Preface

This book would not have seen the light had it not been for David Branski.

It was him who called Stefano asking him if he would consider a second edition of the book 'Textbook of Pediatric Gastroenterology and Nutrition', edited in 2004 by Taylor & Francis, but expanding it to include hepatology. Stefano was reluctant (it takes a huge commitment to edit such a book!), but David had a way of convincing that was hard to resist, and when he brought into the picture Anil as a prospective editor for the liver part, resisting was futile!

The three of us laid out the design of the project together and the enthusiasm about it grew: in fact, David's knowledge, his calm but confident demeanor, his never-ending energy to learn and prolific writing skills were a guarantee of the book's success. Sadly, only few months later, when the details of this book had just been put together, we heard the news of his untimely demise. We debated in panic whether to continue this commitment or abort it, but it did not take us long to agree that we needed to carry this project to completion as a tribute to the doyen of pediatric gastroenterology of our times.

Three sections of this edition, gastroenterology, hepatology and nutrition cover the common disease states with an updated emphasis on pathophysiology and any expected future advances. The chapters are clinically oriented and aim at making easier the decision-making process for trainees in pediatrics and pediatric gastroenterology, pediatricians and nurse practitioners.

The extensive section of gastroenterology covers the main congenital disorders with their newer diagnostic techniques, with chapters specifically dedicated to the term or preterm newborn; common conditions that every pediatric gastroenterologist is likely to face in his/her practice; and conditions that are either relatively new, such as eosinophilic disorders, or in a state of rapidly evolving treatment options like inflammatory bowel diseases. New treatment paradigms (e.g. probiotics or fecal microbial transplantation) are also specifically dealt with.

The chapters on hepatology focus on newer diagnostic techniques, treatment advances and quality of life issues: for instance, the chapter on transition of children with liver disease provides a unique view from a psychologist and adolescent hepatologist on how best to improve the outcome of this group of patients. Some of the chapters like liver transplantation are deliberately longer to give the reader comprehensive information on the state of the art on indications, complications and the management of immunosuppression. Finally, the chapter on the future of hepatology is particularly thought-provoking in that it discusses the role of genomics and other 'omics' in the diagnosis and real options of small molecules, gene therapy and liver cell transplantation in the management of liver disease.

We are humbly but surely confident that David would have loved this book, which we gratefully dedicate to him.

Stefano Guandalini

Anil Dhawan

Acknowledgements

It's hard to summarize in a few lines the gratefulness I feel to so many people whose roles were instrumental in the realization of this book. From the distinguished colleague who picked me and pushed me in the world of pediatric gastroenterology, the late professor Raffaele De Luca, to my splendid mentors at the University of Naples, Salvatore Auricchio and Armido Rubino, to the many, incredibly talented mentees I had the privilege to help as they developed their career in our field, to the many supportive colleagues and friends who wanted me to lead them within ESPGHAN and then FISPGHAN. But above all, had it not been for my wife Greta, who supports and bears me since almost half a century, this work would not have been accomplished. To all of you, and to my patients: thanks.

Stefano Guandalini

I would like to express my sincere thanks to the love of my life, my wife Anita. She has been my friend and a critic who expects excellence only and continues to support me, rather put up with me, to deliver projects like this one, again and again....

My two wonderful sons Atin and Ashish who have been a source of joy and encouragement and I think have forgiven me for not spending much time with them.

To my patients who have helped me to understand the complexity of liver disorders and my personal assistant, Mrs. Kathleen Meader for her hard work that helps me deliver professionally.

Anil Dhawan

Contents

Part I Gastroenterology and Nutrition

1 Microvillus Inclusion Disease and Tufting Enteropathy	3
Agostino Nocerino and Stefano Guandalini	
2 The Spectrum of Autoimmune Enteropathy	13
Natalia Nedelkopoulou, Evangelia Farmaki, Maesha Deheragoda and Babu Vadamalayan

Gastroenterology and Nutrition

Agostino Nocerino and Stefano Guandalini

Introduction

The Larger Group of “Intractable Diarrheas of Infancy”

Before focusing on microvillus inclusion disease and tufting enteropathy, we briefly review similarly presenting entities. In 1968 Avery, Villavicencio and Lilly were the first to describe a severe chronic diarrhea in 20 infants and they named it “infantile intractable diarrhea”; according to their description “(it) was prolonged and intractable despite extensive hospital therapy” [1].

This syndrome was defined on the basis of some clinic characteristics, namely: (1) diarrhea of more than 2 weeks duration, (2) age, less than 3 months, (3) three or more stool cultures negative for bacterial pathogens, (4) necessity of intravenous rehydration, and (5) prolonged and intractable diarrhea despite hospital therapy.

The death rate was very high: 9 out of the 20 babies (45%) in Avery et al.’s record had died; it was even higher in Hyman et al.’s (70%) record [2].

Heterogeneity and lack of specificity are evident in Avery’s original report: different pathologies were grouped in it, some of which with a diagnosis were well defined even at that time. Only autopsic material was available for the first cases, and only after the introduction of total parenteral nutrition (TPN) at the beginning of the 1970s [3] it was possible to study the matter more in depth, thanks to proximal small-intestinal biopsy [4] and later on to the development of

endoscopic techniques, which were safe and adequate for the infant as well. It became consequently possible to discriminate different causes for the so-called intractable diarrhea of infancy [5] but its definition superimposes on the definition of “protracted diarrhea of infancy”: The latter has duration in common with it, but a failure to gain weight is enough to define the picture [6].

Many cases of “protracted diarrhea of infancy” are diet associated, as a consequence of cow milk or lactose intolerance or malnutrition. Malnutrition causes intestinal atrophy and consequently a malabsorption syndrome and diarrhea, which apparently gets better with fasting. These features have almost disappeared in the developed countries.

The main causes of “intractable diarrhea of infancy,” including more severe and longer forms, can thus be summed up (see also Table 1.1):

Autoimmune Enteropathy

This rare disorder mostly occurring in young infants and children (6–18 months old), is characterized by severe diarrhea and small-intestinal mucosal atrophy resulting from immune-mediated injury. It remains a challenging diagnosis because of its clinicopathologic variability. This entity is dealt with in Chap. 2.

Small-Intestinal Enteropathy of Unknown Origin

This entity could be a variation of autoimmune enteropathy, as the increase in inflammatory cells in the lamina propria shows. It appears in less than 12-month-old infants, with a lower death rate compared to those with autoimmune enteropathy, but it can be very severe. Infants can be dependent from TPN [5].

Intractable Ulcerating Enterocolitis of Infancy

A rare disease initially described in 1991 in five children presenting in the first year of life with intractable diarrhea, ulcerating stomatitis, and large ulcers with overhanging edges throughout the colon within the first year of life [7]. The affected infants can show such a severe colitis that a subtotal colectomy is necessary, even if long-term prognosis is good. It has been suggested that the affected children have a genetically determined primary immune dysregulation [8].

Congenital Enterocyte Heparan Sulfate Deficiency

Described in 1995 in three infants who, within the first weeks of life, presented secretory diarrhea and massive enteric protein loss [9]. The small-intestinal mucosa is normal on light microscopy, but histochemical examinations show a complete absence of enterocyte heparan sulfate. The sulfated glycosaminoglycans of the basocellular membrane are mostly deficient, particularly heparan sulfate, while distribution of vascular and lamina propria glycosaminoglycans is normal [9]. Diarrhea is so severe to make TPN necessary, associated to repeated albumin infusions because of severe protein-losing enteropathy. Studies in men and mice show that heparan sulfate is essential in maintaining intestinal epithelial barrier function [10], and that the specific loss of heparan sulfate proteoglycans from the basolateral surface of intestinal epithelial cells is common to many forms of protein-losing enteropathy [11].

Congenital Intestinal Integrin Deficiency

In 1999, Lachaux et al. described an intractable diarrhea starting from 9 days after birth, associated to pyloric atresia and total epithelial detachment of gastric and intestinal mucosa. Immunofluorescence analysis showed $\alpha 6\beta 4$ integrin deficiency at the intestinal epithelium—lamina propria junction [12].

Mutations in $\alpha 6$ or $\beta 4$ integrins cause junctional epidermolysis bullosa with pyloric atresia. In 2008, two Kuwaitian brothers with pyloric atresia were described, respectively affected by intractable diarrhea and episodes of protein-losing enteropathy, with a novel mutation in $\beta 4$ integrin not associated to its reduced expression in tissues [13].

Congenital Secretory Diarrheas

Includes congenital chloridorrhea and congenital sodium diarrhea, dealt with in Chap. 36.

Diseases of the Intestinal Epithelium

Microvillus inclusion disease and tuft enteropathy are the best-known diseases of the intestinal epithelium causing intractable diarrhea of infancy.

In 1994, Girault et al. described eight infants with early-onset severe watery diarrhea associated to facial deformities and unusual tufts of woolly hair with trichorrhexis nodosa. Duodenal biopsies showed moderate to severe villous atrophy, with normal or hypoplastic crypts; colon biopsies were grossly normal. As a consequence, severe malabsorption was present. All patients had no antibody response to immunization antigens; the immunological response to vaccinations was poor. Five children died despite TPN [14]. Two children from the series of Girault et al. had hepatic cirrhosis; six additional patients had signs and symptoms compatible with this new “syndromic diarrhea”, associated to hepatic involvement (Tricho-Hepato-Enteric Syndrome, THES) characterized by fibrotic livers with marked hemosiderosis [15–17].

Nine different mutations in *TTC37* gene (5q14.3–5q21.2) were found in 12 children from 11 families with classical features of THES. *TTC37* codes for a protein that has been named thespin (THES Protein) [18].

Enlarged platelets with abnormal α -granule secretion can be observed in some patients. The estimated incidence of the syndrome is 1 in 400,000 to 1 in 500,000 live births.

Microvillus Inclusion Disease

In 1978, Davidson et al. described five infants presenting an intractable diarrhea of infancy characterized by secretive diarrhea and malabsorption, starting in the first hours after birth with hypoplastic villous atrophy in the small-intestinal biopsy. Four of these infants had a deceased brother who had presented similar features.

In one of these infants, the electron microscopy identified the presence of a peculiar abnormality of the microvilli of the enterocytes [19] (Fig. 1.1).

Three new cases with the same clinic and histological characteristics of the latter were described in France in 1982,

Fig. 1.1 Microvillous in the original label inclusion disease. PAS staining highlights abundant PAS-positive material (*arrows*) in the apical part of the enterocyte cytoplasm. PAS $\times 260$. PAS periodic acid-Schiff (Reprinted from Ref. [20], Fig. 1, with kind permission from Springer Science and Business Media)

and the four of them were grouped in a new disease called congenital microvillus atrophy [21, 22]. Two new cases were described in Great Britain in 1985 [23] and one in Italy in 1986; a subsequently born brother of the latter resulted affected too [24]. A survey completed in 1987 among centers known for their involvement in pediatric gastroenterology identified more than 30 cases worldwide. Additional cases were later published.

In 1989, Cutz et al. proposed the use of the term “microvillus inclusion disease” to highlight the characteristic ultrastructural lesions of the disease [25].

Clinical presentation: case report

First child of parents with no blood relation, A.G. was born after 37 weeks of gestation, the pregnancy having been complicated by a risk of miscarriage in the 5th month. His weight was 3500 g.

The infant was hospitalized when he was 40 days old because of an abundant diarrhea (15–20 evacuations a day of liquid stools), starting on the 6th day of its life and resistant to numerous dietary and pharmacological therapies.

Entering the hospital, the patient weighed 2800 g, it was in severe general conditions with dystrophia and dehydration; a TPN was therefore immediately started. The acid–basic balance showed hyponatremic acidosis (pH 7.2; EB $-8,3$; Na 128 mEq/l). The secretive nature of diarrhea was confirmed by its entity (about 100 ml/kg/die) with a total absence of oral nutrition and with the persistence of TPN in progress.

Moreover, the typical absence of ionic gap in the stools was present: osmolality 226 mOsm/l, Na 86 mEq/l, K 23.5 mEq/l (gap 7 mOsm/l).

Loperamide and chlorpromazine increased intestinal absorption, but did not change the clinical picture.

Microbiological examinations included an electronic microscope examination of the feces for the identification of viruses and the search for enterotoxigenic bacteria and parasites with specific methods were repeatedly negative.

The abdominal ultrasound showed adrenal hyperplasia associated to hyperaldosteronism (1160 ng/ml, v.n. < 125 ng/ml).

Jejunal biopsy showed a picture of villus atrophy with no hyperplastic crypts and periodic acid-Schiff (PAS)-positive material stored in the apical cytoplasm of enterocytes. Electron microscopy was diagnostic for microvillus inclusion disease.

Microvillus Inclusion Disease is a Congenital Secretory Diarrhea Starting in Neonatal Age

Severe diarrhea typically appears in the first days of life, usually within the first 72 h, and it is immediately life threatening. The stools are watery, and the stool output is 100–500 ml/kg/day when the infant is fed, a volume comparable to or higher than that observed in cholera. The diarrhea is of secretory type; therefore, it persists at a stable rate of 50–300 ml/kg/day despite fasting, and the electrolyte content of the stools is increased, without an osmotic gap. However, the mucosal atrophy causes osmotic diarrhea. For this reason, feeding increases the fecal output and oral feeding in nutritionally significant amounts is impossible. Due to the high output, patients can lose up to 30% of their body weight within 24 h, resulting in profound metabolic acidosis and severe dehydration, unless vigorous intravenous rehydration is started.

In a small percentage of cases (which was in the past considered to be around 20%, and presently around 5% of the cases [26]), diarrhea starts later in life, between 1 and 3 months, usually at 6–8 weeks of age. This less severe form has been denominated late-onset microvillus inclusion disease, while the classical form beginning at neonatal age has been denominated early-onset microvillus inclusion disease [27].

The hallmark of the disease is the electron microscopic finding of disrupted enterocytic microvilli (i.e., digitations of the apical membrane of the intestinal epithelial cell protruding into the lumen) and the appearance of characteristic inclusion vacuoles, whose inner surfaces are lined by typical microvilli. Both lesions are seen only with the electronic microscopy.

A few cases have been termed atypical microvillus inclusion disease, in which the onset can be early or late, but the histologic picture is different, particularly for the absence of detectable microvillus inclusions [28].

Therefore, three variants of the disease have been identified: early-onset microvillus inclusion disease, late-onset microvillus inclusion disease, and atypical microvillus inclusion disease. However, because of the sparse distribution of microvillus inclusions, it is not certain that their absence could be limited to the sample.

Microvillus inclusion disease is usually characterized by growth retardation and some developmental delay later in infancy. No other specific findings can be detected. However, the disease can be associated with other abnormalities, indicated in Table 1.2.

Histologic Findings

Findings from duodenal biopsy must not be considered diagnostic. Histologic results of duodenal biopsy samples can range from essentially normal to mildly abnormal, showing the following:

- Thin mucosa caused by hypoplastic villus atrophy
- Diffuse villus atrophy (loss of villus height)
- Crypt hypoplasia

PAS staining of the intestinal biopsy sample does not show the usual linear staining along the brush border, but reveals PAS-positive material in the apical cytoplasm. The PAS staining material corresponds to the increased number of electron dense secretory granules in the epithelium. The abnormal pattern of staining appears in the upper crypt region and continues over the villus [29] (Fig. 1.2).

PAS accumulates in low crypts in atypical microvillus atrophy, in upper crypts in congenital microvillus atrophy, and in low villi in late-onset microvillus atrophy.

Table 1.2 Anomalies described in association to microvillus inclusion disease

Meckel diverticula	Abdominal adhesions
Inguinal hernias	Renal dysplasia
Absent corpus callosum	Hydronephrosis
Mesenteric duct remnants	Craniosynostosis
Abnormal vertebrae	Down syndrome
Aganglionic megacolon	Hematuria
Pneumocystis jiroveci pneumonia	Dihydropyrimidinase deficiency
Autosomal dominant hypochondroplasia	Microcephaly
Renal Fanconi syndrome	Other renal problems
Hypophosphatemic rickets	Diabetes
Cardiac problems	Pulmonary problems
Liver dysfunction	Multiple hepatic adenomas

Inset: Enlargement of the boxed area $\times 6200$, inset $\times 22,500$. (Reprinted from [20, Fig. 5], with kind permission from Springer Science and Business Media)

Similar results were obtained with anti-CD10 immunohistochemistry: In affected children, the normal linear staining in surface enterocytes is absent, while prominent cytoplasmic reactivity is seen [30]. CD10 is a neutral membrane-associated peptidase; thus, abnormal stain findings with PAS or anti-CD10 immunohistochemistry are expressions of the abnormalities in microvillar structure.

Rectal biopsy findings demonstrate microvillus involutions and an increased number of secretory granules. This test has been proposed as a relatively easy method for making an early diagnosis. Anti-CD10 immunohistochemistry can aid in the diagnosis, because abnormal cytoplasmic CD10 staining of absorptive colonocytes has been observed in microvillus inclusion disease [31].

The diagnosis rests on findings demonstrated by electron microscopy (see Figs. 1.3 and 1.4.). Electron microscopy shows well-preserved crypt epithelium with abundant microvilli. Villus enterocytes are severely abnormal, particularly toward the apices of the short villi. The microvilli are depleted in number, short, and irregularly arranged. Some of the enterocytes contain the typical microvillus involutions, which are intracellular vacuoles where microvilli are observed lining the inner surface. A striking feature is a number of small, membrane-bound vesicles containing electron-dense material (see Figs. 1.3 and 1.4.). A few cases have been

Fig. 1.3 Microvillous in the original label inclusion disease. The apical cytoplasm of villous epithelium shows an increased number of secretory granules associated with microvillus alterations $\times 2400$. Fig. 1.4 Microvillous in the original label in the original label inclusion disease. The villous enterocytes lack brush-border microvilli, whereas their apical cytoplasm contains a microvillus inclusion (*MI*) and numerous lysosomes (*L*) $\times 5.500$. (Reprinted from [20, Fig. 2], with kind permission from Springer Science and Business Media)

described in which the classic microvillus inclusions are shadowed by other features, such as large aggregates of electron lucent, vermiform membranous vesicles in enterocyte cytoplasm, corresponding to the PAS-positive material [32].

Epidemiology

The cases published or gathered in an online registry were 137 in 2014 [26].

A female preponderance had been observed among the published cases, with a female-to-male ratio of 2:1, but in the total 137 cases there is a 1.54 male to female ratio. A blood relation is present in 41% of the assessable cases with a genre preference for males. A cluster of cases from the Navajo reservation in northern Arizona suggests an incidence as high as 1 case per 12,000 live births.

Pathophysiology

Due to their alterations, mature enterocytes inefficiently absorb ions and nutrients, causing a malabsorption syndrome; however, the diarrhea is caused mainly by active secretion of water and electrolytes in the intestinal lumen (secretory diarrhea). The pathogenesis of the secretory diarrhea is unknown; it is assumed to result from an imbalance between decreased absorption and unaltered secretion.

Measurement of stool electrolytes and osmolality enables rapid and accurate assessment of the pathogenesis of this chronic diarrhea (osmolar versus secretory) and greatly narrows the differential diagnosis.

Fecal electrolytes demonstrate a typical pattern of secretory diarrhea. Fecal sodium levels are high (approximately 60–120 mEq/l), and no osmotic gap is found. In patients with secretory diarrhea, the following formula applies: $2(\text{Na concentration} + \text{K concentration}) = \text{stool osmolality} \pm 50$. In osmotic diarrhea, stool osmolality exceeds $2(\text{Na concentration} + \text{K concentration})$ by 100 or more.

Secretory diarrhea occurs in the fasting state and is associated with large output losses that cause dehydration and metabolic acidosis.

In osmotic diarrhea, findings on stool microscopy are negative for white blood cells (WBCs), blood (exudative diarrhea), and fat (steatorrhea).

Even if there are data about the anomalies in water and electrolytes transportation in the small intestine, it is not known whether and how the colon mucosa participates to the absorption alterations in the disease.

In one of the Italian cases, we used the technique of rectal perfusion that showed a decrease in sodium absorption, only partially corrected by chlorpromazine administration [33].

Pathogenesis

Severe perturbation of the microvillar cytoskeleton may disrupt the transport of brush border components that have

to be assembled at the apical membrane. The postulated abnormality in the cytoskeleton causes a block in exocytosis, mainly of PAS-positive material (e.g., polysaccharides, glycoproteins, glycolipids, neutral mucopolysaccharides). As a consequence, small secretory granules that contain a PAS-positive material accumulate in the apical cytoplasm of epithelial cells.

In 2008, the presence of mutations in the *MYO5B* gene was described in seven patients (out of ten tested), predominantly of Turkish origin [34]. Homozygous mutations in the same gene were subsequently found in seven cases of Navajo origin; five parents were heterozygote [35]. A total of 41 unique *MYO5B* mutations in 40 patients have been identified so far: in more detail 16 different homozygous mutations in 25 patients, and 25 heterozygous mutations in 15 patients [26].

The *MYO5B* gene codifies myosine Vb, an actin-based motor protein which carries the recycling endosomes to the apical plasma membrane along the actin filaments of the microtubules. The functional deficiency of this protein alters the intracellular trafficking of resident apical plasma membrane proteins to the cell surface, and this could be the cause for the impaired apical brush border membrane development [34]. Actually, in microvillus inclusion disease the *MYO5B* mutations associate to a defective myosin Vb expression in enterocytes.

Myosine Vb carries on its action after having bound to a specific small guanosine-5'-triphosphatase (GTPase) rab proteins, such as Rab 11, located on the surface of recycling endosomes [36]. Thanks to this link the recycling endosomes move along the actine filaments (see Fig. 1.5) [37].

When myosine Vb has an altered function, the recycling endosomes are not carried in a normal way: in the enterocytes of the subjects with microvillus inclusion disease, no regular accumulation of myosine Vb and of the recycling endosome-associated proteins (one of these is Rab 11) can be observed close to the apical membrane, and no specific staining pattern is present [38]. Therefore, the Rab 11 distribution in the enterocytes can be a helpful diagnostic tool [39].

Other biochemical mechanisms depending on myosine Vb which can produce alterations in the structure of the microvilli are presently being studied [40].

Myosine Vb is expressed in all the epithelial tissues and, actually, microvillus inclusions in the stomach and colon, in addition to less well-defined inclusions in gallbladder epithelium and in renal tubular epithelial cells, have been reported in some patients with microvillous inclusion disease (MVID). Nevertheless, no extraintestinal symptoms are generally reported. Two children with renal Fanconi syndrome who carried mutation *MYO5B* did not show alterations in the apical brush border morphology and the PAS staining pattern in renal tubular epithelial cells, which makes it unlikely for it to be the cause of proximal tubular renal dysfunction [41].

Recently, Dutch investigators have found [42] that the mild variant of MVID appears to be caused by loss of function of syntaxin 3 (STX3), an apical receptor involved in membrane fusion of apical vesicles in enterocytes. In fact, whole-exome sequencing of DNA from patients with variant MVID revealed homozygous truncating mutations in STX3; and in addition, patient-derived organoid cultures and overexpression of truncated STX3 in CaCo2 cells recapitulated most characteristics of variant MVID.

Fig. 1.5 Endocytic recycling. Myosin Vb is a conformation-dependent binding partner of Rab11-FIP2. Activation of myosin Vb induces translocation of recycling endosomes and their cargo. Final transport from the recycling endosome to the cell surface is mediated by Rab8. (Reprinted by permission from Macmillan Publishers Ltd and Nature Publishing Group [37])

Prenatal Diagnosis

Pregnancy and birth are usually normal in individuals with microvillus atrophy, and polyhydramnios is usually absent, in contrast to the clinical picture of patients with other causes of congenital secretory diarrhea [43]. Nevertheless, in some cases, polyhydramnios and bowel dilation in the third trimester have been described [44]. In one case, a high fetal alpha-fetoprotein in the second trimester was observed [45]. Authors have speculated that the fetal alpha-fetoprotein elevation might possibly be caused by in utero body fluid leakage into the amniotic fluid through fetal enteropathy.

Identification of the gene responsible for the disease allows its prenatal diagnosis [46].

Treatment

The prognosis of early-onset microvillus inclusion disease is poor. If patients are untreated, the disease is rapidly fatal because of dehydration and malnutrition.

In late-onset microvillus inclusion disease diarrhea tends to be less severe, and some alimentation is possible.

Medical Care

Agents tentatively given to induce a better growth of the intestinal mucosa (e.g., epithelial growth factor, colostrum) are ineffective. Several drugs (e.g., somatostatin, octreotide, loperamide, chlorpromazine) have been tried to counteract the massive secretory diarrhea in patients with microvillus atrophy; however, none has proven effective.

At present, the only available therapy is TPN. Children with late-onset microvillus inclusion disease usually have less severe diarrhea; with age they can reduce the requirements of TPN to 1–2 per week.

If patients are treated with TPN, their prognosis entirely depends on the complications of this approach. These complications include cholestasis with subsequent liver damage leading to cirrhosis, catheter-related sepsis due to infection with bacterial or fungal agents, and progressive lack of vascular access.

In the observed cases, cholestasis appears worsened by transplant.

The study of eight patients who developed cholestatic liver disease suggests that cholestasis is enhanced by the impairment of the *MYO5B/RAB11A* apical recycling endosome pathway in hepatocytes [47].

Surgical Care

Successful outcomes of small-intestinal transplantation have been reported, and evidence suggests that an early transplant might be beneficial. The limited experience accumulated in a few centers worldwide reflects an overall survival rate of

approximately 50% at 5 years after small-bowel transplantation; this is a much better outcome than is seen with other indications for intestinal transplantation [48]. Patients who did not receive colonic transplant weaned later from parenteral nutrition.

The analysis of 16 patients who underwent a small-bowel transplantation shows a lower death rate compared to those who did not (23 versus 37%) after an average observation period of 3.5 years (but variable between 3 months and 14 years). In all of the cases, apart from the first two, colon had been transplanted too [49].

Although only small series have been reported, evidence suggests that early small-bowel transplantation should be performed, at least in children with early-onset microvillus inclusion disease. Patients with late-onset microvillus atrophy appear to have an improved prognosis.

Transplantation appears to be the only option for patients who do not fare well with long-term TPN (e.g., because of sepsis, liver damage, lack of vascular access). For patients in whom transplantation is successful, a gradual return to a normal diet is considered possible.

In the observed cases, TPN-related cholestasis appears worsened by transplant. Therefore, in children with cholestasis, the worsening of this picture after the transplant points to a combined liver-intestinal transplantation.

Tufting Enteropathy (or Intestinal Epithelial Dysplasia)

In 1994, Reifen et al. described two infants less than a month old with protracted diarrhea. The diarrhea was so profuse to make TPN necessary but it improved when enteral nutrition was interrupted. The jejunal biopsies showed a peculiar picture characterized by the presence of focal aggregations of packed enterocytes whose shape resembled of a teardrop, as a consequence of an apical rounding of the plasma membrane. These focal areas resembled a tuft and that is why the term “tufting enteropathy” was coined [50]. Curiously, a case with the same characteristics was identified among those presented by Davidson et al. in the same paper where the first case of microvillus inclusion disease had been described [19].

Clinical Expression

The incidence of the disease has been estimated to be 1:100,000 live births in Western Europe [51], but it seems higher in people of Arabic origin [52].

The picture is a severe secretory diarrhea starting in the first weeks of life. During pregnancy, there is no polyhydramnios, as in the microvillus inclusion disease and

differently from congenital sodium diarrhea and congenital chloridorrhea.

The alterations in the enterocytes, in any case, cause an accentuation of the diarrhea with nutrition, including total enteral nutrition, as it had already been observed since the first described cases.

There are two different clinical forms: one is isolated and the other is syndromic, associated to different anomalies, particularly to facial dysmorphism with choanal atresia and superficial punctuated keratitis [53, 54].

Pathophysiology

In 2008, a mutation of the gene for *Epithelial Cell Adhesion Molecule* (EpCAM) was identified in two ill children in the same family, and in three children from unrelated kindreds [55]. EpCAM is a transmembrane protein involved in cell proliferation, differentiation, and adhesion.

In 2010, a mutation in *SPINT2* gene was found in a case affected by a syndromic form of tufted enteropathy. *SPINT2* is a transmembrane protein that seems to be involved in epithelial regeneration [56].

It is interesting to note how mutations in *SPINT2* gene are also present in the syndromic congenital sodium diarrhea, where choanal atresia, hypertelorism, and corneal erosions are particularly frequent and anal atresia can be found in certain cases [57].

Analyzing 57 patients, mutations in the gene for EpCAM were found in 73% of the cases, all of them presenting an isolated intestinal disease.

But in 21% of the cases, all showing a syndromic form of the disease, there are mutations the *SPINT2* gene.

According to this study, tufted enteropathy could be separated into at least three genetic classes, each with specific phenotypes [58].

However, it seems impossible at present to discriminate “tufting enteropathy” isolated from the syndromic one, even from a genetic point of view.

Histologic Features

Jejunal biopsy shows a picture of partial villous atrophy associated to crypt hyperplasia. The most characteristic feature, the one which gave the name to the disease, is the presence of “tufts,” small focal aggregates of teardrop-shaped enterocytes with an apical rounding (See Fig. 1.6a, b).

The “tufts” are not a characteristic exclusive to intestinal epithelial dysplasia, because they have been observed in other mucosal enteropathies and in normal jejunum. In the latter cases, anyway they were present in <10% of the epithelial surface, while in “tufting enteropathy” they are present in more than 80% of the jejunal surface. But the picture is not always so evident in the earliest period of the disease. Attempts at immunohistochemical analysis (including beta-catenin, E-cadherin, desmoglein, laminins) have not been easily applicable [60]. On the contrary, the staining with EpCAM/MOC31 antibody, an EpCAM antibody clone, showed a sensitivity and specificity of 100% for loss of staining in 15 studied patients [61].

Electronic microscopy shows relatively normal microvilli, and it is not particularly useful for diagnosis, if only to exclude a microvillus inclusion disease.

A mild inflammation of the lamina propria is also present. An infiltration of T lymphocytes within the lamina propria had been observed since the original description, even if inferior to celiac disease, but it sometimes arises suspicion of autoimmune enteropathy [50].

Fig. 1.6 **a** Numerous tufts of enterocytes on the mucosal surface of the duodenum. **b** A characteristic tear-drop-shaped structure (arrow) in an epithelial tuft (H&E stain; original magnification: a—x 80; b—x 400). (Reprinted from Ref. [59, Fig. 1], with kind permission from Springer Science and Business Media)

Treatment

Tuft enteropathy is associated to a severe secretory diarrhea, which worsens with nutrition. That is why affected children have to be treated with TPN.

Some cases seem to have a less severe course and they can be given a partial parenteral nutrition [62].

Cases totally dependent on TPN are candidates for intestinal transplantation.

Introduction

Chronic, unexplained diarrhea in children younger than 3 months old was first characterized as “intractable diarrhea” [1]. The term “protracted diarrhea” was used later to describe infants with frequent and loose stools severe enough to often require parenteral alimentation as nutritional support [2]. The differential diagnosis of enteropathies in infancy and childhood includes inherited epithelial and congenital transport defects, enzymatic deficiencies and allergic enteropathy (Table 2.1).

The most frequent diagnosis in children with protracted diarrhea is autoimmune enteropathy (AIE) [3, 4]. It is a rare, immune-mediated disorder starting usually within the first months of life. The age of onset is between 1 month and 5 years (median age 17 months) [5], but late-onset adult forms have been also reported [6–9]. The disease was first described by Walker-Smith et al. in 1982 in a male child with clinical features of coeliac disease and villous blunting unresponsive to gluten-free diet [10] and represents a heterogeneous group of disorders rather than a discrete entity. The incidence is estimated at less than 1 in 100,000 infants. The diagnostic criteria are debatable but the presence of circulating anti-enterocyte antibodies and the lack of immunodeficiency

have been proposed as the hallmark features of AIE [5, 11]. The latter criterion has been challenged by clinical experience and better understanding of the immunology of autoimmunity and self-tolerance [12].

AIE is characterized by variable clinical expression, ranging from isolated gastrointestinal involvement to severe systemic disease [13, 14]. Patients diagnosed with the disease often exhibit extra-intestinal manifestations of autoimmunity, in contrast to those with tufting enteropathy and microvillus inclusion disease [15]. Based on a genetic approach combined with immunological evaluation, three different forms of AIE have been proposed:

1. A predominately or isolated gastrointestinal form of AIE with typical anti-enterocyte antibodies in both sexes
2. A systemic X-linked form of AIE associated with different endocrinopathies, haematological symptoms and severe eczematous skin disease, known as immune dysregulation, polyendocrinopathy, AIE X-linked syndrome (IPEX) occurring only in males
3. An IPEX-like form, a priori FOXP3 independent occurring in both sexes

IPEX and autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) syndrome (APR-1/autoimmune phenomena, polyendocrinopathy, candidiasis and ectodermal dystrophy) are systemic forms of AIE [16].

Clinical Presentation

Chronic, secretory diarrhea refractory to bowel rest that leads to dehydration, malabsorption and severe weight loss is the typical clinical presentation of AIE. Diarrhea usually begins between 2 and 4 weeks of age and the secretory component can be delayed for a few months [3, 11, 17]. The symptoms are often debilitating and the disease is potentially life threatening. The establishment of the diagnosis is crucial in order to ensure optimal treatment. Patients typically require immunosuppressive therapies and total parenteral

Table 2.1 Differential diagnosis of diarrhea in infancy and childhood

Transport defects and enzymatic deficiencies	Disaccharidase deficiency
	Sodium–hydrogen exchanger (congenital sodium diarrhea)

nutrition (TPN) for hydroelectrolytic balance and nutritional support [18, 19].

Despite the fact that the mucosal abnormality is primarily confined to the small intestine, the term “generalized autoimmune gut disorder” has been used to describe the association between AIE and autoimmune colitis [8]. Emerging evidence suggests that AIE can be a manifestation of a more diffuse autoimmune disorder of the gastrointestinal system, which comprises gastritis, colitis, hepatitis and pancreatitis with positivity of a variety of autoantibodies, including anti-parietal, anti-goblet cell and anti-smooth muscle antibodies [6, 20–22].

Furthermore, the involvement of extra-intestinal organs can be present during the course of the disease. Multisystem extra-intestinal manifestations include endocrine, renal, pulmonary, hematologic and musculoskeletal. Hypothyroidism with interstitial fibrosis and lymphocytic infiltration of the thyroid gland, nephrotic, nephritic syndrome and membranous glomerulonephritis, interstitial pneumonopathy, periportal fibrosis and bronchitis, haemolytic anaemia, rheumatoid arthritis and dermatitis/atopic eczema have all been reported [5, 11, 22, 23].

Thymus plays a key role in the deletion of potentially self-reactive clones of T cells. The association between AIE and thymoma has been described in both pediatric and adult patients and provides further evidence about the role of thymoma and the development of autoimmunity [24, 25].

Pathogenesis

The underlying immunologic and molecular mechanisms in AIE have not yet been fully elucidated and are widely debatable. However, it has been established that an autoimmune response is involved in the pathogenesis of the disease. Thymus orchestrates a healthy immune system. The intrathymic maturation of T lymphocytes is crucial for the deletion of potentially self-reactive clones of T cells. The dysfunction of the thymus results in the non-deletion and presence of self-reactive T cells that can induce the expansion of anti-self B cells [11, 26, 27].

