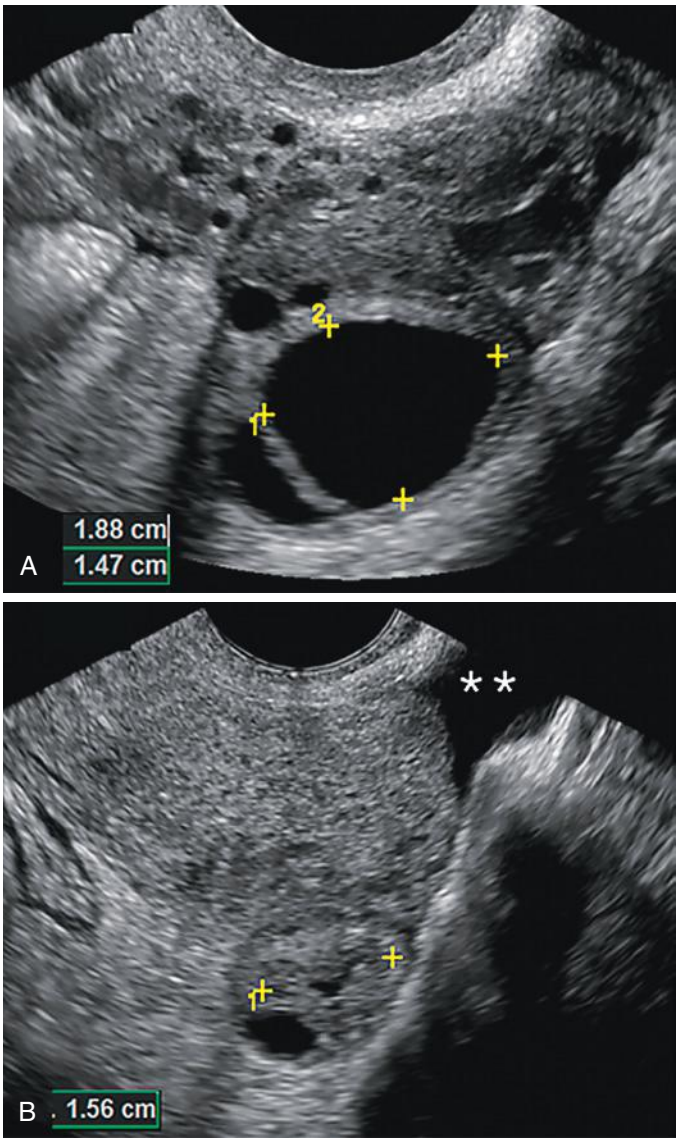

FIG 32-17 Role of ultrasound in monitoring ovarian follicular development. **A,** Coronal gray-scale image of the left ovary shows two anechoic cysts or follicles. The larger follicle measures approximately 19 × 15 mm (*calipers*). **B,** Transvaginal sonographic image of the same ovary, 2 days later. The 19-mm anechoic follicle is no longer seen. There is a small complex cyst (*calipers*) in the same location within the left ovary and new trace volume of free fluid (*asterisks*). These findings suggest interval ovulation with creation of corpus luteum (*calipers*), measuring 1.56 cm in diameter.

Careful planning of this stage permits optimal timing for either intrauterine insemination or oocyte retrieval for IVF. Depending on the cause of infertility, the number of follicles recruited may vary, reaching up to 20, with ovulation triggered when at least 4 follicles are 19 to 20 mm or greater in diameter (Fig. 32-18A and B). For patients undergoing IVF, accurate timing of oocyte retrieval is critical. If done too early, aspiration of the follicles will result in retrieval of immature oocytes and no successful fertilization. If done too late, the oocytes will have spontaneously released into the peritoneal cavity and will be lost. Here again, sonography is an essential component of treatment planning and delivery. Oocyte retrieval is performed under real-time ultrasound guidance, allowing for aspiration of each individual measurable follicle in each ovary, in order to retrieve the maximum number of mature oocytes. In the majority of patients, retrieval is performed via a transvaginal approach. However in some, the ovaries are inaccessible transvaginally and are located high in the abdomen owing to a markedly enlarged uterus, prior surgical pexy of the ovaries beyond a pelvic radiation field, or obesity. In such cases, ultrasound guidance using a transabdominal approach may be required (Fig. 32-19). The ovary demonstrates a very characteristic sonographic appearance following oocyte retrieval. At the time of retrieval, each pierced follicle immediately fills with blood. For several weeks following the procedure, the ovary remains enlarged, with multiple resultant hemorrhagic cysts visible in various stages of evolution and resorption (Fig. 32-20). If conception occurs, one of these cysts will become the corpus luteum of pregnancy.

In efforts to maximize outcomes for assisted fertility, investigators continue to research the potential role of Doppler evaluation of blood flow to the uterus and ovaries. Some Doppler studies have suggested that flow to the endometrium and subendometrium during the early luteal phase is decreased in patients with infertility compared to control subjects.[54-56] More recently, 3D imaging together with power Doppler sonography has been used to evaluate the uterus. However, results in infertile patients remain inconclusive, with reports showing

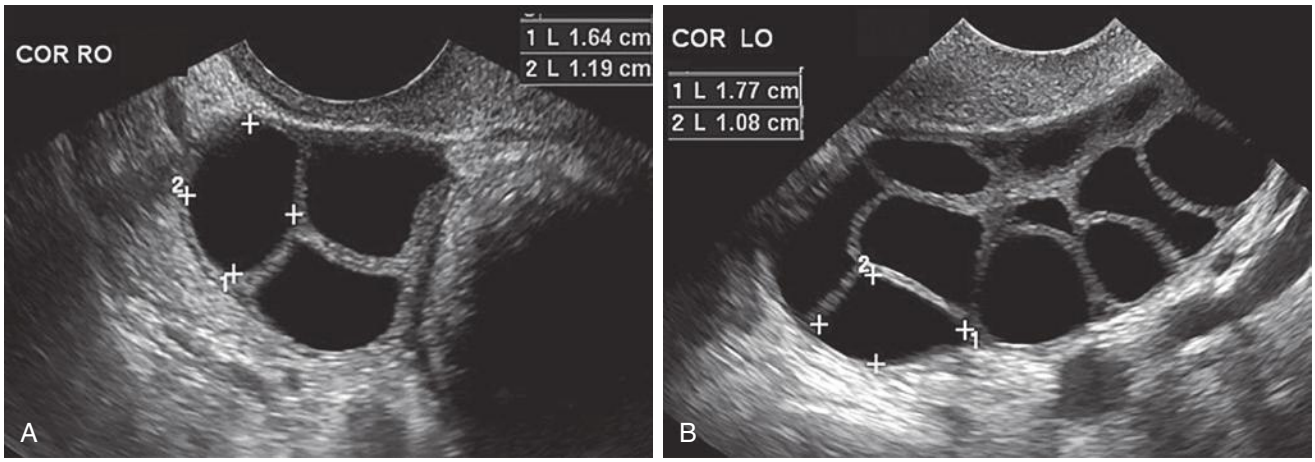

FIG 32-18 Variable appearance of ovaries on follicular monitoring studies. **A,** Three follicles are shown within the right ovary, measuring up to 16 mm in diameter (*calipers*). **B,** In a different patient, undergoing treatment as an egg donor, the follicular monitoring study shows at least 10 follicles within the left ovary, with an average follicle measuring approximately 18 × 11 mm (*calipers*).

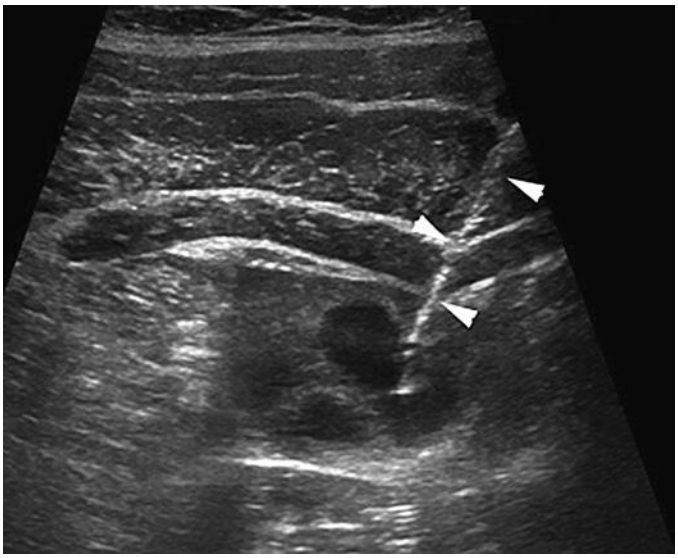

FIG 32-19 Transabdominal ultrasound guidance for oocyte retrieval. The needle (*arrowheads*) approaches from the patient's left and enters one of several anechoic follicles within the prominent ovary.

FIG 32-20 Normal appearance of the ovary following oocyte retrieval. Transverse gray-scale image shows multiple small complex cysts at the periphery of the enlarged right ovary, each containing internal echoes indicating blood.

no documented difference in blood flow to the endometrium and subendometrium,[57] no difference in uterine artery or subendometrial flow but decreased flow to the endometrium,[58] and elevated resistive index (RI) and pulsatility index (PI) of the uterine artery and decreased blood flow to the endometrium and subendometrium.[59] Similarly, the reported utility of Doppler parameters of ovarian blood flow is mixed. In one study, higher blood flow in the ovary correlated with more successful pregnancies as compared to patients with less flow,[60] whereas another group found no such difference.[61]

COMPLICATIONS OF ASSISTED REPRODUCTION

Patients with infertility who undergo assisted reproduction are at risk for several possible complications, including ovarian hyperstimulation syndrome (OHSS), hemorrhage, or infection.[62,63] OHSS is an iatrogenic process that occurs in patients who have undergone ovulation induction with gonadotropins, typically after the administration of hCG. OHSS is estimated to occur in 2% to 10% of patients undergoing assisted reproduction,[63-65] and this complication is more likely to occur in those with higher numbers of developing follicles or high levels of estradiol. OHSS can occur during the luteal phase of the cycle, prior to a positive pregnancy test, or in the early stages of pregnancy. The primary pathophysiologic process involves increased capillary permeability related to the release of ovarian vasoactive angiogenic substances.[66,67] The imaging findings of OHSS include marked enlargement of the ovaries (>10 cm in diameter) with numerous follicles and associated free intraperitoneal fluid because of third spacing. Pleural effusions can be seen in severely affected patients (Fig. 32-21A through D). The ovaries typically contain multiple complex cysts, representing recently instrumented follicles with hemorrhage. Patients may present with abdominal distention, weight gain, and hemoconcentration from third spacing of fluid. Typically, both ovaries are affected, and their large size may cause them to rise out of the pelvis and be situated near the superior aspect of the uterus. For this reason, a transabdominal imaging approach is usually preferable. Although rare, the markedly enlarged ovaries may, on occasion, undergo torsion or even rupture, which can be difficult to diagnose by sonography because the ovaries are already markedly enlarged with numerous cysts. Hence, it can be difficult to distinguish the typical gray-scale sonographic features found with ovarian torsion. Asymmetry in ovarian size or blood flow and marked tenderness to palpation are important clues to the diagnosis. Remember, however, that pain may also be caused by stretching of the ovarian capsule, hemorrhage into one or more cysts, rupture of one of the cysts, or even ectopic pregnancy. Patients with a large

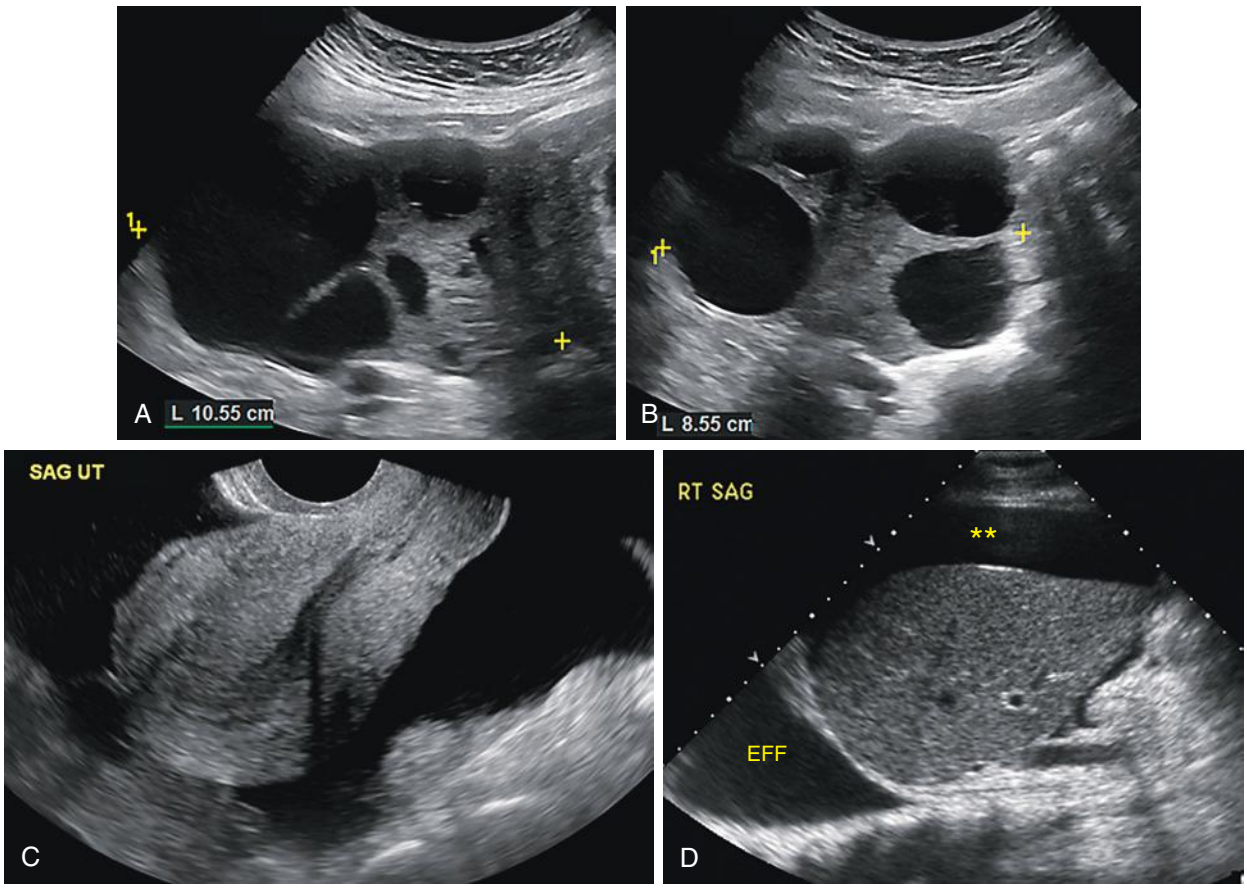

FIG 32-21 Ovarian hyperstimulation syndrome (OHSS), 2 weeks after oocyte retrieval. **A,** Sagittal transabdominal gray-scale image of the enlarged right ovary (*calipers*), which measures approximately 10.5 cm in diameter and contains multiple cysts. **B,** The enlarged left ovary measures approximately 8.5 cm in diameter and has a similar appearance, with multiple cysts shown on this transabdominal transaxial sonographic image. **C,** Sagittal transvaginal gray-scale image of the uterus shows a large amount of anechoic free fluid in the pelvis. **D,** Sagittal transabdominal gray-scale image of the right upper quadrant demonstrates free intraperitoneal fluid *(asterisks)* anterior to the right lobe of the liver and a right pleural effusion (EFF).

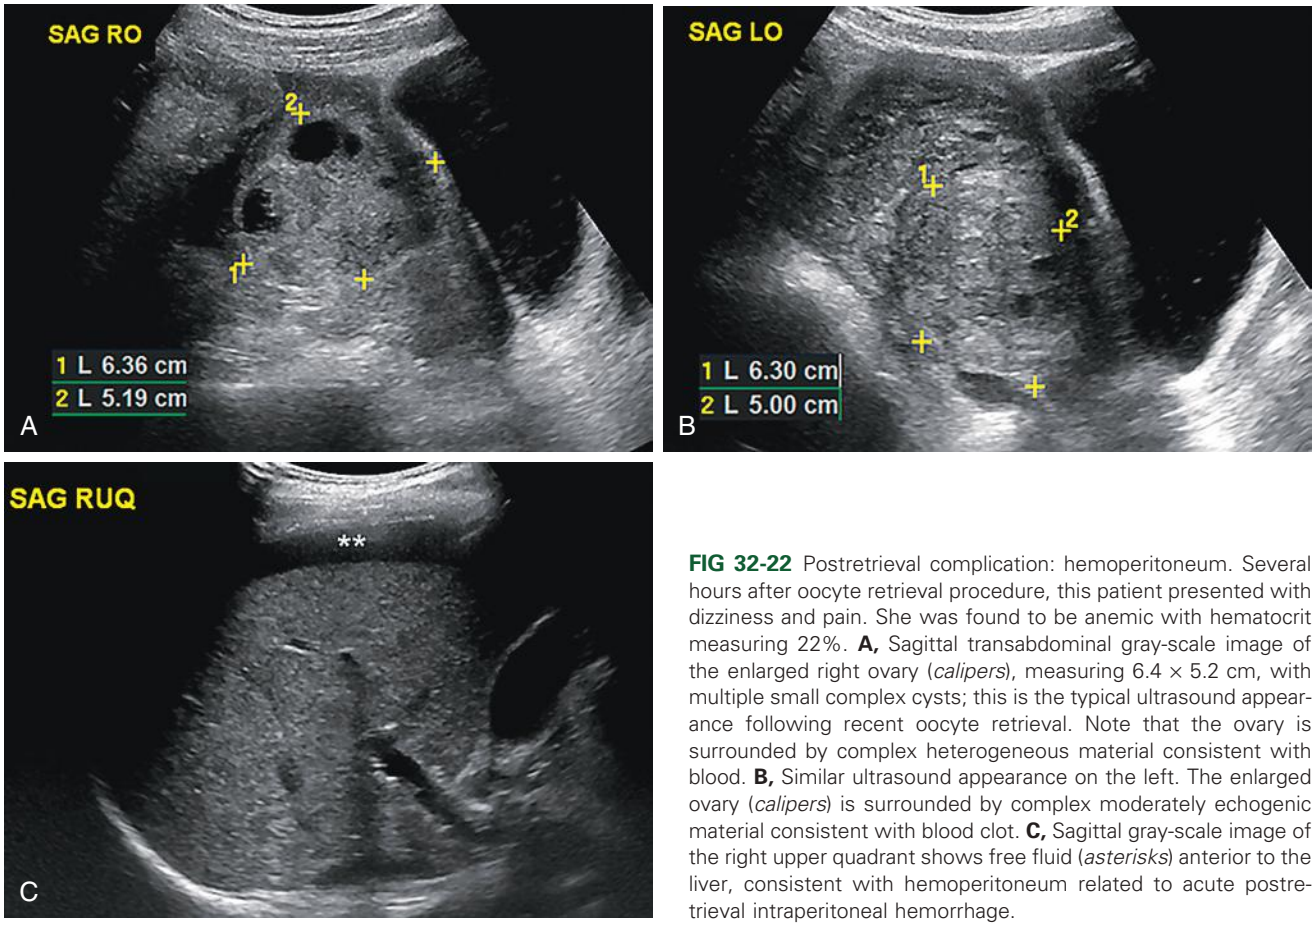

FIG 32-22 Postretrieval complication: hemoperitoneum. Several hours after oocyte retrieval procedure, this patient presented with dizziness and pain. She was found to be anemic with hematocrit measuring 22%. **A,** Sagittal transabdominal gray-scale image of the enlarged right ovary (*calipers*), measuring 6.4 × 5.2 cm, with multiple small complex cysts; this is the typical ultrasound appearance following recent oocyte retrieval. Note that the ovary is surrounded by complex heterogeneous material consistent with blood. **B,** Similar ultrasound appearance on the left. The enlarged ovary (*calipers*) is surrounded by complex moderately echogenic material consistent with blood clot. **C,** Sagittal gray-scale image of the right upper quadrant shows free fluid (*asterisks*) anterior to the liver, consistent with hemoperitoneum related to acute postretrieval intraperitoneal hemorrhage.

volume of peritoneal or pleural fluid may require therapeutic paracentesis or thoracentesis, and preprocedure sonographic localization or guidance may be useful.

The other potential complications of assisted reproduction, such as hemorrhage and infection, are related to the retrieval procedure. Both are fortunately quite uncommon.[63] During oocyte retrieval, multiple punctures of the vaginal wall and ovary are performed. Typically, the amount of bleeding is quite small, in the range of 10 to 20 mL.[68] If a larger vessel is inadvertently punctured during the procedure, the patient may present in the immediate postretrieval period with evidence of hemorrhage or hemoperitoneum, including dizziness or hypotension. The finding of complex echogenic free fluid in the cul-de-sac or elsewhere in the peritoneal cavity correlates highly with hemoperitoneum and helps differentiate intraperitoneal blood from anechoic free fluid, such as is seen in patients with OHSS (Fig. 32-22A through C). If hemorrhage is suspected, it is important to include sonographic evaluation of the upper abdomen, to assess for intraperitoneal blood not visualized using the transvaginal transducer. Postretrieval infection or tubo-ovarian abscess is a rare complication (Fig. 32-23). Of note, patients with preexisting hydrosalpinges that could harbor subclinical infection are reported to be at increased risk.[69,70]

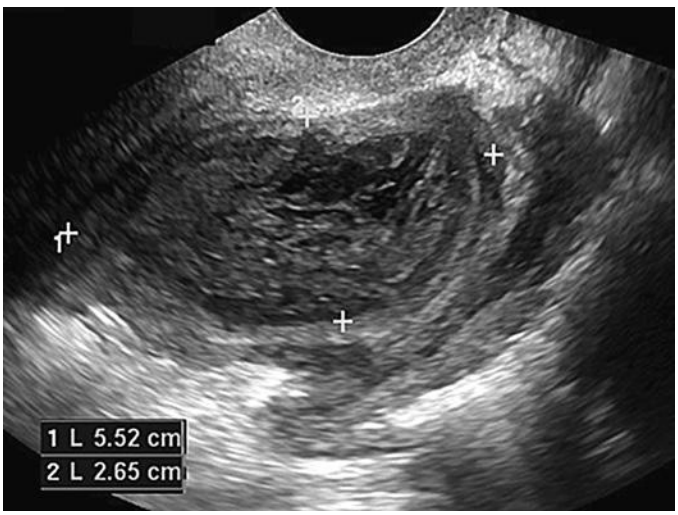

FIG 32-23 Postretrieval complication: abscess/infection. Sagittal gray-scale image of the enlarged right ovary shows a thick-walled, complex cystic structure with internal echoes (*calipers*) in a patient who presented with fever and pain 1 week after oocyte retrieval. Note a small amount of adjacent echogenic fluid inferiorly. Aspiration of the complex cyst revealed pus, consistent with postretrieval ovarian abscess/infection.

CONCLUSION

Infertility continues to be an important health care issue, and the role of sonography in the care of an infertile woman is clearly established.

From baseline evaluation to assess for structural abnormality (such as endometrial mass, uterine anomaly, or hydrosalpinx) or low antral follicular count, to monitoring of folliculogenesis, guidance for oocyte retrieval and detection of possible posttreatment complications, sonography, in particular transvaginal sonography, plays an essential role in the diagnosis and clinical management of these patients.

Ectopic Pregnancy

Oksana H. Baltarowich, Leslie M. Scoutt

SUMMARY OF KEY POINTS

- The incidence of ectopic pregnancy (EP) in the United States is increasing as a result of an increase in the number of patients with risk factors as well as an increase in diagnosis due to earlier presentation and detection.
- Mortality rate from EP is decreasing because of improved diagnostic techniques and heightened awareness among clinicians and patients.
- The most common predisposing risk factor for EP is tubal abnormality. However, up to 50% of patients with EP have no known risk factors.
- The presence of an extrauterine gestational sac containing a yolk sac or embryo (with or without cardiac activity) is the most specific sonographic finding for EP, whereas an echogenic tubal ring in the adnexa is the most common sonographic finding.
- When sonography is inconclusive, follow-up with both serum human chorionic gonadotropin (hCG) and transvaginal sonography (TVS) should be used to differentiate an intrauterine pregnancy (IUP) from an EP, as either test alone is often insufficient.
- The term *pseudogestational sac* should be avoided, because it implies the presence of an EP and turns attention away from the fact that in the pregnant patient, most intrauterine fluid collections are IUPs that could be harmed by inappropriate therapy.
- The incidence of EPs in unusual locations is increasing. Such EPs are often the result of complications from assisted reproductive techniques (ART) and are associated with higher morbidity and mortality rates compared with tubal EPs.
- The term *cornual pregnancy* has been used variably to describe interstitial EPs (located within the interstitial portion of the fallopian tube as it courses through the myometrium in the cornual portion of the uterus), IUPs located in the angular portion of the endometrial cavity, IUPs in the horn of a bicornuate or septate uterus, or pregnancies in the rudimentary horn of a unicornuate uterus. Hence, the authors recommend that the term *cornual pregnancy* be abandoned because it is confusing. Rather, a more precise, complete anatomic description that clearly states if the pregnancy is within or separate from the endometrial cavity should be provided for any eccentrically located pregnancy in the cornual region of the uterus.

OUTLINE

The most accurate definition of an EP is a pregnancy that has implanted in a location other than within the endometrial cavity (Fig. 33-1). In the United States, approximately 2% of all pregnancies are ectopic in location. Worldwide, EP is a significant cause of morbidity and death in women of child-bearing years, especially in countries or areas with poor prenatal care. The mortality rate from EP has decreased in recent years likely in large part attributable to technologic advances in ultrasound imaging, earlier sonographic imaging and diagnosis, more sensitive hCG tests, and improved treatment with laparoscopy and methotrexate (MTX), along with heightened awareness of the diagnosis among clinicians and patients. However, despite the recent improvements in technology and health care, many cases of EPs are still difficult

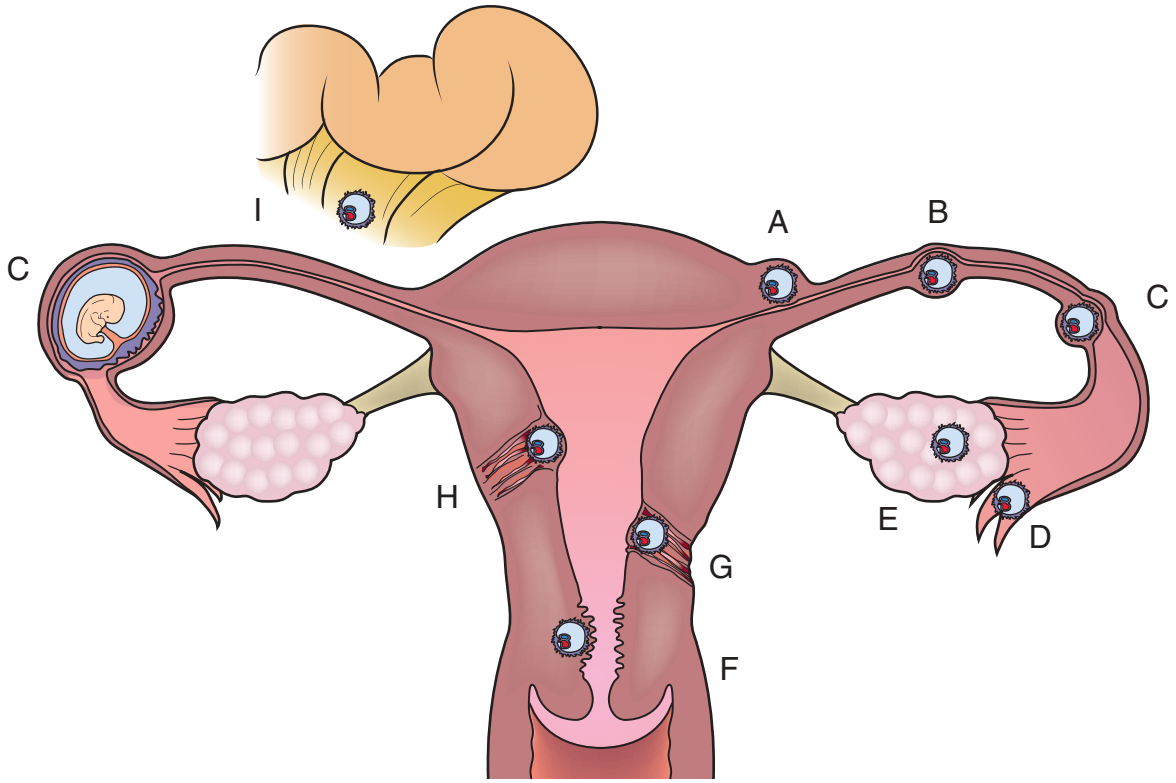

FIG 33-1 Locations of ectopic pregnancies. Ninety-five percent of ectopic pregnancies occur in the fallopian tube: in the interstitial (A), isthmic (B), ampullary (C, most common), and fimbrial (D) portions. Extratubal ectopic pregnancies may be found in ovarian (E), cervical (F), cesarean scar (G), myometrial scar (H), and abdominal (I) locations.

to diagnose, and some cases elude even the best diagnosticians. Optimal care requires balancing an early but possibly incorrect diagnosis and intervening with the progress of a normal IUP, particularly if it is a desired pregnancy, versus waiting too long to be certain and thus endangering a woman's life from rupture of an EP. This chapter will review the role of sonography in the diagnosis and management of EP, including EPs in unusual locations.

EPIDEMIOLOGY

According to data from the Centers for Disease Control and Prevention (CDC), the incidence of EP in the United States rose from 0.5% of all pregnancies in the 1970s to 2% in the 1990s.[1,2] This rise has been linked to an increase in the number of patients with risk factors as well as an increase in the number of pregnancies resulting from ART. However, the reported increased incidence of EP is also almost certainly related to earlier presentation of many patients with EP as well as improved diagnostic techniques, including more sensitive assays for hCG and high-resolution TVS. As a result, some very early EPs are now diagnosed that in years past might have spontaneously resolved without coming to medical attention.

Fortunately, the mortality rate associated with EP has progressively decreased in recent years. The EP mortality ratio in the United States decreased from 1.15 deaths per 100,000 live births in 1980 to 1984 to 0.50 death per 100,000 live births in 2003 to 2007. Based on the current average annual rate of decline, the ratio is expected to further decrease to 0.36 death from EP per 100,000 live births by 2013 to 2017.[3] Nonetheless, recent epidemiologic studies suggest that 6% of maternal deaths in the United States are caused by EPs,[4] and EP remains the leading cause of pregnancy-related death during the first trimester.

TABLE 33-1 Risk Factors for Ectopic Pregnancy

Major Risk Factors
Tubal disease
Pelvic inflammatory disease: salpingitis
Previous ectopic pregnancy
Salpingitis nodosa isthmica
Tubal sterilization
Reconstructive tubal surgery
In utero exposure to dethystilbesterol (DES)
Assisted reproductive technologies (ART)
Intrauterine devices
Minor Risk Factors
Endometriosis
Early age at first intercourse (<18 years)
Older maternal age at first pregnancy (>35 years)
Cigarette smoking
Previous pelvic/abdominal surgery
No known risk factors (50% of cases)

RISK FACTORS

The most common predisposing risk factor for EP is abnormal tubal anatomy, usually tubal scarring, which is most often secondary to salpingitis associated with pelvic inflammatory disease (PID) from sexually transmitted infections (Table 33-1). Salpingitis isthmica

nodosa, which is characterized by nodular thickening of the isthmic portion of the fallopian tube accompanied by multiple diverticula, is found in more than 50% of surgically excised tubal EPs. The diverticula correlate well with the location of the EP implantations.[5] Prior history of EP is also a major risk factor. The rate of recurrent EP is 5% to 20% after a single prior EP, but increases to greater than 30% in women with a history of two consecutive EPs.[6] Other causes of tubal scarring include tubal sterilization, reconstructive tubal surgery, and tubal abnormalities related to diethylstilbestrol (DES) exposure in utero. One study reported the risk of EP within 10 years after tubal sterilization to be 7 per 1000 procedures.[7]

In addition, the incidence of EP is increased in women who have conceived using ART, especially following in vitro fertilization (IVF), even if the fallopian tubes are anatomically normal. Tubal pregnancies may result from inadvertent direct placement of embryos into a diseased tube during embryo transfer (ET). Retrograde migration of a transferred embryo from the uterine cavity into an abnormal tube may also occur.[8] IVF patients are at increased risk of EP because of the high prevalence of tubal damage, the use of ovulation induction therapy, and multiple ETs, which put the patient at risk for heterotopic implantations. The presence of an intrauterine device (IUD) increases the risk for EP by a factor of 2.5. An estimated 25% to 50% of pregnancies conceived with an IUD in place are ectopic, and past IUD use may also pose a small increased risk for EP.[9,10] In general, infertility seems to be a risk factor. There has been no documentation of a clear association between EP and oral contraceptive use, previous elective pregnancy termination, or spontaneous miscarriage.

Other factors with less clear-cut associations have been implicated as risk factors for EP. Epidemiologic studies have shown that cigarette smoking at the time of conception is a risk factor for tubal EP. Possible explanations for this relationship include altered tubal contractility and abnormal ciliary motion from the effect of nicotine or reduced immunity in cigarette smokers, which may affect tubal response to inflammation, as in PID.[11,12] Endometriosis is also associated with higher rates of EP and miscarriage, possibly because endometriosis and other adjacent inflammatory conditions, such as acute or ruptured appendicitis, can secondarily affect the fallopian tube, thereby causing scarring and adhesions. However, more recent studies claim that there is no association between endometriosis and EP.[13] Abnormalities of the zygote and endocrine dysfunction that may affect ovum transport also increase the risk for EP. Age has also been implicated as a risk factor. Women who have their first sexual encounter when younger than 18 years of age or their first pregnancy when older than 35 years of age have a slightly increased risk of tubal pregnancy. Importantly, however, it should be recognized that approximately 50% of patients with EP have no known risk factors.[9]

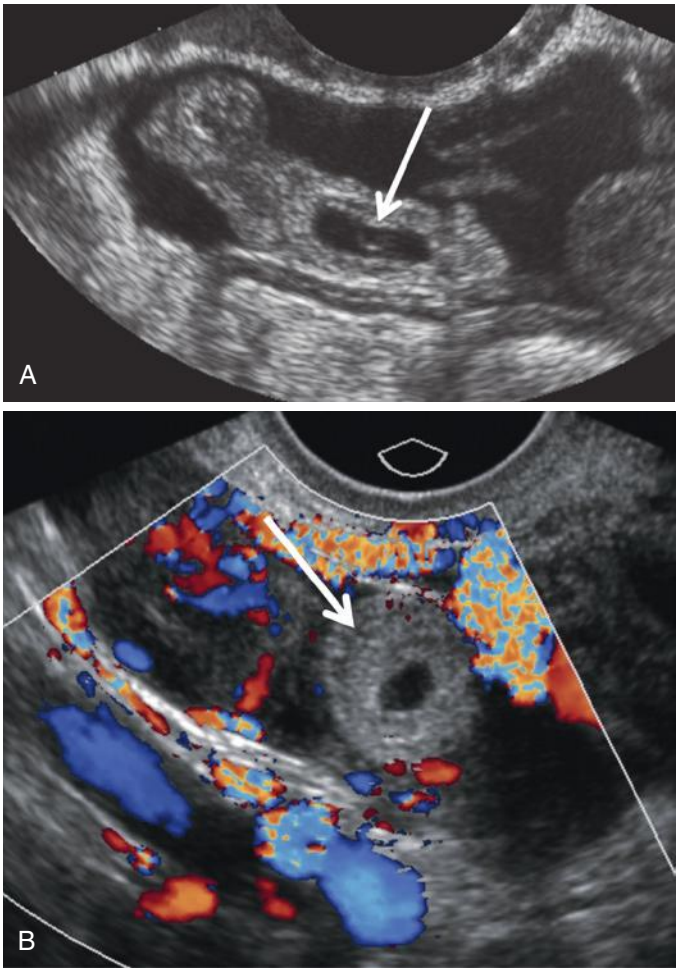

FIG 33-2 Ectopic pregnancy in the ampullary portion of a fallopian tube. The patient presented with vaginal bleeding and a positive serum human chorionic gonadotropin (hCG). **A,** Transvaginal longitudinal scan of the ampullary portion of the fallopian tube shows that it is surrounded by free pelvic fluid and contains a gestational sac with a yolk sac (*arrow*). **B,** Transverse color Doppler transvaginal sonogram of the hyperechoic tubal ring of the ectopic gestation shows no demonstrable blood flow in the echogenic ring surrounding the gestational sac (*arrow*).

PATHOPHYSIOLOGY

Approximately 95% of EPs are located within the fallopian tube (Figs. 33-1 and 33-2): 70% in the ampullary portion of the tube, 12% in the isthmic portion, 11% in the fimbriated end, and 2% to 4% in the interstitial portion.[14] Abnormal locations within the uterus include the cervix, a rudimentary horn, and myometrial scars, including scars following cesarean delivery or myomectomy. Other unusual types of EP include intraovarian, abdominal, retroperitoneal, and mediastinal, as well as chronic and heterotopic (in which there is an ectopic as well as an intrauterine gestation) EPs. EP has also rarely been reported after supracervical hysterectomy and even after total abdominal hysterectomy.

Histologically, the fallopian tube is comprised of mucosal, muscularis, and serosal layers. There is no decidua or decidua basalis as in the endometrium. The syncytiotrophoblast and cytotrophoblast of the EP invade into the muscularis layer of the fallopian tube and in essence create adherent trophoblastic tissue.[15] As the trophoblastic tissue grows and the tube stretches, it becomes prone to rupture. Some tubal pregnancies are expelled through the fimbriated end of the tube if the trophoblastic tissue is sheered from its attachment to the muscularis layer, resulting in a tubal abortion. Most of these do not survive, but rarely an abdominal pregnancy may result. If the EP implants outside the tube, then the syncytiotrophoblast and cytotrophoblast will invade underlying tissues and the placental tissue becomes extremely difficult to separate from these tissues, resulting in a substantial increased risk of hemorrhage.

In general, it is helpful to consider two broad categories that give rise to ectopic implantation. The first includes conditions that interfere with transport of the fertilized ovum to the endometrial cavity. The second includes conditions that predispose to premature implantation of the fertilized ovum before reaching the endometrial cavity. The fallopian tube should not be viewed as a passive conduit, but rather is part of a complex interactive process involving tubal peristalsis, ciliary

motion, tubal epithelium, and flow of tubal secretions along with the sperm, oocytes, and the conceptus. This all contributes to successful movement of the fertilized ovum through the fallopian tube into the endometrial cavity. This process may become disrupted or altered at many points along the way and result in abnormal implantation.[16] Scarring from prior episodes of salpingitis, tubal sterilization, or tubal reconstructive surgery as well as tubal conditions such as salpingitis isthmica nodosa and abnormalities following in utero DES exposure have been postulated to interfere with transport of the conceptus to the endometrial cavity.[17] Conditions that predispose to premature implantation are less well understood. Previously it was believed that embryos that implant ectopically were likely to have abnormal karyotypes; however, no good data support this theory. A study of 30 surgically excised EPs found no difference in the karyotypes of the chorionic villi from the EPs compared with a control group of IUPs.[18]

CLINICAL PRESENTATION

Women with EPs most commonly present with symptoms 5 to 8 weeks after the last normal menstrual period. The classic presenting clinical triad of pelvic pain, vaginal bleeding, and an adnexal mass is nonspecific and is found in 20% to 40% of patients with EP. Many patients with pain and vaginal bleeding are not pregnant, and such symptoms are commonly due to hemorrhagic or ruptured ovarian cysts, PID, or dysfunctional uterine bleeding. Even with the addition of a positive pregnancy test and amenorrhea, such signs and symptoms can occur in the setting of a normal IUP, miscarriage, or gestational trophoblastic disease. In fact, it is estimated that 70% to 90% of pregnant women who present with pain or vaginal bleeding in the first trimester and who are clinically suspected of harboring an EP turn out to have an IUP. Clinical findings may also include abdominal or adnexal tenderness. Less common presenting symptoms include referred shoulder pain from irritation of the peritoneal surface under the hemidiaphragm due to free intraperitoneal hemorrhage (Fig. 33-3), cervical motion tenderness, or the urge to defecate secondary to blood collecting in the cul-de-sac. Signs of rupture include hemodynamic instability, orthostatic hypotension, vertigo, loss of consciousness, syncope, or shock from blood loss. EPs in unusual locations may manifest with findings outside the pelvis.

However, tubal EPs can be very difficult to diagnose at an early stage. Nearly a third of cases exhibit no clinical signs and 9% have no symptoms prior to rupture, which can occur at any stage without warning.[19] Frates and associates[20] found that neither sonographic findings nor serum hCG levels were useful predictors of tubal rupture.

Hence, because of the lack of specificity of clinical presentation and physical findings as well as the absence of known risk factors in up to 50% of patients with EPs, clinicians should have a high index of suspicion for EP in any woman of reproductive age who presents with pelvic pain, vaginal bleeding, or symptoms suggestive of blood loss such as syncope or vertigo, even if her pregnancy status is not known. Certainly, any sexually active woman with lower abdominal/pelvic pain and vaginal bleeding after missing a menstrual period should be considered to have an EP until proved otherwise.

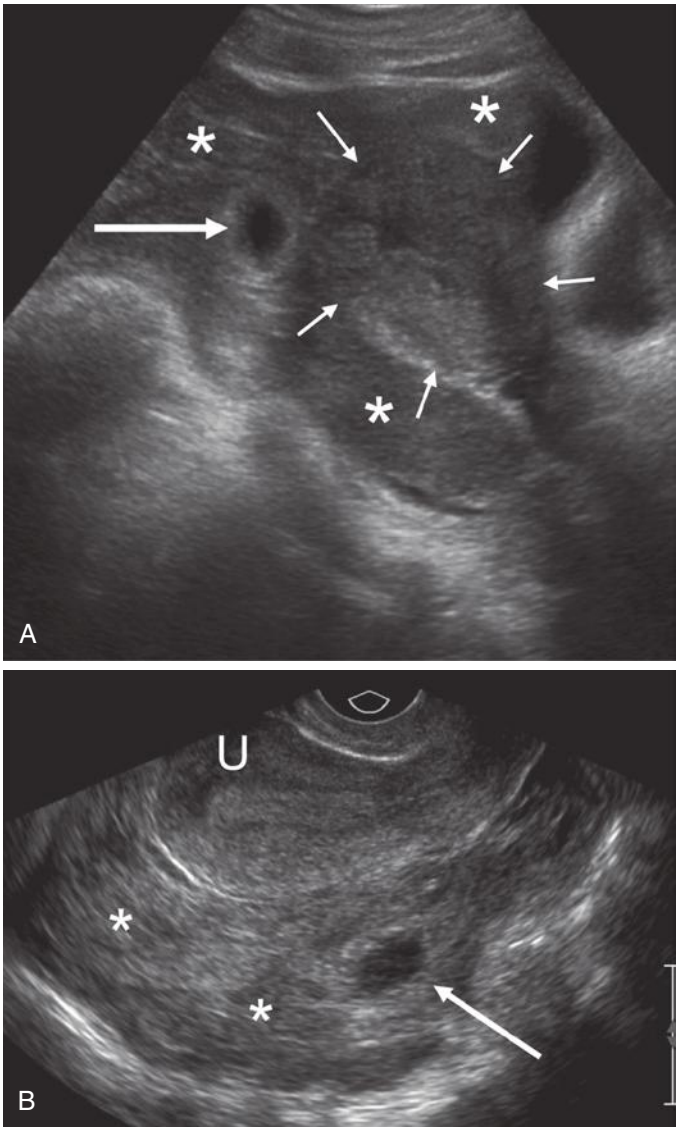

FIG 33-3 Small ruptured ectopic pregnancy causing large hemoperitoneum. The patient presented with vaginal bleeding and low serum human chorionic gonadotropin (hCG) of 240 mIU/mL and was hemodynamically unstable. **A,** Transabdominal midline longitudinal scan demonstrating the uterus (*small arrows*) surrounded by clotted blood (*asterisks*), which also surrounds a small hyperechoic extrauterine tubal ring of the ectopic gestational sac (*large arrow*). **B,** Transvaginal midline sagittal scan of the empty uterus (U) shows clotted blood (*asterisks*) in the cul-de-sac, within which lies the small echogenic ring of the ectopic pregnancy (*arrow*), which, at surgery, was found to have ruptured.

DIAGNOSTIC TESTS

Human Chorionic Gonadotropin

hCG from the blastocyst is first detectable in maternal serum 6 to 8 days following fertilization. Most current urine pregnancy test kits yield positive results 3 to 4 days after implantation. By 7 days after implantation, which is the time of expected menses, 98% of urine pregnancy tests will be positive. Current pregnancy tests are immunoassays of hCG based on monoclonal antibodies to the β-subunit of hCG and are highly sensitive and rapid, with virtually no cross-reactions.[21] If the urine test is negative, suspicion for EP is lowered, but not erased, because a urine pregnancy test will not detect levels of hCG below 25 mIU/mL. Importantly, a quantitative serum hCG test can detect levels approaching zero. If the serum hCG is negative, then an EP is almost certainly excluded, although chronic EP is still possible and rupture of an EP has been reported after the hCG dropped to zero.[22] However, both of these conditions are extremely rare.

There has been much discussion in the literature regarding discriminatory serum hCG levels above which an IUP should be definitively visible by TVS. Levels of 1000 to 2000 mIU/mL (1st International

Reference Preparation [IRP]) were previously used as discriminatory levels for expected visualization of an IUP on TVS. However, most researchers and practitioners now agree that no single serum hCG level should be used to differentiate an IUP from an EP. Rather, analysis of serial hCG levels and follow-up TVS are used to reach the correct diagnosis.[23-25] That said, if the serum hCG level is above 3000 mIU/mL (1st IRP) and the uterus is empty, a normal IUP is unlikely, although there have been anecdotal reports of delivery of a normal pregnancy following an initial TVS demonstrating an empty endometrial cavity with hCG levels as high as 4336 mIU/mL.[26] There are several possible explanations for this shift in discriminatory threshold levels. First, the incidence of multiple gestations has increased, mainly as a result of ART, and hCG levels for a given gestational age would thus be higher in a woman carrying a multiple gestation, compared to a singleton pregnancy, upon which earlier discriminatory numbers were derived. Second, data upon which earlier discriminatory numbers were based came from single institution studies with small patient populations. Third, clinical management and treatment have changed. Now, MTX is often given to treat EPs. If an erroneous, false positive diagnosis of EP is made and an IUP is not recognized, treatment with MTX can result in serious harm to the developing embryo. Hence, the current goal is to achieve 100% specificity with no false positive diagnoses of EP.

In general, the serum hCG level is lower for a given gestational age in the setting of an EP than with an IUP. Hence, when clinical findings are suspicious for possible EP, TVS is indicated even if the serum hCG is very low. Approximately 70% of women with EPs have a slow rise in serum hCG, slower than expected for a normal IUP, or a slow fall in hCG, slower than typical for spontaneous miscarriage.[9] Hence, a suboptimal increase (i.e., <53% in 48 hours) or plateau of serial hCG values suggests an EP.[9,27-29] Of note, serum hCG levels in some women with EPs may be similar to expected hCG levels in women with normal IUPs. One study revealed that up to 27% of women diagnosed with EP had hCG curves resembling normal IUPs.[30] Others have found that 15% to 20% of EPs have hCG doubling times similar to those for IUPs. In addition, studies have shown that serum hCG levels may increase by only 35% to 66% over 48 hours for some normal IUPs, rather than doubling in that time frame, as has been previously expected.[9,27,29] Furthermore, in 8% of spontaneously resolving EPs, the serum hCG level will fall in a pattern mimicking spontaneous miscarriage. As a result, the use of serum hCG levels alone for follow-up is unreliable for the diagnosis and management of EP.[31]

Using sonography alone for follow-up is also not reliable because some EPs are too small to visualize. Additionally, 6% of apparent miscarriages on ultrasound examination may actually have an underlying EP. A presumed completed miscarriage based on TVS findings of an empty uterus should be treated as a pregnancy of unknown location (PUL) until confirmed as a miscarriage based on serial hCG levels and follow-up TVS. There are reports of patients discharged to home with presumed miscarriage subsequently returning with pain, bleeding, and ruptured EP.

PUL is a descriptive term referring to a pregnancy that is detected biochemically (positive pregnancy test), but not yet visible sonographically or laparoscopically.[32] This term, a temporary descriptor, is used as a holding pattern until the location of the pregnancy is established. The incidence of PULs is dependent not only upon the expertise of the examiners and the adequacy of the sonographic evaluation but also upon gestational age. As women present earlier in pregnancy, more PULs are reported. In 1999 Banerjee and colleagues[33] reported an 8% incidence (135 cases) of PULs in their series of first trimester sonograms. On follow-up, 14% of these turned out to be EPs; 27% developed into normal IUPs; 9% resulted in miscarriages; and 50% resolved spontaneously. Kirk and Bourne[34] reported that in 8% to 31% of early pregnancies, the gestation will not be visualized on the initial TVS. The vast majority of PULs are eventually found to be IUPs or failed IUPs, and only approximately 7% to 20% are EPs. However, follow-up is very important. There is no reliable method by which to predict which PULs are IUPs and will either progress normally or miscarry and which PULs are EPs and, of these, which EPs will spontaneously resolve and which are likely to rupture.[35] Unfortunately, rupture of EPs has been reported with declining or very low hCG levels, including some rare cases with negative hCG values. It is therefore incorrect to assume that because the hCG level is low, an EP is unlikely or stable or to assume that an EP is too small to visualize and thus not perform a sonogram (see Fig. 33-3).[22,36,37]

Molecular Biomarkers

Studies are ongoing in attempts to identify diagnostic molecular biomarkers that can reliably distinguish EPs from both normal and abnormal IUPs at an early stage, when the location of the pregnancy is not yet known. These data would be extremely useful in the early diagnosis of EP, obviating the need for multiple follow-up blood tests, ultrasound examinations, and clinic visits, while at the same time decreasing the risk of EP rupture. One of the main challenges in these investigations is that there is no suitable animal model for tubal EP, so research must be performed directly in women. Biomarkers of trophoblastic function, corpus luteal function, angiogenesis, endometrial function, inflammation, muscle damage, and impaired tubal transport are currently being investigated. Although a variety of serum, plasma, and urine biomarkers have been evaluated both independently and in combination, most do not have adequate discriminatory capability to be clinically useful.[38-40] One controlled study of patients with EPs and viable IUPs with hCG levels lower than 1500 mIU/mL demonstrated that a four-marker test, including progesterone, vascular endothelial growth factor (VEGF), inhibin A, and activin A, could predict EP with 100% accuracy. However, additional investigations that include patients with abnormal IUPs are necessary to further assess the utility and reliability of this panel of markers.[41]

Transvaginal Sonography

In a patient suspected of having an EP, quantitative serum hCG levels and TVS are used in conjunction for diagnosis. It is reasonable to proceed with TVS while the quantitative hCG is being measured or independent of hCG level. Justification for performing TVS prior to obtaining the serum hCG results includes reports that up to 50% of ruptured EPs have extremely low hCG levels (<1000 mIU/mL) and that hCG levels do not necessarily correlate with risk of rupture.[22,36,37]

Although TVS is much more sensitive than transabdominal sonography, most experts recommend that scanning begin with transabdominal pelvic ultrasound, albeit without intentional filling of the bladder.[42] The aim of this limited transabdominal pelvic scan is to obtain an overview of the pelvis; establish the size, location, and position of the uterus; locate an ectopic sac in a high location (Fig. 33-4); and assess for free intraperitoneal fluid, including in the Morison pouch, between the liver and right kidney. This is an excellent method for identifying a large hemoperitoneum that may be missed by TVS. In a supine patient, blood may accumulate in the upper quadrants with only a minimal residual amount of fluid seen in the pelvis. Subsequently, a detailed TVS is performed to provide higher resolution evaluation of the uterus and adnexa.

The yield and reliability of TVS depend upon transducer frequency, patient body habitus, uterine position, presence of leiomyomas, and operator expertise. Optimal transducer frequency for TVS is usually between 5 and 10 MHz. Depth is set such that there is visualization of

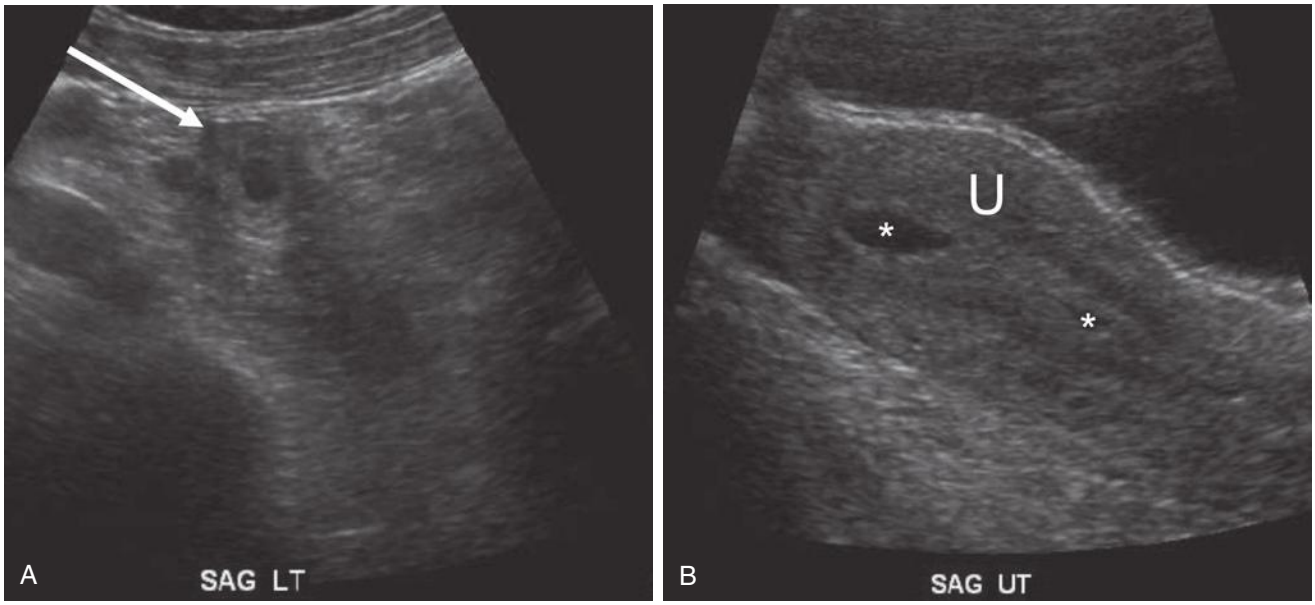

FIG 33-4 Value of a transabdominal scan in finding an ectopic pregnancy. **A,** Transabdominal longitudinal scan of the pelvis showing the echogenic tubal ring of a small ectopic pregnancy (*arrow*) situated above the uterine fundus (not shown). **B,** Transabdominal midline longitudinal scan of the uterus (U) shows a small amount of anechoic fluid in the endometrial cavity (*asterisks*), indicating a small amount of intrauterine blood. Transvaginal sonography could not image the ectopic sac because of its high location.

pelvic structures 2 to 3 cm beyond the margin of the uterus or ovary, so as not to miss an adjacent or exophytic mass. Overall gain and time gain compensation (TGC) curves are set to optimize the image within the field of view. The object of interest is placed within the focal zone, and the use of multiple focal zones improves resolution. Harmonic imaging and spatial compounding will also improve resolution. Magnification of the area of interest within the uterus or adnexa may improve visualization. Gentle bimanual palpation exerted with one hand on the transvaginal transducer and the other hand pressing on the anterior abdominal wall can be helpful and may serve to identify the area of the patient's pain, where disease is most likely to be found. This maneuver may move structures of interest toward the focal zone such that they are easier to see and will compress bowel, thereby eliminating artifact from air within the bowel lumen. In addition, exerting compression on an adnexal mass and ovary can help differentiate an exophytic corpus luteum, attached to the ovary, from an adjacent EP, which typically move apart, separate from the ovary. Three-dimensional (3D) sonography may be helpful, particularly in evaluation of EPs in unusual locations.

The first structure imaged by ultrasound is the cervix; the endocervical canal should be perpendicular to the ultrasound beam and the walls of the cervix in continuity with the myometrium of the uterine corpus. This positioning allows for evaluation of a possible cervical EP or miscarriage in progress and provides optimal visualization of the cul-de-sac, posterior to the cervix. The cul-de-sac is the most dependent portion of the female pelvis and thus is a common location for EPs or hemoperitoneum. Subsequently, the endometrium, myometrium, and adnexa are thoroughly evaluated. Any fluid within the endometrial cavity is assessed for location, shape, rim, and presence of internal echoes to determine the possibility of an IUP. If an ectopic gestational sac is not identified between the uterus and the ovary, one must scan as far lateral as possible in the pelvis, recognizing that this may result in some discomfort for the patient. Potential "blind spots," where EPs can be located and are difficult to detect include the pelvic side walls, deep cul-de-sac, above the uterine fundus, and anteriorly between the uterus and bladder. The examination must include targeted evaluation in the region of the patient's pain. Finally, if the hepatorenal space was not checked at the beginning of the examination, one should keep the patient supine and scan, looking for fluid in the Morison pouch.

Color, power, or spectral Doppler sonography may be used to demonstrate blood flow to an EP and to differentiate between vascularized trophoblastic tissue and avascular hematoma. However, Doppler sonography of the endometrium is not advised in order to avoid insonating a possible early IUP that is not yet visible. Color Doppler ultrasound parameters should be optimized for the detection of slow flow. This includes decreasing the scale or pulse repetition frequency (PRF), increasing gain and color saturation, decreasing the wall filter, setting higher color priority, and using a small color box. Spectral Doppler tracings should be obtained to confirm blood flow demonstrated on color Doppler images, as color Doppler sonography is sensitive to motion, which may create color artifact mimicking blood flow.

SONOGRAPHIC DIAGNOSIS OF ECTOPIC PREGNANCY

Uterine Findings

In the setting of EP, sonographic findings in the uterus are nonspecific and include absence of an intrauterine gestational sac and fluid in the endometrial canal. If there is no visible intrauterine gestational sac, diagnostic possibilities include EP, very early IUP, failed IUP, or heterotopic pregnancies. At this point, the pregnancy is deemed to be a PUL, and, in current practice, the diagnosis of EP should be based upon positive findings rather than on the absence of an intrauterine gestational sac with serum hCG above a specific discriminatory level. Hence, the search continues. Although the presence of an IUP makes the probability of an EP much less likely, heterotopic pregnancies have

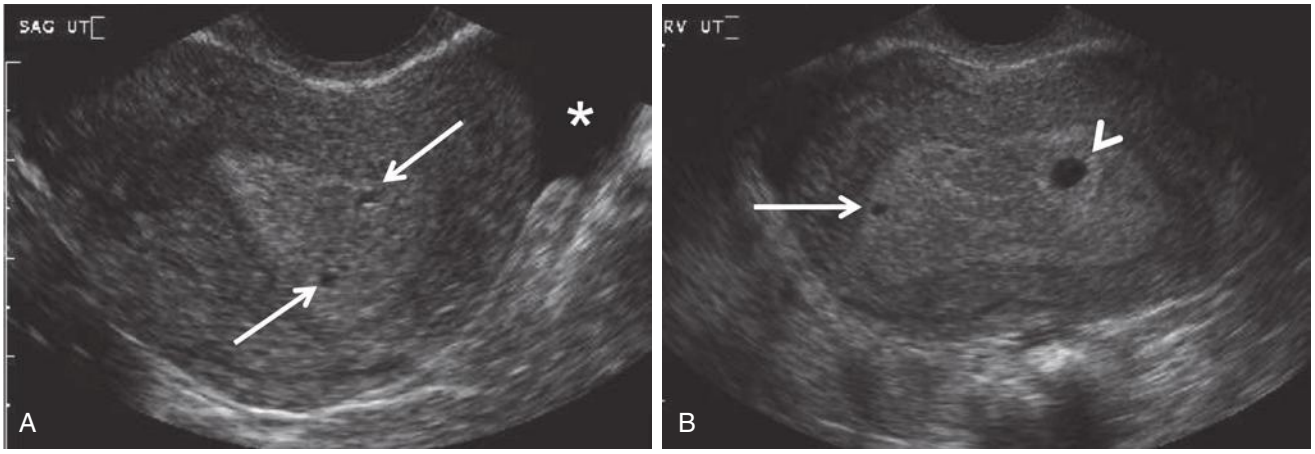

FIG 33-5 Decidual cysts. **A,** Transvaginal sagittal scan of a retroverted uterus demonstrates two small anechoic cysts (*arrows*) within the decidua, neither of which has a thick rim. Note small amount of free fluid (*asterisk*) adjacent to the uterus. This patient had a tubal ectopic pregnancy (not shown). **B,** Transvaginal transverse scan of another patient shows a small decidual cyst (*arrow*) and a very early intrauterine gestational sac (intradecidual sac sign) (*arrowhead*). Note the thicker echogenic rim around the early intrauterine pregnancy.

been reported in 1 out of 4000 pregnancies in the general population, and the incidence is as high as 1 in 100 to 300 pregnancies in women who have undergone ART.[43,44]

Endometrial thickness has not been shown to reliably predict the presence of an EP or the outcome of a PUL.[45] Likewise, decidual cysts have not been proved to be predictive of EPs, despite initial reports that a thin-walled endometrial cyst was associated with a high risk for EP[46-48] (Fig. 33-5). Although Laing and coworkers[49] reported that a thin-walled decidual cyst can be differentiated from an early intrauterine gestational sac with its thicker echogenic wall (intradecidual sac sign) (Fig. 33-5B), most authors rely on the identification of a yolk sac within an endometrial fluid collection to definitively diagnose an intrauterine gestational sac.[50]

In the past, it was thought that intracavitary blood or secretions were relatively common findings in patients with EPs. This fluid, often containing low level echoes, located centrally within the uterine cavity and surrounded by a single echogenic decidual layer, was termed a "pseudogestational sac" or "pseudosac" (Fig. 33-6). Thus, it could be differentiated from a true intrauterine gestational sac, which is either eccentric and embedded in a single layer of the endometrium (intradecidual sign) or surrounded at least partially by two echogenic rims of tissue with an interleaving hypoechoic layer (the double decidual sac sign).[51] However, at present, fluid in the endometrial canal is observed in only 10% to 20% of women with EPs, possibly because of sonographic evaluation at earlier gestational ages. Benson and associates[52] report that in current practice any round or oval well-defined fluid collection in the mid to upper endometrial cavity is statistically more likely to represent an IUP (99.98%) rather than a "pseudosac" associated with an EP (0.02%). Note that an endometrial fluid collection with a tapered or pointed edge is much more likely to be associated with an EP (see Fig. 33-6). In conclusion, the terms "pseudosac" and "pseudogestational sac" should probably be abandoned as they are confusing and of limited use. In current practice, endometrial fluid is infrequently observed in patients with EP.[53,54]

Adnexal Findings

Visualization of an extrauterine gestational sac containing a yolk sac or an embryo with or without a heartbeat is diagnostic of an EP with 100% positive predictive value (PPV)[55,32] (Fig. 33-7). The next most reliable sonographic finding is an adnexal tubal ring representing an empty gestational sac that appears as a round anechoic fluid collection with a thick echogenic rim. This has also been described as the bagel, donut, or sugar donut sign (Figs. 33-2B, 33-3A, and 33-8). The adnexal tubal ring sign has a 95% PPV for EP and is seen in approximately 50% of cases.[55] The PPV increases if the tubal ring is clearly separate from the ipsilateral ovary (Fig. 33-8B). Color Doppler sonographic imaging may increase the conspicuity of a small tubal ring (Fig. 33-8C). Although some EPs will demonstrate circumferential vascularity, most EPs will demonstrate only segmental or focal vascularity, and some may demonstrate no flow at all on color Doppler ultrasound imaging (Figs. 33-2B and 33-6C). EPs may also appear as a nonspecific adnexal mass representing hemorrhage with blood clot. These masses can be homogeneous, heterogeneous, or complex; may appear either predominantly cystic or solid; and have variable echogenicity ranging from hypo- to hyperechoic, depending upon the time course since hemorrhage occurred (Fig. 33-9). Hemorrhage contained within the fallopian tube (hematosalpinx) will appear tubular or ovoid in shape (Fig. 33-10).[56] Internal vascularity increases the likelihood that the mass represents an EP rather than bland hemorrhage from a ruptured corpus luteum. In the setting of a positive pregnancy test and an empty uterus, any adnexal mass that is clearly not either an intraovarian corpus luteum, paraovarian cyst, or pedunculated myoma has a 92% PPV for EP.[55] EPs are most commonly found situated between the ovary and uterus or in the cul-de-sac, which is the most dependent portion of the female pelvis. Although rare, it is possible to occasionally see twinning in ectopic locations. Possibilities include twin sacs in one fallopian tube, one twin in each tube, monochorionic twins, and conjoined twins (Fig. 33-11).

Cul-de-Sac Findings

Echogenic free fluid indicative of hemoperitoneum may be the only initial finding in up to 25% of patients with EPs (Fig. 33-12). Hemoperitoneum typically collects in the cul-de-sac as this is the most dependent portion of the female pelvis in the upright position. A pregnant woman with an empty uterus has a 90% probability of EP if

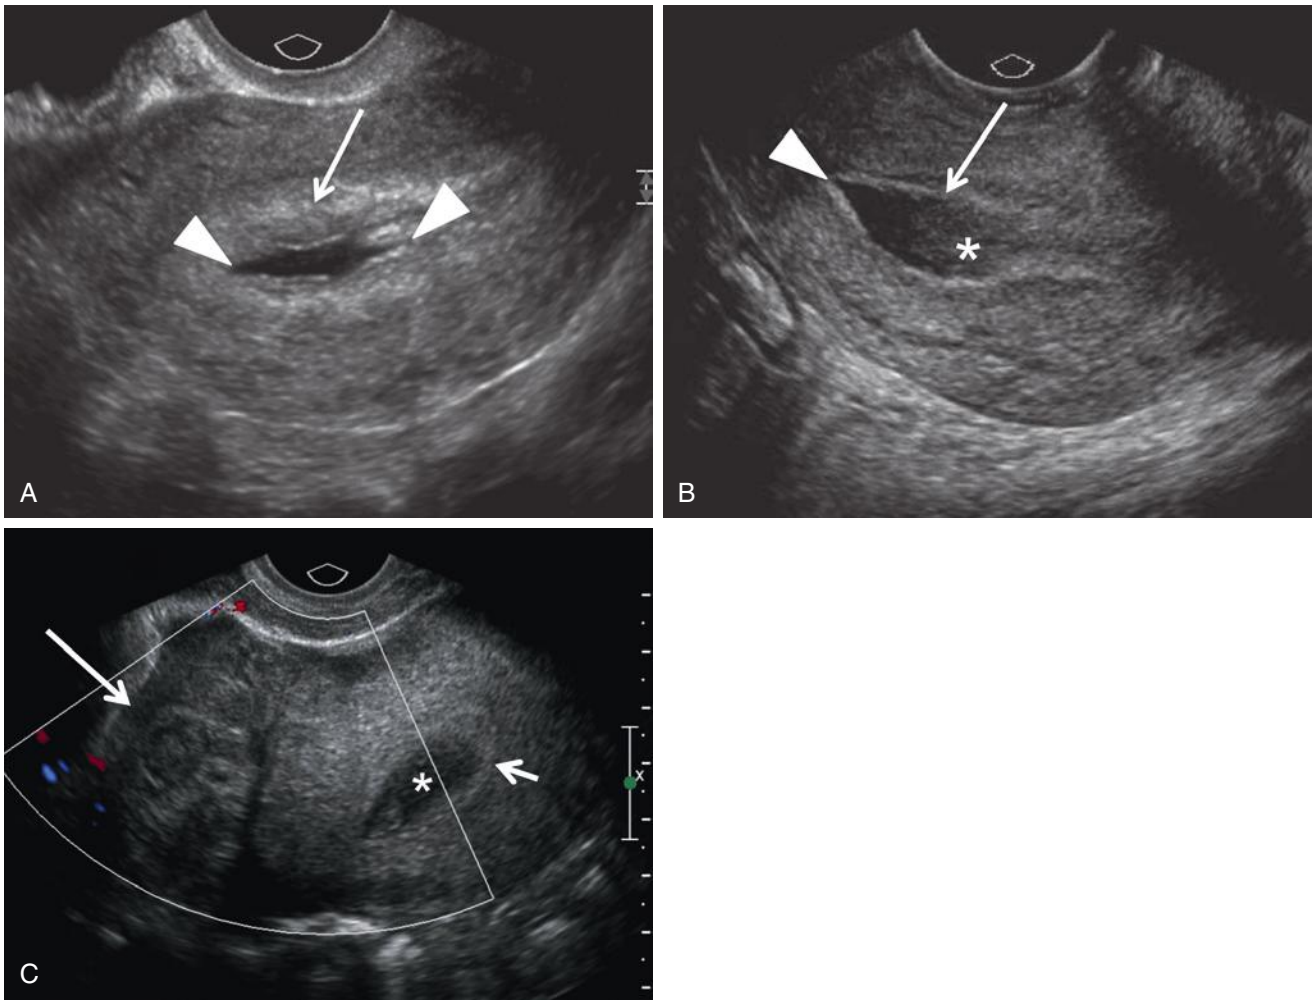

FIG 33-6 Intrauterine fluid associated with EP, referred to as *pseudogestational sacs*. **A,** Transvaginal sagittal scan of the uterus demonstrating an oblong intrauterine fluid collection with pointed margins (*arrowheads*) surrounded by a single decidual lining (*arrow*). There was an adnexal tubal ectopic pregnancy (not shown). **B,** Transvaginal scan of another patient with fluid in the endometrial canal with pointed edge (*arrowhead*). Intraluminal echoes (*asterisk*) represent blood, surrounded by single thin decidual lining (*arrow*). The patient had an ectopic pregnancy (not shown). **C,** Transvaginal color Doppler scan of a third patient demonstrating a right adnexal ectopic pregnancy adjacent to the uterus surrounded by a large hematoma (*long arrow*). The ectopic pregnancy demonstrates no blood flow on color Doppler interrogation. Fluid-containing low level echoes (*asterisk*) consistent with hemorrhage is noted centrally within the endometrial cavity. The fluid is surrounded by a single echogenic rim of decidual tissue (*short arrow*). This appearance has been referred to as a *pseudogestational sac*. However, most authors now prefer to avoid this potentially confusing terminology and use of this phrase is discouraged.

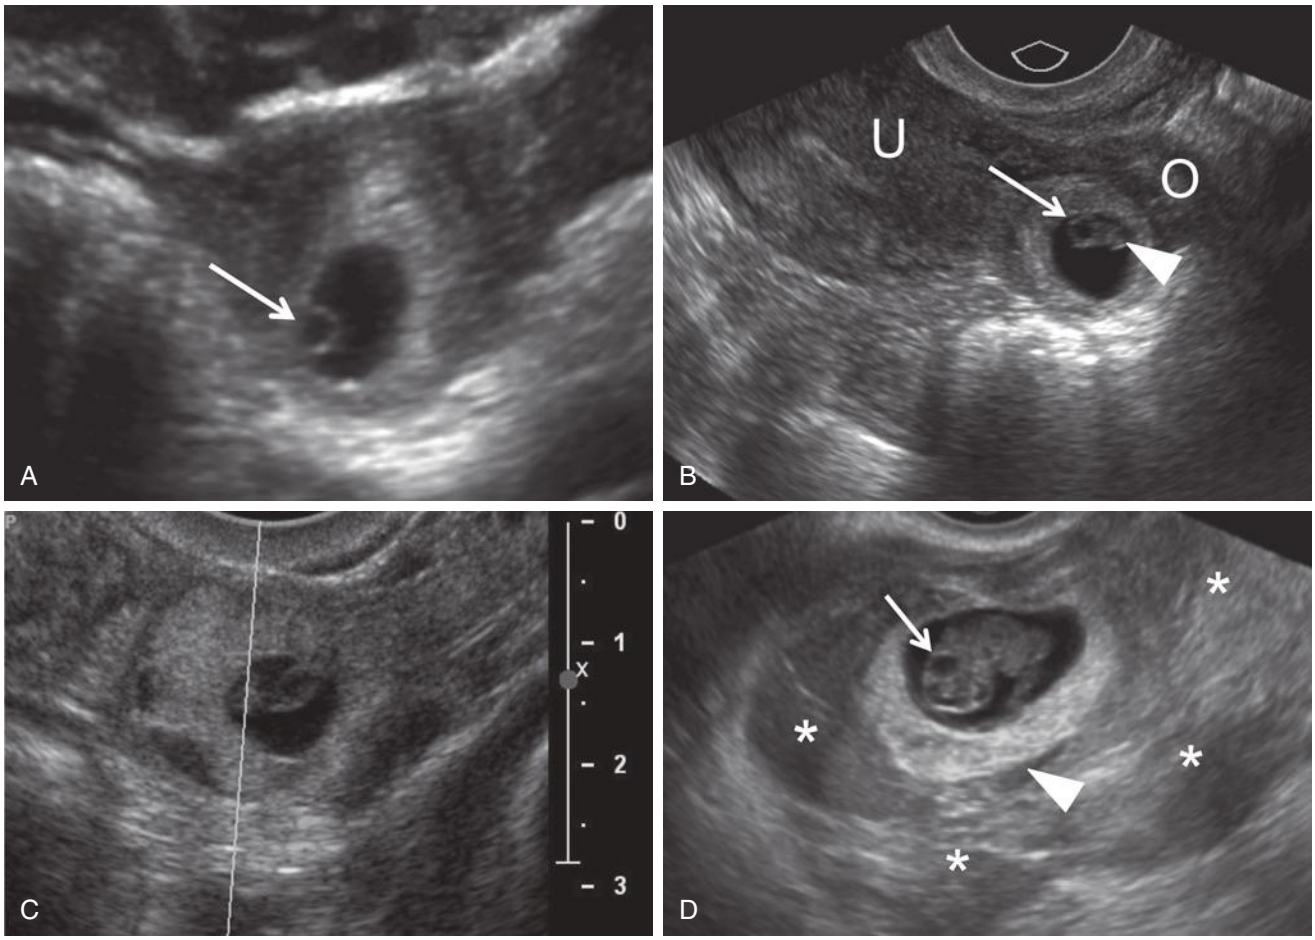

FIG 33-7 Definitive ultrasound findings of ectopic pregnancy. **A,** Transvaginal scan of an ectopic gestational sac showing a thick hyperechoic rim and a yolk sac (*arrow*) within the anechoic center, but no embryo is seen. **B,** Transvaginal scan of an ectopic gestational sac with a thick hyperechoic rim, situated between the uterus (U) and ovary (O). There is a yolk sac (*arrow*) and an adjacent tiny embryo (*arrowhead*) with no cardiac activity. **C,** Transvaginal scan of an ectopic gestational sac shows a very early embryo with M-mode (tracing of cardiac motion not shown). **D,** Transvaginal scan of the adnexa in a patient with an ectopic gestational sac containing a larger embryo. Cardiac activity was noted on real-time imaging. Note the rhombencephalon (*arrow*) in the posterior fossa. There is a large perigestational hematoma (*asterisks*) that is less echogenic than the trophoblastic tissue at the periphery of the gestational sac (*arrowhead*).

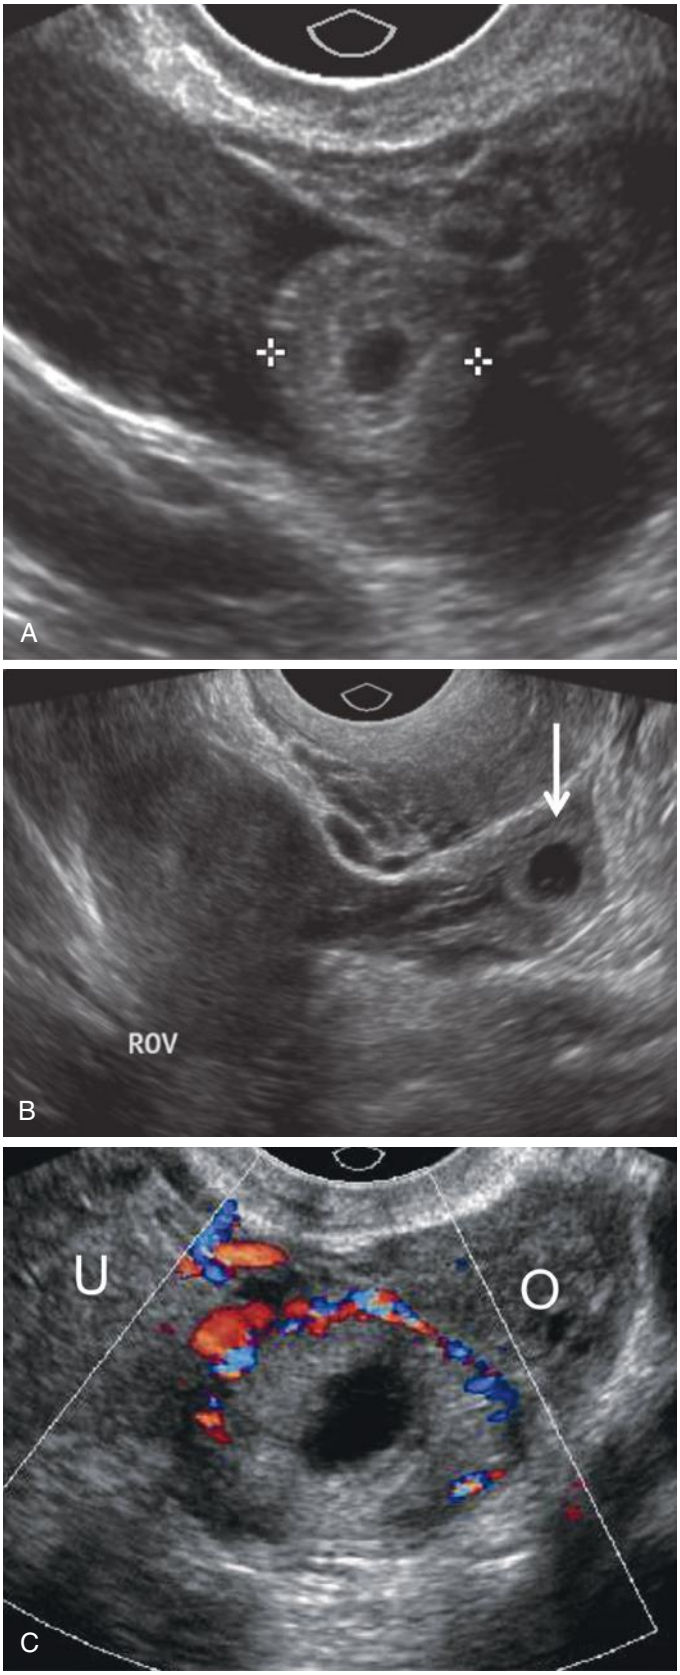

FIG 33-8 Ectopic pregnancies presenting as tubal rings in three different patients. **A,** Transvaginal scan shows a typical adnexal tubal ring (*between calipers*), also called a "sugar donut" or "bagel" sign, representing an empty ectopic gestational sac with a round anechoic fluid-filled center surrounded by a thick echogenic rim. Note a small amount of adjacent free pelvic fluid. **B,** Transvaginal scan shows the small tubal ring of an ectopic pregnancy (*arrow*) separate from and medial to the right ovary (ROV). **C,** Transvaginal transverse color Doppler scan shows the tubal ring of an ectopic pregnancy located between the uterus (U) and left ovary (O). Note the incomplete color Doppler "ring of fire."

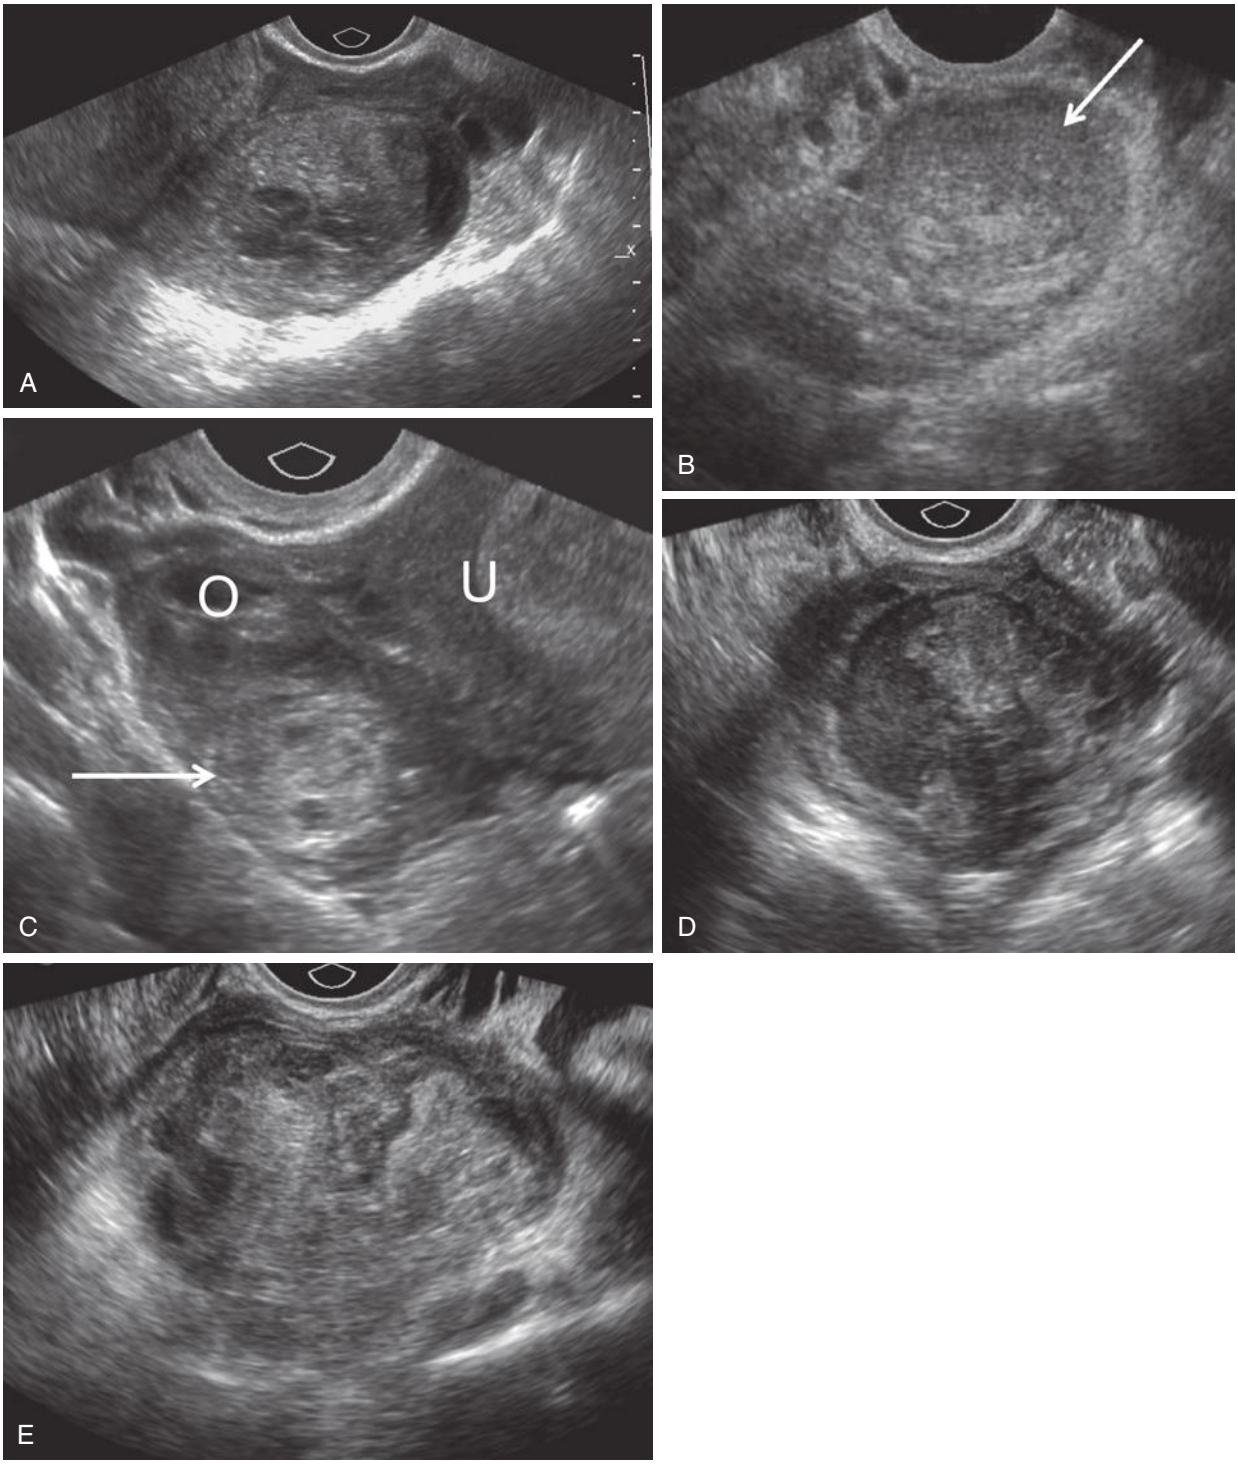

FIG 33-9 Ectopic pregnancies presenting as nonspecific adnexal masses: varying appearances in five different patients. **A,** Transvaginal scan shows a complex, heterogeneous, predominantly solid-appearing mass. **B,** This ectopic pregnancy is well marginated with a relatively homogeneous, echogenic, solid appearance (*arrow*), likely due to blood clot around the ectopic sac within the fallopian tube. **C,** Transvaginal scan shows a complex predominantly solid mass with hyperechoic components (*arrow*) surrounded by more hypoechoic hematoma, representing an ectopic pregnancy situated between the uterus (U) and right ovary (O). **D,** Transvaginal scan shows a large heterogeneous, predominantly cystic mass in the left adnexa. **E,** Transvaginal scan shows a large heterogeneous pelvic mass.

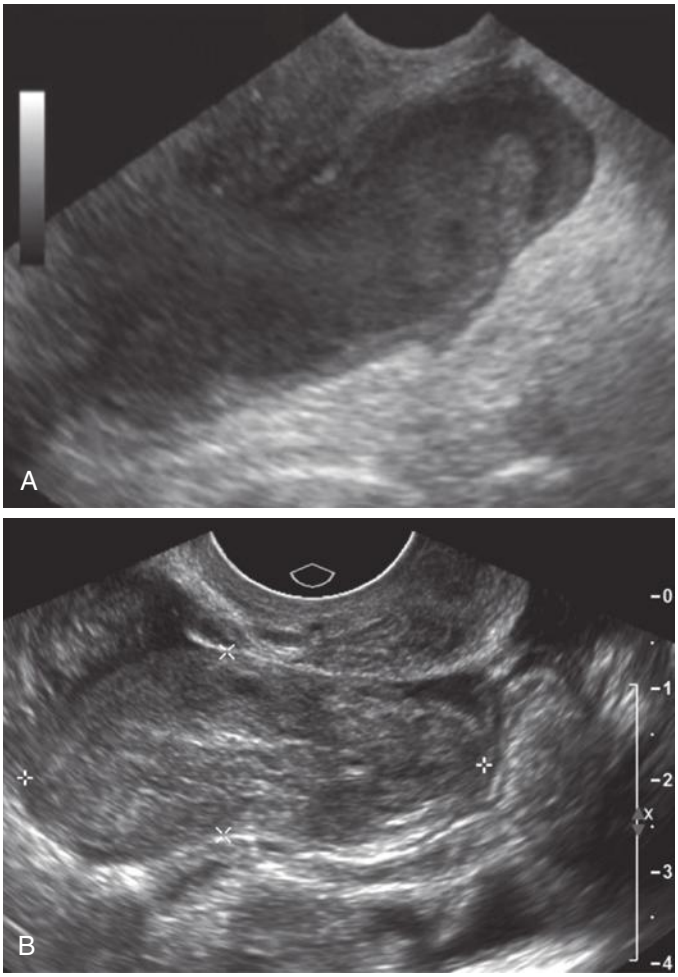

FIG 33-10 Tubular adnexal masses representing hematosalpinges from ectopic pregnancies. **A,** Transvaginal longitudinal scan demonstrates a distended fallopian tube with intraluminal complex fluid representing blood. Pathologic specimen revealed a tubal ectopic pregnancy. **B,** Transvaginal scan in another patient with an ectopic pregnancy demonstrates a well-marginated, tubular heterogeneous structure (*calipers*) consistent with a fallopian tube filled with blood. The gestational sac was not recognizable. A fallopian tube filled with blood (hematosalpinx) will appear oblong on long axis and round on short axis. Smooth well-defined margins and tubular shape help differentiate a tube filled with blood from an adnexal hematoma. (B from Bryan-Rest LL, Scoutt LM: Ectopic pregnancy. In Fielding JR, Brown DL, Thurmond AS (eds): Gynecologic Imaging. Philadelphia, Elsevier, 2011, p 335, Fig. 22-4B, used with permission.)

a moderate to large amount of echogenic free peritoneal fluid is found. However, the volume of free fluid has low sensitivity, specificity, and PPV for determining tubal rupture.[20] The amount of free fluid is a good indicator of the risk of hemodynamic instability. Therefore, the upper abdomen should always be assessed as the presence of free fluid in the Morison pouch suggests that there is a relatively large volume and would increase concern for potential hemodynamic instability. When evaluating free fluid, careful attention should be paid to technique as high gain settings can create artifactual echoes. Comparison of cul-de-sac fluid with known anechoic fluid such as urine in the bladder or fluid in an ovarian cyst/follicle at similar depth will help reveal whether echoes are real or artifactual (Fig. 33-12B). One can also look for layering or movement of low-level echoes. It should be remembered that on occasion acute hemoperitoneum may appear as anechoic fluid. Occasionally, hemoperitoneum in the Morison pouch may appear so echogenic that it approximates the echogenicity of adjacent hepatic parenchyma and may be mistaken for liver because of the silhouette effect (Fig. 33-13). Also, clotted blood may appear echogenic and mass-like, and thus may be difficult to differentiate from loops of bowel (Fig. 33-12D). After the initial clotting stage, fibrinolysis begins and hemoperitoneum will appear heterogeneous, making it more difficult to visualize a small ectopic gestational sac amid amorphous material in the cul-de-sac (see Figs. 33-3 and 33-12B).

Pitfalls

General limitations in the sonographic diagnosis of EP include lack of operator experience, training, skill, persistence, or lack of attention to details. Patient obesity, leiomyomas, uterine anomalies, retroflexion of the uterus, or hydrosalpinx may also limit sonographic evaluation. Careful and complete patient history should address risk factors such as prior EP, ART, PID, or tubal surgery. If the patient presents at an early gestational age, the EP may be too small to visualize and may fall below the limits of resolution of the ultrasound equipment.

Potential pitfalls in image interpretation include misconstruing fragments of decidua or blood clot within an intrauterine fluid collection as either a yolk sac or embryo, thus leading to a false positive diagnosis of IUP[57] (Fig. 33-14). It can also be very difficult to differentiate an exophytic corpus luteum from an EP (Fig. 33-15), particularly because 80% of EPs will be located ipsilateral to the ovarian corpus luteum (Fig. 33-16). There are several useful points of distinction (Fig. 33-17). A corpus luteum arises from the ovary, and intraovarian EPs are extremely rare (see later). Although a corpus luteum can be exophytic, a peripheral crescent of ovarian parenchyma, termed the "claw sign," will typically be observed surrounding at least part of the corpus luteum. However, if a mass adjacent to the ovary represents an EP, it will be separate from the ovary with an acute intervening angle between the structures and no "claw sign" (see Fig. 33-17). When prodded with the transvaginal probe or with palpation on the anterior abdominal wall, the EP will typically slide away from the ovary, whereas a corpus luteum will remain attached to and move with the ovary.[58] The tubal ring of an EP is typically thinner and more echogenic than the homogeneous thick wall of the corpus luteum[59,60] (Figs. 33-15A, 33-15C, 33-16A, and 33-17C). However, there is considerable overlap in the echogenicity and thickness of the walls of a corpus luteum and an EP. As a corpus luteum involutes, the inner margin may become crenated or stellate in appearance (Fig. 33-15A and B). Internal echoes are relatively common as a result of hemorrhage and may mimic a yolk sac or embryo (see Fig. 33-15B). Magnified views using harmonic imaging or spatial compounding may be helpful given that definitive identification of a yolk sac or embryo in an adnexal ring-like structure confirms the diagnosis of EP. Both a corpus luteum and an EP can demonstrate marked peripheral vascularity on color Doppler imaging, termed the "ring of fire," with low-resistance spectral Doppler waveforms with increased diastolic flow. Neither the degree of mural vascularity depicted on color Doppler ultrasound nor the characteristics of flow on spectral Doppler waveforms is helpful in differentiating an EP from a corpus luteum. Although the "ring of fire" sign was initially described as a pattern of color Doppler flow suggestive of EP, subsequent experience has shown that a complete circumferential (360-degree) "ring of fire" is actually more commonly seen with corpora lutea[61] (Figs. 33-15B, 33-15D, and 33-16B). Blood flow in the tubal ring of an EP is more likely to be focal and segmental (Figs. 33-8C and 33-11A).

Other potential sonographic mimickers of EP include degenerated, pedunculated myoma, pelvic abscess, and bowel loops. A painful,

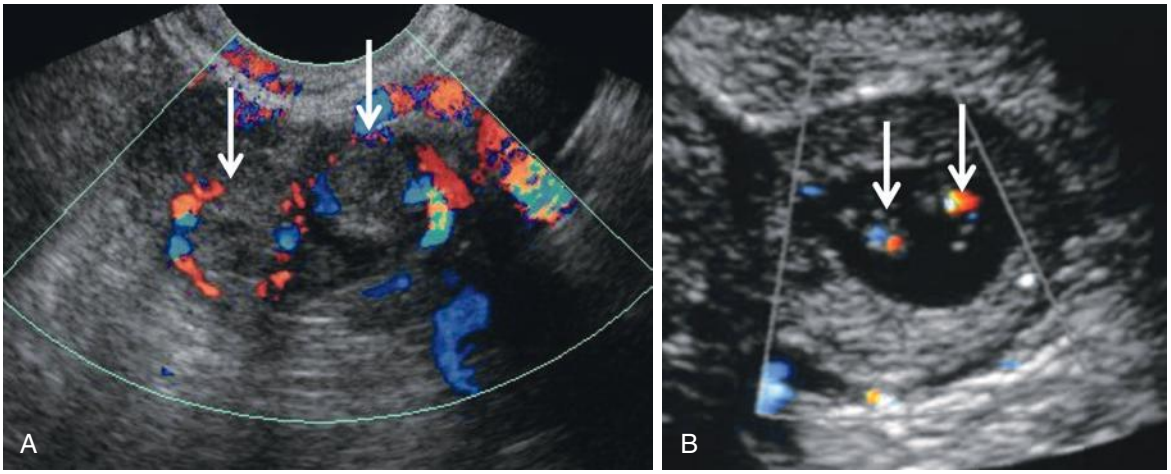

FIG 33-11 Twin ectopic pregnancies. **A,** Transvaginal color Doppler image of dichorionic diamniotic twin ectopic gestational sacs (*arrows*), the most common form of twinning resulting from embryo transfer techniques. Note that blood flow shown in the tubal rings is discontinuous, segmental, and focal, rather than a complete 360 degree ring of vascularity, which is more commonly observed with the corpus luteum. **B,** Transvaginal color Doppler scan shows monochorionic twin embryos with central color pixels (*arrows*) representing cardiac motion in an ectopic tubal pregnancy.

degenerated uterine myoma may have an echogenic rim and a cystic center (Fig. 33-18). Demonstration by Doppler ultrasound of feeding vessels from the uterus establishes the origin of the mass (Fig. 33-18B). A thick-walled abscess with echogenic purulent fluid in the cul-de-sac may mimic an EP (Fig. 33-19). However, most pelvic abscesses will be multilocular and the clinical presentation would include fever and a negative pregnancy test. Bowel loops can potentially mimic a pelvic mass, and, thus, observation of peristalsis is useful in this determination.

ECTOPIC PREGNANCIES IN UNUSUAL LOCATIONS

As previously stated, the most accurate definition of ectopic (Greek *ektopos,* out of place) pregnancy is a pregnancy that has implanted in a location other than the endometrial cavity. Although the vast majority of EPs will implant in the fallopian tube, approximately 4% of EPs are found "out of place" in more unusual locations. These unusual sites of implantation include the interstitial portion of the fallopian tube, cervix, ovary, cesarean incision scar, myometrial scar, abdominal cavity, and even more rarely the retroperitoneum (see Fig. 33-1). Often such EPs are the result of complications from ART, but unusual implantations can also occur spontaneously. These EPs are associated with increased morbidity and mortality rates compared to tubal EPs and are increasing in incidence.[62]

Interstitial Ectopic Pregnancy

Interstitial EPs account for 2% to 4% of all EPs. Predisposing risk factors include salpingectomy, previous EP, uterine anomalies, and in vitro fertilization with embryo transfer (IVF-ET).[63] Interstitial EPs occur when trophoblastic tissue implants within the interstitial (intramural) portion of the fallopian tube as it courses through the myometrium in the cornual region of the uterus (Figs. 33-20 and 33-21A). Interstitial EPs are found lateral to the round ligament and the uterotubal junction. The terminology for EPs occurring in this region is confusing and has been inconsistently reported in the literature. Because a bulge in the outer contour of the cornual portion of the uterus is typically visualized both sonographically and at surgery, the term *cornual EP* has also been used to describe pregnancies in this area, and the terms have often been used interchangeably. Other authors use the term *cornual pregnancy* to describe an IUP in the right or left horn (cornu) of a bicornuate or septate uterus (Fig. 33-21D and E). Still others use the term to refer to a pregnancy located in a rudimentary horn in a patient with a unicornuate uterus (Fig. 33-21B and C). Eccentric IUPs located in the superolateral corner of the endometrial cavity at the uterine fundus have also been referred to as cornual pregnancies. However, these pregnancies have a broad interface with the endometrium and, are intrauterine rather than ectopic in location, and in the authors' opinion are best referred to as *angular pregnancies*[64-67] (Fig. 33-21F). Because the term cornual pregnancy has been used by different authors to describe a variety of findings ranging from a normal IUP to an IUP in the setting of a congenital uterine anomaly to an EP, the authors suggest avoiding the use of the term altogether. In this text, we use the term *interstitial ectopic pregnancy* to refer to a pregnancy implanted in the interstitial portion of the fallopian tube that lies within the myometrium. We do not use the term cornual pregnancy. We use angular pregnancy to describe an IUP located in the lateral angle of the endometrial cavity at the uterine fundus where the fallopian tube joins the endometrial cavity. When reporting sonographic findings, we strongly recommend that the location of the pregnancy be precisely described as intrauterine (i.e., within the endometrial cavity) or ectopic (i.e., outside the endometrial cavity). No matter what term is used, it is necessary to reach agreement, provide careful detailed reports, and avoid confusion and miscommunication with clinicians because maternal morbidity, mortality, and treatment of EPs (interstitial EPs and rudimentary horn pregnancies) and IUPs (angular pregnancies and those within bicornuate and septate uteri) are very different.

The primary diagnostic imaging findings of an interstitial EP are eccentric location of the gestational sac within the myometrium and clear separation from the endometrial cavity (Fig. 33-22). A key feature is demonstration of intervening myometrial tissue separating the medial margin of the gestational sac from the echogenic endometrium. The myometrium surrounding the gestational sac will be markedly thin peripherally; and on occasion, there will be no visible myometrial tissue surrounding the lateral margin of the gestational sac, which bulges beyond the superolateral serosal surface of the uterine fundus.

Text continued on p. 985

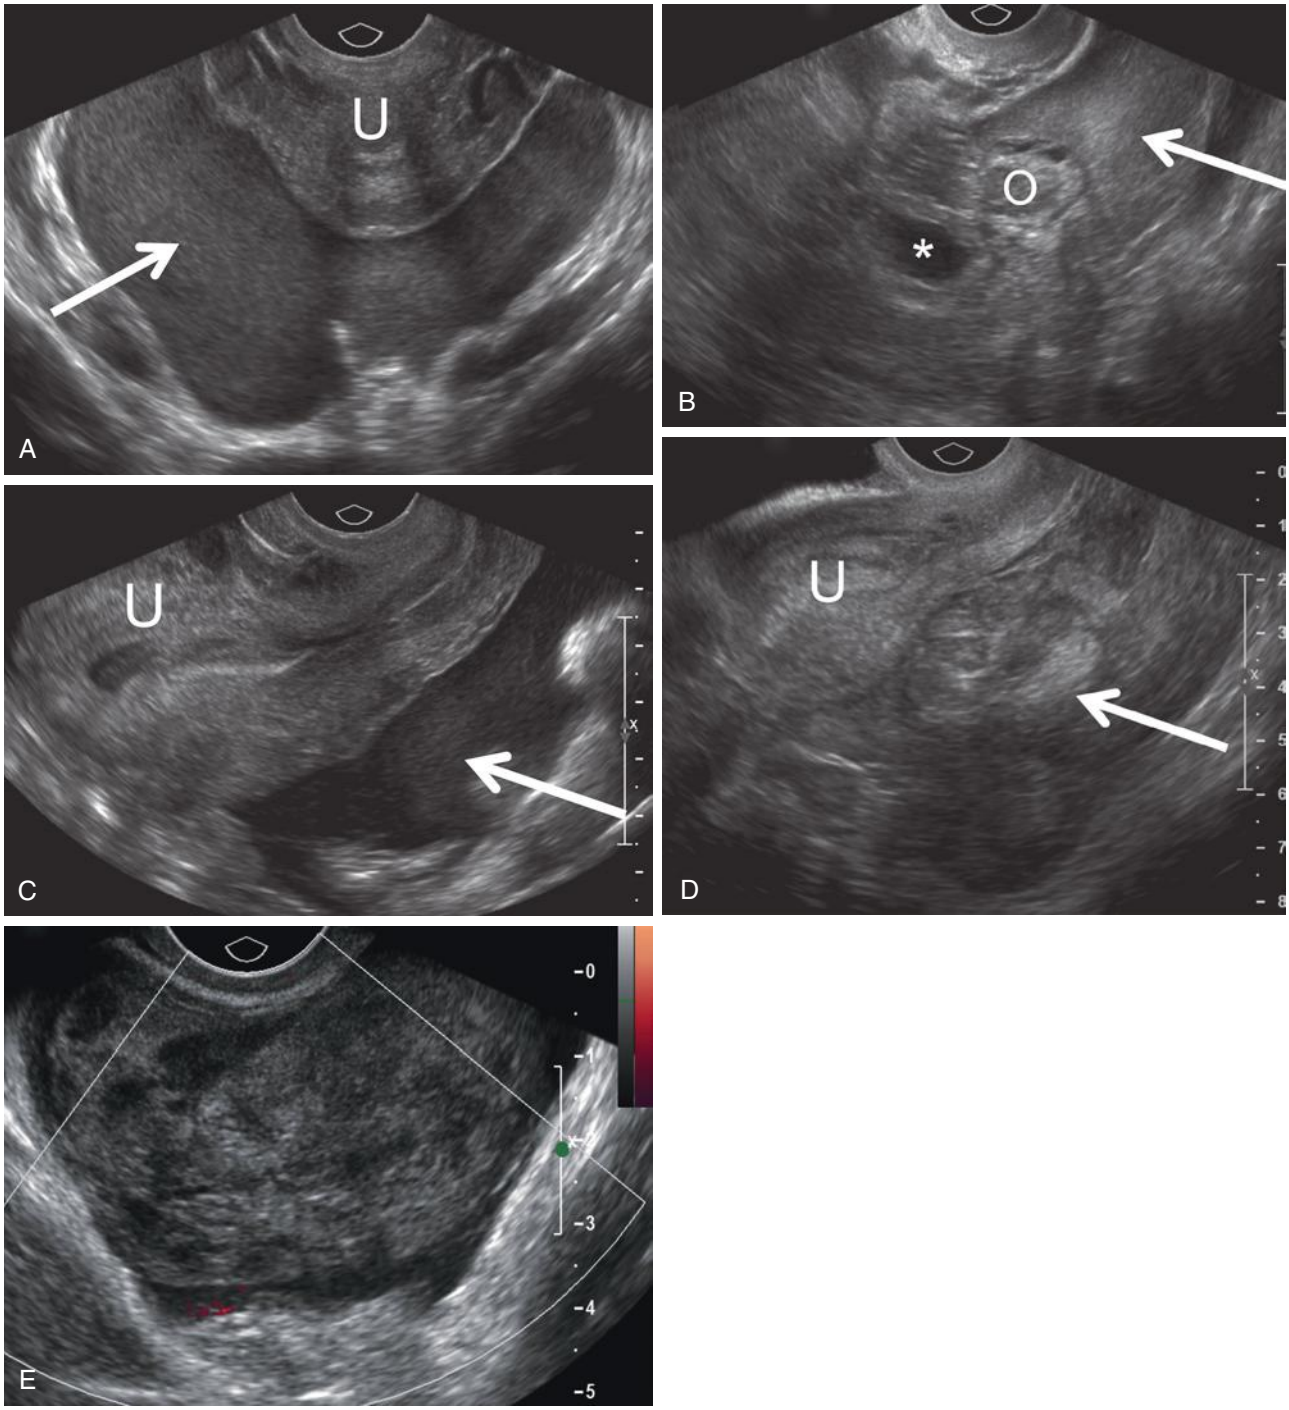

FIG 33-12 Variable sonographic appearance of hemoperitoneum due to rupture of ectopic pregnancy. **A,** Transvaginal transverse scan shows homogeneous, low-level echoes representing blood (*arrow*) in the cul-de-sac, posterior to the uterus (U). **B,** Echogenic hemoperitoneum (*arrow*) outlines the ovary (O), which contains several small anechoic follicles, and an ectopic gestational sac (*asterisk*) with an echogenic rim. **C,** Hemoperitoneum, shown posterior to the uterus (U), is nearly anechoic in this patient with a small area of low-level echoes (*arrow*). Note a small amount of fluid in the endometrial cavity. **D,** Transvaginal longitudinal pelvic scan shows complex heterogeneous clotted blood (*arrow*) posterior to the uterus (U) mimicking bowel loops. **E,** Transvaginal transverse power Doppler scan through the cul-de-sac shows complex heterogeneous material with no demonstrable internal blood flow, consistent with clotted blood. Note that there is a small amount of adjacent anechoic free fluid.

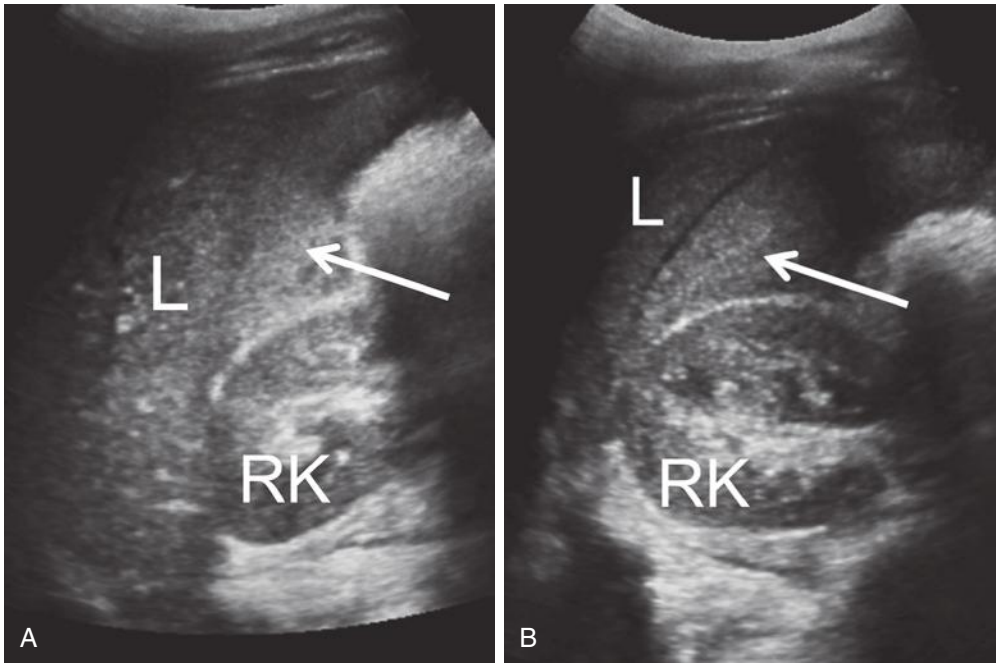

FIG 33-13 Hemoperitoneum from ruptured ectopic pregnancy may mimic liver parenchyma. **A,** In this patient with hypotension and ruptured ectopic pregnancy (not shown), more than a liter of intraperitoneal blood (*arrow*) accumulated in the Morison pouch, between the right lobe of the liver (L) and the right kidney (RK). This was initially overlooked, mistaken for liver parenchyma owing to similar echogenicity. **B,** Hemoperitoneum (*arrow*) under the liver (L) was eventually correctly recognized when an anechoic stripe was noted, separating liver (L) from hemoperitoneum (*arrow*). RK, right kidney. (Images courtesy of Mindy Horrow, MD, Albert Einstein Medical Center, Philadelphia, PA.)

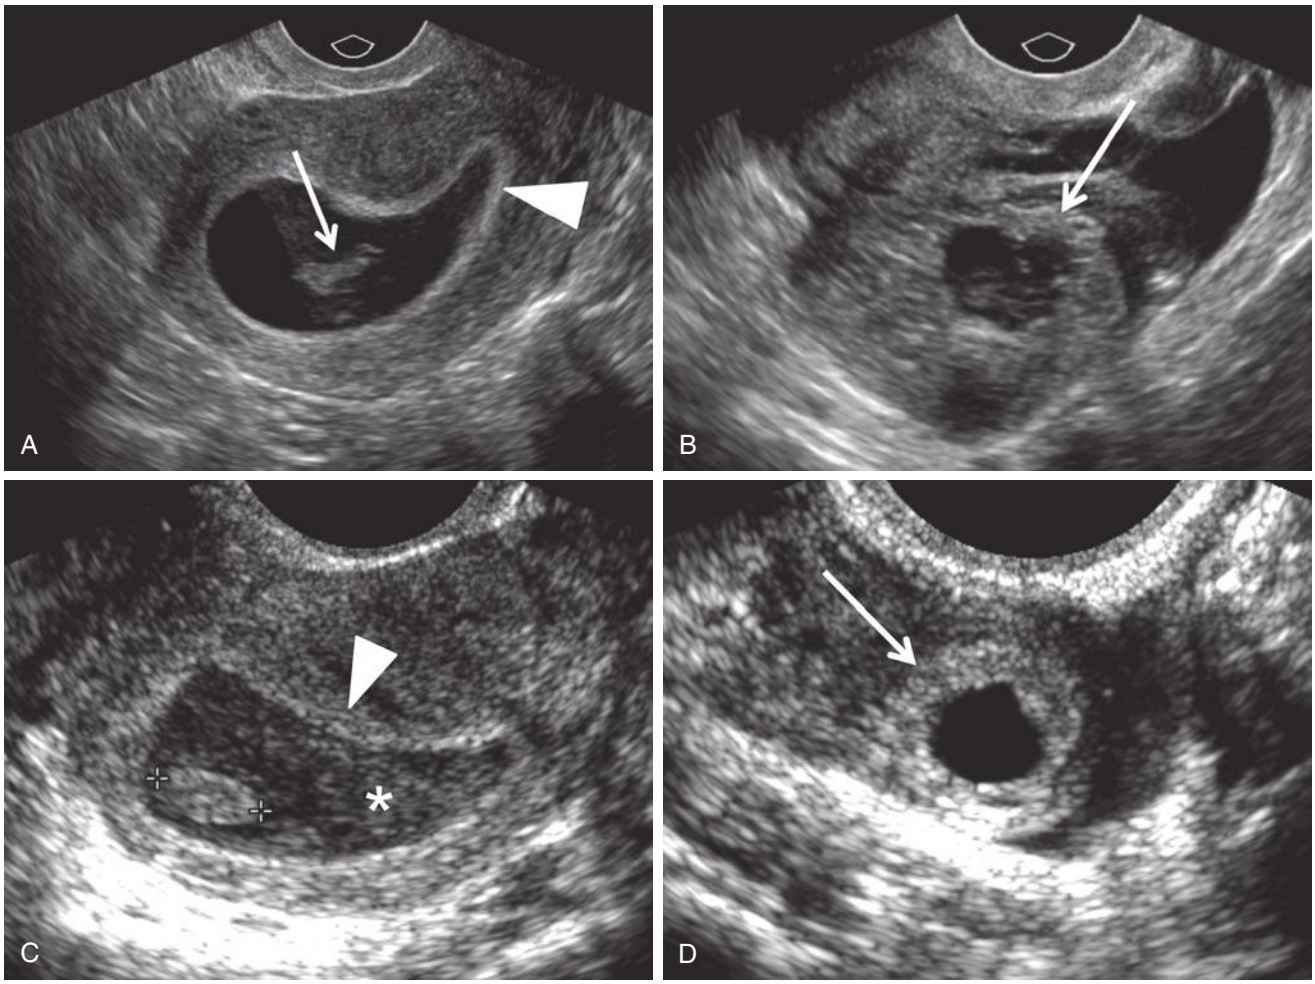

FIG 33-14 Patients with ectopic pregnancies and intrauterine fluid containing blood clots mimicking embryos. **A,** Transvaginal longitudinal scan of the uterus demonstrates fluid distending the endometrial cavity, surrounded by a single decidual lining (*arrowhead*), containing a small echogenic oblong blood clot (*arrow*) simulating an embryo. **B,** In the same patient shown in **A,** an ectopic pregnancy (*arrow*) was noted on transvaginal view of the adnexa. **C,** In another patient, transvaginal longitudinal scan of the uterus shows internal echoes representing blood in the uterine cavity (*asterisk*) with a small focal blood clot simulating an embryo (*calipers*). Note the single decidual lining of the endometrial cavity (*arrowhead*). **D,** In the same patient shown in C, the ectopic adnexal gestational sac (echogenic tubal ring) (*arrow*) is surrounded by echogenic blood.

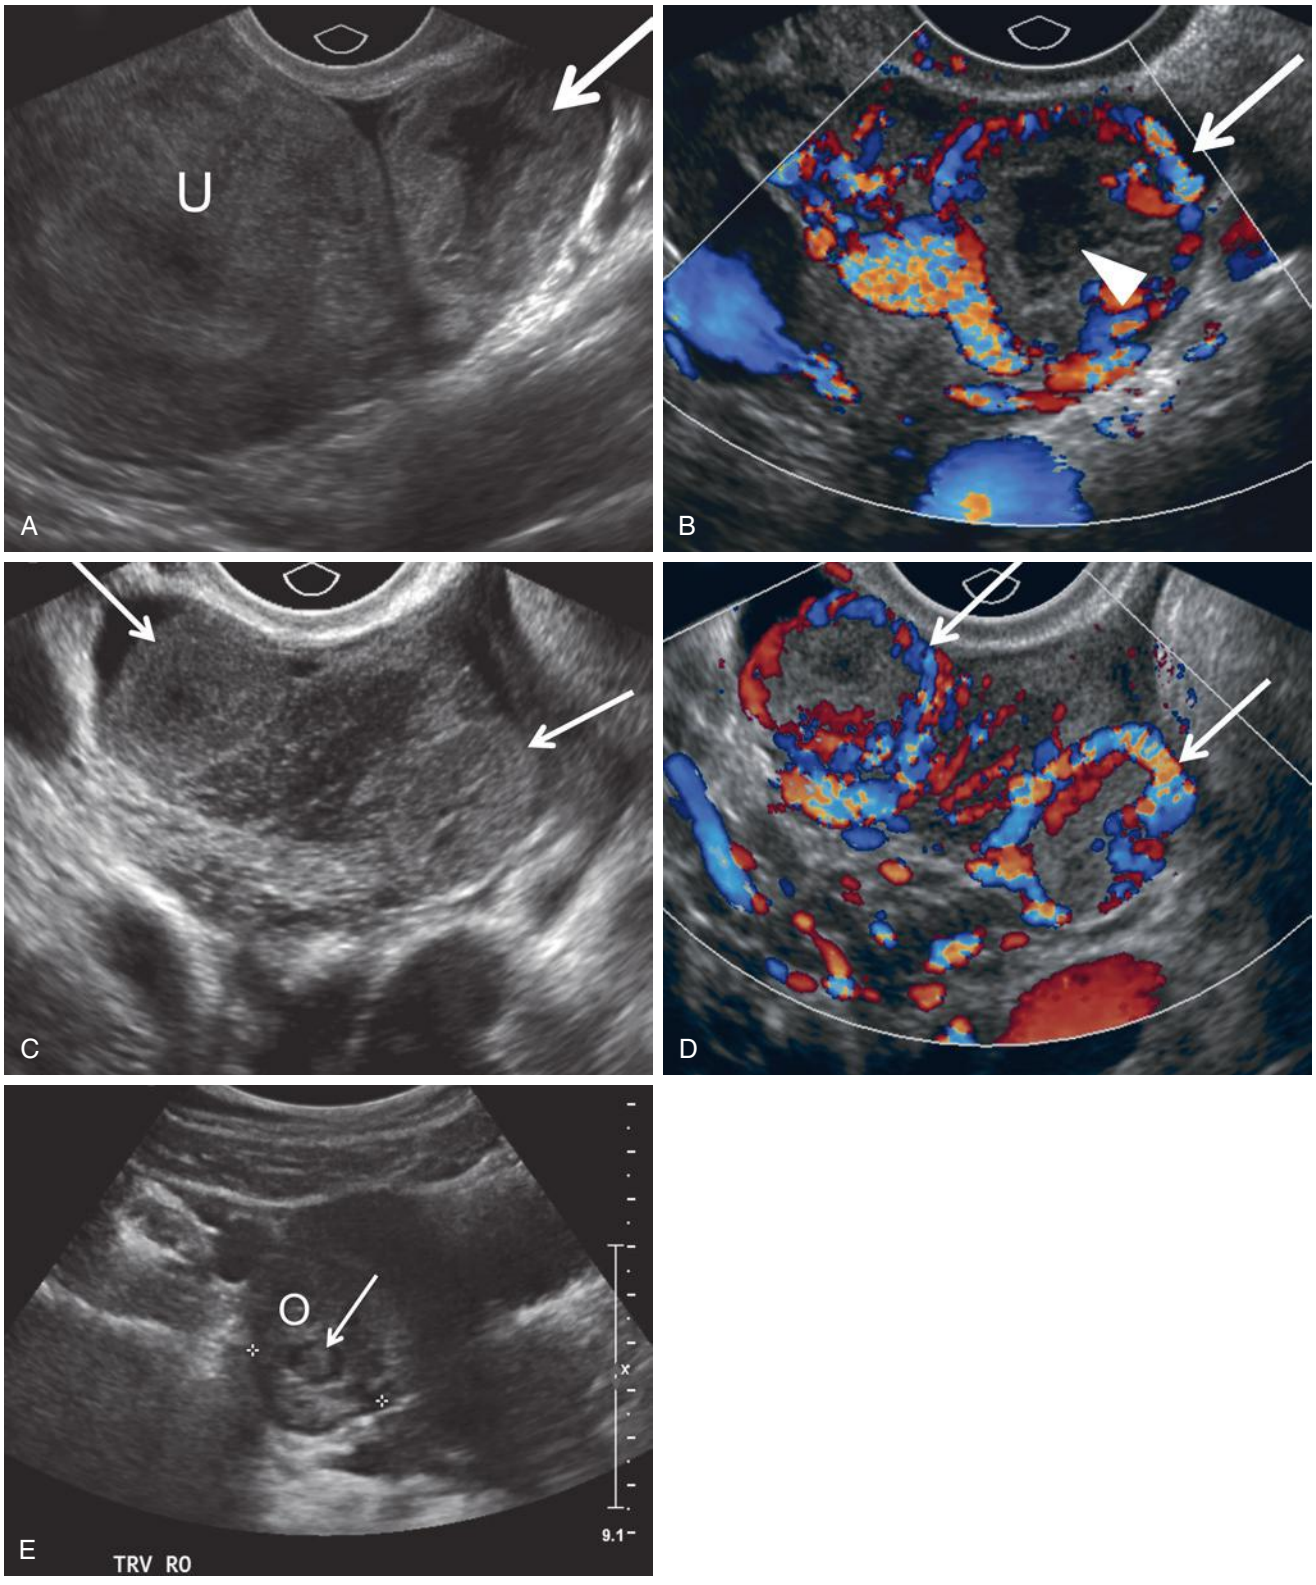

FIG 33-15 Corpora lutea mimicking ectopic pregnancies. **A,** Transvaginal transverse scan of the uterus (U) and left corpus luteum (*arrow*) with thick, crenated, moderately echogenic rim and irregular cystic center with few internal echoes, mimicking the thick rim of an ectopic pregnancy. There is trace free fluid. **B,** Transvaginal color Doppler scan of A shows circumferential "ring of fire" in the wall of the corpus luteum (*arrow*). Note echoes from hemorrhage within the corpus luteum mimic a yolk sac (*arrowhead*). **C,** Two corpora lutea (*arrows*) with thick, moderately echogenic rims resemble tubal rings of ectopic pregnancy in a patient who underwent ovulation induction. **D,** Transvaginal color Doppler scan of C shows "rings of fire" peripheral to the two corpora lutea (*arrows*). Note that the "rings" of blood flow are continuous and completely circumferential on color Doppler imaging, which is more commonly seen with corpus luteum than with ectopic pregnancy. **E,** This corpus luteum (*calipers*) within the right ovary (O) contains a small echogenic blood clot (*arrow*), resembling an embryo, potentially mimicking an ovarian ectopic pregnancy. The pregnancy test was negative. (B from Cicchiello LA, Hamper UM, Scoutt LM: Ultrasound evaluation of gynecologic causes of pelvic pain. Ultrasound Clin 5:209-231, 2010, image 17, p 221, used with permission.)

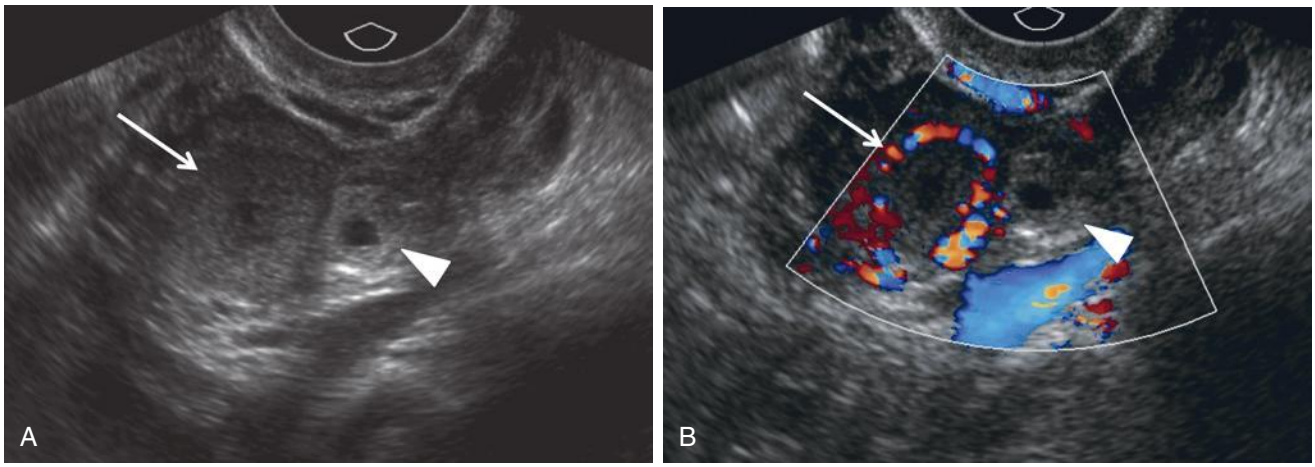

FIG 33-16 Ectopic pregnancy and ipsilateral corpus luteum with color Doppler ultrasound. **A,** Transvaginal scan of an ectopic gestational sac (*arrowhead*) and the ipsilateral intraovarian corpus luteum (*arrow*). The ring of the ectopic pregnancy is more echogenic than the rim of the corpus luteum. **B,** Transvaginal color Doppler scan showing a circumferential vascular "ring of fire" around the corpus luteum (*arrow*) but no flow around the ectopic sac (*arrowhead*). A ring of fire on color Doppler ultrasound is more commonly seen around a corpus luteum than an ectopic pregnancy.

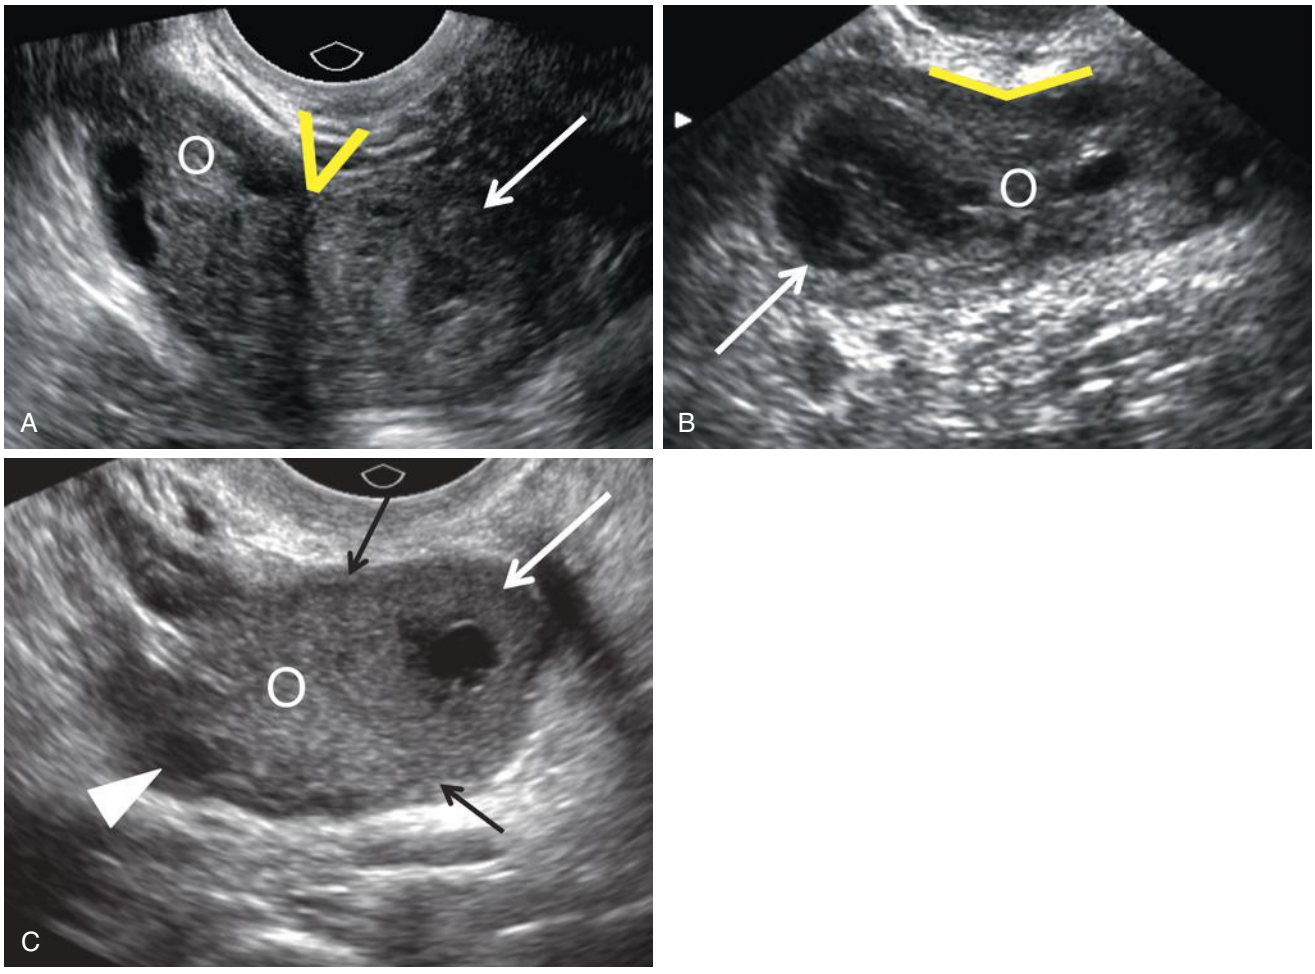

FIG 33-17 Features used to differentiate an ectopic pregnancy from a corpus luteum. **A,** Transvaginal transverse scan shows that the angle (*narrow V*) between the round ovary (O) and the round heterogeneous mass of the ectopic pregnancy (*arrow*) is acute, because they are adjacent separate structures. When this is observed, the examiner should exert gentle pressure with the transducer or on the anterior abdominal wall to attempt to separate the ectopic pregnancy from the ovary. **B,** Transvaginal transverse scan in another patient demonstrates an obtuse angle (*wide V*) between the corpus luteum (*arrow*), which contains internal hemorrhage, and the ovary (O), because the corpus luteum arises from and is part of the ovary. The exophytic corpus luteum protrudes from the ovary and exhibits the claw sign, with a thin surrounding rim of ovarian parenchyma. In this case, applying pressure would cause the corpus luteum to move with (rather than away from) the ovary. **C,** Transvaginal transverse scan of another patient with a small anechoic ovarian follicle (*arrowhead*) and an exophytic corpus luteum (*white arrow*) arising from the ovary (O). The claw sign is shown (*black arrows*) with crescent of ovarian tissue surrounding part of the corpus luteum. Note that the rim of the corpus luteum is thick but not very echogenic.

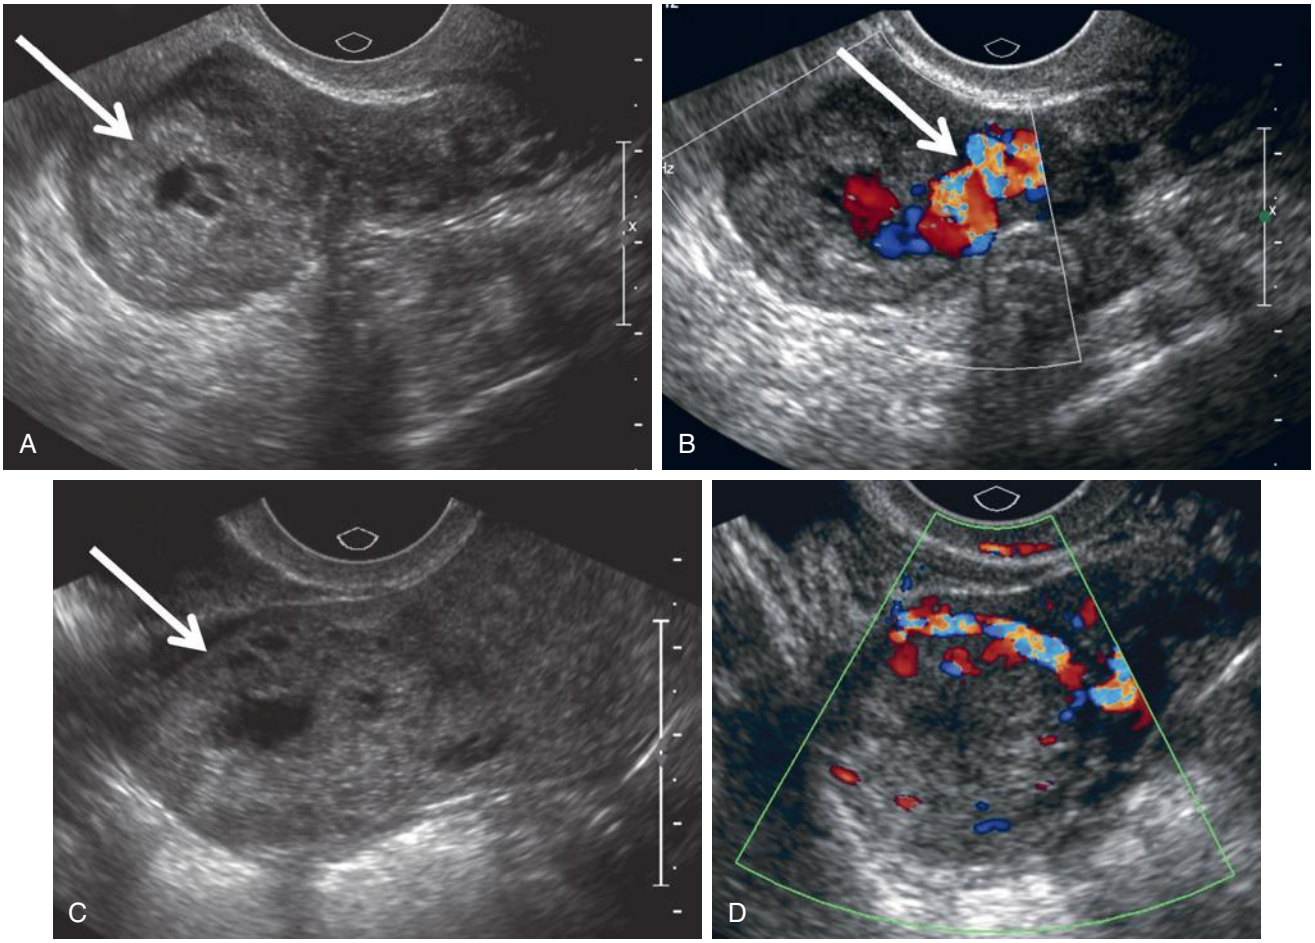

FIG 33-18 Similar ultrasound appearance of a degenerated pedunculated myoma and an ectopic pregnancy. **A,** Transvaginal scan shows a degenerated pedunculated myoma (*arrow*) simulating an ectopic pregnancy with a thick echogenic rim and a central cystic component. **B,** Transvaginal color Doppler scan of the pedunculated myoma in A shows bridging vessels (*arrow*) arising from the uterus, thus establishing the uterine origin of the mass. The pregnancy test was negative. **C,** Transvaginal transverse scan in a second patient shows a similar appearing thick-walled adnexal mass adjacent to the uterus, which represents an ectopic pregnancy (*arrow*). **D,** Transvaginal color Doppler sonogram shows a peripheral ring of vessels, typical of vessels around a gestational sac, in this case an ectopic pregnancy.

