Sinus or Low Atrial Bradycardia. Left and right atrial isomerism can be associated with a low atrial rhythm ranging between 90 and 130 bpm, or dual sinoatrial nodes. Fetuses with heterotaxy syndrome frequently have associated intracardiac anomalies. The sinus node can also have acquired damage, as in fetuses born to women with Sjögren syndrome (SSA or SSB antibodies). The sinus node can be damaged by fetal myocarditis and present with a low atrial bradycardia.[115]

Second-Degree Heart Block. In second-degree heart block, the A-A interval is regular with very little variability, and there are two atrial events for every ventricular event (2:1 block). The ventricular rate ranges between 60 and 75 bpm, and this arrhythmia can be difficult to distinguish from complete heart block. If second-degree heart block is suspected at 16 to 26 weeks' gestation, maternal testing for SSA/SSB antibodies is indicated to determine if the fetal bradycardia may represent evolving fetal complete heart block. Channelopathies, such as Brugada syndrome and progressive cardiac conduction disease (*NKX2.5*, *hERG*, *SCN5A* mutations) and long QT syndromes (LQT2, LQT3, LQT8), can manifest as second- and third-degree heart block, and in some cases genetic testing is helpful.[472]

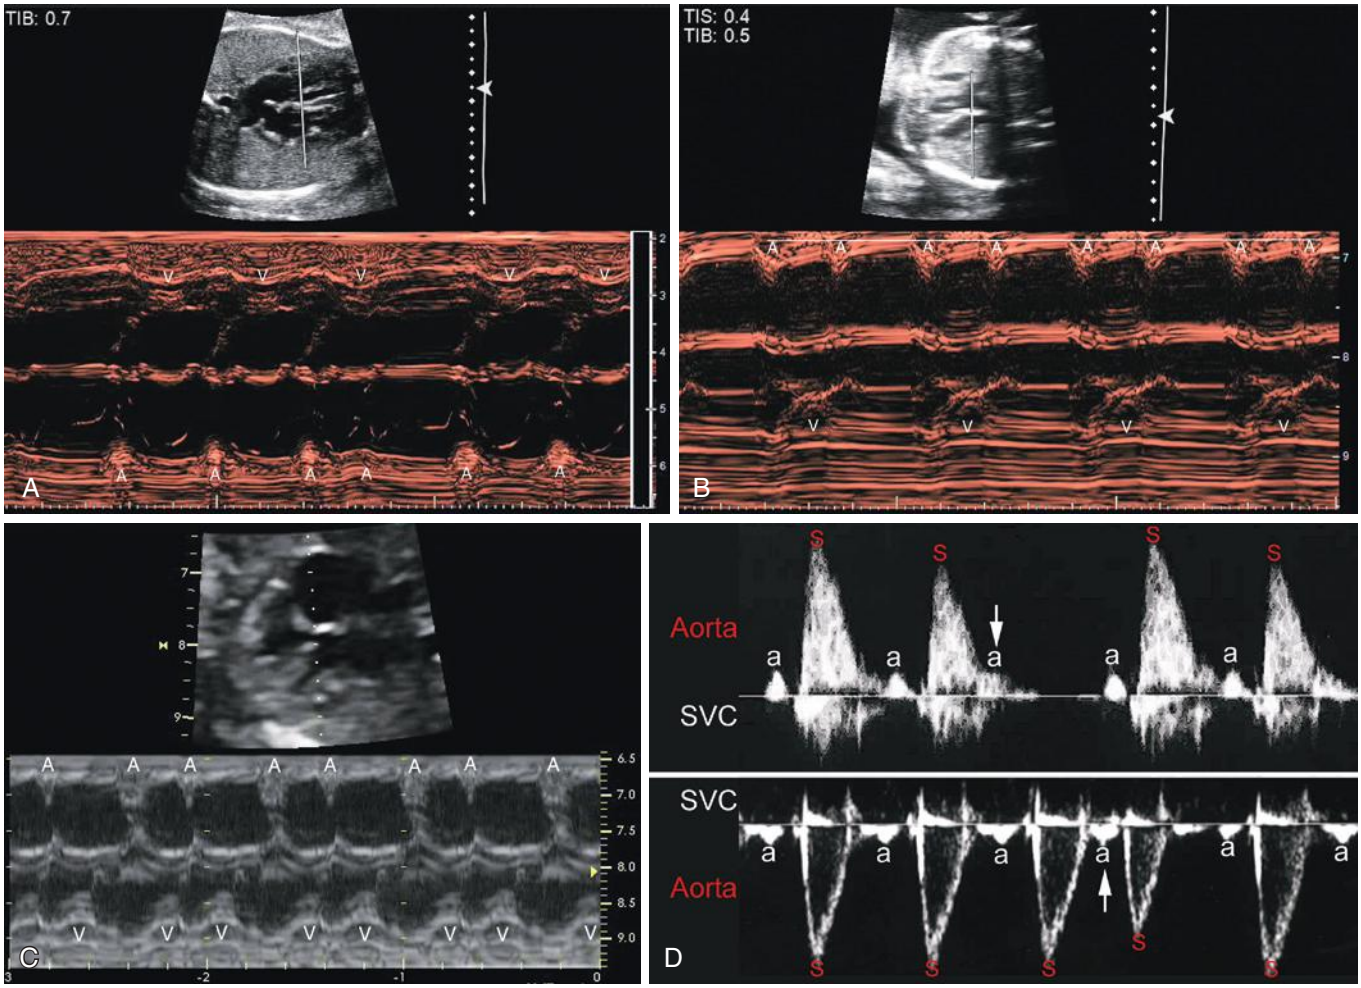

FIG 13-76 Premature atrial contractions. **A,** M-mode through the ventricles (*above*) and atria (*below*) during a single premature atrial contraction that is not conducted (A, atrial contraction; V, ventricular contraction). The fourth atrial contraction is premature and is not followed by a ventricular contraction. **B,** Blocked atrial bigeminy. M-mode through the ventricles (*below*) and atria (*above*). Every other atrial contraction is early; the premature contractions are not followed by a ventricular contraction. **C,** Conducted atrial bigeminy. M-mode through the ventricles (*below*) and atria (*above*). Every other atrial contraction is early; the premature contractions are always followed by a ventricular contraction. **D,** Premature atrial contractions. Simultaneous Doppler tracing of the superior vena cava (SVC) and ascending aorta showing isolated blocked (*upper panel*) and conducted (*lower panel*) premature atrial contractions (*arrows*). a, atrial contraction; s, ventricular contraction.

Third-Degree Heart Block: Congenital Complete Heart Block. With third-degree or complete heart block (CHB) there is atrial and ventricular dissociation with the atrial rate in the normal range and the ventricular rate less than 60 bpm (Fig. 13-77).[471] CHD can be associated with complex cardiac defects and a malformed conduction system (50-55%) or with SSA/SSB antibodies, which represent approximately 40%. Heterotaxy syndrome, complex AVCDs, and congenitally corrected TGA may all present with CHB. A small number of CHB fetuses have no identified cause.[115]

When the FHR is less than 55 bpm, there is a risk of hydrops, and maternal β-sympathomimetics (terbutaline, salbutamol, isoprenaline) are sometimes suggested to augment the FHR. Maternal therapy is sometimes used in the setting of a faster FHR if there is an associated structural cardiac anomaly and signs of fetal cardiac compromise or evolving hydrops. Placement of a fetal pacemaker has not been successful and is considered experimental.[115,472-475]

With immune-mediated CHB, there have been reports of some limited benefit from maternal treatment with fluorinated steroids, IVIG (intravenous immunoglobulin) infusions, or a combination of both. If the fetus has first-degree heart block (defined as a fetal mechanical PR interval of >150 ms[476-478]) or second-degree heart block and additional signs of inflammation, such as echogenicity of the fetal myocardium, valve regurgitation, cardiac dysfunction, or effusions, it has been hypothesized that treatment might prevent progression to CHB. A maternal trial of dexamethasone 4 to 8 mg/day has been proposed as a clinical treatment option.[479] The effect on the fetal heart is closely monitored along with assessment for fetal complications of maternal steroid treatment, which include growth restriction, oligohydramnios, and ductal constriction.[115,477] Once CHB is present, maternal steroids have not been found to be useful. One study reported better outcomes in fetuses treated with maternal steroids compared to untreated fetuses, with improvement in dilated cardiomyopathy,

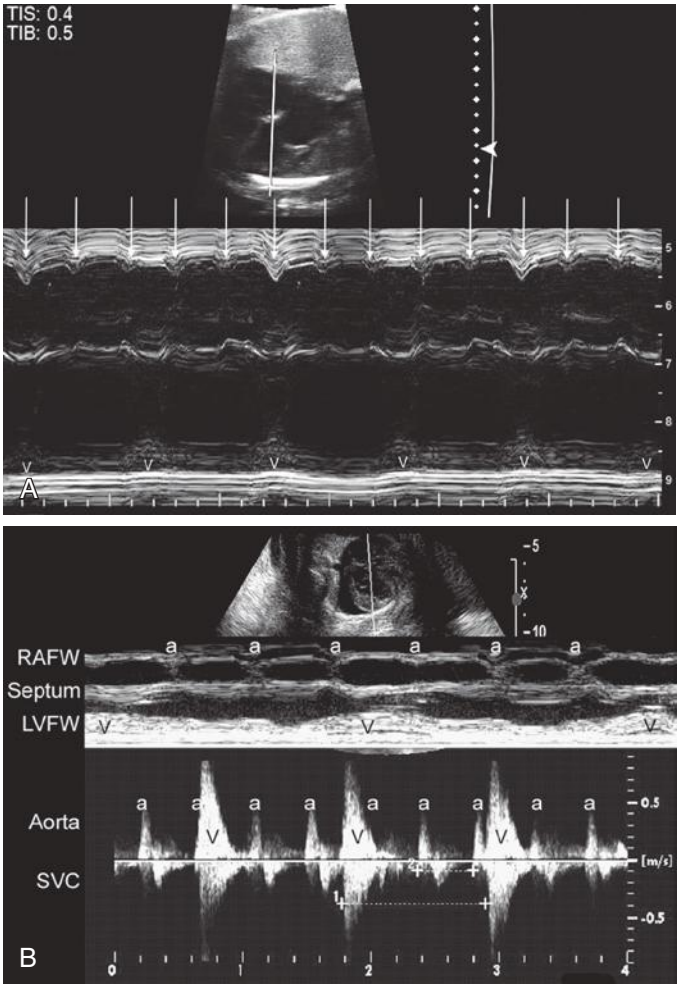

FIG 13-77 Complete heart block. **A,** M-mode through the ventricular (*below*) and atrial (*above*) walls show that there are many more atrial contractions (*arrows*) than ventricular contractions (V). The ventricular rate is 52 beats per minute, whereas the atrial rate is 120 to 130 beats per minute. **B,** Doppler tracing of the superior vena cava (SVC) and ascending aorta (*lower panel*) showing complete atrioventricular dissociation related to complete atrioventricular block. The atrial rate (a-a) is 140 beats per minute, and the ventricular rate (V-V) is 54 beats per minute. LAFW, left atrial free wall; RAFW, right atrial free wall.

myocardial dysfunction, and hydrops. The maternal steroid therapy was speculated to be treating an immune-mediated fetal myocarditis.[480] However, a 2011 large European study of 175 CHB patients reported no overall difference in fetal or neonatal mortality rate in steroid-treated fetuses versus those with no therapy.[481] This study reported that the fetuses with the poorest outcomes were those presenting with CHB at less than 20 weeks' gestation, with FHR 50 bpm or less, ventricular dysfunction, and hydrops.[473,474,481-483]

Fetal Tachycardia

Sinus Tachycardia. With sinus tachycardia, there is a 1:1 ratio of atrial:ventricular events (Fig. 13-78A), and a heart rate in the 160 to 180 bpm range. The rate has some variability and does not abruptly start or stop. Sinus tachycardia is often seen with fetal movement. Some disorders, such as anemia, hypoxemia, maternal infections, and maternal thyrotoxicosis, are also known to cause fetal sinus tachycardia. If there is an underlying maternal or fetal cause, it should be addressed and the FHR will typically return to normal for the gestational age.[472]

Supraventricular Tachycardia. SVT is caused by an AV node reentry accessory pathway, which is a rapidly conducting pathway from the ventricles to the atria. The ventriculoatrial (VA) time interval as measured by Doppler is short because of the fast conduction in the reentry pathway. In reentry SVT, the AV time interval is longer than the VA time interval, there is 1:1 A:V conduction, and the rate is in the 180 to 300 bpm range (Fig. 13-78B). The onset and cessation of SVT are both abrupt. When the fetus is in SVT more than 50% of the imaging time, maternal pharmacologic treatment is indicated as incessant SVT can lead to low cardiac output, myocardial dysfunction, AV valve regurgitation, hydrops fetalis, and fetal demise. The first line of choice is digoxin and if a second antiarrhythmic is needed, options include sotalol or flecainide. Amiodarone has also been used to treat fetal SVT, although it is used less frequently owing to potential maternal and fetal side effects.

Fetal SVT can also occur secondary to an ectopic atrial focus. The ectopic atrial tachycardia has a long VA time interval and measurement of this time interval can be used to differentiate the various causes of fetal SVT.[484] The rate is also 180 to 300 bpm and is managed similar to reentrant fetal SVT. For the fetus presenting late in gestation, an expedited delivery followed by a newborn cardioversion may be the best option.[485-488]

Fetal SVT that exhibits a long VA time interval, which is longer than the AV time interval, is due to atrial ectopic tachycardia (AET) or paroxysmal junctional reciprocating tachycardia (PJRT). This less common form of fetal SVT may be more recalcitrant to therapy. The time intervals are easily measured by spectral Doppler imaging.[472,478]

Atrial Flutter. Atrial flutter is an atrial macroreentry tachycardia that accounts for approximately 30% of fetal SVT and typically occurs in the third trimester. It has been speculated that the fetal atrium reaches a critical size for the appearance of the circuit at 27 to 30 weeks' gestation.[489] Fetal atrial flutter is defined as a rapid regular atrial rate of 300 to 600 bpm and is accompanied by a fixed or variable AV conduction block (Fig. 13-79). Thus, the ventricular rate is slower than the atrial rate, and there is typically a 2:1 A:V block. Atrial flutter is considered incessant if present for more than 50% of a 45-minute study and intermittent if the tachycardia is present less than 50% of the time. Digoxin is often the therapy of choice, as this prolongs the AV conduction and can increase the degree of block. Sotalol has also been effective in converting atrial flutter, especially with hydrops as it crosses the hydropic placenta more effectively.[485-488]

Ventricular Tachycardia. Ventricular tachycardia (VT) is extremely rare in the fetus, with the most important predisposing factor being long QT syndrome (LQTS). LQTS should be considered in the fetus presenting with baseline bradycardia and intermittent tachycardia, which may represent torsades de pointes type of VT. The hallmark of VT is AV dissociation, with the ventricular rate being higher than the atrial rate.

VT may also present in a fetus with myocarditis and ventricular tumors, such as rhabdomyoma and ventricular fibromas. Fetal VT has been treated with maternal IV lidocaine, magnesium, maternal oral mexiletine, sotalol, and amiodarone.[472,490-492]

Diagnostic Imaging Features

- Simultaneous M-mode tracing of atrial and ventricular walls should be performed to determine the sequence and timing of mechanical contraction of the atria and ventricles.
- Simultaneous spectral Doppler of a vein and artery can measure the ratio of atrial to ventricular frequency.
- A:V ratio of 1:1 with a short VA < AV interval is AV node reentry tachycardia.
- A:V ratio of 1:1 with a long VA > AV interval is AET or PJRT.

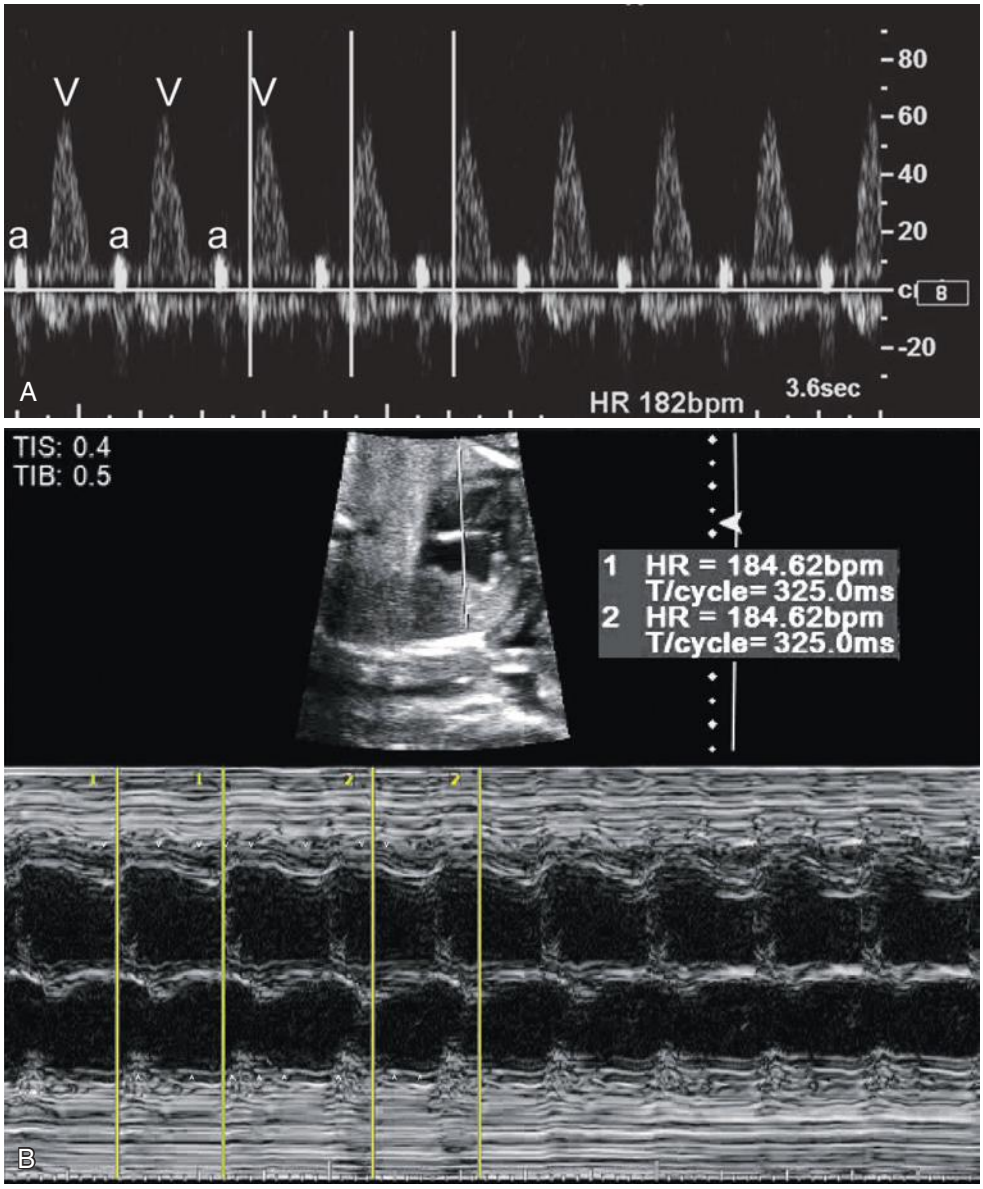

FIG 13-78 Supraventricular tachycardia. **A,** Tachycardia with 1 : 1 atrioventricular relationship. Simultaneous Doppler tracing of the superior vena cava and ascending aorta show fetal tachycardia of 182 beats per minute with normal atrioventricular time intervals. This form of tachycardia may be caused by sinus tachycardia, permanent junctional reciprocating tachycardia (PJRT), and atrial ectopic tachycardia (AET). **B,** M-mode through the ventricles (*above*) and atria (*below*). Tachycardia at 184 beats per minute with 1 : 1 atrioventricular relationship. Although there is a ventricular contraction (V) for every atrial contraction (A), the ventricular contraction is closely followed by the atrial contraction, suggesting a reentrant mechanism to the tachycardia. HR, heart rate.

- A > V ratio represents either atrial flutter or, when consistently irregular, atrial fibrillation.
- A < V ratio is VT or junctional ectopic tachycardia.
- An atrial rate in the normal range and ventricular rate less than 60 bpm is complete heart block and AV dissociation.
- Atrial bigeminy with blocked PACs may have a ventricular rate of 70 to 100 bpm.

Pericardial Effusions

Pericardial effusions are rarely seen in isolation and are typically associated with a primary abnormality (see Fig. 13-24), including structural heart disease, dysrhythmias, chromosomal abnormalities, and extracardiac defects. Although the combination of a pericardial effusion and one of these defects often portends a poor outcome, outcomes of fetuses with isolated pericardial effusions are generally favorable.[493]

Fetal Heart Failure/Impaired Cardiovascular Performance

Fetal cardiovascular performance can be affected by a wide variety of cardiac and noncardiac conditions. Cardiomyopathy, infection, alloimmune disease, anemia, arrhythmia, and exposure to toxins can all directly affect the fetal myocardium. Derangements in fetal preload or afterload due to structural heart disease, mass effect from other

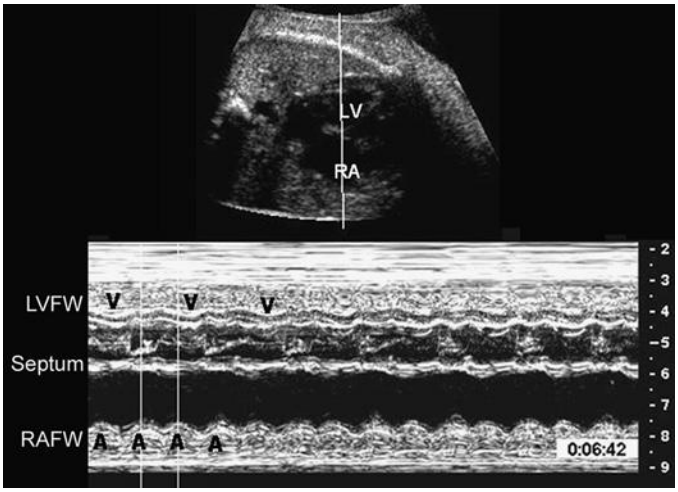

FIG 13-79 Atrial flutter. M-mode tracing through the left ventricle (LV) and right atrium (RA) shows a fast atrial (A) rate (420 beats per minute) that is twice the ventricular (V) rate (210 beats per minute). The underlying arrhythmia is atrial flutter with 2:1 atrioventricular conduction. LVFW, left ventricular free wall; RAFW, right atrial free wall.

congenital anomalies, placental abnormalities, vascular tumors, malformations, and humoral factors can also affect cardiovascular performance (Fig. 13-80).[494-498]

Assessment Parameters. Stroke volume is determined by preload, afterload, and contractility of the ventricle. Cardiac output is a function of both stroke volume and heart rate. Fetal cardiac output stays relatively constant over a wide variety of heart rates, from approximately 50 to 200 bpm. Beyond this range, cardiac output will decrease owing to depletion of glucose and calcium stores. Higher extracellular water content, diminished calcium stores in the sarcoplasmic reticulum, lower albumin concentration, higher heart rate, and lower systemic arterial pressure result in markedly reduced compliance compared with the postnatal myocardium, and thus also respond poorly to increases in preload.[499,500] Fetal cardiac output is also sensitive to afterload. In cases of increased placental resistance, the afterload on the fetal RV increases, resulting in reduced output of that ventricle.[501-503]

The fetal RV and LV have different circulatory responsibilities in comparison to those of the child and adult. The fetal LV, instead of supporting the entire systemic circulation, provides circulation to the head and upper body. The fetal RV, on the other hand, provides circulation to the lower body and placenta (see Fig. 13-1). The fetal circulation, therefore, operates in parallel, and not in series, and the fetal RV is larger and has a larger cardiac output as compared to the left.[32,121,133,341,504,505]

Congestive heart failure is defined as inadequate oxygen delivery for normal end-organ function. Early signs of congestive heart failure include markers of diastolic dysfunction. They include AV valvar regurgitation, umbilical venous pulsations, flow reversal in the DV, and monophasic AV valve inflow. As heart failure progresses, fluid accumulates in a variety of potential spaces, leading to fetal hydrops.[496,506,507] As heart failure advances, systolic dysfunction develops. Although a variety of more sophisticated measures of systolic function exist, the most commonly used is shortening fraction. Shortening fraction of less than 28% is defined as abnormal, regardless of gestational age.

The most common manifestations of abnormal fetal hemodynamics include AV valve regurgitation, monophasic inflow into the ventricles, reduced ventricular stroke volume, and depressed ventricular function with poor cardiac output, which results in the development of pericardial and pleural effusions, ascites, skin edema, and hydrops fetalis.

Cardiomyopathy and Myocarditis. Once a fetus with impaired cardiovascular performance is identified, a thorough evaluation for primary cause should be undertaken. This evaluation includes a thorough maternal history, assessment of fetal heart rhythm, evaluation for anemia, maternal serologic testing to assess for inflammatory and infectious disorders, and detailed structural ultrasound examination of the fetal heart, fetal extracardiac vasculature, and the placenta. If a fetal or maternal cause cannot be found, then myocarditis or cardiomyopathy should be considered.

Viral myocarditis presents as a cardiomyopathy in utero and can be due to a number of agents, including coxsackievirus, adenovirus, parvovirus B19, *Toxoplasma gondii*, herpes simplex virus, and human immunodeficiency virus.[494,508-513] Although large series do not exist, outcomes in fetuses diagnosed with myocarditis and cardiac dysfunction are thought to be quite poor. Prenatal treatment with steroid or immunoglobulins have been suggested, although neither has been studied in a meaningful way.[509]

Abnormally thick or trabeculated myocardium should signal the need for a detailed fetal structural cardiac evaluation. A recent review of fetuses diagnosed with left ventricular noncompaction demonstrated that the majority (92%) had coincident structural heart disease. Compared to other fetuses with structural heart disease, this group of patients represents a particularly high-risk cohort, as 81% of patients with known follow-up died or underwent heart transplantation.[514]

As knowledge of the genetics of myocardial disease advances, so may the accuracy of diagnosis of the cause of a fetal cardiomyopathy. Currently, primary fetal cardiomyopathy is most often a diagnosis of exclusion, and the rarity of this condition makes it difficult to study. The inclusion criteria for the small number of published studies differed, limiting their generalizability.[132,494,513,515] However, these series report generally poor outcomes, which are worse with hydrops and in cases with a cardiovascular profile score 6 or less (see Fig. 13-33). Additionally, a morphologic classification system including nonhypertrophic and hypertrophic cardiomyopathy has been proposed, as those fetuses with nonhypertrophic disease appeared to have better outcomes in one series.[132] Importantly, elevated myocardial performance index (see Fig. 13-34) appears to be a common finding in fetuses with cardiomyopathy but limited in its ability to predict outcome. Overall reported survival rates of fetal cardiomyopathy have improved dramatically over time, likely owing to improved rates of fetal diagnosis in the less severe cases. In contrast to earlier reports, in which the majority of fetuses had severe cardiomyopathy with accompanying hydrops, recent series have reported survival rate to infancy to be as high as 89%, and survival rate to 1 and 5 years to be as high as 85% and 75%, respectively.[132,494,513,515] Figure 13-81 depicts a fetus with cardiomyopathy who was successfully delivered but ultimately died in the neonatal period.

Extracardiac Masses

Extracardiac masses can also affect cardiovascular status. High output vascular malformations such as sacrococcygeal teratoma, chorioangiomas, and arteriovenous malformations can dramatically increase the volume load on the fetal heart, and result in high output cardiac failure. Multiple series exist that describe vascular malformations in the fetus and predictors of poor outcome. Predictors of cardiovascular status or demise have included increased estimated combined cardiac output, cardiomegaly, worsened cardiovascular profile score, and hydrops.[126,516-520] When associated with fetal hydrops at a previable

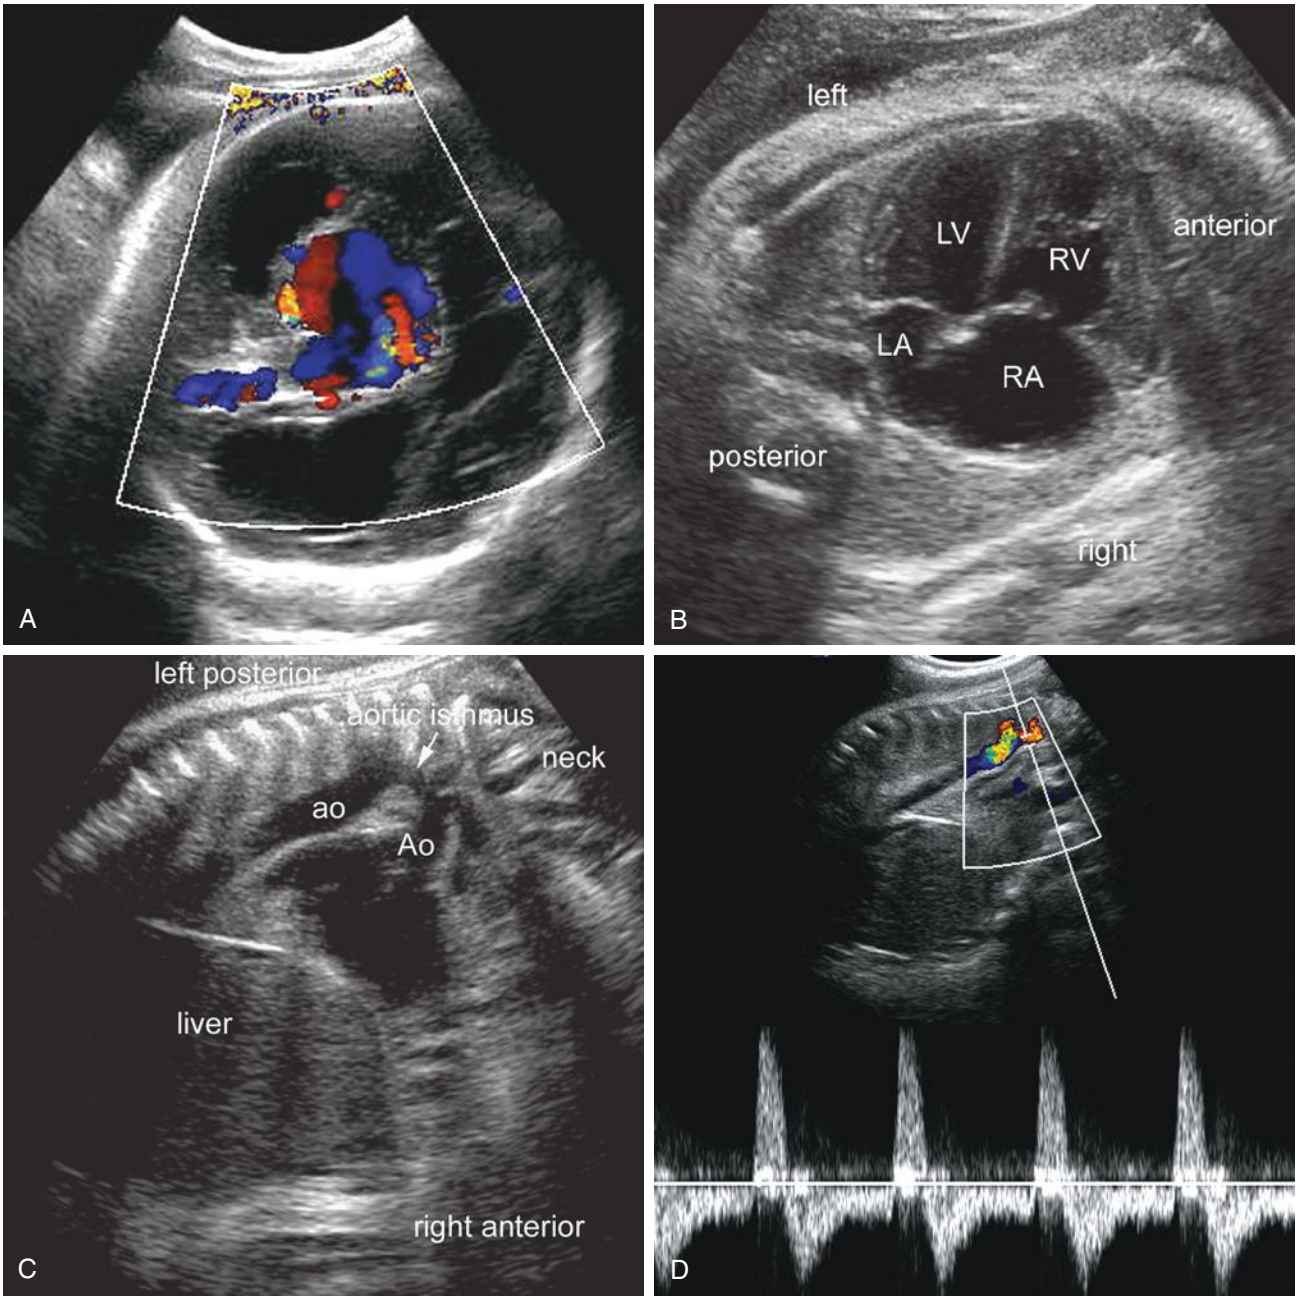

FIG 13-80 Vein of Galen malformation with coarctation of aorta. **A,** Transverse view of the brain shows an aneurysmally dilated vein of Galen and hydrocephalus. **B,** Four-chamber view shows cardiomegaly with dilatation of the right atrium (RA) and right ventricle (RV). The right ventricle is also hypertrophied. **C,** Aortic arch view shows narrow aortic isthmus. **D,** Spectral Doppler tracing of the aortic isthmus shows systolic forward and diastolic retrograde flow. Ao, ascending aorta; ao, descending aorta; LA, left atrium; LV, left ventricle.

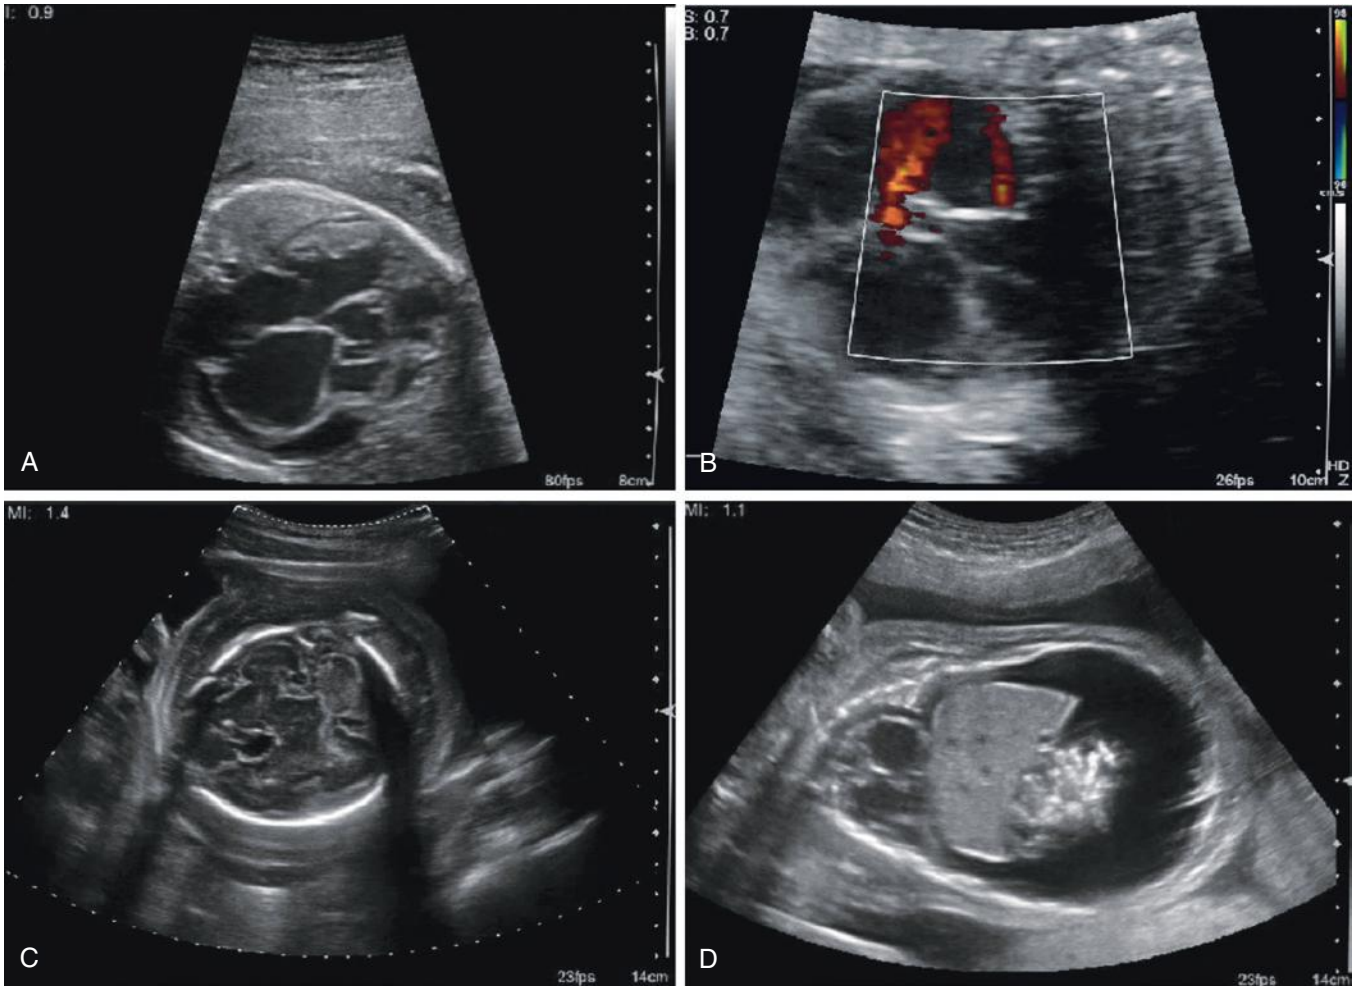

FIG 13-81 Fetus with primary cardiomyopathy. **A,** The four-chamber view demonstrates marked hypertrabeculation of both ventricles with severe enlargement of the atria and a pericardial effusion. **B,** Color Doppler demonstrates moderate mitral and severe tricuspid regurgitation. **C** and **D,** There is fetal hydrops, as evidenced by scalp edema, body wall edema, and ascites.

gestational age, high output vascular malformations are almost universally fatal, although in utero intervention for some of these malformations may improve outcomes.[517,521]

ACKNOWLEDGMENTS

Thank you to Maggie Nguyen, RDCS, and Lacey Schoppe, RDCS, for their constant pursuit of excellence in imaging and preparation of the fetal echocardiography video clips.

Ultrasound Evaluation of the Fetal Gastrointestinal Tract and Abdominal Wall

Allan Nadel

SUMMARY OF KEY POINTS

- Detection of gastrointestinal tract obstruction is often difficult. Duodenal and small intestinal obstructions are easily visualized, but usually not until the third trimester, whereas esophageal atresia and anal atresia may be difficult to detect at any gestational age.
- Echogenic small intestine is a nonspecific finding that is associated with an increased risk for Down syndrome, cystic fibrosis, congenital cytomegalovirus (CMV) infection, fetal growth restriction (FGR), and fetal demise. However, unless there is an increased a priori risk, most fetuses with isolated echogenic bowel have a normal outcome.
- Several sonographic findings in the fetal abdomen can be associated with cystic fibrosis, including echogenic bowel, meconium peritonitis, meconium ileus, and absent gallbladder. If detected, these findings should be correlated with genetic screening results for cystic fibrosis, which is routinely offered in pregnancy.
- Ventral wall defects can often be diagnosed between 11 and 14 weeks, but be aware that isolated small omphaloceles may spontaneously resolve and can perhaps best be thought of as delayed resolution of physiologic bowel herniation.
- Omphalocele can almost always be distinguished from gastroschisis because it involves the umbilicus, is covered by a membrane, and often contains liver. Gastroschisis involves free loops of externalized bowel that have herniated to the right of the umbilical cord insertion site.
- Omphalocele is more likely than gastroschisis to be associated with aneuploidy and other anomalies. Although gastroschisis is typically isolated, affected fetuses have an increased risk of FGR and fetal demise and may have a prolonged course in the neonatal nursery.
- The risk of aneuploidy in a fetus with an omphalocele is directly related to the presence of associated anomalies, and inversely related to the gestational age.

OUTLINE

EMBRYOLOGY

The gastrointestinal tract begins its development early in the 3rd and 4th weeks, as longitudinal and lateral folding of the embryo results in incorporation of the dorsal part of the yolk sac.[1] As this occurs, the endoderm germ cell layer is incorporated into the embryo and forms the primordial (primitive) gut tube (Fig. 14-1).[1] This primitive gut is closed at the cranial end by the oropharyngeal membrane and at the caudal end by the cloacal membrane.[2] The endoderm of the primitive gut gives rise to most of the epithelium and glands of the digestive tract. The epithelium at the cranial and caudal ends of the tract is derived from the ectoderm of the stomodeum (primitive mouth) and proctodeum (anal pit), respectively. The muscular layer, connective tissue, and other layers of the wall of the digestive tract are derived

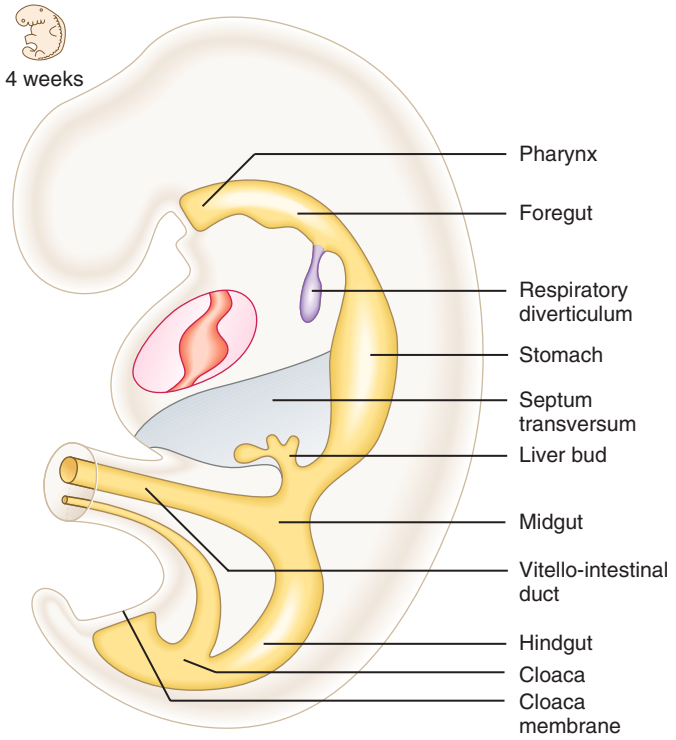

FIG 14-1 The gut tube in a 4-week embryo. (From Mitchell B, Sharma R: Embryology: An Illustrated Colour Text. Edinburgh, Elsevier/Churchill Livingstone, 2005, p 39.)

from the splanchnic mesenchyme surrounding the primitive gut.[2] In the anterior portion of the embryo, incorporation of the endoderm into the head fold results in the formation of the foregut, whereas in the posterior portion of the embryo the hindgut forms.[2] The foregut is divided into a cranial and a caudal portion. The cranial portion develops in the head and neck as the pharynx. In the middle region, the midgut forms, and initially this is in direct continuity with the yolk sac. In addition to the primitive gut tube, the endodermal layer also gives rise to the parenchyma of the two large glandular organs associated with the gastrointestinal duct, the liver and pancreas.[1]

ESOPHAGUS AND STOMACH

The normal esophagus is a collapsed structure that is not routinely imaged. Although it is possible to see the esophagus with a high-frequency transducer after 19 weeks in the majority of cases,[3] this is not part of routine sonography. The presence of a patent and normally functioning esophagus is usually inferred by noting fluid in the fetal stomach, the so-called "stomach bubble." This normally appears as a sonolucent area in the left upper quadrant of the abdomen (Fig. 14-2A and C), which can be seen as early as the first trimester.[4] There may be echogenic material in the fetal stomach bubble, thought to be debris in the amniotic fluid that has been swallowed by the fetus and is of no clinical significance.[5]

The stomach is located on the right side of the abdomen in *situs inversus totalis*, which involves left-right reversal of otherwise normal gross anatomy such that the heart, stomach, and spleen are to the right and the liver is to the left. In about one fourth of cases situs inversus totalis is associated with *primary ciliary dyskinesia (Kartagener syndrome)*, which can cause respiratory distress in newborns, chronic respiratory tract infections, and male infertility.[6]

The stomach can be on the left, in the middle, or on the right side of the abdomen in *heterotaxy syndromes*, a group of disorders of laterality that include polysplenia (bilateral left-sidedness) and asplenia (bilateral right-sidedness).[7,8] Most cases of heterotaxy syndrome are associated with congenital heart disease.

The stomach is frequently displaced by diaphragmatic hernia. It is usually in the thorax, but in milder cases can remain in the abdomen.

The amount of fluid in the stomach is highly variable among normal fetuses as, over time, in an individual fetus the stomach cyclically fills after fetal swallowing and empties through the pyloric valve into the duodenum.[9] A larger than average quantity of fluid in the stomach is common and is generally of no clinical significance as long as there is a normal amount of amniotic fluid and the stomach bubble does not cross the midline, which would suggest duodenal obstruction. *Pyloric atresia* is associated with a large stomach bubble, but is extremely rare and is usually accompanied by polyhydramnios[10] and possibly esophageal dilation.[11] Pyloric stenosis does not become symptomatic until after the child is born and generally cannot be detected in utero.

A small or absent stomach bubble in the absence of polyhydramnios is most often a transient finding seen in a normal fetus. Having the patient return in an hour or so, if at all possible, should cause the patient less anxiety and inconvenience than having her return for a follow-up scan in 1 or 2 weeks.[12] A persistently small or absent stomach bubble, particularly when accompanied by polyhydramnios, suggests an abnormality such as esophageal atresia.

Esophageal Atresia

Esophageal atresia is an interruption of the esophagus such that the upper esophagus ends in a blind pouch, most often at or above the tracheal bifurcation[13] (Fig. 14-3). The prevalence of esophageal atresia is about 2.4 per 10,000.[14] In as many as 90% of cases, esophageal atresia is associated with a tracheoesophageal fistula, which is almost always from the trachea to the distal esophagus.

Associated abnormalities are common. In the EUROCAT (European Registry of Congenital Anomalies and Twins) series of 1222 cases over a 20-year period, esophageal atresia was isolated in less than half of cases[14] (Table 14-1). Associated abnormalities are even more common in prenatal compared to pediatric series of esophageal atresia and indeed may dominate the sonographic picture and result in a poorer prognosis. In an early series, 7 of 16 cases of correctly diagnosed esophageal atresia had trisomy 18, and only 4 survived the neonatal period.[15] Two more recent series found additional abnormalities in 76% of prenatally diagnosed cases.[16,17]

Sonographic Diagnosis

Esophageal atresia is suspected when the amount of fluid in the stomach is less than normal, particularly in the presence of polyhydramnios. The stomach bubble may not be completely absent, because when there is a distal tracheoesophageal fistula (present in the majority of cases) tracheal fluid can flow across the fistula into the distal esophagus and stomach. Even in the setting of esophageal atresia without fistula, gastric secretions may produce a small amount of fluid in the stomach (see Fig. 14-2). Unfortunately, there are no good criteria that define the lower limit of normal size for the fetal stomach. Retrospective reviews describe a "small or absent stomach bubble"[15-19] or an "absent or collapsed fetal stomach"[12] without quantification.

Assessment of stomach size can be subjective and presents a tradeoff between sensitivity and specificity. Sonologists who consider very small stomach bubbles to be normal will occasionally miss an anomalous fetus. Conversely, sonologists who raise concern for these same small stomach bubbles will have many more false positive

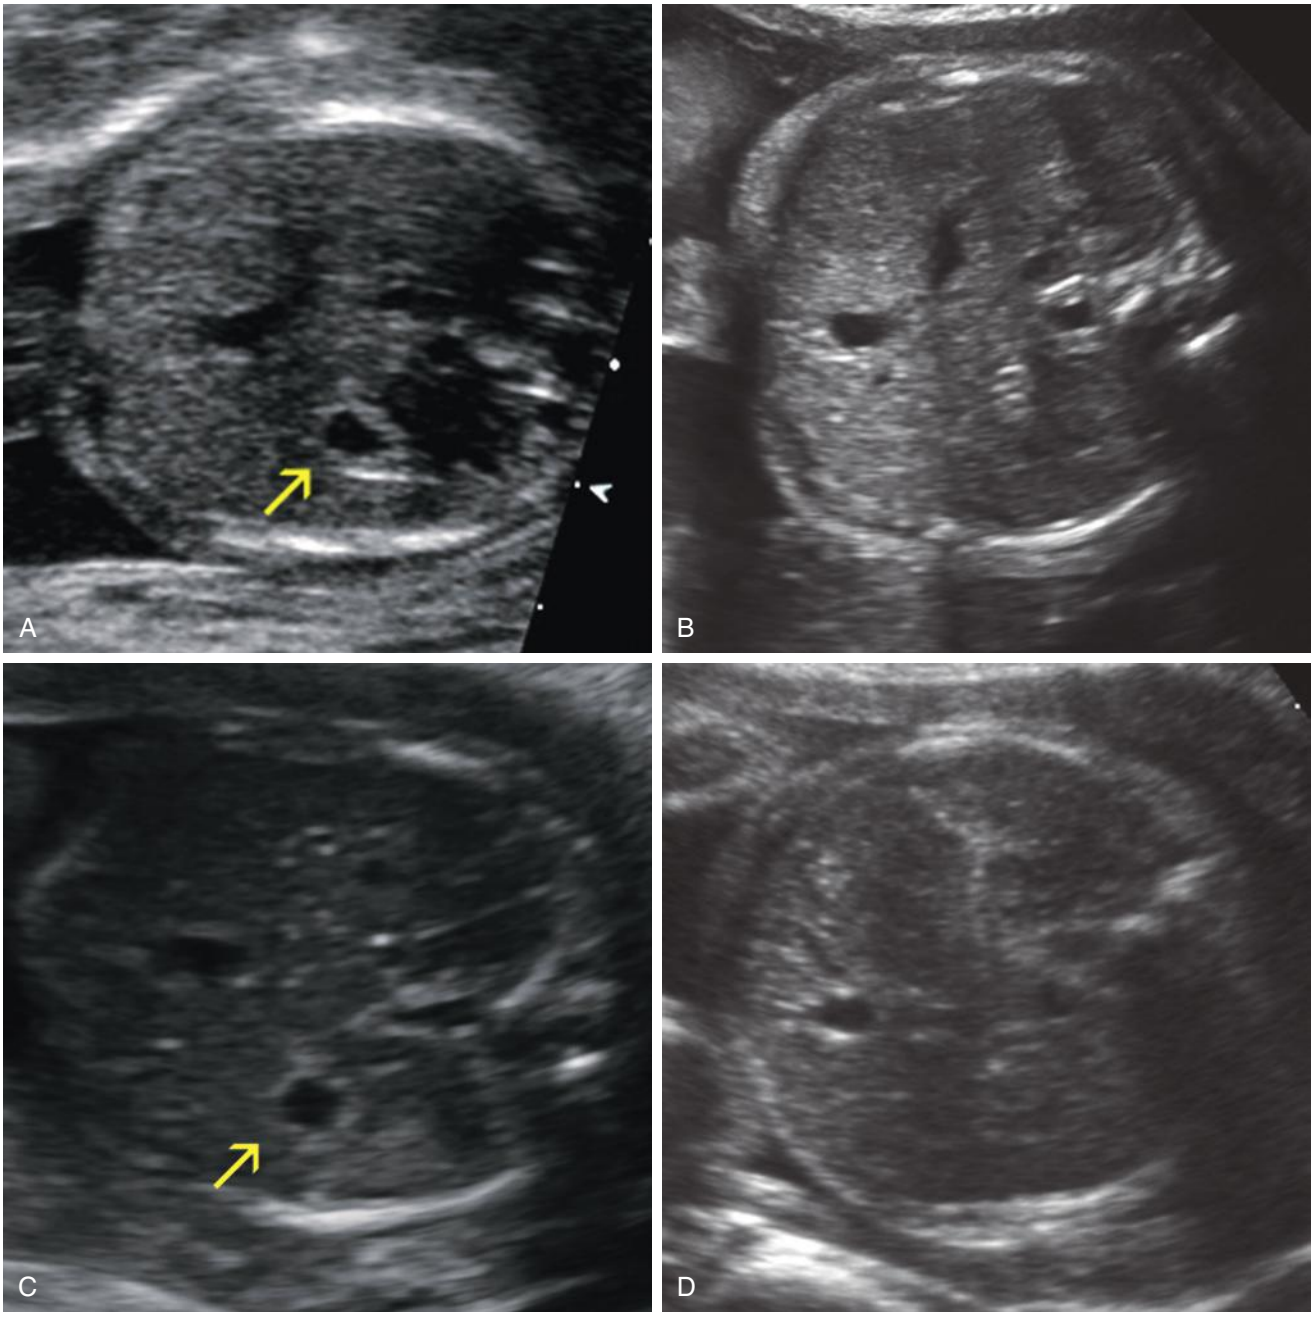

FIG 14-2 Esophageal atresia. **A,** This fetus had multiple anomalies seen at 19 weeks. The stomach bubble (*arrow*) and the amniotic fluid volume were normal. **B,** The same fetus as in A at 30 weeks. At this time the stomach bubble was absent and there was mild polyhydramnios. The child had esophageal atresia with tracheoesophageal fistula and CHARGE syndrome (see Table 14-3). **C,** The patient was 41 years old and declined aneuploidy screening. At 19 weeks, the fetal stomach bubble (*arrow*) and the amniotic fluid volume were normal. **D,** The same fetus as in C at 28 weeks. At this time the stomach bubble was absent and there was mild polyhydramnios. The child had esophageal atresia (without tracheoesophageal fistula) and Down syndrome.

diagnoses, resulting in more anxious patients, an increased number of follow-up sonograms, and potentially unnecessary amniocenteses.

A completely absent stomach bubble is more likely than a small stomach bubble to represent esophageal atresia, particularly in the presence of polyhydramnios. For example, in one study esophageal atresia was present in all five fetuses with polyhydramnios and an absent stomach bubble but was found in only three of six fetuses with polyhydramnios and a small stomach bubble.[20] As expected, a small stomach bubble with normal amniotic fluid volume was often a transient finding in a normal fetus.

Care must be taken to confirm that the stomach is not in an unusual location, as may be the case with situs inversus, heterotaxy syndrome, diaphragmatic hernia, or ventral wall defect. A persistently absent or very tiny stomach bubble suggests an inability of the fetus to swallow amniotic fluid and transport it to the stomach. There are several possible causes in addition to esophageal atresia (Table 14-2).

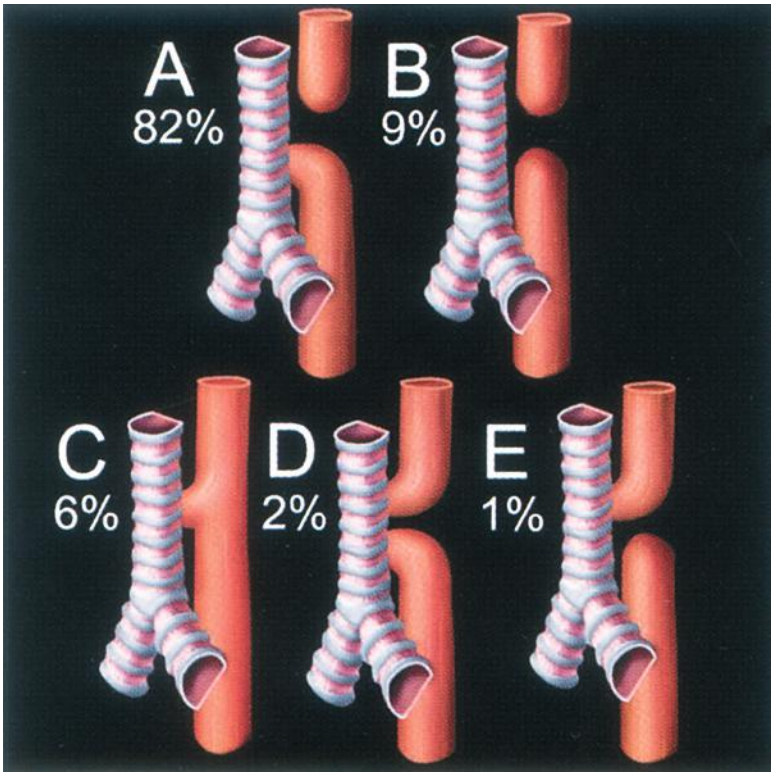

FIG 14-3 Graphic illustration of the five main types of esophageal atresia with and without tracheosophageal fistula. (From Donnelly LF, Jones BV, O'Hara SM, et al [eds]: Diagnostic Imaging, Pediatrics. Salt Lake City, Amirsys, 2005, p 44.)

Data from Pederson R, Calzolari E, Husby S, Garne E; EUROCAT Working group: Oesophageal atresia: prevalence, prenatal diagnosis and associated anomalies in 23 European regions. Arch Dis Child 97(3):227-232, 2012.

TABLE 14-2 Pathologic Causes for Persistently Small or Absent Stomach Bubble in the Fetus

Oligohydramnios from any cause (e.g., preterm premature rupture of membranes, bilateral renal disease, urethral obstruction, donor twin in twin-twin transfusion syndrome) presumably because there is less fluid to swallow.

Neuromuscular disorder that impairs active swallowing: any condition that is associated with hypokinesia and/or arthrogryposis.

Abnormalities of the face or neck that can interfere with active swallowing or cause a mechanical obstruction: micrognathia (often associated with hypokinesia syndromes), orofacial cleft, epignathus (teratoma originating from the mouth), neck mass (teratoma, large goiter).

Esophageal atresia with or without tracheoesophageal fistula.

Therefore, sonographic evaluation of the fetus with a small or absent stomach bubble should always involve meticulous inspection of the rest of the anatomy with particular attention to amniotic fluid volume, fetal activity, and the fetal face, neck, and chest. A 2010 series[12] reported a wide variety of conditions in association with persistent nonvisualization of the fetal stomach: esophageal atresia was found in only 8/48 cases (17%) after excluding those with oligohydramnios or aberrant location of the stomach. Seven fetuses were ultimately found to be normal. Fetal akinesia sequence was present in six cases.

The detection rate of esophageal atresia is poor. There were 152 cases of esophageal atresia with complete data in Northern England between 1985 and 1997; only 14 were prenatally diagnosed, for a detection rate of 9%.[18] The EUROCAT registry reported that the detection rate increased only slightly over time, from 26% during the years 1987 to 1996 to 36% in the following decade.[14] The best results were obtained in Norway: 46% of 46 cases were detected, although 32 of these cases were referred because of sonographic abnormalities.[16] A recent, more representative review of children treated for esophageal atresia in Texas between 2002 and 2014 showed that only 16% of 91 cases were prenatally diagnosed,[21] suggesting that the "real world" detection rate remains low.

In addition, prenatal diagnosis of esophageal atresia, when made, tends to occur late in gestation. Approximately one third are diagnosed prior to 28 to 30 weeks,[15-17] with median gestational age of in utero diagnosis of esophageal atresia of 31 to 32 weeks[16,18] (see Fig. 14-2).

As previously noted, the sonographic diagnosis of esophageal atresia is often incorrect.[12] Esophageal atresia was found in 17% of fetuses with a small or absent stomach bubble; this increased to 34% to 44% when there was also increased amniotic fluid volume.[15,18] In a more recent study, esophageal atresia was found in 8/18 euploid fetuses that had persistent nonvisualization of the stomach and polyhydramnios; 2 fetuses were normal, and the remaining 8 had a variety of other problems.[12] In a series of 22 fetuses with suspected esophageal atresia, the diagnosis was more likely to be correct if subsequent scans showed a persistently absent stomach bubble and development of polyhydramnios[22]; 11 fetuses in this study did not have esophageal atresia, and 5 were found to be normal.

In an effort to improve the accuracy of prenatal sonographic diagnosis of esophageal atresia, several authors have suggested use of the *pouch sign* representing the proximally dilated esophagus in the neck or thorax. This sign was present in 43% of fetuses with esophageal atresia,[16] and most authors feel that it is very specific, so when seen, the diagnosis is most frequently correct. However, an esophageal pouch should not be confused with a normal pharynx; false positive results have been reported.[23]

More recent studies have utilized magnetic resonance imaging (MRI); at a mean gestational age of 30 weeks an esophageal pouch was seen in 10/12 fetuses (83%) with and in 0/11 fetuses without postnatally confirmed esophageal atresia.[24] In another recent (2014) study at a mean gestational age of 32 weeks, an abnormal MRI was correct in all 8 cases, whereas a normal MRI was correct in only 5 of 7.[25] Note that both of these series evaluated fetuses in the third trimester.

Antepartum Management

When esophageal atresia is suspected because of a persistently small or absent stomach bubble, a careful ultrasound examination should be performed, with special attention to the following:

1. Fetal activity to exclude the possibility of diminished fetal swallowing due to fetal hypokinesia
2. The face and neck to exclude the possibility of an anatomic obstruction
3. Findings associated with VACTERL (vertebral anomalies, anal atresia, cardiac defects, tracheoesophageal fistula and/or esophageal atresia, renal anomalies, and limb defects) (Table 14-3): including vertebral bodies, rectum and anus, heart, kidneys, extremities (especially radii and thumbs) and umbilical arteries
4. Findings associated with aneuploidy (especially Down syndrome and trisomy 18)

Because of the high prevalence of associated congenital heart disease, a fetal echocardiogram is recommended. An MRI can be considered, both to evaluate the esophagus and to search for additional anomalies not detected by ultrasound examination. The possibility of fetal aneuploidy should be addressed. If amniocentesis is performed, testing for the *CHD7* gene associated with CHARGE (see Table 14-3). syndrome can be considered.

Serial sonograms should be obtained to search for additional anomalies and evaluate fetal growth. The diagnosis of esophageal atresia typically becomes more evident over time, with a persistently absent stomach bubble and development of polyhydramnios (see Fig. 14-2). A pediatric surgery consult is advised, and delivery should be at a tertiary care center.

TABLE 14-3 Characteristics of VACTERL Association and CHARGE Syndrome

VACTERL is an acronym that refers to an association of nonrandom co-occurring structural anomalies involving multiple body parts and organ systems.[a]
- V: vertebral anomalies such as segmentation defects, e.g., hemivertebrae (60%-80%)
- A: anorectal malformations, e.g., anal atresia (55%-90%)
- C: cardiac abnormalities (40%-80%)
- TE: esophageal atresia with or without tracheoesophageal fistula (50%-80%)
- R: renal abnormalities (50%-80%)
- L: limb malformations, such as radial ray defects (40%-50%)

By common agreement, at least three anomalies must be present to warrant this diagnosis/label, without evidence of overlapping genetic conditions, such as Fanconi anemia.

Additional anomalies are frequently associated with VACTERL. For example, single umbilical artery is seen in 20% of cases.[b]

The prevalence of VACTERL association is reported to be 1:10,000 to 1:40,000.[a] The underlying cause is not known, although changes in genes coding for transcription factors have been implicated.[c] Although most cases are sporadic, 9% of probands have a first-degree relative with at least one component of this association.[d]

CHARGE syndrome is caused by a mutation in *CHD7* gene.
- *C*oloboma of the eye
- *H*eart defects
- *A*tresia choanae (also known as choanal atresia)
- *R*etardation of growth and/or development
- *G*enital and/or urinary abnormalities
- *E*ar abnormalities

Although not part of the acronym, tracheoesophageal fistula is found in 20% of cases (see Fig. 14-2).[e]

Neonatal Management

Feeding should be withheld. Passage of a catheter into the stomach is attempted and a radiograph is obtained. In the presence of esophageal atresia, the tip of the catheter is kinked at about T2 to T4.[13]

Repair of the most common form of esophageal atresia, with a distal tracheoesophageal fistula, can be done via either thoracotomy or thoracoscopic approach. If there is no distal fistula, repair can be more complicated and may require initial placement of a gastrostomy.

Survival rate for full-term infants without associated anomalies approaches 100%.[26] Complications can include anastomotic leaks, esophageal stricture, and recurrent tracheoesophageal fistula. Other

long-term problems include tracheomalacia, disordered esophageal peristalsis, gastroesophageal reflux, vocal cord dysfunction, and respiratory problems.

SMALL INTESTINE

Duodenal Obstruction

Duodenal obstruction can be intrinsic, most commonly because of atresia, or extrinsic, from constriction. An annular pancreas may occur in conjunction with an intrinsic defect rather than representing a true constricting lesion.[27] A duodenal web can cause partial obstruction. The prevalence of duodenal obstruction is about 1.8 per 10,000 births.[28]

Ultrasound Diagnosis

The characteristic "double bubble sign" of duodenal obstruction, usually seen in conjunction with polyhydramnios, was one of the first fetal anomalies that could be detected by ultrasound. However, a more specific diagnosis requires demonstration of continuity of the dilated duodenum with fluid in the stomach, crossing the midline of the fetus[29] (Fig. 14-4). If such continuity cannot be established, other causes of an upper abdominal cyst (such as choledochal, mesenteric, hepatic, or enteric duplication cyst) should be considered. The differential diagnosis also includes duodenal duplication.[30]

Cases of transient duodenal dilation have been reported, presumably caused by transit of fluid across the pyloric valve, so assessment of suspected dilation should include documentation for a reasonable length of time.

Duodenal obstruction can rarely, if ever, be diagnosed in the first trimester.[31,32] At the routine 20-week obstetric sonogram, the detection rate may be as high as 50%,[29,33] but like other obstructions of the gastrointestinal tract, this diagnosis is more reliably made in the third trimester.

Associated Anomalies

Up to one half of children with duodenal obstruction have Down syndrome.[29,34] This is not surprising considering that the relative risks of duodenal atresia and annular pancreas for Down syndrome are 264 and 430, respectively.[35] That is, the finding of duodenal obstruction increases the odds that a fetus has Down syndrome by a factor of at least 264.

In addition to Down syndrome, duodenal obstruction is associated with a wide variety of structural abnormalities, in particular congenital heart disease, additional intestinal problems such as malrotation and atresia, and all of the anomalies that are part of the VACTERL association (see Table 14-3).[29,34]

Prognosis

As is true with many conditions, the prognosis for duodenal obstruction is highly dependent on the presence or absence of associated anomalies. In isolated duodenal obstruction, survival rate approaches 100%[29]; there is a wide variation in mortality rate in complicated cases, dependent on the nature of the associated anomalies.

Antenatal Management

At the time of diagnosis, a detailed search for additional abnormalities should include a fetal echocardiogram. The risk of aneuplopidy should be addressed. Duodenal obstruction is associated with a high rate of prematurity, possibly because of polyhydramnios, and an increased rate of unexpected fetal demise.[36] Antenatal surveillance is sometimes considered, although the benefit is unclear. A pediatric surgery consult is advised, and delivery should be at a tertiary care center.

Neonatal Management

Fluid resuscitation and gastric decompression are followed by surgical repair, which can be either laparoscopic or by open duodenoduodenostomy. Long-term survival is excellent for term infants without associated anomalies but complications such as gastroesophageal reflux and delayed gastric emptying can occur.[37]

Echogenic Bowel

Definition

On second trimester ultrasound imaging, the fetal liver, lung, small intestine, and bone demonstrate increasing echogenicity in that order (Fig. 14-5A). In the 1990s it was noted that sometimes the echogenicity of small intestine is increased, such that it appears as bright as bone. This was referred to as "echogenic bowel," a term often used interchangeably with echogenic small intestine. At that time, standard transducers used for obstetric ultrasound imaging had frequencies of 3.5 to 5 MHz and were without harmonic signal processing. Present-day transducer frequencies are typically 5 to 8 MHz and harmonics are routinely employed. These newer transducers offer improved resolution and thereby enhance prenatal diagnosis. They also make the disparity in echogenicity between small intestine and liver more conspicuous, thereby making the diagnosis of echogenic bowel more difficult[38] (Fig. 14-5B and C).

For these reasons, it is now recommended that when echogenic small intestine is suspected, a low-frequency transducer (≤5 MHz) should be used. Some authors suggest that the gain be turned down to allow for comparison between the echogenicity of small intestine and bone. Despite these caveats, the detection of echogenic small intestine remains very subjective, more than most other sonographic observations[39] (Fig. 14-6A). There are no standardized criteria for the sonographic diagnosis of echogenic small intestine.[40]

A 2011 review states that the prevalence of echogenic small intestine in routine second trimester sonograms ranges from 0.2% to 1.8%.[41] This ninefold range in prevalence attests to the subjectivity of this finding.

Etiology

Echogenic small intestine is thought to be due to abnormal characteristics of intraluminal bowel contents or edema of the bowel wall.[40] Factors such as decreased amniotic fluid volume, presence of meconium, intestinal hypomotility because of ischemia, and swallowed blood after intra-amniotic bleeding have been associated with echogenic bowel.

Association With Adverse Outcomes (Table 14-4)

Down Syndrome. The odds that a fetus has Down syndrome is increased in the presence of echogenic small intestine. The amount that it is increased is defined by the *likelihood ratio* (LR). Owing in part to the subjective nature of echogenic bowel, LR values as disparate as

TABLE 14-4 Adverse Outcomes Associated With Echogenic Bowel

Aneuploidy, in particular Down syndrome
Cystic fibrosis
Growth restriction and fetal demise
Congenital infection, in particular cytomegalovirus (CMV)
Gastrointestinal obstruction

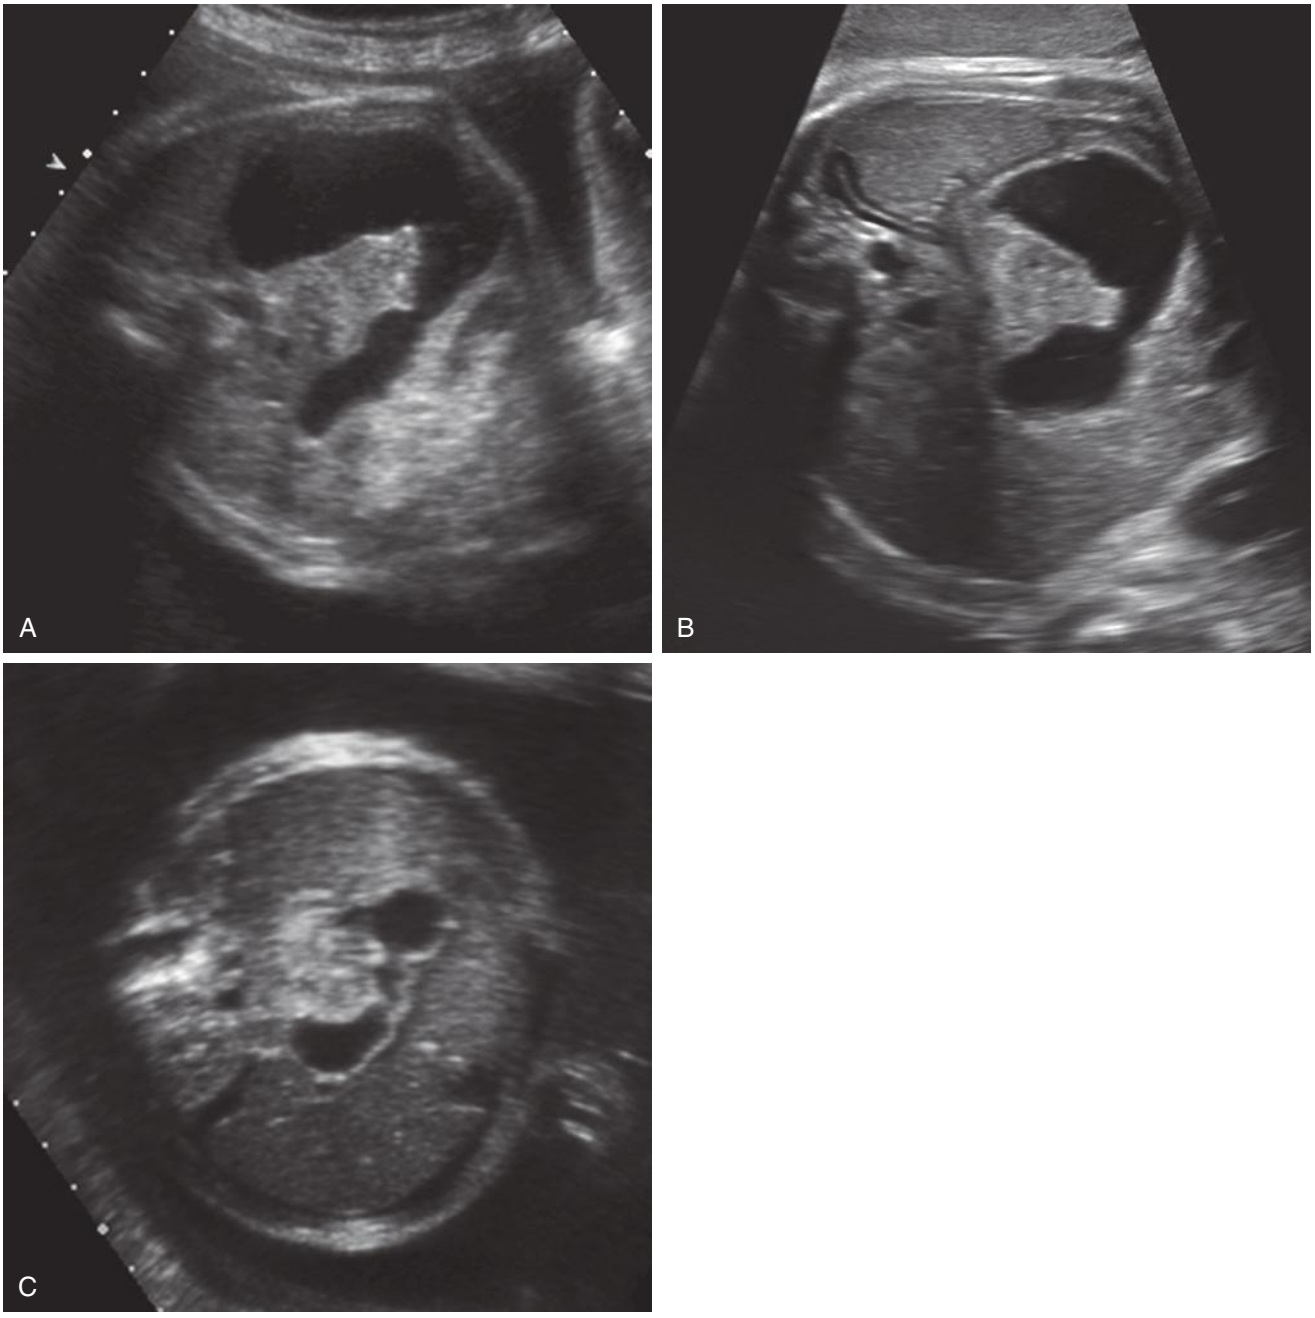

FIG 14-4 Duodenal obstruction. In these three fetuses the diagnosis of duodenal obstruction was made in the third trimester. All three demonstrate similar, characteristic ultrasound findings with fluid shown in the stomach and proximal duodenum. **A,** This fetus was first seen at 34 weeks. On postnatal evaluation, he was found to have an annular pancreas and normal chromosomes. He is doing well except for gastroesophageal reflux. **B,** Duodenal atresia in a fetus with Down syndrome. **C,** This pregnancy was followed for mild fetal ascites (see Fig. 14-18). Evidence of duodenal obstruction and mild polyhydramnios was noted by ultrasound examination at 31 weeks. The child has Down syndrome and underwent an open duodeno-duodenostomy on day 9 of life.

1.7[42] and 5.5 to 6.7[43] have been cited in a meta-analysis and in the executive summary of a National Institutes of Health (NIH)-sponsored workshop, respectively. In addition, the positive LR of an *isolated* finding (such as echogenic bowel) depends on the product of the negative LRs of all of the other sonographic markers, referred to as "soft signs." The earlier studies cited by the NIH workshop[43] did not include evaluation of the nasal bone, which has a negative LR of approximately 0.5. Conversely the meta-analysis[42] considered evaluation for an aberrant subclavian artery, which is not frequently done. If evaluation of the nasal bone is added to the NIH workshop estimate, the LR for isolated echogenic bowel decreases to about 3, and if evaluation of the subclavian artery is removed from the meta-analysis, the LR for isolated echogenic bowel increases to 2.4. Thus the two estimates can be more closely reconciled.

Cystic Fibrosis. Cystic fibrosis has been detected in about 8% of fetuses with echogenic small intestine.[44] However, these patients were

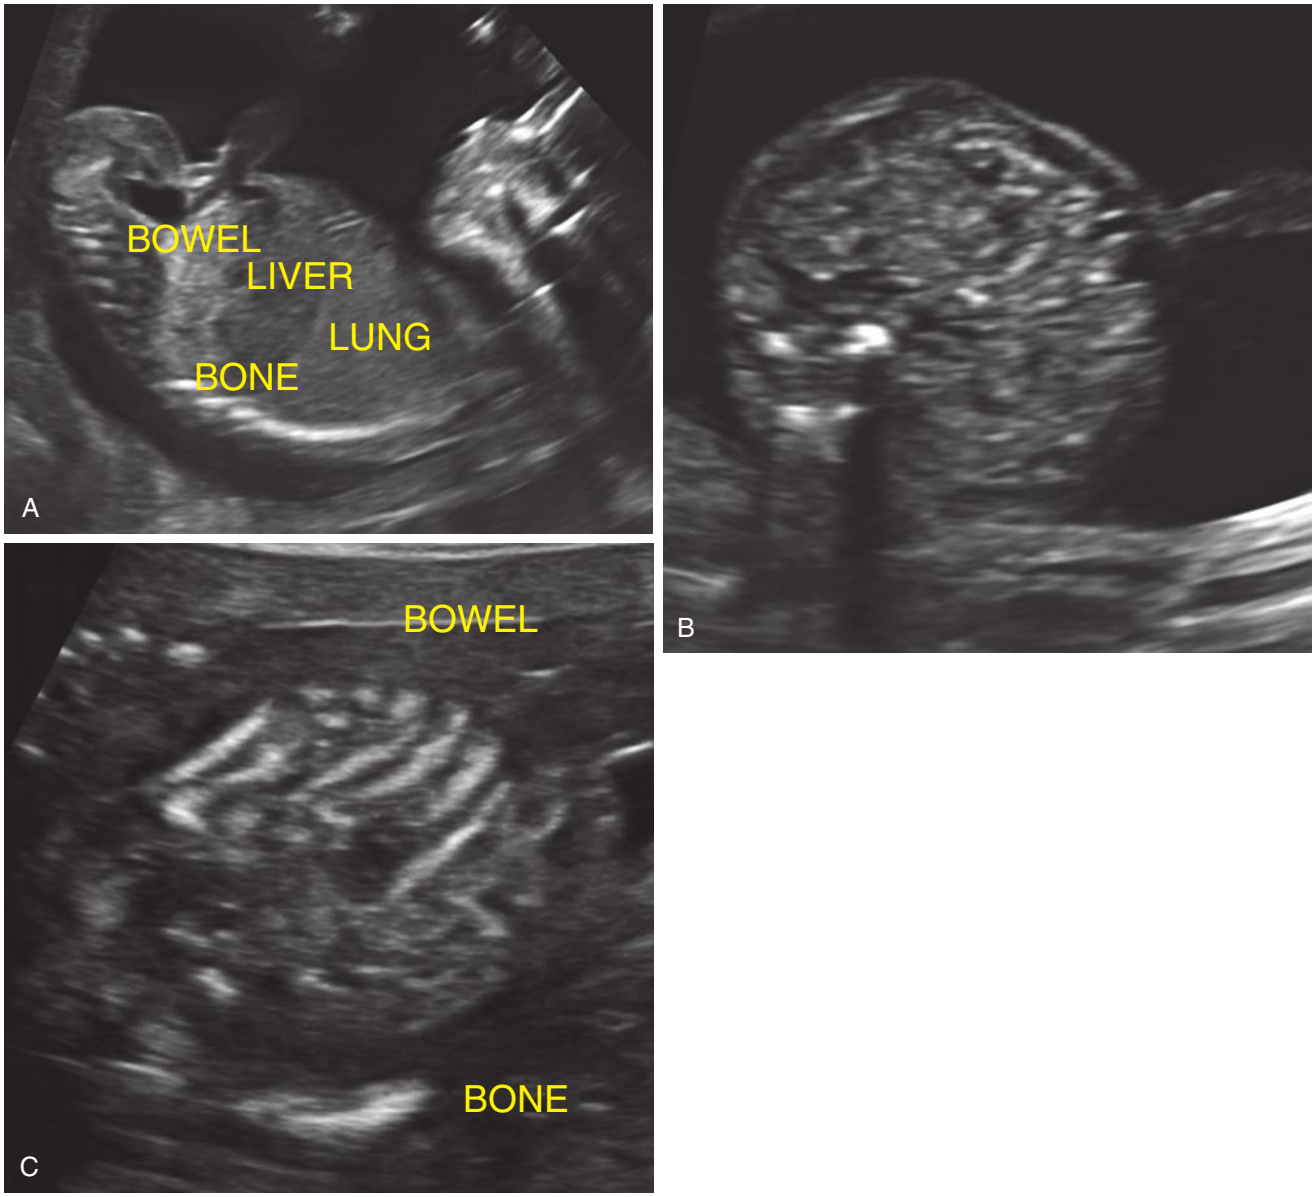

FIG 14-5 Normal intestine in the second trimester. **A,** Midline sagittal view through the normal fetal abdomen. In order of increasing echogenicity: liver, lung, bowel, bone. **B,** Characteristic appearance of fetal intestine in the second trimester, shown on this transaxial view through the midabdomen. **C,** Using a 9-MHz transducer, the settings were deliberately manipulated to give the intestine an abnormal appearance such that, as a result of artifact, the echogenicity of bowel is as bright as iliac bone.

not previously screened for cystic fibrosis carrier status, which can detect approximately 90% of heterozygotes in the caucasian population; offering such screening is the standard of care in the United States. The frequency of cystic fibrosis in a *prescreened* population with echogenic bowel would clearly be much less. In some cases, sequencing of the cystic fibrosis transmembrane receptor gene may be helpful in patients with echogenic fetal bowel and normal cystic fibrosis screening results.

Congenital Infection. In one study, there were reported to be sonographic findings in 30 of 69 cases of congenital CMV infection, including 9 cases of echogenic small intestine.[45] Other sonographic findings associated with congenital CMV infection included growth restriction, head circumference below the 5th percentile, brain calcifications, and ventriculomegaly. An earlier study demonstrated similar results: 7 of 154 fetuses (5%) with documented congenital CMV infection had echogenic bowel, whereas 131 fetuses (85%) had no sonographic findings.[46] Conversely, the likelihood of CMV infection in a fetus with echogenic small intestine is at most 3%[46] and the association with other infections is even less.[40]

Fetal Growth Restriction and Stillbirth. In recent years, increasing attention has been directed toward the association between echogenic small intestine and obstetric complications. The likelihood of fetal demise and of FGR was increased by a factor of 9.6 and 2.1, respectively, in fetuses with echogenic small intestine.[47] The median gestational age at fetal demise was 24 weeks, and in this study all spontaneous fetal losses that were observed in the setting of isolated echogenic small intestine occurred at or before 30 weeks. A subsequent study reported very similar findings, with an increase in the likelihood of growth restriction from 1.3% to 9.9% and an increase in the likelihood of fetal demise from 0.5% to 8.9% in fetuses with isolated echogenic

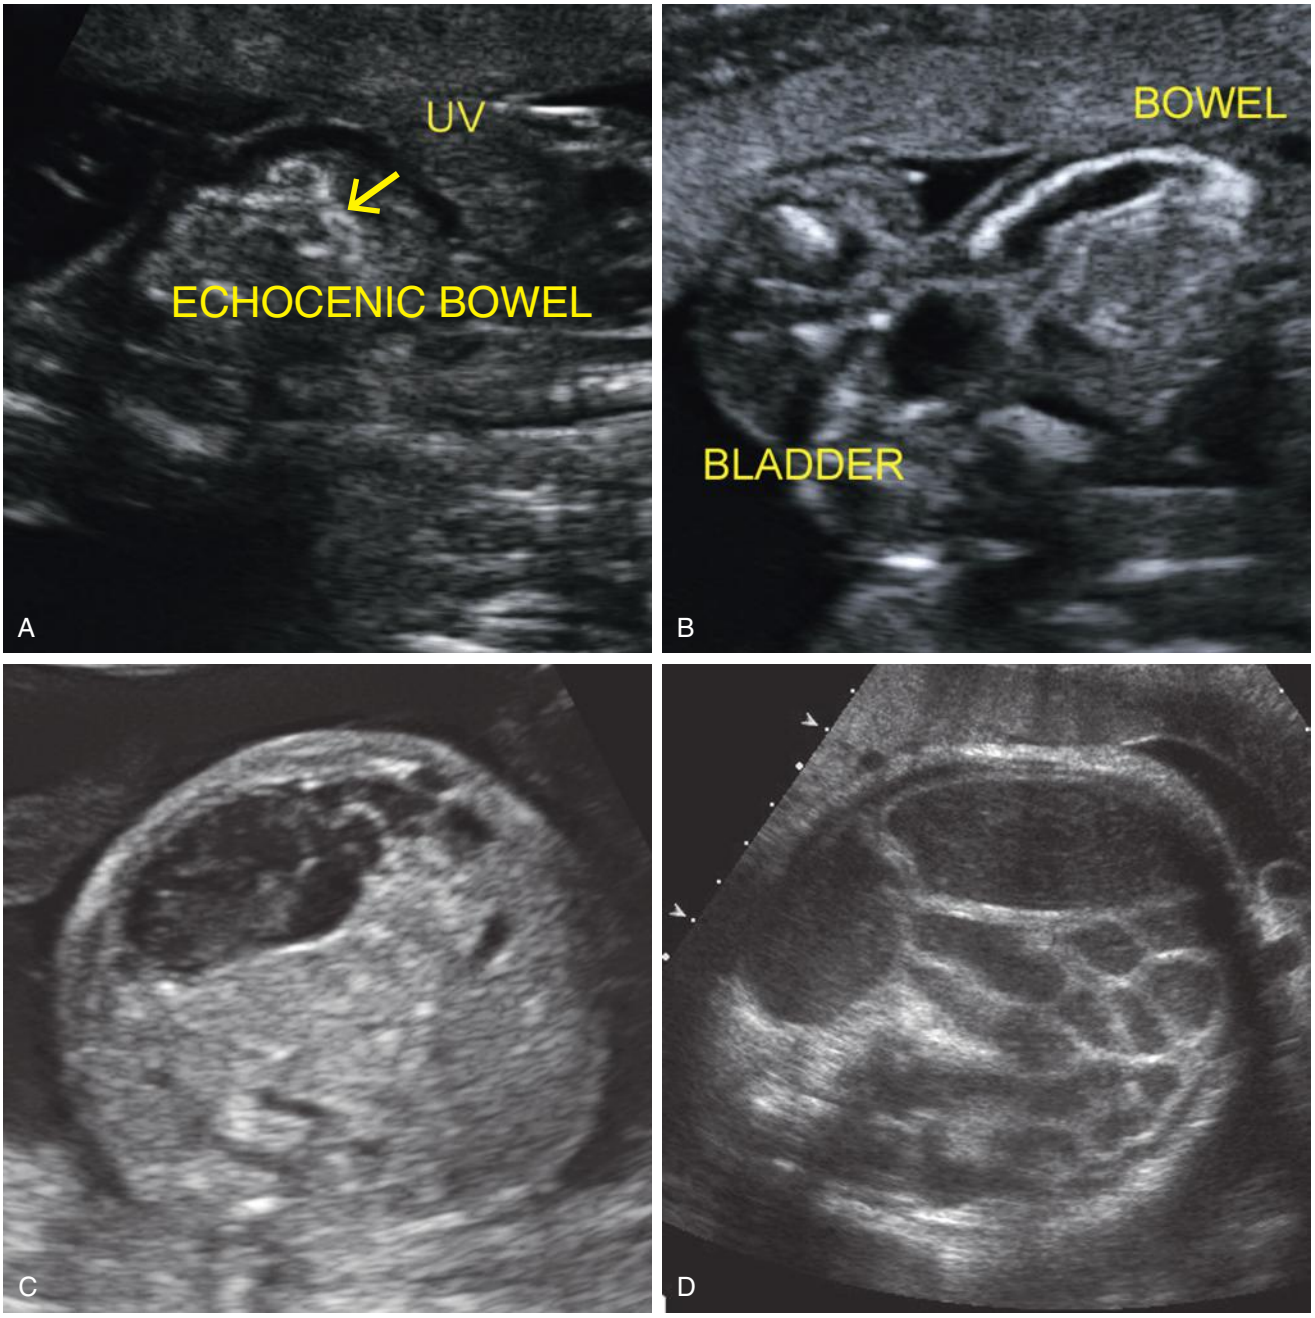

FIG 14-6 Evolution of jejunoileal obstruction. **A,** Typical sonographic appearance of echogenic fetal bowel (*arrow*) at 19 weeks. UV, umbilical vein. **B,** Of note on this follow-up examination, a slightly dilated loop of small bowel with an echogenic rim is shown. **C,** At 23 weeks, a heterogeneous intra-abdominal cystic structure with echogenic margins was noted, indicating a meconium pseudocyst. **D,** Progressive dilatation of fluid-filled small bowel segments was observed on serial obstetric sonograms. This is the appearance at 37 weeks. Immediately after birth, the child underwent resection of 27 cm of small bowel, with anastomosis of 104 cm of proximal to 52 cm of distal small bowel. She is now doing well without nutritional deficiencies. (**D,** Courtesy of Mary Frates, MD.)

small intestine. Again, the median gestational age at fetal demise was 24 weeks and all spontaneous losses occurred prior to 30 weeks.[48] These data suggest that the advantage of antenatal surveillance starting at 32 weeks may be limited.

Additional factors that may further increase the likelihood of obstetric complications in fetuses with echogenic small intestine include elevated maternal serum alpha-fetoprotein[49,50] and abnormal uterine artery Doppler.[51]

Echogenic small intestine is rarely associated with other anomalies, such as α-thalassemia[40] and intestinal obstruction (see Fig. 14-6).

Management of Isolated Echogenic Small Intestine

1. Targeted sonographic evaluation of fetal anatomy, including search for other markers of aneuploidy or evidence of congenital CMV infection, to ensure that the echogenic small intestine is indeed an isolated finding.

2. Evaluation of a priori risk of aneuploidy based on maternal age and previously obtained screening results. If the patient desires, additional prenatal testing for aneuploidy can be offered. Given that the increased risk of aneuploidy is relatively modest and is mainly limited to trisomy 21, cell-free DNA testing is a useful option to consider in this setting.
3. Evaluation of a priori risk of cystic fibrosis based on parental ethnicity and previously obtained carrier screening for *CFTR* mutations, which should be offered if not previously obtained. Even if the mother screened negative, there is a residual risk that she is a carrier, and that the fetus could be affected. If the prospective parents wish to address this concern, the next step would be to obtain blood from the father of the fetus for carrier screening, and if he tests positive, one or both parents could pursue gene sequencing, which can detect mutations not identified through genotyping panels.
4. Evaluation for congenital infection with maternal serologic tests. Blood is routinely drawn to test for CMV antibodies, both IgG and IgM. To help assess if the infection is acute in the setting of positive IgM antibody, IgG avidity can be determined. Although it is possible to have fetal manifestations from recurrent or secondarily infected CMV, the likelihood is low. Unless there are specific concerns, serologic tests for other infections such as toxoplasmosis may not be warranted.[41] If the maternal serologic tests indicate evidence of acute infection, further evaluation such as amniocentesis for CMV RNA using polymerase chain reaction should be offered.
5. Fetal surveillance in the second half of pregnancy. This typically entails serial ultrasound examinations, often every 4 weeks, to assess growth and amniotic fluid volume. Many institutions also institute weekly or biweekly nonstress tests or biophysical profiles after 32 weeks. Follow-up sonograms will detect most cases with bowel complications.

As a rule, providers taking care of the newborn should always be apprised of antenatal sonographic findings. If the child appears well, no further evaluation is necessary after an in utero finding of isolated echogenic small intestine: follow-up of 48 such infants demonstrated a normal outcome.[52]

Jejunoileal Obstruction

When performing a second trimester obstetric sonogram using a high-frequency transducer, particularly in a thin patient, individual loops of fetal bowel can often be discerned (see Fig. 14-5B). During the third trimester, fluid can be seen within the bowel lumen; the maximal diameter of normal fetal small intestine is reported to be 7 mm.[53]

The hallmark of distal small bowel obstruction is dilated loops of bowel (Fig. 14-6D). This is rarely seen before the third trimester. Polyhydramnios, a dilated stomach, and echogenic bowel are nonspecific findings that are sometimes associated with or are precursors to identification of frank obstruction[54] (Table 14-5).

Obstructed fetal small bowel should not be confused with normal fetal colon, which becomes more prominent during gestation, typically appearing as hypoechoic bowel segments, of varying size, at the periphery of the abdomen (Fig. 14-7A). The small intestine tends to

TABLE 14-5 Sonographic Comparison Between Jejunal and Ileal Atresia in the Second Half of Pregnancy

Segment	Intestinal Loops	Stomach	Peritoneal Calcification	Ascites	Associated Anomalies	Polyhydramnions
Jejunum	Marked dilation of loops, most of them on the left abdominal side Enlargement of duodenum is common	Large	Frequent	Very rare	Frequent	Frequent
Ileum	Usually only minor dilation of a few loops	Normal	Frequent	Frequent	Rare	Rare

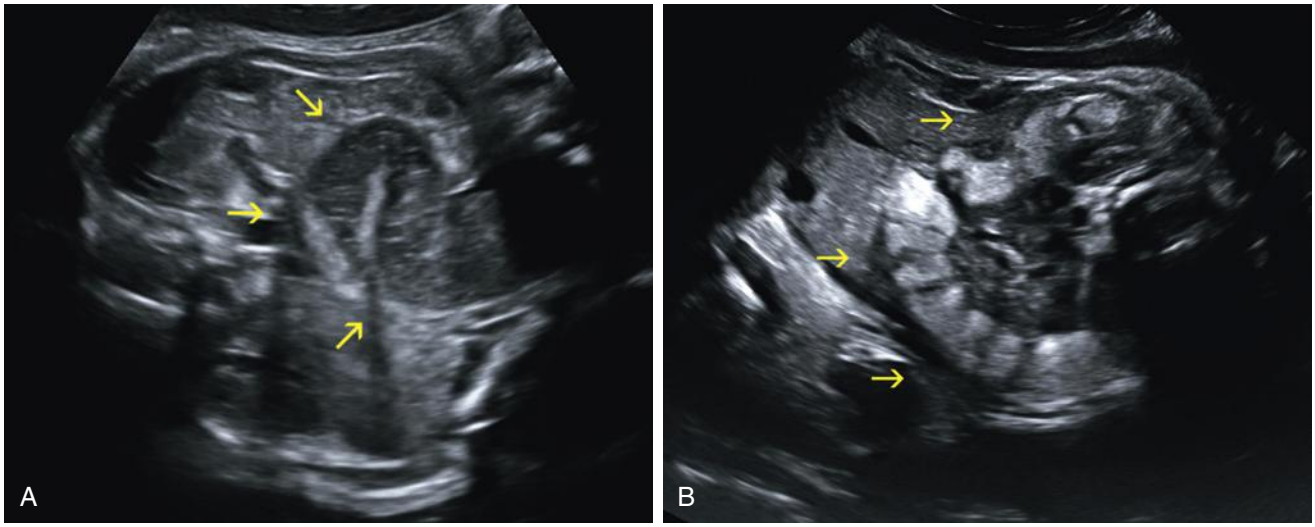

FIG 14-7 Normal fetal colon. **A,** Normal fetal colon in the third trimester appears as hypoechoic loops of varying size at the periphery of the abdomen and in the pelvis (*arrows*). **B,** Echogenic colon (*arrows*) is a benign finding when seen after 36 weeks.

be more centrally located. Rarely, late in the third trimester, the large intestine can have a characteristic echogenic appearance (Fig. 14-7B). This is considered an innocuous finding unless it is detected prior to 36 weeks, when it has been associated with cystinuria.[55]

Etiology

Atresia of a segment of jejunum or ileum is thought to most often be a consequence of vascular disruption leading to ischemic necrosis of a variable length of small bowel.[56] Evidence of swallowed amniotic fluid distal to the atresia suggests that the ischemic event occurred relatively late in gestation.[27] This finding is usually sporadic and the risk of extraintestinal anomalies varies, depending on level of obstruction. In one series of 38 children with jejunal atresia, there were 10 with cystic fibrosis, 4 with congenital heart disease, and 5 with a variety of other defects including one with Down syndrome. In contrast, only 1 of 45 children with ileal atresia had an associated anomaly.[56] Other abnormalities of the gastrointestinal tract, such as esophageal atresia, duodenal obstruction, and anorectal malformation, are sometimes seen in association with jejunoileal obstruction.

Some rare autosomal recessive syndromes are associated with jejunoileal atresia: "apple peel" atresia is associated with an extensive atretic segment and therefore has a guarded prognosis,[57] and another syndrome with multiple atretic segments has a poor prognosis.[58] Midgut volvulus, with[59] or without[60] the whirlpool sign, has also been reported prenatally. Meconium ileus, which is sometimes due to cystic fibrosis, is a common cause of fetal small bowel obstruction. This occurs from an accumulation of inspissated meconium in the distal ileum.

Evaluation and Antenatal Management

The differential diagnosis includes congenital intestinal pseudoobstruction, colonic atresia, Hirschsprung disease, and congenital chloride diarrhea.[61] Hydroureter should be reasonably easy to distinguish from dilated bowel by ultrasound imaging as it can be traced to the bladder or kidney. In some studies, fetal MRI has been reported to be useful.[62]

Fetal small bowel obstruction has been associated with a high incidence of prematurity and growth restriction, possibly related to an inability to obtain oral nourishment from the amniotic fluid.[63]

Neonatal Management

Treatment for jejunoileal atresia is surgical, and the prognosis is excellent unless there are multiple sites of atresia or extensive "apple peel" atresia. The treatment for volvulus is also surgical and prognosis depends on the length and condition of the affected bowel; "short gut" syndrome is the major cause of long-term morbidity.

Initial treatment for simple meconium ileus is one or more isotonic water-soluble contrast enemas, which is successful in the majority of cases.

Meconium Peritonitis

Meconium peritonitis is thought to result from inflammation that occurs in response to intestinal rupture. The perforation can be due to intestinal atresia, volvulus, intussusception, internal hernia, or vascular compromise; often the cause is unknown.[64] In the past, pediatric series of symptomatic newborns reported high rates of morbidity and mortality[65] but the prognosis of sonographically detected prenatal cases is much better; in two recent papers, there were 5 deaths out of a total of 107 cases.[64,66]

Meconium peritonitis is suspected when extraluminal abdominal calcifications and ascites are seen. Extraluminal calcifications form along the visceral or parietal peritoneum, often on the surface of the liver or under the diaphragm, and appear as linear echogenic densities possibly with posterior acoustic shadowing (Fig. 14-8A). These changes may also extend through the patent processus vaginalis into the scrotum[67] (Fig. 14-8B). Ascites may be observed initially and then noted to resolve over time.

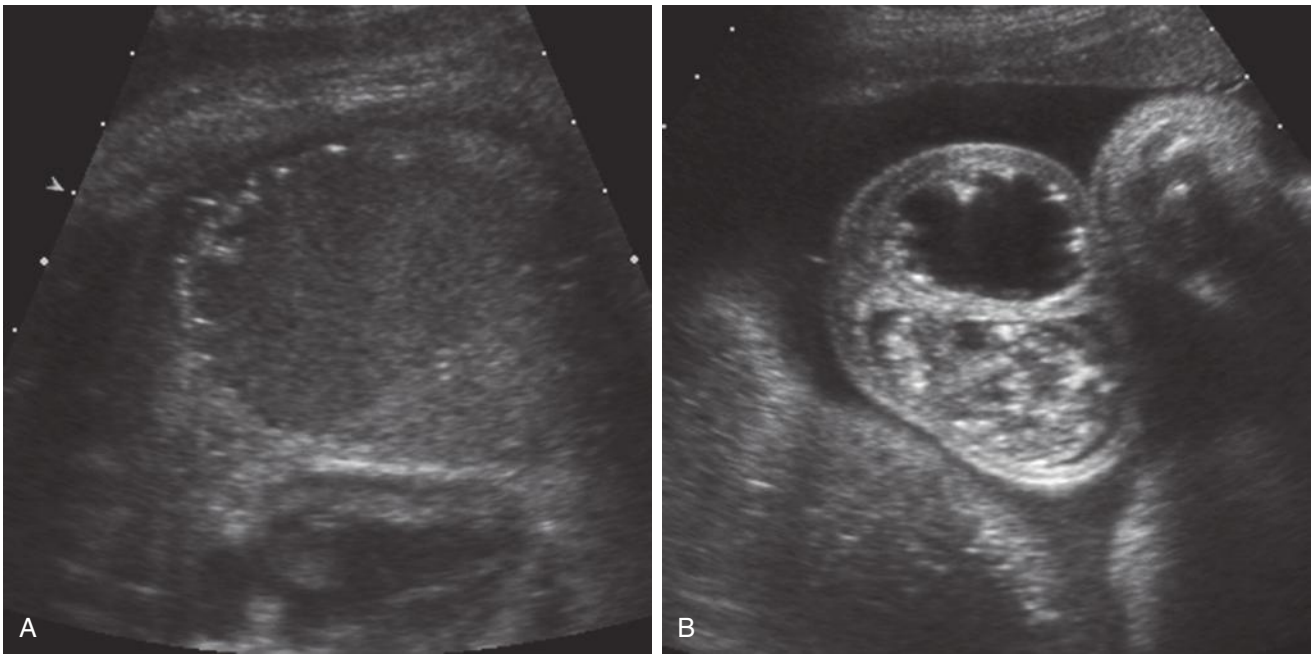

FIG 14-8 Meconium peritonitis. **A,** Multiple tiny echogenic foci indicating peritoneal calcifications along the surface of the liver at 37 weeks. **B,** Because of patency of the processus vaginalis in the fetus, calcifications related to meconium peritonitis may also be seen within the scrotum. The child appeared healthy at birth and was discharged without any special testing, although he did undergo bilateral inguinal hernia repair at 5 weeks of age.

A *meconium pseudocyst* occurs when extravasated intestinal contents become walled off. It typically appears as a complex, round intra-abdominal cystic collection with an echogenic wall (Fig. 14-6C).

Several methods of grading the severity of meconium peritonitis have been suggested; all agree that the greater the severity, the greater the likelihood that the newborn will be symptomatic. Using one such classification system, when sonographic abnormalities included only intraperitoneal calcifications, 0/18 infants required surgical intervention; but when there were additional findings such as ascites, pseudocyst, bowel dilation, or polyhydramnios the likelihood of surgical intervention increased.[64] The authors suggest that it may be safe to deliver a fetus with only scattered intraperitoneal calcifications in a community hospital, but when other sonographic findings are noted, delivery in a tertiary care center is probably warranted.

Pediatric series have demonstrated a strong association between meconium peritonitis and cystic fibrosis.[65] Interestingly, cases associated with cystic fibrosis are less likely to demonstrate intraperitoneal calcifications, perhaps because the intestinal contents are less inflammatory or remain more localized.[68] Genetic testing for cystic fibrosis is routinely offered early in pregnancy, and results of such testing should be evaluated if meconium peritonitis is identified. Other factors that have been reported in association with meconium peritonitis include parvovirus infection[69] and hepatitis A.[70]

RECTUM

Anorectal Malformations

Anorectal malformations result from abnormal partitioning of the cloaca by the urorectal septum into the urogenital sinus anteriorly and the rectum posteriorly (Fig. 14-9); these malformations are also referred to as *urogenital sinus malformations*. Earlier failure of development of the urorectal septum results in a higher, more severe

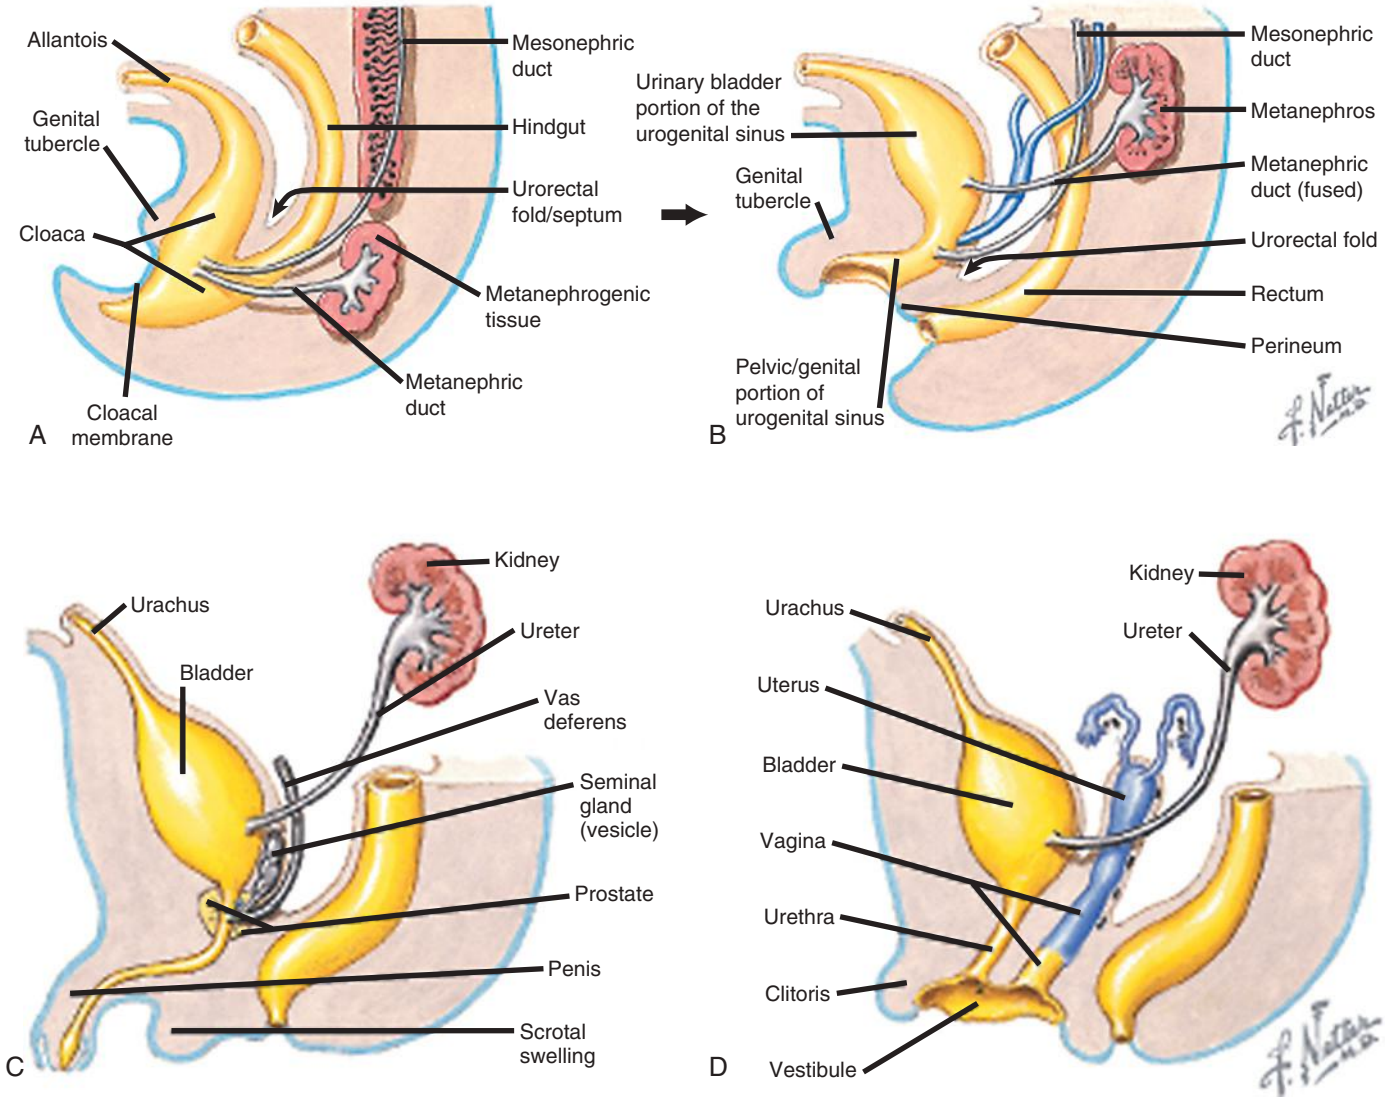

FIG 14-9 Normal embryology: division of the cloaca. The urorectal septum grows in a caudal direction (**A**) until it reaches the cloacal membrane, where it becomes the perineum (**B**). The remaining cloacal membrane perforates posteriorly to form the anus, and anteriorly to form the urethra in males (**C**) and the urethra/vestibule/vagina in females (**D**). (Copyright Netterimages.com.)

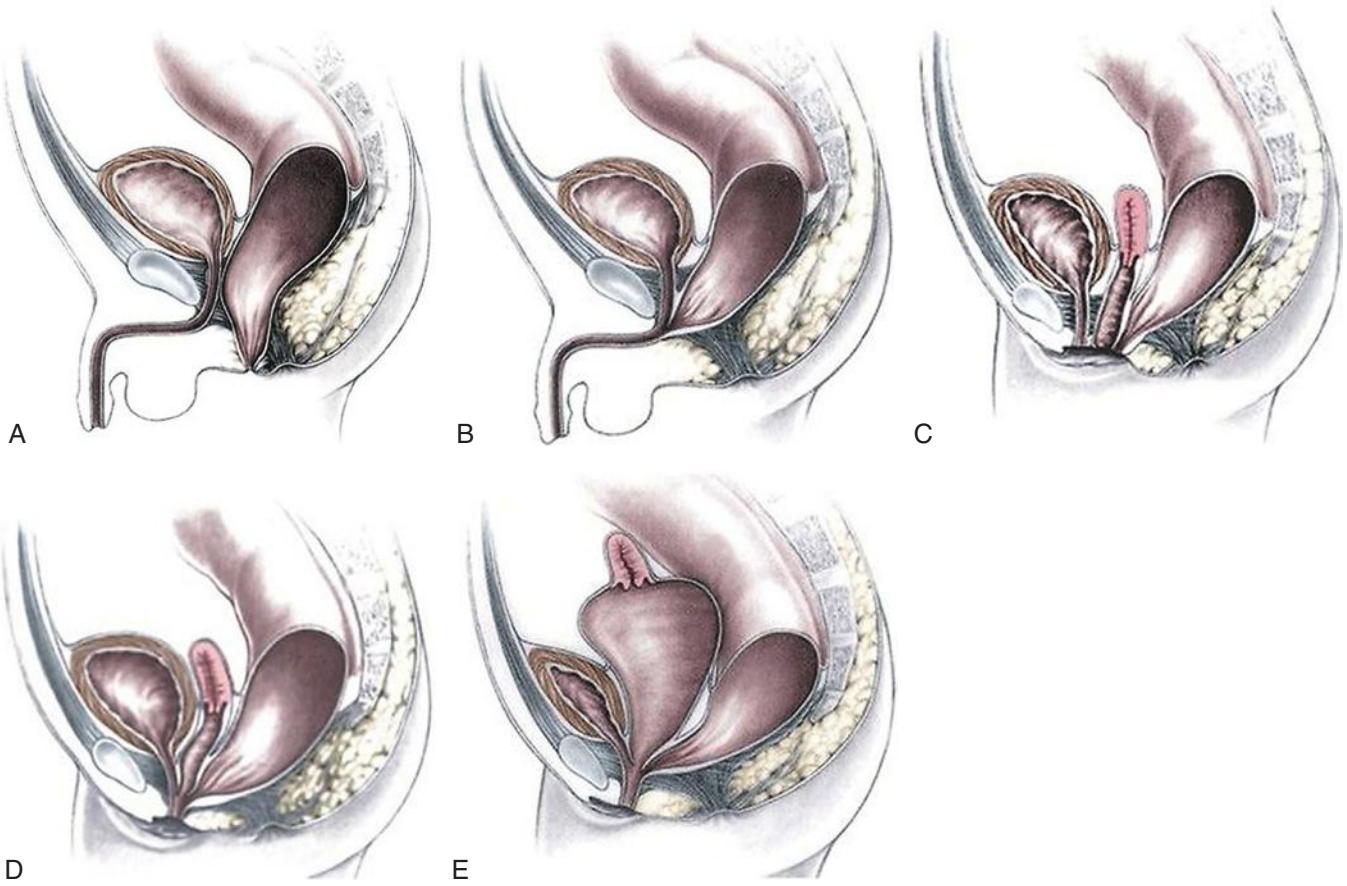

FIG 14-10 Anorectal malformations. **A,** Imperforate anus with rectoperineal fistula opening anterior to the anal muscle complex. **B,** Imperforate anus with rectourethral fistula. This is the most common anorectal defect in males. **C,** Imperforate anus with rectovestibular fistula. This is the most common anorectal defect in females and has an excellent functional prognosis. **D,** Persistent cloaca. **E,** Persistent cloaca with hydrocolpos. The vagina often has a longitudinal septum, not shown in this drawing. (From Holcomb GW, Murphy JP, Ostlie DJ [eds]: Ashcrafts's Pediatric Surgery. Philadelphia, Elsevier, 2014, Figs. 35-1, 35-3A, 35-7A, 35-8B, 35-10A, respectively.)

abnormality. The mildest defects are often referred to as *anal atresia* or *imperforate anus* and often involve a rectal fistula that opens anterior to the anal muscular complex (Fig. 14-10A through C). Anorectal malformation without fistula, which is strongly associated with Down syndrome,[71] accounts for only 4% of anorectal malformations. In females, the most severe abnormality is *persistent cloaca* (Fig. 14-10D), which will be discussed separately.

Prevalence and Associated Anomalies

The EUROCAT survey of 4.6 million births identified 1846 cases of anal anomalies, with a prevalence of 4 per 10,000 births.[72] Fortunately lower lesions are far more common than higher lesions; only 10% of anal atresias were above the level of the levator ani. A wide variety of additional findings are present in the majority of cases and include VACTERL (see Table 14-3), chromosomal abnormalities, other known syndromes and sequences, and multiple anomalies involving the genital system, central nervous system, face, limbs, musculoskeletal system, and to a lesser extent, all other organ systems.[73]

Although most cases are sporadic, like some other abnormalities, there is often a genetic component, and anorectal malformations are associated with a variety of single gene syndromes.[74] There are also reports of familial nonsyndromic anorectal malformations.

Sonographic Diagnosis

Cystic fluid collections in the first trimester have been associated with anal atresia[75] (Fig. 14-11A and B). In the second trimester, observation of a dilated rectum allowed for the prenatal sonographic diagnosis in only 11 of 69 (16%) cases of anal atresia and in only 3 cases when it was isolated.[76] Calcified intraluminal meconium is sometimes seen in cases of anorectal malformations, but it is not known how often this occurs.[77] These findings are likely related to the presence of an enterourinary fistula, which allows urine to distend the rectum and interact with meconium, resulting in a calcified appearance. In contrast, one might not see any sonographic findings in the case of rectoperineal or rectovestibular fistulas (see Fig. 14-10A and C) or of anal atresia without a fistula.

More recent studies address the possibility of direct visualization of the fetal anal sphincter as a circular hypoechoic area with a small echogenic center (Fig. 14-12B), which can be identified in more than 90% of fetuses after 23 weeks' gestation.[78] In one study, inability to image this structure allowed for the prenatal diagnosis of 17 cases of anal atresia.[79] Some groups utilize three-dimensional (3D) sonography for this purpose.[80] A combination of 2D and 3D techniques was used to evaluate 189 fetuses at increased risk for anorectal malformation based on the presence of one or more other congenital structural

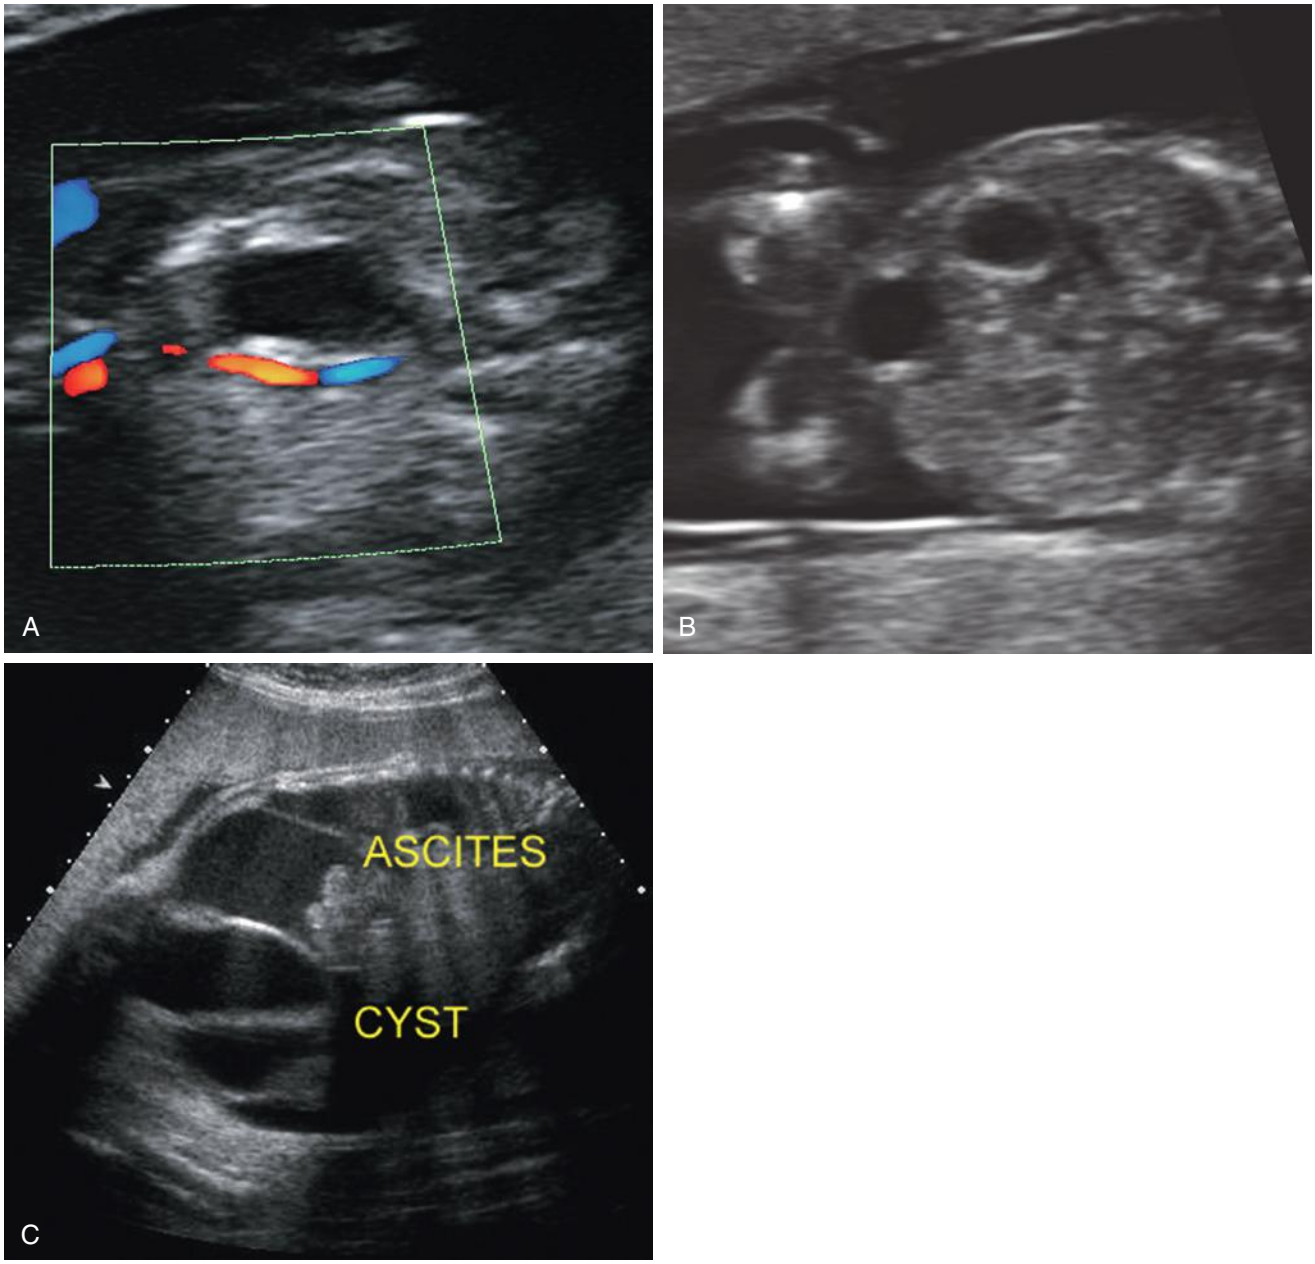

FIG 14-11 Persistent cloaca. **A,** At 13 weeks, fluid-filled structure thought to be a large bladder with adjacent single umbilical artery, shown by color Doppler sonography. **B,** Also observed at 13 weeks was a small round abdominal cyst. The karyotype was normal. The fetal anatomic survey at 18 weeks demonstrated intra-abdominal calcifications, echogenic bowel wall, and umbilical cord cyst. **C,** In the third trimester, a septated cystic mass was shown posterior to a normal-appearing bladder. Also noted was marked ascites, with low level echoes present within the peritoneal fluid. The kidneys appeared normal. The diagnosis was urogenital sinus malformation with septated hydrocolpos (persistent cloaca). There was in utero fetal demise due to thrombosis of the single umbilical artery. The diagnosis was confirmed at autopsy. (**A** and **B,** Courtesy of Rosemary Reiss, MD; **C,** Courtesy of Mary Frates, MD.)

anomalies known to be associated with anorectal malformations. The investigators correctly excluded anorectal malformation in 175 fetuses and correctly detected an abnormality of the anus in the other 14.[81]

Persistent Cloaca

This most severe form of anorectal malformation is found only in females. It is very uncommon, with a prevalence of only 0.2 per 10,000.[72] With persistent cloaca, the distal portion of the urinary tract, vagina, and rectum all lead to a single common channel that opens onto the perineum (see Fig. 14-10D). In 30% of cases, hydrocolpos develops as a result of passage of urine and meconium into the vagina, which is more compliant than the bladder or rectum (Fig. 14-10E).[82] Development of hydrocolpos can result in several additional pathologic changes, some of which can be seen by ultrasound imaging in the third trimester (Figs. 14-11 and 14-13).

Hydrocolpos presents as a midline cystic mass in the pelvis, posterior to the bladder, extending to the perineum (Fig. 14-11C).[83] There is often a longitudinal vaginal septum, and there may be fluid/fluid

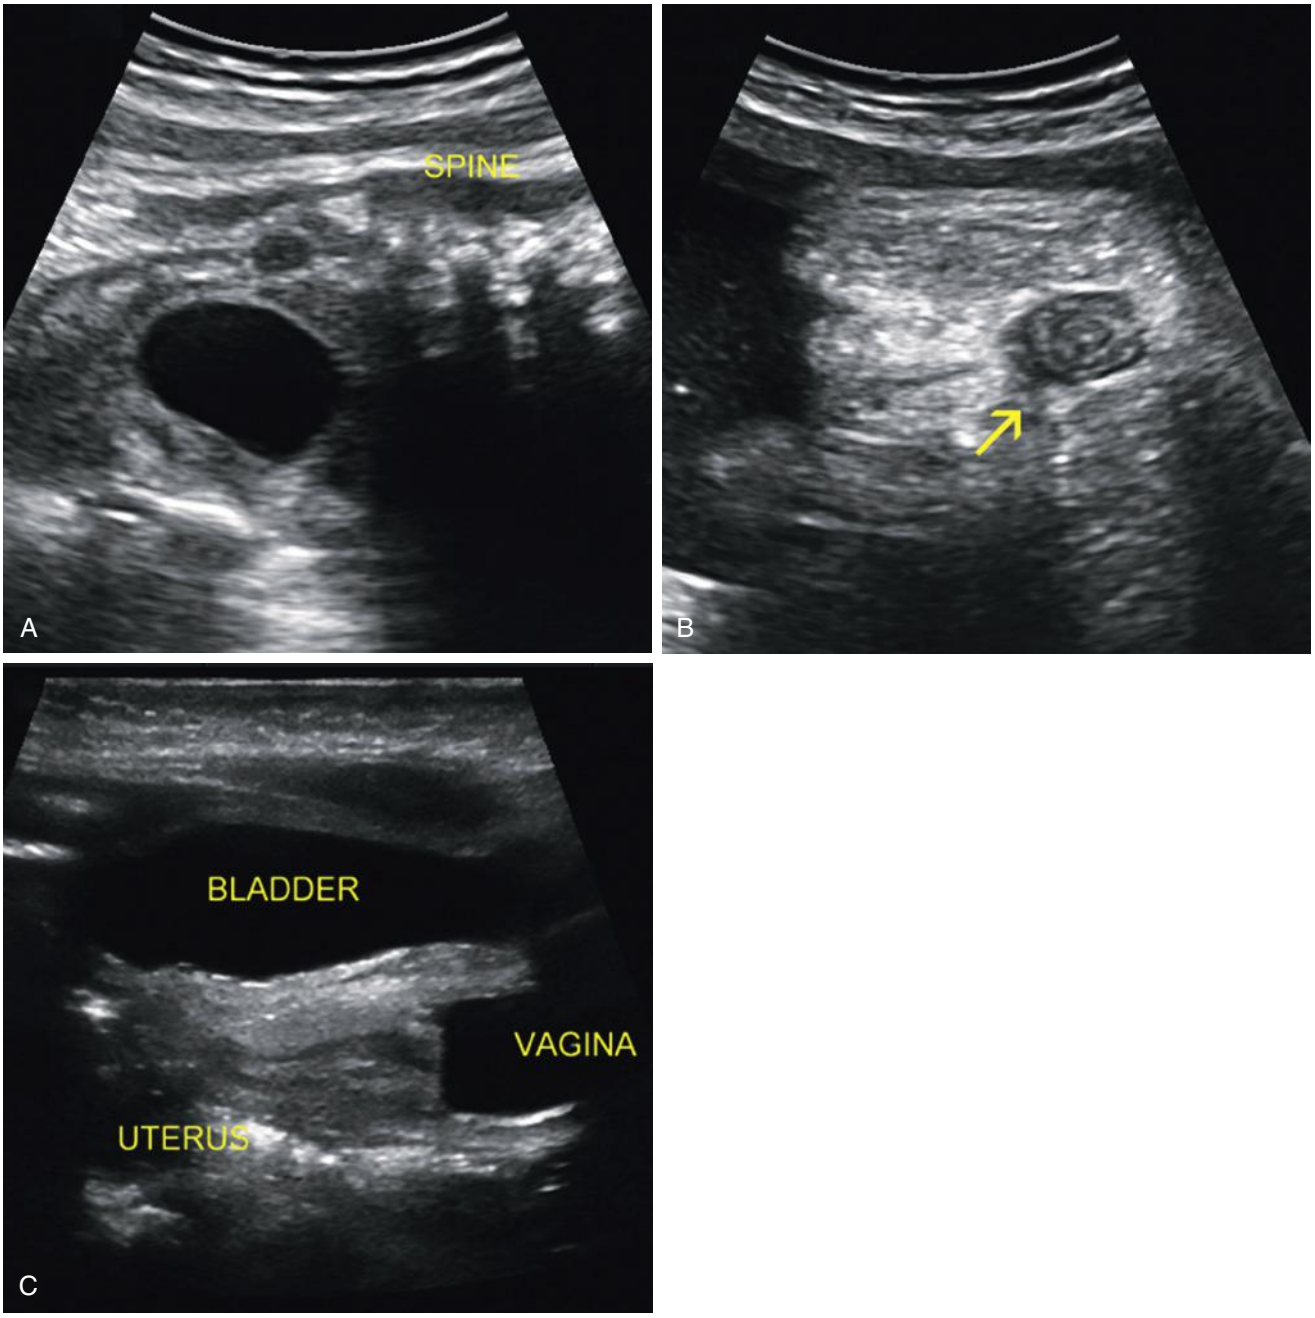

FIG 14-12 Isolated hydrocolpos. **A,** A 2.5-cm anechoic cyst in the pelvis, anterior to the sacrum and posterior to the bladder. **B,** As part of the targeted sonographic evaluation, a normal anus, appearing as a circular structure (*arrow*) with echogenic center, was visualized. **C,** Postnatal transabdominal pelvic sonogram showing fluid in the distended vagina, posterior to the fluid-filled urinary bladder.

levels due to mixture of urine and meconium. The contents of the cystic mass will not be uniformly sonolucent as is the case in megacystis.

Hydrocolpos is frequently associated with urinary tract obstruction; hydronephrosis and oligohydramnios were the next most common abnormalities seen on prenatal ultrasound imaging.[84] If obstruction is at the level of the bladder outlet, there will be megacystis; if obstruction is at the level of the trigone, the bladder will appear normal or small.

Ascites is seen in a minority of cases. It is thought that this occurs as a result of retrograde passage of cloacal contents through the fallopian tubes.[83] Because of the inflammatory response triggered by this material, abdominal calcifications characteristic of meconium peritonitis may be seen.[85,86] In some cases, dilated loops of bowel will demonstrate intraluminal calcifications due to mixing of meconium with urine.[83,84,86] Additional findings that may be seen in this setting include multicystic dysplastic kidney, ectopic/malpositioned kidney, single umbilical artery, and spinal abnormalities.[83]

The prenatal diagnosis of persistent cloaca is challenging, and in two recent series was made in only 6% of cases.[84,86] This is likely related to the rarity of this condition, the complex and variable nature of the ultrasound findings with hydrocolpos present in less than half. When

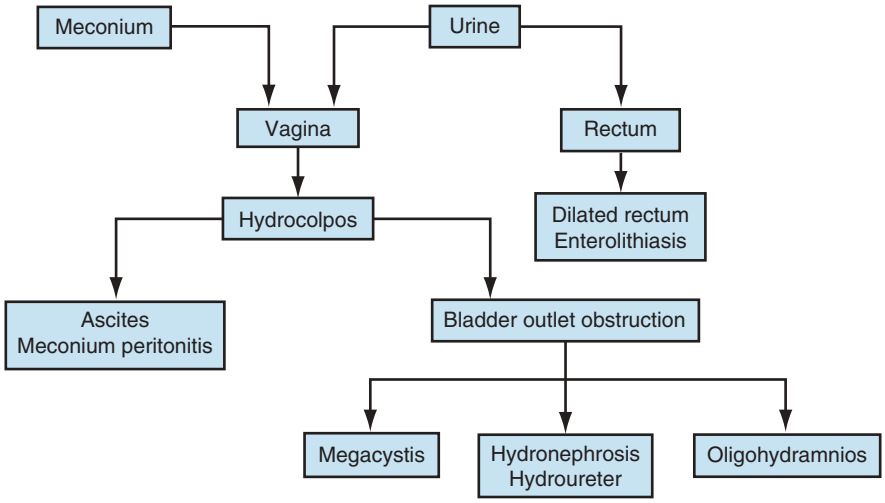

FIG 14-13 Pathophysiology of persistent cloaca with hydrocolpos. In 30% of cases urine and meconium can pass into the most distensible organ, the vagina, causing hydrocolpos. This can be identified as a midline pelvic mass, often with a longitudinal vaginal septation. Some of this fluid can pass in retrograde fashion through the fallopian tubes resulting in free peritoneal fluid, sometimes with evidence of peritonitis and calcifications. Also, some urine can pass into the rectum, causing dilation and enterolithiasis from mixing with meconium. Hydrocolpos may be associated with obstruction of the urinary tract; if there is bladder outlet obstruction, megacystis, hydronephrosis, and hydroureter may be seen. Complete obstruction results in oligohydramnios.

this diagnosis is suspected, fetal MRI is often useful.[85,87] On a sagittal view of a normal third trimester fetus, the rectum should extend at least 10 mm below the bladder; in 5 of 6 fetuses with persistent cloaca, third trimester MRI demonstrated a high and dilated rectum.[88]

Neonatal Management

Examination of the perineum of the neonate will often establish the diagnosis. In males, waiting 24 hours is suggested so that intraluminal pressure in the rectum can increase sufficiently to allow passage of meconium through a fistula, either on the perineum or in the urine. In females, inspection of the perineum can demonstrate a single orifice, signifying the presence of a cloaca, or reveal a fistula in the vestibule or on the perineum. Careful evaluation for associated anomalies by physical examination and imaging is also important.

Definitive surgical repair depends upon the level of the lesion. A low lesion with a fistula on the perineum can undergo primary repair, whereas a higher fistula often requires placement of a colostomy followed by a more complex surgical procedure.

LIVER, SPLEEN, AND GALLBLADDER

Liver

The umbilical vein enters the lower abdomen and travels in a cephalad and posterior direction to enter the liver. Within the liver, the largest branch curves toward the right, away from the stomach, where it connects with the ductus venosus and drains into the inferior vena cava just below the right atrium. In the transverse plane, at the level where abdominal circumference is measured, the vein is a prominent C-shaped structure within the liver, curving away from the stomach bubble (see Fig. 14-2A).

Occasionally the umbilical vein is noted to curve toward the left side of the fetal abdomen, toward the stomach (Fig. 14-14A). This represents *persistence of the right umbilical vein*, which may be associated with other anomalies but when isolated is considered a normal variant.[89]

Choledochal cysts result from dilation of the biliary tract, most often fusiform dilation of the common bile duct (Fig. 14-15). They present as sonolucent cysts at the hepatic hilum. The differential diagnosis includes benign hepatic cyst (Fig. 14-14B). The diagnosis is confirmed after birth by ultrasound imaging and magnetic resonance cholangiopancreatography.[90] Treatment requires surgical excision and biliary-enteric anastomosis (hepatojejunostomy or hepatoduodenostomy) to prevent obstructive jaundice, cholangitis, pancreatitis, liver fibrosis, and malignancy; the timing of surgery is controversial.[90]

Hepatic calcifications/echogenic foci in the liver parenchyma (Fig. 14-14C) should be distinguished from calcifications along the surface of the liver from meconium peritonitis (see Fig. 14-8A) and from echogenic material within the gallbladder (Fig. 14-16B). Hepatic parenchymal calcifications are relatively common; the prevalence may be as high as 1:1000. In the largest reported series, 40 of 61 cases had additional sonographic abnormalities; of these, there were 10 cases with aneuploidy and 1 with congenital CMV infection.[91] Outcomes were better for the 21 cases with isolated hepatic calcifications: 1 fetus had parvovirus and 1 had trisomy 21, but the others fared well. In a review of the four largest series,[92] 93% of 63 cases with isolated intrahepatic echogenic foci had normal outcomes compared with 39% of 54 cases when there were other ultrasound findings.

Therefore, when an echogenic focus in the fetal liver is identified, a detailed study should be performed, searching for additional anomalies, particularly those associated with aneuploidy or congenital infection. Maternal blood should be obtained and tested for possible infection, particularly for CMV. Depending on the a priori risk of aneuploidy related to maternal age and screening test results, amniocentesis or cell-free DNA screening could be considered. If there is no evidence of infection and the risk of aneuploidy is low, the patient whose fetus has an isolated intrahepatic echogenic focus can be reassured.

Hepatic tumors found by prenatal sonography are rare and are the subject of case reports and literature reviews.[93,94] Survival statistics are based on small numbers.

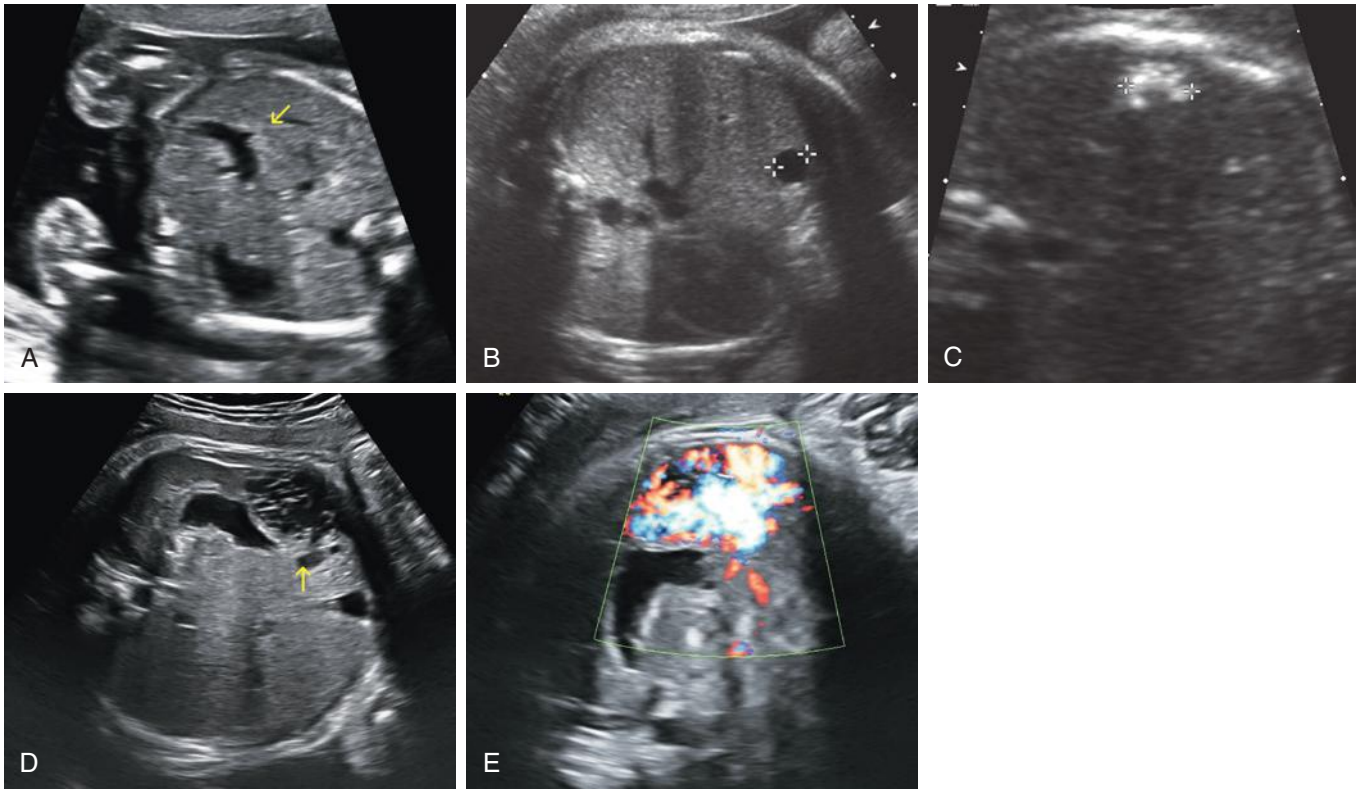

FIG 14-14 Liver malformations. **A,** Persistent right umbilical vein (*arrow*), curving toward the left-sided stomach (compare to Fig. 14-2A). This fetus also had a horseshoe kidney, which was confirmed after birth. **B,** Small round anechoic hepatic cyst (*cursors*) seen on an oblique transaxial sonographic image of the upper abdomen. **C,** Hepatic calcification (*cursors*). Note the intraparenchymal dense echogenic foci at the periphery of the liver with slight posterior acoustic shadowing. This observation would prompt testing for possible infection, such as cytomegalovirus. **D,** Hepatic arteriovenous malformation (*arrow*). Heterogeneous hypoechoic mass within the left hepatic lobe, adjacent to the fluid-filled stomach. **E,** The same fetus as in D, with color Doppler sonography demonstrating marked vascularity. This lesion gradually involuted over the first 6 months of life.

1. *Hemangiomas and hemangioendotheliomas* can be focal, with reported survival rate of 73%, or multifocal. They can appear hypo- or hyperechoic or have mixed heterogeneous echogenicity. They are highly vascular and color Doppler interrogation can be helpful, although hepatic arteriovenous malformations may have a similar appearance (Fig. 14-14D and E). Anemia and coagulopathy can occur as a result of platelet sequestration (Kasabach-Merritt syndrome). These benign tumors tend to regress spontaneously in infancy, and regression may be hastened by administration of corticosteroids.
2. *Mesenchymal hamartomas* have a survival rate of 64%. They may be completely solid or solid with multiseptated cystic components.
3. *Hepatoblastomas* are reported to have a survival rate of only 22%. They can appear as large, echogenic solid masses; one reported case of a very large tumor had focal hemorrhage and necrosis and was highly vascular on Doppler interrogation.[95]
4. *Metastases from congenital neuroblastoma* may present as single or multiple hypoechoic nodules.

Rapid growth of hepatic tumors can lead to high-output cardiac failure and hydrops. If the tumor has a prominent cystic component, the differential diagnosis would include hepatic cyst (see Fig. 14-14B) and choledochal cyst. MRI may be useful in determining the cause of a hepatic mass. Because rupture can lead to massive hemorrhage, elective cesarean delivery is sometimes recommended.

Gallbladder

The fetal gallbladder typically appears as a teardrop-shaped cystic structure in the right upper quadrant of the fetal abdomen angling obliquely toward the pelvis. It can be identified as early as the first trimester and is visualized in most fetuses in the second and third trimesters (Fig. 14-16A). Echogenic material in the fetal gallbladder is occasionally seen, mainly in the third trimester. This is relatively common and has a variable appearance[96] (see Fig. 14-16B). It is attributed to gallstones and is thought to be of no clinical significance because it usually resolves after birth.[97,98] Conservative management with sonographic surveillance of the child until resolution is suggested.

Nonvisualization of the fetal gallbladder is often a transient finding and should be reassessed on a subsequent scan. Persistent nonvisualization of the fetal gallbladder is of greater concern, particularly when associated with additional findings. In a series of 16 fetuses with isolated nonvisualization of the gallbladder, one fetus had cystic fibrosis and the remainder had normal outcomes.[99] In a larger series of 85 cases with persistent nonvisualization of the fetal gallbladder and no other anomalies at a mean gestational age of 23 weeks, the gallbladder was subsequently identified in 55 fetuses; of the remaining 30 fetuses, 22 had congenital agenesis of the gallbladder, which is clinically benign. However, there were three fetuses in this group with cystic fibrosis and five fetuses with congenital biliary atresia.[100]

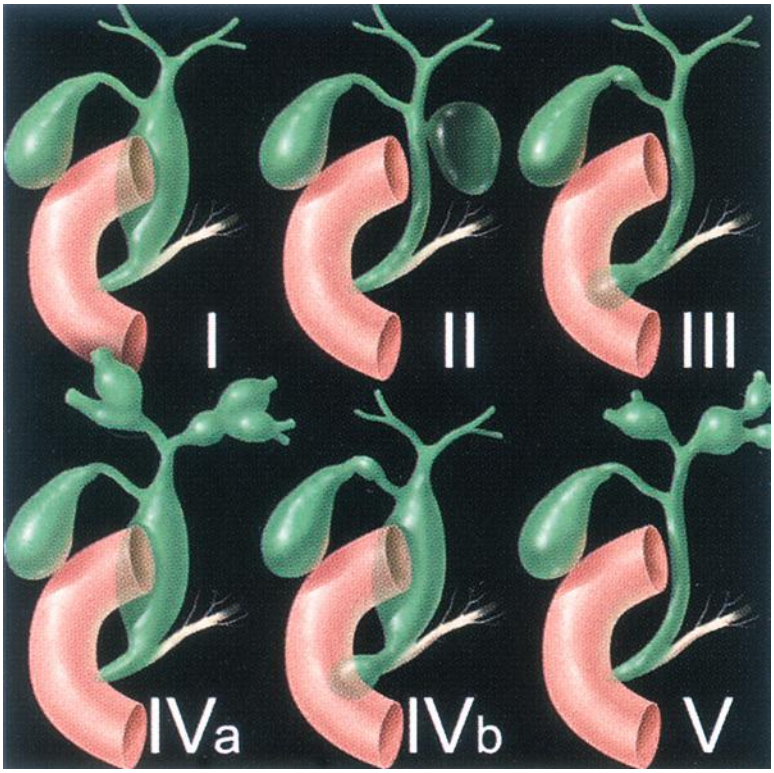

FIG 14-15 Various types of choledochal malformation. Note the anomalous pancreaticobiliary junction; the pancreatic duct inserts into common bile duct proximal to the sphincter of Oddi. (From Donnelly LF, Jones BV, O'Hara SM, et al [eds]: Diagnostic Imaging: Pediatrics. Salt Lake City, Amirsys, 2005, p 96.)

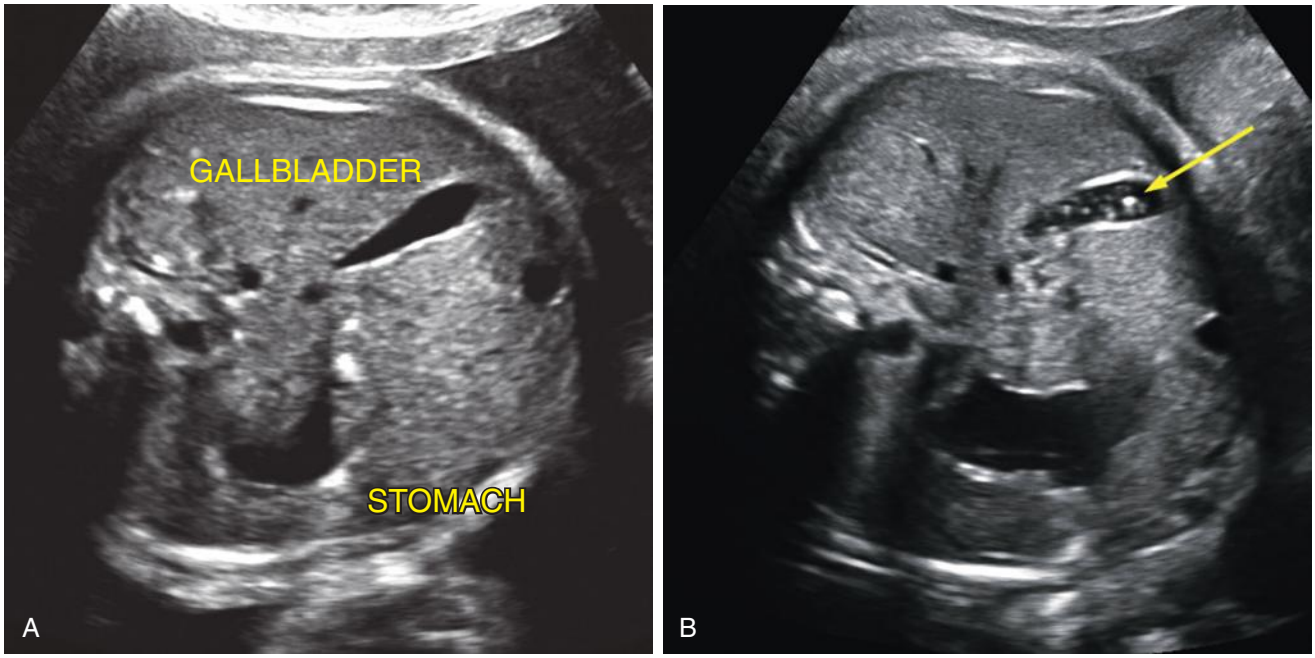

FIG 14-16 Gallbladder. **A,** Normal fetal gallbladder in the third trimester. **B,** Similar transaxial sonographic view of the upper abdomen in a different fetus showing gallstones (*arrow*), which are relatively common and usually resolve spontaneously after birth.

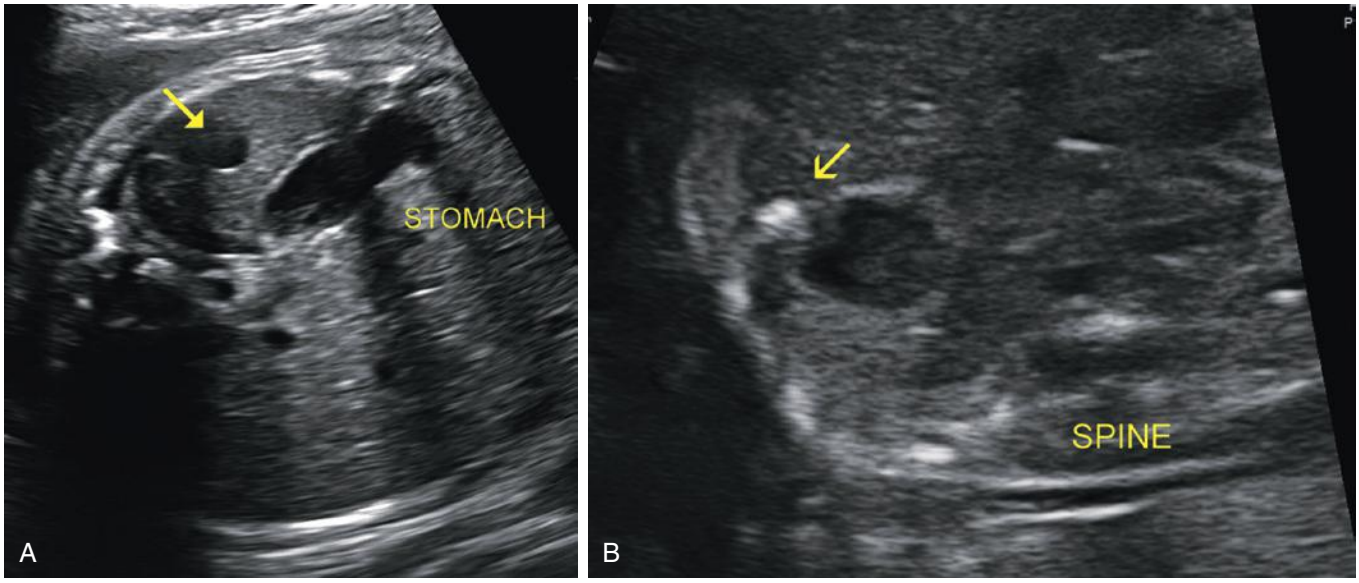

FIG 14-17 Benign findings in the spleen. **A,** Small unilocular anechoic cyst within the spleen (*arrow*). The cyst remained small, stable in size over several weeks. **B,** Small echogenic focus (*arrow*) indicating calcification at the left upper quadrant, adjacent and lateral to the fluid-filled stomach. These are seen fairly often and are considered benign and inconsequential.

In the United States, patients are routinely offered genetic screening for cystic fibrosis early in pregnancy. Therefore, detection of biliary atresia would be the rationale for incorporating visualization of the gallbladder as part of the routine anatomic survey. Biliary atresia is a serious condition that requires postnatal surgical correction and may result in the need for liver transplantation. Fortunately it is rare, with a prevalence of 7 per 100,000 in the United States.[101] Amniocentesis with evaluation of digestive enzymes can provide additional information but cannot always differentiate biliary atresia from more benign conditions. Although some would advocate adding evaluation of the gallbladder to the routine second trimester sonographic survey to detect biliary atresia[102] others have expressed concern about false positive results.

Spleen

Splenic cysts are usually simple serous epithelial cysts. If small and sonolucent, these are likely to regress spontaneously[103] (Fig. 14-17A). A small echogenic focus at the left upper quadrant of the fetal abdomen is not uncommonly visualized on mid-trimester ultrasound imaging; they are typically not clinically significant[104] (Fig. 14-17B).

ASCITES

Ascites is an excess amount of free intraperitoneal fluid in the fetal abdomen. A trace amount of fluid between bowel loops can sometimes be seen in normal fetuses when using a high-frequency transducer. (See Fig. 14-5B.) Mild ascites, when present, can best be visualized adjacent to the cord insertion and bladder (Fig. 14-18). Moderate and severe ascites is readily apparent as fluid surrounds bowel loops and liver. Depending on the cause of the ascites, the amniotic fluid volume can be normal, increased, or decreased. Because there are many causes of fetal ascites and there is overlap with generalized hydrops, a careful evaluation is warranted, starting with maternal and family history and including a detailed sonographic evaluation of the fetus (Table 14-6).[105,106]

Many cases of ascites will have an obvious explanation on ultrasound imaging. Any space-occupying lesion in the chest, including congenital pulmonary airway malformation, pulmonary sequestration, or congenital high airway obstruction can result in ascites.

FIG 14-18 Ascites. Mild ascites is most readily detectable near the cord insertion at the anterior abdominal wall.

In addition, as mentioned earlier in this chapter, abnormalities of the fetal gastrointestinal tract may result in microperforation of bowel, with leakage of intraluminal contents and ascites.

Urinary ascites can be the cause of free fluid within the peritoneal cavity. This results from leakage or rupture of urine from an obstructed urinary collecting system, most commonly bladder outlet obstruction

TABLE 14-6 Sonographically Detectable Causes of Fetal Ascites

Evidence of aneuploidy

due to posterior urethral valves. Sonographic evaluation of the genitourinary system will be abnormal in fetuses with urinary ascites, with findings such as hydronephrosis, hydroureter, and enlarged or ruptured, thick-walled urinary bladder.

Note that ascites may be an early manifestation of generalized hydrops from a systemic cause such as cardiac dysfunction or anemia. Thus, targeted attention to the fetal heart anatomy and function and follow-up examinations are warranted. Very rarely, generalized hydrops might occur as a result of ascites, perhaps secondary to vena caval compression.

It is very important to routinely consider systemic causes of fetal ascites. Fetal echocardiography can be considered. Measurement of the peak systolic velocity in the fetal middle cerebral artery to assess for possible anemia should be performed. Even if the fetus does not appear to be anemic, maternal blood type and antibody screen, Kleihauer-Betke test, and parvovirus titers may be considered. Infectious causes that can lead to ascites include CMV infection, toxoplasmosis, hepatitis, syphilis, and infection from additional organisms.[105] Maternal serologic titers should be obtained, particularly if there are additional findings such as intracranial calcifications or echogenic bowel. The possibility of fetal aneuploidy should be addressed.

Genetic causes of hydrops and congenital ascites include metabolic syndromes such as lysosomal storage diseases. Congenital chylous ascites is due to lymphatic obstruction, similar to chylothorax, and could theoretically be detected by demonstration of elevated lymphocyte count in peritoneal fluid, but this would require fetal paracentesis. As many as 10% of cases of fetal ascites are idiopathic, and they tend to have a favorable prognosis.

The management and ultimate prognosis of fetal ascites depend upon the cause. If no cause is found on the initial evaluation, follow-up sonograms should be performed; occasionally an underlying cause will become apparent. Not surprisingly, severe ascites, early gestational age at diagnosis,[106] and development of hydrops are associated with worse prognosis. When ascites remained isolated and no cause was found, prognosis was favorable in some[107,108] but not all[109] series. Diagnostic or therapeutic paracentesis may be warranted in a minority of cases; because fluid often rapidly reaccumulates, shunt placement has been attempted.[105]

CYSTS

Differential Diagnosis

The differential diagnosis of a fetal abdominal cyst is lengthy and therefore a systematic approach to sonographic assessment is useful (Table 14-7). The first step is to identify normal anatomy: normal cystic structures in the fetal abdomen include the stomach, gallbladder, and urinary bladder. Each of these structures varies in size. When identifying the stomach and gallbladder at the upper abdomen, it is important to confirm normal situs because, although rare, situs inversus or heterotaxy syndrome can cause confusion. A cystic structure in the pelvis almost always represents the urinary bladder; it can be seen to fill and empty during the course of a typical ultrasound examination. Use of color Doppler sonography to identify the umbilical arteries flanking the bladder can be helpful, and many do this routinely to document two umbilical arteries.

Hydrocolpos (isolated, in association with persistent cloaca)
Cystic structures in variable locations
Meconium pseudocyst
Enteric duplication cyst
Mesenteric/omental cyst

The intrahepatic umbilical vein/portal vein has a typical C-shaped appearance, curving away from the left-sided stomach. If there is any doubt, color Doppler sonography may be helpful (see Fig. 14-2A). With an intrahepatic persistent right umbilical vein, the vessel curves in the opposite direction, toward the stomach (see Fig. 14-14A).

The next step is to evaluate the renal collecting system. A fluid-filled structure in or adjacent to one or both kidneys can be due to hydronephrosis, renal cyst(s), or perinephric urinoma. Typically, a normal nondilated ureter cannot be visualized, whereas hydroureter appears as a tortuous, tubular, fluid-filled structure situated between the kidney and bladder. The bladder itself can be dilated because of urethral obstruction. A ureterocele can sometimes be identified within the bladder. An umbilical vein varix adjacent to the bladder can be distinguished from a pelvic cyst by the use of color Doppler sonography.

Dilation of the gastrointestinal tract may demonstrate a cystic appearance by ultrasound imaging. A cystic collection at the right upper quadrant may represent duodenal obstruction if a connection to the stomach can be demonstrated (see Fig. 14-4). Jejunoileal obstruction typically presents as multiple fusiform fluid-filled components rather than a single cystic collection (see Fig. 14-6D).

Having addressed all of these structures, the next step is to consider the location of the cyst (see Table 14-7).

Ovarian Cysts

Ovarian cyst is the most common lower abdominal or pelvic cyst in a female fetus during the second half of pregnancy.[110] These cysts can be thin-walled, anechoic, "simple" cysts (Fig. 14-19A and C), or they may have a heterogeneous appearance; these "complex" cysts can manifest fluid/debris levels, septations, and low level echoes[111,112] thought to be the result of hemorrhage or torsion (Fig. 14-19B). Rarely, ovarian cysts

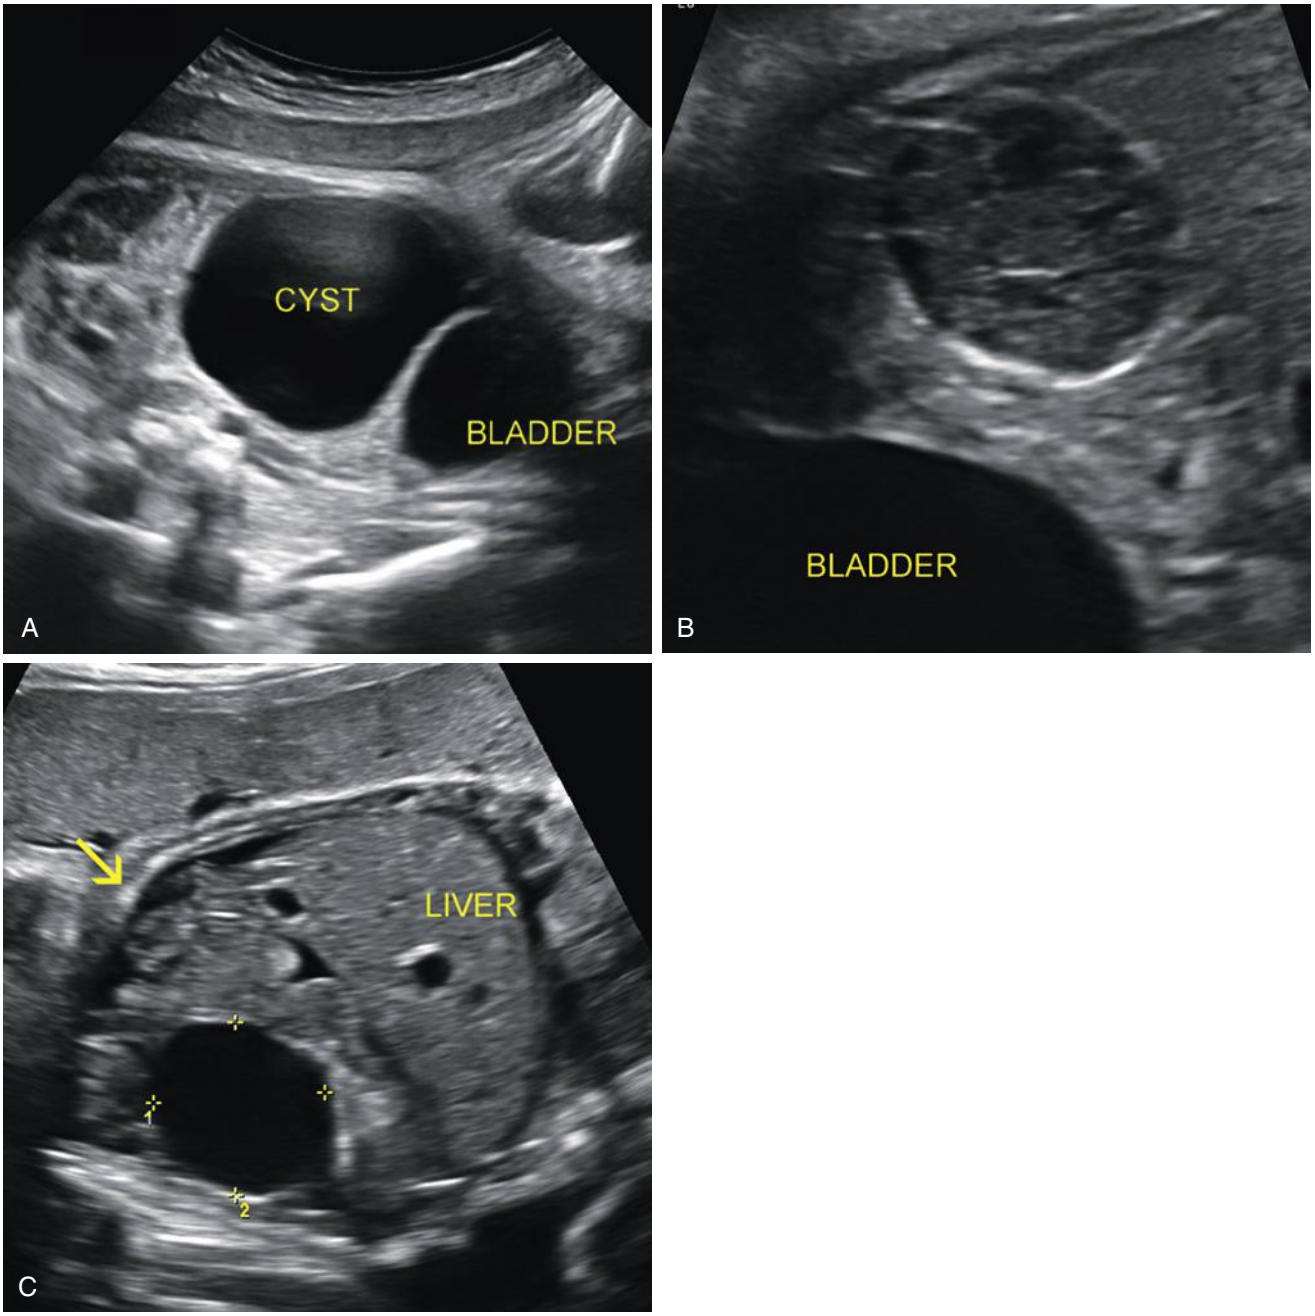

FIG 14-19 Ovarian cyst. **A,** Large thin-walled anechoic cyst, first seen at 36 weeks, adjacent to the urinary bladder. Color Doppler sonography can be used to identify the bladder, flanked by the umbilical arteries. The child underwent percutaneous drainage of the cyst 1 week after birth, but the fluid reaccumulated. Surgical excision was performed at 11 weeks of age and ovarian torsion with necrosis was found. **B,** A 3-cm ovarian cyst, with internal echoes and strands suggesting hemorrhage, adjacent to the bladder. **C,** A 4-cm unilocular thin-walled anechoic ovarian cyst (*cursors*) seen at 36 weeks. Mild ascites (*arrow*) also present. The ascites rapidly resolved, and the cyst gradually involuted postnatally. The child did not require surgery.

can be associated with polyhydramnios, ascites[111] (see Fig. 14-19C), or fetal anemia due to hemorrhage.[112]

The differential diagnosis includes all of the other cysts found in the lower abdomen and pelvis described in this chapter. However, when such a cyst is identified in a female fetus in the third trimester without any additional findings, the likelihood is high that it represents an ovarian cyst. If there is doubt, MRI can be used to confirm the diagnosis.[113]

Fetal ovarian cysts are, with very rare exceptions, functional rather than neoplastic, related to stimulation by maternal hormones; there is generally no concern regarding possible malignancy.[110,114] Management is directed toward preserving ovarian tissue and avoiding unnecessary interventions. Simple cysts are generally managed conservatively. Some authors suggest in utero percutaneous aspiration of simple cysts once they reach a certain size in an effort to prevent torsion and hemorrhage[115]; others oppose this.[110,111] The postnatal management of hemorrhagic cysts is increasingly conservative, as many of these cysts spontaneously resolve. There is little evidence that early neonatal intervention in an asymptomatic child prevents functional loss of the ovary.

Enteric Duplication Cysts

Enteric duplication cysts (Fig. 14-20) can arise at any level of the gastrointestinal tract, although 80% are intra-abdominal.[116] They can be round or tubular, single or multiple. Sonographic demonstration of a double wall sign and the presence of peristalsis support the diagnosis; if there is uncertainty, MRI may be helpful. Associated malformations are seen in one third of cases, so fetal echocardiogram is recommended. Obstetric management includes follow-up sonograms; there are case reports of prenatal ultrasound-guided drainage. The decision regarding delivery at a tertiary care center can be individualized. Because these cysts may cause pain, intussusception, intestinal obstruction, ulceration with perforation, or hemorrhage, they are typically resected within the first 6 months of life, either by laparoscopic or open surgical procedure.

Rare Causes of Cysts

Other relatively rare causes of lower abdominal or pelvic cysts include the following:

Sacrococcygeal Teratoma

Most sacrococcygeal teratomas are external and exophytic; only 10% are type IV, completely internal. Most sacrococcygeal teratomas have a solid or vascular component, although there is at least one case report of a cystic type IV sacrococcygeal teratoma.[117]

Anterior Sacral Meningocele

Anterior sacral meningocele may appear as an anechoic pelvic cyst, possibly mimicking hydrometrocolpos at 20 weeks.[118]

Hydrocolpos

Hydrocolpos is most often seen in association with persistent cloaca (discussed elsewhere in this chapter) but can rarely be isolated, related to vaginal atresia or imperforate hymen; in such cases, spontaneous resolution after birth can be expected.[119] Hydrocolpos should be considered when a hypoechoic structure is seen posterior to the bladder (see Fig. 14-12). MRI may be useful in establishing this diagnosis.[119]

Mesenteric/Omental Cyst

Mesenteric or omental cyst is often a presumptive diagnosis for a small, unilocular, thin-walled anechoic cyst in a variable intra-abdominal location that becomes increasingly inconspicuous with advancing gestation and with fetal growth.

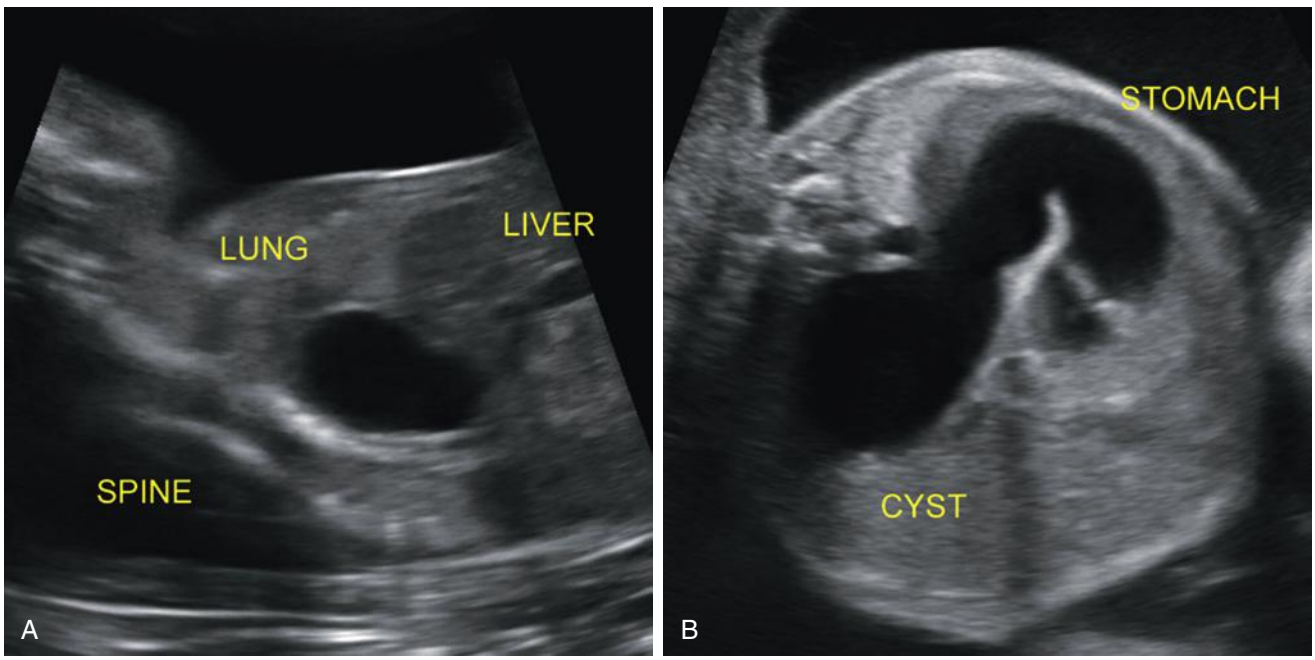

FIG 14-20 Enteric duplication cyst. **A,** At 21 weeks, a unilocular anechoic cyst, shown on this parasagittal ultrasound image, extended above and below the level of the diaphragm. **B,** At 26 weeks, the cyst had enlarged and appeared contiguous with the fluid-filled stomach. The cyst was resected at 3 weeks of age and appeared to originate near the esophageal-gastric junction. Pathologic examination showed it was lined by primitive columnar epithelium with focal areas of gastric epithelium.

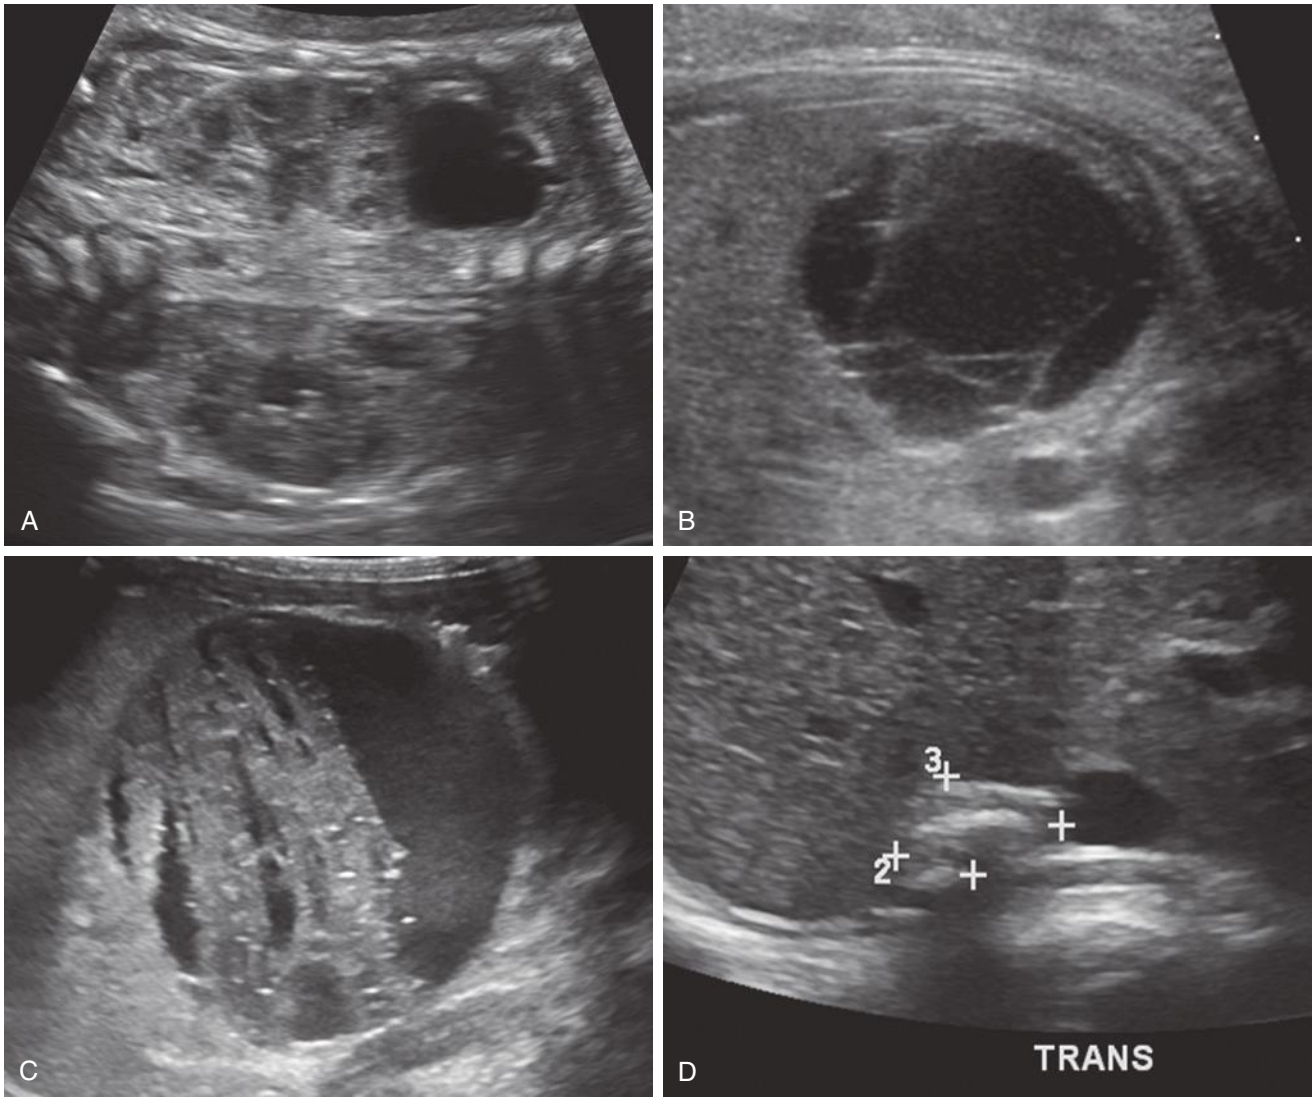

FIG 14-21 Adrenal neuroblastoma, cystic. **A,** Coronal sonographic image obtained at 31 weeks shows a thin-walled anechoic cyst cephalad to the right kidney. The bilateral kidneys appear normal with expected corticomedullary differentiation. **B,** Two weeks later, the mass appears slightly larger with internal echoes and strands suggesting hemorrhage. **C,** Transabdominal sonogram of the hemorrhagic cystic adrenal mass obtained shortly after birth. **D,** The child was managed conservatively with follow-up imaging. At 4 years of age, involution of the adrenal lesion (*calipers*) with calcification is shown.

Adrenal Cyst

Adrenal cyst can be detected in the third trimester in a characteristic location, cephalad to a kidney. The differential diagnosis includes subdiaphragmatic extralobar pulmonary sequestration, benign cyst, and adrenal hemorrhage. Some adrenal cysts detected in utero represent neuroblastomas[120,121] (Fig. 14-21). Hemorrhage is the most common cause of an apparent adrenal mass in a newborn but rarely occurs before birth.[122]

Most neuroblastomas diagnosed in utero are of adrenal origin, and they are often cystic. Fortunately, prenatally diagnosed neuroblastomas, particularly cystic lesions, usually represent localized stage I disease with an excellent prognosis; indeed, they may spontaneously regress, and conservative management is an acceptable strategy[121,123] (Fig. 14-21D).

First Trimester Abdominal Cyst (Fig. 14-22)

With improved ultrasound resolution and increased attention to fetal anatomy early in gestation, a number of cases of first trimester abdominal cysts have been reported.[75] The origin of these cysts is often not determined, in part because spontaneous resolution is common. In 20 cases of apparently isolated first trimester abdominal cysts, 13 resolved and these children did well. However, in this series, 4 fetuses with first trimester lower abdominal cysts were later found to have anorectal malformations. Outcomes were worse if the cysts persisted or if there

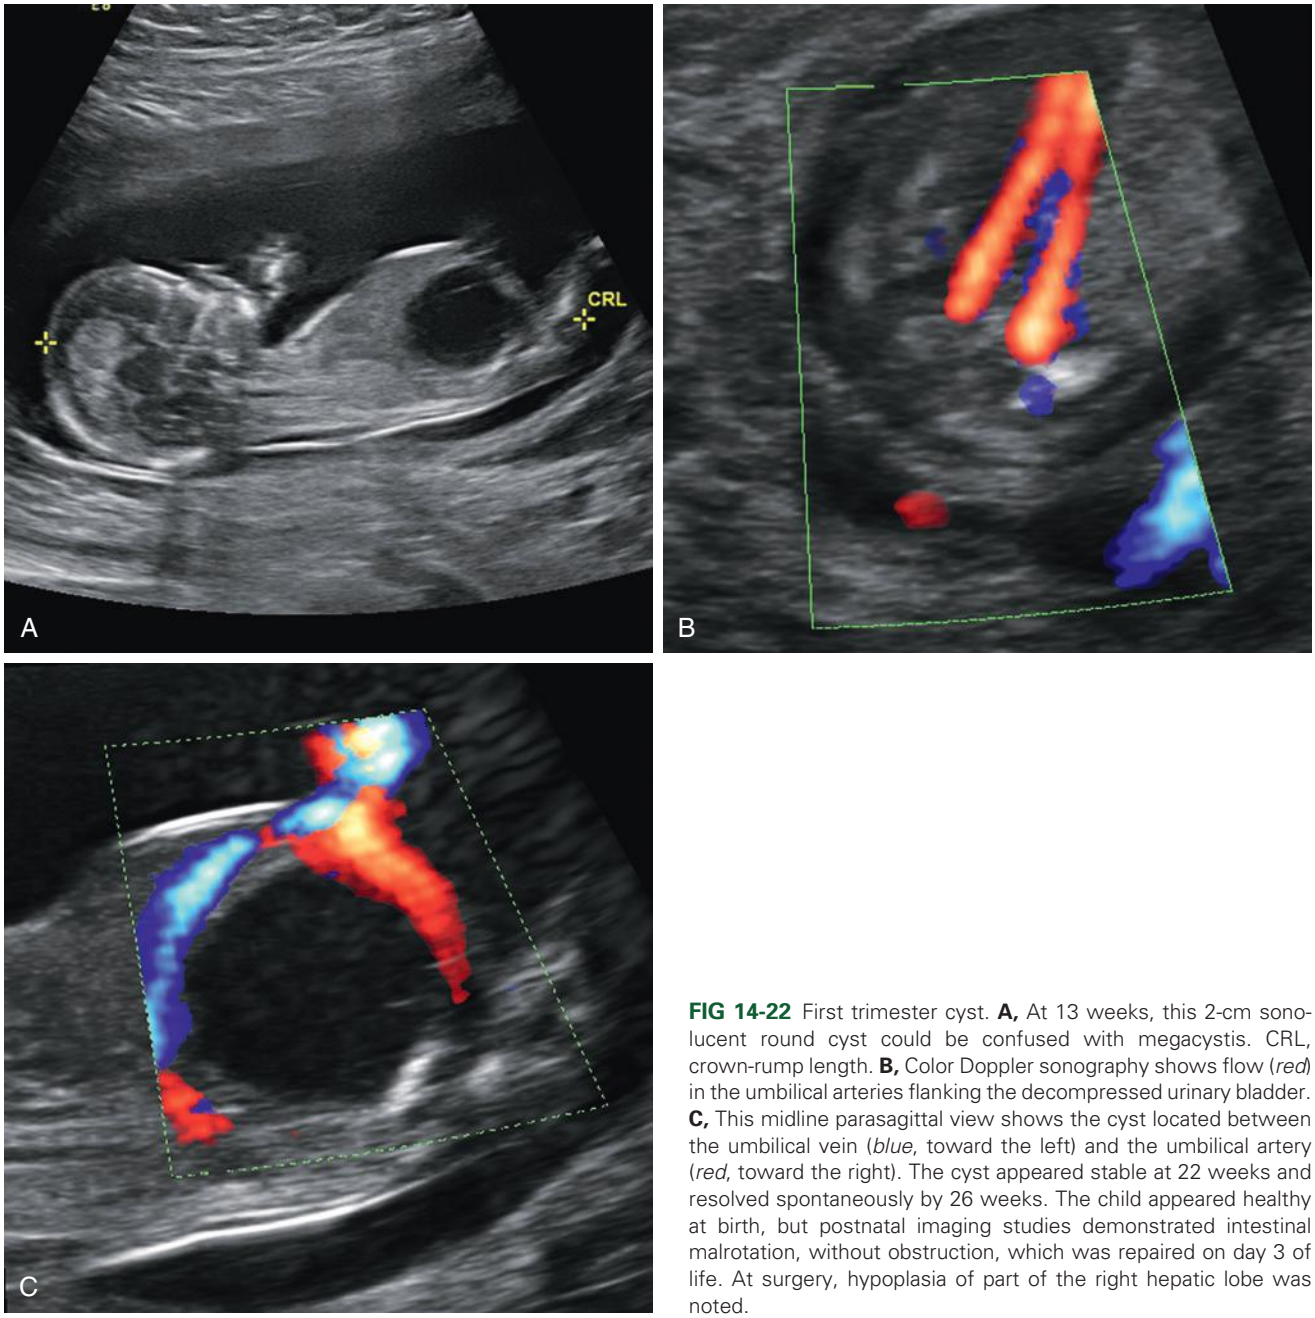

FIG 14-22 First trimester cyst. **A,** At 13 weeks, this 2-cm sonolucent round cyst could be confused with megacystis. CRL, crown-rump length. **B,** Color Doppler sonography shows flow (*red*) in the umbilical arteries flanking the decompressed urinary bladder. **C,** This midline parasagittal view shows the cyst located between the umbilical vein (*blue*, toward the left) and the umbilical artery (*red*, toward the right). The cyst appeared stable at 22 weeks and resolved spontaneously by 26 weeks. The child appeared healthy at birth, but postnatal imaging studies demonstrated intestinal malrotation, without obstruction, which was repaired on day 3 of life. At surgery, hypoplasia of part of the right hepatic lobe was noted.

were additional abnormalities. After considering megacystis, the differential diagnosis consists primarily of cysts originating from the gastrointestinal tract.

VENTRAL WALL DEFECTS

The differential diagnosis for a ventral abdominal wall defect includes several anomalies (Table 14-8), but the most common are omphalocele and gastroschisis. These two entities differ in several important ways (Table 14-9).

Omphalocele

Omphalocele is also referred to by the term *exomphalos*. Omphalocele is often categorized based on whether the omphalocele sac contains liver (extracorporeal liver) or bowel only (intracorporeal liver). The embryology of these two types probably differs, as the latter can be thought of as failure of resolution of physiologic bowel herniation seen in the first trimester. Given that in normal development the liver is never located outside the abdomen, the embryology of omphalocele with extracorporeal liver may be different. The cause of omphalocele is reported by some to be different when diagnosed in the first compared to the second trimester (Table 14-10).

Prevalence

The prevalence of omphalocele among live births, stillbirths, and induced abortions is about 2.0 to 2.6 per 10,000[124-127] and has been reasonably stable since 1980, despite changes in prenatal diagnosis. Despite the strong association of omphalocele with aneuploidy, and of

TABLE 14-9 Sonographic Features Distinguishing Omphalocele From Gastroschisis

Assessment Category	Omphalocele	Gastroschisis
Maternal age	U-shaped age distribution	Younger
Ultrasound findings	Membrane covers intestine	Free loops of externalized intestine
	Cord involvement	Located to right of cord insertion
	Liver out: common	Liver out: rare
	Dilated/thickened bowel: rare	Dilated/thickened bowel: common
Associated nonbowel abnormalities	Common	Uncommon
Aneuploidy	Common	Uncommon
Risk of FGR/IUFD	Uncommon	Common
Surgical complications	Uncommon	Common

FGR, fetal growth restriction; IUFD, in utero fetal demise.

TABLE 14-10 Omphalocele: First Versus Second Trimester Diagnosis

Liver Status	First Trimester Diagnosis	Second Trimester Diagnosis
Intracorporeal liver	May resolve	Will not resolve
	Risk of aneuploidy: high	Risk of aneuploidy: high
Extracorporeal liver	Will not resolve	Will not resolve
	Risk of aneuploidy: high	Risk of aneuploidy: low

aneuploidy with advanced maternal age, the age distribution for omphalocele appears to be U-shaped, highest in the youngest and oldest mothers,[128,129] especially among chromosomally normal cases.[124]

Table 14-11 includes data from recent reported series of omphaloceles. More than half of fetuses with omphaloceles have additional malformations and chromosomal abnormalities, but there are large discrepancies among the reports, likely due to differences in the populations studied. As is the case for many anomalies, prenatally diagnosed cases differ markedly from pediatric series. The EUROCAT registry[124] surveyed birth certificates, maternity and pediatric records, hospital discharge summaries, and pathologic reports in 2.9 million births from 1980 to 1990. In this report, prenatally diagnosed cases were underrepresented, which likely explains the relatively low rates of aneuploidy and additional malformations, and the high rate of isolated omphalocele. In contrast, Brantberg and associates[130] reviewed prenatally diagnosed cases and reported high rates of aneuploidy and multiple malformations and a low rate of isolated omphalocele. The two additional included studies with intermediate prenatal diagnosis rates also had intermediate rates of isolated lesions.

Associated Aneuploidies

Trisomy 18 is the most common aneuploidy associated with omphalocele, accounting for 62% to 75% of aneuploidy found in the four studies referenced. Trisomy 13 is also common, accounting for 11% to 24%. Together, these two trisomies account for 86% of aneuploidies found in cases of omphalocele. Down syndrome, triploidy, and sex chromosome abnormalities were seen less commonly.

The association of aneuploidy with omphalocele is inversely associated with gestational age at diagnosis and directly associated with the presence of additional structural abnormalities. Also, the presence of liver in the omphalocele sac is associated with decreased likelihood of chromosomal abnormality in the second trimester, but not the first.[131]

In addition to abnormalities seen on standard karyotype, microdeletions and microduplications detected as copy number variations by chromosomal microarray have been reported.[132,133]

Associated Syndromes

In the EUROCAT study, Beckwith-Wiedemann syndrome (BWS) was associated with 4% of omphaloceles.[124] In a more recent report, BWS was found in 6 of 30 cases of "isolated" omphalocele without autosomal aneuploidy; 3 of these 6 were conceived using assisted reproductive technology.[134] Fetuses with BWS may demonstrate additional abnormalities such as macrosomia, macroglossia (with a protruding tongue), and polyhydramnios, but these findings are generally not seen until the third trimester. Very rarely, enlarged kidneys or a cystic pancreas may be seen. Because BWS can be caused by a variety of molecular mechanisms affecting the imprinted genes on chromosome 11p15.5,[135] specialized DNA testing is required for diagnosis.

TABLE 14-11 Omphalocele: Etiology and Associated Anomalies

Study	Years	*N*	Prenatal Diagnosis	Abnormal Karyotype	Syndromic	Multiple Malformations	Isolated

Omphalocele is rarely associated with other genetic syndromes.[130,136] There are a total of 73 entries found under "omphalocele" in OMIM (Online Mendelian Inheritance in Man).[137]

Nonchromosomal Anomalies

Even after excluding cases with aneuploidy, omphalocele is associated with a wide variety of anomalies encompassing almost every organ system.[124,126] Of particular importance are cardiac anomalies, which were present in a total of 36% of 97 cases in these two referenced articles.

Sonographic Diagnosis

By ultrasound imaging, exteriorized abdominal viscera are shown, covered by a thin membrane derived from parietal peritoneum and amnion (Figs. 14-23 through 14-25). The umbilical cord inserts into the base of the omphalocele sac (Fig. 14-23B). Most often, segments of small intestine, with or without liver, protrude beyond the abdomen; sometimes other organs including the colon, stomach, spleen, and rarely kidneys can be exteriorized. Ascites or Wharton jelly is often noted within the omphalocele sac.

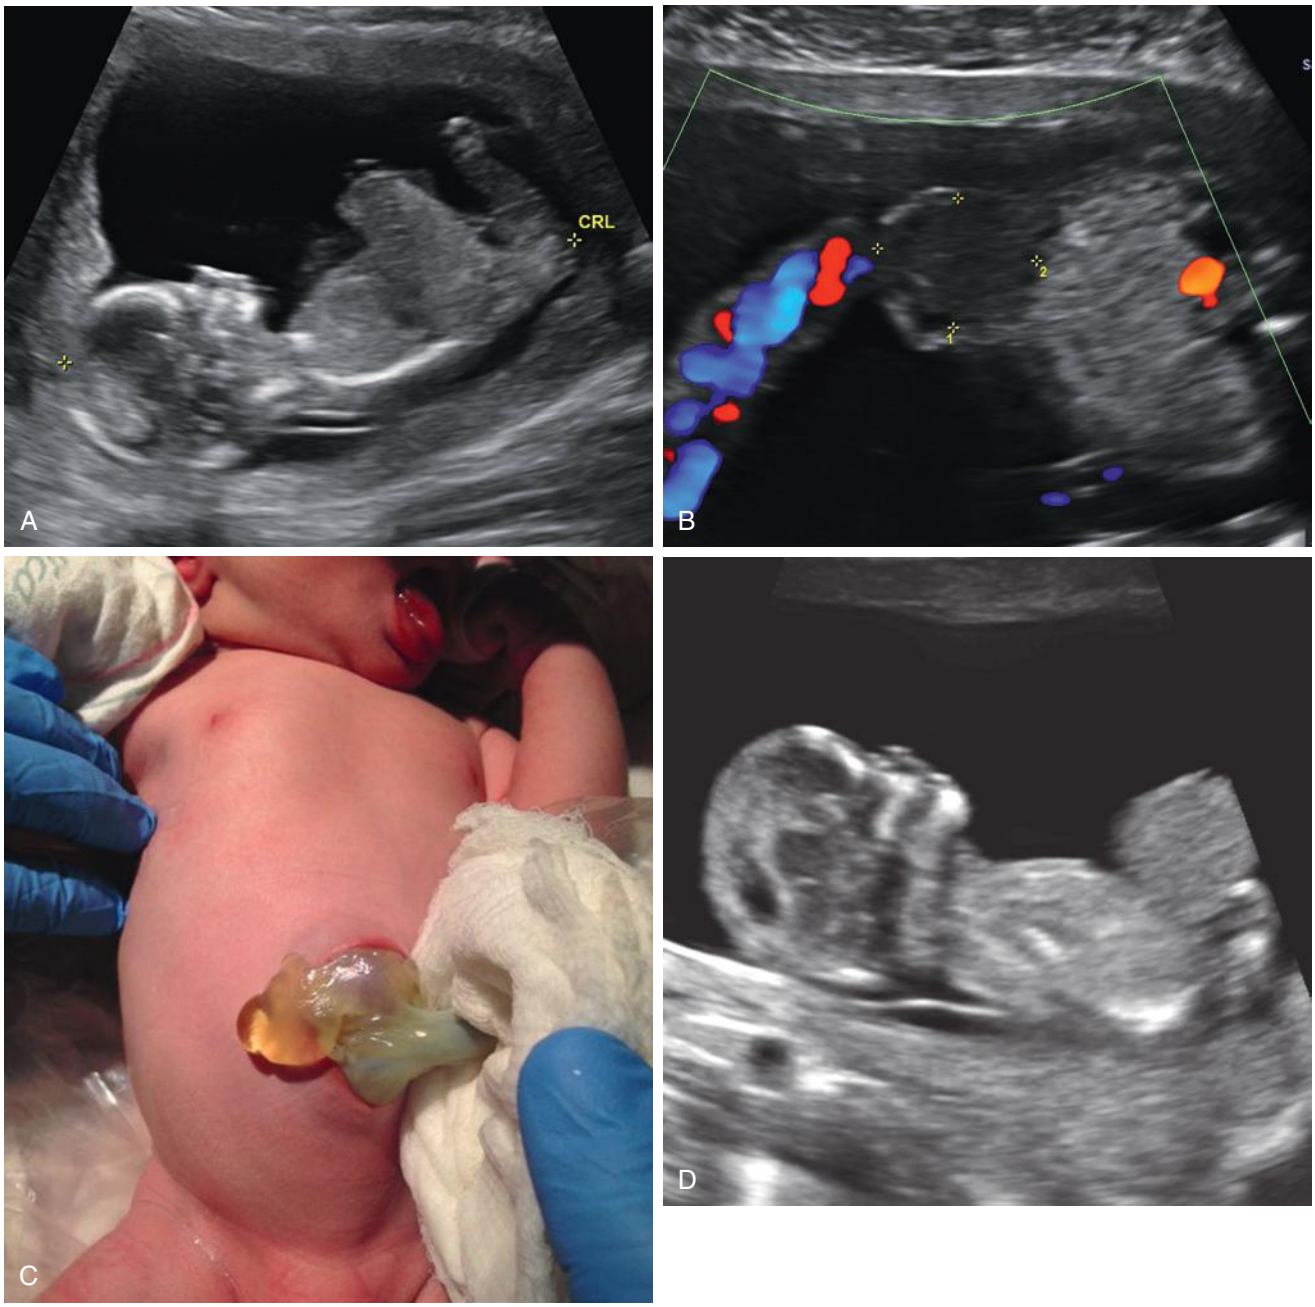

FIG 14-23 Serial assessment of omphalocele. **A,** Moderate-size omphalocele, which appears to contain liver, shown on this midline sagittal ultrasound image at 13 weeks. CRL, crown-rump length. **B,** At 18 weeks, the omphalocele (*calipers*) measures approximately 1.5 cm in diameter. Note the cord insertion into the base of the omphalocele sac. **C,** Photograph of the newborn shows the omphalocele was quite small; it was easily repaired surgically. **D,** Midsagittal view of a different fetus with a similar appearance at 12 weeks. In this case, an abnormal karyotype was found.

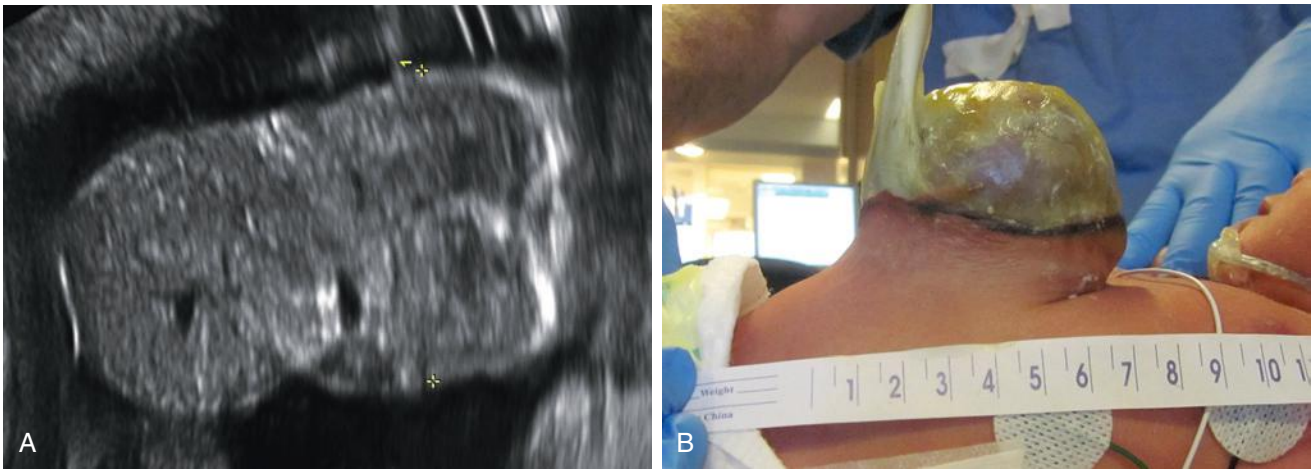

FIG 14-24 Large omphalocele. **A,** Sonogram at 23 weeks. On this transverse view, the fetal abdomen is toward the right, between the cursors. The large liver-containing omphalocele is toward the left. **B,** Photograph obtained after birth showing the large omphalocele. A primary surgical closure was performed.

The differential diagnosis primarily includes other types of ventral wall defects (see Table 14-8 and Figs. 14-26 through 14-35). In gastroschisis, free loops of bowel (and rarely liver) are prolapsed to the right of the cord insertion at the abdominal wall. Pentalogy of Cantrell is a defect of the upper abdominal wall and diaphragm such that part of the heart is also exteriorized. Bladder and cloacal exstrophy are defects of the lower abdominal wall that involve the bladder; demonstration of a normal bladder is essential to exclude these entities. OEIS complex (omphalocele, exstrophy, imperforate anus, spinal defects) can be thought of as cloacal exstrophy with involvement of the spine. Limb–body wall complex is characterized by severe abnormalities of the spine, abdomen, and legs. A urachal cyst may communicate with the bladder and contains urine.

Prognosis

Despite advances in neonatal care and surgical repair, the prognosis for prenatally diagnosed omphalocele is guarded. In a series of 90 cases in Norway from 1985 to 2004, there were 49 pregnancy terminations and 6 antepartum, 5 intrapartum and 9 postnatal deaths.[130] Of the 21 survivors, 13 had various additional anomalies or impairments. Only 8 children (9% of the original cohort) were considered healthy on follow-up evaluation at ages 1 to 17 years. Similar follow-up findings were reported in a series of 445 cases treated in London from 1991 to 2002.[138] Most aneuploid pregnancies were either terminated or died in the antepartum or neonatal period. Of 176 fetuses with normal or unknown karyotype, there were 96 terminations, 27 fetal demises, and 9 neonatal deaths. Only 44 children underwent surgery (10% of the original cohort), and all of them survived.

The poor outcomes for omphalocele are related to the high incidence of associated abnormalities, especially aneuploidy. The prognosis for isolated omphalocele is much better. After birth, these infants often have an easier postoperative course compared to those with gastroschisis, presumably because the omphalocele membrane protects the externalized intestine.

However, those with large liver-containing omphaloceles (see Fig. 14-24) may face additional complications, including respiratory insufficiency and complex extended surgical repair. *Giant omphalocele* is often defined as more than 75% of liver located exterior to the abdomen. As might be expected, prognosis for these fetuses is significantly worse than for those with smaller isolated omphaloceles. In a series of 10 such pregnancies, there were 2 antepartum and 2 infant deaths. Of the 6 survivors, 4 had respiratory insufficiency and there were various long-term problems including developmental delay in 2.[139]

TABLE 14-12 First Trimester Omphalocele

Data from Kagan KO, Staboulidou I, Syngelaki A, et al: The 11-13-week scan: diagnosis and outcome of holoprosencephaly, exomphalos and megacystis. Ultrasound Obstet Gynecol 36:10-14, 2010.

Diagnosis at 11 to 14 Weeks

Ventral wall defects can be reliably diagnosed by ultrasound imaging performed between 11 and 14 weeks (see Fig. 14-23A and D and Fig. 14-25A-C). Indeed, detection rate may approach 100%; in one series, all 60 fetuses with omphalocele (50 with bowel only and 10 with extracorporeal liver) were detected, as were all 19 cases with gastroschisis.[31]

When a ventral wall defect is detected, evaluation of the cord insertion site with color Doppler sonography may be helpful to distinguish omphalocele and gastroschisis (Fig. 14-26B). At times this distinction is deferred until a subsequent ultrasound examination can be performed, typically at about 16 weeks.

The prevalence of omphalocele depends on the gestational age at which the fetus/infant is examined. In a database of 57,119 singleton pregnancies that underwent sonograms between 11 and 14 weeks, there were 150 fetuses with omphalocele (prevalence 26 per 10,000).[140] This is 10 times greater than the reported prevalence found at birth in the EUROCAT registry. Even between 11 and 14 weeks, the prevalence of omphalocele is inversely related to gestational age (Table 14-12).

There are two explanations for the reported high prevalence of omphalocele at early gestational ages. Many of these fetuses are aneuploid and undergo demise in utero. In addition, many of these presumed "omphaloceles" appear to resolve. In one series of 150 cases of omphalocele detected in the first trimester, apparent spontaneous

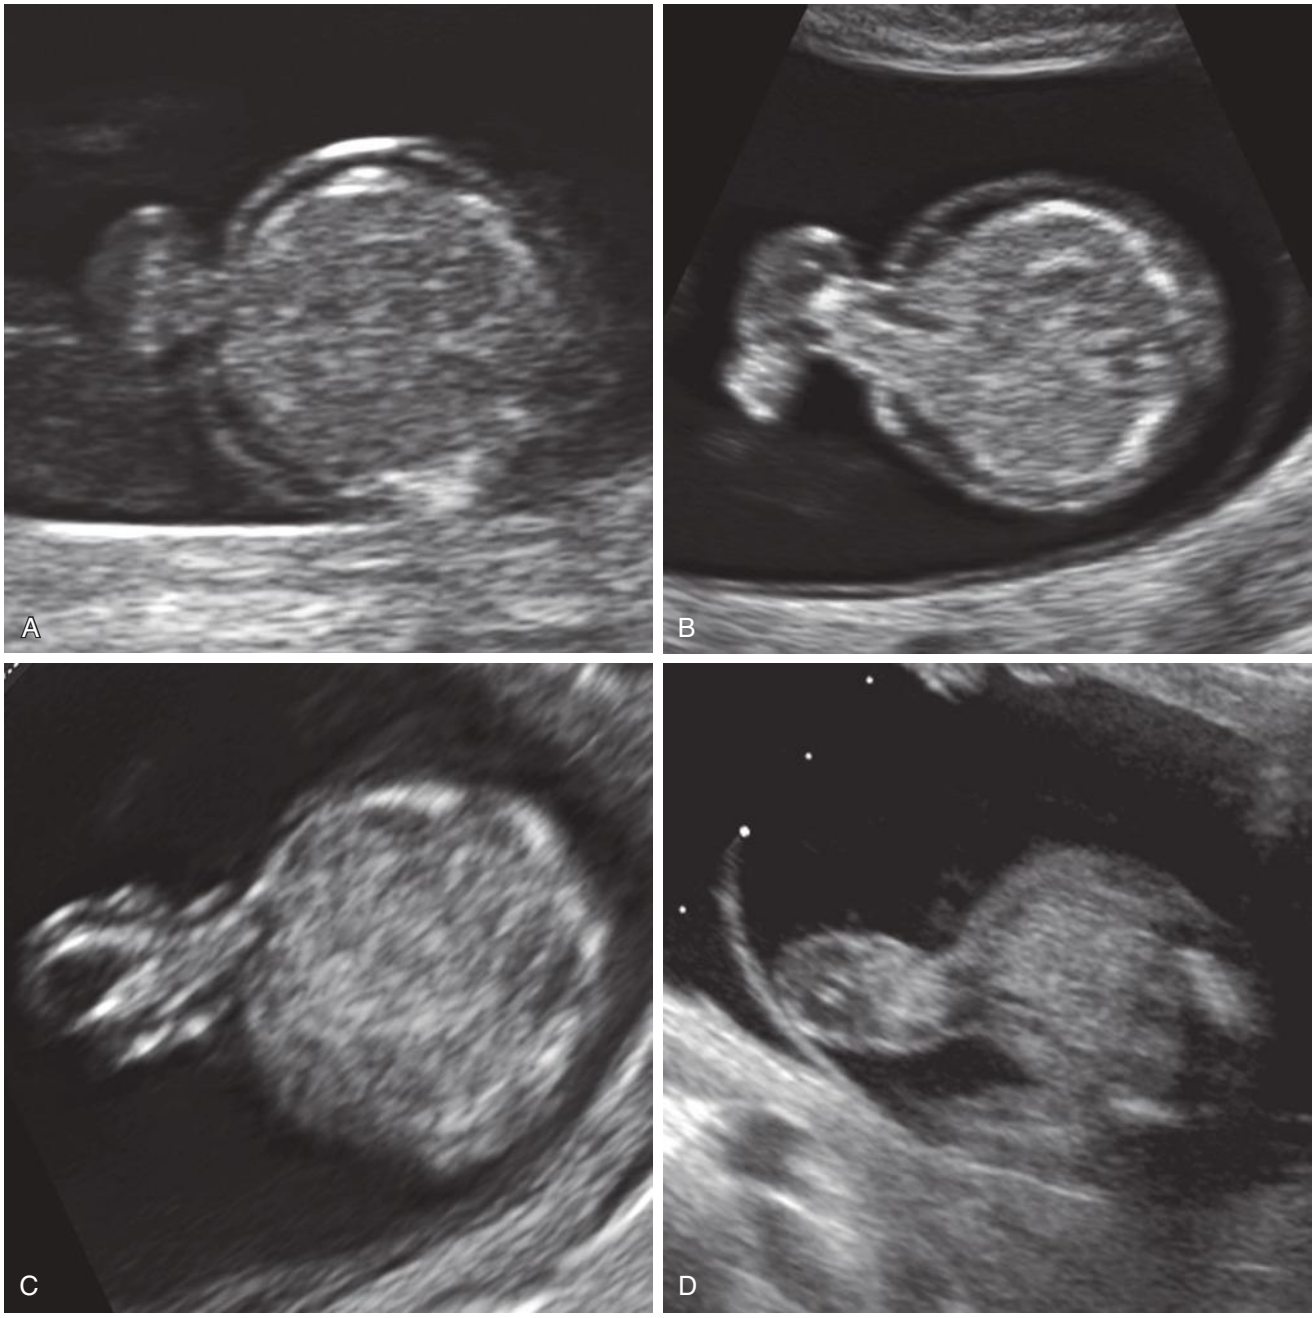

FIG 14-25 Small first trimester omphalocele. **A,** Fetus at 11 weeks 2 days with nuchal translucency measuring 3.0 mm. The small omphalocele resolved and the child was normal at 4 years of age. **B,** Fetus at 11 weeks 4 days with nuchal translucency measuring 4.0 mm. Mild integumentary edema of the abdominal wall is shown. The omphalocele resolved but the fetus developed growth restriction and underwent a difficult delivery; the child now has dysmorphic features, hydrocephalus, and developmental delay. **C,** Small bowel-only omphalocele at 12 weeks 3 days was the only finding by ultrasound imaging. Amniocentesis at 15 weeks revealed a familial unbalanced translocation, despite a normal preimplantation microarray. **D,** Same fetus as in C at 17 weeks 4 days. At this time there were additional sonographic findings including an abdominal cyst and craniosynostosis.

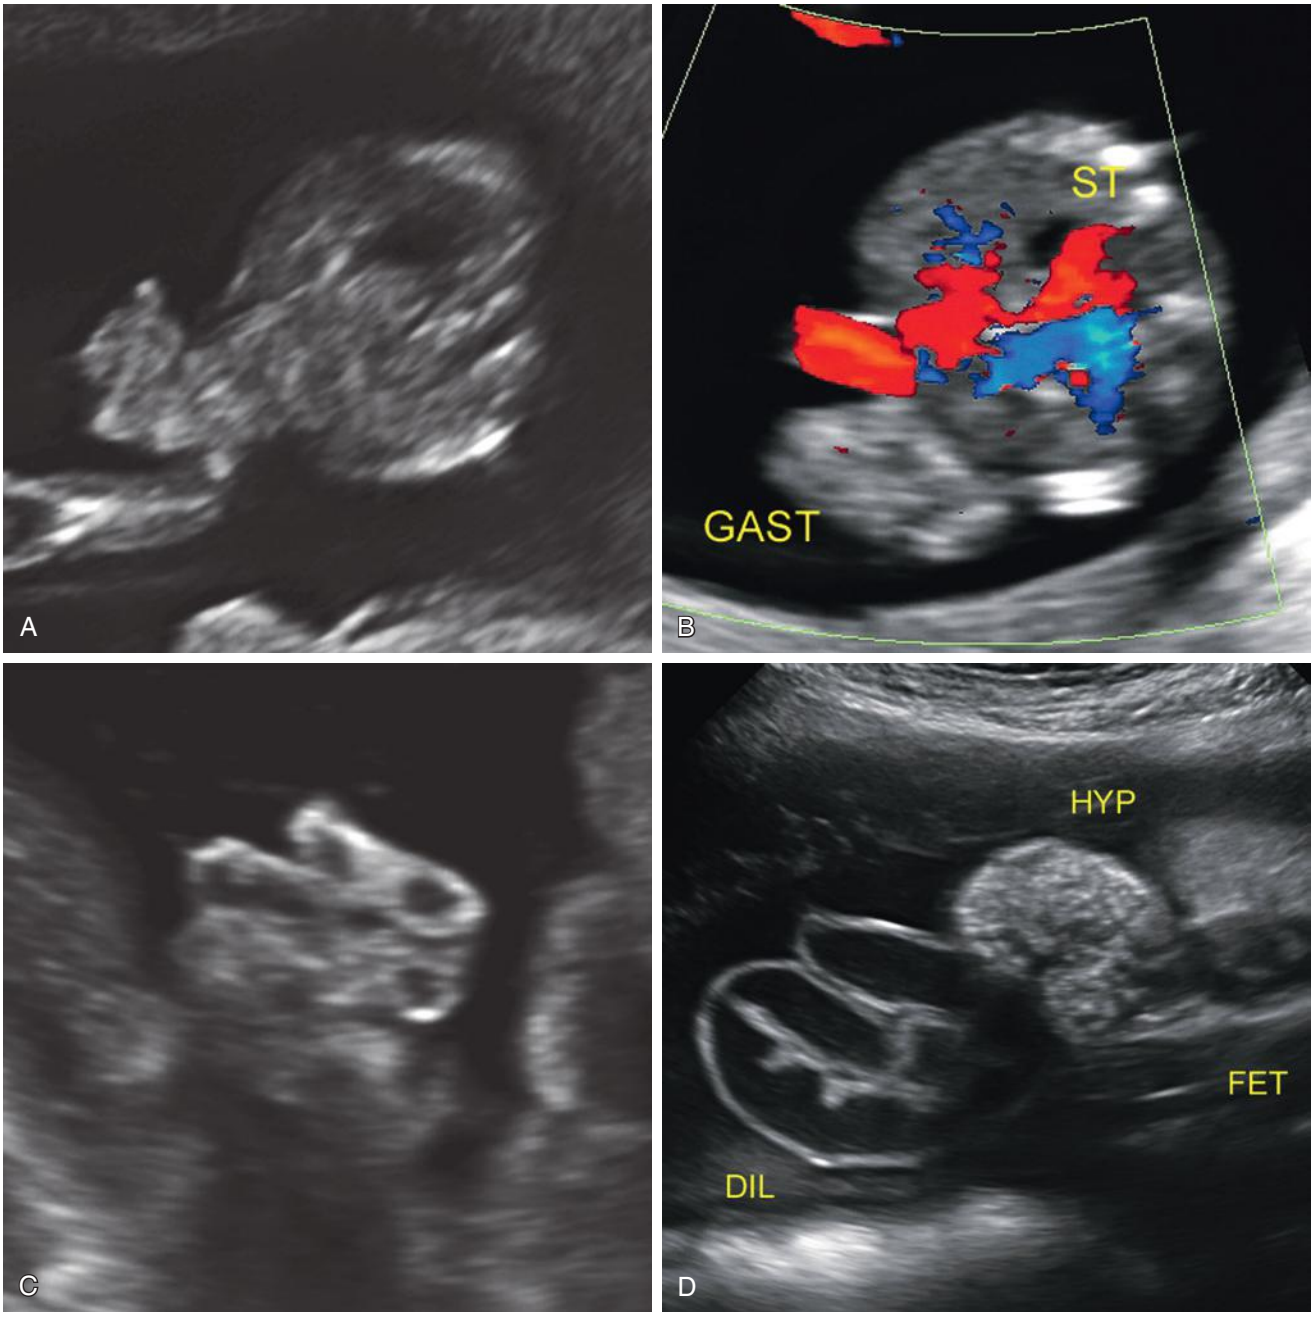

FIG 14-26 Gastroschisis. **A,** At 13 weeks, externalized segments of free-floating bowel are seen, suggesting gastroschisis rather than omphalocele. **B,** Color Doppler sonography demonstrates flow within the umbilical cord. The abdominal wall defect is right paramedian, adjacent to the cord insertion, typical of gastroschisis. ST, stomach; GAST, gastroschisis. **C,** Free loops of externalized nondilated bowel, surrounded by amniotic fluid, are more easily demonstrated at 22 weeks. **D,** In the third trimester, this fetus (FET) developed dilated loops of extra-abdominal intestine (DIL) and a hyperechoic segment (HYP), presumably from inspissated meconium within colon. These findings did not alter obstetric management. The infant weighing 1.7 kg (<1st percentile) was delivered at 37 weeks. The gastroschisis was reduced using a silo, the fascial defect was closed on day 11, and the child was discharged on day of life 55.

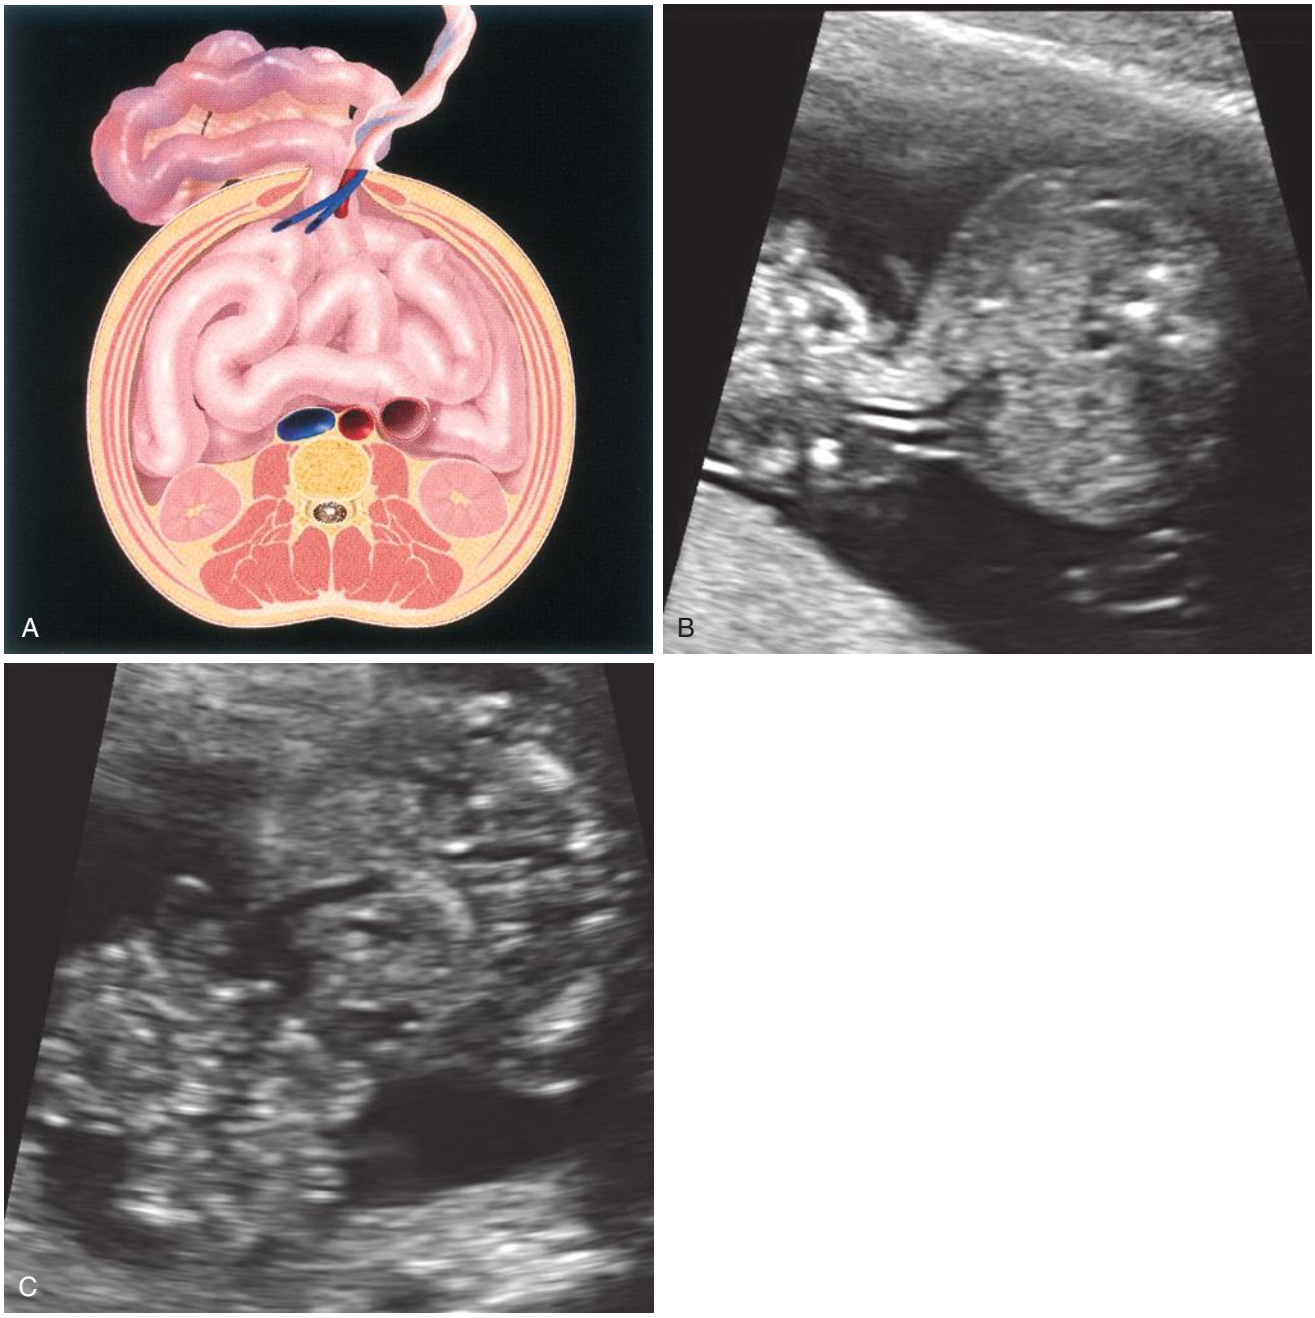

FIG 14-27 Gastroschisis. **A,** Graphic presentation of an abdominal wall defect with herniation of small bowel. The defect is to the right and adjacent to the normally inserted umbilical cord. **B,** At 17 weeks, an anterior abdominal wall defect is shown adjacent to and to the right of the umbilical cord insertion. **C,** Free loops of nondilated externalized intestine are shown surrounded by amniotic fluid. This child had a primary postnatal repair and was discharged on day of life 19. (A from Donnelly LF, Jones BV, O'Hara SM, et al [eds]: Diagnostic Imaging: Pediatrics. Salt Lake City, Amirsys, 2005.)

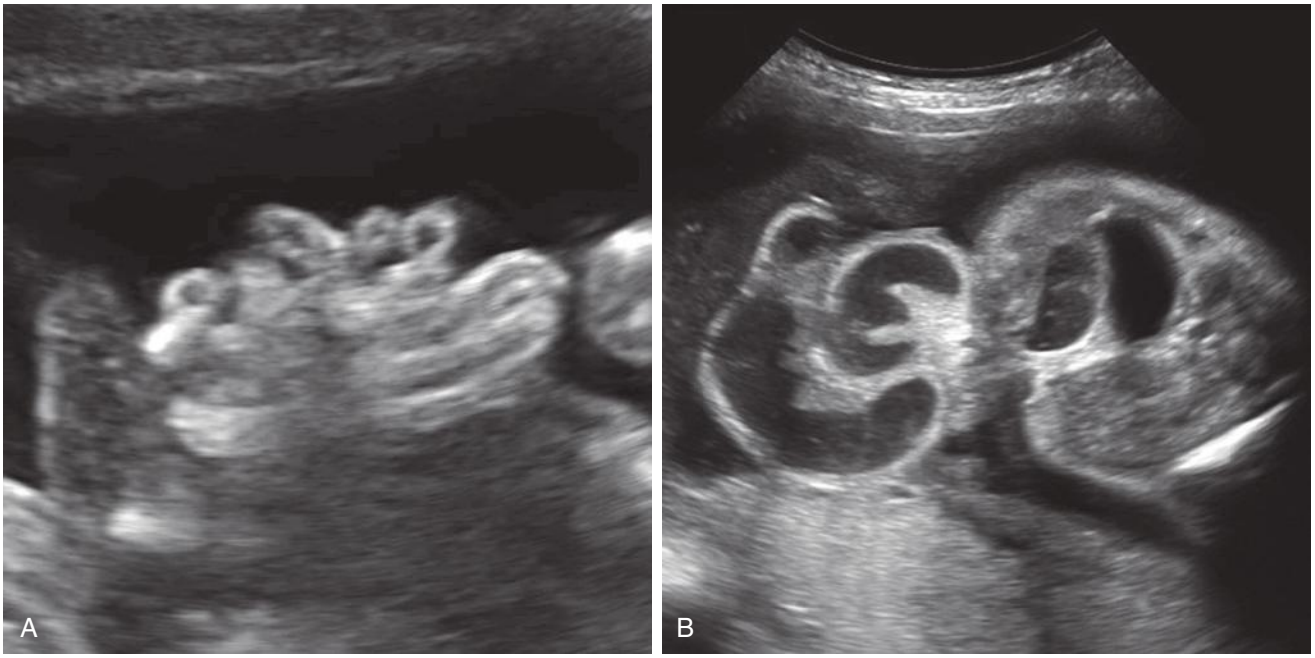

FIG 14-28 Gastroschisis. **A,** Free loops of externalized nondilated, slightly thick-walled bowel at 17 weeks. **B,** Dilated intra- and extra-abdominal bowel segments shown at 32 weeks. These findings did not alter obstetric management. The patient went into labor at 35 weeks and the infant weighing 1.7 kg (<1st percentile) was delivered. The gastroschisis was reduced using a silo, the fascial defect was closed on day 12, and the child was discharged on day of life 79.

resolution occurred by 20 weeks in 83% of 59 euploid fetuses with bowel-only lesions, and in these cases, the infants appeared healthy at birth.[140] These findings raise the possibility that physiologic herniation of bowel into the base of the umbilical cord had been misconstrued as bowel-only omphalocele by early ultrasound examinations.

Although in most cases physiologic bowel herniation resolves by 11 weeks' gestation (crown-rump length 45 mm), there are occasional exceptions. Therefore, an isolated small omphalocele containing only bowel (no other anomalies, normal nuchal translucency) at 11 to 12 weeks may represent delayed resolution of physiologic bowel herniation. Like other manifestations of embryonic dysynchrony, such as delayed development of lymphatics resulting in nuchal edema, delayed ossification of the nasal bone, and delayed coordination of micturition resulting in megacystis, this can be a transient finding that is best regarded as a soft marker for increased risk of chromosomal or other genetic problem, rather than a true structural abnormality.

Another study investigated the outcome of 98 fetuses in whom omphalocele was detected between 11 and 14 weeks.[141] Of 45 fetuses with an additional abnormality on the 11- to 14-week scan, there were no survivors, and there were only 3 survivors among the 22 with increased nuchal translucency. However, the 31 fetuses with apparent isolated omphalocele fared better—in 18, resolution of the omphalocele occurred by 16 weeks and all of these fetuses were liveborn. Of the 11 cases in whom omphalocele persisted, 5 had other anomalies detected at 16 weeks, resulting in 1 surviving infant; 6 had isolated omphaloceles, resulting in 4 surviving infants.

Counseling a patient carrying a pregnancy with ventral wall defect suspected at the 11- to 14-week scan must therefore be done with great care. There is almost a bimodal distribution of prognosis: the majority do poorly, because of aneuploidy or additional structural malformations. Yet a significant fraction, perhaps 1 in 5, result in the birth of a healthy child who does not require surgery. This latter scenario occurs in the majority of cases when the omphalocele is isolated and small, and the nuchal translucency is normal. Management options include noninvasive aneuploidy screening with cell-free DNA or pregnancy-associated plasma protein A (PAPP-A) and human chorionic gonadotropin (hCG), invasive testing by chorionic villus sampling (CVS) or amniocentesis, and follow-up sonograms at 16 and 20 weeks.

Counseling and Obstetric Management

As mentioned previously, counseling patients carrying fetuses with isolated bowel-only omphalocele seen in the first trimester must be circumspect, as many of these fetuses will have normal outcomes. If there is liver in the omphalocele sac, increased nuchal translucency, or associated anomalies, or if the omphalocele persists beyond the first trimester, evaluation for aneuploidy should be offered. If CVS or amniocentesis is performed, consideration should be given to obtaining a microarray and testing for BWS in addition to standard karyotype. If the patient declines diagnostic testing, cell-free DNA screening should detect the majority of trisomies associated with omphalocele. This finding is important because a diagnosis of trisomy 13 or 18 may inform obstetric and neonatal management.

Because of the high risk of associated anomalies and our desire to provide early diagnosis, we offer a structural survey at 16 weeks and again at 20 weeks. A fetal echocardiogram should be performed, although if the heart appears normal on the obstetric sonogram, it may be delayed until 22 weeks. The role of MRI in the evaluation of these fetuses is not well established[142] but can be considered, particularly in unusual or difficult cases.

We routinely obtain follow-up sonograms every 4 to 6 weeks. Macrosomia, polyhydramnios, or macroglossia suggests BWS. We recommend that prospective parents meet with a pediatric surgeon at an appropriate time, usually after 20 weeks when the search for associated anomalies is complete, but earlier if the patient is anxious or is contemplating termination. Delivery should be in a tertiary care center.

FIG 14-29 Gastroschisis repair using a spring-loaded prefabricated silo. The sequential photographs show gradual reduction of herniated bowel. In the final image, the infant is ready to undergo surgical closure of the fascia. (From Holcomb GW, Murphy JP, Ostlie DJ [eds]: Ashcraft's Pediatric Surgery. Philadelphia, Elsevier, 2014, Fig. 48-5.)

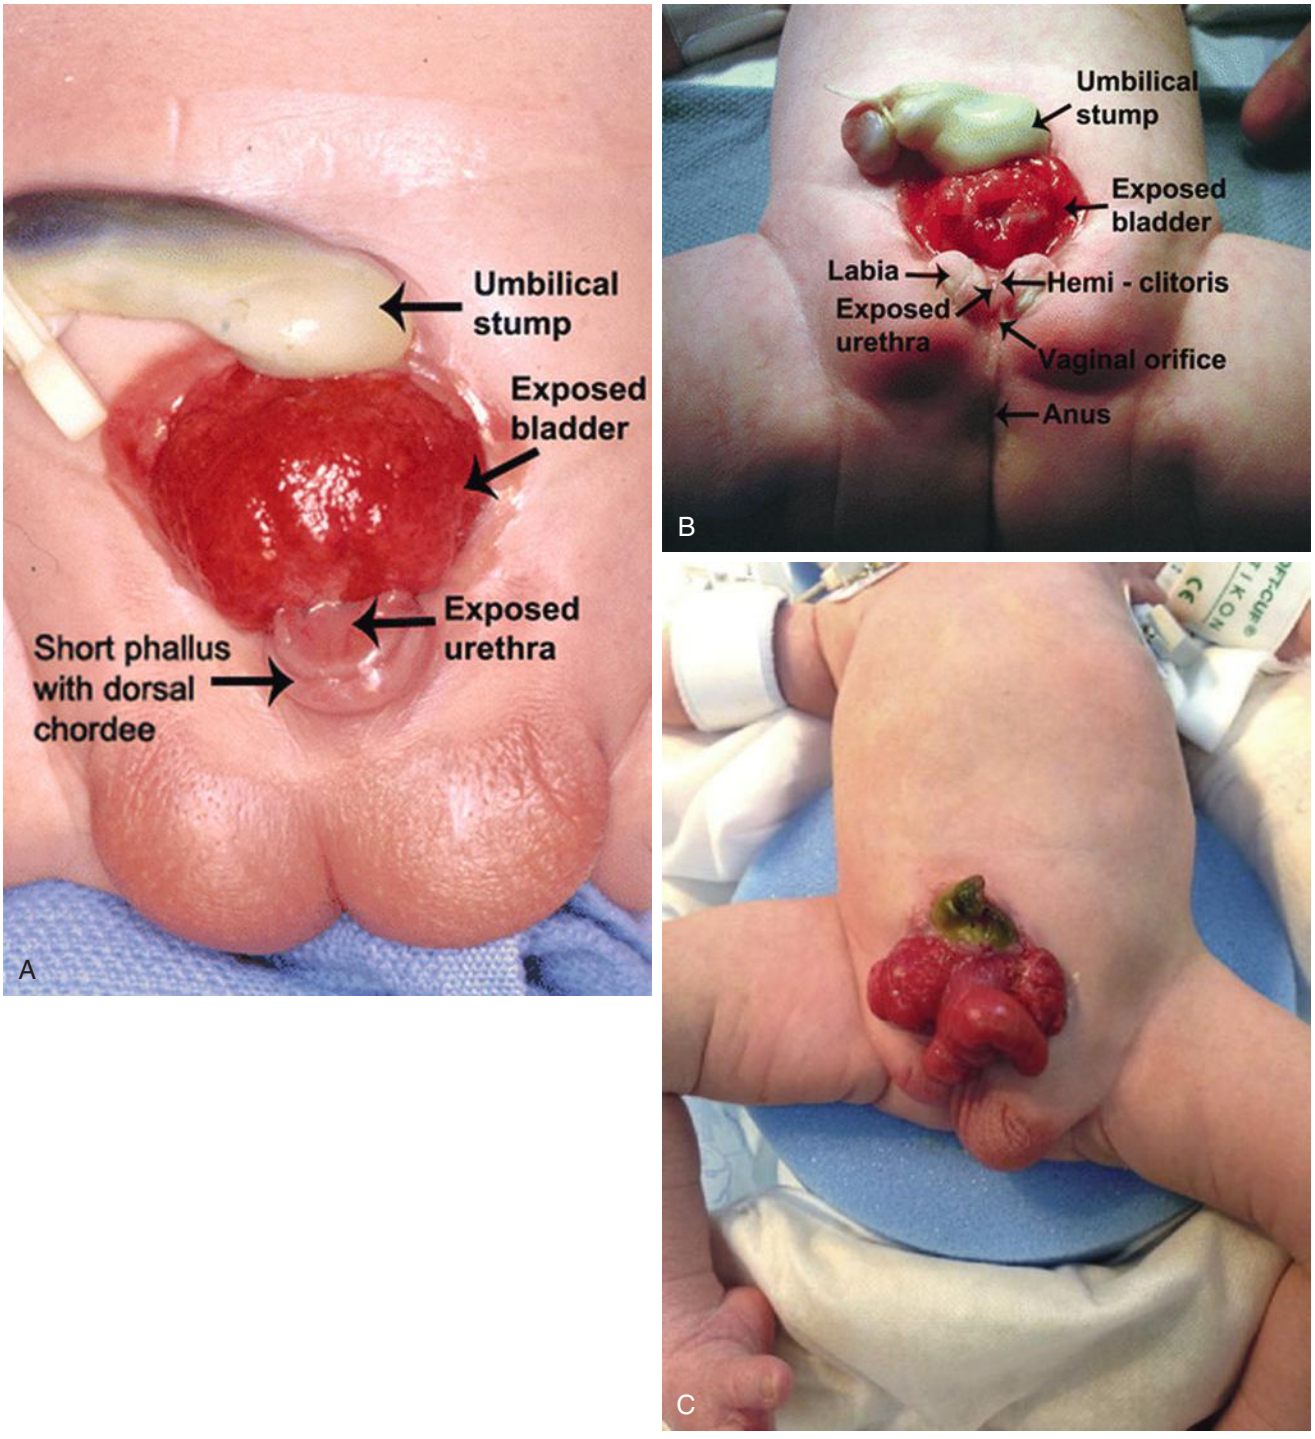

FIG 14-30 Bladder and cloacal exstrophy. **A,** Bladder exstrophy in a newborn male. **B,** Bladder exstrophy in a newborn female. **C,** Cloacal exstrophy. The hindgut is herniated between two exposed hemibladders. (A and B from Pierre K, Borer J, Phelps A, Chow J: Bladder exstrophy: current management and postoperative imaging. Pediatr Radiol 44(7):768-786, 2014, Figs. 2 and 3; C from Clements MB, Chalmers DJ, Meyers ML, Vemulakonda VM: Prenatal diagnosis of cloacal exstrophy: a case report and review of the literature. Urology 83(5):1162-1164, 2014, Fig. 3.)

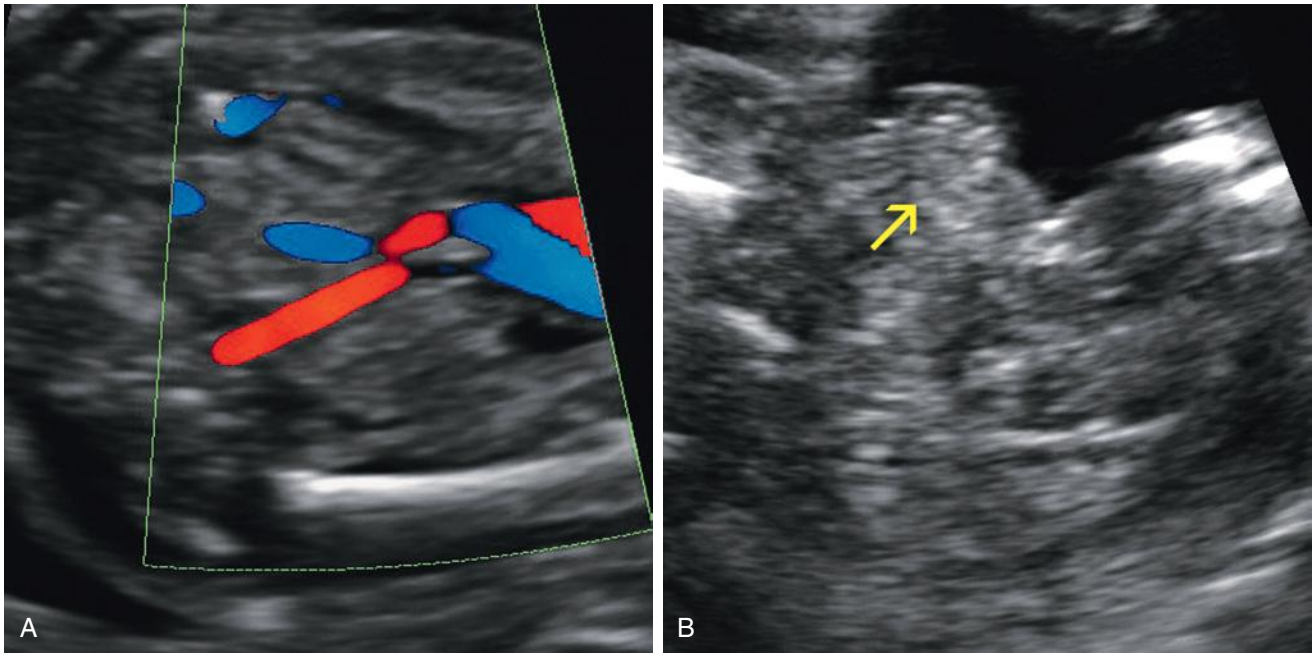

FIG 14-31 Bladder exstrophy. **A,** Color Doppler ultrasound image at the level of the umbilical arteries. The urinary bladder was not visualized and could not be identified on repeated attempts during a prolonged examination. The bilateral fetal kidneys and amniotic fluid volume appeared normal. This constellation of findings suggests bladder exstrophy. **B,** Exposed redundant bladder tissue (*arrow*) is noted at the ventral aspect of the inferior abdominal wall. Compare to Figure 14-30A. This child underwent successful complete primary surgical repair.

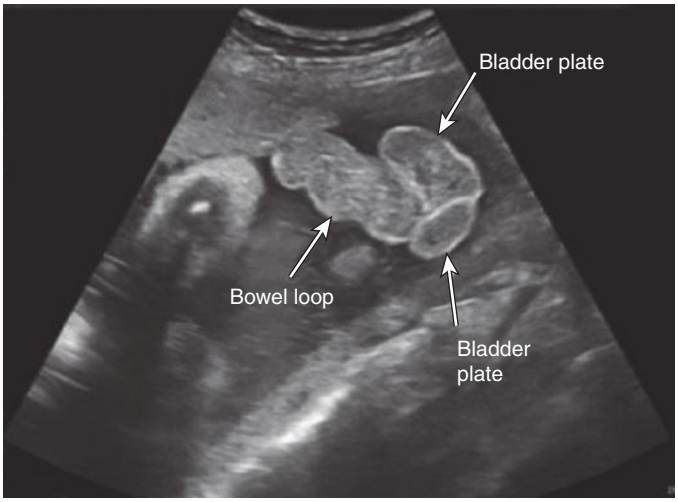

FIG 14-32 Cloacal exstrophy. Bowel loops are herniated between two hemibladders. Compare to Figure 14-30C. (From Clements MB, Chalmers DJ, Meyers ML, Vemulakonda VM: Prenatal diagnosis of cloacal exstrophy: a case report and review of the literature. Urology 83(5):1162-1164, 2014, Fig. 2.)

Cesarean delivery has not been shown to improve outcome, although this option can be considered for giant omphalocele.

Neonatal Management

The exteriorized organs are wrapped in warm saline-soaked gauze covered with plastic to prevent evaporative loss. Intravenous hydration and nasogastric decompression are begun promptly. Serial blood sugar determinations should be obtained because of the possibility of BWS, which can be associated with neonatal hypoglycemia.

The surgical approach depends largely on the size of the lesion. Small omphaloceles are amenable to primary closure. A variety of surgical techniques have been used to repair large omphaloceles. Although there can be issues with gastroesophageal reflux, respiratory problems, and feeding difficulty with failure to thrive, long-term outcomes are determined largely by the presence or absence of associated abnormalities.

Gastroschisis

Definition

The International Clearinghouse for Birth Defects Research and Surveillance defines gastroschisis as "a congenital malformation characterized by visceral herniation through a right-sided abdominal wall defect adjacent to an intact umbilical cord and not covered by a membrane."[143]

Note that almost all cases of gastroschisis are right-sided and consist of externalized bowel, without liver herniation (see Figs. 14-26 and 14-27). Thus left-sided gastroschisis or gastroschisis with liver involvement is rare and atypical. A report of three cases of left-sided gastroschisis noted extraintestinal anomalies in all three.[144] A recent series found liver herniation in 6% of 117 cases of gastroschisis.[145] Some of these atypical cases may represent confusion of gastroschisis with other abdominal wall defects such as omphalocele, limb–body wall complex/amniotic band syndrome/body stalk anomaly, or cloacal exstrophy. In a report of 296 cases with ventral wall defects, the diagnosis was changed in 6%.[146]

Prevalence and Risk Factors

Gastroschisis is nearly unique among congenital anomalies, as there has been a 10- to 20-fold increase in prevalence from the 1960s until the present.[143] The prevalence of gastroschisis is inversely associated

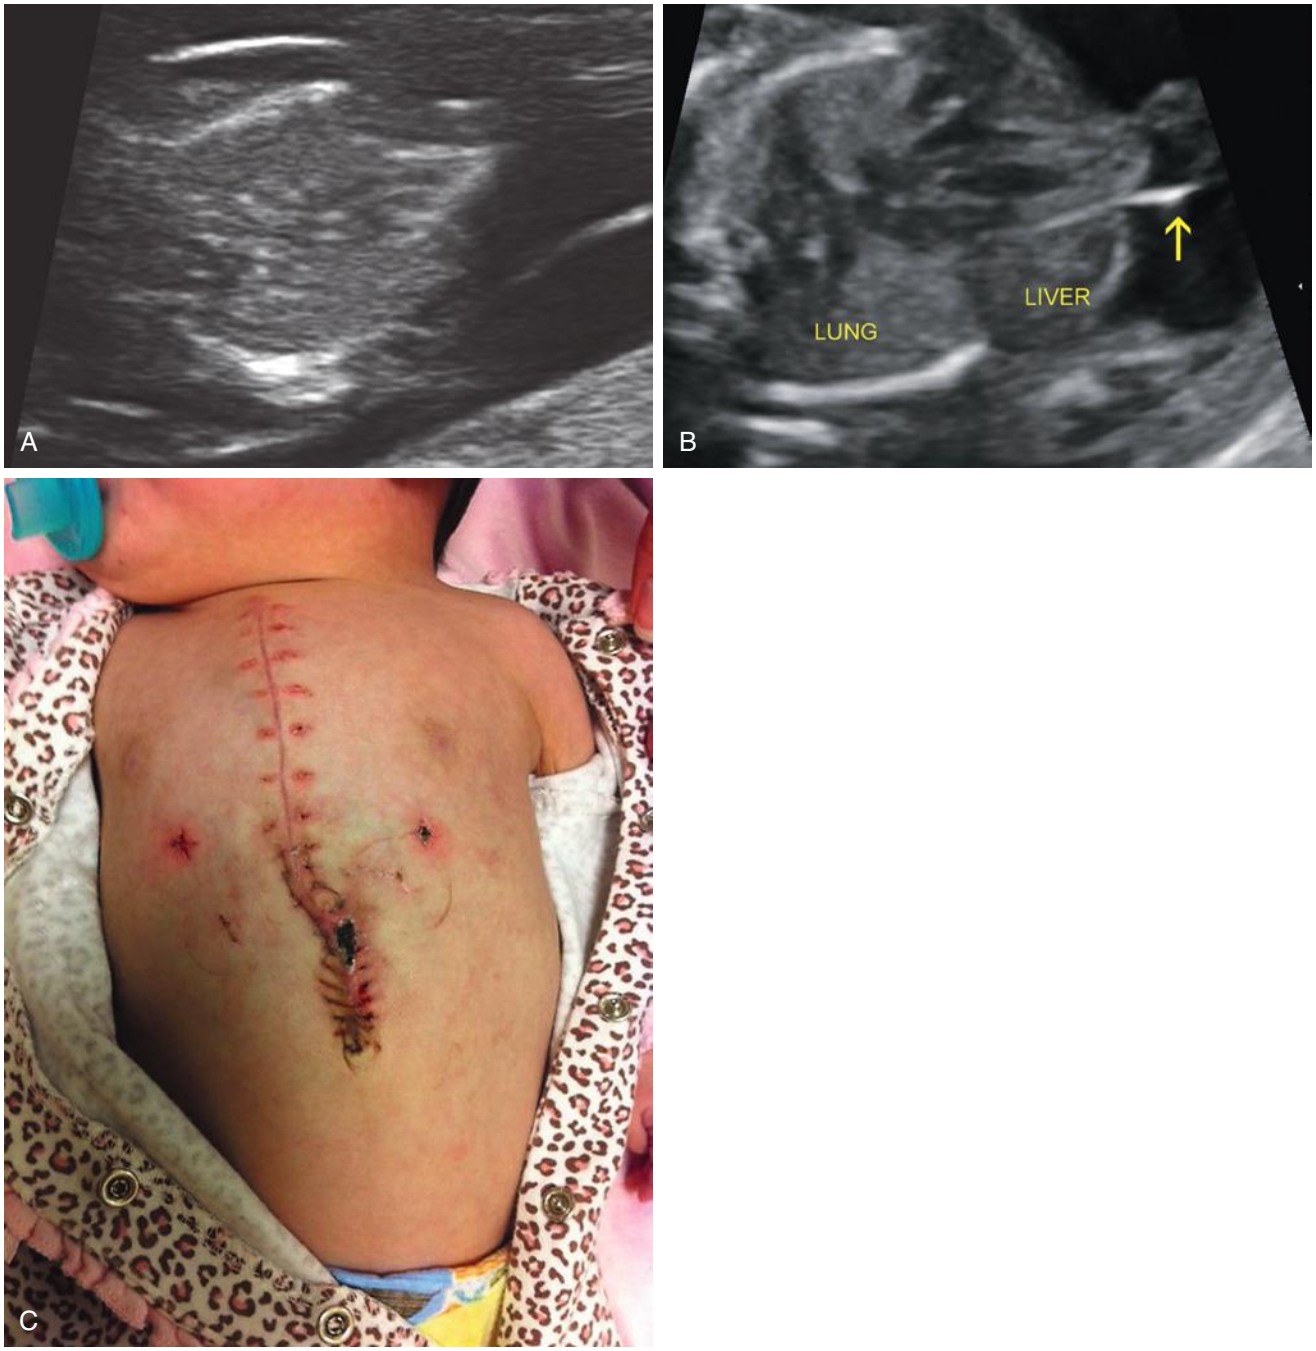

FIG 14-33 Pentalogy of Cantrell. **A,** Fetus referred at 11 weeks 5 days with cystic hygroma. The apex of the heart protrudes through the ventral chest wall. This abnormality was more conspicuous on real-time imaging, with cardiac pulsation observed. **B,** Oblique transaxial sonographic view through the chest and upper abdomen demonstrates caudal angulation of the ectopic heart, herniating through the ventral defect, surrounded by a thin membrane (*arrow*). **C,** Photograph obtained following surgical correction of transposition of the great arteries with pulmonary stenosis and repair of the diaphragmatic defect and omphalocele. The infant was doing well at 6 months of age.

FIG 14-34 Limb–body wall complex at 10 weeks. The cranial portion of the fetus is located in the amniotic cavity, but the caudal portion of the fetus is in the extra-amniotic chorionic space. (Three-dimensional rendering by Bryann Bromley, MD.)

with maternal age; this condition is more than 60 times more common in women younger than 20 years of age, compared to women older than 35.[147] In some studies, exposure to several substances including aspirin, pseudoephedrine and related drugs, and cigarettes and alcohol has been associated with a modest increased risk of gastroschisis.[148,149] The recurrence risk of gastroschisis is thought to be low, although one study calculated a risk of 2.4%.[150] Investigations suggest an environmental rather than genetic cause of this condition.

Associated Anomalies

Abnormalities of the gastrointestinal tract such as atresia, stenosis, necrosis, perforation, malrotation, and volvulus are considered part of the primary defect rather than associated abnormalities. The reported incidence of these bowel complications varies from 4% to 21%,[151-155] with no obvious explanation for the discrepancy in rates.

It is often stated that extraintestinal anomalies are rarely associated with gastroschisis. However, they were found in 6% of 64 prenatally diagnosed fetuses[151] and 7% of 143 registered births.[152] Another study found additional nonbowel anomalies in 5% of 108 fetuses in the prenatal period and a total of 13% of 108 cases after birth.[156] The largest study, a review of 3322 cases of gastroschisis contributed by 24 registries,[157] found that 469 cases (14%) were not isolated: there were 41 cases of aneuploidy, mainly trisomy 13 and 18; 24 nonchromosomal syndromes; and a total of 615 additional defects in 404 fetuses that were grouped together as "multiple congenital anomalies." These anomalies included 147 central nervous system anomalies with 42 cases of hydrocephalus; 83 cardiovascular anomalies; 46 oral clefts; 60 genital anomalies; 61 urinary tract anomalies; and 72 limb anomalies. These authors suggest that some of these cases may be attributed to misclassification. In particular, they propose that cases of trisomy 13 and 18 might have represented misdiagnosed omphaloceles. Still, the incidence of extraintestinal congenital anomalies associated with gastroschisis may be higher than previously reported.[158]

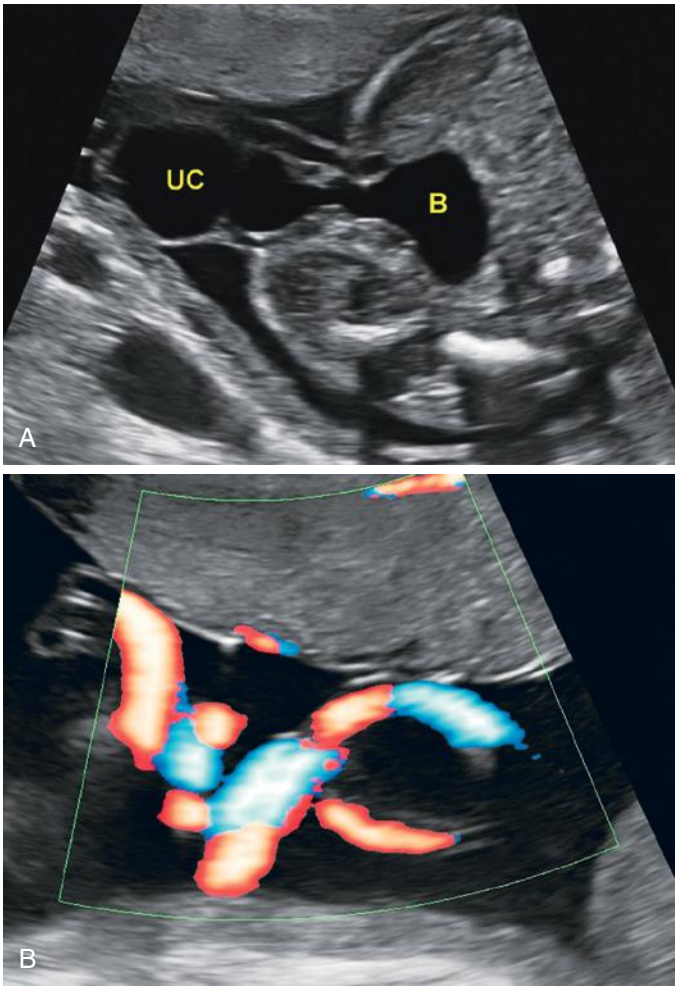

FIG 14-35 Urachal cyst. **A,** Sonolucent urachal cyst (UC) at the ventral aspect of the fetus, near the cord insertion. Initially, this lesion may resemble an omphalocele without prolapsed organs or soft tissue. On closer examination, the cyst can be seen to communicate with the fluid-filled urinary bladder (B). **B,** Color Doppler ultrasound image shows characteristic splaying of the umbilical arteries on either side of the urachal cyst. The urachal remnant was easily repaired with surgery done shortly after birth.

Pathophysiology

Gastroschisis is often thought to be due to a vascular event, perhaps disruption of the right vitelline artery or abnormal involution of the right umbilical vein. However, this does not easily explain the increased risk of associated anomalies. Several additional hypotheses have been suggested: (1) failure of mesoderm to form in the body wall, (2) rupture of the amnion around the umbilical ring, (3) abnormal folding of the body wall resulting in a ventral body wall defect through which the gut herniates,[148] and (4) failure to incorporate the yolk sac and related vitelline structures into the umbilical stalk.[159]

Adverse Obstetric Outcomes

The incidence of growth restriction, fetal demise, and spontaneous preterm delivery is increased. Brantberg and associates[151] found 22% of 64 affected infants weighed less than 2 standard deviations below the mean for gestational age. Netta and colleagues[160] found that 61% of 36 infants were below the 10th percentile and 44% were below the 5th percentile.

In a recent meta-analysis of 3276 pregnancies with gastroschisis, there were 177 stillbirths (risk of fetal demise 4.5%, seven times that in the general population), despite antenatal surveillance and early elective delivery in many of the studies.[161] It is not clear to what extent fetal demise may be due to placental insufficiency as there is not a strong correlation between FGR and stillbirth. Other possible causes of stillbirth include cord compression, protein loss with hypovolemia, cytokine-mediated inflammation, and vascular compromise due to intestinal volvulus.[161]

There is a high rate of spontaneous preterm delivery. In one study, the rate of preterm birth was 28% and the mean gestational age at spontaneous delivery was 36.6 weeks.[162] In a more recent report, 24% of 98 pregnancies were complicated by preterm birth or premature rupture of membranes.[155]

Sonographic Diagnosis and Obstetric Management

Ventral wall defects can reliably be diagnosed by ultrasound examinations as early as 11 to 14 weeks.[31] It is important to confirm the diagnosis of gastroschisis, as opposed to other ventral wall defects, based on the observation of free-floating loops of intestine without a covering membrane herniating to the right of an intact umbilical cord insertion. The use of color Doppler sonography is often helpful (see Figs. 14-26 through 14-28). If the patient fits the demographic profile and there are no additional anomalies in any other organ system, the diagnosis of gastroschisis would seem secure and the prospective parents can be counseled accordingly. A fetal echocardiogram can be offered, although the incidence of congenital heart disease of 2.5%[157] to 4%[163] is somewhat lower than that seen with many other anomalies. Additional testing for aneuploidy can be discussed, although the likelihood of chromosomal abnormality is low. Fetal MRI and amniocentesis add little to the diagnosis after a targeted sonogram performed by an experienced examiner. However, if there are any atypical features, then more extensive evaluation should be recommended.

The most important goal of subsequent obstetric care is to avoid stillbirth, which is not always related to growth restriction. Some form of fetal surveillance is warranted, most often including serial sonographic evaluation for growth, amniotic fluid volume, and appearance of the intestines. Many centers also perform antepartum fetal heart rate monitoring of fetuses with gastroschisis.[164]

Because it is has been suggested that exposure to amniotic fluid progressively damages exposed intestine, some have considered sonographic appearance of the fetal bowel as a criterion for delivery (Figs. 14-26D and 14-28B). Several[165-168] but not all[169] investigators have shown that bowel dilatation is associated with increased risk of postnatal complications, such as atresias, particularly if multiple intraabdominal loops are involved. There is less evidence that thickened bowel wall is an independent risk factor[170] and dilatation of the fetal stomach is not associated with complications.[171]

Of note, change in the sonographic appearance of fetal bowel is not an indication for early delivery, because it is assumed that damage has already occurred. Several studies suggest that delivery prior to approximately 37 weeks is associated with worse outcomes.[172-176] On the other hand, because of the ongoing risk of in utero demise[164] as well as the theoretic possibility of bowel damage, many centers recommend elective delivery at about 37 weeks[177] even if testing remains reassuring. One study showed that this approach is associated with improved outcomes.[178]

In the past, there was a great deal of controversy regarding the appropriate route for delivery. Although there have been no randomized controlled trials, several retrospective series failed to demonstrate improvement in outcome after cesarean delivery. At the present time, most patients with fetal gastroschisis are allowed to labor.[177]

Neonatal Management

Immediately after delivery, intravenous hydration and nasogastric decompression should be initiated. The exteriorized bowel is wrapped with warm saline-soaked gauze and then with plastic to prevent evaporative loss. The child is placed in the right lateral decubitus position to prevent kinking of the mesentery.

Repair of the abdominal wall defect can be done either by primary closure or staged closure, with use of a silo (see Fig. 14-29) followed by closure of the fascia and skin. Regions of atretic bowel can be repaired at the time of primary closure or electively, several weeks later. Return of bowel function might be delayed and prolonged hospitalizations are not uncommon. The neonatal death rate is 4% to 8%.[151,152,154]

Long-term outcome for survivors is excellent**.** The most serious problem is short bowel syndrome (or short gut syndrome), which affects 4% to 10% of children with gastroschisis. Relatively minor gastrointestinal problems may occur, though often growth, neurodevelopment, and life satisfaction are similar to that reported in the general population**.**[177]

Bladder and Cloacal Exstrophy/OEIS Complex

There is a spectrum of abnormalities involving the lower abdomen and genitourinary tract ranging from epispadias at the mild end through bladder exstrophy to cloacal exstrophy/OEIS complex at the severe end.[179,180] The prevalence of bladder and cloacal exstrophy is 3 and 0.5 per 100,000, respectively.[181,182]

Embryology

Approximately 6 weeks after conception, development of the urorectal septum divides the cloaca into the urogenital sinus anteriorly and the hindgut posteriorly (see Fig. 14-9). Simultaneously, the infraumbilical abdominal wall is formed by lateral to medial extension of mesoderm between the ectoderm and the cloaca; if this process is deficient, the cloacal membrane can rupture anteriorly. If rupture of the cloacal membrane occurs after the urorectal septum has reached the urogenital membrane, the result is *bladder exstrophy*, which in the male is accompanied by epispadias (Fig. 14-30A and B). If rupture of the cloacal membrane occurs prior to complete descent of the urorectal septum, the result is *cloacal exstrophy*, involving anterior herniation of bladder and small bowel, preventing normal midline fusion of the hindgut, bladder plate, and genital structures.[180] Exteriorized cecum and terminal ileum lie in the midline between the two hemibladders and hemiphalli (Fig. 14-30C). The distal hindgut ends in a blind pouch. Spinal abnormalities such as hemivertebrae, sacral hypogenesis, and dysraphism are commonly associated with cloacal exstrophy. The acronym *OEIS complex* is sometimes used; some suggest that OEIS is similar or identical to cloacal exstrophy.[183]

Sonographic Diagnosis

Sonographic diagnosis of bladder exstrophy is based on persistent nonvisualization of the bladder in a fetus with normal amniotic fluid volume (Fig. 14-31A). The fetal bladder normally starts to refill within several minutes after voiding; thus, a prolonged period of nonvisualization would suggest an abnormality. In most cases of exstrophy, a small soft tissue mass can be seen at the lower abdominal wall inferior to the umbilical cord insertion, representing redundant bladder mucosa (Fig. 14-31B).

The diagnosis of cloacal exstrophy should be suspected in the second or third trimester if a ventral wall defect is associated with persistent nonvisualization of the bladder; there may also be hemivertebrae with kyphoscoliosis or evidence of lumbosacral meningomyelocele.[184] The prolapsed terminal ileum may have a characteristic

"elephant trunk" appearance[185] (see Fig. 14-32). The sonographic findings are variable,[186] and there are often additional abnormalities.[187]

In the first trimester, a cystic mass can sometimes be identified, prior to rupture of the cloacal membrane.[188] There also appears to be an association between increased nuchal translucency and cloacal exstrophy.[189]

Karyotype with microarray[190] should be considered, in part to ascertain fetal sex, because it is often difficult to determine by ultrasound imaging. This information may be useful for antenatal counseling.[191]

Neonatal Management

The newborn should have its exposed organs moistened with sterile saline solution and covered with a sterile plastic wrap to prevent fluid loss, trauma, and infection. Surgical correction of bladder exstrophy can be done either as a primary repair or in a staged fashion.[192] After repair, the majority of patients with bladder exstrophy are continent.[193]

Surgical repair of the various manifestations of cloacal exstrophy is far more complex, requiring a multidisciplinary approach. Long-term complications including urinary incontinence are common; of particular concern are psychosocial issues related to gender assignment and sexual identity, an area of current interest and investigation. Genetically male infants reared as males may have phallic inadequacy,[194] but attempts at reassignment of female gender to genetic males have proved problematic.[195] Most urologists now recommend that 46,XY infants be raised as males.[196]

Pentalogy of Cantrell

Pentalogy of Cantrell can be thought of as a very high ventral wall defect including a cleft of the distal sternum with some degree of ectopia cordis (Fig. 14-33B), an anterior diaphragmatic defect, a high omphalocele, a pericardial defect, and cardiac malformation. Cases in which some but not all of these features are present can be considered incomplete forms of this condition.[197] The diagnosis can be made by sonography as early as the first trimester if there is ectopia cordis, and there is a reported association with an enlarged nuchal translucency[198] (Fig. 14-33A). Because of the variability in presentation and the small number of cases in the literature, it is best to individualize the prognosis, which can sometimes be favorable (see Fig. 14-33).

Limb–Body Wall Complex/Amniotic Band Syndrome

This group of disruptive processes is referred to by many names, including *amniotic band disruption sequence, body stalk anomaly*, and *short umbilical cord syndrome*. The pathophysiology of these disorders is not known, nor is it established whether they are related.[199,200] Mild cases of amniotic band syndrome involve only limb amputations; more severe forms also manifest craniofacial deformities. The terms *limb–body wall complex* and *body stalk anomaly* refer to severe cases in which there is thoracoabdominoschisis, severe kyphoscoliosis, and abnormally short umbilical cord, in addition to other defects.[201]

The diagnosis of limb–body wall complex has been made as early as the first trimester (see Fig. 14-34); the findings were kyphoscoliosis and large abdominal wall defect, often in association with enlarged nuchal translucency.[202] This particular condition is lethal and should be differentiated from other ventral wall defects, in particular gastroschisis, which has a better prognosis, as do mild cases of amniotic band disruption sequence. Karyotype is usually normal, but may be useful when counseling for future pregnancies. Labor complications are common and cesarean delivery may be necessary for those patients who continue the pregnancy.[203]

Urachal Cyst

The urachus is an embryologic remnant of the allantois, which connects the urogenital sinus and later the bladder with the proximal umbilical cord.[204] The urachus normally atrophies to become the median umbilical ligament. Incomplete atrophy of the urachus results in a urachal cyst, visible by ultrasound imaging as a cystic structure at the ventral aspect of the fetus, communicating with the fluid-filled bladder (Fig. 14-35A). The umbilical arteries are splayed on either side of the urachal cyst and bladder (Fig. 14-35B). Although not a true ventral wall defect, a urachal cyst may resemble an omphalocele. It often resolves in the second half of pregnancy[205] but a partially everted bladder may be seen.[206,207] MRI may be helpful in establishing the diagnosis,[208] which is important because the prognosis for urachal cyst is better than that for omphalocele. The treatment is postnatal surgical resection.

ACKNOWLEDGMENTS

The contributions of several sonographers and sonologists in obtaining and interpreting many of these images are greatly appreciated. In the prenatal diagnosis unit at Massachusetts General Hospital we have a team approach. It is often difficult or impossible to determine who obtained a particular image.

I also want to acknowledge the critical review of the manuscript by Ilona Goldfarb, MD, and Cassandra Kelleher, MD.

Finally, I would like to thank all of those who have taught me ultrasound over the years, and in particular, Beryl Benacerraf, MD.

Fetal Genitourinary Tract

Anthony O. Odibo, Jeffrey M. Dicke

SUMMARY OF KEY POINTS

- Normal renal function is fully established by the 9th week of gestation.
- It is preferable to describe the findings in the fetal renal pelvis, calyces, ureter, and bladder in cases of urinary tract dilation, rather than using nonspecific terms such as pyelectasis, caliectasis, and hydronephrosis.
- Renal cystic anomalies may be a manifestation of underlying genetic disorders.
- Ultrasound findings in cases of lower urinary tract obstruction (LUTO) are more predictive of poor renal function than serial biochemical analyses of fetal urine.
- Although inability to visualize a kidney in its normal location is typically associated with either renal agenesis or ectopia, an abnormal or nonvisualized normal kidney remains a possibility.
- In sonographic terms, dysplasia is nonspecific and refers to a variety of findings.
- Over 50% of all congenital abdominal masses found in the neonate originate in the kidney with the most common fetal renal tumor being mesoblastic nephroma.
- Prominent adrenal glands suggest either renal agenesis, congenital adrenal hyperplasia (CAH), or the presence of a de novo neoplastic process.
- Disorders of sexual differentiation are heterogeneous and may be secondary to hormonal defects or unidentified genetic diseases.
- Fetal ovarian cysts have an excellent prognosis as the majority resolve in the postnatal period spontaneously.

OUTLINE

Congenital abnormalities of the kidneys and urinary tract (CAKUT) affect 1 in 500 live births and constitute about 20% of all major fetal anomalies,[1,2] and autopsy evidence suggests an even higher prevalence.[3] Although antenatal diagnosis of urinary tract malformations appears to be improving secondary to improved resolution of ultrasound equipment, there are relatively high false positive rates. This is compounded by the lack of a consensus on terminology and diagnostic criteria for cases of antenatal urinary tract dilatation.