In AIE, the gut is the site where the autoimmune reaction takes place and is mediated by the activation of self-reactive T cells locally, resulting in the typical histological lesions. In normal states, the expression of human leukocyte antigen (HLA) class II molecules on the enterocyte surface is crucial in establishing and maintaining the oral tolerance as the epithelial cells present exogenous peptides to the clonotypic T cell receptors. The overexpression of HLA-DR antigens in enterocytes and the inappropriate expression of HLA class II molecules in the crypt epithelium of the proximal small intestine in children with AIE have been reported [15, 28].

An increase in the levels of cluster of differentiation CD4 and CD8 lymphocytes in the lamina propria in subjects affected by AIE provides further evidence that the T cells are involved in the pathogenesis of the disease [29, 30]. The intestinal T lymphocytes cause damage to the enterocytes by exerting direct cytotoxicity, via the production of lymphokines or through an antibody-dependent cytotoxicity resulting in cellular apoptosis [31–33]. The loss of the regulatory function of T lymphocytes and the activation of the immune system are implicated in the pathogenesis of IPEX syndrome, whereas AIE is partly attributed to a humoral immune response with the presence of anti-enterocyte antibodies [34].

A variety of circulating autoantibodies, such as antibodies against gastric parietal cells, pancreatic islets, glutamic acid decarboxylase, insulin, smooth muscle, endoplasmic reticulum, reticulon, gliadin, adrenal cells, nuclear antigens, deoxyribose nucleic acid (DNA), thyroglobulin and thyroid microsomes, has been detected in patients with AIE [7, 18]. The presence of antibodies against goblet cells, enterocytes and colonocytes is supportive of the diagnosis. These antibodies are directed against components of the intestinal brush border membrane, with an increasing intensity from the crypts towards villous tip [5, 13]. However, they are neither diagnostic nor specific for the disease and have been also identified in other disorders such as the cow’s milk allergy, inflammatory bowel disease and in adults with human immunodeficiency virus (HIV) infection. Moreover, the appearance of the autoantibodies after the onset of the mucosal damage, the lack of correlation between the titer and the

histological severity and their disappearance after treatment, but before the complete mucosal restoration support the hypothesis that these antibodies are most likely a secondary event in the pathogenesis of the disease in response to bowel injury [10, 35–37].

The nature of the gut antigen that elicits the immune response and results in the alteration of the intestinal permeability has been extensively investigated. A 55-kD protein located in both the gut and renal epithelial cells that reacted with serum autoantibodies was first identified by Colletti et al. in 1991 in a patient with complicated presentation of AIE with small bowel and glomerular involvement [38]. A few years later, a 75-kD auto-antigen that is distributed through the whole intestine and the kidney was recognized in patients with X-linked AIE associated with nephropathy [39]. The intestinal auto-antigen in autoimmune polyendocrine syndrome type 1 (APECED) is tryptophan hydroxylase (TPH), which is mainly present in the enterochromaffin cells of the mucosa [40].

Emerging evidence has pointed towards an uncontrolled inflammatory reaction caused by the disturbance of the effector–regulatory T-cell interaction and leading to the production of autoantibodies, such as anti-enterocyte antibodies [41]. The understanding of the underlying molecular mechanism and the identification of the genetic defect in AIE was achieved due to the clinical similarities between scurfy mice and boys with the disease. Scurfy mice are a naturally occurring X-linked mutant that presents with massive lymphoproliferation, diarrhea, intestinal bleeding, scaly skin, anaemia, thrombocytopenia and hypogonadism [42]. Based on the observation that the disease-causing mutation in scurfy mice was on the X chromosome, the human IPEX locus was identified on chromosome Xp11.23-q13.3 and the gene was named *FOXP3*. It comprises 11 exons which encode the FOXP3 protein or scurfin, a 48-kDa protein of the forkhead (FKH)/winged-helix transcription factor family that is predominantly expressed in CD4+CD25+ T cell with regulatory function, at significantly lower levels in CD4+CD25-T cells and not at all in CD8+ or B220+ cells [43–46].

Increasing experimental evidence has shown that scurfin is implicated in the thymic maturation of T cells that are designated to acquire regulatory function. CD4+CD25+ Treg represent a small subset (5–10%) of CD4+ T helper cells in humans and mice. Studies on CD4+CD25+ T cells from IPEX patients with the use of anti-CD127 have shown that FOXP3 plays a crucial role in the generation of functional T regulatory cells (Treg) and intact FOXP3 is indispensable for the development of fully functional Tregs, whereas FOXP3 with amino acid substitutions in the FKH domain is sufficient for the generation of functionally immature Tregs [47].

FOXP3 has DNA-binding activity and due to its structure may serve as nuclear transcription factor and act as a repressor of transcription and regulator of T cell activation

[48, 49]. The transcription of a reporter containing a multimeric-FKH-binding site is repressed by intact FOXP3. Such FKH-binding sites are located adjacent to nuclear factor of activated T cells (NFAT), regulatory sites in various cytokine promoters such as interleukin (IL)-2, or granulocyte–macrophage colony-stimulating factor enhancer. Therefore, intact scurfin protein appears to be capable to directly repress NFAT-mediated transcription of the *IL-2* gene in CD4+ cells upon activation [50].

Despite the evidence that FOXP3 plays a key role in the development and function of Treg cells, the underlying mechanisms have not been fully understood. Data from animal models with transgenic induction of FOXP3 have shown that the overexpression of scurfin in normal mice leads to a tremendous suppression of immune functions, whereas the depletion of Tregs in healthy mice results rapidly in the development of different T-cell-mediated autoimmune disorders, similar to scurfy in mice or IPEX in humans that go in complete remission upon reconstitution with Treg cells [51, 52].

The three domains that are crucial for the function of FOXP3 are the C-terminal region, which contains the forkhead domain that directly binds DNA regions, the central domain with a zinc finger and leucine zipper that promotes the oligomerization of the FOXP3 molecule and the repressor domain located in the N-terminal region that binds the NFAT [53, 54]. Genetic screening on X chromosome in patients with AIE revealed that the majority of mutations cluster primarily within the FKH domain and the leucine zipper within the coding region of the *FOXP3* gene causing potentially absent FOXP3 protein expression or a protein product with loss of function [13, 53].

Histopathology

Histologic evaluation of the small bowel in typical AIE reveals partial or total villous blunting/atrophy and crypt hyperplasia. In addition, there is a marked infiltration of the lamina propria by mixed inflammatory cells with a prominence of mononuclear cells, including T lymphocytes [15]. Apoptotic bodies and intraepithelial lymphocytes are present in the crypt epithelia. Most cases show a relative paucity of surface lymphocytosis in contrast to coeliac disease. The lymphocytic infiltration of the intestinal mucosa is constituted by CD4–CD8 T lymphocytes and macrophages. Goblet, Paneth and/or enterochromaffin cells may be reduced in number or absent. Cryptitis and crypt abscesses have been reported in severe AIE. Crypt enterocytes commonly show an increased expression of HLA-A, -B, -C molecules [8, 55, 56]. (See Table 2.2; Fig. 2.1) [12].

AIE primarily involves the small bowel with the histologic lesions being most prominent in the proximal small

Table 2.2 Histological findings in autoimmune enteropathy

Histological findings in autoimmune enteropathy
Partial or total villous blunting/atrophy and crypt hyperplasia
Marked infiltration of mononuclear cells, including activated T lymphocytes in the lamina propria
Apoptotic bodies and intraepithelial lymphocytes present in the crypt/gland epithelia, but relative paucity of surface lymphocytosis
Crypt abscesses in severe autoimmune enteropathy
Increased expression of HLA-A, -B, -C molecules in crypt enterocytes

intestine. However, changes have been also described in the oesophagus, stomach and colon in both pediatric and adult patients supporting the hypothesis for a diffuse disease process involving the entire gastrointestinal tract.

Recent reports describe the infiltration of the squamous epithelium by lymphocytes or eosinophils in the oesophagus. Gastric biopsies can show features of chronic nonspecific gastritis with or without reactivity. Atrophic gastritis, intestinal metaplasia and glandular destruction have been also described. There may be increased apoptosis of glandular epithelium [6, 58]. The colonic morphological lesions vary from diffuse mild active colitis with inflammatory cell infiltration to severe active chronic colitis with goblet cell depletion, Paneth cell metaplasia, distortion of crypt architecture and crypt abscess formation. An increase in intraepithelial lymphocytes has also been described [21, 58].

Diagnosis

The diagnostic criteria for AIE were originally proposed by Unsworth and Walker-Smith et al. and included (a) protracted diarrhea and severe enteropathy with small intestinal villous atrophy, (b) no response to exclusion diets, (c) evidence of predisposition to autoimmune disease (presence of circulating enterocyte antibodies or associated autoimmune disease) and (d) no severe immunodeficiency [18]. A more recent adult study proposed the updated criteria and now the diagnosis is established when all of the criteria are present (Table 2.3). The disease should be considered in the differential diagnosis in all patients presenting with severe, unexplained diarrhea requiring parenteral nutritional support particularly in infants, since AIE is the most common cause of protracted diarrhea in infancy [3]. The endoscopic examination with small bowel biopsy is the cornerstone of investigations.

The diagnostic work up should also include information regarding the birth and family history and the time of onset of diarrhea. The disease is characterized by secretory diarrhea, nonresponsive to bowel rest. Most of the affected infants have no history of gluten ingestion at the time of presentation. Furthermore, the lack of response to a gluten-free diet points towards AIE [5, 11, 59].

Serum immunoglobulin assays show normal immunoglobulin (Ig) M and decreased IgG attributed to protein-losing enteropathy. IgA is often within normal range, but

Fig. 2.1 **a, b** Low and high magnifications, respectively. In some cases of pediatric autoimmune enteropathy, the small intestinal biopsies show cryptitis and crypt abscesses that may obscure the salient finding of autoimmune enteropathy, crypt apoptosis (*arrows*). There is also an absence of Paneth cells. **c, d** As described in adult patients, small intestinal biopsies can demonstrate a combination of both autoimmune enteropathy and sprue-like histologic findings, characterized by severe villous blunting, marked intraepithelial lymphocytosis, diffuse mononuclear inflammatory infiltrate and prominent crypt apoptosis. Of note, goblet cells are lacking within this specimen [12]. (Reprinted by permission from Macmillan Publishers Ltd, Nature Publishing Group: Ref. [57])

Table 2.3 Diagnostic criteria for AIE [14, 18]

Diagnostic criteria for AIE by Unsworth and Walker-Smith [18]	Updated diagnostic criteria for AIE by Akram et al. [14]
Protracted diarrhea and severe enteropathy with small intestinal villous atrophy	Chronic diarrhea (>6 weeks)
No response to exclusion diets	Malabsorption
Evidence of predisposition to autoimmune disease (presence of circulating enterocyte antibodies or associated autoimmune disease)	Small bowel histology showing partial or complete villous blunting, deep crypt lymphocytosis, increased apoptotic bodies, minimal intraepithelial lymphocytosis
No severe immunodeficiency	Exclusion of other causes of villous atrophy, including coeliac disease, refractory sprue and intestinal lymphoma
	Presence of anti-enterocyte and/or anti-goblet cell antibody supports the diagnosis and sometimes correlates with disease improvement, but is not required to make the diagnosis

AIE autoimmune enteropathy

IgA deficiency associated with villous atrophy has been also reported in AIE. T and B cell function tests, the lymphocytic subsets and polymorphonuclear cell counts are generally normal. Anti-smooth muscle, anti-nuclear and anti-thyroid microsomal autoantibodies have been identified in the course of the disease [5, 8, 22, 60].

Determination of faecal inflammatory markers, like faecal calprotectin, is a simple method that is helpful in distinguishing constitutive intestinal epithelial disorders, such as microvillus atrophy and epithelial dysplasia from immune-inflammatory etiologies such as AIE and inflammatory colitis. It has been proposed that the dramatically increased levels of faecal calprotectin in neonates and infants with immune-inflammatory disorder can distinguish these disorders from constitutive epithelial disorders with 100% specificity [61].

Treatment

Early recognition and accurate diagnosis of AIE are mandatory to ensure the optimal treatment. The disease is characterized by life-threatening diarrhea often nonresponsive to bowel rest. TPN represents an important step in the management of AIE for nutritional support, adequate rehydration and optimal growth [11, 14, 62]. However, the pediatric patients are not always TPN dependent during the course of the disease [19]. When the gastrointestinal involvement is less severe, elemental or low-carbohydrate-containing formula is recommended to promote enteral delivery of nutrients and calories. The potential tolerance to enteral feeds and the

concomitant inflammatory changes affecting the colon make small bowel transplantation not an ideal treatment option for AIE [17, 63].

Long-term immunosuppression is the mainstay of treatment for the disease. Standard immunosuppressive therapies include corticosteroids, cyclosporine, azathioprine and 6-mercaptopurine. Steroids in the form of prednisolone or budesonide are often needed to induce remission. However, the disease can be refractory to steroids or diarrhea recurs when they are tapered [64].

Since the early 1990s, pediatric patients with AIE have been successfully treated with oral cyclosporine A. Studies have shown that a relatively low drug level (50 ng/mL) led to improvement in growth, intestinal carbohydrate absorption and small bowel histology. However, a number of patients do not respond to the medication and a possible reason is the inefficient absorption of the oral compound due to the underlying chronic enteropathy [65, 66].

Tacrolimus has been used as a therapeutic treatment option with beneficial effects in a variety of autoimmune diseases, including autoimmune hepatitis, primary sclerosing cholangitis and steroid-refractory nephrotic syndrome. Its mechanism of action is similar to cyclosporine. Both drugs block the gene activation for cytokine production by inhibiting the antigenic response of helper T lymphocytes, suppressing IL and interferon- γ [17]. Bousvaros et al. first used tacrolimus as an alternative therapy for AIE and concluded that it can be efficacious if other immunosuppressive regimens fail. Clinical improvement occurred between 1 and 4 months once therapeutic levels were achieved, and serum drug levels were obtained between 5 and 15 ng/mL. Tacrolimus' absorption is less dependent on mucosal integrity compared to cyclosporine; however, mucosal healing improves its absorption, and the dosage should be adjusted to achieve the desired blood levels of the drug. The need for long term or lifelong treatment with tacrolimus in AIE necessitates baseline and frequent monitoring in order to prevent its potential complications, including nephrotoxicity, neurotoxicity, increased predisposition to infections and lymphoproliferative disease [67].

The combination of tacrolimus and infliximab has been proven successful in controlling the inflammation in severe AIE in both pediatric and adult patients. The synergistic effect of these agents is based on the different aspects of the immune system on which they act. Emerging evidence supports that infliximab itself is a highly effective tool for achieving clinical remission and restoring small bowel villous architecture in AIE. The drug has been introduced because of its tumour necrosis factor (TNF)- α antagonistic effect since high levels of this cytokine are being produced by intestinal intraepithelial T lymphocytes of patients with AIE. The response to infliximab is usually rapid and the quality of life of the patients improves dramatically. However, it has

been recognized that aggressive immunosuppressive treatment carries a potential risk of life-threatening hypersensitivity reactions and malignancies that should be also considered [17, 68, 69].

Additional immunosuppressive therapies have been used in AIE. Cyclophosphamide is an alkylating agent related to nitrogen mustard and is a potent immunosuppressive agent used in bone marrow transplantation (BMT) conditioning regimens [70]. Low dose of oral cyclophosphamide led to resolution of the intestinal symptoms in a teenage boy with total villous atrophy, selective IgA deficiency and anti-epithelial cell antibodies [71]. However, the use of cyclophosphamide in doses up to 3 mg/kg/d has not always been successful in the management of the disease [38, 72]. Remission of symptoms and improvement of intestinal histopathology was reported in an infant with severe AIE with a single course of high-dose intravenous cyclophosphamide, approximately 20 times greater than those previously used [73].

Mycophenolate mofetil (MMF) has been proposed as an alternative therapeutic option after the successful induction of remission and the improvement of the intestinal absorption and linear growth in an infant with AIE and concomitant factor V Leiden defect [74].

IPEX Syndrome

IPEX is a rare disease and represents a systemic form of AIE characterized by immune dysfunction, polyendocrinopathy, enteropathy and X-linked inheritance. The prevalence of the syndrome remains unknown. Even though the severity of symptoms is variable, the most common feature of IPEX is the involvement of pancreas and thyroid with an early onset. Glucose intolerance can be present at birth and insulin-dependent diabetes mellitus begins often during the first year of life as a result of the complete inflammatory destruction of the pancreatic islet cells prior to the intestinal symptoms [75]. Thyroiditis presents either in the form of hyperthyroidism, or most commonly as hypothyroidism requiring substitutive therapy [13, 61].

The gastrointestinal involvement in children with IPEX syndrome includes severe, secretory diarrhea that can be bloody or mucousy and generally worsens after the breastfeeding is changed to formula [76, 77]. Protein-losing enteropathy with hypoalbuminaemia and a markedly increased clearance of α -1 antitrypsin are indicators of a poor prognosis [41]. Diarrhea often persists despite bowel rest, and TPN is required for nutritional support.

In addition to the endocrinopathies and the gastrointestinal involvement, the basic triad of IPEX syndrome includes chronic dermatitis, most commonly in the form of eczema. In addition, other immune-mediated dermatological disorders like alopecia, pemphigoid nodularis, psoriasiform der-

Table 2.4 Multisystemic disorders in IPEX syndrome

IPEX syndrome
<i>Endocrine:</i> glucose intolerance, insulin-dependent diabetes mellitus, hypo/hyperthyroidism
<i>Gastrointestinal:</i> secretory diarrhea, protein-losing enteropathy, autoimmune hepatitis
<i>Skin:</i> eczema, alopecia, pemphigoid nodularis, psoriasiform dermatitis
<i>Haematologic disorders:</i> autoimmune haemolytic anaemia, neutropenia, thrombocytopenia
<i>Renal:</i> glomerulonephritis, tubulopathy, nephrotic syndrome
<i>Neurological manifestations:</i> seizures, developmental delay
<i>Other:</i> susceptibility to infections, reactions to vaccines

matitis or resembling onychomycosis have been described [76, 78, 79]. The majority of boys with classical IPEX syndrome develop autoimmune hematologic disorders, such as Coombs—positive haemolytic anaemia, neutropenia or thrombocytopenia with anti-platelet antibodies. Renal involvement affects approximately 30% of the cases and presents as tubulopathy, nephrotic syndrome or glomerulonephritis. Autoimmune hepatitis is also common. The clinical spectrum of the syndrome includes neurological manifestations, such as seizures and developmental delay. Reactions to vaccines and increased susceptibility to infections can be attributed either to neutropenia and the immunosuppressive therapy or to the altered skin/gut barrier (Table 2.4) [61].

FOXP3 mutations can lead to different phenotypes of IPEX syndrome in terms of symptoms and severity. Genetic analysis for FOXP3 mutations is recommended in all patients with symptoms indicative of IPEX syndrome [80]. However, despite the typical clinical presentation of IPEX syndrome in some patients, no mutations were identified within the coding regions of FOXP3, supporting the hypothesis that conditional or regulatory mutations may occur outside FOXP3 [44, 49, 76]. A mutation in the polyadenylation signal following the final coding exon of FOXP3 that results in a decreased FOXP3 messenger RNA (mRNA) expression has been reported [81]. Furthermore, the fact that females heterozygous for FOXP3 mutation remain completely asymptomatic provides evidence that FOXP3-independent forms of AIE exist. It is likely that these independent forms of IPEX or AIE affecting both boys and girls are transmitted either with X-chromosomal or an autosomatic trait. A marked CD25 deficiency on CD4+ cells caused by an autosomal recessive mutation resulted in the IPEX-like clinical presentation in a patient with normal *FOXP3* gene analysis and pointed towards the implication of IL-2 and its high-affinity receptor CD25 in the pathogenesis of FOXP3-independent forms [82]. These findings need to be confirmed by future studies.

The small bowel histopathology of pediatric subjects with IPEX syndrome can range from a graft-versus-host disease-

like pattern with complete villous atrophy, mild inflammation of the lamina propria, apoptotic bodies, crypt abscesses and loss of goblet cells (as described above) to a more coeliac-disease-like pattern with partial villous atrophy, moderate inflammation of the lamina propria, an increase in intraepithelial lymphocytes and crypt hyperplasia. Moreover, a patient with anti-goblet cell antibodies demonstrated partial villous atrophy, moderate inflammation of the lamina propria, an increase in intraepithelial lymphocytosis and complete lack of goblet cells [83]. Depending on the organs involved in IPEX syndrome, the typical lymphocytic infiltration can be also present in thyroid, liver, skin, brain or pancreas with complete destruction of islet cells [62, 84].

The syndrome should be considered in young males presenting with protracted diarrhea with villous atrophy and failure to thrive combined with diabetes mellitus and/or hypothyroidism and skin manifestations. The definite diagnosis is based on genetic studies and mutation analysis of the *FOXP3* gene [85]. Immunocytochemical staining of FOXP3 molecule in bowel biopsies has been proposed as a potential screening test [86].

Given the serious side effects, the toxicity and the limited efficacy for long-term remission of immunosuppressive medication, there is a need for new therapeutic approaches for IPEX and AIE. The most promising is in the form of BMT. Baud and Wildin et al. reported three boys with IPEX syndrome who received BMT as ultimate treatment. Even though BMT was initially successful, lethal complications occurred months to years post transplantation. The authors concluded that BMT is potentially successful in treating resistant IPEX, but further experience must be gained before it is recommended as a rescue therapy for AIE.

Interestingly, the conditioning regimen was itself effective in controlling symptoms in some patients [48, 87] and a reduced-intensity-conditioning regimen prior to engraftment resulted in more FOXP3 T regulatory cells than more aggressive conditioning [88]. Beneficial effect on the pancreatic function and recovery of diabetes mellitus was obtained in some cases; however, the islet damage is often permanent at the time of BMT [86]. Insulin for diabetes and haematic transfusions are often needed for the symptomatic management of IPEX syndrome.

Clinical improvement in patients with IPEX syndrome was also reported after submyeloablative cord blood transplantation [89]. The efficacy of bone marrow-derived mesenchymal stem cells (MSC) in a multi-organ autoimmunity model caused by a deficiency in T cells led to an MSC-specific improvement in the histopathology of the distal ileum of treated mice. This observation necessitates future investigations into the use of MSCs for the treatment of autoimmune disorders [90]. It was also shown that the direct transduction of T cells with FOXP3-expressing vectors could overtake bone marrow gene therapy and provided evidence

that gene therapy of autologous cells could potentially be a future therapeutic approach for IPEX syndrome [91].

APECED Syndrome

APECED, also known as autoimmune polyendocrine syndrome type 1 (APS-1) is a rare, autosomal recessive disease. The understanding of the underlying pathophysiology of this monogenic disease has provided important information on the pathogenesis of organ-specific autoimmunity and T cell selection. The syndrome is characterized immunologically by destruction of the target organs by a cellular- and/or antibody-mediated attack [92, 93]. It has been reported at a relatively higher prevalence in genetically isolated populations like Finns, Sardinians and Iranian Jews [94–97]. The classical triad of APECED consists of Addison's disease, hypoparathyroidism and chronic mucocutaneous candidiasis, and two of them are required for the diagnosis. However, several other endocrine and non-endocrine manifestations accompany the pathognomonic triad.

The onset of APECED is usually in childhood with the first symptoms occurring on average at the age of 5 [98]. The wide spectrum of the clinical manifestations is attributed to a variable pattern of destructive autoimmune reaction mediated by specific antibodies that can attack any tissue or organ [99, 100]. TPH is an enzyme involved in the synthesis of neurotransmitters in the nervous system and in the gastrointestinal endocrine cells. The presence of autoantibodies against this enzyme is associated with AIE in APECED [101–104]. The gastrointestinal involvement also includes diarrhea, constipation, autoimmune hepatitis, chronic atrophic gastritis or autoimmune gastritis with pernicious anaemia [105]. Exocrine pancreatic failure results in malabsorption and steatorrhea in a small subgroup of patients [98].

Children within large Old Order Amish kindred presented with developmental delay, dysmorphic features, failure to thrive, organomegaly and multisystem autoimmune diseases, including AIE. Human ITCH E3 ubiquitin ligase deficiency was recognized as the underlying cause of this syndromic multisystem autoimmune disease. ITCH deficiency results in abnormal T helper cell differentiation and failure of T cell anergy induction. Genetic mapping in patients revealed a truncating mutation in the *ITCH* gene [106, 107].

In autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy, the mutations have been identified in the autoimmune regulatory gene (AIRE) that modulates the transcription of peripheral self-antigens in the thymus presented by HLA molecules to maturing T cells [108]. Patients affected by at least two illnesses among chronic mucocutaneous candidiasis usually starting soon after birth, autoimmune hypoparathyroidism and Addison's disease, especially from populations such as Finns, Sardinians and Iranian Jews

should be investigated for APECED syndrome. The identification of mutations on AIRE gene is recommended to confirm the diagnosis [98].

The treatment of APECED syndrome is challenging and is mainly based on parenteral nutritional support. Immunosuppressive treatment includes high doses of intravenous steroids and methotrexate, which is well tolerated in children. Systemic chemotherapy against *Candida* infection and hormone replacement therapy are also required. Patients with APECED should be closely monitored for new components of the syndrome [109].

Prognosis

AIE is a potentially life-threatening disease. Both intestinal and extra-intestinal manifestations can lead to debilitating symptoms requiring a complex therapeutic approach. The disease itself has not been linked to the development of intestinal malignancies; however, the intensity of immunosuppressive therapy and the increasing longevity of patients potentially increase the risk of malignancy [17]. AIE is now considered as a systemic disease, and, in its most severe form, IPEX syndrome, is often characterized by unresponsiveness to treatment with a high mortality rate [67]. Malnutrition in infants and infections at a later age are the most frequent causes of death. Given the immunologic nature of IPEX syndrome, early BMT currently seems the most promising treatment of choice. However, more experience is needed to ensure that this therapeutic approach leads to permanent remission [48, 87]. Finally, the great variability of the clinical expression and the absence of a clear genotype–phenotype correlation in APECED syndrome create the need for the identification of potential disease-modifying genes that are involved in the clinical expressivity of organ-specific autoimmunity.

Introduction

Congenital abnormalities of the gastrointestinal tract (GIT) are relatively common. Owing to their nature, they frequently require surgical correction, and on occasion this must be undertaken as a matter of emergency in order to avoid catastrophic intestinal ischemia and necrosis resulting in loss of bowel or damage to a secondary organ system. This chapter provides an overview of the most common conditions encountered and those which require intervention as a matter of urgency. It is not possible within the space available to describe in detail all of the variants of congenital GIT abnormalities that may be encountered and the precise nature of the treatment options available. For ease of understanding, we commence with the upper GIT and continue in a caudal direction.

Conditions Affecting the Upper Gastrointestinal Tract

Esophageal Atresia and Trache-esophageal Fistula

This complex group of anomalies with an incidence of 1 in 2440–4500 live births [1, 2] results from failure of correct division of the tracheal primordium from the esophagus during early embryonic development. The precise etiology is unknown with a number of embryological theories proposed to explain the different variants of this anomaly. There is a high incidence of coexisting abnormalities including the VACTERL (Vertebral column, Anorectal, Cardiac, Tracheal, Esophageal, Renal, and Limbs) syndrome, CHARGE (Coloboma of the eye, Heart defects, Atresia of the nasal choanae,

Retardation of growth and/or development, Genital and/or urinary abnormalities, and Ear abnormalities and deafness) association, and isolated cardiovascular anomalies [3].

Classification

A number of classification systems have been proposed over the years. Table 3.1 describes the most commonly encountered anatomical variants (Fig. 3.1), and the Spitz classification (Table 3.2) [3] incorporating birth weight and presence of major congenital heart disease status may be useful in predicting survival.

Clinical Features

EA is commonly associated with maternal polyhydramnios, and with increasing frequency, the diagnosis is being made antenatally particularly if there is no TEF. In the postnatal period, symptoms associated with the condition include excessive salivation, feeding difficulties, respiratory distress, and cyanotic episodes. Cases of EA (with the exception of the rare EA with double fistula) can be confirmed by failure of passage of a nasogastric tube into the stomach. Cases of TEF in the absence of EA (i.e., H-type fistula) may present later, usually with recurrent episodes of respiratory distress or pneumonia.

Treatment

The overall aim of surgical correction is early division of any fistula with the respiratory tract to protect the lungs and airway, and restoration and maintenance of esophageal continuity to allow normal feeding. Following diagnosis, a Replogle tube is placed in the upper esophageal pouch which allows suction of secretions and minimizes the risk of pulmonary aspiration. Surgical repair involves ligation and division of any fistula and primary anastomosis of the two ends of the esophagus where possible. Infants who are too unstable to tolerate primary esophageal repair, typically preterm infants with respiratory distress, may be treated with ligation of the fistula only followed by delayed esophageal anastomosis once a period of cardiorespiratory stability can be achieved.

Most infants with “pure EA,” that is, EA without TEF, and some infants with EA with TEF have a gap between the two ends of the esophagus that is too wide for primary anastomosis to be achieved. This group poses a particular surgical challenge. These infants are typically fed by gastrostomy initially, and the esophageal anastomosis is re-attempted after a period of growth (typically at least 6 weeks) during which the esophageal ends often grow closer together permitting anastomosis. If attempts at anastomosis remain unsuccessful, esophageal replacement such as by gastric transposition is considered.

Outcome

The majority of patients do well following anastomosis, but a number of complications may occur, and they require recurrent procedures. The most common surgical complication is anastomotic stricture. Strictures frequently require dilatation, and balloon dilatation is the preferred technique. Other complications include anastomotic leakage, recurrent TEF, gastroesophageal reflux, and disordered peristalsis. The combination of poor esophageal motility and gastroesophageal reflux with or without anastomotic stricture may lead to long-term feeding difficulties.

The Stomach

The most common abnormality of the stomach in the neonatal period is hypertrophic pyloric stenosis. Whether this is truly a congenital abnormality or an acquired disorder is questionable. It is further discussed in Chap. 4.

Other congenital conditions affecting the stomach including congenital microgastria, gastric volvulus, and congenital gastric outlet obstruction due to a pyloric web or atresia are all extremely rare and are mentioned only for completeness.

Obstructive Lesions of the Duodenum, Jejunum, and Ileum

The most common congenital conditions affecting the duodenum, jejunum, and ileum all result in partial or complete gastrointestinal obstruction. The presenting features and investigations recommended to diagnose the underlying abnormality are similar for all conditions. The clinical features and investigations of these conditions are therefore presented first followed by a description of each type of abnormality and the recommended treatment options.

Table 3.1 Classification of EA/TEF anomalies and frequency. (Reprinted with permission from [4], Table 2.1, and [3], Table 2 and 3, with permission from Elsevier)

Type of lesion	Frequency (%)
EA and distal TEF	88.8
Isolated EA	7.3
H-type fistula	4.2
Distal and proximal TEF	2.8
Proximal TEF	1.1

EA esophageal atresia, TEF trache-esophageal fistula

Table 3.2 Spitz classification of EA/TEF anomalies and outcome. (Reprinted with permission from [4], Table 2.2, and [3], Tables 2 and 3, with permission from Elsevier)

Group	Clinical features	Survival (%)
I	BW \geq 1500 g with no major CHD	97
II	BW < 1500 g or major CHD	59
III	BW < 1500 g and major CHD	22

EA esophageal atresia, TEF trache-esophageal fistula, CHD congenital heart disease, BW birth weight

Clinical Features

Obstructive lesions of the small intestine from the pylorus down to the ileocecal valve may give rise to polyhydramnios in the antenatal period which is detectable by antenatal ultrasonography. As a general rule, the more proximal the lesion the more severe the degree of polyhydramnios, and distal ileal lesions may be present in the absence of polyhydramnios [5]. The list of differential diagnoses giving rise to polyhydramnios is however extensive. Another feature that may be seen on antenatal ultrasonography is the presence of dilated loops of intestine with or without echogenic bowel. While the combination of echogenic and dilated loops of bowel is often a sign of some form of intestinal abnormality, the precise nature of any problem is rarely identified before birth. One exception to this is a diagnosis of congenital duodenal obstruction in which case the appearance of a double bubble on antenatal ultrasonography has high sensitivity and specificity.

Following birth, the most common and important clinical manifestation of obstructive lesions of the GIT is bile-stained vomiting. Vomiting with truly bilious staining is always abnormal in the neonatal period and always requires investigation. Lesions in the duodenum and jejunum usually result in bilious vomiting within hours. In addition, the abdomen may appear empty or even scaphoid, and visible gastric peristalsis may be observed. Lesions lower in the ileum result in a distended abdomen if the obstruction is complete, and there may be failure to pass meconium. Obstructive lesions may also give rise to intestinal perforation in the neonatal period and occasionally antenatally. In all cases of neonatal intestinal obstruction, infants become progressively hypovolemic and are prone to circulatory and respiratory collapse. They require fluid resuscitation and may require ventilatory support. GIT obstruction should therefore be considered in any infant who is dehydrated especially if there is a history of vomiting.

Stenotic lesions of the small bowel in which the obstruction is incomplete may give rise to increased diagnostic difficulty. Affected infants may present with intermittent vomiting and episodes of partial obstruction. They eventually fail to thrive or develop complete obstruction at which stage they are fully investigated and the diagnosis becomes apparent.

Intestinal malrotation is considered separately as it may present with a spectrum of clinical scenarios depending on the degree of intestinal obstruction or midgut volvulus or both. The clinical pictures of all types of abnormal rotation are those of acute or chronic intestinal obstruction and/or acute or chronic abdominal pain suggestive of intestinal ischemia. True malrotation typically presents in the first year of life with symptoms of upper GIT obstruction including vomiting which is usually bile-stained. A coexisting volvulus may be suspected by abdominal pain, peritonitis, and hypovolemic shock associated with intestinal ischemia. However, these signs may be relatively nonspecific in the young infant. Malrotation may also present later in life.

Investigations

The aim of investigating cases of suspected obstruction of the small intestine is twofold. First to identify the nature and anatomical location of the lesion to allow for planning of correct treatment and second to identify cases of malrotation in whom there is a risk of midgut volvulus and intestinal ischemia. These cases require urgent surgical intervention to reduce the risk of potentially catastrophic intestinal necrosis. The history and examination may give clues as to the location of the lesion as described above. An abdominal X-ray may simply confirm the presence of dilated intestinal loops but may also give further clues in some cases. A double bubble appearance on abdominal X-ray with a lack of air in the distal intestine (Fig. 3.2) is characteristic of duodenal obstruction. Multiple air-filled loops of proximal bowel often with air-fluid levels along with a paucity or complete absence of gas in the distal bowel is highly suggestive of obstruction of the ileum. Intestinal perforation if present will usually be apparent on abdominal X-ray, and in the rare cases of antenatal perforation, there may be widespread or localized flecks of calcification representing calcified meconium within the peritoneum.