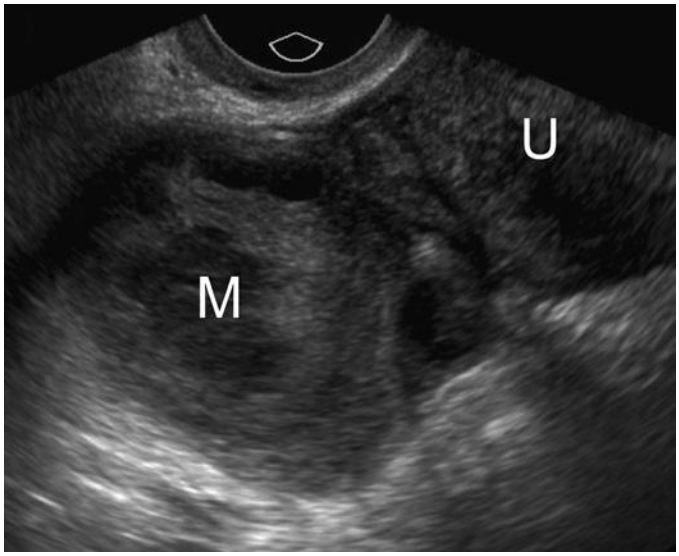

FIG 33-19 Tubo-ovarian abscess mimicking ectopic pregnancy. Transvaginal transverse scan in a patient with a painful, tender right adnexal mass (M) found to be a tubo-ovarian abscess, with a thick echogenic rim and a cystic center with internal echoes, adjacent to the uterus (U). The pregnancy test was negative.

FIG 33-20 Coronal reconstruction of a three-dimensional sonogram of the uterus delineating the interstitial portion of the fallopian tube. The interstitial portion of the fallopian tube (*arrow*) crosses through the myometrium in the cornual portion of the uterine fundus (*asterisks*).

The *interstitial line sign*, namely a thin echogenic line extending from the lateral corner of the endometrium through the myometrium to the ectopic gestational sac or hemorrhagic mass, is believed to represent the proximal lumen of the fallopian tube and is an infrequent but relatively specific finding of an interstitial EP[68,69] (Fig. 33-22B).

There are several important pitfalls in the sonographic diagnosis of interstitial EP and not all eccentric gestational sacs will turn out to be interstitial EPs. Mass effect from leiomyomas or uterine contractions may displace an intrauterine gestational sac into an eccentric location, mimicking an interstitial EP. IUPs in the right or left horn of a bicornuate or septate uterus may also be eccentric in location (Fig. 33-23). However, such pregnancies are intrauterine, located within the endometrial cavity in the uterine horn, and therefore should have a broad interface with surrounding echogenic decidualized endometrium, without intervening hypoechoic myometrium (see Fig. 33-23). An angular pregnancy refers to an eccentrically located but intrauterine gestational sac that implanted into the lateral corner of the endometrial cavity at the uterine fundus near the entrance of the fallopian tube (Fig. 33-24). The distinction between interstitial EPs and eccentric IUPs (whether angular, displaced by myometrial contractions/leiomyomas, or located in the horn of a septate or bicornuate uterus) is more easily made with 3D sonography (with coronal reconstruction) or magnetic resonance imaging (MRI), as it is possible with these imaging techniques to routinely visualize the uterotubal junction, the round ligament, and the interstitial line sign. Specifically, an angular IUP implants in the endometrial cavity medial to the uterotubal junction and round ligament (see Fig. 33-24), whereas an interstitial EP implants lateral to the round ligament. Angular pregnancies are reported to have an increased risk of spontaneous miscarriage, uterine rupture, and abnormal placental implantation. However, the degree of risk remains controversial, as some reported cases may have been misdiagnosed interstitial EPs.[65,66,70,71,72]

Exophytic subserosal uterine leiomyomas may undergo central cystic degeneration and may mimic a gestational sac. Color Doppler ultrasound imaging will often demonstrate a feeding vessel extending from the uterus to the degenerated leiomyomas, whereas an EP tends to have a peripheral ring of surrounding vessels (see Fig. 33-18). Rarely, highly vascular, intramural myometrial lesions can be mistaken for an interstitial EP, including arteriovenous malformations, hemangiomas, and neoplasms. None of these entities would be expected to be associated with a positive serum hCG except for gestational trophoblastic neoplasia (GTN). A choriocarcinoma or invasive mole located laterally at the fundal myometrium would be especially difficult to differentiate from an interstitial EP, although the serum hCG level would be higher than predicted based on estimated gestational age in a patient with GTN.[73] Duplex Doppler sonography would not be particularly helpful because choriocarcinomas, invasive moles, leiomyosarcomas, and interstitial EPs all tend to demonstrate increased vascularity on color Doppler interrogation with low-impedance, high-velocity arterial waveforms.

Because of the robust blood supply from the surrounding myometrium, an interstitial EP often grows over a longer time period, becoming larger and more vascularized as the trophoblastic tissue invades the surrounding myometrium. Hence, interstitial EPs tend to become symptomatic and rupture later than tubal EPs, usually around 12 weeks' gestational age, potentially resulting in massive hemoperitoneum and hemodynamic instability. The morbidity and mortality rates of interstitial EPs are at least double those of ampullary tubal EPs, with maternal mortality rates approaching 2.2%.

Surgical cornual resection and hysterectomy have been the traditional therapeutic options for interstitial EPs. However, in stable patients, laparoscopic resection with or without ultrasound guidance can be successful. Successful treatment of interstitial EPs with direct injection of MTX into the gestational sac or systemic administration of MTX has also been reported.[74,75] However, the success rate for MTX therapy is lower for interstitial EPs than for ampullary or isthmic tubal EPs.[76,77] If bleeding is profuse, selective uterine artery embolization or vasoconstrictive agents, such as vasopressin, have been successful in controlling hemorrhage. Still, hysterectomy is often necessary for advanced or complicated cases presenting with uterine rupture or significant hemoperitoneum. In stable patients presenting at early gestational ages, successful expectant management of early interstitial EPs has also been reported.[78]

Rudimentary Horn Ectopic Pregnancy

An unusual form of EP is the development of a gestation in a rudimentary horn attached to a unicornuate uterus, an anomaly that results from incomplete development of one of the müllerian ducts and abnormal fusion of the rudimentary horn with the banana-shaped contralateral, normally developed horn. If the two endometrial cavities are connected, the blastocyte may implant directly into the endometrial cavity of the rudimentary horn. However, in 83% of patients, the rudimentary horn has no direct connection to the endometrial cavity of the normal horn. In such cases, it is postulated that the sperm or fertilized ovum migrates transperitoneally from the contralateral tube to the tube connected to the rudimentary horn and eventually implants into the small endometrial cavity of that rudimentary horn[79] (Fig. 33-21B). If hemorrhage occurs, blood will not be able to exit through the uterine cavity or cervix and will collect in the cul-de-sac or distend the rudimentary horn. If there is a connection to the endometrial cavity of the normal horn, the patient may present with vaginal bleeding (Fig. 33-21C).

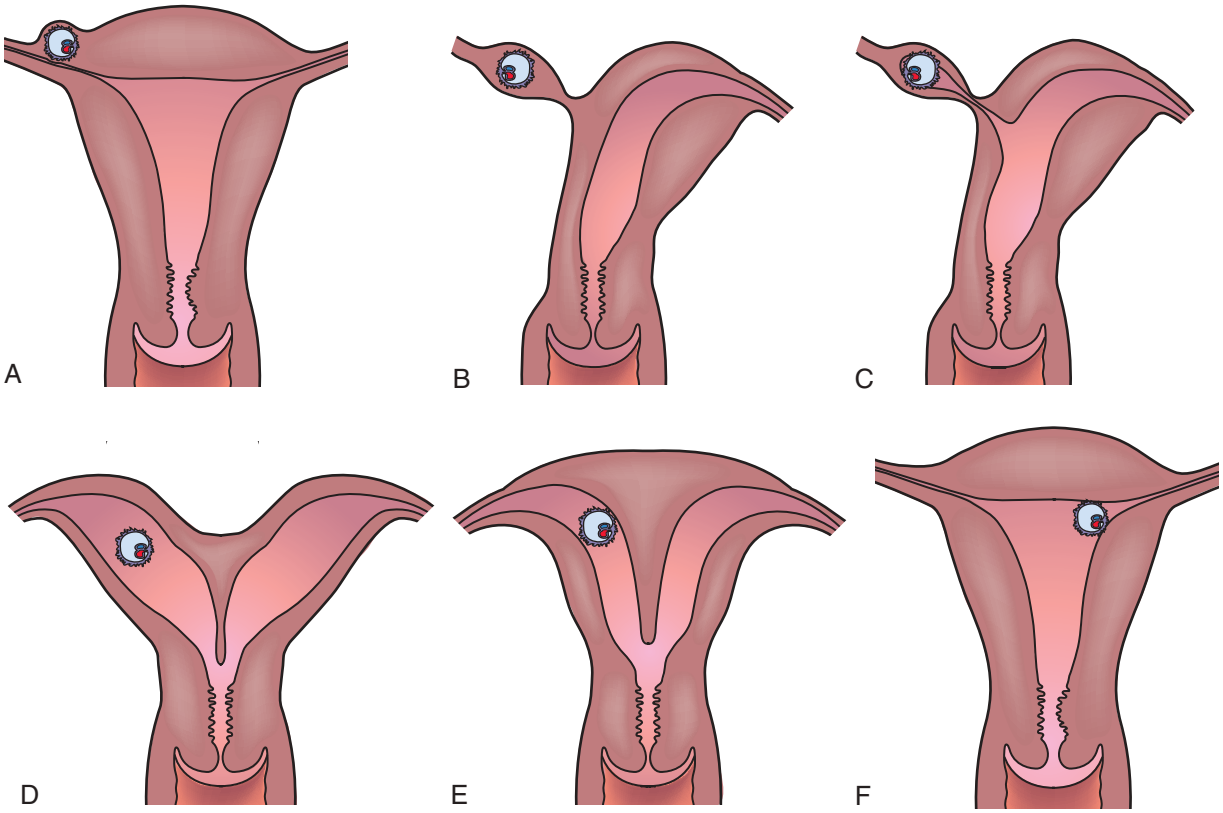

FIG 33-21 Various locations of implanted gestations near the cornual portion of the uterus. In the past, the term *cornual pregnancy* has been used to describe all of these different types of pregnancies. Therefore, the term is potentially misleading, confusing to sonologists and clinicians, and should not be used. **A,** The gestational sac is implanted in the interstitial portion of the right fallopian tube as it passes through the myometrium in the cornual portion of the uterus, most appropriately termed *interstitial ectopic pregnancy*. **B,** This EP is implanted in a right rudimentary horn, which has no connection to the endometrial cavity, associated with a unicornuate uterus. **C,** This EP is implanted in a right rudimentary horn, which has a direct connection to the endometrial cavity. **D,** The pregnancy is implanted in the right horn of a bicornuate uterus, and is therefore an *intrauterine pregnancy*. **E,** This pregnancy is implanted in the right horn of a septate uterus, and is therefore an *intrauterine pregnancy*. **F,** On the left side of the uterus a pregnancy is implanted in the lateral angle of the endometrial cavity, most appropriately termed an *angular pregnancy*, which is an intrauterine pregnancy, not an ectopic pregnancy. In summary, the pregnancies depicted in the top row (**A, B,** and **C**) are EPs, whereas the pregnancies in the bottom row (**D, E,** and **F**) are IUPs.

A pregnancy in this location may be difficult to differentiate from an interstitial EP or a pregnancy in a bicornuate or septate uterus, as all three will present with an eccentric gestational sac. Differentiation is often best accomplished with MRI, which will demonstrate no visible continuity between the endocervical canal and the lumen of the pregnant rudimentary horn, as would be expected in a septate or bicornuate uterus (Fig. 33-25). A 3D sonographic examination may sometimes be helpful.[80]

Rudimentary horn pregnancies have a high rate of spontaneous abortion and fetal growth restriction. They often rupture during the second or third trimester, resulting in fetal demise and significant hemorrhage that can be fatal.[79] Pathologic placentation resulting in a morbidly adherent placenta is common, which further increases the risk of fatal rupture. Hence, if a rudimentary horn is incidentally found, resection is generally recommended to prevent the possibility of ectopic implantation, and pregnancies in rudimentary horns are usually treated with surgical excision or direct injection of potassium chloride (KCl) or MTX. There have been case reports of conservative management and delivery, but these pregnancies were surrounded by thick myometrial tissue and required very close monitoring.[79] Irrespective of pregnancy outcome, ultimately surgical excision of the rudimentary horn is necessary to prevent future implantations and minimize maternal risk.

Cervical Ectopic Pregnancy

Cervical EPs occur when the fertilized ovum implants directly into the wall of the cervix below the level of the internal cervical os (Fig. 33-26). Risk factors for cervical EP include previous instrumentation, cervical or uterine surgery, abortion, curettage, IVF-ET, uterine anomalies, leiomyomas, synechiae, Asherman syndrome, previous cesarean delivery, IUD placement, and PID. On ultrasound images, the gestational sac will appear eccentric in location, embedded in the wall of the cervix as the trophoblastic tissue invades through the cervical mucosa, usually through a defect in the lining from prior instrumentation or injury (see Fig. 33-26). This is often best appreciated on transverse images where it can be easier to recognize that the gestational sac is located within the wall of the cervix, separate from the endocervical canal, which may be deviated or displaced by the sac. Imaging should include and target both the external and internal ostia. A 3D ultrasound examination can be very helpful in delineating the location of the pregnancy. The gestational sac is typically round or oval with a thick, well-formed echogenic rim (Fig. 33-26A through C). Vascularity in the wall of the

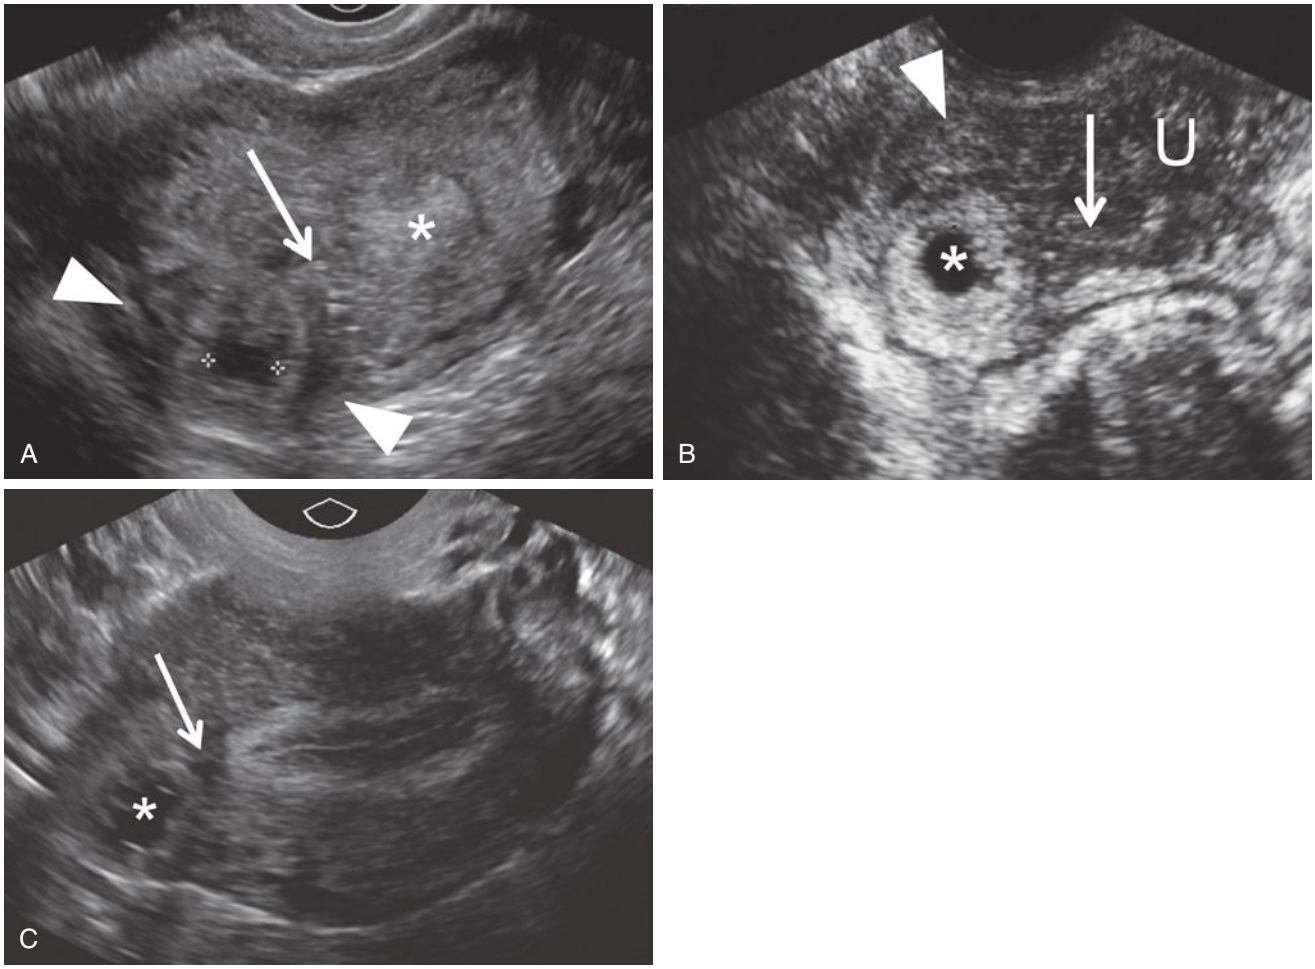

FIG 33-22 Interstitial ectopic pregnancies. **A,** Transvaginal transverse scan of the uterus shows the eccentrically located interstitial ectopic pregnancy (*calipers*) separate from the endometrial cavity (*asterisk*). Myometrium (*arrow*) clearly separates the medial edge of the gestational sac from the echogenic endometrium (*asterisk*) and surrounds the sac (*arrowheads*). **B,** Transvaginal transverse scan of the uterus (U) in another patient demonstrates the interstitial line sign, a thin echogenic line (*arrow*) extending from the endometrium toward the right-sided interstitial ectopic pregnancy (*asterisk*). Note that the myometrium (*arrowhead*) partially surrounds the gestational sac. **C,** Transvaginal transverse scan of the uterus in a third patient with right-sided interstitial ectopic pregnancy (*asterisk*) demonstrates myometrial tissue (*arrow*) intervening between the edge of the gestational sac and the echogenic endometrium. (**A,** Courtesy Department of Obstetrics and Gynecology, Yale University School of Medicine, New Haven, CT.)

gestational sac and feeding vessels extending from the wall of the cervix to the sac are often appreciated on color Doppler ultrasound imaging. Later in pregnancy, the cervix may appear enlarged, bulbous, and hyperemic on inspection. Ultrasound image will reveal an hourglass-shaped uterus composed of the uterine corpus and disproportionately enlarged cervix with a "waist" at the level of the internal os.[81] However, in current practice, it is unusual to diagnose cervical EPs at such a late stage because most such pregnancies present early in the first trimester.

Distinguishing a cervical pregnancy from an impending or inevitable miscarriage, in which the gestational sac is being evacuated and passing through the endocervical canal, may be difficult (Fig. 33-26D). In patients with an impending miscarriage, the gestational sac will be centrally located within the endocervical canal. The surrounding cervical stroma will be symmetric in thickness, often best appreciated on transverse images. The gestational sac may have an irregular, flattened, or crenated border without surrounding vascularity. The presence of trophoblastic blood flow or embryonic cardiac activity increases the likelihood that a gestational sac in the cervix is a cervical EP but can sometimes be seen in aborting IUPs. Jurkovic and coworkers[82] described the sliding sign to help differentiate an aborting gestational sac from a cervical EP. When gentle pressure is applied to the cervix by the transvaginal transducer, the aborting gestational sac will slide up and down in the endocervical canal, whereas such movement will not occur with an implanted cervical EP.

Cervical EPs are at risk for rupture and can cause heavy bleeding, often painless and profuse. Because the cervix is composed primarily of fibrous connective tissue with only 15% smooth muscle, contraction of the cervix is usually inadequate to prevent the dilated cervical vessels from hemorrhaging profusely following dilatation and curettage (D&C) or surgical excision of the gestational sac. Therefore, in the past, emergent hysterectomy was typically performed.[83] If, however, the diagnosis of cervical EP is made early in the first trimester, before bleeding has occurred, preservation of future fertility can be achieved by treating with systemic MTX or by direct injection of the embryo and sac with KCl or MTX.[84,85] Surgical debulking or hysteroscopic

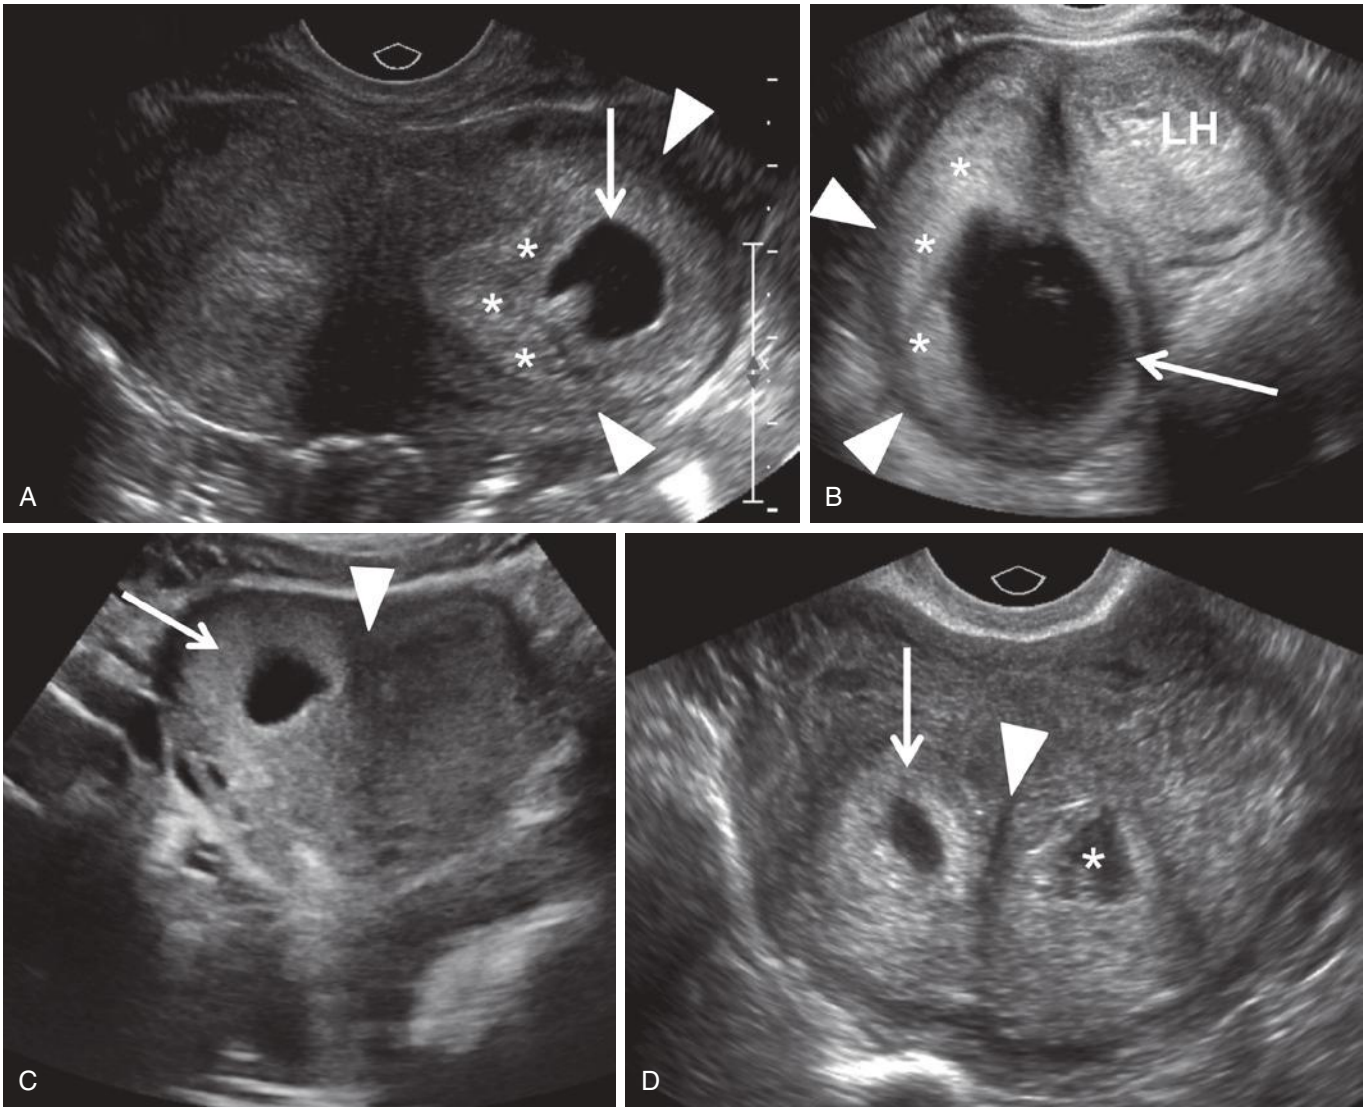

FIG 33-23 Eccentric intrauterine gestational sacs in bicornuate and septate uteri. **A,** Transvaginal transverse scan of the uterus shows an eccentrically located gestational sac (*arrow*) containing an embryo with a very thin mantle of surrounding myometrium (*arrowheads*). However, this is an intrauterine pregnancy in the endometrial cavity of the left horn of a bicornuate uterus. Note the broad interface with the endometrium (*asterisks*). **B,** Transvaginal transverse scan of the uterus shows an eccentrically located gestational sac (*arrow*) and a thin mantle of surrounding myometrium (*arrowheads*). This is an intrauterine pregnancy in the endometrial cavity of the right horn of a bicornuate uterus. Note the broad interface of the gestational sac with the endometrium (*asterisks*) and the empty left uterine horn (LH). Also note the deep cleft in the contour of the uterine fundus between the two horns, diagnostic of a bicornuate uterus. **C,** Transabdominal coronal scan of a septate uterus shows an eccentrically located gestational sac (*arrow*) in the endometrial cavity of the right cornu. This pregnancy is intrauterine and is located to the right of a thin shadowing septum (*arrowhead*). Note the flat to minimally indented outer contour of the uterine fundus, characteristic of a septate uterus. **D,** Transvaginal transverse scan of the uterus shows an eccentrically located gestational sac (*arrow*) in the endometrial cavity of the right cornu of a septate uterus. This pregnancy is intrauterine and is separated from the endometrial cavity of the left cornu (*asterisk*), which contains echogenic fluid suggesting blood, by a thin shadowing septum (*arrowhead*). (**B,** Courtesy Department of Obstetrics and Gynecology, Yale University School of Medicine, New Haven, CT.)

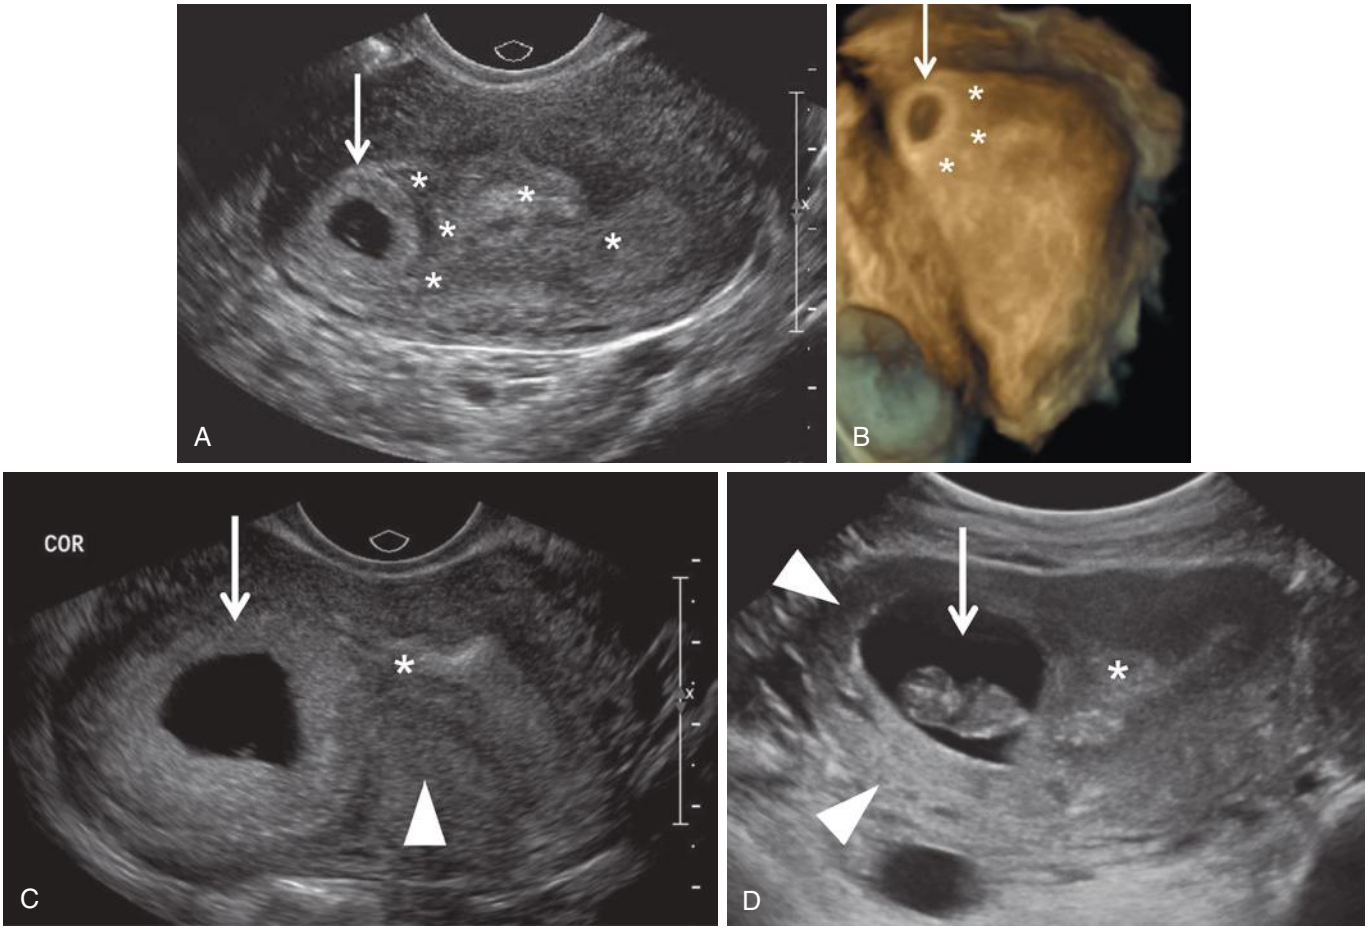

FIG 33-24 Angular pregnancies implant in the lateral corner or angle of the endometrial cavity in the uterine fundus. **A,** Transvaginal transverse scan of the uterus shows an eccentric gestational sac (*arrow*) implanted in the right lateral corner of the endometrial cavity. The pregnancy is intrauterine and has a broad interface with the endometrium (*asterisks*), which completely surrounds the gestational sac. **B,** Three-dimensional coronal reconstruction of the uterus shows an early gestational sac (*arrow*) in the right lateral corner of the endometrial cavity. The pregnancy is intrauterine and has a broad interface with the endometrium (*asterisks*). **C,** Transvaginal transverse scan of the uterus shows a large empty gestational sac (*arrow*) in the right lateral corner of the endometrial cavity (*asterisk*). A focal uterine contraction (*arrowhead*) is partially responsible for displacing this intrauterine pregnancy laterally toward the right. The patient ultimately had a spontaneous miscarriage without complication. **D,** Transabdominal transverse scan of the uterus shows an embryo (*arrow*) in the right lateral angle of the endometrial cavity (*asterisk*) surrounded by a thick layer of myometrium (*arrowheads*). It is important to recognize that with an angular pregnancy there will be no intervening myometrium between the gestational sac and the endometrium. (**B** and **C,** Department of Obstetrics and Gynecology, Yale University School of Medicine, New Haven, CT.)

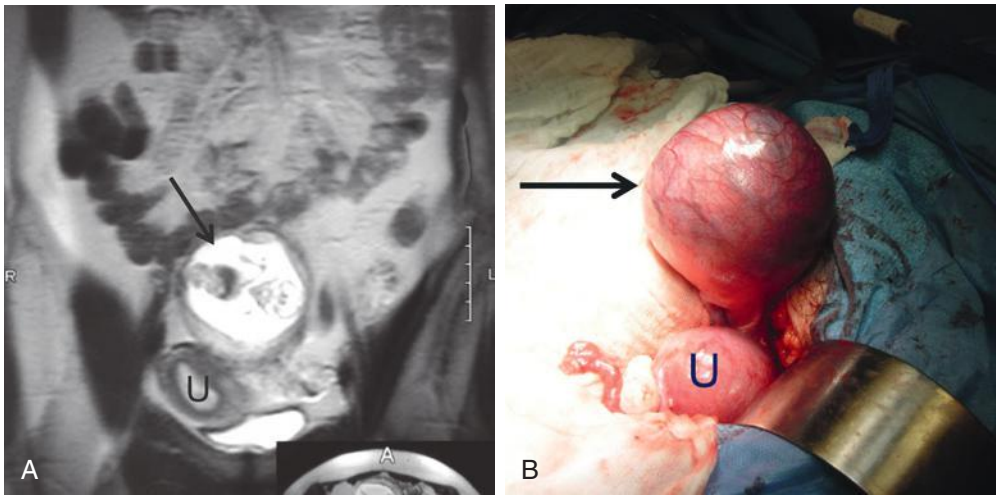

FIG 33-25 Pregnancy within the rudimentary horn of a unicornuate uterus. **A,** Coronal T2-weighted magnetic resonance image of the pelvis shows the uterus (U) and an adjacent ectopic pregnancy (*arrow*) containing a 10-week fetus. The pregnancy appears attached to the uterus. **B,** Intraoperative photograph showing the uterus (U) and the adjacent ectopic pregnancy (*arrow*), which was located in a rudimentary horn attached to a unicornuate uterus. The ectopic pregnancy was excised without incident.

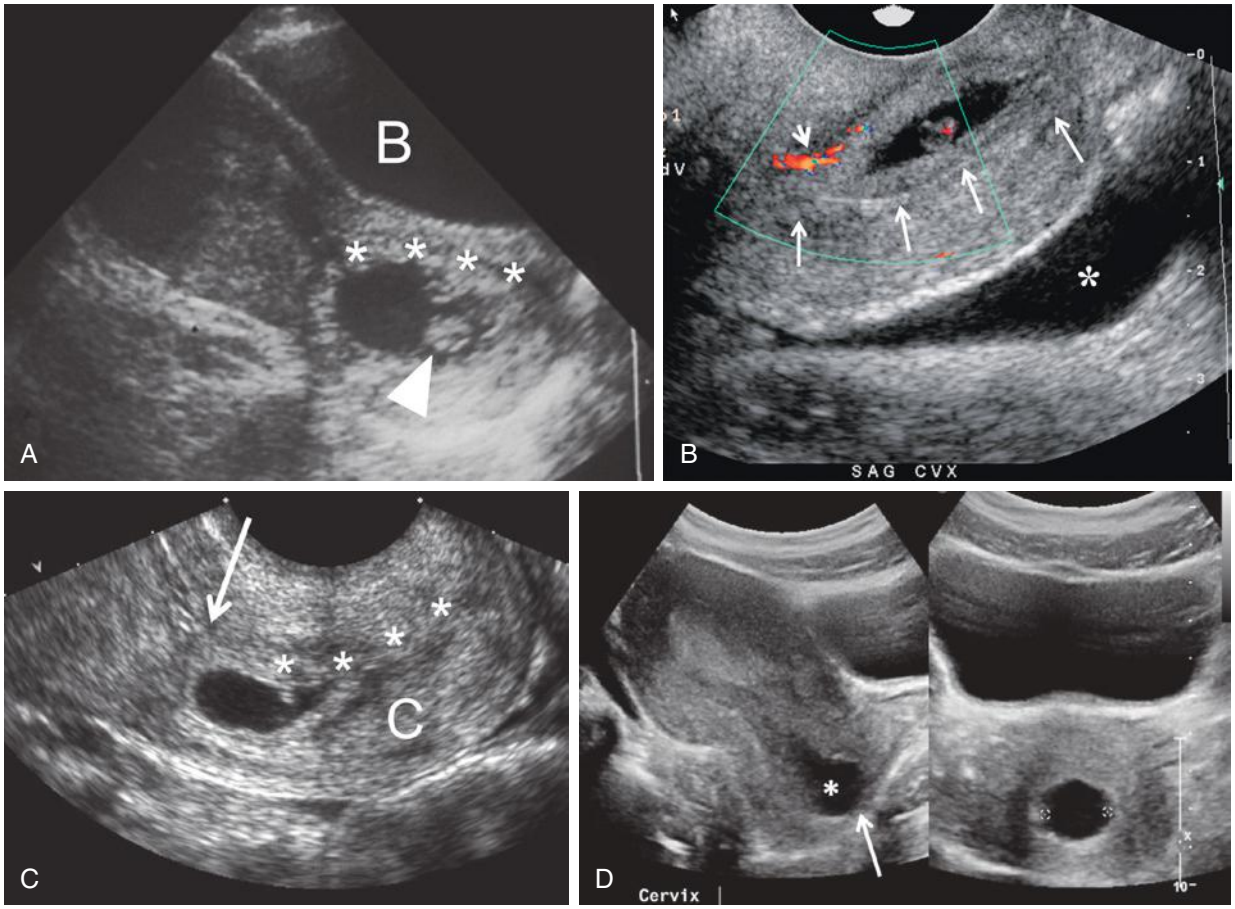

FIG 33-26 Comparison of cervical ectopic pregnancy and inevitable abortion. **A,** Transabdominal sagittal scan of the uterus shows an ectopic gestational sac containing an embryo (*arrowhead*) embedded in the posterior wall of the cervix posterior to the endocervical canal (*asterisks*). (B, bladder.) **B,** Transvaginal sagittal scan of the cervix demonstrates a gestational sac containing an embryo implanted in the anterior cervical wall, adjacent to the echogenic endocervical canal (*long arrows*). Flow is noted within a feeding vessel (*short arrow*) in the cervical wall and red pixels in the embryo flickered on real-time imaging indicating cardiac motion. A small amount of free fluid is shown in the cul-de-sac (*asterisk*). **C,** Transvaginal sagittal scan of the cervix (C) shows an ectopic gestational sac containing an embryo implanted in the posterior cervical wall, deep to the endocervical canal (*asterisks*) and below the level of the internal cervical os (*arrow*). **D,** Transabdominal sagittal (*left*) and transverse (*right*) scans of the uterus show a spontaneous abortion in progress. This patient presented with vaginal bleeding 1 week after documentation of an intrauterine pregnancy. The gestational sac (*asterisk* on left and *calipers* on right) is centrally located within the endocervical canal and appears partially extruded through the external cervical os (*arrow* on left). The sac appeared to slide back and forth (sliding sac sign) on real-time examination until it was extruded from the cervical canal into the vagina. (B from Bryan-Rest LL, Scoutt LM: Ectopic pregnancy. In Fielding JR, Brown DL, Thurmond AS (eds): Gynecologic Imaging. Philadelphia, Elsevier, 2011, p 343, Fig. 22-12C, used with permission.)

resection may be necessary if the gestation is more advanced.[74,85] Bleeding may be controlled by tamponade with a Foley catheter balloon inflated in the endocervical canal, uterine artery embolization, transvaginal ligation of the cervical branches of the uterine arteries, or intracervical vasopressin injection. In current practice, hysterectomy is considered a last resort.

Myometrial/Cesarean Scar Ectopic Pregnancy

Pregnancies may implant in cesarean delivery scars at the anterior wall of the lower uterine segment (Fig. 33-27). The incidence of cesarean scar EPs has increased in recent years as the rate of cesarean deliveries has increased.[86,87] Cesarean scar EPs have been reported to account for up to 6% of EPs in women with prior cesarean delivery. The risk increases as the number of prior cesarean deliveries increases, and approximately 72% of cesarean scar pregnancies occur in women who have had more than two cesarean deliveries.[88] In addition, pregnancies can implant into uterine scars following other surgeries such as hysterotomy, myomectomy, D&C, metroplasty, hysteroscopy, manual removal of the placenta, and uterine trauma.[89] These scars are believed to form a "niche" or "diverticulum," which communicates with the endometrial cavity, allowing the blastocyst to enter and implant. However, the connection or tract may be extremely small, possibly only a microscopic dehiscence.[90] IVF and ET can also lead to myometrial scar EPs, and although rare, even direct myometrial implantation has been reported.

Patients with cesarean scar EPs typically present in the first trimester with painless vaginal bleeding. In general, these pregnancies have poor outcomes with high morbidity and mortality rates due to the risk

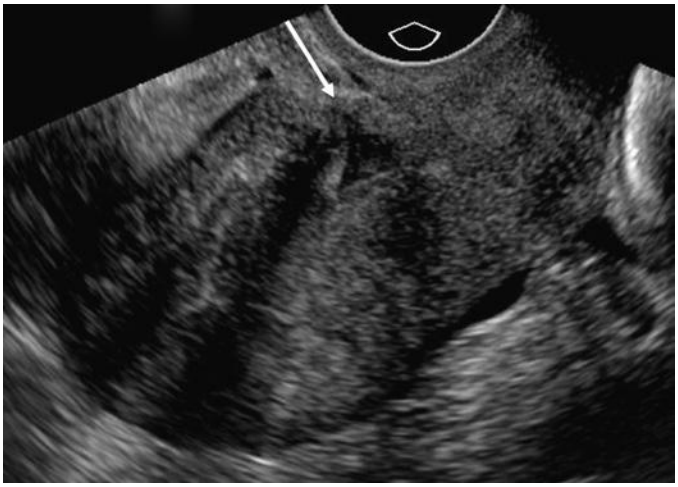

FIG 33-27 Cesarean delivery scar. Prominent cesarean incision scars can serve as a nidus or niche for implantation of ectopic pregnancies. Transvaginal sagittal scan of the uterus shows a triangular fluid collection (*arrow*) in the expected location of a cesarean incision scar, in the anterior wall at the level of the lower uterine segment above the internal cervical os. The apex of the small fluid collection nearly reaches the outer serosal surface of the uterus and the broad base abuts the endometrial cavity. Implantation in this fluid-filled space would result in a cesarean scar ectopic pregnancy that could expand through the myometrial wall, resulting in uterine rupture.

of significant hemorrhage or uterine rupture resulting in hysterectomy in 70% of cases. If growth of the gestation is directed toward the abdominal cavity, uterine dehiscence/rupture and intra-abdominal location of the pregnancy with invasion of placental tissue into adjacent structures (morbidly adherent placenta) becomes likely (Fig. 33-28). If the gestation grows into the endometrial cavity, it is theoretically possible for the pregnancy to progress to term with expectant management (Fig. 33-29). However, term pregnancies arising in cesarean incision scars are at high risk of placenta previa and, almost by definition, morbidly adherent placenta.[91,92] Therefore, the risk of delayed uterine rupture and massive hemorrhage remains and such pregnancies must be carefully monitored. Up to 38% will require hysterectomy at the time of delivery.[91]

On ultrasound imaging, a mass or gestational sac, often triangular and highly vascular, will be observed separate from the endometrial canal extending into the anterior myometrial wall at the lower uterine segment, at the site of the cesarean incision scar just above the internal cervical os. If the sac is large enough, bulging beyond the serosal surface toward the bladder will be observed. It is important to directly search with ultrasound for discontinuity of the anterior uterine surface in the sagittal plane and for trophoblastic tissue situated between the bladder and the anterior uterine wall.[93] Differentiating a cesarean scar EP from a cervical EP depends upon identification of the internal os. A cesarean scar EP implants in the lower uterine segment above the internal os (Fig. 33-29A), whereas a cervical EP implants into the wall of the cervix below the level of the internal os (Fig. 33-26A through C). A 3D ultrasound examination or MRI may be helpful in confirming the diagnosis.

Therapeutic D&C is extremely risky in these patients and may result in massive hemorrhage from inadvertent perforation of the uterus and from invasion of trophoblastic tissue into the myometrium and surrounding tissues. Medical therapy for cesarean scar EPs includes ultrasound-guided injection of KCl or MTX directly into the embryo or the gestational sac, or systemic MTX. Surgical options include excision with revision of the scar or hysterectomy. Adjunctive uterine artery embolization has been used to control hemorrhage.[94] Combined surgical and medical treatment is recommended by many in the field.[95]

Ovarian Ectopic Pregnancy

Ovarian EPs have been reported to account for 1% to 3% of all EPs, but in the authors' experience they are extremely rare, likely representing less than 1% of all EPs.[96] It is postulated that ovarian EPs may result either from fertilization occurring within a follicle that has ruptured but failed to extrude the oocyte or from implantation of a fertilized ovum into the ovary. These two types of ovarian EPs have been referred to as primary and secondary, and as intrafollicular and extrafollicular, respectively. Distinction between these two types of ovarian EPs is not feasible and has neither clinical nor therapeutic significance. Risk factors for ovarian EPs include tubal disease, IUD placement, endometriosis, salpingectomy, and ART. Ovarian EPs may occur during ART as the result of reverse migration of transferred embryos following deep deposition into the uterine cavity or if a large volume of culture fluid is used during ET.[97]

The clinical presentation of abdominal or pelvic pain and vaginal bleeding in a pregnant patient mimics that of a tubal EP or of a ruptured or hemorrhagic corpus luteum.[97] TVS demonstrates a thick echogenic, peripherally vascular ring surrounding a cystic area within the ovary, which may mimic the sonographic appearance of a corpus luteum (Fig. 33-30). Because a hemorrhagic corpus luteum is much more common than an ovarian EP, definitive sonographic diagnosis of an ovarian EP requires visualization of a yolk sac or embryo within the echogenic ring. It should be remembered that a small blood clot within a corpus luteum may mimic an embryo. Color or power Doppler ultrasound evaluation may demonstrate hypervascularity of the adjacent ovarian parenchyma (Fig. 33-30B). If a surrounding rim of ovarian tissue is not identified, gentle pressure with the transvaginal probe can be applied. With an ovarian EP, the ovary and gestational sac move together (negative sliding sign), whereas with a tubal EP, the sac slides separately from the adjacent ovary. Still, it may be extremely difficult to differentiate a tubal EP adherent to the ovary from an exophytic ovarian EP, and differentiating an ovarian EP from a hemorrhagic corpus luteum is not always possible.[99] In some instances, 3D ultrasound examination may be helpful. Most often, the diagnosis of a primary ovarian EP is made histologically after laparoscopy, although this too may be difficult.

Early detection of ovarian EPs is important to prevent rupture, abdominal implantation, and the need for more complex surgery. The goal is to preserve as much normal ovarian tissue as possible while protecting the pregnant woman. Hence, the treatment of choice is ovarian wedge resection or laparoscopic cystectomy. Oophorectomy is reserved for more advanced cases. Because laparoscopy is used for both diagnosis and treatment, medical therapy with MTX is usually reserved as a secondary option or in cases of trophoblastic persistence.

Abdominal Ectopic Pregnancy

Abdominal EPs account for approximately 1.4% of all EPs[100] (Figs. 33-31 and 33-32) and may be classified as primary or secondary. A primary abdominal EP results from intra-abdominal fertilization of an ovum with subsequent direct implantation of the conceptus outside the genital tract. A secondary abdominal EP, which is more common, results from survival of a ruptured tubal or ovarian EP that implants onto the peritoneum, omentum, or abdominal organs (typically bladder and bowel). Implantation on the spleen and in the lesser sac has also been reported.[101-103] An abdominal pregnancy parasitizes blood supply from any vascular surface, which makes this one of the most dangerous types of EP. Such pregnancies are notoriously difficult

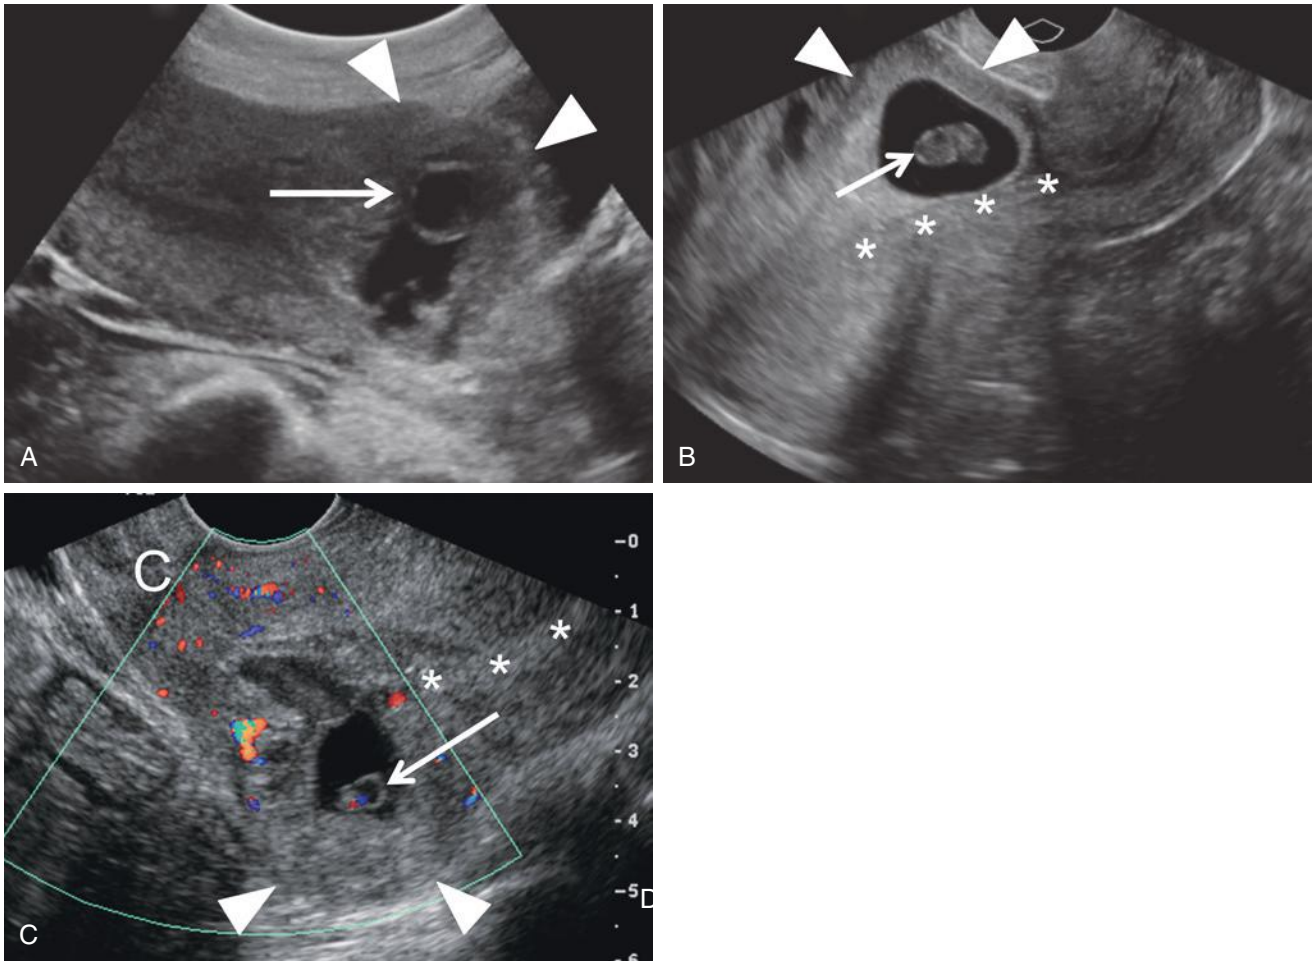

FIG 33-28 Cesarean scar ectopic pregnancies. **A,** Transabdominal sagittal scan of the uterus shows a gestational sac within the cesarean incision scar (*arrow*), bulging the lower uterine contour (*arrowheads*) anteriorly toward the bladder. **B,** Transvaginal sagittal scan of the uterus in a second patient shows an ectopic gestational sac containing an embryo (*arrow*) within a cesarean incision scar, embedded in the myometrium at the lower uterine segment anterior to the endometrium (*asterisks*) and bulging the uterine contour (*arrowheads*) anteriorly toward the abdominal cavity. **C,** Transvaginal sagittal scan with color Doppler ultrasound in a third patient, with a retroverted/retroflexed uterus. There is an ectopic gestational sac containing an embryo with a heartbeat (*dot of color*) next to the yolk sac (*arrow*), bulging beyond the serosal surface of the uterine wall (*arrowheads*), at the level of the cesarean incision scar just above the internal cervical os. *Asterisks* indicate endometrium; C, cervix. (Courtesy Department of Obstetrics and Gynecology, Yale University School of Medicine, New Haven, CT.)

to diagnose and may not be recognized until the third trimester, often resulting in massive hemorrhage threatening the life of both mother and fetus. Abdominal EP should be considered in the differential diagnosis of an acute abdomen and hemoperitoneum in a woman of reproductive age with no obvious cause. Maternal mortality rate is as high as 20%. Morbidity includes the risks associated with hemorrhage, disseminated intravascular coagulation, bowel obstruction, fistula formation, and adherent placenta. The incidence of full-term abdominal EPs resulting in live births is not known because so few cases have been reported.

Risk factors for abdominal EP include PID, tubal abnormalities, endometriosis, ART, and multiparity. Symptoms are nonspecific and include abdominal pain, painful fetal movements, nausea, and vomiting. Physical examination may detect an abnormal lie of the fetus and a pregnancy that is small for gestational age. Careful history may reveal an episode of pain and vaginal bleeding at 6 to 8 weeks of gestation that resolved, presumably representing the time of tubal rupture.

Abdominal EPs may be missed during ultrasound examinations if the sonographer, concentrating on evaluating the fetus, does not recognize that the uterus is displaced deep in the cul-de-sac resembling the cervix, or that there is no myometrial tissue surrounding the pregnancy. Therefore, it is important to always document the presence of myometrial tissue surrounding the gestational sac and located between the pregnancy and the maternal bladder wall (Fig. 33-31A). In addition, when performing an obstetric sonogram, it is necessary to evaluate the configuration of the lower uterine segment and cervix and to document continuity of the endocervical canal with the endometrial canal/uterine cavity. The walls of the cervix should always be continuous with the myometrium both anteriorly and posteriorly. A clumped appearance of the cervix, a narrow waist in the region of the lower uterine segment, or apparent discontinuity between the cervix and the lower uterine segment should alert the sonographer to the possibility of an abdominal EP (Fig. 33-31B). Abnormal lie of the fetus and oligohydramnios are common ultrasound findings.

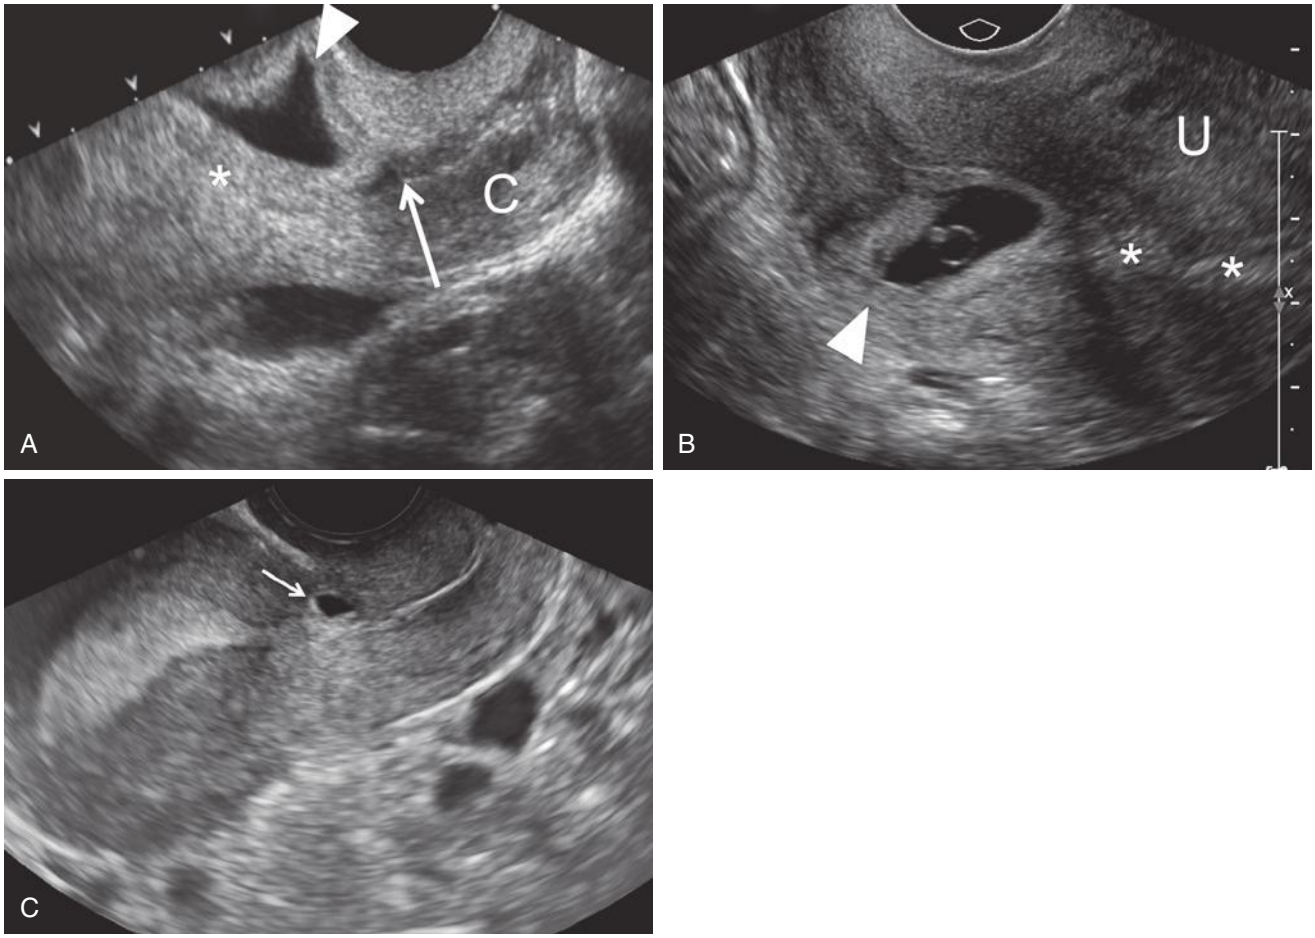

FIG 33-29 Cesarean scar ectopic pregnancies. **A,** Transvaginal sagittal scan of the lower uterine segment and cervix (C) shows a triangular ectopic gestational sac (*arrowhead*) located in the myometrium at the anterior lower uterine segment above the level of the internal cervical os (*arrow*), bulging slightly into the endometrial cavity (*asterisk*). Very early cesarean scar ectopic pregnancies are often triangular in configuration. **B,** Transvaginal sagittal scan of a patient with a retroverted/retroflexed uterus (U) shows a gestational sac (*arrowhead*), containing a yolk sac and adjacent small embryo, implanted in a cesarean incision scar and growing toward the endometrial cavity (*asterisks*). **C,** Early cesarean scar ectopic pregnancy. The gestational sac (*arrow*) is centered in the anterior myometrial wall at the lower uterine segment above the internal cervical os. It is difficult to predict if the pregnancy will grow toward the endometrial cavity or bulge outward and extend beyond the serosal surface of the uterus. Rarely, confirmed abdominal EPs have been allowed to progress into the third trimester (see Fig. 33-32). The fetus is delivered surgically, but removal of the placenta is problematic because of complex vascular attachments or placental invasion into surrounding tissues. Complete removal of the placenta may not be feasible, but resection of as much as possible is recommended because of the substantial risk of secondary infection, hemorrhage, and intestinal obstruction if the placenta is left in situ. Postoperative treatment with MTX has been used to promote involution of residual placental tissue.[103]

Retroperitoneal Ectopic Pregnancy

EPs in the retroperitoneal space are extremely rare.[104-107] They are difficult to detect and may present with massive retroperitoneal hemorrhage. Although the mechanism of implantation in the retroperitoneal space is not known, possible explanations include iatrogenic manipulation with ART resulting in either retrograde migration of the embryo after ET or uterine perforation and direct placement of the embryo into the retroperitoneum during ET. Retroperitoneal EPs have been reported in the absence of IVF-ET. In such cases, it is theorized that the embryo initially implants on the posterior peritoneal surface (i.e., an abdominal pregnancy) with subsequent invasion by the trophoblastic tissue through the peritoneal membrane into the retroperitoneal space or through congenital or acquired (perhaps secondary to conditions such as endometriosis) defects in the peritoneal surface. Another theory involves migration of the conceptus through lymphatic channels, a theory supported by Hall and colleagues,[106] who found lymphatic tissue in the excised ectopic mass. Alternatively, migration might occur alongside the retroperitoneal ovarian vessels as they enter or exit the ovary. In support of this last theory, retroperitoneal EPs have been found near the confluence of the left renal and left ovarian veins (Fig. 33-33).

In a symptomatic pregnant patient with a normal laparoscopic examination of the uterus and adnexa, a pregnancy in an extremely unusual location such as the retroperitoneum should be considered,

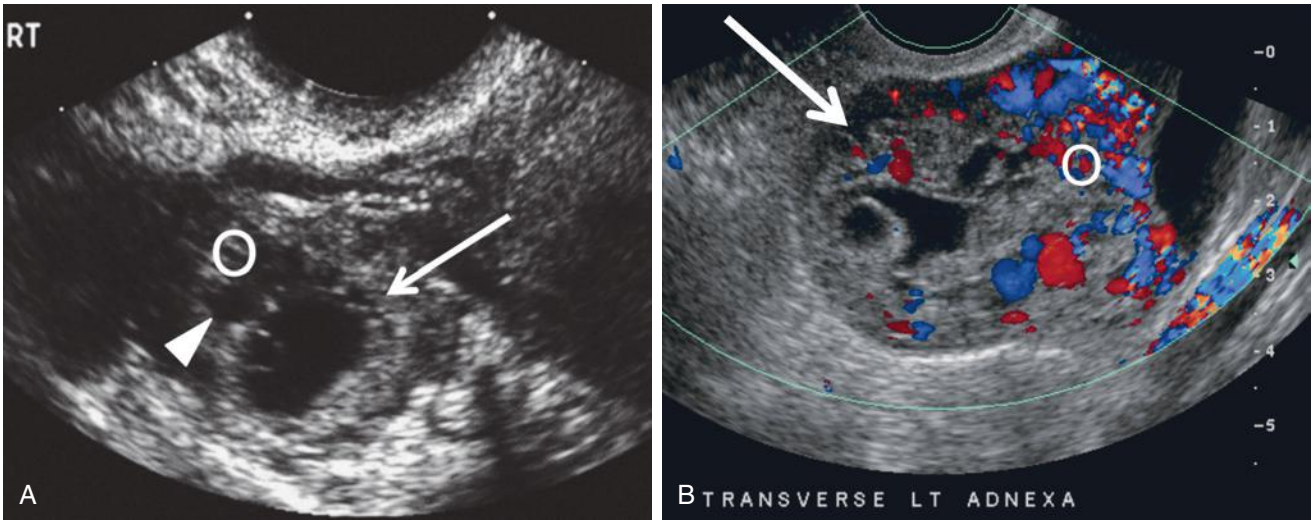

FIG 33-30 Ovarian ectopic pregnancies. **A,** Transvaginal transverse scan shows an ectopic gestational sac (*arrow*), containing a yolk sac, arising and bulging outward from the surrounding ovary (O). Chorionic tissue, partially surrounding a follicle (*arrowhead*), was found to be firmly attached to the ovary, necessitating oophorectomy. This patient had a malpositioned intrauterine device removed 10 days prior, developed pelvic pain, and was found to have a pathologically proved ovarian ectopic pregnancy. **B,** Transvaginal transverse scan with color Doppler ultrasound in another patient shows an ectopic gestational sac (*arrow*) containing a yolk sac in the left ovary (O). The rim of the ectopic pregnancy is heterogeneous and irregular in thickness, making it difficult to differentiate from ovarian tissue. Note increased vascularity of the ovarian parenchyma, which has been described with ovarian ectopic pregnancies but is not a specific finding. It can be difficult to differentiate an ovarian ectopic pregnancy from a corpus luteum. Given the rarity of ovarian ectopic pregnancies, this diagnosis should not be made on the basis of sonographic findings unless a yolk sac or embryo is clearly documented. (Courtesy Department of Obstetrics and Gynecology, Yale University School of Medicine, New Haven, CT.)

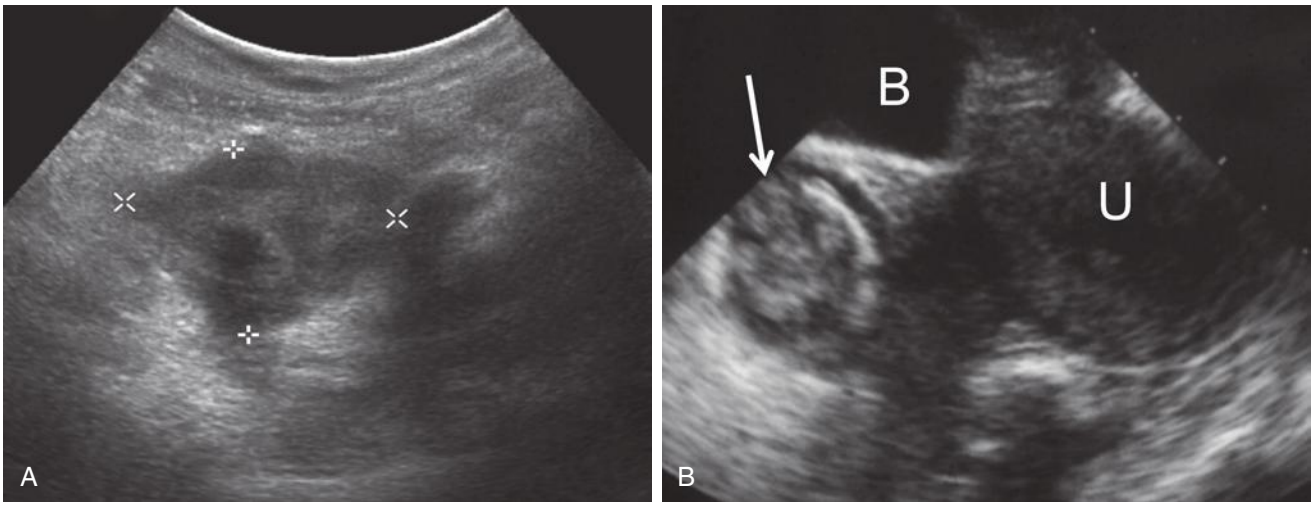

FIG 33-31 First trimester abdominal ectopic pregnancies. **A,** Transabdominal scan of the left flank just below the kidney in the region of patient's pain shows a very early gestational sac with an ill-defined echogenic rim surrounded by heterogeneous hypoechoic hematoma (*calipers*), found to be an intraperitoneal or abdominal ectopic pregnancy. **B,** Transvaginal longitudinal scan of the pelvis in another patient shows the head of a 12-week fetus (*arrow*) far apart from the retroverted/retroflexed uterus (U) and posterior to the maternal urinary bladder (B). The uterus is displaced deep into the cul-de-sac by the developing extrauterine ectopic pregnancy. (A from Bryan-Rest LL, Scoutt LM: Ectopic pregnancy. In Fielding JR, Brown DL, Thurmond AS (eds): Gynecologic Imaging. Philadelphia, Elsevier, 2011, p 344, Fig. 22-14B, used with permission.)

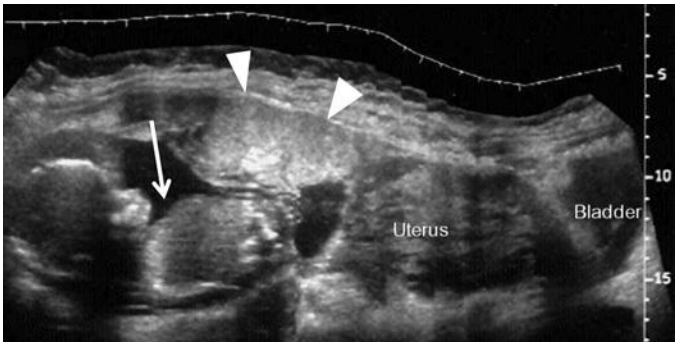

FIG 33-32 Abdominal pregnancy. Transabdominal longitudinal extended field of view ultrasound image of the abdomen and pelvis of a woman with a term fetus (*arrow*) located in an amniotic sac located well above the uterine fundus. Surgery was performed and resulted in delivery of a live, healthy newborn. Placental tissue is located anteriorly (*arrowheads*) implanted into the peritoneum of the anterior abdominal wall. (From TheFetus.net, used with permission.)

particularly if gestational age is estimated to be longer than 6 weeks and if, based on clinical findings, miscarriage seems unlikely.[107] MRI may be helpful to search for an unusual location of an EP, and in a woman with unexplained hemorrhage, CT scan of the abdomen and pelvis with intravenous contrast may help identify a ring of vessels within the hematoma, which is characteristic of a gestational sac (Fig. 33-33B and C).

CHRONIC ECTOPIC PREGNANCY

Chronic EP is a form of tubal pregnancy that manifests as a persistent adnexal mass. Active trophoblastic tissue involutes and the wall of the fallopian tube gradually disintegrates. Repeated small hemorrhages create a pelvic hematocele, which is often walled off by adhesions resulting from an inflammatory response. Symptoms are nonspecific, and usually there is a protracted clinical course. Patients complain of persistent, mild pelvic or lower abdominal pain, and rarely dyspareunia or anal pain during defecation. A woman may have missed a period or had either mild irregular or prolonged vaginal bleeding. A tender

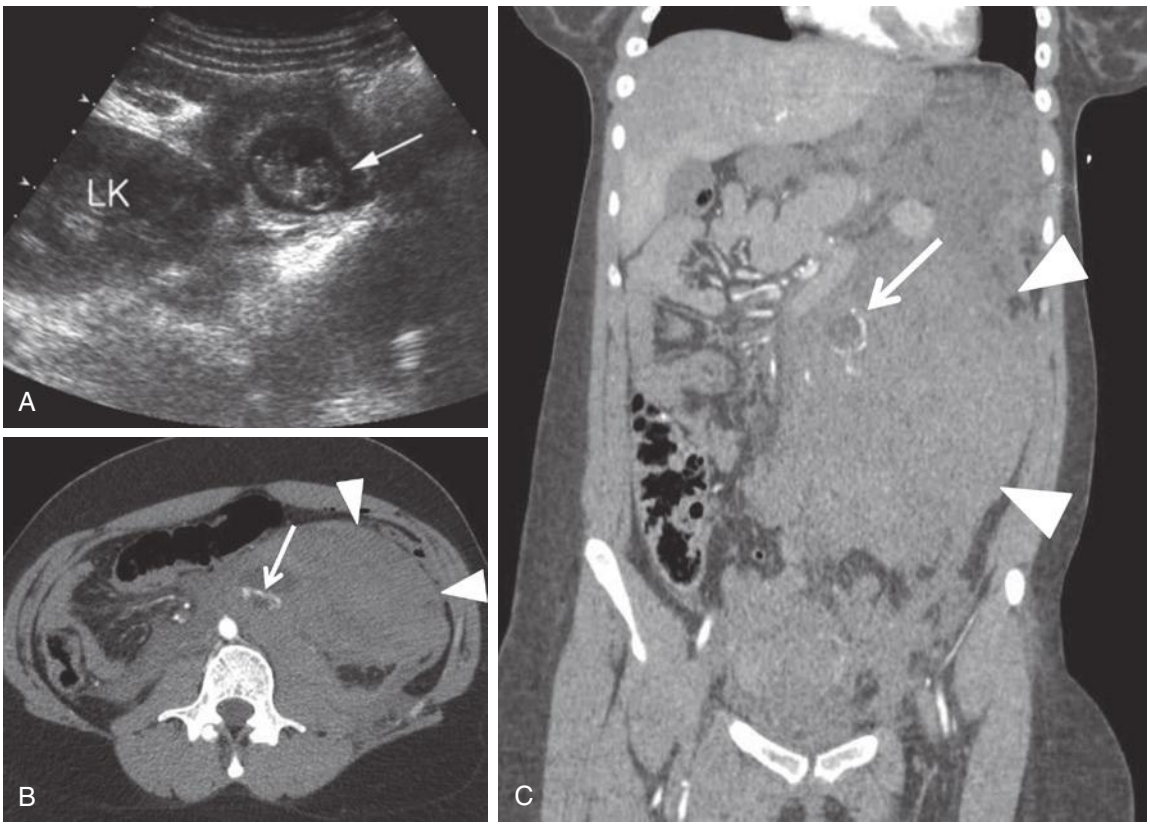

FIG 33-33 Retroperitoneal ectopic pregnancies located inferior to the left kidney. **A,** Transabdominal coronal image of the left kidney (LK) shows an ectopic gestational sac (*arrow*) containing a live embryo located in the retroperitoneum inferior to the left kidney. **B,** Axial computed tomography (CT) angiogram image through the midabdomen of a second patient with human chorionic gonadotropin level of 28,000 mIU/mL, pregnancy of unknown location (PUL), and dropping hematocrit shows a large left retroperitoneal hematoma (*arrowheads*) and a small cluster of vessels (*arrow*). **C,** Coronal CT angiogram image of the same patient as in B shows the large left retroperitoneal hematoma (*arrowheads*) and a ring of vessels (*arrow*) in the region of the left renal vein. Surgery was performed, and the hematoma was evacuated. The pathologic specimen identified chorionic villi within the blood clot, consistent with retroperitoneal ectopic pregnancy. It is theorized that the ectopic pregnancy migrated cephalad along the course of the left ovarian vein and implanted near the confluence of the left ovarian and left renal veins. (A from Lee JW, Sohn KM, Jung HS: Retroperitoneal ectopic pregnancy. AJR Am J Roentgenol 184:1601, 2005, Fig. 1B, used with permission.)

adnexal mass may be palpable. The serum hCG level may be negative or very low. A nonspecific, heterogeneous adnexal mass will be identified on imaging. The natural progression of a chronic EP includes spontaneous resolution, persistence, or rupture.[108] Surgery is often performed for diagnostic purposes, and only when degenerated villi are identified on histologic examination is the definitive diagnosis made.[109,110]

POSTHYSTERECTOMY ECTOPIC PREGNANCY

Posthysterectomy EPs are the rarest of the unusual EPs. They have been reported after both total and supracervical hysterectomy and may be tubal, ovarian, or abdominal in location.[111] A successful pregnancy following total hysterectomy resulting in a healthy 36-week infant delivered by laparotomy has been reported. In this case, hysterectomy was performed 3 days after coitus resulting in an abdominal pregnancy.[112] Posthysterectomy EPs can be divided into two groups: those presenting early after hysterectomy and those presenting late. In the early type, authors postulate that a fertilized ovum was likely present in the fallopian tube at the time of hysterectomy and spilled into the peritoneal cavity during or immediately after surgery. This type of EP can be avoided if precautions are taken to prevent pregnancy or by pregnancy testing prior to performing a hysterectomy in a sexually active woman of reproductive age. In the late presentation type, which is less common, the EP presents months to years after surgery.[113] Such cases may result from a fistula between the vagina or cervical stump and the peritoneal cavity or fallopian tube, allowing sperm access to an ovum. Impeccable surgical technique and prevention of postoperative pelvic hematomas and infection are the best means of preventing this type of EP.[114]

Patients may present acutely or subacutely with pelvic pain or signs of peritonitis with or without vaginal bleeding. Symptoms are nonspecific and similar to those from pelvic hematoma or infection. Diagnosis depends on obtaining an hCG level. The diagnosis is usually delayed, as the condition is so unexpected in a woman who has undergone hysterectomy. Unfortunately, delay in diagnosis can lead to rupture and hemodynamic instability. Therefore, if at least one ovary has been retained, a pregnancy test should be performed in a woman of reproductive age status posthysterectomy who presents with abdominal/pelvic pain of unknown origin. MRI can be very helpful not only in demonstrating the ectopic gestation, but also in delineating the fistulous tract.

HETEROTOPIC PREGNANCIES

The incidence of coexistent intrauterine and ectopic pregnancies (Fig. 33-34) in the general population has increased in recent years from an original estimation of 1 in 30,000 pregnancies to 1 in 4000 pregnancies, according to more recent data.[43,115] Risk factors include all those reported for EP and are additive. The risk of heterotopic pregnancies is particularly high for women undergoing ovulation induction or IVF-ET, in whom the incidence has been reported to be as high as 1 in 100[43,44] (Fig. 33-34E and F). The risk increases with the number of embryos transferred, with incidence reported to be as high as 1 in 45 pregnancies if more than four embryos are transferred.

Heterotopic pregnancies remain a diagnostic and therapeutic challenge.[116] Talbot and coworkers[117] found that in 33% of cases, identification of the normal coexistent IUP gave a false assurance that an EP was unlikely and the heterotopic pregnancy was missed with resultant delay in diagnosis. Hence, heightened clinical suspicion, particularly in patients who have undergone ART, is crucial. The presence of an intrauterine gestation with a coexistent extrauterine gestational sac is diagnostic, whereas an IUP with an adnexal mass, with or without pain and fluid in the cul-de-sac, is concerning. Note that without a good complete clinical history, these findings are much more likely to be misinterpreted as hemoperitoneum due to a ruptured corpus luteum. Persistent pain or increasing hCG levels following spontaneous miscarriage, evacuation of residual products of conception, or elective abortion should raise suspicion of heterotopic pregnancy.

Local injection of KCl or surgical removal of the ectopic gestation allows the IUP to proceed to term in most cases. MTX should be avoided because of the potential risk to the IUP if the pregnancy is desired. Overall, the prognosis for the IUP is good, and approximately 66% of these pregnancies go to term.

MANAGEMENT AND TREATMENT OPTIONS

Treatment of EP includes surgical, medical, combination, and expectant options. Management depends heavily on imaging features including the size of the ectopic sac, presence of cardiac activity, location, and evidence of tubal rupture or hemoperitoneum. The patient's clinical condition, including hemodynamic stability and comorbid medical conditions, as well as compliance for follow-up are also important factors.

In general, laparotomy and salpingectomy have been replaced with less aggressive surgical approaches utilizing minimally invasive surgery to preserve fertility, such as laparoscopic or hysteroscopic resection of the EP, linear salpingostomy, salpingoscopic removal of the ectopic gestational sac, or even manually milking the gestational sac from the fallopian tube. Laparoscopy is the current standard surgical approach. Laparoscopy is rarely required for diagnosis, but occasionally is helpful in finding an EP when a pregnancy cannot be found on ultrasound imaging (PUL) but the serum hCG level continues to rise. The benefits of laparoscopic surgery compared to laparotomy include lower incidence of postoperative adhesions, less blood loss, and faster recovery. However, laparotomy may still be required if the EP cannot be visualized laparoscopically (usually because of dense adhesions or scar tissue) or in patients who are hemodynamically unstable or who have large EPs of advanced gestational age or interstitial EPs. Wedge resection of an EP located within the myometrium, such as an interstitial or cesarean delivery scar EP, is often performed, in part to repair the underlying myometrial defect to prevent recurrent EPs. In cases of ovarian EPs, wedge resection rather than oophorectomy will help to ensure future fertility. In current practice, hysterectomy is considered a last resort, usually in the setting of uncontrollable hemorrhage.

Medical therapy with systemic MTX is often successful in the treatment of EPs. To determine whether a patient is a candidate for systemic MTX therapy, certain criteria must be met. The patient must be hemodynamically stable without signs or symptoms of active bleeding. Hence, ultrasound examination is extremely important in patient management because the ultrasound finding of extensive hemoperitoneum, which suggests tubal rupture, is a contraindication for MTX therapy and will prompt surgical intervention. The maximal diameter of the ectopic mass should not exceed 3.5 to 5 cm, and no embryonic cardiac activity should be identified. Another relative contraindication to the use of systemic MTX is a serum hCG level higher than 10,000 to 15,000 IU/L. In general, the smaller the EP and the lower the serum hCG level, the more likely that a single dose of MTX will be successful. However, these criteria are not absolute. Various medical disorders are also contraindications to the use of MTX, such as known hypersensitivity to MTX; hepatic, renal, or pulmonary diseases; blood dyscrasias; and immunodeficiency disorders. The patient must be reliable and educated to return for follow-up if signs or symptoms of delayed hemorrhage or rupture develop.

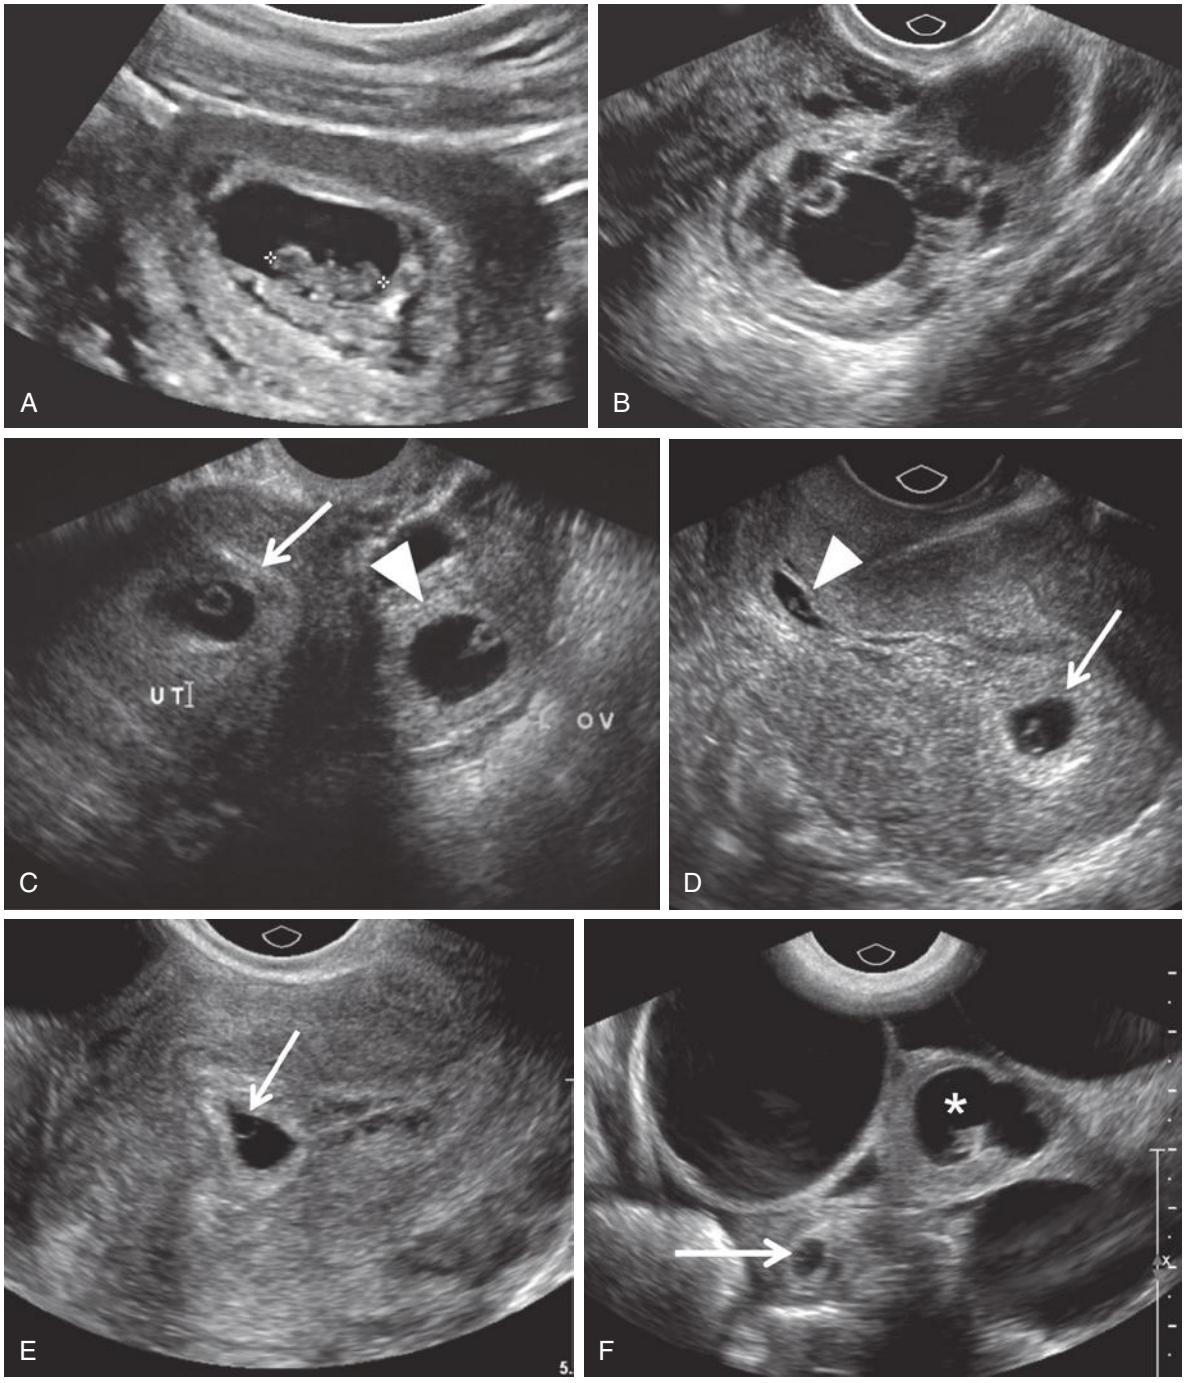

FIG 33-34 Heterotopic pregnancies. **A,** Transabdominal sagittal scan of the uterus shows a gestational sac containing an embryo (*calipers*). Cardiac motion was observed. **B,** Transvaginal scan of the left adnexa of the same patient as in A shows an ectopic pregnancy containing a yolk sac, representing heterotopic pregnancies. The patient had undergone assisted reproductive techniques. **C,** Transvaginal transverse scan of the uterus (UT) and left adnexa from another patient shows an intrauterine gestational sac (*arrow*) and an ectopic pregnancy in the left adnexa (*arrowhead*), both containing yolk sacs. **D,** Transvaginal longitudinal scan of a retroverted/retroflexed uterus from a third patient shows an intrauterine gestational sac (*arrow*) as well as an ectopic cervical pregnancy (*arrowhead*). Both sacs contain yolk sacs and adjacent tiny embryos. **E,** Transvaginal transverse scan of the uterus of a fourth patient who underwent ovulation induction therapy shows an intrauterine gestational sac containing a yolk sac (*arrow*). **F,** Transvaginal transverse scan of the right adnexa in the same patient as in E shows a small ectopic pregnancy with a yolk sac (*arrow*) among several large ovarian cysts due to ovarian hyperstimulation syndrome. One cyst contains clumped echoes indicating blood (*asterisk*). Heterotopic ectopic pregnancies may be difficult to find among multiple ovarian cysts in patients with enlarged ovaries following ovulation induction. (**E** and **F** from Scoutt LM, Hamper UM, Angtuaco T: Ultrasound. New York, Oxford University Press, 2016 (in press). Used with permission.)

Ultrasound evaluation can serve a role in the follow-up of patients after MTX therapy. Approximately 35% to 60% of patients will present with pelvic pain on days 3 through 7 following administration of MTX because of infarction of the trophoblastic tissue. These patients need to be carefully evaluated with vital signs, hematocrit, and follow-up sonographic examination to assess for interval development of hemoperitoneum to determine if delayed rupture has occurred. If the patient's pain is due to tissue infarction, the pain should resolve within 24 to 48 hours. Following MTX therapy, an adnexal mass may still be seen, and it generally takes longer for the EP to resolve on sonographic imaging than for the serum hCG level to fall to zero. Slight growth of the EP with persistence of color Doppler blood flow is considered within normal limits provided that the hCG level is dropping. However, continued progression of the EP such as development of a sonographically visible yolk sac, embryo, or cardiac activity not previously noted is considered indicative of treatment failure.[118]

Ultrasound-guided direct injection of MTX or KCl into the ectopic sac is another therapeutic option. Direct injection of MTX is believed to destroy the embryo and to infarct the surrounding trophoblastic tissue. A combination of direct intra-amniotic injection of MTX and systemic intramuscular injection is used in selected cases, and a combination of medical and surgical treatment is often indicated in cesarean scar, cervical, and interstitial EPs because of the increased risk of hemorrhage or recurrence. Uterine artery ligation, uterine artery embolization, and balloon tamponade are used adjunctively to control hemorrhage in some cases.

Expectant management of EPs without intervention is increasing. First trimester EPs may resolve spontaneously, and some asymptomatic women with EPs have been successfully followed with serial hCG levels until the level drops to zero. However, patients must be followed closely and advised to immediately return if symptoms of rupture develop, as cases of delayed rupture with hCG levels close to zero have been reported.

Another issue related to medical management of women with EP is treatment of the Rh-negative woman with a first trimester pregnancy loss. It is recommended that providers should administer anti-D immunoglobulin to Rh-negative women in all cases of documented first trimester loss of an established pregnancy, which includes complete abortion and EP.[119,120]

When it is difficult to differentiate between an EP and a failing IUP and follow-up ultrasound examination is nondiagnostic, D&C can be helpful by determining the presence or absence of trophoblastic tissue within the endometrium.[27]

CONCLUSION

As patients present earlier for diagnosis, clinicians are requesting earlier ultrasound examinations to discriminate between intrauterine and ectopic pregnancies, and in many cases the location of the pregnancy cannot initially be determined. Hence, follow-up serologic testing and TVS are important for management of patients with PULs. Accurate diagnosis and demonstration of EPs are important because management decisions often depend upon size, gestational age, presence or absence of embryonic cardiac activity, and exact location of the EP. In addition, it should be noted that the incidence of EPs, including those in unusual locations, and heterotopic pregnancies is increasing—particularly in patients undergoing ART. Thus, the presence of an IUP does not completely exclude the possibility of a concomitant EP. Furthermore, EPs in unusual locations that historically presented at an advanced gestational age with increased risk of significant hemorrhage are now more likely to be diagnosed earlier, sometimes at screening sonograms when the patient is asymptomatic, conferring lower risk of uterine rupture and hemodynamic instability. The characteristic imaging features of these unusual ectopic pregnancies have been described, and the management and treatment protocols have evolved. Sonographic evaluation continues to serve an important role in the diagnosis, therapeutic triage, and follow-up of patients with EPs.

Gynecologic Sonography in the Pediatric and Adolescent Patient

Harriet J. Paltiel, Andrew Phelps

SUMMARY OF KEY POINTS

- Reproductive tract anomalies may present at different stages of life. Most abnormalities of the external genitalia are obvious at birth, whereas obstructive and nonobstructive lesions of the reproductive tract may be evident at birth or present later during childhood, at puberty, in adolescence, or during adulthood.
- Sonography is used to determine the presence of a uterus and gonadal location in patients with ambiguous genitalia.
- In preadolescent girls with vaginal bleeding, sonography can be used to confirm or exclude a postpubertal appearance of the internal genitalia; to diagnose an estrogen-secreting adrenal or ovarian tumor; and to diagnose a vaginal foreign body or mass.
- In girls with primary amenorrhea, sonography is useful in determining the presence and morphologic appearance of the uterus and ovaries.
- Sonography is a key tool in evaluating pelvic pain in girls, including those with suspected appendicitis.
- In patients with adnexal torsion, the involved ovary is always significantly enlarged, with a median volume 12 times that of the normal contralateral ovary.
- Bleeding into an ovarian cyst in utero or after birth has a high association with long-term ovarian loss.
- Ovarian tumors in the pediatric population are usually benign, with cystic teratomas accounting for more than 90% of all benign ovarian tumors.

OUTLINE

The most frequent indications for gynecologic ultrasound imaging in the pediatric and adolescent patient are ambiguous genitalia, prepubertal vaginal bleeding, primary amenorrhea, pelvic pain, and pelvic mass. Sonography is the primary imaging modality used in the evaluation of these disorders, with magnetic resonance imaging (MRI) and computed tomography (CT) reserved for further delineation of congenital malformations or tumors.[1-4]

TECHNIQUE

The pediatric vagina, uterus, and ovaries are best imaged with transabdominal ultrasound when the patient's bladder is full. All girls are encouraged to drink fluids and not to void in the hour prior to imaging. Teenagers are asked to drink 16 ounces.

Curvilinear, sector, and linear-array ultrasound transducers are usually sufficient for most pelvic ultrasound examinations. In young girls with urogenital malformation, hydrometrocolpos, a labial mass, or anal atresia, a transperineal approach is often useful[5,6] (Fig. 34-1). A transvaginal approach is used to complement the transabdominal examination in sexually active adolescents. In the patient with a complex congenital anomaly, genitography performed with water-soluble contrast material along with ultrasound examination is frequently helpful in identifying and characterizing the vagina, urogenital sinus, or cloaca.

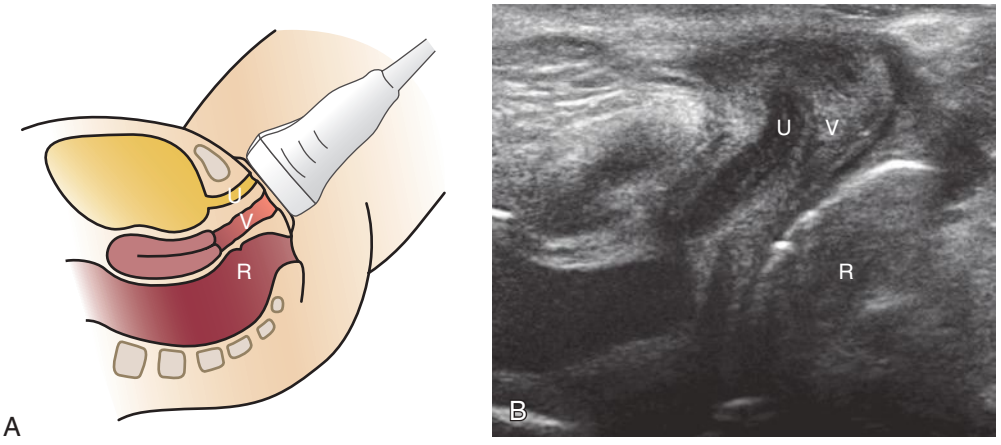

FIG 34-1 Transducer placement and depiction of normal anatomy using perineal approach. **A,** Diagram demonstrates sagittal orientation of a linear-array transducer on the female perineum. **B,** Corresponding transperineal ultrasound image. R, rectum; U, urethra; V, vagina. (From Paltiel HJ, Phelps A: US of the pediatric female pelvis. Radiology 270(3):644-657, 2014, Fig. 1a, used with permission.)

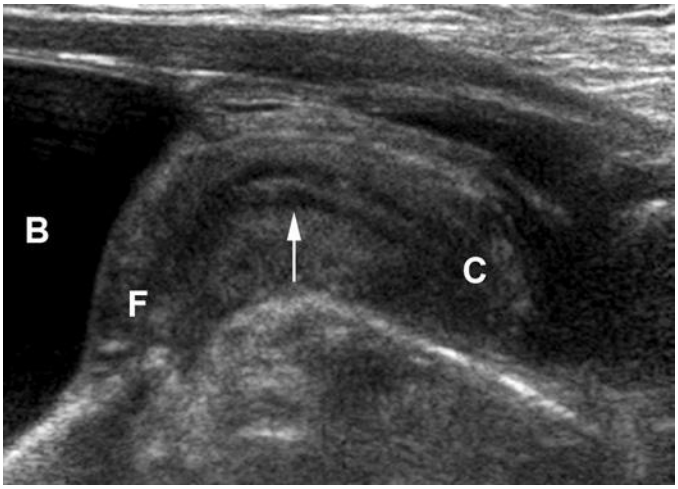

FIG 34-2 Normal neonatal uterus. Sagittal ultrasound image shows a prominent uterine fundus (F) with echogenic endometrium surrounded by a hypoechoic halo (*arrow*). B, bladder; C, cervix.

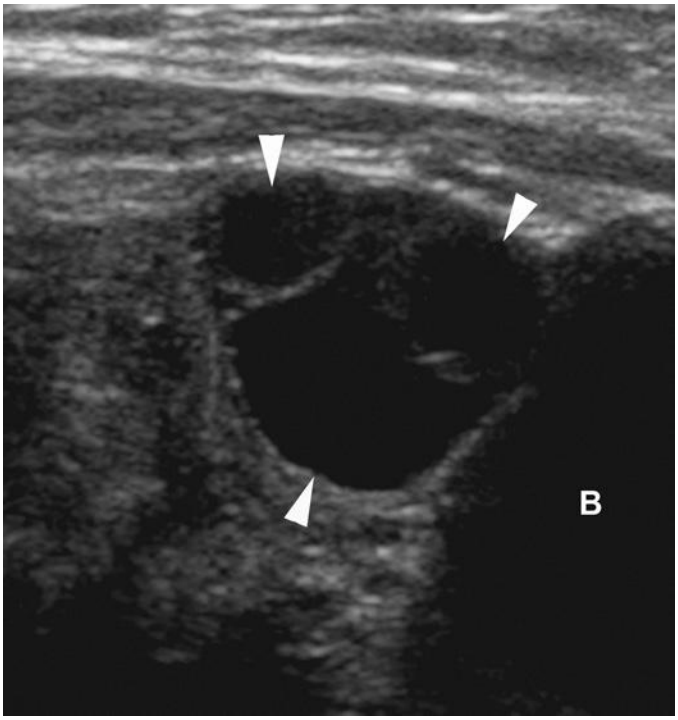

FIG 34-3 Normal neonatal ovary. Sagittal ultrasound image demonstrates multiple anechoic follicles (*arrowheads*). B, bladder.

NORMAL ANATOMY

Uterine and ovarian size and shape are age-dependent and under hormonal influence. Maternal and placental hormonal stimulation lead to a relatively large neonatal uterus and ovaries compared to their size in later infancy, at which point they remain relatively stable in size until a growth spurt occurs at approximately 7 to 8 years of age[7] (Figs. 34-2 and 34-3). Mature ovarian follicles can be identified at all ages owing to the secretion of follicle-stimulating hormone (FSH).[8,9] The prepubertal cervix is greater than or equivalent in thickness to the uterine fundus, and the endometrium is relatively inconspicuous in this age group (Fig. 34-4). Cervical length is approximately twice that of the fundus in the neonate. During childhood, relative cervical length and thickness decrease but uterine fundal length and thickness increase. Average uterine length varies from approximately 2.5 to 4 cm, with thickness less than or equal to 1 cm. Ovarian volume is slightly less than 1 mL. The uterine fundus elongates and thickens during puberty, outstripping the cervix; the endometrium also thickens and undergoes cyclic changes associated with the menstrual cycle.[10]

NORMAL GONADAL AND REPRODUCTIVE TRACT DEVELOPMENT

Development of the female reproductive tract is a complex process that involves cellular differentiation, migration, fusion, and canalization with probable apoptosis (programmed cell death). This integrated sequence of events is associated with many opportunities for abnormal development and structural anomalies. Anomalies of the reproductive tract may present at different time points. Most abnormalities of the external genitalia are obvious at birth, whereas obstructive and nonobstructive lesions of the female reproductive tract may be apparent at birth or only later in childhood, at puberty, in adolescence, or during adulthood.[11]

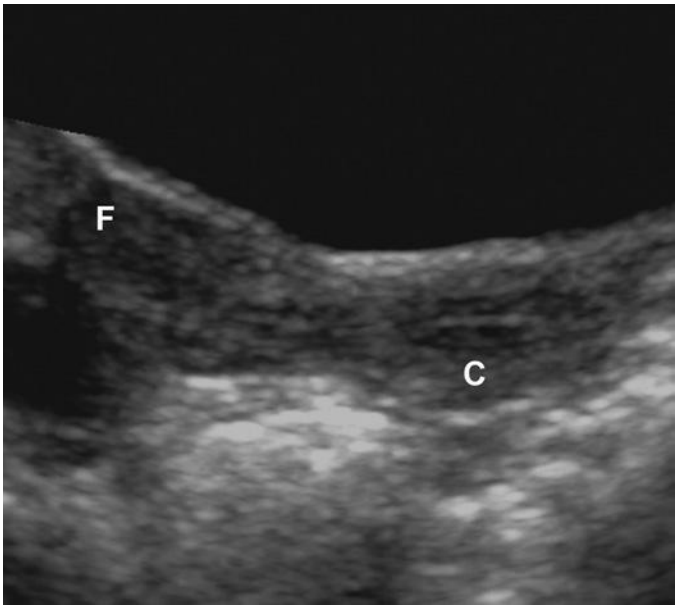

FIG 34-4 Normal uterus in a 19-month-old girl. Sagittal ultrasound image depicts a fundus (F) that is similar in thickness and length to the cervix (C).

In the first 3 months of embryonic life, the primordia of both the female and male reproductive tracts are present and develop together. The gonads arise after migration of germ cells to the genital ridge, whereas the genital tract evolves from the formation and reshaping of the müllerian (paramesonephric) ducts, urogenital sinus, and vaginal plate.

Biologic differences between males and females are determined genetically during embryonic development. Sex development can be divided into two processes: *sex determination*, the developmental decision that directs the undifferentiated gonad to develop as a testis or ovary; and *sex differentiation*, which occurs once the gonad has developed and is induced by the products of the gonad to establish the phenotypic sex. Factors that affect gene expression influence sex determination, whereas factors that influence sex differentiation include hormones and their receptors.[12]

Gonads

In the first and second weeks of development, embryos of both sexes differ only in their sex chromosomes. The gonads arise from the bilateral genital ridges, sites of focal mesothelial thickening of the peritoneum, before 5 to 6 weeks of life. A number of genes are required for development of the bipotential gonad. The bipotential gonad becomes an ovary or testis, depending on differentially expressed genes. Both testicular and ovarian development involve sex-specific pathways that appear to act antagonistically to each other. The normal role of the sex-determining region of the Y chromosome (the *SRY* gene) in XY gonads is to tip the balance in favor of the testis-specific pathway. If it is absent or abnormal, the gonad differentiates into an ovary. The presence of two X chromosomes appears to be important for the development of a normal, functioning ovary.[13]

The bipotential gonad begins to develop into either a testis or ovary in XY and XX individuals, respectively, at about 6 weeks of life. Differentiation of the gonads leads to testicular and ovarian hormone production and subsequent induction of anatomic and psychological differences. The first sign of gonadal differentiation occurs in the male with the appearance of Sertoli cells at 6 to 7 weeks of life. Leydig cells appear at about 8 weeks. At this stage, the only sign of ovarian differentiation is the absence of Sertoli and Leydig cells. At 9 weeks, primordial germ cells begin to differentiate into oogonia followed by normal ovarian development at 12 to 123 weeks of life. In males, testicular cords will form in the absence of germ cells. However, in females, the ovary will not develop in the absence of germ cells.[13]

Testosterone and antimüllerian hormone are secreted by the Leydig and Sertoli cells, respectively, resulting in the differentiation of the genital primordia into the male phenotype. In the absence of a functioning testis, regardless of whether or not an ovary is present, the genital primordia will differentiate into the female phenotype. The presence of a functioning testis is necessary but not sufficient for the development of a male phenotype; normal androgen metabolism is also required.[13]

In adolescence, an increase in adrenal androgen secretion is associated with the appearance of pubic and axillary hair. Estrogen is responsible for breast development; for maturation of the uterus, vagina, and external genitalia; and for the initiation of the menstrual cycle. Excess androgens of either adrenal or ovarian origin may cause acne, hirsutism, clitoromegaly, increased muscle mass, and deepening of the voice.

External Genitalia and Reproductive Tract

External genital development in the male occurs between the 8th and 12th weeks of life and requires high levels of circulating testosterone, the conversion of testosterone to dihydrotestosterone (DHT) by 5α-reductase in the target organs, and functional androgen receptors. Under the influence of DHT, in the male the urogenital sinus gives rise to the prostate gland; the genital tubercle forms the glans penis; the labiourethral folds form the urethra and ventral shaft of the penis; and the labioscrotal folds fuse to form the scrotum. In the female, or in the absence of testicular tissue secreting biologically active testosterone, functioning androgen receptors, or 5α-reductase, the genital tubercle forms the clitoris; the labiourethral folds form the labia minora; and the labioscrotal folds form the labia majora (Fig. 34-5).[13]

The cell layers involved in the formation of the female reproductive tract include the mesoderm, endoderm, and ectoderm. The mesoderm gives rise to the mesonephros and metanephros. In normal development, the mesonephros involutes, leaving only the wolffian ducts, and the metanephros eventually matures into the kidney. A defect within or insult to these mesodermal structures may ultimately result in congenital anomalies of the gonads, kidneys, and associated ducts. The urogenital sinus arises from the endoderm and gives rise to the bladder and urethra in males and females. In females it also forms the vestibule. The urethral and paraurethral glands in girls and the prostate gland in boys develop as outpouchings of the urethra. Nervous tissue, including sensory epithelium, arises from the ectoderm. Fusion of endoderm and ectoderm is involved in the canalization process; defects lead to fusion failure or obstructive lesions.[11]

During the "indifferent" stage of development, two pairs of genital ducts develop from mesodermal tissue in both males and females: the mesonephric (wolffian) and paramesonephric (müllerian) ducts. The paired wolffian ducts connect the mesonephric kidney to the cloaca. The ureteric bud arises from the wolffian duct at about the 5th week of life and induces differentiation of the metanephros, which eventually becomes the functioning kidney; the mesonephric kidney involutes at 10 weeks. The paramesonephric (müllerian) ducts are identified in both sexes at 6 weeks of life. As they grow, the müllerian ducts lie lateral to the wolffian ducts until they reach the caudal end of the mesonephros where they extend medially to nearly touch in the midline near the cloaca. The urorectal septum forms by the 7th week, separating the urogenital sinus from the rectum. In males, regression of the müllerian ducts begins at 8 weeks of life and is almost complete

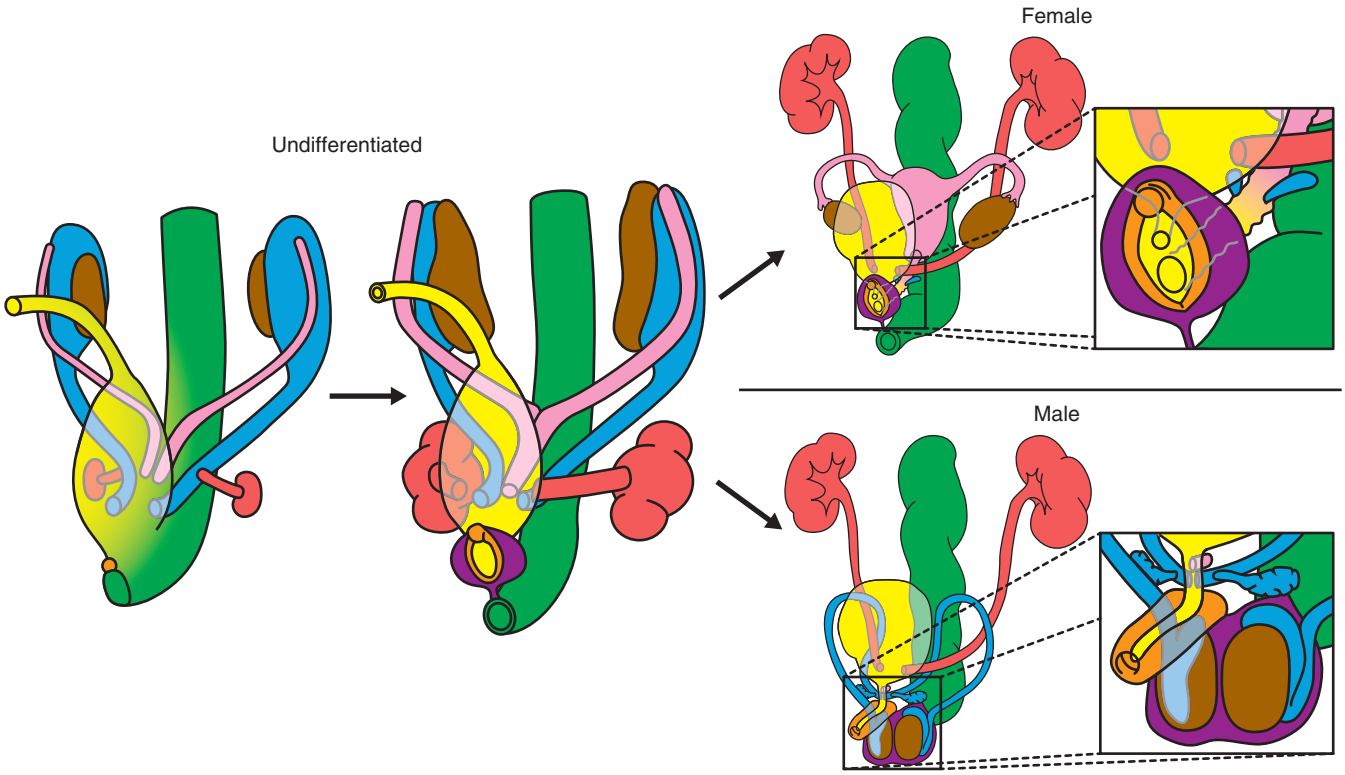

FIG 34-5 Normal genitourinary development and differentiation. Color coding: blue, mesonephric kidneys and mesonephric (wolffian) ducts (become Gartner ducts in female, vasa deferentia in male); brown, gonads; green, gastrointestinal tract; orange, genital tubercle (becomes clitoris and labia minora in female, phallus in male); pink, paramesonephric (müllerian) ducts (become fallopian tube, uterus, and upper vagina in female, utricle in male); purple, labioscrotal swelling; red, metanephros (permanent kidney and ureter); yellow, urogenital sinus (becomes urinary bladder, urethra, vestibule in female; urinary bladder and urethra in male).

by 10 weeks. In females, the müllerian ducts extend caudally, reaching the urogenital sinus by 9 weeks to form the uterovaginal canal, which inserts into the urogenital sinus at the müllerian tubercle. By the 12th week, the two ducts have completely fused into a single tube, the uterovaginal canal. Two solid evaginations of urogenital sinus origin, the sinovaginal bulbs, grow from the distal müllerian tubercle. Proximal to the sinovaginal bulbs, outgrowths from the distal müllerian ducts result in formation of the vaginal plate. The upper portion of the vagina is formed by vacuolization of the vaginal plate, whereas the lower portion is formed by vacuolization of the sinovaginal bulbs. Canalization begins caudally and proceeds proximally; it is complete by the 5th month of gestation. The distal-most portions of the sinovaginal bulbs form the hymenal tissue which perforates prior to birth (Figs. 34-5 and 34-6). The upper portions of the müllerian ducts form the fallopian tubes.[11]

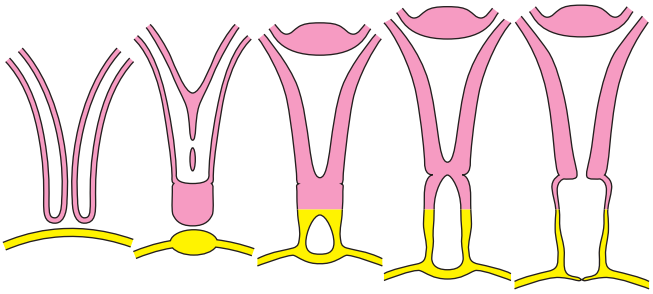

FIG 34-6 Normal embryologic development of the uterus and vagina. Color coding: pink, paramesonephric (müllerian) ducts; yellow, urogenital sinus.

STRUCTURAL ANOMALIES OF THE REPRODUCTIVE TRACT

Abnormalities related to lateral fusion, vertical fusion, or resorption, agenesis and/or hypoplasia result in structural anomalies of the reproductive tract. A number of classifications of these anomalies have been proposed, although none is complete.[14] The American Society for Reproductive Medicine (ASRM) system identifies groups with similar clinical manifestations and prognosis, although vaginal anomalies are not included (Table 34-1, Fig. 34-7). The Vagina Cervix Uterus Adnexa–Associated Malformations classification describes abnormalities not covered by the ASRM classification[15] (Table 34-2).

Vaginal and uterine anomalies may be detected in the neonatal period in children undergoing investigation of multiple congenital anomalies; or in adolescents, during workup of amenorrhea, pelvic or abdominal pain, or mass. An initial ultrasound study is usually sufficient in early childhood, with MRI performed at puberty for a more detailed evaluation. In the patient who first presents in adolescence, MRI is usually done following an abnormal ultrasound examination for a comprehensive assessment of the genitourinary tract.

During development of the uterus, failure of septal resorption between the two embryologic müllerian ducts leads to a septate uterus with two endometrial cavities. The septum can be partial or complete, with extension to the internal cervical os. A single cervix is usually present. The outer fundal contour of the uterus is either normal

TABLE 34-1 Classification of Müllerian Anomalies According to the ASRM Classification System

Type I	**Müllerian Agenesis or Hypoplasia**
	A. Vaginal (uterus may be normal or exhibit a variety of malformations)
	B. Cervical
	C. Fundal
	D. Tubal
	E. Combined
Type II	**Unicornuate Uterus**
	A. Communicating (endometrial cavity present)
	B. Noncommunicating (endometrial cavity present)
	C. Horn without endometrial cavity
	D. No rudimentary horn
Type III	**Uterus Didelphys**
Type IV	**Uterus Bicornuate**
	A. Complete (division down to internal os)
	B. Partial
Type V	**Septate Uterus**
	A. Complete (septum to internal os)
	B. Partial
Type VI	**Arcuate**
Type VII	**DES-Related Anomalies**
	A. T-shaped uterus
	B. T-shaped uterus with dilated horns
	C. Uterine hypoplasia

	#	Unknown

From Oppelt P, Renner SP, Brucker S, et al: The VCUAM (Vagina Cervix Uterus Adnex-associated Malformation) classification: a new classification for genital malformations. Fertil Steril 84(5):1493-1497, 2005.

(Figs. 34-7 and 34-8) or flat and broad. A bicornuate uterus results from incomplete fusion of the müllerian ducts. Leave out the part about incomplete development of the uterine horns. The central myometrium may extend to the level of the internal cervical os (bicornuate unicollis) or external cervical os (bicornuate bicollis), and the external surface is indented, typically by more than 1 cm (Fig. 34-9). Complete

nonfusion of both müllerian ducts leads to a didelphys uterus (Fig. 34-10). Both horns are fully developed and nearly normal in size. There are always two cervices. There may be a transverse or longitudinal vaginal septum. Although a transverse vaginal septum may occur in association with all of the müllerian duplication anomalies, the greatest association is with didelphys uteri. When there is complete or near-complete arrested development of one müllerian duct, a unicornuate uterus develops with a single horn, an ipsilateral round ligament, and fallopian tube. The unicornuate uterus communicates with a single cervix and a normal vagina. In most patients, arrest is incomplete, and a contralateral rudimentary horn with or without functioning endometrium is present (Fig. 34-11). The rudimentary horn may or may not communicate with the developed uterine horn. Sonography may demonstrate two uterine horns of different sizes. Unless functional endometrium within a noncommunicating horn leads to hematometra or endometriosis, no treatment is generally required.[11,16,17] However, because of the potential risk of an ectopic pregnancy developing within a rudimentary noncommunicating horn, some advocate surgical resection.

Failure of fusion and canalization of the müllerian ducts and embryologic urogenital sinus lead to a transverse vaginal septum. Septa are generally less than 1 cm in thickness and extend completely or incompletely across the vagina (Fig. 34-12). There is often a small central or eccentric perforation. A complete vaginal septum may occur in the upper (46%), middle (40%), or lower (14%) vagina.[18] The vagina is short or is a blind-ending pouch. The external genitalia appear normal. Girls may present with mucocolpos in infancy or childhood, hematocolpos in adolescence, or pyohematocolpos from

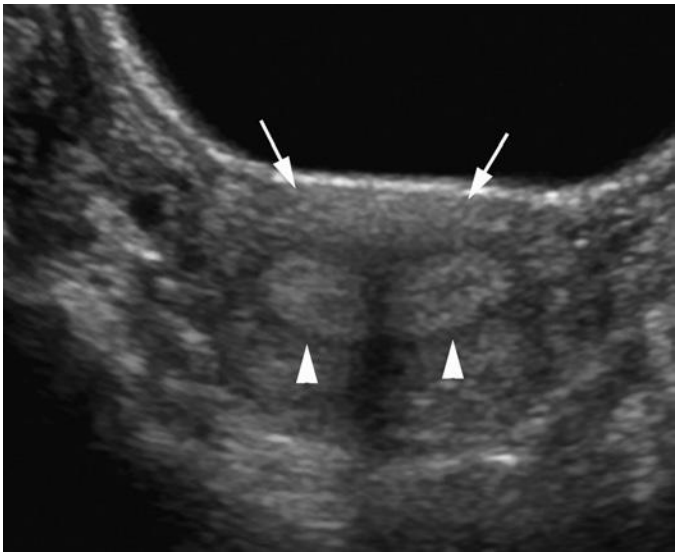

FIG 34-8 Septate uterus. Transverse ultrasound image of the uterus in a 15-year-old girl with dysmenorrhea reveals two distinct endometrial cavities (*arrowheads*). The external myometrial fundal contour is normal (*arrows*).

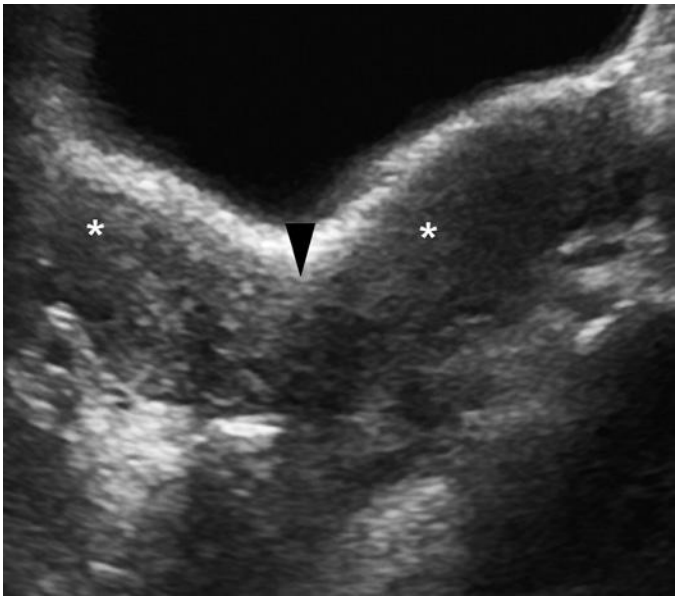

FIG 34-9 Bicornuate uterus in a 13-year-old girl. Transverse pelvic ultrasound image shows two uterine horns (*asterisks*) with a deep central depression of the external myometrial fundal contour (*arrowhead*). The right kidney was absent (not shown).

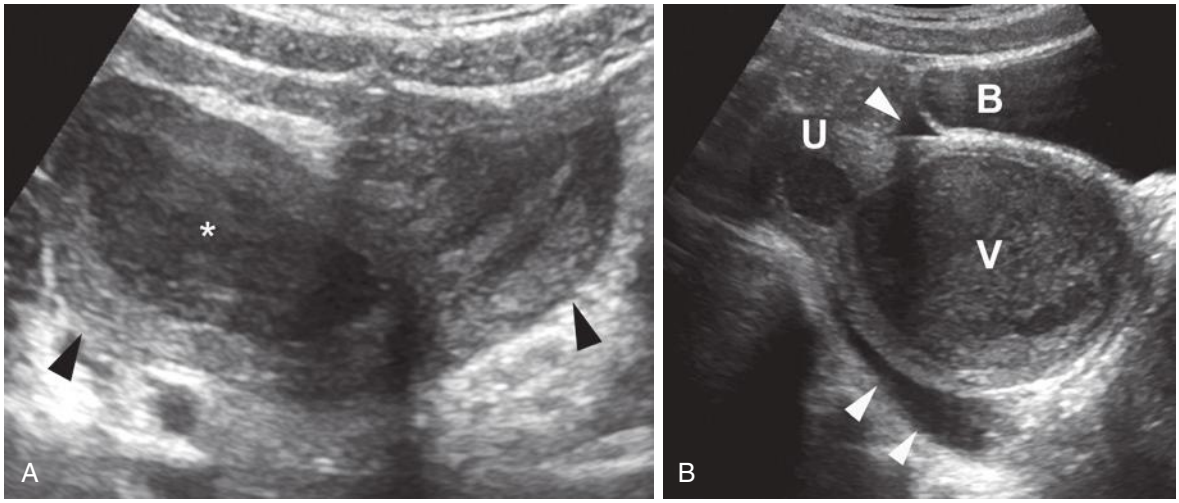

FIG 34-10 Uterus didelphys in a 12-year-old girl with chronic pelvic pain. **A,** Transverse ultrasound image shows two widely divergent uterine horns (*arrowheads*). The right uterine horn is distended with hypoechoic material consistent with blood (*asterisk*). **B,** Right parasagittal ultrasound image demonstrates an obstructed vagina (V) filled with blood. There is a small amount of free fluid in the cul-de-sac and above the bladder (*arrowheads*). B, bladder; U, uterine fundus. The left vagina was normal (not shown).

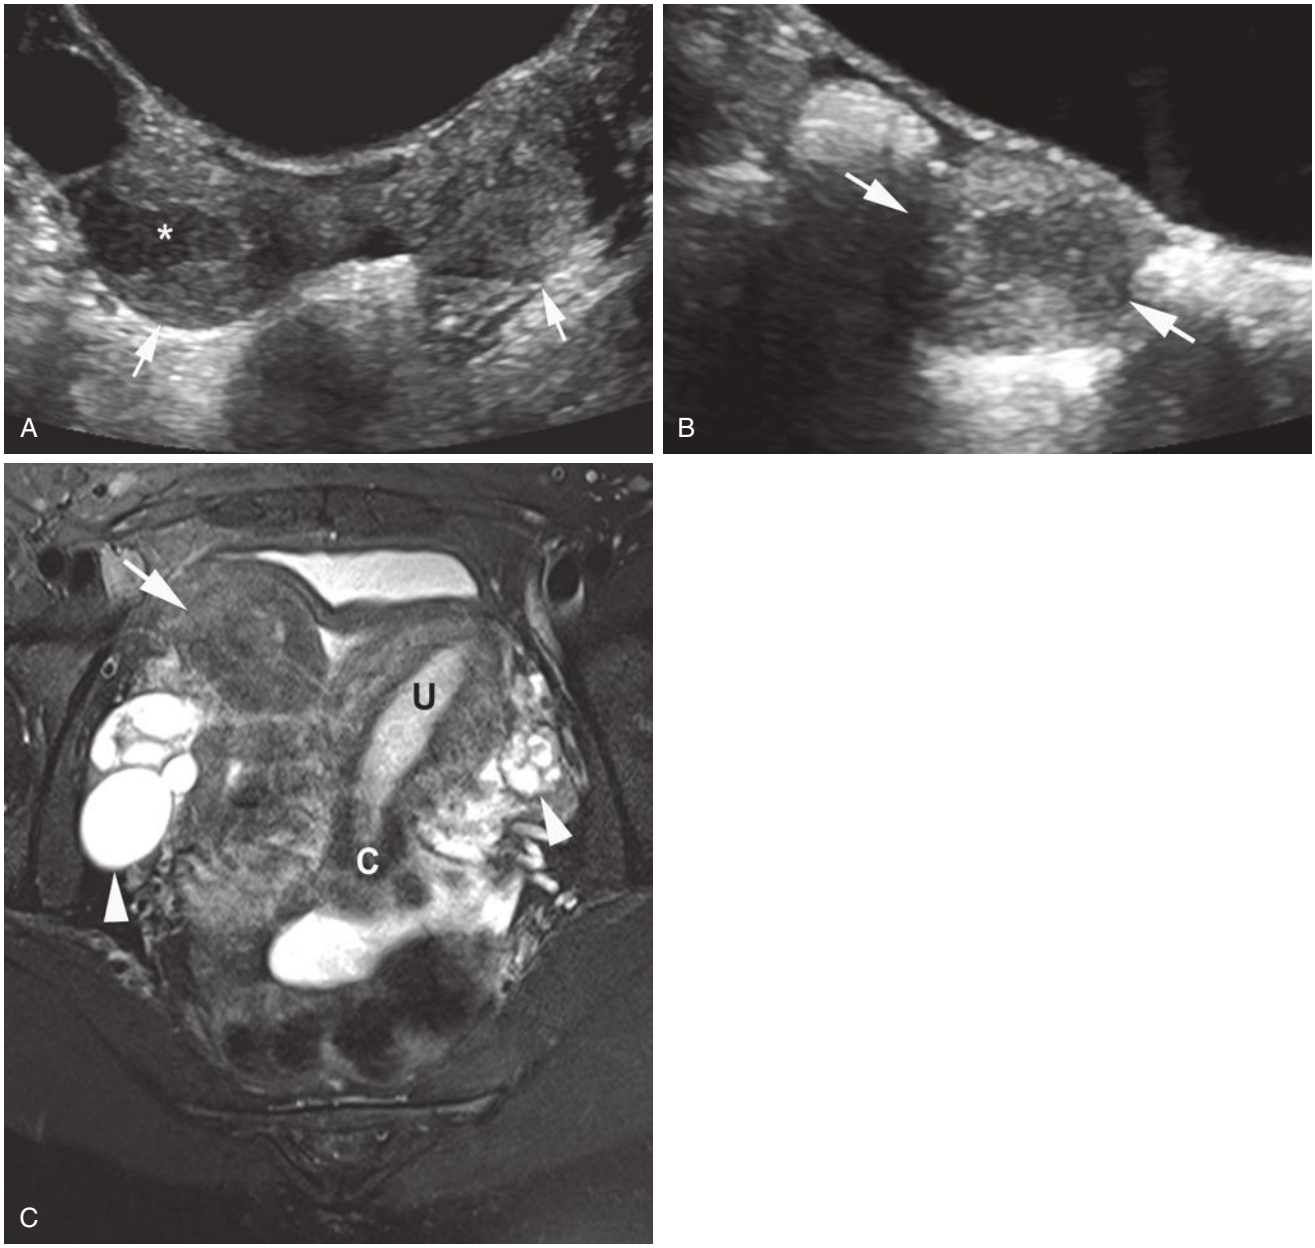

FIG 34-11 Unicornuate left uterus with an obstructed, rudimentary right hemiuterus in a 13-year-old girl with cyclic pelvic pain. **A,** Transverse ultrasound image reveals two uterine horns (*arrows*). Hypoechoic fluid distends the right uterine cavity (*asterisk*). **B,** Sagittal image depicts the truncated right hemiuterus (*between arrows*). **C,** Coronal T2-weighted magnetic resonance image demonstrates a well-developed left hemiuterus (U) and cervix (C). The smaller right hemiuterine cavity contains low signal intensity material compatible with blood products (*arrow*). Both ovaries contain normal follicles (*arrowheads*). The left vagina was normal (not shown). See Videos 34-1 and 34-2.

ascending infection through the small perforation. On imaging studies, it is critical to document the presence of a cervix in order to differentiate between a high vaginal septum and cervical atresia, because treatment and prognosis are very different.[10]

Cervical atresia is rare and occurs in association with absence of the upper vagina. Patients may present with primary amenorrhea, cyclic or chronic abdominal or pelvic pain, or a pelvic mass (Fig. 34-13). The usual treatment is hysterectomy.

Vaginal agenesis (müllerian aplasia, Mayer-Rokitansky-Küster-Hauser syndrome) occurs in approximately 1 in 5000 female births[17] and results in congenital absence of the upper vagina in association with variable müllerian duct anomalies. There is usually associated cervical and uterine agenesis, although approximately 10% of patients have a rudimentary müllerian structure with or without functional endometrium.[17] Skeletal, renal, and auditory anomalies are common. Affected individuals have a normal female 46,XX karyotype with normal oocyte and ovarian hormonal function. Patients exhibit normal secondary sexual characteristics and a normal perineum on physical examination. Because the hymen and distal vagina are both derived embryologically from the urogenital sinus, the hymen is usually present, along with a small distal vaginal pouch or vaginal dimple. Ultrasound examination is done to identify and characterize any

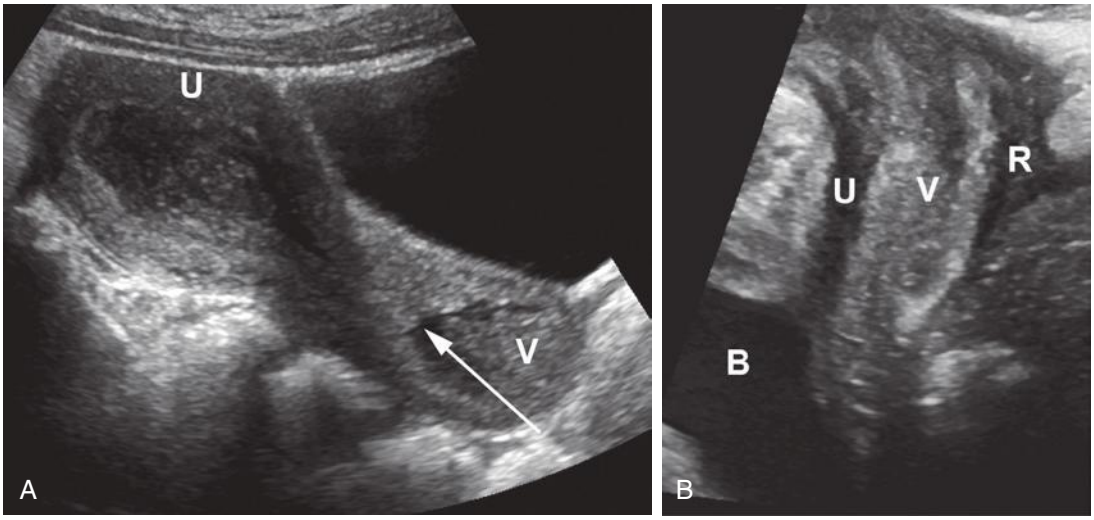

FIG 34-12 Transverse vaginal septum in a 12-year-old girl with normal external genitalia, primary amenorrhea, and pelvic pain. **A,** Sagittal ultrasound image depicts a fluid-distended uterus (U) and upper vagina (V). The arrow indicates the external cervical os. **B,** Sagittal transperineal image shows a collapsed distal vagina (V). B, bladder; R, rectum; U, urethra.

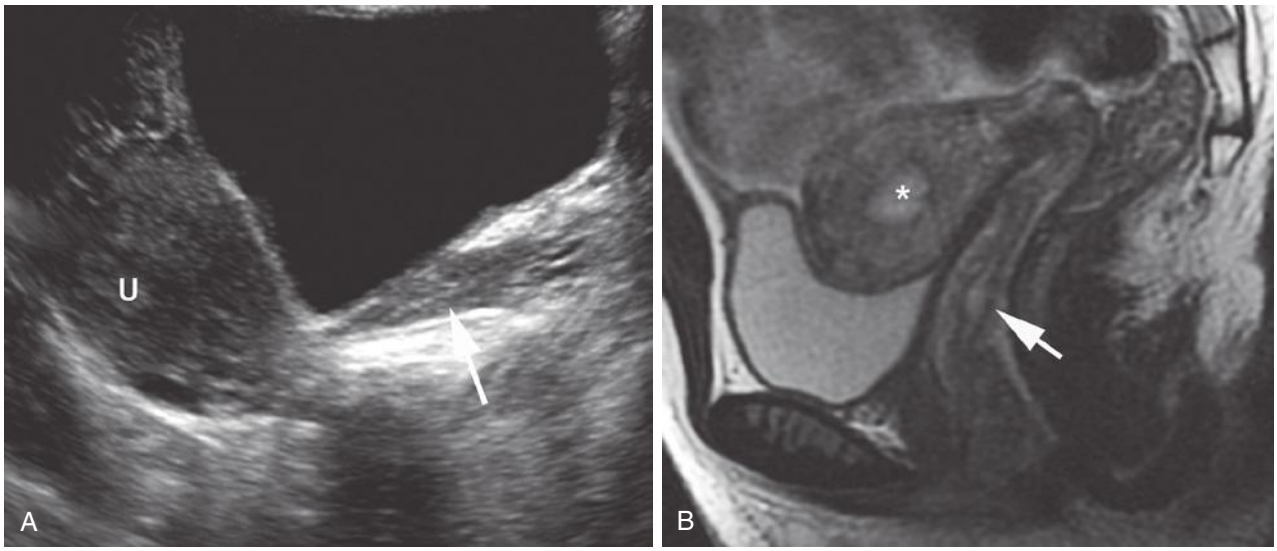

FIG 34-13 Agenesis of the cervix and upper vagina in a 16-year-old girl with pelvic pain. **A,** Sagittal ultrasound image reveals a uterus (U) without evidence of a cervix or upper vagina. The lower vagina is present (*arrow*). **B,** Sagittal T2-weighted magnetic resonance image confirms absence of a normal cervix and upper vagina with no communication between the endometrial cavity (*asterisk*) and the midvaginal canal (*arrow*).

müllerian tissue; to determine renal presence, position, and morphologic appearance; and to confirm the presence of normal ovaries (Fig. 34-14).