EMBRYOLOGY

The urogenital system consists of two structurally and functionally different components—the urinary system and the genital system. Both develop from a common ridge of mesodermal tissue, the intermediate mesoderm, along the posterior wall of the abdominal cavity.

Human embryos develop three sets of excretory organs or kidney systems during intrauterine life.[4] The embryonic kidneys, which form in a cranial to caudal sequence, in order of appearance are the pronephros, the mesonephros, and the metanephros. The pronephros and the mesonephros both regress in utero, and the metanephros ultimately becomes the permanent kidneys[5,6] (Fig. 15-1A and B). The mesonephros serves as an excretory organ for the embryo whereas the definitive kidney begins its development, then regresses by the 4th month. Some elements of the mesonephros are retained in the mature urogenital system as part of the reproductive tract.[6]

The metanephros forms in the sacral region as a pair of structures called the metanephric diverticulum or ureteric bud. It emanates from the distal portion of the mesonephric duct and comes in contact with and penetrates the metanephric mesenchymal blastema (metanephric mesoderm) at approximately the 28th day.[5,6]

The ureteric bud and metanephric mesoderm exert reciprocal inductive effects toward each other, and the proper differentiation of these structures depends on these inductive signals. The metanephric mesoderm induces the ureteric bud to branch, and the ureteric bud induces the metanephric mesoderm to condense and undergo mesenchymal-epithelial conversion. The nephron, which consists of the glomerulus, proximal tubule, loop of Henle, and distal tubule, is thought to derive from the metanephric mesoderm, whereas the collecting system, consisting of collecting ducts, calyces, pelvis, and ureter, is formed from the ureteric bud.[6]

The division of the ureteric bud results in the eventual pelvicalyceal patterns and their corresponding renal lobules. The first few divisions of the ureteric bud give rise to the renal pelvis, major and minor calyces, and collecting tubules. Thereafter, the first generations of collecting ducts are formed. When the ureteric bud first invades the metanephric mesoderm, its expanded end forms an ampulla that will eventually give rise to the renal pelvis. By the 6th week, the ureteric bud has bifurcated at least four times, yielding 16 branches. These branches then coalesce to form two to four major calyces extending from the renal pelvis. By the 7th week, the next four generations of branches also fuse, forming the minor calyces. By the 32nd week, approximately 11 additional generations of bifurcation have resulted in approximately 1 to 3 million branches, which will become the collecting duct tubules. In humans, although renal maturation continues to take place postnatally, nephrogenesis is completed before birth.[6] The kidney moves cephalad from its pelvic position to the lumbar region by the 6th to 9th week of gestation.

Initially, the excretory ducts of both systems enter a common cavity, the cloaca.[4] The urorectal septum develops during the 4th to 6th weeks and separates the cloaca into an anterior urogenital sinus and the rectum posteriorly. The urogenital sinus gives rise to the bladder superiorly and the membranous urethra inferiorly.[7] Initially the bladder is continuous with the allantois, but when the lumen of the allantois is obliterated, a thick fibrous cord, the urachus, remains and connects the apex of the bladder with the umbilicus. The genital ridges can be seen medial to the mesonephros and these form the gonads, which differentiate into male and female testis and ovaries, respectively, by the 8th week.

NORMAL FETAL URINARY TRACT

With the use of transvaginal transducers, the fetal kidneys can be demonstrated at approximately 11 weeks, and they can be visualized by 12 weeks using transabdominal probes (Fig. 15-2). During the first trimester, the kidneys appear as hyperechoic oval structures at both sides of the spine with echogenicity comparable to that of the liver or spleen. The bladder can be seen in most fetuses from the 9th week of gestation (Fig. 15-3). The echogenicity of the fetal kidneys progressively decreases, and by the third trimester, the cortical echogenicity should be less than that of the liver or spleen. Corticomedullary (CMD) differentiation begins at about 14 to 15 weeks and should always be demonstrated in fetuses older than 18 weeks (Fig. 15-4B). Growth and appropriate size of the fetal kidneys can be evaluated by measuring renal length and comparing it to normal charts. The normal kidney grows at an average rate of 1.1 mm per gestational week. During the second and third trimesters, the kidneys are easily identified by imaging the dorsolumbar spine and scanning on either side in parasagittal and transverse axial sections (Fig. 15-4A). Urine distending the renal pelvis may help in their identification. Under normal conditions, the fetal ureters are not visible.[8-10]

Production of urine by the kidneys begins during the 9th week of embryonic life. At this stage, the urine in the bladder allows visualization as a fluid-filled structure within the fetal pelvis (Fig. 15-5).

During the second and third trimester, the bladder will empty and refill continuously every 25 to 30 minutes. This cycle can be monitored during the sonographic examination. Toward the end of the pregnancy, this cycle decreases, especially in female fetuses, possibly from hormonal influence on the fetal bladder neck. The position of the fetal bladder is easily identified, because it lies between the umbilical arteries within the fetal pelvis. These arteries are readily seen with the use of color Doppler imaging.[8,9] The normal thickness of the bladder wall is about 2 mm, and the ideal position to measure this is at the level of the umbilical arteries.

In addition to visualization of the bladder and normal kidneys, the assessment of the urinary tract (UT) should include an evaluation of the amniotic fluid volume. After 14 weeks, two thirds of the normal amniotic fluid is produced by fetal urination and one third comes from pulmonary fluid. A normal volume of amniotic fluid is mandatory for proper development of the fetal lung.[11]

OBSTRUCTIVE URINARY TRACT ABNORMALITIES

Urinary tract dilation is one of the most common sonographic prenatal diagnoses, affecting 1% to 5% of all pregnancies. The condition is most commonly diagnosed by measuring the anteroposterior (AP) diameter of the renal pelvis on a transverse scan of the fetal abdomen (Figs. 15-6 and 15-7). The exact incidence is confounded by the different terms used to describe this condition in the literature, including hydronephrosis, pyelectasis, pelviectasis, and pelvicaliectasis. In an attempt to limit the use of these confusing terms, this chapter will use the term *urinary tract dilation* and be more specific when the underlying renal abnormality is known, as recently suggested in a Consensus Statement endorsed by the major fetal and postnatal renal imaging societies.[12] The proposed classification system suggests describing

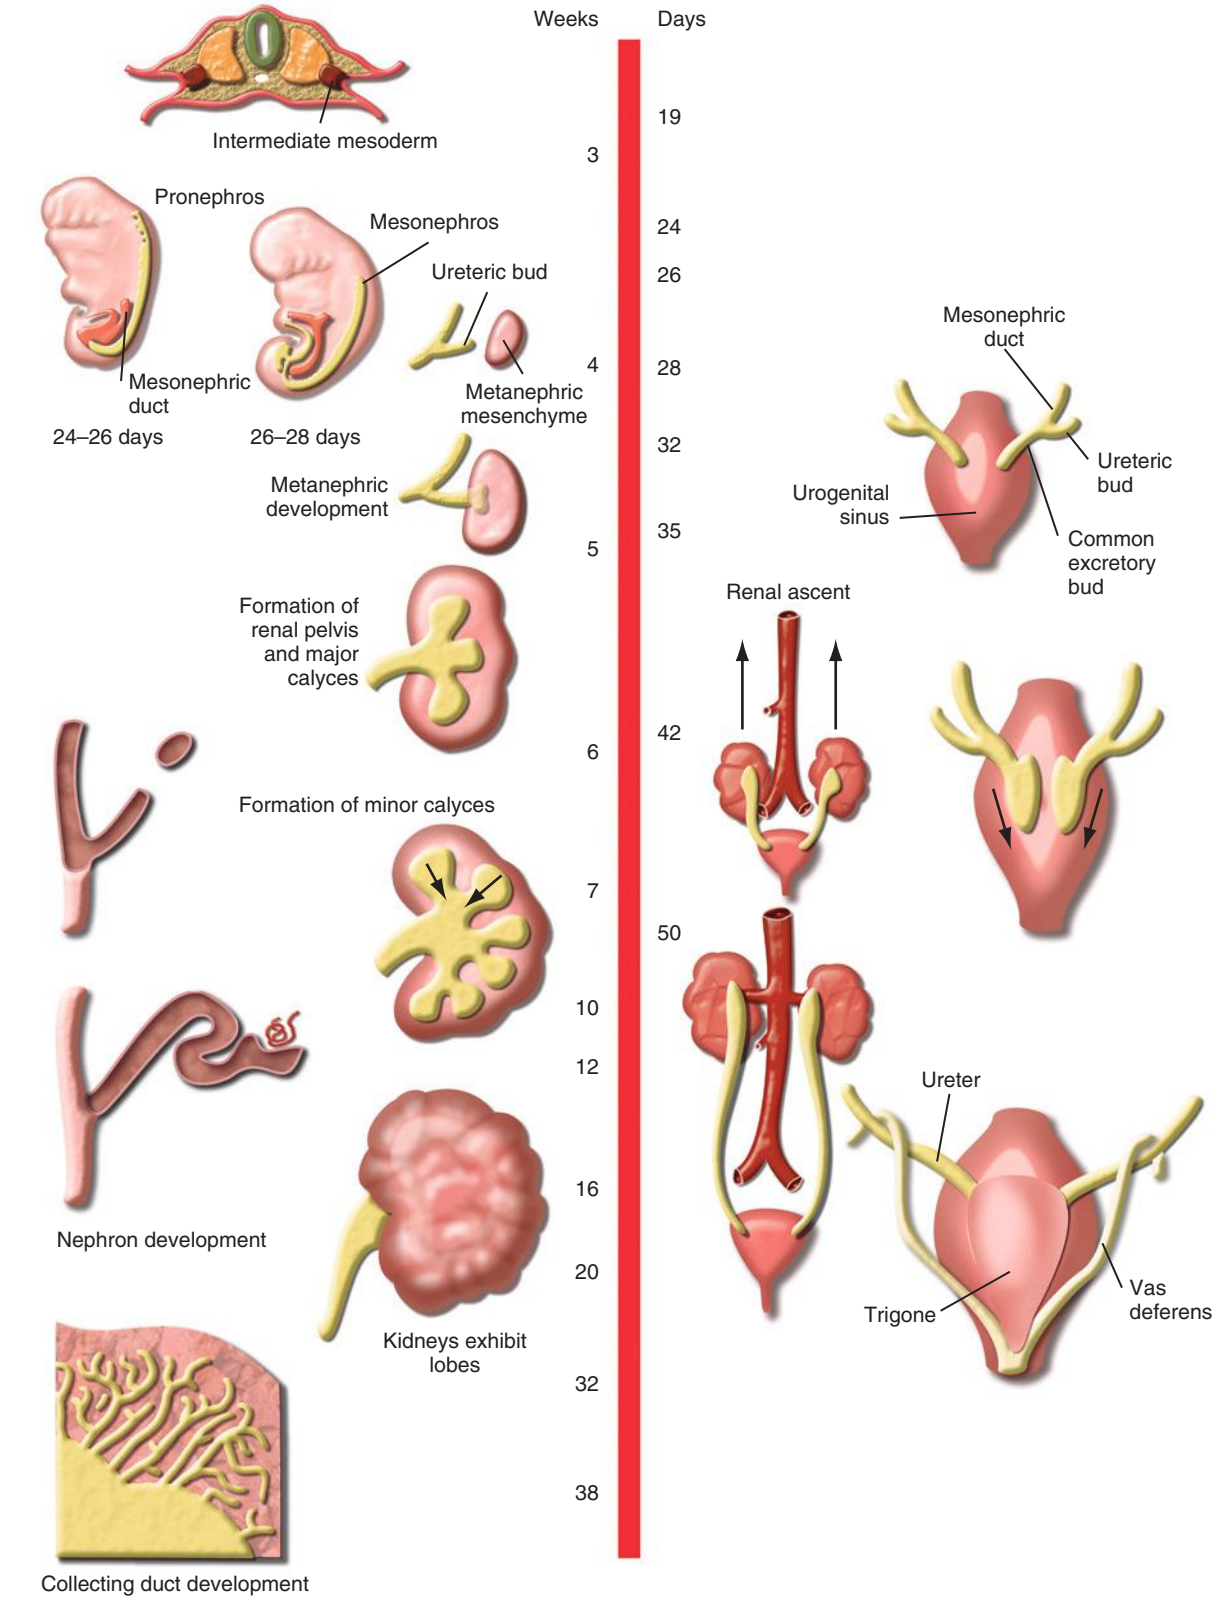

FIG 15-1 The timeline of urogenital system development in the kidney (**A**) and ureter and bladder (**B**). (Modified from Park JM: Normal and anomalous development of the urogenital system. In Walsh PC: Campbell's Urology, 8th ed. Philadelphia, WB Saunders, 2002, p 1737. Copyright © 2002 Saunders, an imprint of Elsevier; and Larsen WJ: Human Embryology. New York, Churchill Livingstone, 1997. Illustration by James A. Cooper, MD, San Diego, CA.)

findings on renal ultrasound examination as shown in Table 15-1 and Figure 15-8 and classifying normal renal findings as in Table 15-2. The panel went on to propose stratifying prenatal risks and management schemes based on findings as shown in Figure 15-9. Examples of sonographic features of common findings associated with urinary tract dilation are shown in Figures 15-8 and 15-10A and B.

In the low-risk group, other than one prenatal follow-up sonogram, no postnatal follow-up is recommended. This approach is in contrast to high-risk groups, which require closer and more frequent evaluation. The proposed classification system builds on that previously proposed by the Society for Fetal Urology (Fig. 15-11A and B), with the advantage of being endorsed by other professional organizations, including the Society for Maternal-Fetal Medicine, the American Institute for Ultrasound in Medicine, and the American College of Radiologists. Prospective studies are needed to evaluate the effectiveness of the classification system in streamlining management of these abnormalities. The common causes, and their incidence, of urinary tract dilation are shown in Table 15-3.[13]

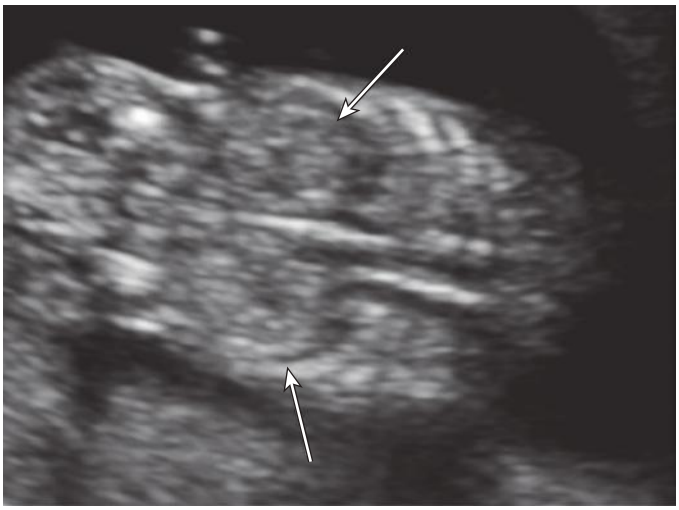

FIG 15-2 First trimester kidneys (*arrows*) appear as hyperechoic structures beside the spine with echogenicity comparable to that of the liver or spleen.

Transient Dilation

The majority of fetuses with an antenatal diagnosis of renal dilation have normal renal findings postnatally. Transient dilation is thought to result from narrowing or natural folds within the urinary tract during the early developmental phase, which eventually resolve. Because this is a retrospective diagnosis, it is difficult to differentiate from other causes of urinary tract dilation. In general, the fetuses with transient dilation tend to have AP diameters of less than 6 mm in the second trimester and less than 8 mm in the third trimester.[14-16]

Ureteropelvic Junction Obstruction

The hallmark of ureteropelvic junction (UPJ) obstruction is the finding of a dilated renal pelvis and calyces without dilation of the ureters. This conditions affects 1 in 2000 births and is responsible for 10% to 30% of all cases of antenatal renal dilation.[16,17] The cause of UPJ obstruction remains unknown, but it is observed more commonly in male fetuses.

The threshold measurement for diagnosis on axial views of the kidney is 7 mm for mild dilation (see Fig. 15-6), between 7 and 15 mm

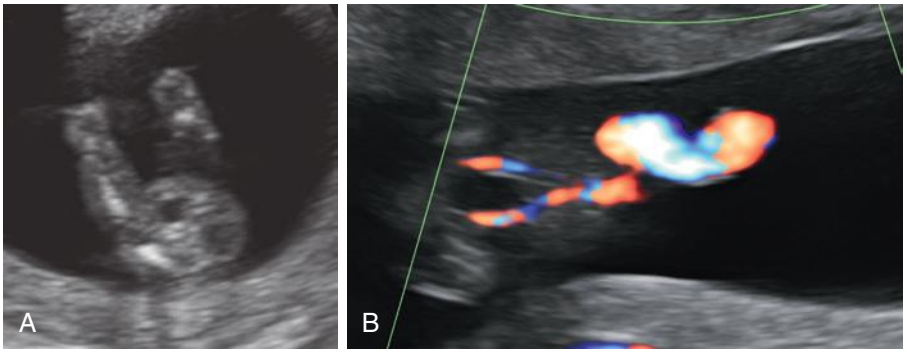

FIG 15-3 Axial view of first trimester fetal bladder (**A**); first trimester bladder delineated by umbilical arteries (**B**).

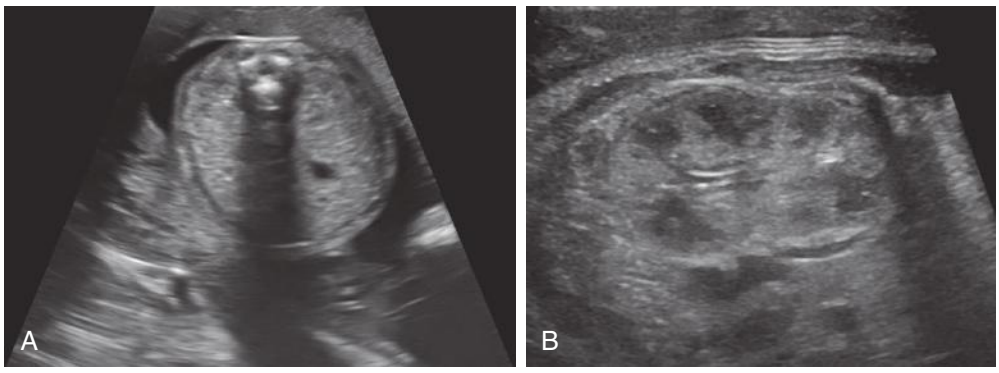

FIG 15-4 Axial view of normal-appearing second trimester kidneys examined with the spines at the ideal position (**A**); normal corticomedullary differentiation in a normal third trimester kidney, demonstrating the difference between the hypoechoic medulla and the echogenic cortex (**B**).

TABLE 15-1 Ultrasound Parameters Included in the Urinary Tract Dilation Classification System

Ultrasound Parameters	Measurement/Findings	Note
Anteroposterior renal pelvic diameter (APRPD)	AP in mm	Measured on transverse image at the maximal diameter of intrarenal pelvis (Fig. 15-7)
Calyceal dilation: central (major calyces)	Yes/no	
Calyceal dilation: peripheral (minor calyces)	Yes/no	
Parenchymal thickness	Normal/abnormal	Subjective assessment
Parenchymal appearance	Normal/abnormal	Evaluate echogenicity, corticomedullary differentiation, and for cortical cysts
Ureter	Normal/abnormal	Dilation of ureter is considered abnormal prenatally, although transient visualization of the ureter is considered normal postnatally
Bladder	Normal/abnormal	Evaluate wall thickness for the presence of ureterocele and for a dilated posterior urethra

Modified from Nguyen HT, Benson CB, Bromley B, et al: Multidisciplinary consensus on the classification of prenatal and postnatal urinary tract dilation (UTD classification system). J Pediatr Urol 10(6):982-998, 2014.

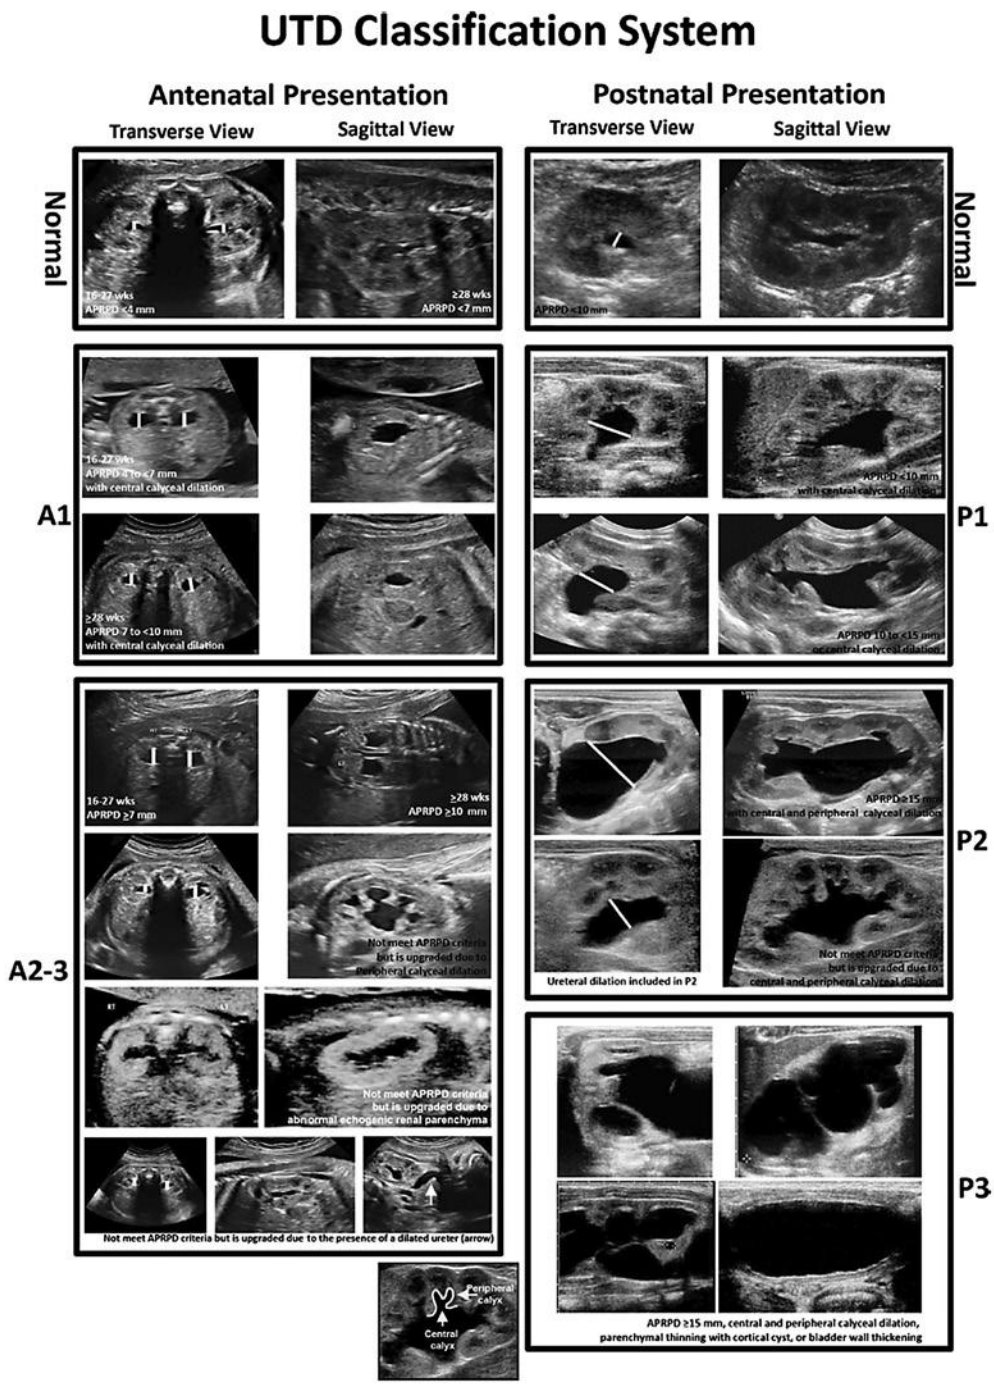

FIG 15-8 The urinary tract dilation (UTD) classification system, which describes the appearance of the urinary tract based on antenatal and postnatal presentation. Antenatal presentation (*left column*) is divided into normal, A1 and A2-3, and measurements between 16 and 27 weeks and 28 or more weeks of gestation. A normal urinary tract is one with no urinary tract abnormalities and anteroposterior renal pelvic diameter (APRPD) measuring less than 4 mm between 16 and 27 weeks' gestation and less than 7 mm at 28 or more weeks of gestation. A1 describes a normal urinary tract with 4 to less than 7 mm pelvic dilation at 16 to 27 weeks' gestation or 7 to less than 10 mm at 28 or more weeks of gestation with or without central calyceal dilation. UTD A2-3 is for fetuses with APRPD of 7 mm or more between 16 and 27 weeks' gestation or 10 mm or greater at 28 or more weeks of gestation, peripheral calyceal dilation, ureteral dilation, renal parenchymal, or bladder abnormalities. The postnatal presentation (*right column*) is divided into normal, P1, P2, and P3. Measurements are more reliable if taken 48 hours after birth or later. A normal urinary tract is one with no urinary tract abnormalities and APRPD less than 10 mm. P1 describes a normal urinary tract with APRPD 10 to less than 15 mm or central calyceal dilation. P2 describes APRPD 15 mm or more or peripheral calyceal dilation. P3 describes additional ureteral dilation, abnormal renal echogenicity, or cysts or bladder abnormalities regardless of APRPD measurement. (From Chow JS, Benson CB, Lebowitz RL: The clinical significance of an empty renal fossa on prenatal sonography. J Ultrasound Med 24(8):1049-1054, 2005.)

TABLE 15-2 Normal Values for Urinary Tract Dilation Classification System

Ultrasound Findings	TIME AT PRESENTATION: 16 to 27.9 Weeks	≥28 Weeks	Postnatal (>48 Hours)
Anteroposterior renal pelvic diameter	<4 mm	<7 mm	<10 mm
Calyceal dilation			
Central	No	No	No
Peripheral	No	No	No
Parenchymal thickness	Normal	Normal	Normal
Parenchymal appearance	Normal	Normal	Normal
Ureter(s)	Normal	Normal	Normal
Bladder	Normal	Normal	Normal
Unexplained oligohydramnios	No	No	NA

N/A, not applicable.

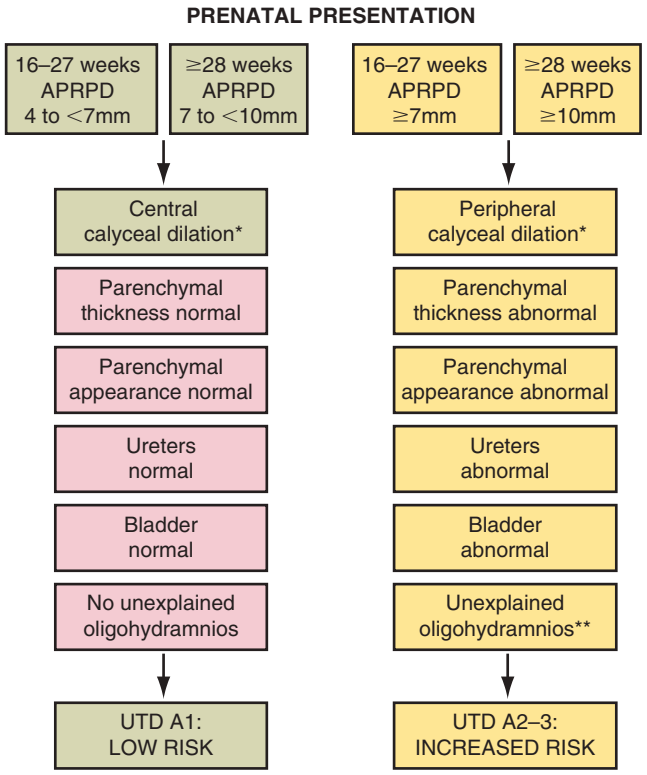
for moderate dilation, and greater than 15 mm for marked dilation by 32 weeks' gestation. The more dilated the system, the more likely it is that renal function will be compromised after birth. In addition to measurement of the renal pelves, it is important to determine and to document whether the central or peripheral calyces are dilated. Evaluation of the kidneys should also include assessment of the appearance of the cortices; thinned, hyperechogenic renal cortices with cysts often represent obstructive dysplasia and impaired function (Fig. 15-12). Although there is inconsistent correlation between the antenatal renal appearance and postnatal function, the presence of cysts commonly indicates the presence of dysplasia and compromised renal function.[18-22]

The differential diagnosis of UPJ obstruction includes reflux, transient dilation, multicystic dysplastic kidney (MCDK), and ureterovesical junction (UVJ) obstruction. Less common differential diagnoses of UPJ obstruction are megacalycosis due to medullary hypoplasia in which the calyces are more dilated than the renal pelvis; infundibular stenosis with no medullary hypoplasia, but calyceal dilation still present; and isolated cysts within the kidney.

Associated renal or extrarenal anomalies are present in 12% to 25% of cases of UPJ obstruction.[23] Once diagnosed in the second trimester, follow-up at or after 32 weeks is recommended to exclude cases with transient dilatation that may have resolved by this time (<7 mm dilated). Conflicting reports have been published regarding the association of isolated mild renal pelvic dilation and aneuploidy, but the overall evidence suggests that although this association is weak, it is significant and should be discussed with patients.[24-26] Patients should be informed of the overall good prognosis for fetuses with UPJ obstruction. Of those cases that are persistent in the postnatal period, 19% to 25% may require some form of surgical intervention.[27,28]

Ureterovesical Junction Obstruction

UVJ obstruction is responsible for 5% to 10% of all cases of urinary tract dilation. In about 25% of cases, the contralateral kidney is also affected. The diagnosis of UVJ obstruction is based on the demonstration of a dilated ureter in the presence of a dilated renal pelvis and a normal bladder.[29-32] Peristaltic waves can often be seen, and they modify the caliber of the ureter (Fig. 15-13). The dilatation may increase in utero, but it usually decreases after birth.



*Central and peripheral calyceal dilation may be difficult to evaluate early in gestation
**Oligohydramnios is suspected to result from a urological cause

FIG 15-9 Urinary tract dilation (UTD) management scheme. APRPD, anteroposterior renal pelvic diameter. (Adapted from Nguyen HT, Benson C, Bromley B, et al: Multidisciplinary consensus on the classification of prenatal and postnatal urinary tract dilation [UTD classification system]. J Pediatr Urol 10(6):982-998, 2014.)

The underlying cause of UVJ obstruction appears to be a localized dysfunction in a region of the lower ureter. In most instances, it is not possible to differentiate between dilation secondary to UVJ obstruction and that occurring secondary to high-grade vesicoureteral reflux (VUR). A clue to the diagnosis is variability in the diameter of the renal pelvis during one single examination, which favors a diagnosis of VUR. It is also important to distinguish the usually tortuous dilated ureter from loops of bowel. Another common cause of a dilated ureter is a ureterocele (discussed later).

The prognosis for UVJ obstruction is generally good, and the degree of ureteric dilation may offer some clue to the long-term prognosis and the need for postnatal surgery.[33,34]

Duplex Collecting System/Ureterocele

Renal pelvic dilation secondary to a ureterocele or ectopic implantation of the ureter causes 5% to 7% of antenatal urinary tract dilation (Fig. 15-14). Renal duplication can occur without dilatation, but is more readily demonstrated once dilation has developed (Fig. 15-15). Most commonly the ureter draining the upper pole moiety has an ectopic insertion located inferior and medial to the normal bladder insertion site. Often an ectopic ureterocele is also seen within the bladder (Fig. 15-14C). Dilatation of the lower pole moiety most commonly occurs because of reflux. Duplex kidneys are thought to arise from an additional ureteric bud from the mesonephric duct.[35]

A ureterocele is visualized as a septum or cyst within the bladder, although the ectopic extravesical insertion may be difficult to diagnose

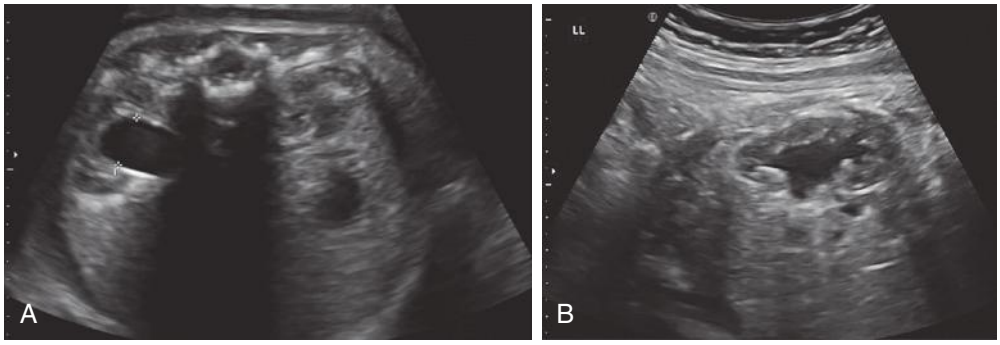


FIG 15-10 Transverse view of unilateral dilated renal pelvis with no evidence of dilated calyces (**A**); sagittal view showing unilateral dilated renal pelvis with both central and peripheral dilation of the calyces (**B**).

A

SOCIETY OF FETAL UROLOGY GRADING SYSTEM OF CONGENITAL HYDRONEPHROSIS		
Grade	*Central renal complex*	*Renal parenchymal thickness*
0	Intact	Normal
I	Mild splitting of pelvis (dilation)	Normal
II	Moderate splitting of pelvis and calyces, but complex, confined within renal border	Normal
III	Marked splitting, pelvis dilated outside renal borders and calyces dilated	Normal
IV	Further pelvicalyceal dilation	Thinned

TABLE 15-3 Etiology of Urinary Tract Dilation

Cause	Incidence
Transient dilation	41-88%
Ureteropelvic junction (UPJ) obstruction	10-30%
Vesicoureteral reflux (VUR)	10-20%
Ureterovesical junction (UVJ) obstruction	5-10%
Duplex collecting system/ureterocele	5-7%
Multicystic dysplastic kidney	4-6%
Lower urinary tract obstruction (LUTO)	1-2%

in utero[36-38] (Fig. 15-14C). In some cases, the renal parenchyma of the obstructed side may be thinned and dysplastic. Although most cases of ureterocele are visible on prenatal ultrasound examinations, sonologists should be aware that a full bladder may sometimes compress the cyst and prevent visualization. A ureterocele may also prolapse into the urethra and result in acute LUTO.

The differential diagnosis of ureterocele includes UVJ obstruction and VUR. It should be remembered that 50% of duplex collecting systems have coexisting VUR in the lower pole moiety. The prognosis is generally good but will depend on the degree of associated renal dysplasia affecting each pole. In the prenatal period, follow-up ultrasound examinations to document worsening urinary tract dilation are

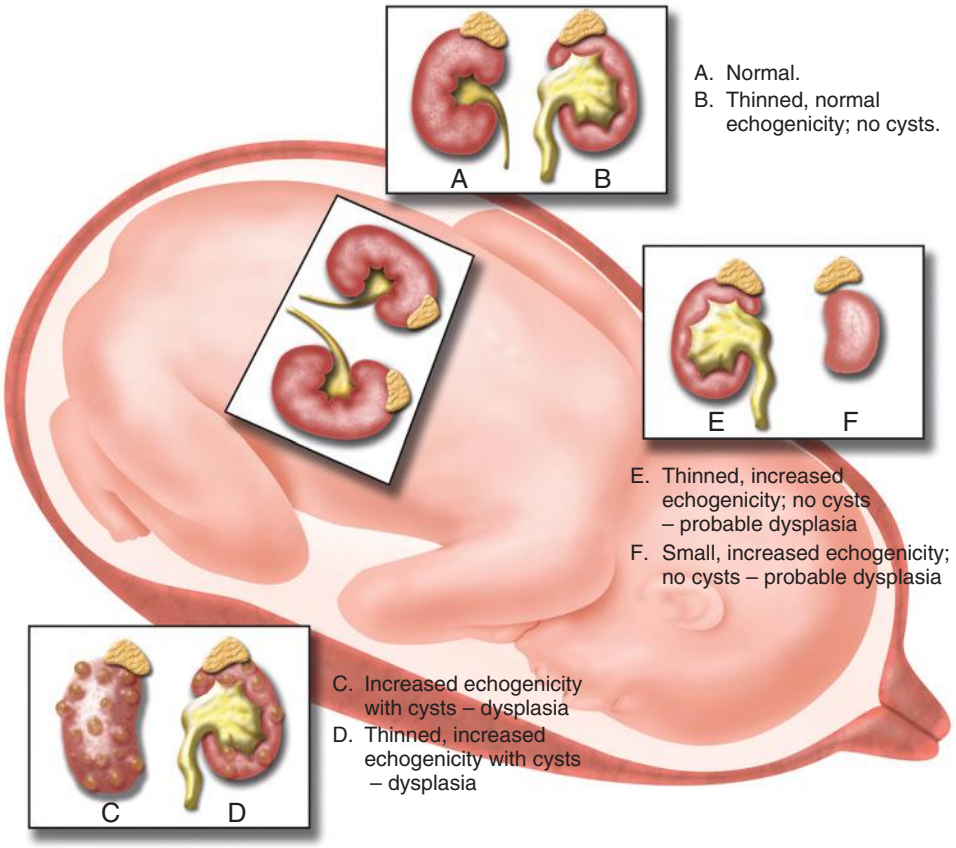

FIG 15-12 Urinary tract obstruction produces a varied response from the kidneys. **A,** The kidney may remain normal in distal obstruction, without reflux. **B,** Pelvocaliectasis may attenuate the parenchymal thickness. **C,** The kidney may suffer cystic dysplasia (parenchymal cysts), become fibrotic (increased echogenicity), and cease to function (lack of pelvocaliectasis). **D,** Alternatively, it may undergo cystic dysplasia with parenchymal cysts and increased echogenicity but continue to have pelvocaliectasis and a thinned parenchyma. If no cysts are visible but the parenchyma is of greatly increased echogenicity, either with (**E**) or without (**F**) pelvocaliectasis, dysplasia is probably, but not invariably, present. (Illustration by James A. Cooper, MD, San Diego, CA.)

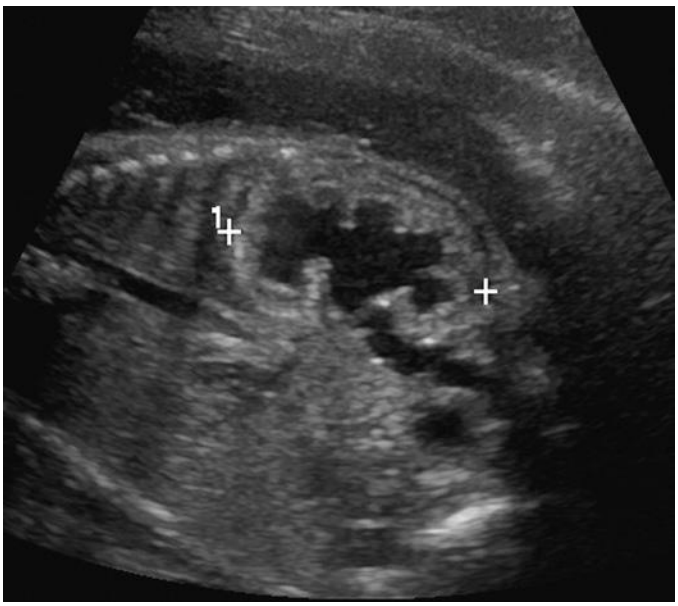

FIG 15-13 Hydroureteronephrosis. There is dilation of the renal pelvis and calyces, as well as of the ureter in this sagittal image.

indicated. Postnatal evaluation with further testing for residual renal function and reflux is recommended.

Vesicoureteral Reflux

VUR constitutes 10% to 20% of all diagnosed cases of antenatal urinary tract dilation. This diagnosis can be challenging to make prenatally and should be suspected in the presence of varying degrees of renal pelvis dilation with an associated either unilateral or bilateral dilated ureter (Fig. 15-16A and B). Proposed causes for VUR include transient bladder outlet obstruction that resolves prior to delivery, high voiding pressure resulting in distortion of the vesicoureteric junction, and delayed maturation of the vesicoureteric junction.[39,40] There also appears to be a strong familial predisposition, raising the possibility of a genetic cause in some cases.[41]

The diagnosis of VUR is important to confirm, as up to 40% of affected infants will develop renal scarring and long-term damage if undetected. The finding of a normal postnatal renal ultrasound examination does not exclude the diagnosis of VUR, and a micturating cystourethrogram may be indicated to completely rule out the diagnosis.[42]

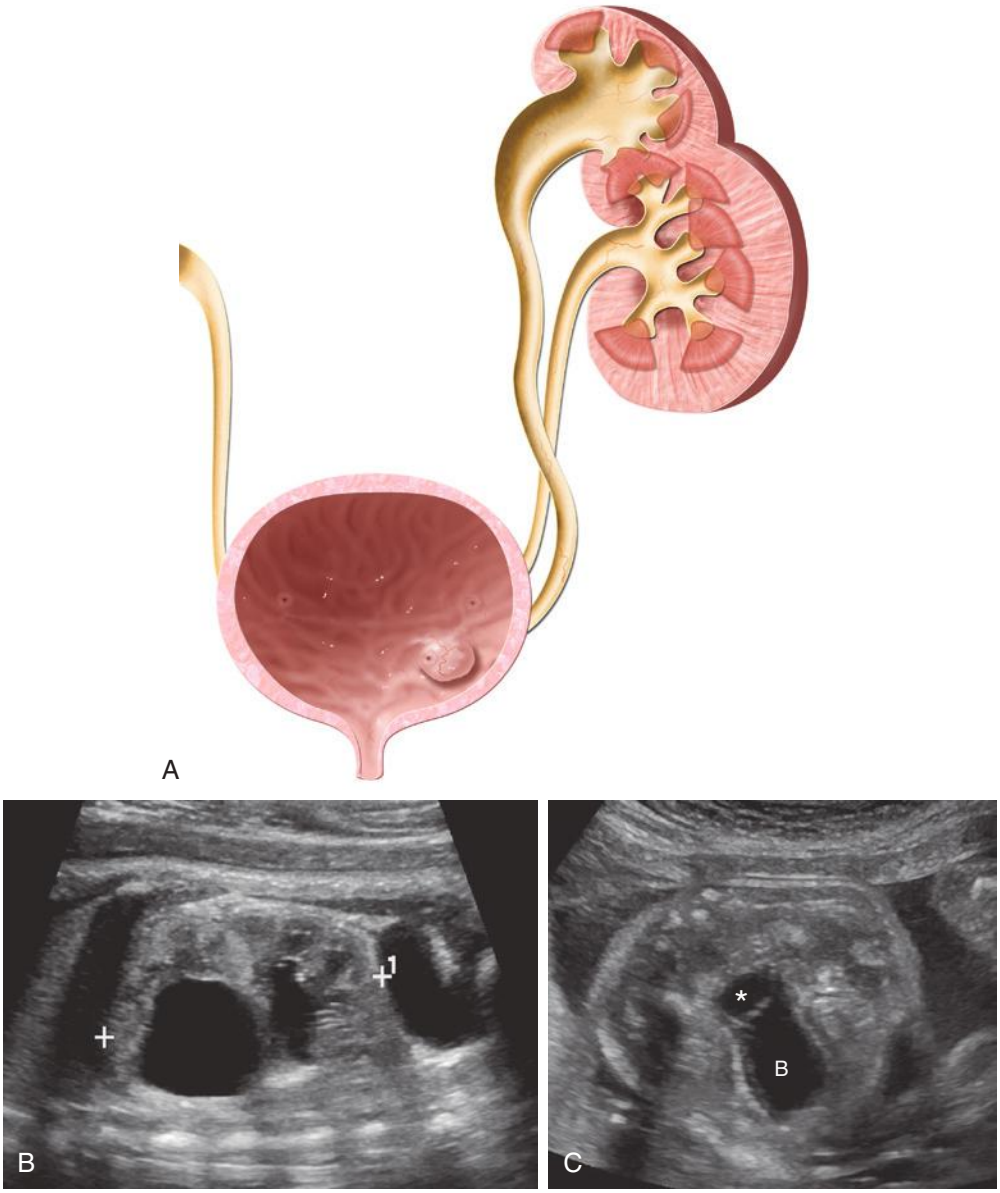

FIG 15-14 Renal duplication with obstructed upper pole and ureterocele. **A,** Illustration demonstrating duplication of the collective system. Typically the upper pole moiety is obstructed, and the lower pole moiety often demonstrates reflux. The ureter from the upper pole moiety inserts more medially and caudally into the bladder than the ureter from the lower pole. This is referred to as the Meyer-Weigert rule. Dilation of the submucosal portion of the ureter results in a ureterocele. **B,** Sagittal scan through the kidney demonstrating a dilated upper pole and normal lower pole; the dilated ureter is also seen. **C,** Sagittal scan through the bladder (B) displaying the ureterocele (*asterisk*). (Illustration by James A. Cooper, MD, San Diego, CA).

Lower Urinary Tract Obstruction

The most common cause of severe bladder outlet obstruction is a *posterior urethral valve* (PUV) (Fig. 15-17). PUVs are membranes within the posterior aspect of the urethra. This condition affects male fetuses and typically presents with an enlarged bladder and dilated urethra, producing the classic keyhole sign seen on ultrasound imaging (Figs. 15-17A and 15-18). The ureters and renal pelves are usually also dilated. With worsening obstruction, the bladder wall becomes hypertrophied with development of trabeculations. Renal parenchymal destruction and dysplasia may result from back-pressure, resulting in atrophic changes. Other findings in severe cases include severe oligohydramnios, perinephric urinomas, and urinary ascites (Fig. 15-19).

The oligohydramnios seen in LUTO can result in phenotypic changes in the newborn, including Potter facies and contractures of the extremities. The most important consequence of oligohydramnios is the development of pulmonary hypoplasia, a significant contributor to infant mortality and morbidity risks.

Prenatal management involves differentiating bladder enlargement secondary to PUV from other causes of LUTO and from causes of nonobstructive bladder enlargement (Table 15-4). The finding of massive bladder distention associated with oligohydramnios in a male

fetus strongly suggests PUV. Careful assessment can identify fetuses with potential to benefit from prenatal intervention.

Features of poor prognosis in cases of LUTO include early diagnosis, bilateral marked dilatation, persistently obstructed bladder, oligohydramnios, and secondary lung hypoplasia. Bilateral renal dilatation and LUTO have an increased risk of associated chromosomal anomalies, and, therefore, evaluation of fetal chromosomes may be warranted. The finding of associated hyperechogenic and cystic renal parenchyma is frequently associated with poor renal outcomes, with a positive predictive value of 59%, and negative predictive value of 56% regarding postnatal renal function. Conversely, although the presence of renal cortical cysts suggests a poor prognosis, normal renal cortical echogenicity does not exclude dysplasia. A systematic review including 13 articles and 215 women showed amniotic fluid volume and renal cortical appearance on ultrasound imaging to have only modest screening accuracy for predicting postnatal outcome (Table 15-5).[43]

FIG 15-15 Sagittal view of a duplicated kidney demonstrating mild dilation of both poles.

The role of measuring urinary electrolytes in the fetal urine obtained through transabdominal vesicocentesis to predict renal function is controversial. The process involves serial drainage of the fetal bladder with urine sent for biochemical analyses (Table 15-6). The initial urine sample obtained may not be reliable for prognosticating renal function as it may have been stagnant over a long time. Furthermore, there are discrepancies in the predictive value of urine biochemistry in published studies on LUTO owing to small sample size, variations in cutoff values used, gestational age at interrogation, and sampling frequency in published studies.[44-48] Fetuses with renal damage show decreased urinary concentrating ability, especially of sodium and calcium.[49-53] Measurements of β_2-microglobulin in the fetal urine has been suggested as demonstrating a better predictive accuracy, but a

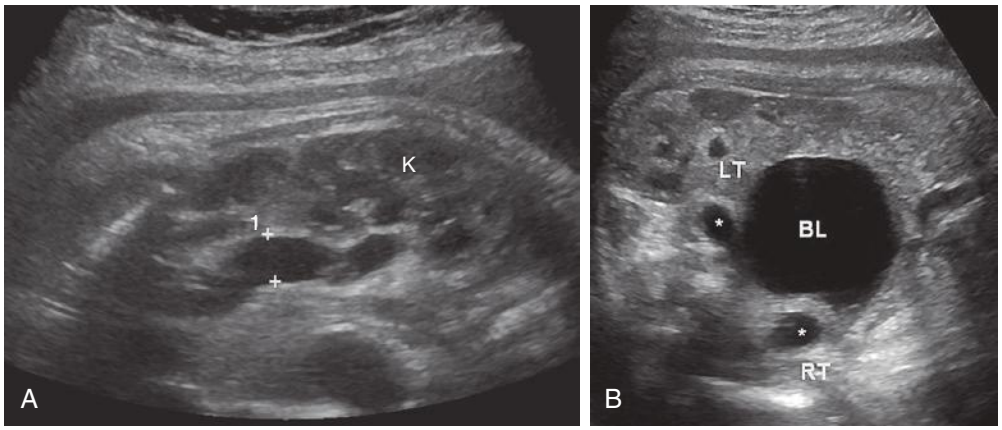

FIG 15-16 Vesicoureteral reflux (VUR). **A,** Sagittal image of kidney (K) without renal pelvic dilation but with a dilated ureter (*calipers*). **B,** Axial image through the bladder (BL) demonstrating dilated left (LT) and right (RT) ureters (*asterisks*). The finding of varying degrees of renal pelvic dilation with associated ureteric dilatation both unilaterally and bilaterally should raise the suspicion for VUR.

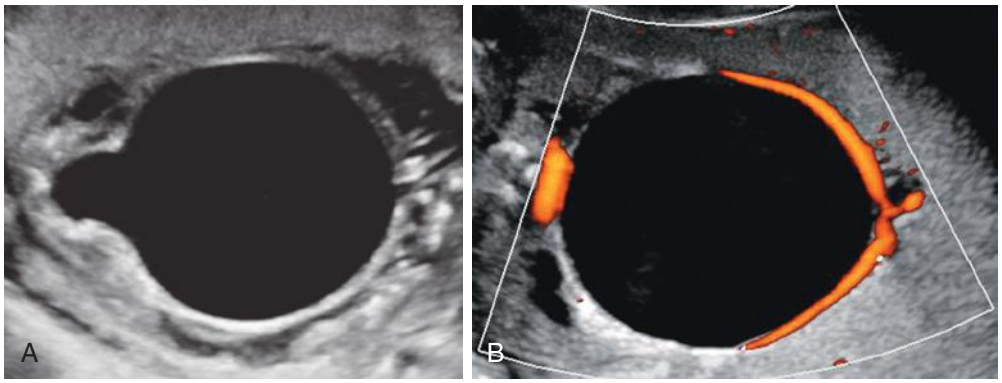

FIG 15-17 Posterior urethral valves. **A,** Enlarged bladder with classic keyhole appearance. **B,** Confirmation that this large fluid-filled structure represents the bladder by demonstration of umbilical arteries using color flow Doppler sonography.

systematic review including 23 articles and 572 women found this protein to be less accurate than measurement of urinary sodium and calcium.[54]

The goals of prenatal intervention are to avoid further renal damage and to prevent pulmonary hypoplasia. Vesicoamniotic shunting to divert urine from the obstructed fetal bladder into the amniotic cavity has been the primary prenatal intervention used for several years. However, the outcomes following vesicoamniotic shunting and the long-term results have not been convincing.[55-57] The only randomized controlled trial evaluating this technique (the PLUTO [Percutaneous shunting in Lower Urinary Tract Obstruction] trial) was stopped early because of poor recruitment. Although the trial suggested a trend toward improved survival in the group that received shunting, the relative risk (RR) was not statistically significant (RR 1.88; confidence interval [CI] 0.71-4.96).[57] The PLUTO trial was limited by a significant number of crossovers in the treatment arms; therefore, the authors performed an "as treated" analysis, which showed significant survival benefit from vesicoamniotic shunting. The long-term outcomes from the study are still pending.

TABLE 15-6 Favorable Prognostic Features in Lower Urinary Tract Obstruction

Features	Levels/Findings
Sodium	<100 mg/dL
Chloride	<90 mg/dL
Osmolality	<200 mg/dL
Calcium	<8 mg/dL
β_2-Microglobulin	<4 mg/dL
Total protein	<20 mg/dL
Amniotic fluid volume	Normal
Renal cortex appearance	Not cystic or echogenic
Gestational age at diagnosis	>24 weeks

Data taken from Morris et al,[43] Glick et al,[44] Nicolaides et al,[45] Mandelbrot et al,[46] Johnson et al,[47] and Muller et al.[48]

Recent case reports have suggested the feasibility of fetoscopic placement of transurethral stents in fetuses with bladder outlet obstruction, although at this time the series are too small for reliable information on outcomes.[58]

Urethral Atresia

Urethral atresia has a sonographic appearance similar to that of PUV and should be considered in female fetuses with bladder outlet obstruction. Unlike PUV, the obstruction is usually complete and may result in megacystis detected during the first trimester (Fig. 15-20). The condition often has a poor prognosis.[59]

Congenital Megalourethra

Congenital megalourethra is a rare condition affecting male infants, and it is usually associated with a dilated and elongated penile urethra that may appear sausage-shaped in continuity with a distended bladder (Fig. 15-21A through C). The proposed cause is delayed apoptosis at the penile meatus; this has also been referred to as "anterior urethral valves," although the condition is not actually caused by valves. This process can lead to abnormal development or hypoplasia of the penile erectile tissue. Other sonographic features are similar to those seen in PUV.[60,61] In some cases, the obstruction resolves spontaneously and the outcome can be favorable.[62,63]

Cloacal Malformation

Cloacal malformation is a rare cause of bladder outlet obstruction affecting 1 in 50,000 pregnancies. It is caused by failure of development

FIG 15-20 Megacystis, early second trimester (case of uretheral atresia). Frontal view through the fetal head and abdomen. The abdomen is filled by the distended urinary bladder.

of the urorectal fold that usually separates the rectum from the genital tract. Consequently, a convergence of the gastrointestinal and genitourinary tracts occurs, with a common opening in the perineum. The condition is seen predominantly in females and can result in the collection of urine in the uterus and vagina (hydrometrocolpos) as well as bladder outlet obstruction and dilated ureters[64-66] (Fig. 15-22). Because of the complex embryologic anomalies involved, cloacal malformation can present with multiple phenotypes and associated anomalies including ureteral ectopia, bladder duplication, renal agenesis, sacral agenesis, open neural tube defects, and vertebral anomalies. The finding of ultrasound features suggestive of PUV in a female fetus should increase the suspicion for cloacal malformations. Transient ascites may be present from chemical irritation of the peritoneum by urine. It may be followed by intra-abdominal calcifications. Depending on the degree of bladder outlet obstruction, profound oligohydramnios may be present.

Prune-Belly Syndrome

Prune-belly syndrome (PBS) refers to an abnormally lax abdominal wall secondary to extensive stretching during early development. Historically, the condition was thought to result from primary partial or complete absence of the abdominal muscles, although it is currently thought that it is more likely a secondary result of overdistention due to bladder dilation that, in some cases, may have resolved spontaneously. The ultrasound features are very similar to those of PUV, but in PBS, the bladder distention and urethral dilation are not as marked. In addition, similar to PUV the condition is more common in male fetuses; therefore, diligent evaluation is required to distinguish these anomalies, as the therapeutic implications are significantly different prenatally.[67-69] The prognosis is often poor, similar to that of PUV, secondary to severe pulmonary hypoplasia if oligohydramnios was present.

Megacystis-Microcolon–Intestinal Hypoperistalsis Syndrome

Megacystis-microcolon–intestinal hypoperistalsis syndrome (MMIHS) is an autosomal recessive condition occurring more commonly in females. It presents with evidence of a functional small bowel obstruction, a microcolon with intestinal malrotation, a markedly enlarged bladder, and bilateral hydronephrosis. The bladder finding is not secondary to a physical obstruction, as the condition is characterized by

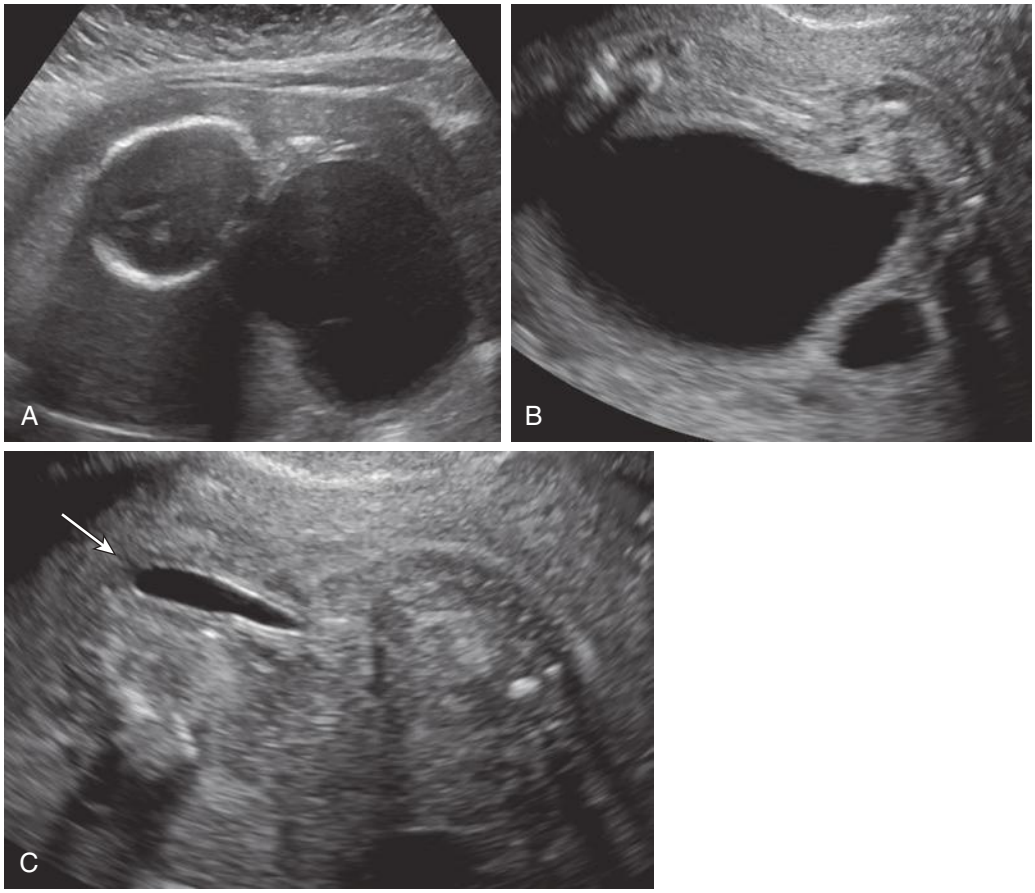

FIG 15-21 Congenital megalourethra. **A,** Breech fetus with severe oligohydramnios and markedly distended urinary bladder. These sonographic findings are similar to those seen with bladder outlet obstruction due to posterior urethral valves. **B,** Coronal view of dilated urinary bladder with dilation of the prostatic urethra. **C,** Targeted transvaginal sonographic images reveal dilated, elongated penile urethra (*arrow*).

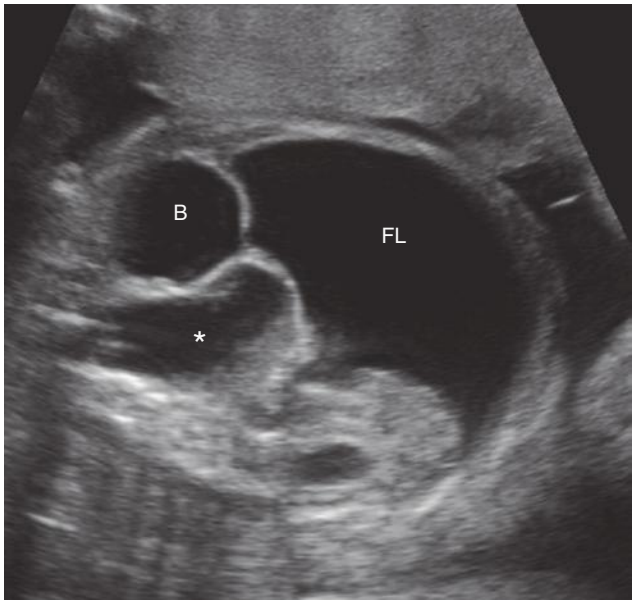

FIG 15-22 Cloacal malformation. Cloacal malformation, related to convergence of the genital, urinary, and intestinal contents, appears as a central pelvic cystic mass (*asterisk*) containing fluid and dependent layering echoes. This structure is located posterior to the urinary bladder (B). There is a large volume of free intraperitoneal fluid (FL) present, presumed to be due to reflux of urine and meconium through the fallopian tubes. This may result in irritation and chemical peritonitis.

normal amniotic fluid volume and even polyhydramnios in late pregnancy. The underlying cause is poorly understood, but myogenic, neurogenic, and even hormonal mechanisms have been proposed.[70-72] There may be associated anomalies of other organ systems, including omphalocele, cleft lip/palate, and cardiac defects, and the condition is associated with a poor prognosis that becomes apparent in the newborn period. The finding of an enlarged bladder with normal amniotic fluid volume suggests the differential diagnosis of MMIHS after excluding cloacal malformation.

Management of Fetal Renal Pelvic Dilation After Birth

Dilation of the renal pelvis is often the initial finding in abnormalities of the fetal urinary tract. Although there is generally a direct relationship between fetal renal pelvis dilation and obstructive processes of the urinary tract, there is considerable overlap with nonobstructive disorders. It should be appreciated that renal pelvis dilation detected prenatally often resolves spontaneously after birth with no correction required. In a series from our institution, 140 of 342 (40.9%) fetuses with renal pelvic dilation had nonobstructive hydronephrosis. In these cases, renal pelvis dilation detected prenatally was confirmed postnatally, but ultimately regressed without therapy.[73]

Similarly, in a study of 350 infants with antenatally detected urinary tract abnormalities born in two Nottingham teaching hospitals in the United Kingdom, 170 of 350 (48.6%) were classified as "non-specific dilatation" (NSD). The majority of these (133/170) were categorized as NSD1. NSD1 referred to those fetuses with a renal pelvic diameter

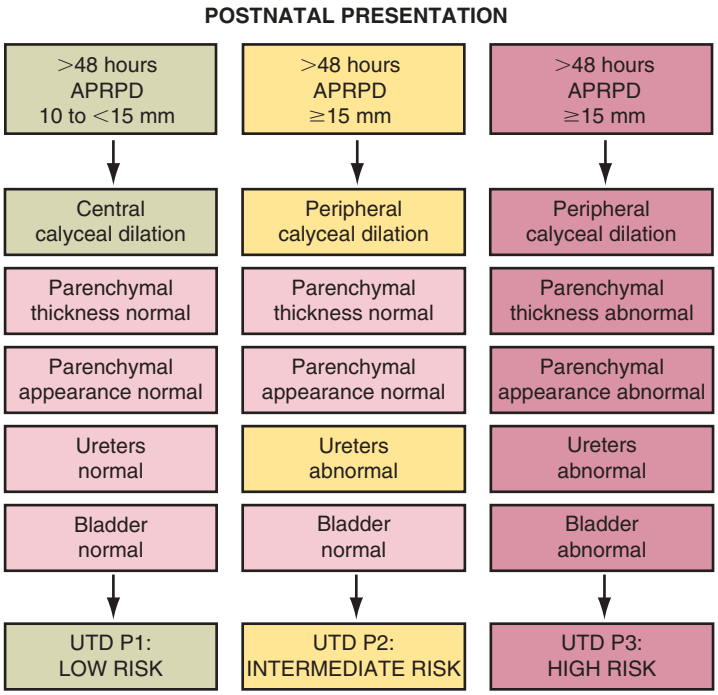

FIG 15-23 Urinary tract dilation (UTD) risk stratification: postnatal presentation for UTD P1 (low risk), UTD P2 (intermediate risk), and UTD P3 (high risk). Note: stratification is based on the most concerning ultrasound finding. For example, if the anteroposterior renal pelvic diameter (APRPD) is in the UTD P1 range, but there is peripheral calyceal dilation, the classification is UTD P2. Similarly, the presence of parenchymal abnormalities denotes UTD P3 classification, regardless of APRPD measurement.

less than 10 mm in the AP diameter, no caliectasis or hydroureter, and normal renal cortex and size on renal ultrasound examination performed 4 to 6 weeks after birth. Infants in this group were exempt from further follow-up unless presenting with signs or symptoms of a urinary tract infection. Infants in the NSD2 group were those with a renal pelvis greater than 10 mm in the AP diameter. These infants subsequently underwent a voiding cystourethrogram (VCUG) or radionuclide renal scan to rule out reflux and renal drainage abnormalities, respectively. If normal, renal ultrasound examination was repeated within the first year of life. If renal pelvic dilatation was less than 10 mm, these infants were discharged from care with no further evaluation unless they developed symptoms of a urinary tract abnormality. The authors concluded that a large percentage of fetuses with renal pelvic dilatation can be served by a single postnatal renal ultrasound examination and that expectant management is appropriate and operative intervention is often unnecessary.[14]

It is important that information relevant for the proper postnatal management of the newborn be transmitted to the pediatric team. In the majority of cases, no significant disease is observed postnatally, and the prenatal dilation represents transient or physiologic hydronephrosis. However, a variety of findings seen in the neonate after birth may suggest an abnormality of the urinary tract (Fig. 15-23). After birth, some conditions require immediate confirmation and therapeutic maneuvers in order to protect renal function and prevent problems such as urinary tract infection, stone formation, and pain. These conditions include obstructive PUVs or the presence of an ectopic ureterocele that has prolapsed into the urethra, leading to oligouria or anuria and necessitating immediate treatment.[57]

However, extensive evaluation is not always necessary and, in addition to time and expense, can result in discomfort and radiation exposure, as well as the consequences of false positive diagnoses and stress for the family. There is therefore some controversy as to which infants require radiologic evaluation and prophylactic antibiotics. In some cases, a workup should be planned but can be done on a less urgent basis. Ultrasound imaging is the least invasive and most common method of postnatal imaging. However, ultrasound examinations can only provide anatomic, not functional, evaluation, and findings are altered by bladder filling and hydration status. Because infants are relatively dehydrated at birth, later ultrasound evaluation (on the second day of life or later) is more accurate in assessing renal tract dilation. A normal ultrasound examination in the week after birth is not sufficient to verify the absence of disease and therefore later follow-up is often recommended (Fig. 15-24).[12]

Historically, all patients with renal tract dilation have been treated with prophylactic antibiotic therapy after birth until a final diagnosis and a final therapeutic decision are made. However, studies have not consistently demonstrated a benefit of antibiotics in preventing urinary tract infection. Therefore, the universal use of antibiotics is controversial,[74,75] particularly in low-risk infants.

NONOBSTRUCTIVE FETAL URINARY TRACT ANOMALIES

Nonobstructive Megaureter

The fetal ureters are not visible sonographically unless dilated. The normal ureteral diameter in children is usually less than 5 mm. A ureteral diameter greater than 7 mm is considered a megaureter and can be obstructive or nonobstructive. Megaureter is considered primary when obstructive processes have been excluded. Nonrefluxing primary megaureter is the most common cause of primary megaureter in the neonate.[76] In this condition, the ureter is enlarged in the absence

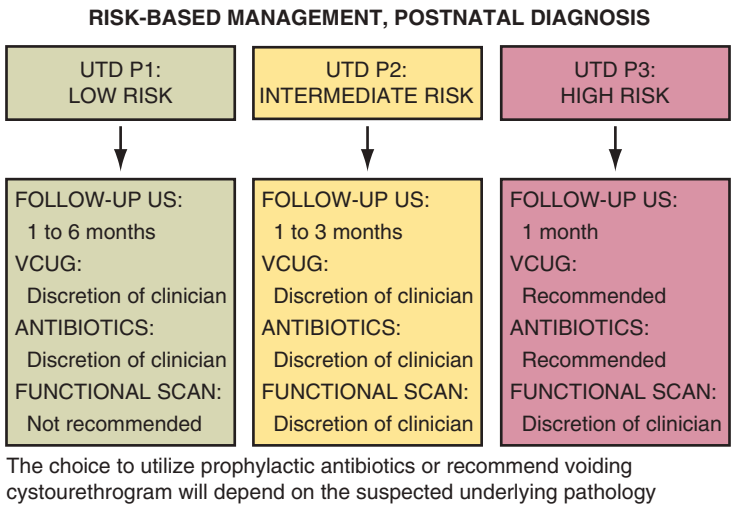

FIG 15-24 Risk-based management for urinary tract dilation (UTD) that persists into the postnatal period. US, ultrasound; VCUG, voiding cystourethrogram. J Pediatr Urol 10(6):982-998, 2014.)

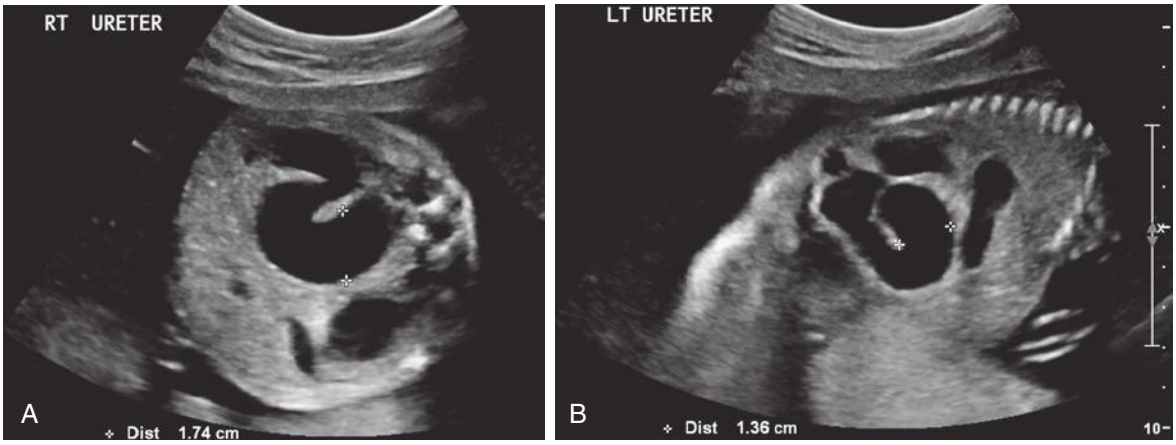

FIG 15-25 Bilateral megaureter. **A** and **B,** Axial images through the abdomen of a fetus with dilated, tortuous ureters.

of reflux or obstruction, and the bladder and bladder outlet are normal. It occurs four times more frequently in males than in females and is bilateral in 25% of cases. Proposed causes include abnormal peristalsis, delayed patency, and sustained folding of the fetal ureter.[77] The most characteristic sonographic finding is a dilated tortuous ureter running from the kidney to the bladder (Fig. 15-25). Peristalsis may be observed. Care should be taken to differentiate a dilated ureter from fluid-filled bowel loops. Renal pelvic dilation may be mild or absent with megaureter. If associated with a duplex collecting system, an ectopic ureterocele may be noted (see Fig. 15-14). Postnatal evaluation of prenatally suspected megaureter involves a VCUG to exclude reflux and radionuclide scanning to assess renal function and rule out obstruction. Patients with nonobstructive, nonrefluxing megaureter are typically asymptomatic with normal renal function and require no therapy.[78]

Empty Renal Fossa

The inability to visualize a kidney in one or both renal fossas raises a number of diagnostic possibilities that vary in prognosis and diagnostic difficulty. Nonvisualization of both kidneys, in conjunction with anhydramnios and prolonged inability to identify the fetal bladder, is characteristic of bilateral renal agenesis (Fig. 15-26). This condition occurs in 0.1 to 0.3 per 1000 births.[79] The diagnosis may be more challenging than expected as a result of the lack of an acoustic window, fetal position, and potential confusion resulting from the presence of the adrenal gland oriented longitudinally in the renal fossa (Fig. 15-27). Fetal adrenal glands are large relative to their adult sizes and may appear similar in contour to the fetal kidney. Visualization of the fetal kidneys in the midtrimester may also be obscured by the presence of bowel in the renal fossa and the lack of perinephric fat, which serves to highlight the renal contours in the third trimester. Diagnostic maneuvers that may be helpful include color Doppler interrogation of the renal arteries and an inability to demonstrate them on a coronal view of the fetal retroperitoneum (Fig. 15-28); fetal magnetic resonance imaging (MRI) may also be useful. A reliable diagnosis, although challenging, is important for parental counseling. Currently, bilateral renal agenesis is considered a lethal disorder, not only because of the absence of functioning kidneys but also secondary to the pulmonary hypoplasia that results from anhydramnios. The demonstration of amniotic fluid in the first trimester does not exclude a diagnosis of bilateral renal agenesis because the fluid at this stage in pregnancy is a dialysate of the fetal and placental membranes. If this diagnosis is

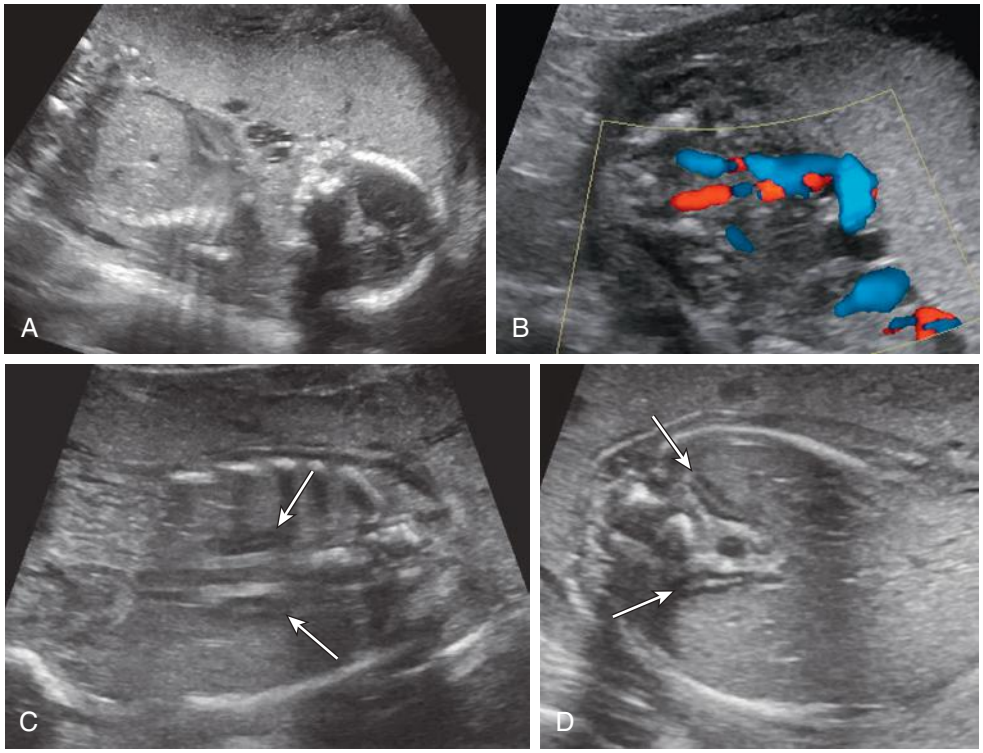

FIG 15-26 Bilateral renal agenesis. **A,** Anhydramnios. **B,** Empty bladder, demonstrated using color Doppler sonography. Coronal (**C**) and axial (**D**) images through the fetal abdomen demonstrating elongation owing to absence of the kidneys bilaterally, the so-called "lying down adrenal" sign.

FIG 15-28 Bilateral renal agenesis. Absence of the renal arteries as demonstrated by color Doppler imaging.

entertained, it is recommended to document the presence of both maternal and paternal kidneys as there is a heritable component to many renal disorders and an affected fetus may be the first indication of risk.[80]

Unilateral Renal Agenesis

Unilateral renal agenesis is three to four times more common than bilateral absence and should be suspected when only one kidney is identified and the contralateral fossa is empty, typically filled with bowel.[79] A thorough search is warranted, as the kidney may be present but ectopic. Hypertrophy of the single identified kidney suggests unilateral agenesis, as enlargement occurs in 90% or more of fetuses with a single functioning kidney (Fig. 15-29).[81,82] Although compensatory nephrogenesis may benefit the fetus, epidemiologic studies indicate that individuals born with a single functioning kidney are at risk for renal dysfunction and hypertension in early adulthood.[83] As agenesis of one or both kidneys is associated with up to a 30% risk of other genetic syndromes or anomalies, care should be taken to exclude other abnormalities.[84]

In one series of 93 fetuses presumed to have unilateral renal agenesis, 10 (11%) were subsequently found to have a normally positioned kidney. Seven were dysplastic, one was neoplastic, and two were normal. This series illustrates the fact that although inability to visualize a kidney in its normal location is typically associated with either renal absence or ectopia, an abnormal or nonvisualized normal kidney remains a possibility.[64]

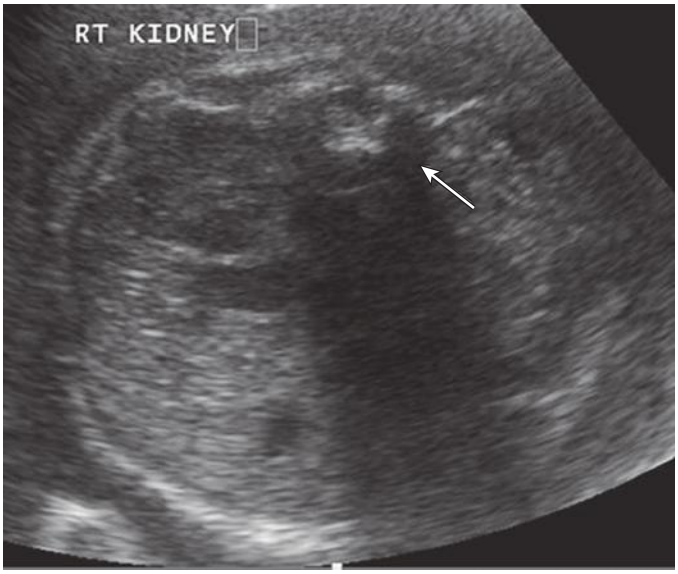

FIG 15-29 Unilateral renal agenesis. Absence of the left kidney with compensatory hypertrophy on the right (RT).

Aberrant Cephalad Migration

Aberrant cephalad migration of the kidneys during early embryologic development may result in renal ectopia. The absence of compensatory hypertrophy in cases of a unilateral empty renal fossa suggests a present but displaced kidney. An unascended or pelvic kidney is estimated to occur in 1:2200 to 1:3000 live births and is the most common manifestation of renal ectopia.[85] Visualization may be challenging because of the presence and sonographic similarity of bowel. The pelvic kidney is typically proximate to the bladder and may be midline or lateral to midline with no right or left dominance (Fig. 15-30). It may be irregular in contour and smaller than normal. The blood supply is variable and feeding vessels arise distal to the aortic bifurcation.[86]

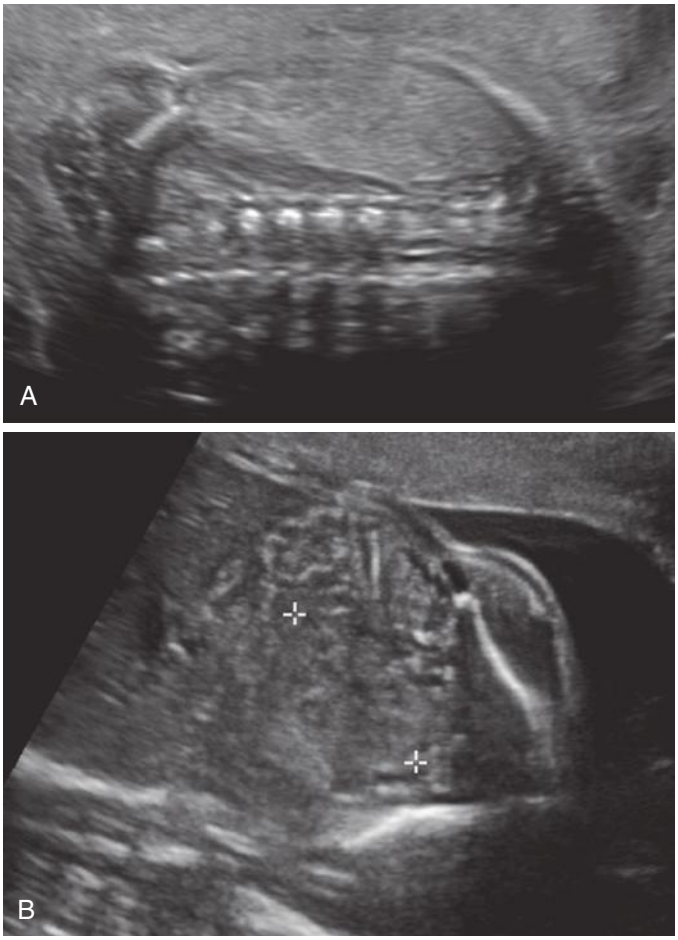

FIG 15-30 Unilateral pelvic kidney. **A,** Empty left renal fossa on this coronal image, with a "lying down adrenal" sign. **B,** Further imaging demonstrates a kidney in the fetal pelvis (*calipers*).

Renal Fusion Abnormalities

Ectopic location of the kidneys is also a feature of renal fusion abnormalities. These typically present as *horseshoe* kidney or crossed fused renal ectopia.

Horseshoe Kidney

Horseshoe kidney is the most common fusion defect, with an estimated incidence of 1 in 400 births and a male preponderance of 2:1. This condition results from abnormal fusion and ascent of the kidneys. In most cases, fusion occurs at the lower poles but it may involve the upper poles or both lower and upper poles. Depending on the position of the kidneys, fusion may be symmetric or asymmetric. The tissue connecting the kidneys is referred to as the isthmus. It is thought that normal ascent of the kidneys is precluded by inability of the kidneys to traverse the inferior mesenteric artery at the level of the isthmus. The distinguishing feature of the horseshoe kidney, the isthmus, is the most reliable sonographic clue to the diagnosis (Fig. 15-31). Visualization of the isthmus and its connection to the lower poles as well as the medial orientation of the lower poles are characteristic findings of this abnormality. However, depending on the thickness of the isthmus, clear identification may not be possible. Other sonographic features that may be observed in cases of horseshoe kidneys include low-lying location, bent or curved contour, elongation of the lower pole, and ill-defined inferior margin of the kidney. The vascular supply is not uniform and may derive from the aorta, the iliac arteries, and less

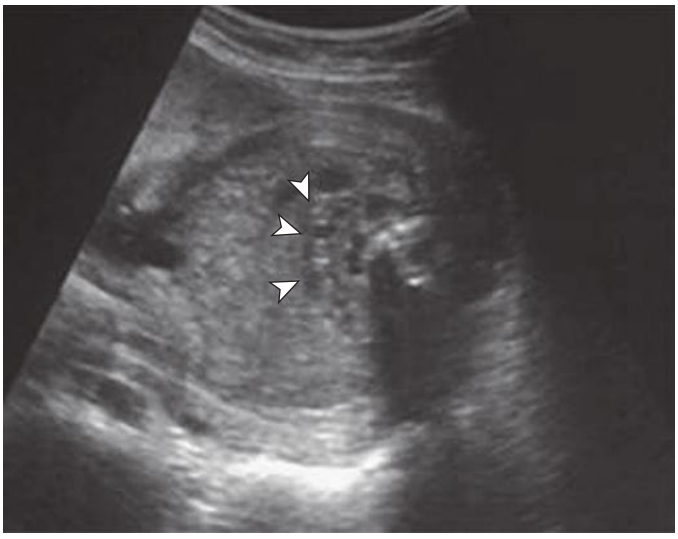

FIG 15-31 Horseshoe kidney. Demonstration of the isthmus is the most reliable sonographic clue to the diagnosis.

commonly the inferior mesenteric artery or the median sacral artery. Despite its relative frequency, prenatal diagnosis is uncommon.[87,88]

Crossed Fused Renal Ectopia

Crossed fused renal ectopia is much less common than horseshoe kidney and is detected in 1:2000 to 1:7000 individuals in postmortem series. This condition results from fusion of one kidney to the other with the ureter crossing the midline to insert appropriately into the bladder. There are multiple varieties of crossed fused kidneys, depending on the site of fusion. The typical sonographic finding, in addition to an empty renal fossa, is a single bilobed mass-like reniform structure. Although the vascular supply may be variable, usually two renal arteries are present, one in the expected location and the other positioned more inferiorly to the crossed kidney. The difficulty in prenatal diagnosis is reflected in the fact that 20% to 30% of postnatally diagnosed cases are detected incidentally. In the absence of other malformations, individuals with crossed fused renal ectopia typically remain asymptomatic. Overall, the clinical prognosis is similar for horseshoe kidney and crossed fused ectopia.[86,87,89]

DYSPLASTIC KIDNEYS

Renal dysplasia is a histologic, not sonographic, diagnosis reflecting either abnormal early development or disturbed terminal maturation. In sonographic terms, dysplasia is nonspecific and generally refers to a variety of findings, including kidneys that are echogenic or bright, abnormal in size and structure, and with or without identifiable cysts of varying sizes (Fig. 15-32). Changes may be unilateral or bilateral and associated with normal or reduced amniotic fluid volume.

Obstruction of the urinary tract is a common antecedent of renal dysplasia, typically associated with MCDKs. Nonobstructive processes are diverse and include heritable conditions, other genetic syndromes, nongenetic sporadic occurrences, and exposure to certain drugs that are renal teratogens. These conditions are not necessarily exclusive and in some cases may be additive.

Polycystic kidney disease refers to two disorders, *autosomal recessive polycystic kidney disease (ARPKD)* and *autosomal dominant polycystic kidney disease (ADPKD)*. The designations ARPKD and ADPKD are preferred to their former monikers, infantile and adult-onset polycystic kidney disease, respectively. This reflects the fact that there can be considerable overlap in age at presentation as well as a better understanding of the genetic basis of these conditions.[90]

ARPKD has an incidence of approximately 1 in 20,000 live births.[91] It is a single gene disorder resulting from mutations in *PKHD1*, a large gene on chromosome 6p12, which encodes for the complex protein fibrocystin/polyductin.[92] Expression of fibrocystin occurs in the primary cilia as well as the basal body of renal and bile duct cells. Histologically, it is characterized by dilatation of the collecting ducts,

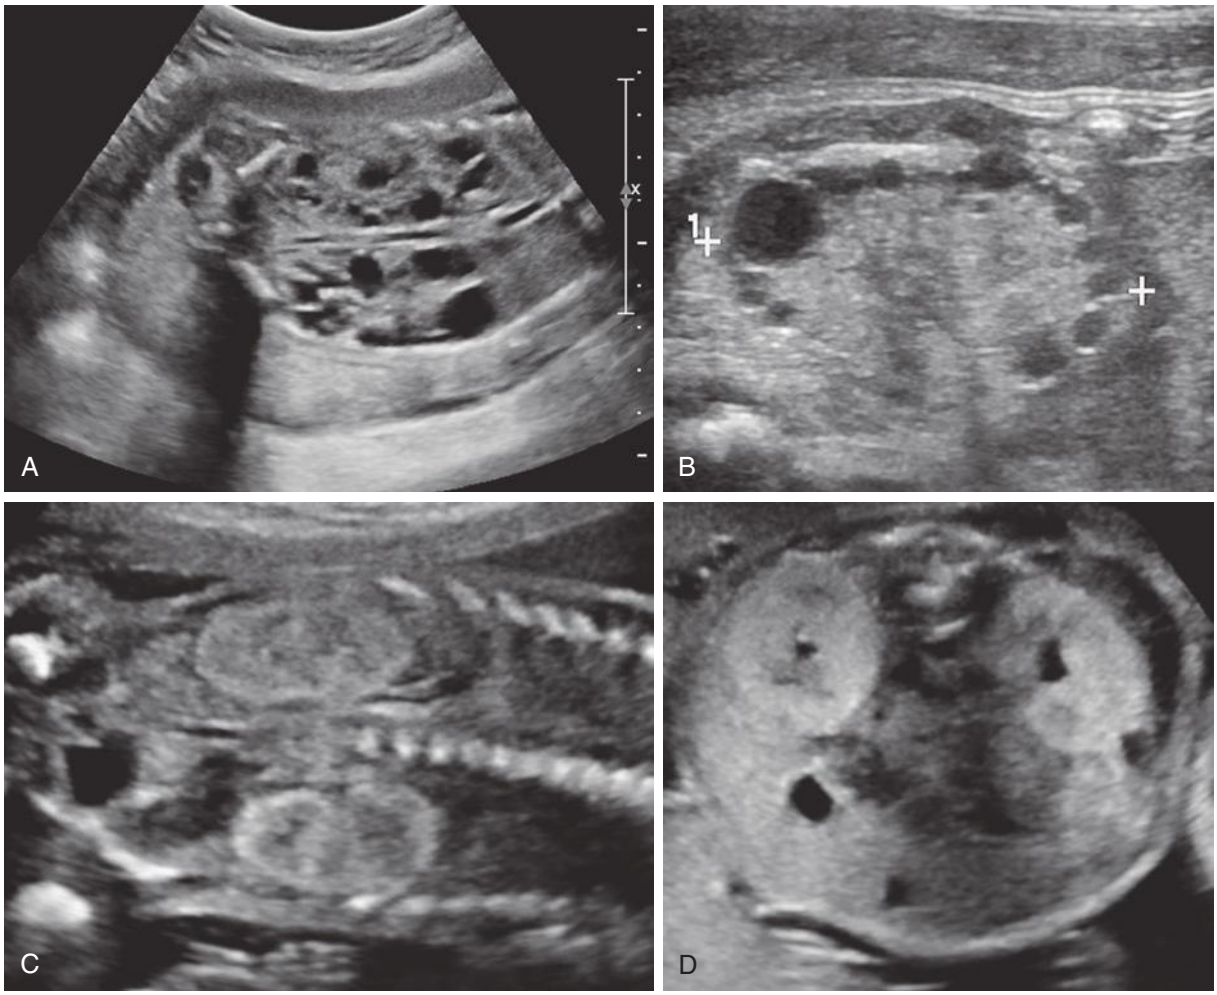

FIG 15-32 A-D, Renal dysplasia. Variable appearance of renal dysplasia, which can include kidneys that are echogenic or bright, abnormal in size and structure, and with or without identifiable cysts of varying sizes.

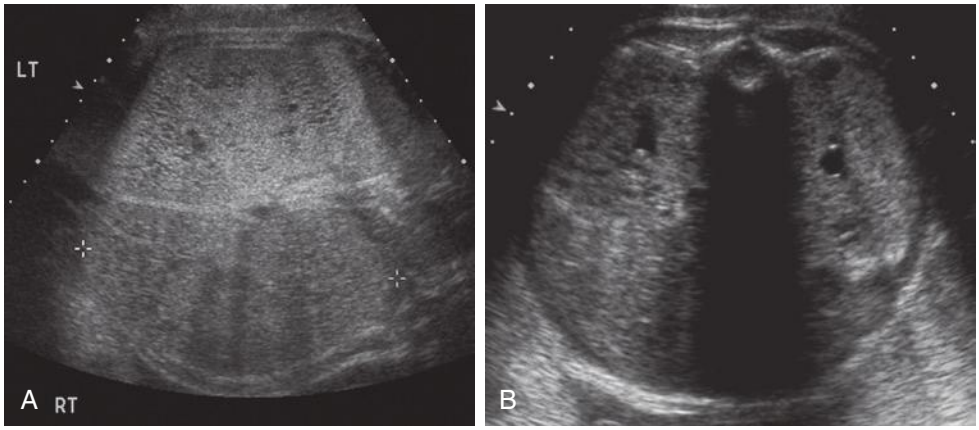

FIG 15-33 Autosomal recessive polycystic kidney disease. Typical appearance of bilaterally enlarged, hyperechoic kidneys with lack of corticomedullary differentiation seen in coronal (**A**) and axial (**B**) views. LT, left; RT, right.

glomerular and cortical tubule lesions, and renal cortical necrosis. This results in multiple small (1-2 mm) peripherally positioned cysts involving the collecting ducts with preservation of the renal pelvis and ureters. In contrast, in ADPKD there are typically fewer, larger cysts that develop within all areas of the nephron or collecting ducts. Concomitant hepatic changes associated with ARPKD include portal fibrosis and biliary dysgenesis. The age of onset is variable, with four subtypes, categorized as perinatal, neonatal, infantile, and juvenile. The perinatal subtype is the most common, accounting for about 40% of cases. It is characterized by fetal renal failure and congenital hepatic fibrosis in 40% to 50%. Perinatal mortality rate is high owing to respiratory failure as a result of oligohydramnios-induced pulmonary hypoplasia.[93]

Ultrasound manifestations of ARPKD typically include bilaterally enlarged, hyperechoic kidneys with lack of CMD differentiation (Fig. 15-33). The bright appearance of the kidneys results from the multiple tissue-fluid interfaces of the numerous microcysts, even though the cysts themselves are too small to be discretely visualized. In contrast to ADPKD, kidney size in ARPKD does not correlate with renal function.[94] In a first pregnancy with sonographic features of ARPKD and subsequent neonatal death, histopathologic examination of the kidneys and liver should be performed to confirm or refute the diagnosis of ARPKD.[95]

It should be appreciated that the typical sonographic features of ARPKD may not develop until beyond 24 weeks of gestation. Failure to make the diagnosis in the first or second trimester does not preclude its later onset. For pregnancies known to be at risk, molecular genetic studies on DNA from chorionic villi or amniocytes can be used for prenatal diagnosis when the causative mutations have been identified.[94]

For individuals who are not diagnosed until late in pregnancy or after birth, more than half will require renal transplantation prior to 20 years of age. Complications of congenital hepatic fibrosis, such as esophageal varices and cholangitis, may present during childhood or later and may be remote from the time of renal transplantation.[96]

Adult type polycystic kidney disease with autosomal dominant inheritance is much more common than ARPKD, with a carrier frequency of the abnormal gene of approximately 1 in 1000 in the general population. It is the most common cause of heritable cystic renal disease in children and adults. Mutations in the *PKD1*, *PKD2*, and *PKD3* genes are found in most individuals with ADPKD. *PKD1* encodes for the polycystin-1 protein and is identified in approximately 85% of individuals with ADPKD. *PKD2* encodes for polycystin-2 and is seen in less severe cases with later onset. Penetrance is nearly 100% if life span allows. However, because of variable expressivity and the 10% incidence of spontaneous mutation, the family history is negative in nearly 50% of cases.[97]

Normally, nephrogenesis begins during the 9th week of gestation and proceeds from the inner to outer cortex until the 36th week when this process is complete. The number of nephrons is a function not only of gestational age but also of fetal growth. Low birth weight is associated with reduced nephron mass and number of glomeruli. This is thought to be a significant contributing factor to the considerable differences in onset and variability of renal compromise in affected families. ADPKD is characterized by normal initial nephron and collecting duct development with their later cystic dilatation, resulting in subsequent loss of adjacent normal anatomy. Disturbed epithelial cell maturation results in the development of variable size cysts within the cortex and medulla, which progressively increase in size, typically allowing detection in early childhood. Although the onset of renal failure is usually not until the fifth or sixth decade of life, cyst formation begins in the fetal to neonatal period. Associated cysts in the central nervous system, pancreas, spleen, and liver have also been described.[98,99]

The ultrasound presentation of ADPKD in the fetus was detailed by Brun and associates[100] in a retrospective multicenter study involving 27 fetuses with a diagnosis of ADPKD. Ultrasound image parameters evaluated included amniotic fluid volume, renal and bladder size, the presence or absence of renal cysts, renal parenchymal echogenicity, and the state of CMD differentiation. Characteristic findings included moderately enlarged (1-2 standard deviations above the mean) kidneys with hyperechogenic cortex and hypoechogenic medulla, resulting in increased CMD differentiation (Fig. 15-34). Cortical echogenicity was thought to be due to the presence of multiple microcysts in the renal cortex. The amniotic fluid volume was normal in most cases, and renal findings were usually observed in the third trimester.[100] The reported experience with prenatal detection of ADPKD is otherwise limited and includes cases of both normal-appearing kidneys and diffusely enlarged and hyperechoic kidneys. The prognosis for fetuses diagnosed with ADPKD in utero is similarly lacking. However, available evidence suggests that in the absence of oligohydramnios, the immediate outcomes are favorable. Risk factors for childhood onset of hypertension and renal failure are thought to include an affected mother or sibling or parental new mutation.[90,101,102]

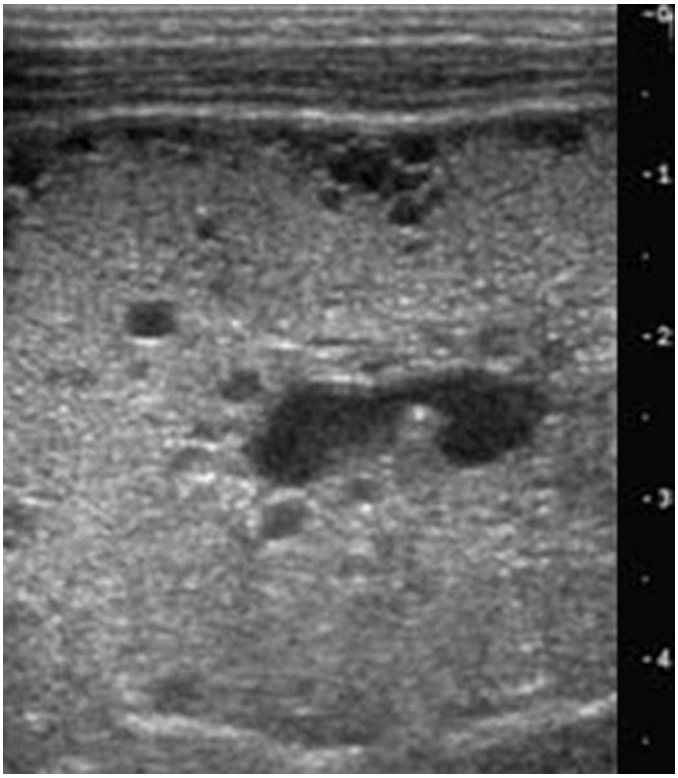

FIG 15-34 Autosomal dominant polycystic kidney disease (ADPKD), glomerulocystic form in a neonate. Sagittal scan through the enlarged kidney, which appears hyperechoic with multiple tiny cysts, mostly peripheral. The father was affected by ADPKD.

Although isolated hyperechogenicity of the fetal kidneys may be secondary to either ARPKD or ADPKD, it is a nonspecific finding. Other reported diagnoses associated with isolated hyperechogenic kidneys include diffuse cortical cysts, cystic dysplasia, nephrocalcinosis, and tubular dysgenesis. There are also cases in which no diagnosis is established postnatally and the children remain symptom free. In some cases, the kidneys become normal appearing and in some there is persistent unexplained hyperechogenicity[103-105] (Table 15-7).

The finding of hyperechogenic fetal kidneys in association with extrarenal malformations has been reported in a number of genetic conditions, including Bardet-Biedl, Meckel-Gruber, Ivemark II, Jarcho-Levin, Beckwith-Wiedemann, and Beemer syndromes, as well as in trisomy 13 (Figs. 15-35 and 15-36).[106] If the diagnosis of a syndrome can be established, this is helpful in determining prognosis. Large hyperechogenic kidneys should prompt consideration of invasive testing for chromosomal microarray analysis.

MISCELLANEOUS CYSTIC RENAL DISORDERS (Table 15-8)

Glomerulocystic Kidneys

Glomerulocystic kidneys (GLCKs) are defined as kidneys that contain cysts that correspond to distended Bowman spaces on histologic examination. From 5% to 10% of the spaces must be affected in order to establish such a diagnosis. Glomerular cysts are not specific to one simple disorder, but they can be present with several types of renal cystic diseases, both inherited and sporadic (Table 15-9).

On sonographic examination, classic GLCKs appear as enlarged hyperechoic kidneys (usually more than 4 standard deviations for the gestation) and they usually lose the normal CMD differentiation. The most suggestive feature is the presence of subcapsular cortical cysts (Fig. 15-37A and B); these cysts can develop in utero or after birth. When present, the diagnosis is straightforward. This finding may help to characterize various syndromes in association with GLCKs when other malformations coexist. The prognosis will be based on associated findings and on the volume of amniotic fluid.[107-110]

Medullary Cystic Dysplasia

Medullary cystic dysplasia is characterized by cystic changes in the kidney involving primarily the medullary tubules. Similar to GLCKs, medullary cystic dysplasia is not a specific clinical condition and may be a feature of many syndromes. It may also coexist with glomerulocystic changes (see Table 15-9). Tubular and interstitial fibrosis may develop progressively. The renal findings seen in medullary cystic dysplasia are the typical renal histologic changes seen in the Meckel-Gruber syndrome. The medullary cystic changes develop very early in the pregnancy and may be obvious as early as the end of the first trimester. The demonstration of anomalies of the central nervous system and of the extremities (polydactyly) renders the diagnosis even more certain. On sonography, the kidneys are enlarged, a pseudo-CMD differentiation is present as early as the end of the first trimester, and the medulla is very prominent. This pattern as demonstrated at this early stage is very typical[111] (see Fig. 15-35). A recent case report suggests a possible role of *HNF1B* genetic mutation in some cases of medullary renal cysts.[112]

Cystic dysplasia is also common in Bardet-Biedl syndrome (renal cystic disease, retinitis pigmentosa, polydactyly, and hypogonadism). The renal lesions are not concentrated in the medullary areas but are more diffuse. The sonographic pattern is that of diffuse hyperechoic, slightly or markedly enlarged kidneys. Cysts may be present in utero or develop after birth. Polydactyly is a classic associated finding in utero. The other abnormalities of Bardet-Biedl syndrome develop later in childhood.[111-115]

UNCLASSIFIED RENAL CYSTIC DISEASES

Macrocysts of the kidney may be encountered in cases of tuberous sclerosis. The cysts have specific histopathologic features that include eosinophilic epithelium. Other evidence of the disease, such as cardiac rhabdomyomas and intracerebral lesions, may be present in utero. Several other syndromes may also have features that include renal microcysts or macrocysts (e.g., Ivemark syndrome) (see Fig. 15-36).[90,116,117]

Multicystic Dysplastic Kidney

MCDK is one of the most common renal disorders (Fig. 15-38). The sonographic findings in patients with MCDK are usually straightforward: unilateral involvement with noncommunicating cysts of variable size, variable amount of hyperechogenic stroma, no normal cortex or medulla, irregular renal contours, and no identifiable collecting system (Fig. 15-39). The cysts can be large, presenting as a large fetal abdominal mass, or on the contrary, microcystic MCDK may develop in the upper part of a duplex system or be located in an ectopic position. The size of the cysts may decrease in utero or after birth. Therefore, the entire MCDK may "disappear" and give the appearance of renal agenesis. Unilateral involvement carries a good prognosis, although there may be an anomaly affecting the contralateral kidney (UPJ obstruction). The condition can be associated with other system's malformations. When MCDK is an isolated finding, there is no increased risk of chromosomal anomaly. Cases with bilateral involvement (about 1 out of 15 cases) are associated with severe oligohydramnios and

pulmonary hypoplasia and carry a poor prognosis (Fig. 15-40A and B).[118-121]

RENAL TUMORS

Over 50% of all congenital abdominal masses found in the neonate originate in the kidney. In the fetus, the most common renal tumor is the mesoblastic nephroma (Fig. 15-41). This appears as a solid tumor that is sometimes difficult to differentiate from the adjacent renal parenchyma. The tumor can appear partially cystic. In utero, associated polyhydramnios is typical, whereas hypertension develops after birth. Cases of fetal renal Wilms tumor have been reported as solid or partially cystic tumors. The prognosis is usually good. Bilateral involvement of the kidneys suggests nephroblastomatosis, a condition associated with multiple benign renal nodular lesions.

Patients with Beckwith-Wiedemann syndrome, congenital aniridia, and Perlman and Drash syndromes are at risk of developing renal tumors. The main differential diagnosis of a cystic renal tumor includes MCDK.[122-125] Solid masses adjacent to the kidney, such as neuroblastoma and subdiaphragmatic bronchopulmonary sequestration (BPS) (see Chapter 12), should be differentiated from true renal masses.

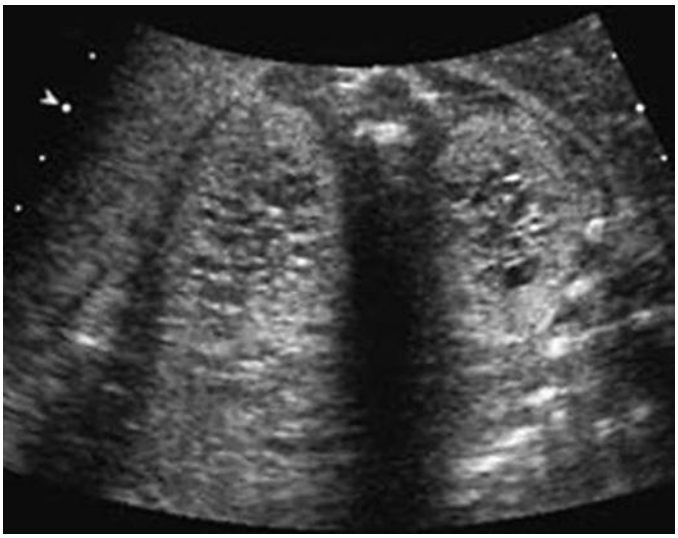

FIG 15-35 Medullary cystic dysplasia, Meckel-Gruber syndrome. Transverse scan of the fetal abdomen. Both kidneys display an abnormal pattern: diffusely cystic changes involving the entire kidney. (An occipital encephalocele was also present, which is not shown.)

TABLE 15-8 Differential Diagnosis of Fetal Renal Cysts

Unilateral Single Cysts
Simple renal cyst
Unilateral dominant cystic disease
Cystic tumor
Nonrenal cyst
Urinoma

Unilateral Multiple Cysts
Multicystic dysplastic kidney (MCDK)
Unilateral obstructive dysplasia
Unilateral dominant cystic disease

Bilateral Multiple Cysts
Bilateral MCDKs (oligohydramnios)
Bilateral obstructive dysplasia (urinary tract dilation)
Autosomal dominant polycystic kidney disease
Autosomal recessive polycystic kidney disease (cysts usually not visualized)
Subcortical cysts (glomerulocystic kidneys)
Syndromes with cystic dysplasia
Meckel-Gruber medullary cysts
Tuberous sclerosis (macrocysts)
Ivemark II syndrome
Bardet-Biedl syndrome (cortical cysts)

TABLE 15-9 Causes of Glomerulocystic Kidneys

Glomerulocystic kidney disease
- Autosomal-dominant polycystic kidney disease in young infants
- Dominant glomerulocystic kidney disease in older patients
- Sporadic nonsyndromal glomerulocystic kidney disease
- Familial hypoplastic glomerulocystic disease

Glomerulocystic kidneys in heritable syndromes
- Tuberous sclerosis
- Orofaciodigital syndrome type 1
- Trisomy 13
- Short rib polydactyly syndromes
- Jeune syndrome (asphyxiating thoracic dystrophy)
- Zellweger syndrome
- Familial nephronophthisis

Glomerular cysts in dysplastic kidneys
- Diffuse cystic dysplasia
- Renal-hepatic-pancreatic dysplasia (Ivemark II syndrome)

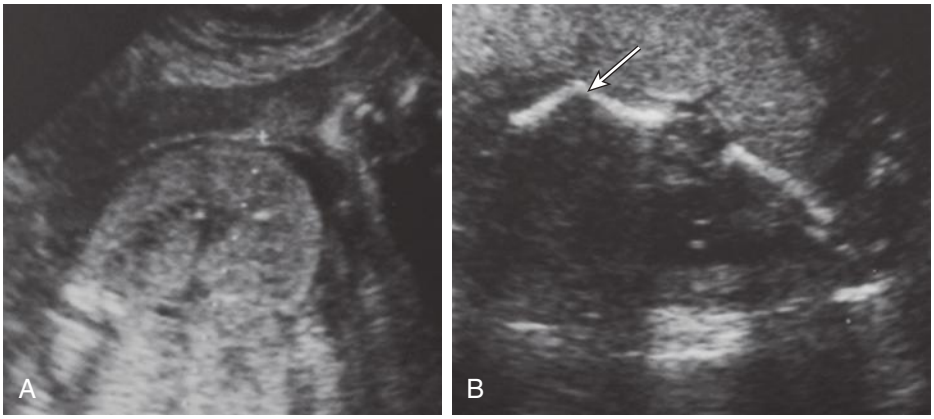

FIG 15-36 Ivemark II syndrome, second trimester. **A,** Sagittal scan through the hyperechoic kidney, corticomedullary differentiaton. **B,** Associated limb deformity: an angulated femur is visible (*arrow*).

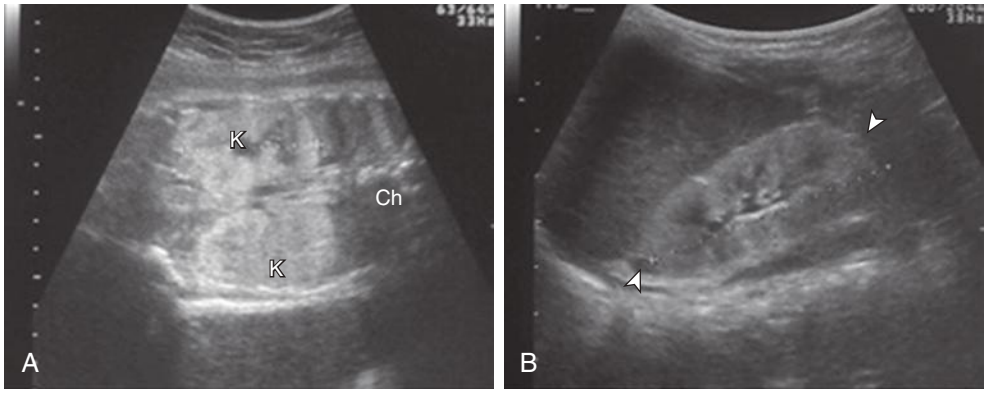

FIG 15-37 Glomerulocystic kidney in a "diabetes and renal cyst syndrome." **A,** In utero, third trimester. Front view through both kidneys (K), which appear enlarged and hyperechoic without corticomedullary differentiation. Ch, chest. **B,** At birth, sagittal scan through the right kidney. Small peripheral cysts have now appeared (*arrowheads*).

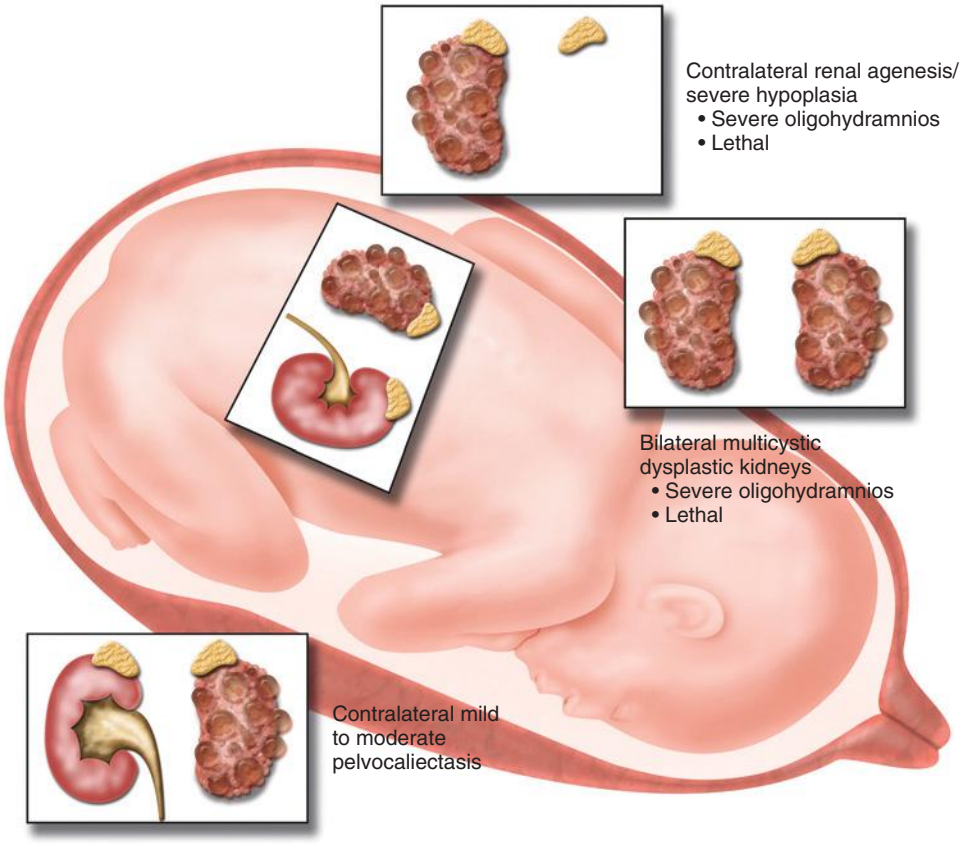

FIG 15-38 The multicystic dysplastic kidney is essentially nonfunctional. Attention must be focused on the contralateral kidney, because it is the only potentially functional kidney. (Illustration by James A. Cooper, MD, San Diego, CA.)

NONOBSTRUCTIVE FETAL BLADDER ABNORMALITIES

Absent or Nonvisualized Bladder

Fetal urine production begins at 8 to 10 weeks of gestation, and visualization of the bladder in the pelvis is typically possible from 11 to 12 weeks' gestational age. Persistent inability to identify the bladder beyond 15 weeks' gestation is a pathologic finding.[8] The presence of normal amniotic fluid volume in the absence of a visible bladder indicates either that the urine produced is unable to reach the bladder or that the bladder is unable to hold the urine.

Epispadias, Bladder Exstrophy, and Cloacal Exstrophy

Epispadias, bladder exstrophy, and cloacal exstrophy represent a spectrum of urologic abnormalities of progressive severity. The reported incidence ranges from 1:117,000 for epispadias to 1:30,000 to 50,000 for bladder exstrophy, to 1:250,000 for cloacal exstrophy.[126]

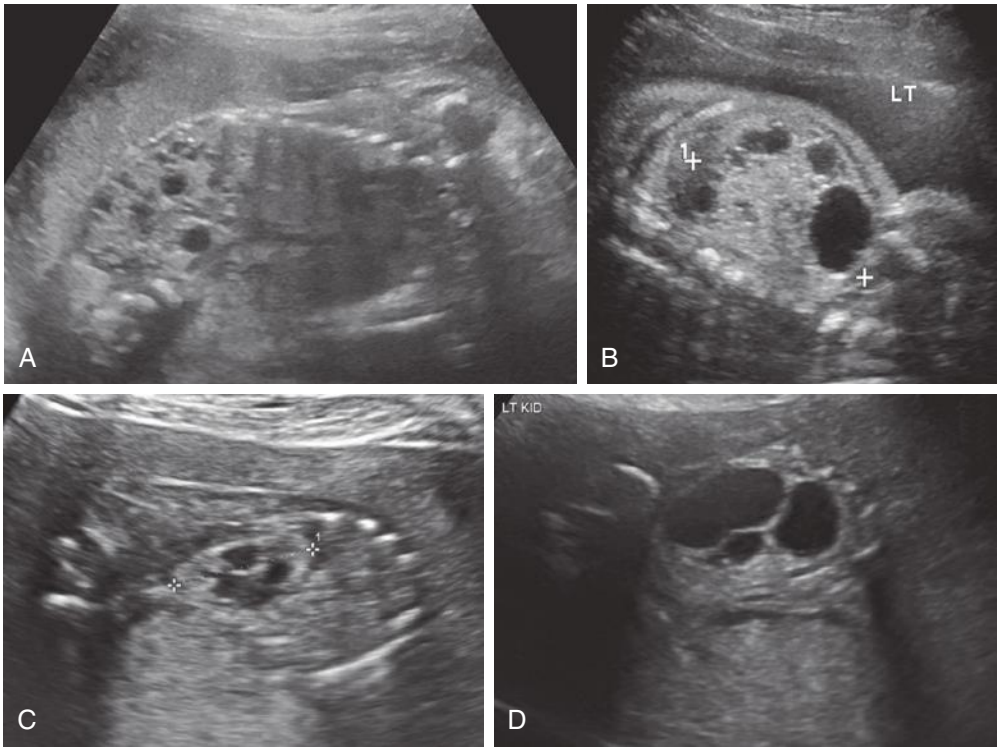

FIG 15-39 Multicystic dysplastic kidney (MCDK). Images **A-D** demonstrate variable appearance in second trimester fetuses. Features include noncommunicating cysts of variable size, variable amount of hyperechogenic stroma, no normal cortex or medulla, irregular renal contours, and no identifiable collecting system. The abnormal MCDK is delineated by the calipers in **B** and **C**. LT, left. (**C** and **D**, Courtesy Department of Obstetrics and Gynecology, Yale University School of Medicine, New Haven, CT.)

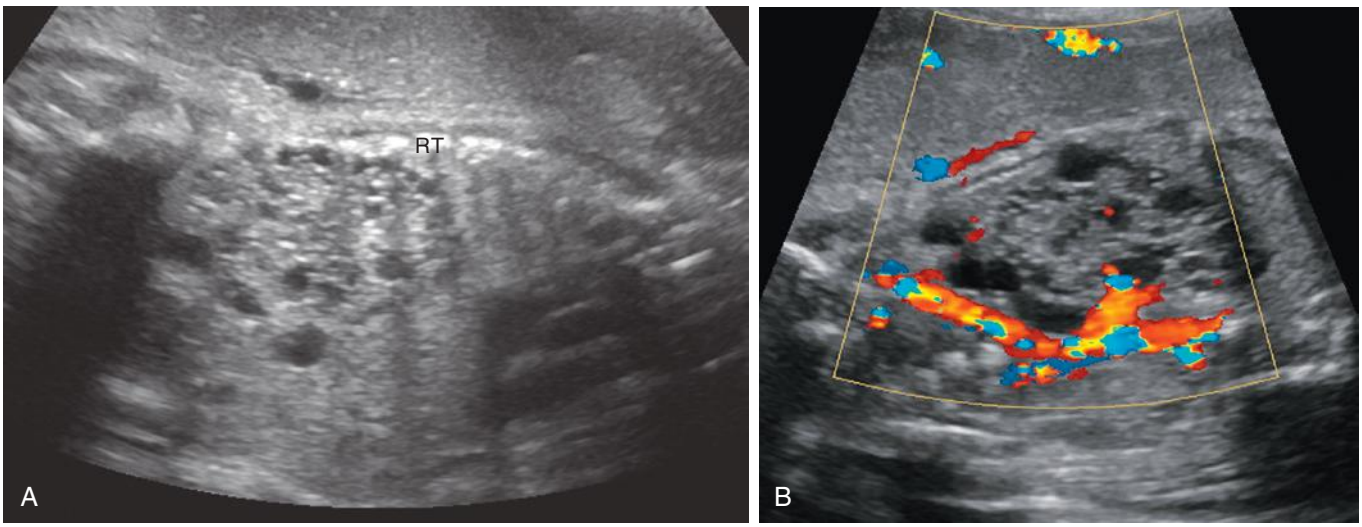

FIG 15-40 Multicystic dysplastic kidney. **A,** Sagittal image of the right (RT) kidney reveals multiple scattered small cysts. **B,** Coronal image with color Doppler interrogation shows flow at the renal hilum. The fluid-filled spaces at the periphery of the kidney are nonvascular and represent cortical cysts.

Epispadias

In males, epispadias is characterized by a broad, short penis, a gap in the pubic symphysis, and dorsal chordee. The scrotum is normal, and the testes are typically descended with normal function. Ejaculation may be abnormal secondary to the abnormal posterior urethra. In females, the clitoris is divided and the vagina is displaced anteriorly. The absence of normal pelvic muscle support can result in uterine prolapse, although fertility is unaffected. A deficient bladder neck leads to constant urinary leakage. This may be manifest prenatally by a small or absent bladder, inferiorly displaced umbilicus, and, in males, abnormal genitalia.[127]

Bladder Exstrophy

The integrity of the fetal ventral wall depends on migration of mesenchymal cells between the abdominal ectoderm and the cloaca. This process is initiated in the 4th week of gestation, and its failure results in a lack of muscle and connective tissue in the infraumbilical abdominal wall. It should be suspected when there is persistent

nonvisualization of the bladder in the setting of normal amniotic fluid volume and absence of other urinary tract abnormalities. The key sonographic features suggestive of bladder exstrophy include absent bladder in the pelvis, a soft tissue mass (the exstrophied bladder) adjacent to the lower abdominal wall, low umbilical cord insertion, abnormal external genitalia (small phallus and anteriorly deviated scrotum), and separation of the iliac crests[128] (Fig. 15-42A and B). Competing conditions that may obscure the diagnosis of bladder exstrophy include other ventral wall defects, such as omphalocele, gastroschisis, and cloacal exstrophy. The accuracy of prenatal diagnosis using ultrasound is lacking, with reported detection rates of 10% to 25%.[129,130] Given the imprecision in sonographic detection, MRI has more recently been advocated as a useful adjunct in evaluation of suspected cases. It is less affected by maternal habitus and fluid volume and allows better resolution of the soft tissue and genitalia.[131] Prenatal detection is important for counseling and planning surgical treatment. Ideally, bladder and abdominal wall closure is performed within the first 48 hours after birth. Additionally, parents should be prepared for the potential long-term morbid conditions of urinary incontinence, reduced fertility, and need for staged genitourinary reconstructive procedures.[132]

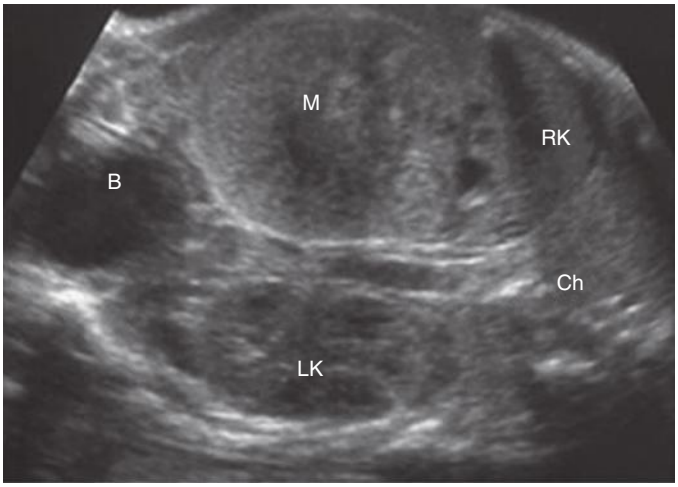

FIG 15-41 Mesoblastic nephroma, third trimester. Sagittal scan of the fetal trunk. A large round solid mass (M) has developed in the lower pole of the right kidney (RK). B, bladder; Ch, chest; LK, left kidney.

Cloacal Exstrophy

Inability to visualize the bladder is also a sentinel feature of cloacal exstrophy, a rare combination of anorectal and urogenital malformations with a reported incidence of 1:200,000 to 400,000.[133] Cloacal exstrophy is in the spectrum of the OEIS complex (omphalocele, cloacal exstrophy, imperforate anus, and spinal anomalies).[134] Other features reported in association with cloacal exstrophy include a cystic anterior abdominal wall mass, presumed to represent a persistent cloacal membrane, abnormal external genitalia, renal anomalies (hydronephrosis, agenesis, and MCDK), lower extremity defects, widened pubic arches, and single umbilical artery.[135] Given its rarity, uniform diagnostic criteria are lacking and prenatal diagnosis is uncommon. A high index of suspicion should be maintained when evaluating any fetal ventral wall defect in which the bladder is not visualized in the pelvis. In a recent retrospective review of eight patients with cloacal exstrophy, the diagnosis was missed in four fetuses using sonography but confirmed in all eight cases with fetal MRI. In addition to nonvisualization of the bladder, the MRI findings allowing a confident diagnosis of cloacal exstrophy included a protruding lower abdominal/pelvic contour and absence of meconium filling of the rectum and colon, a manifestation of the hindgut anomaly. Meconium distention of the rectum is typically observed by 21 weeks of gestation, so failure of detection with MRI after this time strongly suggests cloacal exstrophy[136] (Figs. 15-43 and 15-44). As with bladder exstrophy, prenatal detection is essential for planning the location, route, and tertiary site of delivery. Parents should be counseled that even though postnatal survival rates are near 90%, this achievement is obtained at the cost of multiple corrective procedures and a high risk of urinary and fecal incontinence.[135]

BILATERAL SINGLE ECTOPIC URETERS

Ectopic ureters typically occur in the setting of renal duplex collecting systems, which are more common in females. Ectopic ureters associated with a single renal pelvis are more likely in males. Aberrant ureteric bud development is the underlying disorder that results in ectopic implantation, which may be at the bladder neck, prostate, or posterior urethra. In females, the ureters may communicate with the urethra or vaginal vault. Regardless of gender or site of implantation, the end result is that urine produced by the kidneys can bypass the bladder, which does not fill, whereas normal amniotic fluid volume can be maintained. Although rare, this diagnosis should be entertained when

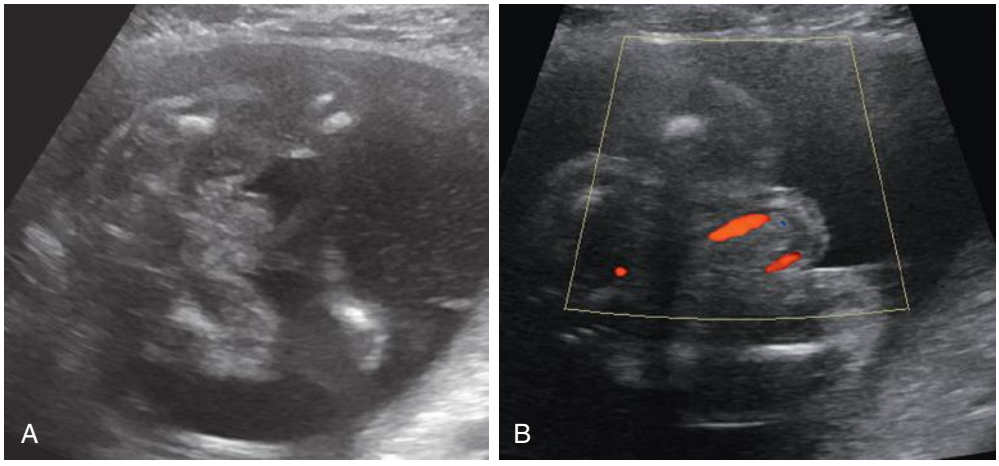

FIG 15-42 Bladder exstrophy. **A,** Axial view of lower abdomen showing absent bladder in the pelvis and a soft tissue mass (the exstrophied bladder) in the anterior lower abdomen. **B,** Nonvisualization of fetal bladder in the pelvis is aided by color Doppler demonstration of the umbilical arteries.

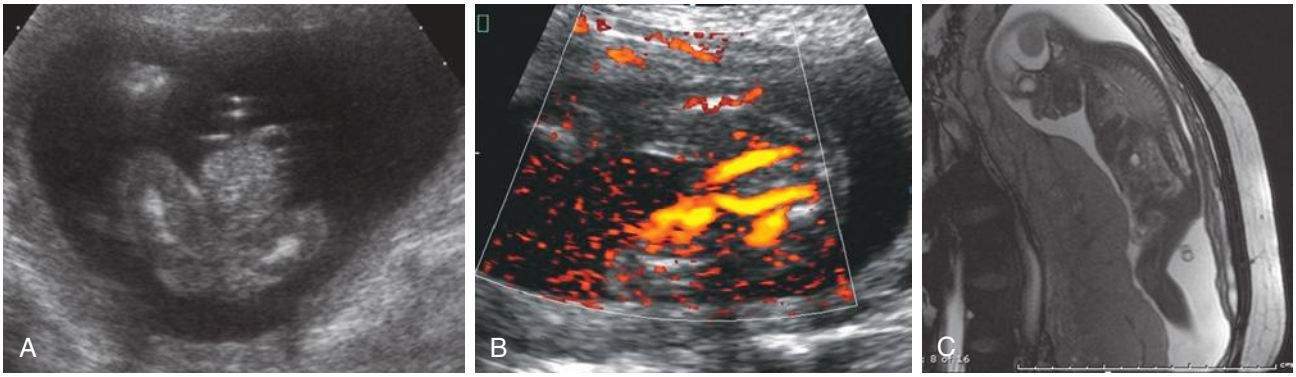

FIG 15-43 Cloacal extrophy. **A,** Axial view of lower abdomen showing mass in the lower anterior abdomen. **B,** Nonvisualization of fetal bladder in the pelvis confirmed by color Doppler identification of umbilical arteries. **C,** Fetal magnetic resonance imaging aids the diagnosis of cloacal exstrophy with demonstration of exteriorized bladder.

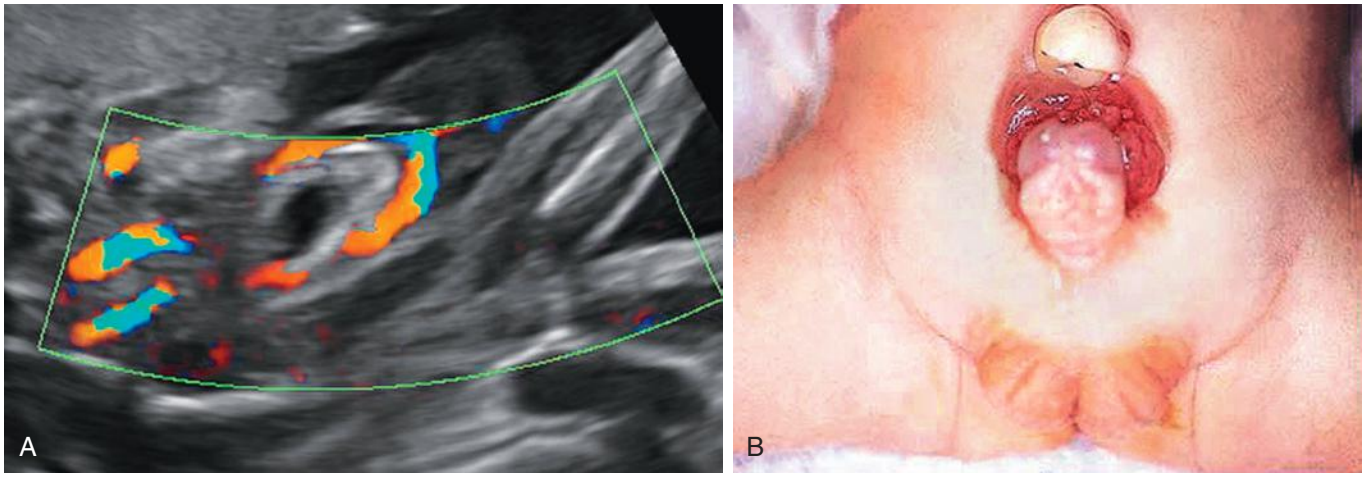

FIG 15-44 Cloacal extrophy. **A,** Exteriorized fetal bladder can occasionally be demonstrated using color Doppler imaging. **B,** Postnatal photograph confirms cloacal exstrophy.

there is nonvisualization of the bladder with none of the accompanying features of bladder or cloacal exstrophy. The lack of normal filling and emptying of the bladder compromises bladder development, which typically necessitates reimplantation and reconstructive procedures. There is a significant residual risk of incontinence and renal impairment. Ureteric reimplantation has been shown to preserve renal function with postsurgical improvement determined by the degree of renal dysplasia.[137,138]

FETAL ADRENAL GLANDS

Normal Adrenal Glands

The fetal adrenal glands are easily demonstrated, especially using transvaginal transducers, by the end of the first trimester. They appear as pyramidal hypoechoic structures at the superior aspect of the hyperechoic kidney (Fig. 15-45). At that stage, their size is approximately half that of the kidney. Progressively, during the second trimester, CMD differentiation is observed with a hypoechoic cortex and hyperechoic medulla. The shape is that of a triangular structure on the superior aspect of the kidney. The size of the gland increases but relatively less than the kidney. During the third trimester, the appearance of the fetal adrenal gland is very similar to that of the neonatal adrenal glands (Fig. 15-46A and B). In cases of renal agenesis, the adrenal gland is more prominent and may be elongated, giving the so-called "lying

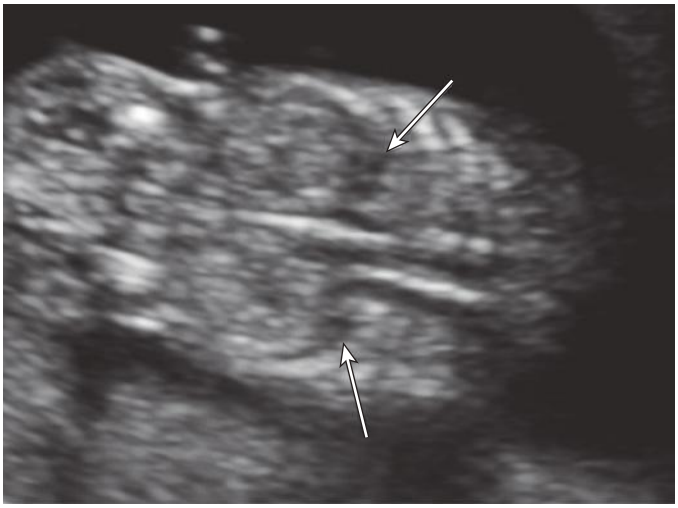

FIG 15-45 Fetal adrenal glands. First trimester image demonstrating normal fetal adrenal glands superior to the fetal kidneys (*arrows*).

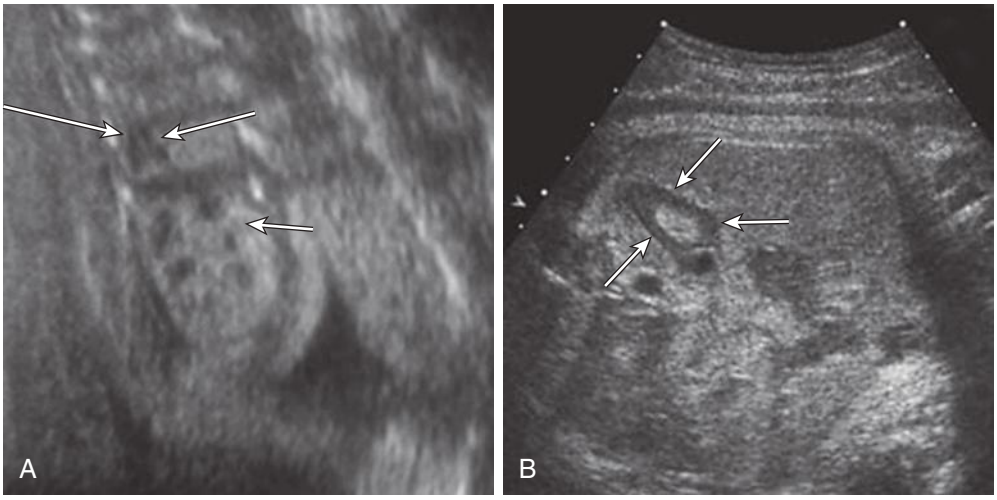

FIG 15-46 Normal fetal adrenal gland. **A,** Second trimester, coronal view. The triangular adrenal gland is visible (*arrows*) above the kidney (*short arrow*). **B,** Third trimester, transverse view. The right adrenal gland is visible (*arrows*) with normal cortico (hypoechoic)-medullary (hyperechoic) differentiation.

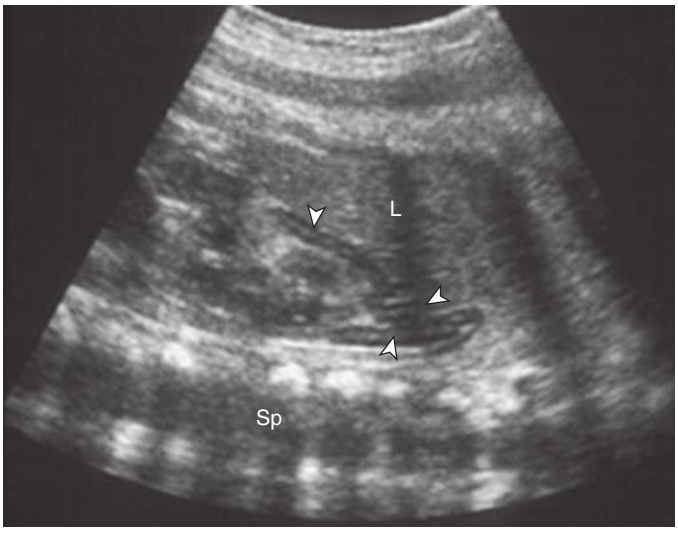

FIG 15-47 Adrenogenital syndrome, third trimester. Sagittal scan through the right flank demonstrating the hypertrophied adrenal gland (*arrowheads*). L, liver; Sp, spine.

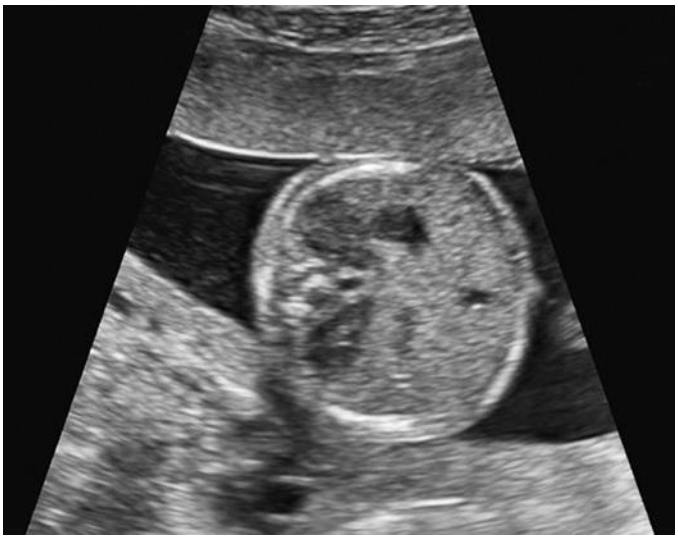

FIG 15-48 Adrenal hemorrhage. Fetus with bilaterally enlarged adrenal gland secondary to adrenal hemorrhage.

down adrenal sign") (see Fig. 15-24). This should not be misinterpreted as a dysplastic kidney.[139-141]

Adrenal Disorders

Adrenogenital Syndrome

Adrenogenital syndrome (AGS) usually occurs secondary to CAH and the adrenal glands may enlarge as early as the second trimester. They may display a cerebriform wrinkled pattern (Fig. 15-47). The condition is associated with disorders of sexual differentiation in the female fetus (see later). Fetal MRI may be needed to differentiate cases of AGS from neuroblastoma; in the former, T2-weighted images will display isointense or hypointense signals, whereas in the latter the signals are hyperintense. Several authors have proposed using maternal corticosteroid therapy, once the condition has been ascertained, in order to reduce the virilization of the female fetus, although this treatment is controversial.[142-146]

Adrenal Masses

Cystic or solid masses in the region of the adrenal gland may be secondary to benign cystic enlargement, hemorrhage, CAH, or adrenal tumors (Figs. 15-48 through 15-50).

Neuroblastoma

Neuroblastoma should be considered when a mass is seen in the suprarenal region, regardless of the specific characteristics of the mass. Neuroblastoma may present with a cystic, solid, or more complex appearance (see Fig. 15-50). Color Doppler imaging may demonstrate increasing vascularization of the hyperechogenic aspects of the mass. The prognosis of antenatal neuroblastoma is excellent even when hepatic metastases are present. Furthermore, some cases of spontaneous involution have been reported. Large adrenal cysts may develop in association with the Beckwith-Wiedemann syndrome. These cysts may bleed, in which case their appearance will become more complex. Extra-adrenal origins of a mass in this region, such as

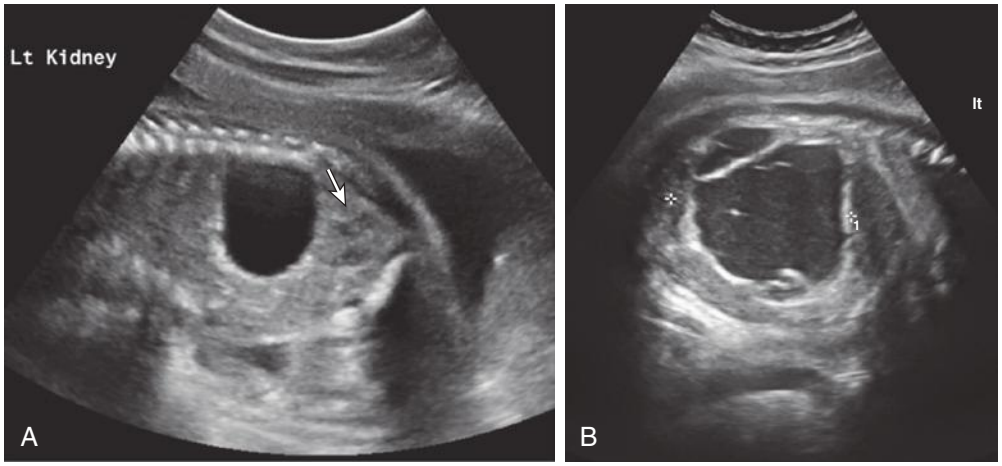

FIG 15-49 Adrenal cyst. **A,** Sagittal image of the left (Lt) fetal kidney (*arrow*) demonstrating a large cyst in the adrenal gland superior to the kidney at 27 weeks' gestation. **B,** The same fetus at 34 weeks' gestation, demonstrating interval evolution of the cyst. subdiaphragmatic pulmonary sequestration, should also be included in the differential diagnosis (Table 15-10).[142,147-160]

FETAL GENITAL ANOMALIES

Current expertise and ultrasound technology allow a confident diagnosis of fetal gender at 13 weeks' gestation or later in 99% to 100% of cases with normal external genitalia. Determination of fetal sex is possible at less than 13 weeks but accuracy is variable and it should not be relied upon to guide pregnancy management at this stage. In the late first and early second trimesters, gender determination is based primarily upon the sagittal sign. When scanned in the sagittal plane, the normal penis points upward, whereas the clitoris is oriented downward. Subsequently, identification of fetal sex depends upon visualization of the scrotum and penis in males and labia in females, which present as either two or more parallel lines (Fig. 15-51). Adjunctive findings that may be useful in uncertain cases include presence or absence of testicular descent, penile/scrotal size, origin and direction of the urinary stream, and visualization of the uterus.[161-163]

Three-dimensional sonography has also proved useful in characterizing genital abnormalities. This is a function of the improved spatial resolution and detailed surface rendering afforded by this modality.[164] The critical period for sexual development appears to be 8 to 12 weeks of gestation. This is suggested by reports of normal-appearing genitalia at 13 to 15 weeks with subsequent abnormalities of size and structure that appear to evolve as pregnancy progresses. This supports the notion that some genital malformations change throughout pregnancy rather than always occurring following a single nonprogressive insult.[165]

Transient clitoromegaly and *hypertrophy of the labia* have also been reported. In one reported series of 62,145 pregnancies, there were four fetuses with isolated clitoromegaly detected at 15 to 16 weeks' gestation. A diagnosis of hypospadias was initially entertained. On follow-up

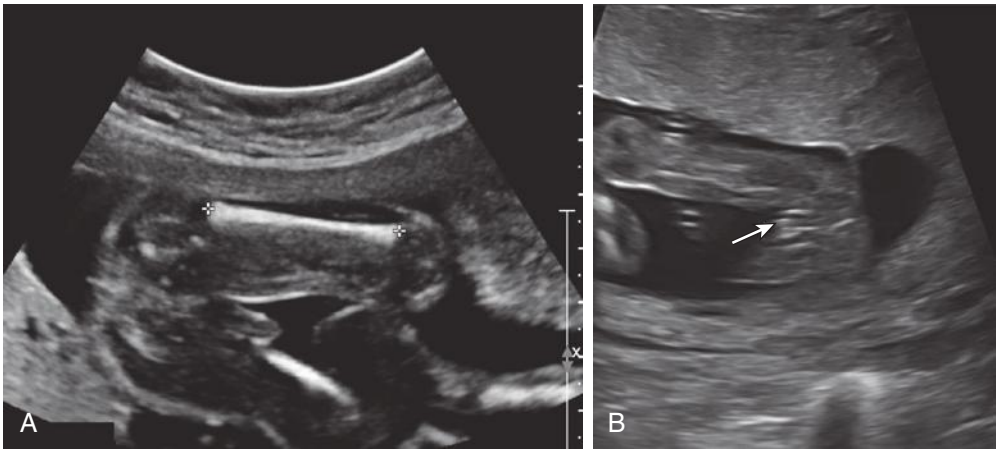

FIG 15-51 Normal fetal genitalia, **A,** Male. **B,** Female; parallel lines indicate labia (*arrow*).

at 22 to 26 weeks, the clitoromegaly was resolved. The three fetuses with isolated hypertrophy of the labia minora had normal-appearing female genitalia at 15 weeks with suspected ambiguous genitalia noted at 21 to 23 weeks. Repeat examinations revealed gradual resolution of the hypertrophy with normal-appearing genitalia at 26 to 32 weeks. All cases had a normal female karyotype and normal external genitalia at birth. It was speculated that transient changes in the size of the clitoris correlate with changes in hormone production by the immature adrenal glands.[166]

Disorders of Sexual Development

In addition to the genital abnormalities associated with bladder and cloacal exstrophy discussed earlier, other genital malformations include hypospadias, virilization syndromes (clitoromegaly, fused labia), incomplete masculinization of male genitalia (micropenis), and discordance between fetal phenotype and karyotype (Fig. 15-52). They are a heterogeneous group of disorders with different defects in hormones or their effects. Multiple as yet unidentified disease genes are implicated.

Hypospadias refers to abnormal location of the urethral orifice, which may be along the penile shaft, in the margin of the scrotum, or in the perineum. It reflects failure of development of the anterior urethra and has a reported incidence of 1:250 to 1:5000 live births. Associated genitourinary anomalies are seen in up to 40% of children with this diagnosis, and nongenitourinary anomalies occur in 7% to 10%. The prenatal sonographic features observed with hypospadias include loss of the pointed tip of the penis, which appears instead as a pointed cone; abnormal ventral curvature of the penis (chordee), presumed secondary to a strand of connective tissue acting as a bowstring between the meatus and glans; a small penile shaft with two parallel echogenic lines representing the remains of the dorsal hood; and the tulip sign, which results from severe curvature of the penis between the two scrotal folds (Fig. 15-53). This represents a severe form of hypospadias. Using power or color Doppler to demonstrate the origin of the urinary stream during bladder emptying can also allow a diagnosis in some cases of hypospadias.[167,168]

In a known genetic female with abnormal external genitalia or a fetus with genital ambiguity (or disorder of sexual development) and unknown karyotype, identification of a normal uterus suggests a likely diagnosis of a virilized female. The absence of a uterus is consistent with an undervirilized male. Transverse scanning through the pelvis at the level of the fetal bladder should reveal a rounded echogenic uterus positioned between the hypoechoic rectum and bladder. Nomograms

FIG 15-52 Disorder of sexual differentiation, third trimester. Scan through the scrotum. The two hemiscrotums are separated by a penis that is too short (*arrowhead*) (split scrotum sign).

of uterine width and circumference are available from 19 through 38 weeks' gestation.[169]

The most common cause of female virilization is *congenital adrenal hyperplasia* (CAH). Most cases of CAH are from 21-hydroxylase deficiency (CYP21 CAH). Definitive prenatal diagnosis of CYP21 CAH is possible in families with a previously affected child if the causative mutations have been identified. Although complex, fewer than 12 mutations represent more than 90% of the mutant alleles, and phenotype does not necessarily predict genotype. This is an autosomal recessive condition with a 25% chance for an affected child in each pregnancy; affected females are at risk for genital virilization. Maternal treatment with steroids early in the first trimester may ameliorate the effects of CYP21 CAH on female genital anatomy. However, the appropriateness, ethics, and outcomes of the prenatal treatment of CAH with dexamethasone remain controversial.[170,171]

FETAL OVARIAN CYSTS

With improved ultrasound imaging, greater numbers of ovarian cysts are being diagnosed prenatally. These cysts are secondary to maternal

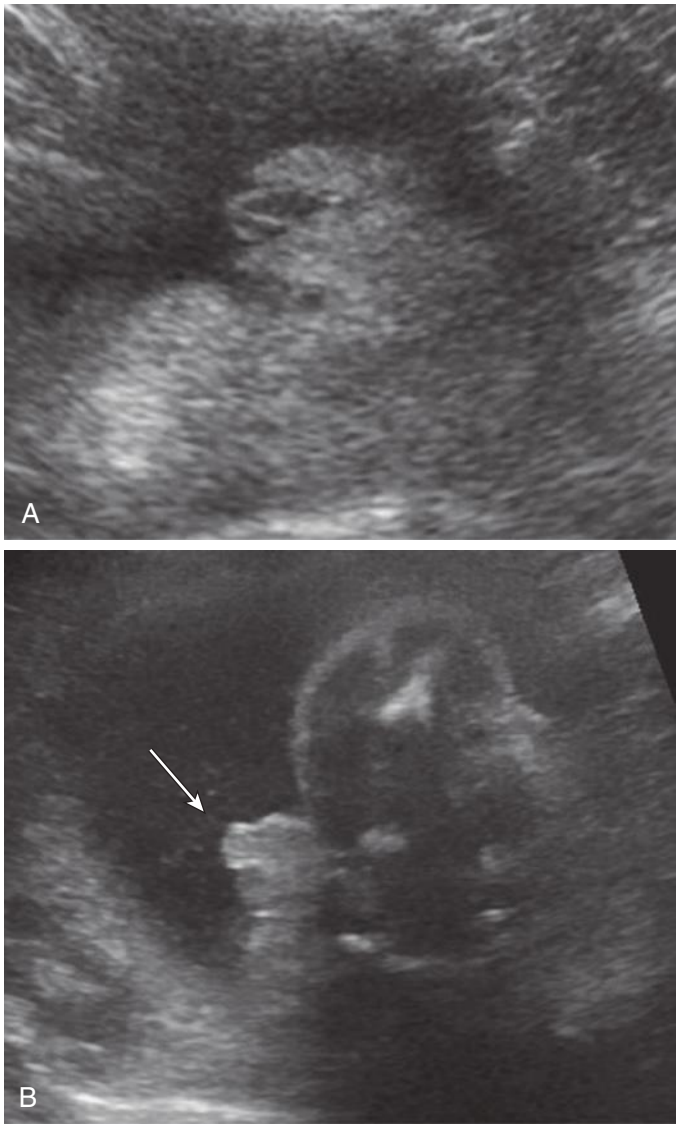

FIG 15-53 Hypospadias, third trimester. **A,** The classic tulip sign. **B,** The penis (*arrow*) appears shortened and the tip is broad without the normal pointed appearance.

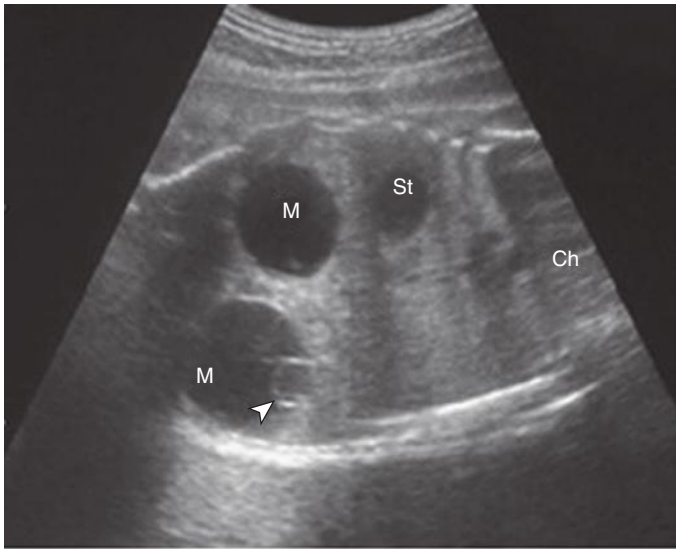

FIG 15-54 Bilateral ovarian cysts, third trimester. Frontal view of the fetal trunk demonstrating two cystic masses (M). In one of them, a smaller cyst is visible (daughter cyst sign) (*arrowhead*). Ch, chest; St, stomach.

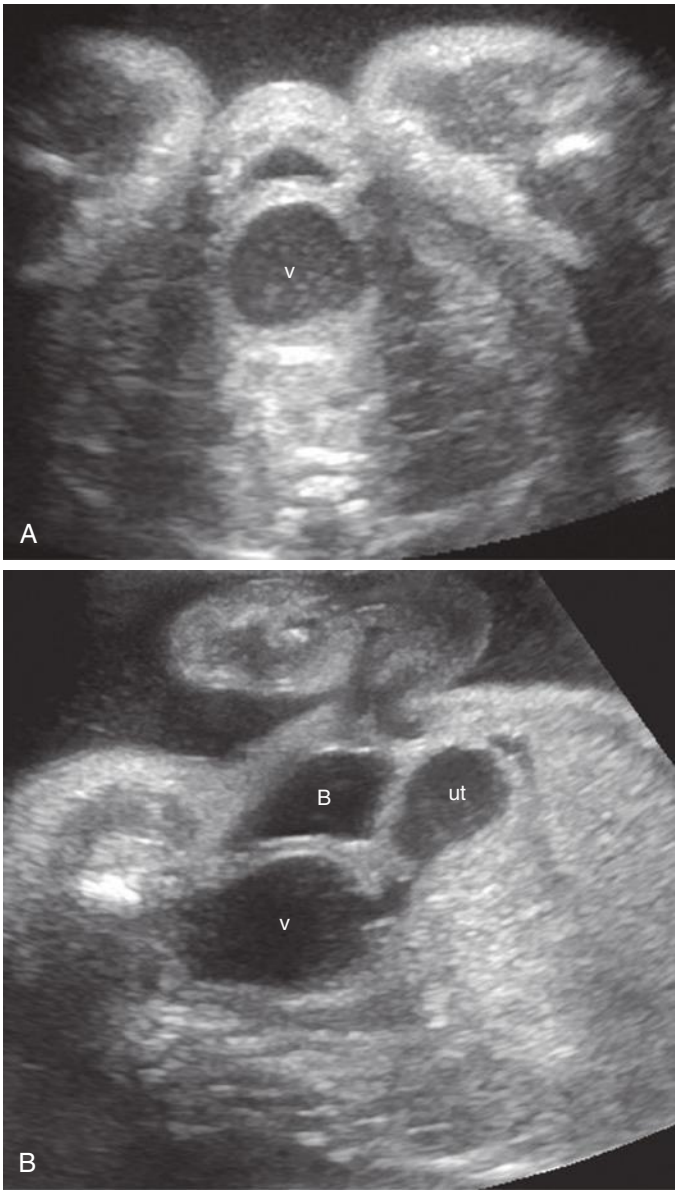

FIG 15-55 Hydrometrocolpos. **A,** Transaxial image of the distended fluid-filled vagina (v). **B,** Sagittal sonographic image of the pelvis in this female fetus demonstrates fluid within the dilated vagina (v) and uterus (ut), located posterior to the normal-appearing urinary bladder (B). A normal volume of amniotic fluid is present.

hormonal stimulation. They can be unilateral or bilateral, they may vary in size, and multiple cysts can occur on the same side (Fig. 15-54). The most common cysts appear as anechoic smooth-walled, avascular cysts that may be functional follicles. However, more complex solid ovarian cysts may be encountered, although rarely. Hemorrhage may occur within these cysts and the larger ones are at risk of torsion. Differential diagnoses of ovarian cysts include duplication cysts, urachal cysts, hydrocolpos, mesenteric cysts, or meconium pseudocysts. Very rarely, a lymphangioma or teratoma may present with features suggesting an ovarian cyst.[172-180] When the diagnosis is unclear, fetal MRI may be helpful. In a series of 56 fetuses who underwent MRI for suspected anomalies, MRI changed the final diagnosis in 4 of 6 with intra-abdominal cysts, with findings including meconium pseudocysts, mesenteric cysts, hydrometrocolpos, and chylous ascites.[181]

Most fetal ovarian cysts resolve spontaneously, either in the antenatal period or in the early postpartum period. The role of surgical intervention, even in the postnatal period, is controversial, as many of these cysts will resolve spontaneously. Very large cysts with potential for torsion may be an indication for either prenatal aspiration or postnatal surgery.

HYDROCOLPOS/HYDROMETROCOLPOS

Malformations of the female lower genital tract resulting in obstruction of the lower half of the vagina can result in fluid accumulation within the vagina (hydrocolpos) or in the vagina and uterus (hydrometrocolpos) (Fig. 15-55A and B). It may be secondary to cloacal malformation (see earlier) or rarely may be due to a persistent urogenital sinus (Fig. 15-56A through D).[182-186] Some cases of hydrocolpos may resolve spontaneously, and, therefore, it is important to exclude any associated anomalies to allow appropriate counseling and planning for postnatal management. The possibility of persistent urogenital sinus should be considered when a presacral cystic mass is seen with either clear fluid (urine) or turbid fluid-debris level thought to be due to cervical or vaginal secretions. Fetal MRI may be useful in differentiating isolated hydrocolpos from that associated with cloacal malformations.[187]

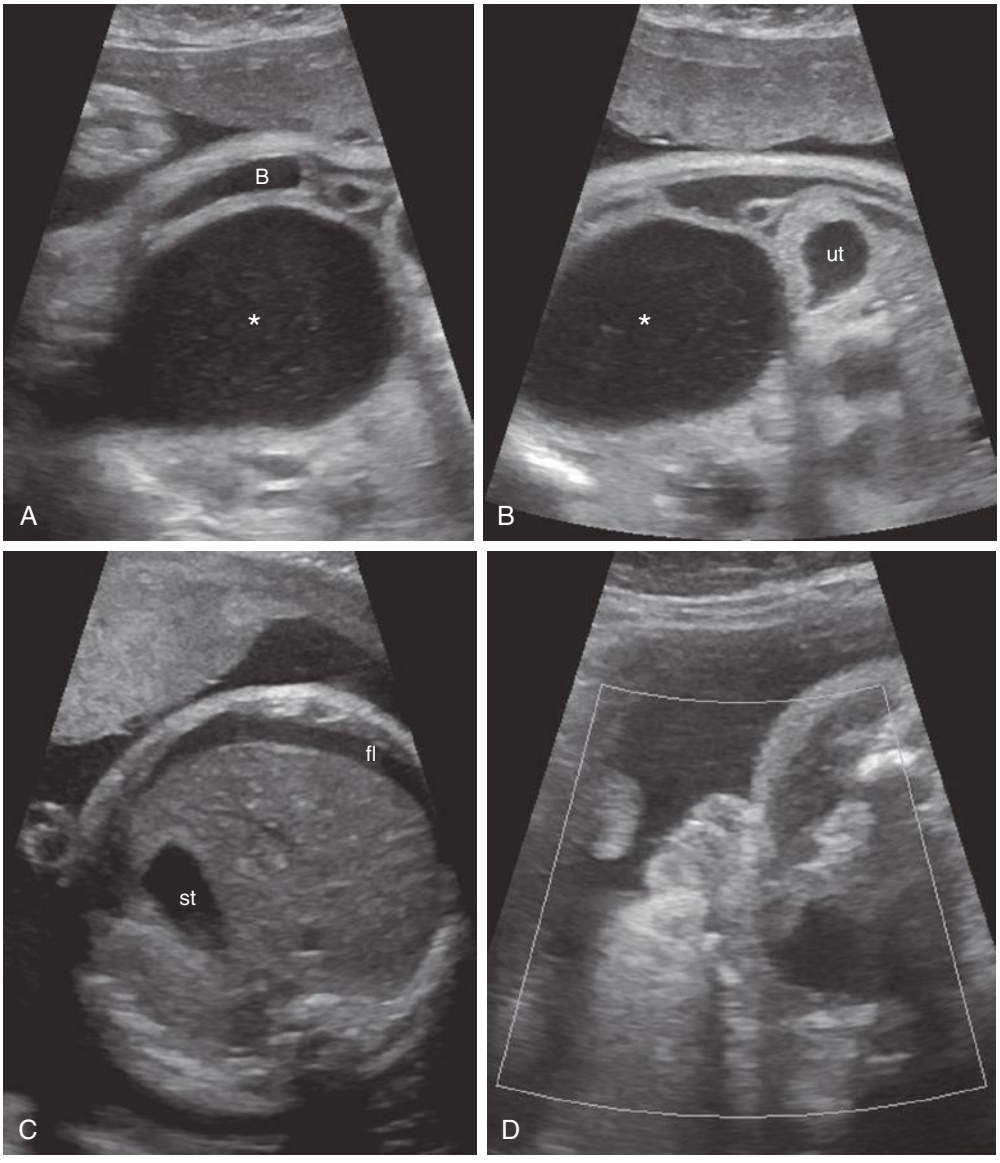

FIG 15-56 Persistent urogenital sinus. **A,** Large fluid-filled structure in the pelvis (*asterisk*) representing the markedly dilated vagina, posterior to the bladder (B). **B,** At the superior aspect of the fluid-filled pelvic mass (*asterisk*), the thick-walled oval structure represents the uterus (ut). Findings indicate hydrometrocolpos. **C,** Transaxial image through the upper abdomen reveals free intraperitoneal fluid (fl), presumed to be due to reflux of urine and vaginal secretions through the fallopian tubes. Normal fluid-filled stomach (st). **D,** Image of external genitalia shows normal labia in this female fetus.

Ultrasound Features of Fetal Syndromes

Kathryn Johnson Gray, Louise Wilkins-Haug

SUMMARY OF KEY POINTS

- Congenital anomalies can occur in isolation or be indicative of a more extensive underlying process.
- The presence of a congenital anomaly should prompt a thorough evaluation for other anomalies and consideration of additional advanced fetal imaging.
- When an underlying global process is suspected, genetic testing is indicated and a geneticist or genetic counselor should be involved.
- With advances in molecular diagnostics, fetal syndromes are more readily diagnosed by use of both chromosomal microarray and next-generation sequencing technologies.
- When fetal syndromes are diagnosed prenatally, a multidisciplinary team should assist in counseling and care coordination for expectant parents.
- Confirmation of an underlying genetic alteration leading to the observed fetal anomalies can both assist in diagnosis as well as provide information crucial for future reproductive planning.

OUTLINE

Prenatally, a congenital anomaly is suspected when images of a fetal organ differ from the expected development for a given gestational age. A congenital anomaly can result from a malformation (an intrinsically abnormal developmental process), deformation (normal development with extrinsic forces), disruption (breakdown of previously normal tissue), or dysplasia (an abnormal organization of cells within tissues which may disrupt more than one organ) (Fig. 16-1). Whenever one congenital anomaly is present, a thorough search for other anomalies and unusual findings (i.e., accelerated or restricted fetal growth, abnormal amniotic fluid levels, altered fetal movements) should be undertaken. Additional imaging modalities may be helpful in completing the full fetal assessment including three-dimensional (3D) ultrasound studies, Doppler interrogations, and fetal magnetic resonance imaging (MRI).

The presence of congenital anomalies should prompt consideration of underlying global disorders, especially when several imaging findings are present. Multiple findings may be the result of a sequence, syndrome, or association. In a sequence, a group of anomalies is caused by an initial malformation, deformation, or disruption (i.e., amniotic band sequence). In a syndrome, a group of anomalies is the result of an underlying genetic cause and is pathogenetically related (i.e., Down syndrome). In an association, a given set of anomalies occurs together more frequently than can be explained by chance and the particular anomalies are not known to be the result of a sequence or syndrome (i.e., VACTERL association [*v*ertebral anomalies, *a*nal atresia, *c*ardiac anomalies, *t*racheoesophageal fistula or *e*sophageal atresia, *r*enal/urinary anomalies, and *l*imb defect]).

As molecular diagnostic technologies have become more refined and accessible, fetal syndromes are more readily diagnosed in both prenatal and postnatal settings. Prenatally, when a congenital anomaly is seen, chromosomal microarray is now recommended as the first-line test. In addition to aneuploidy, chromosomal microarray allows detection of microdeletion and microduplication syndromes and leads to the identification of approximately 5% more cytogenetic abnormalities than can be seen on conventional karyotype alone (Fig. 16-2). However, many syndromes are single gene disorders and cytogenetic testing by both karyotype and chromosomal microarray will be normal. For many of these disorders, individual gene testing and gene panel testing is now available. Cost and time to obtain fetal DNA results prenatally still remain a significant hurdle for many syndromes suspected on prenatal imaging. The prenatal diagnostician should work closely with neonatal care providers to assure completion of a genetic workup.

In the following pages, we review fetal syndromes that are potentially detectable based on prenatal imaging findings and group them by prominent features (either the body system affected or some other hallmark such as altered fetal growth or movement). The review is not exhaustive but serves to highlight fetal syndromes commonly encountered by sonologists and sonographers and presents relevant imaging findings and genetics. Fetal syndromes often come to initial clinical attention based on screening prenatal ultrasound imaging; further imaging with 3D sonography and fetal MRI (especially for evaluation of the central nervous system [CNS]) can aid in delineation of additional features. Other specialties, including genetics, maternal-fetal medicine, and pediatric subspecialties (i.e., cardiology, surgery), can then assist with specialized testing, obstetric care, and postpartum planning for patients continuing with their pregnancies. These providers can give a clear overview of the anticipated process to the parents and convey the time and complexities of reaching a specific diagnosis for the fetus or child.

Given the rapid evolution in genetic testing, involvement of the genetics team is particularly important to assure that the most appropriate diagnostic testing is performed either in the prenatal or postnatal period. For many single gene disorders, multiple causative mutations within one gene have been identified. At times, the mutation may be unique or "private" to the family themselves. Completion of genetic studies provides not only confirmation of the diagnosis but an opportunity for the family to utilize the information in future reproductive planning.

MATERNAL INFECTIONS

Fetal Cytomegalovirus Infection

Definition

Fetal cytomegalovirus (CMV) infection is a congenital disorder characterized by hydrops, ascites, and ventriculomegaly caused by transplacental transmission of CMV to the fetus. The double-stranded DNA herpes group virus causes a mild infection or a mononucleosis-type illness in young healthy adults, chronic disease in older adults, and mild to severe congenital infection. Congenital infection is mostly caused by maternal primary infection.

Synonym

Fetal cytomegalovirus infection is also known as congenital cytomegalovirus infection.

Etiology

Cytomegalovirus (a double-stranded DNA herpes group virus) is the cause of the infection.

Incidence

Congenital CMV infection occurs in approximately 1% of all deliveries and is the most common congenital infection. Intrauterine transmission of CMV takes place in approximately 40% of infections, and approximately 10% of liveborn infants have symptomatic disease at the time of birth and later.

Diagnosis

CMV infection, as well as other congenital infections, should be suspected whenever nonimmune hydrops is found. Other suggestive findings include intracranial calcifications and intracranial hemorrhage, microcephaly, brain atrophy, abnormal periventricular echogenicities, intraparenchymal foci, ventriculomegaly, intraventricular adhesions, periventricular pseudocysts, sulcation and gyral abnormal patterns, hypoplastic corpus callosum, cerebellar and cisterna magna abnormalities, signs of striatal artery vasculopathy, splenomegaly, chorioretinitis, occlusion of the foramen ovale, signs of right-sided heart overload from the premature closure, ascites, hyperechoic bowel, fetal growth restriction, and oligohydramnios. Most features can be found by sonography beginning at approximately 20 weeks' gestation. Whenever maternal infection is confirmed, polymerase chain reaction (PCR) testing of amniotic fluid should be performed. PCR testing of amniocentesis samples should be performed after a 6-week interval following the diagnosis of maternal infection and is most sensitive after 21 weeks' gestation. The diagnosis can also be made by histologic study of typical inclusion bodies in biopsy or autopsy specimens. Focal sonographic periventricular increased echogenicity associated with mild ventriculomegaly, without any abnormalities of the cerebral and cerebellar organogenesis or cephalic biometry alteration in the third trimester of pregnancy, should be considered a marker of encephalitis following CMV infection. Fetal MRI is a useful adjunct in the evaluation of intrauterine infection with CMV.

Pathogenesis

The exact mode of transplacental passage is uncertain. The virus replicates in fetal tissues, producing inflammation, tissue necrosis, and organ dysfunction. CMV hepatitis in the neonate can present with an intense inflammatory response involving the portal triads. In these cases, lobular disarray, degeneration of hepatocytes, and cholestasis are also seen. The cause of ascites in congenital CMV infection is not certain. Contributing factors may include low serum protein levels due to hepatic dysfunction and portal obstruction resulting from periportal inflammation.

Associated Anomalies

Isolated ascites is an uncommon finding in fetuses with CMV infection but may occur. Cardiovascular, gastrointestinal (GI), musculoskeletal, and ocular lesions may be found in association with the classic features. Petechiae, sensorineural hearing loss, and poor intellectual development may also occur after birth.

Differential Diagnosis

Because ascites is often the first manifestation of hydrops, the differential diagnosis for fetal ascites is essentially the same as with generalized hydrops, which includes many congenital infections. Conditions that present with intracranial calcifications (such as tuberous sclerosis), hyperechoic bowel (cystic fibrosis and Down syndrome), and hepatomegaly (primary liver disease or extramedullary hematopoiesis) should be considered.

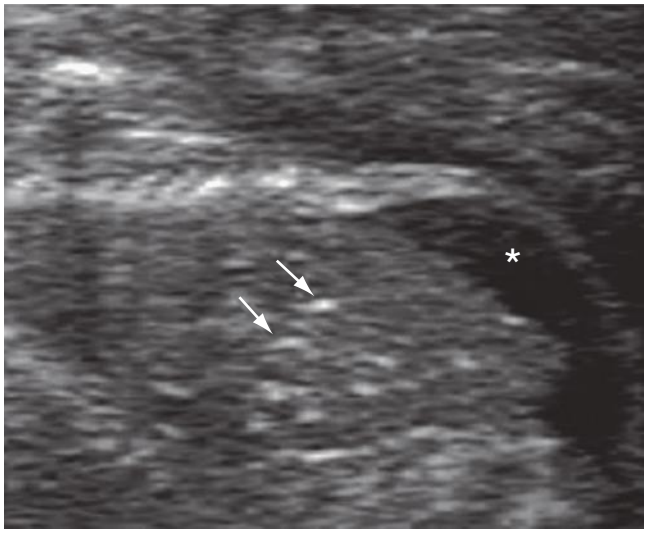

FIG 16-3 Sonogram of a second trimester fetus with proven cytomegalovirus infection. Hepatic calcifications (*arrows*) are seen as well as fetal ascites (*asterisk*).

Prognosis

In general, neonates with symptomatic CMV infection do poorly, with a neonatal mortality rate of 5%, and 50% to 60% of survivors suffer severe long-term neurologic morbidity. CMV hepatitis is reversible in survivors, but intellectual disability, motor deficits, and hearing loss are expected long-term sequelae. Late sequelae, such as sensorineural hearing loss and neurodevelopmental disorders, occur in 10% to 15% of infants lacking symptoms at birth. Pediatric neurologic morbidity is related to the degree of antenatal ventriculomegaly and, when greater than 15 mm, is associated with an increase in abnormal neurologic development. A normal ultrasound examination does not exclude the possibility of symptoms in the newborn or long-term complications.

Recurrence Risk

Given that viral infection confers immunity in most patients, there is only a small theoretical risk of reinfection in another pregnancy.

Management

Termination of pregnancy can be offered before viability. If continuation of the pregnancy is chosen, follow-up with ultrasound examinations every 2 to 4 weeks is recommended to monitor for growth restriction, hydrops, and other fetal manifestations. Antiviral medications have not been shown to decrease the rate of perinatal transmission. Trials are under way for treatment of pregnant women with CMV infection early in pregnancy with hyperimmunoglobulin therapy.

Fetal Parvovirus B19 Infection

Definition

Infection with parvovirus B19 causes erythema infectiosum and is a common childhood illness characterized by a "slapped cheek" facial appearance and a lacy erythematous rash on the trunk and extremities. Patients may have systemic symptoms prior to the appearance of the rash, including arthropathy.

Synonym

Fetal parvovirus B19 infection is also known as fifth disease.

Etiology

Acute maternal parvovirus B19 viremia leads to transplacental passage of the B19 virus and subsequent fetal infection.

Incidence

Acute parvovirus B19 infection occurs in 3% to 4% of pregnant women, with the highest infection rates in school teachers and day care workers. Approximately 35% to 53% of pregnant women have immunity from a prior infection.

Pathogenesis

The interval between maternal infection and fetal hydrops is about 3 weeks, and 93% of cases of fetal hydrops occur within 8 weeks of maternal diagnosis. Acute infection can lead to fetal loss or hydrops fetalis. Hydrops occurs because parvovirus B19 preferentially infects rapidly dividing cells and is cytotoxic to fetal red blood cell precursors, leading in some cases to severe fetal anemia and subsequent hydrops. Parvovirus B19 can also infect myocardial cells and cause myocarditis;

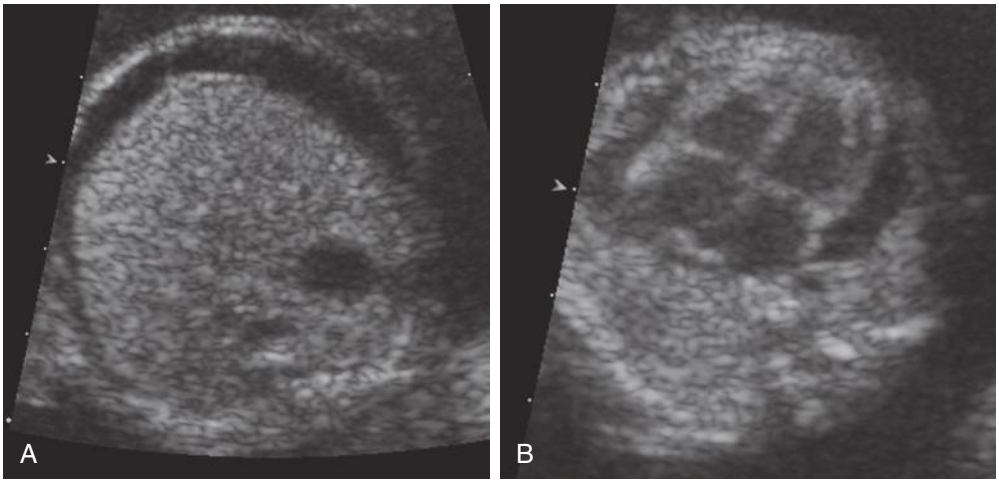

FIG 16-4 Parvovirus infection. Ascites (**A**) and pericardial effusions (**B**) in a fetus with anemia due to parvovirus infection. Fetal ascites is often the initial sonographic finding in parvovirus infection.

this infection may also initiate apoptosis in cells. The risk of hydrops is greater if infection occurs in the first half of pregnancy. Hydrops can either lead to rapid fetal death or resolve spontaneously (although the rate of spontaneous resolution is uncertain).

Associated Anomalies

In case reports, other congenital abnormalities have been noted, including ocular abnormalities, hydrocephalus, cleft lip/palate, joint webbing, musculoskeletal anomalies, hepatocellular damage, myocarditis, congenital cardiomyopathy, and myositis.

Diagnosis

Acute maternal parvovirus infection can be diagnosed by positive IgM serologic findings; IgM can be detected 10 days after infection and may persist for 3 months or longer. IgM can be falsely negative, however, and failure to detect IgM antibodies therefore does not rule out B19 infection. Parvovirus B19 IgG develops several days after IgM and indicates past infection. Maternal B19 viremia can also be confirmed by PCR with improved sensitivity. Fetal parvovirus infections can be confirmed by PCR for B19 DNA in amniotic fluid.

Differential Diagnosis

Differential diagnosis includes other conditions leading to nonimmune hydrops in the fetus.

Prognosis

Risk of fetal death is largely limited to parvovirus B19 infections diagnosed in the first half of pregnancy (13% in first trimester, 9% from weeks 13 to 20, and <1% after 20 weeks). Intrauterine transfusion of hydropic fetuses improves prognosis. In addition to fetal anemia, severe fetal thrombocytopenia can occur and lead to exsanguination at the time of intrauterine red blood cell transfusion. Children who survive fetal hydrops generally do well; an increased risk of developmental delay has been reported, but this has not been demonstrated in all studies.

Recurrence Risk

There is virtually no recurrence risk because pathogenesis occurs with primary maternal parvovirus B19 infection.

Management

Pregnant women exposed to parvovirus should have serologic testing for B19 IgM and IgG; positive IgG indicates maternal immunity, and the fetus should be protected. A positive IgM antibody indicates acute infection. Fetal intervention prior to 18 to 20 weeks is often not feasible, and transfusions this early in gestation are associated with an increased risk for fetal loss. Women diagnosed after 20 weeks should receive weekly ultrasound examinations to assess for fetal anemia and hydrops for at least 8 weeks after infection. If severe anemia is detected, intrauterine fetal blood transfusion is indicated.

Fetal Rubella Syndrome

Definition

Fetal rubella syndrome is a congenital disorder resulting from primary maternal infection with the rubella virus. It is characterized by deafness, mental retardation, congenital cataract, heart defects, and other structural anomalies found with variable severity and frequency. The rate of congenital infection with acute rubella during pregnancy is higher than 90% in the first 12 weeks of pregnancy, approximately 60% in weeks 13 to 17, 25% in weeks 18 to 24, and increases again during the last month of pregnancy.

Synonyms

Synonyms for fetal rubella syndrome are fetal rubella effects, congenital rubella syndrome, and German measles.

Etiology

Fetal rubella is caused by an RNA togavirus, which is the only member of the genus *Rubivirus*. The fetus is infected by transplacental transmission followed by hematogenous spread.

Recurrence Risk

There is no recurrence risk of fetal rubella syndrome.

Incidence

Cases of fetal rubella syndrome are rare in the United States since 2004 following comprehensive vaccination; however, reinfection after vaccination is possible. There were 13 cases reported in the United States between 2001 and 2004. It remains a clinical issue in other parts of the world.

Diagnosis

The most frequent sonographic findings are cardiac malformations (in particular, septal defects), eye defects (cataracts, microphthalmia, and retinopathy), microcephaly, hepatomegaly, splenomegaly, and growth restriction. The risk of congenital defects is limited to maternal infection during the first 16 weeks of pregnancy. Sensorineural hearing loss and developmental delay are also associated with congenital rubella sydrome. The confirmation of fetal infection can be made by isolating rubella viral RNA from amniotic fluid samples and testing using PCR.

Associated Anomalies

Occasionally, the following anomalies can be associated with the classic findings of fetal rubella syndrome: renal disorders, hypospadias, cryptorchidism, meningocele, glaucoma, patent ductus arteriosus, and peripheral pulmonary stenosis.

Differential Diagnosis

Other conditions associated with congenital hepatomegaly and cataracts should be considered. This includes other congenital infections (TORCH [*t*oxoplasmosis, *o*ther infections, *r*ubella, *c*ytomegalovirus, *h*erpes simplex]), fetal anemia, fetal liver tumors, chondrodysplasia punctata, Neu-Laxova syndrome (NLS), Smith-Lemli-Opitz (SLO) syndrome, and Walker-Warburg syndrome.

Prognosis

Spontaneous abortion and intrauterine death may occur. The postnatal impact of intrauterine infection varies from absence of any defect to all the anomalies mentioned earlier with variable severity. The virus may remain for years in body tissues, causing complications of chronic infection (such as diabetes mellitus from chronic viropathy of the pancreas).

Management

Termination of pregnancy should be discussed when fetal infection is detected during the first trimester, owing to the severity of the condition in this group. After viability, monthly ultrasound examinations for growth and follow-up of the anomalies are recommended.

Prevention

Women found to be rubella nonimmune during pregnancy should be offered vaccination postpartum prior to discharge from the hospital. Breastfeeding is not a contraindication to vaccination.

Fetal Syphilis

Definition

Fetal syphilis is caused by fetal infection with the spirochete *Treponema pallidum,* which readily crosses the placenta leading to fetal infection.

Synonym

A synonym for fetal syphilis is congenital syphilis.

Etiology

Maternal infection with *T. pallidum* leads to transplacental transmission of the virus and resultant fetal infection.

Incidence

Incidence in 2008 was 10.1 cases per 100,000 liveborn infants with many cases found in women without prenatal care. The risk of transmission is higher for primary and secondary syphilis (50%) than for early latent (40%) and late (10%) syphilis. Transmission can occur at any gestational age. The frequency of vertical transmission increases as gestation advances but severity decreases with infection later in pregnancy.

Diagnosis

In women with positive syphilis testing, clinical findings concerning for congenital syphilis include growth restriction, as well as liver and placental findings. Signs of liver dysfunction include hepatomegaly and ascites, which can lead to nonimmune hydrops. The placenta is typically large and edematous. Silver-staining of the placenta following delivery is positive for spirochetes. Fetal serologic tests are positive for antitreponemal IgM.

Associated Anomalies

Clinical findings in neonates may include the following:

- Early congenital syphilis: hepatomegaly, syphilitic rhinitis ("snuffles"), maculopapular rash, generalized lymphadenopathy, and skeletal abnormalities.
- Late congenital syphilis (generally a result of gumma formation in various tissues): facial features (frontal bossing, saddle nose, short maxilla), eye findings (interstitial keratitis, glaucoma, corneal scarring, optic atrophy), sensorineural hearing loss, Hutchinson teeth, mulberry molars, perforation of hard palate, rhagades, gummas,

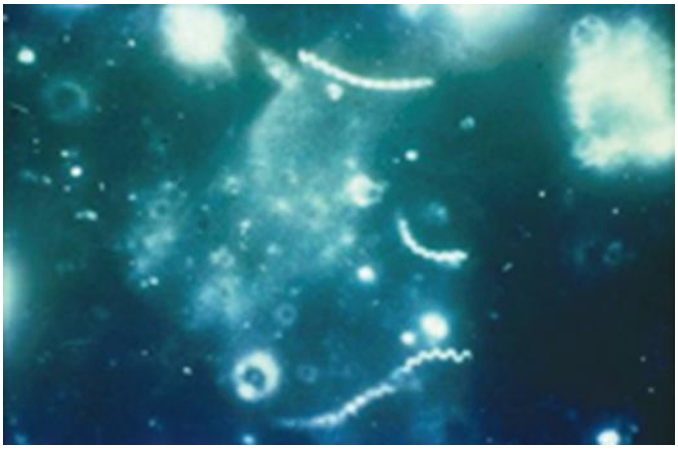

FIG 16-5 Syphilis. Darkfield micrograph of *Treponema pallidum*, the organism that causes congenital syphilis. (From Centers for Disease Control and Prevention: Sexually Transmitted Diseases, 2016. Available at http://www.cdc.gov/std/syphilis/images.htm.)

anterior bowing of shins ("saber shins"), and paroxysmal cold hemoglobinuria.

Differential Diagnosis

Findings in neonates can resemble other congenital infections.

Prognosis

The severity of fetal effects depends on the duration of infection as well as the stage of development at the time of infection.

Recurrence Risk

Recurrence is likely only if maternal syphilis infection remains untreated.

Management

All women presenting for prenatal care should be evaluated for syphilis infection. If positive, penicillin treatment should be given; regimens vary according to the chronicity of the disease. If the duration of the disease is unknown, three doses of benzathine penicillin given at weekly intervals is recommended. If maternal syphilis is treated at least 30 days prior to delivery, only 1% to 2% of infants will be infected. This rate is greater than 70% if maternal syphilis remains untreated. If maternal syphilis is diagnosed after 20 weeks' gestation, an ultrasound examination should be obtained to assess for congenital syphilis.

Fetal Toxoplasmosis Syndrome

Definition

Toxoplasmosis is caused by infection with the protozoan parasite *Toxoplasma gondii*. Toxoplasmosis is normally asymptomatic in immunocompetent individuals. Acute infections in pregnant women can be transmitted to the fetus and cause severe illness (mental retardation, blindness, and epilepsy). The risk of maternal-fetal transmission increases with gestational age at the time of exposure, whereas the incidence of severe disease decreases.

Synonym

Fetal toxoplasmosis syndrome is also known as congenital toxoplasmosis.

Incidence

An estimated 400 to 4000 cases of congenital toxoplasmosis occur annually in the United States. Of the 750 deaths attributed to toxoplasmosis each year, 375 (50%) are believed to be caused by eating contaminated meat, making toxoplasmosis the third leading cause of food-borne deaths in the United States. The incidence of toxoplasmosis acquisition during pregnancy ranges from 1 to 4 per 10,000. Half of fetuses escape the infection, one third have subclinical infection, and about 10% have severe infection.

Etiology

Fetal toxoplasmosis is caused by transplacental transmission of parasites following maternal primary infection. Transmission from mothers with chronic infection via reactivation is rare but can be caused by immunologic dysfunction. The rate of fetal transmission increases greatly as the gestational age at time of seroconversion increases, with transmission rates of 25%, 54%, and 65%, in the first, second, and third trimesters, respectively.

Pathogenesis

The fetus is infected hematogenously through the placenta during parasitemia in the mother. Ocular toxoplasmosis causes irreversible damage to the retina in utero. The fetus and infant mount inflammatory responses that may contribute to ocular damage.

Diagnosis

The classic triad suggestive of congenital toxoplasmosis includes chorioretinitis, intracranial calcifications, and hydrocephalus. Less common findings include ascites, pericardial and pleural effusions, and intrahepatic densities. However, most infants infected in utero are born with no obvious signs of toxoplasmosis on routine examination, but many develop learning and visual disabilities later in life. If left untreated, congenital toxoplasmosis can be associated with severe and even fatal disease. Other findings include microcephaly, encephalomyelitis, seizures, intellectual disability, ascites, and hepatosplenomegaly. The diagnosis can be made by using PCR to detect of *Toxoplasma gondii* in amniotic fluid, with increased sensitivity later in pregnancy.

Differential Diagnosis

Other TORCH infections should be considered.

Prognosis

Approximately 75% of congenitally infected newborns are asymptomatic.

FIG 16-6 Severe dilatation of posterior horns of the lateral ventricles in a fetus with toxoplasmosis infection. (Courtesy of Julio Cesar Coub, 2006.)

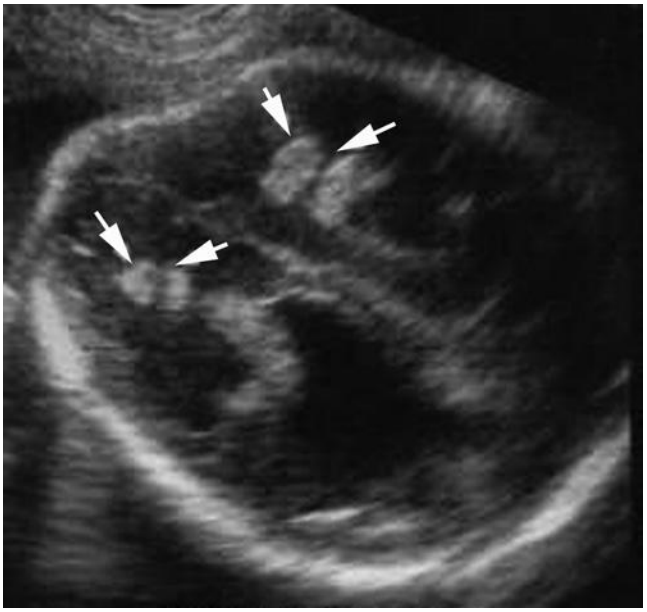

FIG 16-7 Toxoplasmosis. Intracranial calcifications (*arrows*) in a fetus with toxoplasmosis infection. (Courtesy of Julio Cesar Coub, 2006.)

Recurrence Risk

There is typically no recurrence risk.

Management

Depending on gestational age and whether the fetus is known to be infected, pregnant women have been treated with the antibiotic spiramycin or with sulfadiazine alone or the combination of pyrimethamine and sulfadiazine. Treatment of acute infection during pregnancy has been associated with an approximately 50% reduction in fetal infection.

Prevention

Toxoplasmosis infection can be prevented in large part by cooking meat to a safe temperature and peeling or thoroughly washing fruits and vegetables before eating. Pregnant women should avoid changing cat litter or, if no one else is available to change the cat litter, use gloves, then wash their hands thoroughly.

Fetal Varicella Zoster

Definition

Fetal varicella zoster is characterized by abnormalities of multiple organs caused by fetal infection with varicella following maternal chickenpox infection.

Synonyms

Fetal varicella zoster is also known as congenital varicella syndrome, varicella embryopathy, and chickenpox.

Incidence

The incidence of maternal varicella infection was 1 to 5 in 10,000 pregnancies in the United States in the 1980s but has decreased since vaccination began in 1995. The risk of fetal involvement among all pregnant women infected with varicella varies from 1% to 20%. First trimester varicella infections have been associated with an increased risk of spontaneous abortion. Second trimester varicella infections have been associated with 2% risk of a congenital syndrome characterized by limb hypoplasia, cutaneous scars, cataracts, microcephaly, and cortical atrophy.

Etiology

Herpesvirus is the etiologic agent.

Recurrence Risk

Recurrence risk is less than 1%.

Diagnosis

Maternal infection at any time in pregnancy exposes the fetus to a high risk of transplacental contamination and warrants follow-up. The risk of fetal anomalies, however, is the greatest from 8 to 20 weeks' gestation. Sonographic signs of fetal disease include fetal demise, growth restriction, musculoskeletal abnormalities (such as clubfeet and abnormal position of the hands, caused by both necrosis and denervation of the affected tissue), limitation of limb extension due to cicatrices formation, cutaneous scars, limb hypoplasia, chorioretinitis, congenital

cataracts, microphthalmia, hydrops, polyhydramnios, hyperechogenic hepatic foci, cerebral anomalies (such as ventriculomegaly or atrophy and microcephaly), disseminated foci of necrosis and microcalcifications, encephalitis, and echogenic bowel in the second trimester. The placenta can show a multifocal chronic villitis with multinucleated giant cells. Fetal infection can be demonstrated by detection of varicella zoster virus DNA by PCR in fetal blood and amniotic fluid.

Pathogenesis

Maternal viremia leads to placental infection with subsequent fetal transmission. Direct damage occurs to fetal tissues by the neurotropic varicella virus.

Associated Anomalies

Congenital anomalies in multiple organs with variable severity can be seen in varicella embryopathy. Among survivors, intellectual disability, seizures, and limitation of movements may develop after birth. The virus may cause serious infections, particularly pneumonia, in adult women.

Differential Diagnosis

Other viral infections, vascular accidents, and amniotic band syndrome should be considered.

Prognosis

The severity of fetal involvement varies from dermatologic lesions to lethal disseminated disease. Limited scarring tends to have an excellent prognosis. Fetal brain disruptions, or severe maternal varicella with development of lethal maternal pneumonia and encephalitis, are indicators of an extremely high risk for fetal demise. The rate of fetal demise varies from 39% to 61%. Maternal infection in the first and early second trimester has a higher association with fetal anomalies, whereas third trimester infections have a higher risk for varicella zoster development at the neonatal period. A life-threatening illness may occur in the newborn when delivery occurs within 5 days of the onset of maternal illness.

Management

Termination of pregnancy can be offered before viability. If continuation of the pregnancy is chosen, ultrasound follow-up is recommended to assess for fetal anomalies, limb contractures, and other signs of fetal compromise. If maternal seroconversion is suspected for varicella zoster, prenatal sonography and MRI may document the extent of tissue damage and assist in counseling. After a therapeutic abortion, fetal infection can be confirmed by detection of varicella zoster viral DNA in fetal tissues and the placenta, as well as by histopathologic findings such as miliary calcified necroses in fetal organs.

Prevention

Serologic testing and vaccination should be offered to women of childbearing age, and women should be questioned prior to conception about varicella immunity. Susceptible pregnant patients should be counseled to avoid contact with individuals who have chickenpox. If exposure occurs, varicella zoster immunoglobulin should be administered within 96 hours in an attempt to prevent maternal infection. Susceptible neonates should also receive varicella zoster immunoglobulin. Acyclovir is active against the varicella zoster virus, and treatment is indicated in seriously ill adults and neonates.

FIG 16-8 Varicella zoster infection. The fetal face at autopsy (26 weeks). Note the collapsed cranium, intact skin (very little maceration), disproportionate necrosis of the ocular globes, and flattened midface. (Courtesy of R.R. Lebel, 1992.)

TERATOGENS

Fetal Alcohol Syndrome/Fetal Alcohol Effects

Alcohol use during pregnancy results in a spectrum of adverse outcomes known as fetal alcohol spectrum disorders. Fetal alcohol syndrome (FAS) is one of these disorders. FAS is characterized by specific facial abnormalities and significant impairments in neurodevelopment and physical growth. Children exposed to alcohol (approximately 45 to 50 g of ethanol per day or equivalent) in utero suffer from growth and mental retardation, physical abnormalities, and immune dysfunction. There is no "threshold," so some fetuses exhibit signs of fetal alcohol effects at lower exposure. Recommendations for clinicians regarding assessment of thresholds published by the National Institute on Alcohol Abuse and Alcoholism recommend that any woman who reports drinking more than seven drinks per week or more than three drinks on any given day be further assessed for risk of developing alcohol-related problems.

Synonyms

FAS is one of the fetal alcohol spectrum disorders.

Incidence

The incidence of FAS ranges from 2 to 30 per 10,000 live births. FAS is the most common cause of intellectual disability in the United States and is thought to occur in 0.5 to 2.0 in 1000 births. The true extent of teratogenic injury from alcohol exposure exceeds the clinically recognized prevalence of FAS, because behavioral and physical teratogenesis may be present in the absence of full expression of the syndrome.

Etiology/Pathogenesis

FAS is caused by direct toxicity of alcohol and its metabolites that cross the placenta and are not detoxified by the fetal liver. Alcohol is a teratogen and inflicts irreversible damage on the CNS. The rate of alcohol elimination from the fetal compartment is only 3% to 4% that of the maternal rate. Alcohol has fetal effects in all trimesters of pregnancy.

Diagnosis

The findings include microcephaly, long round philtrum, small micrognathia, cleft palate, suppression of the cupid arch, microphthalmia, microcephaly, dysgenesis of the corpus callosum, malformed ears, atrial septal defect (ASD), ventricular septal defect (VSD), and growth restriction predominantly involving the limbs and occurring early without oligohydramnios. This lack of specificity suggests that the FAS facies may be a common teratogenic expression of exposure to a variety of substances occurring during a defined period of fetal development.

Differential Diagnosis

Other conditions that involve growth restriction and microcephaly, such as congenital infections and chromosomal anomalies, should be considered.

Prognosis

Intellectual disability and delayed growth persist postnatally. Most children with FAS have mild to moderate intellectual disability, but this

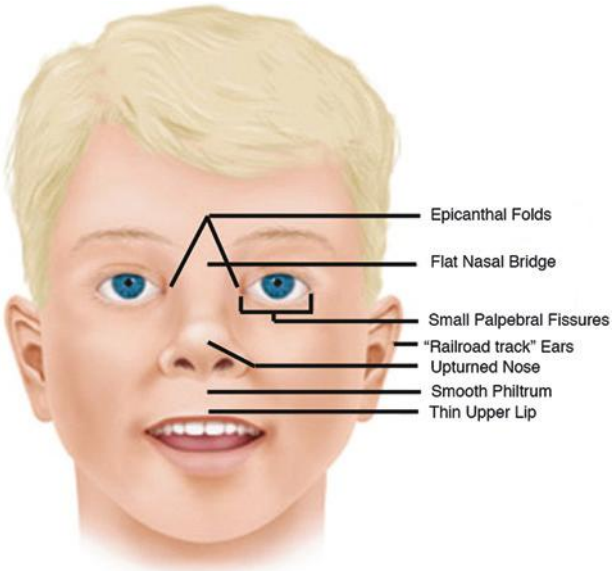

FIG 16-9 Characteristic facial features in a child with fetal alcohol spectrum disorders. Findings may include a smooth philtrum, thin upper lip, upturned nose, flat nasal bridge and midface, epicanthal folds, small palpebral fissures, and small head circumference. (Courtesy Darryl Leja, NHGRI, National Institutes of Health.)

FIG 16-10 Characteristic features of an ear of a child with fetal alcohol spectrum disorders. Note the underdeveloped upper part of the ear parallel to the ear crease below ("railroad track" appearance). (Courtesy Darryl Leja, NHGRI, National Institutes of Health.)

FIG 16-11 Characteristic features of a hand of a child with fetal alcohol spectrum disorders. Note the curved fifth finger (clinodactyly) (*small arrow*) and the upper palmar crease (*large arrow*) that widens and ends between the second and third fingers ("hockey stick" crease). (Courtesy Darryl Leja, NHGRI, National Institutes of Health.)

can vary widely. The severity of intellectual disability appears related to the severity of growth deficits and dysmorphogenesis, such that the more phenotypically affected individuals have lower IQ scores. Hyperactivity is frequently observed. As adults, psychiatric disorders are highly prevalent in individuals with FAS, affecting more than 70% in one series, in which 60% had alcohol or drug dependence, 44% depression, and 40% psychosis.

Recurrence Risk

Recurrence risk is high (up to 70%) in subsequent pregnancies if mothers continue to drink alcohol.

Management

The management of these pregnancies should be aimed at reducing alcohol consumption; few programs have had significant efficacy.

Fetal Valproic Acid Syndrome

Definition

Fetal valproic acid exposure syndrome results from maternal valproate (an anticonvulsant) use during pregnancy and is characterized by CNS dysfunction, spina bifida, developmental delay, fetal growth restriction, and cardiac anomalies.

Synonym

Depakote exposure is a synonym for fetal valproic acid syndrome.

Incidence

Fetal valproic acid syndrome is rare, and the incidence is unknown. Any epileptic pregnant mother has two to three times increased risk for congenital anomalies compared with the general population. If the exposure to valproic acid takes place between the 17th and 30th days after fertilization, the incidence of neural tube defects approaches 1% to 2%. In general, the teratogenic risks are higher with increasing doses of valproic acid, with a significantly higher rate of malformations in doses up to 1000 mg/day.

Etiology

Exposure to valproic acid is the cause of this syndrome.

Pathogenesis

The pathogenesis of fetal valproic acid syndrome is unknown.

Diagnosis

The findings include cardiovascular abnormalities, hypotonia, spina bifida, hypospadias, and limb reduction. The facial appearance can be characterized by an oral cleft, small broad nose, small ears, flat philtrum, a long upper lip with shallow philtrum, and micrognathia/retrognathia. Fetal growth restriction, microcephaly, generalized hypertrichosis sparing palms and soles, coarse face, gum hypertrophy, clubfeet and clubhands, musculoskeletal abnormalities, genital abnormalities, and urogenital defects may also be present. Heart defects have also been reported. In 26% of patients with fetal valproic acid exposure syndrome, cardiovascular abnormalities, most frequently VSDs, aortic or pulmonary stenosis, and persistent ductus arteriosus also occur. Pulmonary hypoplasia is also reported. Epilepsy and intellectual disability may develop after birth.

Associated Anomalies

Associated anomalies include omphalocele, inguinal hernia, duodenal atresia, and scoliosis. Hyperbilirubinemia, hepatotoxicity, transient hyperglycinemia, afibrinogenemia, and fetal or neonatal distress may be found.

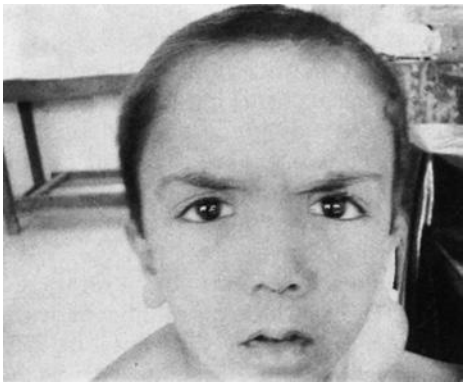

FIG 16-12 Fetal valproate syndrome. Note low-set ears, slanting forehead, broad nasal bridge, hypertelorism, epicanthal folds, depressed nasal bridge, long philtrum, upturned nose, thin upper llip, and small mouth. (From Kulkarni ML, Zaheeruddin M, Shenoy N, Vani HN: Fetal valproate syndrome. Indian J Pediatr 73(10):937-939, 2006.)

Differential Diagnosis

Neural tube defects of alternative origin should be considered. However, the clinical history in the presence of spina bifida and cardiac anomaly should suggest the diagnosis.

Prognosis

Fetuses with major anomalies have a poor prognosis. Metabolic disturbances may also complicate the neonatal period. Affected children can die in infancy, and the surviving patients can have intellectual disability.

Recurrence Risk

If the mother is exposed to valproic acid in a second pregnancy, the teratogenic effect is likely to be similar.

Fetal Warfarin Syndrome

Definition

Fetal warfarin syndrome is characterized by specific bone and cartilage abnormalities in the fetus, including nasal hypoplasia, limb hypoplasia, and stippled epiphyses. It is caused by fetal exposure to warfarin between weeks 6 and 12 of gestation.

Synonyms

Fetal warfarin syndrome has also been described as warfarin embryopathy and coumadin exposure.

Incidence

A wide range has been reported, but the best estimate is that less than 10% of exposed fetuses will have embryopathy. The teratogenic effect is dose-dependent, with greater safety if the dose is less than 5 mg/day.

Etiology

Warfarin freely crosses the placenta and is a known teratogen, with the highest risk between weeks 6 and 12 of gestation.

Pathogenesis

The pathogenesis is unknown. Some hypotheses suggest that the drug interferes with post-translational modification of calcium-binding proteins essential for the development of bony structures.

Diagnosis

Common sonographic findings include developmental abnormalities of bone and cartilage, specifically nasal and limb hypoplasia and stippled epiphyses.

Associated Anomalies

CNS abnormalities have been more rarely reported and include microcephaly, optic atrophy, intellectual disability, hypotonia, and spasticity.

Differential Diagnosis

Differential diagnosis includes other disorders affecting the bone and cartilage, specifically chondrodysplasia punctata.

Prognosis

Because warfarin freely crosses the placenta, it can cause fetal bleeding at any gestational age. The most serious fetal complications are related to cerebral hemorrhage. Data on long-term survivors are lacking.

Recurrence Risk

The recurrence risk is unknown. Fetal warfarin syndrome is related to warfarin exposure in subsequent pregnancy.

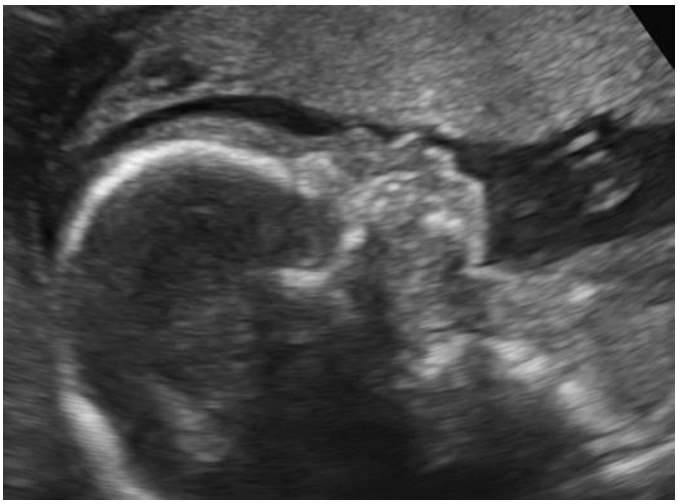

FIG 16-13 Profile of a fetus with nasal hypoplasia, as is seen with fetal warfarin syndrome.

Management

When detected prior to viability, termination of the pregnancy can be offered. If the pregnancy continues, no alteration in management is needed. If warfarin is continued throughout the pregnancy, it should be discontinued at 34 to 36 weeks' gestation and an alternative agent should be used for anticoagulation to minimize the risk of fetal bleeding at the time of delivery.

Maternal Diabetes/Caudal Regression Syndrome

Definition

Caudal regression syndrome is a rare congenital defect, characterized by the absence of the sacrum, variable defects of portions of lumbar spine, and anomalies in other systems.

Synonyms

Caudal dysplasia sequence and sacral agenesis are other terms that have been used to describe caudal regression syndrome.

Incidence

The incidence of caudal regression syndrome is 0.25 to 1 per 10,000 normal pregnancies. This risk is 200 to 250 times higher in diabetic pregnancies.

Etiology

The cause is unknown, but caudal regression syndrome is associated with maternal diabetes in 16% of the affected fetuses.

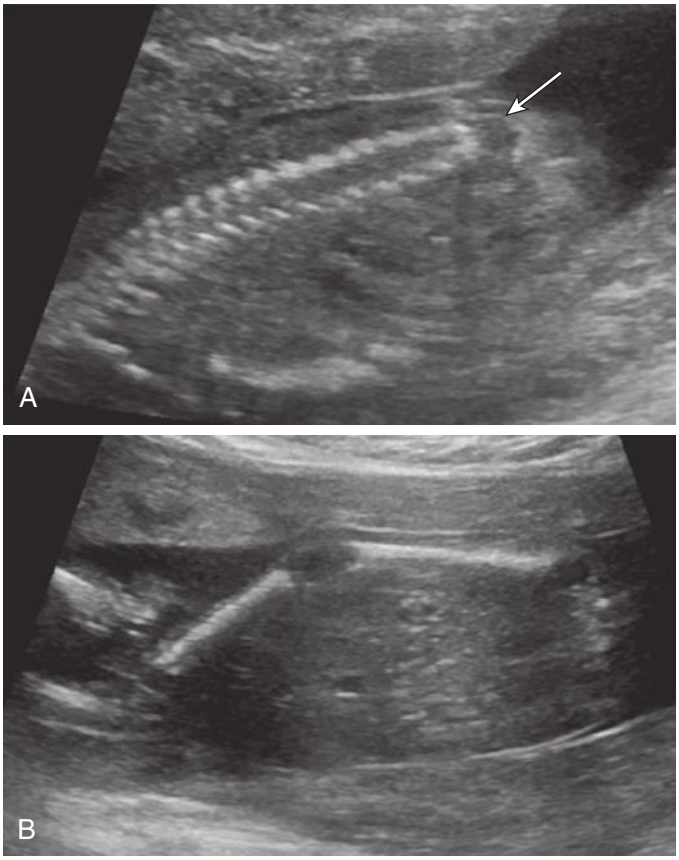

FIG 16-14 Caudal regression syndrome associated with poorly controlled maternal diabetes. **A,** Absent distal sacral spine (*arrow*); **B,** fixed extension of the lower extremity.

Recurrence Risk

This anomaly is not thought to be hereditary, and the recurrence risk is very small, although it is higher in diabetics.

Diagnosis

The sonographic findings are variable, and depend on the extent and severity of the defect. It ranges from complete absence of the sacrum associated with abnormalities of the lumbar spine and lower extremities (such as clubfeet and contractions of the knees and hips) to abnormalities of the sacrum without associated defects. The most typical findings are the absence of a few vertebrae, the shield-like appearance of the fused or approximated iliac wings, and decreased interspace between the femoral heads. Some sonographic planes of section will intersect the fetus at such an angle that no spine is visible, a very striking and probably pathognomonic finding. Decreased movement of the legs is frequently observed. First trimester diagnosis may be difficult because of incomplete ossification of the sacrum at that time. A short crown-rump length and abnormal appearance of the yolk sac have been proposed as early sonographic signs of caudal regression syndrome.

Genetics

The genetics of caudal regression syndrome is unknown.

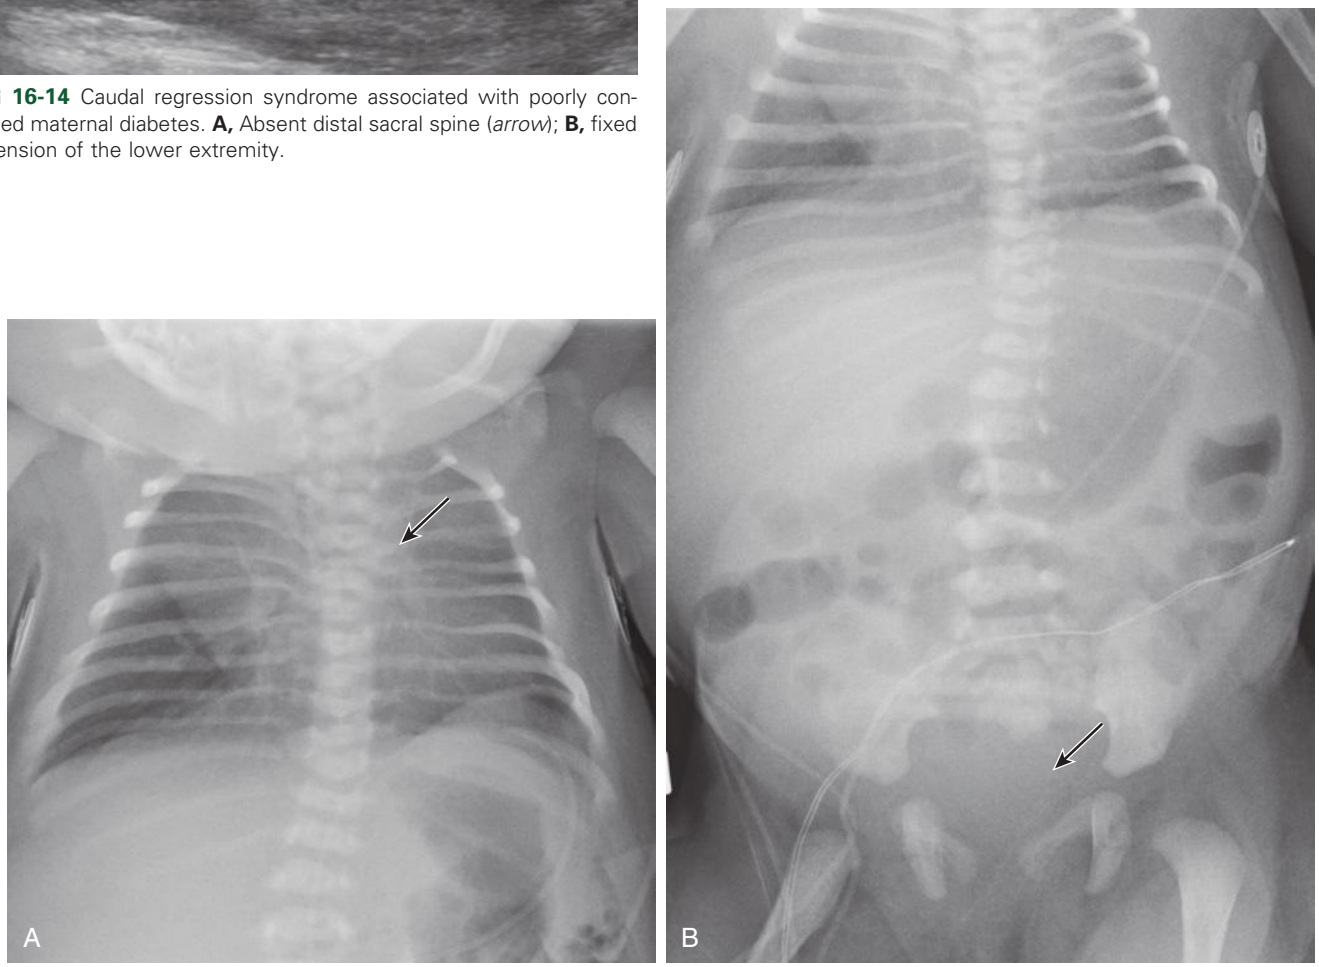

FIG 16-15 Caudal regression syndrome associated with poorly controlled maternal diabetes. Postnatal radiographs demonstrate vertebral segmentation abnormality (**A**) (*arrow*) and absent sacrum (**B**) (*arrow*).

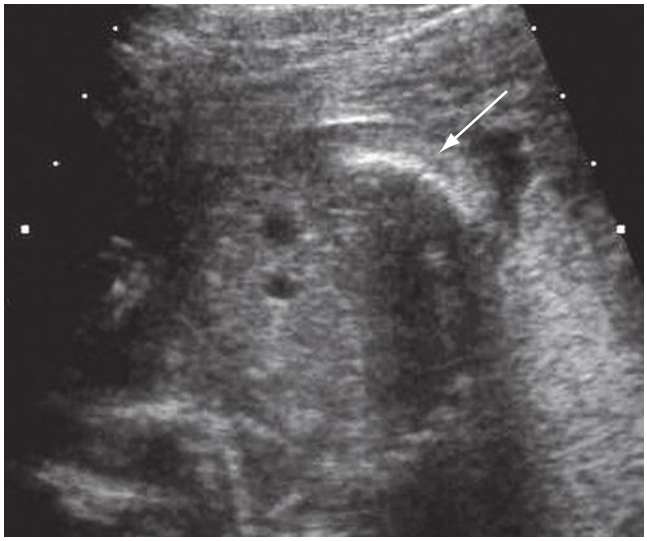

FIG 16-16 Caudal regression syndrome. The lack of sacrum allows the iliac wings to be approximated, giving them a shield-like appearance (*arrow*).

Pathogenesis

This syndrome is thought to be due to disrupted maturation of the caudal portion of the spinal cord complex before 4 weeks' gestation, leading to motricity deficits and neurologic impairment, varying from incontinence of urine and feces to complete neurologic loss.

Associated Anomalies

Anomalies of the central nervous, musculoskeletal, genitourinary, cardiac, respiratory, and GI systems may be found in association.

Differential Diagnosis

Sirenomelia is the main alternative diagnosis and was thought to be the most severe form of caudal regression syndrome previously; it is now considered a separate entity. Fusion of the lower extremities is generally seen in sirenomelia.

Prognosis

Prognosis depends on the severity of the spinal defect and associated anomalies, but the vast majority of survivors require urologic and orthopedic intervention. Severe forms are commonly associated with cardiac, renal, and respiratory problems, which are responsible for early neonatal death.

CENTRAL NERVOUS SYSTEM

Characteristic CNS abnormalities are seen in a majority of genetic syndromes, and, thus, an exhaustive list of associated syndromes is beyond the scope of this chapter. CNS abnormalities can be seen in all regions of the brain and include Chiari malformation, holoprosencephaly, lissencephaly, polymicrogyria, cerebellar hypoplasia, agenesis of the corpus callosum, hydrocephalus, neural tube defects, and CNS tumors. Many of these abnormalities and associated conditions are discussed in more detail in Chapter 9, Ultrasound Evaluation of the Fetal Central Nervous System. In this chapter, several syndromes with prominent CNS findings will be reviewed in greater detail, including Aicardi syndrome, Meckel syndrome (MKS), lissencephaly-associated syndromes (Miller-Dieker, Walker-Warburg, Baraitser-Winter, Norman-Roberts, microlissencephaly, and Neu-Laxova syndromes), septo-optic dysplasia, tuberous sclerosis, and L1 syndrome.

Aicardi Syndrome

Definition

Aicardi syndrome is a neurodegenerative disorder first described in 1965, characterized by cerebral atrophy, intracerebral calcification of the basal ganglia, chronic cerebrospinal fluid lymphocytosis, and negative serologic investigations for common prenatal infections. It was classically characterized by agenesis of the corpus callosum, chorioretinal lacunae, and infantile spasms.

Incidence

More than 100 cases have been reported. It is seen only in females and 47,XXY males.

Etiology

The disorder is thought to be caused by an X-linked dominant de novo gene mutation with lethality in 46,XY males. The causative gene has not been identified.

Genetics

The genetics of Aicardi syndrome are unknown.

Diagnosis

The diagnosis is based on clinical features, including chorioretinal lacunae, brain MRI findings (corpus callosum dysgenesis, cerebral asymmetry, periventricular and intracortical gray matter heterotopia, choroid plexus cysts, choroid plexus papillomas, ventriculomegaly), and skeletal findings (abnormal vertebrae and missing ribs). Increased levels of interferon-α can been found in fetal blood and cerebrospinal fluid.

Associated Anomalies

Other features include characteristic facial features, GI difficulties, small hands, vascular malformations, skin pigmentary lesions, and increased incidence of tumors. Infrequently, there is associated cleft lip and palate.

Differential Diagnosis

Consider other causes of dysgenesis of the corpus callosum, including infectious causes.

Prognosis

Survival is highly variable, with mean age of death at about 8 years old. Patients have profound intellectual disability and severe global

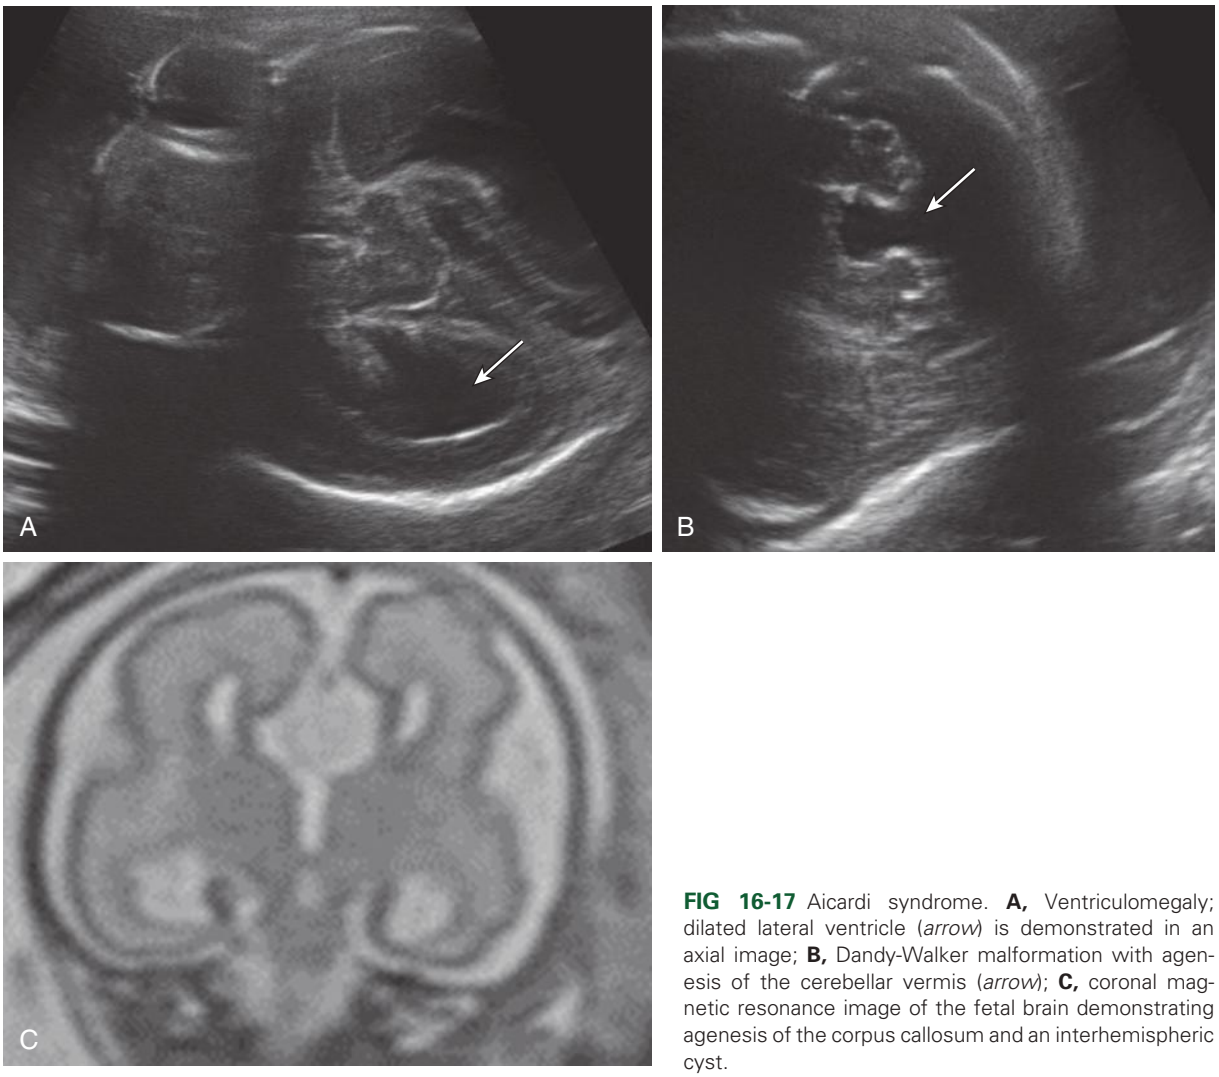

FIG 16-17 Aicardi syndrome. **A,** Ventriculomegaly; dilated lateral ventricle (*arrow*) is demonstrated in an axial image; **B,** Dandy-Walker malformation with agenesis of the cerebellar vermis (*arrow*); **C,** coronal magnetic resonance image of the fetal brain demonstrating agenesis of the corpus callosum and an interhemispheric cyst.

developmental delay. Medically refractory epilepsy with a variety of seizure types develops over time. Multiple antiepileptic drugs are generally required for seizure control. Costovertebral defects can lead to scoliosis. Constipation and other GI problems are frequent.

Recurrence Risk

The recurrence risk is less than 1%.

Meckel Syndrome

Definition

Meckel syndrome (MKS) is a lethal ciliopathy characterized by occipital encephalocele, postaxial polydactyly of the hands and feet, and renal cystic dysplasia. It is commonly associated with ductal plate malformations of the liver.

Synonyms

Dysencephalia splanchnocystica and Meckel-Gruber syndrome are synonyms for MKS.

Incidence

The prevalence of MKS in Finland is estimated to be 1 in 9000. In U.S. and European populations estimates are 1 in 13,250 to 1 in 140,000. MKS is the most common syndromic form of neural tube defects and polydactyly. MKS includes approximately 5% of all neural tube defects.

Etiology

MKS is a ciliopathy, and the proteins encoded by the genes implicated in the disorder encode for proteins involved in primary ciliary function.

Genetics

The disorder is genetically heterogeneous. The earliest implicated genes include *MKS1* and *MKS3*. Polydactyly is commonly found with *MKS1* mutations and is rare with *MKS3* mutations. Milder CNS phenotypes are seen with *MKS3* mutations. The list of involved genes now includes at least 13 genes, *MKS1* through *10*, *TMEM231*, *TMEM237*, and *C5orf42*. Inheritance is autosomal recessive with significant phenotypic variability. Many of the same genes are also involved in Joubert syndrome.

Recurrence Risk

There is a 25% recurrence risk for MKS.

Diagnosis

The disorder can be detected prenatally as early as 11 to 14 weeks. Cystic dysplastic kidneys are seen in almost all cases of MKS (95-100%). The kidneys initially develop microscopic cysts that destroy the parenchyma and enlarge the organ up to 10 or 20 times. Occipital cephalocele is present in 60% to 80%. Maternal serum or amniotic fluid alpha-fetoprotein (AFP) level may be normal, as a membrane may cover the cephalocele. Other CNS findings include Dandy-Walker malformation and hydrocephalus. Postaxial polydactyly is present in 55% to 75% of fetuses. Other limb anomalies, such as bowing and shortening, may also be present. Liver histologic examination commonly demonstrates ductal plate malformations. Unfortunately, the first sonographic finding is often oligohydramnios, which makes the diagnosis more difficult to establish. Oligohydramnios is caused by

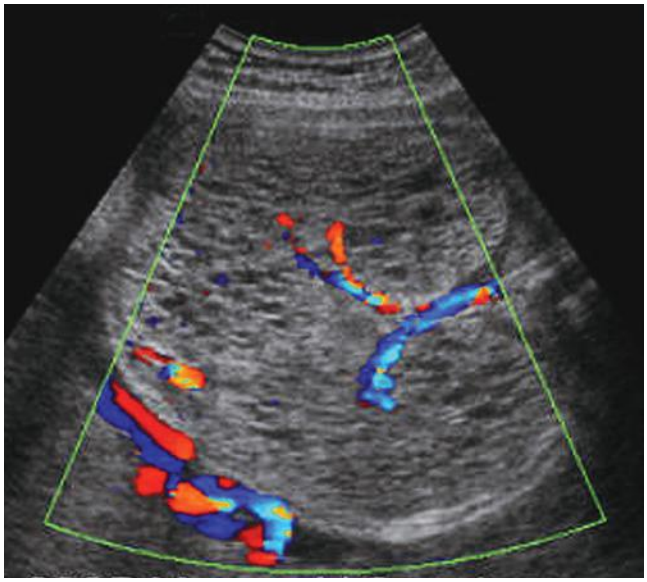

FIG 16-19 Meckel syndrome: cystic dysplastic kidneys. (Courtesy of Marcos V. Sanchez, 2005. Available at thefetus.net.)

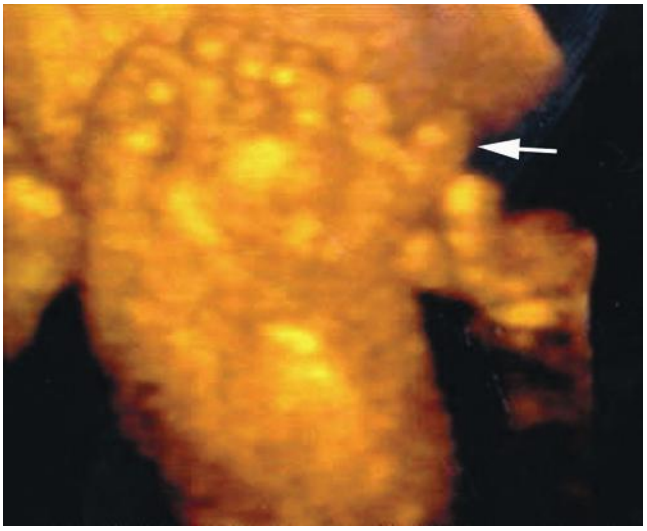

FIG 16-20 Meckel syndrome: polydactyly (*arrow*). (Courtesy of Marcos V. Sanchez, 2005. Available at thefetus.net.)

FIG 16-21 A fetus with Meckel syndrome. Note the small posterior encephalocele, the large abdominal distention due to the bilateral cystic kidneys, and the postaxial polydactyly.

renal dysfunction and develops early in the second trimester when the kidneys replace extracellular diffusion as the main source of amniotic fluid. Some cases of MKS have normal amniotic fluid; thus, the presence of normal fluid does not exclude the diagnosis.

Differential Diagnosis

Conditions that can present with similar findings include trisomy 13 and 18, Joubert syndrome, Bardet-Biedl syndrome, and Smith-Lemli-Opitz syndrome. Karyotype and molecular genetic testing can assist in clarifying the diagnosis.

Prognosis

MKS is a lethal disorder. Most infants are stillborn or die hours or days after birth. A few have survived to a few months of age.

Lissencephaly

Definition

Lissencephaly is a cerebral developmental disorder, with agyria of the brain, which may be accompanied by pachygyria, minimal or no hydrocephalus, a wide cortical mantle, and characteristic dysmorphic features. The reduced or absent brain gyri are caused by disturbed neuronal migration in the neocortex. Miller in 1963 and Dieker in 1969 provided the first descriptions.

Synonyms

See later discussion of specific syndromes.

Incidence

Incidence is uncertain, but estimates range from 11.7 to 40 cases per 1 million births.

Etiology

Many of the causative genes for lissencephaly have now been identified (see later).

Pathogenesis

Lissencephaly is due to abnormal cortical development in which migration of neurons from the ventricular zone (a region close to the lateral ventricles) have slow or arrested migration to the cortical plate, leading to reduced folding or stranded neurons. Lissencephaly is now classified into types including the following.

Classic Types. Classic type lissencephaly is characterized by abnormally thick, four-layer cerebral cortex without other major brain anomalies. It is caused by mutations in 4 genes: *PAFA, H1B1 (LIS1), DCX,* and *TUBA1A*.

Miller-Dieker Syndrome. Miller-Dieker syndrome (classic lissencephaly plus) is characterized by severe, classic lissencephaly, as well as facial dysmorphism (high forehead, micrognathia, short nose with anteverted nares, protuberant upper lip, bitemporal narrowing). Severe developmental delay and intellectual disability are also present. Other associated anomalies include omphalocele, cleft palate, and genital anomalies. Miller-Dieker syndrome results from chromosomal deletions at 17p13.3.

Cobblestone Cortical Malformation. Cobblestone cortical malformation was previously known as type 2 lissencephaly and is distinct from classic lissencephaly. The cortex appears irregular or pebbled and is thinner. There may also be irregularity in the gray-white matter boundary, dilated ventricles, white matter abnormalities, brainstem hypoplasia, and cerebellar abnormalities. Although this group is genetically heterogeneous, it is most commonly due to defects in α-dystroglycan *O*-glycosylation. Known causative genes include *POMT1, POMT2, POMGNT1, FKRP, FKTN, ISPD,* and *LARGE*. The three associated phenotypes are Walker-Warburg syndrome, muscle-eye-brain disease, and Fukuyama congenital muscular dystrophy (ranging from most to least severe).

Walker-Warburg Syndrome. Walker-Warburg syndrome is a congenital muscular dystrophy characterized by eye anomalies and cerebral malformations. A wide variety of eye and cerebral findings have been reported including: microphthalmia, buphthalmos, congenital glaucoma, cataract, optic nerve hypoplasia, persistent hyaloid artery, Dandy-Walker malformation, hydrocephalus, cephalocele, microcephaly, and agenesis of the corpus callosum. Most affected newborns die within the first year of life. No psychomotor development occurs.

Muscle-Eye-Brain Disease. Muscle-eye-brain disease is a milder congenital muscular dystrophy in which ambulation may be acquired. Eye findings are common. The cerebral cortex demonstrates frontoparietal pachygyria, the cerebellar vermis is hypoplastic, and the brainstem is usually hypoplastic.

Fukuyama Congenital Muscular Dystrophy. Fukuyama congenital muscular dystrophy is the most mild of the three phenotypes. Ambulation is often acquired. Eye findings are variable and often mild. Brain findings are variable, but typically less severe than the other phenotypes.

X-Linked Lissencephaly With Ambiguous Genitalia. Males affected with X-linked lissencephaly have severe developmental delay, small or ambiguous genitalia, and seizures. Microcephaly, feeding difficulties, and growth failure are also present. Death in the first year is common. It is caused by muations in the gene *ARX*.

Baraitser-Winter Syndrome. Baraitser-Winter syndrome is a rare syndrome with anterior-predominant pachygyria and characteristic facial features (hypertelorism, broad nose, ptosis, ridged metopic suture, arched eyebrows). Other common features include iris or retinal coloboma, sensorineural deafness, microcephaly, polyhydramnios, increased nuchal translucency, congenital heart defects, and renal tract anomalies. Intellectual disability and epilepsy are common. Caused by gain-of-function mutations in the genes *ACTB* and *ACTG1*.

Lissencephaly With Cerebellar Hypoplasia. Lissencephaly with anterior-predominant pachygyria and severe abnormalities of the cerebellum, brainstem, and hippocampus is caused by mutations in *TUBA1A* and *RELN* (Norman-Roberts syndrome).

Microlissencephaly. Microlissencephaly is lissencephaly with head circumference at birth of less than three standard deviations. It is caused by mutations in the *NDE1* gene.

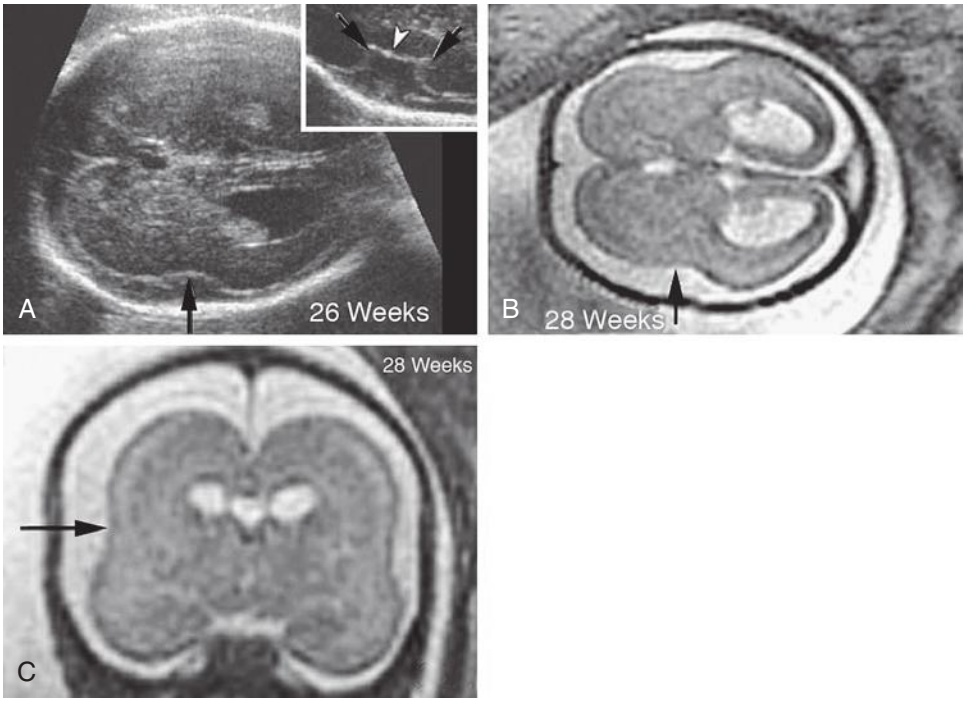

FIG 16-22 Abnormal sylvian fissure/insula at 26 weeks. **A,** Axial ultrasound image at 26 weeks in a fetus with lissencephaly associated with Miller-Dieker syndrome shows a shallow, flat sylvian fissure/insula (*arrow*) with absence of angularity at the insular margins. Inset shows the expected appearance of the sylvian fissure/insula in a 26-week normal fetus. Infolding of the operculum should be seen with acute angles (*black arrows* in inset) at the margins of the insula (*white arrowhead* in inset) at 24.5 weeks' gestation. Axial (**B**) and coronal (**C**) T2-weighted magnetic resonance images at 28 weeks in the same fetus with Miller-Dieker syndrome showing a shallow sylvian fissure (*arrow*). The brain has an hourglass or figure-of-eight appearance on the axial image. Also note the agyria, large subarachnoid space, and mildly dilated occipital horns. (From Fong KW, Ghai S, Toi A, et al: Prenatal ultrasound findings of lissencephaly associated with Miller-Dieker syndrome and comparison with pre- and postnatal magnetic resonance imaging. Ultrasound Obstet Gynecol 24:716, 2004, used with permission.)

Neu-Laxova Syndrome. NLS is a lethal lissencephaly disorder inherited in an autosomal-recessive manner, characterized by growth restriction, microcephaly, agenesis of the corpus callosum, cerebellar hypoplasia, facial dysmorphism, hydrops, ichthyosis, extremity contractures, and syndactyly. It is due to an inborn error of serine metabolism, with causative mutations in the gene *PHGDH*.

Recurrence Risk

Recurrence risk is dependent on the particular lissencephaly syndrome.

Diagnosis

Sonographic diagnosis is difficult prior to the late second trimester, when the characteristic cerebral anomalies can be noted. The progressive microcephaly and failure of development of both sulci and gyri (which normally become well defined by 26 to 28 weeks) are suggestive of lissencephaly. Specific lissencephaly-related syndromes are difficult to differentiate prenatally. First-line genetic investigations involve chromosomal microarray, followed by next-generation sequencing multigene panels or exome sequencing.

Prognosis

Prognosis varies depending on the particular disorder.

Septo-Optic Dysplasia

Definition

Septo-optic dysplasia is a syndrome characterized by anomalies of cerebral midline structures, such as absence of the septum pellucidum, congenital optic nerve dysplasia, and panhypopituitarism, leading to multiple endocrine defects (diabetes insipidus, hypogonadotropic hypogonadism, hypothyroidism, adrenal insufficiency, abnormal thyrotropin-releasing hormone test, gonadotropin-releasing hormone

test, and gonadotropin hormone–releasing hormone test). Septo-optic dysplasia may represent a mild form of holoprosencephaly.

Synonym

Septo-optic dysplasia is also known as de Morsier syndrome.

Incidence

The incidence is estimated at 1 in 10,000 newborns.

Etiopathology

Environmental factors such as viral infections, medications, and vascular disruption have been postulated to play a role. The implicated genes (see later) are involved in embryonic development and are essential for formation of the eyes, the pituitary gland, and forebrain structures such as the optic nerves.

Genetics

Mutations in *HESX1, OTX2,* and *SOX2* are thought to be causative in a small subset of patients.

Recurrence Risk

The recurrence risk is unknown, depending on the cause.

Clinical Findings

- CNS: seizures, mental retardation, atrophy of the optic nerve, dilatation of the suprasellar cistern, empty sella, cortical atrophy and dystrophic corpus callosum, and anterior cephalocele.
- Face: hypotelorism, microphthalmia, visual impairment with nystagmus, unilateral or bilateral optic disk hypoplasia with double rim appearance (choroidal pigment in the outer margin and pale nerve tissue in the inner), variable visual loss, coloboma, strabismus, astigmatism, bilateral cleft lip and palate, high arched palate, and flat nasal bridge.
- Endocrine system: low growth rate and short stature. The most common problem is growth hormone deficiency (93%), followed by adrenocorticotropic hormone (ACTH) deficiency (57%), hypothyroidism (53%), diabetes, and gonadotropin deficiency. Hypothalamic dysfunction is the basic origin of these endocrine abnormalities. Septo-optic dysplasia is responsible for approximately 4% of all growth hormone deficiencies in children.

Diagnosis

Absence of the cavum septum pellucidum (CSP) is the most common finding. Sometimes, the standard sonographic views of the brain, obtained along the axial planes at midgestation, will fail to identify this absence. Absence of the CSP may not be detected because of the close proximity of the walls of the lateral ventricles, which are typically normal in size and may generate an artifact resembling a normal CSP. MRI is helpful for demonstration of hypoplastic optic tracts, allowing more definitive diagnosis. Hypotelorism, enlarged cerebral ventricles, communicating lateral ventricles, and bilateral cleft lip and palate have also been recognized prenatally.

FIG 16-23 Second trimester sonogram of the fetal head in a patient with septo-optic dysplasia. Absence of the septum pellucidum and communication of the frontal horns of the lateral ventricles (*arrows*) is seen.

Differential Diagnosis

Several variants with associated schizencephaly, dysgenesis of the corpus callosum, or microphthalmos, as well as incomplete forms, have been described. Lobar holoprosencephaly may also resemble septo-optic dysplasia.

Prognosis

The variable degree of intellectual disability (from minimal to severe), as well as the presence of multiple endocrine dysfunctions, affects the prognosis for each infant. Hyperthermia (in case of fever), dehydration (fever and diabetes insipidus), and other endocrine dysfunctions should be investigated and corrected.

Tuberous Sclerosis

Definition

Tuberous sclerosis is characterized by abnormalities of the skin (facial angiofibromas, hypochromic patches), brain (cortical tubers, subependymal nodules and giant cell astrocytomas, seizures, intellectual disability), kidneys (cysts, renal cell carcinomas, angiomyolipomas), heart (rhabdomyomas, arrhythmias), and lungs (lymphangioleiomyomatosis).

Synonyms

Tuberous sclerosis is also called Bourneville sclerosis and Bourneville disease.

Incidence

The incidence of tuberous sclerosis is up to 1 in 5800 births. Onset occurs in the first decade of life.

Etiology

Tuberous sclerosis is transmitted through autosomal-dominant inheritance. Two thirds of affected individuals have a de novo mutation. The expression is highly variable.

Pathogenesis

Tubers are the expression of an early disorder of embryogenesis. The greater the number of tubers, the greater the number of neurologic impairments. They can be found throughout the cerebral hemispheres, including in the subependymal region located in the walls of lateral ventricles and on the surface of the basal ganglia. They may extend into the ventricles including in the foramen of Monro area and can cause obstruction and hydrocephalus. They may also appear in the cortical gyri and sulcus terminalis. Tuberous sclerosis induces a reduction of the number of neurons, which are substituted by "monster" multinucleated giant neurons. The overgrowth of the fibrillary astrocytes can result in malignant astrocytomas. The sclerosis induces a demyelination, as well as calcium deposition in the glia and the blood vessels, which go through hyaline degeneration.

Clinical Findings

Tuberous sclerosis can present with a wide variety of signs that involve many organs as a consequence of the multifactorial origin of this genetic disorder (Table 16-1).

Diagnosis

The diagnosis is usually suggested by the discovery of cardiac tumors, which resemble small uterine myomas (round, usually well-delineated homogeneous masses). Between 51% and 86% of cardiac rhabdomyomas are seen in patients with tuberous sclerosis. Occasionally, the finding of a rhabdomyoma during routine second trimester ultrasound examination may lead to the recognition that the mother is affected. Cardiac rhabdomyomas increase prenatally, may regress in early infancy, remain unchanged during childhood, and regress in adolescence. The rhabdomyomas may cause rhythm disruptions (Wolff-Parkinson-White syndrome, supraventricular tachycardia, paroxysmal arrhythmias), as well as obstructions or regurgitation. Renal angiofibromas have not been recognized prenatally, although this may simply be a matter of time. Some recent unpublished reports have demonstrated that the periventricular subependymal nodules may also be detected prenatally. 2D Doppler echocardiography is a useful, noninvasive method to diagnose fetal cardiac rhabdomyomas and to monitor their influence on fetal cardiac function. However, it does not help to determine which fetuses affected by rhabdomyomas have tuberous sclerosis. Some studies report that 39% of prenatal suspected cardiac rhabdomyomas will be diagnosed at birth as a tuberous sclerosis syndrome. Family history remains the strongest predictor of the syndrome in prenatal counseling, whereas size of the cardiac tumor cannot reliably be used. The presence of more than one rhabdomyoma is more likely to be associated with tuberous sclerosis than a single identified lesion. MRI can be performed to assess for the associated malformations.

TABLE 16-1 Main Aspects of Tuberous Sclerosis

Classic triad (<50% of cases)
Facial lesions
Convulsions
Mental retardation
Central nervous system
Cortical hamartomas
Lesion of white substance*
Subependymal hamartomas (95%)
Typical localization: alongside lateral ventricle walls
Astrocytoma of subependymal giant cells*
Localization: foramen of Monro
Obstructive hydrocephaly
Kidney
Cysts
Angiolipoma
Cardiovascular
Rhabdomyoma
Aneurysm, stenosis, and vascular ectopia
Liver
Leiomyoma
Adenoma

*No reports of intrauterine visualization.

FIG 16-24 Tuberous sclerosis. Cardiac rhabdomyoma is demonstrated as a large, solid echogenic mass (*arrow*) in the left cardiac ventricle of this fetus with tuberous sclerosis.

FIG 16-25 The typical café-au-lait spot of tuberous sclerosis. (Courtesy of Philippe Jeanty, 1999. Available at thefetus.net.)

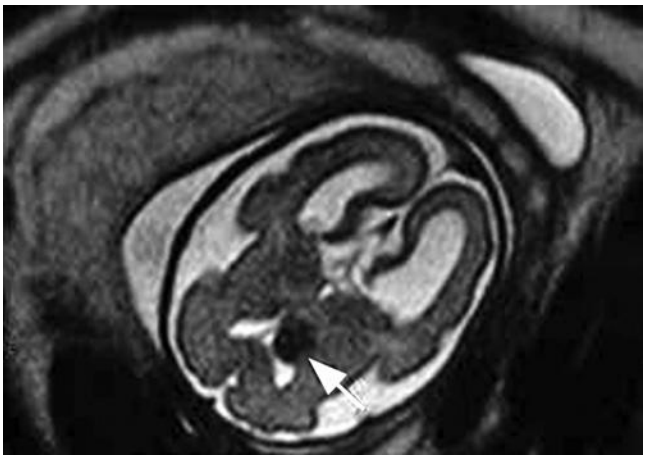

FIG 16-26 Axial view (T2-weighted) in a fetus of 26 weeks' gestation showing a typical subependymal nodule (*arrow*). (Courtesy of Heron Werner, 2005. Available at thefetus.net.)

Genetics

Tuberous sclerosis is caused by defects or mutations in one of two genes, *TSC1* and *TSC2*. *TSC1* produces a protein called hamartin. *TSC2* produces a protein called tuberin. These proteins act as tumor suppressors, which are agents that regulate cell proliferation and differentiation. At least 1% of patients with tuberous sclerosis have somatic mosaicism for *TSC1* or *TSC2*.

Differential Diagnosis

The predominant prenatal finding is rhabdomyomas. Other cardiac tumors, such as a fibroma, should also be considered.

Recurrence Risk

Recurrence risk is generally low in cases of new mutations, but up to 1% to 2% due to gonadal mosaicism, 50% if a parent is affected.

Prognosis

As long as hydrops is not present from the presence of the rhabdomyomas, the prognosis depends on other complications of the disorder. CNS tumors are the leading cause of morbidity and fatality. Renal disease is the second leading cause of early death. Because of the wide variability of expression, an accurate prediction of a child's phenotype is difficult to infer from the status of the parent. Genetic evidence indicates that the degree of intelletual disability depends on the particular genetic alteration present.

L1 Syndrome

Definition

L1 syndrome includes a spectrum of phenotypes (see following synonyms) and is generally characterized by severe hydrocephalus, adducted thumbs, spasticity, and severe intellectual disability.

Synonyms

Synonyms for L1 syndrome include X-linked hydrocephalus with stenosis of the aqueduct of Sylvius (HSAS), MASA (mental retardation, aphasia, spastic paraplegia, adducted thumbs) syndrome, SPG1 (X-linked complicated hereditary spastic paraplegia type 1), and X-linked corpus callosum agenesis.

Incidence

The incidence is 1 in 30,000 births, accounting for 5% to 10% of males with congenital hydrocephalus not associated with another syndrome.

Pathogenesis

Mutations in the *L1CAM* gene are thought to lead to the clinical phenotype. L1CAM is an adhesion surface protein involved in transmembrane signaling and is essential for the development and function of neurons.

Diagnosis

Clinical findings include hydrocephalus with or without stenosis of the aqueduct of Sylvius, as well as corpus callosum agenesis or dysgensis, cerebellar hypoplasia, small brainstem, and bilateral absence of the pyramids. Bilateral absence of the pyramids on MRI or at autopsy is pathognomonic. Prenatally, hydrocephalus can be seen, but is often not seen prior to 20 to 24 weeks' gestation, and sometimes is not seen even in the third trimester of pregnancy.

Genetics

L1 syndrome is caused by mutations in *L1CAM* gene. Inheritance is X-linked recessive.

Recurrence Risk

Recurrence risk is 50% for women who are carriers of an *L1CAM* mutation.

Associated Anomalies

Hirschsprung disease has been seen in some individuals with L1 syndrome.

Differential Diagnosis

Other syndromic and nonsyndromic causes of hydrocephalus should be excluded.

Prognosis

The phenotype can range from mild to severe even within the same family.

Management

A multidisciplinary team is required for optimal management. Head imaging should be performed. Surgical treatment is often required to relieve hydrocephalus. Regular neurologic, developmental evaluation and follow-up are needed. Surgery for adducted thumbs is generally not indicated.

CRANIUM/FACE

Craniosynostoses

Craniosynostosis has been reported in over 150 genetic disorders and is found in 1 per 2000 to 2500 live births. Many of the craniosynostoses are caused by mutations in one of the *FGFR* genes, including Apert syndrome, Beare-Stevenson syndrome, Crouzon syndrome, Crouzon syndrome with acanthosis nigricans, *FGFR2*-related isolated coronal synostosis, Jackson-Weiss syndrome, Muenke syndrome, and Pfeiffer syndrome. Although Muenke syndrome and *FGFR2*-related isolated coronal synostosis are characterized by coronal craniosynostosis only, the others have related facial features and extremity findings. *FGFR*-related craniosynostoses have been associated with advanced paternal age. Syndromic craniosynostoses involving other genes include Antley-Bixler syndrome (caused by mutations in the *POR* gene), Carpenter syndrome (caused by mutations in *RAB23*), and Saethre-Chotzen syndrome (caused by mutations in *TWIST1*).

In general, management of the craniosynostoses should include involvement of a multidisciplinary craniofacial clinic at a pediatric medical center, as a series of staged surgical procedures is often required for treatment and generally involves craniotomy and fronto-orbital advancement. Surgical correction of limb defects may also be needed, depending on the particular anomalies. Early treatment can decrease the risk of secondary complications, such as hydrocephalus and intellectual disability. If proptosis is severe, ophthalmologic lubrication can prevent exposure keratopathy. The prognosis for each affected individual is most dependent on the particular anomalies present and less on the specific craniosynostosis syndrome.

A few of the more common disorders are discussed in more detail above (Table 16-2).

Antley-Bixler Syndrome

Definition. Antley-Bixler syndrome is a sterol biosynthesis disorder characterized by craniosynostosis of the coronal and lambdoidal sutures, brachycephaly with frontal bossing, and facial dysmorphism (proptosis, downslanting palpebral fissues, severe depression of the nasal bridge, choanal stenosis or atresia, small mouth, high-arched narrow palate, low-set protruding ears). Hydrocephalus can be present. Limb anomalies include radiohumeral synostosis, bowing of the ulnas and femurs, slender hands and feet, contractions of the proximal interphalangeal joints, advanced bone age, and fractures.

Synonym. Antley-Bixler syndrome is also known as trapezoidocephaly-multiple synostosis syndrome.

Etiology. Caused by cytochrome P450 oxidoreductase (POR) deficiency, Antley-Bixler syndrome is the most severe end of the phenotypic spectrum of POR deficiency.

Incidence. The incidence is unknown. Since *POR* mutations were first reported in 2004, approximately 50 affected individuals have been reported. More mildly affected individuals are likely underreported.

Pathogenesis. The mechanism by which POR deficiency leads to multiple malformations remains under investigation. Ambiguous genitalia result from disordered steroidogenesis. Recently, cytochrome P450 activity in bone has been implicated in normal bone development, and, thus, POR deficiency may disrupt proper bone formation.

Diagnosis. Malformations that may be detected on prenatal ultrasound examination include abnormal skull shape, facial dysmorphism, skeletal abnormalities (bowed femora, bilateral radioulnar synostosis), and ambiguous genitalia. During pregnancy, low maternal estriol may be found on serum screening. Maternal urine may also have increased fetal steroids, including the pregnenolone metabolite epiallopregnanediol and the androgen metabolite androsterone. POR deficiency can be diagnosed in affected infants by the detection of urinary sterol or steroid abnormalities, including increased pregnenolone and progesterone metabolites and an elevated ratio of metabolites associated with deficiency of 17-hydroxylase and 21-hydroxylase. Serum concentrations of pregnenolone, progesterone, 17-OH pregnenolone, and 17-OH progesterone may be elevated at baseline or following

ACTH stimulation. Some cases are found on newborn screening (NBS), but NBS is not sensitive enough to detect all cases.

Genetics. Antley-Bixler syndrome is caused by mutations in the gene encoding cytochrome P450 reductase (*POR*). Inheritance is autosomal recessive.

Recurrence Risk. Recurrence risk is 25%.

Associated Anomalies. Congenital heart disease, renal anomalies, abnormalities of the female genitalia, and signs of congenital adrenal hyperplasia are also present. Some degree of intellectual disability is often seen, but intelligence can also be normal.

Differential Diagnosis. Other forms of congenital adrenal hyperplasia as well as other craniosynostosis syndromes should be considered.

Prognosis. Prognosis improves with age. In infancy, respiratory complications can lead to early death.

Management. Multidisciplinary evaluation is needed. Airway management is a primary concern owing to choanal atresisa/stenosis. Functional adrenal studies should be performed and hydrocortisone replacement therapy initiated if low cortisol levels are found. Genital abnormalities are often treatable and should be addressed.

Apert Syndrome

Definition. Apert syndrome is characterized by craniosynostosis, midface and orbital hypoplasia, and bilateral syndactyly of the hands and feet. These findings are accompanied by variable degrees of mental retardation in 50% of cases.

Incidence. The incidence of Apert syndrome is 1 per 100,000 live births. It is seen in 4% to 5% of craniosynostosis cases.

Synonyms. Apert syndrome is also known as acrocephalosyndactyly type 1 and Apert-Crouzon disease.

Etiology. Apert syndrome has autosomal dominant inheritance. Most of the cases are sporadic, resulting from de novo mutations. The disorder is associated with advanced paternal age.

Sonographic Findings. Brachycephaly and acrocephaly, high forehead, flat occiput, craniosynostosis involving the coronal sutures, flat face, and hypertelorism are seen. Other ultrasound findings include agenesis of the corpus callosum, mild ventriculomegaly, and fusion of the cervical vertebrae at the level of C5-C6. In the extremities, syndactyly of both bone and soft tissue is seen, involving the second, third, and fourth fingers. Polyhydramnios (caused by the decreased fetal swallowing) and increased nuchal translucency in the first trimester have also been reported.

Diagnosis. Typical findings include bicoronal synostosis of the coronal sutures, flattened occiput, a wide, steep forehead, hypoplastic orbits with exophthalmos and hypertelorism, short nose with depressed nasal bridge, large ears, high palate (occassional cleft palate), and dental crowding. Hydrocephalus is rare. Hearing loss is common. Symmetric syndactyly of the limbs ("mitten-like" hands and feet) is present at least from the second to fourth digits in both the bony and soft tissue. Cardiovascular and genitourinary anomalies are present in 10% of patients.

Genetics. Caused by mutations in the *FGFR2* genes, most commonly substitutions S252W and P253R. Genetic molecular studies are recommended for the fetus (by chorionic villus sampling or amniocentesis) and for parents when Apert syndrome is suspected. Inheritance is autosomal dominant with complete penetrance.

Differential Diagnosis. Other syndromes with craniosynostosis such as Crouzon, Pfeiffer, Carpenter, and Saethre-Chotzen syndromes should be considered. Molecular genetic studies can exclude these disorders. The pattern of syndactyly is the most helpful for the diagnosis of Apert syndrome.

Recurrence Risk. Most mutations are de novo and the recurrence risk is low. If one of the parents carries the disorder, the recurrence risk is 50%.

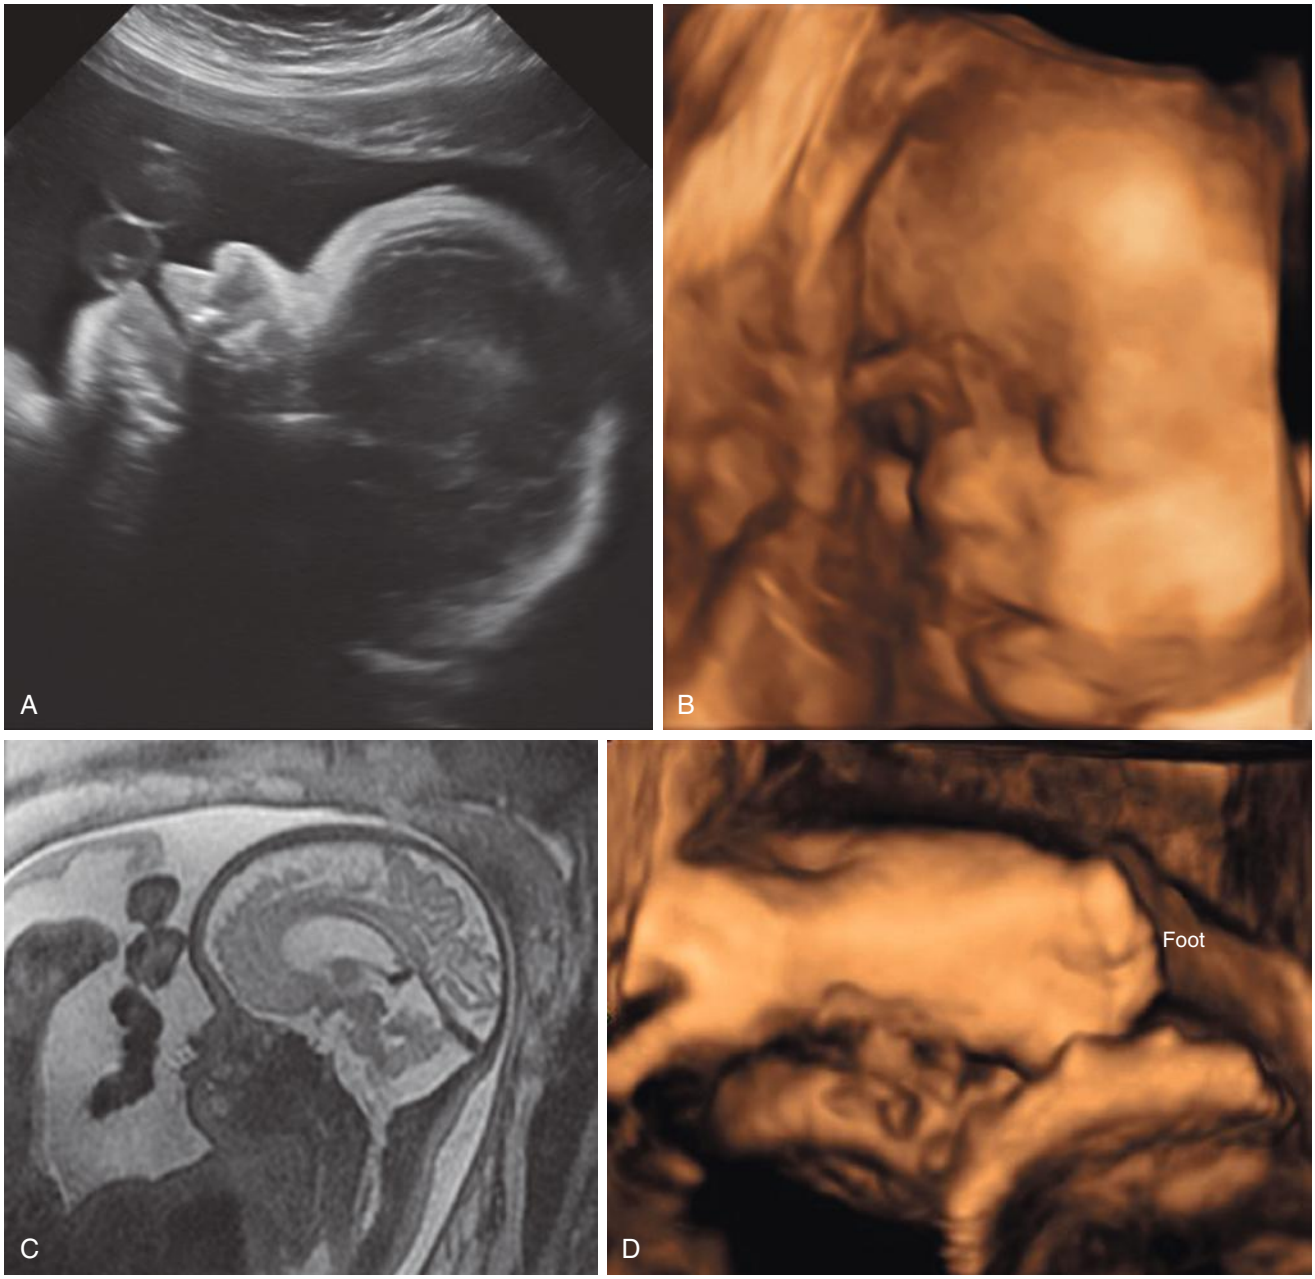

FIG 16-27 Apert syndrome. Ultrasound images demonstrating frontal bossing and midface hypoplasia on two-dimensional (2D) (**A**) and 3D (**B**) images, as well as by magnetic resonance imaging (**C**). Ultrasound image also demonstrated syndactyly of the foot (**D**), which is characteristic of Apert syndrome.

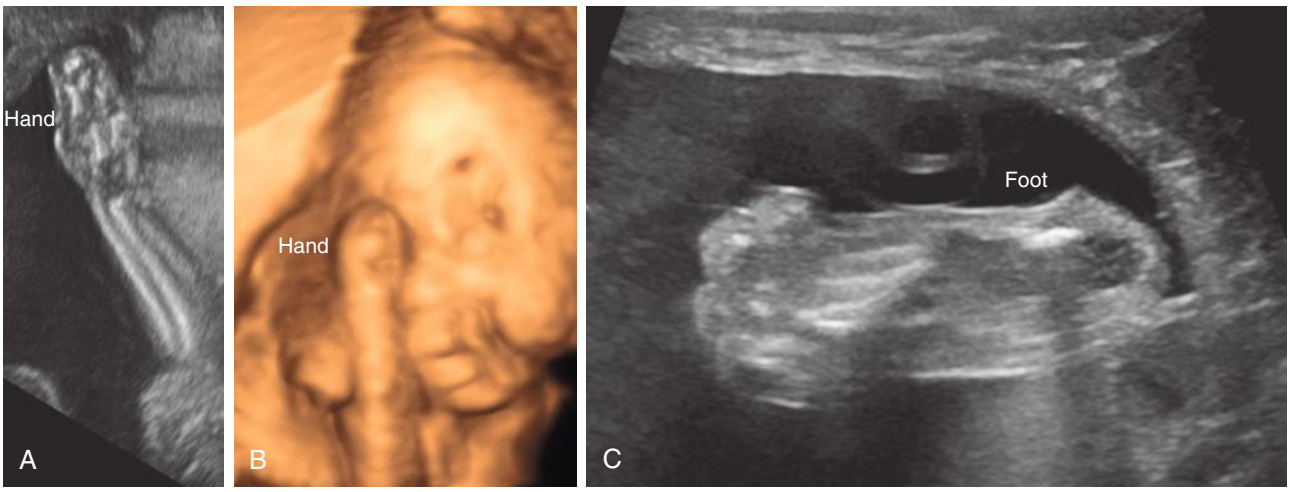

FIG 16-28 Apert syndrome. Syndactyly of the hand demonstrated with two-dimensional (2D) (**A**) and 3D (**B**) ultrasound images. Syndactyly of the foot is also present (**C**).

FIG 16-29 Newborn with Apert syndrome. Note appearance of the head, with frontal bossing (**A** and **B**), and syndactyly of the hand (**C**) and foot (**D**).

Carpenter Syndrome

Definition. Carpenter syndrome is characterized by craniosynostosis with preaxial polydactyly of the feet. Hand anomalies include brachydactyly, syndactyly, and aplasia or hypoplasia of the middle phalanges.

Synonym. Acrocephalopolysyndactyly type II is another name for Carpenter syndrome.

Incidence. Carpenter syndrome is rare. Approximately 70 cases have been described.

Etiology/Pathogenesis. RAB23 is a member of the RAB guanosine triphosphatase (GTPase) family of vesicle transport proteins and acts as a negative regulator of hedgehog signaling. Abnormal hedgehog signaling may lead to much of the clinically recognized phenotype.

Diagnosis. Unlikely other syndromic craniosynostoses, in which coronal sutures are most frequently affected, in Carpenter syndrome, fusion of the midline sutures (metopic and sagittal) is common. In severe cases, this leads to cloverleaf skull. On prenatal ultrasound examination, reported features include cystic hygroma, abnormal skull shape, bowed femora, polydactyly, and complex heart defects.

Genetics. Carpenter syndrome is caused by mutations in *RAB23*. The inheritance is autosomal recessive. A subtype of Carpenter syndrome with lateralization defects is thought to be caused by mutations in *MEGF8*.

Recurrence Risk. Recurrence risk is 25%.

Associated Anomalies. Obesity, umbilical hernia, hearing loss, cryptorchidism, and cardiac defects are often present. Craniosynostosis leads to distinctive facial features. The degree of intellectual disability varies.