In cases in which the diagnosis is not clear on abdominal X-ray or in which midgut malrotation or volvulus is suspected, a limited upper gastrointestinal contrast study is indicated. The classical finding in cases of malrotation is that the duodenojejunal flexure lies to the right side of the spine

Fig. 3.2 Abdominal X-ray of an infant with duodenal atresia showing the “double-bubble” appearance characteristic of duodenal obstruction. (Reprinted with permission from [4], Fig. 2.2)

Fig. 3.3 Upper gastrointestinal contrast study of a case of malrotation. The contrast is seen within the duodenum (*D*) and flowing into the upper jejunum (*J*) both of which lie completely to the *right* of the mid-line. (Reprinted with permission from [4], Fig. 2.3)

instead of its normal left-sided position (Fig. 3.3). This finding should prompt urgent surgical treatment due to the risk of coexisting midgut volvulus. The contrast study may also identify the presence of a stenotic segment or complete obstruction.

Cases of lower ileal stenosis or atresia are often more difficult to diagnose, and a contrast enema is invaluable in distinguishing between ileal and colonic obstruction and could be therapeutic in cases of meconium ileus (see below).

Conditions Affecting the Duodenum

Duodenal atresia and duodenal stenosis both of which may be associated with an annular pancreas are the commonest congenital conditions to affect the duodenum. Both are capable of giving rise to duodenal obstruction. The incidence is reported to be between 1 in 5000 and 10,000 live births [6].

Explanations of the etiology of duodenal atresias are not universally accepted. Unlike atresias of the ileum, they are not thought to be due to vascular accidents, and the most widely

accepted explanation is that of failure of recanalization of the intestinal lumen during early embryonic development.

Classification

There are four basic types of duodenal obstruction (Fig. 3.4). In type 1, there is a stenosis of the duodenum resulting from a diaphragm or web partially or totally occluding the lumen. Due to the incomplete nature of the obstruction, cases may present in childhood rather than in the neonatal period. In type 2 duodenal atresia, the proximal and distal segments end blindly but remain connected by a fibrous cord. There is complete separation of the bowel segments in type 3 and type 4 comprises an atretic segment with an annular pancreas. Multiple atresias are said to occur in up to 15% of cases [7].

Treatment

The principles of treatment are to restore intestinal continuity while avoiding interference with the ductal system draining the pancreas and biliary tree. This is best achieved using a duodenostomy in which the obstructed segment is bypassed by joining the proximal segment directly to the distal segment. Following surgery, the long-term gastrointestinal results are good [8].

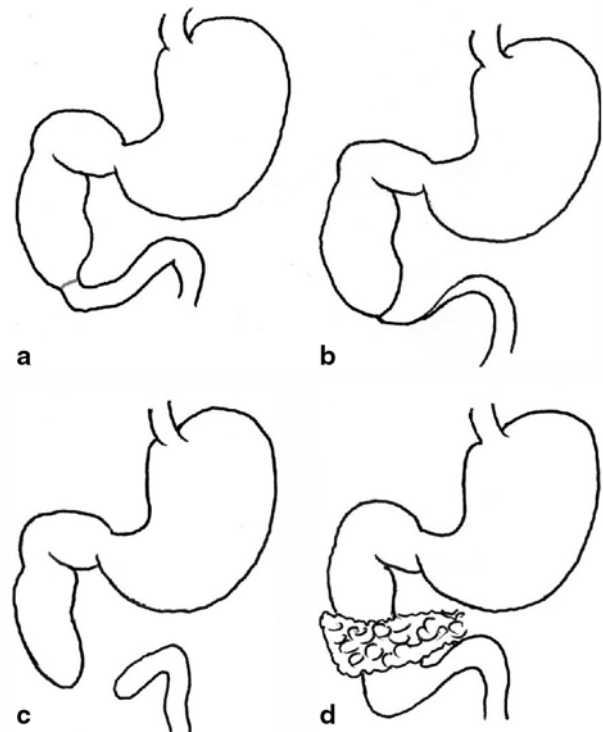

Fig. 3.4 Variants of duodenal atresia. **a** type 1 atresia due to an internal diaphragm, **b** type 2 atresia with blind-ending loops remaining connected by a fibrous cord, **c** type 3 atresia with blind ends completely separated, **d** type 4 duodenal obstruction with an annular pancreas. (Reprinted with permission from [4], Fig. 2.4)

Conditions Affecting the Ileum and Jejunum

The main congenital problems directly affecting the small intestine from the duodenojejunal flexure down to the cecum are atresia and stenosis. Jejunoileal atresia occurs more commonly than its duodenal counterpart with an incidence of varying from 1 in 330 to 3000 live births [9]. Such lesions are one of the most common causes of neonatal intestinal obstruction. The major difference between atresias of the ileo-jejenum and those of the duodenum is in their etiology. It is postulated that atresia or stenosis of the jejunum and ileum is the result of a localized vascular accident during intrauterine life. Subsequent ischemic necrosis and reabsorption of the affected segment or segments result in a contracted scarred bowel wall leading to stenosis at one end of the spectrum to a complete intestinal and mesenteric defect at the other. Fetal animal experiments have confirmed at least in part this hypothesis [10], and the absence of other congenital abnormalities found in association with jejunoileal stenoses and atresias supports the localized vascular accident theory.

Classification

Morphological classification of these lesions allows different surgeons and centers to compare outcomes, and it is also of therapeutic and prognostic value. The most commonly accepted system is that proposed by Louw [11] and modified by Grosfeld [12]. Whether the lesion is classified as ileal or jejunal is determined by the most proximal affected segment (Fig. 3.5).

Stenosis is a localized narrowing of the lumen without any break in the continuity or mesenteric defect. The intestinal wall may be thickened and rigid at the stenotic site, and there is a small, often minute lumen. The overall intestinal length is not shortened. Type I atresia is the result of a membranous web occluding the lumen with no mesenteric defect and no intestinal shortening. The lumen is usually completely occluded, and the proximal bowel therefore dilated but remaining in continuity with the collapsed distal segment. Type II atresia arises from a complete obliteration of the intestinal segment into a fibrous cord which joins two blind ends and runs in the free edge of the mesentery. There is no mesenteric defect, and once again, the total bowel length is usually normal. In both type III(a) and III(b) atresia, the intestine is likely to be shortened, and this may have significant clinical consequences. Type III(a) atresia consists of blind-ending proximal and distal bowel with no connection and an often large mesenteric defect. The blind ends are often physiologically abnormal with decreased or absent peristaltic activity which may give rise to torsion, distension, or perforation. Type III(b) atresia, also known as apple-peel atresia because of its gross morphology, may involve massive intestinal loss. It consists of intestinal atresia near the ligament of Treitz, obliteration of the superior mesenteric artery (SMA) beyond

Fig. 3.5 Variants of ileal atresia. **a** type I due to an internal web (not shown) with no mesenteric defect, **b** type II atresia with blind ends joined by a fibrous cord, **c** type III(a)—blind ends separated with a mesenteric defect, **d** type III(b) in which the ileum is coiled like an “apple peel” around a single vessel and completely separated from the proximal dilated jejunum, **e** type IV or multiple atresias. (Reprinted with permission from [4], Fig. 2.5)

the origin of the middle colic branch, and the absence of the dorsal mesentery. The remaining intestine is coiled helically (like an apple peel) around a single perfusing vessel, often has impaired vascularity, and is almost inevitably short. Furthermore, there may be additional segments of type I or II atresia within the apple-peel segment. Such a configuration most likely arises from occlusion of the SMA due to thrombus, embolus, or strangulation as part of a midgut volvulus. In type IV atresia, there are multiple atretic segments, and the intestine may resemble a string of sausages. Overall, bowel length is usually shortened, and the intestine grossly dilated. It has been proposed that the etiology of type IV atresia may be due to failure of recanalization of solid epithelialization throughout the length of the intestine rather than from multiple single vascular events.

While it is generally accepted that stenosis and atresia of types I, II, and III(b) are the result of intrauterine vascular accidents, a genetic component has been suggested in type III(b) and IV.

Treatment

The mainstay of surgical treatment for this type of lesion is resection of the atretic or stenotic segment and primary anastomosis with closure of the mesenteric defect. The proximal intestinal segment is usually dilated and functionally abnormal with absent or ineffective peristalsis. This dilated proximal segment is excised along with a short segment distal

to the stenosis or atresia. It is essential to establish patency of the distal bowel by irrigation or wash out intestine, and subsequently, a primary anastomosis is performed. There is a balance to be struck between the length of dilated proximal segment resected and the risk of leaving the infant with a short length of small bowel. As such, it is almost inevitable that the caliber of proximal bowel will be greater than that of the distal intestine, and a number of techniques exist to assist construction of the anastomosis in such circumstances.

Outcome following intestinal atresia is dependent primarily on the length of remaining intestine and the presence of the ileocecal valve. Short bowel syndrome has been defined as the presence of less than 75 cm of the small intestine or 30% of the predicted intestinal length in a premature infant [13, 14]. Outcomes following short bowel syndrome vary, and there is a high level of dependence on parenteral nutrition. However, intestinal adaptation can occur such that more than 80% of babies with short bowel syndrome do eventually become entirely enterally nourished [15].

Intestinal Malrotation

The incidence of intestinal malrotation is difficult to truly establish as not all affected patients develop symptoms, but autopsy studies estimate the incidence at approximately 1 in 500.

The traditional embryological basis for disorders of intestinal rotation is that of abnormal positioning of the intestinal loops in relation to one another as they return to the abdominal cavity from the yolk sac. During normal development, the midgut rotates through 270° so that the duodenum lies posterior to the colon, and the duodenojejunal flexure is to the left of the midline. A consistent finding in cases of malrotation is abnormal positioning of the duodenojejunal flexure. However, an alternative hypothesis has been proposed based on animal studies [16]. Kluth proposes that malrotation is the result of failure of localized growth of the duodenal loop rather than a disorder of rotation.

The term “malrotation” covers a spectrum of anatomical abnormalities. In non-rotation, the duodenojejunal flexure lies to the right of the spine along with most of the small intestine. The cecum and colon are typically on the left side of the abdominal cavity. Adhesions formed between loops of bowel or the intestine and abdominal wall are usually responsible for obstructive symptoms at presentation. In malrotation, the distribution of intestinal contents within the abdominal cavity is such that the duodenum again lies to the right of the spine with the cecum anterior to it. Adhesions between these two structures (Ladd’s bands) are often present and may result in partial or total occlusion of the second part of the duodenum. In addition, the mesenteric attachment to the posterior aspect of the abdominal cavity is typically very short, and there is a risk of volvulus with ensuing intes-

tinal ischemia. Other forms of abnormal intestinal rotation (inversed rotation, malrotation with mesocolic hernia, and malposition of the cecum) are all rare.

Treatment

There are two aspects to this disorder which require surgical intervention. The first and most important aspect is that of midgut volvulus. Any infant in whom malrotation is suspected based on clinical findings and radiological investigations should undergo laparotomy as a matter of urgency in order to minimize the risk of intestinal ischemia due to a volvulus. At laparotomy, blood-stained peritoneal fluid may indicate the presence of ischemic intestine. Any volvulus should be derotated (usually in clockwise direction), and the intestine examined for viability. Nonviable bowel is resected, and a primary anastomosis performed. If there is doubt about the viability of remaining intestine, a second-look laparotomy can be performed after 24 h.

In cases of malrotation not complicated by volvulus, the procedure of choice for most surgeons is the Ladd’s procedure. This involves division of all adhesions or adhesive bands between the cecum, duodenum, and parietal peritoneum, broadening of the mesenteric base around the SMA and repositioning of the intestine within the abdominal cavity such that the duodenum is on the right and the cecum lies in the left upper quadrant. Some surgeons recommend performing an appendectomy due to the difficulties of diagnosis should appendicitis develop later in life.

Meconium Ileus

Meconium ileus is a common cause of neonatal intestinal obstruction and the commonest cause of antenatal intestinal perforation [17]. It should be included in the differential diagnosis of infants presenting with GIT obstruction. In approximately 80% of cases, it is associated with cystic fibrosis, [18–20] an autosomal recessive disease affecting predominantly the lungs and pancreas. The underlying defect in cystic fibrosis, an abnormality in a transmembrane chloride channel, results in the production of abnormally viscous and sticky meconium. This meconium sticks to the intestinal mucosa causing intestinal obstruction usually occurring late in gestation. Why some infants with cystic fibrosis do not develop meconium ileus is unclear. Meconium ileus can be classified as: (1) “uncomplicated” when is limited to intraluminal obstruction caused by the abnormal meconium or (2) “complicated” when is associated with intestinal atresia, volvulus, or meconium peritonitis.

Clinical Features

In cases of uncomplicated meconium ileus, the infant usually presents shortly after birth with symptoms of lower gastrointestinal obstruction including abdominal distension and

vomiting which may or may not be bile stained. The rectum may appear empty and narrow on plain radiograph, and the infant does not pass meconium. If meconium ileus is complicated by volvulus, intestinal ischemia, or perforation, the infant can be systemically unwell with acidosis and hypovolemic shock and may require ventilatory support. Abdominal X-ray showing dilated intestinal loops and occasionally abundance of meconium in the right lower quadrant are supportive of the diagnosis as is a gastrografin contrast enema revealing a small collapsed colon (microcolon) and often inspissated pellets of meconium in the right lower quadrant.

Treatment

In some cases, the gastrografin enema mentioned above may relieve the obstruction sufficiently to be curative. However, a number of uncomplicated cases and all complicated cases require surgery. The procedure performed depends on the findings during laparotomy. Atretic or grossly dilated segments of bowel may be resected, the inspissated meconium removed from the intestinal lumen, and the distal bowel flushed through. Occasionally, a stoma is formed to allow intestinal decompression. Outcome of surgical treatment is generally good, and gastrointestinal complications are of lesser significance than the pulmonary disease caused by the underlying cystic fibrosis.

Meckel's Diverticulum

Meckel's diverticulum is the commonest omphalomesenteric remnant with a reported incidence of approximately 2%. Of these, only a small proportion become clinically significant. The diverticulum originates from incomplete obliteration of the omphalomesenteric duct and exists as a free lying diverticulum on the anti-mesenteric border of the ileum.

Clinical Features

There are a variety of disease entities attributed to a Meckel's diverticulum including gastrointestinal hemorrhage, intussusception, diverticulitis, and perforation. The commonest presenting symptom is that of gastrointestinal bleeding due to excessive acid and pepsin production from ectopic gastric mucosa which may be present within the diverticulum. Bloody diarrhea in the absence of abdominal pain is the classical presenting picture. Other complications of Meckel's diverticulum are intussusception in which the diverticulum acts as a lead point, diverticulitis with symptoms similar to those of appendicitis, and perforation.

Treatment

Management of all clinically significant cases of Meckel's diverticulum is resection of the diverticulum after adequate preoperative resuscitation. At operation, the diverticulum and a wedge of ileum are resected. The ileal wedge is

included as ectopic tissue may not be entirely confined to the diverticulum. Following surgical excision outcome is good.

Congenital Hepatic, Pancreatic, and Biliary Abnormalities

Abnormalities of the hepato-pancreato-biliary system are all quite rare. They are included here as knowledge of their existence is important as they form part of the differential diagnosis for infants with jaundice, malabsorption, and hypoglycemia.

The commonest lesions of the biliary tree are biliary atresia and congenital biliary dilatation. In biliary atresia, the biliary tree is obliterated either completely or partially. Congenital biliary dilatation describes a variety of abnormalities of the biliary tree in which the dilated segment may be either intrahepatic or extrahepatic and either fusiform or cystic in nature. Dilatations of the extrahepatic biliary ducts are commonly known as choledochal cysts. The dilated bile duct is both anatomically and functionally abnormal resulting in cholestasis. Infants with biliary atresia and severe cholestasis associated with biliary dilatation present in the neonatal period with prolonged jaundice due to accumulation of conjugated bilirubin. When the degree of obstruction to the biliary tree is not so severe, congenital biliary dilatation may present later in life with malabsorption, intermittent jaundice, abdominal pain, or even pancreatitis. In addition, a choledochal cyst may present as an upper abdominal mass. Treatment of these lesions is based on allowing drainage of the biliary tree into the intestine, and the surgery involved is often complex. The operation of choice for biliary atresia is the Kasai porto-enterostomy [21]. The atretic remnants of the extrahepatic biliary ducts are removed, and the porta hepatis is anastomosed to a defunctioned loop of jejunum. The timing of surgery is of paramount importance to avoid hepatocellular damage, but even with prompt diagnosis and early surgical intervention, infants with biliary atresia often have residual hepatic impairment due to intrauterine cholestasis. In cases of choledochal cysts, the dilated portion of the extrahepatic ducts is removed together with the gallbladder, and the common hepatic duct is anastomosed to the duodenum or a defunctioned loop of jejunum.

There are a number of congenital hepatic anomalies which give rise to structural and/or functional abnormalities of the liver parenchyma or the intrahepatic biliary tree. These include infantile and adult-type polycystic disease, congenital hepatic fibrosis, biliary hypoplasia, and congenital tumors of the liver such as hamartomas and hemangiomas. Presentation is usually with one of hepatomegaly, portal hypertension, or cholangitis. Treatment is that of resection of suitable lesions and prevention or treatment of hepatic disease.

Congenital lesions involving the pancreas are rare, the commonest being annular pancreas (see section on the

duodenum). Other anatomical anomalies are seen including pancreatic ductal anomalies, pancreatic cysts, and very rarely pancreatic agenesis. There are a group of infants who present in the neonatal period with hypoglycemia who are found to have inappropriately high levels of circulating insulin. The condition hyperinsulinemic hypoglycemia (previously commonly referred to as “nesidioblastosis”) is characterized by inappropriate endogenous insulin secretion in the presence of low blood glucose. It may result from an insulin-secreting tumor in the pancreas (a so-called insulinoma), but more commonly, no tumor is identified and the disease is a result of a genetic defect in a membrane channel controlling insulin secretion. Infants require high glucose intake to maintain normoglycemia while investigated for the presence of an isolated secretory tumor. Treatment is by surgical excision of the tumor if present; otherwise, a 90–95% subtotal pancreatectomy is performed.

Conditions Affecting the Lower Gastrointestinal Tract

Hirschsprung Disease

Hirschsprung disease is the commonest congenital malformation of the enteric nervous system with an incidence of approximately 1 in 5000 live births [22–24]. While most cases are sporadic, a positive familial occurrence exists in 3.6–7.8% of cases [25], and the presence of coexisting abnormalities including trisomy 21 suggests a genetic involvement. The condition is fully addressed elsewhere (see Chap. 22).

Anorectal Anomalies

Congenital abnormalities of the anorectal region occur with an incidence of 1 in 4000–5000 live births [26–28]. A very small minority may be familial with the majority being isolated findings or part of a congenital syndrome such as the VACTERL syndrome. There are a number of different types of anorectal anomalies resulting from the complex embryological development of the anorectal region involving differentiation of the cloaca. The Wingspread classification [29] divides them into high, intermediate, or low based on the relationship of the terminal bowel or any fistula arising from the bowel to the pelvic diaphragm. Precise definition of the abnormal anatomy is of paramount importance when planning corrective surgical treatment.

Clinical Features

Abnormalities of the anorectal region are usually diagnosed on inspection during the newborn period, but surprisingly, this

is not always the case. In many cases, the anus will be absent, and meconium may be seen to originate from an abnormal site including a mucocutaneous fistula, the urethra in males, or the vaginal vestibule in females. Anomalies in which the anus is present but abnormally sited or stenosed may be more difficult to diagnose in the absence of adequate experience. The most complex abnormality in females is represented by the cloaca which is represented by a single opening in the perineum with rectum, vagina, and urethra joining a single channel.

Treatment

Treatment is aimed at preventing complications associated with the anomaly including urinary tract infection and lower gastrointestinal obstruction and subsequently restoring the anatomy to as near to normal functional and cosmetic state as possible. In the majority of cases, the initial surgery involves forming a colostomy in the descending or sigmoid colon to allow intestinal drainage and avoid dilatation of the lower bowel [30]. Following assessment, planning of surgery and growth of the infant reconstructive surgery is undertaken most commonly by the posterior sagittal approach [31]. Some anomalies also require a laparotomy to divide a high recto-vesical fistula. Surgery of these cases and particularly of cloaca is complex and should be performed by an experienced surgeon.

Outcome

In similarity to patients with Hirschsprung disease, incontinence and constipation are the most significant long-term complications of anorectal anomalies and often have a significant impact on quality of life. In one large series, soiling occurred in 57% of 387 cases. The incidence of fecal incontinence was 25% and constipation 43% [31]. Ongoing medical and on occasion surgical treatment is necessary to minimize disruption to a normal lifestyle.

Conditions Which May Occur at Any Point in the Gastrointestinal Tract

Gastrointestinal Duplications

Duplication cysts of the GIT are rare congenital abnormalities. They can occur at any point in the GIT from mouth to anus, although they are most commonly found around the ileocecal region. Duplication cysts are defined according to strict criteria as devised by Ladd and Gross; they are closely attached to some part of the GIT, have a smooth muscle coat, and have an epithelial lining which resembles some part of the alimentary canal [32]. Duplications may be spherical or tubular in macroscopic appearance, those that are tubular accounting for 10–20% and often having a communication with the bowel.

Clinical Features

Between 25 and 30% present in the neonatal period and most have presented by the age of 10 years. Clinical features at presentation depend on anatomical site, size, and secondary effects and include an oropharyngeal, abdominal or rectal mass, respiratory distress, gastrointestinal bleeding, obstruction, and intussusception. Duplication cysts may also be found as incidental findings at laparotomy, and some lesions have been detected on antenatal ultrasound [33, 34].

Treatment

The recommended management of duplication cysts is complete surgical excision wherever possible in order to prevent recurrence and complications secondary to ectopic gastric mucosa. When complete excision is not possible, it is essential to remove the mucosal lining.

Conditions Affecting the Walls of the Abdominal Cavity

While not truly conditions of the GIT, there are a number of conditions which cause the abdominal contents to develop outside the abdominal cavity. These conditions are included as they have secondary effects which may significantly affect the GIT and be a cause of gastrointestinal dysfunction.

Congenital Diaphragmatic Hernia

The incidence of congenital diaphragmatic hernia (CDH) varies from 1 in 3500 to 1 in 5000 live births [35]. Its etiology is unknown although is probably multifactorial. The essential anatomical defect is a breach in the continuity of the diaphragm which allows herniation of the abdominal viscera into the thoracic cavity. This has a secondary effect of impeding development of the lungs during intrauterine life. The resulting hypoplastic lungs are a cause of significant morbidity and mortality in this condition. Compression by misplaced abdominal contents does not explain the severity of lung disease seen, and it is well recognized that lung development is markedly abnormal in infants with CDH.

Classification

A number of different defects can occur owing to the complex development of the diaphragm. The majority of cases are of the Bochdalek type in which the defect is posterolateral and most commonly on the left side. The defect can range in size from a small slit to involve almost the entire hemidiaphragm. Defects in the central tendon of the diaphragm result in Morgagni hernias which are retrosternal in nature and most commonly on the right side. Finally, agenesis of the diaphragm may occur which is usually left sided and extremely rare.

Clinical Features

In the current era, diaphragmatic hernia is often diagnosed during prenatal ultrasound scanning. The advantage of prenatal diagnosis is that delivery can be planned to take place in a unit with appropriate pediatric surgical and intensive care facilities. For those infants who avoid prenatal diagnosis for whatever reason, the clinical features depend on the volume of abdominal contents within the thoracic cavity and the degree of lung hypoplasia. In the most severe cases, there will be severe respiratory distress and cyanosis from shortly after birth. At the other end of the spectrum are infants who have minimal if any respiratory symptoms or signs and in whom intestinal loops are noted to be in the abdomen on chest X-ray (Fig. 3.6).

Treatment

While the definitive treatment of diaphragmatic hernia is surgical closure, the timing of this is not of paramount importance and should be undertaken once the infant is stable from a cardiovascular and respiratory point of view. The respiratory management of these infants can be problematic due to the severe lung hypoplasia and associated pulmonary hypertension. Most require conventional ventilatory support as a minimum, and many require high-frequency oscillatory ventilation (HFOV) to ensure adequate oxygenation. Other measures to reduce pulmonary hypertension including inhaled nitric oxide, adenosine, or sildenafil may be effective. Resistant cases may be candidates for extracorporeal membrane oxygenation (ECMO), during which the infant is placed on a life support system in the hope that the lungs and in particular the pulmonary vasculature will mature. Various criteria for ECMO exist [36] with the aim of reserving it for those who have the most severe respiratory failure and those

who are most likely to benefit. There remain unfortunately a number of infants with CDH whose lung disease presents too great a challenge, and they do not survive.

Surgery

The principles of surgical repair are to return the abdominal contents to the abdominal cavity and repair the diaphragmatic defect. It may be possible to repair the defect by simply suturing the edges together. However, if the defect is large, a patch repair may be undertaken using prosthetic material. The long-term outcome of CDH is dependent primarily on the degree of pulmonary hypoplasia. The main gastrointestinal consequence appears to be gastroesophageal reflux seen in up to 62% of cases [37].

Anterior Abdominal Wall Defects

Although separate clinical entities, the two conditions exomphalos and gastroschisis which comprise anterior abdominal wall defects are grouped together due to similarity in their clinical appearance and the recommended course of management. In both conditions, some portion of the viscera lies outside the abdominal cavity extruding through a defect in the anterior abdominal wall.

Exomphalos

The defect on the anterior abdominal wall in cases of exomphalos lies in the midline. Viscera herniate through this defect but remain contained within an avascular hernial sac consisted of peritoneum and amniotic membrane (Fig. 3.7). The size of the defect and hence the size of the sac may vary in size from a small swelling at the base of the umbilical cord (exomphalos minor) to a much larger sac containing liver and

Fig. 3.7 Clinical appearance of an infant with exomphalos. The abdominal contents are enclosed within an avascular hernial sac. (Reprinted with permission from [4], Fig. 2.8)

a large proportion of the small intestine (exomphalos major). The embryological origins of exomphalos are believed to be failure of complete closure of the anterior abdominal wall around a persistent body stalk. Visceral contents continue to develop within this body stalk and thus remain outside the abdominal cavity. While the precise etiology of exomphalos is not clear, it is well recognized that exomphalos often coexists with a number of other congenital abnormalities, and this may suggest at least in part a genetic component. Associated abnormalities include Beckwith–Wiedemann syndrome, the trisomies 13, 18, and 21, and the upper and lower midline associations.

Gastroschisis

The anterior abdominal wall defect in cases of gastroschisis is full thickness and typically to the right of the umbilical cord. Unlike exomphalos, there is no sac covering the eviscerated intestine which is usually dilated and inflamed (Fig. 3.8). The liver is not herniated. The precise embryological basis of gastroschisis is unclear, and a number of hypotheses have been proposed. The fact that gastroschisis is rarely associated with any other congenital abnormalities—with the exception of intestinal atresias and malrotation—suggests that the events resulting in exomphalos are likely to have a separate embryological basis.

Treatment

It is now usual for these two abnormalities to be detected in the antenatal period, and delivery in a specialist center with pediatric surgical facilities is recommended. In gastroschisis, there is no convincing evidence to suggest that preterm or caesarean section delivery confers any distinct advantage [38–40] but delivery is commonly induced at around 37 weeks gestation to avoid late gestation fetal death. What is

Fig. 3.8 Clinical appearance of an infant with gastroschisis. There is no sac enclosing the herniated intestine which is thickened and inflamed. (Reprinted with permission from [4], Fig. 2.9)

of paramount importance is protection of the intestine and prevention of fluid loss in cases of gastroschisis from the moment of delivery. The eviscerated intestine is wrapped in clingfilm and adequate support provided to prevent fluid loss and ischemic damage to the bowel. For exomphalos vaginal delivery is possible except in cases of exomphalos major. The hernial sac in exomphalos provides protection to the underlying bowel and surgical intervention is usually not emergent. However, cases of exomphalos in which the hernial sac ruptures during delivery should subsequently be treated as for gastroschisis.

Surgical Closure

The aim of surgery in both conditions is the return of abdominal contents to the abdominal cavity and closure of the overlying skin. In some cases, this can be achieved in one surgical procedure (primary closure), but in many instances, the abdominal cavity is not of sufficient volume to accommodate the eviscerated organs. In these cases, a staged closure is performed in which a “silo” is attached under the fascia around the base of the defect and completely encloses the eviscerated abdominal contents. This gives the intestine protection from dehydration and contains the bowel within a manageable sac reducing the risk of intestinal damage. Recently some surgeons have been preferentially using a silo for all cases of gastroschisis at least in part due to the belief that a more gradual return of the bowel to the abdomen may result in favourable outcomes [41–43]. The silo is gradually reduced in size as the abdominal cavity allows and the skin closed either in a final operation or using a technique of non-operative closure. In cases of exomphalos major, some surgeons elect not to reduce the viscera to the abdominal cavity in the newborn period but to allow the sac to epithelialise and perform fascial repair during childhood. Following abdominal wall closure there is a period of intestinal dysmotility which is much more pronounced in infants with gastroschisis. During this period nutrition is maintained using parenteral nutrition. The overall prognosis for infants with both these conditions in the absence of coexisting abnormalities is good.

Introduction

Pyloric stenosis is a common pediatric surgery emergency. It involves both narrowing and lengthening of the pylorus due to hypertrophy of the pylorus muscle. As this diagnosis is most often found in the first few months of life, it is often referred to as infantile hypertrophic pyloric stenosis (IHPS).

Hirschsprung first clinically described IHPS in 1888; however, it was much earlier in 1717 that Blair actually reported findings of pyloric stenosis following an autopsy [1]. In 1912, Ramstedt incidentally developed pyloromyotomy, which has remained the standard procedure for the treatment for more than a century.

Incidence

Incidence of IHPS is approximately 4/1000 live births, with a higher prevalence amongst the Caucasian population. Males appear to be affected much more commonly than females, at a 4:1 ratio. The condition is commonly seen between 3 and 12 weeks [2] and is rarely seen in babies over 6 months of age.

Anatomy

The pylorus is a muscle, which forms an anatomical connection between the stomach and the duodenum. It consists of two parts: the pyloric antrum and the pyloric canal, which connect to the body of the stomach and the initial part of the duodenum, respectively, allowing the passage of nutrients from the stomach to the small intestine, aiding the digestive process. Before the pyloric antrum, a pre-pyloric sphincter is

positioned, which can constrict allowing the stomach to be shut as a private entity from the small intestine for brief seconds during peristaltic waves of activity. Additionally, at the end of the pyloric canal, a pyloric sphincter is located, which is fundamental to allow food to be digested from the stomach to the small intestine. The main function of the pylorus is to prevent food from re-entering the stomach once it has passed into the small intestine acting as a muscular valve.

The pyloric sphincter consists of circular smooth muscle, allowing the sphincters to contract and relax as required. As the content of the duodenum increases, this causes an increase in pressure, closing the pyloric sphincter, thus controlling the amount of food that is digested at any one time. A mucosal membrane underlines this sphincter, allowing gastric secretions to enter the pylorus further aiding digestion. As a general rule, the pylorus mainly refers to the pyloric sphincter, and therefore IHPS refers to a narrowing of the sphincter due to hypertrophy of the circular muscle. As hypertrophy occurs, this also causes the pyloric canal to lengthen and leads to a gastric outlet obstruction.

Histology

Under normal conditions, the pylorus, when viewed under a microscope, contains a number of features that allow for successful digestion. These include gastric pits and parietal cells, secreting gastric acid, as well as neuroendocrine cells to allow communication between the brain and gastrointestinal tract, enabling efficient contraction and secretion. Furthermore, Auerbach's plexus is implicated to play an important role in gut motility, by providing sympathetic and parasympathetic innervation to the muscular layers of the gut. However, during IHPS, it has been found that there is a degeneration of intramuscular ganglion cells in Auerbach's plexus, along with the accretion of lysosomes and cytoplasmic bodies in many of the axons [2]. Additionally, the ganglion cells appear reduced in number and smaller [3]. Cameron [4] has suggested that due to both the degeneration

A. P. Desai (✉) · S. Sheth
Department of Pediatric Surgery, King's College Hospital,
Denmark Hill London, SE5 9RS, UK
e-mail: ashishdesai@nhs.net

and consequent reduction in ganglia cells, Auerbach's plexus is ineffective, causing a reduction in neural activity, leading to asynchronous contraction of the pyloric muscle. As contractions are asynchronous, they increase in an attempt to produce a successful contraction, which is thought to lead to hypertrophy of the circular muscle, and hence IHPS.

Etiology and Risk Factors

Etiology-Pathogenesis of pyloric stenosis is still not clearly understood. It is thought to be multifactorial with both environmental and genetic factors contributing towards the disease manifestation.

Genetic Factors

There appears to be a familial link for pyloric stenosis, but the specific genetic factors involved have not yet been identified. In a study conducted in Denmark in 2010, 1,999,738 children were studied in their first year of life, with findings of 3362 having IHPS. From the study, it was identified that, for a singleton, the incidence rate for IHPS was 1.8/1000, compared to 3.1/1000 live births in twins. Additionally, the rate ratio was 182 for monozygotic twins, compared to only 29.4 for dizygotic twins, illustrating a strong genetic link for IHPS. Overall, a heritability of 87% for IHPS was found [5].

Nitric oxide synthase gene (NOS1) could be a susceptibility locus for IHPS [6]. As nitric oxide (NO) is involved in smooth muscle relaxation, NOS must catalyze the production of NO, to allow the pylorus muscle to relax. It is suggested that reduced levels of NOS lead to a reduction in NO and hence diminish smooth muscle relaxation. As a result, increased muscular contraction occurs, leading to hypertrophy. In further support of this theory, Huang et al. [7] generated mice lacking NOS. These mice were found to have enlarged stomachs and hypertrophy of the pyloric sphincter. These findings could have great implications for future non-surgical treatment of IHPS, as early interventions to increase NO production could lead to management, if not prevention, of the disease.

Other factors implying genetic component are male preponderance as well as four times increased risk of a child of a mother who had IHPS to be diagnosed with the condition, compared to the child of a father who had IHPS.

Environmental Factors

In addition to genetic factors, a number of environmental factors have been implicated as risk factors for IHPS. De-

spite the higher incidence in males and the familial heritability pointing to a genetic cause, the decreasing prevalence in some countries such as Denmark points to environmental factors also playing a role in the development of IHPS [4]. Maternal smoking leads to infants having an increased likelihood of developing pyloric stenosis, probably due to interference with mitochondrial oxidative phosphorylation and increase in the concentration of calcium in pylorus muscle, via an unknown mechanism, leading to increased contraction [8]. Nonetheless, more research into the causal mechanisms is still needed. Furthermore, it could be argued that the decrease in incidence of pyloric stenosis in Denmark (from 1.4/1000 to 1.1/1000 live births) may be related to a possible decrease in consumption of cigarettes in Denmark due to increased health warnings in the media.

A further environmental factor that has received plenty of research and promising results is that of feeding methods for babies. It has been implied that babies who are bottle-fed (with formula) are more likely to develop IHPS compared to those that are breast-fed.