When the lower portion of the vagina fails to develop from the urogenital sinus, distal vaginal atresia occurs and fibrous tissue replaces the absent distal vagina. The upper vagina, cervix, and uterus are normal. Primary amenorrhea is the usual clinical presentation. As the upper vagina becomes distended with blood and secretions, patients may develop cyclic or chronic pain and a pelvic or abdominal mass. Affected individuals have normal secondary sexual characteristics, although a vaginal orifice is absent. Transperineal ultrasound can be used to document absence of the distal vagina and to measure the distance between the proximal vagina and the perineal surface. This technique is especially useful intraoperatively[11] (Fig. 34-15).

An imperforate hymen is the most common anomaly of the female reproductive tract. There are usually no other associated abnormalities. The diagnosis can be made at birth, when a bulge from the associated hydrocolpos or mucocolpos is present, as a result of vaginal secretions related to maternal estrogen stimulation. If not diagnosed at birth, the mucus will eventually be resorbed, and the bulge will resolve. After the onset of menarche, the adolescent patient may be asymptomatic or have a history of cyclic abdominal or pelvic pain.[11] An imperforate hymen can usually be diagnosed by physical examination alone. However, in many patients, a complete physical examination is not performed at birth, and cases in symptomatic adolescents are often initially misdiagnosed.[13] Ultrasound imaging depicts distention of the vagina and uterus with fluid. Echogenic debris within the fluid is due to mucous secretions in infants (Fig. 34-16) and blood in

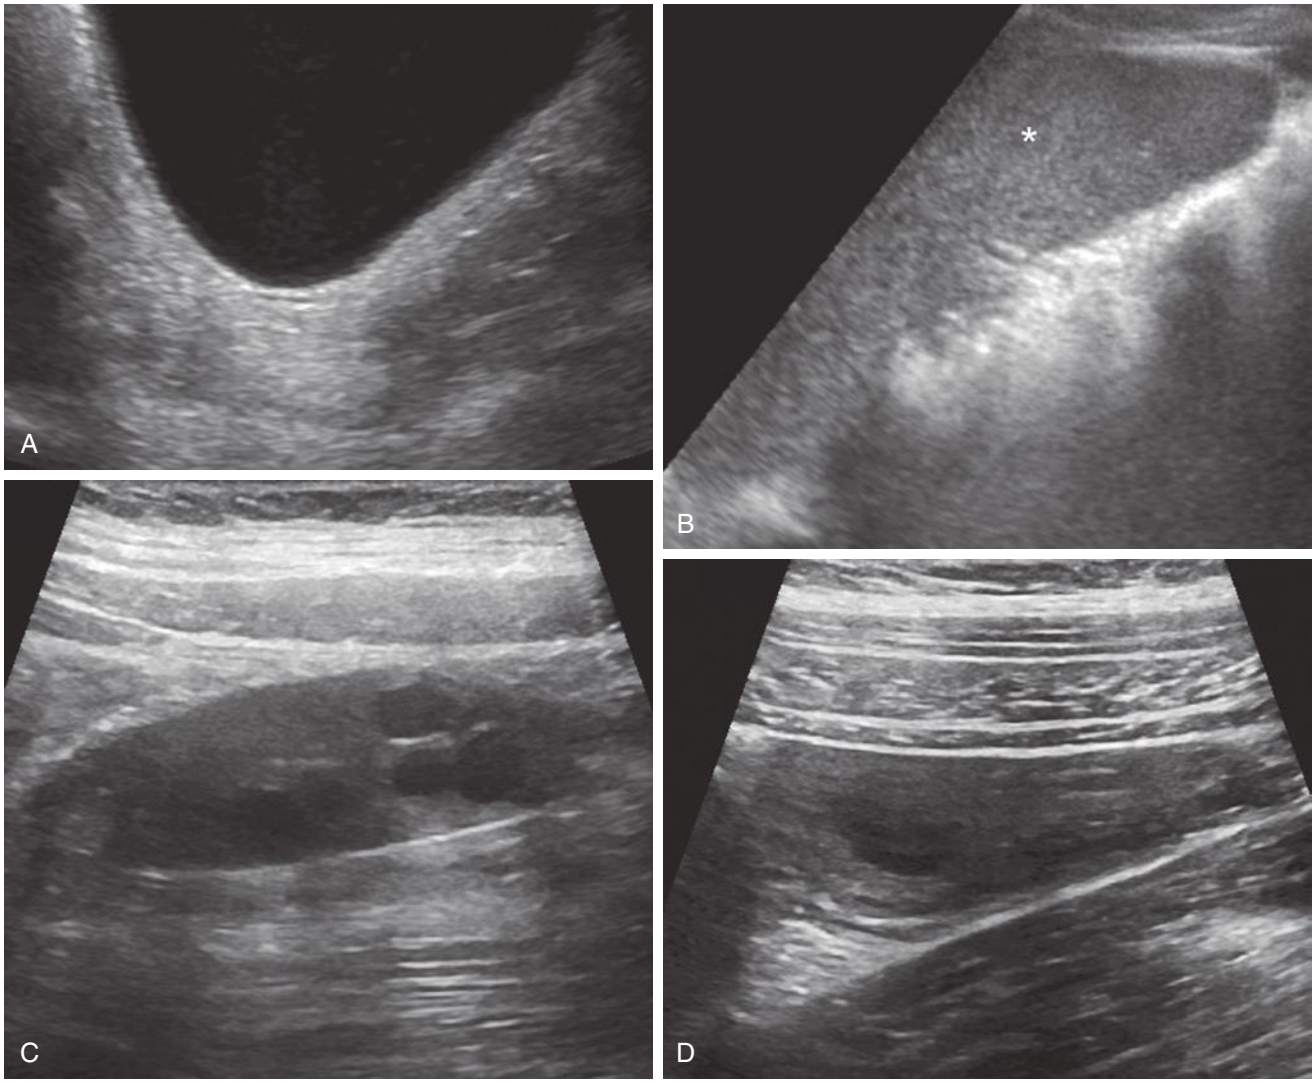

FIG 34-14 Vaginal agenesis in a 17-year-old girl with primary amenorrhea. **A,** Sagittal midline ultrasound image reveals no evidence of a vagina or uterus. **B,** The left kidney was absent, with an empty renal fossa depicted on a sagittal ultrasound image of the left upper quadrant. The spleen is indicated by an asterisk. Normal right (**C**) and left (**D**) ovaries were identified.

postmenarcheal girls. Ascites may develop following spillage of secretions through the fallopian tubes.

AMBIGUOUS GENITALIA

Birth of a child with ambiguous genitalia is rare. However, the substantial risk of psychological damage to the patient and family caused by an incorrect or delayed diagnosis necessitates the need for familiarity on the part of health care providers with the various causes as well as approach to diagnosis and management. Any deviation from the normal appearance of the genitalia, such as clitoromegaly or labial fusion, should lead to immediate evaluation.

An International Consensus Conference on Intersex was organized by the Lawson Wilkins Pediatric Endocrine Society and the European Society for Paediatric Endocrinology in 2006 that resulted in a consensus statement proposing the term *disorders of sex development* (DSD) to encompass congenital conditions with atypical development of chromosomal, gonadal, or anatomic sex.[18,19] The DSDs are classified as sex chromosome DSD (karyotype is not the usual 46,XX or 46,XY); 46,XX DSD (chromosomally female); and 46,XY DSD (chromosomally male) (Table 34-3).[20] Karyotyping, hormonal analysis, and imaging are necessary for adequate delineation of these disorders.

Sonography is used to locate the gonads, to determine the presence or absence of a uterus, and to evaluate the adrenal glands for diffuse enlargement or masses. Retrograde genitography, obtained by injecting contrast material through the urogenital orifice, or voiding cystourethrography will characterize the anatomy of the urethra, vagina (if present), urogenital sinus, and occasionally the cervix. In the presence of a cloacal anomaly, the connections of the genital, urinary, and gastrointestinal tracts to the cloaca can be determined.[21,22]

The most frequent sex chromosome DSD is 45,X (Turner syndrome), which is due to absence of all or part of one of the X chromosomes. Monosomy X is the most common. Characteristic physical features include short stature, low-set ears, webbed neck, and a broad chest. Gonadal dysfunction results in amenorrhea and sterility. The ovaries may not be detected by sonography, and the uterus has a juvenile appearance (Fig. 34-17). Associated conditions include Hashimoto thyroiditis, congenital heart disease, renal anomalies, skeletal abnormalities, and diabetes.

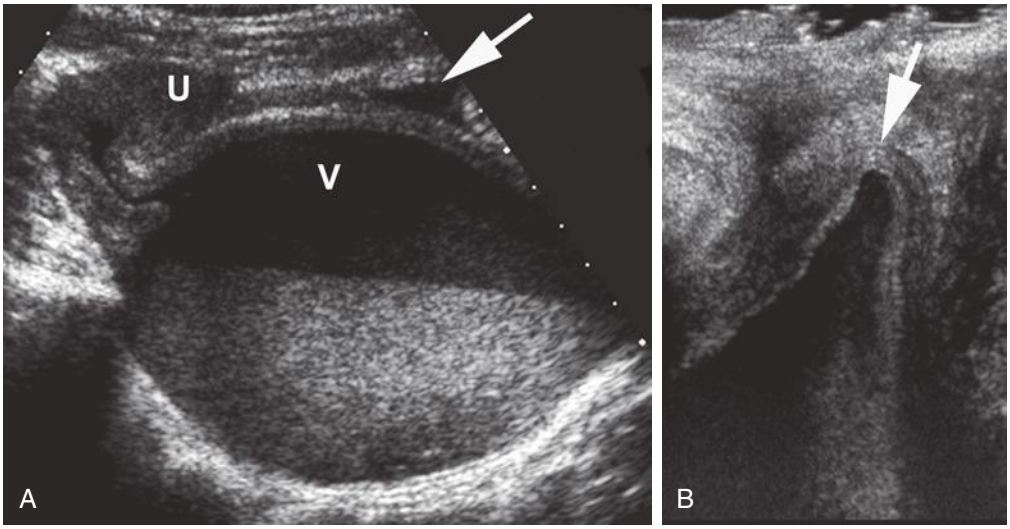

FIG 34-15 Distal vaginal atresia in a 13-year-old girl with primary amenorrhea and an abdominal mass. **A,** Sagittal ultrasound image demonstrates hydrometrocolpos with marked distention of the vagina (V), with layering internal echoes creating a fluid/fluid level. Note mass effect resulting in marked compression of the urinary bladder (*arrow*) anteriorly. U, uterus. **B,** Sagittal transperineal ultrasound image shows a blind-ending distal vagina (*arrow*) located approximately 1.3 cm from the skin surface.

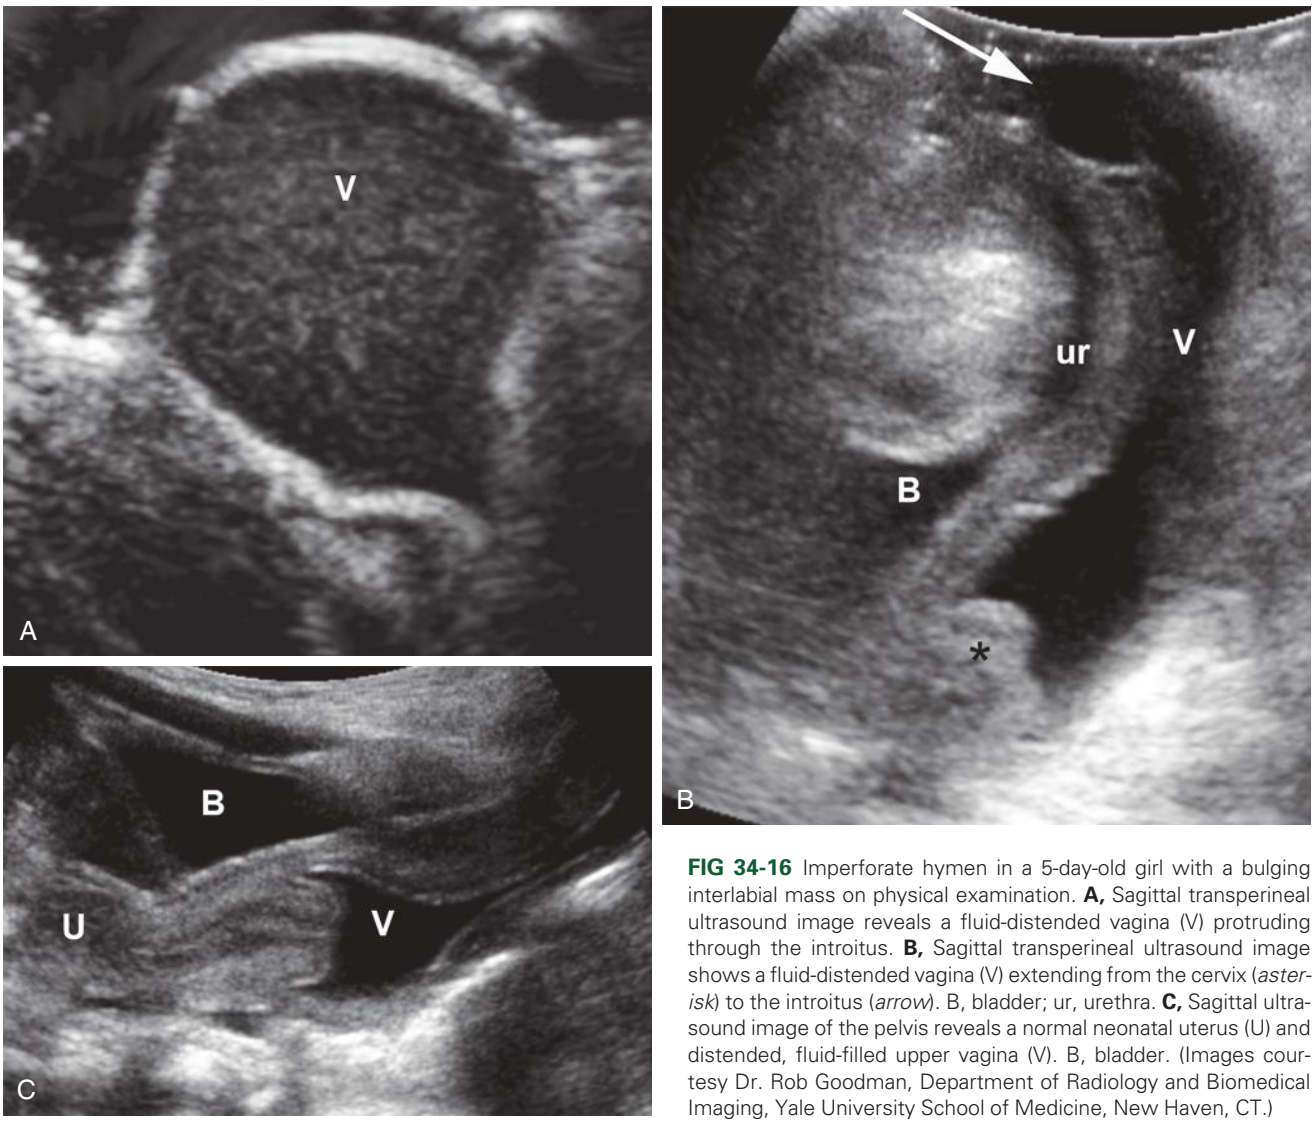

FIG 34-16 Imperforate hymen in a 5-day-old girl with a bulging interlabial mass on physical examination. **A,** Sagittal transperineal ultrasound image reveals a fluid-distended vagina (V) protruding through the introitus. **B,** Sagittal transperineal ultrasound image shows a fluid-distended vagina (V) extending from the cervix (*asterisk*) to the introitus (*arrow*). B, bladder; ur, urethra. **C,** Sagittal ultrasound image of the pelvis reveals a normal neonatal uterus (U) and distended, fluid-filled upper vagina (V). B, bladder. TABLE 34-3 A Proposed Classification for Disorders of Sex Development (DSD)

Sex Chromosome DSD	46,XY DSD	46,XX DSD
A: 47,XXY (Klinefelter syndrome and variants)	A: Disorders of gonadal (testicular) development 1. Complete or partial gonadal dysgenesis (e.g., *SRY, SOX9, SF1, WT1, DHH*) 2. Ovotesticular DSD 3. Testis regression	A: Disorders of gonadal (ovarian) development 1. Gonadal dysgenesis 2. Ovotesticular DSD 3. Testicular DSD (e.g., *SRY+, dup SOX9, RSPO1*)
B: 45,X (Turner syndrome and variants)	B: Disorders in androgen synthesis or action 1. Disorders of androgen synthesis • Luteinizing hormone receptor mutations • Smith-Lemli-Opitz syndrome • Steroidogenic acute regulatory protein mutations • Cholesterol side-chain cleavage (*CYP11A1*) • 3β-Hydroxysteroid dehydrogenase 2 (*HSD3B2*) • 17α-Hydroxylase/17,20-lyase (*CYP17*) • P450 oxidoreductase (*POR*) • 17β-Hydroxysteroid dehydrogenase (*HSD17B3*) • 5α-Reductase 2 (*SRD5A2*) 2. Disorders of androgen action • Androgen insensitivity syndrome • Drugs and environmental modulators	B: Androgen excess 1. Fetal • 3β-Hydroxysteroid dehydrogenase 2 (*HSD3B2*) • 21-Hydroxylase (*CYP21A2*) • P450 oxidoreductase (*POR*) • 11β-Hydroxylase (*CYP11B1*) • Glucocorticoid receptor mutations 2. Fetoplacental • Aromatase (*CYP19*) deficiency • Oxidoreductase (*POR*) deficiency 3. Maternal • Maternal virilizing tumors (e.g., luteomas) • Androgenic drugs
C: 45,X/46,XY (mixed gonadal dysgenesis)	C: Other 1. Syndromic associations of male genital development (e.g., cloacal anomalies, Robinow, Aarskog, hand-foot-genital, popliteal pterygium syndromes) 2. Persistent müllerian duct syndrome 3. Vanishing testis syndrome 4. Isolated hypospadias (*CXorf6*) 5. Congenital hypogonadotrophic hypogonadism 6. Cryptorchidism (*INSL3, GREAT*) 7. Environmental influences	C: Other 1. Syndromic associations (e.g., cloacal anomalies) 2. Müllerian agenesis/hypoplasia (e.g., MURCS association) 3. Uterine abnormalities (e.g., MODY5) 4. Vaginal atresia (e.g., McKusick-Kaufman syndrome) 5. Labial adhesions
D: 46,XX/46,XY (chimerism)		

DSD, disorders of sex development; MODY5, maturity-onset diabetes of the young type 5; MURCS, müllerian duct aplasia, renal aplasia, and cervicothoracic somite dysplasia.
Revised, with permission, from Hughes IA, Nihoul-Fékété C, Thomas B, Cohen-Kettenis PT: Consequences of the ESPE/LWPES Guidelines for diagnosis and treatment of disorders of sex development. Best Pract Res Clin Endocrinol Metab 21(3):351-365, 2007, Table 2.

Most cases of 46,XX DSD result from congenital adrenal hyperplasia. The adrenal glands are enlarged, and there is masculinization of the lower urogenital tract (Fig. 34-18). In patients with a urogenital sinus, reflux of urine into the vagina and uterus can result in hydrometrocolpos (Fig. 34-19). The ovaries and uterus are normal. Rarer causes of a masculinized but chromosomally normal female include a masculinizing ovarian tumor and maternal androgen ingestion in early pregnancy.

A cloacal malformation occurs when there is interruption of the normal differentiation of the genital, urinary, and gastrointestinal tracts. Cloacal malformations occur only in females, with an incidence of 1 in 40,000 to 50,000 newborns. Failure of the urorectal septum to form or fuse appropriately during embryologic development leads to incomplete separation of these tracts with a common confluence, the cloaca, and a single perineal opening. There is usually concomitant failure of müllerian duct fusion resulting in uterine and proximal vaginal duplication. The urogenital sinus persists, and the lower vagina and hymen do not form normally. In order to prevent bladder outlet obstruction, drainage of pooled urine through the vagina is usually required. A colostomy is performed to decompress the gastrointestinal tract. Many of these children have additional congenital anomalies necessitating multiple reconstructive operations. Accurate delineation of anatomic abnormalities usually requires genitography or voiding cystourethrography (Figs. 34-20 and 34-21), as well as contrast material–enhanced examination of the distal colostomy limb.[11,21]

PREPUBERTAL BLEEDING

Vulvovaginitis is the usual cause of prepubertal bleeding. Other causes include precocious puberty, vaginal foreign body, vaginal mass, or genital trauma (either accidental, self-inflicted, or the result of physical or sexual abuse).

Precocious Puberty

Although the definition of precocious puberty in North American girls is somewhat controversial, the traditional definition of the development of breast or pubic hair in girls younger than 8 years of age is still used by most endocrinologists. Precocious puberty may be central and gonadotropin-dependent or peripheral and gonadotropin-independent. Incomplete forms of precocious puberty include

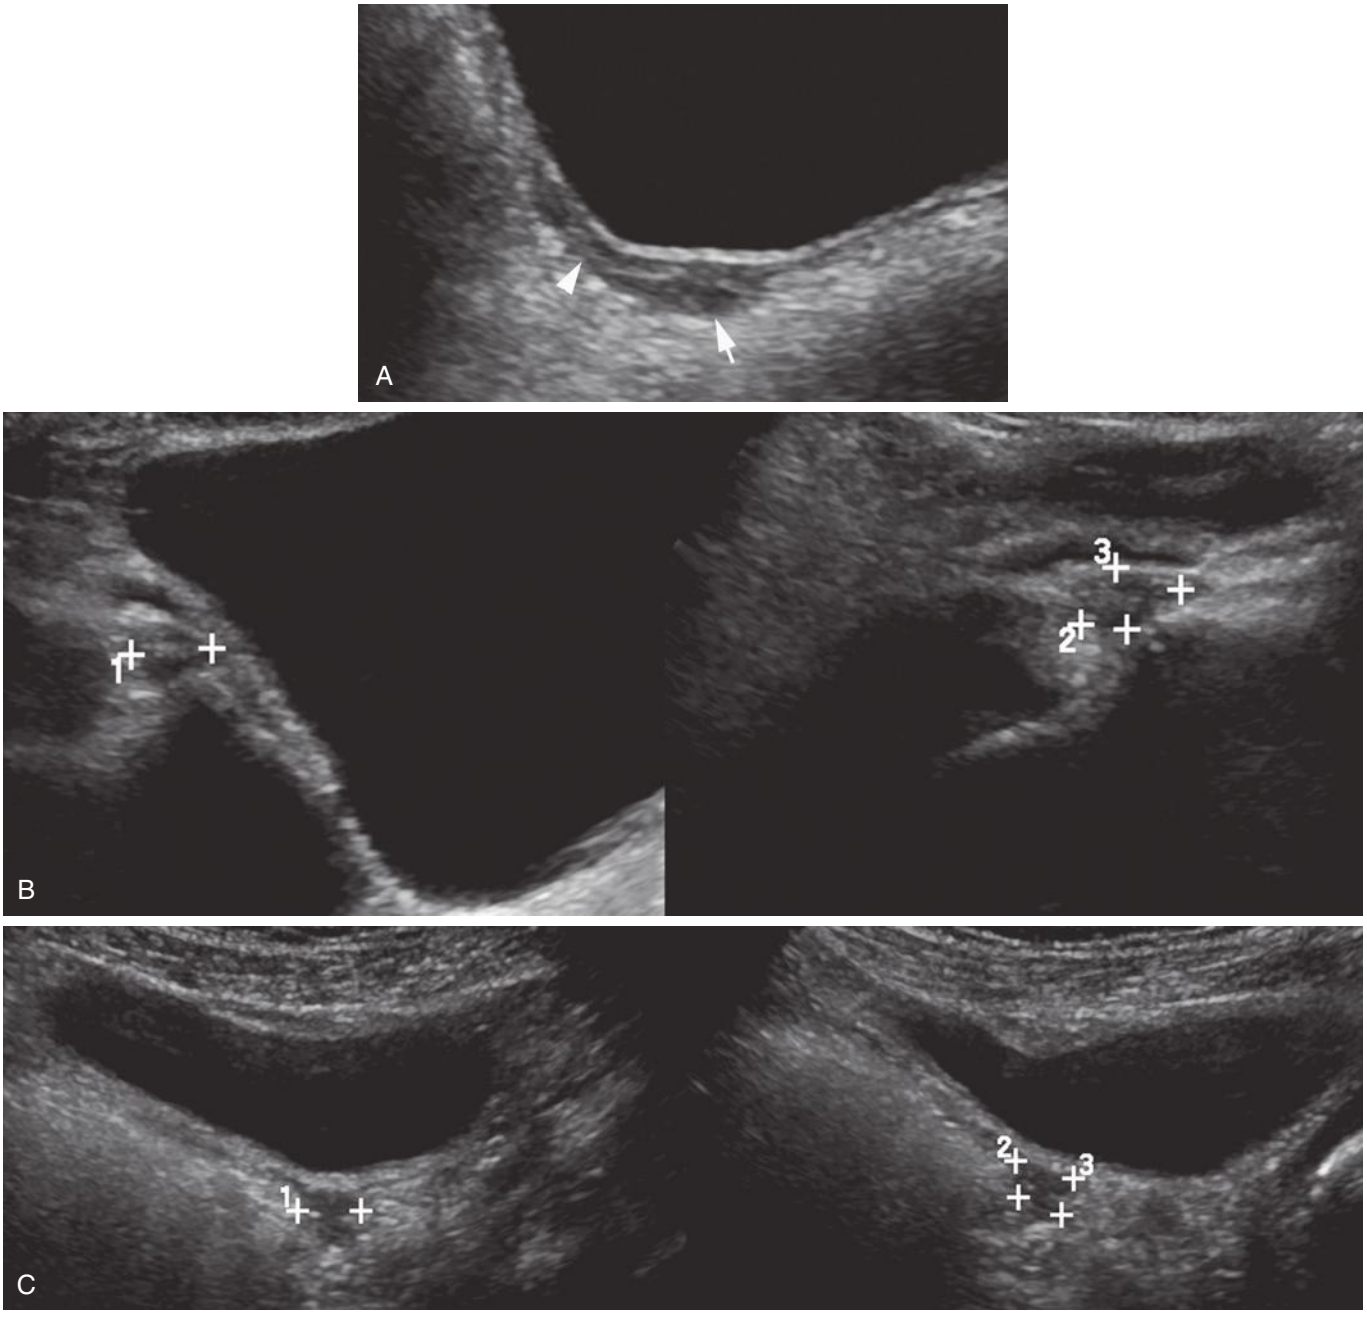

FIG 34-17 Turner mosaicism in a 14-year-old girl with short stature and premature ovarian insufficiency. **A,** Sagittal ultrasound image shows a juvenile uterine appearance posterior to the distended urinary bladder with relative prominence of the cervix (*arrow*) and a small, underdeveloped fundus (*arrowhead*). Transverse (left side of split screen image) and sagittal (right side of split screen image) ultrasound images demonstrate tiny right (**B**) and left (**C**) ovaries, each with a volume less than 1 mL.

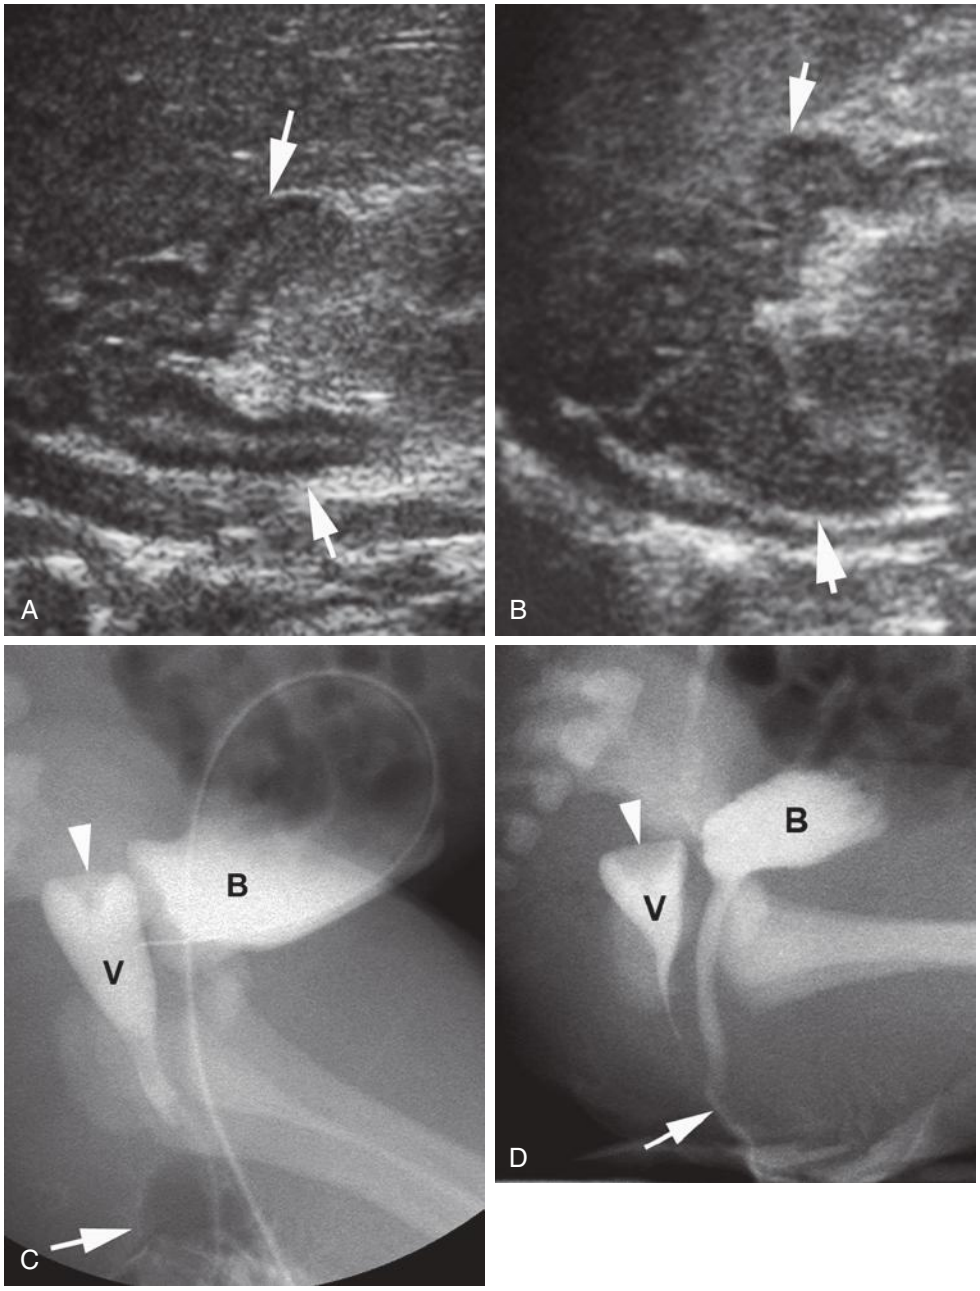

FIG 34-18 Congenital adrenal hyperplasia in a neonate with clitoromegaly. **A** and **B,** Sagittal ultrasound images reveal large, cerebriform right (**A**) and left (**B**) adrenal glands (*arrows*). The outer cortex is hypoechoic, whereas the central medulla is echogenic. **C,** Sagittal image from retrograde genitography shows a catheter placed through the common perineal channel and coiled within the bladder (B). A Foley catheter with air-inflated balloon (*arrow*) was also placed with its tip in the common perineal channel. Injected contrast material outlines the vagina (V) with a cervical impression (*arrowhead*) at its apex. **D,** The distal vagina unites with the urethra to form a common perineal channel (*arrow*). B, bladder; V, vagina; arrowhead, cervical impression.

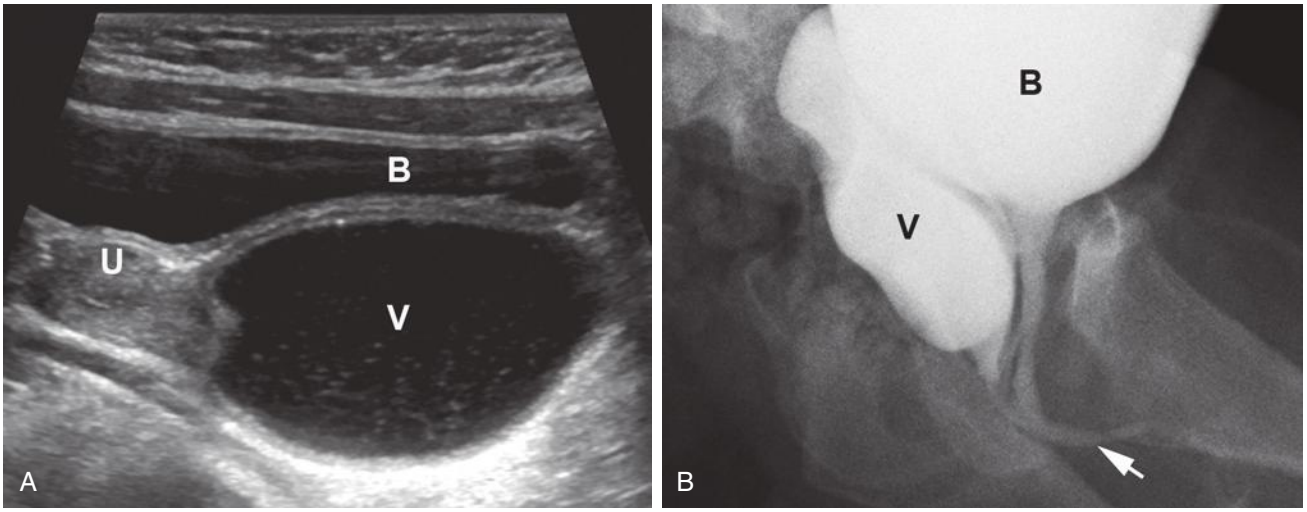

FIG 34-19 Congenital adrenal hyperplasia in a 13-year-old girl with a single opening on the ventral aspect of an enlarged clitoris. **A,** Sagittal ultrasound image demonstrates a dilated, fluid-filled vagina (V) that compresses the posterior aspect of the bladder (B). The uterus (U) appears normal. **B,** Sagittal image from voiding cystourethrography. There was retrograde filling of the vagina (V) from the bladder (B). The distal vagina and urethra unite to form a common perineal channel (*arrow*).

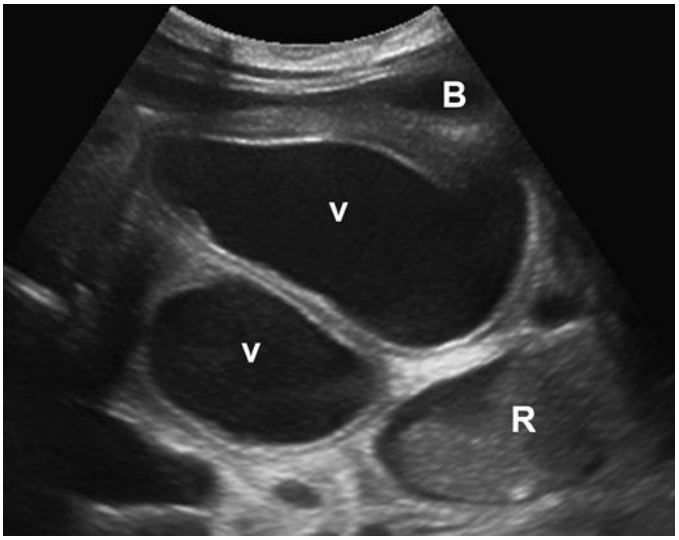

FIG 34-20 Cloacal malformation in newborn girl. Transverse ultrasound image of the pelvis shows duplicated vaginas (v) filled with fluid. The bladder (B) is anteriorly displaced and compressed. R, rectum. See Video 34-3.

premature thelarche (breast development), premature pubarche (adrenarche; axillary or pubic hair), and isolated premature menarche in the absence of other signs of puberty.[23]

In central precocious puberty, activation of the hypothalamic-pituitary-gonadal axis with secretion of gonadotropin-releasing hormone by the hypothalamus leads to isosexual pubertal development. Central precocious puberty is idiopathic in more than 80% of patients. However, lesions of the hypothalamus, pituitary gland, or adjacent structures have been identified by MRI or CT. Central nervous system abnormalities causing precocious puberty can manifest at any time during childhood, although they are more commonly diagnosed in younger children. Some authors have therefore recommended that any girl younger than 8 years of age with progressive central precocity undergo central nervous system imaging.[24] Prolonged exposure to sex steroids from any source can also lead to central precocious puberty.[23]

In gonadotropin-independent (peripheral) precocious puberty, serum gonadotropin levels are low. Autonomous estrogen may be produced by an ovarian cyst (Fig. 34-22), ovarian tumor, or, occasionally, an adrenal tumor. These lesions often produce high levels of estrogen, and pubertal development may proceed more quickly than in children with central precocity. Girls exposed to ingested or topical estrogen or androgen can also develop signs of precocity, such as breast development or virilization.[23] Ultrasound is used to determine ovarian size and morphologic features, to detect the presence of an ovarian cyst or estrogen-secreting tumor of the ovary or adrenal gland, and to confirm or exclude a postpubertal appearance of the uterus, because a postpubertal appearance is a sign of abnormal estrogen production. Sonography is also helpful in tracking the effect of medical or surgical therapy.

Vaginal Foreign Body

The most common vaginal foreign bodies include fibrous material from clothing and carpets and toilet paper. Additional causes include self-exploration and sexual abuse. Patients may present with vaginal discharge, bleeding, urinary symptoms, and abdominal or pelvic pain. Both radiopaque and nonradiopaque objects can appear echogenic on ultrasound examination. There may be a slight indentation on the posterior bladder wall, and distal acoustic shadowing can be present (Fig. 34-23).[2,23]

Vaginal Masses

Benign vaginal masses include polyps and cysts (Fig. 34-24). Malignant masses are rare and include rhabdomyosarcoma, clear cell carcinoma, and endodermal sinus tumor.[25-29]

Vaginal rhabdomyosarcoma has a bimodal distribution, with the first peak between 2 and 6 years of age and the second between 14 and 18 years of age. It arises in the anterior vaginal wall next to the cervix and can involve the uterus via direct extension from the vagina. The embryonal and botryoid subtypes are the most common. Patients may present with vaginal bleeding and a vaginal, vulvar, or perineal mass. The tumor metastasizes to the liver, lung, lymph nodes, and bone.

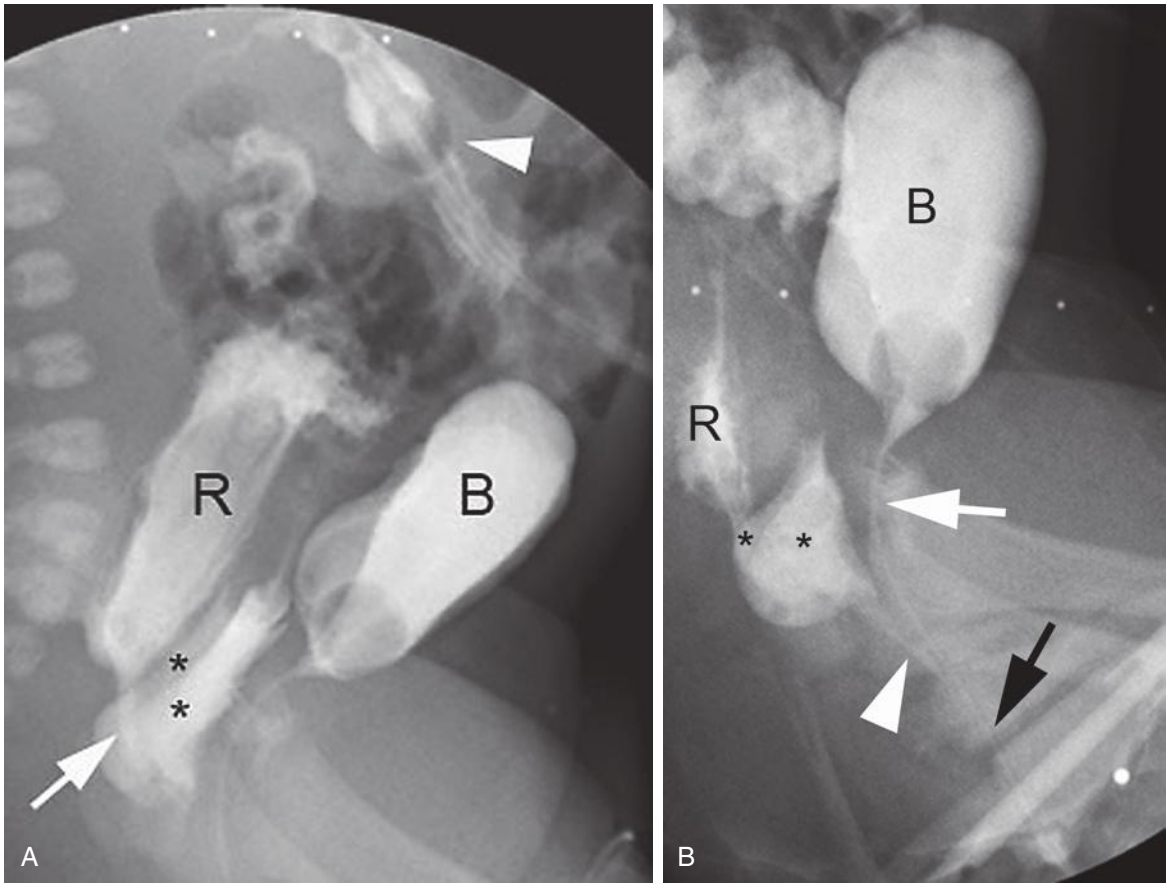

FIG 34-21 Cloacal malformation in a 12-day-old girl evaluated with fluoroscopy after colostomy. **A,** Sagittal image obtained after contrast material was instilled through a Foley catheter into the bladder (B) and through a balloon catheter into the distal colostomy limb (*arrowhead*). Contrast material from the rectum (R) fills the duplicated vaginas (*asterisks*). The narrow distal rectum inserts into a midline septum between the vaginas (*arrow*). **B,** Sagittal fluoroscopic image shows the distal common vaginal channel (*arrowhead*) uniting with the urethra (*white arrow*) to form a common perineal channel (*black arrow*). B, bladder; R, rectum; asterisks, vaginas.

Sonography is often the first imaging modality used in the investigation of girls with vaginal rhabdomyosarcoma (Fig. 34-25). However, MRI or CT is required to fully assess the extent of pelvic disease, and chest CT is performed to assess for pulmonary metastases.

PRIMARY AMENORRHEA

Fewer than 10% of girls have menarche before age 11, whereas 90% have begun to menstruate by age 13.75 years.[30,31] The term *primary amenorrhea* refers to the absence of menarche by the age of 15 years. Causes include gonadal dysgenesis (50%); hypothalamic hypogonadism (20%); absence of the vagina, cervix, or uterus (15%); imperforate hymen or transverse vaginal septum (5%); pituitary disease (5%); and other disorders (polycystic ovary syndrome [PCOS], congenital adrenal hyperplasia, and androgen insensitivity) (5%).[32] Ultrasound imaging is usually performed in the initial evaluation of these patients. The need for additional imaging studies is determined by the associated abnormalities.

PCOS affects 6% to 8% of females of reproductive age and is the most common endocrinopathy in premenopausal women.[33] There is no consensus regarding diagnostic criteria and treatment, despite its high prevalence. The Androgen Excess Society criteria for PCOS include (a) hyperandrogenism (hirsutism or hyperandrogenemia) and (b) ovarian dysfunction (oligoanovulation or polycystic ovaries at ultrasound examination).[34] The diagnosis of PCOS in young adolescents is especially difficult, because mild hyperandrogenemia and transient oligomenorrhea are common in the first years following the onset of menarche.

The ovaries may appear normal or enlarged on ultrasound images, with multiple small follicles (Fig. 34-26). In 2003, the Rotterdam ultrasound criteria defined polycystic ovaries as the presence of 12 or more follicles measuring 2 to 9 mm in diameter or an ovarian volume of more than 10 mL in at least one ovary, as measured at transvaginal sonography.[35] Because most adolescents will undergo transabdominal and not transvaginal sonography, measurement of the number of ovarian follicles is difficult, and volume determinations are usually used as the main sonographic diagnostic criterion for PCOS in adolescents. However, clinical or biochemical evidence of hyperandrogenism is also extremely important in addition to observation of polycystic ovarian morphology (PCOM) in making the diagnosis of PCOS. Recent research and clinical experience have suggested that the number of follicles per ovary required for making the diagnosis of PCOS be increased, partly because of the improvement in technology and the resolution of ultrasound transducers. In 2014, a task force for the Androgen Excess and PCOS Society advised that 25 or more follicles per ovary be observed in women between the ages of 18 and 35 years

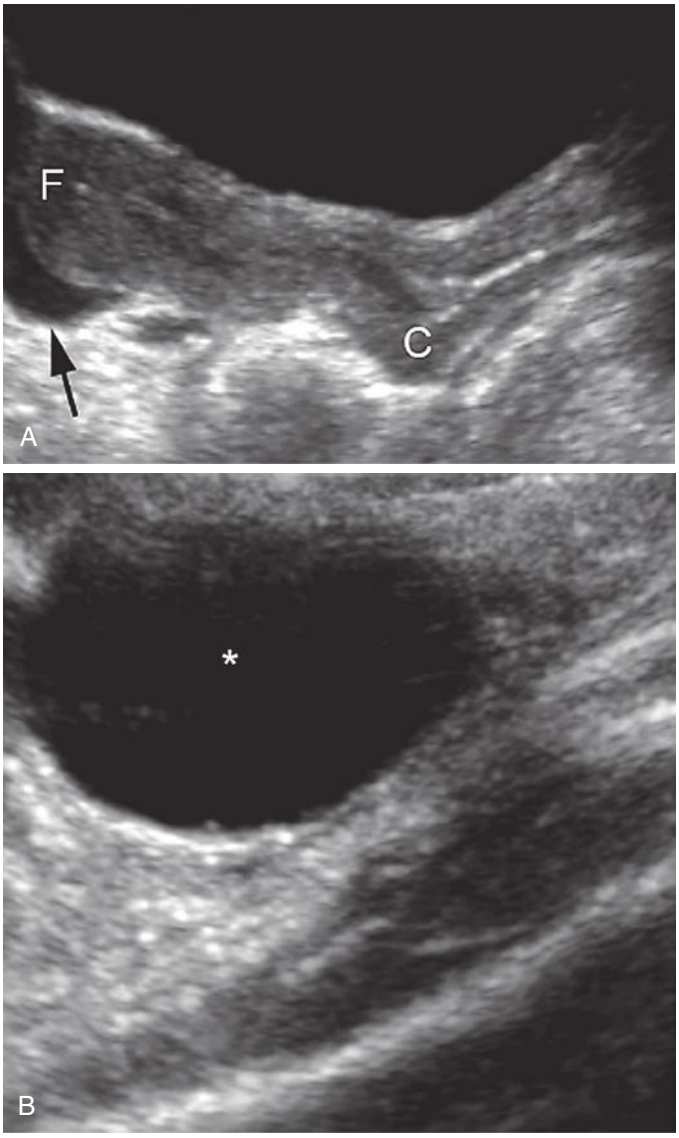

FIG 34-22 Estrogen-secreting ovarian cyst in a 5-year-old girl with premature breast development and vaginal bleeding. **A,** Sagittal ultrasound image of the pelvis depicts a peripubertal appearance of the uterus, with relative prominence of the uterine fundus (F) compared to the cervix (C). There is a small amount of free pelvic fluid (*arrow*). **B,** Sagittal ultrasound image of the right ovary reveals a large (5 cm diameter) simple cyst (*asterisk*).

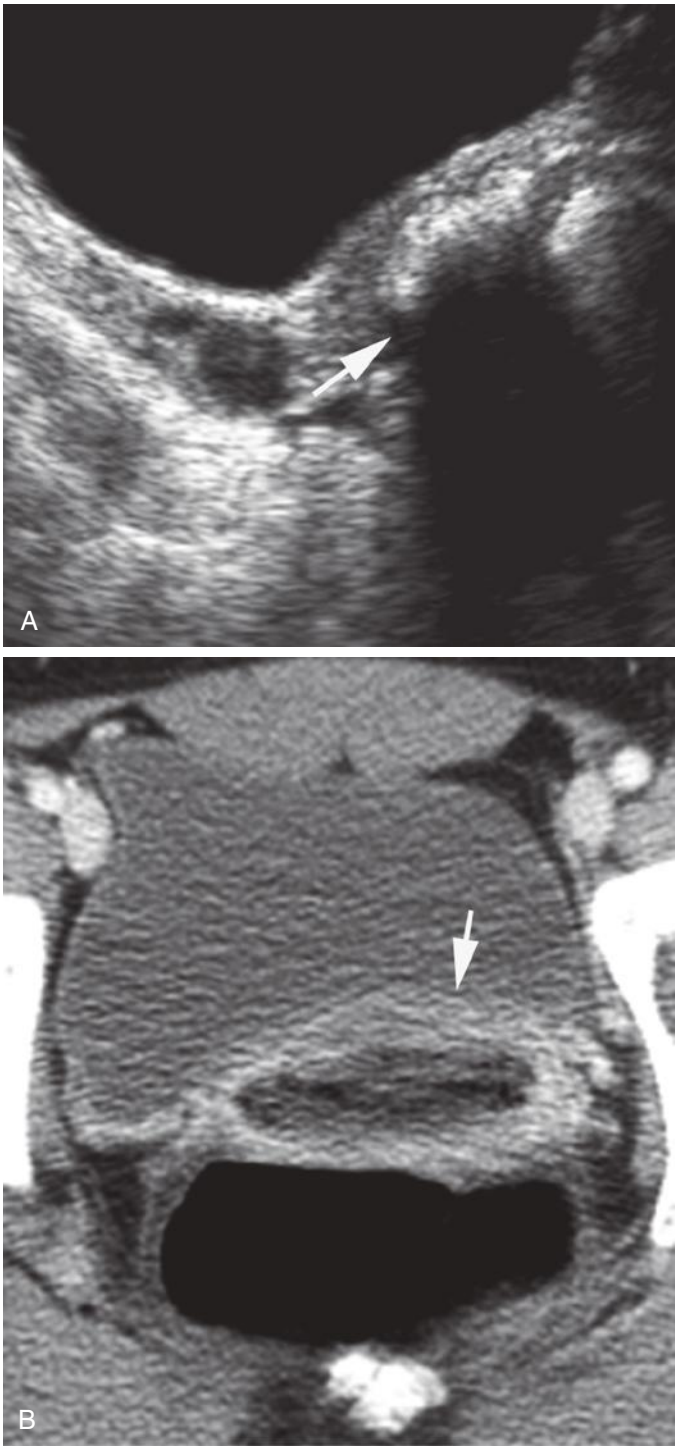

FIG 34-23 Vaginal foreign body in a 16-year-old girl with chronic abdominal pain. **A,** Sagittal ultrasound image of the pelvis shows echogenic material distending the vaginal lumen with pronounced distal acoustic shadowing (*arrow*). **B,** Axial, intravenous contrast-enhanced computed tomography image of the pelvis reveals thickened, hyperemic vaginal mucosa (*arrow*) with air and debris within the vaginal lumen. A retained tampon was discovered on speculum examination.

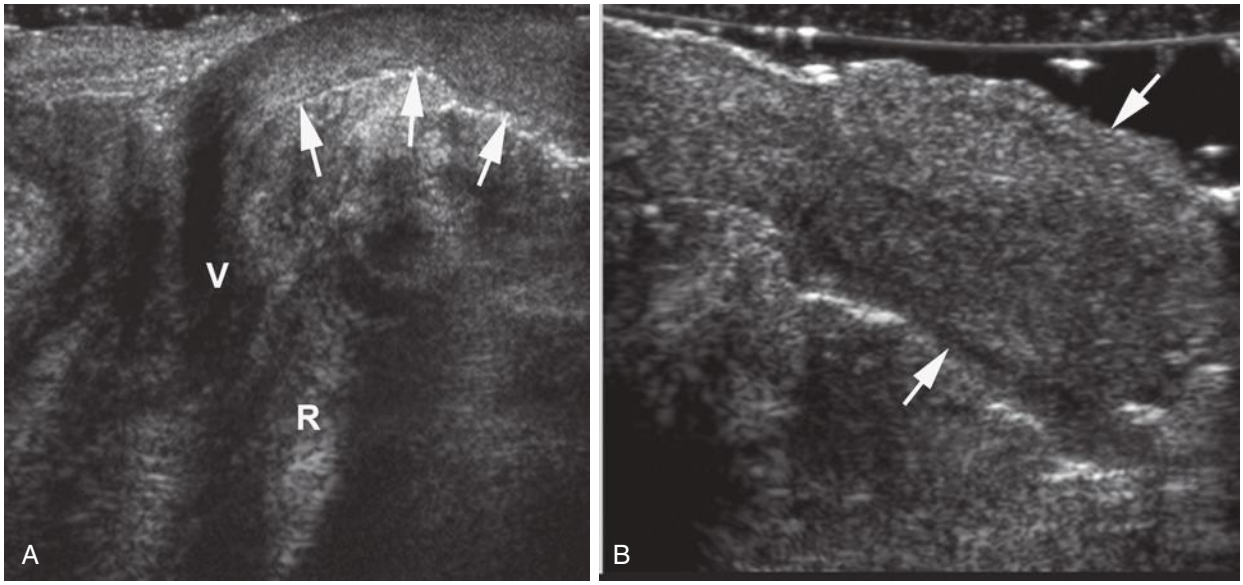

FIG 34-24 Fibroepithelial polyp in a 17-year-old girl with a mass protruding from the vagina. **A** and **B,** Sagittal transperineal ultrasound images depict a solid mass (*arrows*) extending through the vaginal lumen (V). R, rectum.

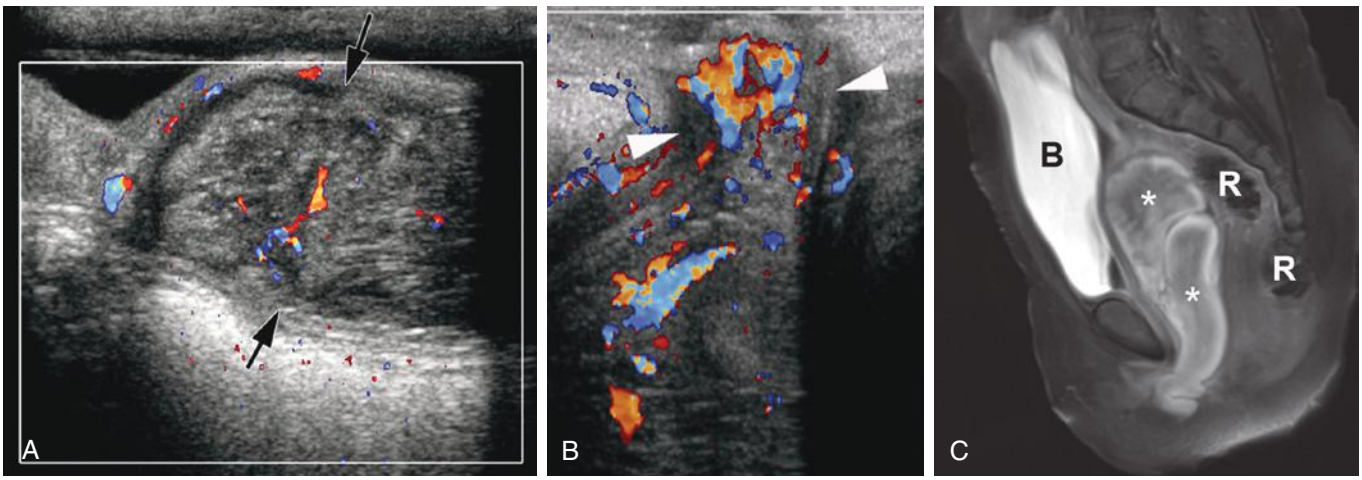

FIG 34-25 Vaginal rhabdomyosarcoma in a 16-month-old girl. **A,** Sagittal color Doppler ultrasound image of the pelvis shows a solid mass with vascularity filling the vaginal lumen (*between arrows*). **B,** Sagittal transperineal color Doppler ultrasound image demonstrates protrusion of the mass through the introitus (*between arrowheads*). **C,** Sagittal, intravenous contrast-enhanced, fat-suppressed, T1-weighted magnetic resonance image of the pelvis depicts the lobulated solid mass (*asterisks*) between the bladder (B) and rectum (R).

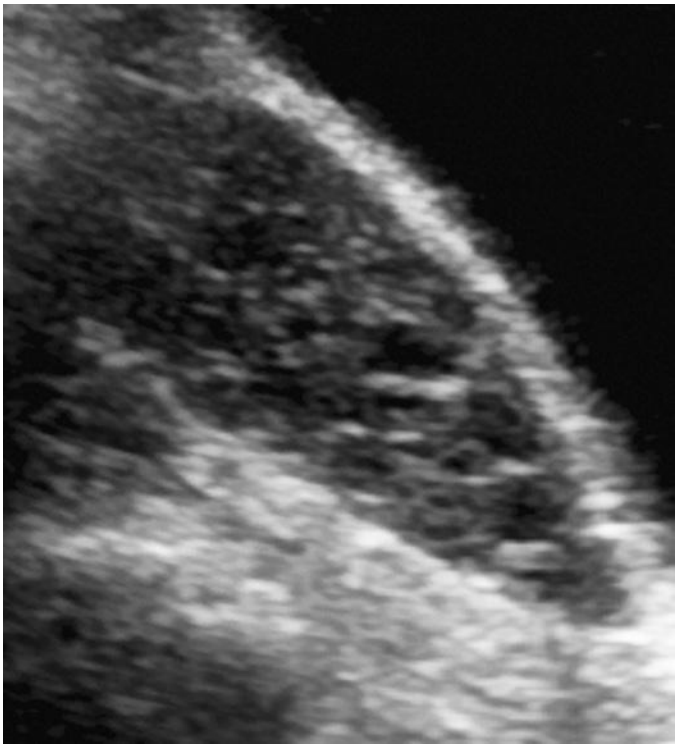

FIG 34-26 Polycystic ovary syndrome in a 14-year-old girl with obesity, hirsutism, and irregular menstrual periods. Sagittal ultrasound image demonstrates an enlarged right ovary (volume 20.3 mL) with numerous small, intraparenchymal follicles. See Video 34-4.

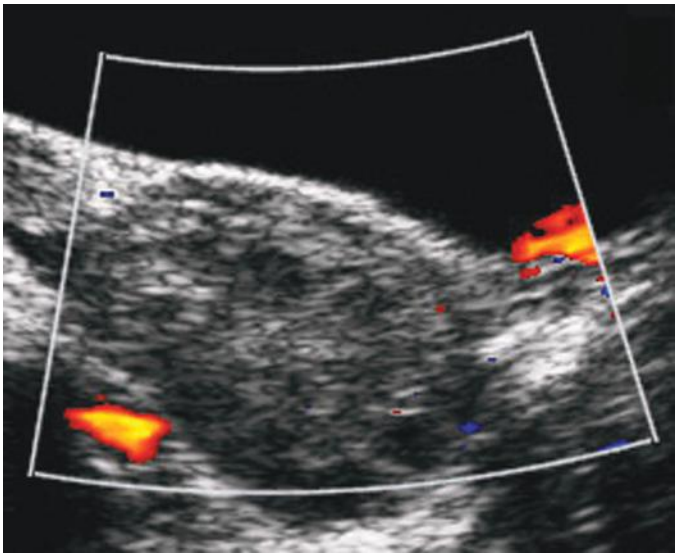

FIG 34-27 Adnexal torsion in a 14-year-old girl with a 3-day history of progressive right lower quadrant pain. Power Doppler ultrasound image of the right adnexa reveals an enlarged, avascular ovary with mildly enlarged, peripheral follicles. Right ovarian volume was 143 mL, and left ovarian volume was 13.7 mL (not shown). At surgery there was no associated right ovarian mass.

before making the diagnosis of PCOM, provided the transducer frequency is 8 MHz or higher.[36] Otherwise, ovarian volume of 10 mL or more was the most reliable finding. The task force also advised that PCOM might be inconsequential or representative of very mild PCOS in women without clinical or biochemical evidence of androgen excess.[36] However, these new recommendations have not been adopted by the ASRM.

PELVIC PAIN

Common causes of pelvic pain in girls include adnexal torsion, hemorrhagic ovarian cyst, pelvic inflammatory disease, ectopic pregnancy, and appendicitis. On rare occasion, the uterus or ovaries may herniate through the canal of Nuck into the labia majora, resulting in a mass with or without associated pain.

Adnexal (Ovarian or Tubal) Torsion

Partial or complete rotation of the ovary around its vascular pedicle compromises venous and lymphatic drainage and arterial inflow. Torsion is almost always unilateral, and pathologic findings range from massive edema to parenchymal necrosis. Peak incidence of adnexal torsion occurs in adolescence and young adulthood.[37] Ovarian torsion in neonates and premenarcheal girls is unusual as most cases are related to the presence of an ovarian cyst, which is rare in this population. However, torsion of a normal adnexum can occur as a result of hypermobility due to lax supporting ligaments.

The affected ovary is always enlarged, with an average volume 12 times that of the opposite normal ovary.[38] A ratio of torsed adnexal volume to normal adnexal volume greater than 20 is predictive of an associated ovarian mass, whereas a ratio less than 20 is predictive of absence of an ovarian mass.[38] The only relatively specific sign of torsion is the presence of multiple mildly enlarged (8-12 mm), peripherally located follicles, thought to be displaced by transudation of fluid into the central ovarian stroma as a result of vascular congestion (Fig. 34-27). Although arterial flow is often absent or reduced, the presence of Doppler detected blood flow does not exclude the diagnosis of ovarian torsion. Isolated torsion of the fallopian tube is rare but can occur in adolescents. On ultrasound image, an anechoic V- or U-shaped tubular structure with a beaked appearance of the ends may be observed, often superior and midline relative to the normal appearing ovary.

Ovarian Cyst

Ovarian cysts may be functional or nonfunctional. Functional cysts result from gonadotropin stimulation of the ovary and can be of follicular, corpus luteal, or theca luteal origin. Nonfunctional cysts include paraovarian and peritoneal inclusion cysts.

Functional cysts have a bimodal age distribution, with peaks of incidence in the neonatal period and in adolescence. Some functional cysts are hormonally active and cause gonadotropin-independent (peripheral) precocious puberty and, therefore, may present with vaginal bleeding or premature breast development (see Fig. 34-22). Nonfunctional ovarian cysts manifest as nonresolving cystic ovarian masses. Both types of cysts frequently present with either increasing abdominal girth noted by a parent or physician or as an asymptomatic abdominal mass. Additional, less common presentations include acute, severe pain that mimics appendicitis or peritonitis due to hemorrhage, torsion, or perforation; intermittent pain from torsion without complete compromise of the vascular supply; or chronic abdominal pain. Nonspecific symptoms also occur, such as bloating, nausea, vomiting, urinary retention, and frequency. Simple ovarian cysts and hemorrhagic corpus luteal cysts are common in postpubertal girls.

Occasionally, ovarian cysts are detected prenatally. They are usually unilateral, and the majority are thought to result from ovarian stimulation by fetal and maternal gonadotropins. They may be simple or complex by ultrasound imaging and are often displaced cephalad into

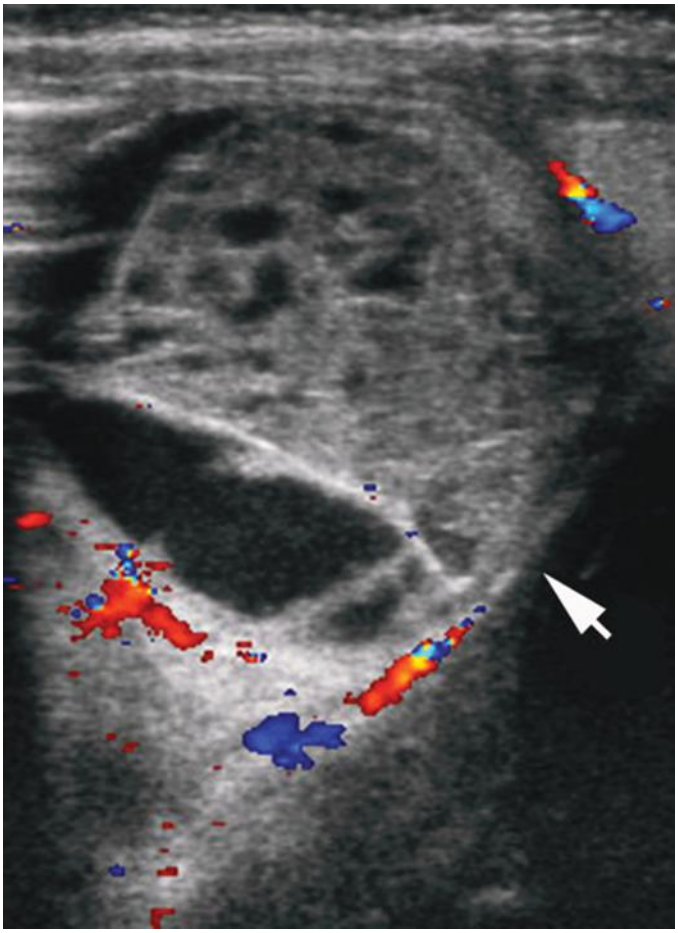

FIG 34-28 Prenatally detected ovarian cyst complicated by torsion. Sagittal postnatal ultrasound image obtained at 37 days of age shows a left adnexal cyst containing heterogeneous, nonvascular, moderately echogenic material consistent with retracting blood clot (*arrow*). Follow-up ultrasound examination at 6 months of age documented resolution of the cyst. The left ovary could not be identified, in keeping with torsion resulting in infarction and loss of left ovarian parenchyma. The right ovary appeared normal (not shown).

the abdomen, where they may be palpable at birth. Most are asymptomatic, and spontaneous regression occurs after birth. Serial ultrasound studies are performed to document regression, which usually occurs within 3 to 4 months but can take as long as a year.[39]

Bleeding into an ovarian cyst in utero or after birth has a high association with long-term ovarian loss, generally thought to be due to torsion (Fig. 34-28), although some experts believe that ovarian dysgenesis may be the underlying cause.[40,41] The age of the blood within a hemorrhagic ovarian cyst will determine its sonographic features. Fresh blood is hyperechoic relative to the ovarian parenchyma, older blood appears heterogeneous and hypoechoic, but a gelatinous blood clot is anechoic. As the red blood cells lyse, a hemorrhagic cyst may develop a lace-like or reticular pattern of internal echoes as a result of the development of fibrin strands. As the clot coalesces, an echogenic mass with retractile or concave/scalloped margins will be observed. Both of these patterns of internal echoes are very specific for the sonographic appearance of hemorrhagic cysts. Eventually as the clot continues to be resorbed, it will develop a lentiform shape and may become adherent to the cyst wall. The pattern of internal echoes will change over time. Color or power Doppler interrogation will demonstrate no evidence of internal vascularity.

Ultrasound imaging is used to assess whether an ovarian cyst is simple or complex and to determine cyst measurement. Simple cysts or cysts with internal debris suggestive of hemorrhage are managed conservatively, with follow-up imaging performed after 4 to 8 weeks to document regression. If the cyst persists at follow-up but the sonographic features are reassuring, continued observation is appropriate. When a simple ovarian cyst persists, increases in size to more than 5 cm in diameter, or becomes symptomatic, surgery should be considered.[42,43]

Pelvic Inflammatory Disease

Pelvic inflammatory disease predominantly affects girls of reproductive age and is most often due to an ascending sexually transmitted infection. Common causative organisms include *Chlamydia trachomatis* and *Neisseria gonorrhoeae,* although many infections are polymicrobial. The diagnosis is usually established clinically on the basis of pelvic pain, tenderness, vaginal discharge, elevated white blood cell count, and fever.[44]

Ultrasound findings depend on the stage of the inflammatory process. Early in the course of infection, minimal (if any) imaging abnormalities are detectable. Ultrasound examination is useful in identifying complications of pelvic inflammatory disease, including pyosalpinx and tubo-ovarian abscess. Pyosalpinx appears either as a round or oval periovarian adnexal mass with low-level echoes due to the presence of purulent debris (Fig. 34-29) or as a thick-walled, fluid-filled tubular structure that is often S- or V-shaped. There is a range of ovarian involvement, including enlargement and increased echogenicity; tubo-ovarian complex, consisting of an abnormal adherence and indistinctness of the ovary and fallopian tube surrounded by complex purulent material; and tubo-ovarian abscess that consists of a complex intraovarian or periovarian mass without identifiable ovarian tissue.[45]

Ectopic Pregnancy

A complete discussion of ectopic pregnancy is beyond the scope of this chapter and is covered in detail in Chapter 33. However, it is important to recognize that ectopic pregnancy may rarely occur in young adolescents, who have the highest reported death rate from this condition. The diagnosis should be considered in the presence of pelvic pain, vaginal bleeding, or a missed menstrual period. Ultrasound examination should be performed, and if an intrauterine pregnancy or ectopic pregnancy is not clearly identified, correlation with serum β-human chorionic gonadotropin (hCG) levels should be obtained.[46] Although no single serum hCG level should be used to definitively differentiate an intrauterine from an ectopic pregnancy, if the serum hCG level is above 3000 mIU/mL (First International Reference Preparation) and the uterus is empty on transvaginal sonography, an ectopic pregnancy should be strongly considered and the patient should be followed carefully with serial hCG levels and transvaginal sonography if clinically stable.[47]

Acute Appendicitis

Acute appendicitis is the most frequent pediatric surgical emergency. Symptoms of acute appendicitis overlap with a number of other gastrointestinal conditions, including Crohn disease and mesenteric adenitis, as well as acute gynecologic conditions. Patients usually present with right lower quadrant pain, tenderness, and leukocytosis.

The appendix is best imaged with a high-frequency linear-array ultrasound transducer using graded-compression technique. The inflamed appendix appears as a noncompressible, tubular, nonperistalsing, blind-ending structure exhibiting a striated gut wall signature and with an outer-to-outer diameter measuring larger than 6 mm.[48]

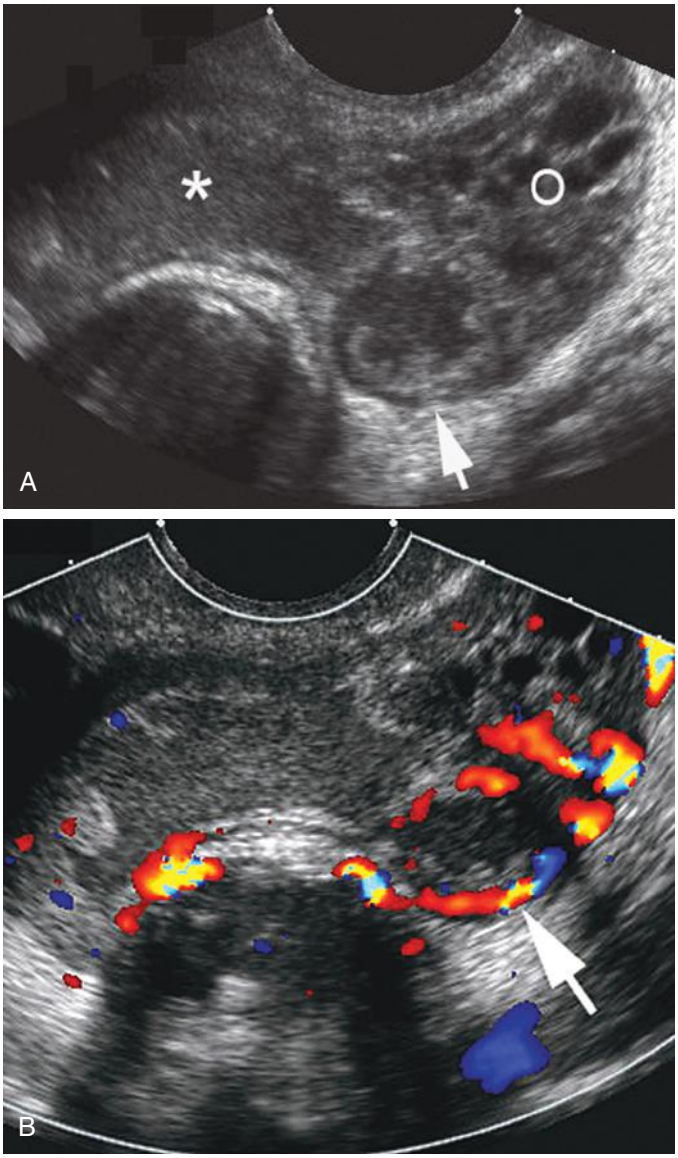

FIG 34-29 Pyosalpinx in a sexually active 18-year-old girl with gonococcal infection. **A,** Transvaginal ultrasound image demonstrates a thick-walled fallopian tube containing echogenic material and redundant nodular echogenic endothelial surface (*arrow*) consistent with chronic inflammation, adjacent to the normal left ovary (O). Echogenic fluid is identified within the pelvis (*asterisk*). **B,** Transvaginal color Doppler ultrasound image reveals hyperemia of the wall of the left fallopian tube (*arrow*). See Video 34-5.

The appendiceal wall may be hyperemic. Echogenic (with or without acoustic shadowing) intraluminal stones (appendicoliths), increased echogenicity and vascularity of the periappendiceal fat indicative of periappendiceal inflammation, and walled-off fluid collections consistent with abscess formation are also readily depicted sonographically (Fig. 34-30). Advantages of using ultrasound for the diagnosis of appendicitis compared to CT include lack of ionizing radiation, no need for sedation or contrast material, and lower cost.

In our practice, we perform an initial ultrasound examination in children with a suspected diagnosis of acute appendicitis. Cross-sectional imaging with CT or MR is performed only in patients in whom the appendix is not visualized by ultrasound, in patients with a strong clinical suspicion for acute appendicitis and an equivocal ultrasound study, or in patients with suspected perforated appendix when more complete assessment of inflammatory changes and fluid collections is necessary for management purposes.[49-51]

Genital Hernia

Inguinal herniation of the uterus or ovaries is a rare condition that may be complicated by torsion, strangulation, and infertility. These indirect, congenital hernias develop when there is a failure of closure of the processus vaginalis between the 36th and 40th weeks of gestation. Abdominal or pelvic contents may herniate through the canal of Nuck into the labia majora (Fig. 34-31).[52] Patients may present with pain or a palpable mass.

GYNECOLOGIC PELVIC MASSES

Gynecologic masses presenting in girls include ovarian cysts, primary ovarian neoplasms, metastatic ovarian disease, hematocolpos, primary vaginal and uterine neoplasms, and pregnancy.

Ovarian Masses

Ovarian masses include non-neoplastic cysts as well as benign and malignant ovarian tumors. Most ovarian tumors in children are benign and of germ cell origin.

Ovarian Tumors

Ovarian tumors may arise from surface epithelium, germ cells, or stroma. The majority develop in the second decade of life, with teratoma (also termed dermoid cyst) being the most common. Teratomas are typically composed of elements of all three germ cell layers, with 90% classified as mature and 10% classified as immature (containing embryonic neural elements) or malignant.[53]

Cystic mature teratomas account for more than 90% of all benign ovarian tumors. They are usually unilateral, although 10% to 20% are bilateral. Most tumors range from 5 to 10 cm in diameter. Ectodermal components predominate, with the sonographic appearance dependent on the relative amounts of calcium, hair, fat, sebum, and serous fluid within the lesion.[29,54,55] The majority are complex in appearance with soft tissue elements composing less than 50% of the mass by volume (Fig. 34-32).

Malignant ovarian tumors are uncommon in the pediatric patient population, accounting for only 1% to 2% of all malignant tumors in children younger than 17 years of age.[56-58] Malignant germ cell neoplasms usually occur in postmenarcheal girls and most often manifest as an asymptomatic abdominal or pelvic mass. They are typically larger than 10 cm in diameter at the time of diagnosis. Intra-abdominal spread occurs to the liver and lymph nodes. Dysgerminoma is the most frequent ovarian malignancy in childhood, and 10% are bilateral. Malignant teratomas contain more than 50% soft tissue elements by volume (Fig. 34-33). Other germ cell tumors may be either homogeneous and echogenic sonographically or complex with cystic areas related to hemorrhage.[29,53-55]

Sex cord–stromal tumors are low-grade malignancies that arise from the Sertoli cells and granulosa theca cells of the embryonic gonad. They usually develop in prepubertal girls and are generally asymptomatic. Sertoli-Leydig cell tumors may cause virilization due to androgen production. Granulosa theca cell tumors may cause isosexual precocity as a result of estrogen production. These tumors appear as heterogeneous masses with cystic foci on ultrasound imaging (Fig. 34-34). Metastases are unusual but may occur within the liver or along the peritoneum.[29,53-55]

The most common epithelial ovarian tumors are serous and mucinous cystadenomas, most of which are large and benign. They do not

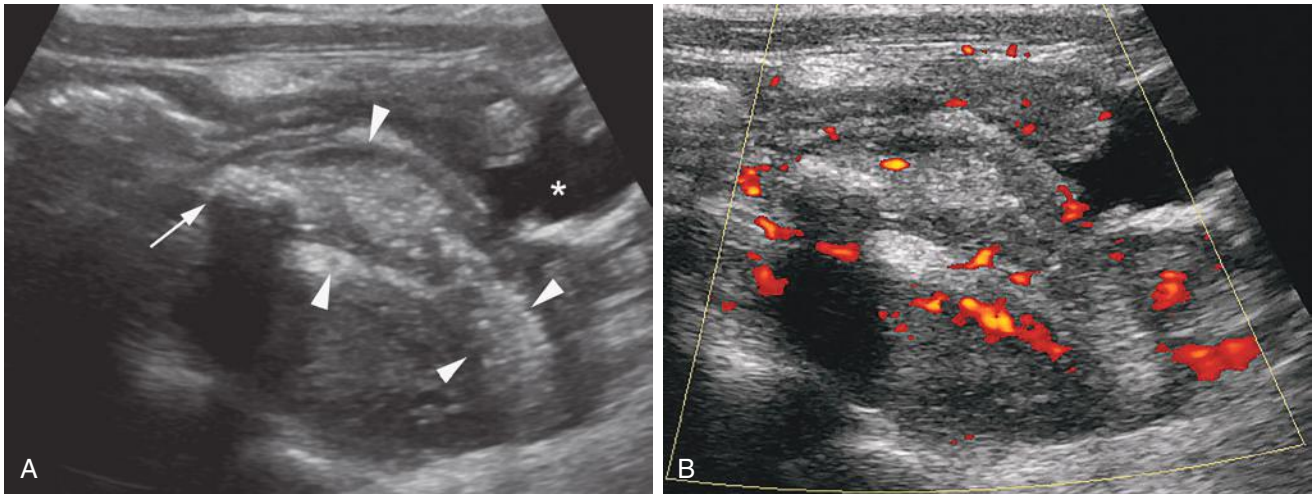

FIG 34-30 Perforated appendicitis in a 5-year-old girl with abdominal pain. **A,** Sagittal ultrasound image of the right lower quadrant of the abdomen reveals a dilated appendix (*arrowheads*) containing echogenic material as well as a hyperechoic appendicolith at its base (*arrow*), associated with distal acoustic shadowing. There is a small amount of adjacent free fluid (*asterisk*). **B,** Sagittal power Doppler ultrasound image depicts hyperemia of the soft tissues adjacent to the inflamed appendix.

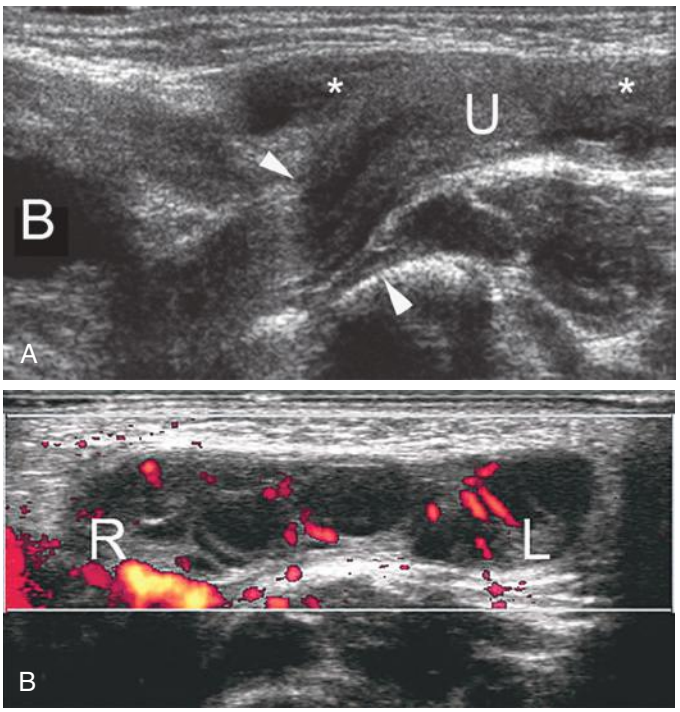

FIG 34-31 Incarcerated inguinal hernia in a 2-month-old girl. **A,** Transverse ultrasound image of the left groin shows the uterus (U) extending through a fascial defect (*between arrowheads*) into the soft tissues of the left labium majus. The uterus is interposed between the right and left ovaries (*asterisks*). B, bladder. **B,** Transverse power Doppler ultrasound image of the left groin demonstrates blood flow to both inguinal ovaries. An incarcerated indirect inguinal hernia was surgically reduced. L, left ovary; R, right ovary. See Video 34-6.

FIG 34-32 Ovarian dermoid cyst (mature teratoma) in a 17-year-old girl. Sagittal ultrasound image of the right adnexa reveals a complex mass containing cystic (*asterisk*) and solid, echogenic (*arrow*) components.

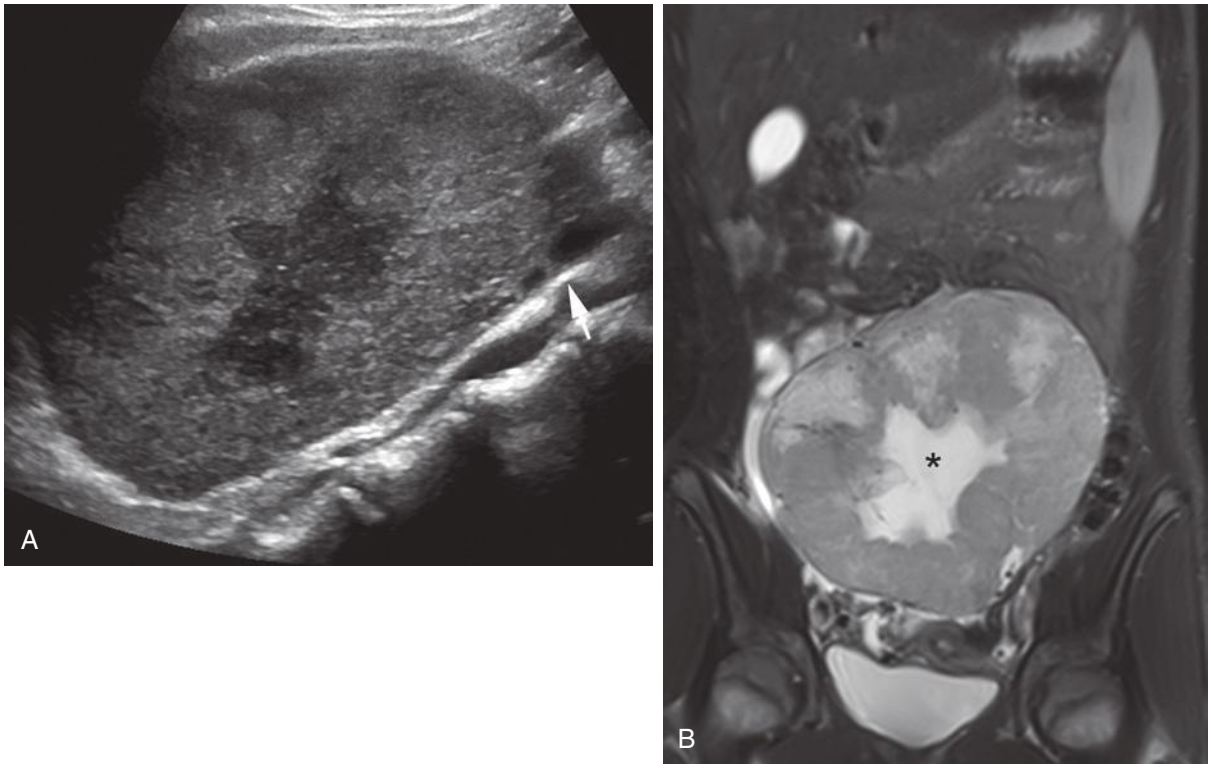

FIG 34-33 Ovarian dysgerminoma in an 11-year-old girl with abdominal pain, large abdominal mass, and an elevated serum hCG level. **A,** Sagittal ultrasound image demonstrates a large, predominantly solid lesion arising from the right ovary. A few normal-appearing ovarian follicles are noted adjacent to the lower pole of the mass (*arrow*). **B,** Coronal T2-weighted, fat-suppressed magnetic resonance image reveals a 14-cm diameter tumor with central necrosis (*asterisk*). Central geographic hypoechoic area likely represents central necrosis or edema. See Video 34-7.

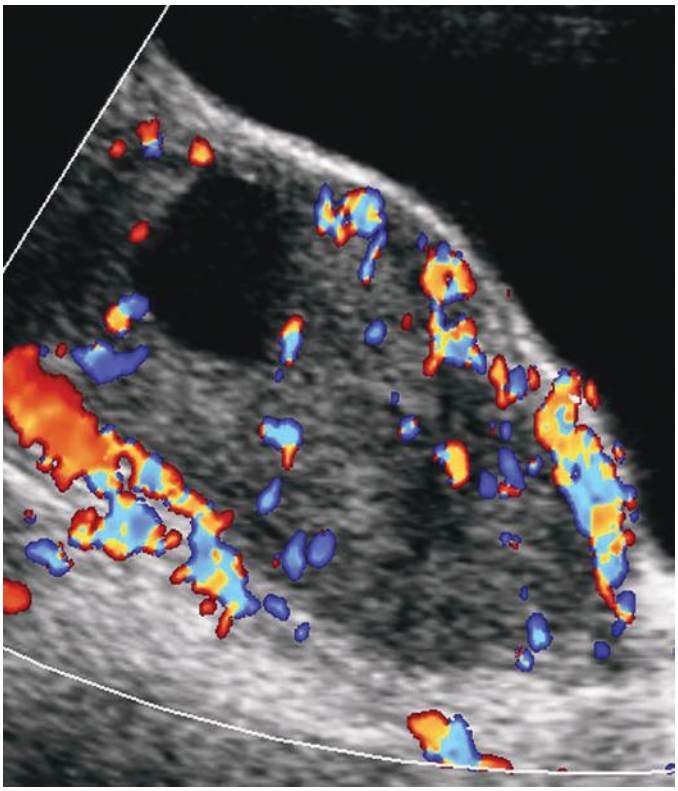

FIG 34-34 Granulosa cell tumor in a 16-year-old girl undergoing evaluation for primary amenorrhea. Sagittal color Doppler ultrasound image shows a predominantly solid pelvic mass with a prominent anechoic cystic component.

usually develop prior to puberty.[59] A serous cystadenoma is usually a unilocular, thin-walled cystic mass that may contain thin septations and papillary projections; about 20% are bilateral. A mucinous cystadenoma most often presents as a multiloculated cystic mass with thin septations (Fig. 34-35). Papillary projections are identified less frequently, and bilateral ovarian involvement is less common than with serous cystadenomas.[29,54]

Although little has been reported on the subject of metastatic ovarian tumors in children, the ovaries can harbor leukemia,[60] and metastatic spread to the ovaries from neuroblastoma, rhabdomyosarcoma,[61] Burkitt lymphoma,[62] and colon cancer has been documented. Metastatic ovarian involvement is frequently asymptomatic and diagnosed only at autopsy.[63]

Pregnancy

Pregnancy should always be a diagnostic consideration when a pelvic mass develops in a girl aged 9 years or older. Complications of pregnancy including preeclampsia, placental abruption, and laceration occur more frequently in pediatric patients than in the adult population. There is also an increased need for cesarean delivery in the pregnant pediatric patient.[64]

CONCLUSION

As the main imaging modality for evaluating the pediatric female pelvis, sonography is useful in depicting ovarian and uterine anatomy; assessing children with ambiguous genitalia; investigating prepubertal bleeding or primary amenorrhea; and in determining the cause of pelvic pain and the origin of pelvic masses.

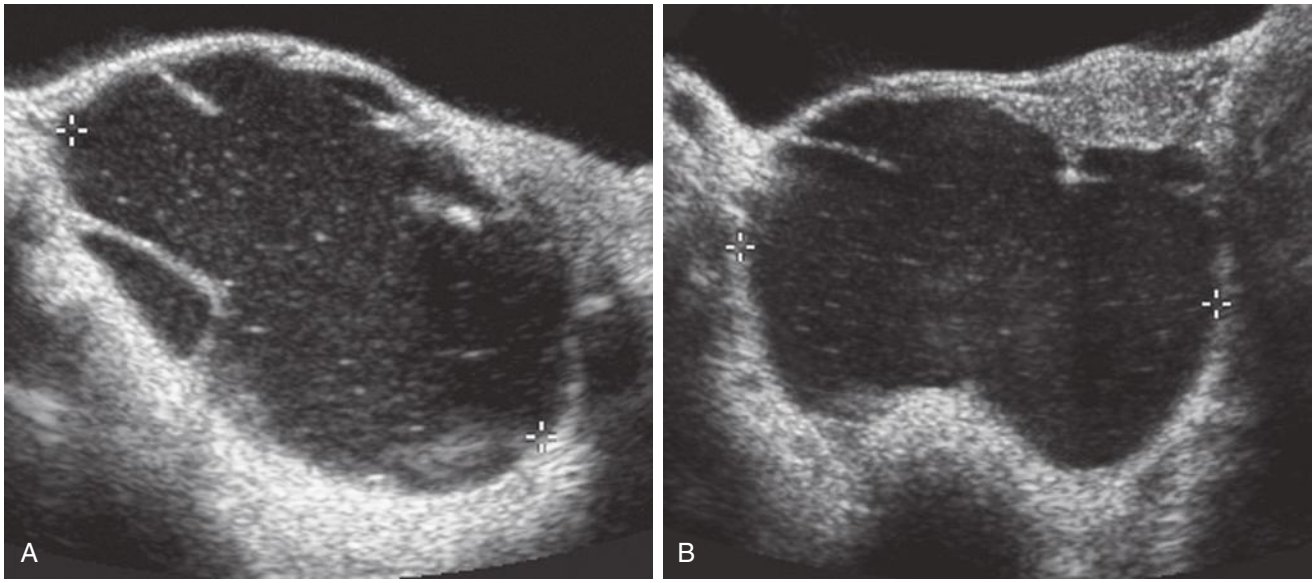

FIG 34-35 Mucinous cystadenoma in a 15-year-old girl with prolonged vaginal bleeding. Sagittal (**A**) and transverse (**B**) ultrasound images depict a large, cystic mass in the right adnexal region (*between cursors*). The mass contains multiple septations and echogenic debris.

Ultrasound and Magnetic Resonance Imaging in Urogynecology

Milena M. Weinstein, Mark E. Lockhart

SUMMARY OF KEY POINTS

- Endoanal sonography has an important role in the assessment of the anal sphincter in patients with fecal incontinence.
- Sonography and magnetic resonance imaging (MRI) of the pelvic floor can be useful in evaluation of women with pelvic floor disorders and in assessment of mesh implants.
- There is no strong evidence for *routine* use of pelvic floor sonography in assessment of women with pelvic floor disorders.
- Fistulas and perirectal abscess can be evaluated well by either sonography or MRI prior to therapy.
- Urethral diverticula are well seen by either sonography or MRI, although the direct connection to the urethra is best depicted with MRI.
- Criteria for postintervention and postsurgical evaluation are less well defined for both sonography and MRI.

OUTLINE

Pelvic organ prolapse (POP), fecal incontinence, and urinary incontinence in women have been largely ignored from an imaging perspective; recent innovations in both imaging and treatment options have increased attention on the evaluation and management of these conditions. Traditionally, there has been limited research focusing on imaging of female pelvic disorders other than malignancy. This may be in part due to reluctance of women to report this constellation of problems to their clinicians because of embarrassment or because they ascribe these symptoms to a "part of life" that is to be expected with aging and childbirth. However, pelvic floor dysfunction is a significant medical and quality of life issue, and pelvic floor disorders have been reported to affect one in four of all women. Although prevalence increases with age,[1] pelvic floor disorders should not be considered a normal part of aging.

Pelvic floor disorders include POP, urinary incontinence, and anal incontinence. These conditions may manifest with a variety of urinary and defecatory symptoms as well as pain and sexual dysfunction. *Urinary incontinence* (UI) is defined as involuntary leakage of urine.[2] There are two common subtypes—stress urinary incontinence and urgency urinary incontinence. *Stress urinary incontinence* occurs in response to increased intra-abdominal pressure that occurs during exertion, strain, coughing, or sneezing. *Urgency urinary incontinence* occurs at the time of sensation of urgency to urinate. The combination of urinary urgency and frequency is also referred to as *overactive bladder syndrome.*

Anal incontinence is the involuntary loss of feces or flatus.[2] The underlying cause of anal incontinence is often an anal sphincter defect following vaginal delivery[3] and less commonly direct trauma, including surgery. However, a variety of other factors can contribute. Neurogenic disorders may result in anal incontinence in the setting of an intact anal sphincter and may be caused by traction neural injury during delivery, as well as by diabetes, certain medications, radiation therapy, and aging. Fecal incontinence is six to eight times more common in women than in men, and the incidence increases with aging. The incidence is highest among multiparous older women, and it is estimated that up to 15% of multiparous women in the United States over the age of 64 years may have fecal incontinence to some degree.

Female pelvic medicine and reconstructive surgery (FPMRS) and urogynecology focus on diagnosis and treatment of pelvic floor disorders. A wide variety of treatment options is available for pelvic floor disorders, ranging from conservative measures, such as pelvic floor muscle training, physical therapy, medications, and supportive devices, to surgical intervention. The lifetime chance of having primary surgery for POP or stress urinary incontinence is estimated to be 20% by the age of 80 years.[4] Many do not seek care, but even the few who seek help may not be effectively treated if multicompartmental disease is not fully appreciated and addressed.[5] Unfortunately, recurrence rate is high, leading to reoperation in 30% of women.[6] Until successful treatment is realized, the impact on a woman's daily quality of life can be

significant. Persistent symptoms such as pain or incontinence can be both debilitating as well as embarrassing and may carry significant psychosocial implications.

Despite ongoing efforts to improve understanding of pelvic floor disorders, the underlying pathophysiologic mechanism is not fully elucidated. Although clinical assessment and examination remain the mainstay of pelvic floor evaluation, imaging has emerged as a potentially useful modality. Indeed, clinicians have begun to avoid using terms such as *cystocele* and *rectocele,* recognizing that the physical examination only identifies prolapse of the vaginal walls—whether anterior and posterior—and cannot identify with certainty the pelvic organs lying behind the vaginal walls. Pelvic floor imaging, however, clarifies the specific anatomy underlying these conditions and potentially helps in understanding the physiologic and pathophysiologic changes. Assessment of anatomy and function using pelvic floor imaging is used increasingly to improve understanding of pelvic floor disorders and hence optimize treatment approaches. However, despite more than 2 decades of imaging research in pelvic floor disorders, imaging still plays a rather limited role in the evaluation of pelvic floor disorders at most institutions.

PELVIC FLOOR ANATOMY AND FUNCTION

The pelvic floor is a complex structure encompassing an interplay of smooth and striated musculature that, along with both fascia and ligaments, supports and assists in the function of the pelvic floor organs. The main muscles of the pelvic diaphragm are the levator ani muscles, comprising the pubococcygeus, puborectalis, and iliococcygeus muscles. These muscles span the space between the obturator internus muscle laterally, the pubis symphysis anteriorly, and the coccyx posteriorly. The levator hiatus is a funnel-shaped cleft in the muscles of the levator ani from which exit the urethra, the vagina, and the anal canal.[7] The puborectalis muscle (PRM) is the most inferior (caudal) muscle of the pelvic floor. The two sides of the PRM attach to the two pubic rami anteriorly and merge posterior to the anal canal to form the anorectal angle.[8] The superficial muscles of the pelvic floor make up the *urogenital diaphragm* and include the ischiocavernosus, bulbospongiosus, and transversus perinei superficialis muscles (Fig. 35-1).

Fecal continence is maintained by both constriction of the anal canal as well as anorectal lift of the pelvic floor. The normal anal canal extends proximally from the puborectalis portion of the levator ani muscles to the anal verge, for a distance of approximately 4 cm. The structures surrounding the anal canal are responsible for maintaining fecal continence and include the *internal anal sphincter* (IAS), the *external anal sphincter* (EAS), and the PRM. The EAS encircles the anal canal and is a striated muscle that is under voluntary control. The superficial portion of the EAS muscle is attached posteriorly to the coccyx through the anococcygeal ligament and anteriorly inserts into the perineal body. The deep portion surrounds the anal canal with some integration with the PRM posteriorly and some fibers of this portion interdigitate with the deep transverse perineal muscles. The subcutaneous portion of the EAS is the portion that surrounds the anal canal most distally, approximately 1 cm below the termination of the IAS. The IAS is a smooth muscle, which is under autonomic control and is responsible for 80% of the resting anal sphincter tone. The IAS is created by thickening of the circular smooth muscle in the rectal wall and represents the terminal portion of the inner circular smooth muscle layer of the intestinal tract. The IAS is shorter in length than the EAS, terminating approximately 1 cm distal to the dentate line. The dentate line represents the junction of the subcutaneous and superficial components of the EAS. In addition to these two circular muscle layers, a longitudinal muscle layer extends between the EAS and IAS

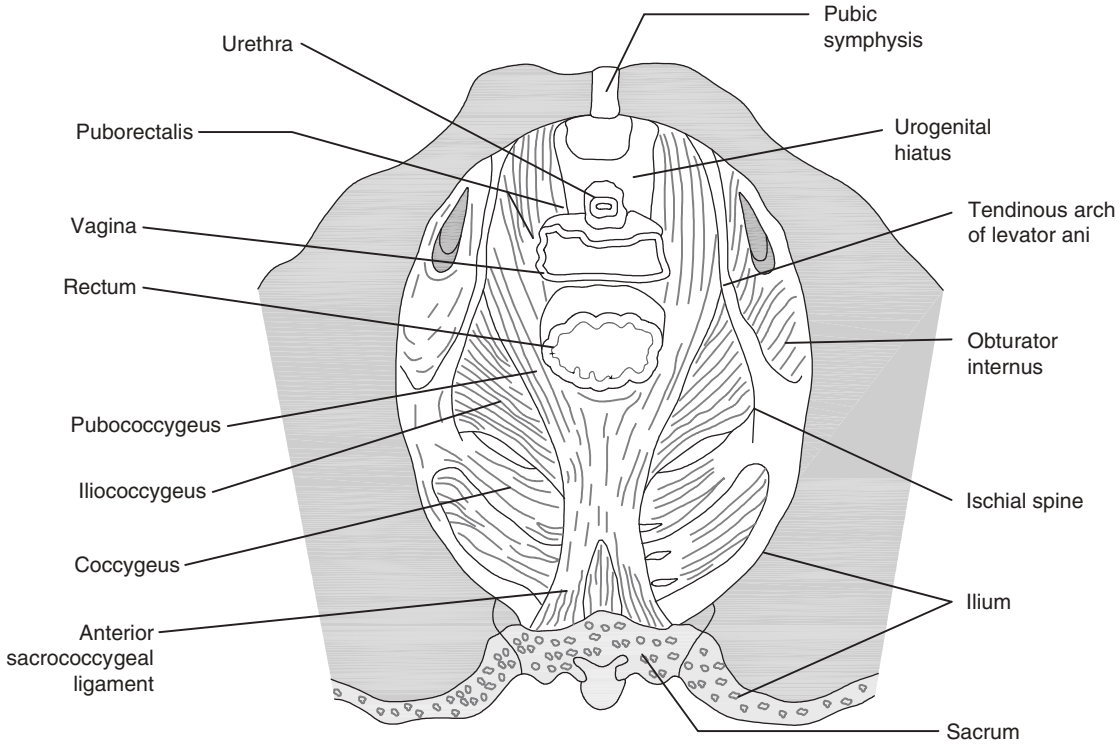

FIG 35-1 Pelvic floor muscle anatomy. Pelvic floor muscles fill up the "bowl" of the pelvis. The levator ani muscles are composed of the puborectalis, pubococcygeus, and iliococcygeus portions. (Illustration by Rose Katz.)

and serves to anchor the sphincter complex to the fascia of the levator ani as well as to the pelvic side wall.[9]

The perineum separates the anus from the vagina. The central portion of the perineum contains the perineal body, which is the point where the EAS, the bulbospongiosus, and the superficial and deep transverse perineal muscles meet. The presence of a thick perineal body is suggestive of a normal anal sphincter.[10]

The female urethra is a tubular conduit that passes through the retropubic space, perforating the perineal membrane to terminate at its external orifice (external urethral meatus) in the vaginal vestibule directly ventral to the vaginal opening. The normal female urethra is approximately 4 cm long. Urethral continence is maintained by the interplay of multiple structures. The urethral muscle layers are composed of both smooth muscle layers and the striated rhabdosphincter. Dorsally the rhabdosphincter is tightly connected to the ventral portion of the vagina.[11] The proximal urethra and the bladder base are supported by the anterior vaginal wall, which creates a sling-like support that connects laterally to the levator ani muscles at the attachments of the *arcus tendineus fasciae pelvis*. As pelvic floor muscles play an important role in urethral closure for urinary continence, pelvic floor physical therapy targets these muscles to improve their function for management of incontinence and other pelvic floor disorders.[12] In addition to the pelvic floor muscles, another factor important in maintaining urinary continence is the contraction of the smooth and striated muscles within the urethral wall, as well as the ligaments and the fascia that support the bladder and urethra in proper position when intra-abdominal pressure is increased.[13] Urinary continence is preserved by support applied to the bladder neck during pelvic floor contraction, as well as constriction of the urethral lumen.[14,15]

The normal function of the pelvic floor musculature aids in control of both urinary and anal function and also supports the pelvic floor contents. Pelvic floor muscles must perform both voluntary contractions as well as involuntary, or reflex, contractions preceding or at the time of increased abdominal pressure. In response to increased abdominal pressure, the superficial pelvic muscles, such as the anal and urethral sphincters, resist these pressures; and the levator ani muscles support the pelvic floor and counteract this increased pressure by contracting and creating a circular closing of the levator hiatus as well as an upward movement of the pelvic floor and perineum.[14-17] The contraction of the PRM leads to reduction of its two limbs, and this change lifts the anal canal anteriorly, compressing the structures within the levator hiatus against each other as well as the back of the pubic symphysis.[18]

RISK FACTORS AND INDICATIONS FOR DYNAMIC PELVIC IMAGING

In the surgical literature, there are well-defined risk factors associated with female pelvic floor disorders. Most studies on this topic suggest that pregnancy and childbirth are risk factors for developing pelvic floor dysfunction. Broadly, the trauma of childbirth plays a key role in the development of tears of the pelvic muscles or the EAS/IAS. Symptoms associated with these tears are worsened in the setting of other risk factors such as age, obesity, or poor stool consistency. However, not all women with muscle or sphincter tears will develop incontinence or prolapse. Risk factors for incontinence in women with sphincter tears are Caucasian race, fourth-degree tear during childbirth, increased age, and increased body mass index.[19]

Only in the last 2 decades has cross-sectional imaging played a critical role in characterization of pelvic floor disorders. Surgeons previously based surgery on physical examination and clinical history. As an early adjunct, radiographic defecography was used to confirm abnormal movement of the pelvic structures, with a positive impact on care. More recently, MRI has been demonstrated to provide exquisite detail of the anatomy of the pelvic floor beyond previous techniques. Further advances with rapid image acquisition have allowed dynamic evaluation of pelvic floor displacement in the setting of strain or evacuation of bowel contents, similar to radiographic defecography. Even more recently, ultrasound has made inroads into pelvic floor imaging and has strengths of its own.

The numerous indications for dynamic pelvic floor imaging range from a bulging mass visualized within the vagina, sensation of pelvic pressure, urinary incontinence, voiding difficulty, anal incontinence, defecatory dysfunction, to postoperative evaluation for complications or recurrent abnormality. In the 2014 ACR Appropriateness Criteria for Pelvic Floor Dysfunction,[20] both transperineal sonography and dynamic MRI are considered "usually appropriate" for symptoms relating to POP, urinary incontinence or dysfunction, and recurrent prolapse after surgical repair. Both "may be appropriate" for anal incontinence, whereas sonography performed with an endorectal probe or MRI with an endorectal coil are highly rated for this indication. For the evaluation of defecatory dysfunction, dynamic MRI or x-ray defecography are considered more appropriate than sonography. However, for evaluation of postoperative complications, standard sonography or MRI may be appropriate, whereas dynamic studies are usually not helpful.

The choice of imaging modality will vary by physician practice pattern and is largely dependent upon surgeon preference and available imaging expertise. Some hospitals may have these studies requested primarily by gastrointestinal surgeons, whereas patients at other sites may be evaluated more often by urogynecologists or gynecologic surgeons. Regardless of the referral source, sonography and MRI are becoming more widely used for evaluation of signs of POP and for workup of urinary and anal incontinence.

Sonography may be performed in the office of the surgeon and is a relatively inexpensive modality. It has been used to explore multiple aspects of pelvic floor dysfunction, including anal and urinary incontinence and POP.[21-23] It is the best means of assessing the integrity of the IAS and EAS. Pelvic floor sonography has been shown to be a superior diagnostic tool in comparison to anal manometry, electromyogram, and conventional defecography.[24] Sonography can also be used to provide biofeedback during pelvic floor training.[16]

MRI may be especially useful in patients who have undergone a failed repair and are being evaluated for further therapy or when there is clinical concern for challenging anatomy or multicompartmental disease. Typically, surgeons make a plan based upon clinical experience, but clinical examination has its limitations in detection and delineation of pelvic floor disorders.[25,26] MRI can directly impact care by refining and improving the surgical plan. In addition, MRI has been clearly shown to detect additional findings beyond clinical examination.[27] Two studies support this concept. In a study reported by Kaufman and associates, MRI changed the surgeon's plan in 41% of complex pelvic surgeries.[28] In another study of 33 patients, the surgeon developed a plan before MRI and revisited the plan afterward. In 67%, the plan was changed based on the imaging findings.[29] A relatively common specific benefit of MRI is the detection of unexpected multicompartmental disease, which substantially improves patient care and has been shown to reduce the rate of reoperation.

ULTRASOUND IMAGING

Endoanal Sonography for Anal Incontinence

Endoanal sonography, like endoanal MRI, is well established in evaluation of the anal sphincter complex in women with fecal incontinence

(FI).[30] Fecal incontinence has been reported to affect 9% to 15% of the female population.[31] Social and psychological consequences can be devastating to patients, and many do not discuss fecal incontinence with their providers. Fecal incontinence is usually multifactorial, and risk factors vary from aging, diabetes, neurologic disease, prior anal surgery, and prior obstetric anal sphincter injuries (OASIS). Endoanal sonography is best performed with two-dimensional (2D) ultrasound imaging with a 7- or 10-MHz rotating 360-degree radial array endoanal transducer. The patient is most commonly placed into the left lateral position with the knees bent upward. However, some imagers advocate using the prone or supine lithotomy position. Using a 360-degree radial array transducer, providers can identify the normal anal sphincter complex anatomy and rapidly delineate tears of the anal sphincters.[32]

Using endoanal sonography, multiple layers or rings of differing echogenicity can be identified[33] (Fig. 35-2). The innermost ring is hyperechoic and represents the interface between the transducer and the anal mucosa and submucosal tissues. The underlying markedly hypoechoic ring represents the IAS. The next layer is the intermediate to hyperechoic longitudinal muscle, which is not always distinct on ultrasound imaging and is an extension of the outer longitudinal layer of the rectum. The outermost layer, which is generally echogenic to mixed echogenic, is the EAS. Endoanal axial imaging of the normal anal canal should include at least three characteristic levels. Images of the proximal (cranial) third of the anal canal should include the sling of the PRM, which is visualized posteriorly as a hyperechoic U-shaped structure that closely apportions the posterior portion of the EAS. At this level the EAS will not be observed anteriorly in women. However, the normal IAS will form a complete hypoechoic ring at this level (Fig. 35-2A). In the middle third, the complete rings of both the hypoechoic IAS and echogenic EAS will be seen (Fig. 35-2B). At the level of the distal anal canal, the normal EAS will extend approximately 1 cm below the IAS (Fig. 35-2C). The anal sphincter thickness has been shown to change with the aging process. The IAS becomes thicker with age, likely because of collagen replacement, whereas the EAS tends to become thinner as the patient ages.

Defects in the anal sphincter complex have been shown to have a strong association with fecal incontinence. Most commonly tears of the anal sphincter are combined and symmetric anterior defects in the EAS and IAS. Isolated EAS defects are also common whereas isolated IAS defects are much less frequent.[34,35] IAS defects usually appear as a hyperechoic disruption of the normally hypoechoic ring of the IAS, whereas EAS tears are seen as hypoechoic, often heterogeneous defects disrupting the continuity of the relatively echogenic EAS. These sonographic changes correspond to the replacement of striated muscle with fibrosis. The extent of the tear is conventionally described as an analogy using the face of a clock, with the 12 o'clock position anterior, the 6 o'clock position posterior above the coccyx, 3 o'clock to the patient's left, and 9 o'clock to the patient's right (Fig. 35-3). In studies in which ultrasound findings have been confirmed by intraoperative findings, the diagnostic accuracy of ultrasound imaging in detecting anal sphincter injury has been reported to have a sensitivity that well exceeds 90%.[36-38] The findings of sonographic anal sphincter defects have been confirmed in multiple studies to correlate with poor sphincter function on anorectal manometry as well as with surgical and histologic findings of sphincter tears.[36,37,39] Endoanal sonography also shows very good interobserver and intraobserver reliability.[40] When added to immediate postpartum clinical assessment, endoanal sonography was shown to enhance recognition of occult anal sphincter tears in postpartum women with second-degree tears who did not have evidence of sphincter tear on clinical examination.[41] Immediate repair of these occult anal sphincter tears reportedly decreased the risk of

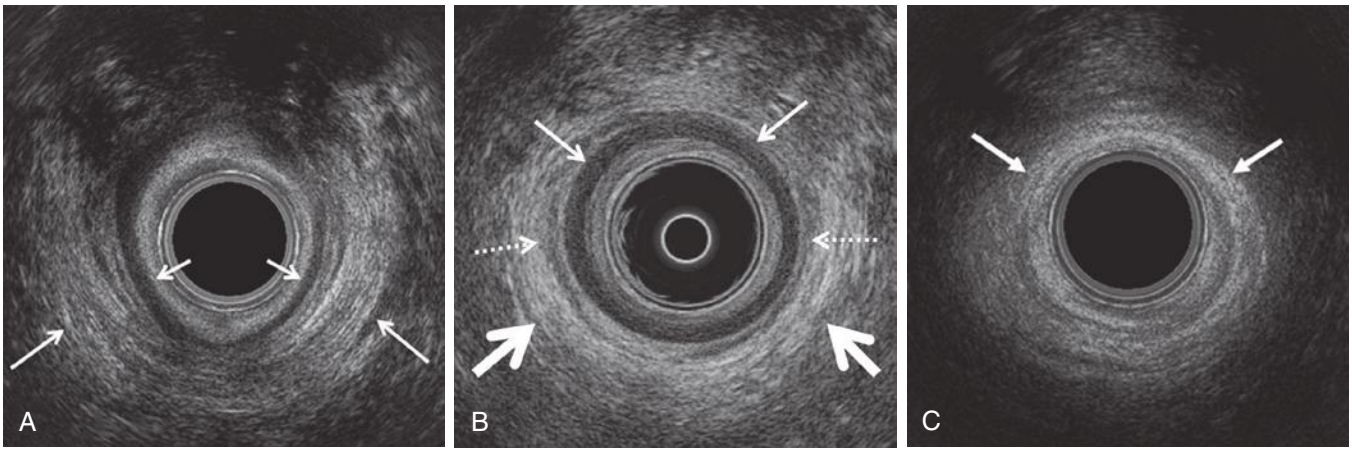

FIG 35-2 Transverse ultrasound images of the normal anal sphincter. Endoanal ultrasound images at three levels (upper sphincter, midsphincter, and caudal sphincter) at the level of the puborectalis muscle (PRM) shows the internal sphincter, intersphincteric fat, and external sphincter as separate structures. **A,** Endoanal ultrasound image: transverse image of the cephalad (upper) anal sphincter demonstrating the striated relatively echogenic U-shaped sling of the posterior PRM (*long arrows*) and the hypoechoic internal anal sphincter (IAS) (*short arrows*). Note that at this level the external anal sphincter (EAS) is absent. The innermost echogenic ring represents the rectal mucosa and interface with the transducer (central round black structure). **B,** Normal appearance on endonanal ultrasound of the anal sphincters at the midsphincteric level demonstrating the characteristic target or layered appearance. The inner echogenic ring represents the mucosa and interface with the transducer, the IAS is the subjacent markedly hypoechoic ring (*thin arrows*) and the outermost ring represents the EAS (*thick arrows*) and is typically either hyperechoic or of mixed echogenicity. Wispy hypoechoic curvilinear strands with a striated appearance (*dotted arrows*) between the IAS and EAS represent the longitudinal muscle layer. **C,** Endoanal ultrasound image: transverse image of the normal caudal or distal anal sphincter image where the echogenic EAS (*arrows*) extends beyond the IAS representing the superficial portion of the EAS.

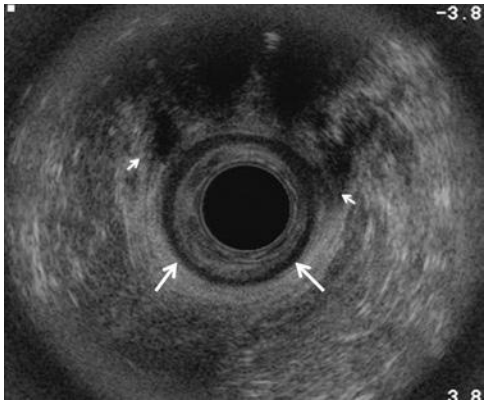

FIG 35-3 Sphincter tear. Endorectal axial ultrasound image demonstrating an intact hypoechoic internal anal sphincter (*arrows*), but disruption of the anterior aspect of the external anal sphincter (*arrowheads*) from the 11 o'clock to the 3 o'clock position.

developing severe postpartum fecal incontinence based on 3 months follow-up examination.

Endoanal Sonography for Fistulas and Perianal Abscesses

Anorectal abscesses and fistulas usually result from anal gland infections secondary to obstruction from fecal impaction. Approximately 10% are reportedly due to inflammatory bowel disease or direct trauma (including anorectal surgical procedures). A perianal abscess is thought to spread in multiple directions along the path of least resistance and can lead to formation of fistulas. Anorectal fistulas are connections between the perianal skin or vagina and the lumen of the anus or the rectum, although some may be blind ending. For planning surgical intervention, the most important factors for surgeons to know are the location and the size of the abscess, the exact location and number of fistulous tracts, and the relationship of these fistulous tracts to the IAS and EAS. Parks and colleagues[42] described four types of fistula tracts based on their relationship to the sphincteric structures: *intersphincteric*—passes through the IAS and then courses between the muscle layers to the perianal skin; *transphincteric*—passes through both the IAS and EAS and then through the ischiorectal fossa to the skin; *suprasphincteric*—passes above the PRM and then courses through the ischiorectal fossa to the skin; and finally *extrasphincteric*—direct communication between perineum and rectum, bypassing the anal canal.

In imaging the fistula tract, the identification of the internal opening can be challenging. The internal opening can appear hypoechoic when acute inflammation is present, or hyperechoic when chronically inflamed or if it contains air.[43] If the external opening of the fistulous tract is visible, injection of hydrogen peroxide into the fistulous opening may improve sonographic identification of the tract as a result of creation of gas bubbles within the fistula (Figs. 35-4 and 35-5).

Transperineal Sonography of the Anal Sphincter

Although endoanal sonography remains a reference standard in anal sphincter assessment, transperineal sonography can be an effective but less invasive and more accessible modality for evaluation of the anal sphincter.[44] The advantage of transperineal sonography for assessment of the anal sphincter is the possibility of dynamic assessment of the pelvic floor structures without interference of the endocavitary transducer.[45] Transperineal assessment of the anal sphincter complex can be performed in the sagittal and transverse (axial) planes. When 3D

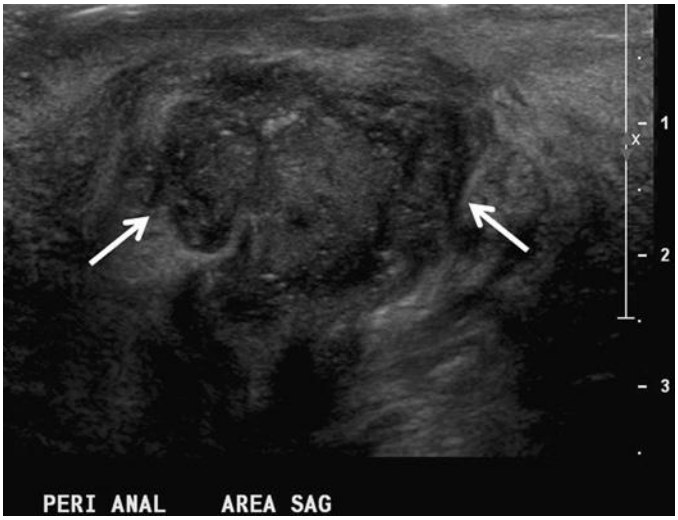

FIG 35-4 Abscess. Sagittal ultrasound image of the ischioanal fat demonstrates a complex fluid collection (*arrows*) consistent with perianal abscess.

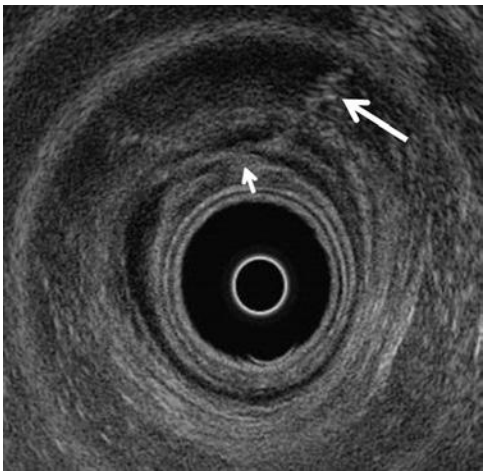

FIG 35-5 Fistula. Endorectal axial ultrasound image showing disruption of the anterior aspect of the external anal sphincter highlighted by echogenic air bubbles (*long arrow*). The fistula extends into the intersphincteric space but not through the hypoechoic internal anal sphincter (IAS). However, the IAS appears disrupted anteriorly at the 11 to 12 o'clock position (*short arrow*).

sonography is used to image the anal sphincter complex, the transducer is oriented toward the anal canal. Postprocessing of the captured 3D volumes then allows detailed evaluation with thin-slice utility (Fig. 35-6).

Using the transperineal technique, the IAS and EAS can be assessed, and the integrity of the PRM can be evaluated. With the transperineal approach, the mucosal folds of the anal canal can be visualized; they are not seen on endoanal imaging because the inserted transducer flattens the folds of the anal mucosa. The stellate-appearing normal folds of the anal mucosa on transperineal imaging have been referred to as the *mucosal star*.[46] Asymmetry in these folds sometimes helps identify disease. Similar to the sonographic findings on endoanal imaging, the appearance of the transverse anal sphincter complex is different, depending on the level of imaging. Some studies suggest that anatomic assessment of the normal anal sphincter is comparable with endoanal and transperineal techniques.[47] Although studies have

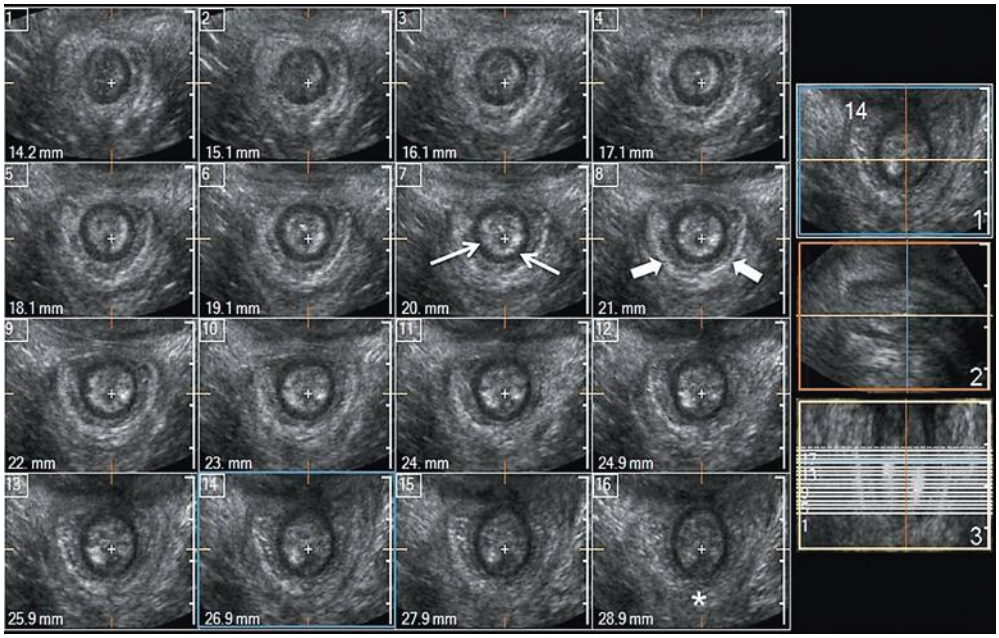

FIG 35-6 Multiplanar three-dimensional transperineal ultrasound image of the anal canal. Multiple axial images of the anal canal depicting the cross section of the anal canal structures from the caudal (1) to the cranial (16) sections. The cranial images show absence of the anterior portion of the external anal sphincter at the level where the puborectalis muscle sling (*asterisk*) is normally visualized behind the anal canal (*asterisk*). The internal anal sphincter (*thin arrows*) and external anal sphincter (*thick arrows*) are well visualized on the crosshair at the midlevel of the anal canal.

suggested good agreement in detection of anal sphincter defects,[48] others report inferior sensitivity of the transperineal approach.[49] In the authors' experience, endoanal sonography is superior to 2D transperineal sonography, unless 3D transperineal sonography is additionally performed.

Pelvic Floor Sonography

Over the past 2 decades, many authors have investigated the usefulness of sonographic assessment in women with POP and urinary incontinence or urinary symptoms. Despite the many reported techniques and approaches, pelvic floor sonography still plays a limited role in the investigation of pelvic floor disorders, and thus there are no standardized indications, terminology, and techniques. In this section, the most common techniques and indications will be summarized. The most commonly utilized protocols assess pelvic floor structures and pelvic floor muscle anatomy, integrity, and function as well as dynamic assessment of the pelvic floor structures with the transperineal or translabial approach. Other indications for pelvic floor sonography include assessment of urethral diverticula (sometimes with a transvaginal approach), surgically implanted mesh, and residual urine volume. Many studies have explored the use of 2D and 3D sonography for evaluation of women with pelvic floor symptoms. However, the exact role of pelvic floor sonography is still under investigation.

Women are usually scanned in the dorsal lithotomy position.[50] However, some investigators use the left lateral decubitus position.[51] The most common method for ultrasound evaluation of the pelvic floor is tranperineal sonography. Transperineal sonography encompasses two distinct techniques: the translabial technique, which uses a curved array transducer positioned on the labia majora or the perineum,[52] and the transintroital[50] technique, which uses a transvaginal transducer placed on the perineum or just within the vaginal introitus. Depending upon equipment availability, goals, and experience of the sonographer 2D, 3D, or 4D imaging is used. Imaging can be obtained under resting or dynamic conditions, during maximal strain (Valsalva maneuver), and with pelvic floor muscle contraction (Kegel exercise). Assessment can include a sagittal view of the pelvic floor viscera to localize the urethra, bladder, urethrovesical junction, vaginal walls, uterus, and anorectum, as well as volume imaging to assess pelvic floor hiatus and muscle anatomy, integrity, and function. Evaluation of the urethrovesical angle and anorectal angle can be performed under dynamic conditions.

The midsagittal view of the pelvic floor anatomy helps identify the relative location of the bladder and the urethra, the vagina, and the anorectum (Fig. 35-7). From this view, the posterior urethrovesical and anorectal angles can be assessed. The posterior urethrovesical angle or urethrovesical junction is measured by creating a perpendicular line from the x-axis on the image and following this line to the margin of the bladder base.[53] The anorectal angle is measured at the cross section of the line designating the longitudinal axis of the anal canal and the line along the posterior border of the rectal wall (Fig. 35-8). These measurements can be performed at rest and with dynamic conditions of pelvic floor muscle contraction and strain.[51] The dynamic displacement of the anorectal angle can provide visual biofeedback for PRM and levator ani activity, which can enhance proper muscle biomechanics and is readily accepted by women.[54] In the sagittal view, the perimeter of the PRM is measured as a line that connects the posterior margin of the pubic symphysis and the anorectal angle and is used to assess the dynamic function of the PRM during contraction.[52] Puborectalis activity can be measured as the difference between the "rest" and the "squeeze" measurement. The muscle usually contracts and moves anteriorly and cephalad during contraction.

Transperineal 3D sonography of the pelvic floor has the advantage of improved visualization of the entire pelvic floor hiatus or anal sphincter complex. The 3D images can be captured using either a curvilinear or transvaginal transducer placed on the perineum or labia. To optimize 3D imaging, the sagittal view should include the pubic

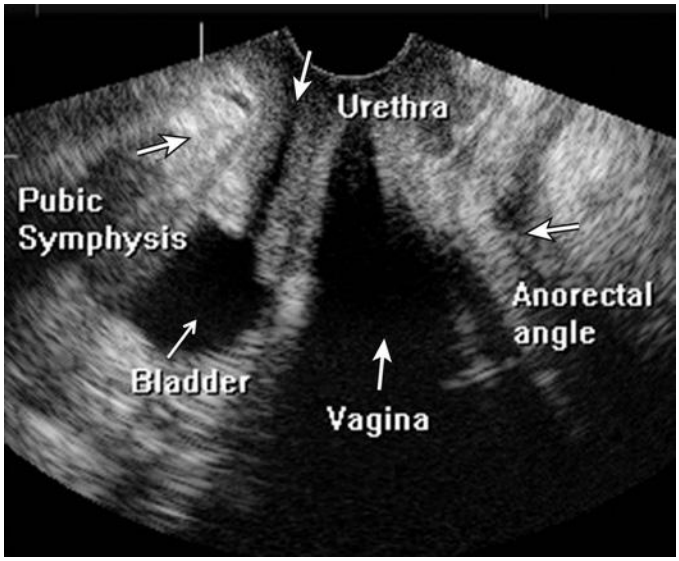

FIG 35-7 Normal pelvic floor anatomy visualized on the sagittal plane during transperineal ultrasound imaging. Annotated normal sagittal reconstructed image of three-dimensional transperineal ultrasound shows the key structures that are evaluated by this technique. The osseous structures such as the symphysis are echogenic (*white*) whereas the fluid-filled bladder is anechoic (*black*). Gas in the vagina creates posterior shadowing, which may partially obscure structures.

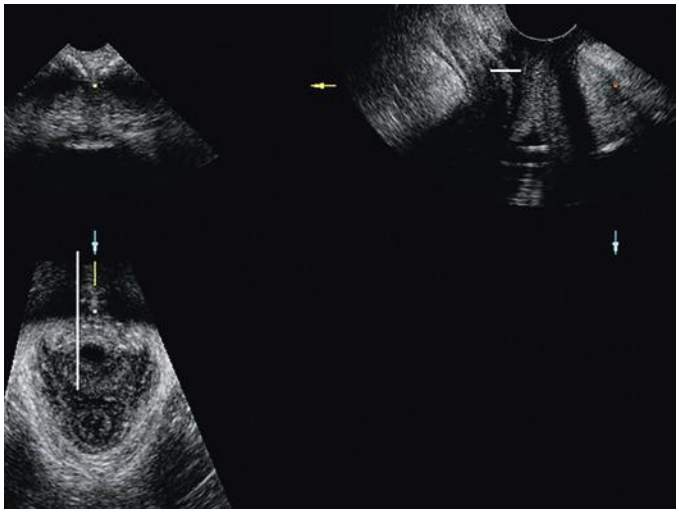

FIG 35-8 Selection of sagittal imaging plane for hiatus measurement. The hiatal dimensions can be measured in the anteroposterior diameter with a line connecting the pubic symphysis to the anorectal angle. This measurement has been shown to shorten with pelvic floor muscle contraction (Kegel exercises).

symphysis and the anorectal angle because it is on this transverse plane that the pelvic floor hiatus (levator hiatus) is described[8] (Fig. 35-9).

Pelvic Floor (Levator) Hiatus and Pelvic Floor Musculature

Injury to the levator muscles can be seen either as an avulsion found at the point of muscle insertion onto the inferior pubic ramus or as a tear along muscle fibers. These injuries are possible consequences of overstretching of the levator ani muscles during the second stage of labor when the fetus travels through the birth canal. Levator muscle injuries can occur in 10% to 36% of women at the time of their first delivery. There is no agreement on classification of these muscle injuries.[55,56] The most common injury related to childbirth is an avulsion injury of the insertion of the puborectalis (or pubvisceralis) muscle onto the pubic ramus[57] (Fig. 35-10).

A variety of studies have assessed pelvic floor morphologic changes related to vaginal delivery and the possible consequences of these changes on future symptoms. Dietz and Lanzarone[58] showed that in a third of women delivering vaginally, avulsions were associated with stress urinary incontinence at 3 months postpartum. Further data from the same group[59] suggest that levator muscle trauma is associated with prolapse of the anterior and apical compartment, but not with bladder dysfunction or urinary incontinence. They also demonstrated that a larger levator hiatus was correlated with POP. Research analyzing a large retrospective cohort suggested that levator ani avulsions are associated with prolapse in women with previous pelvic surgery.[60] Furthermore, some studies suggest that levator avulsion is a predictor of prolapse recurrence after surgical correction of prolapse.[61] Limited reports regarding attempts to surgically repair levator ani muscle avulsions have not been shown to reliably resolve associated pelvic floor disorders or improve symptoms.[61,62] This indicates that restoration of anatomy does not always reconstitute function.

Urinary Incontinence

Pelvic floor sonography has been used to evaluate women with stress urinary incontinence to assess pelvic floor muscle contraction, urethral anatomy, and bladder neck position before and after incontinence procedures and to evaluate implanted materials used to treat stress urinary incontinence. Sonographic assessment of the anatomy and physiology of the urinary tract can provide insight into the pathophysiology of urinary incontinence. There have been many studies reported using sonography to assess women with urinary incontinence; however, there are no definitive studies on normal female sonographic anatomy of the lower urinary tract. With translabial or transperineal sonography the urethra appears in cross section as a hypoechoic structure surrounded by an echogenic layer representing the urethral muscularis and the sphincter. On sagittal view, the urethra usually courses behind the pubic symphysis. Tunn and coworkers[63] suggested measuring the retrovesical angle with transperineal sonography. This measure evaluates urethral mobility. It is usually performed with Valsalva maneuver. In some patients with urinary incontinence, urethral funneling could be observed during Valsalva maneuver and even at rest. Significant funneling correlates with poor urethral closure pressure, suggesting urethral sphincter deficiency. Khullar and associates[64] reported that women with urgency urinary incontinence and overactive detrusor had significantly thicker bladder walls, as did women with stress urinary incontinence.