Differential Diagnosis. Features overlap with Greig cephalopolysyndactyly syndrome. Molecular genetic testing can clarify the diagnosis.

Prognosis. Phenotype is extremely variable, even within the same family. Life expectancy is shortened.

Crouzon Syndrome

Definition. Crouzon syndrome is an *FGFR*-related craniosynostosis characterized by premature fusion of the coronal and frontosphenoidal sutures leading to brachycephaly and a prominent forehead. Facial dysmorphism (proptosis from orbital and midface hypoplasia, external strabismus, mandicular prognathism) is present and extremities are normal.

Incidence. The incidence of Crouzon syndrome is 1.6 per 100,000 live births. It is seen in 4.5% of craniosynostosis cases.

Diagnosis. Sonographic findings include brachycephaly, midface hypoplasia, and a wide anterior cranial base. Hands and feet are normal. Exophthalmos is always present. About 20% of patients develop optic atrophy. Dental crowding and an open bite are common.

Genetics. Caused by mutations in *FGFR2* (except for Crouzon syndrome with acanthosis nigricans, which is caused by mutations in *FGFR3*, seen in ~5% of individuals with Crouzon syndrome). Inheritance is autosomal dominant with complete penetrance and variable expressivity.

Recurrence Risk. Recurrence risk is 50% if one parent carries the causative mutation. Occassionally it appears de novo.

Associated Anomalies. Progressive hydrocephalus is seen in 30% of cases and can lead to tonsillar herniation. Sacrococcygeal tail can also be seen. Cardiovascular anomalies and cleft lip and palate have been reported but are rare.

Differential Diagnosis. Other *FGFR*-related craniosynostoses should be considered, including Crouzon syndrome with acanthosis nigricans (should consider if choanal atresia is present).

Prognosis. Intellect is generally normal, hearing loss is common, and complications related to hydrocephalus can be life threatening if not treated appropriately.

Robin NH, Falk MJ, Haldeman-Englert CR: FGFR-related craniosynostosis syndromes. In Pagon RA, Adam MP, Ardinger HH, et al, editors: *GeneReviews*, Seattle, 1993–2016, University of Washington.

Pfeiffer Syndrome

Definition. Pfeiffer syndrome is characterized by bilateral coronal craniosynostosis, midface hypoplasia, syndactyly of hands and feet, and congenitally enlarged thumbs. Conductive hearing loss is present in more than 80% of patients. The syndrome is divided in three clinical subtypes, with diagnostic and prognostic implications:

- Type I: classic appearance with craniosynostosis (leading to turribrachycephaly), broad thumbs, and syndactyly. This form is compatible with life, and patients often have normal intelligence.
- Type II: cloverleaf skull, ocular proptosis, broad thumbs, variable visceral anomalies, elbow ankylosis, choanal atresia, and CNS involvement (hydrocephalus). Intellectual disability is common, and this form usually results in early death.
- Type III: craniosynostosis, severe ocular proptosis without cloverleaf skull, elbow ankylosis, and variable visceral anomalies. Affected fetuses have severe neurologic compromise (including hydrocephalus and tonsillar herniation), with poor prognosis and early death.

Synonym. Pfeiffer syndrome is also known as acrocephalosyndactyly type 5.

Incidence. The incidence is 1 per 100,000 for all types combined.

Genetics. Pfeiffer syndrome is genetically heterogeneous and is caused by mutations in either *FGFR2* or *FGRF1* (type I). Frequently, no mutation can be identified. Type I has autosomal dominant inheritance with complete penetrance and variable expressivity. Most mutations in type II and III are de novo and associated with advanced paternal age.

Recurrence Risk. Recurrence risk is 50% if a parental mutation is present. If the mutation is de novo, recurrence risk is very low.

Diagnosis. Sonographic signs of Pfeiffer syndrome include craniofacial anomalies (brachycephaly, acrocephaly, craniosynostosis of the

coronal suture, hypertelorism, small nose, and low nasal bridge) and hands and feet anomalies (partial syndactyly of second and third fingers and second, third, and fourth toes, broad thumb, and big toe).

Associated Anomalies. Choanal atresia, tracheomalacia and bronchomalacia, cloverleaf skull, fused vertebra, Arnold-Chiari malformation, hydrocephalus, and imperforate anus are associated with this syndrome. After birth, seizures and intellectual disability may be seen.

Differential Diagnosis. Saethre-Chotzen and Jackson-Weiss syndromes should be considered in the differential diagnosis.

Prognosis. The prognosis depends on the severity of associated anomalies, in particular the severity of the CNS compromise. Type I generally has a good prognosis. Types II and III are not compatible with life, and death occurs early.

Nazzaro A, Della Monica M, Lonardo F, et al: Prenatal ultrasound diagnosis of a case of Pfeiffer syndrome without cloverleaf skull and review of the literature. *Prenat Diagn* 24(11):918–922, 2004.

Robin NH, Falk MJ, Haldeman-Englert CR: FGFR-related craniosynostosis syndromes. In Pagon RA, Adam MP, Ardinger HH, et al, editors: *GeneReviews*, Seattle, 1993–2016, University of Washington.

Saethre-Chotzen Syndrome

Definition. Saethre-Chotzen syndrome is characterized by coronal synostosis (unilateral or bilateral), facial asymmetry, ptosis, and characteristic ear appearance (small pinna with a prominent crus). Often present is 2-3 syndactyly of the hand.

Synonyms. Synonyms include acrocephalosyndactyly type III and Robinow-Sorauf syndrome (a mild variant).

Incidence. Incidence is 1 in 25,000 to 50,000 individuals.

Diagnosis. A clinical diagnosis can be made based on craniosynostosis (usually of the coronal sutures), brachycephaly, low frontal hairline, ptosis, facial asymmetry, small ears, and limb anomalies (2-3 syndactyly of the hand, brachydactyly, hallux abnormalities).

Genetics. Saethre-Chotzen syndrome is caused by mutations in *TWIST1*; sequencing and deletion/duplication analysis should be performed. Mutations have also been reported in *FGFR2*. Inheritance is autosomal dominant with incomplete penetrance and variable expressivity.

Recurrence Risk. If one parent also carries the causative mutation, recurrence risk is 50%. It is significantly less if the mutation is de novo.

Associated Anomalies. Associated anomalies include short stature, parietal foramina, radioulnar synostosis, cleft palate, maxillary hypoplasia, hypertelorism, congenital heart disease, and segmentation defects of the vertebrae.

Differential Diagnosis. Many features are shared with Muenke syndrome, and, thus, genetic evaluation should also include analysis of the *FGFR2* and *FGFR3* genes. Pfeiffer syndrome and Jackson-Weiss syndrome should also be considered.

Prognosis. Intelligence is often normal, although mild to moderate intellectual and developmental delay has been reported. Conductive and sensorineural hearing loss may be present.

REFERENCE

Facial Anomalies

Branchiooculofacial Syndrome

Definition. Branchiooculofacial syndrome (BOFS) is characterized by branchial skin defects (thin skin, erythematous lesions, erosions), ocular anomlies (microphthalmia, anophthalmia, coloboma, nasolacrimal duct stenosis/atresia), and facial anomalies (hypertelorism, broad nasal tip, upslanted palpebral fissues, cleft lip ± cleft palate, upper lip pits, lower facial weakness). Ear anomalies are common.

Incidence. BOFS is rare. Fewer than 100 well-described cases have been reported.

Diagnosis. Diagnosis is made on the clinical constellation of branchial skin defect, ocular anomaly, and characteristic facial appearance.

Genetics. BOFS is caused by mutations in the gene *TFAP2A*. Inheritance is autosomal dominant. De novo mutations are present in 50% to 60% of affected individuals. Penetrance is complete.

Recurrence Risk. Recurrence risk is 50% if a parental mutation is found.

Associated Anomalies. Other anomalies include thymic anomalies, renal anomalies, hypoplastic teeth, dysplastic nails, premature hair graying, and defects in hearing and vision.

Prognosis. Intellect is generally normal. Feeding difficulties, as well as cosmetic, visual, hearing, and speech issues are often present.

Frontonasal Dysplasia

Definition. Frontonasal dysplasia is characterized by a broad forehead, widow's peak hairline, ocular hypertelorism, and abnormal nostrils (notched or completely divided) with absence of the nasal tip. A midline defect in the frontal bone (cranium bifidum) is also commonly seen.

Synonyms. Synonyms include median cleft face syndrome, frontonasal malformation, and frontorhiny.

Incidence. Incidence is unknown. Frontonasal dysplasia is rare; at least 100 cases have been reported in the literature.

Pathogenesis. Frontonasal dysplasia is due to malformation of the frontonasal elevation. The implicated genes (*ALX1, ALX 3,* and *ALX 4*) encode transcription factors that regulate development of the eyes, nose, and mouth.

Diagnosis. The diagnosis is based on the constellation of eye, forehead, and nose findings described earlier.

Genetics. The disorder is genetically heterogeneous, with autosomal recessive, autosomal dominant, and X-linked forms of inheritance all reported. The autosomal recessive form is associated with mutations in *ALX1* and *ALX3*. The autosomal dominant form is associated with *ALX4* gene mutations.

Recurrence Risk. The recurrence risk is dependent on mode of inheritance.

Prognosis. Most individuals have normal intellectual development. Overall prognosis depends on the severity of the malformations and whether or not surgical intervention can improve breathing and feeding issues.

Management. Multistage craniofacial surgery is generally needed; for less severe malformations, surgery is often performed at age 6 to 8 and can have excellent cosmetic results.

Goldenhar Syndrome

Definition. Goldenhar syndrome is characterized by hemifacial microsomia, epibulbar dermoids, preauricular appendages, ear hypoplasia, transverse facial clefts, asymmetry of the skull, and spinal anomalies (vertebral segmentation errors).

Incidence. Incidence is 1 in 3500 to 1 in 26,000 live births. Male-to-female ratio is 3:2.

Synonyms. Synonyms include oculo-auriculo-vertebral dysplasia, hemifacial microsomia, craniofacial microsomia, Goldenhar-Gorlin's syndrome, and facio-auriculo-vertebral dysplasia.

Etiology. Goldenhar syndrome is caused by developmental abnormalities of the first and second branchial arches.

Diagnosis. Findings are similar to Treacher Collins syndrome (see later) except that they are unilateral leading to significant facial asymmetry. Other features include dystopia, microtia, choanal atresia, cleft palate ± lip, jaw malocclusion, vertebral anomalies, cardiac anomalies, genitourinary anomalies, and CNS involvement.

Pathogenesis. Possible fetal hemorrhage in the region of the first and second branchial arches when the blood supply of these arches switches from the stapedial artery to the external carotid artery.

Genetics. Genetics for Goldenhar syndrome are unknown. Most cases are thought to be sporadic, although both autosomal recessive and autosomal dominant inheritance have been reported. Transmission is linked in some cases to a region on chromosome 14q32.

Differential Diagnosis. Treacher Collins syndrome, Kaufman syndrome (oculocerebrofacial syndrome), acrofacial dysostosis, CHARGE syndrome (*c*oloboma of the eye, *h*eart defects, *a*tresia of the choanae, *r*etarded mental and growth development, *g*enital anomalies, and *e*ar anomalies), VACTERL, and Nager syndrome should be considered.

Prognosis. Treatment is generally cosmetic with multiple reconstructions required in some cases. Airway and vertebral complications have been reported.

Recurrence Risk. Recurrence risk is minimal unless an autosomal dominant or autosomal recessive inheritance pattern is suggested.

Management. Malar and orbital reconstructions are generally needed and are often performed after age 6. Structural anomalies of the eyes and ears can be corrected with plastic surgery.

Gorlin Syndrome

Definition. Gorlin syndrome is characterized by the development of jaw keratocysts and multiple basal cell carcinomas, as well as a characteristic facial appearance with macrocephaly, prominent forehead, coarse facial features, and facial milia.

Synonym. Gorlin syndrome has also been referred to as nevoid basal cell carcinoma syndrome (NBCCS).

Incidence. Incidence is estimated to be as high as 1 in 18,976.

Pathogenesis. Mutations in *PTCH1* lead to alterations in the hedgehog signaling pathway leading to neoplastic cell growth.

Diagnosis. Prenatally, cranial and cerebral malformations can be seen, including macrocephaly and ventriculomegaly. Diagnosis is based on major clinical criteria including calcification of the falx, jaw keratocyst, palmar/plantar pits, and multiple basal cell carcinomas, as well as minor criteria.

Genetics. Gorlin syndrome results from mutations in the gene *PTCH1*. Inheritance is autosomal dominant. From 20% to 30% of mutations are de novo. Penetrance is complete; expressivity can be variable.

Recurrence Risk. If a parental mutation is present, recurrence risk is 50%.

Associated Anomalies. Most individuals have skeletal anomalies (bifid ribs, wedge-shaped vertebrae) and ectopic calcification (in the falx). Cardiac and ovarian fibromas can be seen. Children can develop medulloblastoma (5%). Other anomalies include lymphomesenteric or pleural cysts, cleft lip/palate, polydactyly, and ocular anomalies.

Differential Diagnosis. When macrocephaly is detected prenatally, the differential diagnosis includes several overgrowth syndromes, such as Sotos syndrome and Beckwith-Wiedemann syndrome (BWS).

Prognosis. Life expectancy is not changed. Cosmetic issues with multiple skin tumors and their removal can lead to social difficulties and can affect quality of life.

Management/Prevention. Radiotherapy can lead to the development of thousands of basal cell carcinomas and should be avoided if possible. X-ray exposure should be limited. Direct sun exposure should be avoided.

Hallerman-Streiff Syndrome

Definition. Hallerman-Streiff syndrome is characterized by brachycephaly with frontal bossing, micrognathia, beaked nose, eye anomalies (microphthalmia, cataracts), dental anomalies, hypotrichosis, skin atrophy (especially of the face), and short stature.

Incidence. The syndrome is rare, with approximately 150 cases reported.

Diagnosis. Diagnosis is based on the clinical criteria described earlier.

Genetics. Generally thought to be sporadic, in some cases, the syndrome has been associated with mutations in *GJA1* with autosomal recessive inheritance.

Recurrence Risk. Recurrence risk is unknown, but thought to be low.

Differential Diagnosis. Many features overlap with oculodentodigital dysplasia (ODDD) and other progeroid syndromes.

Prognosis. Intellectual disability is present in approximately 15%. Upper airway obstruction can be significant and can lead to cardiac failure and early death.

Management. Initial management is focused on airway issues; later management includes cosmetic surgical procedures.

Nager Syndrome

Definition. Nager syndrome is characterized by preaxial limb anomalies (radial hypoplasia/absence, thumb hypoplasia/absence, triphalangeal thumbs, radioulnar synostosis) and facial anomalies (malar hypoplasia, downward slanting palpebral fissures, lower eyelid coloboma, severe micrognathia).

Synonym. Nager syndrome is also known as preaxial acrofacial dysostosis.

Incidence. Incidence is unknown, but the syndrome is rare.

Diagnosis. Diagnosis is based on the clinical criteria described earlier, including craniofacial and limb malformations. Prenatally, severe micrognathia and upper limb anomalies may be seen.

Genetics. The genetic basis is heterogeneous. Recent reports suggest that haploinsufficiency of the gene *SF3B4* leads to the phenotype in families with suggested autosomal dominant inheritance, as well as many individuals with de novo mutations. Autosomal recessive inheritance has also been suggested in some cases.

Recurrence Risk. Recurrence risk depends on mode of inheritance.

Differential Diagnosis. Facial anomalies are similar to those seen with Treacher Collins syndrome. Differential diagnosis should include Miller syndrome.

Prognosis. Upper airway issues can be significant, requiring tracheostomy. Hearing loss, vision loss, and hand anomalies can affect development and quality of life

Oral-Facial-Digital Syndrome, Type I

Definition. Oral-facial-digital syndrome, type I (OFD1), is characterized by anomalies in multiple areas. including the mouth (lobed tongue, tongue lesions, cleft palate, dental anomalies), face (hypertelorism, alae nasi hypoplasia, median cleft, micrognathia), digits (brachydactyly, syndactyly, polydacyly of the hands, duplicated great toe), brain (intracerebral cysts, cerebellar agenesis, agenesis of the corpus callosum), and kidneys (polycystic kidneys).

Synonym. OFD1 is also known as Papillon-Léage-Psaume syndrome.

Incidence. Almost all affected individuals are female, although males with OFD1 have also been described.

Pathogenesis. OFD1 is due to dysfunction of primary cilia.

Diagnosis. Many individuals are diagnosed at birth based on the characteristic anomalies. Some cases are diagnosed after polycystic kidney disease is found.

Genetics. The syndrome is due to mutations in the *OFD1* gene. Inheritance is X-linked dominant. Approximately 75% of individuals have no family history of OFD1. Penetrance is high, with highly variable expressivity.

Recurrence Risk. Recurrence risk is 50% in pregnancies of a female with OFD1. The risk is low if no maternal mutation is present.

Differential Diagnosis. Differential diagnosis includes the other oral-facial-digital syndromes, types 2 to 9, as well as other disorders with cystic renal disease, and Meckel-Gruber syndrome.

Prognosis. Up to 50% of individuals have intellectual disability, but generally mild. Seizure disorder can be present.

Management. Surgery for oral and facial anomalies is often needed. Renal disease should be monitored.

REFERENCE

Pierre Robin Sequence

Definition. The Pierre Robin sequence consists of the occurrence of three anomalies together: cleft palate, micrognathia, and glossoptosis. These anomalies are found together in multiple syndromes.

Synonyms. Pierre Robin sequence is also called cleft palate-micrognathia-glossoptosis, Pierre Robin syndrome, and Robin anomalad.

Incidence. Incidence is 1 in 8500 to 1 in 14,000 births. One half of patients with Pierre Robin sequence have an underlying syndrome.

Etiology. Inheritance is autosomal-recessive, with a few X-linked cases. Some authors suggest a prenatal and neonatal brainstem dysfunction as a neuroembryologic hypothesis to explain the onset of some cases of Pierre Robin sequence.

Diagnosis. Micrognathia is most visible on prenatal ultrasound imaging. Isolated cleft palate is more difficult to detect prenatally. Polyhydramnios may be seen as a result of swallowing difficulty.

Genetics. This disorder is heterogeneous; it can be monogenic, chromosomal, or related to teratogens. The cause is unknown in some cases. Multiple forms of inheritance are involved, including autosomal dominant, autosomal recessive, and X-linked.

Differential Diagnosis. Differential diagnosis includes syndromes that involve Pierre Robin sequence, such as Stickler syndrome, as well as fetal alcohol syndrome.

Associated Anomalies. Other anomalies depend on the exact diagnosis. Cardiac abnormalities are common with an incidence approaching 20%.

Prognosis. Upper airway obstruction, neonatal respiratory distress, and feeding problems are common issues.

Associated Syndromes. See Table 16-3 for a complete list of associated syndromes.

Stickler Syndrome. Stickler syndrome is characterized by ocular findings (myopia, cataract, retinal detachment) and hearing loss (conductive and sensorineural) in addition to Pierre Robin sequence. Joint issues are also common (hypermobility, spondyloepiphyseal dysplasia, precocious osteoarthritis). Mutations in one of five genes are often present: *COL2A1*, *COL11A1*, and *COL11A2* (autosomal dominant inheritance; *COL2A1* most common, at 80-90%), as well as *COL9A1* and *COL9A2* (autosomal recessive; rare). Penetrance is complete but significant phenotypic variability occurs even within families. From 20% to 30% of patients with Pierre Robin sequence may have Stickler syndrome.

Cerebrocostomandibular Syndrome. Cerebrocostomandibular syndrome (CCMS) is characterized by costovertebral anomalies (dorsal rib defects) in addition to Pierre Robin sequence. Rib defects often lead to a bell-shaped thorax and can result in flail chest. Other anomalies include growth retardation, scoliosis, dental anomalies, feeding issues, and conductive hearing loss. Severity is highly variable, although

TABLE 16-3 Selected Syndromes and Chromosomal Anomalies Associated With Pierre Robin Sequence

Condition	OMIM	Causative Gene	Inheritance Pattern	Additional Features
Primary Skeletal Dysplasias				
Campomelic dysplasia	114290	*SOX9*	Autosomal dominant	Short stature, campomelia, hearing loss, scoliosis
Stickler syndrome	108300, 604841, 184840	*COL2A1, COL11A1, COL11A2*	Autosomal dominant	Myopia, retinal detachment, hearing loss, mild short stature
Spondyloepiphyseal dysplasia congenita	183900	*COL2A1*	Autosomal dominant	Short spine, pectus carinatum, myopia, normal hands and feet
Kniest dysplasia	156550	*COL2A1*	Autosomal dominant	Short trunk, kyphosis, lumbar lordosis, short limbs, reduced joint mobility
Marshall syndrome	154780	*COL11A1*	Autosomal dominant	Hypoplastic nasal bones, congenital cataracts, myopia, sensorineural hearing loss
Otospondylomegaepiphyseal dysplasia	277610, 215150	*COL11A2*	Autosomal dominant	Sensorineural hearing loss, enlarged painful joints, short stature, short limbs
Diastrophic dysplasia	222600	*SLC26A2*	Autosomal recessive	Short stature, short limbs, joint contractures, talipes equinovarus, kyphoscoliosis
Osteopathia striata with cranial sclerosis	300373	*WTX*	X-linked dominant	Macrocephaly, frontal bossing, hearing loss, skull base sclerosis, linear metaphyseal bands
Otopalatodigital syndrome type II	304120	*FLNA*	X-linked semidominant	Frontal bossing, short thumbs and halluces, bowed long bones, conductive hearing loss

Continued

TABLE 16-3 Selected Syndromes and Chromosomal Anomalies Associated With Pierre Robin Sequence—cont'd

Condition	OMIM	Causative Gene	Inheritance Pattern	Additional Features
Multiple Congenital Anomaly Syndromes				
Catel-Manzke syndrome	302380	Unknown	Probably autosomal recessive	Clinodactyly of index finger due to accessory ossicle between metacarpal and proximal phalanx, congenital cardiac defects
Toriello-Carey syndrome	217980	Unknown	Possibly autosomal recessive	Agenesis corpus callosum, telecanthus, developmental delay
Treacher Collins syndrome	154500	*TCOF1*	Autosomal dominant	Downslanting palpebral fissures, lower eyelid colobomas, zygomatic hypoplasia
Nager preaxial acrofacial dysostosis	154400	*SF3B4*	Autosomal dominant	Downslating palpebral fissures, absence of medial third lower lid lashes, conductive hearing loss, radial ray defects
Miller postaxial acrofacial dysostosis	263750	*DHODH*	Autosomal recessive	Lower lid ectropion, cupped ears, hearing loss, bilateral absence of fifth fingers, supernumerary nipples
Mandibulofacial dysostosis Guion-Almeida type	610536	*EFTUD2*	Autosomal dominant	Microcephaly, developmental delay, dysplastic ears, preauricular tags, choanal atresia
Auriculocondylar syndrome	602483, 614669	*GNAI3, PLCB4*	Autosomal dominant	"Question mark" ears, small mouth, prominent cheeks, anomalies of the temporomandibular joint and condyle
Cerebrocostomandibular syndrome	117650	Unknown	Autosomal dominant and recessive reported	Narrow thorax, rib anomalies, conductive hearing loss, growth restriction
Cerebrocostomandibular-like syndrome	606973	*COG1*	Autosomal recessive	Costovertebral defects, microcephaly, growth restriction, developmental delay, brain anomalies, cryptorchidism
Talipes, ASD, PRS, and persistence of left superior vena cava (TARP)	311900	*RBM10*	X-linked recessive	Talipes, congenital cardiac defects, persistence of left superior vena cava
Distal arthrogryposis-PRS (Illum syndrome)	208155	Unknown	Autosomal recessive	Joint contractures, autonomic instability, "whistling face," nervous system classification
PRS, cleft mandible, limb anomalies (Richieri-Costa-Pereira syndrome)	268305	Unknown	Autosomal recessive	Short stature, hypoplastic thumbs, talipes, laryngeal malformations
Andersen-Tawil syndrome	170390	*KCNJ2*	Autosomal dominant	Cardiac arrhythmias, periodic paralysis, low-set ears, short stature, digital anomalies
PRS + oligodactyly	172880	Unknown	Probably autosomal dominant	Oligodactyly
Fetal alcohol syndrome	—	N/A	Teratogenic	Microcephaly, growth and developmental delay, short palpebral fissures
Neuromuscular Conditions				
Congenital myotonic dystrophy	160900	*DMPK*	Autosomal dominant	Severe hypotonia, respiratory insufficiency
Carey-Fineman-Ziter syndrome	254940	Unknown	Probably autosomal recessive	Hypotonia, Moebius anomaly, growth delay, feeding difficulties, scoliosis
Chromosomal Abnormalities				
Trisomy 18	—	Unknown	Sporadic chromosomal	Microcephaly, severe growth and cognitive impairment, prominent occiput, cardiac defects, low-set ears, short sternum, overlapping flexed fingers, prominent calcaneus
22q11 microdeletion	188400/192430	*TBX1*	Autosomal dominant chromosomal	Upslanting palpebral fissures, prominent tubular nose, conotruncal heart defects, renal and endocrine abnormalities, neuropsychiatric problems
17q24 translocations and microdeletions	261800	*SOX9*	Autosomal dominant chromosomal	Isolated PRS
17q21.31q24.3 inversion and deletion	—	*SOX9*	Autosomal dominant chromosomal	PRS with hypoploastic scapula and bilateral clubfeet
2q33 microdeletion	608148	*SATB2*	Autosomal dominant chromosomal	Growth restriction, feeding difficulties, downslating palpebral fissures, prominent nose, dental anomalies, behavioral problems, developmental delay
4q terminal deletion	—	Unknown	Autosomal dominant chromosomal	Cardiac defects, mild developmental delay, but can be normal, stiff hypoplastic fifth fingers with hooked or volar nails

TABLE 16-3 Selected Syndromes and Chromosomal Anomalies Associated With Pierre Robin Sequence—cont'd

Condition	OMIM	Causative Gene	Inheritance Pattern	Additional Features
1q duplication	—	Unknown	Autosomal dominant chromosomal	Bilateral fixed flexion deformities of fingers, cardiac and brain anomalies
Partial trisomy 11q	—	Unknown	Autosomal dominant chromosomal	Developmental delay, congenital heart defects
t(1;2)(p34;q33)	613857	*FAF1*	Chromosomal	PRS in father and son with translocation disrupting *FAF1* at 1p34
20p12.3 microdeletion	112261	*BMP2*	Autosomal dominant chromosomal	Long philtrum, digital anomalies, hypotonia
22q12 microdeletion	—	*MN1*	Autosomal dominant chromosomal	Developmental delay, features of NF2 and Toriello-Carey due to contiguous gene deletion

ASD, atrial septal defect; PRS, Pierre Robin sequence; OMIM, Online Mendelian Inheritance in Man.

FIG 16-30 Micrognathia. Profile of a fetus shows mild micrognathia.

FIG 16-31 Severe micrognathia in a fetus with Nager syndrome. This can result in severe airway compromise at birth.

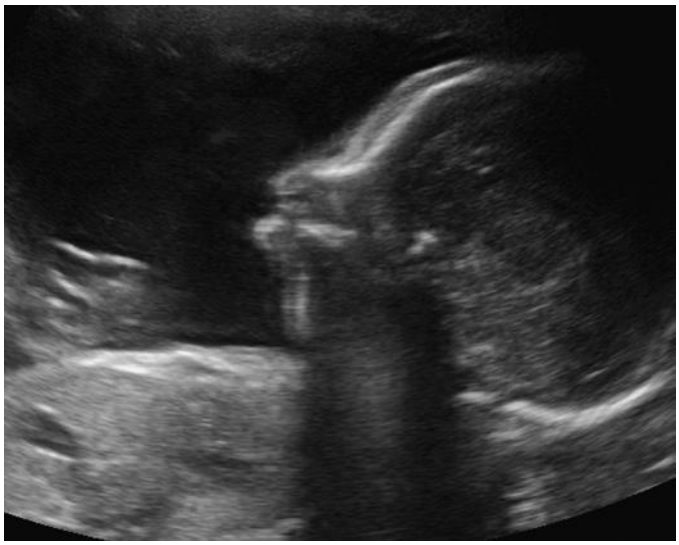

FIG 16-32 Micrognathia in a fetus with Pierre Robin sequence.

prognosis is often poor. This disorder is very rare, with slightly over 80 cases reported. Genetics are unknown, although possible defects in sonic hedgehog signaling have been implicated.

Treacher Collins Syndrome

Definition. Treacher Collins syndrome is characterized by deficient generation of the lower two thirds of the face, including hypoplasia of the zygoma, maxilla, and mandible.

Synonyms. Treacher Collins syndrome is also known as mandibulofacial dysostosis and Treacher Collins-Franceschetti syndrome.

Etiology. The syndrome is due to abnormal development of the first and second branchial arches.

Incidence. Incidence is 1 in 50,000 live births.

Diagnosis. Affected individuals have maxillary and mandibular hypoplasia, choanal atresia/stenosis, downward slanting palpebral fissures, notching of the lower eyelid, sparse or absent eyelashes, microtia/absent external ear, middle ear hypoplasia, cleft palate ± lip, and dental anomalies.

Genetics. Three causative genes have been found: *TCOF1* and *POLR1D* (autosomal dominant inheritance; most common) as well as *POLR1C* (autosomal recessive; only 1% of cases). Sixty percent of cases result from de novo mutations. Significant phenotypic variability is seen, even within families. Penetrance is high, but cases of nonpenetrance have been reported.

Pathogenesis. Mutations in the preceding genes lead to abnormal production of ribosomal RNA important in the development of the first and second branchial arches, leading structural facial anomalies.

Recurrence Risk. Recurrence risk is 50% for the autosomal dominant genes if a parental mutation is present, low if mutation is de novo, and 25% for the autosomal recessive form.

Differential Diagnosis. Differential diagnosis includes the other mandibulofacial dysostoses, such as Toriello syndrome, Bauru syndrome, Hedera-Toriello-Petty syndrome, and Guion-Almeida syndrome. Treacher Collins syndrome also shares some features of Nager syndrome, Miller syndrome, Goldenhar syndrome, and craniofacial microsomia.

Prognosis. Intelligence is normal. Middle ear hypoplasia causes conductive deafness (40-50% of individuals). Vision loss can also occur (37%). Speech issues are common.

Management. Intervention may be needed for the airway and feeding issues.

Van der Woude Syndrome

Definition. Van der Woude syndrome (VWS) is included in a spectrum of *IRF6*-related disorders ranging from isolated cleft lip/palate and popliteal pterygium syndrome. VWS is characterized by lower lip pits, cleft lip and palate, cleft uvula, and hypodontia.

Synonym. VWS has been classified as types 1 and 2.

Incidence. Incidence is 1 in 40,000 to 1 in 100,000 births. VWS is the most common form of syndromic clefting, accounting for 2% of all cases of cleft lip and palate.

Pathogenesis. IRF6 (interferon regulatory factor 6) is a transcription factor involved in orofacial development.

Diagnosis. Prenatal ultrasound examination can detect a cleft lip ± cleft palate, but is likely to miss an isolated cleft palate and lip pits.

Genetics. VWS type 1 is caused by mutations in the *IRF6* gene; type 2 is caused by mutations in the *GRHL3* gene (5% of all VWS cases). Inheritance is autosomal dominant. Penetrance is high but can be incomplete. De novo mutations have been reported.

Recurrence Risk. If a parental mutation is present, recurrence risk is 50%.

Differential Diagnosis. Bartsocas-Pappas syndrome (popliteal pterygium syndrome, lethal type), Kabuki syndrome, BOFS, and

FIG 16-33 Coronal ultrasound image showing unilateral cleft lip (*arrow*) in a fetus with van der Woude syndrome.

isolated cleft lip and palate are considered in the differential diagnosis.

Prognosis. Multiple surgeries are often needed to treat lip pitting and can lead to scarring and decreased ability to open the mouth. Psychomotor development is generally normal.

X-linked Opitz G/BBB Syndrome

Definition. X-linked Opitz G syndrome (XLOS) is characterized by facial anomalies (hypertelorism, prominent forehead, widow's peak, broad nasal bridge, anteverted nares), laryngeotracheoesophageal defects, and genitourinary anomalies (hypospadias, cryptorchidism, bifid scrotum).

Incidence. Incidence is 1 in 50,000 to 1 in 100,000 males.

Pathogenesis. Mutations in *MID1* lead to altered mTORC1 signaling, which is thought to affect the development of ventral midline anatomic structures.

Diagnosis. Diagnosis is most often based on clinical findings with abnormalities in ventral midline structures, as described previously. Prenatally, those cases associated with congenital heart defects and cleft lip are more likely to be detected.

Genetics. XLOS is due to mutations in *MID1*. Inheritance is X-linked. Many individuals are the only ones known to be affected within their families. Penetrance is high; wide phenotypic variability is seen even within families.

Recurrence Risk. If the mother is a carrier, there is a 50% chance of transmitting the disease-causing mutation in each pregnancy. Sons who inherit the mutation will be affected. Daughters will be carriers with isolated hypertelorism.

Associated Anomalies. Other anomalies include cleft lip/palate (50%), congenital heart defects, imperforate or ectopic anus, and midline brain defects.

Differential Diagnosis. FG syndrome, craniofrontonasal dysplasia, and Mowat-Wilson syndrome should be considered.

Prognosis. Intellectual disability and developmental delay are seen in 50% of affected males. Prognosis depends on the severity of the associated anomalies.

Management. A multidisciplinary team is needed to manage the multiple anomalies.

MUSCULOSKELETAL SYSTEM

Skeletal Dysplasias

Overall, skeletal dysplasias are seen in 2.4 per 10,000 births, and of these, 0.95 to 1.5 per 10,000 live births are lethal skeletal dysplasias. As a group, there are more than 450 skeletal dysplasias and the specific disorder can be difficult to determine based on prenatal ultrasound findings alone. A genetic cause has been identified for more than 50% of skeletal dysplasias; many are due to de novo mutations. Those with autosomal recessive inheritance often occur without a family history.

In the prenatal setting, particular emphasis should be given to identifying those disorders with neonatal or infantile lethality. Specific details should be obtained on prenatal ultrasound examination if a skeletal dysplasia is suspected, including length and appearance of long bones, facial features, spine, and extremity anomalies, as well as femur/foot ratio. Measurements that can assist in predicting neonatal lethality include chest circumference/abdominal circumference ratio and femur length/abdominal circumference ratio.

Of the lethal skeletal dysplasias, the most common are thanatophoric dysplasia (TD) and osteogenesis imperfecta (type 2), followed by achondrogenesis. Together, these three disorders represent 40% to 60% of all lethal skeletal dysplasias. Other relatively common lethal skeletal dysplasias include campomelic dysplasia, hypophosphatasia congenita, and short-rib polydactyly syndromes. Lethal disorders seen more rarely include atelosteogenesis, rhizomelic chondrodysplasia punctata, and fibrochondrogenesis. The most common nonlethal skeletal dysplasia is achondroplasia. These disorders are each reviewed in more detail in this section.

Thanatophoric Dysplasia

Definition. TD is the most common lethal skeletal dysplasia and is characterized by severe rhizomelia, small thorax, normal trunk length, normal bone mineralization, no fractures, thickened redundant skin, and platyspondyly (flattened vertebral bodies). TD is divided into two subtypes:

- Type 1: TD1 is the more common form. The femurs have a "telephone receiver" shape, and frontal bossing and midface hypoplasia are present. Cloverleaf skull is not seen. The hands and feet are normal, but the fingers are short.
- Type II: TD2 is the less common form. Femurs are straight with flared metaphyses, and a cloverleaf skull is present (due to craniosynostosis of the lambdoid and coronal sutures).

Incidence. Incidence is 1 in 20,000 births.

Etiology. Mutations in *FGFR3* are gain-of-function mutations that lead to a constitutively active protein. This leads to chondrocyte proliferation and premature maturation of bone.

Genetics. TD1 is caused most frequently by mutations in the fibroblast growth factor receptor 3 gene (*FGFR3*); the most common mutations are R248C and Y373C. TD2 is also caused by mutations in *FGFR3*, specifically the mutation *K650E*. Inheritance is autosomal dominant. Because the disorder is lethal, new diagnoses are generally the result of de novo mutations. Advanced paternal age has been associated with an increased risk.

Recurrence Risk. Recurrence risk is low because most mutations are de novo; germline mosaicism remains a possibility but has not been reported in individuals without signs of skeletal dysplasia.

Diagnosis. Prenatal findings include severe rhizomelia (seen as early as 12-14 weeks) and a hypoplastic thorax. Craniofacial dysmorphisms include macrocephaly, frontal bossing, midface hypoplasia, and cloverleaf skull. Other features include brachydactyly, platyspondyly, hypotonia, and redundant skinfolds. Other brain anomalies may be seen including polymicrogyria, deep and transverse temporal sulci, and temporal lobe enlargement. Polyhydramnios is seen in approximately 50% of cases. Increased nuchal translucency may be present.

Differential Diagnosis. The differential diagnosis includes other types of short-limbed dwarfism and disorders with a cloverleaf skull (such as Apert, Crouzon, Pfeiffer, and Carpenter syndromes). The features can closely resemble homozygous achondroplasia with autosomal recessive inheritance; it can be distinguished from TD by the presence of positive carrier status for heterozygous *FGFR3* mutations in each parent in the case of achondroplasia.

Prognosis. In general, affected infants die shortly after birth of respiratory insufficiency due to a small thorax and lung hypoplasia.

Management. The option of pregnancy termination should be offered before viability. Sonographic evaluation of hydrocephalus is recommended because it can lead to malpresentation and difficult delivery. If massive hydrocephalus has developed, cephalocentesis or

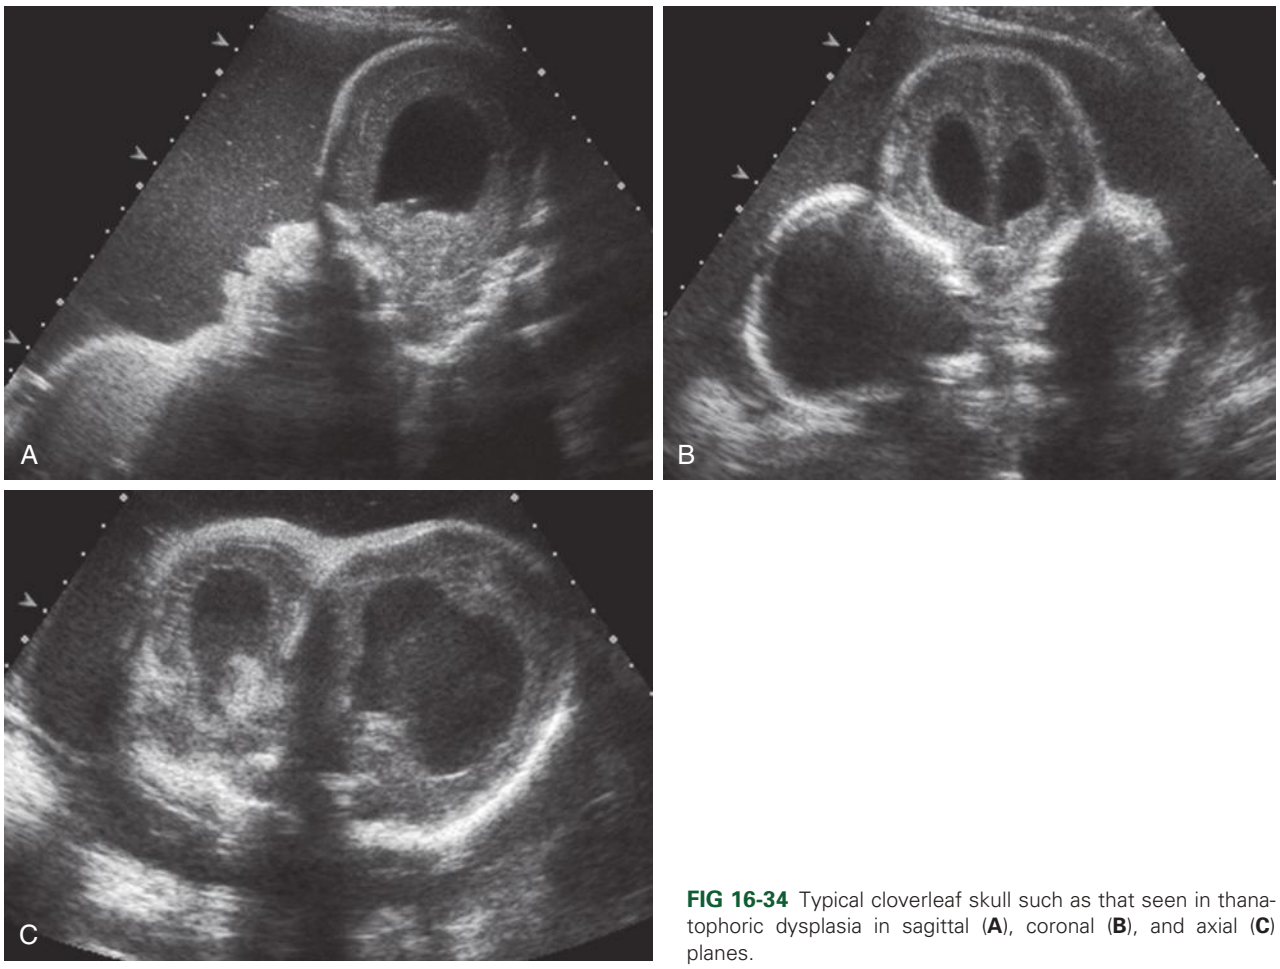

FIG 16-34 Typical cloverleaf skull such as that seen in thanatophoric dysplasia in sagittal (**A**), coronal (**B**), and axial (**C**) planes.

Osteogenesis Imperfecta

Definition. Osteogenesis imperfecta (OI) is a heterogeneous group of genetic disorders (classically divided in four types: I, II [congenital], III, and IV) characterized by severe bone fragility, leading to abnormal ossification and multiple fractures. The clinical features range from perinatal lethality (type II) to severe skeletal deformities to those with minimal features. The four types are described as follows:

- Type I: classic nondeforming OI with blue sclerae. Deformities are not seen prenatally.
- Type II: perinatal lethal OI. This is the most severe form and can be seen prenatally.
- Type III: progressively deforming OI. Some features can be seen prenatally.
- Type IV: common variable OI with normal sclerae. Deformities are not generally seen prenatally.

Synonyms. OI is also called brittle bone disease.

Incidence. The incidence is 6 to 7 per 100,000 for all types of OI, with types I and IV representing more than one half of all cases. Types II and II each have an incidence of 1 to 2 per 100,000.

Etiology. *COL1A1* and *COL1A2* encode for type I collagen (found in skin, ligaments, tendons, demineralized bone, and dentine). Defective production of type I collagen leads to decreased bone mineralization and bone fragility.

Genetics. OI is due to mutations in *COL1A1* or *COL1A2*. Inheritance is autosomal dominant. Approximately 60% of cases of type I and IV OI are caused by de novo mutations, whereas almost 100% of cases of type II and III OI are caused by de novo mutations. Penetrance is complete, but expression can vary significantly.

Recurrence Risk. Recurrence risk depends on whether the mutation was inherited or de novo. Gonadal mosaicism may be present in 3% to 5% of cases with apparent de novo mutations. Less commonly, OI can also be autosomal recessive.

Diagnosis. Type II is the most severe form and affected individuals usually die in utero or shortly after birth from severe fractures and pulmonary hypoplasia. Key prenatal findings include severe micromelia (femur length more than 3 standard deviations [SD] below the mean), small thorax, normal head circumference, short

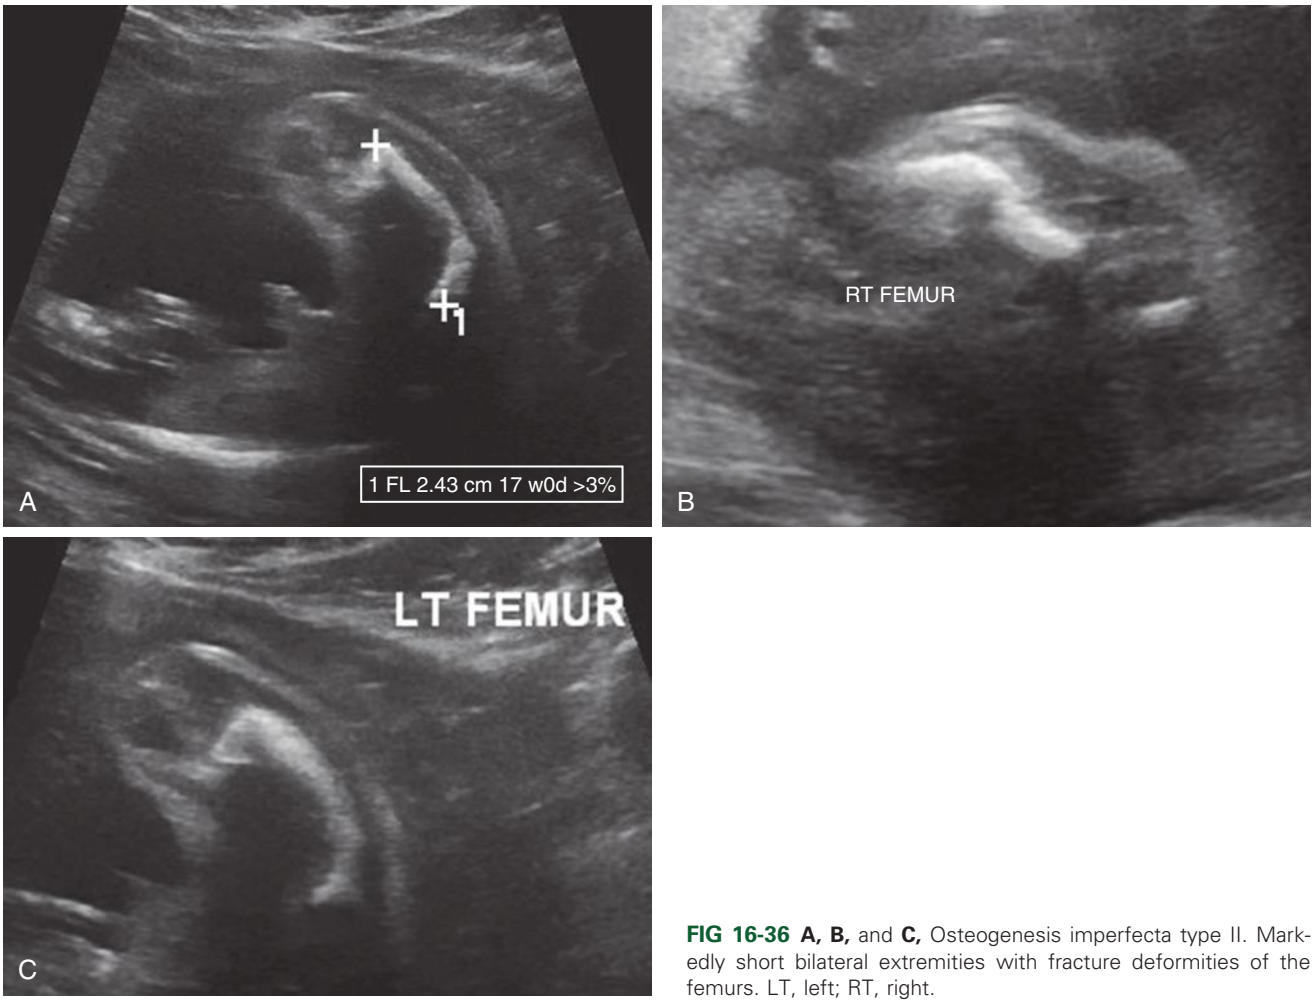

FIG 16-36 **A, B,** and **C,** Osteogenesis imperfecta type II. Markedly short bilateral extremities with fracture deformities of the femurs. LT, left; RT, right.

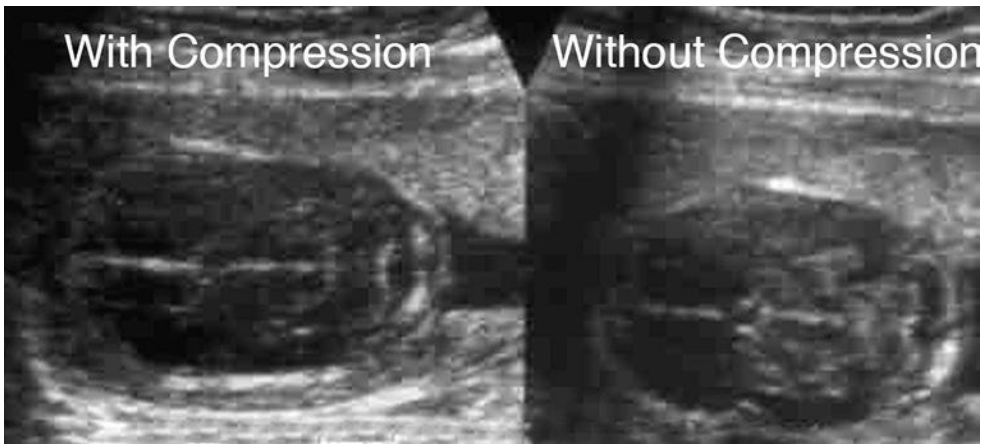

FIG 16-37 The skull demonstrates markedly decreased echogenicity and is readily compressible even with moderate transducer pressure (*left*).

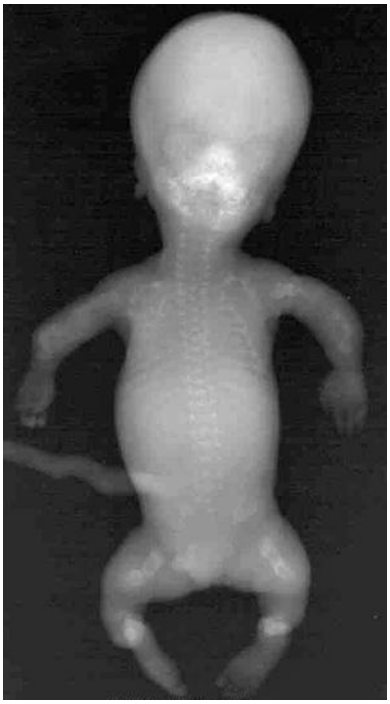

FIG 16-38 Frontal x-ray scans of the fetus. Note the poor mineralization and the numerous fractures.

trunk, decreased bone mineralization (including decreased ossification of the skull), and multiple bone fractures. Multiple fractures may lead the long bones to appear angulated. Both cortices of a bone are often seen. Some findings can be seen as early as 13 to 15 weeks' gestation.

The other types of OI may not be detected prenatally. Type I is characterized by blue sclerae and normal stature. The first fractures generally occur in infancy. Progressive hearing loss is present in 50% of adults. Type III is apparent at birth; fractures may be caused just by handling the infant. Rib fractures can lead to pulmonary failure in the first few weeks or months of life. Those who survive generally need assistance for mobility and are extremely short. Hearing loss often begins in the teenage years. Type IV is characterized by mildly short stature, adult-onset hearing loss, and normal-to-gray sclerae; phenotype is the most variable. Dentinogenesis imperfecta is common.

Differential Diagnosis. The differential diagnosis includes hypophosphatasia (infantile form), achondrogenesis, and other short-limbed dwarfisms.

Prognosis. Type II OI is uniformly lethal. The other forms develop after birth and are characterized by progressive deformities of the long bones and short stature.

Management. Owing to the uniformly fatal outcome, termination of pregnancy should be offered when type II is diagnosed early in pregnancy and palliative care provided if delivery is undertaken. If continuation of the pregnancy is chosen, cesarean delivery is often recommended for nonlethal OI for prevention of fetal and maternal trauma.

Achondrogenesis

Definition. Achondrogenesis is a heterogeneous group of lethal skeletal dysplasias characterized by severe micromelia, small thorax, short trunk, decreased bone mineralization (particularly of the vertebrae, sacrum, and pubic bones), and occasional fractures. The most common types are described here:

- Type 1: includes type 1A and type 1B. Deficient bone mineralization also affects the calvarium.
- Type 2: similar to type 1, with less severe mineralization deficits.

Synonyms. Synonyms include type 1A, Houston-Harris type; type 1B, Fraccaro type; type 2, Langer-Saldino type.

Incidence. Incidence is 0.9 to 0.23 per 10,000 births. Type 1 represents 20% of cases; type 2 represents 80% of cases.

Etiology. In type 1A, *TRIP11* mutations lead to defects in Golgi-mediated glycosylation and altered transport of multiple cellular proteins. In type 1B, mutations in *SLC26A2* impair activity of the sulfate transporter in chondrocytes and fibroblasts leading to defective cartilage matrix assembly. In type 2, *COL2A1* mutations lead to structural abnormalities in type 2 collagen.

Genetics. Type 1 is inherited in autosomal recessive fashion; type 1A is caused by mutations in *TRIP11*, and type 1B is caused by mutations in *SLC26A2* (*DTDST*). Type 2 is an autosomal dominant condition caused by de novo mutations in *COL2A1*.

Recurrence Risk. Recurrence risk depends on the mode of inheritance. Type 1 has a 25% recurrence risk. The recurrence risk for type 2 is low.

Diagnosis. Type 1 is characterized by severe micromelia, facial dysmorphism (flat face), decreased skull, vertebral, and pelvic bone ossification, short thin ribs, and short long bones with deformity. Other features include short fingers and toes (seen more in type 1B), protuberant abdomen, abundant soft tissue (which can lead the fetus to appear hydropic), and short neck with thickened tissue. Skull is normally sized. Polyhydramnios is present in 25% of affected fetuses. Breech presentation is common.

Type 2 presents with similar findings but the mineralization deficit is less severe and the long bones less short. Fingers and toes may appear normal.

Differential Diagnosis. The differential diagnosis includes other lethal chondrodysplasias. Cartilage histologic examination can assist in distinguishing between the subtypes of achondrogenesis. OI (specifically types II and III) and hypophosphatasia also present with bone demineralization, but the limb shortening is not usually as severe. Abnormal mineralization and shortened trunk length distinguish it from TD in which these are normal.

Prognosis. The disorder is perinatally lethal with death occurring prenatally or shortly after birth.

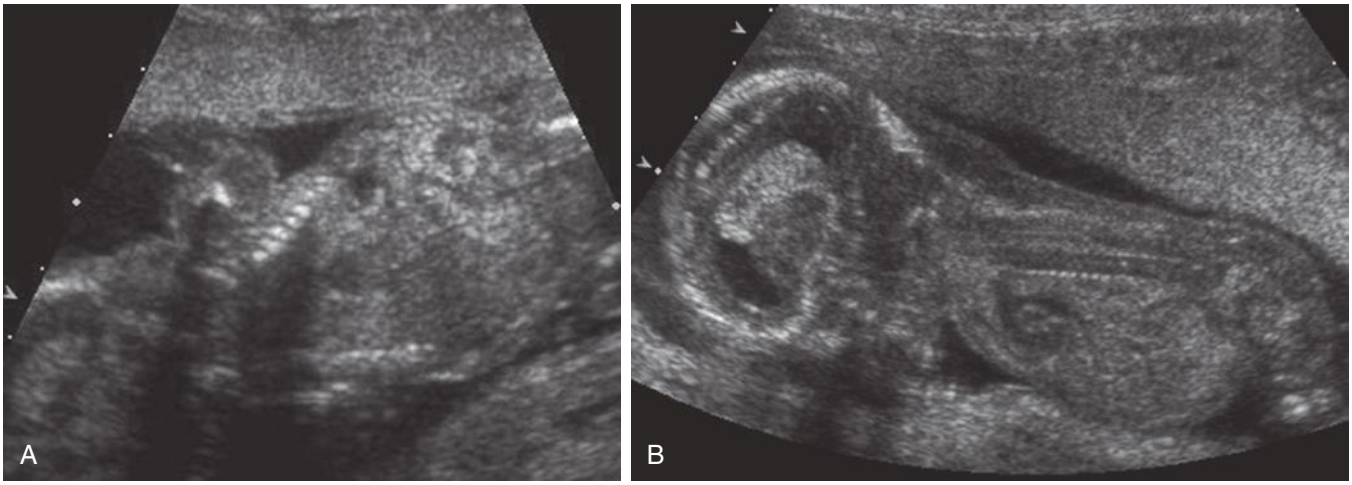

FIG 16-39 Achondrogenesis. **A,** Coronal image of the fetus with a markedly small thorax; **B,** diffuse lack of bony mineralizaton, with particular involvement of the spinal vertebrae.

Campomelic Dysplasia

Definition. Campomelic dysplasia (derived from the Greek word for "bent limb") is a skeletal dysplasia characterized by bowing and shortening of the long bones, club feet, and distinctive facial features including Pierre Robin sequence with cleft palate.

Synonyms. Campomelic dysplasia is also known as campomelic syndrome and campomelic dwarfism.

Incidence. Incidence is 1 in 40,000 to 1 in 80,000 births.

Etiology. *SOX9* regulates chondrocyte differentiation by regulating the expression of several genes, including the collagen genes *COL2A1* and *COL11A2*. It also functions as a testes-determining gene downstream of *SRY*.

Genetics. Campomelic dysplasia is due to mutations in *SOX9*. Inheritance is autosomal dominant; most individuals have de novo mutations, although cases of parental diagnosis following identification of an affected child have been reported.

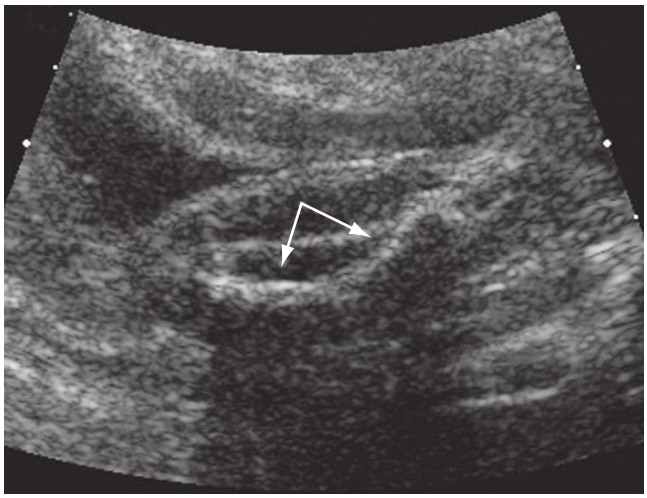

FIG 16-43 Campomelic dysplasia. Bowing of the femur (*arrows*). Note the gentle curve that differentiates this entity from the more acute angles seen in fetuses with osteogenesis imperfecta.

Recurrence Risk. Recurrence risk is low if the parents are unaffected, although germline mosaicism has been reported.

Diagnosis. The most striking feature is anterior bowing of the long bones, particularly the femur and tibia. Other features seen on ultrasound imaging include 11 pairs of ribs, a bell-shaped narrow chest, relatively large head, Pierre Robin sequence with cleft palate, flat face with high forehead, laryngotracheomalacia, cervical spine anomalies, scoliosis, scapular hypoplasia, ambiguous genitalia (or normal female genitalia in a 46,XY individual), dislocated hips, clubfeet, and hydrocephalus. Cardiac and renal anomalies have also been reported. Polyhydramnios may be present.

Differential Diagnosis. The differential diagnosis includes OI types II and III, hypophosphatasia, other disorders leading to congenital bowing of the long bones, TD, and spondyloepiphyseal dysplasia.

Prognosis. Most cases (>75%) are lethal owing to respiratory insufficiency caused by airway instability or cervical spine instability. Survivors may have respiratory issues, hearing loss, and progressive scoliosis. Intellectual abilities are generally normal.

Hypophosphatasia Congenita

Definition. Hypophosphatasia congenita is characterized by severe micromelia, small thorax, normal head circumference, normal trunk length, decreased bone mineralization, and occasional fractures. The cranium is compressible from deficient mineralization.

Synonyms. Hypophosphatasia congenita is also called perinatal lethal hypophosphatasia.

Prevalence. Hypophosphatasia congenita is seen in 1 in 100,000.

Etiology. Hypophosphatasia congenita is associated with reduced activity of serum alkaline phosphatase.

Genetics. Hypophosphatasia congenita is due to mutations in *ALPL*, the gene encoding alkaline phosphatase, tissue-nonspecific isozyme (TNSALP). Inheritance is autosomal recessive. Significant phenotypic variability can occur.

Recurrence Risk. Recurrence risk is 25% if both parents are found to be mutation carriers. Carriers can be asymptomatic (with only biochemical abnormalities) or may have mild clinical features.

Diagnosis. The perinatal lethal form of hypophosphatasia is generally diagnosed on prenatal ultrasound imaging. Features include a small thorax, short bowed limbs, flail chest, and poorly mineralized

skull. Fetal radiographs demonstrate a generalized deficiency in ossification, with tubular bones that appear short, thin, and bowed.

Differential Diagnosis. In the prenatal period, the differential includes OI type II, campomelic dysplasia, and chondrodysplasias with defective bone mineralization.

Prognosis. Pregnancies may end in stillbirth. Liveborn infants most frequently die of pulmonary insufficiency. Hypercalcemia is common and can lead to apnea and seizures.

Short Rib–Polydactyly Syndromes

Definition. Short rib–polydactyly syndromes (SRPSs) are heterogeneous group of lethal skeletal dysplasias typically divided into four subgroups. General findings include severe micromelia, small thorax with short ribs, a trident aspect of the acetabular roof, normal head circumference, normal bone mineralization, and polydactyly. Cardiac and genitourinary abnormalities may be seen. The SRPSs are divided into five subtypes, types I through V. Two related syndromes with a milder phenotype include Ellis–van Creveld syndrome (EVC) and Jeune syndrome. Features of the subtypes can overlap, making diagnosis challenging.

Synonyms. Synonyms include type I, Saldino-Noonan syndrome; type II, Majewski syndrome; type III, Verma-Naumoff syndrome; type IV, Beemer-Langer syndrome; and type V.

Prevalence. Prevalence is unknown; the syndrome is rare.

Etiology. All SRPSs are classified as ciliopathies because of dysfunction of the primary cilium.

Genetics. SRPSs are due to mutations in genes affecting primary cilium function, including mutations affecting the dynein motor (*DYNC2H1*), intraflagellar transport complexes (*IFT80, IFT122, IFT43, WDR35, WDR19, TTC21B*), and basal body (*NEK1, EVC, EVC2*). Other genes identified include *WDR34* and *WDR60* that also are important for primary cilium function. Inheritance is autosomal recessive.

Diagnosis. The most striking ultrasound finding is a very narrow chest with short limbs. The limbs, however, are not as short as those of other lethal conditions such as TD, achondrogenesis, and OI type II.

Differential Diagnosis. The differential diagnosis should include the range of SRPSs.

Prognosis. There is a phenotypic spectrum, and although many affected infants die, some do survive.

Other Lethal Skeletal Dysplasias

Atelosteogenesis, Type 2

Atelosteogenesis, type 2 is a rare lethal skeletal dysplasia characterized by rhizomelia, normal head circumference, hitchhiker thumbs, ulnar deviation of fingers, small thorax, protuberant abdomen, facial dysmorphism (flat midface, micrognathia), cleft palate, clubfeet, and a gap between the first and second toes. Death occurs from pulmonary hypoplasia and tracheobronchomalacia. It is due to mutations in *SLC26A2* (*DTDST*). Inheritance is autosomal recessive.

Fibrochondrogenesis

Fibrochondrogenesis is a rare lethal skeletal dysplasia characterized by short long bones with irregular metaphyses that appear stippled from peripheral spurs and extra-articular calcifications (dumbbell-shaped long bones). Other features include small thorax, normal head circumference, normal hands and feet, flat facies, decreased skull mineralization, and vertebrae with platyspondyly and midline clefts. It is due to mutations in *COL11A1*. Inheritance is autosomal recessive. Carriers of causative mutations can have myopia and early-onset hearing loss.

Rhizomelic Chondrodysplasia Punctata, Type I

Rhizomelic chondrodysplasia punctata, type I is a rare skeletal dysplasia with prevalence less than 100,000 births; the classic type is a peroxisome biogenesis disorder characterized by rhizomelia (humerus shorter than femur), epiphyseal and metaphyseal abnormalities (punctate calcifications), vertebral clefting, and congenital cataracts. Other common features include severe postnatal growth deficiency, seizures, and severe intellectual disability. Some children die in the neonatal period; lifespan is generally less than 10 years. It is due to mutations in *PEX7*, a gene that encodes the receptor for some peroxisomal matrix enxymes. Inheritance is autosomal recessive.

REFERENCE

Braverman NE, Moser AB, Steinberg SJ: Rhizomelic chondrodysplasia punctata type 1. In Pagon RA, Adam MP, Ardinger HH, et al, editors: *GeneReviews*, Seattle, 1993–2016, University of Washington.

Achondroplasia

Definition. Achondroplasia is a relatively common nonlethal skeletal dysplasia characterized by rhizomelia, macrocephaly, and characteristic facial features (frontal bossing and flat midface). Other features include redundant skinfolds on limbs, short fingers, bowed legs, and exaggerated lumbar lordosis.

Incidence. Incidence is 1 in 26,000 to 28,000 live births.

Etiology. The *FGFR3* mutation, p.Gly380Arg, seen in achondroplasia leads to constitutive activation of *FGFR3*. This results in inhibition of chondrocyte proliferation and differentiation and negatively regulates bone growth.

Genetics. Achondroplasia is due to a mutation in *FGFR3*, specifically p.Gly380Arg. Inheritance is autosomal dominant; 80% of mutations are de novo and are exclusively inherited from the father. Advanced paternal age increases the risk of de novo mutations.

Recurrence Risk. Recurrence risk is low if both parents have average stature. If one parent is affected, recurrence risk is 50%. If both parents are affected, the risk to offspring is as follows: 25% will have average stature, 50% will have achondroplasia, and 25% will have homozygous achondroplasia (which is lethal).

Diagnosis. Prenatally, a shortened femur in comparison to the head circumference can been seen in the second trimester; femur length is often at the 3rd percentile or less by 25 weeks' gestation (see Fig. 16-46). Fetuses with normal interval growth in femoral length during the second trimester are expected to be unaffected. The craniofacial features, including macrocephaly, frontal bossing, and flat midface, can also be seen. Occasionally more subtle anomalies, such as the trident hand (an increased space between the third and fourth digit) or the lack of widening of the lumbar canal, can also be identified.

Differential Diagnosis. The differential diagnosis includes TD, hypochondroplasia, achondrogenesis, OI type II, and diastrophic dysplasia.

Prognosis. Developmental milestones are often delayed, but intelligence is normal. Craniocervical junction compression increases the

FIG 16-44 Achondroplasia. Frontal bossing.

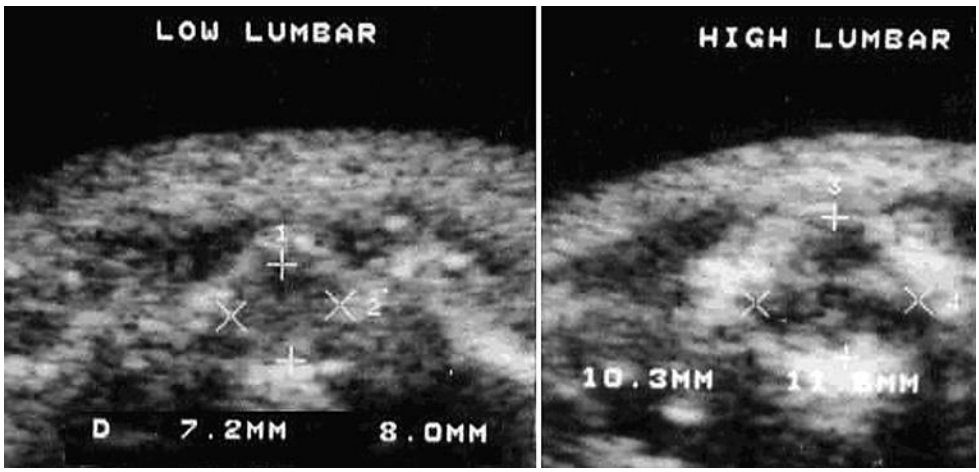

FIG 16-45 Achondroplasia. Lack of widening of the spinal canal.

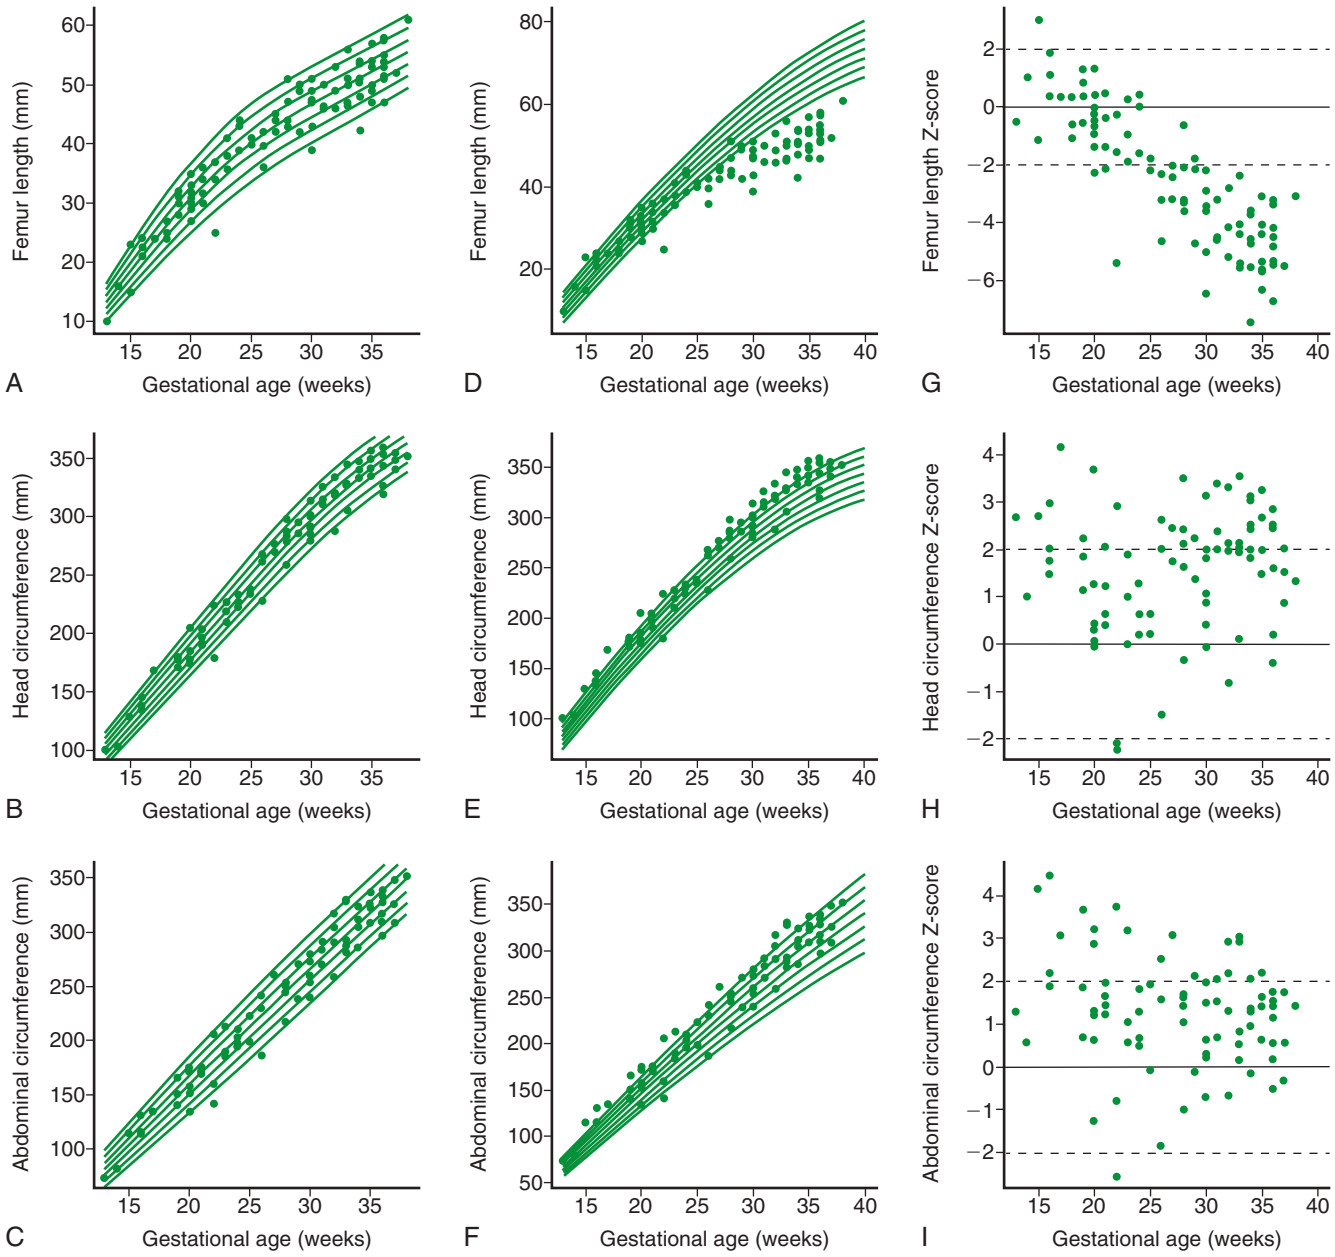

FIG 16-46 Fetal size charts for femur length (**A**), head circumference (**B**), and abdominal circumference (**C**) against gestational age in fetuses with achondroplasia. Note the curvature in the femur length chart as growth declines in the third trimester. Comparison with normal fetuses is demonstrated by overlaying measurements from affected fetuses on charts of fetuses of normal size (**D**-**F**, respectively) and by plots of Z-scores showing the deviation from the normal range (**G**-**I**, respectively). (From Chitty LS, Griffin DR, Meaney C, et al: New aids for the non-invasive prenatal diagnosis of achondroplasia: dysmorphic features, charts of fetal size and molecular confirmation using cell-free fetal DNA in maternal plasma. Ultrasound Obstet Gynecol 37(3):283-289, 2011, Fig. 1.)

risk of death in infancy as a result of central apnea (risk ~ 7.5%). Obesity is a common problem that often begins in childhood. Spinal stenosis at L1-L4 is the most common medical complaint in adulthood.

Management. Medical issues require ongoing surveillance, and guidelines have been established (see Trotter and Hall, 2005). Strong support groups exist, including the Little People of America, Inc.

Vertebral Anomalies

Klippel-Feil Syndrome

Definition. Klippel-Feil syndrome (KFS) is characterized by a classic triad of short neck, low posterior hairline, and fusion of cervical vertebrae. Different classification schemes for subtypes have been proposed. KFS1 and KFS3 are autosomal dominant disorders, whereas KFS2 is autosomal recessive.

Incidence. Incidence is 1 in 40,000 to 42,000 live births. A slight female predominance has been reported.

Etiology. The implicated genes encode for proteins in the bone morphogenetic protein family, which is involved in regulating the differentiation of bone and cartilage.

FIG 16-47 Second trimester sonogram of a fetus with Klippel-Feil syndrome. Persistent retroflexion of the head on the neck should raise suspicion for this diagnosis.

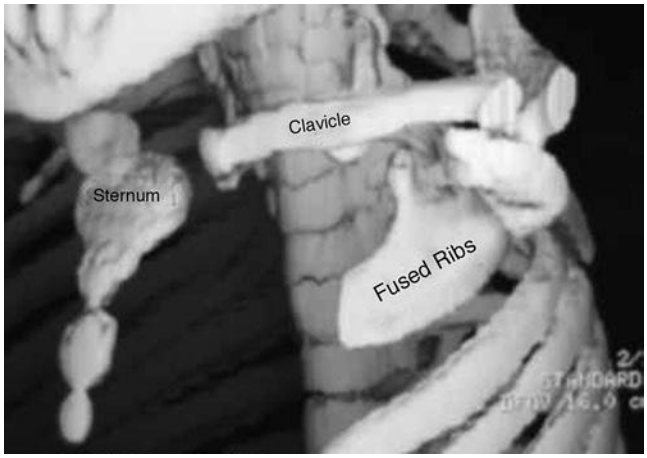

FIG 16-48 Reformatted computer tomographic scan of a 2-year-old child with Klippel-Feil syndrome. Note the fused ribs. (Courtesy of Ian Suchet, 2002. Available at thefetus.net.)

Genetics. KFS1 is due to mutations in the *GDF6* gene, and KFS3 is due to mutations in the *GDF3* gene; both have autosomal dominant inheritance. KFS2 is due to mutations in *MEOX1* and has autosomal recessive inheritance.

Recurrence Risk. Recurrence risk depends on the mode of inheritance and presence of parental mutations.

Diagnosis. The short neck may be associated with opisthotonos (retroflexion of the head), and disorganization of the cervical vertebrae is potentially recognizable. Other associated anomalies include ocular malformations, cleft lip and palate, oligodontia, craniofacial asymmetry, maxillary constriction and velopharyngeal insufficiency, persistent trigeminal artery, congenital heart defects, and urogenital anomalies. Some cases occurring with situs inversus totalis have been reported.

Differential Diagnosis. The differential diagnosis includes other disorders with vertebral anomalies.

Prognosis. Complications result from vertebral fusion and include cord compression syndrome, cervical instability, and motility impairment.

VACTERL Association

See separate entry at the end of this chapter.

FIG 16-49 A child with Klippel-Feil syndrome. Note the opisthotonotic position, low-set ears, and micrognathia.

Spondylocostal Dysostosis

Definition. Spondylocostal dysostosis (SCDO) is characterized by multiple segmentation defects of the vertebrae and rib abnormalities, leading to a short trunk, short neck, and scoliosis.

Prevalence. SCDO is rare; SCDO associated with *DLL3* mutations is the most common.

TABLE 16-4 Some Syndromes That Include Multiple Segmentation Defects of the Vertebrae (Spondylocostal Dysostosis and Spondylothoracic Dysostosis Excluded)

*Underlying cause not known.

†Possible associations reported: *PAX1* (McGaughran JM, Oates A, Donnai D, et al: Mutations in PAX1 may be associated with Klippel-Feil syndrome. Eur J Hum Genet 11:468-474, 2003.) and *WNT4* (Philibert P, Biason-Lauber A, Rouzier R, et al: Identification and functional analysis of a new WNT4 gene mutation among 28 adolescent girls with primary amenorrhea and müllerian duct abnormalities: a French collaborative study. J Clin Endocrinol Metab 93:895-900, 2008.).

CHARGE, coloboma of the eye, heart defects, atresia of the choanae, retarded mental and growth development, genital anomalies, and ear anomalies; OEIS, omphalocele, bladder exstrophy, imperforate anus, and spinal defects; MURCS, müllerian duct aplasia, congenital renal dysplasia, and cervical somite anomalies; RAPADILINO, radial ray defect, patellae hypoplasia or aplasia and cleft or highly arched palate, diarrhea and dislocated joints, little size and limb malformations, and long, slender nose and normal intelligence; VATER/VACTERL, vertebral anomalies, anal atresia, cardiac anomalies, tracheoesophageal fistula or esophageal atresia, renal/urinary anomalies, and limb defects.

From Turnpenny PD, Young E; ICVS (International Consortium for Vertebral Anomalies and Scoliosis): Spondylocostal Dysostosis, Autosomal Recessive. 2009 Aug 25 (Updated 2013 Jan 17). In Pagon RA, Adam MP, Ardinger HH, et al (eds): GeneReviews.® Seattle, University of Washington, 1993-2016, Table 2.

Etiology. The causative genes identified to date all encode key proteins in the Notch-signaling pathway, which is essential for vertebral development.

Genetics. SCDO is due to mutations in one of four genes: *DLL3, MESP2, LFNG, HES7*. Inheritance is autosomal recessive.

Recurrence Risk. Recurrence risk is 25% if both parents are mutation carriers.

Diagnosis. Diagnosis is based on radiologic features including vertebral segmentation defects and rib abnormalities. These features can be seen prenatally as early as the late first trimester.

Differential Diagnosis. The differential diagnosis includes other rarer conditions with similar vertebral anomalies as well as syndromes associated with multiple vertebral segmentation defects (Table 16-4).

Prognosis. The size of the thorax can compromise respiratory function in neonates and can lead to pulmonary hypertension. Males have increased risk for inguinal hernia. Neurologic complications are rare.

REFERENCE

Upper Extremity Anomalies

If an upper limb anomaly is noted, particular attention should be given to evaluating for spine, renal, and cardiac anomalies. If the defect is in an isolated forearm, it is rare for further problems to be found. If bilateral upper limb anomalies are noted and the karyotype is normal, there is a high incidence of genetic syndromes, several of which are reviewed later.

Adams-Oliver Syndrome

Definition. Adams-Oliver syndrome (AOS) is characterized by aplasia cutis congenital of the scalp vertex and terminal transverse limb defects (amputations, syndactyly, brachydactyly, oligodactyly).

Incidence. Incidence is estimated at 1 in 225,000.

Etiology. The implicated genes encode for proteins implicated in embryonic development. Some are thought to affect pericyte function leading to the observed anomalies.

Genetics. The genetic cause is heterogeneous, and includes heterozygous mutations in *ARHGAP31* and *RBPJ* (autosomal dominant inheritance) as well as biallelic mutations in *DOCK6* and *EOGT* (autosomal recessive inheritance). Recently, heterozygous mutations in *NOTCH1* were also implicated in AOS.

Recurrence Risk. Recurrence risk depends on mode of inheritance and presence of parental mutations.

Diagnosis. Prenatally, transverse limb defects may be detected sonographically. Other commonly observed features in affected individuals include vascular anomalies (pulmonary hypertension, portal hypertension, cutis marmorata, venous ectasia, thrombophilia) and congenital heart defects (both right- and left-sided).

Differential Diagnosis. The differential diagnosis includes other causes of transverse limb defects.

Prognosis. Prognosis depends on the associated anomalies, which can range from mild to severe. Pulmonary hypertension can be life threatening.

Stittrich AB, Lehman A, Bodian DL, et al: Mutations in NOTCH1 cause Adams-Oliver syndrome. *Am J Hum Genet* 95(3):275–284, 2014.

Cornelia de Lange Syndrome

Definition. Cornelia de Lange syndrome (CdLS) is characterized by facial dysmorphism (synophrys, arched eyebrows, long eyelashes, small upturned nose, small widely spaced teeth, micrognathia), growth restriction and microcephaly (prenatal onset), hirsutisum, and upper limb reduction defects (phalangeal abnormalities, oligodactyly).

Synonym. It is also known as Brachmann-de Lange syndrome.

Incidence. Estimates range from 1 in 10,000 to 1 in 100,000. The milder form is likely underdiagnosed.

Diagnosis. Diagnosis is based on clinical findings. Other features may include cardiac septal defects, cleft palate, GI dysfunction, hearing loss, myopia, and cryptorchidism. Congenital diaphragmatic hernia (CDH) can occur (1%).

Genetics. Implicated genes include *NIPBL* (60% of cases) as well as *SMC1A* and *SMC3* (5% and <1% of cases, respectively). Inheritance of *NIPBL*- and *SMC3*-related CdLS is autosomal dominant; *SMC1A*-related CdLS is X-linked. Most *NIPBL* mutations are de novo. In general, the phenotype associated with mutations in *SMC1A* and *SMC3* is milder. Phenotypic expression in families is relatively consistent. Penetrance is complete.

Recurrence Risk. Recurrence risk depends on the implicated gene. Germline mosaicism is increased with *NIPBL*-related CdLS and recurrence is estimated to be 1.5%.

Differential Diagnosis. Other disorders to consider include partial duplication of 3q, deletions of 2q31, Fryns syndrome, and FAS.

Prognosis. Intellectual disability is generally present. Autistic and self-destructive tendencies are common. Life expectancy is generally normal, although an increased mortality rate has been reported related to aspiration, apnea, congenital heart disease, volvulus, and postsurgical complications.

Management. Management guidelines have been published and involve multidisciplinary care for both medical and developmental issues.

Ectrodactyly-Ectodermal Dysplasia-Clefting Syndrome

Definition. Ectrodactyly-ectodermal dysplasia-clefting (EEC) syndrome is characterized by abnormalities in ectodermal structures (skin, hair, teeth, nails, sweat glands) as well as cleft lip ± palate and limb defects (ectrodactyly and syndactyly of the hands and feet).

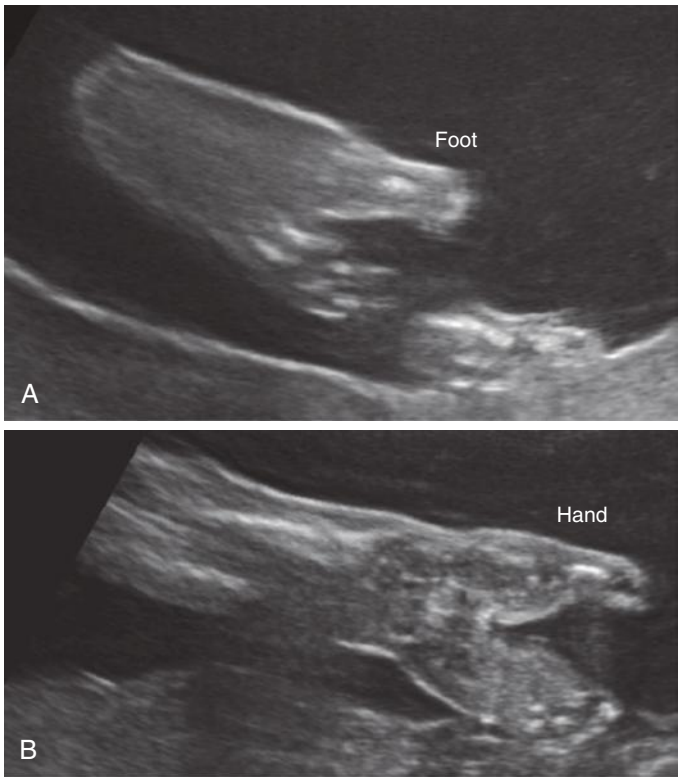

FIG 16-50 Ectrodactyly-ectodermal dysplasia-clefting (EEC) syndrome. Ectrodactyly of the lower (**A**) and upper (**B**) extremities. Sonographic findings of ectrodactyly, especially in association with cleft lip ± palate, should prompt evaluation for EEC syndrome.

Incidence. Incidence is unknown; the disorder is rare.

Etiology. The *TP63* gene encodes for a transcription factor crucial in the development of limbs and ectodermal-derived tissues.

Genetics. EEC syndrome is due to mutations in *TP63*. Inheritance is autosomal dominant. Significant intra- and interfamilial phenotypic variability exists.

Recurrence Risk. Recurrence risk is 50% if a parental mutation is identified.

Diagnosis. Prenatally, ectodactyly and syndactyly of the hands and feet, as well as cleft lip/palate may be detected. The hands may have a "lobster claw" appearance. Renal anomalies may also be present.

Differential Diagnosis. The differential includes other syndromes caused by *TP63* mutations, in particular ankyloblepharon-ectodermal defects-cleft lip/palate syndrome.

Prognosis. Correction of orofacial clefting and hand and foot anomalies may be complicated by the presence of ectodermal dysplasia. Corrective surgery should be performed in centers that perform a greater number of complex repairs.

Fanconi Anemia

Definition. Fanconi amenia (FA) is characterized by structural anomalies, bone marrow failure, and an increased risk of malignancy. Anomalies can include most organ systems, including musculoskeletal, renal, cardiac, GI, skin, and CNS. Absence of physical anomalies does not rule out the disorder.

Incidence. Incidence is approximately 1 in 360,000 births.

Genetics. Molecular genetic testing is complicated because at least 15 genes have been implicated. Diagnosis is based on chromosomal fragility testing. Inheritance is generally autosomal recessive, except for mutations in *FANCB*, which are X-linked.

Recurrence Risk. Recurrence risk depends on mode of inheritance. Risk is 25% for autosomal recessive FA if both parents are mutation carriers.

Diagnosis. The diagnosis should be considered prenatally if abnormal thumbs or radial ray defects are noted. Multiple other major congenital malformations may be present.

Differential Diagnosis. The differential includes other conditions with radial ray defects, including chromosomal disorders, VACTERL, and thrombocytopenia–absent radius (TAR) syndrome.

Prognosis. The cumulative incidence of bone marrow failure is 90% by age 40 to 50. The risk of hematologic malignancy (mostly acute myelogenous leukemia) is 10% to 30% and of nonhematologic malignancy is 25% to 30%.

Holt-Oram Syndrome

Definition. Holt-Oram syndrome (HOS) is characterized by congenital heart disease and anomalies of the upper limbs (specifically anomalies of the carpal, radial, or thenar bones). It is the most common heart-hand syndrome. All individuals have an abnormal carpal bone. Cardiac conduction disease is also common.

Synonyms. HOS has also been called heart-hand syndrome.

Incidence. Incidence is estimated at 1 in 100,000 live births.

Etiology. The *TBX5* gene encodes for a T-box transcription factor important in cardiogenesis and limb development.

Genetics. The majority of affected individuals (70%) have a mutation in *TBX5*. Inheritance is autosomal dominant; 85% of affected individuals have a de novo mutation. Significant phenotypic variability is seen. Penetrance is complete for upper limb anomalies.

Recurrence Risk. Recurrence risk is 50% if one parent is affected. It is low risk if there has been a prior de novo mutation.

Diagnosis. Congenital heart defects are present in 75% of individuals with HOS. The cardiac lesions include ASDs (30-60%) and VSDs, patent ductus arteriosus, endocardial cushion defect, hypoplasia of the left ventricle, and conduction disturbances (atrioventricular block that usually presents as first-degree heart block but can progress to complete heart block ± atrial fibrillation). Radial ray aplasia can vary from a difficult to diagnose triphalangeal thumb to a more obvious clubhand to absence of the thumb.

Differential Diagnosis. The differential diagnosis includes other disorders with radial ray aplasia, such as Duane-radial ray syndrome, Townes-Brocks syndrome, TAR syndrome, FA, VACTERL association, and other heart-hand syndromes.

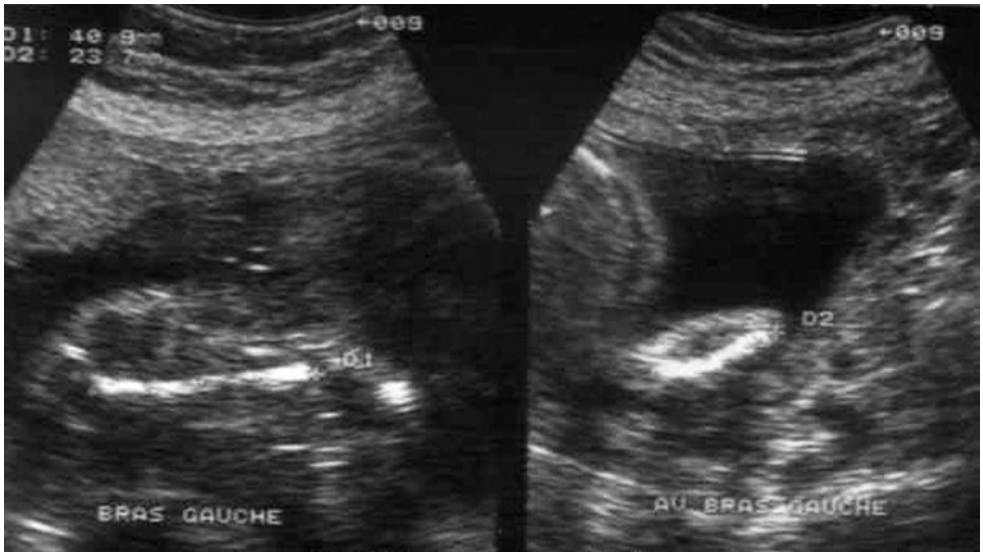

FIG 16-51 Holt-Oram syndrome. Scan of the right forearm at 22 weeks' gestation. The scan showed an isolated ulna with clubbed arm. (Courtesy of Fabrice Cullier, 2003. Available at thefetus.net.)

FIG 16-52 Scan of the left forearm at 24 weeks' gestation. The scan showed the ulna alone. (Courtesy of Fabrice Cullier, 2003. Available at thefetus.net.)

FIG 16-53 Profile of the left forearm of the fetus at 24 weeks' gestation. The thumb is in the same plane as the fingers and is triphalangeal. (Courtesy of Fabrice Cullier, 2003. Available at thefetus.net.)

Prognosis. Outcome is mainly related to the severity of the cardiac and orthopedic disability. Cardiac conduction disease can be progressive, and electrocardiogram should be performed at least annually.

Roberts Syndrome

Definition. Roberts syndrome is characterized by prenatal growth restriction, microcephaly, cleft lip ± palate, and limb anomalies (bilateral tetraphocomelia or hypomelia) with upper limbs more severely affected than the lower. Other features include hand anomalies (thumb aplasia or hypoplasia, syndactyly, clinodactyly), elbow and knee contractures, and facial dysmorphism (micrognathia, hypertelorism, shallow orbits leading to exophthalmos, beaked nose, ear malformations).

Synonyms. Pseudothalidomide syndrome.

Prevalence. The prevalence is unknown; this syndrome is rare. Approximately 150 affected individuals have been reported.

Etiology. The unique cytogenetic abnormality, called premature centromere separation, which disrupts chromatid pairing, is responsible for the multiple observed structural anomalies. *ESCO2* encodes for a protein that is essential for cohesion at heterochromatic regions.

Genetics. Roberts syndrome is due to mutations in *ESCO2*. Cytogenetic testing can confirm the diagnosis. The presence of premature centromere separation is diagnostic. One negative cytogenetic analysis does not exclude the diagnosis. Inheritance is autosomal recessive, and parental consanguinity is common. Wide phenotypic variability is seen.

Recurrence Risk. Recurrence risk is 25% if both parents are mutation carriers.

Diagnosis. Prenatally, the presence of growth restriction with symmetric bilateral limb anomalies (tetraphocomelia or hypomelia) and facial dysmorphism should prompt consideration of the diagnosis. Other associated anomalies include congenital heart defects, diaphragmatic defects, splenic agenesis, umbilical cord cyst, GI obstruction, renal anomalies, and genitourinary anomalies.

Differential Diagnosis. The differential diagnosis should include Baller-Gerold syndrome, FA, TAR syndrome, tetra-amelia syndrome, and HOS.

Prognosis. Significant intellectual disability is present in most individuals. Stillbirth is common, and survival beyond infancy is infrequent, although more mildly affected individuals can survive into adulthood. The prognosis depends on the severity of the anomalies present.

Thrombocytopenia–Absent Radius Syndrome

Definition. TAR syndrome is characterized by bilateral absence of the radii with both thumbs present and thrombocytopenia. The thrombocytopenia is transient and may be present at birth or develop in the first few weeks of life. Other features include other skeletal anomalies, congenital heart defects, and genitourinary anomalies. Thumbs are generally normal size but may be wider and flatter than usual and have limited function.

Synonyms. TAR syndrome is also known as radial aplasia thrombocytopenia syndrome.

Prevalence. Prevalence is estimated at 1 in 100,000 to 200,000.

Etiology. The *RBMA8A* gene encodes for RNA-binding protein 8A, and its deficiency is thought to lead to tissue-specific developmental consequences.

Genetics. TAR syndrome is due to deletion of an at least 200-kb region at chromosome 1q21.1, involving at least 12 known genes. Deletion of the gene *RBM8A* may be largely responsible for the phenotype. Inheritance is autosomal recessive, and, most commonly, individuals have compound heterozygosity of *RBM8A* pathogenic variants (one *RBM8A* hypomorphic mutation and a null mutation due to 1q21.1 deletion). The deletion occurs de novo in 25% to 50% of affected individuals.

Recurrence Risk. Recurrence risk is 25% if both parents are found to be mutation carriers.

Diagnosis. The diagnosis is based on clinical features, specifically absence of the bilateral radii with normal thumbs with thrombocytopenia (generally present in the first few weeks of life). Prenatally, absent radii may be observed as early as the late first trimester.

Differential Diagnosis. The differential diagnosis should include HOS, Roberts syndrome, FA, Duane-radial ray syndrome, VACTERL, and Townes-Brocks syndrome.

Prognosis. Although thrombocytopenia is generally transient, it can lead to life-threatening bleeding. Cow milk allergy is common and can exacerbate the thrombocytopenia. Orthopedic intervention is needed to maximize limb function.

Townes-Brocks Syndrome

Definition. Townes-Brocks syndrome (TBS) is characterized by the triad of imperforate anus, dysplastic ears (preauricular tags, microtia, overfolded superior helices), and thumb anomalies (preaxial polydactyly, triphalangeal or hypoplastic thumbs). Other features include impaired renal function (with or without renal malformations), eye anomalies, hearing loss, congenital heart disease, foot malformations, and genitourinary malformations.

Prevalence. Prevalence is estimated at 1 in 250,000; these numbers are complicated by significant overlap with VACTERL.

Genetics. TBS is due to mutations in *SALL1*. Inheritance is autosomal dominant. Approximately 50% of affected individuals have de novo mutations. Phenotype can be highly variable.

Recurrence Risk. Recurrence risk is 50% if one of the parents is affected.

Diagnosis. The diagnosis is made clinically based on the presence of imperforate anus (84%), dysplastic ears (87%), and typical thumb malformations with normal radius (89%). Only 67% of affected patients have all three features of the classic triad. Prenatally, thumb anomalies may be detected; imperforate anus and ear anomalies are more challenging to detect.

Differential Diagnosis. The differential diagnosis should include hemifacial microsomia, Duane-radial ray syndrome, and VACTERL association.

Prognosis. Immediate surgical intervention is needed for imperforate anus. Orthopedic surgery may be required for thumb anomalies. Renal impairment and hearing loss can both be severe. Intellectual disability is present in 10% of cases.

Lower Extremity Anomalies

If a unilateral leg anomaly is noted, usually other abnormalities are not present. If there are bilateral symmetric anomalies of the lower extremities, skeletal dysplasias should be considered. A few other syndromes leading to prominent lower extremity anomalies exist, including femoral hypoplasia–unusual facies syndrome and sirenomelia. Both are associated with maternal diabetes.

Femoral Hypoplasia–Unusual Facies Syndrome

Definition. Femoral hypoplasia–unusual facies syndrome (FHUFS) is characterized by femoral hypoplasia (or aplasia) and facial dysmorphisms including micrognathia, cleft palate, hypertelorism, long philtrum, and low-set ears. Other associated features include skeletal, renal, neural, and genital anomalies.

Synonym. FHUFS is also called femoral-facial syndrome.

Prevalence. FHUFS is rare; it is described more often in females.

Genetics. Genetics are unknown; most reported cases are sporadic.

Recurrence Risk. Recurrence risk is unknown, but low. FHUFS is strongly associated with maternal diabetes.

Diagnosis. Prenatally, short femurs and other skeletal anomalies can be observed as early as the early second trimester, although prenatal detection can be difficult.

Differential Diagnosis. The differential diagnosis includes other syndromes with femoral hypoplasia, including caudal regression syndrome and campomelic dysplasia.

REFERENCES

Figueroa C, Plasencia W, Eguiluz I, et al: Prenatal diagnosis and tridimensional ultrasound features of bilateral femoral hypoplasia—unusual facies syndrome. *J Matern Fetal Neonatal Med* 22(10):936–939, 2009.

Sirenomelia

Definition. Sirenomelia is characterized by fusion of the lower extremities and is associated with renal agenesis, absence of the sacrum, rectum, and bladder. Renal agenesis leads to oligohydramnios with resultant Potter sequence. Other features include spinal column defects, upper limb anomalies, congenital heart defects, and CNS anomalies. It was previously thought to represent a severe form of caudal regression syndrome, but is now considered to be a separate entity.

Synonyms. Sirenomelia is also known as mermaid syndrome.

Prevalence. Prevalence is estimated at 0.98 per 100,000. Ten to fifteen percent of cases are seen in twin births.

Etiology. Sirenomelia is thought to be caused by an alteration in early vascular development leading to "vitelline arterial steal," in which blood flow is diverted from the caudal region of the embryo to the placenta, resulting in multiple defects of the lower extremities.

Genetics. Genetics are unknown; the syndrome is thought to be sporadic.

Recurrence Risk. Recurrence risk is unknown, but low.

Diagnosis. The diagnosis of sirenomelia is based on the presence of fusion of the lower extremities associated with other skeletal and lumbar spine deformities, bilateral renal agenesis (leading to severe oligohydramnios and pulmonary hypoplasia), and heart and abdominal wall defects. The defect varies from simple cutaneous fusion of the limbs to absence of all long bones but one femur. The defect of the feet is proportional with the defect of the long bones. Because the legs are fused, the rotation of the legs does not occur and they remain in their fetal position.

Differential Diagnosis. Caudal regression syndrome is the main consideration in the differential diagnosis, and it usually presents with milder deformities compared to sirenomelia and normal amniotic fluid volume.

Prognosis. Sirenomelia is a lethal condition owing to renal agenesis and its complications. Exceptional cases that lack renal agenesis may survive.

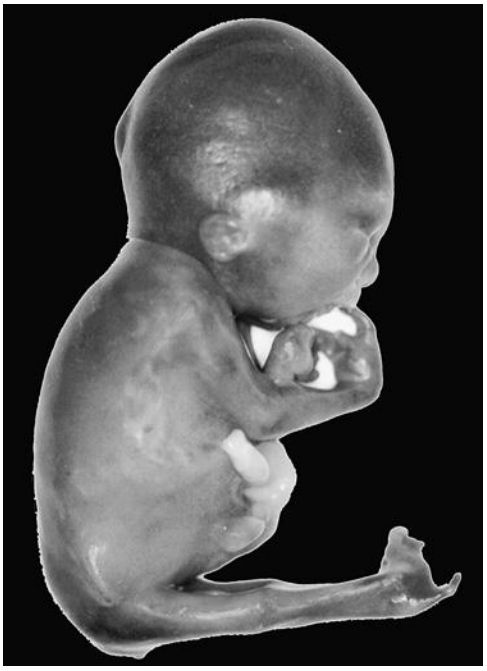

FIG 16-54 Sirenomelia. The fused lower extremity and the flipper-like deformity of the foot are characteristic of sirenomelia.

THORAX

Congenital High Airway Obstruction Syndrome

Definition

Congenital high airway obstruction syndrome (CHAOS) is characterized by obstruction of the fetal upper airways and can be partial or complete.

Etiology

CHAOS is caused by atresia or stenosis of the larynx or trachea.

Pathogenesis

Tracheal atresia is caused by deficient recanalization of the upper airways at 10 weeks' gestation.

Incidence

Incidence is unknown.

Diagnosis

Prenatally, bilaterally enlarged hyperechoic lungs, dilated airways, and flattened or inverted diaphragm can be seen. The enlarged lungs compress the fetal heart, causing it to be displaced centrally and become small and dysfunctional. This can lead to fetal ascites and nonimmune hydrops.

Genetics

CHAOS is mostly sporadic, although some genetic syndromes are associated.

Recurrence Risk

Recurrence risk depends on association with other possible syndromes (see later discussion).

Differential Diagnosis

CHAOS is sometimes misdiagnosed as a bilateral congenital cystic adenomatoid malformation (CCAM). It should also be differentiated from extrinsic causes of tracheolaryngeal obstruction, such as cervical teratoma, vascular rings, and lymphatic malformations.

Prognosis

The disorder in general is incompatable with life if unrecognized during the prenatal period.

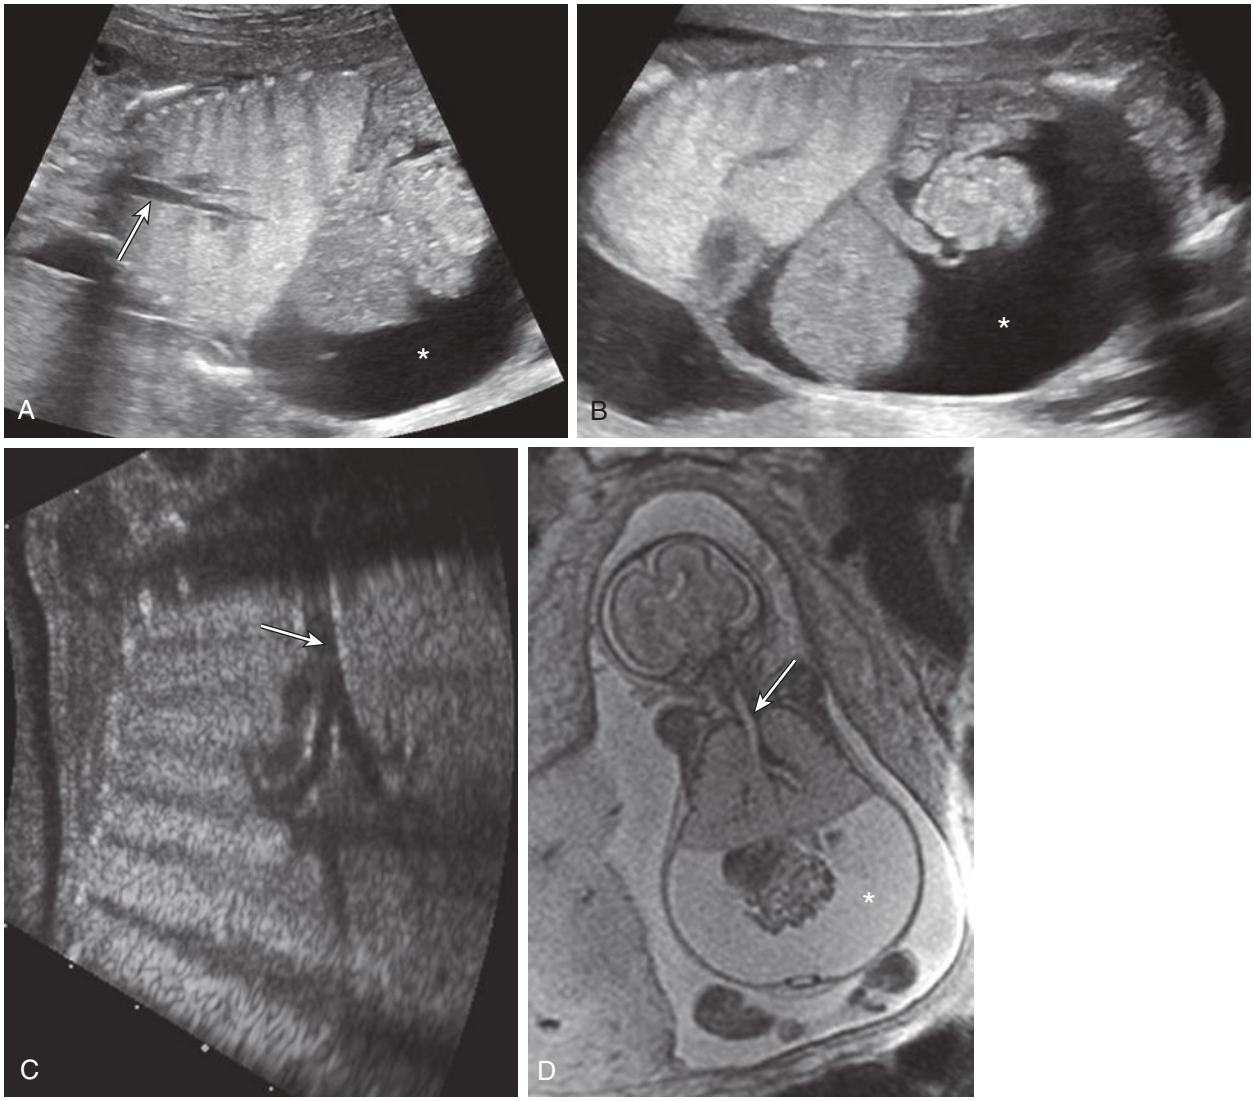

FIG 16-55 Congenital high airway obstruction syndrome (CHAOS). Coronal (**A** and **C**) and sagittal (**B**) images demonstrate dilated fluid-filled trachea (*arrow*), enlarged hyperechoic bilateral lungs, and hydrops with ascites (*asterisk*). **D,** Coronal magnetic resonance image demonstrates the same findings of a dilated trachea (*arrow*) and ascites (*asterisk*).

Management

If CHAOS is diagnosed prior to delivery, incomplete obstruction is present, and fetal hydrops has not occurred, an EXIT (ex utero intrapartum treatment) procedure (to establish a fetal airway prior to cessation of fetomaternal circulation) can be performed for delivery.

Associated Syndromes

CHAOS can occur as part of Fraser syndrome, cri du chat syndrome (5p deletion), short rib–polydactyly syndrome, and 22q11.2 deletion syndrome.

Artunc Ulkumen B, Pala HG, Nese N, et al: Prenatal diagnosis of congenital high airway obstruction syndrome: report of two cases and brief review of the literature. *Case Rep Obstet Gynecol* 2013:728974, 2013.

Hamid-Sowinska A, Ropacka-Lesiak M, Breborowicz GH: Congenital high airway obstruction syndrome. *Neuro Endocrinol Lett* 32(5):623–626, 2011.

Cornelia de Lange Syndrome

CdLS is discussed in detail under "Upper Extremities." It is a rare cause of CDH; 1% to 8% of patients with CdLS have a CDH.

Donnai-Barrow Syndrome

Definition

Donnai-Barrow syndrome is characterized by distinct facial features (hypertelorism, widow's peak, depressed nasal bridge, posteriorly rotated ears, enlarged fontanelle), ocular findings (myopia, vision loss, iris coloboma, retinal detachment), sensorineural hearing loss, corpus callosum agenesis, CDH (50%), and omphalocele (50%). CDH and omphalocele occur together in one third of cases.

Synonym

Donnai-Barrow syndrome is also known as faciooculoacousticorenal (FOAR) syndrome.

Incidence

Incidence is unknown; mutant alleles of *LRP2* are thought to be rare.

Pathogenesis

The gene, *LRP2*, encodes for the protein megalin. When megalin function is abnormal, proximal renal tubule reuptake of megalin ligands is prevented, leading to excess spillage of low-molecular-weight proteins in the urine.

Diagnosis

Diagnosis is based on the clinical features described previously, as well as a distinctive low-molecular-weight proteinuria.

Genetics

Donnai-Barrow syndrome is due to mutations in the gene *LRP2*. Phenotypic variability even within families is observed. Inheritance is autosomal recessive.

Recurrence Risk

Recurrence risk is 25% if both parents are mutation carriers.

Differential Diagnosis

Other conditions with similar features include Pallister-Killian syndrome, Fryns syndrome, acrocallosal syndrome, and craniofrontonasal syndrome.

Prognosis

Perinatal death is common owing to congenital malformations. Progressive vision loss is common. All individuals have sensorineural hearing loss. Intellectual disability is mild to moderate. Seizures often develop.

Management

Management includes surgical repair of CDH and omphalocele, treatment of vision and hearing loss, and medical treatment of seizures.

REFERENCE

Kantarci S, Donnai D, Noonan KM, Pober BR: Donnai-Barrow syndrome. In Pagon RA, Adam MP, Ardinger HH, et al, editors: *GeneReviews*, Seattle, 1993–2016, University of Washington.

Fryns Syndrome

Definition

Fryns syndrome is characterized by diaphragmatic defects (diaphragmatic hernia), facial dysmorphism (hypertelorism, broad/flat nasal bridge, long philtrum, low-set ears, tented upper lip, macrostomia, micrognathia), distal digital nail hypoplasia, and pulmonary hypoplasia. Other anomalies include ocular findings (cloudy corneas, microphthalmia), orofacial clefting, and renal dysplasia.

Incidence

Incidence is estimated at 7 per 100,000 live births in France, and 1% to 10% of patients with CDH.

Genetics

No specific gene has been implicated. Inheritance is autosomal recessive.

Recurrence Risk

Recurrence risk is 25%.

Diagnosis

Diagnosis is based on the clinical findings described earlier. The phenotypic variability makes sonographic diagnosis a challenge. Prenatally, CDH and facial dysmorphism may be seen. Development of polyhydramnios late in the second trimester and normal growth or overgrowth of the fetus are also expected.

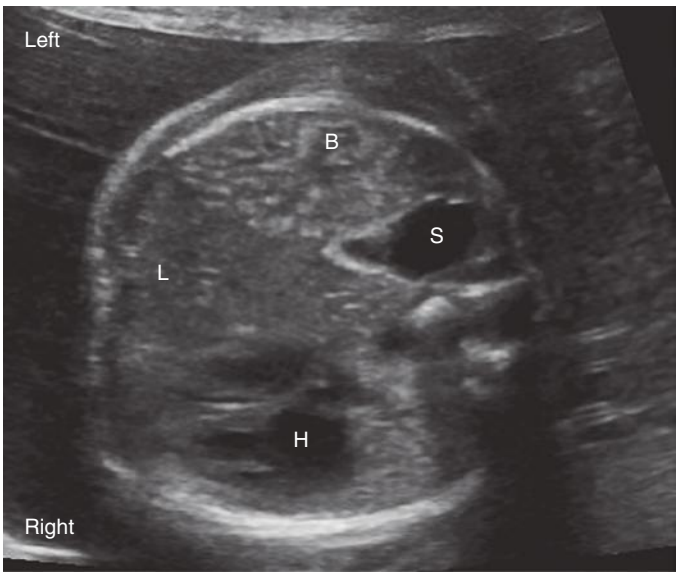

FIG 16-56 Axial sonographic image through the chest in fetus with left congenital diaphragmatic hernia. Fluid-filled stomach (S), bowel (B) and portion of the liver (L) are shown on the left, with displacement of the heart (H) toward the right. It is estimated that 1% to 10% of fetuses with congenital diaphragmatic hernia have Fryns syndrome.

Differential Diagnosis

The differential diagnosis includes chromosomal disorders, Pallister-Killian syndrome (mosaic tetrasomy 12p), Donnai-Barrow syndrome, Zellweger syndrome (deficiency of peroxisomal enzyme), Matthew-Wood syndrome, and CdLS.

Associated Anomalies

Other anomalies include those of the skeletal, cardiac, central nervous, GI, and genitourinary systems.

Prognosis

The majority of affected infants are stillborn or die in early neonatal period. Severe intellectual and developmental delay is often reported in those who survive.

Pallister-Killian Syndrome

Definition

Pallister-Killian syndrome is characterized by CDH, craniofacial dysmorphism (brachycephaly, high broad forehead, hypertelorism, low-set ears, broad nasal bridge, anteverted nares, long philtrum), short neck, short and broad hands, streaks of skin hyperpigmentation, and CNS anomalies. Seizures are common in infancy.

Synonyms

Pallister-Killian syndrome is also known as tetrasomy 12p and Teschler-Nicola/Killian syndrome.

Incidence

Human autosomal tetrasomies are rare. Among them, tetrasomy 12p is undoubtedly the most common.

FIG 16-57 Pallister-Killian syndrome. Postmortem examination demonstrates a flat facial appearance with dysmorphic, low-set ears. (Courtesy of Fabrice Cuillier, 2003. Available at thefetus.net.)

Genetics

Pallister-Killian syndrome is due to tissue-specific mosaic distribution of a supernumerary isochromosome that consists of two copies of the short arm of chromosome 12, 12p. The chromosomal abnormality is observed in either a mosaic or a nonmosaic state for specific tissues, such as bone marrow and skin fibroblasts. The additional isochromosome 12p is readily seen in skin fibroblasts and is detectable in amniotic fluid and chorionic villi. Testing of peripheral blood lymphocytes is generally negative so the diagnosis can be missed. This syndrome is associated with advanced maternal age.

Recurrence Risk

Recurrence risk is low; cases are sporadic.

Etiology

Pallister-Killian syndrome is caused by maternal premeiotic or meiotic error with centromere misdivision.

Diagnosis

The most common prenatal findings include CDH, short limbs, CNS anomalies and ventriculomegaly, craniofacial dysmorphism, increased nuchal translucency, fetal hydrops, and polyhydramnios. Fetal growth is generally normal. Postnatal growth deceleration is commonly seen. The diagnosis can be confirmed by amniocentesis or chorionic villus sampling. Postnatal diagnosis is challenging given tissue mosaicism and the lack of isochromosome 12p in the peripheral blood.

Differential Diagnosis

Other diagnoses to consider include chromosomal disorders, Fryns syndrome, chondrodysplasia of Robinow, acrocallosal syndrome, and VATER (*v*ertebrae, *a*nal atresia, *t*racheo*e*sophageal fistula, *r*enal or kidney anomalies) association.

Associated Anomalies

A wide range of other anomalies can be seen including those involving the cardiac, musculoskeletal, GI, genitourinary, and cutaneous systems.

Prognosis

The prognosis is generally poor, but more mild cases have been reported. Less severely affected individuals have severe intellectual disability, seizures, and developmental delay. Hearing loss is also common. Vertebral and joint deformities are often present, and older individuals have muscular atrophy.

Scimitar Syndrome

Definition

Scimitar syndrome is characterized by right lung hypoplasia and abnormal venous drainage to the inferior vena cava. Cardiac dextroposition and abnormal pulmonary blood supply from the descending aorta are commonly seen. Other congenital heart defects and CDH are also seen.

Synonym

Scimitar syndrome is also called pulmonary venolobar syndrome.

Etiology

The partial anomalous pulmonary venous return is due to a connection failure between the right pulmonary veins and the left atrium during fetal development. It is thought to be a developmental disorder of the entire lung bud early in embryogenesis.

Incidence

Incidence is 2 in 100,000.

Diagnosis

Scimitar syndrome is a complex form of partially anomalous pulmonary venous return. Classically, the scimitar sign is seen on chest radiograph, referring to a half crescent created by the descent of the anomalous pulmonary vein and is seen adjacent to the junction of the diaphragm and right heart border. The diagnosis can be confirmed by angiography or MRI. Prenatally, the majority of congenital heart defects are detected, but abnormal pulmonary veins are difficult to detect. A fetal echocardiogram by experienced providers allows prenatal detection.

Genetics

Gene locus for total anomalous pulmonary venous return has been mapped to 4q12, but the genetics specific to scimitar syndrome are not known.

Recurrence Risk

Recurrence risk is unknown.

Differential Diagnosis

Other forms of anomalous pulmonary venous return should be considered.

Associated Anomalies

Other anomalies include bronchogenic cysts, horseshoe lung, accessory diaphragm, and hernias.

Prognosis

Clinical presentation depends on the shunt volume. The infantile form frequently presents with pulmonary hypertension and is detected based on failure to thrive, respiratory issues, or congestive heart failure. Ultimate prognosis is dependent on the severity of the anomalies.

Management

Surgical correction is often required, and pulmonary hypertension in infancy is an indication for repair.

REFERENCES

Korkmaz AA, Yildiz CE, Onan B, et al: Scimitar syndrome: a complex form of anomalous pulmonary venous return. *J Card Surg* 26(5):529–534, 2011.

Midyat L, Demir E, Askin M, et al: Eponym. Scimitar syndrome. *Eur J Pediatr* 169(10):1171–1177, 2010.

HEART

Congenital heart defects are common and prenatal diagnosis should prompt a detailed fetal survey to look for other anomalies and genetic testing should be offered. Septal and valvular defects are the most frequent anomalies. Similar structural defects are linked to more than one genetic locus and variable cardiac lesions can be seen even within families, making diagnosis of possible underlying genetic causes challenging. Chromosomal disorders, including anueploidies, Turner syndrome, and microdeletion and microduplication syndromes (especially 22q11.2 deletion) should be considered when prenatal cardiac lesions are detected. Many other syndromes caused by single gene defects are also associated with congenital heart defects, some of which are reviewed here.

Nemer M: Genetic insights into normal and abnormal heart development. *Cardiovasc Pathol* 17(1):48–54, 2008.

22q11.2 Deletion Syndrome

Definition

22q11.2 deletion syndrome is characterized by congenital heart disease (74%; conotruncal malformations most common), palate abnormalities (69%; velopharyngeal incompetence, submuscosal or overt cleft palate, bifid uvula), characteristic facial features, learning difficulties (70-90%), and immune deficiency (77%). Other findings include hypocalcemia, feeding problems, constipation, structural GI anomalies, and renal anomalies.

Synonym

Synonyms include DiGeorge syndrome, velocardiofacial syndrome, conotruncal anomaly face syndrome, autosomal dominant Opitz G/BBB syndrome, Sedlackova syndrome, and Cayler cardiofacial syndrome.

Etiology

Most cases are due to a 3 Mb deletion at chromosome 22q11.2, generally caused by a nonallelic meiotic recombination event during spermatogenesis or oogenesis. This region is flanked by low copy number repeats leading to abnormal interchromosomal exchanges.

Incidence

Incidence is 1 in 4000 to 1 in 6395 births, although this figure may be an underestimate.

Diagnosis

Prenatally, the diagnosis is most commonly made because of the presence of a cardiac defect. Conotruncal defects are most common, such as tetralogy of Fallot, interrupted aortic arch, VSD, and truncus arteriosus. The disorder should be suspected in individuals with the combination of congenital heart disease, palate abnormalities, characteristic facial features, and learning difficulties.

Genetics

A microdeletion at chromosome 22q11.2 can be detected by fluorescence in situ hybridization, multiplex ligation-dependent probe amplification (MLPA), or chromosomal microarray. Inheritance is autosomal dominant. Approximately 93% of deletions are de novo; 7% have an affected parent. The gene, *TBX1*, found within the deleted region, is thought to be responsible for many of the typical features including cardiac anomalies. Penetrance of the disorder is complete with marked variability in phenotype.

Recurrence Risk

Recurrence risk is 50% with a known parental mutation.

Associated Anomalies

Other anomalies include laryngotracheoesophageal anomalies, growth hormone deficiency, autoimmune disorders, seizures, CNS abnormalities, skeletal abnormalities, and ocular abnormalities.

Differential Diagnosis

Other disorders to consider include SLO syndrome, Alagille syndrome, VATER association, CHARGE syndrome, and Goldenhar syndrome.

Prognosis

Prognosis depends on the extent of anomalies. Congenital heart defects are the major cause of fatality. Developmental delay and intellectual disability are common. Austism spectrum disorders and schizophrenia are frequent (20% and 25%, respectively), and other psychiatric issues are common (such as attention deficit disorder and anxiety).

Management

Clinical guidelines for affected individuals have been established (Bassett and associates, 2011).

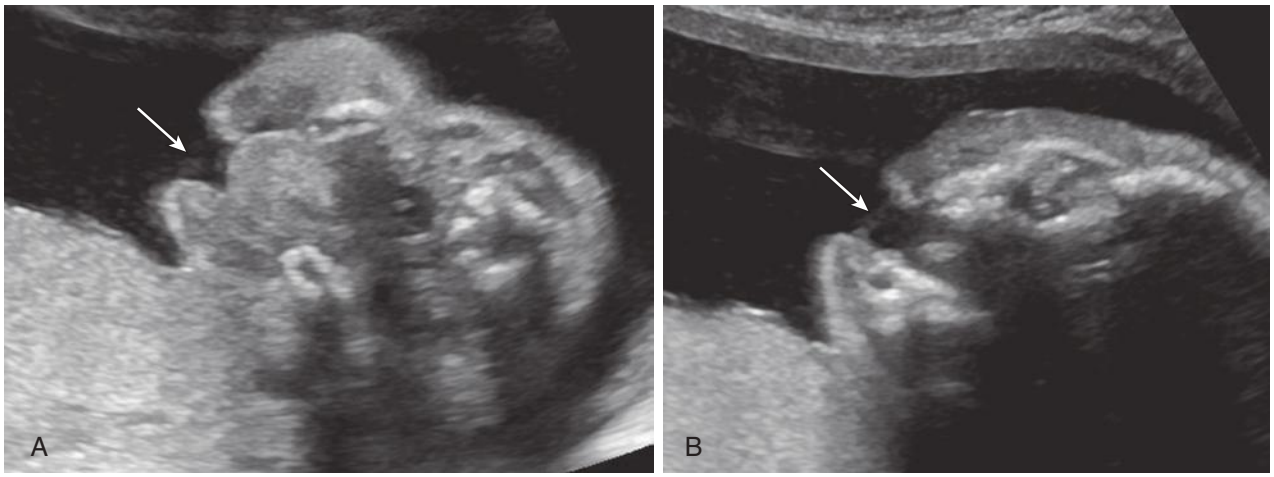

FIG 16-58 The 22q11.2 deletion syndrome. Unilateral cleft lip (**A**) and palate (**B**) in a fetus with congenital heart disease (double outlet right ventricle, not shown).

Alagille Syndrome

Definition

Alagille syndrome is characterized by biliary hypoplasia (manifesting as neonatal cholestasis), cardiovascular anomalies (most commonly pulmonary artery stenosis), vertebral abnormalities (butterfly vertebrae), characteristic facies (broad forehead, pointed mandible, bulbous nose tip), and ocular anomalies (posterior embryotoxon).

Synonyms

Synonyms include Alagille-Watson syndrome, cholestasis with peripheral pulmonary stenosis, arteriohepatic dysplasia, hepatic ductular hypoplasia, and jagged 1 syndrome.

Incidence

Incidence is 1 in 30,000 to 1 in 50,000 live births. The disorder likely remains underdiagnosed.

Etiology

This multisystem autosomal dominant disorder has variable penetrance.

Genetics

Alagille syndrome is due to mutations in *JAG1* (89%) or *NOTCH2* (1-2%). The phenotype is extremely variable even within the same family. Inheritance is autosomal dominant. Approximately 50% to 70% of mutations are de novo, and 30% to 50% are inherited.

Recurrence Risk

Recurrence risk is 50% with known parental mutation. If a de novo mutation is present in another child, recurrence risk is low but slightly increased from germline mosaicism.

Diagnosis

The diagnosis is based on clinical features including bile duct paucity, cholestasis, cardiac defect (most commonly peripheral pulmonary artery stenosis), skeletal abnormalities, ocular abnormalities, and characteristic facial features. Other significant anomalies include those of the kidney, neurovasculature, and pancreas. Prenatally, facial dysmorphism, cardiac anomalies, skeletal anomalies, and growth restriction may be seen.

Differential Diagnosis

Other disorders to consider include other causes of neonatal cholestasis, disorders of intrahepatic cholestasis (Byler syndrome, Aagenaes syndrome), and other syndromes with pulmonary vascular system anomalies (chromosomal disorders, Noonan syndrome, Watson syndrome). α_1-Antitrypsin deficiency may present as neonatal cholestasis with a paucity of intrahepatic bile ducts.

Prognosis

Mortality rate is 10% as a result of cardiac disease, liver disease, and vascular accidents. Vascular accidents are a result of vascular anomalies such as basilar artery aneurysms, internal carotid artery anomalies, middle cerebral artery aneurysm, aortic aneurysms and coarctations, and internal carotid artery anomalies.

Management

This disorder should be suspected in all infants with cholestasis. Given the multisystem involvement, multidisciplinary care is needed.

CHARGE Syndrome

Definition

CHARGE is a mnemonic for a syndrome characterized by *c*oloboma of the eye, *h*eart defects, *a*tresia of the choanae, *r*etarded mental and growth development, *g*enital anomalies, and *e*ar anomalies with or without deafness.

Incidence

Incidence is 1 in 8500 to 1 in 10,000 births.

Genetics

CHARGE syndrome is due to mutations in *CHD7*, which encodes the chromodomain helicase DNA binding protein. Mutations are found in 65% to 70% of patients with clinical features of CHARGE. Not finding a mutation does *not* rule out CHARGE syndrome. Inheritance is autosomal dominant. Penetrance in those with *CHD7* mutations is 100%.

Recurrence Risk

Most cases are the only cases reported within a family. The empiric recurrence risk is 1% to 2%. If one of the parents has CHARGE or a known *CHD7* mutation, the recurrence risk is 50%.

TABLE 16-5 Major Characteristics of CHARGE*

Finding	Includes	Frequency
Coloboma of the eye	Coloboma of the iris, retina, choroids, disc, not including colobomas of the eyelid; microphthalmos (small eyes) or cryptophthalmos (absent eye)	80-90%
Choanal atresia or stenosis	Unilateral or bilateral, bony or membranous; unilateral atresia or stenosis may be difficult to diagnose	50-60%
Cranial nerve dysfunction or anomaly	I: Lack of smell (anosmia)	Frequent
	IX/X: Swallowing difficulties	70-90%
	VII: Facial palsy (unilateral or bilateral)	40%
Characteristic CHARGE ear	Short, wide ear with little or no lobe, "snipped off" helix, prominent antihelix that is discontinuous with the tragus, triangular concha, decreased cartilage, often stick out, usually asymmetric	Frequent
	Middle ear: ossicular malformations seen on MRI	Frequent
	Malformed inner ear (Mondini defect) with deformed cochlea and vestibules seen on MRI	80-90%

MRI, magnetic resonance imaging scan.
*These are very common in CHARGE and relatively rare in other conditions.
Reproduced with permission from the Charge Syndrome Foundation, available at http://www.chargesyndrome.org/index.asp.

Pathogenesis

CHD7 is essential for the formation of multipotent migratory neural crest cells that differentiate into different tissues including craniofacial and heart structures, and it regulates genes involved in neural crest cell guidance. *CHD7* mutations are thought to disrupt this process leading to features of the CHARGE syndrome.

Diagnosis

The diagnosis is based on several associated malformations including colobomas (iris, retina-choroid, disk), choanal atresia/stenosis, cranial nerve dysfunction (anosmia, facial palsy, impaired hearing, swallowing problems), abnormal outer ears, hypogonadotropic hypogonadism, developmental delay, cardiovascular malformations (including conotruncal anomalies, atrioventricular canal defects, and aortic arch anomalies), growth deficiency, orofacial clefts, and tracheoesophageal fistula (see Table 16-5). Specific anomalies seen on temporal bone imaging (hypoplastic semicircular canals) can assist with the diagnosis. The diagnosis may be suspected prenatally from the presence of major anomalies that fit the CHARGE criteria; however, in many cases a cardiac defect is the only anomaly detected prenatally.

Differential Diagnosis

Other disorders to consider include 22q11.2 deletion syndrome, VACTERL association, Kabuki syndrome, renal coloboma syndrome (*PAX2* mutations), cat-eye syndrome, Joubert syndrome, branchio-oto-renal syndrome, and retinoic embryopathy.

Prognosis

Mortality rate in the first 2 years of life is 20% to 25%. Choanal atresia is a threat to life because young infants cannot establish the habit of mouth breathing. Feeding difficulties are common. Both hearing and vision loss are frequent. Motor development is often markedly delayed. Prognosis is dependent on the severity of the associated malformations.

Management

Because of the multiple complex malformations, clinical management requires coordinated multidisciplinary care.

Heterotaxy Syndromes

Definition

This set of syndromes is due to errors of lateralization of the primary field. This leads to either a fetus with a predominant right-sidedness and an isomeric left side (asplenia: a fetus whose left side is a mirror image of its right side) or left-sidedness and an isomeric right side (polysplenia: a fetus whose right side is a mirror image of its left side). These fetuses are usually recognized because of the associated cardiac anomalies.

Synonym

Heterotaxy syndromes include Ivemark syndrome, cardiosplenic syndrome, and asplenia-polysplenia syndrome

Incidence

The incidence is very low, estimated at 1 in 10,000 to 20,000 live births.

Etiology

The cause of most laterality defects remains unknown. A small proportion can be explained by a monogenic cause, including the subset related to primary ciliary dyskinesia.

Genetics

More than 80 genes are required for visceral asymmetry, including the genes *DNAH5* and *DNAI1*. A subset of individuals with heterotaxy have primary ciliary dyskinesia (PCD); at least 6% of individuals with PCD have heterotaxy. Most PCD is inherited in an autosomal recessive manner. The inheritance of heterotaxy in general most often demonstrates autosomal recessive inheritance; autosomal dominant and X-linked inheritance has also been reported.

Diagnosis

Prenatally, the diagnosis is usually made by the recognition of the cardiac anomalies, in particular, the presence of atrioventricular septal defect, mesocardia (the axis of the interventricular septum being almost anteroposterior) with an endocardial cushion defect, an intrahepatic segment of the umbilical vein that is also oriented anteroposteriorly, and an odd-looking stomach. The abnormal lobation of the lungs is difficult to recognize and is generally only recognized when a sliver of pleural fluid is infiltrated between the lobes. Another typical finding is the interruption of the inferior vena cava with azygos continuation. This includes an inferior vena cava that is posterior in the upper abdomen (instead of curving anteriorly to enter the right atrium) and the abrupt decrease in size of the inferior vena cava near the diaphragm. An enlarged azygos arch joining the superior vena cava can also be recognized. Doppler study of the splenic artery has been suggested as an aid in diagnosis. Other findings include agenesis of the corpus callosum with pachygyria and hydrocephalus.

Differential Diagnosis

Other conditions including cardiac anomalies should be considered including trisomy 18.

Associated Anomalies

Associated defects include CNS anomalies, cleft lip ± palate, GI anomalies, and diaphragmatic hernia (Table 16-6).

Prognosis

Asplenia tends to be a more severe disease from cyanotic heart lesions and superimposed infections. Although morbidity and mortality rates in the neonatal period are determined mainly by the cardinal cardiac defects, the visceral anomalies influence the long-term outcome.

Management

Treatment of the infant is dictated by the cardiac defects.

Holt-Oram Syndrome

See discussion under "Upper Extremity."

Noonan Syndrome

Definition

Noonan syndrome is characterized by short stature, characteristic facial features (low-set ears, hypertelorism, depressed nasal bridge, macrocephaly), and congenital heart defects. Other findings included a broad or webbed neck, unusual chest shape, coagulation defects, lymphatic dysplasia, undescended testes, spinal deformity, and eye findings (strabismus, amblyopia, nystagmus, cataracts, fundal changes). Developmental delay and intellectual disability are associated but variable.

Synonyms

Noonan syndrome is also known as Turner syndrome with normal XX or pseudo-Turner syndrome.

Incidence

Incidence is 1 in 1000 to 1 in 2500 live births.

Etiology

Noonan syndrome is due to mutations in genes in the RAS-MAPK signaling pathway.

Genetics

Genes implicated in Noonan syndrome include *PTPN11* (50%), *SOS1* (10%), *RAF1* (10%), and *KRAS* (< 2%). Other genes implicated in fewer than 1% of cases include *NRAS*, *BRAF*, *MAP2K1*, and *RIT1*. Inheritance is autosomal dominant, with frequent de novo mutations. An affected parent is found in 30% to 75% of families. Penetrance is difficult to estimate; expressivity is variable, with many affected adults diagnosed only after the birth of a more severely affected infant.

Recurrence Risk

Recurrence risk is 50% if one of the parents is affected.

Diagnosis

Prenatally, an increased nuchal translucency in the setting of normal chromosome studies may be seen in the first trimester. Other features that may be observed in the second trimester include dysmorphic facial features, congenital heart defects, pleural effusions, renal anomalies, polyhydramnios, and hydrops. Congenital heart disease is present in 50% to 80% of affected individuals. The most common heart defects are pulmonary valve stenosis (20-50%) and hypertrophic cardiomyopathy (20-30%); others include ASD, VSD, peripheral pulmonary artery stenosis, aortic coarctation, and tetrology of Fallot. With prenatal imaging, cardiac defects, especially pulmonary stenosis and cardiomyopathy, tend to be noted less frequently and often not until the third

TABLE 16-7 Management Guidelines in Noonan Syndrome

	At Diagnosis	After Diagnosis	If Symptomatic
General	Complete physical and neurologic examination; medical genetics consultation to confirm diagnosis, consider molecular genetic testing and genetic counseling	Yearly complete physical and neurologic examination; return to geneticist if genotype negative or for multisystem assessment; genetic counseling at adolescence or when a young adult	Orchiopexy by age 1 year for cryptorchidism; if lymphedema, refer to specialty clinic; brain and cervical spine MRI if intracranial pressure increases; electroencephalogram and referral to neurologist if seizures suspected
Developmental	Multidisciplinary developmental assessment	Developmental screening yearly for children aged 5 to 18 years	Neuropsychologist testing if screening abnormal; referral to early intervention if delays detected before age 3 years; individual education plan for children aged 5 to 18 years with delays
Dental	First dental assessment between age 1 year and 2 years	Yearly dental assessment	—

Continued

TABLE 16-7 Management Guidelines in Noonan Syndrome—cont'd

	At Diagnosis	After Diagnosis	If Symptomatic
Growth and feeding	Plot growth on curves for Noonan syndrome	Plot growth on curves for Noonan syndrome three times per year until age 3 years, then yearly	Refer to gastroenterologist for feeding problems or recurrent vomiting, or if evidence of growth failure without comorbid cause exists; thyroid function tests if signs or symptoms of hypothyroidism
Cardiovascular	Cardiac examination, electrocardiogram, echocardiogram	Follow up on the basis of initial findings. If initial assessment normal, repeat every 5 years	—
Ophthalmologic	Baseline eye examination	Repeat every 2 years, sooner if indicated	—
Audiologic	Baseline audiology examination	Repeat if recurrent otitis media or speech delay	Refer to ear, nose, and throat specialist for recurrent otitis media or serous otitis; hearing aids or classroom interventions for hearing loss
Hematologic	Complete blood cell count with differential, and prothrombin time or activated partial thromboplastin time	Repeat complete blood cell count with differential and prothrombin time or activated partial thromboplastin time if aged 6 to 12 months at initial screen; preoperatively: complete blood cell count with differential and prothrombin time or activated partial thromboplastin time, second tier (in consultation with hematologist) factor IX, XI, and XII concentrations, von Willebrand factor, platelet aggregation	Prothrombin time or activated partial thromboplastin time if bleeding abnormal or persistent, refer to hematologist; complete blood cell count with differential for splenomegaly; complete blood cell count with differential and liver function studies for hepatosplenomegaly
Renal	Kidney ultrasound	—	—
Skeletal	Clinical assessment of spine with radiology if indicated by examination	Repeat spinal examination yearly through adolescence; radiology and referral to orthopedic specialist if abnormal	—

From Roberts AE, Allanson JE, Tartaglia M, et al: Noonan syndrome. Lancet 381:333-342, Table 3, used with permission.

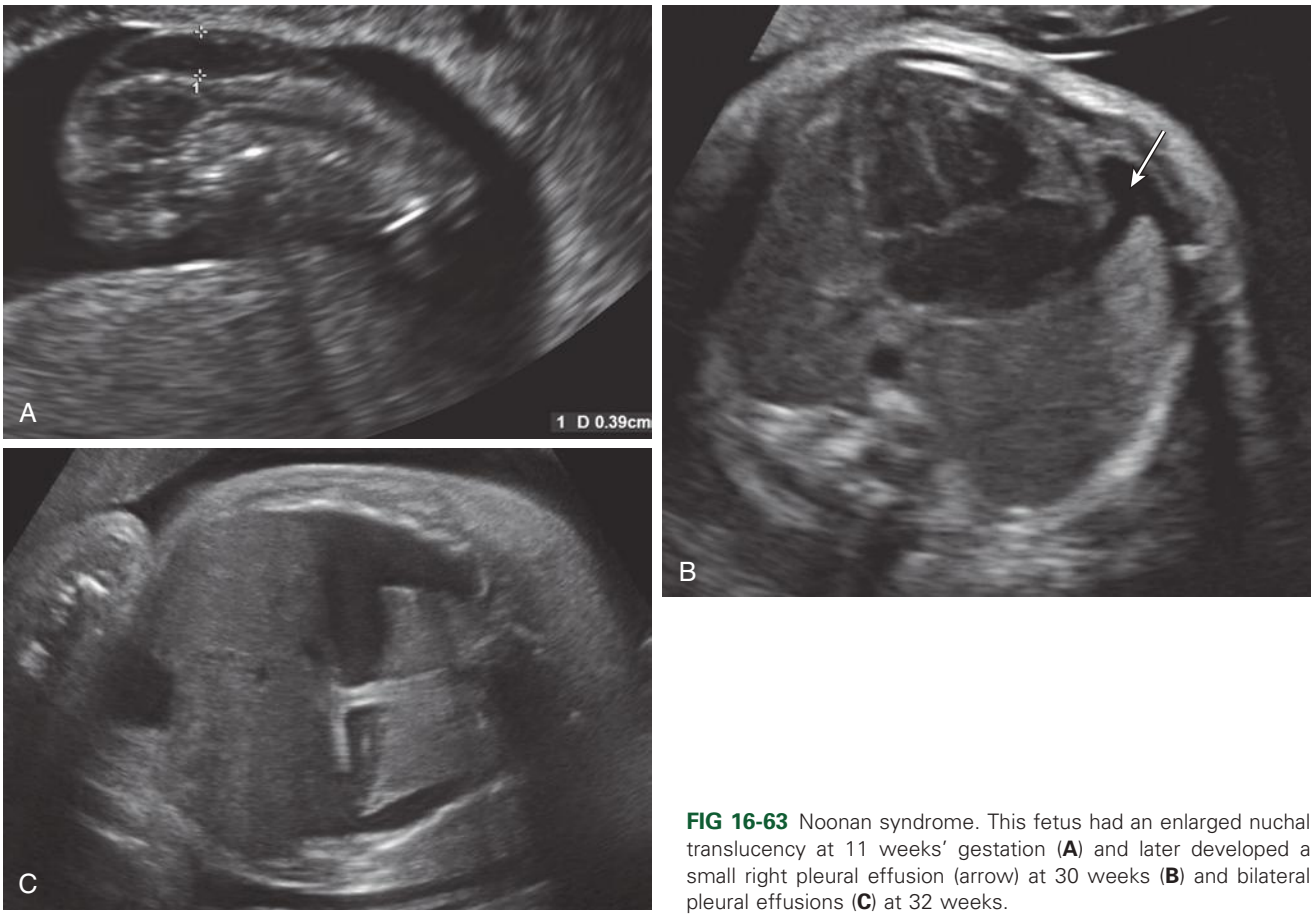

FIG 16-63 Noonan syndrome. This fetus had an enlarged nuchal translucency at 11 weeks' gestation (**A**) and later developed a small right pleural effusion (arrow) at 30 weeks (**B**) and bilateral pleural effusions (**C**) at 32 weeks.

trimester. Birth weight is generally normal with short stature most evident later, especially at the time of puberty.

Differential Diagnosis

An increased nuchal translucency in the first trimester is associated with Turner syndrome and aneuplody; Noonan syndrome should be considered in the presence of an increased nuchal translucency with normal chromosome studies. Other RASopathies (syndromes with mutations in the RAS-MAPK signaling pathway) can be associated with similar findings both prenatally and in infancy, including cardiofaciocutaneous and Costello syndromes. Aarskog syndrome can present with similar facial features and short stature. Molecular genetic testing can aid in diagnosis.

Prognosis

Life expectancy is generally normal for those without major complications of heart disease. Feeding difficulties are often present in infants. Hearing loss is common. Developmental delay is variable; intelligence is generally in the normal range, but mild learning difficulties may be present.

Management

Guidelines for management have been established (Table 16-7).

Pentalogy of Cantrell

Definition

Pentalogy of Cantrell is characterized by five anomalies: deficiency of the anterior diaphragm, midline supraumbilical abdominal wall defect, defect in the diaphragmatic pericardium, intracardiac abnormalities, and lower sternum defect. It was first described in 1958.

Synonyms

Synonyms include thoracoabdominal ectopia cordis, ectopia cordis, and Cantrell-Heller-Ravitch syndrome.

Incidence

Pentalogy of Cantrell is very rare. Incidence is estimated at 5.5 per 1 million live births. There is a 2:1 male-to-female ratio.

Etiology/Pathogenesis

The defects appear to originate from the 3rd week of life with a mesodermal origin, specifically abnormal migration of the splanchnic and somatic mesoderm with premature breakage of the chorion or vitelline sac at days 14 to 18 of gestation.

Genetics

Most cases are sporadic. X-linked inheritance has been suggested in some families.

Recurrence Risk

Recurrence risk is unknown. No recurrence has been recorded. One set of monozygotic twins concordant for the syndrome has been reported.

Diagnosis

Prenatally, the diagnosis can be made as early as the first trimester. Classic findings include complete disruption of the anterior chest and abdominal wall. The finding of cardiac activity outside the chest in association with an omphalocele is diagnostic. Karyotype analysis is recommended to exclude chromosomal anomalies. Ascites and pleural

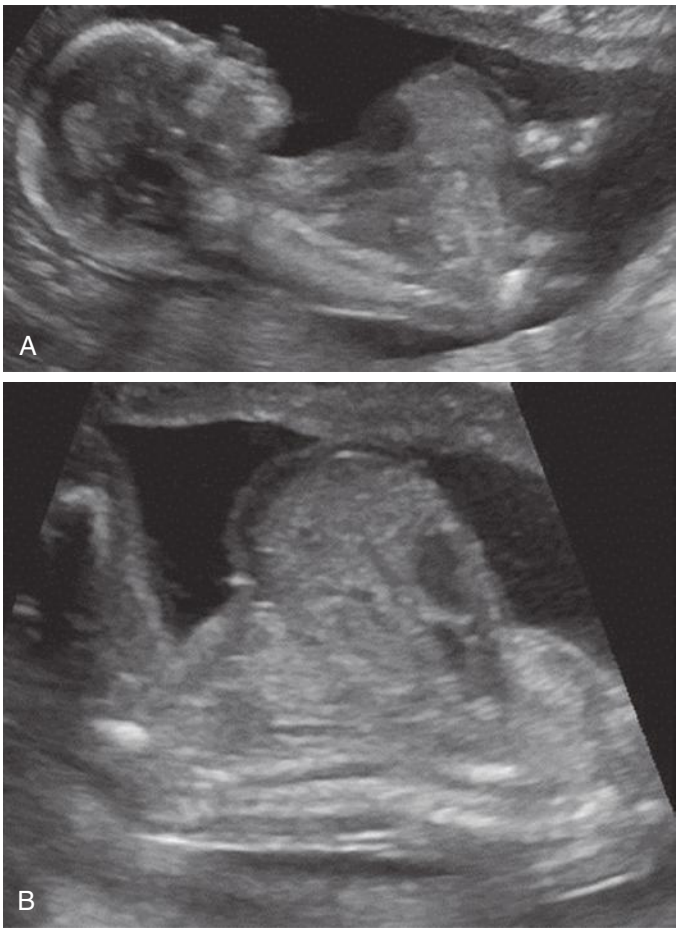

FIG 16-64 Pentalogy of Cantrell. Fetus with midline thoracoabdominal defect with partially externalized heart and large upper omphalocele at 16 weeks' (**A**) and 19 weeks' (**B**) gestation. The fetus also had a conotruncal heart defect (double outlet right ventricle).

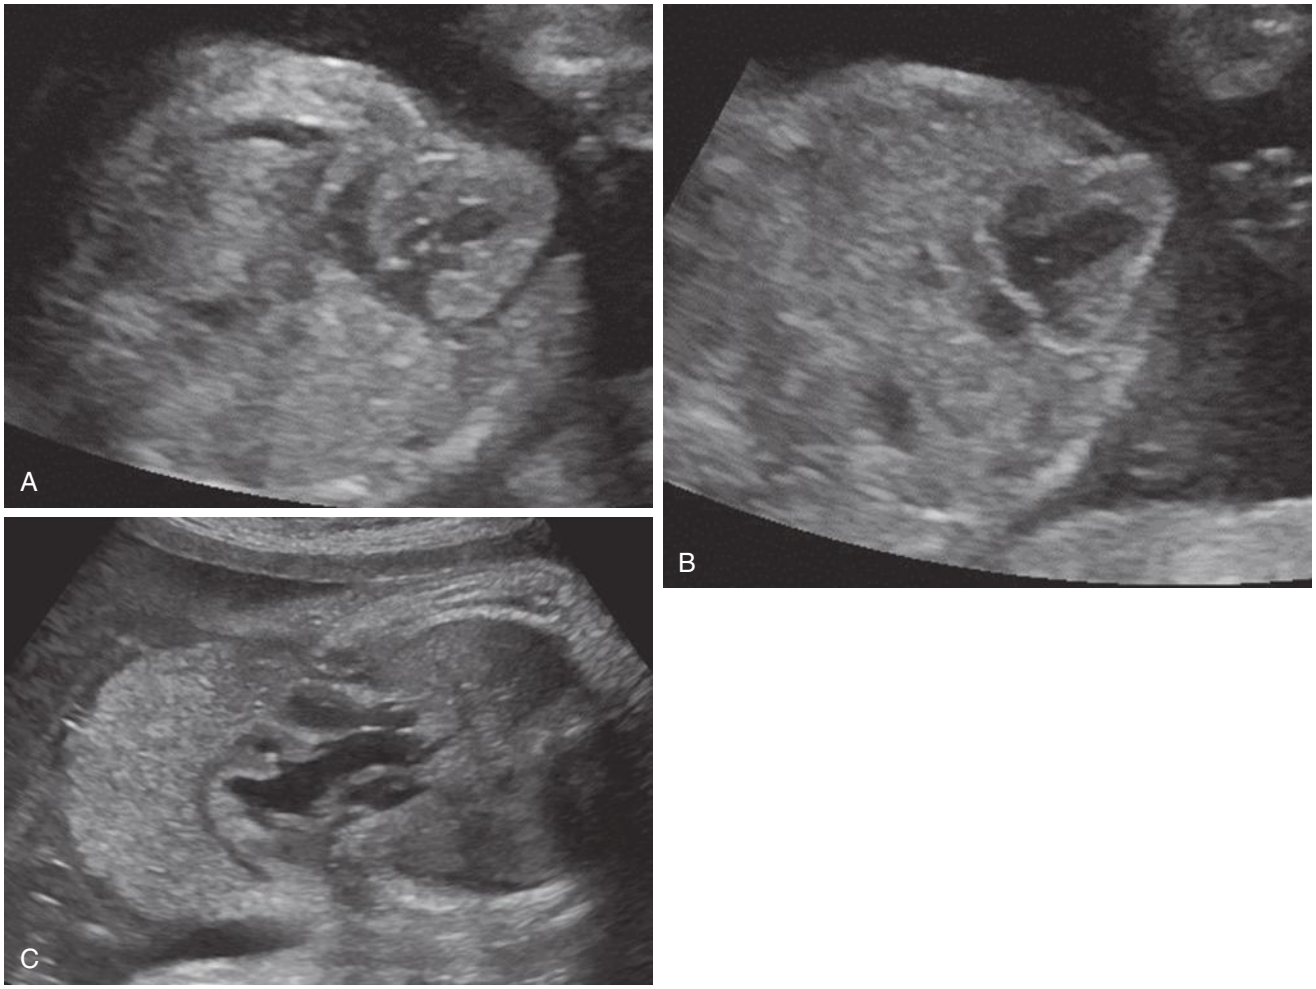

FIG 16-65 Pentalogy of Cantrell. At 24 weeks' gestation (**A** and **B**), the partially exteriorized heart is demonstrated in these views of the fetal chest. At 35 weeks (**C**), the large upper omphalocele is demonstrated in this axial view of the fetal chest.

FIG 16-66 Sonogram of an embryo at 10 weeks' gestation with pentalogy of Cantrell. (Courtesy of Fernando Maia, 2005. Available at thefetus.net.)

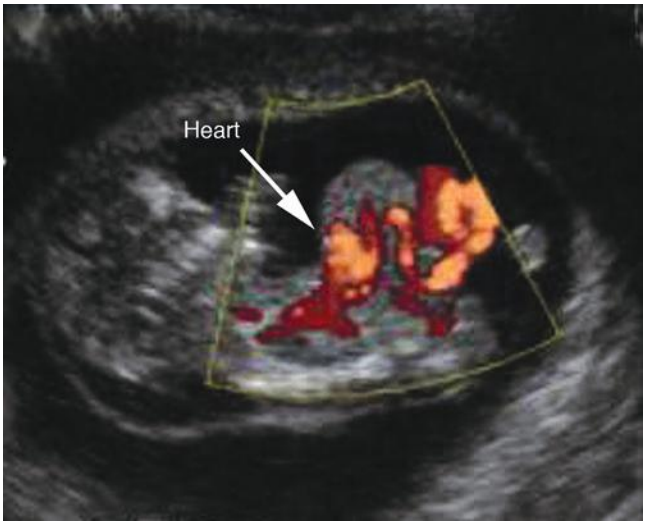

FIG 16-67 Color Doppler sonogram in the same patient with pentalogy of Cantrell. (Courtesy of Fernando Maia, 2005. Available at thefetus.net.)

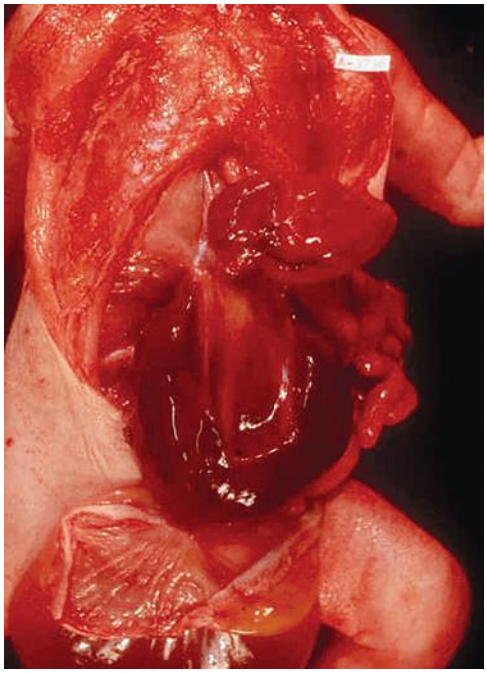

FIG 16-68 Postmortem view of a fetus with pentalogy of Cantrell. (Courtesy of Heron Werner, 2005. Available at thefetus.net.)

effusion may occur from compression of the contents of both the chest and abdomen.

Associated Anomalies

Other anomalies include craniofacial anomalies, CNS anomalies, skeletal anomalies, dermatologic anomalies, spina bifida, anencephaly, hydrocephalus, and clubfeet.

Differential Diagnosis

Differential diagnosis includes isolated thoracic cardiac ectopy, ectopia cordis associated with amniotic band syndrome, body-stalk abnormality, isolated omphalocele, BWS, chromosomal abnormalities.

Prognosis

Survival is rare, and cases presenting a complete extrusion of heart and abdominal contents have an extremely poor prognosis. The prognosis for individuals with milder forms depends on the extent of the anomalies, including size of the abdominal wall defect and extent of the cardiac defect. Congenital heart disease is a source of major morbidity in infants surviving the neonatal period.

Management

After delivery, repair of the omphalocele should not be delayed. Repair of the sternal, diaphragmatic, and pericardial defects can be attempted at the same time. Surgical correction is often difficult secondary to hypoplasia of the thoracic cage and inability to enclose the ectopic heart. Respiratory insufficiency secondary to pulmonary hypoplasia can be present.

Tuberous Sclerosis

See discussion under "Central Nervous System." Cardiac rhabdomyomas (seen as well-delineated homogeneous masses) may be seen prenatally; 51% to 86% of patients with cardiac rhabdomyomas have tuberous sclerosis.

GASTROINTESTINAL SYSTEM/ABDOMINAL WALL

Gastrointestinal System Disorders

Cystic Fibrosis

Definition. Cystic fibrosis (CF) is a complex multisystem disorder affecting the respiratory tract, exocrine pancreas, intestine, hepatobiliary system, exocrine sweat glands, and male genital tract.

Incidence. Incidence is 1 in 3200 live births in persons of northern European heritage; 1 in 15,000 African Americans; and 1 in 31,000 Asian Americans.

Diagnosis. Prenatally, the diagnosis is generally suspected because of the presence of fetal echogenic bowel (owing to intestinal obstruction from abnormal meconium). The risk of CF in a pregnancy with moderate echogenic bowel may be 2% to 3% and, if severe, may be 5% to 20%. Newborns can be diagnosed by an abnormal sweat chloride test, which is positive in more than 90% of individuals with CF. Newborn screening for CF has also now been implemented in most of the United States.

Genetics. CF is caused by mutations in the *CFTR* gene. Inheritance is autosomal recessive.

Recurrence Risk. Recurrence risk is 25% if both parents are carriers.

Differential Diagnosis. The most common other disorders presenting with fetal echogenic bowel include aneuploidy and CMV infection.

Prognosis. From 15% to 20% of infants with CF present with meconium ileus. Pulmonary disease is the major cause of long-term morbidity and even death. Lower airway inflammation and chronic endobronchial infection progress to end-stage fibrotic lung disease. Most individuals also have pancreatic insufficiency, and most males are infertile. Overall median survival time is 36.5 years.

Management. The prenatal finding of echogenic bowel should prompt evaluation for fetal aneuploidy, maternal CF carrier testing, and CMV infection. If these studies return negative, pregnancy surveillance should be increased given the association of echogenic bowel with fetal growth restriction and stillbirth.

FIG 16-69 Cystic fibrosis. Axial image through the abdomen of a fetus with echogenic bowel (*arrow*). Second trimester echogenic bowel may represent cystic fibrosis. Genetic counseling to discuss inheritance, the impact of ethnicity on testing, and the appropriate genetic evaluations should be facilitated.

Epidermolysis Bullosa With Pyloric Atresia

Definition. Epidermolysis bullosa with pyloric atresia (EB-PA) is characterized by fragility of the skin and mucous membranes with blistering with minimal or no trauma, congenital pyloric atresia, and genitourinary anomalies (dysplastic/multicystic kidney, hydronephrosis/hydroureter, ureterocele, duplicated renal collecting system, absent bladder).

Synonym. EB-PA is also known as Carmi syndrome.

Etiology. Mutations in the implicated genes lead to deficiency of either the α6β3 integrin complex or the interacting protein, plectin. These proteins are necessary for epidermal integrity. The association with pyloric atresia is not well understood.

Incidence. EB-PA is very rare. The EB-PA subtype of EB may represent 15% of all cases of EB.

Genetics. Three genes have been implicated in the disorder: *ITGB4* (80%), *ITGA6* (5%), and *PLEC1* (15%). Inheritance is autosomal recessive. Carrier status of both parents should be confirmed because germline mosaicism and uniparental isodisomy are possible. Penetrance is complete.

Recurrence Risk. If both parents are mutation carriers, recurrence risk is 25%.

Diagnosis. Prenatally, suspicion of pyloric atresia may be initially raised based on identification of an enlarged stomach bubble. Intragastric sediment can suggest a possible fetal abrasive skin lesion condition. Polyhydramnios and high amniotic fluid AFP levels (>20 multiples of the median) are often seen.

Associated Anomalies. Other anomalies include localized absence of the skin (aplasia cutis congenita), hypotrichosis, dystrophic nails, contractures, and dilated cardiomyopathy.

Differential Diagnosis. Other disorders to consider include other subtypes of epidermolysis bullosa and isolated pyloric atresia.

Prognosis. The clinical course is usually severe and often lethal in the neonatal period. Affected infants may develop sepsis with severe electrolyte abnormalities as a result of extensive skin blistering and

erosion. Infants who survive generally have less severe cutaneous manifestations and require repair of the pyloric atresia.

Megacystis-Microcolon–Intestinal Hypoperistalsis Syndrome

Definition. Megacystis-microcolon–intestinal hypoperistalsis syndrome (MMIHS) is characterized by a prenatally distended urinary bladder and functional intestinal obstruction.

Etiology. *ACTG2* encodes for the protein γ2 enteric actin and is thought to be important for cell integrity, structure, and motility. It associates with the actin cytoskeletal filament network. Mutations in *ACTG2* lead to dysfunction of enteric smooth muscle.

Genetics. Many cases are caused by heterozygous *ACTG2* mutations. Genetic heterogenity may exist. Most cases are de novo, although less severely affected parents with disease-causing *ACTG2* mutations have now been reported.

Recurrence Risk. For de novo cases, recurrence risk is estimated at approximately 1% because of the risk of germline mosaicism. Recurrence risk is 50% with a known parental mutation.

Incidence. MMIHS is rare. More than 230 cases have been described in the literature.

Diagnosis. Prenatal findings include megacystis, hydronephrosis, dilated stomach, and dilated small intestine. Polyhydramnios can also be seen. Newborns are found to have dilated bladders without structural obstruction, dilated small intestine, and intestinal hypoperistalsis with diminished caliber of the colon. Renal function is preserved.

Differential Diagnosis. The differential should include other disorders leading to fetal megacystis, such as posterior urethral valves.

Prognosis. Death is common in infancy as a result of feeding issues and complications.

Management. Extensive surgical operations are required including transplantation of multiple organs, including the small bowel. Survival rate after multivisceral transplantation is only 12% to 20%. Most survivors are dependent on total parenteral nutrition and urinary catheterization.

Abdominal Wall Defects

Beckwith-Wiedemann Syndrome

Definition. BWS is a growth disorder originally characterized by the classic triad of macrosomia, macroglossia, and omphalocele. Other features include visceromegaly, embryonal tumors, neonatal hypoglycemia, ear creases/pits, and renal abnormalities.

Incidence. Incidence is estimated at 1 in 13,700, but this figure is likely an underestimate given that some individuals have a more mild phenotype and remain undiagnosed.

Etiology. The condition is sporadic in approximately 85% of cases. Assisted reproductive technology increases the risk of imprinting disorders, including BWS.

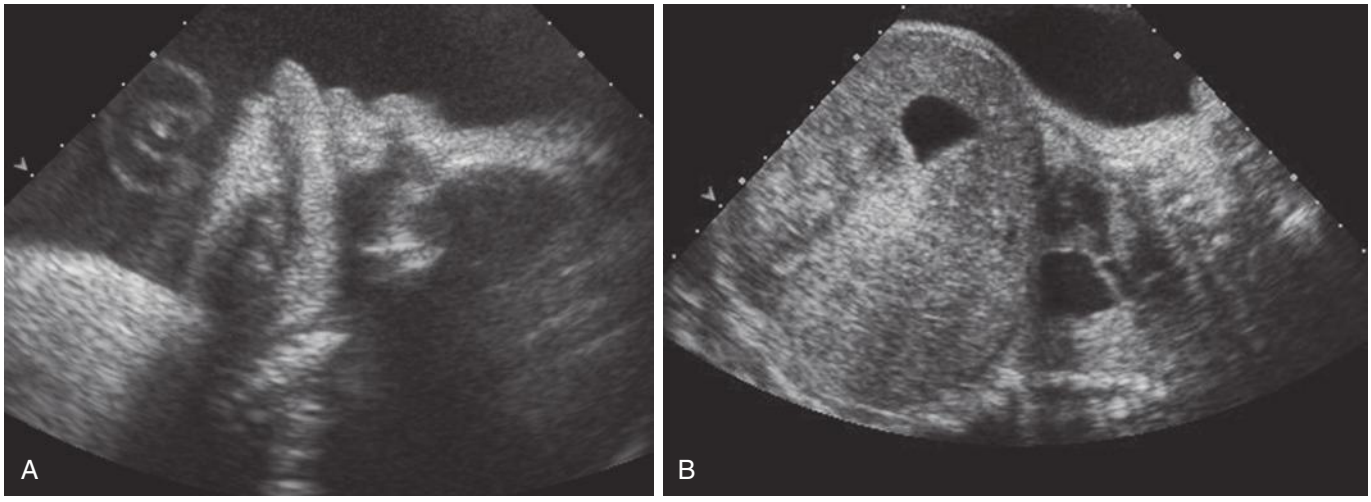

FIG 16-70 Beckwith-Wiedemann syndrome (BWS). Macroglossia (**A**) and hepatomegaly (**B**) are visualized in this fetus with macrosomia and BWS.

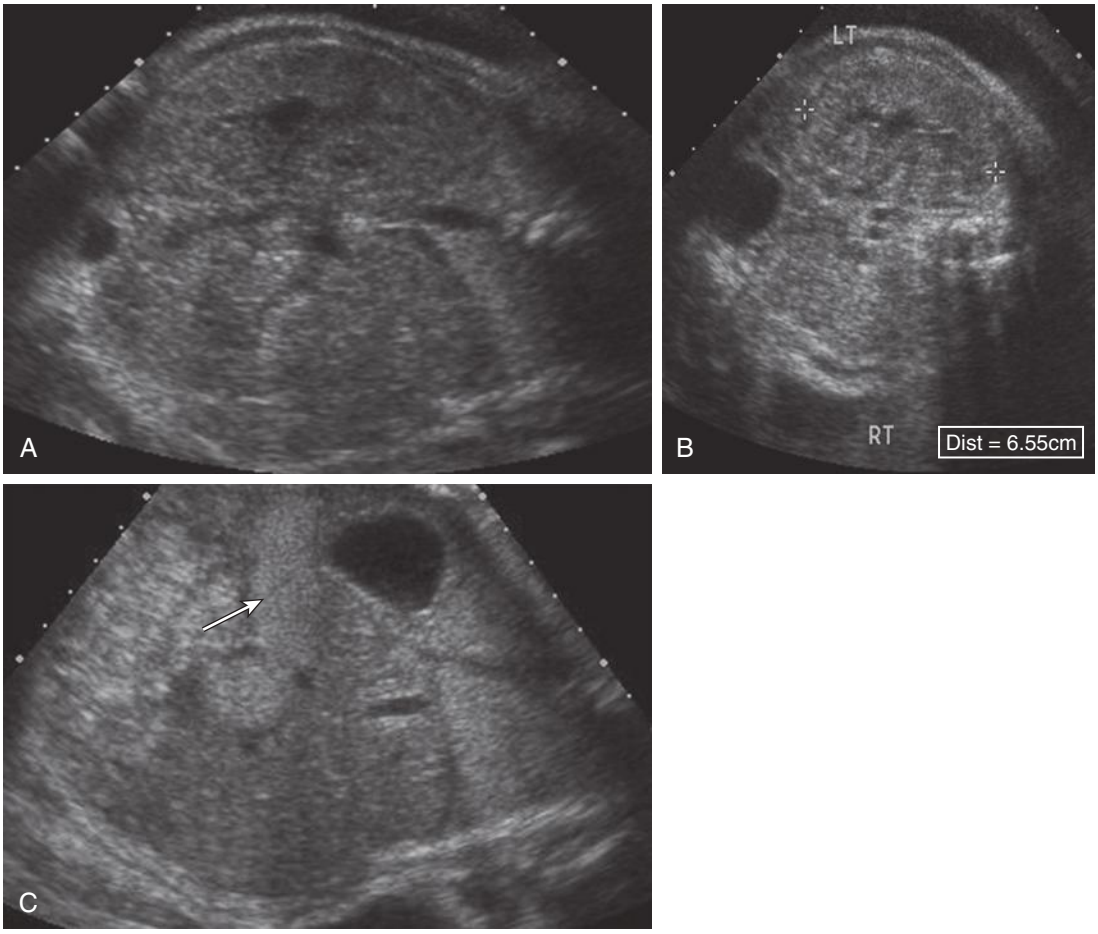

FIG 16-71 Organomegaly is characteristic of Beckwith-Wiedemann syndrome. In this fetus, nephromegaly (**A**) and an enlarged pancreas (**B** and **C**) (*arrow*) are seen. LT, left; RT, right.

FIG 16-72 Beckwith-Wiedemann syndrome. The earlobe groove (*arrow*) can be recognized with detailed examination.

Genetics. BWS is due to epigenetic and genomic alterations at chromosome 11p15. These alterations include loss of methylation on the maternal chromosome at imprinting center 2 (IC2; 50% of individuals); paternal uniparental disomy at chromosome 11p15 (20%); gain of methylation on the maternal chromosome at imprinting center 1 (IC1; 5%). Sequence analysis of *CDKN1C* identifies mutations in 40% of families with the disorder and in 5% to 10% of cases without a family history. Overall, 85% of individuals with BWS have a negative family history, and 15% have a family history consistent with autosomal dominant inheritance. Penetrance is incomplete and expressivity is variable.

Recurrence Risk. Recurrence risk depends on the underlying mechanism leading to BWS.

Diagnosis. Prenatal findings include macrosomia, macroglossia, omphalocele, polyhydramnios, long umbilical cord, and an enlarged placenta. Many of these features are not present until the late second trimester. Renal anomalies may be present and include medullary dysplasia, duplicated collecting system, cystic changes, and nephromegaly. Embryonic tumors may present early in life, including Wilms tumor and hepatoblastoma, as well as neuroblastoma, adrenocortical carcinoma, and rhabdomyosarcoma. Hemihyperplasia can often be seen at birth, but may become less pronounced as a child grows.

Differential Diagnosis. The differential diagnosis includes other growth disorders such as Simpson-Golabi-Behmel syndrome, Perlman syndrome, Costello syndrome, Sotos syndrome, and Proteus syndrome, as well as diabetic fetopathy.

Prognosis. Previously, the neonatal mortality rate was as high as 20%, but this is likely lower now. Recognition of associated issues has improved prognosis. Preterm delivery is a common complication due to polyhydramnios and gestational hypertension. Development is usually normal, and prognosis is generally favorable after childhood.

Management. If severe macrosomia and adrenal cysts are present, cesarean delivery may be needed. Neonatal hypoglycemia should be monitored and treated. Macroglossia can lead to feeding difficulties and airway obstruction. Screening should be performed for embryonic tumors with serum AFP levels and abdominal ultrasound examination until age 8; overall risk for tumor development in children is 7.5%. Tumor development may vary by specific underlying genetic cause of the child's BWS. Omphalocele should be repaired.

Cloacal Exstrophy Sequence

Definition. Cloacal exstrophy is a complex abdominal wall defect characterized by omphalocele, bladder exstrophy, and imperforate anus. Other anomalies include renal malformations, spinal defects, single umbilical artery, and limb defects.

Synonym. Cloacal exstrophy is also known as OEIS complex (*o*mphalocele, bladder *e*xstrophy, *i*mperforate anus, and *s*pinal defects).

Incidence. Incidence is 1 in 200,000 to 1 in 400,000, with a female-to-male ratio of approximately 2:1.

Etiology. Cloacal exstrophy is thought to result from an early embryologic defect involving the caudal eminence.

Genetics. Cloacal exstrophy likely has a heterogeneous cause. Occasionally affected infants have a chromosomal abnormality.

Recurrence Risk. Recurrence risk is unknown.

Diagnosis. Prenatally, findings include a large intraumbilical anterior midline defect, omphalocele, absent bladder, and polyhydramnios. Genital abnormalities include division of the scrotum or labia and separation or absence of the phallic or clitoral halves. In males, the testes are frequently undescended. In females, vaginal duplication and vaginal agenesis are common.

Associated Anomalies. Other defects seen less commonly include esophageal atresia with tracheoesophageal fistula, duodenal atresia, and Chiari I malformation.

Differential Diagnosis. Differential diagnosis includes related anomalies within the exstrophy-epispadias spectrum such as bladder exstrophy.

Prognosis. Survival increased dramatically after corrective surgery was introduced, with current survival greater than 90%. Comorbid conditions include complications with urinary and bowel function as well as gender assignment.

Management. Postnatal management requires a multidisciplinary team and includes multiple surgical procedures. Quality-of-life issues predominate. Gender should be determined by karyotype if not obvious on examination. Plain films of the chest, spine, and pelvis should be obtained. Screening for renal and spinal anomalies should be performed.

Miller-Dieker Syndrome

See "Central Nervous System." This syndrome presents with lissencephaly, as well as other anomalies, including rare cases with omphalocele.

Pentalogy of Cantrell

See "Heart." This syndrome is associated with abdominal wall defects, most commonly omphalocele.

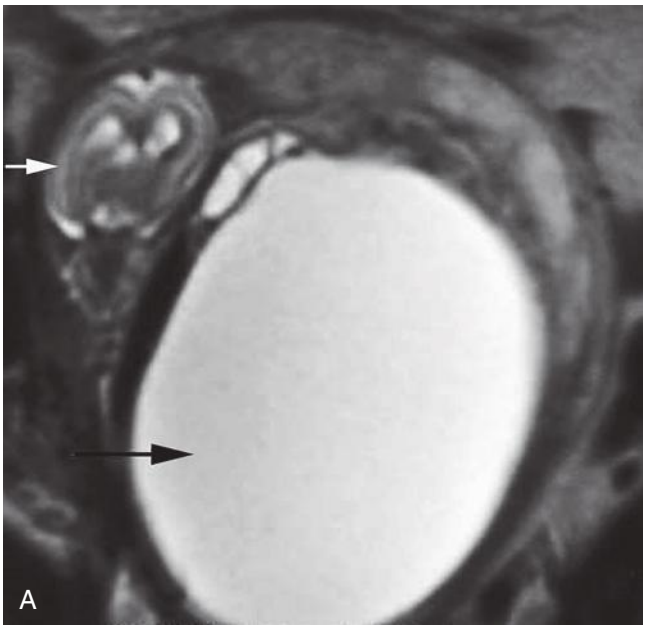
Prune-Belly Syndrome

Definition. Prune-belly syndrome (PBS) is a rare disorder characterized by deficient abdominal wall muscles, urinary tract malformations, and cryptorchidism in boys.

Synonym. PBS is also called Eagle-Barrett syndrome and triad syndrome.

Incidence. Incidence is 1 in 35,000 to 1 in 50,000 live births; PBS is most often seen in males and rarely in females (3-5%). It is seen more often in infants born to younger mothers, in twin gestations, and in pregnancies conceived by assisted reproductive technology.

Etiology. Many theories to explain the disorder have been proposed and two predominate. The first proposes that urethral atresia and stenosis of the posterior urethral valves lead to severe bladder outlet obstruction. The second proposes that developmental arrest of the lateral plate mesoderm in weeks 6 to 7 of pregnancy leads to deficiency of the muscles of the abdominal wall and defective development of the urinary tract.



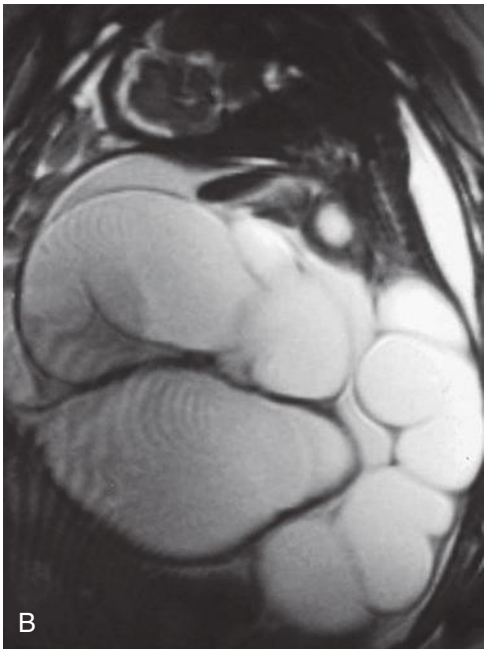


FIG 16-73 A, Sagittal T2 magnetic resonance imaging scan demonstrates high signal from a markedly dilated urinary bladder (*black arrow*). Note the size discrepancy of the fetal head (*white arrow*) at 26 weeks' gestation. **B,** Coronal T2 magnetic resonance imaging scan demonstrates marked dilatation of the fetal ureter. (Courtesy of Heron Werner, 2005. Available at thefetus.net.)

Genetics. Genetics are unknown, but PBS likely has a heterogeneous cause. Occasionally it has been reported in association with aneuploidy as well as with abnormalities of *HNF1*.

Recurrence Risk. Recurrence risk is unknown, but low.

Diagnosis. Prenatally, the diagnosis should be suspected in fetuses with very large abdominal masses. In PBS, the abdominal mass is megacystis (an enlarged bladder); oligohydramnios can be present if lower urinary tract obstruction is severe. Other findings include hyperechogenic kidneys, Potter facies, pulmonary hypoplasia, gastric dilatation, short bowel, microileum, microcolon, malrotation of the intestines, imperforate anus, arthrogryposis, clubfeet, and cardiac defects.

FIG 16-74 Postmortem neonatal photograph demonstrating a markedly enlarged abdomen with redundant skin. (Courtesy of Heron Werner, 2005. Available at thefetus.net.)

Differential Diagnosis. The differential diagnosis includes other urinary tract anomalies, such as posterior urethral valves and MMIHS.

Prognosis. Prognosis depends on the severity of renal dysfunction, duration and degree of oligohydramnios, and presence of pulmonary hypoplasia. Outcome is favorable in cases with normal amniotic fluid volume.

Management. Prenatal management in cases with severe lower urinary tract obstruction is controversial. Fetal intervention aimed at relief of bladder outlet obstruction and restoration of amniotic fluid volume may be beneficial in select cases, but evidence is limited. Postnatal management aims to preserve renal function and prevent urinary tract infection. Abdominal wall reconstruction for both aesthetics and function is often necessary. Orchidopexy is performed to correct intra-abdominal testes. Because extraurinary anomalies are common, a thorough evaluation, especially for cardiac defects, should be performed.

GENITOURINARY TRACT

Renal Tract Anomalies

Mild abnormalities of the kidneys and urinary tract are seen in approximately 5 in 1000 births. Many anomalies are isolated and some, such as autosomal recessive polycystic kidney disease, have a known genetic cause (see Chapter 15, The Fetal Genitourinary Tract). Complete renal agenesis is incompatible with extrauterine life and the resultant oligohydramnios can lead to Potter sequence that includes pulmonary hypoplasia and musculoskeletal abnormalities. Other renal tract anomalies are associated with fetal syndromes, and a few notable examples are reviewed here.

Fraser Syndrome

Definition. Fraser syndrome is characterized by cryptophthalmos, cutaneous syndactyly of the hands and feet, and anomalies of the respiratory and urogenital tracts (ambiguous genitalia and renal agenesis).

Synonym. Fraser syndrome is also known as cryptophthalmos-syndactyly syndrome.

Incidence. Incidence is 0.043 per 10,000 liveborn infants and 1.1 per 10,000 stillbirths.

Etiology. The proteins encoded by *FRAS1* and *FREM* form a complex expressed in basement membranes during embryonic development; this complex is involved in epithelial-mesenchymal integrity. *GRIP1* encodes a scaffolding protein that interacts with FRAS1/FREM protein complexes and helps to localize the complex to the basal side of cells.

Genetics. The genetic cause is heterogeneous and includes mutations in *FRAS1, FREM2*, or *GRIP1*. Inheritance is autosomal recessive with marked intrafamilial variability.

Recurrence Risk. Recurrence risk is 25% if both parents are found to be mutation carriers.

Diagnosis. The diagnosis is based on the combination major and minor characteristics, where three major, or two major and two minor, or one major and three minor diagnostic criteria are present. The

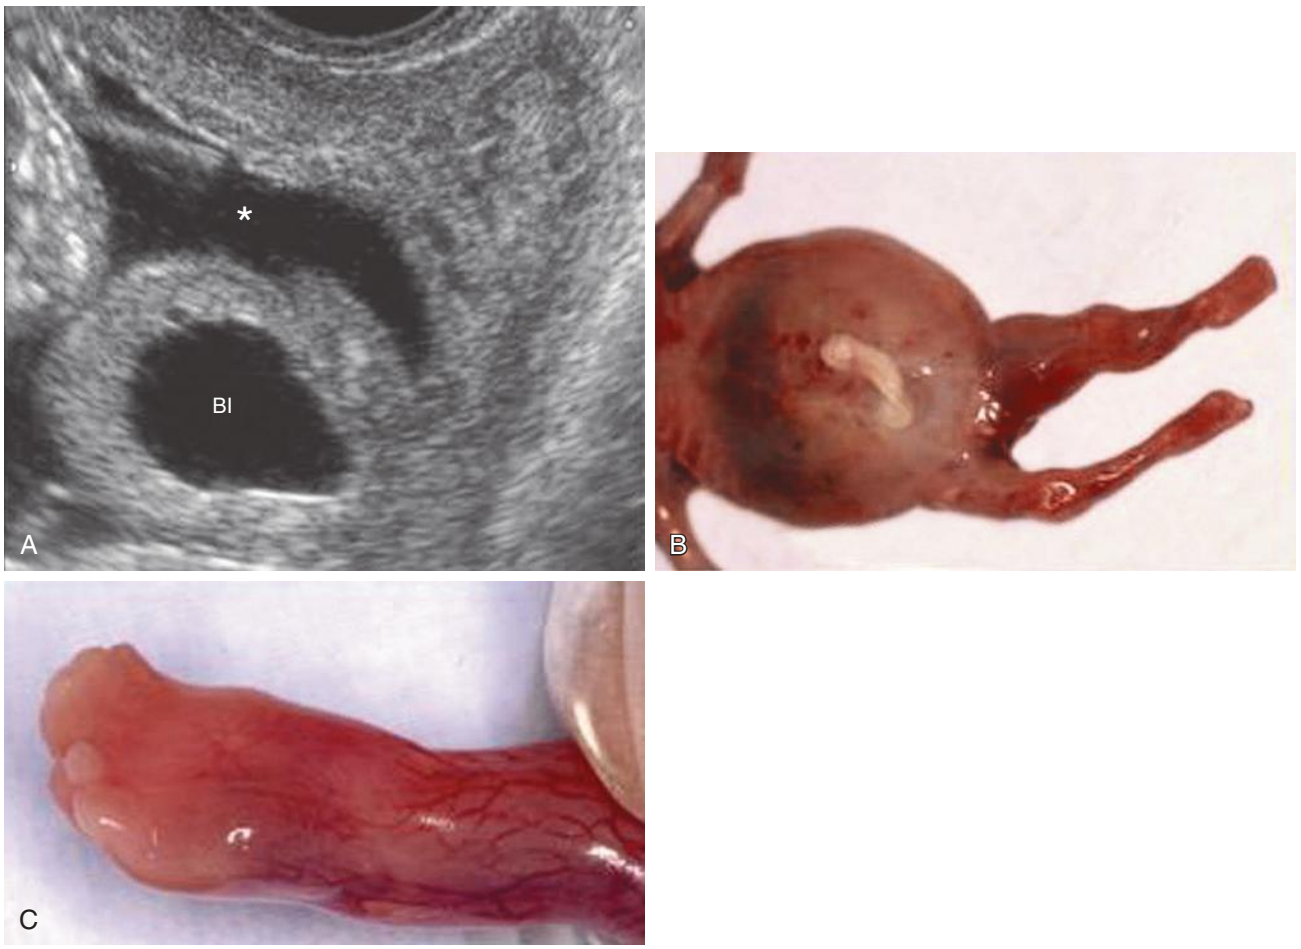

FIG 16-75 A case of Fraser syndrome diagnosed at 16 weeks' gestation. Megacystis, syndactyly, and oligohydramnios were seen. **A,** Sonogram demonstrating megacystis and ascites (*asterisk*). **B** and **C,** Neonatal images. Note the distention of the abdominal wall and the postmortem feet with syndactyly between the first, second, and third digits. (Courtesy of Fabrice Cuillier, 2005. Available at thefetus.net.)

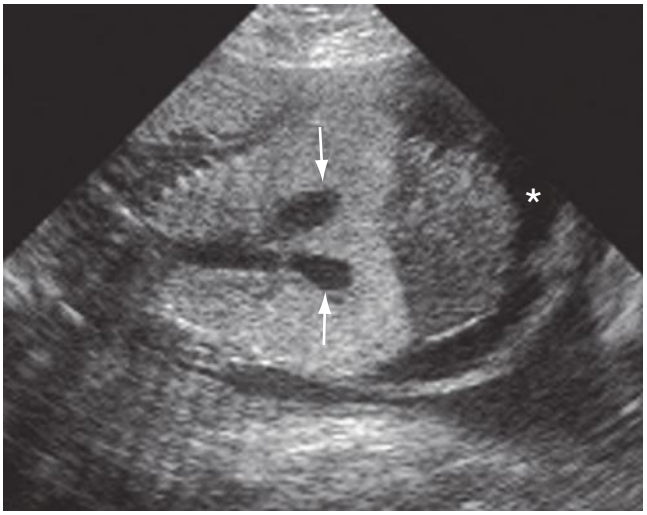

FIG 16-76 Sonogram of another fetus with laryngeal atresia and Fraser syndrome. Bilateral enlarged hyperechogenic lungs, fluid-filled bronchi (*arrows*), and ascites (*asterisk*) were present.

major criteria include syndactyly, cryptophthalmos, urinary tract anomalies, ambiguous genitalia, laryngeal or tracheal anomalies, and positive family history. The minor criteria include anorectal defects, dysplastic ears, abnormal skull ossification, umbilical anomalies, and nasal anomalies. Other features include cleft lip ± palate; skeletal anomalies; cardiac malformations; and anal atresia. Many of these anomalies can be seen prenatally, but the specific diagnosis may be difficult to determine until after birth.

Differential Diagnosis. Other syndromes with syndactyly, renal agensis, and laryngeal anomalies include cutis aplasia, Nager acrofacial dysostosis, and Pallister-Hall syndrome, but they are all distinct from Fraser syndrome.

Prognosis. The syndrome is fatal if laryngeal atresia or bilateral renal agenesis is present. If cryptophthalmos is present, even surgical repair will yield very poor vision (i.e., 20/200 and 20/360) in the rare correctable cases.

Meckel Syndrome

See "Central Nervous System."

Megacystis-Microcolon–Intestinal Hypoperistalsis Syndrome

See "Gastrointestinal System Disorders." This syndrome is associated with megacystis (enlarged fetal bladder) in the absence of urinary tract obstruction.

MURCS Association

Definition. MURCS association is an atypical form of Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome. MURCS stands for müllerian duct aplasia (MU), congenital renal dysplasia (R), and cervical somite anomalies (CS). It is characterized by uterovaginal atresia in females, with associated kidney and skeletal anomalies. Cardiac and otologic anomalies can also be seen.

Synonym. MURCS association is also known as MRKH syndrome type 2 or atypical MRKH.

Incidence. Incidence is estimated at 1 in 50,000.

Genetics. Little is known. A heterogeneous genetic cause has been suggested, with both familial and sporadic cases reported. Some cases of MRKH have been linked to mutations in *LHX1* or *TBX6*. Familial cases appear to demonstrate autosomal dominant inheritance with incomplete penetrance.

Recurrence Risk. Recurrence risk is variable depending on cause.

Diagnosis. Prenatally, müllerian anomalies are difficult to detect, and the diagnosis may be suspected based on renal and vertebral anomalies.

Differential Diagnosis. Other conditions with renal, müllerian, and vertebral anomalies, such as VACTERL, are considered in the differential diagnosis.

Management. First-degree relatives of affected patients can have isolated renal anomalies and should undergo screening by renal sonography.

Perlman Syndrome

See "Fetal Overgrowth." Associated renal anomalies include nephromegaly, as well as hyperechogenic kidneys and hydronephosis.

Genital Anomalies

Male genital anomalies are common, particularly hypospadias and epispadias. These anomalies are often isolated but can be seen in association with many different fetal syndromes. Female genital anomalies can include ovarian cysts, vaginal and uterine malformations, and ambiguous genitalia (particularly in the setting of an adrenogenital syndrome, such as 21-hydroxylase deficiency due to *CYP21A2* gene mutations) (see Chapter 15, The Fetal Genitourinary Tract). Patients with disorders of sex development should be evaluated by a multidisciplinary team. Common diagnoses include congenital adrenal hyperplasia, androgen insensitivity, mixed gonadal dysgenesis, clitoral/labial anomalies, hypogonandropic hypogonadism, and hypospadias. Multisystem genetic conditions associated with ambiguous genitalia include Antley-Bixler syndrome, campomelic dysplasia, CHARGE syndrome, Denys-Drash syndrome, Fraser syndrome, Pallister-Hall syndrome, Robinow syndrome, SLO syndrome, WAGR syndrome, X-linked lissencephaly with ambiguous genitalia (XLAG), and X-linked Opitz G/BBB syndrome. These conditions should be suggested by their associated clinical findings.

Caudal Regression Syndrome

See previous discussion under "Teratogens."

Congenital Ichthyosis

Definition

Congenital ichthyosis represents a group of conditions with varying severity; the most severe form is harlequin ichthyosis. In harlequin ichthyosus, infants are often born prematurely and are noted to be encased in hard, thick skin that appears armor-like and severely restricts movement. The thick skin results in deformities of the face, head, and extremities.

Synonyms

Congenital ichthyosis is also called harlequin syndrome or harlequin ichthyosis.

Prevalence

Prevalence is 1 in 200,000 for all types of congenital ichthyosis; the harlequin ichthyosis phenotype is very rare.

Etiology

ABCA12 encodes for an ATP-binding cassette transporter important for the transport of epidermal lipids and their processing enzymes in the upper layers of the epidermis. Mutations lead to the improper formation of lamellar bodies, thereby preventing formation of lipid bilayers in the stratum corneum and causing hyperkeratosis and abnormal barrier function of the skin.

Genetics

Congenital ichthyosis is caused by mutations in several different genes; harlequin ichthyosis is generally casued by mutations in *ABCA12* (>93%). Inheritance is autosomal recessive.

Recurrence Risk

Recurrence risk is 25% if both parents are mutation carriers.

Diagnosis

The diagnosis is based on skin findings seen at birth. The skin is thick and hard, and plates of cornified skin are often separated by deep fissures. Facial features appear deformed, and microcephaly is often present. Prenatally, facial dysmorphism (fixed open mouth, fringed lip, short nasal bone, hypertrophic palpebral fissures), clenched hands and feet, growth restriction, and hyperechogenic amniotic fluid may be seen. Decreased fetal movement may be reported.

Differential Diagnosis

The differential diagnosis includes Sjögren-Larsson syndrome, Netherton syndrome, Gaucher dusease, ketatitis-ichthyosis-deafness syndrome, trichothiodystrophy, hypohidrotic ectodermal dysplasia, and epidermolytic and superficial epidermolytic ichthyosis.

Prognosis

Harlequin ichthyosis is often lethal from respiratory distress, feeding issues, dehydration, electrolyte imbalance, temperature instability, and systemic infection. Children who survive shed the thick skin and then develop intense redness of the skin with scaling (erythroderma).

Congenital Myasthenic Syndromes

Definition

Congenital myasthenic syndromes (CMSs) are a group of syndromes characterized by fatigability of skeletal muscle. Affected muscles are generally ocular, bulbar, and limb muscles; smooth muscle and cardiac muscle are not involved. In the subtype with neonatal onset, other findings include eyelid ptosis, feeding issues, apnea, and arthrogryposis multiplex congenita (multiple congenital contractures in different body locations).

Synonyms

CMSs include congenital myasthenia.

Prevalence

The CMSs are rare; prevalence is estimated at 2.5 to 12.5 in 1 million.

Etiology

The implicated genes encode for proteins involved in neuromuscular junction function and different types of alterations in these proteins lead to the observed clinical phenotypes.

Genetics

These syndromes are due to mutations in one of multiple genes encoding for proteins expressed at the neuromuscular junction. Implicated genes include *CHRNE, CHRNA1, CHRNB1, CHRND* (autosomal dominant or recessive inheritance), as well as *AGRN, CHAT, COLQ, DOK7, GFPT1, MUSK, RAPSN,* and *SCN4A* (autosomal recessive inheritance). There is significant variability in the severity of clinical disease.

Recurrence Risk

Recurrence risk depends on mode of inheritance. For autosomal recessive subtypes, recurrence is 25% if both parents are carriers. For autosomal dominant subtypes, some are de novo with low recurrence risk; if a parent is affected, the recurrence risk is 50%.

Diagnosis

The diagnosis of CMS is based on a combination of clinical findings, including skeletal muscle weakness, characteristic electromyographic findings (decremental response of the compound muscle action potential with low-frequency stimulation), absence of antiacetylcholine receptor and anti-MuSK antibodies in the blood, and failure of symptoms to improve with immunosuppression. Other features include hypotonia, congenital contractures, facial dysmorphism (high-arched palate, elongated face), and waddling gait. Symptoms usually present in the first 2 years of life. Prenatally, there may be maternal reports of decreased fetal movement. Sonographically, lack of fetal mobility and abnormal fetal positioning may be noted. Fixed flexion abnormalities of the joints may be seen. Additionally, increased nuchal translucency and polyhydramnios have been reported.

Differential Diagnosis

The differential diagnosis includes myasthenia gravis, spinal muscular atrophy, and congenital muscular dystrophies.

Prognosis

The prognosis depends on the severity of the presentation. Sudden apnea and cyanosis can be seen in neonates. Feeding difficulties and choking spells are common. Muscles are easily fatigued, but cognition, sensation, and coordination are normal.

Management

Patients with CMS generally benefit from therapy with acetylcholine esterase inhibitors or the potassium channel blocker 3,4-diaminopyridine.

Congenital Myotonic Dystrophy, Type 1

Definition

Congenital myotonic dystrophy, type 1 (congenital DM1), is characterized by hypotonia and severe generalized weakness at birth. Respiratory insufficiency is common. Less severe forms (mild and classic) associated with later onset and milder symptoms also exist.

Prevalence

Prevalence is 1 in 20,000 for all groups of myotonic dystrophy, type 1.

Etiology

DMPK encodes for myotonin-protein kinase, a serine-threonine protein kinase, that is localized in the heart and skeletal muscle at locations important for intercellular conduction and impulse transmission. The effects of the CTG repeat are complex and still under investigation.

Genetics

Congenital DM1 is due to expansion of a trinucleotide repeat (CTG) in a noncoding region of the gene *DMPK*. This congenital form is due to a CTG repeat size of more than 1000; more than 50 CTG repeats are associated with disease manifestations. Inheritance is autosomal dominant.

Recurrence Risk

If a parent has an expanded CTG repeat, there is a 50% chance for each child to inherit the mutant allele. The CTG repeat can expand during gametogenesis, increasing the risk that children will have more severe disease than their affected parents. Expansion is more likely with maternal transmission of the disease.

Diagnosis

The diagnosis of congenital DM1 is generally suspected on the basis of clinical features in neonates including hypotonia, generalized

weakness (including facial muscle weakness with a tented upper lip), and respiratory insufficiency. CNS findings include cerebral atrophy and ventricular dilation. Prenatally, polyhydramnios, clubfeet, mild ventriculomegaly, and decreased fetal movement are often reported.

Differential Diagnosis

The differential diagnosis includes other myopathies and congenital muscular dystrophies.

Prognosis

Congenital DM1 often leads to early death, with average life span of 4 to 5 years. Fatality from respiratory failure is common. Infants who survive often have gradual improvement in motor function, but develop progressive myopathy and may also have cataracts and cardiac problems. Intellectual disability is present in 50% to 60%.

Fetal Akinesia

Definition

Fetal akinesia is a heterogeneous group of disorders unified by the hallmark of reduced or absent fetal movement. Labels given to subsets of this group include fetal akinesia deformation sequence (FADS), fetal hypokinesia sequence, Pena-Shokeir syndrome, arthrogryposis multiplex congenita, and multiple pterygia syndrome.

Incidence

The incidence is unknown; fetal akinesia is rare.

Etiology

The cause of these disorders is heterogeneous and continues to be elucidated. Implicated defects can be located at any point in the motor system, including the brain, spinal cord, peripheral nerves, neuromuscular junction, skeletal muscle, and connective tissue. Fetal movement begins at 8 weeks' gestation; it begins centrally and moves outward and downward, with all limbs moving by 12 weeks' gestation. Fetal movement is crucial for normal development of the joints and contiguous tissues. The earlier the onset of lack of movement starts and the longer it continues the worse the resulting deformations will be.

Genetics

A subset of cases of fetal akinesia have an identifiable genetic mutation (see Table 16-8); many cases do not have a genetic cause identified. Lethal multiple pterygium syndrome has recently been linked to biallelic mutations in *CHRNG*.

Recurrence Risk

Recurrence risk depends on cause and can range from a low recurrence risk to 25%.

Diagnosis

Multiple anomalies are associated with fetal akinesia. They include arthrogryposis, pterygia, subcutaneous edema/fetal hydrops, cleft palate, retromicrognathia, lung hypoplasia, rocker-bottom feet, brain anomalies, short umbilical cord, and polyhydramnios (as a result of decreased fetal swallowing). The diagnosis may be made by sonography as early as 12 weeks' gestation because of fetal edema and abnormal limb positioning.

Differential Diagnosis

The differential diagnosis includes other conditions with multiple congenital contractures, as well as conditions presenting with fetal hydrops (which includes aneuploidy and Turner syndrome in the first trimester).

Prognosis

Most severe cases result in either stillbirth or death at birth or in the newborn period from pulmonary hypoplasia.

Freeman-Sheldon Syndrome

Definition

Freeman-Sheldon syndrome is a distal arthrogryposis syndrome characterized by multiple congenital contractures of both the upper and lower limbs (as well as facial muscles) and is generally considered to be the most severe of the distal arthrogryposis syndromes. Because of facial muscle contractures, the lips appear pursed and a small oral opening is observed. The hands demonstrate camptodactyly with ulnar deviation of the fingers, and clubfeet are present.

Synonyms

Freeman-Sheldon syndrome is also known as distal arthrogryposis type 2A (DA2A) and whistling-face syndrome.

Prevalence

The syndrome is rare.

Etiology

MYH3 encodes for the embryonic myosin heavy chain and the implicated *MHY3* mutations are predicted to interfere with myosin's catalytic activity, suggesting that defective myofiber force prenatally leads to congenital contractures.

Genetics

Freeman-Sheldon syndrome is due to mutations in *MYH3*. Inheritance is autosomal dominant. More than 70% of cases are sporadic. Wide phenotypic variability is seen.

Recurrence Risk

With sporadic mutations, recurrence risk is low. Recurrence risk is 50% with an affected parent.

Diagnosis

The diagnosis is based on clinical features including multiple distal contractures and characteristic facial appearance (small oral opening, hypertelorism, epicanthus, telecanthus, hyplastic nasal alae, low-set ears, "H-shaped" chin dimple). Other anomalies may include scoliosis, rib anomalies, short stature, dental crowding, spinal bidifa occulta, cryptorchidism, and congenital hip dysplasia or dislocation. Prenatally, joint contractures and facial dysmorphism may be appreciated.

Differential Diagnosis

The differential diagnosis includes other distal arthrogryposis syndromes, in particular distal arthrogryposis type 2B. Molecular genetic testing can assist in confirming the diagnosis.

Prognosis

Anesthesia complications are common (including malignant hyperthermia, arrhythmias, and difficulties with intubation and IV access), and multiple surgeries are needed. Feeding difficulties and aspiration are common. Intelligence is normal.

Prader-Willi Syndrome

Definition

Prader-Willi syndrome (PWS) is characterized by severe infantile hypotonia and feeding difficulties. Subsequently, excessive eating in childhood leads to the development of morbid obesity. Other features include developmental delay, cognitive impairment, behavioral issues, hypogonadism, short stature, and characteristic facial features (narrow bifrontal diameter, almond-shaped palpebral fissures, narrow nasal bridge, thin upper lip, downturned mouth).

Synonym

Prader-Labhart-Willi syndrome is another name for the syndrome.

Prevalence

Prevalence is 1 in 10,000 to 30,000.

Etiology

The exact function of the genes within the Prader-Willi critical region are still being investigated.

Genetics

Abnormal imprinting within the paternally derived Prader-Willi critical region (PWCR) on chromosome 15 (15q11.2-q13) can be detected by DNA methylation analysis. Abnormal imprinting can be caused by paternal deletion, maternal uniparental disomy 15, or an imprinting defect. Although DNA methylation can establish the diagnosis, it cannot determine the mechanism; thus, further testing is needed if DNA methylation testing is positive for PWS.

Recurrence Risk

Recurrence risk depends on the mode of abnormal imprinting. Generally, recurrence risk is less than 1% if the prior child had a deletion or uniparental disomy, 50% with an imprinting defect, and 25% with a parental chromosomal translocation.

Diagnosis

Ultrasound examination may reveal polyhydramnios, decreased fetal movements, malpresentation, characteristic craniofacial features, large biparietal diameter, slightly enlarged lateral ventricles, hypoplasia of the corpus callosum, abnormal fetal heart rhythm with prolonged inactive periods and diurnal variation of the incidence of heart rate accelerations, and hypoplastic male external genitalia. Fetal size is generally normal. Other features include strabismus; hypopigmented hair, eyes, and skin; hip dysplasia; and scoliosis.

Differential Diagnosis

The differential diagnosis includes Angelman syndrome, fragile X syndrome, several myopathies and neuropathies, congenital DM1, and *MECP2*-related disorders.

Prognosis

Severe hypotonia with associated feeding difficulties lead to failure to thrive in early infancy; enteral feeds are commonly needed. Global developmental delay is generally seen. Choking is a reported cause of death in up to 8% of affected individuals. Feeding improves by age 1 to 2 years, and hyperphagia becomes more prevalent in early childhood. After age 8, hyperphagia predominates and obesity is common.

Hyperphagia has been linked to a hypothalamic abnormality leading to lack of satiety. Obesity is a major cause of morbidity and fatality.

Management

Guidelines for management have been published (Cassidy SB and colleagues, 2012; McCandless SE, 2011).

FETAL OVERGROWTH

Congenital overgrowth refers to a newborn weight greater than the 97th percentile and is caused by a heterogeneous group of conditions. A subset of these conditions are overgrowth syndromes and include chromosomal disorders as well as the following syndromes: Bannayan-Riley-Ruvalcaba, Beckwith-Wiedemann, Klippel-Trenaunay, megalencephaly-polymicrogyria-polydactyly-hydrocephalus (MPPH), Perlman, Proteus, Simpson-Golabi-Behmel, Sotos, and Weaver syndromes. Of these syndromes, the ones with the most striking degree of prenatal overgrowth are Beckwith-Wiedemann, MPPH, Perlman, Simpson-Golabi-Behmel, and Sotos syndromes. Each of these syndromes is described in further detail in this section.

Bannayan-Riley-Ruvalcaba Syndrome

Definition

Bannayan-Riley-Ruvalcaba syndrome (BRRS) is the most severe disorder in the *PTEN*-related overgrowth spectum. It is characterized by macrocephaly, lipomatosis, intestinal hamartomatous polyposis, and pigmented penile macules. Developmental delay is common. Capillary malformations can be present, but are generally isolated.

Prevalence

The prevalence is unknown, but the syndrome is likely underdiagnosed.

Etiology

Mutations in *PTEN* (a tumor suppressor gene) lead to absent or decreased PTEN protein resulting in uninhibited phosphorylation of AKT1. This results in abnormal cell proliferation.

Genetics

The syndrome is due to mutations in *PTEN*. Inheritance is autosomal dominant.

Recurrence Risk

Recurrence risk is 50% with an affected parent.

Diagnosis

Diagnosis is based on the cardinal features described earlier. Official diagnostic criteria have not been set. Other features can include macrosomia at birth, myopathy of the proximal muscles, joint hyperextensibility, scoliosis, and pectus excavatum.

Differential Diagnosis

The differential diagnosis postnatally includes other hamartoma syndromes and *PTEN*-related disorders (such as Cowden syndrome).

Prognosis

Developmental delay and intellectual disability are common (~50% of individuals).

Beckwith-Wiedemann Syndrome

See "Abdominal Wall Defects." This is the most common overgrowth syndrome.

Klippel-Trenaunay Syndrome

Definition

Klippel-Trenaunay syndrome (KTS) is characterized by congenital vascular malformations (capillary, venous, or lymphatic) and altered growth of bone and soft tissues (hypertrophy [most common] or hypotrophy [less common] of a small or large body part). Capillary malformations can be located anywhere on the body. The other malformations are generally on the extremities and adjacent regions of the trunk. The vascular malformations are often located in the same body site as the growth disturbance.

Synonyms

KTS was previously used synonymously with Klippel-Trenaunay-Weber syndrome and Parkes Weber syndrome. KTS and Parkes Weber syndrome are now considered separate entities, and the use of Klippel-Trenaunay-Weber syndrome is discouraged.

Incidence

Incidence is unknown; the syndrome is rare.

Etiology

Many hypotheses have been proposed, including multifactorial, polygenic, or a mosaic mutation. A mosaic gene mutation is likely the most plausible, as somatic mutations in components of the PI3K-AKT pathway have been identified in other patchy overgrowth syndromes.

Genetics

Genetic factors are unknown; it generally occurs sporadically. It is differentiated from Parkes Weber syndrome by testing for *RASA1* mutations, which are found in Parkes Weber syndrome but not in KTS.

Recurrence Risk

Recurrence risk is thought to be low.

Diagnosis

The diagnosis is based on the clinical features of vascular malformations and disturbed growth of bony and soft tissues. Other common features include limb anomalies (polydactyly, syndactyly), skeletal malformations (scoliosis, hip dislocation, clubfeet), and autonomic dysfunction. Prenatally, asymmetric limb growth may be detected. Other reports of nonimmune hydrops, polyhydramnios, cardiac failure, and ventriculomegaly attributed to KTS may be associated instead with Parkes Weber syndrome.

Differential Diagnosis

The differential includes *PI3KCA*-related segmental overgrowth syndromes (such as CLOVES [congenital, lipomatous overgrowth, vascular malformations, epidermal nevi and scoliosis/skeletal/spinal anomalies]), Parkes Weber syndrome, and Proteus syndrome.

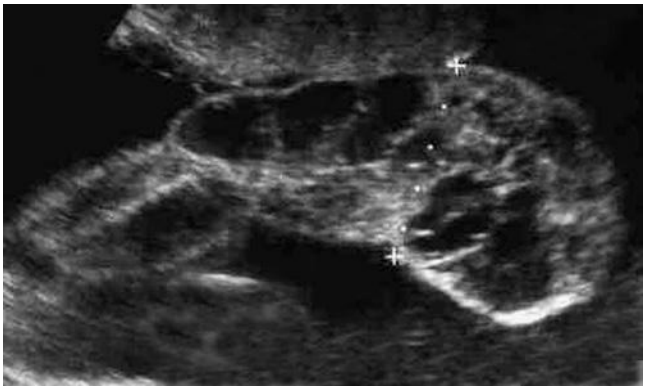

FIG 16-79 Klippel-Trenaunay syndrome. Sonogram of the leg of a fetus at 20 weeks' gestation with marked edema. (Courtesy of Carlos Alberto Mejia Escobar, 2000. Available at thefetus.net.)

Prognosis

Patients with KTS are at risk for superficial thrombophlebitis, deep venous thrombosis, pulmonary embolism, and infection. Leg length discrepancy is common. Procedures to remove excess girth of soft tissues are possible.

Megalencephaly-Polymicrogyria-Polydactyly-Hydrocephalus Syndrome

Definition

MPPH syndrome is characterized by congenital megalencephaly, bilateral perisylvian polymicrogyria, and postaxial polydactyly. It is associated with an increased risk of hydrocephalus.

Prevalence

Prevalence is unknown; the syndrome is only recently recognized.

Etiology

The implicated genes are involved in the PI3K-AKT signaling pathway. Mutations are gain of function and lead to activation of

this pathway, resulting in uncontrolled cellular proliferation and survival.

Genetics

MPPH is due to de novo mutations in *PIK3R2*, *AKT3*, and *CCND2*.

Recurrence Risk

Recurrence risk is thought to be low.

Diagnosis

The diagnosis of MPPH is based on characteristic brain findings including megalencephaly, ventriculomegaly or hydrocephalus, and cortical brain abnormalities (perisylvian polymicrogyria). Postaxial polydactyly is present in a subset of affected individuals.

Differential Diagnosis

Many features overlap with megalencephaly-capillary malformation (MCAP) syndrome, but MPPH syndrome lacks vascular malformations, focal somatic overgrowth, and syndactyly. Additionally, overgrowth in MPPH tends to be symmetric; asymmetric overgrowth can be seen in MCAP. Other conditions to be considered include hemimegalencephaly, Proteus syndrome, and other disorders due to mutations in the PI3K-AKT pathway.

Prognosis

Progressive ventriculomegaly can lead to hydrocephalus, and Chiari malformations may be present. Head size can be as large as 10 SD above the mean. An increased risk of malignancy has been reported (~3%).

Perlman Syndrome

Definition

Perlman syndrome is characterized by prenatal overgrowth, dysmorphic facial features (small upturned nose, small mouth, deep-set eyes, low-set ears, crease over the nasal bridge), visceromegaly, and predisposition to Wilms tumor.

Prevalence

The syndrome is rare.

Etiology

DIS3L2 is important in regulation of mitosis and cell proliferation. The mechanism by which mutations lead to the clinical phenotype of Perlman syndrome is currently under investigation.

Genetics

Perlman syndrome is due to mutations in *DIS3L2*. Inheritance is autosomal recessive.

Recurrence Risk

Recurrence risk is 25% if both parents are mutation carriers.

Diagnosis

Prenatally, polyhydramnios, fetal macrosomia, nephromegaly, and fetal ascites are common. Neonatal findings include macrosomia, nephromegaly, hepatomegaly, hypotonia, abdominal distention, cryptorchidism, and dysmorphic facial features. Nephroblastomatosis and Wilms tumor are common.

Differential Diagnosis

The differential diagnosis includes other overgrowth syndromes, particularly Simpson-Golabi-Behmel and Beckwith-Wiedemann syndromes.

Prognosis

Perlman syndrome has a high mortality rate and occurs both as stillbirths and neonatal deaths; more than 50% of affected individuals die in the neonatal period. Approximately two thirds of survivors develop Wilms tumor. Intellectual disability and developmental delay are common.

Proteus Syndrome

Definition

Proteus syndrome is characterized by progressive, segmental overgrowth of body tissues, most commonly the skeleton, skin, adipose tissue, and CNS. Most overgrowth occurs postnatally.

Prevalence

Proteus syndrome is very rare; approximately 120 cases have been reported.

Etiology

AKT1 encodes for a tyrosine kinase. The particular mutation (p.Glu17Lys) associated with Proteus syndrome leads to constitutive kinase activation, which is thought to lead to the observed clinical features.

Genetics

Proteus syndrome is due to mosaic somatic mutations in *AKT1* (p.Glu17Lys). It is thought that germline *AKT1* mutations would be lethal in early development.

Recurrence Risk

There is no known risk to offspring of an affected individual because the implicated mutation is somatic.

Diagnosis

It is distinct from other overgrowth syndromes because most overgrowth is postnatal and is distorting and progressive. A few individuals (<5%) may have the prenatal finding of hemimegalencephaly. Distortion of the skeletal system is characteristic (for example, leg length discrepancy of up to 20 cm and scoliosis greater than 90 degrees). Cerebriform connective tissue nevi are present in most individuals and are virtually pathognomonic. Other features include adipose dysregulation, vascular malformations, bullous pulmonary degeneration, and overgrowth of other organs (spleen, liver, thymus, gut).

Differential Diagnosis

The differential diagnosis includes PTEN hamartoma tumor syndrome, CLOVES syndrome, hemihyperplasia, and KTS.

Prognosis

The overall prognosis depends on the location and degree of overgrowth, as well as coexistent complications. Overgrowth progresses rapidly in childhood and leads to severe disfigurement. The risk of tumor development is increased (most commonly ovarian cystadenomas, testicular tumors, and meningiomas), as along with pulmonary problems and risk of thrombophilia (deep venous thrombosis and pulmonary embolism).

REFERENCE

Biesecker LG, Sapp JC: Proteus syndrome. In Pagon RA, Adam MP, Ardinger HH, et al, editors: *GeneReviews*, Seattle, 1993–2016, University of Washington.

Simpson-Golabi-Behmel Syndrome

Definition

Simpson-Golabi-Behmel syndrome is characterized by pre- and postnatal overgrowth, a characteristic facial appearance (macrocephaly, coarse facial features, macrostromia, macroglossia, palate anomalies), and intellectual disability. Affected individuals are at high risk for the development of embryonal tumors (~10% of individuals), including Wilms tumor, hepatoblastoma, adrenal neuroblastoma, gonadoblastoma, and hepatocellular carcinoma.

Prevalence

Prevalence is unknown.

Etiology

GPC3 and *GPC4* encode for glypicans, which are important in cell growth and division; the exact mechanisms leading to the clinical features of the syndrome remain unknown.

Genetics

The syndrome is due to mutations in *GPC3* and *GPC4*. Inheritance is X-linked.

Recurrence Risk

With a maternal mutation carrier, there is a 50% chance of transmitting the mutation to each child. Males who inherit the mutation will be affected. Females will be carriers, although they can exhibit clinical features owing to skewed X-inactivation.

Diagnosis

The diagnosis is based on clinical features and a family history suggestive of X-linked inheritance, along with molecular genetic testing. The diagnosis should be considered in the setting of macrosomia, characteristic facial features, and associated congenital anomalies. These anomalies can include CNS anomalies, supernumerary nipples, umbilical hernia, diaphragmatic hernia, congenital heart defects, genitourinary defects, GI anomalies, skeletal anomalies (scoliosis, rib anomalies, fused vertebrae, congenital hip dislocation), and hand anomalies (large hands, postaxial polydactyly). Elevated maternal serum AFP (in the absence of abdominal wall or spine defects) has been reported.

Differential Diagnosis

The differential diagnosis includes other fetal overgrowth syndromes, including BWS, Weaver syndrome, and Perlman syndrome.

Prognosis

The intellectual disability can range from mild to severe. Screening for embryonic tumors is generally recommended. The overall prognosis depends on the other anomalies present. Up to 50% of affected males die in the neonatal period.

Sotos Syndrome

Definition

Sotos syndrome is characterized by pre- and postnatal overgrowth, characteristic facial features, and intellectual disability.

Synonym

Cerebral gigantism is a synonym.

Incidence

Incidence is 1 in 14,000 live births.

Etiology

NSD1 encodes for a histone methyltransferase involved in transcriptional regulation through histone modification and chromatin remodeling. The mechanism by which *NSD1* mutations lead to the clinical features of Sotos syndrome is not currently known.

Genetics

Sotos syndrome is due to mutations in *NSD1*. Inheritance is autosomal dominant. More than 95% of mutations are de novo.

Recurrence Risk

Recurrence risk is low (<1%) if neither parent is a mutation carrier.

Diagnosis

Sotos syndrome should be considered with overgrowth (>2 SD above the mean) with advanced bone age and characteristic facial features. Facial features include malar flushing, frontal bossing, sparse hair in the frontotemporal region, downslanting palpebral fissures, long narrow face (triangular shape), and prominent jaw. These features are most apparent between ages 1 and 6. Other associated features include CNS anomalies (ventriculomegaly, midline defects), congenital heart defects, renal anomalies, scoliosis, seizures, and behavioral problems. Maternal preeclampsia occurs in approximately 15% of pregnancies of children with Sotos syndrome.

Differential Diagnosis

The differential includes other fetal overgrowth syndromes, including BWS, Weaver syndrome, Simpson-Golabi-Behmel syndrome, and Bannayan-Riley-Ruvalcaba syndrome.

Prognosis

Intellectual disability can range from mild to severe. Developmental delay is common and thought to be due to the overgrowth, as well as hypotonia and poor coordination. Tumors occur in approximately 3% of individuals and include hematologic malignancies, neuroblastoma, and sacrococcygeal teratoma.

Weaver Syndrome

Definition

Weaver syndrome is characterized by tall stature, characteristic facial features, and other clinical features (advanced bone age, poor coordination, umbilical hernia, abnormal tone, hoarse cry, camptodactyly of fingers or toes).

Synonym

EZH2-related overgrowth also describes Weaver syndrome.

Prevalence

Prevalence is unknown; the genetics were recently discovered and more mildly affected individuals are likely to remain undiagnosed.

Etiology

EZH2 encodes for a histone methyltransferase involved in regulation of transcription. The mechanisms by which *EZH2* mutations lead to the clinical features of Weaver syndrome are currently unknown.

Genetics

The sundrome is due to mutations in *EZH2*. Inheritance is autosomal dominant. Many mutations are de novo.

Recurrence Risk

Recurrence risk is 50% with an affected parent.

Diagnosis

The diagnosis is based on tall stature (height > 2 SD), characteristic facial appearance (retrognathia, large fleshy ears, "stuck on" appearance of chin with central dimple, hypertelorism, round face and cheeks, broad forehead, and almond-shaped palpebral fissures), and other associated anomalies.

Differential Diagnosis

The differential diagnosis includes other fetal overgrowth syndromes, including Sotos syndrome, BWS, and Simpson-Golabi-Behmel syndrome.

Prognosis

Intellect can range from normal to severe intellectual disability. Malignancies may occur more frequently, in particular neuroblastoma and hematologic malignancies.

REFERENCE

Tatton-Brown K, Rahman N: EZH2-related overgrowth. In Pagon RA, Adam MP, Ardinger HH, et al, editors: *GeneReviews*, Seattle, 1993–2016, University of Washington.

FETAL GROWTH RESTRICTION

Although fetal growth restriction is relatively common, severe early-onset growth restriction should raise concern for an underlying genetic or metabolic disorder. Underlying chromosomal disorders, including aneuploidy, triploidy, and microdeleltion syndromes, should be at the top of the differential diagnosis. Metabolic disorders should also be considered (see later). Many of the single gene disorders discussed in the preceding sections are also associated with growth restriction and should be considered based on other sonographic findings that are present. A few additional syndromes with the hallmark of severe prenatal growth restriction are discussed here, specifically Russell-Silver syndrome (RSS) (characterized by severe growth restriction and normal head circumference) and Seckel syndrome (characterized by growth restriction and severe microcephaly).

Russell-Silver Syndrome

Definition

RSS is characterized by severe fetal growth restriction (with birth weight > −2 SD below the mean), as well as postnatal growth deficiency. Other features include short stature, normal head circumference, clinodactyly of the fifth finger, characteristic facial features (triangular facies with a broad forehead and narrow chin), and asymmetry of the limbs, body, and/or face.

Prevalence

Prevalence is estimated at 1 in 100,000.

Etiology

The mechanisms by which the identified genetic alterations lead to RSS are not yet fully understood.

Genetics

The genetics are heterogeneous, and the disorder most commonly occurs sporadically. Some individuals have hypomethylation of the paternal IC1 on chromosome 11p15.5 (35-50%). Others have uniparental disomy for chromosome 7 (UPD7; 10%).

Recurrence Risk

Recurrence risk is low if RSS in the proband was due to paternal hypomethylation at IC1 or maternal UPD7.

Diagnosis

The diagnosis is difficult to make prenatally because growth restriction may be the main presenting feature, is relatively common, and may not be identified until the third trimester. Postnatally, low birth weight, postnatal growth deficiency, normal head circumference, triangular facies, and asymmetry may assist in the diagnosis. Skin pigmentary changes, genitourinary anomalies, and hypoglycemia are also seen.

Differential Diagnosis

The differential diagnosis includes other disorders leading to intrauterine growth retardation and short stature, specifically chromosomal disorders and disorders of DNA repair (such as FA and Bloom syndrome).

Prognosis

Developmental delay and intellectual disability are common. Early issues with feeding, hypoglycemia, and growth are the most frequent problems. Growth hormone therapy has been shown to improve growth and final height.

REFERENCE

Saal HM: Russell-Silver syndrome. In Pagon RA, Adam MP, Ardinger HH, et al, editors: *GeneReviews*, Seattle, 1993–2016, University of Washington.

Seckel Syndrome

Definition

Seckel syndrome is part of a primary autosomal recessive microcephaly spectrum of disorders characterized by severe microcephaly in the absence of visceral malformations. The microcephaly begins during the second trimester of gestation, is less than −2 SD at birth, and has a slow rate of increase following birth. Fetal growth restriction and slow postnatal growth are seen in Seckel syndrome.

Synonym

Primary autosomal recessive microcephalies and Seckel syndrome spectrum disorders.

Prevalence

Seckel syndrome is rare and was likely previously overdiagnosed. Fewer than 50 definitive cases of Seckel syndrome have been reported. Primary microcephaly has an incidence of 1 in 30,000 to 250,000.

Etiology

Mutations in the implicated genes are thought to lead to general growth failure and brain growth failure resulting in the observed clinical phenotype.

Genetics

Implicated genes in Seckel syndrome include *ATR, NIN,* and *ATRIP*, as well as *RBBP8, CEP152, CENPJ, CEP63,* and *PHC1*. Inheritance is autosomal recessive.

Recurrence Risk

Recurrence risk is 25% if both parents are carriers.

Diagnosis

The diagnosis is based on clinical features, normal brain architecture (with reduced brain volume), and family history suggestive of autosomal recessive inheritance. In addition to severe microcephaly, other findings include brain abnormalities (most commonly reduced brain

volume with normal structure), cognitive impairment, short stature, and craniosynostosis.

Differential Diagnosis

The differential diagnosis includes all causes of primary and secondary microcephaly, including CNS malformations, associated syndromes, chromosomal disorders, and teratogens (such as alcohol).

Prognosis

Intellectual disability is generally moderate to severe in Seckel syndrome. Survival has been reported in individuals older than age 50.

REFERENCE

Verloes A, Drunat S, Gressens P, Passemard S: Primary autosomal recessive microcephalies and seckel syndrome spectrum disorders. In Pagon RA, Adam MP, Ardinger HH, et al, editors: *GeneReviews*, Seattle, 1993–2016, University of Washington.

MICRODELETION SYNDROMES

Deletion 4p (Wolf-Hirschhorn Syndrome)

Definition

Wolf-Hirschhorn syndrome (WHS) is characterized by craniofacial features, including "Greek warrior helmet appearance" of the nose and forehead, microcephaly, hypertelorism, high-arched eyebrows, downturned mouth, micrognathia, and malformed ears with pits/tags. All affected individuals have prenatal growth restriction followed by postnatal growth delay. Other common features include seizures, skeletal anomalies, congenital heart defects, hearing loss, urinary tract anomalies, and CNS anomalies.

Incidence

Incidence is estimated at 1 in 50,000 births, although WHS is likely underdiagnosed. The female-male ratio is 2:1.

Etiology

Deletion of the Wolf-Hisrchhorn syndrome critical region (WHSCR) at 4p16 leads to the phenotype of WHS. Candidate genes in this region potentially responsible for the clinical phenotype are *LEMT1* and *WHSC1*. The exact function of each of these genes is not currently well understood.

Genetics

The syndrome is due to a chromosomal 4p16.3 deletion that includes the WHSCR (between 1.4 to 1.9 Mb from the 4p terminus). This deletion can be detected by chromosomal microarray. As many as 50% to 60% of individuals have an isolated de novo deletion of 4p16, and 40% to 50% have an unbalanced translocation with both 4p deletion and partial trisomy of a different chromosome arm.

Recurrence Risk

Translocations can be de novo or inherited from a parent with a balanced translocation. Recurrence risk depends on the origin of the deletion.

Diagnosis

The prenatal diagnosis is suggested by the presence of severe fetal growth restriction, normal amniotic fluid, midline defects, and craniofacial dysmorphisms. The diagnosis can be confirmed antenatally or postnatally by chromosomal microarray.

Differential Diagnosis

The differential diagnosis includes Seckel syndrome, CHARGE syndrome, SLO syndrome, Opitz G/BBB syndrome, Williams syndrome, Rett syndrome, Angelman syndrome, and Smith-Magenis syndrome.

Prognosis

All individuals have developmental delay and intellectual disability, which can vary in severity. Most patients have multiple seizures. Feeding issues are common.

Deletion 5p (Cri du Chat Syndrome)

Definition

Cri du chat syndrome (CdCS) is characterized by a high-pitched ("cat-like") cry, microcephaly, and facial dysmorphisms (broad nasal bridge, epicanthal folds, micrognathia). Other reported features include cardiac defects, renal anomalies, CNS anomalies, preauricular tags, syndactyly, hypospadias, and cryptorchidism.

Incidence

CdCS is seen in 1 in 1500 to 50,000 live births.

Etiology

Deletion of particular regions of 5p are thought to be responsible for specific aspects of the clinical phenotype. Genes within 5p15 potentially linked to the clinical features include *CTNND2, SEMA5A, TERT, SRD5A1,* and *TPPP*.

Genetics

CdCS is due to deletion on the short arm of chromosome 5 (5p-). The deletion can range in size from 5 to 40 Mb and can include the entire p arm or just the region 5p15. The deletion can be an isolated de novo deletion (80%), the result of a familial translocation (12%), a de novo translocation with deletion of 5p and partial trisomy of another chromosomal arm (3%), or the result of mosaicism (3%) or ring chromosomes (2.4%). Eighty percent of the de novo deletions are paternal in origin.

Recurrence Risk

Recurrence risk depends on the mechanism of the deletion. De novo deletions and de novo translocations are unlikely to recur.

Diagnosis

The diagnosis is based on clinical features and can be confirmed by karyotype or chromosomal microarray. The cat-like cry is thought to be due to anomalies of the larynx and epiglottis. Prenatally, CdCS often remains undetected owing to mild and nonspecific sonographic markers. Cases associated with more significant fetal anomalies are more likely to be detected.

Differential Diagnosis

The differential diagnosis includes other disorders with microcephaly and facial dysmorphisms, in particular other chromosomal disorders. The high-pitched cry is characteristc of CdCS. Chromosomal microarray can aid in confirmation of the diagnosis.

Prognosis

Affected individuals have severe intellectual and developmental delay. Neonatal issues include poor feeding, hypotonia, and cyanosis. Mortality rate is estimated at 10% in the first year of life; after the first year, survival expectation is high.

Deletion 11q (Jacobsen Syndrome)

Definition

Jacobsen syndrome (JS) is characterized by pre- and postnatal growth restriction, characteristic facial features (prominent forehead, trigonocephaly, facial asymmetry, hypertelorism, ptosis, coloboma, downslanting palpebral dissues, epicanthal folds, broad nasal bridge, short nose, V-shaped mouth, small and low-set ears), and abnormal platelet function/thrombocytopenia. Other common anomalies include heart defects, and anomalies of the kidneys, skeletal system, GI tract, genitalia, and CNS.

Incidence

Incidence is estimated at 1 in 100,000 births. Female-male ratio is 2:1.

Etiology

The chromosomal region 11q23 includes 342 genes; the minimal region for the JS phenotype is the 11q24.1 qter, which includes 174 genes. Some of these genes have been linked to clinical features of JS.

Genetics

JS is due to partial deletions in the long arm of chromosome 11. The deletion size ranges from 7 to 20 Mb, extending from 11q23.3 to the telomere. The deletion can be isolated and arise de novo (85% of individuals) or can be due to an unbalanced translocation that is de novo or inherited as the result of a balanced familial translocation. The diagnosis can be confirmed by karyotype or chromosomal microarray.

Recurrence Risk

Recurrence risk depends on the mechanism leading to the deletion. De novo chromosomal translocations are unlikely to recur. Recurrence of isolated terminal 11q deletions has been reported. If a parent is affected with JS, the recurrence risk is 50%.

Diagnosis

The diagnosis is based on the key clinical findings described previously and can be confirmed by genetic testing. The more mild the phenotype, the less likely affected children are to be diagnosed early. The diagnosis is often not made prenatally, and cases detected antenatally tend to be those with more severe congenital malformations. Prenatal diagnosis can be confirmed by chromosomal microarray performed on amniotic fluid or chorionic villi. Smaller deletions may not be appreciated by G-banded karyotypes.

Differential Diagnosis

The differential diagnosis includes other chromosomal disorders, Turner syndrome, Noonan syndrome, and other causes of thrombocypopenia.

Prognosis

Prognosis depends on the associated anomalies. Cardiac defects can be severe, requiring surgery shortly after birth. Vision, hearing, immunologic, and hormonal problems are common. Feeding issues are also frequent. Approximately 20% of affected individuals die during the first 2 years of life. Intellectual disability ranges from mild to severe and is associated with the size of the chromosomal deletion. Life expectancy for survivors is unknown.

Deletion 22q11.2 (DiGeorge Syndrome)

See discussion of DiGeorge syndrome under "Heart."

METABOLIC SYNDROMES

Many metabolic syndromes lack any striking prenatal features. Some present with isolated fetal growth restriction or nonimmune hydrops. A few are associated with multiple, characteristic congenital anomalies and are discussed in this section.

Neu-Laxova Syndrome

Definition

NLS is characterized by fetal growth restriction, microcephaly, characteristic facial features (short eyelids, proptosis, gaping mouth), flexion deformities, and skin abnormalities (ichthyosis, hyperkeratosis). Other features include edema of the hands and feet, limb anomalies, brain malformations, and neural tube defects.

Prevalence

NLS is rare; more than 70 individuals have been reported to date.

Etiology

Several serine-deficiency disorders have been reported and NLS may represent the more severe end of the disease spectrum. High serine levels are necessary during cell proliferation in order to replenish the one-carbon pool required for synthesizing nucleotides and other cellular components. Serine deficiency is thought to lead to the growth issues and malformations seen in NLS.

Genetics

NLS is due to defects in enzymes in the L-serine biosynthesis pathway, including the genes *PHGDH, PSAT1,* and *PSPH.* Inheritance is autosomal recessive.

Recurrence Risk

Recurrence risk is 25% if both parents are mutation carriers.

Diagnosis

Prenatally, growth restriction, microcephaly, facial dysmorphism, joint contractures, skin edema, and CNS anomalies may be seen. Postnatal diagnosis is based on clinical features, a family history suggestive of autosomal recessive inheritance, and confirmation by molecular genetic testing.

Differential Diagnosis

The differential diagnosis includes other disorders with similar features, in particular chromosomal disorders.

Prognosis

NLS leads to death in the prenatal or early postnatal period. Discovery of the implicated metabolic pathway may lead to potential therapies in the future.

Smith-Lemli-Opitz Syndrome

Definition

SLO syndrome was the first genetic syndrome to be identified that had a metabolic cause. It is characterized by pre- and postnatal growth restriction, microcephaly, characteristic facial features (narrow forehead, ptosis, epicanthal folds, short mandible, short nose, anteverted nares, low-set ears), and other congenital anomalies. Common malformations include cleft palate, congenital heart defects, postaxial polydactyly, 2-3 syndactyly of the toes, and genital anomalies. Anomalies in all body systems have been reported (Table 16-9).

Incidence

Incidence is 1 in 20,000 to 40,000 live births.

Etiology

Mutations in *DHCR7* lead to deficiency of the enzyme 7-dehydrocholesterol reductase resulting in defective cholesterol biosynthesis. Cholesterol deficiency during development is thought to lead to the observed clinical phenotype of SLO syndrome.

Genetics

SLO syndrome is due to mutations in *DHCR7*, leading to deficiency of the enzyme 7-dehydrocholesterol reductase and elevated serum concentrations of 7-dehydrocholesterol (7-DHC). Inheritance is autosomal recessive.

Recurrence Risk

Recurrence risk is 25% if both parents are mutation carriers.

TABLE 16-9 Anomalies Associated With Smith-Lemli-Opitz Syndrome

Anatomic Area	Anomaly
Limbs	Syndactyly (of the second and third toes in particular)
	Postaxial polydactyly
	Short limbs
	Clinodactyly
	Dislocated hips
	Valgus deformity
	Radial deviation of the hands
	Ulnar deviation of the fingers
	Rocker-bottom feet
	Abnormal palmar creases
	Digital whorl dermal ridge pattern
CNS/Head	Microcephaly
	Trigonocephaly
	Agenesis of the corpus callosum
	Seizures
	Demyelination of cerebral hemispheres, cranial nerves, and peripheral nerves
	Hydrocephalus
	Cerebral hypoplasia
	Cerebellar hypoplasia
Cardiac	Ventricular septal defect
	Atrial septal defect
	Atriomegaly
	Ventriculomegaly
Genitourinary	Hypospadias
	Cryptorchidism
	Micropenis
	Bifidum scrotum
	Hypoplastic scrotum
	Microurethra
	Ambiguous genitalia
	Prominent clitoral hood
	Redundant labia minora
	Hypoplastic labia
	Rudimentary uterus
	Ureteropelvic junction obstruction
	Renal hypoplasia
	Urethral stenosis
	Cystic renal dysplasia
	Male pseudohermaphroditism

CNS, central nervous system.

Diagnosis

The detection of an extremely reduced concentration of cholesterol and abnormal accumulation of serum 7-DHC can confirm the diagnosis in infants and adults. Prenatally, either biochemical or molecular genetic testing can be performed. Elevated 7-DHC can be found in the amniotic fluid in the second trimester or in chorionic villi in the first trimester; normally, 7-DHC is undetectable in both specimens. Decreased levels of estriol in both the maternal circulation and maternal urine may be decreased, especially in later pregnancy. On prenatal ultrasound images, growth restriction and multiple congenital anomalies may be seen. Increased nuchal translucency, cystic hygroma, and nonimmune hydrops have also been reported.

Differential Diagnosis

The differential diagnosis includes other disorders with growth restriction and multiple congenital anomalies, in particular aneuploidy (trisomies 13, 18, and 12), other chromosomal disorders, Dubowitz syndrome, Meckel-Gruber syndrome, and Noonan syndrome.

Prognosis

Prognosis depends on the severity of the malformations, and the clinical spectrum of phenotypes is wide. Intellectual disability is generally moderate to severe. Feeding issues and failure to thrive are common.

Zellweger Syndrome

Definition

Zellweger syndrome (ZS) is one (and the most severe) of three phenotypes of the peroxisome biogenesis disorders; the others are neonatal adrenoleukodystrophy and infantile Refsum disease. Affected infants present with hypotonia and poor feeding; they are noted to have characteristic facies (flat face, large anterior fontanelle, broad nasal bridge), seizures, and liver cysts with hepatic dysfunction. The long bones may be noted to have distinctive stippling (chondrodysplasia punctata).

Synonym

ZS is also known as cerebrohepatorenal syndrome.

Prevalence

Prevalence is estimated at 1 in 50,000.

Etiology

The implicated *PEX* genes encode for a class of proteins called peroxins that are required for normal peroxisome assembly. Peroxisomes are the site of many anabolic and catabolic pathways, and deficiency in their formation is thought to be responsible for the observed clinical phenotype of ZS.

Genetics

ZS is due to mutations in 1 of 12 *PEX* genes; approximately 68% of individuals have mutations in *PEX1*. Inheritance is autosomal recessive.

Recurrence Risk

Recurrence risk is 25% if both parents are mutation carriers.

Diagnosis

The diagnosis can be determined by biochemical testing. Initial screening is performed with measurement of plasma very long chain fatty acid (VLCFA) levels. Elevated C26:0 and C26:1, as well as increased ratios of C24/C22 and C26/C22, indicate a defect in peroxisomal fatty acid metabolism. Peroxisomal mosaicism can exist with different tissues having disparate biochemical testing results. Molecular genetic testing can assist in confirmation of the diagnosis. Prenatally, growth restriction, decreased fetal movement, and increased nuchal translucency may be noted. Other sonographic features reported include an abnormal head shape, facial dysmorphism, ventriculomegaly, hepatomegaly, and cardiac defects.

Differential Diagnosis

The differential diagnosis includes other disorders with significant hypotonia, including trisomy 21, PWS, congenital DM1, and spinal muscular atrophy.

Prognosis

Most infants with ZS do not progress developmentally and die within the first year. Seizures may be difficult to control. Death is due to apnea, respiratory issues, or secondary to infection.

OTHER MALFORMATIONS

Amniotic Band Sequence

Definition

Amniotic band sequence is a set of congenital malformations ranging from minor constriction rings and lymphedema of the digits to complex, bizarre multiple congenital anomalies that are attributed to amniotic bands that stick, entangle, and disrupt fetal parts.

Synonyms

Historically, diverse nomenclature has been used to describe the anomalies, including amniotic band syndrome, amniotic band disruption complex, and limb body wall complex.

Incidence

Estimates range from 1 in 1200 to 1 in 15,000 live births.

Genetics

In general, amniotic band sequence is not thought to have a genetic cause.

Recurrence Risk

No increased recurrence risk is expected.

Etiology

The cause is not precisely known. Some theories have been suggested including teratogenic, multifactorial, and genetic factors that cause early rupture of the amnion.

Pathogenesis

Rupture of the amnion in early pregnancy leads to entrapment of fetal structures by "sticky" mesodermic bands that originate from the chorionic side of the amnion, followed by disruption. It has been suggested that the bands lead to a decreased blood flow in the constricted limb and subsequent natural amputation. This exogenous mechanistic theory does not explain several features of this syndrome, such as why there are reported cases of amniotic band syndrome with histologically normal and intact amniotic lining; why internal abnormalities such as holoprosencephaly, cerebellar dysplasia, heterotopia, cardiac, and renal abnormalities can be seen; and why monozygotic twins are more often affected than dizygotic twins.

Diagnosis

The syndrome results in structural anomalies that vary from minor to lethal forms. The most common findings are constriction rings around the digits, arms, and legs; swelling of the extremities distal to the point of constriction; amputation of digits, arms, and legs; asymmetric face; facial clefts; cephalocele; anencephaly; acrania; multiple joint contractures; pterygium; clubfeet, clubhands, and pseudosyndactyly; and microphthalmia, uveal coloboma, corneal metaplasia, and unilateral chorioretinal lacunae. A detailed view of the fetus's face, digits, and body with 3D sonography may assist with the diagnosis.

Differential Diagnosis

A uterine synechia or septation can simulate an amniotic band.

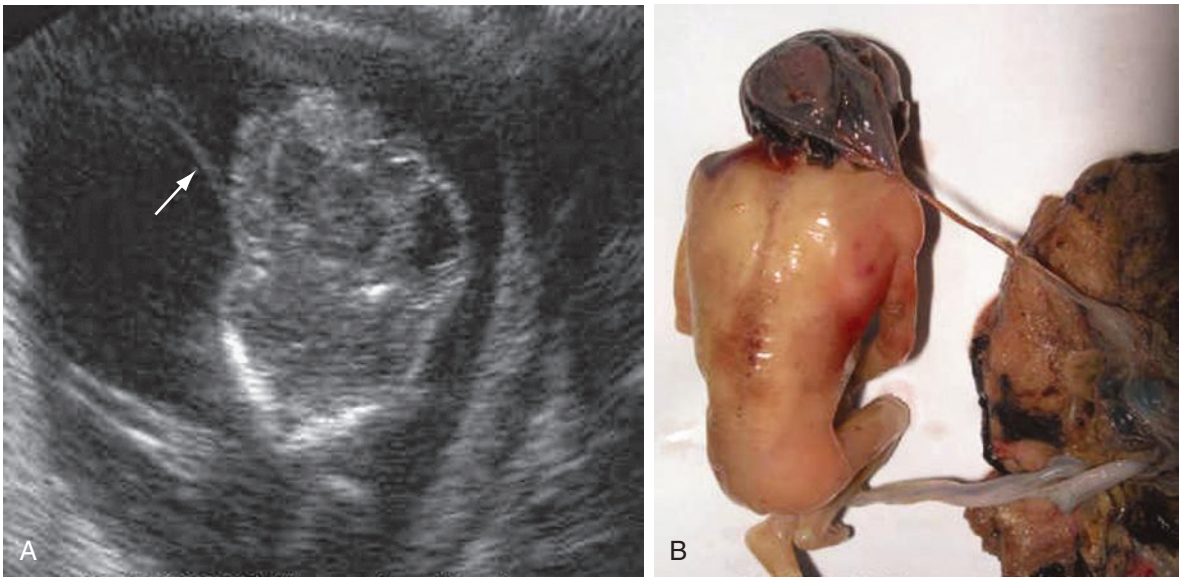

FIG 16-83 A, Amniotic band attached to the fetal head. **B,** Postnatal image showing an amniotic band attached to the skull and the exencephaly. (Courtesy, Vicente Ruiz, 2005. Available at thefetus.net.)

Prognosis

The more severe forms are lethal. Mild manifestations sometimes are found just at birth and do not have an impact on survival.

Management

Management depends on the extent of the anomalies. Endoscopic release has been reported and may prove beneficial in releasing the constriction band in threatened limb amputation, but this procedure remains controversial.

VACTERL Association

Definition

VACTERL is a mnemonic for a nonrandom association of malformations including *v*ertebral anomalies, *a*nal atresia, *c*ardiac anomalies, *t*racheoesophageal fistula or *e*sophageal atresia, *r*enal/urinary anomalies, and *l*imb defect. Patients are considered to have the VACTERL association when three or more organ systems are involved. The associated defects occur with the following frequencies: 50% to 80% tracheoesophageal fistula, 60% to 90% anal atresia, 60% to 80% vertebral anomalies, 40% to 80% cardiac defects, 50% to 80% renal anomalies, and 40% to 50% limb abnormalities.

Incidence

VACTERL is seen in 1 in 10,000 to 40,000 live births.

Etiology

VACTERL is thought to be due to defective mesodermal development of unknown origin.

Genetics

Genetic involvement is unknown; most cases are sporadic.

Recurrence Risk

Recurrence risk is estimated at 1%.

Diagnosis

The diagnosis of VACTERL can be difficult to make prenatally because many of the features can be difficult to determine sonographically. A small stomach in association with polyhydramnios may suggest

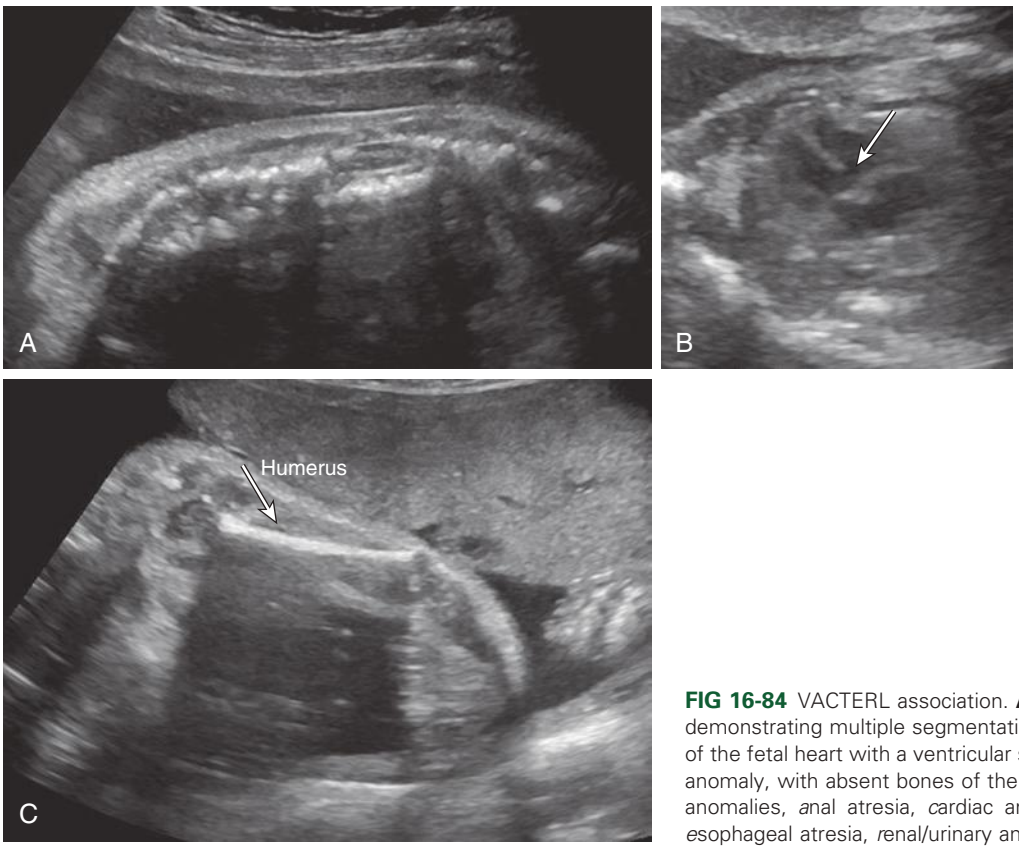

FIG 16-84 VACTERL association. **A,** Longitudinal image of the fetal spine demonstrating multiple segmentation abnormalities; **B,** four-chamber view of the fetal heart with a ventricular septal defect (VSD) (*arrow*); **C,** radial ray anomaly, with absent bones of the forearm and hand. VACTERL, *v*ertebral anomalies, *a*nal atresia, *c*ardiac anomalies, *t*racheoesophageal fistula or *e*sophageal atresia, *r*enal/urinary anomalies, and *l*imb defect.

FIG 16-85 VACTERL association. Sonogram of a fetus with anal atresia and a dilated segment of large intestine. VACTERL, *v*ertebral anomalies, *a*nal atresia, *c*ardiac anomalies, *t*racheoesophageal fistula or *e*sophageal atresia, *r*enal/urinary anomalies, and *l*imb defect.

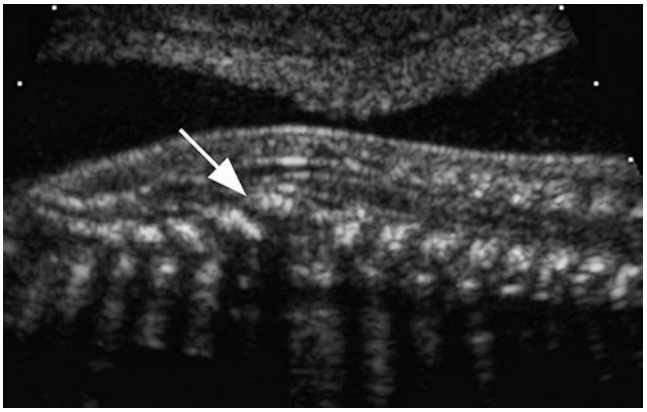

FIG 16-86 Abnormal vertebrae (*arrow*) in association with the previously mentioned findings and a radial abnormality (not shown) should arouse suspicion of VACTERL association. VACTERL, *v*ertebral anomalies, *a*nal atresia, *c*ardiac anomalies, *t*racheoesophageal fistula or *e*sophageal atresia, *r*enal/urinary anomalies, and *l*imb defect.

tracheoesophageal fistula. Vertebral anomalies can be subtle. The constellation of limb defects (particularly radial anomalies), renal anomalies, and cardiac defects should raise suspicion. Seeing as there is not a known genetic cause for VACTERL, it remains a diagnosis of exclusion, and postnatal examination is necessary for comprehensive evaluation.

Differential Diagnosis

The differential diagnosis includes chromosomal disorders, CHARGE syndrome, 22q11 deletion syndrome, Feingold syndrome, Holt-Oram syndrome, Townes-Brockes syndrome, Fanconi anemia, and Pallister-Hall syndrome.

Prognosis

The prognosis depends on the particular association of anomalies. If surgical correction is achieved, the outcome can be positive. Some patients will be affected by their congenital malformations throughout their life. Intellectual ability is generally normal.

Evaluation of Hydrops Fetalis

Hector Mendez-Figueroa, Suneet P. Chauhan

SUMMARY KEY POINTS

- Diagnosis of hydrops fetalis requires two or more of the following sonographic abnormalities: scalp and body wall edema (defined as skin thickness >5 mm), ascites, pleural effusion, pericardial effusion, polyhydramnios, and placental thickening (≥4 cm in the second trimester and ≥6 cm in the third trimester).
- *Immune hydrops* refers to cases in which the underlying condition is due to fetal anemia developing from maternal red blood cell alloimmunization. *Nonimmune hydrops* refers to cases resulting from all other conditions.
- Almost 90% of cases of hydrops are secondary to a nonimmune mechanism.
- For women with a prior history of a fetus or child with alloimmunization, defined as requiring intrauterine transfusion or exchange transfusions after birth, the use of serial maternal titers to identify the fetus at risk is not indicated because these measures are no longer predictive in these circumstances.
- Measurements of the peak systolic velocity (PSV) in the middle cerebral artery (MCA) are highly predictive of fetal anemia and are the preferred method to manage pregnancies at risk for immune hydrops.
- If MCA PSV measurements reach a value greater than 1.5 MoM (multiples of the median), fetal blood sampling via cordocentesis should be performed.
- During fetal transfusions, the blood should be transfused at a rate of 5 to 10 mL/minute, and if feasible, an attempt should be made to reach a final hematocrit of 50% to 65%.
- The most common causes of nonimmune hydrops are cardiovascular conditions, which include arrhythmias, structural abnormalities, and diverse cardiomyopathies.
- A fetal echocardiogram should be part of the initial evaluation of nonimmune hydrops.

OUTLINE

BACKGROUND AND DEFINITION

Hydrops fetalis has been defined as the pathologic accumulation of excessive fluid within two or more fetal compartments. These features can be detected sonographically and include scalp and body wall edema (defined as skin thickness greater than 5 mm),[1] ascites, pleural effusion, pericardial effusion, presence of polyhydramnios (amniotic fluid index greater than 25 cm or maximum verticle pocket greater than 8 cm),[2] and placental thickening (≥4 cm in the second trimester and ≥6 cm in the third trimester)[3,4] (Figs. 17-1 through 17-8).

The use of this term should be limited to cases that meet the criteria outlined here because the diagnosis is associated with a poor prognosis and the workup for the cause may be extensive. The presence of one but not two of these criteria may be secondary to different causes and may also be associated with a better outcome than hydrops fetalis. In certain situations, the finding of a single abnormal fluid accumulation may be a sign of progressive and evolving hydrops fetalis and may warrant more frequent imaging and surveillance.

Based on the cause, the condition should be classified either as immune or nonimmune hydrops. Immune hydrops refers to all cases in which the underlying condition is due to fetal anemia developing from red blood cell (RBC) alloimmunization. The term *nonimmune hydrops* was reserved for the cases that resulted from all other conditions. Immune hydrops was probably first described in 1609 when a French midwife delivered a set of twins: the first one was hydropic and stillborn, whereas the second twin was noted to be severely jaundiced and subsequently died, most likely from kernicterus.[5] This association was then again reported in 1932 when Diamond and colleagues

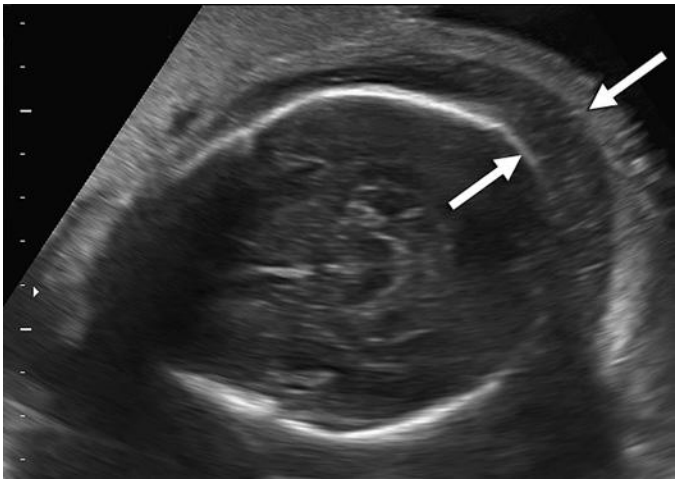

FIG 17-1 Scalp edema noted (between *arrows*) at 32 weeks' gestation. Cause: idiopathic. (Courtesy of Anthony Swartz, BS, RT(R), RDMS.)

FIG 17-2 Cross-sectional view of the fetal thoracic cavity at 19 weeks' gestation. Note pericardial effusion (*arrow*). Also note the cardiomegaly. Cause: maternal RhD alloimmunization and resulting hemolytic disease of the fetus/newborn.

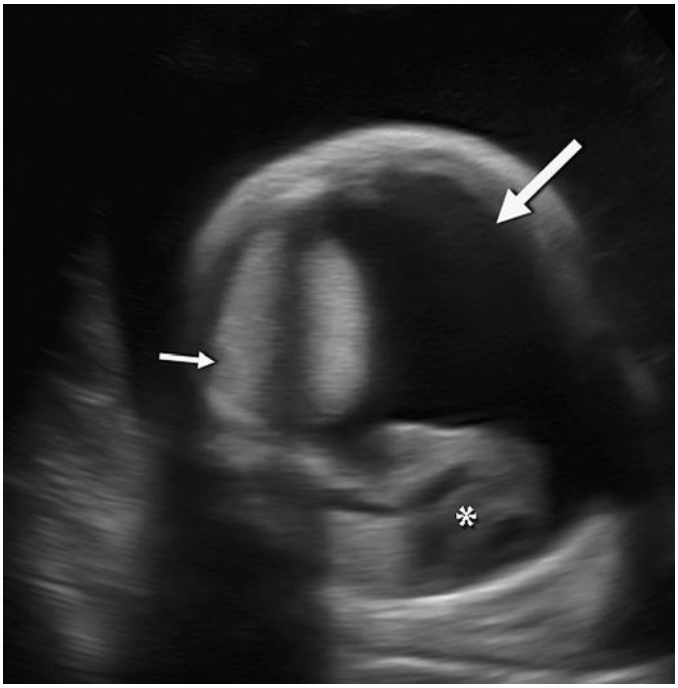

FIG 17-4 Predominantly left-sided pleural effusion (*large arrow*) at 30 weeks' gestation. Fetal heart (*asterisk*) is displaced to the right side of the chest. Large left-sided pulmonary sequestration is noted (*small arrow*). Note extreme polyhydramnios as well. Cause: intrathoracic mass with deviation of mediastinum. (Courtesy of Sharon Pinette, RDMS.)

described a disease characterized by anemia and jaundice that was associated with erythroblastosis and RBC hemolysis.[6] Although the clinical features were described, the cause and pathogenesis were largely unknown. In 1938 Darrow described the concept of an antigen-antibody reaction leading to icterus gravis neonatorum.[7] In 1940, the work by Landsteiner and Weiner led to the discovery of the rhesus (Rh) antigen that was expressed on the surface of RBCs.[8] Later, in 1941 Levine and associates described the pathophysiology of the disease in a case series involving five patients. They observed that Rh-negative women form antibodies to Rh-positive RBCs, and transplacental passage of these antibodies to the fetus can lead to erythroblastosis fetalis.[9]

Prevention of immune hydrops would have to wait decades. William Pollack, working in collaboration with Vincent J. Freda and John G. Gorman, developed a gamma globulin from anti-D serum. This gamma globulin was administered to RhD-negative inmates who then failed to develop anti-D antibodies when exposed to RhD-positive RBCs.[10] At the same time, Finn and colleagues were also investigating the potential prevention of Rh hemolytic disease. They injected radioactive-labeled Rh-positive RBCs into Rh-negative men; they were able to demonstrate that administration of anti-D gamma globulin not only led to Rh-positive cells being coated by antibodies but also to a much more rapid destruction of these cells.[11] Later, Hamilton treated RhD-negative women following their first delivery and showed that this strategy prevented formation of anti-D antibodies in the second pregnancy and led to improved perinatal outcomes.[12] A subsequent multicenter clinical trial directed by Pollack led to the widespread use

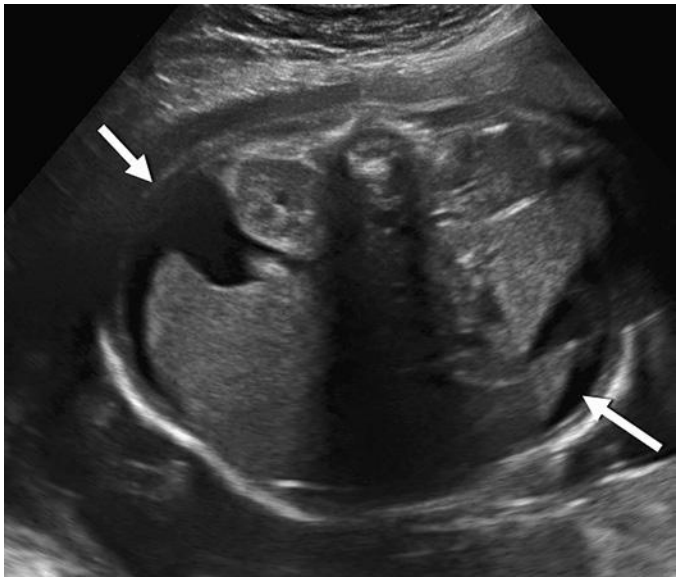

FIG 17-5 Cross-sectional view of the fetal abdomen at 32 weeks' gestation. Note ascites (*arrows*). Cause: fetal cytomegalovirus infection.

FIG 17-6 Cross-sectional view of the fetal abdomen at 19 weeks' gestation. Note ascites (*arrow*). Cause: trisomy 22. (Courtesy of Sharon Pinette, RDMS.)

of anti-D immune globulin in clinical practice.[13] The work by these pioneers helped the development of the current practice guidelines presently used throughout most of the world.

INCIDENCE

The true incidence of hydrops fetalis is difficult to quantify. Many studies differ on the definition of cases included in their series as well as the study population. The reported incidence ranges from 1:424[14] to 1:2000[15] live births admitted to a neonatal intensive care unit

FIG 17-7 Longitudinal section of the fetal abdomen (fetal head on left) at 19 weeks' gestation—same fetus as illustrated in Figure 17-6. Note ascites (*arrow*). Cause: trisomy 22. (Courtesy of Sharon Pinette, RDMS.)

(NICU). The widespread use of anti-D immune globulin has led to a decrease in the overall incidence of immune hydrops over the past few decades. Macafee and coworkers reported that in 1970, 82% of the hydrops cases were secondary to immune hydrops.[16] The incidence of nonimmune hydrops has been reported to range from 1:1500 to 1:3800 births.[17,18] More recent publications have reported a shift in incidence; currently almost 90% of cases of hydrops are secondary to a nonimmune mechanism.[17]

IMMUNE HYDROPS

Mechanism

The pathophysiology of immune hydrops is exemplified by RhD isoimmunization. However, several other RBC antigens have been linked to the development of immune hydrops (Table 17-1). The RhD antigen is one of the most immunogenic antigens expressed on the surface of RBCs[19]; other antigens differ in their ability to cause the disease.

From Moise KJ. Fetal anemia due to non-Rhesus-D red-cell alloimmunization (level III). Semin Fetal Neonatal Med 2008;13:207-214.

Maternal alloimmunization results from the exposure to foreign RhD-positive cells that eventually lead to an immunologic response. The most common cause of this phenomenon is a transplacental passage of fetal cells into maternal circulation, such as during a miscarriage, amniocentesis, trauma, or delivery (Fig. 17-9). Using Kleihauer-Betke stain, as many as 75% of women have some evidence of the presence of fetal RBCs in maternal circulation during pregnancy or delivery.[20]

The risk of fetal-maternal hemorrhage also increases with gestational age: 0.01 mL of fetal blood may be detected in 3% of pregnancies the first trimester and 46% during the third trimester.[20] The probability of alloimmunization is directly proportional to the amount of fetal blood that crosses the placental barrier. It has been estimated that 0.25 mL of fetal blood is the minimum amount required to lead to alloimmunization. For these reasons, delivery poses the greatest risk for Rh sensitization. The proper administration of RhD immune globulin, however, can effectively prevent the formation of maternal antibodies. Transfusion of incompatible blood can also lead to maternal sensitization; this is the most common mechanism explaining alloimmunization from other RBC antigens.

The genetics of the Rh system are complex. The Rh factor is among the largest of the blood groups and contains well over 50 different recognized antigens.[21] Rearrangements in the Rh locus can result in hybrid proteins that can lead to additional antigen expression. Only a small number of these antigens are actually clinically relevant. During pregnancy there are three antigens that can lead to the formation of antibodies and alloimmunization, Rh (D) and Rh (CcEe). These antigens are encoded by two genes located on the short arm of chromosome 1, the RhD and RhCE genes.[22] Each gene contains 10 exons. It has been speculated that through a mechanism involving alternative splicing these two genes could direct the synthesis of different proteins corresponding to different variations in Rh antigens.[23] Fischer and Race have proposed a concept to explain the inheritance of the alleles in the Rh genes.[24] In the majority of patients, three pairs of Rh antigens are inherited from each parent—Cc, Dd, and Ee. An individual can be heterozygous or homozygous for each allele. The Rh-positive or Rh-negative status of a patient is determined by the presence or absence (or possible nonexpression) of the D antigen site. The Rh (CcEe) has fewer alleles and a limited number of mutations reported. The Cc and the Ee alleles are codominant and expressed in a heterozygous fashion. It should also be noted that the symbol "d" simply indicates the absence of D antigen; there is no "d" allele.

The D antigen is a transmembrane protein located on the surface of the erythrocyte that contains several extracellular loops. More than 150 different alleles for the Rh (D) gene have been reported, most likely a byproduct of numerous mutations within the gene.[25] The complete absence of the RhD antigen is called a *negative allele.* The gene frequency varies according to race and ethnicity. Rh-negative individuals are reported in approximately 1% of the Chinese and Japanese populations, whereas the Basque tribe in northern Spain has a reported incidence of approximately 30%.[26] In the patient population of the Americas, the difference among races and various ethnic backgrounds is also noticeable. Caucasians of European descent have an Rh-negative incidence of 15%, whereas Hispanics and African Americans have an incidence closer to 8%. Among several African populations, a variant of Rh (D) gene referred to as the RhD pseudogene (Rh ψ) has also been described.[27] This gene contains all the 10 exons normally found on the Rh (D) gene but has a difference in gene expression due to the presence of a stop codon in the intron between exons 3 and 4. Because of this change, the Rh (D) protein is not synthesized, and the patient is phenotypically Rh (D) negative. This gene is detected in more than 60% of Rh-negative black Africans.[27]

After the first exposure to the D antigen, a weak immunologic response is mounted over 6 weeks to a year. The predominant immunoglobulin produced in this first interaction is immunoglobulin (Ig) M. This large protein does not cross the placenta, and therefore the first pregnancy is usually not affected. However, a second exposure to the antigen can cause B lymphocytes to differentiate into plasma cells and proliferate. This amnestic response in the immune system is characterized by the production of IgG almost entirely; these IgG antibodies can cross the placental barrier. Two IgG subclasses have been shown to be produced during this stage, IgG1 and IgG3.[28] Disease severity appears to be lower in cases in which IgG1 is almost exclusively present.

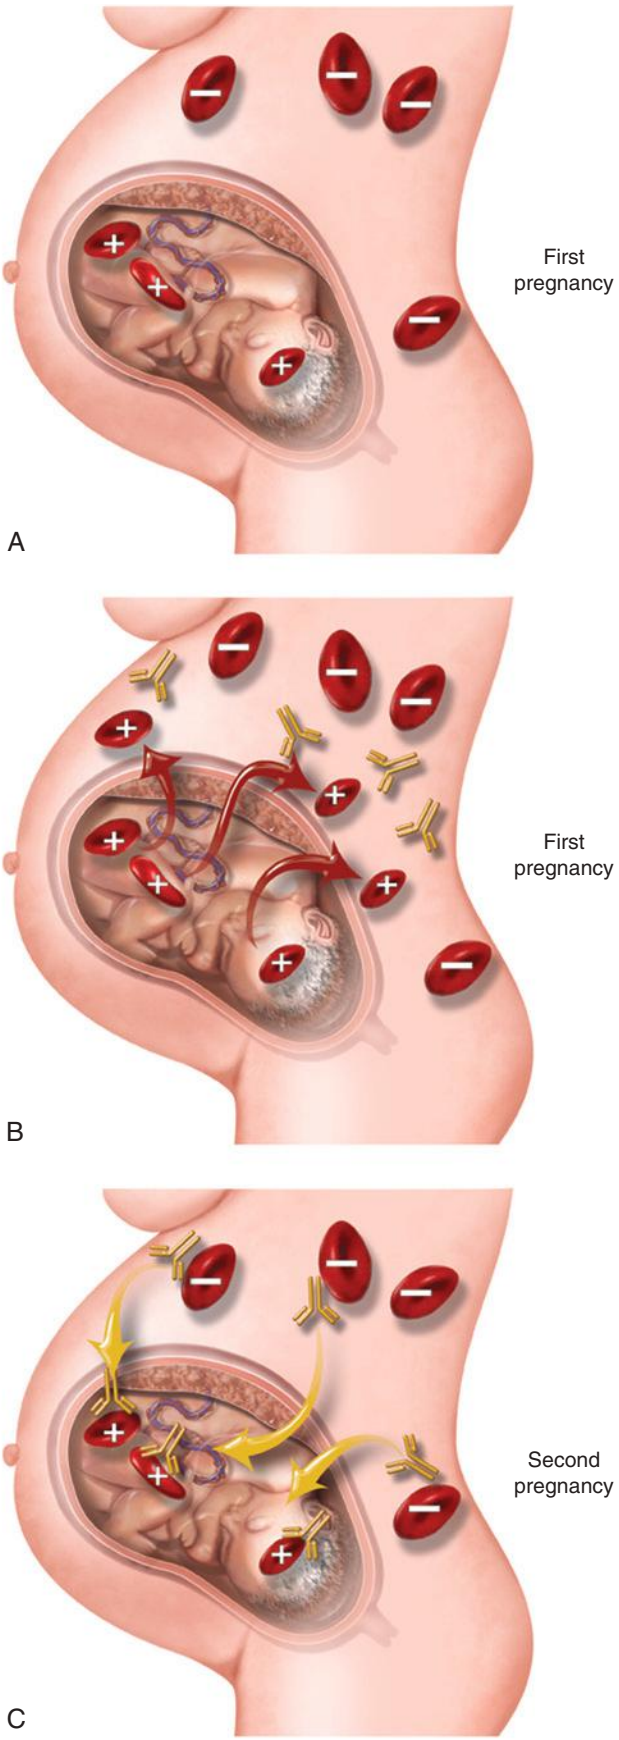

FIG 17-9 **A,** Initial pregnancy in which the mother is Rh negative and is carrying a fetus that is Rh positive. **B,** At the time of delivery, the fetal Rh-positive red blood cells enter the maternal circulation and initiate an antibody response. **C,** In a subsequent pregnancy, antibodies enter the fetal circulation, attaching to the red blood cells and resulting in the sequestration and destruction of these cells. (Illustration by James A. Cooper, MD, San Diego, CA.)