Interestingly, Krogh et al. [9] conducted a study to compare feeding practices and identify their relationships, if any, with IHPS; 70,148 infants were involved in the study, and of that 65 had IHPS, 29 of which were bottle-fed for the first 4 months of life. When looking at the odds ratio, for those who were bottle-fed compared to breast-fed it was 4.62, indicating that babies who were bottle-fed were 4.62 times more likely to suffer from IHPS compared to those who were breast-fed. Furthermore, when comparing babies who were both breast- and bottle-fed to those who were never breast-fed, those who were never breast-fed had a higher risk of developing IHPS. Additionally, McAteer et al. [10], very recently found that, in a state in Washington, the incidence of pyloric stenosis had decreased from 14/10,000 to 9/10,000 whilst the likelihood of breast feeding had increased from 80 to 94%, therefore, supporting the findings of Krogh et al. [11]. The exact reasons for this are unknown; however, it has been argued that breast milk contains a number of peptide hormones that relax the pylorus, such as vasoactive intestinal peptide (VIP), whereas formula milk has a higher gastrin content, which is thought to be involved in promoting smooth muscle contractions and could therefore be involved in pyloric muscle hypertrophy. However, these theories are still very tentative.

Other risk factors for pyloric stenosis are the first-born children (76.3% risk if first child, 19.6% if second), older maternal age, preterm delivery and caesarean section, amongst others [11]. Interestingly, it was also found that if these risk factors were reduced, it also reduced the incidence of pyloric stenosis occurring in males and made the prevalence between males and females much more similar.

Metabolic Changes in Pyloric Stenosis

A fluid electrolyte imbalance is usually present in individuals with IHPS. Classically, child presents with hypochloremic, hyponatremic metabolic alkalosis. Hydrochloric acid is lost, resulting in metabolic alkalosis due to the loss of hydrogen and chloride ions via vomiting (chloride-responsive metabolic alkalosis). Usually, the parietal cells of the stomach secrete H^+ ions via carbonic acid, which cross the lumen membrane to enter the stomach. These are then transported to the duodenum via the spasmodic contraction of the pyloric muscle. However, in pyloric stenosis, this passage of ions from the stomach to the duodenum is not possible due to the anatomical changes, consequently preventing the duodenum from secreting pancreatic bicarbonate that is usually stimulated by the hydrogen ions. This lack of hydrogen ions further adds to the metabolic alkalosis [12]. Selective absorption of H^+ ions in the renal tubules due to metabolic alkalosis leads to loss of Na^+ & HCO_3^- further increasing hypokalemia and hyponatremia.

In children with prolonged fluid loss and vomiting due to delayed diagnosis, kidneys try to compensate for the fluid loss by reducing urine output. However, the kidneys also prevent the loss of potassium ions initially followed by that of sodium ions, at the expense of hydrogen ions, due to a cation exchange. This causes a paradoxical aciduria. Hence, paradoxical aciduria is a sign of prolonged dehydration.

Clinical Features and Differential Diagnosis

The main symptom of this condition, distinguishing it from other gastrointestinal conditions, is that of non-bilious, projectile vomiting after feeding which progressively worsens. Milk often changes from being white to becoming an off-white, pale yellow colour, as it becomes curdled due to mixing with stomach acids whilst it remains stagnant in the stomach. The vomiting causes the metabolic changes of pyloric stenosis to manifest.

Additionally, infants with pyloric stenosis report feeling very hungry immediately after vomiting. Further symptoms relating to the inefficient digestion include a change in stools, with very small, insignificant stools being produced. The reduced intake of food and nutrients inevitably leads to severe weight loss.

The longer the condition progresses, the more severe the symptoms become. If not treated in time, infant is severely dehydrated and has decreased urine output.

Differential diagnosis of pyloric stenosis should include medical conditions like gastro-oesophageal reflux, sepsis, raised intracranial pressure, gastroenteritis and other metabolic conditions. Surgical conditions mimicking symptoms

of pyloric stenosis are rare and include pyloric web and pyloric atresia.

Investigations and Diagnosis

A diagnosis of pyloric stenosis is made clinically based on the symptoms and metabolic changes at presentation. A test feed is the common term used for the process of diagnosis. This involves examination of the abdomen, whereby a small 'olive-sized' mass may be palpable in the epigastric region. This mass is the hypertrophic pylorus muscle, indicative of IHPS. Additionally, visible peristalsis in epigastrium is often present due to increased muscular contraction of the stomach and duodenum in an attempt to push food from the stomach to duodenum.

Imaging studies to confirm pyloric stenosis will most often include an ultrasound investigation to assess the level of thickening of the pylorus. On most occasions, a muscle wall thickness of more than 3 mm (usually between 3 and 8 mm) on ultrasound investigation is diagnostic of pyloric stenosis with an average of 5 mm thickness in most cases [13]. Furthermore, a pyloric canal length of more than 14 mm and pyloric diameter of more than 12 mm are set as the parameters for diagnosing IHPS [14] (Figs. 4.1 and 4.2).

However, in a recent article published in *the Permanente Journal*, it was inferred that these parameters can be misleading as both the height and weight of infants can alter the pyloric thickness, although the thickness may be less than 3 mm for an infant of lower than average weight pyloric stenosis may still be present. This study clearly illustrates the importance of taking all factors into account when making a diagnosis, rather than relying solely on imaging techniques. A positive correlation can be seen between both age and weight of the infant with thickness of pyloric muscle [15].

Occasionally, a barium swallow is done, in which a characteristic 'string sign' is found, illustrating the narrowing of the pylorus allowing very limited barium to travel from the stomach to the duodenum. Other signs present on a barium swallow include the 'shoulder sign' which occurs when the hypertrophied pyloric muscle indents into the pyloric antrum and the 'mushroom sign' in which the hypertrophied pyloric muscle indents into the initial part of the duodenum.

Treatment

Preoperative Management

On suspicion of pyloric stenosis, the child should be kept nil by mouth. A nasogastric tube should be inserted and kept on free drainage. All fluid losses should be replaced using normal saline with 10 mmol/l potassium.

Fig. 4.1 Pyloric stenosis ultrasound transverse view

Fig. 4.2 Pyloric stenosis ultrasound longitudinal view

Fluid resuscitation usually using 5% dextrose with 0.45% saline should be used. The amount should be adjusted after assessing the amount of dehydration. Once urine output is established, 20 mmol/l of potassium should be added to IV fluid.

Surgical Treatment

Once the child is fully resuscitated, pyloromyotomy is the treatment of choice.

A pyloromyotomy is a simple procedure during which the hypertrophied pyloric muscle is cut longitudinally and then separated with the pyloric spreader. This releases the tension in the thick hypertrophied muscle and consequently allows the muscle to relax, relieving the stenosed muscle. This procedure is known as the Ramstedt's pyloromyotomy, as he initiated this technique of just spreading the muscle rather than doing pyloromyotomy.

Surgical approaches could be either by right upper transverse abdominal incision or the transumbilical pyloromyotomy, which involves a supraumbilical skinfold incision. Laparoscopic approach is also increasingly utilised. A number of studies have been conducted to establish the differences, if any, between the two. Nonetheless, most studies have suggested that both are effective, with different studies giving contradicting evidence on what form of procedure is more superior. In one study, it was suggested, however, that laparoscopic surgery is slightly superior in that babies are able to have a full feed in a shorter duration of time compared to open pyloromyotomy (18.5 versus 23.9 h), as well as having a shorter duration of stay in hospital [16]. However, in a study by Lemoine et al. in 2011 [17], it has been suggested that a transumbilical pyloromyotomy is associated with increased postoperative pain compared to the laparoscopic approach.

Complications

Most common complications of surgery include inadvertent opening of the mucosa and incomplete myotomy. Other complications include wound infection and self-resolving vomiting.

Complications of surgery are minimal, and in most cases, a pyloromyotomy is said to be very effective. Hulka et al. [18] reviewed 901 pyloromyotomies to assess for both intra- and postoperative complications, with findings that only 4% of individuals had complications during surgery. The main complication was duodenal perforation. Further, 6% of individuals had postoperative complications, which most often included vomiting, resolving itself within 5 days. As with many surgeries, wound infection is a further possible complication. An incomplete pyloromyotomy can also be listed as a complication.

Outcome

The death rate for pyloromyotomy is extremely low, at only 0.1%. It usually does not have any long-term consequences.

Gastrointestinal Problems of Term Babies

Normal feeding is essential to the growth and development of newborns: They are able to eat, digest food, and absorb nutrients, with normal bowel movements after being fed. Difficulties may occur, meaning a temporary adjustment or suggesting a more serious problem. Symptoms indicating gastrointestinal (GI) problems need to be recognized.

Difficult Feeding

The clinical evaluation of a neonate with complex issues related to feeding and swallowing includes a physical examination and feeding observation. Instrumental assessments of swallowing may be needed when concerns are noted regarding pharyngeal phase physiology and risks for aspiration with oral feeding. An interdisciplinary approach is often needed. Feeding difficulties may herald more severe and general disorders, listed in Table 5.1 [1]. Some diseases need urgent treatment. Hypothyroidism is diagnosed through a blood sample (low T3 and T4 and high TSH). Prader–Willi syndrome is characterized by hypotonia in an otherwise normal child and may require tube feeding at the beginning. Among a variety of craniofacial syndromes, Pierre Robin syndrome is characterized by retrognathism, glossoptosis, and sometimes cleft palate, with difficulties in breathing and swallowing which need immediate prevention measures such as lying in prone position and tube feeding [1].

Gastroesophageal Reflux

Gastroesophageal reflux (GER) occurs when stomach contents backs up into the esophagus.

GER is most of the time benign, due to high volume inside the stomach and/or temporary cardiac insufficiency, and manifested only by regurgitations, spitting up, and dribbling milk with burps or after feedings, without any other symptoms, especially pain. This situation characterizes the “happy spitters.” These babies may be helped with feeding of smaller amounts and more frequent, burping the baby often during the feedings, holding the baby in an upright position for about 30 min after feeding, and making sure that the baby’s diaper is not too tight. When the child is not breast-fed, using an infant formula enriched with food thickeners may also help [2].

GER may also be more severe. Several symptoms can be related to neonatal gastroesophageal reflux disease (GERD), Table 5.2. After feeding, there may be forceful or projectile

Table 5.1 Disorders that affect hunger/appetite, food-seeking behavior, and ingestion in newborn infants

Anatomic abnormalities of the oropharynx
Anatomic/congenital abnormalities of the larynx and trachea
Anatomic abnormalities of the esophagus
Disorders affecting suck–swallow–breathing coordination
Disorders affecting neuromuscular coordination of swallowing
Disorders affecting esophageal peristalsis
Mucosal infections and inflammatory disorders causing dysphagia
Other miscellaneous disorders associated with feeding and swallowing difficulties, for example, xerostomia, hypothyroidism, trisomy 18 and 21, Prader–Willi syndrome, allergies, lipid and lipoprotein metabolism disorders, and a variety of craniofacial syndromes

Table 5.2 Symptoms of neonatal gastroesophageal reflux disease (GERD)

Typical or atypical crying and/or irritability
Sleep disturbances
Apnea and/or bradycardia
Poor appetite; weight loss or poor growth (failure to thrive)
Apparent life-threatening event
Vomiting
Hematemesis and/or melena
Recurrent pneumonitis and/or pulmonary atelectasis
Severe laryngomalacia

vomiting or spitting up of large amounts of milk. Reflux may also lead to esophageal irritation by the stomach contents, that is, esophagitis. When the stomach content reaches the pharyngeal regions, it can be aspirated into the lungs, a phenomenon recognized by “rattling,” heard and felt in the baby’s chest and back. Babies may also gag and choke during feedings.

GERD may be primary, related to several mechanisms mainly of motor origin [2]. Variations during sleep and wakefulness suggest the involvement of autonomic nervous activity changes [3]. Signs and symptoms of GERD traditionally attributed to acidic reflux in neonates do not seem to be significantly altered by proton pump inhibitors (PPI) treatment. In a study, esomeprazole was well tolerated and reduced esophageal acid exposure and the number of acidic reflux events in neonates [4].

GERD may also be secondary, related to either medical or surgical disorders, Table 5.3. Food allergy dominates, especially for milk, to which the child may react either in infant formulas or in breast milk [5, 6]. Diagnosis is based on elimination diets using milk-free infant formulas or cow’s milk elimination in mother’s diet, since allergy testing is rarely positive at this age [5, 6]. The neonatal period remains a critical period for diagnosing conditions leading to vomiting, such as neonatal medical or surgical conditions. The latter must be kept in mind despite the wide use of prenatal diagnosis.

Table 5.3 Secondary neonatal gastroesophageal reflux disease (GERD)

<i>Medical disorder:</i>
Milk allergy, in formula-fed infants or to milk ingested by mothers in breast-fed children
Other food allergy
<i>Surgical conditions:</i>
Esophageal atresia
Hiatal hernia
Diaphragmatic hernia
Omphalocele
Gastroschisis
Other rare causes of neonatal intestinal obstructions

Diarrhea

In a newborn, the first bowel movements expel meconium, a sticky, greenish-black substance that forms in the intestines during fetal life. Yellow stools appear after the first few days. In breast-fed babies, stools tend to be soft, seedy, yellow-green, often as every few hours with feedings and at least several times a day. In formula-fed babies, stools are yellow and formed and occur once or twice a day.

In a baby with diarrhea, stools are watery, very loose, and occur very frequently. Signs of cramping are absent or difficult to perceive. Different causes may be considered, as indicated in Table 5.4 [7]. Diarrhea may reveal neonatal-onset Crohn’s disease and intractable ulcerating enterocolitis [8] or neonatal enteropathies [9]. Several viral infections may be responsible, such as cytomegalovirus even in immunocompetent babies [10]. Other viruses may be involved [11], such as adenoviruses [12], parechoviruses [13], rotavirus, norovirus, astrovirus, and some infections being potentially associated with necrotizing enterocolitis (NEC) [11].

Diarrhea in a newborn can quickly lead to severe dehydration and thus needs immediate oral rehydration. The European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) solution contains 60 mOsm/L of Na and is recommended for children of Europe, but it seems to be effective in children living in developing countries

Table 5.4 Frequency, etiology, and current management strategies for diarrhea in newborn infants [7]

Food allergy (20.5%)
Gastrointestinal infections (17.9%)
Antibiotic-associated diarrhea (12.8%)
Congenital defects of ion transport (5.1%)
Withdrawal syndrome (5.1%)
Hirschsprung’s disease (2.5%) and parenteral diarrhea (2.5%)
Cystic fibrosis (2.5%)
Metabolic disorders (2.5%)
Incidence 6.72 per 1000 hospitalized child, 39 cases of diarrhea (36 acute, 3 chronic); 3 patients died

[14]. Maintenance of breast feeding in breast-fed infants is always recommended.

Constipation

Constipation is characterized by rare bowel movements, less than once a day, sometimes less than once every 3 or more days. Generally, stools are very compact and free from moisture, appearing as hard balls or pebbles. Signs of discomfort or pain are frequent, quick drawing up of the legs, accompanied by a red-faced grunting as baby attempts to have a bowel movement. Examination of a constipated newborn needs checking the quality of feeding, the presence of abdominal distension, and gently analyzing the anal region.

Delay in passing meconium, abdominal distension, and low weight gain suggest or are associated with organic disturbances, such as Hirschsprung's disease, often requiring a specific surgical procedure. Other severe presentations may need medical treatment such as meconium ileus (MI) (see below) [15].

Functional constipation is the more likely. Breast-feeding newborn babies may pass 3–4 bowel movements per day within the first 2 weeks. The bowel movements of bottle-fed babies may be a bit less frequent. Apply a small dab of lubricating gel on baby's anus to protect the sensitive area and allow stool to pass a bit easier. Avoid using mineral oil as a lubricant.

Anal fissures are possible even in neonates, in the form a small tear in the anus. When limited, anal fissures may occur from baby forcing the passage of hard stool, usually with recurrent straining. Anal fissures may be associated with milk allergy [16]. What appears as a larger anal fissure may be an anomaly of the anal regions participating in the process of anorectal malformations and requiring a surgical procedure.

Colic

Colic is a problem that affects many babies during the first 3–4 months of life, starting typically by 3 weeks of age but sometimes much earlier. It is defined as prolonged or excessive crying in an infant whose examination is normal, often associated with gas, irritability, and sleeping disorders. The crying can be very loud, can last for several hours a day, and predisposes to the shaken baby syndrome [17], hence the necessity for appropriate handling. What causes colic is still unclear. Studies show an increased fecal content of calprotectin [18] a marker of an intestinal inflammation, thereby suggesting a physiological inflammation during the first months of life. Another possible reason for excessive crying in babies might be that they are oversensitive to gas in the intestine, similarly to what is observed in older children

during irritable bowel syndrome, although this disorder is lacking evidence-based approaches [19]. Milk allergy is also possible, thus leading to a trial elimination diet using cow's milk protein hydrolysates [6].

GI Problems of Preterm Infants

Feeding Difficulties

Digestive tolerance of preterm infants is one of the major problems of neonatal wards. Preterm infants have the paradoxical situation of a considerable demand in nutrients contrasting with a low digestive tolerance, owing to immaturity of the digestive tract, low oral sucking, and swallowing maturity, and with the need to interrupt as soon as possible parenteral feeding to reduce the infectious and metabolic risks and to introduce progressively enteral feeding to enhance the digestive tube maturity [20]. Although incompletely understood, difficulties that preterm infants face in the neonatal intensive care unit (NICU) may be related to the potential consequences of an immature intestinal barrier defense and bacterial colonization disturbances [21]. What is at stake in this age range is the need to increase as far and as rapidly as possible the rate of enteral feeding with the constant need to avoid GI signs of bad tolerance, especially trying to avoid NEC.

Progressive Increment of Oral Feeding in Premature Infants

Premature infants of gestational age (GA) >34 weeks are usually able to coordinate sucking, swallowing, and breathing, and so establish breast or bottle feeding. In less mature infants, oral feeding may not be safe or possible because of neurological immaturity or respiratory compromise [20]. In these infants, milk can be given as a continuous infusion or as an intermittent bolus through a fine feeding catheter passed via the nose or the mouth to the stomach [22]. In older babies, around 34 weeks of GA, the infant begins to suckle, and the bottle progressively replaces the tube feeding.

Several Cochrane reviews [23–26] confirm that the introduction of enteral feeding for very preterm infants, that is, less than 32 weeks of GA or very low birth weight (VLBW) <1500 g infants, is often delayed due to the bad clinical tolerance of early enteral introduction and may increase the risk of developing NEC. However, the available trial data suggest that introducing progressive enteral feeding before 4 days after birth and advancing the rate of feed quantities at more than 24 ml/kg/day do not increase the risk of NEC in very preterm infants and VLBW infants [23–26]. In contrast, prolonged enteral fasting may diminish the functional adaptation of the immature GI tract and extend the need for parenteral nutrition with its attendant infectious and metabolic risks [26]. Also, delayed introduction or slow advancement

of enteral feeding results in several days of delay in the time taken to regain birth weight and establish full enteral feeds [26]. Trophic feeding, giving preterm infants very small quantities of adapted preterm milk formulas to promote intestinal maturation, may enhance feeding tolerance and decrease the time taken to reach full enteral feeding independently of parenteral nutrition [23–26]. Although it is well agreed that oral feeding should be initiated slowly first by the help of nasogastric tube and then progressively followed by oral feeding, the way in which the preterm infants are introduced and advanced varies widely. The use of dilute formula in preterm or VLBW infants might lead to an important reduction in the time taken for those infants to achieve an adequate daily energy intake [27]. Uncertainty also exists about the risk–benefit balance of different enteral feeding strategies in human milk-fed versus formula-fed very preterm or VLBW infants as the trials and reviews did not contain sufficient data for subgroup analyses [26].

Gastroesophageal Reflux

GER is very common among preterm infants, due to several physiological mechanisms. Its real frequency in preterm and VLBW infants is not well established. The responsibility of GER is suspected in the occurrence of apnea, bradycardia, pallor, cyanosis with or without oxygen desaturation, severe malaise, feeding difficulties with weight loss or poor growth (failure to thrive), crying, hematemesis, melena, and finally sudden infant deaths (SIDs) [2], although GER could be diagnosed for extra-digestive manifestations by 24-h pH-metry monitoring and for digestive manifestations by upper GI endoscopy with specific neonatal endoscopes [28].

The therapeutic management of GER still represents a controversial issue among neonatologists. Overtreatment, often unuseful and potentially harmful, is increasingly widespread. Hence, a stepwise approach, firstly promoting conservative strategies such as body positioning (the best position is the ventral decubitus associated with a 30° of orthostatism position under continuous monitoring in the NICU) or changes of feeding modalities, should be considered the most advisable choice in preterm infants with GER [2]. Non-pharmacological management of GER might represent a useful tool for neonatologists to reduce the use of anti-reflux medications, that is, prokinetics and anti-H₂ blockers or PPI, which should be limited, due to their side effects, to selected cases of severe symptomatic infants [29].

Enteropathy

In neonatal units, there is a tendency to assume that any acutely sick infant with gastrointestinal symptoms has

NEC. All digestive issues however are not related to as a matter of fact; a better definition of enteropathy in preterm neonates and their risk factors need to be done. Neonatal enteropathy is considered in the presence of feeding difficulties, increased gastric residual, abdominal distension associated with sensitive and/or surgical abdominal examination, and rectal bleeding with bloody stool (hemorrhagic recto-colitis). Sometimes, preterm infants present with sub-occlusion (transient) or complete permanent occlusion syndrome.

In a prospective study by Suc et al. [30], 351 preterm infants admitted to a neonatal ward were fed similarly, depending on their maturation, GA, and GI status; 53 developed GI symptoms: 23 transient obstructions, 6 NEC, and 24 hemorrhagic colitis. Ten risk factors were found to be significantly correlated with GI disturbances: umbilical venous catheter, benzodiazepines, birth weight <1.500 g, patent ductus arteriosus, ventilatory assistance, abnormal amniotic fluid, GA <32 weeks, early antibiotic treatment, passage of meconium >48 h, and episodes of apnea and/or bradycardia. GI problems might thus be separated into three groups: (1) isolated intestinal obstruction, seen in the most immature babies during the first week of life with the risk of developing NEC; (2) frank blood in the stool, indicating colitis and possibly minor forms of NEC; (3) combined obstructive and hemorrhagic symptoms, typical of NEC.

The diagnosis of enteropathy relies on clinical examination associated with biological parameters (complete blood count, C-reactive protein, and bacteriological cultures) and radiological exploration (abdominal X-ray and/or ultrasonography).

Specific treatment is offered according to diagnostic work-up analysis, that is, enteral and/or parenteral nutritional assistance as well as antibiotics treatment and sometimes acute life-threatening events supports.

Necrotizing Enterocolitis

Background of Prematurity and NEC

NEC is a devastating GI disease dominating in preterm infants. The pathogenesis, likely multifactorial, is incompletely understood. At this age, infants experience multiple perturbations to normal postnatal intestinal and immune development, all of which increase their vulnerability to NEC. The prevalence is increased in formula-fed infants, suggesting protection by the bioactive compounds of breast milk. The intestinal microbiota profiles observed during NEC as compared to control infants, suggests a lack of benefits from commensal bacteria and an increased risk of intestinal inflammation and bacterial translocation by pathogenic bacteria [31]. NEC incidence also seems reduced by prebiotics and probiotics and increased after prolonged antibiotics

exposure use leading to delayed bacterial colonization, with preference for pathogenic microorganisms. H2-blocker or PPI, decreasing gastric acidity, might dampen one component of the first-line defense against pathogenic antigens provided by intestinal tract [32].

The role of Toll-like receptor-4 (TLR4) is likely to be critical in the postnatal susceptibility to NEC of preterm infants [33]. In animal models, the absence of TLR4, such as in TLR4 knockout mouse, prevented the development of NEC [34]. Downregulation of TLR4 suppresses downstream pro-inflammatory signaling, such as observed with postnatal intestinal bacterial colonization by commensal organisms, whereas TLR4 activation increases pro-inflammatory signaling. TLR4 activation might also mediate other downstream pathways and reduce the epithelial cells capacity for regeneration and proliferation [35].

Signs and Symptoms

NEC affects typically premature infants, with a timing of onset generally inversely proportional to the GA of the child. Initial symptoms include feeding intolerance, increased gastric residuals, abdominal distension, and bloody stools. Symptoms may progress rapidly to abdominal discoloration with intestinal perforation and peritonitis and systemic hypotension requiring intensive medical support [36].

Diagnosis

The diagnosis is usually suspected clinically but often requires the aid of diagnostic imaging modalities. Radiographic signs of NEC include dilated bowel loops, paucity of gas, a “fixed loop” (unaltered gas-filled loop of bowel), pneumatosis intestinalis, portal venous gas, and pneumoperitoneum (extra-luminal or “free air” outside the bowel within the abdomen). More recently, ultrasonography has proven to be useful as it may detect signs and complications of NEC before they are evident on radiographs [37]. Recently, fecal biomarkers, such as fecal calprotectin, have been tested as noninvasive markers for diagnosis and follow-up [38, 39].

Three stages exist:

Stage 1: Apnea, bradycardia, lethargy, abdominal distension, and vomiting

Stage 2: Pneumatosis intestinalis and the above features

Stage 3: Low blood pressure, bradycardia, acidosis, disseminated intravascular coagulation (DIC), and anuria

Treatment

Primary treatment consists of supportive care. Bowel rest is obtained by stopping enteral feeds, intermittent suction to obtain gastric decompression, fluid repletion to correct electrolyte abnormalities and third space losses, adapted support for blood pressure, parenteral nutrition, and prompt antibiotic therapy. Monitoring is clinical, although serial supine and left lateral decubitus abdominal roentgenograms should be

performed every 6 h. Where the disease is not halted through medical treatment alone, or when the bowel perforates, immediate emergency surgery to remove the dead bowel is generally required. Surgery may require a colostomy, which may be able to be reversed at a later time. Some children may suffer later as a result of short bowel syndrome (SBS) if extensive portions of the bowel had to be removed.

Prevention

The American Academy of Pediatrics, in a 2012 policy statement, recommended feeding preterm infants human milk, finding “significant short- and long-term beneficial effects,” including lower rates of NEC. Meta-analyses of four randomized clinical trials performed over the period 1983–2005 support the conclusion that feeding preterm infants human milk is associated with a significant reduction (58%) in the incidence of NEC. A more recent study of preterm infants fed an exclusive human milk diet compared with those fed human milk supplemented with cow-milk-based infant formula products noted a 77% reduction in NEC [40].

A study demonstrated that using a higher rate of lipid (fats and/or oils), infusion for preterm or VLBW infants in the first week of life resulted in zero infants developing NEC in the experimental group, compared with 14% with NEC in the control group [41].

Neonatologists from NICU reported on the importance of providing small amounts of trophic oral feeds of human milk starting, while the infant is being primarily fed intravenously, to prime the immature gut to mature and become ready to receive greater oral intake [40]. Human milk from a milk bank or donor can be used if mother’s milk is unavailable [40]. Finally, probiotic and prebiotic supplementation is a promising approach for the prevention of NEC in preterm and VLBW infants [42].

Typical recovery from NEC if medical, nonsurgical treatment succeeds includes 10–14 days or more without oral intake and then demonstrated ability to resume feedings and gain weight. Recovery from NEC alone may be compromised by comorbid conditions that frequently accompany prematurity. Long-term complications of medical NEC include bowel obstruction, anemia, and SBS.

Meconium Ileus

Definition and Etiology

MI results from an intra-luminal intestinal obstruction produced by thick inspissated meconium. Most patients have cystic fibrosis (CF) disease (90% of cases), others having a history of isolated simple MI. The abnormal meconium is very dry, contains higher-than-usual concentrations of protein, and adheres firmly to the mucosal surface

of the distal small bowel, creating an intra-luminal obstruction [43]. This leads to poor intestinal motility, low-grade obstruction, distended loops without air fluid levels. Associated risk factors are severe prematurity and low birth weight, caesarean delivery, maternal MgSO₄ therapy, and maternal diabetes. The incidence of MI has shown to increase while its management continues to be challenging and controversial for the risk of complicated obstruction and perforation [44].

Diagnosis

MI is usually manifested by intestinal obstruction. This situation is more common in the very preterm and VLBW infants than preterm infants more than 32-week GA. Clinically, in an otherwise healthy-appearing infant, abdominal distension is visible in the first 12–24 h of life, without meconium elimination in the first 48 h. Physical examination reveals firm palpable masses throughout the abdomen without real surgical signs. There may be feeding difficulties with increased gastric residuals but without vomiting.

MI may be complicated in utero by volvulus, atresia, perforation, and meconium peritonitis, in 30–50% of the cases. When infants born with those complications, infants appear sicker, with often vomiting and signs of neonatal sepsis and more marked abdominal distension causing respiratory distress.

Radiological examination shows dilated bowel loops, and the viscous nature of meconium produces a “ground-glass” appearance. Perforation after birth results in free intraperitoneal air. Newborns suspected of MI or any other distal bowel obstruction are diagnosed with a contrast enema study.

All newborns with MI need to be assessed for CF with the sweat chloride test and the genetic assessment of the several mutations of Cystic fibrosis transmembrane conductance regulator gene (CFTR gene) [43].

Treatment

In case of simple MI, approximately 60% of infants have their obstruction successfully relieved by diagnostic contrast enema, ideally using a water-soluble contrast agent [43]. Failure of the contrast to dislodge the inspissated meconium after two attempts is an indication for surgical intervention and for enterotomy with acetylcysteine irrigation and immediate closure. When the enema fails, acetylcysteine, 5 ml every 6 h, may be given via a nasogastric tube to help complete the clean-out. Complicated MI always requires surgical interventions, and the choice of operations depends on the pathologic findings [43].

Congenital Anomalies

Esophageal Atresia

Definition

Esophageal atresia (EA) is a congenital anomaly of the tracheoesophageal separation where the development of the mid-esophagus is lacking and that occurs either rarely isolated or frequently associated with tracheoesophageal fistula (TEF). In the most frequent case (85%), the TEF is located in the distal esophagus (see Table 5.5).

Table 5.5 Classification of esophageal atresia (EA) [45–47]

Gross et al. [45]	Vogt et al. [46]	Ladd et al. [47]	Names	Description	Frequency
	Type 1		Esophageal agenesis	Very rare complete absence of the esophagus, not included in classification by Gross or Ladd	N/A
Type A	Type 2	I	“Long gap,” “pure,” or “isolated” esophageal atresia	Characterized by the presence of a “gap” between the two esophageal blind pouches with no fistula present	7%
Type B	Type 3A	II	Esophageal atresia with proximal tracheoesophageal fistula (TEF)	The upper esophageal pouch connects abnormally to the trachea. The lower esophageal pouch ends blindly	1%
Type C	Type 3B	III, IV	Esophageal atresia with distal TEF	The lower esophageal pouch connects abnormally to the trachea. The upper esophageal pouch ends blindly	86%
Type D	Type 3C	V	Esophageal atresia with both proximal and distal TEFs	The upper and lower esophageal pouches make an abnormal connection with the trachea in two separate, isolated places	2%
Type E	Type 4		TEF only with no esophageal atresia, H-type	Esophagus fully intact and capable of its normal functions, however	4%
Type F			Congenital esophageal stenosis	A congenital form of esophageal stricture. Esophagus is fully intact and connected to the stomach, however, the esophagus gradually narrows, causing food and saliva to become “caught” in the esophagus. On occasion, this type can go undiagnosed until adulthood. Not included in classification by Vogt or Ladd	N/A

N/A not known

The incidence of EA varies from 1 in 3000 to 1 in 4000 live births, with a slight predominance in male and in pre-term infants. The role of genetic remains unclear.

Diagnosis

In approximately one third of pregnancies with EA, the presence of polyhydramnios, due to the inability of the fetus to swallow amniotic fluids, may suggest the disease. Antenatal ultrasound then may show, after about 26 weeks of gestation, an absent or small stomach, which, in the setting of polyhydramnios, strongly suggests EA. The upper neck pouch sign is another sign that may help antenatal diagnosis.

In almost all types of EA, a feeding tube will not pass through the esophagus at the first neonatal examination in the delivery room. Within first hours, the newborn will present oral secretion followed by severe cough and choking episodes. The infant may become cyanotic and may even stop breathing as the overflow of fluid from the blind pouch is aspirated the trachea. If cyanosis results in laryngospasm (basically a protective mechanism to prevent aspiration into the trachea), a severe respiratory distress will rapidly develop.

Digestive symptoms occur immediately. Infants vomit when they are fed, and owing to the passage of air through the distal TEF, abdominal distension develops. A flat or a gasless abdomen suggests an EA without fistula. The most dramatic presentation of the TEF occurs with a proximal fistula. Affected infants develop life-threatening respiratory failure from aspiration almost immediately after birth. In contrast, with the so-called H-type, infants usually do not develop any symptom in the neonatal period, but present later on with a history of recurrent mild respiratory distress related to feeding or pneumonia.

Other birth defects may coexist in other organs, such as in the VACTERL (Vertebral column, Anorectal, Cardiac, Tracheal, Esophageal, Renal, and Limbs) association involving other organs.

If any of the above signs/symptoms or malformation is noticed, it is mandatory to pass a catheter into the esophagus to check, prompting other tests to confirm the diagnosis if a resistance is noted. This can be done with a catheter visible on a regular X-ray film, demonstrating the blind pouch ending. A small amount of barium placed through the mouth may help.

Treatment

If EA or TEF is suspected, all oral feedings are stopped and replaced by intravenous fluids. Appropriate positioning will help the infant draining the secretions and decrease the risk of aspiration. A tube with a continuous aspiration placed into the proximal esophagus pouch can minimize the aspiration of saliva. Also, minimizing positive pressure ventilation approximately minimizes gastric distension and reflux. The use of systemic anti-H₂ or PPI can reduce the toxicity of acid

secretion on the lung and the distal esophagus pouch, but reflux in itself might help the development of the lower pouch. If gastric distension occurs progressively, surgery becomes an emergency.

Surgery to fix EA is a semi-emergency. Once the baby is in condition, surgery is made by thoracotomy, thoracoscopy, and robot surgery. The esophagus can usually be sewn together. Following surgery, the baby may be hospitalized for a variable length of time depending mainly on associated malformations. Care for each infant is individualized [47]. Long-term follow-up is mandatory, owing to the risk of chronic reflux (see Table 5.3).

Imperforate Anus

Definition

Anorectal anomalies occur in 1 out of 2500–5000 births, slightly more commonly in males and with associated anomalies in more than half of affected infants. These are vertebral, genitourinary tract, and GI malformations. Imperforate anus may actually occur in the setting of the VACTERL association. The anatomical variability of these anomalies renders genetic analysis complex, so that genetic factors are clearly associated with anorectal anomalies in only 8% of patients. In infants with trisomy 21 and 18, 95% of those with anorectal malformations have imperforate anus without fistula, as opposed to only 5% of all patients with anorectal anomalies.

Imperforate anus is the most common anomaly, but other forms of anorectal malformations may occur, such as anterior ectopic anus [48]. This form is more commonly seen in females and presents with constipation [49].