Pelvic floor exercises are the mainstay of conservative measures for treatment of urinary incontinence. Bernstein and coworkers showed that pelvic floor muscle thickness and function could be reproducibly assessed by transperineal sonography.[65] He also demonstrated that pelvic floor muscles were thinner in women older than 60 years and in women with stress urinary incontinence compared with continent control subjects. After pelvic floor muscle training, all groups showed increase in muscle thickness, and 60% of women with stress urinary incontinence showed subjective and objective improvement in symptoms. Dietz and coworkers[54] used translabial sonography to provide biofeedback in teaching women to perform proper pelvic floor muscle contraction and showed that translabial sonography is a useful adjunct in pelvic floor muscle training.

Postintervention Imaging

Since the late 1990s, placement of minimally invasive slings has become a mainstay in surgical treatment of stress urinary incontinence. These

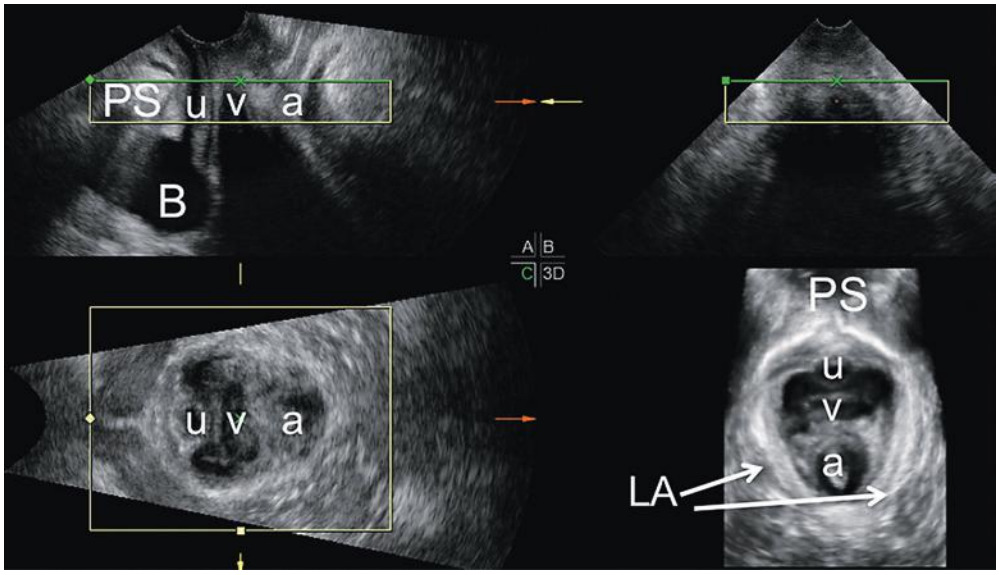

FIG 35-9 Rendered three-dimensional (3D) image of the normal pelvic floor hiatus demonstrating symmetry of the levator ani muscles. Transperineal pelvic floor 3D sonography: multiplanar view with rendered transverse plane. The four parts of the figure show the midsagittal plane (A), coronal plane (B), axial (transverse) plane (C), and rendered 3D axial (transverse) plane (D). The normal anatomic orientation of pelvic structures is shown in the midsagittal, axial, and rendered planes. The rendered axial image is taken across the plane of "smallest dimension," and the outline of the inferior pubic rami is seen below the pubic symphysis. Rendered reconstruction in an axial plane shows symmetric levator ani muscles (LA and *arrows*). a, anal sphincter; B, bladder; PS, pubic symphysis; u, urethra; v, vagina.

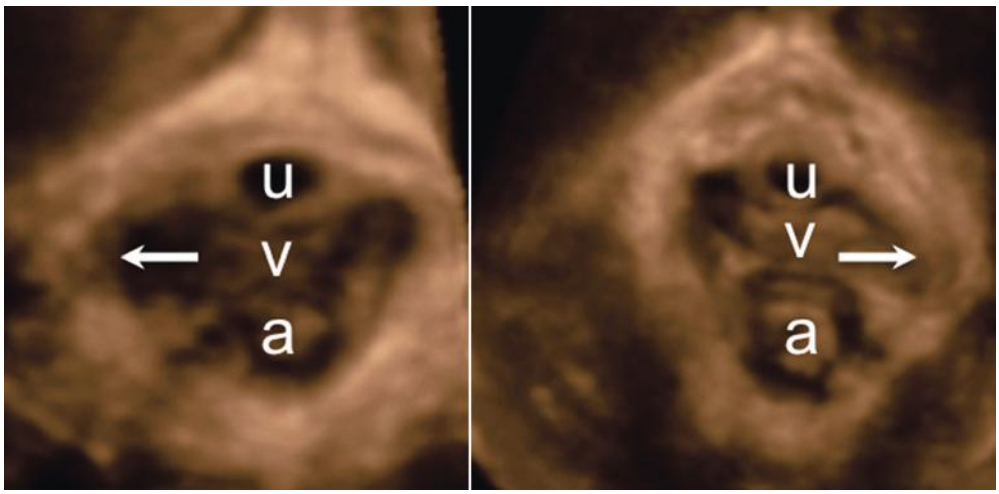

FIG 35-10 Three-dimensional (3D) transperineal ultrasound image demonstrating asymmetric hiatus with levator ani muscle avulsion. Rendered 3D transperineal transverse ultrasound image of the pelvic floor hiatus. The pronounced asymmetry of the vagina (v) is easily recognized. This asymmetry is a result of avulsion of the levator ani muscle (*arrows*) from its attachment at the pubic bone. Contrast this image to the normal appearance of the pelvic floor hiatus in Figure 35-9. a, anal sphincter; u, urethra.

slings are composed of synthetic material, most commonly prolene mesh, that is implanted around the urethra to restore anatomic support.[66] The original retropubic placement of the slings was later modified with an option of using a transobturator placement. The sling is usually placed over the midurethra; however, position may vary. The mesh is highly echogenic and can be easily visualized with pelvic floor sonography (Fig. 35-11). Using pelvic floor sonography, some researchers suggest that sling position along the length of the urethra (i.e., midurethral or in the proximal or distal third of the urethra) is not essential in restoring continence.[67] In one study, Schuettoff and associates[68] compared assessment of mesh slings with MRI and sonography. They suggested that sonography is most suited for assessment of suburethral and periurethral portions of the sling, whereas MRI is better for evaluating the retropubic portion of the mesh. Pelvic floor sonography can also demonstrate details of the relationship between the suburethral portion of the sling, the urethra, and the symphysis pubis.

For women with stress urinary incontinence and intrinsic sphincter deficiency, different types of urethral bulking agents have been used to improve continence by enhancing urethral coaptation. Transperineal

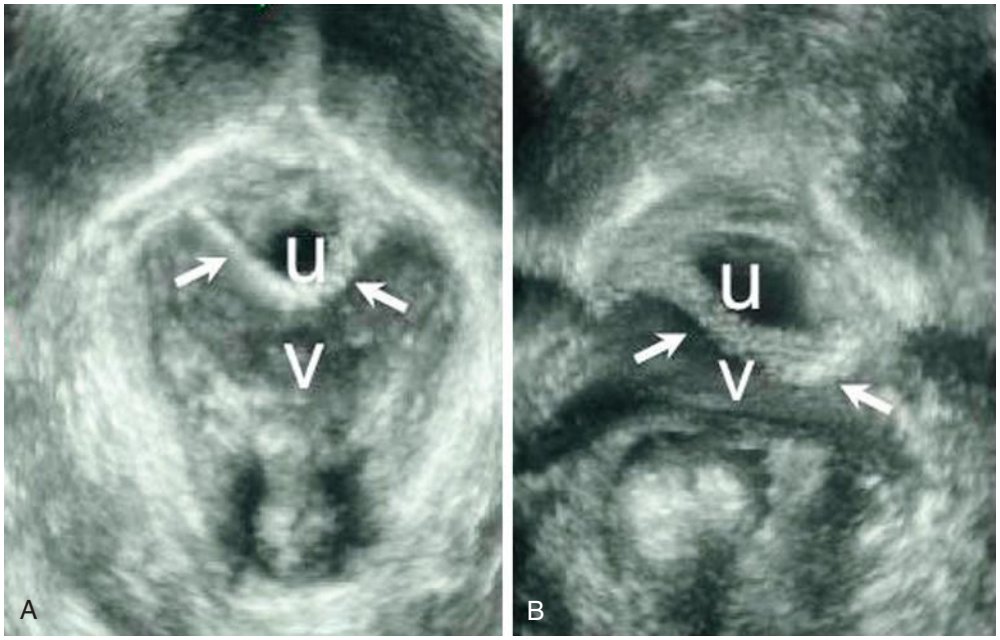

FIG 35-11 Axial (transverse) images of two types of midurethral synthetic mesh slings (*arrows*). **A,** A retropubic sling. **B,** A transobturator sling (Monarch) sling. The synthetic mesh is woven and this woven mesh-like quality is easily captured by ultrasound imaging as a highly echogenic structure. The normal anatomic landmarks are annotated on the images: u, urethra; v, vagina.

sonography has been used to optimize and guide placement of the bulking agents. Elia and Bergman found that optimal positioning of the collagen implant was less than 7 mm from the bladder neck.[69] Defreitas and colleagues used 3D transperineal sonography and concluded that circumferential distribution around the urethra achieves better continence than asymmetric distribution of periurethral bulking with collagen.[70] Poon and Zimmern used pelvic floor 3D sonography in their standard algorithm for managing incontinent patients who undergo periurethral collagen injection. In their study, if a patient had no or minimal improvement after periurethral collagen injection and sonography showed low volume retention of collagen or asymmetric distribution, the patient was offered a repeat injection in the area of deficiency. If there is no subsequent improvement in symptoms but a circumferential pattern of distribution is seen on sonography, the injection is considered technically optimal although ineffective, and the patient is offered an alternative treatment.[71]

Urethral Diverticulum

Female urethral diverticulum can be challenging to diagnose and patients may present with multiple nonspecific urinary symptoms. The most common symptoms are summarized by a triad of the "three Ds": dysuria, dribbling, and dyspareunia. Patients can also present with recurrent urinary tract infections. Anatomically, a urethral diverticulum is a herniation between the periurethral fibromuscular layer and anterior vaginal wall. Urethral diverticula are thought to be a result of repeated infection and abscess formation within the periurethral and urethral glands (Skene glands), which are usually located in the midurethra along the posterolateral wall near 3 and 9 o'clock. It can be challenging to differentiate diverticula from other vaginal cysts (like Gartner duct cysts and others). Many authors consider MRI a reference standard for diagnostic evaluation of suspected urethral diverticulum (Fig. 35-12). However, pelvic floor sonography is a more accessible technique for such assessment. Transperineal or transvaginal techniques are most commonly used. Information regarding size and number of diverticula as well as location can be determined by sonography. Characterizing the relationship to the bladder, delineating the ostium of the diverticula and even identifying stones within the lumen of the diverticulum are possible on sonography (Fig. 35-13). However, MRI often helps to delineate the connection to the urethra, which may be difficult to identify with sonography.

Pelvic Organ Prolapse

Pelvic floor sonography can be used as an adjunct in diagnostic evaluation of women with POP. However, the role of sonography in routine care for women with POP is not yet well defined. In a pilot study, Beer-Gabel and coworkers[51] used dynamic transperineal sonography to identify pelvic floor descent. Assessment of the anorectal angle was comparable to defecography, and rectoceles were easily identified. Dietz and Steensma[72] showed that rectovaginal septal defects could be easily seen on translabial sonography, but a third of women with rectoceles had no detectable sonographic abnormality. Grasso and associates[73] found good to excellent correlation of introital sonographic findings and defecography in evaluation of the anorectal angle, presence of intussusception, and rectocele. Weemhoff and colleagues[74] reported that a pelvic floor sonographic finding of intussusception was predictive of abnormal evacuation proctography. However, prediction of enterocele by sonography was poor compared with evacuation proctography.

POP is clinically measured by a widely accepted technique called the Pelvic Organ Prolapse Quantification (POP-Q)[75] system. In this system the descent of each compartment of prolapse—anterior, posterior, and apical—is measured. A splint-speculum is used to aid in isolation of each of the compartments. This measurement is done while the patient is in the low lithotomy position at maximum Valsalva using the plane of the hymen as a reference. Several studies have attempted to correlate clinical findings on POP-Q to the sonographic findings, but the reference for measurement on sonography is different from the reference that is used in POP-Q. For sonographic

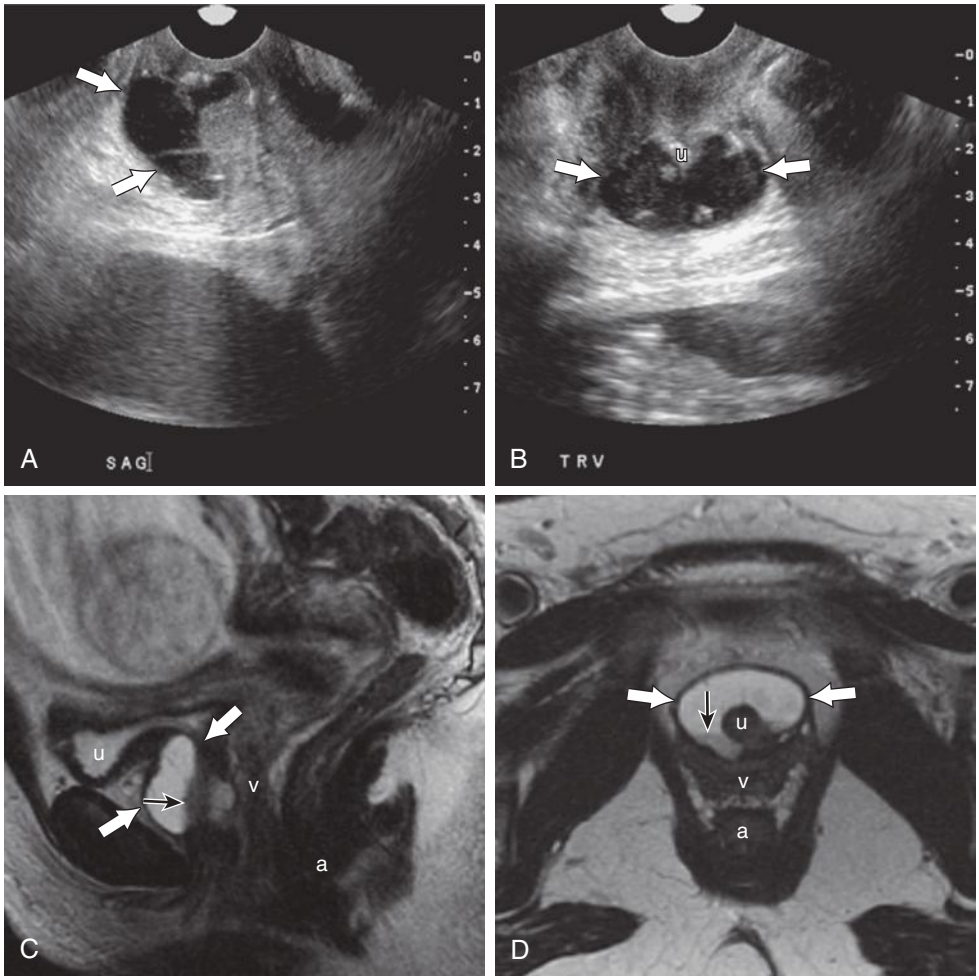

FIG 35-12 Urethral diverticulum on ultrasound imaging and magnetic resonance imaging. Sagittal (**A**) and axial (**B**) gray-scale ultrasound images demonstrate anechoic collection (*white arrows*) surrounding the urethra. Sagittal (**C**) and axial (**D**) T2-weighted images of the pelvis show a high signal intensity horseshoe-shaped cystic lesion (*white arrows*) surrounding the urethra (u). Note layering dependent debris (*black arrow*). The location and shape are typical of a urethral diverticulum. a, anal sphincter; v, vagina.

measurements of prolapse, the reference line is usually drawn parallel to the inferoposterior margin of symphysis pubis[76,77] (Fig. 35-14).

Lone and coworkers[78] assessed the relationship between validated POP-Q measures and assessment made by dynamic 2D transperineal sonography. In this study only women with prolapse at or above the hymen were included for analysis. They also adjusted for reference points to minimize the difference between the reference lines used with POP-Q and sonographic measures and found that the proportion of correctly assessed prolapse was around 60% for the anterior and posterior compartments and only 33% for the apical compartment. In addition to difference in reference lines, another possible explanation for this discrepancy is the use of a speculum to examine each compartment in the clinical assessment of prolapse with the POP-Q system.

DYNAMIC PELVIC FLOOR MAGNETIC RESONANCE IMAGING

As noted in the introductory section, MRI can provide exquisite anatomic and dynamic detail of pelvic floor disorders and is widely used for evaluation of these patients. However, the higher costs of these studies and lack of outpatient office availability can provide barriers to the consideration of MRI relative to ultrasound imaging. There are also significant differences in the protocols for the acquisition of images and the diagnostic criteria between the two techniques.

Technical Considerations

Upon arrival to the MRI suite, the patient is dressed in a gown and instructed to empty the bladder and bowel. There is usually an intrinsic short delay until images are obtained which allows partial refilling of the bladder without overdistention. The patient is escorted to the magnet after appropriate safety checks. Approximately 120 mL of sonographic gel is injected into the rectum using two catheter-tipped syringes and a short soft enema tip. This volume of gel distends the rectum, displaces rectal gas, and allows for an evacuation series to be obtained. Larger amounts of gel, up to 200 mL, have been recommended by some experts.[79] However, this may cause overdistention of the rectum. Smaller volumes may leave the patient unable to evacuate the gel during the dynamic part of the evaluation. In our experience, if an evacuation series is not planned, 60 mL of gel will provide adequate distention of the rectum.

The most basic component of the dynamic MRI examination includes a high-resolution anatomic evaluation performed with respiratory gating in the transverse (axial) and coronal planes, centered on the vagina. The images are obtained without fat saturation during

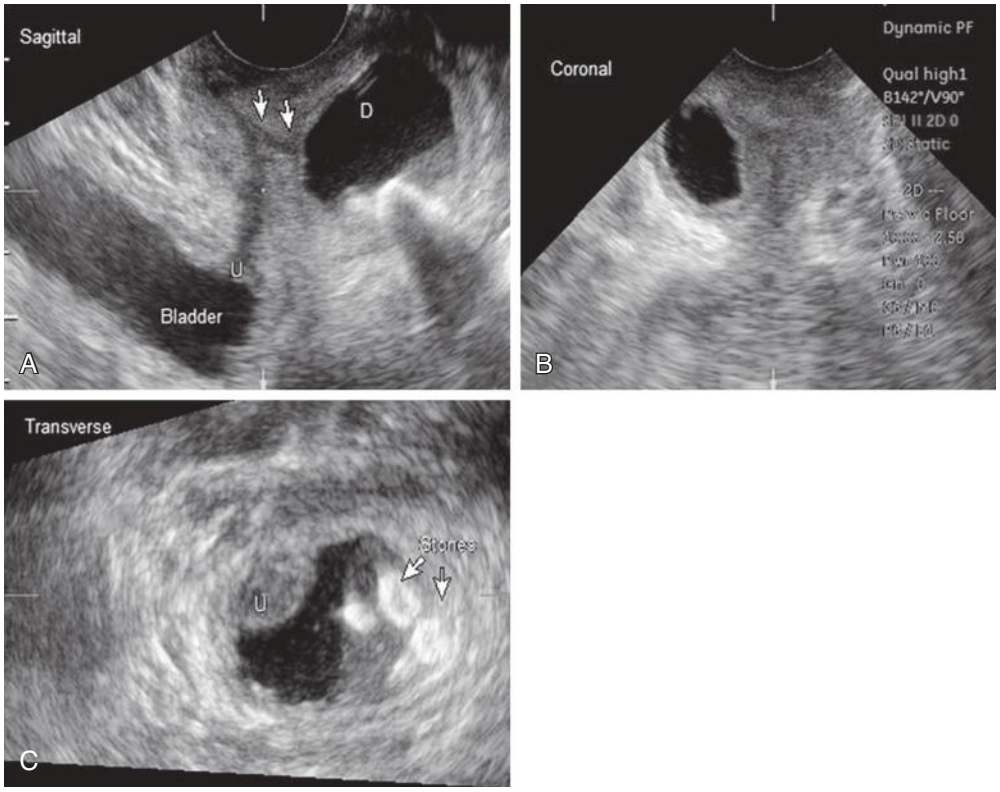

FIG 35-13 Urethral diverticulum on ultrasound imaging showing sagittal (**A**), coronal (**B**), and transverse (**C**) planes. Multiplanar ultrasound images showing a large diverticulum (D) with multiple echogenic stones (*arrows* in transverse image) and dependent layering debris. Urethra (u) and fluid-filled anechoic bladder are seen. The hypoechoic diverticular tract is also well visualized on the sagittal image (*arrows*).

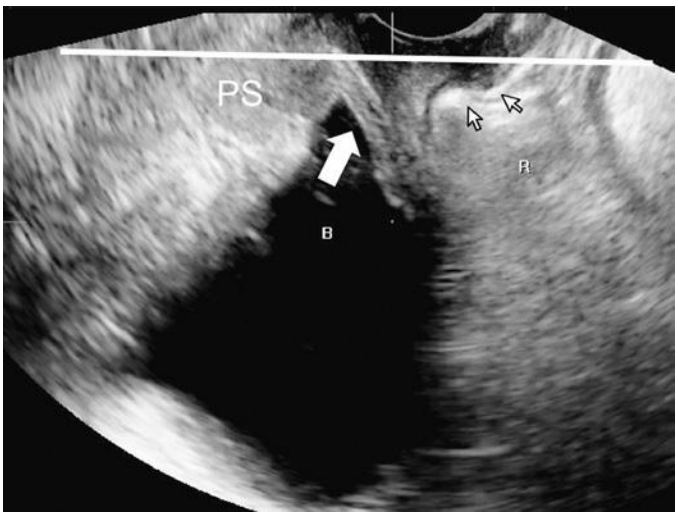

FIG 35-14 Transperineal ultrasound image in the sagittal plane demonstrating anterior and posterior vaginal wall prolapse (cystocele and rectocele). The thick arrow indicates the cystocele and the two smaller arrows point to the rectocele. The reference line for measurement of prolapse is drawn parallel to the inferior edge of the pubic symphysis. B, bladder; PS, pubic symphysis; R, rectum.

quiet breathing within 4 to 5 minutes. The technologist should ensure that the phased array coil is centered over the low pelvis so that the amount of detected signal at the introitus is not limited. The transverse images should be performed low enough that only the upper thighs are on the lowest images beyond the perineum. Coronal images are centered on the vagina and include the femoral heads laterally with craniocaudal coverage from the introitus to at least the sacral promontory. The patient should be carefully coached that any movement can degrade the study.

Using the transverse series as a reference, a set of sagittal 10-mm thick images are obtained covering the pelvis between the femoral heads and centered on the lower vagina. From these, a single image can usually be identified that contains the important structures, including the symphysis, urethra, bladder, vagina, rectum, and coccyx. This plane is repeated as a single image in 0.6 to 1.0 second, at rest, and then is subsequently repeated during maximal strain. Balanced steady-state free-precession, half-Fourier acquisition single-shot turbo spin echo, or balanced fast field echo sequences can be used, but one study favors TruFISP technique (true fast imaging with steady-state precession) over half-Fourier acquisition single-shot turbo spin echo.[80] The patient must be adequately coached to strain as if having a bowel movement and to push downward through the pelvis toward the feet. The patient should be reassured that some leakage is expected and even preferred for study quality. If the first strain image appears weak, repeated coaching may be needed. This should be repeated with at least two additional strains if an evacuation series is not performed.[81] Lastly, a cine sequence of the same 10-mm thick slice should be obtained every second for 30 to 60 seconds as the patient evacuates rectal contents into a group of peripads. We instruct the patient to begin when she hears the third sound of the repetitious "knocking" scanner sounds so that we initially have images at rest. Some sites will then repeat the axial high-resolution at-rest images to evaluate recoil or persistence of the displacement of the pelvic structures, but this is not widely performed. If there is concern for obstructed defecation symptoms, the strain sequences are followed by squeeze or Kegel exercise sagittal images to evaluate the anorectal angle.

Uncertainty still remains regarding many aspects of the MRI examination protocol. Intravenous contrast agent is not typically administered. Some investigators recommend intraluminal contrast material to opacify the vagina and small bowel. Although small bowel contrast could aid in detection of an enterocele, it is not widely given because the bowel is well seen without it. Vaginal gel can provide clearer definition of the anterior and posterior vaginal walls in research, but is not widely used as this level of detail is not needed in routine clinical evaluation for surgery.

Most MRI units image the patient in the supine position, which promotes less efficient straining than the seated position on a defecogram commode. However, a small study by Fielding and associates reported no lack of study success using the supine position when there is adequate coaching and strain.[82] Another study showed more laxity in the sitting position, but no difference in detection of clinically relevant abnormalities[83]; whereas another study using orthostatic positioning in an open MRI did detect additional prolapse relative to the supine position.[84] Regardless of positioning, inclusion of evacuation phase cine images has become standard of care. Studies have shown significantly higher sensitivity for abnormalities beyond strain imaging alone,[85] but threshold MRI criteria for evacuation imaging cannot be assumed to mirror strain imaging and have not been defined in the literature. The dynamic images at 10 mm can be easily obtained with any current scanners, but the detail and image quality of the axial and coronal sequences can be improved by use of a 3-tesla (T) scanner over a 1.5-T unit. Evaluation of submuscle groups between the magnet strengths has not been fully evaluated, but using a 3-T magnet could provide benefit in this area as well.

Imaging with an external phased array coil provides poor definition of small tears of the IAS and EAS. These tears can be better imaged with placement of a coil within the anal canal. However, the endoanal coil can distort the pelvic anatomy and is less well tolerated by patients than routine MRI.

Anatomy and Magnetic Resonance Imaging Reference Lines

Normal Coronal and Axial Planes

As noted in earlier sections, the pelvic floor is composed of a combination of muscle groups. The three major muscles anchor anteriorly onto the symphysis pubis. The pubovaginalis muscle courses posteriorly around the vagina, whereas the PRM courses posteriorly around the rectum for support. The iliococcygeus muscle forms an oblique sheet of muscle that tracks posterior and cranially to insert broadly onto the inner surface of the iliac wings. Each of these muscles can be separately seen on axial images and should be symmetric right to left. Symmetric thinning may be a normal finding if the normal insertions are intact, and this can be a source of error in MRI interpretation. Typically, the levator muscles will measure 4 to 5 mm in thickness at the level of the midvagina. If the support structures around the vagina are intact, the vagina should have a symmetric appearance on transverse images, often with a butterfly or H shape. The anal sphincter will be best seen on either the axial or coronal series, depending upon its orientation relative to the imaging plane. The circular fibers of the internal sphincter subjacent to the mucosa will be continuous and symmetric. A thin layer of intersphincteric fat coats the IAS and separates it from the EAS muscles, which may be more discontinuous and difficult to fully visualize even in the normal patient.

Pubococcygeal Line Versus Midpubic Line

Although the pelvic floor is not a linear structure and has more of a bowl shape, a reference point is needed on imaging to allow for the determination of abnormal from normal. On sagittal imaging, two reference lines are most commonly used[86] (Fig. 35-15). The pubococcygeal line (PCL) is drawn from the inferior edge of the symphysis pubis to the last vertically oriented joint of the coccyx and provides a reference point by which to measure the location and vertical movement of mobile organs. The last vertical joint is chosen because the horizontal tip of the coccyx may move during strain or evacuation, which would alter the measurements. The second most common reference line is the midpubic line. It is drawn on the sagittal view through the pubic bone long axis from the upper anterior pubis through the inferior posterior edge of the pubis, and the line is continued caudally through the anterior pelvic tissues. Proponents of this technique favor its better approximation of the hymen, even though it has only moderate correlation to clinical examination.[87]

Normal Sagittal Plane

In the sagittal plane, the symphysis, neck of the urinary bladder, bladder neck, cervix, vagina, low rectum, and coccyx should all be visible on a single 10-mm thick image (Fig. 35-15D and E). A series of sagittal images is initially obtained to visualize the entire region and to assess for additional findings, but most of all to localize the optimal plane for dynamic imaging. The normal bladder neck should be no more than 10 mm below the PCL at rest or during strain.[88] The cervix should remain above the PCL at rest and during strain.[89] The posterior plate (posterior wall) of the rectum should nearly parallel the PCL at rest and drop no more than 10 degrees below the PCL with strain.[90] The hiatus should remain normal in size. This is represented as the H-line drawn on sagittal images from the inferior posterior edge of the symphysis to the posterior margin of the circular anal fibers. For evaluation of craniocaudal pelvic descent, the M-line is drawn from these fibers to the PCL such that the line forms a right angle with the PCL. An H-line measuring less than 5 to 6 cm and an M-line less than 2 cm are considered normal.[79,90] The change in urethral angle relative to a vertical reference (urethral rotation) from rest to strain should measure less than 30 degrees.[91]

Abnormal Findings on Magnetic Resonance Imaging

Pelvic floor disorders are all somewhat interrelated but fall into three main groups: incontinence, obstructed defecation, and prolapse. Incontinence may involve unplanned loss of urine spontaneously or with cough or strain. This is usually related to an anterior compartment abnormality. For anal incontinence, there may be loss of flatus or feces, and this is most typically attributed to posterior compartment or sphincter abnormalities. Obstructed defecation describes the abnormal coordination of muscle relaxation during attempted defecation that prevents adequate emptying of the rectum, whether or not associated with rectocele. Prolapse describes a constellation of clinical findings that most commonly involve a bulge or sensation of fullness in the perineum and vagina. It should be noted that there is significant overlap between the signs/symptoms of incontinence and prolapse in this patient population.

Anal Incontinence

Incontinence is a multifactorial problem that may specifically involve the anal sphincter complex or can be associated with POP. The imaging of incontinence involves both static and dynamic pelvic floor techniques. With regard to the sphincter, the concentric anal sphincter fibers are most commonly disrupted by prior childbirth, especially if there has been an episiotomy. This disruption can be seen with high-resolution MRI using distention of the sphincter with an endoanal coil. In the short-axis view of the sphincter, a tear will be detected as a focal linear or geographic signal abnormality in the otherwise T2-weighted

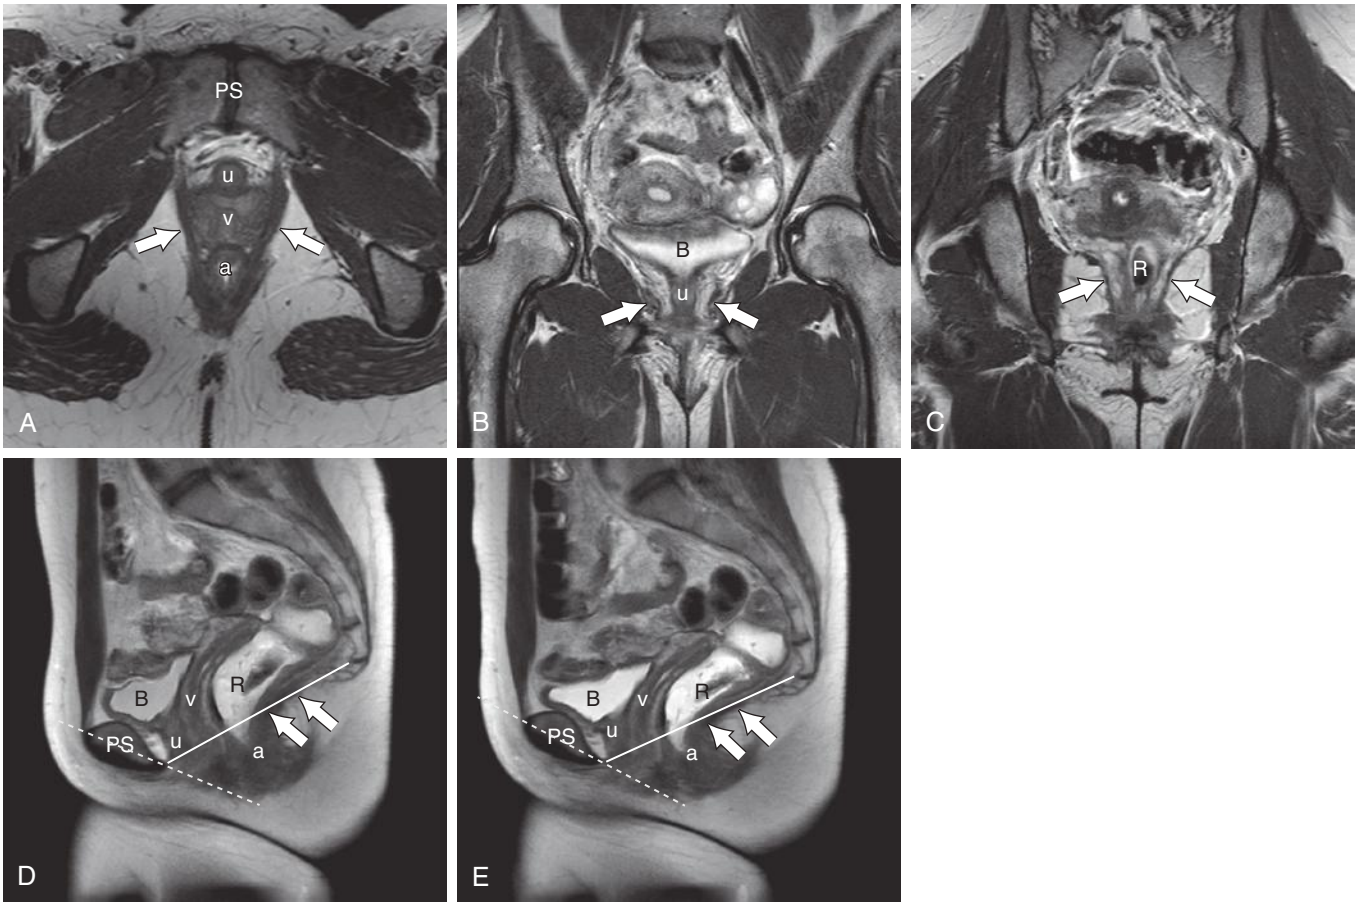

FIG 35-15 Normal pelvic floor structures on magnetic resonance imaging (MRI). Dynamic T2-weighted MRI of asymptomatic normal subject. **A,** Axial T2-weighted image shows symmetric appearance of bilateral levator muscles (*block arrows*) inserting onto the pubic bones. **B,** Coronal image at the level of the insertion shows symmetric levators as well. **C,** Coronal image at the level of the rectum shows normal levators (*arrows*). **D,** Sagittal T2-weighted image shows normal position of the bladder, vaginal apex, and posterior plate of the rectum (*block arrows*) above the pubococcygeal line (PCL), a representation of the pelvic floor. **E,** With strain, there is little descent of these organs, which remain above the PCL line (*block arrows*). a, anal canal; B, bladder; dotted line, midpubic line; PS, pubic symphysis; R, rectum; u, urethra; v, vagina.

hypointense muscle. However, for standard MRI without an endocoil, the sensitivity and interreader reliability for detecting IAS or EAS tears are low.[92]

On the other hand, research using dynamic MRI has documented a strong correlation between incontinence and tear of the levator muscles at the point where they insert onto the symphysis bone.[93] In this multireader study with good interobserver variability, muscle loss in this region was associated with incontinence. Bilateral partial levator tears correlated with incontinence. Even unilateral disease correlated with symptoms if the tear was complete (Fig. 35-16). If complete, the adjacent paravaginal fat may asymmetrically bulge into the adjacent fat to help identify the abnormality. Focal thinning without bulge may be harder to appreciate, and evaluation should use both axial and coronal images to detect asymmetry of muscle volume. Asymmetric focal thinning of the levator muscles is less challenging to detect than differentiating neuromuscular injury with diffuse muscle atrophy from normal thin muscles. It should be noted that levator atrophy can be present in a subset of nulliparous asymptomatic women, so care should be taken with the diagnosis if thinning is symmetric.[94]

Incontinence is a muscular and neuromuscular abnormality, but osseous structures may contribute to risk. Pelvimetry has been used to predict risk of difficult labor for decades. In a prospective trial, it has been shown that women with a wide pelvis as measured by intertuberous diameter are at increased risk for urinary incontinence.[95] Similar data suggesting that a wide pelvis is associated with urinary incontinence were again reported in a subsequent study,[96] but another study found no association.[97] A deep sacral curve has been associated with fecal incontinence, possibly due to abnormal pressure on nerves accentuated by this anatomic variation. Most recently, a short anteroposterior diameter of the pelvis on transverse MRI has been shown to be associated with severe levator ani defects.[98] Potential mechanics have been theorized, but the literature in this area is still incomplete and evolving.

Perianal Fistulas

MRI for the evaluation of perianal fistulas in the setting of inflammatory bowel disease differs in technique and diagnostic considerations in comparison to other anal sphincter imaging. As noted earlier, there are a variety of fistula types to be considered in this disease process, and MRI can provide exquisite detail of fistulous tracts. Dynamic sequences are not required for imaging of perianal fistulas or abscesses, so acquisition times may be longer to provide better signal to noise and spatial resolution. Multiplanar T2-weighted sequences are the mainstay of the technique. A combination of series without fat

FIG 35-16 Right levator ani muscle tear with vaginal asymmetry. Axial TruFISP (true fast imaging with steady-state precession) image of the low pelvis shows a normal left levator muscle, but there is asymmetric bulging of the vagina with disruption of the right levator muscles (*arrow*). a, anal canal; u, urethra; v, vagina. (Courtesy Gaurav Khatri, MD, UT Southwestern Medical Center.)

saturation for better anatomic detail and with fat saturation to highlight the presence of fluid signal is commonly applied. After precontrast T1-weighted images, intravenous contrast is frequently used with subsequent multiplanar T1-weighted sequences to evaluate for enhancement and acute inflammation of the fistulous tracts. Abscesses with high T2-weighted signal intensity fluid and low central T1-weighted signal with surrounding hyperemia are easily identified (Fig. 35-17). Inflammatory tracks into the high pelvis can be well characterized by MRI but may be challenging with sonography.

Obstructed Defecation

Constipation and incomplete emptying of the rectum is a common presentation of pelvic floor disorders. These patients often present to a gastroenterologist or surgeon who may not be familiar with pelvic floor imaging. The findings on MRI are focused around dyssynergy of pelvic floor relaxation and detection of prolapse. In one series of patients with obstructed defecation symptoms, MRI detected a wide variety of abnormalities, and MRI changed the treatment decision in 20% of symptomatic patients.[99] In one cause of obstructed defecation, the normal relaxation of the anal sphincter is impaired, and there is often paradoxic elevation of the posterior plate with acute angulation of the posterior rectal wall relative to the posterior wall of the anus. This is best visualized on the sagittal strain and evacuation sequences, but there is no universal diagnostic MRI criterion in the literature. The normal anorectal angle range is likely between 94 and 127 degrees, depending on the source in the literature.[79] In general, the normal anorectal angle should increase by 15 to 20 degrees during evacuation. If the angle decreases during evacuation, this is consistent with the diagnosis of obstructed defecation.

Obstructed defecation may be complicated by rectal prolapse. During strain or evacuation attempts, the mucosa or full thickness of the rectal wall may invaginate into the distal lumen of the rectum. MRI provides excellent differentiation between mucosal and full-thickness intussusceptions.[100] This differentiation is clinically important as full-thickness invagination is more likely to be symptomatic and requires a more extensive surgical procedure for correction. Extension of the prolapsed mucosa into the anal canal may be termed rectal intussusception, and there may be prolapse of the anal mucosa external to the skin in severe cases. However, even mucosal prolapse without extension through the anus can result in incomplete rectal evacuation. Treatment may include stapled transanal resection, transanal Delorme procedure, multicompartmental repair, biofeedback, or conservative management.[99,101]

Prolapse

Prolapse can occur in any of the three compartments of the pelvis and frequently is multicompartmental (Fig. 35-18). The anterior compartment includes the bladder and urethra. Anterior prolapse includes cystocele, urethral hypermobility, and urethrocele. Each of these is best diagnosed on the sagittal dynamic sequences with strain or evacuation. Cystocele is diagnosed when the bladder neck descends to a level 1 cm or more below the PCL (Fig. 35-19). It is mild when less than 3 cm, moderate when greater than 3 to 6 cm, and severe when greater than 6 cm below the PCL.[102] It is often accompanied by rotation of the urethra from the normal craniocaudal orientation to a more horizontal path beneath the symphysis pubis. Urethrocele is diagnosed as hypermobility of the urethra with movement more than 1 cm below the PCL. Abnormal rotation of the urethra is defined as greater than 30 degrees from baseline angle[103] (Fig. 35-20). Abnormal urethral rotation helps in the diagnosis of anterior compartment prolapse, but it does not alter the management beyond other MRI findings such as bladder descent below the PCL.

Apical compartment prolapse often is concomitant with either anterior or posterior compartment involvement. It is diagnosed on the sagittal dynamic images as prominent descent of the cervix or vagina below the PCL.[104] One study has classified mild apical prolapse as 1 to 2 cm, moderate as 2 to 4 cm, and severe more than 4 cm below the PCL.[80] There may be a combination of elongation of the vagina and anterior rotation of the posterior vaginal wall. When there is a levator muscle tear on axial images as part of apical compartment disease, the vagina may distort and protrude laterally into the paravaginal space. This may be detected as vaginal asymmetry on the axial images. Likewise, an enterocele may protrude into the paravaginal region, representing an apical compartment disorder, or it may also involve the posterior compartment between the vagina and rectum (Fig. 35-21). There is clinical significance of these findings because they may require added complexity of the repair procedure, which may include mesh support.

The posterior compartment includes the rectum and anal sphincter complex. The most common posterior compartment prolapse is the rectocele. When rectal support is compromised, the rectum may bulge anteriorly into the vagina on clinical examination. On sagittal strain or evacuation images, this is represented as a bulge of the anterior rectal wall greater than 2 cm perpendicular beyond the expected course of the anterior wall of the anal sphincter. Some researchers have classified mild rectocele as 2 to 4 cm, moderate 4 to 6 cm, and severe more than 6 cm.[80] Often an anterior rectocele will fill with gas if the patient is supine (Fig. 35-22), but this should not limit its detection.

Posterior compartment laxity is defined as abnormal descent of the rectum during strain. In normal individuals, there should be minimal descent of the posterior plate during strain.[105] When the posterior plate (wall) of the rectum descends more than 15 to 20 degrees below the PCL using the junction of the two lines at the coccyx as the intersection, the diagnosis is suggested.[80] This can be diagnosed also by descent of the circular fibers of the anus. However, a 2014 study found at least

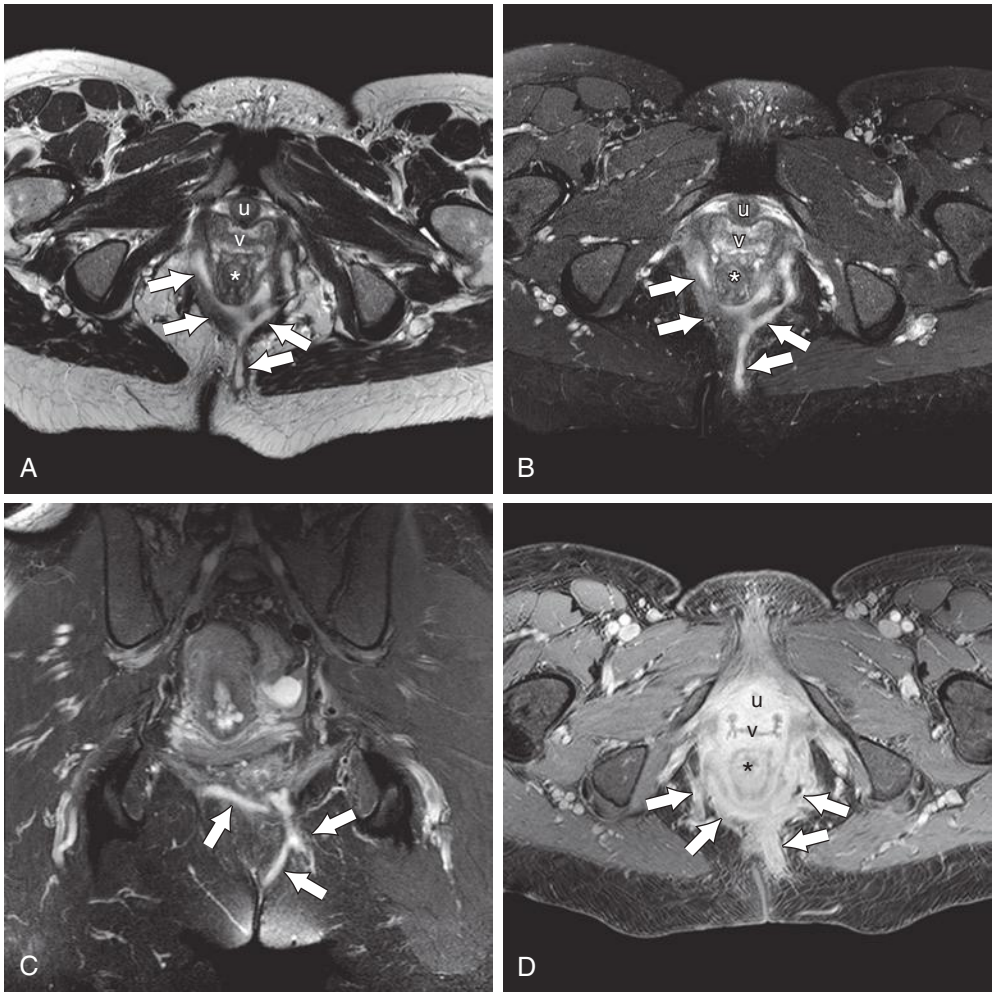

FIG 35-17 Perianal fistula on magnetic resonance image. Axial T2-weighted images without (**A**) and with (**B**) fat saturation show a complex fistulous tract (*arrows*) partially encircling the internal anal sphincter (*asterisk*) (on T2-weighted sequences, fluid appears bright). The fistula tracks posteriorly, which may be difficult for ultrasound imaging to characterize. Coronal series (**C**) shows the cranial extent of the inflammation, which may also be difficult to detect by ultrasound imaging. On postcontrast T1-weighted series (**D**), there is bright enhancement of the inflammatory tracts without drainable abscess, and the tracts extended to the skin. u, urethra; v, vagina.

moderate posterior descent relative to the PCL in 25% of asymptomatic patients,[106] so the diagnosis should be questioned in the absence of posterior compartmental symptoms or clinical signs.

When the anus descends posteriorly, the pelvic hiatus is enlarged. This pelvic hiatus or the enlargement is represented as the H-line drawn on sagittal images from the inferior posterior edge of the symphysis to the posterior margin of the circular anal fibers. For evaluation of craniocaudal descent of the pelvic floor, the M-line is drawn from these fibers to the PCL such that the line forms a right angle with the PCL. An H-line greater than 6 cm and an M-line greater than 2 cm are considered abnormal for pelvic floor dysfunction.[79] A larger hiatus suggests the need for surgical repair, but the clinical significance depends upon the severity of patient symptoms in association with these imaging findings.

Limitations of Magnetic Resonance Imaging

Pelvic floor MRI is still a maturing field of imaging, and there are times that the technique may not provide optimal or complete diagnosis of this complex constellation of disorders. Claustrophobia because of the small imaging acquisition space has been a persistent concern for standard MRI, and open MRI units may not provide equivalent or adequate spatial resolution for visualization of small muscle groups in the deep pelvis. Potentially, premedication of patients with anxiolytics could inhibit full strain effort, but this has not been studied. Furthermore, a medicated patient who is not fully awake and alert may be less attentive to lying still. Motion can not only directly degrade image quality, but it can also result in change of patient position such that the sagittal imaging plane no longer shows all the necessary structures during the strain or evacuation dynamic sequences.

Other limitations lie beyond the patient. Correlation of MRI findings with clinical pelvic examination performed by the gynecologist has been shown to be limited, and when the imaging does not correlate with what the surgeon feels, it lowers confidence. The PCL does not approximate the hymen, which is a landmark for clinical characterization of prolapse. Although the PCL measures downward descent, the clinical examination measures movement of structures anteriorly and inferiorly along the course of the vagina, contributing to differences between imaging and clinical findings. However, the high interobserver

FIG 35-18 Sagittal magnetic resonance image of multicompartmental prolapse. Sagittal TruFISP (true fast imaging with steady-state precession) image of the pelvis during strain shows descent of all three compartments, a common finding in pelvic organ prolapse. Cystocele (*arrow*) is greater than 2 cm below the pubococcygeal line (*solid line*). Uterovaginal decent is present, and there is abnormal descent of the posterior rectal plate (*dotted line*). B, bladder; PS, pubic symphysis; R, rectum; v, vagina. (Courtesy Gaurav Khatri, MD, UT Southwestern Medical Center.)

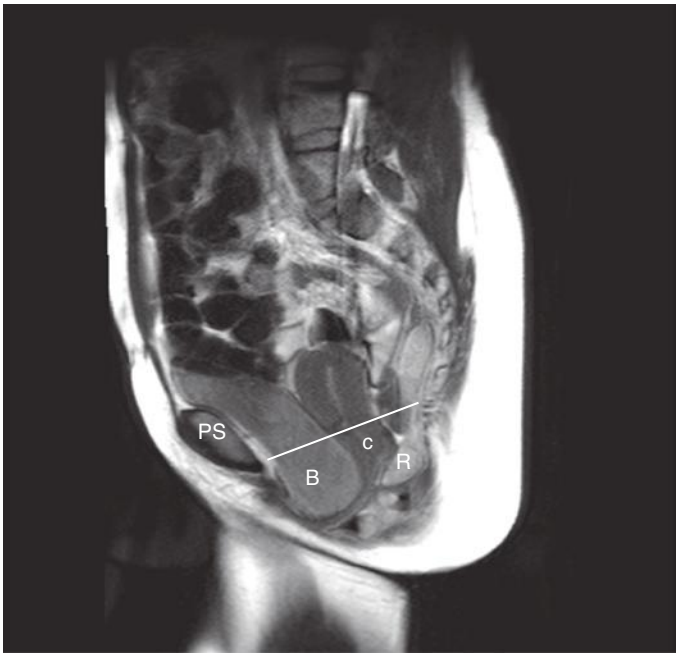

FIG 35-19 Cystocele on sagittal strain magnetic resonance image. Sagittal T2-weighted image of the pelvis during strain demonstrates anterior compartment descent of the urinary bladder (B) below the pubococcygeal line (*white line*) with some apical component as noted by partial descent of the uterus and cervix (c). PS, pubic symphysis; R, rectum.

variability of clinical examination limits its use as a reference standard. Likewise, there is interobserver variability of the MRI measurements. Thus, the imaging and clinical findings are difficult to align.[92] MRI measurement variability arises from a variety of problems that mostly stem from reader inexperience and training. Muscles are not smooth consistent structures, and muscle irregularity and variations may lead to interreader variability regarding grading of muscle tears. Also, the choice of landmarks for soft tissue structures has shown more variability than for parameters that use osseous landmarks. Despite these problems, there is hope that many of these limitations can be improved with additional training. Beyond the imaging, there is still disagreement among surgeons regarding the best treatments for various forms of POP, including preference for transabdominal versus transvaginal approach. In addition, choice of tissue or mesh for support remains controversial.

SUMMARY AND FUTURE DIRECTION

Pelvic floor sonography and MRI can be used to evaluate pelvic floor anatomy and function, complementing the clinical assessment of patients with pelvic floor disorders. Pelvic floor imaging techniques have promising utility as an adjunct diagnostic modality for pelvic

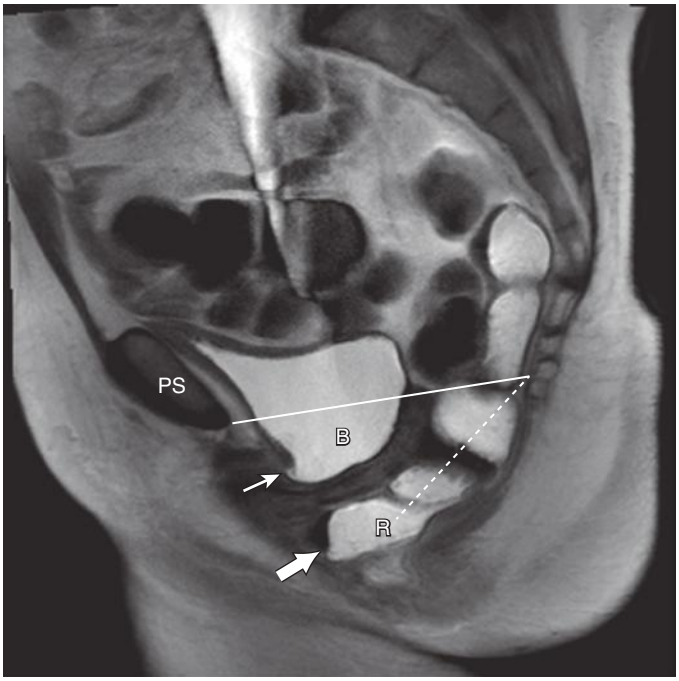

FIG 35-20 Cystocele with urethral rotation on sagittal strain magnetic resonance image. Sagittal T2-weighted image of the pelvis during strain demonstrates multicompartmental descent of the pelvic organs. The urinary bladder (B) is well below the pubococcygeal line (*solid line*). Posterior plate descent (*dotted line*) and rectocele (*thick arrow*) are also present. Of note, there is significant rotation of the urethra with nearly horizontal course (*thin arrow*). PS, pubic symphysis; R, rectum.

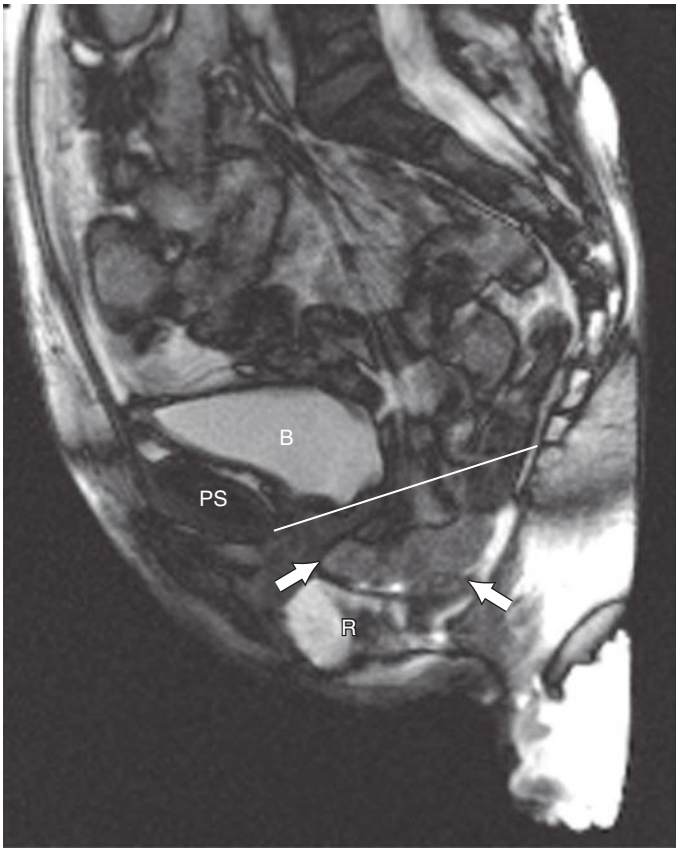

FIG 35-21 Enterocele on strain magnetic resonance image. Sagittal T2-weighted image of the pelvis during strain shows the protrusion of multiple loops of bowel below the pubococcygeal line (PCL) (*white line*) between the displaced rectum (R) and urinary bladder (B), consistent with enterocele (*arrows*). The vagina is not well seen in this plane. PS, pubic symphysis. (Courtesy Gaurav Khatri MD, UT Southwestern Medical Center.)

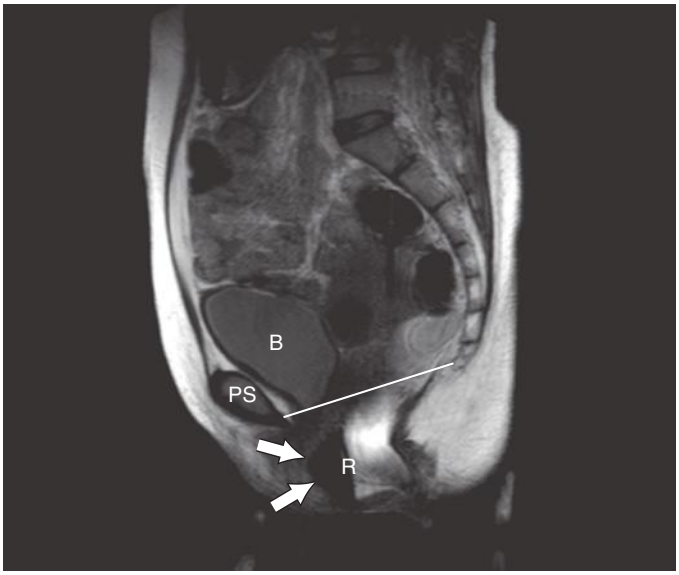

FIG 35-22 Rectocele during strain sagittal magnetic resonance imaging (MRI). Sagittal T2-weighted MRI obtained during strain shows abnormal anterior bulge of the anterior wall of the rectum greater than 2 cm from the midaxis of the anal canal (*arrows*). B, bladder; PS, pubic symphysis; R, rectum.

floor disorders. However, a lack of universal standards has hampered widespread adoption of these imaging techniques.

Endorectal sonography has an important role in assessing the integrity of the IAS and EAS and can be used effectively as a screen for urethral diverticula. Some of the promising applications of pelvic floor sonography include assessment of the integrity of the pelvic floor muscles and biometry. It can be a useful adjunct to pelvic floor muscle training and biofeedback. Other potentially useful applications include investigation of posterior vaginal wall prolapse and assessment of implanted supporting or bulking materials. However, lack of standardized technique, terminology, objective parameters for assessment of pelvic floor disorders, and validation of diagnosis are barriers in the acceptance of pelvic floor sonography as a primary imaging modality in urogynecology. In 2011, an international panel attempted to perform a meta-analysis to analyze the pelvic floor sonographic literature. They deemed the production of a systematic review impossible based on the type and quality of the published literature.[69] They did, however, identify research priorities and advised more coordinated and structured research into internal and external validation of pelvic floor sonography in assessment of pelvic floor disorders.

Over the past 2 decades, MRI has already demonstrated excellent capability to evaluate pelvic floor disorders and has proved to be useful in assisting the surgeon to plan intervention and, thereby, to improve patient outcomes. Continued research including prospective ongoing trials should improve this area further. In addition to recent American College of Radiology Appropriateness Criteria guidelines, additional practice statements are planned from societies in Europe and North America, and it is hoped that they will provide more standardization of both the acquisition and interpretation of pelvic floor MRI studies. Standardization of the threshold dynamic values and nomenclature is needed. Also, semiautomation of 3D modeling of the pelvic floor structures is only in its early days and may provide additional information with less interobserver and intraobserver variability. Finally, better guidelines for reader/interpreter training may help to reduce variability in the quality of this technique and yield better outcomes for patients.

Role of Magnetic Resonance Imaging in the Evaluation of Gynecologic Disorders

Priya Bhosale, Catherine Devine, Carly S. Gardner, Aliya Qayyum

SUMMARY OF KEY POINTS

- Magnetic resonance imaging (MRI) is a problem-solving tool and has greater accuracy and specificity for characterization of gynecologic masses than sonography or computed tomography (CT), but should generally be performed after pelvic sonography.
- High resolutionT2-weighted sequences are the mainstay images for evaluation of nonobstetric gynecologic disorders.
- T1-weighted imaging must be performed with and without fat suppression if characterization of fat or blood products is required.
- The uterine corpus is best assessed in the parasagittal plane.
- The cervix is best assessed in the axial plane.
- MRI is the method of choice for evaluation of congenital uterine anomalies, including associated renal anomalies.
- Water-based gel instilled into the vagina is helpful in cervical and vaginal cancer assessment.
- Gadolinium is helpful in defining the extent and vascularity of tumors.
- Many tumors demonstrate restricted diffusion.
- Staging of gynecologic malignancy is based on the International Federation of Gynecology and Obstetrics (FIGO) system, and cross-sectional imaging is helpful in preoperative planning.

OUTLINE

This chapter describes the main indications for MRI in the evaluation of nonobstetric gynecologic disorders. In the first two sections, normal anatomy of the female pelvis and common congenital anomalies are discussed. In subsequent sections, the use of MRI in the setting of common benign diseases, namely leiomyomas, adenomyosis, and endometriosis is outlined. Finally, the role of MRI in patients with malignant neoplasms of the reproductive organs is discussed. The main clinical and epidemiologic aspects of gynecologic disease are presented, in addition to the imaging features, in order to emphasize a practical clinical approach to patient management.

IMAGING TECHNIQUES

Although a detailed discussion of imaging techniques and protocols used in MRI is beyond the scope of this chapter, some of the most important basic concepts with regard to MRI techniques are included to aid in interpretation of images presented herein, targeting those readers unfamiliar with MRI.

T2-weighted images provide the foundation for MRI of the female pelvis. These images are used for evaluation of normal anatomy and detection of most uterine and adnexal abnormalities. T1-weighted images, especially when used in conjunction with fat suppression, are helpful in characterizing the content of adnexal lesions, namely in the identification of blood and fat. When used after the administration of intravenous gadolinium, T1-weighted images also assist in the characterization of some benign and malignant tumors. As a general rule, on T1-weighted images, fat-containing lesions are bright (high signal intensity), whereas water, such as urine in the bladder, is dark (low signal intensity). However, water is bright on T2-weighted images. Therefore, tissues with higher amounts of water, such as tumors and cysts, have high signal intensity on T2-weighted images. Water-based gel instilled into the vagina can be used to distend the vaginal lumen and outline the cervical contour, but this technique is not widely used.[1] Gadolinium-based contrast agents are most commonly used as intravenous contrast media in MRI. Tissues that are infused with gadolinium increase in signal intensity on T1-weighted images when compared with images acquired before contrast administration. Hence, gadolinium is used to increase the contrast between normal and abnormal tissues in the body and to detect vascularity of tissues. For instance, many neoplastic processes enhance more avidly than adjacent normal tissues and thus become more easily visible. Newer techniques such as dynamic multiphase contrast-enhanced MRI (DCE-MRI) and diffusion-weighted imaging (DWI) provide functional information. In DCE-MRI, images are acquired at multiple times following injection of contrast agent, allowing assessment of tissue vascularity and enhancement patterns. DWI does not use intravenous contrast, but displays contrast between tissues based on different rates of diffusion of water molecules. Many malignant tumors are bright on DWI.[2,3]

ANATOMY AND PHYSIOLOGY

Although it is not within the scope of this chapter to fully discuss the normal anatomy of the female pelvis, a few words regarding specific features on MRI are important. A basic concept that must be remembered is that the patient's hormonal status affects the imaging features of the female reproductive organs, irrespective of the imaging modality.[4-7]

Uterus

The uterus typically measures from 6 to 9 cm in length in women of reproductive age; the cervix accounts for approximately 30% to 50% of the total uterine length in this age group, but is proportionally larger before the menarche. Uterine zonal anatomy is best visualized using T2-weighted images, typically acquired in the axial and sagittal planes, and may be described by considering two separate regions, the cervix and the uterine body.

The cervical anatomy is divided into three zones on T2-weighted sequences: the endocervical mucosa centrally, which demonstrates high signal intensity as a result of the presence of mucus within glands; the cervical stroma, which demonstrates low signal intensity owing to the presence of fibrous connective tissue; and the peripherally located smooth muscle, which demonstrates intermediate signal intensity (Fig. 36-1). Varying amounts of mucus may be seen within the endocervical canal, which has a very high signal intensity similar to that of fluid.[5,6,8]

The zonal anatomy of the body of the uterus also consists of three distinct regions on T2-weighted sequences: centrally, the endometrium

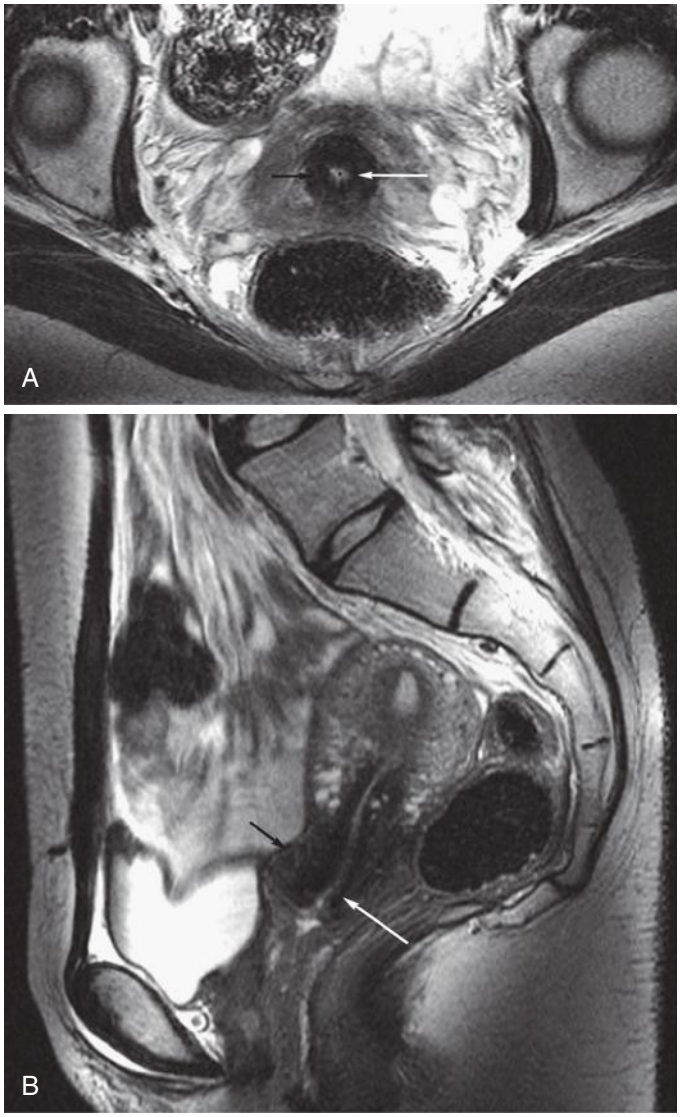

FIG 36-1 Normal cervix. Axial (**A**) and sagittal (**B**) T2-weighted images demonstrating the normal zonal anatomy of the cervix, composed of an outer rim of smooth muscle (*short black arrow* on A and B) of intermediate signal intensity, a dark low signal intensity ring of fibrous stroma (*long white arrow* on A and B), and the high signal intensity endocervical mucosa (*asterisk* on A).

demonstrates very high signal intensity; subjacent to the endometrium, the junctional zone, which represents the innermost layer of the myometrium, demonstrates low signal intensity; and the outer myometrium, which demonstrates intermediate signal intensity (Fig. 36-2). At its inferior aspect, the junctional zone is continuous with the low signal intensity fibrous cervical stroma.[8-10]

Identification of the junctional zone is extremely important when evaluating the uterine magnetic resonance zonal anatomy. Studies have shown that the appearance of the zonal anatomy on MRI is influenced by female hormones.[4-6] Normally, the junctional zone should not measure more than 11 mm in thickness in women of reproductive age. In postmenopausal women, women taking oral contraceptives, or in girls before menarche, the zonal anatomy is frequently indistinct and the junctional zone may be very thin.[8]

The MRI appearance of the endometrium is also hormonally influenced and varies with the menstrual cycle. The endometrium becomes progressively thicker between the early follicular (proliferative) phase and ovulation, increasing from 1 to 3 mm in thickness to an average of 8 to 9 mm. The endometrium should not measure more than 15 mm in thickness in women of menstrual age, and typically it measures 11 mm or less in postmenopausal women who are not on hormonal replacement therapy.[11,12] The endometrium is highest in signal intensity during the luteal (secretory) phase.[4,6,8] It is imperative to recognize that the evaluation of endometrium thickness using T2-weighted images may result in overestimation because fluid within the endometrial cavity is also high in signal intensity on T2-weighted sequences (Fig. 36-3).

Unlike the uterine corpus, the cervical zonal anatomy does not demonstrate significant changes during the menstrual cycle. In addition, because the cervix is composed largely of fibrous elastic tissue, enhancement of the cervix following the administration of intravenous gadolinium differs from enhancement of the uterine corpus. The uterine corpus is a very vascular structure when compared to the cervix and enhances earlier and more avidly than the cervix (Fig. 36-4). This is important because this difference in enhancement pattern may give the appearance of a pseudomass and lead to a misdiagnosis of cervical cancer.

Ovaries

The normal ovaries demonstrate homogeneous intermediate T1-weighted signal intensity; however, on T2-weighted sequences, an outer high signal intensity cortex and a hypointense central medulla will be observed.[13,14] The ovaries measure approximately $2 \times 2 \times 3$ cm; however, their size fluctuates according to hormonal status, largely because of follicle production and enlargement during the menstrual cycle. The ovaries are most readily identified in women of reproductive age by the presence of such follicles, which appear as small simple cysts of high signal intensity on T2-weighted sequences and low signal intensity on T1-weighted sequences (Fig. 36-5). Primordial follicles are usually smaller, measuring up to 9 mm in diameter, whereas stimulated graafian follicles may reach up to 3 to 5 cm. Other features of these

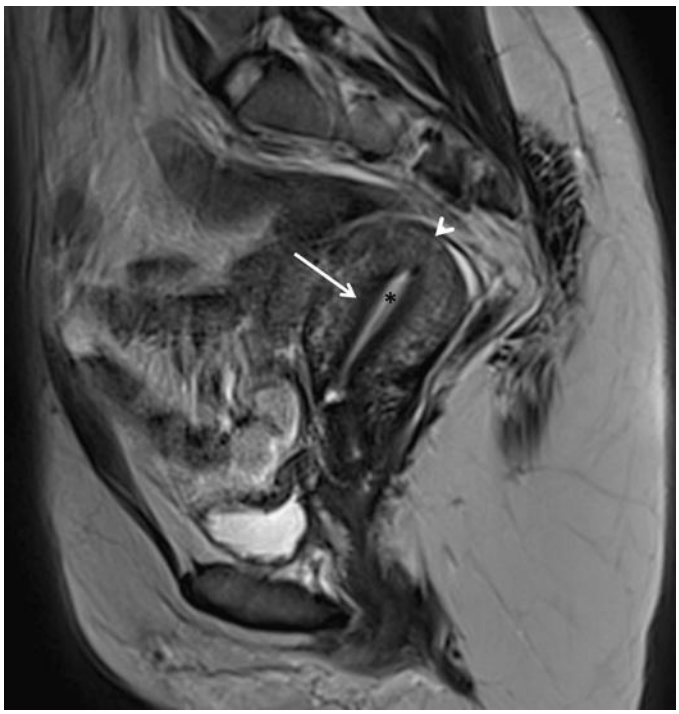

FIG 36-2 Normal uterus. Sagittal T2-weighted image demonstrating the high signal intensity of the endometrium (*asterisk*) and the zonal anatomy of the uterus, characterized by the low signal intensity (*dark*) junctional zone (*arrow*) subjacent to the endometrium and the intermediate signal intensity outer myometrium (*arrowhead*).

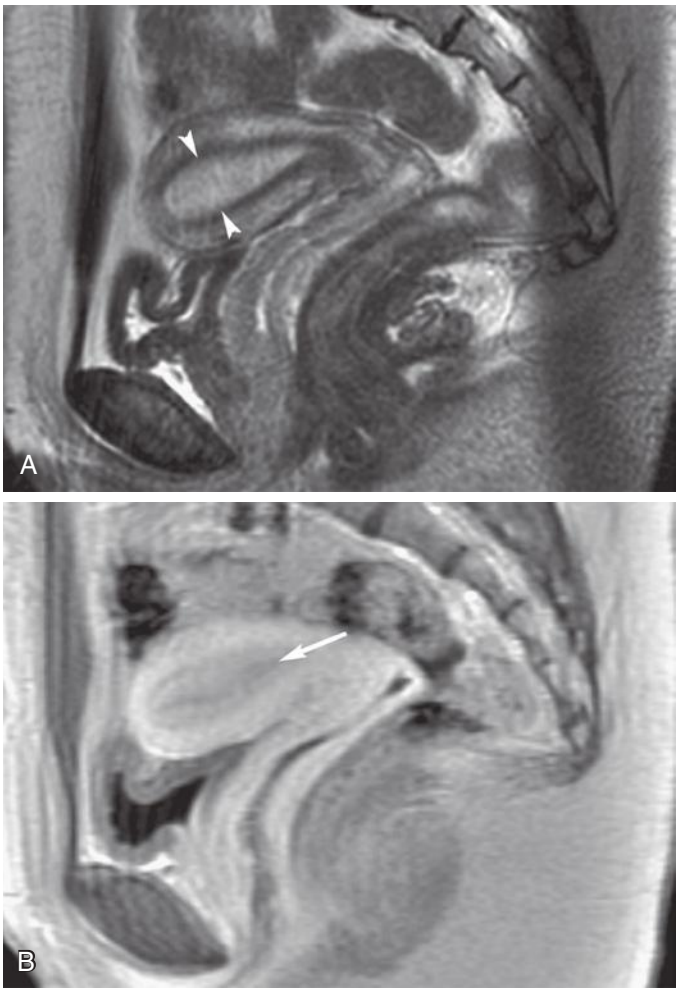

FIG 36-3 Apparent endometrial thickening. Sagittal T2-weighted (**A**) and postcontrast T1-weighted fat-suppressed (**B**) images. Apparent thickening of the endometrium is seen on the T2-weighted image (*arrowheads* in **A**); however, after administration of gadolinium, while the endometrium enhances, a dark central band of nonenhancing fluid within the cavity becomes evident (*arrow* in **B**).

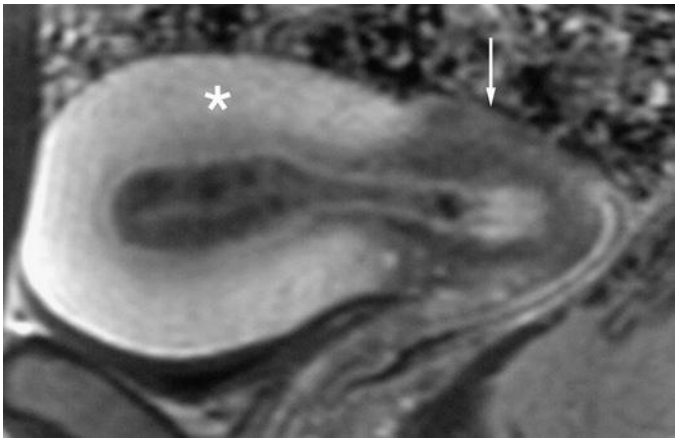

FIG 36-4 Normal uterus. Gadolinium-enhanced sagittal T1-weighted fat-suppressed image demonstrates the normal difference between enhancement of the myometrium (*asterisk*) and cervical stroma (*arrow*).

FIG 36-5 Normal ovaries. Axial T2-weighted image demonstrates the presence of multiple hyperintense follicles in both ovaries (*arrows*), one of which represents the dominant follicle (*asterisk*).

physiologic cysts seen on T2-weighted sequences include imperceptible or thin walls (less than 3 mm) and absence of mural nodules (see Fig. 36-5).[13,14] The number of ovarian follicles decreases following menopause in women who are not taking hormonal replacement therapy. However, simple ovarian cysts are a common incidental finding in postmenopausal women, seen in 14% of women over 55 years of age, and may resolve or remain stable.[10] Ovarian stroma enhances after intravenous contrast agent administration and the use of fat-suppressed sequences helps to identify the ovaries when follicles are not visible. The normal fallopian tubes are not visualized on MRI.[14]

CONGENITAL ANOMALIES

MRI is the imaging method of choice for evaluation of congenital anomalies of the female reproductive tract. Advantages of MRI include noninvasiveness, lack of ionizing radiation, multiplanar capability enabling visualization of the fundal contour of the uterus, and excellent soft tissue characterization. The use of MRI may reduce the number of invasive procedures and related costs by guiding management decisions.[15]

Müllerian Duct Anomalies

The müllerian ducts are paired embryologic structures that normally fuse between the 6th and 11th weeks of gestation, forming the uterus, fallopian tubes, cervix, and most of the upper vagina.[16] However, in 0.1% to 10.0% of the general population, either fusion fails to occur or the ducts do not develop normally, resulting in one of the multiple types of anomalies.[17-19] Although müllerian duct anomalies may be asymptomatic depending upon the exact type, they may be associated with primary amenorrhea, infertility, obstetric complications, and endometriosis.[16,17,20,21] It is estimated that as many as 25% of women who present with infertility and miscarriage have müllerian duct anomalies.[22] In addition, 30% to 50% of these women have concurrent renal anomalies, which include renal agenesis, ectopia, fusion, malrotation, and duplication.[16,20,23] Patients suspected of having müllerian duct anomalies are often initially investigated with transvaginal sonography, because it is widely available, safe, and of relatively low cost. Although MRI is considered the reference standard for the evaluation of müllerian duct anomalies with a diagnostic accuracy of almost 100%,[23-29] it is frequently reserved for indeterminate cases or cases in which further information is needed. T2-weighted sequences are the most useful because identification of the zonal anatomy is necessary for complete evaluation and analysis. In addition, the study must include an oblique coronal and axial plane to ensure adequate visualization of the uterine fundal contour.

Although there are many different classifications of müllerian duct anomalies, the American Society for Reproductive Medicine classification is perhaps the most widely used and the best known (Fig. 36-6).[30]

Agenesis/Hypoplasia

The anomalies within this group result from bilateral nondevelopment or arrested development of the müllerian ducts. Agenesis of the upper vagina and uterus is the most common anomaly in this group and part of the spectrum of the Mayer-Rokitansky-Küster-Hauser syndrome. Patients with this syndrome may present with an atrophic uterus, however, and vaginal abnormalities can range from hypoplasia to agenesis. Urinary system malformations are sometimes associated with the Mayer-Rokitansky-Küster-Hauser syndrome. The second most common anomaly in this class is segmental vaginal agenesis. Isolated agenesis or hypoplasia of the uterus is very rare. In complete uterine agenesis, MRI demonstrates only a short blind-ending vagina, whereas in cases of uterine hypoplasia, the uterus is small and the intercornual diameter of the endometrial cavity is reduced, measuring less than 2.0 cm.

Unicornuate Uterus

A unicornuate uterus is the consequence of complete arrest or partial development of one müllerian duct in utero. In 90% of cases, partial

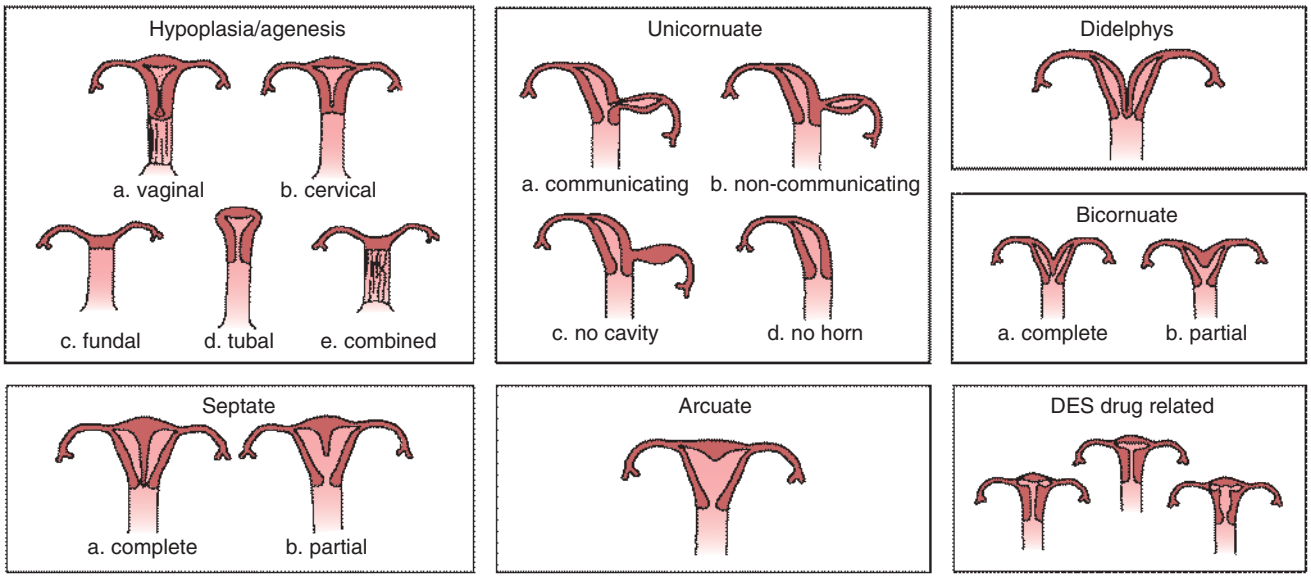

FIG 36-6 Classification of müllerian duct anomalies used by the American Society for Reproductive Medicine. DES, diethylstilbestrol.

development of the duct occurs, with an ensuing rudimentary horn, which may or may not contain functioning endometrium. The rudimentary horn may be obstructed or may communicate with the main uterine cavity. Clinical associations include very high rates of spontaneous miscarriage, obstetric complications, and endometriosis. A unicornuate uterus will have normal zonal anatomy and has a characteristic banana-shaped configuration. A rudimentary horn can be seen as an adjacent soft tissue mass and may be distinguished from a tumor by virtue of signal intensity characteristics that are similar to myometrium on T2-weighted images. An obstructed (noncommunicating) rudimentary horn may become enlarged as a result of distention from blood products, identified as high signal intensity central material on T1-weighted sequences.

Uterus Didelphys

Uterus didelphys arises through complete failure of müllerian duct fusion in utero and is characterized by the presence of two separate uteri and cervices with a vertical septum in the upper vagina. Very rarely, two completely separated vaginas and vaginal orifices may be present. Patients are usually asymptomatic, but hematometrocolpos may occur in the presence of an obstructing transverse hemivaginal septum. Clinical complications are similar to those associated with a unicornuate uterus. MRI may be used to readily diagnose uterus didelphys by demonstration of two widely separated uterine horns and two cervices (Fig. 36-7). The zonal anatomy is preserved. Vaginal septa may not always be identified with MRI, and physical examination may be necessary for confirmation and differentiation from a bicornuate bicollis uterus.

Bicornuate Uterus

This anomaly is the result of partial failure of fusion of the müllerian ducts. It is characterized by an increased intercornual distance, reportedly measuring wider than 4 cm; a concave external contour of the fundus, measuring more than 1 cm in depth; and a fibrous-muscular septum bisecting the endometrial cavity. The septum may be incomplete, partially dividing the uterine cavity (bicornuate unicollis [Fig. 36-8]), or complete, extending all the way to the external cervical os (bicornuate bicollis). The vagina develops normally. Images obtained in the oblique coronal plane, along the long axis of the uterus, are useful in assessing the fundal contour. The dividing septum often exhibits signal characteristics similar to myometrium, but may be of low signal intensity inferiorly when fibrous tissue is present.

Septate Uterus

Septate uterus is the most common müllerian duct anomaly and is thought to result from failure of resorption of a fibrous septum in later stages of development.[16] The result of such failure of resorption is a characteristically small endometrial cavity with a dividing septum, which may be partial or may extend to the external cervical os. Reproductive complications are greatest in this class of müllerian duct anomaly and are attributed to difficulties of implantation. Identification of a convex, flat, or minimally indented fundal contour without a fundal cleft on MRI obtained in the coronal plane (Fig. 36-9) is decisive in distinguishing a septate from a bicornuate uterus. Other diagnostic MRI features include an intercornual distance of less than 4 cm (i.e., not increased) and a thin, dividing, often fibrous septum typically of low T1- and T2-weighted signal intensity, although the septum may have a signal intensity similar to that of myometrium if myometrial smooth muscle is the primary component of the septum. The septum may be partial or complete.

Arcuate Uterus

This anomaly is recognized by mild indentation of the myometrium into the fundal aspect of the endometrium, attributed to minimally incomplete resorption of the uterovaginal septum. It is classified separately because it is a benign variant without clinical significance. On MRI, the arcuate uterus is typically of normal size with a single endometrial cavity that is minimally indented superiorly by the small nonresorbed septal remnant and may be associated with a small fundal cleft less than 1.0 cm in depth.

Diethylstilbestrol Exposure

Diethylstilbestrol is a synthetic estrogen that was historically prescribed to prevent miscarriages until 1971. It is estimated that approximately two thirds of patients exposed to this drug while in utero have uterine anomalies. The most common of these anomalies is the classic

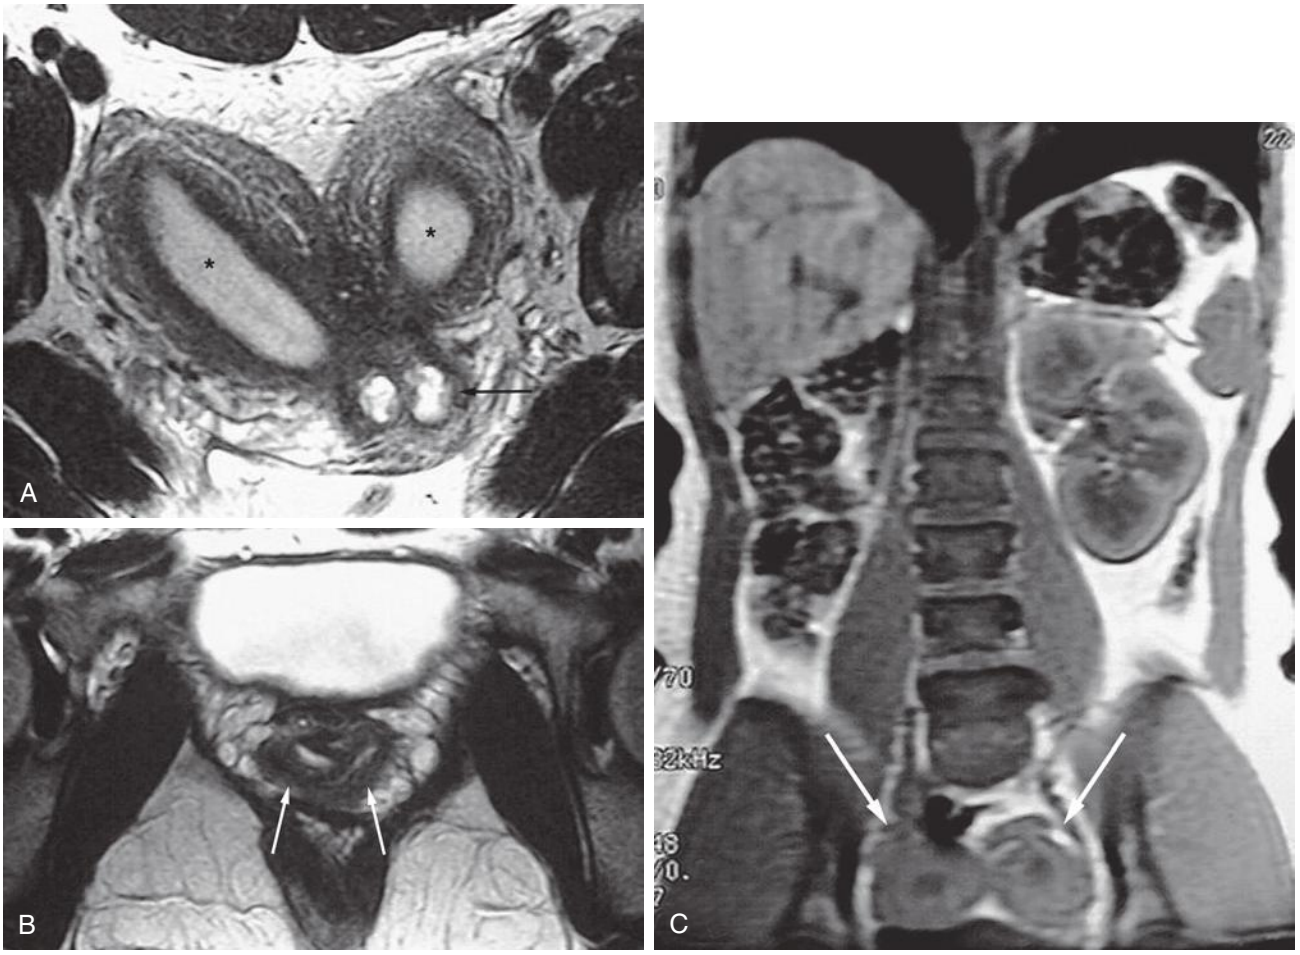

FIG 36-7 Uterus didelphys. Axial T2-weighted images of the pelvis (**A** and **B**) and coronal T1-weighted image of the abdomen (**C**) demonstrate two separate uteri (*asterisks* on A and *arrows* on C) and cervices (*black arrow* on A), as well as two separate vaginas (*white arrows* on B). The right kidney was congenitally absent (C).

FIG 36-8 Bicornuate unicollis uterus. Axial T2-weighted image demonstrates a deep cleft (*double-headed white arrow*) in the uterine fundus widely separating the right and left horns. There is a single cervix (*black arrow*).

FIG 36-9 Septate uterus. Axial T2-weighted image demonstrates a partial septum dividing the endometrial cavity (*arrow*) and a flat fundal contour (*arrowhead*).

hypoplastic T-shaped uterus, but other deformities of the uterine horns and endometrial cavity have been reported.

Vaginal Anomalies

The lower third of the vagina originates from the urogenital sinus rather than the müllerian ducts and is developmentally distinct. Absence of the distal or lower third of the vagina or the presence of a transverse membrane (mimicking an imperforate hymen) results from failure of urogenital sinus development. In both eventualities, the vaginal obstruction causes the vagina and uterus to distend with fluid, referred to as hematometrocolpos when blood products are identified. The upper vagina demonstrates very thin walls, whereas the uterus may have either thin or thick myometrium (Fig. 36-10).

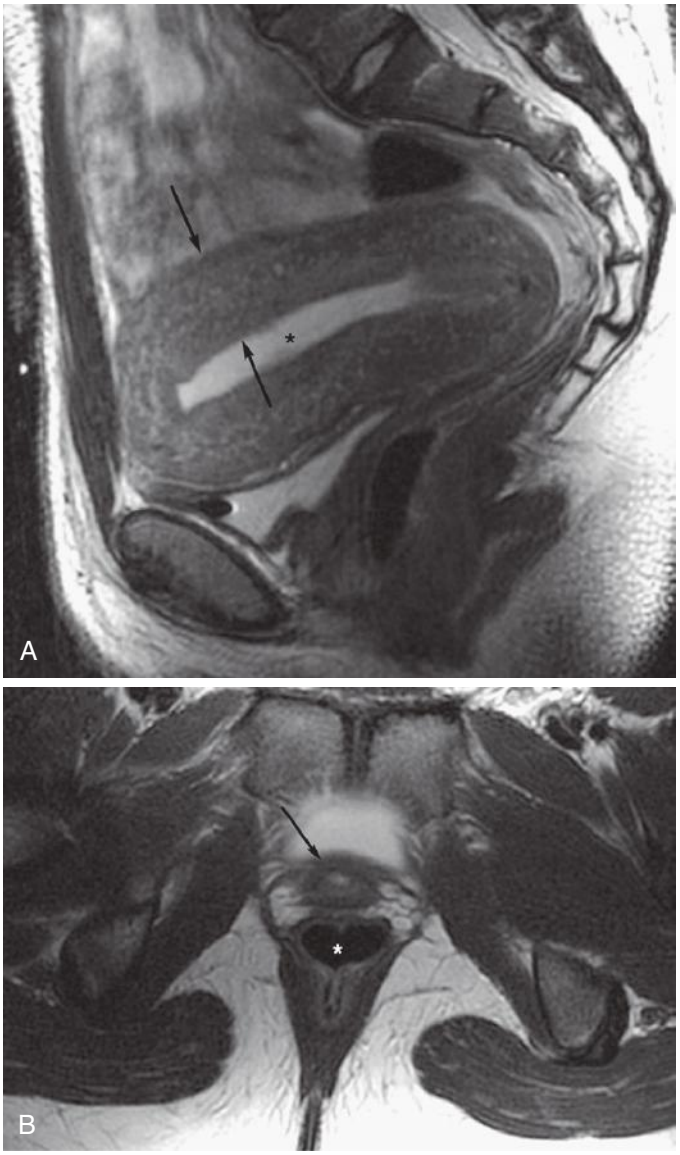

FIG 36-10 Vaginal agenesis. Sagittal T2-weighted (**A**) and axial T2-weighted (**B**) images demonstrate mild distention of the uterine cavity (*asterisk* on A) and thickening of the myometrium (*arrows* on A) as well as absence of the vagina between the normal urethra (*arrow* on B) and rectum (*asterisk* on B).

Hematometrocolpos is characterized as a heterogeneous collection with high T1- and intermediate or low T2-weighted signal intensity.

Ovarian Anomalies

The ovaries arise from primitive germ cells that migrate to the embryonic gonadal ridge and subsequently descend into the pelvis. Congenital anomalies of the ovaries are typically associated with chromosomal disorders and include gonadal dysgenesis, commonly occurring with Turner syndrome (45,X karyotype) and Turner syndrome mosaicism (45,X/46XX karyotype). The ovaries of patients with gonadal dysgenesis are absent or seen as fibrous streaks. Fat-suppressed T2-weighted and gadolinium-enhanced T1-weighted sequences are most helpful in the identification of the ovaries.

LEIOMYOMAS

Definition and Epidemiology

Leiomyomas are benign tumors arising from uterine smooth muscle cells and occur in more than 80% of African-American women and in approximately 70% of Caucasian women by age 50 years.[31] African-American women are diagnosed with leiomyomas at earlier ages, are more likely to be symptomatic, and are more likely to undergo myomectomies and hysterectomies compared to Caucasian women.[32] Leiomyomas have a significant impact on public health, accounting for at least one third of the 600,000 hysterectomies performed each year in the United States.[33]

Clinical Aspects

Most patients with leiomyomas are asymptomatic.[31] Clinical symptoms associated with leiomyomas include dysfunctional uterine bleeding, pelvic pressure, and pelvic pain. In addition, there is an association with impaired reproductive function, which may be related to impaired implantation, tubal obstruction, and an increased rate of miscarriage as well as preterm labor.[34,35] Approximately 90% of leiomyomas occur in the uterus, whereas 5% to 10% are cervical in location. Leiomyomas can enlarge during pregnancy, and cervical leiomyomas may cause dystocia.[36,37] A minority of leiomyomas occur in the round and broad ligaments (Fig. 36-11) or adnexa.

Location of the leiomyoma often predicates the symptoms. Uterine leiomyomas are classified as submucosal, intramural, or subserosal (Fig. 36-12). Approximately 5% of leiomyomas are submucosal in location (Fig. 36-13).[37] Submucosal leiomyomas typically present with menometrorrhagia. In addition, a submucosal leiomyoma is more likely to be associated with infertility, dysfunctional uterine bleeding, dysmenorrhea, and anemia. Submucosal leiomyomas are often effectively treated with hysteroscopic resection, depending upon size and intracavitary extent of the mass. Submucosal leiomyomas are distinguished from large intramural leiomyomas based on identification of the lesion's epicenter within the endometrial cavity rather than within the myometrium, and less than 180-degree encirclement by surrounding myometrium.

Subserosal leiomyomas account for approximately 10% to 20% of uterine leiomyomas, are located just under the uterine serosa, and may be pedunculated or sessile (Figs. 36-13 and 36-14). Symptoms are associated with large size owing to mass effect or torsion of a pedunculated lesion. The bridging vascular sign (vessels originating from the uterus and feeding a pelvic mass) is seen in approximately 77% of exophytic leiomyomas and is helpful in differentiating these tumors from solid adnexal masses.[38] Conversely, an ovarian vascular pedicle (identified by the presence of a gonadal vein) may be helpful in establishing that a mass is ovarian in origin. A pedicle is seen in 92% of ovarian masses and 13% of pedunculated subserosal leiomyomas.[39]

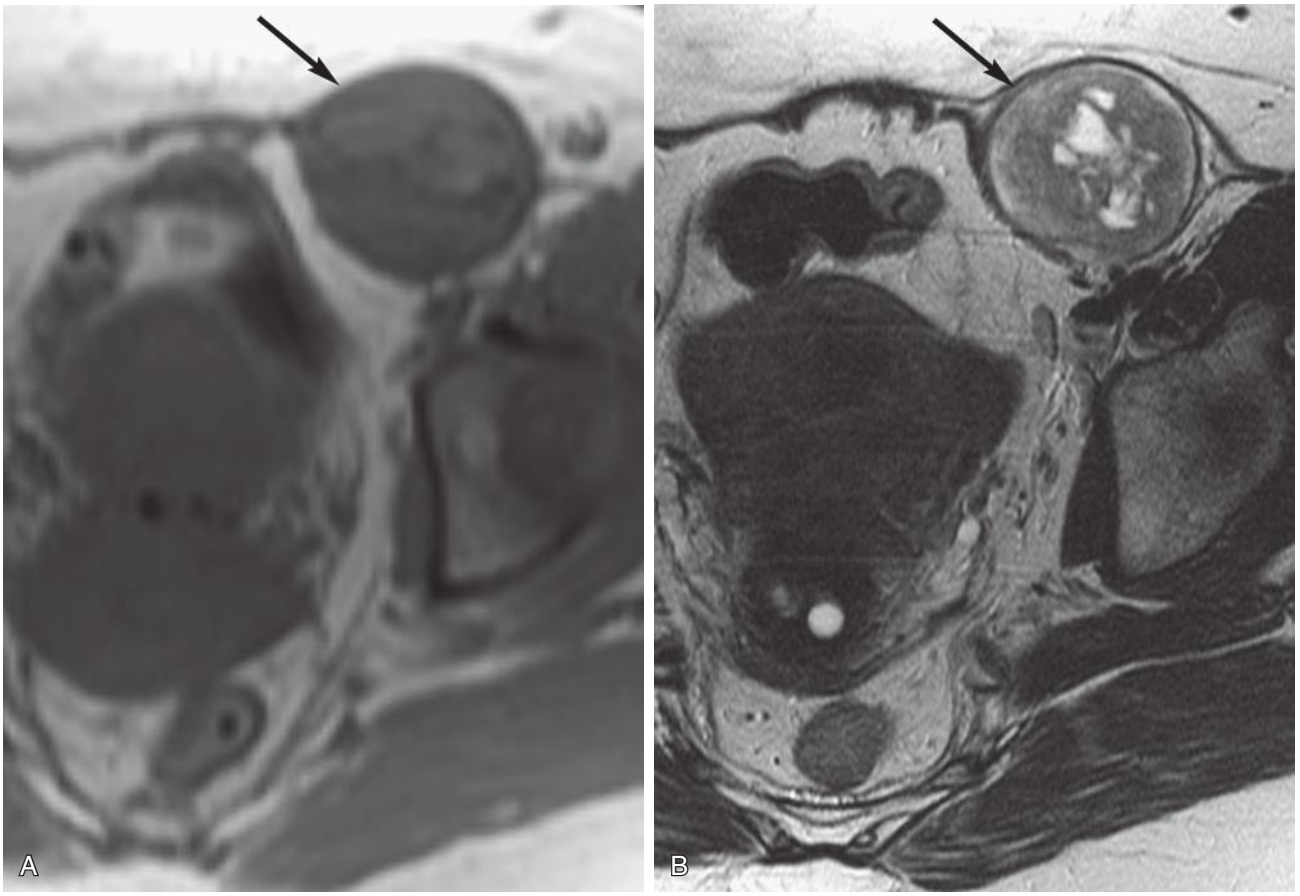

FIG 36-11 Round ligament leiomyoma. Axial T1-weighted (**A**) and T2-weighted (**B**) images demonstrate a round mass (*arrows*) with the typical appearance of a degenerating leiomyoma, predominantly low signal intensity on both sequences but with central irregular areas of high signal intensity on the T2-weighted image consistent with cystic degeneration. However, the mass is separate from the uterus and has herniated into the left inguinal canal. This mass was surgically proved to be a leiomyoma of the round ligament.

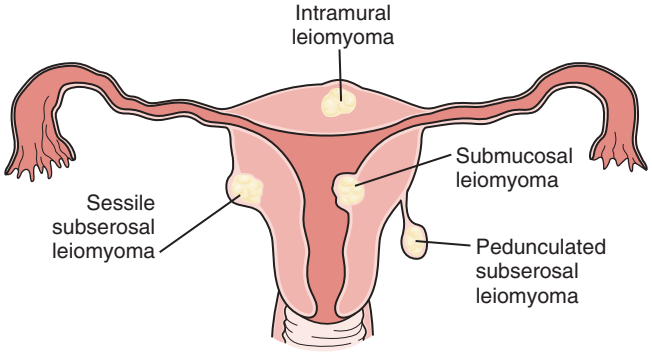

FIG 36-12 Graphic representation of a sessile subserosal leiomyoma, a pedunculated subserosal leiomyoma, an intramural leiomyoma, and a submucosal leiomyoma.

Pathophysiology

The pathophysiology of leiomyomas is unknown; however, genetic predisposition and hormonal status are involved in tumor development and growth.[31] Responsiveness of leiomyomas to hormonal stimulation frequently results in enlargement during pregnancy and involution following menopause. Various types of benign degeneration are common, particularly in large leiomyomas, and include hyaline (most common and present in at least 60% of leiomyomas), cystic, myxoid, fatty, and hemorrhagic degeneration (Fig. 36-15).[40] Imaging-based differentiation between the types of degeneration is usually not possible; however, certain features may favor one or another type. Degeneration within a leiomyoma may make the sonographic diagnosis difficult as a degenerated leiomyoma may have cystic components and, thus, may mimic the sonographic appearance of a complex ovarian mass. In such cases, MRI may be used for diagnosis.[41,42]

Knowledge of atypical locations and presentations, such as benign metastasizing leiomyomas, intravenous leiomyomas, diffuse leiomyomatosis, and peritoneal disseminated leiomyomatosis, is important. Although these uncommon presentations may suggest a malignant process, they are essentially a variation in the growth pattern of this benign lesion.[40] Uterine leiomyosarcomas have been reported to occur in association with leiomyomas.[43] However, genetic studies suggest that these are two different entities arising from separate pathways.[31] Malignant degeneration of a benign leiomyoma into a leiomyosarcoma is considered by most pathologists to be extremely rare, if it occurs at all. Sometimes, the distinction between a leiomyoma and a leiomyosarcoma cannot be reliably made based on MRI characteristics of the primary lesion; however, rapid growth, irregular borders, evidence of extrauterine extension, lymphadenopathy, and metastases are, to different degrees, suggestive of malignancy (Fig. 36-16).

FIG 36-13 Myomatous uterus. Sagittal T2-weighted image demonstrates a small low signal intensity submucosal leiomyoma (*white arrow*) and distention of the endometrial cavity with intraluminal blood (*asterisk*). Numerous subserosal leiomyomas are noted, including one at the uterine fundus (*black arrow*).

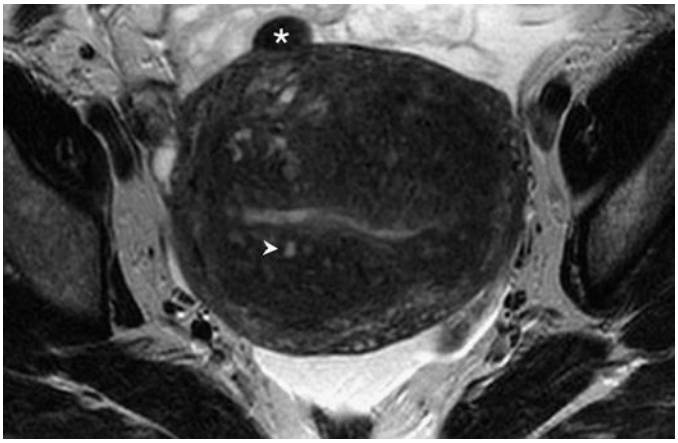

FIG 36-14 Leiomyoma and adenomyosis. Axial T2-weighted image demonstrates a small low signal intensity subserosal leiomyoma anteriorly (*asterisk*). The junctional zone is markedly thickened and has indistinct margins. Multiple punctate foci of high signal intensity (starry sky appearance) (*arrowhead*), characteristic of adenomyosis, are seen.

Treatment

The preferred treatment for leiomyomas depends upon their size and location, as well as clinical presentation. The most common therapeutic options are hysterectomy, myomectomy (transabdominal, laparoscopic, or hysteroscopic), myolysis, and uterine artery embolization (UAE).[31,35] Hysterectomy is usually performed in women who have completed childbearing and do not wish to preserve the uterus. Myomectomy is often the choice for those patients who wish to preserve the uterus. In these cases, an abdominal approach is used for multiple large leiomyomas; the laparoscopic approach is appropriate for resection of subserosal and pedunculated lesions, whereas the hysteroscopic technique is preferred for patients with submucosal lesions that are greater than 50% intracavitary. UAE is a newer, safe, and effective technique with the potential to become the treatment of choice for symptomatic uterine leiomyomas.[44] Contraindications to UAE include active pelvic infection, renal insufficiency, and contrast agent allergy. The reported principal advantage of UAE in appropriate candidates is lower morbidity compared to more invasive surgical techniques.

Diagnosis

The most common indication for MRI of symptomatic patients is to determine the size and location of leiomyomas and to assess for the presence of necrosis or hemorrhage in lesions that appear worrisome on ultrasound imaging, as such factors are essential for guiding appropriate patient management. The initial diagnosis of leiomyoma is typically confirmed and then monitored, as clinically indicated, by pelvic sonography. Ultrasound evaluation may be limited in a number of situations, such as retroverted or retroflexed uterus; uterine or leiomyoma enlargement beyond the sonographic field of view, precluding complete visualization; pedunculated subserosal leiomyomas, which can be difficult to distinguish from adnexal masses; and atypical imaging features. In such cases, MRI is useful as a problem-solving tool and for preprocedural assessment when limited or conservative treatment is planned. Although MRI and sonography have similar overall sensitivity (99% for each) for detection, sonography has a lower reported specificity than MRI (86% and 91%, respectively). Furthermore, MRI is better for determining the total number of lesions.[45] The advantages of MRI over sonography in this application are primarily due to the larger field of view and to significantly improved soft tissue characterization.[45] An additional clinically important benefit of MRI is the ability to readily differenetiate leiomyomas from focal adenomyosis, as these two entities are managed differently if uterine preservation is desired.[46,47] Finally, MRI has a role in predicting and monitoring treatment response, especially in patients treated with UAE.[48-50] Pretreatment imaging features predictive of a good response to UAE include submucosal location, small size, avid contrast enhancement (vascularity), and high T2-weighted signal intensity. Conversely, the presence of hemorrhagic degeneration or lack of contrast enhancement before embolization often predicts a poor response. Successful UAE results in hemorrhagic infarction and ultimate reduction in size of both the uterus and any leiomyomas.[48,49,51]

Imaging Characteristics

On MRI, a simple nondegenerating leiomyoma is depicted as a well-circumscribed, round mass with low signal intensity on both T1- and T2-weighted sequences (see Fig. 36-15).[37] Intramural leiomyomas may demonstrate a high signal intensity pseudocapsule on T2-weighted sequences, which has been attributed to edema and vascular or lymphatic congestion within the surrounding myometrium (Fig. 36-17).[52] Calcifications may be seen as areas of signal void but are generally not well visualized with MRI. Nondegenerating leiomyomas typically show marked enhancement after gadolinium administration, but the use of

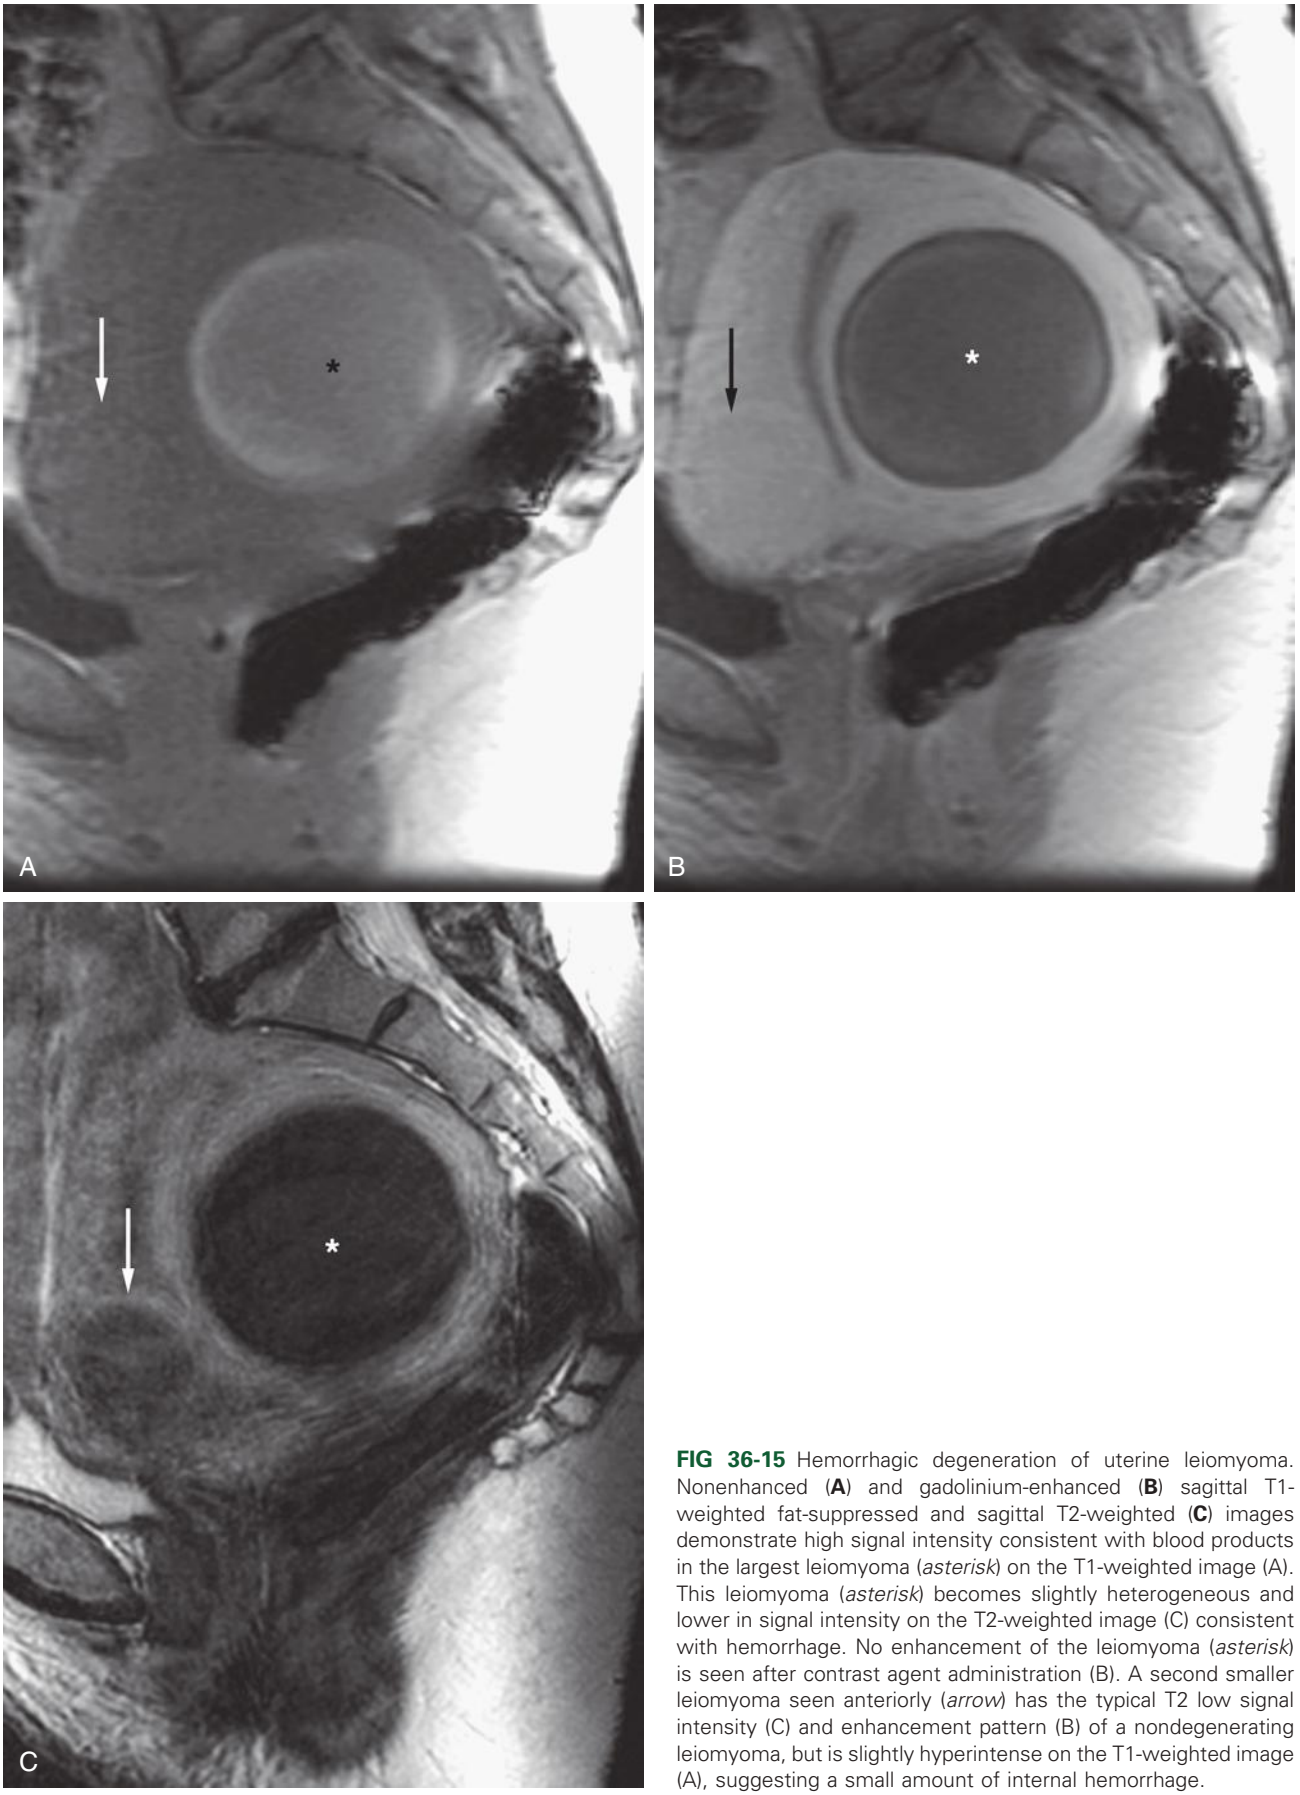

FIG 36-15 Hemorrhagic degeneration of uterine leiomyoma. Nonenhanced (**A**) and gadolinium-enhanced (**B**) sagittal T1-weighted fat-suppressed and sagittal T2-weighted (**C**) images demonstrate high signal intensity consistent with blood products in the largest leiomyoma (*asterisk*) on the T1-weighted image (A). This leiomyoma (*asterisk*) becomes slightly heterogeneous and lower in signal intensity on the T2-weighted image (C) consistent with hemorrhage. No enhancement of the leiomyoma (*asterisk*) is seen after contrast agent administration (B). A second smaller leiomyoma seen anteriorly (*arrow*) has the typical T2 low signal intensity (C) and enhancement pattern (B) of a nondegenerating leiomyoma, but is slightly hyperintense on the T1-weighted image (A), suggesting a small amount of internal hemorrhage.

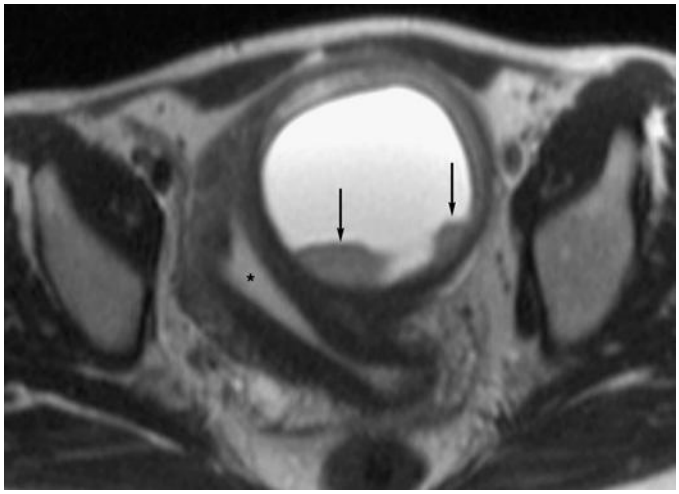

FIG 36-16 Uterine sarcoma. Axial T2-weighted image. The high signal intensity endometrial cavity (*asterisk*) is displaced by a large cystic (high signal intensity central component) myometrial mass that contains intermediate signal intensity mural nodules (*arrows*) posteriorly; pathologic examination proved the mass to be a uterine sarcoma.

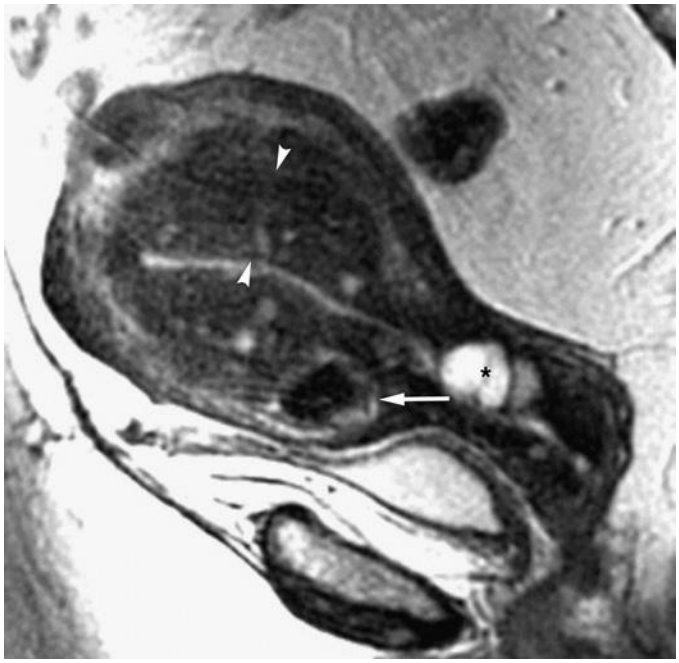

FIG 36-17 Leiomyomas and adenomyosis. Sagittal T2-weighted image demonstrates a pseudocapsule of high signal intensity around a well-defined myometrial mass (*arrow*) in the anterior wall of the lower uterine segment, diagnostic of a leiomyoma. The low signal intensity junctional zone (*arrowheads*) is diffusely thickened and has the characteristic starry sky appearance with numerous punctate foci of high signal intensity consistent with adenomyosis. *Asterisk*, nabothian cyst.

contrast material is required only for the purpose of determining lesion vascularity when considering UAE (see Fig. 36-15).

As mentioned previously, imaging characteristics of degeneration are nonspecific, but some MRI features may suggest specific types. Leiomyomas with cystic degeneration present with very high signal intensity on T2-weighted sequences (Fig. 36-18).[37] Heterogeneous low T2-weighted signal intensity and a cobblestone or whorled appearance in a leiomyoma is usually associated with hyaline degeneration.[40,37]

FIG 36-18 Cystic degeneration of a uterine leiomyoma. Axial T1-weighted (**A**) and sagittal T2-weighted (**B**) images demonstrate a well-circumscribed mass (*asterisks*) arising from the uterus. The lesion demonstrates signal intensity characteristic of a cyst (low signal intensity on T1-weighted images and high signal intensity on T2-weighted images). A few thin septations are seen on the T2-weighted image (B). Pathologic examination proved this to be cystic degeneration of a leiomyoma.

Hemorrhagic degeneration commonly occurs following UAE or as a sequela of rapid lesion enlargement during pregnancy. Hemorrhagic degeneration characteristically manifests as high signal intensity on T1-weighted sequences because of the high proteinaceous content of blood or the presence of methemoglobin (see Fig. 36-15).[40,37] A rim

of low signal intensity on T2-weighted sequences and high signal intensity on T1-weighted sequences may be present and is thought to represent obstructed veins around the lesion.[37] Myxoid degeneration is associated with multiple areas of cystic change and very high T2-weighted signal intensity.[40,37] No specific MRI features have been described that reliably differentiate a leiomyoma from a leiomyosarcoma. However, an irregular, infiltrative, ill-defined border; extrauterine extension; and associated pelvic lymphadenopathy are worrisome features for malignancy, as noted earlier (see Fig. 36-16).

ADENOMYOSIS

Definition and Epidemiology

Adenomyosis refers to the presence of intramyometrial endometrial mucosa (both glands and stroma) surrounded by hypertrophied myometrium. Typically, adenomyosis is diagnosed in a multiparous woman in the fourth or fifth decade of life. Although common, the exact prevalence of adenomyosis is difficult to establish. Autopsy and clinical studies on prevalence vary, with a range of 20% to 67% in autopsy studies[53] and 10% to 88% in clinical studies[54-57]; this wide range of reported prevalence is likely a reflection of several factors, including inconsistent pathologic definition of adenomyosis, different uterine specimen processing protocols, and varied patient inclusion criteria.

Clinical Aspects

The classic clinical scenario is that of a patient who presents with menorrhagia, dysmenorrhea, and metrorrhagia accompanied by an enlarged, smooth-contoured soft uterus that may be tender to palpation. However, one third of patients with adenomyosis are asymptomatic. Both the frequency and severity of symptoms appear to correlate with the extent and depth of myometrial involvement.[53,58,59]

Pathophysiology

Adenomyosis causes globular enlargement of the uterus with cystic areas, some filled with degraded red blood cells. Adenomyosis may be described as focal, diffuse, or a combination, depending on its distribution within the myometrium. Irrespective of presentation, these lesions have ill-defined margins, unlike leiomyomas, which are sharply marginated with a smooth, regular border.[53]

There are three general hypotheses that attempt to explain the development of adenomyosis.[53] Two hypotheses suggest a process of invagination of the basalis layer of the endometrial mucosa, either between muscle fibers or along the intramyometrial lymphatic system. The third theory suggests that adenomyosis develops as a result of metaplasia from de novo ectopic intramyometrial endometrial tissue. In up to 80% of cases, there are additional uterine pathologic findings, most commonly leiomyomas, but also endometrial polyps, endometrial hyperplasia, and endometrial adenocarcinoma.[53]

Diagnosis

Although presentation may strongly suggest adenomyosis, clinical diagnosis is not accurate, and imaging is often used prior to treatment selection.

Imaging Characteristics

Transvaginal sonography is generally the first choice imaging modality in symptomatic patients with adenomyosis. It is widely available, safe, and low cost with good accuracy, similar to that reported for MRI. Reported sensitivity of transvaginal sonography ranges from 57% to 89% and specificity from 65% to 98%.[60-65] However, ultrasound evaluation is somewhat operator dependent, with the best results obtained by experienced examiners. In addition, the accuracy of sonography decreases in patients who present with large uteri and concurrent leiomyomas. The reported sensitivity and specificity of MRI range from 70% to 86% and 86% to 93%, respectively.[60-62] MRI is generally recommended if sonographic results are equivocal or when additional information is needed, especially for treatment planning.

The diagnosis of adenomyosis on MRI is based on findings identified on T2-weighted sequences. Classically, adenomyosis appears on MRI as focal or diffuse widening of the junctional zone (inner myometrium) or as an ill-defined, hypointense, myometrial mass (see Figs. 36-14 and 36-17). The normal junctional zone in premenopausal women appears as a band of low signal intensity between the endometrium and outer myometrium. Based on the study by Reinhold and associates,[60] identification of a junctional zone wider than 12 mm is diagnostic of adenomyosis, whereas a width of 8 mm or less reliably excludes the condition. For patients with measurements that fall in the indeterminate category (junctional zone measuring between 9 mm and 11 mm), secondary findings including hyperintense punctate foci on T2-weighted images, hyperintense thin parallel lines radiating out from the endometrium into the myometrium (also on T2-weighted images), and ill-defined margins to the areas of low signal intensity (either diffuse or focal thickening of the junctional zone or focal areas within the myometrium near the junctional zone) may help establish the diagnosis (see Fig. 36-14).[47,61,66] The high-signal punctate foci are thought to represent dilated endometrial glands, whereas the striations may represent endometrial invasion into the myometrium.[66]

One of the diagnostic challenges for both sonography and MRI can be differentiating between focal adenomyosis and leiomyoma, because both lesions will be of low signal intensity on T2-weighted MRI sequences and are concomitantly seen in 35% to 55% of patients.[53] This distinction is important, as it helps to determine the choice of expectant, medical, or surgical management. MRI features that suggest the diagnosis of focal adenomyosis include visualization of the characteristic punctate foci of high signal intensity within a lesion that is of low signal intensity on T2-weighted sequences, an ovoid rather than round shape, indistinct margins, absence of a pseudocapsule, minimal mass effect, and continuation with the junctional zone (though this is not essential for diagnosis) (Fig. 36-19).[66,67] Although small hyperintense areas of hemorrhage are occasionally identified on T1-weighted sequences,[68] T1-weighted images, with or without contrast enhancement, are generally not helpful in the diagnosis. The distinction between focal adenomyosis or an adenomyoma from a leiomyoma based on imaging findings may sometimes be challenging.[60,62]

ENDOMETRIOSIS

Definition and Epidemiology

Endometriosis refers to the presence of ectopic functional endometrial tissue, which may proliferate in response to hormonal secretion. Caucasian women between 25 and 40 years of age are more commonly affected by this process.[68] Endometriosis affects 5% to 45% of women of reproductive age, but up to 50% of infertile patients.[59,68-70] The overall incidence of endometriosis is 298/100,000 person-years. However, the incidence is five times greater if there is a history of infertility, especially if due to müllerian duct anomalies.[68]

Etiology

The cause of endometriosis remains unclear; proposed theories include peritoneal seeding from retrograde transport of endometrial cells through the fallopian tubes, development from müllerian remnants, and metaplasia of peritoneal epithelium. These etiologic mechanisms may be complementary, although at present, the theory of retrograde transport of cells seems favored.[71]

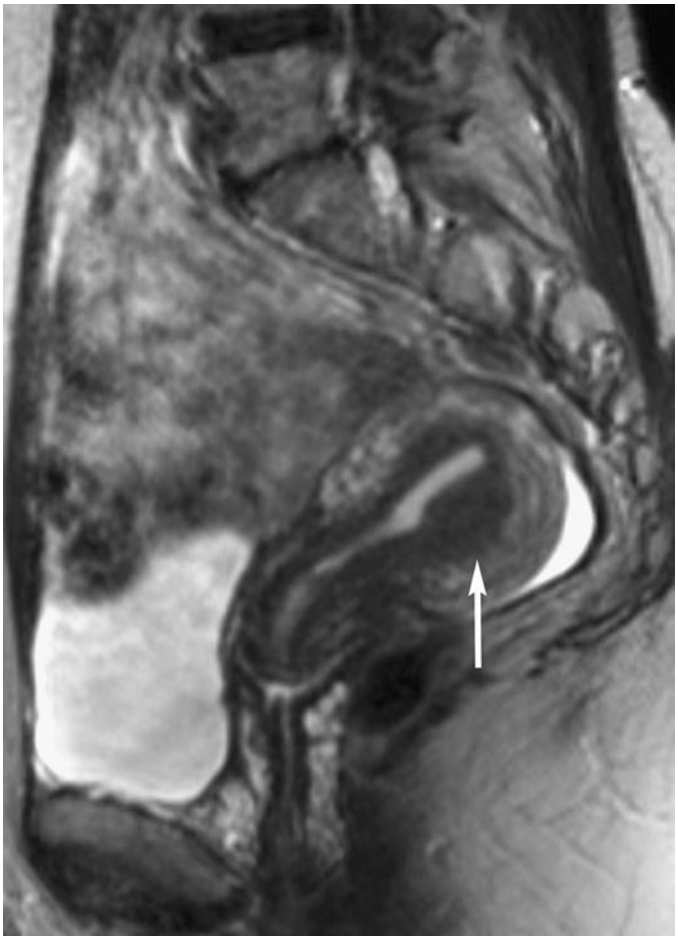

FIG 36-19 Focal adenomyosis. Sagittal T2-weighted image demonstrates a region of focal thickening of the junctional zone (*arrow*) with indistinct margins.

Clinicopathologic Aspects

Typical symptoms of endometriosis include dysmenorrhea, dyspareunia, chronic pelvic pain, and infertility. Although most frequently identified within the pelvis, endometriosis has been described in remote and unusual locations, including the lungs, abdominal wall, and central nervous system.[72-74] Within the pelvis, the sites of involvement in order of decreasing frequency are the ovaries (endometriomas), uterine ligaments, pouch of Douglas, and pelvic peritoneal surfaces. Ovarian involvement is bilateral in 30% to 50% cases.[75]

Endometriomas are one of the most common blood-containing ovarian lesions and are usually found in association with more extensive endometriosis. The ovarian tissue may be partially or completely replaced by the ectopic endometrial tissue, with glands and stroma seen lining the wall of the lesion. A thick, dense fibrous capsule is almost always present at the periphery of an endometrioma. Although endometriomas usually contain old degraded blood products, fresh hemorrhage and clots may also be identified. Adhesions to surrounding structures and internal septations are common and may lead to the misdiagnosis of an ovarian malignancy by sonography.

Imaging

MRI is usually reserved for cases in which sonography is inconclusive or when there is failure of regression of an ovarian mass seen in the context of endometriosis. Although there are MRI features that suggest the diagnosis of endometrioma, differentiation of a solitary endometrioma from a hemorrhagic cyst is not always possible based on imaging criteria alone. Often, patients have undergone multiple pelvic ultrasound examinations prior to MRI, and the persistence of a hemorrhagic adnexal mass favors the diagnosis of endometrioma.[76]

The main advantage of MRI over sonography is the ability to confirm the presence of blood within the lesion. Blood products demonstrate high signal intensity on T1-weighted images, which characteristically persists with the application of fat suppression (Fig. 36-20).[77] On T2-weighted sequences, the contents of an endometrioma typically demonstrate low or intermediate signal intensity, depending on the concentration of methemoglobin and other iron products.[78] The loss of signal intensity on T2-weighted images compared to the T1-weighted images is referred to as T2 shading, and may be observed as a diffuse loss of signal intensity or with a layered configuration, with low signal intensity blood products layering dependently within the cyst, sometimes described as the *parfait sign* (Fig. 36-21).[79] A black peripheral rim representing hemosiderin deposition, consequent to recurrent and chronic episodes of hemorrhage, is another typical feature; however, it is not a specific finding of endometrioma (see Fig. 36-21).[76] The fibrous wall of an endometrioma typically is of low signal intensity on both T1- and T2-weighted sequences and may also show contrast enhancement.[80] Although uncommon, malignancy has been reported in association with endometriomas and should be suspected if an enhancing solid nodule or mass is noted within the lesion (Fig. 36-22).[81] In a study by Brinton and colleagues,[43] patients with a longstanding history of ovarian endometriosis had increased risk of ovarian cancer (standardized incidence ratio of 4.2, ranging from 2.0 to 7.7), which is most commonly endometrioid or clear cell type.