Fetal erythropoiesis begins in the yolk sac by day 21. The Rh antigen can be expressed as early as day 30 of gestation. After the second exposure, there is an increase in the production of IgG antibodies leading to an increase in maternal titers. These antibodies recognize and attach to the foreign antigen on the fetal RBC surface. The IgG antibody lacks the ability to bind complement, and therefore, the antibody-coated fetal RBCs are sequestered by macrophages and are destroyed by the reticuloendothelial system extravascularly. This chain of events leads to the development of fetal anemia.

As the life span of the fetal RBC is reduced, a greater burden is placed on the hematopoietic system. It has been proposed that medullary hematopoiesis is stimulated in the early stages of mild anemia and that recruitment of extramedullary sites occurs only after anemia has progressed and become severe. This is evidenced by the fact that in severe disease, both the liver and the spleen become enlarged because of congestion and increased extramedullary hematopoiesis, causing the release of nucleated RBC precursors (erythroblasts). In a study evaluating umbilical cord samples from 127 pregnancies, Nicolaides and associates showed that significant erythroblastosis was present only when the hemoglobin deficit was greater than 7 g/dL[29] (Fig. 17-10). Severe anemia can lead to decreased oxygen delivery and hypoxia in certain end organs, causing cardiac output to increase as a compensatory mechanism. However, these mechanisms may be inadequate to maintain adequate perfusion. The loss of the buffer function of fetal RBCs also contributes to worsening acid-base disturbances. Soothill and colleagues reported an increase in the lactate concentration in the umbilical artery when hemoglobin levels were below 8 g/dL and an increase in umbilical vein concentration when this level

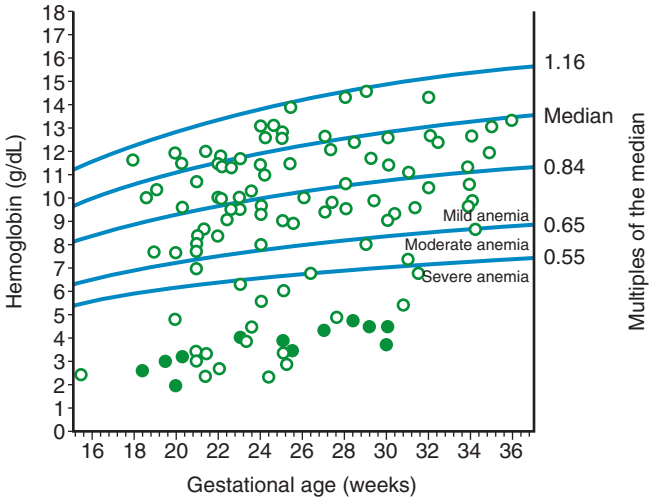

FIG 17-10 Relationship between fetal hemoglobin and gestational age. (From Mari G, Deter RL, Carpenter RL, et al: Noninvasive diagnosis by Doppler ultrasonography of fetal anemia due to maternal red-cell alloimmunization. Collaborative Group for Doppler Assessment of the Blood Velocity in Anemic Fetuses (Level II-1). N Engl J Med 342:9-14, 2000; used with permission.)

dropped to 4 g/dL.[30] This finding implies that disease progression leads to a shift in cellular metabolism to a predominantly anaerobic state.

The exact mechanism leading to fetal hydrops is incompletely understood. It is well known that anemia must be severe before hydrops develops and that fetal hemoglobin must fall below six standard deviations from the mean for that gestational age.[29] Initial studies indicated that low fetal albumin levels leading to decreased colloid pressure and increased extravasation could be a contributing factor leading to hydrops.[31,32] However, more recent studies have shown that hypoalbuminemia is found in only a small percentage of fetuses with hydrops[33] and that drops in albumin levels appear to be a component of the very late stages of the disease.[34] Other factors may also lead to increased vascular permeability facilitating the development of hydrops. Berger and coworkers demonstrated that concentration of ferritin and lipid-peroxidation products were increased, leading to the suggestion that iron overload and free radical damage may contribute to the pathogenesis.[35] Cardiac dysfunction is also common among fetuses affected by severe anemia and could possibly play a role in the disease process. Affected fetuses develop an increase in both biventricular cardiac diameter and umbilical venous pressure.[36,37] The increase in venous pressure may potentially lead to increased fluid extravasation, favoring the development of hydrops. The increase in venous pressure could also lead to an obstruction of lymphatic flow. Interestingly enough, it has also been shown that umbilical venous pressure decreases as early as 24 hours following therapeutic fetal intravascular transfusion.[38]

Management

Severe fetal anemia that eventually leads to hydrops has direct implications for both fetal survival and long-term neonatal and infant outcomes. Cases of fetal anemia characterized by severe hydrops have a 74% survival rate compared to a 94% survival rate seen in nonhydrops cases.[39] In a longitudinal study evaluating the long-term neurologic outcomes following intrauterine transfusion for RBC alloimmunization, over 95% of the 291 children followed were found to have normal developmental outcomes. However, a history of hydrops was found to be a significant risk factor for neurodevelopmental impairment.[40]

Prevention is the key to management of alloimmunization. This starts at the first prenatal visit; a detailed history should be obtained from all patients. Specifics and details on past obstetric events as well as any previous transfusion of blood products are crucial to determining patients who may be at risk. Initial laboratory workup should include ABO typing with determination of RhD status as well as an antibody screen via a maternal indirect Coombs test. If a patient is found to be RhD negative, it should be determined if she is a candidate for prophylactic Rh immunoglobulin. If the antibody screen is positive, the blood bank should report the identity and the titer of the antibody. Titer levels are used to assess the likelihood of risk that the fetus may become affected. Antibodies that have been associated with hemolytic disease of the newborn are listed in Table 17-1.

A repeat antibody screen for RhD should be done at 24 to 28 weeks. If this screen is negative, the patient is a candidate for anti-D prophylaxis via passive immunoglobulin administration. Although the exact mechanism of action is unknown, this strategy has been shown to be effective. In the United States, it is recommended that a single dose of 300 μg of anti-D immunoglobulin be administered at 28 weeks' gestation.[41] Immune prophylaxis probably works through the antigen clearance hypothesis. In this scenario, the administered immunoglobulin attaches to the RBCs. This interaction favors the removal of the coated cells by the mononuclear phagocytic system, particularly the macrophages, therefore not allowing these antigens to be recognized by the immune system.[42] However, recent studies using several different animal models have shown that this hypothesis does not explain the entire mechanism of action. Other antigen-presenting cells, capable of initiating an immune response, also play a role in the clearance of D-positive RBCs.[43]

After the administration of the immune prophylaxis at 28 weeks' gestation, some experts recommend that a second dose of 300 μg be administered if the woman has not delivered within 12 weeks of her dose.[44] One prophylactic dose of 300 μg of anti-D immunoglobulin is enough to prevent exposure produced by 30 mL of RhD-positive blood or 15 mL of fetal cells.[45] Current guidelines dictate that if an RhD-negative woman delivers an RhD-positive infant, she should have a quantitative test (i.e., Kleihauer-Betke stain) done to determine the exact amount of anti-D immune globulin to be administered. The result of this test is typically multiplied by a factor of 50 to determine the total amount of fetomaternal hemorrhage. The dose should be administered within 72 hours of delivery, although this strategy has been shown to be effective up to 28 days after delivery.[44] Also, women at risk for RhD alloimmunization should also receive a dose of prophylactic immunoglobulin after any obstetric event or procedure that puts her at risk for maternal-fetal hemorrhage.

Women who have been sensitized against RhD should have maternal antibody titer levels repeated every 4 weeks during the first and second trimesters and every 2 weeks during the third trimester in order to determine the risk of developing hemolytic disease. Maternal-fetal ABO incompatibility may be protective and decreases the risk of D alloimmunization.[21] If a fetus is both RhD positive and ABO incompatible with the mother, this reduces the risk of alloimmunization to about 2%. Variations in the techniques used to determine the antibody level have led to the use of different thresholds to determine when a fetus is at risk for developing anemia. The titer value that is determined to be critical varies from 1:8 to 1:32. Clinicians should be familiar with the reference value used within their facilities.

Paternal testing can also be used to determine the risk of developing fetal anemia. RhD-positive fathers have a probability of being heterozygous. In the past, mathematical modeling along with ethnicity was used to determine the probability of heterozygosity. Advances in genetic testing have now allowed for the direct determination of paternal zygosity. If paternity is assured, this test can be used in the management algorithm of an RhD-negative woman. If the father is found to be heterozygous, the fetus has a 50% chance of being RhD negative. If the father is RhD negative, the fetus will likewise be RhD negative and therefore will not be at risk.

It has been estimated that 40% of RhD-negative women carry an RhD-negative fetus. For this reason, some have advocated for a more direct approach attempting to eliminate excessive testing and anxiety. Direct assessment of fetal blood type can be done via invasive prenatal testing. Amniocentesis can allow for the determination of the fetal genotype.[46] Because genotype may not correlate with the RBC antigen expression in some rare instances, direct fetal blood sampling can also be used to determine the fetal phenotype. However, this technique is associated with a higher complication rate and a greater risk of fetal demise as compared to amniocentesis. Recently, newer noninvasive methods to determine fetal genotype have become available. As early as 1997, it was recognized that cell-free fetal DNA could be detected in the maternal circulation,[47] with reports indicating that it was present in detectable quantities as early as 38 days' gestation.[48] Throughout the years, several companies developed different techniques to identify different loci on the fetal RhD gene. This test became commercially available in Europe and North America. Reports from several European centers specializing in the treatment of RhD disease started to emerge indicating the high accuracy of this test.[49,50] A meta-analysis looking at over 30 articles concluded that the overall accuracy of this test was around 94% with a sensitivity of 95.4% and a specificity of

98.6%.[51] Several European countries, with different patient populations and insurance payment plans, have started to adopt noninvasive RhD testing as part of the management protocol of women at risk for RhD alloimmunization with success.[52] More worldwide widespread use was limited by the concerns of the lack of data regarding cost analysis. A recent cost analysis done in the United States by Hawk and associates concluded that with the current cost of RhD typing, routine antenatal anti-D immunoglobulin prophylaxis was still less costly.[53] It is possible that with more automated techniques and increased competition driven by higher demand, the cost of testing may decrease, leading to the expansion of the acceptance of this test as part of the RhD alloimmunization management protocol. However, some have raised concern that, because cell-free DNA screening does not detect 100% of RhD-positive fetuses, routine use of cell-free DNA to target RhD immune globulin for RhD-negative women would cause increased sensitization compared with routine RhD immune globulin administration. Assays for detecting RhCc, RhE, and Kell typing via cell-free fetal DNA are also currently available.[54]

Prediction of Anemia

Once a patient has been sensitized, there is a risk for fetal anemia. Several invasive techniques allow for the direct evaluation of fetal hemoglobin and hematocrit. Normally, fetal hemoglobin concentration increases with advancing gestation, and reference ranges for fetal hemoglobin have been established using fetal blood sampling (Table 17-2). Cordocentesis can accurately detect fetal anemia; however, this technique carries with it a risk of pregnancy loss and fetal demise reported to range from 0.9% to 3.2%.[55] Historically, another method used in the prediction of fetal anemia was through amniocentesis. Levels of bilirubin within the amniotic fluid were measured using the ΔOD_{450} assay to predict hemolysis. The values obtained would be later plotted against published nomograms to determine the risk of severe fetal anemia[56,57] This approach had the downside that in many cases serial amniotic fluid samplings were required to assess the severity and progression of the disease. These two procedures have been relegated to the past by the widespread use of sonographic Doppler evaluation of the middle cerebral artery (MCA).[58]

Advances in ultrasound technology have led to this technique now being the preferred method of prediction of fetal anemia. As mild to moderate anemia develops, the fetus responds with several compensatory mechanisms. The increased demand is thought to lead to increased ventricular output and stroke volume. These changes, along with a decrease in fetal blood viscosity secondary to the loss of RBCs, lead to an increase in flow velocity. Several fetal vessels were interrogated in an attempt to identify an easily accessible window for evaluation of blood flow. Measurements of the peak systolic velocity (PSV) in the MCA have been found to be highly predictive of severe fetal anemia. This vessel has the benefit of being easily identifiable with low intraobserver and interobserver variability. Because this measurement varies across gestational ages, the Collaborative Group for Doppler Assessment of the Blood Velocity in Anemic Fetuses has developed a reference in which the PSV measurement obtained is converted to multiples of the median (MoM) and used to predict the probability of fetal anemia (Table 17-3).[59] Using a hemoglobin concentration of 5 g/dL as a threshold, a cutoff of 1.5 MoM has been found to be highly predictive of severe fetal anemia requiring therapy in RBC alloimmunization affected pregnancies (Figs. 17-10 and 17-11). This approach led to a false positive rate of approximately 12%. Later studies comparing the accuracy of this measurement to serial amniocentesis determined that this sonographic measurement has a better sensitivity and specificity.[60] With the increasing experience and standardization in obtaining this measurement as well as the improvement in ultrasound

TABLE 17-2 Reference Ranges for Fetal Hemoglobin Concentration as a Function of Gestational Age

	HEMOGLOBIN CONCENTRATION (g/dL)			
Gestational Age (weeks)	1.0 MoM (Median)	0.55 MoM	0.65 MoM	0.84 MoM
18	10.6	5.8	6.9	8.9
19	10.9	6.0	7.1	9.1
20	11.1	6.1	7.2	9.3

technology, measurement of PSV in the MCA has become the surveillance modality of choice in alloimmunized pregnancies.

The MCA can be easily identified at the base of fetal skull. Color Doppler is utilized to identify the entire circle of Willis (Figs. 17-12 and 17-13). The examiner should interrogate the MCA closest to the transducer. If this is not possible, evaluation of the MCA in the far field may provide reliable results.[61] The 1- to 2-mm Doppler gate should then be placed just distal to the origin of the MCA from the carotid siphon. The ultrasound probe should be manipulated so a 0-degree angle of insonation is obtained. One approach to help achieve this angle is to start by obtaining the view for a biparietal diameter measurement. The probe should then be angled slightly toward the fetal skull and moved sideways in order to "tilt" the fetal head on the ultrasound screen. This will allow the MCA to be viewed in an almost completely vertical position. Angle correction can sometimes be used if the 0-degree angle insonation cannot be obtained effectively,[62] although this approach is not preferred. Several measurements of the MCA PSV should be obtained, as these can be distorted by fetal movement or breathing. All measurements should have similar values to one another. The best measurement obtained should be used; the values obtained should not be averaged.

MCA PSV can be obtained as early as 16 to 18 weeks' gestation. A multicenter prospective trial has shown that this measurement has a high false positive rate when measured after 35 weeks' gestational age.[63] Measurements should be repeated every 1 to 2 weeks depending on the clinical presentation. If MCA PSV measurements reach a value greater

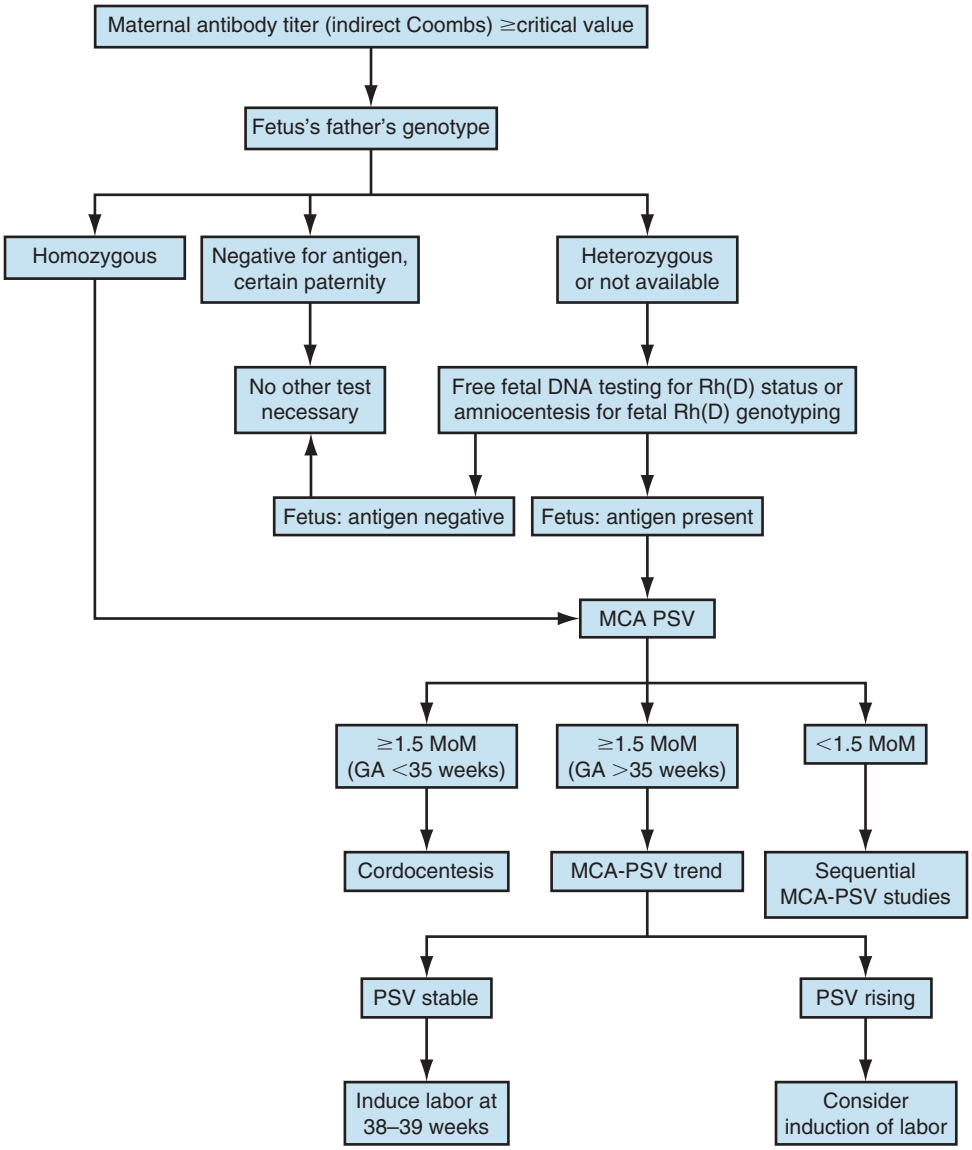

FIG 17-14 Algorithm for the clinical management of the red blood cell alloimmunized pregnancy. GA, gestational age; MCA, middle cerebral artery; MoM, multiples of the median; PSV, peak systolic velocity. (Modified from Moise KJ Jr, Argoti PS: Management and prevention of red cell alloimmunization in pregnancy: a systematic review (level I). Obstet Gynecol 120:1132-1139, 2012.)

than 1.5 MoM, fetal blood sampling via cordocentesis should be performed. Should the fetal hematocrit be found to be below 30%, intrauterine transfusion is indicated. Many experts recommend that if the serial evaluation of MCA PSV remains below the established threshold, monitoring should be continued, with a plan for induction of labor at 37 to 38 weeks. Delivery is also warranted if there is any evidence of fetal compromise. Antenatal testing via nonstress test or biophysical profile should also be instituted starting at 32 weeks' gestation.

Elevated MCA PSV after 35 weeks represents a therapeutic challenge. In the past, some investigators advocated performing amniocentesis to obtain both levels of bilirubin within the amniotic fluid measured using the ΔOD_{450} assay as well as testing fetal lung maturity. However, the lack of familiarity with performing fetal lung maturity assays within several referral centers added to the fact that there has been a move toward abandonment of fetal lung maturity testing in well-dated pregnancies[64] has led to the abandonment of the practice of amniocentesis beyond 35 weeks for this indication.

For women with a prior history of an affected fetus or child, defined as a fetus requiring intrauterine transfusion or exchange transfusions after birth, the use of serial maternal titers is no longer indicated because they are no longer predictive after an affected pregnancy. Fetal RhD status can be established; if the fetus is RhD positive, monitoring with serial MCA Doppler tests should commence around 16 to 18 weeks. Figure 17-14 summarize a proposed protocol for evaluation and management of affected pregnancies.

Intrauterine Transfusion

Access into the fetal circulation is obtained under ultrasound guidance using a 22-G needle. Venous access is the goal; inadvertent arterial puncture can be associated with vasospasm, bradycardia, and sudden death. If the placenta is anterior, direct puncture at the site of cord insertion may be possible (Fig. 17-15). A free loop of cord or the intrahepatic portion of the umbilical vein can also be used. After gaining access, a sample of fetal blood should be sent for analysis of

FIG 17-15 Packed red blood cells seen streaming in the fetal umbilical vein (*arrow*) at the time of an intravascular transfusion at 26 weeks' gestation. The cord insertion into the anterior placenta is located at the asterisk.

fetal ABO and Rh type, direct Coombs test, and complete blood count including platelets, reticulocyte count, and total bilirubin level. To decrease fetal movements during the procedure, an intravenous dose of a paralytic agent such as pancuronium at a dose of 0.2 mg/kg using the estimated fetal weight may be administered.[65,66] Although several centers include the use of furosemide within their treatment protocol, this strategy has not been shown to be beneficial.[67]

Transfused blood should be compatible with both mother and fetus. With a first transfusion, when the fetal blood type is not known, O negative blood is used. Typically, the hematocrit of the unit of blood used is increased to 70% to 80% to reduce the volume of transfused blood to the fetus. The unit should also be tested for cytomegalovirus; hepatitis A, B, and C; and human immunodeficiency virus (HIV) and should also be leukocyte depleted in order to decrease the risk of viral transmission and graft-versus-host disease. Several methods have been proposed to calculate the amount of blood to transfuse. One of simplest methods has been described by Giannina and colleagues.[68] Once the starting hematocrit is known, the estimated fetal weight determined sonographically in grams is multiplied by a fixed coefficient to determine the amount of blood in milliliters required to reach the target fetal hematocrit. A coefficient of 0.02 is used to increase the hematocrit by 10%, and for every 5% above this value the coefficient is increased by 0.01 (i.e., 0.04 to increase by 20%). If, for example, the starting hematocrit is 15% and the estimated fetal weight is 1000 g, then 50 mL of blood would need to be transfused to reach a target hematocrit of 40% (increase by 25% using a coefficient of 0.05) (Tables 17-4 through 17-7).

The ultimate goal of fetal transfusions is not only to correct anemia but also to suppress fetal erythropoiesis. The blood should be transfused at a rate of 5 to 10 mL/minute. Most referral centers attempt to reach a final hematocrit of 50% to 65%. One exception to this rule is the hydropic fetus. A fetus with hydrops is not able to tolerate severe volume overload, and for this reason the hematocrit should not be increased greater than fourfold.[69] A repeat procedure can be done 48 hours later to achieve the target hematocrit.

TABLE 17-4 Method for Calculating Volume for Fetal Transfusion Using Transfusion Coefficient

Desired Increment in Hematocrit (%)	Transfusion Coefficient
10	0.02
15	0.03
20	0.04
25	0.05
30	0.06

Estimated fetal weight (g) × transfusion coefficient = volume to transfuse.

Modified from Moise KJ, Whitecar PW: Antenatal therapy for hemolytic disease. In Hadley A, Soothill P (eds): Alloimmune Disorders of Pregnancy. Anemia, Thrombocytopenia and Neutropenia in the Fetus and Newborn. Cambridge, UK, Cambridge University Press, 2002.

From Plecas DV, Chitkara U, Berkowitz GS, et al: Intrauterine intravascular transfusion for severe erythroblastosis fetalis: how much to transfuse (level II-3)? Obstet Gynecol 1990;75:965-969.

Prior to the use of intravenous transfusion (IVT), intraperitoneal transfusions were advocated as a method of administering blood to the anemic fetus. With advances in real-time ultrasound technology and the increased experience with intravenous access to the fetal circulation, the use of peritoneal transfusion has fallen into disfavor. One approach that has been advocated has been the use of combined intravenous and intraperitoneal transfusion. This method is used within certain centers to allow an increase in the interval between scheduled

TABLE 17-6 Predicted Volume of Packed Red Blood Cells Required for Desired Level of Hematocrit Increase According to Gestational Age

Gestational Age (weeks)	LEVEL OF DESIRED INCREASE IN HEMATOCRIT				
	10%	15%	20%	25%	30%
21	13.1	14.2	15.2	16.3	17.3

fetal transfusions, because it is known that the fetal hematocrit declines approximately 1% per day.[70] This approach allows for a more stable fetal hematocrit between transfusions.[71] Although the decline in fetal hematocrit is more rapid between the first few transfusions, on average a 14-day interval should be used between IVTs. This schedule can be safely continued until around 35 weeks, with a plan for delivery 2 to 3 weeks later. The need for exchange transfusion postnatally has been reported to be decreased with the administration of oral phenobarbital 30 mg three times a day to enhance liver maturation.[72]

Patients who develop severe Rh alloimmunization prior to 20 weeks' gestation may not always be treated with IVT. The small size of the fetal vessels makes this strategy technically difficult. Intraperitoneal transfusion can sometimes be employed, although there is no formula available to calculate the amount of blood to transfuse. The use of suppressive therapy has also been presented as an option for treatment in these patients. Maternal administration of intravenous immunoglobulin (IVIG) has been used in some cases. It is thought that this strategy works by inhibiting the maternal antibody synthesis and by blocking the transport of antibodies transplacentally. Some studies have demonstrated that this strategy, followed by IVT, led to improved survival rate as compared to IVT alone.[73] A case series of patients followed in Sweden showed that this strategy, along with maternal plasma exchange, may be beneficial when used prior to the development of severe fetal anemia.[74] The high cost of this therapy and the limited data should be considered when deciding which treatment modality to employ.

Prognosis

With the advent of fetal transfusion and the improvements in the NICU, the prognosis of immune hydrops has improved. Because one of the goals of intrauterine transfusions is to suppress hematopoiesis, neonates born after receiving this therapy have suppressed bone marrow function and a decrease in the reticulocyte production. Several of these newborns may require transfusions after birth, commonly referred to as "top-up" transfusions.

A retrospective review of 208 women who were treated with over 590 transfusions demonstrated that this strategy was associated with an overall survival rate of 86%. The diagnosis of hydrops as well as the need for transfusions prior to 20 weeks' gestation was associated with a lower survival rate. The overall fetal loss rate attributed to the procedure was calculated to be 4.8%.[75] Short-term neonatal outcomes were also reviewed in a study from Scotland that evaluated 116 pregnant women who underwent 457 intrauterine fetal transfusions over a 10-year period. The survival rate quoted in this cohort was 97.4%. After delivery, 33% of neonates required respiratory assistance, 16% had an exchange transfusion, and 54% required a top-up transfusion. The authors quoted a procedure-related loss rate that ranged from 0.8% to 2.3%.[76]

Neurodevelopmental outcomes were evaluated in the LOTUS (long-term neurodevelopmental outcome after intrauterine transfusion for hemolytic disease of the fetus/newborn) study that assessed 291 children followed to median age of 8.2 years. The authors reported a high rate of intact survival, with only 2.1% of the cohort being diagnosed with cerebral palsy. The development of hydrops fetalis was a major risk factor associated with adverse neurodevelopmental outcomes.[40]

NONIMMUNE HYDROPS

Nonimmune hydrops fetalis (NIHF) is a heterogeneous condition that may be secondary to multiple causes. Several publications have identified over 100 different conditions that are associated with NIHF; some associations between NIHF and certain pathologic conditions are limited to case reports or small case series. Table 17-8 lists the conditions associated with NIHF that have been reported. It has been reported that up to 60% of cases detected prenatally can have a cause specifically identified[77]; this number increases to 85% when postnatal evaluation is taken into consideration.[78] However, a significant percentage of cases will still not have an identifiable cause. Most reports indicate that cardiovascular causes, which include arrhythmias, structural abnormalities, and diverse cardiomyopathies, are the most common conditions leading to NIHF. Up to 16% of all cases can be explained by a chromosomal cause, whereas hematologic abnormalities contribute to approximately 4% to 12% of NIHF cases.[78,79]

Mechanism

Owing to the variety of causes, determining the exact mechanism(s) of development of NIHF is challenging. The precise pathophysiologic pathway will depend on the underlying cause, but in some cases this remains unclear. It appears that the underlying process in several conditions can be explained by a dysregulation of fluid movement between the vascular and interstitial spaces, caused by either an increase in interstitial fluid production or a decrease in lymphatic return.[80] Examples of these conditions include structural heart defects leading to an increased right cardiac pressure causing increased central venous pressure; an obstruction of venous or arterial blood flow such as the one caused by obstructive chest masses; inadequate diastolic ventricular filling as seen in fetal arrhythmias; fetal hepatic fibrosis leading to decreased liver function and hypoalbuminemia; or the reduced osmotic pressure exemplified by congenital nephrosis. Severe fetal anemia secondary to a lack of RBC production, blood loss, or increased RBC destruction may lead to high-output cardiac failure causing fluid imbalance leading to hydrops.

Certain congenital infections may also lead to NIHF. Several mechanisms have been proposed and vary by the underlying infectious

TABLE 17-7 Example Setup for Fetal Blood Sampling and Transfusion

1. Obtain O-negative, CMV-negative, irradiated packed red blood cells from the blood bank. O-positive blood may be needed when antibodies to the c antigen are present because O-negative, c-negative blood is very rare (prevalence of 0.0001%).
2. Under sterile conditions, open:
   a. Four paper or cloth drapes or single sterile drape (as used for cesarean delivery)
   b. Towel clips as needed
   c. One spinal needle,* 20 or 22 gauge (22 gauge for transfusions before 24 weeks of gestation or if thrombocytopenia is suspected), prepared with heparin to prevent clot formation
   d. Sterile ultrasound probe cover
   e. Sterile ultrasound gel
   f. A skin preparation solution (Betadine- or chlorhexidine-based solution)
   g. Eight to ten 1-mL syringes, flushed with heparin to avoid clot formation
   h. One 1-mL syringe for paralytic agent (atracurium or vecuronium)
   i. Five to ten 20-mL syringes (for storing blood)
   j. Four 12-mL syringes
   k. One 3-mL syringe
   l. Three needles, 18 or 20 gauge, for drawing blood from blood bank into 20-mL syringes
   m. One 22- or 25-gauge needle
   n. A 5.5-inch small-bore extension set with T-connector and Luer adaptor)
   o. Three-way stopcock
3. Fill two 5-mL syringes with physiologic saline solution.
4. Flush 1-mL syringes with heparin; save one unflushed 1-mL syringe for vecuronium (or atracurium).
5. Draw up normal saline to make three saline flushes; remove air bubbles by holding syringes upright and tapping to release bubbles to top; then attach small-bore connection tubing and flush air through.
6. Reconstitute vecuronium with 10 mL of normal saline.
   a. Draw up 1 mL of vecuronium and 9 mL of normal saline in a 12-mL syringe.
   b. Transfer 1 mL of vecuronium mixture to an unheparinized 1-mL syringe.
   c. Mark both the 12-mL and 1-mL syringes containing vecuronium, to avoid confusion.
   d. Usual dose of vecuronium is 0.1 mg/kg and of atracurium is 0.4 mg/kg.
7. Draw up 2% lidocaine in 3-mL syringe, attached to a 22- or 25-gauge needle, for injection at puncture site for maternal local anesthesia.
8. Care should be taken to maintain sterility when drawing up solutions: Either have an assistant hold the containers of saline, vecuronium, lidocaine, and blood from the blood bank, or use single-operator technique, keeping one hand sterile and one hand unsterile.
9. Attach intravenous connection tubing to unit of packed red blood cells.
10. Attach stopcock, taking care to maintain sterility on one end of the stopcock.
11. Fill 20-mL syringes with blood by opening stopcock.
    a. Remove any air bubbles that may be present by holding syringe upright and tapping side of syringe to release air bubbles.
12. Have tubes available to send for laboratory studies.
    a. Remember to include not only initial, midway, and final blood count samples but also any additional tubes for genetic studies, liver function studies, or other tests.

*Length of needle is determined beforehand by measuring the distance on the ultrasound image from maternal abdominal wall to cord insertion site.

From Society for Maternal-Fetal Medicine (SMFM) clinical guideline #7: Nonimmune hydrops fetalis. Am J Obstet Gynecol 2015;212(2):127-139; used with permission.

agent involved. Some pathogens may cause an inflammatory reaction leading to an increased capillary permeability; the microorganism may also attack the liver and cardiac tissue, directly causing fetal hepatitis or myocarditis, or may cause bone marrow suppression such as in the case of parvovirus B19.

Chromosomal abnormalities, such as Turner syndrome (45,X), can cause lymphatic vessel dysplasia and obstruction that can lead to cystic hygroma formation. Fetal structural abnormalities in multiple organ systems such as the musculoskeletal, neurologic, and gastrointestinal systems, have also been associated with the development of hydrops, although the exact mechanism may not always be known.

Evaluation and Management

Every effort should be made to identify the underlying cause. A detailed maternal history that includes exposures to infectious agents or toxins, the presence of pets, or any unusual travel or eating habits should be collected and recorded at the time of diagnosis. A detailed pedigree may identify consanguinity, increasing the likelihood of an autosomal recessive disorder. Comprehensive fetal anatomy evaluation via a detailed high-resolution ultrasound may reveal an abnormality causing NIHF. A fetal echocardiogram should also be part of the initial evaluation. Doppler evaluation of the PSV of the MCA will lead to the identification of fetal anemia in some cases of NIHF. Immune hydrops should be excluded by determining maternal blood type and RhD antigen status. To rule out fetal-maternal hemorrhage, a Kleihauer-Betke smear, showing the presence of fetal cells in the maternal peripheral blood, or flow cytometry analysis, estimating the volume of fetal bleeding, may also be indicated.

Maternal serologic antibody titers for congenital infections, especially for parvovirus B19, or direct isolation of viruses and parasites from amniotic fluid with polymerase chain reaction evaluation should be considered. Prenatal diagnostic testing, including karyotype,

TABLE 17-8 Causes and Associations of Nonimmune Hydrops

Cause/Association	Frequency*
Focal Abnormalities	
Cranial	
Fetal intracranial hemorrhage	Low
Vein of Galen aneurysm	Low
Cerebral tumor	Low
Thoracic	
Cardiac structural defects	
AV septal defect, isolated or in association with Down syndrome	Low
AV septal defect in combination with heterotaxia syndrome (sinus ambiguus, left or right atrial isomerism) and bradyarrhythmia	High
Tricuspid dysplasia and Ebstein anomaly	Low
Severe obstruction of right ventricular outflow tract by pulmonary stenosis, pulmonary atresia, and premature closure of the ductus arteriosus (occurring spontaneously or induced with indomethacin)	Low
Absent pulmonary valve syndrome (typically combined with tetralogy of Fallot or agenesis of the ductus arteriosus)	Low
Truncus arteriosus communis with truncal valve insufficiency	Low
Premature closure of the foramen ovale	Unknown
Severe obstruction of left ventricular outflow tract by aortic stenosis and atresia leading to interatrial left-to-right shunt or premature closure of foramen ovale	Low
Cardiac tumors	
Rhabdomyoma, often associated with tuberous sclerosis	Low
Hemangioma	
Hamartoma	
Intrapericardial teratoma	
Cardiomyopathy	
Dilated	
Restrictive	
Myocarditis	
Myocardial infarction	
Idiopathic arterial calcification	High
Arrhythmias	
Tachyarrhythmias	High
Supraventricular tachycardia	
Atrial flutter	
Ventricular tachycardia	
Bradyarrhythmias	
Sinus bradycardia	Low
Complete heart block	
Combined with atrial isomerism and structural defect (see above)	High
In presence of maternal autoimmune antibodies (anti-SSA, anti-SSB)	Low
Pulmonary and Mediastinal	
Primary unilateral/bilateral hydrothorax, chylothorax	High
CPAM	
Macrocystic CPAM	Low
Microcystic CPAM	Low
Extralobar pulmonary sequestration	Low
Laryngeal atresia (CHAOS)	
Mediastinal teratoma	
Fibrosarcoma	
Intrathoracic alimentary tract duplication cyst	
Diaphragmatic hernia	Low
Pulmonary lymphangiectasia	
Gastrointestinal	
Diaphragmatic hernia	Low
Meconium peritonitis caused by bowel perforation; spontaneous bowel obstruction (various types of atresias of the intestinal tract, volvulus), or infection	Low
Intestinal hemorrhage caused by bowel perforation	Low
Hepatitis	
Hepatic fibrosis	
Hemachromatosis	
Cholestasis	
Cirrhosis with portal hypertension	
Congenital portal dysplasia	
Polycystic disease of liver	
Giant cell hepatitis	
Torsion of ovarian cyst	
Renal	
Congenital nephrosis (Finnish type)	Low
Urethral obstruction with rupture of bladder	Low
Polycystic kidney diseases (ARCKD, ADCKD)	Low
Renal vein thrombosis	
Tumor and Vascular Disorders	
Teratoma (sacrococcygeal, mediastinal, intracerebral, intrapericardial)	Low
Mediastinal fibrosarcoma	
Disseminated congenital neuroblastoma	
Hepatoblastoma	
Hamartoma	
Mesoblastic nephroma	
AVM	
Fetal hemangioma (liver, neck, chest)	Low
Diffuse neonatal hemangiomatosis	High
Klippel-Trenaunay-Weber syndrome	Low
Umbilical cord hemangioma	Low
Chorioangioma	Low
Vena cava interior thrombosis	
Renal vein thrombosis	
Idiopathic arterial calcification	High

*Rate of the occurrence of hydrops if the fetus has the respective disease. In the vast majority of cases and associations, the incidence is too low for giving reliable information.

fluorescence in situ hybridization (FISH) analysis, or chromosomal microarray may be offered to these patients in an attempt to identify any chromosomal abnormality or pathogenic copy number variant (see Chapter 2). Percutaneous umbilical blood sampling (PUBS) may be part of the diagnostic evaluation in cases of elevated MCA PSV with a negative workup.[81] Diagnostic testing may also allow for specific testing for lysosomal storage disorders, which have been reported to cause as many as 25% of unexplained NIHF[82] (Figs. 17-16 and 17-17). Amniotic fluid level of alpha-fetoprotein should be obtained. After birth, a thorough physical examination of the newborn along with a detailed evaluation of the products of conception could lead to the underlying cause. A detailed histologic evaluation of the placenta may also yield important diagnostic information. Figure 17-18 summarizes the evaluation for cases of NIHF.

Treatment

The treatment of nonimmune hydrops is determined by the gestational age at which the diagnosis is made, as well as the ability to identify the cause of the NIHF. Appropriate counseling should be offered to parents; NIHF associated with structural anomalies carries a poor prognosis. In some cases, termination of pregnancy may be an option available to the patient. Certain fetal conditions, such as congenital pulmonary airway malformations and twin-to-twin transfusion syndrome, may benefit from fetal intervention. Open fetal surgery may be of benefit in some cases such as sacrococcygeal teratomas or obstructive chest lesions.[83] Intrauterine fetal transfusion may be a therapeutic option if severe fetal anemia is determined to be the cause of NIHF, as in cases of parvovirus B19 infections. Shunt placement for certain obstructive procedures or paracentesis and thoracocentesis may be both diagnostic and therapeutic in these conditions (Table 17-9) (see Chapter 24).

Antenatal medical treatment has also been described in certain conditions, with some authors reporting complete resolution of hydrops and improved outcomes.[84] Fetal arrhythmias may be converted back to normal sinus rhythm with administration of antiarrhythmic medication to the mother. Several protocols have been described such as the use of sotalol for the treatment of supraventricular tachycardia[85] or the administration of flecainide or digoxin in the treatment of fetal atrial flutter.[86] The dose, indication, and side effects of these medications are listed in Table 17-10. Congenital cytomegalovirus infection has been treated with maternal intravenous administration of hyperimmune globulin (IVIG) with varying results. Some authors have reported the resolution of ascites in fetuses affected with this condition that were treated with IVIG,[87] whereas others have failed to show such promising results.[88] When congenital syphilis was determined to be the cause of NIHF, patients have been treated with a continuous infusion of 18 million U of penicillin G daily for 10 days with resolution of hydrops.[89,90] The use of pyrimethamine, sulfadiazine, and folinic acid at 27 weeks in a pregnancy complicated by congenital toxoplasmosis led to the complete resolution of hydrops 4 weeks later.[91]

Once the diagnosis of NIHF has been established, careful fetal surveillance is necessary. A multidisciplinary approach may be required in some cases. Antenatal testing may be indicated, although the precise method and frequency have yet to be established. Serial ultrasonographic evaluation both to evaluate fetal growth and to possibly detect undiscovered structural abnormalities may assist in the management of such pregnancies. Delivery should be done at a tertiary care hospital

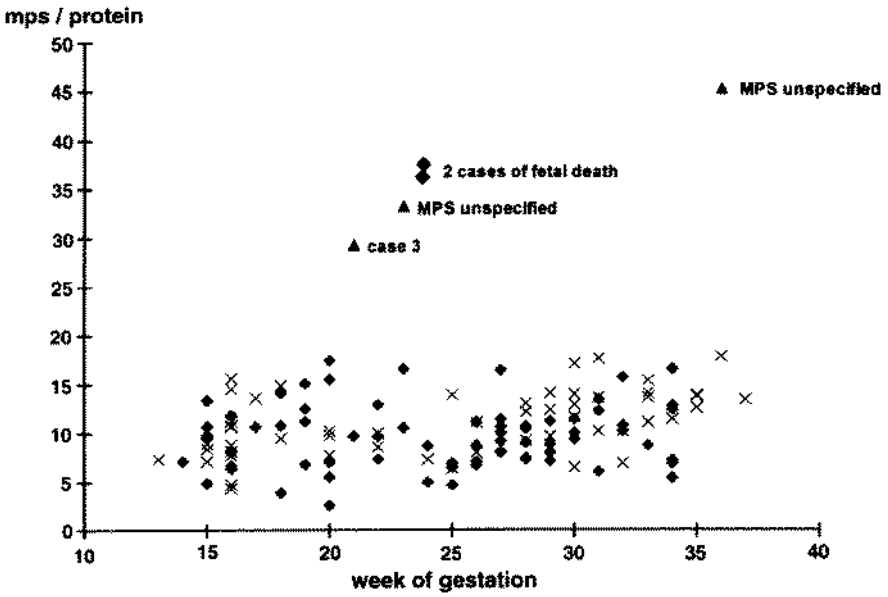

FIG 17-16 Normal values for amniotic fluid mucopolysaccharides (MPS) corrected for total protein. × marks represent 40 normal control patients; ◆ symbols represent 71 cases of nonimmune hydrops fetalis. Note: in two cases of fetal death elevated levels of MPS were found, although cultured amniocytes for 21 different lysosomal enzymes were normal. Three abnormal cases are depicted. (From Kooper AJ, Janssens PM, de Groot AN, et al: Lysosomal storage diseases in non-immune hydrops fetalis pregnancies. Clin Chim Acta 371:176, 2006; reprinted with permission.)

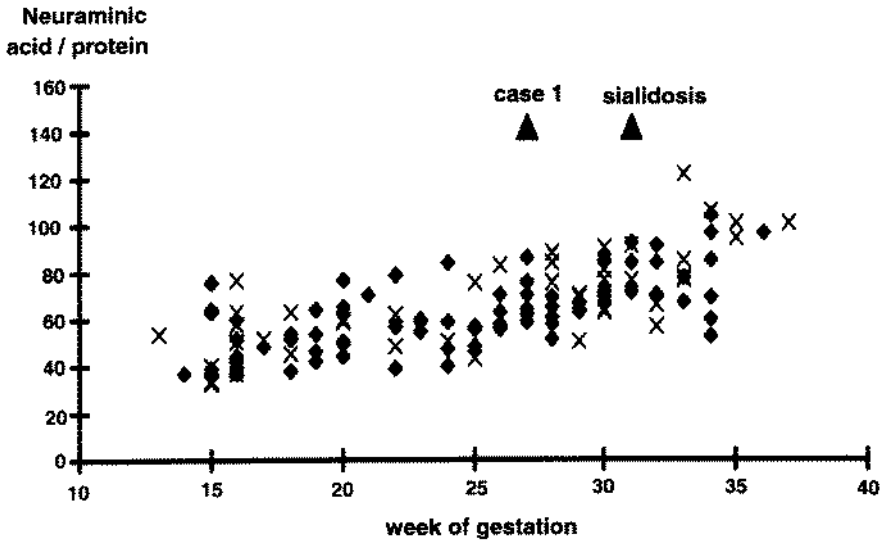

FIG 17-17 Normal values for amniotic fluid bound and free neuraminic acid corrected for total protein. × marks represent 40 normal control patients; ◆ symbols represent 71 cases of nonimmune hydrops fetalis (NIHF). Two abnormal cases are depicted. (From Kooper AJ, Janssens PM, de Groot AN, et al: Lysosomal storage diseases in non-immune hydrops fetalis pregnancies. Clin Chim Acta 371:176, 2006; reprinted with permission.)

to allow for the appropriate neonatal interventions and a thorough newborn examination, attempting to determine the underlying cause. The timing and the mode of delivery will be determined by a number of factors, most importantly fetal status. With cases of hydrops causing massive fetal fluid retention, difficulty at delivery with risk of dystocia and fetal trauma may prompt the need for a cesarean delivery in cases of NIHF in which fetal survival is possible.

Prognosis

In cases of NIHF, the prognosis is dependent on the underlying cause. NIHF secondary to treatable causes such as fetal arrhythmia, chylothorax, or infection with parvovirus B19 have a better survival rate. The development of intrauterine therapies such as intrauterine transfusions and minimally invasive fetal surgery have contributed to improved outcomes. The rate of intrauterine survival is also dependent on

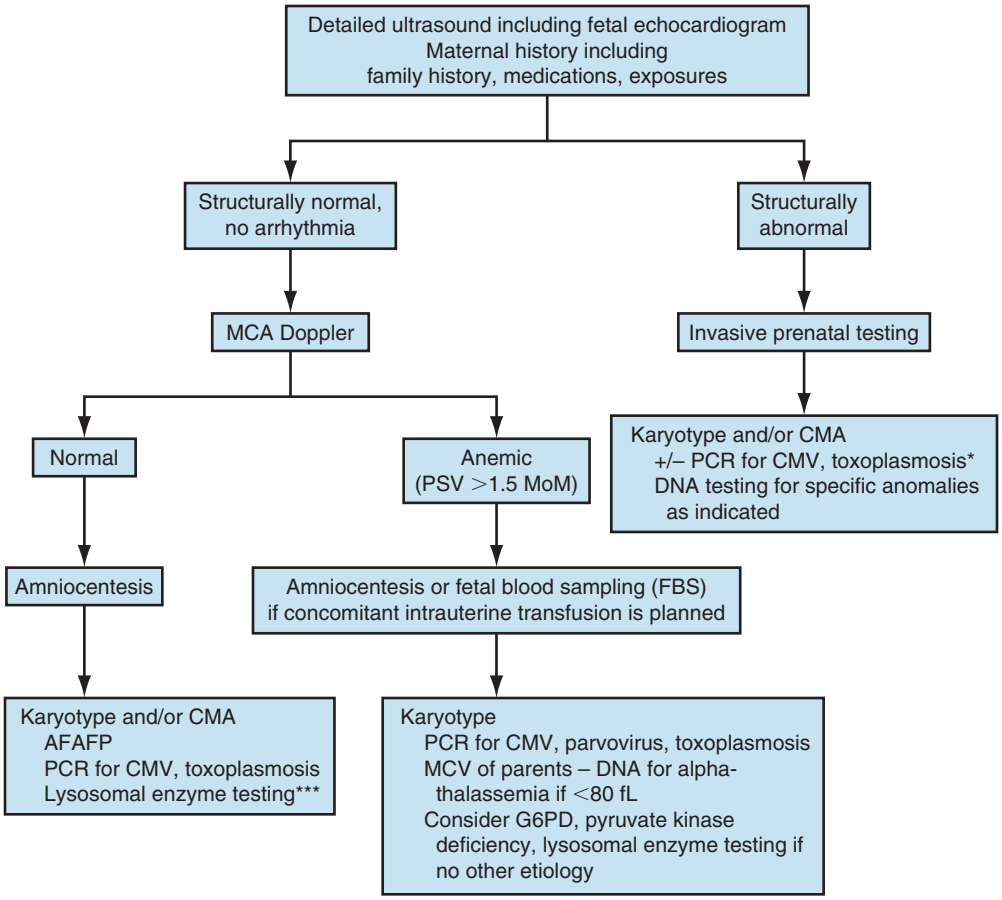

FIG 17-18 Algorithm for the diagnosis and management of nonimmune hydrops. AFAFP, amniotic fluid alpha-fetoprotein; CMA, chromosomal microarray analysis; CMV, cytomegalovirus; G6PD, glucose-6-phosphate dehydrogenase; MCA, middle cerebral artery; MCV, mean corpuscular volume; PCR, polymerase chain reaction; PSV, peak systolic velocity. (Modified from Norton ME, Chauhan SP, Dashe J, Society for Maternal-Fetal Medicine: Evaluation of non-immune hydrops. Am J Obstet Gynecol Dec. 2014 [Epub ahead of print].)

gestational age at diagnosis, with a 31% survival rate if diagnosed prior to 24 weeks and a 48% survival rate if the diagnosis is made later.[17] Among pregnancies that result in a liveborn infant, the neonatal mortality rate has been reported to be as high as 60%.[92] This rate does not appear to have improved over the past couple of decades. This increased survival rate may also be a consequence of increased antenatal detection during the same time period. In a series evaluating 568 newborns with hydrops admitted to a NICU, higher mortality rates were associated with a younger gestational age, a low 5-minute Apgar score, and a need for high levels of support during the first day after birth.[14] The risk of recurrence in future pregnancies will again depend on the underlying cause. Some cases of recurrence in idiopathic NIHF have been reported and are likely due to undiagnosed genetic disorders.[93]

Long-term outcomes will also be dependent on the underlying cause. In a cohort of anemic fetuses secondary to parvovirus B19 infection that were treated with intrauterine transfusion, at a median of 5 years 11% of the children had been diagnosed with neurodevelopmental impairment.[94] In a series of 51 newborns affected with NIHF, the rate of normal development of infants who had survived to 1 year of life was 68%.[95]

MATERNAL RISKS FROM HYDROPS

There are maternal risks associated with the diagnosis of fetal hydrops. A constellation of symptoms referred to as *mirror syndrome* may develop in a small percentage of women. This complication is characterized by the combination of symptoms mimicking preeclampsia with edema (90%), hypertension (60%), and proteinuria (40%).[96] Pulmonary edema, which may develop in as many as 21% of women, is another major morbid condition associated with hydrops.[97] Other symptoms include headache, oliguria, and visual disturbances as well as abnormal laboratory values including low platelet count, anemia, and elevated creatinine and liver function test values. The only apparent cure for this condition appears to be delivery. Several case reports have described cases in which the complete resolution of symptoms is seen after the underlying cause of fetal hydrops is either treated or corrected.[98,99]

If polyhydramnios is associated with fetal hydrops, this can lead to other complications including preterm uterine contractions, preterm labor and premature rupture of membranes, maternal discomfort, and respiratory distress. The use of serial amnioreductions may lead to the improvement of symptoms; others have advocated for the use of prostaglandin inhibitors to decrease amniotic fluid production.

CONCLUSION

In this chapter, the incidence, mechanism, diagnosis, and treatment of both immune and nonimmune hydrops have been presented. Although several advances have been made in the treatment of this disease, it is clear that many questions are still unanswered. With the evolution of

TABLE 17-9 Therapy for Selected Etiologic Categories of Nonimmune Hydrops

Etiologic Category*	Therapy	Recommendation
Cardiac tachyarrhythmia, supraventricular tachycardia, atrial flutter, or atrial fibrillation	Maternal transplacental administration of antiarrhythmic medication(s)	Treatment with antiarrhythmic medication unless gestational age is close to term or there is maternal or obstetric contraindication to therapy
Fetal anemia secondary to parvovirus infection or fetomaternal hemorrhage	Fetal blood sampling followed by intrauterine transfusion	Fetal intrauterine transfusion if anemia is confirmed, unless pregnancy is at an advanced gestation age and risks associated with delivery are considered to be less than those associated with procedure
Fetal hydrothorax, chylothorax, or large pleural effusion associated with bronchopulmonary sequestration	Fetal needle drainage of effusion or placement of thoracoamniotic shunt; if gestational age is advanced, needle drainage before delivery in selected cases	Consider drainage of large unilateral pleural effusion(s) resulting in NIHF, or, if gestational age is advanced, consideration of needle drainage before delivery
Fetal CPAM	*Macrocystic type*: fetal needle drainage or effusion or placement of thoracoamniotic shunt; *microcystic type*: maternal administration of corticosteroids, bethamethasone 12.5 mg IM q24h × 2 doses *or* dexamethasone 6.25 mg IM q12h × 4 doses	Consider drainage of large macrocystic CPAM that has resulted in NIHF; if large microcystic CPAM has resulted in NIHF, suggested management options include maternal corticosteroid administration
TTTS or TAPS	Laser ablation of placental anastomoses or selective termination	Consideration of fetoscopic laser photocoagulation of placental anastomoses for TTTS or TAPS that has resulted in NIHF < 26 weeks
Twin reversed arterial perfusion sequence	Percutaneous radiofrequency ablation	Referral for consideration of percutaneous radiofrequency ablation that has resulted in NIHF

*For each of these etiologic conditions, it is recommended that treatment be performed at a tertiary care center or a center with expertise in relevant therapy.
CPAM, congenital pulmonary airway malformation; IM, intramuscular; NIHF, nonimmune hydrops fetalis; TAPS, twin anemia-polycythemia sequence; TTTS, twin-twin transfusion sequence.

TABLE 17-10 Medications Used to Treat Fetal Arrhythmia: Dose, Contraindications, and Side Effects

Medication	Dosage	Contraindications	Side Effects
Sotalol	160 mg PO q12h; may increase to 320 mg q8h	Maternal history of cardiac disease, maternal bradycardia or prolonged QTc interval	Prolongation of maternal QTc interval, potassium and magnesium abnormalities
Flecainide	100 μg q8h	Second- or third-degree AV block	Prolongation of maternal QTc interval, headache, palpitations
Digoxin	500 μg loading PO/IV; then 250 μg q12h PO	Maternal history of cardiac disease	AV block, severe bradycardia, palpitations, visual disturbances
Amiodarone	600 mg PO q8h; then decrease to 200-400 mg per day	Maternal history of cardiac disease, second- or third-degree AV block, prolonged QTc interval	Prolongation of maternal QTc interval, bradycardia, nausea/vomiting

AV, atrioventricular; IV, intravenous; PO, by mouth; q, every.
Data from treatment protocols in Shah A, Moon-Grady A, Bhogal N, et al: Effectiveness of sotalol as first-line therapy for fetal supraventricular tachyarrhythmias. Am J Cardiol 2012;109:1614-1618.

diagnostic tests, including more sophisticated DNA testing for genetic disorders, and the advances in minimally invasive fetal surgery, the overall spectrum and prognosis of this disease may change. Continued research is required to determine the best treatment algorithm that can be offered to patients with this diagnosis.

Ultrasound Evaluation of the Gravid Cervix

Vincenzo Berghella, Adeeb Khalifeh

SUMMARY OF KEY POINTS

- Transvaginal ultrasound (TVU) for cervical assessment is one of the best techniques for predicting preterm birth (PTB).
- A cervical length (CL) of less than 25 mm between 16 and 24 weeks' gestation is the most reliable threshold for an increased risk of PTB.
- The shorter the cervix and the earlier in gestation the shortening occurs, the higher the risk of PTB.
- TVU is the gold standard for ultrasound cervix measurements because a short cervix can be missed on transabdominal scans.
- Appropriate technique is key to accurate TVU measurement of CL.
- With a dynamic cervix, or in the presence of funneling, practitioners should report the shortest optimally imaged transvaginal ultrasound measurement of closed CL as the one single measurement to guide clinical decisions.
- The same transvaginal CL has very different positive predictive values depending on the a priori individual patient characteristics.
- The predictive value of sonographic CL determination in twins between 24 and 34 weeks' gestation is low.

OUTLINE

Ultrasound assessment of the cervix during pregnancy has become an essential part of modern clinical care. Significant advances have been made in understanding the proper role of this sonographic screening test. In this chapter we will review the technique of transvaginal cervical assessment and discuss its expanding role in clinical practice.

ULTRASOUND EXAMINATION TECHNIQUES

Transabdominal Ultrasound

In the 1970s, the first attempts at evaluating the cervix used transabdominal ultrasound (TAU). Unfortunately, this technique has

relatively poor reliability and validity because of the following shortcomings: (1) the bladder often needs to be adequately filled to obtain a good image, resulting in elongation of the cervix and masking of any funneling of the internal os; (2) fetal parts can obscure the cervix, especially after 20 weeks; (3) the distance from the probe to the cervix results in degraded image quality; and (4) obesity and manual pressure interfere with the resulting image.[1] Therefore, it is generally suggested that TAU should not be used for assessment of the cervix, even as a screening test, because its sensitivity for prediction of disease (e.g., increased risk for PTB) is unacceptably low (8%)[2] in comparison to TVU. All randomized controlled trials (RCTs) that proved benefit with different treatments for a sonographically detected short cervix used TVU: vaginal progesterone,[3,4] cerclage,[5-9] and pessary.[10,11] The sensitivity of TVU has been shown to be significantly higher than TAU in detecting a short cervix[12-16] (Table 18-1).

As can be seen from the studies described in Table 18-1, it is still unclear if TAU is better done before or after voiding; only two studies report blind results. The cutoff for TAU-detected CL measurement needs to be high (usually >35 mm) to achieve a sensitivity of more than 90% for a shortened cervix by TVU, in which case most patients screened with TAU would need a subsequent TVU to confirm or rule out a short cervix. In 9% to 51% of attempted TAU, CL was not obtainable. Moreover, TVU CL screening has been shown to have superior cost-effectiveness compared to TAU, with TVU associated with slightly better prevention of PTB, resulting in cost savings of millions of dollars.[17] All major guidelines that have described CL screening have clearly recommended TVU, including the Society for Maternal-Fetal Medicine (SMFM),[18] the American College of Obstetricians and Gynecologists (ACOG),[19] and the Royal College of Obstetricians and Gynaecologists.[20] Given the preponderance of the evidence, TAU is less effective than TVU and should not be used for CL screening.

Translabial Ultrasound

Translabial (also known as transperineal) ultrasound (TLU) was first described in France in the early 1980s. This technique involves having the woman lie on the examination table with her hips and knees flexed. Adjusting the examination table to place her in a Trendelenburg position can be helpful. A covered transducer (using a probe cover, or glove, and sterile gel) is positioned in a sagittal orientation on the perineum between the labia majora at the level of the vaginal introitus (Fig. 18-1). Elevation of the woman's hips with a cushion or by positioning her hands to achieve a pelvic tilt can be used to improve visualization. Unlike TAU, this technique does not require bladder filling, is not impaired by obscuration by fetal parts, and with the transducer closer to the cervix, achieves close to 100% visualization. Other advantages of this technique are that the transducer does not enter the vagina (so no pressure can be exerted on the cervix thus no alteration in appearance from mechanical effect), it does not require an additional

TABLE 18-1 Transabdominal Ultrasound in Detection of Short Cervix

Study*	GA, Week (Mean)	N (TVU CL < 25 mm)	Bladder	Blind	TAU Cutoff (mm)	TA Variation (Longer/Shorter)	Sensitivity	Need TVU (TAU Not Obtainable)

			Postvoid		≤36		96%	NA (17%)

*These studies are listed in the references at the end of the chapter.
CL, cervical length; GA, gestational age; TAU, transabdominal ultrasound; TVU, transvaginal ultrasound.

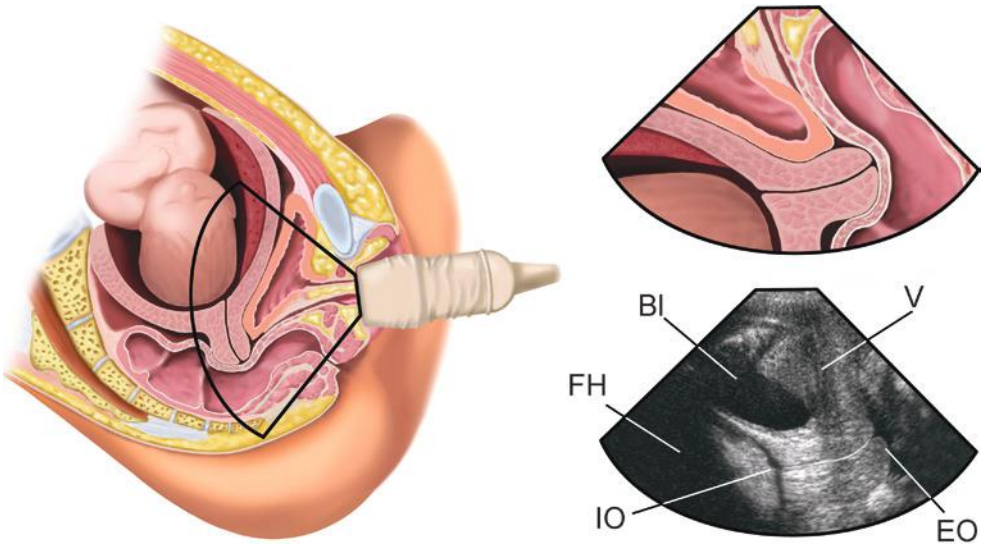

FIG 18-1 Diagrams and sonogram of the female pelvis demonstrating placement of the ultrasound transducer for translabial imaging of the gravid cervix. Bl, bladder; EO, external os; FH, fetal head; IO, internal os; V, vagina. (Illustration by James A. Cooper, MD, San Diego, CA.)

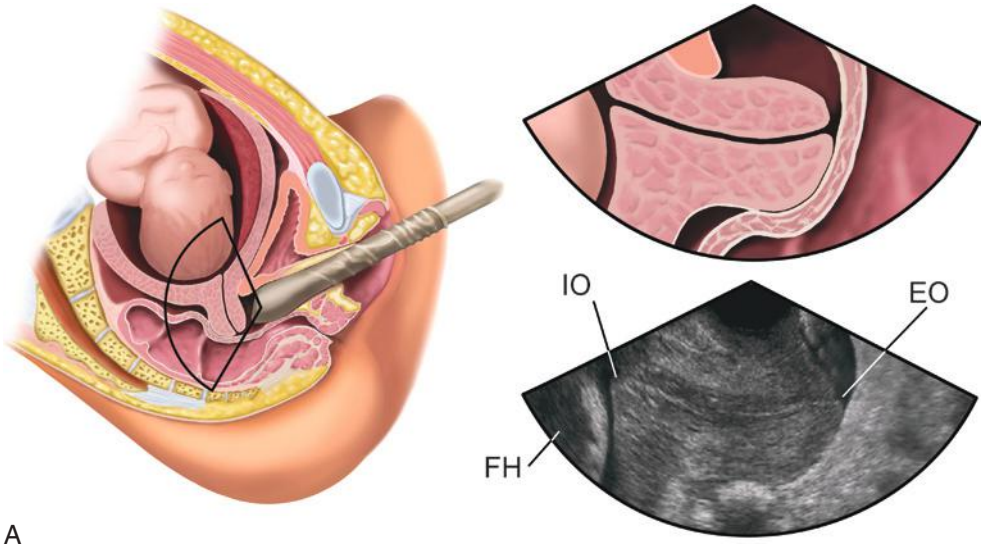
transducer, it can be performed in the setting of ruptured membranes, and it is well accepted by most women. The main drawback of TLU, however, is that gas in the rectum sometimes impedes visualization of the cervix, especially the external os. TLU is also more difficult to master than TVU and has been reported to be an unsatisfactory alternative.[21] However, with experience in using TLU, adequate visualization of the cervix can often be obtained.

Transvaginal Ultrasound

The first studies of the human cervix using TVU date back to the late 1980s. A clean transvaginal probe covered by a condom is gently inserted into the vagina (Fig. 18-2A and B). The technique shares the advantages of TLU; however, the probe is close to the cervix, without the problem of obscuring bowel gas. Thus, TVU has become the preferred approach for sonographic evaluation of the gravid cervix in virtually all clinical settings (Fig. 18-3A to C). Current recommendations for the performance of TVU of the cervix are shown in Table 18-2.[22]

The total time for TVU of the cervix is approximately 5 minutes. For optimal results, the following criteria should be sought: the internal os should be either flat or at an isosceles angle with respect to the uterus, the whole length of the cervix should be visualized, a symmetric image of the external os should be obtained, the distance from the surface of the posterior lip to the cervical canal should be equal to the distance from the surface of the anterior lip to the cervical canal, and there should be no increased echogenicity in the cervix (a sign of excessive pressure).[23]

Successful completion of the education program, examination, and continuing image review, all provided by the Perinatal Quality Foundation of the SMFM, is available and is recommended.[22] Ideally, TVU CL assessment should only be performed after this program has been completed.



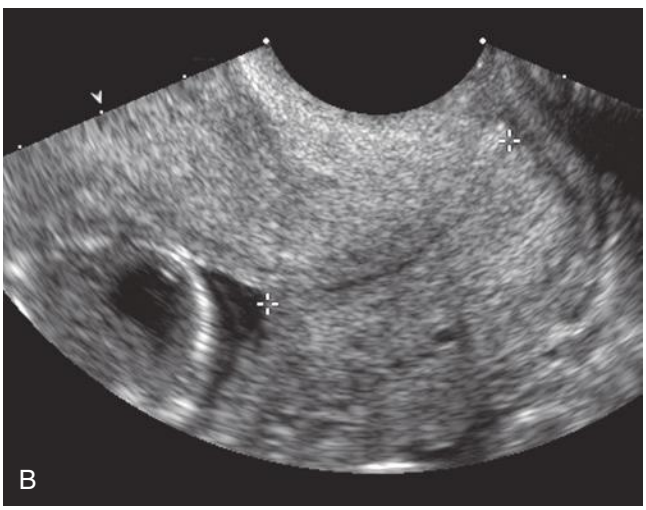


FIG 18-2 A, Diagrams and sonogram of the female pelvis demonstrating placement of the ultrasound transducer for transvaginal imaging of the gravid cervix. EO, external os; FH, fetal head; IO, internal os. **B,** Two-dimensional ultrasound image of the cervix in its longest axis in the sagittal view. The internal and external os (*calipers*) and the entire endocervical canal can be clearly seen, and the image is enlarged so that it occupies more than 75% of the screen. (Illustrations by James A. Cooper, MD, San Diego, CA.)

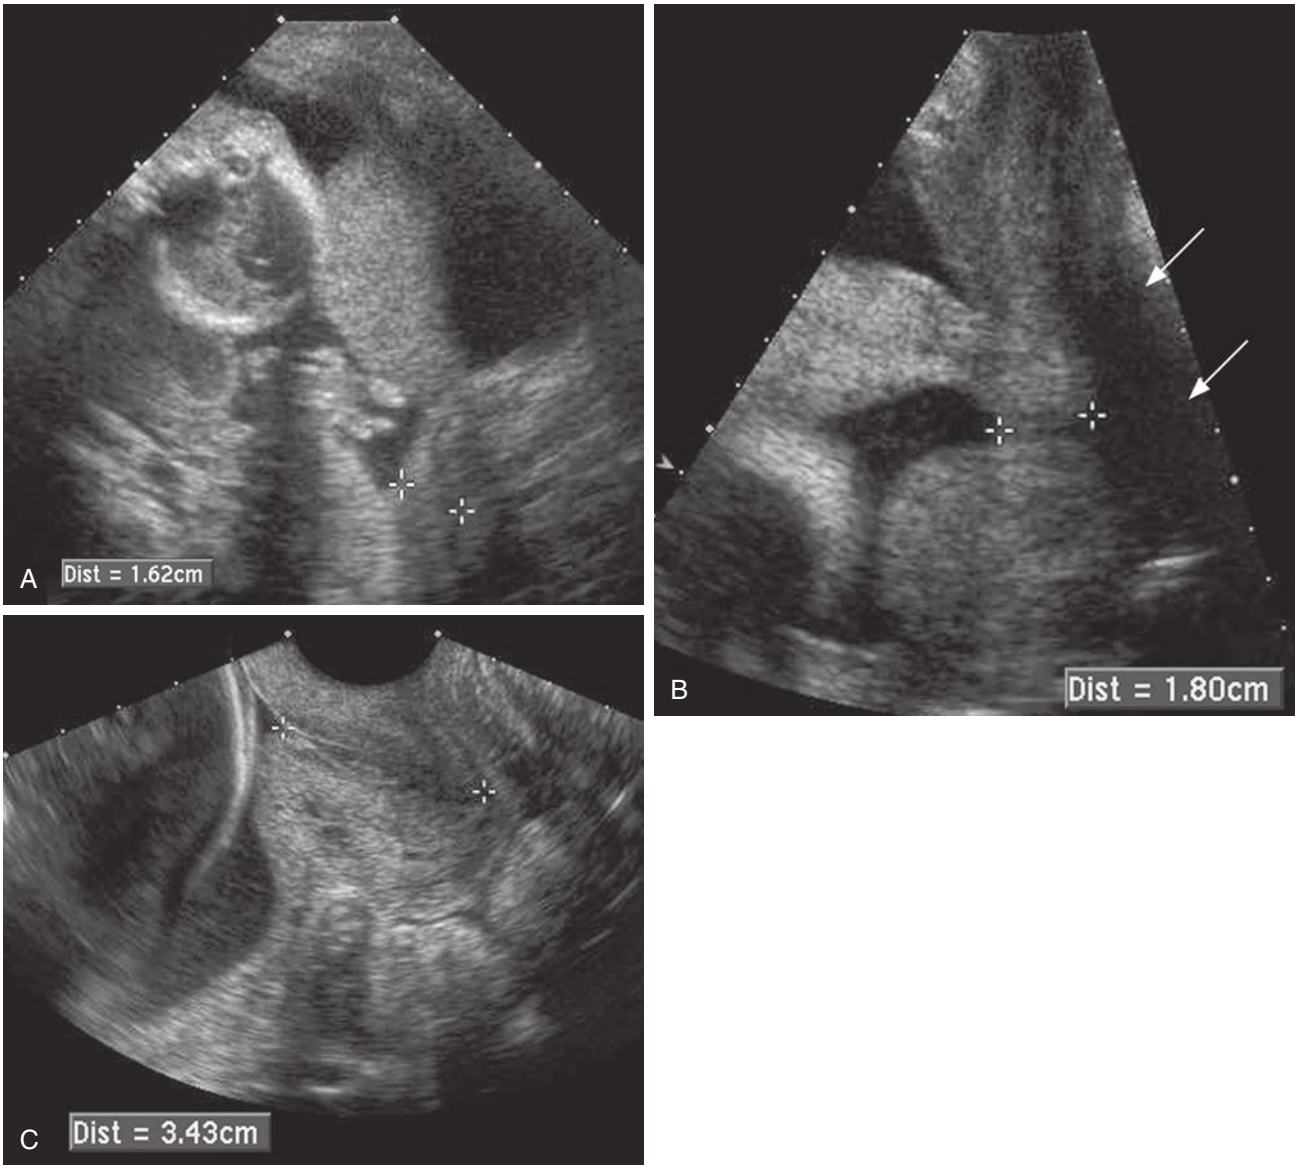

FIG 18-3 Three methods of imaging the cervix. **A,** Transabdominal sonogram. The cervix, which is distant from the ultrasound transducer, is poorly seen and appears to measure 1.62 cm in length (*calipers*). **B,** Translabial sonogram in the same patient. With this approach, visualization of the cervix is somewhat clearer, but shadowing from air in the rectum (*arrows*) partially obscures the view, resulting in undermeasurement of the cervical length (*calipers*). **C,** Transvaginal sonogram. The cervix is well seen and measures 3.43 cm in length (*calipers*).

LIMITATIONS AND PITFALLS

Although TVU of the cervix is usually straightforward, an anatomic or technical difficulty is encountered in approximately one fourth of patients.[24]

Full Bladder

A bladder that is not completely empty of urine can exert pressure on and appear to elongate the cervix or might mask funneling or opening of the internal os.

Excessive Pressure

Excessive pressure by the examiner with the transvaginal transducer can also mask funneling or opening of the internal os and can elongate the cervix. This can be recognized by alterations in appearance including asymmetry in thickness of the anterior and posterior walls of the cervical canal and by increased echogenicity of the cervix (Fig. 18-4).

Contraction

Uterine segment contractions may mimic the appearance of funneling of the internal cervical os. In such cases, there is rounded myometrium around the cervix and a normal cervix distal to the contraction (Fig. 18-5).

Underdeveloped Lower Uterine Segment

Before 14 weeks, the lower uterine segment is difficult to distinguish from the endocervical canal, because the gestational sac has not reached a sufficient size to completely expand the lower part of the uterus.

TABLE 18-2 Recommendations for the Technical Performance of Transvaginal Ultrasound Examination of the Cervix

Measurement is taken on a transvaginal image:
- Transvaginal measurements are the gold standard for ultrasound cervix measurements.
- The short cervix can be missed on transabdominal scans.

The transvaginal image is filled primarily with the cervix, and the field of view is optimized for measurement:
- The cervix occupies approximately 75% of the image.
- The bladder area is visible.

The anterior width of the cervix equals the posterior width:
- The anterior cervical thickness is equal to the posterior cervical thickness.
- The echogenicity is similar for both anterior and posterior portions.
- There is limited concavity created by the transducer.

The maternal bladder is empty:
- The maternal bladder has a variable effect on the cervical length.

The external os is seen:
- The external os is a small triangular area at the inferior portion of the transervical canal.
- The anterior and posterior portions of the cervix come together at the external os.

The endocervical canal is visible throughout:
- The endocervical canal is a linear echogenicity created by the interface between the anterior and posterior walls of the cervix.
- The canal extends between the internal os and external os.

Caliper placement is correct:
- Calipers are placed where the anterior and posterior walls of the cervix touch at the internal os and external os.
- Calipers do not extend to the outermost edge of the cervical tissue.

Cervix mobility is considered:
- Insert transvaginal probe to view the cervix, withdraw probe until the image blurs to reduce compression from the transducer, then reapply just enough pressure to create best image.
- Apply mild suprapubic or fundal pressure to watch for funneling. Reduce probe pressure while fundal or suprapubic pressure is applied.
- Visualize the cervix for 3-5 minutes and watch for shortening or funneling.

Modified from Perinatal Quality Foundation: Cervix Measurement Criteria. 2015. Available at www.clear.perinatalquality.org/.

Therefore, the measurement of the true CL is difficult before 14 weeks. At other times, particularly between 14 and 18 weeks' gestation, the presence of a contraction can close the lower uterine segment and make the distinction between this structure and the true CL difficult.

CLINICAL APPLICATIONS

Transvaginal Ultrasound of the Cervix for Prediction of Preterm Birth

Screening Test Criteria

TVU of the cervix is most often used in obstetrics as a screening test for the prediction of PTB.[1] To be clinically beneficial, a screening test must fulfill specific criteria (Table 18-3).[3,5-9,17,24-32]

Important and Prevalent Condition. First, a good screening test must evaluate for a clinically important and prevalent condition. PTB occurs in 11.5% of births, or approximately 500,000 pregnancies, per year in the United States alone.[26] It is the leading cause of perinatal morbidity and fatality in the United States and as such may be the most important pathologic condition in obstetrics. In terms of years of life lost, PTB is one of the most important diseases in all of medicine.

Technique Well Described. The technique is well described (see Table 18-2).

Safe and Acceptable. TVU of the cervix is very safe. There is no inoculation of bacteria with TVU. In a randomized trial comparing the use of TVU or the nonuse of TVU in the presence of premature preterm rupture of membranes (PPROM), there was no increased risk of infection for mother or fetus with TVU of the cervix compared with no TVU of the cervix.[28] TVU is also well accepted by pregnant women. Pain and severe discomfort are experienced by fewer than 2% of women undergoing TVU, and more than 99% of women would agree to a similar procedure in the future.[32,33]

Reliable/Reproducible. The interobserver and intraobserver variability scores of TVU are both less than 10%.[34] This low variability between operators is achieved only after adequate training with supervised scans and with strict adherence to proper technique, as described earlier.

Recognizable Early Asymptomatic Phase. The changes of the cervix that are associated with preterm or term labor have been demonstrated by TVU. These changes include initial opening of the internal os, progressive cervical shortening and widening along the endocervical canal from the internal to the external os, and ultimate opening of the external os. The earliest changes at the internal os are almost always asymptomatic and can be detected only by TVU.

Accuracy of Prediction: Valid Comparison With Manual Examination of the Cervix. Cervical assessment by manual (digital) examination was a traditional method for prediction of PTB. Digital and transvaginal ultrasound examinations of CL every 2 weeks from 14 to 30 weeks' gestation were compared in one study (with examiners blinded to the results of the alternate technique)[34] and found to both independently predict PTB, but TVU had a much stronger association with PTB than manual examination of the cervix. The mean sonographic CL of the PTB group was significantly shorter than that of the term delivery group, whereas there was no difference in manual cervical measurements between the two groups.[34]

The relative lack of success of the digital examination in predicting PTB is probably due to the fact that it is subjective (interobserver variability of 52%),[35] not accurate for evaluating the internal os (the upper half of the cervix is not measurable by this method),[36] and nonspecific (15% to 16% of primiparous women and 17% to 35% of multiparous women who are delivered at term have cervices that are 1 cm to 2 cm dilated by manual examination in the late second trimester).[37] Sonographic CL measurements are, on average, 11 mm longer than manual estimations. The majority, about three fourths, of asymptomatic women with funneling of the internal os have a cervix felt to be closed and at least 2 cm long by manual examination.[38] These data demonstrate clear benefits of TVU over manual examination for evaluation of the cervix and prediction of PTB.

Measurements

Cervical Length. Different cervical parameters have been evaluated as predictors of PTB (Fig. 18-6). CL, as measured from the internal to the external os along the endocervical canal, is the most reproducible and reliable measurement (Figs. 18-2B and 18-7A and B). If the cervical canal is curved, defined as a deviation of the canal of more than 5 mm, the CL can be preferably measured as the sum of two straight lines that essentially follow the curve (Fig. 18-7C).[37] A short CL is usually straight, whereas the presence of a curved cervix generally

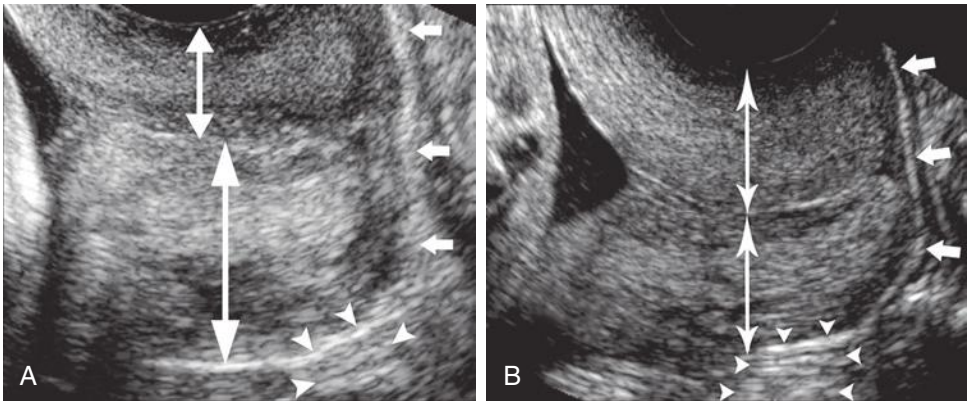

FIG 18-4 A, Ultrasound image of the cervix with excess manual pressure from the transvaginal probe. The anterior lip of the cervix appears significantly thinner than the posterior lip of the cervix (*double-headed arrows*). Small triangular markers (*arrowheads*) show increased echogenicity below the posterior lip of the cervix, an indication of excess pressure. **B,** The anterior and posterior portions of the cervix appear equal in thickness (*double-headed arrows*). The transvaginal transducer should be inserted just enough to adequately visualize and obtain a reliable measurement of cervical length, without altering anatomy. Vaginal mucosa appears hyperechoic (*small short arrows*).

FIG 18-5 Cervix with lower uterine segment contractions (*asterisks*). Lower uterine segment contractions should be considered whenever the apparent cervical length (CL) measures more than 50 mm, the cervical canal assumes an S shape, or the lower uterine segments (either anteriorly, posteriorly, or both) appear thickened and asymmetric. Lower uterine segment contractions can distort the landmarks of the cervix resulting in inaccurate CL measurement.

signifies a CL of more than 25 mm and, therefore, is a reassuring finding. If the cervical canal is closed, CL is the only parameter that needs to be measured.

Funneling. In about 10% of low-risk women[29] and 25% to 33% of high-risk women,[34,38,39] the internal os is open (Fig. 18-8). In this case, the open portion of cervix (funnel length) and internal os diameter (funnel width) can be measured. The percentage of funneling is calculated as funnel length divided by total CL. Total CL is equivalent to the sum of funnel length and functional CL. Functional CL in this case is the closed portion of the endocervical canal only. Functional CL is the sonographic CL used for calculations and predictions, and the term CL, if not otherwise specified, refers to the functional CL.

If funneling is present, the shape can be recorded. A continuous process of funneling has been described, going from a normal T shape, to Y, then V, and finally a U shape (Figs. 18-9 and 18-10).[40] It appears that U-shaped funneling is more likely to be associated with PTB compared with a V-shaped funnel[41]; however, these distinctions are somewhat subjective.

Careful evaluation of the apparent funneling with TVU over several minutes (at least 5) should resolve any question of the morphologic character of the upper cervical canal. In some instances, the depth of a true funnel may be difficult to quantify, because the funneled portion may merge with the lower uterine segment and the characteristic shoulder that depicts the border between lower uterine segment and the true cervix may be flattened. Funneling has been reported to have higher interobserver variability among examiners and different centers than CL.[29]

In spite of these difficulties, funneling has been reported to have better or similar predictive accuracy for PTB than CL.[29,34,38] In one high-risk population, minimal funneling (<25%) noted between 14 and 22 weeks was not associated with a significant increase in PTB, whereas moderate funneling (25-50%) and severe funneling (>50%) were associated with a 50% or more probability of PTB.[34] The fact that less than 25% funneling is not associated with an increased risk of PTB is important, because this is a common finding that should not raise alarm or result in intervention. Funneling has been shown in all

TABLE 18-3 Criteria for Clinical Benefits of Screening Test

Characteristic of Screening Test	Comments
Disease	
Disease is clinically important	PTB: 1 million deaths annually worldwide[25]
Disease is clearly defined	Birth < 37weeks
Disease prevalence is well known	11.5% in United States; about 10% worldwide[25,26]
Disease natural history is known; recognizable early asymptomatic phase	First cervical changes occur at the internal os[27,31]
Screening	
Screening technique well described	Several articles
Screening is safe and acceptable	RCT on PPROM showing safety[28]; 99% would have it again; <2% experience severe pain[32,33]
Screening has a reasonable cutoff identified	20 mm is the 5th percentile, 25 mm is the 10% percentile in the general U.S. population[29]
Results are reproducible (reliable)	<10% intraobserver and interobserver variability[34]
Results are accurate (valid)	Better than manual examination; predictive in all populations studied (hundreds of studies)
Intervention, Cost-Effectiveness, and Feasibility	
"Early" intervention is effective	Two RCTs for vaginal progesterone[3-29]; five RCTs for cerclage[5-9]
Screening and treating abnormal findings is cost-effective	Two cost-effectiveness manuscripts published[17,30]
Facilities for screening are readily available	All pregnancies are offered a sonogram for fetal anatomy screening at around 18-24 weeks
Facilities for treatment are readily available	Vaginal progesterone is easily administered on an outpatient basis

PPROM, premature preterm rupture of membranes; PTB, preterm birth; RCT, randomized controlled trial.

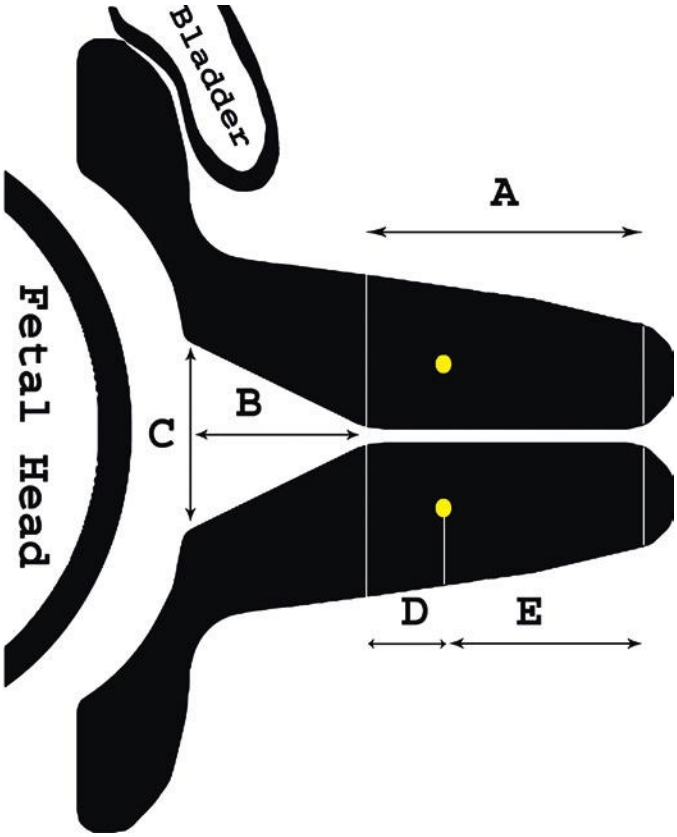

FIG 18-6 Diagram illustrating major landmarks of the cervix, in the sagittal plane, and adjacent structures. In this example, a cerclage is present, represented by two yellow dots. A indicates the length of closed cervical canal (effective cervical length), B is the funnel length, C is the funnel width, D is the distance from the internal os to the level of cerclage, and E is the distance from the level of cerclage to the external os. In this example, the fetal head is the presenting part and the maternal bladder is seen anteriorly.

studies, not just those focused on high-risk pregnancies, to predict PTB.[29,34,38,39,42-47] If funneling is present, the CL is almost always short (<25 mm). In the presence of a short CL, the presence of funneling may[29,43,46,47] or may not[39,42,44,45] add to the prediction of PTB or adverse perinatal outcome. Compared with a CL less than 25 mm alone, adding funneling can increase the sensitivity for PTB (from 61-74%) without major changes in specificity, and positive and negative predictive values.[43] In addition, the risk of PTB is higher if both a short CL and funneling are detected, compared with a short CL without funneling.[47] On the contrary, the presence of funneling in a woman with a normal (≥25 mm) CL does not seem to increase her risk of PTB (see funnel Y in Fig. 18-9).[48]

Given these shortcomings, as well as the fact that almost all intervention trials are based on TVU-detected CL (TVU-CL) alone, we do not recommend recording funneling on ultrasound reports. Following this recommendation will help to avoid confusion, as only CL is needed for clinical care.

Sludge. Free-floating echogenic material within the amniotic fluid has been referred to as sludge, or debris. Sludge has been proved to be an independent risk factor for PTB,[49,50] microbial invasion of the amniotic cavity, and histologic chorioamnionitis.[51,52] There are, however, no studies on interventions specific to intra-amniotic sludge or to prevent its consequences when present.

Other Measurements. Many parameters other than CL and the presence or absence of a funnel have been studied in relation to PTB,[53] including funnel width, funnel length, endocervical canal dilatation, cervical index (funnel length + 1/functional length), anterior and posterior cervical width, cervical angle, cervical canal contour (straight versus curved), cervical position (horizontal versus vertical), lower uterine segment thickness, vascularity, visibility of chorion-amnion membranes at the internal os, cervical gland area,[54] quantitative tissue characterization,[55] and others. None of these parameters has proved more reliable or predictive than CL. Additionally, there is insufficient evidence to assess if the addition of any of these parameters improves the predictive accuracy already provided by CL. Several other measurements may be taken in the presence of a cerclage (Figs. 18-11 through

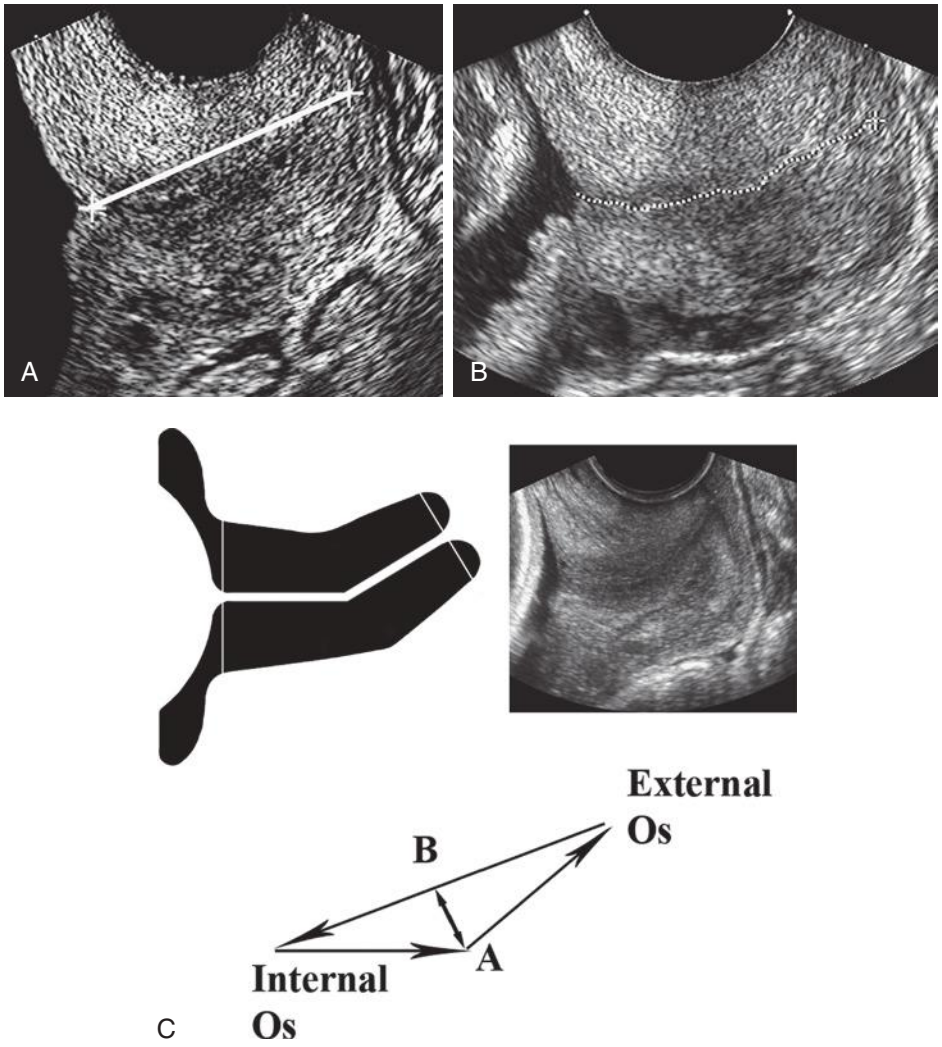

FIG 18-7 Measurement of the cervix using three techniques. **A,** The cervical length (CL) is measured in a linear fashion from the internal os to the external os because the cervical canal appears straight. **B,** The canal is measured using the manual draw feature of the ultrasound equipment. The draw feature will not always properly draw the cervical canal and might overestimate the CL. **C,** The diagram and the ultrasound image illustrate a curved cervix, which can be measured in a single straight line or by summing two components. The curved cervix can be measured by drawing a line connecting the internal os to the point where the straight canal bends upward and then drawing another line connecting that point to the external os (sum of those two measurements = A). Or a straight line can be drawn from the internal os to the external os (B). If the difference between A and B is more than 5 mm, then the cervical canal should be measured in two steps and summed (A).

18-14). Although some of these measurements may be predictive of PTB, **TVU-CL alone should be reported in all populations in which TVU for prediction of PTB is performed.**

DYNAMIC CHANGES (SPONTANEOUS OR AFTER TRANSFUNDAL PRESSURE)

In less than 5% of transvaginal sonographic examinations, CL may change dynamically during the course of a 5- to 10-minute examination, and in some cases, funneling of the upper cervical canal may appear and resolve. This usually happens if the woman is having contractions. Similarly, the cervix will shorten in response to transfundal pressure (TFP) in approximately 5% of cases.[56] When changes occur, the shortest CL should be recorded. In most cases in which the cervix shortens spontaneously or in response to TFP, it is already abnormal at baseline. There is conflicting evidence concerning whether TFP increases the screening potential of TVU. In one study, only one of nine patients with an initially normal cervix who had abnormalities after the application of TFP delivered preterm,[34] and adding response to TFP as a screening criteria for PTB did not significantly increase predictive accuracy. In contrast, in a larger study, dynamic changes, either spontaneous or after TFP, significantly improved the predictive accuracy of TVU for PTB.[39] Dynamic changes may indeed improve predictive accuracy; *practitioners should report the shortest optimally imaged CL as the one single measurement to guide clinical decisions.*

NORMAL VERSUS ABNORMAL CERVICAL LENGTH

A normal CL measures 25 to 50 mm at 14 to approximately 30 weeks of gestational age. A measurement of 25 mm is approximately the 10%

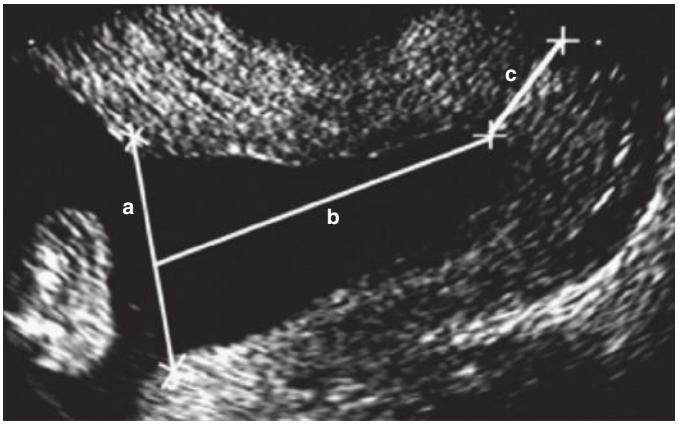

FIG 18-8 Transvaginal sonogram in a patient with cervical funneling. Funnel width (a) is usually measured by identifying the lower uterine segment notch (or genu) either anteriorly or posteriorly (or both) and drawing a connecting line perpendicular to the axis of the cervical canal. The funnel length (b) is measured by drawing a line connecting the middle of the funnel width to the tip of the funnel. Cervical length is measured from the tip of the funnel to the external os (c).

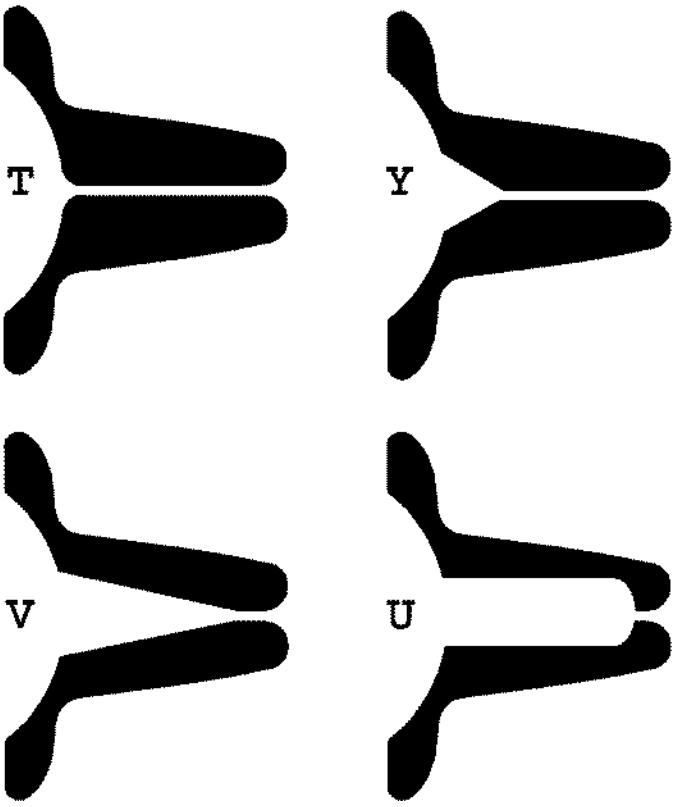

FIG 18-9 Diagrams of typical shapes of cervical funneling. T represents a closed normal cervix. Y represents a small funnel, which if less than 25%, with residual cervical length of 25 mm or greater, may not be clinically significant. V represents a more significant funnel, extending closer to the external os. U represents the funnel of most concern; in this situation, the cervix can often be dilated clinically as noted by manual examination.

percentile for low-risk (i.e., without a prior spontaneous PTB) singletons[29] and approximately the 25% percentile for high-risk (i.e., with a prior spontaneous PTB) singletons.[34,39] A short CL is less than 25 mm at these gestational ages, with the best prediction for PTB obtained at 16 to 24 weeks. The shorter the CL, the higher the risk of PTB.[29] A short CL is a better predictor of early PTB than later PTB.[56] A CL greater than 50 mm can be normal but warrants scrutiny, for it may reflect a measurement that includes the lower uterine segment, as often happens before 16 weeks.

BEST GESTATIONAL AGE AND FREQUENCY OF EXAMINATIONS

Almost all patients, even those at the highest risk, have a normal CL (i.e., ≥25 mm) in the first and early second trimesters. Before 14 weeks, measuring CL may be predictive only in very high-risk women, such as those with a prior second trimester loss or history of a large or repeated cervical cone biopsy. In a study of TVU of the cervix in high-risk women, only 5% had a CL less than 25 mm between 10 and 14 weeks, and these women were indeed very high risk based on prior history (i.e., pregnancy losses or major cervical surgery).[57] Sensitivity for the prediction of PTB is very low in this time interval, because most women who eventually deliver preterm typically have cervical shortening detected at 16 weeks or later. An additional drawback of very early screening is that the lower uterine segment is difficult to distinguish from the true cervix in the late first and early second trimesters.

After 30 weeks, the CL progressively shortens in preparation for term labor. CL less than 25 mm, in particular CL measuring 15 to 24 mm, after 30 weeks can be physiologic and not associated with an increased risk of PTB in asymptomatic women. When it occurs, the most common gestational age for short cervix or funneling to develop in women destined to deliver preterm is 18 to 22 weeks.[34,38] Therefore, if a screening program is to include only one CL assessment, it should be done in this time frame. High-risk patients destined to deliver preterm may have earlier cervical changes. The earlier the short CL is detected, the higher the risk of PTB. A cervix length measuring less than 25 mm has been reported to have a positive predictive value of 70% when detected between 14 and 18 weeks, and of 40% when detected between 18 and 22 weeks, in high-risk women.[34] Therefore, it may be that women with the highest risk of PTB (e.g., patients with classic histories of cervical insufficiency, prior second trimester losses, early PTBs, or large cone biopsies) may benefit from early (e.g., 12-14 weeks) TVU of the cervix to determine the need for intervention.

The benefits of repeated TVU examinations and the optimal interval for follow-up TVU assessments have not been clearly established. If a screening program were employed in relatively low-risk women, one TVU measurement of the cervix at approximately 18 to 22 weeks would likely be most effective. It appears that one normal TVU-CL assessment between 14 and 18 weeks and another between 18 and 22 weeks is reassuring and adequate in most high-risk women.[41] In women at very high risk for PTB, such as those with prior second trimester loss or very early spontaneous PTB, some have advocated TVU of the cervix every 2 weeks, at least between 14 and 24 weeks. If the CL measures 25 to 29 mm, the interval can be increased to every week. The fact that TVU at 14 to 22 weeks is at least as predictive of PTB as TVU after 22 weeks is important, because interventions to prevent PTB are most effective when changes predisposing to PTB are detected early in the process.

POPULATIONS

Numerous studies have evaluated the predictive accuracy of TVU to measure CL for PTB in many different populations.[1] Populations screened include asymptomatic women with singleton (low- or high-risk), twin, and triplet pregnancies, and symptomatic women with preterm labor (PTL) or PPROM. Although the TVU technique in these studies is similar, study population (in particular, prior PTB or not),

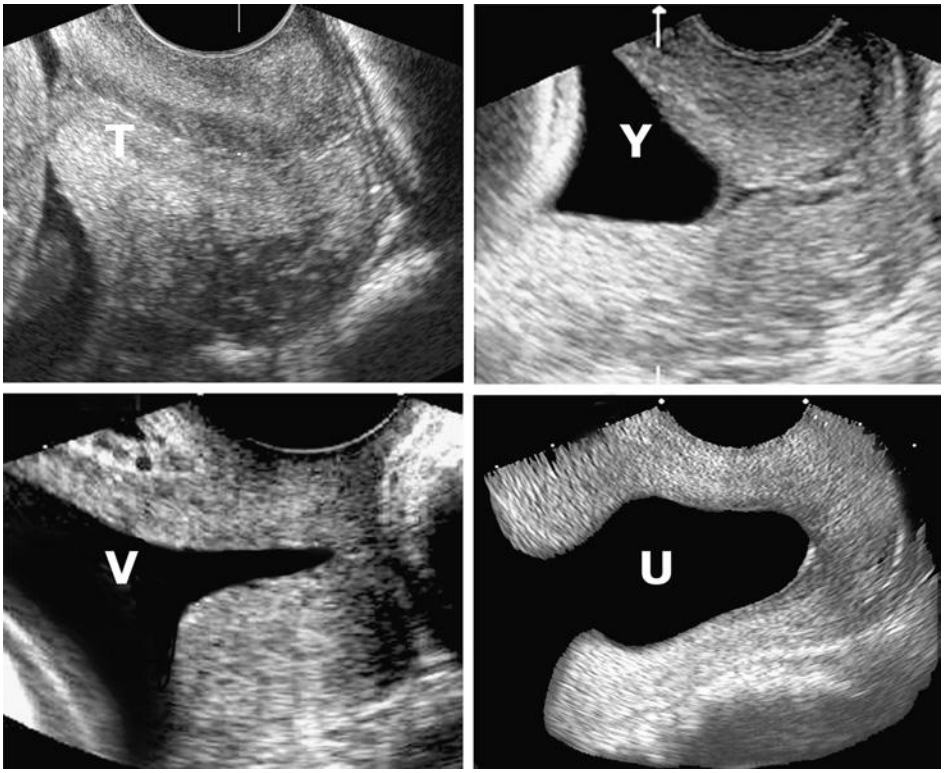

FIG 18-10 These ultrasound images show the respective funnel shapes, as depicted graphically in Figure 18-9.

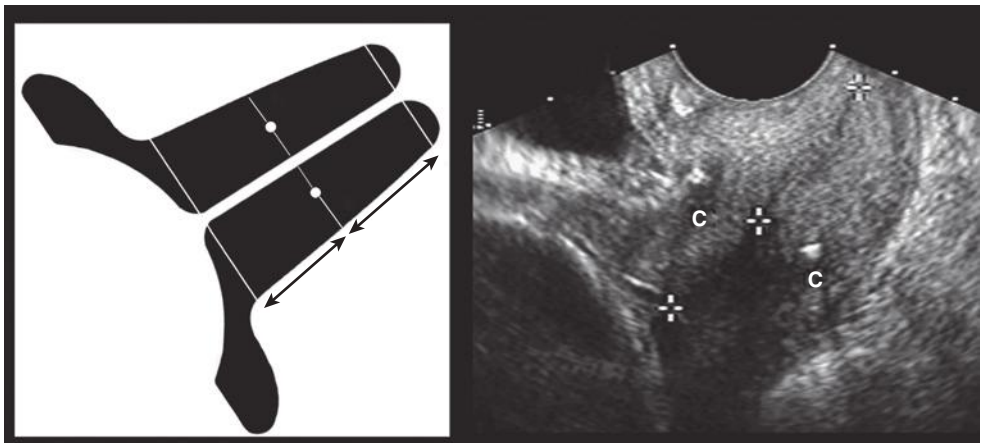

FIG 18-11 Diagram and sagittal transvaginal ultrasound image of a cervix with cerclage in place. The cerclage (c) is seen as two bright spots, in the anterior and posterior lips of the cervix. In this case, the measurement of the cervix is obtained by summing the distance from the internal os to the level of cerclage and from the level of cerclage to the external os (*calipers*). Note that the orientation of the cervix in this image is not quite horizontal but oblique/vertical, making identification of cervical landmarks more difficult because the ultrasound beam is not perpendicular to the endocervical canal.

gestational age at which TVU was done, frequency of TVU cervical parameters studied, and outcomes vary. In reviewing the available studies, it is important to include those with the best design, that is, those that describe proper technique, blinding of managing physicians to ultrasound results, and the inclusion of large numbers of patients. In most studies, the cervical parameter found to have the best predictive accuracy, as determined by receiver operating characteristic curves, is an TVU-CL less than 25 mm. The screening interval is early in the second trimester, usually between 16 and 24 weeks. The most common primary outcome is spontaneous PTB at less than 35 weeks' gestation (Table 18-4).[29,39,58-63] It is of utmost importance to recognize that *the same TVU-CL measurement confers very different positive predictive values depending on the a priori individual patient characteristics.* For example, a CL less than 25 mm is associated with a risk of PTB less than 35 weeks of 18% to 30% in a singleton without prior spontaneous PTB,[29] and a risk of 55% in a singleton with prior spontaneous PTB.[39] *Sensitivity and specificity of TVU-CL for prediction of PTB change substantially depending on the population studied* (see Table 18-3).

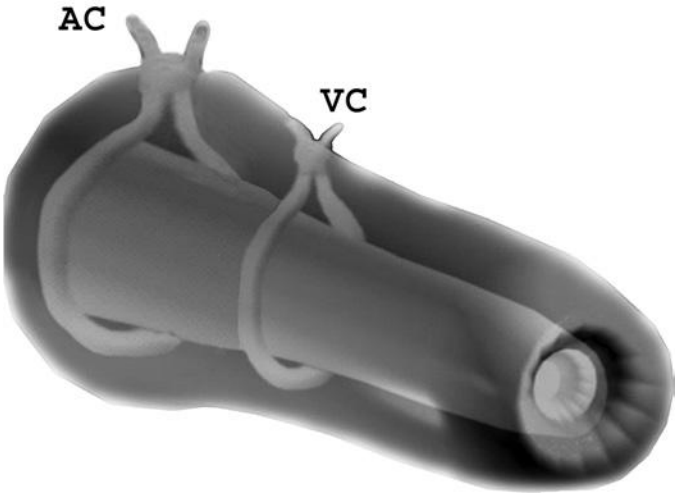

FIG 18-12 Three-dimensional graphic of the cervix showing the usual locations of abdominal cerclage (AC) and vaginal cerclage (VC) placement. The AC is located high, close to the level of the lower uterine segment, whereas the VC is usually placed close to the middle of the length of the cervix.

Singleton Without Prior Spontaneous Preterm Birth (Low Risk)

Numerous studies have reported nomograms for CL in either nonselected (mostly low risk, defined as with no prior PTB, and some with prior PTB) or low-risk (with no prior PTB) pregnant women with singleton gestations.[29,64,65] In these women, CL is a continuous variable, with a mean of 35 to 40 mm measured between 14 to 30 weeks, with the lower 10th percentile measuring 25 mm and the upper 10th (90th percentile) measuring 50 mm.[29,65] A progressive and natural shortening of CL is observed after 30 weeks, even in patients destined to deliver at term.[64] There may be a very slight progressive linear reduction of CL before 30 weeks.[66] There seems to be no difference in CL between nulliparous and multiparous women throughout pregnancy, whereas risk factors for PTB such as African origin, age younger than 20 years, low body mass index, and prior miscarriage or PTB are associated with a shorter CL.[66]

In asymptomatic singleton gestations, as in all other groups, the shorter the cervix, the higher the risk of PTB.[1] Using different cutoffs for CL from 15 to 34 mm, the positive predictive values ranged from 6% to 44%.[1] These relatively low values are likely due, at least in part, to the low prevalence of PTB in this population (0.8% to 15%). In one

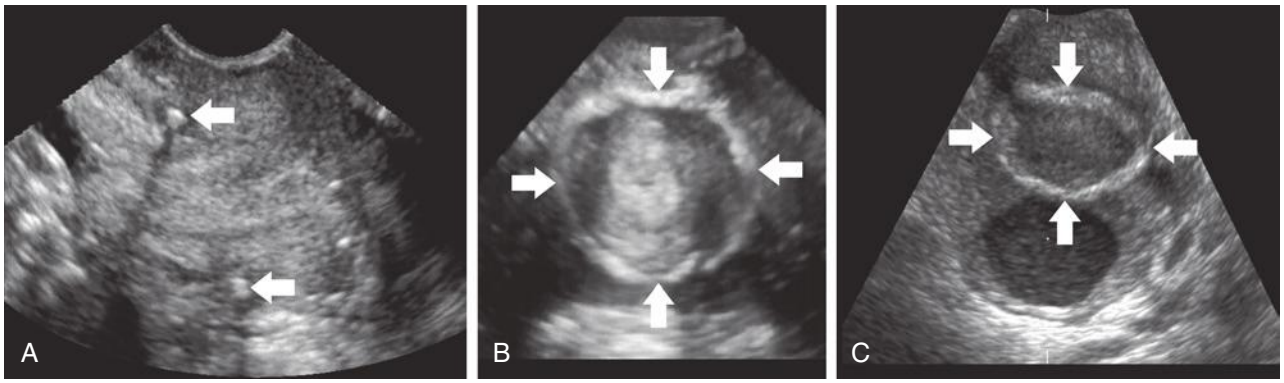

FIG 18-13 Transvaginal ultrasound images of the cervix with vaginal cerclage. **A,** Two-dimensional (2D) sagittal ultrasound image of the cervix. In this plane of section, the cerclage suture appears as two bright echoes (*arrows*) within the anterior and posterior cervical stroma, surrounding the endocervical canal. **B,** Three-dimensional (3D) ultrasound-derived image in the axial plane. In this view of the cervix, the vaginal cerclage suture is depicted in its entirety (*arrows*). **C,** 3D ultrasound-derived image in the axial plane. In this case, the vaginal cerclage suture (*arrows*) is well visualized and noted to have pulled through, located within the anterior lip of the cervix, anterior to the dilated endocervical canal.

of the better-designed, larger studies,[29] the sensitivity was only 37% and the positive predictive value only 18%. This means that the majority (63%) of the few women without risk factors who delivered preterm were not identified by TVU screening, and that 82% of these low-risk patients who were found to have a short CL less than 25 mm at 24 weeks delivered at or after 35 weeks.

Singleton With a Prior Spontaneous Preterm Birth (High Risk)

There are over 30 different risk factors for PTB.[67] Several studies have assessed the predictive value of TVU-CL in women with some of the most important risk factors, including prior PTB,[39] cone biopsy,[58] two or more voluntary terminations,[59] or müllerian anomaly.[60] As Table 18-4 shows, CL between 14 and 24 weeks is predictive of PTB in all of these high-risk populations. In fact, the more worrisome the obstetric history, the shorter the cervix, because prematurity risk is a continuum.[68] A woman with clinical risk factors for PTB who has a normal (≥25 mm) CL between 18 and 22 weeks has a less than 10% risk of PTB, representing a significant reduction in risk and potentially preventing unnecessary interventions. On the contrary, the sensitivity of TVU-CL to determine which high-risk women will deliver preterm is about 70%, much higher than in low-risk women. The incidence of PTB at less than 35 weeks is often greater than 50% when the additional risk factor of TVU-CL less than 25 mm is discovered before 24 weeks in these high-risk women. The positive predictive values are also much higher in high-risk than in low-risk women (see Table 18-4). PTB within 4 weeks of TVU occurs in about 13% of asymptomatic women with short CL and in none of the pregnancies without such ultrasound findings; thus, steroid therapy for fetal lung maturity is rarely indicated, even in asymptomatic women with a short CL.[43] It is important to note that, at least in high-risk patients, PTB following the detection of a short CL is most often preceded by PPROM (48-68%) instead of PTL.[34,69] CL less than 10 mm in these women is particularly predictive of PPROM.[70] TVU in women with prior PTB at less than 32 weeks demonstrated that the best predictive accuracy is achieved with serial TVU examinations, assessing the shortest CL after spontaneous or TFP-elicited changes.[39] The sensitivity and positive predictive value reached 69% and 55%, respectively. This was the only blinded multicenter study controlled for quality performed in women at high risk for PTB and, therefore, contains the most reliable and valid predictive data in this population.[39]

Women With Cerclage

TVU of the cervix has been evaluated in women with history-indicated, ultrasound-indicated, or physical examination–indicated cerclage in place. Most studies have shown that transvaginal cerclage is placed in the middle portion of the cervix in the vast majority of cases (see Fig. 18-13).[71-73] Transabdominal cerclage is instead placed at the level of the internal os (see Fig. 18-14). The higher (closer to the internal os) the cerclage suture is placed, the more effective the prevention of PTB.[74,75] Evaluation of precerclage and postcerclage TVU-CL has shown that CL measurement usually increases after cerclage, and that an increase in CL is associated with a higher rate of term delivery.[76,77]

Studies evaluating the accuracy of TVU for predicting PTB in patients with cerclage[71-73,76] show that TVU-detected cervical parameters are predictive of PTB. CL less than 25 mm and upper cervix (the closed portion located above the level of the cerclage; see Fig. 18-13) less than 10 mm are probably the two best predictive parameters.

Women With Pessary

Despite the lack of widespread evidence of the benefit of a pessary in preventing PTB,[78] interest in using a pessary has resurfaced as a result of the PECEP trial, an RCT showing a significant decrease in PTB and improved neonatal outcome.[10] Several studies are under way to provide

guidance supporting or refuting the use of a pessary. Some clinicians follow-up CL assessment with TVU without removing the pessary. One study has shown minimal interobserver difference using this method.[79]

Twins

Despite the significant risks of perinatal morbidity and mortality resulting from PTB in twin pregnancies, the prediction of PTB in twins using traditional clinical means is limited. A CL of 25 mm or less at 24 weeks' gestation has been found to be the best predictor of PTB in twins, including studies evaluating fetal fibronectin and bacterial vaginosis[61] (see Table 18-4). Compared with singleton pregnancies, twin pregnancies that deliver at term have been shown to have a similar TVU-CL at 14 to 19 weeks but a progressively shorter cervix after 20 weeks' gestation.[80] Because cervical shortening can occur after 20 weeks' gestation even in some twin pregnancies destined to deliver at term, TVU of the cervix before 20 to 24 weeks may lead to better prediction of PTB. Unfortunately, the predictive value of sonographic CL determination in twins between 24 and 34 weeks' gestation is low.[81] As with high-risk singletons, a short cervix is a good predictor of PTB in twins. Importantly, fewer than 10% of twin pregnancies with sonographic CL measuring greater than 35 mm between 18 and 26 weeks deliver before 35 weeks.[82] This reassuring finding could allow obstetricians to avoid instituting bed rest or other interventions commonly used in management of twin pregnancies. Unfortunately, sensitivity of TVU-CL to predict which twin gestations will deliver preterm is only 30%. Some multiple gestations likely deliver preterm not primarily because of cervical insufficiency but because of rapid uterine expansion leading to contractions, a process not well screened by TVU-CL.[1]

Triplets

Few studies have reported on TVU of the cervix and prediction of PTB in triplet pregnancies. As shown in Table 18-4, sensitivity of TVU-CL to predict which triplet gestations will deliver preterm is low, as in twin gestations, making this screening test relatively ineffective in multiple pregnancies.[62]

THREE-DIMENSIONAL TRANSVAGINAL ULTRASOUND EXAMINATION OF THE CERVIX

Three-dimensional volume data, including for TVU-CL assessment, can be presented in a variety of orthogonal multiplanar displays in which sagittal, axial, and coronal views of the cervix are shown simultaneously (Fig. 18-15). The multiplanar view allows for visualization of anatomic planes that are not possible with two-dimensional ultrasound imaging (i.e., planes that are perpendicular to the ultrasound beam, such as the coronal view of the cervix). In addition, the three-dimensional multiplanar display makes possible visualization of the true midsagittal plane of the cervix by objectively selecting this plane in the coronal view. The coronal view of the cervix is a unique image obtained only with three-dimensional ultrasound, providing additional information regarding the shape and dimensions of the endocervical canal. Evaluation of the funneled cervix is also improved by using three-dimensional ultrasound, as it can be visualized in all three

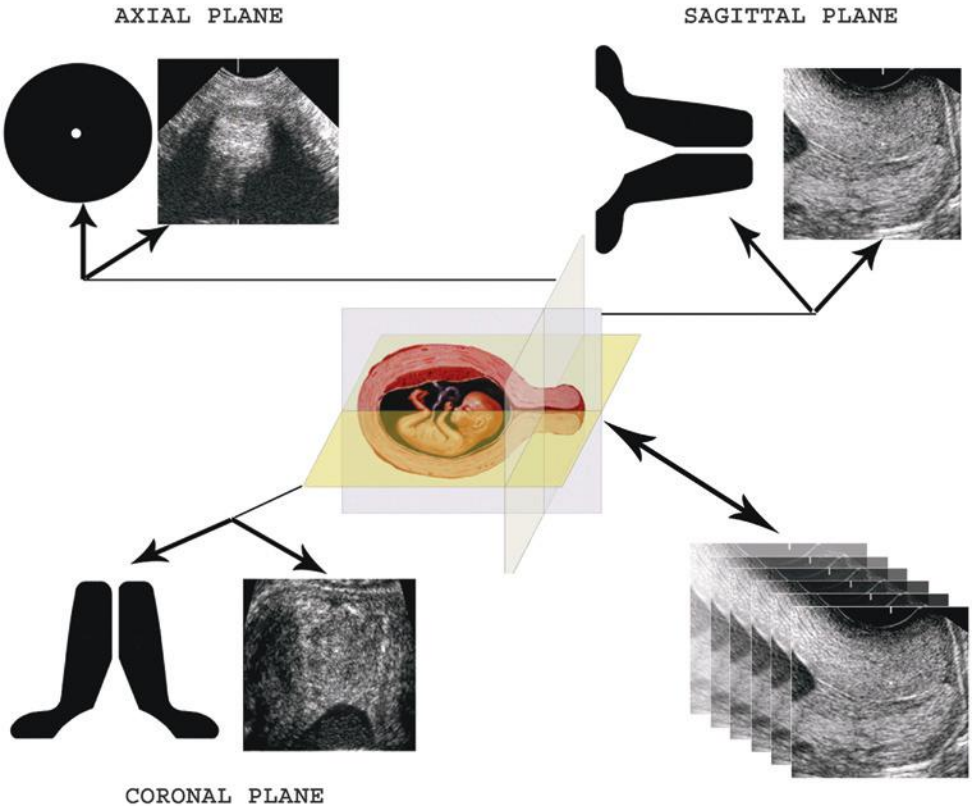

FIG 18-15 Diagram illustrating three-dimensional volume acquisition of two-dimensional images of the cervix in the sagittal plane and subsequent display of the cervix in three orthogonal planes (sagittal, axial, and coronal). Note that these three planes simultaneously shown are interactively linked to each other in a 90-degree (orthogonal) relationship. The evaluation of the cervix is not limited to the sagittal plane but extends with imaging in the axial and coronal planes. Note that cervical length and funnel length and width are shown both in the sagittal and coronal planes.

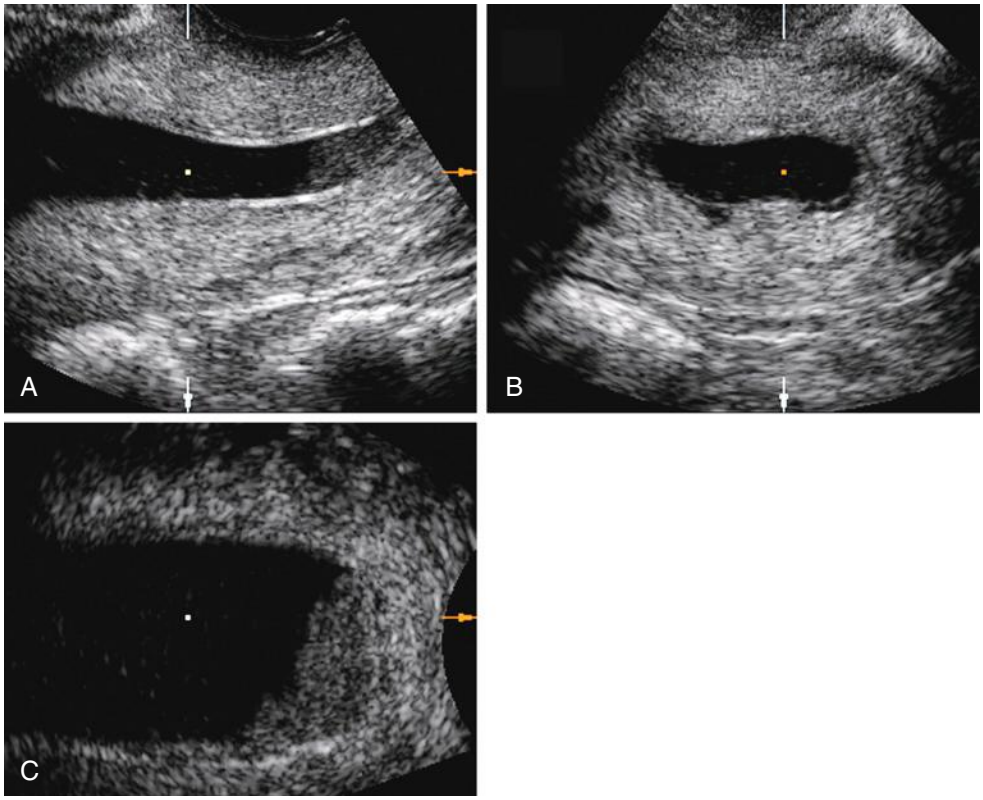

FIG 18-16 Multiplanar display of the cervix in sagittal (**A**), axial (**B**), and coronal (**C**) planes. Significant funneling of the cervix with low level echoes is referred to as sludge in the dilated endocervical canal. The sludge is best visualized in the coronal plane (C). Note that the width of the funnel as shown in the coronal plane (C) is more than twice its height as shown in the sagittal plane (A).

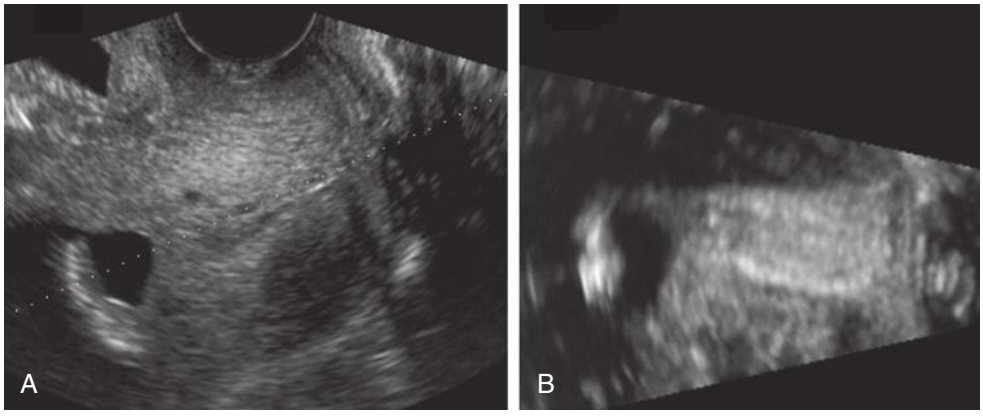

FIG 18-17 Virtual contrast imaging (VCI) of the cervix, also referred to as thin volume imaging. Two-dimensional (2D) sagittal ultrasound image of the cervix (**A**) displayed simultaneously with a VCI-derived image of the cervix in the coronal plane (**B**). This dual view enables the operator to evaluate the cervix in real time in both the sagittal and the true coronal planes. This is done by properly placing the dotted line along the preferred axis in the 2D image, as shown in A.

planes: sagittal, axial, and coronal. Measurements of the funnel or endocervical canal widths in the coronal plane are not necessarily the same as their respective sagittal values, which may provide additional, potentially useful information[83] (Fig. 18-16). Three-dimensional ultrasound makes it possible to obtain an axial plane through the cervix at the level of a cerclage, demonstrating the entire stitch (see Figs. 18-13 and 18-14).[83] This view is not readily obtainable with conventional two-dimensional sonography. Whether three-dimensional ultrasound imaging enhances clinical management in patients with or without cerclage in place is unknown. New display and acquisition methods enable the operator to view the cervix in multiple slices in operator-selectable distances and planes (Fig. 18-17). Further research is needed to evaluate whether this additional information is of clinical benefit.

WHAT PATHOPHYSIOLOGIC MECHANISMS ASSOCIATE A SHORT CERVICAL LENGTH WITH PRETERM BIRTH?

Three primary mechanisms have been associated with the development of an asymptomatic short TVU-CL. First, a short CL can be

caused by a specific weakness of the cervix, or cervical insufficiency (this term is preferred rather than "cervical incompetence").[84] Cervical insufficiency is due in most cases to traumatic or surgical damage. Women with one or more dilatation and evacuation or curettage procedures for termination of pregnancy have a higher incidence of short TVU-CL, as well as an increased risk of PTB.[85] Clinically, it is extremely rare to observe a short TVU-CL due to a maternal congenital disorder or connective tissue disease. It is interesting to note that almost no pregnant women, even those at high risk, have a short CL in the first trimester.[59] It is thought that the early developing intrauterine pregnancy exerts little pressure on the cervix and is unlikely to result in dilatation, even in the setting of cervical insufficiency.

Second, a short CL can develop secondary to an inflammatory or infectious process. There is a strong association between short TVU-CL and infection. High amniotic fluid interleukin 6 (IL-6), later development of chorioamnionitis,[86] and acute inflammatory lesions of the placenta[87] have all been associated with short CL. Women with both a short CL and bacterial vaginosis have a higher incidence of PTB than matched women with a short CL but no bacterial vaginosis.[88] Short CL leading to PTB is often associated with PPROM and not with PTL, providing additional evidence for the role of infection.[89] There is insufficient evidence thus far to determine if infection results in the development of short CL or, alternatively, if this association between infection and short CL occurs because short CL allows ascending infection from the vagina. A short CL can allow easier access of potentially pathologic vaginal organisms into the intrauterine environment, leading to prolonged subclinical chorioamnionitis and subsequent PTB. Women with a normal CL have mechanical and immunologic protection against the ascent of lower vaginal organisms.

Third, studies have shown that the majority of asymptomatic women with CL less than 25 mm before 24 weeks have contractions more often than control subjects with normal CL.[90,91] It is unclear whether contractions cause the short CL, are a result of the short cervix, or whether these two factors exert interactive effects.

Most probably, the three aforementioned mechanisms, in addition to other factors, act synergistically in some women to contribute, in different ways in each individual, to the development of a short CL.

CLINICAL USE OF CERVICAL LENGTH FOR PREVENTION OF PRETERM BIRTH

TVU-CL is a predictor of PTB. As with any predictor, an effort to avoid its occurrence is the first step toward prevention. There are limited studies on the primary prevention of short CL. Progesterone therapy has been associated with preventing the development of a short CL,[92] but more studies are needed in this area investigating the impact on reducing PTB.

Algorithms for care using TVU-CL measurements to screen for PTB risk are evolving, particularly as more randomized studies on interventions based on short TVU-CL are published and as professional societies disseminate updated guidelines.[18-20] Included here are the currently recommended evidence-based management schemes.

Asymptomatic Singletons Without Prior Spontaneous Preterm Birth

An TVU-CL assessment can be offered to *all* pregnant women carrying singletons at 18 to 22 weeks (i.e., the time of the "anatomy" ultrasound examination) including those without prior PTB. Screening based on other risk factors is not recommended, as it has not been sufficiently studied, and because in many populations the large majority of pregnant women have at least one risk factor for PTB (96% in our urban U.S. population).[93]

The algorithm shown in Figure 18-18 has been recommended for clinical use by SMFM[18] and was subsequently endorsed by ACOG.[19]

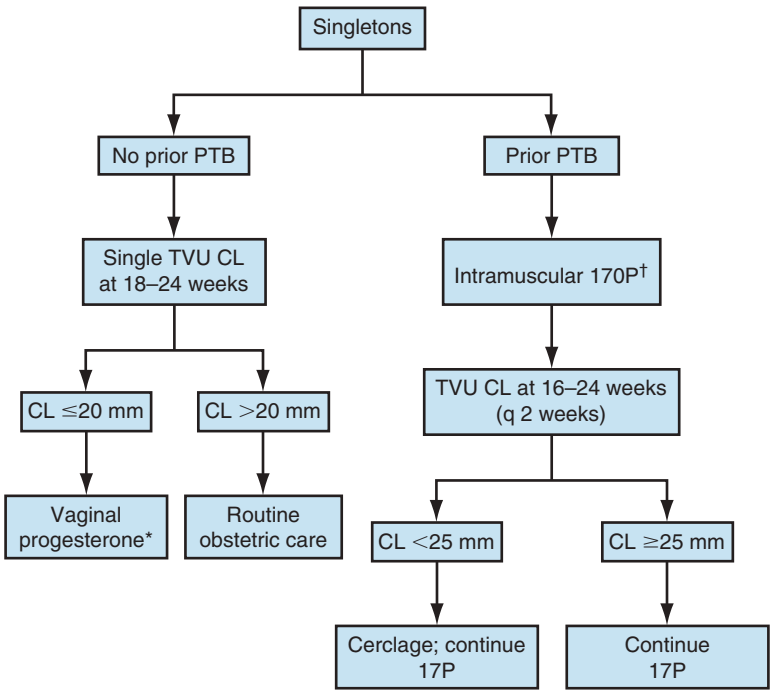

FIG 18-18 Algorithm for use of progestogens in prevention of preterm birth in clinical care. CL, cervical length; PTB, preterm birth; 17P, 17α-hydroxyprogesterone caproate; TVU, transvaginal ultrasound. *For example, daily 200 mg suppository or 90 mg gel from time of diagnosis of short CL to 36 weeks. †250 mg intramuscularly every week from 16 to 20 weeks to 36 weeks. (Adapted from Society for Maternal-Fetal Medicine Publications Committee, with assistance of Vincenzo Berghella: Progesterone and preterm birth prevention: translating clinical trials data into clinical practice. Am J Obstet Gynecol 206(5):376-386, 2012.)

The term *universal CL screening* has been used to refer to TVU-CL screening in singleton pregnancies without prior PTB. In general, over 80% to 90% of women accept TVU-CL screening, especially if offered with an opt-out approach, in the absence of a language barrier.[94] Women with a prior term birth tend to have a lower acceptance rate,[95] as they likely are less concerned about the possibility of PTB. Approximately 1% of women carrying singletons without prior PTB who accept TVU screening have a short CL of 20 mm or less before 24 weeks.[94] Vaginal progesterone is recommended to reduce the risk of PTB in an asymptomatic woman with a singleton gestation without a prior PTB found to have TVU-CL of 20 mm or less before or at 24 weeks of gestation.[18,19] This recommendation is based on the reported approximate 45% decreased risk of PTB associated with this intervention found in two separate randomized trials.[3,4] Analyses of this management scheme (see Fig. 18-18) predict that up to 100,000 PTBs could be prevented, 1000 infants saved, and $13 billion saved annually in the United States.[17,30] Both SMFM and ACOG have therefore stated that implementation of such a screening strategy can be viewed as reasonable and can be considered by individual practitioners, following strict guidelines.[18,19]

Interestingly, in these women found to have short CL, activity restriction, such as bed rest, is *not* recommended, as it is associated with an *increase* in PTB compared to normal levels of activity.[96]

Cerclage has also not been shown to be associated with a significant reduction in PTB in singletons without prior PTB and a short TVU-CL less than 25 mm before 24 weeks, but the nonsignificant 24% reduction deserves further study.[97]

As previously discussed, pessary has been associated with a significant reduction in PTB in singletons without prior PTB and a short TVU-CL less than 25 mm before 24 weeks in one trial,[10] but a subsequent trial failed to confirm these results.[11] Further trials are in progress to assess the efficacy of pessary for prevention of PTB in women with short CL.

Asymptomatic Singletons With Prior Spontaneous Preterm Birth

Based on randomized trial data, it is recommended that women with singleton pregnancies with prior spontaneous PTB should start intramuscular injections of 17α-hydroxyprogesterone (17P) weekly at 16 weeks and continue until 36 weeks for prevention of PTB.[98] Although this regimen is associated with a 34% decrease in PTB, 36% of these women nevertheless delivered before 37 weeks (see Fig. 18-18).[98] Another trial reported a lower incidence of recurrent PTB in singletons with prior PTB in those who were randomized to vaginal progesterone 90 mg compared to 17P.[99]

Because cervical insufficiency as a cause of short CL is one of the leading hypotheses, cervical cerclage was the first intervention postulated to be of benefit in this clinical situation. Randomized studies on history-indicated (previously referred to as prophylactic, or elective) cerclage without the use of TVU have shown that this procedure does not prevent PTB in high-risk singleton gestations,[100,101] except for the subgroup of women with three or more prior second trimester losses or PTBs.[102] Nor is it beneficial in twin gestations.[103] Following these disappointing results, researchers have hypothesized that a subgroup of women could be identified with TVU of the cervix in whom cerclage may be beneficial. Cerclage was indeed devised more than 50 years ago for women with both a poor obstetric history characterized by second trimester losses and cervical changes in the current pregnancy.[104,105] The four randomized trials[7,9,106,107] on the efficacy of ultrasound-indicated cerclage have been analyzed in meta-analyses,[108,109] which allowed for larger numbers with more robust statistics and offered careful assessment of different populations of women with short CL. In fact, ultrasound-indicated cerclage has different effects in different populations (Table 18-5).[110,111] In women with singleton gestation and prior PTB or second trimester loss, the use of cerclage (performed if TVU-CL measures less than 25 mm prior to 24 weeks) is associated with a 30% significant decrease in recurrent PTB, and—most importantly—a 36% significant decrease in perinatal morbidity and mortality rates.[112] Based on these data, SMFM,[18] ACOG,[19] and RCOG[20] have all recommended that cerclage be offered to women with singleton gestations, prior spontaneous PTB, and TVU-CL less than 25 mm before 24 weeks.

TABLE 18-5 Efficacy of Ultrasound-Indicated Cerclage[110,111,138]

Population	Effect of Cerclage on PTB < 35 Weeks
Singleton gestations	
Low risk for PTB (no other risk factors)	No significant difference
Prior PTB at 16-36 weeks	30% decrease
Prior second trimester loss	43% decrease
Twin gestations	No significant difference

PTB, preterm birth.

The randomized trial[107] that showed the most benefit from cerclage included administration of indomethacin to the women studied, and not to the control subjects, raising the possibility that indomethacin may have contributed significantly to the prevention of PTB. Analysis of the effect of indomethacin indeed reveals that it can prevent PTB less than 24 weeks and PPROM in women with short CL.[113] Given that women with short CL are often found to have contractions,[90,91] it is possible that one of the efficacious interventions in this setting is tocolytic therapy.

A short CL has also been associated with infection. Analysis of the use of antibiotics reveals no effect of this therapy on prevention of PTB in women with short CL.[108] Unfortunately, antibiotics have often failed to prevent PTB when used for other risk factors for PTB, such as prior PTB,[114] positive fetal fibronectin,[115] or symptomatic PTL.[116]

An added benefit of screening with TVU to determine CL in this population is that it can be used to avoid performing unnecessary interventions (e.g., cerclage) in high-risk women whose TVU-CL remains normal. About 60% of such high-risk women, who are carrying singleton pregnancies with prior history of spontaneous PTB, maintain a normal CL until after 24 weeks and deliver at term and can thus be spared any intervention. Only about 40% of such high-risk women develop a short CL and are at true risk of PTB, and these women can be offered intervention. Management of singleton gestations with prior spontaneous PTB, even early in gestation, with serial TVU-CL appears to be a safe alternative to a policy of placing history-indicated cerclage in all such women, as confirmed by a meta-analysis studying approximately 400 women included in four randomized trials that addressed this issue.[109]

Asymptomatic Multiple Gestations

Currently no interventions have been definitively shown to be beneficial in preventing PTB and its consequences in multiple gestations with short CL. Cerclage is not beneficial and may in fact be harmful, but this procedure been evaluated in a total of only 49 twin pregnancies with TVU-CL less than 25 mm before 24 weeks randomized to cerclage or no cerclage.[117] Pessary has been associated with significant reductions in PTB less than 28 weeks and less than 32 weeks as well as with composite poor perinatal outcome in a secondary analysis of an RCT including 133 twin pairs with TVU-CL less than 38 mm before 23 weeks, but more data from dedicated RCTs are needed.[118]

17P caproate has been found to not be beneficial when studied in 175 twin pregnancies (>90% of whom had no prior spontaneous PTB) with TVU-CL 25 mm or less before 24 weeks in a recent meta-analysis.[119] In contrast, vaginal progesterone has been found to have some benefit in preventing either PTB or adverse perinatal outcome in a limited number (<60) of twin pregnancies (>95% of whom had no prior spontaneous PTB) with TVU-CL 25 mm or less before 24 weeks in two meta-analyses,[119,120] but again more data from dedicated RCTs are needed.

In summary, the evidence is insufficient to support TVU-CL screening in all twin pregnancies for PTB prevention. If large, well-designed RCTs confirm the benefits of pessary or vaginal progesterone in twins with short TVU-CL before 24 weeks, then TVU-CL could become an effective screening test for this very high risk population.

Preterm Labor

TVU of the cervix has been studied extensively as a predictor of PTB in women with symptoms of PTL (see Table 18-4). All studies have reported a statistically significant positive predictive accuracy of TVU-CL for PTB.[121] The presence of sludge (see Fig. 18-16) in women with suspected PTL is associated with intra-amniotic infection and high risk for PTB.[49] TVU-CL is helpful in the clinical management of women with suspected PTL. First, it helps confirm or exclude the diagnosis. The diagnosis of PTL has usually been made between 20 and 36 weeks by documenting regular uterine contractions and cervical change by manual examination. However, more than 70% of women given the diagnosis of PTL deliver at term and thus might receive unnecessary intervention. Women with these clinical findings but TVU-CL 30 mm or greater have less than 1% chance of delivering within 1 week and less than 10% chance of delivering before 35 weeks. Such women therefore are unlikely to benefit from administration of corticosteroids for fetal lung maturity, tocolysis, or other interventions. The diagnosis of PTL should be confirmed by documenting TVU-CL less than 20 mm, and only those women in whom such measurement is confirmed should receive interventions.[121]

A randomized trial studying the use of the algorithm shown in Figure 18-19 for management of women with PTL at 24 to 34 weeks was associated not only with a shorter time in triage, but also with a 65% decrease in PTB less than 37 weeks.[122] We recommend use of this protocol, based primarily on TVU-CL assessment, for management of women with threatened PTL.

The potential utility of repeat measurements of CL following tocolysis for PTL has been studied and found to predict PTB, but not with any more accuracy than the first measurement at presentation. The variation in CL between the first and subsequent measurements seems not to be predictive of PTB, such that the authors of this study concluded that "to repeat ultrasonographic CL measurement after successful tocolysis [may be] useless."[123]

Preterm Premature Rupture of the Membranes

Several studies have evaluated the utility of TVU of the cervix in women with PPROM. A randomized trial demonstrated the safety of performing TVU in this group, finding that women who had TVU experienced similar incidences of maternal and neonatal infections as did control subjects who did not undergo TVU.[29] The latency from PPROM to delivery is directly correlated with CL; thus, women with shorter CLs have shorter latencies.[124,125] No studies have assessed whether this clinical knowledge affects outcomes.

Prediction of Start of Spontaneous Labor

TVU of the cervix can also be useful in predicting onset of labor in pregnant women at term.[126,127] Based on TVU-CL measurements at 37 weeks, the mean gestational age at delivery increased from 38 weeks for women with CL of 10 mm to 41 weeks for women with CL of 35 mm. There is a 68% chance of delivering after 41⅐ weeks if CL measures greater than 40 mm (Fig. 18-20).[131] CL was also found to be an independent predictor of spontaneous labor in nulliparous women and of vaginal delivery in nulliparous and parous women.[128]

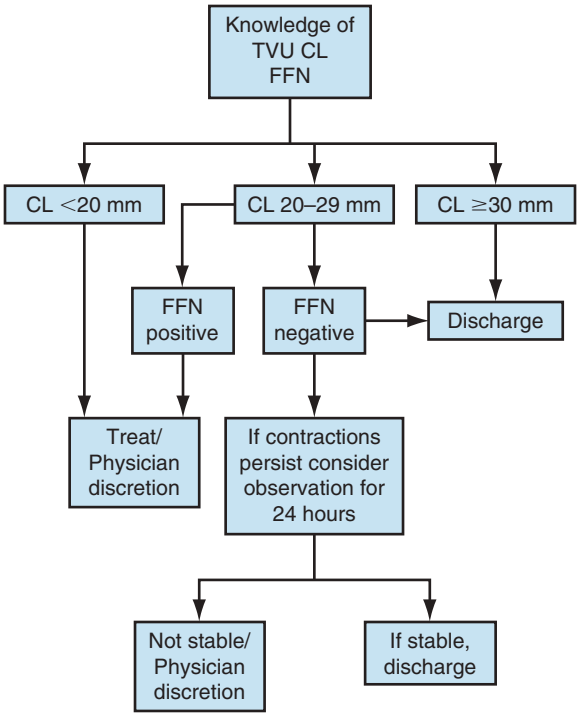

FIG 18-19 Algorithm for management of women with preterm labor based mainly on cervical length. CL, cervical length; FFN, fetal fibronectin; TVU, transvaginal ultrasound. (Adapated from Ness A, Visintine J, Ricci E, Berghella V: Does knowledge of cervical length and fetal fibronectin affect management of women with threatened preterm labor? A randomized trial. Am J Obstet Gynecol 197(4):426.e1-e7, 2007.)

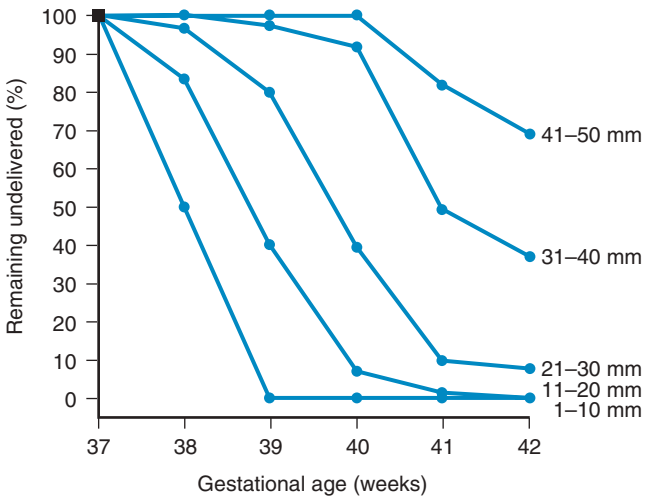

FIG 18-20 Survival curve estimates of percentages of women not delivered at different gestational ages, according to sonographically measured cervical length at 37 weeks. (From Ramanathan G, Yu C, Osei E, et al: Ultrasound examination at 37 weeks' gestation in the prediction of pregnancy outcome: the value of cervical assessment. Ultrasound Obstet Gynecol 22:598, 2003, redrawn with permission.)

Predicting the Success of Labor Induction and Mode of Delivery

Several studies have evaluated the predictive accuracy of TVU of the cervix in term gravidas to predict the length of induction and incidence of success (vaginal delivery). Short CL (<30 mm,[129] <28 mm,[130] <26 mm,[131] or wedging[132]) is associated with short duration of labor and higher incidence of vaginal delivery compared with a longer cervix. Although some studies did not find that TVU of the cervix added significantly to the prediction obtained by noting dilatation of the cervix on manual examination,[133,134] most did find that TVU-CL was a better predictor than any Bishop score parameter.[127,129-131] A randomized trial showed that the use of TVU-CL instead of Bishop score for management of labor induction is associated with a decreased need for intracervical prostaglandin treatment, without adverse effects on the success of induction.[135] Women in spontaneous labor with TVU-CL less than 20 mm have been found to have just a 4% incidence of cesarean delivery, whereas women in labor with TVU-CL greater than 40 mm have a 12% chance of cesarean delivery.[127]

CONCLUSIONS

TVU for cervical assessment is one of the best techniques for predicting PTB. The use of TVU of the cervix has been found to be safe and acceptable to patients. CL measuring less than 25 mm between 16 and 24 weeks of gestation has been shown to be the most reliable threshold associated with an increased risk of PTB. The shorter the cervix and the earlier in gestation the shortening occurs, the higher the risk of PTB. The role of TVU of the cervix has been studied in a wide variety of clinical settings and with different patient populations, consistently finding good prediction of PTB risk. Screening frequency should depend on detailed obstetric history, with serial TVU of the cervix having a better predictive accuracy than a single evaluation, especially in high-risk populations.

The algorithms shown in Figures 18-18 and 18-19 guide evidence-based use of TVU-CL in three populations: singletons without prior spontaneous PTB; singletons with prior PTB; and singletons with threatened PTL. In all these settings, use of TVU-CL, with appropriate intervention if CL is found to be short, has been associated with significant reductions in PTB. The decreased incidence of PTB in the United States seen between 2006 (12.8%) and 2012 (11.5%) may indeed have been due, at least in some part, to the use of TVU in CL screening.

Moreover, TVU-CL can be used to safely avoid unnecessary interventions in women with normal CL measurements. There are still limited data concerning whether TVU of the cervix is clinically useful for the prediction of the start of labor or success of labor induction. Future research on all these clinical applications of TVU of the cervix has the potential to further improve the health outcomes of pregnant women and their babies.

Ultrasound Evaluation of the Placenta, Membranes, and Umbilical Cord

Jodi S. Dashe, Barbara L. Hoffman

SUMMARY OF KEY POINTS

- Assessment of the relationship between the placenta and the internal cervical os is an essential component of sonography in the second and third trimesters.
- Placenta previa is identified in 1% to 5% of second-trimester sonograms but is present at birth in only 3/1000 births.
- Transvaginal sonography is considered safe regardless of placental location, even in the presence of bleeding.
- Conditions associated with vasa previa include resolved placenta previa or low-lying placenta, velamentous cord insertion, and succenturiate or bilobate placenta.
- Sonographic criteria for detection of placenta accreta include placental lacunae, thinning of the retroplacental myometrium, and irregularity or disruption of the bladder-serosal interface, with bridging vessels between the placenta and the bladder-serosal interface on color Doppler imaging.
- A placental hematoma initially appears isoechoic to the placenta, becoming hypoechoic within 1 week and sonolucent in approximately 2 weeks.
- Targeted sonography is indicated if there are abnormalities of the umbilical cord or its vessels, including umbilical cord cyst, single umbilical artery, or persistent right umbilical vein, to evaluate for the presence of associated fetal anomalies.

OUTLINE

PLACENTAL DEVELOPMENT

In early human development, the blastocyst typically implants in the upper uterine corpus and contains two cell types. The outer *trophoblast* layer will form the placenta. The inner cell mass or *embryoblast* gives rise to the embryo, amnion, and umbilical cord (Fig. 19-1). Following implantation, trophoblast cells at the embryoblast pole proliferate and become a double layer, each with its own function. The outer *syncytiotrophoblast* is a multinucleate syncytium that lacks distinct cells. It produces multiple hormones and is responsible for maternal-fetal gas, nutrient, and waste exchange. In contrast, the inner *cytotrophoblasts* have distinct cell membranes, are mitotically active, and serve as stem cells for the syncytiotrophoblast. During its life cycle, a cytotrophoblast first divides and proliferates. Then later, its cell walls disintegrate, and its contents merge into the expanding syncytiotrophoblast. At day 7 after conception, the syncytiotrophoblast at the embryoblast

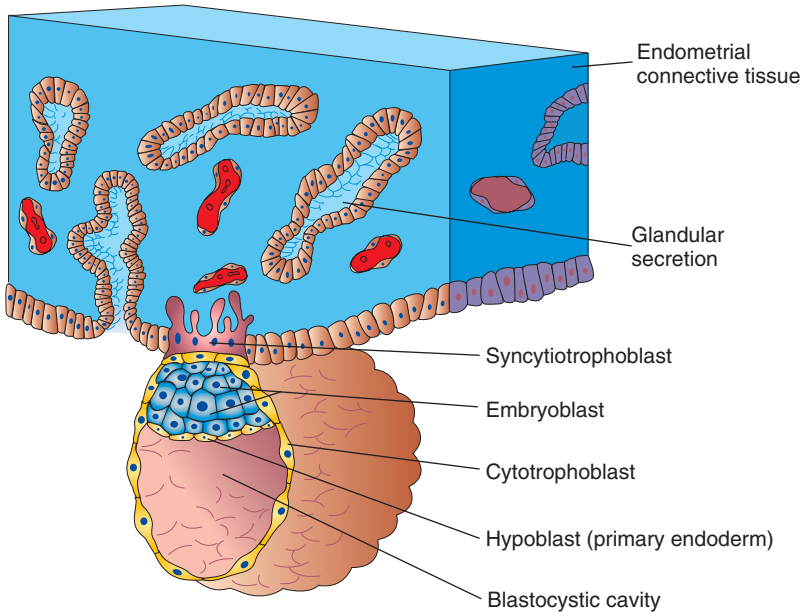

FIG 19-1 Following blastocyst attachment, the syncytiotrophoblast invades the endometrium, which is hormonally prepared for implantation. (From Moore KL, Persaud TVN, Torchia MG: The first week of human development. In Moore KL, Persaud TVN, Torchia MG [eds]: The Developing Human: Clinically Oriented Embryology, 9th ed. Philadelphia, WB Saunders, 2013, p 37, Fig. 2-19B.)

pole invades the decidua, which is endometrium that has been primed for pregnancy. Following initial invasion, the syncytiotrophoblast grows and spreads to surround the entire conceptus. During invasion, decidual blood vessels and glands are entered, and released blood fills lacunae or lakes within the syncytium (Fig. 19-2). These lacunae eventually form the intervillous spaces. The syncytium is then invaded by cytotrophoblasts, and by definition, *primary villi* are thereby formed. Penetration extends the full thickness of the syncytiotrophoblast, and cytotrophoblasts meet at the bottom to form a circumferential trophoblast shell. Here, the primary villi are anchored.

Following cytotrophoblast invasion, extraembryonic mesenchyme moves into the primary villi to form *secondary villi* (Fig. 19-3). Next, angiogenesis begins within secondary villi, which are then termed *tertiary villi*. During this same time, vasculature from the early umbilical cord fuses with vessels of the *chorionic plate*, that is, the fetal surface of the placenta (Fig. 19-4). The *basal plate* is the opposite side, where the deeper invading trophoblast and the maternal decidua, specifically the decidua basalis, meet.

During the 7th week after menstruation, tertiary villi increase in diameter and develop into immature *intermediate villi*, which are important growth centers for villous tree branching. New branches begin first as syncytial sprouts. They are invaded by cytotrophoblasts and then by mesenchyme. Last, vessels develop within the mesenchyme. With this repeated branching and sprouting, the villous tree begins to attain its final form. Finally, at the beginning of the third trimester, slender mature intermediate villi branch to form *terminal villi*. During terminal villi angiogenesis, capillary growth exceeds villous growth. As a result, capillaries begin to coil and bulge to the periphery of a given villus. This bulging thins the trophoblast layers and creates the small diffusion distance needed for maternal-fetal exchange.

Distinct from these *villous trophoblasts*, some cytotrophoblasts break through the trophoblast perimeter and continue to invade into maternal tissue as *extravillous cytotrophoblasts*. These cells are further classified as *interstitial trophoblasts* and *endovascular trophoblasts*. The

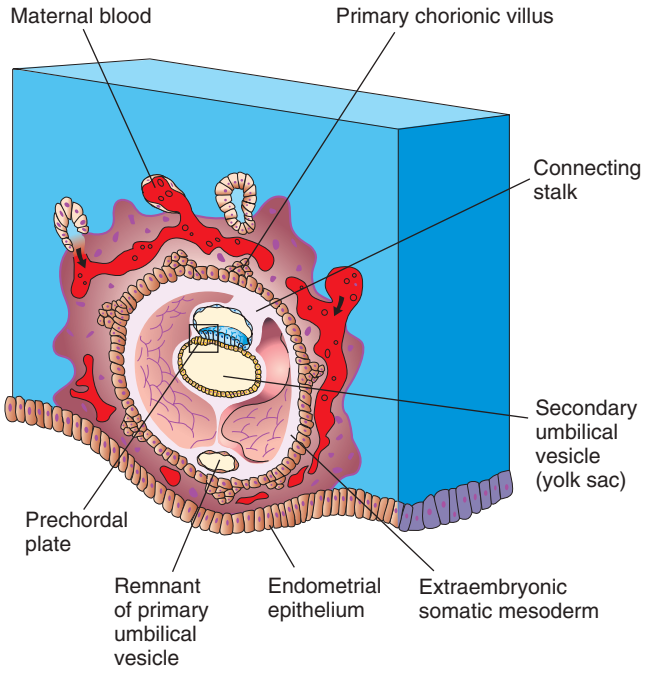

FIG 19-2 Syncytiotrophoblasts surround the entire conceptus and invade decidual blood vessels and glands. (From Moore KL, Persaud TVN, Torchia MG: Second week of human development. In Moore KL, Persaud TVN, Torchia MG [eds]: The Developing Human: Clinically Oriented Embryology, 9th ed. Philadelphia, WB Saunders, 2013, p 45, Fig. 3-5B.)

endovascular trophoblasts penetrate and plug maternal spiral arteries, which supply the decidua and intervillous space. Later, these cytotrophoblasts reverse their action and work to increase intervillous blood flow. For this, they invade the vascular media layer and replace its smooth muscle with fibrinoid material. This remodeling converts

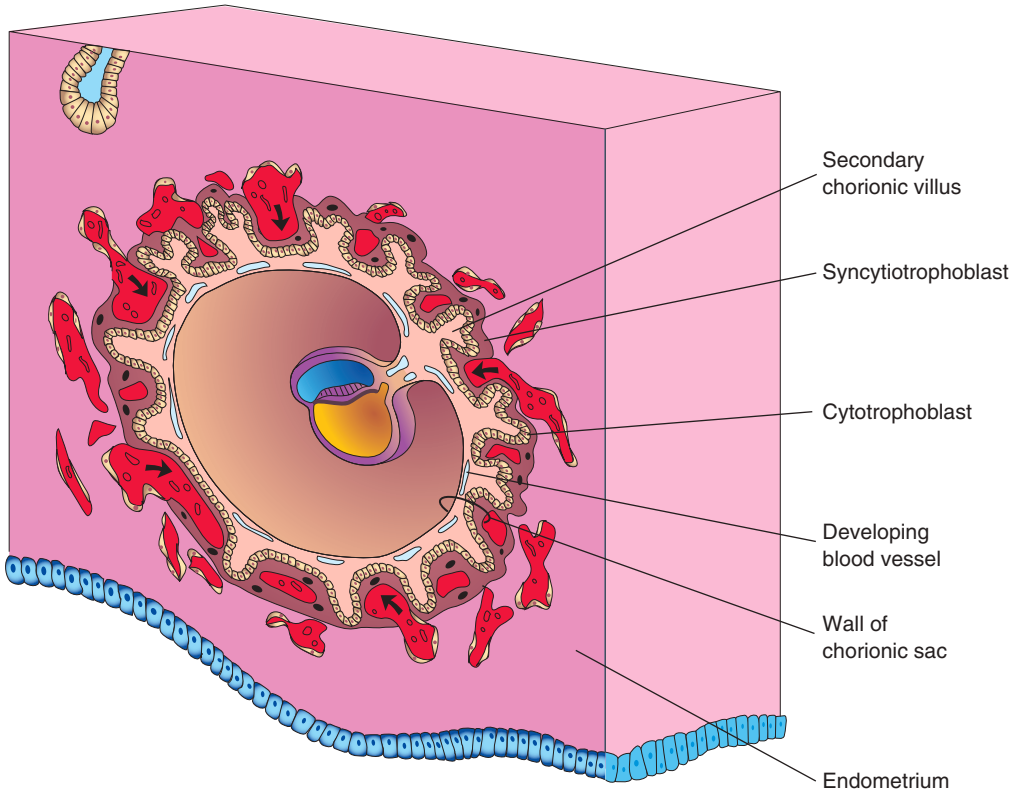

FIG 19-3 Extraembryonic mesenchyme (*light orange*) moves into the primary villi to form secondary villi. (From Moore KL, Persaud TVN, Torchia MG: Third week of human development. In Moore KL, Persaud TVN, Torchia MG [eds]: The Developing Human: Clinically Oriented Embryology, 9th ed. Philadelphia, WB Saunders, 2013, p 68, Fig. 4-14A.)

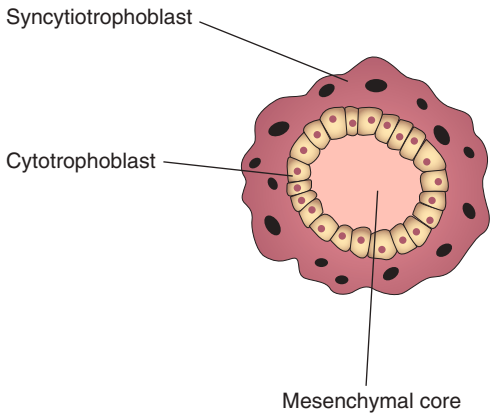

FIG 19-4 Angiogenesis begins within secondary villi, which are then termed tertiary villi. Concurrently, vessels of the chorionic plate join vessels within these villi and also fuse with vessels from the connecting stalk, which is part of the early umbilical cord. At this stage, the amnion (*blue*) surrounds the embryo. (From Moore KL, Persaud TVN, Torchia MG: Third week of human development. In Moore KL, Persaud TVN, Torchia MG [eds]: The Developing Human: Clinically Oriented Embryology, 9th ed. Philadelphia, WB Saunders, 2013, p 68, Fig. 4-14B.)

narrow-lumen, muscular spiral arteries into dilated, low-resistance uteroplacental vessels. In contrast, the interstitial trophoblasts invade the decidua and surround spiral arteries. Their functions are less well understood and may include vessel preparation for endovascular trophoblast remodeling.

Within the mature maternal-fetal circulation, oxygen-carrying maternal erythrocytes first enter the intervillous space via spiral arteries. Here, maternal blood is forced into close contact with terminal villi. Oxygen diffuses through the syncytiotrophoblast and then through the widely spaced but contiguous cytotrophoblast layer into fetal erythrocytes within capillaries of each terminal villous branch. Capillaries coalesce into larger fetal vessels within the main villus. From here, oxygenated fetal blood ultimately drains into the single umbilical vein and back to the fetus.

Normal Placenta

At term, the typical placenta weighs 470 g, is round to oval with a 22-cm diameter, and has a central thickness of 2.5 cm.[1] It is composed of a placental disk, extraplacental membranes, and a three-vessel umbilical cord. The maternal surface is the *basal plate*, which is divided by clefts into portions—termed *cotyledons.* These clefts mark the site where internal septa originating from the decidua basalis push up into the intervillous space. The fetal surface is the *chorionic plate*, into which the umbilical cord inserts, typically in the center. Large fetal vessels that originate from the cord vessels then spread and branch across the chorionic plate before entering stem villi of the placental parenchyma. When examining the placenta, either following delivery or during fetoscopic surgery—for example, during laser therapy for twin-twin transfusion syndrome—the fetal arteries almost invariably cross over fetal veins. The chorionic plate and its vessels are covered by amnion.

Sonographically, the placenta in the first and early second trimesters appears homogeneous in echotexture and mildly hyperechoic compared with the underlying myometrium. It then becomes more isoechoic with advancing gestation (Fig. 19-5). As examples, after

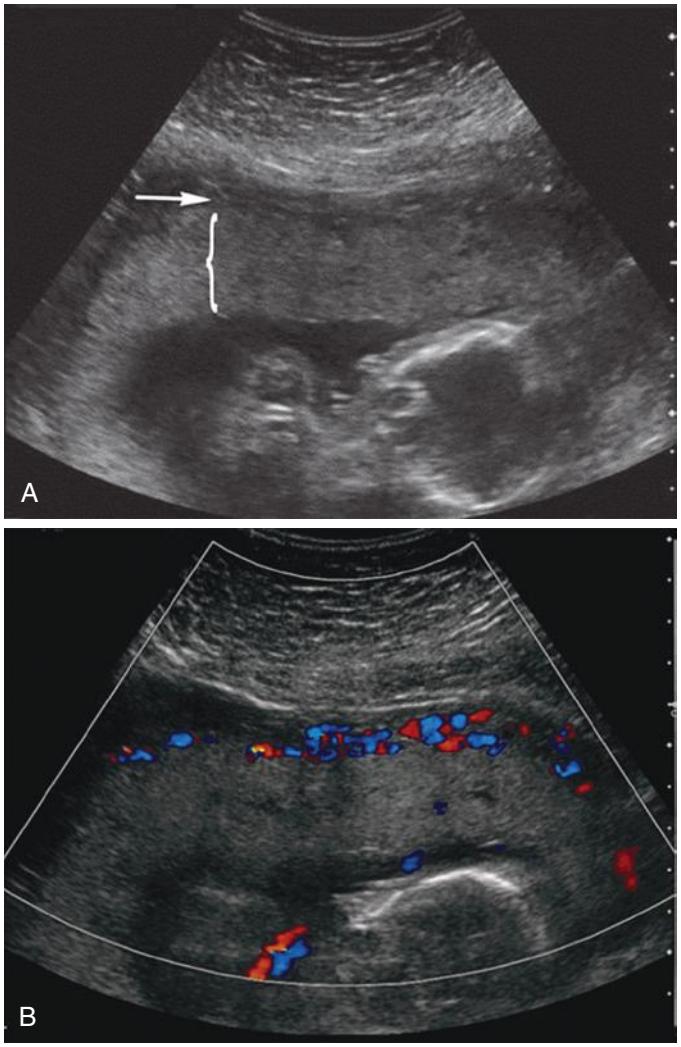

FIG 19-5 Second-trimester placenta. **A,** The placenta is isoechoic with its adjacent myometrium, its thickness is marked by the bracket, and an arrow points to the retroplacental space. **B,** With color Doppler, vessels are seen spanning the retroplacental space. (Courtesy of Adriana Male, RDMS, Parkland Health and Hospital Systems, Dallas, Texas.)

midpregnancy, it is common to identify small placental sonolucencies, and in the third trimester, the placenta may appear more heterogeneous, with visible calcifications.

The sonographic thickness is usually greater than that of the gross specimen owing to collapse of intervillous spaces as blood drains from the placenta. As a general rule, the placental thickness in millimeters roughly approximates the gestational age in weeks.[2-4] It does not normally exceed 4 cm in the second trimester or 6 cm in the third trimester. The retroplacental "clear" space normally measures less than 1 to 2 cm and, as the name suggests, appears hypoechoic. The retroplacental space is a common location of hematoma development. Inability to visualize the retroplacental space in a woman at risk for placenta accreta raises concern.

ABNORMALITIES OF PLACENTAL SHAPE AND THICKNESS

Abnormal Placental Shape

In contrast to the normal architecture described previously, placentas may form as separate disks of nearly equal size. This bilobate or bilobed placenta is also known as *placenta duplex*. The cord inserts *between* the two placental lobes, either into a connecting chorionic bridge or into intervening membranes. Sonographic detection of a bilobate placenta that has a chorionic bridge—normal placental tissue connecting the two lobes—is not likely, particularly if not specifically sought. However, if placental lobes are separated by intervening membranes and the cord inserts directly into these membranes, such that the cord insertion is *velamentous*, then sonographic detection may help to avoid cord avulsion at delivery. A placenta containing three or more equal-sized lobes is rare and termed *multilobate*.

FIG 19-6 This succenturiate lobe has vessels that travel within intervening membranes and connect it to the main placental disk. (Courtesy of Dr. Jaya George, University of Texas Southwestern Medical Center, Dallas, Texas.)

A *succenturiate lobe* is an accessory placental lobe that develops away from the main placental disk. The umbilical cord inserts into the main body of the placenta, and prominent vessels may be visible coursing along the intervening membranes (Figs. 19-6 and 19-7). If an accessory placental lobe is suspected, color Doppler sonography may be particularly helpful in identifying the location and path of these vessels. Occasionally, the vessels that connect the main body of the placenta to a succenturiate lobe overlie the cervix, a form of vasa previa. Clinically, an accessory lobe may be retained in the uterus after delivery and cause postpartum uterine atony and hemorrhage. Succenturiate lobe is encountered more frequently with in vitro fertilization and twin gestations.[5,6]

There are other rare placental shapes in which varying portions of the fetal membranes are covered by functioning villi. With *placenta membranacea,* all or nearly all of the membranes are covered with villi. This form of abnormal placentation may lead to serious hemorrhage, preterm delivery, and hysterectomy because of associated placenta previa or accreta.[7,8] With *ring-shaped placenta,* the placenta is annular, and a partial or complete ring of placental tissue is present. With *placenta fenestrata*, the central portion of a placenta disk is missing. These variants are not typically visible sonographically.

Abnormal Placental Thickness

Placentomegaly, an abnormally thickened placenta, is diagnosed if the placental thickness exceeds 4 cm in the second trimester or 6 cm in the third trimester (Fig. 19-8). There are numerous causes of placentomegaly, including maternal diabetes, severe maternal anemia, severe fetal growth restriction, aneuploidy, and congenital infections.[9-12] The latter include syphilis, parvovirus infection, cytomegalovirus infection,

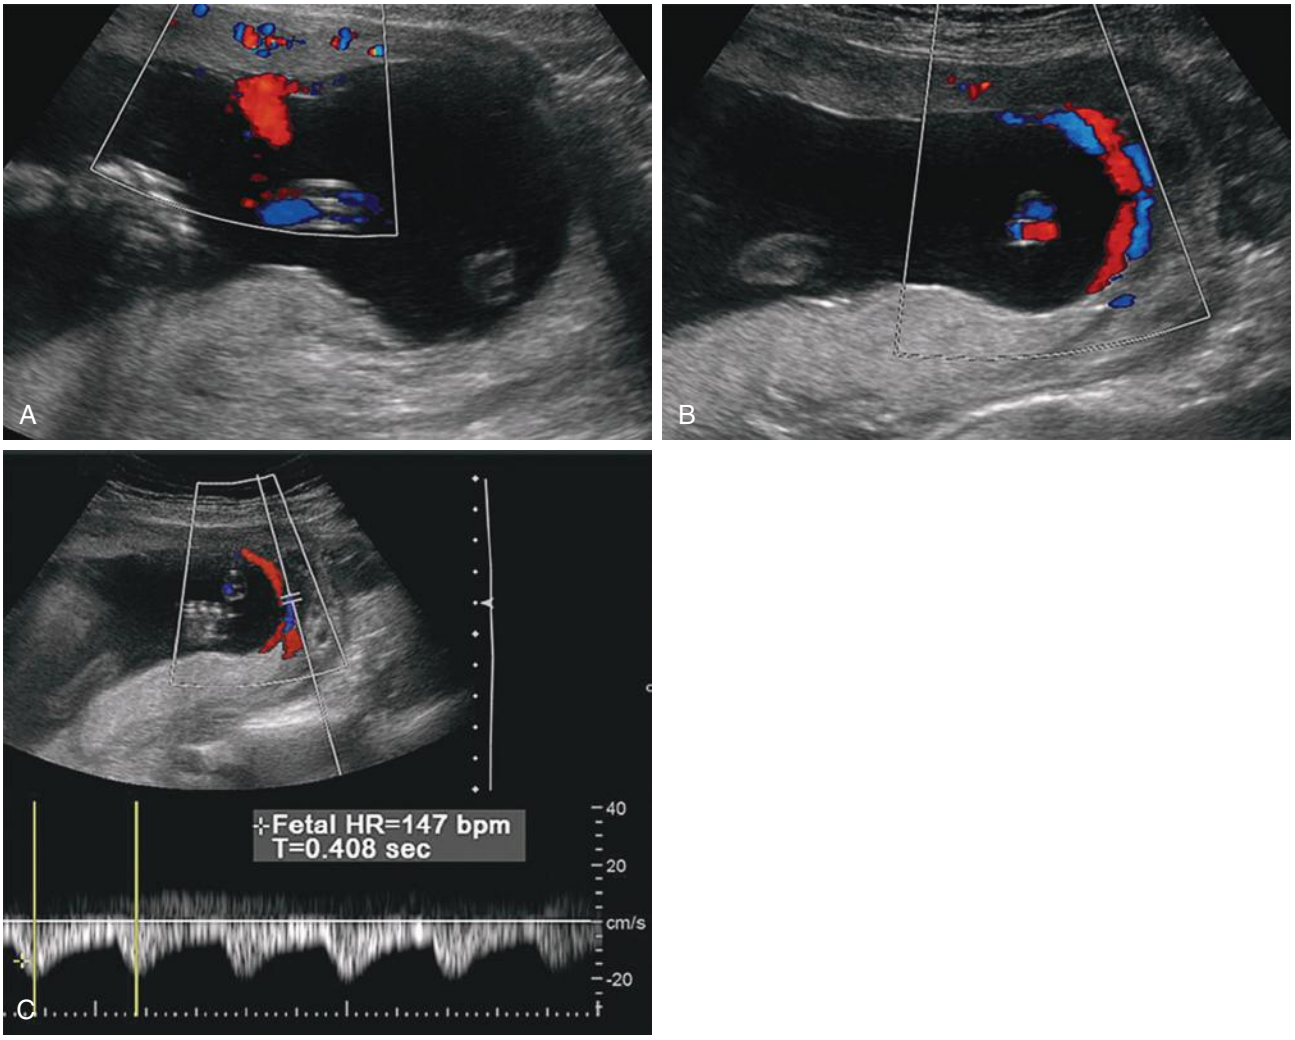

FIG 19-7 Succenturiate lobe. **A,** In this 20-week gestation, the umbilical cord inserts at the main body of the placenta, which is implanted anteriorly. **B,** Color Doppler sonography shows vessels connecting the main portion of the placenta to a posterior succenturiate lobe. **C,** Spectral Doppler interrogation of the arterial vessels connecting the succenturiate lobe to the placenta demonstrates a normal fetal heart rate (HR), 147 beats per minute (bpm).

toxoplasmosis, herpesvirus infection (rarely), and if at risk, rubella or schistosomiasis. Placentomegaly is a component of hydrops fetalis, and any cause that can result in immune or nonimmune hydrops may present with placentomegaly as a component. In some cases, placentomegaly may result from collections of blood or fibrin within the placenta. Examples include massive perivillous fibrin deposition, intervillous or subchorionic thromboses, and large retroplacental hematomas, which are described later. Neoplasia is a rare cause. Benign vascular lesions include chorioangioma and chorangiosis, also described in subsequent sections.

Gestational trophoblastic disease creates a thick cystic-appearing placenta. Cystic vesicles are also seen with placental mesenchymal dysplasia. Vesicles in this rare condition correspond to dilated stem villi that result from stromal expansion.

A placenta is not generally considered too thin, although focal attenuation may occur if a hematoma develops and subsequently resolves. A pregnancy with severe polyhydramnios may appear to have a thin placenta as a function of compression by fluid. A small placenta associated with a growth-restricted fetus may also appear thinner.

ABNORMALITIES OF PLACENTAL LOCATION

The placental location may reliably be assessed by 16 weeks' gestation. The location, whether anterior, posterior, left- or right-lateral, or a combination of these, should be noted in the sonogram report. A survey of the uterus for accessory placental tissue—a succenturiate lobe—and an assessment of the placental cord insertion site, if visible, should also be performed and documented. An evaluation of the relationship between the placenta and the internal cervical os is a component of the standard obstetric sonogram that is performed at approximately 18 to 20 weeks.[13]

Transabdominal sonography is typically used to screen for abnormalities of placental location, and if the placenta is either clearly over the cervix or away from the lower uterine segment, its sensitivity and negative predictive value are excellent (Fig. 19-9).[14,15] However, if the lower uterine segment cannot be clearly visualized, transvaginal sonography is the most accurate method—the "gold standard"—for assessing the relationship between the inferior placental edge and the internal cervical os (see Fig. 19-9).[16-18] Transvaginal sonography is

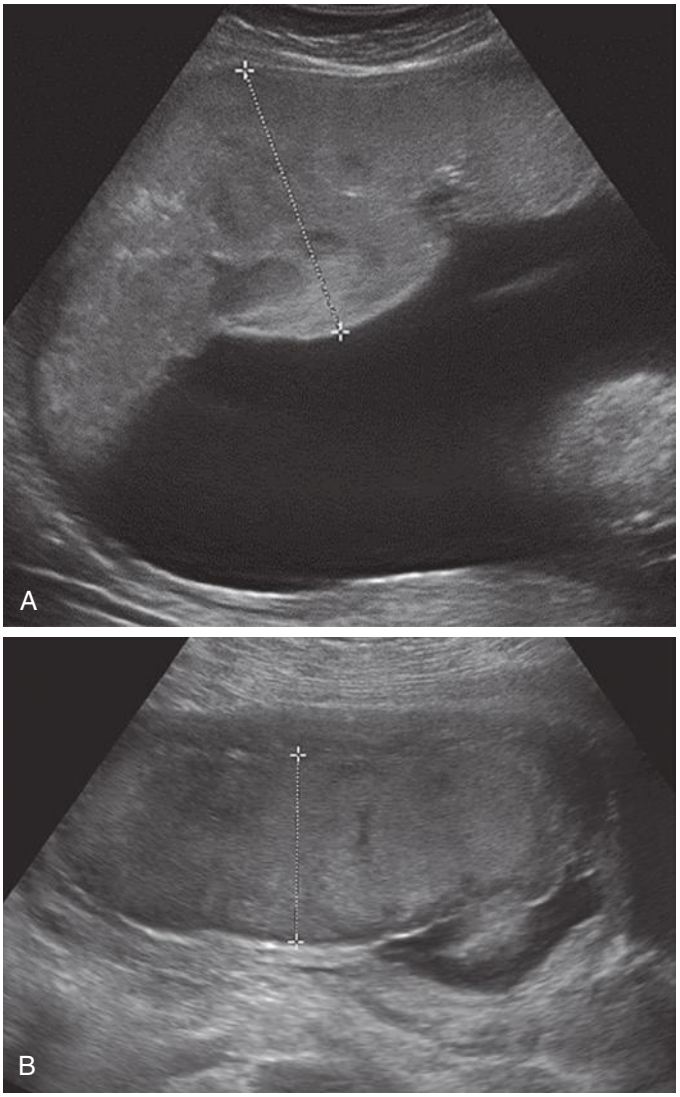

FIG 19-8 Placentomegaly. **A,** This anterior placenta measured 7.1 cm in thickness at 28 weeks' gestation. The fetus was hydropic in the setting of trisomy 21. **B,** The placental thickness measures 4.6 cm at 20 weeks' gestation. Oligohydramnios was also present, and the maternal serum alpha-fetoprotein level exceeded 18 multiples of the median. Pathologic examination following delivery confirmed a large intervillous thrombus.

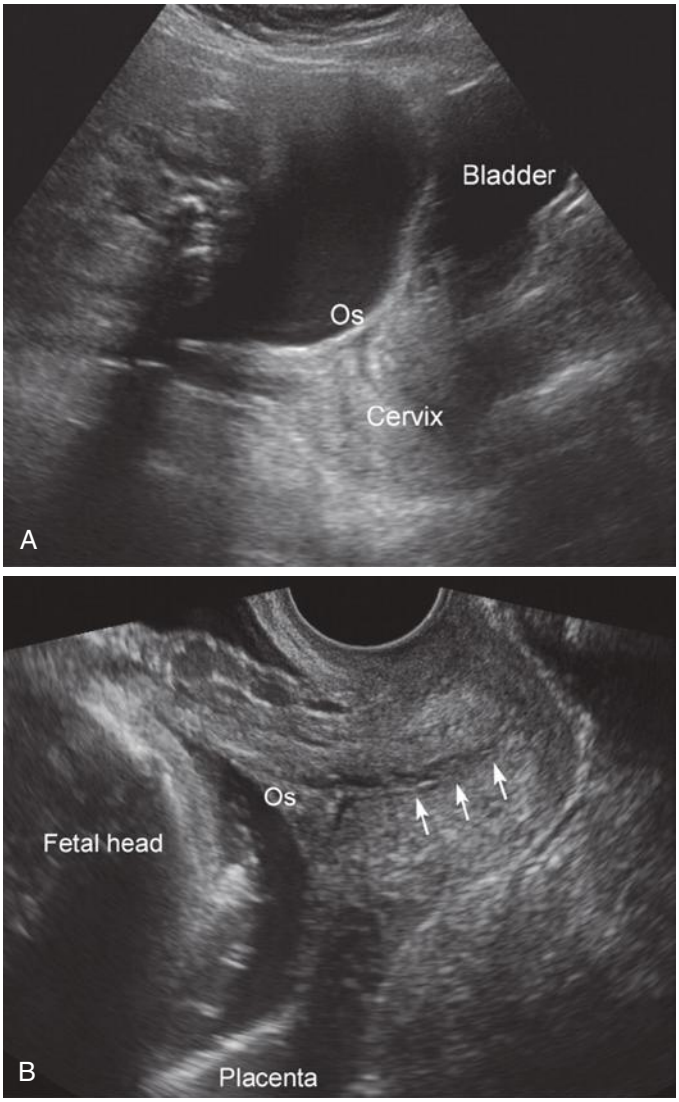

FIG 19-9 Normal lower uterine segment. **A,** Transabdominal image at 35 weeks demonstrating no evidence of placenta previa or low-lying placenta. **B,** Transvaginal image at 36 weeks, similarly demonstrating no evidence of placenta previa or low-lying placenta. The posterior placental edge is well away from the closed internal cervical os. Arrows depict the endocervical canal.

considered safe regardless of placental location, even in the presence of bleeding.[19] Translabial sonography is less commonly used, but it may be of benefit if transabdominal images are suboptimal and transvaginal sonography is not available or is contraindicated. Abnormalities of placental location include placenta previa and low-lying placenta.

Placenta Previa

Derived from the Latin *praevia,* for *going before*, placenta previa indicates that the placenta is the presenting part rather than the fetus. Sonographic identification of placenta previa is essential because affected pregnancies are at risk for vaginal bleeding, which is often initially painless—a *herald bleed*—but requires urgent evaluation as hemorrhage may ensue. Women with prior cesarean delivery and placenta previa are at risk for placental invasion, and the risk increases with the number of prior cesarean deliveries.

Prevalence

Placenta previa complicates approximately 3/1000 singleton births in population-based series.[20-23] Risk factors include older maternal age, multiparity, multifetal gestation, cigarette smoking, and especially prior cesarean delivery.[20,24-26] Previa is present at delivery in fewer than 1/1500 women younger than age 20 but in more than 1% of those older than age 35.[27] It is largely a complication of multiparous women, as only 20% of cases occur in first pregnancies.[24] It is also more common in twins and is found in approximately 4/1000 twin births.[20] Placenta previa is particularly prevalent among dichorionic pregnancies and attributed to two implantation events covering a larger area.[26]

Terminology

As sonography has replaced physical examination of the cervix in cases of suspected previa, terminology has changed. Largely based on

findings from the clinical "double set-up" examination in preparation for delivery of suspected placenta previa, three general categories were formerly used:

- *Complete placenta previa* referred to a placenta that completely covered the cervix, or more specifically, the internal cervical os.
- *Partial placenta previa* indicated that the placenta partially covered the cervical os. Clinically, this could occur and be detected only when cervical dilatation was present, because one had to visualize the placental edge crossing over the dilated cervix.
- *Marginal placenta previa* indicated that the placental edge just reached the margin of the internal cervical os, generally noted via gentle palpation during double set-up examination.

Sonographically, it is not usually possible to differentiate between the categories of partial and marginal placenta previa, because if the cervix is closed the internal cervical os appears as a "point" (Fig. 19-10). All women in whom the placenta covers the cervix or reaches the cervical os will require cesarean delivery, such that a distinction between complete, partial, and marginal previa as defined earlier does not change pregnancy management.

Recently, the classification of placenta previa was revised by a workshop that included the National Institute of Child Health and Human Development (NICHD), Society for Maternal-Fetal Medicine, American Institute of Ultrasound in Medicine, American College of Obstetricians and Gynecologists, American College of Radiology, Society for Pediatric Radiology, and Society of Radiologists in Ultrasound.[28,29] Using the new classification, the diagnosis of *placenta previa* is made when the placenta covers or just reaches the internal cervical os, eliminating the terms complete, partial, and marginal. If the inferior placental edge *encroaches* upon the cervix, such that it is within 2 cm of the internal os but does not overlie it, the diagnosis is *low-lying placenta*. If the inferior placental edge is 2 cm or more from the internal cervical os, the placental location is considered normal.

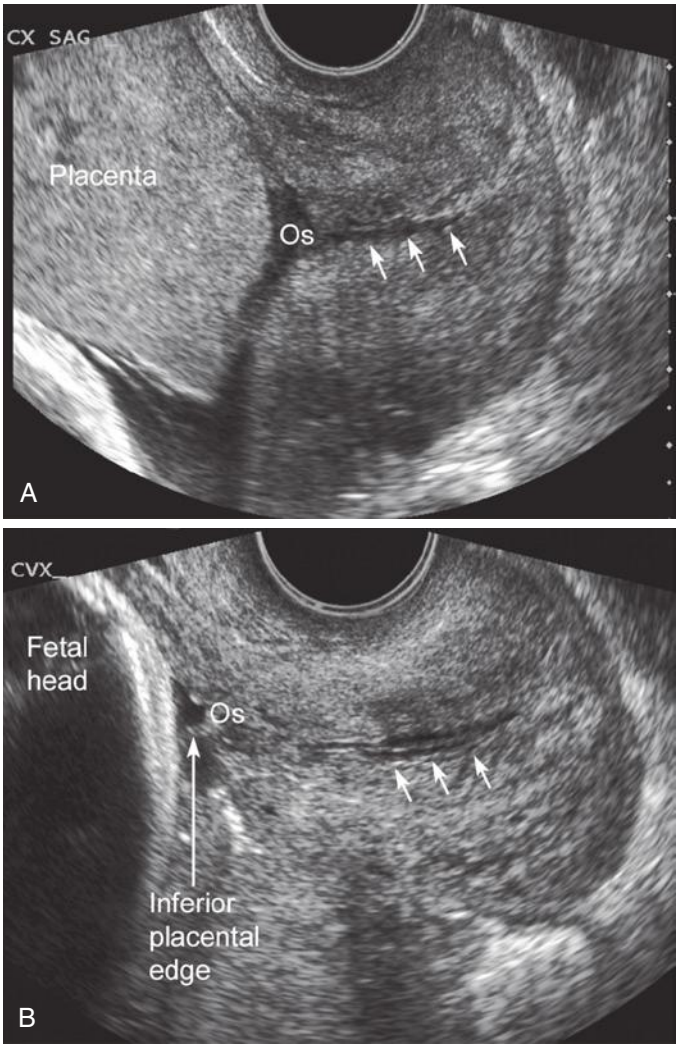

FIG 19-10 Placenta previa. **A,** In this transvaginal image at 32 weeks' gestation, the anterior placenta previa completely covers the internal cervical os. **B,** In this image from a different patient, also at 32 weeks' gestation, the inferior edge of the posterior placenta just reaches the level of the internal cervical os. Whether the placenta partially covers the closed os or just reaches its margin is not a distinction that is technically feasible or clinically helpful. Short arrows depict the endocervical canal in both images.

Placental "Migration"

Most women diagnosed with placenta previa or low-lying placenta in the second trimester will have normal placental location by the end of pregnancy. This apparent "migration" of the placenta away from the lower uterine segment with advancing gestational age has been well described but is not completely understood. Enlargement of the uterus may result in differential growth of the placenta toward the well-vascularized fundus, a phenomenon known as *trophotropism.* Visualization of the lower uterine segment also may become clearer later in gestation, and placental tissue that previously appeared to have implanted over the cervix, particularly with transabdominal sonography alone, may have been merely adjacent to the region of the cervix and may seem, on follow-up, to have moved several centimeters away.

With transabdominal sonography, approximately 5% of pregnancies are thought to have placenta previa in the second trimester.[30] However, when imaged transvaginally, only 1% to 2% are diagnosed with placenta previa in the second trimester.[31-33] Overall, about 90% of previas diagnosed prior to 20 weeks' gestation resolve before delivery.[24] The later in gestation that previa is identified, the higher the likelihood that it will persist until delivery. Specifically, placenta previa identified at about 24 weeks' gestation persists in approximately half of cases, whereas previa identified at 32 weeks persists in nearly 75%.[24] The degree to which the placenta overlaps the cervical os increases the likelihood that placenta previa will persist, as does a history of one or more prior cesarean deliveries.

Management

Persistent placenta previa will require cesarean delivery. Because of the frequent resolution of previa with advancing gestational age, sonography is indicated if a woman with suspected previa develops bleeding. In the absence of bleeding, follow-up sonography is recommended at approximately 32 weeks' gestation.[29] If there is any question about placental location, transvaginal sonography should be performed. And, because resolved placenta previa is associated with vasa previa, color and spectral duplex Doppler sonographic scans are recommended to evaluate for possible abnormalities of the umbilical cord insertion. If placenta previa or low-lying placenta are found to persist at the 32-week sonogram, transvaginal sonography is recommended at 36 weeks' gestation.[29]

Low-Lying Placenta

Placentation is termed *low-lying* if the inferior placental edge *encroaches* upon the cervix, such that it does not overlie but is within 2 cm of the internal os (Fig. 19-11). The prevalence of low-lying placenta is approximately 3/1000 pregnancies at approximately 36 weeks' gestation,

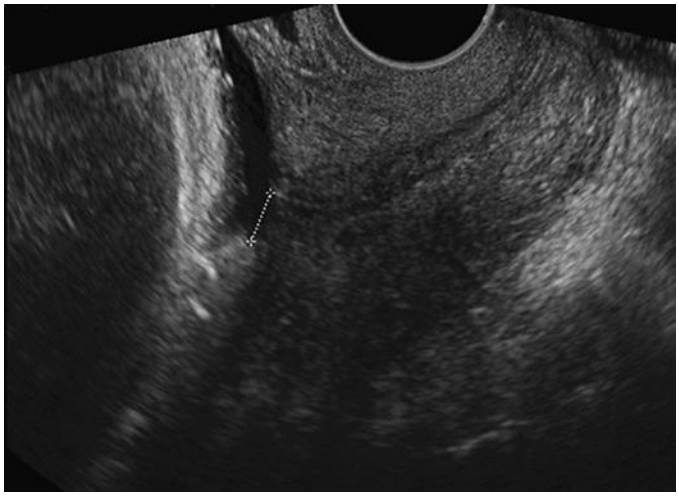

FIG 19-11 Low-lying placenta. In this transvaginal image at 34 weeks' gestation, the measurement from the inferior edge of the posterior placenta to the internal os is approximately 8 mm.

thus similar to placenta previa.[34] As with placenta previa, a low-lying placenta identified in the early second trimester often resolves prior to delivery. In one series of 1240 pregnancies with low-lying placenta diagnosed between 16 and 24 weeks' gestation, 90% had resolved by 32 weeks and 98% had resolved by delivery.[35]

Management

If low-lying placenta is identified in the second trimester, a follow-up sonogram is recommended at approximately 32 weeks' gestation. If the placenta is low-lying in the third trimester, transvaginal sonography is recommended: (1) to aid in accurate measurement of the distance from the inferior placental edge to the internal cervical os and (2) to exclude vasa previa. If the placenta is low-lying at 32 weeks' gestation, transvaginal sonography is recommended at 36 weeks.[29]

Unlike placenta previa, low-lying placenta is not a contraindication to vaginal delivery. However, the risks of vaginal bleeding and need for blood transfusion are increased. In studies of women with low-lying placenta who have labored, approximately one third required cesarean delivery specifically for bleeding.[36-38] In two series, vaginal delivery was more likely if the distance from the placental edge to the internal cervical os (as measured by sonography) was between 1 and 2 cm than if the placenta was within 1 cm of the os.[34,38] However, whenever the placenta has implanted in the lower uterine segment, even when greater than 2 cm from the internal cervical os, there is an increased risk of bleeding, and excessive bleeding may occur regardless of whether the patient is delivered vaginally or via cesarean.[36,37]

PLACENTAL CORD INSERTION ABNORMALITIES

The umbilical cord usually inserts centrally into the placenta (Fig. 19-12). Not uncommonly, however, the cord inserts into the edge of the placenta—a *marginal insertion*, which is also known as a *Battledore placenta* (see Fig. 19-12B). The prevalence of marginal insertion of the umbilical cord is approximately 6% in singleton births and 10% to 15% in twin gestations.[39,40] Marginal cord insertion, usually defined as cord insertion less than 2 cm from the placental edge, may confer a small increase in the risk for adverse pregnancy outcomes. In a population-based series of more than 600,000 singletons, marginal insertion was associated with placental abruption (odds ratio 1.5), placenta previa (odds ratio 1.8), and small-for-gestational age (SGA) neonate (odds ratio 1.2), but not perinatal deaths.[40] Marginal cord

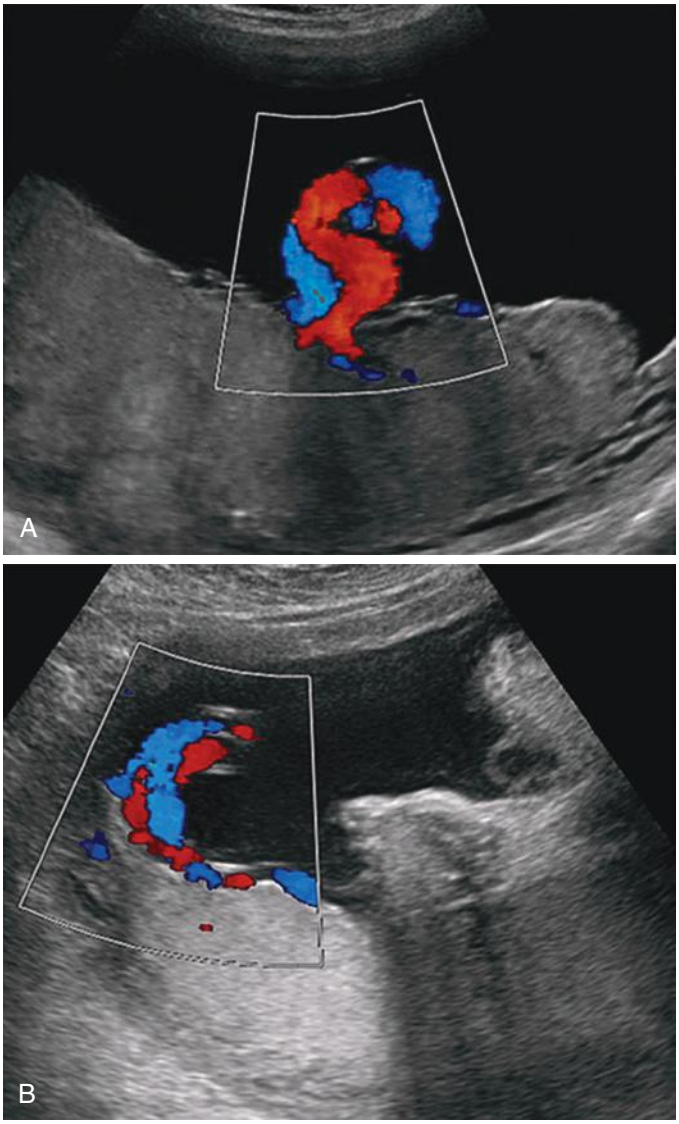

FIG 19-12 Placental cord insertion. **A,** Central (normal) placental cord insertion. **B,** Marginal cord insertion, also known as *Battledore placenta.*

insertion appears to be particularly common in monochorionic twins, and it has been associated with an increased risk for an SGA newborn in monochorionic but not dichorionic twin pregnancies.[39]

Velamentous Cord Insertion

With this abnormality, the umbilical cord does not insert directly into the placenta but rather into the membranes usually a short distance away from the placental edge (Fig. 19-13). Sonographically, the umbilical arteries and vein may be visible traversing the membranes along the wall of the uterus, unprotected by Wharton jelly, before inserting at the margin of the placenta (Fig. 19-14). Color Doppler sonography assists with visualization. Theories regarding the development of velamentous cord insertion include trophotropism, described earlier, or an error in initial blastocyst attachment that orients the fetus a distance away from the decidua basalis rather than directly opposite it.[41]

In population-based series, velamentous insertion occurs in approximately 0.5% to 1.5% of singleton births and 6% of twins.[40,42] It is more prevalent in monochorionic twins, particularly in the smaller twin of a monochorionic pair, and it is associated with birth weight discordance.[39] In a population-based review of more than 600,000

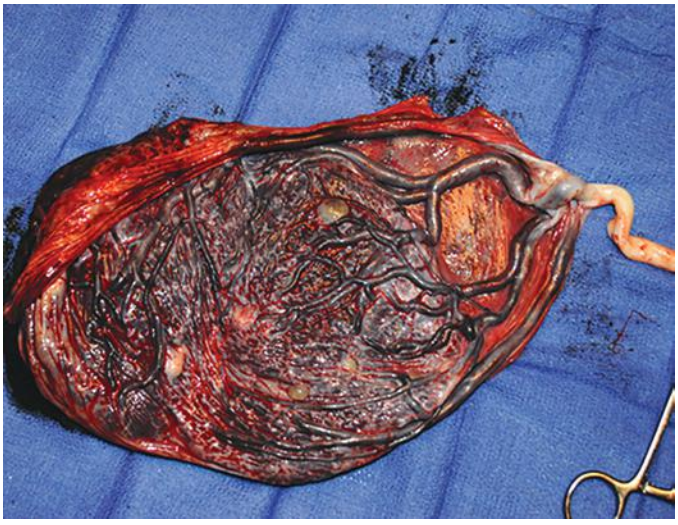

FIG 19-13 Velamentous cord insertion. In this gross placental specimen, several large vessels are supported only by intervening membranes as they extend from the umbilical cord to the placental disk. (Courtesy of Dr. David Nelson, University of Texas Southwestern Medical Center, Dallas, Texas.)

singleton births, velamentous insertion was associated with an approximately twofold increased risk for placental abruption, SGA neonate, and perinatal death.[40] It has also been reported in 7% of fetal deaths prior to 24 weeks' gestation.[43] The risk for placenta previa is increased, and this is the most common precursor of *vasa previa,* discussed next. Care should be taken at delivery to avoid avulsing the umbilical cord when delivering the placenta, as velamentous insertion is associated with a greater than 10-fold increase in need for manual placental extraction.[42]

Vasa Previa

In approximately 1/2500 deliveries, fetal vessels course within the membranes that overlie the cervix, a potentially devastating complication termed *vasa previa* (Fig. 19-15).[44-46] Vasa previa can develop in two settings: either with a velamentous cord insertion—connecting the umbilical cord to the placenta, or with a succenturiate or bilobed placenta—connecting the two placental lobes.[46] In one review, each of these causes accounted for approximately 50% of prenatally diagnosed vasa previa cases.[47] Multiple gestations are a recognized risk factor, and twins comprise 12% to 25% of those with vasa previa in published series.[44,48] Pregnancies resulting from assisted reproductive technologies appear to be at particular risk.[49]

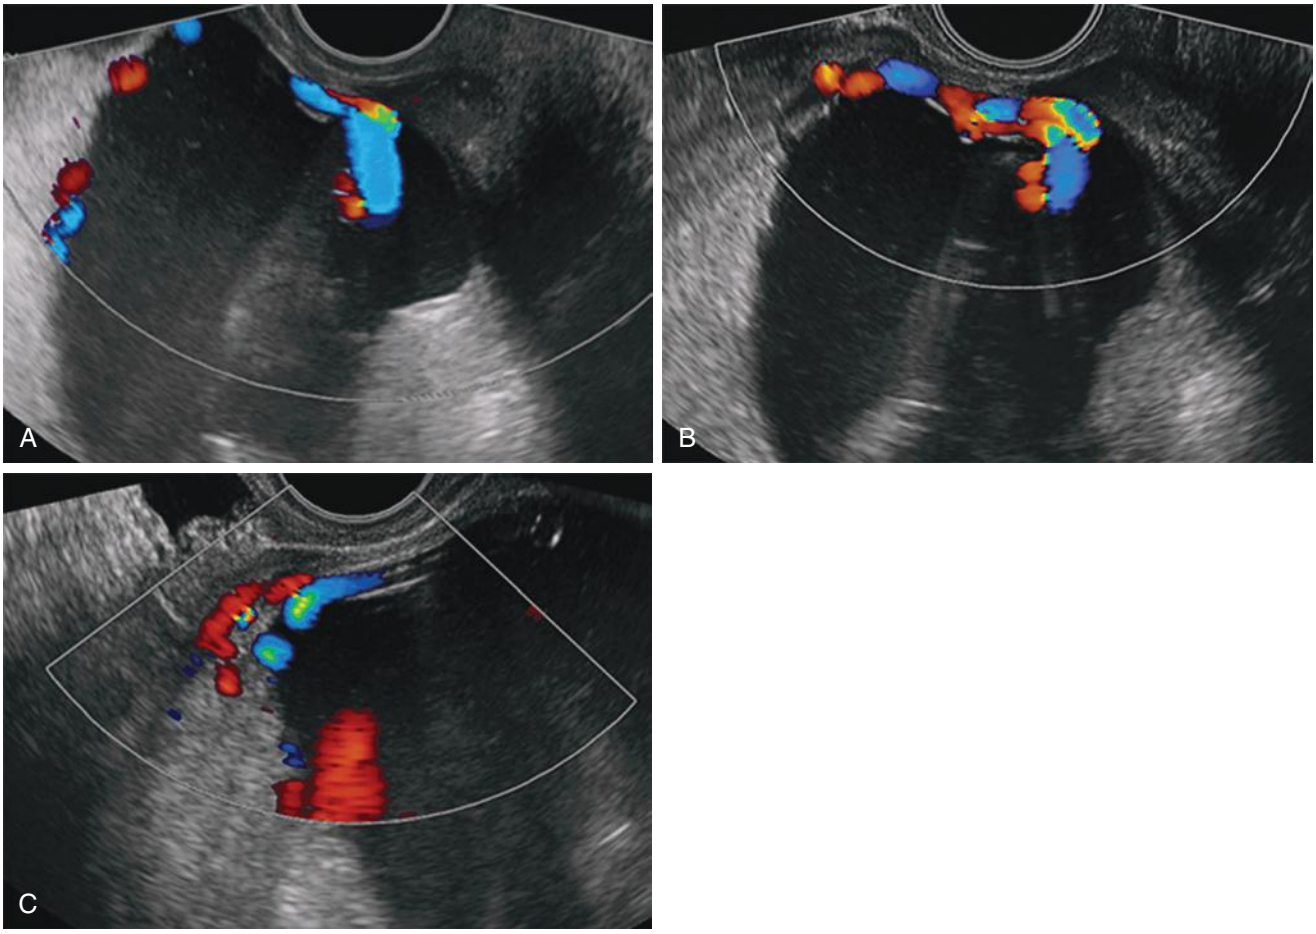

FIG 19-14 Velamentous cord insertion. **A,** In this transvaginal color Doppler ultrasound image at 22 weeks' gestation, the umbilical cord is seen inserting into the membranes along the anterior wall of the lower uterine segment, a short distance away from the anterior placenta. **B,** The umbilical vessels run along the anterior uterine wall. **C,** The umbilical vessels insert into the inferior margin of the anterior placenta.

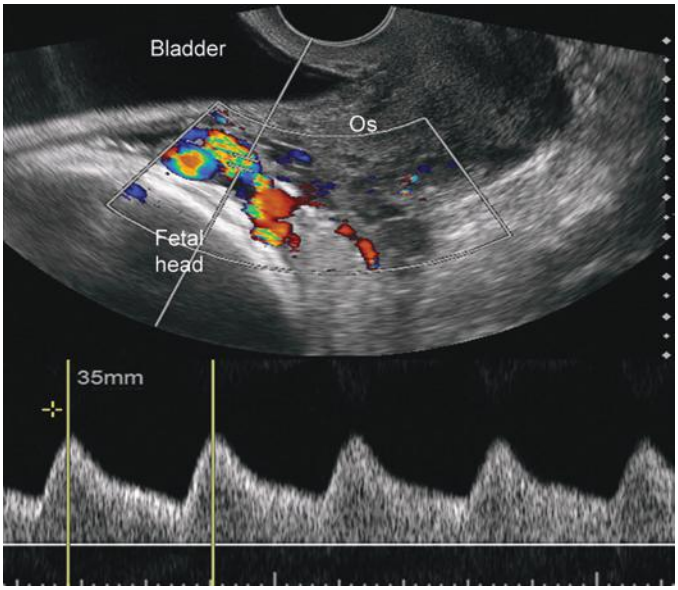

FIG 19-15 Vasa previa. The placenta is posterior and low-lying, and the umbilical cord insertion is velamentous, directly into the membranes just anterior to the cervix, such that unprotected fetal vessels course directly over the internal os.

There are no standardized criteria for how close the fetal vessels must be to the internal cervical os to constitute vasa previa, and a threshold of "within 2 cm of the os" has been proposed.[48] In one series, all emergent deliveries with vasa previa had a fetal vessel within 2 cm of the internal cervical os.[44]

Vasa previa is potentially catastrophic if unrecognized, because the fetal vessels are prone to compression during labor and because the fetus can quickly exsanguinate when the membranes rupture. With prenatal detection, reported survival rate exceeds 95%.[44,47,48] In the absence of prenatal diagnosis, however, the perinatal mortality rate is as high as 50%.[47]

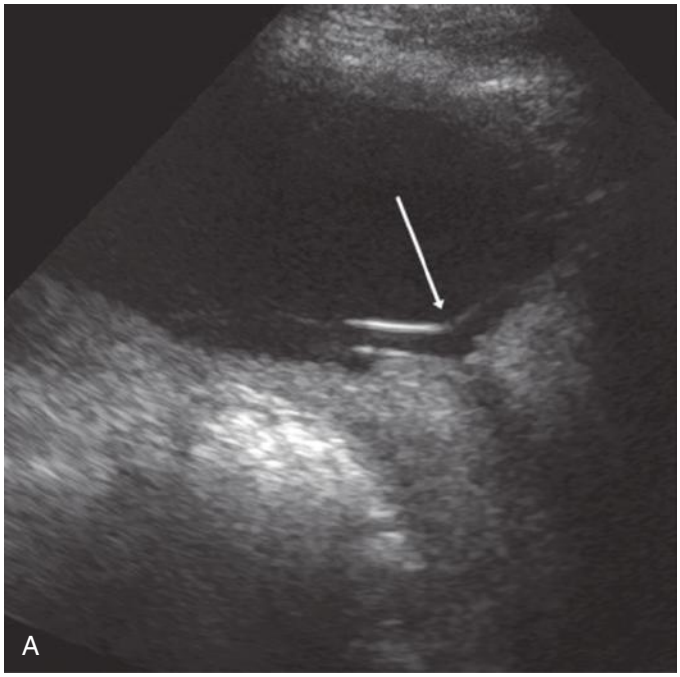
If the diagnosis is suggested sonographically in the second trimester, up to 25% of cases may resolve prior to delivery.[48] If vasa previa persists, scheduled cesarean delivery is recommended prior to the onset of labor.[50] Some have advocated that this occur prior to 36 weeks' gestation.[47,48]

Vasa previa should be considered whenever one encounters a low-lying placenta or a resolved placenta previa, as well as in the setting of velamentous cord insertion, succenturiate lobe, or bilobate (bilobed) placenta. Careful sonographic assessment should include color and spectral duplex Doppler evaluation to identify fetal vessels overlying the cervix, which confirms the diagnosis (Fig. 19-16). Routine evaluation of the placental cord insertion site may help to avoid missing this rare but devastating entity. However, it is recognized that even with transvaginal imaging and color Doppler sonography, not all cases of vasa previa will be detected antepartum.[50]

MORBIDLY ADHERENT PLACENTA—PLACENTA ACCRETA

Disorders of abnormal placental attachment or invasion include three entities, based on the degree to which chorionic villi invade myometrial tissue:

- *Placenta accreta*: implantation of placental villi directly *onto* myometrial tissue rather than the decidua basalis
- *Placental increta*: invasion of placental villi *into* the myometrium



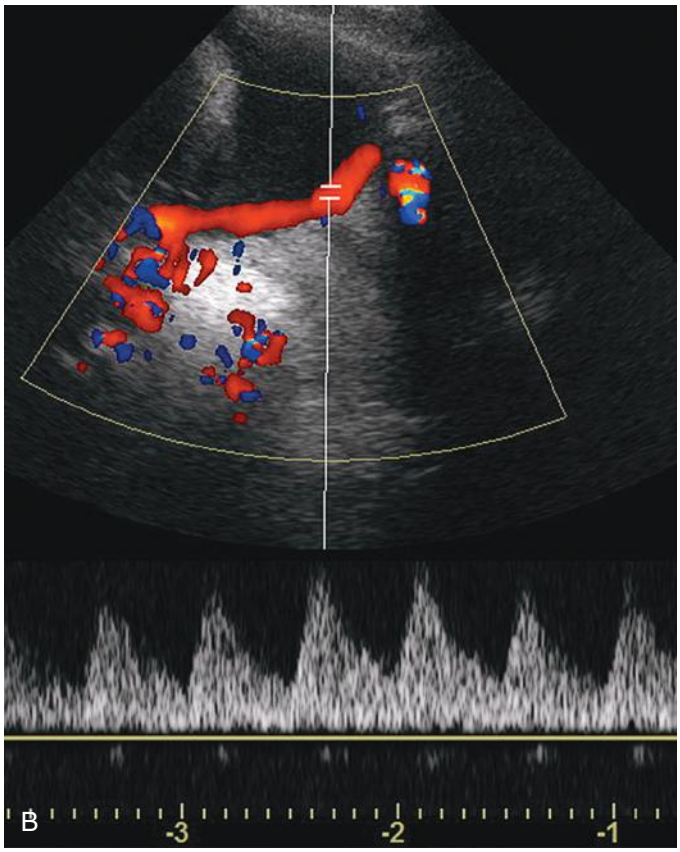


FIG 19-16 Vasa previa. **A,** A tubular structure (*arrow*) is shown overlying the cervix on this transabdominal sagittal sonographic image. **B,** With color and spectral duplex Doppler interrogation, this structure is shown to be a fetal vessel, confirming vasa previa. In many instances, the unprotected fetal vessel crossing the cervix is not appreciated on gray-scale images and is only detected with careful Doppler evaluation.

- *Placenta percreta*: placental growth *through* the myometrium, extending to or through the uterine serosa

Clinically, of these three forms of abnormal attachments, placenta accreta is encountered in approximately 75% of cases, whereas increta develops in 15% to 20% and percreta in 5% to 10%.[51] However, *placenta accreta* is also the general term frequently applied to encompass all three of these conditions, a practical consideration in that the distinction is often not made until delivery.[52] Abnormal implantation of the placenta is believed to result from partial or total absence of the decidua basalis and imperfect development of the fibrinoid or Nitabuch layer—the normal physiologic line of cleavage.[27] Involvement of the entire placenta is termed *total accreta,* whereas if not all placental lobules are involved, the condition is called *partial* or *focal placenta accreta.*

At delivery, the placenta fails to separate normally, leading to significantly increased maternal morbidity. Severe hemorrhage may necessitate cesarean hysterectomy and often massive transfusion of blood products with need for intensive care (Fig. 19-17).[52-54] Thus, to minimize both maternal and neonatal morbidity and mortality rates, prenatal detection is important to permit timely coordination of multidisciplinary care and to arrange for maternal transfer to a center with adequate resources.[52,54,55]

Epidemiology and Risk Factors

The prevalence of placental invasion has increased in recent years in parallel with the rise in cesarean delivery rates.[56] Series from the past decade suggest that the prevalence has increased to 1/500 to 1/900 pregnancies.[57-59]

An overwhelming majority of cases occur in the presence of two factors: placenta previa and prior cesarean delivery. The risk increases sharply with each subsequent cesarean delivery. In the setting of placenta previa, the risk for placental invasion is approximately 3% at the first cesarean delivery, 11% by the second, 40% by the third, and 60% to 70% for subsequent cesarean deliveries.[53] However, in the absence of previa, the risk for placenta accreta is only 0.03% at the initial cesarean and remains less than 1% up to the fifth cesarean.[53] Regardless of whether the placenta previa is anterior or posterior, placental invasion also may develop if the placenta overlies uterine scarring, resulting from prior uterine leiomyoma resection,[60] endometrial ablation,[61-63] or Asherman syndrome.[64]

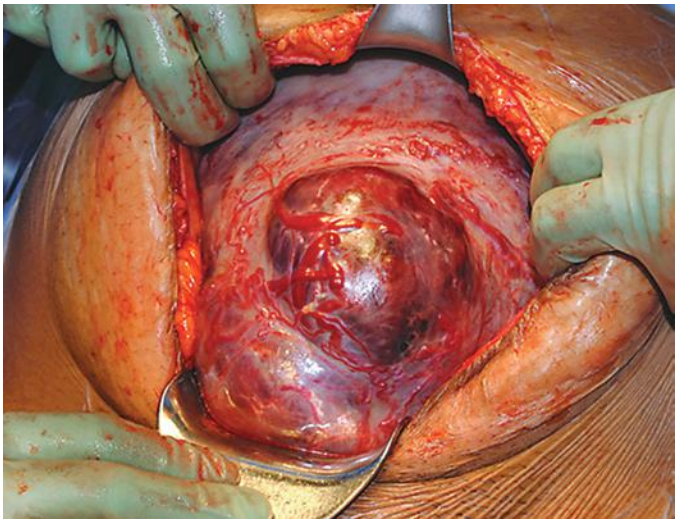

FIG 19-17 Placenta percreta. At the time of cesarean delivery, the placenta is seen bulging through the attenuated lower uterine segment myometrium and is covered only by uterine serosa.

Sonographic Findings: Second and Third Trimesters

Sonographic criteria for detection of morbidly adherent placenta or placental invasion include the following:

- Multiple placental *lacunae.* These irregularly shaped hypoechoic vascular spaces may give the placenta a "Swiss cheese" appearance. They contain turbulent flow shown with color Doppler imaging (Fig. 19-18).
- Thinning of the retroplacental myometrium, with the smallest myometrial thickness measuring less than 1 mm in the sagittal plane (Fig. 19-19).
- Irregularity or disruption of the echogenic interface between the maternal bladder and uterine serosa—*the bladder-serosal interface*—on gray-scale imaging.
- Increased vascularity of the bladder-serosal interface, with *bridging vessels* that course from the placenta to the region of the bladder-serosal interface (and sometimes farther into the bladder) shown with color Doppler imaging (Fig. 19-20).
- Loss of the normal linear hypoechoic area between the placenta and the wall of the uterus, called the *retroplacental clear space* (see Fig. 19-19).

Evaluation for suspected placenta accreta is not straightforward and can be quite challenging. In addition to transabdominal scanning, transvaginal sonography should be performed with the patient's bladder partially filled, using both gray-scale and color Doppler sonography.[65] The utility and accuracy of the sonographic findings associated with accreta vary in reported series according to which individual factors were noted, the total number of factors identified, and whether the analysis was prospective or retrospectively performed. In a woman with a prior cesarean delivery and placenta overlying the lower uterine segment, *any* individual sonographic finding heightens the index of suspicion and should prompt investigation for other features of invasion.

Several observations and investigations regarding the sonographic findings of accreta have been reported. Loss of the retroplacental clear space is a common cause of false positive reports and is therefore best used in conjunction with other findings.[66-68] As single factors, lacunae and interruption of the bladder-serosal interface, particularly when color Doppler sonography confirms hypervascularity, appear to have higher positive-predictive values for invasion than other characteristics.[69] Placental lacunae can vary in degree. Finberg and Williams (1992) developed a grading scale for lacunae: grade 1+ for one to three lacunae, usually small; grade 2+ for four to six lacunae, typically larger; and grade 3+ for diffuse lacunae throughout the placenta.[66] More extensive lacunae throughout the placenta have been associated not just with placental invasion but with placenta percreta.[66] Another finding that may be associated with placenta percreta is hypervascularity of the entire bladder-serosal interface shown with three-dimensional (3D) power Doppler sonography.[67]

In a recent meta-analysis of 23 series that included 3700 pregnancies at risk for placenta accreta, the pooled sensitivity of sonography to identify invasion was 91% and the specificity was 97%.[70] However, the reported sensitivity for the individual studies ranged from 60% to 100%, and the specificity ranged from 50% to 100%.[70] Thus, although the overall utility of sonography for suspected placental invasion is good, there is considerable variability in published reports. More recently, investigators have tried to combine the various sonographic findings with clinical parameters, such as number of prior cesarean deliveries, to more accurately predict placental invasion.[58,71]

Magnetic Resonance Imaging for Placenta Accreta

Magnetic resonance imaging is not recommended for routine evaluation of suspected placental invasion, as its sensitivity and specificity are

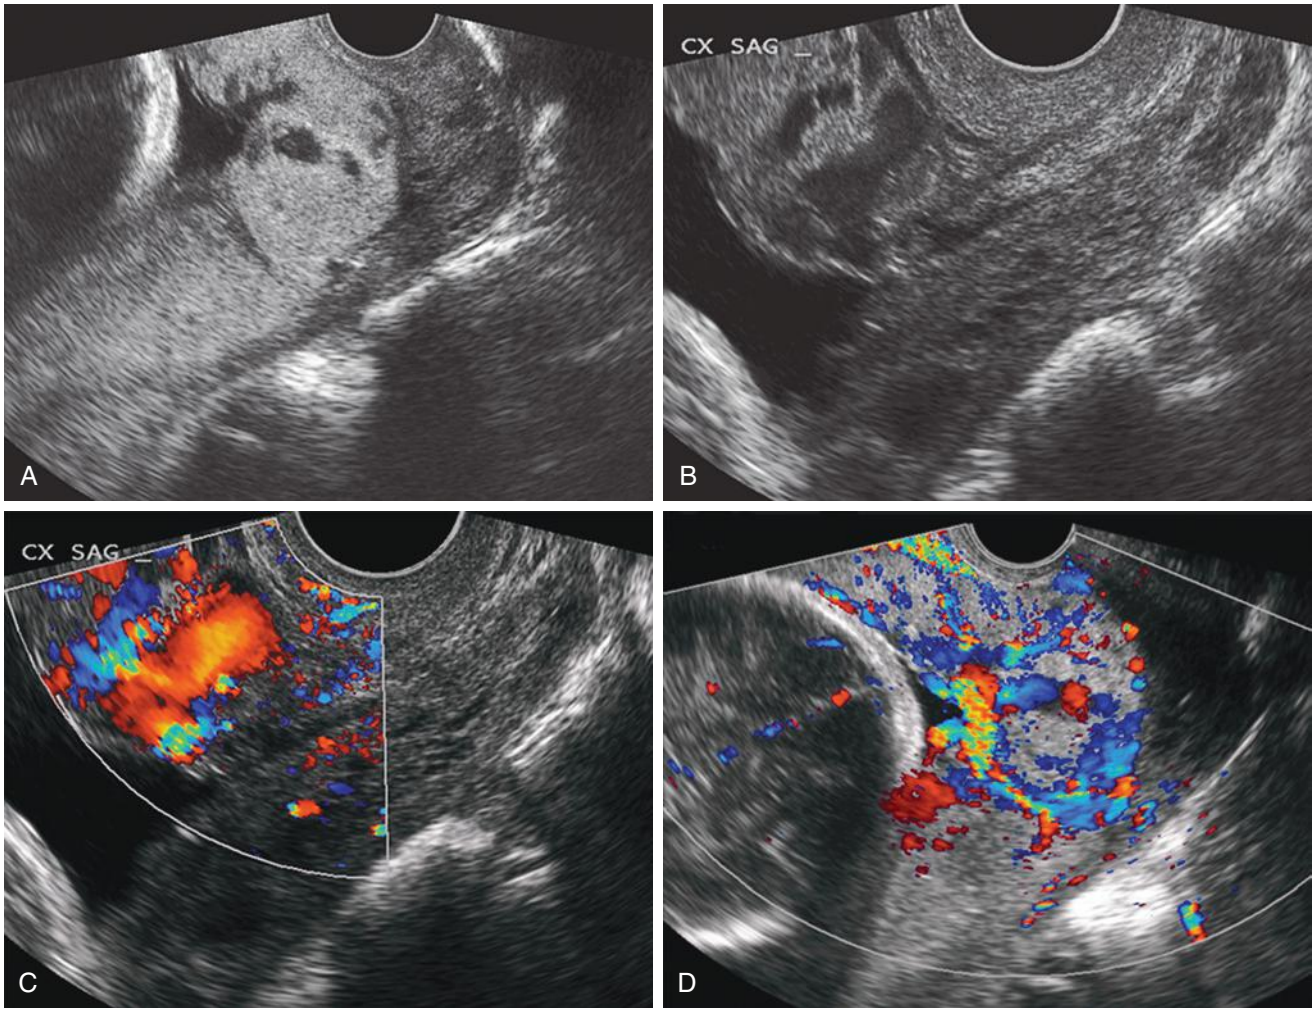

FIG 19-18 Placental lacunae. **A** and **B,** Transvaginal images in the sagittal plane depict placenta previa with multiple placental lacunae. The images are from two different pregnancies, each at 28 weeks of gestation. **C** and **D,** Color Doppler ultrasound imaging (from the patients shown in A and B, respectively) demonstrates turbulent flow within these irregularly shaped vascular spaces.

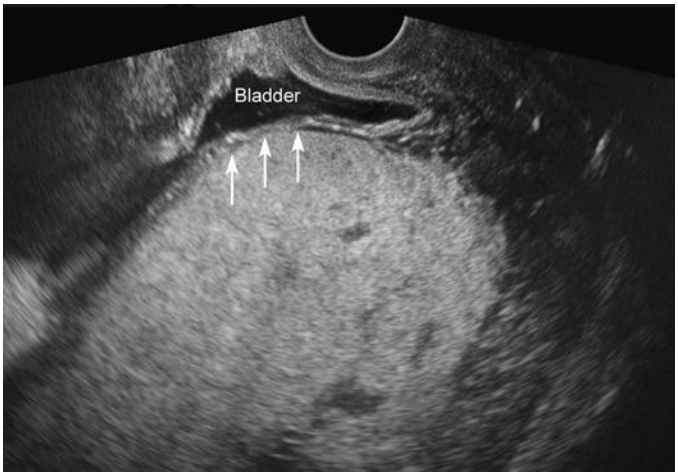

FIG 19-19 Thinning of retroplacental myometrium. This transvaginal image at 32 weeks of gestation shows the placenta (previa) filling the lower uterine segment, and there is marked attenuation of the retroplacental myometrium (*arrows*). The smallest myometrial thickness is below 1 mm.

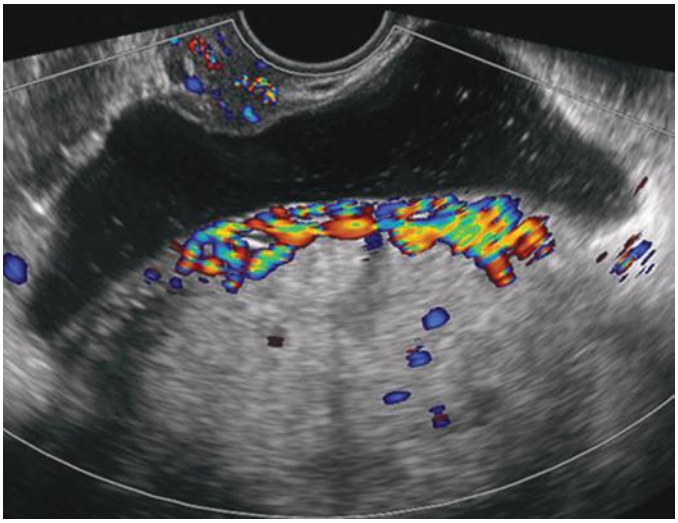

FIG 19-20 Bridging vessels. This transvaginal sonographic image at 32 weeks' gestation was obtained in the transverse plane and depicts prominent bridging vessels, shown with color Doppler, that course from the placenta to the bladder-serosal interface. They correspond to the irregularities along the bladder-serosal interface visible with gray-scale imaging.

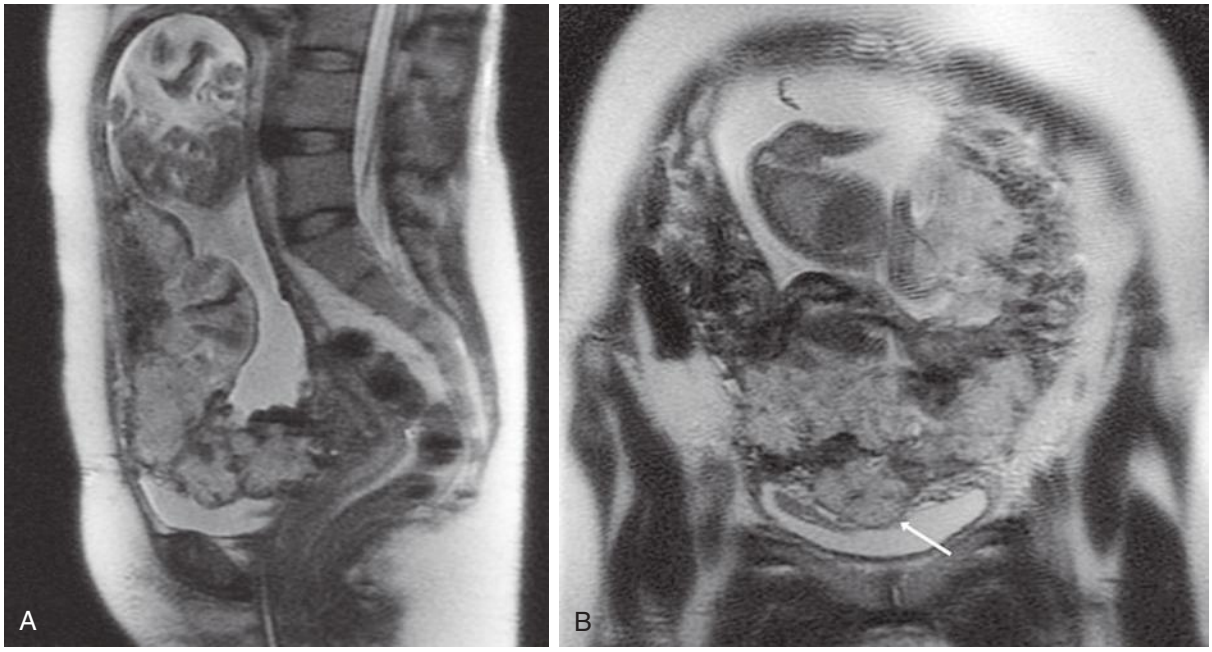

FIG 19-21 Placenta percreta. Placental invasion with involvement of the maternal bladder wall, indicating placenta percreta, is shown on these sagittal (**A**) and coronal (**B**) single shot fast spin echo magnetic resonance images, obtained for purposes of surgical planning. The heterogeneity of the placenta is due to lacunae. Irregularity of the placental interface is noted with extension into the bladder wall (*arrow*). Intraluminal material within the bladder represents blood clot. (Courtesy of Dr. Liina Poder, University of Texas Southwestern Medical Center, Dallas, Texas.)

similar to sonography, and it has not been shown to affect mode of delivery or need for cesarean hysterectomy.[72,73] It may be useful, however, when ultrasound findings are inconclusive or additional information is needed (Fig. 19-21).[29,72] For example, in a patient with prior uterine surgery, instrumentation, or injury involving the posterior myometrium, sonographic visualization may be limited by fetal position or other factors. In such cases in which concern for possible placental invasion is raised, targeted magnetic resonance imaging might be of benefit.

First-Trimester Placenta Accreta and Cesarean Scar Pregnancy

The rising prevalence of placental invasion, coupled with increasing use of first-trimester sonography, has led to recognition of placenta accreta in the first trimester. As previously stated, most pregnancies with placental invasion have placenta previa overlying a prior hysterotomy scar. Similarly, it is possible for implantation to occur in the region of the scar tissue at the anterior lower uterine segment—termed *cesarean scar pregnancy*—which may result in early uterine rupture.[74] Multiple investigators have found that cesarean scar pregnancy and placenta accreta share the same pathogenesis and that cesarean scar pregnancy, rather than being a separate entity, may be a precursor to second- or third-trimester placenta accreta.[75-77]

First-trimester sonographic findings of cesarean scar pregnancy include the following:[75,78,79]

- Gestational sac implantation that is low and anterior in the uterus, in the region of the hysterotomy scar. Before 8 weeks, the sac may fill the "niche" of the scar in a triangular configuration, and by 8 weeks, the gestational sac shape may appear more rounded.[78]
- Attenuation of the myometrial layer between the gestational sac and bladder, such that the measured distance from the anterior trophoblastic border to the uterine serosa is 1 to 3 mm (Fig. 19-22).[75] This measurement is comparable to the smallest myometrial thickness reported on sonographic imaging done later in pregnancy.
- Visible irregularities along the placental-myometrial interface.
- Echolucent areas within the placenta, a precursor to the lacunae visible later in gestation (Fig. 19-23).
- Prominent vascularity in the region of the prior hysterotomy scar shown with color Doppler ultrasound imaging.

The utility of these sonographic criteria for prediction of invasion has not as yet been established. In one series of suspected cesarean scar pregnancies that were expectantly managed, 90%—9 of 10 pregnancies—delivered liveborn neonates in the third trimester.[80] However, in each of these cases, the eventual pathologic diagnosis was placenta *percreta*, suggesting that pregnancies that come to attention in the first trimester may have more severe invasion. Concerns have been raised that a higher index of suspicion is required to identify pregnancies with placental invasion in the first trimester.[74]

A caveat in the management of suspected first-trimester placental invasion is that none of the aforementioned sonographic findings differentiates pregnancies that will experience early uterine rupture from those that will result in placenta accreta/percreta but with delivery of a term or near-term infant. It has been hypothesized that the clinical course may depend on factors such as depth and progression of abnormal placental invasion.[76] In some cases, the gestational sac appears to bulge or "balloon" outward from the uterus toward the bladder, which is particularly worrisome (see Fig. 19-22).[81] The sensitivity and positive-predictive value of this sonographic finding have not been established.

Identification of suspected first-trimester invasion poses challenges regarding patient counseling. Regardless of whether a woman decides to continue or terminate the pregnancy, she is at significant risk for hemorrhage and for hysterectomy—although certainly not invariably.

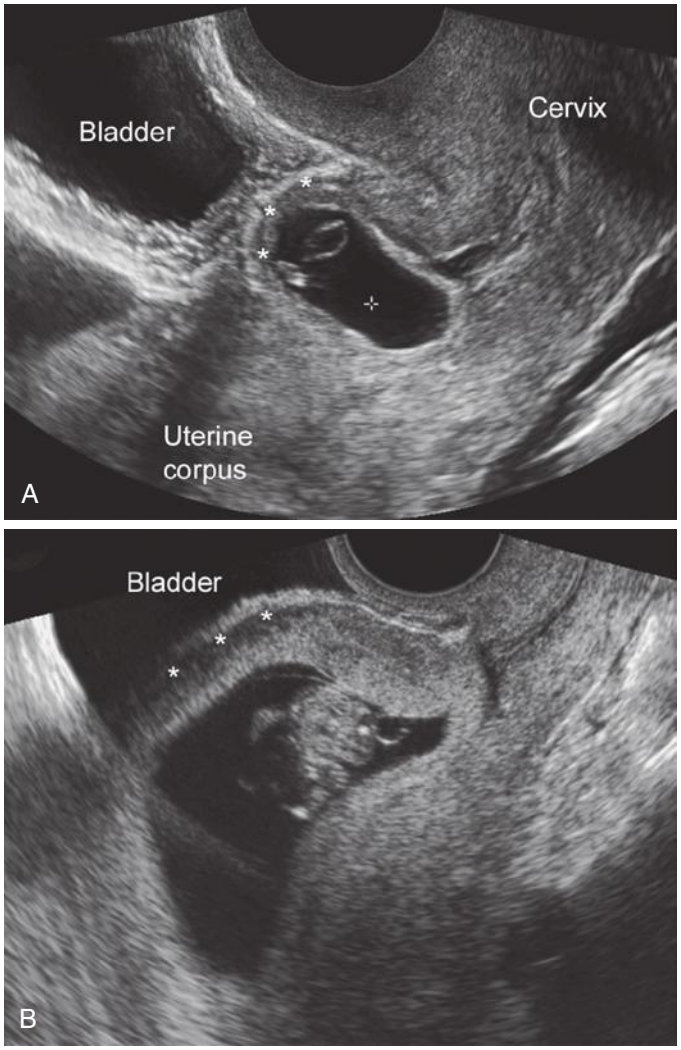

FIG 19-22 Cesarean scar pregnancy with attenuation of retroplacental myometrium. **A,** In this transvaginal image of a 6-week gestation, the gestational sac is implanted low and anteriorly in the uterus (in the region of the hysterotomy scar) and appears to bulge outwardly; there is no visible myometrial layer (*asterisks*) between the gestational sac and maternal bladder. **B,** This transvaginal sonogram at 11 weeks shows thinning of the myometrial layer (*asterisks*) between the gestational sac and the bladder.

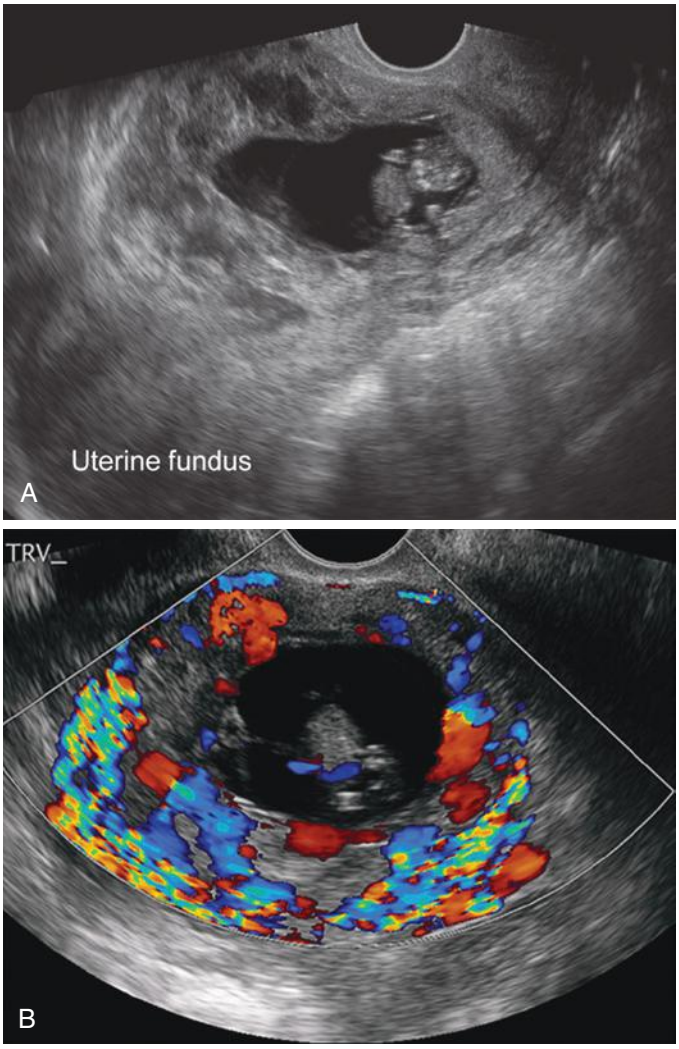

FIG 19-23 Cesarean scar pregnancy with echolucent placental spaces. **A,** This transvaginal image in the sagittal plane at 10 weeks' gestation depicts numerous hypoechoic areas within the placenta. Not only has the gestational sac implanted inferior and anterior within the lower uterine segment, but also the sac appears to bulge or "balloon" outward from the uterine serosa. **B,** Color Doppler sonographic imaging demonstrates prominent turbulent flow within the echolucent areas. This cesarean scar pregnancy was treated with methotrexate and evacuation of the uterus.

If she continues the pregnancy, she will require close surveillance and coordination of delivery planning. If she elects to terminate, local injection of methotrexate and hysteroscopic-guided procedures have been reported to have the lowest complication rates.[74]

VASCULAR ABNORMALITIES OF THE PLACENTA

Placental Sonolucencies

Within the maternal-fetal circulation of the placenta, blood may accumulate abnormally at various points. These abnormalities can mechanistically be organized into those that develop from disrupted maternal blood flow and those from altered fetal circulation. Of the two types, maternal blood flow abnormalities are more commonly seen sonographically. They can broadly be grouped as: (1) fibrin collections within the intervillous space, namely, subchorionic and perivillous fibrin deposition; (2) placental infarction, caused by spiral artery occlusion; (3) intervillous thrombus, created by villous breaks that permit mixing of maternal and fetal blood within the intervillous space; and (4) hematomas. Despite specific histologic differentiation of these entities, the sonographic appearances of these collections are more generic. In some instances, location may best suggest the origin.

Many of these collections appear on ultrasound images as variably sized anechoic or hypoechoic areas typically lacking flow with color Doppler interrogation (Fig. 19-24). These placental sonolucencies often represent sites of fibrin deposition or intervillous thrombus. Less frequently they represent a mature hematoma, as hematomas are typically hypoechoic or anechoic in the acute phase, heterogeneously echogenic in the subacute phase, and anechoic in the chronic phase. Although not the result of vascular disruption, for completeness in this discussion, another sonolucency to consider is the decidual septal cyst. This is an area of focal degeneration within the maternal decidual septa, described earlier, that bulges up from the basal plate.

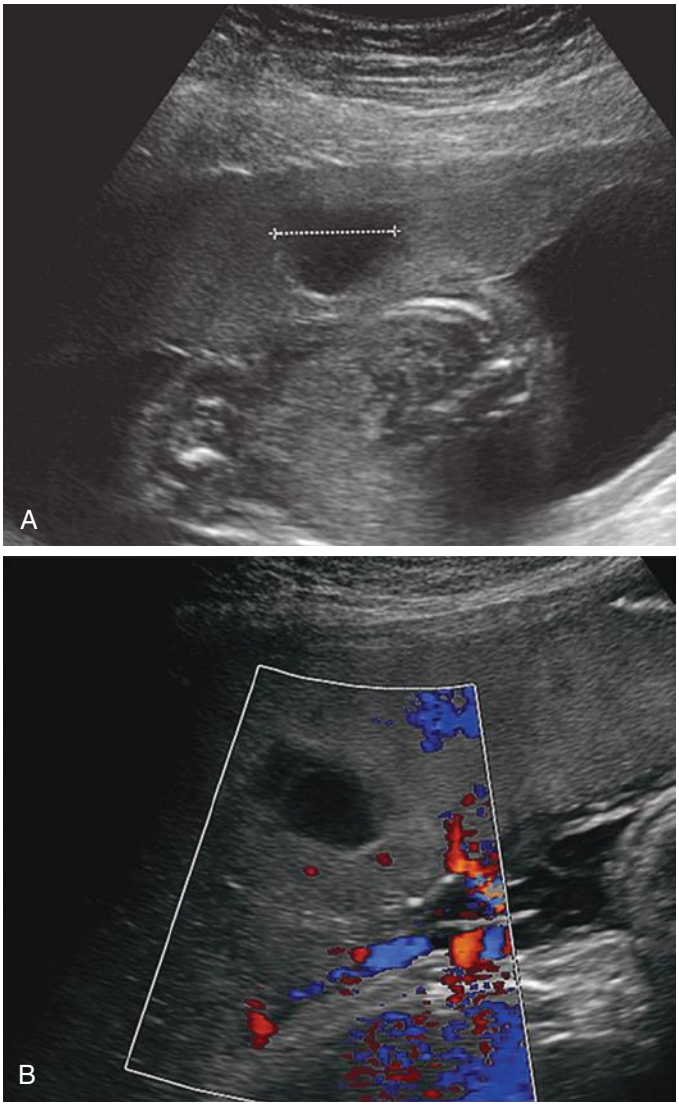

FIG 19-24 Placental sonolucencies. **A,** A sonolucency measuring 2 cm in diameter is visible within an otherwise homogeneous placenta at 20 weeks' gestation. **B,** Color Doppler sonographic imaging at 34 weeks' gestation demonstrates absence of flow within the hypoechoic cystic space.

Placental lacunae or lakes initially appear similar to placental sonolucencies on gray-scale images but display internal blood flow when color Doppler ultrasound is applied.[82] These lakes are homogeneous, anechoic, avillous vascular spaces in the placenta, surrounded by normal echogenic placental parenchyma. They can be seen within placentas implanted anywhere in the corpus. However, they are especially important when seen in association with placenta previa, as they may be a marker for placental invasion (accreta) in that setting (see Fig. 19-18).

Of the remaining vascular-disruption histologic types, most placental infarcts are initially hypoechoic and difficult to discern sonographically. With time, areas of involvement may calcify, making sonographic detection easier. *Maternal floor infarction* refers to the presence of dense fibrinoid layer within the placental basal plate and is erroneously termed an infarction. These lesions are not reliably imaged but may result in a thicker basal plate and heterogeneous placenta. Massive perivillous fibrin deposition and intervillous or subchorionic thrombosis in some cases may result in a jelly-like placenta. On ultrasound images, these placentas appear thickened, with patchy hypoechogenicity and an abnormal echotexture that seems to "wobble."

As stated, strict correlation between sonographic appearance and ultimate histologic diagnosis is imprecise. And variability in terminology and definitions used by sonologists and pathologists adds to the disparity among studies. In general, small placental sonolucencies or placental "lakes" are clinically insignificant, whereas larger or numerous lesions have been linked to fetal growth restriction.[83]

Placental Calcification

Calcium salts can be deposited throughout the placenta but are most common at the basal plate. Calcification accrues with advancing gestation, increasing maternal serum calcium levels, and smoking.[84,85] Echogenic foci representing calcifications can easily be seen and recognized sonographically. Grannum and coworkers (1979) created a grading scale from 0 to III that reflected increasing calcification with increasing numeric grade.[86] In the first and second trimesters, the normal homogeneous placenta lacks echogenic foci (grade 0). A grade I placenta displays 1-mm to 4-mm scattered horizontal hyperechoic lines within the placenta but not in its most basal layer. Grade II placentas show these echogenic lines throughout all depths as well as hyperechoic, comma-shaped curves extending from the chorionic plate into the placenta. In grade III placentas, the echogenic lines persist, and the deep hyperechoic indenting curves reach the basal plate (Fig. 19-25).

Such grading criteria are vulnerable to interobserver variability and show limited ability to predict neonatal outcome in low-risk general pregnancy populations.[87-89] However, some investigators note that placental calcification at an early gestational age may be associated with poor uteroplacental blood flow, placental abruption, and some adverse neonatal outcomes, including low birth weight.[90-94]

Placental Hematomas

The diagnosis of subchorionic or retroplacental hematoma is based on identifying an anechoic or hypoechoic fluid collection behind or adjacent to the gestational sac in the first trimester, or a similar fluid collection behind the placenta or membranes in the second trimester. Hematomas can also occur within the placenta or may be preplacental (Figs. 19-26 and 19-27). They are often identified in the setting of vaginal bleeding, particularly in the first trimester. Initially, a retroplacental hematoma typically is isoechoic or slightly hyperechoic compared to the placenta—so it may at first appear that the placenta is thickened or inhomogeneous. However, the hematoma generally becomes hypoechoic relative to the placenta within 1 week, and by 2 weeks the placental hematoma appears sonolucent.[95] When describing a hematoma, it is suggested that use of the term *hemorrhage* be avoided.

In population-based series, the prevalence of subchorionic hematoma is approximately 2% to 3% in the first or second trimester.[96,97] First-trimester hematoma has been associated with increased risk for adverse pregnancy outcome regardless of whether the sonographic findings are accompanied by vaginal bleeding[98] and regardless of hematoma size.[99] In one series of more than 1000 pregnancies with subchorionic hematoma identified during routine second-trimester ultrasound examination, the finding was associated with a 50% increase in the preterm birth rate and a threefold increase in the placental abruption rate.[97] A meta-analysis of seven series of subchorionic hematoma reported a twofold increase in risk for fetal death and stillbirth, such that approximately 1% of women with hematoma experienced a stillbirth.[100] No specific surveillance protocol has been demonstrated to have clinical utility in reducing rates of adverse outcome in this setting. Importantly, pregnancy outcomes are good

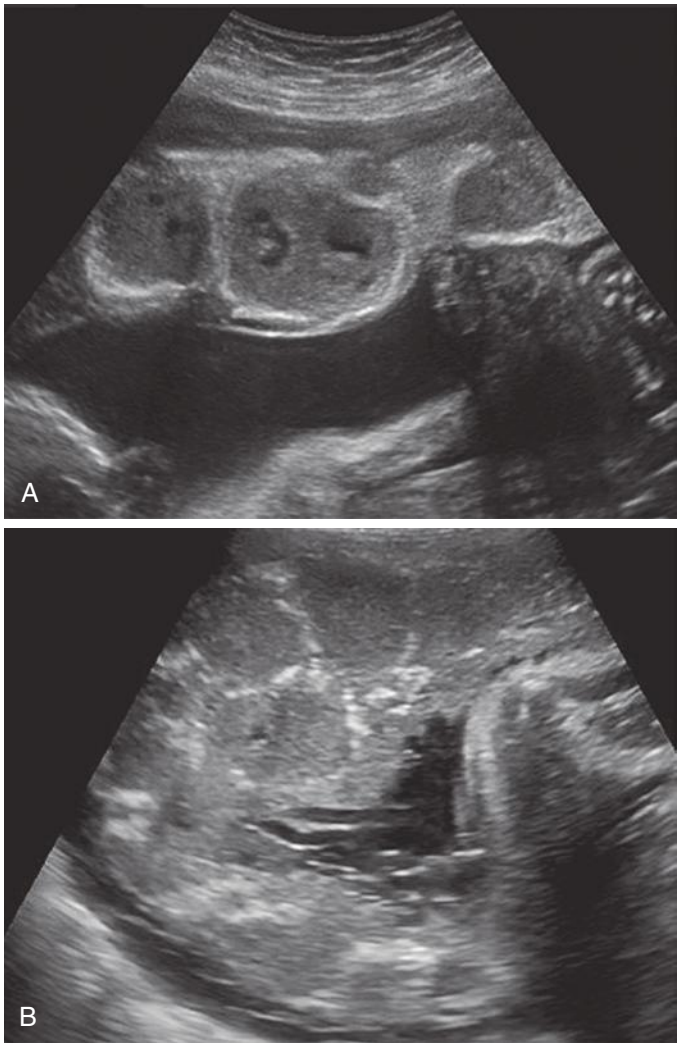

FIG 19-25 Placental calcifications. **A,** Extensive placental calcifications and small hypoechoic areas are visible in this 32-week gestation. The woman developed preeclampsia, and her fetus was growth restricted. **B,** Placental calcifications may be a normal finding, as in this 36-week gestation. The birth weight was appropriate for gestational age at delivery.

in most of those in whom subchorionic hematoma is an incidental sonographic finding.

Placental Abruption

Placental abruption, also termed *abruptio placentae*, is defined as the premature separation of a normally implanted placenta. It complicates approximately 1% of pregnancies.[101] Abruption is characterized by hemorrhage into the decidua basalis, resulting in an expanding decidual hematoma that prematurely detaches the placenta from the uterine wall. Risk factors include chronic hypertension, preeclampsia, preterm rupture of membranes, cigarette smoking, cocaine abuse, prior pregnancy complicated by abruption, and maternal trauma.[27] Pregnancies with first- or second-trimester bleeding may be found to have chronic placental abruption at delivery. With these, a retroplacental hematoma and a visible depression at the maternal surface of the placenta are seen during clinical inspection. The risk for abruption is reported to be increased about fivefold—a risk of approximately 5%—in the setting of a visible hematoma.[96,97]

Acute abruption constitutes an obstetric emergency that can lead to fetal death and, without prompt treatment, even maternal cardiovascular collapse. Although sonography is often used to evaluate the cause of third-trimester vaginal bleeding, acute placental abruption is *not* usually a sonographic diagnosis. One study of women being evaluated because of concern for abruption found that fewer than 25% of those with actual abruption at delivery had sonographic evidence of a subchorionic or retroplacental hematoma.[102] Thus, a normal sonogram cannot be used to exclude placental abruption.

There are no established sonographic criteria to define when a retroplacental hematoma is extensive enough to be considered an abruption. That said, use of the term implies that a hematoma has the potential to result in maternal or fetal compromise or has already done so. The sonographic appearance of placental abruption will depend in part on the size and location of the hematoma and, importantly, on the time elapsed between its development and the sonographic examination. Characteristics are shown in Figure 19-28.

CHORIOANGIOMA

These benign tumors are discrete masses composed of multiple fetal capillaries supported by stroma. Also called *chorangioma,* the incidence of these placental tumors approximates 0.2% to 0.6%.[103,104] In some instances, maternal serum alpha-fetoprotein levels are

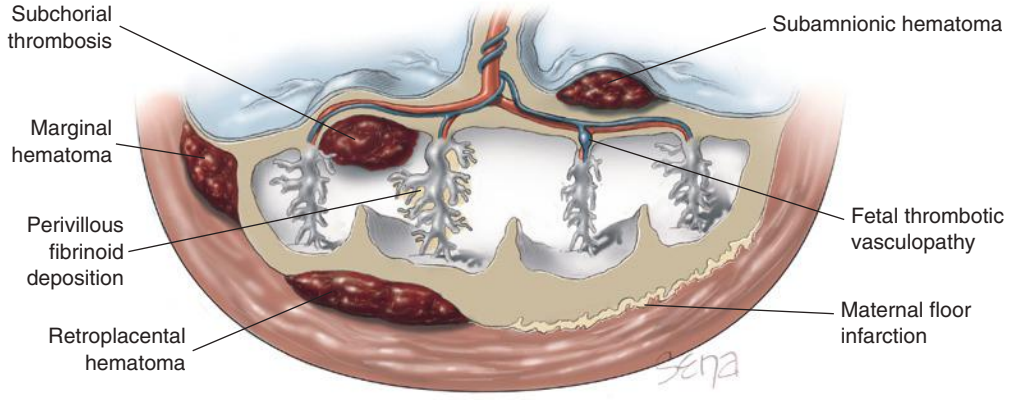

FIG 19-26 This drawing shows the locations of various placental hematomas. (From Hoffman BL, Cunningham FG: Placental abnormalities. In Cunningham FG, Leveno KL, Bloom SL, et al [eds]: Williams Obstetrics, 24th ed. New York, McGraw-Hill, 2014.)

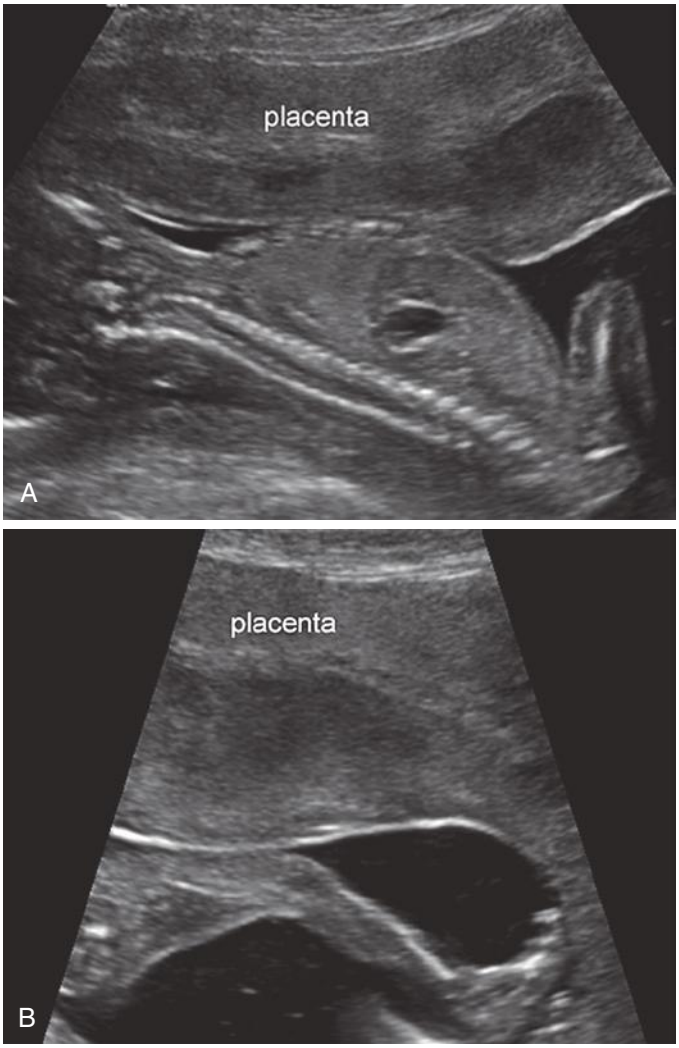

FIG 19-27 Placental hematoma. **A** and **B,** This patient presented with vaginal bleeding at 18 weeks and was found to have a large preplacental hematoma. The hematoma is similar in echogenicity to the underlying placenta, slightly hypoechoic, in the setting of acute bleeding.

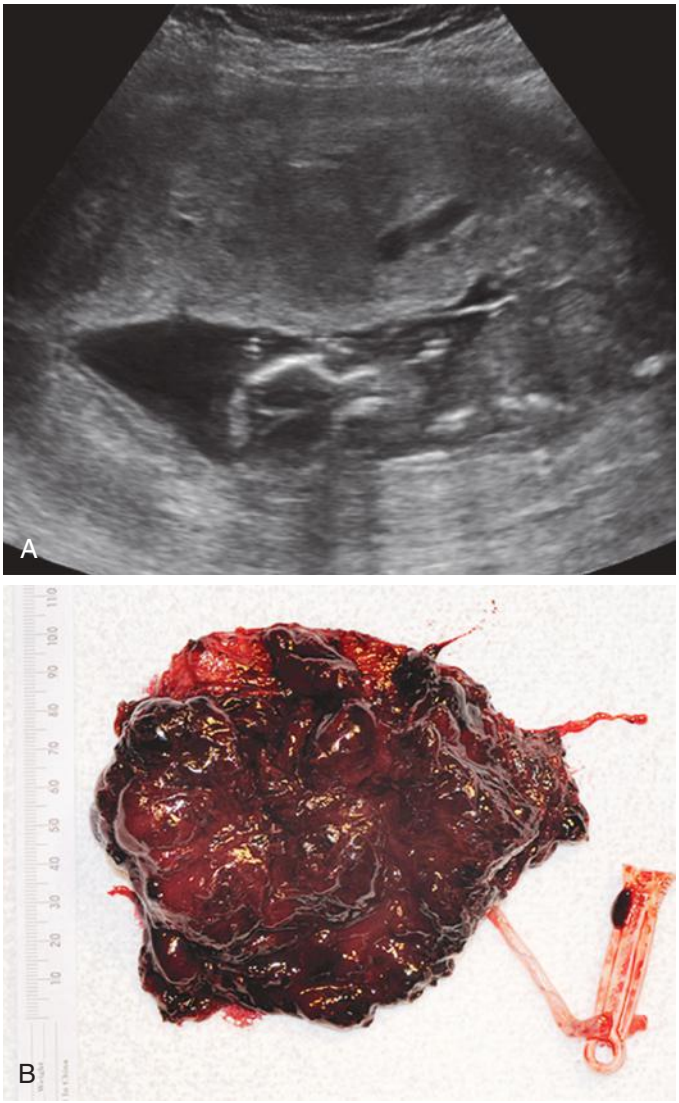

FIG 19-28 Placental abruption. **A,** This patient presented at 16 weeks with vaginal bleeding and pain. The placenta appears thickened and inhomogeneous. The fetus died during the sonogram. **B,** At delivery, more than 90% of the placenta was covered with adherent clot.

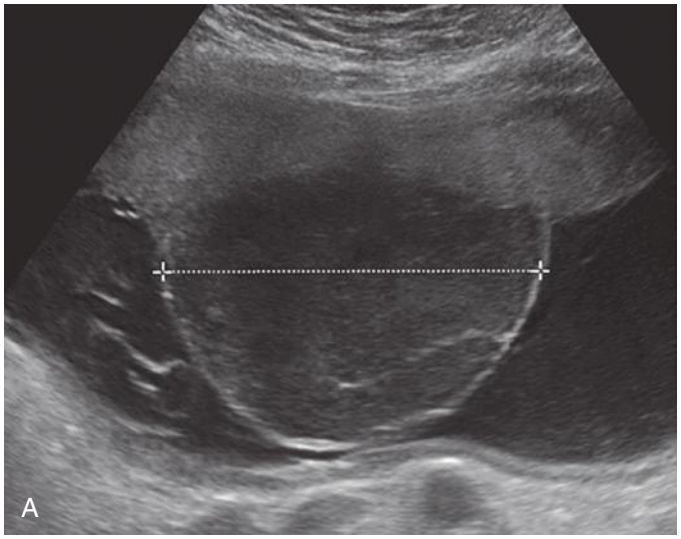
elevated.[105] On ultrasound images, a chorioangioma appears as a well-circumscribed, round, heterogeneous predominantly hypoechoic mass often near the cord insertion site along the fetal surface of the placenta and protrudes into the amniotic cavity (Fig. 19-29).[106] Variations may include tumors with internal septations or calcifications. Increased blood flow may be visible with color Doppler sonography and may help to distinguish these lesions from other placental masses. The differential diagnosis includes hematoma, partial hydatidiform mole, teratoma, tumor metastasis, and leiomyoma. Chorioangiomas with arterial or venous spectral Doppler waveforms have been identified.[107] During obstetric management, surveillance with serial sonograms is recommended to assess for possible rapid tumor growth, which has been reported and associated with rapid fetal decline.[108]

Physiologically, these tumors are predominantly perfused by the fetal circulation. Thus, chorioangioma size and degree of vascularity correlate with the volume of fetal blood shunted to the mass and are thereby predictive of fetal outcome. Small chorioangiomas are usually asymptomatic. Large tumors, typically those measuring more than 4 cm, may be associated with significant arteriovenous shunting resulting in fetal high-output cardiac failure and hydrops.[109] Platelet sequestration and erythrocyte damage within the mass can also cause fetal microangiopathic anemia and thrombocytopenia. Marked polyhydramnios can develop, and postulated theories include transudate from tumor vessels across the chorionic plate and increased fetal urine production associated with the hyperdynamic cardiac state.[110,111] Hemorrhage, preterm delivery, and fetal growth restriction may also complicate large tumors.[104,112,113] Because of these risks, some have treated large tumors in very preterm pregnancies by interdicting excessive blood flow using vascular occlusion or ablation techniques.[114-117] Successful prenatal intervention may best be achieved in those cases in which the chorioangioma is located remote from the umbilical cord insertion site and not supplied directly by the umbilical artery but rather by its secondary branches.[114,118] Fetal therapy for chorioangioma is discussed in Chapter 24.

In contrast to this focal mass, chorangiosis is an increased density of capillaries within villi and is one of the many causes of placentomegaly. Chorangiosis is found in approximately 5% of placentas submitted for histologic analysis.[119] Associated conditions include



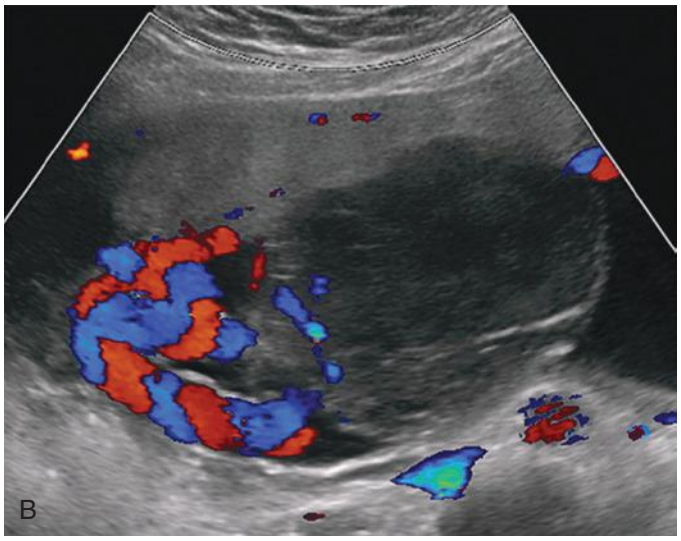


FIG 19-29 Placental chorioangioma. **A** and **B,** An inhomogeneous mass measuring more than 8 cm in diameter is visible bulging from the fetal surface of the placenta, adjacent to the placental cord insertion, in this 28-week gestation. The pregnancy was followed with frequent surveillance. Pathologic examination following delivery confirmed placental chorioangioma.

preeclampsia, maternal diabetes mellitus, placental abruption, cord anomalies, maternal infection, and pregnancy at high altitude.[120-122]

PLACENTAL MEMBRANE ABNORMALITIES

In early human development, the inner cell mass develops a small space, the future amniotic cavity, that is lined by amnioblasts and that lies above the embryoblast (Fig. 19-30). With expansion, the amnion eventually surrounds the embryo and sheaths the future umbilical cord (see Figs. 19-3 and 19-4).

In the early first trimester, the amnion and chorion are separated by the exocoelomic cavity, and this relationship is often seen sonographically (see Fig. 4-18). These layers later fuse and line the entire uterine cavity as the chorioamnion or placental membranes. Alterations in this relationship create membranes or bands seen sonographically and listed in Table 19-1. Those related to multifetal gestation and müllerian anomaly are discussed in their respective chapters.

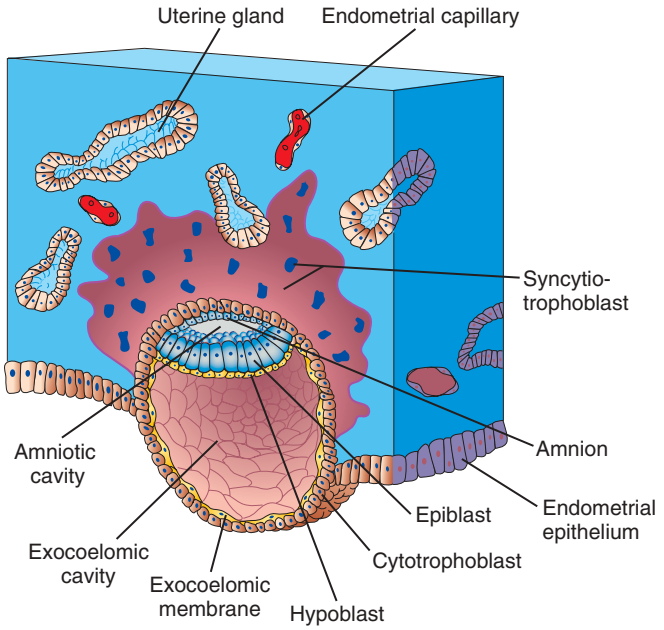

FIG 19-30 In early human development, the forming amnionic cavity is lined by amnioblasts (labeled amnion) and lies above the embryo's epiblast layer. (From Moore KL, Persaud TVN, Torchia MG: Second week of human development. In Moore KL, Persaud TVN, Torchia MG [eds]: The Developing Human: Clinically Oriented Embryology, 9th ed. Philadelphia, WB Saunders, 2013, p 42, Fig. 3-1A.)

Placenta-related hemorrhage was discussed earlier in this chapter, whereas extrachorial placentation, uterine synechiae, and amniotic band sequence are described here.

Extrachorial Placentation

Extrachorial placentation is the broader term used to describe both *circummarginate* and *circumvallate placentas.* Both are developmental variants in which the surface area of the chorionic plate is significantly smaller than that of the underlying placenta. This leaves a ring of placenta uncovered by chorionic plate, and hence, *extrachorial.* In this condition, the chorionic plate and its large vessels appear to stop abruptly, well short of the placental edge. From this abrupt line of transition, only amnion and chorionic membranes, without fetal vessels, cover the exposed outer ring of placenta. With circummarginate type, a smooth layer of amniochorion extends and covers the exposed peripheral placenta. With circumvallate placenta, the amniochorion folds back onto itself at the perimeter before extending across the outer rim of placenta (Fig. 19-31).

As a result, circummarginate placenta has no distinct sonographic findings. In contrast, with circumvallate placenta, ultrasound may reveal a thin curvilinear sheet or shelf of tissue bounded on each side by amniotic fluid. The sheet or shelf arises from and is attached to the peripheral margin of the placenta (Fig. 19-32). Despite these characteristic findings, the sensitivity of sonography for this diagnosis is poor.[123]

The clinical significance of extrachorial placentation has been debated. Associations between circumvallate placenta and adverse outcomes are reported by some but not all investigators and include antepartum bleeding, preterm labor, abruption, and perinatal death.[5,6,124-126] Moreover, it may be that larger rings of exposed placenta are linked with abnormal outcomes.[127] In contrast, these same studies show circummarginate placenta to be benign.

TABLE 19-1 Linear Structures and Bands Seen by Ultrasound During Pregnancy

Entity	Sonographic Findings
Normal early separation of the chorion and amnion	Cresent-shaped amnion mirrors the chorion's curvature. Distinct from the fetus. Fuses after 16 weeks' gestation.
Subchorionic hematoma	Echogenic blood lies between the myometrium and chorioamnion. The chorioamnion is seen as a thin linear reflector spanning the cavity. The hemorrhage and apparent band resolve with time.
Uterine synechiae (amniotic sheet)	Broad-based band, 2.5-4.0 mm thick, protrudes into and crosses the cavity. On cross section, appears shelf-like.
Circumvallate placenta	Broad-based curled wedge of tissue extends from one placental edge across to the other, just above the placental surface. On cross section, appears shelf-like.
Amniotic band	Thin wispy strands cross and appear to tether/entangle/distort fetal parts.
Uterine septum	Early intrauterine pregnancy is situated in one horn of a septate or bicornuate uterus. Thick band of echoes, which may be wedge-shaped, extend from uterine fundus in the midline.
Membranes from vanishing twin	Depending on chorionicity, either a thin amnion or thicker chorioamnion spans the cavity.
Placental vessels supported by membranes: Velamentous insertion	On gray-scale ultrasound imaging, vessel walls may appear as bands. Color Doppler interrogation will clarify by showing intraluminal flow.
Succenturiate lobe	

FIG 19-31 Circumvallate placenta. Chorionic plate vessels stop abruptly at this ringed perimeter. Here, the amniochorion folds back upon itself to create the characteristic circumferential curled edge. (Courtesy of Dr. Irwin Kerber, University of Texas Southwestern Medical Center, Dallas, Texas.)