Diagnosis

Anorectal malformations have been classified according to the level of the rectal pouch, that is, “high,” above the elevator sling; “low,” below the elevator sling; or “intermediate” and to the presence or the absence of an associated fistula. The latter is present in 95% of cases, either externally as an ano-cutaneous fistula or internally as a recto-urinary tract fistula [50].

Diagnosis relies on clinical examination of the perineal region at birth, completed with X-ray studies in cases of diagnostic uncertainty and for the assessment of the associated malformations.

Females may pass meconium through a perineal, vestibular, or vaginal fistula. Infants with a “low” defect may have cutaneous fistulas, meconium present at the perineum, a bulging anal membrane, and well-formed buttocks. Males with a “low” defect may have a bucket-handle malformation or cutaneous fistulas along the midline raphe toward the penis, discharging meconium drops. Finding meconium in

the urine or air in the bladder may identify the presence of an internal fistula [50].

Plain abdominal X-ray may show progressive distal bowel obstruction. To identify the distance between the rectal pouch and the skin, a cross-table prone film is obtained with the pelvis elevated, after the first 24 h of life, during which the gap may appear falsely increased. Perineal ultrasound examination may prove to be more accurate than plain films. Abdominal ultrasound, cardiac echography, and skeletal films may be required to rule out other associated anomalies.

Treatment

Several procedures aim at restoring the anorectal canal in “low” defects, by cut-back of a cutaneous fistula, anal transposition, or limited posterior sagittal ano-rectoplasty.

“High” and so-called intermediate defects require an immediate colostomy, followed by elective repair of the localized fistula. Several approaches to the definitive correction of the anorectal anomalies have been described; the aim is always to close all fistulas and then tunnel the rectal pouch through the anatomic sphincter muscle to the anoderm. Actually, a posterior sagittal ano-rectoplasty is often the choice.

Children born with “low” defects often will be constipated, whereas incontinence may occur in one third of patients with “high” defects. Quality of life correlates closely with whether continence can be established. Nevertheless, a majority of those infants can be rendered functionally continent through a bowel management program with medical laxative treatment, anal enema, and anorectal biofeedback rehabilitation program.

Abdominal Wall Problems

Umbilical Hernia

Umbilical hernia is in infants and is manifested by the intestine protruding through an opening in the abdominal muscles in the navel region. In an infant, it may be hernia may be especially evident when the infant cries, causing the baby’s bellybutton to protrude. Many umbilical hernias close on their own by age 1, though some take longer to heal. Surgical repair to prevent complications is needed only when umbilical hernias do not disappear by age 3.

Omphalocele

An omphalocele is an abdominal wall defect where the intestines, liver, and also other organs remain in a sac outside of the abdomen because of a defect in the development of the muscles of the abdominal wall. Omphalocele occurs in 2.5/10,000 births and has a high rate of mortality (25%)

and of association with other severe malformations, cardiac anomalies (50%), and neural tube defect (40%) and may be associated with pulmonary hypoplasia. The digestive omphalocele can be associated with Beckwith–Wiedemann syndrome. Chromosomal abnormalities are seen in approximately 15% of live-born-affected infants, such as trisomy 13 or 18. Long-term complications include parenteral nutrition dependence, GER, parenteral-nutrition-related liver disease, feeding intolerance, and neurodevelopmental delay, owing to the difficulties encountered during intensive care and long-lasting stay in the hospital [51]. Omphalocele is usually detected during routine ultrasonographic surveillance, during an investigation of a disparity of uterine size with time from conception or during an evaluation of an increased maternal serum alpha-fetoprotein level. Death rate amounts to 15% of cases and in giant malformations including liver.

Gastroschisis

Gastroschisis is a congenital defect of the anterior abdominal wall, usually less than 4 cm, almost always to the right of the umbilicus, through which the abdominal contents freely protrude. There is no overlying sac as opposed to omphalocele (which involves the umbilical cord itself and where the organs remain enclosed in visceral peritoneum). The defect may be due to a disruption of the blood supply of the abdominal wall in the first weeks after conception. Antenatal ultrasound examination has made the detection of gastroschisis possible in the first trimester of pregnancy. Surgical management at the birth is an emergency and depends on the presence of perivisceritis. It may require numerous surgical procedures. The neonatal management needs to be careful and done by trained specialists early minimal enteral feeding and gradual enteral nutrition increment and progressive refeeding considerably improve the prognosis [52].

Prune Belly Syndrome

Prune belly syndrome is a group of birth defects that involve three main problems, a poor development of the abdominal muscles, causing the skin of the belly area to wrinkle like a prune, cryptorchidism, and urinary tract problems. The latter are the most common issue in the long-term outcome of affected patients.

Inguinal Hernia

Inguinal hernia occurs when the contents of abdominal cavity protrude through the inguinal canal. Inguinal hernia is very frequent, affecting predominantly male infants, especially premature infants. Inguinal hernia repair in infants is a routine surgical procedure. However, numerous issues, including timing of the repair, the need to explore the contralateral groin, use of laparoscopy, and anesthetic approach, remain unsettled [53].

Omphalomesentéric Band

The omphalomesenteric cord (band) represents the distal residual of the omphalomesenteric duct and may be an origin of obstruction in early infancy with various radiographic presentations, including intermittent obstruction [54]. The treatment requires surgery.

Upper and Lower Endoscopy

Upper Digestive Neonatal Endoscopy

Endoscopy is usually performed at the practitioner's request, upon clinical symptoms that may be considered symptomatic of endoscopic lesions, affecting the sole esophagus or also the stomach, Fig. 5.1. These are mainly hematemesis, of course, but also retching, regurgitation, increased crying, anorexia, difficult feeding and/or failure to thrive, and malaise. In a multicentric study [55], a large range of symptoms led to endoscopy, hematemesis (55.5%), malaise-like sudden pallor, bradycardia or cyanosis with or without hypotonia (39.4%), feeding problems, and vomiting (53.3%).

Upper bleeding is considered to usually affect sick premature infants and to be unusual in term healthy newborns. In 100 infants treated in a NICU [56], 20% showed GI bleeding and mechanical ventilation was the only risk factor. Several studies described healthy full-term neonates who, after an uneventful delivery, had with more or less profuse bleeding in the first 48 h of life. In a case–control study comprising 5180 newborn babies, 64 (1.23%) suffered from upper GI bleeding [57]. In the case–control study recently published in neonates with upper gastrointestinal bleeding [57], esophageal damage

was observed in 24/53 patients. Esophageal lesions were isolated in nine cases and occurred jointly with gastric or duodenal damage, respectively, in 14 and 1 cases. Gastric lesions were seen in 43/52 patients, and duodenal ones in 1/52. There were 17 gastric ulcers and 1 duodenal ulcer [57]. Massive bleeding with life-threatening proportions in the first 24 h of life may allow discovering hemorrhagic gastritis, profuse upper GI bleeding, and duodenal ulcers. Antenatal bleeding seems also possible, with esophagitis and gastritis revealed by a bloody amniotic fluid [58]. Fatalities during the first day of life resulting from bleeding due to gastric ulceration have also been described [59]. However, the exact incidence of endoscopic lesions in newborns still remains debatable. Endoscopic examination of newborns is rarely readily available, and even severe lesions in the upper GI tract probably often remain undiagnosed or are not detected until the condition of the patient deteriorates because of perforation or hemodynamically significant bleeding. Also, owing to the abovementioned lesions, already well known by neonatologist, the use of PPI or anti-H₂ drugs in neonates at risk may have considerably reduced the actual occurrence of these lesions.

Endoscopy may also be prompted by severe general symptoms, in the form of apparent life-threatening events (ALTEs) led to discovery of severe lesions of esophagus and stomach in two different neonatal cases [60, 61]. If severe esophagogastritis lesions are shown, an antacid treatment is able to control the symptoms and be perhaps lifesaving. In addition, the disease has a spontaneously favorable outcome ruling out the need for home monitoring and alleviating considerably the strain on the family. In the presence of neonatal ALTEs, upper digestive endoscopy might be proposed as part of the initial work-up, along with other mandatory investigations, such as diagnosis of the cardiac rhythm anomaly long QT syndrome, detected by electrocardiogram (ECG). This does not preclude the use of other means of investigation of GER, such as pH-metric esophageal recording.

Mucosal lesions seen at endoscopy may affect the esophagus, in the form of severe esophagitis appearing as ulcers covered with fibrinous material, occupying the whole perimeter of the esophagus and up to 1/3 or 2/3 of its distal part. The cardiac orifice is usually constantly open with a frequent local inflammation. Gastric lesions usually appear in the form of petechiae or aphthous ulcers, associated or not to blood in the lumen. Duodenal lesions are limited to erythema and mucosal ulcers being rare. In the group with esophagitis and gastritis, severe mucosal lesions could be found following minor symptoms.

Lower Digestive Neonatal Endoscopy Findings (Colonoscopy)

In infants, rectal bleeding may be confusing when it is due to swallowed maternal blood during delivery or during

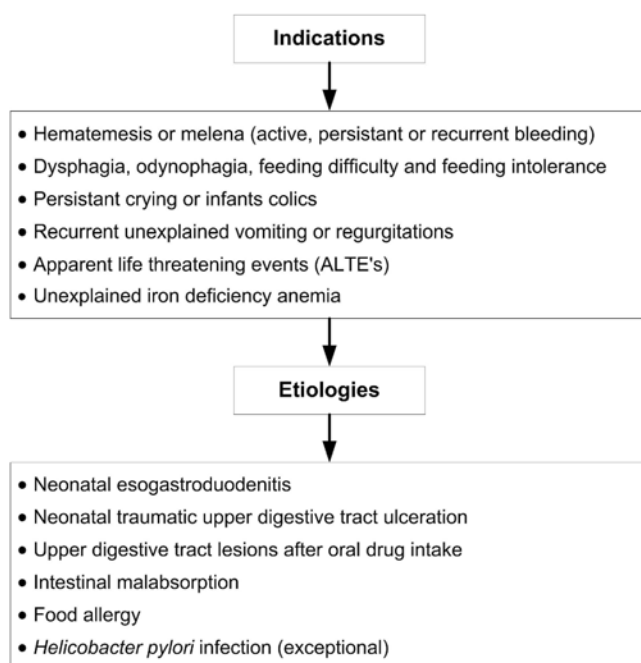

Fig. 5.1 Indications and etiologies of upper digestive endoscopy in the neonate

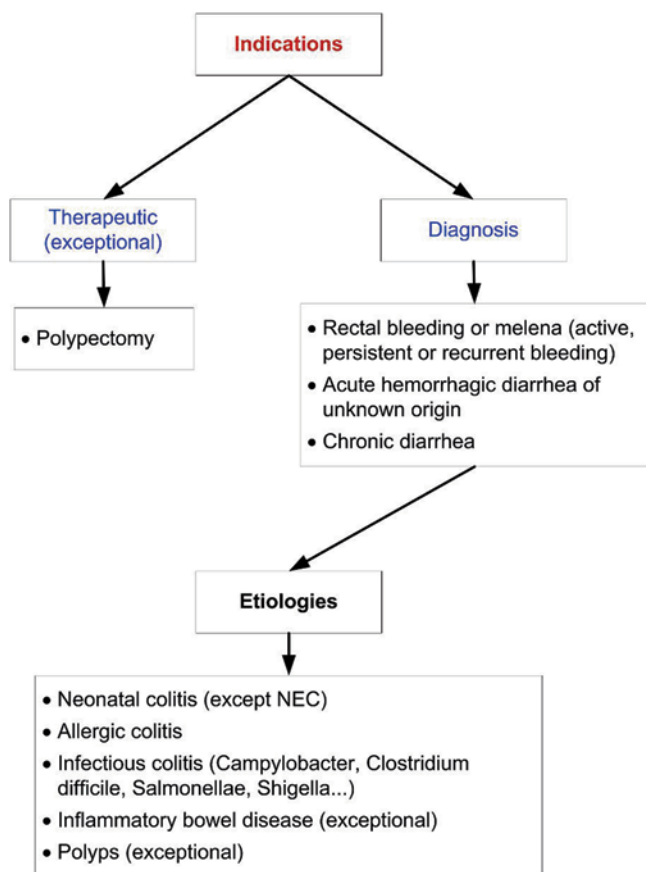

Fig. 5.2 Indications and etiologies of lower digestive endoscopy in the neonate. *NEC* necrotizing enterocolitis

breast-feeding (Fig. 5.2). The stool may be black or bright red, and the infant may be without symptoms. The Apt–Downey test distinguishes fetal from maternal hemoglobin and helps distinguishing the source of bleeding. Hemorrhagic disease of the neonate is now uncommon after prophylactic administration of vitamin K at delivery. Finally, maternal drug such aspirin, phenytoin, cephalothin, and phenobarbital may interfere with clotting function and cause hemorrhage [62]. Anal fissures are regarded as the most common cause. Giacoia and Williams [63] report two cases in which the presence of an anal fissure delayed the diagnosis of nonspecific colitis in premature infants. It is the authors’ experience that the aspect of anal fissure in the term or preterm neonate is often the exteriorization of a rectal inflamed mucosa and that such a diagnosis should probably prompt the systematic search for an underlying condition, such as colitis [28].

Rectal bleeding in the neonatal period is nonetheless an alarming event that suggests possible NEC, the latter being associated with a string of other clinical features which may render the diagnosis likely and the need for urgent hospital care and investigation. Early reports, which lack reliability in the absence of endoscopy, had already addressed the issue

of rectal bleeding and NEC. In a 1979, survey of 69 infants referred to hospital for rectal bleeding in the first month of life, in which NEC accounted for only 3% of cases [64]. Six infants born at term and had normal perinatal courses developed an inflammatory proctocolitis in the first month of life while being exclusively breast-fed and had sigmoidoscopy showing focal ulcerations, edema, and increased friability [65]. A personal study [66] aimed at a better appraisal of unexplained neonatal rectal bleeding using rectosigmoidoscopy. Mucosal alterations were ecchymotic patches, either in the form of one or several longitudinally stretched ecchymotic stripes on an otherwise normal mucosa or in the form of shapeless ecchymosis irregularly dispersed on a friable and congestive mucosa. In 18 neonates with rectal bleeding, colonoscopy revealed a colitis characterized endoscopically by ecchymotic mucosal lesions, the so-called ecchymotic colitis [67].

Colonoscopic changes during the neonatal period may involve NEC, *Campylobacter* infection, *Clostridium difficile*, and dietary protein intolerance [28]. Rectal bleeding and/or colonoscopic changes have also largely been associated with blood transfusion or exchange transfusion [28]. Ulcerative colitis, a rare condition during infancy [28], may be recognized on the association to rectal bleeding and colonoscopic lesions of a severe and progressively worsening alteration of the general condition (see Fig. 5.2).

Introduction

In the past decades, there has been a significant increase in the survival rate of preterm infants, especially very-low-birth-weight (VLBW, <1500 g) neonates. The nutritional problems of preterm babies have become particularly relevant, as numerous studies have underlined the importance of early feeding on short- and long-term development [1]. The gastrointestinal (GI) tract of preterm infants and especially of VLBW infants is immature at birth and initially incapable of receiving full enteral feeding [2]. Retard in maturation of GI motility manifests itself in so-called “neonatal feeding intolerance” which is characterized by delayed gastric emptying, abdominal distension, and constipation. This parapsychological condition may evolve in necrotizing enterocolitis (NEC), a major GI emergency in preterm newborn. NEC almost always occurred in infants who received enteral nutrition and who show sign of feeding intolerance. For these reasons, the introduction of feeding was frequently delayed, often for prolonged periods, increasing the risk of malnutrition.

Nutrition Objectives in Premature Neonates

The vast majority of infants born at a gestational age lower than 29 weeks do not achieve the median birth weight of the reference fetus at theoretical term or 40 weeks postmenstrual age (PMA) [3, 4]. At discharge, the estimates of growth failure range from 30 to 67%. To reduce the risk of cumulative nutritional deficit and malnutrition, enteral nutrition should be introduced appropriately. However, it remains unclear which postnatal artificial feeding regimens are more appropriate to support postnatal growth adequately [1]. Age of life and clinical conditions influence modalities of enteral nutrition administration. We can differentiate neonatal period in two phases: (i) the early adaptive period of clinical instability (from birth to approximately day 7) and (ii) the intermediate stable growing period (from approximately day 7 to near term/discharge). Recommended intakes and modalities of enteral feeding during these two different phases are reported below.

Enteral Nutrition During the Early Adaptive Period

The main goal of neonatal nutrition during this phase is to provide immediately the recommended intakes in order to limit the cumulative deficit and to reach a positive nitrogen balance since the first days of life [1, 3–5]. Despite many studies enrolling VLBW infants demonstrated that early-optimized nutritional support significantly reduces growth restriction during the first days after birth, it might be difficult to satisfy all nutritional needs. In this period, total fluid intake should be limited in order to prevent neonatal complications (i.e., persistent ductus arteriosus and bronchopulmonary dysplasia). Parenteral nutrition must be started immediately after birth in all VLBW neonates to maintain adequate fluid, electrolytes, and nutrients intake, until full enteral feeding (120 kcal/kg/day) is reached. In this phase, small amounts of enteral feeding (also called “minimal enteral feeding (MEF),” “GI priming,” “trophic feeding,” and

“hypocaloric feeding”) could improve the maturation of the GI tract, digestive hormone release, and gut motility. On the other hand, receiving nothing by enteral route predisposes neonates to the consequences of starvation (i.e., GI atrophy, malnutrition, infections). Thus, MEF should be started possibly in the first 24–48 h of life, if the patient is stable, at a minimal volume of 10–30 ml/kg of body weight, and it could be increased by 20–30 ml/kg of body weight per day when clinical conditions remain stable and feeding intolerance does not occur (Fig. 6.1). In the VLBW infant with prenatal history of blood uteroplacental flow alterations, a delayed onset of MEF could be considered. Measurement of flow in mesenteric vessels, by ultrasonography, could be useful in deciding if starting MEF is safe, in particular for these neonates. [6]. Results of clinical trials in premature infants support the opinion that MEF, preferentially by human milk, has some clinical benefits such as reducing the time to reach full enteral feeding and length of hospitalization without increasing the risk of NEC [7]. MEF could be adopted not only early in life to start enteral feeding but also during the periods of feeding intolerance. When signs of feeding intolerance are neither specific nor systemic (Fig. 6.1), MEF

could be continued in order to reduce the duration of parenteral nutrition and to limit the risk of infections [8]. MEF mainly serves as trophic gut feeding. Therefore, should not be considered in the total energy intakes during total parenteral nutrition (see Chap. 7).

Nutrition During the Intermediate and Stable Growing Period

During this period, parenteral fluid is progressively reduced and, thus, interrupted as soon as 120 ml/kg/day (100 kcal/kg/day) by enteral route is well tolerated. Subsequently, enteral feeding can be slightly increased, up to 140–180 ml/kg/day (115–135 kcal/kg/day), according to nutritional requirements and type of formula used. During any phase of nutritional approach, protein to energy ratio (PER) should be conserved and parenteral nutrition adjusted in relation to nutrients given by enteral route. Human milk is the preferred feed for preterm infants during the intermediate and stable growing period. Weaning period from parenteral nutrition may be at high risk of relative malnutrition, contributing to

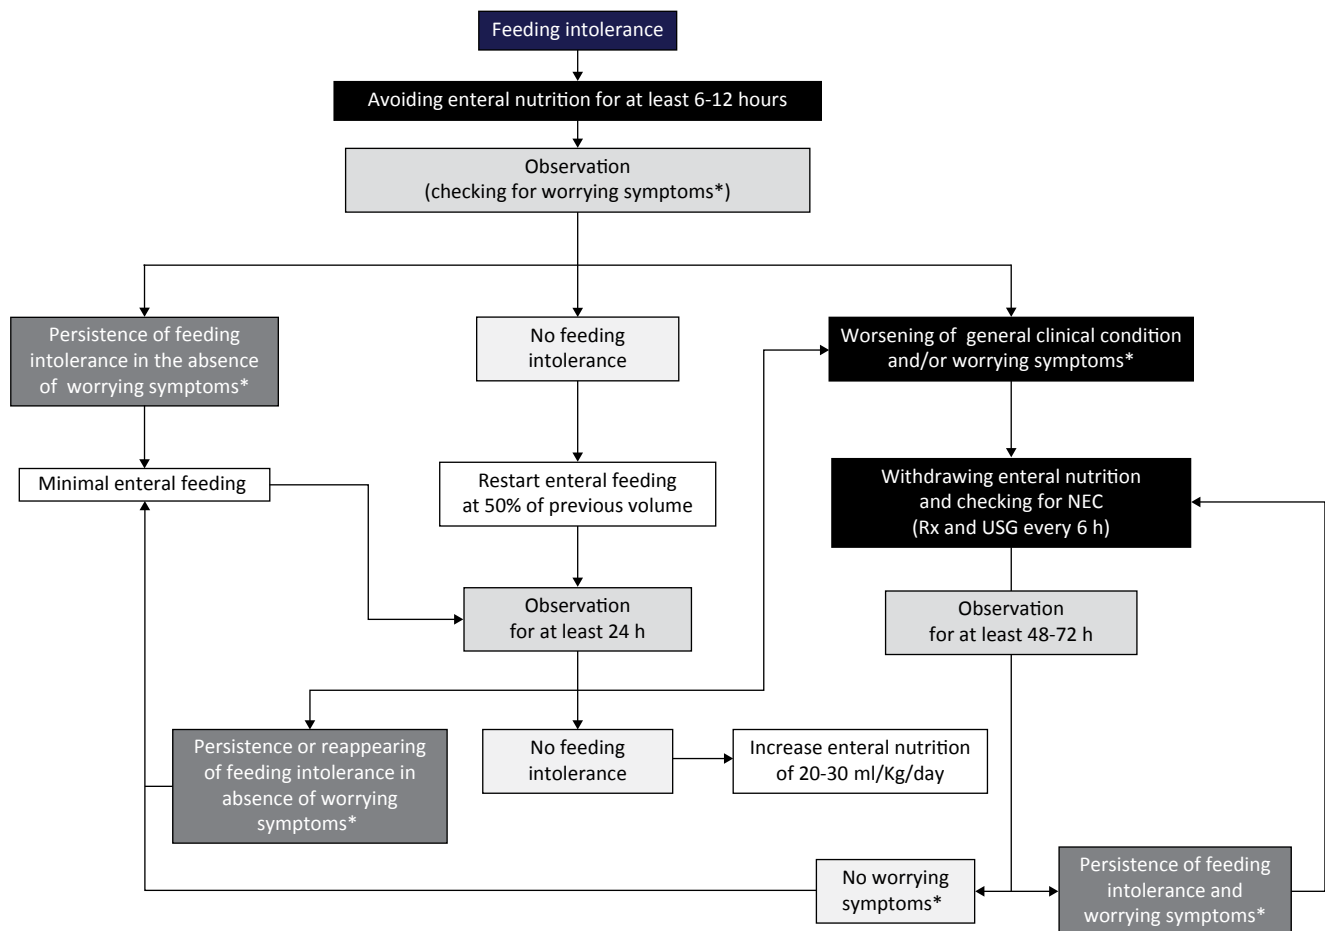

Fig. 6.1 Flow diagram for the management of preterm newborns with feeding intolerance. Note: *Erythematic abdominal wall, absence of

bowel sounds, blood in the stools or in aspirates, bile in the aspirate, or radiological or ultrasonographic markers of NEC Bell’s stage >I

cumulative nutritional deficit and postnatal growth restriction [9]. It is commonly accepted that human milk needs to be fortified to meet the nutrient needs of the preterm infant. Fortified human milk feeding regime significantly improves growth. Fortification provides adequate intakes when the composition of human milk plus fortifier reaches 2.5 g protein/100 ml with a PER of 3.2 g/100 kcal [1]. Measuring the composition of human milk feeds prior to fortification and targeting the fortification according to individual needs of each infant would be ideal [9]. When human milk is unavailable, preterm formula is used for feeding very preterm infants. All preterm formulas are protein and energy enriched (~80 kcal/dl, PER 3.0–3.6 g/100 kcal), have low osmolarity (325 mmol/kg H₂O), and typically contain added whey protein, glucose polymers, medium-chain triglycerides (MCT), a source of long-chain polyunsaturated fatty acids (LCPUFAs), calcium, phosphorus, electrolytes, folate, and fat-soluble vitamins. Upper limits of recommended nutritional intake are met when preterm formula is fed at rates approaching 160 ml/kg/day [5].

Feeding Mode

Bolus or (Semi-) Continuous Feeding

Bolus feeding results in a significant increase in blood flow to the portal-drained viscera (i.e., stomach, spleen, intestine, and pancreas). There is a surge in GI hormones, which is higher than when neonates are fed continuously. It has been also suggested that in preterm infants fed with fortified human milk, continuous feeding leads to important nutrients' loss on nasogastric tube walls (i.e. fat and calcium). However, it has been demonstrated better tolerance with continuous milk feeding in preterm neonates [10, 11]. Bolus feeding may result in apnea, deteriorating respiratory mechanics with decreased tidal volumes, and transient presence of blocking materials of the nostrils, such as nasogastric tubes, or noninvasive respiratory support devices. However, a large randomized controlled trial showed that even extremely-low-birth-weight (ELBW, <1000 g) infants may tolerate bolus feeding well [10, 11]. In conclusion, there is still not enough evidence to recommend either bolus or (semi-) continuous feeding as the preferred method, but the change from one to another can be justified when feeding intolerance persists in smaller neonates.

Oral Feeding

Oral feeding is possible when an infant is capable of an adequate suck–swallow reflex. In the term infant, the full, complex, integrated mechanism of swallowing, with the movement of the bolus of milk into the stomach, protection of the

airway, inhibition of respiration, and appropriate relaxation of the esophageal sphincter and gastric fundus is achieved within 2 days of life. The swallow function is present from 16 weeks of gestational age, and GI motor activity, in small bursts, from 24 weeks onwards [2]. Organized motility is present from around 30 weeks of gestation and nutritive and swallowing function from 32 weeks. Enteral nutrition promotes postnatal maturation of intestinal motor activity. It follows that oral feeding is only possible from 32 weeks onwards, but Nonnutritive sucking can start earlier. The very preterm infant (<32 weeks) may be put on the breast but the likelihood that the infant will ingest a significant volume of milk is very small. However, it may offer the mother a considerable psychological benefit and should therefore be strongly encouraged.

Intragastric Feeding

As oral feeding is not possible in VLBW infants, most frequently gastric tubes are used [11]. Either nasogastric or orogastric tubes can be installed, both checked in the right position (i.e., fundus) by measuring external distance (i.e., distance from nose or mouth to ear plus distance from umbilicus and xiphoid process), and checking the aspirate for acidity with litmus paper. Correct position should be confirmed at the first radiographic examination performed for such reasons and reported in the clinical chart. The nasogastric tube has the advantage of easier fixation but has the disadvantage of (partially) blocking one nostril. With the use of some respiratory devices, only the orogastric tube is possible. Finally, tubes and syringes may lead to loss of nutrients such as lipids and calcium that may not reach the infant [11].

Transpyloric Feeding

Although transpyloric feeding is frequently used in pediatric intensive care, no proven benefits in tolerance, growth, or in aspiration rates have been reported in neonates. Additionally, such evidences showed that mortality rates increase in neonates receiving transpyloric feeding [1, 5].

Start, Check the Tolerance and Increments of Enteral Feeding

Enteral nutrition is started at 10–30 ml/kg of body weight per day. Feeds could be given by gavage or with a continuous infusion pump and increased by 20–30 ml/kg/day according to feeding tolerance. [12]. Feeding intolerance may sometimes be obvious when severe GI manifestations are identified

(emesis, vomiting, severe abdominal distension, ileus with visible intestinal loops, blood in the stools) or when GI symptoms are associated with systemic disorders like apnea, bradycardia, poor perfusion, and/or hemodynamic instabilities. However, intermediate situations are frequent in VLBW infants. In particular, abdominal distension is frequently observed during noninvasive ventilation and antegrade peristalsis with bilious gastric aspirates is also commonly described during the first week of life in VLBW infants.

The aspiration of gastric residuals is common practice while tube-feeding infants and aspirate usually need to be re-feeding to reduce the loss of enzymes and electrolytes. Most clinical studies demonstrated little if any predictive value of gastric residuals $>3\text{--}4$ ml/kg or $>30\text{--}50\%$ of the previous feed and of bilious-stained feed [12]. Therefore, in the absence of significant clinical signs or symptoms, the presence of gastric residuals <4 ml/kg or $<50\%$ of 3-h previous feed is not a valid reason to interrupt or reduce enteral feeding [12]. Maintaining sufficient enteral feeding can in fact improve GI maturation and feeding tolerance. If enteral feeding has been interrupted but clinical evolution rules out a significant disease, enteral feeding need to be restarted as soon as possible to promote intestinal maturation.

In the absence of signs of feeding intolerance, the volume of enteral nutrition could be daily increased. The ideal rate of progression of milk volume given to VLBW infants is controversial. Cochrane Review has concluded that a rapid rate of advancing feeds was not associated with a higher risk of NEC [13]. Although additional studies are needed, a small progressive increment of 20 ml/kg/day after a few days of stabilization can be suggested. (Fig. 6.1). In the presence of erythematous abdominal wall, absence of bowel sounds, blood in the stools or in aspirates, enteral nutrition should be discontinued and serial abdominal ultrasounds and radiological examinations should be started in order to early identify NEC [8, 12, 14].

Nutrient Needs in Enterally fed Neonates

Protein

Protein Requirements

The optimal quantity of dietary protein for preterm infant formulas is still a matter of debate. Dietary protein needs for preterm infants were calculated through two different methods [15]. The first, the empirical approach, measures biochemical or physiological responses to graded intakes. The second method, the factorial approach, considers the requirements as the sum of the essential losses (e.g., urine, feces, skin), plus the amount incorporated into newly formed tissues accounting theoretical fetal accretion at the same PMA. The empirical approach evaluates physiological and

biochemical variables to determine minimum and maximum protein needs in the growing preterm infant.

In the factorial approach, compositional analysis of fetal tissues has been a valuable source of data for our understanding of the nutrient needs of the fetus and, by extension, those of the growing preterm infant. Fetal accretion rates have been obtained from compositional analyses of aborted fetuses or stillborn infants. From these data, the protein increment for growth has been estimated as approximately 2.5 g/kg/day [5]. Protein requirement is thus calculated by adding to this value the obligatory losses, and the amount needed for the additional catch-up growth. In a large population of preterm infants receiving a controlled energy intake, the minimal protein supply necessary to obtain a zero nitrogen balance (to cover all nitrogen losses) was calculated to be 2 g/kg/day. A similar value was estimated to cover the need for catch-up growth. Thus, the protein requirements of premature infants are between 3.5 and 4.0 g/kg/day (Fig. 6.2) [5].

Protein intake must be sufficient to achieve normal growth without negative effects such as acidosis, uremia, and elevated levels of circulating amino acids [1, 15, 17]. A recent Cochrane analysis aimed to determine whether higher (≥ 3.0 g/kg/day) versus lower (< 3.0 g/kg/day) protein intake during the initial hospital stay of formula-fed preterm infants or LBW infants (< 2500 g) results in improved growth and neurodevelopmental outcomes without evidence of short- and long-term morbidity [17]. Five studies comparing low versus high protein intake were included. Improved weight gain and higher nitrogen accretion were demonstrated in infants receiving formula with higher protein content while other nutrients were kept constant. No significant differences were seen in rates of NEC, sepsis, or diarrhea. One study compared high (3 g/kg/day) versus very high (> 4 g/kg/day) protein intake during and after an initial hospital stay [18].

Fig. 6.2 Recommended protein intake and protein to energy ratio for preterm infants to obtain optimal protein retention [5, 16]

Very high protein intake improved gain in length at term, but differences did not remain significant at 12 weeks corrected age. Three of the 24 infants receiving very high protein intake developed uremia, defined as serum urea nitrogen level greater than 6 mM/ml. Formula with higher protein content improves all growth parameters and neurodevelopment [19, 20]. However, available evidence is not adequate to permit specific recommendations regarding the provision of very high protein intake (≥ 4.5 g/kg/day) from formula during the initial hospital stay or after discharge.

Enteral Nutrition Protein Composition

Nitrogen absorption rate (absorbed/intake) differs significantly according to the feeding regimen (Fig. 6.3) [21]. It is higher with powder whey-predominant protein preterm formulas than with human milk supplemented with fortifiers powder protein hydrolyzed formulas or ready-to-use liquid whey-predominant preterm formulas. These differences result from the nature of the various types of protein supply. Also net protein utilization is higher for preterm formulas compared with human milk, with or without protein supplementation. Technical processes (i.e., hydrolysis) may alter macronutrient concentrations of formula and the pasteurization of human milk before delivery to newborn also cause a reduction in the protein concentration of about 4% [22].

The whey/casein ratio significantly influences individual amino acid intakes and plasma amino acid concentrations. Plasma threonine increases and tryptophan relatively decreases in infants fed a whey-predominant formula, whereas methionine and aromatic amino acids increase in those fed a casein-predominant formula [23]. The high plasma threonine

concentration observed in preterm infants fed whey-predominant formulas is related to the glycomacropeptide obtained from casein by enzymatic casein precipitation of cow's milk proteins. Acidic precipitation, by contrast, removes the glycomacropeptide rich in threonine from the soluble phase [23]. In preterm infants receiving either an enzymatic or an acidic whey-predominant formula, a significant reduction in plasma threonine concentration was observed in acidic whey protein formula-fed infants, compared to those receiving conventional enzymatic whey protein formulas. All other plasma amino acid concentrations were similar, with the exception of valine, which was slightly reduced in acidic whey protein formula-fed infants [15, 24].

The relative percentage of α -lactalbumin depends on the cow's milk protein content [25]. This protein fraction is naturally rich in tryptophan and helps normalize the low levels of this amino acid frequently observed in whey-predominant formula-fed infants. The use of a higher percentage of whey in protein-hydrolyzed formulas may worsen the plasma amino acid pattern by increasing threonine and decreasing aromatic amino acid concentrations [25]. Moreover, a significant decrease of plasma histidine and tryptophan concentrations, probably due to a relative reduction in amino acid bioavailability, could be also observed. Using a more appropriate technology, these formulas have been corrected for the threonine content and supplemented with histidine and tryptophan.

An interesting observation is the relatively lower absorption rate of ready-to-use liquid preterm formulas or protein hydrolyzed preterm formulas, where the technical process seems to impair nitrogen absorption in relation to heat treatment—inducing some Maillard reaction—or to preliminary

Fig. 6.3 Nitrogen balances according to feeding regimen in preterm infants [21]

hydrolysis, altering the physiological absorption process in the lumen or at the border of the GI tract. Formulas based on hydrolyzed proteins have been recently proposed for the feeding of preterm infants to reduce GI problems such as delayed gastric emptying, abdominal distension, hard stools, and feeding intolerance [26]. The technological processes of hydrolysis may modify the amino acid content and/or amino acid bioavailability [27]. The efficiency of protein differs also according to non-protein nitrogen content of different feeding regimens. The highest values were obtained in preterm infants fed powder and liquid preterm formulas. It was significantly lower in those fed protein-hydrolyzed formulas and fortified human milk. The lower value obtained with fortified human milk may be related to nonprotein nitrogen content, which represents 20–25% of total nitrogen content of human milk, but still 13.5–17% of total nitrogen content of fortified human milk. The contribution of nonprotein nitrogen fraction of fortified human milk to protein gain is lower than that of the α -lactalbumin or the casein content of human milk [1, 15, 23, 24]. Due to its biological activities, the nonprotein nitrogen of human milk may not be included in protein intakes when human milk is compared to formulas. This may explain why we still frequently observe differences between infants fed human milk or PTF with theoretical similar nitrogen content.