In some instances, it may be difficult sonographically to correctly identify an obstructed, blood-filled dilated fallopian tube (hematosalpinx), which often occurs in the setting of endometriosis. This diagnostic dilemma may be resolved with MRI, owing to its large field-of-view and multiplanar imaging capabilities. Endometrial implants are usually hyperintense on both T1- and T2-weighted images (Fig. 36-23); however, small endometrial implants ranging from 2 to 3 mm in diameter are often not detected by any imaging modality. MRI does appear to be fairly accurate for the detection of lesions greater than 1 cm in diameter, and the use of fat-suppressed T1-weighted images reportedly increases the detection of smaller implants.[82,83] Stratton and associates[84] reported a sensitivity and specificity of 69% and 75%, respectively, for detection of endometriosis on MRI using laparoscopy as the standard of reference. Another study reported similar results comparing MRI to laparoscopy; in this series MRI had a diagnostic accuracy of approximately 77%, and statistical analysis demonstrated excellent agreement regarding stage of disease as determined by the two methods ($\kappa = 0.916$, $P < 0.001$).[85] MRI appears to be especially useful for the evaluation of deep pelvic endometriosis and cul-de-sac obliteration (which can be difficult to visualize laparoscopically) with reported sensitivities and specificities ranging from 68% to 94% and 76% to 100%, respectively.[86-88]

CERVICAL CANCER

Epidemiology and Clinical Presentation

Cervical carcinoma represents the third most common gynecologic malignancy in the United States. It is diagnosed in 1 in every 154 American women over their lifetime. The American Cancer Society estimates that 12,990 new cases of cervical carcinoma will be diagnosed and that 4,120 cancer related deaths will occur in the United States in 2016.[89] Patients typically present between the third and fourth decades. Most noninvasive cervical cancers are asymptomatic and detected only

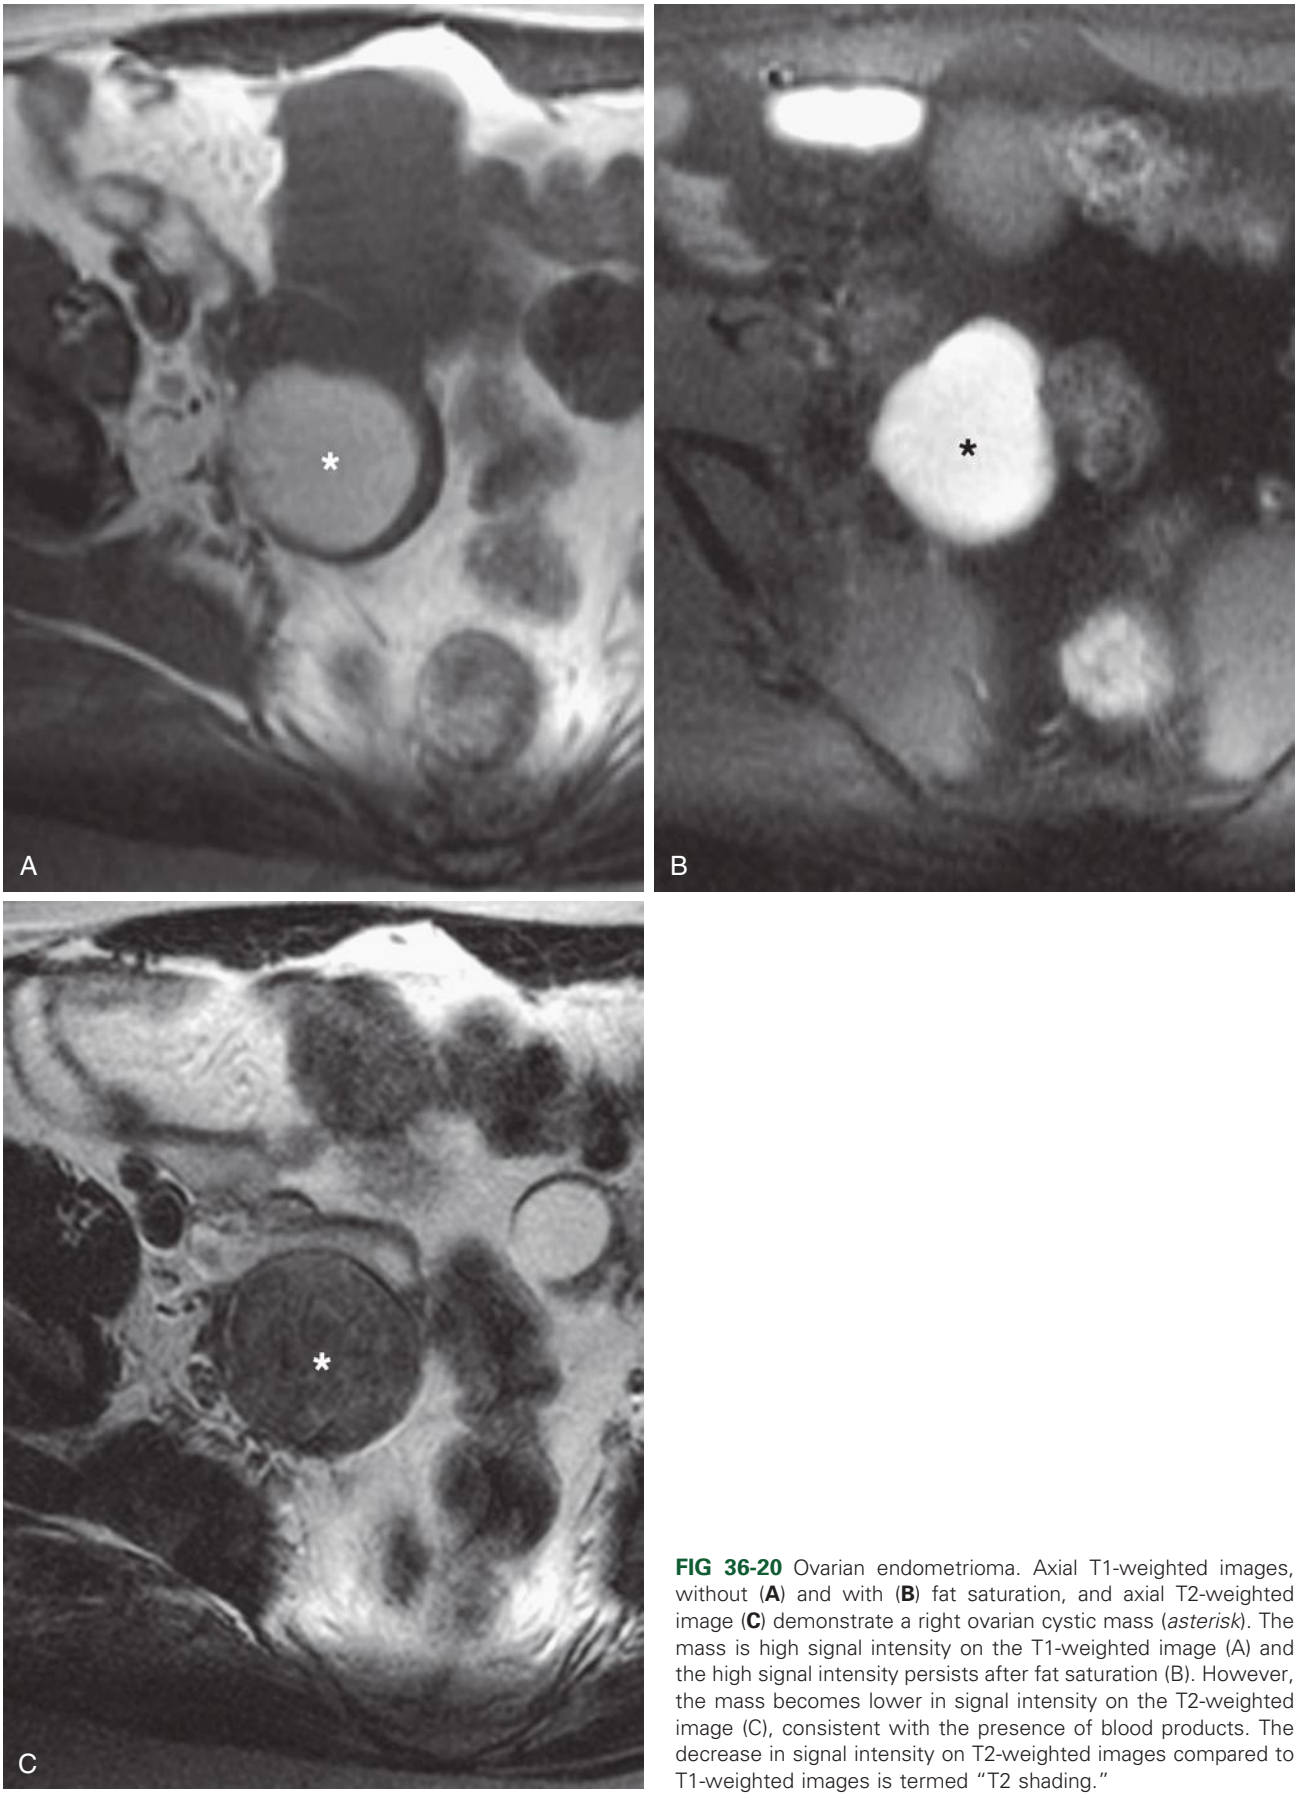

FIG 36-20 Ovarian endometrioma. Axial T1-weighted images, without (**A**) and with (**B**) fat saturation, and axial T2-weighted image (**C**) demonstrate a right ovarian cystic mass (*asterisk*). The mass is high signal intensity on the T1-weighted image (A) and the high signal intensity persists after fat saturation (B). However, the mass becomes lower in signal intensity on the T2-weighted image (C), consistent with the presence of blood products. The decrease in signal intensity on T2-weighted images compared to T1-weighted images is termed "T2 shading."

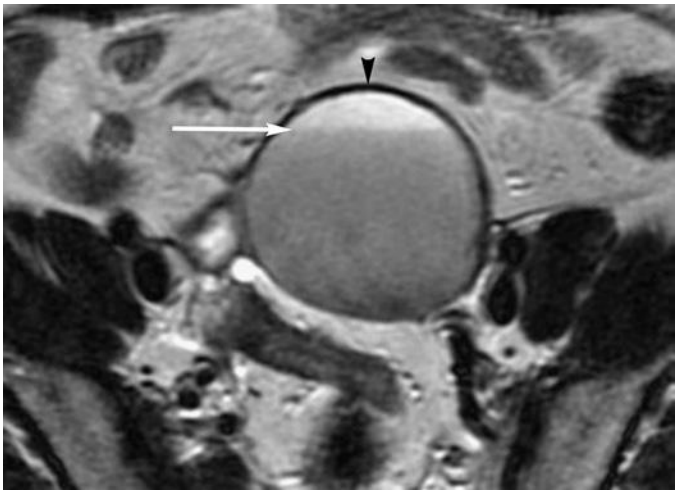

FIG 36-21 Ovarian endometrioma. Axial T2-weighted image shows a fluid-fluid level (*arrow*) with decreased signal intensity of the dependent portion, darker than the nondependent fluid seen anteriorly. This dependent area demonstrated higher signal intensity on the corresponding T1-weighted image (not shown). The drop in signal intensity between T1- and T2-weighted sequences is termed shading and is believed to be due to the presence of methemoglobin or other iron products. This layering effect has been referred to as the parfait sign and indicates the presence of blood products of varying ages within the endometrioma. Another common finding on magnetic resonance imaging of endometriomas is a very dark peripheral rim (*arrowhead*) due to hemosiderin deposition, also the result of blood degradation.

FIG 36-23 Endometriosis. Axial fat-saturated T1-weighted image of the pelvis demonstrates multiple masses of high signal intensity (*asterisks*), consistent with endometriosis.

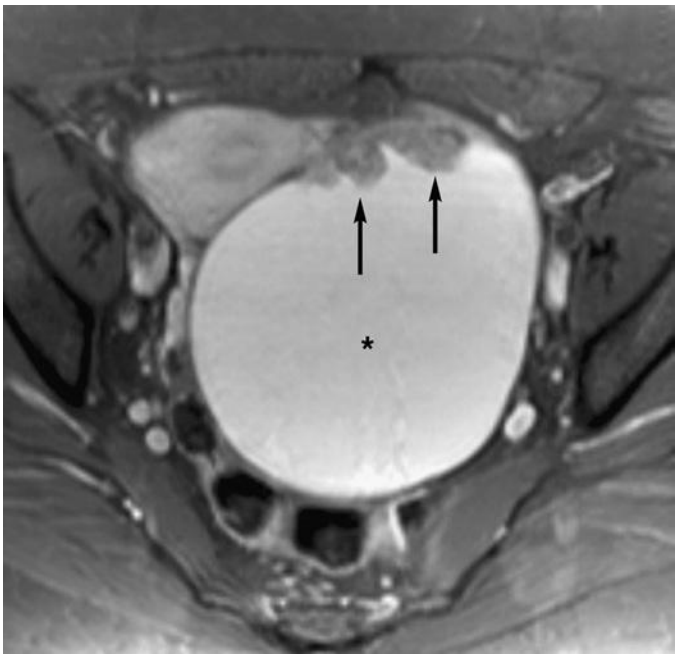

FIG 36-22 Clear cell carcinoma. Gadolinium-enhanced T1-weighted axial image with fat saturation. A large cystic mass (*asterisk*) that contains fluid of high signal intensity after fat saturation, consistent with blood, is seen within the pelvis. Enhancing mural nodules (*arrows*) anteriorly are suggestive of malignancy, and pathologic examination proved the lesion to be a clear cell carcinoma arising within an endometrioma.

by the Papanicolaou (Pap) smear. Patients with invasive cancer typically report a history of intermenstrual or postcoital bleeding but may also be asymptomatic.

Human papillomavirus (HPV) is the most important etiologic factor in cervical cancer. HPV 16 and 18 account for at least two thirds of cervical carcinomas on all continents, followed by HPV 31, 33, 35, 45, 52, and 58 as the next most common types in cancers worldwide. Squamous cell carcinomas are related to HPV infection in more than 99% of cases and the presence of HPV 18 DNA is associated with poor prognosis.[90] Several other risk factors have been reported, including early sexual activity, multiplicity of sexual partners, low socioeconomic status, smoking, and use of oral contraceptives; however, it is unclear if these represent independent risk factors or are directly or indirectly related to HPV infection.[91] HPV vaccination of adolescents was introduced in the United States in 2006 with the goal of decreasing the incidence of HPV-related cervical carcinoma.

Histopathology

The vast majority of cervical cancers are squamous cell carcinomas arising from foci of dysplasia and atypia at the squamocolumnar junction. The remaining 10% to 15% of cervical cancers arise from the endocervical glands and include adenocarcinoma, adenosquamous carcinoma, adenocystic carcinoma, small cell carcinoma, and lymphoma.[92,93] Adenoma malignum is a very rare subtype of cervical adenocarcinoma (3%) and is associated with Peutz-Jeghers syndrome. It is a multicystic lesion associated with copious watery vaginal discharge and is diagnosed only with deep biopsies of the cervix. Although it is histologically a well-differentiated lesion, in reality, adenoma malignum has very poor prognosis and responds poorly to therapy. The MRI appearance of adenoma malignum may be indistinguishable from a nabothian cyst. It is important to remember that this cancer is exceedingly uncommon and should not be diagnosed based on imaging

findings alone.[94] A few other rare tumors, such as villoglandular tumors, may be seen in the uterine cervix.[95]

There are three patterns of spread of squamous cell carcinoma of the cervix: direct invasion of adjacent organs, which is most common; lymphatic dissemination to pelvic and para-aortic lymph nodes; and rarely, hematogenous spread to the lungs and bones.[96]

Diagnosis

Imaging has no role in the initial diagnosis of cervical cancer. In the majority of cases, the cancer is detected through Pap smear or exfoliative cytologic tests. The effective use of screening has resulted in a decline in the incidence and mortality rate of invasive squamous cell carcinomas but a relative increase in the incidence of adenocarcinomas.[97-99]

Treatment

Treatment of cervical cancer largely depends on the stage of disease.[92,100] Patients with microinvasive (stage IA) and early macroinvasive (stage IB1, IIA < 4 cm) disease are usually offered curative surgery—total hysterectomy, with or without lymphadenectomy. If fertility is desired, patients with microinvasive cervical cancer can be treated with cone biopsy. Primary radiotherapy is an alternate option for early macroinvasive disease. For more advanced cases, treatment is usually a combination of surgery, radiotherapy, and chemotherapy.

Clinical Staging

Staging of cervical cancer is aimed at determining whether or not the tumor is resectable and is currently based on the International Federation of Gynecology and Obstetrics (FIGO) classification system, most recently updated in 2009 (Table 36-1) and unchanged in 2014.[100]

The FIGO classification represents a clinical approach based on findings from physical examination, which may be performed under anesthesia. However, many studies have demonstrated the value of cross-sectional imaging over clinical staging.[101-105] The most recently updated FIGO staging system encourages, but does not mandate, the use of diagnostic imaging techniques to assess the size of the primary tumor. In addition, other investigations, such as cystoscopy, sigmoidoscopy, and intravenous pyelography, are increasingly of historic interest and no longer considered mandatory.

The FIGO staging system is used as a predictor of patient survival,[106,107] but it has limitations. Studies have shown poor correlation between clinical FIGO stage and surgical-pathologic findings. Errors in staging have been reported to be as high as 30% for stage I, 50% for stage II, and 75% for stage III tumors.[93,108,109] These limitations primarily relate to failure in accurately estimating tumor size and in detection of parametrial, pelvic sidewall, bladder, and rectal wall invasion or of metastases to distant organs.[93] In addition, nodal status, known to be one of the most important prognostic factors for patients with cervical carcinoma, is not included even in the most recent revision of the staging system.[93,96,100,108,110]

Accurate staging influences clinical management. Current FIGO guidelines suggest surgical treatment or radiotherapy alone for patients with early disease (i.e., stages IA, IB1, and IIA, with tumor size less than or equal to 4 cm). Patients who have more extensive early disease, stage IB2 (tumor size greater than 4 cm) and stage IIA (upper vaginal involvement), may require radiation and chemotherapy. Furthermore, stage IIB disease (limited extrauterine extension to the parametrium) or greater precludes curative surgical treatment.

Imaging

MRI is highly accurate for staging cervical cancer, surpassing clinical staging when only stages IIA or greater are considered (73-81% vs. 53%).[111] T2-weighted sequences are most valuable in the evaluation of cervical cancer. On T2-weighted images, cervical cancer will be identified as a mass of intermediate signal intensity within the normally low signal intensity cervical stroma.[38,93] Dynamic gadolinium-enhanced T1-weighted imaging has been shown to improve detection of cervical cancer and may be especially useful for the evaluation of depth of stromal invasion, parametrial involvement, and bladder wall invasion.[93,105,112] However, the use of single-phase contrast-enhanced T1-weighted images may result in overestimation of disease.[93,104]

Early Stage Disease

Microinvasive cervical carcinoma (stage IA) cannot be detected by MRI; however, macroinvasive disease (stage IB) can be detected, with an accuracy of 91%.[38,93] In addition, MRI may be used to determine the depth of stromal invasion.[105] In stage IB disease, the low signal intensity cervical stromal ring completely surrounds the tumor (Fig. 36-24).[38,93] Stage II disease is characterized by local extension of tumor beyond the uterus. Stage IIA indicates invasion of the upper two thirds

TABLE 36-1 Carcinoma of the Uterine Cervix—Federation of Gynecology and Obstetrics (FIGO) Staging

FIGO Stage	Stage Description
I	Tumor confined to the cervix
IA	Microscopically invasive
IA1	Measured stromal invasion of ≤3.0 mm in depth and extension of ≤7.0 mm
IA2	Measured stromal invasion of >3.0 mm and ≤5.0 mm with an extension of ≤7.0 mm
IB	Clinically visible lesions limited to the cervix
IB1	Clinically visible lesion ≤4.0 cm
IB2	Clinically visible lesion >4.0 cm
II	Cervical carcinoma invades beyond the uterus but not to pelvic wall or lower third of the vagina
IIA	Without parametrial invasion
IIA1	Clinically visible lesion ≤4.0 cm
IIA2	Clinically visible lesion >4.0 cm
IIB	With parametrial invasion
III	Tumor extends to the pelvic wall, involves lower third of vagina, and/or causes hydronephrosis
IIIA	Tumor involves lower third of the vagina with no extension to the pelvic wall
IIIB	Extension to the pelvic wall and/or hydronephrosis/nonfunctioning kidney
IV	Tumor extends beyond the true pelvis or involves mucosa of bladder or rectum
IVA	Invasion of adjacent organs
IVB	Distant metastases

Cervical Cancer—5-year relative survival rate by stage

Stage	Survival Rate
All stages	68%
Localized (confined to primary site)	91%
Regional (spread to regional nodes)	57%
Distant (metastases)	16%

Data from Pecorelli S: Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. Int J Gynaecol Obstet 105:103, 2009; and American Cancer Society: Cancer Facts & Figures 2014. Atlanta, American Cancer Society, 2014.

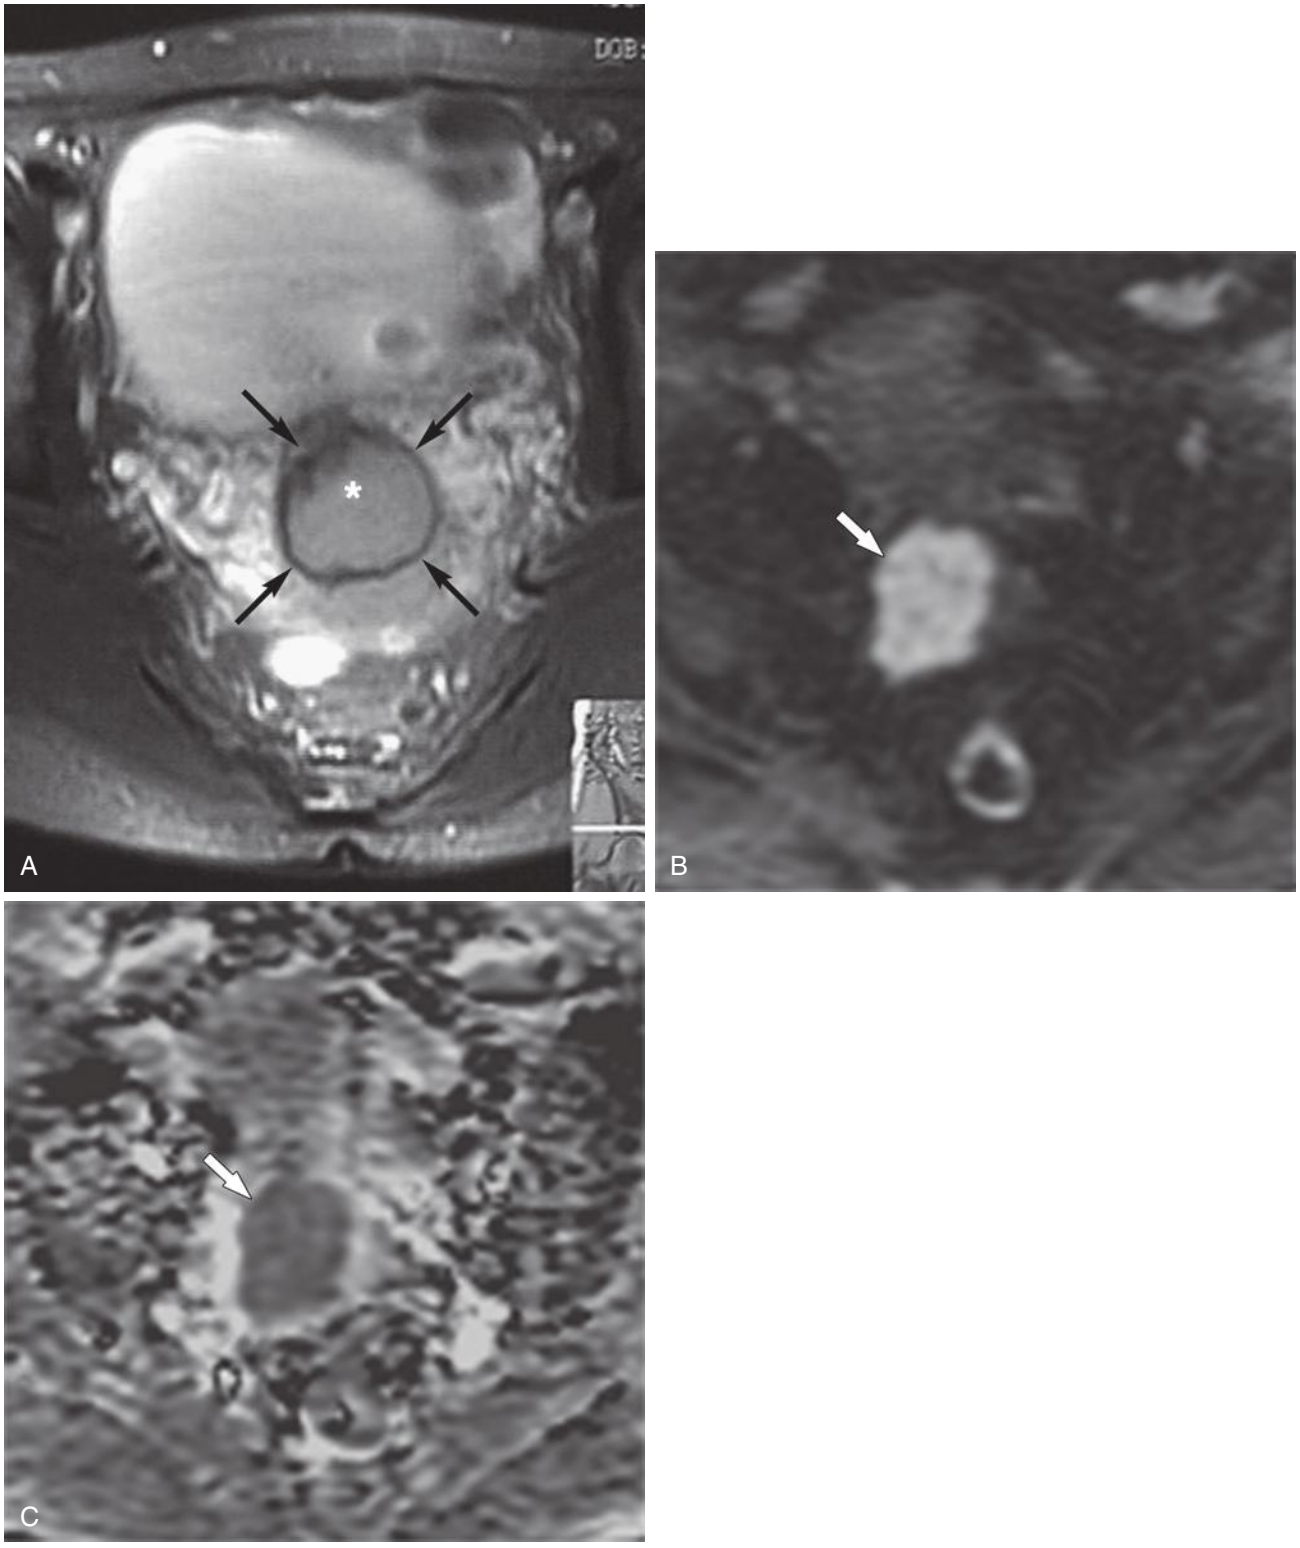

FIG 36-24 Stage IB cervical cancer. Axial T2-weighted (**A**), diffusion-weighted (**B**), and absolute diffusion coefficient or ADC (**C**) images. T2-weighted image (A) shows a mass (*asterisk*) of intermediate signal intensity confined to the cervix, with a preserved peripheral T2-weighted hypointense cervical stromal ring (*arrows* in A). Increased signal intensity (*arrow*) on diffusion-weighted image (B) and hypointense signal intensity (*arrow*) on the ADC image (C) within the mass indicate restricted diffusion.

of the vagina and stage IIB indicates parametrial extension (Fig. 36-25). Vaginal wall extension is best evaluated in the sagittal plane on MRI. Invasion of the vagina should only be diagnosed in the presence of vaginal wall thickening and an increase in the signal intensity of the normally low signal intensity vaginal wall on T2-weighted sequences or avid enhancement of the vagina on DCE-MRI images.[38,93]

Parametrial Extension

Axial T2-weighted images are used to assess for parametrial invasion. Parametrial extension (stage IIB disease) is diagnosed in the presence of partial or complete disruption of the dark ring of the cervical stroma, associated with an irregular interface between the cervix and adjacent fat (see Fig. 36-25). The presence of a definite bulge of asymmetric high signal tissue is a more specific finding of parametrial invasion. Occasionally, encasement of parametrial vessels may also be seen. Parametrial invasion is demonstrated with an accuracy of 68% to 96% on MRI.[93,105,109] More importantly, MRI has a high negative predictive value for parametrial invasion, ranging from 79% to 100%.[93,109,110,113] The positive predictive value of MRI for parametrial invasion is low, because MRI cannot accurately differentiate benign reactive changes seen adjacent to the cervix from actual tumor invasion.

Stage III Disease

Invasion of the lower third of the vagina (IIIA) and of the pelvic sidewall (IIIB) (Fig. 36-26) characterizes stage III disease. Pelvic sidewall invasion (stage IIIB) is demonstrated by the loss of fat planes between the tumor and the iliac blood vessels or the muscles of the pelvic sidewall.[93] Increased signal intensity of these muscles may also be observed on T2-weighted sequences (see Fig. 36-26).[93] An important indicator of pelvic sidewall invasion is the presence of hydronephrosis; therefore, MRI evaluation must include imaging of the upper abdomen, more specifically the kidneys, for assessment of hydronephrosis.[38,93] MRI has an accuracy of approximately 95% in characterizing stage III disease.[113]

Stage IV Disease

Bladder and rectal invasion are also characterized by loss of fat planes between these organs and the tumor, as well as by increased T2-weighted signal intensity, enhancement, thickening, and irregularity of the bladder and rectal walls (Fig. 36-27).[38,93] MRI has been reported to be 96% accurate in making the diagnosis of bladder and rectal invasion.[113]

Tumor Size Assessment

Tumor size has been shown to be a significant prognostic factor, and several studies have demonstrated that MRI is an accurate technique for assessing this.[93,108,110,113,114] MRI is far more reliable than clinical examination in assessing tumor size, with reported accuracy approximating 90%.[115]

Lymph Node Assessment

The latest revision of the FIGO staging system for cervical cancer does not include evaluation of lymph nodes, although it has been shown that lymph node metastases have an impact on prognosis. The presence of nodal metastases has been reported to decrease the 5-year survival rate from 89% to between 48% and 57%.[116]

MRI determination of lymph node involvement is largely dependent on size criteria. A threshold of 1 cm or greater diameter in short axis is generally accepted as indicative of metastatic involvement.[117-119] However, enlarged lymph nodes are a nonspecific finding and may represent merely reactive, hyperplastic lymph nodes in patients with malignancy. Furthermore, small lymph nodes may contain

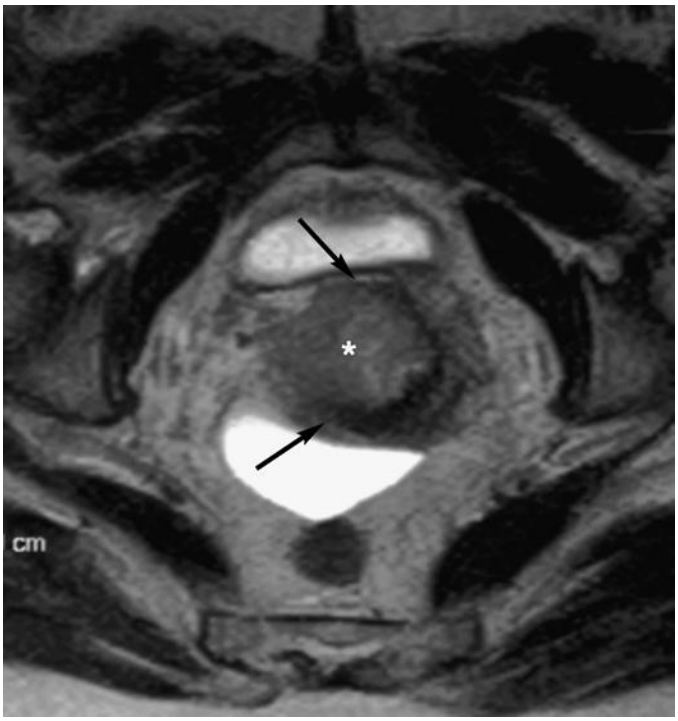

FIG 36-25 Stage IIB cervical cancer. Axial T2-weighted image. There is interruption of the hypointense ring of cervical stroma (between the *arrows*) by a large moderately hyperintense cervical mass (*asterisk*) that bulges into the adjacent fat.

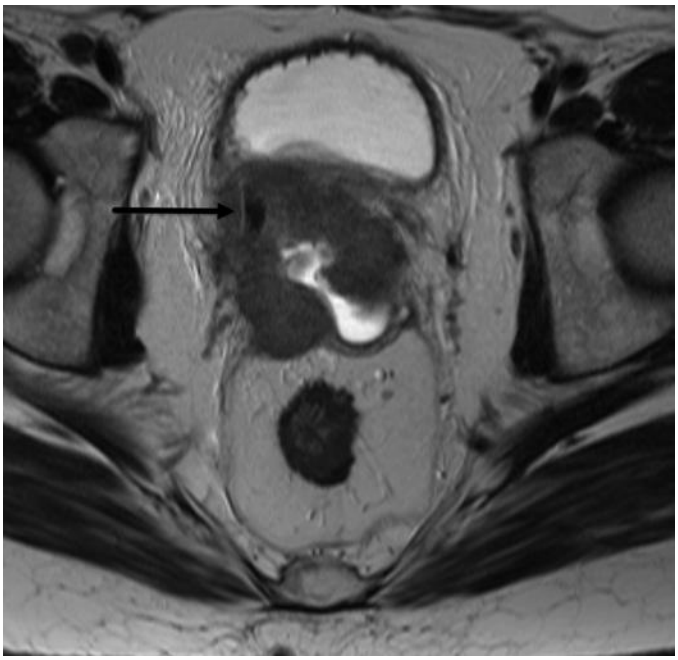

FIG 36-26 Stage IIIB cervical cancer. Axial T2-weighted image shows an irregular mass extending beyond the cervix into the parametrium bilaterally. Right hydronephrosis was present (not shown) with a stent in the right ureter (*arrow*). The mass appears to be contiguous with the bladder wall; cystoscopy revealed external mass effect, but no invasion into the bladder.

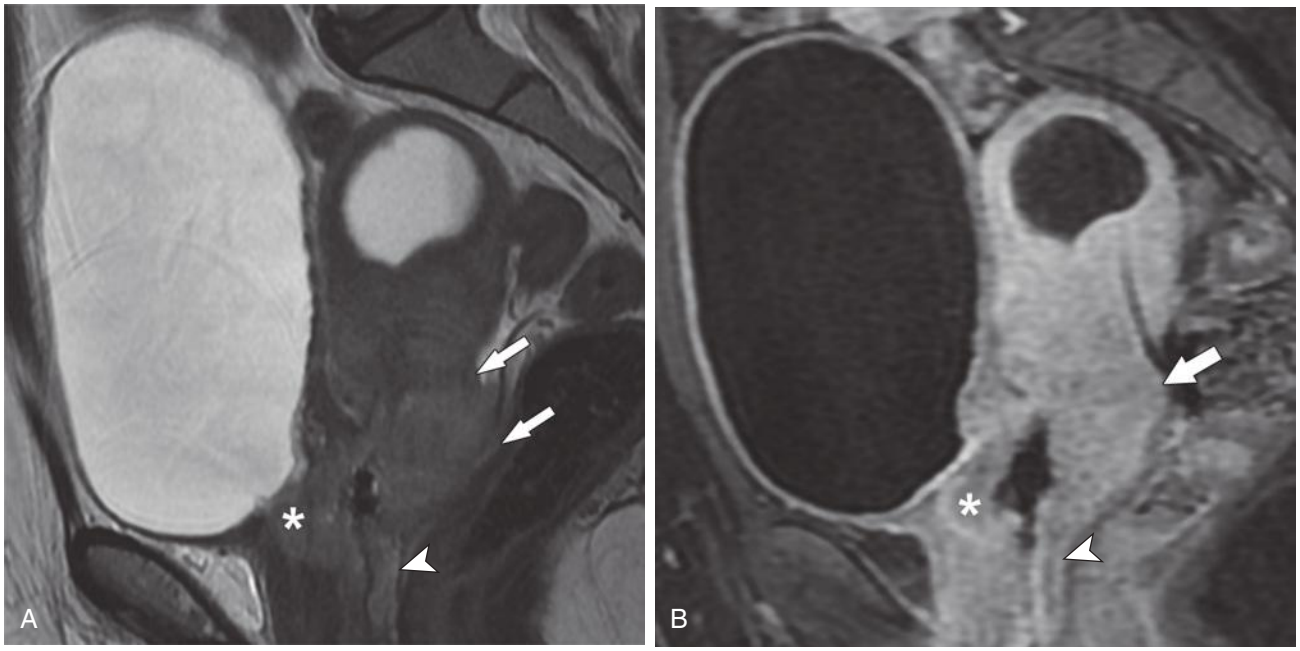

FIG 36-27 Stage IV cervical cancer. Sagittal T2-weighted image (**A**) and gadolinium-enhanced fat-saturated T1-weighted image (**B**) show a large cervical mass extending into the lower uterine segment (*arrows*) and vagina (*arrowhead*). The mass also involves the bladder neck (*asterisk*). Note the distended urinary bladder related to bladder outlet obstruction.

microscopic foci of metastatic disease. The use of lymph node–specific contrast agents, MR lymphography with ultra-small superparamagnetic iron oxide particles, remains under investigation, but sensitivities of 90% to 100% and specificity greater than 95% have been reported for the detection of nodal metastases.[118]

ENDOMETRIAL CANCER

Epidemiology and Clinical Presentation

Endometrial cancer is the 10th most common cancer in women and the most common invasive gynecologic malignancy. The American Cancer Society estimates that 60,050 new cases of cancer of the uterine corpus will be diagnosed and that 10,470 cancer related deaths will occur in the United States in 2016.[89] Despite the high incidence compared with other gynecologic malignancies, endometrial cancer has the most favorable prognosis, and most patients with newly diagnosed disease are cured by surgery alone or in combination with adjuvant radiation therapy.[120] Endometrial cancer occurs more frequently in Caucasians and typically presents during the 6th and 7th decades with painless postmenopausal bleeding.[121,122] Many risk factors have been described; most are directly or indirectly related to increased estrogen exposure, including early menarche, late menopause, nulliparity, Stein-Leventhal syndrome (polycystic ovary syndrome), diabetes, and obesity. In addition, a higher incidence of endometrial cancer is associated with adenomatous polyps, breast cancer, and the use of unopposed estrogen therapy.[121-124]

Histopathology

More than 80% of endometrial cancers are of the endometrioid type, which refers to the presence of endometrial type glands of varying degrees of differentiation. These cancers are subdivided into two groups: type 1 (low grade) and type 2 (high grade). Type 1 endometrial cancers are related to long-term unopposed estrogen therapy; they originate from endometrial hyperplasia and have a more favorable prognosis. Type 2 cancers account for approximately 10% of endometrial cancers; they are most often seen in association with an atrophic endometrium and have a poorer prognosis. Other histologic types include serous and clear cell carcinomas. Approximately 8% of patients with endometrial cancer present with a synchronous ovarian carcinoma of the same histologic type.[121]

Endometrial carcinoma may present as a localized endometrial lesion, mimicking a polyp, or as diffuse thickening of the endometrium. Tumor spread initially occurs by direct myometrial or cervical extension. Lymphatic invasion is usually limited to the pelvis but may extend to periaortic and aortocaval nodes.[121] Transtubal peritoneal seeding and hematogenous dissemination to the lungs or other sites may occur.[125]

Diagnosis

The diagnosis of endometrial cancer is based on histologic evaluation of endometrial biopsy specimens, which is highly accurate, especially in symptomatic postmenopausal women. The two most common pathways to diagnosis are immediate endometrial biopsy in a symptomatic woman or transvaginal sonography, followed by biopsy.[121] Estimation of the risk of endometrial cancer following transvaginal sonography in a postmenopausal woman depends upon the presence or absence of vaginal bleeding, the thickness of the endometrial stripe, and the patient's age. In postmenopausal women with vaginal bleeding, an endometrium measuring more than 4 to 5 mm translates to a risk of approximately 7.3%, whereas in the absence of bleeding, a similar risk (6.7%) is seen if the endometrium measures 11 mm or more in thickness.[8] In these two situations, biopsy is warranted. MRI has no role in diagnosing endometrial cancer and is usually reserved as an aid for pretreatment planning.

Treatment

The primary treatment modality for endometrial cancer is total hysterectomy with bilateral salpingo-oophorectomy and peritoneal fluid

aspiration and washings. In selected cases, omentectomy and retroperitoneal lymph node dissection are performed.[121] Radiation therapy is generally prescribed as an adjuvant treatment to target microscopic metastatic lymphadenopathy. In patients who are not operative candidates because of medical comorbid conditions, radiation therapy may be used with curative purpose. Systemic adjuvant chemotherapy is reported to have results similar to radiation therapy, but with greater toxicity. In patients with more advanced disease, the use of systemic chemotherapy is palliative.[121]

Staging

Patients with endometrial cancer are staged surgically, usually using the system proposed by FIGO (Table 36-2)[124] or the American Joint Committee on Cancer.[126] Surgical staging provides prognostic information, but is also important for guiding treatment selection.

A poorer prognosis is expected in patients who present with deep myometrial invasion (>50%, stage IB), cervical extension (stage II), and nodal involvement (stage IIIC). Other important prognostic factors include positive peritoneal cytologic findings, poorly differentiated cancer, serous papillary tumor, and clear cell tumors.

Depth of myometrial invasion was found to be the single most important predictor of survival at 5 and 10 years, in a series of 1566 women with endometrial carcinoma.[127] Women with superficial myometrial invasion (invasion of <50% of the myometrial wall thickness, stage IA) have a 3% to 9% incidence of lymph node metastases and a survival rate of 85% at 5 years. Deep myometrial invasion (invasion of >50% of the myometrial wall thickness, stage IB) is associated with a 20% to 40% risk of nodal disease and a survival rate of only 63% at 5 years.[127] Besides providing prognostic information, staging is also important for treatment selection. For instance, there is evidence that radiation therapy is not indicated in low- or intermediate-risk stage I disease (stage IA and IB) but may be beneficial for patients with more advanced disease and higher risk.[128] Similarly, surgical treatment is dictated by staging, and patients with stage IA disease may not require radical lymphadenectomy, depending on the size and grade of the tumor.[128]

MRI is an accurate tool for endometrial cancer staging, with an overall staging accuracy of approximately 85%.[104,129] The use of gadolinium is an important part of the examination and has been shown to increase the accuracy for assessing depth of myometrial invasion.[104,130-132] The reported accuracy of MRI for identification of deep myometrial invasion varies from 74% to 95%,[129-137] compared with 68% to 73% for transvaginal sonography.[130,138] However, MRI can overestimate depth of myometrial invasion, especially when bulky disease is present that stretches and thins the surrounding myometrium.[134,135] Finally, MRI can also assess cervical extension of tumor (stage II) and extrauterine disease (stages III and IV).

Although imaging evaluation of nodal metastasis has not been reported to be as reliable as surgical sampling, because of the limited accuracy when using size criteria on imaging to characterize and assess for lymph node involvement (see discussion earlier under "Lymph Node Assessment"), results of studies applying ultra-small particles of iron oxide or ultra-small superparamagnetic iron oxide (unavailable in the United States, as its use is not yet approved by the Food and Drug Administration) have been promising. Rockall and coworkers[118] reported excellent sensitivity and specificity for the detection of nodal metastasis on analyses performed per node and per patient, ranging from 82% to 100% and 87% to 97%, respectively. The negative predictive value varied between 96% and 100%.

TABLE 36-2 Carcinoma of the Endometrium—Federation of Gynecology and Obstetrics (FIGO) Staging

FIGO Stage	Stage Description
0	Carcinoma in situ
I	Limited to the body of the uterus
IA	No or less than 50% myometrial invasion
IB	Equal to or greater than 50% myometrial invasion
II	Cervical stromal involvement Endocervical glandular involvement only is stage I
III	Local or regional spread of the tumor
IIIA	Tumor invades the serosa of the body of the uterus and/or adnexa
IIIB	Vaginal or parametrial involvement
IIIC	Pelvic or para-aortic lymphadenopathy
IIIC1	Positive pelvic nodes
IIIC2	Positive para-aortic nodes with or without pelvic nodes
IV	Involvement of rectum and/or bladder mucosa and/or distant metastases
IVA	Bladder or rectal mucosal involvement
IVB	Distant metastases, malignant ascites, peritoneal involvement

Endometrial Cancer—5-year relative survival rate by stage

Stage	Survival Rate
All stages	82%
Localized (confined to primary site)	95%
Regional (spread to regional nodes)	68%
Distant (metastases)	17%

Data from Pecorelli S: Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. Int J Gynaecol Obstet 105:103, 2009; and American Cancer Society: Cancer Facts & Figures 2014. Atlanta, American Cancer Society, 2014.

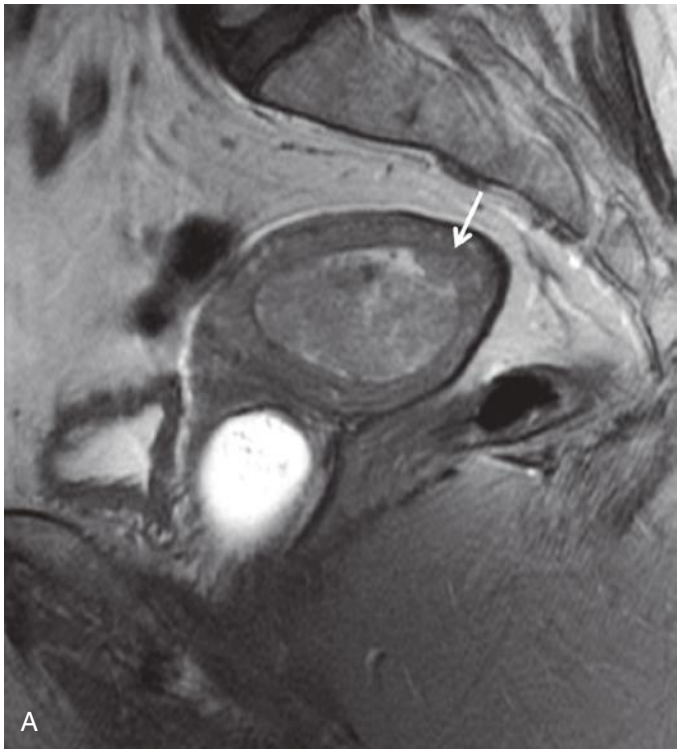
Imaging

As mentioned previously, MRI is not used for the diagnosis of endometrial carcinoma, but it is an established part of the imaging evaluation when locally extensive disease is suspected or when physical examination is limited.

Endometrial carcinoma is usually depicted on MRI as an endometrial mass that is iso- or hypointense to normal endometrium on T1-weighted sequences and slightly hyperintense or heterogeneous on T2-weighted sequences. After intravenous gadolinium contrast administration, tumor enhancement is variable, depending upon histologic type and temporal resolution. Endometrial carcinoma is usually hypointense to the myometrium on early phase images. The administration of gadolinium allows vascularized tumors to be distinguished from debris or fluid in the endometrial cavity or endocervical canal. In addition, dynamic gadolinium enhancement facilitates visualization of the junctional zone and the tumor-myometrium interface, as the uterine zonal anatomy may be poorly defined on T2-weighted images in postmenopausal women.

Superficial myometrial invasion (stage IA) is suspected in the presence of interruption of the dark, low signal junctional zone on T2-weighted sequences or subendometrial band of enhancement after contrast administration (Fig. 36-28).[129,130,137] Deep myometrial invasion (stage IB) is characterized if tumor is seen extending into more than 50% of the myometrial thickness, with an intact outer rim (Fig. 36-29).

Cervical extension of tumor (stage II) is best evaluated using sagittal T2-weighted or contrast-enhanced images and may appear as a



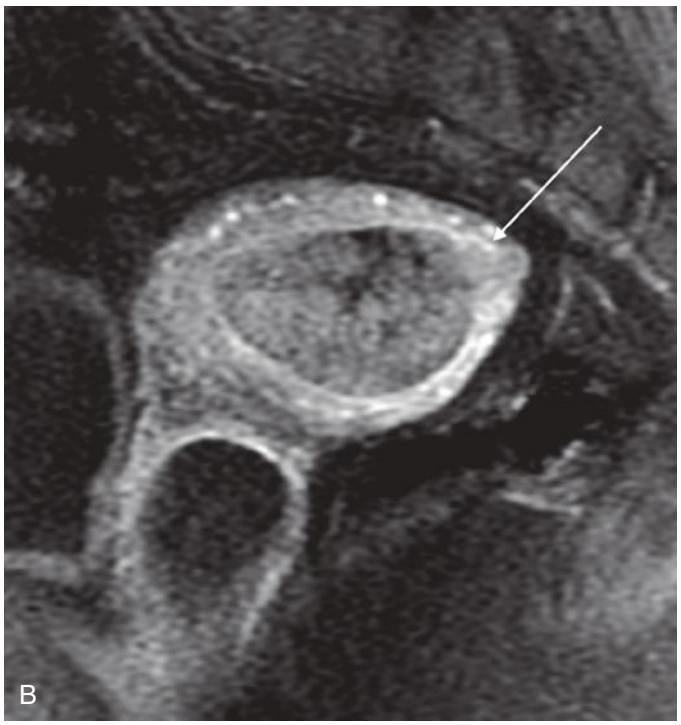


FIG 36-28 Stage IA endometrial cancer. Sagittal T2-weighted (**A**) and sagittal dynamic gadolinium-enhanced fat-saturated T1-weighted (**B**) images show a tumor filling the endometrial cavity with irregularity at the endometrial-myometrial interface posteriorly (*arrows*). Additional images were used to diagnose less than 50% myometrial invasion. Pathologic examination confirmed that the tumor invaded 4 mm into a 12-mm thick myometrium.

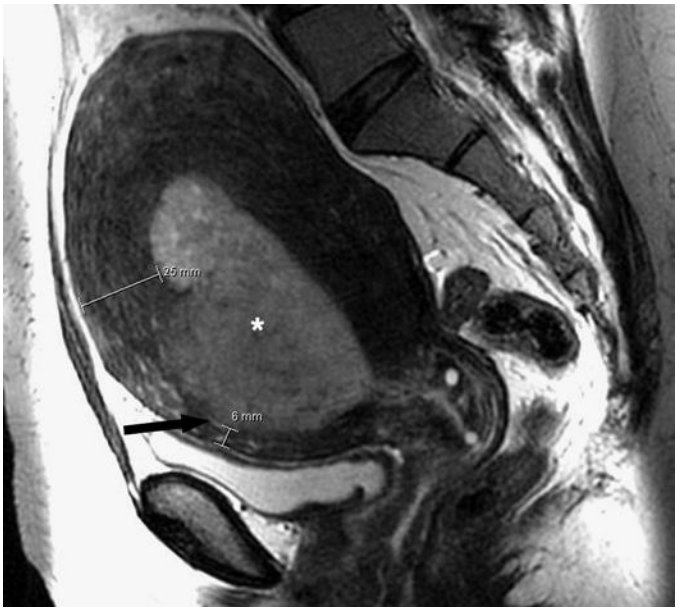

FIG 36-29 Stage IB endometrial cancer. Sagittal T2-weighted image demonstrates a large hyperintense mass (*asterisk*) invading through more than 50% of the myometrial wall thickness anteriorly (*arrow*).

mass expanding the cervical canal (Fig. 36-30). Stage III disease is characterized by extension of tumor beyond the serosa, to the adnexa and parametrium, positive peritoneal cytologic finding, invasion of the vagina, and metastatic pelvic and para-aortic lymph nodes (Fig. 36-31). Stage IV is defined as bladder or rectal invasion and distant metastases. Invasion of the bladder and rectum is suggested by the loss of normal tissue planes, especially fat planes, associated with an increase in signal intensity and thickness of the bladder or rectal walls on T2-weighted images. Contrast administration is also useful to make this diagnosis.

ADNEXAL MASSES

Epidemiology and Clinical Significance

It is very common for premenopausal women to develop self-limiting cystic adnexal lesions related to ovulation. In the vast majority of cases these are asymptomatic functional cysts that involute and go undiagnosed; however, approximately 1.5% of women develop a malignant ovarian tumor.[1] Ovarian cancer is the fifth leading cause of cancer-related death among women in the United States and the leading cause of death from gynecologic malignancy. The American Cancer Society estimates that 22,280 new cases of ovarian cancer will be diagnosed and that there will be 14,240 cancer related deaths in the United States in 2016.[89,139] Gynecologic surgery is often prompted by the presence of an adnexal lesion, irrespective of the histologic diagnosis. Approximately 5% to 10% of women in the United States undergo surgery because of a suspected ovarian mass. Imaging plays an important role in lesion characterization, staging, and treatment planning in patients with ovarian cancer.[140]

Many factors must be considered when evaluating a patient with an adnexal mass. They include the patient's age and menopausal status, cancer antigen 125 levels, risk factors, and clinical history. Accurate diagnosis of benign lesions is crucial, as further workup can then be avoided, resulting in reduction of overall health care costs, morbidity, and patient anxiety. Even if resection of a benign lesion is warranted, a less invasive approach, such as laparoscopic surgery, may be used.

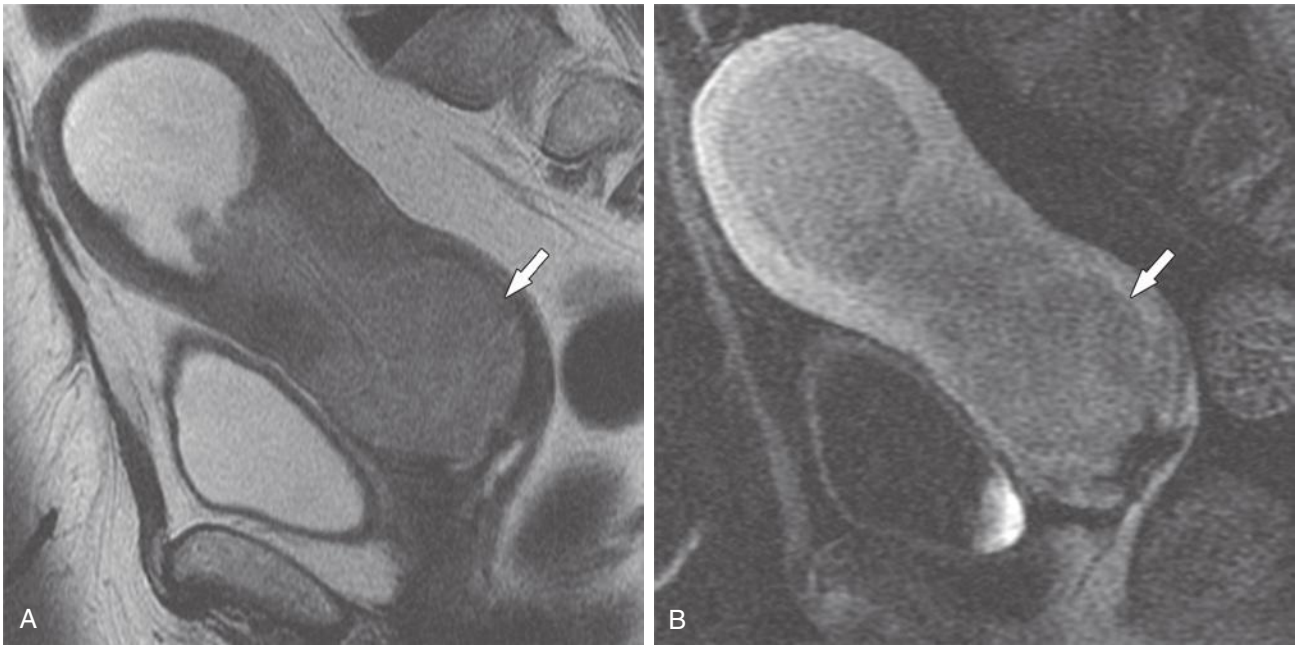

FIG 36-30 Stage II endometrial cancer. Sagittal T2-weighted (**A**) and sagittal dynamic gadolinium-enhanced fat-saturated T1-weighted (**B**) images show a large endometrial cancer invading and distending the cervix (*arrows*).

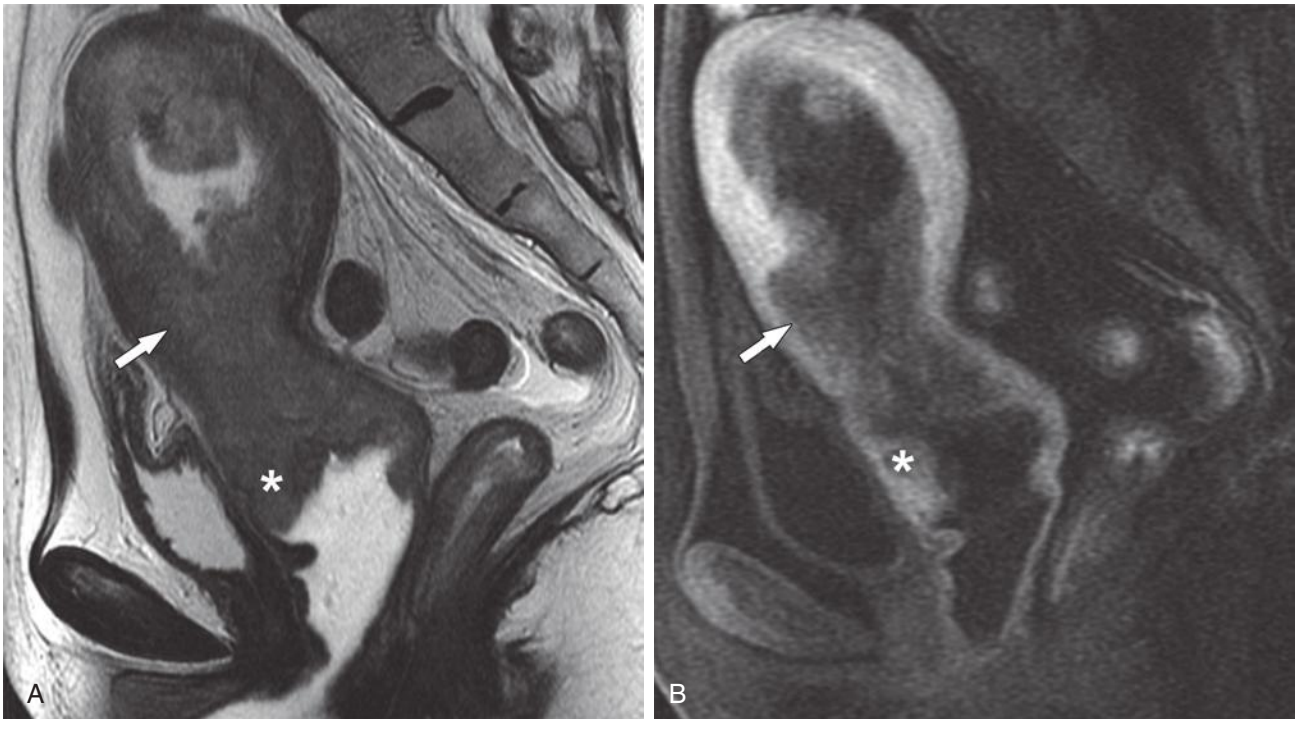

FIG 36-31 Stage IIIB endometrial cancer. Sagittal T2-weighted (**A**) and sagittal dynamic gadolinium-enhanced fat-saturated T1-weighted (**B**) images show an irregular endometrial tumor with greater than 50% myometrial invasion (*arrows*) and extension into the cervix and upper vagina (*asterisks*).

Those patients found to have malignant lesions should be referred to gynecologic oncologists, as specialized management has been shown to result in improved survival.[141] In patients with ovarian malignancies, initial surgery can be both diagnostic and therapeutic and is best performed by a surgeon with subspecialized expertise.

Imaging Diagnosis and the Role of Magnetic Resonance Imaging

Sonography is the primary initial imaging modality for the evaluation of an adnexal mass. The sensitivity and specificity of ultrasound imaging for differentiating benign from malignant adnexal masses

range from approximately 50% to 100% and 46% to 100%, respectively. Ultrasound imaging is particularly useful in distinguishing simple cysts from complex cystic or solid lesions. MRI is beneficial in the evaluation of women with sonographically indeterminate ovarian lesions and low risk for malignancy. In women with indeterminate lesions at high risk of malignancy, imaging should focus on staging the tumor.[142,143]

Advantages of MRI over ultrasound imaging relate to its ability to more precisely identify the composition of soft tissue masses by using differences in tissue relaxation times. MRI is not considered a first-line modality of choice in evaluating adnexal masses because it is expensive, and pelvic sonography often provides all the information necessary to guide patient management. However, MRI is an excellent problem-solving tool, and allows confident diagnosis of many common benign adnexal lesions.[143,144] When an indeterminate mass is seen on ultrasound imaging, contrast-enhanced MRI can diagnose malignancy with a sensitivity and specificity of 100% and 94%, respectively.[142,145] The Radiology Diagnostic Oncology Group study showed that MRI was the most accurate technique in the preoperative evaluation of adnexal masses to assess for possible ovarian malignancy, whereas there was no significant difference between sonography and CT.[146]

Differentiation of Benign and Malignant Lesions

In general, benign ovarian masses are cystic with thin walls and septa (less than 3 mm); however, there are exceptions to this rule, as will be discussed subsequently. Malignant adnexal masses often manifest internal complexity, referring to the presence of mural nodules, thick septa, solid components, and necrosis. Another feature that suggests malignancy is bilaterality.[81] Malignant tumors are rarely subtle lesions, and peritoneal spread is frequently identified at the time of imaging.[146] Although size has been reported to be a useful feature in differentiating benign from malignant lesions,[147] it is important to remember that even large tumors are more often found to be benign. Although a solid adnexal mass is suggestive of malignancy, and possibly metastasis, not all solid tumors are malignant,[148] and with MRI some benign solid ovarian entities can be diagnosed with adequate accuracy to avoid further workup.

A helpful diagnostic approach is to categorize adnexal masses into one of the following groups: lesions with distinctive features (fat, blood, or fibrous tissue) and a specific diagnosis; cystic, benign-appearing lesions; cystic, malignant-appearing lesions; and predominantly solid lesions.

Specific Diagnosis Based on Magnetic Resonance Imaging Findings

Adnexal Masses With Distinctive Imaging Features (Fat, Blood, or Fibrous Tissue)

Dermoid cysts, also known as benign mature teratomas, are hamartomas that may contain hair, teeth, fat, and mural nodules.[81,149,150] Usually identified during the first 3 decades of life, these lesions are not uncommon but may be missed on pelvic sonogram.[150] In some cases, the ultrasound finding of echogenic fat in the dermoid cyst may simulate adjacent normal structures, such as gas-filled bowel. In contrast, these tumors can be readily identified on MRI because characteristic high signal intensity of fat on T1-weighted images is lost when fat suppression techniques are applied (Fig. 36-32).[81,149]

The two most common adnexal lesions that contain blood are hemorrhagic ovarian cysts and endometriomas. Endometriomas were discussed earlier in this chapter. MRI of hemorrhagic cysts is not commonly performed, because these cysts usually resolve spontaneously, and follow-up sonogram after 6 to 8 weeks is sufficient. As a general rule, if MRI confirms the presence of blood within an ovarian cyst, no further diagnostic tests are necessary.

Fibromas are the most common sex cord tumors and represent 4% of all ovarian neoplasms. Because of their solid nature, they may be misdiagnosed on sonography as malignant or suspicious lesions or mistaken for exophytic uterine myomas. Classic sonographic features include a markedly hypoechoic solid ovarian mass with attenuation of the sound beam, related to their fibrous composition. On MRI, fibromas demonstrate characteristic morphologic features. Fibromas are composed of bundles of spindle cells resembling fibroblasts, collagen, and hyalinized fibrous tissue and demonstrate low signal intensity on both T2- and T1-weighted sequences and only slight enhancement after gadolinium administration (Fig. 36-33). Ascites may be present in up to 40% of cases, more often when the lesion is large. Meigs syndrome refers to an association with pleural effusions.[81,149,151,152] The malignant potential of fibromas is reported to be less than 1%. Two other ovarian lesions that often manifest foci of low signal intensity on both T2- and T1-weighted MRI sequences are fibrothecoma and cystadenofibroma. Fibrothecoma is a variant of fibroma containing a small population of thecal cells with intracellular lipid. It is similar in MRI appearance to a fibroma, but can be hormonally active and may be associated with endometrial polyps and endometrial hyperplasia.[81,149,151,152] Cystadenofibroma is a variant of serous cystadenoma with very low malignant potential. In most cases, it appears as a multiseptated mass, although small mural nodules may be noted in some.[81,149]

Cystic Benign-Appearing Lesions

The most common entity in this category is a physiologic cyst (including follicular cysts). Other possibilities include corpora lutea, theca-lutein cysts, paraovarian cysts, hydrosalpinges, peritoneal inclusion cysts, and cystadenomas. In the vast majority of patients, ultrasound imaging correctly diagnoses and classifies these cysts as benign. However, MRI may provide additional information in the unusual case complicated by infection or hemorrhage.

Cystic Malignant-Appearing Lesions

Epithelial tumors represent the most common primary ovarian cancers[81,153]; therefore, they are the most common malignant-appearing cystic adnexal masses. Histologically, these tumors are classified as serous, mucinous, endometrioid, and mesonephroid (clear cell), although recent pathologic analysis suggests that most high-grade serous ovarian tumors actually originate from cells lining the fallopian tube. Most often, these malignancies are cystadenocarcinomas or borderline tumors. Distinguishing these two entities can be difficult because they present with similar imaging features, namely, thick walls or septations and solid mural components (Figs. 36-34 and 36-35).[81] The absence of invasion or metastatic disease favors the diagnosis of a borderline tumor. Ascites is considered a sign of more aggressive disease. In addition, extensive calcifications usually indicate malignancy, particularly in the case of serous tumors. The T1- and T2-weighted signal intensities of cystic areas in a mucinous tumor are often variable, owing to different amounts of mucin within locules.[81]

Predominantly Solid Lesions

Predominantly solid lesions of the adnexa may represent primary ovarian lesions, leiomyomas, or nonovarian origin tumors, such as metastases or lymphoma.

The ovary is the most common site of metastasis to the female genital tract. The primary tumors that most commonly spread to the ovaries are endometrial, cervical, gastric, colorectal, and breast cancers.[154] Metastases to the ovaries have no specific appearance but

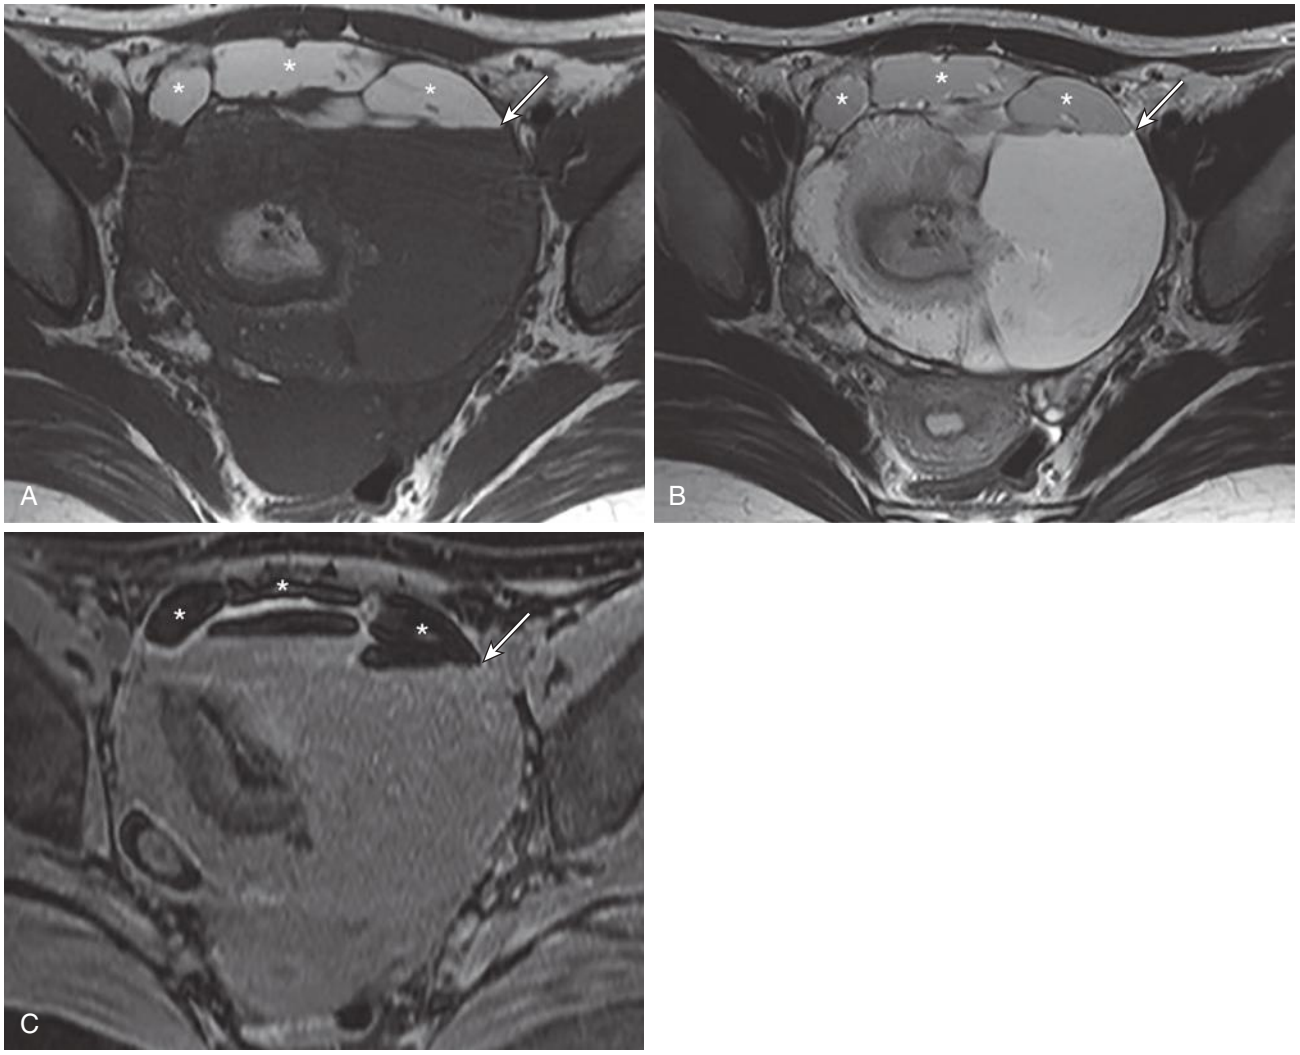

FIG 36-32 Benign mature cystic teratoma of the ovary. Axial T1-weighted (**A**), T2-weighted (**B**), and fat-saturated T1-weighted (**C**) images. Complex adnexal mass with fat-fluid level (*arrows*). Areas of increased signal intensity (*asterisks*) on T1-weighted (A) and T2-weighted (B) images and corresponding low signal intensity on fat-saturated T1-weighted image (C) are consistent with macroscopic fat, characteristic of a teratoma. (Courtesy of Lisa M. Ho, MD, Duke University, Durham, NC.)

are commonly bilateral masses with marked contrast enhancement. They can be predominantly cystic with necrotic areas or appear primarily solid. The primary tumor is usually clinically apparent with metastatic disease elsewhere (often grade IV).[154-157] Ovarian lymphoma is exceptionally rare but should be suspected in the presence of extensive lymphadenopathy in order to avoid unnecessary surgery.[158]

Primary ovarian tumors can also present as predominantly solid masses; examples include dysgerminomas, granulosa cell tumors, and Sertoli-Leydig cell tumors, also known as androblastomas and arrhenoblastomas. All such tumor types are uncommon, without specific imaging features. They are predominantly solid, though they may demonstrate associated cystic areas (Fig. 36-36). They are most frequently diagnosed in patients younger than 30 years of age, although granulosa cell tumors also have a second peak incidence in postmenopausal women. Dysgerminomas are responsible for one third of all ovarian tumors during pregnancy, and a disproportionate degree of adenopathy, relative to the size and appearance of the ovarian lesion, is sometimes noted.[96] Granulosa cell tumors and Sertoli-Leydig cell tumors are hormonally active, the former producing estrogen and the latter androgen.[151,159,160] Hence, granulosa cell tumors may be associated with thickening of the endometrium owing to endometrial hyperplasia. Clinical evidence of hormonal effect may help guide the differential diagnosis.

A pedunculated subserosal leiomyoma or a leiomyoma arising from the broad ligament and adnexa may be misdiagnosed as a solid ovarian lesion on ultrasound imaging, as the origin of the lesion can be difficult to determine. In this situation, MRI may prove very helpful in reaching the correct diagnosis given the characteristic appearance of leiomyomas on MRI, as discussed previously, and clear visualization of the pedicle attaching the leiomyoma to the uterine surface.[39,42,54]

Preoperative Staging

The new revised FIGO staging system adopted in 2014 (Table 36-3) considers fallopian tube, peritoneal, and ovarian tumors as one type of disease and several additional changes in staging were incorporated.[161] Current recommendations include recording histologic type, identifying grade of tumor, and documenting stage IC disease (i.e., evidence of tumor rupture during surgery or positive peritoneal

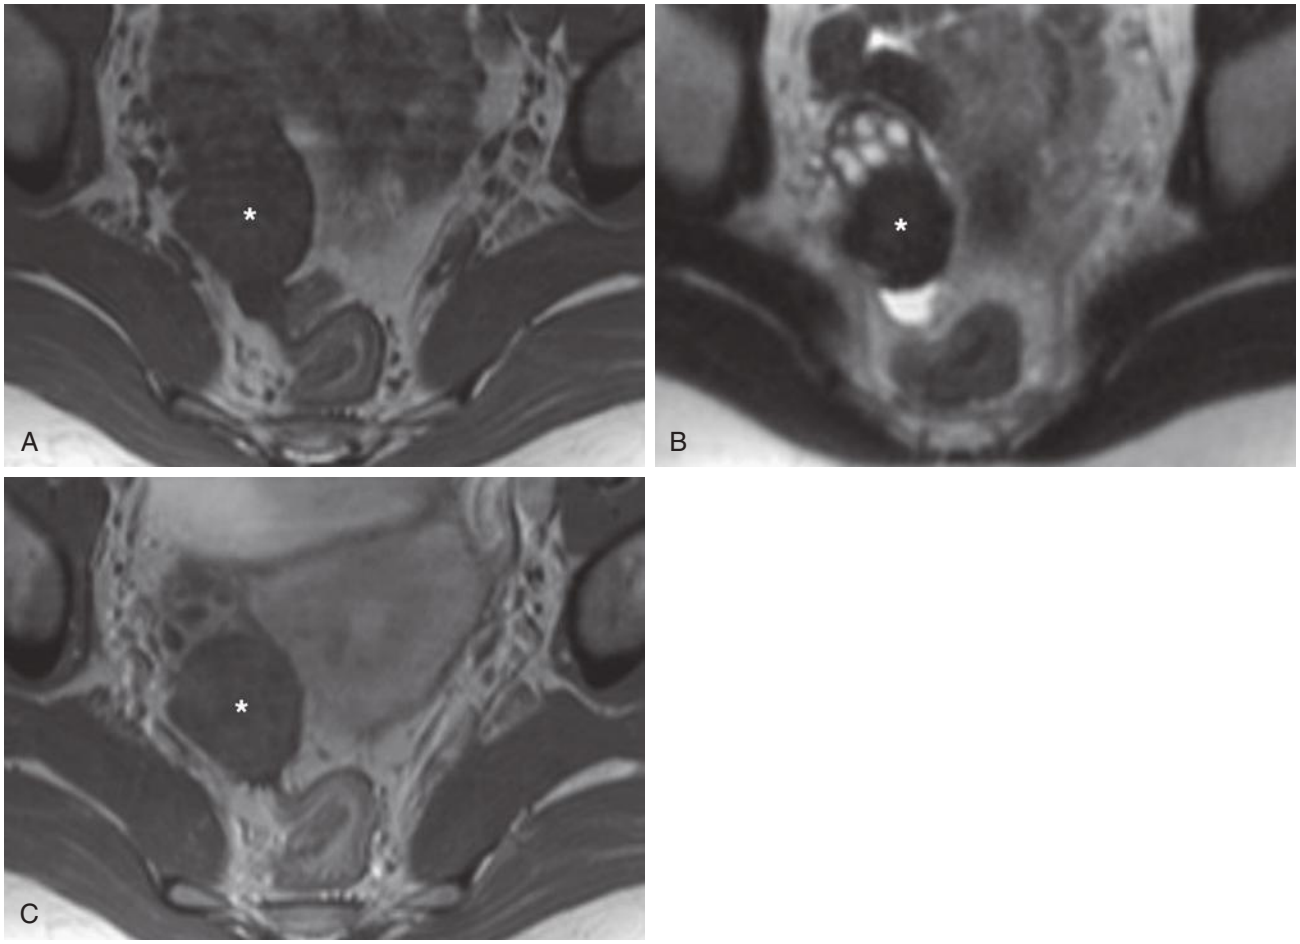

FIG 36-33 Ovarian fibroma. Axial T1-weighted (**A**), T2-weighted (**B**), and gadolinium-enhanced T1-weighted (**C**) images demonstrate a hypointense solid mass in the right ovary (*asterisk*). This mass has low signal intensity on both T1-weighted (A) and T2-weighted (B) images and demonstrates only slight enhancement after intravenous gadolinium administration (C), typical for an ovarian fibroma. Note numerous small hyperintense ovarian follicles anteriorly on T2-weighted image (B) that do not enhance following the administration of gadolinium (C).

washings). Lesions with dense adhesions that contain tumor cells are now upgraded to stage II. In stage II disease, tumor involves one or both ovaries or fallopian tubes with direct extension to the uterus or the fallopian tubes (stage IIA) or extends to other pelvic intraperitoneal tissues below the pelvic brim (stage IIB). As such, involvement of the sigmoid colon is now considered stage II disease.[161] The new FIGO system eliminated stage IIC because of recognition of a clear difference in terms of survival between stages II and III disease (A1). The subdivision of stages IIA and IIB remains the same. In stage III disease, tumor involves one or both ovaries with pathologically confirmed spread to the retroperitoneal lymph nodes and involvement of the peritoneum outside the pelvis. FIGO has added stage IIIA disease, which specifically refers to the presence of retroperitoneal adenopathy (A1). Tumor implants along the surface of the liver and spleen are still considered stage IIIC disease. Stage IV disease includes malignant pleural effusion (stage IVA), hepatic or splenic parenchymal metastases, extra-abdominal metastases, inguinal and supraclavicular metastatic lymph nodes, and transmural involvement of visceral structures (stage IVB).

Ovarian cancers most often present at an advanced stage with widespread intraperitoneal metastases. The disease is surgically and pathologically staged; the surgical procedure is most often performed by laparotomy including total abdominal hysterectomy, bilateral salpingo-oophorectomy, and omentectomy. In addition, biopsy of multiple frequently involved sites is recommended, including the mesentery, diaphragm, peritoneal surfaces, pelvic nodes, and para-aortic nodes.

Although final staging usually results from postoperative histologic findings, this may be modified after imaging analysis. Besides detecting and characterizing adnexal masses as likely malignant, imaging is used to demonstrate metastases, thus preventing understaging. CT and MRI can often detect specific sites of disease that may be unresectable, potentially preventing optimal primary surgical cytoreduction. In such patients, neoadjuvant chemotherapy with interval debulking rather than primary debulking with adjuvant chemotherapy may be utilized.[162,163] Qayyum and associates[164] found that preoperative CT and MRI were equally accurate in the detection of inoperable tumor and prediction of suboptimal debulking in newly diagnosed epithelial ovarian cancer. Imaging sensitivity, specificity, positive predictive value, and negative predictive value were 76%, 99%, 94%, and 96%, respectively. Subdiaphragmatic implants that infiltrate into the liver, serosal involvement of the colon and small bowel, tethering of the mesentery, and implants present in the supracolic omentum and involving the stomach usually require preoperative chemotherapy to make surgical resection feasible.

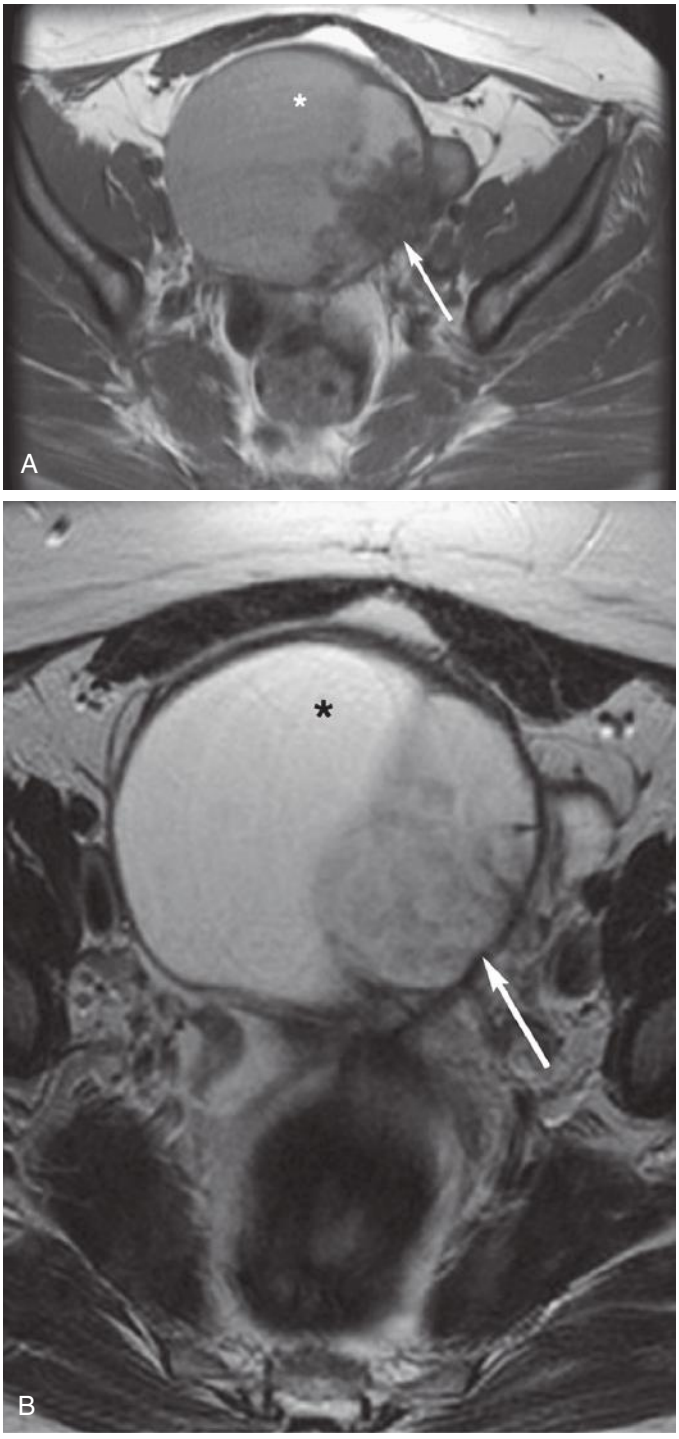

FIG 36-34 Borderline epithelial ovarian tumor. Axial T1-weighted (**A**) and T2-weighted (**B**) images demonstrate a large ovarian mass with solid (*arrow*) and cystic (*asterisk*) components. The findings are consistent with a malignant neoplasm, but not specific for any particular histologic finding. Histopathologic analysis confirmed a borderline ovarian cancer. Signal intensity of the cystic component may vary depending on content.

Both CT and MRI have been shown to accurately identify foci of small peritoneal implants, with sensitivities of 95% and 92%, respectively.[165] Similar results were obtained by the Radiology Diagnostic Oncology Group, investigating and comparing the use of Doppler and conventional sonography, CT, and MRI for staging of ovarian cancer.

FIG 36-35 Ovarian serous cystadenocarcinoma. Sagittal T2-weighted image demonstrates a large ovarian mass with solid (papillary projection) (*arrow*) and cystic (*asterisk*) components. The findings are consistent with a malignant neoplasm, but are not specific for a particular histologic finding. This tumor is indistinguishable from a borderline tumor (see Fig. 36-34) based on radiologic findings in the absence of metastatic disease. Histopathologic analysis diagnosed an invasive serous adenocarcinoma.

In this study, for differentiating early stage disease (benign lesions, stages I and II cancers) from advanced malignancy (stages III and IV cancers), the specificity of MRI was 88% and the sensitivity 98%. Sonography had the highest specificity (96%) but the lowest sensitivity (75%), whereas CT results were similar to those from MRI (specificity 89% and sensitivity 92%).[146]

CONCLUSION

In current practice, MRI is commonly used as a problem-solving tool in the evaluation of benign and malignant gynecologic disease. Multiplanar capacity and soft tissue characterization allow for superior imaging assessment of indeterminate gynecologic masses compared with sonography or CT. Future areas of investigation include high-resolution intravoxel incoherent motion (IVIM) MRI, pharmacokinetic analysis, and positron emission tomography/MRI, particularly with respect to assessment of tumor biology and response to cancer therapy.

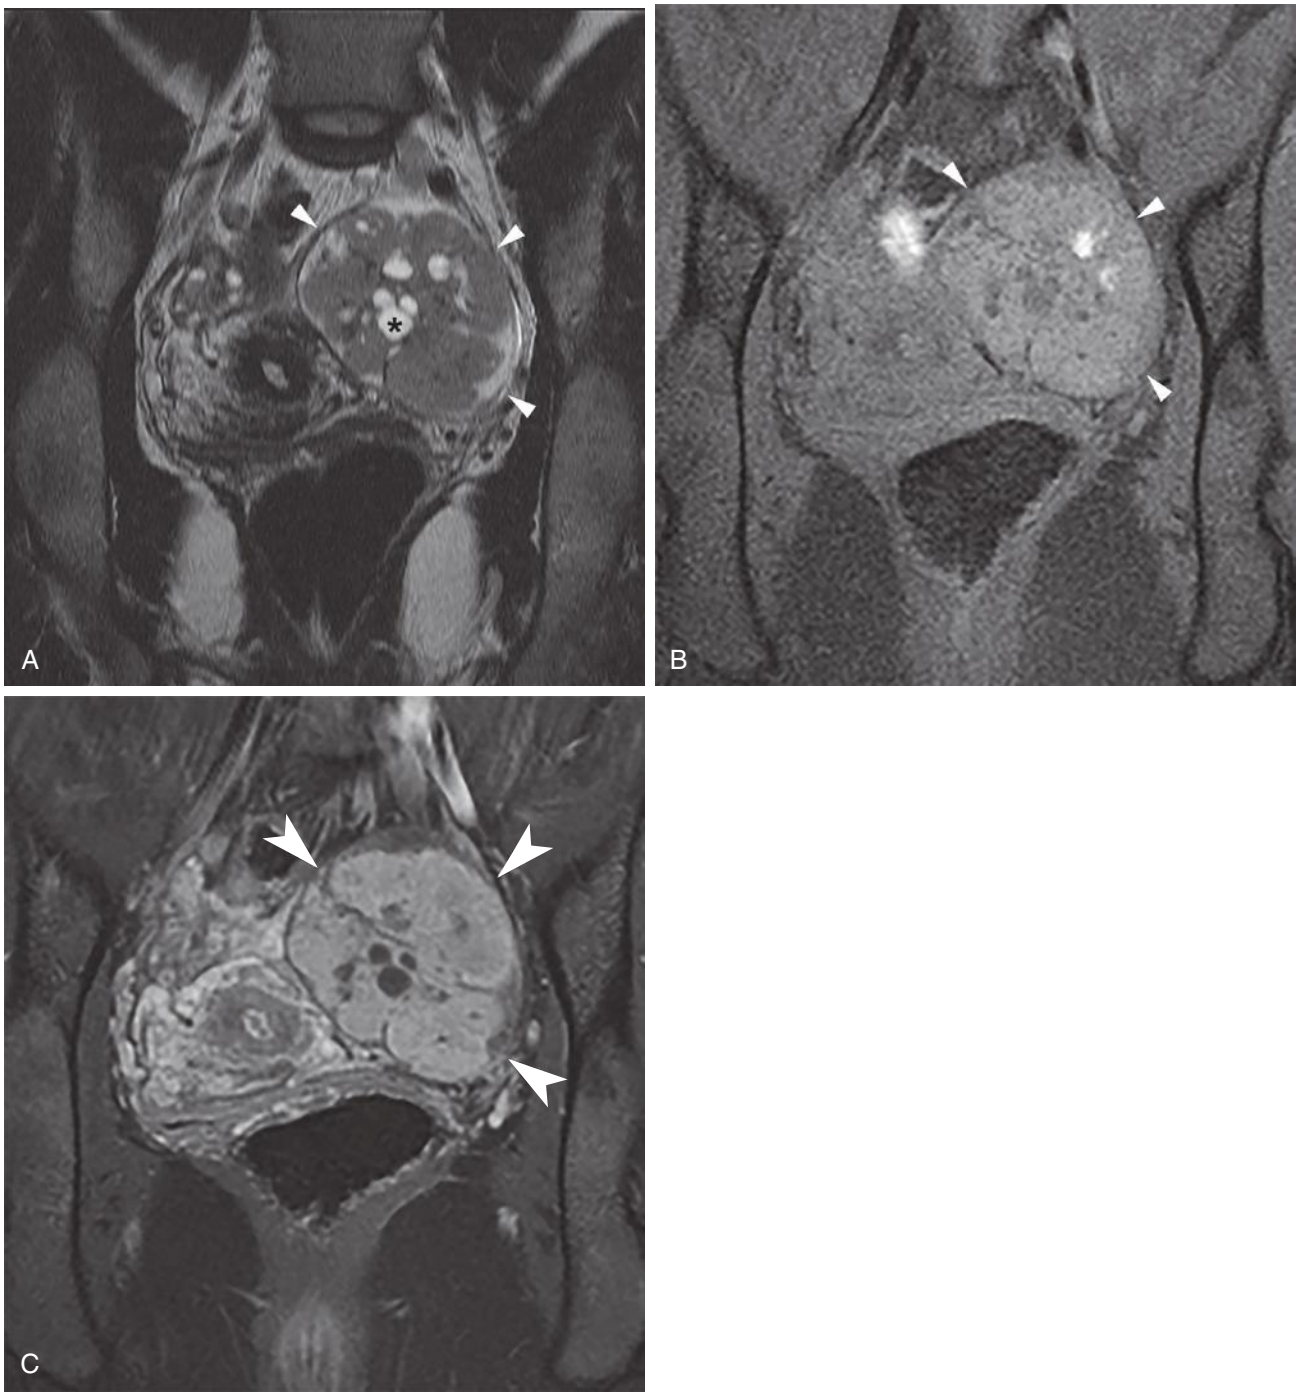

FIG 36-36 Granulosa cell tumor of the ovary. Coronal T2-weighted (**A**), fat-saturated T1-weighted (**B**), and gadolinium-enhanced fat-saturated T1-weighted (**C**) images show a heterogeneous predominantly solid left ovarian mass (*arrowheads*) with multilocular cystic spaces and enhancement of the solid component (C). Several of the small cystic spaces are hyperintense on T1-weighted image (B), suggesting that they contain proteinaceous material or blood products.

TABLE 36-3 Carcinoma of the Ovary/Fallopian Tube—Federation of Gynecology and Obstetrics (FIGO) Staging

FIGO Stage	Stage Description
I	Tumor grossly confined to ovaries/fallopian tubes
IA	Unilateral
IB	Bilateral
IC1	Intraoperative tumor rupture
IC2	Preoperative rupture
IC3	With malignant ascites or positive peritoneal washings
II*	Involves one or both ovaries/fallopian tubes
IIA	Direct extension and/or implants on uterus and/or fallopian tubes
IIB	Extension to other pelvic intraperitoneal tissues (below the pelvic brim, e.g., sigmoid)
III	Nodal or extrapelvic peritoneal spread
IIIA1	Positive retroperitoneal lymph node
IIIA2	Microscopic, extrapelvic (above pelvic brim) peritoneal involvement ± positive retroperitoneal lymph node
IIIB/IIIC	Macroscopic, extrapelvic peritoneal involvement ± positive retroperitoneal lymph node (≤2 cm stage IIIB; >2 cm stage IIIC)
IV	Distant metastases
IVA	Pleural effusion with positive cytologic finding
IVB	Hepatic and/or splenic parenchymal metastases; metastases to extra-abdominal organs

Ovarian Cancer—5-year relative survival rate by stage

Stage	Survival Rate
Overall	45%
Localized (15% at presentation, confined to ovary/fallopian tubes)	92%
Distant stage (61% at presentation)	27%
Overall for women 65 years and older	27%
Overall for women under 65 years	58%

*Major change: IIC (IIA or IIB with positive washings/ascites) removed based on survival data.

Role of Sonography in Gynecologic Interventions

Howard T. Sharp, Thomas C. Winter

SUMMARY OF KEY POINTS

- Ultrasound (US) has an important role in planning and guiding many gynecologic interventions.
- Prior to endometrial ablation, US may be used to detect focal lesions (e.g., polyps or leiomyomas), assess for tubal disease such as hydrosalpinx, and search for uterine anomalies.
- Whereas magnetic resonance imaging (MRI) remains the gold standard for evaluating patients prior to uterine artery embolization (UAE), US can be used to identify several relative contraindications. Following UAE, US has an important role in assessing post procedural complications such as necrosis or superinfection of the uterus or leiomyomas.
- MRI remains the gold standard for diagnosis and classification of congenital uterine anomalies. However, three dimensional (3D) US can provide important information with significant impact on counseling regarding reproductive prognosis and approach to repair.
- Transabdominal US guidance is extremely useful when accessing the endometrial cavity in patients with cervical stenosis and Asherman syndrome, or when placing brachytherapy devices; direct guidance reduces the risk of uterine perforation or creation of a false channel during instrumentation.
- US is increasingly used to assess for correct placement of Essure microinsert devices in the proximal fallopian tube, although hysterosalpingography still remains the gold standard.
- 3D US is considered the gold standard to document correct IUD placement in the endometrial cavity.
- US guidance can be used to safely guide transvaginal or transabdominal percutaneous biopsies of pelvic masses and drainage of pelvic fluid collections following careful consultation with the referring gynecologist.

OUTLINE

Gynecologic interventions have undergone significant changes over the past few decades. Procedures once exclusively performed in the operating room under general anesthesia may now be performed under local anesthesia in an office setting. Sonography has been a factor in allowing better preoperative investigation by excluding certain gynecologic disease, and its use in the clinic can guide access that previously required surgical exploration. The goal of this chapter is to describe the information required from ultrasound imaging of the pelvis to assist in gynecologic interventions. This chapter is organized according to gynecologic intervention, in hopes of better conveying the information that is necessary for a safe and successful procedure. Seven common gynecologic interventions and treated conditions will be covered: endometrial ablation, uterine artery embolization (UAE), repair of congenital anomalies of the uterus, guidance for endometrial interventions for cervical stenosis and Asherman syndrome, confirmation of correct Essure microinsert placement for tubal sterilization, location of malpositioned IUDs, and pelvic biopsies and drainages. Chapters on abnormal uterine bleeding, adnexal masses, ectopic pregnancy, and infertility are presented elsewhere in this textbook and, therefore, are not covered in this chapter.

ENDOMETRIAL ABLATION

Key questions to consider before endometrial ablation:

- Is an endometrial polyp or mass present?
- Is a leiomyoma present? If so, is it submucosal?
- Is there evidence of tubal disease such as hydrosalpinx?
- Is a uterine anomaly present?

Endometrial ablation is an intervention offered to women who suffer from heavy menstrual bleeding that interferes with normal daily activities enough to warrant intervention, but without a known lesion causing bleeding. Known causes for uterine bleeding such as uterine leiomyomas, endometrial polyps, endometrial cancer or precancerous lesions are more effectively treated by other methods. Furthermore, endometrial ablation in the presence of an endometrial cancer or precancer may lead to a delay in diagnosis.

Historically, endometrial ablation was performed in the operating room under general anesthesia via hysteroscopy. Use of a hysteroscope provides the surgeon with the ability to look into the uterine cavity and manually ablate the endometrium with a ball electrode (rollerball). This procedure causes desiccation of the endometrium in hopes that the endometrium will no longer bleed. Laser energy has also been used, as well as a loop electrode to shave or resect the endometrium. However, these three methods require advanced hysteroscopic skills and may expose the patient to hypotonic fluids to distend the endometrial cavity, thus placing her at risk for hyponatremia which, in some cases, can be associated with life-threatening herniation of the brainstem. Because these surgeries can be difficult to perform, five newer endometrial ablation devices have been approved by the U.S. Food and Drug Administration (FDA). These newer endometrial ablation methods have been approved since 1997 and are often referred to as *global endometrial ablation* (GEA) devices because the endometrial cavity is treated as a whole through a more automated process, rather than by a manual approach that ablates sections of the endometrium with a rollerball, laser, or loop resection. GEA methods employ a variety of modalities to ablate the endometrium, including a thermal balloon, circulated hot fluid, cryotherapy, radiofrequency electrosurgery, and microwave energy. GEA devices allow endometrial ablation to be performed with greater ease in the office, without the risk of fluid overload syndrome that has been associated with traditional hysteroscopic surgery performed with electrolyte-poor fluid. Though rates of amenorrhea have a wide range (14-55%) among GEA methods, patient satisfaction rates are uniformly high, at approximately 85%.[1]

Before considering endometrial ablation, a number of contraindications should be excluded (Table 37-1). Gynecologic ultrasound and particularly saline infusion sonohysterography (SIS) are helpful in assessing for submucosal leiomyomas (Fig. 37-1) and endometrial polyps, which would be optimally treated with hysteroscopic resection. Excluding such conditions prior to endometrial ablation avoids exposing patients to unnecessary risks of a treatment that will have a lower efficacy as a result of underlying abnormality.

Complications of endometrial ablation may be found on ultrasound examination in the postoperative patient who presents with pain or bleeding. Such complications include infection; uterine perforation; thermal injury to bladder, bowel, or ureter; hematometra (Fig. 37-2); pregnancy-related complications; and the development of subsequent endometrial cancer (not detected with the preoperative biopsy). In a meta-analysis comparing endometrial ablation procedures, the incidence of infectious complications included endometritis

TABLE 37-1 Contraindications to Global Endometrial Ablation

Pregnancy or desire to be pregnant in the future
Known or suspected endometrial carcinoma
Premalignant change of the endometrium*
Active pelvic inflammatory disease or hydrosalpinx*
Prior classic cesarean delivery or transmural myomectomy
Uterine anomaly, e.g., septate uterus, bicornuate uterus, or unicornuate uterus
Intrauterine device in place
Submucosal leiomyoma or other endometrial mass
Active urinary tract infection at the time of treatment*

*Relative contraindications.

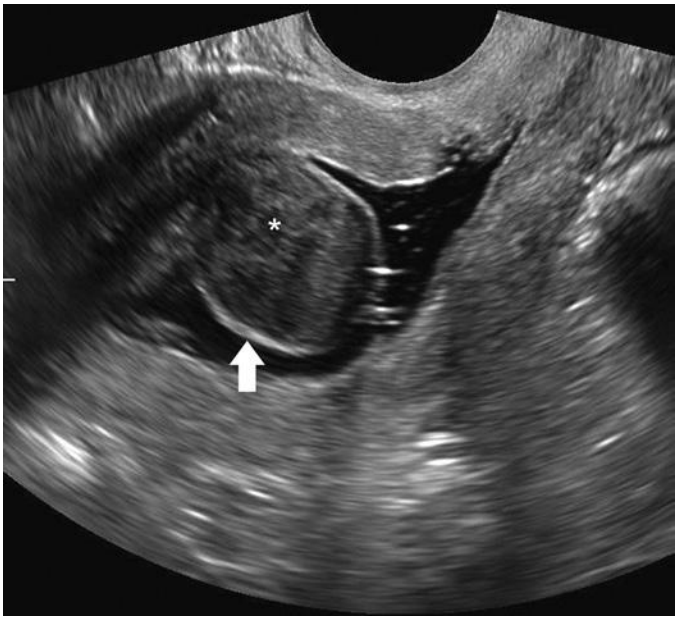

FIG 37-1 Submucosal, predominantly intracavitary leiomyoma (*asterisk*) well demonstrated by saline infusion sonohysterography on this sagittal transvaginal ultrasound image. Note the thin overlying rim of echogenic endometrium (*arrow*) covering the myoma.

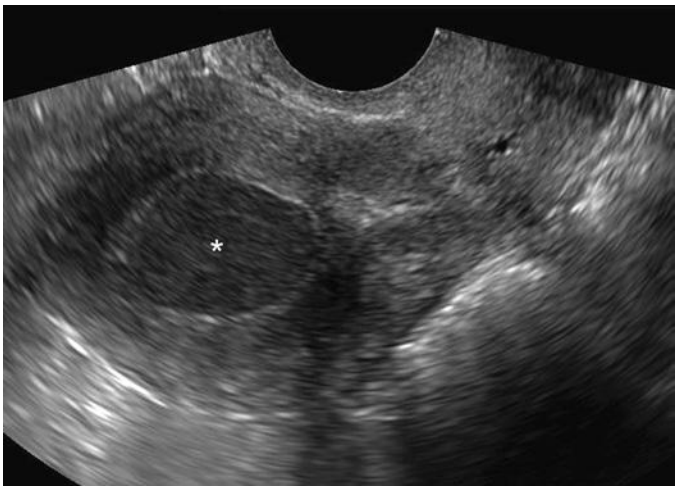

FIG 37-2 Hematometra following incomplete endometrial ablation. This 51-year-old patient presented with crampy pelvic pain but no bleeding. Transvaginal sagittal image of the uterus demonstrates the endometrial cavity distended with homogeneous hypoechoic material (*asterisk*) that was avascular on color Doppler imaging (not shown). The patient spontaneously bled and decompressed 1 day before her planned cervical dilation.

(1.4-2.0%), myometritis (0-0.9%), pelvic inflammatory disease (1.1%), and pelvic abscess (0-1.1%).[2]

Pregnancy following ablation has been reported to occur in 0.7% of women who have undergone endometrial ablation and is associated with poor obstetric outcomes.[3] It has been reported as early as 5 weeks after ablation and as late as 12 years postoperatively (following tubal reanastomosis in a planned pregnancy).[4] The chance of pregnancy occurring after endometrial ablation with tubal sterilization is even lower, estimated to be 0.002%, or 1 in 50,000. Though successful pregnancies have been reported, there appears to be a greater risk of complications including preterm birth, intrauterine scarring/uterine chambering (creating separate uterine compartments), and postpartum hemorrhage.[5] It is hypothesized that the risk of preterm birth is in part due to narrowing or chambering of the endometrial cavity, resulting in a smaller area for the gestation. One of the unintended consequences of office endometrial ablation is the inability to perform concomitant tubal sterilization, which could lead to an undesired increased incidence of pregnancy in this population.

Contracture and scarring of the endometrium constitute an expected effect of endometrial ablation. However, when focal areas of normal endometrium persist after a partial ablation, obstructed egress of menses with associated pain may occur. This can manifest as hematometra within the body of the uterine cavity (central hematometra) or at the cornual region. Postablation tubal sterilization syndrome (PATSS) was initially reported in 1993 in a series of six patients presenting with unilateral or bilateral pelvic pain and vaginal spotting subsequent to tubal sterilization and endometrial ablation.[6] The patients were all noted to have scarring of the endometrial cavity with swelling of the proximal portion of one or both fallopian tubes. Symptomatic relief was achieved in five out of six patients with removal of the fallopian tubes. The incidence of PATSS is approximately 6% to 8%, and it usually develops within 2 to 3 years of endometrial ablation. A high index of clinical suspicion is key to the diagnosis of PATSS, as patients typically present with cyclic cramping with or without menses in the setting of prior endometrial ablation and tubal sterilization. The role of sonography in diagnosing PATSS has not been well evaluated. Usually the confirmatory diagnosis is made surgically. However, magnetic resonance imaging (MRI) during periods of symptomatic cramping may be useful using T2-weighted images to look for blood trapped in the uterine cornu.[7] Another concern regarding the scarring of the endometrium that accompanies endometrial ablation is the difficulty with subsequent evaluation of the endometrium with endometrial sampling, sonography, or SIS. The safety of endometrial ablation has not been well studied in women who are at an increased risk of developing endometrial cancer or endometrial hyperplasia. These risks include nulliparity, chronic anovulation, obesity, diabetes mellitus, tamoxifen or selective estrogen receptor modulator (SERM) therapy, and hereditary nonpolyposis colorectal cancer.

Approximately half of the serious complications associated with contraindications to endometrial ablation may be identified preoperatively, as was demonstrated in a series of patient reports entered using the FDA Manufacturer and User Facility Device Experience (MAUDE) database.[8] The initial MAUDE database report described 85 complications in 62 patients. They included major complications, such as 8 cases of thermal bowel injury, 30 cases of uterine perforation, 12 cases requiring emergent laparotomy, and 3 intensive care unit admissions. One patient developed necrotizing fasciitis and eventually underwent vulvectomy, ureterocutaneous ostomy, and bilateral below-the-knee amputations. One of the patients with thermal injury to the bowel died. The contraindications to GEA are summarized in Table 37-1.

Though pelvic ultrasound examination is often performed as part of the preoperative evaluation, a strong case for the use of SIS could be made as a better modality to exclude contraindications such as submucosal leiomyomas.[9-11] If a polyp is present, endometrial ablation is not necessary, as a simple polypectomy can be performed and bleeding will most often resolve. Likewise, if submucosal leiomyomas are present, hysteroscopic resection of the leiomyoma is indicated; this is an outpatient procedure not associated with the same risk of endometrial scarring as endometrial ablation. Tubal disease such as hydrosalpinx or tubo-ovarian abscess should be treated prior to endometrial ablation to avoid postoperative infectious complications. Lastly, the presence of a uterine septum or other uterine anomaly would make several of the described automated ablation technologies impossible to perform, as the devices may not fit within the endometrial cavity and thus would place the patient at risk for unnecessary anesthesia. Of note, superficial adenomyosis is reasonable to treat with endometrial ablation, although there are reports of decreased efficacy if adenomyosis is extensive.

UTERINE ARTERY EMBOLIZATION

Key questions to consider for UAE:

- Is the leiomyoma pedunculated?
- Is the leiomyoma submucosal in location?
- Is there leiomyoma growth in a postmenopausal woman?
- Is there concurrent endometrial disease that may be causing bleeding?
- Is adenomyosis present?
- Is there unsuspected adnexal abnormality?

UAE for the treatment of leiomyomas was first described in 1995.[12] In most circumstances, this procedure is performed by interventional radiologists. A 4F or 5F catheter is placed into the uterine arteries via a transcutaneous femoral approach. Polyvinyl alcohol particles or trisacryl gelatin microspheres are injected into the uterine arteries to devascularize the uterus and therefore cause shrinkage of leiomyomas. Supplemental metal coils may be used to assist with vascular occlusion. The patient is usually able to return home within 23 hours of the procedure. There is typically a period of ischemic pain for 2 to 3 hours after embolization, followed by a plateau of pain, and then gradual reduction of pain over the next 2 to 3 days. The advantages of this procedure compared to myomectomy or hysterectomy are a faster recovery and return to normal activities.

Since 1995, there has been considerable progress in the successful performance of UAE. Most initial published reports were case series describing the technique or reports of short-term outcomes.[13,14] Subsequently, larger multicenter series and nonrandomized controlled studies and, finally, randomized clinical trials (RCTs) have been published. Unfortunately, the information from RCTs regarding long-term outcomes is limited owing to short follow-up intervals, although long-term outcomes have been reported in nonrandomized trials. Broder and associates reported up to 5-year follow-up data in an observational study of UAE compared to myomectomy.[15] In the UAE group, there was a higher reoperation rate of 29% (15/51) compared to 3% (1/30) in the myomectomy group ($P = 0.004$). When considering subjective variables, such as worsening of symptoms and being dissatisfied, 39% (20/51) were considered clinical failures in the UAE group compared to 30% (9/30) in the myomectomy group, a nonsignificant difference ($P = 0.4$). Additional 5-year follow-up data were published in a case series by Spies and colleagues.[16] In patients undergoing UAE, they reported a 20% reoperation rate (hysterectomy 13.7%, myomectomy 4.4%, repeat embolization 1.6%) and a 25% chance of failure to control symptoms. Short-term failure (at 12 months) was three times more likely in those with less than the median shrinkage of a dominant leiomyoma. Failure to shrink at the 12-month interval was associated with a five times greater likelihood of long-term failure.

Regarding short-term outcomes, a large multicenter study of over 500 patients undergoing UAE in eight Ontario hospitals reported favorable 3-month outcomes with regard to dominant leiomyoma volume reduction (42%), median leiomyoma life-impact scores, mean menstrual duration, dysmenorrhea, and urinary frequency/urgency.[17]

The EMMY trial (EMbolization vs. hysterectoMY) was a RCT involving 28 Dutch hospitals and compared UAE to hysterectomy. Comparison of safety demonstrated a similar major complication rate of 4.9% for UAE and 2.7% with hysterectomy ($P = 0.68$), but a higher rate of readmission and minor complications in the UAE group (11.1% vs. 0%; $P = 0.003$ and 58.0% vs. 40.0%; $P = 0.024$; risk ratio 1.45 [1.04-2.02]), respectively.[18] Another multicenter comparative trial of UAE versus myomectomy reported similar clinical findings.[19] A second EMMY publication reported a comparison of the short-term outcomes of pain and time until return to daily activities.[20] Compared to patients undergoing hysterectomy, patients undergoing UAE had significantly less pain during the first 24 hours postoperatively ($P = 0.012$) and returned to work sooner (28.1 vs. 63.4 days). Five RCTs comparing UAE to myomectomy and hysterectomy were also evaluated in a Cochrane review.[21] The review found that outpatient UAE resulted in a similar satisfaction rate compared with hysterectomy and myomectomy, but offered the advantage of a shorter hospital stay and quicker return to activities. However, UAE was associated with a higher minor complication rate and an increased likelihood of surgical intervention within 2 to 5 years of the initial intervention.

The overall complication rate of UAE has been reported to be 5% and is similar when applying the American College of Obstetricians and Gynecologists (ACOG) criteria for perioperative morbidity.[22] Complications range from fever to uterine necrosis and, very rarely, death. Collateral damage to the ovary resulting in premature ovarian failure has also been reported. However, this complication has been reported primarily in patients over age 45 years and may be associated with reduced ovarian reserve.

Pregnancy after UAE remains understudied, with variable complication rates reported. An observational study reported a higher rate of preterm delivery compared to laparoscopic myomectomy (odds ratio 6.2 [1.4, 27.7]).[23] Other studies have raised concerns regarding abnormal placentation (12.5%)[24] and high cesarean delivery rates (88%), but did not report other major risk factors.[25] The effect of UAE on pregnancy is therefore uncertain. However, careful surveillance is required should a patient become pregnant following UAE.

Although MRI has become the standard preprocedural imaging tool in women considering UAE, most women with symptoms first undergo pelvic ultrasound imaging for confirmation of the presence of leiomyomas. Though ultrasound imaging is not as useful as contrast-enhanced MRI in determining leiomyoma characteristics such as tissue viability, ultrasound imaging can be helpful in assessing for pedunculated submucosal and subserosal (Fig. 37-3) leiomyomas, both of which have been associated with an increased risk of complications following UAE.

Pedunculated submucosal (type 0) leiomyomas are defined as being located entirely within the endometrial cavity with no myometrial extension. It should be noted that although leiomyomas may be associated with abnormal uterine bleeding or pelvic pressure symptoms involving the bladder or rectum, leiomyomas are also commonly asymptomatic. Therefore, it is important to exclude other causes of abnormal uterine bleeding (especially endometrial cancer) and to assess for possible endometrial polyps or submucosal leiomyomas. Ultrasound imaging may also detect adenomyosis, which may cause similar symptoms as leiomyomas and, if present, may decrease the efficacy of UAE. Lastly, enlarging leiomyomas, though usually not associated with sarcoma in reproductive age women, are of great concern in postmenopausal women. An increase of more than 20% in measured leiomyoma diameter by ultrasound imaging is considered to represent true growth, not measurement variation.[26] Typically, leiomyomas will reduce in size during menopause. Thus, treatment of leiomyomas with UAE is generally contraindicated in postmenopausal women. The prevalence of sarcomas is approximately 0.2% (1 in 500) in women undergoing hysterectomy or myomectomy for presumed benign leiomyomas; this potential complication has gained attention with recent publicity regarding the dangers of power uterine morcellation.[27] There are currently no ultrasound imaging or MRI features that allow the accurate diagnosis of uterine sarcoma. Contrary to prior belief, rapidly enlarging leiomyomas in reproductive age women have specifically not been found to predict sarcoma.[28] Contraindications to UAE are summarized in Table 37-2.

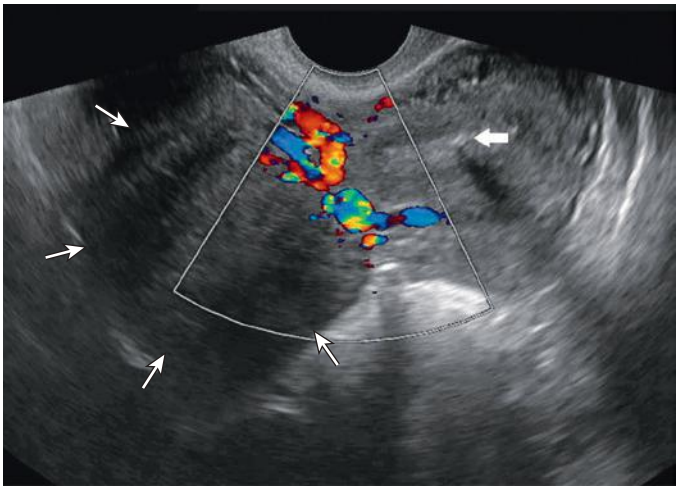

FIG 37-3 Pedunculated leiomyoma. Transaxial transvaginal color Doppler sonogram of the uterus demonstrating an echogenic focus (*large arrow*) with associated posterior shadowing within the endometrium, indicating an intrauterine device. Note right-sided hypoechoic solid mass (*small arrows*) in direct continuity with the myometrium, consistent with a large pedunculated subserosal leiomyoma. Note that color Doppler sonogram imaging can be used to show bridging myometrial vessels.

Previous internal iliac artery ligation
Active genitourinary infection*
Malignancy
Pregnancy
Significant immunosuppression

*Relative contraindications.

REPAIR OF CONGENITAL ANOMALIES OF THE UTERUS

Key questions to consider for repair of congenital anomalies of the uterus:

- Does the patient have two structurally normal kidneys?
- If there is a midline septum, is there notching at the uterine fundus?
- Are two ovaries present?

- Is a vagina present?
- Is there a portion of uterine tissue that may become obstructed?
- Are there one or two cervices?

The prevalence of congenital anomalies of the reproductive tract is estimated to be as high as 7% in the female population.[29] These anomalies are usually not recognized until they present with pain (obstructed menses), pregnancy complications (fetal malpresentation, preterm labor, recurrent pregnancy loss), or infertility. There are a number of classification systems for müllerian anomalies. The American Fertility Society/American Society of Reproductive Medicine (AFS/ASRM) proposed a standard classification of müllerian anomalies based on vertical fusion defects (Table 37-3 and Fig. 37-4).[30,31] Because of the many variations and complexities associated with these defects, a system known as the Vagina Cervix Uterus Adnexa-associated Malformation (VCUAM) classification system was proposed after being validated in a group of 99 women. (Table 37-4).[32] In 2013, the European Society of Human Reproduction and Embryology (ESHRE) and the European Society for Gynaecological Endoscopy (ESGE) established a common working group and developed a classification system based largely on anatomy that is clinically oriented (Fig. 37-5).[33]

In a review of the clinical implications of uterine anomalies, the frequency of anomalies by type was septate (35%), bicornuate (26%), arcuate (18%), unicornuate (10%), didelphys (8%), and agenesis (3%).[34] Of the developmental defects, there are three categories to consider: agenesis, lateral fusion defects, and vertical fusion defects. Historically, the workup of these anomalies was quite cumbersome and invasive, typically involving hysterosalpingography often with concomitant hysteroscopy, and laparoscopy under general anesthesia. More recently, MRI has become the standard diagnostic imaging modality, obviating the need for these invasive tests. With the refinement and availability of three-dimensional (3D) sonography (Fig. 37-6), some groups have argued that this may become the new gold standard, offering excellent diagnostic imaging at lower cost and with less discomfort than MRI.[35]

Agenesis

Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome is the absence of the vagina and is usually also associated with uterine and cervical agenesis. A small subset of patients will also have an obstructed or rudimentary uterus. The ovaries are less likely to be affected. One series of 106 patients reported normal ovaries in 78%, extrapelvic ovaries in 16%, and unilateral, hypoplastic ovaries in 6%.[36] Urologic abnormalities are seen in 25% to 50% of patients including unilateral renal agenesis and pelvic or horseshoe kidney.

TABLE 37-3 Müllerian Anomalies According to the American Fertility Society Classification System[30]

Type I: Müllerian agenesis or hypoplasia
- A. Vaginal (uterus may be normal)
- B. Cervical
- C. Fundal
- D. Tubal
- E. Combined

Type II: Unicornuate uterus
- A1a. Communicating (no endometrial cavity present)
- A1b. Noncommunicating (endometrial cavity present)
- A2. Horn without endometrial cavity
- B. No rudimentary horn

Type III: Uterus didelphys

Type IV: Uterus bicornuate
- A. Complete (division down to internal os)
- B. Partial
- C. Arcuate

Type V: Septate uterus
- A. Complete (septum to internal os)
- B. Partial

Type VII: Diethylstilbestrol-related anomalies
- A. T-shaped uterus
- B. T-shaped with dilated horns

	#	Unknown

VCUAM, Vagina Cervix Uterus Adnexa-associated Malformation. From Oppelt P, Renner SP, Brucker S, Strissel PL, et al: The VCUAM (Vagina Cervix Uterus Adnex-associated Malformation) classification: a new classification for genital malformations. Fertil Steril 84(5):1493-1497, 2005.

Ultrasound evaluation should include assessment for the presence of kidneys, ovaries, uterus, and cervix. In clinical practice, these findings inform counseling about unilateral renal agenesis and surgical repair. Though there is no consensus on the optimal repair for MRKH syndrome, the presence of an obstructed uterus will likely result in symptoms, including pain following menarche, and therefore should be addressed. In general, a nonsurgical treatment (called the Frank procedure) involving creation of a functional vagina with dilators has been fairly successful. Surgical procedures are typically presented as an option for women who have failed dilator therapy. These procedures include the McIndoe procedure (split-thickness graft), Williams vaginoplasty (creation of a vaginal pouch from the labia majora), sigmoid vaginoplasty (resection of a segment of the sigmoid colon brought down to the vagina), and the Vecchietti procedure performed by laparotomy or laparoscopy (a system of traction to gradually create a vagina at the vaginal dimple).

Lateral Fusion Defects

Lateral fusion defects are the most common types of müllerian defects and result from failure to form one müllerian duct or to resorb the intervening septum, or from failure of migration or fusion of the müllerian ducts.

A *septate uterus* is the most common congenital uterine anomaly, resulting from defective resorption of the tissue between the fused müllerian ducts. The residual septum may extend inferiorly for a portion or for the full length of the uterus, from the fundus to the cervix. The key feature of a septate uterus is a normal smooth external contour at the uterine fundal surface. Septate uteri are often treated, because of the association with recurrent pregnancy loss and preterm labor in 12% to 44% of pregnancies.[37] This anomaly can be treated hysteroscopically as an outpatient procedure with excellent results. There is no need for surgical intervention involving the myometrium, and therefore, patients can subsequently undergo vaginal delivery. Hysteroscopic uterine septum resection may be performed with concomitant laparoscopy to ensure that the uterine fundus is not perforated. Real-time sonography can also be used to guide and monitor such procedures. The plane in which the uterus is imaged should be the same as the plane/axis of the operating instrument; this plane changes with movements that occur during surgery. With experience, these techniques can be mastered, and sonography can be a useful means for guiding such interventions. The arcuate uterus, a subset of septate uterus, has little clinical significance and is therefore not treated surgically.

The *unicornuate uterus* is important to understand for two reasons. First, it is an example of asymmetric lateral fusion: one cavity is usually normal, but small, with an accompanying cervix and fallopian tube. The small endometrial cavity predisposes to preterm birth as well as abnormal fetal lie (e.g., breech), which may lead to cesarean delivery. Second, one müllerian duct may not develop at all, or it may partially develop resulting in a rudimentary horn that may or may not communicate with the myometrium or the endometrial lining of the contralateral uterine horn. If a noncommunicating rudimentary horn has functioning endometrium, it may cycle and slough in response to ovarian hormonal changes and cause chronic pain. The unicornuate uterus may also be associated with an ectopic ovary, which may be an issue in women undergoing ovulation induction or who develop an ovarian neoplasm. Rarely, an ectopic pregnancy can occur in a noncommunicating rudimentary horn. MRI may be a better modality to make this diagnosis and to localize the ovary owing to the larger field of view. A noncommunicating rudimentary horn will usually require surgical removal because of pain and reproductive issues.

The endometrial cavity of a *bicornuate uterus* can have a similar appearance to that of a septate uterus. The primary difference between these anomalies is the indentation of the serosal contour at the fundus of the bicornuate uterus, resulting in two small horns, leading to risks of abnormal fetal lie and preterm birth. The fundal indentation is defined as larger than 1 cm. The clinical significance of notching or an indentation at the fundus (an external contour deformity) is that if repair is performed, it cannot be done with simple hysteroscopic resection, but instead requires laparotomy, with a much lower success rate than that of the septate uterus. Furthermore, future pregnancies would therefore require cesarean delivery because of the high risk of uterine rupture at the repair site. However, most of these patients can conceive and successfully carry a pregnancy, and therefore, surgical repair is seldom required.

Uterus didelphys is essentially a double uterus, each with a cervix and often associated with a vaginal septum as well. However, there are several variations, which may involve unilateral findings such as obstructed hemivagina or renal anomalies. These conditions typically require additional imaging with MRI and possibly with hysterosalpingogram (HSG) to evaluate for communication between the endometrial cavities. Surgery is performed for symptomatic patients with a septate vagina and dyspareunia, and often for patients with recurrent miscarriages or preterm birth. Depending upon clinical factors, metroplasty may be considered.

A *longitudinal vaginal septum* is usually associated with uterine anomalies. It may be difficult to detect by ultrasound, as a vaginal transducer may be inadvertently inserted on either side of the septum. One or two cervices may be present. Alternatively, the septum may originate between two cervices and fuse into the right or left lateral vaginal wall, concealing one cervix. In the latter case, the septum may result in hemihematocolpos.

Vertical Fusion Defects

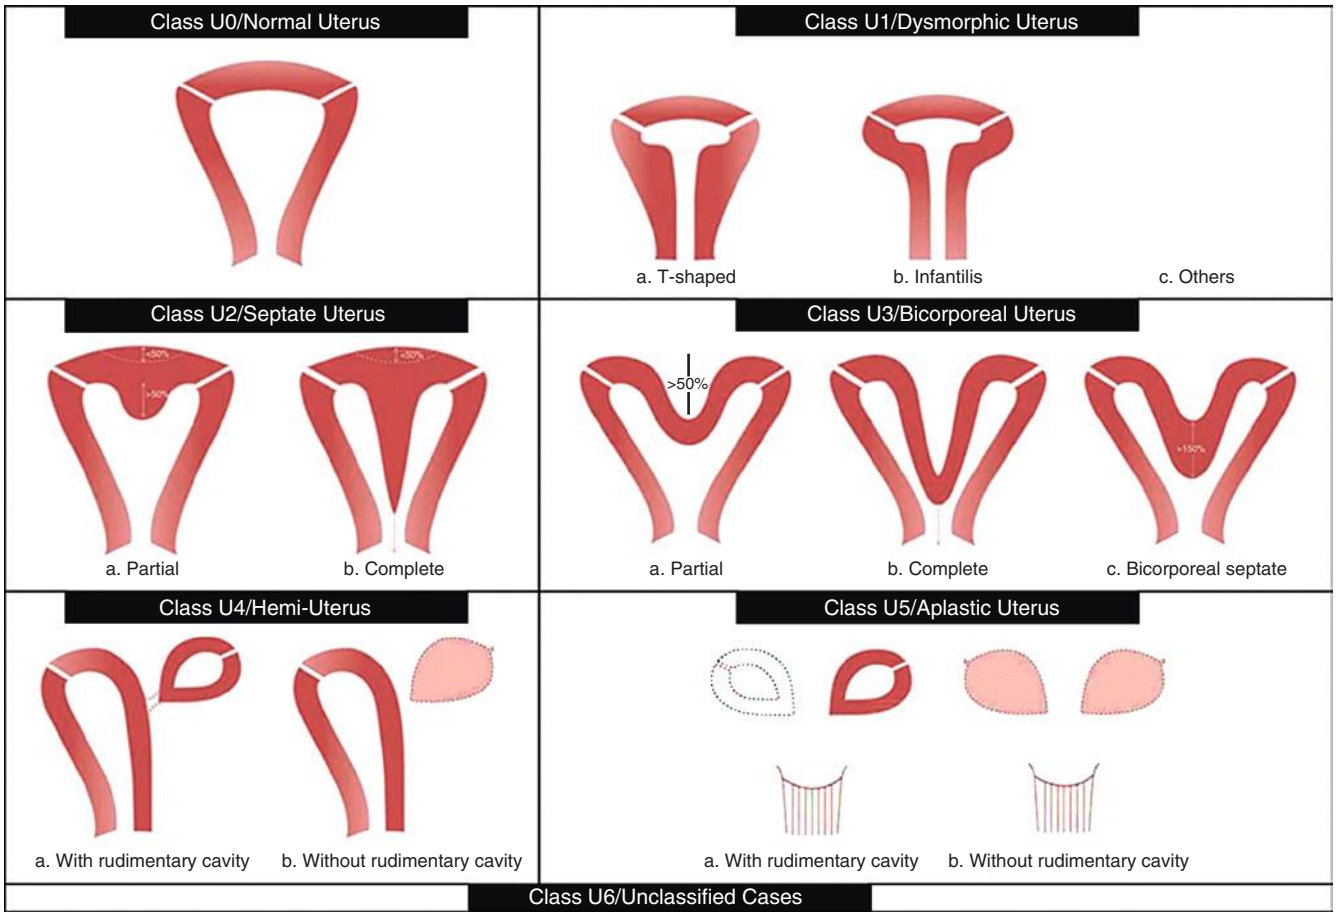
This group of defects results from abnormal fusion of the caudal end of the müllerian duct and the urogenital sinus. With a *transverse vaginal septum*, the external genitalia typically appear normal, whereas the vagina is short because of the transverse septum. Ultrasound imaging may help determine the thickness of the septum in the setting of hematocolpos, which may require treatment by septum resection.

GUIDANCE FOR ENDOMETRIAL INTERVENTIONS (CERVICAL STENOSIS, ASHERMAN SYNDROME)

Key question to consider for endometrial interventions:

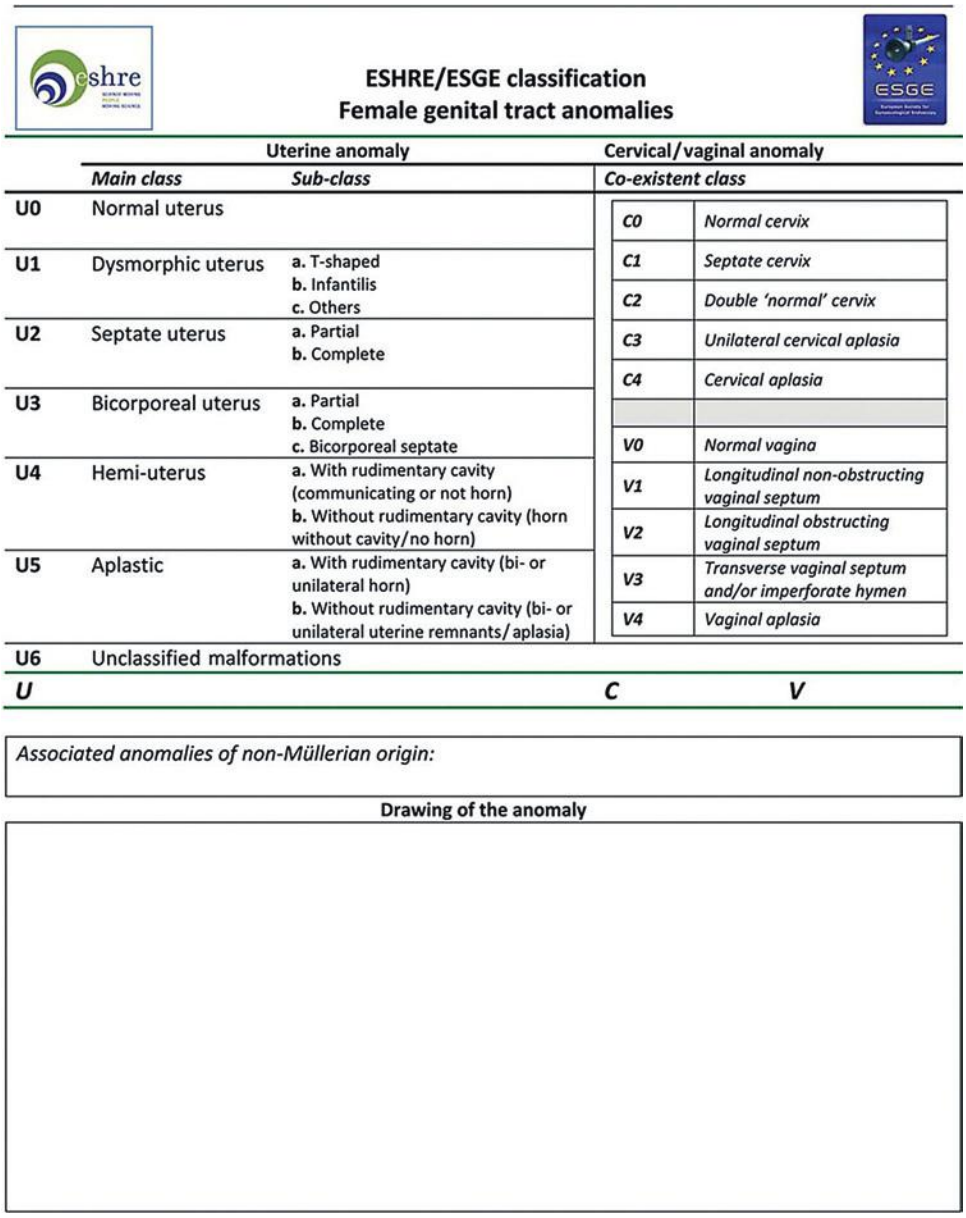
- Can an endometrial stripe be seen?

Ultrasound evaluation and guidance are extremely useful in cases of marked cervical stenosis, which can make it difficult to gain access to the endometrial cavity in patients undergoing endometrial sampling



A

FIG 37-5 European Society of Human Reproduction and Embryology (ESHRE)/European Society for Gynaecological Endoscopy (ESGE) classification of female genital tract congenital anomalies. **A,** Diagram.



ESHRE/ESGE classification
Female genital tract anomalies

	Uterine anomaly		Cervical/vaginal anomaly	
	Main class	*Sub-class*	*Co-existent class*	
U0	Normal uterus		C0	*Normal cervix*
U1	Dysmorphic uterus	a. T-shaped b. Infantilis c. Others	C1	*Septate cervix*
U2	Septate uterus	a. Partial b. Complete	C2	*Double 'normal' cervix*
U3	Bicorporeal uterus	a. Partial b. Complete c. Bicorporeal septate	C3	*Unilateral cervical aplasia*
U4	Hemi-uterus	a. With rudimentary cavity (communicating or not horn) b. Without rudimentary cavity (horn without cavity/no horn)	C4	*Cervical aplasia*
U5	Aplastic	a. With rudimentary cavity (bi- or unilateral horn) b. Without rudimentary cavity (bi- or unilateral uterine remnants/aplasia)	V0	*Normal vagina*
			V1	*Longitudinal non-obstructing vaginal septum*
			V2	*Longitudinal obstructing vaginal septum*
			V3	*Transverse vaginal septum and/or imperforate hymen*
			V4	*Vaginal aplasia*
U6	Unclassified malformations

or IUD placement.[38] Cervical stenosis may be seen following menopause or may result from cervical trauma such as lacerations, cervical cone biopsy, loop electrosurgical excision procedures (LEEP), or other cervical interventions. The presence of cervical stenosis significantly increases the risk of uterine perforation or creation of a false passage into the uterus during instrumentation to gain access to the endometrial cavity.

For guidance of such procedures, transabdominal sonography is performed through a distended urinary bladder. If necessary, retrograde filling of the bladder with sterile water or saline can be done using a Foley or red rubber catheter and a catheter-tipped syringe. This allows transabdominal sonographic visualization of the endocervical canal and the endometrial cavity to the uterine fundus. A similar approach is employed when real-time intraoperative ultrasound-guided imaging is provided for placement of brachytherapy devices into the uterus, ensuring that the device is properly centered within the cavity and does not penetrate the myometrium or perforate the uterus (Fig. 37-7). Similarly, in patients with Asherman syndrome (intrauterine adhesions), ultrasound imaging may assist in identification and delineation of the endometrial cavity. This application of real-time ultrasound-guided imaging to minimize endometrial transgression is useful in patients with other conditions as well, including curettage for retained products of conception, pregnancy termination (especially in the setting of a uterine anomaly), hysteroscopic biopsy, and difficult IUD placement. Although rarely indicated, ultrasound-guided endometrial sampling may be performed by traversing the myometrium when severe cervical stenosis precludes conventional access (Fig. 37-8).