Uterine Synechia(e)

This term refers to one or more linear bands of scar tissue within the uterus. In the setting of an intrauterine pregnancy, it may also be called an amniotic sheet, to indicate that the amnion and chorion layer (like a sheet) cover an intrauterine adhesion. The prevalence of this finding ranges from 0.5% to 1%.[128-131] The most common antecedent is prior uterine surgery such as curettage, which is reported to be 15% to 30% more common in those with synechiae than among control subjects.[129,130]

Sonographically, a thick, linear echogenic structure is seen to extend from one wall of the uterine cavity across to the other (Fig. 19-33). It may appear wider at its base. The fetus moves freely and untethered. There may be color Doppler flow along the sheet, but Doppler findings are considered variable.[128] A uterine synechia may resemble the thick dividing membrane of a dichorionic twin gestation or the linear echoes overlying a resorbed placental hematoma. It may also resemble the curled peripheral edge of a circumvallate placenta, though it can be distinguished from that entity in that its location is not restricted to the placental margin (see Fig. 19-31). The differential diagnosis of linear structures within the cavity includes both uterine synechia and amniotic band sequence. These entities can be distinguished by ultrasound given that uterine synechiae are prominent, echogenic, and isolated findings, whereas amniotic bands are thin and generally identified after associated fetal anomalies are recognized.

Previously, an amniotic sheet was considered a benign finding, and a goal of ultrasound evaluation was to exclude other conditions. However, in recent series, synechiae have been associated with preterm premature membrane rupture, preterm birth, and placental abruption.[129-131] Other outcomes, including fetal growth restriction and stillbirth, do not appear to be more common, and there is no evidence to support altering prenatal care or surveillance if a uterine synechia is identified.[129,131]

Amniotic Band Sequence

This rare sequence is caused and characterized by thin bands of amnion that cut across, tether, constrict, or amputate fetal parts. It is also called *amniotic band disruption complex (ABDC)* and *amniotic deformity adhesion and mutilation (ADAM)* complex. At least 80% of reported cases are associated with limb anomalies—primarily limb reduction defects.[132,133] Amputation of a distal extremity or digit(s) is common, and hands are involved more often than feet. Other abnormalities can include nonanatomic clefts of the face, cleft lip/cleft palate, or encephalocele.[134] Umbilical cord involvement is also frequent. In milder cases, a fetal extremity can appear entangled by faint linear echoes that represent bands of amnion. However, extensive defects involving multiple limbs and organ systems also may occur (Fig. 19-34). Severe defects of the spine or ventral wall that accompany amniotic bands suggest *limb-body wall complex*, which is discussed in Chapter 14 (Ultrasound Evaluation of the Fetal Gastrointestinal Tract and Abdominal Wall).

This condition is variably called a *syndrome*, meaning that all of the abnormalities result from the same cause, and a *sequence*, meaning that the abnormal findings developed sequentially from an initial insult. This reflects controversy about the underlying cause. Torpin (1965) proposed a theory implicating early rupture of the amnion, which allowed the embryo-fetus to become entangled in "sticky" mesodermal bands arising from the underlying chorion.[135] Torpin's *extrinsic* theory contrasted with the *intrinsic* theory proposed earlier by Streeter (1930)—namely, that an abnormality of the embryonic germinal disk was the primary insult and that the amniotic bands were secondary.[136] Astute

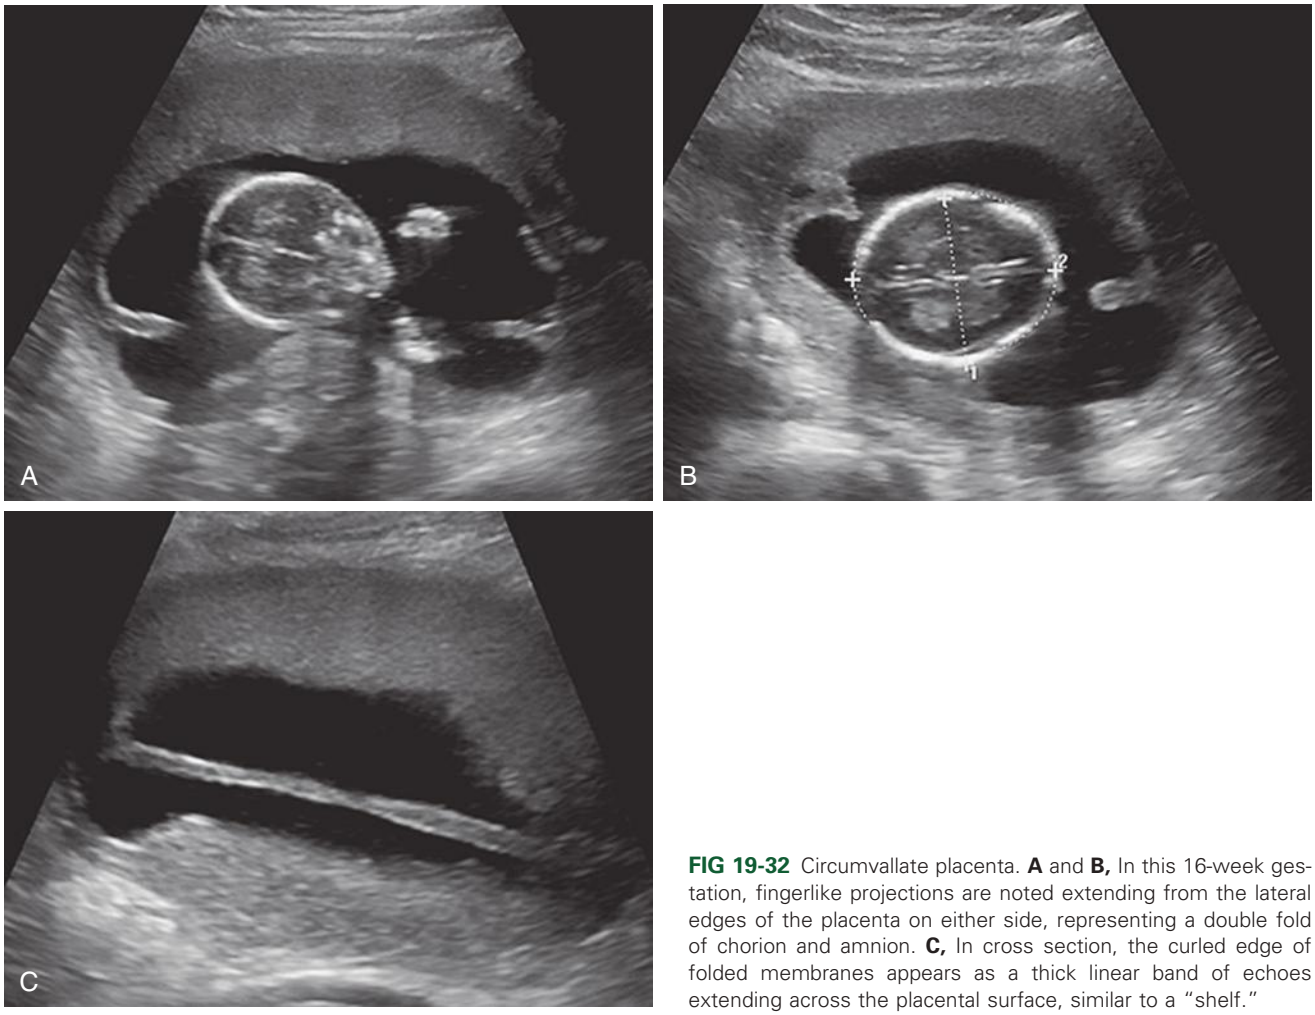

FIG 19-32 Circumvallate placenta. **A** and **B,** In this 16-week gestation, fingerlike projections are noted extending from the lateral edges of the placenta on either side, representing a double fold of chorion and amnion. **C,** In cross section, the curled edge of folded membranes appears as a thick linear band of echoes extending across the placental surface, similar to a "shelf."

FIG 19-33 Uterine synechia (amniotic sheet). A thick linear band of echoes extends anteroposteriorly across the uterine cavity in this 19-week singleton gestation. It has no relationship to the placental location, differentiating it from circumvallate placenta, and it does not involve fetal parts.

observations that amniotic bands cut across transversely rather than diagonally, and that they encircle fetal parts rather than coiling along them, are not fully explained by either theory (Bronshtein and Zimmer, 1997).[137] Nonetheless, most agree that fetal abnormalities associated with amniotic band sequence are disruptions, and the condition is virtually always sporadic.

Not infrequently, fetal morphologic abnormalities associated with amniotic band sequence are more obvious sonographically than the bands themselves (see Fig. 19-34). As with any fetal anomaly, targeted sonography is indicated. Identification of a limb reduction defect or an encephalocele in an atypical location—sites other than the occipital midline—should prompt careful evaluation for amniotic bands. Similarly, edema of a distal extremity or positional deformity of an extremity raises suspicion. With improvements in ultrasound imaging technology and routine first-trimester evaluation, the sequence has been detected in the late first trimester.[133] Counseling regarding prognosis generally depends on the fetal abnormalities visible by ultrasound. Fetal surgery for amniotic band sequence is discussed in Chapter 24 (The Role of Ultrasound in Fetal Procedures).

UMBILICAL CORD

Normal Development

Formed during embryogenesis, the umbilical cord contains the omphaloenteric duct, developing from the yolk sac, and the body stalk,

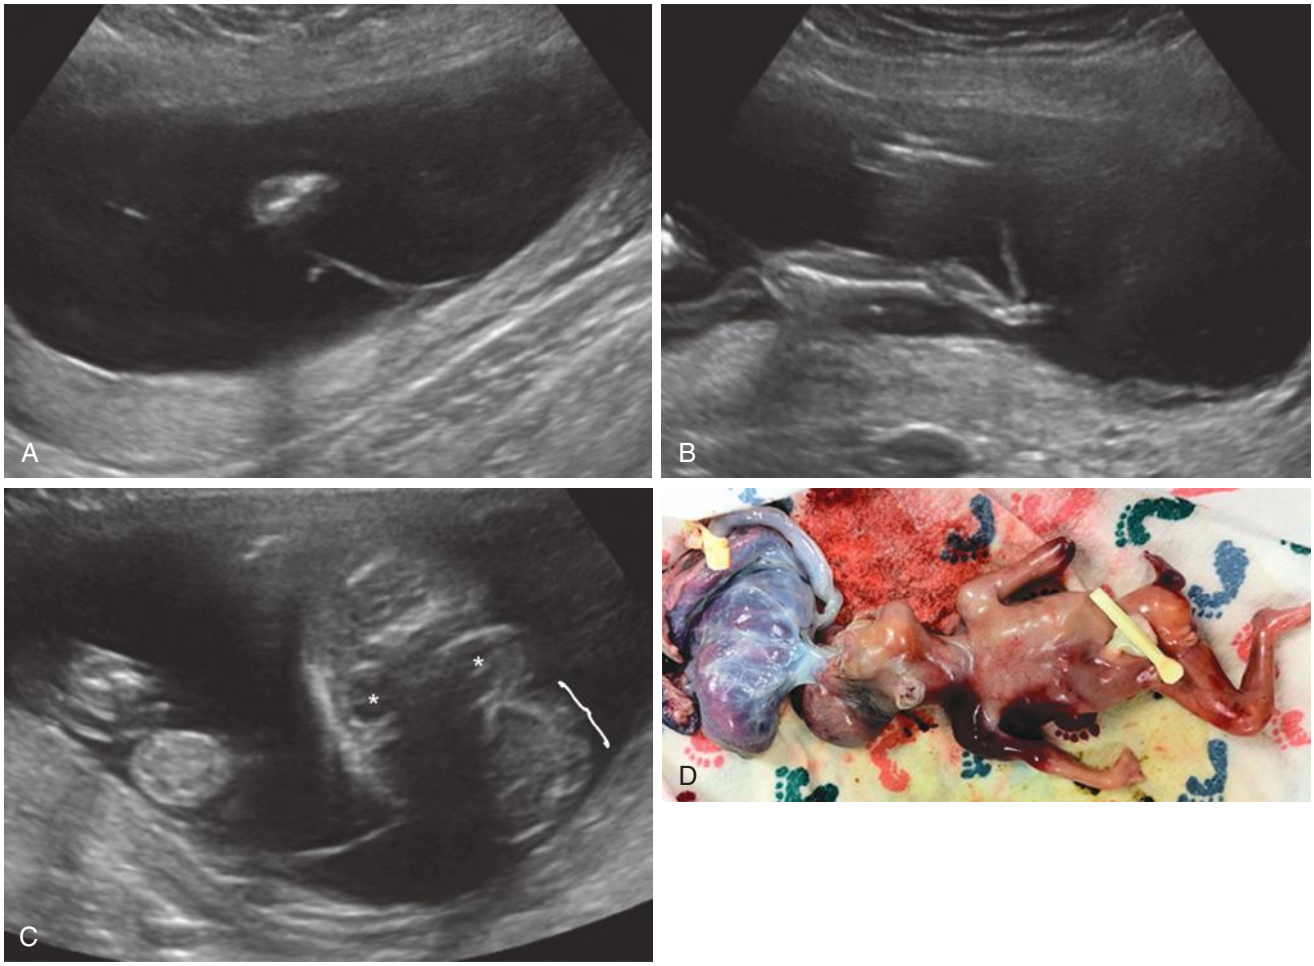

FIG 19-34 Amniotic band sequence. **A,** A wispy thin, discontinuous linear structure extends from the uterine wall in this singleton pregnancy at 19 weeks' gestation. **B,** The fetal arms appear entangled in these amniotic bands. Further imaging revealed significant disruption of the hands and fingers. **C,** The amniotic bands have resulted in a severe atypical encephalocele (*bracket*). Asterisks mark the orbits. **D,** Gross pathologic specimen of the fetus.

connecting the embryo and placenta (see Fig. 19-4). Within the body stalk, there are two umbilical arteries, which arise initially from the dorsal aorta and, after further development, from the internal iliac arteries. Also within this stalk, the allantois is a diverticulum of the yolk sac, and both umbilical veins arise from coalescing venules that drain the allantois. Ultimately, the extraembryonic portion of the allantois degenerates, the right umbilical vein becomes obliterated, and a single left umbilical vein remains. The omphalomesenteric or vitelline duct connects the primitive intestines with the yolk sac and usually regresses between the 7th and 10th weeks of gestation.

The final umbilical cord contains specialized mucopolysaccharide-rich mesenchyme, Wharton jelly, which surrounds the two umbilical arteries and one umbilical vein. This substance is not typically seen by ultrasound, and the cord is visually identified by its three vessels (Fig. 19-35).

Remnants and Cysts

Several structures are present within the umbilical cord during fetal development, and their remnants may be seen when the mature cord is cut transversely. Indeed, Jauniaux and colleagues (1989) sectioned 1000 cords, and in one fourth, they found remnants of vitelline duct, allantoic duct, and embryonic vessels.[138] These remnants were not associated with congenital malformations or perinatal complications. However, because of their small size, most are not identified sonographically.

Cysts occasionally are found along the course of the cord. They are designated histologically according to their origin. True cysts are epithelium-lined remnants of the allantoic or vitelline ducts and tend to be located closer to the fetal insertion site (Fig. 19-36). An allantoic cyst may be associated with a urachal anomaly, and evaluation may identify a persistent communication between the bladder and the umbilical cord—a *patent urachus*. In contrast, more common pseudocysts form from local degeneration of Wharton jelly and occur anywhere along the cord. True cysts and pseudocysts can have a similar sonographic appearance.

Single umbilical cord cysts are identified in approximately 1% of first-trimester sonograms.[139,140] Most are isolated and resolve, and these are not associated with adverse pregnancy outcomes.[140,141] Multiple cysts, in contrast, may confer increased risk for spontaneous abortion or aneuploidy.[139] Cysts persisting into the second or third trimester are associated with an increased risk for fetal abnormalities, particularly omphalocele and patent urachus, and if abnormalities are present, the aneuploidy risk is also increased.[142] Thus, an umbilical cord cyst is an indication for a targeted obstetric sonogram. However,

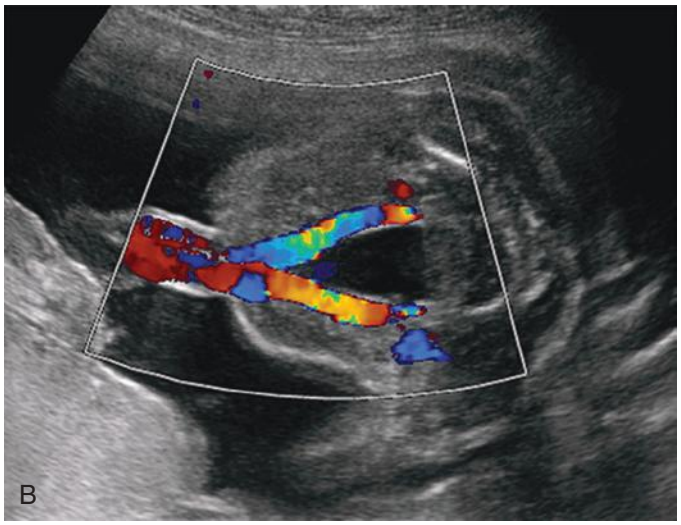

FIG 19-35 A, Normal three-vessel umbilical cord in cross section, comprising two umbilical arteries and a larger umbilical vein. **B,** Color Doppler image of the fetal bladder encircled by the two umbilical arteries, which are a continuation of the superior vesical arteries, confirms that the cord has three vessels.

if no associated anomalies are identified, the prognosis appears to be favorable.

Dimensions and Coiling

Most umbilical cords are 40 to 70 cm long, and few measure less than 32 cm or greater than 100 cm. Cord length is influenced positively by both amniotic fluid volume and fetal mobility. Short cords may be associated with fetal growth restriction, congenital malformations such as body stalk anomaly, intrapartum distress, and a twofold increased risk for stillbirth.[143,144] Excessively long cords are more likely to be linked with cord entanglement or prolapse and with fetal anomalies, acidemia, and demise.

Antenatal determination of cord length is technically challenging. Although not part of standard sonographic evaluation, cord diameter has been used as a predictive marker for fetal outcomes. The main variable resulting in differing diameters is the Wharton jelly content. Some have linked lean cords with poor fetal growth and large-diameter cords with macrosomia. However, the clinical utility of this parameter is still unclear.[145-148]

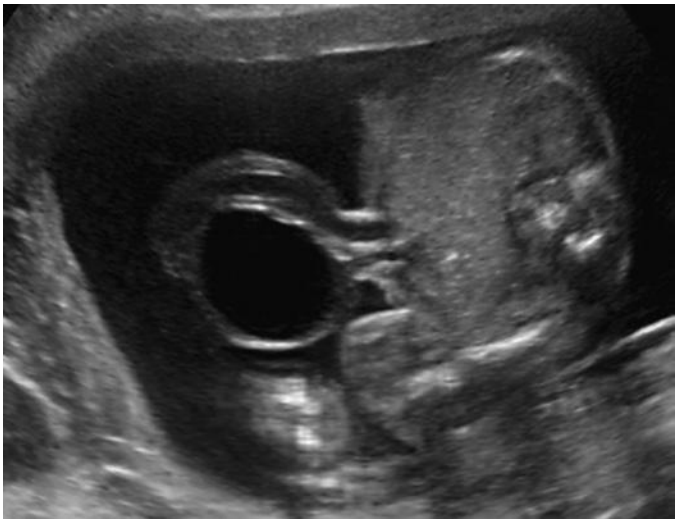

FIG 19-36 Umbilical cord cyst. A 2-cm anechoic cyst is visible eccentric to the cord vessels and within millimeters of the fetal ventral abdominal wall in this 20-week gestation. The differential diagnosis for this finding includes an omphalomesenteric duct cyst, allantoic duct cyst, and amniotic inclusion cyst. Pseudocysts, which are not lined by epithelium and represent focal absence of Wharton jelly, are also common.

Cord coiling characteristics have also been reported, although this too is not part of standard sonographic evaluation. The umbilical vessels usually spiral through the cord in a sinistral (left-twisting) direction.[149] The number of complete coils per centimeter of cord length has been termed the *umbilical coiling index (UCI)*.[150] The reported normal sonographic index is 0.4, which contrasts with the normal value of 0.2 derived by actual cord measurement postpartum (Figs. 19-37 and 19-38).[151]

Most pregnancies with an abnormal UCI have a normal outcome. Some, but not all, pathologic studies of delivered placentas and cords report an increased association of hypo- or hypercoiling and stillbirth, fetal growth restriction, intrapartum distress, and chromosomal or anatomic abnormalities.[152-156] However, sonographically estimated UCI may be less helpful, as it may not correlate with the measured value obtained from the postpartum specimen.[153,157-159] Moreover, cord coiling varies along the length of the cord, and it is more coiled near the fetus, which may affect measurement accuracy.[160]

Vascular Abnormalities of the Umbilical Cord

Single Umbilical Artery

A single umbilical artery (SUA), resulting in a two-vessel umbilical cord, is usually identified sonographically when an artery is visible coursing adjacent to the fetal bladder along only one side (Fig. 19-39). A SUA may be visible in the first trimester. It is readily identified during the routine second trimester fetal anatomic survey, and documentation of umbilical cord vessel number is a standard component of this examination.[13] In a cross section of the umbilical cord, only a single artery and the vein are visible (see Fig. 19-39). The diagnosis of suspected SUA should be verified at the level of the fetal bladder, as the two umbilical arteries may occasionally fuse near their placental insertion. Theories regarding the pathogenesis of SUA include primary agenesis or secondary atrophy of one of the two umbilical arteries.[161]

In population-based series, the prevalence of SUA identified during second-trimester sonographic examination is 0.4% to 0.6% in singleton pregnancies or approximately 1/200 births.[162-164] The prevalence is

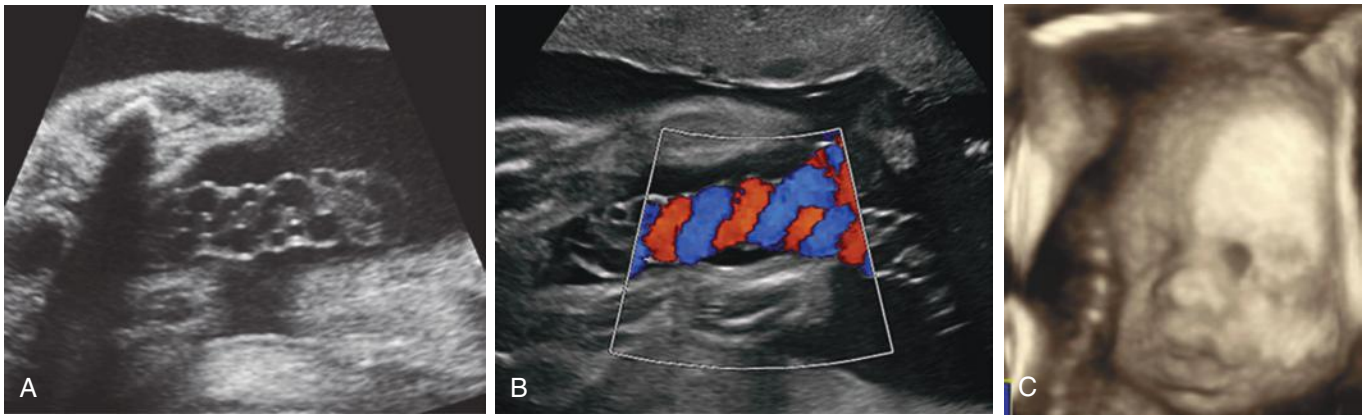

FIG 19-37 Hypercoiled umbilical cord. **A,** Hypercoiling of the umbilical cord vessels was incidentally noted during a routine second-trimester sonogram. **B,** Color Doppler imaging depicts the coiled loops of cord. **C,** Three-dimensional sonography shows the coiling of this umbilical cord in the third trimester.

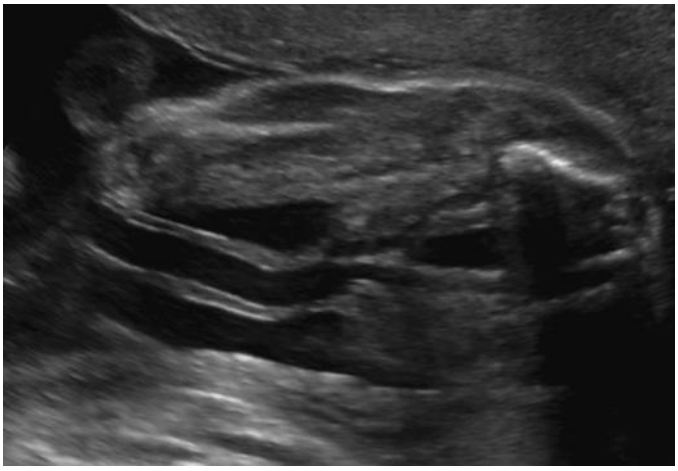

FIG 19-38 Hypocoiled umbilical cord. The vessels of the umbilical cord appear undercoiled throughout its course. The two umbilical arteries are visible on either side of the larger umbilical vein.

higher in populations referred for risk factors such as maternal age, abnormal aneuploidy screening, or suspected fetal abnormalities.[165] An important consideration and observation is whether the SUA is *isolated*, namely, whether it occurs without associated major fetal structural abnormalities or aneuploidy. In approximately 80% of cases, SUA is an isolated finding.[162-164]

Of those cases with SUA, the left umbilical artery is absent in approximately 70%,[165] and in some but not all reports, absence of the left umbilical artery is more strongly linked with structural anomalies and aneuploidy.[166,167] Tobacco use is associated with a twofold increased risk.[164] The prevalence of SUA in one fetus in a twin pregnancy is approximately 2%, with no relation to chorionicity, thus affecting 1% of twin fetuses overall.[168]

SUA has been consistently associated with an increased risk for congenital abnormalities—in particular, cardiac and renal anomalies. In population-based series, the risk for cardiac anomalies in nonaneuploid fetuses with an SUA is 7%, and the risk for renal anomalies approximates 5%, most commonly with renal pelvis dilatation.[162-164] This amounts to a 20-fold increase in the risk for cardiac anomalies and a threefold increase in the risk for renal anomalies in singleton

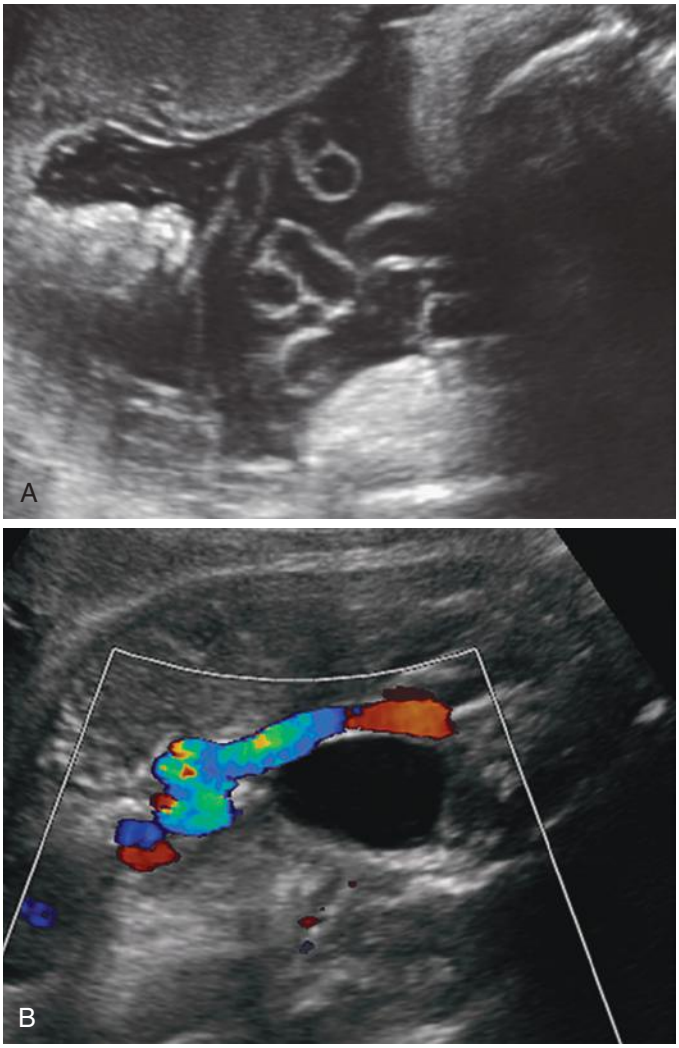

FIG 19-39 Single umbilical artery, also called two-vessel cord. **A,** In cross section, only one umbilical artery and vein are visible. Because two umbilical arteries may sometimes fuse near the placental cord insertion, suspected single umbilical artery should be confirmed at the level of the fetal bladder. **B,** Color Doppler imaging shows only one umbilical artery adjacent to the fluid-filled bladder.

pregnancies.[163] Targeted sonographic evaluation is recommended when an SUA is identified. It is somewhat controversial whether fetal echocardiography is also indicated, particularly if the finding appears isolated.[162,169]

When SUA is seen in association with fetal morphologic abnormalities, the aneuploidy risk is considerably increased. With one major structural anomaly and SUA, the aneuploidy risk is approximately 4%, increasing to as much as 50% if more than one major anomaly is present.[170] Among aneuploid fetuses, approximately 15% have an SUA.[165] The most common chromosomal abnormality associated with SUA is trisomy 18, followed by trisomies 13 and 21 and triploidy.[165,170] Importantly, in the absence of associated anomalies, multiple investigators have reported that the risk for aneuploidy is *not* increased with isolated SUA.[165,167,170]

An association between isolated SUA and fetal growth restriction has been well described but remains controversial. Several recent series have identified an approximate twofold increase in the prevalence of low birth weight (at or below the 10th percentile for gestational age) with isolated SUA.[163,164] However, other researchers have found no increase in rates of fetal growth impairment.[166,171,172] A recent systematic review of more than 900 pregnancies with isolated SUA found that affected infants weighed approximately 50 g less than those with three-vessel umbilical cords, a difference that did not reach statistical—or clinical—significance.[173] The authors of this meta-analysis concluded that serial sonograms for growth assessment should not be routine practice.[173]

Persistent Right Umbilical Vein

As noted earlier, the vein in the fully developed umbilical cord is normally the left umbilical vein. The right umbilical vein is present early but then atrophies in most cases. When the right umbilical vein persists, the left umbilical vein atrophies—such that the cord has three vessels. This variant is appreciated on views through the fetal abdomen but not the umbilical cord. In a transverse image of the fetal abdomen at the level at which the abdominal circumference is measured, the intrahepatic persistent right umbilical vein is visible lateral and to the right, rather than to the left, of the fetal gallbladder and it courses toward, rather than away from, the left side of the fetal stomach (Fig. 19-40).

As an isolated sonographic finding, an intrahepatic persistent right umbilical vein would not be apparent at birth unless specifically sought. In sonographic series, the reported prevalence approximates 1 in 1000.[174,175] Associated anomalies, particularly cardiovascular and renal abnormalities, have been described in 25% to 40% of cases.[174-176] It is plausible that because anomalies associated with persistent right umbilical vein may be more obvious during a screening sonogram than the venous variant, the reported prevalence may be underestimated. Nonetheless, targeted sonographic evaluation is recommended if a persistent right umbilical vein is identified. If the anomaly is isolated, it is not associated with aneuploidy, and the fetal prognosis is considered excellent.[174-176]

Umbilical Vein Varix

An umbilical vein varix is a focal dilatation of the umbilical vein within the fetal abdomen. Thus, the umbilical *cord* is normal. A varix is diagnosed based on the transverse diameter measurement of the umbilical vein at its widest point, which is typically just within the fetal abdominal wall. The caliber of the vein normally increases with advancing gestational age, from approximately 3 mm at 15 weeks to 8 mm by term.[177] The image is obtained with a transverse sonographic view of the abdomen (Fig. 19-41). In most research studies and case reports, varix is diagnosed when the measurement is 9 mm or greater or if the

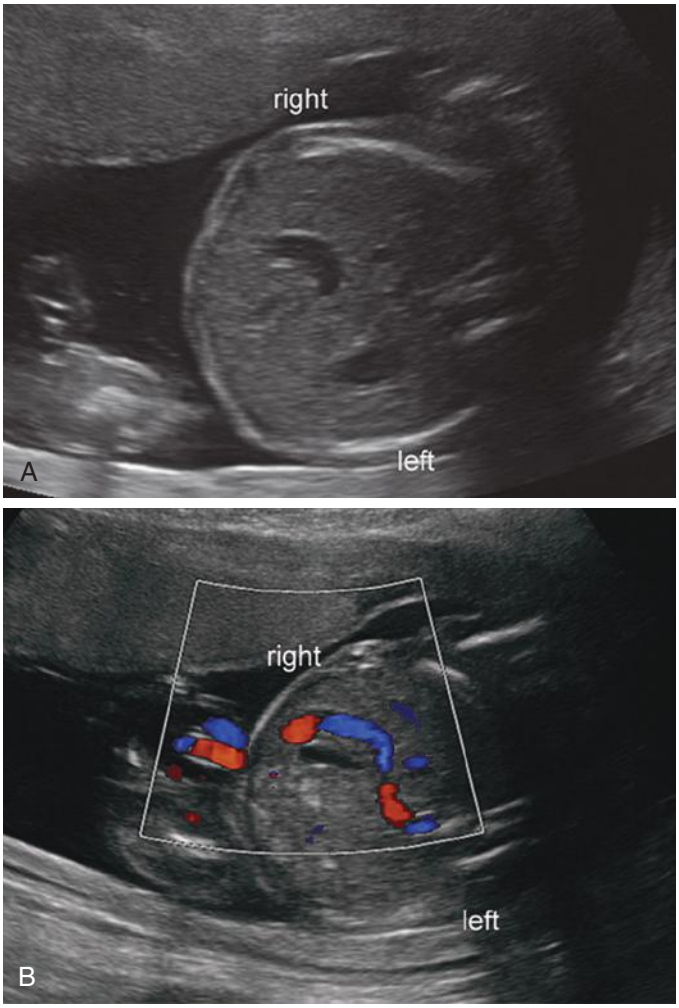

FIG 19-40 Persistent right umbilical vein. **A,** In this transverse view of the fetal abdomen at 19 weeks, the J-shaped intrahepatic umbilical vein courses toward (rather than away from) the left side of the fetal stomach. **B,** Color Doppler sonography reveals the course of the persistent right umbilical vein, located lateral and to the right of the gallbladder.

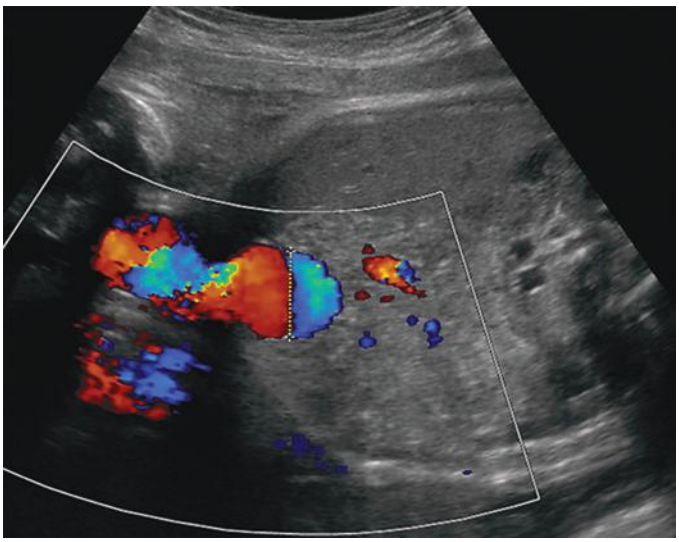

FIG 19-41 Umbilical vein varix. Color Doppler sonography depicts focal enlargement of the intra-abdominal umbilical vein in this 36-week gestation. The diameter of the vein measured 17 mm.

measurement of the extrahepatic portion of the umbilical vein is at least 50% larger than the intrahepatic portion.[178-182]

The reported prevalence of umbilical vein varix ranges from approximately 1/400 to 1/2000 pregnancies, with the diagnosis typically made in the third trimester.[178,180,182] Umbilical vein varix is associated with major fetal anomalies in approximately 5% to 10%, and minor aneuploidy markers in another 10% to 15%.[178,180,182] The aneuploidy risk is increased when structural anomalies or minor markers are visible, with trisomy 21 the most commonly reported. These findings are in contrast to early studies, which reported a strong association between umbilical cord varix and major abnormalities, as well as fetal demise.[177,183] However, in recent series, at least 80% of cases were found to be isolated, and good outcomes have been consistently described.[178,179,182] This may reflect greater awareness of this finding and improved visualization with modern sonographic equipment.

It is believed that the extrahepatic portion of the vein within the abdomen represents the weakest part of the umbilical circulation.[182] This weakness may account for dilatation of the umbilical vein observed in cases of hydrops fetalis and other conditions with fetal volume overload or heart failure, such as alloimmunization, twin-twin transfusion syndrome, and twin-reversed arterial perfusion sequence.[178,180,182] Because of the association with other abnormalities, targeted sonographic evaluation is recommended. Fetal surveillance has also been advocated, although evidence that this results in improved pregnancy outcomes is lacking.

Knots, Nuchal Cords, and Cord Entanglement

A knot or "true knot" in the umbilical cord is occasionally encountered by ultrasound, although it is more likely to be an unexpected finding at delivery (Fig. 19-42). The prevalence at birth approximates 1%.[184,185] Factors associated with cord knots include longer umbilical cord and multiparity. In population-based series, a knot in the umbilical cord is associated with a 4- to 10-fold increase in the risk for fetal death.[184,185] In case reports, color Doppler, power Doppler, and 3D or 4D sonography have been used to improve image quality in suspected cases.[186-189] Based on expert opinion, fetal surveillance has been suggested if this finding is incidentally discovered, but there is no evidence to support a specific modification to prenatal care.[187-190] Focal redundancy of the umbilical cord vessels has been termed a *false knot* (Fig. 19-43). This redundancy of cord vessels is of no clinical significance.

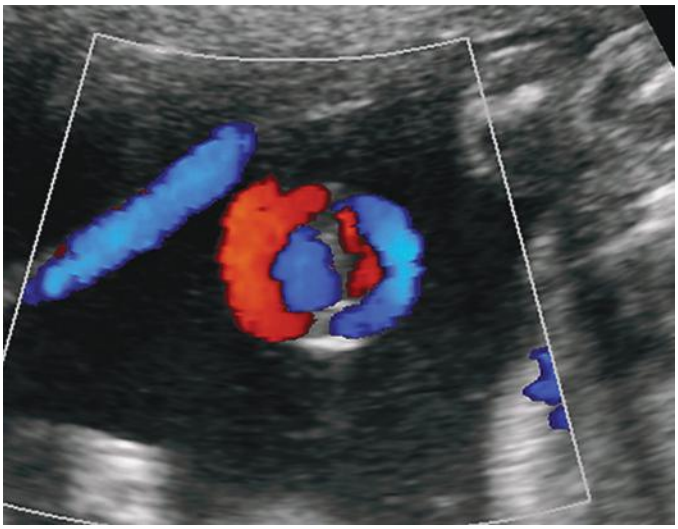

FIG 19-42 Umbilical cord knot suggested by color Doppler sonography at 22 weeks' gestation.

Nuchal cord is present in approximately 15% to 30% of births, and it is not considered a complication of either pregnancy or delivery. If sought, it is often identified by in utero ultrasound. However, prenatal detection of a nuchal cord is not associated with adverse fetal outcome, and no form of surveillance is recommended.

Umbilical cord entanglement is frequently identified when scanning monochorionic, monoamniotic twins, and it is invariably encountered at delivery (Fig. 19-44). In one recent series, all monoamniotic twin gestations had sonographic evidence of cord entanglement when this finding was specifically sought (Fig. 19-45).[191] Cord entanglement is no longer believed to be a major contributor to perinatal morbidity or mortality risks in these rare pregnancies.[192] Rather, adverse outcomes in monoamniotic pregnancies are more commonly attributable to other complications such as twin-reversed arterial perfusion sequence, to prematurity, or to associated anomalies. Surveillance is commonly instituted once viability is reached.

FIG 19-43 Knotting and coiling of the umbilical cord. **A,** A false knot is shown and the cord segment toward the right of this is hypocoiled. **B,** A complex true knot is shown and the cord segment toward the right of this is hypercoiled.

FIG 19-44 Umbilical cords from a monochorionic-monoamniotic twin pair after cesarean delivery show marked entanglement. (Courtesy of Dr. Seth Hawkins, University of Texas Southwestern Medical Center, Dallas, Texas.)

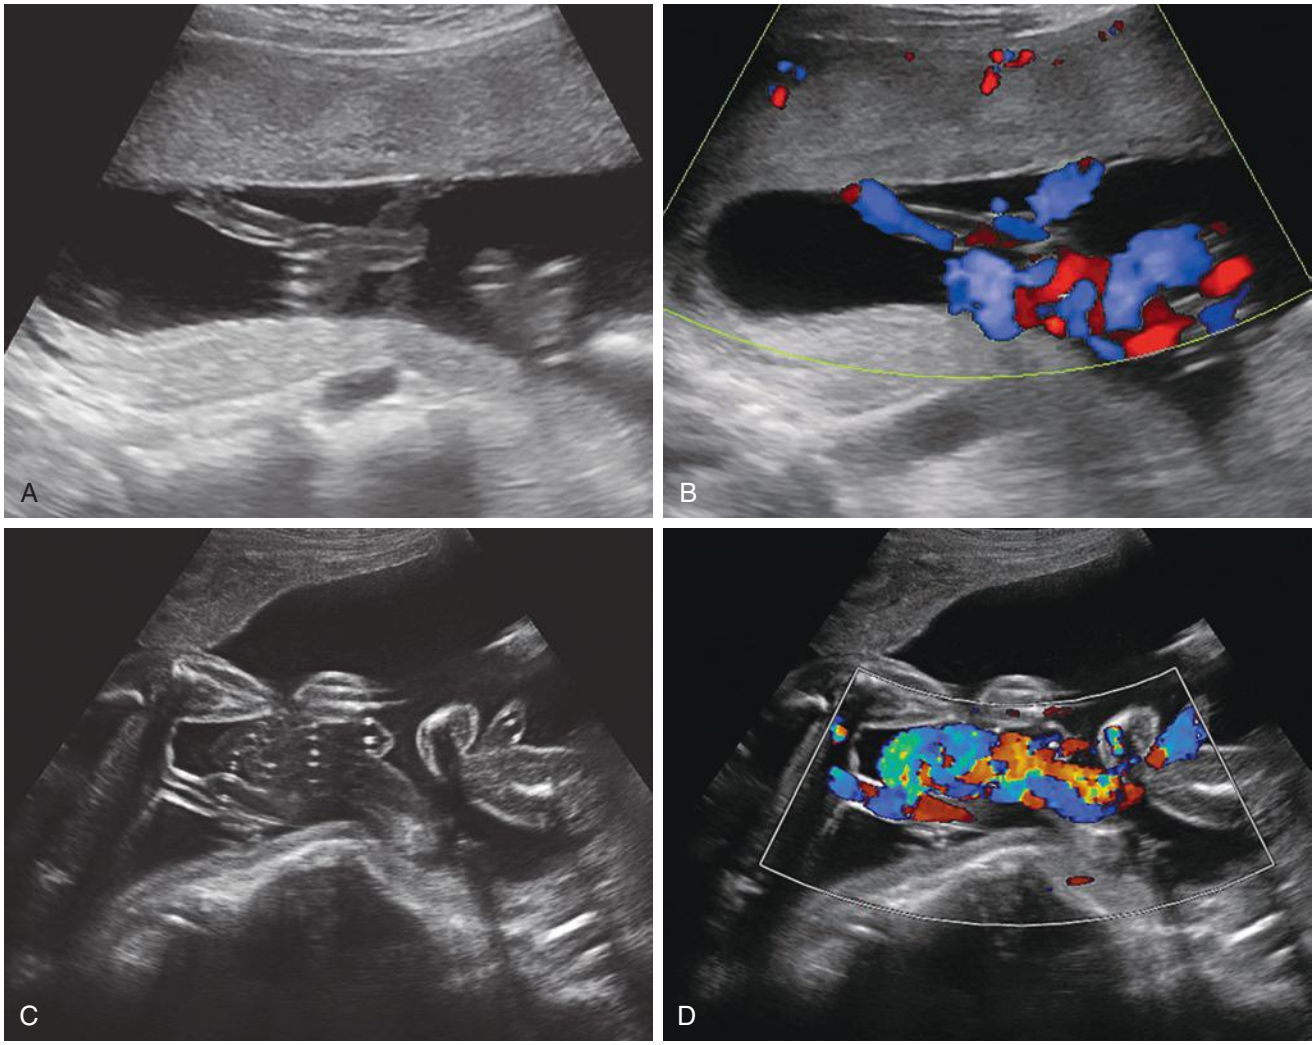

FIG 19-45 Cord entanglement. **A,** In this monochorionic-monoamniotic twin gestation at 20 weeks, there is cord entanglement near the level of the placental cord insertion sites—which are in close proximity to one another. **B,** Color Doppler sonography may help facilitate visualization of cord entanglement. **C,** Cord entanglement is also apparent near the insertion of the umbilical cord at the fetal ventral abdominal wall. **D,** Again, color Doppler sonography demonstrates the two entwined cords. The infants were delivered by cesarean at 32 weeks, without incident.

SUMMARY

Evaluation of the placenta and umbilical cord is an important component of obstetric sonography. Assessment of the relationship between the placenta and the internal cervical os is essential in the second and third trimesters. Conditions associated with vasa previa include resolved placenta previa or low-lying placenta, velamentous cord insertion, and succenturiate or bilobate placenta. Sonographic criteria for detection of placenta accreta include placental lacunae, thinning of the retroplacental myometrium, and irregularity or disruption of the bladder-serosal interface, with bridging vessels between placenta and the bladder-serosal interface on color Doppler imaging. Targeted sonography is indicated if there are abnormalities of the umbilical cord or its vessels, including umbilical cord cyst, SUA, or persistent right umbilical vein, to evaluate for the presence of associated fetal anomalies. Finally, and importantly, transvaginal sonography is frequently key to accurate placental assessment and is considered safe regardless of placental location, even in the presence of bleeding.

Amniotic Fluid Volume in Fetal Health and Disease

Everett F. Magann, Adam T. Sandlin

SUMMARY OF KEY POINTS

- The pathways influencing amniotic fluid volume (AFV) are dynamic and complex and are not completely understood.
- The balance of maintaining the overall AFV occurs at three key areas: fetal urine production and fetal swallowing, the intramembranous pathway, and the osmotic fluid gradient created between the mother and the fetus.
- There are several published curves that attempt to define a normal AFV.
- Abnormal fluid volumes should be defined as specific high or low values across gestation that are linked with adverse pregnancy outcomes.
- The single deepest pocket measurement for estimation of the AFV is the preferred technique for assessment during the ultrasound evaluation.

OUTLINE

Amniotic fluid provides an ideal setting for the developing fetus by providing an environment that protects from trauma, provides a source of water, allows for normal fetal movements essential for anatomic development, and contributes to the development of the fetal lungs.[1] The amniotic fluid volume (AFV) can reflect fetal well-being, and changes in the volume may indicate maternal or fetal disease processes. Therefore, the assessment of the AFV is an essential component to the sonographic evaluation of the gravid patient.

AMNIOTIC FLUID PHYSIOLOGY AND DYNAMICS

Once thought to be a static collection of fluid with turnover once per day, the AFV is now recognized to be a complex system involving multiple dynamic pathways that influence the inflow and outflow of fluid and solutes within the amniotic space. The physiologic processes that influence the AFV are complex and not yet completely understood. In order to appreciate the AFV, knowledge of the pathways for potential amniotic fluid movement and the regulatory mechanisms involved need to be considered.

Several potential variables influence the overall AFV. Most influential are fetal urine production and fetal swallowing.[2] Others include secretion of fetal lung fluid, the intramembranous pathway (movement of water and solutes between amniotic fluid and fetal blood and the placenta), the transmembranous pathway (movement of water and solutes across the surface area of the amnion and chorion), secretions by the fetal oronasal cavities, and movement of water across the highly permeable fetal skin during early gestation.[2] Amniotic fluid consists primarily of water (98-99%).[2] In early pregnancy, amniotic fluid is isotonic with maternal or fetal plasma and contains a small amount of proteins.[2] Although amniotic fluid is present in early gestation prior to fetal urine production, not much is known regarding the dynamics of amniotic fluid early in human pregnancy. However, there is likely an active transport of solutes across the amnion into the amniotic space with water moving passively down an osmotic gradient.[2] A transudate of plasma may also occur across nonkeratinized fetal skin or from the mother across the uterine decidua and the placental surface, which may contribute to the AFV in early pregnancy[1] (Fig. 20-1).

Much more is known about the dynamics of the AFV in the latter half of pregnancy. Fetal skin keratinizes at approximately 22 to 25 weeks' gestation, preventing further movement of water across the fetal skin.[2] As a result of an increasing production of dilute fetal urine, amniotic fluid osmolality and sodium concentrations decrease as the gestational age increases.[2] Ultimately amniotic fluid osmolality reaches 250 to 260 mOsm/mL at term.[2] Fetal osmolality (≈278 mOsm/mL) remains close to maternal osmolality (280 mOsm/mL), thereby

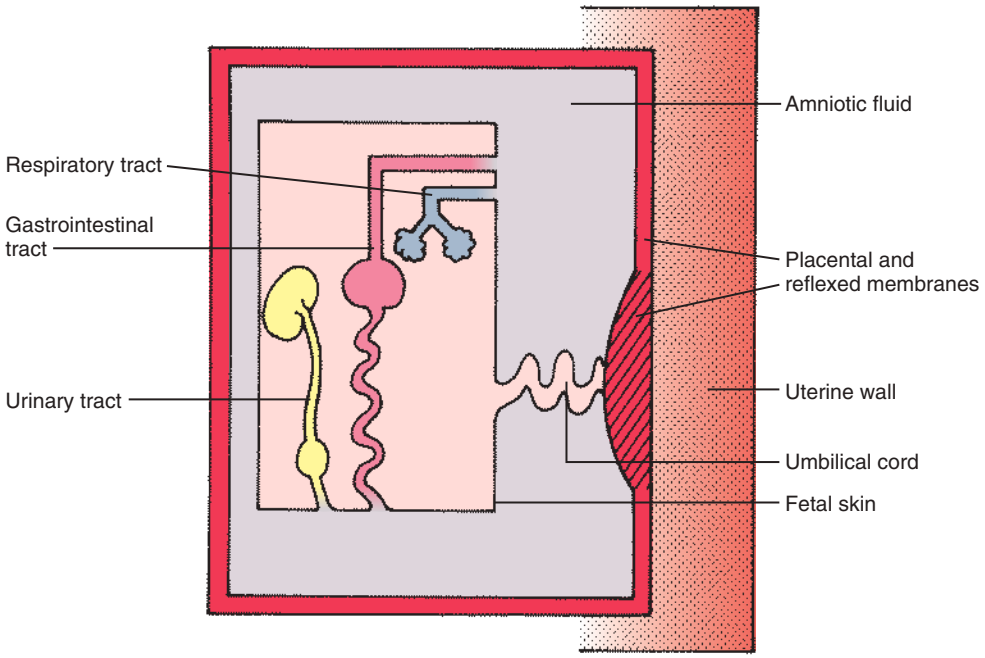

FIG 20-1 The major fetal and maternal amniotic structures involved in the formation and reabsorption of amniotic fluid. (From Wallenburg HCS: The amniotic fluid. J Perinatal Med 5:193, 1977.)

limiting the amount of water transfer between the fetal and maternal circulations under normal conditions.[3]

Fetal urine production is the primary source of amniotic fluid in the second half of pregnancy. This is supported by the near complete absence of amniotic fluid in the setting of renal agenesis or fetal urinary tract obstruction. Fetal urine first enters the amniotic space at 8 to 11 weeks' gestation and continually increases throughout gestation.[4] Fetal urine production per kilogram of fetal body weight at 25 weeks' gestation is approximately 110 mL/kg per 24 hours, and it increases to approximately 190 mL/kg per 24 hours at 39 weeks' gestation.[5] Based on sonographic studies of the fetal bladder measured at regular intervals, the human fetal urine output at term is estimated to be 700 to 900 mL/day.[2] In order to contribute to the regulation of the AFV, the fetus is able to respond to changes in fluid status by adjusting urine flow.[1] Thurlow and Brace[6] observed fetal ovine hypoxia to be associated with increased urine flow, as opposed to the often associated chronic fetal hypoxia and low AFV. Similarly, Gagnon and associates[7] found the reduction in overall AFV in the setting of chronic severe placental insufficiency in sheep was due to an increase in the intramembranous absorption of amniotic fluid, not a decrease in fetal urinary production. This finding suggests that human regulation of the AFV is mediated by other mechanisms (e.g., intramembranous absorption) in addition to changes in fetal urine production at times of fetal hypoxia.[7]

Fetal swallowing plays a key role in maintaining a stable AFV. In humans, the fetus begins to swallow around the same time that fetal urine first enters the amniotic space, at 8 to 11 weeks' gestational age.[2] An estimated 210 to 760 mL/day is swallowed by the near term fetus.[8] In the ovine fetus, hypoxia has been shown to suppress fetal swallowing,[9] whereas decreases in amniotic fluid osmolality and increases in fetal plasma osmolality will increase fetal swallowing.[10] In primates, esophageal ligation leads to the development of hydramnios; however, the AFV returns to normal before delivery.[11] It is thought the maintenance of a constant AFV despite esophageal ligation in the presence of continued urine production is a result of increasing intramembranous absorption.[12] Based on these studies, it seems the human fetus is able to alter its swallowing to some degree under various conditions; however, it is unlikely that this represents the major regulatory mechanism by which the human fetus maintains its AFV.

Secretion of fetal lung fluid into the amniotic cavity is well established. This concept is supported by the fact that phospholipids are present in the amniotic fluid that can be used as tests for fetal lung maturity. These phospholipids are of pulmonary origin and are not present in substantial quantities in the fetal urine. Ligation of the trachea in utero in other animal species results in expansion of the fetal lung seemingly due to the continued production of fetal lung fluid.[2] Fetal lung fluid secretion allows for pulmonary expansion serving to promote fetal lung development.[1] Near term fetal sheep demonstrate an outflow of lung fluid of 200 to 400 mL/day.[13] Approximately half of the secreted lung fluid enters the amniotic fluid, and the remainder is swallowed as it exits the trachea,[9] resulting in a net secretion of 100 to 200 mL/day. Secretion flow is likely the result of active transport of chloride ions across the epithelial lining of the developing lungs.[2] The fetal glottis serves to prevent backflow of amniotic fluid into the trachea; thus, there appears to be little osmotic exchange between amniotic fluid and fetal plasma in the lung.[3] Secretion of lung fluid into the amniotic fluid is likely a main contributor to the AFV, although factors that regulate fetal lung fluid secretion are poorly understood, and the exact amount secreted into the amniotic cavity in the human fetus has not yet been quantified.

An excess of approximately 400 mL is present within the amniotic cavity after considering the volume of fetal urine production and secreted lung fluid less the amount removed via fetal swallowing.[3] Furthermore, as gestation advances, fetal urine production as well as secreted lung fluid increases. The process by which this excess volume is compensated to maintain AFV balance is referred to as the *intramembranous pathway.* Based on studies in the near term ovine fetus, it is estimated that approximately 200 to 500 mL/day of amniotic fluid is absorbed via the intramembranous pathway.[14] Studies in other animal species have demonstrated that the AFV returns to a homeostatic state

even after large volumes of fluid are infused into the amniotic fluid cavity or after esophageal ligation.[1] This finding suggests there is a continuous flow of water and solutes from the amniotic fluid into the fetal circulation. The osmotic gradient between the fetal circulation and the amniotic fluid appears to influence the intramembranous movement of water and solutes across the fetal vessels on the surface of the placenta into the fetal circulation. However, in one ovine study, it was demonstrated that only approximately 35% of the intramembranous movement of fluid depends on the osmotic difference between the amniotic fluid and the fetal circulation.[15] Consequently, there must be other nonpassive mechanisms that contribute to this pathway.

The maternal fluid status can influence the fluid balance between the fetal circulation and the AFV. At times of maternal dehydration, the intramembranous pathway likely plays a role in correcting the fetal volume status. With maternal dehydration, the maternal serum osmolality increases, resulting in water movement from the fetal circulation to the maternal circulation. This results in a fetal dehydration state causing increased fetal osmolality and promoting movement of water from the amniotic fluid back into the fetal circulation in order to restore the fetal intravascular volume, leading to a decrease in the AFV.[3] The reverse is also true. As demonstrated by Magann and colleagues, intravenous maternal hydration with 1 L of fluid increased both the actual and sonographically estimated AFV in the human fetus, with an average increase in the actual AFV of 188 mL.[16] Similarly, Kilpatrick and coworkers showed that in a patient with a low AFV, maternal hydration with 2 L of water can increase the human fetal amniotic fluid index (AFI) by up to 31%.[17] There is little evidence to support the movement of fluid via the transmembranous pathway as a major contributor to the overall AFV. Studies in sheep suggest that only 10 mL/day is absorbed by the uterus in late gestation in the setting of normal osmolality.[18] Given the large surface area of the amnion and chorion, it is clear why membrane permeability has been proposed as a regulator of the AFV. However, very little is known regarding the permeability and filtration characteristics of the membranes as they relate to amniotic fluid dynamics.

The amount of fluid secreted by the fetal oronasal cavities is small and not considered a main contributor to the AFV. Studies in sheep demonstrate that approximately 25 mL/day is secreted by the fetal oronasal cavities in late gestation.[19] Based on information regarding transepidermal water loss in the preterm infant, it is generally believed there is movement of water across the fetal skin before 22 to 25 weeks' gestation, which contributes to the AFV in the first half of pregnancy. It seems reasonable to assume there may be a relationship between fetal weight and the AFV because a larger fetus would presumably produce more urine output. However, neonatal birth weight has not been shown to be correlated with a either a dye-determined or an ultrasound-estimated AFV.[20] In addition, no clinical correlation has been shown between the AFI and estimated human fetal weight[21] (Fig. 20-2).

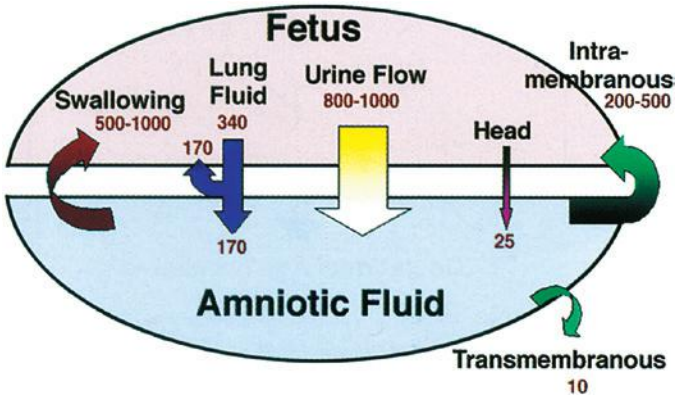

FIG 20-2 Summary of the flow of fluids into and out of the amniotic space in late gestation. (From Brace RA: Physiology of amniotic fluid volume regulation. Clin Obstet Gynecol 40:286, 1997.)

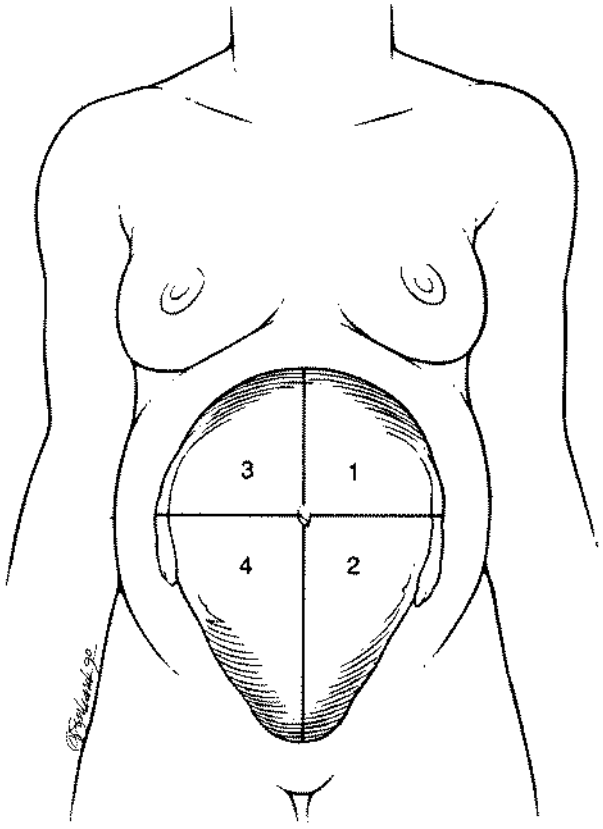

FIG 20-3 Diagram of the division of the uterus into four equal quadrants for determination of the amniotic fluid index (AFI). With the patient supine and the ultrasound transducer perpendicular to the table, the vertical depth (measured in centimeters) of the largest amniotic fluid pocket free of umbilical cord in each quadrant is measured. AFI is calculated by summing these four measurements. (From Gabbe SG, Niebyl JR, Simpson JL: Obstetrics: Normal and Problem Pregnancies, 2nd ed. New York, Churchill Livingstone, 1991.)

DETERMINATION OF AMNIOTIC FLUID VOLUME

How does one measure the AFV during pregnancy? The true AFV can be measured by dye-dilution techniques utilizing amniocentesis or can be directly measured at the time of cesarean delivery.[22-24] However, these methods are obviously not practical for routine clinical use. Alternatively, the AFV is commonly estimated with the use of ultrasound techniques. In the literature, four techniques have been described to estimate the AFV: the AFI[25-27]; the single deepest pocket (SDP), also referred to as the deepest vertical pocket (DVP) or maximal vertical pocket (MVP)[28,29]; the two-diameter pocket[30]; and subjective assessment.[31,32] The two methods most commonly used are the AFI and DVP. The two-diameter pocket measurement (horizontal and vertical dimensions of the maximum vertical pocket are multiplied together to obtain a single value, in cm^2) was shown to not be a better predictor of AFV than the AFI and is no longer widely used.[33] As originally described by Phelan and associates, in order to calculate the AFI, the abdomen is divided into four quadrants in which the umbilicus divides the upper and lower halves and the linea nigra divides the right and left halves (Fig. 20-3).[34] With the patient supine, the linear (or

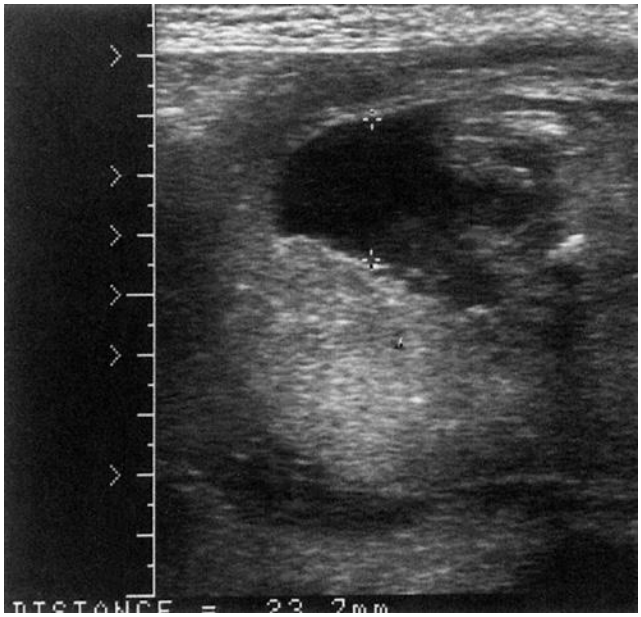

FIG 20-4 Normal amniotic fluid volume assessed by measurement of the largest single pocket of fluid. In this 22-week gestation, the largest vertical pocket of amniotic fluid, devoid of umbilical cord, is 24 mm.

FIG 20-5 Longitudinal sonogram in a second trimester gestation with normal amniotic fluid. Subjective evaluation of normal amniotic fluid depends on the relationship between amniotic fluid and the space occupied by the fetus and placenta.

curvilinear) transducer is placed along the maternal anterior abdominal wall and held perpendicular to the floor. The maximum vertical pocket of fluid (usually reported in centimeters) is measured in each of the four quadrants, and the AFI (in centimeters) equals the sum of these four measurements.[25,34] The DVP is simply the largest single vertical pocket of fluid that is at least 1 cm in width, obtained following the same criteria described here[29,31] (Fig. 20-4).

Studies have demonstrated that the dye-determined amniotic fluid calculation and direct measurement at the time of cesarean delivery have good concordance ($r = 0.99$) and either can be used to determine actual AFV.[35] It has been shown that both the AFI and the DVP technique can reliably identify normal AFVs. Unfortunately, most studies have demonstrated poor reliability for ultrasound-estimated AFVs to predict actual low or high volumes.[22-24,30,36,37] Subjective assessment (visual interpretation without ultrasound measurements) of AFV has been compared with dye-determined or directly measured AFV, and studies have shown no difference in the accuracy of subjective compared to objective assessment (visual interpretation with ultrasound measurements) in the correct determination of AFV.[38] Likewise, when comparing subjective assessment of AFV in the second and third trimesters and objective assessment with dye-determined fluid volumes, neither operator experience nor sonographic technique was found to affect the accuracy of ultrasound estimates of the AFV[31] (Figs. 20-5 and 20-6).

Traditionally, pockets filled with umbilical cord have not been used in measurement of the AFV. The use of color Doppler ultrasound can help detect umbilical cord, which may be present within an apparent pocket of amniotic fluid. Thus, it has been suggested that color Doppler be applied during evaluation of the AFV to identify segments of umbilical cord that may not be appreciated on standard gray-scale ultrasound images (Fig. 20-7) in order to improve detection of low AFV.[39] However, the use of color Doppler in the sonographic estimation of AFV has been shown to result in overdiagnosis of low AFV (oligohydramnios).[40] In a study by Magann and colleagues, the use of color Doppler inappropriately diagnosed 21% of women with low AFV who actually had normal dye-determined AFVs.[41] In addition, color Doppler did not identify any more pregnancies with true dye-determined low AFVs compared with traditional gray-scale ultrasound imaging.[41]

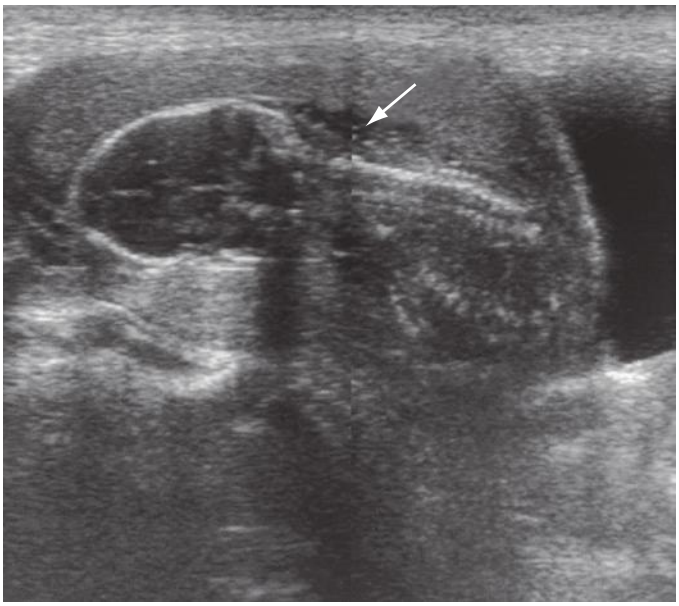

FIG 20-6 Sonogram of a fetus with renal agenesis. Virtually no amniotic fluid is seen. The fetus is "crowded" within the uterus. The only relatively anechoic space is occupied by the umbilical cord (*arrow*).

POTENTIAL DIFFICULTIES IN AMNIOTIC FLUID VOLUME ESTIMATION USING ULTRASOUND

Determining an estimated AFV either objectively or subjectively is generally straightforward. However, a few potential pitfalls are worth mentioning. Maternal positioning, whether supine or at a 45-degree semierect position, does not appear to influence the measurement of

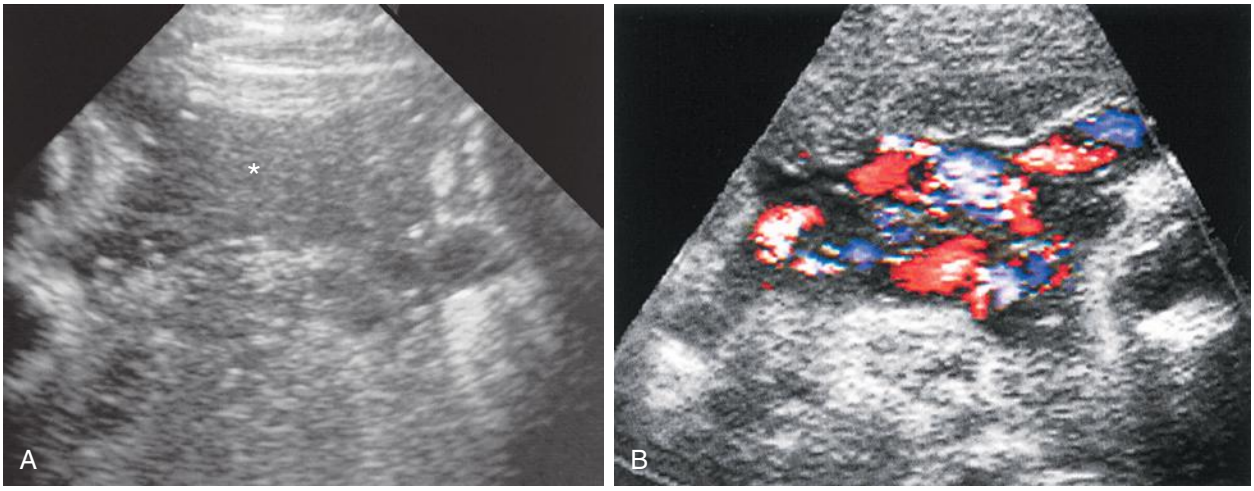

FIG 20-7 A, Apparent amniotic fluid pocket (*asterisk*) in a third trimester pregnancy. **B,** Color Doppler interrogation reveals that this pocket is entirely filled with umbilical cord.

the AFV.[42] However, as demonstrated by Fok and coworkers,[43] fetal positioning can influence the calculation of the AFI, although it does not appear to influence the DVP measurement (Fig. 20-8). Fetal movements do not appear to alter the assessment of AFV, nor does the choice of the transducer, whether curvilinear or sector.[44]

Excessive pressure with the transducer while scanning can negatively influence the estimation of AFV. Flack and associates demonstrated that excess pressure on the maternal abdomen resulted in a 21% decrease in calculated AFI measurement.[45] It is important to remember that maternal adipose tissue tends to scatter the ultrasound beam, which may result in artificial echoes suggested within pockets of amniotic fluid. Thus, obese women may appear to have reduced volume of amniotic fluid as a result of these artifactual echoes (Fig. 20-9). It may help to use a lower frequency transducer when assessing the AFV in these patients. Also, measurements of amniotic fluid pockets may be made in varying locations by different examiners; this too can lead to variation in estimates of AFV (Fig. 20-10).

NORMAL AMNIOTIC FLUID VOLUME IN SINGLETON PREGNANCIES

In order to establish what constitutes an abnormal AFV, methods for assessing normal amniotic fluid for singleton pregnancies must be determined. Based on published studies in the literature, there are multiple accepted definitions of an abnormally low or high AFV. An abnormally low AFV (referred to as *oligohydramnios*) has been defined as any one of the following: a total volume less than 200 mL[22] or less than 500 mL,[23,24] a value below the 5th percentile for gestational age,[46] an SDP less than 2 cm,[28,47,48] an AFI less than 5 cm,[25-27,48,49] or a subjectively low AFV.[31] An increased AFV (referred to as *polyhydramnios*) can be defined as any one of the following: a total volume greater than 2000 mL,[30] a value above the 95th[27] or 97th percentiles for gestational age, an SDP greater than or equal to 8 cm,[50] an AFI greater than or equal to 24 cm[51] or greater than 25 cm,[52] or a subjectively increased AFV.[31]

Several studies have attempted to define normal AFVs across gestation. The AFV deemed normal is to a certain degree dependent upon the gestational age at which it was measured. There are multiple published reference curves demonstrating changes in AFV across gestation and a few notable studies evaluating either dye-determined or directly measured AFVs. Queenan and colleagues,[53] in 1972, used dye-determined methods to assess the AFVs of 187 patients across gestation from 15 to 16 weeks to 41 to 42 weeks. They demonstrated an increase in AFV as pregnancy advanced from the 15th to the 20th week, and then AFV remained relatively constant from the 20th through the 41st week. Their study showed that the AFV peaked at 33 to 34 weeks' gestation, then gradually decreased until term, decreasing at a greater rate after 41 weeks.[53] Brace and Wolf[54] in 1989 derived normal values from a compilation of 705 pregnancies from 12 previously published studies[53,55-65] with gestational ages ranging from 8 to 43.2 weeks. They reported a peak AFV of 931 mL at 33.8 weeks with a decrease in the AFV thereafter (Fig. 20-11). Using polynomial regression and log transformation of the data, the authors found no statistically significant change in the AFV from 22 to 39 weeks' gestation, with an average volume of 777 mL and a range of 630 to 817 mL.[54] They showed a decrease in the AFV after 40 weeks by 8% per week.[54] Magann and coworkers, in 1997, measured the AFVs of 144 singleton pregnancies between 15 and 40 weeks also using a single dye-dilution technique with analysis performed in the same laboratory; the AFV was found to increase across gestation with a peak at 40 weeks.[66] In 2014, Sandlin and associates[67] modeled AFVs across gestation in normal singleton pregnancies using the statistical method *quantile regression* (QR). In their study, 379 women with singleton pregnancies were evaluated and their amniotic volumes were calculated by either dye-dilution technique or direct measurement at the time of cesarean delivery between 16 and 41 weeks' gestation.[67] These authors were then able to derive a normative chart for AFVs across each week of gestation (16-41 weeks) at the 5th, 25th, 50th, 75th, and 95th percentiles (Table 20-1).[67] The authors point out in their study that the use of quantile regression enabled them to relax the stringent assumptions of standard regression models and overcome several of those limitations, thereby allowing them to more appropriately estimate values at the extremes of a distribution (e.g., below the 5th and above the 95th percentiles). Because those values are labeled as abnormal, this is where clinical interest and concern lie—the relationship of abnormal amniotic fluid values and their subsequent association with perinatal outcome.[67]

Given that the actual AFV can only be directly calculated by amniocentesis with dye-dilution techniques or directly measured at the time of cesarean delivery, in clinical practice, the AFV is estimated by ultrasound evaluation using the AFI, the DVP, or subjective assessment. An often-cited reference for normal ultrasound-estimated AFV is an article by Moore and Cayle,[27] published in 1990, in which the authors attempted to define the normal AFI in pregnancy. They evaluated the

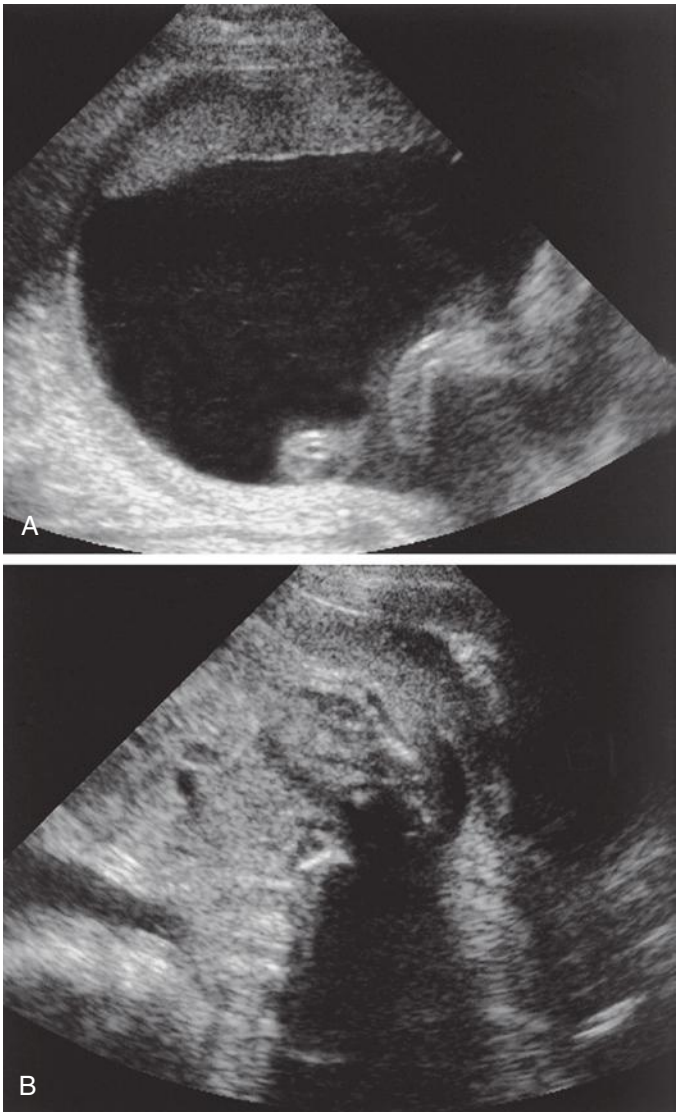

FIG 20-8 **A,** Sonogram of the fundic portion of the uterus in a second trimester pregnancy. Although this single large amniotic fluid pocket simulates polyhydramnios, it was the only area of amniotic fluid. **B,** Sonogram of the same patient in the mid- to lower uterine segment. No amniotic fluid is seen in this scan. If amniotic fluid volume had to be assessed on the basis of this image alone, it would be interpreted as oligohydramnios.

FIG 20-9 Sonogram in a moderately obese patient. Artifactual echoes within the amniotic fluid make the actual amniotic fluid less apparent.

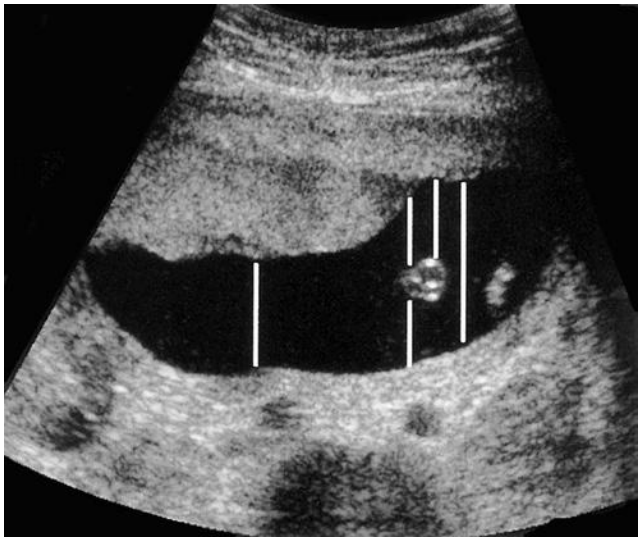

FIG 20-10 Sonogram of a second trimester pregnancy. Measurements of this amniotic fluid pocket might be made in a variety of locations by different examiners, and some examiners may choose not to use this pocket for measurement.

AFI, as described by Rutherford and colleagues,[25] in 791 patients with normal pregnancies between 16 and 44 weeks. Using polynomial regression and logarithmic transformation, they found the mean AFI curve to rise beginning at 16 weeks, peak at 27 weeks, plateau until 33 weeks, and then decline until 42 weeks. They observed that the AFI decreased by 12% per week after 40 weeks[27] (Table 20-2). In 2000, Magann and coworkers[48] performed a prospective study to determine normal values for sonographically measured AFI, SDP, and two-diameter pocket in normal human pregnancy. They recruited 50 patients at every gestational age between 14 and 41 weeks, for a total of 1400 patients. The data were analyzed using linear regression and logarithmic transformation, and they found that when AFI is used to define fluid status across gestation, it increases from 14 to 31 weeks and then declines thereafter; when SDP or two-diameter pocket is used, the AFV increases from 14 to 20 weeks' gestation, plateaus between 20 and 37 weeks, and then gradually declines thereafter through the 41st week. If one were to consider the individual cases in the study by Magann and coworkers[48] but use the curve reported by Moore and Cayle,[27] one would find that 36% of the patients in the study by Magann and coworkers[48] who had normal outcomes would have been labeled as having abnormally low or high AFVs. In 2007, Machado and associates[68] evaluated the AFIs of 2868 pregnant women. Using multiple linear regression and quadratic polynomial adjustments, they found the AFIs across gestation to be essentially constant between 20 and 33 weeks' gestation, decreasing after 33 weeks, with the most significant decrease after the 38th week of gestation.[68] Lei and Wen[69] constructed an AFI curve by gestational week based on data from 5496 Chinese women. The 5th, 50th, and 95th percentiles of this study were different from the curves of both Moore and Cayle[27] and Magann and coworkers[48] across gestation. The curves of both Lei and

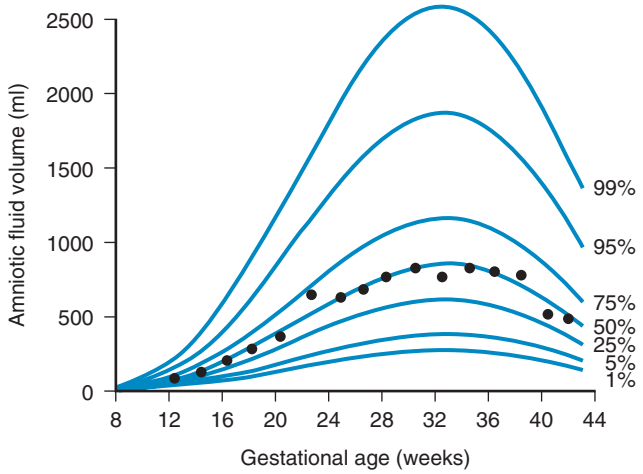

FIG 20-11 Nomogram shows amniotic fluid volumes as a function of gestational age on a linear scale. Dots are means for each 2-week interval. Percentiles are calculated from polynomial regression equation and standard deviation of residuals. (From Brace RA, Wolf EJ: Normal amniotic fluid volume changes throughout pregnancy. Am J Obstet Gynecol 161:386, 1989.)

Amniotic fluid index values are obtained by measuring the vertical depth of the largest clear amniotic fluid pocket in each of four equal uterine quadrants. The values from each quadrant are measured in millimeters and added together.
From Moore TR, Cayle JE: The amniotic fluid index in normal human pregnancy. Am J Obstet Gynecol 162:1168, 1990.

Wen[69] and Magann and coworkers[48] reported AFIs less at each gestational age than in the curve of Moore and Cayle.[27]

These findings suggest that what may be considered normal AFV at any point during gestation is likely different depending on the population being investigated. Thus, population-specific curves should be considered in order to more appropriately define normal AFV. Despite many years of investigation and several reported studies, there has yet to be a clearly defined, widely accepted normal estimated value for AFV at each week of gestation; therefore, what truly constitutes abnormal AFV cannot be precisely determined. Whether the AFV decreases in late gestation, remains steady throughout most of the third trimester, or increases throughout gestation with a peak at term has not been clearly established. Ideally, normal AFV should be defined as a value between established high and low volume cutoffs, at which associations with adverse pregnancy outcomes are clearly linked.

AMNIOTIC FLUID VOLUME AND PREGNANCY OUTCOMES

There are few investigations evaluating intrapartum and perinatal outcomes within 72 hours of the true dye-determined AFV calculations.

In one study,[30] no differences were observed between groups with oligohydramnios, normal AFV, or polyhydramnios and complications including risk of meconium-stained amniotic fluid, variable decelerations influencing delivery, or low 5-minute Apgar scores. In another study, 100 unlabored women had AFV determined by dye-dilution technique just before elective cesarean delivery, and oligohydramnios was not predictive of low umbilical artery pH at delivery.[70] In a third analysis, intrapartum and perinatal outcomes including fetal heart rate variability, variable decelerations, late decelerations, fetal labor intolerance, need for amnioinfusion, fetal growth restriction (FGR), birth weight, mode of delivery, umbilical artery pH less than 7.2, and neonatal intensive care unit (NICU) admission were evaluated in 74 pregnancies with dye-determined AFV and with delivery within 72 hours.[71] The dye-determined fluid volumes labeled as oligohydramnios, normal, and polyhydramnios were not predictive of adverse intrapartum or neonatal outcomes.[71]

Oligohydramnios

An increased risk for adverse pregnancy and neonatal outcomes such as nonreactive nonstress tests (NSTs), fetal heart rate decelerations, meconium staining, cesarean delivery for labor intolerance, and low Apgar scores have been shown in women with an AFI of 5 cm or less in several studies.[25,49,72] However, not all of the studies are consistent, and furthermore, not all investigators agree that an AFI of 5 cm or less is associated with adverse pregnancy outcomes. In other studies evaluating both low-risk[73] and at-risk patients,[74-77] oligohydramnios was not linked with adverse pregnancy or perinatal outcomes. It is imperative that estimates of AFV be accurate and correlate with outcomes for them to be useful in management of at-risk pregnancies; thus, contradictory studies regarding the cutoff for oligohydramnios and its relationship to intrapartum and perinatal outcomes make interpretation and decision making difficult for the practitioner.

In a study by Casey and colleagues,[49] which evaluated adverse outcomes after 34 weeks' gestation in pregnancies with oligohydramnios, after correction for fetal malformations and congenital syndromes, there was no difference between pregnancies with an AFI 5 cm or less and those with an AFI greater than 5 cm in the risk of cesarean delivery for fetal labor intolerance, umbilical cord arterial pH of less than 7, NICU admissions, seizures in the first 24 hours after delivery, or neonatal death. It is important to note that in studies comparing pregnancies with AFIs 5 cm or less and those greater than 5 cm, many of the intrapartum outcomes evaluated, such as fetal heart rate tracing influencing delivery, cesarean delivery for fetal labor intolerance, and Apgar scores, are subjective measures. The only two objective assessments are the presence or absence of meconium staining and umbilical cord arterial pH. In a meta-analysis by Chauhan and coworkers,[78] increased risk of cesarean deliveries for fetal labor intolerance and Apgar score less than 7 at 5 minutes was demonstrated in the group with AFI 5 or less cm compared to those with AFI greater than 5 cm; however, no difference between these two groups was observed in the risk of neonatal acidosis (umbilical cord arterial pH < 7.0), an objective outcome. Chamberlain and associates[28] evaluated 7582 referred high-risk patients and the relationship of a single DVP measurement, after correction for major congenital anomalies, as a predictor of perinatal mortality rate. The perinatal mortality rates were 1.97/1000 (~0.2%) for a DVP greater than 2 cm to less than 8 cm, 37.74/1000 (~3.8%) for a DVP 1 cm or greater to 2 cm or less, and 109.4/1000 (~11%) for a DVP less than 1 cm.

In 2008, a Cochrane review compared the use of the AFI measurement to the DVP measurement as a screening test for the prediction of adverse pregnancy outcome.[79] In this review, no significant differences were identified in the primary outcomes of NICU admissions or perinatal deaths. However, there were more women with a diagnosis of oligohydramnios, more labor inductions, and more cesarean deliveries for a nonreassuring fetal heart rate tracing when using the AFI. There were no differences in the number of nonreassuring fetal heart rate tracings, assisted vaginal deliveries with or without a nonreassuring fetal heart rate tracing, umbilical artery pH of less than 7.1, Apgar score of less than 7 at 5 minutes, presence of meconium, or NICU admissions.[79] The authors of the review concluded that DVP was the better measurement because the use of the AFI increased the diagnosis of oligohydramnios and labor inductions without improvement in peripartum outcomes.[79] Likewise, a 2009 meta-analysis of randomized controlled trials comparing the AFI to the DVP during antepartum fetal surveillance concluded that the DVP measurement is the method of choice in the assessment of AFV.[80]

The cause of oligohydramnios can generally be divided into one of three categories: fetal anatomic abnormalities (e.g., bladder outlet obstruction, renal agenesis), premature rupture of membranes (PROM), or a reflection of a maternal or fetal disease state as a result of uteroplacental insufficiency (e.g., hypertensive disorders such as preeclampsia, FGR, postterm pregnancy). Oligohydramnios can also result from maternal exposure to medications such as angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs),[81] or nonsteroidal agents such as indomethacin.[82] Once low AFV is identified, a targeted sonographic examination should be performed to evaluate for fetal anomalies as well as fetal growth assessment. A detailed maternal history and physical examination should be obtained to evaluate for specific conditions that can be associated with oligohydramnios (e.g., hypertensive disorders, PROM). Depending on the gestational age, antenatal testing should be considered (e.g., fetal NST, biophysical profile [BPP]) along with consultation with a maternal-fetal medicine specialist. Serial ultrasound evaluations for fetal growth (every 3-4 weeks) and for AFV assessment (e.g., weekly when less than 41 weeks' gestational age, twice weekly after 41 weeks or if FGR) as well as Doppler flow studies (e.g., umbilical artery Doppler flow) (particularly in the setting of FGR) are warranted. Pregnancies complicated by prolonged oligohydramnios from an early gestational age can result in fetal deformations (e.g., Potter sequence or oligohydramnios sequence) and fetal pulmonary hypoplasia, which can be lethal. Unfortunately, treatment for oligohydramnios (e.g., amnioinfusion) has not been shown to improve neonatal outcomes. Oligohydramnios at term is generally considered an indication for delivery.

Pulmonary Hypoplasia

Patients with prolonged oligohydramnios from any cause, including renal causes or preterm PROM (PPROM), are at increased risk for pulmonary hypoplasia, which is frequently fatal. It has long been known that amniotic fluid is important for normal development of the fetal lungs. What has been less clear is how oligohydramnios interferes with the normal developmental process. During human gestation, there are five main stages of fetal lung development: embryonic, from approximately the 3rd to the 6th week; pseudoglandular, from the 5th to the 17th week; canalicular, from the 16th to the 26th week; saccular, from the 24th to the 36th week; and alveolar, from the 32nd week to term and beyond (see Chapter 12). By the 16th week of gestation, all of the branches of the tracheobronchial tree, up to the terminal bronchioles, are established.[83] Oligohydramnios that results in pulmonary hypoplasia, which is characterized by inadequate development of pulmonary acini and restricted vascularization, normally must occur during the canalicular stage of development.

Several theories have been postulated as to the basis for pulmonary hypoplasia in patients with severe oligohydramnios, including abnormal fetal breathing, increased pressure on the fetal thorax, and

abnormal pulmonary fluid egress.[83] Abnormalities of fetal breathing are unlikely to be the cause, because normal fetal breathing movements are documented to occur in animals as well as in humans with oligohydramnios-related pulmonary hypoplasia. Compression of the fetal thorax is also an unlikely cause because pressure within the amniotic sac in patients with oligohydramnios is low. Normally, the pressure in the amniotic space is between 1 and 14 mm Hg. When oligohydramnios is present and the membranes are intact, the intra-amniotic pressure is 1 mm Hg or less.[84,85] It has been postulated that fetal lung fluid acts as an internal stent for the developing surrounding lung.[86] Normally, the upper airways produce resistance to the egress of fluid out of the trachea. In the presence of oligohydramnios and low amniotic pressure, it is theorized that the pressure gradient results in the loss of this lung fluid.[85] In addition, work by Harding, Hooper, and Dickson[87] in sheep has demonstrated that the rise in pulmonary airway pressure relative to amniotic sac pressure may be caused by increased spinal flexion and resulting increased abdominal and thoracic pressure in the fetus with oligohydramnios. In a 1996 study, Kilbride, Yeast, and Thibeault[88] evaluated patients who experienced PPROM at less than 29 weeks' gestation. Most patients did not experience a change in amniotic fluid status over time; however, as many as 20% of patients did. Although the prognosis was poor and the likelihood of pulmonary hypoplasia was high in the group in which the amniotic fluid pockets were less than 1 cm, there was no association between moderate oligohydramnios (1- to 2-cm pockets) and pulmonary hypoplasia. Thus, on the basis of this study, it is inappropriate to group all patients with an AFI less than 5 cm together in an attempt to prognosticate on the development of pulmonary hypoplasia.

In one review of 11 studies, the reported incidence of pulmonary hypoplasia secondary to midtrimester PPROM ranged widely from 1% to 48%.[89] Another review of six studies on PPROM before 24 weeks reported an incidence of pulmonary hypoplasia of 19% ($n = 120$).[90] These percentages do not represent the true natural history, given the limitations inherent in these reviews that summarize only retrospective cohorts reported from tertiary care centers. The wide range in prevalence is partly explained by the absence of uniform pathologic and clinical definitions. Histologic findings form the basis of the diagnosis of pulmonary hypoplasia, but complete autopsy data were often not available.

Amnioinfusion has been proposed as a means to potentially improve outcomes in cases of PPROM by preventing pulmonary hypoplasia, limiting fetal deformation abnormalities, increasing time to delivery interval, and improving fetal BPP through reduction in risk of umbilical cord compression. However, at this time there is no solid evidence to support this practice.[91] A large randomized trial is under way to determine whether there is benefit from serial amnioinfusions in the setting of PPROM.[92]

Prediction of Pulmonary Hypoplasia in the Setting of Oligohydramnios

Prediction of pulmonary hypoplasia after midtrimester PPROM is important for optimal management. Once midtrimester PPROM has occurred, an assessment of the probability of pulmonary hypoplasia is important both for clinical decision making and for counseling of patients. Previous studies have shown that gestational age at the time of rupture of the membranes is strongly associated with the occurrence of pulmonary hypoplasia. Other factors that have been associated with pulmonary hypoplasia are the duration of the rupture of the membranes and the degree of oligohydramnios.[93]

Sonography has been proposed as potentially useful in the prediction of lethal pulmonary hypoplasia. Prediction of lethal pulmonary hypoplasia has been attempted based on fetal thoracic circumference (TC) and sagittal lung length or transverse lung diameter measurements, as well as cardiac/thoracic circumference (CC/TC) and thoracic/abdominal circumference (TC/AC) ratios. However, in one study, TC, CC/TC, and TC/AC measurements failed to provide an acceptable prenatal prediction of lethal pulmonary hypoplasia in either the total study group or the subset with PPROM. In the latter, the clinical parameters provided better prediction than biometric parameters, whereas the combination of clinical, biometric, and Doppler findings were most accurate. Doppler velocimetry was used to detect changes in pulmonary artery waveforms that may be useful in the prediction of pulmonary hypoplasia.[94] In general, fetal two-dimensional biometric indices are late indicators of pulmonary hypoplasia, with a sensitivity and specificity not satisfactory for use in clinical management. Data on the predictive value of the presence or absence of fetal breathing movements are contradictory. Furthermore, the applicability of three-dimensional sonography, computed tomography, and magnetic resonance imaging for accurate measurement of fetal lung volume in the prediction of pulmonary hypoplasia still needs to be determined.

ASSESSMENT OF AMNIOTIC FLUID VOLUME IN THE HIGH-RISK PATIENT

One question that often arises is how frequently one should perform semiquantitative assessment of AFI during antepartum testing in the high-risk patient. Wing and colleagues[95] and Lagrew and coworkers[96] evaluated this issue. Wing and colleagues concluded that for patients at less than 41 weeks of gestation undergoing antepartum testing, weekly assessment of AFI is probably adequate if the initial measurement is in the normal range (≥8 cm) because the risk of developing oligohydramnios within 4 days is only 1.7% and within 7 days only 2.2%. As they stated in their report, "for patients at less than 41 weeks of gestation whose initial AFI measurement is in the low-normal range (5 to 8 cm), twice-weekly assessment is justified on the basis of a higher risk for an AFI 5 cm or less within 4 days (12.3%). For all patients at 41 or more weeks of gestation, twice-weekly AFI assessments are recommended regardless of the initial measurement." In 1992, Lagrew and coworkers[96] addressed the issue of frequency of AFV assessment. They concluded that there is minimal risk (<0.5%) of oligohydramnios within 4 days after a normal AFI; therefore, AFI measurements in patients less than 41 weeks of gestation should be performed weekly. It should be noted that these evaluations were done using AFI calculations, and no similar data are available using DVP measurements.

Polyhydramnios

The incidence of polyhydramnios (also referred to as *hydramnios*) ranges from 0.2% to 2.0%.[97] The degree of polyhydramnios can be described using the terms *mild, moderate,* and *severe.* Mild polyhydramnios has been defined as an AFI of 25 to 30 cm[98,99] or a DVP of 8 cm or greater,[100] moderate polyhydramnios as an AFI of 30.1 to 35 cm[98,99] or a DVP of 12 cm or greater,[100] and severe polyhydramnios as an AFI of 35.1 cm or greater[98,99] or a DVP of 16 cm or greater[100] (Figs. 20-12 and 20-13).

Idiopathic polyhydramnios accounts for approximately 50% to 60% of cases.[50,101] The remaining cases typically fall into one of the following categories: congenital anomalies and genetic disorders (8-45%), maternal diabetes (5-26%), multiple gestations (8-10%), fetal anemia (1-11%), and other (e.g., hydrops fetalis, Bartter syndrome, and congenital viral infections).[100-110] The mechanism by which idiopathic polyhydramnios develops is not known. Membrane-bound water channels, called *aquaporins,* may play a role in the development of polyhydramnios, but the exact physiology is not yet understood.[111-113]

FIG 20-12 Sonogram of a patient with marked polyhydramnios. The fetus is surrounded and virtually floating in the amniotic fluid.

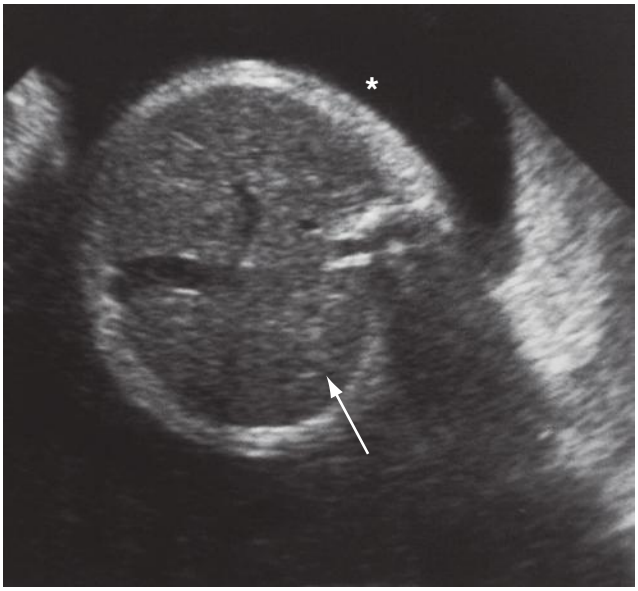

FIG 20-13 Sonogram of a patient with esophageal atresia and polyhydramnios showing absence of the fetal stomach (*arrow*) and increased amniotic fluid (*asterisk*).

Increasing severity of polyhydramnios correlates with an increased risk of perinatal death and congenital abnormalities.[114-116] Up to 31% of pregnancies with severe polyhydramnios (AFI ≥ 35 cm) have a major congenital anomaly.[104] The most common structural anomalies associated with polyhydramnios are central nervous system (28%), cardiac (22%), or gastrointestinal malformations (14%).[117] The risk of fetal aneuploidy in those fetuses found to have an anomaly by sonography is 10%.[104] In those fetuses without sonographic evidence of an anomaly, the risk of aneuploidy is only 1%.[104] The most common aneuploidies associated with polyhydramnios are trisomy 21, trisomy 18, and trisomy 13, although other chromosomal abnormalities can also occur.[118,119] There is not a significant difference in the reported risk of fetal aneuploidy with increasing severity of polyhydramnios.[104]

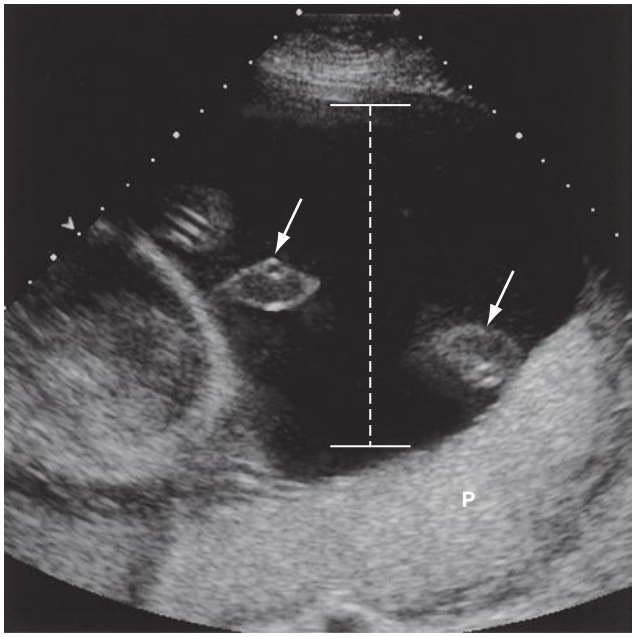

FIG 20-14 Sonogram of a pocket of amniotic fluid in a patient with hydrops fetalis and polyhydramnios. Two small segments of umbilical cord (*arrows*) are seen traversing the measured pocket of amniotic fluid. The placenta (P), which appears normal to prominent in this case, is, in fact, abnormally thickened.

The proposed mechanism of polyhydramnios associated with maternal diabetes is related to fetal polyuria due to increased osmotic diuresis as a result of fetal hyperglycemia.[120] Poorer glucose control has been shown to correlate with higher amniotic glucose concentration and higher AFI.[121] There may also be an increase in fetal urinary output in macrosomic fetuses (which are often seen in diabetic pregnancies).[121] The incidence of polyhydramnios in mothers with pregestational diabetes after 24 weeks' gestational age has been shown to be 18.8%.[122] In the setting of gestational diabetes, the incidence of polyhydramnios ranges from 8% to 20%[123] and is found up to 30 times more often than in nondiabetic pregnancies.[124]

As with oligohydramnios, sonographic evaluation of amniotic fluid in the setting of polyhydramnios has not been found to be very accurate in reflecting actual AFV.[37] The predictive ability of AFI and DVP to identify polyhydramnios above the 95th or 97th percentile has been shown to be 33% and 46%, respectively.[46] Using color flow Doppler sonography in the assessment of amniotic fluid does not increase ability to detect polyhydramnios via sonography.[125] Ultrasound imaging is often challenging in the setting of polyhydramnios. Excessive fetal movement, due to the large amount of intrauterine fluid, may make it very difficult to obtain the necessary images. In addition, the fetus may be positioned deep within the uterus and thus far from the maternal anterior abdominal wall and far from the transducer. Therefore, depth settings often need to be adjusted to better visualize fetal anatomy. Another consideration when scanning a patient with polyhydramnios is that, as the uterus expands because of increasing fluid volume, the placental thickness may appear to decrease. Thus, an abnormally thickened placenta (e.g., related to fetal hydrops) may measure within normal limits (Figs. 20-14 and 20-15).

Pregnancies complicated by polyhydramnios are at increased risk for adverse outcomes, including perinatal fatality.[123,126-128] This increased perinatal mortality risk is reported both in pregnancies complicated by idiopathic polyhydramnios as well as those in which polyhydramnios is related to fetal structural anomalies.[97] The presence of

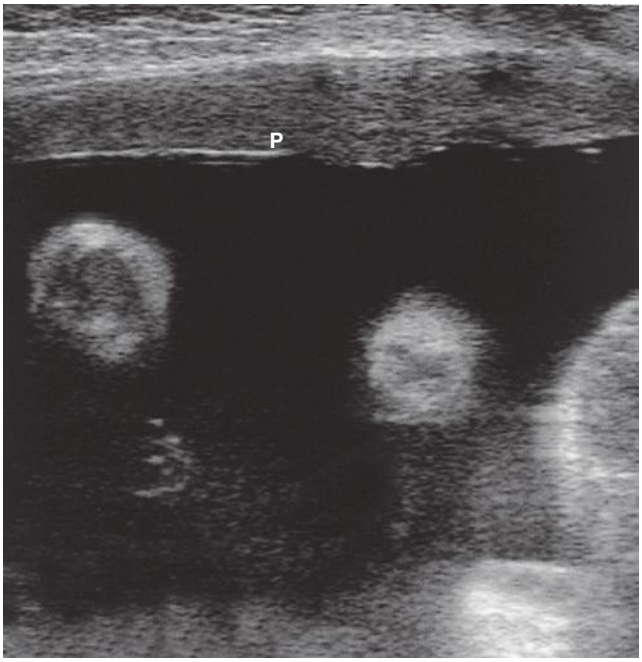

FIG 20-15 Sonogram in a patient with marked polyhydramnios. The placenta (P) becomes thin as the uterus expands from the increased amniotic fluid volume.

polyhydramnios in a pregnancy complicated by diabetes does not, however, appear to result in additional increased risk of perinatal fatality; rather, it is primarily the poorly controlled diabetes and underlying maternal disease process that is related to adverse pregnancy outcomes in diabetic pregnancies.[97] A review of all cases of idiopathic polyhydramnios found an overall twofold to fivefold increased risk of perinatal mortality.[123]

Once polyhydramnios is detected by ultrasound, a targeted sonographic examination should be performed to evaluate for possible fetal morphologic anomalies or fetal hydrops. In addition, maternal glucose screen should be administered, if not already performed, to assess for maternal diabetes.[97] If a structurally abnormal fetus is identified, evaluation for fetal aneuploidy should be offered. Ultrasound surveillance for fetal growth and AFV assessment is warranted. The form of antepartum fetal surveillance in the setting of idiopathic polyhydramnios depends in part upon the gestational age.[97] Symptomatic polyhydramnios has been treated with large volume amnioreduction or medical therapy (e.g., indomethacin) or a combination of the two.[97] A multidisciplinary team approach, including maternal-fetal medicine specialists, neonatologists, genetic counselors, and possibly pediatric surgeons or pediatric cardiologists, is recommended for management and treatment of a pregnant patient with significant polyhydramnios.[97]

Fetal Growth Restriction and Amniotic Fluid Volume

In the setting of FGR due to uteroplacental insufficiency, it is hypothesized that hypoxemia leads to decreased perfusion of the fetal kidneys, due to shunting of fetal blood flow to the brain, heart, and adrenal glands, thus resulting in decreased urine output and oligohydramnios. It has been shown that when oligohydramnios is present in the setting of FGR, the perinatal mortality rate is increased 47-fold.[28] Thus, in the setting of FGR, fetal surveillance with either NST or BPP is recommended twice weekly in conjunction with weekly AFV assessment and Doppler flow studies (e.g., uterine artery Doppler). FGR complicates approximately 3% to 6% of cases with polyhydramnios.[126,128,129] The finding of polyhydramnios with FGR has been referred to as an "ominous combination" and raises high suspicion for underlying major fetal anomalies, chromosomal abnormalities, or both.[119] In a study of 39 fetuses with polyhydramnios and FGR, Sickler and associates found major anomalies in 92% including chromosomal abnormalities in 38%.[119] The overall mortality rate in this group of 39 fetuses with both polyhydramnios and FGR was 59%.[119]

Umbilical artery Doppler interrogation in the setting of polyhydramnios but without FGR is not routinely indicated. In some cases, polyhydramnios may resolve during the pregnancy. In these cases, the fetuses are not at increased risk of intrauterine or neonatal death compared to those with persistent or worsening hydramnios.[130] There does appear to be a distinction between acute versus chronic development of polyhydramnios.[102] Queenan and Gadow describe acute polyhydramnios as "a rampant fulminating process terminating in spontaneous labor, usually before the end of the second trimester."[102] In their study of six cases with acute polyhydramnios diagnosed before 24 weeks' gestation, all six resulted in perinatal death.[102]

Amniotic Fluid Volume in Twin Pregnancies

The assessment of AFV as part of the sonographic evaluation is as important in twin pregnancies as it is in singleton pregnancies, both for the detection of fetal anomalies and for the evaluation of those at risk for adverse pregnancy outcomes. Additionally, twin pregnancies can be complicated by discordant growth or other unique conditions, such as twin-to-twin transfusion syndrome. The increased risk of anomalies and adverse outcomes in twins and higher order multiple pregnancies emphasize the importance of accurate assessment of AFV. In twin pregnancies, chorionicity and amnionicity are significant factors in the risks of associated perinatal morbidity and mortality.

Normal Amniotic Fluid Volume in Twins

As with singletons, in order to understand and identify twins with abnormal AFV, it is helpful to review and recognize normal AFV in this setting. Only one study to date has defined AFV in twins, reporting findings in 45 third trimester diamniotic twin pregnancies.[131] Of the 45 twin pairs evaluated, none was found to have fetal anomalies, growth restriction, discordant growth, or evidence of twin-to-twin transfusion syndrome. The AFV was determined by amniocentesis with dye-dilution techniques.[132] The mean AFV for each twin was 877 mL, with 90% of the volumes between 215 and 2500 mL.[131] These volumes were very similar to the calculated normal volumes of fluid in singleton pregnancies.[53,54,66]

Ultrasound Estimation of Amniotic Fluid Volume in Twins

As with singletons, ultrasound is used to estimate AFV in twins. Although some investigators have advocated the use of summated AFI technique to estimate volumes in twins,[133-135] such methods will fail to identify many twin pregnancies complicated by discordant or abnormal AFVs. The technique estimates AFV by identifying and measuring the single DVP in each of the four quadrants of the maternal abdomen (divided vertically into right and left by the linea nigra and horizontally into upper and lower by the umbilicus [the same technique used to estimate AFV in singletons]) and summing those four measurements to determine the AFI in centimeters. This calculation is done without taking membrane placement into consideration. An analysis to assess the accuracy of the summated AFI in 62 normal diamniotic twin pregnancies in which AFV had been determined by dye-dilution technique revealed that summated AFI would have classified 58 of the 62 twin pairs (93.5%) as having normal fluid when only 32 pairs (51.6%) actually had normal fluid based on dye-dilution technique.[136] Additionally, 10 of the 62 twin pairs had oligohydramnios determined by

dye dilution in both sacs, but the summated AFI incorrectly identified 80% of these as having normal AFV for both twins.[136] Clearly, ultrasound evaluation must include documentation of the intertwin membrane and address AFV measurement on either side in order to identify those twin pregnancies with abnormal AFV (oligohydramnios or polyhydramnios). Other ultrasound techniques[136-138] have been used to estimate amniotic fluid for each twin. Gerson and colleagues[137] identified the dividing intertwin membrane and then measured the largest pocket of amniotic fluid in each sac, both above and below the level of the fetal diaphragm (a two-quadrant measurement). Hill and coworkers[138] located the dividing membrane and used the longitudinal axis of the fetus to divide each amniotic sac into right and left halves and the horizontal axis of the fetal diaphragm into upper and lower halves (a four-quadrant measurement). Magann and associates[136] identified the dividing membrane by ultrasound and measured the DVP of fluid in each of the four quadrants of the maternal abdomen as used for AFI calculation in singleton pregnancies (another two-quadrant measurement). Only the study by Magann and associates[136] was compared to dye-dilution technique, which revealed 35 twins with low fluid, 48 with normal fluid, and 7 with high fluid volumes. The two-quadrant Magann technique identified 98% of those with normal fluid but only 20% of those with low volumes.[136]

The subjective estimation of AFV in twins (visual assessment without measurements) was found to be as accurate as objective numeric determination (with use of AFI or DVP) in correctly identifying those with normal fluid, oligohydramnios, or polyhydramnios confirmed by dye-dilution technique.[137] Now, though not validated by dye-determined studies, for twins and higher order multiples, the DVP of fluid (in centimeters) in each amniotic sac is used to estimate AFV following the same approach as in singleton pregnancies.[28] Using this technique, DVP of 2 cm or less is defined as oligohydramnios and greater than 8 cm is defined as polyhydramnios, with measurements in between deemed normal AFV (Figs. 20-16 and 20-17).

Amniotic Fluid Volume and Pregnancy Outcomes in Twins

It is important to address whether AFV considered abnormal by ultrasound is correlated with adverse pregnancy outcome. There is limited information regarding estimated AFV in twins in relation to pregnancy outcome. In one study correlating dye-determined AFV and delivery outcome within 48 hours, there was no significant association between oligohydramnios, normal fluid volume, or polyhydramnios and neonatal outcomes.[139] Another study evaluated 299 normal dichorionic diamniotic and monochorionic diamniotic twin pregnancies followed by serial sonograms. The last recorded estimated AFV based on SDP was correlated with intrapartum and neonatal outcomes.[140] Pregnancies with polyhydramnios in one sac were more likely to have an abnormal fetal heart rate tracing and more likely, based on that, to undergo cesarean delivery.[140] In addition, fetuses with polyhydramnios were more likely to have 5-minute Apgar scores less than 7, umbilical artery pH less than 7, respiratory distress syndrome, and transient tachypnea of the newborn compared with fetuses with oligohydramnios or normal fluid volume.[140] Other authors have also observed an increased risk of early gestational age at delivery, increased perinatal loss, and increased neonatal fatality associated with polyhydramnios in twin pregnancies.[141,142] As with singletons, once abnormal AFV is detected in a twin or high order multiple pregnancy, further evaluation should be performed to assess for possible conditions, such as PROM, twin-to-twin transfusion syndrome (Fig. 20-18), structural anomalies, abnormalities of fetal growth, or maternal conditions such as hypertensive disease or diabetes. Consultation with a maternal-fetal medicine specialist is recommended in patients carrying a multiple pregnancy with abnormal fluid volumes.

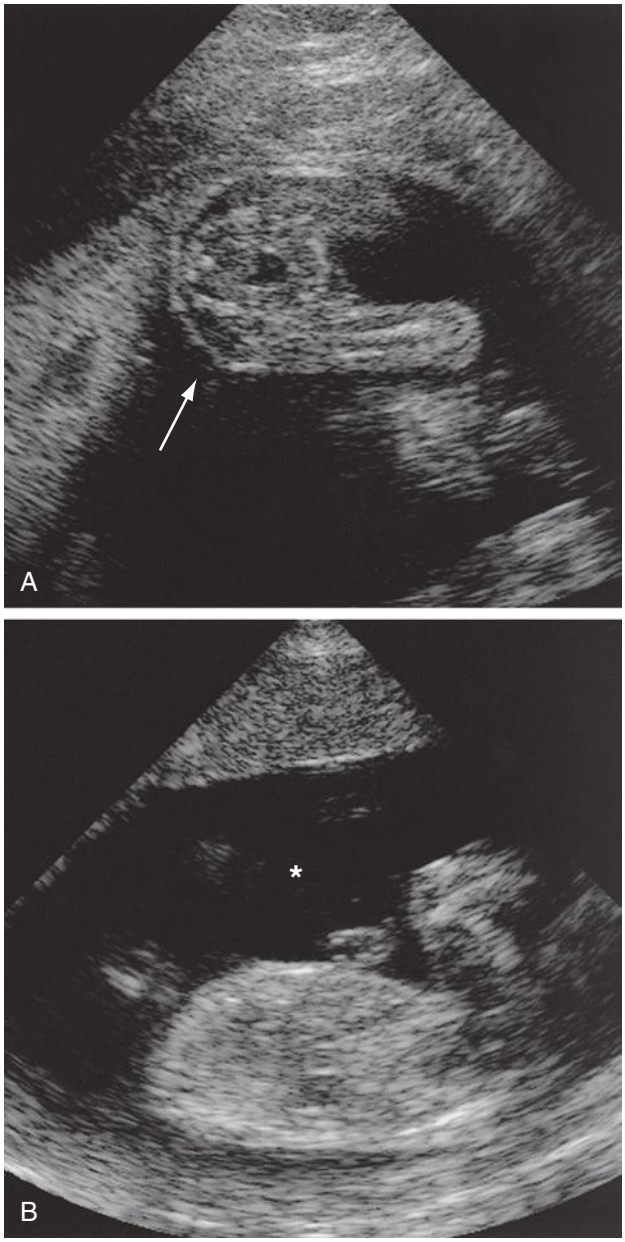

FIG 20-16 Sonogram of a patient with a monochorionic twin pregnancy with twin-to-twin transfusion syndrome. **A,** The donor fetus in the oligohydramniotic sac (*arrow*) is "stuck" to the anterior uterine wall. **B,** The recipient fetus is in a polyhydramniotic sac (*asterisk*). Often the dividing amniotic membrane cannot be identified.

CONCLUSIONS

It is helpful to understand the dynamics of amniotic fluid and recognize normal fluid volume in singleton and twin pregnancies. Various techniques for ultrasound assessment of AFV have been described. There are significant implications of abnormal AFV, low or high, detected sonographically. Although AFV dynamics are multifaceted and not fully understood, the regulatory balance of AFV is concentrated at three main levels: fetal urine production and fetal swallowing, the intramembranous pathway, and the osmotic fluid gradient generated by the maternal-fetal relationship. Normal values and ranges for AFV are difficult to define. Efforts have been made to establish cutoff values for abnormal high and low volumes (polyhydramnios and

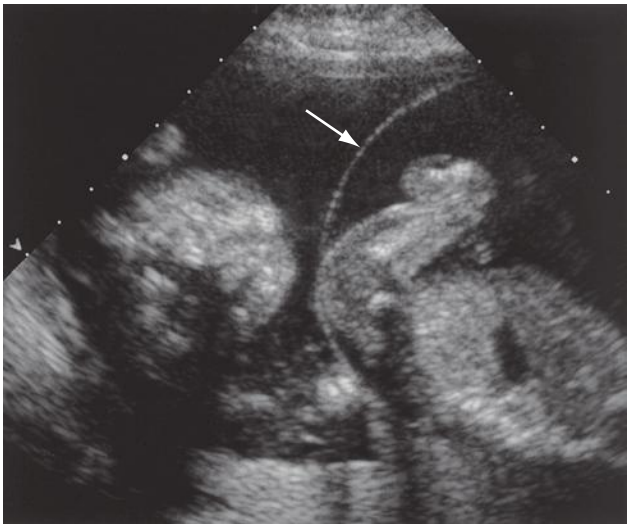

FIG 20-17 Sonogram from a patient with a diamniotic dichorionic twin pregnancy. Subjective evaluation revealed normal amniotic fluid in each gestational sac on either side of the amniotic membrane (*arrow*).

oligohydramnios, respectively) determined based on correlation with adverse pregnancy outcomes. Two main techniques are used to numerically estimate AFV by ultrasound: AFI and DVP. It has been found that, of these, DVP is the preferred method. There are potential pitfalls in this assessment, and both techniques can be unreliable when correlated with actual AFV. Often, subjective assessment is used in the initial determination of fluid status.

Assessment of amniotic fluid is used as a vital sign for fetal well-being. AFV evaluation is an essential component of the BPP in antenatal testing.[29] Abnormalities in AFV may be a reflection of the status of the uteroplacental unit. Thus, an obstetric ultrasound examination must include attention to amniotic fluid. A working knowledge and basic understanding of the physiology that maintains balance of intrauterine amniotic fluid is essential in order to promptly identify abnormalities in this process, which may result from maternal or fetal conditions. Importantly, normal AFV cannot by itself assure good perinatal outcome; additional information regarding the patient's history, physical examination, fetal status, and the remainder of the sonographic evaluation of the fetus is necessary to complete the picture.

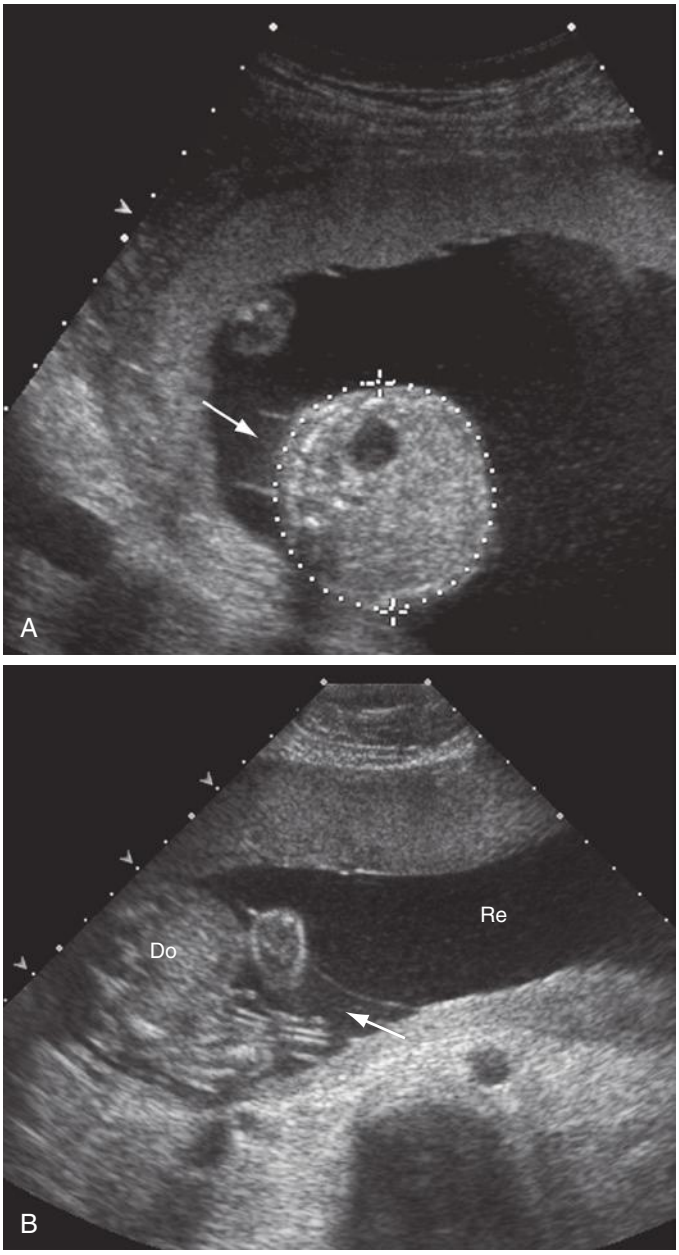

FIG 20-18 **A,** Sonogram of the fetal abdomen and surrounding amniotic fluid in a case of twin-to-twin transfusion syndrome. At first glance the fluid surrounding the donor abdomen appears to reside within its amniotic sac. In fact, there is only a small amount of hyperechogenic fluid (*arrow*) seen within the amniotic sac that enshrouds the fetus. **B,** Sonogram of the two amniotic sacs in a pregnancy with twin-to-twin transfusion syndrome. The amniotic fluid (*arrow*) surrounding the donor twin (Do) is more echogenic than the fluid in the recipient sac (Re).

Antepartum Fetal Surveillance and the Role of Ultrasound

Sarah Ellestad, Sarah Wheeler, Jeffrey A. Kuller

SUMMARY OF KEY POINTS

- The goal of antepartum testing is to prevent fetal death.
- Antepartum testing is most commonly performed in pregnancies identified as high risk due to maternal conditions or following the identification of fetuses at risk for intrauterine compromise so that intervention and timely delivery can prevent progression to stillbirth.
- Antepartum surveillance may also be used to confirm the well-being of the normal fetus so as to prevent unnecessary intervention and iatrogenic prematurity.
- Real-time ultrasonography, including assessment of fetal heart rate patterns and umbilical artery Doppler velocimetry, is a component of antepartum surveillance.
- Surveillance techniques include fetal kick counts, nonstress test (NST), contraction stress test (CST), biophysical profile (BPP), modified biophysical profile, and umbilical artery Doppler velocimetry.

OUTLINE

Antepartum fetal assessment is used to assess the risk of fetal death in pregnancies complicated by maternal medical problems or fetal compromise.[1] Multiple techniques can be utilized to assess fetal status, including fetal kick counts, nonstress test (NST), contraction stress test (CST), biophysical profile (BPP), modified BPP, and umbilical artery Doppler velocimetry. All of these techniques are aimed at identifying hypoxemic or acidemic fetuses with the intention of providing an opportunity to intervene before permanent damage or death results. As such, antenatal surveillance can be used to screen for fetal compromise when it is suspected (i.e., maternal report of decreased fetal movement) or anticipated (cyanotic maternal heart disease). Ultrasound can be particularly valuable because it provides a real-time view of fetal activity and assessment of the intrauterine environment. Acute events, however, such as abruption or cord accident, cannot be predicted by such techniques.

Serial antepartum surveillance using one or multiple fetal assessment techniques is the standard of care for pregnancies complicated by maternal or fetal complications. There is little evidence from randomized controlled trials that antepartum testing actually decreases the risk of fetal death, and some evidence suggests that it may actually be harmful as a result of increases in the rate of iatrogenic prematurity.[2] Nevertheless, antenatal testing remains a mainstay of prenatal care to assess fetal well-being for a wide range of maternal and fetal indications (Table 21-1). The primary measure of antepartum testing efficacy is the false negative rate, which is defined as the incidence of fetal death within 1 week of a normal test result. Among the aforementioned antepartum testing techniques, false negative rates range from a low of 0.4/1000 for CSTs to a high of 3.2/1000 for NSTs.[3] However, the high false positive rate of various testing protocols (up to 50% with the NST), defined as an abnormal test result in the setting of an uncompromised fetus, limits the utility of interpreting a test in isolation without considering the clinical situation or utilizing subsequent surveillance measures[3] (Table 21-2).

ASSESSMENT OF FETAL MOVEMENT

Quickening, or the time at which fetal movement is first perceptible to the mother, typically occurs at about 19 to 20 weeks.[4] With advancing gestation, fetal movement becomes more pronounced and peaks at approximately 38 weeks. Periods of active movement generally last about 40 minutes whereas quiet periods last about 20 minutes.[5] The fetus is most active between 9:00 PM and 1:00 AM, which correlates with falling maternal glucose levels.[5]

Fetal physiology studies performed in the setting of growth-restricted fetuses demonstrate that fetal movement decreases with increasing hypoxia.[6] Thus, maternal assessment of fetal movement is a potentially simple and inexpensive method of monitoring fetal well-being. Physicians routinely inquire about fetal activity as part of the standard prenatal visit.[7] In the low-risk pregnancy, this technique is often the only form of fetal surveillance that is performed.

Numerous protocols can be used for quantifying normal movement; however, there are no high-quality studies indicating a superior

TABLE 21-1 Indications for Antepartum Fetal Surveillance Testing

Maternal Conditions

- Pregestational diabetes mellitus
- Hypertension
- Systemic lupus erythematosus
- Chronic renal disease
- Antiphospholipid syndrome
- Hyperthyroidism (poorly controlled)
- Hemoglobinopathies (sickle cell, sickle cell–hemoglobin C, or sickle cell–thalassemia disease)
- Cyanotic heart disease

Pregnancy-Related Conditions

- Gestational hypertension
- Preeclampsia
- Decreased fetal movement
- Gestational diabetes mellitus (poorly controlled or medically treated)
- Oligohydramnios
- Fetal growth restriction
- Late-term or postterm pregnancy
- Isoimmunization
- Previous fetal demise (unexplained or recurrent risk)
- Monochorionic multiple gestation (with significant growth discrepancy)

methodology or parameters for normal amounts of fetal movement.[8] Most often, women are advised to do "kick counts" by lying on their side and counting the number of fetal movements. The perception of 10 distinct movements in 2 hours is commonly regarded as reassuring.[9,10] Once 10 movements have been recognized by the mother, the count may be discontinued. Kick counts can be repeated as often as daily. It may, however, be just as useful to encourage the mother to report any change from what she perceives as "normal."

Multiple factors other than deteriorating fetal status can affect maternal perceptions of movement, including gestational age, placental location, medications, maternal activity, position, and obesity.[11,12] However, decreased fetal movement has been associated with an increased risk of stillbirth.[11] Further evaluation, therefore, is always warranted once decreased maternal perception of fetal movement is reported both to exclude potentially reversible factors that may be responsible and to ensure fetal well-being.

There is only one randomized controlled trial evaluating formal fetal movement counting. During this study, over 68,000 low-risk women were enrolled and randomized to regular fetal movement evaluation (intervention group) or routine care (control group). The antepartum death rate was statistically equal in both groups, 2.9/1000 in the intervention group versus 2.7/1000 in the control group.[13] Reporting compliance was a major limitation of this study and may have affected the results. Only 46% of women in the intervention group were compliant in reporting decreased fetal movement. In contrast, a prospective cohort study performed in Norway found that providing written information about fetal activity, including a definition of what constitutes decreased fetal movement, as well as an invitation to monitor fetal movements via kick charts, reduced the incidence of stillbirth by almost 50% in women who presented with a complaint of decreased fetal movement (odds ratio [OR] 0.51, 95% confidence interval [CI] 0.32-0.81).[14] There have been no randomized controlled trials evaluating fetal movement counting in women with high-risk pregnancies. A systematic review published in the Cochrane Database concluded that there is insufficient evidence to recommend routine fetal movement counting to prevent stillbirth.[15]

NONSTRESS TEST

The NST is the most common screening test used in antepartum surveillance. A cardiotocograph, or external fetal monitor, is used to simultaneously record the fetal heart rate (FHR) and maternal uterine activity with Doppler ultrasound transducers that are placed on the maternal abdomen. NST interpretation is based on the premise that a healthy, well-oxygenated fetus will demonstrate accelerations of the heart rate with movement. During an NST, the uterus is quiescent (hence the term *nonstress*) and the FHR is evaluated for a period of up to 20 minutes, although it may be extended for up to 40 minutes to allow for variations in the fetal sleep-wake cycle. The FHR pattern, including baseline heart rate, variability, and the presence or absence of accelerations and decelerations are evaluated in NST interpretation (Figs. 21-1 and 21-2). These parameters reflect a fetus's ability to adapt effectively to the intrauterine environment and can give the provider information about fetal well-being.

The FHR baseline is regulated by the autonomic nervous system. The parasympathetic innervation of the heart is mediated by the vagus nerve and is responsible for a chronotropic effect that slows down the FHR, as well as an oscillatory effect that alters R wave intervals, resulting in the heart rate variability. The sympathetic nervous system, on the other hand, releases norepinephrine when stimulated, which accelerates the FHR and improves inotropy, or contractility.[16] The FHR baseline is the average number of beats per minute (rounded to 0 or 5) over a 10-minute period. Periods of marked variability (amplitude of the FHR greater than 25 beats per minute above the baseline) should not be used to determine the baseline. Additionally the baseline should be identifiable for at least 2 minutes during the NST, although the 2 minutes may not be contiguous.[17] Most clinicians do not use a computerized model to determine baseline and instead "eyeball" the

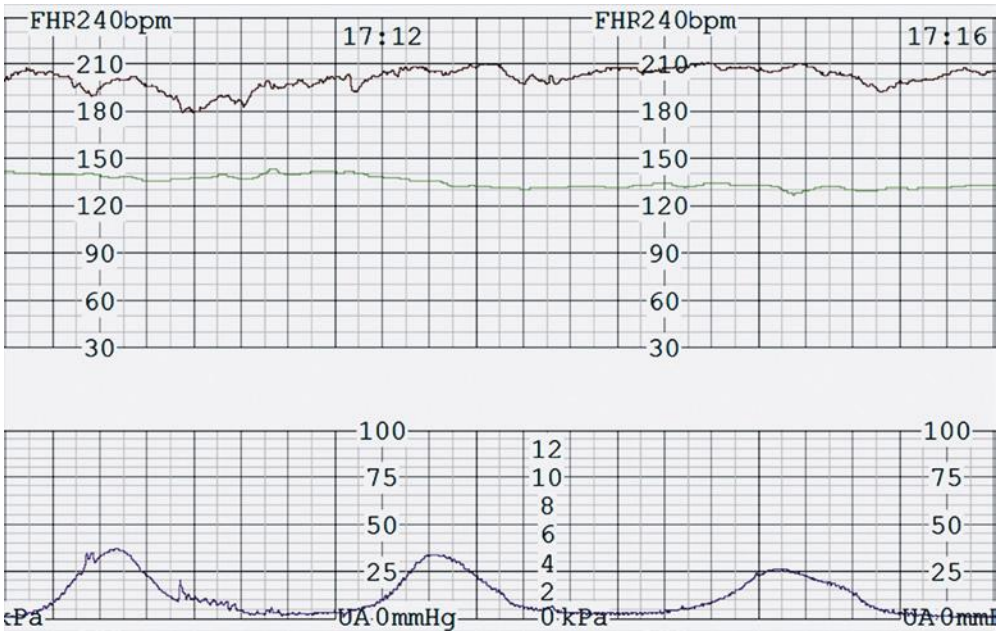

FIG 21-1 Fetal heart rate (FHR) tracings demonstrating fetal tachycardia with a baseline fetal heart rate (*top line*) of about 200 beats per minute (bpm). The green line demonstrates maternal pulse; the bottom tracing shows uterine activity (UA).

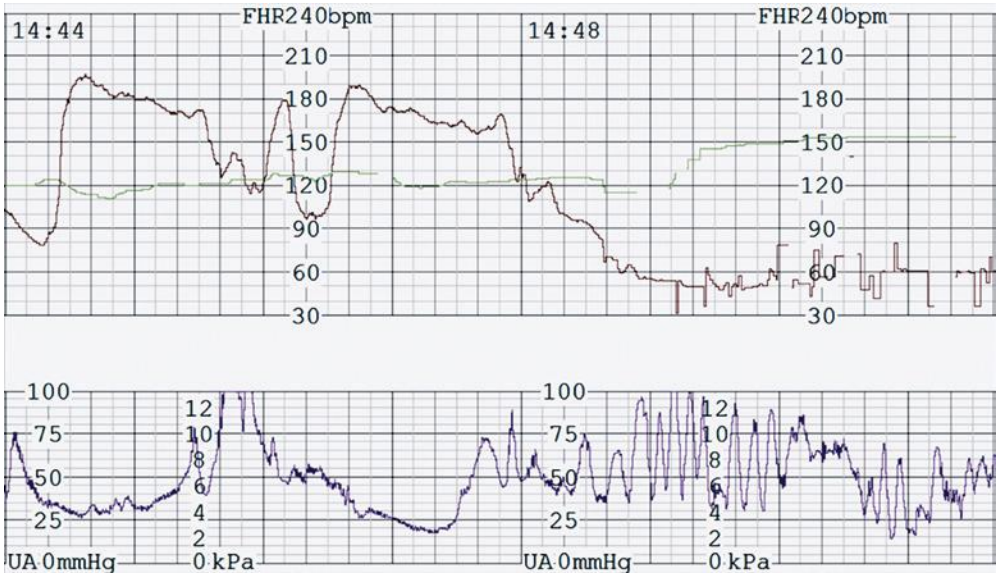

FIG 21-2 Fetal terminal bradycardia, with an initial fetal heart rate (FHR) of about 180 bpm (beats per minute) that decreases to 60 bpm at the end of the tracing. The green line shows maternal pulse; the bottom tracing shows uterine activity (UA).

tracing, leading to subjectivity in interpretation. Additionally, the baseline may be indeterminate, meaning the NST cannot be interpreted. The normal baseline FHR ranges from 110 to 160 beats per minute; the baseline is usually in the higher end of the normal range early in gestation and decreases as gestation advances.[18]

Variability refers to the expected fluctuations in the baseline FHR that are irregular in amplitude and frequency and are quantified as the amplitude of the peak-to-trough in beats per minute.[17] Variability can be absent, minimal, moderate, or marked (Fig. 21-3). Moderate variability, in which the amplitude ranges between 6 and 25 beats per minute, is considered reassuring.[1] FHR variability is rare before 24 weeks but should be present after 28 weeks. Absence of variability in the third trimester should be considered abnormal until further evaluation. Tracings demonstrating minimal variability (amplitude less than 6 beats per minute) or absent variability (amplitude range is undetectable) warrant further investigation, especially when the gestational age is in the mid- to late third trimester.

Accelerations are defined as a visually abrupt increase in FHR with onset to peak less than 30 seconds. In a fetus that is 32 weeks' gestation or greater, the acceleration should peak at least 15 beats per minute above the baseline and persist for at least 15 seconds from baseline to baseline. In a fetus younger than 32 weeks the peak of the acceleration should be at least 10 beats per minute above baseline and persist for at least 10 seconds.

Decelerations are classified as late, early, or variable (Fig. 21-4) and differ in their onset, nadir, and recovery in relation to uterine

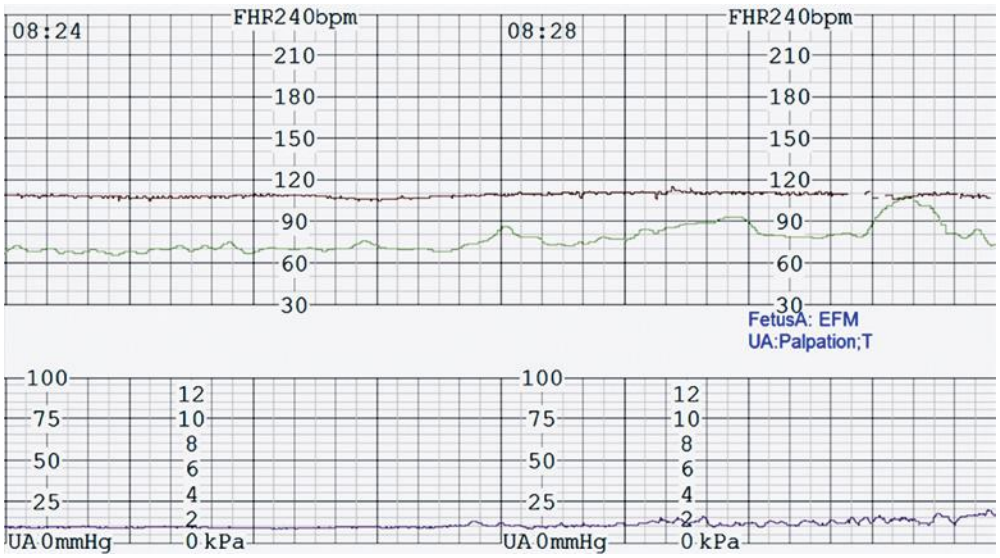

FIG 21-3 Fetal heart rate (FHR) tracing (*top line*) with a heart rate of 110 bpm (beats per minute) and a nearly flat line consistent with minimal variability. Absence of variability is abnormal and requires further evaluation. EFM, electronic FHR monitoring; UA, uterine activity. The green line shows maternal pulse. The bottom tracing shows uterine activity (UA).

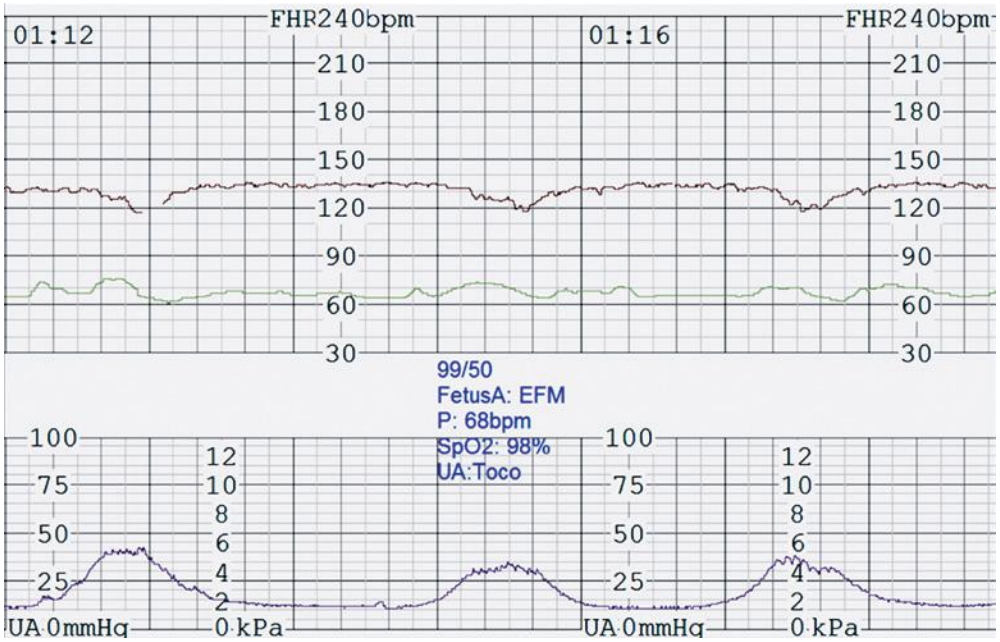

FIG 21-4 Fetal heart rate (FHR) tracing demonstrating early decelerations, in which the FHR (*top line*) decreases gradually with a nadir at the same time as the uterine contraction (*lower green line*). EFM, electronic FHR monitoring; SpO_2, oxygen saturation as measured by pulse oximetry; UA, uterine activity. The green line shows maternal pulse. The bottom tracing shows uterine activity (UA).

contractions. Each type of deceleration has a different cause (hypoxemia, head compression, and cord compression, respectively). Correct identification of the type of deceleration can therefore impact FHR interpretation and management.

A sinusoidal FHR is relatively rare and is defined as a smooth, sine wave–like undulating pattern in the FHR baseline with a cycle frequency of 3 to 5/minute that persists for over 20 minutes (Fig. 21-5). This pattern is highly associated with fetal anemia. It is considered abnormal and requires prompt attention. Given the association with fetal anemia, assessment by measurement of the peak systolic velocity of the fetal middle cerebral artery (MCA) using Doppler velocimetry is warranted in the absence of a known cause (see Chapter 22).

Ultimately, the NST is interpreted as "reactive" or "nonreactive." A reactive NST is defined as the presence of at least two accelerations of the FHR 15 beats per minute or greater above the baseline for a minimum of 15 seconds within a 20-minute period of monitoring. A nonreactive NST lacks the appropriate number of accelerations or doesn't meet criteria for acceleration but does not demonstrate absence of variability or decelerations. In 2008, the Eunice Kennedy Shriver National Institute of Child Health and Human Development in conjunction with the American College of Obstetricians and Gynecologists and the Society for Maternal-Fetal Medicine published recommendations for the terminology and interpretation of FHR tracings and described a new three-tiered system. Although the emphasis

FIG 21-5 A sinusoidal fetal heart rate tracing (*top line*), suggestive of fetal anemia (see text). The bottom tracing shows uterine activity (UA). bpm, beats per minute; FHR, fetal heart rate. (From Catanzarite VA, Schrimmer DB, Madia C, Mendoza A: Prenatal sonographic diagnosis of intracranial haemorrhage: report of a case with a sinusoidal fetal heart rate tracing, and review of the literature. Prenat Diagn 15(3):229-235, 1995, used with permission.)

in this report is on intrapartum FHR patterns, these definitions may also be extrapolated to the antepartum setting[19] (Figs. 21-6 through 21-8 and Table 21-3).

Maturation of the fetal nervous system occurs throughout gestation and affects NST interpretation. Between 24 and 28 weeks, up to 50% of NSTs will not be reactive because of immaturity of the fetal nervous system, which limits the utility of the test in the midtrimester.[20] This number of nonreactive tests decreases to 15% between the gestational ages of 28 and 32 weeks.[21,22] Frequency and amplitude of FHR accelerations increase with advancing gestational age, which contributes to the decrease in nonreactive NSTs as gestational age increases.[23,24]

Despite widespread use of the NST, there are limited data to support its efficacy in the prevention of stillbirth. A Cochrane review reported that performing an NST had no significant effect on the rate of stillbirth or any measure of perinatal morbidity.[25] However, the trials included in this meta-analysis were conducted in the early 1980s, when testing was first being introduced and may not reflect how these tests are utilized and interpreted today.[25] Likewise, the use of sonography as an adjunct to fetal assessment as well as advances in neonatal care have changed since the studies included in the meta-analysis were performed.

Traditionally, the NST was performed on a weekly basis. Starting in 1981, Boehm and associates began increasing the frequency of testing to twice a week in women with at-risk pregnancies and found that the rate of stillbirth after a reactive NST decreased to 1.9/1000 compared to their previously published rate of 6.1/1000.[26] Twice weekly testing remains the most common recommendation in most clinical circumstances.

Vibroacoustic stimulation may be used to decrease the number of nonreactive NSTs related to the fetal sleep cycle. Using an artificial larynx on or just above the maternal abdomen and delivering short bursts of sound to the fetus over 1 to 5 seconds, fetal movement may be stimulated, potentially shortening the waiting period before an acceleration is produced without compromising the test's validity.[27-29] A 2014 systematic review found that the use of vibroacoustic stimulation shortened the mean overall testing time by almost 7 minutes –6.93 minutes, (95% CI 12.09 minutes to –1.76 minutes) and reduced the frequency of nonreactive NSTs by 40% (OR 0.62, 95% CI 0.48-0.81).[29]

CONTRACTION STRESS TEST

A CST evaluates the FHR using cardiotocography during uterine contractions, which cause transient decreased oxygenation. Therefore, this test assesses the fetal oxygenation status during periods of "stress."[7] Contractions can occur spontaneously or can be induced via nipple stimulation or intravenous oxytocin administration. The goal of a CST is to identify the fetus at risk for compromise by observing the fetus in the presence of (reversible) stress before permanent damage occurs.[30] Once three contractions in a 10-minute period are achieved, the CST is characterized as negative if no late or significant variable

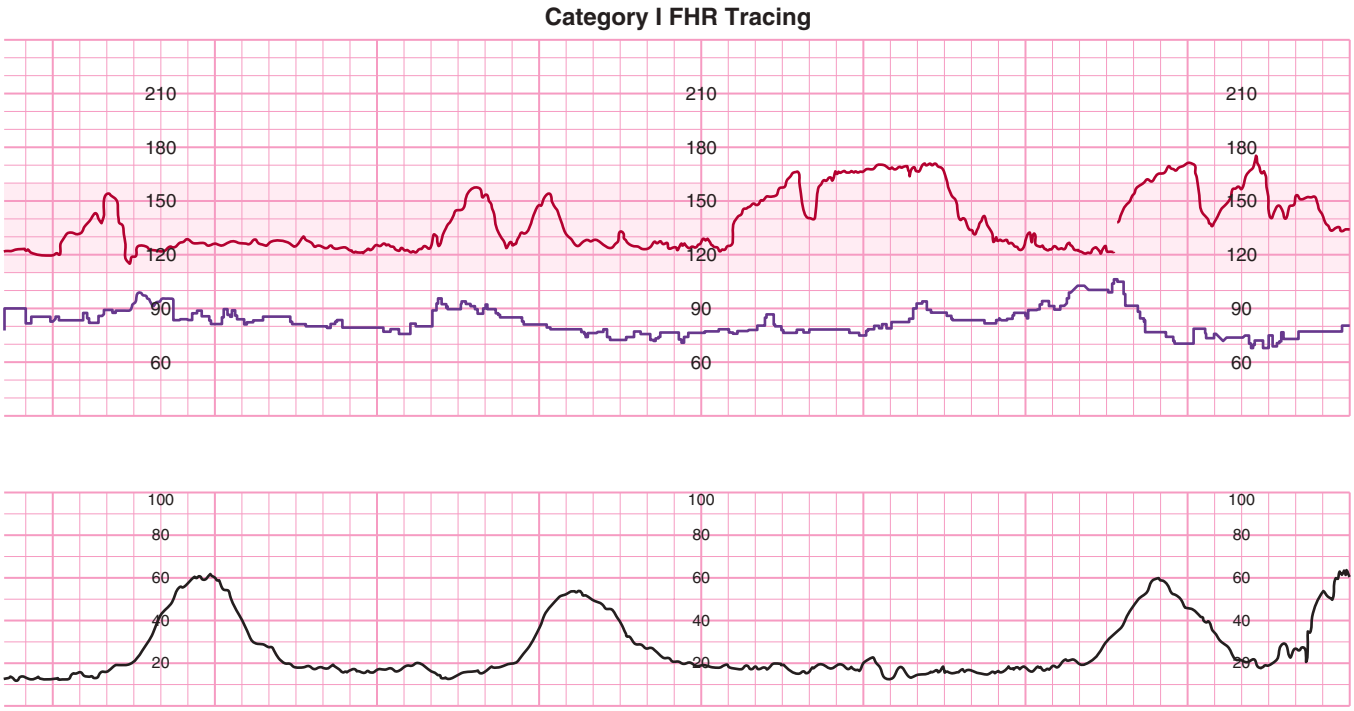

FIG 21-6 Category I tracing. See classification in Table 21-3. BPM, beats per minute; FHR, fetal heart rate. (Personal file of Dr. Leo Brancazio, Duke University.)

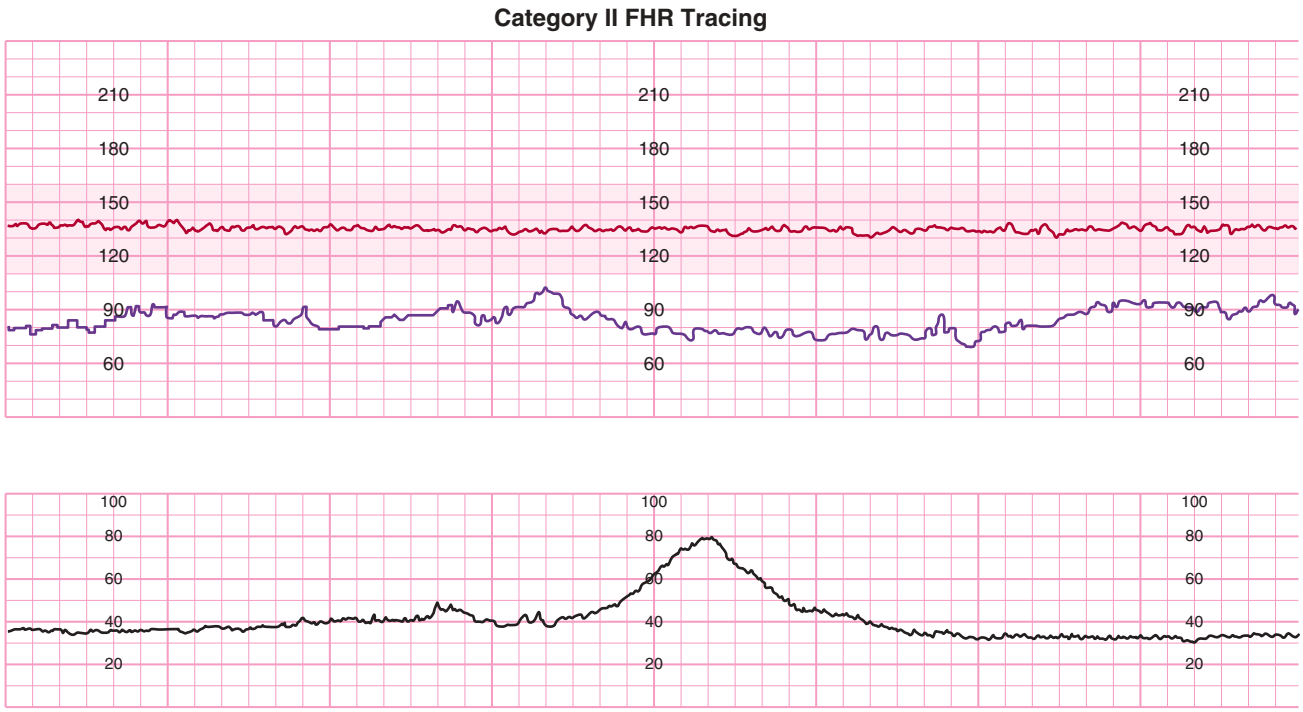

FIG 21-7 Category II tracing. See Table 21-3. BPM, beats per minute; FHR, fetal heart rate. (Personal file of Dr. Leo Brancazio, Duke University.)

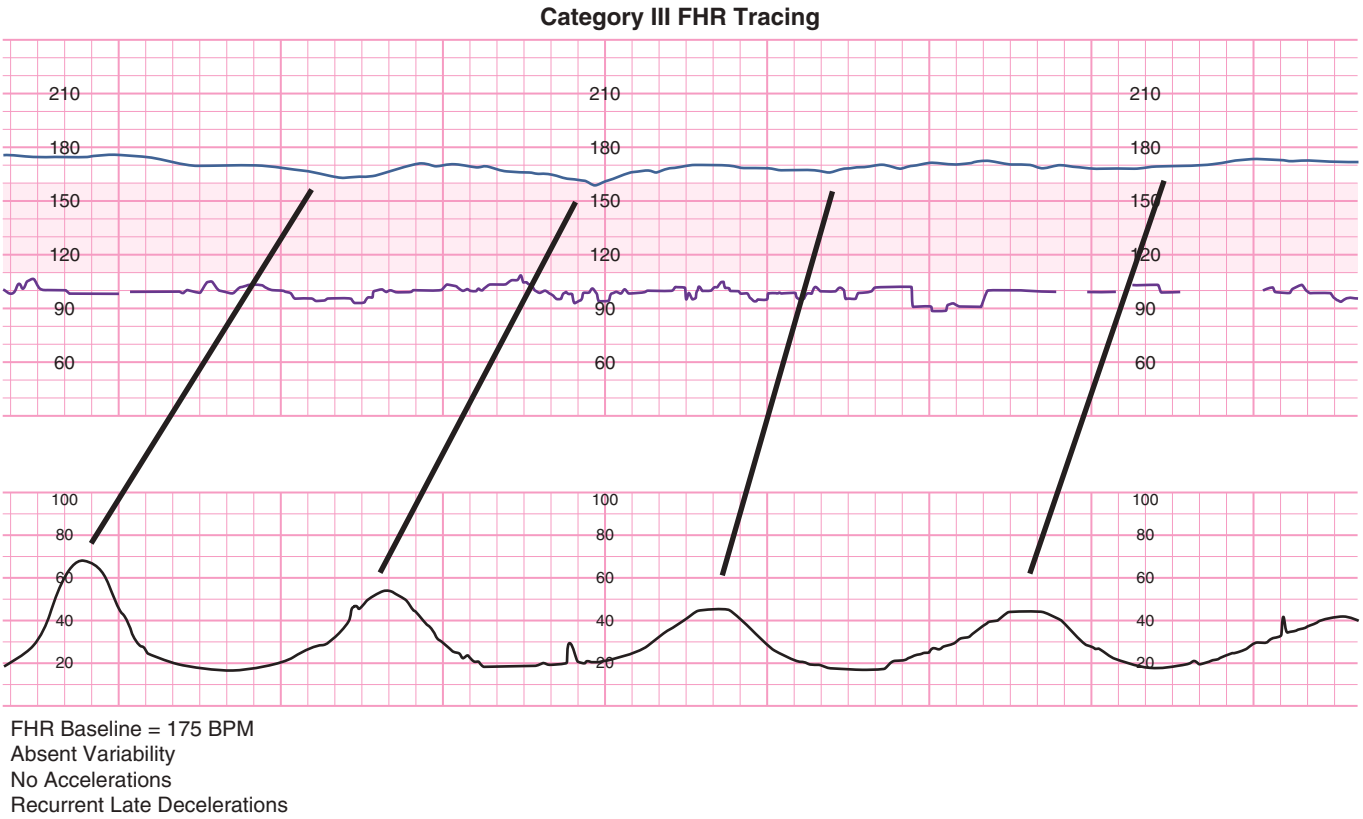

FIG 21-8 Category III tracing. See Table 21-3. BPM, beats per minute; FHR, fetal heart rate. (Personal file of Dr. Leo Brancazio, Duke University.)

decelerations are noted. A positive CST is defined by the presence of late decelerations following 50% or more of the contractions and necessitates further evaluation.[9] CST results can be additionally categorized as equivocal-suspicious (intermittent late decelerations or significant variable decelerations), equivocal (FHR decelerations that occur in the presence of contractions more frequent than every 2 minutes or lasting longer than 90 seconds), and unsatisfactory (fewer than three contractions in 10 minutes or an uninterpretable tracing).[7]

Contraindications to CST include conditions that contraindicate contractions and labor and preclude a vaginal delivery or increase the risk of preterm delivery, uterine rupture, or bleeding and include preterm labor, preterm premature rupture of membranes (PPROM), a history of extensive uterine surgery, classical cesarean delivery, or known placenta previa. A CST may also be used to help determine mode of delivery in situations of potential or suspected fetal compromise including PPROM or fetal growth restriction.

BIOPHYSICAL PROFILE

A BPP integrates ultrasound observations and cardiotocography. A BPP is a noninvasive and relatively quick method of assessing fetal well-being that utilizes multiple components that can be independently affected by fetal hypoxemia. The BPP score may provide more in-depth information regarding severity or chronicity of the fetal oxygen state. It is composed of four acute biophysical components and one chronic biophysical component. Each of the acute components, which include the NST, fetal breathing, fetal movement, and fetal tone, is controlled by a discrete regulatory center in the central nervous system (CNS). These centers begin functioning at different gestational ages.[31] Tone, controlled by a center in the cortex-subcortical area, is the earliest physical activity to appear and can first be observed at about 8 weeks' gestational age. Next is fetal movement, which is regulated by a center in the cortex nuclei and appears at about 9 weeks' gestation. Breathing movements can be visualized at about 21 weeks and are controlled by a center in the ventral surface of the fourth ventricle. The last of the acute biophysical activities to appear is FHR reactivity, which isn't present until the late second trimester or early third trimester and is regulated in the posterior hypothalamus and medulla.[32] Fetal breathing movements and FHR reactivity, therefore, are more gestational age dependent than tone and movement, both of which should be present early in the first trimester.

To perform a BPP, real-time ultrasound is used to observe the fetus over a maximum period of 30 minutes and either 2 points or 0 points are awarded based on the presence or absence of each parameter. A maximum of 10 points can be achieved during the BPP. Points are awarded for fetal movement if two or more discrete body or limb movements are observed within 30 minutes. Fetal tone is defined as one or more episodes of extension with return to flexion in a limb or opening and closing of the hand (Video 21-1). Fetal breathing is defined as an episode of chest wall movements that are sustained for more than 20 seconds (Video 21-2). Points are also awarded for a reactive NST and an amniotic fluid index (AFI) of 5 cm or more or a deepest vertical pocket (DVP) of at least 2 cm (Fig. 21-9, Table 21-4).

The *gradual hypoxia concept* is a theory that the biophysical activities that appear first embryologically are the last to disappear with worsening hypoxia; the activities that are the most sensitive to hypoxia are those that develop last. The more components of the BPP that are absent, the higher the incidence of acidemia.[32-35] Fetal breathing center neurons and the cardioregulatory neurons controlling the coupling of fetal movement and heart rate acceleration are most susceptible to

TABLE 21-3 Three-Tiered Fetal Heart Rate Interpretation System

Category I

Category I fetal heart rate (FHR) tracings that include *all* of the following:

- Baseline rate: 110-160 beats per minute (bpm)
- Baseline FHR variability: moderate
- Late or variable decelerations: absent
- Early decelerations: present or absent
- Accelerations: present or absent

Category II

Category II tracings include all FHR tracings not categorized as category I or category III. Category II tracings may represent an appreciable fraction of those encountered in clinical care. Examples of category II FHR tracings include any of the following:

Baseline Rate

- Bradycardia not accompanied by absent baseline variability
- Tachycardia

Baseline FHR Variability

- Minimal baseline variability
- Absent baseline variability not accompanied by recurrent decelerations
- Marked baseline variability

Accelerations

- Absence of induced accelerations after fetal stimulation

Periodic or Episodic Decelerations

- Recurrent variable decelerations accompanied by minimal or moderate baseline variability
- Prolonged deceleration ≥ 2 minutes but < 10 minutes
- Recurrent late decelerations with moderate baseline variability
- Variable decelerations with other characteristics, such as slow return to baseline, "overshoots," or "shoulders"

Category III

Category III FHR tracings include either:

- Absent baseline FHR variability and any of the following:
  - Recurrent late decelerations
  - Recurrent variable decelerations
  - Bradycardia
- Sinusoidal pattern

Macones GA, Hankins GD, Spong CY, et al: The 2008 National Institute of Child Health and Human Development workshop report on electronic fetal monitoring: update on definitions, interpretation, and research guidelines. Obstet Gynecol 112(3):661-666, 2008.

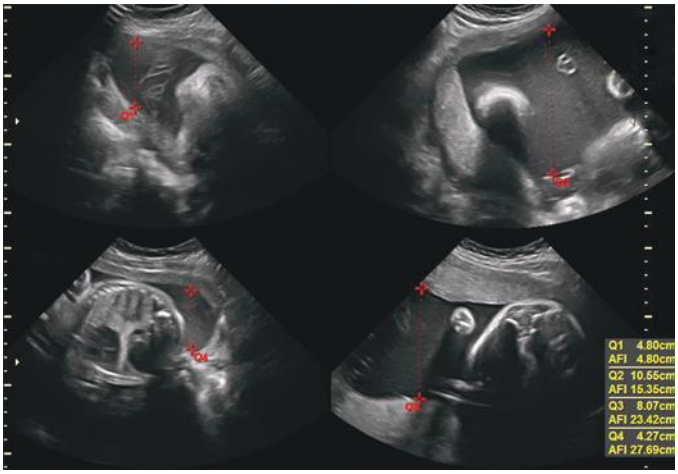

FIG 21-9 Determination of the amniotic fluid index, with measurement of the deepest vertical pocket in each of the four quadrants of the uterus.

changes in fetal oxygenation. The centers regulating fetal movement are more resistant to changes in fetal status, and the center regulating fetal tone is the most resistant. Thus, there is a predictable response in the loss of biophysical activities to hypoxemia with loss of fetal breathing movements and FHR acceleration/NST reactivity first, followed by decreased fetal movement and finally loss of tone.[32] This predictable response helps to estimate not only the presence of hypoxemia but also the duration and severity. This is further demonstrated in a study that looked at the relationship between fetal biophysical scores and cord blood gases and acid-base measurements in nonlabored fetuses within 3 hours of a cesarean delivery. As expected, the first manifestations of fetal hypoxemia and acidemia were loss of FHR reactivity and breathing movements; fetal movements and tone were subsequently compromised with increasing degrees of hypoxemia, acidemia, and hypercapnia[31] (Figs. 21-10 through 21-13).

Figure 21-14 displays the inverse relationship between increasingly abnormal BPP scores and presence of fetal distress, admission to neonatal intensive care unit (NICU), fetal growth restriction, low 5-minute Apgar scores, and low cord pH. Likewise, Figure 21-15 demonstrates the linear relationship between lower BPP scores and perinatal morbidity and mortality rates, and Figure 21-16 shows the inverse relationship noted between the last BPP score before delivery and incidence of cerebral palsy.[36] These three figures, which all demonstrate the exponential and highly significant relationship between the BPP in closest proximity to delivery and umbilical venous pH and perinatal morbidity and mortality, provide further proof that the last BPP reflects the presence and degree of acidemia, that acidemia is a manifestation of asphyxia, and that asphyxia can contribute to death or fetal damage.[37]

The chronic component of the BPP is the amniotic fluid volume. Points are awarded if one or more pockets of fluid without umbilical cord or fetal small parts measuring at least 2 cm in the vertical axis are noted.[38] Alternatively a formal AFI can be performed by dividing the uterus into four quadrants and adding up the single deepest pocket in each quadrant (see Fig. 21-9). The range of normal for an AFI is based on gestational age; however, points are awarded for an AFI over 5 cm.[39] In the setting of placental dysfunction, a decrease in amniotic fluid volume takes about 15 days to progress from normal to barely abnormal; the average time to reach severe oligohydramnios is about 23 days in fetuses with growth restriction.[40]

A normal BPP score (8/10 or 10/10) effectively rules out the presence of hypoxemia. However, an abnormal score does not necessarily prove that hypoxemia is present. The more components that are absent, and the longer period of time those variables are absent, the higher the likelihood that pathologic change exists. The fetus has adaptive responses to states of low oxygen, which include decreasing activity, increased oxygen extraction, increased fetal hemoglobin (with increased oxygen-carrying capacity), and redistribution of blood flow to increase perfusion to the fetal brain, heart, and adrenals.[41] In some cases of chronic fetal disease, such as growth restriction, biophysical variables may initially be absent but can subsequently reappear. As such, the presence of certain components of the BPP does not guarantee that the fetus is not hypoxic and may explain why stillbirths still occur following a "normal" BPP.[41] The false negative rate, or risk of

TABLE 21-4 Fetal Biophysical Profile Scoring

Variable	Score 2	Score 0
Fetal breathing movements	Presence of at least 30 seconds of sustained fetal breathing movements in 30 minutes of observation.	Less than 30 seconds of fetal breathing movements in 30 minutes.
Fetal movements	Three or more gross body movements in 30 minutes of observation. Simultaneous limb and trunk movements are counted as a single movement.	Two or less gross body movements in 30 minutes of observation.
Fetal tone	At least one episode of motion of a limb from a position of flexion to extension and a rapid return to flexion.	Limb in a position of semi- or full-extension with no return to flexion with movement; absence of fetal movement is counted as absent tone.
Fetal activity	Presence of two or more fetal heart rate accelerations of at least 15 beats per minute and lasting at least 15 seconds and associated with fetal movement in 40 minutes.	No acceleration or less than two accelerations of the fetal heart rate in 40 minutes of observation.
Qualitative amniotic fluid volume	A pocket of amniotic fluid that measures at least 1 cm in two perpendicular planes.	Large pocket of amniotic fluid measures less than 1 cm in two perpendicular planes.
Maximal score	10	
Minimal score		0

From Manning FA, Platt LD, Sipos L: Antepartum fetal evaluation: development of a fetal biophysical profile score. Am J Obstet Gynecol 136:787, 1980.

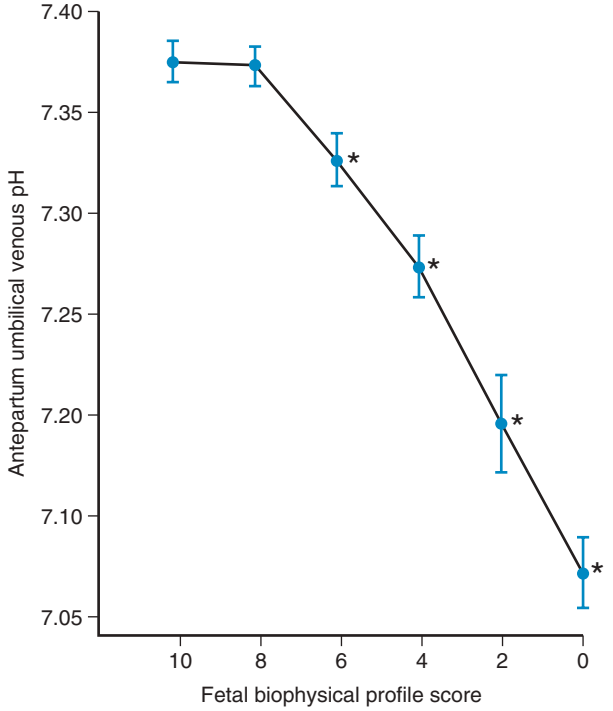

FIG 21-10 The relationship between fetal umbilical venous pH (±2 SD [standard deviation]) by cordocentesis and the fetal biophysical profile score. The correlation was linear, inverse, and very significant (r^2 = 0.912; $P < 0.01$). (From Manning FA: Dynamic ultrasound-based fetal assessment: the fetal biophysical profile score. Clin Obstet Gynecol 38(1):26-44, 1995.)

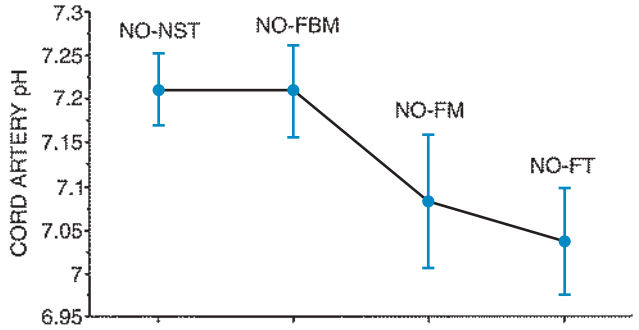

FIG 21-11 Relationship between cord artery pH and absent fetal biophysical activities. The pH tends to be lower in the absence of movements or tone compared with nonreactive nonstress testing or absence of breathing. Results are expressed in means (95% error bars). NO-FBM, absent fetal breathing; NO-FM, absent fetal movements; NO-FT, absent fetal tone; NO-NST, nonreactive nonstress test. (From Vintzileos AM, Fleming AD, Scorza WE, et al: Relationship between fetal biophysical activities and umbilical cord blood gas values. Am J Obstet Gynecol 165(3):707-713, 1991.)

fetal death within a week of a normal test result, ranges between 0.4 and 0.6/1000 live births, a rate that is about 10% of the observed perinatal mortality rate in any high-risk study population.[42,43] These deaths may also be due to acute events that cannot be anticipated such as a cord prolapse, abruption, or accidental cord compression.

The amniotic fluid volume component of the BPP greatly influences BPP interpretation and pregnancy management. With a BPP of 8/10 or 10/10 (including 2 points for amniotic fluid), the risk of developing fetal asphyxia within 1 week with no intervention is low (about 1/1000). When the BPP is 6/10 or 8/10 (with no points awarded for amniotic fluid) the risk of developing fetal asphyxia within 1 week without intervention is increased, from 20/1000 to 30/1000 to more than 50/1000. A 6/10 score, which includes 2 points for amniotic fluid, is considered equivocal, and management depends on gestational age and the indication for testing. The possibility of developing fetal asphyxia cannot be excluded with an equivocal test result, and the test should be repeated within 24 hours in the setting of prematurity; if the fetus is at or near term, delivery may be recommended. A score of 0/10 to 4/10 is more ominous and is associated with a 115/1000 to 550/1000 risk of fetal asphyxia within 1 week if no intervention occurs.[44]

Management, however, must be individualized. A low biophysical score warrants immediate investigation for factors other than hypoxia that may be present, such as prolonged fetal sleep cycles, maternal sedative medications, fetal anomalies, and maternal disease. If confounding factors are absent, a low score increases the risk for fetal acidemia and the likelihood of fetal compromise and death. It is important to note that BPP score does not dictate or predict delivery mode.

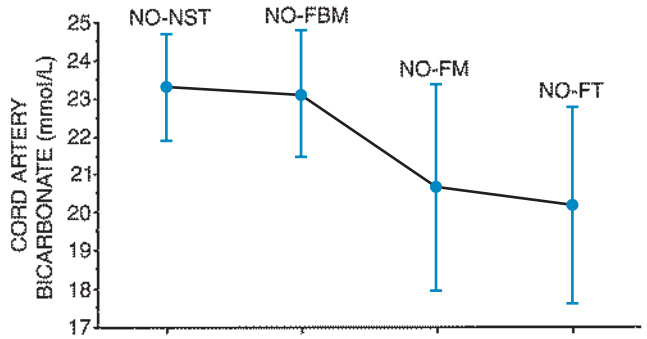

FIG 21-12 Relationship between cord artery bicarbonate level and absent fetal biophysical activities. The bicarbonate level tends to be lower in the absence of movements or tone compared with nonreactive nonstress testing and absence of breathing. Results are means expressed in millimoles per liter (95% error bars). NO-FBM, absent fetal breathing; NO-FM, absent fetal movements; NO-FT, absent fetal tone; NO-NST, nonreactive nonstress test. (From Vintzileos AM, Fleming AD, Scorza WE, et al: Relationship between fetal biophysical activities and umbilical cord blood gas values. Am J Obstet Gynecol 165(3):707-713, 1991.)

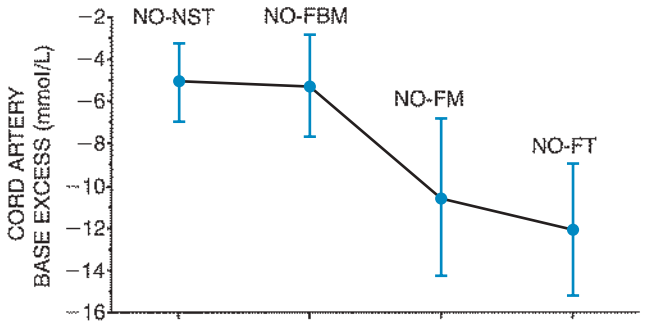

FIG 21-13 Relationship between cord artery base excess and absent fetal biophysical activities. The base excess tends to be lower in the absence of movements or tone compared with nonreactive nonstress testing and absence of breathing. Results are means expressed in millimoles per liter (95% error bars). NO-FBM, absent fetal breathing; NO-FM, absent fetal movements; NO-FT, absent fetal tone; NO-NST, nonreactive nonstress test. (From Vintzileos AM, Fleming AD, Scorza WE, et al: Relationship between fetal biophysical activities and umbilical cord blood gas values. Am J Obstet Gynecol 165(3):707-713, 1991.)

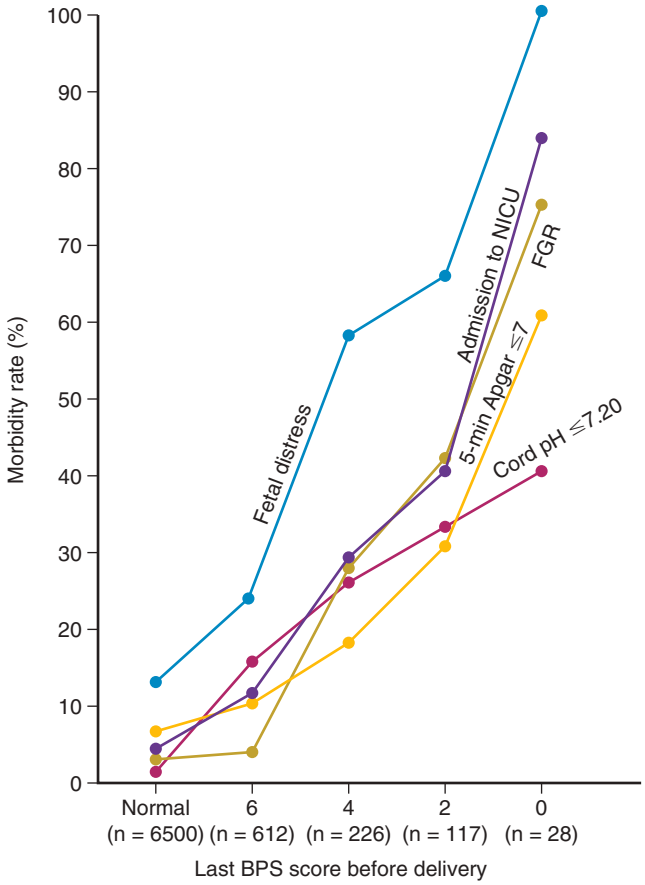

FIG 21-14 Relationship between perinatal morbidity rate measured by five outcome variables and last biophysical profile scoring (BPS) result before delivery. A significant inverse linear correlation is observed for each variable. FGR, fetal growth restriction; NICU, neonatal intensive care unit. (Modified from Manning FA, Harman CR, Morrison I, et al: Fetal assessment based on fetal biophysical profile scoring. IV. An analysis of perinatal morbidity and mortality. Am J Obstet Gynecol 162(3):703-709, 1990.)

Modified Biophysical Profile

Performing a full BPP requires a trained sonographer and a clinician trained to interpret an NST and can take up to 50 minutes, including 30 minutes for the ultrasound examination and 20 minutes for the NST. Given the resources needed to perform a complete BPP, modifications were proposed. In 1989 Clark and colleagues[27] first introduced the modified BPP, which combines the NST and the AFI. The original study used vibroacoustic stimulation after 5 minutes of the NST if spontaneous accelerations were absent. A second stimulus was administered if no accelerations were noted in 10 minutes. Once two accelerations were noted, the NST was discontinued. The AFI was measured via the four quadrant technique. The NST, using vibroacoustic stimulation if needed, served as an indicator of short-term fetal oxygenation status, whereas the AFI served as an indicator of long-term fetal renal perfusion and uteroplacental function.[45] Today the modified BPP is often performed using a traditional NST along with an amniotic fluid assessment via formal AFI or DVP. The modified BPP is considered normal if the DVP is over 2 cm or AFI is at least 5 cm and the NST is reactive. If either of these parameters is not met, further investigation including a full BPP is indicated.

In a review of 26,257 tests among 12,620 high-risk patients, the predictive value of the four ultrasound components of the BPP (when normal) was found to be equivalent to that of the full BPP (including the NST).[46] This observation was demonstrated in a subsequent prospective study evaluating the use of NST only when values for one or more of the ultrasound components was abnormal and was found to reduce the need for NSTs in 95% of cases.[47] An NST should always be performed if any of the ultrasound components is abnormal. However, a BPP score of 8/10 is as accurate as a score of 10/10 for the prediction of fetal well-being, as long as points are not deducted for fluid.[48]

There is a paucity of studies comparing the full BPP to the modified BPP. In the single trial comparing the two, no difference was noted in neonatal outcomes between the groups.[49] Comparing the modified BPP as the primary testing method and the complete BPP as the backup test, antepartum fetal death was 6.75 times less common in high-risk women who were tested than in their nontested counterparts. However, the modified BPP is associated with a high rate of false positive results (60%), which led to iatrogenic prematurity in 1.5% of women tested before term.[49] Despite the limited data, the modified

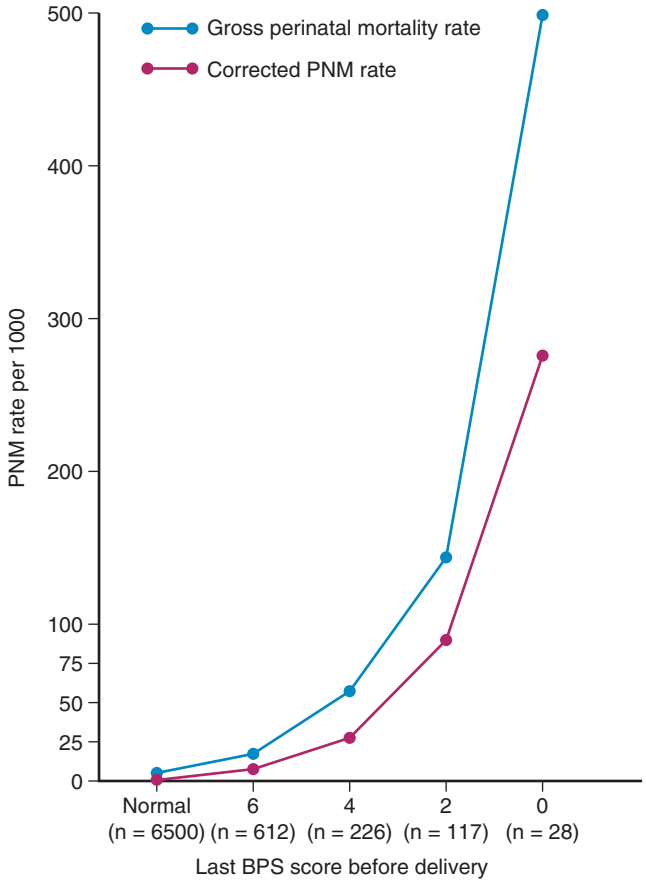

FIG 21-15 Relationship between perinatal mortality (PNM) rate, either total or corrected for major anomaly, and the last biophysical profile scoring (BPS) result. The relationship is exponential and yields a highly significant correlation with $\log_{10}$ conversion. (From Manning FA, Harman CR, Morrison I, et al: Fetal assessment based on fetal biophysical profile scoring. IV. An analysis of perinatal morbidity and mortality. Am J Obstet Gynecol 162(3):703-709, 1990.)

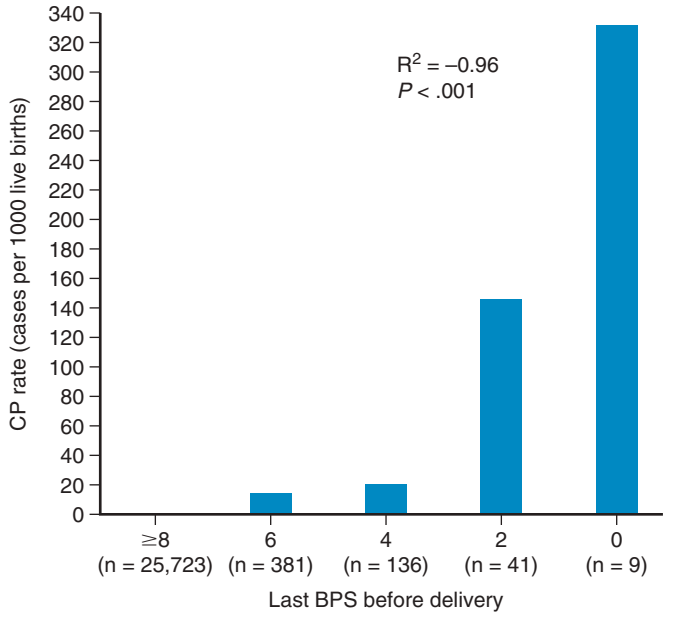

FIG 21-16 The relationship between the fetal biophysical profile score (BPS) and cerebral palsy (CP) rate is inverse, exponential, and highly significant (R^2 = –0.965; P < 0.001). Infants were followed for 5 years after birth. (From Manning FA, Bondaji N, Harman CR, et al: Fetal assessment based on fetal biophysical profile scoring. VIII. The incidence of cerebral palsy in tested and untested perinates. Am J Obstet Gynecol 178(4):696-706, 1998.)

BPP is widely utilized for fetal surveillance as it requires less expertise and is less time consuming than a full BPP yet provides additional information over an NST alone.

UMBILICAL ARTERY DOPPLER VELOCIMETRY

Doppler velocimetry can be used to observe flow velocity waveforms in the fetal umbilical arteries. In the normal fetus, high-velocity systolic and diastolic flow is noted within the umbilical artery such that the ratio between systolic and diastolic flow is low (Fig. 21-17). Increased resistance in placental vasculature may create impedance to flow resulting in diminished diastolic flow such that the ratio of systolic to diastolic flow is high.[50-52] In the setting of growth restriction, studies have shown that a systolic/diastolic ratio two standard deviations above the mean for a given gestational age is abnormal, warrants close surveillance, and consideration of antenatal steroids or delivery depending on gestational age.[53]

As flow resistance increases, absent or reversed diastolic flow can be observed (see Fig. 21-17). Both of these findings are ominous and increase the risk for perinatal fatality. Demonstration of absent or reversed end-diastolic flow in the umbilical artery, therefore, requires further investigation and consideration of delivery depending on the gestational age and clinical context.[54,55] The addition of Doppler interrogation of the umbilical artery to standard antepartum testing in the setting of fetal growth restriction is associated with a reduction in the rate of perinatal death by as much as 29%.[56,57]

Doppler technology is further discussed in Chapter 22, The Role of Doppler Ultrasound in Obstetrics.

CONCLUSIONS

Despite limited scientific evidence supporting the use of antenatal testing to decrease the perinatal mortality rate, antenatal surveillance is considered standard of care in the management of pregnancies affected by maternal or fetal disease. As such, future research investigating the effectiveness of antenatal testing techniques is unlikely to take the form of randomized controlled trials, and recommendations will continue to be based largely on consensus and expert opinion.

However, antenatal testing does provide an opportunity to evaluate the health of both the mother and the fetus on a more frequent basis and allows the provider an opportunity to educate the mother on findings and expectations regarding the pregnancy, her health, and the well-being of her fetus. Because of the high rate of false positive findings with each of the testing methods described, providers should be prepared to interpret the findings in the context in which they are undertaken, which includes the test indication, fetal gestational age, and whether the condition at present is temporary or reversible.

As a general rule, because the goal of antepartum fetal surveillance is to prevent fetal death, testing should not be performed in pregnancies that are previable or complicated by lethal abnormalities unless other circumstances apply. Frequency and duration of surveillance will depend on the indication and chronicity of the maternal and fetal condition. Abnormal test results may be followed up with a subsequent test (i.e., a nonreactive test may be followed by a BPP) and may provide an opportunity to increase maternal/fetal surveillance, administer steroids, and help plan for delivery.

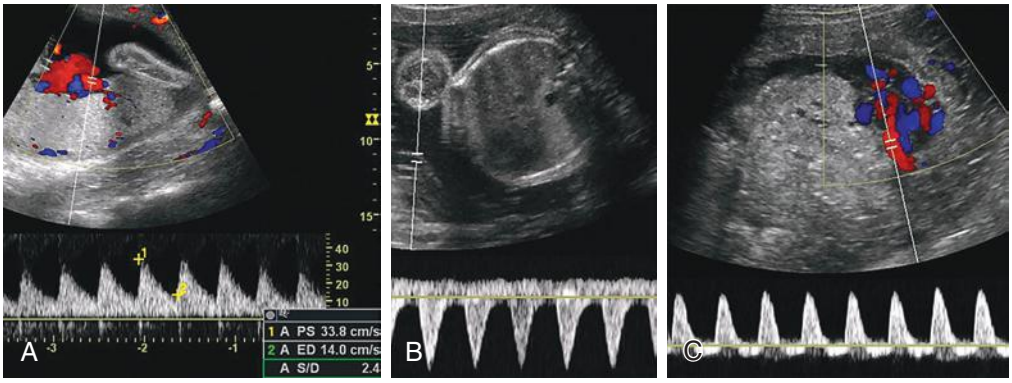

FIG 21-17 Umbilical artery Doppler velocimetry. **A,** Normal umbilical artery Doppler waveform with diastolic flow present. Systolic/diastolic (S/D) ratio 2.4. **B,** Absent diastolic flow. **C,** Reversed end-diastolic flow.

Role of Doppler Sonography in Obstetrics

Malgorzata Mlynarczyk, Letty Romary, Alfred Z. Abuhamad

SUMMARY OF KEY POINTS

- Absent or reverse flow during diastole in the umbilical artery represents an advanced stage of placental compromise and is associated with more than 70% of placental arterial obliteration.
- In the presence of fetal hypoxemia, central redistribution of blood flow occurs, resulting in an increased blood flow to the brain, heart, and adrenals and a reduction in flow to the peripheral and placental circulations, known as the *brain-sparing effect*.
- Middle cerebral artery (MCA) peak systolic velocities (PSVs) are increased in the presence of fetal anemia. The greater velocity results from decreased blood viscosity and increased cardiac output.
- Pulsed Doppler velocimetry of the uterine artery should be obtained immediately after the vessel crosses the hypogastric artery and before it divides into the uterine and cervical branches. Abnormal uterine artery circulation has been associated with fetal growth restriction (FGR), preeclampsia, preterm delivery, and nonreassuring fetal status in labor.
- Doppler flow studies of the inferior vena cava and ductus venosus in the fetus provide information with regard to right ventricular preload, myocardial compliance, and right ventricular end-diastolic pressure.
- Inferior vena cava Doppler waveforms are triphasic in shape, with the first phase corresponding to ventricular systole, the second phase to early diastole, and the third phase to late diastole or the atrial kick. Ductus venosus Doppler waveforms are biphasic in shape, with the first phase corresponding to ventricular systole, the second phase to early diastole, and the nadir of the second phase to late diastole or the atrial kick.
- Reversed flow in the ductus venosus during atrial systole may be due to worsening placental disease, impaired cardiac function secondary to metabolic compromise, congenital heart defects, redistribution of hepatoportal blood flow through the liver, or a combination of these factors.
- To obtain accurate Doppler indices in fetal echocardiography, the sample volume is placed distal to the respective valves, the insonating angle should be within 0 to 20 degrees of the direction of blood flow, Doppler waveforms should be obtained during fetal apnea, and multiple measurements should be made.
- Doppler waveforms across the atrioventricular valves are bicuspid in shape. The first peak (E wave) corresponds to early ventricular filling of diastole, the second peak (A wave) corresponds to atrial systole or the atrial kick, with the E/A ratio being an index of ventricular preload and compliance.
- Doppler waveforms across the semilunar valves are uniphasic in shape. PSV and the time to peak velocity (TPV) increase with advancing gestation. These Doppler indices reflect ventricular contractility, arterial pressure, and afterload.
- Umbilical artery Doppler surveillance should be initiated when a growth-restricted fetus is considered viable. Abnormal Doppler waveforms of the umbilical artery have been associated with adverse perinatal outcome.
- Obtaining umbilical artery Doppler screening routinely in low-risk pregnancies has not been shown to improve outcome.

OUTLINE

PHYSICAL PRINCIPLES

The Doppler effect, first reported by Christian Doppler in 1842,[1] describes the apparent variation in frequency of a light or a sound wave as the source of the wave approaches or moves away relative to an observer. The traditional example that is given to describe this physical phenomenon is the apparent change in sound level of a train as it approaches and then departs a station. The sound seems higher in pitch as the train approaches the station and seems lower in pitch as the train departs the station. The actual sound of the train is constant, it is the apparent change in sound pitch to a stationary observer that describes the Doppler effect. This apparent change in sound pitch (Doppler effect), or what is also termed the *frequency shift,* is proportional to the speed of movement of the sound-emitting source. In

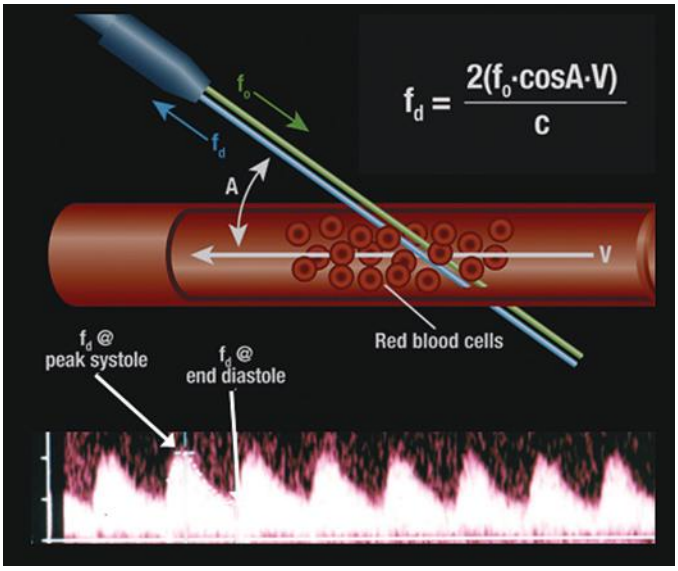

FIG 22-1 The Doppler effect (f_d) is dependent on the initial frequency of the ultrasound transducer (f_0), the velocity of flow (V) of the blood within a vessel, and the cosine of the angle (A) that the ultrasound beam makes with the direction of blood flow. The frequency shift (f_d) is displayed as a time-dependent plot within a cardiac cycle and is inversely proportional to the constant (c), which reflects a constant related to the medium in which the sound is traversing.

clinical applications, when an ultrasound beam with a certain frequency is used to insonate a blood vessel, the reflected frequency or frequency shift is directly proportional to the speed with which the red blood cells are moving (blood flow velocity) within that particular vessel. This frequency shift of the returning signal is displayed in a graphic form as a time-dependent plot. In this display, the vertical axis represents the frequency shift, and the horizontal axis represents the temporal change of this frequency shift as it relates to the events of the cardiac cycle (Fig. 22-1). This frequency shift is highest during systole, when the blood flow is at its fastest, and lowest during end diastole, when the blood flow is at its slowest in the peripheral circulation. Given that the velocity of flow in a particular vascular bed is inversely proportional to the downstream impedance to flow, the frequency shift therefore derives information on the downstream impedance to flow of the vascular bed under study. The frequency shift is also dependent on the cosine of the angle that the ultrasound beam makes with the direction of blood flow in the targeted blood vessel (see formula in Fig. 22-1). When the sound beam is parallel to the blood vessel of interest and thus the moving red blood cells, the entire Doppler shift is measured. However, when an angle exists between the direction of flow and the sound beam, the measured velocity is less than the true velocity.[2] The degree to which the velocity is accurately measured depends on the angle of incidence (cosine Q). At an angle of 0 degrees, the measured velocity is equal to the true velocity. When the sound beam is perpendicular to the direction of flow (90 degrees), the measured velocity is zero, because the cosine of 90 degrees is zero.[2] Thus, ideally, one wants to measure the velocity with as small an angle as possible.

Given that the insonating angle is difficult to measure in clinical practice, indices that rely on ratios of frequency shifts were developed to quantitate Doppler waveforms. By relying on ratios of frequency shifts, these Doppler indices are thus independent of the effects of the insonating angle of the ultrasound beam. Doppler indices that are commonly used in obstetric practice are shown in Figure 22-2.

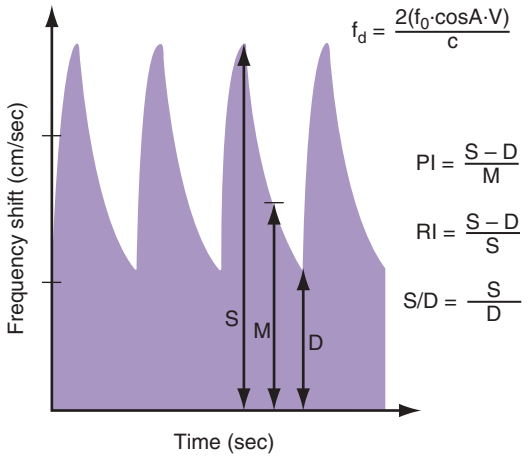

FIG 22-2 Doppler indices commonly used in obstetric imaging. c, constant related to the medium in which the sound is traversing; D, diastole; M, mean; PI, pulsatility index; RI, resistance index; S, systole.

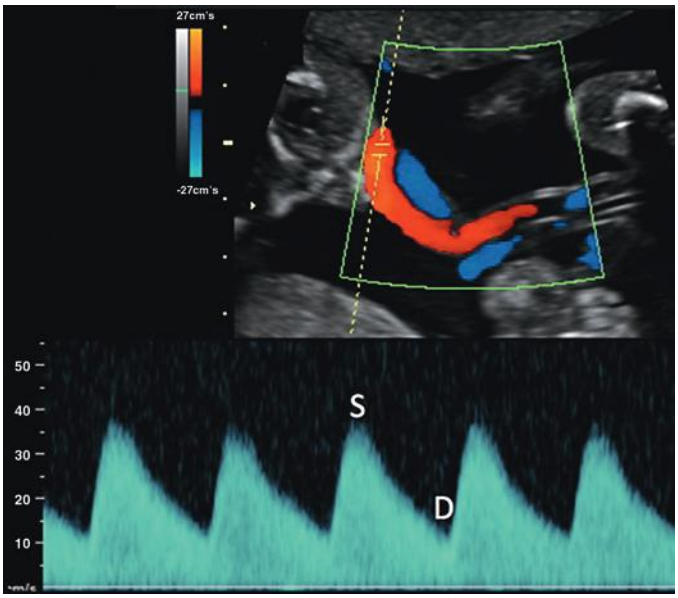

FIG 22-3 Doppler waveforms of the umbilical artery in a normal fetus in the third trimester of pregnancy. Note the increased end-diastolic velocity (D), consistent with a low impedance circulation. S, peak systole.

FETAL ARTERIAL DOPPLER

Umbilical Artery

The umbilical arterial circulation is normally a low-impedance circulation, with an increase in the amount of end-diastolic flow with advancing gestation.[3,4] Umbilical arterial Doppler waveforms reflect the status of the placental circulation, and the increase in end-diastolic flow that is seen with advancing gestation is a direct result of an increase in the number of tertiary stem villi that takes place with placental maturation (Fig. 22-3).[5,6] Diseases that obliterate small muscular arteries in placental tertiary stem villi result in a progressive decrease in end-diastolic flow in the umbilical arterial Doppler waveforms until absent, and then reverse flow during diastole is noted (Fig. 22-4).[7,8] Reversed diastolic flow in the umbilical arterial circulation represents an advanced stage of placental compromise and is associated with more than 70% of placental arterial obliteration.[9-12] The notation of absent or reversed end-diastolic flow in the umbilical artery is commonly associated with

severe FGR and oligohydramnios.[13,14] Only in pregnancies with suspected FGR does the use of umbilical artery Doppler sonography reduce the number of perinatal deaths and unnecessary obstetric interventions.[15,16]

Doppler waveforms of the umbilical arteries can be obtained from any segment along the umbilical cord. Waveforms obtained from the placental end of the cord show more end-diastolic flow and thus lower ratio values (resistive index [RI], systole/diastole [S/D] ratio) than waveforms obtained from the abdominal cord insertion.[17] There are differences in Doppler indices of arterial waveforms obtained from different anatomic locations of the same umbilical cord, but they are generally minor and have no significance in clinical practice (Tables 22-1 through 22-3).[3,4] In 2013, the International Society for Ultrasound in Obstetrics and Gynecology (ISUOG) recommended taking Doppler measurements from a free loop of cord for the sake of simplicity and consistency.[18]

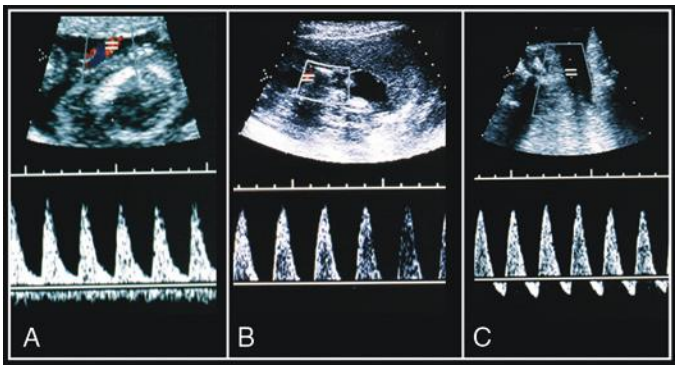

FIG 22-4 Abnormal umbilical artery Doppler waveforms; decreased end-diastolic velocity (**A**), absent end-diastolic velocity (**B**), reversed end-diastolic velocity (**C**).

Middle Cerebral Artery

The MCA is the most accessible cerebral vessel to ultrasound imaging in the fetus, and it carries more than 80% of cerebral blood flow.[19] The cerebral circulation is normally a high-impedance circulation with continuous forward flow throughout the cardiac cycle.[20] In the presence of fetal hypoxemia, central redistribution of blood flow occurs, resulting in increased blood flow to the brain (Fig. 22-5), heart, and adrenals and a reduction in flow to the peripheral and placental circulations. This blood flow redistribution is known as the *brain-sparing effect* and plays a major role in fetal adaptation to oxygen deprivation.[20-22]

The right and left middle cerebral arteries represent major branches of the circle of Willis in the fetal brain. The circle of Willis, which is supplied by the internal carotid and vertebral arteries, can be imaged with color flow Doppler sonography in a magnified axial plane of the fetal head obtained at the base of the skull, at the level of the thalami and wings of sphenoid bone (Fig. 22-6). In this plane, the proximal and distal middle cerebral arteries are seen in their long axis, with their course almost parallel to the ultrasound beam. As such, the insonating beam, which is parallel to the vessel and thus has an angle of insonation of 0 degrees, will result in a measured velocity that accurately reflects the true velocity of blood in this vessel (cos 0 = 1). MCA Doppler waveforms, obtained from the proximal third portion of the vessel, immediately after its origin from the circle of Willis, have shown the best reproducibility (Tables 22-4 and 22-5 and Fig. 22-7).[22]

MCA evaluation is often used to assess well-being in the fetus with suspected growth restriction (see later) as well as fetuses with hemolytic disease due to Rh isoimmunization or parvovirus B19 infection (see Chapters 6 and 17) (Fig. 22-8). In cases of isoimmunization, MCA PSVs are increased in relation to decreased fetal hemoglobin, decreased blood viscosity, and increased cardiac output (Table 22-6). Care should be taken to optimize Doppler settings to reliably evaluate flow in the vessel and to accurately measure PSV in the MCA (Fig. 22-9). In the case of FGR, hemoglobin is typically unaffected, and it is speculated that the increase in MCA blood flow with subsequent increased diastolic waveforms on Doppler is a result of elevated fetal blood pressures. PSV above 1.50 multiples of the median (MoM) in fetuses at risk have been reported to have sensitivity of 100% in cases of red blood cell isoimmunization and other causes of fetal anemia.[23,24]

Uterine Artery

Pregnancy is associated with physiologic changes at the level of the uterine vasculature, resulting in a progressive decrease in impedance with advancing gestation.[25] This maternal adaptation to pregnancy is

thought to result from the trophoblastic invasion of the maternal spiral arterioles in the first half of pregnancy.[26] The invaded maternal spiral arterioles are rendered maximally dilated and minimally responsive to the sympathetic and parasympathetic systems. This adaptation is intended to ensure a sustained increase in blood flow to the uterus during pregnancy.

The uterine circulation can be assessed by Doppler velocimetry of the uterine arteries. Each uterine vessel can be demonstrated by color Doppler as it crosses over the hypogastric artery and vein just before it enters the uterus at the uterine-cervical junction (Fig. 22-10). Pulsed Doppler velocimetry of the uterine artery should be obtained immediately after the vessel crosses the hypogastric artery and before it divides into the uterine and cervical branches. The presence of a notch in the waveform and an increase in the impedance index after 22 weeks of gestation characterizes an abnormal uterine circulation (Fig. 22-11 and Tables 22-7 and 22-8).[27] A substantial risk of complication is noted in pregnancies that show an abnormal uterine circulation in the late second and third trimesters.[28,29] Pregnancy complications include FGR, preeclampsia, preterm delivery, and nonreassuring fetal status in labor.[28,29]

Women with abnormal serum analyte screening results, such as elevated alpha-fetoprotein, inhibin, human chorionic gonadotropin,

or decreased free estriol are potential candidates for uterine artery Doppler assessment. The combination of an abnormal analyte in the presence of abnormal uterine artery Doppler has been associated with markedly increased risk of preeclampsia, FGR, placental abruption, and fetal demise.[23,30,31]

Although in general, uterine artery Doppler studies are better at predicting early preeclampsia than term preeclampsia,[32] the use of this parameter alone has low predictive value for the development of preeclampsia. At this time, there is insufficient evidence to support the utility of uterine artery Doppler studies as a screening tool for preeclampsia, as randomized clinical trials have failed to find any improvement in maternal or fetal outcomes.[33]

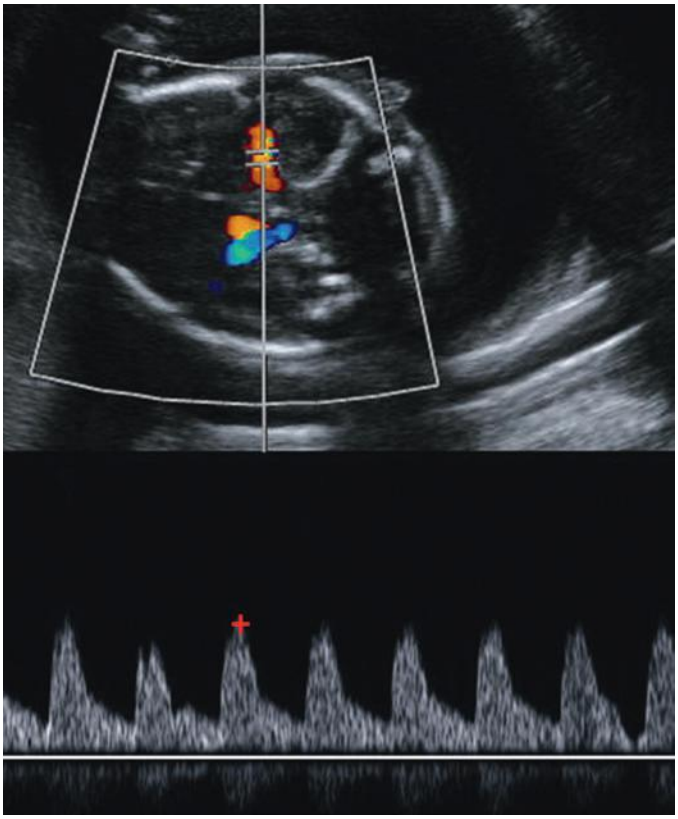

FIG 22-8 Doppler imaging and measurement of peak systolic velocity in the fetal middle cerebral artery.

FETAL VENOUS DOPPLER

Doppler waveforms obtained from the central venous circulation in the fetus reflect the physiologic status of the right ventricle. Specific information with regard to right ventricular preload, myocardial compliance, and right ventricular end-diastolic pressure can be derived from Doppler flow studies of the inferior vena cava and ductus venosus in the fetus.[34-39]

After 15 weeks of gestation, the umbilical vein normally has continuous monophasic blood flow but becomes pulsatile with fetal breathing or in pathologic cases, such as in severe FGR or fetal hydrops. In general, umbilical venous flow is assessed qualitatively as either continuous (monophasic) or pulsatile[40] (Fig. 22-12).

Inferior vena cava Doppler waveforms can be obtained from a coronal plane of the chest and abdomen. In this view, the inferior vena cava can be imaged as it enters into the right atrium, joined by the ductus venosus and the left hepatic vein (Fig. 22-13). The inferior vena cava can be studied at two locations: at the inlet into the right atrium or in the segment between the entrance of the hepatic vein and the ductus venosus. A good correlation coefficient exists between these two measurement sites, and the location that provides the smallest angle of insonation with the vector of blood flow should be chosen.[38] Inferior vena cava Doppler waveforms are triphasic in shape, with the first phase corresponding to ventricular systole, the second phase to early diastole, and the third phase to late diastole or the atrial kick (Fig. 22-14).

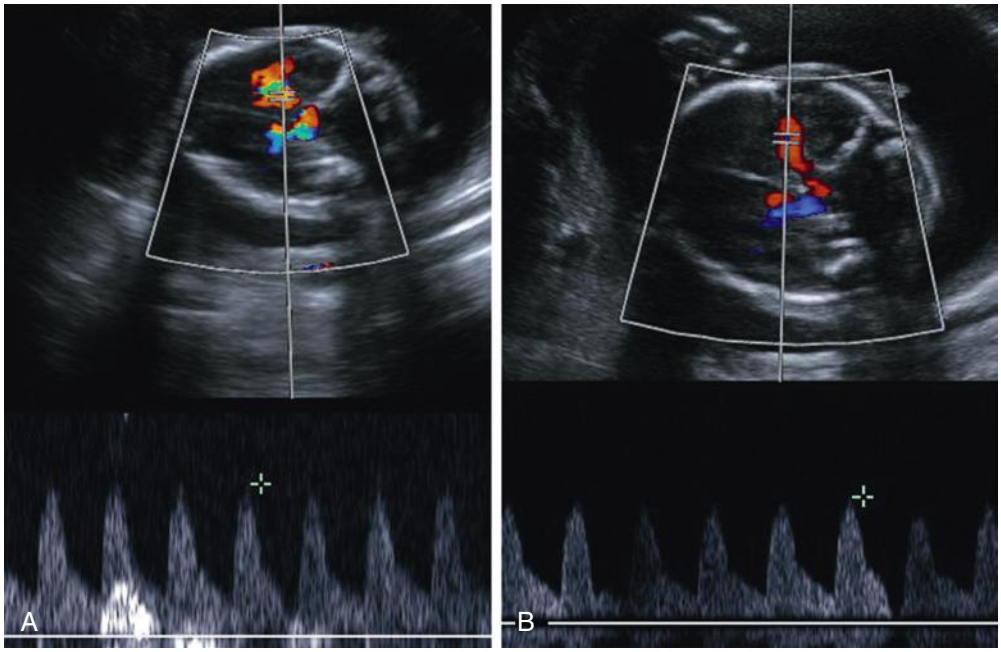

FIG 22-9 Color and spectral Doppler imaging of fetal middle cerebral artery (MCA) with measurement of peak systolic velocity (PSV). **A,** PSV measured 39 cm/second. Because of suboptimal technique with high gain and low scale settings and incorrect placement of sample gate, the peak velocity was erroneously undermeasured. **B,** With improved technique, including adjustments in gain, scale, angle of insonation, and sample gate placement, true peak velocity in the MCA was obtained and found to be 46.5 cm/second.

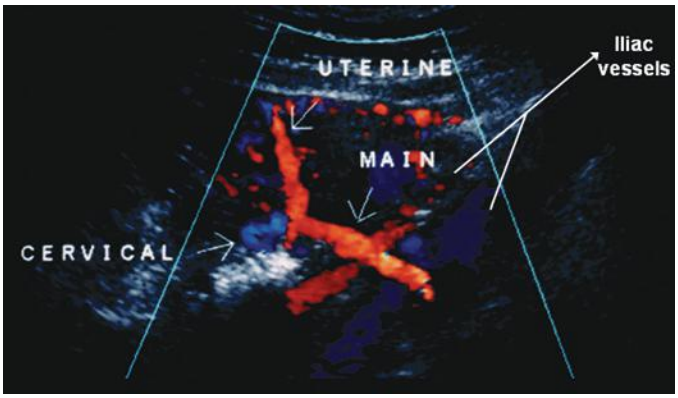

FIG 22-10 Color Doppler imaging in the lateral lower uterine segment showing the main uterine artery as it crosses over the hypogastric iliac vessels before it enters the uterus and then divides into a uterine branch and a cervical branch.

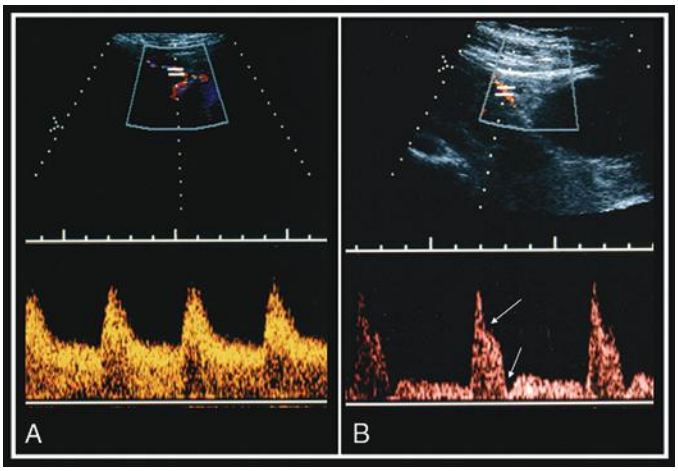

FIG 22-11 Doppler waveforms of the uterine artery obtained in the late second trimester of pregnancy showing normal uterine circulation (**A**) with increased end-diastolic velocity implying low-impedance circulation and abnormal uterine artery circulation (**B**) with a waveform notch (*top arrow*) and low end-diastolic velocity (high impedance) (*lower arrow*).

Ductus venosus Doppler waveforms can be obtained from a transverse view through the fetal abdomen at the same anatomic plane as the abdominal circumference (Fig. 22-15). By superimposing color flow Doppler image on the gray-scale image, the ductus venosus can be identified as it branches from the portal vein. High-velocity turbulent flow with color aliasing is commonly seen within the ductus venosus given its narrow lumen. The presence of aliasing on color flow Doppler image helps in identifying the ductus venosus in early gestation. Adjusting gain and scale settings allows the ductus venosus to be optimally visualized (Fig. 22-16). Ductus venosus Doppler waveforms are biphasic in shape, with the first phase corresponding to ventricular systole, the second phase to early diastole, and the nadir of the second phase to late diastole or the atrial kick (Fig. 22-17 and Tables 22-9 through 22-12).

Blood flow through the umbilical vein carrying oxygenated blood to the fetus can be assessed either within the fetal abdomen or within the amniotic fluid (Table 22-13).

Reversed flow in the ductus venosus results from a decline and subsequent reversal in forward flow velocity during atrial systole. It may be due to worsening placental disease, impaired cardiac function secondary to metabolic compromise, congenital heart defects, redistribution of hepatoportal blood flow through the liver, or a combination of these factors[25] (Fig. 22-18).

FETAL CARDIAC DOPPLER

Optimizing the Image

Adequate imaging of the fetal heart is essential for accurate Doppler measurements. Several steps can improve ultrasound imaging when faced with suboptimal scanning conditions. Resort to the echocardiography settings on the ultrasound equipment as the first step in optimizing the image. The echocardiography settings allow for enhanced image contrast, tissue characterization, and a faster frame rate, which improve cardiac imaging. Other steps include minimizing the depth on the display monitor, insonating the heart through an angle that avoids shadowing by the fetal ribs and sternum, adjusting the focal zones to the area of interest, and most importantly enlarging the area of interest (zoom), which allows visualization of details within the heart. These simple steps result in adequate visualization of the fetal heart in most conditions. When adding color Doppler to the gray-scale image, select high-velocity scales given that the velocity of cardiac blood flow is higher than that of the peripheral fetal circulation. By adjusting the filters to a high setting and by directing the angle of insonation of the ultrasound beam parallel to the direction of blood flow, the color Doppler image is optimized, and wall motion artifact is significantly reduced.

Doppler indices in fetal echocardiography are quantitative parameters and, for the majority, are angle dependent. To obtain accurate Doppler indices in fetal echocardiography, the sample volume is placed distal to the respective valves, the insonating angle should be within 0 to 20 degrees of the direction of blood flow, Doppler waveforms should be obtained during fetal apnea, and multiple measurements should be obtained. Color Doppler is used to direct placement of the sample volume; placing the sample volume at the brightest colors of the blood flow segment will ensure the best measurements. Figure 22-19 shows Doppler indices commonly used in fetal echocardiography.

The fetal circulation is different from the adult circulation in many aspects. The fetal circulation is in parallel rather than in series, and the right ventricular cardiac output is greater than the left ventricular cardiac output.[41,42] The progressive development of organs during gestation influence blood distribution and vascular impedance.[41] With advancing gestation, ventricular compliance is increased, total peripheral resistance is decreased, preload is increased, and combined cardiac output is increased.[41] Compliance of the left side of the fetal heart increases more rapidly than compliance of the right side of the fetal heart with advancing gestation.[41] The pulmonary vascular resistance is high in the fetus, and the pulmonary arterial pressure is almost systemic.[43,44] Flow to the pulmonary vascular bed is maintained at a low rate, with a noted increase toward the end of gestation.[42,43] Cardiac output in the fetus is mainly affected by preload and ventricular compliance.[41] Right-to-left shunts at the level of the foramen ovale and ductus arteriosus have a significant impact on cardiac flow patterns and affect the distribution of blood and oxygen to various organs. Flow across the foramen ovale contributes to the majority of blood entering the left ventricle, and more than two thirds of right ventricular output is directed to the ductus arteriosus.[42,45] This shunting mechanism

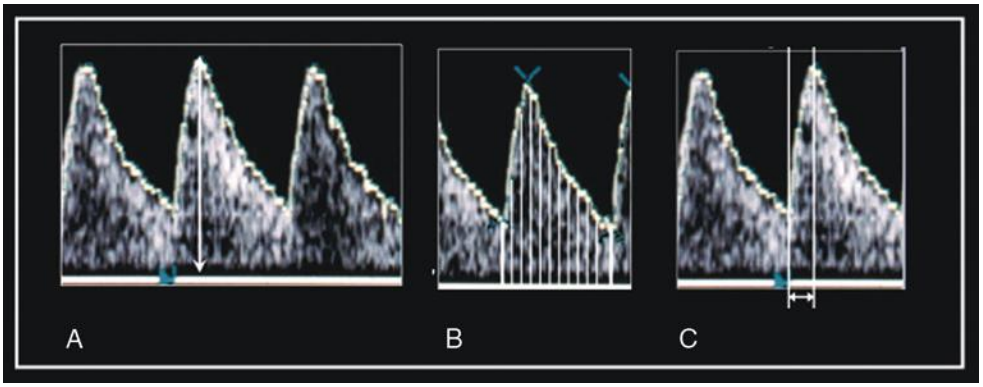

FIG 22-19 Doppler indices that are commonly used in fetal echocardiography: peak-systolic velocity (**A**), time-velocity integral (**B**), and time-to-peak velocity (**C**).

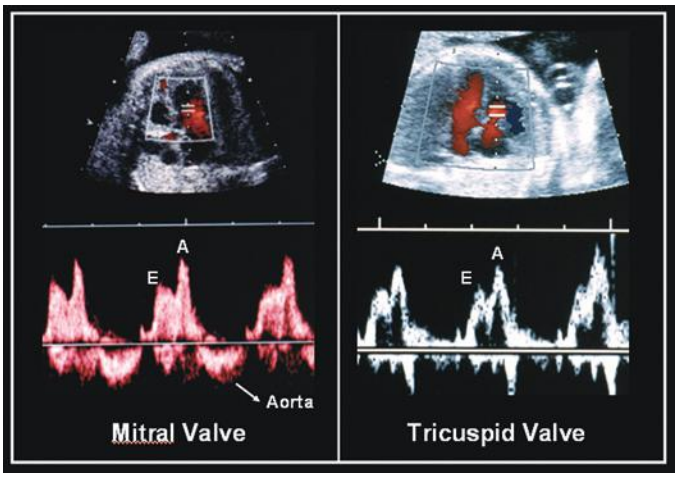

FIG 22-20 Doppler waveforms obtained across the mitral and tricuspid valves. Owing to the proximity of the mitral and aortic valves, a portion of the aortic outflow is noted during systole (*arrow*, aorta). A, A wave; E, E wave.

ensures the delivery of blood with high oxygen content to the coronary and cerebral circulations.

Doppler waveforms across the atrioventricular valves are bicuspid in shape (Fig. 22-20). The first peak (E wave) corresponds to early ventricular filling of diastole, and the second peak (A wave) corresponds to atrial systole or the atrial kick. Unlike in postnatal life, the velocity of the A wave is higher than that of the E wave in the fetus.[41,46] This highlights the importance of the role that atrial systole plays in cardiac filling in the fetus. The E/A ratio increases with advancing gestation and reflects ventricular diastolic function.[41,46] E and A velocity peaks are higher in the right ventricle, and this right ventricular dominance is noted from the first trimester.[41,46,47] Shifting to left ventricular dominance starts in utero toward the end of gestation.[41] The E/A ratio is an index of ventricular preload and compliance (Table 22-14).[41]

Doppler waveforms across the semilunar valves are uniphasic in shape (Fig. 22-21). Indices most commonly used for the semilunar Doppler waveforms include the PSV and the TPV. PSV and TPV increase with advancing gestation across the semilunar valves.[41,45,48-51] PSV is higher across the aorta than across the pulmonary artery owing to a decreased afterload and a smaller diameter across the aorta.[41,45,48-51] These Doppler indices reflect ventricular contractility, arterial pressure, and afterload (Table 22-15).

FETAL DOPPLER AND FETAL GROWTH RESTRICTION

Arterial Doppler abnormalities, at the level of the umbilical and middle cerebral arteries (brain-sparing reflex), confirm the presence of hypoxemia in the growth-restricted fetus and present early warning signs (see Table 22-5).[52-55] Once arterial centralization occurs, however, no clear trend is noted in the observational period, and thus, arterial redistribution may not be helpful for the timing of the delivery.[52] On the other hand, the presence of reversed end-diastolic flow in the umbilical arteries is a sign of advanced fetal compromise, and strong consideration should be given for delivery except for extreme prematurity. Cesarean

delivery should be given preference in this setting because labor may cause further fetal compromise.

For best results, umbilical artery Doppler surveillance should be initiated when a growth-restricted fetus is considered viable.[56] Absent or reversed end-diastolic flow in the umbilical artery is the only vessel abnormality that has been definitely associated with adverse perinatal outcome.[56,57] Doppler studies of the ductus venosus, MCA, and other vessels have some prognostic value for FGR, but they have not been sufficiently evaluated in randomized trials to recommend routine use in clinical practice.[57]

The current literature suggests that venous Doppler abnormalities in the inferior vena cava and ductus venosus and abnormal fetal heart rate monitoring, even in its computerized version, follow arterial Doppler abnormalities and are thus associated with a more advanced stage of fetal compromise.[52-56,58]

Furthermore, in the majority of severely growth-restricted fetuses, sequential deterioration of arterial and venous Doppler precedes biophysical profile score deterioration.[53] At least one third of fetuses show early signs of circulatory deregulation 1 week before biophysical profile deterioration, and in most cases, Doppler deterioration precedes biophysical profile deterioration by 1 day.[53]

The occurrence of such abnormal late stage changes of vascular adaptation by the growth-restricted fetus appears to be the best predictor of perinatal death, independent of gestational age and weight.[55] In a longitudinal study of the use of Doppler in growth-restricted fetuses, all intrauterine deaths and all neonatal deaths, with the exception of one case, had late Doppler changes at the time of delivery, whereas only a few of the surviving fetuses showed such changes.[55] These findings have been confirmed by a large prospective multicenter study that demonstrated that, prior to 27 weeks of gestation, gestational age is the most important factor determining neonatal outcome in growth-restricted infants delivered before 33 weeks of gestation. However, after 27 weeks, abnormality of ductus venosus becomes a very important cardiovascular predictor of neonatal complications.[59] Despite these findings, there is insufficient evidence to recommend using ductus venosus Doppler as a routine screening tool in growth-restricted fetuses.

This sequential deterioration of the hypoxemic, growth-restricted fetus is rarely seen at gestations beyond 34 weeks.[60,61] Indeed, normal umbilical artery Doppler findings are common in growth-restricted fetuses in late gestations, and cerebroplacental ratios also have poor correlation with outcome of growth-restricted fetuses at greater than 34 weeks of gestation.[62] Therefore, caution should be exercised when Doppler is used in the clinical management of fetuses with FGR beyond 34 weeks of gestation.

The largest to date prospective observational trial (PORTO study) recently demonstrated the presence of not one but multiple potential patterns of Doppler deterioration in FGR pregnancies.[57] None of the patterns were particularly predominant in either the entire cohort of growth-restricted fetuses or in those that required delivery prior to 34 weeks.[63] These findings have not been confirmed by an interventional trial.

The pathophysiology of FGR has not been fully described because recent studies have highlighted the presence of significant variation in fetal adaptation to hypoxemia. The pattern of incremental deterioration of arterial Doppler abnormalities, followed by venous Doppler abnormalities, and then followed by abnormal fetal heart tracings and biophysical profile abnormalities is not seen in approximately 20% of preterm fetuses.[52] Furthermore, only 70% of fetuses with FGR show

significant deterioration of all vascular beds by the time they are delivered, and about 10% show no significant circulatory change by delivery time.[53] In a prospective, observational study, more than 50% of fetuses with FGR delivered because abnormal fetal heart rate tracings did not have venous Doppler abnormalities.[55] In view of these findings, the universal introduction of venous Doppler into the clinical management of the growth-restricted fetus should await the results of randomized trials on this subject. Subanalysis of the TRUFFLE study (Trial of Randomized Umbilical and Fetal Flow in Europe) (a prospective, multicenter randomized trial) suggests that when an abnormality of the ductus venosus is used as one of the main criteria for delivery of a growth-restricted fetus, the neonatal morbidity and time interval from diagnosis to delivery are related to the presence and severity of maternal hypertensive conditions.[64]

FGR is associated with several changes at the level of the fetal heart involving preload, afterload, ventricular compliance, and myocardial contractility. An increase in afterload is seen at the level of the right ventricle owing to increased placental impedance.[65] A decrease in afterload is noted at the level of the left ventricle owing to decreased cerebral impedance associated with the brain-sparing reflex.[65] These changes in afterload result in a redistribution of the cardiac output from right to left ventricle.[65] Preload is reduced at both atrioventricular valves owing to hypovolemia and decreased filling associated with FGR.[49,60,66,67] This decrease in preload is reflected by a decrease in the E/A ratio, decreased atrial peak, and decreased time velocity integral at the mitral and tricuspid valves.[49,66,67]

Evidence of reduced myocardial contractility in the presence of severe FGR has also been reported. Ventricular ejection force, an index of ventricular systolic function that is independent of preload and afterload, is decreased at the level of the right and left ventricles in FGR.[68] Growth-restricted fetuses with reduced ventricular ejection force have a shorter time to delivery, a higher incidence of nonreassuring fetal heart rate tracing, and a lower pH at birth when compared with control subjects.[68] A significant correlation between the severity of fetal acidosis at cordocentesis and ventricular ejection force values validates the association of this index and the severity of fetal compromise.[68] Myocardial cell damage, demonstrated by elevated levels of cardiac troponin T, is seen in some fetuses with severe growth restriction.[65] This advanced stage of fetal compromise is associated with signs of increased systemic venous pressure, a change in the distribution of cardiac output, a rise in right ventricle afterload, and a high incidence of tricuspid regurgitation.[65] These findings suggest that Doppler abnormalities in the proximal venous system of the growth-restricted fetus result from fetal myocardial cell damage and increased systemic venous pressure.[65]

The fetal heart plays a central role in the adaptive mechanisms for hypoxemia and placental insufficiency. As discussed in this chapter, longitudinal data on the hemodynamic sequence of the natural history of FGR show that the umbilical artery and MCA are the first variables to become abnormal.[69] These arterial Doppler abnormalities are followed by abnormalities in the right cardiac diastolic indices, followed by the right cardiac systolic indices, and finally, by both left diastolic and systolic cardiac indices.[69] Preserving the left systolic function as the last variable to become abnormal ensures an adequate left ventricular output, which supplies the cerebral and coronary circulations.

Several of the Doppler changes seen in association with FGR in the peripheral circulation are directly related to the adaptation of the fetal heart. The current management of FGR involves the use of Doppler at the peripheral arterial circulation (middle cerebral and umbilical arteries), at central venous vessels (ductus venosus and inferior vena cava), and with cardiotocography. Adding cardiac Doppler may improve management of the fetus with FGR, but studies are lacking on the prospective clinical evaluation of the FGR with cardiac Doppler. However, it is becoming more obvious that those changes in the central venous circulation reflect an advanced stage of fetal compromise, commonly associated with myocardial dysfunction and damage.

Role of Magnetic Resonance Imaging in Obstetrics

Sherelle Laifer-Narin, Diane M. Twickler

SUMMARY OF KEY POINTS

- Magnetic resonance imaging (MRI) does not use ionizing radiation, and no known biologic risks are associated with this imaging modality.
- MRI is an important tool for the evaluation of maternal complications in pregnancy, including the evaluation of atypical advanced ectopic pregnancies, suspected appendicitis, pelvic masses, hepatic and genitourinary diseases, and placenta accreta.
- In the fetus, MRI is a useful adjunct to the sonographic diagnosis of suspected central nervous system (CNS) lesions, particularly isolated mild ventriculomegaly.
- MRI may provide additional information for certain fetal thoracic lesions, can aid in predicting prognosis in diaphragmatic hernias, and can provide additional information in the setting of complex fetal genitourinary abnormalities.
- MRI studies add important information for the potential fetal surgery candidate and may direct crucial decisions for delivery management, as with the ex utero intrapartum treatment (EXIT) procedure.
- MRI has been found to be useful in the diagnosis of abnormal placental implantation in cases with an equivocal diagnosis on ultrasound imaging.
- Advances in MRI technology continue to allow for better resolution of fetal structures, and it is likely that this technique will have increasing application in prenatal diagnosis and evaluation of fetal abnormalities.

OUTLINE

The role of MRI in managing the obstetric patient is increasingly expanding. Although sonography is the primary imaging modality for evaluation of the pregnant patient, MRI has been in use for the past 30 years and is now considered an established adjunct imaging modality for obstetric management. Maternal obesity, oligohydramnios, fetal positioning, and fetal ossification can hamper ultrasound evaluation. Advantages of MRI include lack of ionizing radiation, superior soft tissue contrast, wide field of view imaging, and image acquisition in multiple true orthogonal planes. Various sequences allow us to discern soft tissue, fluid, hemorrhage, fat, and meconium. Additional sequences allow us to identify regions of hypoxia/ischemia. Limitations of MRI include maternal anxiety and claustrophobia, maternal habitus, and fetal motion when evaluating for anomalies. In this chapter we address the utility of MRI as an adjunctive second-line imaging modality in evaluating the symptomatic pregnant patient, the fetus, and the abnormally adherent placenta.

SAFETY

No known biologic risks are associated with MRI. No delayed sequelae from MRI examination have been encountered, and it is expected that the potential risk for any such delayed sequelae is extremely small or nonexistent. MRI utilizes no ionizing radiation, although concerns include exposure to fluctuating electromagnetic fields, high sound intensity levels, and effects on fetal heart rate patterns during the procedure. Several animal and tissue studies have been conducted to determine the biologic effects of electromagnetic fields with conflicting reports. An early study looked at the long-term effects of repetitive exposure to a static 1.5-tesla (T) magnetic field on human lung fibroblasts.[1] Study and control group proliferations were similar, indicating no adverse effect from repetitive MR exposure.

Few human studies on risks of MRI and early development have been completed. A large epidemiologic retrospective study compared

spontaneous abortion rates, infertility rates, incidence of low birth weight, and premature delivery among nurses and technologists working with MRI before and after employment.[2] There were no increased incidences of adverse outcomes in the MR-exposed group. Two studies reported follow-up on children exposed to echo-planar MR in utero. The first by Baker and associates completed a 3-year follow-up on 20 children with no demonstrable increase in the occurrence of disease or disability.[3] These patients were imaged with a 0.5-T superconductive magnet from 21 weeks to term. In the second case-controlled prospective observational study of 20 infants exposed to echo-planar imaging, pediatric assessments completed on these infants at 9 months of age were normal.[4]

In reference to the sound intensity and exposure, one study assessed the sound level experienced by the fetal ear during an MR procedure by having a volunteer swallow a microphone connected to a thin lead and filling the stomach with a liter of fluid to represent an amniotic sac.[5] There was at least 30-dB attenuation in intensity from the body surface to within the fluid-filled stomach, which reduced the acoustic sound pressure down from the dangerous threshold of 120 dB to an acceptable level of less than 90 dB. This level is lower than the 135 dB experienced when vibroacoustic stimulation is used. No evidence of hearing loss was found in one study after 450 babies were exposed to this noise intensity from vibroacoustic stimulation.[6]

Studies have also looked at fetal heart rate patterns during MR procedures and reported no change in heart rate patterns or incidence of fetal movements.[7] Recommendations from the latest document from the American College of Radiology concerning safe practices for MRI have determined that MRI can be performed in pregnancy if the data are needed to affect the care of the fetus or mother during pregnancy.[8] Because of the potential for dissociation of the chelate molecule in the amniotic fluid, MRI contrast agents should not be routinely administered. The longer the chelate molecule remains in a protected space such as the amniotic sac, the greater the potential for dissociation of the potentially toxic gadolinium ion, which can lead to nephrogenic systemic fibrosis in at-risk adults.[8] Gadolinium is listed as a category C drug in pregnancy based on Food and Drug Administration classifications, implying that it should be administered only if potential benefits warrant use of the drug despite potential risks. It is recommended that women undergoing MRI during pregnancy provide informed written consent documenting that they understand the potential risks and benefits of the procedure.

TECHNIQUE

Fetal and maternal studies are generally performed on a 1.5-T magnet or less, and it is recommended that informed consent be obtained for all patients in the settings of either institutional review board (IRB)-approved protocols or as a clinically indicated procedure. In addition, all women complete a written MRI safety screening questionnaire including information regarding metallic implants, pacemakers, or other metal- or iron-containing devices that may impact the study.[8] Iron supplementation may rarely cause artifact in the colon but does not usually affect the fetal resolution. Portable devices and monitors must be evaluated using U.S. Food and Drug Administration labeling criteria to prevent ferrous objects from entering unsafe zones within the MRI areas.[8] Anxiolytics are not routinely administered because significant maternal anxiety is a very rare event (less than 1% in our population), but in those unique circumstances, short-acting benzodiazepines may be administered. The recommended weight limit is approximately 400 pounds (but dependent on body habitus) on most closed current MR units; therefore, the extremely obese woman may not be a candidate for MRI.

Women are placed feet first in the supine or left lateral decubitus position. A torso coil is used in most circumstances, with the occasional use of either the body or cardiac coil, depending on maternal size, fetal size, and area of interest. A triplanar balanced steady-state free precession (bSSFP) sequence through the entire maternal uterus is initially obtained for localization purposes and planning subsequent sequences, which have a large field of view (350-400 mm), using 6-mm slice thickness with 3-mm interslice gap.

T2-Weighted Imaging

T2-weighted image acquisitions are utilized to define fetal anatomy and dysmorphologic features that have certain tissue characteristics based on a specific spin echo sequence using relatively long repetition time (TR) and long echo time.

Half-Fourier single shot RARE (rapid acquisition with relaxation enhancement) has become the mainstay of maternal pelvic and fetal imaging because of its high tissue resolution and rapid acquisition times. This ultrafast single shot imaging has an average acquisition time of less than 1 second, depending on imaging parameters. Other names for this sequence include single shot fast spin echo (SSFSE) and half-Fourier acquisition single shot turbo spin echo (HASTE). Specifics of the sequence vary, but for the single shot acquisition one signal and one measurement is acquired, the TR range is 800 to 1100 ms, echo time is 60 to 90 ms, flip angle is 130 to 150 degrees with 0- to 2-mm gap, and field of view is 300 to 350 mm.[9]

Fetal images may be obtained contiguously or interleaved, both having distinct advantages. Fetal movement degrades MR images, and contiguous slices may allow for better visualization of some contiguous structures in some slices, even if movement occurs during other slices in the acquisition. The interleave method allows for improved signal-to-noise ratio by obtaining every other image with an interslice gap and repeating process to include that missed gap; this prevents excitation of adjacent and consecutive sections.[10,11]

T1-Weighted Imaging

The use of T1-weighted gradient echo sequences provides additional information, owing to very short T1 relaxation times and allowing for improved visualization of subacute blood, fat, and proteinaceous fluid as well as fetal liver and meconium. Hyperintense pituitary and thyroid glands can also be seen. Late in gestation the fetal bones have a hypointense appearance. The images are less sensitive in defining some solid organ anatomy because of less tissue contrast.

In the setting of obstetric imaging, T1-weighted sequences are utilized to assess for the presence and distribution of T1 hyperintense meconium, to determine the size and location of the fetal liver, and to evaluate fetal or maternal hemorrhage or fat-containing lesions. Some T1-weighted sequences require more than one single shot with short TR (range 7.7-112 ms), echo time (4.2-5 ms), and flip angle (130-150 degrees). T1-weighted sequences may be obtained by single shot T1-weighted sequences or three-dimensional (3D) imaging techniques, with or without fat suppression. Because of improved signal-to-noise ratio, breath-hold T1-weighted gradient recalled echo sequences are generally used. T1-weighted breath-hold images are acquired with 5.5-mm slice thickness and 10% (0.5-mm) gap with field of view range of 300 to 350 mm.[12,13]

Balanced Steady-State Free Precession

bSSFP acquisitions have manufacturer acronyms such as True-FISP and FIESTA (fast imaging with steady-state precession and fast imaging employing steady-state acquisition) and are complex in terms of how they derive their contrast, the result of which is high T2 weighting in fluid and high T1 weighting in tissue.[14] Vessels are displayed quite well,

especially when surrounded by dense tissue such as liver parenchyma or the vertebral disk spaces.[15] Tissue contrast tends to be quite good, with slice thickness for bSSFP in the range of 5 to 6 mm and field of view ranging from 260 to 300 mm.[14]

Diffusion-Weighted Imaging

Diffusion-weighted imaging (DWI) is based on echo-planar imaging that produces images of water diffusion; this diffusion of water may be restricted in certain disease states, such as hypoxic edema (ischemia) of the brain. Diffusion anisotropy has the potential to characterize premyelination structures and can identify the corpus callosum and other white matter tracts, which will be discussed in Emerging Concepts.[12,14,15]

Other Magnetic Resonance Acquisitions

Many other acquisitions can be applied, some of which will be discussed in Emerging Concepts and are briefly reviewed. Short tau inversion recovery (STIR) images may provide improved resolution of tissue characteristics when the water contents of structures are similar. Additional sequences such as fluid attenuated inversion recovery (FLAIR), hydrography, blood oxygen level–dependent (BOLD) imaging, and certain echo-planar imaging may be performed as needed.[16]

MATERNAL IMAGING

In an effort to image the pregnant patient with abdominal pain rapidly and efficiently, the MRI protocol includes multiplanar T2-weighted SSFSE images (with and without fat saturation) of the abdomen and pelvis, gradient echo sequences, and a single plane T1-weighted sequence.

A wide range of pathologic conditions can cause abdominal pain in the pregnant patient. Clinical diagnosis is often challenging because of nonspecific leukocytosis, compression and displacement of organs by the gravid uterus, and nonspecific nausea and vomiting.[17] It is important to differentiate obstetric from nonobstetric causes of the acute abdomen in an effort to minimize maternal and fetal morbidity and mortality risks.[18] Conditions that necessitate surgical intervention must be identified.

Ectopic pregnancy continues to be the leading obstetric cause of death in early pregnancy.[19] MRI has been shown to be useful in delineating unusual implantation sites, including pregnancies implanted in the interstitium, cervix, cesarean scar, and rudimentary horn of an anomalous uterus, and within the peritoneal cavity (Fig. 23-1). T1-weighted sequences can depict blood products, and the presence of hemoperitoneum and hematosalpinx are highly suggestive of ectopic pregnancy in a patient with a positive pregnancy test and no intrauterine gestational sac. The large field of view and multiplanar capability of MRI allow exact delineation of advanced first trimester and second trimester ectopic pregnancies, which might not be appreciated on ultrasound imaging. Late presentation of ectopic pregnancy can be catastrophic and fatal because of risk of rupture and hemorrhage. The late presentation of an advanced cesarean scar pregnancy that has grown cephalad might mimic a normal intrauterine pregnancy. Demonstration of myometrial tissue surrounding a gestational sac without continuity to the cervix can help discriminate between a pregnancy in a bicornuate uterus versus a rudimentary horn pregnancy.[20]

Acute appendicitis is the most common nonobstetric cause for surgical intervention during pregnancy. Early diagnosis is essential, as surgical delay is associated with increased risk of appendiceal perforation, leading to an increased rate of maternal morbidity and fetal loss[19] (Fig. 23-2). Other gastrointestinal causes of abdominal pain include inflammatory and infectious bowel disease, bowel obstruction, and diverticulitis (Fig. 23-3). Symptoms (abdominal pain, nausea, vomiting) are similar to those that occur with normal pregnancy. Comprehensive cross-sectional imaging is essential for evaluation, and MRI is preferable to computed tomography because of lack of ionizing radiation.

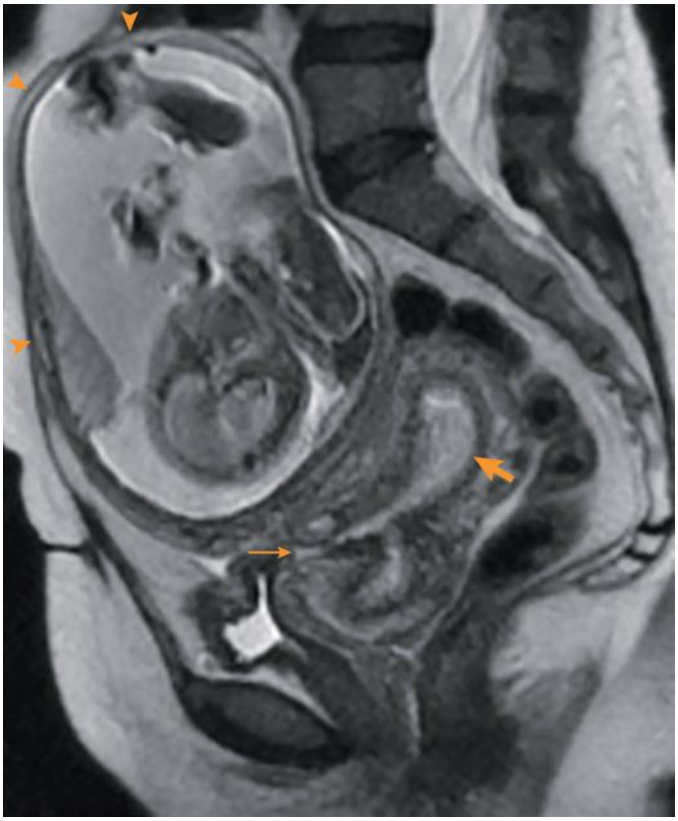

FIG 23-1 Rudimentary horn ectopic pregnancy at 19 weeks' gestation. Sagittal T2-weighted imaging demonstrates ectopic pregnancy implanted within a noncommunicating rudimentary horn of an anomalous uterus (*arrowheads*). The unicornuate endometrial cavity is empty (*bold arrow*) and there is a previous cesarean scar (*small arrow*).

Physiologic dilatation of the urinary tract occurs in up to 90% of pregnant patients. MR urography can differentiate obstructive hydronephrosis caused by renal calculi from physiologic hydronephrosis if renal enlargement, perinephric fluid, and abrupt caliber change of the ureter are demonstrated (Fig. 23-4).

Hepatobiliary causes of abdominal pain include HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count) and acute fatty liver of pregnancy, hepatitis, gallbladder disease, and pancreatitis. MRI and MR cholangiopancreatography can be useful in demonstrating choledocholithiasis and pseudocysts in the patient suspected of having pancreatitis.

Gynecologic causes of pain during pregnancy include ovarian cysts, masses, and torsion and uterine abnormalities, such as leiomyomas and congenital müllerian anomalies. Fluid, solid components, septations, nodularity, edema, hemorrhage, and fat content can be seen on MRI. If a primary pelvic mass is suspicious for malignancy, MRI can depict ascites, peritoneal implants, and lymphadenopathy.

The hypercoagulable state of pregnancy, venous compression by the gravid uterus, and hormone-induced venodilatation put the pregnant patient at increased risk for venous thromboembolic disease, most of

FIG 23-2 Ruptured appendicitis at 6 weeks' gestation. Sagittal T2-weighted imaging demonstrates complex fluid collection with fluid-debris level (*arrowheads*) consistent with abscess in the cul-de-sac. Surgery confirmed ruptured appendicitis with resultant abscess; intrauterine fetal demise occurred 3 days later.

FIG 23-3 Community-acquired *Clostridium difficile* colitis at 16 weeks' gestation with severe crampy lower abdominal pain. Coronal T2-weighted imaging with fat saturation demonstrates diffuse descending colonic wall thickening (*arrowheads*).

which occurs in the lower extremities. However, thrombosis can also develop in the hepatic, mesenteric, gonadal, and pelvic veins, and these sites can be demonstrated by MRI.

FETAL IMAGING

Fetal MRI has emerged as an accepted and essential adjunct imaging modality for prenatal diagnosis. Not only does fetal MRI provide additional information useful in patient counseling and management, it also helps determine mode of delivery, location of delivery (community versus tertiary center, labor and delivery room versus operating room), multidisciplinary involvement (pre-, peri-, and postnatal), and decisions regarding fetal intervention. These issues include in utero procedures as well as requirement for airway establishment during delivery.

The fetal MRI examination is conducted to evaluate the fetus within the gravid uterus. Detailed analysis is performed, including placental location, cervical length, amniotic fluid volume, placental cord insertion, and fetal anatomic evaluation. Imaging may be focused on a specific region of interest, but the entire fetus is typically evaluated. Imaging begins with a triplanar scout sequence (axial, coronal, and sagittal to the mother), followed by three-plane orthogonal imaging of normal and pathologic fetal anatomy. Multiplanar T2-weighted images, as noted earlier, are the mainstay of fetal imaging sequences with bSSFP, T1-weighted images, DWI, and other acquisitions applied, depending upon clinical circumstances.

Anomalies of the Central Nervous System

In 1997, Levine and colleagues reported the utility of MRI as an adjunctive modality for CNS anomalies suspected at ultrasound examination (Fig. 23-5). MRI not only corroborated ultrasound findings but also demonstrated additional findings that could alter patient counseling and management.[21] The goal of MRI is to perform an anatomic survey documenting normal intracranial structures and to identify and characterize abnormalities in order to provide a comprehensive, precise diagnosis. In a study evaluating the utility of MRI with respect to gestational age, it was found that if an MRI examination was performed prior to 24 weeks' gestational age, decisions influenced the continuation or termination of a pregnancy, particularly in the United States. Management decisions that occurred if an MRI examination was performed after 24 weeks of gestation were those relating to delivery location, mode of delivery, and postnatal care.[22] Major CNS indications for referral to fetal MRI include ventriculomegaly, midline defects, posterior fossa abnormalities, and neural tube defects. Additional indications include, but are not limited to, cortical abnormalities, encephaloclastic abnormalities, cystic masses, and tumors (Table 23-1).

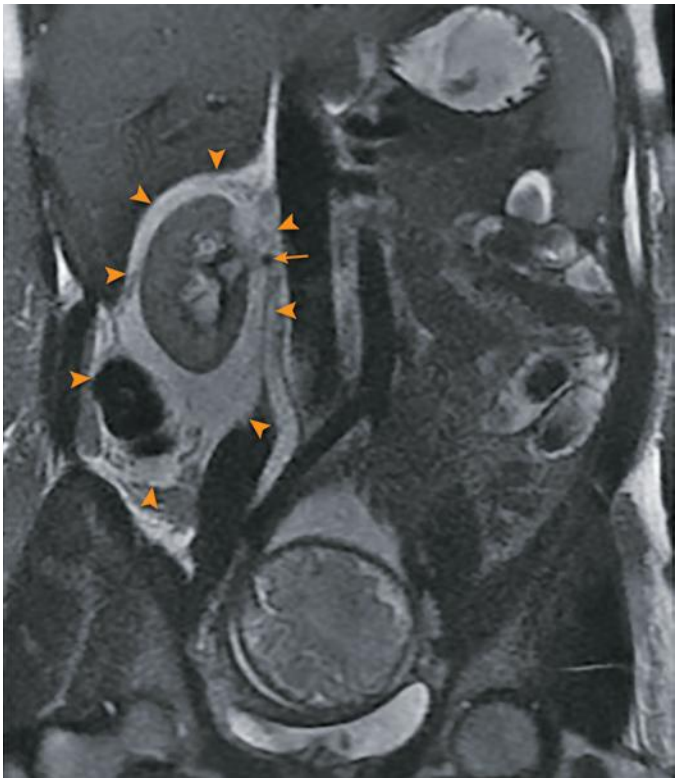

FIG 23-4 Forniceal rupture at 32 weeks' gestation. Coronal T2-weighted imaging with fat saturation demonstrates an obstructing right ureteropelvic junction (UPJ) calculus (*arrow*) with large amount of retroperitoneal perinephric fluid (*arrowheads*). In addition, the right ureter distal to the calculus is dilated, related to the gravid state.

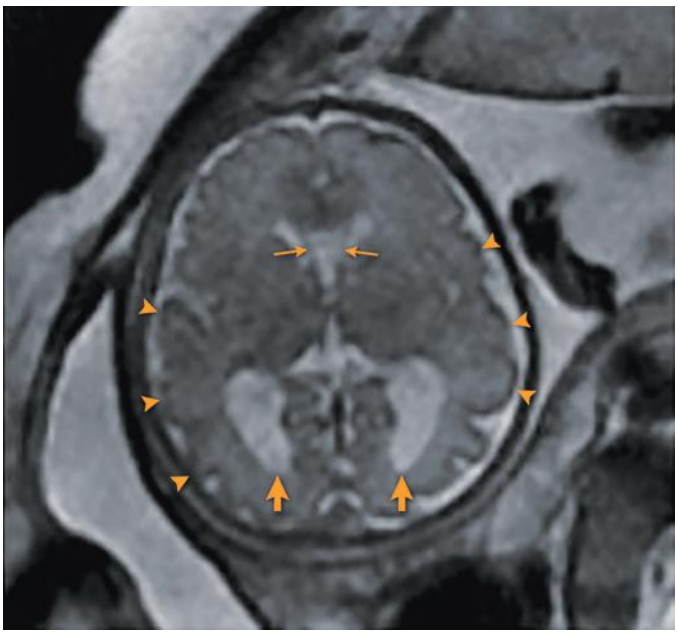

FIG 23-5 Normal fetal brain at 34 weeks' gestation. Axial balanced steady-state image demonstrates normal lateral ventricles (*bold arrows*), cavum septum pellucidum (*small arrows*), and cortical sulci (*arrowheads*).

TABLE 23-1 Summary of Fetal Magnetic Resonance Imaging Indications

Brain and Spine

Congenital anomalies of the brain suspected or not adequately assessed by sonography
- Ventriculomegaly
- Agenesis of the corpus callosum
- Holoprosencephaly
- Posterior fossa anomaly
- Cerebral cortical malformations

Vascular abnormalities of the brain suspected or not adequately assessed by sonography
- Vascular malformations
- Hydranencephaly
- Infarction
- Monochorionic twin pregnancy complications

Congenital anomalies of the spine suspected or not adequately assessed by sonography
- Neural tube defect
- Sacrococcygeal teratoma
- Caudal regression/sacral agenesis
- Sirenomelia
- Vertebral anomaly

Skull, Face, and Neck

Masses of the face and neck suspected or not adequately assessed by sonography
- Venolymphatic malformation
- Hemangioma
- Goiter
- Teratoma
- Micrognathia

Thorax

Masses in the thorax suspected or not adequately assessed by sonography
- Congenital pulmonary airway malformations (including congenital cystic adenomatoid malformation, pulmonary sequestration, and congenital lobar emphysema)
- Congenital diaphragmatic hernia
- Laryngeal obstruction

Volumetric assessment of fetal lung parenchyma, particularly in fetuses at risk for pulmonary hypoplasia secondary to oligohydramnios, chest mass, or skeletal dysplasia

Abdomen, Retroperitoneum, and Pelvis

Abdominal or pelvic mass suspected or not adequately assessed by sonography
- Abdominopelvic cyst
- Tumors such as hemangiomas, neuroblastomas, sacrococcygeal teratomas, and suprarenal or renal masses
- Complex genitourinary anomalies, including cloacal malformation
- Renal anomalies, particularly those associated with severe oligohydramnios
- Bowel anomalies such as megacystis microcolon

Complications of Monochorionic Twins

Fetal Surgery Assessment

Modified from American College of Radiology (ACR) and the Society for Pediatric Radiology (SPR): ACR-SPR Practice Parameter for the Safe and Optimal Performance of Fetal Magnetic Resonance Imaging (MRI). 2014. Available at http://www.acr.org/guidelines.

Ventriculomegaly is defined as dilatation of the lateral ventricle greater than 10 mm at the level of the atria and is one of the most common indications for fetal MRI. Ventriculomegaly may be isolated or may be associated with an underlying cause including obstruction from congenital aqueductal stenosis, dysmorphologic appearance such as agenesis of the corpus callosum, intracranial hemorrhage, or syndromal ventriculomegaly, as part of a complex malformation[23] (Fig. 23-6). MRI has been shown to be useful in fetuses with ventriculomegaly, allowing for assessment of degree of enlargement, search for underlying cause, and presence/absence of additional findings[22,24] (Fig. 23-7). Because the prognosis is related to the presence of additional abnormalities,[25] prenatal detection of associated anomalies is essential. Sonographically occult findings can include agenesis of the corpus callosum, cortical malformations, cerebellar abnormalities, and destructive changes.[26]

Corpus callosal agenesis is a disorder of prosencephalic midline development.[27] The corpus callosum can be visualized on midline sagittal MRI after 20 weeks' gestational age. Fetal MRI has been able to delineate a normal corpus callosum in 20% of cases referred for suspected callosal agenesis and has detected occult abnormalities including gyral abnormalities, posterior fossa abnormalities, brainstem anomalies, and periventricular nodular heterotopia in up to 63% of cases[28] (Figs. 23-8 and 23-9).

Holoprosencephaly is a complex anomaly of the prosencephalon manifested by lack of cleavage of midline structures. This malformation is classified into subtypes representing a continuum of midline nonseparation. In decreasing order of severity, they include alobar, semilobar, lobar, and middle interhemispheric variant types of holoprosencephalies[29] (Figs. 23-10 and 23-11).

Fetal MRI can help distinguish an abnormal from a normal posterior fossa and can aid in determining true defects from normal variants. Prognosis and neurodevelopmental outcome depend on the degree of vermian dysplasia and presence of additional supratentorial anomalies (Figs. 23-12 and 23-13). Diagnoses of Dandy-Walker malformation, vermian agenesis, and brainstem anomalies portend a poor prognosis; cerebellar hypoplasia is associated with an uncertain prognosis; and mega cisterna magna, Blake pouch cyst, and retrocerebellar arachnoid cyst are associated with a good neurologic prognosis[30,31] (Fig. 23-14).

Although neural tube defects such as myelomeningocele are easily visualized and diagnosed on ultrasound imaging, MRI can depict degree of cerebellar herniation and ventriculomegaly and the level and length of dysraphic defect and can detect associated anomalies including callosal agenesis, cerebellar dysplasia, spinal cord abnormalities (split cord malformation), and masses[32] (Fig. 23-15). In a study following the outcomes of 36 fetuses with spina bifida, it was found that worsening cerebellar herniation on MRI was significantly associated with childhood seizure activity, high risk of bladder dysfunction, and lack of independent ambulation, which are findings important for prenatal counseling.[33]

Disorders of cortical formation are an important cause of developmental delay and epilepsy. Malformations can occur at different stages of cortical maturation, resulting in abnormalities that reflect the time of insult. Recognition of normal cortical development as well as abnormal morphologic features is essential for accurate diagnosis. These abnormalities include microcephaly, hemimegalencephaly, lissencephaly, heterotopias, polymicrogyria, and schizencephaly[34,35] (Figs. 23-16 through 23-18). Glenn and associates reported a high degree of accuracy for diagnosis of polymicrogyria and schizencephaly by fetal MRI, with 100% specificity achieved for polymicrogyria, schizencephaly, and heterotopia if malformation was identified, in later gestations, in at least two planes.[36]

When encephaloclastic changes of the fetal brain are seen, one must suspect acquired injury for which the primary cause is ischemia

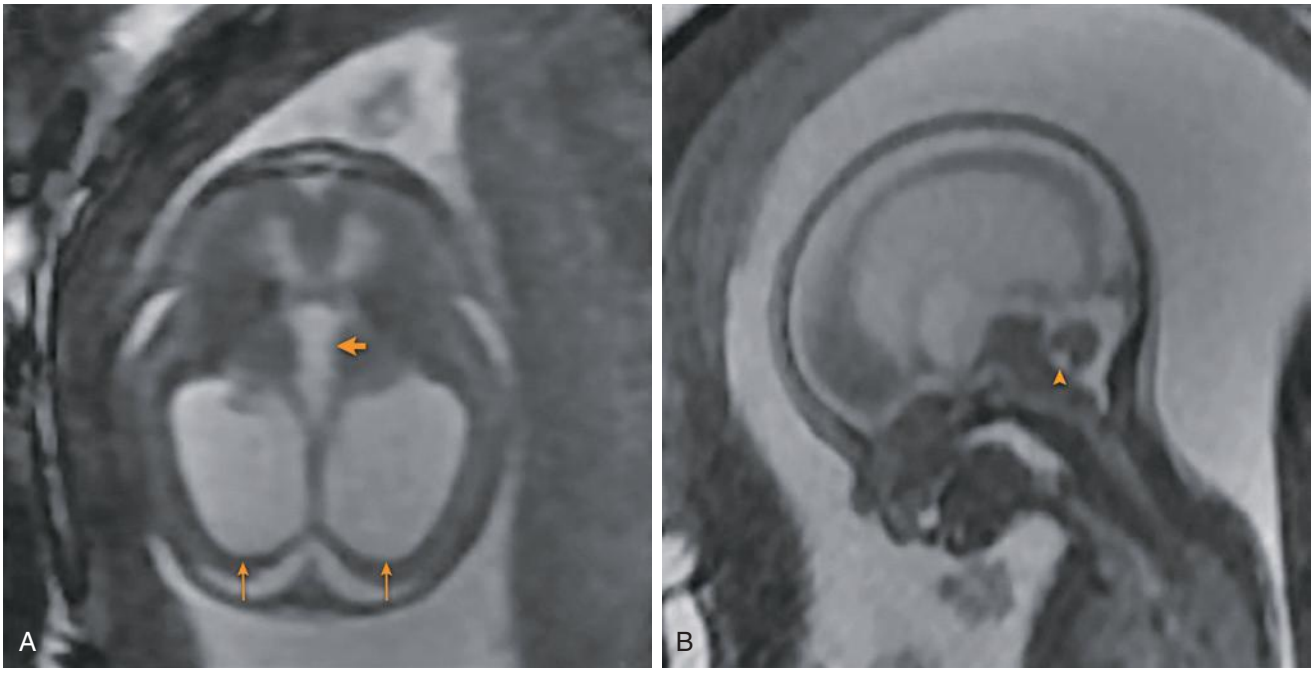

FIG 23-6 Ventriculomegaly secondary to aqueductal stenosis at 20 weeks' gestation. Axial (**A**) and sagittal (**B**) balanced steady-state images demonstrate dilated lateral ventricles measuring 17 to 19 mm in diameter (*small arrows*), dilated third ventricle (*bold arrow*), and normal size fourth ventricle (*arrowhead* in B), consistent with aqueductal stenosis.

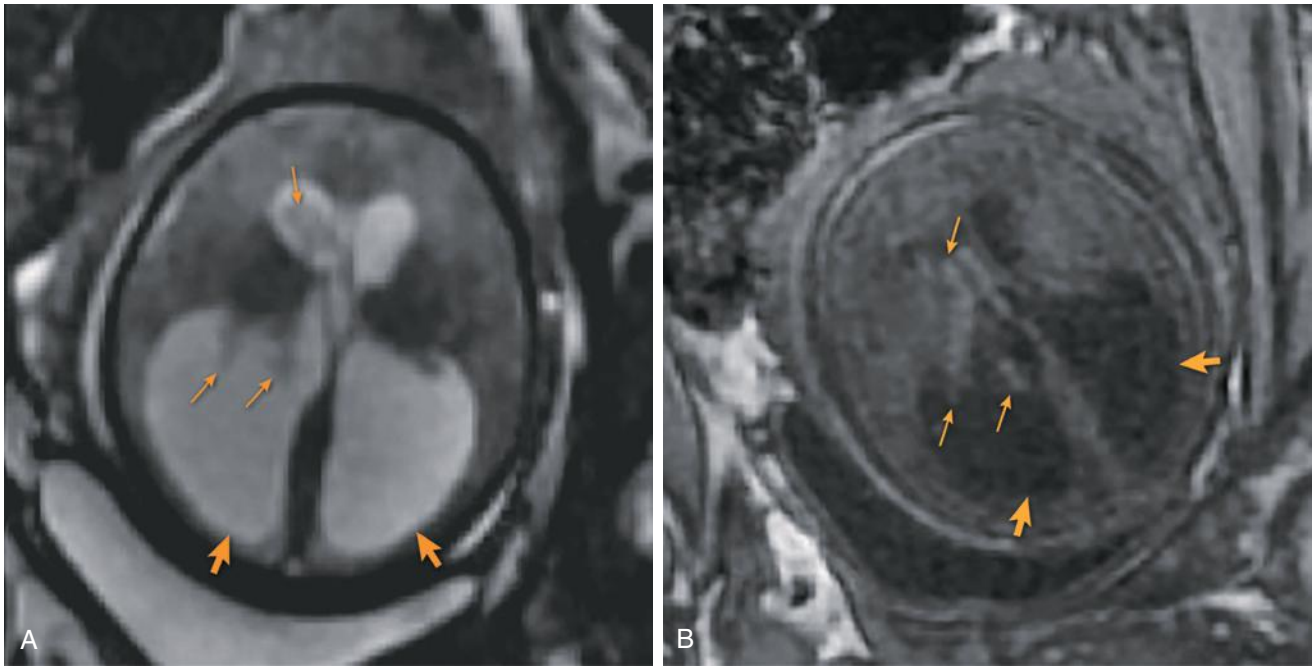

FIG 23-7 Intracranial hemorrhage causing new-onset hydrocephalus at 34 weeks' gestation. **A,** Axial balanced steady-state image with dilated lateral ventricles (*bold arrows*) and thrombus shown in right lateral ventricle (*small arrows*). **B,** Axial T1-weighted imaging bright signal in right germinal matrix and in dilated right lateral ventricle (*small arrows*) consistent with hemorrhage.

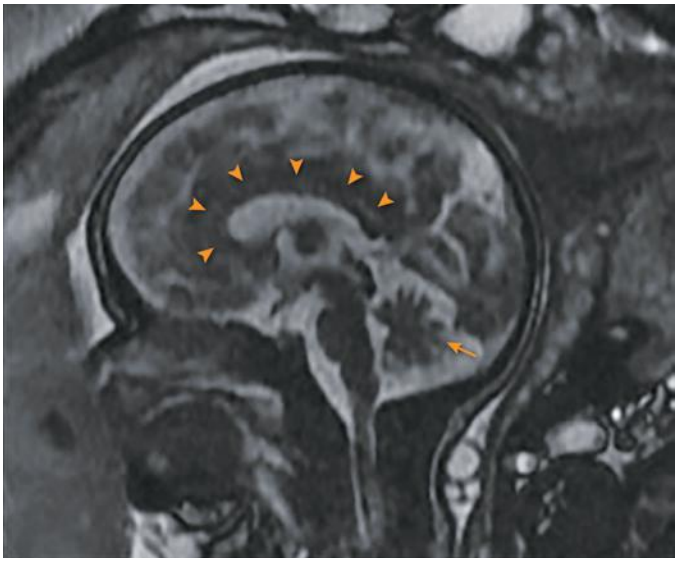

FIG 23-8 Normal corpus callosum at 34 weeks' gestation. Sagittal balanced steady-state image demonstrates normal midline structures—corpus callosum (*arrowheads*), fourth ventricle, and cerebellar vermis (*arrow*).

(Fig. 23-19). The cause of fetal brain damage may include maternal, fetal, placental, infectious, toxic/metabolic, or mechanical/traumatic conditions (Fig. 23-20). Fetal MRI demonstrates not only chronic structural encephaloclastic changes, including ventriculomegaly, parenchymal defects, porencephaly, and volume loss, but also acute changes such as recent hemorrhage and ischemia (Fig. 23-21). The workup can be extensive and includes searching for an underlying cause.[37,38]

Differential diagnosis of intracranial cystic lesions includes primary arachnoid cysts; encephaloclastic lesions resulting from hemorrhage, trauma, or infection; glioependymal cysts; schizencephaly; and cystic neoplasms. Arachnoid cysts are composed of a fibrous connective tissue wall, whereas glioependymal cysts have an ependymal lining. The prognosis of fetuses with an arachnoid cyst depends on the presence or absence of associated intracranial anomalies and aneuploidy.[39] It is important to recognize normal fetal anatomy and not mistake enlargement of the cavum septum pellucidum, cavum vergae, or cavum velum interpositum for pathologic cysts[40-42] (Fig. 23-22).

Anomalies of the Face, Neck, and Thorax

The EXIT procedure is performed to secure the airway in a fetus with airway obstruction. During the EXIT procedure, the fetal head is partially delivered through a cesarean incision while remaining attached via the umbilical cord to the placental circulation, during which time a fetal airway is established. The key tenet of the EXIT procedure is maintenance of uterine relaxation and uterine volume to prevent placental detachment and preserve uteroplacental blood flow. Once the airway is established and ventilation can be performed, the umbilical cord is clamped and cut and the infant is fully delivered. The EXIT procedure, as described, is referred to as the EXIT-to-airway procedure. Additional indications have led to adjunct procedures, including EXIT-to-resection, EXIT-to-ECMO (extracorporeal membrane oxygenation), and EXIT-to-separation procedures.[43] With sonographically suspected airway obstruction, MRI is particularly helpful in defining the presence or absence of free egress of amniotic fluid into the hypopharynx and bright signal of fluid in the trachea.