Formulas do not contain any of the biologically active immune proteins nor enzymes, hormones, or growth factors are found in human milk [2]. The long-term implications of this deficiency have not been completely determined. Further long-term randomized studies with higher number of patients, and standardized supplemental amounts and experimental conditions are needed to establish the efficacy of non-nutritional compounds, such as nucleotides, polyamines, and growth factors supplementation in preterm formula [1, 5].

Energy

The energy demands for preterm infants depend on many factors including PMA, genetically determined metabolic rate, thermal environment, activity, sleep status, nutritional status, nutrient intake, body composition, and occurrence of illness [1]. Energy expenditure, measured by indirect calorimetry, increases with postnatal age and varies from 45 to 55 kcal/kg/day. The energy cost for a postnatal weight gain of 17–20 g/kg/day with adequate lean body mass (LBM) accretion vary widely from 50 to 70 kcal/kg/day in premature infants [5, 15, 28]. Energy absorption from enteral nutrition, in healthy growing premature neonates after the first 2–3 days of life, is about 80–90% of the energy intake. The remainder is lost in stool and a small quantity as urea in the urine. Energy absorbed is in part stored in tissues, mainly as fat but also as protein, and in part spent by the metabolism (energy ex-

penditure). Energy intakes less than or equal to 100 kcal/kg/day may not meet the needs of some preterm infants before discharge. Where PER are adequate (3.2–3.6 g/100 kcal) in a formula providing well-absorbed nutrients, an energy intake around 120 kcal/kg/day is generally appropriate and may result in a fat mass deposition close to intrauterine references. Small-for-gestational-age (SGA) infants, in particular if they experienced intrauterine malnutrition, may need higher energy intake than appropriate-for-gestational-age (AGA) infants [1]. Energy intake recommended for preterm infants is 115–135 kcal/kg/day [5]. All recommendations are related to preterm formula, but energy requirement could differ in preterm receiving human milk in contrast to those fed with preterm formula [22, 28–30].

Protein:Energy ratio

Protein intake and PER are the main determinants of weight gain [17]. Protein intake is the only determinant of LBM gain in contrast to fat mass gain, which is positively related to energy intake and negatively to PER. Protein and energy needs are reciprocally limiting, the intake of one affecting the ability of the infant to assimilate the other [29, 30]. A suboptimal range of the PER leads to untoward consequences [1]. If energy intake is inadequate, proteins are used as an energy source and the nitrogen balance becomes less positive. Increasing the caloric intake will spare protein loss and improve nitrogen retention. If there is a surfeit of energy with limited protein intake, the protein retention reaches a plateau and the energy excess is used for excessive fat deposition. Thus, an adequate PER should be respected at all PMA, with adequate partition of energy intake between fat and carbohydrates. This crucial point should be respected particularly in the period of clinical instability, when nutritional regimens in a significant part depend on parenteral nutrition [16]. Recommended intakes for preterm infants at 26–30 weeks' PMA should be 3.8–4.2 g of protein/kg per day with a high PER above 3.2 g/100 kcal and ideally around 3.6 g/100 kcal [5]. A recent experts panel has recommended 3.6–4.1 g/100 kcal in VLBW infants while the European Society for Pediatric Gastroenterology Hepatology and Nutrition (ESPGHAN) have recommended 3.6–4.1 g/100 kcal in ELBW infants and 3.2–3.6 g/100 kcal for other preterm infants < 1800 g [5, 16].

Fat

Fat Requirements

Fat provides the major source of energy in growing preterm infants. Recommended fat intake is 4.8–6.6 g/kg/day [5]. Although some infants with restricted fluid may need high fat content in their feeds to meet energy needs, 4.4–6.0 g/100 kcal

is a reasonable range for most preterm infants [16]. Lipid availability by enteral route depends more on digestion and absorption capability than on enteral nutrition content and composition. Digestion of lipids is not fully developed in premature infants [2]. Lipid malabsorption is the result of low levels of pancreatic lipase and bile salts. The bile acid pool is only half the size of that of a full-term infant. Human milk provides additional lipases: lipoprotein lipase and bile salt-stimulated lipase, which contribute to intestinal lipolysis. However, additional fat should be also provided to human milk because of the possible reduction of fat content in expressed human milk, especially when various processes are applied to human milk prior to delivery to neonates [19, 20].

Enteral Nutrition Fat Composition

Fats represent approximately 50% of the nonprotein energy content of human or formula milk. Fat could be provided in different form with different nutritional power.

Medium Chain Triglycerides MCTs are hydrolyzed more readily than long-chain triglycerides (LCT) and fatty acids with more double bonds are absorbed more efficiently [16]. In order to improve fat absorption, commercial formulas contain a significant quantity of MCTs that are more easily absorbed than LCTs and transported directly to the liver via the portal vein as nonesterified fatty acids. The use of MCTs instead of LCTs in preterm infant formulas can reduce the formation of calcium and magnesium soaps with unabsorbed long-chain saturated fatty acids and, thereby, increase calcium and magnesium absorption. However, it needs to be stressed that the energy content of MCTs corresponds only to 85% of that of LCTs, the use of MCTs in formulas induces an increase in plasma ketones as well as in urinary excretion of dicarboxylic acids, suggesting that MCT metabolism could be slightly limited in preterm neonates [16]. Moreover, since MCTs do not contain essential fatty acids, a high MCT intake can reduce the availability of the essential long-chain fatty acids. For these reasons, it is recommended to limit the maximum MCT intake in preterm formula at 40% of the total fat content [5, 31].

Long-Chain Triglycerides Because humans cannot insert double bonds at the *n*-3 and *n*-6 positions, fatty acids with double bonds in these positions cannot be synthesized endogenously. Therefore, either specific *n*-3 and *n*-6 fatty acids or the precursor of each series such as linoleic acid (LA; 18:3*n*-3) and α -linolenic acid (ALA; 18:2*n*-6) must be provided as a component of the diet [5, 15]. Both LA and ALA acid are metabolized by a series of desaturation and elongation reactions to more unsaturated longer-chain fatty acids. Important metabolites of these two fatty acids include 20:5*n*-3 eicosapentaenoic acid (EPA), 22:6*n*-3 docosahexaenoic acid (DHA), and 20:4*n*-6 arachidonic acid (AA) [32–34].

Recent studies have reported outcome data in preterm infants fed milk with a DHA content two to three times higher than the current concentration in infant formulas. Overall, these studies show that providing larger amounts of DHA supplements, especially to the smallest infants, is associated with better neurologic outcomes in early life [34]. DHA intakes of 55–60 mg/kg/day from the time of preterm birth to expected term have been tested and appear to be safe, to promote normal DHA status, and to improve visual and neurocognitive functions. These values are likely to represent an adequate intake for very preterm infants, but further research is needed to confirm that they represent adequate intake for other infants subgroups (i.e., extremely, very, and moderately preterm infants, with or without intrauterine growth restriction, and males and females). Because the maximum DHA content of human milk is 84 mg/kg/day (equivalent of 1.5% of fatty acids), and because no studies with such a high intake in preterm infants have been reported, no upper limit can be set with certainty.

Synthesis of long-chain LCPUFAs is limited in preterm infants, thus, these molecules are considered as semi-essential or essential. Several studies have suggested that the LCPUFAs supply in preterm infants has a beneficial effect on growth, visual, and cognitive function, as well as on the immune system. Although some methodological issues in these studies do not allow definitive conclusions to be drawn, most of the formulas in Europe and the USA are currently supplemented with LCPUFAs [32–34].

Recommended intakes are 12–30 mg/kg/day or 11–27 mg/100 kcal for DHA and 18–42 mg/kg/day or 16–39 mg/100 kcal for AA [5]. The ratio of AA to DHA should be in the range of 1.0–2.0 to 1 (wt/wt), and EPA supply should not exceed 30% of the DHA supply [5, 34]. Recently, an experts panel has recommended (18-) 55–60 mg/kg/day or (16.4-) 50–55 mg/100 kcal for DHA and (18-) 35–45 mg/kg/day or (16.4-) 32–41 mg/100 kcal for AA [16].

Fat Composition of Human Milk Human milk composition of fat is highly variable and is affected within hours and to a large extent by maternal nutrition intake. Gestation, lactation, parity, milk volume, caloric, and carbohydrate intake, and weight changes are among the maternal factors that can alter the fat content and composition of human breast milk. The lengths of both gestation and lactation affect the lipids that constitute the milk fat globule membrane. Total phospholipid and cholesterol level is higher in colostrum and transitional milk than in mature milk. The period of colostrum lasts less than 10 days, but during this short time the higher lipid levels are beneficial in such processes as neonatal cell membrane production needed for growth, brain development, and bile salt synthesis. Preterm milk may contain a slightly higher proportion of medium- and intermediate chain fatty acids than term milk, which may

be advantageous for fat and calcium absorption in preterm infants. LCPUFA are higher in preterm and transitional milk and remain high for the first 6 months in women who deliver preterm. In term milk, on the other hand, LCPUFA declines throughout the first 6–12 months of lactation. Fatty acids rise with a high-carbohydrate maternal diet. Palmitic acid content of breast milk increases in a low-caloric diet. Weight gain during pregnancy is positively associated with higher milk fat content. Milk fat content changes during each feeding. During feedings, foremilk has less fat content than hind milk. Also, the higher the volume of breast milk, the lower the milk fat concentration. Modalities of human milk collection and storage may also influence fat composition. The estimated mean fat content in banked human milk is around 3.2 g/100 ml, somewhat lower than the generally accepted value for mature human milk [35]. This may be related to inadequate emptying of the breast during pumping or to processes applied before delivery bank human milk to neonates.

Pasteurization and storage of banked human milk induces lipolysis, inactivates bile salt-stimulated lipase and lipoprotein lipase, reduces fats, and increases the absolute amount of free fatty acids in pooled samples. Holder pasteurization involves a modification of the biological activity of a large number of enzymes, including lipases [19, 20]. These effects alter the integrity of human milk and may contribute to slower growth in preterm infants fed banked milk versus their mothers' own milk. On the basis of these evidences, a further supplementation with specific fatty acids could be considered for these infants [34–36].

Carbohydrates

Carbohydrates Requirements

Carbohydrates are essential to provide adequate energy supply and they represent a major source of dietary energy. Based on carbohydrate equivalents of total energy expenditure, the experts have recommended a minimum of 10.5 g/100 kcal and a maximum of 12.0 g/100 kcal [5, 16]. Carbohydrates are essential to provide adequate energy supply. Additionally, carbohydrates promote epithelial cell proliferation, insulin secretion, and calcium absorption [5, 16]. Thus, they are also essential to the overall health of the GI tract other than the fulfillment of energy requirements.

Enteral Nutrition Carbohydrates Composition

The predominant carbohydrate in mammalian milk and in term infant formula is lactose. After digestion by lactase, lactose is absorbed as glucose and galactose, which utilize the same carrier mechanism. In the human fetus, intestinal lactase activity is measurable by 10–12 weeks of gestation [37]. There is a gradual increase in lactase activity with advancing gesta-

tion, although the activity remains low until about 36 weeks of gestation, when it reaches the levels seen in full-term neonates [37]. Based on the low lactase activity in early gestation and the estimated length of the bowel, it was calculated that a preterm infant weighing 1300–1400 g might be expected to absorb only 30–50% of the ingested lactose. The lactose that is not fully digested serves as a source of nutrition for bacterial flora in the colon, where it is transformed into short fatty acids and then absorbed [2]. Through the process of fermentation, this not only facilitates colonic water and electrolytes absorption but also stimulates cell turnover of both the colon and the small intestine. After lactose, oligosaccharides are the largest other carbohydrates component in mature human milk. They represent the third largest solute load of the diet after lactose and fat [37]. Oligosaccharides are hydrolyzed by salivary, pancreatic, and intestinal amylase and maltase to free glucose, which is rapidly absorbed. Many of the protective effects of human milk (i.e., against diarrheal diseases, respiratory, and ear infections) have been attributed to oligosaccharides. A further advantage of oligosaccharides for preterm infant formulas includes the improved gastric emptying [38, 39]. Oligosaccharides may be considered as prebiotics. There are some reports that such prebiotics have beneficial effects on various markers of health. For example, primary prevention trials in infants have provided promising data on prevention of infections and atopic dermatitis. However, additional well-designed prospective clinical trials and mechanistic studies are needed to advance knowledge further in this promising field.

Fluids and Electrolytes

The goal of fluid administration is to replace water loss, maintain water and electrolyte homeostasis to provide extra water and electrolytes to build up new tissues. Total fluid intake is related to ingested caloric and protein intake as well as to the renal solute load [40–44]. Randomized controlled trials on enteral fluid intake of preterm infants are lacking as are studies comparing different fluid volumes providing identical nutrient intakes. From data of combined parenteral/enteral regimens, and assuming full enteral absorption, it follows that fluid volumes between 96 and 200 ml/kg/day are tolerated, and that these values may serve as lower and upper limits [5]. When exclusively enteral feeding is reached, a rate of 150–180 ml/kg/day by standard formula or fortified breast milk should be provided to meet nutrient requirements. Some infants may need higher volumes to meet higher requirements of substrates other than fluid. Preterm infants of less than 35 weeks gestation have obligate high renal and intestinal sodium losses during the first 2 weeks of life, leading to cumulative negative sodium balance in most and hyponatremia in many. It has been demonstrated that in-

creasing dietary sodium intake to 4 mmol/kg/day for infants born at 31–34 weeks, and to 5 mmol/kg/day for those born before 31 completed weeks, prevent the negative sodium balance and hyponatremia and led to more rapid weight gain and earlier discharge from hospital [42, 43]. Premature infants require a higher sodium intake in the first 2 weeks of postnatal life than those born at or near at term, and failure to provide such an intake may predispose to poor neurodevelopmental outcome [43]. Due to the rapid rate of growth and the requirements for intracellular potassium in LBM accretion, potassium intakes are estimated around 2–3 mmol/kg/day and are also high in very preterm infants, like for protein [5, 16].

Calcium and Phosphorus

Calcium and Phosphorus Requirements

Several nutrients cause a reduction of calcium bioavailability [45–47]. Various factors affect calcium absorption: vitamin D status, solubility of calcium salts, and the quality and quantity of fat intake. In preterm infants, the vitamin D body stores at birth depend mainly on maternal vitamin D status. In the USA, where dairy products are routinely supplemented with vitamin D, a daily additional intake of 400 IU in the formula may sometimes be sufficient to maintain an adequate plasma concentration of 25-OH and 1–25(OH)₂ vitamin D. By contrast, in most parts of Europe, cord blood concentration of 25-OH vitamin D of premature infants is frequently less than 10 µg/ml; in this case, up to 1000 IU/day of vitamin D are recommended [5]. The increased needs of premature infants could be partly due to a relative malabsorption of vitamin D, resulting from a low secretion of bile acids [48]. A calcium retention close to 90 mg/kg/day could currently be expected in preterm infants fed preterm formula with a highly soluble calcium content. These values are still lower than the estimated fetal accretion during the last trimester of gestation (100–120 mg/kg/day). However, there are dramatic physiological changes in bone metabolism resulting from various factors after birth: disruption in maternal mineral supply, stimulation of calciotropic hormone secretion, change in hormonal environment, and relative reduction in mechanical stress. These events stimulate the remodeling process leading to an increase in endosteal bone resorption and a decrease in bone density. In preterm infants, these adaptation processes modify the mineral requirement, since, by itself, the increased remodeling and bone turnover provides a part of the mineral requirement necessary for postnatal bone growth [46].

Phosphate is one of the main intracellular ions present in the cytoplasm. The provision of adequate amounts of nitrogen, potassium, and phosphorus is the condition required to

obtain adequate LBM accretion and rapid cell growth. The phosphorus to nitrogen ratio in the cells is not stable and it is increased in the rapidly growing tissues. A large amount of phosphorus is also deposited in the bone in a fixed proportion with calcium and can act as minerals reservoir. In fact, regardless of the proper bone metabolic status, phosphorus consumption by the cell metabolism is privileged in the growing newborn and phosphorus may be released into circulation from the bone if necessary for cellular requirements. In the case of insufficient phosphorus intakes, hypophosphatemia occurs due to cells metabolism requirements. Afterwards, and due to bone phosphorus mobilization from the bone, bone calcium release induces hypercalcemia and hypercalciuria [45]. The strict relationship among amino acid, calcium, and phosphorus intakes is not specific to the first days of life of parenterally fed neonates. This phenomenon of phosphorus deprivation may also be observed in preterm infants enterally fed when a supplementation of protein was not accompanied by a modification of the Ca/P ratio. Calcium retention level ranging from 60 to 90 mg/kg/day assures appropriate mineralization, it decreases the risk of fracture and it diminishes the clinical symptoms of osteopenia. An intake of 100–160 mg/kg/day of highly bioavailable calcium salts, 60–90 mg/kg/day of phosphorus, and 800–1000 IU of vitamin D per day is recommended [5].

Calcium and Phosphorus Composition in Enteral Nutrition

In preterm infants fed human milk, calcium absorption range from 60 to 70% depending on the calcium salts and intake. Calcium retention is mainly related to phosphorus supply, which is frequently the limiting factor of bone mineralization. Supplementation of human milk with phosphorus alone improves calcium retention from 25 to 35 mg/kg/day. When calcium and phosphorus are provided together or as human milk fortifiers, calcium retention may reach 60 mg/kg/day. Recent use of human milk fortifiers containing highly soluble calcium glycerophosphate has improved calcium retention up to 90 mg/kg/day at intake of 140 mg/kg/day [47]. In formula-fed infants, calcium absorption is usually less than with human milk, ranging from 35 to 60% of intake. Calcium absorption is related to calcium, fat intakes, and techniques of milk preparation [19, 20]. With ready-to-use liquid formulas, calcium absorption is usually lower than with powder formulas. With the use of formulas with a well-absorbed fat blend of about 85%, the formation of calcium soap is of minimal interest in clinical practice. Finally, owing to the poor solubility of calcium salts, especially calcium phosphate, the calcium content measured in the formula could be significantly lower than the claimed value, and additional loss due to precipitation may occur before feeding.

Iron

Preterm infants require iron for erythropoiesis, brain development, muscle function, and cardiac function. The symptoms of iron deficiency are not due to anemia only but are also due to tissue losses of iron containing enzymes and iron-sulfur proteins. It has been estimated that, in the absence of iron supplementation, a VLBW preterm infant has enough iron stores to last 2 months [49]. However, due their growth requirements and blood samples, preterm infants need supplemental iron after 2 weeks of age. Enteral dose of iron for the preterm infant ranges from 2 to 4 mg/kg/day, depending on the degree of prematurity and the amount of phlebotomy. The introduction of erythropoietin puts a greater stress on iron balance, forcing the infant to mobilize endogenous iron stores at a faster rate. For infants receiving this medication, an enteral dose of 6 mg/kg/day is recommended. No study has demonstrated oxidative toxicity from enteral iron given at conventional doses in preterm infants. Iron needs of preterm infants remain greater than those of term infants because of their more rapid relative rate of growth and therefore blood volume expansion. Given their lower endogenous iron stores, it would be prudent in preterm to monitor the presence of anemia earlier than in term infants.

Trace Elements

Trace elements contribute less than 0.01% of the total body weight. They function as constituents of metalloenzymes, cofactors for metal ion-activated enzymes, or components of vitamins, hormones, and proteins. Because the fetus accumulates important stores of trace elements during the third trimester of pregnancy, premature infants have low stores at birth and are at high risk of developing mineral deficiencies if intakes are inadequate for their growth requirements. Trace minerals with established physiological importance in humans include zinc, copper, selenium, manganese, chromium, molybdenum, and iodine. Recently, it has been suggested that dose of zinc higher than those recommended by the ESPGHAN may reduce morbidity and mortality in preterm neonates [5, 50].

Oral Vitamin Requirements

Vitamins are organic compounds that are essential for metabolic reactions but are not synthesized by the body [1, 5, 28]. Vitamins are classified as water soluble or fat soluble, based on the biochemical structure and function of the compound. Water-soluble vitamins cannot be formed by precursors (with the exception of niacin from tryptophan) and do not accumulate in the body (with the exception of vitamin B12).

They include B complex vitamins and vitamin C. They serve as prosthetic groups for enzymes involved in amino acid metabolism, energy production, and nucleic acid synthesis. A daily intake is required to prevent deficiency. Excretion occurs in the urine and bile. Altered urinary losses due to renal immaturity during the first week of life predispose a preterm infant to vitamin deficiency or excess [1]. Fat-soluble vitamins include vitamin A, D, E, and K. Fat-soluble vitamins require carrier systems, usually lipoproteins, for solubility in blood, and intestinal absorption depends on fat absorption capability [5].

Breast Milk

Benefit of Breast Milk

Since 20 years, the American Academy of Pediatrics (AAP) has acknowledged the advantages of human milk feeding with the statement that it is the preferred feeding for all infants, including those born preterm [51]. The benefits of human milk for host defense, GI function, and neurodevelopmental outcome are briefly reported in Table 6.1. Preterm infants fed human milk have fewer infections than those fed on formula. This advantage has been observed with both fresh and pasteurized human milk [52, 53]. There are studies showing a protective effect of breast milk on the incidence of NEC [53–55]. Feeding with donor human milk was also associated with a significantly reduced risk of NEC [54]. The recent development of human-milk-based human milk fortifier suggest a possibility to decrease the risk of NEC compared with the use of conventional bovine milk fortifier or preterm formula [55, 56]. However, the significant reduction of the cases of NEC may depend on high basal incidence of NEC (>15%) observed only in several settings. This aspect limits the generalization of the data to other clinical setting with lower incidence of NEC. The protective effect of human milk has been attributed to several factors, such as macrophages, lymphocytes, sIgA, lysozyme, lactoferrin, oligosaccharides, nucleotides, cytokines, growth factors, and enzymes present in breast milk. Immune defense can be provided by an interaction between these factors [2]. Breast milk enhances the growth, motility, and maturity of the GI tract compared to formulas. It also induces faster gastric emptying. The mother's presence in the neonatal nursery combined with breast milk expression, particularly the premature infant's skin-to-skin contact with the mother, may reduce the risk of infections by nosocomial pathogens by passive immunization [57]. Preterm infants fed human milk during hospitalization showed better neurological development and a higher intelligence quotient compared to those formula fed, even after controlling for the mother's educa-

Table 6.1 Benefits and limits of human milk and formula for preterm neonates

	Nutritional power	Effects on infectious diseases	Effects on the risk of necrotizing enterocolitis (NEC)
<i>Human milk</i>			
Fresh	Risk of nutrient deficiencies and slower neonatal growth compared to fortified human milk and preterm formula	Reduced risk of infection (sepsis and urinary tract infection) compared to preterm formula feeding Risk of transmission of CMV infection	Reduced risk of NEC compared to preterm formula feeding
Holder pasteurization	Minimal reduction in fat and energy content compared to fresh human milk Partial reduction in nutritional and biological quality compared to fresh human milk	Reduced risk of infection compared to preterm formula feeding. Similar rate of sepsis compared to fresh human milk No risk of transmission of CMV infection compared to fresh human milk	Reduced risk of NEC compared to preterm formula feeding
Short-term heat pasteurization (5 s at 72°C)	No evidences available	No risk of transmission of CMV infection compared to fresh human milk	No evidences available
Freezing (−20°C)	Preserve nutritional and biological quality of human milk	Higher risk of transmission of CMV infection compared to holder pasteurized human milk, but reduced compared to fresh human milk	No evidences available
<i>Human fortified milk</i>			
Fortified with bovine milk-based fortifiers	Improvements in growth (weight, length, and head circumference) during hospital stay compared to not-fortified human milk Nutrient availability and properties of human milk may be changed by fortification Lower growth compared to preterm formula feeding Improved growth using target fortification	Lower risk of sepsis compared to preterm formula feeding	Lower risk of NEC compared to preterm formula feeding No significantly increased risk of NEC compared to not fortified human milk
Fortified with human milk-based fortifiers	Similar rate of growth compared to human milk fortified with bovine-based products	Similar rate of sepsis compared to human milk fortified with bovine-based product	Reduced risk of NEC compared to feeding with preterm formula or human milk fortified with bovine-based product
<i>Preterm formula</i>			
Powdered	Improvement of fat absorption, nitrogen retention, bone mineralization, and growth compared to pooled human milk	Higher risk of sepsis compared to human milk feeding Risk of <i>Enterobacter sakazakii</i> infection	Higher risk of NEC compared to human milk feeding
Liquid	Improvement of fat absorption, nitrogen retention, bone mineralization, and growth compared to pooled human milk Reduced bioavailability of various nutrients (proteins, calcium, or copper) compared to powdered formulation due to precipitation or heat treatment	Higher risk of sepsis compared to human milk feeding	Higher risk of NEC compared to human milk feeding

CMV cytomegalovirus

tion and social class [58–61]. Higher mental developmental index scores were reported in VLBW infants at 18 months of age who received human milk compared to those who never received human milk in hospital [59]. At 16 years follow-up, the percentage of expressed breast milk in the neonatal

diet correlated significantly with verbal IQ and white-matter volume in males [60]. Potential factors of human milk that might contribute to neurodevelopment are net protein utilization, amino acids and fat composition, other than hormone, growth factor, and micronutrients [2].

Limits of Breast Milk

Despite many benefits, human milk and its nutrients content are not sufficient to cover the greater needs of VLBW infants. Breast milk composition depends on the gestational age at delivery, collection methods (e.g., drip method vs. expression with a pump), and whether pooled milk or the infant's own mother's milk is used [53]. Greater concentrations of nitrogen, immune proteins, total lipids, medium-chain fatty acids, energy, vitamins, some minerals (calcium and phosphorus), and trace elements in milk from mothers who give birth prematurely (preterm milk) compared with milk of mothers giving birth at term (term milk) have been observed [53]. The higher concentrations of these nutrients tend to decline as lactation progresses, so exclusive feeding of mature preterm milk from 2 weeks postnatally may lead to nutrient deficiencies in the rapidly growing preterm infant [35]. The reason for the difference in nutrient density between preterm and term milk is not well known. Early interruption of pregnancy might induce an incomplete maturation of mammary glands leading to paracellular leakage of serum proteins and ions through junctions that have not completely closed. Also, a different hormonal profile in women who deliver prematurely compared with those who deliver at term could be responsible for a different milk composition. The greater nutrient density in preterm milk could also be related to the higher concentration of nutrients in a lower volume of milk. In fact, the main limits of human milk for preterm infants is its production. Mothers of preterm infants, for several reasons (stress, poor maternal health, delayed initiation of lactation), frequently produce an insufficient quantity of milk [57]. The difficulties faced by mothers trying to provide milk for their preterm infant must not be underestimated. They may need to express milk for a period of weeks or months in the absence of significant suckling stimulus and in the presence of a great deal of stress. Increasing the frequency of expression, kangaroo care or skin-to-skin contact, relaxation tapes may improve milk volume produced by mothers. Moreover, a restriction of fluid intake in VLBW infants could reduce the volume of human milk given, and thus not offer a sufficient quantity of nutrients.

Breast Milk Fortification

Human milk fortifiers have been produced to increase the nutritional content of human milk in order to meet the nutritional requirements of VLBW infants and to preserve the benefits of human milk [61]. The protein content of human milk is too low to permit a weight gain similar to the intrauterine fetus. The low sodium level may lead to hyponatremia. The amounts of calcium and phosphorus are widely below the intake needed to achieve adequate bone mineral accretion and to avoid severe osteopenia. Through a process of

human milk lacto-engineering, human milk can be fortified with skim and cream components derived from heat-treated, lyophilized mature donor human milk to produce a "human milk formula." This method of fortification avoids cow's milk proteins but it is impractical for most neonatal units, since it involves a complex and costly process and requires a large supply of donor milk. Preterm human milk, fortified with protein of bovine origin, has become the standard practice in most neonatal units. The composition of several fortifiers expressed per gram of protein varies both qualitatively and quantitatively [61]. In general, they contain bovine whey protein (intact or hydrolyzed), carbohydrates (mainly or exclusively glucose polymers or maltodextrins), minerals, and electrolytes such as sodium, calcium, phosphorus, and magnesium, and some also contain micronutrients and vitamins. The properties of human milk may be changed by nutrient fortification. Fortification may influence nutrient availability and may alter some biological properties of human milk. This is the result of the osmotic content of the fortifier but also of the rapid and continuous activity of human milk amylase on the dextrin content of fortifiers. High osmolality may induce abdominal discomfort and delayed gastric emptying. Recently, in order to avoid these problems, fortifiers with whole proteins, reduced carbohydrate content and fat supplementation have been proposed [61, 62]. The presence of fat in fortifiers has the advantage of increasing the energy intake of human milk without increasing osmolality values [62].

A review for the Cochrane collaboration concluded that the use of multinutrient fortifiers is associated with short-term improvements in weight gain and increments in both length and head circumference growth during hospital stay [62]. Although the fortification of human milk improves the general growth of preterm infants, growth of specific parameters such as LBM, fat mass, and bone mineral content is significantly lower in fortified human milk-fed infants than in those fed preterm formula [63]. These differences could be related to the lower protein content of human milk compared with hypothetical values used to establish fortification. Indeed, the variability in expressed human milk with respect to its protein and energy content is high. This variability may result in undernutrition after standard fortification method. A recent trial demonstrated that individualized fortification may optimize protein and energy intake [9]. Compared with standard fortification, individual fortification significantly reduces the variability in nutritional intakes, allowing the maintenance of protein intake and the PER in the range of the current recommendations. Further studies are advocated to verify the long-term effects of individualized fortification method.

When compared with premature infants fed preterm formula, infants fed exclusively fortified human milk had a significantly lower incidence of NEC and/or sepsis, had fewer positive blood cultures, and required less antibiotic administration [61]. When fortified human milk was evaluated under

simulated nursery conditions, bacterial colony counts were not significantly different after 20 h of storage at refrigerator temperature, but increased from 20 to 24 h when maintained at incubator temperature [61, 64]. In conclusion, early use of a human milk fortifier up to 1.3 g of protein per 100 ml may be recommended for more immature or smaller preterm infants, beginning from the time when they are able to tolerate 60–80 ml/kg/day of milk [12].

Expressed Donor Milk

Expressed donor milk can be foremilk or hind milk. These two types of milk, respectively, have lower or higher fat and energy contents than milk received by the breastfed infant [64]. Mature donor milk will have a lower protein sodium, zinc, and copper content than that of milk produced in early lactation. Feeding donor breast milk is classically associated with poor weight gain and growth restriction. However, analysis of available evidences revealed that most of the studies considered were 20–30 years old and from an era when donor breast milk was fed without fortification or mineral supplements, often as the sole diet. It is not clear whether similar effects would be seen when supplementation with fortifiers is adopted. Additionally, infant fed donor breast milk had a significantly reduced risk of NEC [52–54].

Treatment of donor breast milk (i.e., collection, store, froze, pasteurization, exposition to light,) may induce qualitative alteration [21, 22]. Breast milk in human milk banks is stored at low temperatures and subjected to thermal processing to guarantee its microbiological safety. Holder pasteurization (heating at 62.5 °C for 30 min and subsequent fast cooling) is the most frequent. Such pasteurization has been mainly assessed in terms of reduction in the activity of proteins of major biological relevance, such as immunoglobulins, lactoferrin, lysozyme, and GI enzymes such as lipase. It decreases fat and energy content of human milk [65]. Frozen storage at –20 °C of pasteurized milk further reduces fat, lactose, and energy content of human milk [21, 22]. These aspects may influence macronutrients and energy intake and may affect growth and neurodevelopment.

Breast milk transmission of human immunodeficiency virus (HIV) is considered an important mode of neonatal infection. Despite this fact, many researchers have observed that corresponding to the volume of milk consumed by the infant, maternal transmission via breast milk is still comparatively low. Some have noted the long latency period of breast milk HIV transmission with evidence of numerous anti-HIV factors in breast milk [66]. The presence of HIV or of other viruses in maternal milk seems to be a requisite to spur immunological defenses to optimize necessary protection to the infant. Because the only intervention to completely prevent HIV transmission via human milk is not to breast-

feed, the AAP recommends that HIV-infected mothers not breastfeed their infants regardless of maternal viral load and antiretroviral therapy. Despite the use of human breast milk from HIV-infected mother is not recommended in industrialized countries, an HIV-infected woman receiving effective antiretroviral therapy with repeatedly undetectable HIV viral loads may choose to breastfeed in particular circumstances. This rare condition generally does not constitute grounds for an automatic referral to child protective services agencies. Infant HIV infection status should be monitored by nucleic acid amplification testing throughout lactation and at 1, 3, and 6 months after weaning.

Some concerns about CMV infection in preterm infants receiving breast milk from seropositive mothers exist because CMV is excreted in breast milk in most lactating mother after a few weeks [67]. Differences in CMV acquisition from fresh or frozen milk have been suggested. Short-term high-temperature pasteurization techniques were found to prevent CMV transmission more effectively than freezing [68]. Cryotreatment preserves the nutritional quality of human milk, but unfortunately does not cancel the risk of CMV transmission. In contrast, compared with freezing, holder pasteurization and short-term heat inactivation for 5 s at 72 °C partially destroy the activity of some digestive enzymes, but contemporarily eliminates viral infectivity in milk in each stage of lactation [69]. Decisions about breastfeeding of VLBW infants by mothers known to be CMV-seropositive should be made with consideration of the potential benefits of human milk versus the risk of CMV transmission.