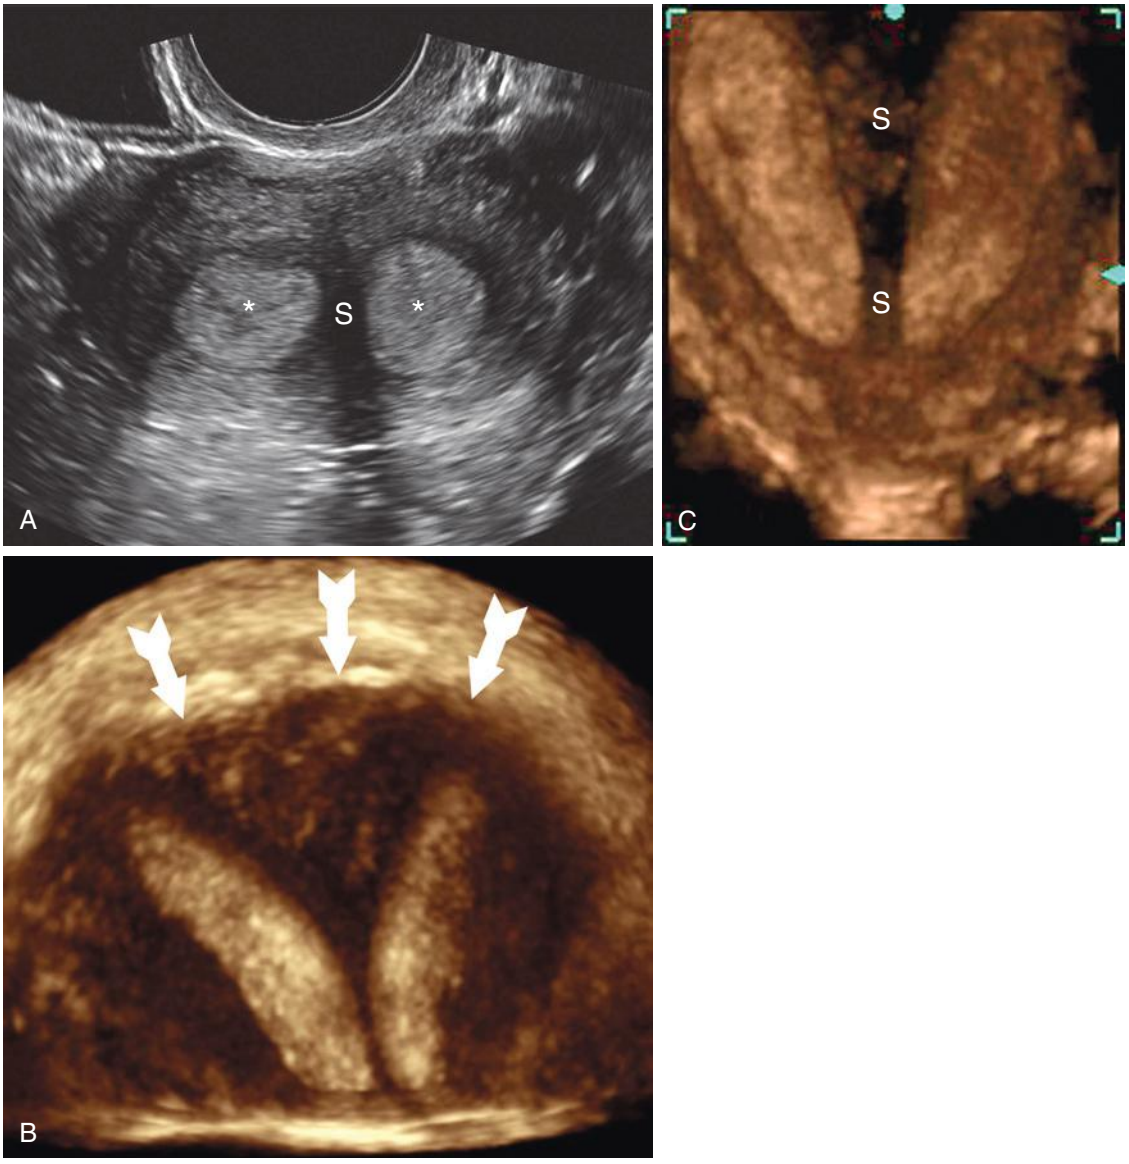

FIG 37-6 Three different patients with septate uterus. **A,** Two-dimensional (2D) transverse transvaginal ultrasound image shows two portions of the divided endometrial cavity (*asterisks*) with intervening hypoechoic septum (S). **B,** Three-dimensional (3D) sonographic coronal display of a septate uterus demonstrating the important feature used to distinguish this type of anomaly from a bicornuate uterus. Note the preserved, outwardly convex, smooth external uterine contour (*arrows*). **C,** 3D ultrasound coronal image shows the dividing uterine septum (S) extending from the fundus caudally to the cervix.

CONFIRMATION OF CORRECT ESSURE MICROINSERT PLACEMENT FOR TUBAL STERILIZATION

Key question to consider for confirmation of correct Essure microinsert placement for tubal sterilization:

- Do the reflections of the microinsert cross the outer line/serosa of the uterine wall, and are the proximal ends of both devices visualized medial to the outer line or within the endometrial cavity?

Essure (Bayer AG, Leverkusen, Germany) is a dynamically expanding microinsert device placed within the proximal fallopian tube transcervically, via a hysteroscopic approach, for tubal occlusion. Essure devices are used as a permanent form of birth control as an alternative to laparoscopic tubal ligation. The insert is composed of an inner stainless steel coil and an outer expanding coil of nitinol (a nickel and titanium alloy). The inner coil contains polyethylene terephthalate fibers, which induce local tissue ingrowth. Optimal placement is defined as having 3 to 8 mm of the device visible at the proximal ostium, which translates to approximately three to eight visible coils (Fig. 37-9). To ensure proper placement, an HSG should be performed 3 months following the insertion procedure. Less invasive means of confirming proper placement include transvaginal ultrasound, SIS, and 3D sonography. However, HSG is still considered the standard of care to assure proper placement, as determined by the FDA.

Verification of proper Essure placement is clinically important. This intervention is effective with a reported 5-year cumulative pregnancy rate of only 2.6 pregnancies per 1000 procedures.[39] However, rarely, expulsion or migration of the device, placement in the endometrium, perforation of the uterus or fallopian tube, and postprocedure

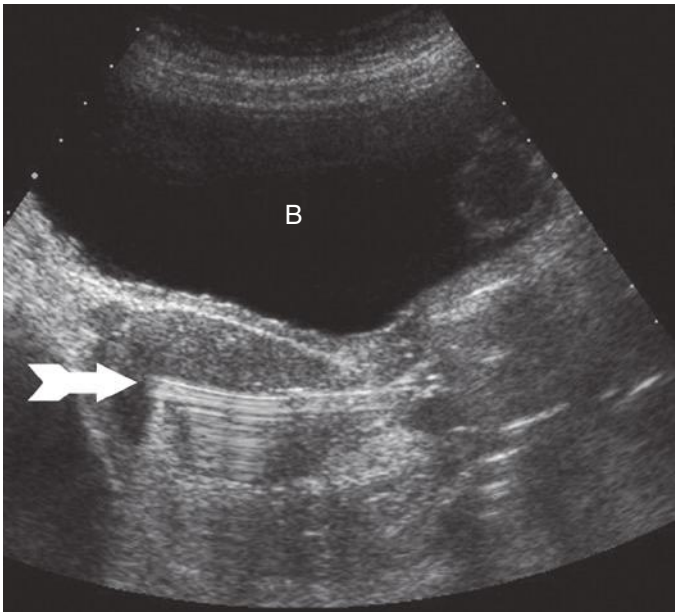

FIG 37-7 Intraoperative transabdominal sagittal image through a distended urinary bladder (B) showing appropriate placement of a brachytherapy tandem (*arrow*) centered within the uterus. (Courtesy of Mike Ledwidge, RDMS.)

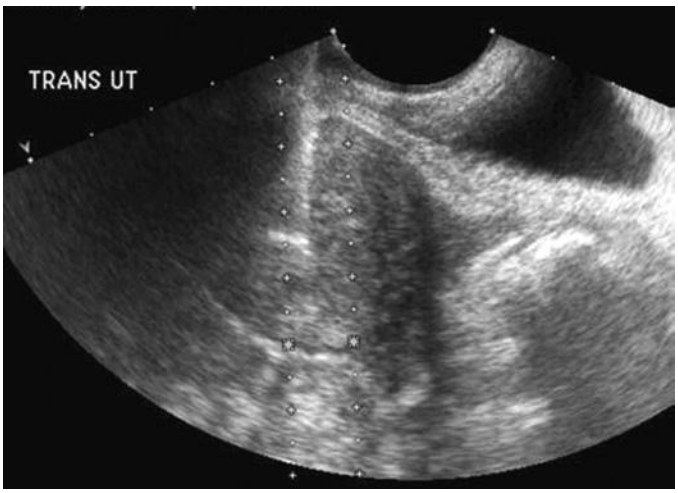

FIG 37-8 Unusual transuterine approach for endometrial biopsy. Because of marked cervical stenosis, an endometrial biopsy catheter could not be introduced through the cervical canal into the uterus. Real-time transvaginal sonographic guidance was used during sampling of the endometrium, performed after advancing a cutting needle through the uterine serosa and myometrium. Pathologic examination revealed endometrial adenocarcinoma. The echogenic vertical line situated between the guiding dotted lines represents the 18-gauge core biopsy needle.

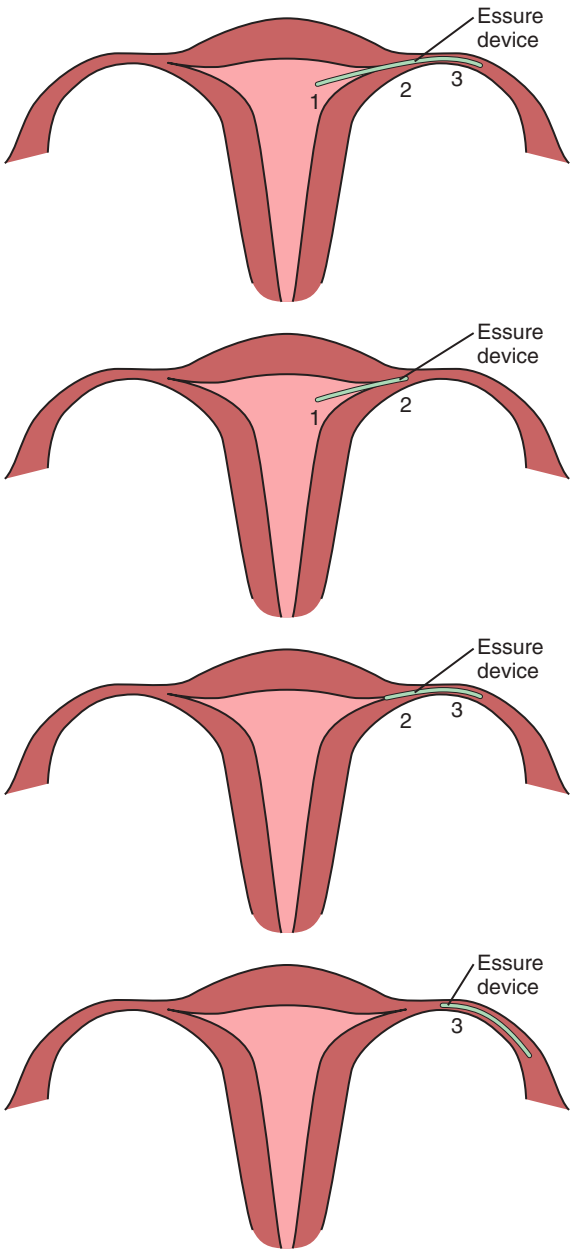

FIG 37-9 Three-dimensional sonographic classification system for the placement and positioning of Essure microinsert tubal occlusion devices.[41] Perfect position (1 + 2 + 3), proximal position (1 + 2), distal position (2 + 3), and very distal position (3 only).

pregnancy can occur. A systematic review of complications associated with Essure devices found that the most common were malposition, chronic pain, unintended pregnancy, infection, and nickel allergy.[40] The authors also found that complications can involve uterine or tubal perforation or device expulsion or migration and that these complications—along with failure of timely diagnosis of these conditions—were associated with consequences beyond ineffective contraception. In some patients, such complications can result in severe morbidity. Given that patients with pelvic pain after Essure placement are often evaluated by sonography, one should be familiar with the sonographic findings associated with these devices.

Although sonography is not currently the accepted standard imaging modality to confirm correct Essure placement, investigations are underway to determine the utility and reliability of sonography in this setting. If proved effective, use of sonography could potentially avoid the cost, radiation exposure, and discomfort of conventional fluoroscopic HSG.

One retrospective observational study examined the records of 311 patients who underwent Essure microinsert placement followed 3 months later by 3D sonographic evaluation to verify position. HSG was performed when 3D sonographic findings were inconclusive, or for comparative purposes in a prospective trial. The device was

visualized in 99.6% of 3D ultrasound examinations. Compared to HSG, the sensitivity and specificity of 3D sonography for determining correct Essure placement was 100% and 76.6%, respectively.[41] The authors used a classification system to report four different positions observable with 3D sonography (see Fig. 37-9):

1. Perfect position (1 + 2 + 3): including an intrauterine (endometrial) portion, an interstitial tubal portion, and an isthmic tubal portion
2. Proximal position (1 + 2): including an intrauterine and interstitial tubal portion (suboptimal)
3. Distal portion (2 + 3): including interstitial and isthmic tubal portions, but with no intracavitary portion (suboptimal)
4. Very distal position (3 only): located in the isthmic tubal portion (inadequate)

By identifying abnormally positioned Essure devices using sonography, issues may be addressed and resolved sooner and postprocedure morbidity avoided.

In another prospective observational study of 182 patients who underwent Essure placement, a total of 300 correctly positioned bilateral devices (two microinserts in each of 150 patients) could be identified by transvaginal sonography (Fig. 37-10; also see Chapter 31).[42] The position of the microinserts was determined by sonography, and the reflection of the device in relation to the outer line (serosal surface) of the uterus was described. The position was considered satisfactory when the specular reflections of the microinserts crossed the outer line of the uterine wall and the proximal ends of both devices were visualized medial to the outer line or within the endometrial cavity. Nine patients had unsatisfactory sonographic identification of the bilateral devices. Compared with HSG as the reference test, the sensitivity and specificity of sonography were 50% and 95%, respectively. The predictive value of a satisfactory transvaginal sonography result was 99%, and the predictive value of an unsatisfactory result was 11%.

MALPOSITIONED INTRAUTERINE DEVICE

Key questions to consider for malpositioned IUD:

- Is it a copper IUD or progestin-releasing IUD?
- Is it located midline in the endometrial cavity within the uterine body?

A commonly encountered clinical scenario faced by physicians caring for patients with prior insertion of an IUD is that of a missing IUD string. In such cases, it is important to determine if the IUD is present and appropriately positioned within the endometrial cavity. It

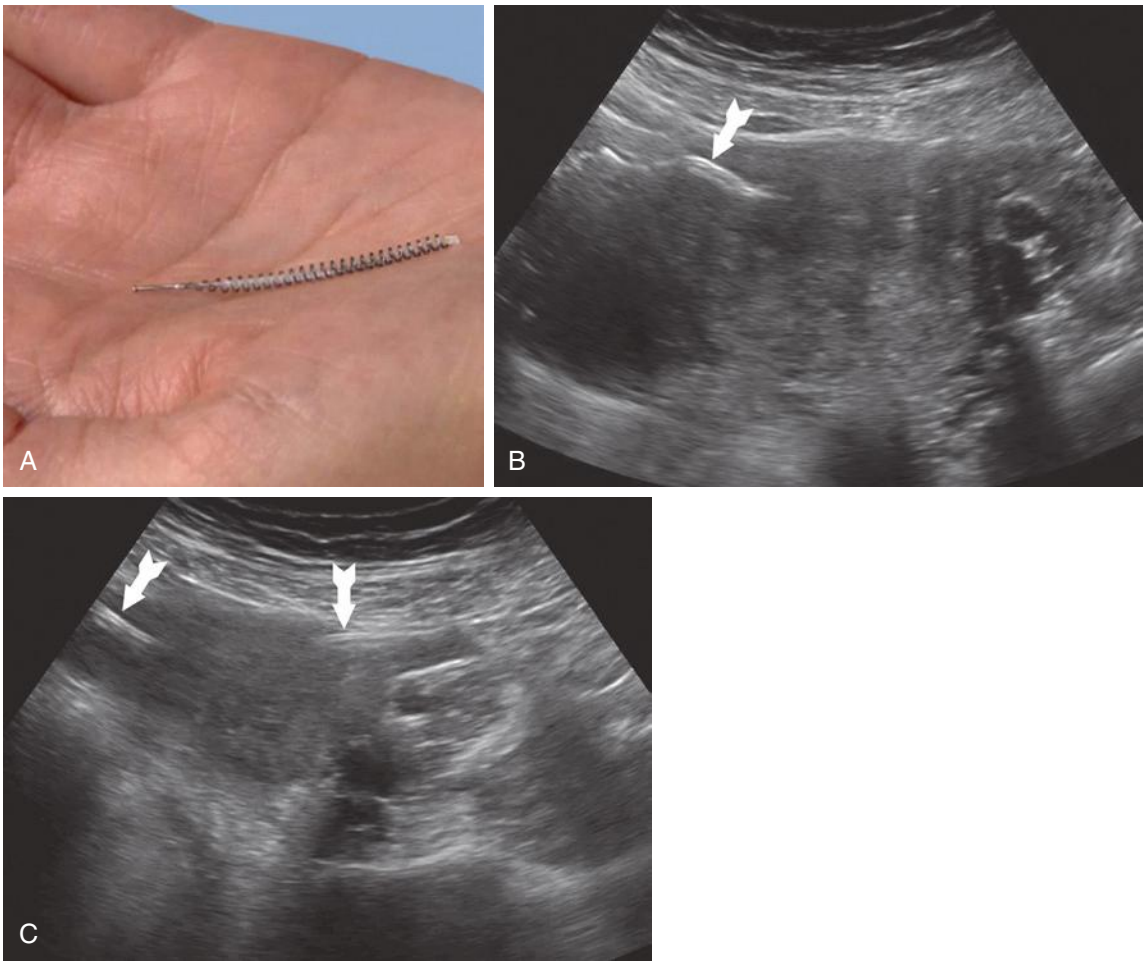

FIG 37-10 Essure microinserts. **A,** Photographic image from the manufacturer's website (device is placed in a human hand to show scale). **B,** Transabdominal, transverse sonographic image of the uterus showing the right-sided linear echogenic insert (*arrow*) in the interstitial portion of the fallopian tube, traversing the myometrium. **C,** Additional transabdominal transverse view of the uterus showing both right and left echogenic linear inserts (*arrows*). (A from Bayer HealthCare Pharmaceuticals: What is Essure? September 2015. Available at www.essure.com.)

is possible that the string has receded into the endocervical canal or endometrial cavity and the IUD is in place, in which case contraception is still considered effective. If the IUD is not demonstrated by sonography to be within the endometrial cavity, it must be determined if it has become dislodged and expelled or if the IUD has migrated into the myometrium or through it into the pelvic/abdominal cavity, or in rare cases, into the colon or bladder. This can be assessed by radiograph, although occasionally a perforated IUD can be identified by sonography in the cul-de-sac, posterior to the uterus. In such cases, laparoscopic removal of the IUD is necessary. There is controversy regarding management of an IUD that is malpositioned within the endometrial cavity and is either low-lying or has one or both arms partially embedded in the myometrium. Intervention is not always necessary for a malpositioned IUD.[43]

A correctly positioned IUD has its superior portion near the uterine fundus, with its horizontal limbs fully expanded toward the cornual/angular portions of the endometrial cavity (where the interstitial portion of the fallopian tube joins the endometrial cavity), and its vertical portion extending straight down, centrally positioned within the uterine corpus. The copper IUD (such as Paragard) and synthetic progestin hormone–releasing IUD (such as Mirena) can be identified and distinguished if one is familiar with their basic imaging features (Fig. 37-11). The copper IUD has a central stem that is uniformly echogenic with posterior shadowing from its upper metallic coils and is more conspicuous on ultrasound than the levonorgestrel-releasing Mirena IUD, which has a plastic sleeve on the central stem containing progestin.[44,45] This configuration causes reverberation artifact and acoustic shadowing with visible parallel white lines. This IUD also has echogenic arms due to barium sulfate with echogenic tips. When pelvic sonography is performed and a malpositioned IUD seen (Fig. 37-12), the findings should be reported and described as follows:

- Located in the cervix or lower uterine segment
- Partially expelled with part of the IUD extending through the external cervical os

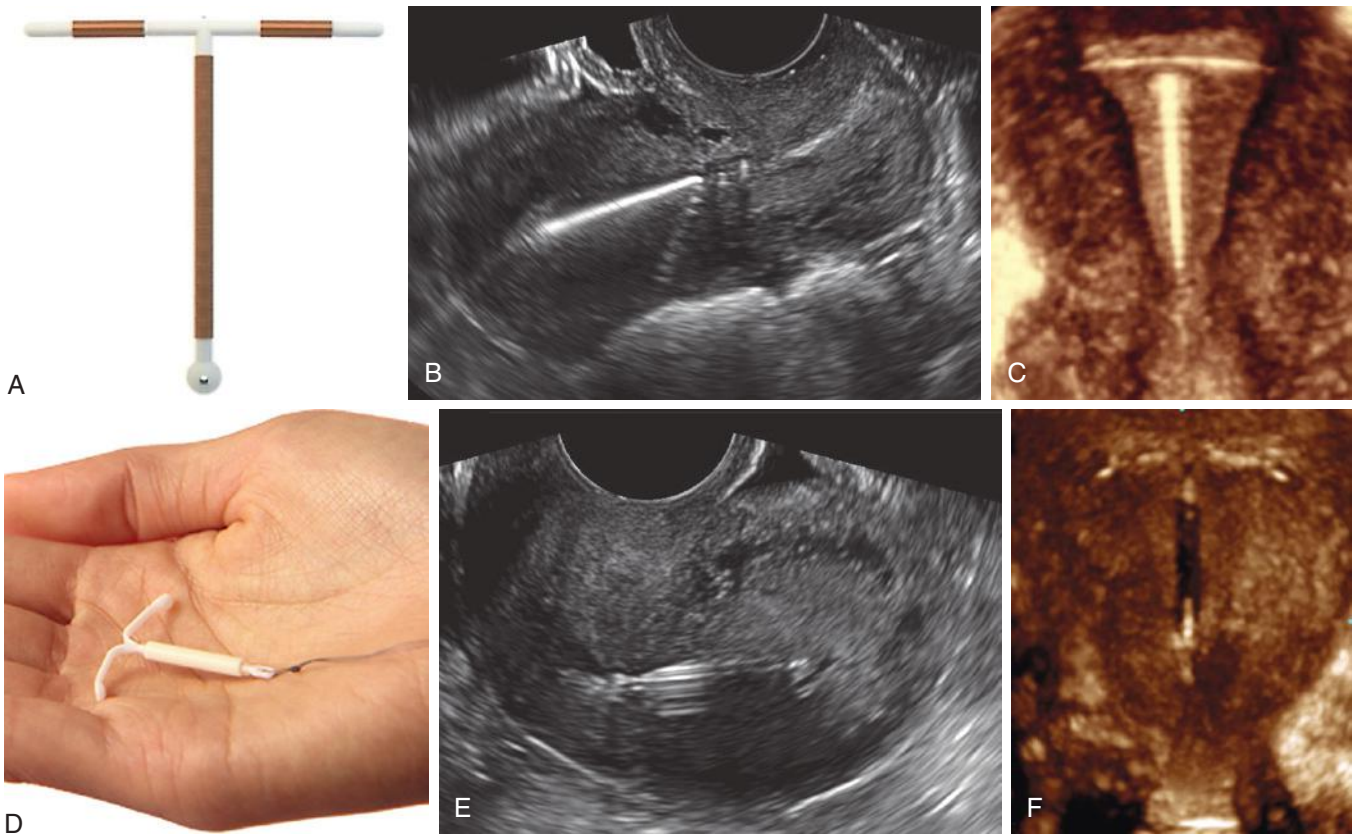

FIG 37-11 Intrauterine devices (IUDs). **A,** Photograph of a copper IUD from the manufacturer's website. **B,** Transvaginal longitudinal sonographic image of a well-positioned copper IUD showing the characteristic, uniformly echogenic appearance of the linear stem due to the copper coils. **C,** Three-dimensional coronal ultrasound image of a centrally positioned copper IUD. **D,** Photograph of a levonorgestrel (LNG)-releasing IUD from the manufacturer's website. Note the progestin-containing plastic sleeve that surrounds the central stem. **E,** Longitudinal transvaginal ultrasound image of LNG-releasing IUD well positioned within the retroverted, retroflexed uterus. The plastic sleeve adjacent to the central stem results in the characteristic laminated ultrasound appearance with posterior parallel lines and acoustic shadowing. **F,** Three-dimensional coronal ultrasound image of a well-positioned LNG-releasing IUD. Note linear hypoechoic area in the region of the plastic stem. (**A** from Teva Women's Health: What is Paragard? September 2015. Available at http://www.paragard.com/What-is-Paragard.aspx. **B** and **E** description of appearance from Stalnaker ML, Kaunitz AM: How to identify and localize IUDs on ultrasound. OBG Manag 26(8):40-42, 2014. D from Bayer HealthCare Pharmaceuticals: What is Mirena? December 2015. Available at http://www.mirena-us.com.)

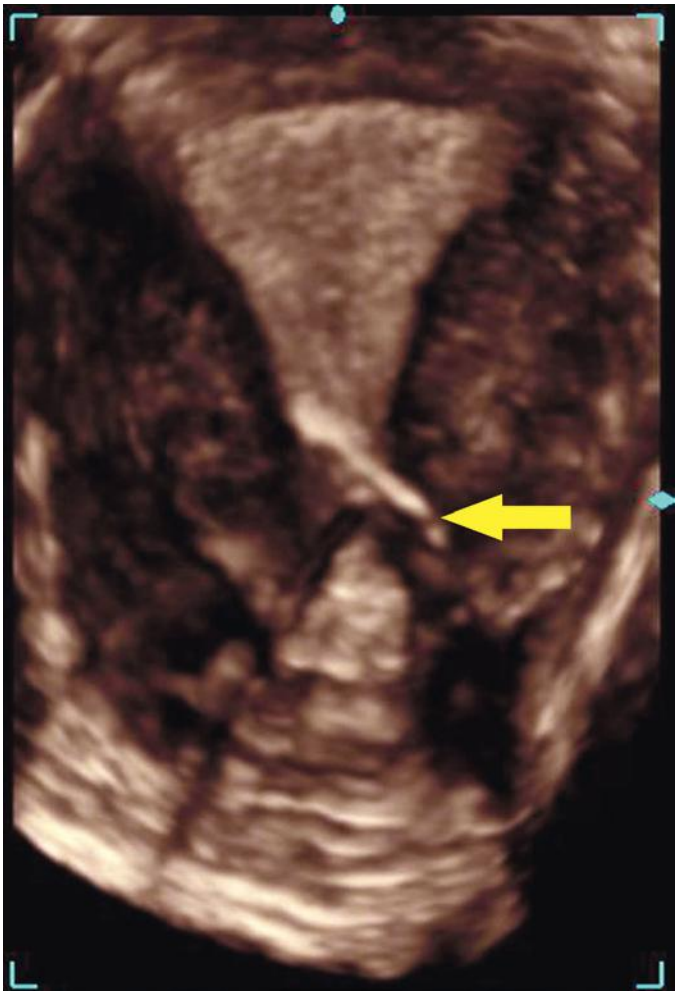

FIG 37-12 Malpositioned intrauterine device (IUD). Three-dimensional coronal transvaginal ultrasound image of the uterus shows the abnormally situated echogenic IUD. The IUD is malrotated and inferiorly positioned, in the lower uterine segment, with one of the side arms embedded in the myometrium (*arrow*).

- Malrotated
- Partially or fully embedded in the myometrium
- Extending beyond the uterine serosa or within the pelvic or abdominal cavity

The primary clinical concerns with a malpositioned IUD are potential tissue damage and the risk of pregnancy. The most common presenting symptoms of a malpositioned IUD are pain and bleeding. In this setting, IUD removal will usually result in resolution of symptoms.[46] Interestingly, complete perforation with penetration of an IUD through the myometrium into the peritoneal cavity is often asymptomatic. A woman with a malpositioned copper IUD is at greater risk to become pregnant than one with a malpositioned hormone-containing IUD, which works primarily via hormonal effects on the endometrium, and thus, optimal positioning of the device is less critical. In a study of 97 women with copper IUDs, the odds ratio for becoming pregnant with a malpositioned IUD compared to a properly positioned IUD was 13.93.[47]

When assessing IUD placement, there are distinct advantages of 3D as compared to 2D sonography, including the enhanced conspicuity of both types of devices and the ability to reconstruct a true coronal imaging plane[44] (Fig. 37-13). 3D sonography is now considered standard care and is routinely performed for assessment of IUD position. Minor inner myometrial penetration of the arms is often seen with this improved technology and is of uncertain but doubtful clinical significance.

PELVIC BIOPSIES AND DRAINAGES

Key questions to consider for pelvic biopsies and drainages:

- Is it safer and easier to access the target transvaginally or percutaneously?
- If the target is potentially ovarian in origin, has malignancy been considered?

The use of computed tomography (CT) for imaging-guided biopsies and drainages of pelvic masses and collections is well established. However, in the recent past, the many advantages of sonography (less expensive, faster, safer, no radiation exposure, and higher rate of successful tissue sampling) have resulted in widespread use of sonography as the modality of choice for guiding such procedures in many cases.[48-50]

Transvaginal access to pelvic masses or fluid collections is an underutilized approach. Use of transvaginal sonography is often safer and less painful than the conventional CT-guided posterior approach through the region of the piriformis muscle, coursing near the internal iliac vessels and sciatic nerve. Prior to the procedure, the patient's coagulation status is evaluated[51] and moderate sedation is usually administered. A needle guide, attached to a transvaginal sonographic transducer, is used to access the target (Fig. 37-14). A similar approach is used for ovum retrieval in women undergoing assisted reproductive techniques.

Although it has been hypothesized that suspected ovarian masses should not be needled owing to fear of potentially seeding tumor, reported low sensitivity of cytologic tests for the detection of malignancy, and risk of cyst recurrence, more recent investigations have shown that fine needle aspiration biopsy is an acceptable and valuable tool for the evaluation and management of ovarian cysts and masses.[52,53] Ultrasound-guided ovarian biopsy is often useful when patient comorbid conditions render surgery or general anesthesia too risky. A guideline followed by the authors is to never undertake an ovarian biopsy or aspiration until direct approval has been obtained from the gynecologic oncology service. This assures a multidisciplinary team approach to appropriately considering the risks and benefits of all diagnostic and treatment options.

CONCLUSIONS

In summary, ultrasound imaging has greatly enhanced the ability to safely and effectively perform select gynecologic procedures. This widely available, low-risk modality is ideally suited for evaluating patients and assisting with and guiding many gynecologic interventions.

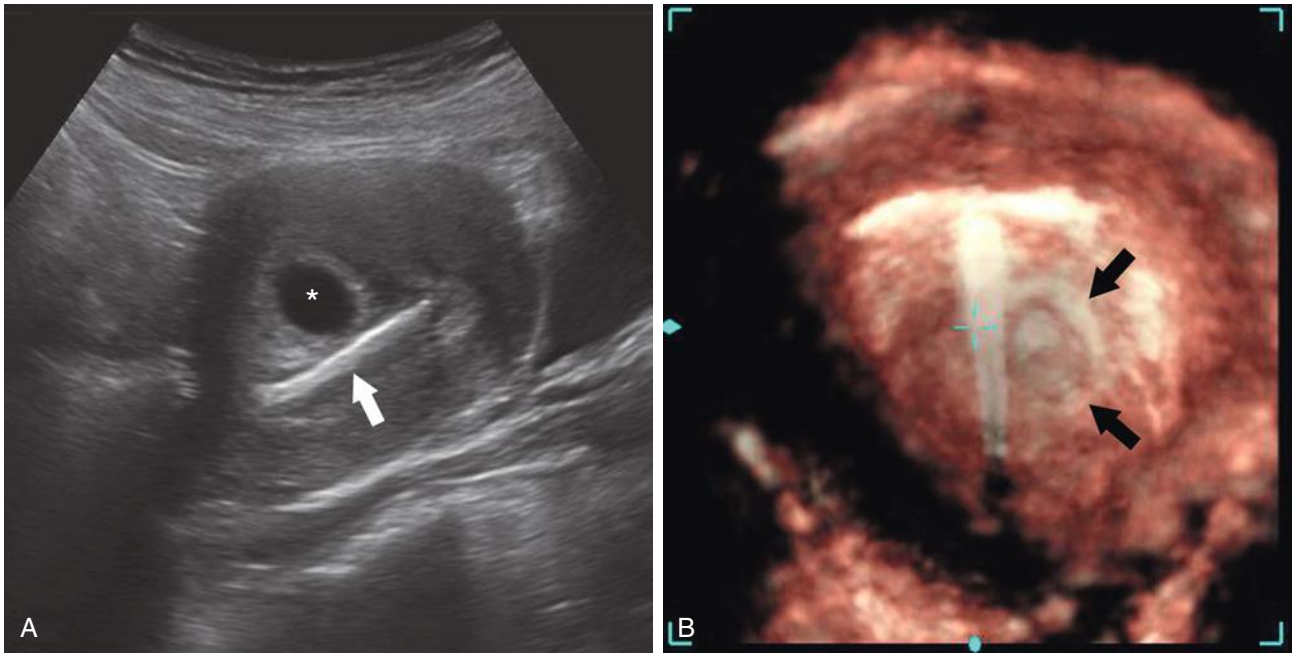

FIG 37-13 Intrauterine device (IUD) and intrauterine pregnancy. **A,** Longitudinal transabdominal ultrasound image shows linear echogenic IUD stem (*arrow*) directly adjacent to an intrauterine fluid collection (*asterisk*), representing an early gestational sac. **B,** Three-dimensional coronal ultrasound image better delineates the relationship and relative position of the T-shaped IUD to the intrauterine gestational sac (*arrows*).

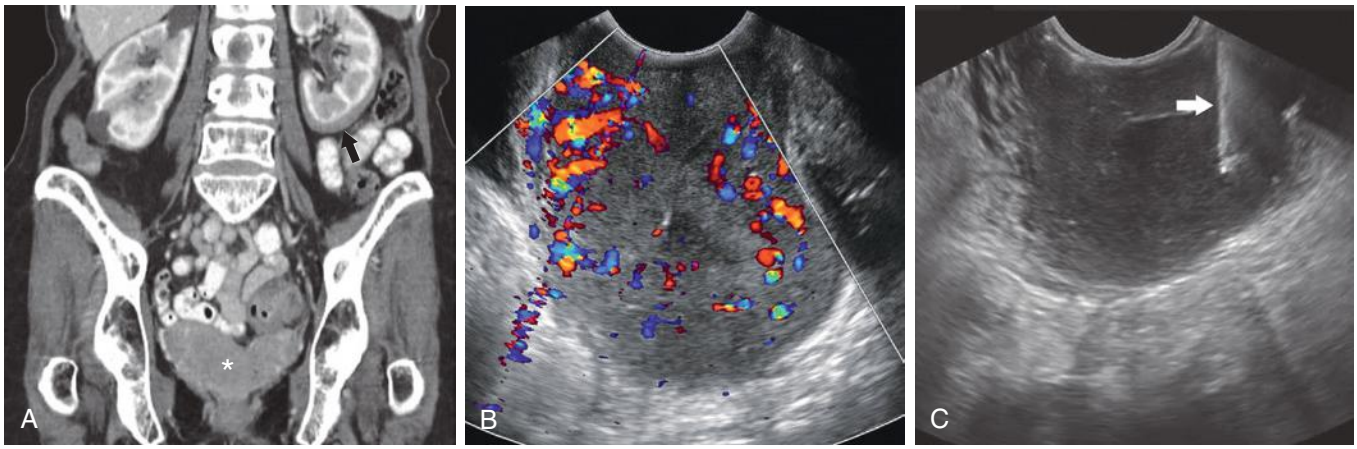

FIG 37-14 Pelvic lymphoma diagnosed by means of transvaginal ultrasound-guided biopsy. **A,** Reconstructed coronal image from contrast-enhanced computed tomography scan. Note lobulated soft tissue mass (*asterisk*) adjacent to the vaginal cuff. The uterus is surgically absent. It was deemed too difficult to safely obtain a large core tissue sample of this mass via a percutaneous approach. Also note thin rim of lymphomatous tissue surrounding the left kidney (*arrow*). **B,** Transvaginal ultrasound image with color Doppler interrogation shows the moderately echogenic solid pelvic mass with peripheral vascularity. **C,** Using real-time transvaginal sonographic guidance, biopsy of the solid pelvic mass, using an 18-gauge core biopsy needle (*arrow*), was successfully performed without incident.

SECTION III

Technical Considerations and Aberrations

38

Artifacts, Pitfalls, and Normal Variants

Peter W. Callen

OUTLINE

When I began my involvement with diagnostic sonography nearly 4 decades ago, this chapter would have been considered ludicrous. Virtually all of sonography was considered to be either an artifact or a pitfall. Clinicians did not take this modality seriously, and few critical decisions were ever based on the results of the ultrasound examination alone. With time, improvements in both technology and our understanding of normal and abnormal findings made this a useful clinical diagnostic modality. It did not take long for important clinical decisions to be based solely on the results of the ultrasound examination, including surgery, early delivery of the fetus, or even termination of the pregnancy. This evolution, although welcomed by many, has placed a large responsibility on the sonologist. The phrase "primum non nocere"—first do no harm—has never been more true.

This chapter is not an attempt to explain the physical principles of sonography or artifact production. It is also unlikely that such a chapter could ever be all-inclusive. I have attempted to find examples of pitfalls, the diagnostic dilemmas that have the potential to lead us to the wrong diagnosis. I have tried to cover both basic potential pitfalls and some of the more esoteric normal variants. Undoubtedly, some readers will find examples here that are so basic as to seem almost insulting. I apologize in advance and will only respond that this chapter is meant to appeal to a wide audience that includes beginners and seasoned experts. I also do not attempt to give an overly detailed explanation for each example but try to offer what is theorized currently.

If I am able to avoid one false positive diagnosis and prevent unnecessary surgery, termination of a pregnancy, or even 20 weeks of an emotional roller coaster for expectant parents, I have fulfilled my goal.

AN UNFORTUNATE BUT COMMON PITFALL

I begin this chapter as the subheading suggests, with a common but unfortunate pitfall.

A 34-year-old woman presented to the emergency department complaining of mild pelvic pain with a known history of positive pregnancy test. A quantitative serum β-hCG (human chorionic gonadotropin) revealed a value of 3870 mIU/mL. (This value is nearly double most centers' "discriminatory zone.") A diagnostic ultrasound examination revealed no evidence of an intrauterine pregnancy (IUP) or adnexal masses. As a result, the patient was presumed to have an ectopic pregnancy (EP) and was treated with intramuscular methotrexate. A repeat sonogram obtained 1½ weeks later revealed a living IUP. The patient elected to terminate the pregnancy.

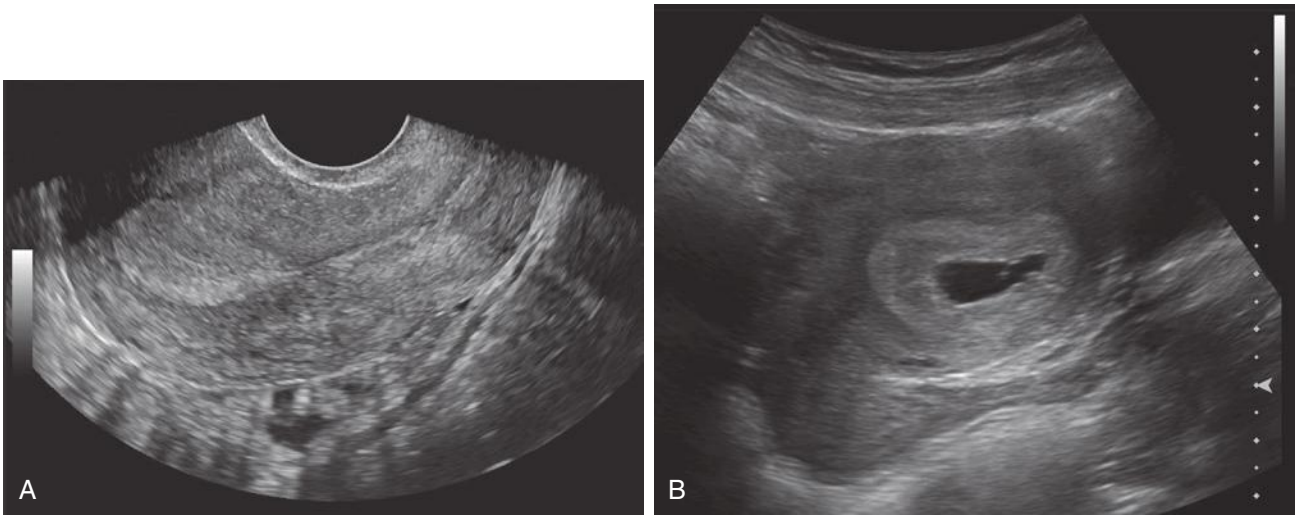

FIG 38-1 **A,** Transvaginal sonogram obtained at approximately 4.5 weeks demonstrating no evidence of an intrauterine pregnancy. Additional scans revealed normal ovaries without evidence of an adnexal mass. **B,** Transabdominal sonogram obtained 1.5 weeks later revealed a living intrauterine pregnancy.

When a woman of child-bearing age presents to her clinician or emergency room with pelvic pain or bleeding and a positive pregnancy test, clearly the first thought in the diagnostic tree is the possibility of an EP. Most clinicians are aware that the risk of a heterotopic pregnancy (in which both an extrauterine [ectopic] and IUP occur simultaneously) is quite low (1 in 15,000 to 1 in 30,000), although this phenomenon is more common in patients following assisted reproduction. Thus, the goal of sonography is to identify an IUP, making an EP unlikely. Two factors have helped achieve this goal:

1. In the early 1980s, Kadar and others attempted to determine the maternal serum hCG level above which a gestational sac should be consistently seen during sonograms in a patient with a normal IUP. The value was termed the "discriminatory zone." It should be noted that the values initially reported were significantly higher prior to the advent of transvaginal sonography in use today. Although this upper limit value today is variable at differing institutions, it tends to be between 1500 and 2000 mIU/mL (first IUP).
2. With the advent of high-resolution transvaginal sonography, early pregnancies can now often be identified within the uterus when gestational sacs are as small as 2 to 3 mm.

A noninvasive method of treating EPs with methotrexate became available in the early 1980s. As a result, some clinicians, then and now, treat the patient with methotrexate when both an "empty uterus" at the time of sonography and an elevated β-hCG level (above the discriminatory zone) are present, in an attempt to treat the EP. Unfortunately, some of these patients subsequently have been found to have IUPs, not EPs, on follow-up. It is quite clear that even marked elevations of β-hCG above the discriminatory zone are not always reliable in excluding an intrauterine pregnancy when a gestational sac is not seen at sonography. In these cases, follow-up, rather than immediate treatment, is indicated. Likewise, even in the best of hands and with excellent ultrasound equipment, at 4 to 5 weeks' gestation an IUP may not be identified sonographically, though the patient may in fact have an IUP. The report should ideally read "An ectopic pregnancy, or a pregnancy too early to be seen within the uterus, cannot be excluded."

In October 2012, the Society of Radiologists in Ultrasound convened a multispecialty consensus conference to establish criteria on early first trimester diagnosis of miscarriage and exclusion of a viable IUP when seen in the uterus, as well as to discuss diagnosing and ruling out a viable IUP in a woman with a pregnancy of unknown location. These criteria and an editorial discussion were published in the *New England Journal of Medicine* (Doubilet and associates, 2013; Kaunitz et al 2013). The takeaway points from this panel regarding this pitfall were as follows:

- A single hCG assessment, regardless of level, does not reliably determine a pregnancy's location or viability (this is because hCG levels in women with nonviable IUPs, viable IUPs, and EP overlap substantially).
- A single hCG level less than 3000 mIU/mL should not elicit treatment for presumed EP because there is a substantial risk that administering methotrexate will damage a normal IUP.
- A single hCG level 3000 mIU/mL or higher in the absence of a sonographically visualized IUP indicates that a viable IUP is possible but unlikely. The most likely diagnosis is failed IUP, so if methotrexate is administered, it is more likely being given unnecessarily to a woman with a failed IUP than to one with an EP. At least one additional hCG level should be measured before initiating treatment for EP.

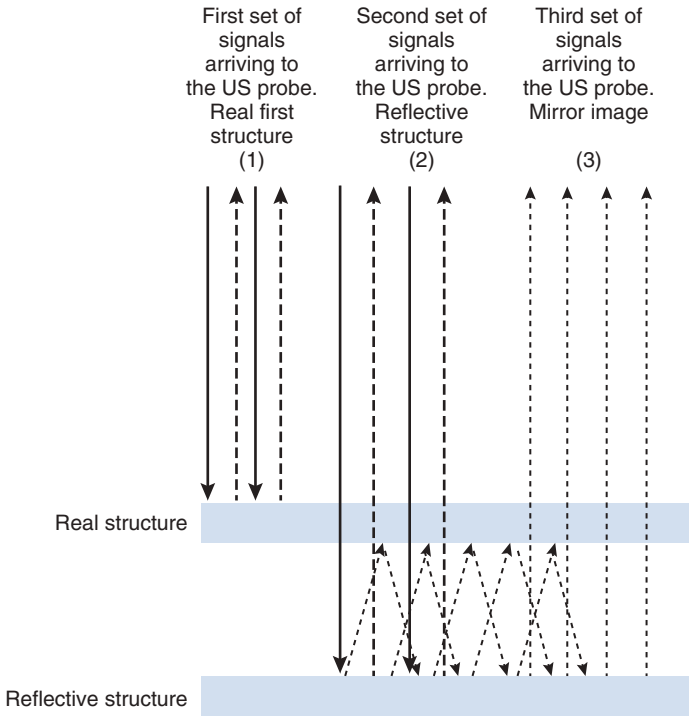
TECHNICAL CONSIDERATIONS

Mirror Image Artifact

A mirror image artifact is created when the ultrasound beam is reflected from a strong reflector that is often obliquely oriented and redirects the echoes off a secondary reflector back to the transducer. The ultrasound computer assumes the sound traveled in a straight line. The mirrored image results in the copy appearing on the same image, though deeper because of the additional time for the mirrored image to return to the transducer. In conventional gray-scale imaging, as well as color Doppler imaging, the mirrored artifact will always be the deeper structure.



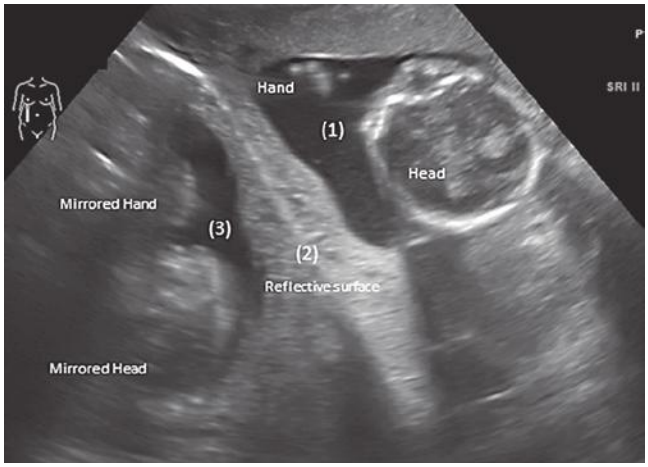


FIG 38-2 Schematic representation of the mirror image artifact. Ultrasound (US) signals are normally reflected by the structure (fetal head) and by the reflective surface (posterior uterine wall and bowel) arriving on time to the transducer. Some ultrasound signals bounce back and forth between the head and the reflective surface, finally returning to the transducer. Because they arrive later than the original signals, they are represented as another structure behind/deep to the reflective surface. (From Ahn H, Hernandez-Andrade E, Romero R, Ptwardhan M, et al: Mirror artifacts in obstetric ultrasound: case presentation of a ghost twin during the second-trimester ultrasound scan. Fetal Diagn Ther 34:248-252, 2013, used with permission.)

FIG 38-3 **A,** Longitudinal transvaginal sonography demonstrating an intrauterine pregnancy on the left and the mirror image artifact of the image on the right. **B,** Longitudinal transvaginal ultrasound image demonstrating an intrauterine pregnancy on the left and mirror image artifact on the right. (From Malhotra R, Bramante RM, Radomski M, Nelson M: Mirror image artifact mimicking heterotopic pregnancy on transvaginal ultrasound: case series. West J Emerg Med 15(6):712-714, 2014, used with permission.)

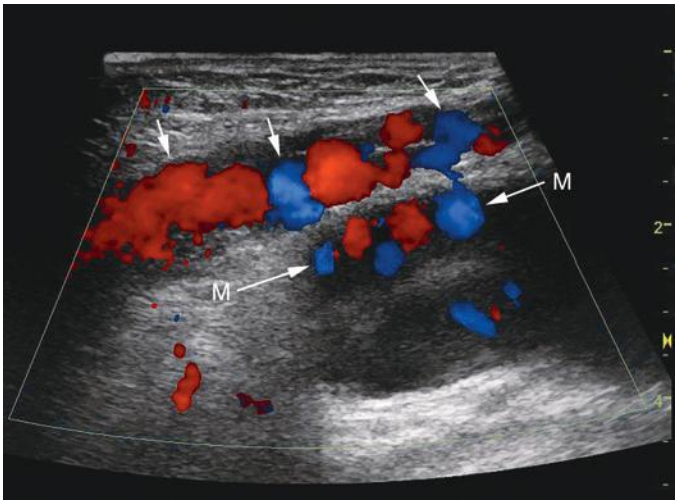

FIG 38-4 Sonogram over the inguinal area in a gravid patient at 34 weeks with round ligament varices. Color Doppler imaging demonstrates prominent vessels with venous flow (*arrows*). A mirror image (M) of the varices is seen deep to the vessels.

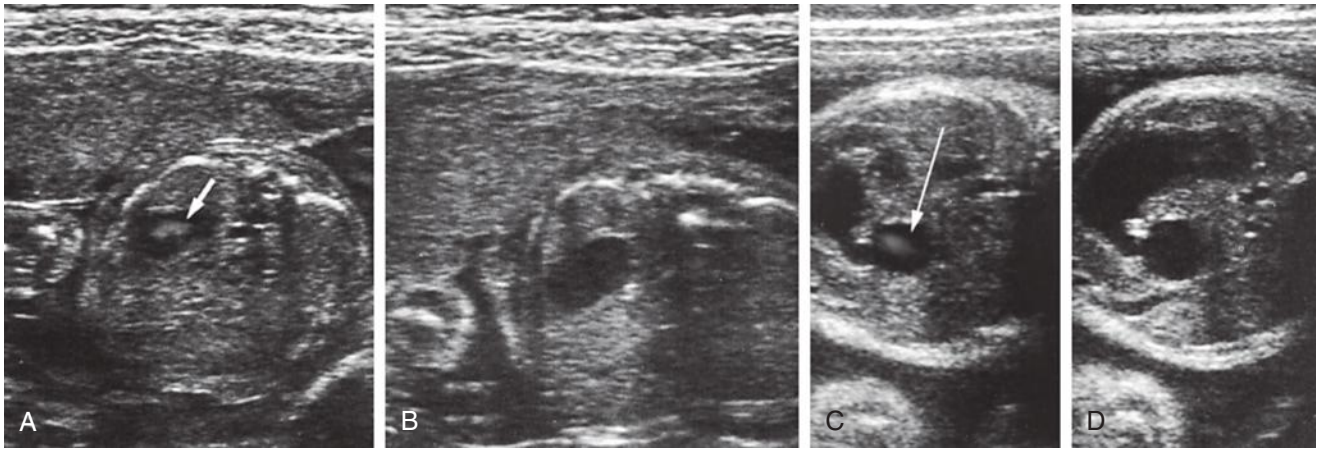

FIG 38-5 **A** and **C,** Two cases of artifact (*arrows*) appear in the fetal stomach and duodenum. **B** and **D,** If one changes the scanning plane, these echoes will disappear from the area of concern.

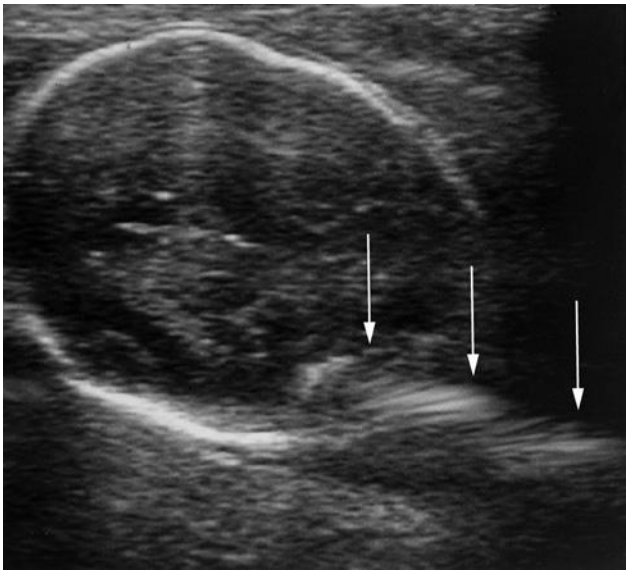

FIG 38-6 Side lobe (gradient) artifact can occur with even the most sophisticated ultrasound scanning equipment. In this case, a side lobe artifact is seen overlying the fetal head (*arrows*). The artifactual nature of these echoes can be confirmed by noting that these echoes are not confined to the head but extend beyond its confines. In addition, changing the scan plane orientation will show the region to be normal.

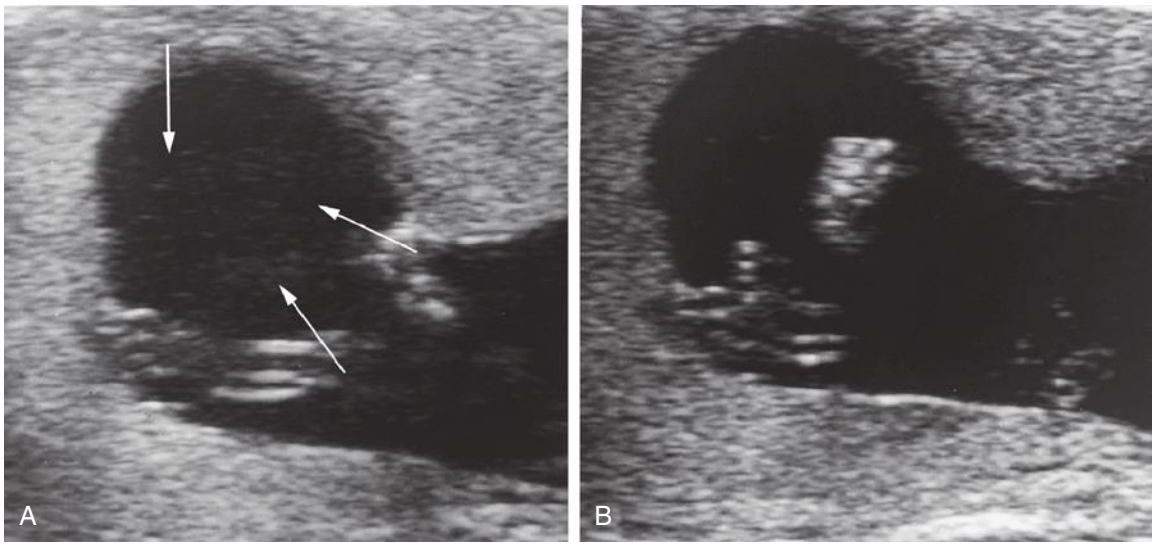

FIG 38-7 The differentiation of real from artifactual echoes is often problematic during sonographic scanning. A common misconception is that changing to a lower frequency transducer and decreasing the overall system gain or just reducing the system gain will only cause the artifactual echoes alone to disappear. Although it is true that artifactual echoes will not be displayed with these maneuvers, it should be remembered that the real echoes will not be displayed either. **A,** In this patient, numerous low-level echoes (*arrows*) were seen swirling in the amniotic fluid during real-time scanning. Although the origin of the echoes is not known, they may represent shed fetal epithelial cells. **B,** When the system gain was decreased, these real echoes virtually disappeared. Although the hard copy images do not resolve this dilemma, the echoes were clearly seen to be moving and real when the sonologist was performing the scan.

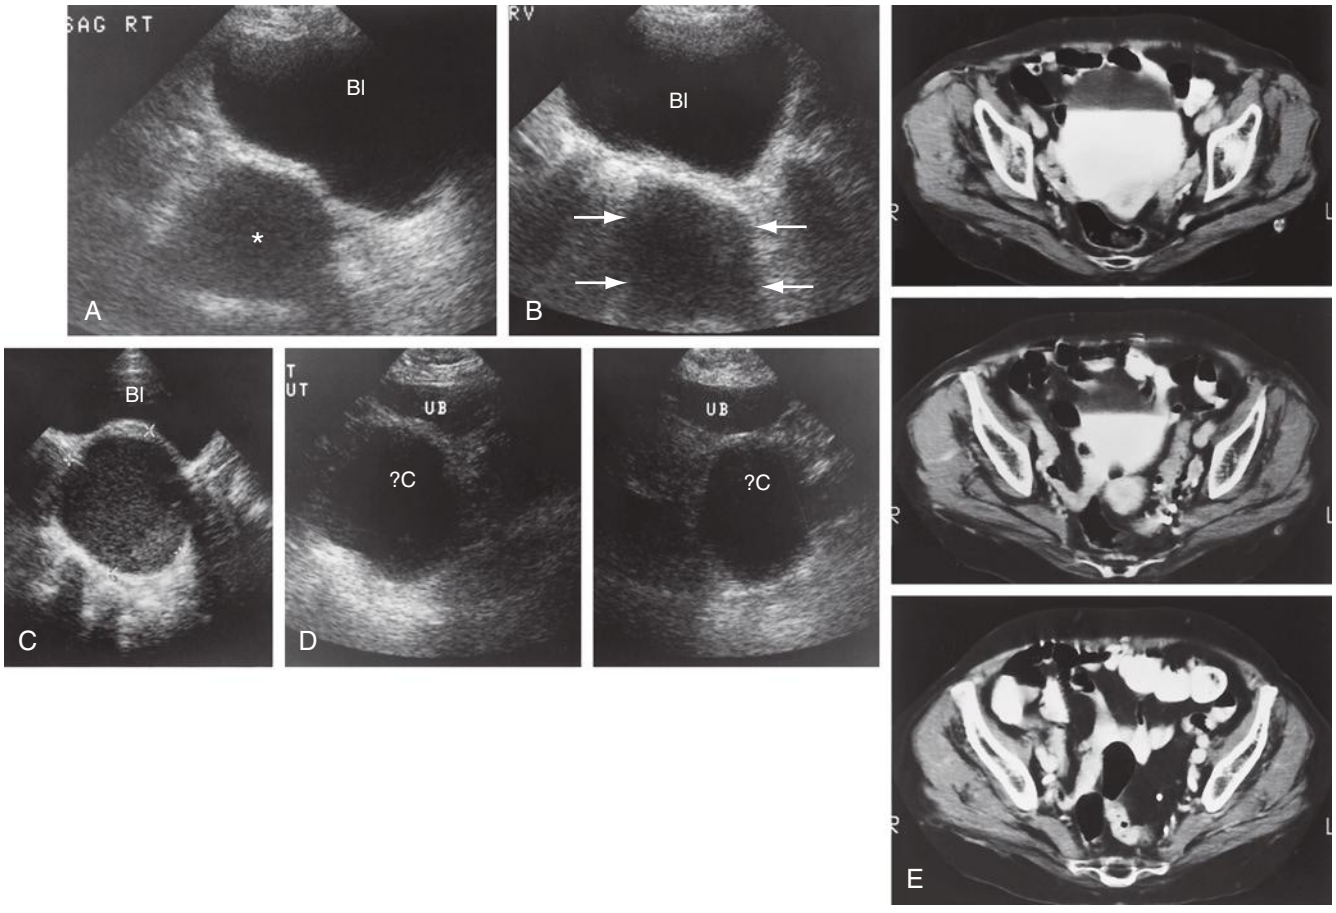

FIG 38-8 Bowel within the pelvis can masquerade as ovarian cysts. **A,** In this patient, bowel gas and its shadowing create the appearance of a mass (*asterisk*). Bl, bladder. **B,** The strong reflection adjacent to the urinary bladder (Bl) or the "squared" appearance (*arrows*) to the "cyst" should make one suspicious that bowel gas artifact is causing this appearance. **C,** In a different patient, a true ovarian cyst (*cursors*) has borders on nearly every side and has enhanced through-sound transmission and internal echoes. Bl, bladder. **D,** In another patient, two different planes of section demonstrate what appears to be a large pelvic cyst (?C). In fact, this was due to bowel gas artifact. UB, bladder. **E,** Because this appearance was virtually indistinguishable from a pelvic cyst, a computed tomographic scan was performed immediately after the sonogram, confirming the artifactual nature of this "cyst." The scans were normal without evidence of a pelvic mass.

PELVIS, GRAVID AND NONGRAVID UTERUS

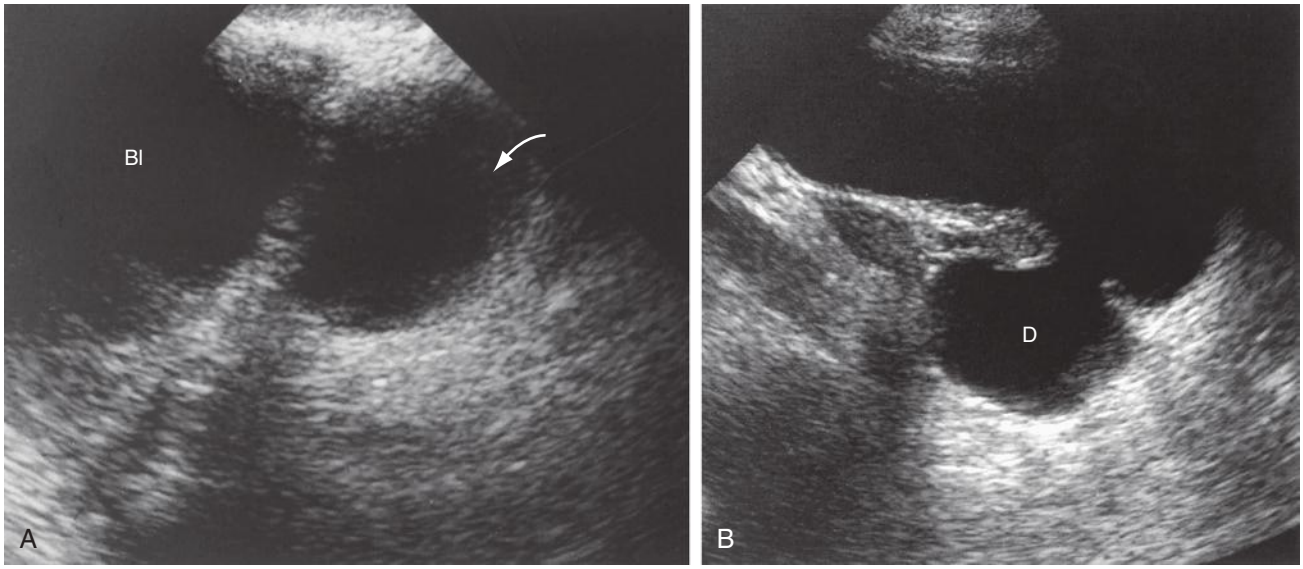

FIG 38-9 **A,** What appears to be a large pelvic cyst (*arrow*) is seen in this patient. Bl, bladder. **B,** Although the connection to the bladder was not seen in A, this bladder diverticulum (D) is clearly seen in another plane of section.

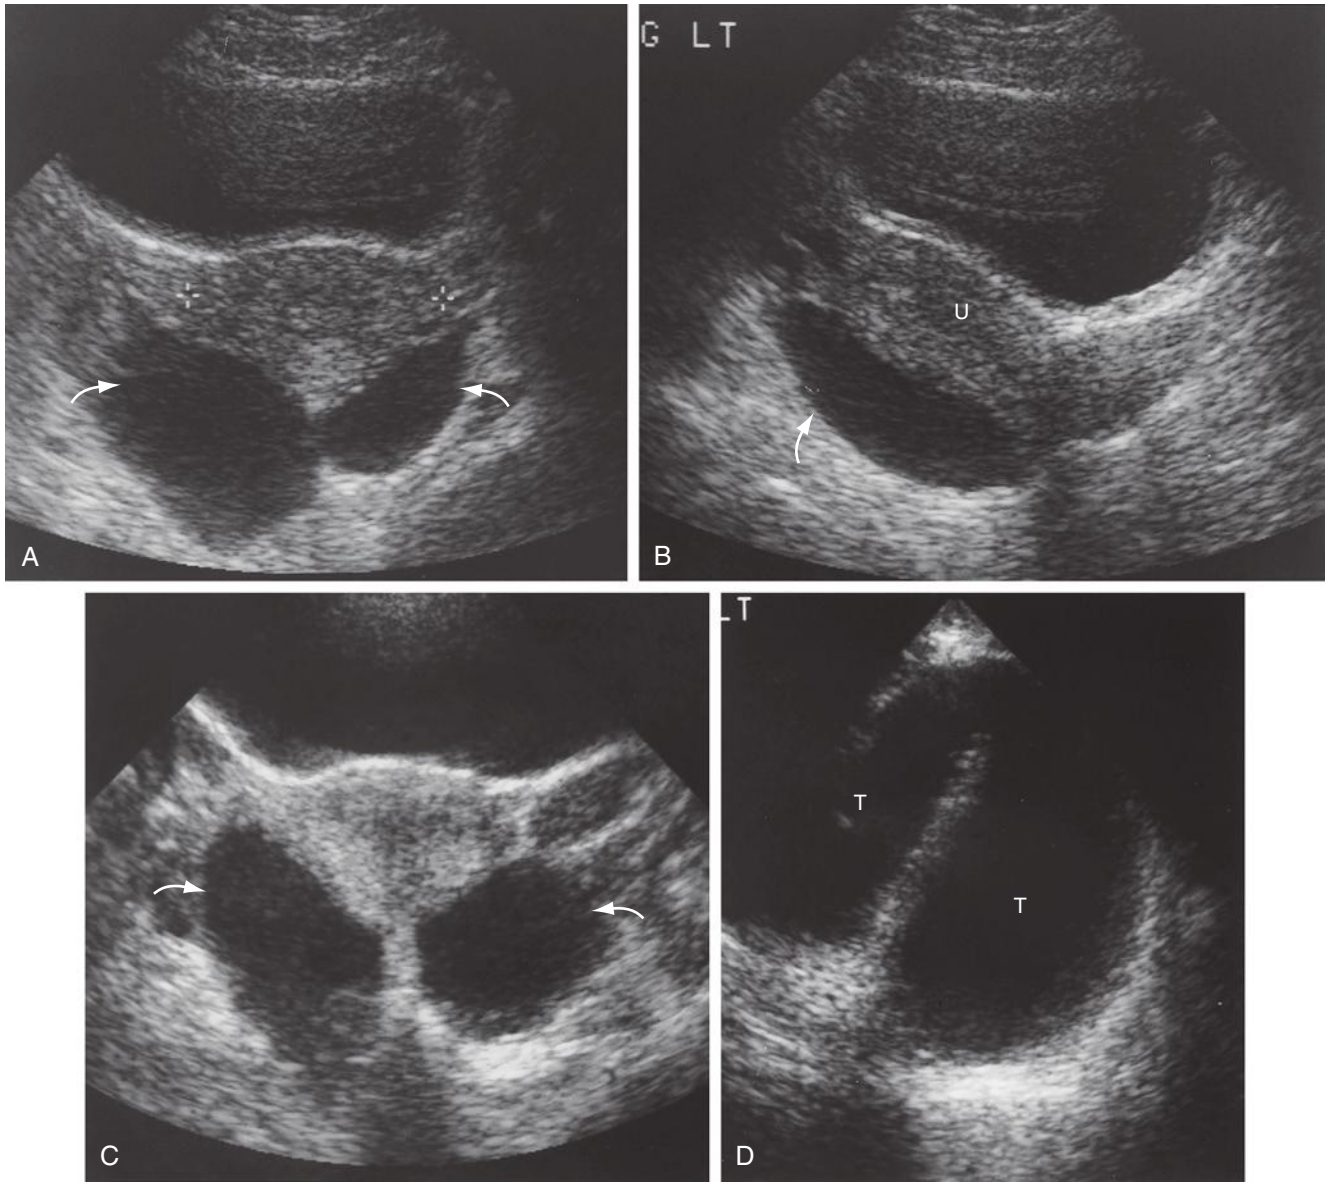

FIG 38-10 Dilated fallopian tubes simulating ovarian cysts. **A,** A transverse sonogram in this patient demonstrates what appear to be two ovarian cysts (*arrows*) posterior to the uterus (*cursors*). **B,** A longitudinal sonogram displays the elongated tubular nature of this fluid collection (*arrow*), which is more compatible with a dilated fallopian tube. U, uterus. **C,** In another patient, two large, rounded fluid collections are seen (*arrows*) simulating ovarian cysts. **D,** A longitudinal plane of section through one of these collections demonstrates the tubular (T) retort nature of these dilated fallopian tubes.

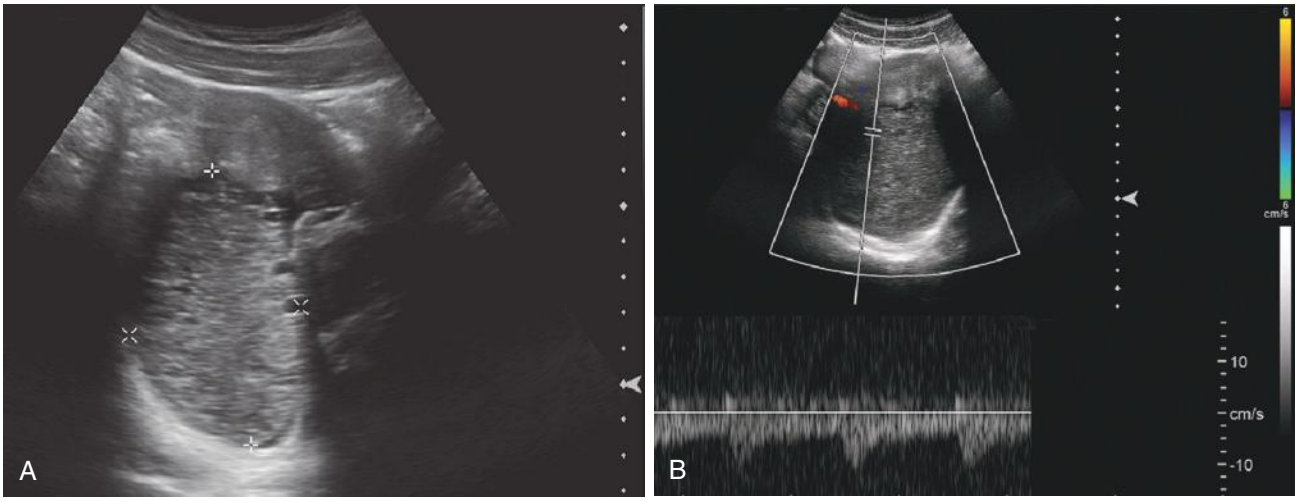

FIG 38-11 A 19-year-old woman presented with severe pelvic pain and negative pregnancy test. She had been in an emergency room 1 month earlier with the same symptoms. **A,** A pelvic sonogram demonstrates an enlarged ovary with peripheral small cysts. **B,** Doppler sonogram of the ovary demonstrates arterial and venous blood flow. Three hours later an avascular necrotic ovary from ovarian torsion was removed at surgery. Don't be falsely reassured by an apparently normal Doppler sonogram when ovarian torsion is suspected.

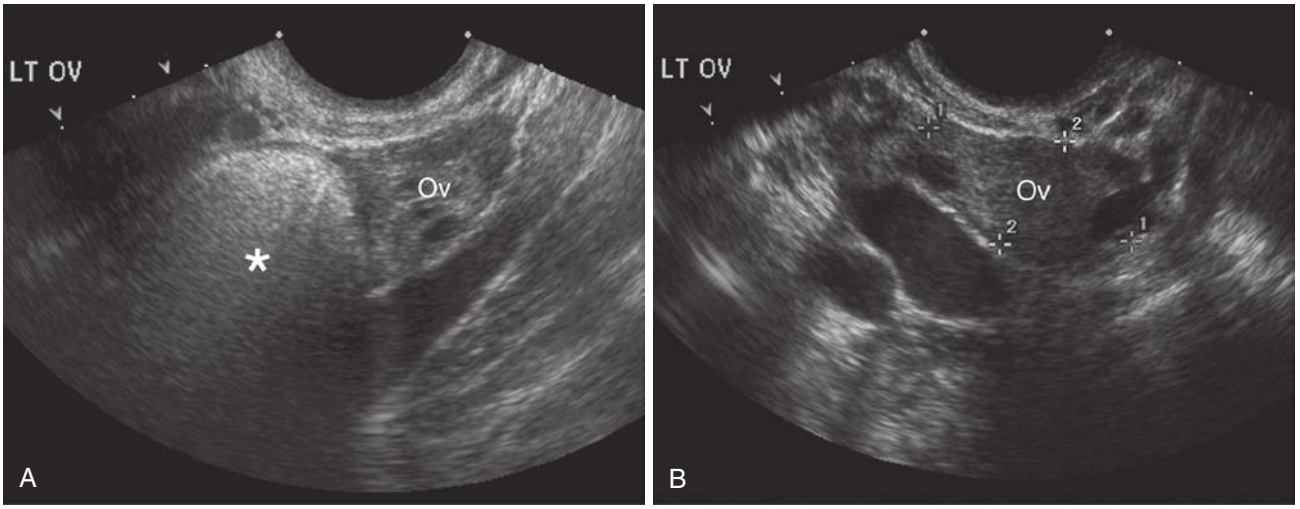

FIG 38-12 Bowel simulating an ovarian cystic teratoma (dermoid). **A,** A large shadowing mass (*asterisk*) is seen adjacent to or possibly emanating from the ovary (Ov). **B,** Minutes later the normal ovary and adnexal structures are well seen. The bowel, which was the cause of the shadowing, was not seen.

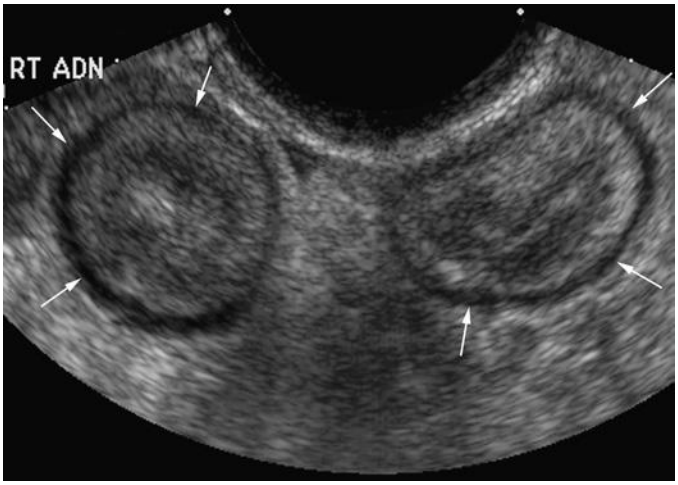

FIG 38-13 Two round and oval structures are seen in the right adnexa. Although they might be mistaken for abnormal ovaries or paraovarian masses, they represent normal prominent bowel. Typical hypoechoic muscularis (*arrows*) is seen.

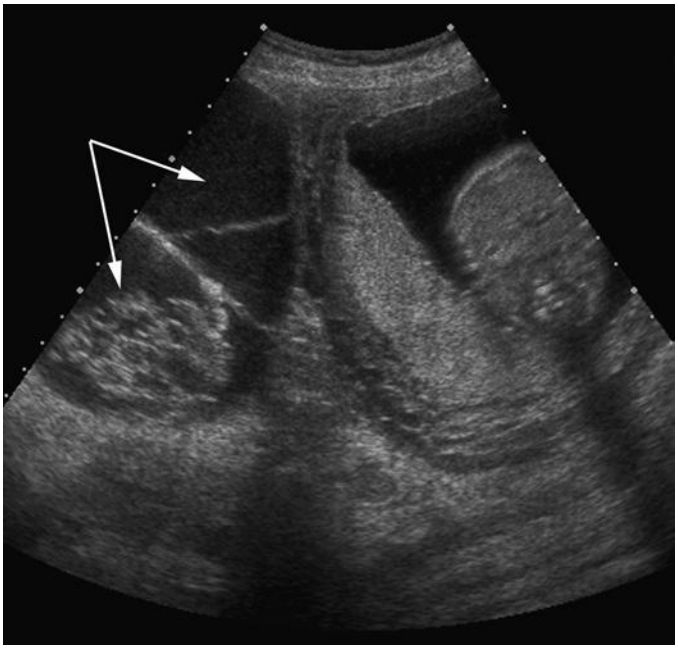

FIG 38-14 Pregnancy with coexistent ovarian carcinoma. Unfortunately, just because a patient is pregnant does not mean that she cannot have a concomitant ovarian cancer. A multilocular cystic mass (*arrows*) with solid components is seen adjacent to the gravid uterus.

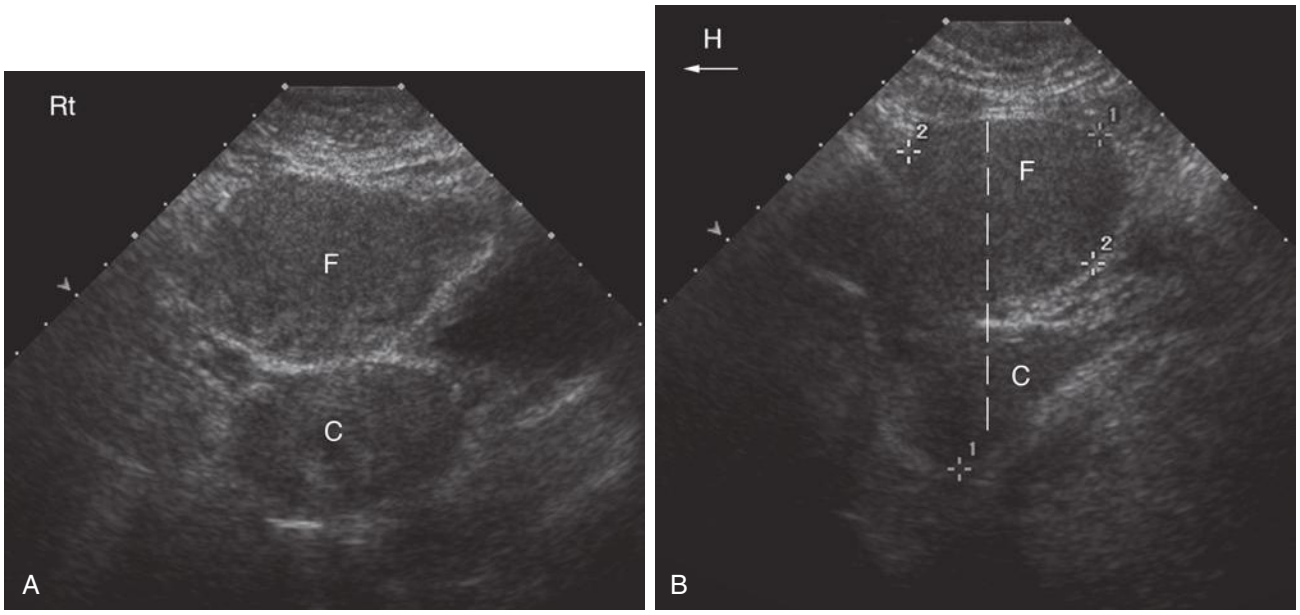

FIG 38-15 **A,** Transverse axial sonogram of the pelvis in a nongravid patient. There appears to be either a duplication of the uterus or the uterus and an adjacent mass (C, F). Rt, right. **B,** A sagittal scan demonstrates that what was seen in the transverse scan was the cervix (C) and fundus (F) of an anteverted uterus. The dashed line represents the plane of section in A. H, head.

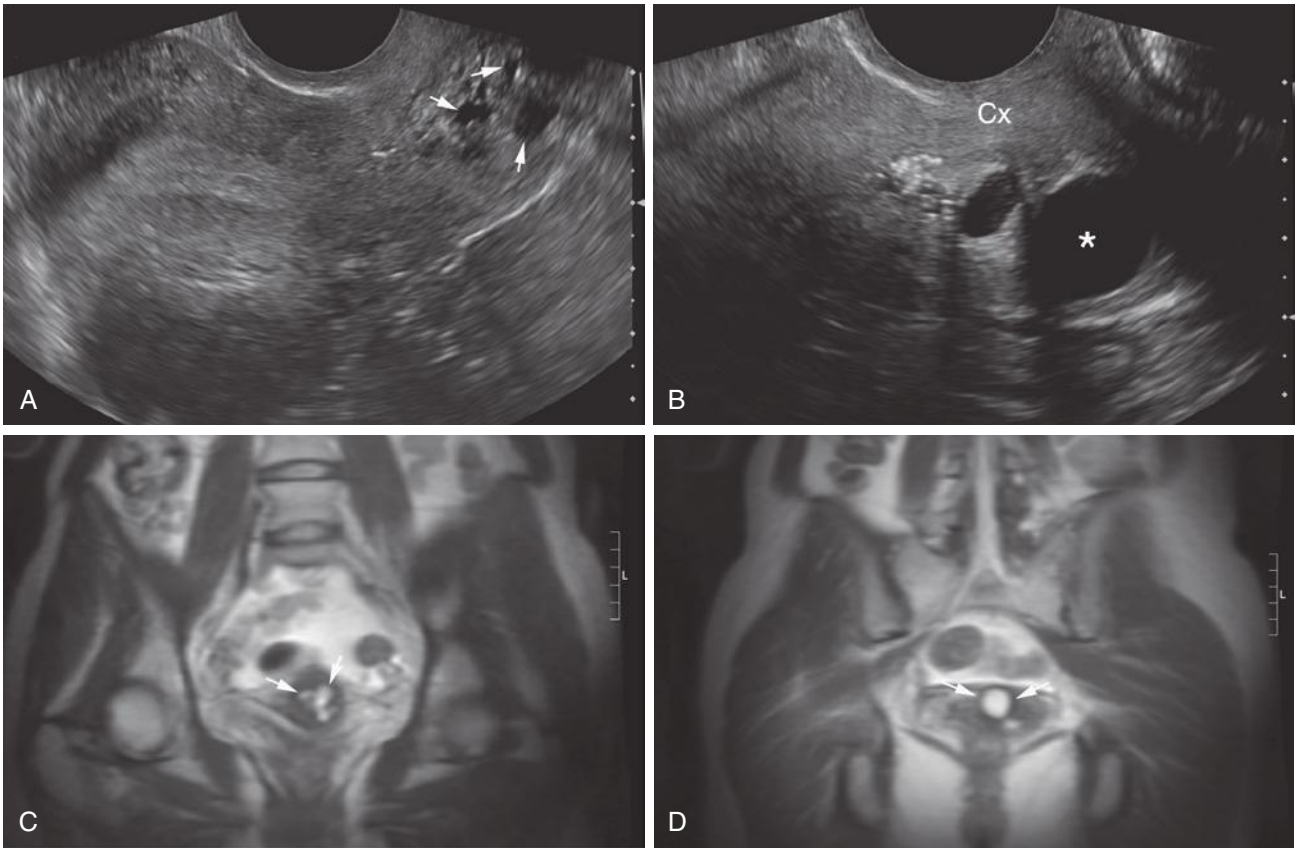

FIG 38-16 Longitudinal transvaginal sonogram through the cervix of a nongravid uterus. **A** and **B,** Multiple nabothian cysts (*arrows*) are seen in the cervix (Cx). At times these cysts can be quite large (*asterisk*). These retention cysts are quite common and should not be confused with low-implanted gestational sacs or other abnormalities. **C** and **D,** Two coronal T2-weighted magnetic resonance images through the cervix demonstrate multiple, round, T2-weighted hyperintense structures compatible with nabothian cysts (*arrows*).

FIG 38-17 **A,** Transverse scan through the gravid uterus demonstrates a uterine synechia (*arrow*) crossing the uterine cavity from the anterior to the posterior wall. The singleton fetus moved freely around the synechiae. This should not be confused with an amniotic band. **B,** In another patient a uterine synechia (*arrow*) is seen adjacent to the fetal head. **C,** Three-dimensional rendered image of the fetus in **B** demonstrating the synechia (*arrows*).

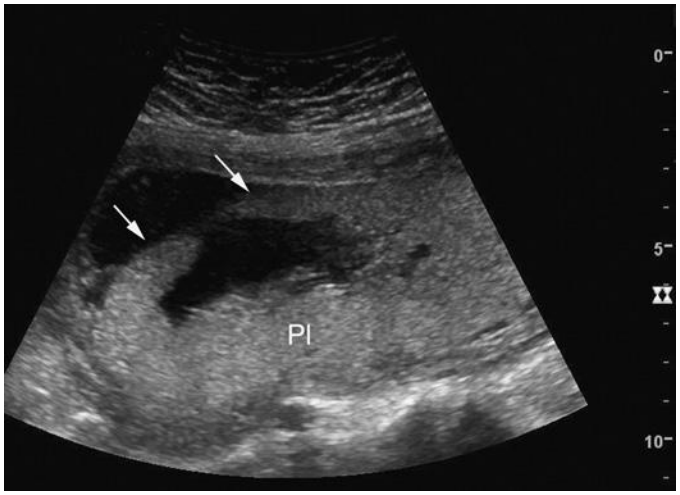

FIG 38-18 Sonogram of a gravid uterus in the second trimester demonstrating a circumvallate placenta (Pl). The infolding of the edge of the placenta (*arrows*) should not be confused with a uterine synechia.

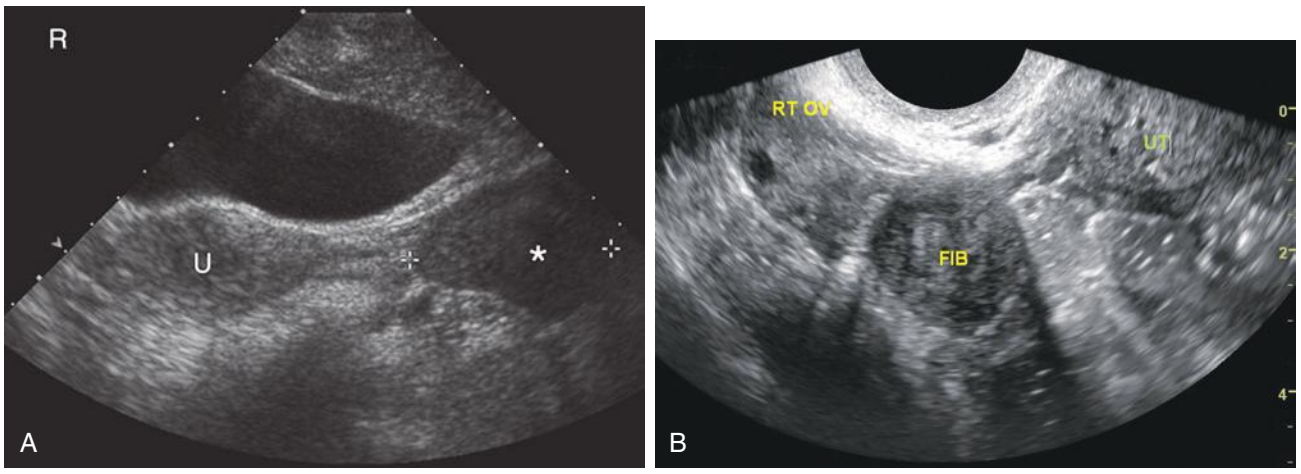

FIG 38-19 **A,** Transverse scan of the pelvis demonstrating a left adnexal solid mass (*asterisk*). Although the anatomic position might suggest an ovarian lesion, the solid nature of the mass should suggest the possibility of a broad ligament myoma, which was ultimately demonstrated on magnetic resonance imaging. U, uterus, R, right. **B,** Coronal transvaginal scan demonstrating a broad ligament myoma (FIB) clearly separate from the uterus (UT) and ovary (RT OV).

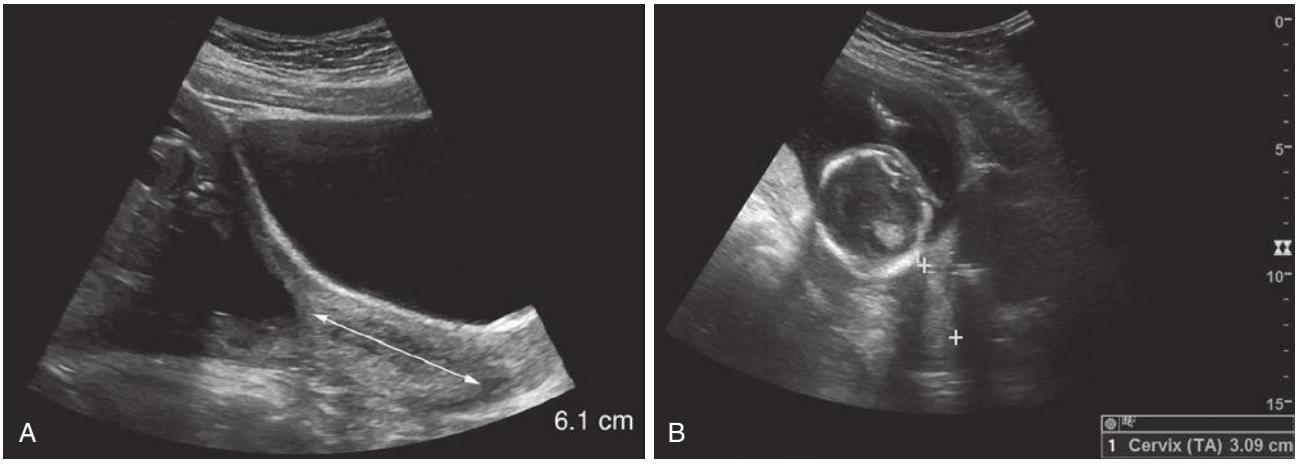

FIG 38-20 **A,** Significant overdistention of the urinary bladder results in the appearance of a markedly elongated cervix (*double-headed arrow*) measuring 6.1 cm. One is visualizing not only the cervix but the apposed anterior and posterior walls of the lower uterine segment. **B,** Once the patient has emptied her urinary bladder, the true cervical length (*between calipers*) can be accurately measured at 3.09 cm.

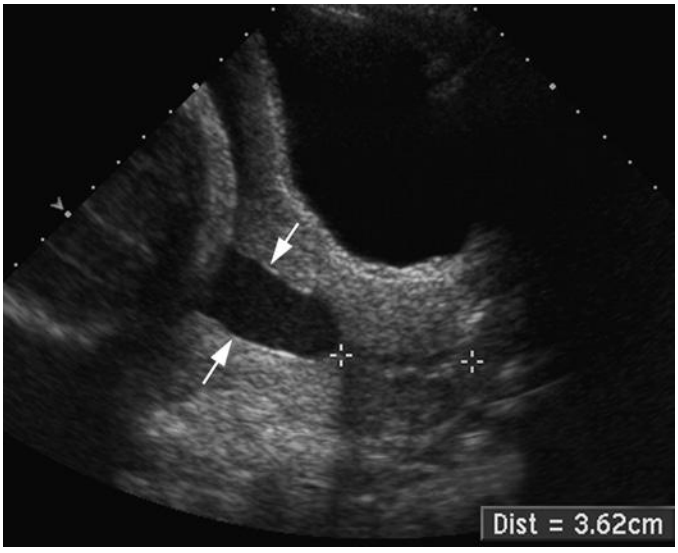

FIG 38-21 A distended urinary bladder has caused the anterior and posterior walls of the lower uterine segment (*arrows*) to come near one another. The trapped amniotic fluid gives the appearance of an incompetent cervix. The cervix was normal in this case.

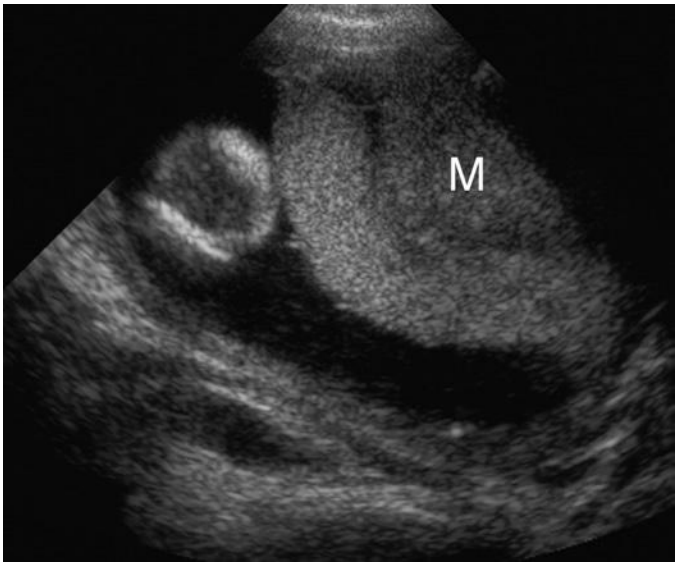

FIG 38-22 A myometrial contraction (M) is common in first and second trimester sonograms. This should not be confused with a myoma. Two features help make this distinction: First, in general, myometrial contractions tend to bulge inwardly without affecting the outer contour of the uterus. Uterine myomas tend to bulge inward and outward. Second, myometrial contractions may resolve during the time of scanning.

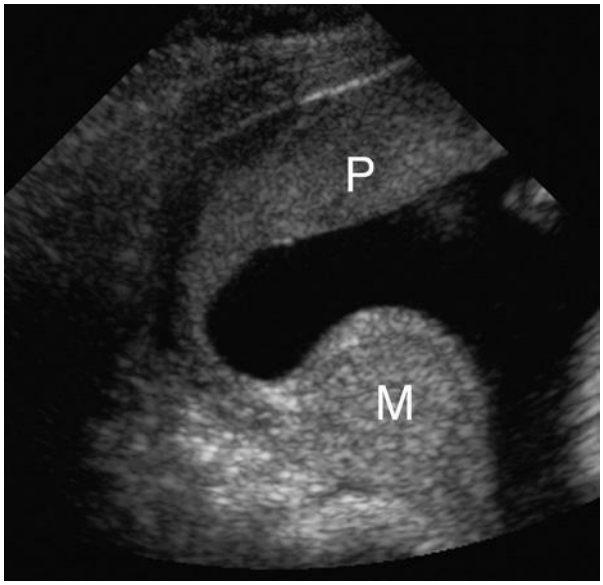

FIG 38-23 A myometrial contraction (M) in this second trimester pregnancy simulates a myoma. This should not be confused with a succenturiate lobe of the placenta. P, placenta.

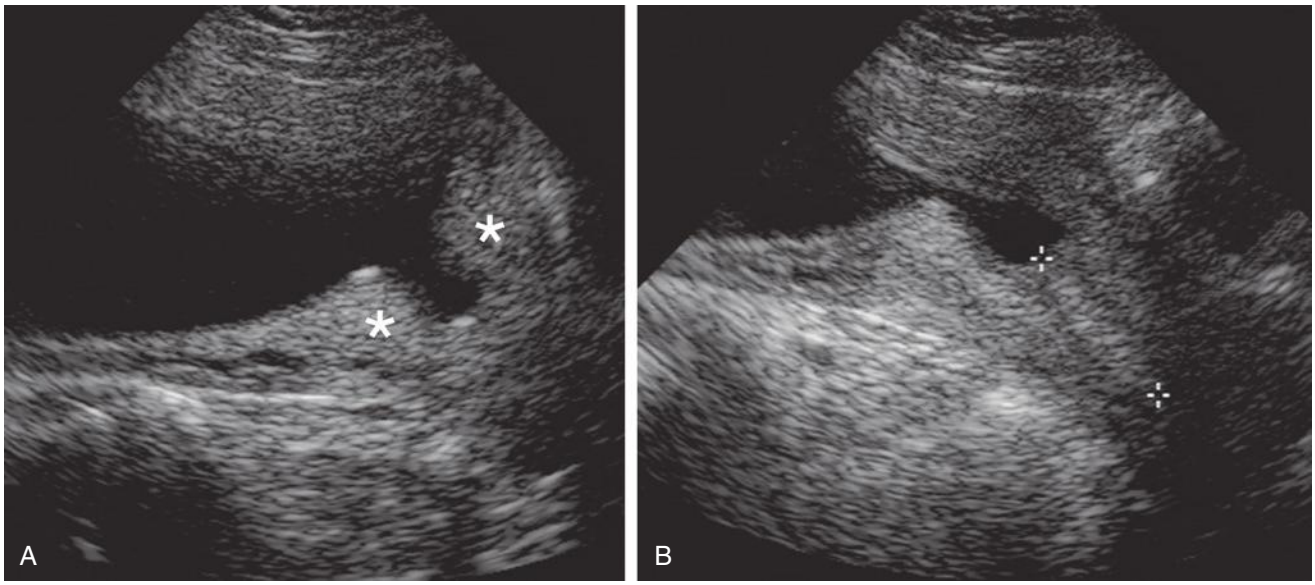

FIG 38-24 Myometrial contractions of the lower uterine segment are common and may often touch one another. **A,** In this case the contractions (*asterisks*) of the lower uterine segment simulate an open and incompetent cervix. **B,** The normal-appearing cervix, in fact, is well seen (*calipers*) caudal to this contraction.

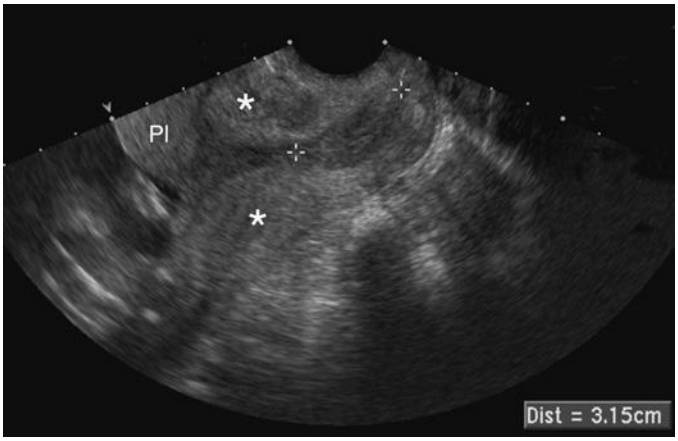

FIG 38-25 Myometrial contractions of the lower uterine segment may touch one another (*asterisks*). These opposed contractions have been referred to as "kissing contractions." In this case, it gives the impression that the placenta (Pl) overlies the internal cervical os.

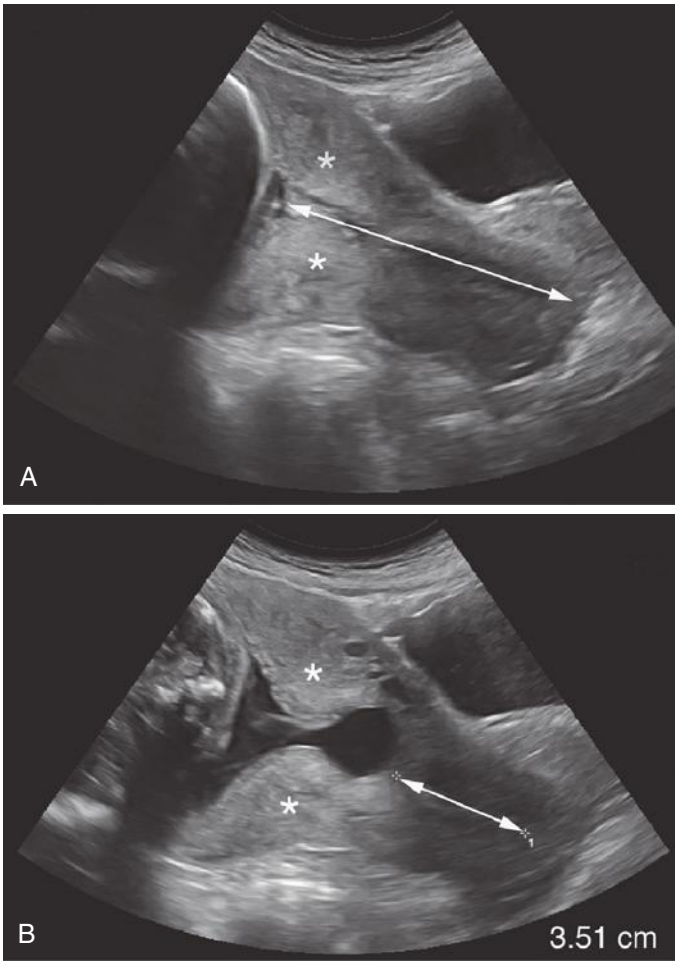

FIG 38-26 A, "Kissing contractions" of the lower uterine segment (*asterisks*). These contractions should not be confused with the cervix (*arrow*). **B,** With time there was partial resolution of the contractions (*asterisks*), so that the true cervical length (3.51 cm) could be measured (*arrow*).

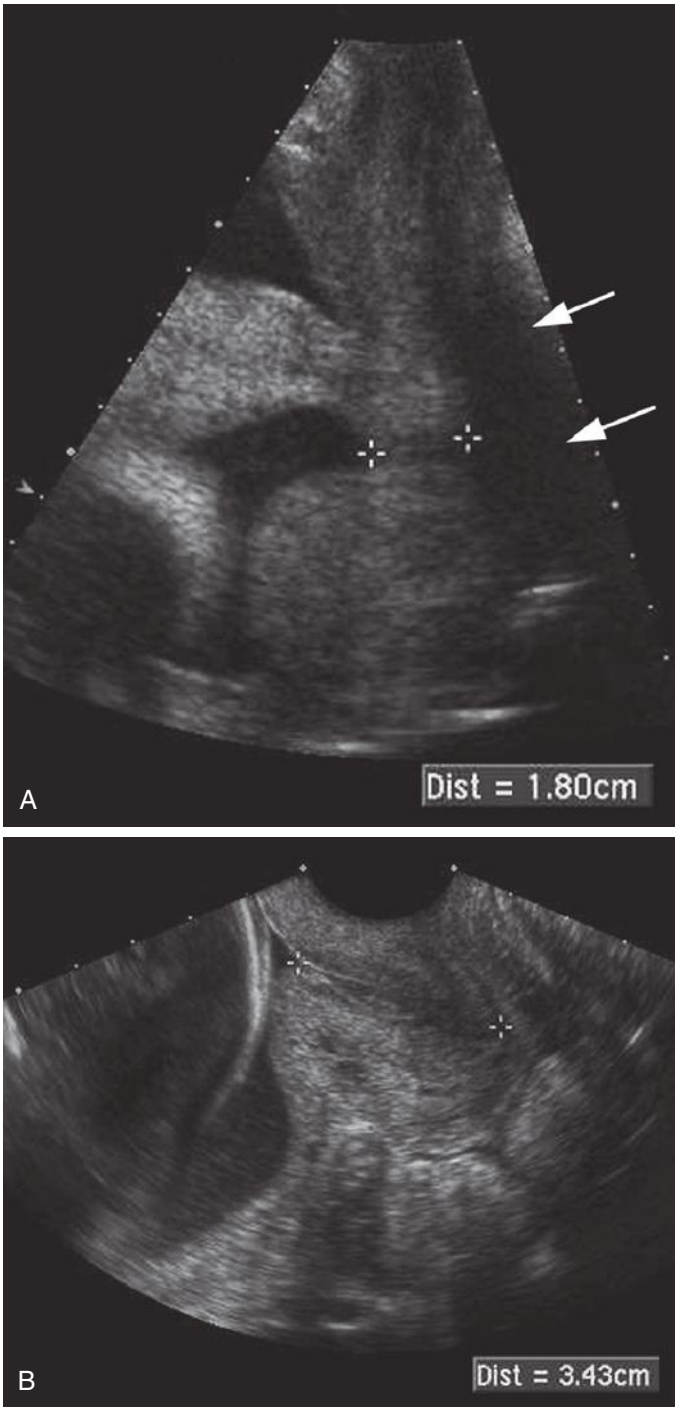

FIG 38-27 Artifactual short cervix. **A,** Transperineal scan demonstrates a short cervix (*between calipers*) measuring 1.8 cm. Shadowing (*arrows*) from the rectum obscures the remainder of the cervix. **B,** A transvaginal scan in the same patient demonstrates a normal length to the cervix (*between calipers*) of 3.43 cm.

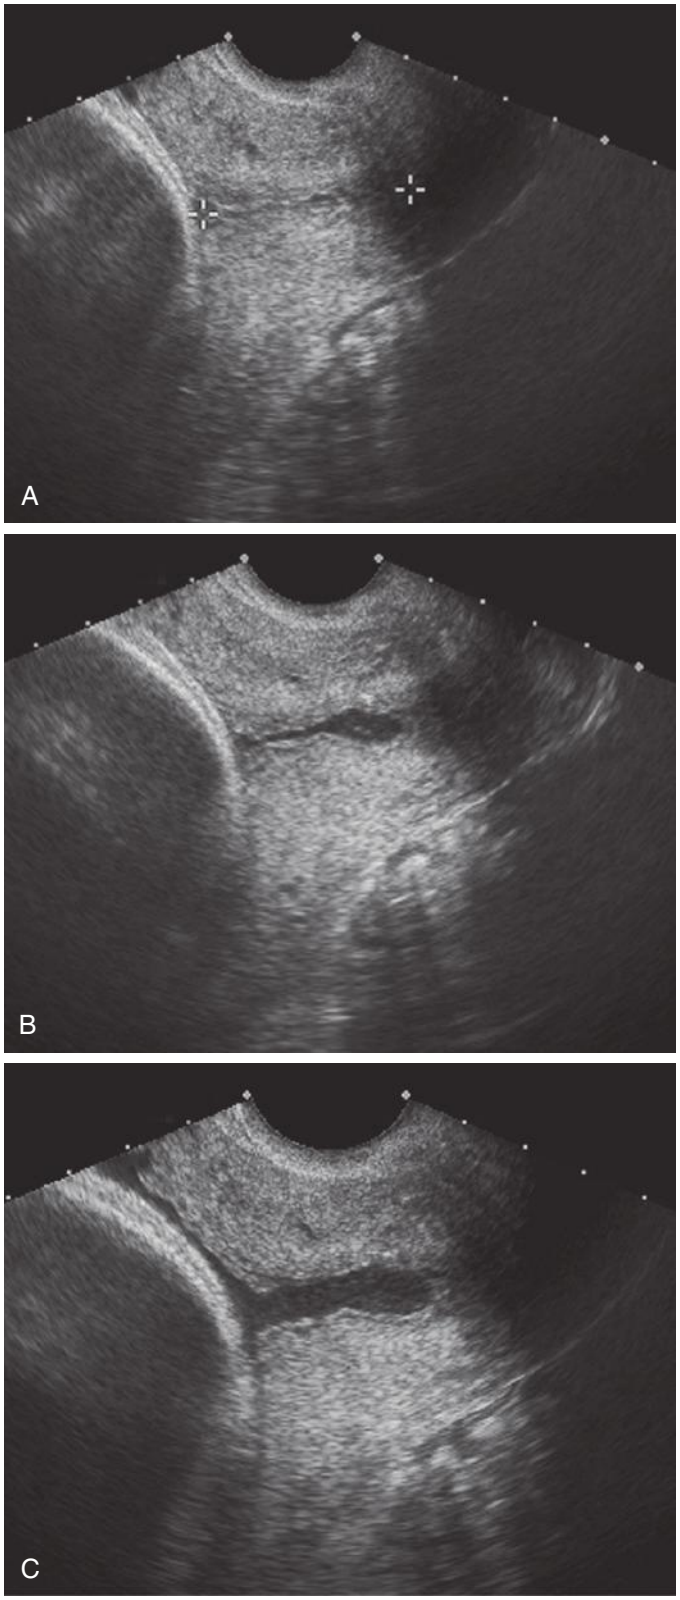

FIG 38-28 Dynamic changes of cervix. Three transvaginal scans of the cervix (**A** to **C**), taken minutes apart, demonstrate progressive dilatation of the cervix with fluid entering the endocervical canal. This finding should be reported to the referring obstetrician and the residual shortened closed length of the cervix should be reported, as well as the total cervical length.

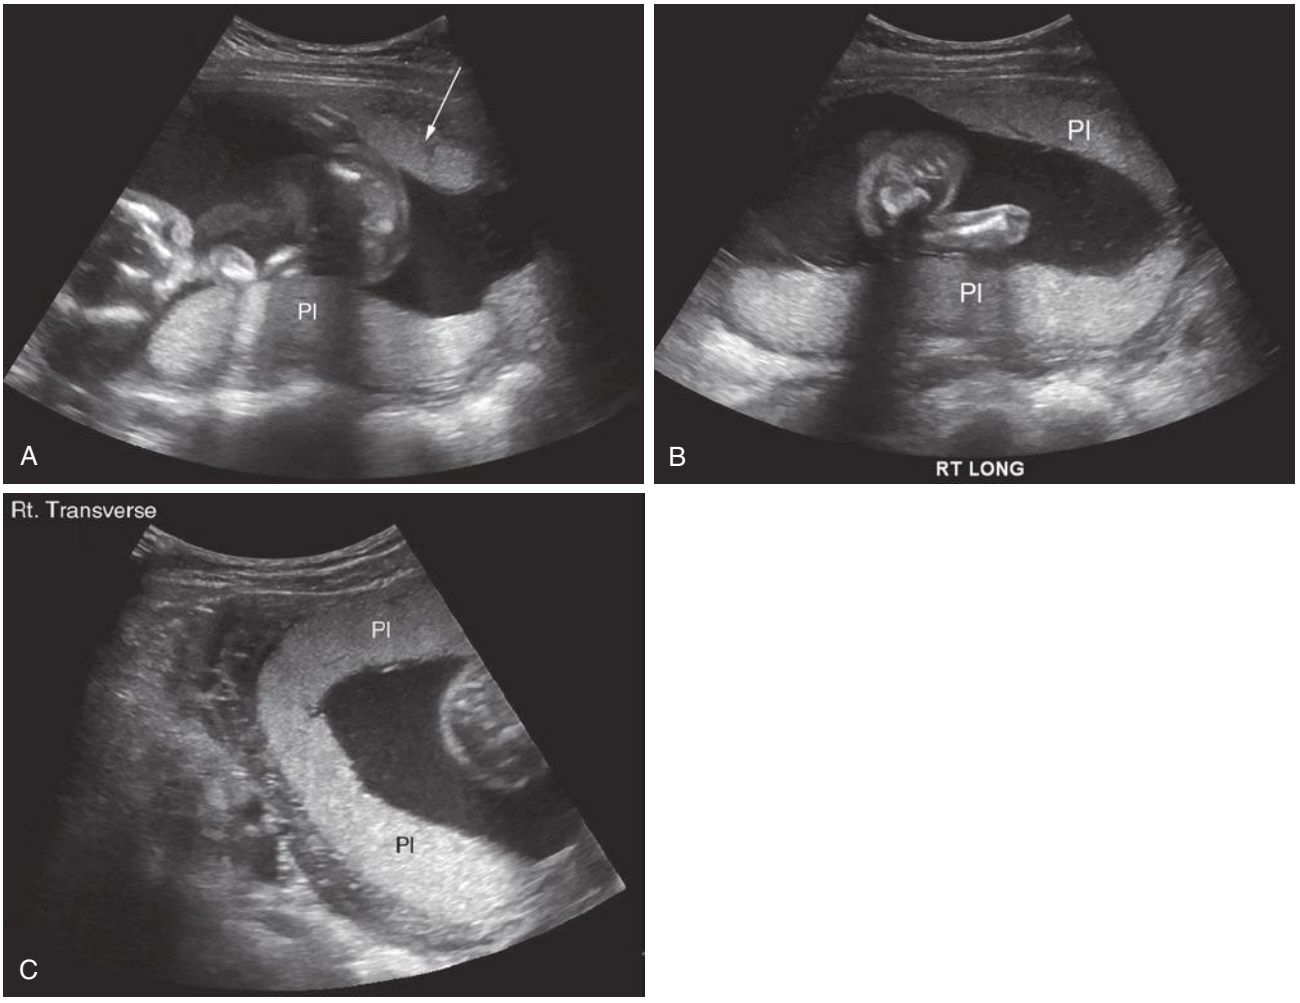

FIG 38-29 **A,** A slightly oblique longitudinal scan through the uterus. A small area of placental tissue (*arrow*) appears separate from the major portion of the posterior placenta (Pl). This appears to be a succenturiate lobe of the placenta. **B,** When the scan plane is aligned slightly more midline the anterior placental tissue (Pl) in A can be seen to be continuous with the remainder of the placenta. **C,** A transverse axial plane of section demonstrates continuity between the anterior and posterior placental tissue (Pl).

FIG 38-30 In some patients, the surface area over which the placenta implants may be small. This short insertion site may create the false appearance of a thickened hydropic placenta (P).

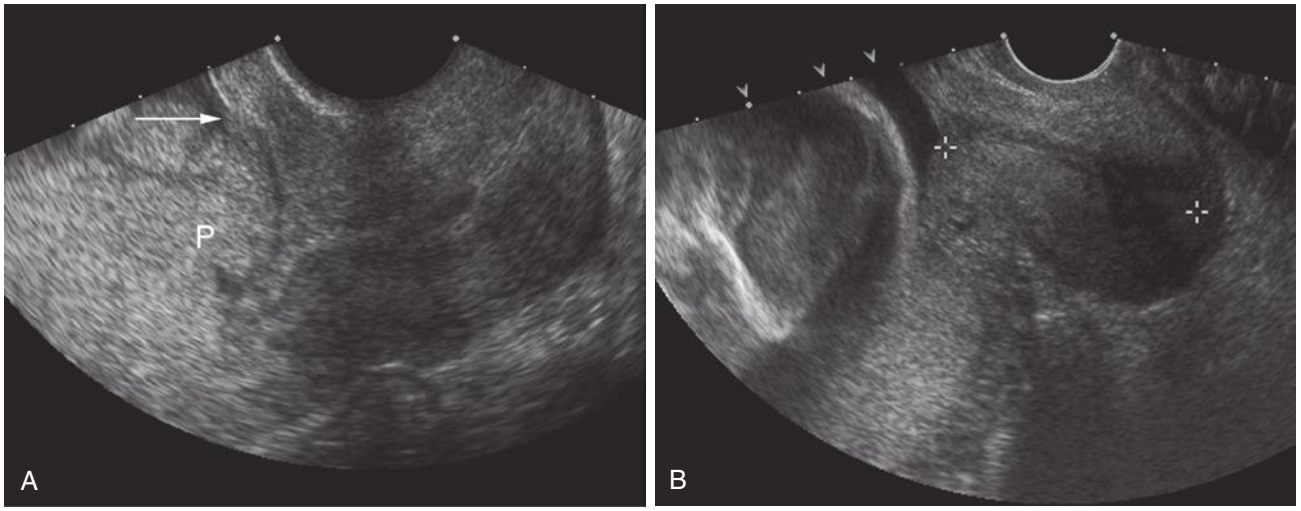

FIG 38-31 Changing placenta previa. **A,** A transvaginal scan in a patient at 17 weeks demonstrates a complete placenta previa. The leading edge (*arrow*) of the posterior placenta (P) extends across the internal cervical os. **B,** Six weeks later at 23 weeks, the leading edge of the placenta extends to but not beyond the internal cervical os.

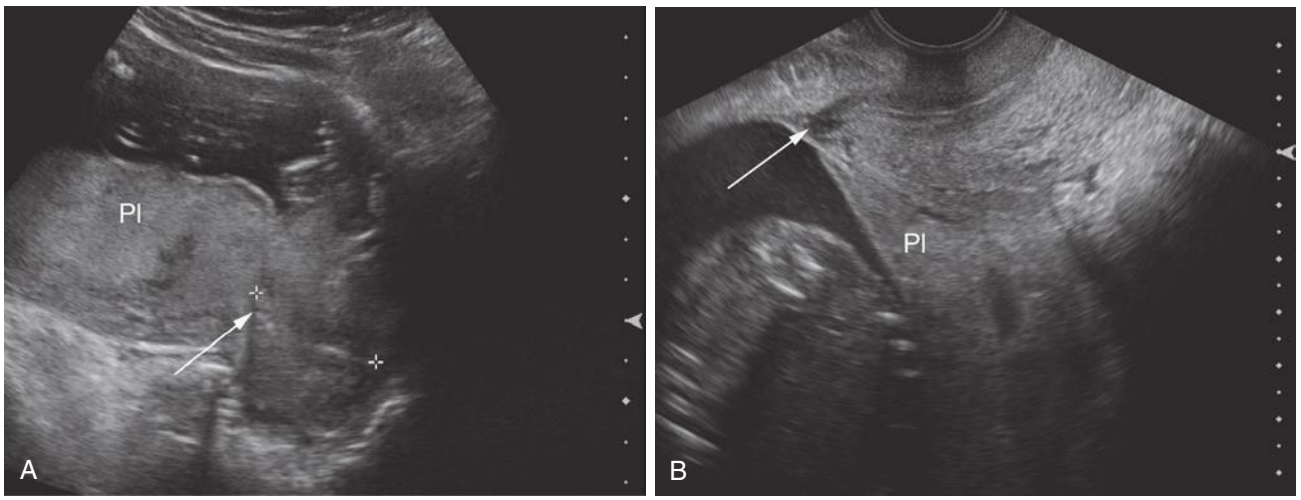

FIG 38-32 **A,** Transabdominal longitudinal sonogram demonstrating what appears to be complete placenta previa. The placenta (Pl) appears to completely cover the internal cervical os (*arrow*). **B,** Transvaginal sonogram from the same patient demonstrates the placenta (Pl) extends to but does not cover the internal cervical os (*arrow*).

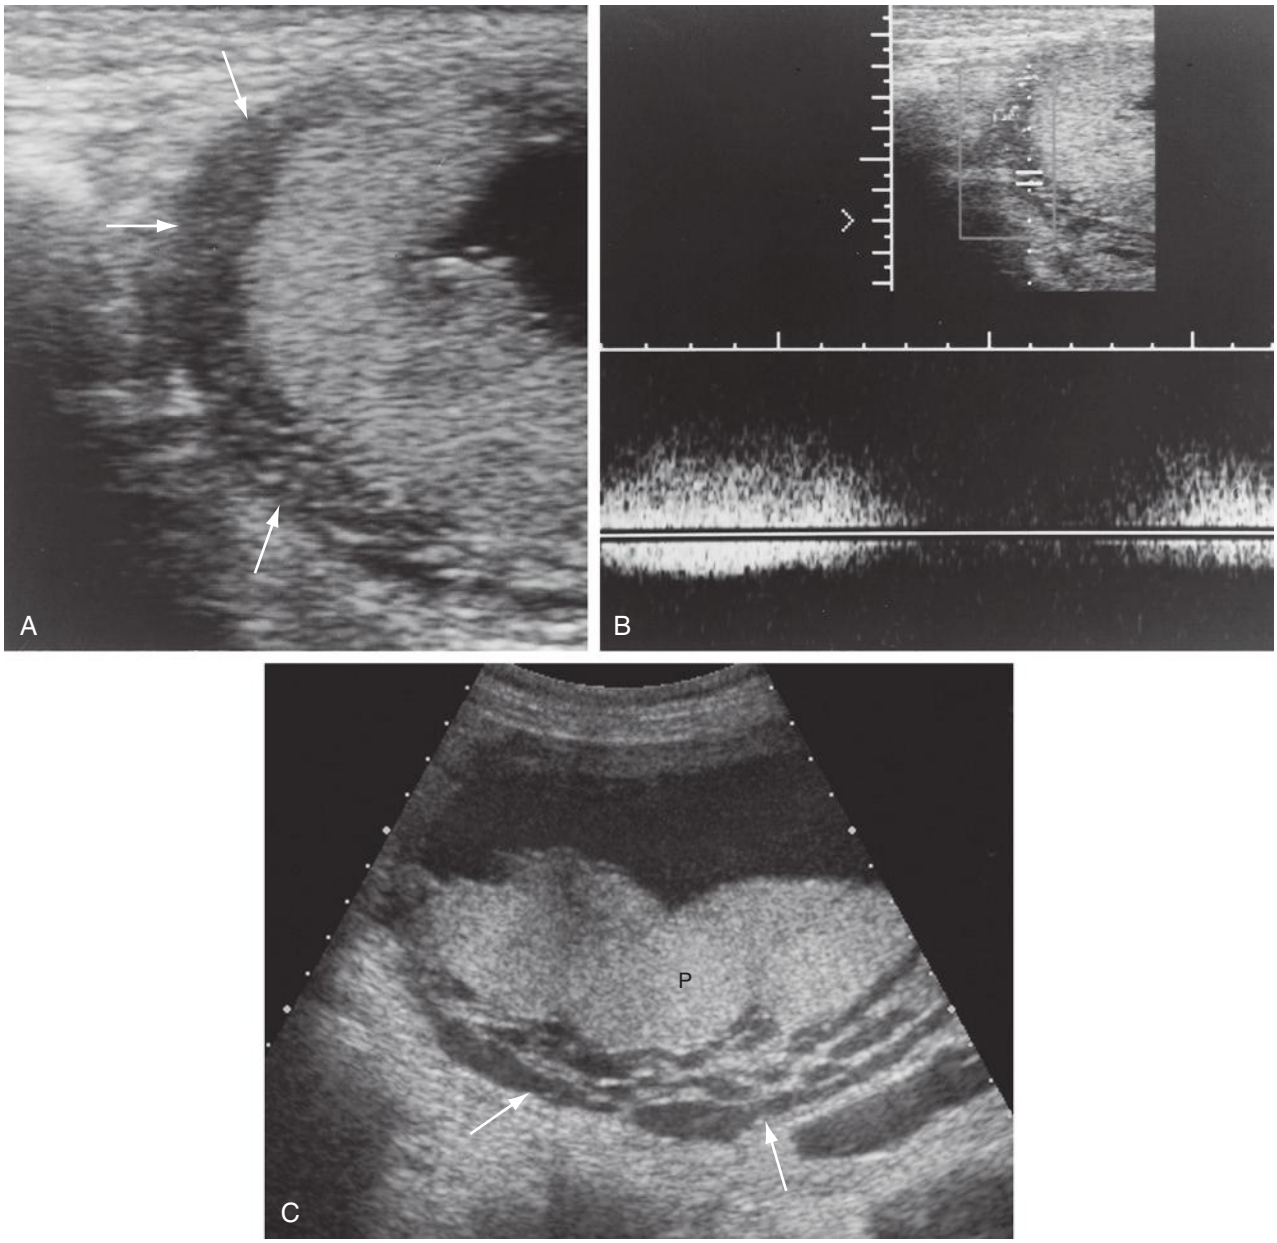

FIG 38-33 A, Veins present in the decidua basalis and myometrium contribute to a hypoechoic region beneath the placenta (*arrows*). This should not be misinterpreted as an abruption. **B,** Doppler interrogation of this region will often confirm the venous nature of this area. **C,** In this case, the veins (*arrows*) deep to the placenta (P) are clearly seen.

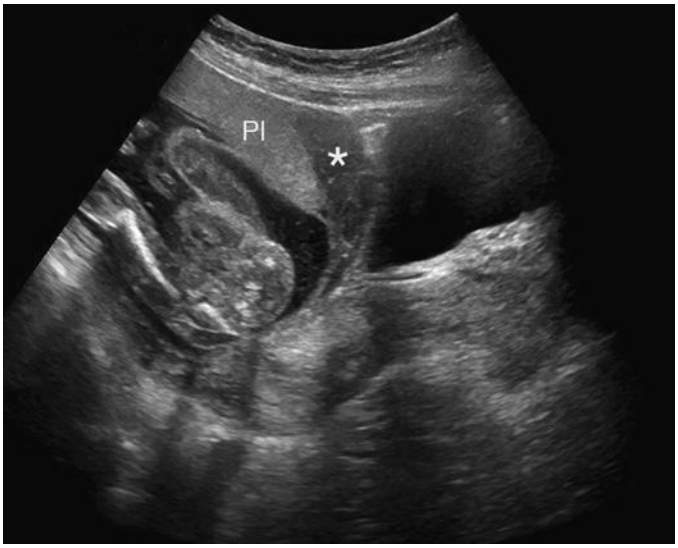

FIG 38-34 A hypoechoic area (*asterisk*) behind the placenta (Pl) simulates placental abruption. Rather, this represents a focal myometrial contraction that resolved during the examination.

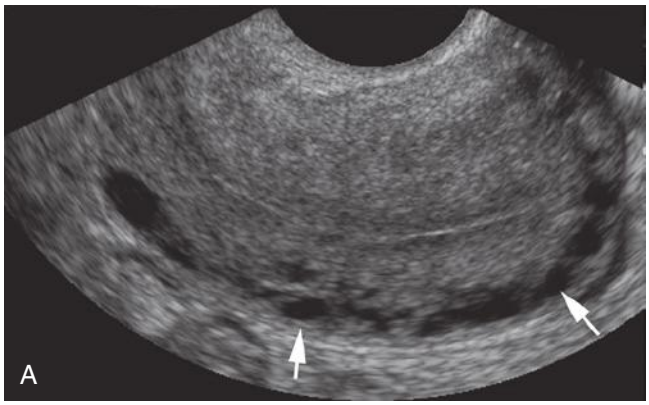

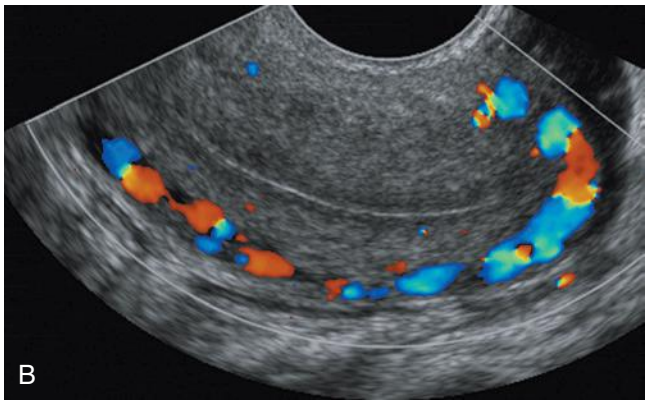

FIG 38-35 Prominent vessels (*arrows*) at the periphery of the uterus are common in the uterus and should not be mistaken as a precursor to an abruption or as trophoblastic disease. **A,** In this patient, the arcuate vessels (*arrows*) at the periphery of the uterus are quite prominent. **B,** With color Doppler flow imaging, the vascular nature of these structures is well seen.

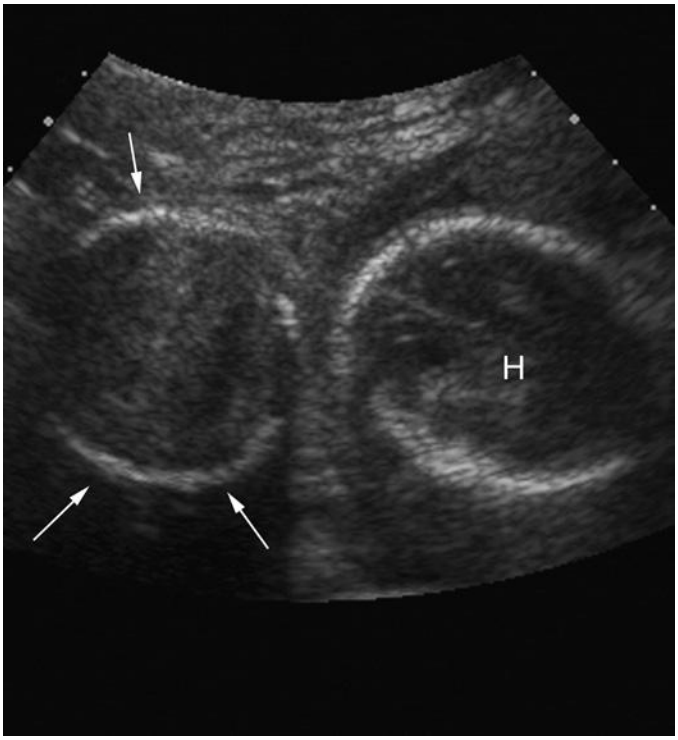

FIG 38-36 Transverse scan of the gravid uterus demonstrates the fetal head (H). A calcified structure (*arrows*) is seen adjacent to the fetal head. At first glance, this appears to be another fetus but in fact it represents a calcified myoma.

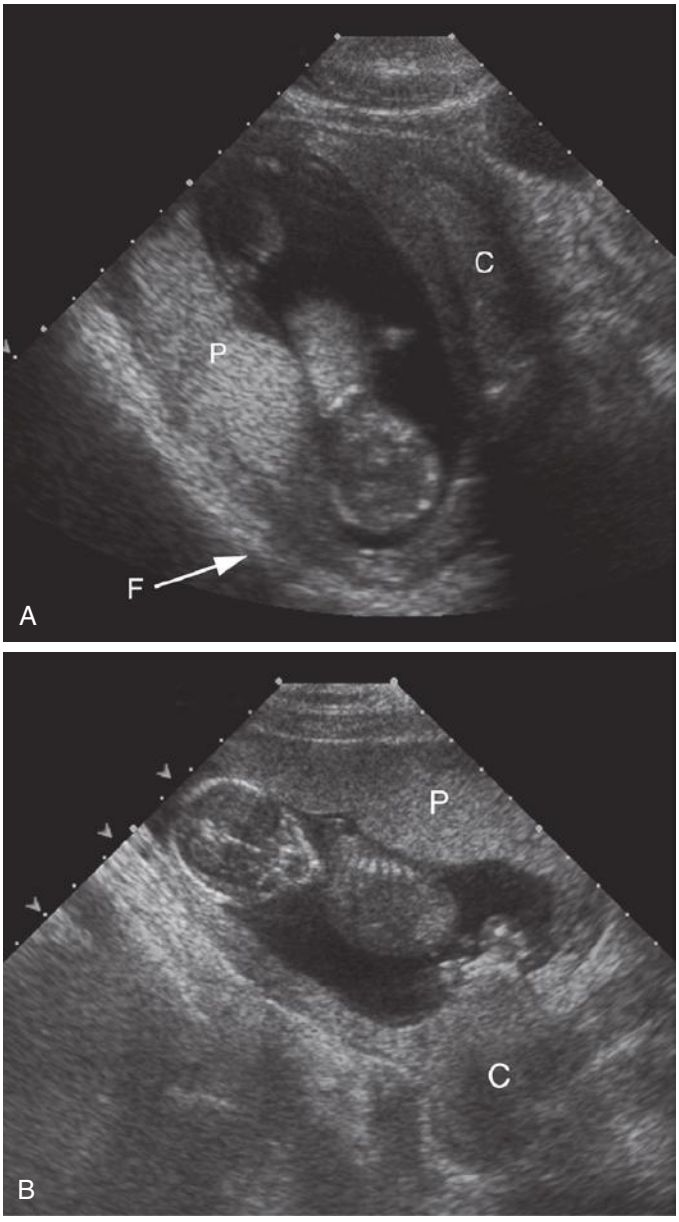

FIG 38-37 Incarcerated uterus. A persistently retroflexed or retroverted uterus may become "trapped" within the sacral hollow. **A,** Longitudinal scan demonstrating an incarcerated uterus in the early second trimester. What appears to be the lower uterine segement is in fact the fundus (F) that is stuck within the sacral hollow. The cervix (C) is drawn anteriorly and superiorly. The urethra often becomes obstructed, and these patients are often seen in the emergency room with urinary obstruction. P, placenta. **B,** After manual reduction, the cervix (C) and uterus now have a more normal appearance. The placenta (P), which appeared to be posterior in the prereduction scan, is now seen anteriorly.

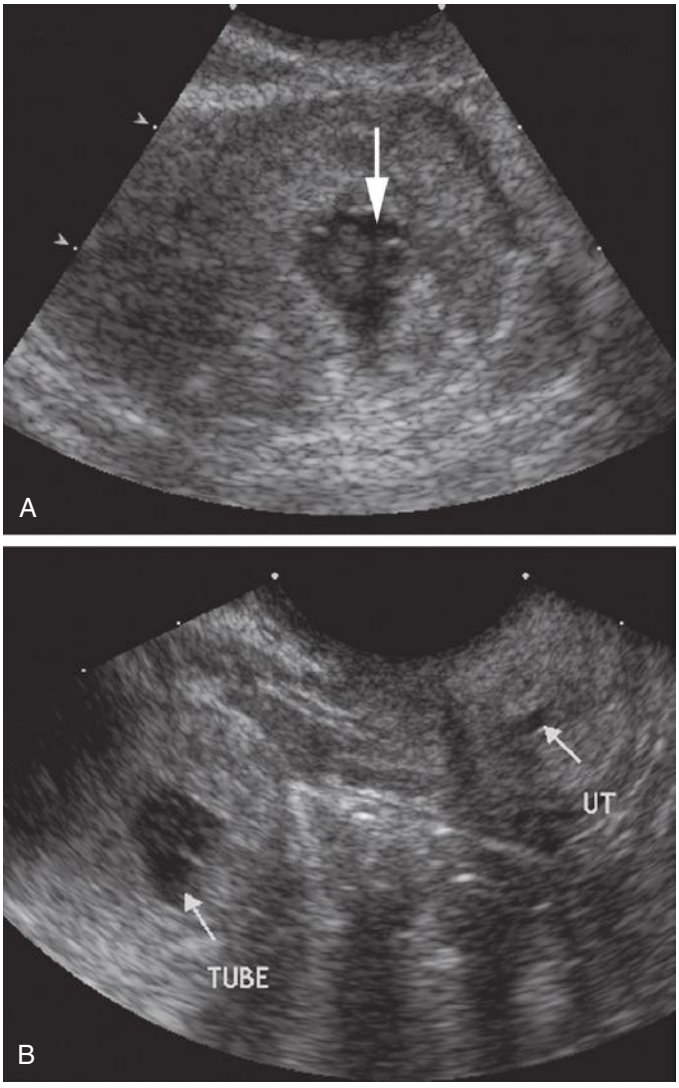

FIG 38-38 **A,** A transvaginal sonogram demonstrates an embryo and yolk sac (*arrow*) centrally positioned in what appears to be the uterus. **B,** A transabdominal sonogram of the same patient demonstrates that the pregnancy was in the fallopian tube (TUBE). A small fluid collection representing fluid within the endometrial cavity (decidual cast) of the uterus (UT) is seen. The patient had an ectopic pregnancy.