The two most common giant neck masses are cystic lymphangiomas (also known as *lymphovenous malformations*) and teratomas (Fig. 23-23). Cystic lymphangiomas present as septated, fluid-filled masses. They are most commonly posterolateral in location. Cervicofacial teratomas are typically anterior, large, and bulky, with cystic and solid

Text continued on p. 761

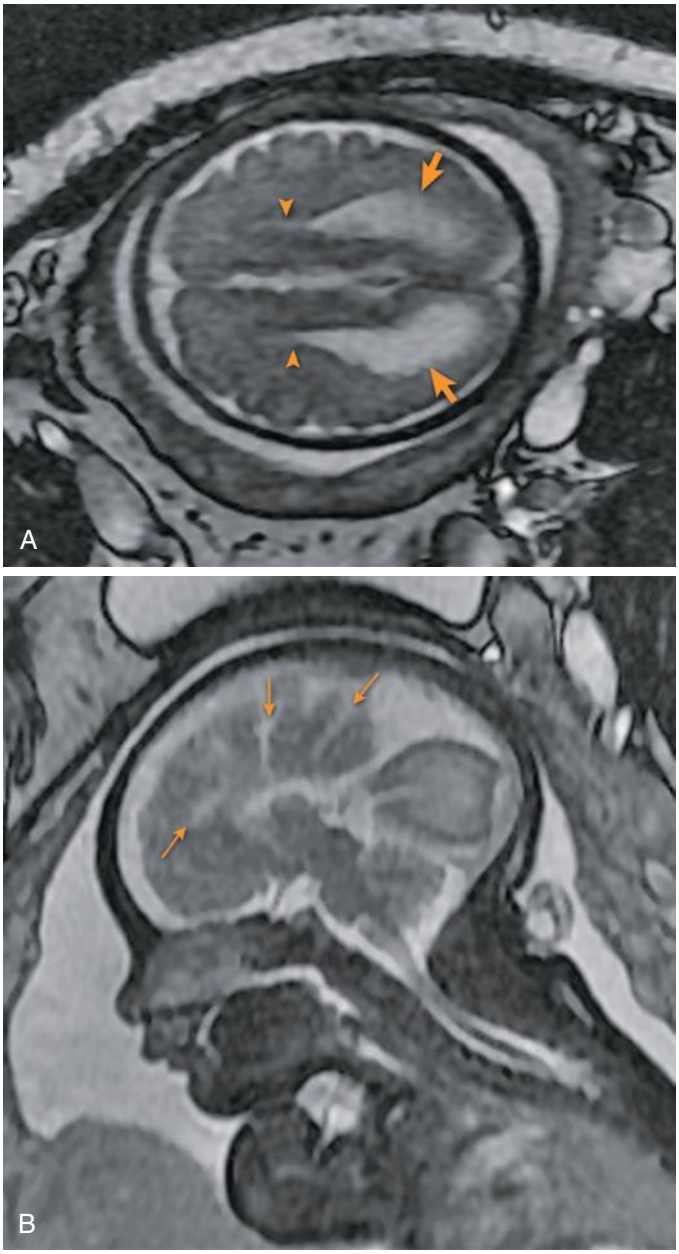

FIG 23-9 Agenesis of the corpus callosum at 31 weeks' gestation. Axial (**A**) and sagittal (**B**) balanced steady-state images demonstrate wide separation of the frontal horns of the lateral ventricles (*arrowheads*) and colpocephaly (*bold arrows*), sometimes referred to as the *teardrop appearance* with radial orientation of the gyri (*small arrows*).

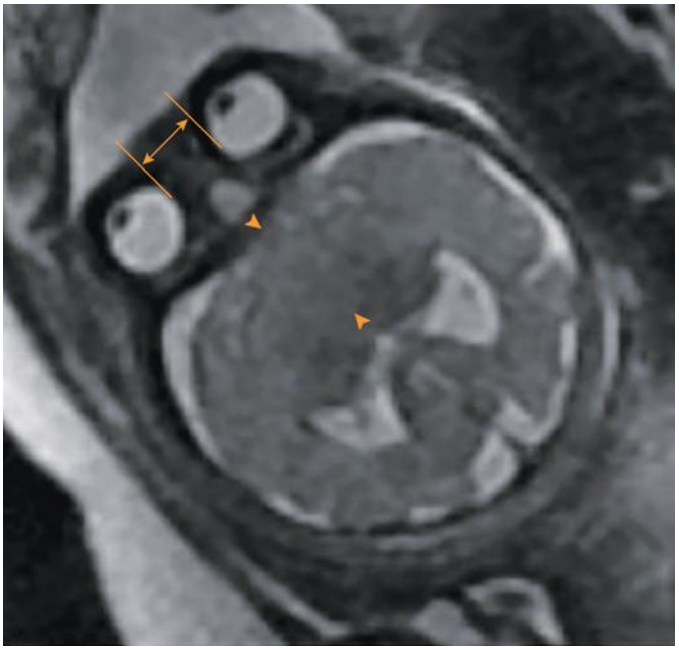

FIG 23-10 Semilobar holoprosencephaly at 36.5 weeks' gestation. Oblique axial balanced steady-state image demonstrates interdigitation (*arrowheads*) of the cortex of the frontal lobes, absent anterior horns of the lateral ventricles, and subtle hypotelorism (*double-headed arrow*), consistent with semilobar holoprosencephaly.

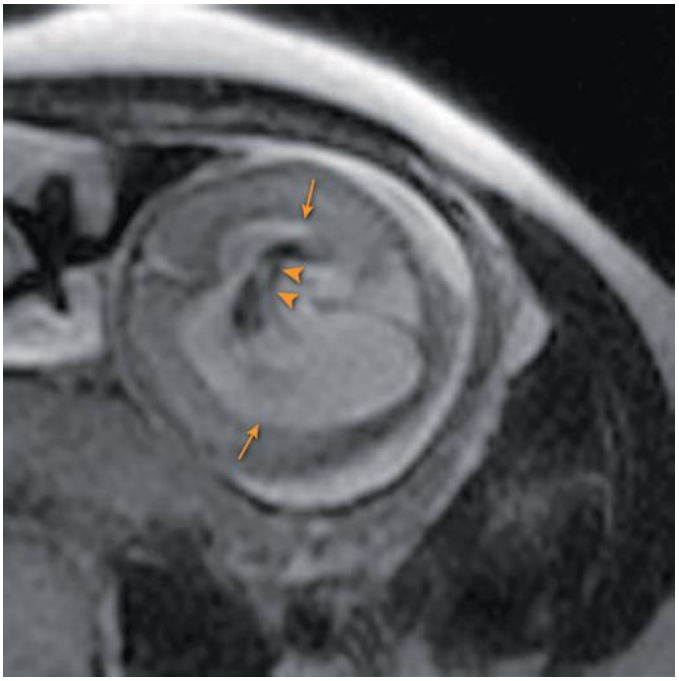

FIG 23-11 Holoprosencephaly spectrum at 23.5 weeks' gestation. Axial T2-weighted imaging demonstrates bilateral ventriculomegaly (*arrows*) and flow void artifact across the midline (*arrowheads*) confirming communication of the ventricles, with falx present anteriorly and posteriorly.

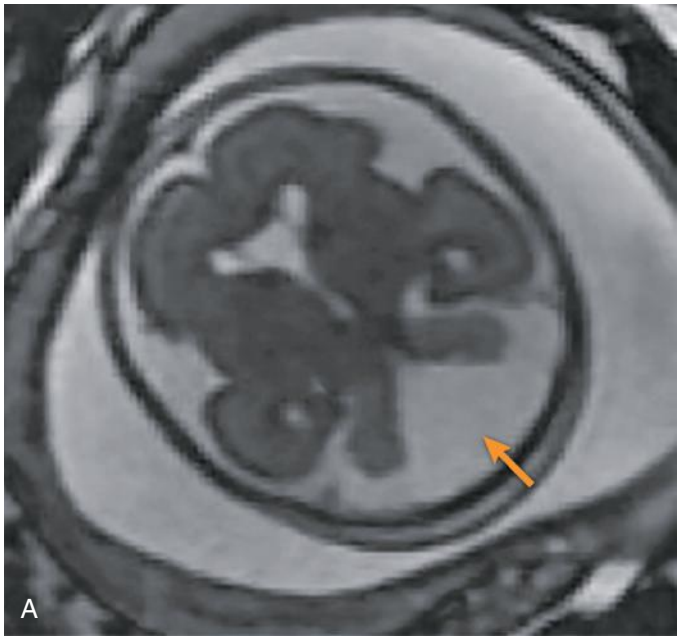

FIG 23-12 Dandy-Walker malformation at 24.5 weeks' gestation. Axial (**A**) and sagittal (**B**) balanced steady-state images demonstrate the fourth ventricle communicating with cisterna magna (*arrow*), and marked hypoplastic, raised vermis (*arrowhead*) with tentorial elevation.

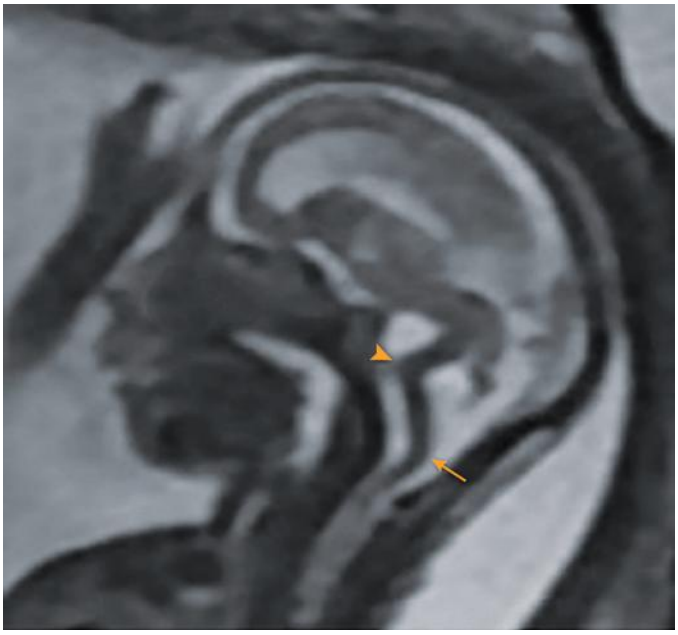

FIG 23-13 Pontocerebellar hypoplasia at 20 weeks' gestation. Sagittal balanced steady-state image demonstrates abnormally thin brainstem, hypoplastic pons, anterior kinking of the brainstem at the level of the fourth ventricle (*arrowhead*), and posterior kinking at the pontomesencephalic junction (*arrow*), consistent with pontocerebellar hypoplasia.

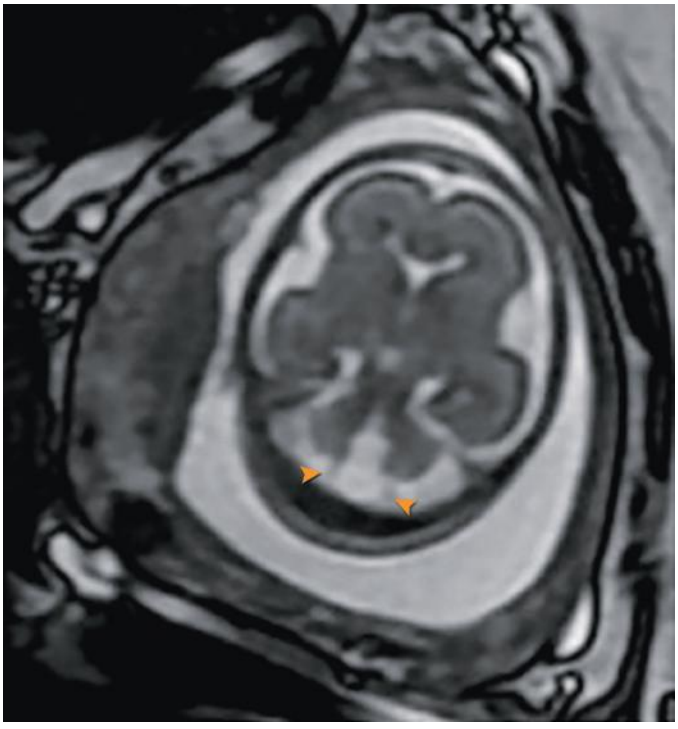

FIG 23-14 Blake pouch cyst at 23 weeks' gestation. Axial balanced steady-state image demonstrates retrocerebellar cystic lesion with a limiting membrane ballooning out from the fourth ventricle consistent with a Blake pouch cyst (*arrowheads*). Postnatal magnetic resonance findings were normal.

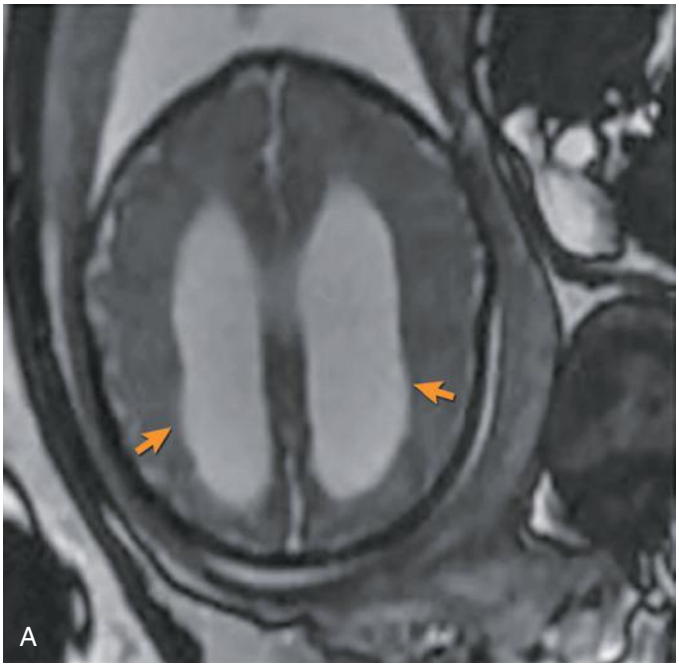

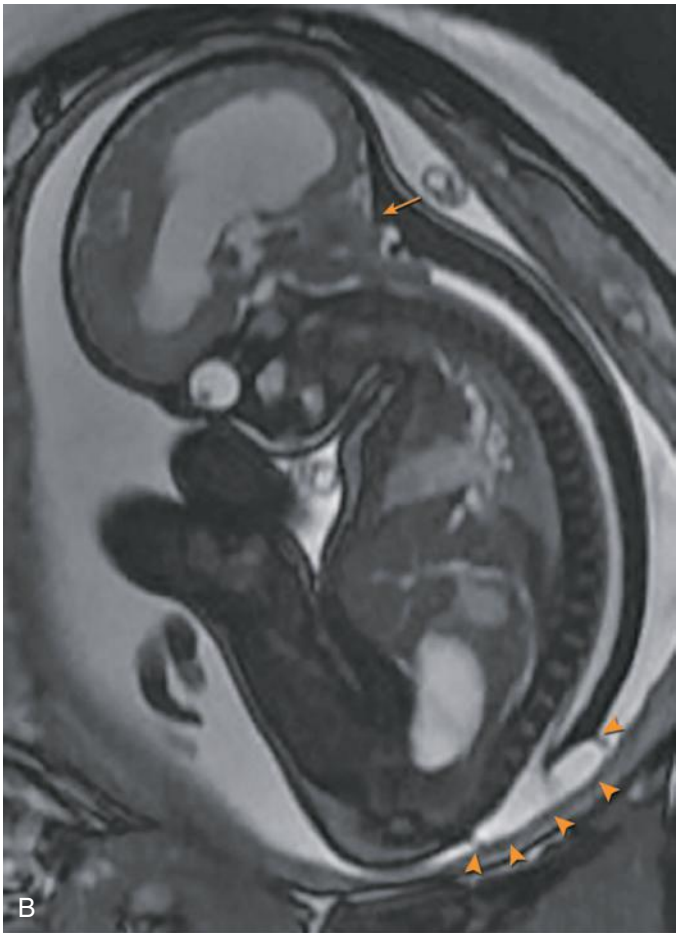

FIG 23-15 Chiari II malformation at 32 weeks' gestation. Axial (**A**) and sagittal (**B**) balanced steady-state images demonstrate ventriculomegaly (*bold arrows*), downward herniation of cerebellar tonsils (*small arrow*), spina bifida defect with tethered cord, and lumbosacral myelomeningocele (*arrowheads*).

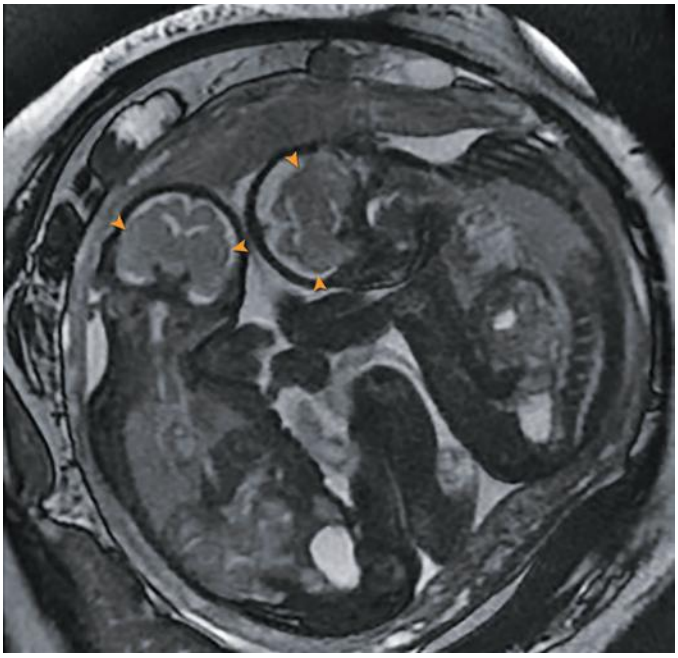

FIG 23-16 Abnormal cortical formation at 29 weeks in monochorionic diamniotic twin gestation. Coronal balanced steady-state image demonstrates abnormal sulcation (*arrowheads*), difficult to detect by ultrasound imaging. Head measurements were markedly small, consistent with microcephaly.

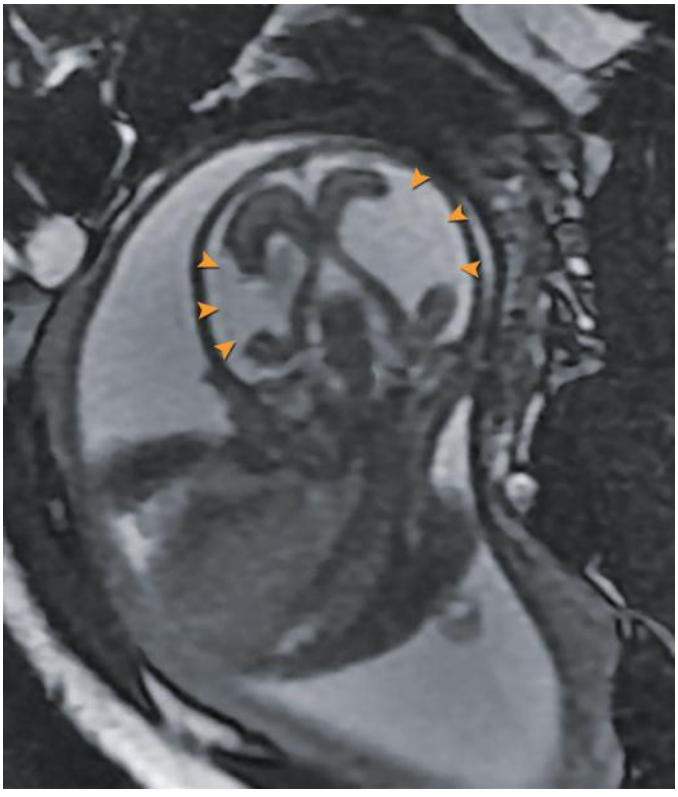

FIG 23-17 Bilateral open lip schizencephaly at 21.5 weeks' gestation. Coronal balanced steady-state image demonstrates large bilateral schizencephalic defects (*arrowheads*) lined with gray matter.

FIG 23-18 Hemimegalencephaly at 19.5 weeks' gestation in a patient referred for ventriculomegaly. Axial T2-weighted imaging demonstrates asymmetric cerebral hemispheres, with increased cortical thickness (*arrows*) and pachygyria involving the right cerebral hemisphere. The right lateral ventricle is mildly dilated and there are multiple subependymal and cortical low signal intensity foci (*arrowheads*).

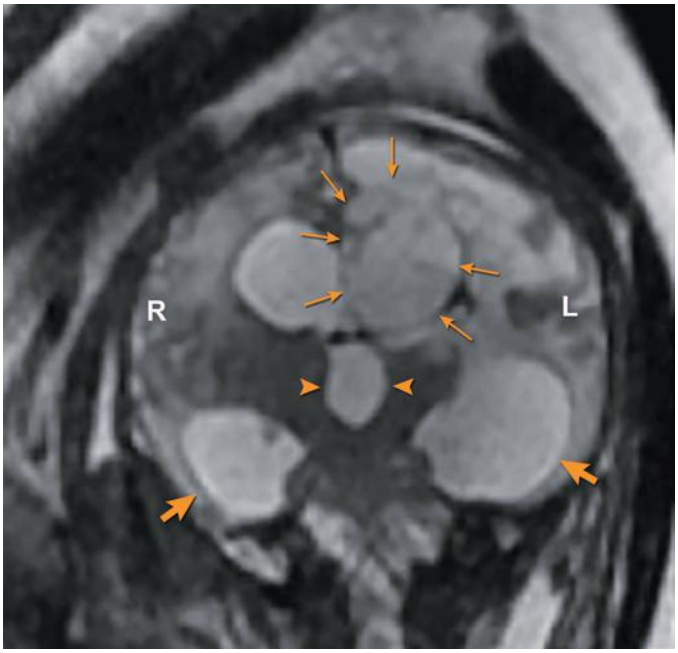

FIG 23-19 Grade IV hemorrhage with encephaloclastic changes at 35 weeks' gestation. Coronal balanced steady-state image demonstrates left germinal matrix hemorrhage with extension into the left lateral ventricle. There is intraventricular clot (*small arrows*), marked ventriculomegaly (*bold arrows*), and enlarged third ventricle (*arrowheads*). Loss of cerebral cortex in the bilateral, left (L) greater than right (R), hemispheres, consistent with infarcts and encephalomalacia noted involving the left cortex.

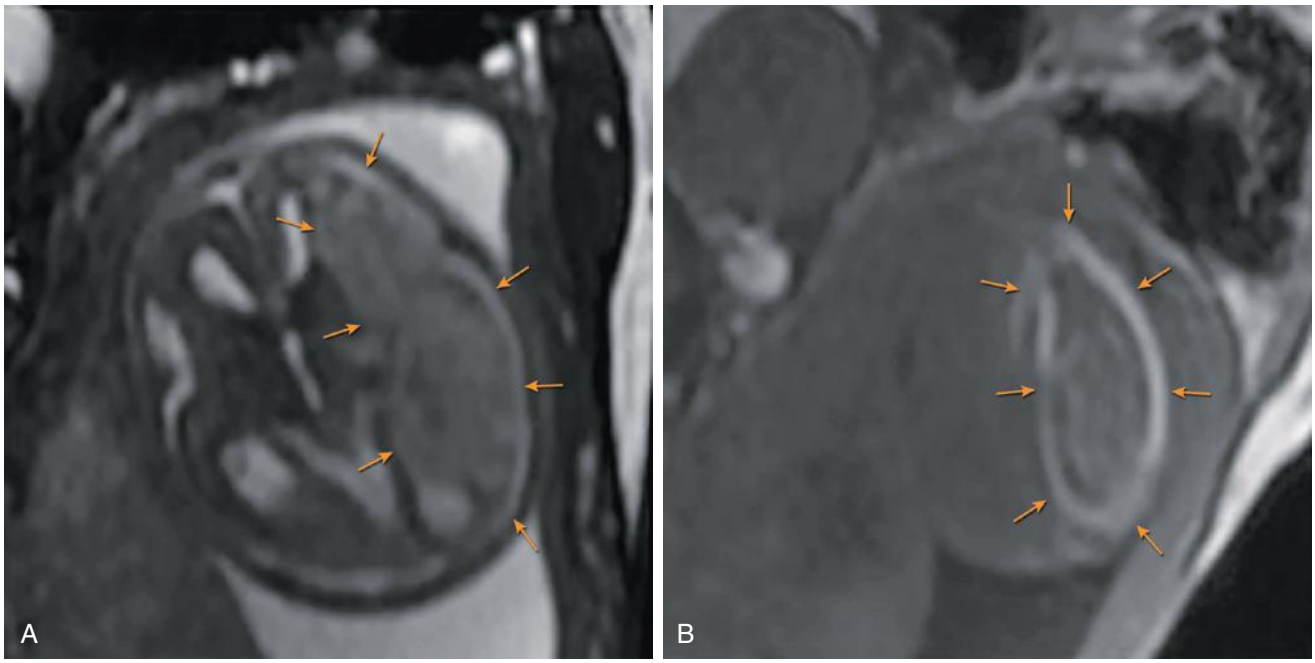

FIG 23-20 **A** and **B,** Large intracranial hemorrhage at 21 weeks' gestation in a patient with cytomegalovirus infection. Axial balanced steady-state image (**A**) and T1-weighted imaging (**B**) demonstrate large hematoma (*arrows*) compressing the lateral ventricle.

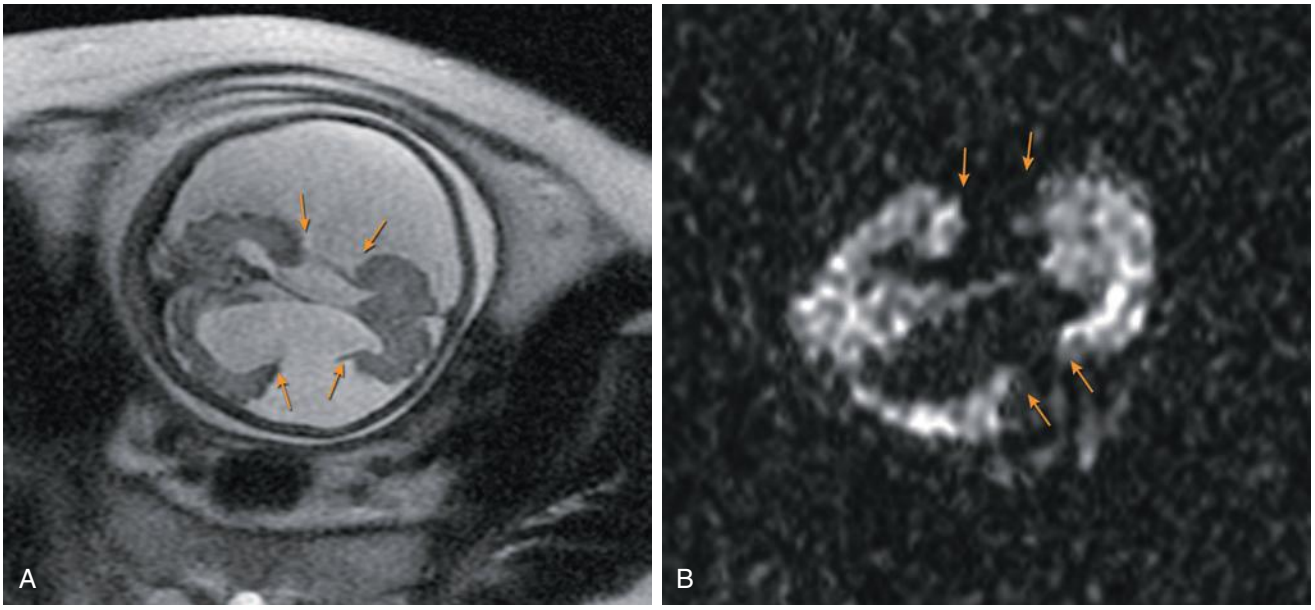

FIG 23-21 Schizencephaly, cerebral volume loss, and diffuse restricted diffusion at 33 weeks' gestation in a fetus with hypoplastic left side of heart. **A,** Note generous extra-axial fluid collections bilaterally, secondary to parenchymal volume loss with bilateral open lip schizencephaly (*arrows*). **B,** Diffusion-weighted imaging shows global restriction, consistent with diffuse ischemia.

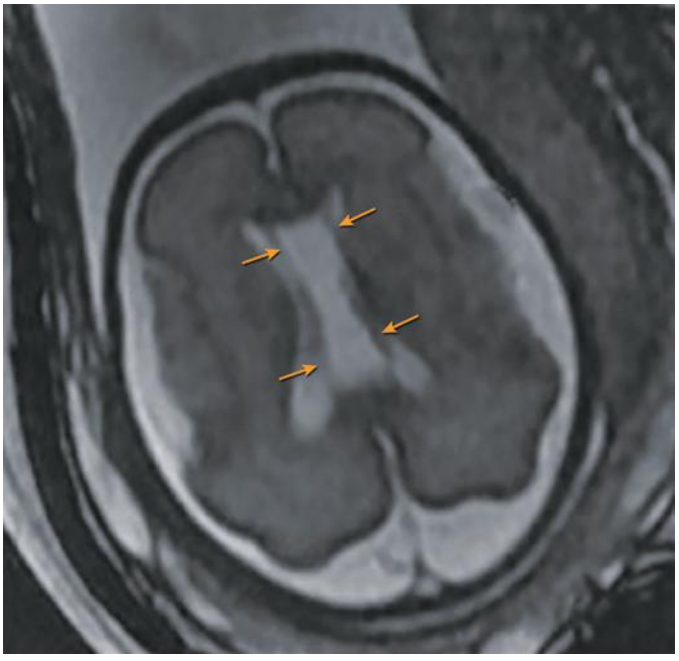

FIG 23-22 Cavum septum pellucidum et vergae at 24.5 weeks' gestation in a patient referred for suspicion of a dilated third ventricle. Axial balanced steady-state image demonstrates fluid separating the leaflets of the septum pellucidum (*arrows*), with posterior extension to the splenium of the corpus callosum.

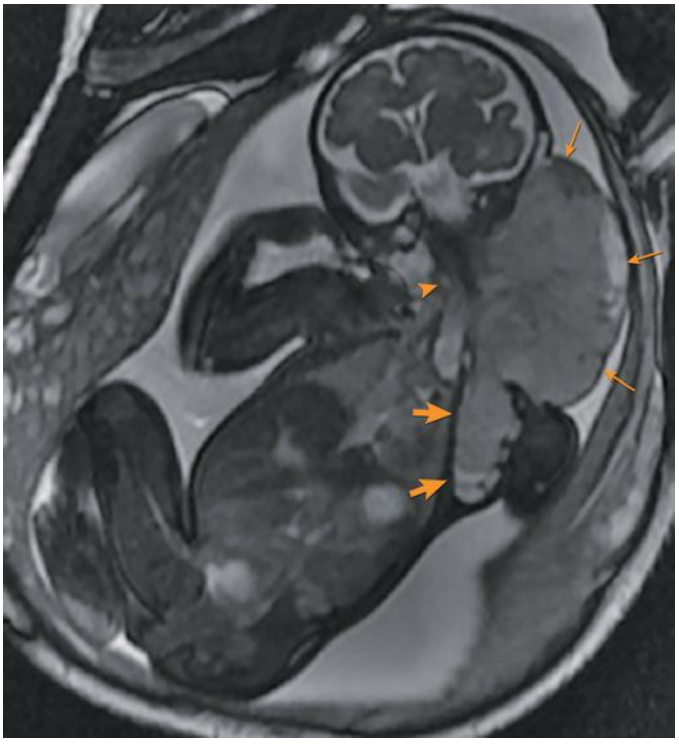

FIG 23-23 Venolymphatic malformation at 31 weeks' gestation. Coronal balanced steady-state image demonstrates extensive multiloculated neck mass (*arrows*) with subcutaneous and deep muscular tissue involvement, extending cephalad to the skull base and periauricular region, medially involving the retropharynx (*arrowhead*) and prevertebral and paravertebral spaces, and caudally to the shoulder joint and thoracic inlet (*bold arrows*). The airway was compressed but patent.

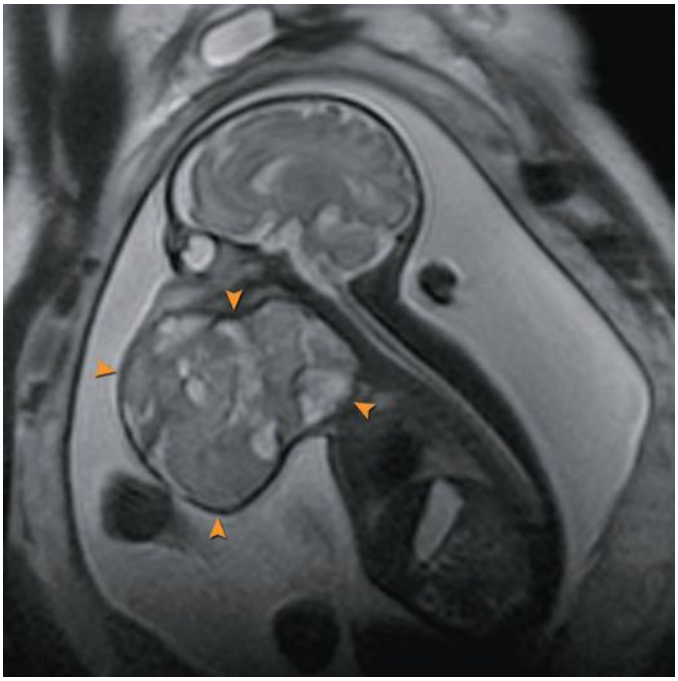

FIG 23-24 Large oropharyngeal teratoma at 32 weeks' gestation. Sagittal T2-weighted imaging demonstrates a mixed cystic and solid mass (*arrowheads*) involving the mandible, maxilla, and oropharynx with airway obstruction, necessitating an EXIT (ex utero intrapartum treatment) procedure at delivery.

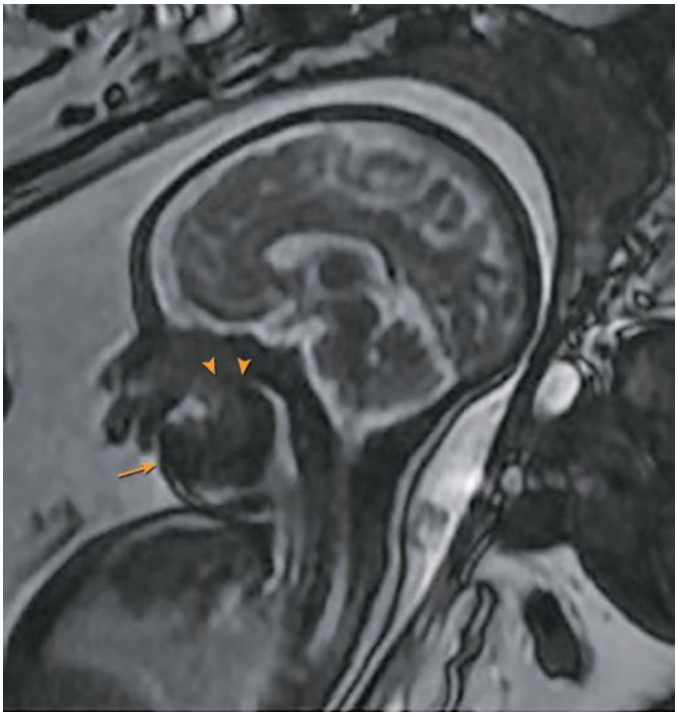

FIG 23-25 Pierre Robin syndrome at 37 weeks' gestation. Sagittal balanced steady-state image demonstrates retrognathia and micrognathia (*arrow*) and isolated cleft palate (*arrowheads*). Polyhydramnios was also present.

elements (Fig. 23-24). Epignathus teratomas arise from the hard or soft palate and present as a fungating mass extending out of the oral cavity.

Micrognathia, characterized by mandibular hypoplasia and a small chin, is a feature of several congenital syndromes (Fig. 23-25). If severe micrognathia is seen in association with polyhydramnios and an absent stomach, sagittal MR images may be useful in demonstrating not only micrognathia but also glossoptosis, retroposition of the tongue, and abnormal positioning of the glottis, with resultant airway obstruction.

Tracheolaryngeal airway obstruction is life threatening, with a reported mortality rate of 80% to 100% if unrecognized prior to delivery. Causes may be intrinsic, including tracheolaryngeal web or atresia, or extrinsic due to tumor or vascular ring. Obstruction of the airway leads to hyperexpanded lungs, flattened/everted hemidiaphragms, fetal hydrops, and ascites, a constellation of findings known as congenital high airway obstruction syndrome (CHAOS)[44] (Fig. 23-26).

MRI has altered the approach to the fetus with a cervicofacial anomaly. In utero detection of airway obstruction can allow for planning of an EXIT procedure in fetuses diagnosed with giant neck masses, severe micrognathia, or tracheolaryngeal obstruction, thereby avoiding neonatal hypoxia and asphyxia.[45,46] Mortality rate in infants undergoing EXIT is reported at 8%, whereas the rate in those treated without EXIT with similar diagnoses ranges from 10% to 57%. Without EXIT, there may be increased neonatal morbidity and developmental delay due to hypoxia.[47] Additionally, MRI can detect the site of fetal tracheolaryngeal obstruction in CHAOS, allowing for more effective airway establishment.[45,48]

The presence of polyhydramnios and nonvisualization of the stomach bubble suggest esophageal atresia, although these signs are nonspecific and have been reported in normal fetuses, along with a wide variety of conditions, including CNS, tracheopharyngeal, thoracic, and neuromuscular abnormalities; congenital heart disease; aneuploidies; twins; and diabetes.[49] MRI has correctly identified the presence or absence of esophageal atresia based on the observation of a dilated esophageal pouch as a positive predictor[50] (Fig. 23-27).

The use of dynamic cine MRI performed in the sagittal plane can be useful in documenting isolated cleft palate,[51] assessing foregut duplication cyst of the tongue and determining airway patency,[52] and visualizing a blind-ending, dilated esophageal pouch during swallowing to reach a reliable diagnosis of esophageal atresia.[53]

Congenital diaphragmatic hernia (CDH) is the principal indication for fetal thoracic MRI. Numerous articles have compared ultrasound imaging with MRI in predicting outcomes and survival in fetuses with CDH based on calculation of lung volume and degree of liver herniation, the major prognostic factors in the setting of CDH, as postnatal morbidity and death are primarily due to pulmonary hypoplasia and pulmonary hypertension.[54-60] MRI can depict herniated intrathoracic contents in a fetus with CDH. Liver is well demarcated on T1-weighted images, and discrimination of large versus small bowel can be performed because of T1 bright appearance of meconium in large bowel[13] (Fig. 23-28).

Congenital lung lesions encompass a spectrum of abnormalities, including congenital pulmonary airway malformation (CPAM), bronchopulmonary sequestration (BPS), and congenital lobar overinflation (CLO). CPAMs account for approximately one half of all lesions and contain either macrocystic or microcystic components (Fig. 23-29). Blood supply to a CPAM is via the pulmonary artery and vein. BPS accounts for approximately one third of lesions and consists of nonfunctioning bronchopulmonary tissue with systemic arterial blood supply. The majority of BPSs are supradiaphragmatic (85%-90%), with 10% to 15% found in an infradiaphragmatic location. Of all BPS

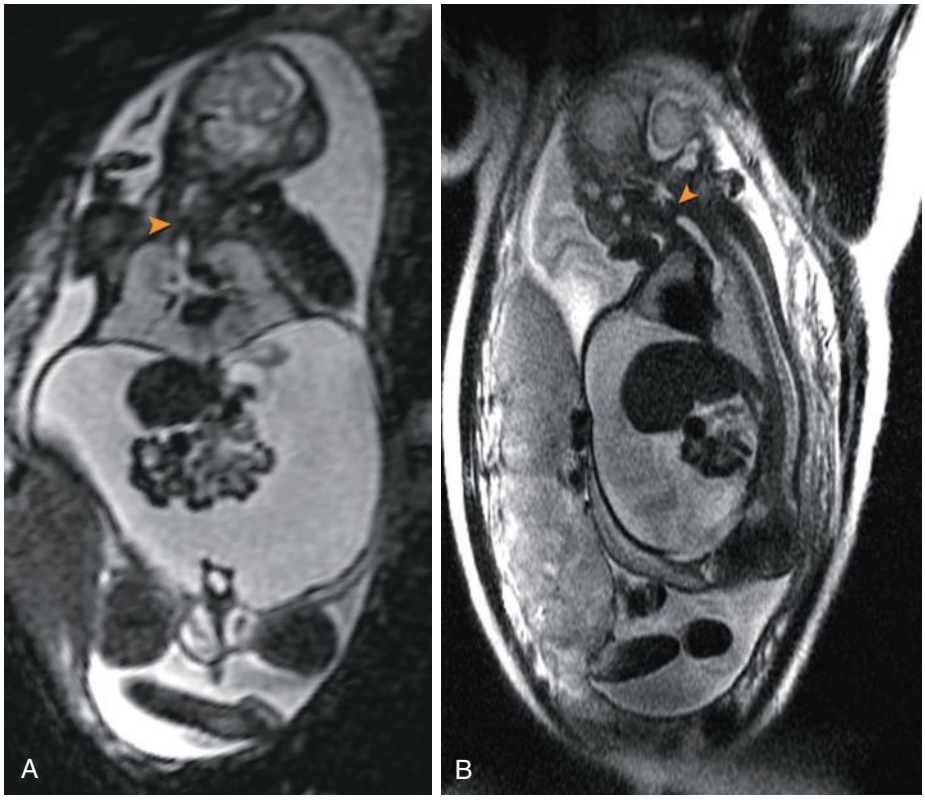

FIG 23-26 Congenital high airway obstruction syndrome (CHAOS) at 23 weeks' gestation. T2-weighted coronal (**A**) and sagittal (**B**) images demonstrate bright lungs, bell-shaped thorax, and large volume of ascites. The dilated fluid-filled trachea can be seen distal to the laryngeal obstruction (*arrowhead*).

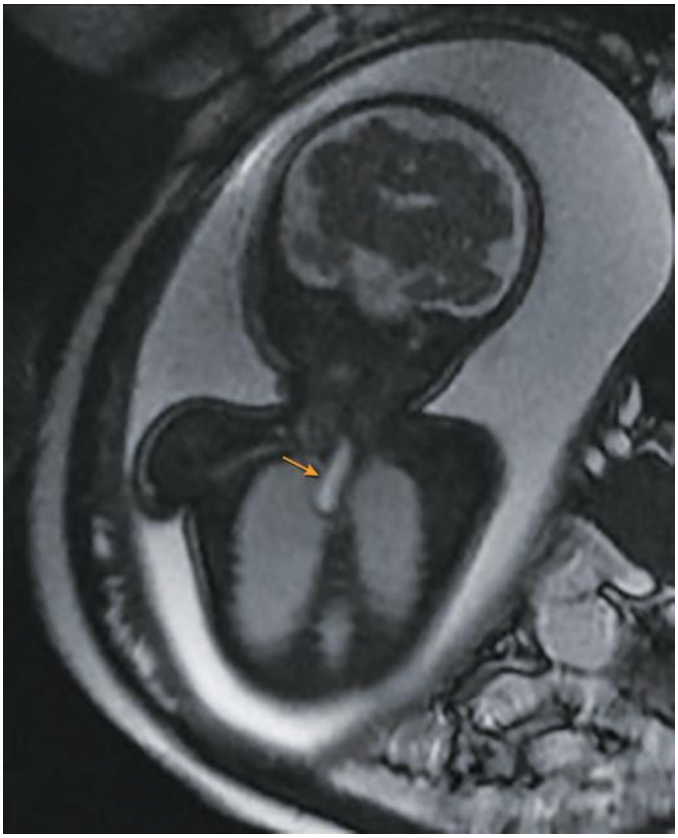

FIG 23-27 Esophageal atresia at 34 weeks' gestation. Coronal balanced steady-state image demonstrates blind-ending, dilated, tubular, fluid-filled structure consistent with dilated esophagus (*arrow*).

masses, three fourths will be hybrid lesions, with components of both CPAM and sequestration. CLO results from bronchial obstruction of a main or lobar bronchus, either from mucous plug or extrinsic compression due to vessel or mass (Fig. 23-30). Macrocystic CPAMs tend to be more heterogeneous, multilocular, and cystic in appearance with architectural distortion (see Fig. 23-29). Microcystic CPAMs are homogeneous but also demonstrate architectural distortion. BPS lesions appear homogeneous, without architectural distortion and, if a feeding vessel is visualized, can be diagnosed with confidence. Hybrid lesions demonstrate features common to both CPAM and BPS. CLO appears uniformly hyperintense on T2-weighted imaging secondary to fluid overdistention of pulmonary segments and lobes.[61-63] MRI plays a complementary role to ultrasound imaging, confirming or providing alternate diagnoses.

Abnormalities in the Fetal Abdomen

Abnormalities in the fetal abdomen are an infrequent indication for MRI evaluation. Fetal abdominal disease encompasses abnormalities of the hepatobiliary system, gastrointestinal tract, genitourinary tract, and abdominopelvic masses.

Hyperintense T1 signal within bowel loops can indicate the presence of meconium, which is usually seen in the distal ileum or colon. T2 hyperintense bowel dilatation usually indicates proximal small bowel dilatation, whereas T1 hyperintense bowel dilatation typically represents distal ileal or colonic obstruction[64] (Fig. 23-31). However, a 2010 study demonstrated proximal jejunal atresia in nine cases of suspected ileal atresia, revealing the imprecision of determining the exact site of obstruction by imaging.[65]

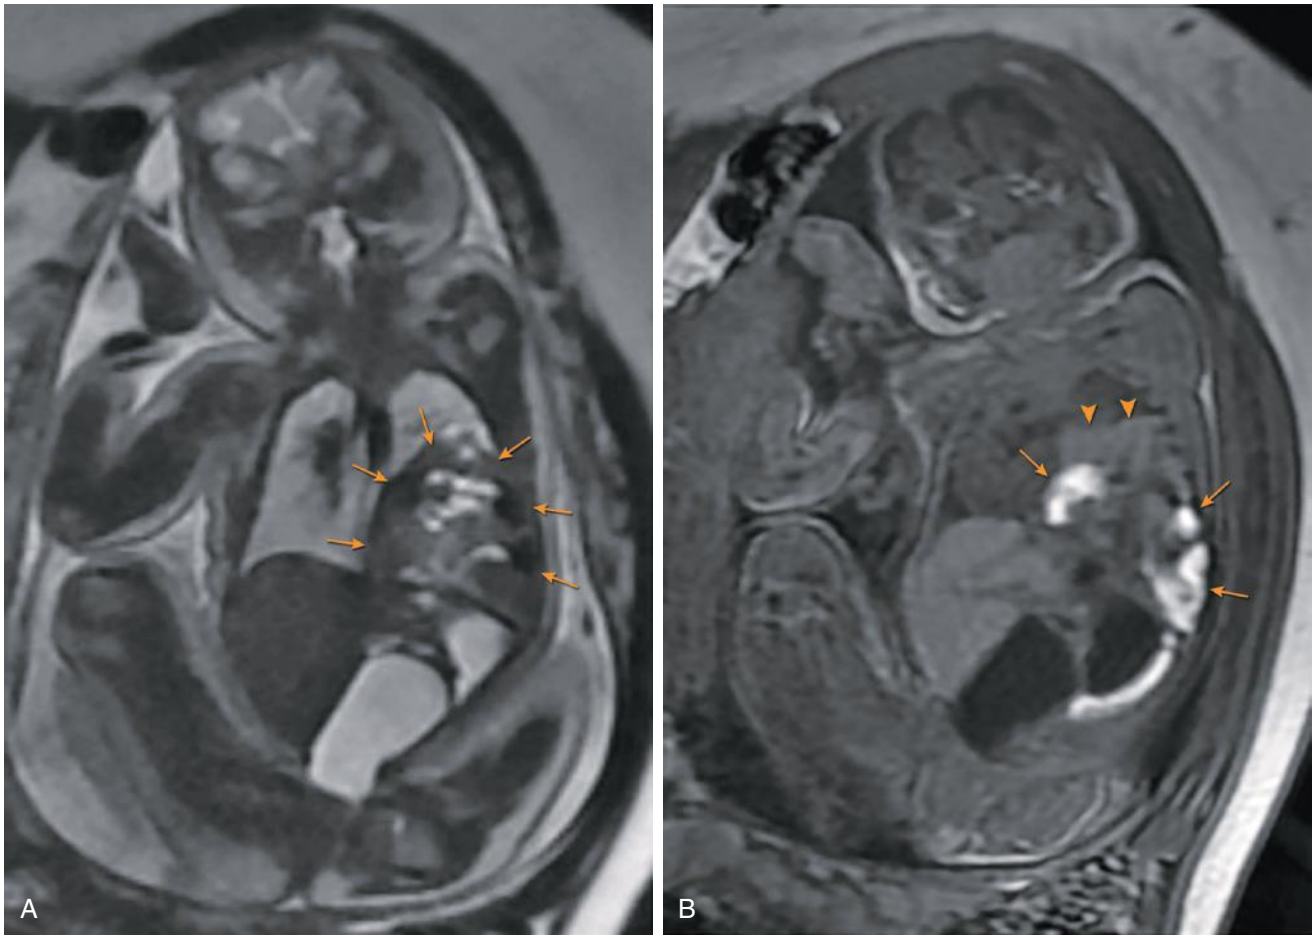

FIG 23-28 Congenital diaphragmatic hernia (CDH) at 35.5 weeks' gestation. Coronal T2-weighted imaging (**A**) and T1-weighted imaging (**B**) demonstrate a large left-sided CDH (*arrows*) containing left lobe of liver and small and large bowel. The fluid-filled stomach is not herniated, located within the abdomen. T1-weighted imaging demonstrates herniated left lobe of liver (*arrowheads*) and large bowel segments containing high signal meconium (*arrows*).

Genitourinary anomalies are well demonstrated on MRI, and imaging is not hindered by oligohydramnios. Renal cystic disease, duplication of the collecting system, hydroureteronephrosis, megacystis-microcolon–intestinal hypoperistalsis syndrome, and cloacal exstrophy with two characteristic hemibladders can be visualized by fetal MRI.[66]

Cystic masses within the abdominal cavity may be categorized according to location: upper abdominal, lower abdominal, and retroperitoneal. Most fetal abdominopelvic masses occur in the lower abdomen and are urogenital or gynecologic in origin, including ovarian cysts and hydrometrocolpos (Figs. 23-32 and 23-33). Upper abdominal cysts include choledochal, mesenteric, hepatic, and splenic cysts. Retroperitoneal masses include lymphangiomas, adrenal cysts, and adrenal neuroblastomas. MRI has shown benefit in evaluating cystic abdominal masses with respect to both improved tissue characterization and anatomic localization.[67]

Abdominal wall defects include gastroschisis, omphalocele, cloacal exstrophy, limb body wall complex (LBWC), and pentalogy of Cantrell. Recognition of common features of each entity and potential pitfalls is essential for proper diagnosis. Ruptured omphalocele may mimic gastroschisis, congenital hernia of the umbilical cord may mimic omphalocele, and dilated vagina may be mistaken for normal urinary bladder in cases of cloacal malformation.[68] MRI is of benefit in visualizing omphalocele sac content, size of anterior abdominal wall defect, quantity of extruded bowel, suggestion of bowel atresia, and presence of additional anomalies[69] (Fig. 23-34). Omphalocele may be isolated, or part of a severe anomaly, such as cloacal exstrophy, LBWC, or pentalogy of Cantrell. Fetal MRI is particularly helpful in defining and assessing the more complex lesions. Differentiation of treatable abdominal wall defects from lethal entities can help guide appropriate counseling and management.[70]

Tumors

Teratomas are the most common fetal neoplasm, with the sacrococcygeal region being the most common site (Fig. 23-35). However, these tumors can also occur in the head, neck, chest, abdomen, and pelvis (Fig. 23-36). They are typically bulky and heterogeneous, with mixed solid and cystic appearance. Sacrococcygeal tumors can become very large and vascular, leading to atrioventricular shunting, high-output cardiac failure, and hydrops, with a reported fetal mortality rate of 50%.[71] In a study of prognostic factors predictive of outcome in fetuses with sacrococcygeal teratomas, a tumor volume/fetal weight ratio (TFR) lower than 0.12 before 24 weeks' gestation predicted an uncomplicated perinatal course with 100% survival. A TFR higher than 0.12 had an increased risk of complications and perinatal demise.[72]

FIG 23-29 Congenital pulmonary airway malformation (CPAM) at 20 weeks' gestation. Coronal balanced steady-state image demonstrates a large macrocystic, multilocular mass occupying the left hemithorax (*arrows*).

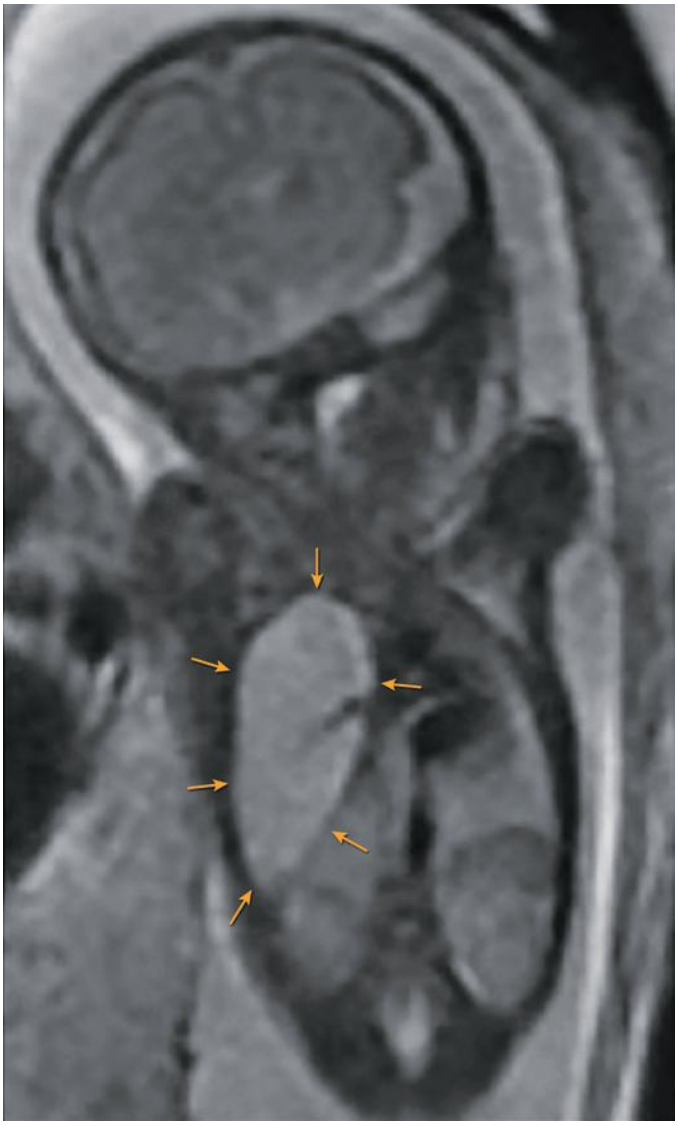

FIG 23-30 Congenital lobar overinflation at 26 weeks' gestation. Coronal T2-weighted imaging demonstrates expanded, hyperintense right mid-upper lobe (*arrows*) compared with normal-appearing right lower lobe and left lung. Postnatal computed tomography confirmed congenital lobar emphysema likely due to right middle lobe bronchial atresia.

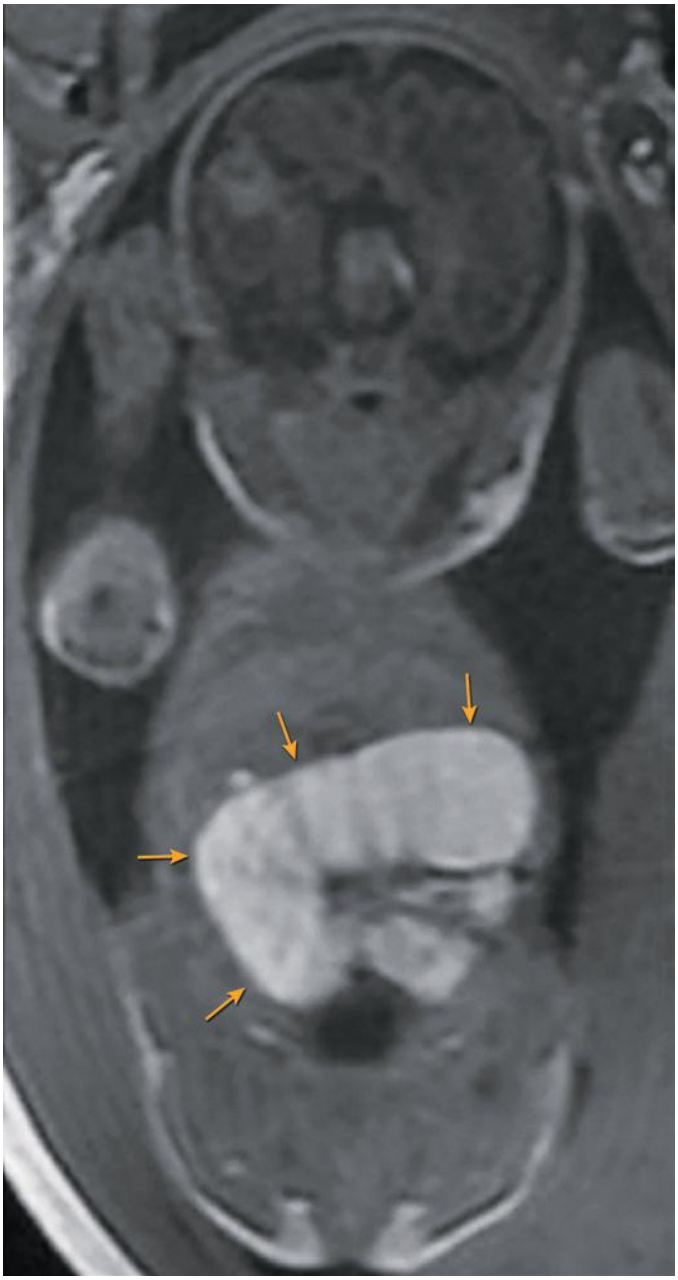

FIG 23-31 Meconium ileus at 32.5 weeks' gestation. Coronal T1-weighted imaging demonstrates high signal intensity dilated distal loop of small bowel (*arrows*). Infant tested positive for cystic fibrosis.

Lymphangiomas are malformations of the lymphatic system that belong to the spectrum of venolymphatic malformations. Lymphangiomas can occur anywhere and are classified into simple, cavernous, and cystic forms. MRI can depict size and extent of lymphangiomas.[73] Those with a vascular component are called *hemangiolymphangiomas* and may be associated with Klippel-Trenaunay syndrome if there is soft tissue hypertrophy of the affected limb and one or more port wine stains found on physical examination[74] (Fig. 23-37).

Monochorionic Twins

A distinct spectrum of complications may affect monochorionic twin pregnancies, many due to vascular anastomoses in the shared placenta. These complications include twin-twin transfusion syndrome (TTTS), twin anemia-polycythemia sequence, selective fetal growth restriction (sFGR), and neurologic damage following spontaneous death of a co-twin. In addition, interventions may be performed, including selective reduction or laser ablation of inter-twin vascular connections in the shared placenta with risk of subsequent neurologic sequelae in the surviving twin. Historically, it was thought that injury occurred as a result of transfusion of thromboplastic proteins from the dead twin into the survivor's circulation (twin embolization syndrome) resulting in disseminated intravascular coagulation. More recently, the proposed mechanism is thought to be related to blood loss from the survivor into the placental territory of a dead co-twin through vascular anastomoses in the shared monochorionic placenta.[75,76] This can lead to hypotension and underperfusion of the living twin with resultant ischemia and infarction of susceptible organs, with intracranial injury most apparent.[77] A study evaluating CNS findings in surviving fetuses following spontaneous co-twin demise identified abnormalities on MRI in 33% of cases; these observations included polymicrogyria, intracranial hemorrhage, and ventriculomegaly[78] (Fig. 23-38). More recently, DWI has been shown to detect acute ischemic cerebral lesions in a surviving fetus within 3 to 4 days of co-twin demise. This was seen following spontaneous intrauterine fetal demise (IUFD), fetal death after treatment for TTTS, and following selective termination.[79,80]

The use of MRI in the evaluation of conjoined twins was first reported in 1986[81] (Fig. 23-39). MRI can accurately depict the shared fetal anatomy, organ fusion, and associated malformations, allowing identification of conjoined twin pairs who may be amenable to postnatal surgical separation.

Abnormal Placentation

Abnormal placentation refers to abnormal placental adherence to the myometrium and is classified according to depth of invasion. In placenta accreta, chorionic villi are attached directly to the myometrium without normal intervening decidua basalis. Chorionic villi partially invade the myometrium in placenta increta, and chorionic villi penetrate the myometrium to the level of the serosa or beyond in placenta percreta.[18,82] The proposed pathogenesis is twofold. Scarring from a variety of processes, including prior cesarean delivery, uterine surgery, myomectomy, or curettage, leads to a defect in the decidua basalis, with concomitant local hypoxia posing an increased risk for placental invasion. This defect in the decidua basalis and excessive trophoblast invasion lead to development of placenta accreta.[83] In 2005, Wu and coworkers reported a 20-year analysis of abnormal placentation, finding that the incidence of placenta accreta had risen from 1/2500 deliveries in 1982 to 1/533 deliveries.[84] This correlated with the rising cesarean delivery rate and increased incidence of placenta previa. The most important risk factors for placenta accreta were found to be prior cesarean delivery, placenta previa, and advanced maternal age.[84] In a study by Miller and associates, 9.3% of women with placenta previa had placenta accreta, but placenta accreta occurred in only 0.005% of women without placenta previa.[85] Silver and colleagues found that maternal morbidity increases with increasing number of prior cesarean deliveries, with risk of abnormal placentation following the first cesarean delivery of 3%, increasing to 40% following the third cesarean delivery, and 67% following the fifth cesarean delivery.[86]

Some published series require histopathologic proof for confirming the diagnosis of placenta accreta, and others will employ clinical criteria, as histologic examination may be unreliable because of sampling error or there may be incidental positive findings in asymptomatic cases. Clinical criteria include difficult manual removal of the placenta and continued bleeding from the implantation site after placental delivery. In a cohort of 111 cases of abnormal placentation, clinical criteria were used in 35 of the 111 (31.5%) to diagnose placenta accreta.[84]

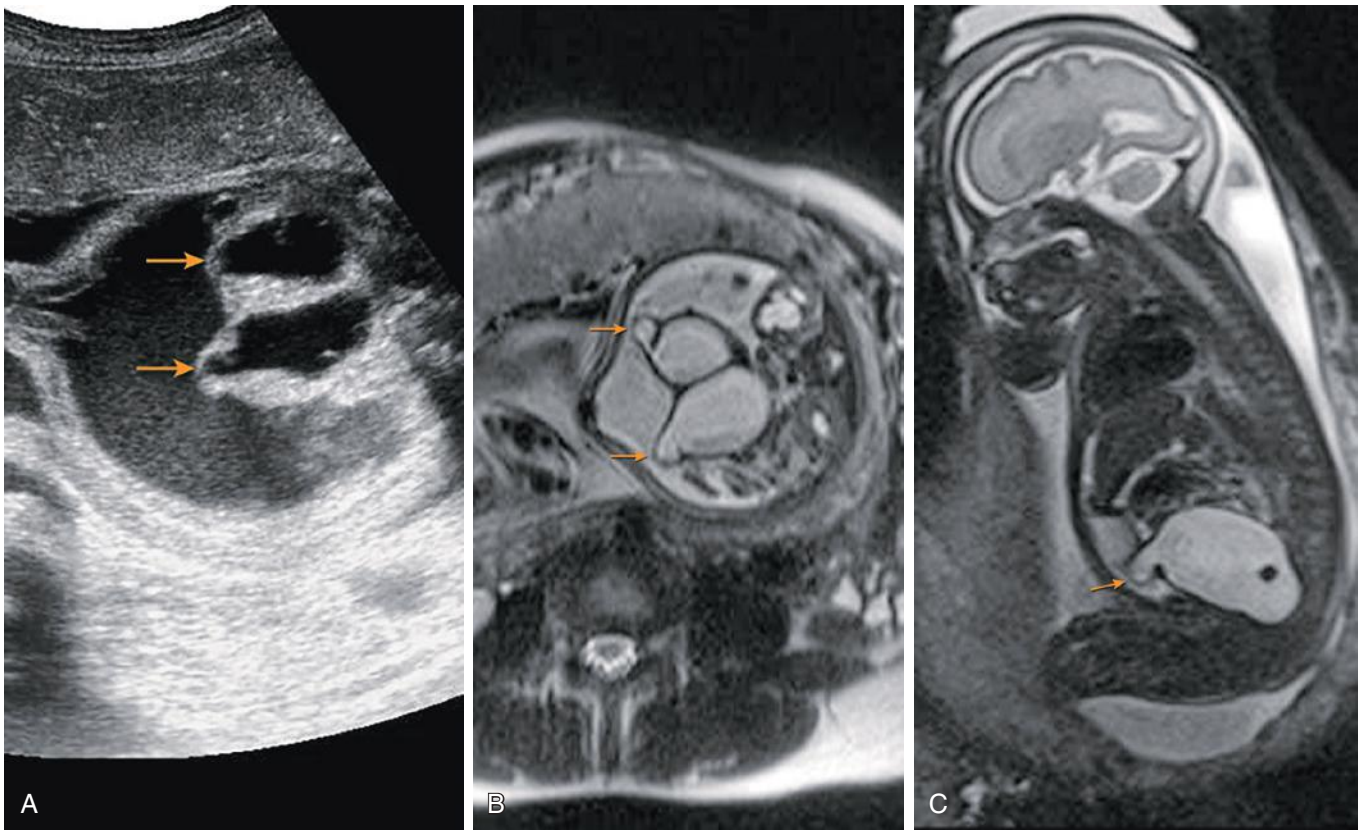

FIG 23-32 Hydrometrocolpos with uterine duplication in complex chloacal malformation at 31 weeks' gestation. Axial ultrasound image (**A**) and axial (**B**) and sagittal (**C**) magnetic resonance images are shown. Dilated proximal fallopian tubes (*arrows*) communicate with fluid-filled duplicated endometrial cavities. Complex pelvic ascites is adjacent to hydrometrocolpos.

FIG 23-33 Left ovarian and fallopian tube torsion and infarction at 32 weeks' gestation. Coronal balanced steady-state image demonstrates large pelvic cystic mass (*arrows*) with septation and solid nodule (*arrowhead*).

FIG 23-34 Giant omphalocele at 29 weeks' gestation. Sagittal balanced steady-state image demonstrates giant omphalocele (*arrows*) containing liver, bowel, and large volume of ascites.

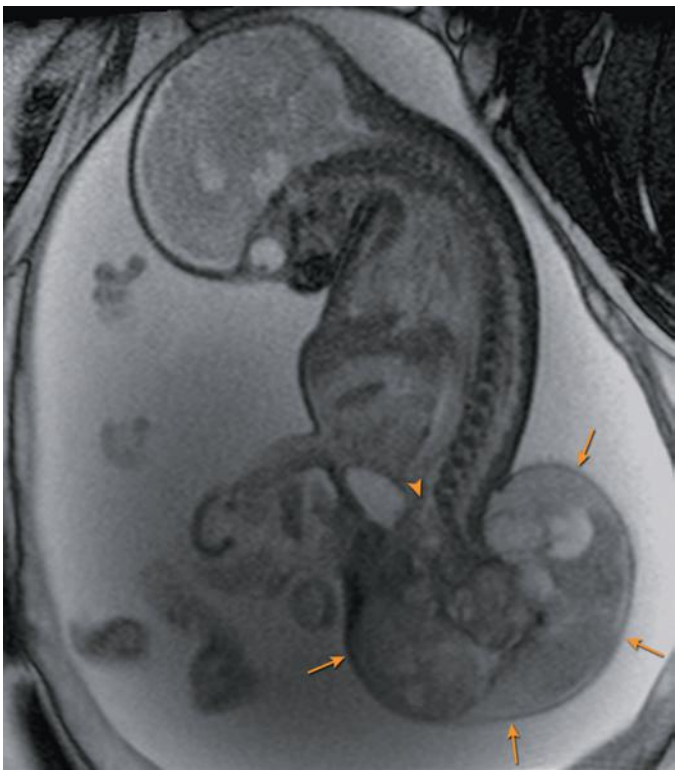

FIG 23-35 Sacrococcygeal teratoma at 26 weeks' gestation. Sagittal T2-weighted imaging demonstrates a large complex exophytic cystic and solid sacrococcygeal mass (*arrows*) with minimal intrapelvic extension in the presacral region (*arrowhead*).

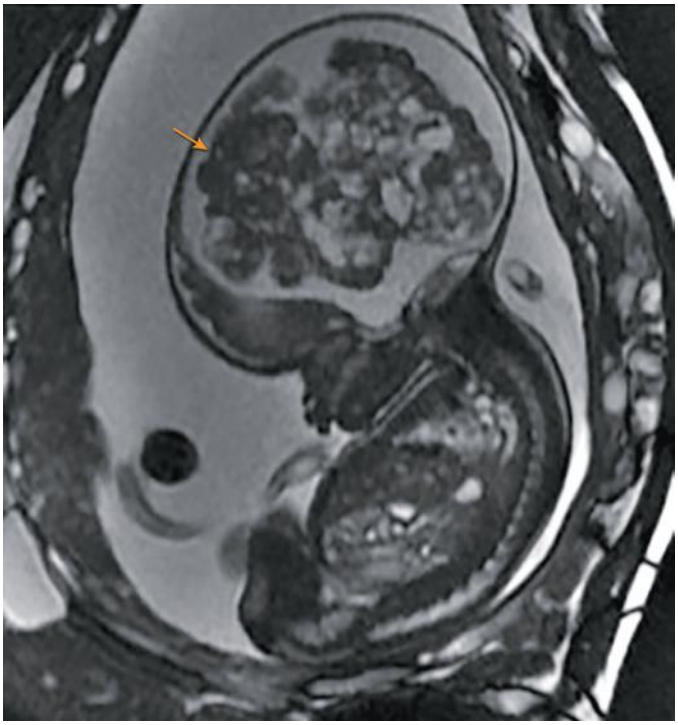

FIG 23-36 Large intracranial teratoma at 32 weeks' gestation. Sagittal balanced steady-state image demonstrates complex cystic and solid intracranial mass (*arrow*) expanding the cerebral hemisphere. Pathologic examination demonstrated malignant immature teratoma.

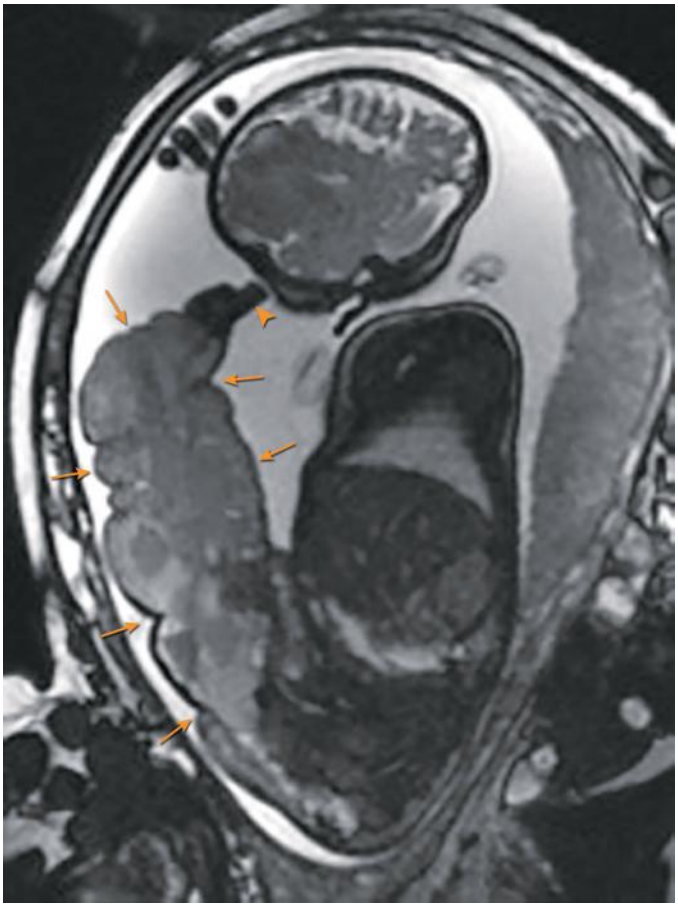

FIG 23-37 Klippel-Trénaunay syndrome at 37 weeks' gestation. Sagittal balanced steady-state image demonstrates large venolymphatic malformation involving nearly the entire lower extremity (*arrows*) sparing the toes (*arrowhead*), with intrapelvic extension.

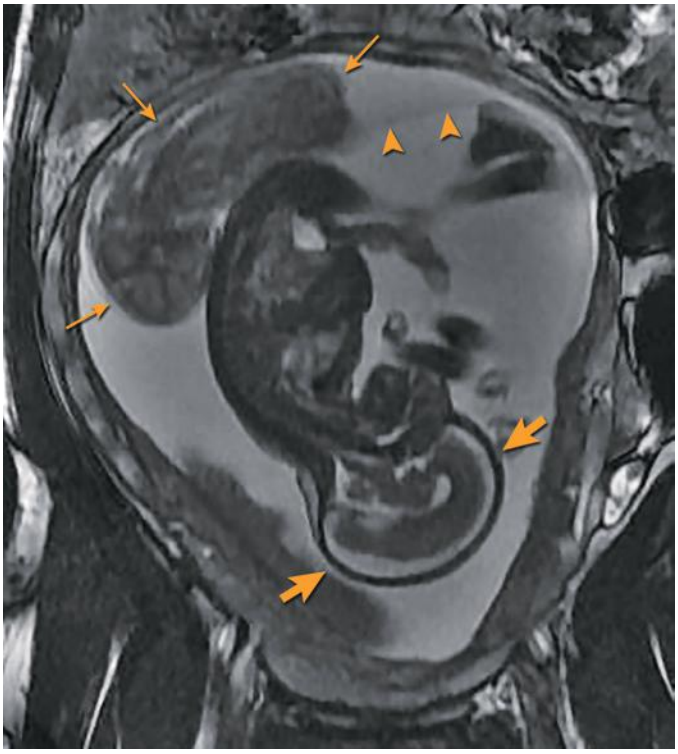

FIG 23-38 Monochorionic diamniotic twins at 23.5 weeks' gestation, status post demise of twin B. Coronal balanced steady-state image performed 3 weeks following co-twin demise demonstrates mass-like appearance of the stuck demised twin B (*small arrows*), thin intertwin membrane (*arrowheads*), and no evidence of intracranial hemorrhage or ischemia in surviving twin A (*bold arrows*).

Abnormal placental adherence can result in catastrophic, life-threatening hemorrhage; therefore, the diagnosis of this potentially morbid condition is of utmost importance. Multidisciplinary planning has been shown to reduce maternal morbidity.[18] Prenatal MRI diagnosis of placenta percreta was first reported in 1992, with placenta previa and loss of the myometrial contour at the lower uterine segment detected by MRI.[87] Our placental MRI protocol consists of sagittal, coronal, and axial T2-weighted RARE and gradient echo images to image the entire gravid uterus, and one T1-weighted sequence in the sagittal plane, with the maternal bladder partially full.

Lax and coworkers found that the most useful criteria for diagnosing abnormal placentation using MRI were uterine bulging, heterogeneous signal intensity within the placenta, and T2 dark intraplacental bands[88] (Figs. 23-40 through 23-43). MRI has been shown to be useful in the determination of abnormal placental implantation in cases with equivocal diagnoses on ultrasound imaging.

Although reports in the medical literature question the accuracy and cost effectiveness of MRI for abnormal placentation,[89,90] many conclude that predelivery confirmed diagnosis of placenta accreta is associated with decreased maternal hemorrhagic morbidity.[91,92] More recently, MRI was shown to accurately delineate topographic extension into the parametrial regions and to identify cervicotrigonal vascular hyperplasia, significant prognostic details informing surgical approach and dissection.[93]

Emerging Concepts

As MRI acquisition times shorten and technology allows for improved resolution of structures without degradation due to motion, fetal imaging may progress in three potential directions. One is volume

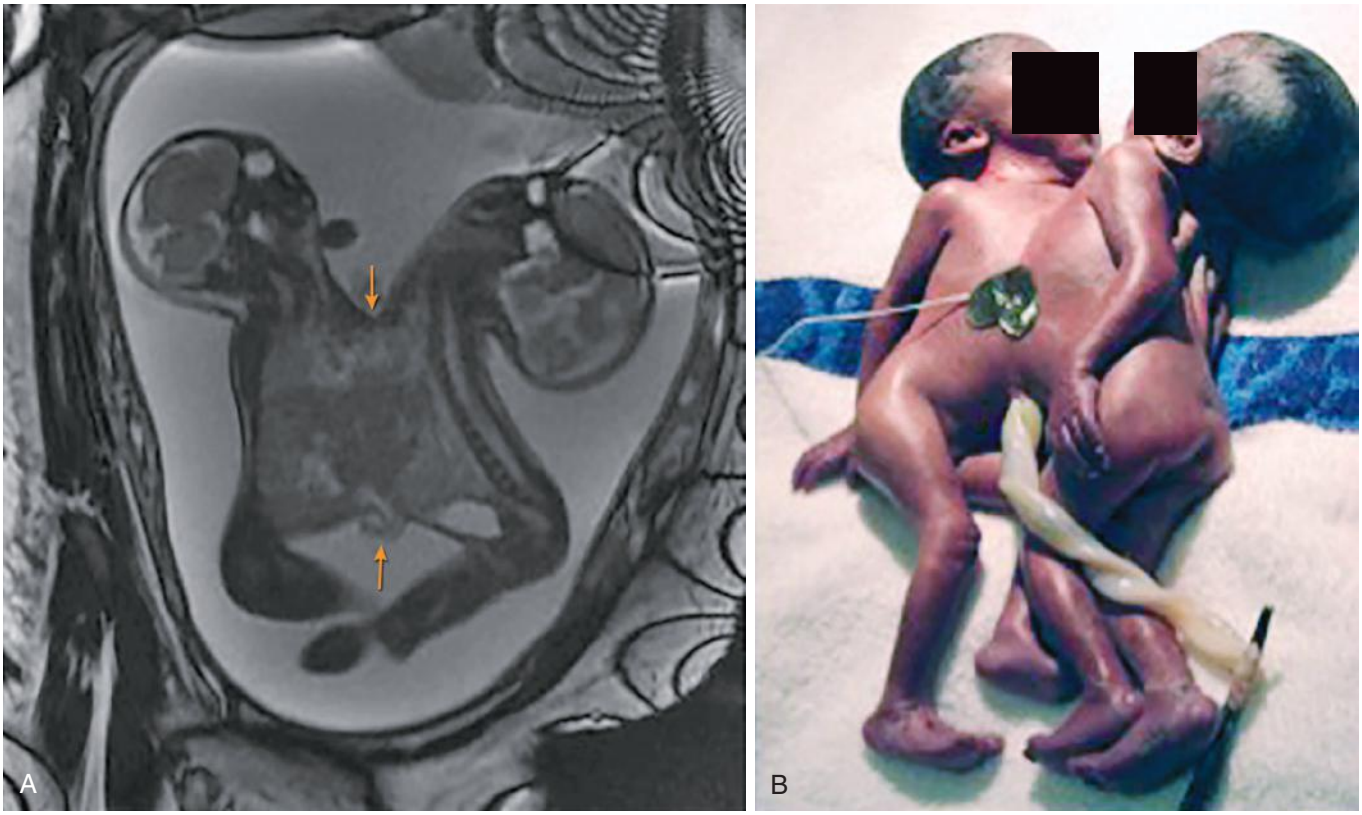

FIG 23-39 A and **B,** Thoraco-omphalopagus conjoined twins at 28 weeks' gestation. Coronal balanced steady-state image demonstrates fusion of the anterior chest and abdominal wall (*arrows*), with shared liver and heart. Separation could not be performed. Twins expired soon after birth.

acquisition and 3D postprocessing. This technique is similar to advances in spiral computed tomography with multiple channel detectors, in which one large high-resolution image can be processed in any plane of section. Applying this to imaging detailed fetal anatomy of interest requires faster acquisition times, ability to correct for fetal motion, and improved field of view options. New vendors have been developing these systems. Studies have looked at combined orthogonal views that create a volume of the fetal brain with subsequent postprocessing of improved images that correct for motion and limited resolution.[93,94] One study described actual alterations of development in the fetal brain in the setting of mild ventriculomegaly, based on 3D volumetric and surface analysis.[94]

The second direction is dynamic, real-time MRI for evaluation of the fetal heart and other moving structures. A feasibility study reviewed MRI examinations of the chest to delineate certain components of fetal cardiac anatomy.[95] They found that bSSFP acquisitions such as True-FISP and FIESTA were helpful in defining certain atrial, ventricular, conotruncal, and venous relationships. This technique must be coupled with an acquisition that captures the anatomy in some predictable fashion when the fetal heart rate is 120 to 160 beats per minute.

Finally, many of the already established acquisitions that assess physiologic functions commonly referred to as functional MRI (fMRI) may be explored in the fetus. This approach includes spectroscopy for investigating brain and pulmonary maturity, which has been addressed in small series.[96,97] As discussed previously, DWI and apparent diffusion coefficient (ADC) have been used for evaluating the fetal CNS[12,14,98-100] and placental hypoxemia/ischemia.[101] DWI and ADC mapping of the fetal brain have the added advantage of providing diffusion tensor and white matter tract imaging.[98-100] Fetal tractography with diffusion tensor imaging (DTI) has been used to delineate fetal sensorimotor tracts and corpus callosum as they develop in utero.[102] BOLD MRI has also been employed in the sheep model to demonstrate changes in fetal tissue oxygenation and display the fetal brain-sparing mechanism.[103] Recently, sophisticated postprocessing techniques and fMRI have been adapted to correlate macroscopic scale activations in the fetal brain with gestational age in vivo. This fMRI study was able to demonstrate the heterogeneous development of emerging human brain networks of the fetus in utero.[104]

In spite of new and exciting advances, these emerging technologies are still in experimental stages and should undergo rigorous investigations before their clinical applications become established.

CONCLUSIONS

In summary, MRI is emerging as an important tool for the evaluation of maternal complications in pregnancy, including the evaluation of atypical advanced ectopic pregnancies, suspected appendicitis, pelvic masses, hepatic and genitourinary diseases, and placenta accreta. In the fetus, it is an important adjunct to the sonographic diagnosis of suspected CNS lesions, in particular, isolated ventriculomegaly. Fetal MRI may provide additional information for certain intrathoracic lesions, aid in predicting prognosis in CDHs, and help delineate complex genitourinary abnormalities. MRI studies add important information in the care of potential fetal surgery candidates and may direct crucial decisions for delivery management, such as use of the EXIT procedure. Evaluation of the fetal heart, brain function, and fetal-placental physiology are possible and may become clinically applicable as new and improved technologies emerge.

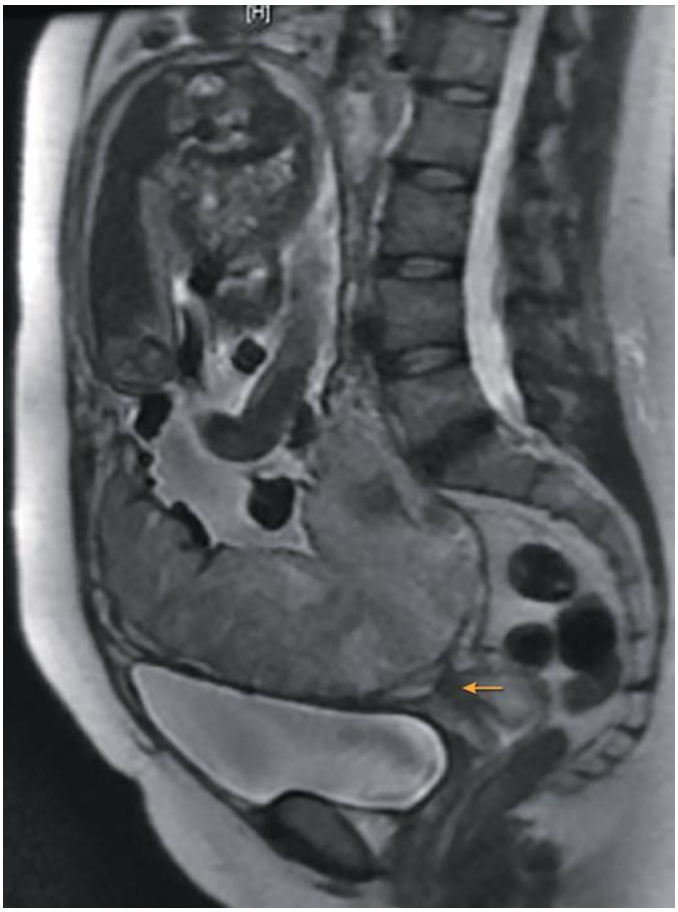

FIG 23-40 Central placenta previa at 34 weeks' gestation, history of one prior cesarean delivery. Sagittal T2-weighted imaging demonstrates a central placenta previa covering the internal os of the cervix (*arrow*). The placenta is homogeneous in signal intensity, normal in thickness, with an intact myometrial margin.

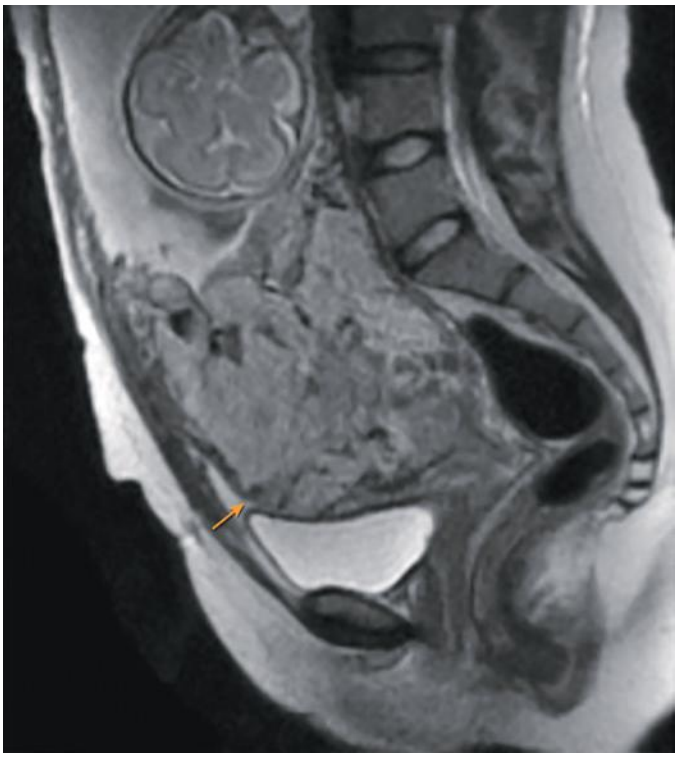

FIG 23-41 Placenta accreta at 25 weeks' gestation, history of two prior cesarean deliveries. Sagittal T2-weighted imaging demonstrates a central placenta previa. The placenta demonstrates heterogeneous signal intensity, with disordered T2-weighted dark intraplacental bands, with loss of normal placental-myometrial interface and bulging contour (*arrow*).

FIG 23-42 Placenta percreta at 27 weeks' gestation, history of two prior cesarean deliveries. Sagittal T2-weighted imaging demonstrates a thickened heterogeneous placenta with lobulation (*arrows*), mass effect and thickened dark nodular contour at the interface with the urinary bladder, and loss of the normal myometrial margin anteriorly (*arrowhead*).

FIG 23-43 Placenta percreta at 21 weeks' gestation, history of two prior cesarean deliveries, presenting with vaginal bleeding. Sagittal T2-weighted imaging demonstrates a markedly thickened, heterogeneous central placenta previa. There are intraplacental dark bands (*small arrows*), lobulation and mass effect with extension through the myometrium and superior urinary bladder surface (*bold arrow*), and involvement of the cervix (*arrowhead*).

Role of Sonography in Fetal Procedures

Ramen H. Chmait, Paulo Nassar de Carvalho, Robert H. Ball

SUMMARY OF KEY POINTS

- Sonography has transformed the field of fetal therapy and serves as the widely available, necessary diagnostic and intraoperative guidance tool.
- The potential benefits of open maternal-fetal surgery must be weighed against the potential maternal and fetal risks, which have the potential of complicating the index pregnancy and subsequent pregnancies.
- Minimally invasive fetal surgery is associated with much lower maternal risks and is the preferred surgical approach for most fetal conditions amenable to in utero therapy.
- Monochorionic diamniotic twin pregnancies are associated with significant morbidity and mortality risks, and close surveillance with serial sonograms is warranted.
- Prenatal repair of myelomeningocele (MMC) is associated with improved neurologic outcomes and increased likelihood of an ability to ambulate without need for orthotics.
- The role of fetal therapy in severe congenital diaphragmatic hernia (CDH) remains under investigational protocols.
- The finding of fetal hydrops should be investigated carefully for underlying conditions that are potentially treatable in utero, such as anemia, congenital pulmonary airway malformation (CPAM), primary pleural effusion, sacrococcygeal teratoma (SCT), and chorioangioma.
- The field of fetal therapy is rapidly evolving. With further improvement of surgical equipment and prenatal diagnostic modalities, access to the fetal-placental unit via minimally invasive methods will likely become increasingly refined and provide a conduit for additional novel treatments of the fetus.

OUTLINE

Intrauterine fetal transfusion for severe fetal anemia secondary to Rh hemolytic disease was the first invasive prenatal therapy performed in humans. It is difficult for current practitioners to imagine that initial efforts in the 1960s were performed in the absence of ultrasound guidance.[1] Abdominal palpation and intrauterine and intraperitoneal instillation of contrast agent followed by fluoroscopy were used to perform the first fetal transfusions. Sonography has transformed the field of fetal therapy and serves as the ubiquitous diagnostic and intraoperative guidance tool.

An accurate detailed anatomic diagnosis is critical in determining the appropriateness of fetal surgical intervention. Fetal malformations that are not isolated or are associated with aneuploidy or a syndrome have generally been excluded as candidates for intervention. However, over the last few years, with the development of less invasive therapeutic options as well as increased accommodation for parental choice, this paradigm has shifted (e.g., pleuroamniotic shunting for effusions and hydrops in a fetus with trisomy 21). Great effort should be made to confirm both the accurate diagnosis of a malformation and to determine if it is isolated or if other, possibly subtle associated abnormalities are present. In addition to targeted obstetric sonography, ancillary techniques to ensure full and accurate assessment include fetal echocardiography, magnetic resonance imaging (MRI), and genetic studies such as karyotyping and chromosomal microarray analysis. Counseling of patients and their families regarding the fallibility of the process, explaining that abnormalities initially believed to be isolated may not ultimately prove to be so, is a must.

In addition to its role as the primary tool for fetal diagnosis, sonography is routinely used during fetal interventions, both for instrument guidance and to monitor the fetus. In the following sections, fetal conditions amenable to in utero therapy as well as the role of

sonography in the diagnosis and treatment of various fetal abnormalities will be highlighted.

OPEN MATERNAL-FETAL SURGERY

Maternal laparotomy/hysterotomy was historically the primary approach to fetal therapy (Fig. 24-1). Over time there has been a shift away from this technique toward minimally invasive fetal interventions. The development of small-diameter endoscopes has enabled surgical access into the womb with less perturbation to the pregnancy. Still, maternal laparotomy/hysterotomy remains the primary surgical approach for in utero repair of MMC and is one treatment option for fetal lung lesions and teratomas.[2]

Early experience with open maternal-fetal surgery was plagued by significant immediate postoperative complications, including maternal pulmonary edema related to use of multiple tocolytics, intraoperative blood loss, and refractory preterm labor.[3] With refinement of surgical technique, anesthesia, and immediate postoperative care, the risks of open maternal-fetal surgery have decreased, although they still remain high compared to minimally invasive approaches. In 2011, the results of a randomized controlled trial comparing prenatal versus postnatal surgical repair of MMC (MOMS [Management of Myelomeningocele Study] trial) were published.[2] In 78 patients who underwent open fetal surgery, the rate of maternal pulmonary edema was 6%, blood transfusion 9%, and preterm delivery before 30 weeks' gestation 13%. The postprocedure rate of oligohydramnios was 21%, and the rate of placental abruption was 6%. With respect to maternal risk, uterine dehiscence at the time of delivery was noted in 10% of cases, with an additional 25% of cases described as having a very thin lower uterine segment. There were no maternal deaths or uterine ruptures. The procedure also has significant impact on future pregnancies, with a 28% risk of subsequent uterine dehiscence or rupture.[4] All patients who undergo open maternal-fetal surgery require cesarean delivery before the onset of labor for the index pregnancy and all future pregnancies. As an *American College of Obstetricians and Gynecologists Committee Opinion* states, "Maternal-fetal surgery is a major procedure for the woman and her fetus, and it has significant implications and complications that occur acutely, postoperatively, for the duration of the pregnancy, and in subsequent pregnancies."[5]

Patients contemplating open maternal-fetal surgery undergo lengthy discussion about the risks of the procedure, with an emphasis on differentiating the risks to the mother, the fetus, and the pregnancy.

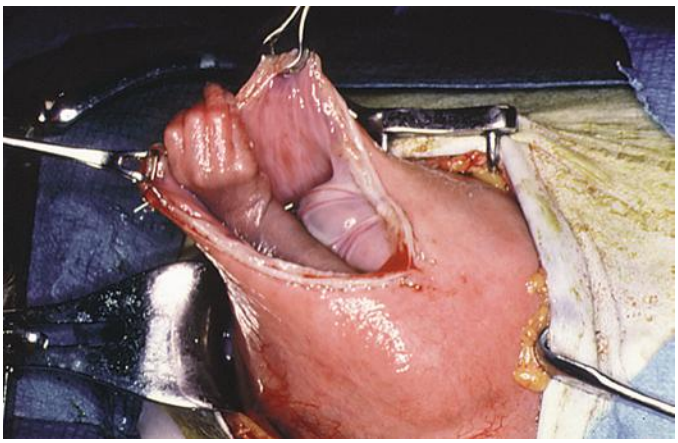

FIG 24-1 Photograph of operative laparotomy and hysterotomy in a Rhesus monkey. This early work paved the way for the ability to perform such procedures safely in the mother carrying a fetus with a variety of malformations.

The risks to the mother are similar to those for any major abdominal surgery, although in this case, there is no direct physical benefit to her. General anesthesia risks are relatively increased owing to the high levels of inhalational anesthetics required to achieve uterine quiescence.[6] In addition, there are risks associated with aggressive tocolytic therapy and bed rest in pregnant women, who are in a hypercoagulable state. The risks to the fetus are primarily vascular instability and hypoperfusion intraoperatively, leading to organ injury or death, and prematurity due to postoperative complications. The risks to the pregnancy are primarily preterm labor and preterm premature rupture of membranes (PPROM) resulting in preterm delivery. Infectious complications are rare, except when PPROM leads to prolonged latency. As mentioned previously, an important additional discussion point is that all subsequent deliveries, as well as the index pregnancy, must be via cesarean delivery. Data regarding future fertility are reassuring, with no documented increased incidence of infertility.[7] Another potential risk in subsequent pregnancies is placenta accreta; the site of a hysterotomy performed for fetal surgery in the second trimester is not the same as a lower segment cesarean delivery. Thus, placental implantation in a subsequent pregnancy is more likely to overlie the uterine scar, increasing the risk of accreta, and this factor must be considered in the sonographic evaluation of a subsequent pregnancy.

Sonography is used for guidance before the hysterotomy procedure in open maternal-fetal cases. Once general anesthesia and intubation of the patient have been initiated, and the sterile field is established, sonography is used to assess fetal lie, fetal location within the uterus, and position of the placenta. If needed, transabdominal manipulation is used to position the fetus such that the fetal surgical site is near the fundus. Laparotomy is then performed and the sonography transducer, covered in a sterile sleeve, is placed directly on the surface of the uterus. The location and edge of the placenta are identified, because this information is critical in determining where to safely enter the uterus. Generally, one wants to make the uterine incision as far from the placental edge as possible. Once the incision is made, and the amniotic fluid drains, the uterus shrinks. If the placental edge is too close to the uterine incision, there is a risk of bleeding and abruption, which cannot readily be controlled and, if significant, will usually necessitate immediate delivery for maternal safety.

Sonography is also used for transuterine monitoring of the fetal heart during the surgical repair of the MMC (Fig. 24-2). Following completion of the fetal intervention, the membranes and myometrium are closed with several layers of suture. A catheter is left in the uterine cavity to allow lactated Ringer solution to be infused together with antibiotics. Sonography is used to determine the volume of "amniotic" fluid instilled to achieve a low-normal level, aiming to minimize stress on the suture line.

Postoperative management generally involves 24 hours of intravenous tocolysis with magnesium sulfate as well as maintenance with oral indomethacin for a total of 48 hours. Antibiotic "prophylaxis" is continued for 24 hours. Typically, ultrasound monitoring to evaluate the fetus, amniotic fluid volume, cervical length, and ductal patency is performed daily. Hospital discharge generally occurs 4 to 5 days after surgery. If the patient is stable without complications, long-term monitoring with follow-up sonograms usually involves weekly evaluation.

MINIMALLY INVASIVE MATERNAL-FETAL SURGERY

Minimally invasive fetal surgery generally refers to all invasive fetal interventions performed without the need for hysterotomy. Depending on the indications and goals of the procedure, minimally invasive fetal therapy may be performed under ultrasound guidance alone, such as

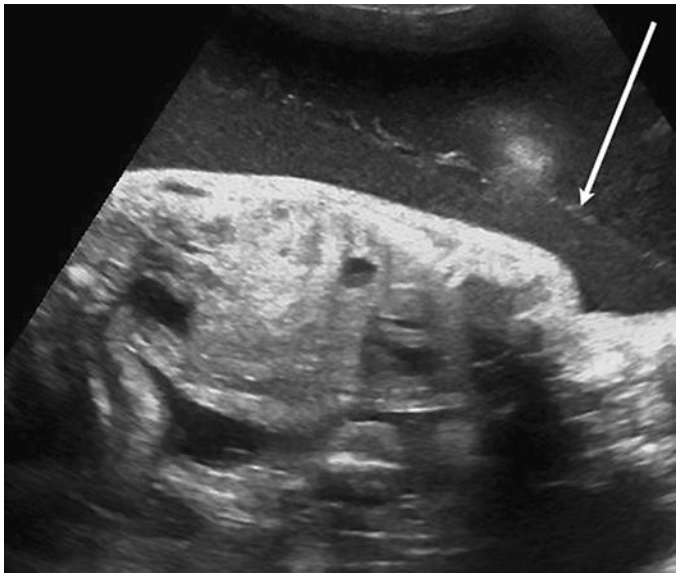

FIG 24-2 Chorioamniotic separation noted, with amniotic fluid seen on either side of the membrane (*arrow*), following fetal procedure.

FIG 24-3 EXIT (ex utero intrapartum therapy) procedure. Photograph obtained following reversal of fetal tracheal occlusion for congenital diaphragmatic hernia demonstrates intubation of the neonate while placental umbilical circulation is maintained.

TABLE 24-1 List of Fetal Conditions Amenable to Minimally Invasive Fetal Treatment

Condition	Procedure
Needle and Shunts	
Alloimmunization	Transfusion
Bronchopulmonary sequestration	Interstitial ablation of feeding vessel
Congenital pulmonary airway malformation	Thoracoamniotic shunt or sclerotherapy
Critical aortic stenosis	Balloon valvuloplasty
Iatrogenic preterm premature rupture of fetal membranes	Amniopatch
Lower urinary tract obstruction	Vesicoamniotic shunt
Pleural effusion	Thoracoamniotic shunt
Pericardial teratoma with effusion	Pericardioamniotic shunt
Symptomatic polyhydramnios	Amnioreduction
Operative Fetoscopy	
Amniotic band syndrome	Lysis of constriction bands
Chorioangioma	Ablation of feeding vessels
Congenital diaphragmatic hernia	Tracheal occlusion
Myelomeningocele	Fetoscopic patch or closure
Twin reversed arterial perfusion sequence	Umbilical cord occlusion
Twin-twin transfusion syndrome	Laser photocoagulation of communicating vessels
Vasa previa (type II)	Laser occlusion of vasa previa
Sacrococcygeal teratoma	Interruption of vascular supply

needle or shunt placement procedures, or may require a combined approach with both sonography and endoscopy, also known as operative fetoscopy (Table 24-1).

Ultrasound-guided needle interventions include intrauterine transfusion (IUT) and amnioreduction. Shunts are used when indicated for chronic drainage of abnormal, fluid-filled fetal cavities, organs, and cysts. A wide variety of fetal conditions have been surgically managed via operative fetoscopy.[8,9] This technique, which utilizes a 3.3-mm or smaller endoscope, is associated with significantly lower risk of preterm birth, neonatal morbidity, and maternal morbidity as compared to open fetal surgery.[3] There is a lower rate of preterm labor and of PPROM. The length of hospitalization and time until return to normal maternal activity are also shorter. In addition, patients who have undergone minimally invasive fetal therapy do not require cesarean delivery for the index pregnancy or for future pregnancies.

Minimally invasive procedures are performed under local or regional anesthesia. Depending on the gestational age and the protocols of the medical center, the procedure may be performed in the surgical operating room, labor and delivery unit, or ultrasound examination suite. Operative fetoscopy requires simultaneous utilization of ultrasound and fetoscopic imaging. Access to the amniotic cavity is achieved with thin-walled semiflexible plastic cannulas and either a plastic blunt-ended obturator using the Seldinger technique or sharp trocars. Specifics have been reviewed in several texts.[8] Ultrasound imaging is used to identify an appropriate entry point and then to direct the instrument into the amniotic cavity, avoiding the placenta and the fetus and maternal organs such as bowel and bladder. The obturator/trocar is replaced by the fetoscope. Sonography is still used to direct the scope within the uterus, because its field and depth of view can be relatively limited. At the conclusion of the procedure, the sheath is removed. As the puncture is only 1 to 3 mm in size, the uterine wall spontaneously closes with minimal risk of amniotic fluid leak from the insertion site. In many cases, little or no tocolytic medication is needed, and patients are generally discharged from the hospital within 24 hours following the procedure.

EX UTERO INTRAPARTUM THERAPY

The ex utero intrapartum therapy (EXIT) procedure is a specialized surgical procedure performed at the time of delivery. It was first developed in the early 1990s to permit the controlled reversal of tracheal occlusion performed in utero for the treatment of severe CDH (Fig. 24-3).[10] This procedure is utilized in cases in which prenatal ultrasound findings predict significant neonatal airway compromise, resulting from lesions such as large oral or neck masses, or congenital

high airway obstruction syndrome (CHAOS). Maternal general endotracheal anesthesia with high levels of an inhalational agent is provided to maintain uterine quiescence. The fetal head and neck are delivered through a low transverse uterine incision, protecting the umbilical cord and maintaining uteroplacental blood flow for an extended period of time. This allows for the performance of a surgical procedure or life-saving intervention while the fetus continues to be oxygenated and ventilated through placental support. The EXIT procedure has been used to perform fetal bronchoscopy, laryngoscopy, tracheostomy, cannulation for extracorporeal membrane oxygenation (ECMO), and even resection of a lung mass or lobectomy.[11]

Once the uterus is exposed, intraoperative ultrasound assessment is required to confirm placental location and fetal position. The hysterotomy is performed, avoiding placental margins along the lower uterine segment. Preventing complete decompression of the uterus is important to reduce the likelihood of placental separation. This can be achieved by keeping the lower part of the fetal body within the uterus and by performing continuous amnioinfusion with a catheter. The EXIT procedure is not a simple variation of a cesarean delivery and should be carried out in specialized centers. The presence of a complete multidisciplinary team is required to perform appropriate preoperative evaluation, including discussion of the fetal diagnosis, counseling, and planning for the EXIT procedure. The intraoperative team includes an anesthesiologist, maternal-fetal medicine specialist, pediatric surgical subspecialist(s), and operating room nursing assistants. Neonatologists and a second complete operative team should be prepared to receive the newborn in the event that corrective measures performed while still on umbilical circulation are unsuccessful.[11]

CONDITIONS AMENABLE TO FETAL THERAPY

Complicated Monochorionic Twins

Monochorionic twin gestations are associated with a high risk of significant perinatal morbidity and mortality as compared to dichorionic twins and singletons.[12,13] This increased risk is partially attributed to the unique placental vascular communications present in monochorionic twin gestations. Because the circulatory systems communicate, the death of one monochorionic twin may result in acute hypotension in the survivor; this hemodynamic instability may result in subsequent death or injury to the co-twin.[14] A systematic review of 28 primary studies, including over 4500 twin pregnancies with in utero demise of one twin, reported that the rate of monochorionic versus dichorionic co-twin demise was 12% versus 4%, and the rate of neurologic abnormality in the surviving co-twin was 18% versus 1%, respectively.[15] Placental vascular communications are also thought to be important factors in the development of twin-twin transfusion syndrome (TTTS), twin anemia-polycythemia sequence (TAPS), and twin reversed arterial perfusion (TRAP) sequence.

Placental share is an additional factor with significant impact on perinatal outcomes in monochorionic twins. Marked unequal partitioning of the placental mass may be manifest clinically by selective fetal growth restriction (sFGR). Finally, the risk of structural anomalies is increased in monochorionic twins, including in particular those involving the central nervous system as well as cardiac and gastrointestinal tract abnormalities. Over 80% of such anomalies are discordant (only one twin affected).[16,17] Some of these anomalies are associated with a high risk of fetal demise if managed expectantly. Even without the previously described complications, monochorionic twins are at an increased risk of neurodevelopment impairment. In one study, Ortibus and colleagues prospectively followed 136 monochorionic twin pregnancies from the first trimester through infancy.[18] After excluding pregnancies complicated by TTTS, discordant growth, intrauterine fetal demise (IUFD), and prematurity (birth before 32 weeks' gestation), the authors found that the 160 remaining infants had a 7% risk of neurodevelopmental impairment and a 0.6% risk of cerebral palsy.

Complications affect approximately 20% of monochorionic twins, and, thus, accurate diagnosis and close surveillance of these pregnancies are recommended.[19] Chorionicity should be established as early as possible in the pregnancy.[20] First and early second trimester ultrasound examination has been shown to be highly accurate in determining chorionicity and should be performed to allow for appropriate triage and management of the pregnancy.[21] Close surveillance of monochorionic twins should include frequent sonograms, typically performed every 2 weeks, to monitor amniotic fluid volumes and fetal bladders.[22,23] Cervical length assessment and Doppler interrogation should be performed, if necessary. If TTTS, TAPS, TRAP, sFGR, or discordant structural anomalies are suspected, the patient should be referred to an experienced center.

Twin-Twin Transfusion Syndrome

TTTS occurs in approximately 10% of monochorionic twins.[19] Most experts believe that TTTS develops in monochorionic twin pairs as a result of unbalanced net flow of blood through vascular communications in the shared placenta.[24,25] A series of pathophysiologic changes ensue from the net shunting of blood from one twin (donor) to the other twin (recipient), resulting in hypovolemia and oliguria in one, and volume overload and polyuria in the other (Fig. 24-4A). These hemodynamic derangements result in a cascade of physiologic changes[26,27] leading to donor twin oligohydramnios, recipient twin polyhydramnios, and characteristic anatomic and arteriovenous flow alterations that can be identified by sonography with Doppler.[28-30] Without intervention, early severe TTTS has a very high rate of perinatal injury or death.[31]

The diagnosis of TTTS is based on the following in utero ultrasound-based criteria: (1) monochorionicity and (2) single maximal vertical pocket (MVP) of amniotic fluid less than 2.0 cm on one side of the dividing membrane, and MVP of more than 8.0 cm on the other side.[28] Once the diagnosis has been established, the syndrome may be staged according to the Quintero staging system (Table 24-2). The establishment of diagnostic criteria and the classification of TTTS by Quintero and associates.[28] have allowed researchers to compare outcome data following various therapeutic interventions and to predict perinatal survival after treatment.[32]

The perinatal mortality rate of expectantly managed TTTS has been reported to be as high as 95%.[31] Of the various treatment approaches that have been considered for TTTS, those with the best-reported outcomes are serial amniocenteses and selective laser photocoagulation of communicating vessels (SLPCV) via operative fetoscopy (Fig. 24-4B). Serial amniocentesis (or amnioreduction) involves drainage of amniotic fluid from the polyhydramniotic recipient sac using vacuum-assisted devices attached to an 18- to 20-gauge spinal needle. The volume of amniotic fluid that should be withdrawn has not been standardized, although usually the MVP of amniotic fluid in the recipient sac is reduced to approximately 8 cm or less. Serial amniocenteses serve to significantly reduce the amount of amniotic fluid in the recipient sac, thereby diminishing overall uterine distention.

SLPCV is performed via operative fetoscopy, allowing direct visualization of the vessels on the placental surface. Once mapping of vascular communications has been performed, those vessels are occluded using laser energy (Figs. 24-5 and 24-6). The basic principle of SLPCV is that the causative inter-twin vascular communications are ablated, thus treating the underlying pathogenic cause of this syndrome.[33] With laser surgery, the circulations in a shared placenta are

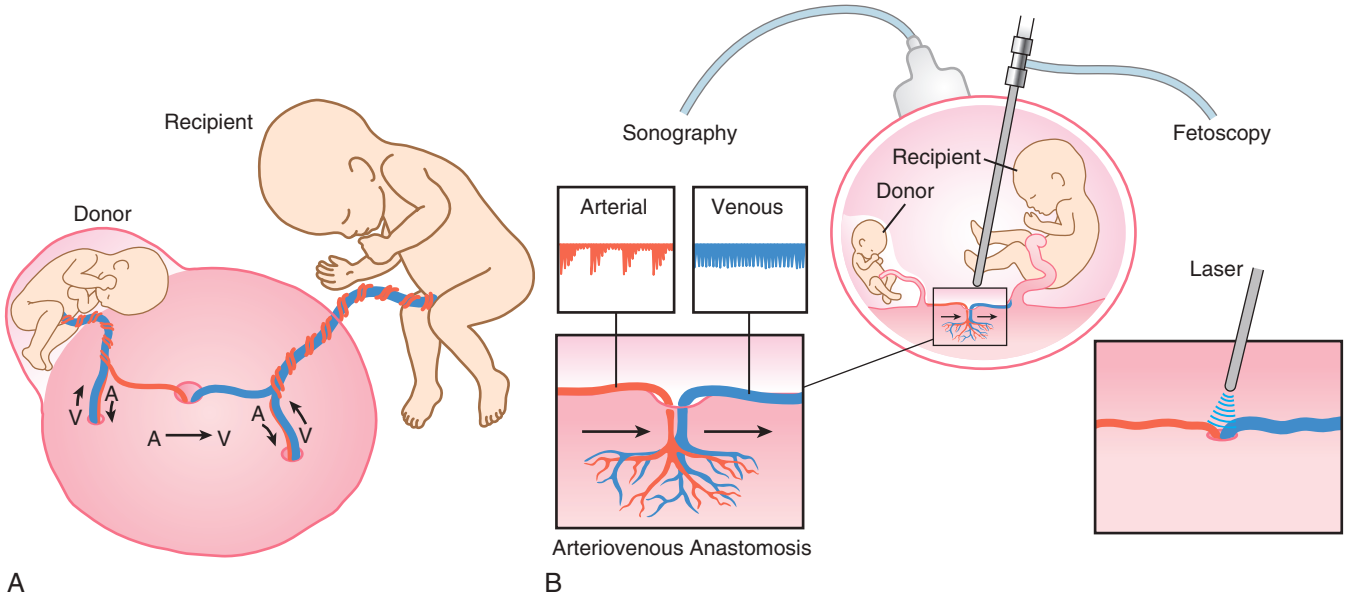

FIG 24-4 A, Monochorionic twin placenta, demonstrating arteriovenous vascular (A → V) connection. **B,** Diagram illustrating sonographic guidance for laser ablation for twin-twin transfusion syndrome. Doppler interrogation is used to identify arterial and venous connections, and laser energy is applied to the site of anastomosis.

TABLE 24-2 Staging of Twin-Twin Transfusion Syndrome

Stage	Polyhydramnios/ Oligohydramnios*	Persistently Empty Bladder in Donor	Abnormal Doppler†	Hydrops	Demise
I	X				
II	X	X			
III	X	X	X		
IV				X	
V					X

*Polyhydramnios is defined as deepest vertical pocket 8 cm or greater; oligohydramnios is defined as deepest vertical pocket 2 cm or less.
†At least one of the following: (1) umbilical artery absent/reserved end-diastolic flow, (2) absent/reversed end-diastolic flow in the ductus venosus, (3) pulsatile umbilical venous flow.
Modified from Quintero RA, Morales WJ, Allen MH, et al: Staging of twin-twin transfusion syndrome. J Perinatol 19:550, 1999; and Taylor MJO, Jolly M, Wee L, et al: Validation of the Quintero staging system for twin-twin transfusion syndrome. Obstet Gynecol 100:1257, 2002.

divided, functionally converting it to a dichorionic twin pregnancy, with improved perinatal outcomes.[34]

After the introduction of laser ablation as a treatment option for TTTS, the Eurofetus group conducted a randomized controlled trial that compared serial amniocentesis to SLPCV.[35] Pretrial power analysis projected the need for a total of 172 patients to demonstrate a significant difference in outcomes between the two treatment arms. However, after enrollment of 142 patients, interim analysis revealed that the perinatal survival rate of at least one twin was 51% (36/70) in the amnioreduction arm versus 76% (55/72) in the laser therapy arm. Based on this statistically significant difference, the study was halted. In addition, in the laser group, pregnancy duration was approximately 4 weeks longer (33 weeks vs. 29 weeks, $P = 0.003$). The amnioreduction group had a significantly higher rate of neurologic complications (14% vs. 6%, $P = 0.02$), and this difference persisted at the 6-month follow-up evaluation.

Most subsequent studies have confirmed that SLPCV is the optimal treatment for TTTS.[36] Intervention with laser surgery has resulted in survival rates for at least one twin ranging from 65% to 93% and dual survival rates ranging from 18% to 62%.[37] Although several factors may influence perinatal outcomes in laser-treated TTTS patients, one important consideration is disease severity.[38] Knowledge of perinatal outcomes of TTTS pregnancies treated with laser, stratified by Quintero stage, may facilitate patient selection and counseling. In a series of 682 consecutive cases of TTTS treated via SLPCV, there was a 91% perinatal survival rate of at least one twin and 67% survival rate of both twins.[39] Of note, perinatal survival of at least one fetus has been reported to be independent of Quintero stage, whereas dual twin survival does appear to differ based on stage. This is predominantly because stage III pregnancies are associated with decreased donor twin survival (Table 24-3), particularly in those with growth restriction of the donor. These pregnancies are nearly twice as likely as those without growth restriction to suffer in utero demise of the donor.[40] The average gestational age at delivery following laser surgery is approximately 33 weeks, with 10% delivering between 24 and 28 weeks' gestation.[41] The laser surgical technique has undergone recent modifications that may further improve perinatal outcomes.[42,43]

The surgical goal of SLPCV is to completely occlude all placental vascular connections between the twin pair. A missed or inadequately lasered vessel, referred to as a residual anastomosis (RA), may be associated with adverse perinatal outcomes such as persistent or reversed TTTS or TAPS.[44-46] Pathologic confirmation of complete ablation of

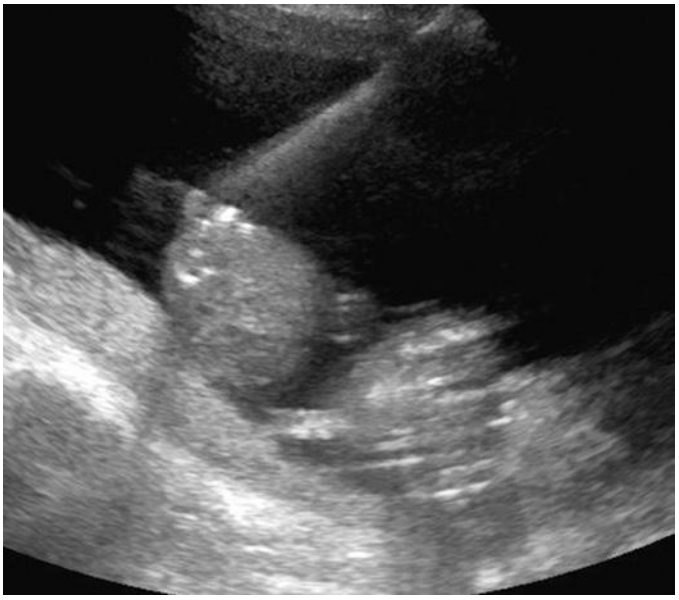

FIG 24-5 Laser for twin-twin transfusion syndrome. Fetoscope can be seen adjacent to twin A in the polyhydramniotic sac. The placenta is posterior.

vascular communications can be ascertained via ex vivo placental injection studies in cases without placental maceration related to IUFD.[44] RA after SLPCV has been reported to be as low as 4%[47] to 5%,[48] although some studies have reported frequencies of RA ranging from 32%[44-46] to as high as 75%[49] of cases. In a 2014 trial investigating laser coagulation of the entire vascular equator, the rate of RA was still 19%.[50] The wide range of RA rates in these studies has been attributed to the laser technique employed and to the method of placental evaluation.[45]

Despite evidence that SLPCV improves neonatal survival and reduces morbidity, cerebral injury is not fully prevented. Periventricular infarction, hemorrhagic injury, and ischemic white matter damage have been detected prenatally in fetuses treated with laser surgery for TTTS.[51] The incidence of cerebral damage may be underestimated, because neurodevelopmental impairment and intellectual disability may only manifest several months or years after birth.[52,53] Thus, a major concern for clinicians and parents is the rate of neurologic impairment in survivors. A systematic review found that the risk of neurodevelopmental impairment after laser therapy for TTTS is about 11%.[54] Cerebral palsy was the most frequent diagnosis, accounting for about 40% of abnormal neurologic outcomes.[54] In a cohort of 100 TTTS survivors treated with in utero laser surgery, formal neurodevelopmental testing, performed at 2 years of age, revealed normal range mean Battelle Developmental Inventory, 2nd edition (BDI-2)[11] scores of 101.3 (standard deviation [SD] = 12.2) for the entire cohort.[55] The overall rate of neurodevelopmental impairment, defined as blindness, deafness, cerebral palsy, or BDI-2 score less than 70, was 4%.[55]

Selective Fetal Growth Restriction

sFGR, defined as one twin with an estimated fetal weight (EFW) below the 10th percentile for gestational age, is reported to occur in at least 10% of monochorionic twin pairs.[56] It is important to note that significant growth discordance with or without amniotic fluid discordance is not required for the diagnosis of sFGR. sFGR appears to be distinct from TTTS, although there may be significant overlap in these conditions.[57] It is believed that sFGR develops because of unequal placental share, with the sFGR fetus perfusing a smaller portion of the single shared placenta.[58]

Although disproportion in placental territories allocated to monochorionic twin pairs appears to be the primary contributor to sFGR, the presence of vascular communications plays an important role in

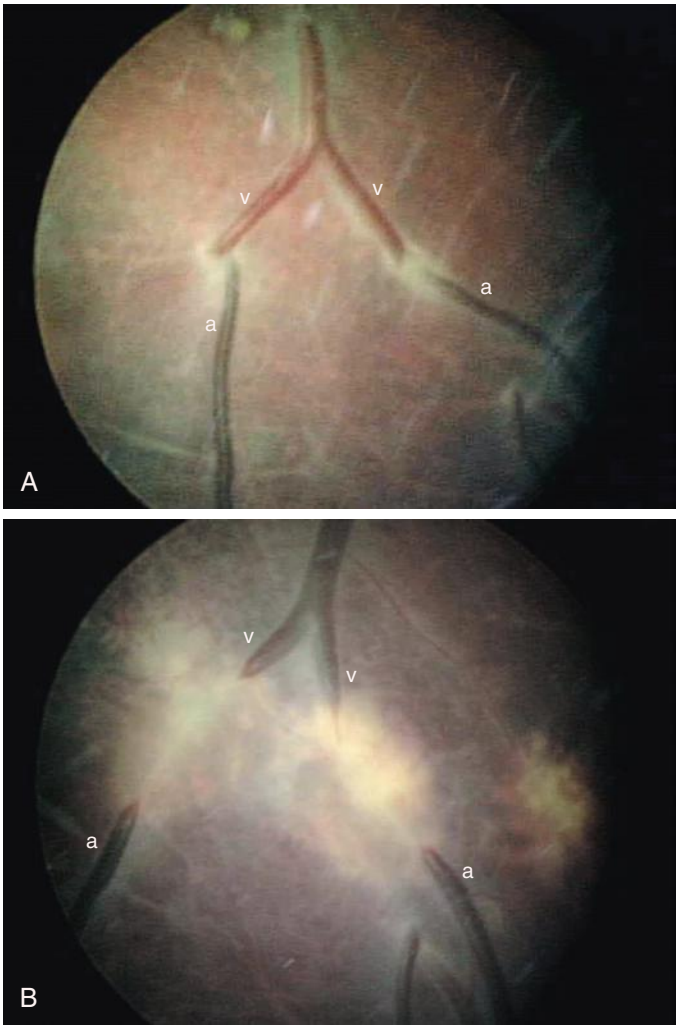

FIG 24-6 Fetoscopic image of the fetal surface of a monochorionic twin placenta in the region of the vascular equator. Two placental arteries (a) from the donor twin communicate with placental veins (v) of the recipient twin, shown before (**A**) and after (**B**) laser photocoagulation.

TABLE 24-3 Stage-Based Perinatal Survival After Laser Surgery for Twin-Twin Transfusion Syndrome

	Stage I (*n* = 114)	Stage II (*n* = 177)	Stage III (*n* = 328)	Stage IV (*n* = 63)
At least 1 survivor	92%	93%	88%	92%
Dual survival	79%	76%	59%*	68%

*Decreased dual twin survival in Quintero stage III patients predominantly from decreased donor twin survival in cases complicated by severe growth restriction.
Modified from Chmait RH, Kontopoulos EV, Korst LM, et al: Stage-based outcomes of 682 consecutive cases of twin-twin transfusion syndrome treated with laser surgery: the USFetus experience. Am J Obstet Gynecol 204(5):393.e106, 2011.

perinatal outcome.[56] There is increased likelihood of spontaneous in utero demise of the sFGR fetus, which may result in concomitant demise or severe neurologic handicap of the co-twin.[15] Following demise of the sFGR twin, sudden redistribution of blood flow via placental vascular connections can lead to acute hypotension in the surviving co-twin. Thus, the larger (appropriately grown for gestational age, AGA) twin may face an increased risk of neurodevelopmental impairment related to co-twin demise or prematurity.[59] One observational study monitored 84 consecutive monochorionic twin pairs with discordant amniotic fluid that did not meet criteria for TTTS and showed a 60% (23/38 fetuses) overall survival rate in the subgroup that met criteria for sFGR.[60] In another study of 17 pregnancies with sFGR that were managed expectantly, the survival rate of the sFGR twin was 59%.[61] The rate of short-term intracranial injury (including periventricular leukomalacia, intraventricular hemorrhage, and ventriculomegaly) in this group of patients was 14%. In a separate review, the overall incidence of severe cerebral injury in survivors of pregnancies complicated by sFGR was found to be approximately 8%.[59] Factors associated with poor neurologic outcomes included abnormal umbilical artery Doppler waveforms, intrauterine co-twin demise, and earlier gestational age at birth.[59]

The understanding of the pathophysiologic changes of sFGR has advanced significantly in recent years. A staging system based on umbilical artery Doppler findings was proposed by Gratacos and colleagues in 2007 and is now used by some centers.[56] The authors classified monochorionic twin pregnancies complicated by sFGR into three categories based on umbilical artery Doppler waveforms of the sFGR twin, as follows: type I with persistent forward diastolic flow; type II with persistent absent or reversed end-diastolic flow (AREDF); and type III with intermittent absent or reversed end-diastolic flow (iAREDF). These three groups are associated with different patterns of placental anastomoses and with different clinical courses, which can influence prenatal monitoring and management.

In type I sFGR, the median age at diagnosis is approximately 20 weeks' gestation. In utero deterioration is not common in this group. Once this diagnosis is made, umbilical artery Doppler findings in the sFGR twin usually remain normal until delivery.[58] It is reasonable to maintain close surveillance with weekly sonograms with Doppler, and to escalate follow-up as necessary. There appears to be no benefit from fetal intervention in this group, and it is reasonable to plan delivery at 34 to 35 weeks' gestation in the absence of obstetric indications for earlier delivery.[62]

At this time, the optimal treatment strategy for monochorionic twin pregnancies complicated by sFGR type II, with persistent AREDF in the umbilical artery, is not clear. Expectant management requires close monitoring of the pregnancy with sonography or fetal heart rate monitoring, often in the hospital setting, from 24 weeks' gestation until delivery, aiming to prolong the pregnancy yet intending to deliver the twins prior to demise of the growth-restricted fetus. The umbilical artery Doppler findings cannot be used to predict imminent fetal demise. Doppler interrogation of the ductus venosus (DV) appears to be the best adjunct for fetal surveillance, as is done in singleton pregnancies complicated by FGR.[62] Observation of absent or reversed a-wave flow on DV waveforms should prompt the clinician to consider delivery or fetal intervention, depending on gestational age. If the DV waveform remains normal, the patient can be followed once or twice a week. Expectant management is associated with a very high (nearly 100%) rate of prematurity, with risk of neurologic injury to the AGA twin. Intervention may be considered in cases of type II sFGR, particularly when the diagnosis is made prior to viability. One therapeutic option is to perform operative fetoscopic ablation of all intertwin vascular communications, thereby creating a "functionally" dichorionic twin gestation.[61] The surgical intervention is similar to the laser technique used for treatment of TTTS, although the procedure may be technically more difficult. Quintero and coworkers performed a feasibility study that showed a trend toward decreased rate of neurologic deficits in the AGA twin (14% rate of neurologic injury in the expectantly managed group versus 0% in the SLPCV group).[61] Chalouhi and associates found that SLPCV resulted in a survival rate of 52% in sFGR twins and 74% in AGA twins.[63] As an alternative to fetoscopic SLPCV, umbilical cord occlusion (UCO) or radiofrequency ablation (RFA) of the sFGR twin has been offered.[58] These techniques aim to protect the AGA twin from potential injury or death resulting from spontaneous in utero demise of the sFGR co-twin. These approaches, by definition, result in demise of the sFGR fetus. Selective reduction in these circumstances has resulted in survival rates of the AGA co-twin of 74%.[63]

Type III sFGR is characterized by iAREDF in the umbilical artery of the sFGR twin. The umbilical artery Doppler waveform pattern displays cyclic changes during diastole, such that there is alternating positive AREDF.[62] This unique Doppler waveform suggests the presence of a large arterioarterial (AA) anastomosis within the shared placenta, coursing between the twins' cord insertion sites.[64] Outcomes of pregnancies with evidence of type III sFGR may be difficult to predict.[56] Unexpected IUFD has been reported in approximately 15% of cases, with sudden death documented hours after a normal Doppler ultrasound examination.[65] Another study has reported that the AGA twin has an elevated risk of postnatal white matter lesions, even if the smaller twin is born alive.[66] Thus, management of these pregnancies is challenging. Fetoscopic laser ablation of vascular connections has been attempted in this population, but the results were not favorable compared to expectant management.[67] SLPCV could not be completed in over 10% of cases owing to technical difficulties, and overall perinatal survival rate was 64% in the laser group compared to 86% in those managed expectantly. However, it should be noted that the prevalence of leukomalacia in the larger infant was 1/17 (5.9%) in the laser group versus 4/28 (14.3%) in the expectantly managed group.[67]

Late-onset sFGR, referring to the development of growth restriction of one twin after 26 weeks' gestation, is another previously described subgroup of complicated monochorionic twin gestations.[68] The prevalence of late-onset sFGR among monochorionic twin pairs has been reported by Lewi and colleagues to be 6.3% in a cohort of 208 pregnancies.[68] Mean gestational age at delivery was 35 weeks and 38% of infants met postnatal diagnostic criteria for TAPS. There was one intrauterine death.[68]

Twin Anemia-Polycythemia Sequence

TAPS is an atypical form of TTTS that also appears to be caused by a net transfer of blood from one monochorionic twin to the other. TAPS is characterized by large inter-twin hemoglobin differences in the absence of oligohydramnios and polyhydramnios. This condition may develop spontaneously (2-6% of monochorionic twins) or as a result of residual vascular communications following laser surgery (2-13% of monochorionic twins who have had laser).[44,69-72] Unlike TTTS, which is likely due to more acute hemodynamic imbalances, the pathogenesis of TAPS has been attributed to chronic net transfusion from one twin to the other, presumably at a slow enough rate to allow for hemodynamic equilibration.[73,74] TAPS may result in severe anemia in one twin and polycythemia in the other (Fig. 24-7). Placental pathologic studies have shown that pregnancies complicated by TAPS have relatively few, small-caliber (<1 mm) arteriovenous communications as compared to larger arteriovenous communications seen in placentas from pregnancies affected by classic TTTS.[74]

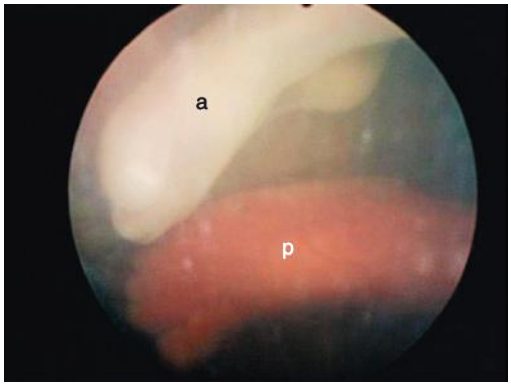

FIG 24-7 Fetoscopic image demonstrating striking discordance in coloration between monochorionic twin fetuses with TAPS (twin anemia polycythemia syndrome). The red foot belongs to the polycythemic (p) twin and the pale white foot belongs to the anemic (a) twin.

Although there is not consensus in the literature, the antenatal definition of TAPS usually requires that the middle cerebral artery (MCA) peak systolic velocity (PSV) measures greater than 1.5 multiples of the median (MoM) in the anemic twin and less than 1.0 MoM in the polycythemic twin, and that the pregnancy is not affected by oligohydramnios or polyhydramnios.[69] An antenatal staging system has been proposed, and although it has not been validated clinically, it is useful to facilitate communication between practitioners.[74] Stage 1 is defined as MCA PSV measurement greater than 1.5 MoM in one twin and less than 1.0 MoM in the other, without evidence of fetal compromise. Stage 2 is defined as MCA PSV greater than 1.7 MoM in one twin and less than 0.8 MoM in the other, also without signs of fetal compromise. Stage 3 requires fulfillment of stage 1 or 2 criteria, with additional finding of critically abnormal Doppler waveforms (defined as AREDF in the umbilical artery, pulsatile flow in the umbilical vein, or reversed a-wave flow in the DV) in the anemic twin. Stage 4 includes hydropic changes in the anemic twin, whereas stage 5 is defined as demise, preceded by TAPS, of one or both twins. Postnatal diagnostic criteria and classification, described by the same investigators, requires an inter-twin hemoglobin difference of more than 8 g/dL and at least one of the following: reticulocyte count ratio more than 1.7 and placental pathologic findings of only small (<1 mm diameter) inter-twin vascular communications.[74]

Given the relatively low prevalence and lack of clinical awareness of this condition, the natural history of TAPS is unclear and decision making regarding antenatal treatment is controversial. Case series have reported expectant management with timed delivery,[69,75-77] intrauterine fetal transfusion,[78] and fetoscopic laser treatment.[77-82] Favorable outcomes have been described in pregnancies with uncomplicated TAPS using expectant management or other conservative measures, particularly in those diagnosed in the third trimester. Spontaneous resolution of TAPS has also been reported.[83] However, TAPS may progress and result in perinatal death or neurologic injury.[72,76] Polycythemia can lead to vascular sludging, which may lead to cerebral venous thrombosis resulting in intraventricular hemorrhage and parenchymal infarction, and fetal anemia may affect cerebral oxygenation resulting in hypoxic-ischemic cerebral injury.[76] Timed delivery, on the other hand, must be weighed against the risks of prematurity. Although survival rates of 75% can be obtained with expectant management, it has been suggested that treatment with IUT or laser surgery can increase survival to over 90%.[74] A recent 2014 study has reported that neurodevelopmental impairment and cognitive delay were found in almost 20% of children surviving posttreatment for TAPS, with the lowest cognitive scores detected in the subgroup of TAPS survivors treated with IUT.[84] It is not known whether survivors of spontaneously resolved TAPS face a similar risk for neurodevelopmental impairment or cognitive delay.

IUT has been suggested as a temporizing, symptomatic treatment of the anemic twin in a pair affected by TAPS. However, there is concern that transfused blood may worsen symptoms in the recipient (polycythemic) twin, which might then develop iatrogenic complications related to hyperviscosity, such as limb necrosis.[72] Two cases have exhibited spontaneous placental vascular thromboses, possibly because of hyperviscosity in the polycythemic twin.[82] Thus, IUT (without definitive laser surgery) may exacerbate the risk of vascular thromboses and other complications. The use of intrauterine partial exchange transfusion may help reduce the risk of severe polycythemia complications.[85] On the other hand, partial exchange transfusion in the neonate has been associated with suboptimal coagulation with subsequent disseminated intravascular coagulation, so this procedure is not without risk.[76]

Fetoscopic laser surgery is the only definitive treatment for TAPS. Laser surgery may be beneficial in pregnancies complicated by TAPS, particularly in high-risk cases in which additional ultrasound findings suggest fetal compromise. However, laser surgery may be technically more challenging in TAPS than in TTTS given the absence of polyhydramnios, absence of a "stuck" twin, slack inter-twin membrane, and difficulty visualizing the very small communicating vessels. Nevertheless, reports of fetoscopic laser treatment for TAPS have indicated that this intervention can be effective.[77-82,86] Further research is needed to establish selection criteria for in utero treatment of TAPS, possibly based on the presence of coexisting amniotic fluid discordance; Doppler waveform abnormalities in the umbilical artery, umbilical vein, or DV; sFGR; hydrops fetalis; cervical insufficiency; or gestational age at onset.

Twin Reversed Arterial Perfusion Sequence

TRAP sequence affects approximately 1% of monochorionic twins, or about 1 in 35,000 pregnancies.[87] The presence of direct artery-to-artery and vein-to-vein placental anastomoses allows one fetus (pump twin) to perfuse the other anomalous fetus, typically referred to as an acardiac fetus (perfused twin). The term *acardiac fetus* is at times a misnomer, as the perfused twin may rarely have a rudimentary heart. The perfused twin is supplied with blood flowing in a reversed direction (the umbilical artery delivers blood to the perfused twin and the umbilical vein carries blood away, toward the placenta). Because of the direct artery-to-artery anastomosis, the deoxygenated blood from the pump twin is carried to the perfused twin through that twin's umbilical artery or arteries. The perfused twin, typically with no functional beating heart, has severe maldevelopment of cephalic, thoracic, and upper extremity structures, which is not compatible with postnatal survival.

Ultrasound diagnosis of TRAP sequence can be made in the first and early second trimesters, particularly with the aid of color and spectral Doppler techniques.[88] Note that the lack of a beating heart within the perfused twin may be misinterpreted as co-twin demise. In some cases, the presence of a rudimentary heart may be confusing. In this setting, it is important to interrogate the cord insertion site at the anterior abdominal wall of the anomalous fetus to assess for reversal of flow direction in the umbilical artery (Fig. 24-8).

The risk of pump twin demise is as high as 50% to 75% due to the hemodynamic burden and volume overload.[89] Risk factors for poor perinatal outcome include polyhydramnios in the pump twin, critically abnormal Doppler waveforms, hydrops, or a large perfused anomalous twin measuring greater than 50% of the pump twin's estimated weight.[90] If at least one of these factors is present between 16

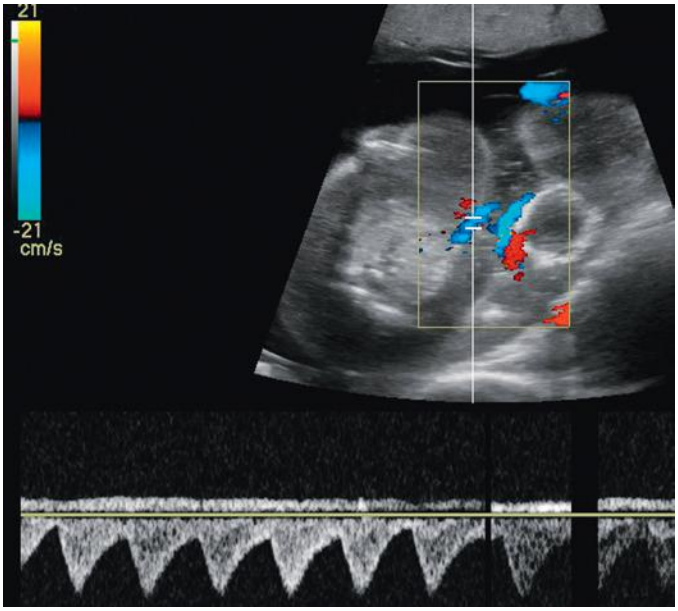

FIG 24-8 Twin reversed arterial perfusion (TRAP) sequence. Transaxial ultrasound image of the acardiac twin at the level of the umbilical cord insertion. Color and spectral Doppler interrogation demonstrates reversed pulsatile arterial flow (in *blue*), directed away from the transducer toward the acardiac fetus. This Doppler ultrasound finding is pathognomonic of TRAP sequence.

and 26 weeks' gestation, the patient should be offered the option of intervention to achieve UCO of the perfused twin. In one study of 74 cases complicated by TRAP sequence, high-risk factors were defined as at least one of the following ultrasound findings: (1) abdominal circumference of the perfused twin equal to or greater than that of the pump twin, (2) polyhydramnios (maximum vertical pocket > 8 cm), (3) abnormal Doppler waveform in the pump twin, (4) hydrops of the pump twin, or (5) monoamniotic twins.[90] The perinatal survival rate for the high-risk pump twins in those patients who did not elect to undergo UCO was 43%.[90] Current reported perinatal survival rates of high risk pump twins who have undergone UCO is approximately 80% to 90%.[91,92]

A variety of techniques have been used to achieve UCO of the acardiac twin. Fetoscopic UCO is one common approach, and can be performed using a variety of surgical techniques, such as umbilical cord laser photocoagulation, laser of the placental vascular communications, and suture ligation.[90] Similar results can be achieved with bipolar electrocautery[93] and intrafetal RFA[94,95] (Fig. 24-9). Each approach is particularly suited to a given clinical circumstance, and the UCO modality is usually dictated by technical considerations, availability of instrumentation, and surgeon preference.[96,97]

Twins With Discordant Structural Anomalies

Monochorionic twins may be affected by discordant structural anomalies. Patients with monochorionic twins discordant for a severe congenital anomaly, particularly those at significant risk of in utero demise, should be offered the option of selective reduction by UCO. Treatment via intravascular potassium chloride (KCl) injection is the primary method for selective reduction in dichorionic twins[98] but is contraindicated in monochorionic twin gestations for two reasons.[99] First, vascular communications within the monochorionic placenta may serve as a conduit for passage of the injected agent to the co-twin. Second, following reduction, acute exsanguination or hypotension of the co-twin via the connections in the shared placenta can result in neurologic injury or death. Thus, in these cases, UCO can be performed in a similar fashion to that described for TRAP sequence. As there are potential complications, including injury to the co-twin, those monochorionic twin pregnancies with discordant anomalies for whom UCO is considered require careful assessment and counseling of the risks and benefits particular for each case.[100]

Myelomeningocele

Spina bifida is one of the most common birth defects in the United States,[101] occurring in approximately 1 in 1500 liveborn infants annually.[5] Spina bifida occurs when the embryonic neural plate fails to complete its development and does not fully close along its length. Failure of the posterior neuropore to close can result in meningocele (only the meninges protrude through the spinal defect) or MMC (both neural and meningeal elements protrude).[102,103] Both lesions are referred to by the generic term spina bifida, with MMC being the more common type. Infants born with MMC require neurosurgical closure within the first days of life, and face lifelong disabilities, including varying degrees of sensorimotor paralysis below the level of the lesion, as well as bladder and bowel incontinence, musculoskeletal deformities, and spinal cord tethering at the site of surgical repair. For most individuals with MMC, lifelong support, rehabilitation, and medical interventions are likely.[104-106]

The combination of maternal serum alpha-fetoprotein (MSAFP) screening and routine use of obstetric ultrasound imaging in the second trimester has resulted in approximately a 90% detection rate of MMC.[107] Sonography typically reveals spinal dysraphism with splayed vertebral arches. The spina bifida lesion may appear flat with no overlying sac or may have a thin-walled sac filled with cerebrospinal fluid covering the placode. The sac may contain neural elements that can be seen on sonography (see Chapter 9, Fig. 9-7). Search for associated intracranial ultrasound findings is critical for maximizing in utero sonographic detection of spina bifida. The cisterna magna may appear obliterated and the cerebellum banana-shaped because of downward herniation of this structure into the upper cervical spinal canal (Chiari II malformation). A characteristic lemon-shaped calvarium may be seen, with inward scalloping of the frontal bones. Dilatation of the lateral cerebral ventricles is another common finding. Finally, equinovarus (clubfoot) deformity of one or both lower extremities can be found in fetuses with spina bifida.[107]

MMC leads to injury and loss of spinal cord tissue at and below the level of the lesion. Abnormal spinal cord development may explain some of the neurologic deficits associated with MMC. However, mounting evidence suggests that intrauterine trauma and toxic exposure to amniotic fluid may contribute to the newborn's neurologic impairment.[108-110] The "two-hit hypothesis" of spinal cord injury in MMC has been shown in a variety of animal models, including sheep, rhesus monkey, pig, rabbit, rat, mouse, chick, and duck.[111] The majority of these experiments have involved surgically created MMC, in which a multilevel laminectomy and dural opening are performed midgestation. Later in pregnancy, repair of the lesion is performed in one set of animals, whereas the lesion is left unrepaired in the others. The control group is then compared to the study group. The theoretical advantage of fetal repair of MMCs is that the neural tube is covered and protected many months before the expected delivery date. The basis for anticipating improved neurologic function is that coverage and restoration of the dysplastic neural placode within the spinal canal isolate it from amniotic fluid and prevent ongoing injury.

In animal models, prenatal correction of iatrogenic MMC has led to the birth of offspring with preserved motor function and sphincter control. Reversal of cerebellar herniation has also been noted in sheep

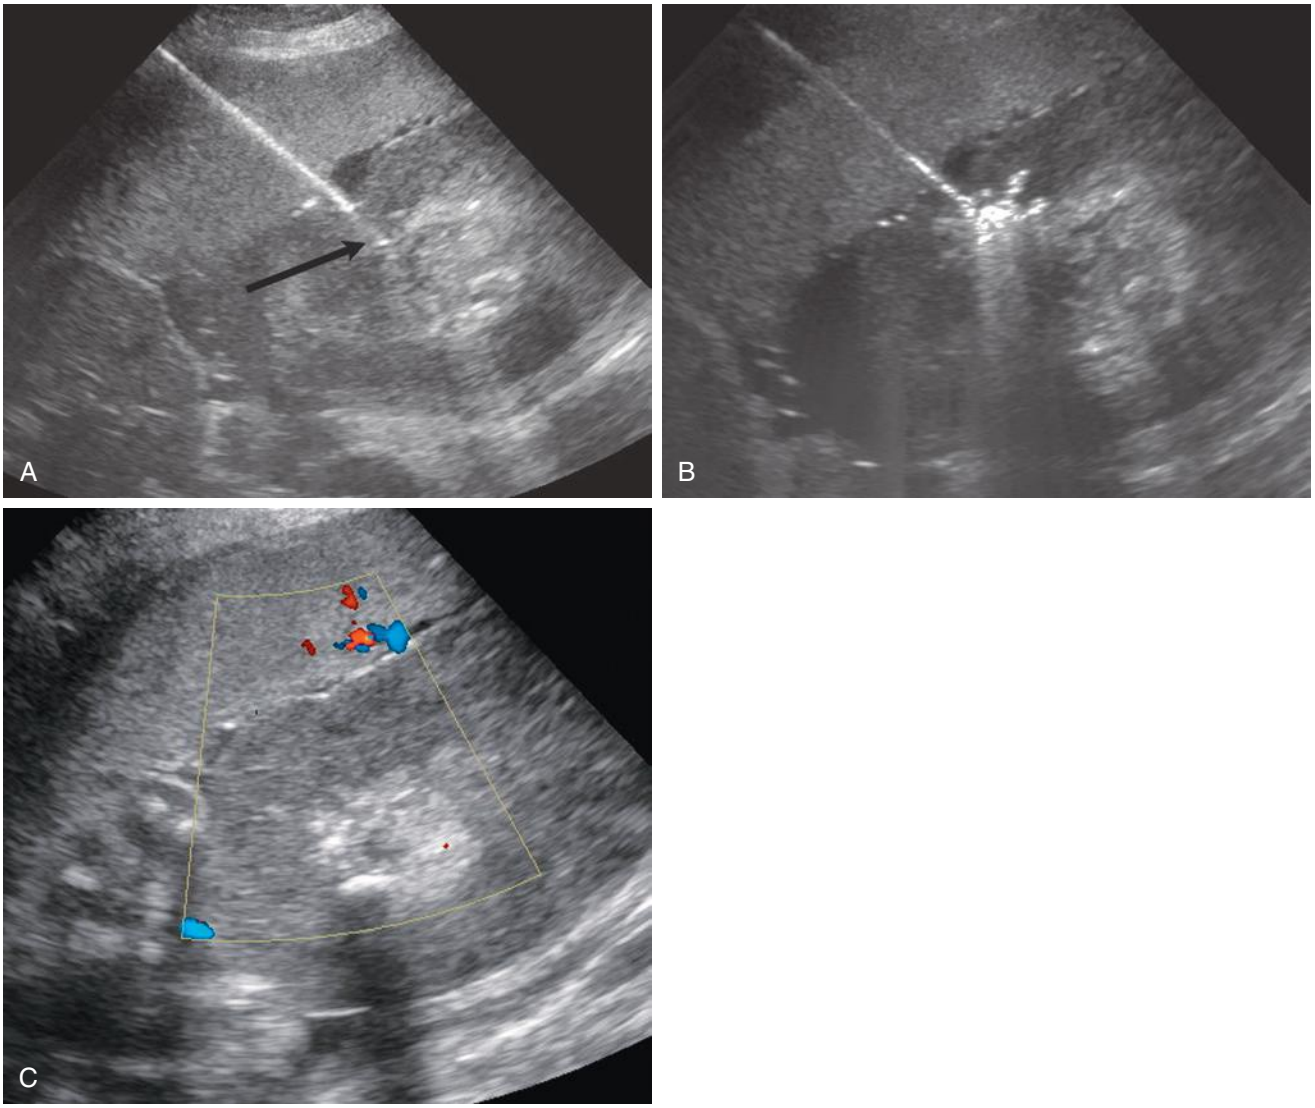

FIG 24-9 Radiofrequency ablation of acardiac fetus. **A,** Device is deployed into fetal abdomen at level of cord insertion (*arrow*). **B,** Bright reflection from gas bubbles created during radiofrequency ablation procedure. **C,** Color Doppler confirms absent flow in acardiac fetus following procedure.

that underwent intrauterine operations. Mueli and colleagues surgically created a spinal cord lesion in fetal sheep at 75 days of gestation that simulated an MMC lesion.[112-114] Following delivery, pathologic evaluation of the exposed spinal cord in the control group resembled a human spina bifida lesion. These animals were incontinent and had loss of sensation and motor function below the level of the lesion. Other animals with surgically created spina bifida lesions were treated using a myocutaneous flap at 100 days of gestation. These animals subsequently had near-normal motor function and bowel and bladder control. In another animal experiment, hindbrain herniation mimicking Chiari II malformation was surgically created prenatally by establishing leakage of spinal cord fluid at the level of the distal cord. Fetal repair subsequently reversed this hindbrain herniation.[115]

Encouraged by results in animal models, investigators began to repair MMC in human fetuses. Owing to technologic constraints, the surgical approach adopted has been open in utero repair (Figs. 24-10 and 24-11).[116] This procedure requires general anesthesia of the mother to maintain uterine quiescence, maternal laparotomy, hysterotomy, and neurosurgical closure of the fetal MMC. In 1999, Tulipan and coworkers reported outcomes of 26 of their first 28 cases of in utero MMC repair in humans, comparing them to historic MMC control subjects treated with postnatal surgical repair.[117,118] Intrauterine MMC repair was associated with reduced incidence of moderate to severe hindbrain herniation (4% vs. 50%) and reduced occurrence of shunt-dependent hydrocephalus (58% vs. 92%). However, the average level of lower extremity function closely matched the average anatomic level of the MMC lesion in both groups. Similar findings were noted by other investigators.[119] In 2003, the National Institutes of Health (NIH) funded a multicenter randomized controlled trial of open in utero surgical repair of fetal MMC versus standard neonatal repair. The results of this MOMS trial were published in 2011.[2] Inclusion criteria specified a singleton gestation with upper level of the MMC lesion between T1 and S1, evidence of hindbrain herniation, gestational age at surgery between 19.0 and 25.9 weeks, normal karyotype, absence of anomalies unrelated to the MMC, absence of severe kyphosis, and maternal body mass index less than 35. Prenatal repair resulted in

reduced need for ventriculoperitoneal shunting at 12 months of age, decrease in the rate of hindbrain herniation at 12 months, doubling of the ability to ambulate without the assistance of orthotics, and level of sensorimotor function two or more levels better than expected based on anatomic level of the defect. However, open in utero repair was associated with significant risks, including higher rates of preterm birth, fetal intraoperative bradycardia, oligohydramnios, placental abruption, maternal pulmonary edema, and maternal transfusion and a 35% risk of uterine thinning or dehiscence.

A fetoscopic approach for in utero correction of open spina bifida was first reported in 1997 by Bruner and colleagues.[120] By 2011, a total of 19 surgeries with complete in utero treatment of MMC had been attempted by Verbeek and colleagues.[121] With growing experience, Kohl and his team have demonstrated that fetoscopic treatment of MMC may achieve perinatal outcomes similar to those reported in the MOMS trial, which involved the open fetal surgical approach.[122,123] Pedreira and associates have reported on four cases treated fetoscopically using a simplified surgical technique to achieve watertight closure, taking advantage of the unique healing characteristics of the fetus (Fig. 24-12).[124] Because of the decreased maternal risks with operative fetoscopy as compared to open fetal surgery, it is highly likely that if neurodevelopmental outcomes of MMC are found to be comparable, this surgical approach will replace open maternal-fetal surgery for this condition.

Congenital Diaphragmatic Hernia

CDH is a sporadic birth defect that occurs in 1 in 2500 to 3000 pregnancies.[125] Approximately 80% of CDHs are left-sided, 15% are right-sided, and 5% are bilateral. About 50% to 60% are isolated abnormalities and the remaining cases are associated with genetic syndromes and other anomalies.[126] With CDH, the diaphragmatic defect results in herniation of abdominal organs into the thoracic cavity, causing displacement and compression of the fetal lungs. The abnormal in utero lung development is clinically manifest after birth by neonatal respiratory insufficiency and pulmonary hypertension.[127] The natural history of isolated CDH depends on the degree of pulmonary compromise

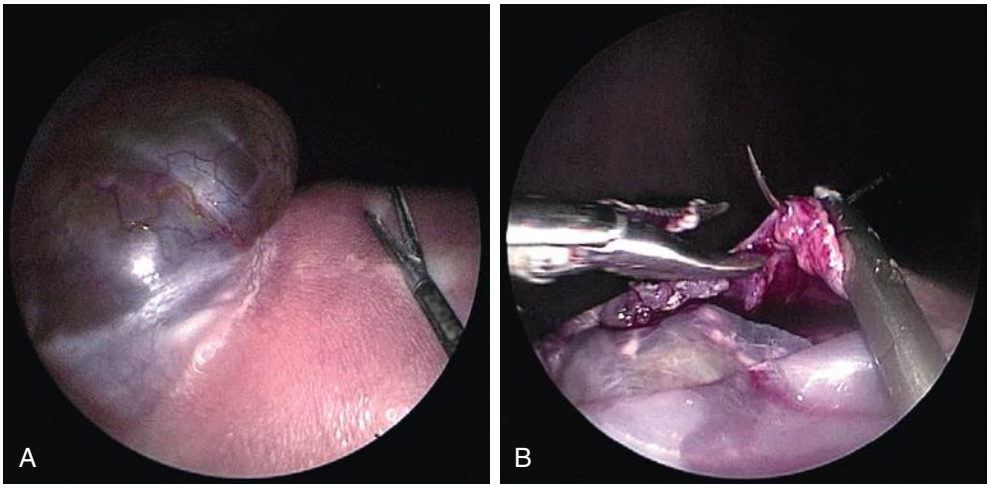

FIG 24-12 Images from fetoscopic fetal myelomeningocele repair. FIG 24-13 Illustration of the method for measuring lung-to-head ratio (LHR) in a fetus with left congenital diaphragmatic hernia (CDH). The measurement of the right lung (in a fetus with typical left CDH) uses a transverse axial plane of section through the fetal thorax at the level of the four-chamber view of the fetal heart. The ultrasound section should be symmetric so that a single rib is seen on each side. The longest axis of the right lung is measured (in millimeters) and is multiplied by the longest perpendicular measurement (in millimeters). This product (mm^2) is then divided by the measurement of the head circumference (in millimeters), obtained at the level of the standard biparietal diameter view, to obtain the LHR.

present at birth. Overall, perinatal mortality risk has remained high despite advances in neonatal intensive care.[126,128-131] Of liveborn cases with prenatally diagnosed CDH, the pulmonary hypoplasia is lethal in 30% to 40%.[129] Thus, the goal of prenatal assessment of CDH is twofold: (1) determine if the CDH is isolated and (2) assess the degree of mass effect upon the developing lungs.

A variety of indirect measures have been used to more precisely determine the prognosis of fetuses with CDH. In addition to identifying herniation of liver into the thorax, the area of the contralateral lung and its relationship to the head circumference (lung-to-head ratio, LHR) has been assessed as a prognostic indicator. LHR was first proposed by Metkus and coworkers in 1996 as a sonographic parameter to predict neonatal outcome in fetuses with CDH.[132] LHR is calculated by dividing the product of the largest perpendicular diameters of the contralateral lung on a transaxial image at the level of the four-chamber view of the heart (lung area, in mm^2) by the head circumference (in mm) (Fig. 24-13). The margins of the contralateral lung may also be traced manually to provide a more accurate determination of lung

area. Division of the calculated lung area by the head circumference, used as an internal control, was suggested to provide a gestational age-independent measure of CDH severity.[132] However, use of LHR as a predictor for neonatal outcomes and as a sonographic criterion for surgical intervention in CDH has come into question.[133,134] Peralta and associates, in a study of 650 normal fetuses with gestational ages of 12 to 32 weeks, demonstrated that LHR increases with advancing gestation, indicating that this parameter is not independent of gestational age.[135] Jani and colleagues proposed the use of observed versus expected (o/e) LHR to correct for the effect of gestational age.[133] However, o/e LHR was able to identify only 46% of CDH fetuses that did not survive, with an attendant 10% false positive rate.[133] Others have suggested that the suboptimal performance of LHR may be related to variability in ultrasound technique and methodology used to calculate this ratio.[136]

Another reason why LHR is a problematic measure is related to its mathematical formula.[137] The lung area (numerator) is measured in mm^2 (area), whereas the head circumference (denominator) is measured in mm (length). This results in a first-degree polynomial equation, which, in the case of LHR, has a persistent positive slope.[137] LHR increases with advancing gestation. The same holds true for o/e LHR.[138] Using mathematical modeling, a gestational age-independent sonographic index of lung size, the quantitative lung index (QLI), was developed by Quintero and coworkers.[137] This calculation involves the division of two second-degree polynomials:

$$QLI = LA/(HC/10)^2$$

where LA is the traced lung area (in mm^2) of the contralateral lung at the level of the four-chamber view of the heart and HC is the head circumference (in mm).[137] The 50th percentile of QLI is approximately 1.0 from 16 to 32 weeks of gestation, whereas a small lung (<1st percentile) is defined as QLI less than 0.6[137] (Fig. 24-14).

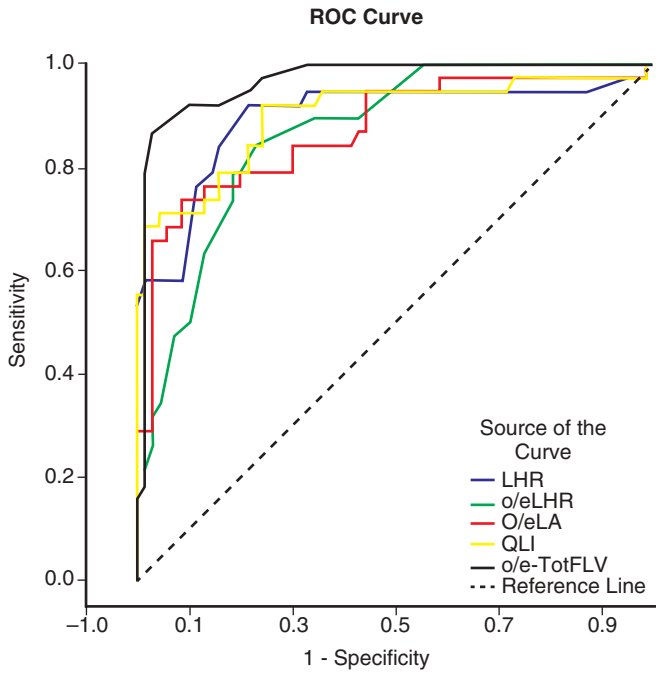

FIG 24-14 Receiver operating characteristic (ROC) curve for prediction of neonatal death using the quantitative lung index (QLI), observed versus expected contralateral lung area (O/eLA), lung-to-head ratio (LHR), observed versus expected lung-to-head ratio (o/eLHR), and observed versus expected total lung volume (o/e-TotFLV).

Other methods to evaluate lung size include measuring total lung volume using MRI or three-dimensional (3D) sonography.[139] Although these modalities provide enhanced visualization of lung fields, they have not been shown to provide more accurate prognosis compared to standard 2D sonography. Liver herniation is consistently associated with higher postnatal mortality rate; thus, quantification of the degree of liver herniation is another method that has been used to predict outcome.[140,141]

Using the previously described prenatal assessment techniques, fetal intervention has been proposed for severe forms of isolated CDH, defined as LHR less than 1.0, o/e LHR less than 25%, or QLI less than 0.6.[138,139] Mild to moderate CDH is not considered an indication for in utero surgery at this time because of the relatively high survival rates with postnatal care.[139] In the past, prenatal surgical intervention emulated postnatal surgery for CDH, intending anatomic repair of the diaphragm. The procedure was shown to be feasible in the fetus, except when the liver was herniated. Acute reduction of the liver back into the fetal abdomen resulted in kinking of the DV and obstruction of blood flow from the umbilical vein. Therefore, fetuses with "liver up"—that is, those that would most benefit from in utero repair, were not candidates for fetal surgery. Based on observations made regarding lung growth in fetuses with congenital high airway obstruction, the concept of iatrogenic reversible fetal tracheal occlusion (to promote pulmonary development) was proposed and carefully investigated. In 2003, a randomized clinical trial conducted in the United States compared tracheal occlusion via open fetal surgery to expectant management.[142] Entry criteria for the study included LHR 1.4 or less. The study did not show a benefit of in utero surgery over standard postnatal care. However, a post-hoc analysis of the data suggested that a more restrictive LHR of less than 1.0 might have been more appropriate, because survival rate in this subgroup of CDH fetuses was only 33% compared to nearly 100% in fetuses with LHR greater than 1 in both the surgical and expectant management groups.[142] Since then, the approach to in utero management of CDH has undergone a paradigm shift, with abandonment of all open fetal surgery techniques (whether to correct the defect or perform external tracheal occlusion[143]) in favor of ultrasound-guided, fetoscopic tracheal occlusive procedures.

Tracheal occlusion has been offered as a prenatal intervention for severe CDH in the hopes of improving perinatal survival.[144,145] Animal and human studies have shown that the lungs of CDH fetuses have morphologic abnormalities,[146,147] manifest by fewer alveoli with increased interstitial tissue[148] and decreased number but excessively muscularized intrapulmonary arteries[149,150] as well as impaired lung mechanics.[151] The concept of prenatal tracheal occlusion is based on experimental data suggesting there is accelerated lung growth following this intervention owing to mechanical stretching forces from the increased hydrostatic lung fluid pressure.[152] However, despite a gross increase in lung mass, sustained fetal tracheal occlusion results in histologic abnormalities in the lung, including oligomacroalveolar development[153] and decreased number of type II alveolar cells.[154] Therefore, intermittent tracheal occlusion was proposed to better emulate normal fetal lung growth and maturation, which appear to be related to both tonic stretching forces due to in utero pulmonary fluid secretion as well as cyclic stretching forces from intermittent fetal breathing activity.[155,156]

The current clinical strategy is to perform tracheal occlusion between weeks 26 and 28, followed by removal of the occlusion at 34 weeks' gestation,[143,145] although there is some controversy regarding optimal timing and duration of occlusion.[157] Insertion of the tracheal occlusive device is performed under combined ultrasound and fetoscopic guidance. The endoscope is introduced into the amniotic cavity and is advanced into the fetal mouth and through the pharynx, larynx,

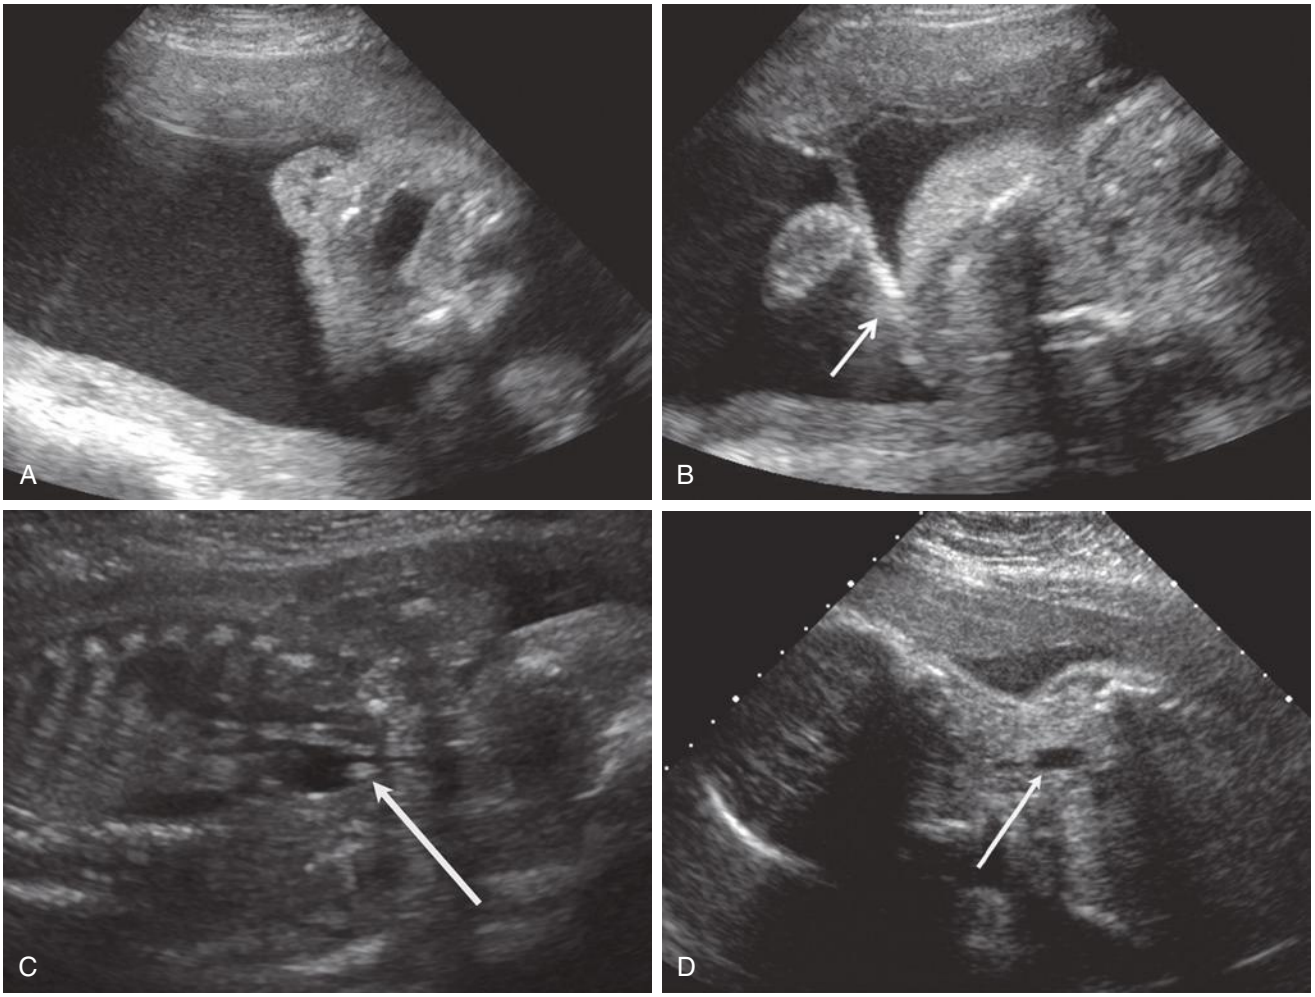

FIG 24-15 Tracheal balloon occlusion for congenital diaphragmatic hernia. **A,** Fetal mouth is identified. **B,** Device is seen adjacent to fetal mouth (*arrow*). **C,** Device is seen in fetal trachea deploying balloon (*arrow*). **D,** Balloon is seen in fetal trachea (*arrow*).

past the epiglottis, and into the fetal trachea. Once the carina is identified, the device is deployed (Fig. 24-15). Two tracheal occlusive devices have been utilized: a detachable balloon[158] and a modified 8-mm Z-stent.[159] Removal of the tracheal occlusive device is performed at approximately 34 weeks' gestation via fetoscopic retrieval or at the time of delivery via EXIT procedure. Studies of fetuses with severe isolated CDH have demonstrated significant improvement in survival rates in those who underwent fetoscopic tracheal occlusion compared with control subjects.[144,160] Additional trials, including one being conducted by the fetal endoscopic tracheal occlusion (FETO) task group in Europe, are ongoing. Interpretation and applicability of the results of these trials must take into account the inclusion criteria, local resources, and postnatal care provided to these infants.

Congenital Pulmonary Airway Malformation

CPAM, previously termed congenital cystic adenomatoid malformation, is an abnormality of lung development characterized by hamartomatous overgrowth of the terminal bronchioles with subsequent suppression and lack of differentiation of normal alveoli.[161] CPAMs are classified into three major types.[162] Type I CPAM is defined as a distinct, thin-walled cyst that measures greater than 2 cm in diameter and is lined with ciliated pseudostratified columnar epithelium. In contrast, types II and III lesions consist of multiple microcysts lined by cuboidal epithelium (each cyst measuring <2 cm in diameter in type II and <0.5 cm in diameter in type III) and may contain large solid components. CPAM type can be determined using ultrasound imaging, as type I lesions are composed of large echolucent cysts and types II and III lesions are of mixed echogenicity with areas of increased echogenicity corresponding to microcysts (Fig. 24-16).

The vast majority of CPAMs are clinically benign, both prenatally and postnatally. They are usually resected because of the risk of infection and a remote risk of malignant transformation. Once the diagnosis is made, management consists of in utero surveillance with ultrasound, appropriate counseling, and ensuring that the relevant specialists are involved in postnatal evaluation and treatment.

Although most CPAMs remain asymptomatic during fetal life and carry a good prognosis, large CPAMs can lead to a number of complications in the developing fetus, including hydrops and death.[163] Hydrops can result from mass effect by a large CPAM with obstruction of the vena cava and cardiac compression, resulting in decreased venous return to the heart. The presence of fetal hydrops in association with CPAM is the most important prognostic factor. In the absence of hydrops, live birth rates are reported to be higher than 95%.[164] However, the presence of hydrops carries a grave prognosis, with risk of perinatal mortality close to 100% without fetal intervention.[165] Thus, fetal therapy is indicated when hydrops develops in the second or early third

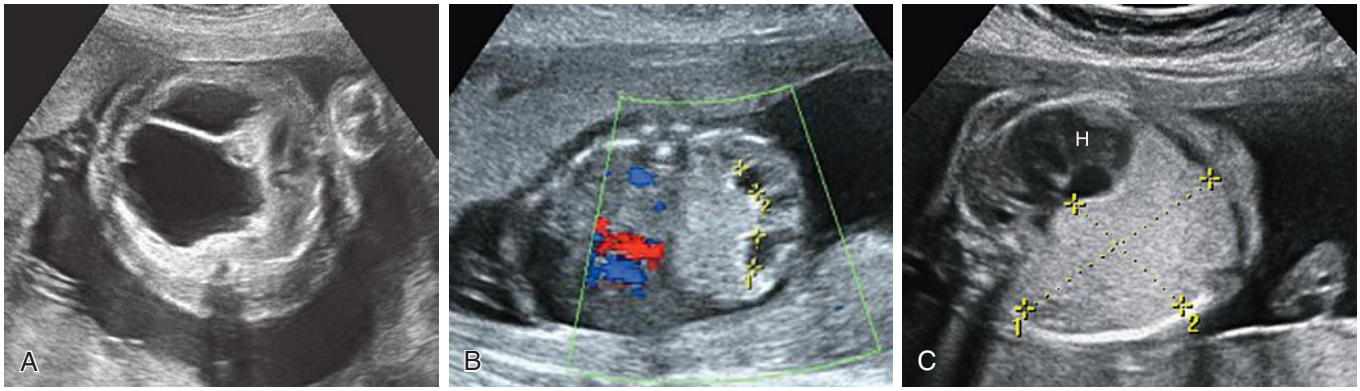

FIG 24-16 Ultrasound images of three types of congenital pulmonary airway malformations (CPAM). **A,** Type I CPAM (macrocystic) with several cysts measuring greater than 2 cm in diameter. **B,** Type II CPAM (mixed macrocysts and microcysts) with several distinct small cysts measuring less than 2 cm in diameter (*calipers*), surrounded by hyperechoic, solid-appearing tissue that represents the microcystic component. **C,** Type III CPAM (microcystic), a hyperechoic, solid-appearing lesion (*calipers*) with no sonographically resolvable distinct cysts. H, heart.

trimester.[165] In an attempt to predict which fetuses with CPAM are at risk of developing hydrops, calculation of the ratio of the lesion volume (in cubic centimeters) divided by the head circumference (in centimeters) (CPAM volume ratio [CVR]) has been proposed.[166] When the calculated CVR is greater than 1.6, there is approximately 80% risk for subsequent development of fetal hydrops.

If fetal hydrops develops before 32 to 34 weeks' gestation, fetal intervention can be lifesaving. Fetal treatment for large type I CPAMs involves percutaneous aspiration and drainage via thoracoamniotic shunt placement.[167] In general, prognosis is favorable. Types II and III CPAMs are composed of multiple microcysts with solid components and are not amenable to aspiration or thoracoamniotic shunting. Historically, these lesions have been treated with open maternal-fetal surgery, fetal thoracotomy, and tumor resection, resulting in resolution of hydrops and a fetal survival rate of approximately 50%.[168] However, less invasive alternatives have been sought.[169] Maternal administration of steroids (the same protocol as that used to promote fetal lung maturity, or 12 mg of betamethasone × 2, every 24 hours) has been demonstrated to be very effective in preventing or reversing hydrops secondary to large CPAMs and is now widely offered.[170-172] Percutaneous laser ablation, coil embolization, and RFA have all been utilized in attempts to reduce tumor size. Of these modalities, percutaneous laser ablation may be associated with the lowest procedure-related risk.[170] Percutaneous sclerotherapy of semisolid CPAMs has also been successfully performed, with subsequent reduction in tumor size and resolution of hydrops.[173] Since the recognition of the effectiveness of maternal corticosteroids, however, such surgical interventions are much less commonly required.

Pleural Effusion

Isolated fetal pleural effusion (also referred to as hydrothorax) is uncommon, with a reported incidence of 1/10,000 to 1/15,000 pregnancies.[174] Prenatal sonographic diagnosis is made by identification of anechoic fluid adjacent to and partially surrounding the lung. When pleural effusions are large and unilateral, they can exert mass effect with significant mediastinal shift, which can secondarily lead to hydrops, an independent risk factor for perinatal death.[175] Prognosis largely depends on the underlying cause of the fetal hydrothorax. There is a significant association between fetal pleural effusions and aneuploidy as well as other structural abnormalities.[176] Thus, detailed anatomic survey and fetal genetic testing should be offered.[177] Unilateral fetal hydrothorax appears to more often occur sporadically and is associated with a more favorable prognosis than bilateral effusions. Unilateral hydrothorax may be caused by congenital malformation of the thoracic duct or the pulmonary lymphatic system.[178] Hydrothorax resulting from lymphatic malformations may be supported by the finding of an elevated lymphocyte count (>80%) in aspirated pleural fluid (fetal chylothorax).[174] Large unilateral hydrothorax with associated mass effect can progress to bilateral pleural effusions and subsequent hydrops fetalis, thereby complicating the clinical picture. Determination of whether a hydropic fetus has a primary pleural effusion or pleural fluid from generalized hydrops can be challenging. In cases of fetal hydrops with large asymmetric pleural effusions and evidence of associated mass effect with mediastinal shift and eversion of the hemidiaphragm, many authors will assume that the larger pleural effusion is the primary cause.[179]

Fetal intervention in the setting of hydrothorax is typically reserved for cases that develop secondary hydrops and has been shown to improve survival rate in this group.[180,181] Perinatal survival rate of hydropic fetuses with a dominant pleural effusion treated with thoracoamniotic shunting is approximately 50%.[179] Some authors offer fetal treatment in cases considered high risk for developing hydrops, such as those with rapidly enlarging effusions, polyhydramnios, significant mediastinal shift, or evidence of cardiac compromise,[182] evidenced by fetal echocardiography documenting abnormal ventricular filling.[183] Several different therapeutic modalities for management of fetal hydrothorax have been described, including repeated thoracenteses, thoracoamniotic shunting, maternal blood injection into the fetal pleural cavity, and pleurodesis. Of these, the most commonly employed technique is thoracoamniotic shunting.[184]

Fetal Cardiac Interventions

An emerging area of fetal therapy is in the treatment of congenital heart defects. Some cardiac defects are structurally simple, but because of the dynamics of fetal growth and circulation, progressive abnormal development of the great vessels, outflow tracts, and ventricles can ensue, resulting in a poorly functioning heart after birth. An example of this is critical aortic stenosis, which may progress to hypoplastic left heart syndrome (HLHS). It has been speculated that in utero reversal of aortic valve stenosis can prevent progression to ventricular hypoplasia. At present, the standard postnatal treatment for a single-ventricle heart, such as HLHS, is staged palliative surgery (Norwood

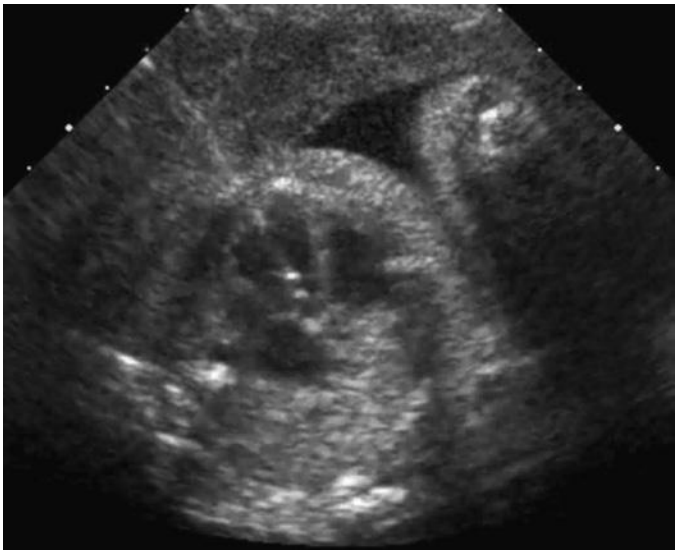

FIG 24-17 Aortic valvuloplasty. Needle device is in the left ventricle with tip at the aortic valve.

operation, followed by Fontan procedure). The goal of fetal cardiac intervention for critical aortic stenosis with evolving HLHS is to alter left-sided heart physiology and promote ventricular growth in utero to allow for postnatal survival with healthy biventricular circulation.[184]

There is increasing experience with ultrasound-guided fetal cardiac catheterization and valvular balloon dilatation. In most cases, this procedure can be done using a percutaneous approach. An 18- to 19-gauge needle is introduced into the fetal left cardiac ventricle using real-time ultrasound guidance (Fig. 24-17 and Video 24-1). A balloon angioplasty catheter is passed over a wire that has been advanced across the stenotic valve. Once it is determined that the angioplasty balloon is in the appropriate position at the level of the aortic valve annulus, it is inflated under ultrasound guidance. After balloon inflation, the wire and balloon are removed, and the fetus is closely monitored for bradycardia or pericardial effusion. The multidisciplinary team at Boston Children's/Brigham and Women's Hospital reported successful valvular dilation in approximately 80% of cases. Of the technically successful cases, over 30% have biventricular circulation after birth, with another 8% converted to biventricular circulation after initial univentricular palliation.[184]

Experience in fetuses with HLHS with restrictive or intact atrial septum is more limited, as is experience with intervention for pulmonary atresia or stenosis with intact ventricular septum. However, further research will determine optimal patient selection, timing, and technique of intervention for different types of potentially correctable fetal heart defects. As noted earlier, these procedures are performed percutaneously, and, therefore, maternal and pregnancy risk profile is relatively low. This advantage may allow for a lower threshold for innovative intervention and may expand the indications, even if the success rate is variable.

Lower Urinary Tract Obstruction

Fetal urethral abnormalities resulting in lower urinary tract obstruction (LUTO) are associated with significant morbidity and mortality risks. LUTO occurs in approximately 1/5000 to 1/8000 male fetuses. The most common cause of LUTO is posterior urethral valves in males[185] and urethral atresia in females.[186] Complete obstruction leads to progressively severe oligohydramnios and then anhydramnios.

TABLE 24-4 Fetal Urine Prognostic Thresholds*

	Good Prognosis	Poor Prognosis
Sodium	<90 mmol/L	>100 mmol/L
Chloride	<90 mmol/L	>100 mmol/L
Osmolality	<180 mOsm/L	>200 mOsm/L
Total protein	<20 mg/dL	>40 mg/dL
β_2-Microglobulin	<6 mg/L	>10 mg/L

*Thresholds are based on urine obtained between 18 and 24 weeks estimated gestational age. Values that fall between good and poor prognosis are considered "gray zone" with expectation for moderate or greater postnatal renal impairment, but potential for postnatal pulmonary survival.

Depending upon the gestational age when this occurs, pulmonary hypoplasia often ensues. In addition, vesicoureteral reflux and elevated back-pressure affecting the renal parenchyma can cause cystic dysplasia and renal failure. Untreated, LUTO leads to hydronephrosis, renal dysplasia, and perinatal death in up to 90% of patients.[187] Death is attributed to pulmonary hypoplasia and renal dysplasia.

Aiming to reconstitute amniotic fluid volume and decompress the high-pressure urinary system, vesicoamniotic shunt placement into the distended fetal bladder has, for several years, been offered to patients with LUTO and secondary oligohydramnios. With experience, it has been recognized that case selection is critical. In some fetuses with irreversible renal damage, pulmonary growth could be salvaged, but the morbidity of neonatal renal failure with need for long-term dialysis and eventual renal transplantation became evident. This has led to attempts to better predict fetal and thus neonatal renal function and to identify those for whom shunting might benefit pulmonary as well as renal outcome. It was hypothesized that the best method to assess renal function would involve sampling fetal urine with analysis of urinary electrolytes and other analytes. Evaluation of urinary electrolytes appears to be most predictive when two or three sequential vesicocenteses are performed several days apart, in fetuses in whom bladder refilling and normal-appearing renal parenchyma are shown by sonography (Table 24-4).[188] Nicolini and Spelzini suggested modifying the algorithm of assessing patients with LUTO by performing a single cordocentesis.[189] This may allow determination of fetal karyotype and assessment of fetal urinary function based on serum β_2-microglobulin level with one diagnostic procedure.

Percutaneous ultrasound-guided vesicoamniotic shunt placement in fetuses with LUTO and secondary oligohydramnios is offered to those with normal karyotype, no sonographic or biochemical evidence of renal cystic dysplasia, and no additional major structural anomalies (Fig. 24-18). Data regarding short- and long-term outcomes following fetal intervention demonstrate improved survival rate but relatively high rates of renal and pulmonary morbidity. An overview by Clark and associates of 16 studies including 342 fetuses reported a 73% intact survival rate, with increased overall perinatal survival rate after bladder drainage via vesicocentesis or vesicoamniotic shunt compared to no intervention.[190] A multinational randomized clinical trial comparing treatment versus expectant management could not be completed because of difficulties with recruitment.[191] A case series of 20 pregnancies complicated by LUTO with well documented in utero findings and subsequent 5-year follow-up revealed that children treated with vesicoamniotic shunting had normal neurodevelopment. However, in the 18 survivors, 6 had acceptable renal function, 4 had mild renal insufficiency, and 6 required dialysis and eventual transplantation.[192] In

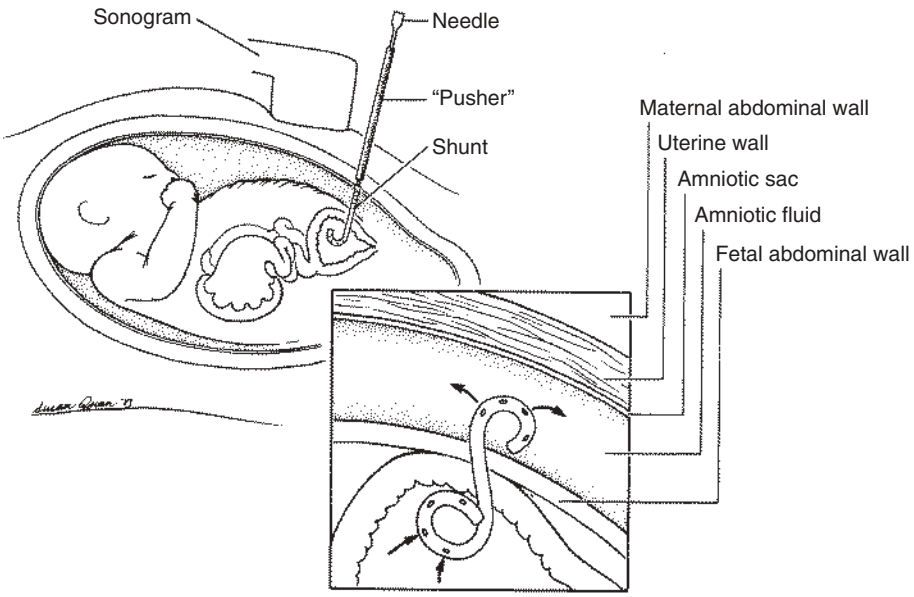

FIG 24-18 Placement and deployment of a fetal bladder shunt. The double pigtail catheter is pushed off the needle so that one end is within the fetal bladder and the other end is in the amniotic space. (From Adzick NS, Flake AW, Harrison MR: Recent advances in prenatal diagnosis and treatment. Pediatr Clin North Am 32:1103, 1985.)

addition, many were lagging in growth and had persistent pulmonary issues. Similar experience is reported by other centers, with chronic renal insufficiency in one half to two thirds of survivors, despite having had favorable fetal urine profiles as a prerequisite for in utero intervention.

Shunt-related complications occur in approximately 40% of cases.[193] The shunt may withdraw into the fetal abdomen, resulting in iatrogenic urinary ascites, or pull out of the fetal bladder or out of the fetus entirely. Replacement of the shunt is associated with additional risk of fetal demise, chorioamnionitis, PPROM, miscarriage, or preterm delivery, leading to a total perinatal loss rate of approximately 4% per procedure. Effective and reliable treatment is likely to change the course of the disease in utero and possibly provide a more favorable outlook for these pregnancies. Thus, several alternative treatment approaches to obstructive uropathy have been proposed. One refinement, aiming to reduce the risk of catheter dislodgement, is the development of a novel double-disk/double pigtail catheter shunt.[194] Another treatment approach is fetal cystoscopy with endoscopic fulguration of the posterior urethral valves.[195] With cystoscopy, it may be possible to correct the outlet obstruction and allow normal bladder cycling for the remainder of the pregnancy. This approach has compared favorably to vesicoamniotic shunting, but there remains concern regarding the potential for additional injury to the fetus and possible subsequent fistula formation.

Sacrococcygeal Teratoma

SCTs are cystic and solid tumors arising from the area of the coccyx. The SCTs relevant to this discussion of fetal therapy are large, predominantly solid, and highly vascularized. Large SCTs with marked blood flow can lead to high-output cardiac overload, hydrops, and death. Assessment of tumor size, growth rate, and fetal cardiac function allow for identification of those fetuses at risk for decompensation. Fetuses with large SCTs and secondary heart failure with hydrops before viability have a dismal prognosis, with nearly 100% mortality rate, and are considered candidates for fetal intervention.[196]

Attempts have been made to perform either definitive resection or devascularization of the tumor in hopes of allowing cardiac recovery. Tumor resection via open maternal-fetal surgery has been associated with suboptimal outcomes, with inherent major fetal and maternal risks.[197] Various minimally invasive treatment approaches aimed at interrupting blood supply to the SCT have been attempted, including coiling, embolization, sclerotherapy, monopolar cautery, laser ablation, and RFA. A 2014 review identified 34 cases of fetal SCT treated via a minimally invasive approach; the overall survival rate was 44%, with 30% survival rate in cases with and 67% survival rate in cases without evidence of secondary cardiac decompensation.[198] An additional 12 cases were treated via an open maternal-fetal surgical approach, and the survival rate was 50%.[198] Long-term outcomes have not been reported in detail.

Amniotic Band Syndrome

Amniotic band syndrome (ABS) is a sporadic congenital anomaly thought to result from amnion rupture followed by attachment of fibrous amniotic strands to the fetus. Adherence to or entanglement of the fetus in amniotic remnants may lead to fetal deformation, malformation, or disruption.[199] Estimates of ABS incidence range from 1 in 1200 to 1 in 15,000 live births.[200]

Depending both on the degree of adherence of the amniotic band as well as its location along the fetus, outcomes can vary widely. ABS may result in minor single digit abnormalities, distal extremity amputations, and craniofacial or thoracoabdominal destructive eviscerations. Constriction of extremities is the most common form of ABS and causes edema distal to the constricted site, amputation, and other deformities (Fig. 24-19).[201] Amputations occur as a result of progressive adherence and strangulation of the extremity as the fetus grows and develops.[202] Animal studies have shown that in utero band release can restore normal circulation and function to the extremity.[203]

Similar to animal models, release of the amniotic band constriction in human fetuses results in reduction of distal limb edema, restoration of limb structure and function, and avoidance of amputation.

Quintero and coworkers performed the first two cases of minimally invasive surgery to release constricting bands in utero, utilizing scissors under endoscopic guidance in one case and a YAG (yttrium-aluminum-garnet) laser fiber in another.[201] Hüsler and colleagues reported seven cases using the same transecting instruments.[204] Several additional case series have described similar results with improvement in structure and function after fetoscopic amniotic band release. It is important to note that constrictions can develop over the course of the pregnancy as the fetus grows. One case report describes a fetus with a tight constricting band of the right lower extremity with secondary distal swelling, whereas a loose nonconstricting band was noted around the normal-contoured left lower extremity. Fetoscopic release of the right lower extremity band was performed at 29 weeks' gestation.[205] The right leg, on which band release was done in utero, had normal function at 2 years of age. However, the opposite (left) leg, which was minimally involved at 29 weeks' gestation, subsequently developed a tight constriction as the fetus grew, and residual deficits in that extremity were documented at age 2. Thus, serial sonographic surveillance is recommended to monitor for the development of constriction bands over the course of the entire pregnancy.

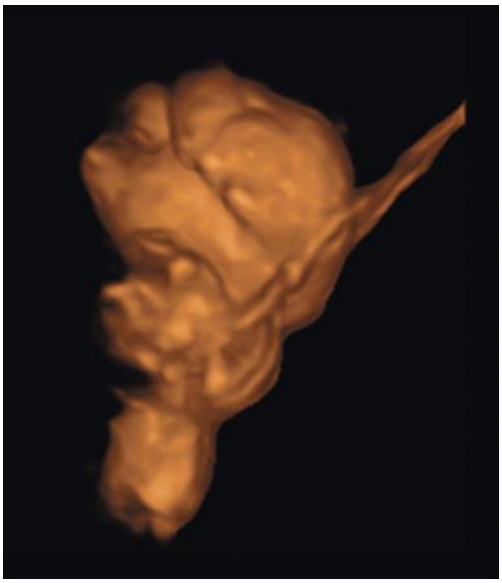

FIG 24-19 Amniotic band syndrome affecting fetus at 22 weeks 4 days. Ultrasound image with three-dimensional surface rendering demonstrates effects of a tight constricting amniotic band around the fetal forearm with marked distal swelling of the wrist and hand. (Modified from Assaf R, Llanes A, Chmait R: In utero release of constriction amniotic bands via blunt dissection. Fetal Pediatr Pathol 31(1):25-29, 2012.)

Fetal demise may occur if an amniotic band incorporates a segment of umbilical cord, thereby resulting in cord compression. Therefore, another indication for amniotic band release is for cases in which bands involve the umbilical cord, with hopes of preventing fetal demise from cord strangulation.[206]

It is important to note that ABS rarely involves just one fetal part. There is often multifocal involvement that may or may not be detected by prenatal imaging techniques or fetoscopy, and the patient should be counseled accordingly.

Chorioangioma

Placental chorioangiomas are abnormal proliferations of chorionic tissue and are present in up to 1% of placentas.[207] Most placental chorioangiomas are small and not associated with risk to the fetus. Large chorioangiomas, those that measure greater than 4 cm in diameter, can have significant fetal consequences, including polyhydramnios, microangiopathic hemolytic fetal anemia, high-output cardiac failure resulting in nonimmune hydrops, and fetal growth restriction.[208] Large chorioangiomas are associated with a 40% risk of intrauterine demise.[209] Fortunately, large chorioangiomas are rare with a reported incidence of 1:3500 to 1:9000 pregnancies.[207]

On ultrasound imaging, placental chorioangioma appears as a well-circumscribed, vascularized, solid mass bulging along the fetal surface of the placenta. Color flow Doppler sonography is a useful tool to assess for tumor vascularity (Fig. 24-20A). More vascular and hypoechoic tumors are associated with greater risk of pregnancy complications, whereas nonvascular and hyperechoic lesions tend to have more favorable outcomes.[207]

Because large chorioangiomas are associated with poor perinatal outcomes, fetal therapy has been proposed in cases with evidence of high-output cardiac compromise or hydrops. Fetal anemia is not

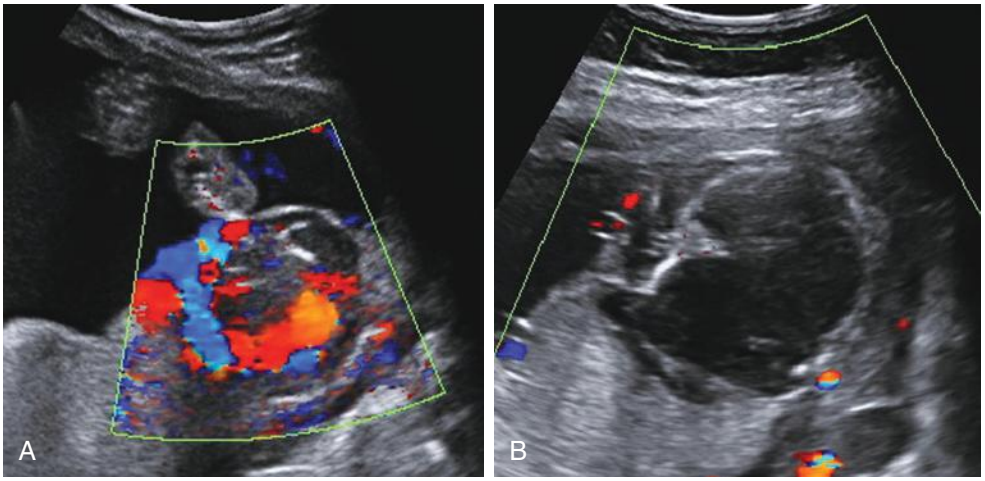

FIG 24-20 Placental chorioangioma. **A,** Color Doppler sonography at 25 weeks' gestation reveals a large, markedly vascular, well-circumscribed mass protruding from the fetal surface of the placenta. **B,** Sonogram performed at 29 weeks' gestation, following laser photocoagulation of the feeding vessels. The chorioangioma has decreased in size, appears predominantly cystic, with no demonstrable internal flow shown by color Doppler interrogation.

uncommon in these patients. Thus, monitoring of MCA PSV and other ultrasound markers of fetal anemia is recommended. IUT may improve outcomes in cases with significant anemia. Development of severe polyhydramnios is also not uncommon. Amnioreduction may help ameliorate maternal symptoms and reduce the risk of preterm labor. However, the drop in intrauterine pressure from amniotic fluid decompression may result in increased tumor perfusion, thereby promoting fetal deterioration.[210] Definitive treatment aiming to interrupt blood supply to the chorioangioma has been attempted using a variety of approaches (Fig. 24-20B).[211] Ultrasound-guided percutaneous treatment options include alcohol injection, embolization, and interstitial laser therapy. Endoscopic methods include suture ligation and laser photocoagulation of feeding vessels. Endoscopic occlusion of feeding vessels to the chorioangioma has been associated with an 80% survival rate in one small series.[211]

SUMMARY

Sonography has allowed the field of fetal therapy to evolve and provides diagnostic information as well as intraoperative guidance. Although open maternal-fetal surgery was the primary method of accessing the fetus with initial attempts at fetal surgical intervention, this approach is associated with significant maternal and fetal risks. Minimally invasive fetal surgery is associated with much lower maternal risks and is currently the preferred surgical approach for most fetal conditions amenable to in utero therapy. Such interventions typically are performed under ultrasound guidance. With further improvement of surgical equipment and prenatal diagnostic modalities, access to the fetal-placental unit via minimally invasive methods will likely become increasingly refined and provide a conduit for additional novel treatments of the fetus.

Obstetric Ultrasound Imaging and the Obese Patient

Beryl Benacerraf

SUMMARY OF KEY POINTS

- Obesity is epidemic and a significant public health problem.
- Obese women are at increased risk of maternal complications of pregnancy compared to women of normal weight.
- Fetuses of obese gravidas are at increased risk of malformations compared to those of normal weight women.
- Ultrasound imaging of obese patients is hampered by acoustic noise, artifacts, and thicker anterior abdominal wall, all of which degrade the image.
- Although ultrasound examinations of obese gravidas often are repeated in order to obtain adequate images, fetal anatomic evaluation is frequently suboptimal despite several attempts.
- There are several ways to optimize the image quality while scanning obese patients.

Over 60% of the population of the United States is considered overweight, and more than one third is obese, making obesity a significant public health problem.[1,2] In 2005, the World Health Organization estimated that 1.6 billion adults worldwide were overweight and 400 million were frankly obese (body mass index [BMI] ≥ 30).[3] This worldwide epidemic shows no sign of abating and continues to increase, especially in the United States. A growing body of evidence shows that obese patients have a higher risk of a multitude of health problems, including heart disease, type 2 diabetes, hypertension, stroke, "metabolic syndrome," arthritis, cancer, respiratory problems, sleep apnea, pregnancy complications, and more (Table 25-1).[4] The National Institutes of Health and the World Health Organization define obesity according to the BMI (in kg/m^2). A BMI of 18 to 24.9 is normal, and a BMI of 25 to 29.9 is overweight. Classes I, II, and III obesity are defined as BMIs of 30 to 34.9, 35 to 39.9, and 40 or higher, respectively.[5]

Obese women have an increased risk for adverse pregnancy outcomes that impact both the mother and the fetus.[2,3,5-22] Sebire and associates described 287,213 patients, of which 39% were obese, and reported that several maternal complications increased with the degree of obesity.[6] Table 25-1 lists the most common maternal and fetal complications associated with maternal obesity. In addition, an increased risk of fetal malformations has been associated with obesity,[7-10] and fetal anomalies such as neural tube defects, cardiac anomalies, anal atresia, and limb reduction abnormalities are reported to be significantly more common with obese patients compared to the normal weight population (Table 25-2).[10]

Uhden and colleagues reported that the relative risk of heart defects is 2.04 in fetuses of obese compared to normal weight women.[11] Watkins and coworkers also demonstrated that obese compared to average weight women have an elevated risk of fetal anomalies such as spina bifida (odds ratio [OR] 3.5; 95% confidence interval [CI] 1.2-10.3), omphalocele (OR 3.3; 95% CI 1.0-10.3), and heart defects (OR 2.0; 95% CI 1.2-3.4), as well as multiple anomalies (OR 2.0; 95% CI 1.0-3.8).[7] In a study evaluating risk factors for fetal malformations, Waller and associates showed that patients who had infants with spina bifida, heart defects, anorectal atresia, hypospadias, limb reduction defects, diaphragmatic hernia, and omphalocele were significantly more likely to be obese, with ORs between 1.33 and 2.10.[8] A meta-analysis of 12 studies demonstrated that the OR for having a fetus with a neural tube defect was 1.22, 1.70, and 3.11 for overweight, obese, and severely obese patients compared to normal weight patients, indicating that the risk rises with increasing obesity.[9]

Obese gravidas require more medical resources than normal weight patients and often present difficult technical problems for the medical personnel providing their care.[12] High BMI patients have been reported to require more interventions and care of all types, including obstetric ultrasound examinations, medications, telephone calls to providers, and prenatal visits with physicians compared to women of normal weight.[12]

In addition to requiring more numerous ultrasound examinations, the examinations required to detect fetal anomalies and pregnancy complications are often more technically challenging in obese compared to thinner patients.[13-22] The quality of the ultrasound examination done on an obese patient is technically inferior when compared to the same scan done on slimmer patients owing to the distance traversed by the sound beam and the density of adipose tissue. Hence, the quality of the ultrasound image relates inversely to the distance that the beam must travel to reach the fetus. The ultrasound beam is absorbed, dispersed, and attenuated in adipose tissue, limiting the image quality in evaluation of the fetus.[13-22] The ultrasound image is further degraded with each centimeter that it penetrates through the body to reach the fetus. As a result, the most obese patients who are at the highest risk of maternal and fetal complications also have the poorest quality imaging by ultrasound. Over time, advances in ultrasound technology have resulted in improved image quality even in the more challenging patients. Preprocessing and postprocessing filters, speckle-reduction filters, compound imaging, and tissue harmonic imaging have all contributed to improved image quality.[2,3] Despite

these new tools, the ultrasound image in obese gravidas often remains fuzzy and noisy and suffers from excessive backscatter and artifacts (Fig. 25-1).

A number of studies have compared the ability to evaluate the fetus and detect fetal anomalies in obese versus normal weight women. Stothard and colleagues showed that although the risk of many fetal anomalies is significantly higher in obese compared with normal weight patients, a fetal anatomic survey was not completed at the time of the first ultrasound detailed scan in more than 50% of obese women.[10] Dashe and associates evaluated the quality of second trimester ultrasound studies done at 18 to 24 weeks on a cohort of 10,112 patients, 34% of whom were overweight and 26% of whom were obese.[13] The following 10 anatomic views were evaluated for adequacy: cerebral ventricles, posterior fossa, midline face (profile), four-chamber view of the heart, spine, ventral wall, cord vessels, stomach, kidneys, and bladder. Table 25-3 lists the relationship between successful scans and obesity class, showing a steady decline in scan quality with increasing BMI.[13] Maxwell and coworkers compared patients with a BMI of 30 or higher (average 35.7) with those having a BMI lower than 25 and found that 26% of the anatomic surveys in obese women were incomplete compared to 2.5% of those in women with a normal BMI.[15] Uhden and colleagues also reported that the percentage of poor ultrasound images rose from 6.4% to 17.4% when comparing normal weight to obese patients, whereas the prevalence of heart defects was higher (relative risk = 2.04) in obese and overweight women when compared to normal weight patients.[11]

Several other investigators have also reported that poor fetal anatomic visualization increases with maternal BMI, although the imaging improves with advancing gestational age in most patients.[19] Hence, it is recommended that obese gravidas be imaged later in gestation to avoid excessive repeat ultrasound examinations to complete the fetal survey.[22] In one study of 7140 patients, maternal BMI was inversely proportional to the rate of completion of anatomic surveys, and the number of scans required to obtain satisfactory images increased directly with BMI. Delaying the initial survey until 20 weeks (rather than 18 weeks) has been reported to increase the chance that the fetal anatomic survey can be completed in a single ultrasound examination.[21]

Hendler and associates evaluated the rate of poor visualization of specific fetal parts on ultrasound scans and found that it correlated linearly with the degree of the patient's obesity and was significantly worse in the obese group for both the fetal spine (43% vs. 29%) and heart (37% vs. 19%).[16] Although visualization of cardiac anatomy improved when the scan was repeated at 21 weeks' gestation, the heart was still inadequately imaged in 20% of the obese population even after multiple scans.[16]

Fuchs and coworkers reported on several factors associated with successful completion of ultrasound scans in overweight and obese patients, including having 10 additional minutes for the scan, moving the fetus so that the back was in posterior or lateral position, having a more experienced person perform the scan, and body habitus that

TABLE 25-1 Risks Associated With Maternal Obesity

Maternal Risks	Fetal Risks
Cardiovascular disease	Congenital anomalies
Hypertension	Lower detection of fetal anomalies
Recurrent miscarriage	Macrosomia
Gestational diabetes	Inaccurate fetal weight estimate
Preeclampsia	Preterm birth
Cesarean delivery	Stillbirth and neonatal death
Postpartum hemorrhage	
Wound infection	
Thromboembolism	
Maternal death	

TABLE 25-2 Fetal Anomalies Associated With Maternal Obesity

Anomaly	OR (95% CI)
Anal atresia	1.48 (1.12-1.97)
Cardiac defects	1.30 (1.12-1.51)
Hydrocephalus	1.68 (1.19-2.36)
Limb reduction	1.34 (1.03-1.73)
Neural tube defect	1.87 (1.62-2.15)

CI, confidence interval; OR, odds ratio.
Modified from Stothard KJ, Tennant PWG, Bell R, Rankin J: Maternal overweight and obesity and the risk of congenital anomalies. A systematic review and meta-analysis. JAMA 301(6):636-650, 2009.

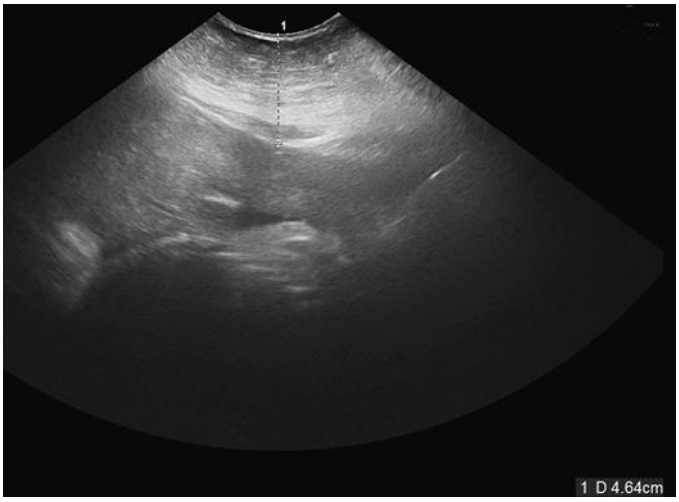

FIG 25-1 This is an attempt at imaging a third trimester fetus in an obese patient. Note the very echogenic adipose tissue in the anterior abdominal wall that attenuates the sound before it reaches the fetus.

TABLE 25-3 Percentage of Patients in Whom the Fetal Anatomic Survey Was Completed by BMI Category

	Normal Weight (BMI < 25)	Overweight (BMI 25-29)	Class I Obesity (BMI 30-34)	Class II Obesity (BMI 35-39)	Class III Obesity (BMI ≥ 40)
Dashe et al[13]	72%	68%	57%	41%	30%
Thornburg et al[17]	79%	76%	72%	61%	49%

BMI, body mass index (in kg/m^2).

included a thinner maternal abdominal wall thickness.[18] Another study found that sonologists with more than 20 years' experience were more likely to complete a successful fetal ultrasound scan on obese patients (adjusted OR 3.27; 95% CI 1.15-9.25) compared to their less experienced colleagues, suggesting that experience also plays a role in obtaining satisfactory images on challenging patients as well as perhaps in confidence in reporting on suboptimal examinations.[20]

Several studies have evaluated the use of ultrasound in screening for Down syndrome in obese gravidas.[22-24] As the maternal BMI increases, it takes significantly more time to obtain a nuchal translucency measurement, and the failure rate of obtaining an adequate measurement increases.[22] Tsai and colleagues studied 5690 patients and reported that the degree of obesity hampered performance of the genetic sonogram.[23] This study also showed that the chance of finding one or more ultrasound markers for aneuploidy screening differed significantly among BMI groups (16% in normal, 13% in overweight, 15% in class I, 12% in class II, and 10% in class III obese women, $P < 0.02$), indicating that obese women are less likely to have soft signs identified by ultrasound.[23]

The FaSTER trial was a large prospective cohort study performed to compare a variety of first and second trimester screening strategies for Down syndrome. A secondary analysis of this study reported on the detection of anomalies in obese gravidas.[24] Cardiac anomalies were identified with a higher sensitivity and specificity in women with a BMI lower than 25 compared to obese women. In a logistic regression model, maternal obesity diminished the likelihood that fetal malformations would be identified sonographically (OR 0.7; 95% CI 0.6-0.9; $P = 0.001$).[24]

In patients in whom fetal anatomy is poorly visualized because of increased maternal abdominal wall thickness, the American Institute of Ultrasound in Medicine guidelines suggest that the report of the sonographic examination should document the nature of the technical limitation.[25] Although a follow-up examination may be helpful and should be performed in 2 to 4 weeks, in some cases the fetal anatomy is still not optimally visualized. In such cases, it is suggested that further follow-up is recommended only if clinically indicated.[26]

There is evidence that high maternal BMI is also associated with a reduced accuracy of the sonographic fetal weight estimate. Fox and associates demonstrated that maternal BMI is associated with an increased absolute error and absolute percent error in sonographic fetal weight calculation, even after controlling for birth weight.[27] It has been suggested that customized fetal growth curves may improve the accuracy of fetal weight estimates and better predict fetal growth restriction in obese patients.[28]

As noted earlier, a number of advances in ultrasound technology have improved image quality and include speckle-reduction filters, tissue harmonic imaging, and other noise-reducing methods to enhance the penetration of the sound beam and clarity of the image.[29,30] Nonetheless, the distance between the transducer and the fetus remains the greatest obstacle to adequate fetal imaging in the obese patient.

Table 25-4 lists several strategies that can help improve imaging in these circumstances.[31] Use of different transducers, including sector probes with smaller footprint and narrower field of view, as well as lower frequency, may improve tissue penetration and, thus, image quality. Ultrasound equipment allows selecting preset parameters optimized for challenging patients, including maternal obesity. Use of the umbilicus as an acoustic window requires traversal of less adipose tissue between the transducer and the uterus and fetus. Unfortunately, this window is generally small, thus limiting the improved visualization to a small portion of the uterus (Fig. 25-2). One can also lift the panniculus and scan beneath it, just over the pubic symphysis. This approach affords access to the lower uterine segment but again results

TABLE 25-4 Techniques to Improve Ultrasound Image Quality in Obese Gravidas

1. Transducer selection: smaller footprint (sector); narrow field of view; lower frequency
2. Use of preset parameters optimized for obesity
3. Improve signal-to-noise ratio
   a. Compound imaging, speckle-reduction filters, preprocessing and postprocessing, and tissue harmonics
4. Transvaginal ultrasound with external manipulation of fetus
5. Use of umbilicus as acoustic window
6. Patient positioning
   a. Sitting while imaging above panniculus
   b. Modified Sims position with imaging from flank or groin
7. Full maternal bladder

Modified from Benacerraf BR: The use of obstetrical ultrasound in the obese gravida. Semin Perinatol 37:345-347, 2013; Benacerraf BR: A technical tip on scanning obese gravidas. Ultrasound Obstet Gynecol 35:615-616, 2010.

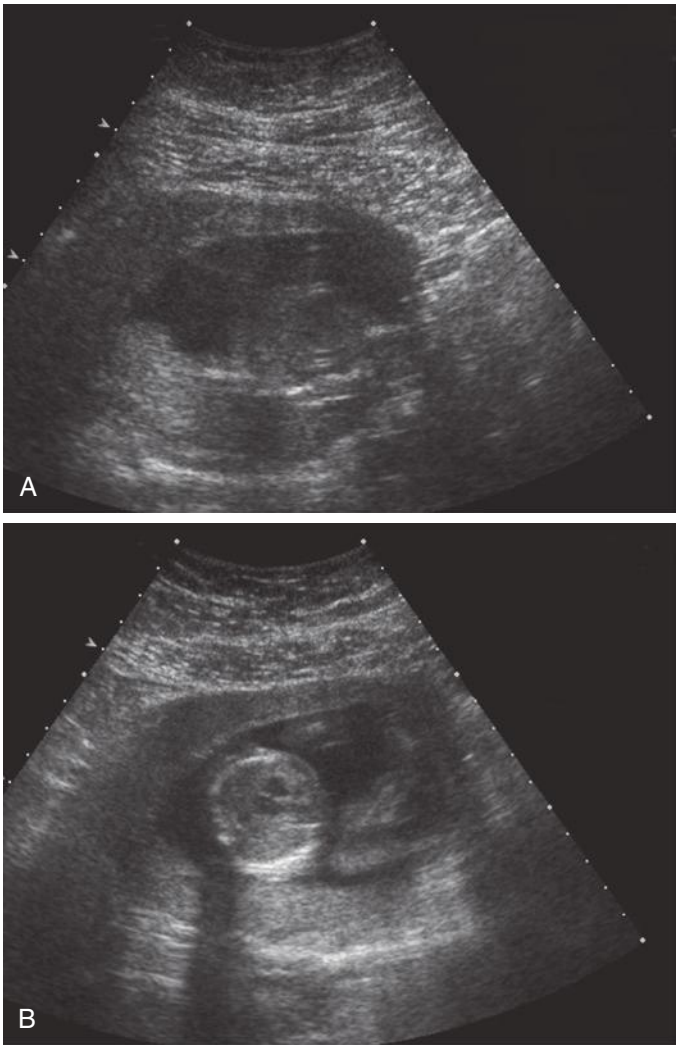

FIG 25-2 Transabdominal scan of a 16-week fetus in a severely obese patient. **A,** The fetal chest is seen from the midabdomen through the panniculus. **B,** The fetal chest of the same fetus is seen through the umbilicus. Note that the ultrasound beam is severely degraded in A. In B, there is less adipose tissue and a clearer image of the fetal heart when imaging through the umbilical area.

in limited visualization of the body and fundus of the uterus. Alternatively, one can scan the patient in a sitting position and scan directly above the panniculus, in the midabdomen, pushing the panniculus down. Because the mid- to upper abdomen has less adipose tissue than the lower abdomen, this approach allows scanning through a decreased distance between the skin surface and the fetus. Filling the patient's bladder will raise the fundus of the uterus to a more cephalad position and may improve visualization by allowing scanning through a thinner portion of the anterior abdominal wall.

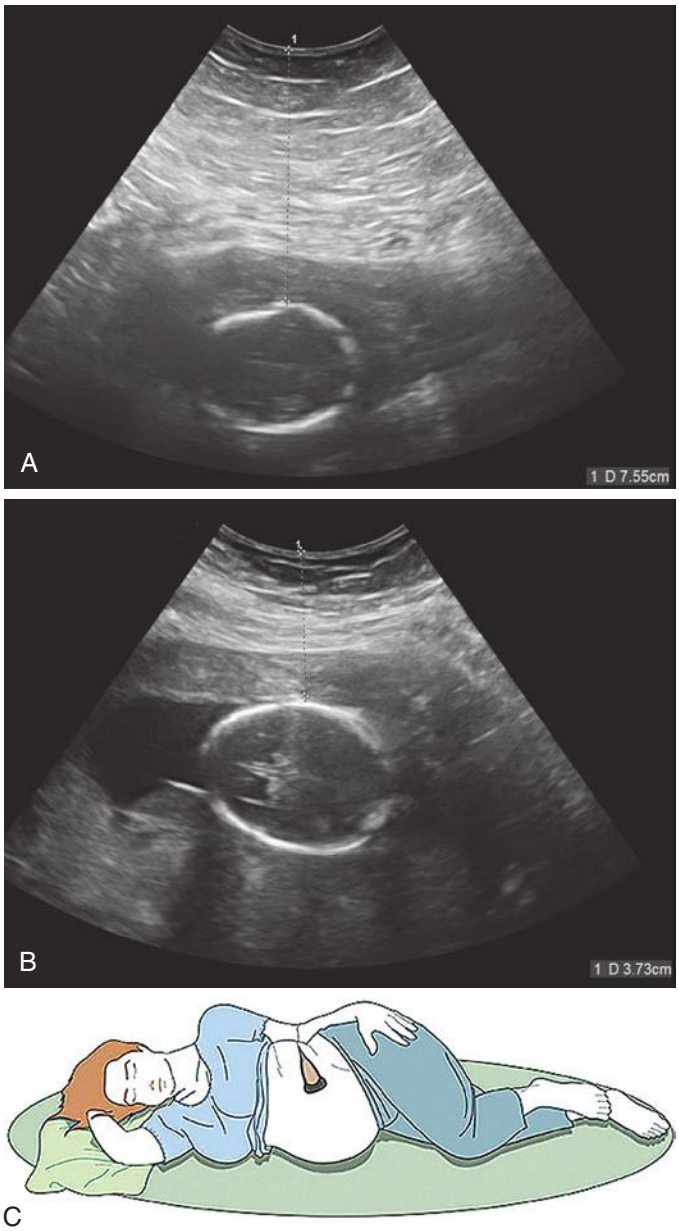

FIG 25-3 Scan of the fetal head at 17 weeks in a severely obese patient. **A,** Image of the fetal head when the patient is lying on her back with the transducer on the surface of the maternal belly. Note that the transducer is 7.5 cm from the uterine wall. When the same patient is placed in the modified Sims position, the distance is reduced to 3.7 cm and the quality of the image is improved (**B**). **C,** Drawing of a patient in the modified Sims position, showing the panniculus on the table and the position of the transducer on the flank. (From Benacerraf BR: The use of obstetrical ultrasound in the obese gravida. Semin Perinatol 37:345-347, 2013, used with permission.)

Especially in the early second trimester, scanning the obese patient transvaginally can provide images that are produced with a higher frequency transducer at a shorter distance to the fetus than when using the traditional transabdominal methods. One can also attempt to manipulate the fetal position using the free hand on the maternal abdomen to shift the fetal presenting part during the transvaginal scan so as to better visualize all the fetal anatomy. Lastly, use of a modified Sims position (Fig. 25-3C) allows the examiner to scan the fetus through the mother's flank or groin, which typically have less tissue, and therefore less depth of penetration is required when compared to the anterior abdominal wall.[32] In the modified Sims position, the patient is placed on her side and further rotated ventrally so that the panniculus lies on the ultrasound table. Figure 25-3 shows the effect of the narrower distance between the transducer and the fetal part when using the modified Sims position. It is important to try this position on both sides because one side is typically better than the other, but the optimal side is unpredictable and varies for each patient and fetal position.

In conclusion, obesity is a rapidly growing public health problem and is epidemic in the United States. Maternal obesity results in a significantly elevated risk for adverse outcome for both mother and fetus, including a higher frequency of fetal anomalies. Obese patients present a difficult technical problem for the ultrasound examiner because sound penetrates adipose tissue poorly and produces images limited by noise and artifact, often requiring repeat examinations to adequately assess fetal anatomy. Scans performed later in gestation may be useful to complete the fetal anatomic survey, and special techniques such as patient positioning or transvaginal scanning can enhance the sonographic image quality in these patients.

Normal Anatomy of the Female Pelvis and Transvaginal Sonography

Jill E. Langer

SUMMARY OF KEY POINTS

- Transabdominal sonography (TAS) and transvaginal sonography (TVS) are often complementary, providing different diagnostic information. TAS provides a wider field of view and better visualization of superficial structures and large pelvic masses but has limited resolution. The transvaginal approach allows the probe to be placed closer to the "target organs," providing higher resolution imaging, but has a limited field of view.
- Because of the ability to use higher frequency probes, TVS usually provides the best anatomic detail. Therefore, TVS is considered the optimal sonographic technique with the highest diagnostic yield and should be incorporated into the sonographic examination of the female pelvis unless there are reasons that the transvaginal approach should be avoided.
- Not all patients are appropriate candidates for transvaginal examination. The examination should not be performed on any patient who does not or cannot willingly consent to the procedure, as well as on most virginal patients and those who experience marked discomfort with probe insertion.
- The appearance of the normal endometrium and ovary varies significantly throughout the menstrual cycle in women of reproductive age. It is important to be cognizant of the expected changes in order to avoid misinterpreting physiologic changes as pathologic.
- Transperineal, translabial, and transrectal sonography should be considered alternative approaches for imaging the female pelvis and are particularly useful for evaluation of the postmenopausal uterus, the cervix, and the lower urinary tract.

OUTLINE

Pelvic sonography is considered the initial imaging tool of choice for assessing suspected gynecologic disorders in patients of all ages. Sonography offers the advantages of widespread availability, low cost, and lack of exposure to ionizing radiation and is often the only imaging examination necessary for diagnosis of uterine, ovarian, and adnexal disease. In addition, sonography is extremely useful in the evaluation of pathologic changes affecting the pelvic portions of the urinary system, gastrointestinal tract, and musculoskeletal structures that may mimic the clinical presentation of gynecologic disease. In many ultrasound laboratories, the standard protocol for ultrasound examination of the female pelvis begins with TAS using the filled urinary bladder as the acoustic window, followed by TVS after emptying the bladder and placing the patient in the lithotomy position.[1,2] The two imaging techniques are complementary, often providing different diagnostic information. TAS provides a wider field of view than the transvaginal approach and provides better visualization of superficial structures and structures remote from the vagina. However, by placing the probe closer to the "target organs," the transvaginal approach requires less depth of penetration and bypasses the attenuating soft tissues overlying the pelvic organs, allowing utilization of a higher frequency probe, which provides higher resolution and anatomic detail of the uterus, ovaries, and adnexa (Fig. 26-1). The normal sonographic anatomy described in this chapter reflects a combined transabdominal and transvaginal approach and is weighted, as in clinical practice, to emphasize the positive attributes of both TVS and TAS.

INDICATIONS AND CONTRAINDICATIONS

High-resolution TVS has been widely available since the mid-1980s and is considered an integral part of gynecologic as well as early obstetric sonographic examinations.[1,2] TVS typically provides more anatomic detail of the uterus, endometrium, ovaries, and adnexa than does TAS. This is because the probe is placed closer to the organs of interest and requires less depth of penetration; therefore, a higher frequency probe with ensuing higher resolution can be utilized (Figs. 26-2 and 26-3).

An additional advantage of TVS is the capability of using the probe tip to assess pelvic structures for tenderness. By applying gentle

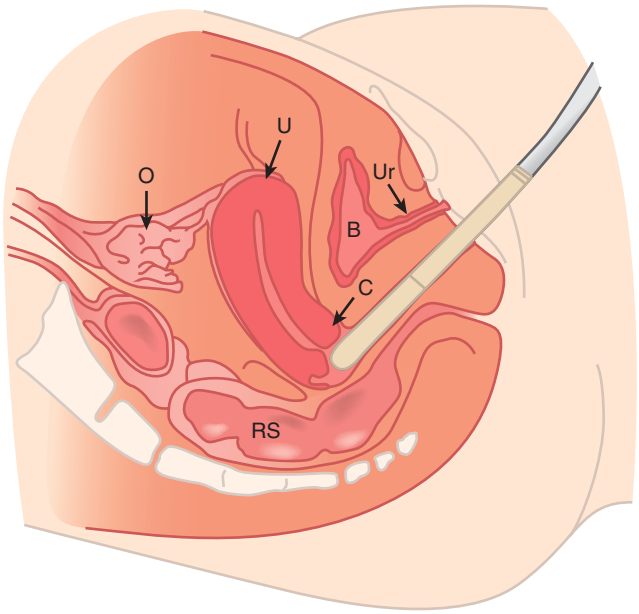

FIG 26-1 Diagrammatic representation of the transvaginal ultrasound examination. Insertion of the probe into the vaginal canal allows the transducer to be placed in close proximity to the pelvic organs, bypassing the overlying soft tissues. Because less depth of soft tissue penetration is required, a higher frequency transducer can be utilized, providing better resolution in comparison to the transabdominal approach. B, urinary bladder; C, cervix; O, ovary; RS, rectosigmoid colon; U, uterine body; Ur, urethra.

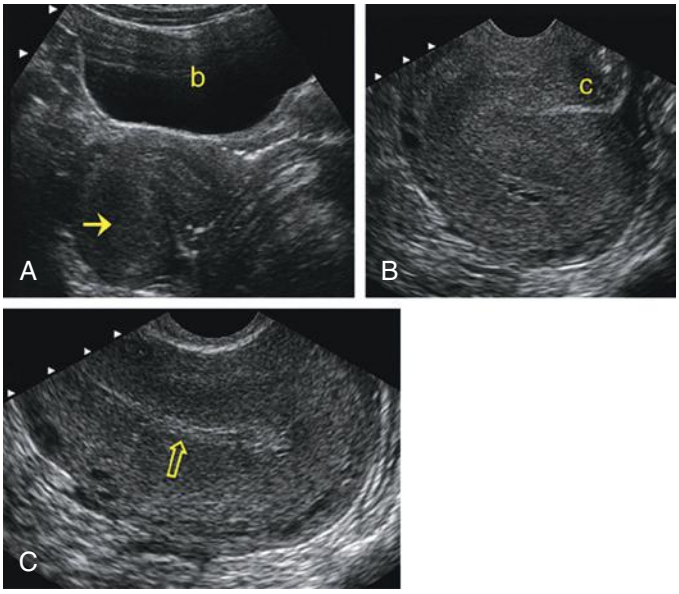

FIG 26-2 Improved visualization of the uterus with transvaginal imaging. **A,** Longitudinal transabdominal sonogram of a retroflexed uterus performed through a full urinary bladder (b). The endometrial canal (*arrow*) in the body of the uterus is not well seen as it lies parallel to the ultrasound beam. **B,** Transvaginal sonogram of the same patient. The cervix (c) is interposed between the transvaginal probe and the body of the uterus. This gives suboptimal visualization of the myometrium and endometrial canal. **C,** Transvaginal sonogram of the body and fundus of the uterus after the probe has been repositioned beyond the cervix and angled posteriorly. The probe now lies immediately adjacent to the retroflexed uterus, providing much improved visualization of the endometrium (*open arrow*).

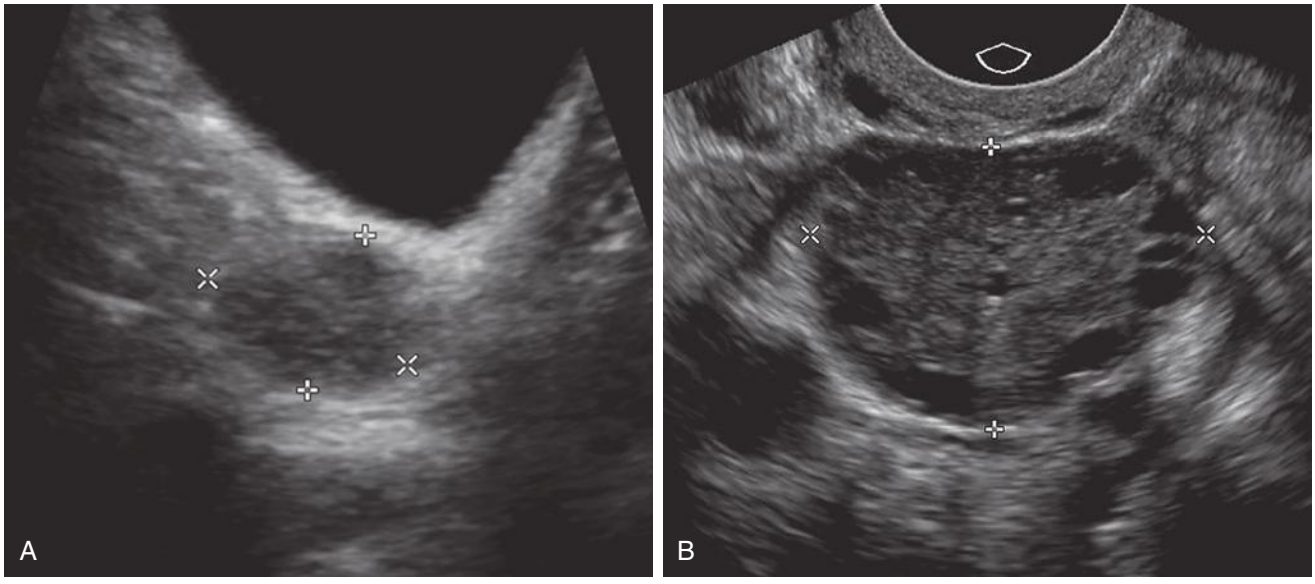

FIG 26-3 Improved characterization of ovarian morphologic appearance with transvaginal imaging. **A,** Longitudinal transabdominal scan of the right ovary (*calipers*) provides little anatomic detail. **B,** Transvaginal scan of the right ovary (*calipers*) in the sagittal plane demonstrates multiple small peripheral anechoic follicles and central echogenic stroma in this patient with polycystic ovary syndrome.

pressure with the transducer tip to pelvic structures, it is possible to localize the region of tenderness with greater specificity than with TAS or bimanual examination. Hence, TVS is considered the optimal sonographic technique for imaging the female pelvis and should be incorporated into the sonographic examination in all situations for which it will provide additional clinically useful diagnostic information, barring contraindications to the transvaginal approach (see later).[1-8]

Indications for pelvic sonography include but are not limited to the following[1]:

- Evaluation of pelvic pain and pelvic masses
- Evaluation of endocrine abnormalities, including polycystic ovaries
- Evaluation of dysmenorrhea, amenorrhea, abnormal vaginal bleeding, and delayed menses
- Evaluation, monitoring, and treatment of infertility patients
- Evaluation of pelvic anatomy in the setting of a limited clinical examination
- Evaluation of suspected pelvic infection
- Further characterization of a pelvic abnormality noted on another imaging study
- Evaluation of congenital uterine and lower genital tract anomalies
- Evaluation of excessive bleeding, pain, or signs of infection after pelvic surgery, delivery, or abortion
- Localization of an intrauterine contraceptive device
- Screening for malignancy in high-risk patients
- Evaluation of incontinence or pelvic organ prolapse
- Evaluation for possible ectopic pregnancy
- Evaluation of a first trimester gestation for viability, growth, and anomalies
- Evaluation of the placenta, cervix, and other pelvic structures in second and third trimester gestations
- Evaluation of fetal anatomy in second and third trimester gestations
- Guidance for interventional or surgical procedures

However, not all patients are appropriate candidates for TVS. The transvaginal examination should not be performed in any patient who does not or cannot willingly consent to the procedure. There may be cultural, religious, or social reasons why TVS is inappropriate. In addition, TVS is rarely recommended in premenarchal or virginal patients, and if deemed necessary, it should be performed only after careful discussion with the individual and parent or guardian, as appropriate.[1,2] If a patient experiences anxiety or discomfort at the time of attempted probe insertion (e.g., in the setting of a narrow introitus or vaginal abnormality such as atrophic or inflammatory vaginitis), termination of the transvaginal portion of the examination is recommended. It may be helpful to allow the patient to insert the probe herself. In many postmenopausal women, TVS is required to adequately image the endometrium and ovaries, because the TAS examination may be compromised by a variety of senescent changes, including decreased urinary bladder capacity, increased body habitus, an atrophic and ill-defined endometrium, and small ovarian size. Fortunately, postmenopausal patients tolerate the transvaginal examination well, with an overall patient acceptance rate that is only slightly less than that in women of reproductive age.[3] Transrectal sonographic imaging may be performed as an alternative to TVS to image the uterus and adnexal structures in postmenopausal women with their consent. Transperineal and translabial scanning can be used in patients who are not candidates for the transvaginal approach and is also useful for evaluation of pelvic organ prolapse, as well as of the cervix and the lower urinary tract[1] (Fig. 26-4). TVS may also be contraindicated in some second and third trimester obstetric patients with active bleeding or ruptured membranes.

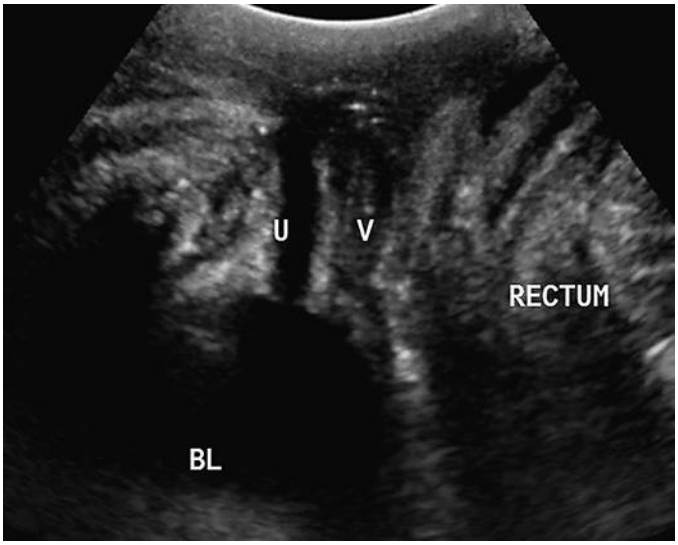

FIG 26-4 Transperineal image of the urethra. Longitudinal image obtained by placing the probe on the perineum shows a normal urethra (U), which appears as a nearly anechoic linear channel arising from the bladder cephalad and parallel to the vagina (V) in this patient with symptoms concerning for lower urinary tract disease. BL, urinary bladder.

Although TVS offers superior resolution to TAS, TVS maybe compromised by sound attenuation (e.g., by large or calcified leiomyomas in the lower uterus) or by positioning of the ovaries or other lesions high in the pelvis beyond the field of view of the transvaginal probe. Large uterine size and fixation of the uterus to the anterior abdominal wall by adhesions, such as after cesarean delivery, can also limit the ability of TVS to assess the entire uterus for pathologic change or to perform accurate measurements. In these situations, TAS provides a wider field of view than the transvaginal approach and thus allows better visualization of structures in the upper pelvis or in a superficial location. Furthermore, TAS can provide a more panoramic view of the entire pelvis, which is helpful in the setting of a large pelvic mass (Fig. 26-5). TAS also allows assessment of related intra-abdominal disease and structures, such as quantification of free intraperitoneal fluid in the hepatorenal space and paracolic gutters, hydronephrosis in the setting of a large pelvic mass or malignancy, and, more rarely, identification of peritoneal implants.

PROTOCOLS

Protocols for pelvic sonography vary between institutions and can be tailored according to the specific clinical indication. In some institutions, it is routine to perform a complete transabdominal pelvic sonogram using the distended urinary bladder as an acoustic window, followed by a complete transvaginal pelvic sonogram with an empty bladder. In other institutions, women are not asked to fill their bladders before routine pelvic sonograms, but initially have a limited transabdominal examination, irrespective of the fullness of the urinary bladder, to screen for large pelvic masses and to measure the uterus. Subsequently, the patient is asked to void and a complete transvaginal sonogram is performed. At other sites, patients initially undergo TVS with an empty bladder, because this examination alone will provide diagnostic imaging in the majority of cases.[1,9] In this scenario, if TVS does not provide adequate imaging, most commonly because one or both of the ovaries are not visualized or there is incomplete visualization of an enlarged uterus or pelvic mass, TAS with an empty or partially filled urinary bladder is then performed.[9] In a small minority of

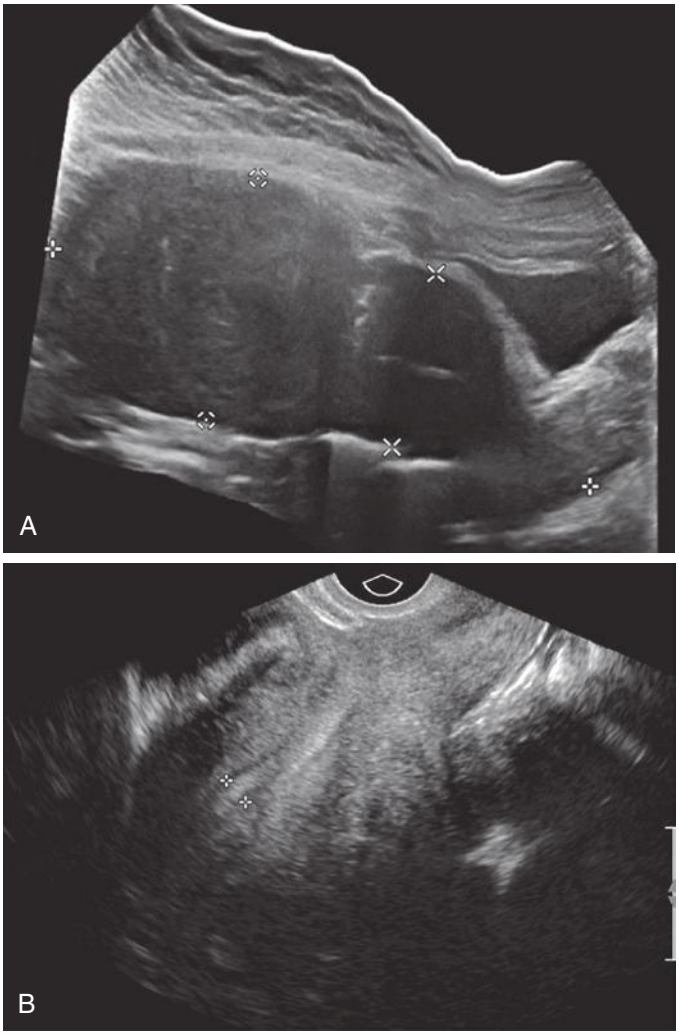

FIG 26-5 Pelvic mass only visible on transabdominal sonography. **A,** Longitudinal midline extended field of view transabdominal sonogram of the uterus demonstrates a large fundal leiomyoma (*calipers with central dot*) extending to the level of the umbilicus. Measurement of the uterus includes the large leiomyoma (*calipers*). **B,** Longitudinal transvaginal image does not image the leiomyoma, as it was located above the uterine fundus, beyond the field of view of the transvaginal probe. Calipers show endometrium.

patients, the combination of these two examinations will still fail to visualize an ovary or the entire pelvic anatomy, and the patient is then asked to fill her bladder and the transabdominal examination is repeated with a distended bladder.

Patients who undergo serial pelvic sonography for specific targeted indications, such as follicle monitoring, are often only examined by TVS. When pelvic sonography is performed in emergent clinical situations, TAS may be initially and quickly performed in the setting of an empty or incompletely filled bladder to assess for the presence of hemoperitoneum, a large pelvic mass, or other pathologic features, and TVS is then performed if considered necessary as guided by the clinical scenario (Fig. 26-6).

PATIENT AND PROBE PREPARATION

As with all ultrasound applications, it is standard practice to use the highest possible transducer frequency that allows visualization of the target organs.[1,2] During TAS, visualization of the pelvic organs is typically limited by sound attenuation by the intervening anterior abdominal wall and subcutaneous and preperitoneal fat, as well as fat in the mesentery and omentum. As a result of this attenuation and the distance of the area of interest from the anterior abdominal wall, it is often not possible to use transducers with frequencies above 6 MHz for TAS, unless the patient is very thin. TVS is typically performed using a probe of 7.5 MHz or higher frequency, taking advantage of the ability to place the probe closer to the pelvic organs because of fewer intervening structures and resulting in less sound attenuation.

The patient should void immediately before the transvaginal examination so that the urinary bladder is as empty as possible. This will improve visualization of the reproductive organs, especially the adnexal structures, which may be displaced out of the pelvis when the bladder is distended, and will reduce patient discomfort. The sonologist or sonographer should obtain a pertinent history from the patient, explain the rationale for performing the TVS as well as how the examination is performed, and obtain verbal consent before beginning the examination.[1,2] If a male sonologist or sonographer is to perform the examination, a female staff member (an aide, nurse, or other staff member) should be present in the room for the entire transvaginal examination to act as a chaperone. Consideration of having a chaperone present for all TVS, even if performed by a female, should be in accordance with local policy and is recommended in some institutions.[1,10] The patient should be positioned as comfortably as possible in the lithotomy position using either a gynecologic examination table with stirrups or by placing cushions or folded linens underneath the buttocks to elevate and abduct the hip region. The patient should be appropriately covered and draped, and the examination should be conducted with the same respect for privacy afforded patients during the performance of a bimanual pelvic examination.[2]

To prevent the spread of infectious disease, the transvaginal probe should be appropriately disinfected using high-level disinfection protocols between uses according to the manufacturers' and Occupational Safety and Health Administration (OSHA) recommendations. Following disinfection, the probe is wiped clean, and either a small amount of transducer coupling gel is placed inside a probe cover or a pregelled probe cover is placed over the probe. Because of concern for latex allergies, many laboratories use nonlatex probe covers for all patients. Care is taken to minimize air bubbles over the transducer face when applying the probe cover, and if they are noted, the probe cover should be readjusted. The final step in the process of probe preparation is to lubricate the tip of the covered probe with a sterile, nonspermicidal lubricant. Individual packets are preferred over large multiuse containers to minimize the potential for contamination of the gel and reduce the risk of transmission of infection. The sonographer should wear gloves while preparing the probe and performing the examination.[1,2]

IMAGING TECHNIQUE

The patient, the sonographer, or the physician may introduce the transvaginal transducer, preferably under real-time monitoring. After insertion, the sonologist should position the probe to optimize imaging of the pelvic organs, usually by placement of the probe in the anterior or lateral vaginal fornix and by the application of gradually applied firm pressure against the vaginal wall as tolerated by the patient. The orientation of the image is controlled by probe rotation and angulation (Fig. 26-7). Before recording any images, many sonologists will perform a pelvic survey by slowly sweeping the ultrasound beam in a long-axis orientation from the midline through the adnexa continuing out to the pelvic sidewalls on each side. The probe is then rotated 90 degrees counterclockwise into the short axis, and the beam is swept from the

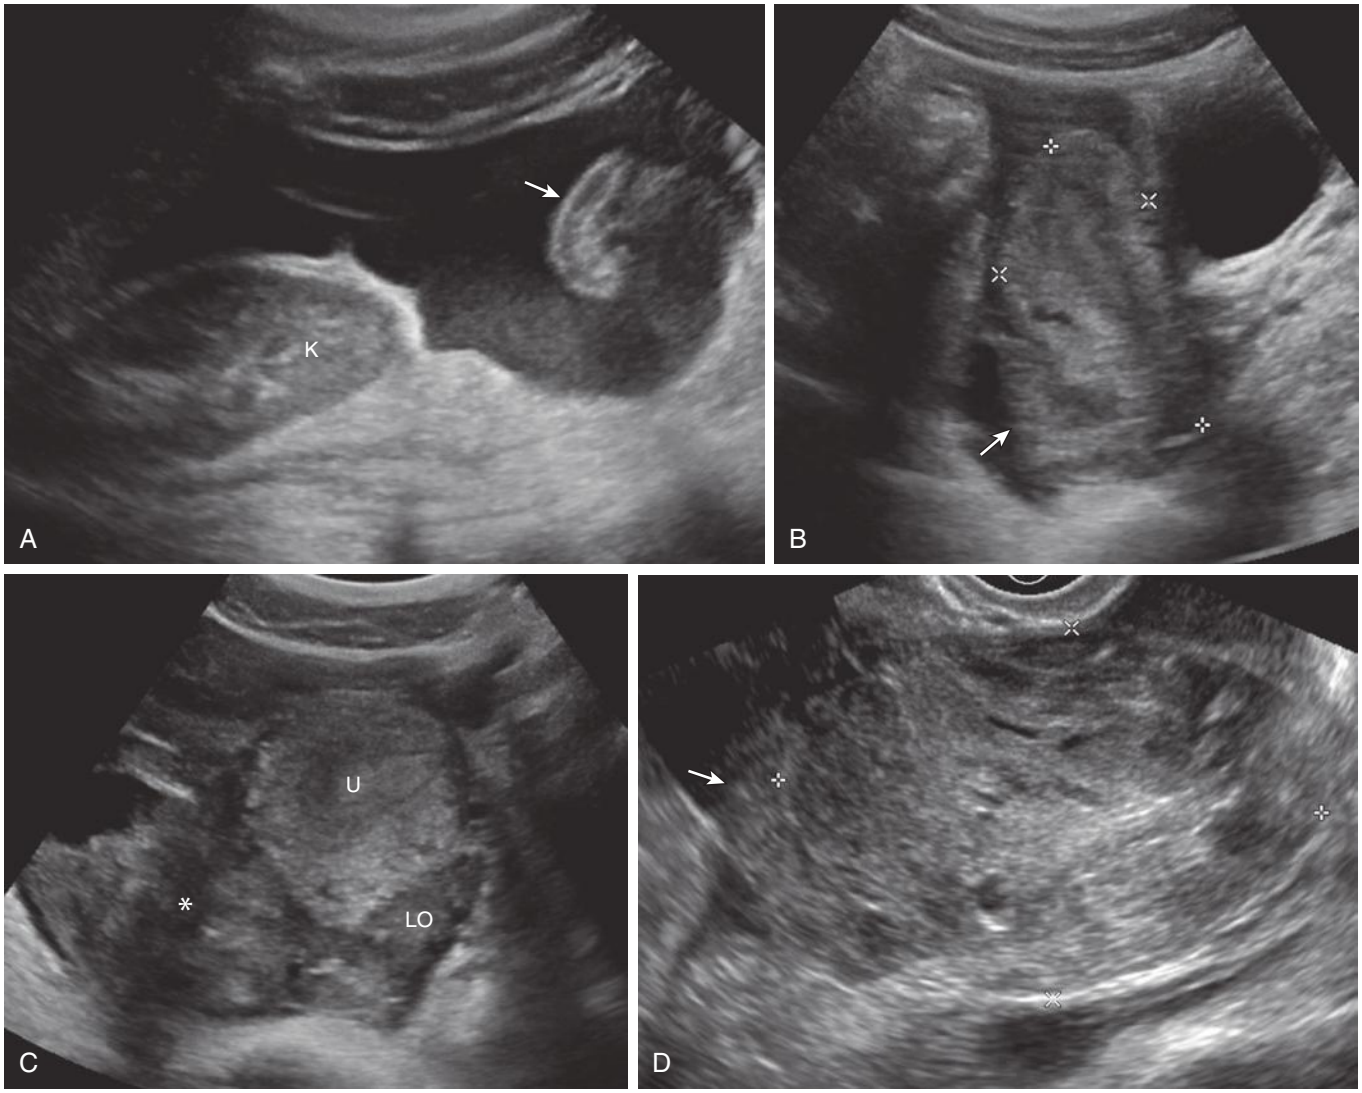

FIG 26-6 Hemoperitoneum from a ruptured ovarian cyst in a nongravid patient. **A,** Longitudinal image of the right flank demonstrates a large amount of intraperitoneal fluid containing low-level dependent echoes, most consistent with hemoperitoneum surrounding a bowel loop (*arrow*). K, lower pole of the right kidney. **B,** Longitudinal scan of the pelvis shows the uterus (*calipers*) surrounded by pelvic fluid and echogenic material representing intraperitoneal hemorrhage in the cul-de-sac (*arrow*). **C,** Transabdominal transverse scan of the pelvis shows a large amount of echogenic material (*asterisk*) in the right adnexa, obscuring the right ovary. LO, left ovary; U, uterus. **D,** Transvaginal longitudinal scan of the right adnexa shows altered morphologic appearance of the right ovary from a ruptured cyst. Note clotted blood (*arrow*) along the superior aspect of the ovary (*calipers*). The patient was stable at the time of the ultrasound examination, allowing the transvaginal scan to be performed to confirm the suspected diagnosis of a ruptured ovarian cyst with hemoperitoneum.

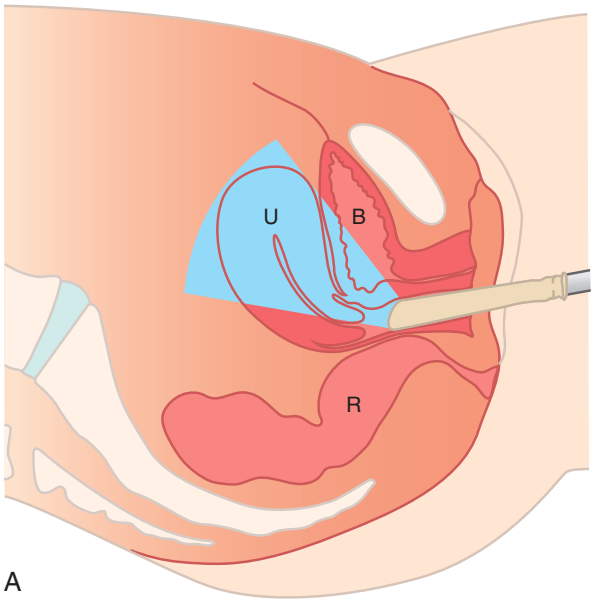
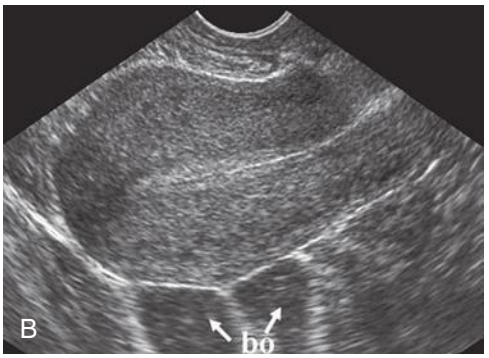
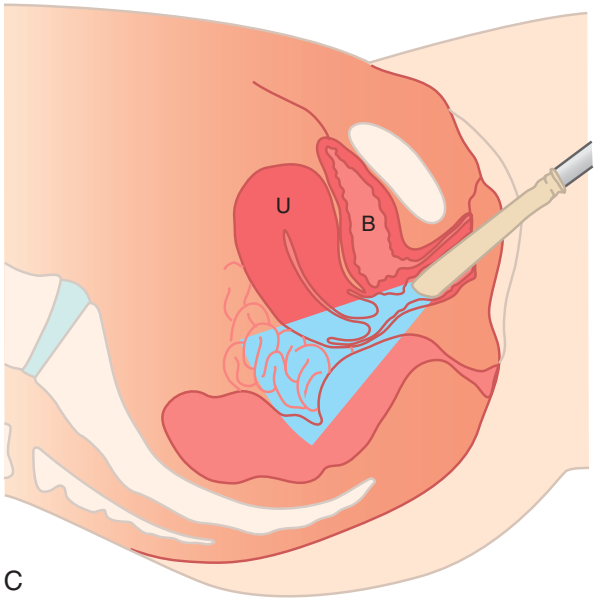
cervix to the fundus of the uterus. The probe is then angled to each side of the pelvis, and scanning is performed by sweeping both superiorly and inferiorly through each adnexal region. The survey quickly ascertains the relative positions of the uterus and ovaries and identifies any obvious disease. Additionally, the probe can be advanced or withdrawn, which will move adjacent pelvic viscera and displace bowel and allow structures to be placed in the focal zone of the transducer or moved out of regions with near-field artifact. In response to gentle pressure with the transvaginal probe, the pelvic organs should normally slide over one another. Any restriction to normal motion may indicate the presence of adhesions.[11] Visualization of the pelvic anatomy can also be facilitated by applying pressure on the patient's anterior abdominal wall with the sonologist's nonscanning hand, thereby pushing a mobile ovary or a mass down into the field of view of the transvaginal probe.[2] In addition, the bimanual approach is extremely helpful in localizing pelvic tenderness or pain, allowing the sonographer to focus on the region most likely to harbor some pathologic problem.

After the survey, a set of static images (or video clips) is obtained and each is appropriately labeled to indicate the anatomic structure or region imaged, as well as the orientation of the probe.[1] In many patients, the long axis of the uterus and the ovary may be slightly oblique with respect to the long axis of the patient's body, and the

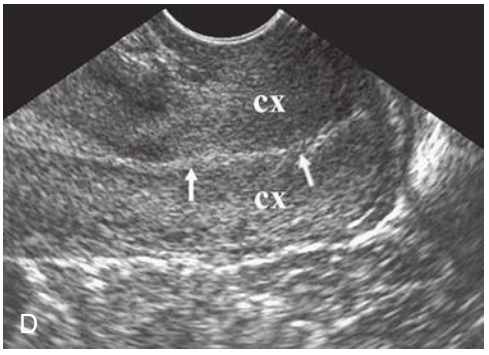


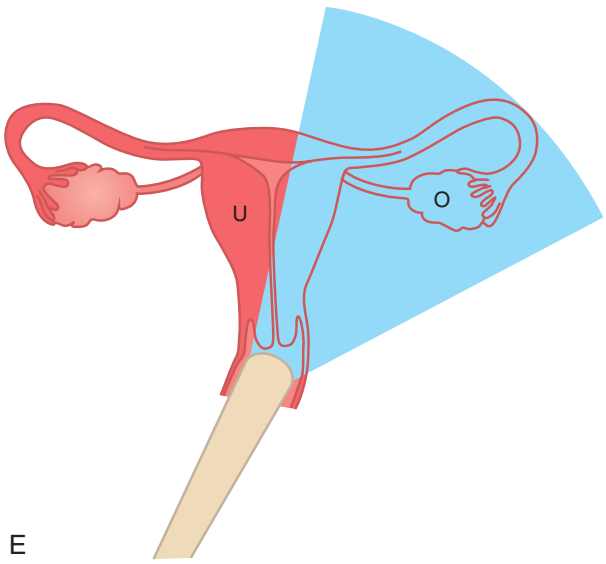
A



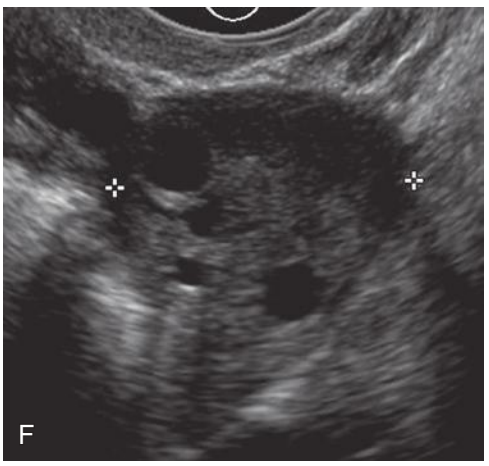


C





E



probe should be oriented along that same obliquity to image in the uterus and ovary each along its long axis. The long-axis TVS view is usually referred to as a sagittal imaging plane, and the short-axis view as a coronal or transverse imaging plane.[2] At our institution, the imaging protocol includes one or more static sagittal views of the posterior cul-de-sac, cervix (including the endocervical canal from internal to external os), midline uterus with and without the maximum anteroposterior (AP) dimension and length measured, parasagittal right and left uterine body, midline sagittal endometrium with and without the maximum AP dimension measured, and right and left ovaries with and without the maximum AP dimension and length of each measured. Coronal or transverse static images include posterior cul-de-sac; cervix; uterus at the fundal, midbody, and lower uterine segment levels with and without the maximum width measured; midbody and fundal endometrium; and right and left ovaries with and without the maximum width measured (Fig. 26-8).

Additionally, any disease or variant of normal must be assessed and appropriate additional images recorded. Most laboratories now include cine clip acquisition in addition to static images. Color Doppler, power Doppler, and pulsed Doppler are often added to the protocol depending upon the clinical situation and abnormality demonstrated on gray-scale imaging. The use of three-dimensional (3D) sonography also has become standard in many laboratories (Fig. 26-9). By capturing a volume of data, 3D imaging permits a display of any desired plane through the uterus, cervix, ovaries, and adnexa and optimizes assessment of the entire endometrial canal. 3D imaging is particularly useful for the assessment of intrauterine device (IUD) positioning and submucosal myomas, as well as uterine fundal contour and morphologic appearance in the setting of suspected congenital anomalies[1,12-14] (Fig. 26-10).

PELVIC ANATOMY

The pelvis, so-called because of its resemblance to a basin, is divided into two structurally continuous compartments, the true (or lesser) pelvis and the false (or greater) pelvis, by an oblique plane passing from the sacral promontory, the arcuate and pectineal lines, and the superior margin of the symphysis pubis (Fig. 26-11). The circumference of this plane is called the linea terminalis, or pelvic brim.[15] The true pelvis is the lower portion and is bounded anteriorly by the pubis and pubic rami, posteriorly by the sacrum and coccyx, laterally by the fused ilium and ischium, and inferiorly by the muscles of the pelvic floor. The false pelvis is bounded laterally by the flanged portions of the iliac bones, the base of the sacrum posteriorly, and the abdominal wall anteriorly and laterally. In the absence of masses in the nongravid patient, the uterus, ovaries, adnexa, and collapsed urinary bladder are located in the true pelvis.[16] As the urinary bladder fills, the dome of the bladder extends into the false pelvis and displaces the loops of small bowel superiorly, providing an acoustic window for transabdominal imaging. Intracavitary probes (transvaginal and transrectal) allow visualization of the pelvic viscera from within the true pelvis. Translabial and transperineal sonography view the true pelvis from the pelvic floor.

The anterior surface of the uterus is covered with peritoneum to the level of the upper cervix. The peritoneal space anterior to the uterus and posterior to the urinary bladder is the vesicouterine pouch or anterior cul-de-sac (Figs. 26-11 and 26-12). This space is usually empty, but it may contain loops of small bowel. Posteriorly, the peritoneal reflection extends to the posterior fornix of the vagina (Fig. 26-13), forming the posterior cul-de-sac or rectouterine pouch, which is the peritoneal space posterior to the uterus and anterior to the rectosigmoid colon.[16] On transvaginal imaging, a small amount of free fluid is often demonstrated in the posterior cul-de-sac in normal women of menstruating age, likely from fluid released at ovulation. However, the presence of fluid in the anterior cul-de-sac or lateral pelvic recesses, a large amount of fluid in the posterior cul-de-sac, and the presence of pelvic fluid in nonovulatory female patients all raise concern for intraperitoneal disease (Fig. 26-14).

Laterally, the peritoneal reflection forms the broad ligaments, which extend from the lateral aspect of the uterus to the lateral pelvic side walls bilaterally (Fig. 26-15). The broad ligaments divide the pelvic cavity into anterior and posterior compartments. The free border of the broad ligaments contains the fallopian tubes.[16] The broad ligaments may be identified sonographically when they are outlined by free intraperitoneal fluid (Fig. 26-16). The ovary is attached to the posterior layer of the broad ligament by reflections of peritoneum referred to as the mesovarium (see Fig. 26-12). The superior margin of the portion of the broad ligament containing the fallopian tube is referred to as the mesosalpinx. The superior margin of the broad ligament lateral to the fimbriated end of the fallopian tube is the suspensory ligament of the ovary (infundibulopelvic ligament), through which the ovarian vessels and nerves course.[17] The round ligaments arise at the uterine cornua, anterior to the fallopian tubes in the broad ligaments, and extend anterolaterally to run beneath the inguinal ligament and insert into the fascia of the labia majora. The ovarian (utero-ovarian) ligaments arise from the uterine cornua posterior to the fallopian tubes and attach to the inferior extremity of the ovary. In the absence of free intraperitoneal fluid, the fallopian tubes, mesovarium, mesosalpinx, and ovarian and round ligaments are not usually identified sonographically (Fig. 26-17). The suspensory ligament of the ovary is usually not directly visible. However, the ovarian artery within the suspensory ligament of the ovary is often identified with color Doppler on TAS or TVS[18,19] (Fig. 26-18). The base of the lateral margin of the broad ligament is continuous with the dense connective tissue of the pelvic floor, which unites with the supravaginal portion of the cervix. The lower medial margin of the broad ligament is widely attached to the connective tissues adjacent to the cervix known as the parametrium. The uterosacral ligaments extend posterolaterally from the supravaginal cervix, encircle the rectum, and insert into the fascia over the sacrum. The uterosacral ligaments form the lateral boundaries of the rectouterine pouch.[20]

The posterior wall of the vagina (*long arrow*) is seen merging with the posterior lip of the cervix (P). The posterior fornix is demonstrated by a thin echogenic line (*dashed arrow*). The external cervical os is seen at the end of the echogenic endocervical canal (*short, thick arrow*).

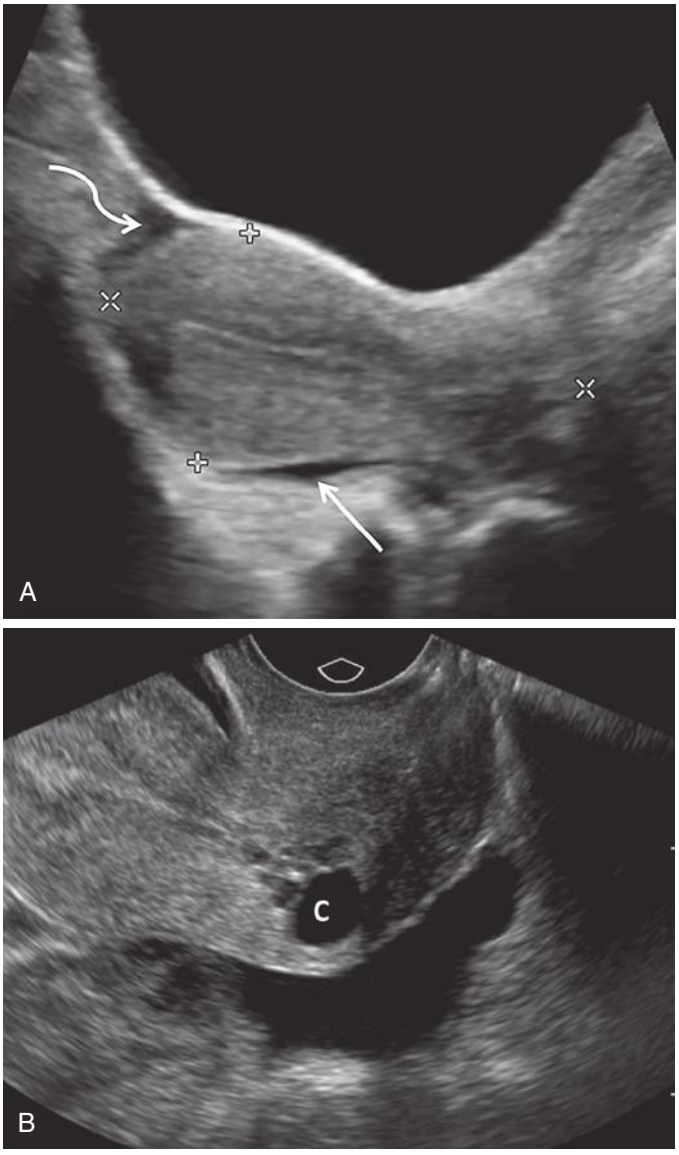

FIG 26-14 Free pelvic fluid. **A,** Longitudinal transabdominal sonogram of the uterus (*calipers*) shows a small amount of fluid in the anterior (*curved arrow*) and posterior cul-de-sac (*straight arrow*). **B,** Longitudinal transvaginal scan in a different patient shows anterior and posterior cul-de-sac free fluid. A nabothian cyst (C) is visible in the cervix.

VASCULAR ANATOMY

The aorta bifurcates into the common iliac arteries, which enter the pelvis anterior and medial to the psoas muscles. The common iliac arteries bifurcate into the external and internal iliac (or hypogastric) arteries approximately at the level of the L5/S1 disk. The external iliac artery is larger than the internal iliac artery and lies just medial to the psoas muscle, exiting the pelvis via the femoral canal to supply the lower extremity. The internal iliac arteries supply the pelvic viscera, walls of the pelvis, perineum, and gluteal region.[17] It is the anterior division that supplies branches to the bladder, uterus, cervix, and vagina. Anterior to the internal iliac arteries are the ureters, ovaries, and fimbriated ends of the fallopian tubes. The internal iliac veins lie posterior to their respective arteries.

The uterine artery ascends in a tortuous course lateral to the uterus in the broad ligament to the junction of the fallopian tube and the uterus (see Fig. 26-19). From the cornua of the uterus, the uterine artery gives rise to a branch that courses laterally to reach the hilum of the ovary, where it anastomoses with the ovarian artery, and another branch supplies the fallopian tube. The uterine artery also supplies the cervix via multiple branches, some of which anastomose with branches of the vaginal artery to form the azygos arteries of the vagina, one of which is anterior to and the other posterior to the vagina. The uterine arteries provide the main arterial supply to the uterus via multiple branches that pierce the uterine wall and then divide into the anterior and posterior arcuate arteries, which anastomose extensively with each other across the midline between the middle and outer layers of the myometrium (Fig. 26-20). The radial arteries arise from the arcuate arteries and travel centrally to supply the rich capillary network in the deeper layers of the myometrium and the endometrium (Figs. 26-20 and 26-21). The radial arteries give rise to the straight and spiral arteries of the endometrium. The straight arteries supply the basalis layer of the endometrium. The spiral arteries supply the superficial two thirds of the endometrium and become longer and more tortuous as the endometrium thickens in the secretory phase of the menstrual cycle (Fig. 26-22). Blood flow is generally detectable in the uterine

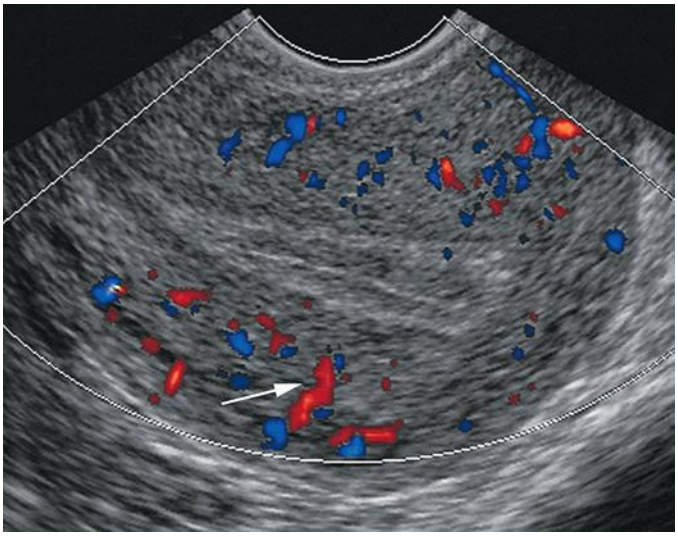

FIG 26-21 Uterine radial artery. Transvaginal color Doppler sagittal image in a patient with a retroverted uterus. A radial artery (*arrow*) is demonstrated coursing perpendicularly from the arcuate arterial plexus toward the endometrium. The thickness and trilaminar appearance of the endometrium indicate that the patient is in the periovulatory stage of the menstrual cycle.