Preterm Formulas

When human milk is not available or limited, cow's-milk-based formulas for preterm infants must be used. Over the past 20 years, there has been a significant improvement in the nutrient composition of preterm formulas in order to meet the high nutritional needs of growing preterm infants. VLBW infants fed these formulas showed an improvement of fat absorption, nitrogen retention, bone mineralization, and weight gain, when compared to VLBW infants fed standard term formulas or pooled human milk [1]. Although numerous consensus conferences have been organized, the optimal formula for VLBW infants has not yet been designed. European preterm formulas present several differences in the nutrient composition when compared to American formulas [1, 5, 28]. The latter have a higher MCT and a lower LCPU-FA content, provide less lactose, and have a higher mineral intake. Nevertheless, according to more recent data, a general profile in macronutrients could probably be suggested. Energy content could be slightly higher than at present. Current recommendation for energy intakes are 110–135 kcal/kg/day for the ESPGHAN 2010 and 110–130 kcal/kg/day

for experts' panel. According to the protein requirements, the protein content would represent 3.2–3.6 g/100 kcal, that is, 2.4–3.2 g/100 ml [5]. Whey-predominant protein with reduced glycomacropeptide and α -lactalbumin enrichment could be used to optimize the amino acid profile [14, 21]. Up to now, the use of protein-hydrolyzed formulas has not been recommended [26, 70]. The partition of the nonprotein energy supply would favor the carbohydrate content up to 50–60% in view of its suggested benefits in sparing protein oxidation, enhancing growth and protein accretion as well as improving quiet sleep and influencing the distribution of behavioral activity states in VLBW infants. The remaining energy supply would be covered by fat with a fat blend carefully designed to reduce the long-chain saturated fatty acids content, and provide the essential fatty acids (LA and ALA) in an appropriate ratio as well as the LCPUFAs such as DHA and AA [34]. MCT could be used with a maximum of 30–40% of lipids content [5]. Highly metabolizable (50–60% absorption rate) calcium content would be limited to 100–120 mg/100 ml. According to the expected nitrogen and calcium retention, the phosphorus content of this formula would represent 55–65 mg/100 ml, considering phosphorus absorption close to 90%. Preterm formulas are available as powder or liquid in glass bottles or cans. Liquid formulas have the advantage that they provide sterile feeding thereby reducing possible infections reported in preterm infants fed powder formulas, such as by *Enterobacter sakazakii* [71]. Nevertheless, it worth remembering that with liquid formulas, there is frequent discordance between claimed and available content of several nutrients. For instance, part of the calcium content of liquid formula may precipitate on the wall of the receptacle reducing the calcium truly available to the preterm infants. In addition, the heat treatment necessary to sterilize the liquid formulas reduces the bioavailability of various nutrients such as proteins, calcium, or copper. In consequence, when human milk is not available, powder formulas allowing adaptation of nutrient density and being of higher nutritional value remain the formulas of choice for the feeding of VLBW infants.

Side Effects and Complications of Enteral Nutrition

Enteral nutrition could present side effects and complications including the risk of NEC and problems associated with the use of tube support for feeding. The risk of NEC could be reduced by employment of breast milk, early introduction of enteral nutrition, slow advancement (maximum 25–30 ml/kg/day), and careful check of the appearance of the first clinical and radiological signs of disease [12]. Contemporarily, the use of MEF in the VLBW newborns with the suspected signs of feeding intolerance may reduce the risk of

prolonged total parenteral nutrition and sepsis without additional risk for NEC [8].

Monitoring Effects of Artificial Nutrition on Growth

Anthropometric Measurements

Overall growth is monitored by anthropometry: measurement of body weight, length, head circumference, and, to a lesser extent, skinfold and arm circumference [73]. Anthropometric method to monitor growth and assess nutritional status in infants is rapid, inexpensive, and noninvasive. Body weight comprises the total mass of the infant's lean tissue, fat, and extracellular and intracellular fluid compartments. Weight gain or loss, reflects also changes in body composition. In utero, the fetus experiences a decrease in extracellular fluid volume and an increase in lean tissue and fat mass as gestational age increases. The initial postnatal weight loss is attributed to contraction of body water compartments and catabolism of endogenous glycogen, fat stores, and lean tissue in the absence of adequate energy and nutrients. Physiologic postnatal weight loss is 5–10% of total body weight. Maximum initial weight loss usually reaches its nadir by the 3–6 day of life and birth weight is usually regained by 7–10 days of age. Body weight should be measured daily to assess growth and fluid and electrolytes status in order to define optimal management. Once birth weight is regained, subsequent weight gain of 17–20 g/kg/day is desirable for infants up to 32 weeks PMA. Weight gain should be evaluated weekly to identify infants with average weight gains of <15 or >25 g/kg/day. Unfortunately, poor weight gain is common in infants with extreme prematurity or pathological conditions (chronic lung disease, severe intraventricular hemorrhage, NEC, and late-onset sepsis). Postnatal growth restriction is mainly due to insufficient nutritional support and can be avoided in most VLBW infants if they received recommended nutritional intakes [73].

Anthropometric measurements should be plotted on percentile growth curves for comparison against established reference data. Plotting weight on classic intrauterine growth charts can determine whether an infant is SGA (weight <10th percentile or <2 standard deviation score), AGA, or large for gestational age (LGA weight >90th percentile or >2 standard deviation score). Serial measures of growth and nutritional status are helpful in assessing response to nutrition support in hospitalized VLBW infants and to define if they develop a growth restriction. Growth restriction is usually defined for infants who cross (decrease) the percentile curves, when their standard deviation score decrease by more than 0.6 or 1.0, or if they become SGA. Using the growth chart, optimal weight for length is identified by finding the weight, which is ap-

proximately on the same percentile as the infant's length measurement. Current weight expressed as a percentage of optimal weight for length can be used to identify infants at risk for under- or overnutrition [72]. Term neonates use to accumulate significant fat mass during the first months of life, and it is not known whether preterm neonates need to accumulate the same amount of fat mass during their first months of life, which would be significantly different from fetuses of the same PMA. Despite most experts agree that low weight-for-length status correspond to growth restriction, it is not known what is the optimal weight-for-length status for preterm infant when they are plotted on intrauterine growth charts.

Neonates with a history of intrauterine growth restriction may have growth delays in weight, length, or head circumference. With symmetric or proportionate growth restriction, all parameters are affected, resulting in a greater risk of neonatal morbidity, future growth problems, and neurodevelopmental delay. In asymmetric growth restriction, only one parameter displays impaired growth. If weight is low compared with length and head circumference, catch-up growth may be expected. When head circumference is low compared with weight and length, neurological or developmental impairment may occur.

The type of growth charts used to assess anthropometric measures may influence these evaluations [72, 74–76]. The use of charts based on fetal growth until term (intrauterine curves) or on observed postnatal growth of preterm infants (longitudinal curves) should lead to different interpretations. The first describes how fetuses grow and a possible standard. The second represents how preterm infants actually grow and usually describes a postnatal growth restriction. In addition and after 36 weeks PMA, intrauterine charts usually demonstrate slower weight gain due to progressive placental insufficiency (late intrauterine growth restriction). Preterm infants do not describe similar weight gain at theoretical term that term neonate do with their initial physiologic weight loss. Therefore, it is not easy to monitor and to interpret preterm infants' growth after plotting anthropometric data on charts. To address these issues, the Fenton's charts were designed to commence monitoring infants at 22 weeks' PMA and continue for 10 weeks post term according to gender [74]. In particular, the use of gender-related growth charts reduces the false detection of intrauterine growth retardation in girls [75].

It is not easy to assess LBM and fat mass with classic anthropometric measurements, especially when edema or dehydration is present. Many tools have been tested to define better body composition. Regional anthropometry, triceps skinfold, and mid-arm circumference, or the ratios and formulae derived from these measurements, have been proposed as predictors of infant body composition. Standards are available for infants between 24 and 41 weeks gestation and can be used to compare those of an individual infant with reference values or to assess individual changes over time

[76]. However, intra- and inter-examiner measurement technique variability, critical illness, hydration status, and positioning of infants can contribute to measurement of errors. In addition, the use of calipers to measure triceps skinfold may not be feasible in extremely immature infants who have delicate, easily punctured skin. For these reasons, regional anthropometry is not routinely assessed.

Laboratory and Biomedical Tools

Serum nutrient levels can be used as markers of nutritional status in VLBW infants, but many factors not related to nutrition can alter laboratory results and must be considered when interpreting biological data. Technical factors, such as storage and processing of the specimen, type of laboratory method used, and technician accuracy, may affect the validity of laboratory tests. Blood urea nitrogen (BUN), a by-product of protein degradation, is frequently used to monitor protein intake in premature infant fed human milk after the first month of life [77]. However, BUN does not measure protein nutritional status but reflects dietary intakes, hydration status, renal function, and the presence of catabolism. Serum concentrations of transport proteins albumin, transferrin, prealbumin (transthyretin), and retinol-binding protein (RBP) have also been proposed as indicators of protein nutritional status [78]. Both albumin and transferrin have a longer half-life than prealbumin or RBP, thus serum concentrations of different transport proteins reflect different nutritional intake at different time periods. Prealbumin and RBP concentrations appear to correlate better with nitrogen balance during artificial nutritional therapy. Serum transferrin and RBP levels may be influenced by suboptimal iron, zinc, or vitamin A status. Low values of these proteins are usually described in premature infants during the first 3 months of life when compared to term infants suggesting insufficient nutritional support in premature infants. However, if transport protein concentrations are normal but growth is poor, nutritional supply needs to be increased to meet the nutritional demands of VLBW infants.

Alkaline phosphatase (ALP) is an enzyme predominantly produced in liver and bone. It may be elevated during normal growth conditions, liver diseases, or bone diseases. In preterm neonates an increase of ALP may suggest the presence of an osteopenia of prematurity secondary to calcium, phosphorous, magnesium, or vitamin D deficiencies [79]. As previously discussed, hypophosphatemia and hypercalciuria should also be regularly ruled out to avoid severe osteopenia.

Iron deficiency is frequent in premature infants and typically occurs after 4–8 weeks. Serum ferritin may be use as a good marker of iron store and values above 116 $\mu\text{g/l}$ are advised. Indeed, iron deficiency anemia and low ferritin stores below 75 $\mu\text{g/l}$ have been associated with nonoptimal developmental outcomes. Classical prevention strategy of iron

deficiency in preterm infants are delayed (30–120 s) cord clamping at birth and systematic 2–3 mg/kg/day supplementation from the 3rd week of life. On another side, excessive iron intakes may be toxic leading to some oxidative stress, increased risk of infection and retinopathy, and poor growth without any advantages on developmental outcomes. High ferritin concentration above 400 µg/l might be considered as iron overload, and iron intakes should be decreased [80].

Despite premature infants are at high risk for developing complications from deficiencies of zinc, vitamin B12, folate, vitamin E, and copper, laboratory tests used for diagnosis of vitamin deficiency are expensive and should be reserved to the infants at high risk of deficiencies such as malabsorptive diseases and long-term (>3 weeks) parenteral nutrition [81].

Advances in imaging techniques have allowed more direct in vivo measurement of body composition. Dual-energy X-ray absorptiometry (DEXA), requiring minimum radiation exposure (<0.3 mrem), has been successfully used for measurement of lean mass, fat mass, and bone mineral content in newborns. DEXA remains the most widely used method for the in vivo measurement of whole-body composition in humans. However, there are concerns on the accuracy in VLBW infants, especially in regard to determination of fat mass. In particular, the diagnostic power of this method for body composition determination depends on model of device, software, and scanning mode. These aspects limit the possibility to use DEXA reference ranges for preterm neonates. Nowadays, air displacement plethysmography has recently emerged as a noninvasive technique to determine body fat mass and fat-free mass in preterm infants [81, 82]. It is based on the measurement of body volume using gas laws, and several studies have confirmed the reliability and accuracy of air displacement plethysmography in animals, infants, and neonates [81]. Further validation of these techniques is advocated for routine use.

Post-discharge Nutrition in Preterm Infants

In most neonatal units, the discharge of VLBW infants usually occurs when premature infants reach 35–36 weeks PMA and/or a weight of about 1800–2100 g. By that time, they have frequently accumulated energy, protein, and mineral deficits and have developed a growth restriction. Additionally, they still present higher nutrient requirements than healthy term infants and premature infants born at the same PMA [83–85]. Protein- and mineral-enriched formulas have been proposed to feed preterm infants after discharge with the aim of minimizing as much as possible, postnatal growth restriction during the early weeks of life, inducing early catch-up growth and reducing the adverse effects of early malnutrition [83–85]. Energy intakes are the main determinant of milk volume intakes. Compared to regular (standard) formula, a simple increase in energy density without changes

in nutrients proportion had no influence on nutrients supply except in infants with limiting feeding self-sufficiency, not able to drink their quantity for several reason (bronchopulmonary dysplasia, cardiac insufficiency, neurologic insufficiency, “quickly tired” infants) [86]. In contrast, an increase in protein density with high PER influences protein intake and protein metabolism and a positive effect of growth parameters was not observed in all studies [83–85]. The benefit of the nutrient-enriched formula on VLBW infants’ growth was mainly seen during the early post-discharge period, between discharge and theoretical term (40 weeks PMA). This increased growth rate is observed in all preterm infants, even in those without postnatal growth deficit at the time of discharge. Additionally, there is a strong gender influence on the result of diet manipulation during the post-discharge period and the main positive results are more obvious in boys [87].

Considerable attention should be focused on specific nutrients, particularly calcium, phosphorus, iron, LCPUFAs, and vitamin A. Feeding post-discharge preterm infants formulas or human milk with greater concentrations of calcium and phosphorus than those contained in term formula improves bone mineralization, particularly if the special formulas used during hospitalization are continued after hospital discharge [88]. However, the relative osteopenia of VLBW infants observed at the time of hospital discharge usually improves spontaneously in most VLBW infants after discharge, in a manner similar to that induced by the acceleration of growth at the first stage of adolescence. Therefore, provision of large amounts of calcium and phosphorus for long periods may not be necessary. With regard to vitamin D intake, there is no evidence that preterm infants should receive greater doses than term infants to maintain a normal plasma vitamin D concentration after discharge [89]. Body iron stores are highly variable at discharge, so it is important to screen for iron deficiency at discharge and during the first year of life [49]. Scientific Societies recommend that preterm infants receive iron supplements for up to 1 year after discharge [49]. Preterm infants fed human milk should receive an iron supplement of 2 mg/kg/day by 1 month of age, and this should be continued at least until the infant is weaned to iron-fortified formula or begins eating complementary foods that supply 2 mg/kg/day of iron. Infants who have received iron loads from multiple transfusions of packed red blood cells may not require supplements. LCPUFAs need to be added in VLBW infants’ feeds to improve brain development and the retina in particular [83–85]. Vitamin A status may be suboptimal in formula-fed VLBW infants for many months after discharge. Contrasting data exist regarding the utility of aggressive enteral supplementation with vitamin A (3000 IU/day) after discharge. At the moment, additional studies are needed to determine the dose and duration of vitamin A supplementation that allows infants to reach full repletion values [83–85].

Growth at 4 and 12 months and mineralization at 4 months after discharge are better in VLBW infants fed preterm formula during the first 2 months after discharge than in those fed term formula [83–85]. Protein and nutrient-enriched formula provided after term seems to improve the quality of growth in preterm infants. Infants fed nutrient-enriched formula have lower fat mass, corrected for body size at 6 months' corrected age, than infants fed standard formula or human milk. Preterm infants fed nutrient-enriched formula after discharge exhibit an increase in LBM and peripheral fat mass but not central adiposity compared with infants fed term formula. These data indicate that nutrient-enriched formulas do not promote central adiposity in preterm infants, a feature that is associated with metabolic syndrome later in life.

Even if low protein intakes and poor growth during initial hospitalization in VLBW infants has been associated with poor adverse developmental outcomes, the safety of prolonged high-protein intake in preterm infants after discharge has not been completely established [27]. Thus, further studies are necessary to address this crucial safety aspect. Since early nutrition should not only be considered simply in terms of weight gain but also for the biological effects with possibly lasting or lifelong significance, it seems prudent to suggest an enriched formula only in infants at risk of future growth failure.

Among the preterm infants, not all are at similar risk of later growth failure and adverse developmental outcomes after discharge. SGA infants and preterm infants who have developed a postnatal growth restriction seem to be the population at higher risk, boys in particular. In these infants, breastfeeding should always be promoted with or without a transient fortification of expressed-human milk up to 40–52 weeks PMA. If breastfeeding is not possible, a preterm formula or a special post-discharge formula that contains more protein, minerals, trace elements, and LCPUFAs should be preferred to a standard term formula until the preterm infant reaches between 40 and 52 weeks PMA to improve catch-up growth. AGA infants without growth restriction at the time of discharge from the hospital usually continue to maintain appropriate growth. In these infants, exclusive breastfeeding should be encouraged at discharge and if not possible, a term infant formula with relatively low protein density (2.2 g/100 kcal) should be provided with particular attention to its LCPUFAs, mineral and trace element content.

In conclusion, breastfeeding should always be encouraged in all preterm infants after discharge. In those with high risk of longitudinal growth restriction, fortified human milk or enriched formula (protein, energy, LCPUFA, micronutrients) may also be added to breastfeeding in order to improve the nutrient supply and to promote catch-up growth [83–85]. Immediately discharge, growth should be monitored weekly to adapt feeding and to avoid growth failure, especially in VLBW infants.

Introduction

Major improvements have been made in neonatal care during the past decade leading to a dramatic decrease in neonatal mortality [1]. The impact of perinatal undernutrition on growth and brain development has been well known for years from both human and animal studies [2–5]. In premature infants, reports also suggest that postnatal protein and energy malnutrition increase the severity of postnatal diseases and induce postnatal growth restriction, inadequate brain development, and poor neurodevelopmental outcomes [3, 6–12].

During the early days or weeks of life, parenteral nutrition (PN) is frequently required in premature infants, especially in very low birth weight (VLBW, <1500 g) infants, due to the immaturity of their gastrointestinal tract. Despite recent recommendations from scientific experts, PN practices are currently nonoptimal [13–15]. A recent survey in the UK observed a high variability in PN composition, supply, and administration in the health-care organization and in the quality assurance [15]. A “good standard of care” was only observed in 24% of cases with frequent delay in recognizing the need for PN (28%), delay in the administration of PN (17%), inadequate intakes for needs (37%), inadequate monitoring

(19%), and few multidisciplinary nutritional team [15]. In addition, Lapillonne et al. [14] recently demonstrated that neonatal unit PN protocols were rarely compliant with international guidelines, particularly during the first days of life. Such practices lead to severe cumulative nutritional deficits and postnatal growth restriction that may be considered as iatrogenic malnutrition [13].

Several recent reports have evaluated how to optimize PN support in premature infants [16–24]. This chapter discusses the most important features regarding PN in premature infants, outlining most recent practical aspects and guidelines.

The Standard for Premature Infants Growth

Optimal growth for premature infants is generally defined as similar to that of the fetus of similar gestational age (GA) up to the due date and similar to that of the breast-fed term infant afterwards [25–27]. Fetal growth rate is extremely high during the third trimester of gestation and much greater than during any other periods of life (Fig. 7.1). If the mean fetal weight gain during the last trimester of gestation is around 15 g/kg/day, it must be emphasized that fetal weight gain usually decreases from ~20 g/kg/day at 24–28 weeks of gestation to ~10 g/kg/day at 39–40 weeks [27]. The body weight composition also changes during the last trimester of pregnancy explaining why nutritional requirements also vary in relation to postmenstrual age. Even if these concepts are well accepted, they are not easy to apply in clinical practice due to the major differences observed between the intrauterine and the extrauterine physiology. Postnatal growth is physiologically associated with an increase in fat-mass deposition. Therefore, it has been suggested that lean body mass (LBM) gain should be regarded as the gold standard reference for growth in premature infants [28, 29].

Nutritional Support in Premature Infants

Nutrition of VLBW infants may be divided into two distinct periods: the immediate adaptive or “transitional” period during the first 3–7 days of life and a stable “growing” period up to discharge from the neonatal intensive care unit (NICU). Depending on birth weight (BW) and GA, the transitional period including the immediate postnatal adaptation of the premature newborn to the extrauterine environment may be prolonged, particularly in the more vulnerable infants with major clinical disorders. The more premature a neonate is the more challenging is the influence of the immaturity and the accompanying morbidity on the nutritional supply [13, 14, 30, 31]. During this period, most of these infants require PN as their major source of nutrients despite frequent initiation of enteral nutrition. Recently, several studies have highlighted the importance of reducing the transitional period by rapidly providing sufficient intakes to promote anabolism and to reach stable-growing requirements [16–18, 20, 21].

Energy

Postnatal Energy Metabolism

The Atwater’s factors are usually used to calculate the metabolizable energy contents and intakes both in PN and enteral nutrition. However, the energy available from macronutrients is not exactly similar. The gross energy content of 1 g of amino acid (AA, ~4.75 kcal/g) is about 10% lower than that of 1 g of protein (~5.25 kcal/g). By contrast, the energy provided after oxidation of AA in urea is ~3.75 kcal/g, whereas the energy of AA stored in protein is ~4.75 kcal/g, a value identical to gross energy. Gross and metabolizable energy content of glucose (~3.75 kcal/g) is less than that of more complex carbohydrate (~4 kcal/g). For intravenous lipid emulsions (IVLE), metabolizable energy content is also similar to gross energy (~10 kcal/g including glycerol energy content) but could be lower in IVLE containing medium-chain triglycerides (MCT) [32, 33]. These differ-

Table 7.1 Advisable nutritional intakes for premature infants requiring parenteral nutrition

	Initial dose after birth	Target dose
Amino acids (g/kg/day)	2–3	3–4 3.5–4.5 (VLBW)
Glucose (g/kg/day)	6–7	12–17
Lipids (g/kg/day)	1–2	3–4
Energy (kcal/kg/day)	40–60	95–125
Water (mL/kg/day)	60–90	120–180
	80–100 (ELBW)	
Sodium (mmol/kg/day)	0–1	3–5 3–7 (VLBW)
Potassium (mmol/kg/day)	0–1	2–3
Chloride (mmol/kg/day)	0–1	3–5
Calcium (mmol/kg/day)	0.6–1	1.6–2.5
Phosphorus (mmol/kg/day)	0.6–1	1.6–2.5
Magnesium (mmol/kg/day)	0.1–0.2	0.2–0.4

ELBW extremely low birth weight infants (<1000 g), *VLBW* very low birth weight infants (<1500 g)

ences are not easy to incorporate into practice. This explains why energy requirements in PN are close to that in enteral nutrition when the Atwater's factors are used.

The energy requirements for premature infants correspond to the sum of total energy expenditure plus the energy stored in the new tissue with growth. Energy expenditure measured by indirect calorimetry increases slightly with postnatal age and varies from 45 to 55 kcal/kg/day. The energy cost of growth implies making allowance for fetal LBM accretion, postnatal fat deposition, and the cost of tissue deposition. The energy cost for a postnatal weight gain of 17–20 g/kg/day with adequate LBM accretion vary from 50 to 70 kcal/kg/day in premature infants. Therefore, metabolizable energy requirements for premature infants on PN are estimated to be between 95 and 125 kcal/kg/day [32, 34, 35]. Taking into account the potential need for a prior energy deficit and for catch-up growth, 120 kcal/kg/day is required for most premature infants.

Recommendations for Energy Supply During Total P N

Current recommendations suggest providing a minimum of 40–60 kcal/kg/day on the first day of life followed by a rapid increase of energy intakes up to 95–125 kcal/kg/day within the first week of life. This needs to be adjusted according to growth and metabolism during the stable growing period (Table 7.1).

Recommendations for Energy Supply During Partial PN

Nutritional recommendations include early introduction of enteral feeding in premature infants [36]. However, minimal feeding below 25 mL/kg/day mainly serves as trophic gut feeding. It may not be well absorbed, and therefore, it should not be considered in the total energy intakes. Thereafter, when feeding increases above 40 mL/kg/day, total energy intakes would be calculated as the sum of the parenteral and the enteral intakes taking into account an energy absorption rate of 80% with human milk and 90% with preterm formula [16, 33].

Amino Acids

Intravenous AA Solutions

Considerable improvements in intravenous AA solutions have been achieved since the 1960s. Specific pediatric AA solutions were designed in the early 1990s with high essential and conditionally essential AA content for use in premature infants [28]. Three different standards of AA profile have been suggested for premature infants: umbilical fetal cord blood AA during last trimester of gestation, healthy breast-fed term infant's plasma AA, and human milk AA composition. Due to the poor solubility of tyrosine and cystine, current AA solutions have some relative AA imbalance compared to enteral nutrition. The ideal intravenous AA mixture for PN in premature infants is still a matter of debate. Nevertheless, biochemical tolerance and nitrogen utilization in infants do not change significantly despite the different compositions of current pediatric intravenous AA solutions [28, 37, 38].

Postnatal AA Requirements

Fetal protein accretion is estimated around 2–2.5 g/kg/day during the last trimester of gestation [39]. Isotope studies in animals and in human fetuses have demonstrated that fetal AA not only are used for protein synthesis but also serve as an energy source by oxidation [40]. The fetal AA uptake during the last trimester of gestation has been estimated to be between 3.5 and 4.5 g/kg/day up to term [41, 42]. Similarly, Postnatal nitrogen balances in premature infants on PN have shown that an AA intake above 1.5–2.0 g/kg/day from the first day of life allows the infants to avoid a negative nitrogen balance. Thereafter, during the stable growing period, AA intake between 3.5 and 4.5 g/kg/day enables infants to obtain a nitrogen retention between 360 and 400 mg/kg/day, similar to fetal accretion [16, 32, 39, 43, 44]. In addition,

an AA intake as high as 2.5–3.5 g/kg/day from the first day of life with current available intravenous AA solutions improves nitrogen retention, protein synthesis, insulin secretion, glucose tolerance, and early postnatal growth without inducing metabolic disturbances and adverse effects [20, 45–50]. In a recent cohort study, Senterre and Rigo demonstrated that providing such AA intakes with a well-balanced PN solution from the first day of life was not only feasible but also improved electrolyte and minerals homeostasis during the first 2 weeks of life, thereby reducing postnatal cumulative nutritional deficits, and may abolish postnatal growth restriction at discharge [17, 21, 47, 51].

Despite any evidence, several concerns persist about potential toxicities of such high AA intakes. The association that has been described between PN and metabolic acidosis is not related to early high AA intakes but is mainly due to imbalance in the electrolyte content in PN solutions [49, 52–54]. Uremia, or blood urea nitrogen (BUN), is frequently used to evaluate the adequacy of protein intakes in infants considering that BUN reflects protein degradation and AA oxidation. However, in VLBW infants during the first 2 weeks of life, BUN is poorly related with AA intakes and mainly reflects renal immaturity and hydration status [48, 55]. Indeed, BUN is highly correlated with plasma creatinine concentration and postnatal increase of BUN is inversely related to GA and BW and normalizes progressively during the first month of life [48, 56]. Therefore, high BUN cannot be used as a marker of protein or AA overload during the first week of life in premature infants.

Recommendations for AA Supply

Practical recommendations for premature infants on PN are to provide 2–3 g/kg/day of AA on the first day of life and to rapidly increase AA intake up to 3–4 g/kg/day within 2–3 days in moderately premature infants and to 3.5–4.5 g/kg/day in VLBW infants (Table 7.1).

Carbohydrates

Intravenous Carbohydrates Solutions

Glucose is the only intravenous carbohydrate used for nutritional support with the exception of the glycerol content in IVLE. Early provision of carbohydrate supply is required to prevent hypoglycemia in premature infants. Glucose is readily available for brain metabolism and represents its main source of energy during PN.

Postnatal Glucose Metabolism

Early postnatal glucose infusion is essential in VLBW infants and an intake of 6–7 g/kg/day (4.2–4.9 mg/kg/min) is necessary to prevent early postnatal hypoglycemia resulting from the interruption of the materno-foetal glucose transfer and the low glycogen reserves of premature infants [34, 57, 58].

After birth, glucose metabolism is frequently impaired and VLBW infants are not only at risk of early hypoglycemia but are also prone to hyperglycemia, in particular during PN. The incidence of hyperglycemia increases with prematurity and has been associated with insulin resistance, persistence of glucose production, and clinical disorders like sepsis or pain. In VLBW infants, the mechanisms for glucose homeostasis are still immature. The endogenous glucose production is not completely suppressed by glucose intakes and the maximal glucose oxidation rate is generally limited to 17 g/kg/day (11.8 mg/kg/min) or less in critically ill VLBW infants [34, 42, 58, 59].

Hypo- and Hyperglycemia in Premature Infants

The definition of hypo- and hyperglycemia, as well as long-term consequences of glucose metabolism disorders, remains controversial in neonates. Reference plasma glucose concentrations are generally defined between 2.6 mmol/L (0.47 g/L) and 6.6 mmol/L (1.2 g/L). In premature infants, hypoglycemia is always a metabolic emergency that needs to be rapidly corrected with 200 mg/kg glucose slow bolus infusion (2 mL/kg of 10% glucose solution) and by increasing the nutritional intakes.

In contrast, while on PN and due to the continuous glucose infusion rate, the highest reference plasma glucose concentrations needs to be adjusted. A plasma glucose concentration up to 10 mmol/L (1.8 g/L) is usually well tolerated without significant adverse effects. When faced with high plasma glucose concentrations, the first step is to evaluate the various contributing factors and to try to correct them (high glucose and energy intakes, hypophosphatemia, stress, sepsis, pain, dehydration, and steroid treatment). Glycosuria also needs to be ruled out to avoid osmotic diuresis, dehydration, and plasma hyperosmolarity [57, 59].

In the case of persistent hyperglycemia during the early transitional and the stable-growing periods, glucose intakes might be initially reduced by 10–15% for a transient period of time. Nevertheless, high AA intakes and high protein to energy ratio are important contributing factor to improve glucose tolerance and decrease the incidence of hyperglycemia. Additionally, considering that adequate protein and energy intakes need to be maintained to avoid nutritional deficits and postnatal growth restriction, insulin treatment could be required when hyperglycemia persists above 10 mmol/L

(1.8 g/l) or if it occurs with glucose intakes below 12–14 g/kg/day (8.3–9.7 mg/kg/min) during the stable-growing period. The initial dosage should be between 0.02 and 0.05 IU/kg/h and needs to be adjusted to avoid hypoglycemia. To adapt insulin infusion rate, the time necessary to adjust the plasma insulin concentration needs to be factored in during the correction of glycemic perturbations, in particular, to avoid any iatrogenic hypoglycemia [59, 60].

Recommendations for Glucose Supply

In premature newborns and especially in VLBW infants, 6–7 g/kg/day (4.2–4.9 mg/kg/min) glucose infusion should be started as soon as possible to avoid hypoglycemia. Afterwards, intakes may be gradually increased during the transitional period up to 12–17 g/kg/day (8.5–11.8 mg/kg/min) according to tolerance in order to provide adequate energy intakes (Table 7.1). The maximum glucose intake should not exceed the maximum glucose oxidation rate and more than 60–75% of the nonprotein energy intakes.

Lipids

Intravenous Lipid Emulsions

IVLE are important constituents of PN because they are the only source of essential fatty acids: linoleic acid (LA, C18:2n-6) and alpha-linolenic acid (ALA, C18:3n-3). IVLE also represent a high-density energy substrate that can be readily utilized. They are isotonic and can be easily infused in peripheral veins [34].

Initially, IVLE were only based on soybean oil which contained about 45–55% LA, 6–9% ALA, and very little saturated or monounsaturated fatty acids. Although apparently safe, experimental reports and clinical studies indicate that these purely soybean-based IVLE could exert an oxidative stress, a negative influence on immunological functions, and a role in PN-associated liver disease. These findings were related to its absolute high polyunsaturated fatty acids (PUFA) content favoring lipid peroxidation and the relative excess of n-6 PUFA favoring pro-inflammatory effects [10].

Newer IVLE have been developed and differ by their fatty acids content and sources: soy, safflower, coconut, olive, and/or fish oil [10, 61, 62]. Composition of IVLE available for clinical use is shown in Table 7.2. These new IVLE have a smaller proportion of soybean oil. MCT are frequently added as they may be preferentially metabolized even if they provide less energy than long-chain triglycerides (LCT). Indeed, structured MCT/LCT emulsions formulated from a random combination of triglycerides synthesized on the same glycerol carbon chain have a less tendency to accumulate in the

reticuloendothelial system and are cleared faster from blood in moderately catabolic patients. The addition of olive oil provides derived n-9 monounsaturated fatty acids that are less immunosuppressive and inhibits pro-inflammatory cytokine's release. Olive oil is also less susceptible to peroxidation and well tolerated in critically ill neonates. Fish oil provides predominantly n-3 PUFA and improves PN-associated liver disease. However, it lacks some essential fatty acids and needs to be used as a supplement or manufactured as physical oils mixture (10% fish, 40% soy, and 50% MCT or 30% soy, 30% MCT, 25% olive oil, and 15% fish) [10, 61–63].

Direct comparisons between purely soybean-based IVLE to some of the more recent IVLE have shown several disadvantages for purely soybean-based IVLE [10, 62–64]. A recent systematic review suggests that these IVLE are deleterious to VLBW infants by increasing the incidence of sepsis [62]. Therefore, it seems logical that the routine use of purely soy-based IVLE for VLBW infants should be abandoned [62–64]. Recent studies comparing IVLE containing fish oils to exclusive soybean IVLE have demonstrated several benefits from increasing n-3 PUFA intakes, which include a reduction of oxidative stress, liver diseases, and severity of retinopathy of prematurity [63, 65–68]. Although promising, more research is required to determine the advantages of these newer IVLE with fish oil compared to other mixed IVLE and the safety of providing as much eicosapentaenoic acid as docosahexaenoic acid and no arachidonic acid in premature infants [63].

Postnatal Lipid Metabolism

Lipid oxidation depends on lipid intakes, energy intakes, and energy needs for metabolism. During PN, lipid oxidation is inversely related to glucose intakes that promote lipid storage. Carbon dioxide production is lowered when a part of energy intakes is provided by IVLE instead of a high proportion of glucose. Maximum lipid oxidation in neonates usually occurs when IVLE intakes provide 40% of nonprotein energy intakes, corresponding to 1 g of lipid for 3.6 g of glucose. Additionally, it has been suggested that nitrogen retention could also be improved by adding IVLE to PN [34].

In the past, many pediatricians have expressed concerns about IVLE in neonates due to perceived potential adverse effects. However, recent studies do not support these concerns, especially with the most recent IVLE, which can be used from the first days of life [18, 34, 62, 69]. Continuous lipid infusion is generally preferred in neonates, and plasma triglyceride levels need to be monitored to avoid hyperlipidemia, particularly in VLBW infants, in small for gestational age (SGA) infants, and in neonates with high lipid intakes, hyperglycemia, sepsis, hypoxemia, or severe hyperbilirubinemia. Even if there are some controversies about the level of maximal plasma triglycerides tolerance in premature infants because high concentration may be deleterious, there is general consensus that lipid intakes should be reduced when plasma triglycerides concentrations exceed 2.85 mmol/L (250 mg/dL) during continuous IVLE infusion [34].

The use of carnitine supplementation during PN in premature infants is still controversial. Carnitine is necessary for the transportation of long-chain fatty acids through the mitochondrial membranes and the lipids metabolism. Its synthesis and storage are insufficiently developed at birth particularly in premature infants and carnitine is not available through commercial intravenous solutions. In parenterally fed infants, plasma and tissue carnitine levels decline with postnatal age suggesting that carnitine supplementation could be necessary [70]. However, a meta-analysis based on 14 randomized controlled studies showed no effect of carnitine supplementation on lipid metabolism, lipogenesis, or weight gain suggesting that up to now, there is no evidence to support the systematic addition of carnitine supplementation during short-term (<3 weeks) PN in preterm infants. In newborns who require prolonged PN of more than 2 weeks, carnitine supplementation at a dose of 10–20 mg/kg/day could be suggested [63, 71].

Recommendations for Lipid Supply

Lipid intakes during PN should represent 25–40% of non-protein energy intakes in order to promote lipid oxidation and to reduce lipid deposition in fat mass. Current recommendations encourage the provision of IVLE as soon as possible after birth in all premature infants at dosage of 1–2 g/kg/day. Thereafter, IVLE need to increase by 0.5–1 g/kg/day up to 3–4 g/kg/day during the transitional postnatal period according to metabolic tolerance (Table 7.1).