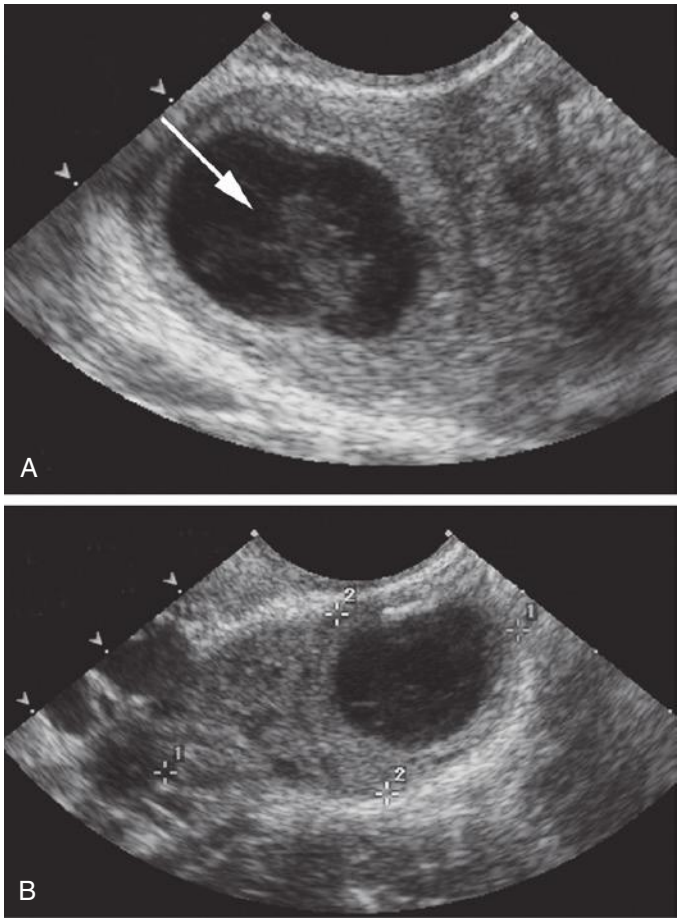

FIG 38-39 **A,** A transvaginal sonogram demonstrates an ill-defined soft tissue mass (*arrow*) in a cystic fluid collection within the ovary. The uniformly thick wall of the cyst simulates a decidual reaction. This has the appearance of a disorganized embryo within a gestational sac. **B,** An additional scan of the same adnexa demonstrates a more characteristic fishnet appearance of hemorrhage within an ovarian cyst.

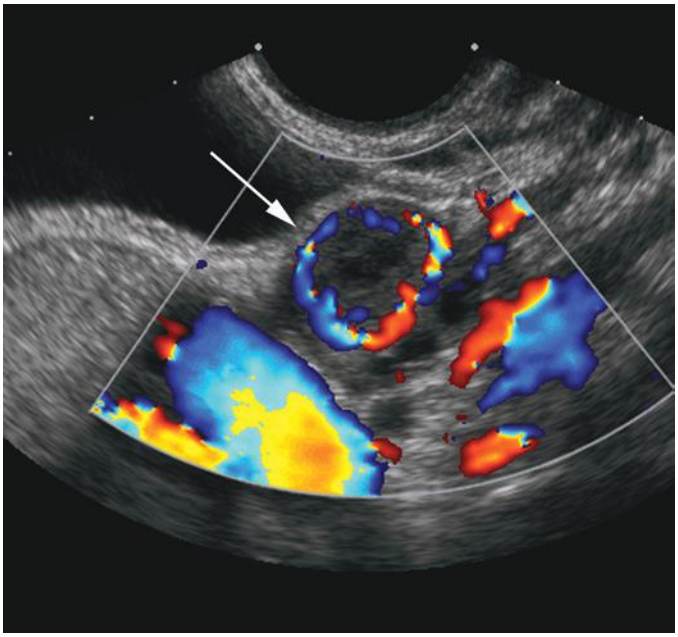

FIG 38-40 A vascular ring (*arrow*) is seen around a cyst within the adnexa. Although this "ring of fire" was once thought to be characteristic of an ectopic pregnancy, it is recognized that a corpus luteum cyst, as in this case, may produce a similar appearance.

THE FIRST TRIMESTER

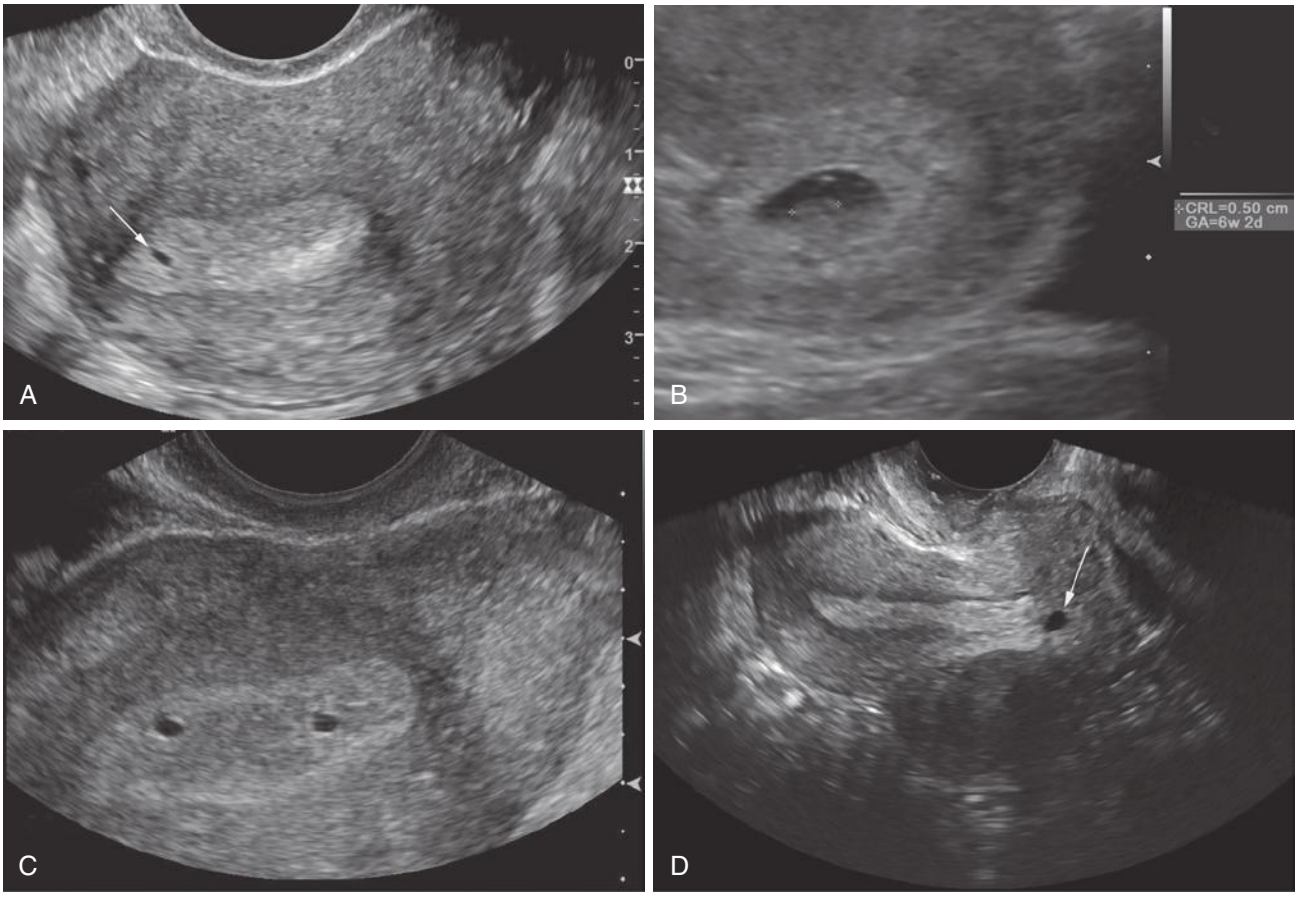

FIG 38-41 **A,** Very small gestational sac (*arrow*) too early to characterize is seen within the decidualized endometrium. **B,** Two weeks later, normal early intrauterine pregnancy is identified, with embryo visualized. **C,** Two small decidual cysts are seen within the endometrium in a patient with negative pregnancy test. **D,** A small cyst (*arrow*) is seen adjacent to the endometrium. Although this has the appearance of a gestational sac or decidual cyst, it is a nabothian cyst within the cervix.

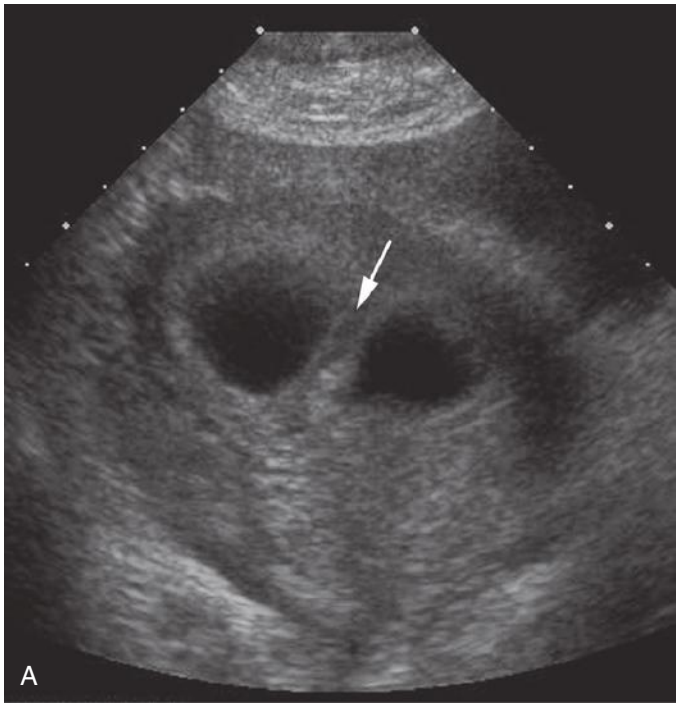

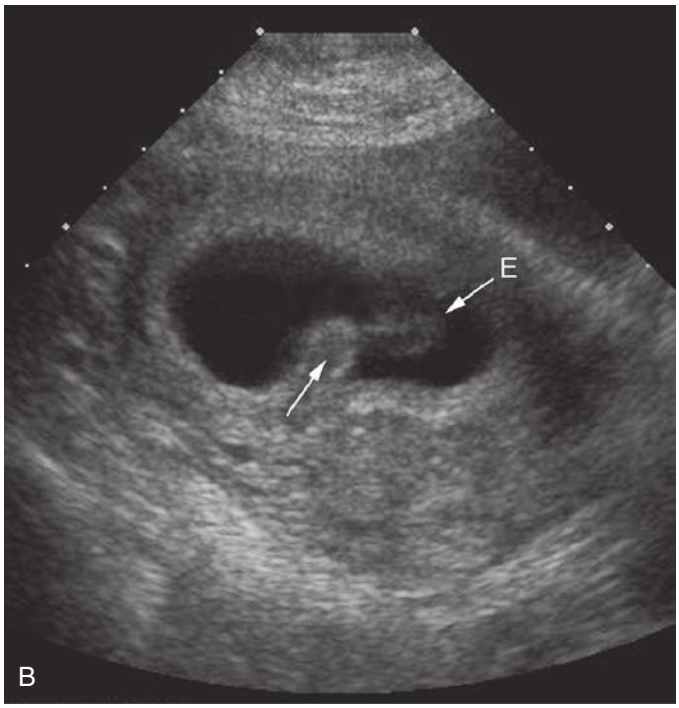

FIG 38-42 **A,** A sonogram of the gravid uterus in the first trimester demonstrates what appears to be two gestational sacs divided by a thick intertwin membrane (*arrow*). **B,** With slight angulation one can see that the structure dividing the gestational sac was a uterine synechia (*arrow*). E, embryo.

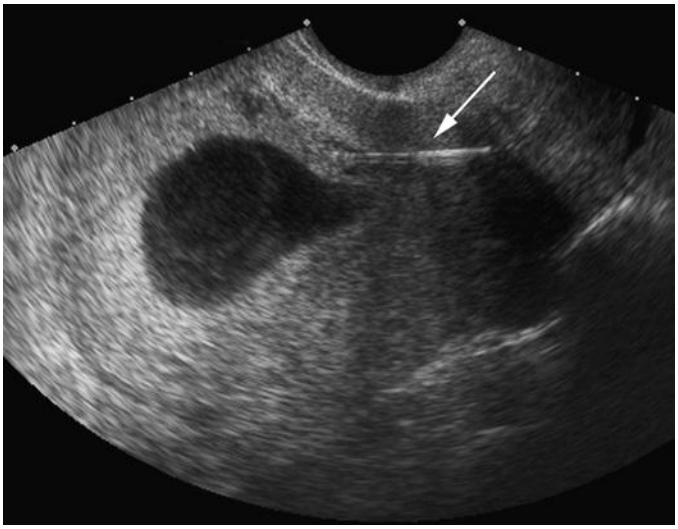

FIG 38-43 Transvaginal sonogram of an early intrauterine pregnancy and intrauterine device (IUD). The linear structure (*arrow*) seen in the lower uterine segment is an IUD. The relationship of the IUD and the gestational sac should be reported.

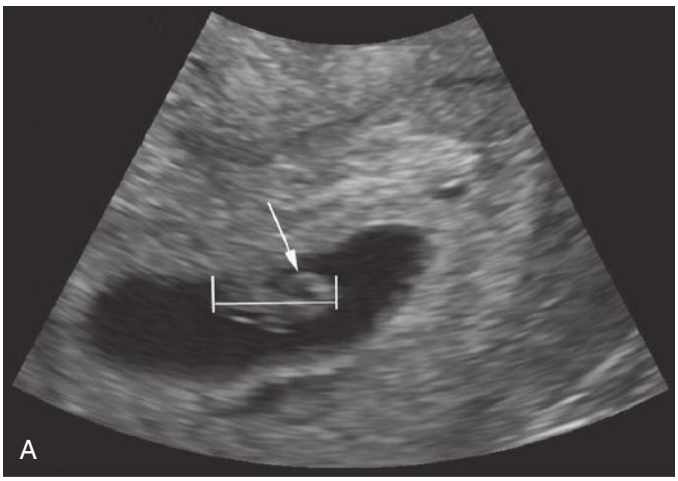

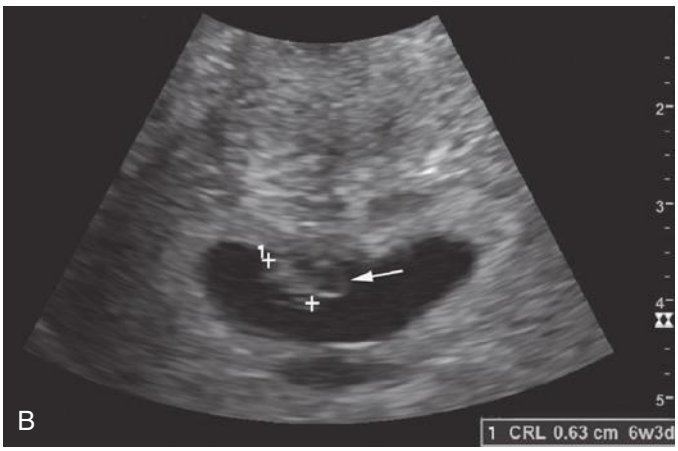

FIG 38-44 **A,** Attempted (and incorrect) measurement of the crown-rump length in a first trimester pregnancy. The measurement includes the embryo toward the left and the yolk sac (*arrow*) toward the right of the image. **B,** In the same pregnancy, the embryonic crown-rump length is correctly measured and does not include the adjacent yolk sac (*arrow*).

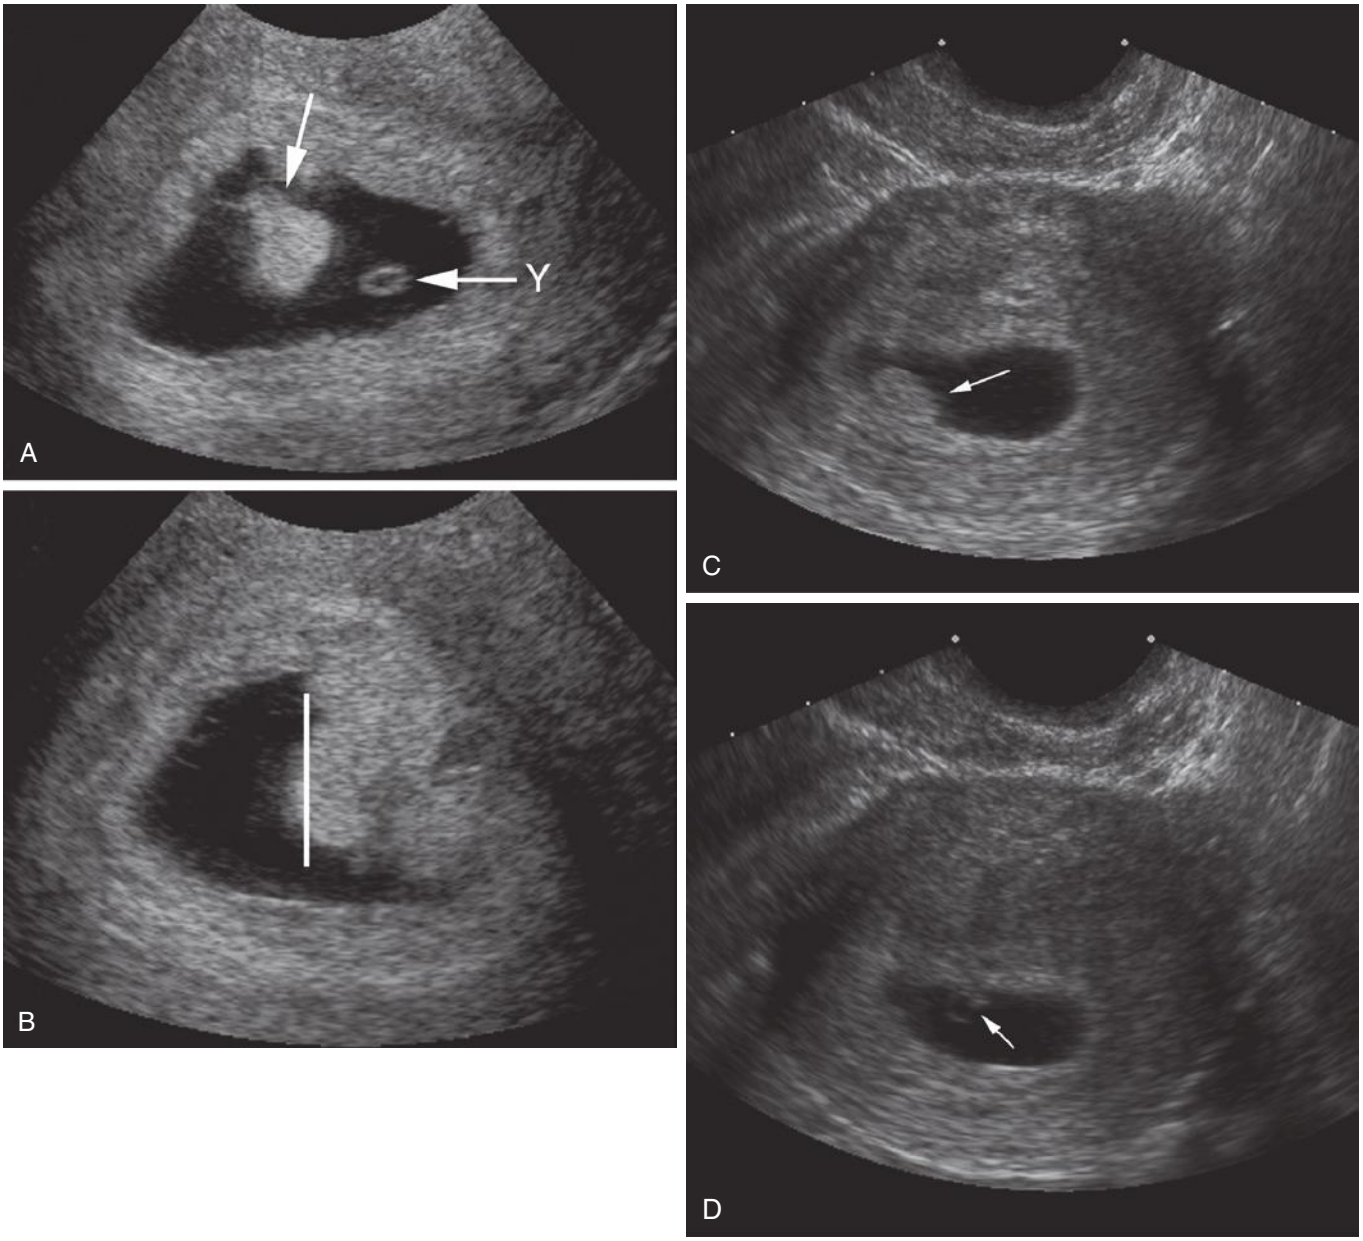

FIG 38-45 **A,** Longitudinal section through the uterus of a patient presenting with vaginal bleeding during early pregnancy. A yolk sac (Y) is seen in addition to what appears to be an abnormal embryo (*arrow*). **B,** A transverse scan reveals that no embryo is present and that the tissue seen in A was due to partial volume through the developing placenta (*line*). This was a case of early pregnancy failure. **C,** Sonogram of another patient with a first trimester pregnancy at 6 weeks and 2 days. A soft tissue area is seen apparently within the gestational sac simulating a nonviable embryo (*arrow*). **D,** On the opposite side of the gestational sac, a yolk sac and embryo are seen (*arrow*). The patient's pregnancy was subsequently uneventful, and she delivered a normal infant. The structure seen in (C) was a lobular portion of the placenta referred to recently as the "chorionic bump." (Term from Harris RD, Couto C, Karpovsky C, et al: The chorionic bump: a first-trimester pregnancy sonographic finding associated with a guarded prognosis. J Ultrasound Med 25:757, 2006; Arleo EK, Troiano RN: Chorionic bump on first-trimester sonography: not necessarily a poor prognostic indicator for pregnancy. J Ultrasound Med 34:137-142, 2015.)

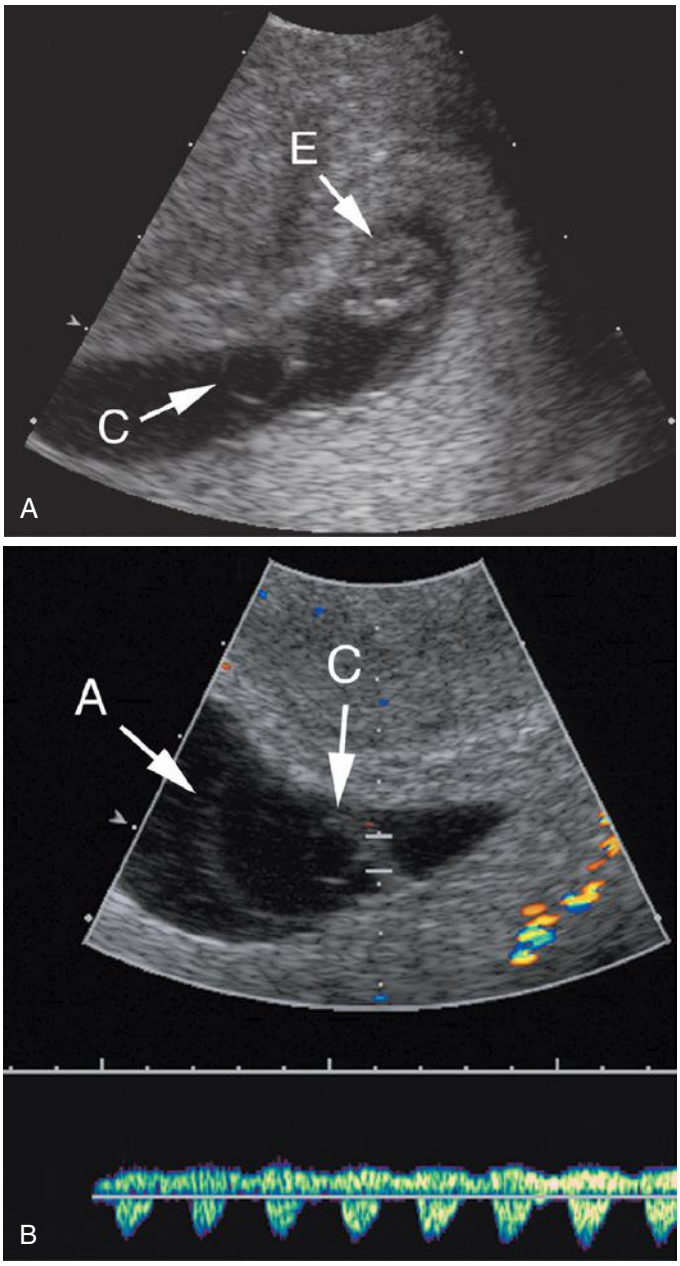

FIG 38-46 **A,** An umbilical cord cyst (C) is seen in this first trimester pregnancy separate from the embryo (E). **B,** Doppler interrogation of the umbilical cord demonstrates that the cyst (C) is associated with the umbilical cord. A, amnion.

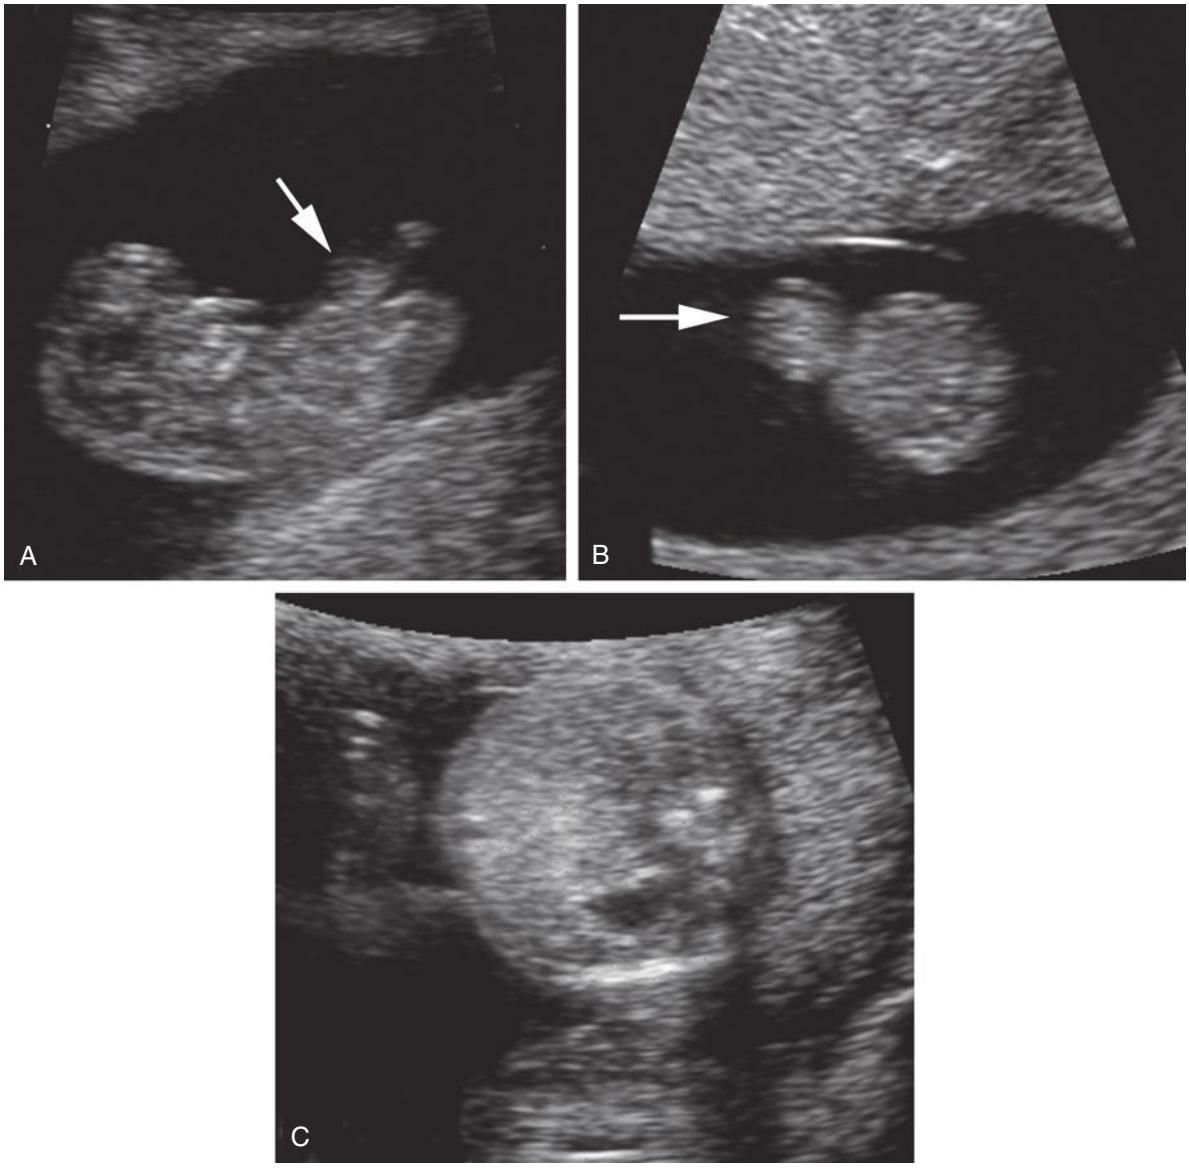

FIG 38-47 **A,** Sonogram of an embryo demonstrates normal herniation of bowel (*arrow*) into the umbilical cord adjacent to the anterior abdominal wall. **B,** Sonogram of another embryo demonstrates an even larger but normal appearance to the herniated bowel (*arrow*). **C,** A follow-up scan of the patient in B demonstrates a normal anterior abdominal wall without evidence of an anterior abdominal wall defect. If there is any question, a follow-up scan, as was done in this case, should be performed.

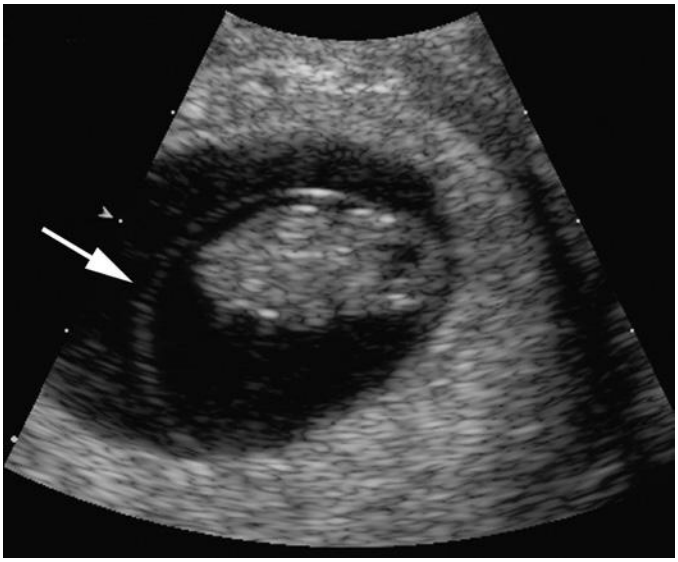

FIG 38-48 The amnion (*arrow*) is frequently identified in first trimester gestations. It apposes the chorion between 12 and 16 weeks' gestation. It should not be mistaken for amniotic band syndrome.

FIG 38-49 A prominent fluid-filled intracranial area (*arrow*) can be seen in the cranium of the embryo, particularly with transvaginal sonography. This area represents the developing rhombencephalon and should not be mistaken for either hydrocephalus or holoprosencephaly.

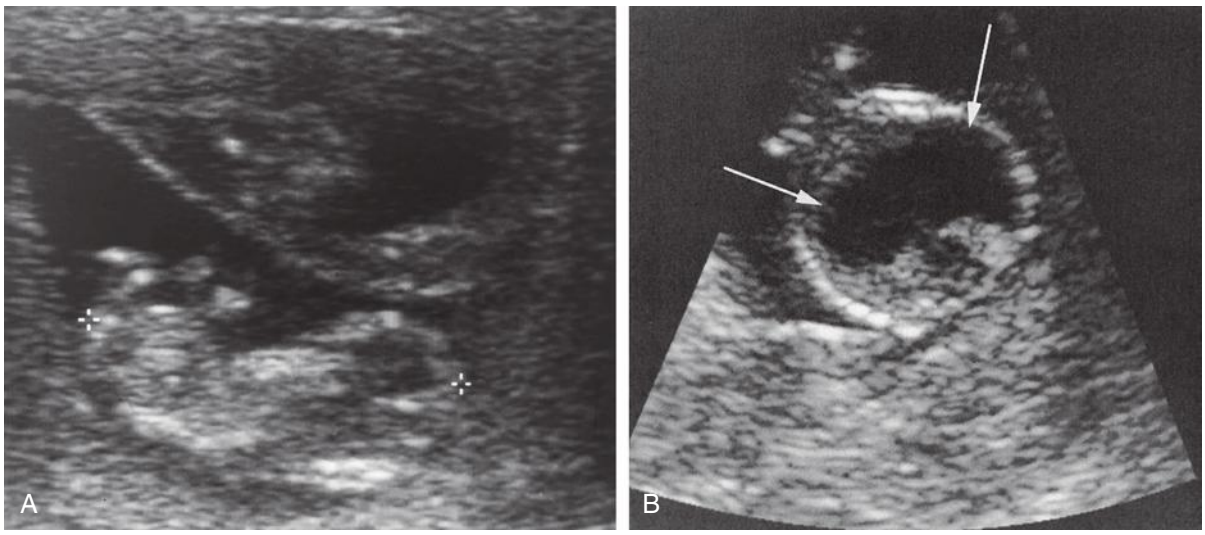

FIG 38-50 **A,** A transabdominal sonogram of the gravid uterus demonstrated what appeared to be a normal embryo. **B,** A transvaginal sonogram of the same patient done at the time of chorionic villus sampling demonstrates a large monoventricular cavity (*arrows*) consistent with holoprosencephaly. Trisomy 13 was detected.

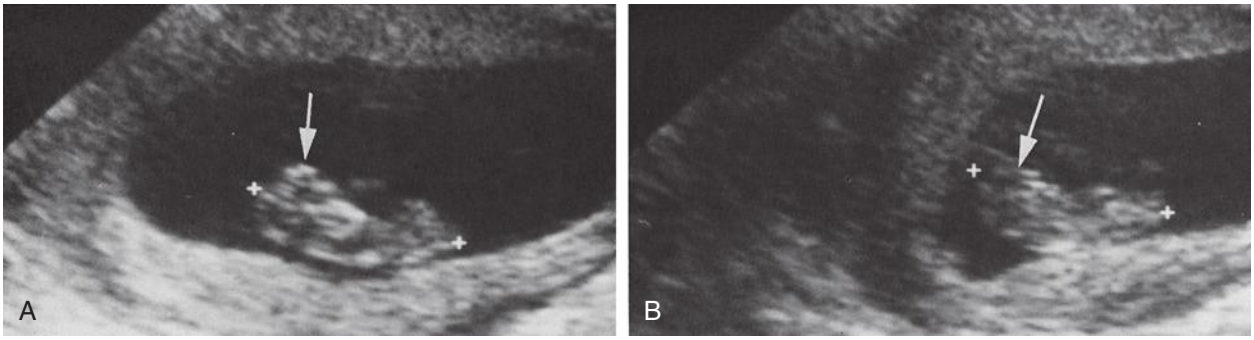

FIG 38-51 Although the diagnosis of anencephaly is certainly possible in the first trimester, the likelihood of a false negative diagnosis is high. The angiomatous stroma (**A,** *arrow*) in a case of anencephaly simulates the normal brain in another case (**B,** *arrow*).

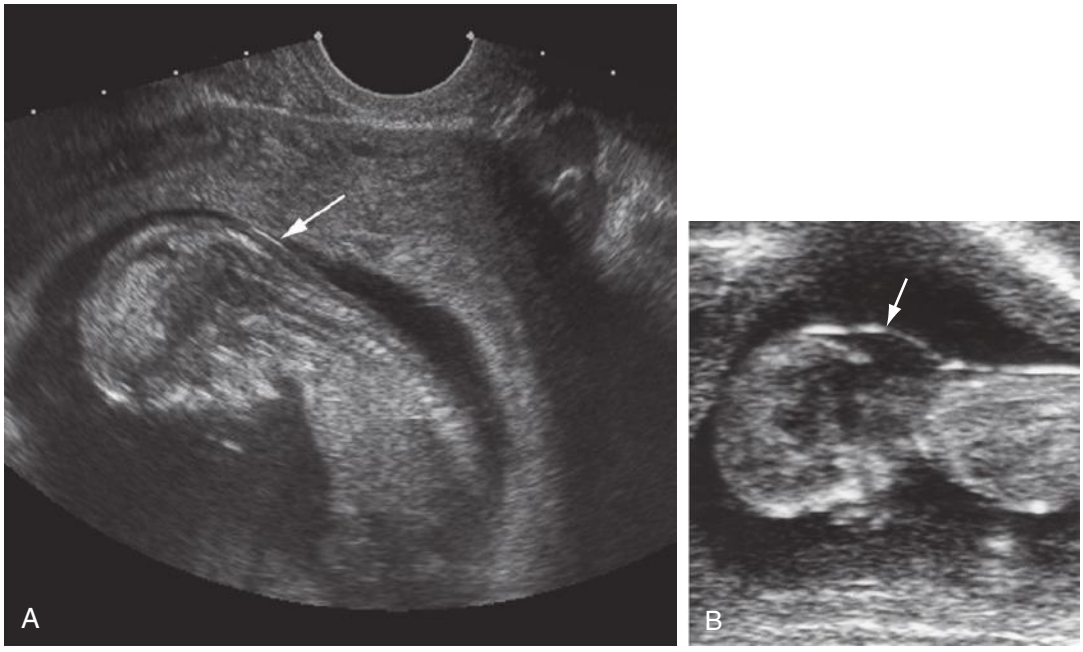

FIG 38-52 **A,** Normal integument (nuchal translucency) (*arrow*) in an early second trimester fetus. **B,** Normally, the nuchal translucency is measured to determine if it is abnormally increased in thickness. In this fetus, the large rounded configuration to the nuchal translucency (*arrow*) can readily be determined to be abnormal subjectively.

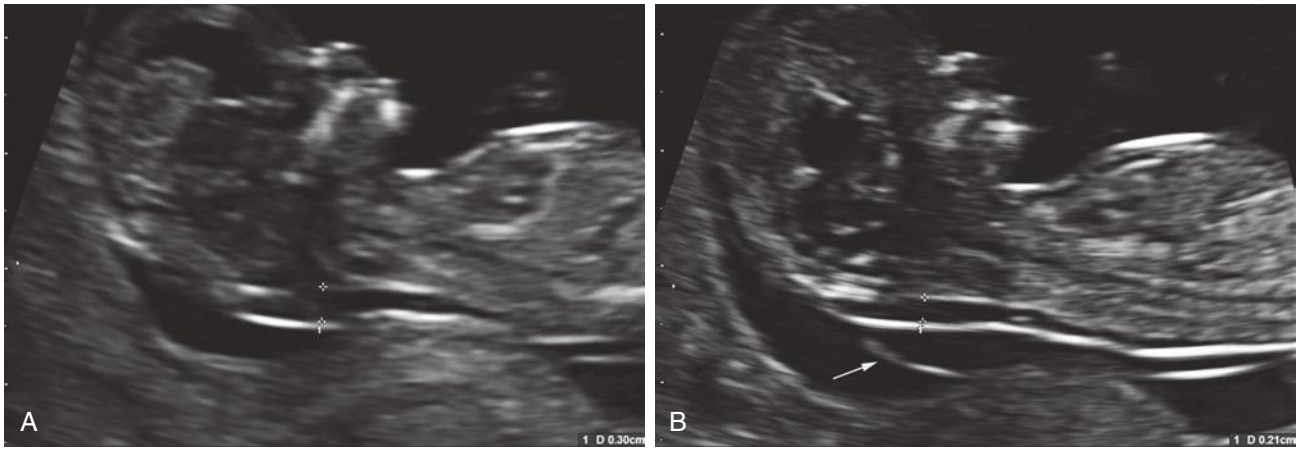

FIG 38-53 **A,** Erroneous measurement of the nuchal translucency. This abnormal measurement between the calipers extends to the amnion rather than to the integument. **B,** In the same pregnancy, the nuchal translucency is correctly measured and is normal. The amnion (*arrow*) can be seen separate from the fetus.

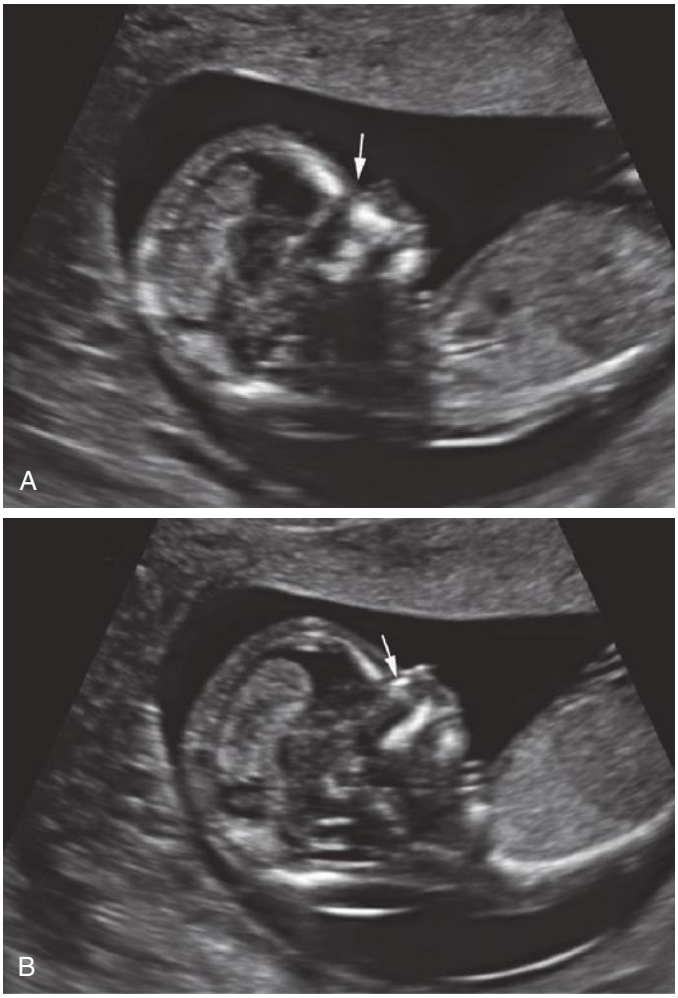

FIG 38-54 **A,** On this near sagittal plane of section, the nasal bone (*arrow*) appears to be absent. **B,** In a more midline sagittal scan, the nasal bone (*arrow*) can clearly be seen.

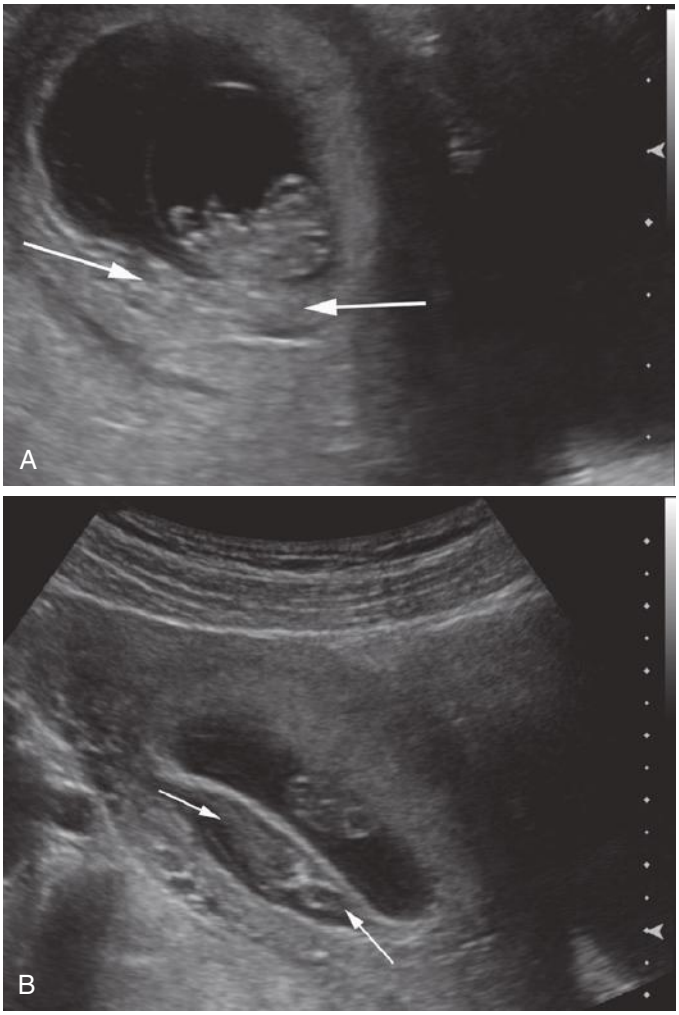

FIG 38-55 **A,** On many scans through the gravid uterus, there appeared to be a singleton gestation with prominent myometrium posteriorly (*arrows*). **B,** On an oblique plane of section it became clear that there was a dichorionic twin pregnancy with demise of the second twin (*arrows*).

THE FETAL HEAD AND NECK

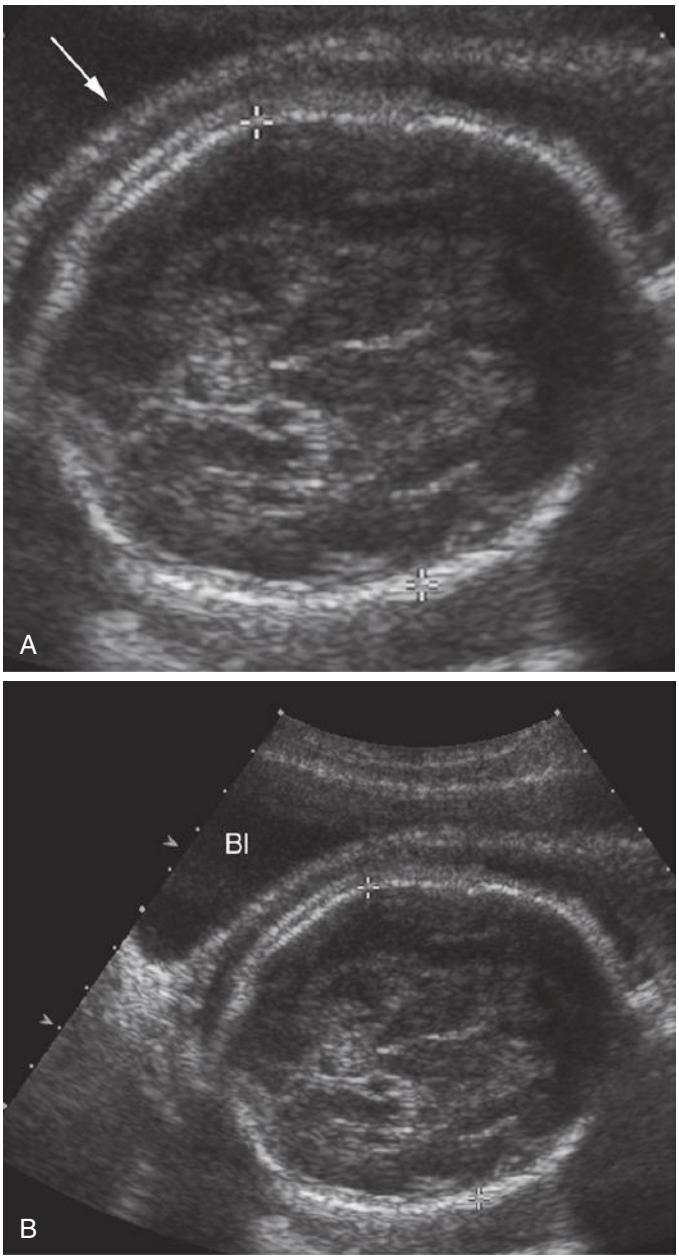

FIG 38-56 **A,** Sonogram of a third trimester fetus demonstrates what appears to be scalp thickening (*arrow*). **B,** In a slightly wider field of view, it can be clearly seen that what appeared to be fetal scalp was in fact the wall of the maternal urinary bladder. Bl, bladder.

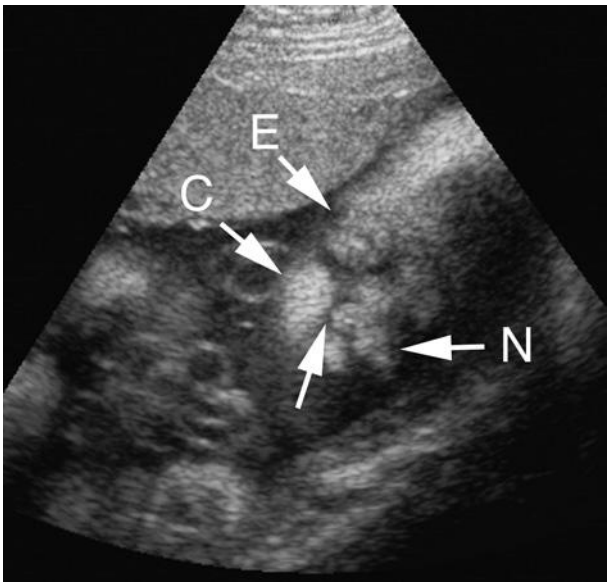

FIG 38-57 Pseudocleft of the face. The space (*arrow*) between the fetal nose (N) and cheek (C) should not be misinterpreted as a cleft. E, eye.

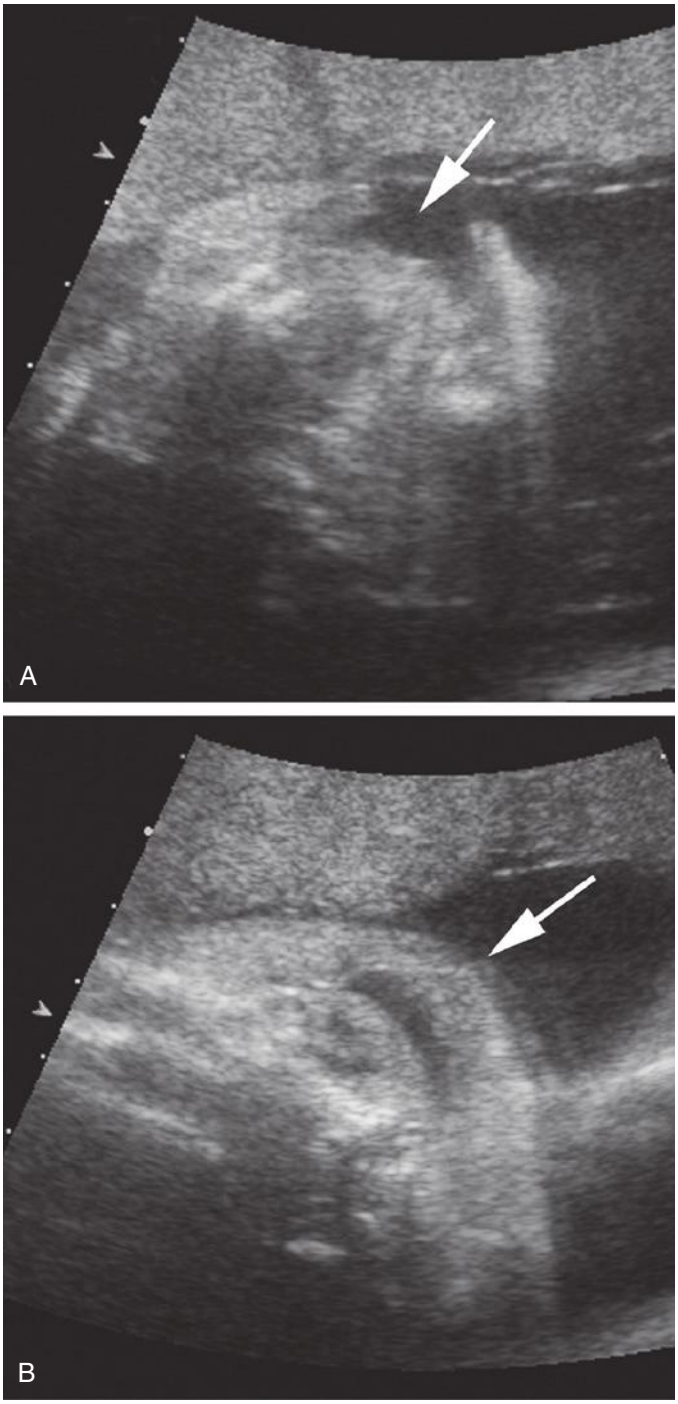

FIG 38-58 Pseudocleft lip. **A,** An angled "oblique" view of the face demonstrates what appears to be a gap in the lip (*arrow*). **B,** Normal-appearing lip (*arrow*) obtained on a slightly different plane of section.

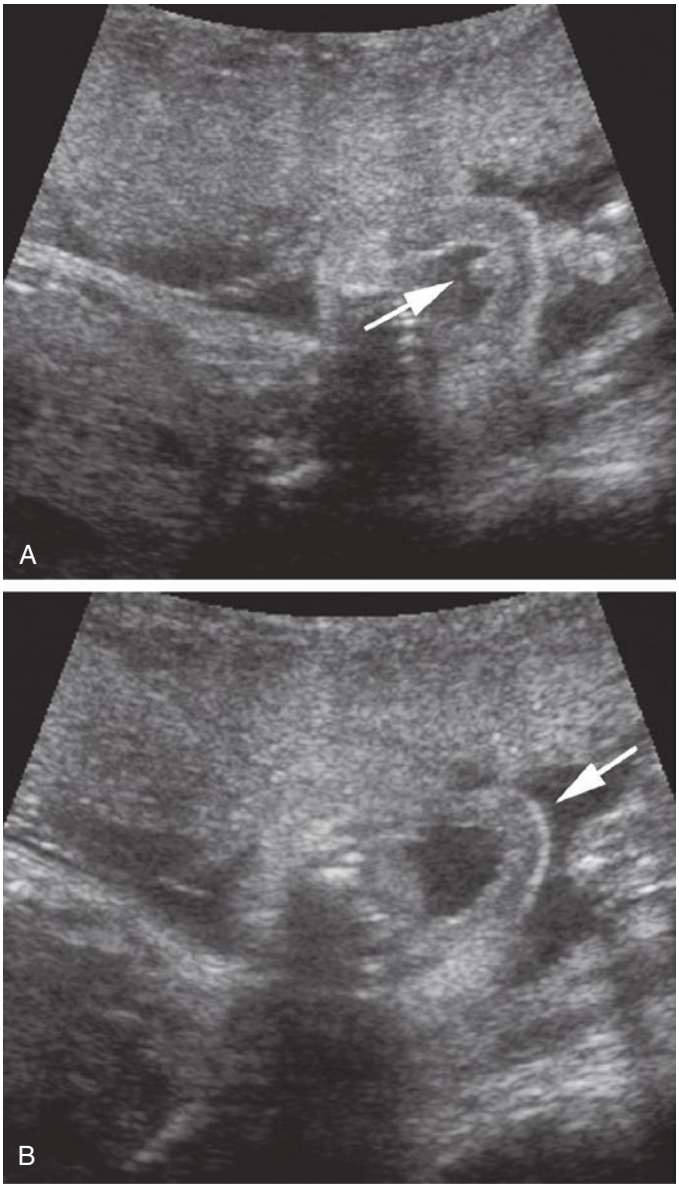

FIG 38-59 **A,** Coronal plane of section of the fetal face. Because of a slight compression of the fetal face, the upper lip creates the appearance of a mass (*arrow*). **B,** As the mouth opens wider, the upper lip (*arrow*) appears normal.

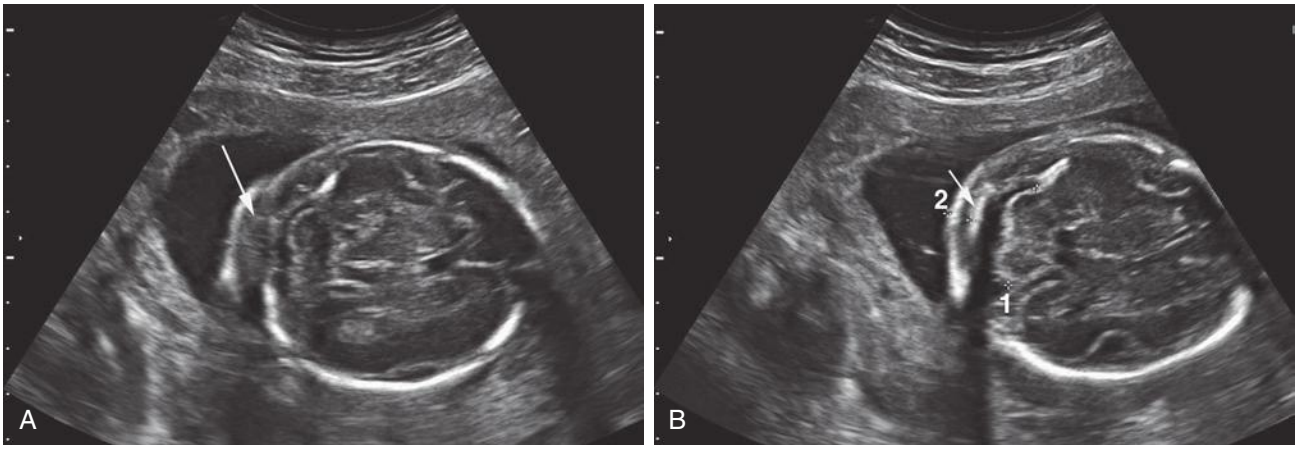

FIG 38-60 **A,** Transverse axial plane of section of the fetal head at 20 weeks' gestation. The nuchal fold area (*arrow*) appears abnormally prominent. **B,** Normal appearance of the nuchal fold in the same fetus. To accurately measure the nuchal fold the posterior surface of the occipital bone should be imaged (*arrow*). This can often be achieved by scanning from a 30-degree occipital direction. (From Cho JY, Kim KW, Lee YH, Toi A: Measurement of nuchal skin fold thickness in the second trimester: influence of imaging angle and fetal presentation. Ultrasound Obstet Gynecol 25:253-257, 2005.)

FIG 38-61 The nuchal fold (*asterisk*) appears prominent on this sagittal scan through the posterior cervical region. However, this is related to fetal position with extension of the cervical spine.

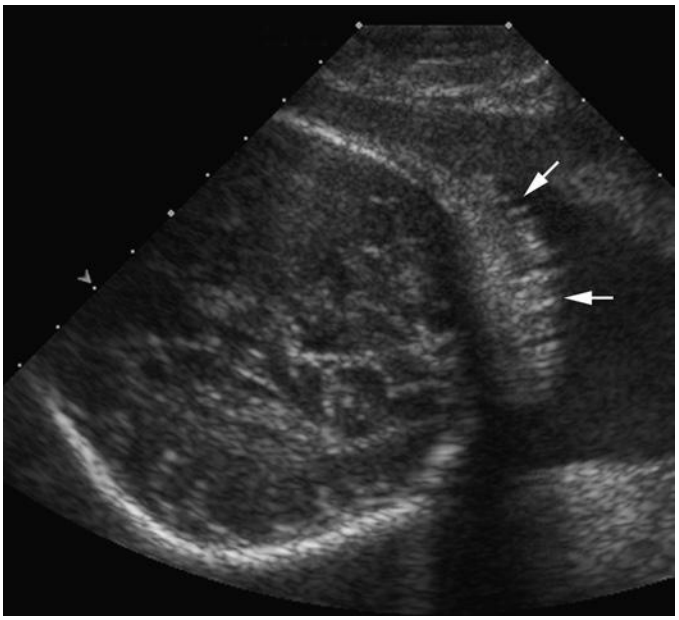

FIG 38-62 Normal fetal hair (*arrows*) may be seen commonly in third trimester fetuses and should not be mistaken for a calvarial mass or scalp edema.

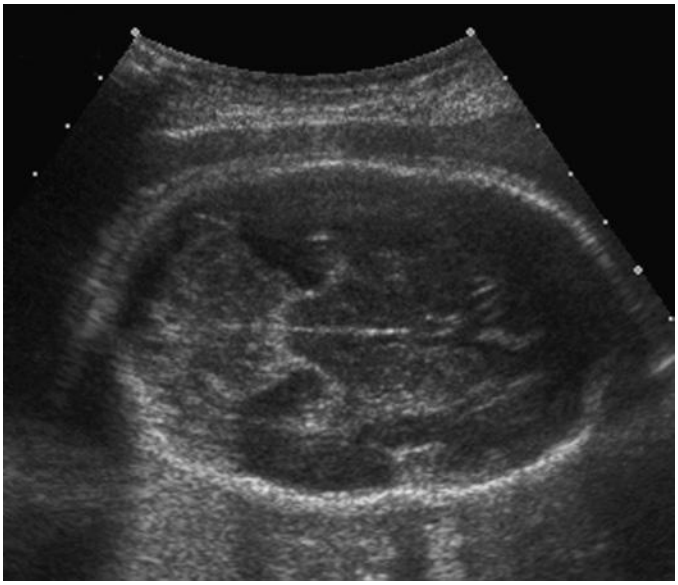

FIG 38-63 Sonogram of the fetal head commonly used for measurement of the biparietal diameter and head circumference. This case has a common variation referred to as dolichocephaly. The importance is that measurement of the biparietal diameter in such fetuses will tend to underestimate gestational age. Dolichocephaly may also be seen in cases of breech presentation, oligohydramnios, and myelomeningoceles.

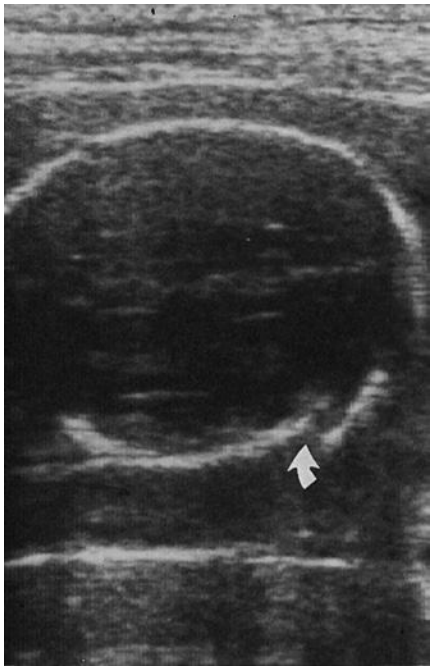

FIG 38-64 Interaction of the sound beam with the curved surface of the calvarium produces troubling appearances. This fetus appears to have overlapping sutures (*arrow*). In fact, this was an artifact related to refraction of the sound beam. The fetal calvarium was normal when the transudcer angle was changed.

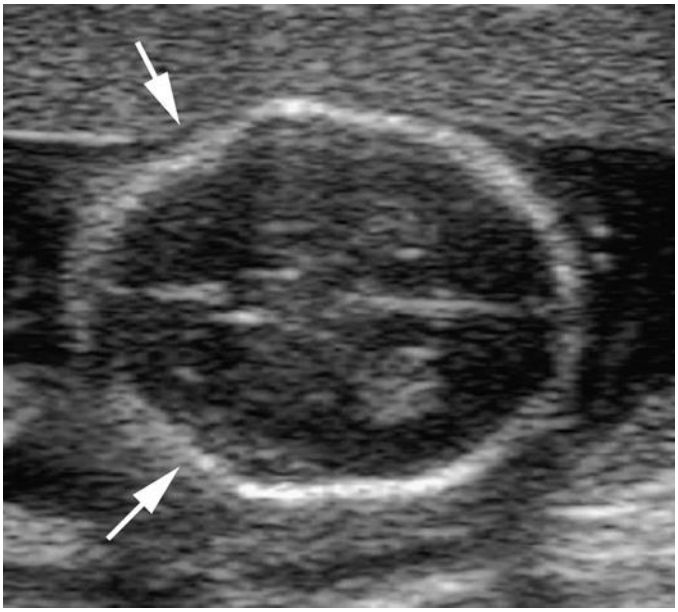

FIG 38-65 Frontal concave scalloping (*arrows*), the so-called lemon sign, has been described in patients with a myelomeningocele. This may also be a normal finding, as it was in this case.

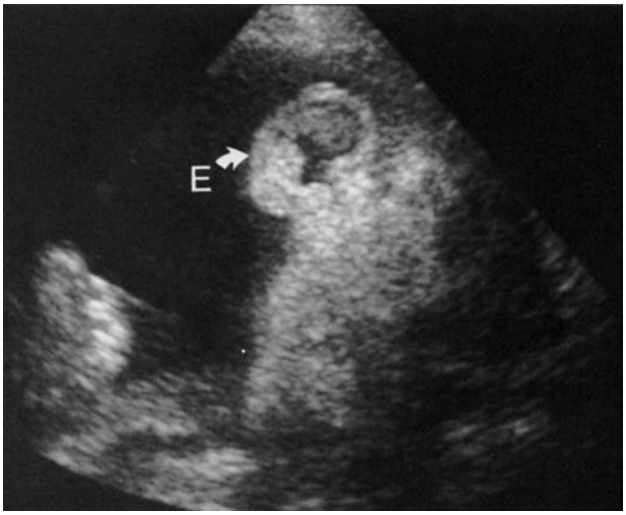

FIG 38-66 Projections from the fetal cranium can often be disturbing. In cases of polyhydramnios, the fetal ear (E) can be seen perpendicular to the fetal skull and may simulate an encephalocele, which would be uncommon in this location.

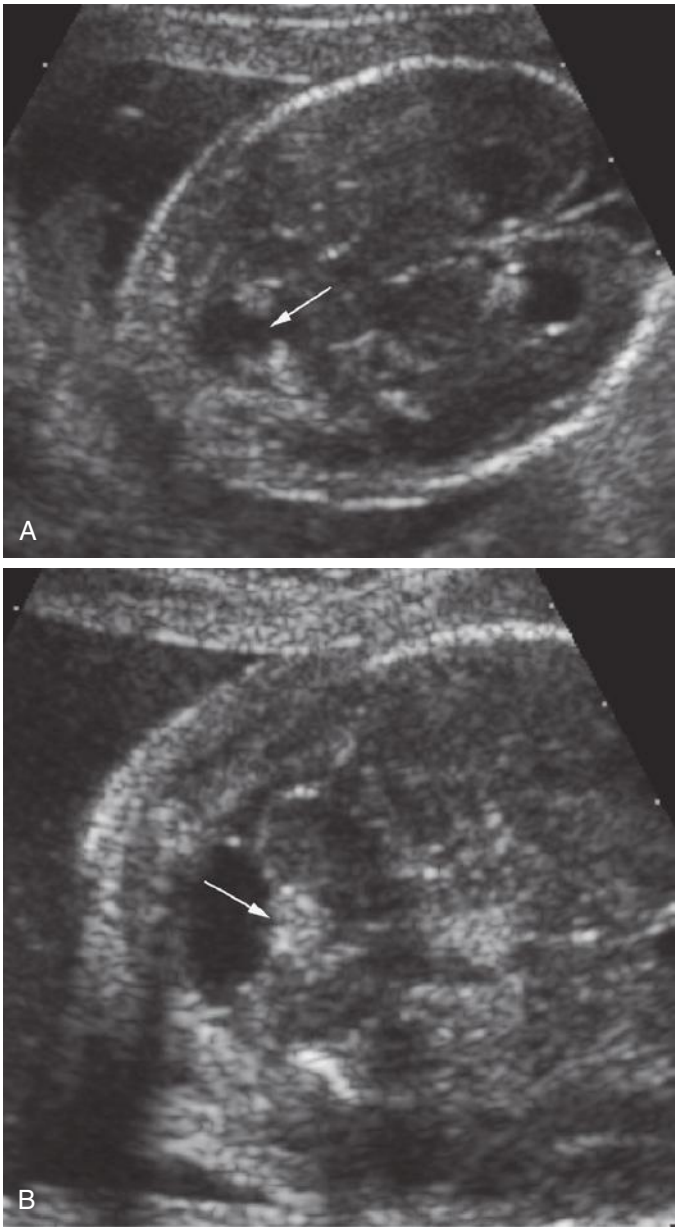

FIG 38-67 **A,** Sonogram of a fetus at 17 weeks' gestational age. In the posterior fossa, fluid is seen in the midline (*arrow*) and the cerebellar vermis appears to be absent. **B,** A scan of the same patient at 25 weeks reveals a normal vermis (*arrow*), which does not fully form until the middle of the second trimester.

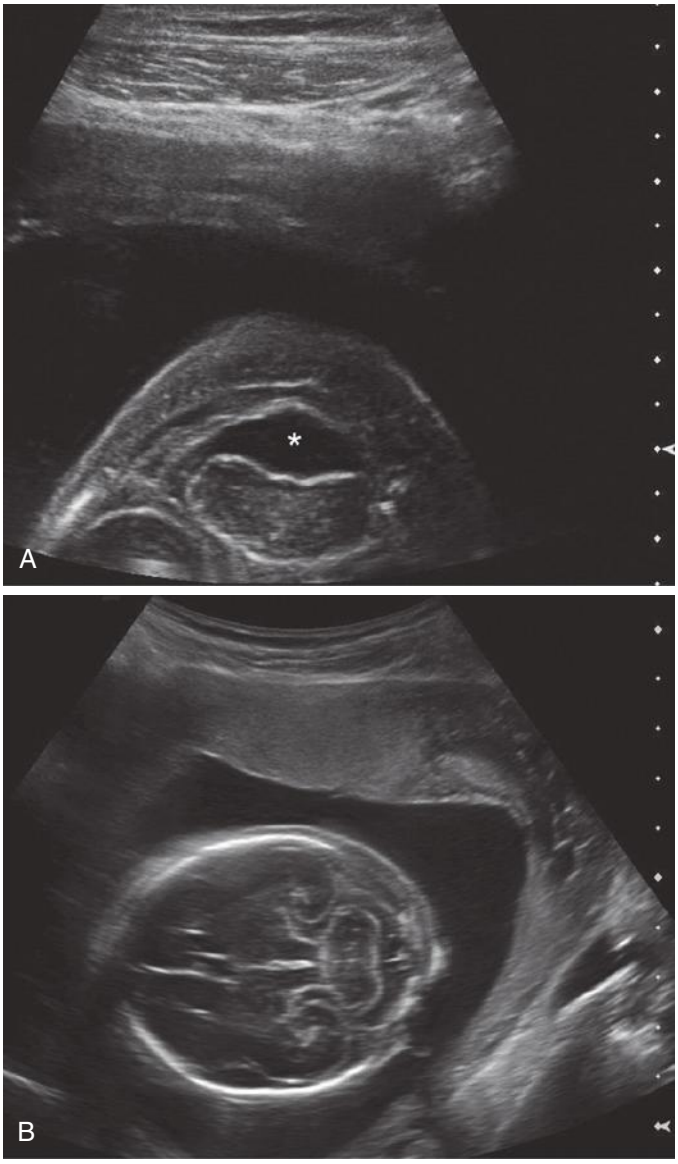

FIG 38-68 **A,** Steeply angled oblique scan through the posterior fossa makes the cisterna magna (*asterisk*) appear abnormally enlarged. **B,** In a more conventional transverse axial plane of section, the cisterna magna is shown to be normal in size.

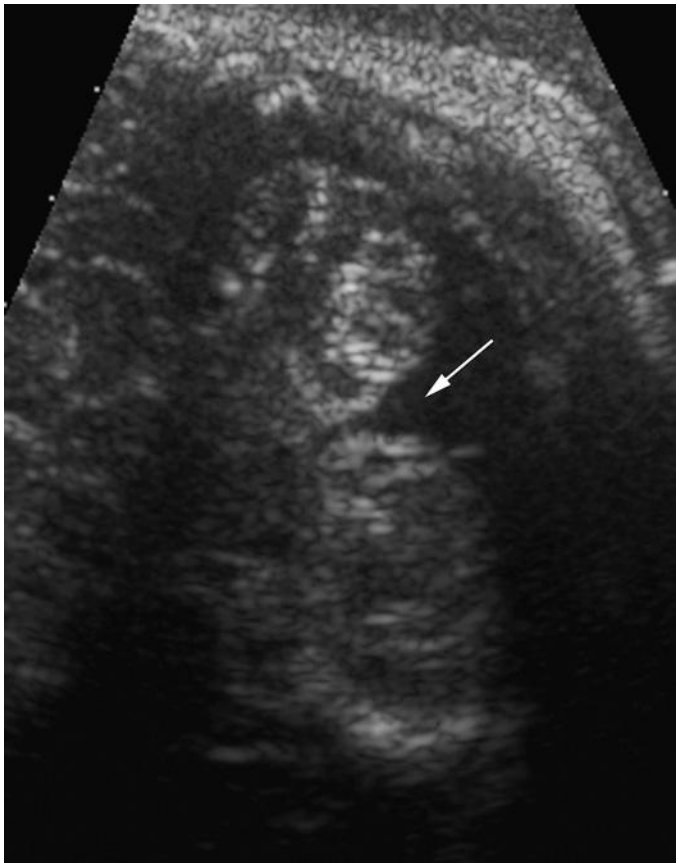

FIG 38-69 Steep transverse scan through the posterior fossa may contribute to a pitfall. The normal space (*arrow*) between the cerebellar hemispheres (vallecula) may appear overly prominent and simulate vermian agenesis.

FIG 38-70 Linear echoes (*arrows*) seen in the region of the cisterna magna should not be mistaken for either an arachnoid cyst or a dilated sinus. The exact cause is controversial, although a recent hypothesis is that these echoes may represent the vestigial remnants of Blake pouch. (From Robinson AJ, Goldstein R: The cisterna magna septa: vestigial remnants of Blake's pouch and a potential new marker for normal development of the rhombencephalon. J Ultrasound Med 26:83, 2007.)

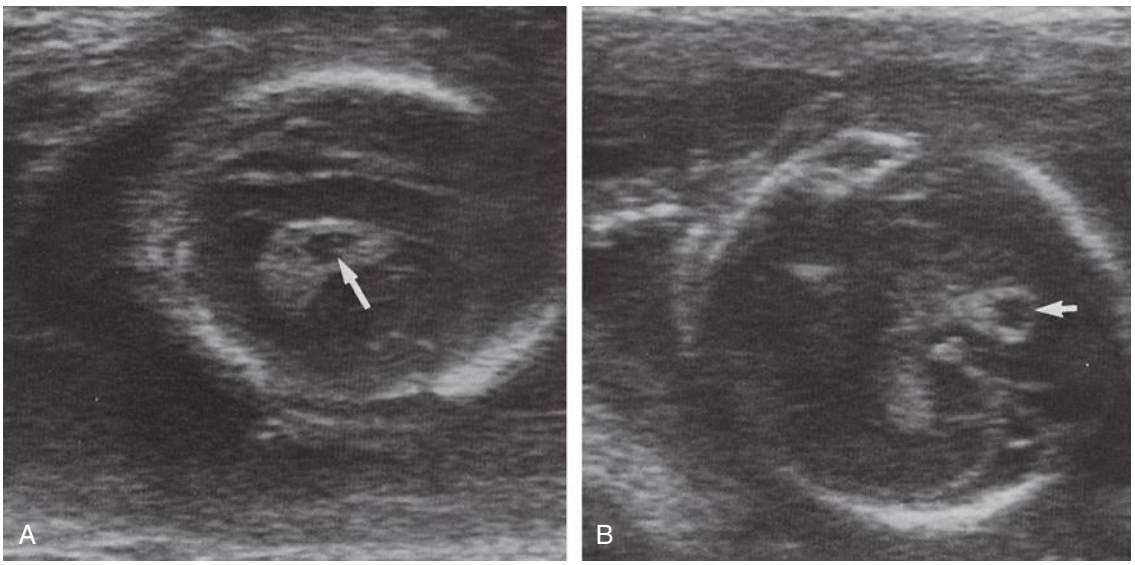

FIG 38-71 **A** and **B,** The choroid plexus cyst (*arrow*) is a normal variant that has been the subject of much controversy during the past several years. Although most cases are simply normal variants that will resolve by 24 to 26 weeks' gestation, some cases may be associated with other anomalies and trisomy 18.

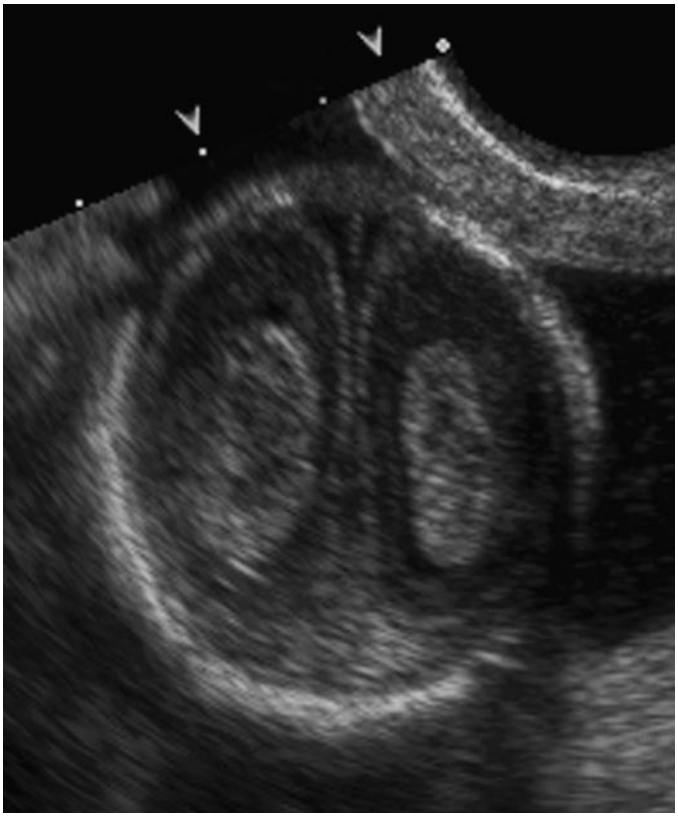

FIG 38-72 Heterogeneous choroid plexus bilaterally. No defined cysts were seen. The fetus and neonate developed normally.

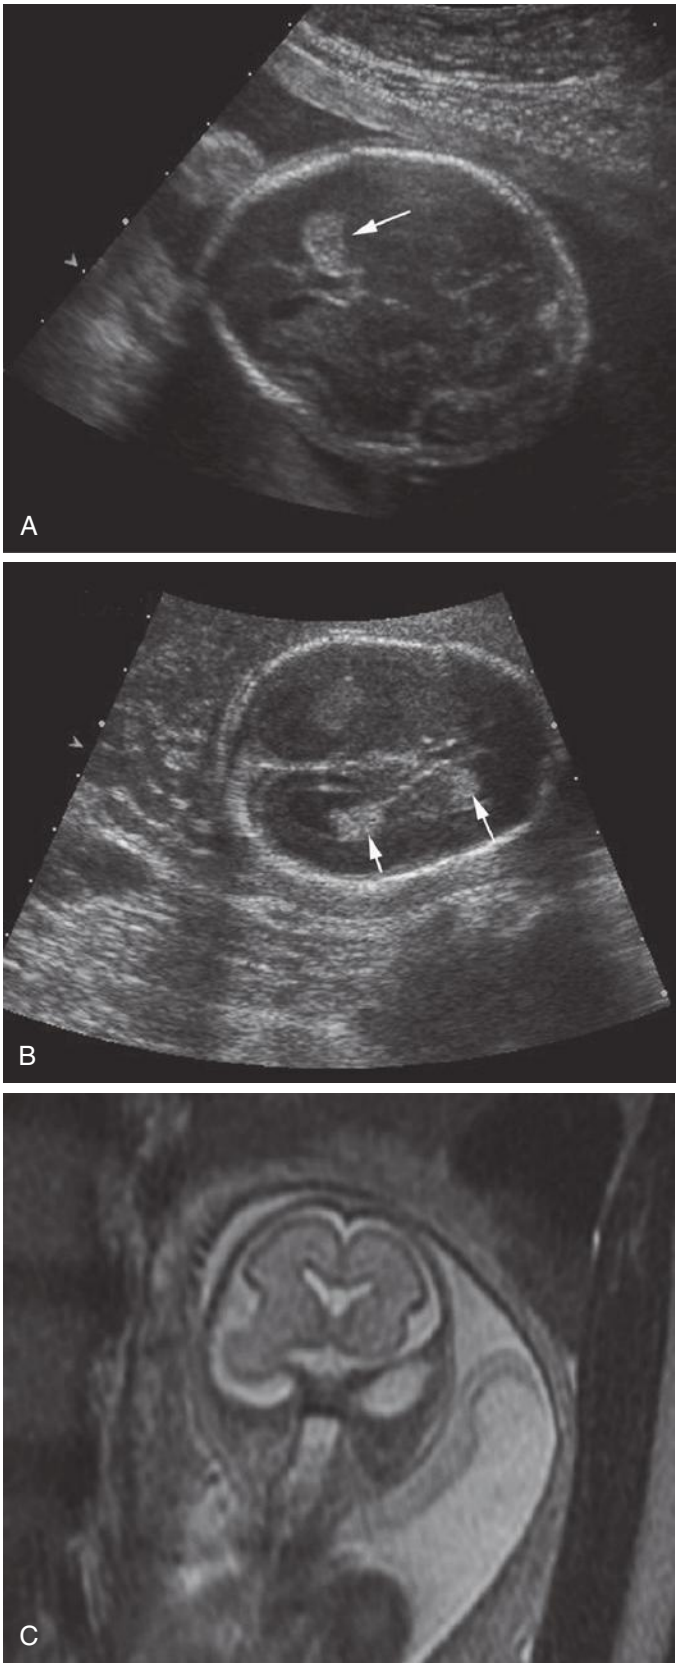

FIG 38-73 **A,** Sonogram performed at 18 weeks demonstrated a focal area of increased echogenicity thought to possibly represent intraventricular hemorrhage (*arrow*). **B,** In another plane of section from the same fetus, the area of increased echogenicity was thought to represent normal echogenic choroid plexus (*arrows*). **C,** Because of concern by the patient, she underwent a magnetic resonance imaging scan, which revealed the fetal brain to be normal without intracranial hemorrhage.

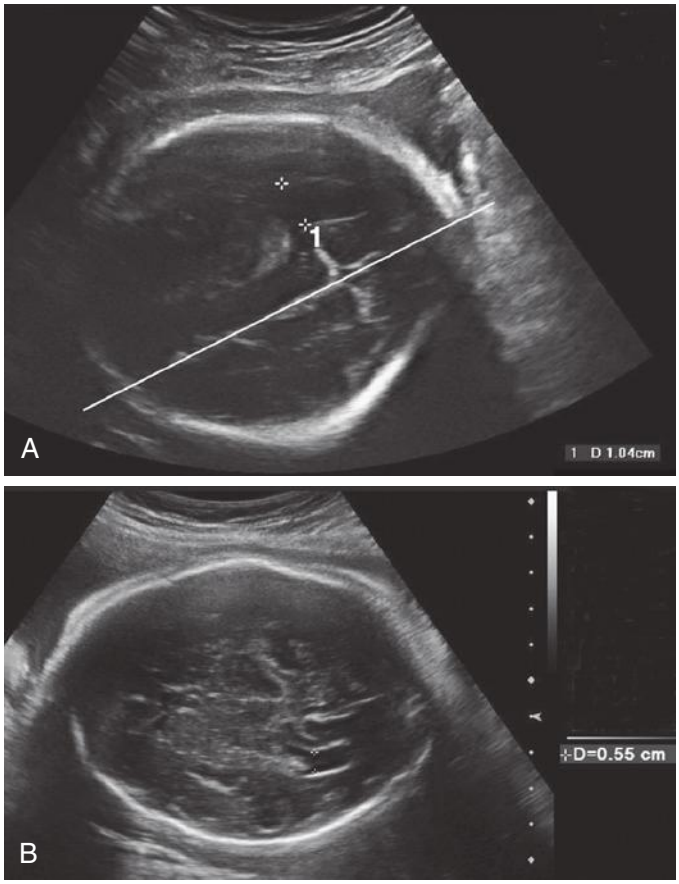

FIG 38-74 **A,** A patient was referred because a sonogram performed at 31 weeks' gestation revealed a mildly dilated cerebral ventricle. Note that the scan plan is angled (oblique axial) such that the midline (*line*) is off-center. **B,** When the scanning plane was corrected (true transverse axial) such that the brain anatomy appeared symmetric, the lateral ventricle is shown to be of normal size.

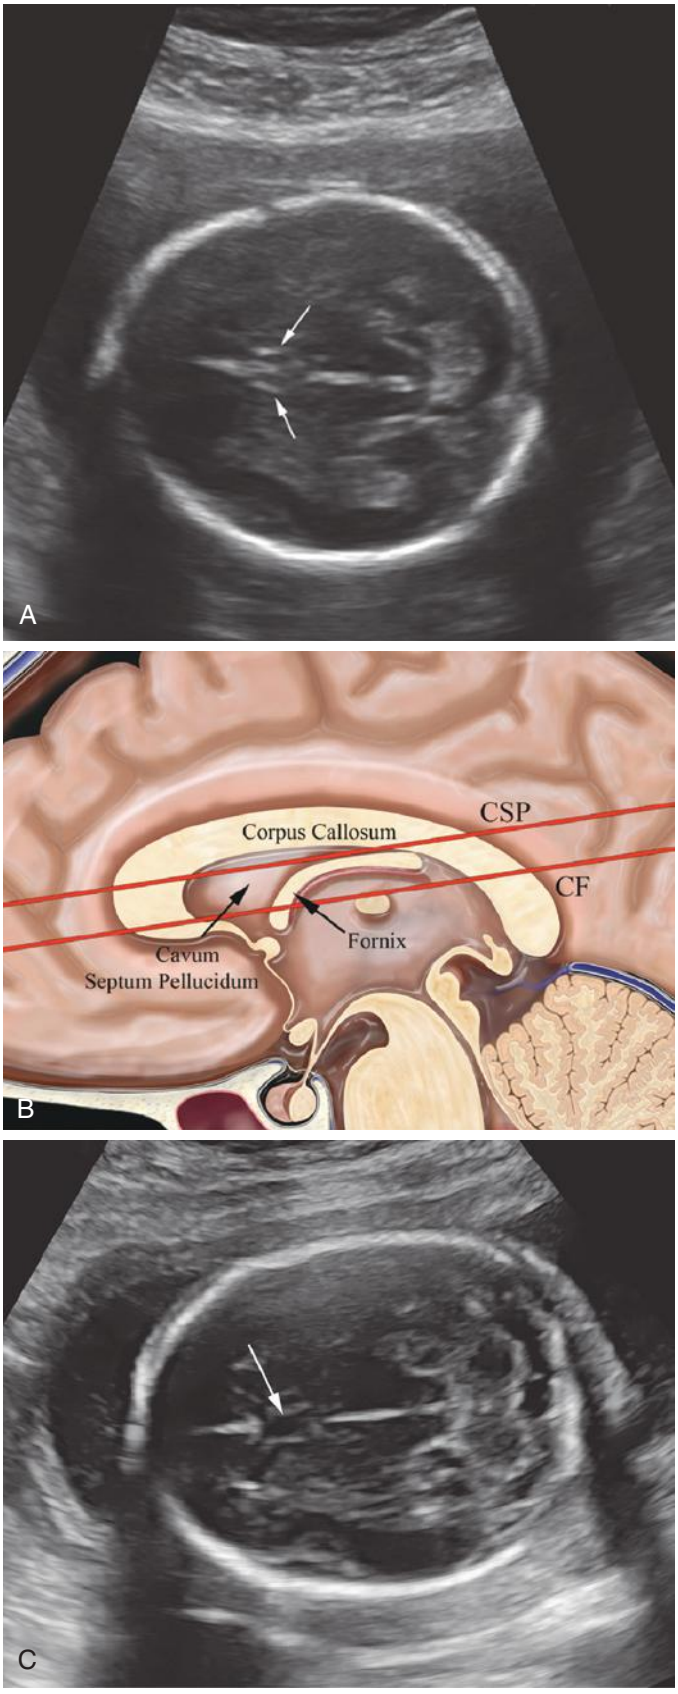

FIG 38-75 **A,** Transverse axial sonogram of the fetal brain performed at an outside institution at 18 weeks' gestation. The structures between the arrows were interpreted as the normal cavum septi pellucidi. **B,** Midline sagittal illustration demonstrating the relationship of the corpus callosum, cavum septum pellucidum, and the fornix. The planes of section demonstrating the cavum septum pellucidum (CSP) and the columns of the fornix (CF) on corresponding transverse axial planes of section are depicted. **C,** Transverse axial sonogram in an 18-week gestation fetus. The cavum septum pellucidum (*arrow*) appears as a fluid-filled "box" between the frontal horns of the lateral ventricles. (B by James A. Cooper, MD, San Diego, CA.)

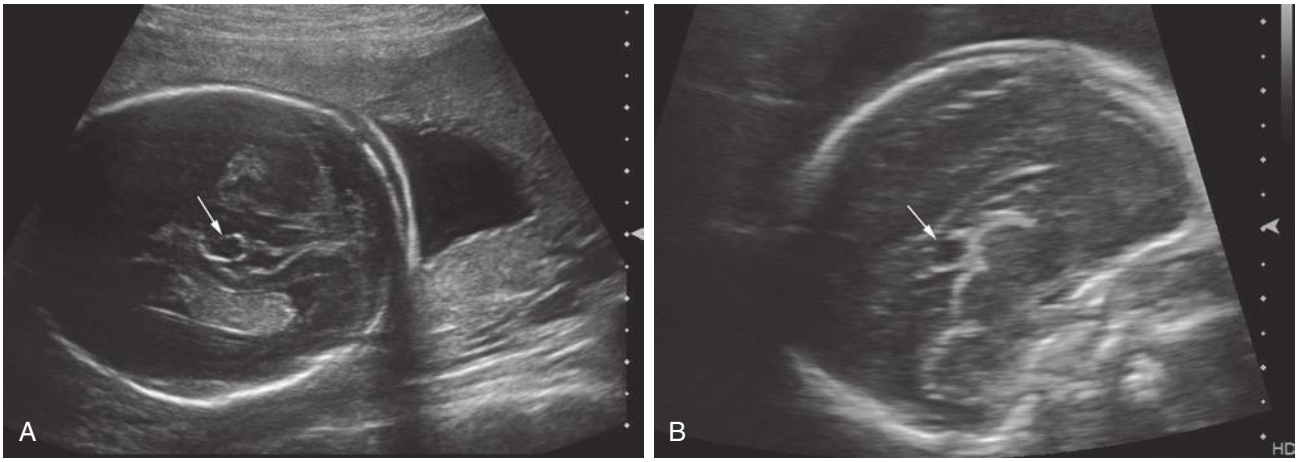

FIG 38-76 **A,** Cyst of the velum interpositum. A small midline cystic structure (*arrow*) is seen on this transverse axial sonogram. This finding may mimic a dilated third ventricle. **B,** On this sagittal view, the "cyst" (*arrow*) is located anteroinferior to the splenium of the corpus callosum, superior and posterior to the thalami. It is most often a benign finding. The differential diagnosis of a cyst of the velum interpositum would include dilated cavum vergae or arachnoid cyst of the quadrigeminal cistern.

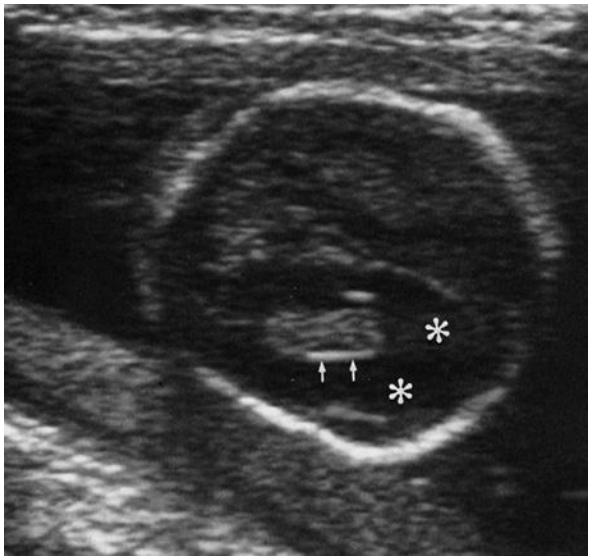

FIG 38-77 The normal fetal brain is sonolucent (*asterisks*) and may simulate cerebrospinal fluid. This appearance may incorrectly lead to the diagnosis of hydrocephalus. Identification of the lateral ventricular walls (*arrows*) and the choroid plexus within will help resolve this confusion.

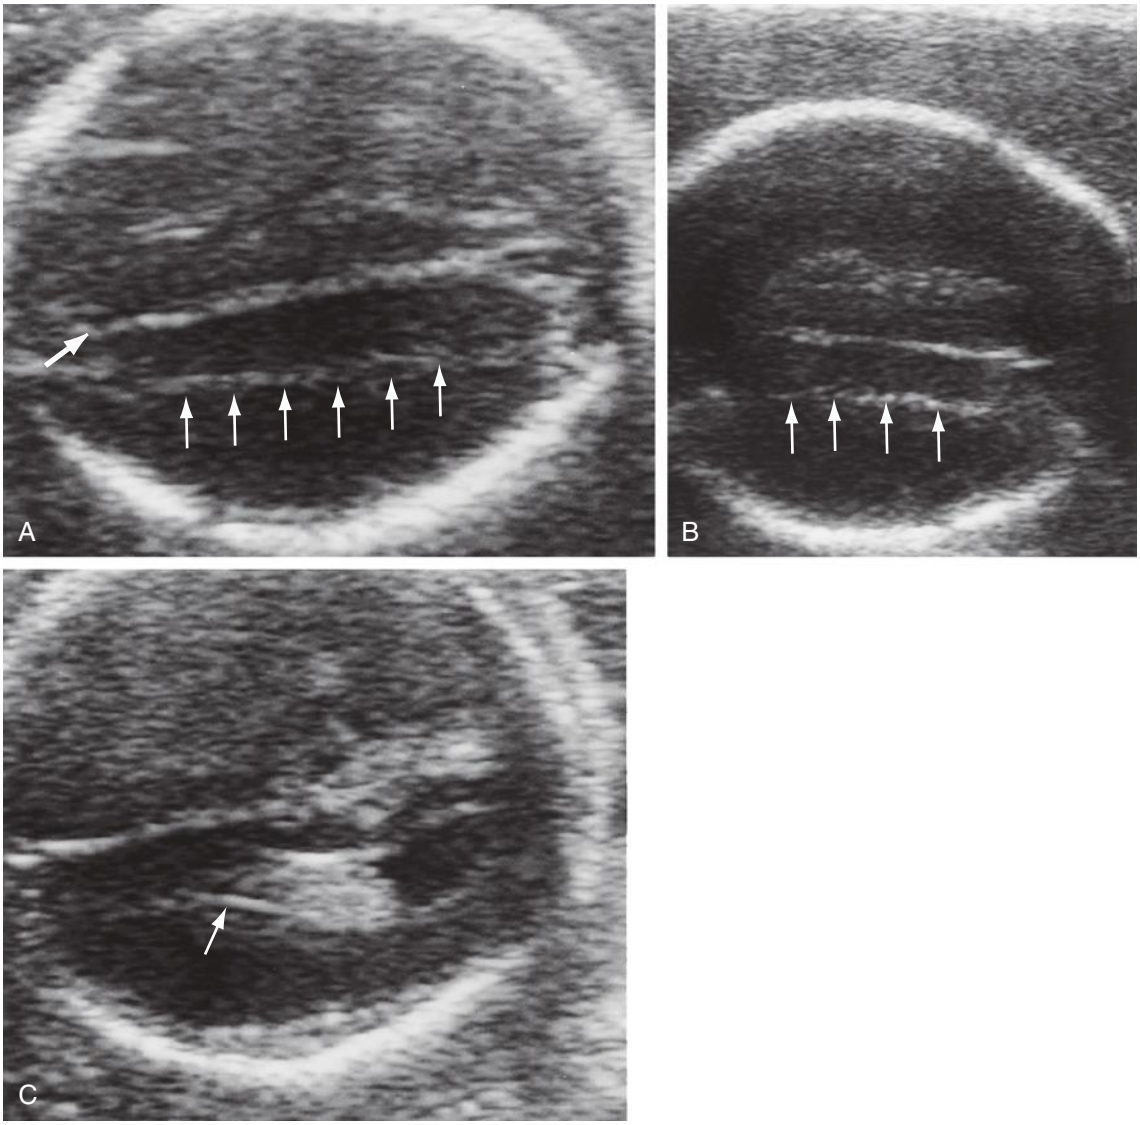

FIG 38-78 **A** and **B,** Transverse axial plane of section in two normal patients. The paramedian lines (*thin arrows*) paralleling the midline interhemispheric fissure echo (*thick arrow*) are due to deep cerebral medullary white matter veins and not the lateral wall of the lateral ventricle. **C,** The lateral wall of the lateral ventricle (*arrow*) is seen at a slightly more basal level and angling laterally away from the midline.

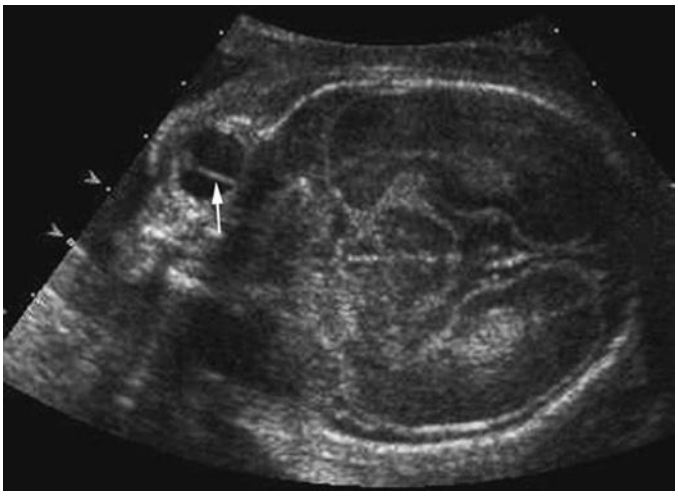

FIG 38-79 The hyaloid artery (*arrow*) can often be seen in the second trimester. It disappears between 23 and 28 weeks of gestation and is normally not visible by ultrasound after 29 weeks of gestation.

THE FETAL THORAX

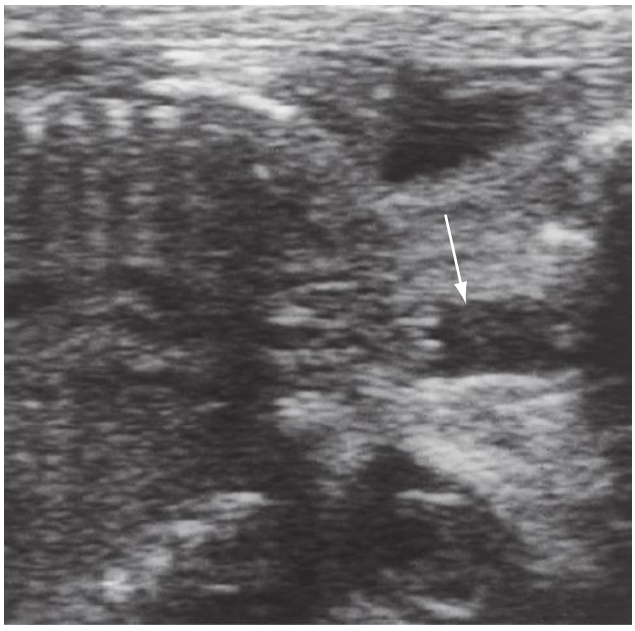

FIG 38-80 The fetal hypopharynx (*arrow*) may be prominent. It may be seen to fill and empty with fluid during the examination. This should not be mistaken as representing esophageal obstruction.

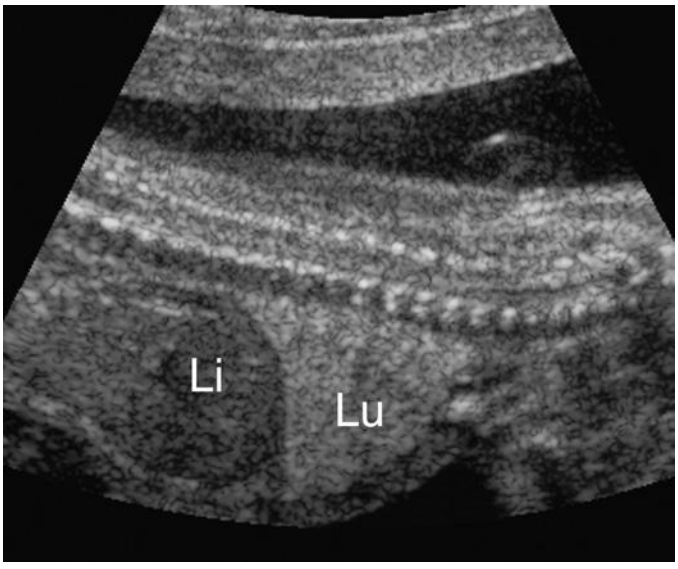

FIG 38-81 The echogenicity of the fetal lung (Lu) may often be misleading. The lung in this oblique coronal scan appears brightly echogenic compared with the liver (Li); however, this fetus neither is mature nor has lung disease.

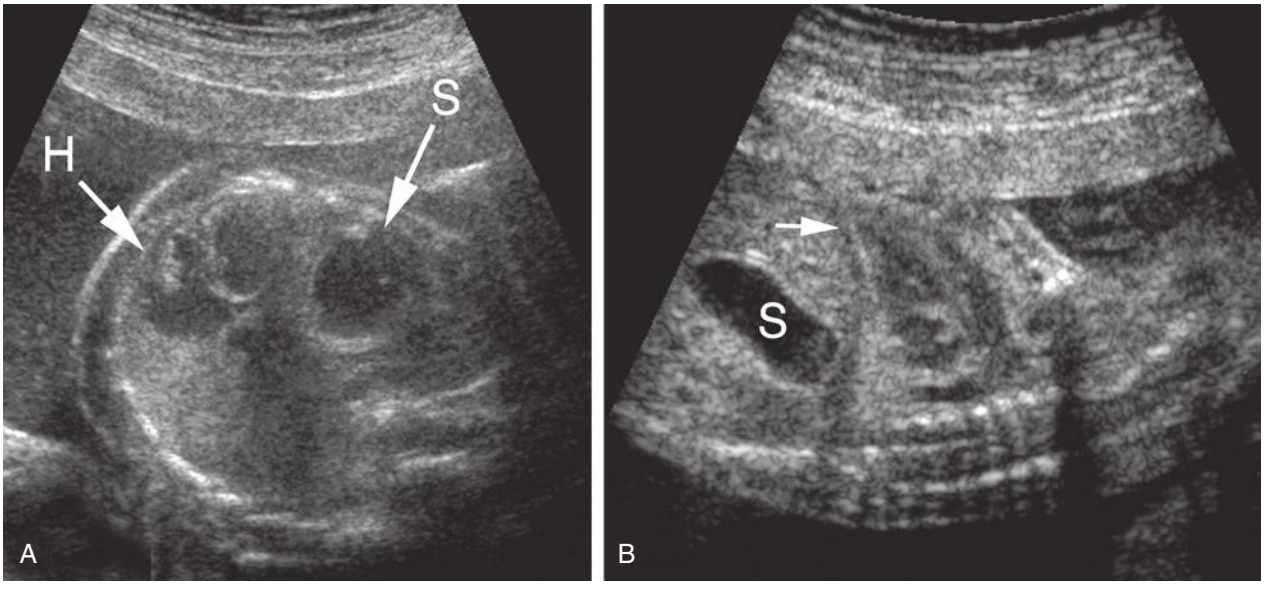

FIG 38-82 **A,** Angled transverse axial plane of section at the level of the fetal heart (H). The fetal stomach (S) is seen at the same level as the heart, raising the possibility of a diaphragmatic hernia. **B,** This sagittal plane of section from the same patient reminds us that the diaphragms (*arrow*) are curved, and a slightly angled transverse plane of section will portray what appears to be a diaphragmatic hernia, although the stomach (S) is, in fact, below the diaphragm.

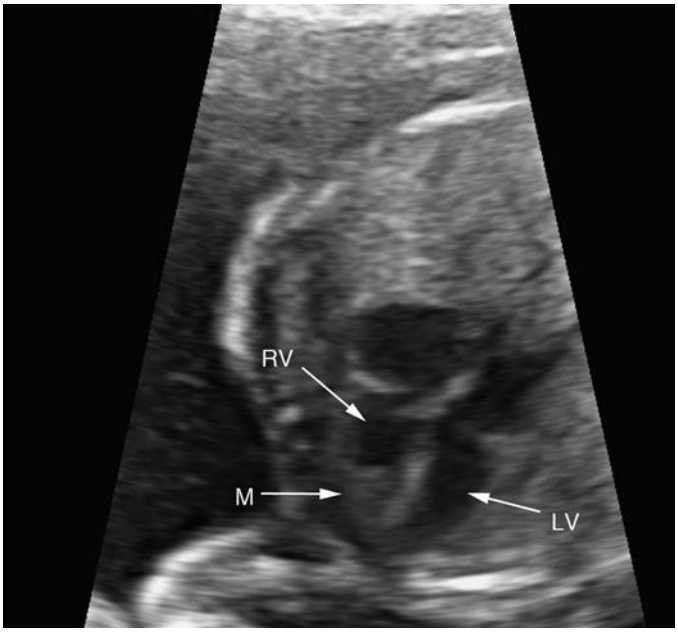

FIG 38-83 Soft tissue suggested within the right ventricle may be considered worrisome for either thrombus or neoplasm. In this patient, the normal but prominent moderator band (M) of the right ventricle (RV) is seen. LV, left ventricle.

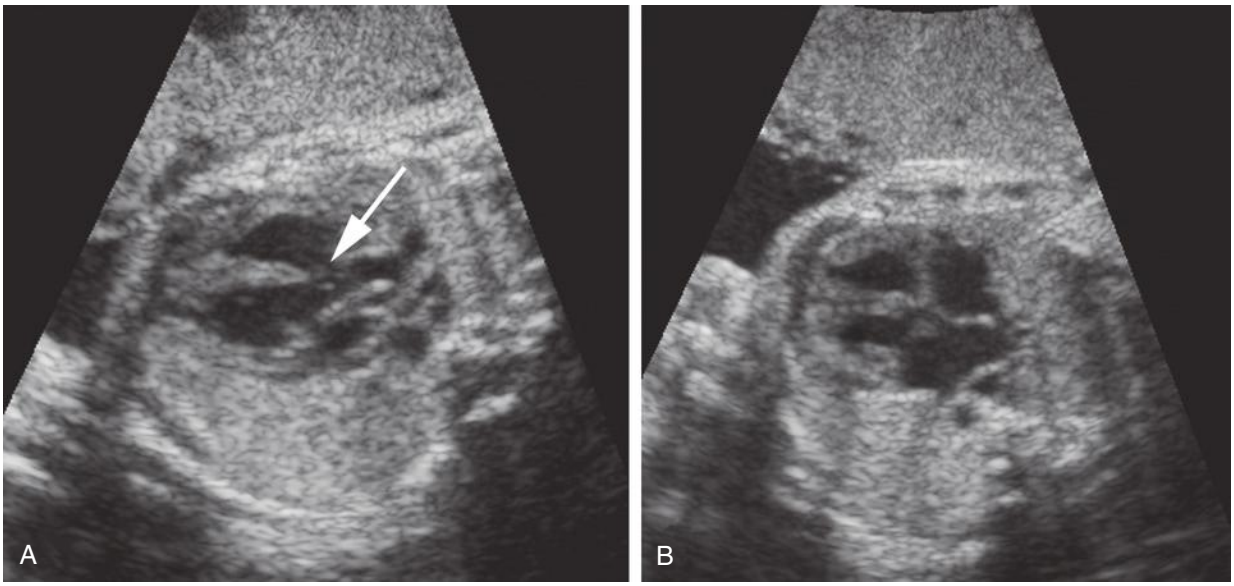

FIG 38-84 **A,** An apparent defect in the ventricular septum (*arrow*) is seen. This may be due to the origin of the aortic root and the thin membranous septum. **B,** Slight change of the transducer position demonstrates a normal-appearing septum.

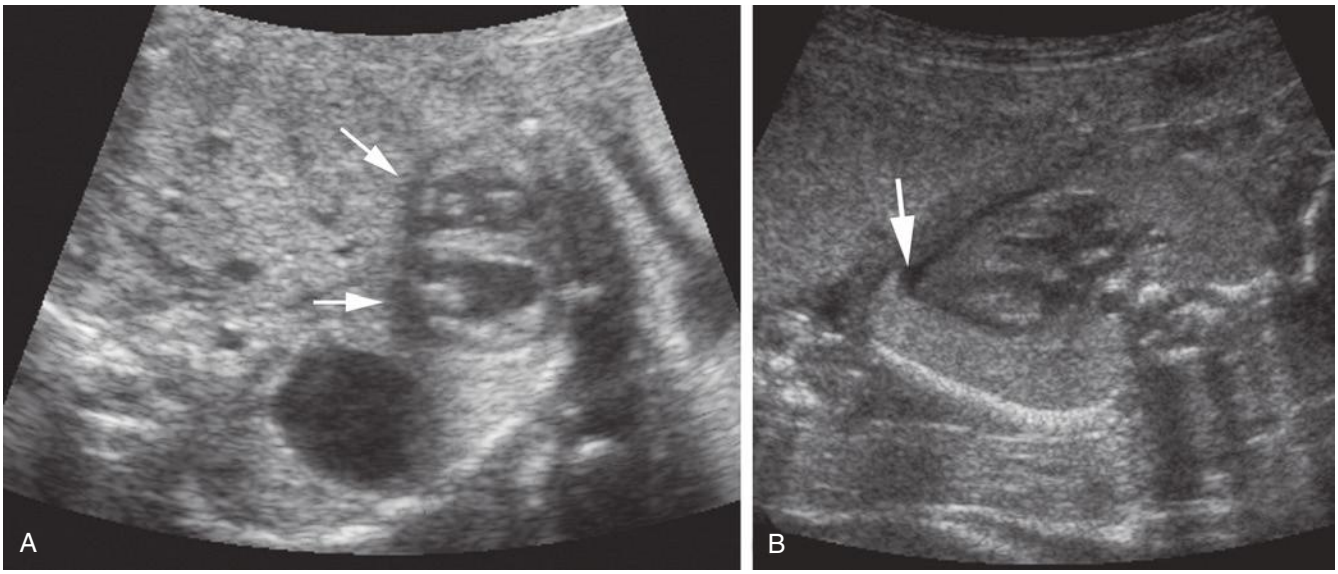

FIG 38-85 **A,** The poorly echogenic myocardium (*arrows*) may simulate pericardial fluid. The observation that this area blends imperceptibly with the intraventricular septum should alert one that this is a normal cardiac structure and not pericardial fluid. **B,** The case in A should be contrasted with real pericardial fluid (*arrow*), which contains no echoes.

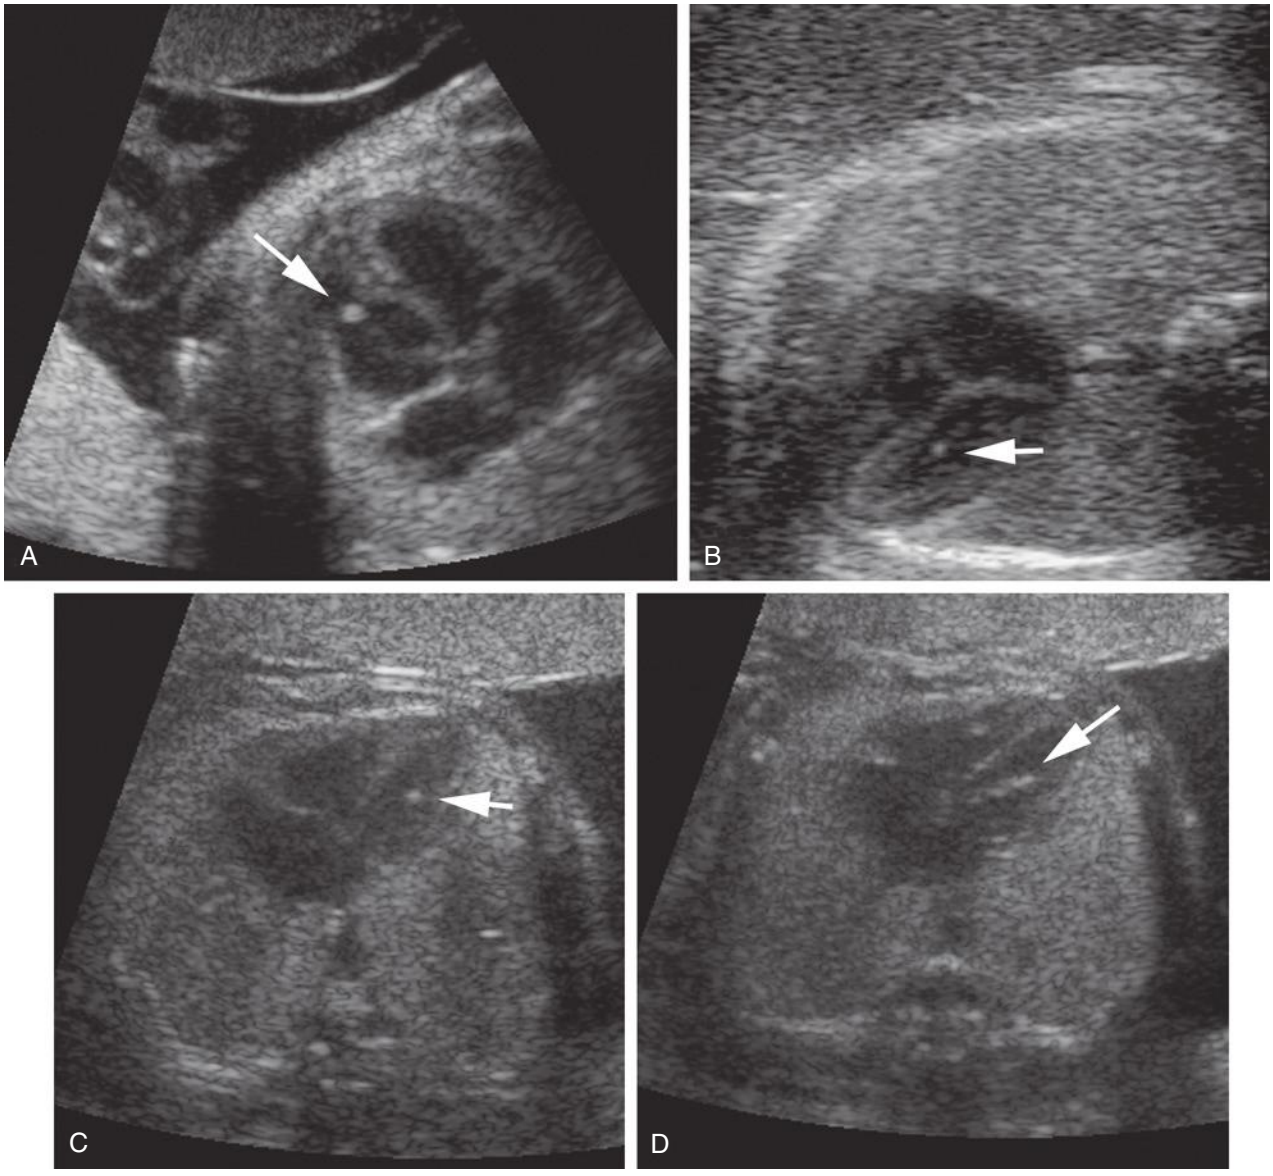

FIG 38-86 Echogenic intracardiac focus. **A,** A high-amplitude echo (*arrow*) is seen in the left ventricle in this patient. This appearance is believed to be due to reflection from calcification in the papillary muscle. In this case, the echogenic structure was fairly large. The significance of this finding is controversial; in some cases, it is associated with karyotype abnormalities. **B,** A smaller echogenic intracardiac focus (*arrow*) is seen in another patient. **C,** In this patient, a reflection (*arrow*) from the atrioventricular valve is seen. It appears similar to an echogenic intracardiac focus. **D,** The reflection from the surface of the valve (*arrow*) is better seen in another plane of section.

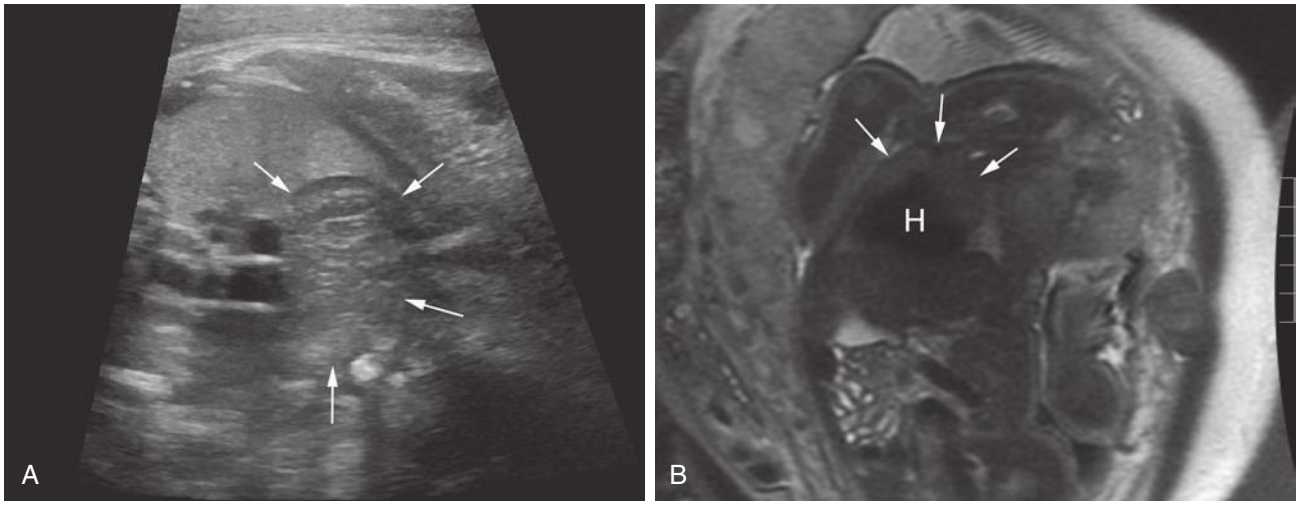

FIG 38-87 Normal thymus. **A,** The normal thymus (*arrows*) may appear quite prominent in a fetus. It is usually seen as an oval soft tissue structure anterior to the great vessels, as in this case. It should not be misinterpreted as a chest mass. **B,** A magnetic resonance imaging scan of the same patient demonstrates the normal thymus (*arrows*). H, heart.

THE FETAL ABDOMEN

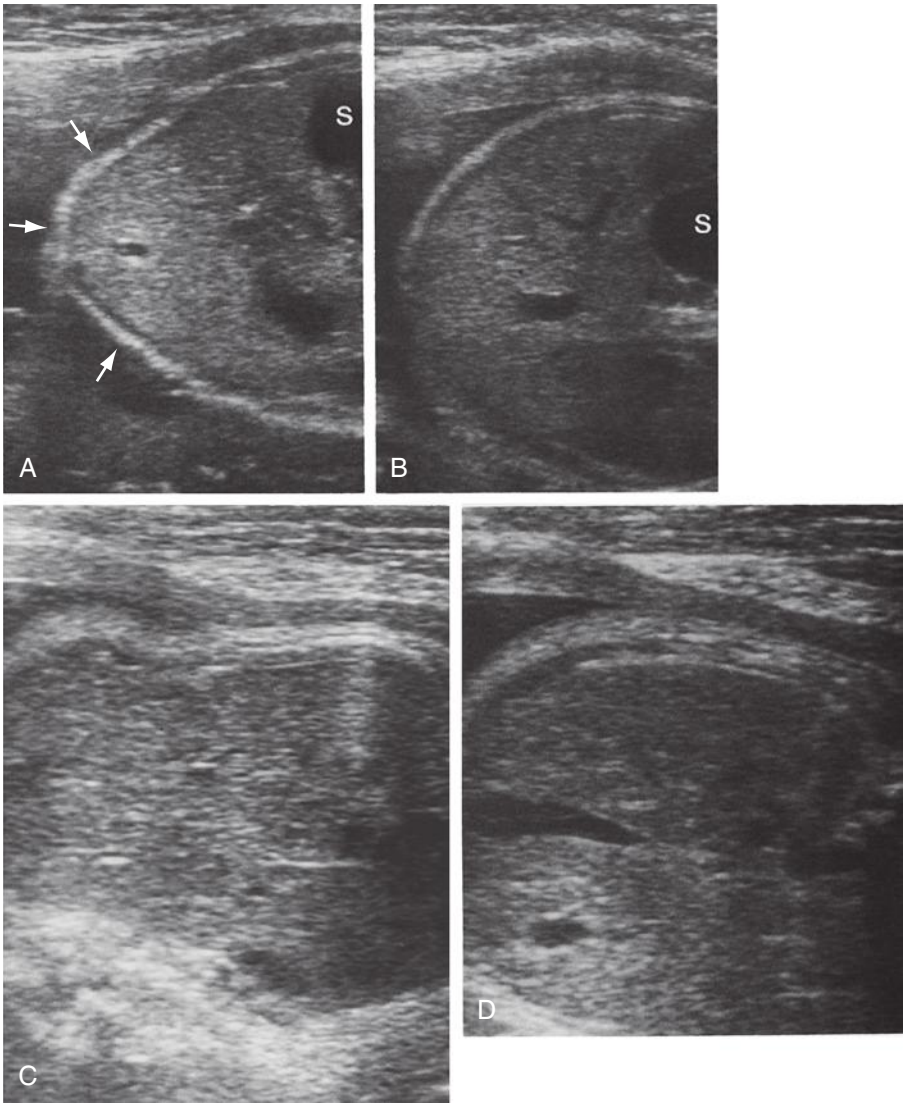

FIG 38-88 Pseudo-omphalocele in two patients. **A** and **C,** Excessive pressure with the linear array transducer causes deformation of the abdominal wall, simulating an abdominal wall defect. Identification of the normal skin covering this protuberance (*arrows*) and less pressure on the maternal abdomen will usually resolve the confusion. **B** and **D,** Same patients demonstrating normal anterior abdominal wall with light pressure on the maternal abdomen. S, stomach.

FIG 38-89 Focal laxity of the anterior abdominal wall (*arrow*) is seen in this second trimester sonogram. The anterior abdominal bulge was accentuated when the fetus flexed its thighs. Although this may have the appearance of an anterior abdominal wall defect, it was eccentric and skin covered. The neonate was normal at birth.

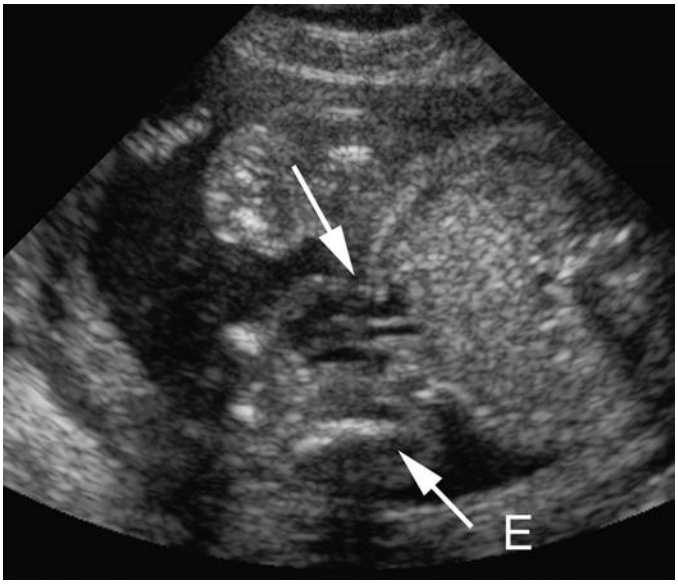

FIG 38-90 Pseudogastroschisis caused by an extremity (E) adjacent to the umbilical cord insertion site (*arrows*).

FIG 38-91 Gastroschisis in a second trimester pregnancy. Multiple loops of bowel are seen adjacent to the fetal abdomen within the amniotic fluid. What appears to be dilated bowel is normal colon (*arrow*), which may appear to be prominent although nondilated.

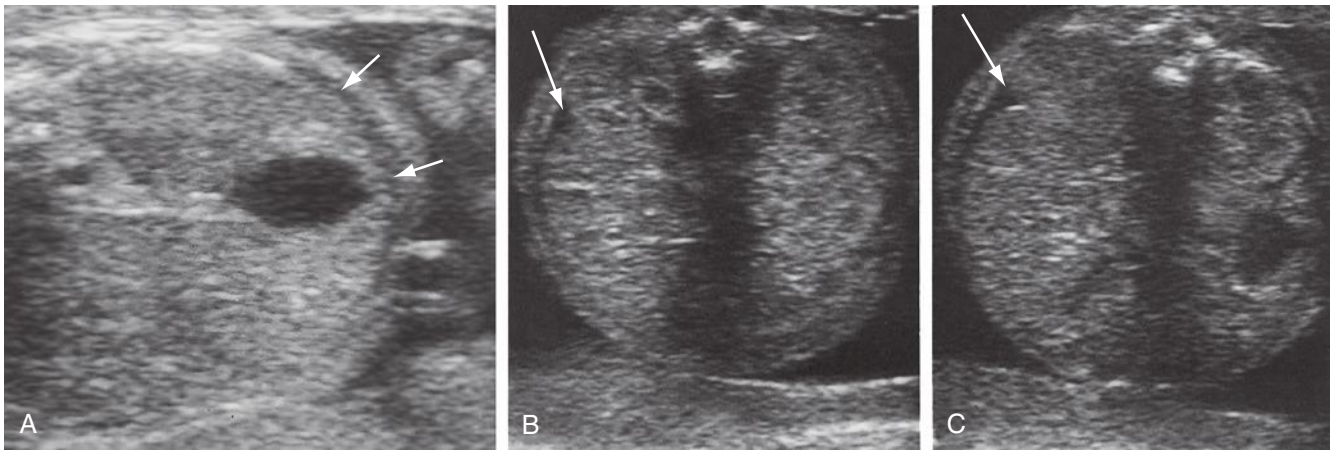

FIG 38-92 **A,** Pseudoascites resulting from the poorly echogenic appearance of the normal integument (*arrows*). **B** and **C,** A small amount of real ascites is identified in this patient. Notice that the fluid invaginates between the viscera on the right side (*arrows*).

FIG 38-93 Debris within the fetal stomach (*arrow*). Although occasionally the cause may be known (i.e., swallowed blood from an intrauterine transfusion), most often it is unknown. This is almost always an innocuous finding.

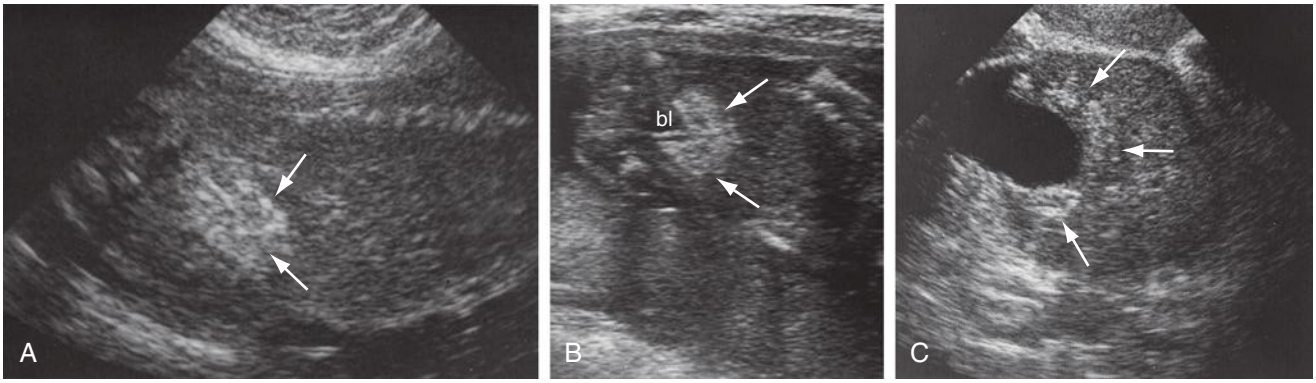

FIG 38-94 Hyperechogenicity within the fetal abdomen (*arrows*). This finding has received recent attention in the literature as a possible clue to the diagnosis of either cystic fibrosis or aneuploidy. The problem is in differentiating normal from abnormal. **A** and **B,** Normal chromosomes and no evidence of cystic fibrosis. bl, bladder. **C,** A case of meconium ileus and cystic fibrosis at birth (*arrows*). To be called echogenic bowel the echogenicity of the bowel should be similar to that of adjacent bone.

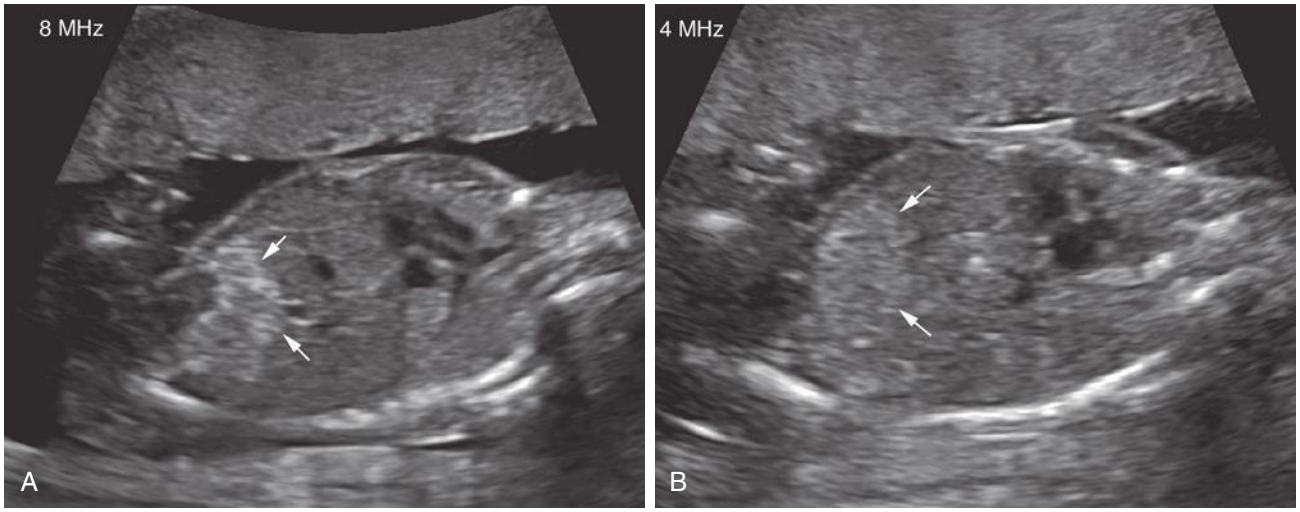

FIG 38-95 Pseudo-hyperechogenic fetal bowel. **A,** Sonogram of the fetal abdomen obtained with an 8-MHz frequency transducer demonstrates hyperechogenic fetal bowel (*arrows*). The bowel wall is accentuated at this frequency. **B,** Sonogram of the same patient obtained with a 4-MHz frequency transducer demonstrates more normal-appearing fetal bowel (*arrows*). This is a common phenomenon and the sonologist should be aware of the effect of transducer frequency on apparent bowel echogenicity. Caution should be taken before declaring abnormal bowel echogenicity and prompting invasive testing.