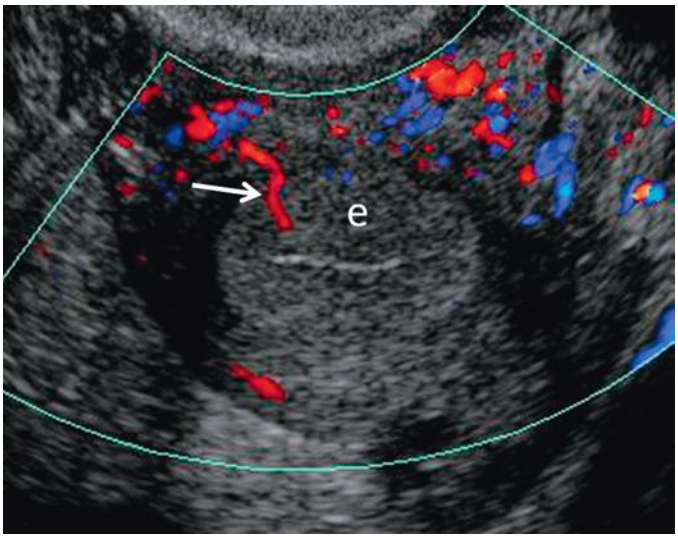

FIG 26-22 Spiral artery. Transvaginal color Doppler short-axis or transverse view of the uterus demonstrating flow within a spiral artery (*arrow*) within the relatively homogeneous thick echogenic secretory endometrium (e).

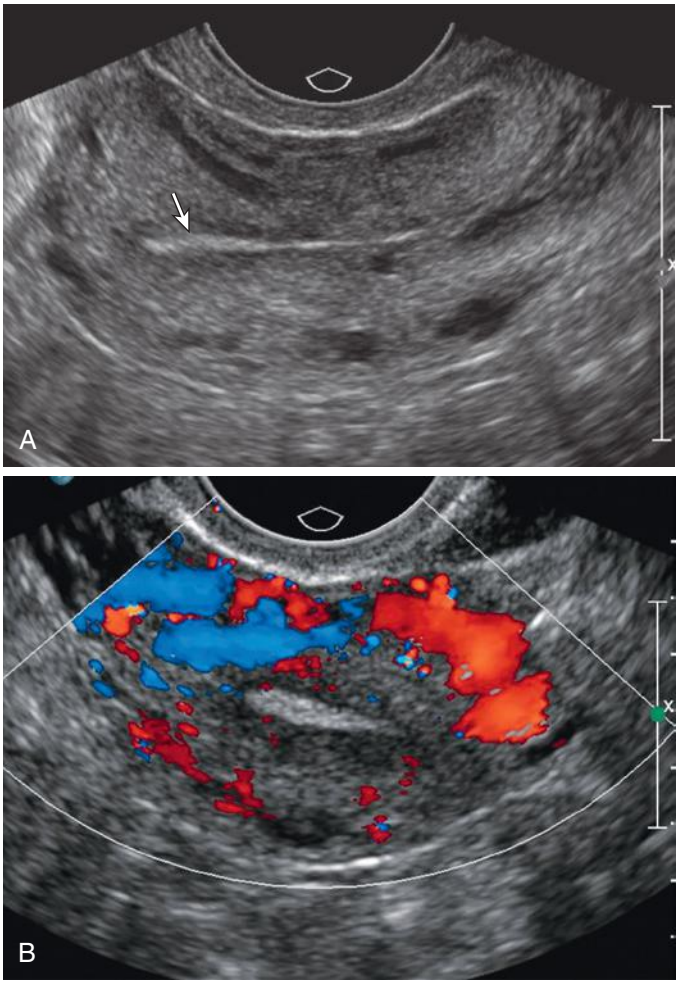

FIG 26-23 Arcuate venous plexus. **A,** Longitudinal gray-scale image of the uterus shows linear/tubular and circular anechoic regions representing the arcuate venous plexus in the uterine body separating the outer one third of the myometrium from the inner two thirds. Note the thin echogenic, early proliferative appearance of the endometrium (*arrow*). **B,** Transverse color Doppler image shows flow within these veins.

arteries on Doppler sonography in women of all ages, but visualization of the radial arteries becomes progressively more difficult following menopause.[21] Endometrial spiral arterial flow is generally seen throughout the menstrual cycle in healthy women, but is most readily detected in the secretory phase of the cycle.[21-23] However, endometrial arterial flow is only detectable on Doppler sonography in approximately 30% of women 1 to 5 years after menopause, and in one study, no Doppler-detectable endometrial blood flow was found in women who were more than 5 years postmenopausal.[21]

The arcuate venous plexus accompanies the arcuate arteries and is frequently identified sonographically running between the outer one third and inner two thirds of the myometrium on gray-scale or color Doppler imaging (Fig. 26-23). Spectral Doppler waveforms of the normal uterine artery in the nongravid premenopausal woman typically have a high-resistance waveform pattern, with an early diastolic notch and relatively little diastolic flow (Fig. 26-24). The arterial waveform pattern does not change significantly during the menstrual cycle. However, increased diastolic flow in the uterine artery is observed during pregnancy as well as in the setting of endometritis or malignancy.

The ovarian arteries arise from the lateral margin of the aorta at a level slightly inferior to the renal arteries. At the pelvic brim, they cross the external iliac artery and vein and course medially within the suspensory (infundibulopelvic) ligament (see Figs. 26-12 and 26-19). Ovarian arterial blood flow varies according to the stage of the menstrual cycle likely because of hormonally mediated changes in vessel wall compliance, resulting in increased blood flow to the ovary in the late follicular and early luteal phases.[19] Hence, in the first half of the menstrual cycle or in the nonovulating ovary, a spectral tracing from the ovarian artery will demonstrate relatively low peak systolic velocity (PSV) and end-diastolic velocity (EDV). However, at the time of ovulation the arterial waveform from the ovulating ovary will change and both PSV and EDV will increase with a resultant decrease in resistive

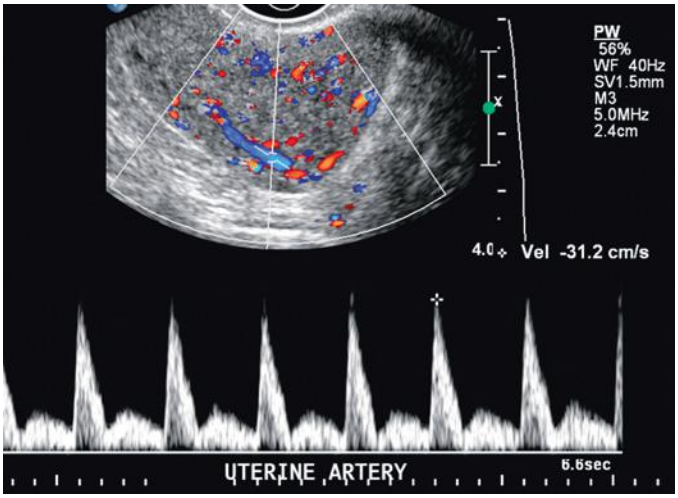

FIG 26-24 Normal uterine artery. A uterine artery is seen flowing toward the fundus (away from the transducer) and demonstrates a typical high-resistance waveform pattern with a sharp systolic upstroke and thin, pointed systolic peak with relatively little diastolic flow and prominent early diastolic notch.

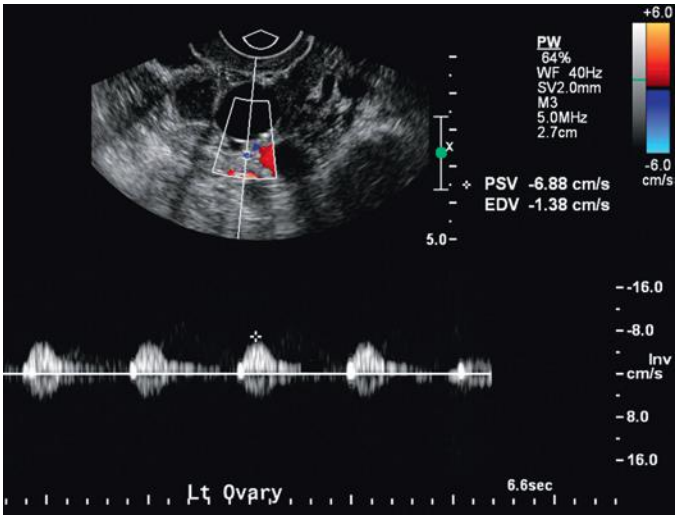

FIG 26-26 Spectral Doppler waveform of the postmenopausal ovary. Spectral Doppler tracing from the left ovary of a postmenopausal woman. Note low peak systolic velocity (PSV) and complete absence of end diastolic flow. The resistive index (RI) is 1.00.

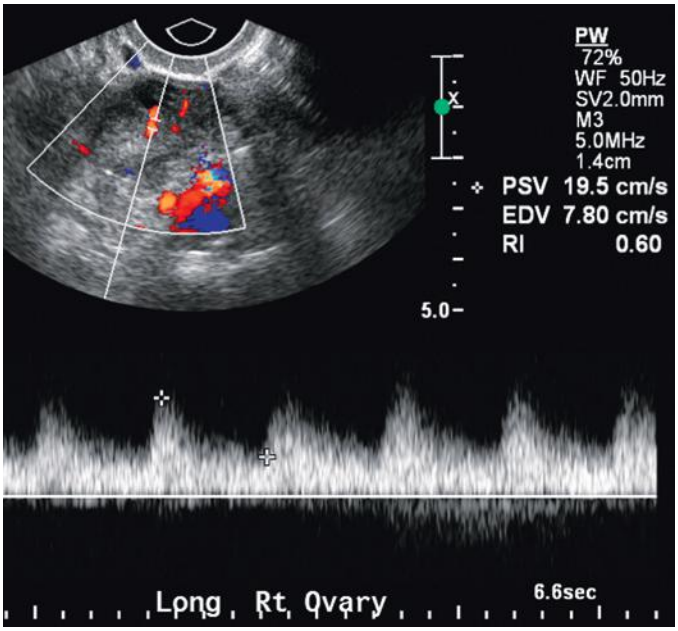

FIG 26-25 Ovarian artery. Spectral Doppler waveform from the right ovarian artery obtained just prior to ovulation reveals spectral broadening, slight rounding of the systolic peak, and pronounced diastolic flow consistent with a low-resistance waveform. The resistive index (RI) is 0.60.

index (RI) (Fig. 26-25). Following menopause, both PSV and EDV in the ovarian artery will decrease. Often no diastolic flow will be observed, yielding an RI of 1.0 (Fig. 26-26).[23] The ovarian veins ascend out of the pelvis adjacent to the ovarian artery, with the right ovarian vein draining into the inferior vena cava just below the renal vein and the left ovarian vein emptying into the left renal vein.[17]

THE UTERUS

The uterus consists of two major parts: the body (or corpus) and the cervix. The corpus is predominantly muscular, whereas the cervix is composed predominantly of collagenous and elastic tissue and has only 10% smooth muscle. The isthmus is a narrow portion or "waisting" of the uterus that corresponds to the approximate position of the internal os and demarcates the boundary between the lower uterine segment of the corpus and the cervix. The anterior surface of the corpus is almost flat, whereas the posterior surface is convex. The fallopian tubes emerge from the cone-shaped cornua of the uterus, situated at the junction between the superior and lateral uterine margins. The fundus of the uterus is the superior portion of the uterus above the level of the insertion of the fallopian tubes[24] (see Fig. 26-9).

The overall uterine length is measured on a midline sagittal image from the tip of the serosal surface of the fundus to the distal aspect of the cervix (i.e., the external os). The AP dimension of the uterus is measured on the same sagittal image from its outer anterior to outer posterior wall, in a plane perpendicular to the longitudinal axis. The maximum width is measured outer wall to outer wall on the transverse or coronal view.[1,24,25] Uterine size varies with age as well as with parity in the reproductive age patient. The uterus measures approximately 6 to 8.5 cm in length in nulliparous women and 8 to 10.5 cm in multiparous women.[25-27] The AP diameter ranges from 2 to 4 cm in nulliparas and 3 to 5 cm in multiparas,[26] whereas the width of the corpus measures approximately 3 to 5 cm in nulliparous women and 4 to 6 cm in multiparas.[25-27] Following menopause, the uterus atrophies with the most rapid decline in uterine size occurring within the first 10 years. In women who are more than 5 years postmenopausal, the uterus typically measures 3.5 to 7.5 cm in length, 1.7 to 3.3 cm in AP dimension, and 2 to 4 cm in width.[26,27] The uterus is typically pear-shaped, with the body twice the size of the cervix during the reproductive years. In the postmenopausal and pediatric patient, the uterus is more tubular in configuration, with the body and cervix nearly equivalent in length.[24]

Uterine position is highly variable and changes with varying degrees of distention of the urinary bladder. The cervix is anchored at the angle of the bladder by the parametrium and is less freely movable than the corpus and fundus. Uterine position is described in relation to the angle of the long axis of the uterine body with the long axis of the cervix (flexion) and the long axis of cervix to the long axis of the vagina

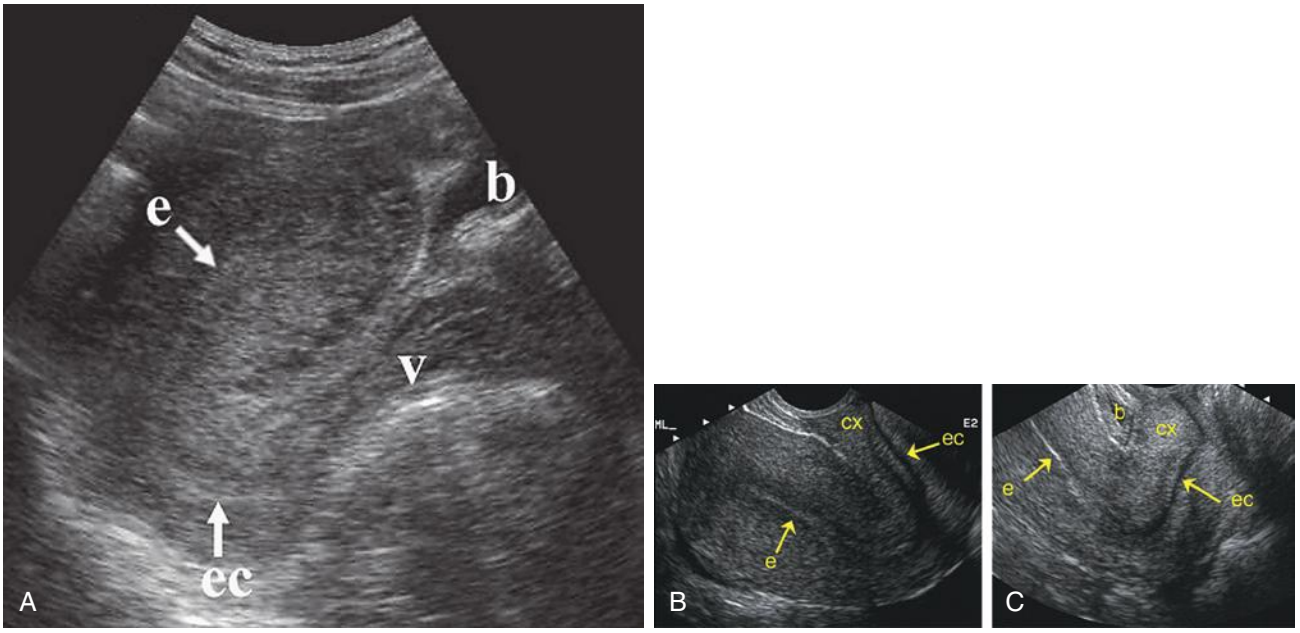

FIG 26-27 Anteflexed uterus. **A,** Transabdominal sonogram in the midline sagittal plane through the uterus. The bladder (b) is almost completely empty. **B,** Transvaginal midsagittal scan of an anteflexed uterus. **C,** Transvaginal scan of the cervix and lower uterine segment. The bladder (b) is almost empty. The endocervical (ec) and endometrial (e) canals form an angle of approximately 90 degrees in all three images at the level of the internal os. cx, cervix; v, vagina.

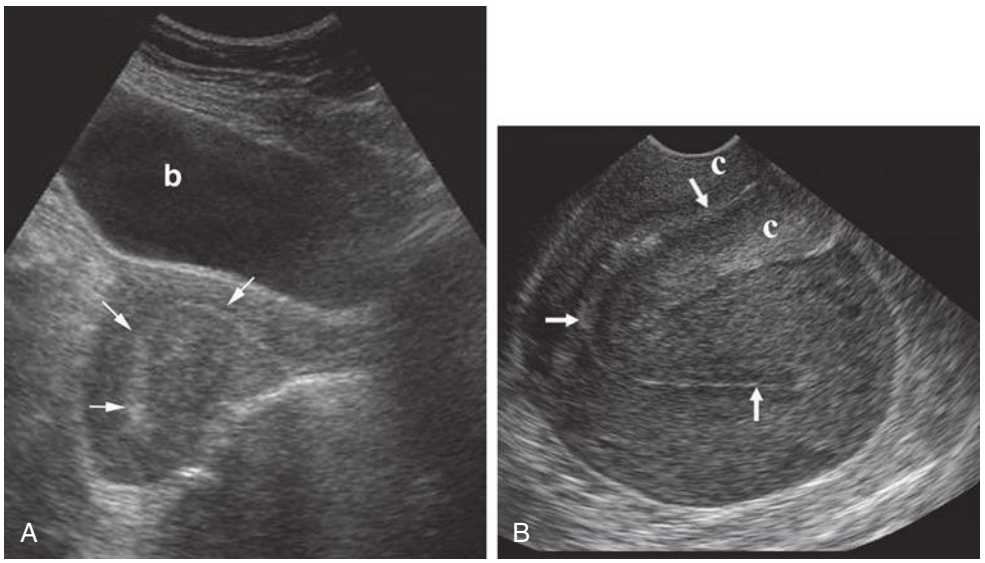

FIG 26-28 Retroflexed uterus. Transabdominal (**A**) and transvaginal (**B**) sonograms of a retroflexed uterus. The uterine body is bent backward or posteriorly at the level of the internal os of the cervix (c), well over 90 degrees. On the transabdominal image, the cervix is tilted upward with respect to the vagina, indicating anteversion. In B, when the bladder is emptied to perform the transvaginal examination, the cervix points slightly posteriorly, indicating a change to retroversion. Note the endometrial and endocervical canals (*arrows*). b, bladder.

(version).[28] The most common position on TAS, with a distended urinary bladder, is anteversion without flexion (Fig. 26-11B). Anteflexion (Fig. 26-27), retroflexion (Figs. 26-2 and 26-28), retroversion (see Fig. 26-28), and tilting of the uterus to the right or the left are considered to be normal variants in position, unless the uterus is displaced by pelvic disease.

The anteverted or anteflexed uterus is usually well imaged on TAS because it lies in a superficial location, just behind the acoustic window of the urinary bladder, and is oriented perpendicular to the ultrasound beam. When the uterus is retroverted or retroflexed, it is often difficult to evaluate by TAS and ideally is imaged with the transvaginal probe[28] (see Figs. 26-2 and 26-28). TAS of the retroverted and retroflexed uterus requires the sound beam to travel deeper into the pelvis and along a path parallel to the length of the uterus, as compared to the anteverted or anteflexed uterus, resulting in marked attenuation of sound, which limits evaluation of the endometrium and may cause the

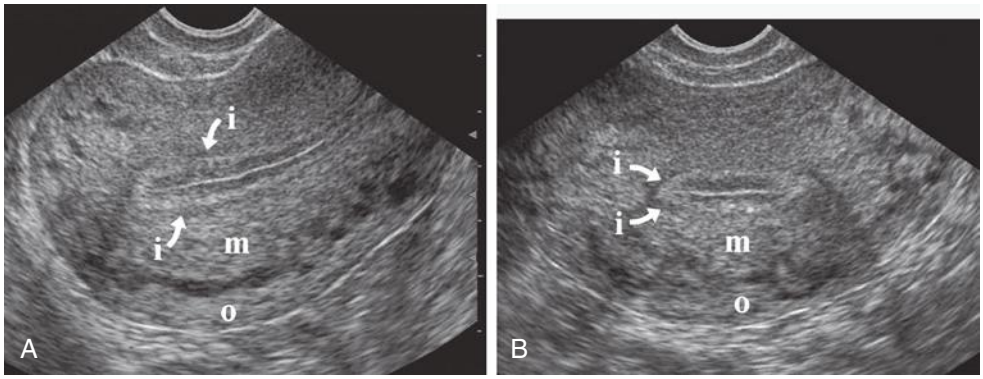

FIG 26-29 Myometrial layers. Transvaginal longitudinal (**A**) and transverse (coronal) (**B**) sonograms demonstrating the three layers of the myometrium: the outer (o), intermediate (m), and hypoechoic inner (i) layers (*arrows*).

fundal myometrium to appear more hypoechoic and simulate the appearance of a fundal myoma or other disease. The transvaginal approach allows the probe to be positioned immediately adjacent to the body of the retroverted or retroflexed uterus, without intervening structures and at a perpendicular imaging plane, providing better visualization of the endometrium and the fundal myometrium than the transabdominal technique. When the uterus is retroflexed, the cervix may be interposed between the probe and the body of the uterus. To improve uterine visualization with the transvaginal probe, one must position the probe around the cervix and angle it posteriorly so that the probe now lies immediately adjacent to the body and fundus of the uterus (see Fig. 26-28).

The myometrium of the uterus is composed of bundles of smooth muscle fibers, intermixed with connective tissue, blood vessels, lymphatics, and nerves, and is divided into three zones: the inner, intermediate or middle myometrium, and outer myometrium[3,28] (Fig. 26-29). The outer layer of the myometrium consists of longitudinally oriented muscle fibers that course over the fundus and converge at the cervix and cornua. The outer layer is separated from the intermediate or middle layer by the arcuate vessels. The intermediate layer is usually the thickest of the three layers and its muscle layer consists of spiral bands extending from cornua to cervix, which interdigitate in the midsagittal plane. The inner myometrium is the thinnest layer and has both longitudinal and circular muscle fibers. The inner layer may be extremely hypoechoic. When it is observed to be hypoechoic, it has been termed the subendometrial halo (Fig. 26-30) and is believed to correspond to the markedly hypointense junctional zone observed on T2-weighted magnetic resonance (MR) sequences.[23] However, the hypoechoic subendometrial halo is not visualized in all patients and may not be circumferentially intact in many patients, appearing as an incomplete or fragmented hypoechoic subendometrial band of tissues. The thickness and echogenicity of the subendometrial halo do not appear to vary significantly during the menstrual cycle. The inner myometrial myometrium and endometrial mucosa both arise from the paramesonephric ducts, whereas the remainder of the myometrium is mesenchymal in origin. The inner myometrial-endometrial junction (EMJ) is histologically unique in the human body in that it lacks a submucosal layer.[29]

The nongravid uterus is not quiescent but demonstrates transient myometrial contractions and organized wave-like activity in the inner myometrium. These wave patterns change their frequency, intensity, and directionality throughout the phases of the menstrual cycle. Waves travel from cervix to fundus in the periovulatory phase of the menstrual cycle, presumably in an effort to promote sperm transport within the endometrial canal, and are reversed in the menstrual phase.[30] Uncoordinated or absent wave activity has been associated

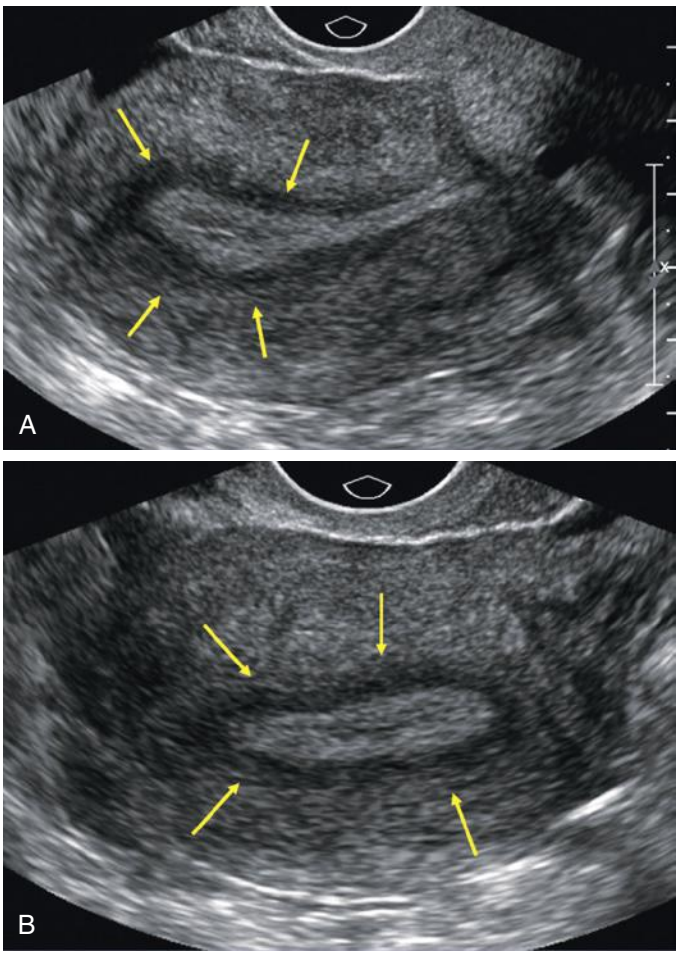

FIG 26-30 The inner myometrium. Transvaginal longitudinal (**A**) and transverse (coronal) (**B**) gray-scale images demonstrating the hypoechoic inner myometrium (*arrows*), which has been termed the subendometrial halo.

with higher rates of infertility, and wave activity can be suppressed by oral contraceptives.[31]

The endometrium is composed of a superficial layer (zona functionalis) and a deeper basalis layer. The thickness and sonographic appearance of the endometrium change cyclically during the menstrual cycle.[32-34] In the menstrual and very early proliferative phase, the endometrium is thin, usually under 4 mm, and appears brightly echogenic and homogeneous (Fig. 26-31). Throughout the mid to late

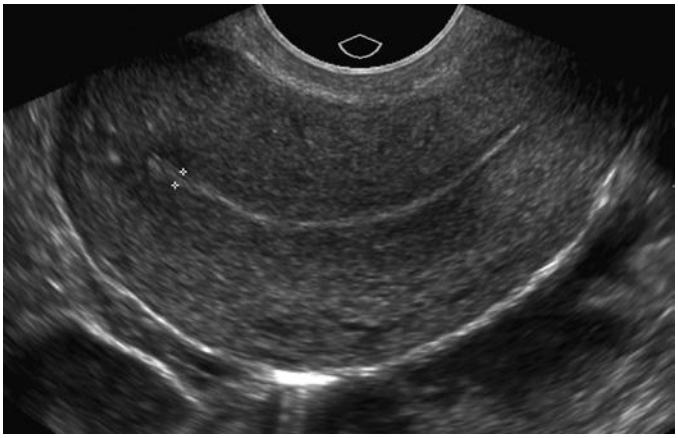

FIG 26-31 Early proliferative phase endometrium. The endometrium (*calipers*) appears as a thin, echogenic, and slightly irregular line in this patient on day 5 of the menstrual cycle.

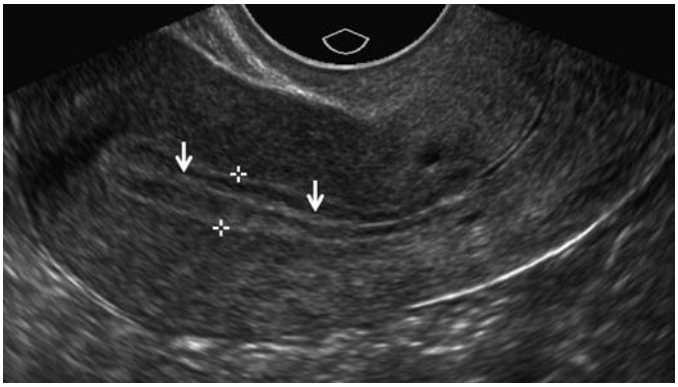

FIG 26-32 Periovulatory endometrium. Transvaginal longitudinal sonogram demonstrates the normal trilaminar appearance of the endometrium (*calipers*) in the late proliferative phase of the cycle. The basal layer of the endometrium is echogenic, but the more superficial functional layer has become hypoechoic as a result of estrogen effects. The central echogenic line (*arrows*) represents the interface where the endometrium lining the anterior and posterior walls of the uterine cavity meet.

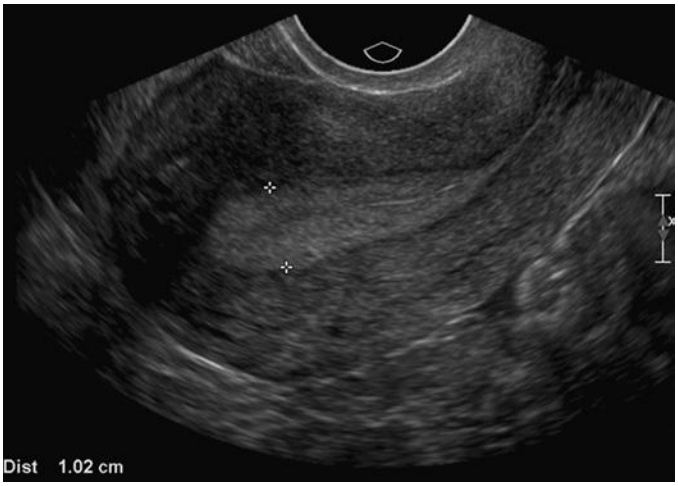

FIG 26-33 Secretory endometrium. Transvaginal sonogram in the sagittal plane on day 19 of the menstrual cycle shows a uniformly echogenic endometrium (*calipers*) measuring 10.2 mm. The functional layer of the endometrium has become isoechoic with the basal layer, and the trilaminar appearance is therefore no longer evident.

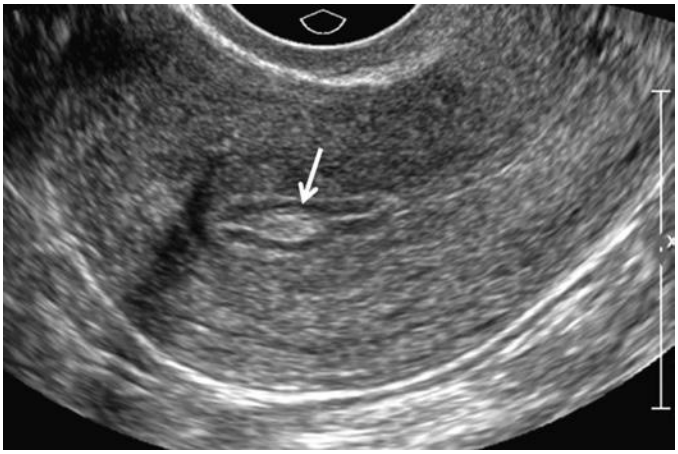

FIG 26-34 Endometrial polyp. The central echogenic line representing the interface of the anterior and posterior endometrial layers of the proliferative endometrium with its characteristic trilaminar appearance is interrupted by an oval echogenic lesion (*arrow*), which proved to be a benign endometrial polyp. This is sometimes referred to as the "bead on a string" sign.

proliferative phase of the cycle (days 5 to 14) the functionalis layer of the endometrium increases in thickness under the influence of estrogen and becomes more hypoechoic compared to the basalis layer, such that the endometrium develops a trilaminar or striated appearance, typically measuring 12 to 13 mm (normal range 10-16 mm) at ovulation[33] (Fig. 26-32). During the secretory phase (days 15 to 28), the functional layer becomes thickened, soft, and edematous under the influence of progesterone (Fig. 26-33). A glycogen-rich fluid is secreted by the glandular epithelium, and the spiral arteries become tortuous. The resultant effect is that the functional layer increases in echogenicity to become once again isoechoic to the basalis layer.[32,33] At the end of the secretory stage, the endometrium may measure up to 16 to 18 mm in thickness and is homogeneous in echotexture.

Endometrial thickness is best assessed on TVS, and by convention is reported as the sum of the measurement of both the anterior and posterior layers of the endometrium at the thickest segment on a midline longitudinal image.[35,36] It is critical that the measurement be made on a midline sagittal image, as imaging obliquely or too close to the uterine cornua will result in an overestimation of endometrial thickness. If the endometrium can be shown to be continuous with the endocervical canal, the sonographer can be certain that the imaging plane is midline. If the endometrium appears triangular or bulbous rather than symmetric, or oval or cigar-shaped in configuration, the imaging plane is likely off-axis and not midline.

The central thin echogenic line represents the interface between the two layers of the endometrium and should be continuous. Disruption of the central echogenic white line or heterogeneity of the endometrium may indicate an underlying intracavitary lesion, such as a polyp, myoma, or adhesion (Fig. 26-34). The subjacent hypoechoic subendometrial halo just peripheral to the endometrium represents the innermost layer of the myometrium and should not be included in the endometrial measurement.[35] A small amount of hypoechoic fluid or mucus within the endometrial cavity may be a normal finding, but should not be included in the endometrial thickness measurement (Fig. 26-35). Larger amounts of fluid or retained echogenic blood clots are considered abnormal and raise suspicion for underlying disease or obstructed menstrual flow, such as may be seen with adhesions or cervical stenosis. In women taking oral contraceptives or using other

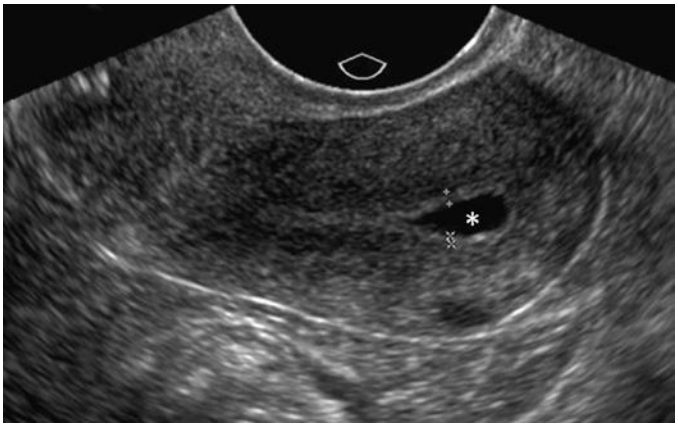

FIG 26-35 Endometrial fluid. Transvaginal longitudinal sonogram of a retroverted, retroflexed uterus shows a small amount of anechoic fluid in the uterine cavity (*asterisk*). The endometrial thickness measurement is determined by measuring the anterior and posterior endometrial layers individually, as shown by the "+" and "x" electronic calipers. These two numbers are then summed to obtain the double thickness measurement.

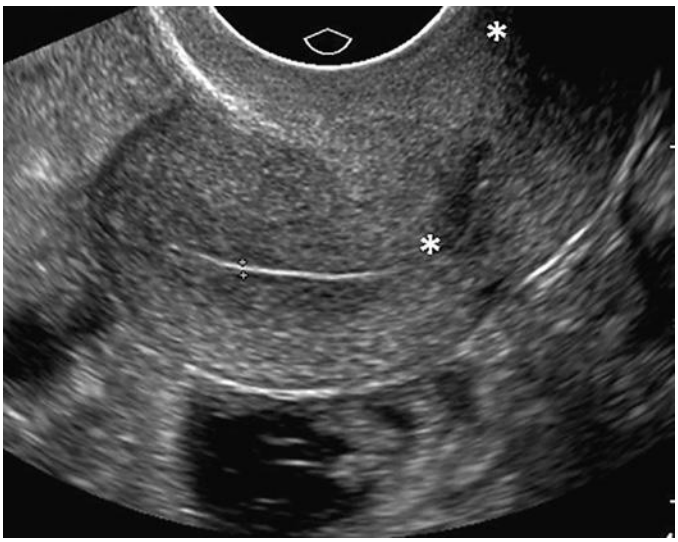

FIG 26-36 Normal postmenopausal endometrium. The endometrium (*calipers*) is atrophic, appearing as a thin white line measuring under 1 mm in a patient who has been postmenopausal for 10 years. The hypoechoic tissue subjacent to the endometrium represents the inner compact layer of myometrium and is referred to as the subendometrial halo. The subendometrial halo should not be included in the measurement of the endometrial thickness. Note that the cervix (length indicated by *asterisks*) is approximately equal in size to the uterine body and the uterine body is more tubular in configuration, as is commonly seen following menopause, rather than pear-shaped, which is the typical configuration of the uterus during the reproductive years.

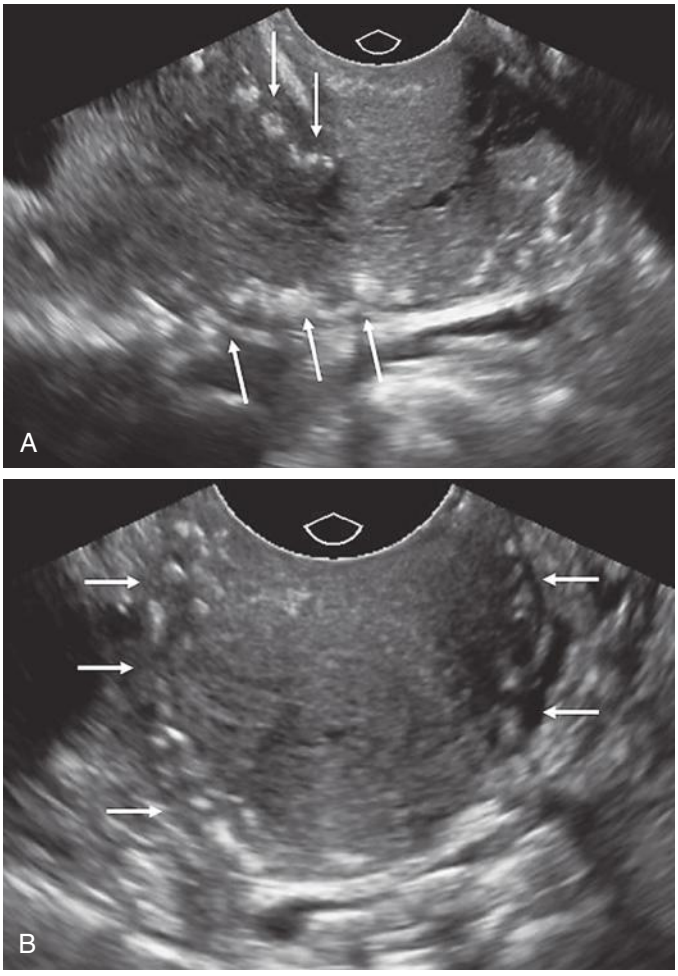

FIG 26-37 Arcuate artery calcifications. Longitudinal (**A**) and transverse (**B**) images from a transvaginal ultrasound examination performed on a postmenopausal woman showing calcification of the arcuate vessels (*arrows*) in the typical location along the periphery of the uterus.

hormonal contraceptives, such as progesterone-bearing IUDs, the endometrium is generally thin throughout the month.

The postmenopausal endometrium is typically atrophic, from lack of estrogen stimulation, and appears on ultrasound imaging as a thin, homogeneous echogenic line that measures less than 3 mm in most postmenopausal women[37] (Fig. 26-36). It has been shown that the measurement of the endometrium obtained by TVS corresponds within 1 mm of that measured on pathologic examination,[25,36] allowing TVS to play an important role in diagnostic evaluation of women with suspicion for endometrial cancer.[36-38] In a postmenopausal woman who presents with vaginal bleeding, endometrial cancer is considered to be extremely unlikely when the endometrium is homogeneous, regular, and measures less than 4 to 5 mm in maximal diameter, provided that the endometrium is completely visualized on the TVS. If the endometrium exceeds 4 to 5 mm in a postmenopausal woman with vaginal bleeding, endometrial sampling is usually obtained to evaluate for possible malignant or premalignant endometrial changes. However, the threshold for recommending endometrial biopsy in the asymptomatic postmenopausal woman is somewhat more controversial, and is reported to range from 8 to 11 mm.[38]

Calcified uterine arcuate vessels are commonly noted in elderly postmenopausal women, especially those with diabetes, vascular disease, hypertension, or hypercalcemia.[39] These vessels appear as peripheral linear reflectors in a circumferential pattern in the superficial myometrium between the outer one third and inner two thirds of the myometrium (i.e., between the outer and inner layers of the myometrium, see earlier) (Fig. 26-37).

The cervix is best visualized and assessed by TVS. However, the probe often has to be partially withdrawn and angled posteriorly or anteriorly for optimal visualization, depending on the orientation of the uterus.[28] The endocervical canal is continuous with the endometrial canal, appearing as a thin, echogenic stripe (Figs. 26-8A, 26-13, and 26-27). Fluid or mucus is sometimes seen in the endocervical canal,

particularly in the preovulatory period. Color Doppler imaging can be useful to distinguish mucus from small endocervical polyps, which are common findings. Subjacent to the endocervical canal is a hypoechoic band that represents the fibrous cervical stroma and is continuous with the subendometrial halo or inner layer of the myometrium. The outer wall of the cervix is similar in echogenicity to the outer myometrium (Figs. 26-13 and 26-28). Numerous cervical glands extend from the endocervical mucosa into the adjacent connective tissue of the cervix.[40] Occlusion of the cervical glands results in the formation of retention cysts, known as nabothian cysts, which lie close to the endocervical canal. They may be single or multiple. Nabothian cysts typically contain simple fluid and are asymptomatic. Uncommonly, nabothian cysts may be complicated by hemorrhage or infection or grow to large size[28] (see Fig. 26-14). The cervix extends inferiorly into the upper vagina and is surrounded by the anterior, posterior, and the two lateral fornices of the vaginal canal (Figs. 26-8A and 26-13). Occasionally, air can be seen in the vaginal fornices surrounding the cervix on TAS. The vagina is seen on ultrasound imaging as a hypoechoic tubular structure with an echogenic lumen that curves inferiorly over the muscular perineal body at the introitus (see Figs. 26-4 and 26-27).

THE OVARIES

The normal ovary is ellipsoid in shape and is variable in both location and orientation, depending upon the age and parity of the patient as well as the degree of bladder distention. In the nulliparous adult female, the ovaries are situated in the ovarian fossa (also known as the fossa of Waldeyer), which is adjacent to the lateral pelvic side wall and is bounded by the obliterated umbilical artery anteriorly, the ureter and internal iliac artery posteriorly, and the external iliac vein superiorly[16] (see Fig. 26-12). The inferior aspect of the ovary is slightly smaller than the superior or tubal aspect and is bound to the uterine cornua by the ovarian ligament, which lies within the broad ligament. The lateral surface of the ovary is in contact with the parietal peritoneum lining the ovarian fossa, and most of the medial surface is covered by the fallopian tube (Fig. 26-38). The anterior border of the ovary is attached to the mesovarium, through which the vascular channels and nerves pass into the ovarian hilum.[16]

Ovarian volume is calculated by measuring the ovary in three dimensions (length, width, and depth) on two orthogonal planes and using the formula for the prolate ellipse ($L \times W \times D/2$). Ovarian size depends upon age, menstrual status, pregnancy status, body habitus, and phase of the menstrual cycle.[41-43] In premenopausal women, the mean ovarian volume is 9.8 mL (with 5% and 95% confidence intervals of 2.5 and 21.9 mL), with the highest volumes found in the preovulatory phase and the lowest volumes in the luteal phase.[41] Normal ovarian volume decreases after the age of 30 years. In one large study, mean ovarian volume significantly decreased in each decade up to age 60 years, measuring 6.6 mL in women under 30 years of age, 6.1 mL in women 30 to 39 years old, 4.8 mL at ages 40 to 49 years, 2.6 mL at ages 50 to 59 years, 1.98 mL at ages 60 to 69 years, and 1.85 mL over age 70 years. The authors found a statistically significant increased ovarian size in tall women but no relationship to weight.[42] Despite the small size of the postmenopausal ovary, the majority are detectable by TVS.[42,43]

The normal ovary in women of reproductive age has a variable appearance over the course of the menstrual cycle.[44] Developing and immature follicles can be seen throughout the entire menstrual cycle and appear as anechoic, unilocular, sharply marginated cysts, measuring from 2 to 9 mm (Figs. 26-8F and 26-38). By days 8 to 12 of the menstrual cycle, one or more dominant follicles will grow to a diameter of approximately 20 to 25 mm and then rupture at ovulation, releasing the oocyte.[44] Up to 80% of patients have a second nondominant follicle that becomes almost as large as the dominant follicle. The preovulatory dominant follicle may have a slightly complex appearance, with the oocyte and its supporting structures appearing as a ring-like structure within the follicle (the cumulus oophorus) (Fig. 26-39). Following ovulation, the corpus luteum evolves from the remnant of the mature follicle through a process of cellular hypertrophy and increased vascularization of the cyst wall. Therefore, a corpus luteum is typically visible in the secretory phase of the menstrual cycle and in the first few weeks of early pregnancy. On sonographic imaging, the corpus luteum

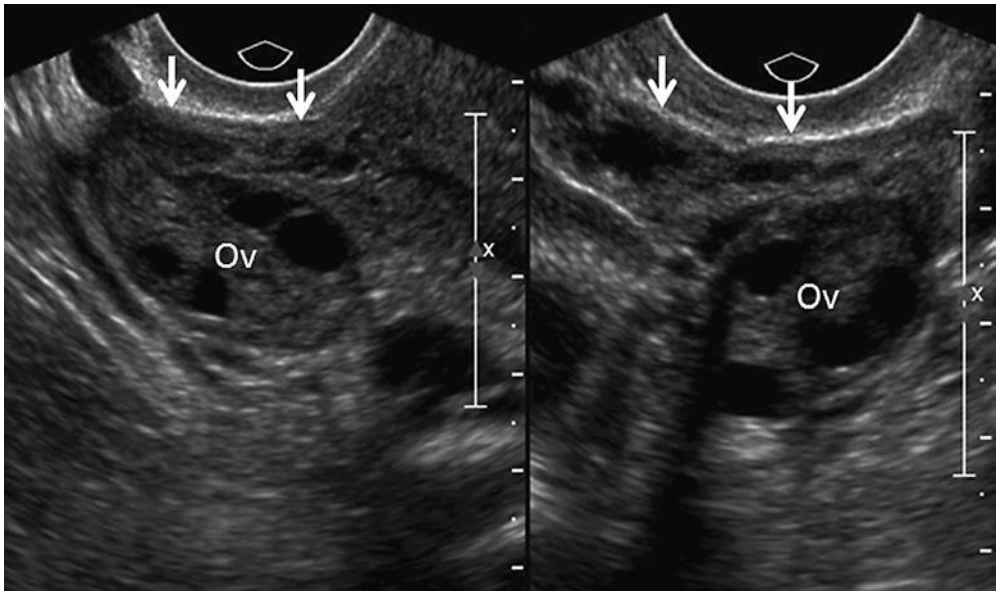

FIG 26-38 Normal ovary. Transvaginal gray-scale images displayed in split-screen format (longitudinal orientation on the right and the coronal or transverse orientation on the left) show a normal left ovary (Ov). Note the distal fallopian tube (*arrows*) overlying the ovarian surface. Multiple small subcentimeter anechoic follicles are noted in the ovarian parenchyma, although most are relatively peripheral.

typically has a relatively thick, homogeneously echogenic wall, the inner margin of which may be slightly irregular with a crenulated appearance. On color Doppler, the wall of the corpus luteum often demonstrates a circumferential ring of arterial flow with a low resistance spectral Doppler waveform.[45-47] Internal echoes are common, reflecting variable amounts of internal hemorrhage that occurred at the time of ovulation, and occasionally a corpus luteum may be filled with homogeneous low level echoes mimicking a solid mass. However, there is usually evidence of enhanced through transmission because of the fluid content and there will be no central vascularity (Fig. 26-40). Typically the corpus luteum is under 3.0 cm in maximal dimension, but rarely it may become larger.[45,46] If pregnancy does not occur, the corpus luteum gradually involutes and atrophies to become the corpus albicans, which is typically not sonographically identifiable. Small echogenic foci, measuring 1 to 3 mm, may be noted in the periphery of otherwise normal appearing ovaries in approximately half of women undergoing TVS, particularly in the perimenopausal age group. These foci often demonstrate ring down artifact and are a benign finding, likely related to the presence of tiny cysts, possibly cholesterol or hemosiderin deposition, and less likely tiny calcifications. These tiny echogenic foci may come and go underneath the surface epithelium and should not raise concerns or result in follow-up imaging.[48]

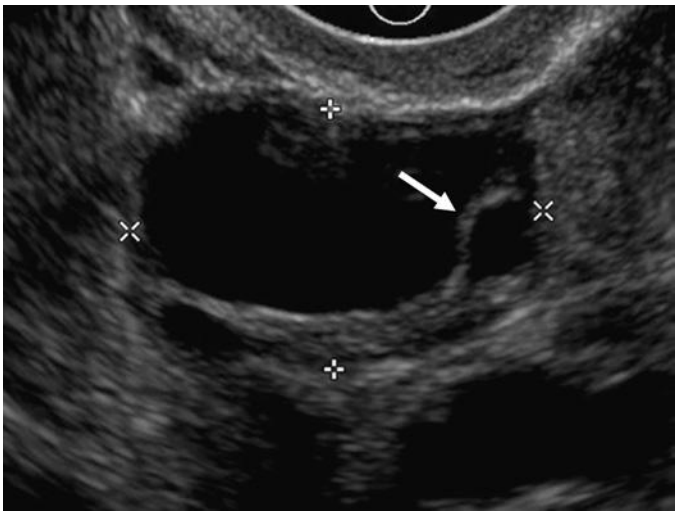

FIG 26-39 Dominant follicle. Transvaginal longitudinal sonogram of the right ovary (*calipers*) shows a dominant anechoic follicle with a peripheral ring representing the cumulus oophorus (*arrow*).

In the postmenopausal patient, ovarian size decreases correlating with hormonal status and length of time since menopause. Mean postmenopausal ovarian volumes have been reported to range from 1.2 to 5.8 mL, with an ovarian volume of greater than 8 mL considered abnormal in all cases.[41,49] Some authors have suggested that a unilateral ovarian size twice that of the opposite side, regardless of the size, should also be considered abnormal.[41] Even though folliculogenesis has ceased, the postmenopausal ovaries are not as quiescent as initially thought. Small simple adnexal cysts, measuring as large as 3 cm, have been reported in up to 15% of postmenopausal women; most of these spontaneously regress on serial sonographic examinations.[46,50,51] These simple cysts, seen early in menopause, most likely represent an occasional ovulatory event or an atretic follicle. However, any anechoic cystic lesion in a postmenopausal ovary should generally be referred to as a cyst.[46] In late menopause, although ovulation is rare, smaller cysts less than or equal to 1 cm have been reported in up to 21% of women.[50,51] TVS will detect these cysts more readily than TAS because of the higher resolution of the higher frequency transvaginal probe (Fig. 26-41). These simple-appearing cysts, measuring less than 1 cm in maximal diameter, do not need further follow-up, and whether or not they are described in the final report can be left to the discretion of the interpreting physician.[46]

THE FALLOPIAN TUBE

The fallopian tubes are variable in length, measuring approximately 7 to 12 cm. Each tube is situated in the superior free margin of the broad ligament and is covered by peritoneum. The fallopian tube is narrowest in the interstitial or intramural portion as it travels through the muscular wall of the uterus to open into the cornual region of the endometrial cavity. The interstitial portion of the fallopian tube measures approximately 1 cm in length and can be visualized with TVS in the superior right and left lateral corpus of the uterus as a fine, echogenic line arising from the angular, most lateral cephalad edge of the endometrial canal and running somewhat obliquely through the uterine wall toward the serosal surface (Fig. 26-42). Using 3D sonography, one

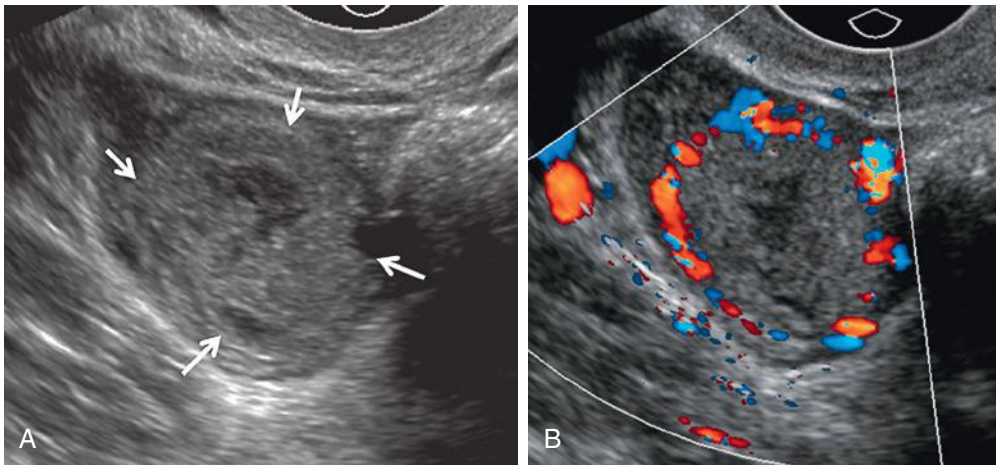

FIG 26-40 Corpus luteum. **A,** Transvaginal sonogram demonstrating a slightly echogenic lesion within the right ovary (*arrows*), with a complex cystic central component and thick homogeneous wall. **B,** Color Doppler imaging shows markedly increased blood flow in a peripheral ring-like pattern, sometimes described as a "ring of fire," a characteristic appearance of the corpus luteum.

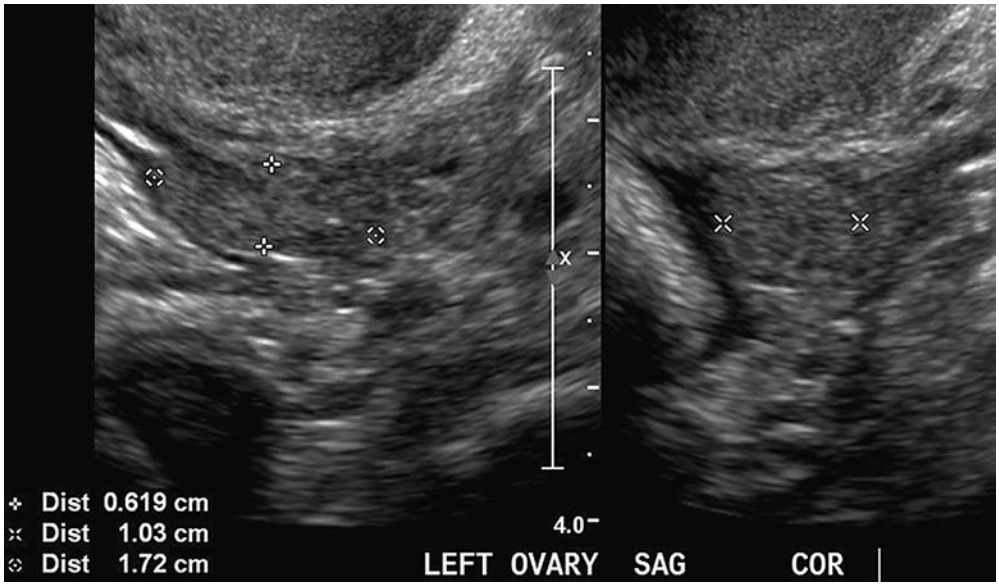

FIG 26-41 The postmenopausal ovary. Transvaginal gray-scale images displayed in split-screen format (longitudinal orientation on the right and coronal or transverse orientation on the left) show the typical appearance of a postmenopausal ovary (*calipers*). The ovarian volume is less than 2 mL and no clear follicles are seen.

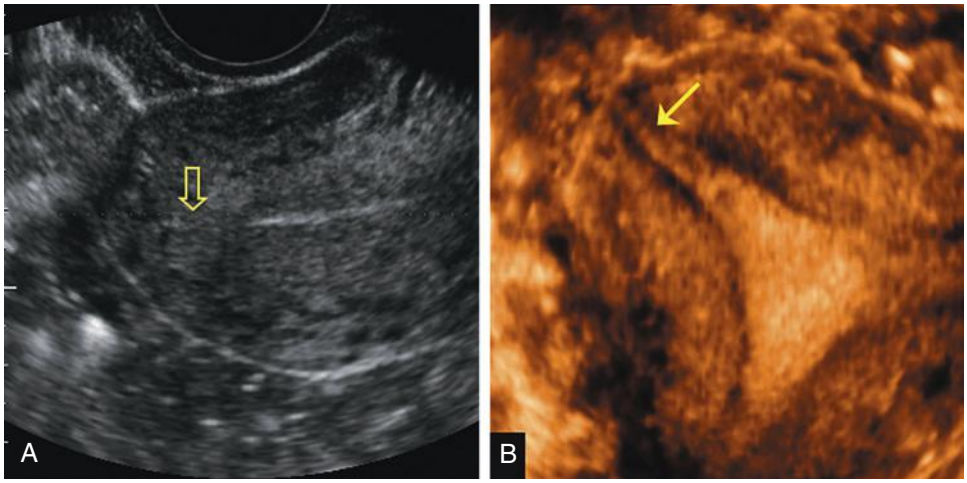

FIG 26-42 Interstitial portion of the fallopian tube. **A,** Transverse transvaginal scan of the uterine fundus showing a thin echogenic line extending from the cornual portion of the endometrium toward the serosal surface of the uterus representing the interstitial portion of the fallopian tube (*open arrow*). **B,** Three-dimensional (3D) coronal view of the uterine fundus showing the echogenic, triangular endometrial canal and the interstitial portion of one fallopian tube (*arrow*) extending to the serosal surface. On 3D sonography, this portion of the tube appears thicker than its true size.

can often visualize the interstitial portion of the fallopian tube on a superior coronal view.[12] The isthmus is the narrow segment of the tube immediately adjacent to the uterine wall. As the tube extends laterally, it widens forming the ampullary and infundibular regions. The infundibulum is funnel-shaped, terminates as the fimbriated end of the tube, and opens into the peritoneal cavity. The isthmus, ampulla, and infundibulum are usually not visualized on either TAS or TVS unless there is tubal disease or free fluid in the lateral pelvic recess (see Fig. 26-17). The vascular supply of the fallopian tube comes from the vascular arch formed by the anastomosis of the uterine and ovarian arteries.

Part of the cranial end of the paramesonephric duct (which normally forms the uterus, fallopian tube, and fibromuscular wall of the vagina) may persist as a vesicular appendage to the fallopian tube referred to as a hydatid cyst of Morgagni or a paratubal cyst. Sonographically, paratubal cysts usually appear as small, unilocular, round thin-walled anechoic structures and are most easily seen when surrounded by free intraperitoneal fluid (Figs. 26-17B and 26-43). The mesonephric ducts, which form the efferent ductules, epididymis, ductus deferens, seminal vesicles, and ejaculatory ducts in male fetuses, may persist as rudimentary, blind tubules in women. Mesonephric duct remnants may appear as parovarian cysts in the loose connective tissue adjacent to the ovary. Closer to the uterus, the mesonephric duct may persist as a Gartner duct cyst along the lateral wall of the uterus and vagina, superior to the hymen[16,24,52] (Fig. 26-44).

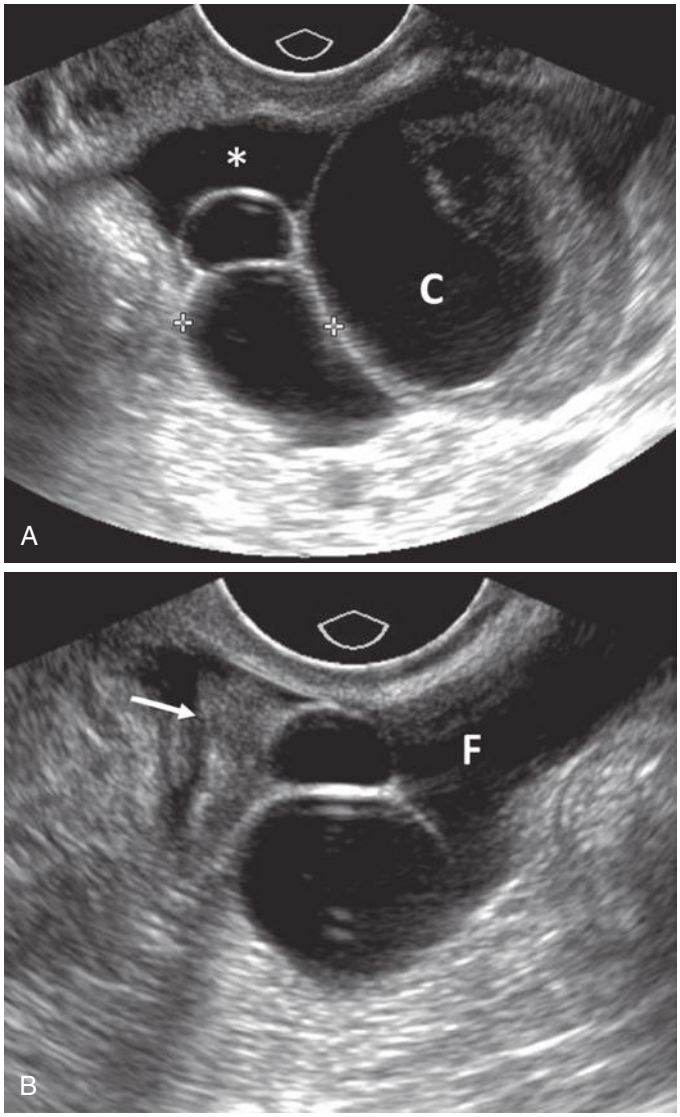

FIG 26-43 Paratubal cyst. **A,** Transvaginal sonogram shows a bilobed cystic structure (*calipers*) abutting a hemorrhagic cyst (C) within the adjacent ovary. Note small amount of free fluid anteriorly (asterisk). **B,** An image obtained slightly more lateral than the plane of image in A demonstrates that the bilobed cyst abuts the fallopian tube (*arrow*), which is outlined by pelvic fluid (F). Although the bilobed configuration is slightly atypical, this lesion proved to be a paratubal cyst.

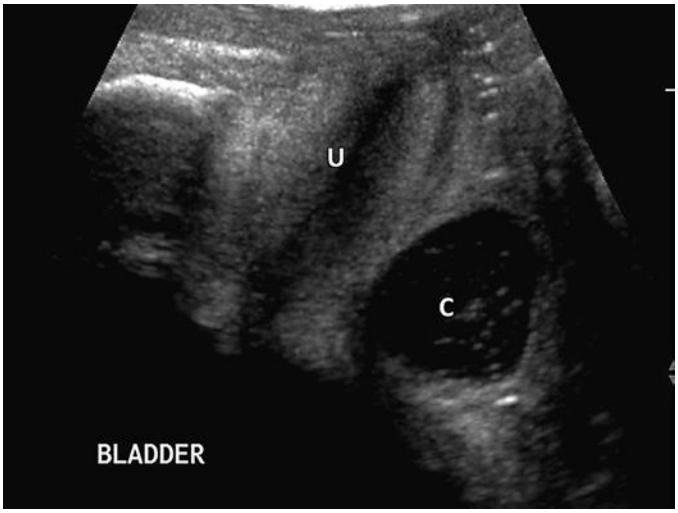

FIG 26-44 Gartner duct cyst. A transperineal sonogram shows a minimally complicated Gartner duct cyst (C) within the connective tissue adjacent to the vagina. U, urethra.

THE URINARY BLADDER, DISTAL URETERS, AND URETHRA

The appearance of the urinary bladder depends on the degree of distention. The distended bladder will be round on a superior transverse imaging plane. More inferiorly, the pelvic musculature and bones cause the bladder to be square in the transverse plane (Fig. 26-45). The bladder wall is homogeneously echogenic and should be uniform in thickness, measuring less than 3 mm when well distended. The ureteric and urethral orifices are visualized at the base and neck of the bladder, respectively. In the upper pelvis, the ureter lies anterior to the internal iliac artery and posterior to the ovary. More inferiorly, the ureter courses anteromedially to lie within the inferomedial portion of the broad ligament, where it is in close proximity to the uterine artery. The ureter then runs anteriorly, situated in front of the lateral fornices of the vagina, about 2 cm lateral to the supravaginal cervix, and then passes medially to enter the trigone of the bladder anterior to the vagina (Fig. 26-46). The relationship of the ureter to the ovary, cervix, uterine artery, and vagina is of clinical importance because pelvic disease may obstruct the ureter, resulting in secondary hydronephrosis. The distal portion of the ureter just proximal to the ureteral orifice is often well seen on TAS through the distended bladder. The distal ureter and ureterovesical junction (UVJ) can also be well seen on TVS if the bladder is partially distended. Hence, TVS is an excellent means of searching for UVJ stones, especially in the pregnant patient (Fig. 26-47). The presence of a ureteral jet in the bladder on color Doppler imaging as urine is expelled by the peristalsing ureter into the bladder is a normal finding on both TAS and TVS and indicates that the ureter is at least partially patent.

TVS enables better visualization of the trigone and posterior wall of the urinary bladder, as well as the urethra in comparison to TAS. To visualize the urethra, the probe is placed at the introitus or just partially inserted into the vagina and directed upward (Fig. 26-48). Surrounding the inner echogenic layer of the mucosa, there is a thin layer of smooth muscle and then an outer sheath of striated muscle. The longitudinally oriented smooth muscle is thicker anteriorly in the middle third of the urethra. The paraurethral glands of Skene lie posterior to the urethra near the UVJ and empty through the paraurethral duct near the external urethral orifice. Urethral diverticula are distended and/or obstructed urethral mucous glands and are found posterior and lateral to the urethra anywhere along its length. They may be a source of pelvic pain and recurrent urinary tract infection and can be easily documented on TVS. They may be round or horseshoe-shaped, partially encircling the urethra (Fig. 26-49). Although these diverticula are usually anechoic, internal echoes may be observed, either diffuse or layering. This nonspecific finding may be secondary to infection or debris from stasis or chronic inflammation. Echogenic shadowing calculi may also be observed in urethral diverticula as stasis predisposes to calculus formation as well as infection.

THE RECTOSIGMOID COLON

The sigmoid colon begins at the inlet of the true pelvis and is extremely variable in length. It has a mesentery, and its course is variable, looping

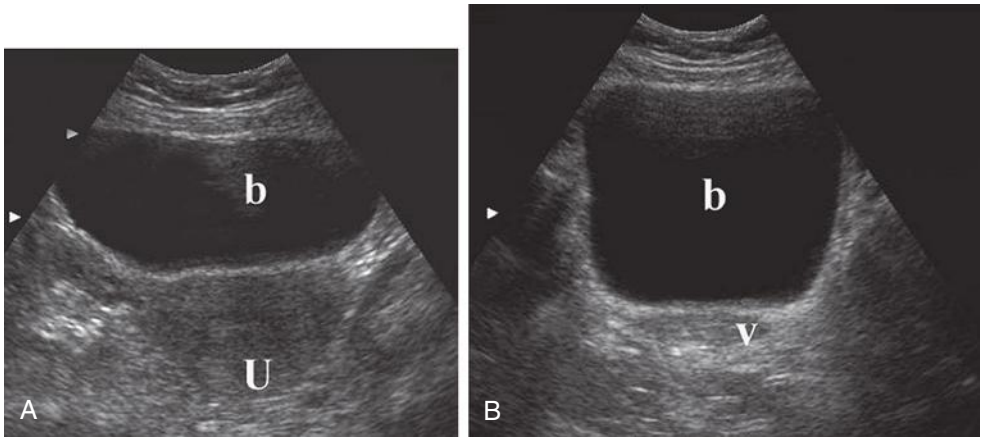

FIG 26-45 Normal urinary bladder. **A,** Transverse transabdominal sonogram of the urinary bladder at the level of the corpus of the uterus (U). At this level, the bladder (b) has a rounded or oval configuration. **B,** Transverse transabdominal sonogram of the urinary bladder at the level of the vagina (v). At this level, the bladder (b) has a square configuration. The normal bladder wall is thin, echogenic, and regular, measuring less than 3 mm in thickness.

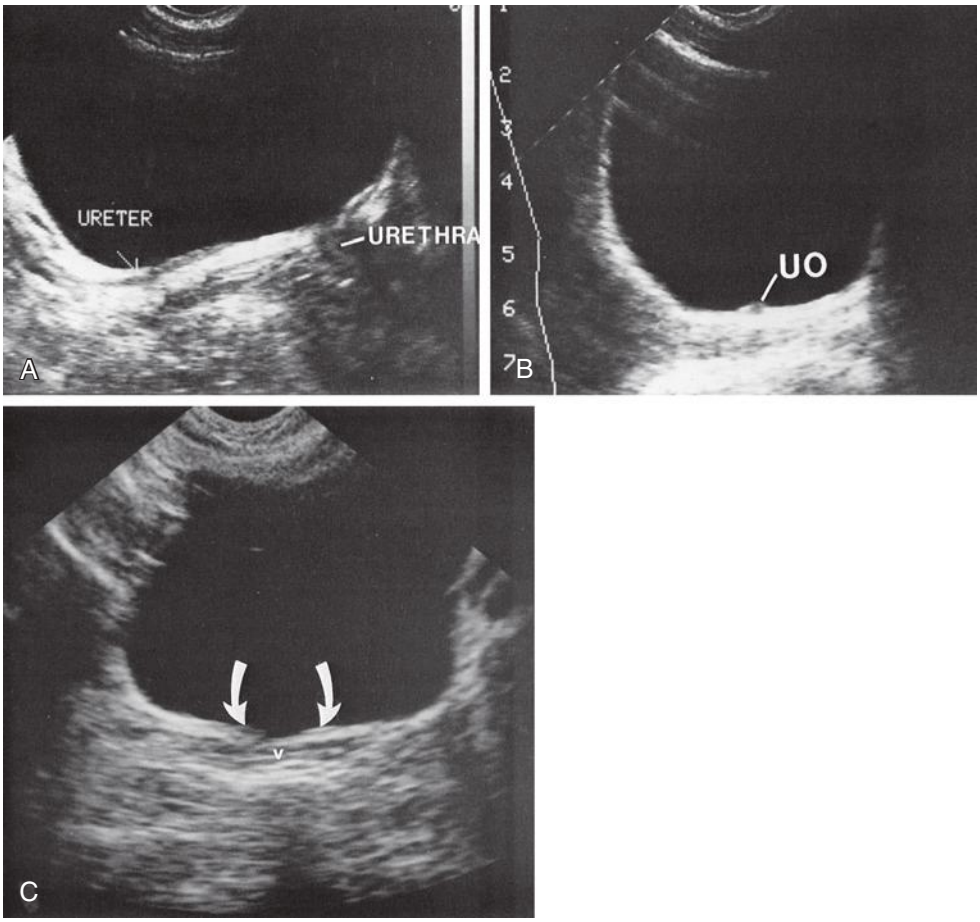

FIG 26-46 **A,** Longitudinal transabdominal sonogram of the right ureter and urethra. **B,** Longitudinal transabdominal sonogram of the right ureteric orifice (UO). **C,** Transverse transabdominal sonogram of both ureteric orifices (*curved arrows*). v, vagina.

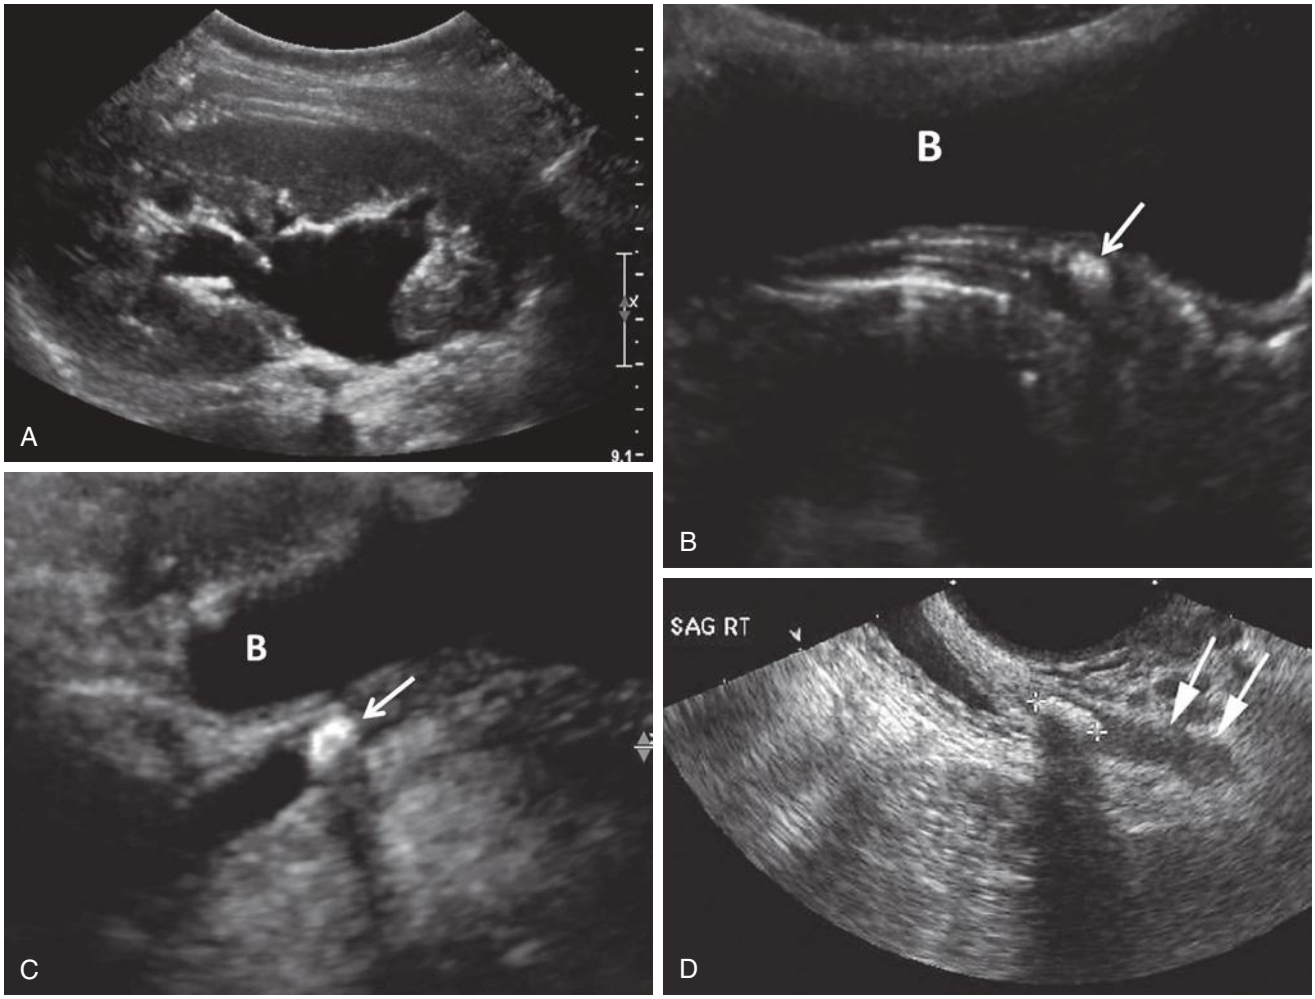

FIG 26-47 Distal ureteral calculus. **A,** Longitudinal image of the left kidney demonstrates moderate hydronephrosis. **B,** Transverse transabdominal sonogram (TAS) of the urinary bladder shows an echogenic calculus (*arrow*) in the distal left ureter at the ureterovesicular junction (UVJ) posterior to the bladder (B). **C,** Longitudinal TAS shows the distal left ureteral calculus (*arrow*) with posterior acoustic shadowing. The distal left ureter is dilated proximal to the calculus. Note how the distal ureter courses ventrally to enter the bladder (B). **D,** Longitudinal transvaginal image in a different patient shows an obstructing ureteral calculus (*calipers*) at the UVJ that was not evident on TAS. Note the obstructed, dilated ureter (*arrows*) proximal to the echogenic shadowing calculus.

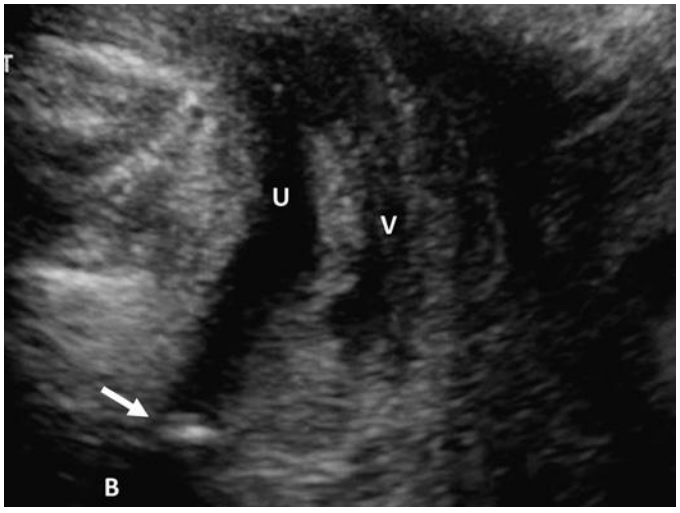

FIG 26-48 Urethra. Longitudinal image of the urethra obtained with minimal insertion of the probe into the vaginal canal shows the anechoic tubular urethra (U) above the vagina (V). A small air bubble (*arrow*) is noted in the proximal urethra, just beyond the bladder neck. B, bladder.

either to the left or right before ascending on the left to join the descending colon. The rectum begins at the third sacral vertebra and is fixed in position. The rectosigmoid colon usually contains gas and fecal material that cast an acoustic shadow and may make identification or differentiation from pelvic masses difficult. Often, differentiation between a pelvic mass and the rectosigmoid colon can be made on real-time imaging if peristalsis can be documented or if the characteristic appearance of the bowel wall can be identified (Fig. 26-50). Differentiation between bowel contents and a mass is not usually a problem if the transvaginal approach is used. The sigmoid colon is best imaged with the transvaginal probe directed posteriorly toward the adnexa and gently pushed deeper into the pelvis. The sigmoid colon should be examined if the patient's symptoms cannot be explained by examination of the rest of the pelvic organs.

The pelvic organs can be examined via the transrectal approach in patients for whom a transvaginal scan is not possible. Using a conventional transvaginal probe, one can obtain images of the uterus, ovaries, and adnexa that have superior resolution compared with the transabdominal approach (Fig. 26-51). This technique is not commonly used, but should be considered in the appropriate patient. Verbal consent should be obtained and the probe should be inserted gently using generous lubrication.

CONCLUSIONS

The sonographic appearance of the female reproductive tract changes dramatically over the course of a lifetime and throughout the menstrual cycle in women of reproductive age. A thorough understanding

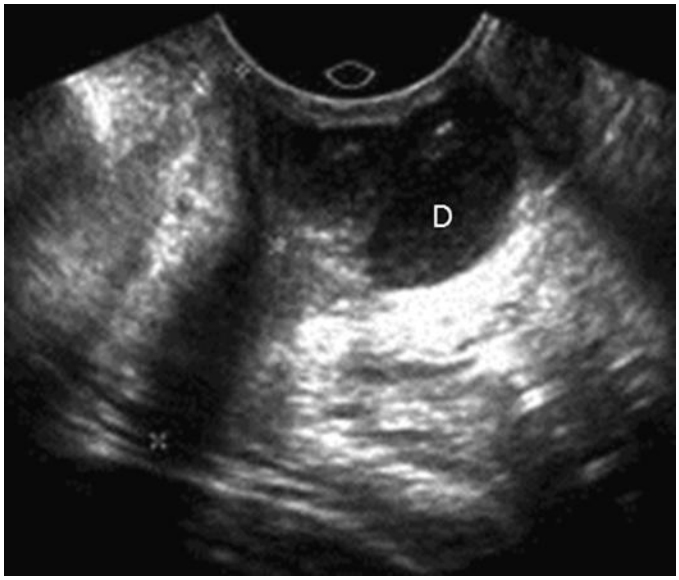

FIG 26-49 Urethral diverticulum. Longitudinal image obtained with minimal insertion of the probe into the vaginal canal demonstrating a urethral diverticulum (D) containing echogenic fluid and small stones posterior to the urethra (*calipers*).

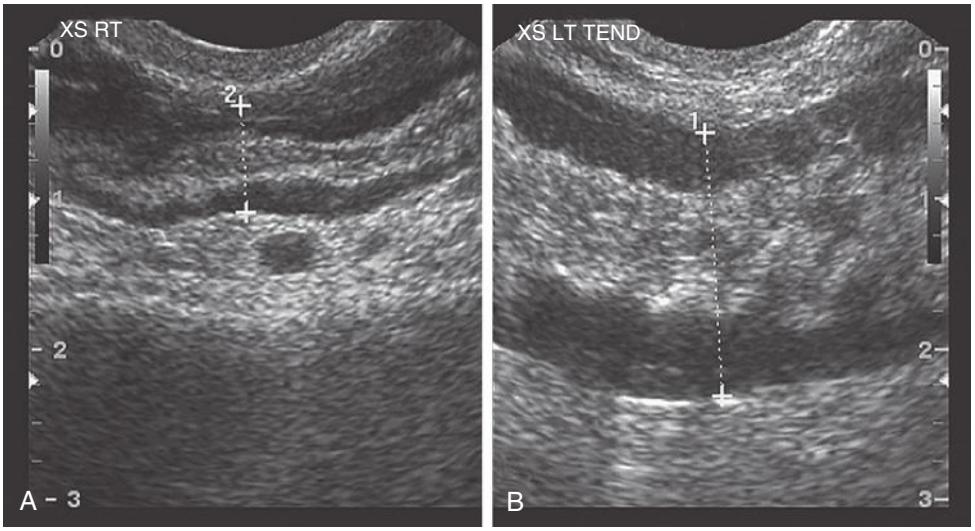

FIG 26-50 Rectosigmoid colon. **A,** A transverse transvaginal scan through a section of normal sigmoid colon to the right of the midline. The overall thickness is 0.71 mm (calipers 2) compared with the abnormal segment in B. **B,** A scan in a similar plane, obtained to the left of the midline showing a thick-walled loop of bowel in a patient with inflammatory bowel disease. The overall thickness is 1.7 cm. The muscularis layer (hypoechoic) and the submucosa (echogenic) are thicker in the abnormal, inflamed segment than in the normal segment. The inflamed segment was also focally tender when compressed with the transvaginal probe.

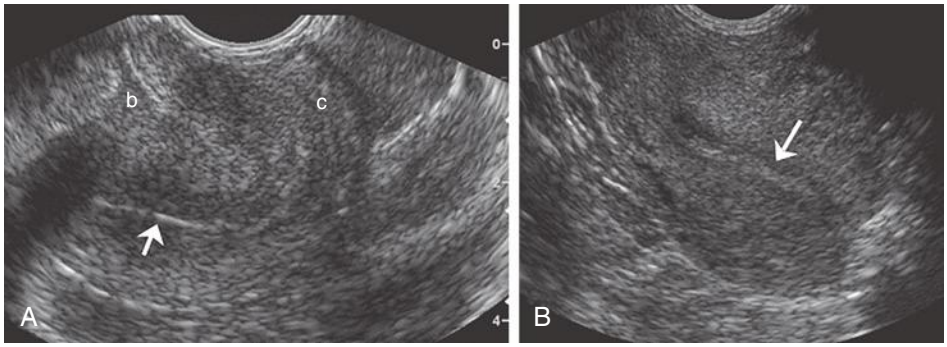

FIG 26-51 Transrectal scan. Longitudinal transrectal scan of an anteverted uterus (**A**) and a retroverted uterus (**B**). The bladder (b) is almost empty. The endometrium (*arrows*) is thin in both patients. c, cervix.

of how hormonal changes affect the sonographic appearance of the uterus and ovaries is critical in differentiating normal physiologic change from pelvic disease. In addition, the experienced sonographer should be aware of the normal sonographic appearance of surrounding structures as pelvic sonography may be extremely useful in the evaluation of disease affecting the pelvic portions of the urinary system, gastrointestinal tract, and musculoskeletal structures that may mimic gynecologic disease.

Abnormal Uterine Bleeding: The Role of Ultrasound

Maryam Rezvani, Thomas C. Winter

SUMMARY OF KEY POINTS

- Abnormal uterine bleeding is most commonly due to dysfunctional anovulatory bleeding in premenopausal women and endometrial atrophy in postmenopausal women.
- Approximately 90% of endometrial cancer occurs after age 50, with the most common symptom being abnormal vaginal bleeding.
- Transvaginal sonography (EVS) is the initial step in the workup of postmenopausal bleeding; however, if the endometrium is not adequately visualized EVS must be followed with biopsy or additional imaging.
- Saline infusion sonohysterography (SIS) is a simple, low-cost, minimally invasive procedure with a high level of diagnostic accuracy.
- SIS is more sensitive than EVS for the detection of focal endometrial abnormalities and rivals hysteroscopy in the identification and characterization of focal lesions.
- SIS can be used to triage patients with abnormal uterine bleeding to the appropriate biopsy technique.
- Tamoxifen, a selective estrogen receptor modulator (SERM), induces endometrial proliferation, which can take the form of hyperplasia, polyp, cancer, or cystic atrophy.

OUTLINE

Abnormal uterine bleeding accounts for up to 20% of all gynecologic visits. Once pregnancy has been excluded, the most likely cause of uterine bleeding in premenopausal women is dysfunctional anovulatory bleeding. However, as women get older, organic pathologic conditions such as endometrial polyps, submucous myomas, endometrial hyperplasia, and even frank endometrial carcinoma become more likely. The Surveillance Epidemiology and End Results (SEER) database reports that the incidence of endometrial carcinoma is 25.1/100,000 women per year.[1] The incidence of endometrial cancer increases with age, with the median age at diagnosis being 62 years.[1] The SEER program reports that 5.6% of new cases occur in women age 35 to 44 years, 18.4% in women age 45 to 54 years, 33.9% in women age 55 to 64 years, 23.4% in women age 65 to 74 years, and 12.6% in women age 75 to 84 years, with the remaining 6.1% at the extremes of the age spectrum.[1] Therefore, in postmenopausal women who are not on hormonal replacement therapy, any vaginal bleeding is considered to be secondary to endometrial cancer until proved otherwise, although the incidence of malignancy in such patients ranges from 2% to 10%, depending upon risk factors.

Nonetheless, the vast majority of patients with abnormal vaginal bleeding will have either dysfunctional uterine bleeding in association with episodes of anovulation that can best be managed hormonally or expectantly with reassurance (premenopausal women), or endometrial atrophy (postmenopausal women). The utility of ultrasound to distinguish such patients from those with organic pathologic conditions in a safe, painless, and convenient manner is clear.

EVOLUTION OF ENDOMETRIAL ASSESSMENT

Endometrial curettage was first described in 1843, and for many years it was the gold standard for evaluation of the endometrium, becoming the most common hospital-based operation performed on women worldwide. However, in the mid-1900s, it was realized that the technique missed endometrial lesions in approximately 10% of cases; of these, 80% were polyps.[2] In the 1970s, vacuum-suction curettage devices allowed endometrial sampling to be performed without anesthesia in an office setting. Subsequently, cheaper, smaller, and less painful plastic catheters with their own internal pistons to generate

suction became popular (e.g., Pipelle device, Unimar, Wilton, CT). They were found to have similar efficacy but better patient acceptance. Still, the Pipelle catheter was found to sample as little as 4% of the surface area of the endometrium and, therefore, had limited ability to identify malignancy confined to a polyp or localized to less than 50% of the endometrial surface.[3,4] Thus, focal endometrial abnormalities such as polyps, focal hyperplasia, or carcinoma involving small areas of the uterine cavity may go undetected with undirected endometrial sampling, whether by curettage or various types of suction aspirations.

Transvaginal Sonography

Pelvic sonography is considered the first-line imaging modality of the uterus. Transabdominal imaging can be helpful in the setting of large leiomyomas or a globally enlarged uterus. However, the mainstay of endometrial evaluation is transvaginal sonography (EVS) with higher frequency transducers and, hence, better resolution. In premenopausal women, the examination should be performed early in the proliferative phase at about days 4 through 6 of the menstrual cycle. Postmenopausal women can be examined any time unless they are on cyclic hormone replacement, in which case imaging should be performed about 5 to 10 days after the last progestin tablet.[5]

The endometrium should be evaluated in both the sagittal and transverse planes. Measurement of endometrial thickness is obtained in the midline sagittal plane perpendicular to the long axis of the endometrium at the site of maximal thickness. By convention, endometrial thickness is measured to include both the anterior and posterior layers (double layer thickness) (Fig. 27-1).[5] Fluid in the endometrial cavity should not be included in the measurement; rather, the single layer thickness of the anterior plus the posterior layer of the endometrium should be measured and summed. If the endometrium is not adequately visualized in its entirety, it should be reported as nonmeasurable and incompletely visualized. Poor visualization of the endometrium has been reported in 10% to 24% of cases and may be due to uterine position, distortion by leiomyomas or adenomyosis, or distortion of the endometrial-myometrial interface from endometrial carcinoma.[5,6]

In the setting of intracavitary disease, the endometrial thickness measurement should include the lesion.[5] A three-dimensional (3D) coronal view of the uterus has been found to be a useful adjunct to two-dimensional (2D) sonography in patients with suspected endometrial abnormalities (Fig. 27-2). One study reported that additional information was obtained from the 3D coronal reconstruction in 39% of patients with an endometrial thickness of 5 mm or more.[7] The presence and location of leiomyomas were more confidently diagnosed, in particular those in a submucosal location.[7] Intracavitary fluid is quantified by measuring its maximal thickness in the sagittal plane.[5]

Saline Infusion Sonohysterography

Sonohysterography, hysterosonography, EVS with fluid contrast augmentation, saline-infused sonography, and saline infusion sonohysterography (SIS) are the many appellations used to describe the instillation of sterile saline into the endometrial cavity during EVS to better evaluate the endometrium and fallopian tubes. Echogenic contrast agents such as air bubbles may be used, especially when evaluating

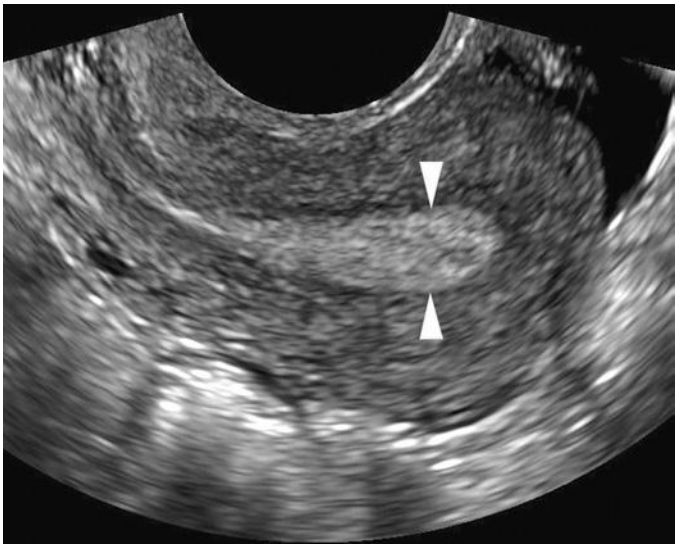

FIG 27-1 A 25-year-old woman referred for sonographic evaluation for oligomenorrhea. Longitudinal transvaginal sonographic image of the retroverted uterus shows a normal homogeneous endometrial echo complex measuring 8 mm in thickness. Standard measurement of the endometrium is performed at its thickest part (*arrowheads*) in the midsagittal plane.

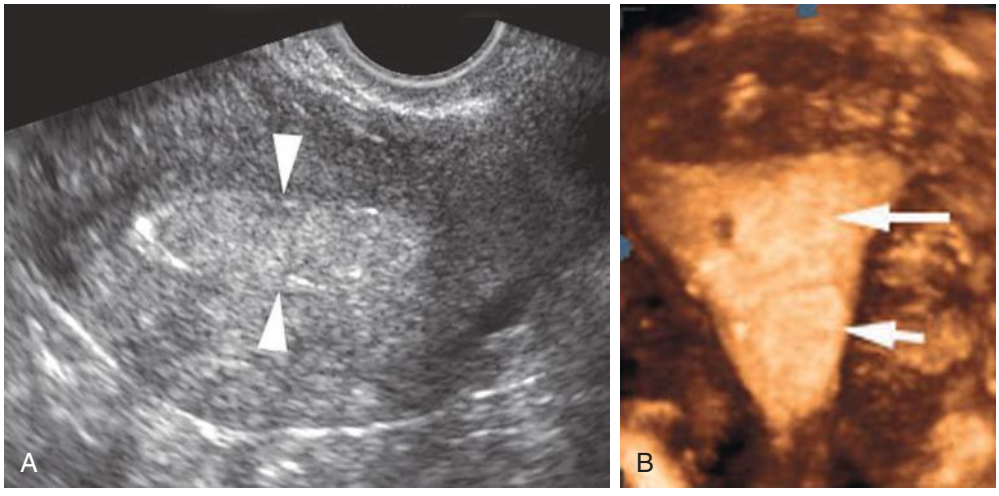

FIG 27-2 A 62-year-old woman with postmenopausal bleeding. **A,** Transvaginal sonography shows homogeneous echogenic thickening of the endometrial echo complex (*arrowheads*). **B,** Coronal three-dimensional image shows two subtle hyperechoic intracavitary masses (*arrows*). The additional information allowed triage to hysteroscopically guided biopsy and removal, confirming endometrial polyps.

for patency of the fallopian tubes. An examination performed with particular attention to the fallopian tubes is known as *sonosalpingography.* SIS is a simple, low cost, minimally invasive procedure with a high level of diagnostic accuracy. Specific advantages over hysterosalpingography are the lack of ionizing radiation and the ability to more accurately characterize masses in the endometrial cavity.[8]

Preprocedure Considerations

The SIS examination should be scheduled close to days 4 through 7 of the menstrual cycle in premenopausal women to decrease the possibility of false positive results because of the common normal irregularity and increased thickness of the secretory phase endometrium,[9] as well as to avoid the possibility of performing the examination in a pregnant patient. However, in a patient with dysfunctional uterine bleeding it may not be possible to optimally time the examination. In these patients, a course of medroxyprogesterone acetate 10 mg daily for 10 days may be considered with the procedure timed to the withdrawal bleeding. The SIS patient should be advised to take a nonsteroidal anti-inflammatory drug (NSAID) approximately 30 minutes prior to her procedure to reduce discomfort. If this has not been done, an NSAID can be administered and the examination delayed by 30 minutes. The benefits of premedication outweigh the short delay. Prophylactic antibiotics may be prescribed if pelvic inflammatory disease is suspected or if the patient requires systemic prophylaxis for bacterial endocarditis.[8]

Examination Technique

A calm, quietly confident demeanor and the use of familiar language without negative connotations can be very helpful in overcoming patient apprehension about the procedure.[10] Including a female attendant in the room regardless of physician gender is recommended. Written informed consent is obtained from the patient, at which time the procedure is explained to the patient and all her questions are answered. Preparing patients for the possibility of cramping during speculum and catheter placement improves their tolerance of any discomfort.[8]

The urinary bladder should be emptied before proceeding in order to optimize patient comfort and image quality. The examination is performed with the patient in the lithotomy position with the buttocks positioned past the edge of the table. Elevation of the pelvis with a pillow or by having the patient place her hands under her hips can improve the angle of the vaginal vault, making the pelvis more accessible. Avoiding sudden movements and unnecessary noise as well as keeping instruments out of the patient's view will help to maintain a calm atmosphere. Initial physical examination should be performed to exclude genital inflammation, determine the position of the cervix, and estimate the appropriate size and type of speculum to be used. A warm speculum is placed in the vagina to localize the cervix, which is then cleansed with antiseptic solution. Abdominal pressure on the uterus just above the pubic symphysis may help bring a posterior cervix into view. A variety of catheters may be employed to infuse fluid, but we will describe one of the easiest systems for the beginner, the dedicated balloon-tipped catheter.[11] Before inserting the catheter, the lumen should be flushed with saline to remove all air. The catheter is then passed into the uterine cavity past the internal os (Fig. 27-3) but with care not to touch the fundus, which can cause pain and elicit a vasovagal response. As much air as possible should be removed from the balloon, which is then filled with saline; otherwise posterior structures will be obscured by shadowing from air in the balloon. With experience, the balloon may be inflated within the cervix itself to decrease pain and to successfully perform studies in which one is unable to pass the catheter all the way through the cervix into the endometrial cavity.[12] The speculum is carefully removed without dislodging the catheter.

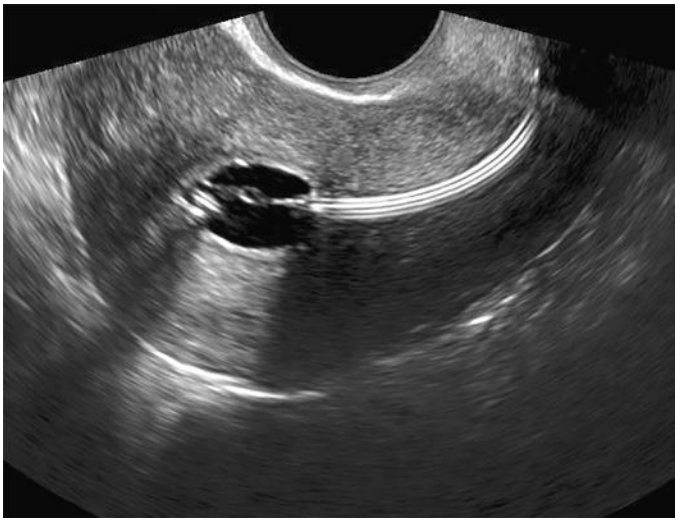

FIG 27-3 A 28-year-old woman with menorrhagia. Longitudinal transvaginal sonography of the uterus obtained during a normal saline infusion sonohysterographic examination shows insertion of the catheter and inflation of the balloon just past the internal cervical os. The balloon is inflated with saline to avoid shadowing and obscuration of the posterior uterine wall by gas.

FIG 27-4 A 33-year-old woman with menometrorrhagia actively bleeding at the time of the examination. Longitudinal transvaginal sonography of the retroverted uterus obtained during saline infusion sonohysterography shows the balloon (*arrowhead*) dislodging echogenic clot (*arrow*) in the endometrial cavity.

The vaginal transducer is introduced and positioned for longitudinal imaging of the uterus. The uterine cavity is distended with sterile saline under direct visualization. A slow rate of saline infusion will reduce cramping. Once adequate distention is achieved, multiplanar 2D EVS, with Doppler interrogation if necessary, as well as a 3D volume acquisition of the uterus is performed. Once the upper uterus has been satisfactorily evaluated, the balloon is deflated and additional sterile saline injected for evaluation of the lower uterine segment.[8]

Challenges

Blood in the endometrial cavity may cause confusion. Direct visualization of the cavity during gentle catheter manipulation and saline flushes can be helpful in differentiating mobile blood products (Fig. 27-4) from a true endometrial abnormality. Both the stenotic and

patulous cervix can be a challenge. Cervical stenosis may be encountered in a nulliparous patient, a patient who has previously had cone biopsies or loop electrosurgical excision procedure, or in perimenopausal and postmenopausal patients.[8] A metal stylet introduced through the catheter may increase stiffness sufficiently to allow passage of the catheter into the uterine cavity. Alternatively, a small diameter sound may be used to probe the cervix, determine cervical orientation, straighten the cervix, and remove adhesions. Although not routinely used while performing SIS, a single tooth tenaculum may be used at the 12 o'clock position if the uterus is markedly flexed to put gentle traction on the cervix and straighten the uterus, allowing passage of the catheter.[8] If a tenaculum is used, the speculum should be replaced at the conclusion of the procedure to check for cervical bleeding. The uterine cavity may be difficult to distend if fluid escapes via a patulous cervix or patent fallopian tubes. Appropriate catheter position should be confirmed, and slow injection of saline with minimal pressure may help reduce spillage from the fallopian tubes. A balloon system or 8-Fr pediatric Foley catheter should be used if the cervix is incompetent or patulous.[8] Although there are theoretical concerns regarding the possibility of spreading adenocarcinoma into the peritoneal cavity or in causing endometriosis with SIS, neither of these considerations has proved to be relevant in practice.[13-15]

ABNORMAL UTERINE BLEEDING

Postmenopausal Bleeding

Postmenopausal vaginal bleeding is extremely common and is estimated to occur in up to 55% of postmenopausal women. The Society of Radiologists in Ultrasound (SRU) defines postmenopausal bleeding as bleeding that occurs outside the expected window in women on sequential hormone replacement therapy (HRT) or any bleeding in a postmenopausal woman not on HRT.[16] Most common are benign causes, including endometrial atrophy, polyps, hyperplasia, and uterine leiomyomas. However, approximately 7% to 14% of women with postmenopausal bleeding will have endometrial cancer (range 1-25% depending on age and risk factors; see later discussion).[16,17] Women with recurrent bleeding are a particularly high-risk group.[18] Furthermore, more than 90% of endometrial cancer occurs after age 50, with the most common symptom by far being abnormal vaginal bleeding.[16] This statistic alone warrants evaluation of all women with postmenopausal bleeding.

Following clinical evaluation, EVS is the initial step in the workup of a postmenopausal woman with abnormal bleeding (Fig. 27-5). Ultrasound is better tolerated and more often diagnostic (>95%) compared with endometrial biopsy (EMB). The false negative rate for endometrial cancer following in-office biopsy is 5% to 15%; the rate can be reduced to 2% to 6% but only if dilation and curettage (D&C) is performed.[17] Even with D&C, only 60% of the endometrium may be sampled and focal lesions may be missed.[19] Up to 28% of endometrial biopsies may be nondiagnostic or insufficient.[17] Cervical stenosis and patient intolerance may prevent EMB, and even when technically successful, an inadequate specimen may be obtained in 5% to 15% of patients.[16] Blind biopsy is further limited by its decreased sensitivity for focal endometrial abnormalities. Although reliable for the detection of endometrial cancer occupying more than 50% of the uterine cavity, EMB can miss up to 33% of malignancies occupying a smaller area.[4] Unfortunately, just under half of endometrial cancers have been reported to occupy more than 50% of the uterine cavity.[4,20]

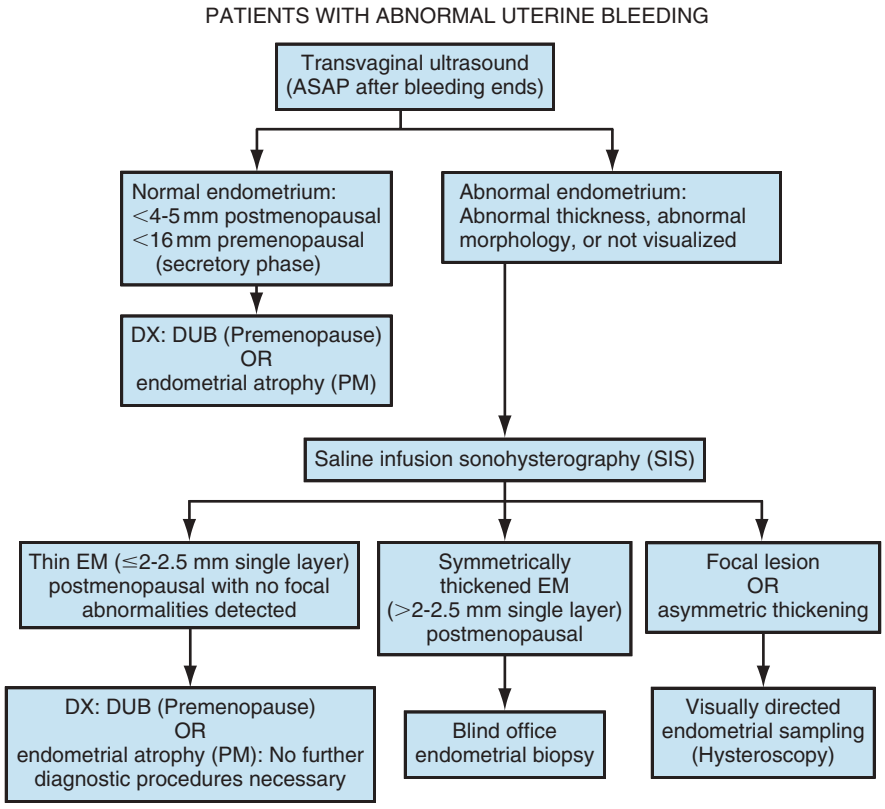

FIG 27-5 Algorithm for evaluation and management of patients with abnormal uterine bleeding. ASAP, as soon as possible; DUB, dysfunctional uterine bleeding; DX, diagnosis; EM, endometrium; PM, postmenopause; SIS, saline-infused sonohysterogram.

Endometrial carcinoma is rare when the endometrium is adequately visualized, thin, and homogeneous on EVS. In fact, when the endometrial thickness measures less than 4 to 5 mm on EVS, the negative predictive value for endometrial carcinoma is 99% to 100% if the endometrium is adequately visualized in its entirety. In such patients, the cause of vaginal bleeding is most likely endometrial atrophy, and no further evaluation is needed with either biopsy or additional imaging unless symptoms persist or worsen. The SRU consensus statement recommends using an endometrial thickness threshold of 5 mm or less, whereas the ACOG (American College of Obstetricians and Gynecologists) committee opinion is that the threshold should be 4 mm or less.[21,22] Both societies recommend reporting the endometrium thickness on EVS as a double thickness measurement of the thickest segment of the endometrial echo complex (usually in the fundus) obtained in the midline sagittal plane and agree that further evaluation is necessary if the complex is indistinct, heterogeneous, or focally thickened. Nondiagnostic transvaginal studies occur in 2.8% to 10% of patients and are likely because of factors such as the orientation of the uterus, prior surgery, obesity, and coexisting adenomyosis or leiomyomas.[20,23] Alternative evaluation should be performed if the endometrium is not visualized in its entirety, given the 15% incidence of endometrial cancer in this patient population.[23]

Approximately 50% of cases of premenopausal and postmenopausal abnormal uterine bleeding are caused by focal abnormalities of the endometrium.[24] SIS is more sensitive than EVS for the detection of focal endometrial abnormalities and rivals hysteroscopy in the identification and characterization of focal lesions.[24,25] Furthermore, SIS can be used to triage patients with abnormal uterine bleeding to the appropriate biopsy technique. EMB or D&C is considered adequate for evaluation of a diffuse process, whereas hysteroscopy is recommended for focal abnormalities due to the risk of sampling error with EMB and D&C for focal disease as described previously. Because of the increased sensitivity of SIS for the detection of focal endometrial abnormalities, it may also be helpful in the case of discordant EVS and EMB results. One study found that 14% of patients with abnormal vaginal bleeding had abnormalities on SIS despite a normal appearance of the endometrium on EVS.[26]

When using an endometrial thickness threshold of 5 mm, the sensitivity of EVS for endometrial cancer is 96%, with the positive predictive value increasing as the thickness of the endometrium increases.[16-18] This compares with a sensitivity of greater than 85% for EMB.[16] If the threshold for endometrial thickness is decreased to 4 mm, there is no significant change in the sensitivity of EVS for detecting endometrial cancer. However, specificity decreases and there will be more false positive diagnoses.[16] However, this opinion was not uniformly shared by all participants at the SRU consensus panel on postmenopausal bleeding, with the dissenters recommending 4 mm as a threshold.[22] All agree that the use of HRT increases the false positive rate at either threshold.

Although much energy has been devoted to determining the threshold endometrial thickness in a postmenopausal woman with vaginal bleeding, there is no consensus on the normal endometrial thickness in a postmenopausal woman without vaginal bleeding. However, the latter scenario is not infrequently encountered due to the widespread use of EVS for evaluation of the female pelvis. If the threshold of greater than 5 mm that is recommended by the SRU for women with postmenopausal vaginal bleeding is applied to asymptomatic women, the false positive rate and consequently the number of biopsies performed in normal women would be unacceptable.[27] Although there is no standardized cutoff for endometrial thickness in a postmenopausal woman without vaginal bleeding, all agree it should be higher than 5 mm in this patient population with low pretest probability of endometrial cancer.[21]

When applying a decision analysis approach to determine the endometrial thickness in asymptomatic postmenopausal women at which the risk of endometrial cancer approaches that of symptomatic postmenopausal women with vaginal bleeding and an endometrial thickness more than 5 mm, the result has been reported to be over 11 mm.[28] An endometrial thickness over 11 mm in an asymptomatic postmenopausal woman carries an endometrial cancer risk of 6.7%, comparable to that of 7.3% in a postmenopausal woman with vaginal bleeding and an endometrial thickness greater than 5 mm.[28] This threshold would result in biopsy of only 0.25% of women to detect 87% of occult endometrial cancers.[28] For the more conservative endometrial thickness threshold of 4 mm recommended by ACOG for symptomatic postmenopausal women, the corresponding normal endometrial thickness in asymptomatic postmenopausal women is considered to be less than 10 mm, with an endometrial thickness more than 10 mm in an asymptomatic postmenopausal woman carrying a 5.8% risk of endometrial cancer.[28]

EVS is not recommended as a screening tool for endometrial cancer in asymptomatic postmenopausal women, but this analysis provides some guidance on how to manage the thickened endometrium incidentally observed in a postmenopausal woman without bleeding on an ultrasound scan performed for other reasons. However, the decision to biopsy the endometrium will no doubt include overall assessment of the patient, including risk factors for endometrial cancer.

Premenopausal Bleeding

Dysfunctional uterine bleeding in a nonpregnant premenopausal woman occurs as menorrhagia, metrorrhagia, or menometrorrhagia. There is no widely accepted threshold for abnormal endometrial thickness in premenopausal women, although typically diffuse homogeneous thickening greater than 16 mm in the secretory phase is used (there is no accepted threshold value in the proliferative phase). However, a thickened endometrium in the late secretory phase of the menstrual cycle is often normal, so routine studies ideally should be performed in the early proliferative phase to minimize false positive results. The sensitivity and specificity of EVS for detecting endometrial disease in the premenopausal population using a cutoff value of more than 16 mm are not optimal at 67% and 75%, respectively.[29,30] In the setting of a diffusely thickened endometrium or persistent bleeding unresponsive to hormonal therapy, SIS is indicated because of its ability to detect abnormalities in patients with normal EVS and to differentiate focal from diffuse processes, allowing triage to the appropriate biopsy technique.[26] Focal abnormalities such as asymmetric thickening, cystic change, and the hyperechoic line sign should be further evaluated regardless of endometrial thickness and be triaged to hysteroscopy for direct visualization and biopsy.[19] The hyperechoic line sign is indicative of a focal intracavitary process and is thought to represent the echogenic endometrium abutting the intracavitary mass or the interface between the mass and surrounding endometrium. Overall, SIS is better tolerated and more often technically successful in premenopausal women than in postmenopausal women.[24]

ENDOMETRIAL PATHOLOGY

Endometrial Atrophy

Endometrial atrophy is the most common cause of postmenopausal bleeding, representing 50% to 75% of cases.[31] Atrophy of the functional, more superficial, layer of the endometrium occurs in response to a prolonged hypoestrogenic state. Only a thin basalis layer remains at the endometrial/myometrial junction, leaving the underlying myometrial vessels exposed. Menopause is the most common cause of endometrial atrophy; other causes include prolonged oral contraception.

EVS typically demonstrates a thin uniform endometrium measuring less than 5 mm (Fig. 27-6). There may be cystic dilatation of the endometrial glands that may cause pseudo-widening of the endometrium, an appearance often seen in women taking tamoxifen (see later). The single layer thickness of the endometrium should be less than 2.5 mm on SIS in patients with endometrial atrophy without areas of focal thickening or irregularity.

Endometrial Hyperplasia

Endometrial hyperplasia accounts for 4% to 8% of cases of postmenopausal bleeding.[32] Unopposed estrogen stimulation leads to a proliferation of endometrial glands. Unlike normal proliferative phase endometrium, there is a higher gland-to-stroma ratio and the glands are irregular in size and shape.[33] Endometrial hyperplasia can be seen with chronic anovulatory states, unopposed exogenous estrogen exposure, tamoxifen use, obesity, and estrogen-secreting ovarian tumors.[32] There are four categories of endometrial hyperplasia based on the glandular and stromal architecture and the presence of nuclear atypia. The presence of nuclear atypia in the hyperplastic endometrium increases the risk of coexisting foci of endometrial carcinoma and the future development of malignancy. The incidence of endometrial cancer in simple hyperplasia without atypia is 1%, and in simple atypical hyperplasia it is 8%.[33] Complex hyperplasia without atypia has a cancer incidence of 3%, whereas complex atypical hyperplasia has a cancer incidence of 29%.[33] Unfortunately, the pathologic diagnosis of atypia is not easy and has a low level of interobserver agreement. Often women with atypical hyperplasia have coexistent foci of endometrial carcinoma. Up to one third of cases of endometrial cancer are preceded by hyperplasia.[33]

In patients with endometrial hyperplasia, ultrasound demonstrates thickening of the endometrial echo complex, which is typically diffuse, echogenic, and homogeneous, with a well-defined myometrial interface (Fig. 27-7). There may be foci of cystic change, which correspond to dilated endometrial glands (Fig. 27-8). Focal endometrial thickening (Fig. 27-9) and areas of heterogeneity are less common and better demonstrated with SIS. Generally accepted thresholds for abnormal endometrial thickening are greater than 5 mm for postmenopausal women not on HRT and more than 16 mm for premenopausal women in the secretory phase of the menstrual cycle, although there is some controversy over these numbers, as discussed earlier. Additionally, focal endometrial thickening or heterogeneity is considered abnormal even if below these thresholds for endometrial thickening.

Endometrial Polyps

Endometrial polyps are hyperplastic growths consisting of dense fibrous tissue or smooth muscle with disorganized endometrial glands. Polyps can be asymptomatic or cause dysfunctional uterine bleeding in premenopausal women and account for up to 30% of postmenopausal bleeding.[32] Polyps may spontaneously resolve, particularly when small (<1 cm) and occurring in asymptomatic postmenopausal women.[34] Polyps can be hyperplastic, atrophic, or rarely, functional.

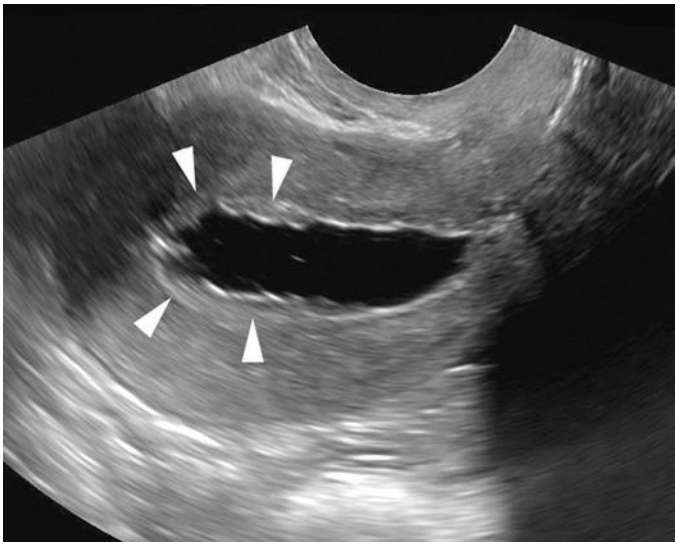

FIG 27-7 A 32-year-old woman with bleeding and cramping. Longitudinal transvaginal sonography of the uterus obtained during saline infusion sonohysterogram demonstrates diffuse thickening of the endometrium (*arrowheads*) consistent with endometrial hyperplasia.

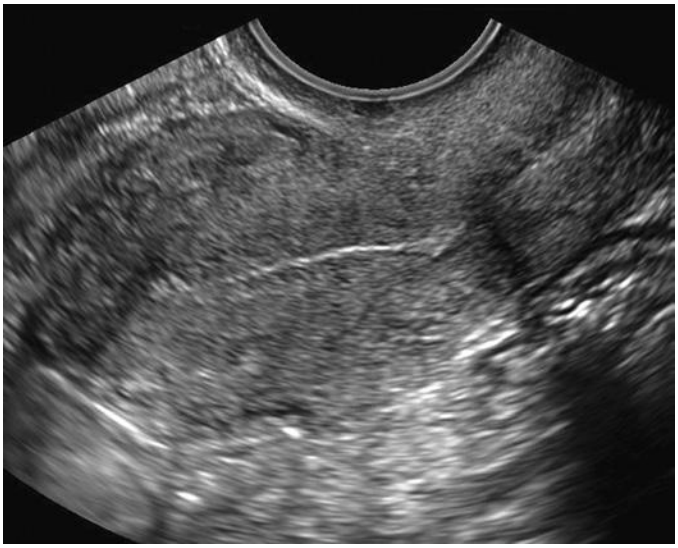

FIG 27-6 Longitudinal transvaginal sonography of the uterus shows a uniformly thin endometrial stripe measuring 1 mm in thickness. When adequately visualized, a thin endometrium less than 4 to 5 mm essentially excludes malignancy in a postmenopausal woman with vaginal bleeding.

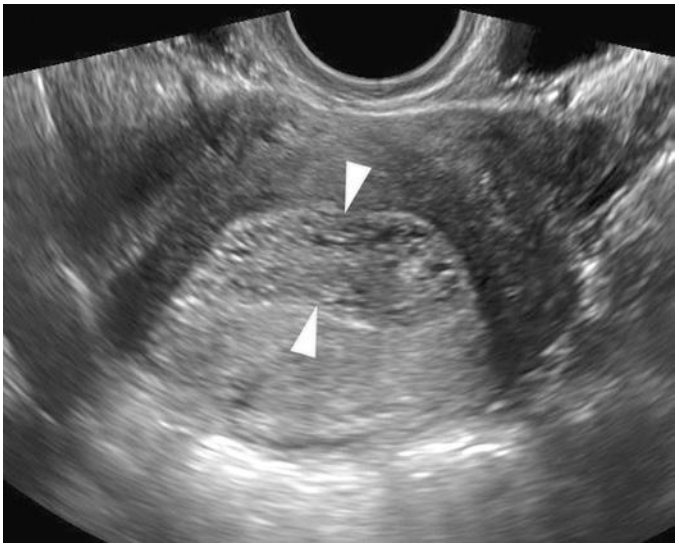

FIG 27-8 A 41-year-old woman with menorrhagia. Transverse transvaginal sonography shows diffuse thickening of the endometrium (*arrowheads*) with internal areas of cystic change resulting in the typical "swiss cheese" appearance of endometrial hyperplasia.

FIG 27-9 A 57-year-old woman with postmenopausal bleeding and transvaginal sonography (EVS) showing a possible endometrial polyp, later shown to be endometrial hyperplasia at hysteroscopy. Longitudinal EVS of the uterus obtained during saline infusion sonohysterography demonstrates plaque-like focal thickening (*arrow*) of the fundal endometrium with internal cystic change.

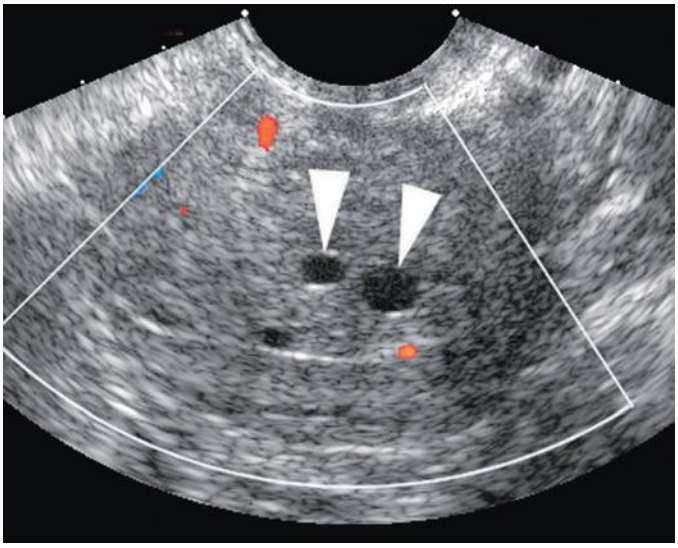

FIG 27-10 A 57-year-old woman with postmenopausal bleeding and negative endometrial biopsy. Transverse color Doppler image of the uterus shows endometrial thickening with several anechoic internal cysts (*arrowheads*) corresponding to dilated endometrial glands in a polyp. Hysterectomy confirmed a 2-cm endometrial polyp attached to the right uterine cornu. Endometrial biopsy is unreliable for detection of focal endometrial disease, thus making sonographic evaluation an essential part of the workup of postmenopausal bleeding.

Atrophic polyps occur in postmenopausal women and are composed of atrophic but dilated glands. Rarely endometrial polyps harbor atypia (3.1-4.7%) or foci of malignancy (0.8-1.4%). The likelihood of neoplastic polyps is higher in women with symptomatic bleeding and in those who are postmenopausal.[34] Although 8% to 36% of postmenopausal women on tamoxifen develop endometrial polyps, it is unclear whether there is an associated increased risk of malignancy.[34] Endometrial polyps can be sessile or pedunculated, are multiple in 20% of women, and are reported to range from 1 mm to a few centimeters in size. Women on tamoxifen tend to have larger and multiple polyps. Large size is defined as greater than 1 cm, and a polyp is considered pedunculated if the maximum transverse diameter of the lesion is larger than its diameter at the level of the endometrium.[5,34] Pedunculated polyps have a vascular fibrous stalk. They most commonly arise in the uterine cornua or fundus and rarely can prolapse through the cervix. Intralesional cysts represent dilated endometrial glands.

Ultrasound demonstrates diffuse or focal echogenic thickening of the endometrial echo complex.[35] One study found 79% of polyps to be hyperechoic, with the remainder having variable echogenicity, and 59% will have internal cystic spaces[19] (Fig. 27-10). The endometrial-myometrial interface is typically intact, with the polyp forming an acute angle with the endometrium.[35] Color Doppler imaging can be helpful by demonstrating the vascular pedicle (Fig. 27-11), seen in just under half of polyps.[35] A single feeding artery is typically seen in functional polyps, whereas half of polyps, usually the atrophic type, show no flow on color Doppler imaging.

SIS is particularly helpful in demonstrating focal endometrial lesions with an otherwise normal endometrial thickness elsewhere in the uterine cavity, whereas diffuse endometrial thickening on EVS is nonspecific and may be caused by focal lesions as well as by diffuse disease (Fig. 27-12). The majority of polyps have a narrow attachment to the endometrium, although less commonly they may be sessile or broad-based (Fig. 27-13).[19] SIS is useful not only for triaging patients with endometrial thickening seen on EVS to hysteroscopically guided biopsy for removal of focal endometrial abnormalities but also for differentiating endometrial from myometrial lesions such as submucosal leiomyomas (Fig. 27-14).[32] The broad attachment to the myometrium and the intact overlying rim of endometrium help to distinguish submucosal leiomyomas from other focal endometrial processes.[19] Leiomyomas are also more likely to be hypoechoic compared to the endometrium as well as to the myometrium.

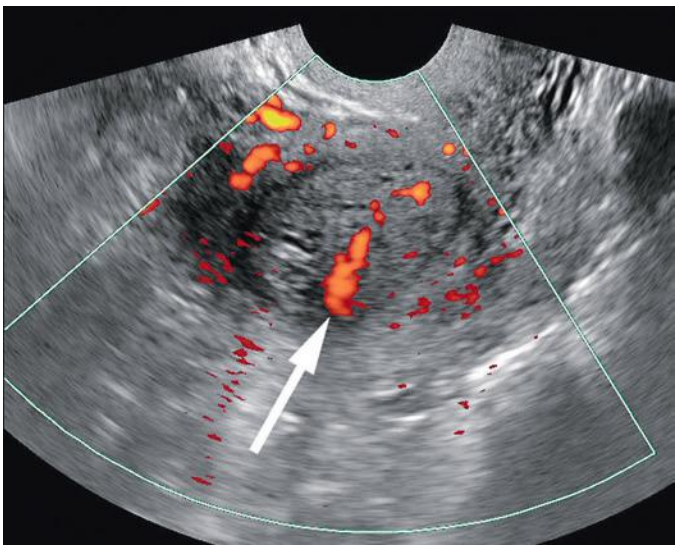

FIG 27-11 A 68-year-old woman with postmenopausal bleeding. Transverse power Doppler image of the uterus shows cystic endometrial thickening with a single vascular pedicle (*arrow*) consistent with a focal abnormality, specifically an endometrial polyp. As is often the case with focal endometrial abnormalities, blind endometrial biopsy was negative, but a benign polyp was diagnosed on hysteroscopic polypectomy.

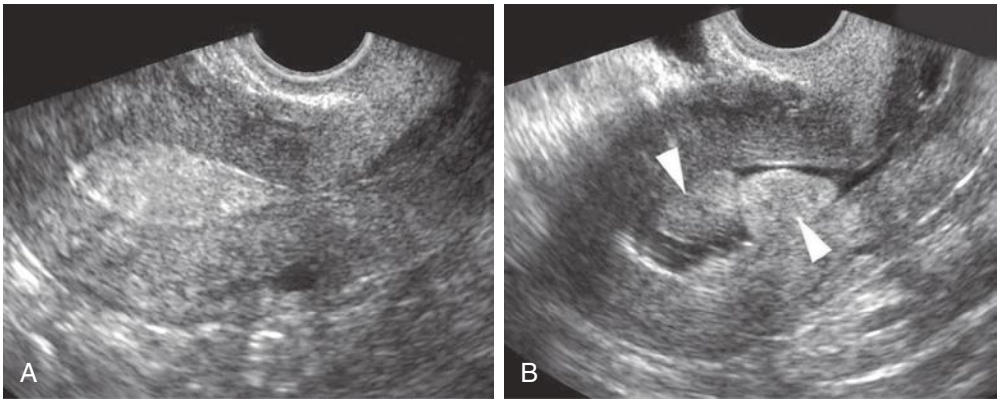

FIG 27-12 A 62-year-old woman with postmenopausal bleeding. **A,** Transvaginal longitudinal ultrasound image of the uterus shows diffuse echogenic thickening of the endometrium. **B,** Longitudinal saline infusion sonohysterography (SIS) shows two echogenic polypoid masses (*arrowheads*) with otherwise normal thin endometrium. SIS is helpful in triaging patients with diffuse endometrial thickening to blind biopsy or, in the case of a focal abnormality as shown here, to hysteroscopic removal.

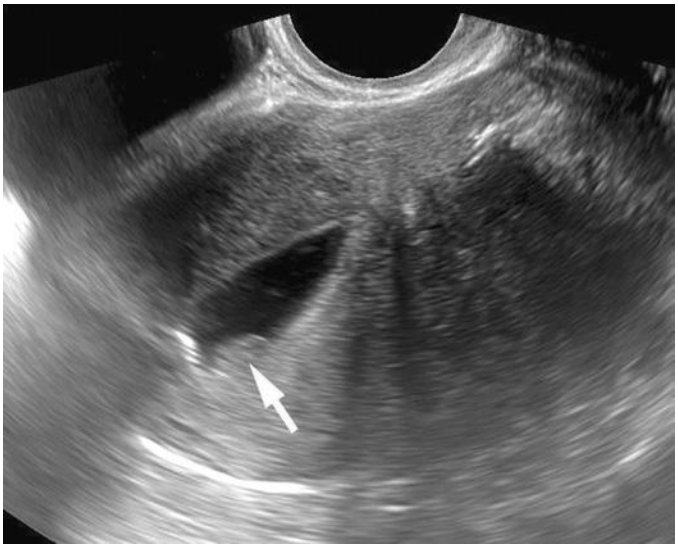

FIG 27-13 A 39-year-old woman referred for saline infusion sonohysterography (SIS) to evaluate possible filling defect seen on conventional hysterosalpingogram (HSG). Longitudinal SIS image of the uterus shows focal posterior endometrial thickening (*arrow*). The maximum diameter of the lesion is smaller than its base, consistent with a sessile polyp. Subsequent hysteroscopic removal of the lesion confirmed a 5-mm benign polyp. SIS is helpful both for demonstrating small abnormalities that may be missed on transvaginal sonography (EVS), as well as for confirming normal endometrium in the remainder of the uterine cavity. SIS can detect abnormalities missed on EVS in 14% to 24% of cases.[6,26]

Endometrial Carcinoma

Endometrial carcinoma is defined as cancer occurring above the level of the internal cervical os involving the upper two thirds of the uterus. It is the most common of the gynecologic cancers and represents 95% of uterine malignancies and 6% of all cancers in women. It is the fourth most common cancer in women.

Endometrial carcinoma most commonly presents with abnormal uterine bleeding, allowing early diagnosis and treatment. EVS is the best and most commonly used imaging modality for the detection of endometrial cancer. EVS is readily available and can virtually exclude endometrial cancer in women with a thin endometrium. Endometrial carcinoma is most common in the sixth and seventh decades of life, with more than 90% occurring after age 50. Women under age 40 constitute only about 5% of cases. The majority of patients (75-80%) are diagnosed with stage I disease, which has an overall 5-year survival rate of 80% to 85% and a cancer-specific survival rate of 90% to 95%.[17] Risk factors for endometrial cancer include estrogen HRT, obesity, polycystic ovary syndrome, chronic anovulation, tamoxifen, nulliparity, early menarche, late menopause, hypertension, and diabetes mellitus. The majority of cases are of endometrioid histology, which is associated with chronic estrogen exposure, a common theme noted among the risk factors.

EVS typically demonstrates diffuse endometrial thickening (Fig. 27-15) or an endometrial mass. The thickened endometrial echo complex is most often hyperechoic but may have areas of decreased echogenicity. The myometrial interface can be well defined with an intact subendometrial halo if no myometrial invasion has occurred. However, focal or diffuse disruption of the subendometrial halo or extension of the echogenic endometrial lesion into the more hypoechoic underlying myometrium is concerning for myometrial invasion. Doppler evaluation has not been found to be helpful, as there is significant overlap of findings (such as resistive index and pulsatility index measurements) seen with benign and malignant endometrial thickening. Mass-like lesions may be homogeneous or heterogeneous and often have an irregular surface. Polypoid masses may be superficially attached to the endometrium and otherwise expand the uterine cavity. Occasionally endometrial cancer may appear as an ill-defined and poorly visualized endometrial echo complex, which may be misinterpreted as poor visualization because of technical factors. If the endometrium is not adequately visualized in a postmenopausal woman with abnormal vaginal bleeding, additional evaluation should be performed to exclude endometrial cancer given the 15% incidence of endometrial cancer in this population[23] (Fig. 27-16). Findings suggestive of endometrial cancer on SIS include irregular endometrial thickening, endometrial heterogeneity, an irregular focal endometrial mass with or without myometrial invasion or irregular vascularity on color Doppler, and a rigid or poorly distensible uterine cavity.[36]

Tamoxifen

Tamoxifen, a selective estrogen receptor modulator (SERM), is used to treat breast cancer or as prophylaxis to prevent breast cancer in high-risk patients. Although an antiestrogen agent in breast tissue, tamoxifen and other SERMs bind to estrogen receptors at the uterine

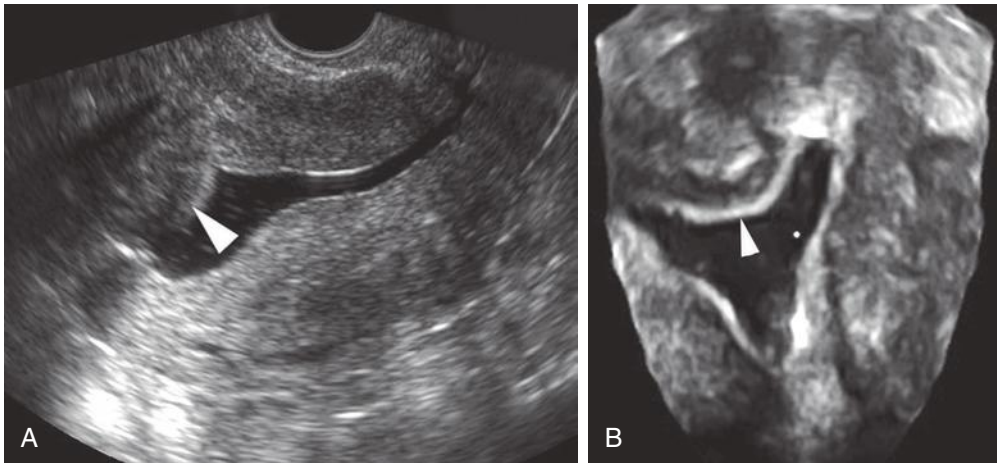

FIG 27-14 A, Longitudinal image of the uterus obtained during saline infusion sonohysterography (SIS) shows a hypoechoic submucosal mass (*arrowhead*) protruding into the uterine cavity at the fundus. **B,** Coronal three-dimensional (3D) image better demonstrates the thin layer of overlying echogenic endometrium (*arrowhead*), further confirming the submucosal location of this leiomyoma. If available, 3D volume acquisition of the uterus should be performed routinely with SIS.

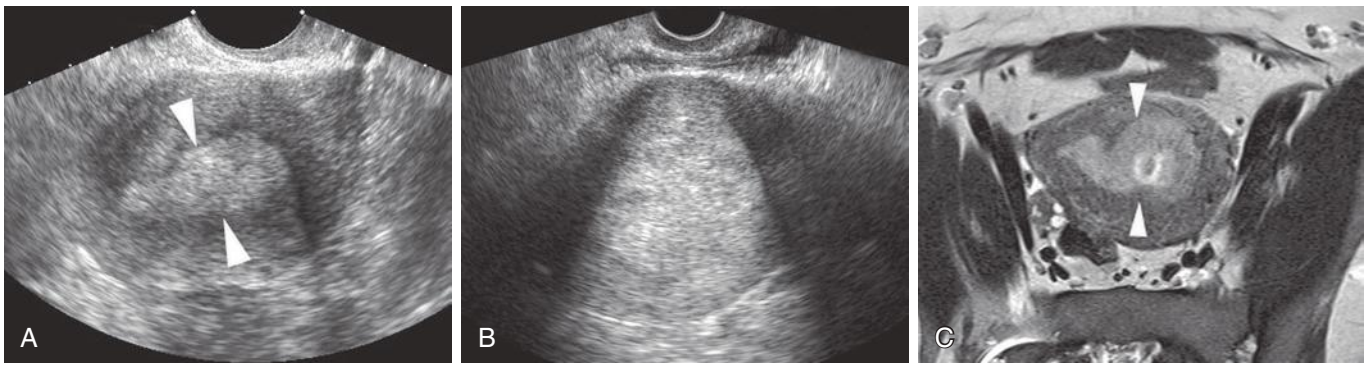

FIG 27-15 A 26-year-old premenopausal obese woman with dysfunctional uterine bleeding. **A,** Transverse transvaginal sonogaphy (EVS) image of the uterus demonstrates irregular and asymmetric echogenic thickening of the endometrial echo complex (*arrowheads*). Dilation and curettage (D&C) was performed, showing chronic endometritis but no evidence of malignancy. **B,** EVS performed 2 years later in the setting of continued abnormal bleeding shows increased endometrial thickening with an ill-defined endometrial-myometrial interface. Given the results from prior D&C, magnetic resonance imaging was performed. **C,** Axial oblique T2-weighted image of the uterus shows mass-like irregular thickening of the endometrium (*arrowheads*) with less than 50% thickness myometrial invasion. Hysterectomy confirmed stage 1A endometrial carcinosarcoma.

level and have a paradoxic effect in the uterus, inducing endometrial proliferation, which can take the form of hyperplasia, polyp, cancer, or cystic atrophy. Not only can these endometrial abnormalities coexist, but tamoxifen is also associated with adenomyosis, enlargement of leiomyomas, and ovarian cysts. Tamoxifen "mucosa" or cystic atrophy differs from endometrial atrophy seen in postmenopausal women not on tamoxifen both on hysteroscopic and histologic evaluation.[37] Scattered protuberances are seen in the background of hypervascularized and atrophic endometrium. Microscopically, cystic spaces within a fibrous stroma are lined by atrophic endometrium. The exact location of the cysts is controversial; the two main theories being within the endometrium at the endometrial/myometrial junction, within the inner myometrium (subendometrium) or both.[37,38] Up to 50% of women develop endometrial abnormalities while on tamoxifen therapy, usually in the first 36 months of treatment. Most patients are asymptomatic and in this population no surveillance imaging is recommended. Symptomatic patients typically have abnormal uterine bleeding. Further investigation of the bleeding is undertaken when the endometrium is more than 5 mm in a postmenopausal woman.

Tamoxifen-induced proliferation of the endometrium has a nonspecific sonographic appearance of endometrial thickening with cystic dilation of the endometrial glands. This may represent endometrial hyperplasia, polyps, or carcinoma, as well as the pseudo-thickening of cystic endometrial atrophy (Fig. 27-17).[29] In this patient population, metastatic breast cancer (Fig. 27-18) should always be considered in the differential diagnosis. Polyps tend to be multiple and larger in women taking tamoxifen, with a median size of 2.9 cm (range of 0.3-11 cm).[39] Following discontinuation of tamoxifen, endometrial thickening slowly decreases at a rate of approximately 1.3 mm per year. Therefore, the endometrium may remain thickened for 6 to 12 months following discontinuation of tamoxifen therapy.[40]

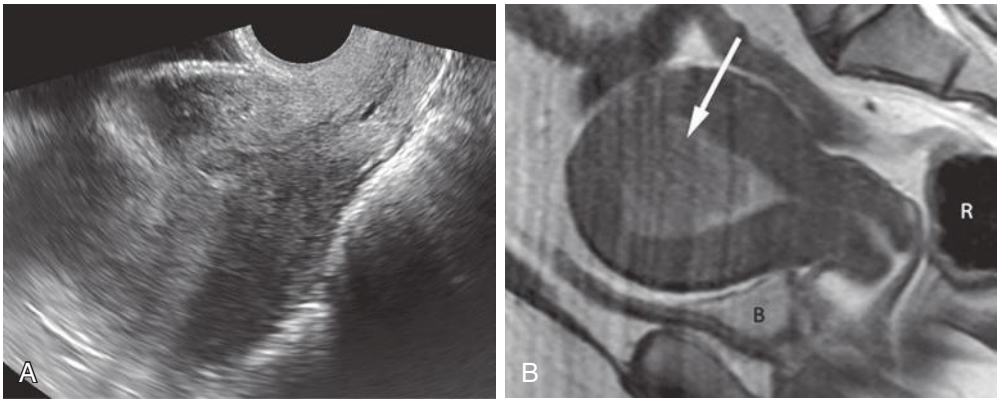

FIG 27-16 A 43-year-old premenopausal nulliparous woman with history of endometrial hyperplasia, obesity, and hypertension now with abnormal bleeding. **A,** Longitudinal transvaginal sonographic image of the uterus demonstrates a poorly visualized endometrial stripe. It could not be determined if this was due to technical factors or true endometrial disease, and therefore, a magnetic resonance imaging scan was performed. **B,** Sagittal T2-weighted image of the uterus shows a polypoid endometrial mass (*arrow*), hypointense relative to the normal high signal intensity endometrium. The mass-myometrial interface at the uterine fundus is ill defined, concerning for invasion; however, this is less than 50% of the myometrial thickness. Stage 1A endometrial cancer was confirmed at hysterectomy. B, bladder; R, rectum.

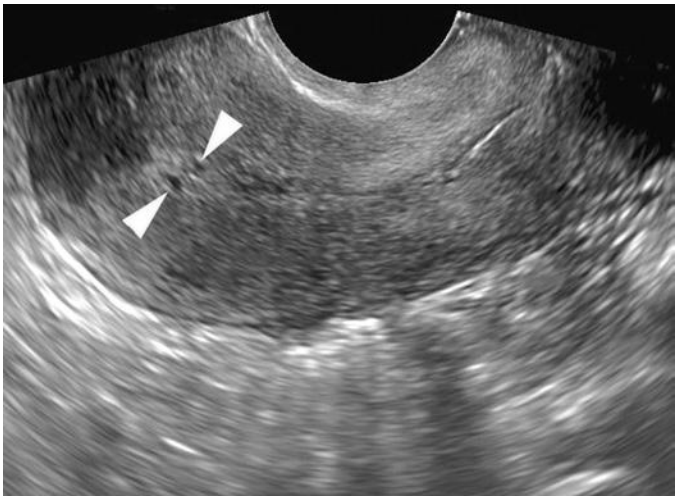

FIG 27-17 A 43-year-old woman with breast cancer and chemotherapy-induced ovarian failure now with abnormal uterine bleeding. Longitudinal transvaginal sonographic image of the uterus shows a thin endometrial stripe with small cysts (*arrowheads*) at the endometrial-myometrial junction, typically seen in cystic endometrial atrophy induced by tamoxifen. This sonographic appearance could mimic a small focal endometrial polyp with cysts.

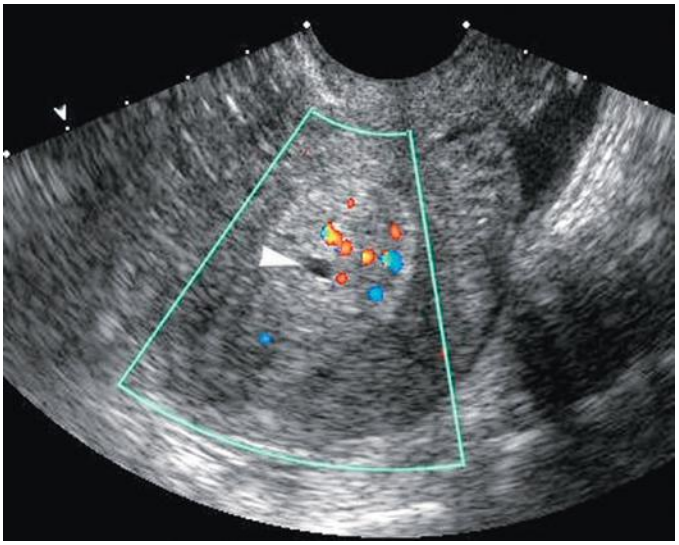

FIG 27-18 A 50-year-old woman with breast cancer on tamoxifen therapy with intermittent vaginal bleeding. Transverse color Doppler transvaginal sonographic image of the uterus shows endometrial thickening with internal cystic change (*arrowhead*) and diffusely increased vascularity. This appearance is nonspecific and may represent endometrial hyperplasia, polyp, or carcinoma, particularly in the setting of tamoxifen therapy. Although much less common, metastatic breast cancer can have this appearance. Endometrial biopsy was negative; however, the patient underwent hysterectomy with the goal of inducing surgical menopause prior to initiation of an aromatase inhibitor. Final surgical disease demonstrated poorly differentiated metastatic breast cancer.

SUMMARY

Abnormal uterine bleeding is most commonly due to dysfunctional anovulatory bleeding in premenopausal women and endometrial atrophy in postmenopausal women. However, endometrial assessment is mandatory to exclude focal endometrial disease and endometrial carcinoma. The latter is of particular concern in the symptomatic postmenopausal population. EVS provides noninvasive high-resolution imaging of the endometrium, allowing triage of patients to medical treatment, blind endometrial sampling, or direct hysteroscopic visualization with sampling or removal of focal disease. The high negative predictive value of EVS essentially excludes significant disease when a thin distinct endometrial echo is seen. If the endometrium is abnormal or not adequately visualized with EVS, SIS can help stratify patients into the following categories: (1) no anatomic abnormality, (2) diffuse endometrial abnormality that may then be evaluated with blind endometrial sampling, or (3) focal endometrial abnormality that must be evaluated under direct visualization. Such an ultrasound-based approach will not only help exclude endometrial carcinoma but will also identify the source of any bleeding and allow for better clinical management.

Ultrasound Evaluation of the Uterus

Liina Põder

SUMMARY OF KEY POINTS

- Sonography is the imaging modality of choice for evaluation of the myometrium, with magnetic resonance imaging (MRI) reserved as a problem-solving technique.
- Many müllerian duct anomalies can be accurately diagnosed with sonography, and three-dimensional (3D) imaging of the fundal contour is diagnostic in differentiating the bicornuate uterus (>1 cm fundal cleft between the two horns) and the septate uterus.
- Adenomyosis presents most commonly in middle-aged multiparous women with uterine tenderness, dysmenorrhea, and menorrhagia and most commonly appears on ultrasound images as an ill-defined or poorly marginated area within the myometrium or thickening of the hypoechoic subendometrial halo. The most specific findings are myometrial cysts and echogenic linear or nodular extension of the endometrium into the subjacent myometrium.
- Leiomyoma is the most common uterine neoplasm. Symptoms are primarily related to location and size. Although most leiomyomas are sharply marginated, well-circumscribed hypoechoic masses, leiomyomas may be isoechoic or echogenic relative to the myometrium.
- There is overlap in the sonographic and MRI appearance of leiomyomas and adenomyosis/adenomyomas, and the entities may coexist.
- Lipoleiomyomas are typically extremely echogenic and sharply marginated with posterior attenuation.
- Leiomyosarcomas may be difficult to differentiate from degenerating leiomyomas on both sonography and MRI.
- Patients with gestational trophoblastic disease (GTD) most commonly present with an echogenic endometrial mass containing numerous small cysts and demonstrating increased vascularity. Fetal parts may be seen in partial moles or coexistent twin pregnancy. Myometrial invasion can be seen with persistent disease or choriocarcinomas, but on imaging may be difficult to differentiate from increased vascularity and "pseudoinvasion" from the placental bed, arteriovenous malformations (AVMs), or retained products of conception (RPOC).
- Uterine AVMs are most often traumatic in origin but may also be congenital or diagnosed in the setting of persistent GTD and RPOC.
- Sonography may be helpful in the diagnosis of endocervical polyps. However, the sonographic appearances of cervical leiomyoma and carcinoma overlap.

OUTLINE

Sonography is clearly the modality of choice for imaging the female pelvis, including the uterus and adnexal structures. In our clinical laboratory, a combination of transabdominal pelvic scanning as well as transvaginal examination is performed in most patients. This approach allows the examiner to evaluate the true pelvis in its entirety with a wide field of view on transabdominal imaging, as well as to assess specific structures using high-resolution images obtained on transvaginal scanning. Primary evaluation with ultrasound in conjunction with clinical information is often sufficient for diagnosis and patient management and will help optimize recommendations for further imaging as necessary. When ultrasound evaluation fails to provide adequate information or does not answer the clinical question,

further evaluation with MRI, computed tomography (CT) scanning, hysterography, or saline infusion sonography (SIS) can be performed. MRI of the uterus is discussed in detail in Chapter 36.

In this chapter, we discuss ultrasound evaluation of the normal uterus, anatomic variants, and benign and malignant conditions. A discussion of the normal and abnormal endometrium in the patient who presents with abnormal uterine bleeding is presented in Chapter 27.

IMAGING

Guidelines

The American Institute of Ultrasound in Medicine (AIUM) guidelines for imaging of the uterus have been developed to assist physicians in performing sonographic studies of the female pelvis.[1] Knowing the potential, but also the limitations, of ultrasound helps us to maximize the probability of detecting most significant abnormalities. As with any clinical test, ultrasound examination of the pelvis should be performed only if there is a valid clinical reason. Following the AIUM guidelines, the indications for pelvic sonography include, but are not limited to, the following:

1. Evaluation of pelvic pain
2. Evaluation of pelvic masses
3. Evaluation of endocrine abnormalities, including polycystic ovaries
4. Evaluation of dysmenorrhea (painful menses)
5. Evaluation of amenorrhea
6. Evaluation of abnormal bleeding
7. Evaluation of delayed menses
8. Follow-up of a previously detected abnormality
9. Evaluation, monitoring, and/or treatment of infertility patients
10. Evaluation in the presence of a limited clinical examination of the pelvis
11. Evaluation for signs or symptoms of pelvic infection
12. Further characterization of a pelvic abnormality noted on another imaging study
13. Evaluation of congenital uterine and lower genital tract anomalies
14. Evaluation of excessive bleeding, pain, or signs of infection after pelvic surgery, delivery, or abortion
15. Localization of an intrauterine contraceptive device
16. Screening for malignancy in high-risk patients
17. Evaluation of incontinence or pelvic organ prolapse
18. Guidance for interventional or surgical procedures; and
19. Preoperative and postoperative evaluation of pelvic structures[1]

Techniques

All relevant anatomic structures in the pelvis should be identified first by transabdominal technique, and then more detailed evaluation of the deep pelvic structures should be performed using the transvaginal technique. In specific situations when transvaginal evaluation cannot be performed or tolerated, transrectal or transperineal evaluation can be very useful.

The transducer should be selected to operate at the highest clinically appropriate frequency that will allow adequate visualization of deep pelvic structures. For transabdominal evaluation, a 3.5-MHz or higher transducer is employed. Curved linear array transducers, as well as sector transducers with a smaller footprint, are most often employed. For transabdominal evaluation, the bladder should be adequately distended to displace bowel superiorly out of the true pelvis and to provide an acoustic window to visualize the uterus and adnexa (Fig. 28-1).

For transvaginal evaluation, the urinary bladder should be emptied and the patient placed in a comfortable position but with her pelvis tilted either with the use of stirrups or by the placement of padding under the patient to elevate the hips. The patient or the sonographer, depending upon the patient's preference, may introduce the vaginal transducer with real-time monitoring. For transvaginal evaluation, the AIUM recommends using probe frequencies of 5 MHz or higher (Fig. 28-2). If a male sonologist is performing the examination, a female member of the staff should be present as a chaperone. However, in some clinical situations, a chaperone is helpful and recommended even for a female sonologist.

The vagina, uterus, and the urinary bladder are used as reference points for identification of the remaining normal and abnormal pelvic structures. The uterine size, shape, and orientation should be assessed and documented in both sagittal (long-axis) and transverse (axial or short-axis) planes. The endometrium, myometrium, and cervix should be carefully evaluated, and their appearance documented. The uterine

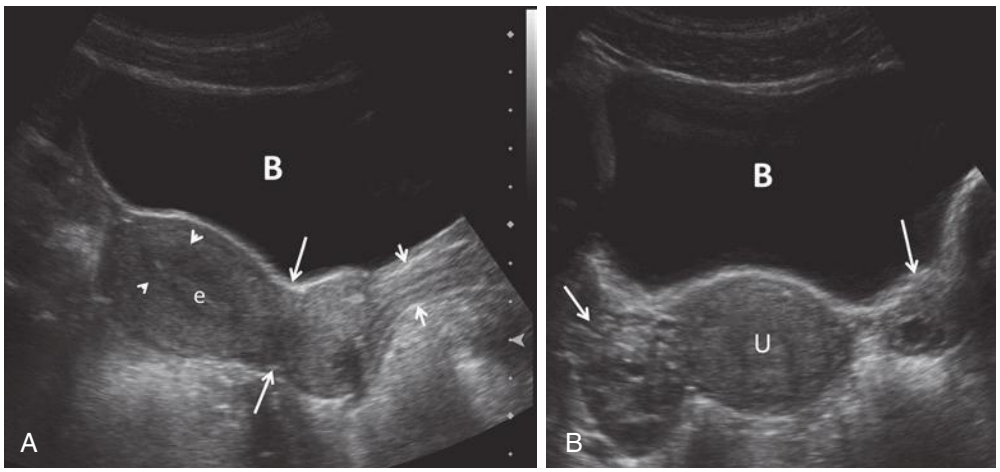

FIG 28-1 Transabdominal gray-scale ultrasound images of the normal uterus. **A,** Sagittal imaging plane. Note indentation below the lower uterine segment indicating the level of the internal os (*long arrows*), the striated appearance of the vagina (*short arrows*), the linear homogeneously echogenic endometrium (e), and the surrounding hypoechoic subendometrial halo (*arrowheads*). Note the acoustic window provided by the distended urinary bladder (B). **B,** Transverse imaging plane. Note the bladder (B), right and left ovaries (*arrows*), and uterus (U).

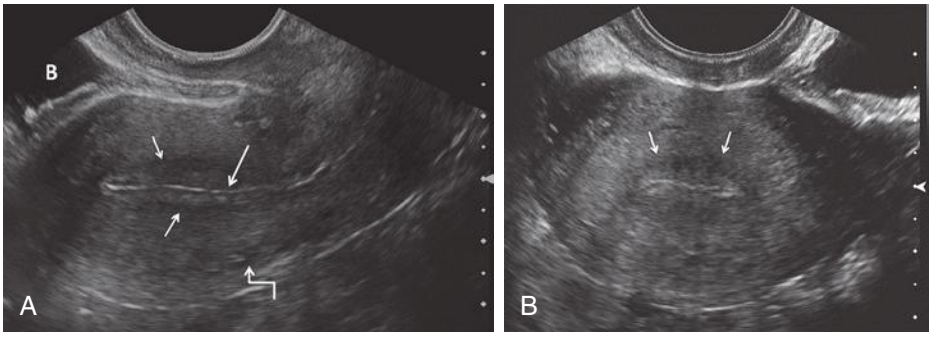

FIG 28-2 Transvaginal gray-scale ultrasound images of the normal uterus. **A,** Sagittal imaging plane. Note thin brightly echogenic line (*long arrow*) representing artifact or mucus between the echogenic anterior and posterior layers of the endometrium and the subjacent hypoechoic subendometrial halo (*short arrows*). The anechoic tubular arcuate vessels separating the outer from the intermediate layer of the myometrium are faintly visualized (*crooked arrow*). B, bladder. **B,** Transverse imaging plane. The hypoechoic subendometrial halo (*arrows*) can be seen surrounding the echogenic endometrium. Note significantly improved resolution and visualization of the normal zonal anatomy in these higher frequency transvaginal images in comparison to the lower frequency transabdominal images (Fig. 28-1). However, the transabdominal images have a larger field of view, providing a better overview of pelvic structures.

length is measured in long axis from the fundus to the external os of the cervix, and the anteroposterior dimension is measured on the same image perpendicular to the long axis. The width is measured on either a transaxial or coronal imaging plane. If the volume of the uterine corpus is assessed, the cervical component should be excluded.[1] Myometrial masses and contour abnormalities should be recorded in two different planes and their locations recorded.[1] Assessment of the endometrium is performed primarily in the sagittal (or sometimes coronal) plane. Variations of the normal appearance of the endometrium during different phases of the menstrual cycle and with hormonal supplementation should be considered (Fig. 28-3) and have been described in detail in preceding chapters. Doppler evaluation of the uterus and endometrium can be of added value. 3D imaging is increasingly available and can also provide valuable additional information, particularly by providing a coronal image of the fundal contour of the uterus in women with suspected uterine congenital malformations and to localize leiomyomas.

SIS, or as it is often referred to, sonohysterography, is an innovative technique used to evaluate a variety of endometrial and myometrial processes that involve the endometrial canal. The most common indications for SIS include, but are not limited to, evaluation of the following:

1. Abnormal uterine bleeding
2. Uterine cavity, especially with regard to uterine leiomyomas, polyps, and synechiae
3. Abnormalities detected on transvaginal sonography, including focal or diffuse endometrial or intracavitary abnormalities
4. Congenital abnormalities of the uterus
5. Infertility
6. Recurrent pregnancy loss

SIS is contraindicated in women who could be pregnant or have an active infection. Because the normal secretory endometrium may be thick and simulate endometrial disease, the examination should be scheduled in premenopausal women during the follicular phase of the menstrual cycle, after menstrual flow has ceased but prior to ovulation, no later than the 10th day of the menstrual cycle. Active vaginal bleeding is not generally a contraindication but can make imaging challenging or even nondiagnostic.[2]

At our institution, we perform a preliminary transabdominal and transvaginal sonogram before SIS. After the procedure is explained to the patient, the external os is cleansed before catheterization of the cervical canal using aseptic technique. A sonohysterography catheter (flushed with saline to remove any air bubbles) is then advanced into the endometrial canal. Once in the endometrial canal, the balloon is inflated (preferably with saline rather than air to avoid shadowing) so that the catheter does not become dislodged. However, some clinicians prefer to use a catheter without a balloon. The speculum is removed, and the transvaginal probe is reinserted adjacent to the catheter. Under ultrasound guidance, the balloon is gently retracted to occlude the internal os. Sterile saline should be administered under real-time sonography. The amount of saline introduced is variable, often between 5 and 30 mL. Normal anatomy and abnormal findings should be documented in two separate imaging planes using a high-frequency transvaginal probe, and the endometrium should be fully evaluated from one cornua to the other (Fig. 28-4). Additional techniques such as color Doppler and 3D imaging may be helpful in evaluating both normal and abnormal findings.

Anatomy

The uterus is a hollow organ in which the myometrium is firmly adherent to a thin internal layer of endometrium. Externally the uterus is embedded between the two layers of the broad ligament. Anatomically, the uterus lies between the bladder anteriorly and the rectosigmoid colon posteriorly. The uterus is divided into two major parts, the body or corpus and the cervix. The most superior aspect of the uterus is referred to as the fundus and the area where the fallopian tubes enter into the uterus is referred to as the cornua. Anterior to the fallopian tubes are the round ligaments, one on each side, which extend anterolaterally, coursing through the inguinal canals and inserting onto the fascia of the labia majora. The uterus has a dual arterial blood supply. The majority of the blood supply comes from the uterine arteries, which arise from the internal iliac arteries, and a minor source of blood supply is the ovarian arteries.

The uterus is most often anteverted and anteflexed (Fig. 28-5), but it may also be retroflexed (Fig. 28-6) or retroverted (Fig. 28-7). Descriptions of flexion refer to the relationship of the body of the uterus to the cervix at the level of the internal os (usually the angle is about 270 degrees), whereas version refers to the cervical relationship to the vagina. The cervix of the uterus is fixed in the midline. However, the body of the uterus can be mobile, and uterine position and orientation

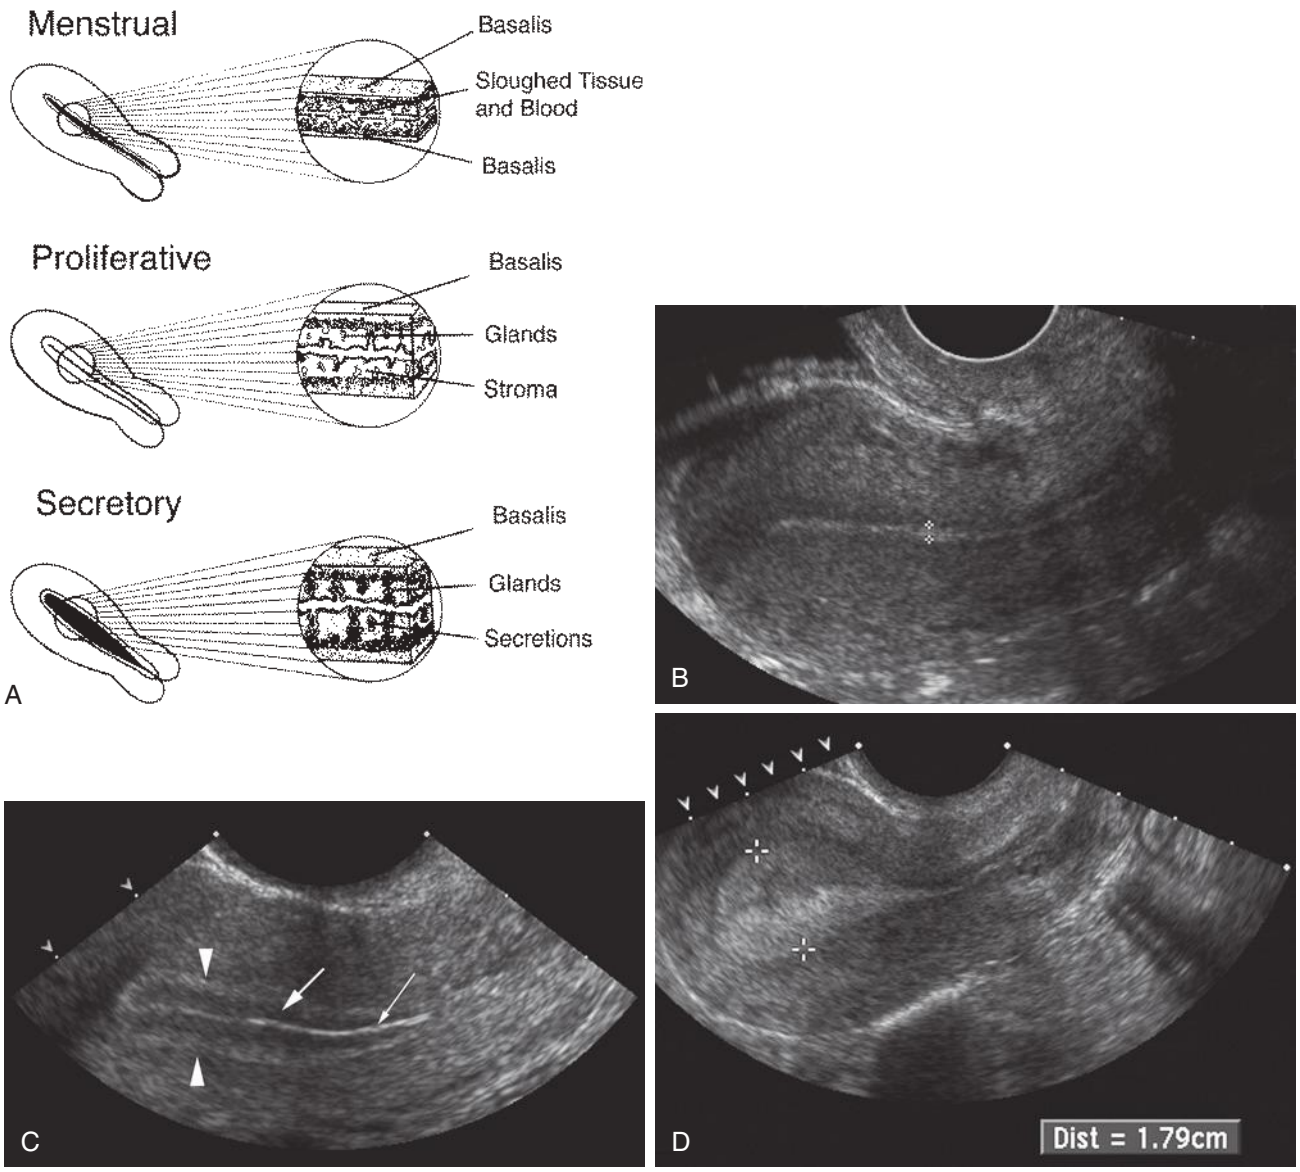

FIG 28-3 **A,** Diagram depicting normal development of the endometrium during the menstrual, proliferative, and secretory phases. In the menstrual phase, the endometrium appears as a thin, irregular interface. The central echogenicity probably arises from sloughed tissue and blood. In the proliferative phase, the endometrium is relatively hypoechoic, likely a reflection of the straight and orderly arrangement of the glandular elements. The central thin, echogenic line is likely a specular reflection from the endometrial surfaces. In the secretory phase, the endometrium achieves its maximum thickness and echogenicity. This appearance is from the distended and tortuous glands, which contain secretions. **B,** Postmenstrual transvaginal sagittal image of the uterus demonstrating the normal thin homogeneously echogenic early proliferative endometrium (*calipers*). **C,** Transvaginal sagittal image of the periovulatory endometrium. A three-layered endometrium is seen, giving the endometrium a striated appearance: the collapsed endometrial lumen is demonstrated by the very thin central echogenic line (*thin arrow*). The surrounding hypoechoic layer representing the edematous functionalis endometrium (*thick arrow*) and an outer hyperechoic layer representing the basal endometrium (*arrowheads*) are seen. **D,** Transvaginal sagittal image of the secretory endometrium. In the secretory stage of the menstrual cycle, the endometrium (*calipers*) becomes thick and more homogeneously echogenic. (A from Fleischer AC, Kalemeris GC, Entman SS: Sonographic depiction of the endometrium during normal cycles. Ultrasound Med Biol 12:271, 1986, Pergamon Journals Ltd. Reprinted by permission of Elsevier Science. Copyright 1986 by World Federation of Ultrasound in Medicine and Biology.)

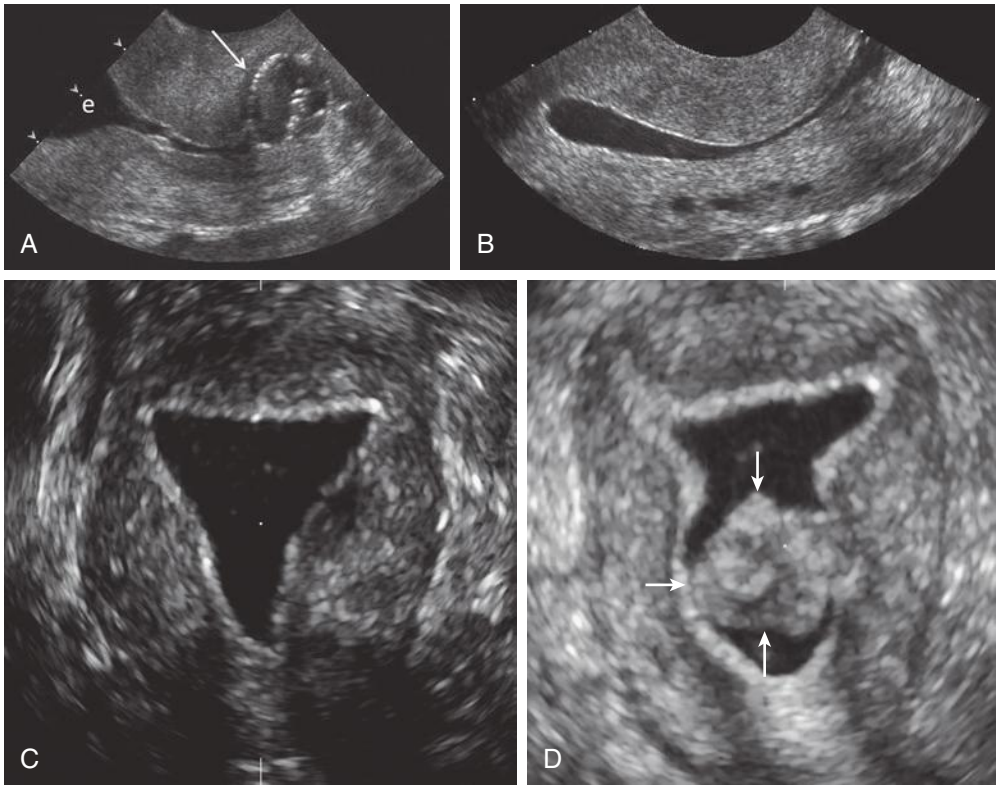

FIG 28-4 Saline-infused sonohysterogram. **A,** Transvaginal sagittal image of the cervix demonstrating the catheter balloon (*arrow*) positioned in the lower endocervical canal. Anechoic fluid is in the upper endocervical canal and lower endometrial cavity (e). **B,** Transvaginal sagittal image after saline infusion. The normal thin echogenic endometrium is well seen circumferentially. The endometrial cavity is filled with anechoic fluid. Note several small, round anechoic structures in a linear configuration in the posterior wall of the myometrium. These are the arcuate vessels and would fill in with color Doppler. **C,** A coronal three-dimensional reconstruction after saline infusion, demonstrating the normal regular, thin, echogenic endometrium without any intracavitary abnormalities. **D,** In comparison, a coronal three-dimensional reconstruction after saline infusion revealed a 100% intracavitary leiomyoma (*arrows*), separate from the thin, regular echogenic endometrium.

may change with varying degrees of bladder and rectal distention. Retroversion and retroflexion are not infrequent in the nongravid state. In such cases the fundus of the uterus is positioned in the sacral hollow. During pregnancy the uterus enlarges and physiologically undergoes reduction by the 14th to 16th weeks of gestation. The fundus of the uterus then rises into the false pelvis. If this fails to happen, the uterus becomes "trapped" in the sacral hollow, often referred to as "incarcerated." In cases of incarceration of the uterus, the cervix is drawn upward either against or above the symphysis pubis, resulting in distortion of the bladder and urethra as the gestation progresses. The posteriorly positioned fundus can cause pressure on the rectum. Typically, patients present between the 13th to 17th weeks of pregnancy with symptoms of bladder outlet obstruction. A history of multiple trips to the emergency room for bladder outlet obstruction should raise suspicion.

A constellation of three findings on sonography is diagnostic of an incarcerated uterus:

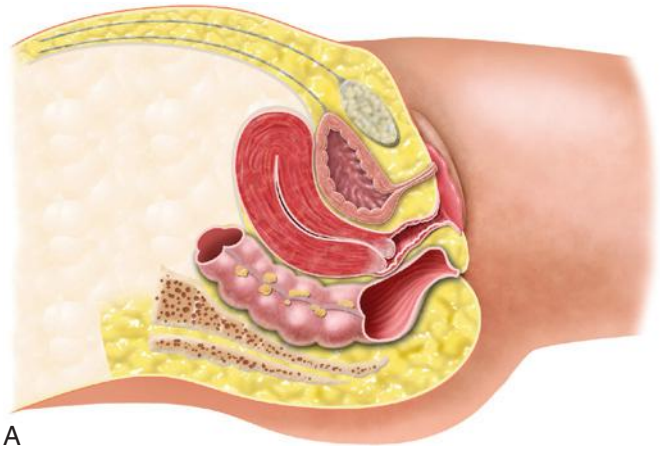
1. The pregnancy is deep within the cul-de-sac.
2. The maternal urinary bladder lies anterior rather than inferior to the uterine corpus and marked bladder distention is noted.
3. A soft tissue structure (the cervix) is seen between the bladder and pregnancy. This appearance can be misconstrued as an empty uterus associated with an ectopic or abdominal pregnancy.

Failure to recognize an incarcerated uterus can result in compromise of the uterine circulation, leading to spontaneous abortion or even uterine rupture. If recognized early, manual uterine repositioning is usually possible (Fig. 28-8).

The shape and size of the uterus vary throughout life, affected mostly by hormonal status. The mean measurement of the prepubertal uterus is 2.8 cm in length and 0.8 cm in maximum anteroposterior dimension, with the cervix accounting for two thirds of the total length and contributing to the pear-shaped appearance (Fig. 28-9).[3] It is important to remember that in the immediate postdelivery state, the neonatal uterus can be slightly larger owing to the effects of residual maternal hormones. For the same reason, the echogenic endometrium is well seen and a small amount of fluid can be present in the endometrial cavity.

From birth until 4 years of age, the uterus decreases in size. At approximately 8 years of age, the uterus starts to grow preferentially in the fundus. The uterus continues to grow for several years after menarche until it reaches the mean dimensions of a reproductive age uterus, which are approximately 7 cm long and 4 cm wide. Parity increases the size of the uterus, with a multiparous uterus measuring approximately 8.5 cm by 5.5 cm.[4]

Following menopause, the uterus decreases in size. The decrease in size is related to the number of years since menopause,[4] although the



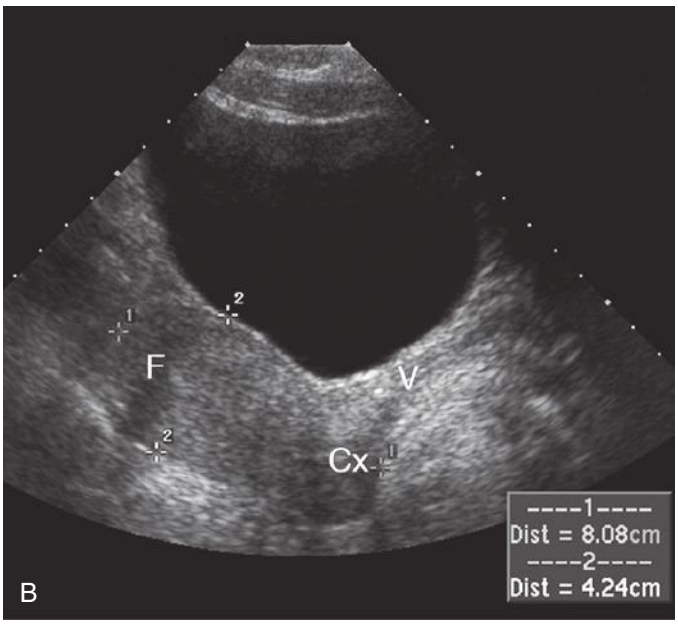


FIG 28-5 A, Illustration demonstrating an anteflexed, anteverted normal uterus. The cervix is pointing slightly more posterior in relationship to the vagina, and the fundus is flexed anterior in relation to the cervix. **B,** Midline sagittal sonogram demonstrating anteversion of the cervix (Cx) to the vagina (V). A distended urinary bladder slightly displaces the fundus (F) posteriorly. Standard measurements of the uterine size are made from fundus to cervix *(calipers 1)* and from anterior to posterior uterine wall *(calipers 2)* on sagittal transabdominal view. (A from James A. Cooper, MD, San Diego, CA.)

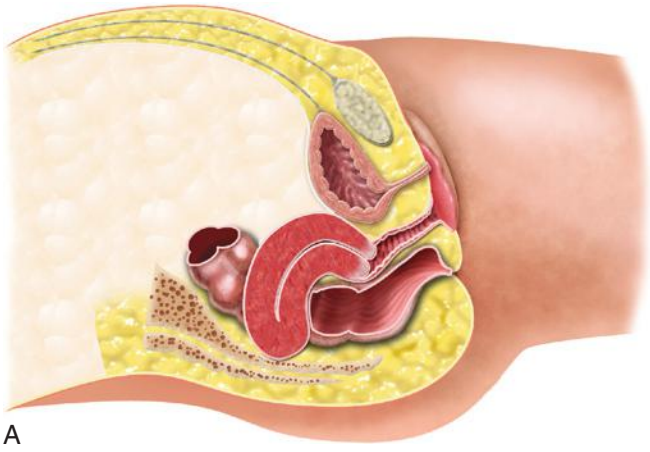

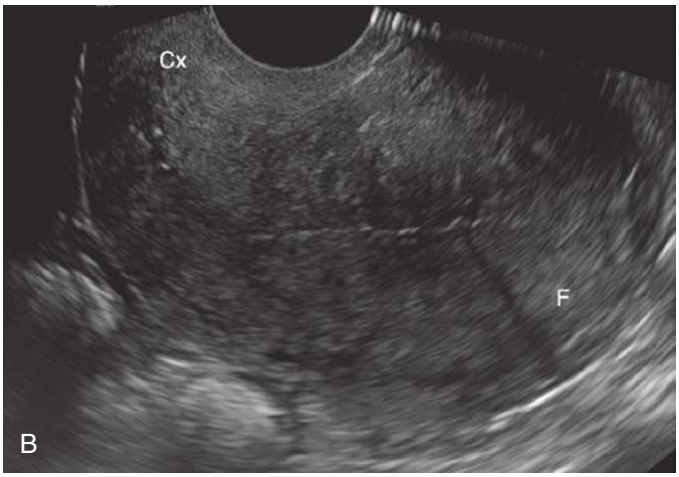

FIG 28-6 A, Illustration demonstrating a retroflexed uterus. The cervix is in conventional position in relationship to the vagina. However, the uterine fundus is flexed posteriorly at the level of the internal os in relation to the cervix. **B,** Midline sagittal transvaginal sonogram demonstrating uterine retroflexion. Uterine fundus (F) is positioned posterior and retroflexed in relation to the cervix (Cx). Note angulation between the echogenic endocervical canal and thin echogenic endometrium (owing to the flexion). (A from James A. Cooper, MD, San Diego, CA.)

reduction in size is believed to be most rapid during the first decade following menopause. The length of the normal postmenopausal uterus has been reported to range from 3.5 to 6.5 cm and the anteroposterior dimension from 1.2 to 1.8 cm.[5]

The normal myometrium is composed of three layers. The innermost layer, immediately subjacent to the endometrium, is the thinnest and is relatively compact histologically. This layer is also both hypovascular and hypoechoic when compared to the echogenic endometrium and surrounding middle layer of the myometrium. This layer is often referred to as the subendometrial halo and may not always be visualized sonographically. Sometimes, small extremely echogenic foci, usually less than a few millimeters in size and without posterior shadowing, are seen in the inner myometrium at the endometrial/myometrial interface. These foci are thought to represent dystrophic calcifications due to previous intrauterine instrumentation and have no clinical significance. The middle or intermediate layer lies between the subendometrial halo and the arcuate vessels. This is the thickest myometrial layer and is normally uniform and intermediate in echogenicity. The outer layer lies peripheral to or above the arcuate vessels. This layer is relatively thin and slightly less echogenic compared to the intermediate layer in most patients. The cervix is measured from the internal os, identified by narrowing or "waisting" of the uterus at the junction of the lower uterine segment with the cervix to the lips of the external os, which can be seen to project into the lumen of the vagina. The central endocervical canal is echogenic and continuous with the endometrium. The surrounding fibrous cervical stroma is quite hypoechoic and is continuous with the subendometrial halo, if present. The outer cervical muscular layer is continuous with and similar in echogenicity to the intermediate layer of the myometrium (Fig. 28-10).

The arcuate vessels separate the outer layer from the intermediate layer of the myometrium. The arcuate veins are larger than the arcuate arteries and are potentially compressible with excessive probe or manual pressure. The arcuate vessels (particularly the veins) can be prominent and mimic cystic changes. This potential misinterpretation can easily be clarified by using color Doppler imaging (Fig. 28-11).

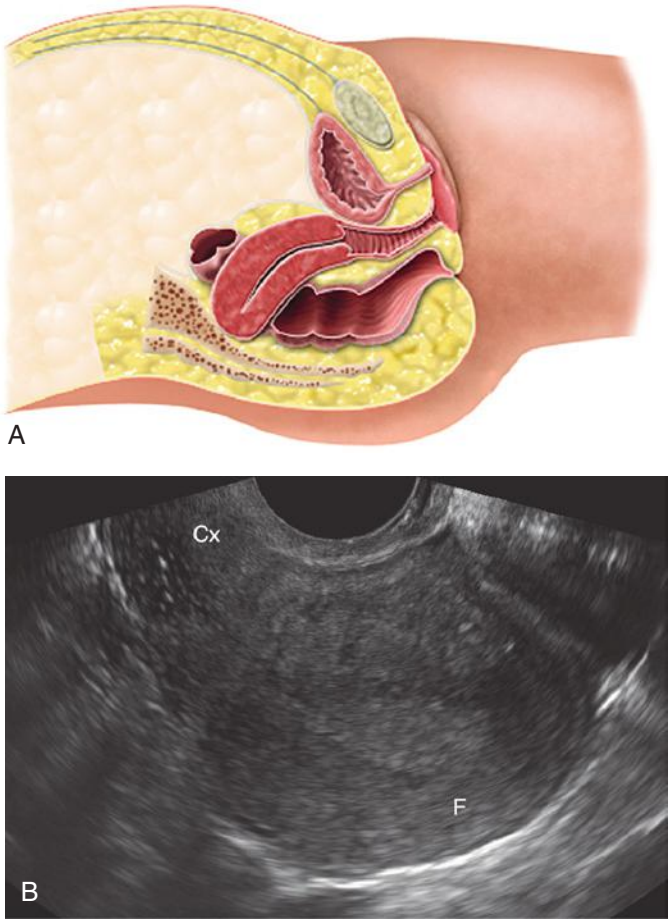

FIG 28-7 **A,** Illustration demonstrating a retroverted uterus; the cervix is angled slightly posterior in relation to the vagina, and the fundus is bent slightly posterior in relation to the cervix, indicating retroflexion as well. **B,** Midline sagittal transvaginal sonogram demonstrating posterior displacement of the fundus (F) and posterior angulation of the cervix (Cx). (A from James A. Cooper, MD, San Diego, CA.)

The arcuate arteries branch into radial arteries that penetrate the intermediate layer and reach the level of the inner layer. The arcuate arteries may calcify in postmenopausal women, and this process can be seen earlier in diabetic patients. This change is considered part of the normal aging process (Fig. 28-12).

CONGENITAL MALFORMATIONS

The incidence of congenital müllerian duct anomalies is estimated to be approximately 0.5% in the general population. However, they are more often diagnosed during workup for infertility, frequent miscarriages, or menstrual disorders. Embryologically, the two paired müllerian ducts ultimately develop into the fallopian tubes, uterus, cervix, and the upper two thirds to four fifths of the vagina. The lower one fifth to one third of the vagina and the ovaries have a separate embryologic origin. Uterine malformations arise from three different causes: failure of development of the müllerian ducts, failure of fusion of the müllerian ducts, or failure of resorption of the median septum (Fig. 28-13). There is a strong association of upper urinary tract anomalies with congenital uterine malformations. These anomalies have been reported to be most common in patients with hypoplasia or agenesis, occurring in as many as 30% to 40% of patients. Ispilateral renal agenesis and ectopic pelvic kidney are most common.

Early developmental failure of the müllerian ducts can result in agenesis or hypoplasia of the proximal two thirds of the vagina, cervix, and uterus, being part of the Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome. This syndrome is an extreme form of müllerian duct anomaly with complete agenesis of the proximal vagina and anomalous cervix and uterus, and patients usually present in early puberty with primary amenorrhea.[6] The ovaries are normal but the fallopian tubes may be closed and the uterus is often anomalous. The vaginal aplasia can vary from complete absence to a blind-ending pouch. Associated renal anomalies are common, in particular absence or ectopia of the kidney. Because there can be subtypes of MRKH syndrome as well as overlap with other rare müllerian duct hypoplasia/aplasia syndromes, it is important to describe findings rather than trying to fit them into a strict category. MRI is usually the most helpful imaging modality for diagnosis of this entity given the complex spectrum of findings. Most important is communication with the clinical team regarding the relevance of findings and preoperative planning.

Arrested development of the müllerian ducts can also cause uterine agenesis or hypoplasia. This abnormality may present as vaginal, cervical, fundal, tubal, or combined agenesis or hypoplasia.

Complete or partial agenesis of a unilateral müllerian duct leads to development of a unicornuate uterus with a single fallopian tube (Fig. 28-13).[6] The unicornuate uterus accounts for approximately 20% of all müllerian duct anomalies. In some cases, a rudimentary horn on the opposite side can be seen. This rudimentary horn may or may not communicate with the endometrial cavity in the normal side. If there is no communication between the endometrial cavities of the rudimentary and normal horns, retrograde menstruation may occur, leading to the development of endometriosis. Ectopic pregnancies may also rarely occur in the rudimentary horn. Such ectopic pregnancies can lead to massive hemorrhage as they can grow to relatively large size before rupturing. Therefore, if a rudimentary horn is documented, surgical resection is usually recommended. The poorest fetal survival among all müllerian duct anomalies has been reported with the unicornuate uterus. Spontaneous abortion has been reported to occur in 34%, preterm labor in 20%, and intrauterine demise in 10%.[6,7] The live birth rate is estimated to be only 50%.[7] The unicornuate uterus seems to be the most difficult müllerian duct anomaly to confidently diagnose on sonography because it can be confused and misdiagnosed as a small uterus. Looking for the contralateral rudimentary horn, which can be filled with blood, may sometimes help. The rudimentary horn may have a distended and dystrophic appearance and should not be mistaken for an adnexal mass. MRI is considered the study of choice in resolving these complicated situations. Recently 3D ultrasound has been reported to be useful in diagnosis, allowing visualization on the coronal imaging plane of a single asymmetric endometrial cavity that is laterally deviated, with or without a rudimentary horn. Forty percent of cases are reported to have renal anomalies, typically ipsilateral to the rudimentary horn, most often renal agenesis or pelvic kidney.[6]

Complete failure of fusion of the müllerian ducts leads to development of two separate uteri, each with its own cervix, termed *uterus didelphys* (Fig. 28-13). This is a relatively rare anomaly accounting for fewer than 5% of all müllerian duct anomalies. The endometrial cavities of each hemiuterus do not communicate. A longitudinal or oblique vaginal septum is common, but not always present. An oblique septum may be obstructive and such patients will present with hematocolpos, dysmenorrhea, pelvic mass, vaginal discharge, or pelvic pain. The vaginal septum may also lead to dyspareunia and even rarely vaginal dystocia during vaginal delivery. If no obstruction is present, most patients are asymptomatic and uterus didelphys is an incidental finding. Patients with uterus didelphys usually successfully carry pregnancies to term, and infertility is an uncommon presentation.[6] On

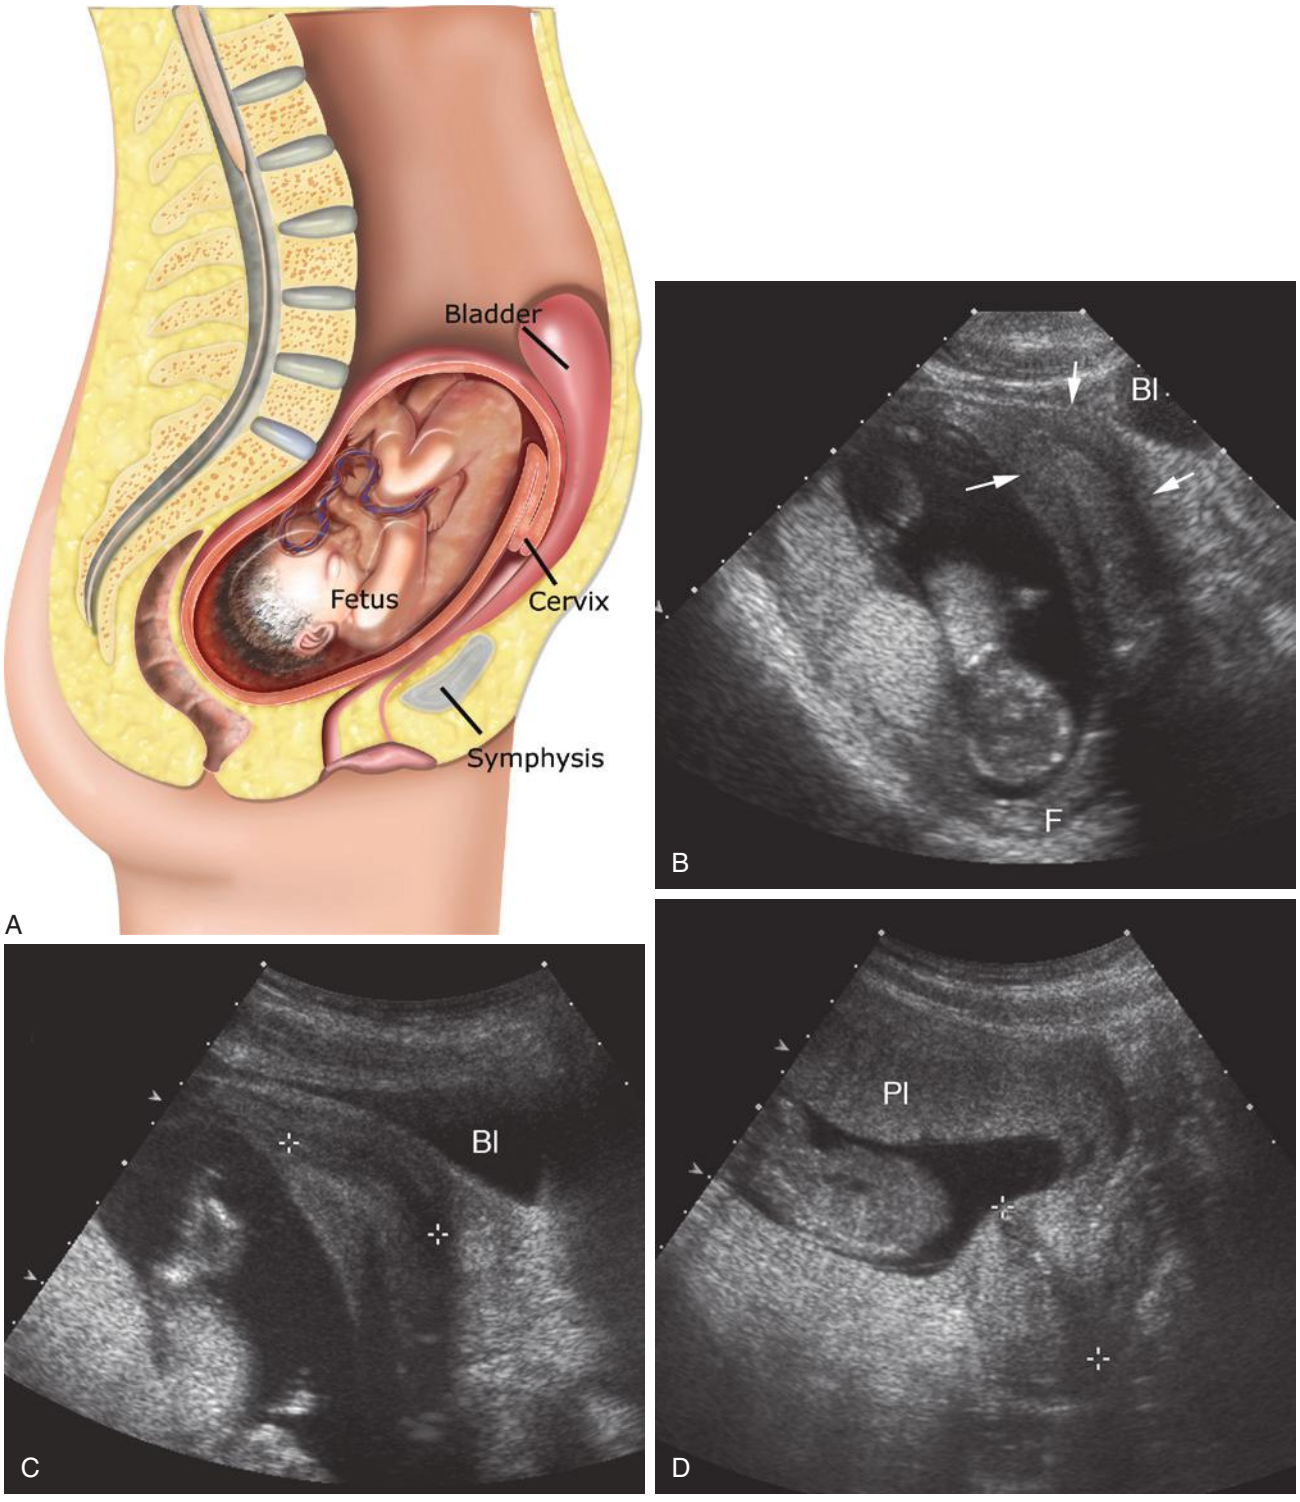

FIG 28-8 **A,** Illustration demonstrating an incarcerated uterus. If a retroflexed uterus fails to reduce and the gestation progresses, the fundus will become incarcerated deep in the pelvis within the sacral hollow. The cervix will be drawn anteriorly and superiorly and the bladder will be displaced superiorly. **B,** Transabdominal sagittal image of an incarcerated uterus in a patient with a 14-week-old gestation. The patient presented with inability to empty the urinary bladder. The uterine fundus (F) is trapped in the sacral hollow. The cervix (*arrows*) is drawn anteriorly and superiorly and can be misconstrued as an empty uterus, thereby suggesting an ectopic or transabdominal pregnancy. Bl, bladder. **C,** Sagittal view of the same patient demonstrating the degree to which the bladder (Bl) is drawn superiorly. Note abnormal position of the cervix (*calipers*). **D,** Following manual reduction, note normal physiologic relationship of the uterus and cervix (*calipers*). The placenta (Pl) is located anteriorly although it appeared posterior in location when the uterus was incarcerated. (A from James A. Cooper, MD, San Diego, CA.)

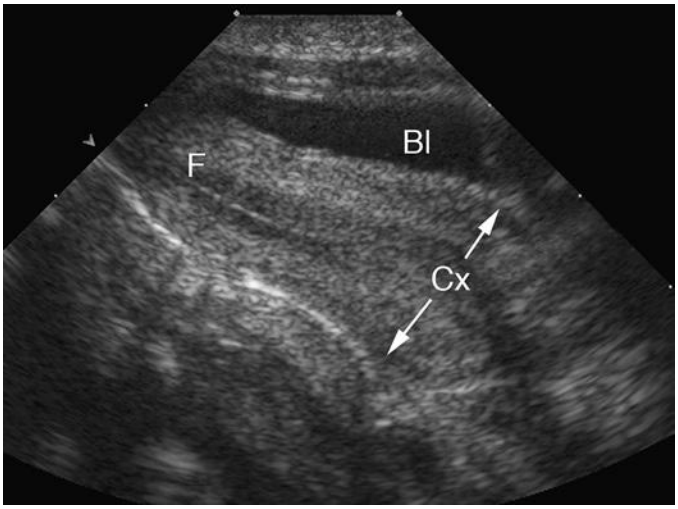

FIG 28-9 Transabdominal sagittal view of the normal prepubertal uterus. The cervix (Cx) is significantly more prominent than the body or fundus (F) of the uterus. Bl, bladder.

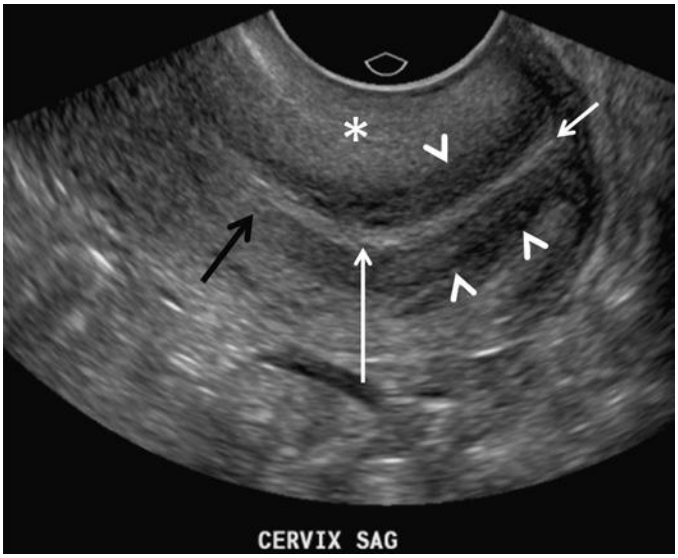

FIG 28-10 Normal sonographic zonal anatomy of the cervix. Note central linear echogenic endocervical canal (*long white arrow*), subjacent hypoechoic fibrous cervical stroma (*arrowheads*), outer muscular layer of intermediate echogenicity (*asterisk*), external os (*short white arrow*) between the lips of the cervix, and internal os (*black arrow*) at the level of narrowing or constriction between the body of the uterus and the cervix.

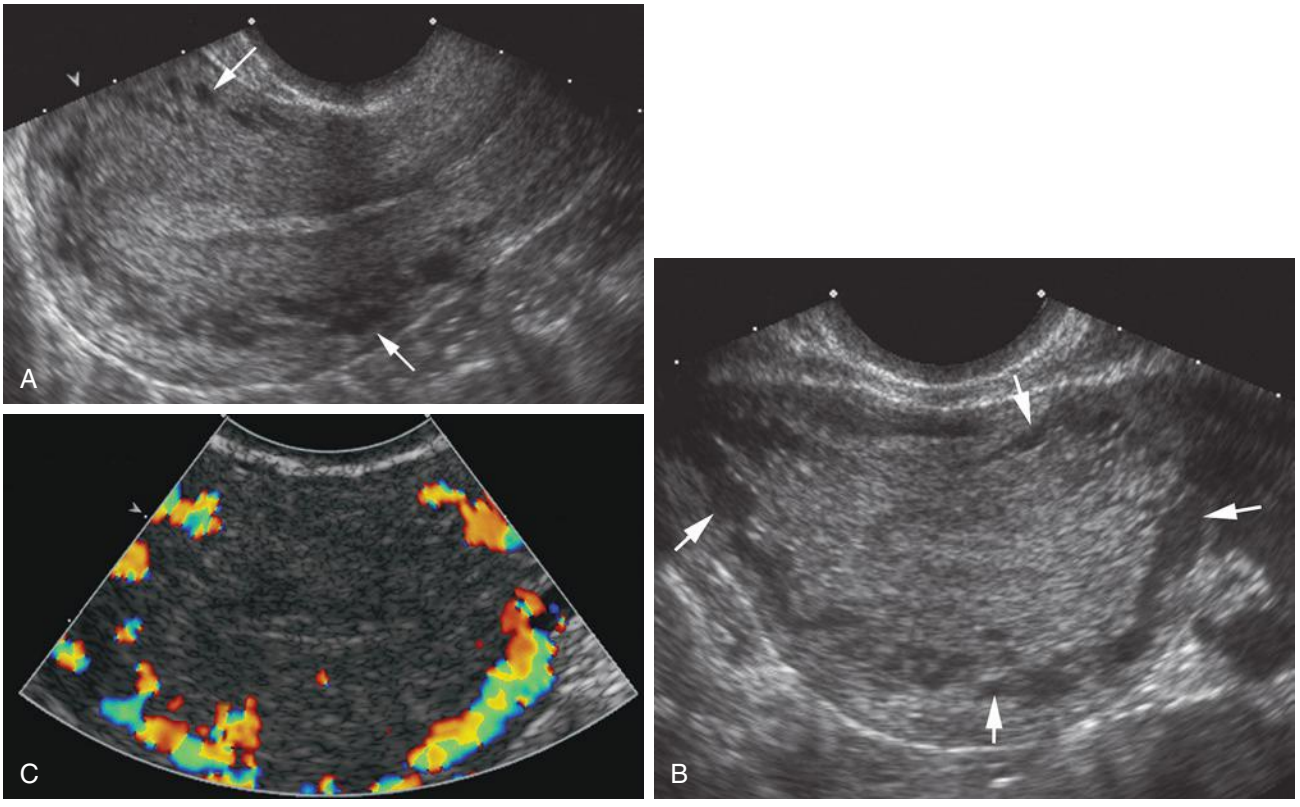

FIG 28-11 Transvaginal sagittal (**A**) and transverse (**B**) sonograms of the uterus demonstrating prominent anechoic round areas (*arrows*) between the outer third and inner myometrium. These are the arcuate vessels, which can mimic cystic changes. **C,** These cystic appearing spaces are confirmed to be arcuate vessels by applying color Doppler.

ultrasound images, the two widely separated fundal horns with a deep fundal cleft, two uterine cavities, and two separate cervices can be identified. However, the vaginal septum is better evaluated on physical examination and with MRI or CT (Fig. 28-14), although occasionally 3D ultrasound imaging may be helpful. Unilateral renal agenesis is often present, particularly in the setting of obstructed uterus didelphys.[6]

A rare syndrome that can be seen in the setting of uterus didelphys is obstructed hemivagina and ipsilateral renal anomaly (OHVIRA); some cases do not fit the classic definition. An absent kidney in the expected anatomic location should trigger a search for an ectopic or possibly a dysplastic/atrophic kidney. If obstructed hemivagina is seen, this finding should also trigger a search for possible ectopic insertion of a ureter.[8,9] Obstructed hemivagina and ipsilateral renal agenesis syndrome should be redefined as ipsilateral renal anomalies: cases of symptomatic atrophic and dysplastic kidney with ectopic ureter to obstructed hemivagina.

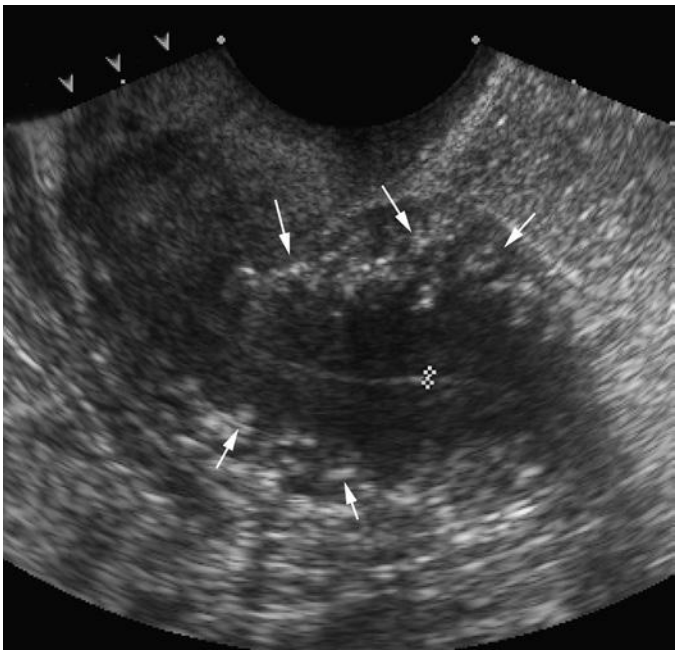

FIG 28-12 Transvaginal sagittal view of small retroverted and retroflexed uterus in a postmenopausal woman demonstrating arcuate artery calcifications (*arrows*). Calipers show the endometrium.

Partial fusion of the two müllerian ducts with incomplete fusion at the fundus leads to formation of a bicornuate uterus and a single cervix (Fig. 28-13). The bicornuate uterus is estimated to account for approximately 10% of all müllerian duct anomalies. The fundal contour of the bicornuate uterus is concave, and the two horns are divergent. MRI criteria based on this appearance are an intercornual distance greater than 4 cm and a fundal cleft depth 1 cm or more between the horns.[6] Patients with bicornuate uterus have few reported obstetric problems, and most cases are discovered incidentally. However, an increased incidence of cervical incompetence has been reported.[10] Decreased size of the uterine cavity has also been reported to be associated with poor fetal outcome.[11] Sonographically, in a bicornuate uterus, the endometrial cavities are widely separated, and a deep indentation in the fundal contour is obvious. Imaging of the fundal contour requires obtaining an image in a coronal plane, which is often easiest with transabdominal pelvic ultrasound if the uterus is anteverted and anteflexed or with 3D transvaginal imaging. MRI is often recommended for definitive diagnosis. The bicornuate uterus should be distinguished from a uterine didelphys, and a single cervix should be documented to confirm the diagnosis of a bicornuate uterus (Fig. 28-15). However, if two endocervical canals are present, such as in the bicornuate bicollis uterus, identification of a vaginal septum can be the only way to discriminate between a bicornuate bicollis and didelphys uterus. Unfortunately, one fourth of bicornuate uterus cases have been reported to have a vaginal septum as well, which makes them indistinguishable from didelphys.[6] MRI is the optimal imaging technique for evaluation of vaginal septa. Often in these complex cases with overlapping appearances, it is best to describe what is seen on MRI rather than to attempt to categorize.

Failure of resorption of the septum after complete fusion of the müllerian ducts leads to formation of a septate uterus (Fig. 28-13), which is the most common type of müllerian duct anomaly,

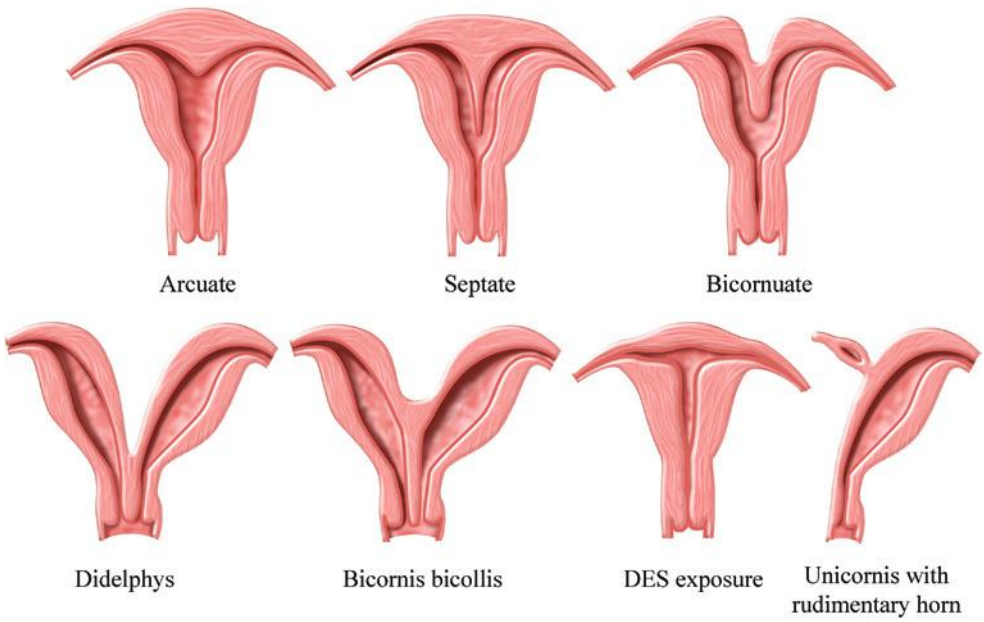

FIG 28-13 Most common uterine anomalies. DES, diethylstilbestrol. (Illustration by James A. Cooper, MD, San Diego, CA.)

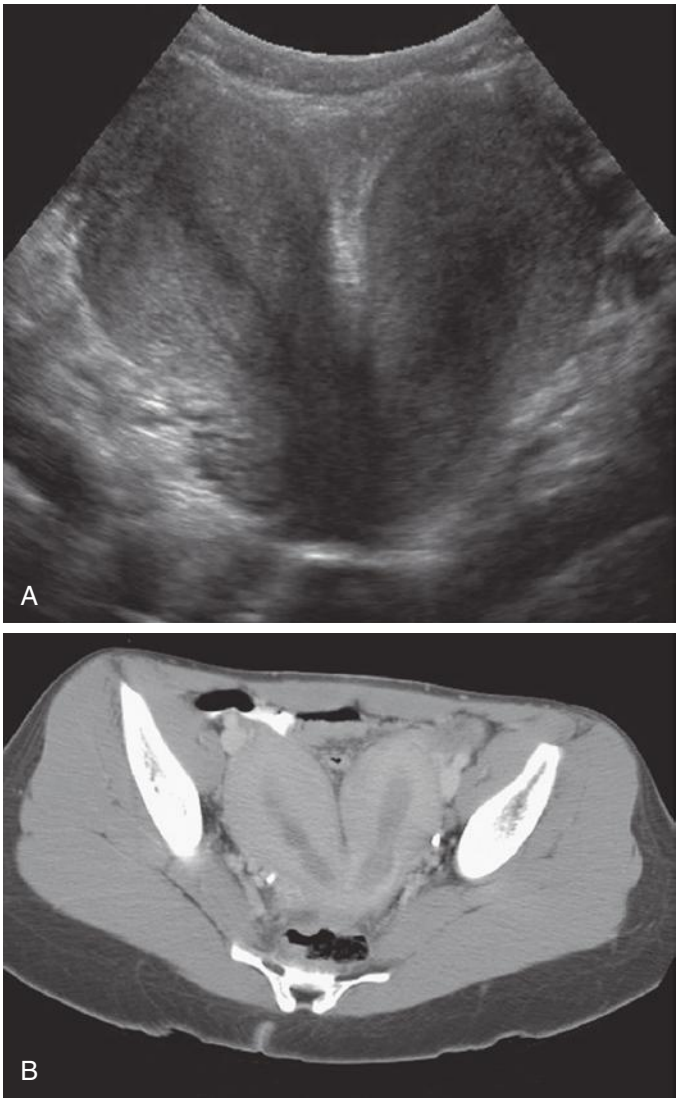

FIG 28-14 A, Coronal transvaginal view of a didelphys uterus with completely separate right and left cavities and deep intervening cleft between the two horns. **B,** Axial computed tomography scan of the same patient demonstrating a uterine didelphys with widely splayed uterine horns.

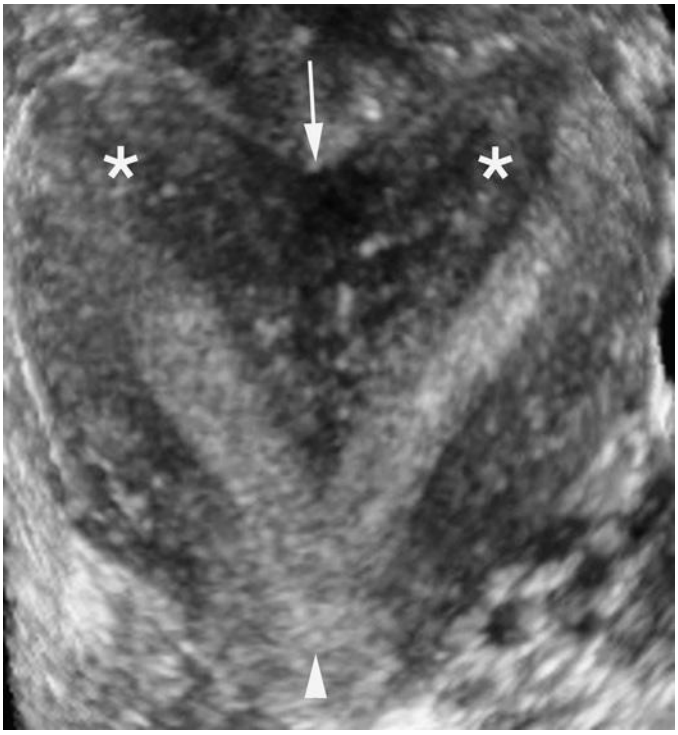

FIG 28-15 A coronal three-dimensional image demonstrating a heart-shaped bicornuate uterus. Fundal indentation is well seen (*arrow*), as well as the widely divergent horns (*asterisks*) with a single cervix and endocervical canal (*arrowhead*). (Courtesy of Dr. Beryl R. Benacerraf, Boston, MA.)

accounting for close to 55%. The fundal contour between the two endometrial cavities is convex, flat, or indented less than 1 cm. The septum may be partial (if partial resorption has occurred) or complete, extending to the internal cervical os and sometimes through the cervix to the external os. The septum can contain fibrous or myometrial tissue. The endometrial cavities are typically symmetric. Many women with a septate uterus experience repeated miscarriages, usually in the first trimester, with a reported incidence of miscarriage of 65% and an incidence of premature birth of nearly 20%.[11] Confirming this type of anomaly is clinically important because metroplasty is reported to improve fetal survival.[6,12] Metroplasty may be performed hysteroscopically in women with a septate uterus, whereas surgical repair/resection in a patient with a bicornuate uterus must be performed transabdominally, although surgical correction is less often required. On sonography, the smooth fundal contour (either convex, flat, or indented <1 cm) is diagnostic, but requires obtaining an image of the fundus in the coronal plane, which can be difficult on transvaginal imaging and is more easily accomplished with 3D imaging or occasionally with transabdominal imaging if the uterus is anteverted and anteflexed. There is less divergence between the two endometrial cavities, which are usually separated by a very thin septum (Fig. 28-16). The septum can extend all the way to the external os or even upper vagina.[6] If the septum does not extend to the internal cervical os, it should be described as a partial septate uterus. Because of superior multiplanar imaging capability, MRI is generally considered the most definitive imaging modality for distinguishing a septate from a bicornuate uterus as obtaining a true coronal image through the uterine fundus is routinely possible on MRI. It is the depth of the fundal notch between the two uterine horns that is the primary diagnostic criterion rather than the composition of the septum. Evaluation of associated renal anomalies and for the presence of a vaginal septum is also easily accomplished with MRI. However, advances in the use of 3D ultrasound have made it possible to visualize the fundal contour in many patients, and 3D sonography is replacing MRI in some centers for at least initial evaluation of uterine congenital anomalies.

An arcuate configuration of the uterus is a normal variant in which the thickened fundal portion of the myometrium slightly indents the endometrial canal, creating a heart-shaped endometrial cavity (Fig. 28-17). This variant occurs when there is near complete resorption of the uterovaginal septum. The external contour of the uterus is normal, either convex or flat. There is a single uterine cavity, and as such, there is little effect on pregnancy outcome, although a high prevalence (12%) of arcuate uterus has been reported in women who have repeated second trimester miscarriages.[13]

Diethylstilbesterol, in use from 1940 to 1970 to prevent miscarriage, was reported to cause uterine anomalies in the female fetus, specifically resulting in a T-shaped endometrial cavity and hypoplastic uterus. Patients with this anomaly are at increased risk for spontaneous abortions, preterm deliveries, and ectopic pregnancies.[6] Sonography will

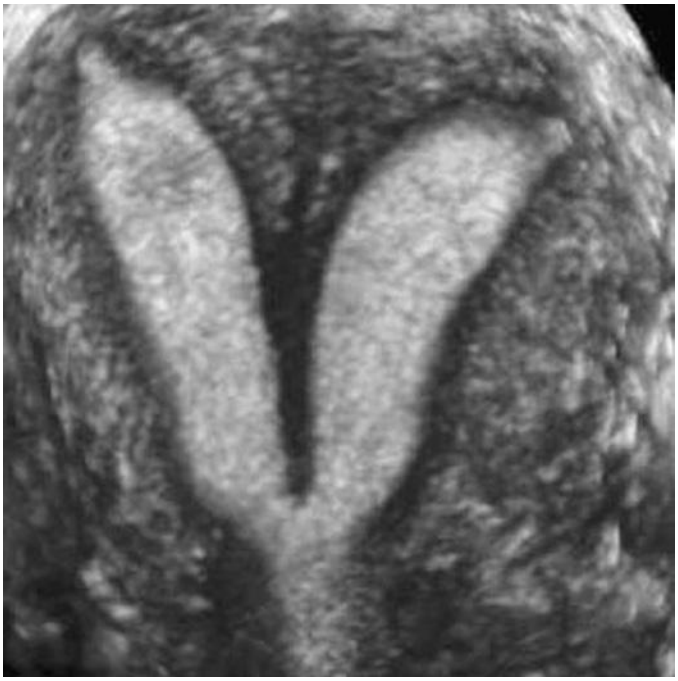

FIG 28-16 Coronal three-dimensional image of a septate uterus. Note two separate, but close endometrial cavities, thin hypoechoic septum extending to the level of the internal os, and smooth convex fundal contour without indentation between the two horns. (Courtesy of Dr. Beryl R. Benacerraf, Boston, MA.)

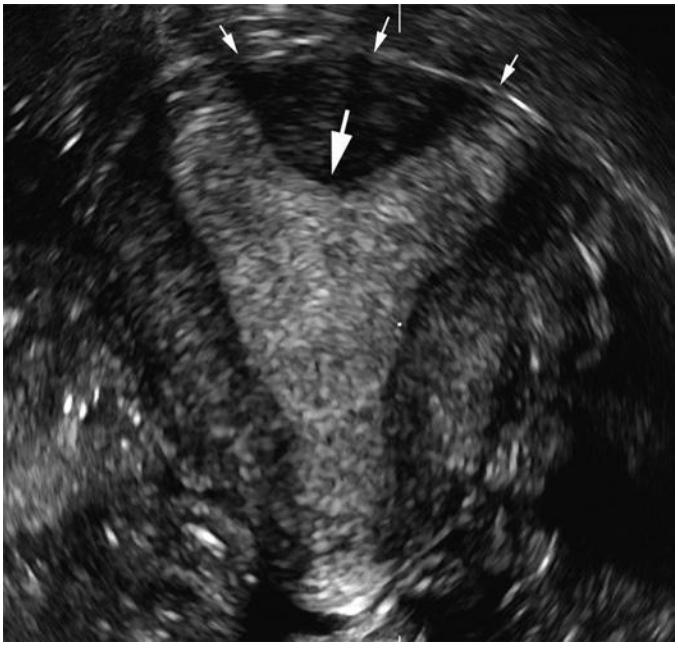

FIG 28-17 Coronal three-dimensional image of an arcuate uterus with a small myometrial indentation into the fundal aspect of the endometrium (*large arrow*). The outer serosal contour of the uterus is smooth and outwardly convex (*small arrows*).

reveal a small uterus with an irregular T-shaped appearance to the endometrial cavity. 3D sonography with multiplanar capabilities can be of assistance in evaluation of the internal and external contours in these cases. Transvaginal sonography remains the primary imaging modality, although MRI is used as a problem-solving technique in more challenging cases.[14]

In conclusion, the visualization of the fundal contour is paramount, looking for a cleft larger or smaller than 1 cm in differentiating fusion anomalies (didelphys and bicornuate) from resorption anomalies (septate and arcuate). 3D imaging can be very effective, but if inconclusive, MRI is helpful for definitive diagnosis.

BENIGN UTERINE CONDITIONS

Adenomyosis

Although often overlooked, adenomyosis is a common condition, reported in up to 70% of hysterectomy specimens. Adenomyosis is characterized by migration of endometrial glands and stroma from the stratum basale into the myometrium. This often occurs in association with reactive hyperplasia of the surrounding myometrial smooth muscle, which interdigitates with the ectopic endometrial tissue. The ectopic endometrial glands tend to be found at least 2 to 3 mm below the endometrial-myometrial junction. Two widely accepted theories for the cause of adenomyosis are that it either results from a defect in or absence of the basement membrane at the endometrial-myometrial junction or that it is related to endometrial migration through lymphatic or vascular channels. Possible risk factors include uterine trauma such as childbirth or uterine instrumentation, chronic endometritis, and hyperestrogenism.[3,4,15,16]

Adenomyosis is most prevalent among middle-aged women who have had children and is much less commonly seen in nulliparous or postmenopausal patients. Although many patients are completely asymptomatic, common presenting symptoms include uterine tenderness, dysmenorrhea, menorrhagia, and uterine enlargement. These symptoms are nonspecific and are very similar to the symptoms seen in patients with uterine leiomyomas, pelvic congestion syndrome, endometriosis, endometrial polyps, and endometrial carcinoma. Given the marked differences in prognosis and therapy between these entities, accurate diagnosis is extremely important. Symptoms can be extremely debilitating, and misdiagnosis can prolong the time course before appropriate care is instituted. Therapeutic regimens such as gonadotropin-releasing hormone inhibitors, oral contraceptives, nonsteroidal anti-inflammatory drugs, oral contraceptives, and endometrial ablation are available, but are not always fully effective.[3,4,15,16] An emerging therapy for adenomyosis is uterine artery embolization (UAE), but reported results from this treatment are inconsistent and the use of UAE to treat patients with symptomatic adenomyosis remains controversial. The only definitive treatment at this time remains hysterectomy.[17]

Both sonography and MRI play an important role in the diagnosis and management of women with adenomyosis. Imaging is also used to evaluate response to treatment and progression of the disease. For optimal diagnosis, transvaginal sonography should be performed using high-frequency transducers, between 5 to 10 MHz. The reported sensitivity and specificity of transvaginal sonography for identifying adenomyosis range from 53% to 89% and 67% to 98%, respectively, and overall accuracy is reported to range from 68% to 86%. The sensitivity of MRI is reported to range from 78% to 88% and specificity from 67% to 93%.[4,16] Although MRI and sonography are reported to have similar accuracy in diagnosing this condition, sonography is most often the first imaging study obtained in patients with the symptoms described previously.[3,4,15] However, MRI is considered to have better specificity and accuracy, particularly in women with associated disorders,[18] and it is also important to recognize that leiomyomas and adenomyosis often coexist (>60%), making accurate and specific diagnosis of the cause of symptoms more difficult.

The imaging features of adenomyosis derive from the presence of the ectopic endometrial glands within the myometrium, as well as the

surrounding stromal reaction of densely packed smooth muscle cells. This process often results in globular enlargement of the uterus without a discrete mass or contour deformity. Although focal adenomyomas can develop, they are rare and are unlikely to cause a contour abnormality, as leiomyomas often do. The previously described sonographic zonal anatomy of the uterus is altered in patients with adenomyosis. The subendometrial halo becomes thicker and more irregular, either diffusely or focally. Poor definition of the endometrial myometrial junction with pseudo-widening of the endometrial echo complex is caused by heterotopic endometrial tissue extending from the stratum basale. The subjacent myometrium may become heterogeneous with areas of increased or decreased echogenicity. Tiny punctate echogenic foci may be noted in the involved area. Hypoechoic striations may radiate throughout the involved parenchyma and extend posteriorly, believed to be edge shadowing due to the extensive smooth muscle hypertrophy. Although this shadowing is very similar to shadowing caused by leiomyomas, areas of adenomyosis lack distinct margins and mass effect and are more irregular and less rounded, as opposed to leiomyomas, which are typically round and sharply marginated. Small anechoic cysts, which on pathologic examination correspond to dilated endometrial glands, are often observed in the subendometrial myometrium, particularly during the secretory stage of the menstrual cycle. Hyperechoic foci, either linear or nodular, may extend directly from the endometrium into the myometrium and are believed to represent foci of ectopic endometrial tissue (Fig. 28-18). Color Doppler examination can also be helpful in differentiating adenomyosis from leiomyomas. Areas of adenomyosis often demonstrate diffuse hypervascularity throughout the lesion, whereas peripheral rather than internal blood flow is most commonly observed on color Doppler interrogation of leiomyomas.

Focal adenomyosis, or adenomyoma, presents with a more atypical appearance (see Fig. 28-18) and is visualized as a focal mass with poorly defined margins, in contrast to leiomyomas, which have distinct margins. Occasionally a focal adenomyoma is primarily cystic in appearance and may sometimes be found on MR to be filled with blood products. It is important to differentiate between adenomyomas and leiomyomas. At surgery, leiomyomas can often be easily separated and removed from the adjacent myometrium, whereas adenomyomas are not easily separated from the surrounding myometrium because of the surrounding smooth muscle hypertrophy. Therefore, adenomyosis or adenomyomas cannot be focally excised for cure.

Sonography has a reported sensitivity of 80% to 87% and a specificity of 94% to 98% in differentiating between adenomyosis and leiomyomas. The most specific ultrasound findings are the small anechoic myometrial cysts (seen best in the second half of the menstrual cycle) and the echogenic linear striations or nodules extending from the endometrium into the subjacent myometrium. Myometrial contractions can cause heterogeneity of the myometrium and apparent thickening of the subendometrial halo on ultrasound images and the junctional zone on MRI, thereby mimicking adenomyosis. When difficulties arise in sonographic diagnosis, MRI can be helpful in achieving a more definitive diagnosis. However, focal adenomyomas may be difficult to differentiate from leiomyomas with both imaging modalities.[4,16] In particular, on the rare occasions when an adenomyoma protrudes into the endometrial cavity, it will appear identical to a intracavitary polyp or pedunculated submucosal or intracavitary leiomyoma. Some authors consider polypoid adenomyomas a separate entity from adenomyosis.[19]

Endometrial abnormalities, such as hyperplasia and carcinoma, are reported to occur more often in patients with adenomyosis.[3,15] Rarely, an adenocarcinoma has been reported to arise from within a focus of adenomyosis. Adenocarcinoma would be very difficult to distinguish on any imaging modality from typical adenomyosis without malignancy (see Fig. 28-18). A more common scenario would be an endometrial carcinoma extending into foci of adenomyosis. In cases in which adenomyosis coexists with endometrial cancer, it is very difficult to determine whether the cancer is insinuating into preexisting areas of adenomyosis or if there are areas of true myometrial invasion. This distinction is crucial because myometrial invasion is an important prognostic indicator. However, it cannot always be achieved on imaging and can even be very difficult to determine on histopathologic examination (Table 28-1).[20]

TABLE 28-1 Features of Adenomyosis

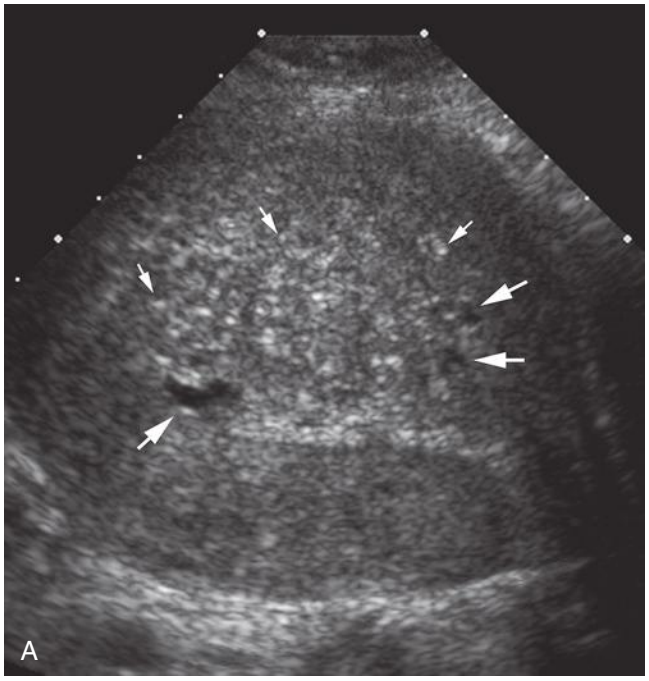
Diffusely globular uterus with smooth external uterine contour
Asymmetric globularity
Myometrial cystic areas/echogenic foci
Pseudo-thickening of the endometrium
Diffuse increased internal vascularity
Striated edge shadows/"venetian blind" shadowing without a discrete mass
Focal ill-defined mass
Features that help to differentiate from leiomyomas
Smooth external contour of uterus
Minimal mass effect on serosa/endometrium relative to the size of the lesion
Lack of calcification
Ill-defined margins
Central versus peripheral vascularity

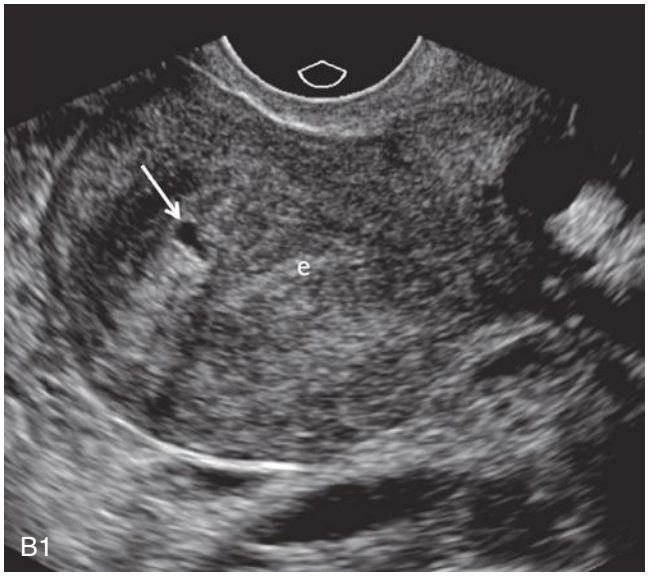
Leiomyomas

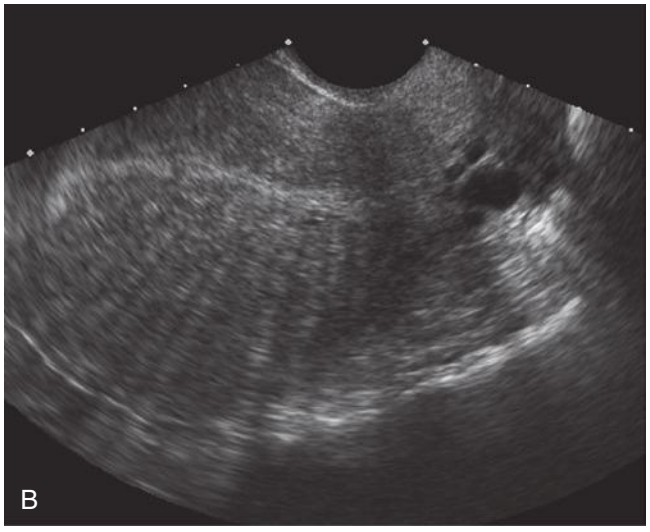
Leiomyomas (fibroids or myomas) are benign smooth muscle neoplasms with varying amounts of fibrous tissue and are the most common uterine neoplasm, reported in 20% to 30% of women over 30 years of age. Leiomyomas are more common in African-American women. Other risk factors include obesity, early age of onset of menstruation, and a diet rich in red meat. There may be a genetic predisposition. These tumors are usually multiple, causing enlargement of the uterus with a lobular serosal contour unlike adenomyosis, which results in globular but smooth-contoured uterine enlargement.

Leiomyomas most commonly present with a palpable pelvic mass, uterine enlargement, pelvic pain, anemia, and dysfunctional uterine bleeding. Symptoms are largely related to location and size. The vast majority of leiomyomas are intramural, submucosal (including intracavitary), or subserosal in location. Subserosal leiomyomas may be exophytic or pedunculated (Fig. 28-19). Intramural leiomyomas are most common, but are least likely to be symptomatic. On rare occasions, an exophytic leiomyoma will project into the broad ligament (intraligamentous). In these instances, the leiomyoma may clinically and radiologically simulate an ovarian mass (Fig. 28-20). A leiomyoma can also arise in the cervix (see later). An unusual form of leiomyoma is the parasitic leiomyoma, a pedunculated subserosal myoma that, if in close contact with an adjacent structure, can parasitize the blood supply and even become detached from the uterus. This classification of leiomyomas is relevant because symptoms and treatment vary according to their location and subtype.[21] However, when leiomyomas are large, they may be difficult to classify according to this scheme (Fig. 28-21).

Growth of leiomyomas is dependent on estrogen levels. Rapid growth in pregnancy is reported in about 50% of patients (Fig. 28-22). When rapidly growing, leiomyomas can outgrow their blood supply, resulting in degeneration or infarction.[21] Leiomyomas are associated with increased risk of early pregnancy failure, especially in women with multiple gestations.[22] Leiomyomas located in the cervix and lower uterine segment can interfere with vaginal delivery and should be







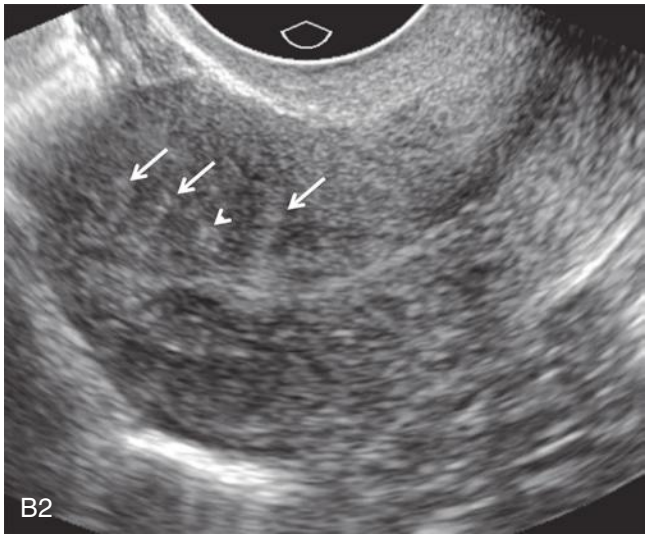


FIG 28-18 Adenomyosis: spectrum of appearances. **A,** Enlarged uterus with typical features of adenomyosis. Multiple bright echogenic foci are seen throughout the myometrium (*small arrows*) in addition to numerous subendometrial myometrial anechoic cysts (*large arrows*). **B,** Sagittal sonogram of the uterus demonstrating numerous thin hypoechoic, "venetian blind" or "comb-like" striations in the posterior myometrium. Although a similar pattern of striations may be seen with leiomyomas, the absence of a focal mass, the increased thickness of the posterior wall of the uterus compared to the anterior wall, and the presence of several small subendometrial myometrial cysts make this more characteristic of adenomyosis. **B1,** Sagittal transvaginal sonographic image demonstrating heterogeneity of the myometrium and two adjacent small myometrial cysts (*arrow*) with increased through transmission. Such myometrial cysts are believed to be a very specific finding for adenomyosis. e, endometrium. **B2,** Sagittal transvaginal sonographic image demonstrating heterogeneity of the myometrium, which is also relatively hypoechoic. Note several echogenic linear striations extending from the endometrium into the myometrium (*arrows*) and one nodular echogenic area (*arrowhead*) in the subendometrial tissue. A similar pattern of endometrial tissue extending into the myometrium can be seen on magnetic resonance imaging (MRI) and is believed to be another relatively specific finding for adenomyosis.

Continued

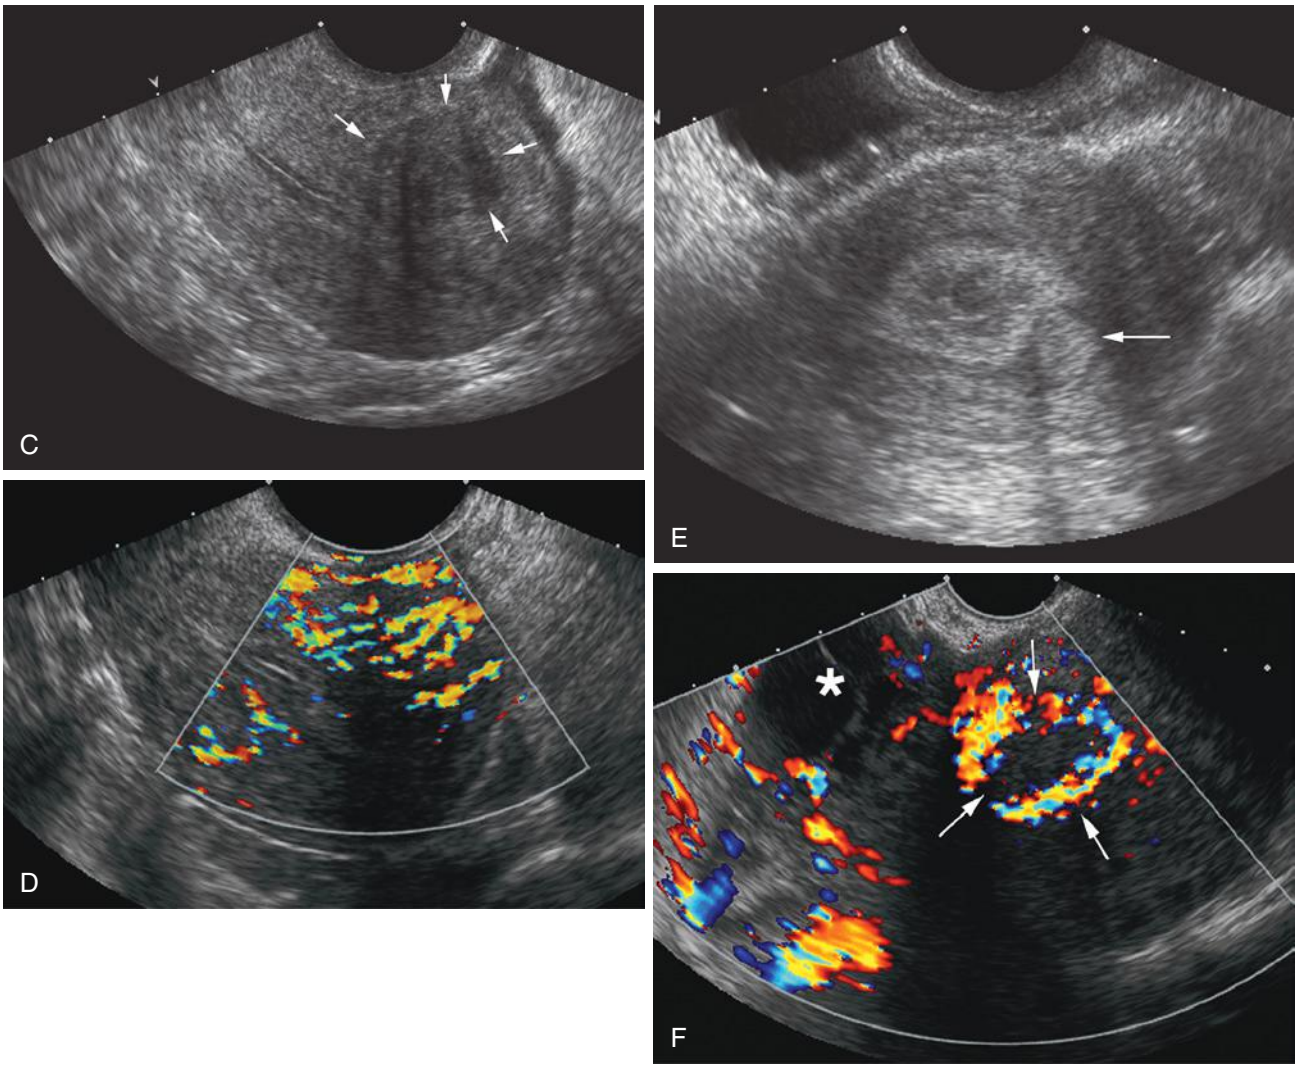

FIG 28-18, cont'd C, Transvaginal sonogram in a patient with a focal hypoechoic adenomyoma (*arrows*). On gray-scale imaging it can be very difficult to differentiate a focal adenomyoma from an intramural leiomyoma. **D,** Color Doppler image of the same patient in C, demonstrating increased vascularity within the adenomyoma. Such increased vascularity would be atypical for a leiomyoma. **E,** Another patient with an adenomyoma. In this case the adenomyoma is hyperechoic (*arrow*), indenting but separate from the endometrium. **F,** Transvaginal color Doppler image of a patient with an adenosarcoma arising in the background of adenomyosis with sarcomatous overgrowth. Note intense peripheral vascularity (*arrows*) surrounding a mass thought to represent an adenomyoma arising in the background of diffuse adenomyosis. A large cystic and solid mass (*asterisk*) is seen on the right, which was thought to be of ovarian origin.

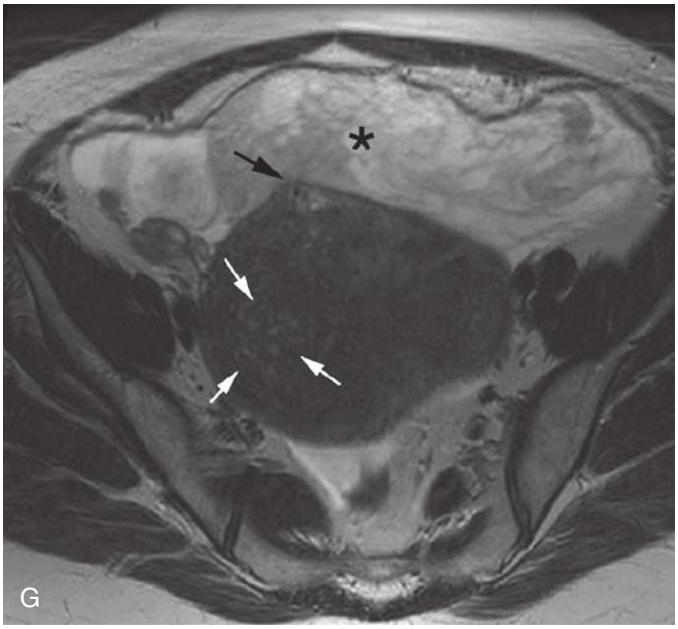

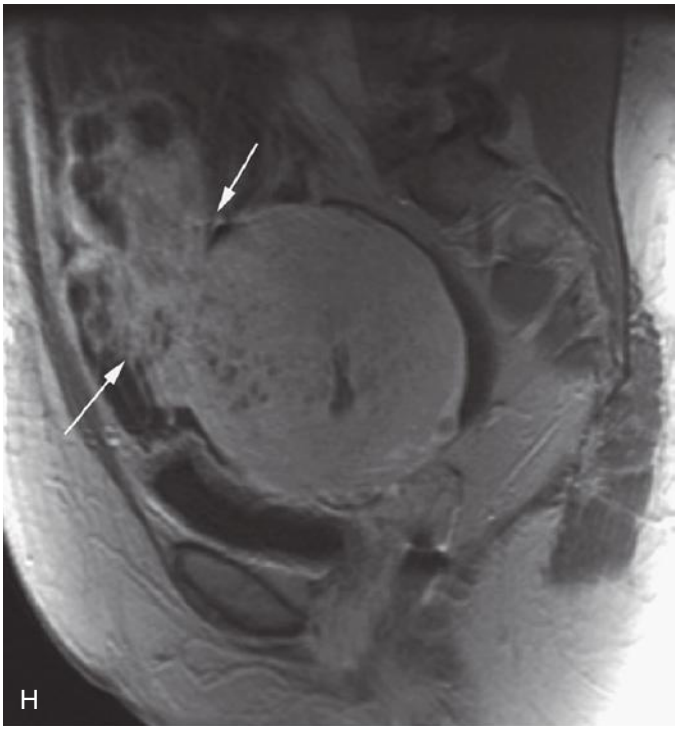

FIG 28-18, cont'd G, Axial T2 weighted MRI image better demonstrates the extent of the adenomyosis (diffuse low signal intensity of the myometrium) as well as the more focal adenomyoma (*white arrows*) with numerous small hyperintense foci. A small subtle area of serosal breakthrough is noted (*black arrow*), which represents "expelling" of the adenosarcoma depicted as a large high T2W signal heterogeneous mass noted anteriorly (*asterisk*). **H,** Sagittal postcontrast T1W image demonstrates tumor extending from the uterine wall through the serosal surface into the anterior pelvis (*arrows*). The final pathologic image demonstrated endometrial stromal sarcoma with heterogeneous differentiation, FIGO stage III (International Federation of Gynecology and Obstetrics).

monitored during pregnancy. Conversely, leiomyomas may precipitously decrease in size and even infarct following delivery as estrogen levels drop. As estrogen levels decline in older women, leiomyomas typically regress and thus are rarely symptomatic in postmenopausal patients.[21]

Leiomyomas are readily recognized on sonography, although the sonographic appearance is variable. In the past, the diagnosis of leiomyomas was often suggested on ultrasound images if the uterus was heterogeneously enlarged, especially if the contour was lobular. However, in today's ultrasound practice, most leiomyomas are readily identified as focal, sharply marginated myometrial masses, and a diffusely heterogeneous enlarged uterus is more likely to indicate adenomyosis. Leiomyomas may be hypoechoic, isoechoic, or echogenic relative to the myometrium, although the majority are hypoechoic. The surrounding myometrium can become compressed and form a pseudocapsule, which can be readily identified on ultrasound images as well as MRI (Fig. 28-23). Occasionally compressed lymphatics and vessels can create a thin hypoechoic rim around intramural leiomyomas (Fig. 28-21A). Although small leiomyomas are typically homogeneous, leiomyomas larger than 3 cm in diameter are often heterogeneous (Fig. 28-24). As leiomyomas increase in size, they tend to outgrow their blood supply, which leads to degeneration: hyaline, myxoid, cystic, or hemorrhagic (Fig. 28-25). Degenerated leiomyomas have a more atypical appearance on sonography and MRI (Fig. 28-26).[21,22] Degeneration may result in edema with cystic spaces, echogenic hemorrhagic areas, and dystrophic calcification. Dystrophic calcification occurs predominantly in postmenopausal patients. The calcifications can be curvilinear and peripheral or clump-like and will demonstrate dense posterior shadowing. Many leiomyomas demonstrate areas of acoustic attenuation even if they do not contain obvious calcifications. The posterior shadowing may be dense or striated (comb-like). This attenuation is believed to be caused by the transitional zone between apposed tissues of different acoustic properties such as fibrous tissue and smooth muscle, as well as refraction from the edges of whorls and bundles of smooth muscle.[23] This characteristic shadowing is very helpful in differentiating an exophytic leiomyoma from an adnexal or ovarian mass. However, the smooth muscle hypertrophy associated with adenomyosis may also cause a striated pattern of posterior shadowing and a similar appearance (Fig. 28-27). Edge refraction at the interface of the leiomyoma with the normal surrounding myometrium is common and may help to identify a leiomyoma that is isoechoic to the normal myometrium. Peripheral blood flow is commonly observed on color or power Doppler images; it is much less common to detect internal vascularity in a benign leiomyoma with color Doppler imaging.

Submucosal leiomyomas may present with menorrhagia, menometrorrhagia, and even anemia, requiring definitive treatment with resection. Submucosal leiomyomas can have varying degrees of intracavitary extension. Both size and the degree to which a leiomyoma projects into the endometrial cavity will determine the likelihood of successful hysteroscopic resection. Leiomyomas with 50% or greater intracavitary extension are more easily resected via hysteroscopy. Until recently, sonohysterography was considered the best modality to determine the degree of intracavitary extension of a leiomyoma (Fig. 28-28). More recently, 3D sonography has proved to be useful as well (Fig. 28-29).

Transvaginal imaging may be limited if the leiomyomas are large or pedunculated. In this situation, transabdominal imaging may improve visualization. MRI is a valuable modality to evaluate large or atypical leiomyomas, as the multiplanar capability and larger field of view are particularly useful.

Text continued on p. 866

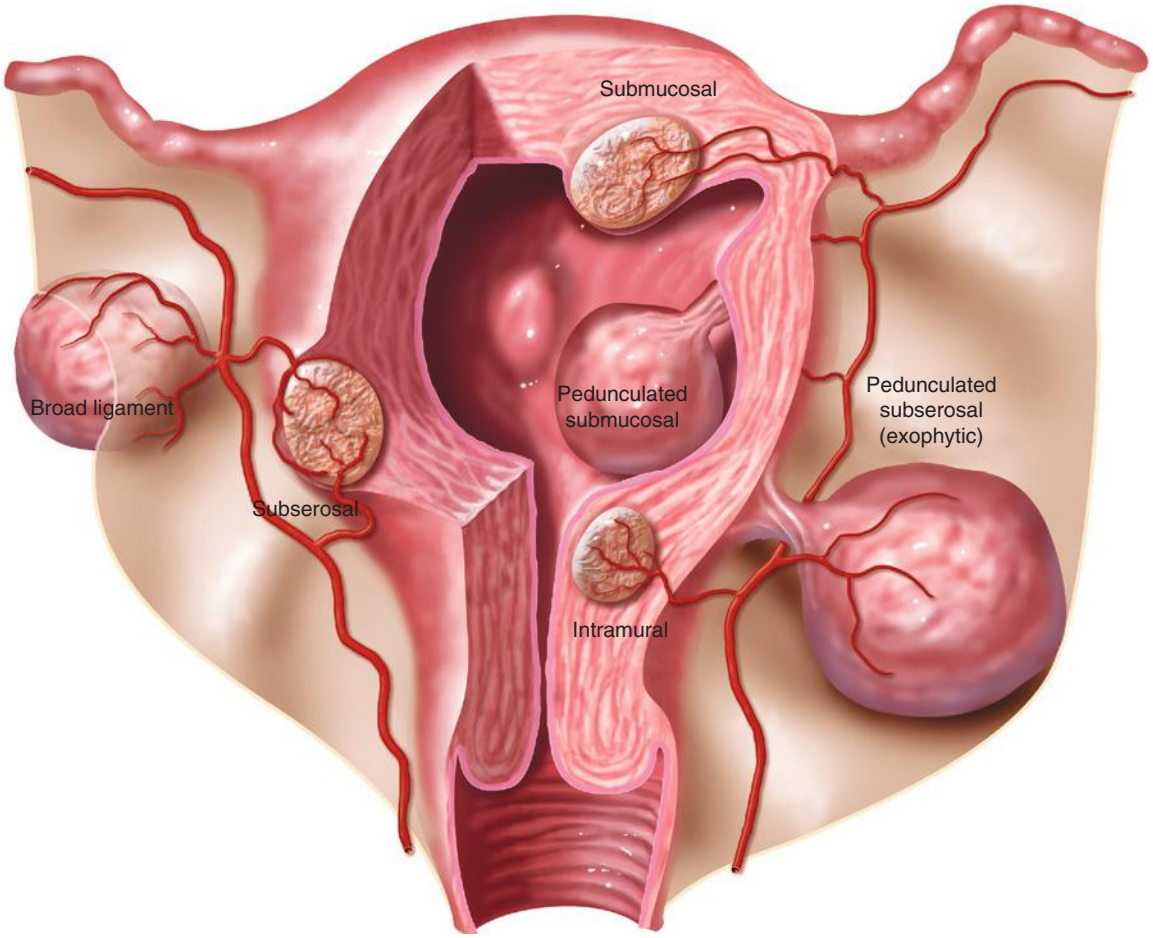

FIG 28-19 Common locations of leiomyomas. (Illustration by James A. Cooper, MD, San Diego, CA.)

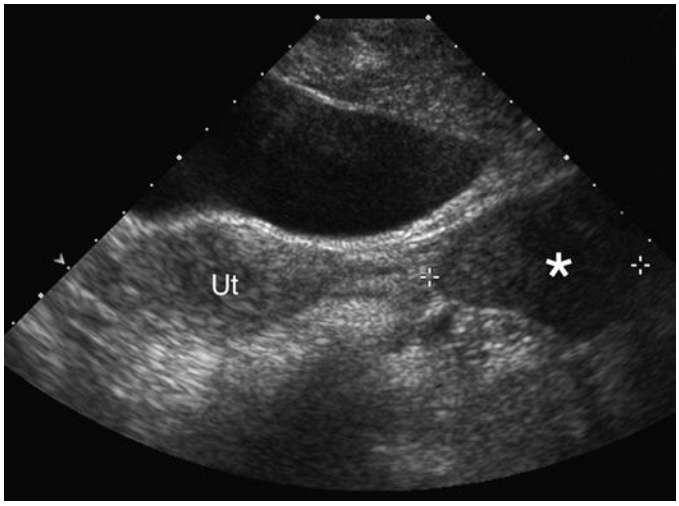

FIG 28-20 Transverse abdominal sonogram. A left adnexal solid mass (*asterisk* and *calipers*) is seen. Although the location would make one think of an ovarian mass, it was in fact a broad ligament myoma. Ut, uterus.

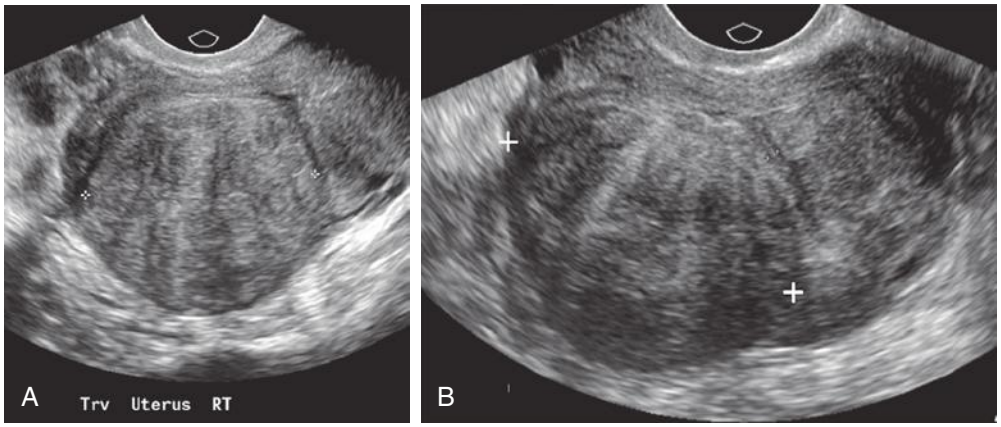

FIG 28-21 Classification of large leiomyomas. **A** and **B,** When leiomyomas are large, they may appear to be intramural as well as either submucosal or subserosal in location. In these two patients, the leiomyomas (*calipers*) appear to have their epicenter in the myometrium, hence they are predominately intramural in location. However, they both extend beyond the serosal contour of the uterus, giving the uterus a lobular configuration. Thus, they both appear to have a subserosal component. These large masses are somewhat heterogeneous in echotexture. Note the thin peripheral hypoechoic rim partially encompassing the leiomyoma in A, likely representing compressed lymphatics or vessels. The lesion in B demonstrates several linear areas of shadowing, likely due to dense fibrous or collagenous material within the leiomyoma.

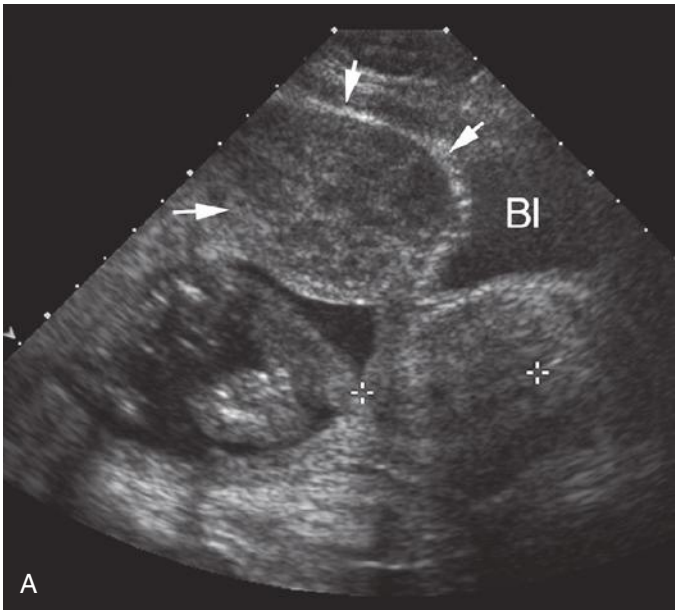

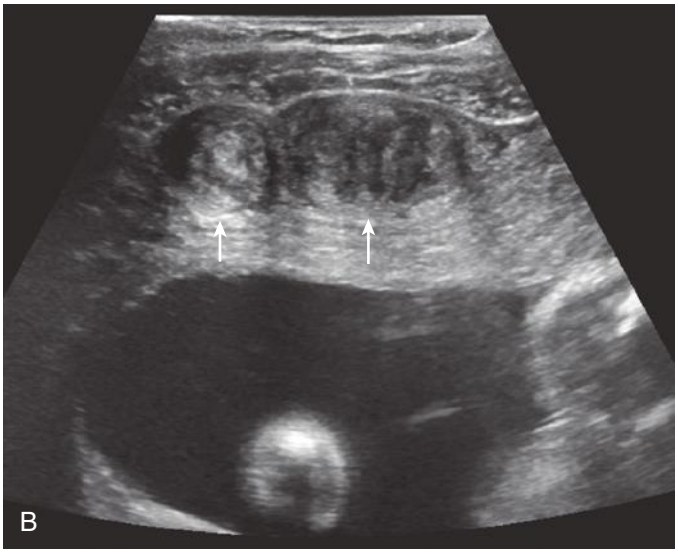

FIG 28-22 **A,** Longitudinal sonogram in a pregnant patient at 18 weeks' gestational age. An anterior lower uterine segment leiomyoma (*arrows*) is seen. It does not obstruct the cervix (demarcated by *calipers*). Bl, bladder. **B,** Well-circumscribed, heterogeneous leiomyomas (*arrows*) in the anterior wall of the uterus in another pregnant patient.

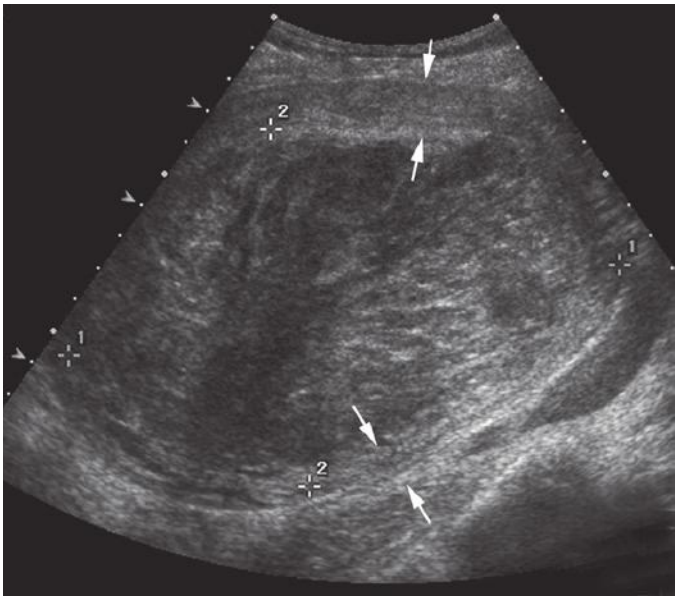

FIG 28-23 Large uterine myoma (*calipers*). Surrounding compressed myometrium (*arrows*) has created a pseudocapsule.

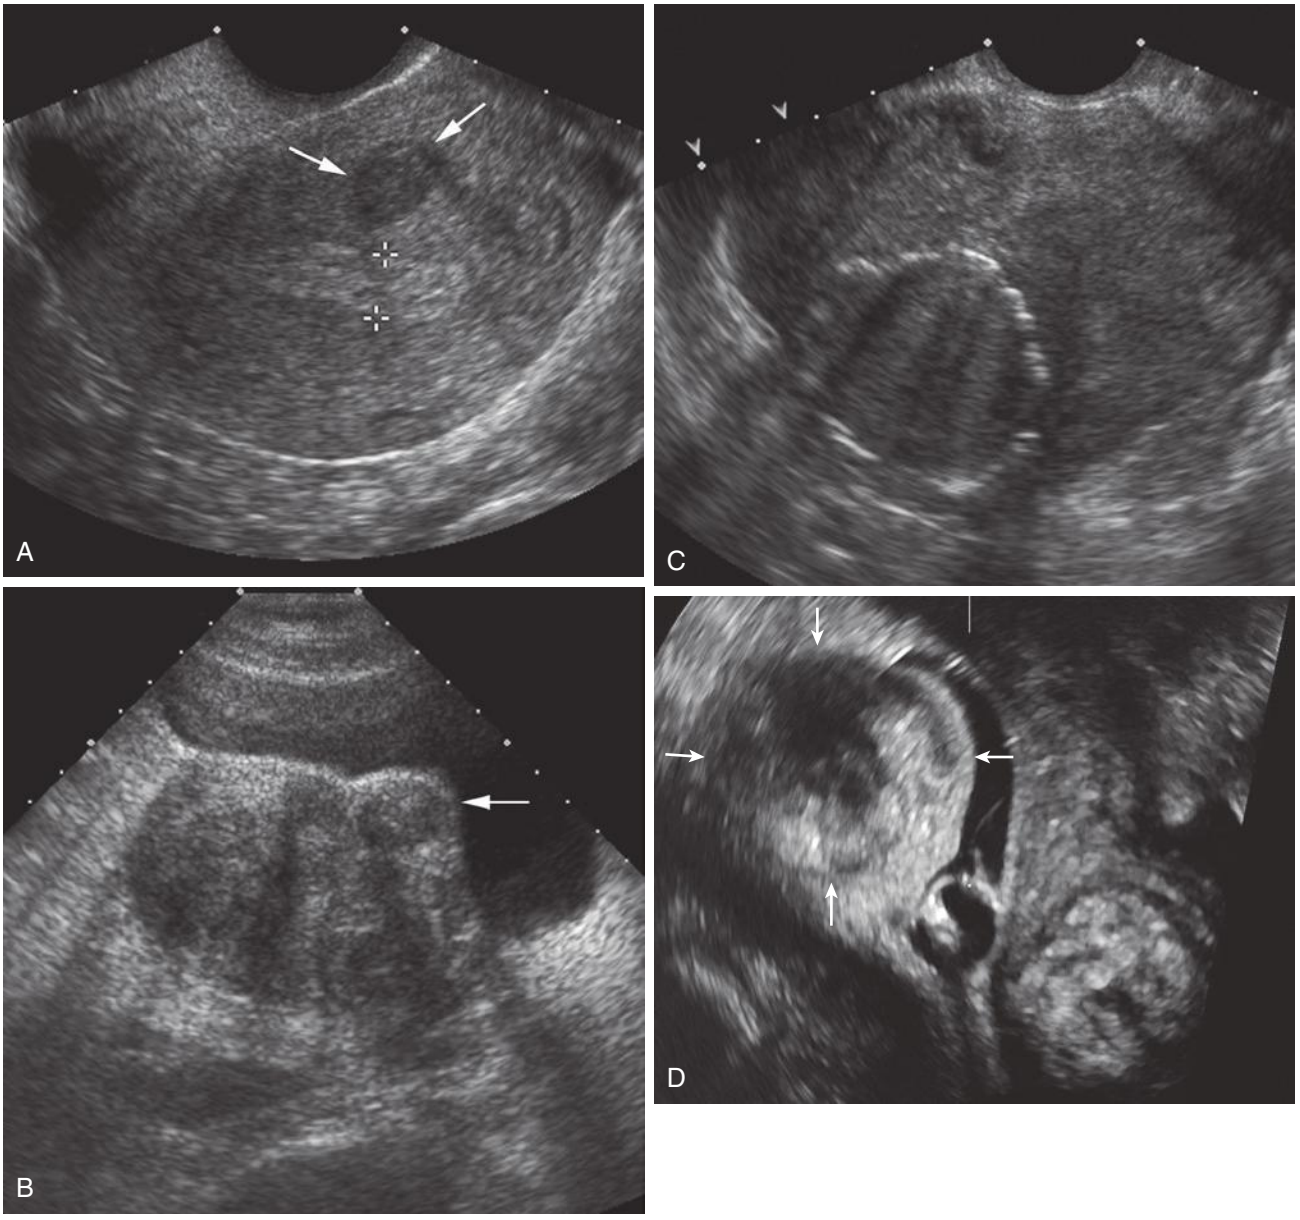

FIG 28-24 Variable appearance of uterine leiomyomas. **A,** Sagittal transvaginal sonogram demonstrating a small, round, well-circumscribed hypoechoic intramural leiomyoma (*arrows*) separate from the endometrium (*calipers*) in a patient with a retroflexed uterus. **B,** Longitudinal transabdominal sonogram in a patient with multiple uterine leiomyomas. The normal morphologic appearance of the uterus is markedly distorted. The myometrium is heterogeneous and the endometrium could not be identified. An anterior subserosal leiomyoma (*arrow*) distorting the serosal contour projects into the urinary bladder. **C,** Transvaginal sonogram of a leiomyoma demonstrating peripheral echogenic thin rim calcification. **D,** Coronal three-dimensional reconstruction after saline infusion demonstrates a heterogeneous but predominantly echogenic submucosal leiomyoma (*arrows*) with a near 50% intracavitary component.