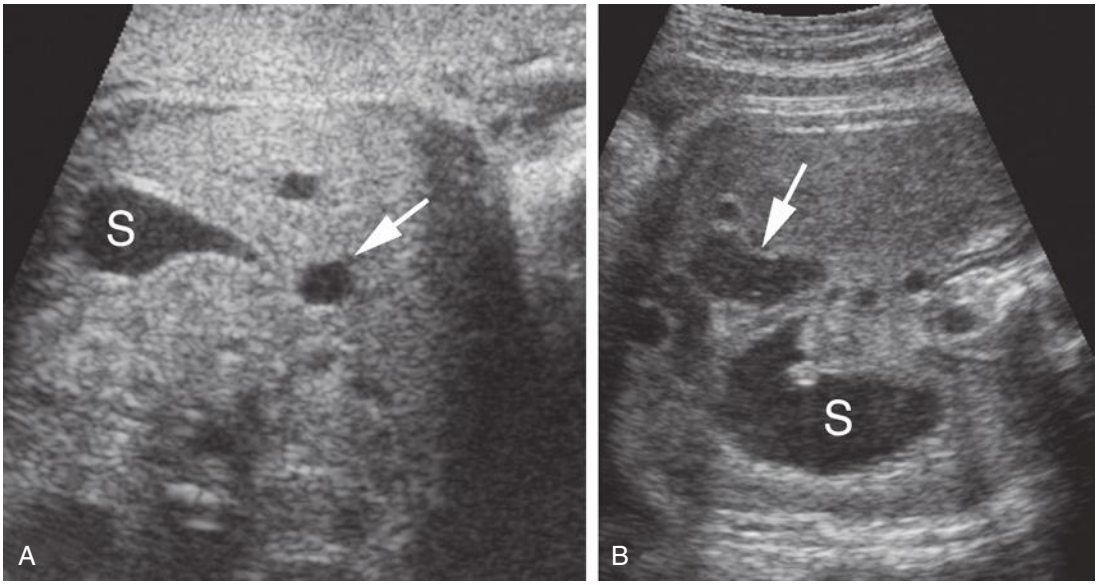

FIG 38-96 Pseudo-double bubble sign. The double bubble may be seen in cases of duodenal obstruction and has been associated with trisomy 21. **A,** In this case, the fluid-filled structure adjacent to the stomach (S) is the gallbladder (*arrow*) and not the duodenum. **B,** A sonogram of the fetal abdomen in the third trimester demonstrates a prominent segment of colon (*arrow*) adjacent to the fetal stomach (S) and should not be misinterpreted as dilated duodenum.

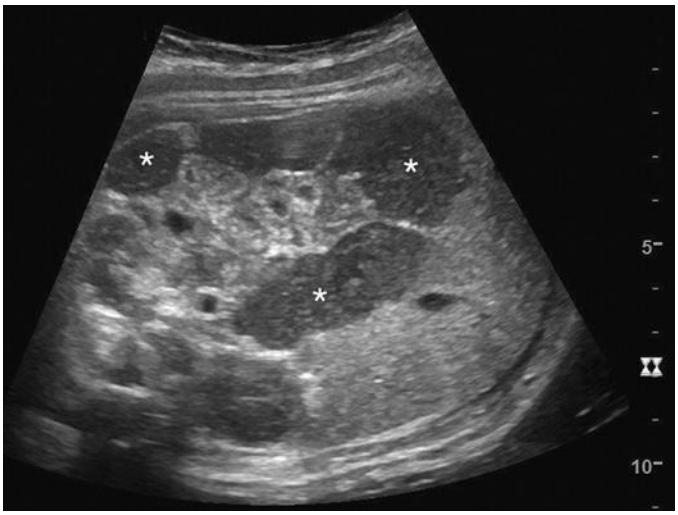

FIG 38-97 The fetal colon may be quite prominent in the third trimester. The colon (*asterisks*) is prominent but normal in this patient.

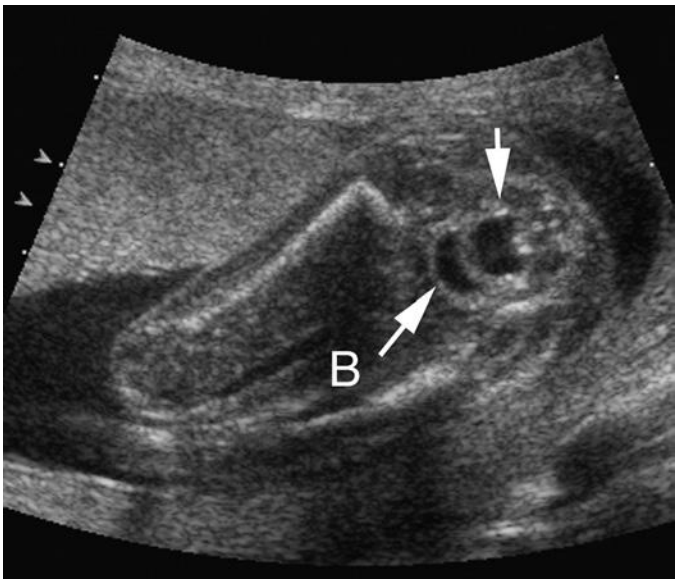

FIG 38-98 The normal rectum (*arrow*) can occasionally be seen in the second and third trimester fetus. This should not be mistaken for a myelomeningocele or other intrapelvic defect. B, bladder.

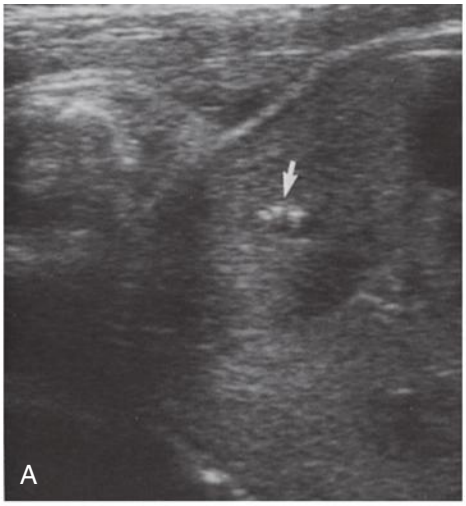
FIG 38-99 In the presence of fetal ascites (A), fluid may enter the lesser sac and result in outlining of the greater omentum (*arrow*). This should not be mistaken for a dilated loop of intestine. L, liver.

FIG 38-100 The fetal intestine (*arrow*) may simulate other nonintestinal structures such as a dilated ureter. This is especially true in the second trimester, when the meconium-filled distal small bowel and colon are sonolucent. K, kidney.



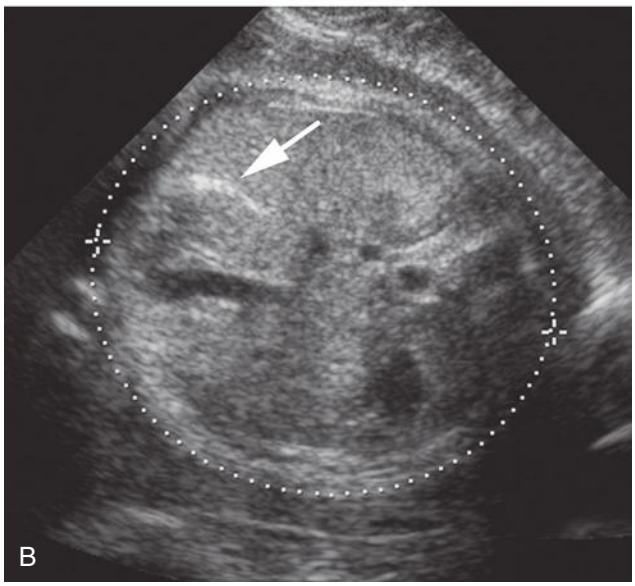


FIG 38-101 **A** and **B,** Fetal gallstones (*arrows*) seen in two third trimester fetuses. In both cases, the fetus was otherwise normal. This finding does not indicate biliary disease and may resolve before birth.

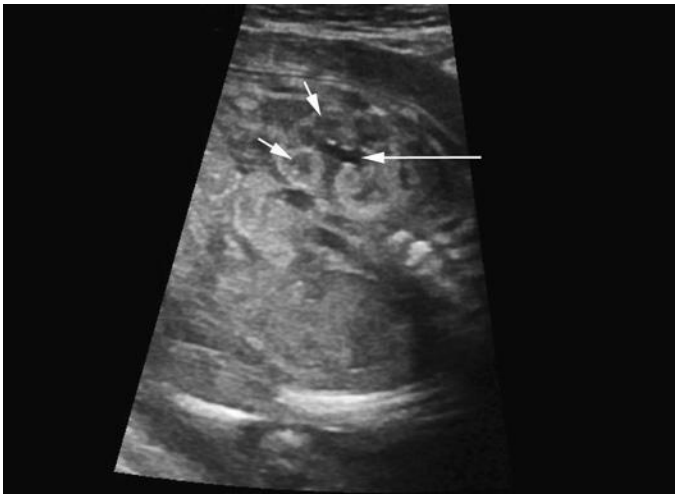

FIG 38-102 The normal fetal renal medullary pyramids often appear quite sonolucent (*short arrows*), which may simulate hydronephrosis. This appearance with corticomedullary differentiation is a normal and expected finding. In this case, minimal pelviectasis (*long arrow*) is seen.

FIG 38-103 An oval paraspinous soft tissue structure is seen simulating the fetal kidney (*arrow*). This structure is the normal adrenal gland, which often is quite prominent in the fetus. The hyperechoic medulla and hypoechoic cortex are well seen.

FIG 38-104 Splenic cyst. A benign simple small splenic cyst (*arrow*) is seen in this fetus. This is a normal variant and is of no pathologic significance. St, stomach.

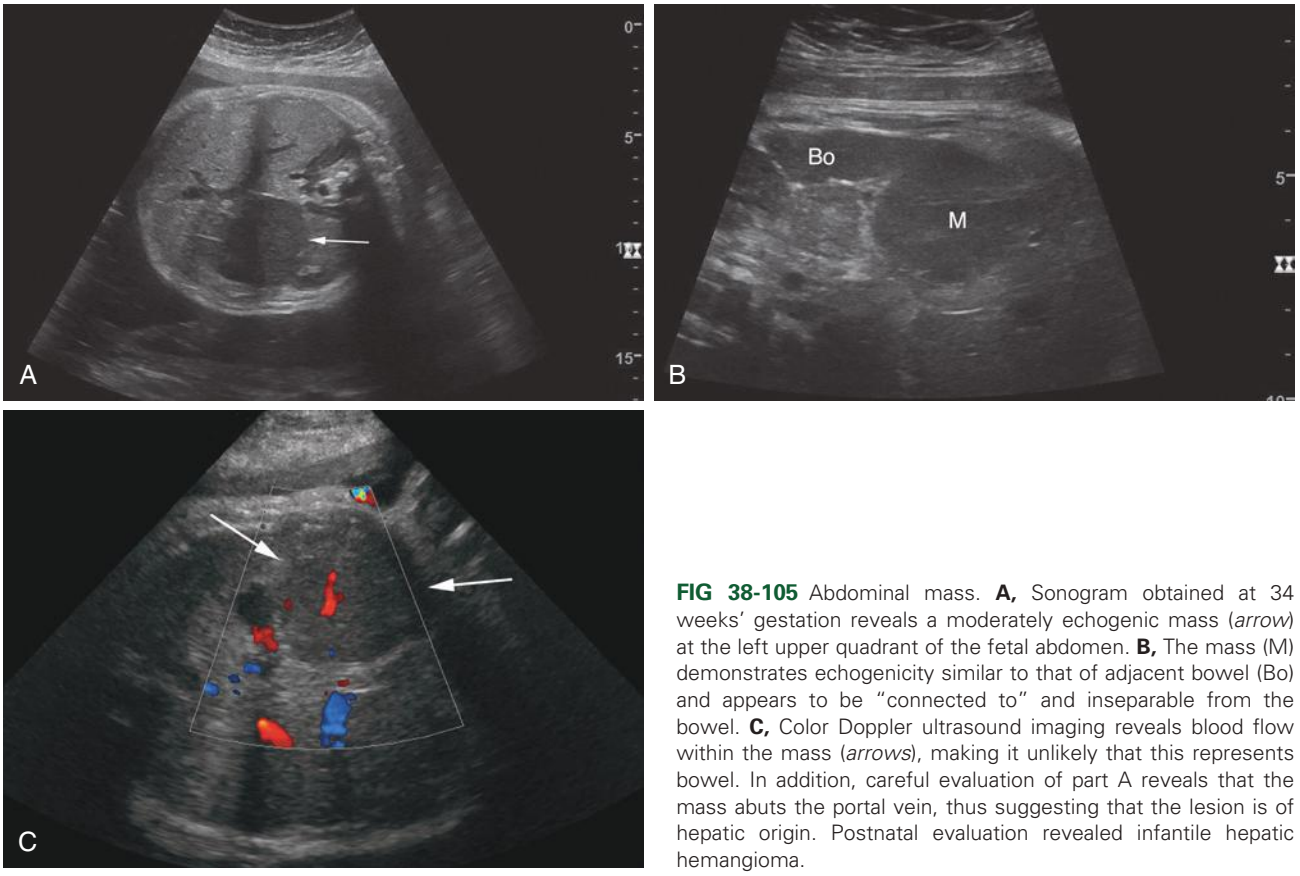

FIG 38-105 Abdominal mass. **A,** Sonogram obtained at 34 weeks' gestation reveals a moderately echogenic mass (*arrow*) at the left upper quadrant of the fetal abdomen. **B,** The mass (M) demonstrates echogenicity similar to that of adjacent bowel (Bo) and appears to be "connected to" and inseparable from the bowel. **C,** Color Doppler ultrasound imaging reveals blood flow within the mass (*arrows*), making it unlikely that this represents bowel. In addition, careful evaluation of part A reveals that the mass abuts the portal vein, thus suggesting that the lesion is of hepatic origin. Postnatal evaluation revealed infantile hepatic hemangioma.

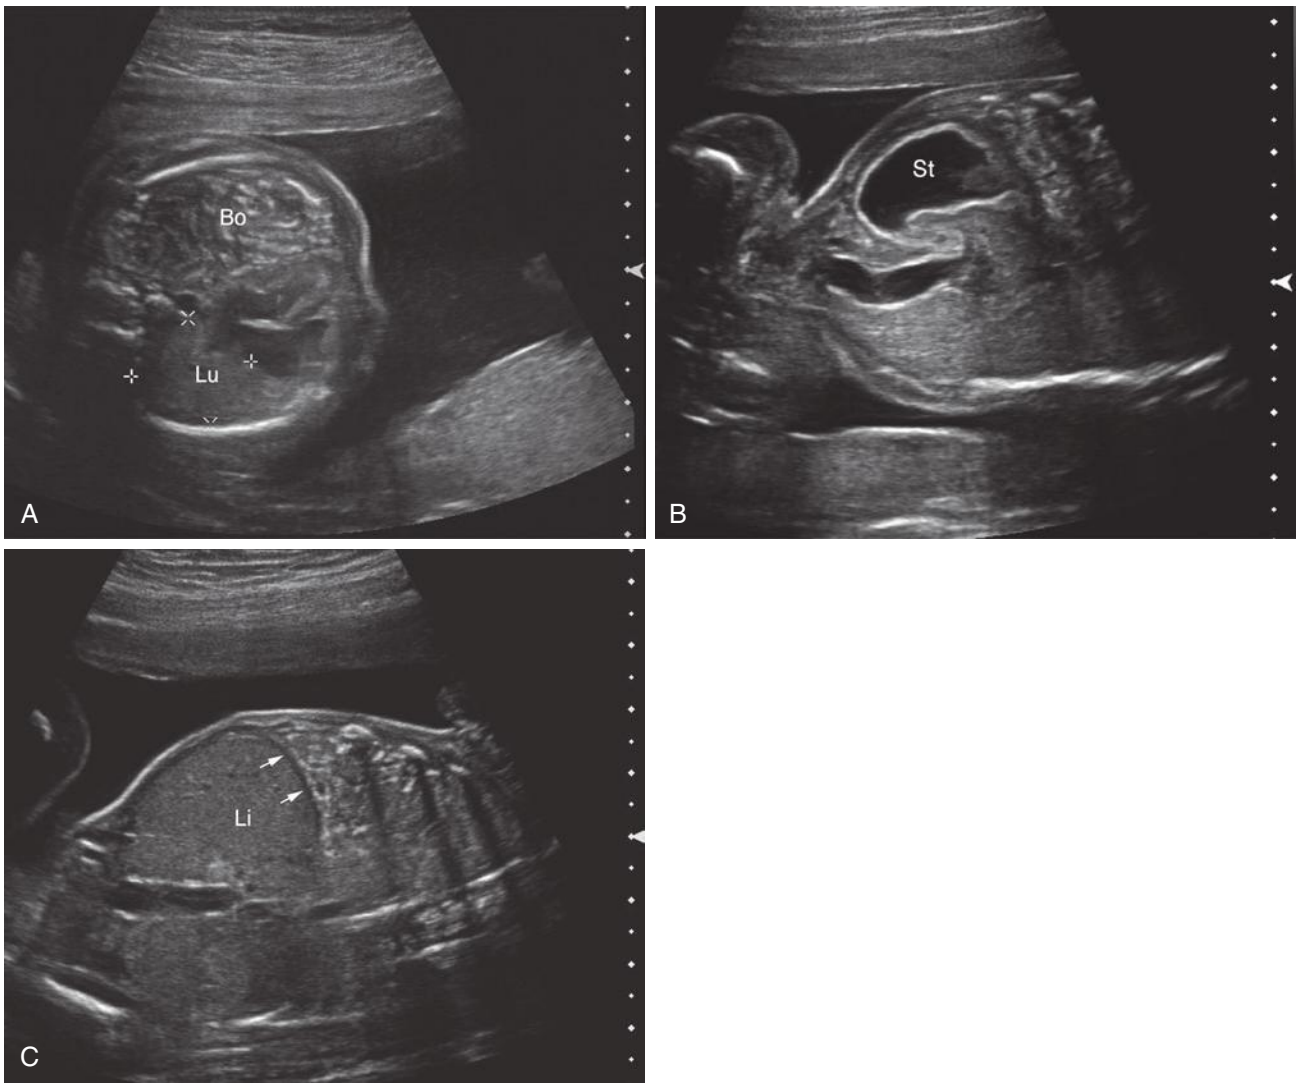

FIG 38-106 Left congenital diaphragmatic hernia. **A,** Sonogram of a fetus with a left congenital diaphragmatic hernia. Typically this diagnosis is made by observing the fluid-filled stomach within the thorax adjacent to the heart. In this case, bowel loops (Bo) fill the left hemithorax. Electronic calipers are placed measuring the right lung (Lu). These dimensions are needed to calculate the lung-head ratio (LHR), useful in assessing prognosis. **B,** Coronal plane of section of the same fetus demonstrates the stomach (St) normally positioned within the upper abdomen. **C,** The liver (Li) is normally positioned within the abdomen, below the diaphragm (*arrows*). Lack of herniation of liver into the chest is associated with better prognosis.

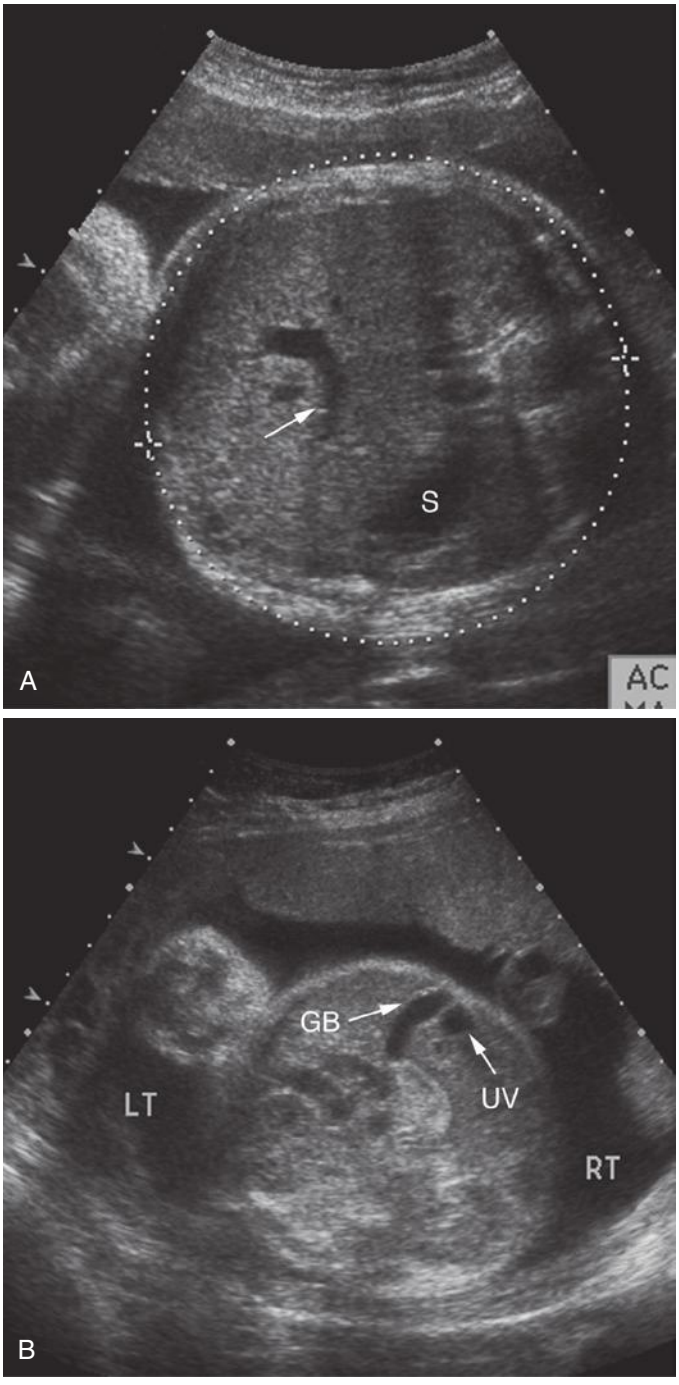

FIG 38-107 Persistent right umbilical vein. **A,** In this transverse axial scan, the portal vein (*arrow*) is curving toward, rather than away from, the stomach (S). This is a case of persistent right umbilical vein. No other anomalies were detected. **B,** In another case of persistent right umbilical vein, the umbilical vein (UV) is to the right rather than the left of the gallbladder (GB).

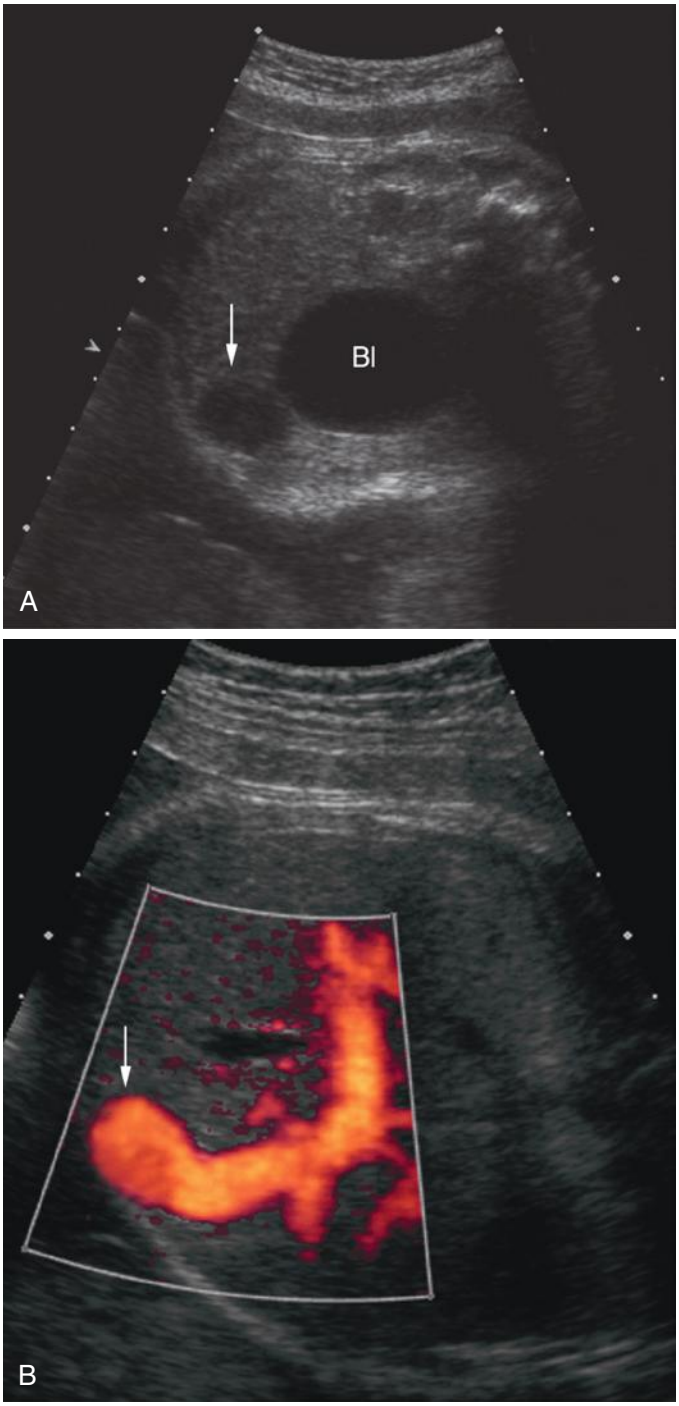

FIG 38-108 Umbilical vein varix. Initially it was thought that the prognosis in cases of umbilical vein varix was uniformly poor. However, if there are no associated abnormalities, most cases do well. **A,** Umbilical vein varix (*arrow*) seen adjacent to the anterior abdominal wall and the urinary bladder (Bl). **B,** Color Doppler imaging of an umbilical vein varix (*arrow*). In neither case were there associated abnormalities, and the outcomes were normal in both cases.

AMNIOTIC FLUID AND MEMBRANES

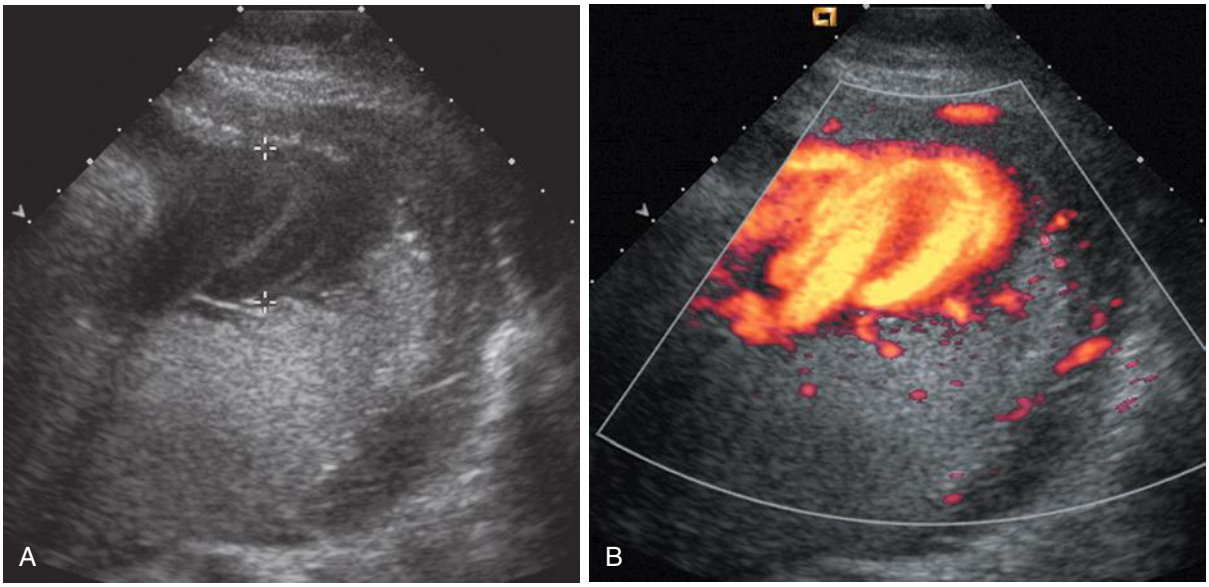

FIG 38-109 When amniotic fluid volume is assessed, the "pocket" of fluid should be free of umbilical cord. **A,** In this patient, there appears to be a 3-cm pocket of amniotic fluid (*calipers*). **B,** Doppler evaluation of this area revealed that this "pocket" was not amniotic fluid but all umbilical cord.

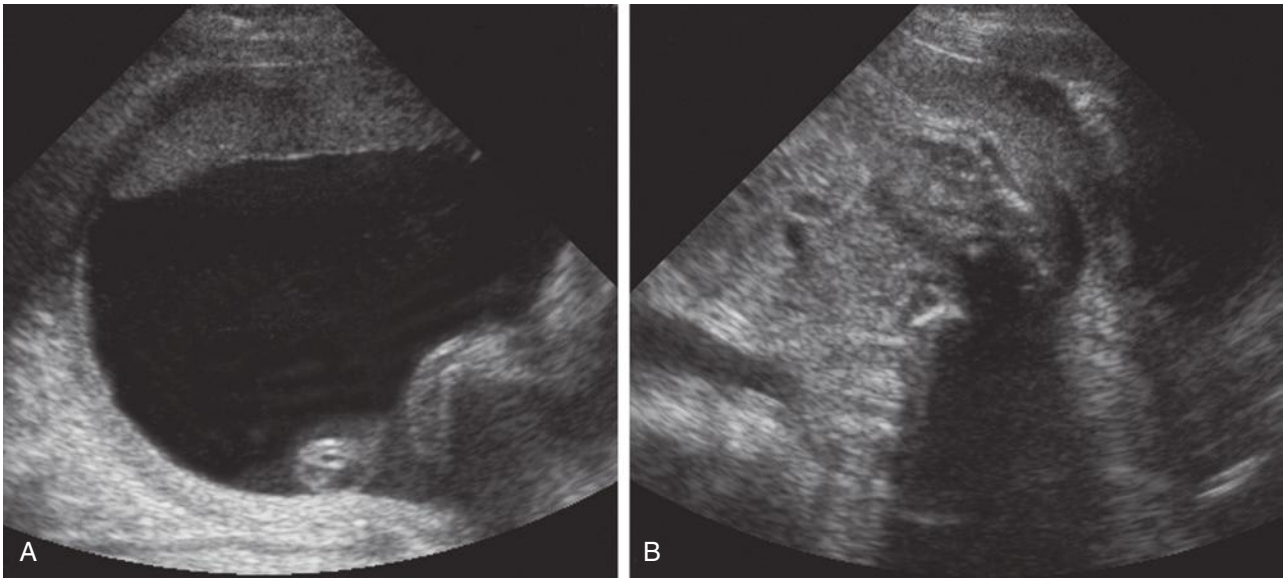

FIG 38-110 **A,** In this scan of a second trimester pregnancy, a large amniotic fluid pocket is seen, suggesting polyhydramnios. **B,** Little amniotic fluid is seen in a scan near the lower portion of the uterus. The total volume of amniotic fluid was normal. Thus, single views of the gravid uterus may be misleading as to the correct volume of amniotic fluid.

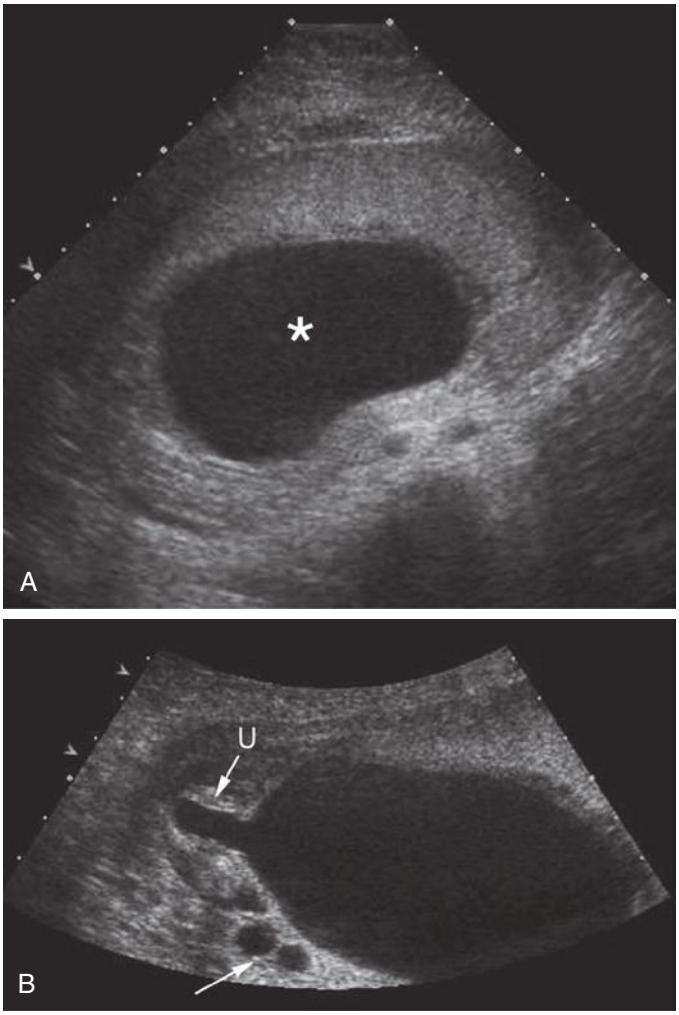

FIG 38-111 **A,** Large fluid collection (*asterisk*) appears to be amniotic fluid; however, it represents a markedly dilated urinary bladder in a patient with posterior urethral valves. In fact, there was virtually no amniotic fluid. **B,** Another sonogram in the same case demonstrates a dilated posterior urethra (U) and dilated ureters (*arrow*) in addition to the dilated urinary bladder.

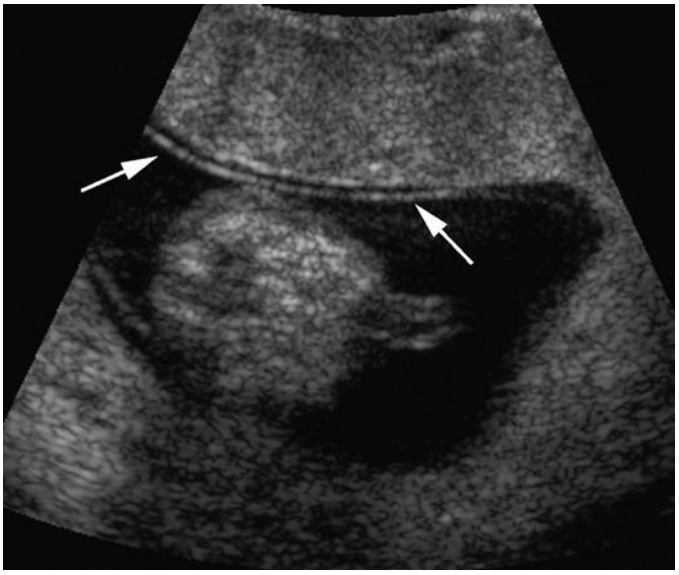

FIG 38-112 In this early second trimester fetus, the amnion (*arrows*) is seen slightly separated from the chorion. This is normal until the 12th to 14th weeks of gestation, at which time the two membranes appose one another.

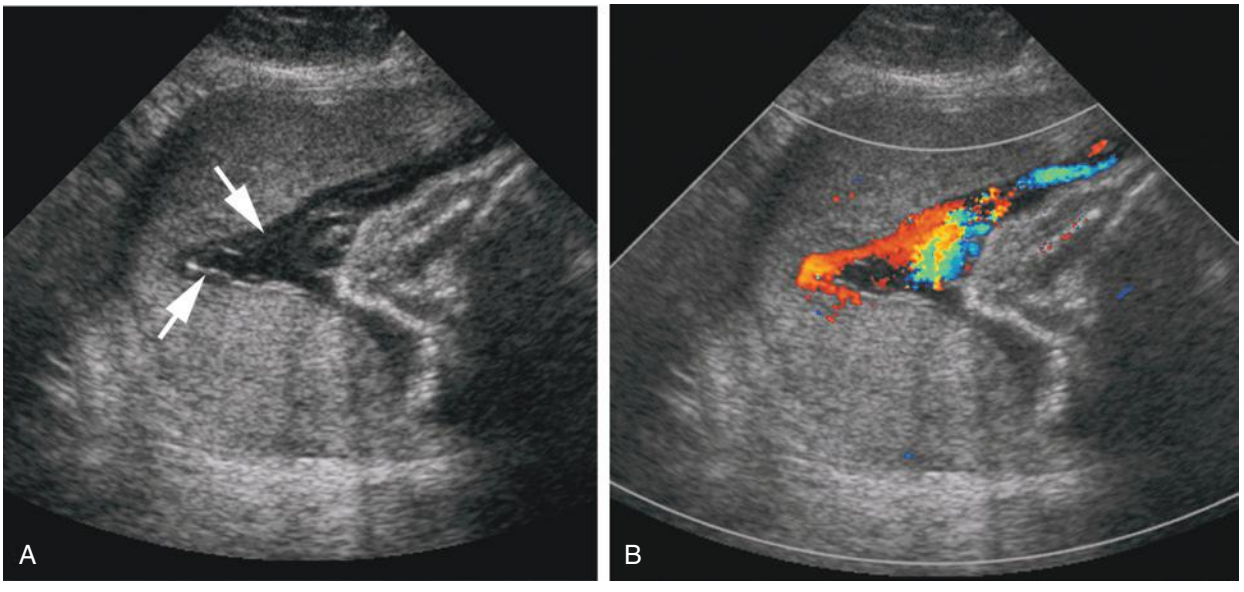

FIG 38-113 Pseudochorioamniotic separation. **A,** Apparent chorioamniotic separation is seen with an unapposed amniotic membrane (*arrows*). **B,** Color Doppler imaging reveals that the structure thought to represent membrane was, in fact, umbilical cord.

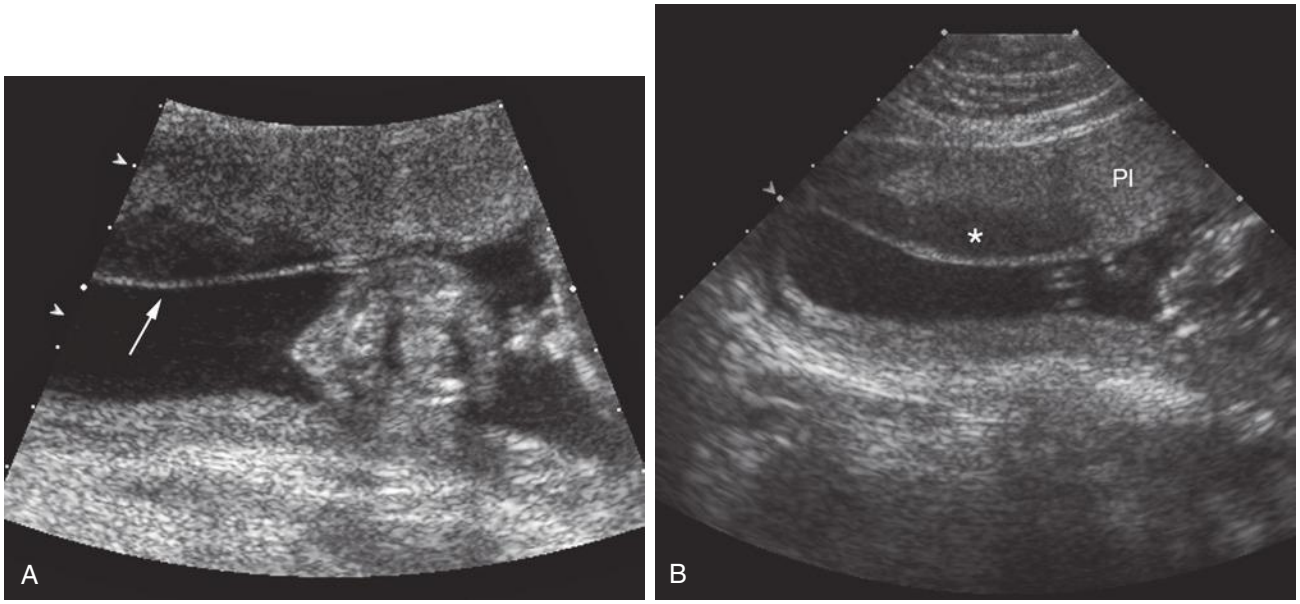

FIG 38-114 **A,** A linear structure (*arrow*) is seen anteriorly adjacent to the fetal head and placenta. It has the appearance of a free-floating amniotic membrane. **B,** With a larger field of view, the membrane is seen to represent the surface of the placenta (Pl), under which is a hypoechoic area (*asterisk*), likely representing a subchorionic plate hematoma.

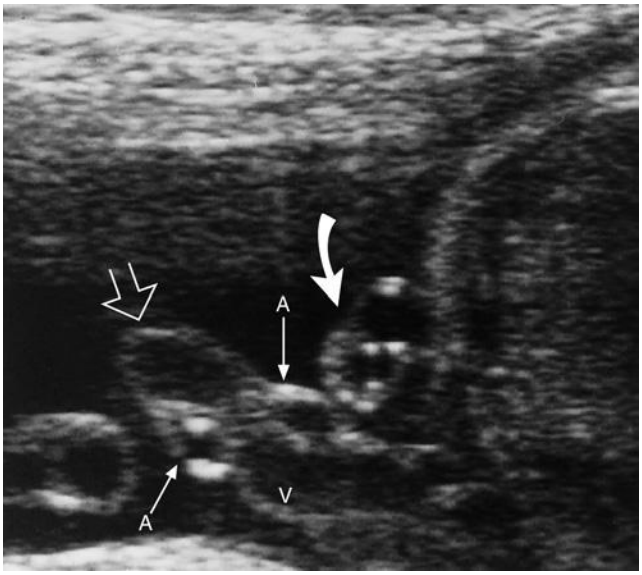

FIG 38-115 A short-axis view of the umbilical cord should always be obtained when attempting to identify the number of vessels. In this case, the long-axis view (*open arrow*) appears to show two umbilical arteries (A) and one vein (V). In the short-axis view (*curved arrow*), the correct interpretation of a single umbilical artery in a two-vessel cord can be made.

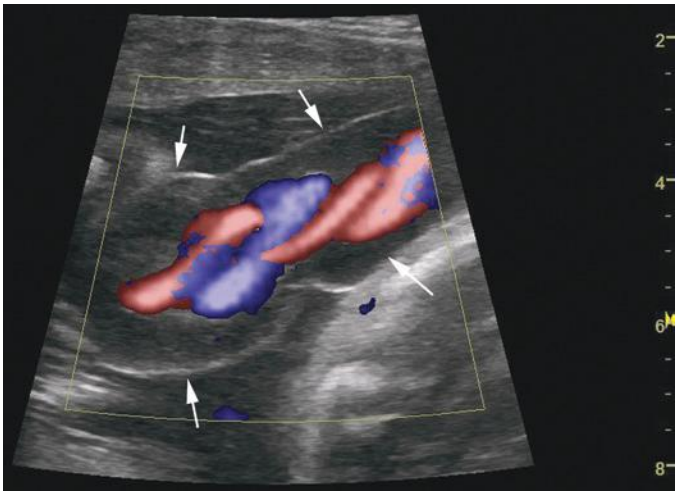

FIG 38-116 Thick umbilical cord. This patient was noted to have a markedly thickened umbilical cord (*arrows*) with prominent Wharton jelly. The fetus was otherwise normal with normal karyotype and no structural abnormalities. Thickened umbilical cords have been associated with gestational diabetes and karyotype abnormalities but can also be a normal finding, as in this case.

THE FETAL SKELETON

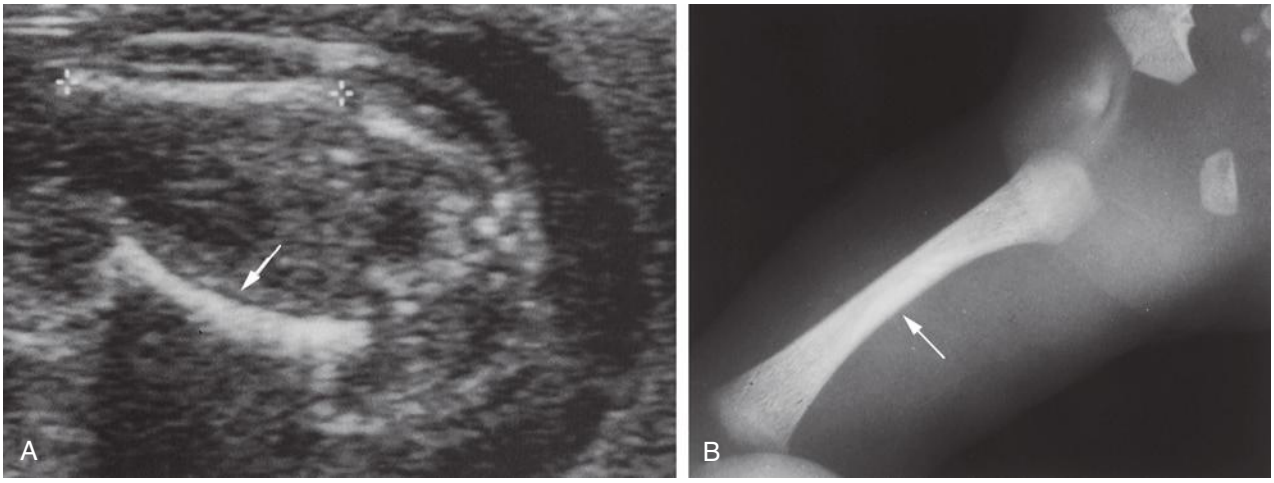

FIG 38-117 **A,** The normal fetal femur has a medial curve to the metadiaphyseal region. This is seen in the femur farthest from the transducer (*arrow*). The femur closest to the transducer (*cursors*) will demonstrate a straight appearance because the lateral aspect is reflecting the sound and the medial aspect is within its shadow. **B,** Radiograph of a normal neonatal femur demonstrating the normal curved appearance of its medial aspect (*arrow*).

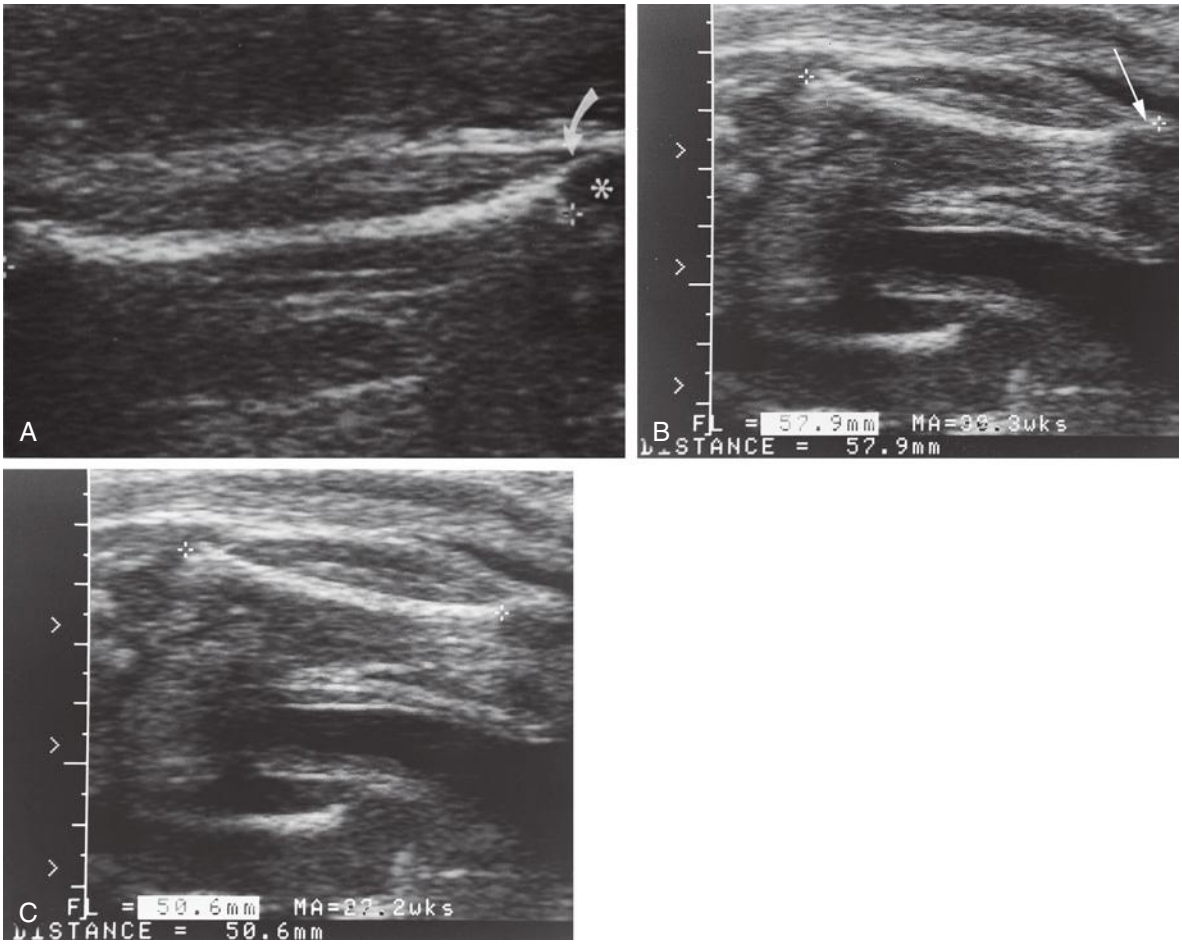

FIG 38-118 Scans of the fetal femur often demonstrate a linear projection from the distal end. **A,** This projection (*arrow*) is a specular reflection from the distal epiphyseal cartilage (*asterisk*). **B,** The measurement of the femur should not include this reflection (*arrow*). **C,** The measurement should include only the calcified bone. Inclusion of this reflection would have overestimated the gestational age by as much as 3 weeks.

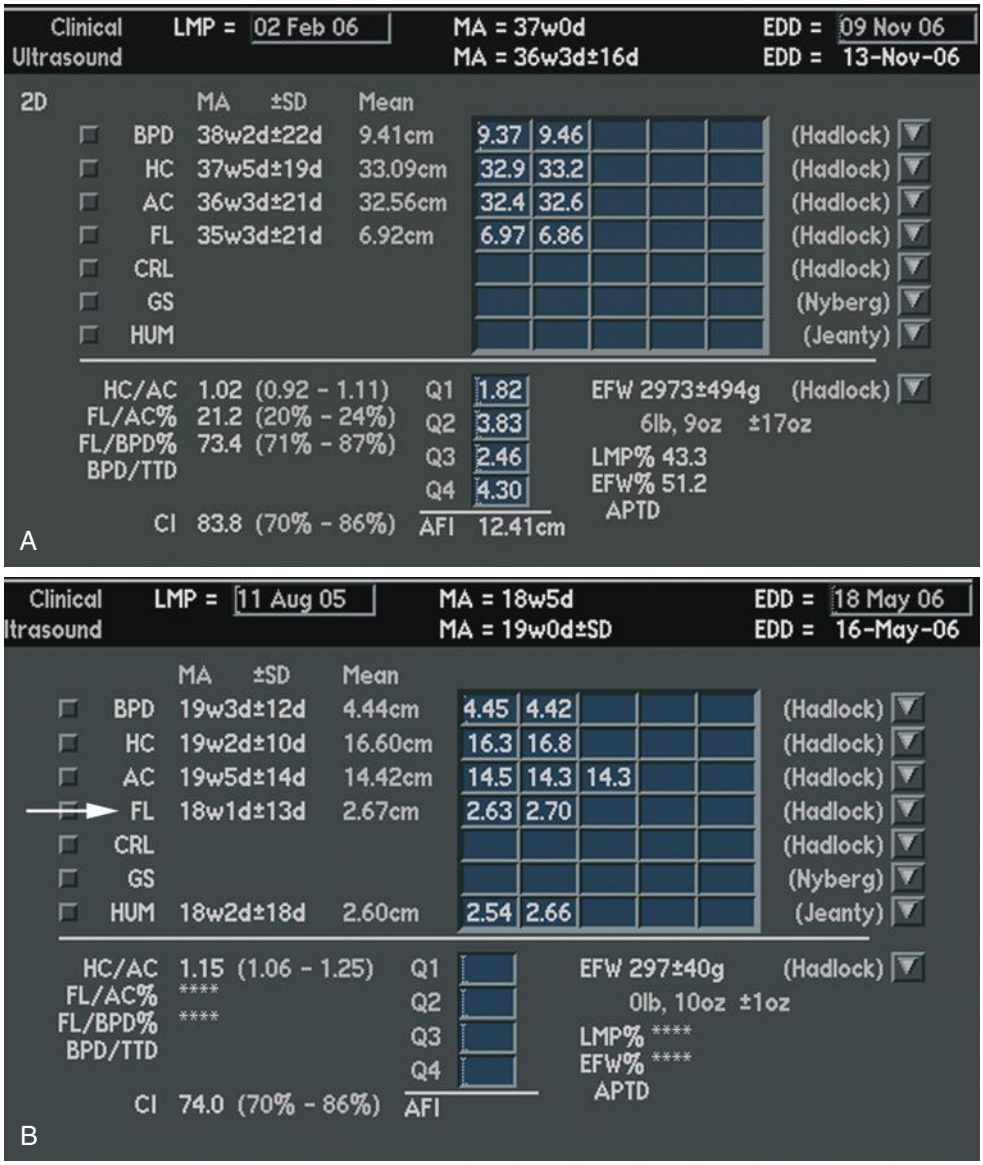

FIG 38-119 Significance of short femoral length. **A,** In the mid to late third trimester, it is not unusual for the femur to be significantly shorter than the other measurements used to estimate gestational age. In this case, the femur is approximately 2 weeks less than the head circumference and menstrual age. The cause of this is uncertain, and the short femur is often attributed to biologic variation or ethnicity. If the bones appear normal morphologically and no anomalies are seen, it is likely a normal variant. This fetus was from white parents of normal height and middle socioeconomic status. **B,** Although the femur can be smaller than other measurements in the third trimester, it is not acceptable for it to be greater than 1 week less than the other measurements in the late first and early to mid second trimesters, as it was in this case (*arrow*). Although this deviation may be nothing more than a temporary growth lag or normal variation at this stage, it may also be a sign of trisomy 21 or an early manifestation of a short-limb skeletal dysplasia. This was a case of trisomy 21. One should not take comfort in comparing the femur measurement to the estimated gestational age by ultrasound imaging. Remember that, unless excluded, the femur measurement is included in the sonographic estimation of gestational age.

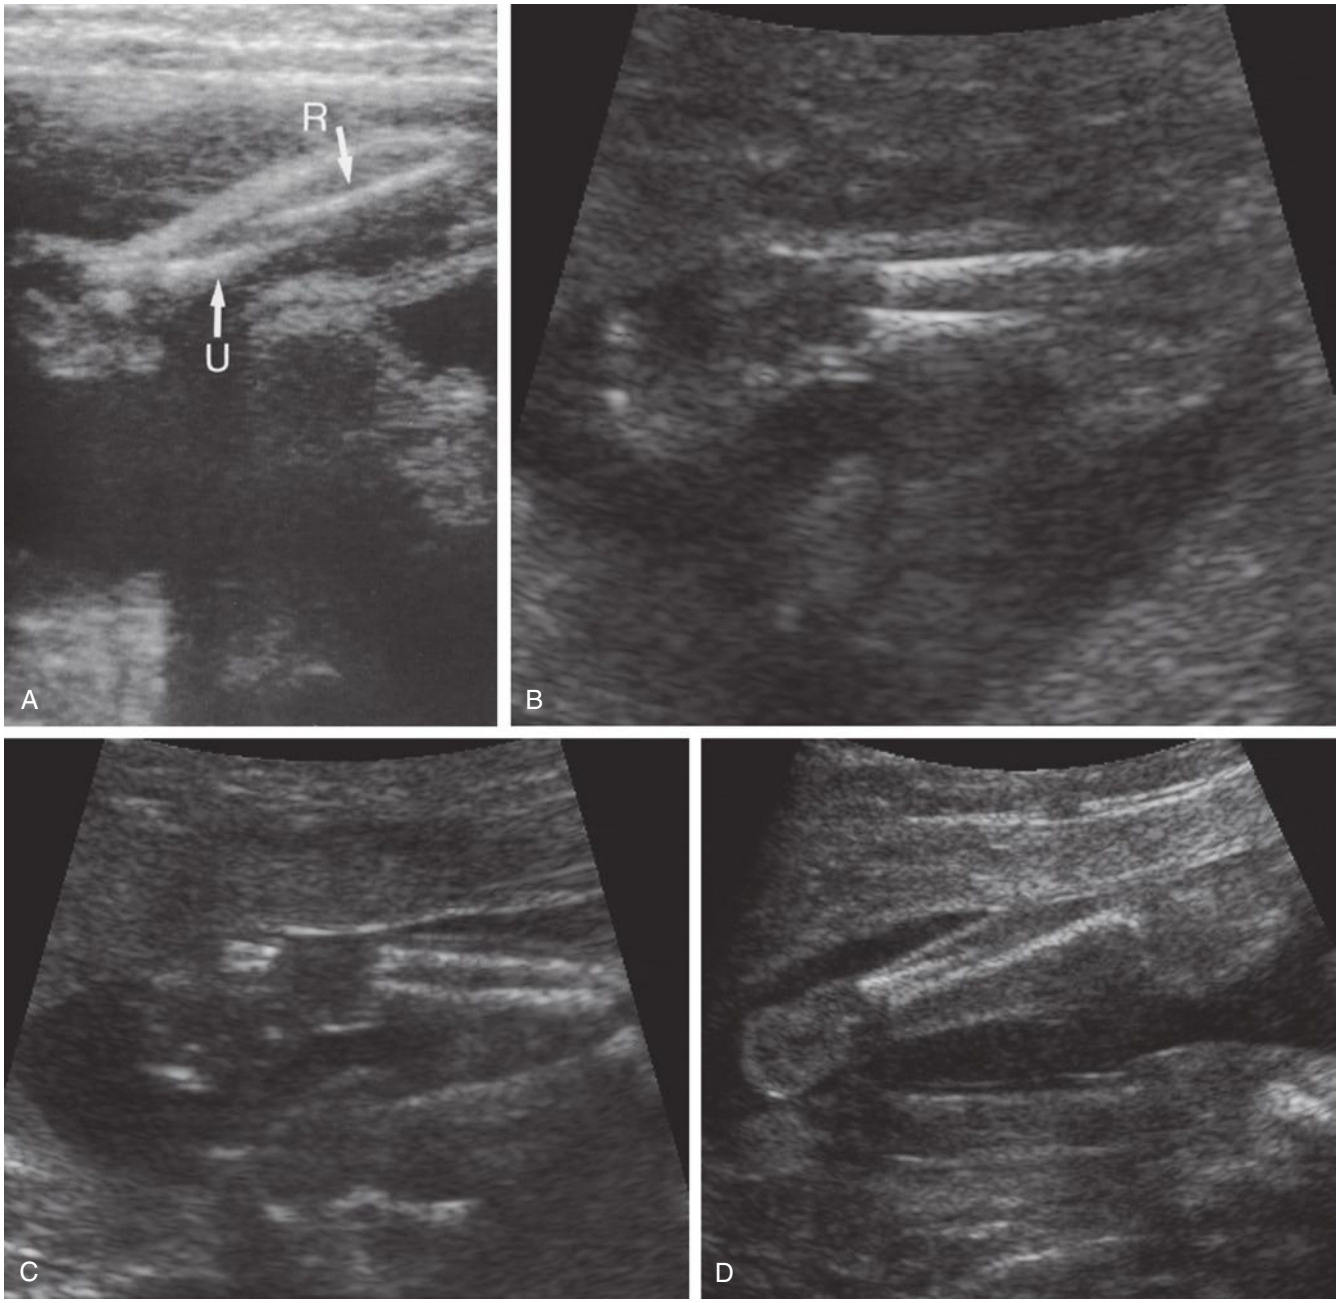

FIG 38-120 Pseudolimb reduction. **A,** Pronation and supination of the forearm may create the appearance that the radius (R) or the ulna (U) is abnormally short (limb reduction abnormality). When both bones are "short" at opposite ends in the same scan, one should be suspicious that this is a technical rather than a real abnormality. **B,** Partial volume of the proximal forearm makes it appear as though the radius and ulna are hypoplastic. **C,** Slight change in transducer angulation reveals that both bones of the forearm are present and normal. **D,** Again, a tomographic plane of section demonstrating only part of the fibula. Both bones of the leg were present and normal.

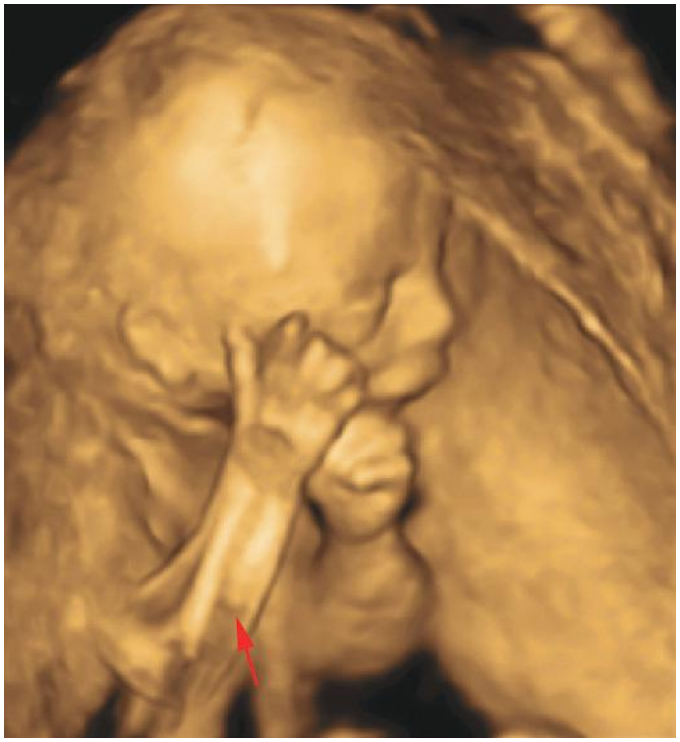

FIG 38-121 Pseudo-ulnar hypoplasia. In this three-dimensional rendered image, it appears that the more proximal portion of the ulna is absent (*arrow*). The remainder of the ulna was out of the plane of imaging and was shown on other views to be present and normal.

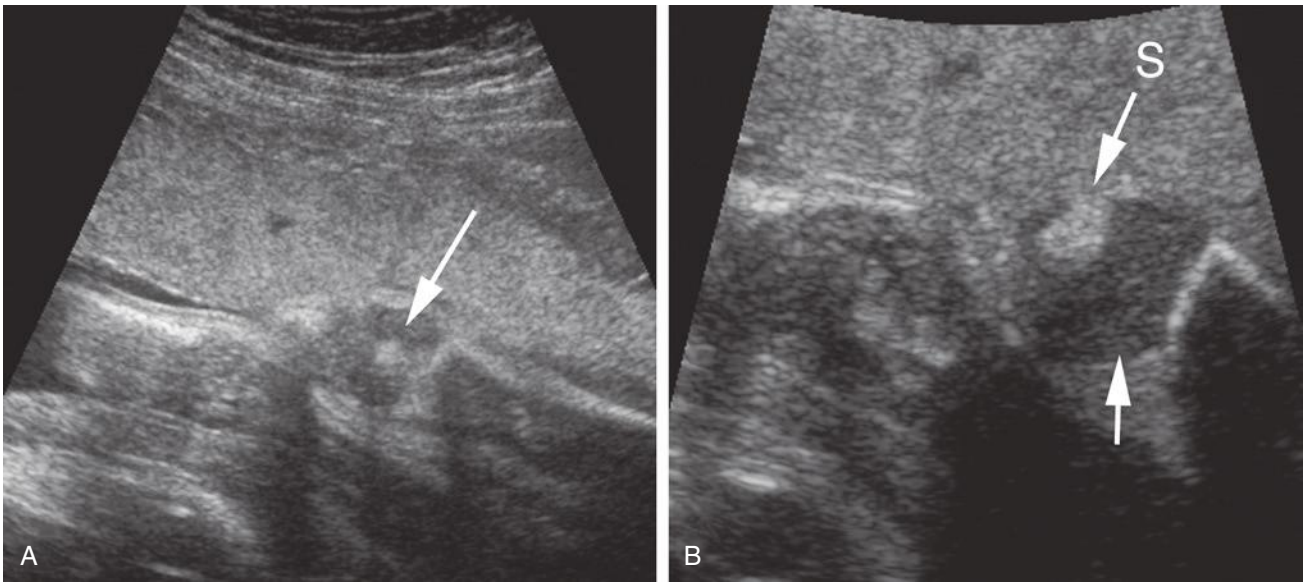

FIG 38-122 The appearance of the epiphyseal ossification centers is helpful in assessing gestational age. **A,** The synovial tissue is echogenic (*arrow*) and may simulate the appearance of one of these centers, as in this case. The real epiphyseal center would be slightly more proximal. **B,** Synovial tissue (S) is well seen in the same case, without evidence of calcification within the epiphyseal center (*arrow*).

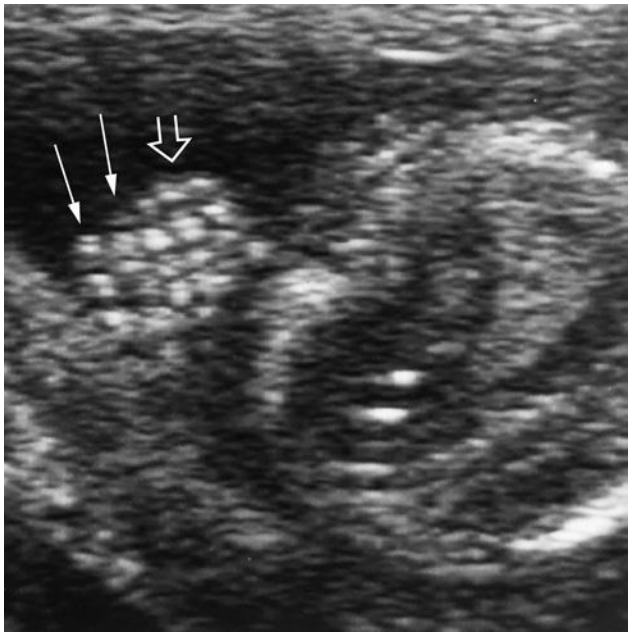

FIG 38-123 In this case, both hands of the fetus are adjacent to one another. The fingers (*arrows*) from one hand and the fingers (*open arrow*) from the other simulate the appearance of polydactyly.

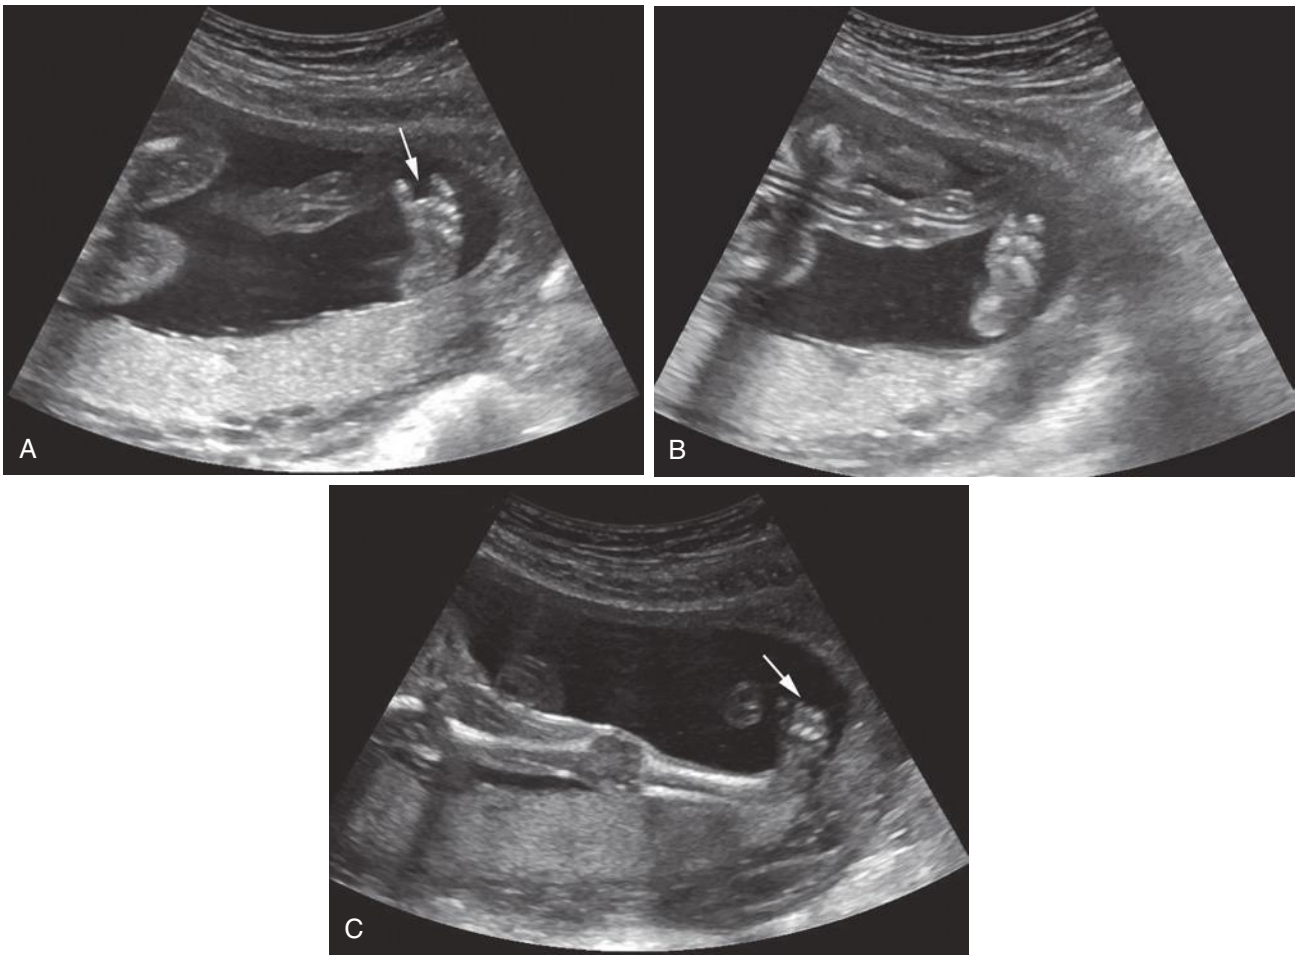

FIG 38-124 Apparent missing digits. **A,** Sonogram of the fetal foot appears to show missing second and third digits (*arrow*). This image may suggest missing toes or may mimic the "sandal gap" deformity. **B,** In the same patient, a scan through the foot with slightly different angulation reveals the presence of the second digit. **C,** In an additional view, all remaining digits of the foot were shown (*arrow*). This is another example in which an abnormality is mimicked because not all portions of a fetal body part are included in the same plane of section in a single image.

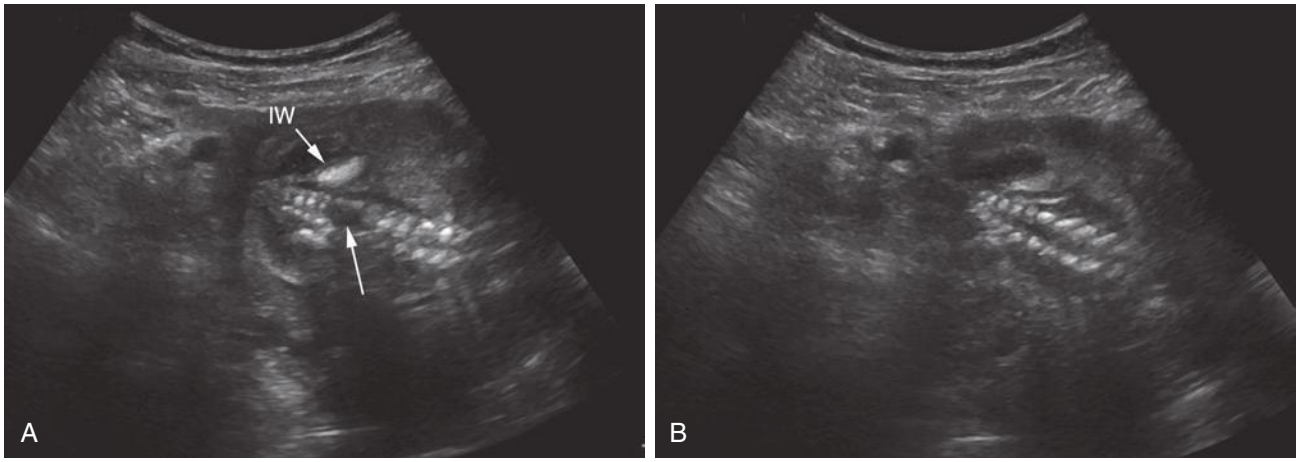

FIG 38-125 Apparent spinal defect. **A,** Coronal sonogram of the distal spine suggests absent spinal segments (*arrow*) as might be seen with spinal bifida. In fact, this appearance is due to shadowing from the overlying iliac wing (IW). **B,** With slightly different angulation and plane of section, the normal distal spine is better visualized and shown to be intact.

MULTIPLE GESTATIONS

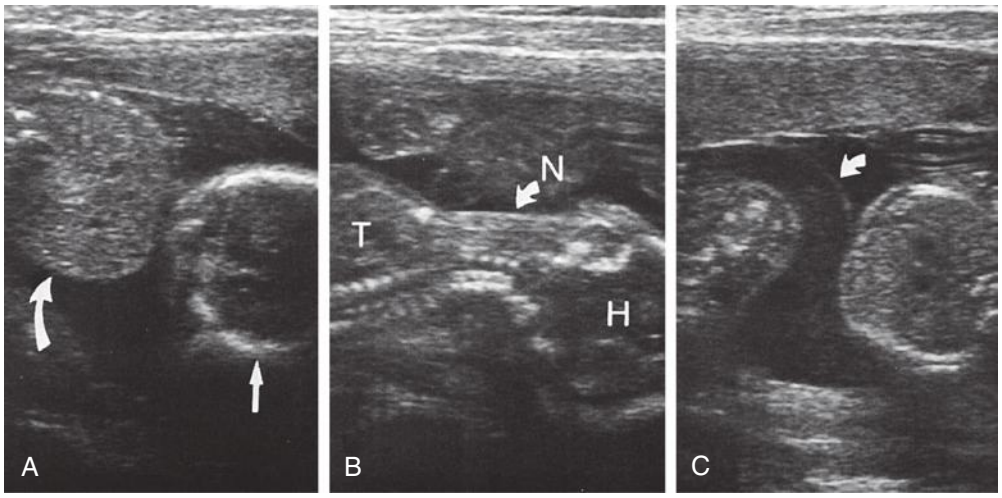

FIG 38-126 The false negative diagnosis of twins is unusual in the second trimester. If this occurs, it likely results from not "connecting" the fetal head to its body during routine scanning. **A,** In this patient, the fetal head (*straight arrow*) and body (*curved arrow*) are seen in this longitudinal plane of section. Unfortunately, these structures are from different fetuses in this twin pregnancy. **B,** The only way to be absolutely sure of the relation of the head (H) to the body is to demonstrate both structures on the same scan connected to one another through the neck (N). T, thorax. **C,** The dividing membrane (*arrow*) is seen on another plane of section clearly dividing the two fetuses.

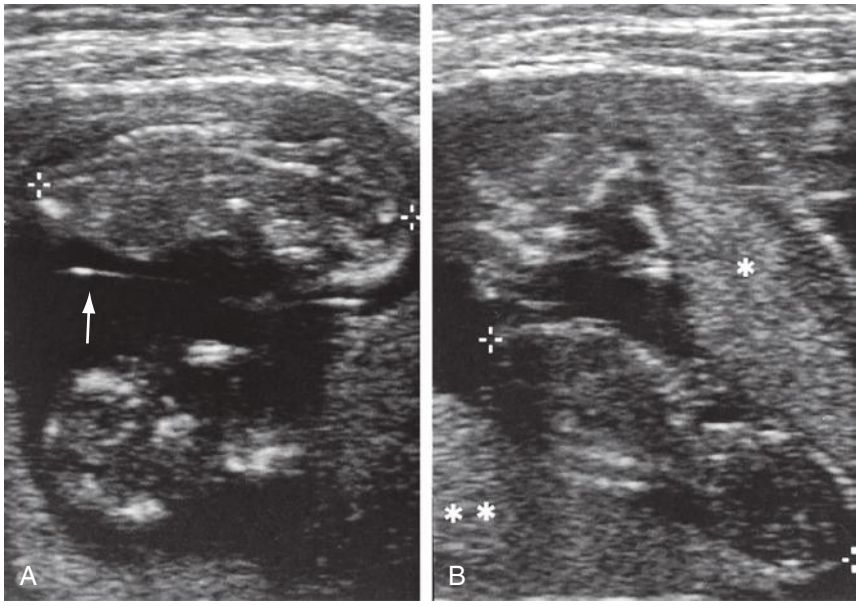

FIG 38-127 Membrane thickness is often useful in differentiating between monochorionic twins (thin membrane) and dichorionic twins (thick membrane). This method is not always successful, however. **A,** In this twin pregnancy, a scan at 14 weeks' gestation demonstrates a thin membrane (*arrow*) dividing the two gestational sacs. This implies monochorionicity. **B,** A longitudinal plane of section at the same time reveals both an anterior placenta (*asterisk*) and a posterior placenta (*double asterisks*).

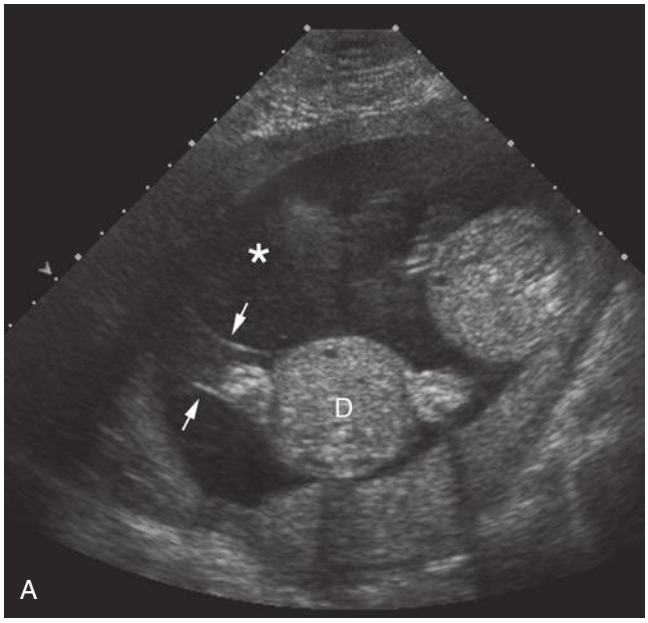
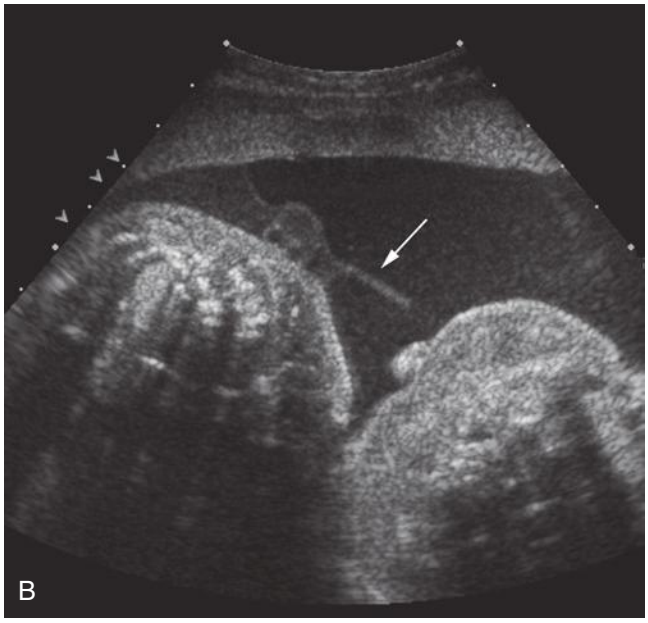
FIG 38-128 In this twin gestation, one of the twins was noted to be fixed to the anterior uterine wall. It was initially assumed that this was a monoamniotic twin gestation. Careful inspection reveals that the membrane (*arrow*) dividing the twins can be seen. The anterior fetus is in an oligohydramniotic sac and is smaller than the other twin. This was a case of twin-to-twin transfusion syndrome.





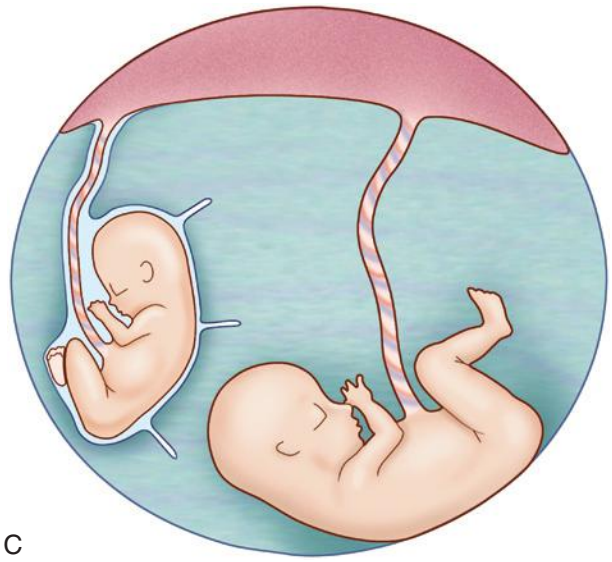


FIG 38-129 **A,** Monochorionic diamniotic twin pregnancy with twin-to-twin transfusion syndrome. Although it appears as if there is a large amount of fluid (*asterisk*) surrounding the donor twin (D), in fact only a small amount of fluid is seen within the surrounding membrane (*arrows*). **B,** Monochorionic diamniotic twin pregnancy with twin-to-twin transfusion syndrome. Membrane surrounds the donor twin in an oligohydramniotic sac. The membrane has a free edge (*arrow*) projecting into the amniotic fluid surrounding the recipient twin. **C,** Drawing demonstrating the collapsed membrane surrounding the donor twin in an oligohydramniotic sac, similar to what is seen in B.

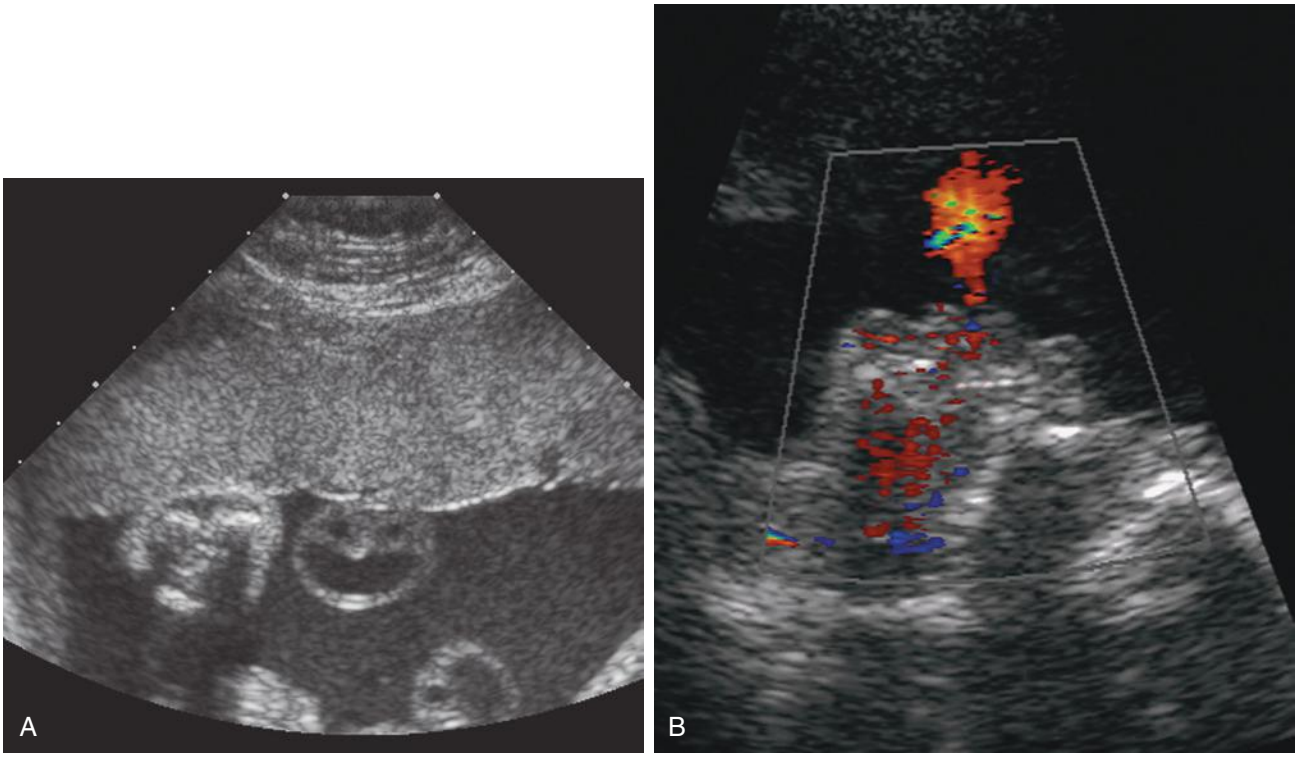

FIG 38-130 After viewing so many artifacts, pitfalls, and normal variants, you wonder whether: **A,** The umibilical cord is smiling back at you. **B,** The fetus is blowing bubbles.

APPENDIX A

Measurements Frequently Used to Estimate Gestational Age and Fetal Biometry

TABLE A-1 Methods for Determining Menstrual Age

Clinical or Sonographic Parameter	Variability Estimate (2 SD)
In vitro fertilization*	±1 day
Ovulation induction*	±3 days
Artificial insemination*	±3 days
Single intercourse record*	±3 days
Basal body temperature record*	±4 days
First trimester physical examination	±2 weeks
Second trimester physical examination	±4 weeks
Third trimester physical examination	±6 weeks
First trimester sonographic examination (CRL)	±8% of the estimate
Second trimester sonographic examination (HC, FL)	±8% of the estimate
Third trimester sonographic examination (HC, FL)	±8% of the estimate

CRL, crown-rump length; FL, femur length; HC, head circumference.
*Indicators of conceptual age (menstrual age = conceptual age + 14 days).
Adapted from Frank P. Hadlock, MD, and James D. Bowie, MD.

TABLE A-2 Normal Transvaginal Sonographic Findings in the Early First Trimester

Gestational Age (wk)	Structure First Appears on Ultrasound*	Mean Sac Diameter (mm)[8]	Crown-Rump Length (mm)[10]
5.0	Gestational sac	2	—
5.5	Yolk sac	6	—
6.0	Embryo with heartbeat	10	3
6.5		14	6
7.0	Amnion	18	10
7.5		22	13
8.0		26	16

*±0.5 week age range for first visibility of each structure.
Superscript numbers in table indicate references at the end of Chapter 4.

TABLE A-3 Approach to Gestational Age Assignment by Ultrasound on Initial Scan

Stage of Pregnancy	Basis for GA	Accuracy (wks)*
First Trimester		
Early (5-6 weeks)	Sonographic milestones	±0.5
	or MSD	±0.5
Mid to late (6-13 weeks)	CRL	±0.5-1.0
Second Trimester		
If OFD measurable	BPDc or HC	±1.2 (14-20 wks)
		±1.9 (20-26 wks)
If OFD not measurable	BPD or FL	±1.4 (14-20 wks)
		±2.1-2.5 (20-26 wks)
Third Trimester		
If OFD measurable	BPDc, HC, or FL	±3.1-3.4 (26-32 wks)
		±3.5-3.8 (32-42 wks)
If OFD not measurable	FL	±3.1 (26-32 wks)
		±3.5 (36-42 wks)

*Two standard deviations, or 95% confidence interval.
BPD, biparietal diameter; BPDc, corrected BPD; CRL, crown-rump length; FL, femur length; HC, head circumference; MSD, mean sac diameter; OFD, occipitofrontal diameter.

TABLE A-4 Variability in Predicting Menstrual Age From Sonographic Measurements (14-20 Weeks)

	VARIABILITY (2 SD)			
Parameter	Hadlock et al*	Rossavik and Fishburne†	Persson and Weldner‡	Benson and Doubilet§
BPD	0.94 wk	1.02 wk	0.92 wk	1.40 wk
HC	0.84 wk	0.92 wk	ND	1.20 wk
AC	1.04 wk	1.12 wk	ND	2.10 wk
FL	0.96 wk	ND	0.98 wk	1.40 wk
BPD, FL	0.80 wk	ND	0.78 wk	ND
HC, FL	0.76 wk	ND	ND	ND

AC, abdominal circumference; BPD, biparietal diameter; FL, femur length; HC, head circumference; ND, no data.

TABLE A-8 Combined Data Comparing Menstrual Age With Mean Gestational Sac Diameter, Crown-Rump Length, and hCG Levels*

Menstrual Age (days)	Menstrual Age (wk)	Gestational Sac Size (mm)	Crown-Rump Length (cm)	HCG LEVEL (FIRST IRP)	
				Mean (U/L)	Range (U/L)
30	4.3				
31	4.4				
32	4.6	3		1710	(1050-2800)
33	4.7	4		2320	(1440-3760)
34	4.9	5		3100	(1940-4980)
35	5.0	5.5		4090	(2580-6530)
36	5.1	6		5340	(3400-8450)
37	5.3	7		6880	(4420-10,810)
38	5.4	8		8770	(5680-13,660)
39	5.6	9		11,040	(7220-17,050)
40	5.7	10	0.2	13,730	(9050-21,040)
41	5.9	11	0.3	15,300	(10,140-23,340)
42	6.0	12	0.35	16,870	(11,230-25,640)
43	6.1	13	0.4	20,480	(13,750-30,880)
44	6.3	14	0.5	24,560	(16,650-36,750)
45	6.4	15	0.6	29,110	(19,910-43,220)
46	6.6	16	0.7	34,100	(25,530-50,210)
47	6.7	17	0.8	39,460	(27,470-57,640)
48	6.9	18	0.9	45,120	(31,700-65,380)
49	7.0	19	0.95	50,970	(36,130-73,280)
50	7.1	20	1.0	56,900	(40,700-81,150)
51	7.3	21	1.1	62,760	(45,300-88,790)
52	7.4	22	1.2	68,390	(49,810-95,990)

TABLE A-24 Predicted Menstrual Ages for Transverse Cerebellar Diameters of 14 to 56 mm

Cerebellum Diameter (mm)	Menstrual Age (wk)	Cerebellum Diameter (mm)	Menstrual Age (wk)
14	15.2	35	29.4
15	15.8	36	30.8
16	16.5	37	30.6
17	17.2	38	31.2
18	17.9	39	31.8
19	18.6	40	32.3
20	19.3	41	32.8
21	20.0	42	33.4
22	20.7	43	33.9
23	21.4	44	34.4
24	22.1	45	34.8
25	22.8	46	35.3
26	23.5	47	35.7
27	24.2	48	36.1
28	24.9	49	36.5
29	25.5	50	36.8
30	26.2	51	37.2
31	26.9	52	37.5
32	27.5	54	38.0
33	28.1	55	38.3
34	28.8	56	38.5

VARIABILITY ESTIMATES (±2 SD)	
12-18 wk	±1.0 wk
18-24 wk	±1.8 wk
24-30 wk	±2.0 wk
30-36 wk	±2.4 wk
36-42 wk	±3.2 wk

TABLE B-1 Equations for the Estimation of Fetal Weight—cont'd

Source	Year	Equation
AC/HC/BPD/± FL Equations		
Jordaan	1983	Log_{10} EFW = 2.3231 + 0.02904 (AC) + 0.0079 (HC) 0.0058 (BPD)
Hadlock et al	1985	Log_{10} EFW = 1.3596 + 0.0064 (HC) + 0.0424 (AC) + 0.174 (FL) + 0.00061 (BPD) (AC) – 0.00386 (AC) (FL)
Maternal Characteristics Equation		
Nahum et al[‡]	2002	EFW = Gestational age (d) × (9.38 = 0.264 × fetal sex[§] + 0.000233 × maternal height [cm] × maternal weight at 26.0 wks [kg] + 4.62 × third-trimester maternal weight gain rate [kg/d] × [parity + 1])[¶]

AC, abdominal circumference; BPD, biparietal diameter; EFW, estimated fetal weight (expressed in grams); FL, fetal length; HC, head circumference; Ln, natural logarithm.

AC, FL, BPD, and HC are expressed in centimeters.

*The estimated fetal weight for these six algorithms is expressed in kilograms rather than grams.

[†]The equation of Shinozuka et al has been modified from its original form to include the fetal AC instead of the fetal transverse and anteroposterior abdominal diameters, as were described in the original equation. (Shinozuka N, Okai T, Kohzuma S, et al: Formulas for fetal weight estimation by ultrasound measurements based on neonatal specific gravities and volumes. J Obstet Gynecol 157:1140, 1987; Combs CA, Jaekle RK, Rosenn B, et al: Sonographic estimation of fetal weight based on a model of fetal volume. Obstet Gynecol 82:365, 1993.)

[‡]This equation applies only to healthy white mothers who carry term singleton pregnancies. Fetal weight estimates that use this equation should be adjusted systematically for (1) black maternal race (decrement by 161 g), (2) East Asian maternal race (decrement by 291 g), (3) chronic hypertension (decrement by 161 g), (4) pregnancy-induced hypertension/preeclampsia (decrement by 105 g), (5) maternal cigarette smoking (decrement by 17 g per cigarettes smoked per day), and (6) high altitude (decrement by 102 g for every 1000 m in altitude above sea level).

[§]Fetal sex independently explains approximately 1% of the variance in term fetal weight. It is a significant predictor of birth weight (F test, $P < 0.001$), but it has little overall impact in birth weight predictions. When 0 is entered for fetal sex so that sex is ignored, the mean absolute prediction error does not change, and the median absolute prediction error increases only slightly by 10 g (0.2%). Thus, fetal sex, although potentially useful if available, is nonessential for use of the maternal characteristics equation.

[¶]Where fetal sex = +1 for male, –1 for female, and 0 when sex is not known; gestational age = days since the onset of the last normal period = the conception age (in days) + 14. (Nahum GG, Stanislaw H: Ultrasonographic prediction of term birth weight: how accurate is it? Am J Obstet Gynecol 188:566, 2003.)

39	78.3	80.8	22.2	22.3
40	78.3	81.0	22.4	22.4

AC, abdominal circumference; BPD, biparietal diameter; HC, head circumference; SD, standard deviation.
*Data from Hadlock FP, Deter RL, Carpenter RJ, et al: The effect of head shape on the accuracy of BPD in estimating fetal gestational age. AJR 137:83, 1981.
†Data from Hohler CW, Quetel TA: The relationship between fetal femur length and biparietal diameter in the last half of pregnancy. Am J Obstet Gynecol 141:759, 1981.
‡Data from Hadlock FP, Harrist RB, Shah YP, et al: The use of femur length/head circumference relation in obstetrical sonography. J Ultrasound Med 3:439, 1984.
§Data from Hadlock FP, Deter RL, Harrist RB, et al: A date-independent predictor of intrauterine growth retardation: femur length/abdominal circumference ratio. AJR 141:979, 1983.

TABLE B-13 Comparison of Fetal Parameters in LGA and AGA Fetuses

Parameter	AGA Group (mean ± SD)	LGA Group (mean ± SD)	*P* Value
BPD (cm)	9.2 ± 0.4	9.6 ± 0.4	<.0001
HC (cm)	33.7 ± 1.1	35.2 ± 1.3	<.0001
AC (cm)	33.6 ± 1.6	37.4 ± 1.3	<.0001
FL (cm)	7.4 ± 0.4	7.6 ± 0.3	<.0001
HC/AC	1.0 ± 0.05	0.94 ± 0.04	<.0001
FL/AC*	22.0 ± 1.0	20.5 ± 1.0	<.0001

AC, abdominal circumference; AGA, appropriate for gestational age; BPD, biparietal diameter; FL, femur length; HC, head circumference; LGA, large for gestational age.
*FL/AC expressed as FL/AC × 100.
From Hadlock FP, Harrist RB, Fearneyhough TC, et al: Use of femur length/abdominal circumference ratio in detecting the macrosomic fetus. Radiology 154:503, 1985.

TABLE B-14 Conventional Sonographic Criteria for Fetal Growth Restriction: Performance Characteristics

Criterion	Sensitivity (%)*	Specificity (%)*	PREDICTIVE VALUES (%)*†	
			Positive	Negative
Advanced placental grade	62	64	16	94
Elevated FL/AC	34-49	78-83	18-20	92-93
Low TIUV	57-80	72-76	21-24	92-97
Small BPD	24-88	62-94	21-44	92-98
Small BPD and advanced placental grade	59	86	32	95
Slow rate of BPD growth	75	84	35	97
Low EFW	89	88	45	99
Decreased AFV	24	98	55	92
Elevated HC/AC	82	94	62	98

AFV, amniotic fluid volume; BPD, biparietal diameter; EFW, estimated fetal weight; FL/AC, femur length/abdominal circumference ratio; HC/AC, head circumference/abdominal circumference ratio; TIUV, total intrauterine volume.
*A range of values is given for a criterion when different studies apply that criterion in two or more ways.
†Computed using Bayes' theorem and assuming a fetal growth restriction prevalence rate of 10%.
From Benson CB, Doubilet PM, Saltzman DH: Intrauterine growth retardation: predictive value of US criteria for antenatal diagnosis. Radiology 160:415, 1986.

Measurements for Amniotic Fluid Assessment

39	1.288	2.118	2.948
40	1.285	2.115	2.945

From Baschat AA: Relationship between placental blood flow resistance and precordial venous Doppler indices. Ultrasound Obstet Gynecol 22:561, 2003.

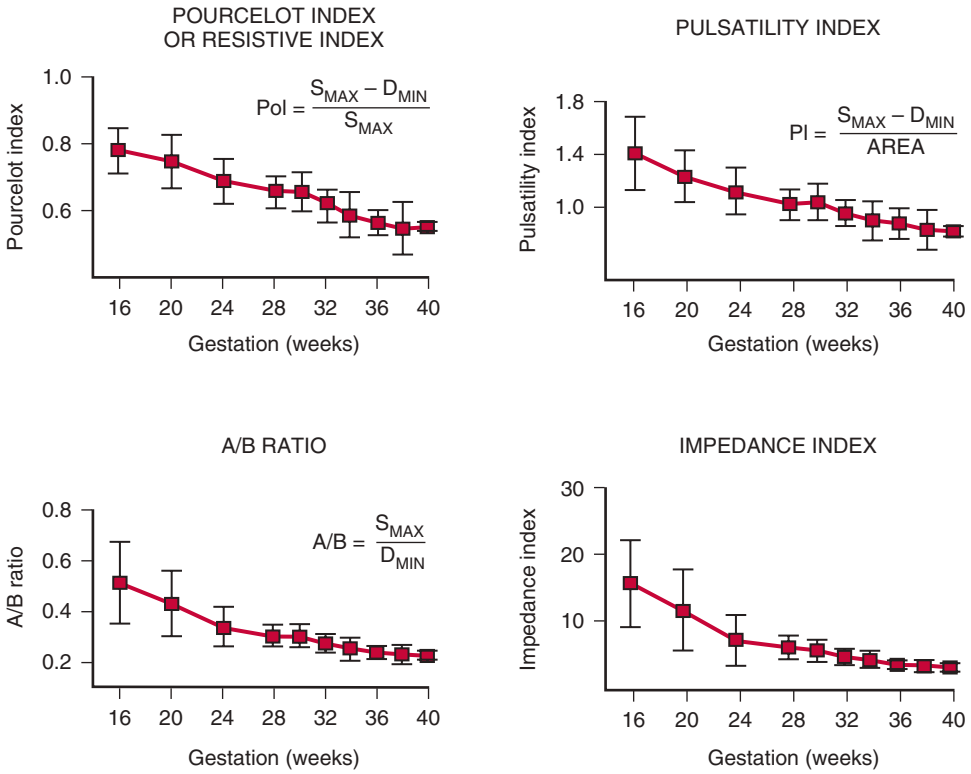

FIG D-1 Doppler waveform analysis of the fetal umbilical artery. With advancing gestation and increasing compliance of the placenta, there is a progressive decrease in the systolic/diastolic ratio (A/B ratio), Pourcelot index (PoI), and pulsatility index (PI) of the umbilical artery that is a result of increased placental flow owing to decreased resistance. (Modified from Erskine RLA, Ritchie JWK: Umbilical artery blood flow characteristics in normal and growth retarded fetuses. Br J Obstet Gynecol 92:605, 1985.)

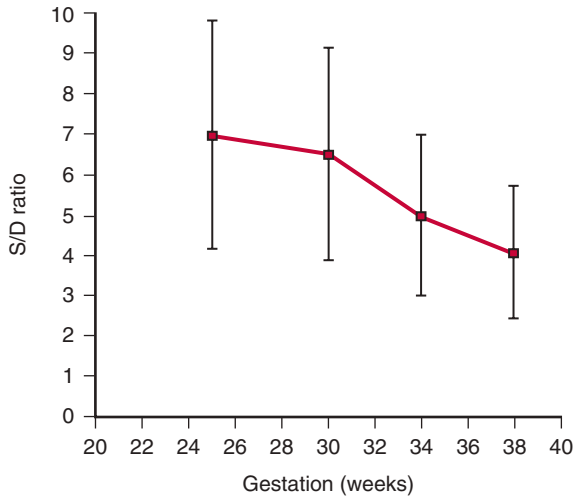

FIG D-2 Middle cerebral artery Doppler systolic/diastolic (S/D) ratios. (Modified from Woo JSK, Liang ST, Lo RL, Chan FY: Middle cerebral artery Doppler flow velocity waveforms. Obstet Gynecol 70:613, 1987. Reprinted with permission from the American College of Obstetricians and Gynecologists.)

APPENDIX E

Doppler of the Middle Cerebral Artery to Assess Fetal Anemia

TABLE E-1 Threshold of Peak Velocity of Systolic Blood Flow in the Middle Cerebral Artery Above Which Mild, Moderate, and Severe Anemia Occurs

	THRESHOLD OF PEAK VELOCITY OF MIDDLE CEREBRAL ARTERY (cm/sec) ABOVE WHICH DEGREE OF ANEMIA IS CLASSIFIED			
Gestation (wk)	1.00 (Median)	Mild Anemia (1.29 MoM)	Moderate Anemia (1.50 MoM)	Severe Anemia (1.55 MoM)
18	23.2	29.9	34.8	36.0
20	25.5	32.8	38.2	39.5
22	27.9	36.0	41.9	43.3
24	30.7	39.5	46.0	47.5
26	33.6	43.3	50.4	52.1
28	36.9	47.6	55.4	57.2
30	40.5	52.2	60.7	62.8
32	44.4	57.3	66.6	68.9
34	48.7	62.9	73.1	75.6
36	53.5	69.0	80.2	82.9
38	58.7	75.7	88.0	91.0
40	64.4	83.0	96.6	99.8

MoM, multiple of median.

From Mari G, Deter RL, Carpenter RL, et al: Non-invasive diagnosis by Doppler ultrasonography of fetal anemia due to maternal red-cell alloimmunization. Collaborative Group for Doppler Assessment of the Blood Velocity in Anemic Fetuses. N Engl J Med 342:9, 2000.

Retinoblastoma	13q14.2	1/15,000-1/20,000

APPENDIX H

Medications and Reported Associated Malformations

TABLE H-1 Selected Medications and Reported Associated Malformations*

Drug	Malformation(s)
Acetazolamide	Sacrococcygeal teratoma
Acyclovir	CDH, neural tube defect, cleft lip, clubfoot, transposition
Alprazolam	Umbilical hernia, clubfoot
Albuterol	Cleft palate, cranioschisis, cardiovascular defect, spina bifida, polydactyly, fetal tachycardia
Amantadine	Cardiac defects
Aminopterin	Neural tube defects, hydrocephalus, limb shortening, cleft lip/palate, clubfoot
p-Aminosalicylic acid	Ear deformity, limb deformity, hypospadias
Amiodarone	FGR, ventricular septal defect, micrognathia
Amitriptyline	Limb reduction, micrognathia, hypospadias, cleft palate, thanatophoric dysplasia
Ampicillin	Transposition of the great vessels
Amobarbital	Anencephaly, cardiac defects, limb deformity, cleft lip/palate, polydactyly, genitourinary defects, clubfoot
Amphetamine	Cerebral injury in neonates
Aspirin	Intracranial hemorrhage, FGR
Atenolol	Hypospadias, cardiovascular defects
Atropine	Polydactyly, limb reduction
Azatadine	Oral cleft, limb reduction
Baclofen	Spina bifida
Belladonna	Eye/ear malformations, hypospadias
Benztropine	Cardiovascular defects
Bromides	Polydactyly, gastrointestinal anomalies, clubfoot, FGR
Busulfan	FGR, cleft palate, neural tube defects
Captopril	Second-trimester hypocalvaria, oligohydramnios, renal dysfunction
Carbamazepine	Neural tube defects, cardiac defects
Carisoprodol	Oral clefts
Cephalexin	Cardiovascular defects, oral clefts
Cephradine	Cardiovascular defects
Chlorambucil	Renal agenesis, cardiac defects
Chlordiazepoxide	Microcephaly, duodenal atresia, cardiac defects
Chloroquine	Wilms tumor, hemihypertrophy, tetralogy of Fallot
Chlorothiazide	Fetal bradycardia
Chlorpheniramine	Polydactyly, gastrointestinal defects, hydrocephalus
Chlorpromazine	Microcephaly, syndactyly
Chlorpropamide	Microcephaly, hand anomalies
Ciprofloxacin	Hypospadias, cerebellar hypoplasia, cardiovascular defect, femoral aplasia
Clarithromycin	Craniofacial abnormalities, absent clavicles, spina bifida, cleft lip, pulmonary hypoplasia; coloboma, heart anomaly, choanal atresia, retardation (mental and somatic), genital and ear anomalies (CHARGE) association
Clomiphene	Microcephaly, neural tube defects, cleft lip/palate, cardiac defects, syndactyly, clubfoot, hypospadias
Clonazepam	Cardiovascular defects
Clorazepate	Bifid foot, absent scrotum, short femur, absent fibula, absent metacarpal bones, renal agenesis
Cloxacillin	Cardiovascular defects
Cocaine	Spontaneous abortion, placental abruption, cardiac defects, urinary tract and limb abnormalities, bowel atresias, FGR
Codeine	Pulmonary and genitourinary defects, hydrocephalus, cleft lip/palate
Colchicine	Cardiac malformation, syndactyly, cleft palate
Cortisone	Cataracts, cyclopia, VSD, coarctation of the aorta, clubfoot, cleft lip, gastroschisis
Coumarin derivatives	Spontaneous abortion, FGR, neural tube defects (open and closed) (dorsal midline dysplasia), cardiac defects, scoliosis, limb hypoplasia, cleft palate

Continued

TABLE H-1 Selected Medications and Reported Associated Malformations*—cont'd

Drug	Malformation(s)
Cyclophosphamide	Cleft palate, hand abnormalities, cardiac defects, FGR
Cyclosporine	Limb hypoplasia, agenesis of the corpus callosum, anencephaly, FGR
Cyproheptadine	Cleft lip/palate, hypospadias
Cytarabine	Hand abnormalities (lobster claw deformity), lower limb defects, neural tube defects, cardiac defects
Dacarbazine	Limb reduction defects, cleft palate, encephalocele
Danazol	Ambiguous genitalia
Daunorubicin	FGR
Dexfenfluramine	Hand malformation, anencephaly, vertebral abnormality
Diazepam	Cleft lip/palate, cardiac defects
Dicyclomine	Polydactyly
Dilantin	Microcephaly, hypertelorism, cleft lip/palate, hypoplasia of distal phalanges, short neck, broad nasal ridge
Diltiazem	Cardiovascular defects
Dimenhydrinate	Cardiovascular defects
Diphenhydramine	Cleft lip/palate, genitourinary defects, clubfoot, cardiac defects
Disulfiram	Clubfoot, vertebral defects, anal atresia, cardiac anomalies, tracheoesophageal fistula with esophageal atresia, renal anomalies, limb anomalies (VACTERL) syndrome, phocomelia
Doxepin	Oral clefts, polydactyly
Droperidol	Hydrocephalus, cerebral hypoplasia
Enalapril	Hypocalvaria, renal defects
Ephedrine	Clubfoot
Ethanol (alcohol)	FGR, microphthalmia, micrognathia, microcephaly, hypoplastic maxilla, cardiac defects, gentourinary defects, radioulnar synostosis, Klippel-Feil anomaly, diaphragmatic hernia
Ethoheptazine	Umbilical hernia, hip dislocation
Ethotoin	Cleft lip/palate, patent ductus arteriosus
Ethosuximide	Cleft lip/palate, hydrocephalus, patent ductus arteriosus, spontaneous hemorrhage in the neonate
Etretinate	Neural tube defects, facial dysmorphia, multiple synostoses, syndactylies, limb reduction
Fluconazole	Craniosynostosis, cleft palate, limb shortening
Fluorouracil	Radial aplasia, pulmonary hypoplasia, esophageal and duodenal atresia, cloacal malformation
Fluphenazine	Ocular hypertelorism, cleft lip/palate, imperforate anus
Furosemide	Hypospadias
Griseofulvin	Conjoined twins
Haloperidol	Limb reduction, aortic valve defect
Heparin	Cardiovascular defects
Heroin	FGR, multiple and varied congenital malformations
Hydroxyprogesterone	Spina bifida, anencephaly, tetralogy of Fallot, truncus arteriosus, VSD
Hydroxyzine	Oral clefts
Hyoscyamine	Polydactyly, limb reduction
Ibuprofen	Oligohydramnios, premature closure of patent ductus arteriosus
Imipramine	Diaphragmatic hernia, cleft palate, exencephaly, renal cystic dysplasia, amelia
Indomethacin	Oligohydramnios, premature closure of patent ductus arteriosus, phocomelia, penile agenesis
Isoetharine	Clubfoot
Isotretinoin	Hydrocephalus, neural tube defects, microphthalmia, microcephaly, cardiac defects, limb abnormalities, cleft palate
Itraconazole	Limb defect
Ketoconazole	Limb defect
Ketorolac	Constriction of the ductus arteriosus, fetal renal impairment
Levothyroxine	Cardiac defects, polydactyly
Lindane	Hypospadias
Lisinopril	Hypocalvaria, polydactyly, oligohydramnios
Lithium	Cardiac defects (Ebstein anomaly, VSD, coarctation, mitral atresia), neural tube defects
Lovastatin	Aortic hypoplasia, VSD, anal atresia, renal dysplasia, radial aplasia
Lysergic acid diethylamide	FGR, limb reduction, neural tube defects, cardiac defects
Marijuana	FGR, facial anomalies
Mechlorethamine	FGR, oligodactyly, malformed kidneys
Medroxyprogesterone	Cardiovascular defect
Meclizine	Eye and ear defects, hypoplastic heart, respiratory defects
Mefenamic acid	Constriction of the ductus arteriosus
Melphalan	FGR
Meprobamate	Cardiac defects, omphalocele, joint abnormalities

TABLE H-1 Selected Medications and Reported Associated Malformations*—cont'd

Drug	Malformation(s)
Mercaptopurine	Cleft palate, microphthalmia, FGR
Metaproterenol	Polydactyly
Methimazole	Patent urachus
Methotrexate	FGR, hypertelorism, dextroposition of the heart, absent digits, absence of frontal bone
Methotrimeprazine	Hydrocephalus, cardiac defects
Metronidazole	Spontaneous abortion, limb, cardiac, urinary, and facial abnormalities
Mifepristone	Sirenomelia, caudal regression syndrome
Minoxidil	Omphalocele, clinodactyly, cardiac defects (VSD and transposition)
Misoprostol	Limb defects, hypocalvaria, cleft lip, clubfoot, gastroschisis
Norethindrone	Neural tube defects, hydrocephalus
Norethynodrel	Cardiac defects, hypospadias
Nortriptyline	Limb reduction
Ofloxacin	Myelomeningocele, hydrocephalus, hypospadias
Omeprazole	Anencephaly, hydranencephaly, clubfoot
Oxazepam	Neural tube defects, FGR
Paramethadione	Spontaneous abortions, FGR, cardiac defects
Penicillamine	Hydrocephalus, flexion deformities, perforated bowel
Pentoxifylline	Cardiac defects
Phenacetin	Craniosynostosis and atresia, musculoskeletal and urinary tract defects
Phenobarbital	Cardiovascular defects
Phensuximide	Ambiguous genitalia
Phenylephrine	Eye and ear abnormalities, syndactyly, clubfoot, musculoskeletal defects
Phenylpropanolamine	Eye and ear abnormalities, polydactyly, hypospadias
Phenytoin	Microcephaly, hypertelorism, cleft lip/palate, hypoplasia of distal phalanges, short neck, broad nasal ridge
Podophyllum	Limb reduction
Procarbazine	FGR, cardiac defects, oligodactyly, malformed kidneys
Prochlorperazine	Cleft palate/micrognathia, cardiac defects, skeletal defects
Propoxyphene	Limb abnormalities, omphalocele, micrognathia, clubfoot, microcephaly
Quinacrine	Renal agenesis, neural tube defects
Quinine	Neural tube defects, hydrocephalus, limb defects, facial defects, cardiac defects, urogenital abnormalities, vertebral abnormality, gastrointestinal anomaly
Reserpine	Microcephaly, hydronephrosis
Retinoic acid	Hydrocephalus, neural tube defects, microphthalmia, microcephaly, cardiac defects, limb abnormalities, cleft palate
Rifampin	Anencephaly, hydrocephalus, limb malformation
Sodium iodide	Ablation of fetal thyroid gland
Sulfasalazine	Cleft lip/palate, hydrocephalus, cardiac defects, urinary tract abnormalities
Sulfonamides	Limb hypoplasia, urinary tract abnormalities
Sumatriptan	Phocomelia, tibial aplasia, clubfoot, cleft palate
Tamoxifen	Ambiguous genitalia
Tazarotene	Reduced skeletal ossification, hydrocephaly, spina bifida, cardiac defects
Temazepam	Oral clefts
Terfenadine	Polydactyly
Tetracycline	Hypospadias, limb hypoplasia
Thioguanine	Absent digits
Tolbutamide	Syndactyly, cardiac defects, clubfoot
Trifluoperazine	Phocomelia, transposition of the great vessels
Trimethadione	FGR, microcephaly, cleft lip/palate, cardiac defects, malformed hand, clubfoot, ambiguous genitalia, esophageal atresia, tracheoesophageal fistula
Trimethoprim	Cardiovascular defects
Valproic acid	Neural tube defects, cardiac defects, facial dysmorphism, hypertelorism, protruding eyes, micrognathia, hydrocephalus, cleft lip/palate, microcephaly, limb reduction, scoliosis, renal hypoplasia, duodenal atresia, hand deformity
Zidovudine	Renal agenesis, microphthalmus, polydactyly, cleft lip/palate, clubfoot, VSD

CDH, congenital diaphragmatic hernia; FGR, fetal growth restriction; VSD, ventricular septal defect.

*This list represents selected medications and their possible associations with fetal structural abnormalities. Many of the listed associations are based on isolated case reports that have appeared in the medical literature for which the association is unproved or in animal studies in which the dosage of medication far exceeded the clinical amount normally used. It is likely that in many cases the reported association was coincidental to, rather than resultant from, the medication. This list is not intended for patient counseling regarding the likelihood of fetal malformations or abnormalities. The table should be used by the sonologist/sonographer as a guide for evaluating specific organ systems in addition to a thorough sonographic examination. In all cases of suspected teratogenetic effects, a reproductive geneticist or teratologist and the drug manufacturer should be consulted.

Modified from Briggs GG, Freeman RK, Yaffe SJ: Drugs in Pregnancy and Lactation, 7th ed. Philadelphia, Lippincott Williams & Wilkins, 2005.

I APPENDIX

Estimated Radiation Exposure to the Fetus During Radiographic Examinations

TABLE I-1 Estimated Fetal Radiation Dose From Abdominopelvic Radiography*

PROCEDURE TYPE (# OF CASES)	FETAL DOSE (mGy)		RANGE OF GESTATIONAL AGE
	Range of Dose	Mean	Weeks + Days
Abdominal radiography (n = 19)	0.45–7.20	2.44	1w + 0d–17w + 2d
Abdominopelvic radiography (n = 1)	3.60	3.60	11w + 0d
Pelvic radiography (n = 12)	1.70–9.45	4.77	3w + 1d–18w + 5d

TABLE I-3 How to Estimate Fetal Radiation Dose From an Abdominopelvic CT Examination*

An estimate of fetal radiation dose from an abdominopelvic CT examination is calculated as follows:

1. Determine your scanner model type and detector collimation.
2. Calculate total beam collimation using the following equation:

$$\text{Total beam collimation} = \#\text{ of detector rows} \times \text{detector collimation}$$

3. Select the desired kVp for scanning.
4. Use Table I-2 (above) to identify the corresponding estimated fetal radiation dose, specified in units of mGy per 100 mAs_{eff}.
5. Calculate the mAs_{eff} using the following equation:

$$mAs_{eff} = \text{current (mA)} \times \text{time per rotation (s)/pitch}$$

If Automatic Tube Current Modulation (ATCM) is enabled, tube current (mA) is automatically adjusted. This adjustment occurs according to the size of the patient and to the attenuation values of the anatomy being imaged. If ATCM is used, a mean mA value should be used here. Because the mean mA will vary with each patient, the mean value can only be estimated. If the calculation is being performed after scanning, the mean mA can be obtained from the mA range in the examination dose report.

6. Estimated fetal radiation dose (mGy) = mGy/100 mAs_{eff} (result of step 4) × mAs_{eff} (result of step 5) / 100.

Example:

1. LightSpeed VCT (GE Healthcare) 64 MDCT scanner with a detector collimation of 0.625 mm
2. Total beam collimation = 64 × 0.625 = 40 mm
3. 140 kVp selected for scanning
4. With these parameters, Table 2 indicates an estimated fetal radiation dose of 17.92 mGy per 100 mAs_{eff}.
5. Calculate mAs_{eff}. For example, with a current setting of 300 mA, time per rotation of 0.6 sec, and a pitch of 1.375:

$$mAs_{eff} = 300 \times 0.6/1.375 = 130.9$$

6. Estimated fetal radiation dose (mGy) = 17.92 mGy per 100 mAs_{eff} (result of step 4) × 130.9 mAs (result of step 5) / 100 =23.45 mGy.

Magnetic Resonance Imaging of the Female Pelvis: Representative Protocols*

TABLE J-1 Pelvic Mass Magnetic Resonance Imaging Protocol

Sequences

- **Sag T2 Fast Spin Echo (FSE)**
  - Free breathing
  - May need to try phase S/I and A/P to see which gives best quality
  - Consider anterior or superior suppression pulses
- **Axial T2 FSE Fat Saturation (FS)**
  - Free breathing
  - Phase L/R
- **Axial T2 FSE**
  - Free breathing
  - Phase L/R
- **Coronal T2 FSE**
  - Free breathing
  - Phase L/R
- **Axial T1 In and Opposed Phase**
  - End expiration is preferred. Inspiration is acceptable.
- **Axial Isotropic T1 FS pre (3D Vibe)**
  - Free breathing
  - **PHASE L/R** (not A/P)
- **Inject Contrast**
- **Axial Isotropic T1 FS post (start 1 minute following initiation of the injection)**
  - Free breathing
- **Axial Vibe (only if necessary to cover the anatomy)**
  - End inspiration is acceptable
  - FS

If the pelvic pathology is too large to perform the isotropic T1 FS images in a reasonable amount of time, use Vibe pre- and post-contrast images similar to a Liver Mass Protocol and acquire breath hold axial, sagittal, and coronal pre- and post-contrast images.

TABLE J-2 Uterine Anomaly Magnetic Resonance Imaging Protocol

Sequences

- **LOCALIZER free breathing**
  - Run in ISO mode to see where the uterus is centered in the coil.
- **LOCALIZER free breathing**
  - Run in ISO mode.
  - Center the uterus in the center of the field view.
  - When this is finished, remove the previous series from the sequence list and remove its images from the thumbnails. If you prescribe off this localizer using the REF mode, the uterus will remain in the center of the magnet.
- **HASTE LOCALIZER (T2)**
  - Run in the following planes centered on the uterus. Make sure you are in reference mode and prescribe off the second localizer above.
  - *Straight Axial*
  - *Straight Sagittal*
  - *Straight Coronal*
- **"Coronal of Uterus" T2 Fast Spin Echo (FSE)**
  - Use the above HASTE localizers to create a plane that parallels the endometrium to make a true coronal of the uterus.
  - Free breathing
  - Phase L/R
- **"Sagittal of Uterus" T2 FSE**
  - Use of the above HASTE localizers to create a parasagittal plane that parallels the endometrium.
  - Free breathing
  - May need to try phase S/I and A/P to see which gives best quality.
  - Consider anterior or superior suppression pulses.
- **"Axial of Uterus" T2 FSE**
  - Use the above HASTE localizers to create a plane that is perpendicular to the plane of the endometrium.
  - Free breathing
  - Phase L/R
- **3D T2 SPACE SAG**
  - Free breathing
- **Axial T1 In and Opposed Phase**
  - End expiration is preferred. End inspiration is acceptable.
- **Axial Isotropic T1 Fat Saturation (FS) pre (3D Vibe)**
  - Free breathing
  - **PHASE L/R** not A/P
- **Axial Isotropic T1 FS post (only if giving contrast) (3D Vibe)**
  - Free Breathing
  - **PHASE L/R** not A/P
- **CORONAL HASTE (T2) to include kidneys**

*Protocols will vary depending upon indication, institution, and manufacturer. These representative protocols were provided courtesy of Dr. Steffen Huber, Department of Radiology and Biomedical Imaging, Yale University School of Medicine, New Haven, CT.

TABLE J-3 Magnetic Resonance Imaging Protocol for the Pregnant Patient With Right Lower Quadrant Pain

- **Patient Position**
  - Head first
  - Supine
- **Coils**
  - Place sufficient matrix coils to cover the abdomen and pelvis (or chest, abdomen, and pelvis if necessary).
  - Make supercoils if the patient is large and there are enough (4) matrix coils.
- **"Zero" the scanner at the center of the top coil.**
- **Assess the patient's ability to breath hold.**

Sequences

- **Axial T2 HASTE (2 station Set-and-Go)**
  - Multiple short and expiration breath holds.
  - Send the composed images to PACS.
- **Coronal T2 HASTE**
  - Navigator triggered or short end expiration breath holds.
- **Sagittal T2 HASTE**
  - Navigator triggered or short end expiration breath holds.
- **Axial T2 HASTE Fat Saturation (FS) (2 Station Set-and-Go)**
  - Multiple short end expiration breath holds.
  - Send the composed images to PACS.
- **T1 In and Out of Phase (cover Uterus and Adnexa)**
  - End expiration is preferred. End inspiration is acceptable.

Notes:

IMPORTANT! These HASTE Sequences Are Different!

- 5 mm thick with 10% slice spacing
- Matrix of 256 x 256 is acceptable, but 320-256 is preferable if signal is OK.
- HASTE in these cases is run without parallel imaging. If you want to turn on parallel imaging, then phase oversample (with no time penalty) to avoid artifact.
- ***Image the cecum in all planes.*** (Since the appendix is attached to the cecum, if you image the cecum, you will also include the appendix.)
- ***Do not let the images "bounce."*** The appendix measures 5mm. Each pixel is 2mm. Even 2 mm of bouncing can make the appendix "disappear." Use *breath holds if possible* and only use navigator as the last resort. You can Navigator off the bottom of the liver, spleen, or even the top of a moderate sized uterus!

HASTE Coverage

- Axial: gallbladder to pubis in the axial plane
- Coronal: front to back to include from the gallbladder superiorly to the pubis inferiorly
- Sagittal: midline to right skin surface

Axial Dual Echo VIBE Through the Uterus and Pelvis Is a Breath Hold Image.

- The purpose of this image is to look for hemorrhage in the uterus (placenta, fibroids) or fat in the adnexa (dermoid cysts).
- Use iPAT 2
- Choose from the appropriate breath hold protocol
- If these images are blurry, use free breathing T1 protocol. Copy the slices from the Axial T2 HASTE.

Abbreviations:

HASTE: Single shot T2 weighted sequence
VIBE: Volume interpolated gradient echo T1 weighted sequence
iPAT: Parallel imaging
FS: Fat supression

TABLE J-4 Urethral Diverticulum Magnetic Resonance Imaging Protocol

Feet first
Supine
Coil coverage over deep pelvis and perineum

Sequences

- **Sagittal Hi Res T2 Fast Spin Echo (FSE) Fat Saturation (FS)**
  - Free breathing
  - Since there is rarely motion this deep in the pelvis, set phase A/P.
- **Axial Hi Res T2 FSE**
  - Free breathing
  - Phase L/R
- **Axial T1 FSE**
  - Free breathing
  - Phase L/R
- **Axial Isotropic T1 FS pre (3D Vibe)**
  - Free breathing
  - **PHASE L/R** not A/P
- **Inject Contrast**
- **Axial Isotropic T1 FS post (start 30 seconds following initiation of the injection) (3D Vibe)**
  - Free breathing
  - **PHASE L/R** not A/P

Note: These T2's Are Different.

- Small FOV, 180-220 depending on patient size. Important to cone down on the urethra. Use enough phase oversampling on the axial images to avoid wrap into the image.
- Axial images should be *perpendicular* to the urethra. This is almost always a straight axial. Phase is placed L/R. Use enough oversampling to avoid wrap. Image from the top of the bladder to the perineum.
- On the sagittal images set phase A/P as there is almost never respiratory motion at the level of the pubis.
- The slices for the Axial T1 FSE can be copied from the Axial T2.

TABLE J-5 Endometrial Cancer Magnetic Resonance Imaging Protocol (for Local Staging)

Place patient feet first, supine.
Use enough coils to cover from perineum to aortic bifurcation.
10ccs of ultrasound gel should be inserted into the vagina (via syringe, preferably by patient).
1 mg Glucagon IM prior to scout sequence.

Sequences

- **LOCALIZER free breathing**
  - Run in ISO mode to see where the uterus is centered in the coil.
- **LOCALIZER free breathing**
  - Run in ISO mode.
  - Center the cervix in the center of the field of view.
  - When this is finished, remove the previous series from the sequence list and its images from the thumbnails. If you prescribe off this localizer using the REF mode, the uterus will remain in the center of the magnet.
- **HASTE LOCALIZER (T2)**
  - Run in the following planes centered on the cervix.
  - Make sure you are in Reference Mode.
  - Prescribe off the second localizer above.
  - *Straight Axial*
  - *Straight Sagittal*
  - *Straight Coronal*
- **Diffusion Weighted Imaging (DWI) in the "Sagittal Plane of Uterus"**
  - B values (50, 400, 800)
  - Apparent Diffusion Co-efficient (ADC) maps
- **"Transverse of Uterus" T2 FSE**
  - Use the above HASTE localizers to create a plane that runs perpendicular to the uterus.
  - Free breathing
  - Phase L/R
- **"Coronal of Uterus" T2 FSE**
  - Use the above HASTE localizers to create an oblique coronal that parallels the uterus.
  - Free breathing
  - May need to try phase S/I and A/P to see which gives best quality.
  - Consider anterior or superior suppression pulses.
- **"Sagittal of Uterus" T2 FSE**
  - Small FOV
  - Use the above HASTE localizers to create a parasagittal plane that is parallel to the plane of the uterus.
  - Free breathing
  - Phase L/R
  - Only cover the uterus
- **3D T2 SPACE**
  - Free breathing
  - Only cover the uterus
- **Axial Isotropic T1 Fat Saturation (FS) pre**
  - Free breathing
  - **PHASE L/R** not A/P
- **Optional Sagittal Dynamic Contrast Enhanced (DCE) (depending on protocol)**
  - Free breathing
- **Isotropic T1 FS post (30 seconds after injection)**
  - Free breathing
  - **PHASE L/R** not A/P
- **Vibe post from bifurcation down**

TABLE J-6 Cervical Cancer Magnetic Resonance Imaging Protocol (for Local Staging)

Place patient feet first, supine.
Use enough coils to cover from perineum to aortic bifurcation.
10cc of ultrasound gel should be inserted into the vagina (via syringe, preferably by patient).
1 mg Glucagon IM prior to scout sequence.

Sequences

- **LOCALIZER free breathing**
  - Run in ISO mode to see where the uterus is centered in the coil.
- **LOCALIZER free breathing**
  - Run in ISO mode.
  - Center the cervix in the center of the field of view.
  - When this is finished, remove the previous series from the sequence list and its images from the thumbnails. If you prescribe off this localizer using the REF mode, the uterus will remain in the center of the magnet.
- **HASTE LOCALIZER (T2)**
  - Run in the following planes centered on the cervix.
  - Make sure you are in Reference Mode.
  - Prescribe off the second localizer above.
  - *Straight Axial*
  - *Straight Sagittal*
  - *Straight Coronal*
- **Diffusion Weighted Imaging (DWI) in the "transverse plane of cervix"**
  - B values (50, 400, 800)
  - Apparent Diffusion Co-efficient (ADC) maps
- **"Transverse of Cervix" T2 FSE**
  - Use the above HASTE localizers to create a plane that runs perpendicular to the cervix.
  - Free breathing
  - Phase L/R
- **"Coronal of Cervix" T2 FSE**
  - Use the above HASTE localizers to create an oblique coronal that parallels the cervix.
  - Free breathing
  - May need to try phase S/I and A/P to see which gives best quality.
  - Consider anterior or superior suppression pulses.
- **"Sagittal of Cervix" T2 FSE**
  - Small FOV
  - Use the above HASTE localizers to create a parasagittal plane that is parallel to the plane of the cervix.
  - Free breathing
  - Phase L/R
  - Only cover the uterus
- **3D T2 SPACE**
  - Free breathing
  - Only cover the uterus/cervix
  - Sagittal
- **Axial Isotropic T1 Fat Saturation (FS) pre**
  - Free breathing
  - **PHASE L/R** not A/P
- **Optional Sagittal Dynamic Contrast Enhanced (DCE) (depending on protocol)**
  - Free breathing
- **Axial Isotropic T1 FS post (30 seconds after injection)**
  - Free breathing
  - **PHASE L/R** not A/P
- **Axial Vibe post from bifurcation down**

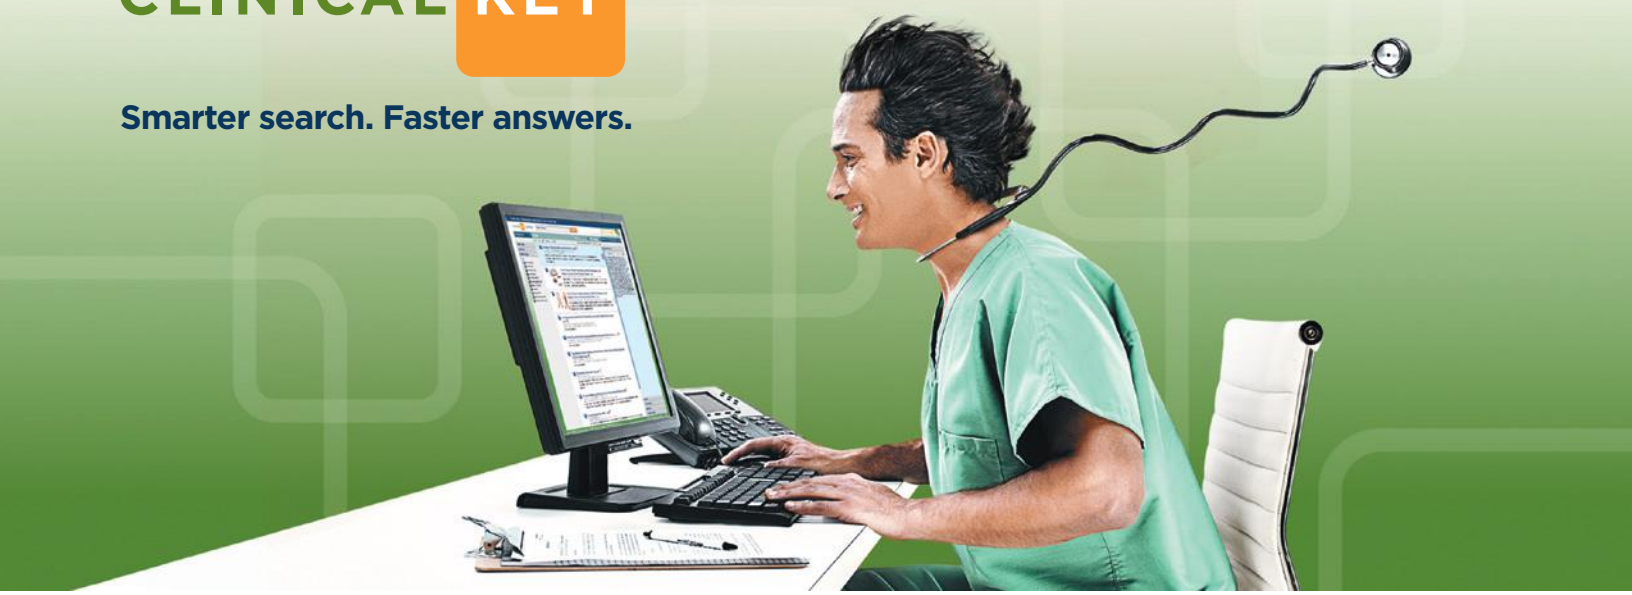
CLINICAL KEY™

Smarter search. Faster answers.



Smarter, Faster Search for Better Patient Care

Unlike a conventional search engine, ClinicalKey is specifically designed to serve doctors by providing three core components:

1 Comprehensive Content

The most current, evidence-based answers available for every medical and surgical specialty.

2 Trusted Answers

Content supplied by Elsevier, the world's leading provider of health and science information.

3 Unrivaled Speed to Answer

Faster, more relevant clinical answers, so you can spend less time searching and more time caring for patients.

Start searching with ClinicalKey today!

Visit ***ClinicalKey.com*** for more information and subscription options.