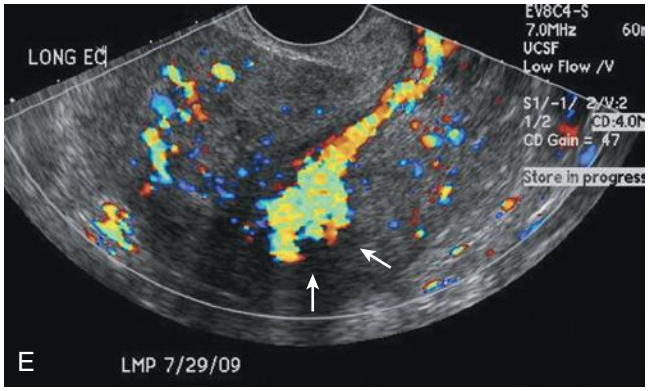

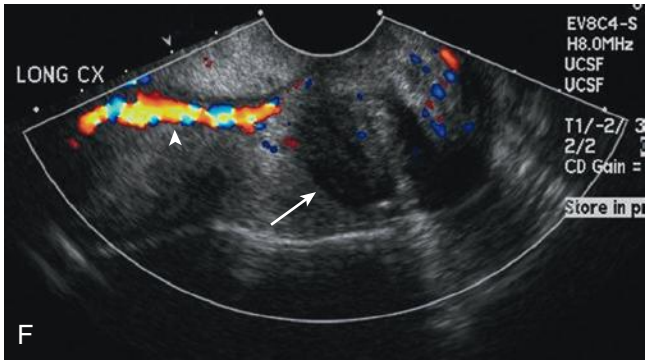

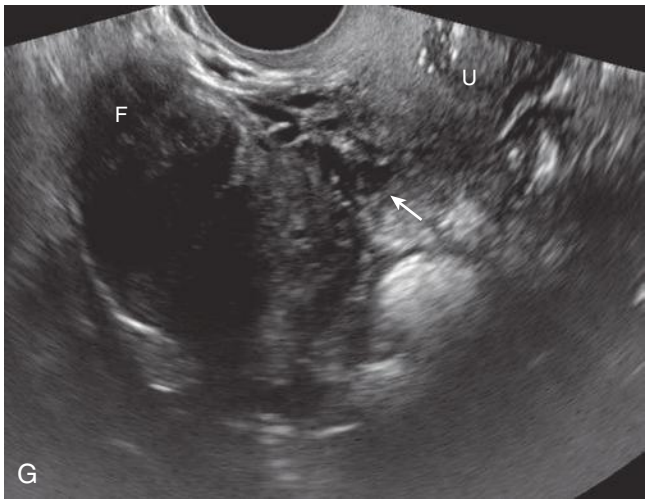

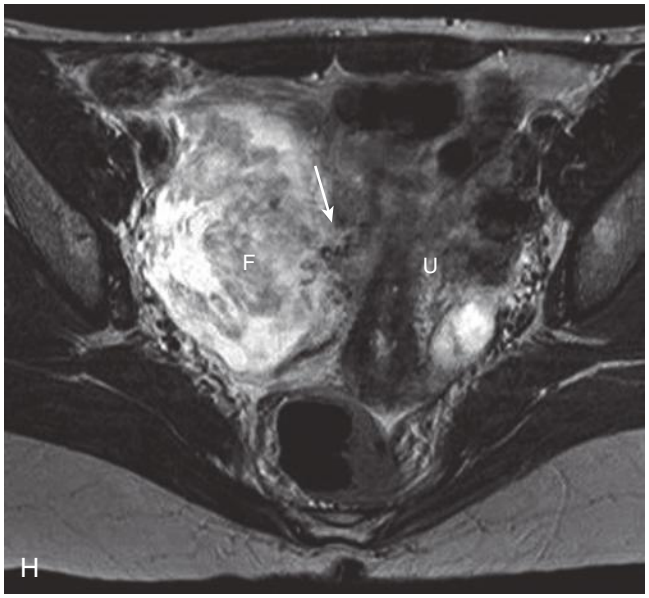

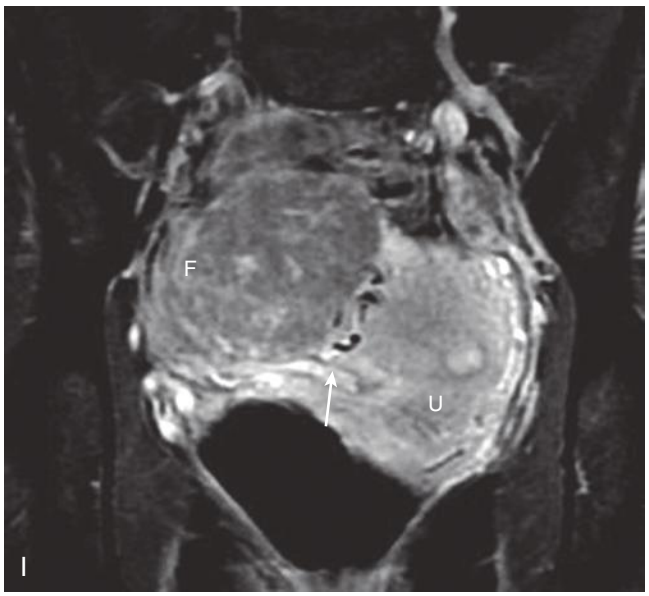

FIG 28-24, cont'd **E,** Transvaginal sagittal view of the uterus demonstrating a hypervascular stalk (*arrows*) arising from the posterior wall of the uterus and extending through the endometrial canal into the endocervical canal (right side of image). **F,** The hypervascular stalk (*arrowhead*) is connected to a well-demarcated, rounded, hypoechoic mass (*arrow*) with posterior shadowing that splays the endocervical canal, consistent with a prolapsed leiomyoma. Without the color Doppler demonstration of the vascular stalk, these findings could mimic a cervical leiomyoma. **G,** Transvaginal transverse view of a hypoechoic, slightly lobular shadowing pedunculated leiomyoma (F) in right adnexa. Uterus (U) is medial to the leiomyoma. Tubular anechoic structures (*arrow*) between the leiomyoma and the uterus represent vessels in the bridging pedicle. The bridging vascular pedicle sign is often better seen on magnetic resonance imaging (MRI) and has been reported to be present in more than 70% of pedunculated leiomyomas. **H,** Axial T2-weighted (T2W) MRI image of the right pedunculated leiomyoma (F), demonstrating black (T2 dark) squiggly flow voids of vessels within the pedicle (*arrow*). U, uterus. **I,** Coronal T2W with fat saturation MRI image demonstrating the pedunculated right leiomyoma (F), medially displaced uterus (U), and T2 dark flow voids (*arrow*) in the vascular pedicle.

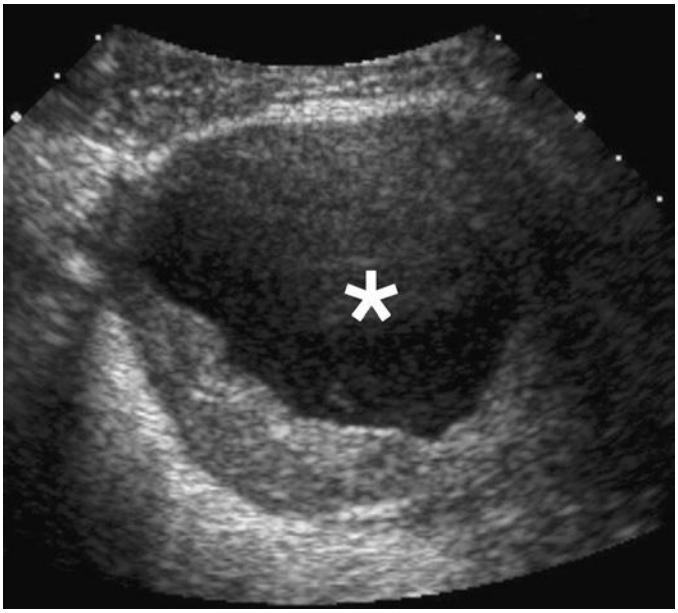

FIG 28-25 Marked cystic degeneration with large anechoic fluid component (*asterisk*) of a large intramural leiomyoma.

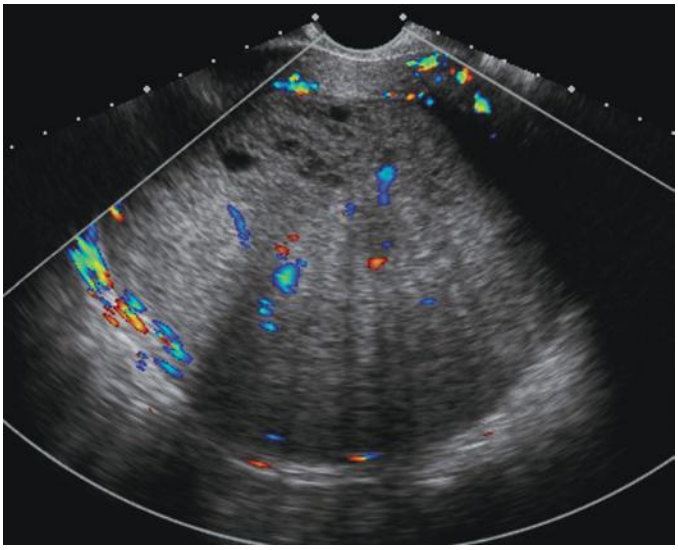

FIG 28-27 Large relatively echogenic leiomyoma demonstrating small anechoic rounded areas of cystic change anteriorly as well as "venetian blind" shadowing. Both of these features are quite similar to ultrasound findings of adenomyosis.

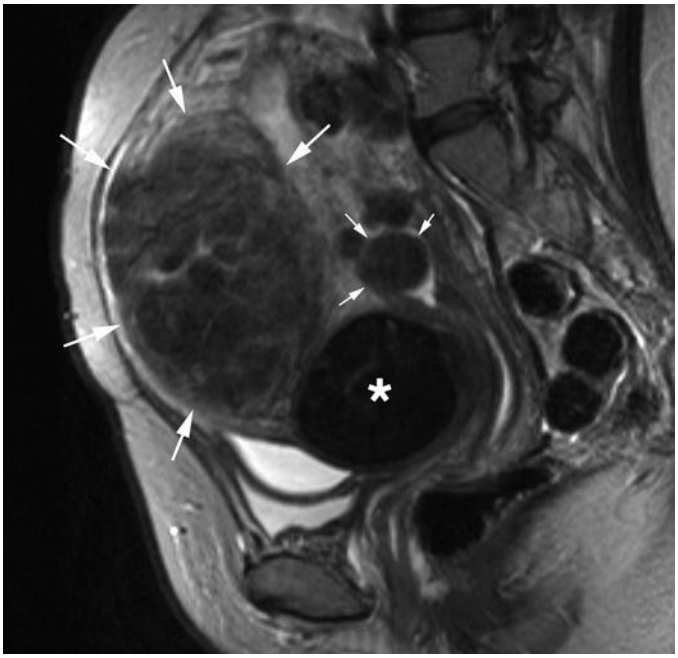

FIG 28-26 Sagittal T2-weighted (T2W) magnetic resonance image demonstrating various different but common appearances of leiomyomas: small submucosal leiomyoma impressing the endometrial canal with typical low T2W signal (*small arrows*), large anterior intramural leiomyoma (*large arrows*) with internal edema and degeneration (*white areas*), and anterior lower uterine segment leiomyoma (*asterisk*) with extremely low T2W signal consistent with internal blood products/hemosiderin from "red degeneration."

Lipomatous Uterine Tumors

Lipomatous tumors of the uterus are rare benign neoplasms and are readily recognized on ultrasound images. The histologic spectrum includes pure lipomas, lipoleiomyomas, fibrolipomas, and myolipomas (Fig. 28-30).[24] A lipoleiomyoma is characterized histologically by the presence of mature lipocytes as well as smooth muscle cells and fibrous tissue. Sonographically, these lesions are characteristically extremely echogenic and located within the myometrium. However, occasionally cellular leiomyomas can be extremely echogenic. The margins are typically sharp, but can be lobular. Posterior attenuation may be observed owing to the fat content. Usually there will be no demonstrable color Doppler flow. Lipomatous lesions are usually asymptomatic and do not require surgery. Because mixed lesions can have a more heterogeneous appearance and less characteristic appearance on ultrasound images, MRI can be used to confirm the presence of macroscopic fat within the lesion and therefore confirm that they are benign.

MALIGNANT CONDITIONS

Gestational Trophoblastic Disease

GTD is a spectrum of rare diseases characterized by the presence of abnormal trophoblastic proliferation that includes genetically abnormal conceptions with neoplastic potential (i.e., complete hydatidiform moles [CHMs] and partial hydatidiform moles [PHMs] as well as gestational trophoplastic neoplasms [GTNs] or persistent trophoblastic neoplasia [PTN]) including invasive moles and choriocarcinomas (Fig. 28-31A). Risk factors for GTD include extremes of maternal age (under the age of 20 and over the age of 35 years, especially over the age of 50 years) as well as history of prior molar pregnancy. In addition, GTD is much more common in women of Asian origin. The presence of a highly sensitive biomarker, beta-human chorionic gonadotropin (hCG), as well as the availability of effective chemotherapeutic regimens has dramatically improved survival rates.[25]

The most common type of GTD is the CHM. CHMs constitute 80% of GTD, with an incidence of approximately 0.5 to 1 per 1000.[26] Patients most commonly present with vaginal bleeding, sometimes with passage of vesicles, and with markedly elevated serum hCG levels. As the diagnosis is now most often made earlier in the first trimester, hyperemesis and an enlarged uterus for dates are less commonly observed. The genetic material in a CHM is entirely paternal in origin. Most CHMs have a 46,XX diploid karyotype secondary to fertilization of a genetically empty egg by two haploid sperm. At pathologic

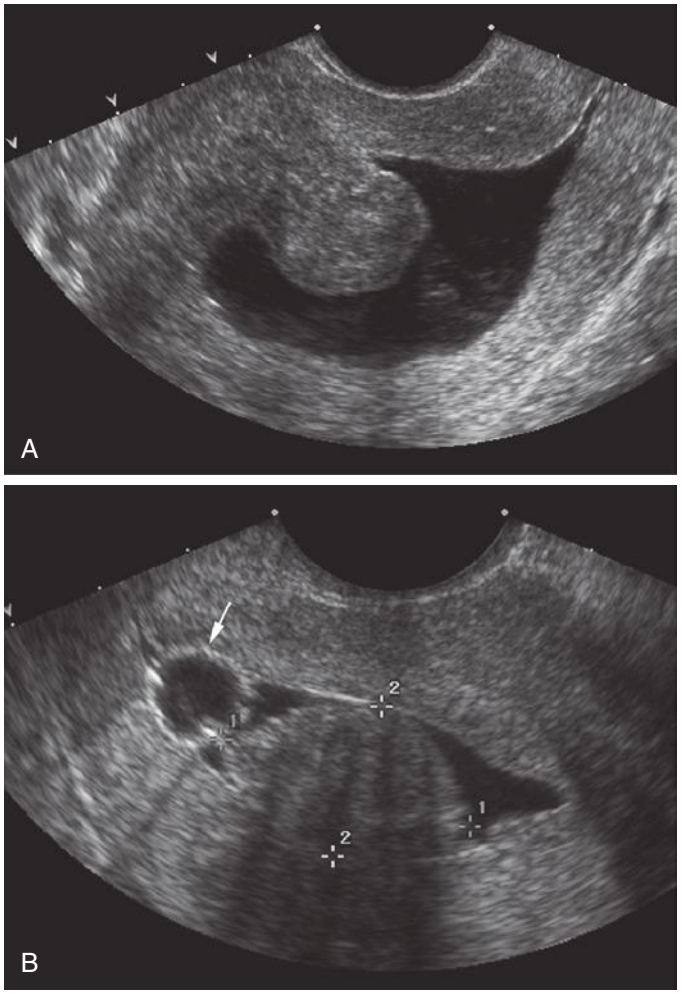

FIG 28-28 Saline infusion sonohysterography (SIS) in two patients with submucosal, predominantly intracavitary leiomyomas. **A,** Sagittal view from a sonohysterogram demonstrating a myoma that is isoechoic to the myometrium projecting into the uterine cavity that is distended with anechoic fluid. More than 50% of the submucosal leiomyoma is intracavitary. Note overlying echogenic thin layer of endometrium, which helps to differentiate a submucosal leiomyoma from a broad-based endometrial polyp. This leiomyoma was resected hysteroscopically. **B,** Sonohysterogram of another patient with a submucosal leiomyoma (*calipers*) projecting into the uterine cavity. Note parallel hypoechoic regular bands extending from the anterior surface of the leiomyoma posteriorly, so-called "venetian blind" shadowing. The distended balloon filled with anechoic fluid (*arrow*) is seen as well on this image.

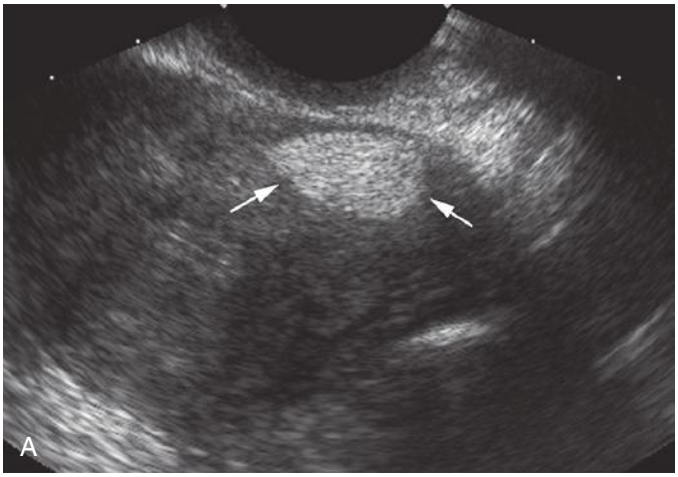
FIG 28-29 Three-dimensional image of a submucosal intracavitary leiomyoma (*asterisk*) indenting the echogenic endometrium. (Courtesy of Dr. Beryl R. Benacerraf, Boston, MA.)

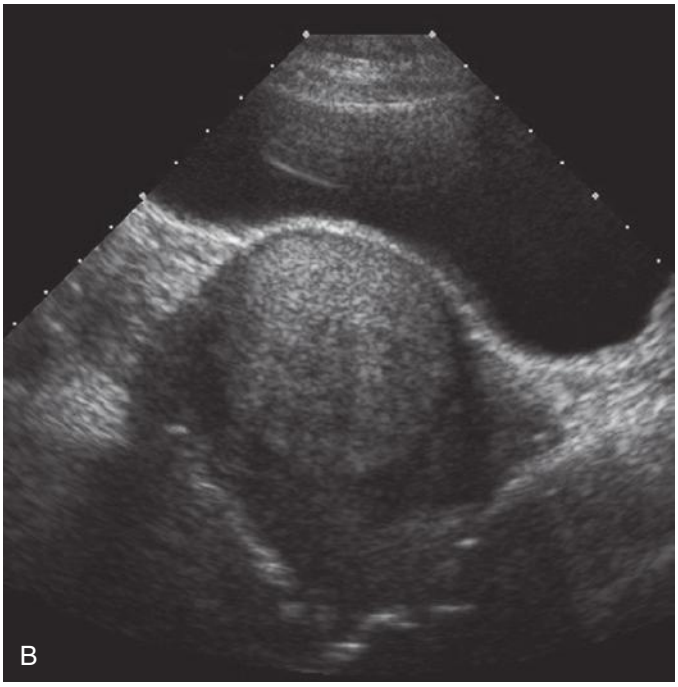
examination, no fetal tissue will be identified. The risk of developing PTN is estimated to be approximately 20% following evacuation. However, it is not possible to predict which CHMs will develop persistent disease by either imaging or pathologic characteristics, although women over the age of 40 years and with hCG levels greater than 100,000 mIU/mL, excessive uterine enlargement, theca lutein cysts larger than 6 cm in diameter, and repetitive molar pregnancies seem to be at higher risk for invasion.[27] Hence, women with CHMs are counseled not to become pregnant for a full year following evacuation and are followed carefully with serum hCG levels.

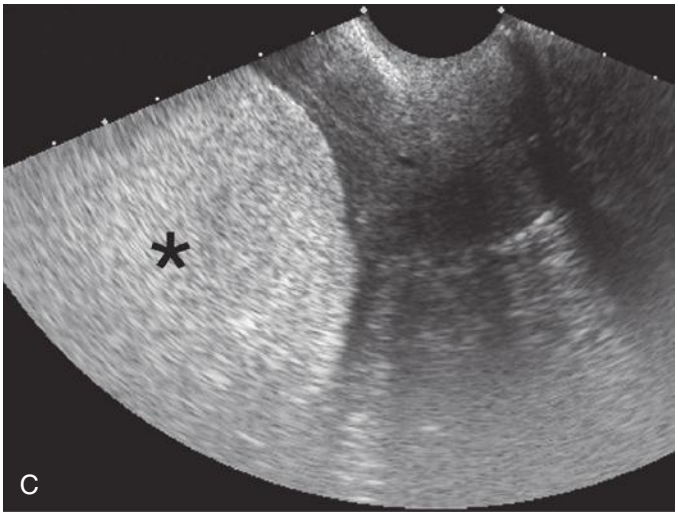
PHMs are the second most common type of GTD.[26] Patients with PHMs typically have less trophoblastic proliferation, milder symptoms, and lower hCG levels. Most PHMs have a 69,XYY or 69,XXY triploid karyotype and will have fetal tissue identified on pathologic examination. These patients are estimated to have a risk of approximately 5% for developing PTN.

Sonography is the primary imaging modality used for diagnosis, and many cases are detected incidentally during first trimester ultrasound examinations. MRI is reserved for problem solving, primarily for assessing the extent of uterine invasion and residual disease before and after treatment. However, it can be difficult on both MRI and sonography to accurately identify myometrial invasion. Distinction between CHM versus PHM is important, given the higher invasive potential of CHM.[26]

The typical ultrasound appearance of CHM in the late first or second trimester is an enlarged uterus with the endometrial cavity distended by an echogenic, vascular mass containing clusters of tiny cysts (hydropic villi), sometimes described as the "snowstorm" or "cluster of grapes" appearance. There are no visible fetal parts. The presence of theca lutein cysts in the ovaries may help confirm the diagnosis. However, in today's practice, theca lutein cysts are infrequently visualized, most likely because patients are imaged and diagnosed at an earlier gestational age. Early in the first trimester, there is a spectrum of sonographic findings ranging from a thickened endometrium without a discrete mass or cystic areas to the more classic appearance of an echogenic endometrial mass with the so-called "cluster of grapes" multicystic appearance (Fig. 28-31B, C1, and C2). Classically, color or power Doppler imaging will reveal increased vascularity within the endometrium or mass. However, not all molar pregnancies will demonstrate increased vascularity on Doppler







interrogation (Fig. 28-31B and C2). Early in the first trimester, a CHM may not be distinguishable from a normal or failed early pregnancy (Fig. 28-31C and Fig. 28-32), and correlation with serum hCG levels is paramount as well as genotyping of the products of conception if evacuated.[28] Interestingly, detection of CHM at an earlier gestational age does not appear to change the incidence of postmolar GTNs.[29] This supports the concept that the diagnosis should not be reached in haste but only after careful correlation with imaging, laboratory, and clinical findings.

PHM has a similar ultrasound appearance to CHM, except that either normal or abnormal appearing fetal parts will be also identified (Fig. 28-33). However, there is a spectrum of disease, and CHM has been reported to occur in conjunction with a normal live twin fetus (Fig. 28-31D and E). The presence of myometrial invasion or retained endometrial tissue on the first follow-up examination after evacuation has been reported to be predictive of risk of GTN or PTN (Fig. 28-34).[30]

Dedicated pelvic MRI is superior to sonography for the detection of myometrial invasion and is used to assess for myometrial invasion as well as extrauterine extension. The appearance of CHM on MRI is described as T1-weighted hypointense, T2-weighted hyperintense tissue/mass with disruption of the junctional zone and enhancing multicystic tissue within the enlarged uterus (Fig. 28-31F and G). However, hypervascularity in the myometrial wall is not predictive of invasive disease and can be seen with normal implantation, RPOC, and AVM.

Uterine Sarcomas

Although leiomyomas are most often benign lesions, leiomyosarcomas do rarely occur. The cause of leiomyosarcomas remains uncertain. Although in some cases it is postulated that leiomyosarcomas develop secondary to degeneration of a preexisting leiomyoma, most leiomyosarcomas are believed to arise independently rather than from a preexisting leiomyoma.[31] Uterine sarcomas are typically extremely aggressive malignancies with poor prognosis. However, early diagnosis can improve survival rates, and therefore, attention to imaging clues is crucial. Clinically, rapid growth of a leiomyoma in a perimenopausal or postmenopausal woman raises the possibility of sarcomatous change or degeneration. Ultrasound findings suggestive of malignancy include rapid change in size, indistinct or infiltrative margin, unusually complex echo pattern, and internal vascularity, especially if the distribution of the vessels is irregular. However, these findings are neither sensitive nor specific, and there may be no significant sonographic difference between a rapidly growing or degenerating myoma and a sarcoma. The internal architecture can change markedly and the amount of solid tissue can even increase in degenerating myomas, although such features raise concern for malignancy. MRI can be obtained to confirm the avid enhancement of solid components. However, MRI findings are also nonspecific, and if there are no prior studies, it is very difficult to determine if solid components in a degenerated myoma represent residual viable benign leiomyoma tissue versus a newly developing leiomyosarcoma, and surgical resection may be indicated. Other signs of malignant degeneration include local

FIG 28-30 Spectrum of lipoleiomyomas. **A,** Sonogram demonstrating a well-marginated 1.5-cm focal hyperechoic anterior myometrial mass (*arrows*) that was a lipoleiomyoma. **B,** Transabdominal sonogram demonstrating a large 5-cm lipoleiomyoma. This mass is less echogenic and more heterogeneous than the lipoleiomyoma in A, but it also demonstrates some posterior linear shadowing. **C,** Transvaginal sonogram of a 7-cm extremely hyperechoic mass (*asterisk*) arising from the lower uterine segment posteriorly with marked posterior attenuation due to the fat content. This mass was also a lipoleiomyoma.

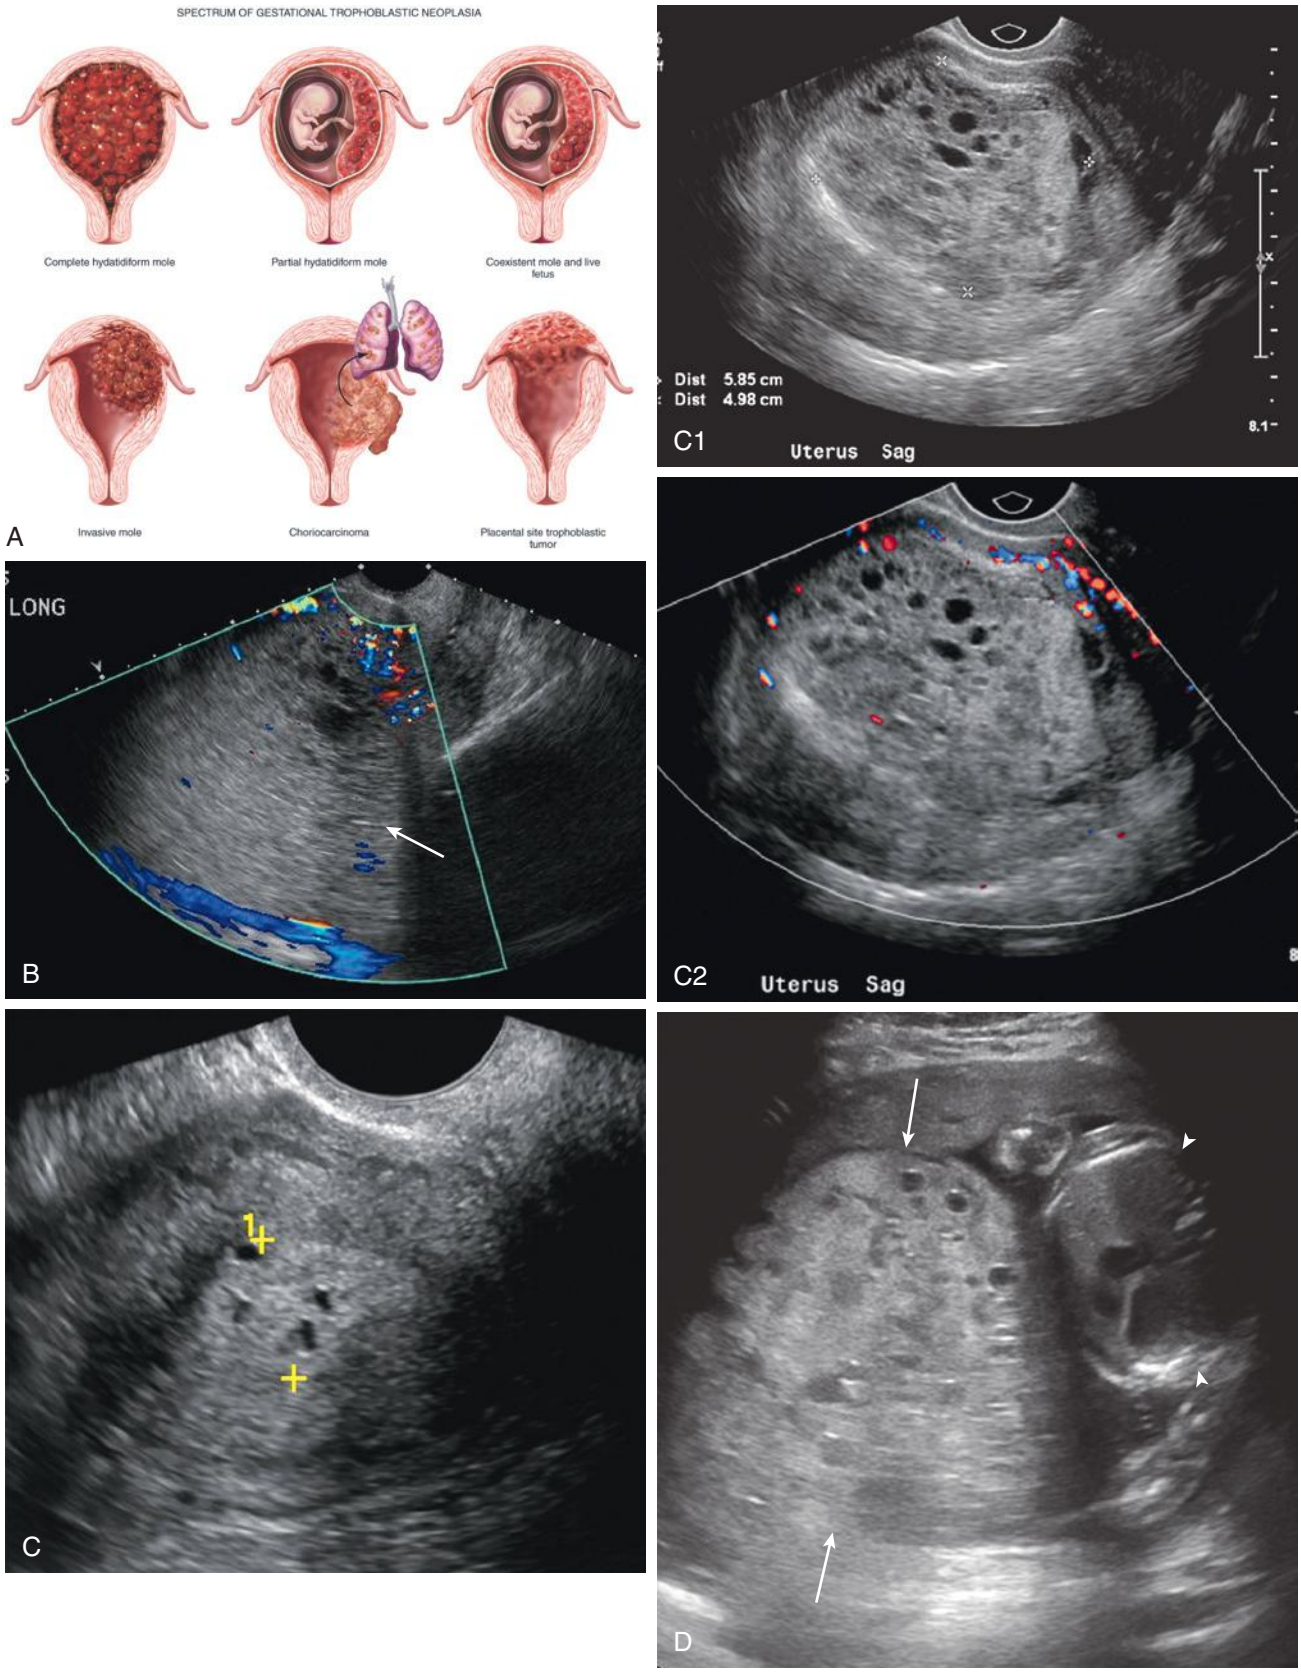


FIG 28-31 **A,** Schematic demonstrating the spectrum of gestational trophoblastic neoplasia. **B,** Transvaginal longitudinal image from a first trimester sonogram demonstrates that the endometrial cavity is distended and filled with echogenic, cystic material (*arrow*). No significant internal color Doppler flow is present. However, internal vascularity can be difficult to detect on Doppler imaging and is usually better demonstrated on magnetic resonance imaging (MRI). There were no visible fetal parts, and dilatation and curettage procedure confirmed complete hydatidiform mole (CHM). **C,** Transvaginal longitudinal image from a first trimester sonogram in another patient demonstrates decidual cysts in the endometrium (*calipers*). This patient had a normal intrauterine pregnancy. Suspicious ultrasound findings should be correlated with human chorionic gonadotropin levels before the final diagnosis. **C1,** Transvaginal sagittal image demonstrating a large mass measuring 5.85 × 4.98 cm distending the endometrial cavity with numerous cysts, the classic "cluster of grapes" appearance of a molar pregnancy. **C2,** Transvaginal color Doppler image of the same patient as in C1 does not demonstrate significant vascularity within the CHM, although a small amount of peripheral blood flow is present. **D,** Transabdominal image of 20-week twin gestation with CHM (*arrows*) and normal twin (*arrowheads*). (**C1** and **C2**, Courtesy Department of Obstetrics and Gynecology and Department of Radiology and Biomedical Imaging, Yale University School of Medicine, New Haven, CT.)

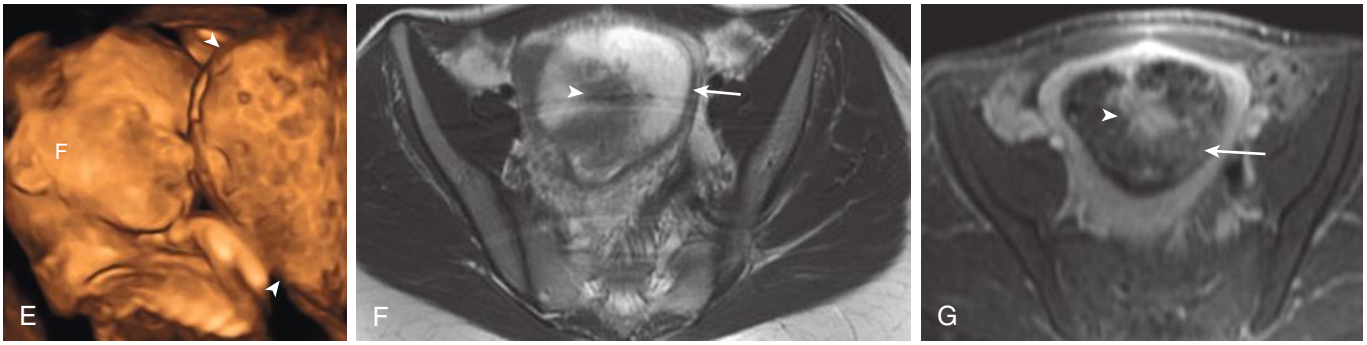

FIG 28-31, cont'd **E,** Three-dimensional sonogram demonstrating normal fetus (F) with CHM (*arrowheads*) twin gestation. **F,** Axial T2-weighted MRI image demonstrates an enlarged uterus and endometrial cavity filled with high signal cystic areas (*arrow*) with central low signal more solid-appearing tissue (*arrowhead*). **G,** Axial postcontrast fat-suppressed MRI image confirms central more solid enhancing core (*arrowhead*) and surrounding lacelike enhancement of cystic tissue (*arrow*). No extrauterine extension is seen.

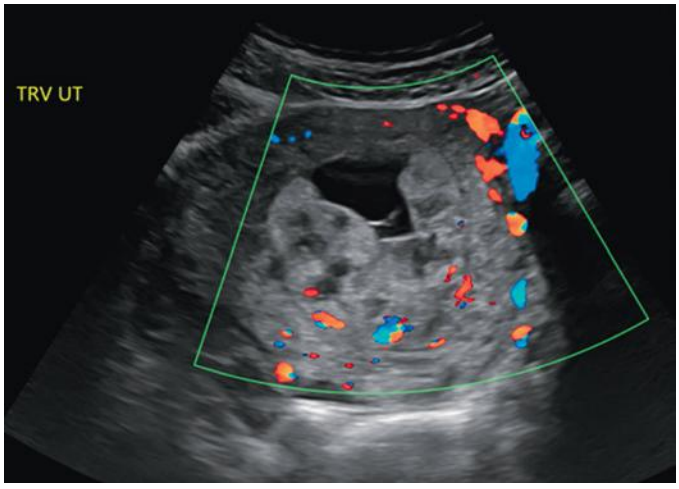

FIG 28-32 Hydropic degeneration of the placenta. This patient presented with vaginal bleeding in the late first trimester. The placenta is enlarged, echogenic, and vascular, with numerous anechoic to hypoechoic cystic areas, which raised concern for a molar pregnancy. However, upon histologic and genetic analysis, findings were consistent with hydropic degeneration of the placenta with no evidence of a molar pregnancy. (Courtesy Department of Obstetrics and Gynecology, Yale University School of Medicine, New Haven, CT.)

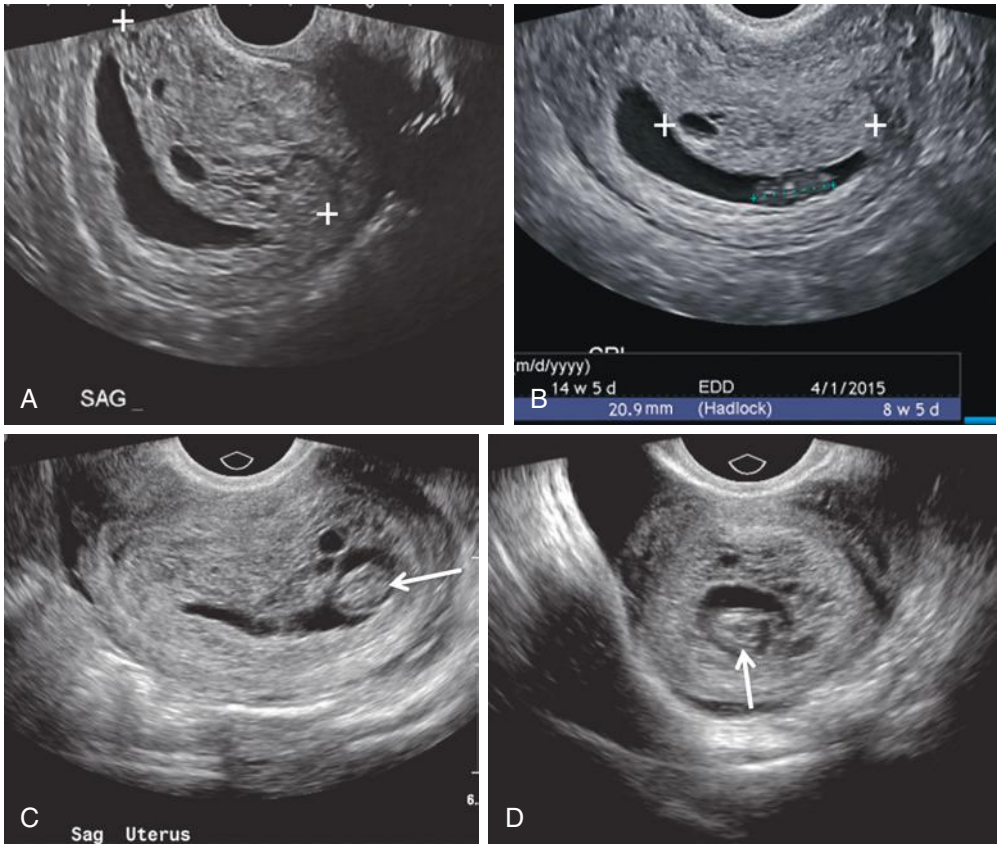

FIG 28-33 Partial molar pregnancy. **A** and **B,** Gray-scale images from a woman presenting in the first trimester for gestation dating. There is an intrauterine gestational sac containing an embryo (*dotted blue-green line* in B). The crown-rump length corresponds to an estimated gestational age of 8 weeks 5 days. Note anterior echogenic trophoblastic tissue with numerous cysts (*white calipers*). Histologic and genetic analysis revealed a partial hydatidiform mole. **C** and **D,** In a second patient with a partial hydatidiform mole, note relative thickening of the trophoblastic tissue anterior to the embryo (*arrows*). The abnormal tissue also contains numerous small cysts. (Courtesy Department of Obstetrics and Gynecology and Department of Radiology and Biomedical Imaging, Yale University School of Medicine, New Haven, CT.)

invasion and distant metastases, which are more readily detected on MRI or CT than on sonography (Fig. 28-35).

IATROGENIC PROCESSES

Arteriovenous Malformations

AVMs consist of multiple communications between the arterial and venous systems without an intervening capillary network. These lesions can be congenital, but are more often iatrogenic as a result of intrauterine instrumentation or are secondary to trauma, malignancy, or infection. Specific causes include miscarriage, therapeutic abortion, dilatation and curettage, cesarean delivery, carcinoma of the cervix or endometrium, uterine infection, trophoblastic disease, leiomyomas, endometriosis, and uterine surgery.[32] Acquired AVMs consist of multiple small arteriovenous fistulas (AVFs). Patients most often present with excessive or dysfunctional uterine bleeding, and sonography is often the first imaging study performed. Color and duplex Doppler sonography have very characteristic findings. Serpiginous cystic areas or a tangle of tubular anechoic blood vessels can be seen on gray-scale sonography; they fill in with avid flow on color or power Doppler imaging. High-velocity, low-resistance (increased end-diastolic velocity) waveforms in the feeding artery and pulsatile high-velocity flow in the draining vein are seen on spectral Doppler. These Doppler characteristics overlap in appearance with the Doppler findings in patients with GTD and RPOC, both of which histologically may also be characterized by small AVFs. Therefore, when these imaging findings are seen, GTD and RPOC should always be excluded by measuring the serum hCG level (Fig. 28-36A and B).[33,34]

Pseudoaneurysms (PSAs) may also develop as a complication of intrauterine procedures. They can be distinguished from AVMs by color and spectral Doppler imaging. A PSA will appear on gray-scale imaging as an anechoic cystic structure. On color Doppler, swirling blood flow with a "yin-yang" pattern will be observed.[33] A "to-and-fro" pattern with flow heading toward the PSA during systole and away from the PSA during diastole will be noted in the neck of the PSA on spectral Doppler interrogation.

Knowing that uterine curettage or surgical trauma can cause uterine vascular abnormalities such as PSAs and AFVs is useful when imaging patients with such clinical history and abnormal vaginal bleeding. Recognizing these lesions on imaging is important because treatment is quite different than for other causes of dysfunctional uterine bleeding. These abnormalities can be treated safely with transcatheter arterial embolization and may be worsened by uterine curettage. Acquired AVMs are reportedly easier to treat than congenital AVMs because they usually have only one or two feeding arteries. In addition, they are generally not fed by extrauterine vessels and lack a nidus, unlike congenital lesions.[33] In our experience, iatrogenic AVFs that develop following uterine instrumentation such as dilatation and

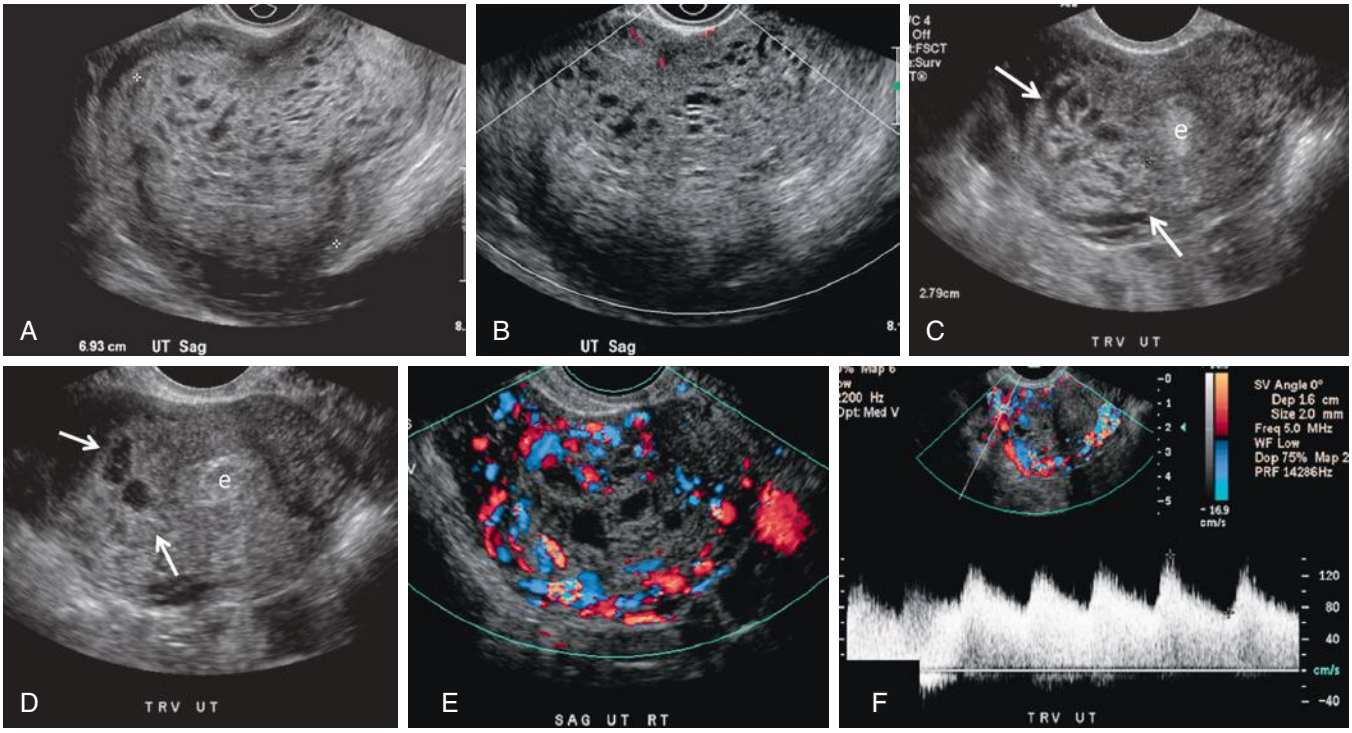

FIG 28-34 Persistent trophoblastic neoplasia (invasive mole). **A,** Sagittal gray-scale image of the uterus from a woman presenting with vaginal bleeding in the first trimester. The endometrial cavity is markedly distended by a lobular echogenic mass (*calipers*) measuring 6.93 cm containing numerous small cysts. Although the surrounding myometrium is thinned, there is no evidence of myometrial invasion. No gestational sac was identified. Findings are most consistent with a complete hydatidiform mole. **B,** Color Doppler imaging did not reveal increased vascularity within the molar tissue. Although increased vascularity is a common finding in molar pregnancies, the absence of significant Doppler-detected blood flow does not exclude the diagnosis. **C** and **D,** Six months following treatment, the patient returned with elevated serum human chorionic gonadotropin levels. Transverse gray-scale images reveal a complex myometrial mass (*arrows* and *calipers* in **C;** *arrows* in **D**) containing numerous cystic spaces and clearly separate from the endometrium (e). The endometrium (e) appeared normal. **E,** Sagittal color Doppler image reveals increased flow within the mass and in the surrounding myometrium. **F,** Spectral Doppler image demonstrates the classic "trophoblastic" waveform of gestational trophoblastic neoplasia characterized by increased peak systolic and end-diastolic velocity with a low resistive index (0.50). Findings are most consistent with recurrent, invasive gestational trophoblastic neoplasia.

curettage (D&C) rarely require treatment and most often resolve on their own. If they do not resolve and have developed a nidus, they can be difficult to treat, even with multiple attempts with UAE. In such instances, the nidus may need to be treated directly (Fig. 28-36C and D).

Intrauterine Contraceptive Devices

Contemporary intrauterine devices (IUDs) for contraception are easily visualized with transabdominal and transvaginal sonography as brightly echogenic structures with dense posterior shadowing located within the endometrial cavity. Transvaginal sonography is commonly used to evaluate placement as well as complications such as migration into the myometrium.[35] 3D sonography has been used with great success to improve visibility in technically challenging situations, as well as to confirm the specific type of IUD (Fig. 28-37), and is now considered state of the art for evaluating IUD placement at most institutions.[36] It is important that the reconstructed image is of the actual IUD and not from the shadow from the IUD.

If an IUD is not seen on sonography and history confirms placement, a pelvic radiograph should be obtained to exclude perforation and expulsion into the peritoneal cavity. Blood products as well as products of conception can obscure visualization of an IUD. Occasionally, an IUD is seen associated with an intrauterine pregnancy. Although IUDs can be easily identified during the first trimester, they are rarely visualized in the second or third trimester of pregnancy. If removal is under consideration, the relationship of the IUD to the gestational sac, whether superior or inferior to the sac, becomes important.

It is not often that sonography is used to evaluate for Essure device placement, because tubal occlusion is usually confirmed with hysterosalpingography. However, ultrasound findings can comment on the proper anatomic placement in the ostia of the fallopian tubes (Fig. 28-37F and G).

The Postpartum and Postabortive Uterus

Not infrequently, the sonologist is asked to evaluate a woman presenting with bleeding or pain in the first trimester or after delivery or therapeutic abortion. The question most commonly asked is whether or not there are RPOC or a large hematoma within the uterine cavity. A basic knowledge of the normal postpartum uterus is necessary to accurately diagnose pathologic conditions.

The normally enlarged gravid uterus begins to decrease in size several days after delivery.[37] The uterus rapidly decreases in size during the first 1 to 2 postpartum weeks and is usually back to its

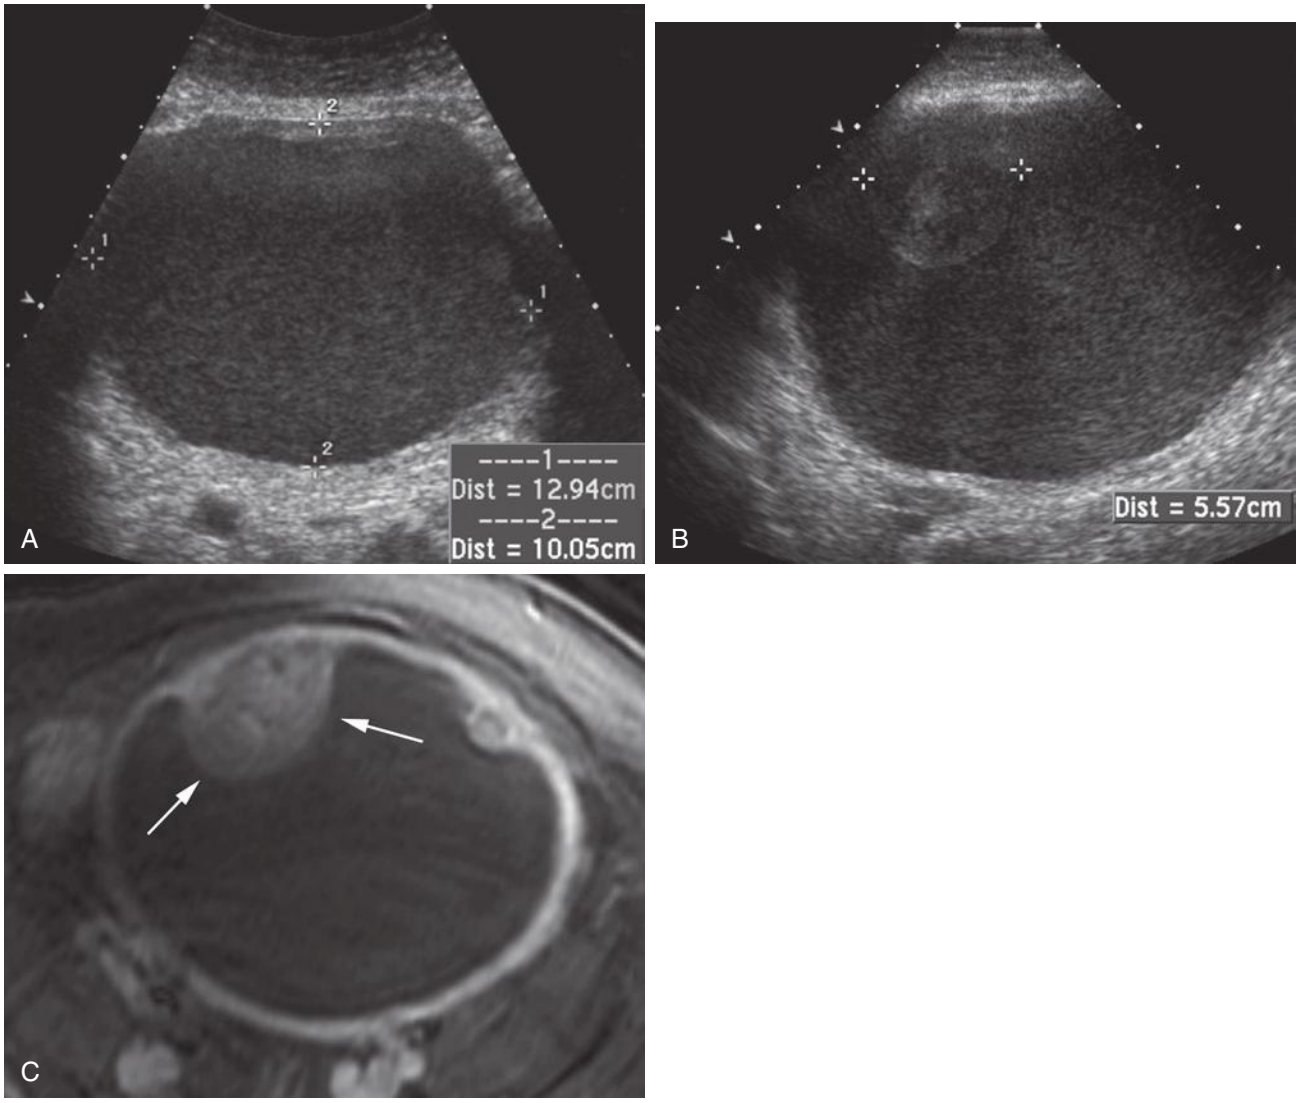

FIG 28-35 Leiomyosarcoma. Postmenopausal woman with history of stable degenerating leiomyoma. **A,** Transabdominal sonogram demonstrating cystic degeneration of a leiomyoma (*calipers*). Note low level homogeneous internal echoes and increased through transmission. **B,** Transabdominal sonogram 2 years later demonstrates a new mural nodule (*calipers*). **C,** Axial T1-weighted with fat saturation postcontrast magnetic resonance image demonstrates enhancement of the mural nodule (*arrows*). Surgical removal and pathologic examination revealed low-grade sarcoma without myometrial invasion.

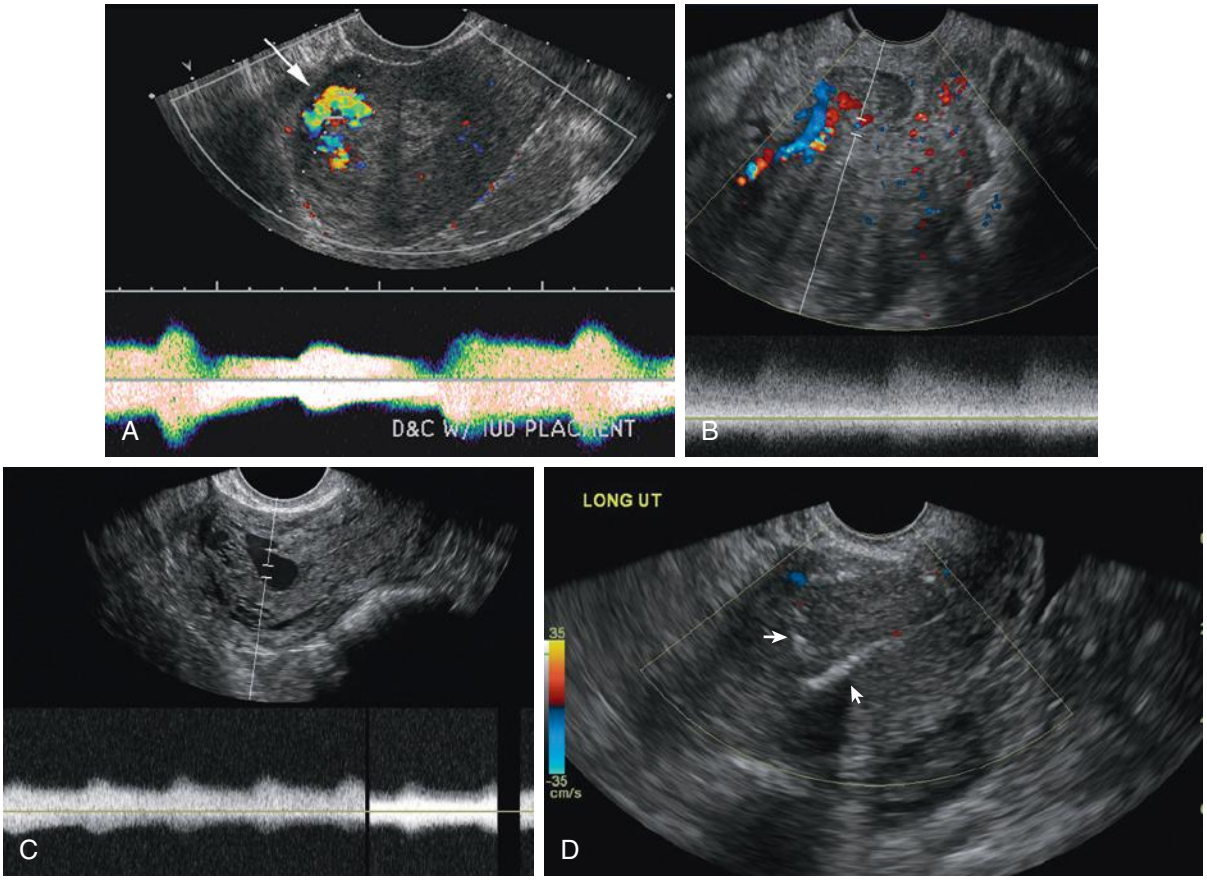

FIG 28-36 **A,** Intrauterine arteriovenous malformations (AVMs). This patient presented after dilatation and curettage (D&C) and intrauterine device placement with prolonged heavy bleeding for 1 week. Transvaginal image with color and spectral Doppler demonstrates a large fundal iatrogenic AVM (*arrow*) with characteristic low-resistance arterial flow pattern with increased systolic and diastolic flow. Gestational trophoblastic disease was excluded by negative human chorionic gonadotropin levels. **B,** Exactly similar Doppler appearance in a different patient with retained products of conception (RPOC). **C,** Transvaginal sonogram of 23-year-old woman who presented with an AVM from previous D&C with persistent vaginal bleeding following uterine artery embolization × 2. Persistent dominant vascular nidus was noted in the anterior myometrium demonstrating a high-velocity low-resistance spectral Doppler waveform. **D,** After direct treatment of the nidus as well as repeat uterine artery embolization the AVM is no longer present and the vaginal bleeding resolved. Note echogenic embolization material in the anterior wall of the uterus and endometrial canal (*arrows*).

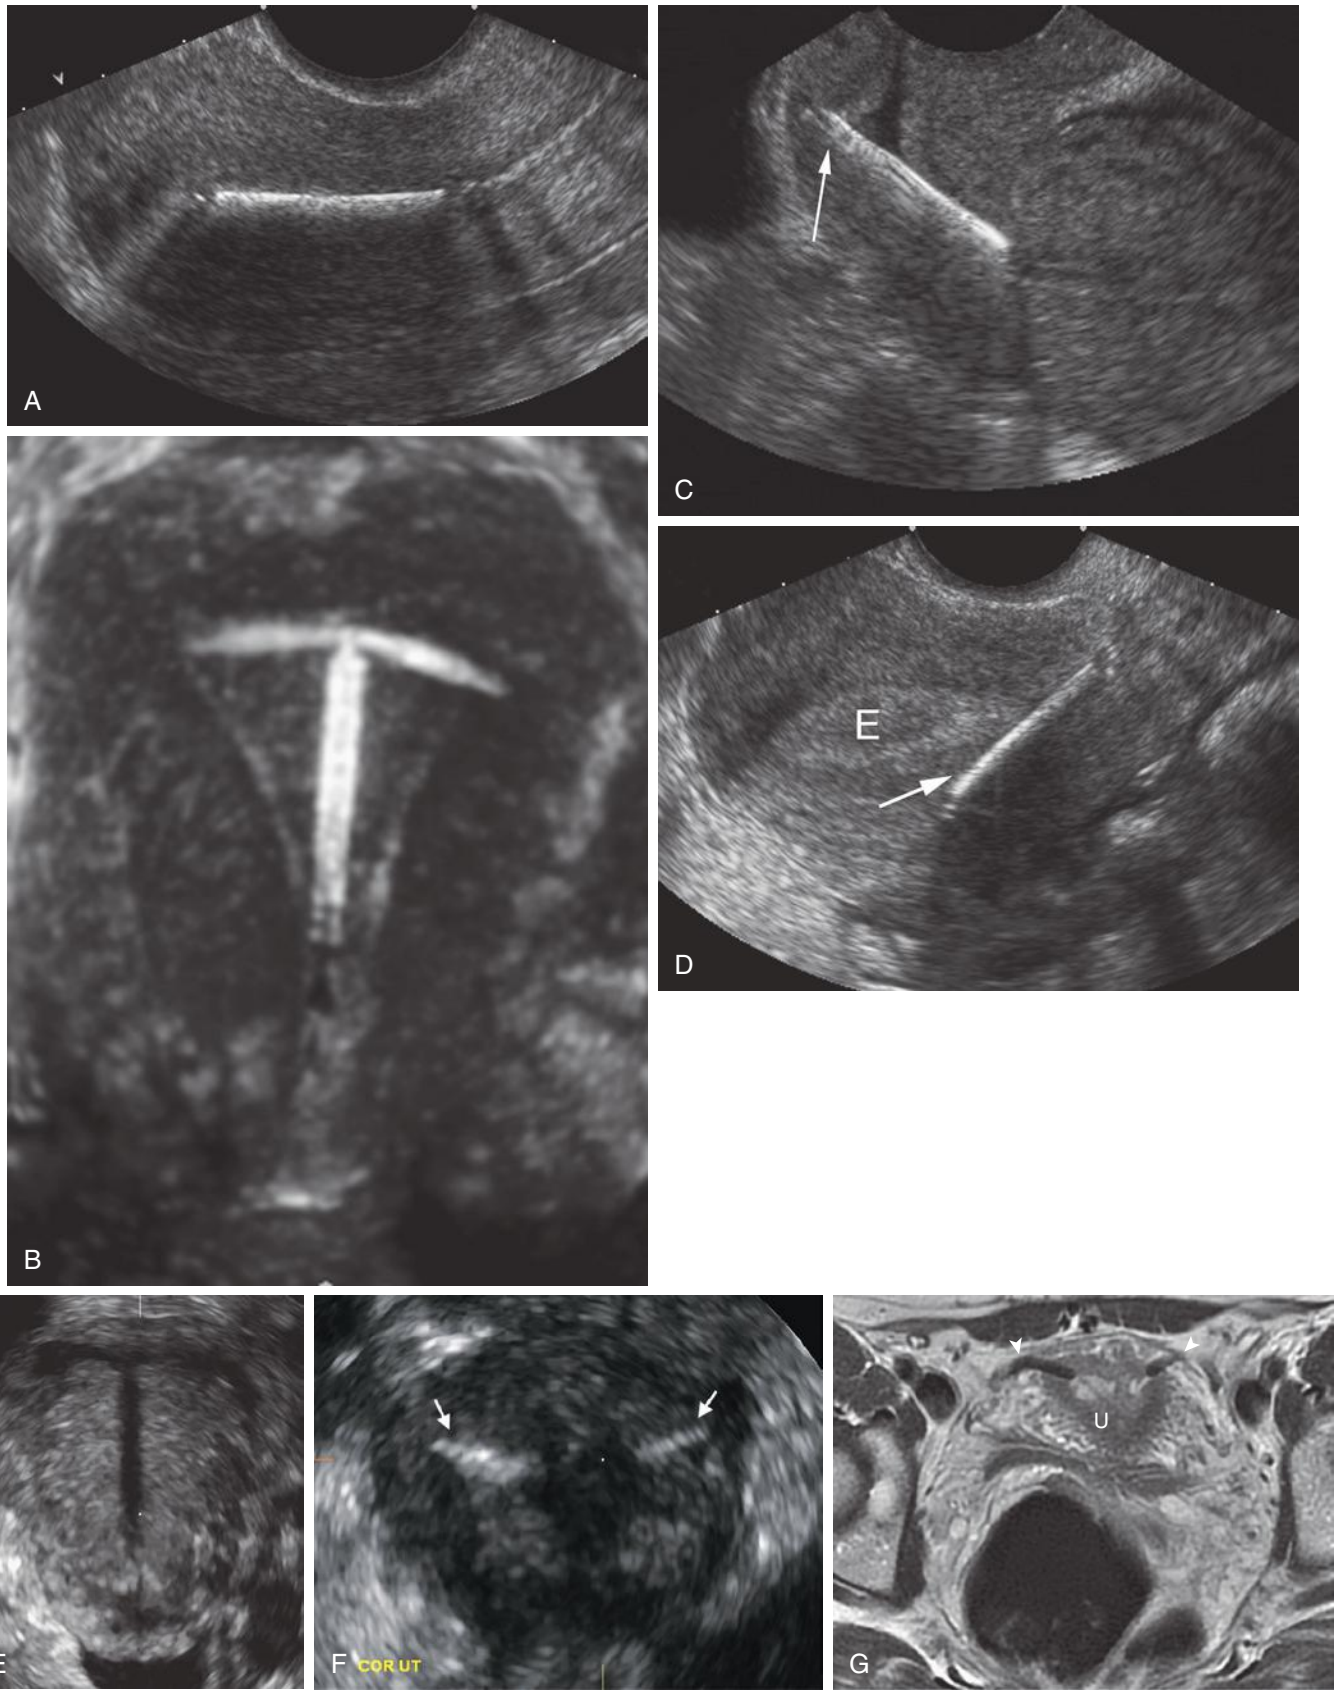

FIG 28-37 Intrauterine contraceptive devices. **A,** Transvaginal sagittal image demonstrating proper central position in the uterine fundus of an intrauterine device (IUD), which is linear and echogenic with dense posterior shadowing. **B,** Three-dimensional (3D) coronal sonogram demonstrating central positioning in the uterine fundus of an IUD. **C,** Transvaginal sonogram in a patient with a retroverted uterus demonstrating penetration of an IUD into the cervix (*arrow*). **D,** Transvaginal sonogram of an IUD extending into the posterior myometrium (*arrow*). E, endometrium. **E,** 3D coronal sonogram demonstrating reconstruction from the shadow (black contour rather than white as expected) of an IUD, which can lead to misinterpretation of the true location of the IUD. **F,** Linear, echogenic Essure devices (*arrows*) in proper position in both the right and left ostia of the fallopian tubes, seen on this 3D sonogram. **G,** Extension of the Essure devices (*arrowheads*) into the proximal portion of the fallopian tubes was confirmed on this T2-weighted axial magnetic resonance image. U, uterus.

nongravid size by 6 to 8 weeks postpartum.[37-39] The endometrium returns to its pregravid state by 3 to 6 weeks postpartum.[37] Small amounts of fluid and echogenic material (likely representing blood clot) may be seen in the normal postpartum endometrial cavity (Fig. 28-38).[37,40] Brightly echogenic foci, likely secondary to air, can also be seen within the endometrial cavity and may persist for several weeks postpartum (Fig. 28-39), particularly following cesarean delivery.[37,41]

FIG 28-38 Transabdominal sagittal sonogram in a patient 3 days postpartum presenting with more than expected residual postpartum bleeding. Fluid and tissue (*arrows*) are seen in the endometrial cavity, consistent with hemorrhage. There was no evidence of retained products of conception.

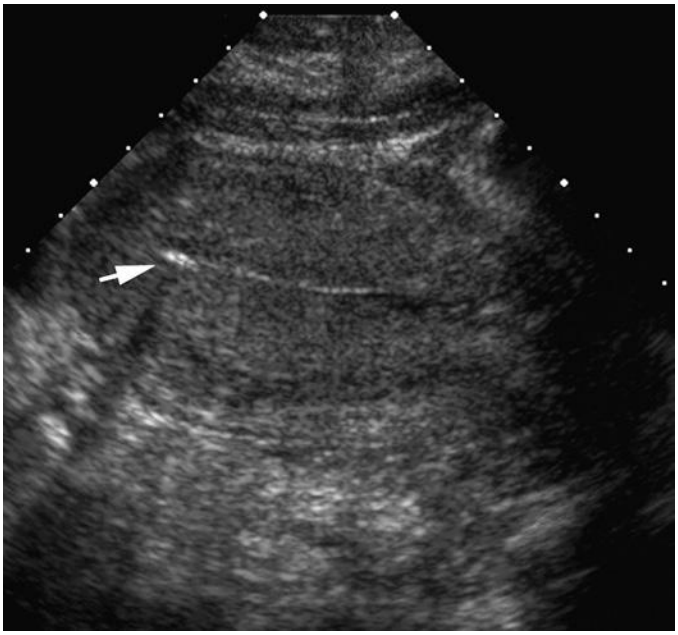

FIG 28-39 Transabdominal sagittal sonogram in a patient 1 week after cesarean delivery. Linear echogenic focus with dirty shadowing (*arrow*) consistent with air is seen within the endometrial cavity in the fundus. The endometrium was thin and normal. Air in the endometrial cavity can be a normal finding up to 2 weeks following cesarean delivery and can also be seen normally after vaginal delivery.

The thickness of the postpartum endometrium is variable, ranging in one study from a mean value of 15.8 mm on day 1 to a mean of 5.5 mm on day 28.[42]

Several studies have evaluated endometrial thickness as a potential sign of RPOC.[37,43-50] Although there does not appear to be a cutoff value above which RPOC are certain, if the endometrium is extremely thin, it is unlikely that there are RPOC. One study found that in the absence of an endometrial mass or when the endometrial thickness was less than 10 mm, RPOC were extremely unlikely.[37,50] Thus, sonography appears to be more useful in excluding the diagnosis than in accurately making the diagnosis. A focal echogenic mass is suggestive of RPOC (Fig. 28-40A and B).[37,43,51] This appearance, however, is not a specific or reliable sign, because hemorrhage or blood clot may also be echogenic.[37] Doppler sonography has proved useful in some cases to assist in the diagnosis of RPOC.[37,52] Although flow within a focal

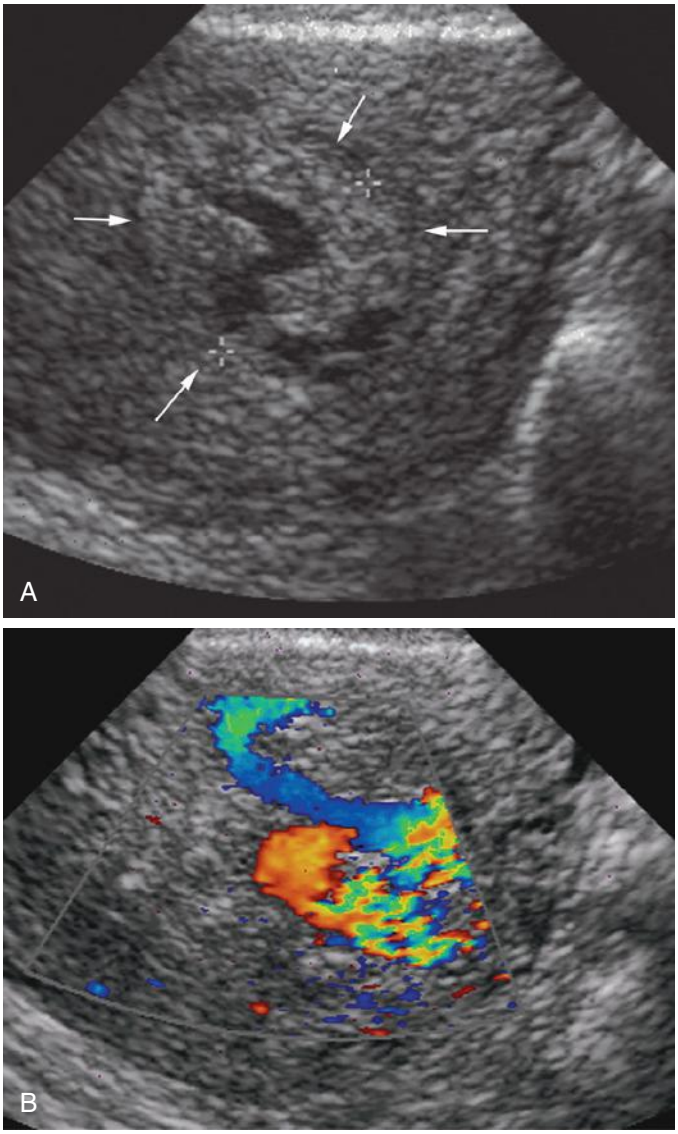

FIG 28-40 A, Sonogram from a patient with persistent bleeding following a first trimester therapeutic abortion. Tissue and fluid (*arrows*) representing retained products of conception (RPOC) are seen within the distended endometrial cavity (*calipers*). **B,** Doppler imaging of the same patient demonstrates markedly increased vascularity within the tissue consistent with RPOC.

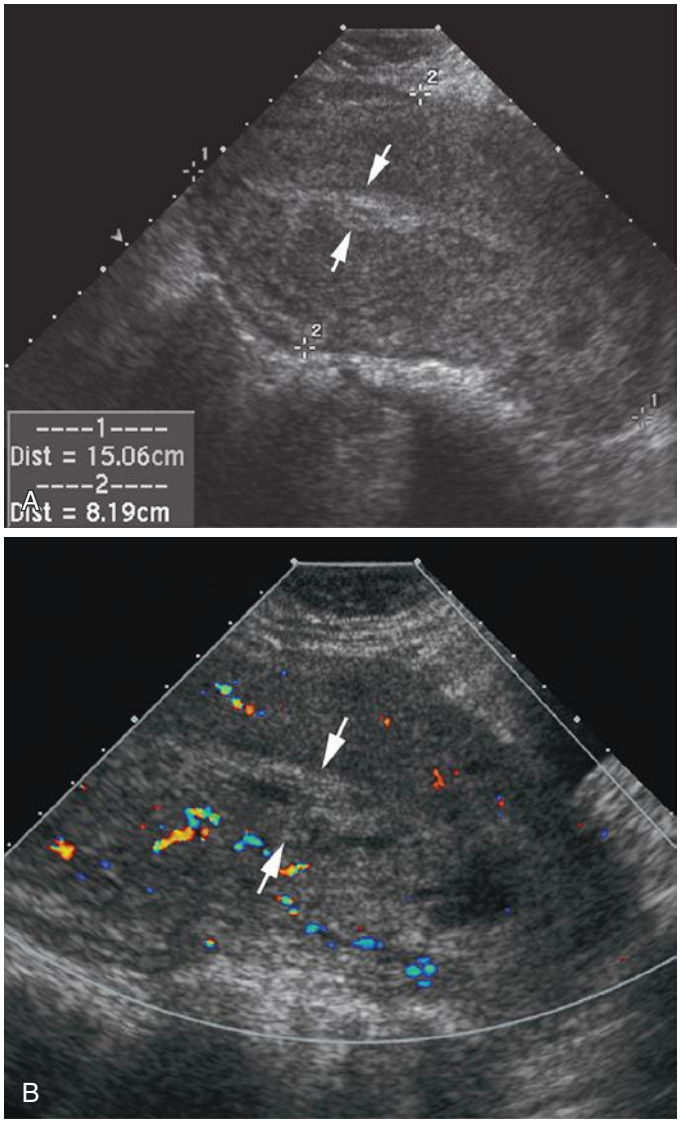

FIG 28-41 **A,** Sagittal sonogram from a patient presenting with bleeding 1 week postpartum. Tissue (*arrows*) was seen within the endometrial cavity, which is distended, measuring 15 mm. **B,** Corresponding color Doppler imaging demonstrated no evidence of blood flow within the tissue (*arrows*). This represented blood clots without retained products of conception.

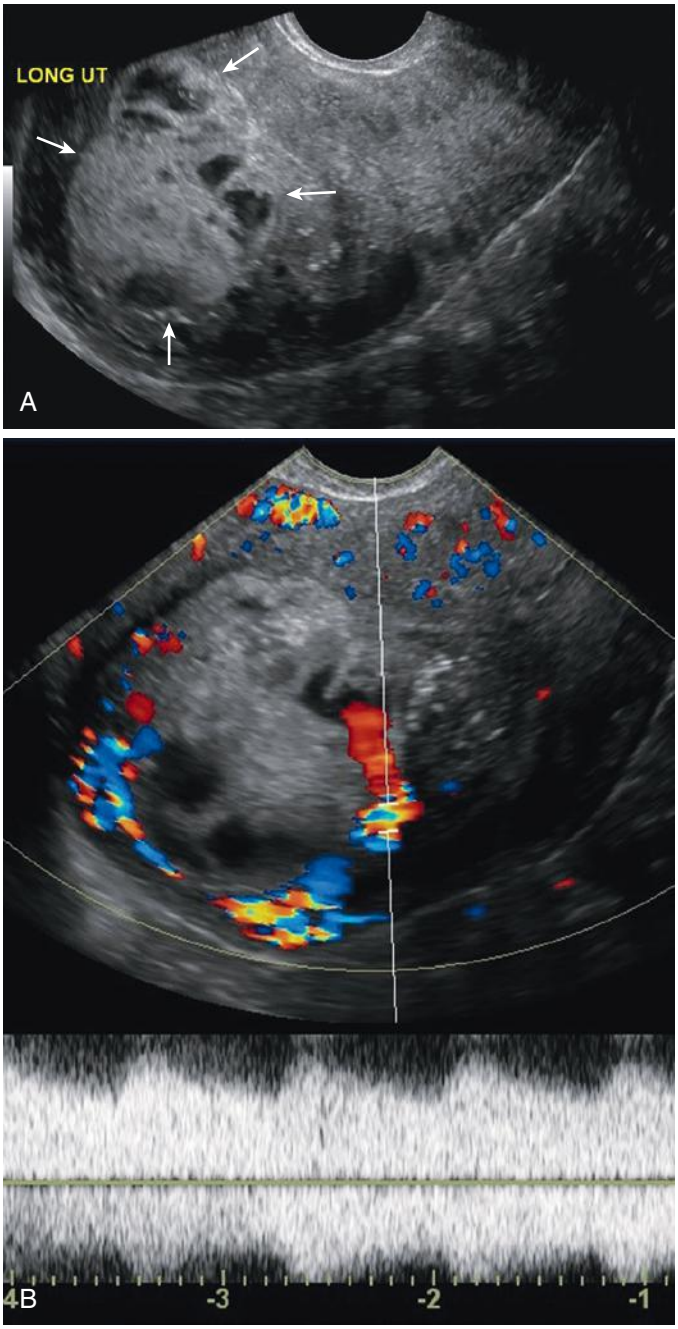

FIG 28-42 Transvaginal sagittal sonogram from a patient presenting with continuous vaginal bleeding 2 months after delivery. **A,** A complex predominantly hyperechoic solid mass (*arrows*) was seen within the uterine fundus. **B,** Doppler evaluation demonstrates high-velocity low-resistance flow. This was retained placental tissue.

intracavitary mass is suggestive of RPOC in the appropriate clinical setting, the absence of flow does not exclude the diagnosis.[37,50] Placental tissue may persist for months after delivery and be a source of persistent hemorrhage (Fig. 28-41A and B). If the placental tissue is quite sizeable, there is usually an element of placenta accreta (Fig. 28-42A and B).

In all cases of persistent vaginal bleeding in the postgravid state, when a large amount of tissue is seen within the endometrial cavity, the diagnosis of GTD should be considered, although it is much less likely than RPOC (Fig. 28-3A and B). Clinical correlation as well as correlation with serum hCG levels is often diagnostic in excluding GTD, as the hCG level is much higher with GTD than with RPOC.

In summary, we have found at our institution that there is significant overlap in the gray-scale and Doppler findings of RPOC and AVMs as well as GTD. MRI is not generally useful in differentiating between these entities. Statistically, RPOC is by far the most common of the three. Hence, every case should be addressed individually and correlated both with the patient's symptoms as well as serum hCG levels.

CERVICAL CYSTS AND POLYPS

The normal zonal anatomy of the cervix is well appreciated on transvaginal imaging. The endocervical canal and mucosa typically appear as a central echogenic linear stripe that is continuous with the echogenic endometrium in the body of the uterus. The endocervical canal is generally thin and homogeneous in appearance without variation in thickness along its length, although small cystic areas are occasionally observed, likely representing dilated glands. The subjacent fibrous cervical stroma appears as a markedly hypoechoic band of variable thickness and is continuous with the subendometrial halo in the body of the uterus. Hormonal stimulation does not appear to affect the appearance of the fibrous cervical stroma. The outer muscular cervical layer is intermediate in echogenicity and is continuous with the middle and outer layers of the myometrium (see Fig. 28-10). Nabothian cysts, retention cysts that develop secondary to obstruction of the cervical glands or crypts, are common incidental findings and are usually asymptomatic. They can be found anywhere along the length of the endocervical canal and can vary in size and number. On ultrasound images, nabothian cysts are most commonly anechoic, well-circumscribed, and avascular with increased through transmission, consistent with the sonographic appearance of simple cysts (Fig. 28-43), but internal echoes may be observed owing to mucus, debris, and rarely infection.

Endocervical polyps are most common in premenopausal women over the age of 20 years who have been pregnant. The exact cause is not known, but chronic inflammation and elevated estrogen levels have been reported to be predisposing factors. Patients may present with vaginal bleeding, although many are asymptomatic. On ultrasound images, an endoluminal cervical mass will be identified. The presence of vascularity or a vascular stalk will differeniate endocervical polyps from debris, blood clot, or a mucous plug (Fig. 28-44). If large, an endocervical polyp may obstruct the endocervical canal, resulting in hydrometrocolpos, or may prolapse into the vagina. Cervical leiomyomas appear on ultrasound images as well-circumscribed masses of variable echogenicity and are typically relatively avascular. They most commonly arise from the muscular layer and, hence, are most commonly exophytic and separate from the endocervical canal (Fig. 28-45). However, the sonographic appearance of cervical leiomyomas is nonspecific and may mimic the sonographic appearance of cervical carcinoma.

Ultrasound imaging does not play a significant role in the screening, diagnosis, or staging of cervical carcinoma. Screening and diagnosis are performed effectively with Pap (Papanicolaou) smear and cone biopsy, with subsequent staging performed clinically according to the International Federation of Gynecology and Obstetrics (FIGO) staging system (see Chapter 36). If further imaging is required, it is usually performed with MRI to assess extent of local disease and lymph node involvement, or with CT to assess for lymphadenopathy and distant metastases. However, sonography may occasionally be the first imaging modality performed in a patient who presents with vaginal bleeding or pelvic pain and can also be used to assess complications. On ultrasound images, cervical cancer will appear as a mass of variable echogenicity. Although tumors may be well defined and sharply marginated, especially if small and early stage, cervical cancers will often infiltrate and obliterate the normal zonal anatomy of the cervix, and in particular distort the endocervical canal, which is where cervical cancers originate. Differentiating a small, well-circumscribed cervical cancer from a cervical leiomyoma on ultrasound imaging is extremely difficult, although increased vascularity and heterogeneity favor the diagnosis of a cervical cancer. Larger masses may obstruct the endocervical canal, resulting in hydro- or hematometrocolpos, and irregularity of the outer margin suggests parametrial invasion (Fig. 28-46).

CONCLUSIONS

Sonography remains the first-line and most valuable imaging modality for the evaluation of uterine anatomy, as well as most benign and malignant processes of the myometrium. However, imaging findings should always be correlated with the clinical scenario. If the ultrasound findings remain equivocal, MRI is recommended as the next imaging modality of choice in most cases. Correlation of imaging findings between the two modalities and expertise of the reader remain paramount for achieving an accurate diagnosis.

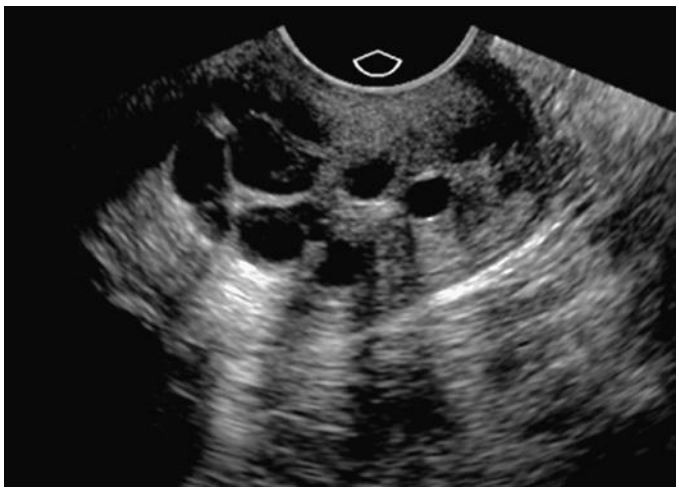

FIG 28-43 Nabothian cysts. Note numerous anechoic cysts of varying sizes along the length of the cervix, several demonstrating increased through transmission.

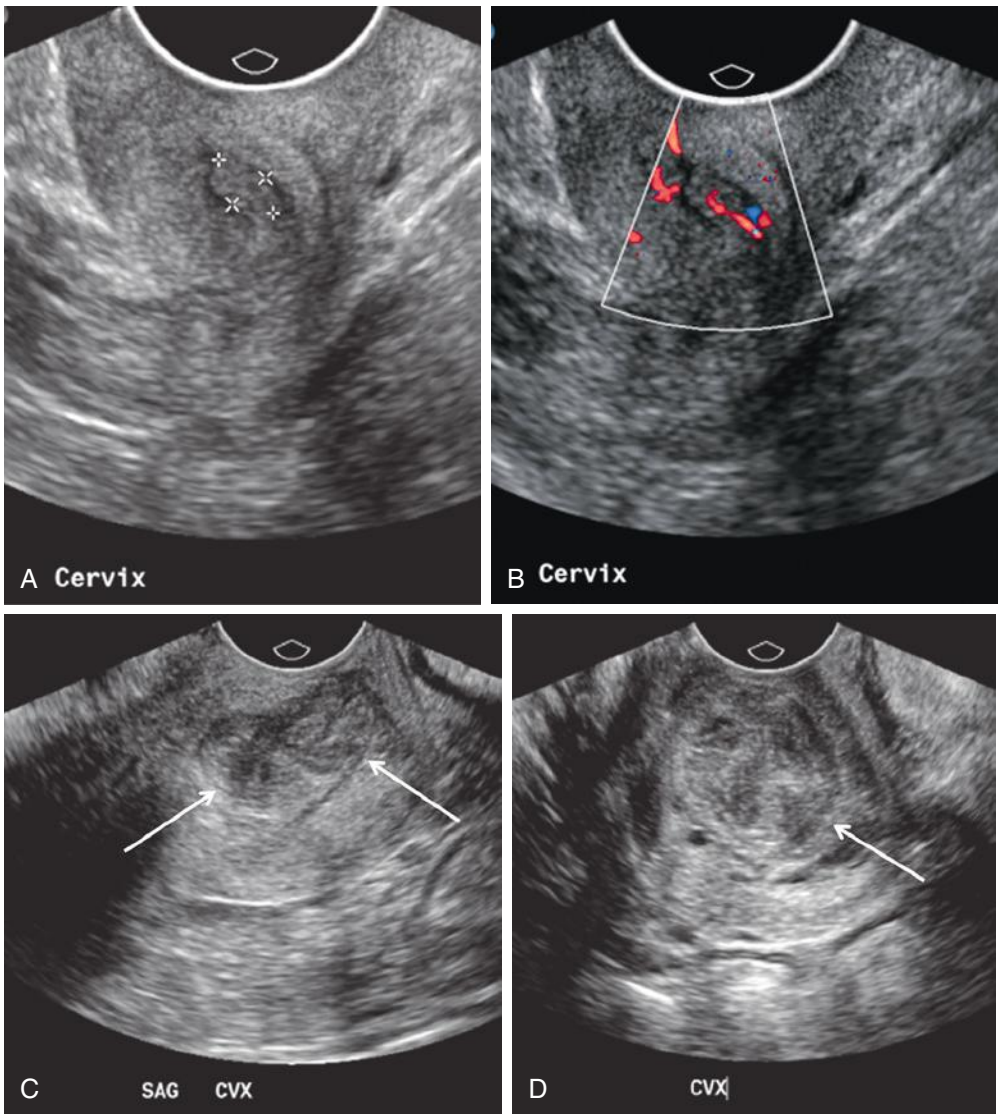

FIG 28-44 Endocervical polyps. **A,** Transvaginal gray-scale image of the cervix demonstrates a small mass (*calipers*) within the endocervical canal. The differential diagnosis includes blood clot, mucous plug, and debris as well as endocervical polyp. **B,** Corresponding color Doppler image reveals internal vascularity and a feeding vessel, confirming that this is a soft tissue mass, most likely an endocervical polyp rather than blood clot or mucous plug. **C** and **D,** Sagittal and transverse transvaginal gray-scale images of the cervix from another patient with a large, slightly heterogeneous endocervical polyp (*arrows*) distending the endocervical canal.

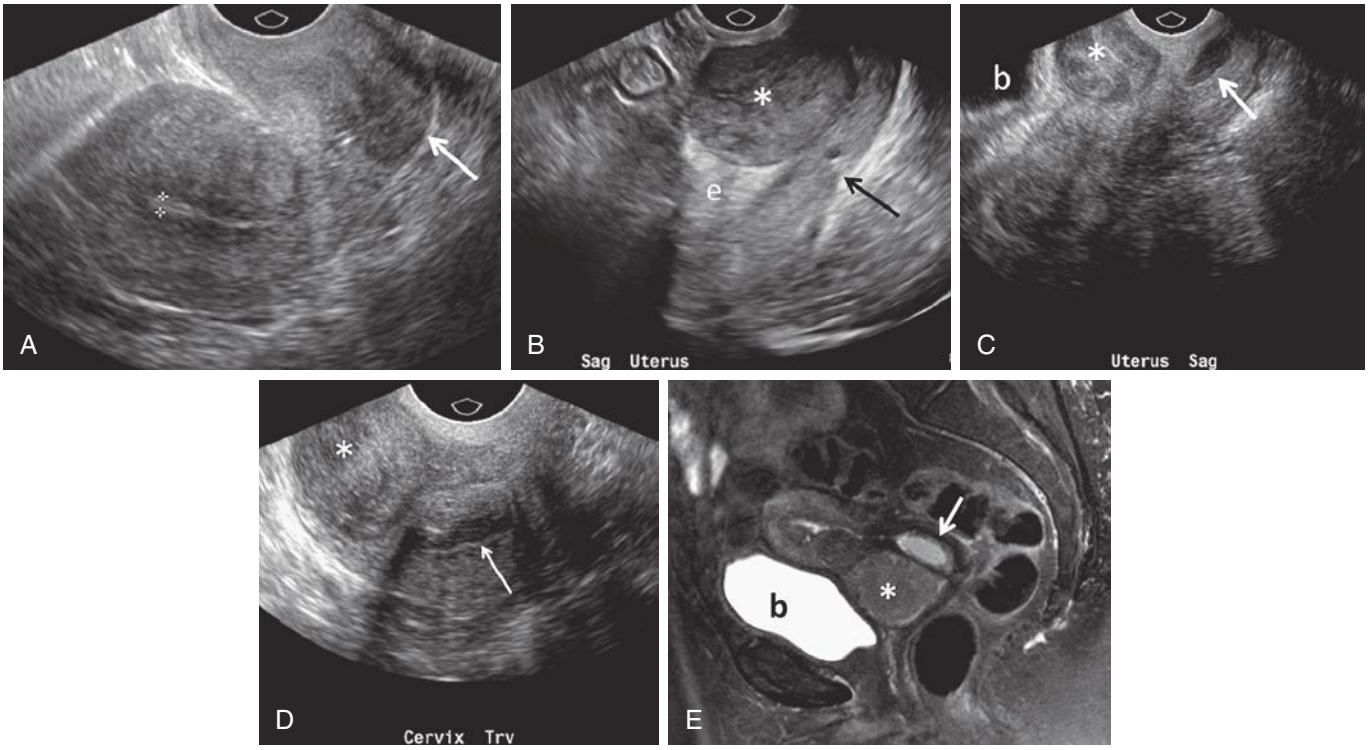

FIG 28-45 Cervical leiomyomas. **A,** Note hypoechoic mass (*arrow*) arising within the posterior wall of the cervix but separate from the endocervical canal, which appears normal, suggesting that this is not a cervical carcinoma but a lesion arising from the muscular layer of the cervix. Note normal endometrium (*calipers*). **B,** Large exophytic mass (*asterisk*) arising from the anterior wall of the cervix but extending into the lower uterine segment in a second patient with a cervical leiomyoma. There is a small anechoic nabothian cyst in the posterior wall of the cervix, just below the level of the internal os (*arrow* at indentation between the lower uterine segment and upper cervix). e, endometrium. **C** and **D,** Sagittal and transverse transvaginal gray-scale images from a third patient with an exophytic cervical leiomyoma (*asterisks*) that is clearly separate from the endocervical canal, which is distended with anechoic fluid (*arrows*). This cervical leiomyoma also extends into the lower uterine segment. b, bladder. **E,** Sagittal T2-weighted fat saturation magnetic resonance image of the same patient as in C and D demonstrates similar findings. Low signal intensity cervical leiomyoma (*asterisk*) extends into the lower uterine segment; endocervical canal is distended with high signal intensity fluid (*arrow*). b, bladder.

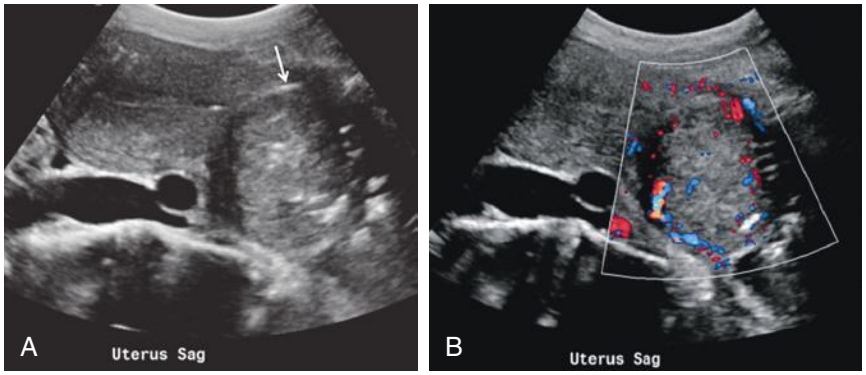

FIG 28-46 Cervical carcinoma. Sagittal gray-scale (**A**) and color Doppler (**B**) images of the uterus reveal a heterogeneous well-defined, sharply marginated vascular cervical mass compressing the iliac vessels posteriorly. The endocervical canal (*arrow* in **A**) is displaced anteriorly and partially obliterated, suggesting that the mass might have originated from the endocervical canal. There is no evidence of parametrial invasion nor is there extension into either the lower uterine segment or vagina, although the mass is large. However, the sonographic appearance is nonspecific and could be mimicked by a cervical leiomyoma.

Evaluation of Pelvic Pain in the Reproductive Age Patient

Genevieve L. Bennett

SUMMARY OF KEY POINTS

- Pelvic pain in the reproductive age patient often presents a diagnostic challenge as there are many causes, including both gynecologic and nongynecologic disorders with overlap in clinical symptoms.
- Pregnancy status must always be determined to exclude a pregnancy-related complication, particularly ectopic pregnancy.
- Pelvic sonography is the well-established first-line imaging method of choice and may require both a transabdominal and transvaginal approach to increase diagnostic accuracy.
- Computed tomography (CT) and magnetic resonance imaging (MRI) may be of added value in evaluation of pelvic pain when ultrasound findings are not definitive.
- Adnexal torsion cannot be excluded in the presence of preserved ovarian blood flow, and gray-scale features along with the clinical picture are more reliable in making this diagnosis.
- Hemorrhagic ovarian cysts demonstrate a wide spectrum of sonographic appearances that may overlap with those of other complex cystic masses, and if greater than 5 cm these cysts may require follow-up imaging to confirm resolution.
- Endometriosis may demonstrate variable sonographic findings and cause both chronic and acute pelvic pain if there are associated complications.
- Most leiomyomas are benign; however, atypical imaging features should prompt further evaluation to exclude the possibility of a malignant uterine neoplasm.
- Focal adenomyosis may mimic myomas sonographically, and MRI can be helpful for more definitive characterization.
- Many nongynecologic causes of pelvic pain, including gastrointestinal and genitourinary disorders, may be identified when ultrasound examination is performed for suspected pelvic disease, and recognition of these disorders may enable prompt diagnosis and eliminate the need for further imaging.

OUTLINE

Pelvic ultrasound imaging is the well-established first-line imaging method of choice for evaluation of pelvic pain in the reproductive age patient when a gynecologic or obstetric disorder is suspected.[1] Ultrasound imaging is widely available; allows for high-resolution, dynamic real-time evaluation of the uterus, adnexa, and adjacent structures; is relatively low cost; and, importantly, involves no exposure to ionizing radiation. A transvaginal approach should be utilized whenever possible because it yields improved visualization of pelvic anatomy. This approach should be supplemented with transabdominal imaging when uterine or adnexal structures are beyond the field of view of the transvaginal probe or if an abnormality outside the pelvis is suspected. Occasionally, a transvaginal examination may not be tolerated and only a transabdominal scan can be performed. Duplex and color or power Doppler sonography are essential adjuncts to gray-scale imaging. Although CT may be more useful for evaluation of gastrointestinal or genitourinary disease, because of considerable overlap in clinical symptoms and laboratory findings, these disorders may not initially be suspected, and pelvic sonography should be the first imaging study performed. However, many of these nongynecologic disorders can also be recognized by sonography, and if a diagnosis is established

sonographically, further imaging may not be necessary. In the pregnant patient, ionizing radiation should be avoided when possible, and sonography plays an even greater role.

When a patient complains of pelvic pain, it is critical to establish her pregnancy status as this information will help to narrow the differential diagnosis and direct an appropriate imaging workup. In the pregnant patient with pelvic pain, ectopic pregnancy is often the leading concern, and this important topic is covered in Chapter 33. The primary focus of this chapter is the ultrasound evaluation of pelvic pain in the nonpregnant patient, although the impact of pregnancy on some disorders that cause pelvic pain is discussed when appropriate. Both gynecologic and nongynecologic causes of pelvic pain are reviewed. Disorders that may cause acute or chronic pelvic pain (or both), and conditions that can be medically managed as well as those that require urgent surgical intervention are included. The added value of other imaging modalities in the evaluation of pelvic pain, including CT and MRI, is also addressed.

ADNEXAL CAUSES OF PELVIC PAIN

Adnexal Torsion

Adnexal torsion occurs when there is partial or complete rotation of the adnexal structures around their vascular pedicle with associated obstruction of venous outflow and arterial inflow. The true incidence of this disorder is unknown as the diagnosis is made definitively only during surgery. It is estimated that up to 3% of female patients with acute pelvic pain who come to the emergency department have adnexal torsion.[2,3] Adnexal torsion may involve either the ovary or the fallopian tube or both when they twist around the infundibulopelvic ligament and tubo-ovarian ligament. Concomitant ovarian and tubal torsion has been shown to occur in up to 67% of cases.[4] Twisting of the vascular pedicle initially leads to compromise of lymphatic and venous outflow, resulting in diffuse ovarian edema and enlargement. Arterial inflow may initially be sustained because the arteries have thicker, muscular walls and are less collapsible.[5] If left untreated, arterial thrombosis, ischemia, and ultimately infarction and necrosis of the ovary occur. Early diagnosis and surgery are essential to salvage the viable ovary. Predisposing factors for adnexal torsion include an ipsilateral adnexal mass (particularly if larger than 5 cm), pregnancy, ovulation induction, polycystic ovary syndrome, prior pelvic surgery (including tubal ligation), and hypermobility of the adnexal structures (more common in children and adolescents).[3,6,7]

Adnexal torsion may occur at any age, although it occurs predominantly in reproductive age women, most likely because of increased incidence of both physiologic and pathologic ovarian masses. However, up to 24% of cases occur in postmenopausal women.[7] There is a reported higher frequency on the right, perhaps because the sigmoid colon is a relatively fixed structure occupying the left pelvis, which helps to prevent torsion of the left ovary and adnexa. An adnexal mass is reported to be present in 22% to 73% of cases.[6] Large simple cysts and cystic neoplasms such as benign cystic teratomas, hemorrhagic cysts, and cystadenomas are the most commonly associated masses. Large ovaries in the setting of ovarian hyperstimulation are another predisposing factor. The absence of associated ovarian abnormality is more common in premenarchal girls, with 46% of cases of torsion involving normal-appearing ovaries.[3] Potential causes in these patients include increased mobility of the fallopian tubes and mesosalpinx, elongated pelvic ligaments, fallopian tube spasm, strenuous exercise, or abrupt changes in intra-abdominal pressure.[5] Approximately 10% to 25% of cases of adnexal torsion occur during pregnancy, with an incidence of 1:1000 pregnancies, most commonly in the first trimester.[8-10] Torsion is less likely to occur in the setting of pelvic inflammatory disease (PID), endometriosis, or malignant neoplasms because in these conditions associated adhesions serve to fix the pelvic structures in place.[3]

The clinical presentation of adnexal torsion is variable and may overlap with other causes of acute abdominal or pelvic pain, such as a ruptured ovarian cyst or appendicitis, leading to a diagnostic challenge.[3,11] Classically, patients present with sudden acute onset of intense lower abdominal and pelvic pain, with a palpable painful adnexal mass and peritoneal signs. Additional symptoms may include nausea, vomiting, flank pain, and fever with a slight leukocytosis. A pregnancy test should be performed to exclude the possibility of a pregnancy-related complication such as ectopic pregnancy. The pain may be constant or intermittent, due to intermittent torsion and detorsion of the adnexa, and the intensity of pain experienced may vary with the degree of torsion or traction on the twisted pedicle. When symptoms are intermittent, the diagnosis is even more challenging. A high degree of clinical suspicion is necessary to avoid treatment delay and irreversible damage to the adnexa. Pain that lasts for more than 10 hours is associated with increased likelihood of adnexal necrosis at surgery.[12]

If a patient presents with pelvic pain, and adnexal torsion is suspected, prompt emergent pelvic sonography, including gray-scale, color, and spectral Doppler, is the imaging study of choice. However, as with the clinical diagnosis, the sonographic diagnosis may be challenging because the findings vary with degree and duration of torsion, involvement of the fallopian tube, and the presence of an associated mass.[6,13] The most consistently reported gray-scale ultrasound finding is the presence of a unilaterally enlarged ovary, usually larger than 4 cm, with or without an associated mass[4,5,7,14-17] (Figs. 29-1 and 29-2). Houry and Abbott found that in a series of 87 cases of torsion, the mean ovarian size was 9.5 cm, with 89% measuring greater than 5 cm.[16] In a study by Chiou and colleagues, an underlying mass was found in 65% of 34 cases of adnexal torsion and a large ovary without a mass in 32% of cases.[7] An additional ultrasound finding is the presence of multiple peripherally located small follicles in the enlarged hypoechoic ovary, the "string of pearls" sign (see Fig. 29-1), which is thought to occur as a result of peripheral displacement of the ovarian follicles secondary to stromal edema and venous congestion,[5] although the reported incidence of this finding varies.[7,14,18] In more longstanding cases, the ovarian stroma may become more heterogeneous in echotexture because of foci of hemorrhage or necrosis. Comparison with the asymptomatic ovary is often helpful in recognizing these findings. An abnormal position of the ovary, which may be located in the midline either superior to the uterus or inferiorly in the pouch of Douglas, or displacement to the contralateral side of the pelvis is an important observation (see Figs. 29-1 and 29-2). The twisted and congested vascular pedicle may appear as an ill-defined adnexal mass adjacent to the torsed ovary. In cross section, it may demonstrate a target appearance with alternating hyperechoic and hypoechoic bands, the so-called "whirlpool" sign[15] (see further discussion later). The amount of associated free fluid around the ovary or in the cul-de-sac is variable, but free fluid is observed in up to 87% of cases.[5]

A more recently described gray-scale sign of ovarian torsion is the *follicular ring sign*. A follicular ring is defined as a perifollicular hyperechoic rim, 1 to 2 mm in thickness, seen surrounding the small (3 to 7 mm) peripheral antral follicles of the torsed ovary[19] (Fig. 29-3). In a series of 15 patients with surgically proven torsion, Sibal observed the follicular ring sign in 12, the whirlpool sign in 7, and absent ovarian blood flow in 7.[19] The follicular ring sign was the only sonographic finding in 4 patients. On microscopic examination, the follicular rings were found to be areas of hemorrhage and edema surrounding the antrum of small follicles. The authors caution that this sign may not

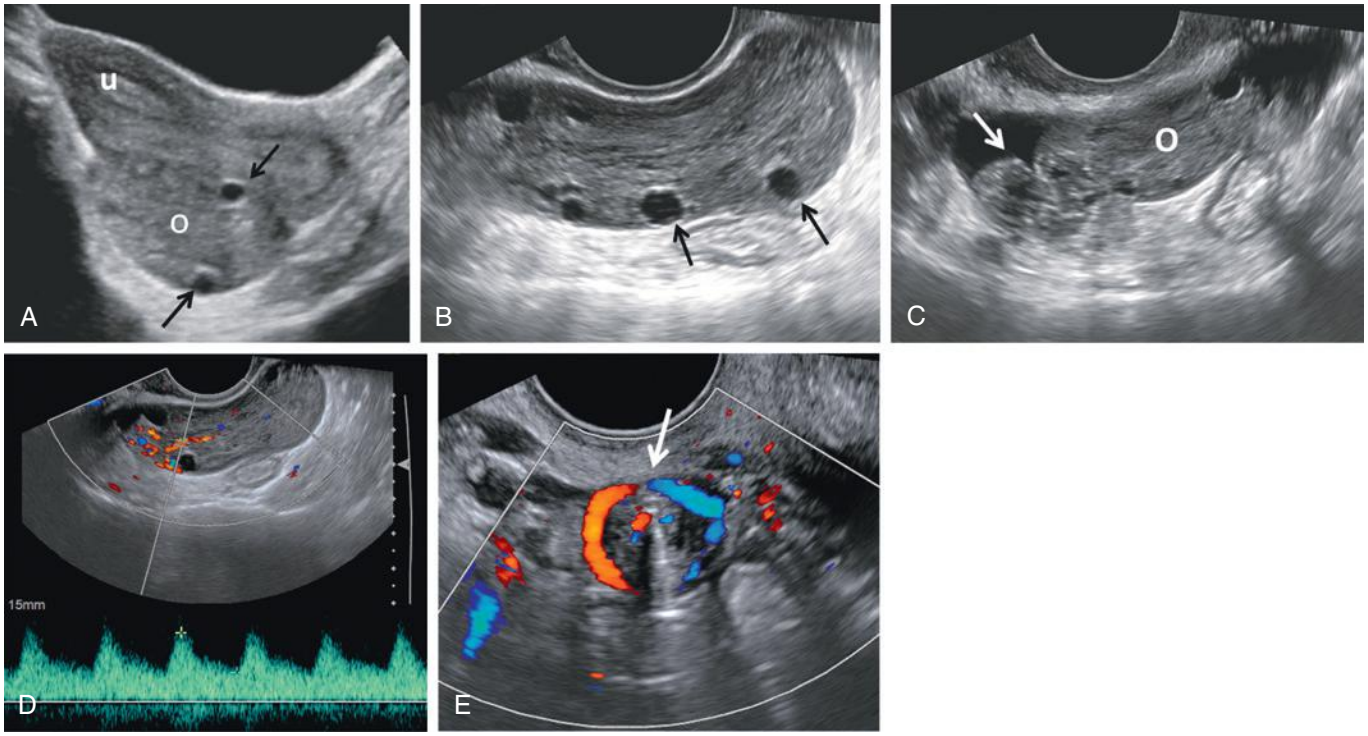

FIG 29-1 Ovarian torsion without associated mass and viable ovary. **A,** Transabdominal scan demonstrates the enlarged ovary (o) containing multiple peripherally arranged follicles (*arrows*). The ovary is located posterior to the uterus (u) midline in the cul-de-sac. **B,** At transvaginal evaluation, the ovary is enlarged and edematous with heterogeneous echotexture and peripherally located follicles (*arrows*), the "string of pearls" sign. **C,** Thickened congested vascular pedicle (*arrow*) is noted lateral to the ovary (o). There is a small amount of adjacent free fluid. **D,** Arterial flow to the ovary is preserved, shown with color and spectral duplex Doppler sonography. **E,** Whirlpool appearance of vascular pedicle (*arrow*) on color Doppler sonogram.

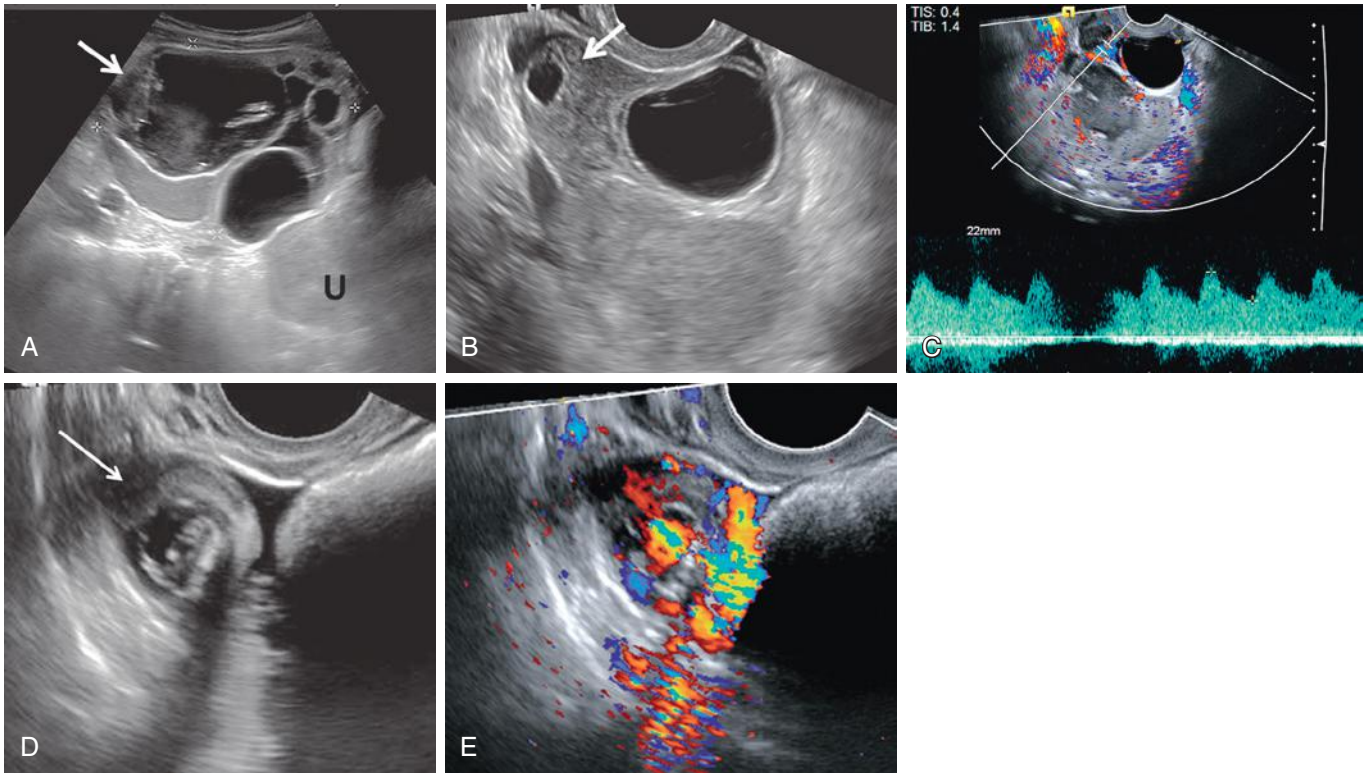

FIG 29-2 Ovarian torsion with mucinous cystadenoma and viable ovary. **A,** Transabdominal scan demonstrates large multiloculated complex cystic mass (*arrow* and *calipers*) located superior to the uterus (U). **B,** Transvaginal scan demonstrates edematous ovarian tissue around the mass with peripheral follicle (*arrow*) and a small amount of adjacent free fluid. **C,** Arterial and venous flow to the ovary are preserved, shown on color and spectral Doppler sonogram. **D,** Gray-scale image of twisted pedicle with "target" appearance (*arrow*). **E,** "Whirlpool" appearance of vascular pedicle on color Doppler sonogram.

be seen if the ovary is necrotic or if a large cyst or mass compresses the follicles.

In addition to gray-scale findings, color and spectral Doppler evaluation is an important component of the pelvic ultrasound examination in the assessment of adnexal torsion. As with gray-scale imaging, Doppler findings vary with the degree of torsion, time course, and vascular compromise. Absence of detectable blood flow in the affected ovary allows for a confident diagnosis, with a positive predictive value (PPV) of 94% in one series.[20] However, this is a late finding and suggests that there has already been infarction and that the ovary is no longer viable (Fig 29-4). It may be difficult to detect flow if the ovary is mostly replaced by a large mass, and in this setting an attempt should be made to identify and search for flow in the rim of ovarian parenchyma around the mass. Many reports in the literature have shown that the detection of flow in an ovary on color and spectral Doppler sonography cannot exclude the presence of torsion. The dual arterial supply to the ovary may allow for early preservation of arterial flow, with initial loss of venous flow, although if the torsion is early, intermittent, or only partial, both arterial and venous flow may be preserved (see Figs 29-1 and 29-2). In a study by Mashiach and associates[21] 13% of women with laparoscopically proven ovarian torsion had normal ovarian blood flow on Doppler. In a study by Chiou and colleagues[7] arterial and venous flow was considered normal in 19% of cases of proven torsion. Bar-On and coworkers[22] reported abnormal ovarian flow on Doppler sonography in only 43.8% of ovarian torsion cases, with a specificity of 91.7%. Shadinger and associates[17] reported preserved arterial flow in 54% and preserved venous flow in 33% of cases in a series of 39 patients with pathologically proven ovarian torsion. Other reports have also demonstrated that Doppler findings can be normal in 45% to 61% of cases of ovarian torsion.[9,23,24] However, analysis of spectral Doppler waveforms may increase sensitivity for the diagnosis of torsion. An arterial waveform with reversal of diastolic flow, a high resistance pattern, may suggest the diagnosis.[25] Recently, an abnormal discontinuous pattern of venous flow has been suggested as a clue to the presence of ovarian torsion when arterial and venous flow is preserved,[26] although this result has not been reproduced in larger studies. In general, the gray-scale findings as well as the clinical picture are thought to be more reliable than Doppler in the diagnosis of adnexal torsion.

A twisted vascular pedicle or "whirlpool sign" is an additional gray-scale and color Doppler finding useful for the diagnosis of adnexal torsion (see Figs. 29-1 and 29-2). The twisted vascular pedicle is the rotation site of the pedicle on itself and appears as a round or beaked mass with concentric alternating hyperechoic and hypoechoic circles or rings on gray-scale sonography.[15,27] The rings are composed of the components of the pedicle, including the broad ligament, fallopian tube, and branches of the ovarian artery and vein. At color Doppler, the twisted vessels in the pedicle appear to be coiled or swirling, as a whirlpool. This finding is best detected when the probe is moved back and forth in a transverse plane along the central axis of the twisted pedicle, which may be located either medial or lateral to the ovary.[27,28] In a study by Lee and colleagues[15] this finding was observed in 88% of cases of torsion. This finding may be a more direct sign of adnexal torsion and may be particularly useful in equivocal cases because it represents the actual site of torsion rather than the secondary effects on the ovary. In a study by Valsky and coworkers[29] there was an increase in true positive cases from 55% to 90% when this sign was observed. The presence of flow in the whirlpool is reportedly a useful predictor of ovarian viability.[15,27]

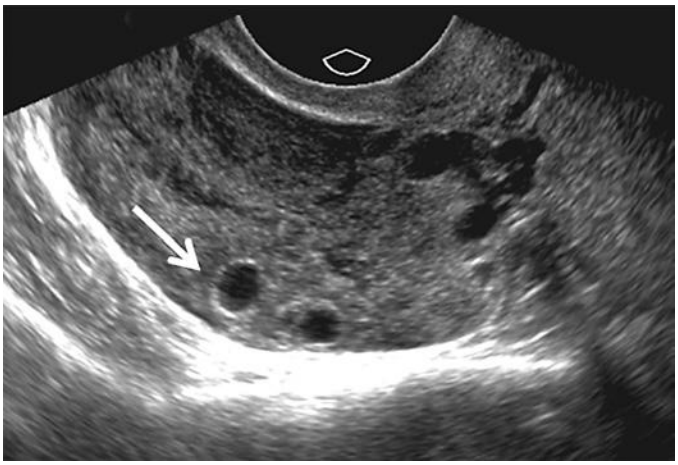

FIG 29-3 Follicular ring sign in a patient with ovarian torsion. Transvaginal scan demonstrates an enlarged, edematous ovary with peripherally displaced small follicles, several of which have thin echogenic walls (*arrow*).

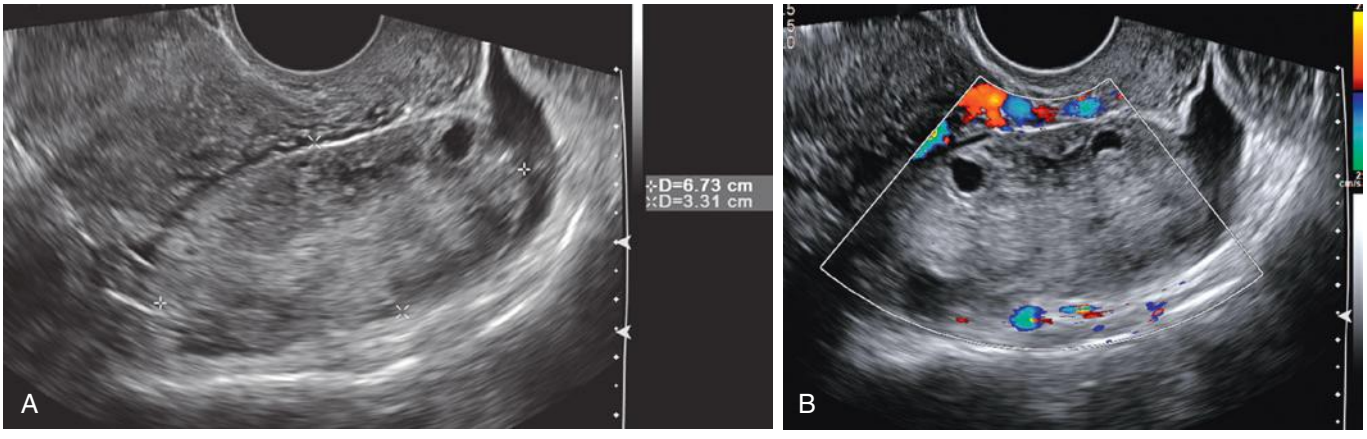

FIG 29-4 Ovarian torsion with infarcted necrotic ovary. **A,** Transvaginal scan demonstrates an enlarged ovary (*calipers*) with heterogeneous echotexture and a small amount of adjacent free fluid. **B,** Color Doppler image, optimized with "low flow" settings, demonstrates no flow to the ovary. Note thin echogenic walls of the anterior peripherally displaced follicles, the follicular ring sign. At surgery, the ovary and tube were twisted three times and appeared necrotic. Pathologic examination confirmed hemorrhage, congestion, and infarction of the ovary and fallopian tube.

Although sonography is the primary modality of choice for evaluation of clinically suspected ovarian torsion, CT may be the first study performed in the emergency room setting if ovarian torsion is not initially considered. CT findings have been well described and parallel those observed sonographically, including an enlarged ovary with or without an associated mass, ovarian stromal edema with peripheral follicles, inflammatory stranding in the periovarian fat, a twisted vascular pedicle, a thickened fallopian tube, pelvic free fluid, midline position of the ovary, and deviation of the uterus to the side of the twist[23,30,31] (Fig. 29-5). Lack of enhancement or hematoma may suggest hemorrhagic infarction. In the author's experience, the twisted pedicle may be better appreciated in a nonaxial imaging plane, and multiplanar reformatted images should be reviewed (Fig. 29-6). Recently, in 2014, it was suggested that CT may be more accurate than ultrasound imaging in detection of ovarian torsion. In one series, CT was performed prior to pelvic ultrasound examination in 70% of cases.[32] In this study, ultrasound imaging was 80% sensitive and 85% to 95% specific for ovarian torsion, whereas CT had a sensitivity of 90% to 100% and specificity of 85% to 90%; however, this was a retrospective study and the results have not been duplicated in larger prospective series. Hence, pelvic sonography remains the first-line imaging test of choice and, importantly, does not expose the patient to radiation or intravenous iodinated contrast agents.

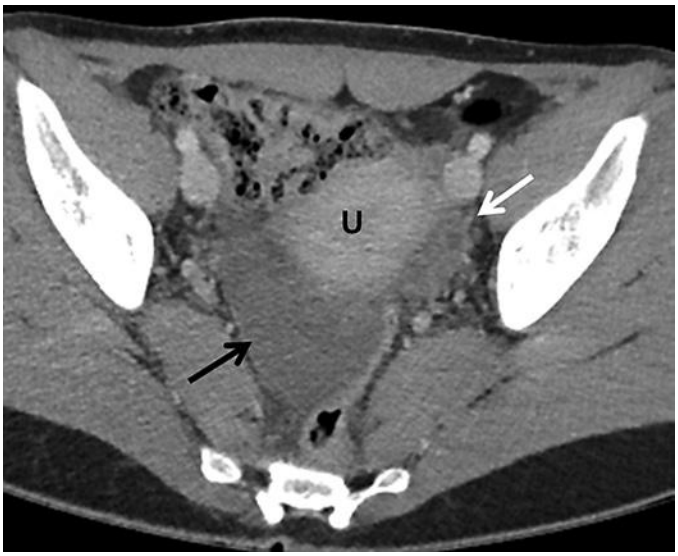

FIG 29-5 Computed tomography (CT) findings in ovarian torsion with no associated mass. Ovarian torsion in a patient evaluated with contrast-enhanced CT for possible appendicitis. The appendix was normal (not shown); however, the right ovary is enlarged (*black arrow*) and is located posterior to the uterus (U). The left ovary is normal size (*white arrow*) and normally located. Torsion with viable ovary was found at surgery.

MRI features of ovarian torsion have also been well described and parallel those seen by ultrasound imaging[30,31,33] (Fig. 29-7). MRI may serve as an adjunct to sonography in equivocal cases, enabling better visualization of the twisted pedicle and ovarian edema. MRI is particularly helpful in evaluating the patient with hyperstimulated ovaries in whom the diagnosis of torsion can be particularly challenging because of underlying ovarian enlargement.[34] However, MRI may not be readily available in the emergency setting, and inability to obtain an MRI scan should not result in treatment delay.

Isolated tubal torsion is very rare and usually associated with tubal disease.[35,36] Clinical symptoms are similar to those for ovarian torsion, although imaging features may vary. The most common sonographic appearance is a tubular, dilated fluid-filled structure, often with pointed or "beaked" ends where the twist occurs, in an unusual position in the pelvis and without demonstrable flow in the wall, in association with a normal-appearing ovary (Fig. 29-8). The whirlpool sign may also help with this diagnosis.[37,38]

Ruptured or Hemorrhagic Ovarian Cyst

Ovarian cysts are common in women of reproductive age, and most are physiologic (functional) cysts. Ovarian cyst rupture and hemorrhage are common physiologic events during the ovarian cycle, involving the follicle or corpus luteum. Although follicular rupture occurs unnoticed in most women, the term *mittelschmerz* (middle pain) is used to describe pain resulting from the release of fluid into the peritoneum with rupture of the normal follicle during ovulation.[39] Hemorrhage into the corpus luteum is common and is due to the increased vascularity of this structure. As the maturing graafian follicle enlarges and the surrounding stromal cells undergo luteinization, the luteinized theca cells become more vascular. During ovulation at midcycle when

FIG 29-6 Computed tomography (CT) findings in ovarian torsion associated with mature cystic teratoma. **A,** Axial contrast-enhanced CT image demonstrates large fat-containing mass (*white arrow*) located anteriorly in the midline of the upper pelvis. Note twisted vascular pedicle (*black arrow*). **B,** Coronal reformatted image shows the large mature cystic teratoma (*white arrow*), containing fat and calcifications, in the midline superior to the bladder (B) and the twisted vascular pedicle (*black arrow*).

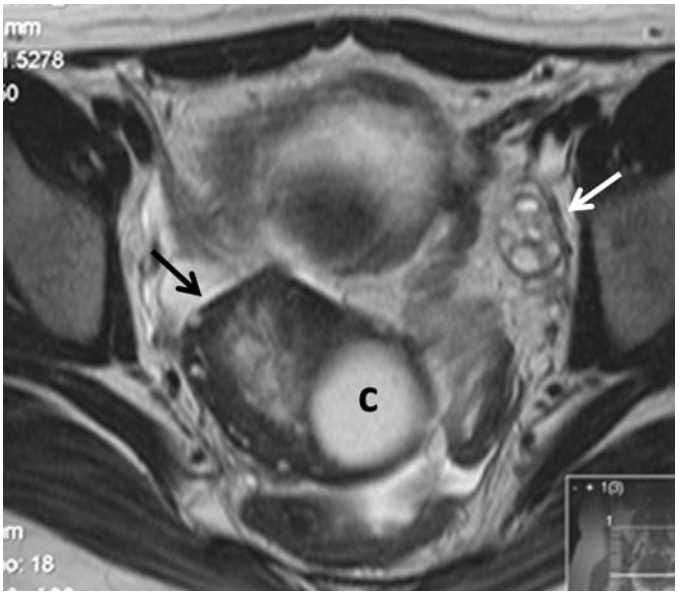

FIG 29-7 Magnetic resonance imaging findings in ovarian torsion with associated serous cystadenoma. Axial T2-weighted image shows enlarged right ovary (*black arrow*), located in the cul-de-sac at the posterior midline, with T2-weighted hyperintense cyst (c). The ovarian stroma demonstrates heterogeneous signal intensity due to hemorrhage and edema, and there are multiple small peripheral follicles. The left ovary (*white arrow*) is normal in size and appearance.

the follicle ruptures and expels the oocyte, the corpus luteum is formed and the granulosa layer becomes vascularized. The vessels within the wall rupture easily, giving rise to a hemorrhagic cyst.[40] Usually, symptoms are mild and self-limited. However, patients may present to the emergency department with more significant pain if there has been a greater degree of hemorrhage into the cyst or into the peritoneal cavity. Pain is usually sudden in onset, localized to one side of the pelvis, and gradually improves. Peritoneal signs are variable in intensity depending upon the amount of fluid and hemorrhage causing peritoneal irritation. There may be considerable overlap in clinical presentation with other gynecologic and nongynecologic disorders including ovarian torsion, ectopic pregnancy, and acute appendicitis. In one recent series of reproductive age women who presented with right lower quadrant pain and clinical suspicion for appendicitis, 12.8% had gynecologic causes, including 7.2% with cyst rupture, 4.2% with ruptured hemorrhagic corpus luteum, and 1.4% with adnexal torsion.[41] Most of the time, the process is self-limiting, although severe life-threatening hemorrhage may occasionally occur and require urgent surgical intervention. Women with clotting disorders are at a higher risk for severe hemorrhage.[42]

If ovarian cyst rupture or hemorrhage is suspected, sonography is the study of choice. The cyst may not be visualized if it has ruptured and completely decompressed; however, there will generally be free pelvic fluid. Hence, ovarian cyst rupture is often a diagnosis of exclusion if no other cause for the patient's pain is identified. Although variable in appearance, the ruptured or leaking corpus luteum

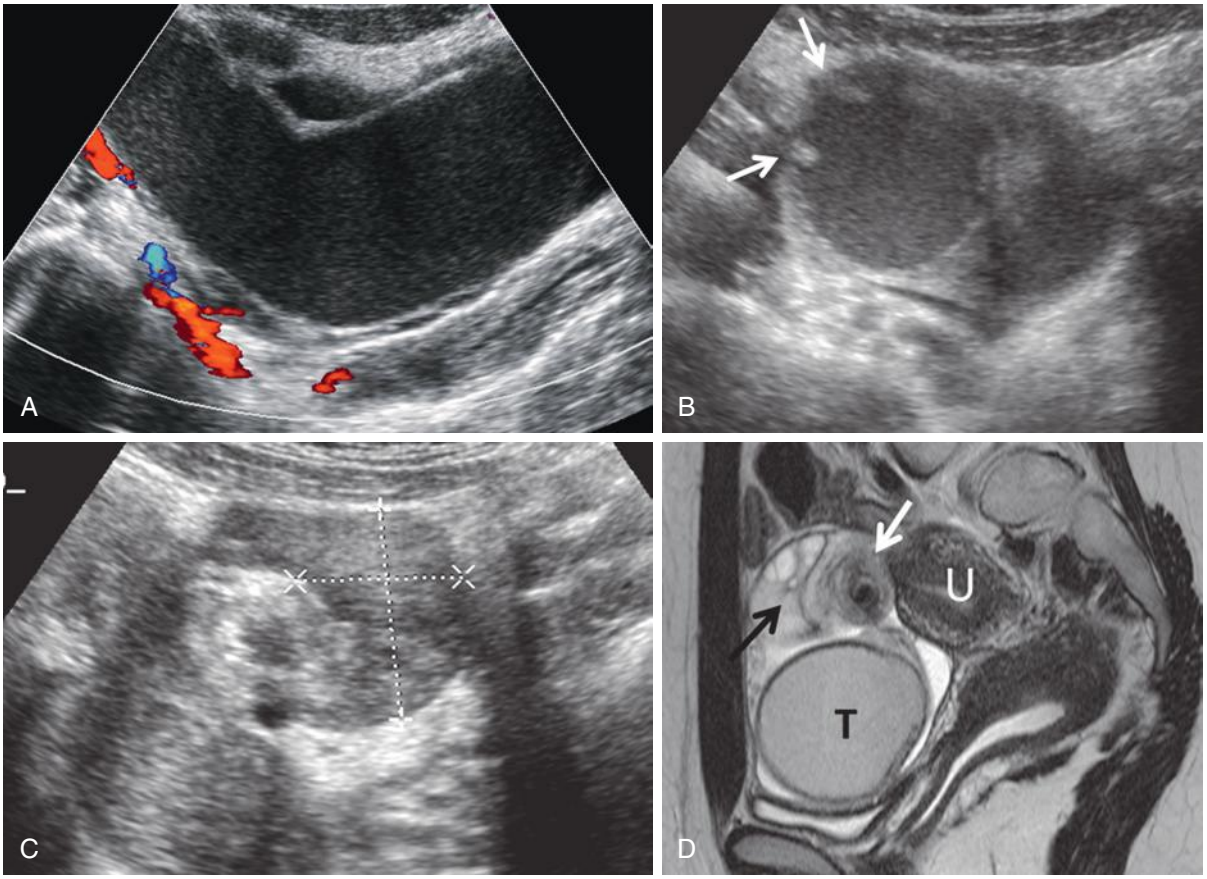

FIG 29-8 Isolated fallopian tube torsion. **A,** Color Doppler image shows tubular structure filled with complex fluid and no blood flow, corresponding to hematosalpinx. **B,** On cross section, the endosalpingeal folds (*arrows*) are visualized. **C,** The left ovary (*calipers*) was normal in size and echotexture and had normal blood flow (not shown). **D,** Sagittal T2-weighted magnetic resonance image shows the site of the twist (*white arrow*), the normal left ovary (*black arrow*), and the blood-filled dilated fallopian tube (T) anterior to the uterus (U).

classically appears on ultrasound imaging as a small cystic lesion with a crenulated homogeneously hypoechoic wall and low-level internal echoes during the luteal phase of the menstrual cycle.[43] Size is variable, but is typically less than 3 cm. In most cases, there is a peripheral rim of increased vascularity, the "ring of fire" appearance[44] (Fig. 29-9). The sonographic appearance of a hemorrhagic cyst is also quite variable, depending upon when in the evolution of the hemorrhage the patient undergoes imaging. There is a continuum, from acute hemorrhage to clot formation followed by clot retraction. Because of the wide spectrum of appearance, hemorrhagic cysts may mimic other processes and have been referred to as the "great imitator."[45] However, the characteristic sonographic features have been well described[40,43,46-48] (Fig. 29-10). Size may vary considerably from 2.5 to 10 cm. Acutely, hemorrhage into a cyst has a sonographic pattern of diffuse, homogeneous low-level echoes. A fluid-fluid level may be observed with the dependent echogenic component corresponding to blood. Over time, as red blood cells lyse and fibrin strands form, a reticular pattern of internal echoes is observed (also described as fishnet, cobweb, spider web, or lace-like) (Fig. 29-10B). Fibrin strands produce a network of fine linear echoes and are distinct from true septations in that they are usually innumerable, thinner, and discontinuous, with an irregular fine branching pattern; lack vascularity; and do not extend from wall to wall as a true septation would.[46] An acute clot filling the cyst may appear as dense internal echoes that simulate a solid mass, although lack of blood flow on Doppler imaging and demonstration of increased posterior through transmission are helpful features in suggesting the diagnosis. As the clot retracts and lyses, it may appear on gray-scale sonography as an echogenic mural component within a cystic lesion and thus may simulate a solid neoplastic mural nodule. However, the retracting clot will often demonstrate concave or straight margins with acute angles, is often triangular, and may have a moth-eaten echotexture[46] (Fig. 29-10C). Lack of Doppler flow is an important feature suggesting mural thrombus as opposed to a tumor nodule, although low-levels of flow in solid tissue may not be detectable by Doppler sonography. Hence, absence of Doppler-detected blood flow is not an entirely reliable feature for a clot in a hemorrhagic cyst. The diagnostic performance of sonography in discriminating hemorrhagic ovarian cysts from other adnexal lesions, including malignancies, has been investigated in a study by Patel and associates,[46] who reported that the reticular or fishnet pattern had a sensitivity of 90%, specificity of 98%, and positive likelihood ratio (LR) of 40 for a hemorrhagic cyst; a retracting clot (solid echoes with a concave margin) was found to have a higher LR (>67) and specificity (100%) but lower sensitivity of 30%, although the combination of fibrin strands, no septations, and smooth wall was found to have an LR of 200, with sensitivity of 90% and specificity of 100%. Approximately 90% of hemorrhagic ovarian cysts will exhibit these features.

For some hemorrhagic ovarian cysts, there is overlap in imaging features with other complex cystic masses, including endometriomas, tubo-ovarian abscesses (TOAs), and cystic ovarian neoplasms, and definitive diagnosis may not be possible at the time of the initial sonogram.[49] The clinical setting is often helpful in focusing the differential

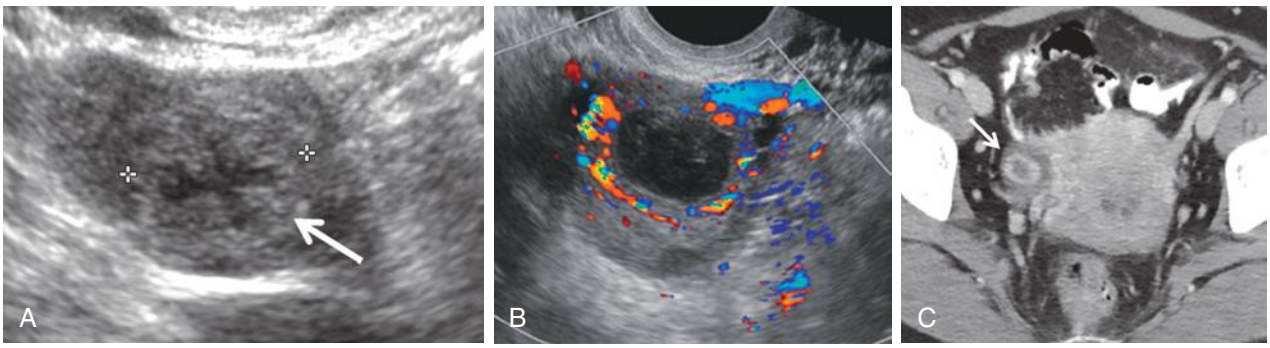

FIG 29-9 Spectrum of appearances of the corpus luteum. **A,** Cyst with thickened, crenulated wall (*arrow* and *calipers*). **B,** Typical "ring of fire" appearance on color Doppler sonogram. **C,** Typical appearance of corpus luteum (*arrow*) in the right ovary at contrast-enhanced computed tomography. Note enhancement of the wall of the corpus luteum.

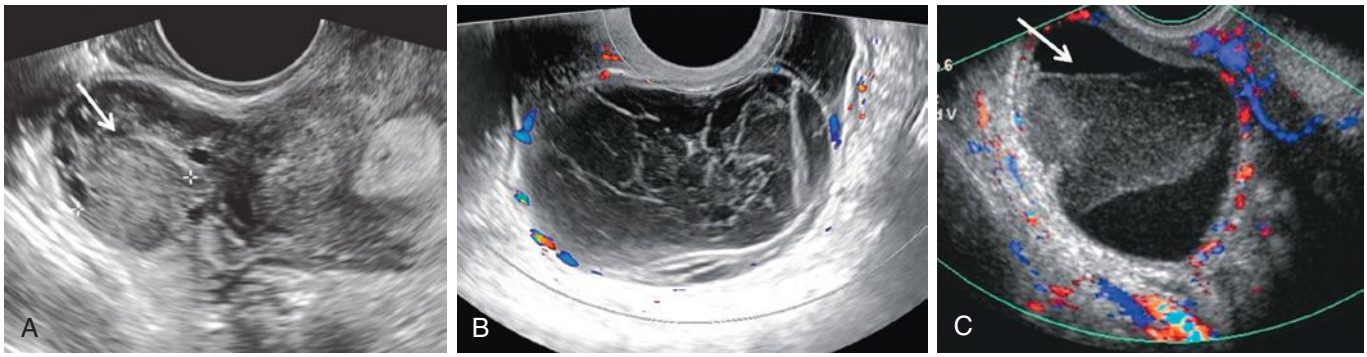

FIG 29-10 Sonographic spectrum of hemorrhagic ovarian cysts. **A,** Acute hemorrhage may appear as a solid lesion (*arrow* and *calipers*) with homogeneous low-level echoes. **B,** Typical fishnet or lace-like appearance representing fibrin strands. No internal vascularity is demonstrated with color Doppler sonography although vascularity is noted in the wall of the cyst. **C,** Retractile clot (*arrow*) possibly mimicking a solid nodule but recognized as a clot due to straight margins, acute angles, and lack of internal blood flow. Blood flow is shown in the wall of the cyst.

diagnosis. However, if a hemorrhagic cyst is of primary consideration based on imaging features, short-interval follow-up sonography to confirm resolution is recommended because most hemorrhagic cysts typically resolve within 8 weeks.[50] This approach will prevent unnecessary surgical intervention. However, for a classic-appearing hemorrhagic cyst, defined as demonstrating either the reticular fibrin strand or retractile clot patterns, the Society of Radiologists in Ultrasound Consensus Conference Statement for management of asymptomatic ovarian cysts offers the following guidelines:[51] In women of reproductive age, hemorrhagic cysts 3 cm or less need not be described in the sonogram report, and no follow-up is necessary. Hemorrhagic cysts between 3 and 5 cm should be described in the report, but require no follow-up. Hemorrhagic cysts more than 5 cm should undergo short-interval follow-up sonography (6-12 weeks) with imaging optimally performed on days 3 to 10 of the menstrual cycle. In early postmenopause, all suspected hemorrhagic cysts should be described in the report, and short-interval follow-up sonography recommended in 6 to 12 weeks. Because women in late menopause should never develop hemorrhagic ovarian cysts, suspicion for neoplasm is heightened in this setting and surgical evaluation or additional imaging evaluation should be considered.

If a hemorrhagic ovarian cyst ruptures, the cyst may decompress and might not be identified as a discrete finding at sonography. Color Doppler sonography may identify the residual wall of the cyst (Fig. 29-11). A sentinel clot is sometimes identified in the adnexa as a complex mass of mixed echogenicity without blood flow. A variable amount of hemoperitoneum will be observed as free fluid containing low-level echoes, primarily within the pelvis. However, hemoperitoneum may also be noted in the upper abdomen if there has been a large amount of bleeding. Thus, the Morison pouch and the left upper quadrant should be surveyed to assess the amount of intraperitoneal blood. A ruptured ectopic pregnancy could present with similar sonographic and clinical findings; therefore, a human chorionic gonadotropin (hCG) level should always be measured to exclude this possibility. Infected fluid could also mimic the sonographic appearance of hemoperitoneum; therefore, clinical correlation and laboratory findings are important.

CT may occasionally be requested if a ruptured hemorrhagic ovarian cyst is not initially suspected when a patient presents with diffuse abdominal pain. CT findings include a high attenuation adnexal mass compatible with clot and high attenuation peritoneal fluid compatible with hemoperitoneum[52-55] (Fig. 29-12). A rim-enhancing

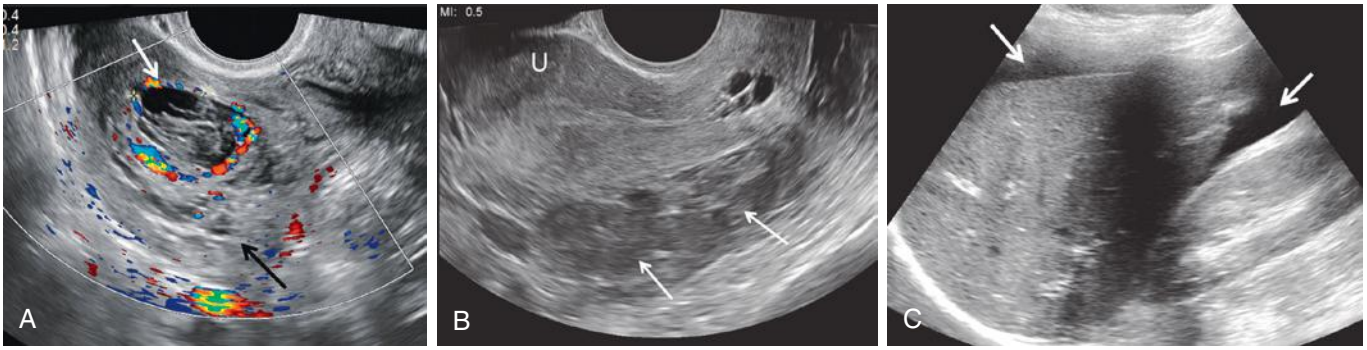

FIG 29-11 Ruptured hemorrhagic ovarian cyst. **A,** Color Doppler sonographic image demonstrating the "ring of fire" appearance of a hemorrhagic corpus luteum (*white arrow* and *calipers*), which is still recognized despite rupture. The ovary is not identified as a discrete structure as it is surrounded by complex material of mixed echogenicity compatible with blood clot (*black arrow*). **B,** Large amount of complex fluid containing echoes (*arrows*) compatible with blood in the cul-de-sac posterior to the uterus (U). **C,** Large amount of hemoperitoneum (*arrows*) in the upper abdomen adjacent to the liver and in the Morison pouch.

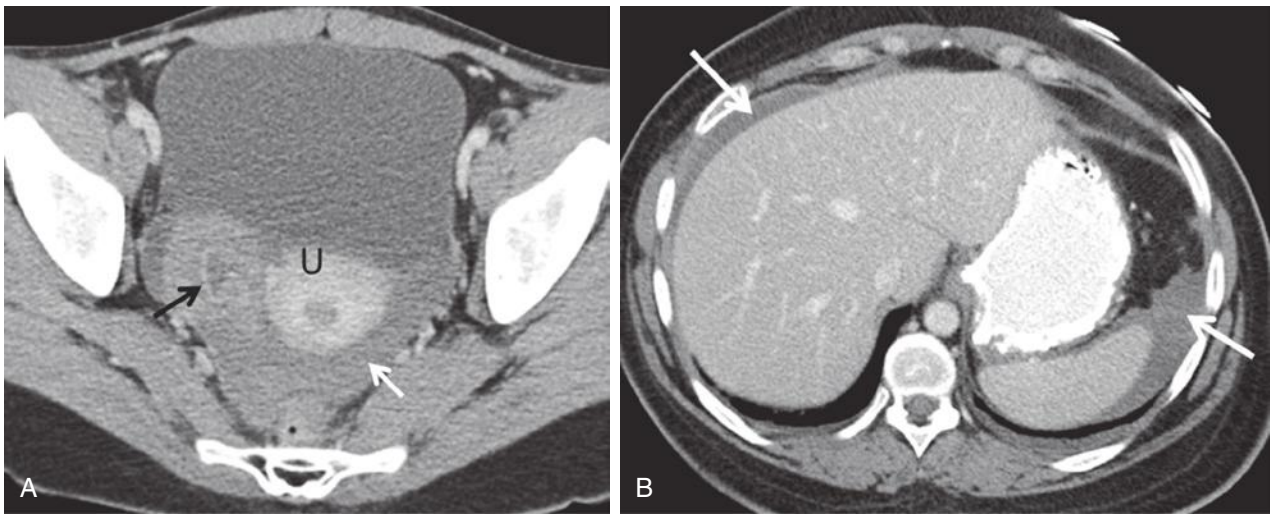

FIG 29-12 Ruptured hemorrhagic cyst at contrast-enhanced computed tomography (CT). **A,** An irregular, crenulated rim-enhancing cyst (*black arrow*) is visible in the right adnexa surrounded by a high attenuation blood clot. High attenuation fluid compatible with blood (*white arrow*) is present in the cul-de-sac posterior to the uterus (U). **B,** More superior CT image demonstrates blood in the upper abdomen adjacent to the liver and spleen (*arrows*).

ovarian cyst may be identified, and even if the cyst has ruptured, a remnant of the cyst wall may remain visible. If there is active bleeding at the time of the scan, extravasation of contrast material with pooling in the pelvis will be observed.

Other cysts may also rupture, including cystic neoplasms, most commonly mature cystic teratomas. Rupture of ovarian teratomas has been reported to occur in 1% to 4% of cases.[56] Leakage of the liquefied sebaceous contents into the peritoneal cavity results in chemical peritonitis. Chronic leakage from the cyst may result in chronic granulomatous peritonitis.[57] If an adnexal mass is identified that exhibits classic sonographic features of a mature cystic teratoma and the patient has pain, either torsion or rupture of the mass should be considered. A large volume of intraperitoneal fluid, distorted or flattened shape of the mass, and discontinuity of the cyst wall suggest rupture.[57] CT may be helpful for further evaluation, as it may show scattered fat droplets outside the mass, peritoneal fluid, and findings of peritonitis (Fig. 29-13). The peritoneal inflammatory changes may mimic peritoneal carcinomatosis or tuberculous peritonitis, possible diagnostic pitfalls.

Pelvic Inflammatory Disease

PID refers to a spectrum of disease that occurs when microorganisms ascend from the lower genital tract to infect the uterus, fallopian tubes, and ovaries[58] and is a common cause of emergency room visits and hospitalizations for acute gynecologic disorders.[59] The continuum of infection begins with cervicitis and progresses to endometritis, salpingitis, pyosalpinx, tubo-ovarian complex (TOC), and, ultimately, tubo-ovarian abscess (TOA). One third to one half of cases are due to *Chlamydia trachomatis* or *Neisseria gonorrhoeae*. However, PID is most commonly a polymicrobial infection, and a substantial proportion of cases are nongonococcal and nonchlamydial in origin,[60] involving vaginal flora, anaerobic gram-negative rods, and *Mycoplasma* bacteria. The adnexa may also become secondarily infected from other inflammatory processes, usually gastrointestinal in origin, including appendicitis and diverticulitis. The clinical diagnosis may be challenging, as symptoms and signs vary widely and overlap with other processes including endometriosis, appendicitis, and ectopic pregnancy. Pelvic pain is the most common presenting symptom, although it may be absent or mild in some patients. On physical examination, cervical motion tenderness as well as uterine and adnexal tenderness are classic findings. There may be associated mucopurulent vaginal discharge, white blood cells on saline microscopy of vaginal secretions, elevated erythrocyte sedimentation rate, and C-reactive protein, leukocytosis, and fever. A delay in treatment may result in significant reproductive and gynecologic morbidity such as infertility, increased risk of ectopic pregnancy, chronic pelvic pain, and recurrent infection. Most patients can be effectively treated as outpatients with broad-spectrum antimicrobial therapy. However, hospitalization may be required for severe cases (including TOAs) or if the diagnosis is in doubt.

Imaging evaluation of patients with suspected PID may be necessary if the symptoms are nonspecific and diagnosis is uncertain, if the patient is not responding to treatment, or if complications such as abscess formation are suspected. If a TOA has formed, imaging may aid in determining the most appropriate method of treatment, with possible options including percutaneous drainage and surgery.

Pelvic ultrasound examination is the first-line imaging method of choice for the evaluation of PID. Ultrasound examination findings vary depending upon the stage of infection, and if PID is early or mild, findings may be nonspecific.[61,62] Patients with endometritis may not exhibit any sonographic imaging findings. A fluid-filled endometrial cavity is suggestive in the clinical setting of fever, vaginal discharge, and uterine tenderness on physical examination (Fig. 29-14). However, intrauterine fluid is a nonspecific finding. Gas in the endometrial cavity will appear on ultrasound imaging as foci of increased echogenicity with associated posterior acoustic shadowing. Although the presence of gas increases concern for possible infection, gas in the endometrial cavity may also be observed postpartum or post instrumentation. Free fluid in the cul-de-sac is also a nonspecific finding, although echoes within the fluid raise suspicion for infection (or hemorrhage). Enlargement and hyperemia of the ovaries with multiple small cysts indicate oophoritis.[63,64]

Findings involving the fallopian tubes are more specific for PID. Although isolated salpingitis may not always be recognizable by sonography, infected fallopian tubes may demonstrate wall thickening and hyperemia.[65] Obstruction at the fimbrial end of the tube due to inflammation will result in a pus-filled dilated tube or pyosalpinx, which

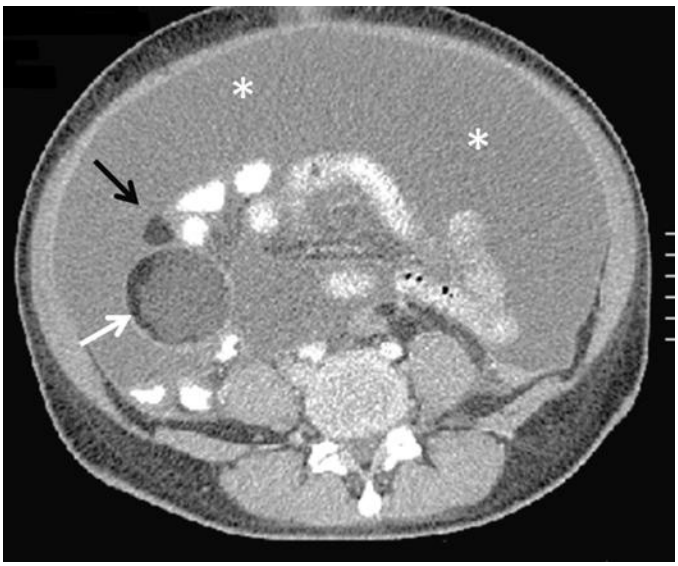

FIG 29-13 Ruptured mature cystic teratoma. Patient presented to the emergency department with diffuse abdominal pain. There is a fat density mass compatible with mature cystic teratoma in the right adnexa (*white arrow*). Note focus of fat density separate from the mass (*black arrow*) and large amount of ascites (*asterisks*). A ruptured mature cystic teratoma with associated peritonitis was identified at surgery.

FIG 29-14 Endometritis. Distended endometrial cavity (*arrow* and *calipers*) containing complex predominantly hypoechoic fluid in a febrile patient with purulent vaginal discharge.

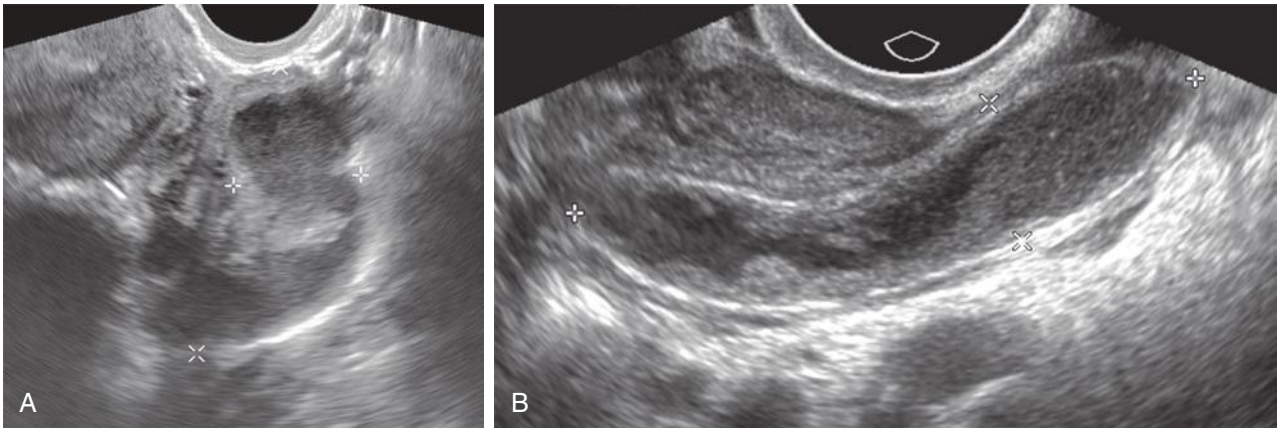

FIG 29-15 Pyosalpinx. **A,** Distended thick-walled fallopian tube (*calipers*) containing complex fluid compatible with pyosalpinx. **B,** Pitfall: acute appendicitis. Debris-filled tubular structure (*calipers*) in the right adnexa was initially thought to represent pyosalpinx. However, no endosalpingeal folds are identified and this is a blind-ending structure. Computed tomography scan (not shown) confirmed acute appendicitis.

appears as a tubular structure distended with echogenic intraluminal fluid and debris, sometimes with layering echoes indicating a fluid-debris level, and thick hypervascular walls (Fig. 29-15A). Thickened and inflamed endosalpingeal folds may suggest small mural nodules, which give the appearance of a "cogwheel" when imaged in cross section. This finding helps differentiate a pyosalpinx from an inflamed appendix, which is blind-ending and does not have endosalpingeal folds (Fig. 29-15B). If untreated, PID progresses to form a TOC as the inflammation spreads to the adjacent ovary, which becomes enlarged with indistinct contours and increased vascularity, although the ovary remains identifiable as a discrete structure. The inflamed fallopian tube is often adjacent or adherent to the ovary. The final stage is TOA, in which the normal ovary is no longer delineated and an inflammatory mass replaces the ovary and fallopian tube. This appears as a complex multiloculated cystic adnexal mass with internal echoes, layering debris, and thick septations (Fig. 29-16). The mass will be markedly vascular on color Doppler interrogation. The presence of gas in a TOA is very rare. It is estimated that TOAs complicate approximately 10% to 15% of cases of PID.[66] TOA rupture may result in septic shock.

PID most often involves both adnexa, but may occasionally be unilateral. If the process is right-sided, a perforated appendicitis with abscess formation could have a similar appearance, and if left-sided, perforated diverticulitis may give a similar picture. Assessment of patient risk factors for PID is very important in this setting. CT may be required to exclude appendicitis or diverticulitis as the cause of the abscess (Fig. 29-17). CT also may be helpful in detecting complications such as extension of inflammation out of the pelvis and involvement of adjacent structures including the bowel or ureter. A blood-filled fallopian tube (hematosalpinx) in the setting of endometriosis may mimic pyosalpinx and is another diagnostic pitfall. A complex or infected endometrioma may mimic a TOA (see further discussion later). MRI can serve as a useful complementary imaging technique because signal intensity characteristics compatible with chronic blood products will be observed in endometriosis but not in PID. One series evaluating patients with both ultrasound imaging and MRI reported the sensitivity and specificity of MRI for laparoscopically proven PID to be 95% and 89% and of ultrasound imaging to be 81% and 78%, respectively.[67]

Chronic PID may result in obstruction of the ampullary segment of the fallopian tube, causing hydrosalpinx with fluid-filled dilatation of the fallopian tube. Although PID is the most common cause of hydrosalpinx, other causes include tubal ligation, hysterectomy without salpingo-oophorectomy, endometriosis, prior surgery, and malignancy.[65] Hydrosalpinx may be a cause of pelvic pain and infertility. At sonography, a dilated fallopian tube in the absence of infection appears as a C-, U-, or S-shaped anechoic, avascular tubular structure, generally with a thin wall less than 5 mm thick (Fig. 29-18). Small 2 to 3 mm nodules representing the remnants of the endosalpingeal folds may appear as "beads on a string."[61,68] In one study, hydrosalpinx was diagnosed with the highest likelihood when a tubular mass with small round mural projections or a waist sign was visualized.[69] The incomplete septation sign, due to the distended tube folding on itself, may also be observed but is a less reliable finding. If these features are not observed, hydrosalpinx may be difficult to distinguish from a cystic ovarian neoplasm. Three-dimensional (3D) sonography may increase specificity.[70,71] MRI may be helpful by demonstrating the tubular nature of the mass and intraluminal fluid content.[65] PID may also result in formation of a peritoneal inclusion cyst (discussed later).

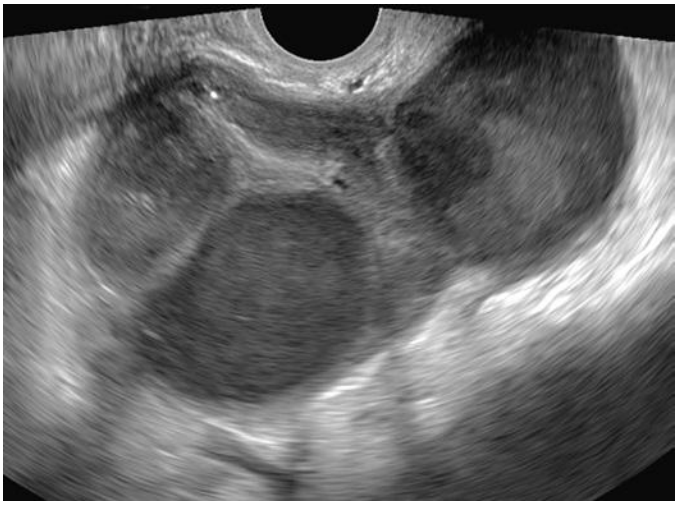

FIG 29-16 Tubo-ovarian abscess. Multiloculated adnexal mass containing complex fluid. No normal ovary was identified.

Endometriosis

Endometriosis is defined as the presence of endometrial glands and stroma in ectopic locations outside the uterus.[72,73] Neoangiogenesis

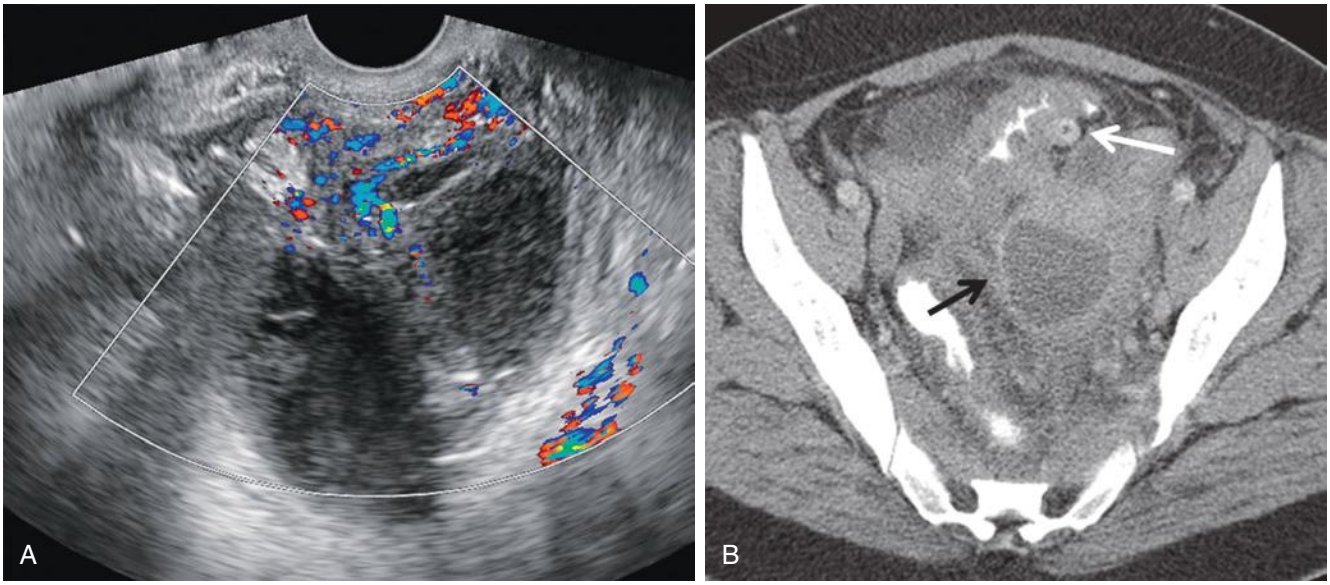

FIG 29-17 Tubo-ovarian abscess secondary to diverticulitis. **A,** Ultrasound image demonstrates a complex multiloculated pelvic mass with increased peripheral blood flow in a patient with left lower quadrant pain and fever. Note increased echogenicity in the surrounding pelvic fat consistent with inflammation. The patient had no risk factors for pelvic inflammatory disease. **B,** Computed tomography demonstrates the left pelvic abscess (*black arrow*). Note mural thickening of the adjacent sigmoid colon with numerous diverticula (*white arrow*) compatible with diverticulitis, which was the source of the abscess, confirmed at surgery.

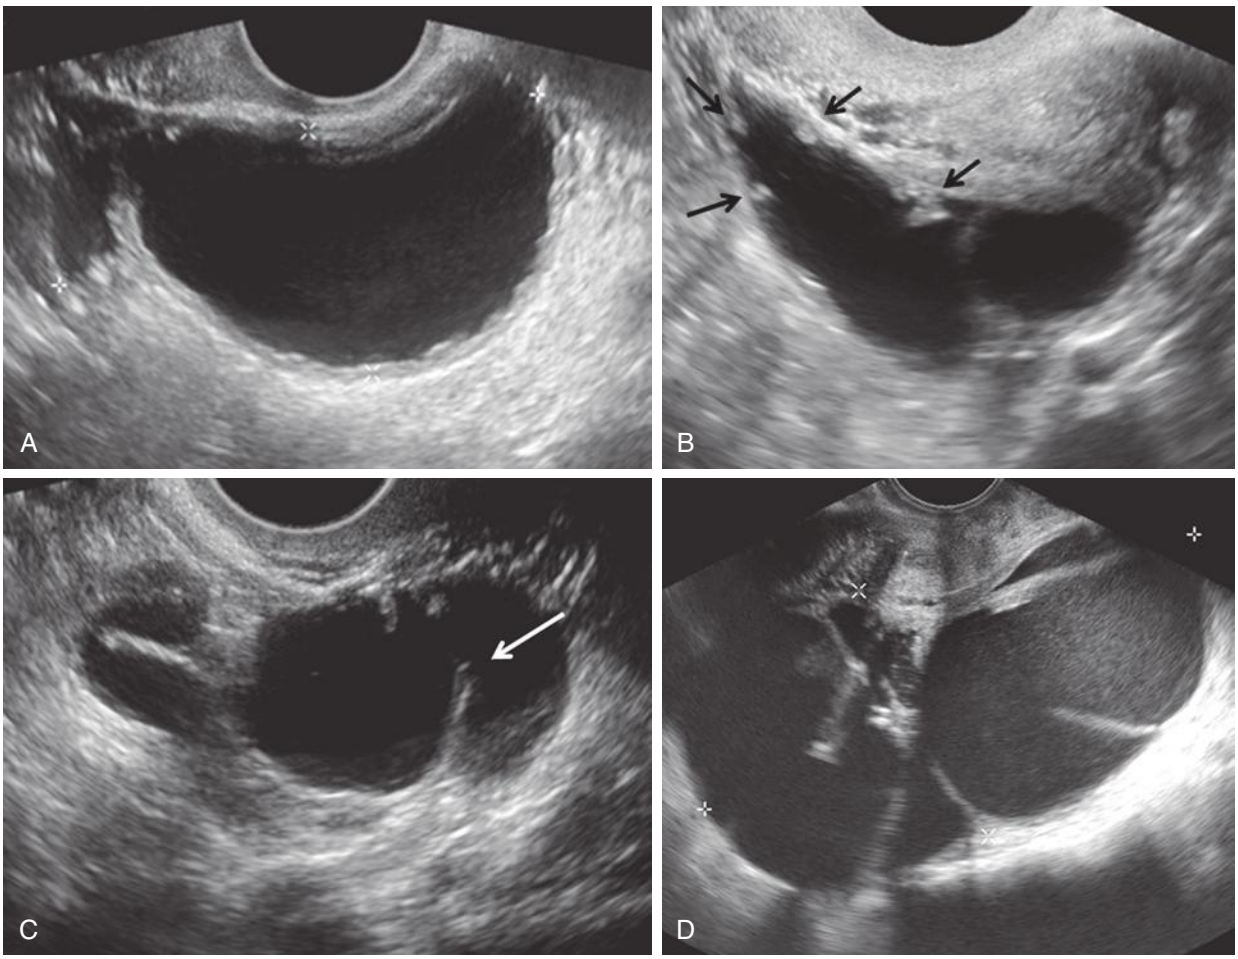

FIG 29-18 Sonographic spectrum of hydrosalpinx. **A,** Dilated fallopian tube appears as an anechoic fluid-filled, avascular tubular structure (*calipers*). **B,** The endosalpingeal folds (*arrows*) appear as beads on a string. **C,** Incomplete septation (*arrow*) is formed by the tube folding upon itself. **D,** Pitfall: mucinous cystadenoma (*calipers*) appears tubular in configuration with incomplete septations and mimics a distended fallopian tube.

and capillary recruitment are associated with endometriotic lesions at laparoscopy, and there is an associated inflammatory response ultimately progressing to fibrosis.[74] This disorder is associated with a wide variety of symptoms including dysmenorrhea, dyspareunia, chronic pelvic pain, and dysfunctional uterine bleeding.[74] Although pain is usually chronic, complications of endometriosis may result in a more acute presentation. Infertility is an important consequence of endometriosis, due to associated anatomic distortion of the pelvic structures and obstruction of the fallopian tubes. Endometriosis affects up to 10% of women of reproductive age,[75] although in women with pelvic pain, infertility, or both, the prevalence is estimated to be as high as 35% to 50%.[76] Because endometriosis is hormonally responsive, symptoms are often cyclic in nature, and there is repetitive hemorrhage into these lesions. The pathogenesis of endometriosis is complex and remains the subject of debate.[74] Proposed theories include origin of implants from the uterine endometrium, possibly from lymphatic or hematogenous dissemination of endometrial cells or retrograde menstruation. Other theories propose that implants arise from tissues outside the uterus, for example, coelomic metaplasia with transformation of peritoneal tissue to ectopic endometrial tissue or embryonic müllerian rests that develop into endometriotic lesions under the influence of estrogen. A more recent theory suggests that extrauterine stem/progenitor cells originating from bone marrow may differentiate into endometriotic tissue, and this topic is currently an active area of investigation.[77]

The most common sites of endometriotic implantation include the surface of the ovary, uterine suspensory ligaments, uterus or fallopian tube, and the peritoneal surfaces of the pouch of Douglas. Less common sites of implantation include vagina, bladder, cervix, intestine, cesarean delivery scars, abdominal scars, or the inguinal ligament. Deep pelvic endometriosis is defined as invasive tissue that infiltrates structures at a depth of more than 5 mm from the peritoneal surface and is associated with fibrosis and muscular hyperplasia.[78-80] This preferentially affects the dependent portions of the posterior peritoneal spaces, most commonly the uterosacral ligaments, torus uterinum, rectovaginal pouch, rectum, and rectovaginal septum, with anterior involvement less common. Current treatment options for endometriosis include both medical (primarily hormonal) and surgical management. Diagnostic laparoscopy remains the reference standard for diagnosis and staging of endometriosis, although the role of imaging in endometriosis has continued to evolve. The ovaries are the most common sites of endometriosis and are frequently involved with multiple and bilateral lesions. The classic sonographic appearance of an endometrioma, often referred to as a chocolate cyst because of the presence of thick, dark, degenerated blood products from repetitive cyclic episodes of bleeding, is that of a homogeneous, hypoechoic lesion with low to medium level echoes and no internal vascularity (Fig. 29-19).[81-85] This has often been referred to as a "ground glass" appearance[48] and is highly predictive of an endometrioma, with one retrospective series reporting this appearance in 95% of endometriomas.[84] However, there is a spectrum of sonographic appearances, and in another series, 13 of 87 surgically proven endometriomas were felt to be atypical.[83] In an investigation by Patel and coworkers[84] echogenic mural foci, thought to represent cholesterol deposits, were observed in 36% of endometriomas compared with 6% of nonendometriomas, and septations were found in 45% of endometriomas. In that study, if

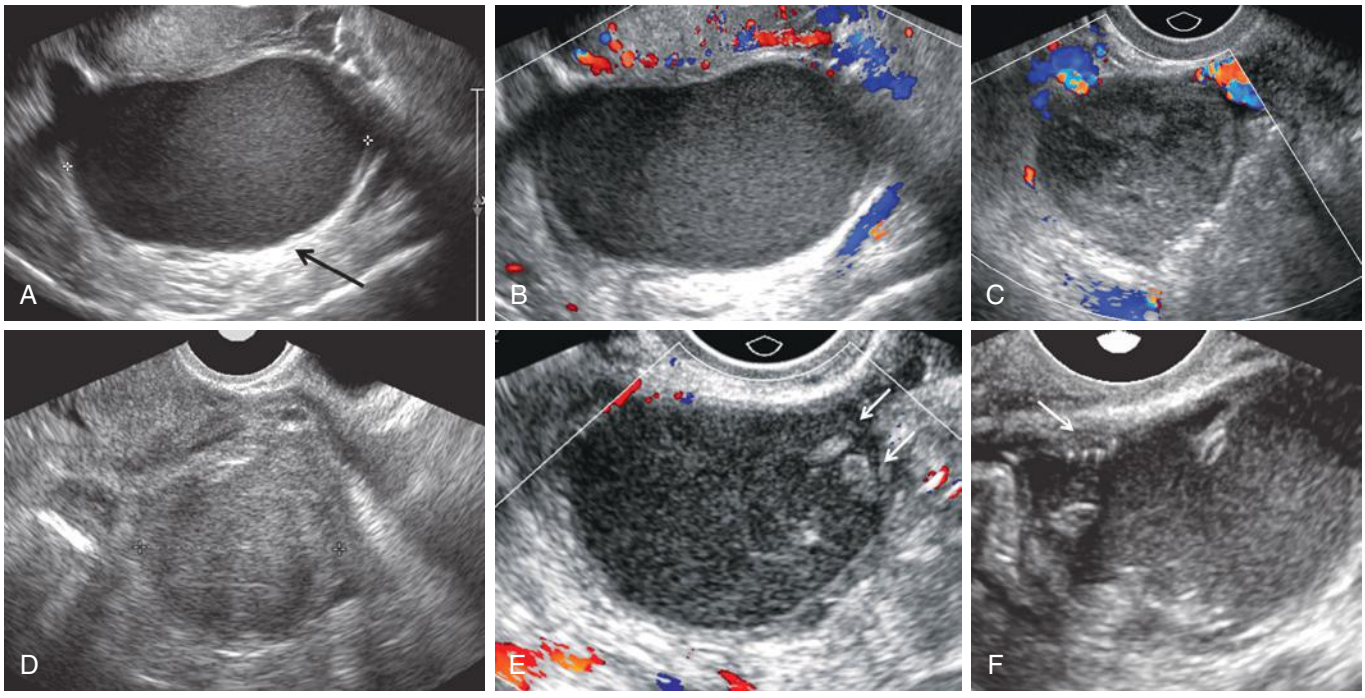

FIG 29-19 Sonographic spectrum of endometriomas. **A,** Classic appearance of a chocolate cyst (*calipers*) with homogeneous low-level echoes, the ground glass appearance. Posterior acoustic enhancement (*arrow*) confirms a cystic lesion. **B,** No vascularity is demonstrated within the lesion on color Doppler interrogation. **C,** More complex, heterogeneous appearance in another patient as a result of acute hemorrhage into an endometrioma. No internal blood flow is detected on color Doppler sonogram. **D,** Solid appearance of a chronic endometrioma (*calipers*) mimicking a solid adnexal mass. **E,** Avascular mural nodules suggested (*arrows*), representing adherent blood clot. **F,** Complex cystic lesion with possible mural nodules suggested. Appearance simulates an ovarian neoplasm. Echogenic foci along the wall (*arrow*) with comet-tail artifact help suggest the diagnosis of endometrioma.

an adnexal mass had diffuse low-level echoes, as well as hyperechoic mural foci and multilocularity, as well as no evidence of other neoplastic features, it was 32 times more likely to be an endometrioma than any other adnexal mass. Occasionally an endometrioma can mimic a simple ovarian cyst and appear completely anechoic. Other findings include fluid-fluid level, thickened wall, and mural or central calcifications. Avascular mural nodules representing an adherent or retracting blood clot can occasionally be observed, but a clot is less commonly observed in endometriomas than in hemorrhagic ovarian cysts. Rarely, flow within nodular areas has been described, possibly due to endometrial stromal tissue.[43] However, tumor nodules due to malignant degeneration (usually into clear cell or endometroid carcinoma) of an endometrioma may mimic this appearance and demonstrate Doppler-detected blood flow. Chronic endometriomas may mimic solid masses due to the presence of older blood products and fibrosis.[43] However, typically, there is only perilesional blood flow with no internal vascularity.[86] Doppler waveform analysis is not helpful in diagnosis as low resistance waveforms resembling malignancy can be observed in the wall of an endometrioma.[81]

Ultrasound examination findings of endometriomas may overlap considerably with other adnexal masses including hemorrhagic cysts, TOAs, dermoids, and cystic ovarian neoplasms (Fig. 29-20). In a meta-analysis by Moore and colleagues,[87] the sensitivity of transvaginal sonography for the diagnosis of an endometrioma ranged from 64% to 89% with specificity of 89% to 100%. The most common misdiagnoses were hemorrhagic cysts and dermoids. If a hemorrhagic cyst is a diagnostic consideration, short-interval follow-up ultrasound examination is useful because a hemorrhagic cyst should resolve whereas an endometrioma will persist. If ultrasound findings are not definitive and if ovarian neoplasm is of concern, MRI is the next recommended step.[88-90] As a result of the repeated cycles of bleeding, endometriomas will contain old blood products with high iron and protein concentration creating characteristic findings at MRI with increased signal intensity on T1-weighted images and decreased signal on T2-weighted images, sometimes referred to as *shading*.[91] Mural nodules representing an adherent clot will not enhance on postcontrast subtraction images. An enhancing nodule following the administration of gadolinium is indicative of either malignant degeneration or endometrial stromal tissue. Fat-sensitive images help to identify macroscopic fat in a dermoid (Fig. 29-21). MRI has a greater than 90% sensitivity and specificity for endometriomas.[91]

Endometrial implants involve the fallopian tubes in approximately 6% of women with endometriosis, and adhesions involve the tubes in 26%.[92] Endometriotic implants are most common on the serosal surface, with transmural and mucosal involvement occurring less frequently. Hematosalpinx may be an isolated finding in patients with endometriosis.[89] At sonography, low-level echoes, corresponding to blood products, may be identified in the dilated fallopian tube (Fig. 29-22). This appearance may simulate that of pyosalpinx, and clinical findings are important to differentiate between these entities. MRI may also be helpful by confirming the presence of blood products in the tube.

Endometriotic implants may occur in the anterior abdominal wall, which is the most frequent site of extrapelvic disease. Endometriosis in the abdominal wall is usually found next to a surgical scar or a needle or laparoscopic trocar tract. One of the most common associations is with prior cesarean delivery, reported in 0.03% to 1% of women.[93] In a series of 455 cases of abdominal wall endometriosis, 57% were associated with cesarean delivery scar, and 11% were associated with hysterectomy.[94] Spontaneously occurring implants may be seen adjacent to the umbilicus. Among women with scar endometriosis, only 14% to 26% have concomitant pelvic endometriosis.[95]

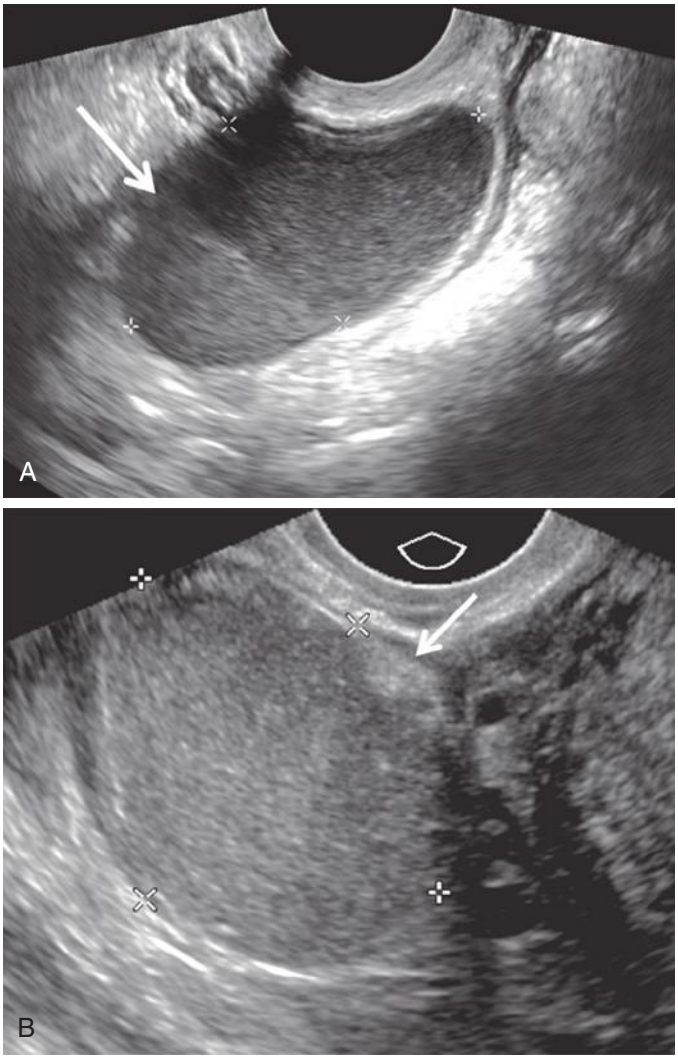

FIG 29-20 Mimics of endometriomas. **A,** Mucinous cystadenoma (*calipers*) containing layering low-level echoes and fluid-fluid level (*arrow*). Lesion was observed in a postmenopausal patient who underwent surgical evaluation and resection. **B,** Pathologically proved mature cystic teratoma (*calipers*) was originally thought to be an endometrioma with adherent clot (*arrow*). The echogenic mural nodule corresponded to a focus of fat at pathologic examination.

Implants may be confined to the superficial subcutaneous soft tissues but may also involve the rectus muscle. The most widely held theory of pathogenesis states that these implants arise from transportation and direct implantation of endometrial cells during procedures that open the uterus.[96] Women may present with a tender abdominal wall mass adjacent to a scar or with an asymptomatic palpable lump. Pain and swelling may be cyclic, correlating with menstruation. Imaging findings vary depending upon phase of the menstrual cycle, chronicity, number of stromal and glandular elements, and degree of associated bleeding and inflammation.[96] Sonography is usually the first-line imaging study performed, using a high-resolution linear transducer, which will identify a solid, heterogeneous hypoechoic mass with scattered internal echoes, although the appearance is variable[93,97,98] (Fig. 29-23). Areas of cystic change may be observed and the margins may be spiculated with infiltration of adjacent soft tissues.[99,100] Most implants will demonstrate some vascularity at Doppler evaluation.[93,97,99] Differential diagnostic considerations include abdominal wall masses such as desmoid tumor, metastasis, lymphoma, melanoma, hematoma,

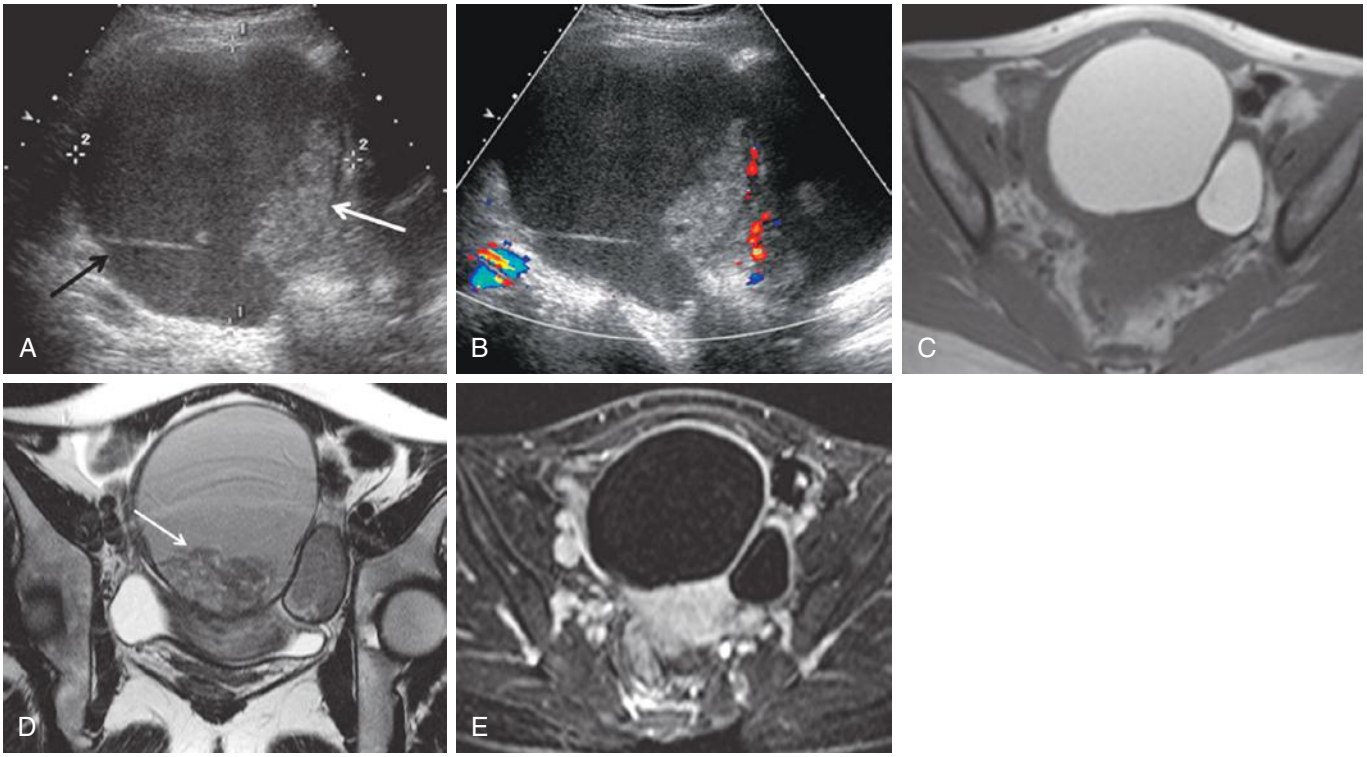

FIG 29-21 Complex endometrioma mimicking ovarian neoplasm. **A,** A 10-cm complex cystic mass (*calipers*) with septation (*black arrow*) and echogenic, lobulated mural nodule (*white arrow*). **B,** No flow was demonstrated in the nodule with color Doppler interrogation, suggesting the possibility of an adherent blood clot. **C,** Axial T1-weighted magnetic resonance (MR) image demonstrates that the lesion is T1-weighted hyperintense suggesting hemorrhagic content. Note adjacent smaller similar appearing lesion. **D,** Decrease in signal intensity within both lesions on T2-weighted axial MR image represents "shading." A dependent clot is visible in the larger midline lesion (*arrow*). **E,** Postcontrast subtraction image demonstrates no enhancing solid component. Endometriomas were confirmed at surgery.

suture granuloma, or incisional hernia. Location of the mass next to a scar and history of cyclic pain related to menses suggest the diagnosis. MRI may also be a useful adjunct because it may identify the typical imaging characteristics of hemorrhage as well as avid gadolinium enhancement.[96] The extent of disease may also be better depicted on MRI. Fine-needle aspiration/biopsy with cytologic analysis may help confirm a definitive diagnosis. Wide surgical excision with clear margins to prevent local recurrence is the treatment of choice.

In the past, ultrasound examination was considered most useful for characterization of an adnexal mass as an endometrioma, whereas extraovarian disease and deep pelvic endometriosis was better evaluated with MRI, offering important mapping of extent of disease prior to surgical intervention. However, more recently, an increasing role for sonography in identification of nonovarian disease has been advocated.[101] Gentle probing with the transvaginal ultrasound transducer may identify extraovarian disease, particularly in the deep pelvis.[102,103] Recent studies have shown that sonography may be useful for detecting implants in the bladder, rectovaginal septum, rectum, and sigmoid colon.[104,105] Bazot and associates[106] evaluated a group of women with deep endometriosis and found that sonography had a sensitivity and specificity for detection of disease of 78.5% and 95.2%, respectively, with the highest sensitivity for detecting intestinal and bladder disease. Endometriosis of the uterine serosa, uterosacral ligaments, and retrocervical and retrovaginal spaces may be diagnosed as hypoechoic solid lesions with indistinct margins due to smooth muscle proliferation and prominent fibrotic component[88] (Fig. 29-24). Occasionally, these lesions may also contain cystic spaces. Pelvic adhesions can be evaluated by moving the transducer back and forth to assess whether the uterus, adnexa, and bowel slide freely. Bowel implants may be more conspicuous after bowel preparation and appear as hypoechoic nodules with variable extension into the bowel wall.[107] A recent meta-analysis showed that transvaginal sonography with or without bowel preparation is an accurate test for noninvasive presurgical detection of deep infiltrating endometriosis of the rectosigmoid with pooled estimates of sensitivity and specificity of 91% and 98%, respectively, and positive and negative predictive value (NPV) of 98% and 95%.[108] Another study reported that transvaginal sonography yields few false positive results but that negative findings are less reliable and that the accuracy of sonography is affected by the location and number of endometriotic lesions.[109]

Although endometriosis most often causes chronic pelvic symptoms, complications may lead to acute pelvic pain. Occasionally an endometrioma may rupture and have a clinical presentation similar to a ruptured hemorrhagic ovarian cyst. On sonography, complex free fluid compatible with hemoperitoneum will be noted in addition to a hemorrhagic-appearing adnexal mass (Fig. 29-25). This occurs more frequently during pregnancy as a result of rapid growth from hormonal stimulation and may become a surgical emergency if there is extensive bleeding.[110] A known history of endometriosis is helpful in establishing the diagnosis. Endometriosis may also be associated with massive hemorrhagic ascites, usually in the setting of pelvic adhesions and ovarian endometriomas.[111] Exudative ascites may result from peritoneal inflammation due to hemoperitoneum following rupture of an endometrioma. An endometrioma may also become superinfected,

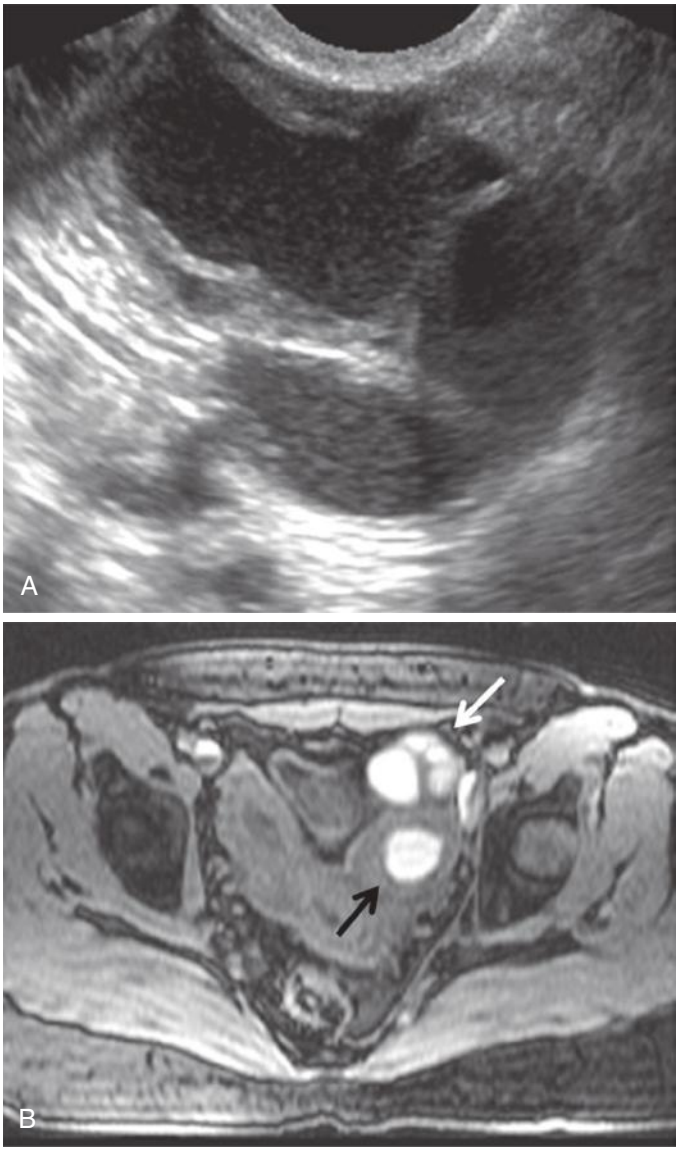

FIG 29-22 Endometriosis involving fallopian tube with hematosalpinx. **A,** Dilated fallopian tube with low-level intraluminal echoes compatible with blood. **B,** Axial fat-suppressed T1-weighted magnetic resonance image confirms high signal intensity in the tube (*white arrow*) compatible with hematosalpinx. The patient also has a unicornuate uterus with an obstructed left rudimentary horn containing blood (*black arrow*).

clinically mimicking PID. This most commonly occurs after surgical drainage or aspiration.[112] Direct spread from adjacent inflammation or hematogenous spread in a bacteremic patient may also cause superinfection. The sonographic appearance of an infected endometrioma may be identical to an uninfected endometrioma or may appear more complex (Fig. 29-26). Clinical signs of infection are thus crucial in establishing the diagnosis.

During pregnancy, decidualization of an endometrioma may occur as a result of hypertrophy of the ectopic stromal cells, primarily from the effects of progesterone.[113] A decidualized endometrioma increases in size and becomes more complex in appearance, with solid mural nodules or papillary excrescences that may be vascular on Doppler imaging. These changes may mimic a malignant ovarian neoplasm.[114-116] Prior documentation of an endometrioma can be helpful in suggesting this diagnosis, allowing for sonographic surveillance rather than surgical intervention. MRI may also be useful by demonstrating that the mural nodules have signal intensity and texture similar to the decidualized uterine endometrium.[116,117]

Malignant transformation is a well-described but rare complication of endometriomas, with an estimated incidence of approximately 1%.[118] Women with a history of endometriosis are 4.2 times more likely to develop ovarian cancer than other women, the most common histologic findings being clear cell carcinoma and endometrioid carcinoma arising from glandular elements.[119] Less commonly, endometrial stromal sarcoma can arise from stromal elements.[120] A specific genetic mutation (*ARID1A*) has been implicated in this process.[121] Because of this malignant potential, the Society of Radiologists in Ultrasound Consensus Conference Statement on management of asymptomatic ovarian cysts advised that adnexal masses with classic features of endometriomas be followed at least yearly with serial ultrasound examinations to search for worrisome features, including development of solid vascular components, usually mural based, and rapid interval growth (Fig. 29-27).[51] If such findings are observed, surgical exploration should be recommended. MRI may be helpful to confirm the diagnosis of malignant transformation.[122,123] The frequency of follow-up will vary depending on the patient's age and symptoms. With advancing age, patients may be followed more closely owing to increased incidence of malignant transformation in older women.[124]

Peritoneal Inclusion Cyst

Peritoneal inclusion cysts are benign fluid-filled lesions lined by mesothelium that occur in the abdomen and pelvis. Although their pathogenesis is a subject of some debate, with both hyperplastic and neoplastic origins proposed, they are generally thought to arise secondary to intra-abdominal inflammation with reactive mesothelial proliferation and impaired absorption of peritoneal fluid. Histologically, mesothelial cells are arranged in a single layer with surrounding reactive stroma and fibrovascular tissue.[125] They occur almost exclusively in premenopausal women with functioning ovaries and a history of abdominal or pelvic surgery or inflammation, including PID, endometriosis, and inflammatory bowel disease. It is believed that the small amount of fluid normally produced by the ovaries and fallopian tubes is loculated by surrounding pelvic adhesions and that absorption of this fluid is impaired by the surrounding fibrous tissue, forming a loculated cystic collection. Although peritoneal inclusion cysts may be incidental findings, they may also be associated with abdominal/pelvic pain or palpable mass. Accurate diagnosis is important to guide patient management. Options for treatment include oral contraceptives to decrease the amount of fluid produced by the ovary, percutaneous drainage, sclerotherapy, or surgical resection.[125] However, these cysts often recur following surgery as new adhesions form. Hence, conservative management is the preferred option in most cases. If mistaken for a cystic ovarian neoplasm, unnecessary or more aggressive therapy may be undertaken.

The imaging features of peritoneal inclusion cysts reflect their pathogenesis, and recognition of these features often allows differentiation from a cystic ovarian mass.[126-128] As the fluid surrounds the ovary, the ovary is entrapped within the cyst and is often identifiable along the cyst wall (Figs. 29-28 and 29-29). Fibrous bands mimicking septations and extending to the ovarian surface may suspend the ovary within the fluid collection, creating a "spoke wheel" or "spider web" appearance. Because these cysts lack a true wall, they typically conform to the shape of the surrounding pelvic organs or peritoneal cavity, becoming irregular in shape with angular margins. They can, however, be ovoid or spherical. Occasionally, features overlap with those of cystic ovarian masses, particularly if the ovary cannot be identified as a discrete structure within the cyst. Rarely, hemorrhage into these lesions

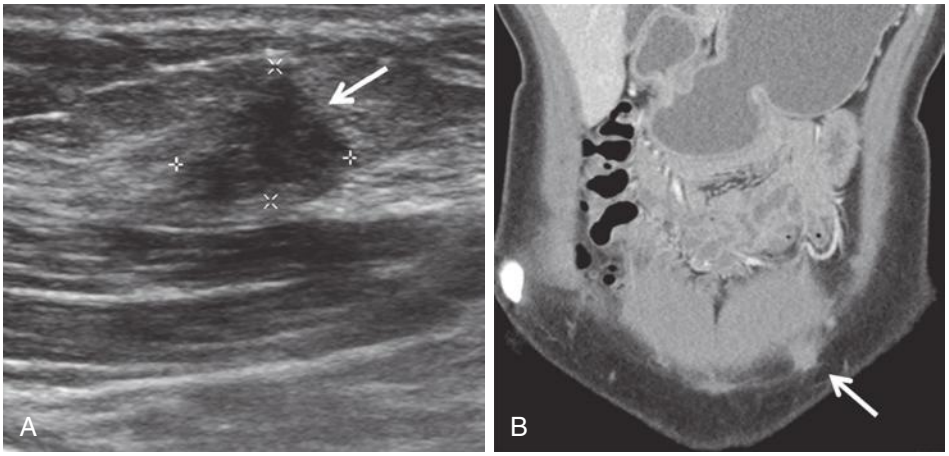

FIG 29-23 Abdominal wall endometriotic implant. **A,** Hypoechoic, irregularly marginated solid nodule (*arrow* and *calipers*) in the subcutaneous soft tissues at the anterior abdominal wall, ventral to the rectus muscle near the surgical scar. The patient, with history of open myomectomy 2 years prior, has a palpable lump. **B,** Coronal computed tomography image demonstrates the nodule (*arrow*) in the subcutaneous soft tissues, corresponding to the finding on ultrasound imaging.

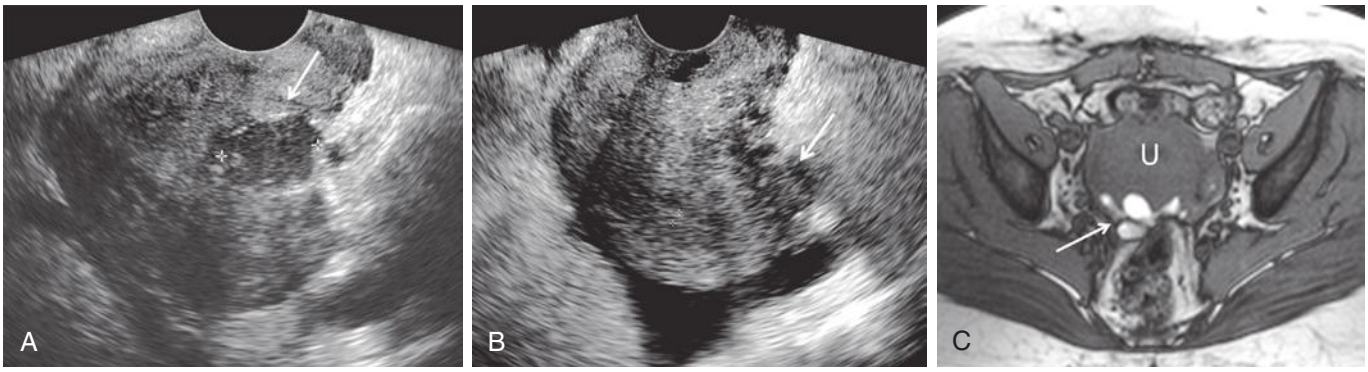

FIG 29-24 Endometriotic implant at posterior serosal surface of uterus. **A,** Hypoechoic nodule (*arrow* and *calipers*) along the posterior surface of uterus. **B,** Additional hypoechoic implants (*arrow*) are less well defined and have more irregular margins. **C,** Fat-suppressed axial T1-weighted magnetic resonance image showing the hyperintense implants (*arrow*) along the posterior surface of the uterus (U).

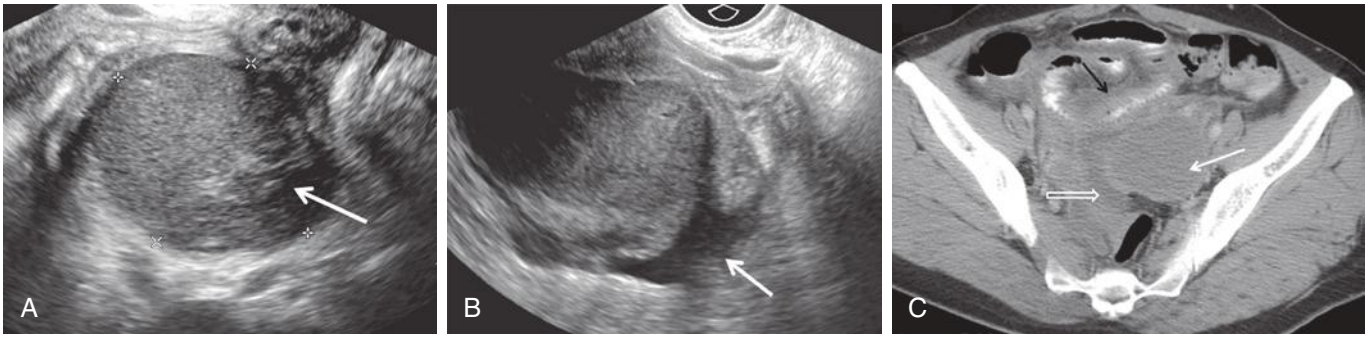

FIG 29-25 Ruptured endometrioma in a patient with acute onset of left lower quadrant pain **A,** Complex mass (*calipers*) with internal echoes and echogenic focus compatible with clot (*arrow*). **B,** There is associated free fluid (*arrow*) containing echoes, most consistent with hemoperitoneum. **C,** Computed tomography shows the endometrioma (*solid white arrow*). There is a small amount of free fluid (*open arrow*) and pelvic inflammatory changes. There is reactive thickening of an adjacent loop of small bowel (*black arrow*). Ruptured endometrioma was confirmed at surgery.

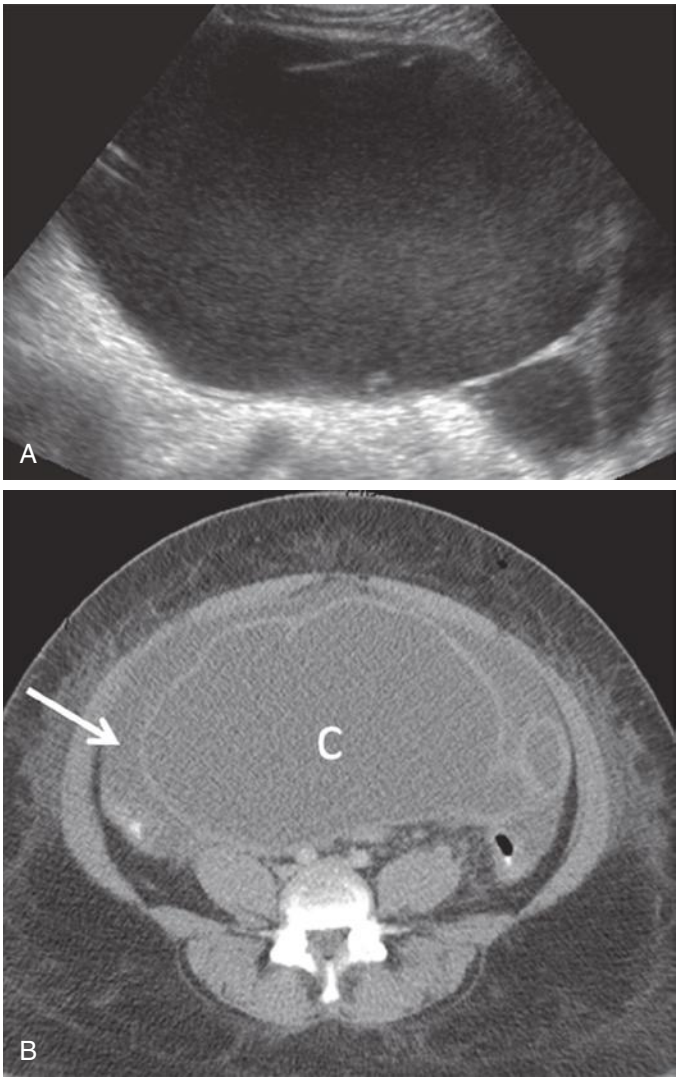

FIG 29-26 Infected endometrioma with rupture in a patient with abdominal pain and sepsis. **A,** Ultrasound image shows a large complex cystic mass with low-level echoes and incomplete septation. **B,** Computed tomography demonstrates the large cystic mass (C) with incomplete septation anteriorly and associated ascites (*arrow*). Ruptured endometrioma with superinfection was confirmed at surgery.

may occur, creating a more complex appearance.[127] The presence of mural nodularity, papillary excrescences, or other solid components should exclude this diagnosis. MRI may allow better appreciation of the shape of the cyst and visualization of the ovary[128] (Fig. 29-28C), confirming the diagnosis. The need for follow-up should be based on patient age and symptoms.

UTERINE CAUSES OF PELVIC PAIN

Leiomyomas

Uterine leiomyomas (also termed *fibroids* or *myomas*) are the most common tumor of the female reproductive tract and are found in up to 60% of reproductive age women and in 80% of women during their lifetime.[129] Leiomyomas are benign tumors of smooth muscle origin and have a higher concentration of estrogen and progesterone receptors than normal myometrium.[130] As a result, they grow in response to hormonal stimulation, including during pregnancy, and generally regress after menopause. Although many remain asymptomatic, up to 25% may be associated with symptoms significant enough to warrant treatment.[131] Symptoms include chronic pain, pelvic pressure, dysmenorrhea, infertility, and abnormal vaginal bleeding and vary depending on size, location, and associated complications such as degeneration and infarction.[132] Leiomyomas may undergo various types of degeneration including hyaline, myxomatous, calcific, cystic, fatty, and carneous (red) degeneration.[133] Compression of the ureters by a large myoma may lead to hydronephrosis and flank pain. Uterine leiomyomas are classified by location as intracavitary, submucosal, intramural, subserosal, or exophytic/pedunculated. Recently, a detailed subclassification system to more completely describe the relationship of a leiomyoma to the endometrium and serosa has been described,[134] as these features may impact clinical management. Leiomyomas may occasionally arise outside the uterus in the broad ligament, mimicking an adnexal mass. More unusual manifestations of extrauterine leiomyomas include disseminated peritoneal leiomyomatosis, intravenous leiomyomatosis, and benign metastasizing leiomyomatosis.[135]

Uterine leiomyomas are often suspected upon palpation of an enlarged, lobulated uterus on physical examination with suggestive clinical symptoms. If imaging is required, sonography is the first-line imaging test of choice and is usually sufficient for evaluation. A transabdominal approach is often used to supplement the transvaginal examination when the uterus is enlarged or when location of the leiomyoma prevents adequate sound penetration and visualization. Most

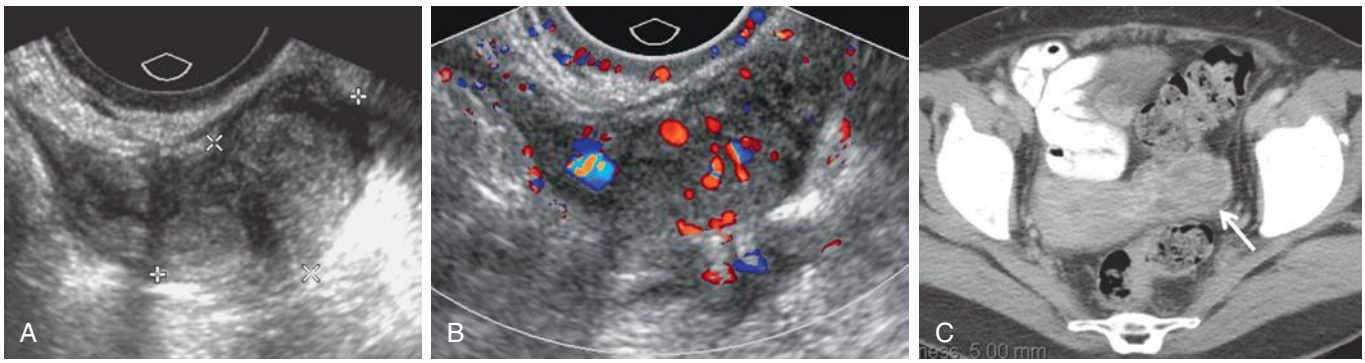

FIG 29-27 Enlarging solid ovarian mass found on serial sonograms in patient with history of endometriosis. **A,** Transvaginal sonography demonstrates a solid mass (*calipers*) in the left ovary. **B,** Increased vascularity is demonstrated in the mass with color Doppler sonography, confirming solid nature. **C,** Contrast-enhanced computed tomography scan demonstrates the primarily solid, heterogeneously enhancing left ovarian mass (*arrow*). Patient underwent surgery and was found to have endometrioid adenocarcinoma with foci of squamous and clear cell differentiation involving the left ovary and fallopian tube arising in a background of endometriosis.

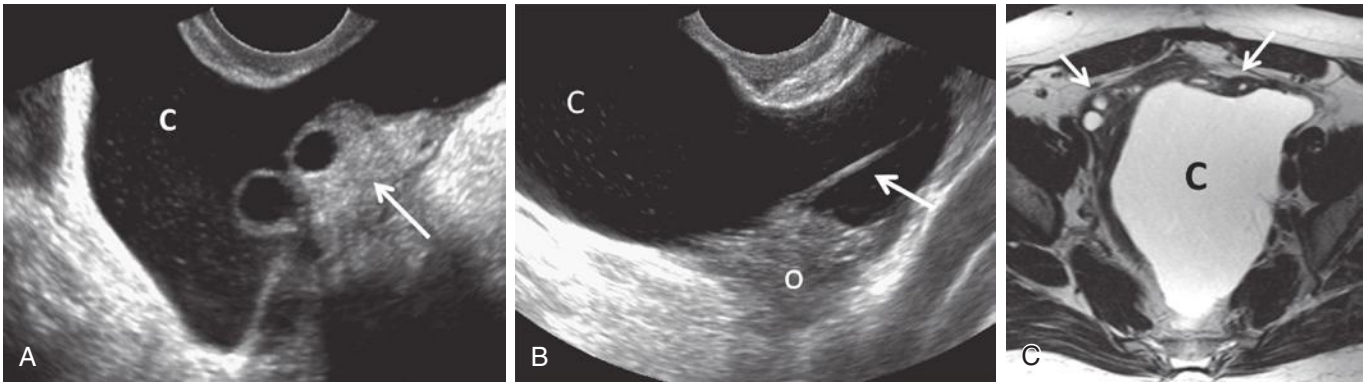

FIG 29-28 Peritoneal inclusion cyst. **A,** Normal ovary (*arrow*) identified at the margin of the cyst (c), which contains a small amount of echogenic debris. **B,** A fibrous band (*arrow*) extends from the ovary (o). The irregular shape of the cyst (c) conforms to adjacent pelvic structures. **C,** T2-weighted axial magnetic resonance image demonstrates both ovaries (*arrows*) along the anterior wall of the cyst (c).

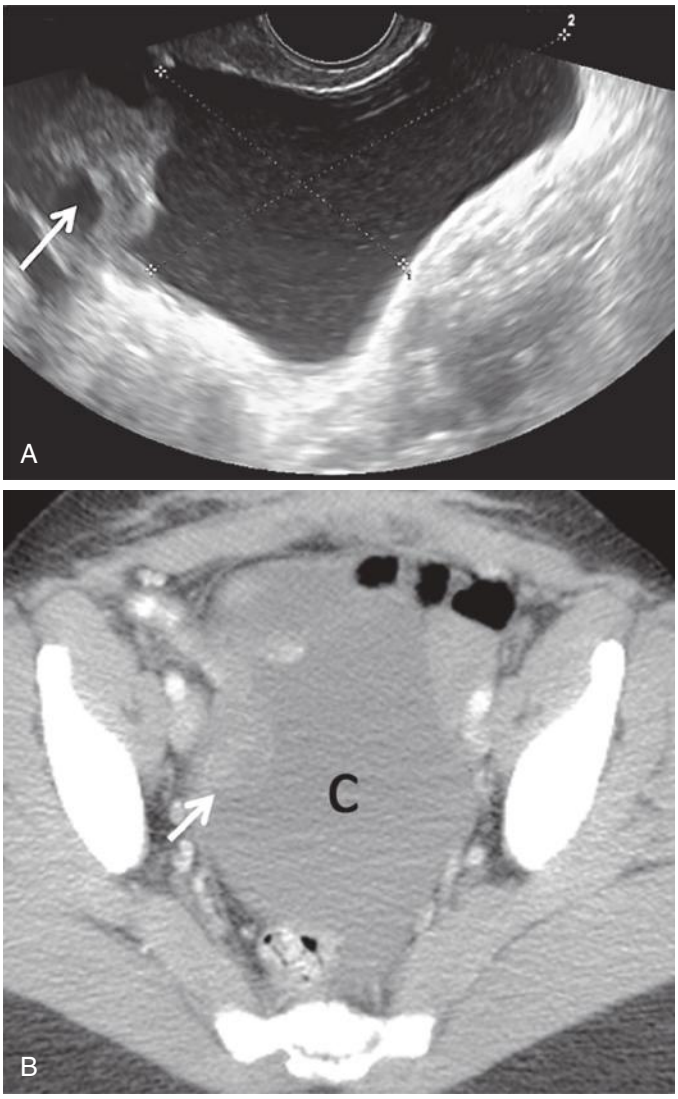

FIG 29-29 Peritoneal inclusion cyst. **A,** The right ovary (*arrow*) is noted along the superior wall of the cyst (*calipers*). Low-level echoes are present in the cyst fluid. **B,** Contrast-enhanced axial computed tomography shows the right ovary (*arrow*) along the cyst wall. The shape of the cyst (c) conforms to adjacent pelvic structures. The patient had previously undergone hysterectomy for leiomyomas.

often, a leiomyoma appears as a well-defined hypoechoic solid mass arising from the myometrium with a well-defined border or pseudocapsule resulting from compression of adjacent myometrium[136] (Fig. 29-30). However, the echogenicity of the mass varies depending on the relative amount of fibrous tissue and smooth muscle. The amount of fibrous tissue also likely determines the degree of attenuation of the ultrasound beam and posterior acoustic shadowing. As leiomyomas enlarge, they may undergo degeneration or necrosis leading to a heterogeneous appearance with cystic spaces within the lesion. Calcification is more common in older patients and may be present in a peripheral distribution or scattered throughout the lesion. An exophytic or pedunculated myoma may be difficult to differentiate from a solid adnexal mass. Demonstration of a normal ipsilateral ovary and vascular supply derived from the uterus, the *bridging vascular sign*, helps confirm the diagnosis.[137]

Additional Imaging Modalities

Although a combination of transvaginal and transabdominal sonography is generally sufficient for evaluation of most leiomyomas, supplemental imaging techniques may at times be helpful. If there are multiple large leiomyomas, ultrasound imaging may be very limited owing to associated acoustic attenuation. The endometrium may be obscured, precluding definitive evaluation. Coexisting adenomyosis also may be difficult to diagnose in this setting. Precise mapping of size and location of leiomyomas may be required prior to either surgical or nonsurgical intervention. Sonohysterography is a helpful adjunct for evaluation of submucosal leiomyomas to determine the degree of intracavitary versus intramyometrial extension, which may affect the surgical approach[138] (Fig. 29-31). 3D sonography may also be helpful in this regard. Often, MRI better defines size and location of leiomyomas prior to surgical intervention[139,140] and may also help identify patients who are the most appropriate candidates for uterine artery embolization (UAE) and other treatment options[141-143] (Fig. 29-32). The role of MRI is growing as minimally invasive therapeutic techniques including percutaneous MRI-guided cryoablation and MRI-guided focused sonographic ablation continue to evolve.[144]

Lipoleiomyoma

An uncommon subtype of leiomyoma is lipoleiomyoma, which has a reported incidence of 0.03% to 0.2%.[145] These tumors contain variable amounts of mesodermal tissue including fat, smooth muscle, and fibrous tissue. They may arise from misplaced embryonic fat cells in the uterus, lipocytic differentiation of primitive connective or

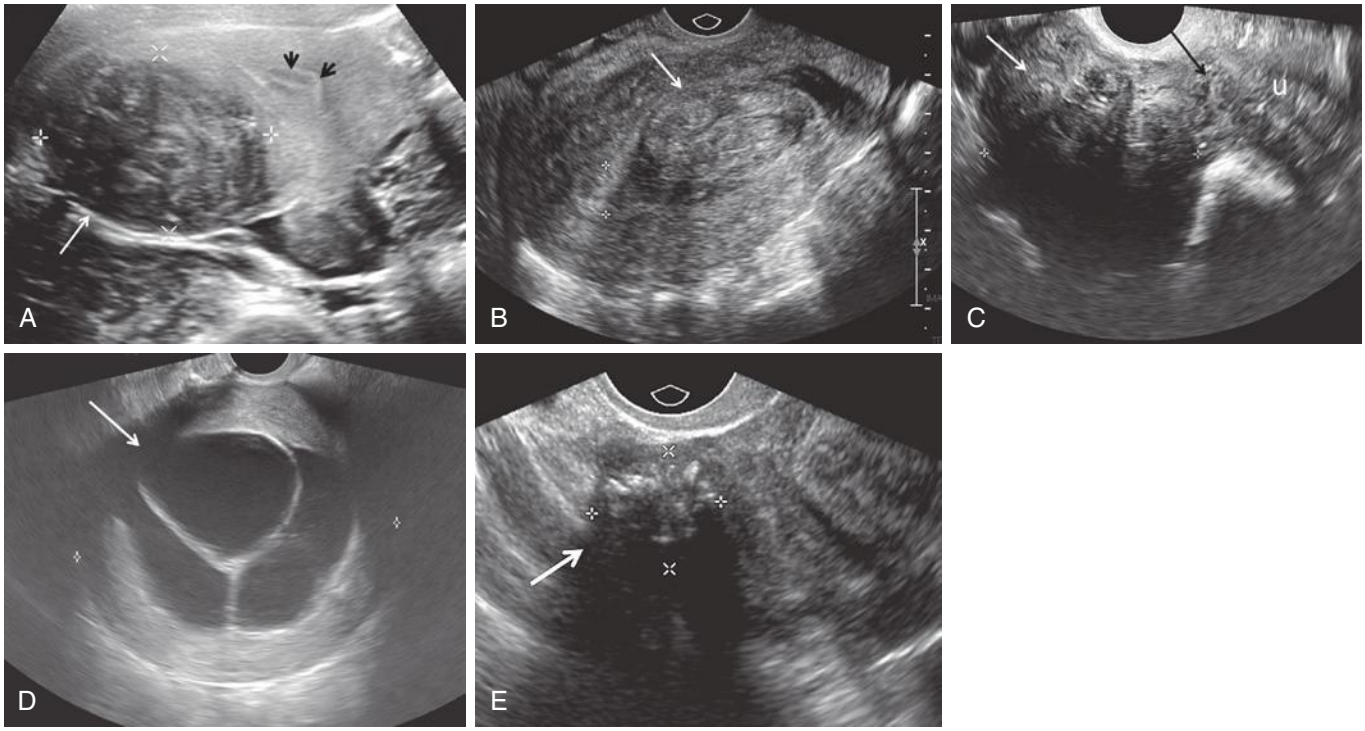

FIG 29-30 Imaging spectrum of leiomyomas. **A,** Transabdominal scan shows a large heterogeneous intramural leiomyoma (*arrow* and *calipers*) separate from the endometrium (*short black arrows*) and surrounded by a thin rim of myometrium. **B,** Intracavitary submucosal leiomyoma (*arrow*) splaying the endometrium (*calipers*). **C,** Exophytic pedunculated leiomyoma (*white arrow* and *calipers*) arising from the uterine fundus (u) mimicking a solid adnexal mass. Note bridging soft tissue pedicle (*black arrow*) connecting the leiomyoma to the uterus. **D,** Leiomyoma with large areas of cystic degeneration (*arrow*) on transverse view of the uterus (*calipers*). **E,** Leiomyoma with echogenic foci (*arrow* and *calipers*) indicating coarse calcifications.

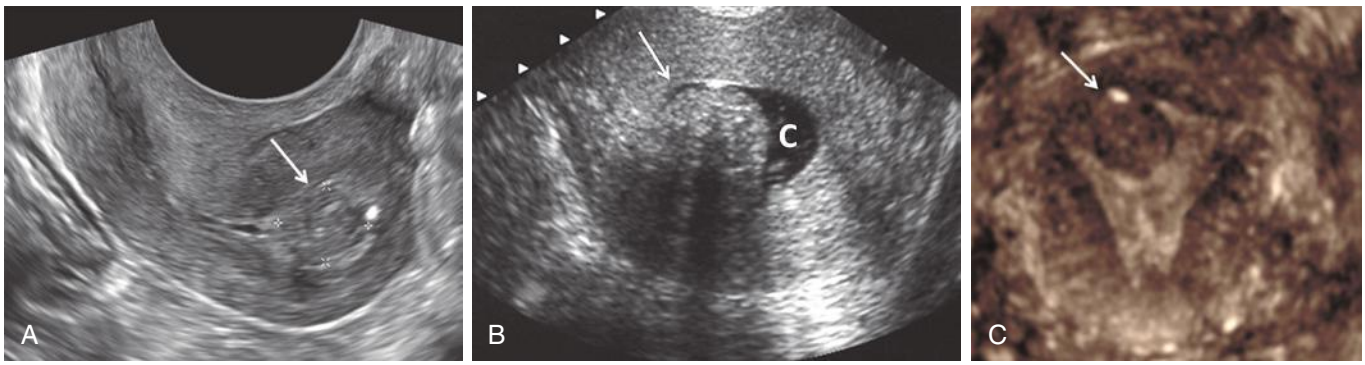

FIG 29-31 Submucosal leiomyoma. **A,** Transvaginal sonogram demonstrating a submucosal leiomyoma (*arrow* and *calipers*) that is isoechoic to the myometrium and appears to be intracavitary in the fundus of a retroverted uterus. **B,** Sonohysterogram with instilled fluid in the endometrial cavity (c) partially outlining the protruding submucosal leiomyoma (*arrow*), which demonstrates posterior acoustic shadowing. **C,** Three-dimensional coronal ultrasound image demonstrates the relationship of the leiomyoma (*arrow*) to the endometrium and confirms that the myoma is predominantly intracavitary.

mesenchymal tissue, or fatty metaplasia of muscle or connective tissue.[146,147] Clinical presentation is generally identical to typical leiomyomas. Imaging characteristics of lipoleiomyomas vary depending upon proportion of fat, muscle, and connective tissue. Because of the fat content in these lesions, they generally appear as hyperechoic masses at sonography, often with posterior attenuation[145,148,149] (Fig. 29-33). A leading differential diagnostic consideration is a mature cystic teratoma of the ovary, which is the most common fat-containing mass in the female pelvis. If the origin of the mass is uncertain, CT or MRI may be performed to confirm the diagnosis.[148-150]

Acute Complications of Leiomyomas

Although leiomyomas primarily cause chronic symptoms, associated complications may cause acute pelvic pain. Leiomyomas may undergo various types of benign degeneration, the most common being hyaline degeneration consisting of mucopolysaccharide deposits around muscle fibers. An acute form of degeneration is red (carneous) degeneration. This occurs when there is acute infarction of a leiomyoma and is associated with severe acute pelvic pain with local peritoneal symptoms,[151] which may mimic other entities, such as appendicitis (Fig. 29-34). Such degeneration occurs primarily during pregnancy when

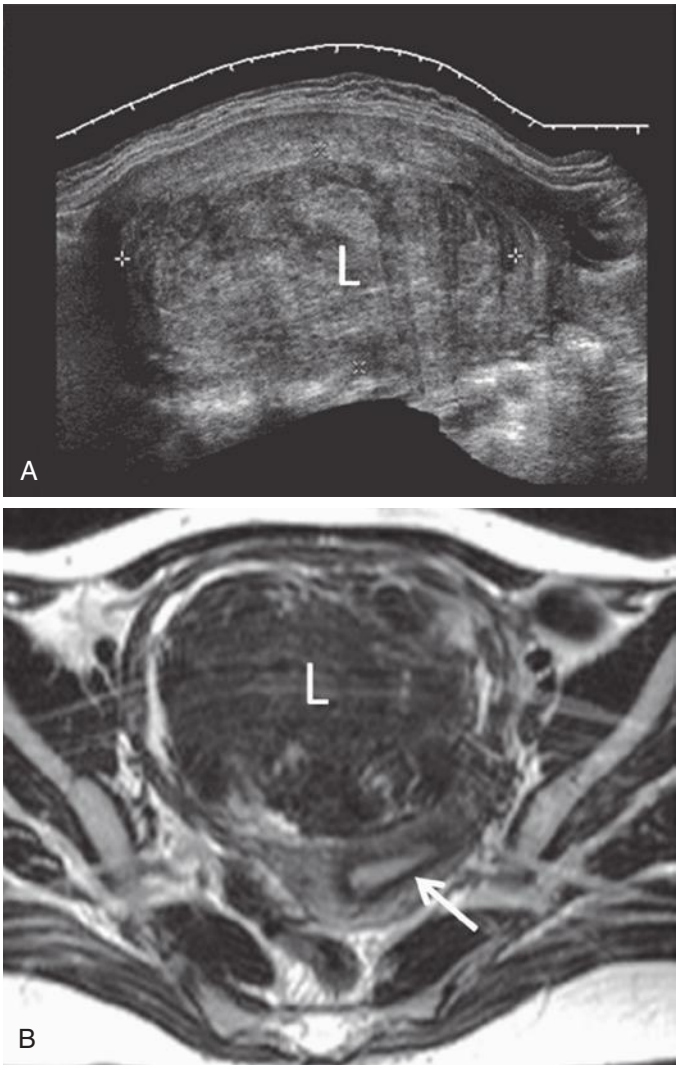

FIG 29-32 Large intramural leiomyoma. **A,** Extended field of view ultrasound image demonstrates a large (18.3 cm) leiomyoma (L and *calipers*) occupying most of the uterus. The relationship to the endometrium, which is not visualized, cannot be determined. **B,** T2-weighted axial magnetic resonance image demonstrates that the large leiomyoma (L) is intramural in location. The high signal intensity endometrium (*arrow*) is delineated, shown to be displaced posteriorly but otherwise unremarkable.

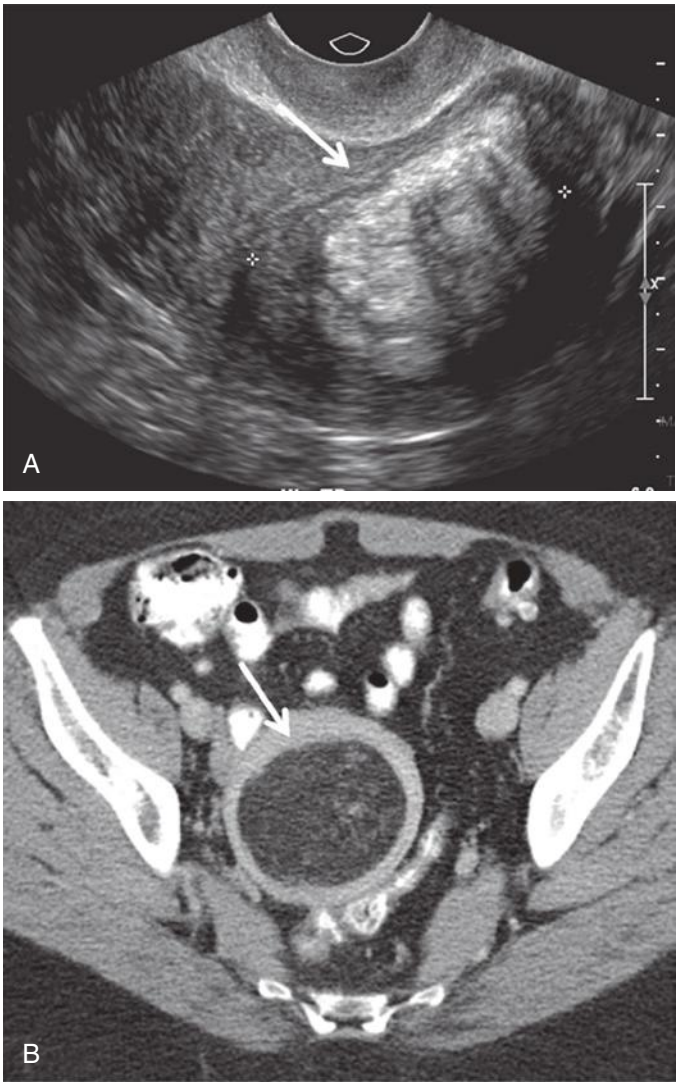

FIG 29-33 Lipoleiomyoma. **A,** Hyperechoic heterogeneous mass (*arrow* and *calipers*) in the uterus with a slightly lobular contour. **B,** Computed tomography confirms the presence of low attenuation fat within the uterine mass (*arrow*) confirming the diagnosis of intramural lipoleiomyoma.

leiomyomas may grow rapidly owing to hormonal stimulation and thus undergo hemorrhagic infarction, or following delivery when hormonal levels rapidly decline. Clinical symptoms and sonographic evidence of degeneration occur in about 5% of pregnant women with known leiomyomas.[132] Rupture of a degenerated leiomyoma is a rare complication that may result in an acute abdomen and potentially life-threatening hemoperitoneum.[152,153]

Leiomyomas may also present with acute pain if they are pedunculated and undergo torsion, mimicking ovarian torsion.[152] Sonography will demonstrate a hypovascular or avascular mass separate from the ovaries, and occasionally a twisted or "beaked" pedicle may be observed. A pedunculated submucosal myoma may protrude into the endometrial cavity on a stalk. These leiomyomas may be expulsed from the uterus into the endocervical or vaginal canal and present as an "aborting" or prolapsing mass.[154] In one series, this complication was observed in approximately 2.5% of all leiomyomas.[155] Prolapsing leiomyomas may twist on their vascular pedicle causing infarction and are then at risk for superinfection. Often, the findings on pelvic examination are limited in this situation because of profuse vaginal bleeding, and pelvic sonography is helpful in establishing the diagnosis. At sonography, a well-circumscribed solid mass is identified in the endocervical canal, with the cervix splayed around the mass, or within the vagina[156] (Fig. 29-35). Slight withdrawal of the transvaginal probe or translabial views may aid in visualization of an intravaginal mass. These masses may be echogenic or heterogeneous owing to associated hemorrhage, edema, and degenerative change. A vascular stalk or pedicle is often demonstrated with targeted color Doppler sonography (Fig. 29-35B). Other intracavitary endometrial masses may also prolapse, including polyps and malignant neoplasms. MRI can be helpful in further evaluation if sonographic findings are equivocal[157,158] (Fig. 29-35C), particularly in determining the extent of myometrial involvement and the thickness of the stalk, which may alter the surgical approach.

Patients may present with pain following UAE. Postembolization syndrome, which occurs in approximately 40% of women following the procedure, consists of fever, pelvic pain, and vaginal discharge, which usually resolves in 24 to 48 hours.[159] The imaging appearance of

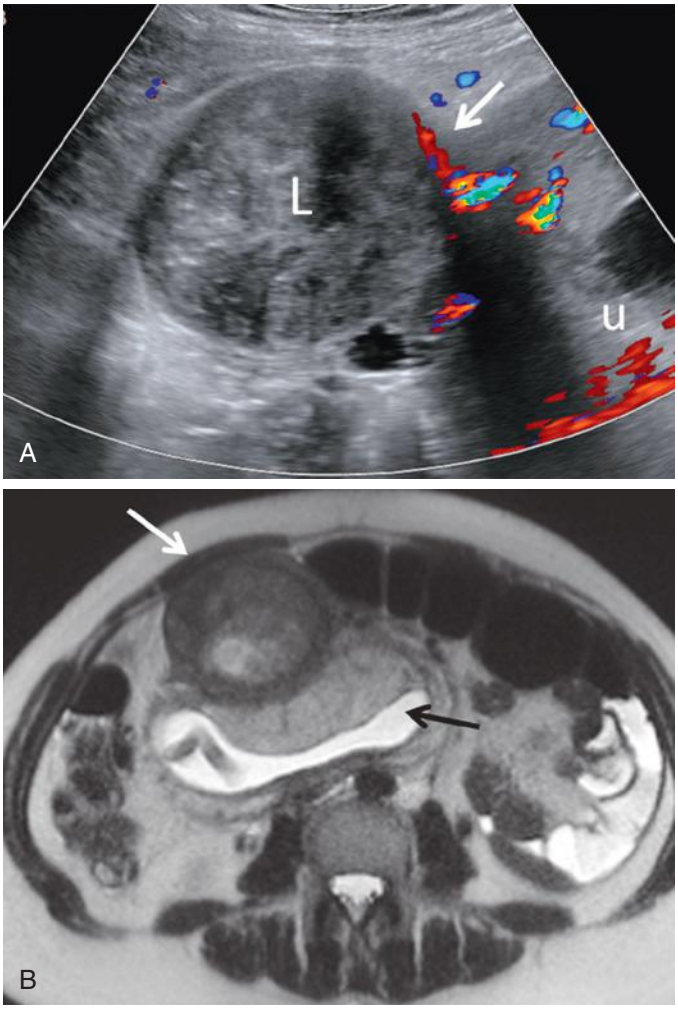

FIG 29-34 Degenerated exophytic leiomyoma in pregnant patient with right lower quadrant pain, initially evaluated for appendicitis. **A,** Transabdominal ultrasound image demonstrates an exophytic leiomyoma (L) with a bridging vascular sign (*arrow*) confirming origin from the gravid uterus (u). No flow is demonstrated in the leiomyoma owing to hemorrhagic degeneration. **B,** Magnetic resonance imaging was performed to assess for possible appendicitis. Axial T2-weighted image demonstrates heterogeneous, increased signal intensity in the leiomyoma (*white arrow*) owing to degeneration. The exophytic myoma is at the anterior aspect of the gravid uterus (*black arrow*).

leiomyomas after a UAE procedure is variable.[159-162] Air may be seen within a leiomyoma after UAE, thought to be the result of gas filling potential spaces due to tissue infarction and necrosis, and its presence alone does not indicate infection. However, correlation with patient symptoms and clinical findings is critical to promptly diagnose superinfection and to assess for possible development of pyomyoma (suppurative leiomyoma), which may be a life-threatening emergency leading to septic shock and necessitating emergent hysterectomy.[161] Ultrasound findings include a poorly defined mass with internal echoes and reverberation artifacts secondary to the presence of gas[163] (Fig. 29-36). CT can be performed to evaluate for associated complications such as pelvic abscess, uterine rupture, or septic thrombophlebitis of the ovarian vein.

Malignant Uterine Tumors

Although the diagnosis of uterine leiomyomas is generally straightforward, occasionally there may be concern for a malignant uterine neoplasm, such as leiomyosarcoma, carcinosarcoma (malignant mixed müllerian tumor), endometrial stromal sarcoma, or smooth muscle tumor of uncertain malignant potential (STUMP). Uterine sarcomas are very rare and account for approximately 3% to 6% of uterine cancers.[164,165] They generally occur in older patients who present with abnormal vaginal bleeding, an enlarging pelvic mass, and pelvic pain. Although these symptoms overlap with those of benign leiomyomas, features such as rapid growth of a myoma in a postmenopausal woman not on hormone replacement therapy should raise concern.

Clinical features are important for diagnosis as there is considerable overlap in imaging features of these malignant tumors with benign leiomyomas. Benign leiomyoma variants, such as cellular leiomyomas, may also exhibit concerning atypical imaging features.[166] Sonographic features that raise concern for leiomyosarcoma include a single large dominant myoma with large areas of cystic change/necrosis, ill-defined, infiltrative margins, and increased peripheral and central vascularity with high peak systolic velocity[167-169] (Fig. 29-37).

MRI may help delineate the infiltrative nature and irregular margins of the lesion and may reveal extrauterine extension. Malignant uterine neoplasms also typically have higher signal intensity on T2-weighted images and larger areas of necrosis with regions of increased T1-weighted signal intensity due to hemorrhage, as well as increased contrast enhancement, although there is significant overlap of these features with those of benign leiomyomas.[170-173] More recently, a role for diffusion weighted imaging (DWI) in differentiating benign from malignant uterine tumors has shown promise.[174,175] Unfortunately,

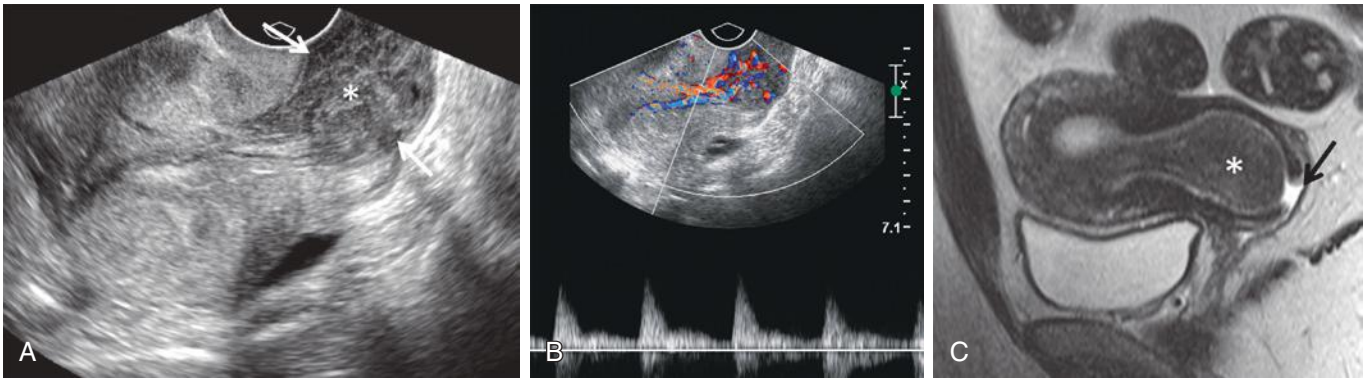

FIG 29-35 Prolapsing submucosal leiomyoma in patient with pelvic pain and vaginal bleeding. **A,** The prolapsing leiomyoma (*asterisk*) splays the cervix and extends through the endocervical canal into the upper vagina (*arrows*). **B,** Vascular pedicle with arterial flow is demonstrated with color and spectral duplex Doppler sonography. **C,** T2-weighted sagittal magnetic resonance imaging in another patient demonstrates a prolapsing leiomyoma (*asterisk*) splaying the cervix. Note high signal intensity fluid at the level of the open external cervical os (*arrow*).

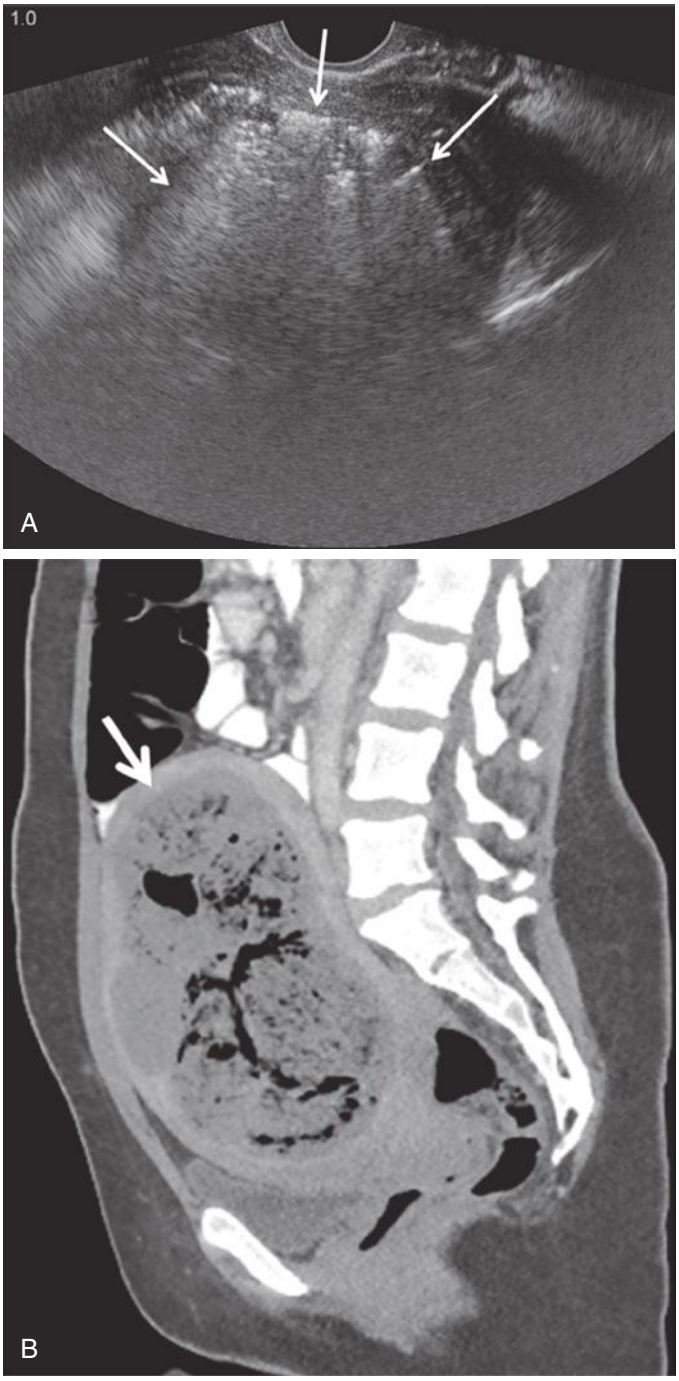

FIG 29-36 Infected and infarcted leiomyoma (pyomyoma) in patient with fever, vaginal discharge, and pelvic pain 2 weeks following uterine artery embolization. **A,** Transvaginal sonography demonstrates a large mass in the uterus containing echogenic foci (*arrows*) with posterior acoustic shadowing and reverberation artifact compatible with gas. **B,** Sagittal reformatted computed tomography image demonstrates the large leiomyoma (*arrow*) with extensive infarction and foci of gas. The patient underwent emergent hysterectomy shortly after this scan.

despite advanced MRI techniques, there continues to be considerable overlap with benign leiomyomas, particularly for myomas with large areas of degeneration and those of the cellular subtype (Fig. 29-38). Much investigation in this area is currently underway as the role of minimally invasive techniques, including laparosopic and robotic morcellation and excision of leiomyomas, is increasing, and identification of neoplasms prior to surgery has become critical to minimize the risk of intraperitoneal dissemination of malignancy.[176]

Adenomyosis

Adenomyosis is characterized by the presence of ectopic non-neoplastic endometrial glands and stroma within the myometrium surrounded by hypertrophied smooth muscle.[177] The pathogenesis is unknown but may in part be related to absence or defect of the basement membrane at the endometrial-myometrial junction, allowing for abnormal invagination of the basal endometrium into the myometrium.[178] Risk factors include a traumatized endometrial-myometrial interface related to procedures such as curettage; hormonal, genetic, and immunologic factors also play a role.[178] The true incidence of this condition is unknown but it has been estimated to occur in 20% to 30% of the general female population and is found in up to 70% of hysterectomy specimens.[136] An increased incidence in patients with endometriosis has been reported.[179] Symptoms are nonspecific and generally include uterine tenderness and enlargement, dysmenorrhea, and menorrhagia and are more common in older reproductive age women. Adenomyosis may be a diffuse process; however, it may also be focal and limited to one portion of the uterus (adenomyoma). In the past, hysterectomy was considered definitive therapy; however, treatment has evolved to include both medical and surgical therapy, including uterine sparing options such as resection of focal disease, endometrial ablation, UAE, and MR-guided high-frequency sonography.[136]

Sonography is the first-line imaging test of choice to diagnose adenomyosis. The 2D gray-scale sonographic findings of adenomyosis include globally or asymmetrically enlarged uterus, inhomogeneous myometrial echotexture with regions of increased echogenicity corresponding to heterotopic endometrial tissue and decreased echogenicity corresponding to smooth muscle hyperplasia, intramyometrial hypoechoic linear striations radiating throughout the involved parenchyma ("rain shower" or "Venetian blind" appearance), subendometrial echogenic linear striations located near the endometrial-myometrial interface, and thickening of the hypoechoic subendometrial halo (Fig. 29-39).[180-186] Small myometrial cysts may be observed corresponding to dilated glands or hemorrhagic foci. There may be poor definition of the endometrial-myometrial junction with apparent pseudo-widening of the endometrium. In a study by Kepkep and colleagues,[187] subendometrial linear striations had the highest accuracy for the diagnosis. Color and power Doppler sonography often demonstrate diffuse hypervascularity without large feeding vessels. In a meta-analysis of 14 studies including 1898 women who underwent sonography for evaluation of uterine lesions, the pooled sensitivity and specificity of transvaginal sonography for the diagnosis of adenomyosis was 82.5% and 84.6%, respectively.[188] However, detection of adenomyosis at transvaginal sonography may be limited if there are coexisting uterine tumors, such as leiomyomas. In one study, the sensitivity and specificity of transvaginal sonography for diagnosing adenomyosis in patients with leiomyomas was 33.3% and 78%, and in those without leiomyomas was 97.8% and 97.1%, respectively.[189]

More recently, 3D sonographic features of adenomyosis have been described.[186,190] Reconstructed images in the coronal plane demonstrate the subendometrial halo as a hypoechoic zone around the endometrium. In adenomyosis, there is disruption and infiltration of the subendometrial halo by the hyperechoic endometrium. The thickness of the subendometrial halo can be measured at sonography and can be helpful in diagnosing adenomyosis, as has been described for MRI.[186,190]

There is significant overlap between adenomyosis and leiomyomas in terms of clinical symptoms and imaging. In fact, confusion with leiomyomas is one of the most common sonographic pitfalls of

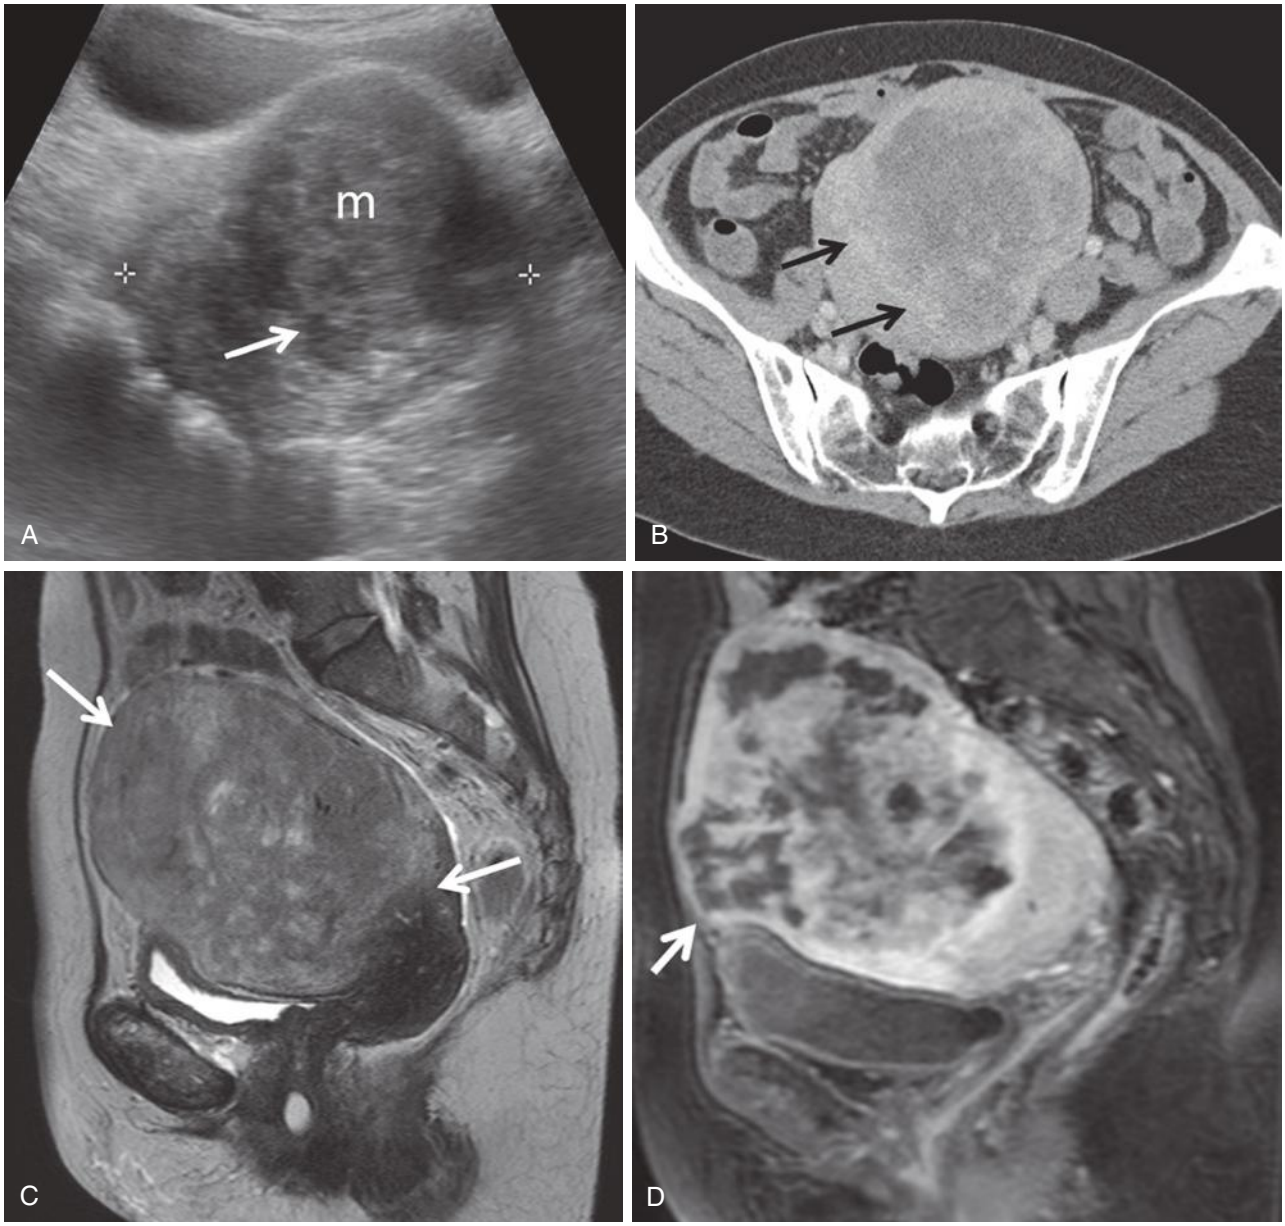

FIG 29-37 Leiomyosarcoma in postmenopausal patient with pelvic pain and enlarging pelvic mass. **A,** Transabdominal ultrasound image demonstrates large partially exophytic mass (m) arising from the uterus (*calipers*). The margins of the mass (*arrow*) appear irregular. **B,** Contrast-enhanced axial computed tomography scan demonstrates infiltrative margins of the mass (*arrows*) along the border with adjacent myometrium. **C,** T2-weighted sagittal magnetic resonance (MR) image demonstrates heterogeneous increased signal within the large uterine mass (*arrows*). The margins of the lesion with adjacent myometrium are indistinct and difficult to appreciate, suggesting the infiltrative nature of the mass. **D,** Postcontrast sagittal T1-weighted fat-suppressed MR image demonstrates heterogeneous enhancement of the mass with areas of necrosis, irregular borders, and infiltration of the ventral abdominal wall (*arrow*).

adenomyosis. However, distinction is important as treatment strategies often differ. This is particularly important in patients for whom surgical intervention with myomectomy is considered. Sonography has a reported sensitivity (80-87%) and specificity (94-98%) in distinguishing the two conditions.[183,191,192] A focal adenomyoma is less well defined than a leiomyoma and does not distort the uterine contour (Fig. 29-40). However, as noted previously, the presence of coexisting leiomyomas may make the identification of adenomyosis more difficult and these processes occur together in up to 63% of cases.[193] MRI has been shown to be a helpful adjunct to ultrasound examination, with reported accuracy ranging from 85% to 95% and specificity of 67% to 99%.[180,182,186,194-196] On sagittal T2-weighted sequences, MRI findings of adenomyosis include diffuse or focal thickening of the junctional zone to greater than 12 mm, T2-weighted hyperintense foci within the junctional zone, and corresponding high signal on T1-weighted images corresponding to hemorrhage in ectopic endometrial glands. A focal adenomyoma has less mass effect than a leiomyoma and is recognized by the T2-weighted hyperintense foci. Adenomyotic cyst (cystic

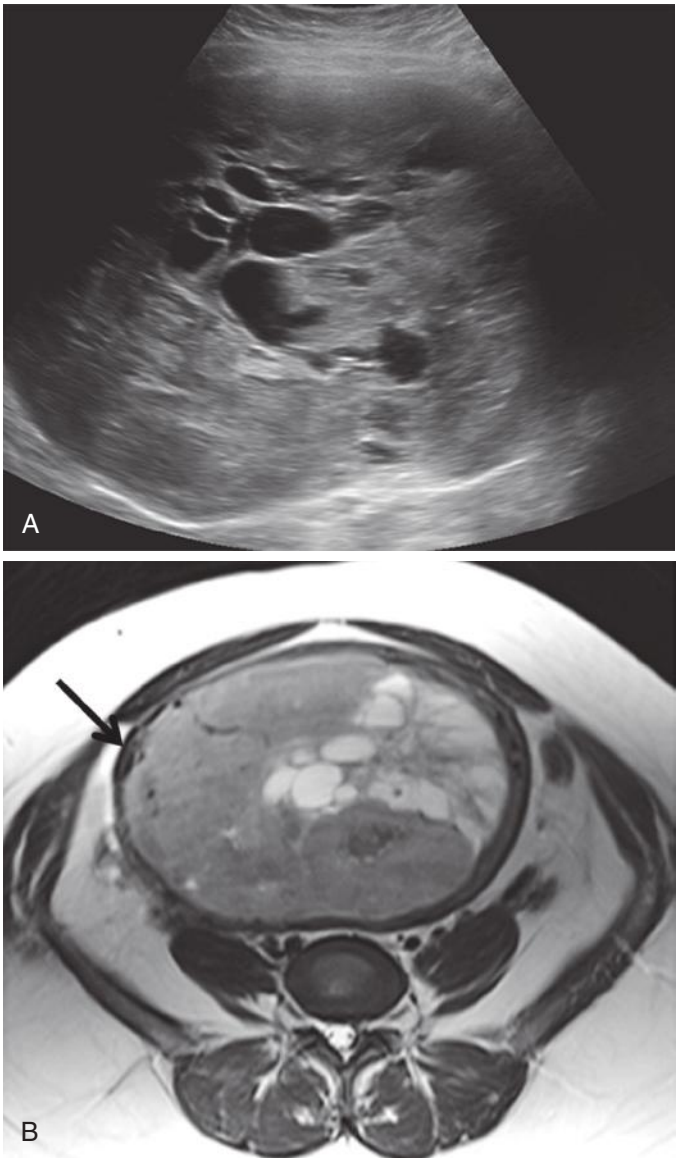

FIG 29-38 Cellular leiomyoma with imaging features concerning for leiomyosarcoma. **A,** Ultrasound image demonstrates a large dominant mass with irregular, indistinct borders and areas of cystic change within the uterus. **B,** Axial magnetic resonance image demonstrates areas of heterogeneity and increased T2-weighted signal, consistent with necrosis/cystic change. There was questionable invasion of the myometrium (*arrow*). However, benign cellular leiomyoma was found at myomectomy.

adenomyosis) is a rare variant of adenomyosis that appears similar to an endometrioma, with features of an intramyometrial hemorrhagic cystic mass that occasionally is intracavitary.[197,198]

Malpositioned Intrauterine Device

The intrauterine device (IUD) is one of the most widely used reversible methods of contraception worldwide and the contraceptive method of choice in 5.6% of women in the United States.[199] Ultrasound evaluation is important for verification that an IUD is in the appropriate location and to evaluate for complications. The Copper T-380A (ParaGard; Barr Pharmaceuticals, Montvale, NJ) IUDs typically have a straight shaft and crossbars that form the shape of a 7 or a T. They are strongly echogenic with associated posterior acoustic shadowing, and both the side arms and stem are readily visualized (Fig. 29-41). Hormone-containing IUDs are also in widespread use and most commonly contain synthetic progestogen-levonorgestrel within an internal reservoir. The Mirena (Bayer Healthcare Pharmaceuticals, Wayne, NJ) IUD is used most commonly in the United States and has a T-shaped polyethylene frame with side arms that contain barium sulfate. This type of IUD is more difficult to visualize with ultrasound, particularly the crossbars, although the stem will demonstrate characteristic posterior ring-down artifact.[200] The shaft should be centered within the uterine cavity at the miduterus with the crossbars located within the endometrium just below the fundal myometrium.[201] Complications include fragmentation; rotation; migration into the myometrium, lower uterine segment, cervix, or through the myometrium into the peritoneal cavity; and expulsion from the uterus. Inappropriate IUD positioning may result in diminished efficacy as well as pelvic pain and abnormal vaginal bleeding.

In recent years, 3D transvaginal sonography with images reconstructed in the coronal plane has been shown to be an important adjunct to 2D techniques if initial ultrasound findings are equivocal[200,202,203] (see Fig. 29-41). The rendered 3D coronal view is the most useful.[200] On this view, the IUD should be completely visualized with simultaneous depiction of the shaft and the crossbars. If the IUD cannot be visualized in the uterus, abdominal radiograph or noncontrast CT may be helpful for localization.

VASCULAR CAUSES OF PELVIC PAIN

Pelvic Congestion Syndrome

Pelvic congestion syndrome (PCS) may be a cause of chronic pelvic pain and results from incompetent valves in the ovarian veins resulting in reflux into pelvic veins, which dilate and become tortuous, forming pelvic varices.[204-207] Venous obstruction, such as a retroaortic left renal vein, compression of the left renal vein by the superior mesenteric artery (nutcracker syndrome), or left iliac vein compression by the right internal iliac artery (May-Thurner syndrome), as well as hormonal factors may contribute to the development of painful pelvic varicosities.[207] Patients most commonly present between the ages of 20 and 40 years with dull pelvic pain, ache, pressure, or heaviness made worse after prolonged periods of standing, while lifting, or during the premenstrual period. Other risk factors include multiparity, retroverted uterus, and pelvic surgery.

Sonography is the first-line imaging choice for assessment of chronic pelvic pain, and PCS may be considered if other more common causes such as endometriosis and leiomyomas have been ruled out. Sonographic findings include multiple dilated veins adjacent to the ovaries and uterus, measuring greater than 5 mm in diameter, and dilated (>5 mm) arcuate veins (especially if observed to cross the myometrium and connect to the pelvic varicosities).[208,209] Dilatation of the ovarian veins more than 6 mm with retrograde flow is a more specific finding, but can be much more difficult to document on ultrasound imaging in large patients. Scanning with the patient in the upright position may help distend the pelvic veins.[210] Velocity of intraluminal flow and diameter of the pelvic varices often increases following Valsalva maneuvers. Polycystic ovarian changes have also been associated with PCS. However, not all patients with pelvic varicosities develop pain. It has been estimated that 40% to 60% of women with pelvic varices and reflux will develop PCS.[204,211,212] Contrast-enhanced MR venography (MRV) can be helpful in establishing the diagnosis, and retrograde reflux into the gonadal veins may be demonstrated utilizing time-resolved MR techniques.[212-214] Using this technique, the pelvic venous system can be imaged in a single breath-hold. Images are obtained after bolus injection of gadolinium with automatic bolus

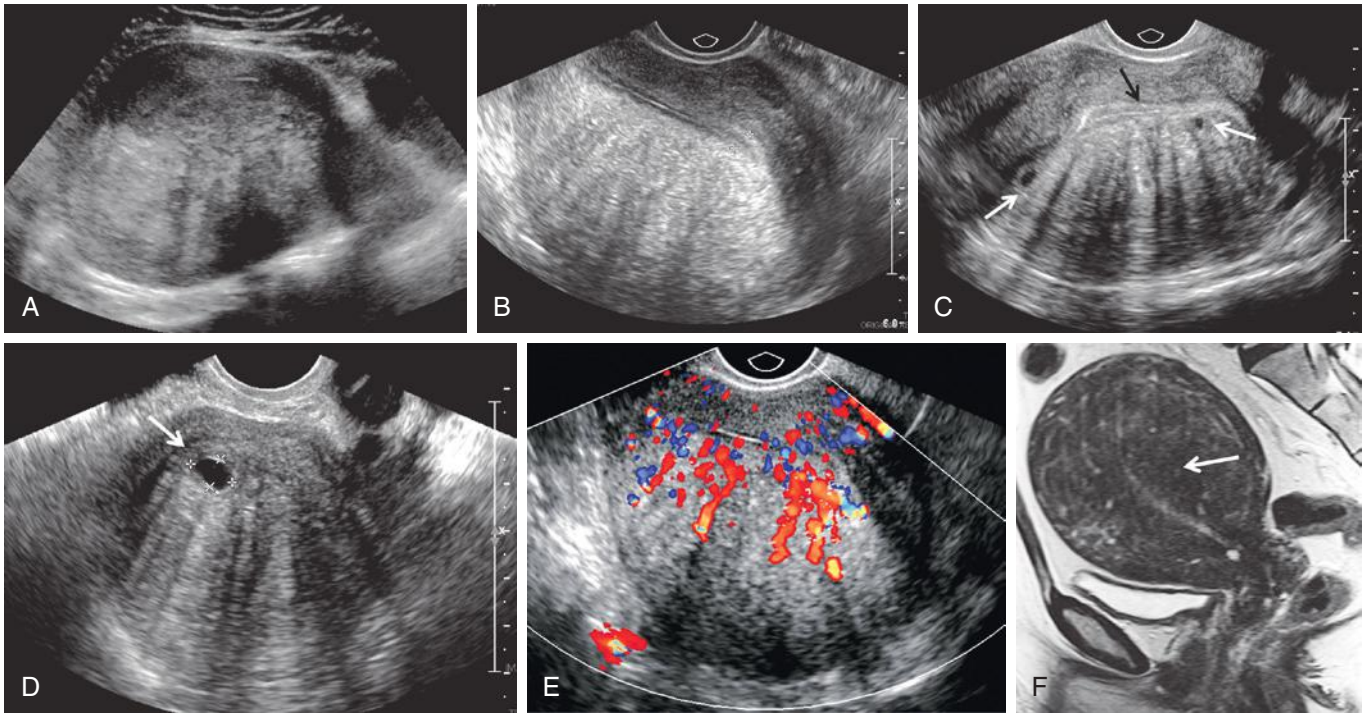

FIG 29-39 Spectrum of ultrasound findings of adenomyosis. **A,** Transabdominal sagittal ultrasound image demonstrates enlarged, heterogeneous, globular uterus with asymmetric thickening of the posterior myometrium. **B,** Transvaginal sagittal scan from a second patient demonstrates asymmetric thickening of the anterior myometrium, with markedly heterogeneous echotexture, hypoechoic linear striations, and shadowing. Endometrial thickness is measured (*calipers*). The uterus is retroverted. **C,** Transvaginal scan from a third patient demonstrates heterogeneity of the posterior myometrium with small myometrial cysts (*white arrows*) and linear striations. Note linear rays of shadowing in a "comb-like" or "Venetian blind" pattern. The region of abnormal myometrial echotexture is posterior to the endometrium (*black arrow*). **D,** Larger myometrial cyst (*arrow* and *calipers*), with asymmetric thickening, heterogeneity of the myometrium, and "comb-like" shadowing. **E,** Color Doppler sonogram demonstrates diffuse hypervascularity of the asymmetrically thickened posterior myometrium. **F,** Sagittal T2-weighted magnetic resonance image of a different patient with diffuse adenomyosis demonstrating marked diffuse thickening of the junctional zone (*arrow*) and scattered tiny T2-weighted hyperintense foci.

detection and tracking systems (Fig. 29-42). Catheter-directed venography is more invasive and is usually only performed immediately prior to intervention, but it is considered the gold standard for diagnosis. Bilateral ovarian vein embolization with or without direct sclerotherapy of the pelvic varices is the current favored treatment approach.[210,215] Stent placement may be performed for obstructing anatomic abnormalities.

Gonadal Vein Thrombosis

Patients with thrombosis of the gonadal vein generally present with acute pelvic pain and may also have fever and leukocytosis if there is associated septic thrombophlebitis, which is most common in postpartum patients, in those with PID, or following pelvic surgery. Ovarian vein thrombophlebitis is estimated to occur following less than 0.05% of vaginal deliveries and 1% to 2% of cesarean deliveries.[216] The right gonadal vein is more commonly involved, likely because of increased pressure on the right gonadal vein. The left ovarian vein is felt to be protected owing to retrograde flow from the left renal vein.[13] Ovarian vein thrombosis will appear on ultrasound images as a tubular or serpentine avascular structure, often anechoic to hypoechoic, in the region of the right adnexa and psoas muscle corresponding to the thrombosed vein. Extension into the inferior vena cava may occur. However, these structures may be difficult to visualize at sonography, particularly in the postpartum setting, because of overlying bowel gas. Contrast-enhanced CT or MRI should generally be performed to establish the diagnosis and evaluate the extent of thrombosis and will show a distended ovarian vein expanded by intraluminal thrombus with a thickened enhancing wall and surrounding inflammation[217] (Fig. 29-43).

NONGYNECOLOGIC CAUSES OF PELVIC PAIN

Although the primary role of ultrasound examination in a woman presenting with pelvic pain is to evaluate the female reproductive tract, abnormalities of the gastrointestinal or genitourinary tract may occasionally be detected. Recognition of these nongynecologic disorders at ultrasound examination not only enables prompt diagnosis, but may eliminate the need for additional imaging and potentially unnecessary exposure to radiation and intravenous contrast agent.[218-220]

Acute Appendicitis