Fluids and Electrolytes

Postnatal Fluid and Electrolytes Metabolism

Birth is associated with major changes in fluid and electrolytes homeostasis. Water as part of the body composition

significantly decreases. This is due to physiological contraction of the extracellular compartment. It leads to the so-called postnatal physiological weight loss of the newborn [72].

Compared to term infants, premature infants are characterized by higher transcutaneous and insensible water losses. Due to their renal immaturity, urine output and fractional sodium excretion might also be deregulated. Therefore, fluid and electrolytes disturbances are frequently observed and are associated with increased morbidity, mortality, and adverse developmental outcomes, especially in VLBW infants [54, 73–75]. In particular, dehydration (weight loss above 10%) combined with or without inadvertent increase sodium intake frequently induces severe hypernatremia above 150 mmol/L and brain injuries [54, 74, 76–78]. On the other hand, excessive water intake and relative hyponatremia below 130 mmol/L might also compromise cardio-respiratory functions and induce brain injuries in premature infants. Fluid overload is associated with patent ductus arteriosus, bronchopulmonary dysplasia, necrotizing enterocolitis, and long-term adverse outcomes [34, 79].

Catabolic state induced by insufficient protein and energy intakes during the first week of life can also induce non-oliguric hyperkalemia. Hyperkalemia can also be potentiated by dehydration, renal failure, and postnatal use of nonsteroidal anti-inflammatory drugs (indomethacin, ibuprofen) to treat patent ductus arteriosus [80, 81].

In order to reduce the occurrence of fluid and electrolytes disorders, previous recommendations were to provide 90–120 mL/kg/day of water on the first day of life and to progressively increase intakes up to 140–180 mL during the stable-growing period [34, 58, 74]. In addition, it was also advised to postpone sodium and potassium supplementation until after 48 h of life or after the increase of urinary output over 1.5 mL/kg/h [34, 58, 74].

Recent studies, however, suggest that optimizing early PN intakes from the first hour of life positively influences postnatal fluid and electrolytes homeostasis [47, 82, 83]. By optimizing early AA and energy intakes combined with early electrolytes supplies from the first day of life with a reduction of insensible water losses, it is possible to limit postnatal weight loss to 6–7% and to regain BW after 7 days on average in both VLBW and extremely low birth-weight (ELBW, <1000 g) infants, [21, 51]. Such strategy also improves the electrolyte homeostasis during the first 2 weeks of life decreasing dramatically the incidence of hypernatremia and non-oliguric hyperkalemia in VLBW infants [47, 82, 83]. As a result of early induction of an anabolic status, the new strategy could induce a “new” metabolic disorder during the first days of life, especially in SGA and VLBW infants, in the form of hypophosphatemia and hypokalemia and sometimes hyponatremia and hypercalcemia [19, 47, 84–88]. These studies suggest that actual optimized PN strategy needs to be accompanied by an increase in early electrolyte and mineral intakes during the first days of life to ensure a complete bal-

anced PN solution from the first day of life in VLBW infants [16, 21, 47, 89].

Chloride homeostasis is also important in premature infants because imbalance between sodium, potassium, and chloride intakes may promote metabolic acidosis or alkalosis [49, 47, 72]. Chloride requirements are generally considered similar to sodium requirements and pediatricians frequently do not control chloride intakes transferring chloride content in PN to the authority of the pharmacist. Hidden chloride intakes are frequent and combined with many other intakes like sodium, potassium, calcium, AA, and also in some drugs like dopamine and dobutamine. Therefore, as a result of the poor ability of the premature kidney to eliminate acid load, an excessive chloride intake frequently induces metabolic acidosis. Thus, limiting chloride intakes and providing sodium and potassium intakes as organic phosphate or as sodium or potassium acetate/citrate in PN preparation might prevent hyperchloremic metabolic acidosis [49, 47, 54, 72, 90–94].

Postnatal Fluid and Electrolytes Monitoring

Rigorous monitoring of fluid and electrolyte homeostasis is required during the first week of life for all premature infants, especially VLBW and ELBW infants with high insensible water losses. The idea is the close assessment of fluid and electrolyte balance every 6–12 h during the first days of life to monitor intakes, urinary output, and body weight. Prevention of excessive insensible water losses is essential to maintaining fluid and electrolyte homeostasis. Insensible water losses can be easily estimated by subtracting from the total fluid intakes the weight change and the urinary output in order to adapt fluid intakes. Additionally, excessive urine output above 5 mL/kg/h needs to be rapidly compensated volume for volume with 0.45% sodium chloride infusion to balance water and sodium losses. Excessive sodium intakes from medications should be controlled to avoid any sodium overload and hypernatremia [54, 76–78]. In VLBW infants, urine sodium fractional excretion is high due to immature kidney functions. Regular determination of plasma and urine electrolyte concentrations may also be helpful to adjust intakes.

Recommendations for Fluid and Electrolytes Supply

Current recommendations advocating for revisions are based on the most recent publications. Our suggestion is to provide an initial fluid supply on the first day of life at 60–80 mL/kg/day in VLBW infants and 80–100 mL/kg/day in ELBW infants combined with double wall incubator and high-humidity environment. Then, fluid supply should be increased

progressively with careful monitoring of hydration, allowing for a weight loss of 5–10% during the first 3 days of life. A target fluid intake of between 120 and 160 mL/kg/day is estimated to maintain adequate fluid and electrolyte homeostasis and an appropriate weight gain (Table 7.1).

For sodium and potassium, an initial intake of around 1 mmol/kg/day is currently recommended on the first day of life to match an optimized high protein and energy intake from birth. Thereafter, intakes should be increased up to 3–5 mmol/kg/day for sodium (up to 7 mmol/kg/day in VLBW infants) and 2–3 mmol/kg/day for potassium in order to meet requirements for growth (Table 7.1).

For chloride, an intake of around 1 mmol/kg/day is recommended on the first day of life, then 3–5 mmol/kg/day afterwards assuming the maintenance of a positive difference of 1–2 mmol/kg/day between the sum of sodium and potassium intakes and chloride intakes ($\text{Na} + \text{K} - \text{Cl} = 1 - 2$ mmol/kg/day). The use of acetate or lactate (1–2 mmol/kg/day) instead of chloride in PN could be helpful to prevent hyperchloremia and metabolic acidosis (Table 7.1).

Minerals: Calcium, Phosphorus, and Magnesium

Minerals Sources

In contrast to enteral nutrition, calcium and phosphorus in PN are directly available for metabolism. Calcium may be provided in the form of calcium gluconate, calcium chloride, or calcium glycerophosphate. Due to aluminum contamination, calcium gluconate is now being progressively phased out by the industry to meet the rule of < 5 $\mu\text{g}/\text{kg}/\text{day}$ of aluminum exposure in infants but it still remains frequently used in homemade hospital pharmacy preparations [95, 96]. Calcium chloride is easy to use but its high chloride content needs to be considered in the electrolytes balance of the PN solution. Calcium glycerophosphate with one to one calcium to phosphorus ratio (mmol/mmol) is an adequate source but is not registered for use in PN and need to be prescribed from powdered anhydrous calcium glycerophosphate.

Phosphorus may be provided in the form of inorganic (sodium and potassium phosphate) or organic salts (glucose 1 phosphate, fructose 1–6 diphosphate, sodium glycerophosphate). Thus, phosphorus intake is also associated with sodium or potassium intake. Inorganic potassium phosphate induces a risk of precipitation that limits its use in PN. Organic phosphorus salts and especially disodium glucose-1-phosphate are widely used in PN solutions. However, their sodium content limits their utilization for premature infants, especially during the first days of life. Frequently, potassium salts could be preferred to sodium salts and used as the unique source of potassium in the PN solution.

Magnesium is generally provided as magnesium sulfate because magnesium chloride could induce anionic–cationic imbalance with the risk of metabolic acidosis.

Postnatal Mineral Metabolism

Calcium and phosphorus fetal retention is high during the last trimester of gestation: 2.3–3.2 mmol/kg/day (90–130 mg/kg/day) and 2.4–2.7 mmol/kg/day (65–75 mg/kg/day), respectively. Magnesium fetal accretion is lower at 0.12–0.20 mmol/kg/day (2.9–4.8 mg/kg/day). Due to the interruption of placental transfer at birth and the high metabolic demand, a decrease in blood minerals concentrations may be rapidly observed. In particular, it is well known that early hypocalcemia may rapidly occur during the first days of life due to the relative immaturity of hormonal control [97]. Therefore, minerals need to be provided from the first day of life [97, 98].

In addition to its implication in bone metabolism, phosphorus also plays a critical role in energy metabolism and severe deficiency may induce several clinical disorders including muscle weakness, delay in weaning from respiratory support, glucose intolerance, and nosocomial infections [88, 97, 98]. VLBW infants and SGA premature infants are particularly at risk for early hypophosphatemia due to their limited store and their high needs for growth. Recently, it has been shown that severe hypophosphatemia is frequently observed in VLBW infants and is potentiated by optimized AA intakes. These observations linking hypophosphatemia and hypokalemia have been interpreted as resulting from a potential refeeding-like syndrome [19, 47].

Reference values for hypophosphatemia differ in adults (1.0 mmol/L, 3 mg/dL) and in preterm infants (1.6 mmol/L, 5 mg/dL) [97]. Unfortunately, most pediatricians are unaware that most laboratories use adult reference of plasma phosphate concentration in VLBW infants. Therefore, the diagnosis of hypophosphatemia may be easily missed with the risk of hypercalcemia, hypercalciuria, osteopenia, and nephrocalcinosis [97, 98].

Optimal calcium to phosphorus ratio differs in parenteral and enteral nutrition due to the bypass of the gastrointestinal tract with PN. Phosphorus retention is related to not only bone mineralization with a 1.7 calcium to phosphorus ratio (mmol/mmol) but also LBM accretion with the deposition of nearly 0.3 mmol (10 mg) of phosphorus for 1 g of protein accretion [97, 98]. Therefore, considering the high phosphorus requirements for LBM accretion when optimizing growth with high protein and energy intakes, early provision of calcium and phosphorus are necessary from the first day of life and the optimal calcium to phosphorus ratio on PN is probably between 0.8 and 1.0 (1–1.3 w/w) [16, 17, 47, 85].

Optimal magnesium requirements are not well defined for preterm infants on PN, and little attention is generally

focused on postnatal magnesium homeostasis in neonates unless hypomagnesemia below 0.66 mmol/L (1.6 mg/dL) occurs in association with persistent and refractory hypocalcemia. Until recently, plasma magnesium determination was rarely included in the routine biochemical evaluation of premature infants on PN. Like for phosphorus, reference values of serum magnesium provided by laboratories are frequently the adult reference values (0.6–1.0 mmol/L). Recent studies in premature infants during the first 2 weeks of life showed that their reference values are significantly higher than adult reference values and are estimated to be between 0.75 and 1.5 mmol/L. These studies also suggest that plasma magnesium concentrations are related to magnesium intakes, BW, and GA. Magnesium concentrations are also increased in cases of relative renal failure and in infants of mothers that have received magnesium sulfate before delivery. Some other studies have shown that antenatal magnesium sulfate administration prior to delivery might be neuroprotective for premature infants [99, 100]. In those infants, the postnatal magnesium concentrations are higher than that of controls and are frequently between 1.4 and 1.8 mmol/L without demonstrating any adverse effects. This finding tends to suggest that such a level could not be considered as deleterious when renal function is normal. In fact, clinical symptoms with central nervous system depression and hypotonia are generally not observed with a magnesium concentration below 2.0–2.5 mmol/L [97].

Current recommendations for magnesium intakes are based on fetal accretion and on enteral metabolic balance studies suggesting that magnesium retention accounted for 60–70% of the absorbed magnesium. With such data, magnesium requirement for premature infants on PN is estimated between 0.2 and 0.3 mmol/kg/day in several international recommendations [34, 58]. Besides, some other authors have suggested that higher intake of between 0.3 and 0.4 mmol/kg/day may be needed [101–103]. Additional studies are required to better define magnesium requirements in VLBW infants.

Recommendation for Mineral Supply

With the most recent data on VLBW infants receiving optimized PN, on the first day of life, we recommend providing 0.6–1 mmol/kg/day of calcium (25–40 mg/kg/day) and phosphorus (18–31 mg/kg/day) and 0.1–0.2 mmol/kg/day of magnesium (2.4 mg/kg/day). Afterwards, intakes should increase progressively with macronutrients up to 1.6–2.5 mmol/kg/day for calcium (65–100 mg/kg/day) and phosphorus (50–78 mg/kg/day) and 0.2–0.4 mmol/kg/day for magnesium (5–7.5 mg/kg/day). Such mineral intakes are lower than fetal accretion but are usually higher than the retention observed with enteral nutrition (Table 7.1).

Table 7.3 Reasonable trace elements intakes for premature infants on parenteral nutrition

Iron	100–250 µg/kg/day
Zinc ^a	400–500 µg/kg/day
Copper ^b	20–40 µg/kg/day
Selenium	5–7 µg/kg/day
Chromium	0.05–0.2 µg/kg/day
Molybdenum	0.01–0.25 µg/kg/day
Manganese ^b	0.5–1.0 µg/kg/day
Iodine	1–10 µg/kg/day

^aZinc to copper ratio should not exceed 20

^bCopper and manganese intakes should be decreased in cholestatic liver disease

Trace Elements

Trace elements are essential micronutrients involved in many metabolic processes. Their needs in premature infants during PN are not well defined and Table 7.3 summarizes recent recommendations [34, 58, 104]. There are few trace element solutions available and designed for neonates. Commercial mixtures usually do not provide iron, but supplements can usually be postponed during short-term PN (<3 weeks). Chromium frequently contaminates PN solution during preparation and additional supplementation is rarely necessary. Micronutrient deficits are rare with current preparations of trace elements, except for zinc, which usually requires supplements, even during short-term PN. In the case of long-term PN (>4 weeks), plasma levels of trace elements should be monitored. Excessive intakes are rare with current neonatal preparations, but in the case of cholestatic liver disease, copper, and manganese toxicity may occur.

Vitamins

Vitamins are essential organic substances that humans cannot synthesize. Neonates have small vitamin stores and deficiencies may occur rapidly if not provided, especially in premature infants with high nutritional requirements and high metabolic rates. The optimal intake of vitamins for premature infants on PN is not well defined, and most studies were undertaken with commercial mixtures. Table 7.4 summarizes most recent recommendations [34, 58, 105].

There are few vitamin preparations designed for neonates on PN available on the market. They distinguish water-soluble and fat-soluble vitamins. Most pediatric vitamin formulations that are currently used in neonatal units are not designed for VLBW infants. Recent data suggest that additional intakes of fat-soluble vitamins A and E may provide some value for VLBW infants [106–109]. For premature infants, vitamin deficiencies are usually defined as below 200 µg/L for vitamin A and below 1 mg/dL for vitamin E, but for vitamin E a ratio below 0.8 mg/g of total lipid is usually

Table 7.4 Reasonable vitamins supply for premature infants on parenteral nutrition

<i>Hydrosoluble vitamins</i>	
Thiamin (vitamin B1)	350–500 µg/kg/day
Riboflavin (vitamin B2)	150–200 µg/kg/day
Niacin	4–6.8 mg/kg/day
Pyridoxine (vitamin B6)	150–200 µg/kg/day
Folic acid	56 µg/kg/day
Cobalamin (vitamin B12)	0.3 µg/kg/day
Panthenic acid	1–2 mg/kg/day
Biotin	5–8 µg/kg/day
Ascorbic acid (vitamin C)	15–25 mg/kg/day
<i>Liposoluble vitamins</i>	
Vitamin A	700–1500 IU/kg/day
Vitamin D	40–160 IU/kg/day
Vitamin E ^a	2.8–3.5 IU/kg/day
Vitamin K ^b	10 µg/kg/day

1 mg niacin = 1 niacin equivalent (NE) = 60 mg tryptophan; 1 µg retinol equivalent = 3.33 IU vitamin A; 1 µg vitamin D (cholecalciferol) = 40 IU vitamin D (cholecalciferol); 1 mg tocopherol = 1 IU vitamin E

^aVitamin E need may be increased when using DHA and ARA parenterally

^b0.5–1.0 mg vitamin K need to be given at birth

preferred. However, biological assessment of premature infant's vitamins status is only required in the case of long-term PN [34, 58, 105].

Fat-soluble vitamins are generally prepared in a 10% IVLE, and water-soluble vitamins are usually presented as powder that needs to be dissolved by addition to IVLE, sterile water, or glucose solution. Several vitamins are light sensitive and need to be protected from light even if significant clinical consequences are not obvious in premature infants [110]. Therefore, dilution of water- and lipo-soluble vitamins in IVLE should be done to increase vitamin stability and to reduce peroxide load.

Individualized and Standardized PN Solutions

PN solutions can be prescribed using either of two formats: individualized or standardized [111–113]. Individualized solutions are formulated specifically to meet the daily nutritional requirements of each patient, whereas standardized solutions are designed to provide a formulation that may meet most of the nutritional needs while maintaining these infants in stable biochemical and metabolic parameters. Both of these methods have advantages and disadvantages associated with their use.

Individualized solutions are based on the principle that no single standardized solutions can be ideal for all patients, for a wide variety of pathological processes, for all age groups, or for the same patient during a single disease course. The main advantage of individualized solutions is

their flexibility. Each solution is formulated for one individual patient and they can be modified when the patient's nutritional needs and metabolic, electrolytes or clinical status change. The disadvantage of these solutions is linked to the expertise and the time required for prescription and the time involved in daily preparation, which may be reduced with the use of specific computer programs. These solutions should be prepared every day with strict aseptic techniques, in the pharmacy, not in the ward, and stored in a refrigerator at 4°C. They are stable for 96 h and should be rewarmed slowly up to room temperature before infusion [114].

Standardized solutions contain fixed amounts of each component per unit volume. In some hospitals, there are few types of fixed standardized solutions to cover the nutritional requirements of premature infants. The advantage of these solutions is that they include all the essential nutrients in fixed amounts, which eliminates the chances of inadvertent omission or overload. The disadvantage of standardized solutions is their lack of patient specificity and the persistent need for some minimal adjustments, particularly during the first days of life [114]. Some recent surveys suggest that the availability of a unique well-balanced standardized PN solution helps improve nutritional support, postnatal growth, and biological homeostasis in VLBW infants [21, 22, 24, 47, 51, 83].

The development of ready-to-use industrially manufactured multi-chamber bags containing the three macro-nutrient solutions (amino acids, glucose, and lipids) in separate chambers of a single closed plastic system represents a major technological advances for PN in adults [115, 116]. It assures sterility, longer shelf life, and it also minimizes the risks of inadvertent contamination during compounding and storage [116]. It may also contribute to reduced nosocomial infection, especially by reducing lipid manipulations. Recently, an all-in-one standardized PN solution has been evaluated in premature infants [113]. It demonstrated the ease of use of such a system with intakes in the range of recommended doses. Most importantly, it facilitates the prevention of early malnutrition and the promotion of postnatal growth in premature infants [113].

Conclusion

Prematurity occurs during a critical period of development, and optimal nutritional support represents a major challenge for pediatricians. PN plays a major role for all premature infants who cannot be enterally fed from the first day of life and sometimes for a prolonged period. Recent studies demonstrate that optimizing early nutritional support from birth allows reducing or abolishing postnatal cumulative nutritional deficit and postnatal growth restriction in VLBW infants. However, they also highlight the need to upgrade the current recommendations for PN to improve the electrolyte and mineral homeostasis, especially during the first 2 weeks of life.

In summary, the following guidelines could be useful in the management of premature infants requiring PN, especially VLBW infants.

- Well-balanced PN solutions should be available at all the times for any premature infant who cannot be totally fed enterally within a few days. In VLBW infants, PN should be initiated in the first hour of life.
- Nutritional supply during the first days of life requires consideration of the clinical conditions and biochemical homeostasis. After a short transitional period, all premature infants should receive appropriate nutritional intakes in order to maintain biological homeostasis and promote optimal growth and development.
- Amino acid intakes should be initiated at a starting dose of 2–3 g/kg/day to induce positive nitrogen balance and anabolism. Thereafter, amino acids intakes should be progressively increased to 3.5–4.5 g/kg/day by the end of the first week of life.
- Energy intakes should cover the energy expenditure and be above 40 kcal/kg/day from the first day of life and progressively increased to 95–125 kcal/kg/day by the end of the first week of life.
- Glucose intakes should be initiated with 6–7 g/kg/day (4.2–4.7 mg/kg/min) and increased progressively to a maximum of 17 g/kg/day (12 mg/kg/min) as tolerated. All plasma glucose concentrations above 10 mmol/L (180 mg/dL) require the evaluation of the contributing factors and their correction (infection, pain, stress, dehydration, high intakes, hypophosphatemia, and steroid treatment). The initial treatment of hyperglycemia is a 10–15% reduction of the glucose infusion rate. Continuous insulin infusion with a strict blood glucose monitoring is mandatory in persistent hyperglycemia while maintaining protein and energy intakes within recommendations.
- Most recent lipid emulsions need to be use in premature infants. A initial lipid intake of 1–2 g/kg/day is recommended from the first day of life. Thereafter, intakes should be progressively increased to 3–4 g/kg/day and adjusted to maintain a plasma triglyceride concentration below 250–300 mg/dL during continuous lipid infusion.
- After birth, initial fluid intake should be 60–80 mL/kg/day and need to be adjusted to postnatal weight evolution to allow for an initial weight loss of 5–10% of BW during the first 3–4 days of life. Fluid intake should be increased when daily weight loss is above 5%, total weight loss above 10%, or plasma sodium concentration above 145 mmol/L but also in premature infants on a radiant warmer or during phototherapy. In contrast, fluid intake should be reduced if initial daily weight loss is below 2% or if plasma sodium concentration is below 135 mmol/L.

- The use of a relatively concentrated PN solution to provide all the nutritional intakes with 120–140 mL/kg/day could facilitate the fluid control without impairment of the nutritional requirement.
- Electrolyte intake should be initiated on the first day of life with about 1 mmol/kg/day of sodium, potassium, and chloride; this will allow early provision of phosphorus and the development of LBM gain. Thereafter, electrolyte intake may then be progressively increased to 3–7 mmol/kg/day for sodium, 2–3 mmol/kg/day for potassium, 2–5 mmol/kg/day for chloride. Careful monitoring of hydration, plasma electrolytes concentrations, and urinary excretions is necessary to adjust the intakes and to improve electrolyte homeostasis. The anion gap (Na+K–Cl) in the PN solution should be maintained between 1 and 2 mmol/kg/day to maintain adequate acid–base homeostasis.
- Mineral intake should be initiated on the first day of life with 0.6–1 mmol/kg/day of calcium and phosphorus and a balanced calcium to phosphorus ratio of 0.8–1.0 to avoid hypocalcemia and hypophosphatemia. Initial magnesium intake should be 0.1–0.2 mmol/kg/day. Thereafter, mineral intake should be progressively increased up to 2.0–2.5 mmol/kg/day for calcium and phosphorus and 0.2–0.4 mmol for magnesium. Careful monitoring of the plasma concentrations and of urinary excretion of minerals is necessary to ensure appropriate intake and to avoid the development of nephrocalcinosis.

Introduction

Infectious esophagitis is relatively rare in an immunocompetent host and usually is an indicator of a primary or secondary immunodeficiency. In immunocompetent children, infectious esophagitis frequently is associated with conditions that compromise esophageal defence mechanisms [1–3]. The spectrum of esophageal infections has changed over the past few decades. Infectious esophagitis was rare before the advent of acquired immune deficiency syndrome (AIDS) and post-transplant immunosuppressive treatment regimens [1].

Though immunosuppression, in general, can result in infectious esophagitis, infections are most likely to occur in children with HIV infection, during chemoradiotherapy for hematologic malignancies and after solid organ and hematopoietic stem cell transplantation [3–7]. Infectious esophagitis has also been reported in 3% of patients with ataxia-telangiectasia [8].

The risk of opportunistic infectious esophagitis in HIV is related to the CD4 count with patients noncompliant to highly active retroviral therapy (HAART) more likely to be infected [9]. Chemotherapy and radiation may predispose to esophageal infections due to the immunosuppression as well as the direct cytotoxic effects on the mucosal barrier. Hematological malignancies are more likely to be associated with infectious esophagitis than solid tumors, though the risk is attenuated with routine antimicrobial prophylaxis [10]. The risk of esophageal infections in bone marrow transplantation is higher in allogeneic than autologous transplants.

In an immunocompetent individual, impaired esophageal clearance of swallowed organisms may foster a permissive environment for the development of esophageal infections.

These would include impaired saliva production, altered esophageal motility contributing to stasis, and gastric hypochlorhydria. Injury to the esophageal mucosa either from inflammation or endoscopic procedures may facilitate infection in certain instances [3, 4].

Clinical Features

The clinical approach to evaluate a suspected infectious esophagitis is guided by the presence of any underlying immunosuppression, the presenting symptoms, and the physical findings. Pathologic gastroesophageal reflux is the most common cause of esophagitis in children. In previously healthy children, esophageal symptoms are likely to be caused by reflux esophagitis, whereas in immunocompromised patients, the physician needs to rule out infectious esophagitis. Secondary bacterial or fungal infections can be present in reflux esophagitis and Chagas disease, especially with severe inflammation and obstruction. Absence of reflux symptoms (long-standing heartburn, a water brash taste in the mouth, vomiting, spitting up in infants, pillow wetting, or coughing) does exclude reflux esophagitis. Achalasia, diffuse esophageal spasm, foreign body impaction, and mediastinal or retropharyngeal abscesses can cause esophageal symptoms and may result in secondary infection [2].

Patients with infectious esophagitis can present with esophageal, abdominal, or systemic symptoms. Odynophagia and dysphagia are the most common symptoms of esophagitis, but they may not be apparent in small children [5]. In adults, only 59–79% of patients with documented infectious esophagitis had these symptoms [4]. Odynophagia is usually indicative of underlying esophageal ulceration. The absolute CD4 count stratifies the risk of an opportunistic infection in HIV and coinfections may occur, especially with profound immunosuppression [11].

Diagnosis

Establishing a specific diagnosis is essential for managing of infectious esophagitis, particularly because fungal and bacterial superinfections occur commonly in viral esophagitis.

A key diagnostic challenge in infectious esophagitis is ascertaining the role of an isolated microorganism in disease causation as many purported pathogens are commensals that may be found even in healthy individuals [1]. Colonization of the oral cavity facilitates colonization of the esophagus following deglutition. Hence diagnosis of infection requires corroborative endoscopic and histological findings. The use of viral culture and polymerase chain reaction (PCR) may increase the diagnostic yield, however decreasing specificity partly due to contamination from latently infected cells. Serologic testing has little role in the evaluation of esophageal infection [1–3].

Esophagoscopy, Biopsy, and Brushing

The technique for performing endoscopy with videoendoscopes miniaturized to a diameter of 4.8 mm has made the procedure far more tolerable in immunocompromised patients, requiring less sedation and anesthesia and allowing the procedure to be performed even in newborns. These new instruments have biopsy capabilities comparable to older, wider endoscopes [2].

Characteristic macroscopic lesions are associated with some infectious agents. Macroscopic appearances overlap considerably, however, and histopathologic or immunohistochemical analysis (or both) of endoscopic and brush biopsy specimens is essential for diagnosis.

Endoscopic biopsy specimens should be obtained from the edge and the base of the lesions. In cytomegalovirus (CMV) infection, specimens from the edge do not yield diagnostic information [12]. The pathologist should be alerted to the possibility of fungal, viral, and polymicrobial infection. Appropriate fixatives should be used for routine hematoxylin and eosin stain, Gram stain, and special stains for fungi and bacteria such as *Mycobacterium*. Immunohistochemical studies and DNA hybridization techniques often are required to establish the diagnosis [1].

Fungal Esophagitis

Candida

Candida is the most common cause of infective esophagitis [13] and immunosuppressed patients are prone to this infection. Candida esophagitis is common in human immunodeficiency virus (HIV)-infected patients, in whom it

tends to occur when CD4 counts fall below 200 μ l. Treatments with broad-spectrum antibiotics, acid-suppressive therapy and inhaled corticosteroids are also risk factors [14–16]. In apparently immunocompetent individuals, predisposing medical conditions or risk factors are often identified [17, 18]. The causative organism is almost always *Candida albicans*, although other species are occasionally found [19].

Patients present with dysphagia, odynophagia, and/or retrosternal chest pain. Esophageal candidiasis may be the initial presentation of disseminated disease in an immunocompromised patient. The majority of patients, particularly those who are immunocompromised, also have concomitant oropharyngeal candidiasis [19, 20]. Nearly all patients with AIDS and oral candidiasis and odynophagia have endoscopic evidence of esophageal candidiasis [5, 21, 22]. However, some of these patients ultimately proven to have esophagitis have no signs or symptoms at presentation. Children who develop esophageal candidiasis, despite being treated with HAART, are less likely to have typical symptoms (e.g., odynophagia and retrosternal pain) or to have concomitant oropharyngeal candidiasis [11].

A specific etiological diagnosis is established by endoscopy with or without biopsy or brushings. Endoscopy reveals the presence of characteristic confluent yellow-white plaques overlying and adherent to an erythematous mucosa. Remarkably, the presence of ulceration is unusual and should prompt further evaluation for an alternative etiology. Endoscopic findings without biopsy have been reported to have a sensitivity and specificity of 100 and 83%, respectively, for a diagnosis of candida esophagitis [23].

The histological examination shows active esophagitis with budding spores and pseudohyphae within squamous debris, ulcer slough, and fibrino-purulent exudate. Invasion of mucosal and submucosal blood vessels is sometimes a prominent feature of invasive candidiasis [24]. *Candida* species are commensal organisms of the gastrointestinal tract, and colonize the esophagus in about one-fifth of healthy adults, making histological evidence of fungal invasion into tissue or ulcer slough important [15]. Parakeratosis with neutrophils may call attention to the presence of *Candida*.

Brushings may be obtained and stained with Gomori silver or periodic acid-Schiff stains. Fungal culture is not performed routinely as it is generally not useful except in defining the species and drug sensitivities, especially in treatment resistant cases [24].

Candida can colonize preexisting ulcers or damaged mucosa of any etiology, and the pathologist should consider the possibility of dual pathology.

Expert consensus guidelines recommend systemic therapy with newer azole medications (fluconazole, itraconazole solution, or voriconazole) for esophageal candidiasis. Topical therapy may produce an initial response, but early treatment

failures are common. Oral fluconazole 200–400 mg (3–6 mg/kg) daily for 14–21 days is recommended. If oral therapy cannot be tolerated, intravenous fluconazole 400 mg daily, amphotericin B, or an echinocandin, such as caspofungin, micafungin, or anidulafungin may be used [25–27]. Oral fluconazole and itraconazole suspension seem comparable in efficacy for initial therapy, and some patients whose disease fails to respond to fluconazole may see improvement with subsequent itraconazole therapy [28]. Although voriconazole has efficacy similar to that of fluconazole, it is associated with a higher rate of adverse events [29].

Other Causes of Fungal Esophagitis

Cases of esophagitis caused by *Aspergillus*, *Blastomyces*, *Cryptococcus*, and *Histoplasma* spp. have been described. Unlike *Candida*, these are not commensals and are acquired by significantly immunocompromised individuals from the environment. Primary infection of the esophagus is very unusual and has been described in immunocompromised patients. *Aspergillus* infection occurs as a result of contiguous spread from mediastinal infection [30, 31]. *Blastomyces* and *Histoplasma* infect the esophagus from a concomitant pulmonary infection or from disseminated infection [1]. Mediastinal fibrosis with esophageal obstruction and esophageal fistula may occur with histoplasmosis [31].

Optimal therapy has not been established, but systemic therapy, as for other manifestations of invasive infection with these organisms, has been successful. Currently, this approach would involve intravenous or oral azole agents or an amphotericin B preparation. Echinocandins (micafungin, caspofungin, or anidulafungin) may be useful for *Aspergillus* or *Histoplasma* infections, but they have no activity against cryptococci.

Viral Esophagitis

Herpes Simplex Virus

Herpes Simplex Virus (HSV) esophagitis is primarily a disease of immunocompromised patients and occurs most commonly in patients with solid organ and bone marrow transplants [32–34]. These patients may have life-threatening disseminated infection at the time of diagnosis [32]. It has also been reported in the setting of acute rejection [34]. In contrast to transplant recipients, it accounts for only 3–5% of esophagitis in HIV patients [35–37]. Most infections in immunocompromised patients probably represent viral reactivation as these patients have higher baseline seroprevalence rates. HSV esophagitis can occasionally occur in

subjects with normal immune function, who usually have a self-limiting infection that resolves spontaneously within 1–2 weeks [38, 39].

Although the esophagus is the most frequent site of gastrointestinal involvement, HSV esophagitis is uncommon. The vast majority of documented cases are due to HSV-1, though HSV-2 esophagitis from heterosexual orogenital contact in an immunocompetent patient has been described [40].

Symptoms are similar in both immunocompetent and immunocompromised patients. HSV in the immunocompetent is characterized by the acute onset of odynophagia, while 60–76% of patients exhibit retrosternal chest pain or heartburn [38, 41]. This may be associated with fever and systemic manifestations. Unlike in *Candida*, where oral disease is present in the majority of patients, coexisting herpes labialis and oropharyngeal ulcers are only seen in about one-fourth of patients [4, 38]. Symptoms may be more severe in immunocompromised patients with bleeding, perforation, tracheoesophageal fistula, and necrotizing esophagitis having been reported [42–46].

Endoscopic findings include nonspecific erosive esophagitis and discrete or coalescent superficial ulcers with an exudate. Vesicles that are the earliest manifestations are rarely seen. They coalesce to form ulcers often with normal intervening mucosa. Multiple esophageal ulcers are the commonest endoscopic finding seen in 59–86% of HSV patients, but these are nonspecific [38, 41]. The ulcers are usually small and discrete or occasionally confluent. The ulcers are “volcano-like” in appearance, in contrast to CMV ulcers which are linear or longitudinal and deeper. In addition to ulcers, friable mucosa and white exudates are commonly seen on endoscopy in HSV esophagitis. The distal esophagus is the commonest site of involvement; the entire esophagus may be involved in 15% of patients [38].

The diagnosis is usually based on a combination of histological findings and viral isolation from culture. Biopsies from the edge of the ulcers provide the highest diagnostic yield as the base of the ulcers often lack epithelial cells. Ulceration with neutrophils and an inflammatory exudate may be seen. Squamous cells may show viral cytopathic effects, including multinucleation, groundglass nuclei, and dense eosinophilic inclusions with a thickened nuclear membrane and a clear halo (Cowdry type A inclusion bodies). However, viral inclusions and multinucleated cells are not always identifiable in endoscopic biopsies [32] and may also be seen in other viral infections such as those caused by CMV and Varicella-zoster Virus (VZV). Aggregates of macrophages with convoluted nuclei have been identified adjacent to infected epithelium and may make the pathologist suspect herpes virus infection and prompt further investigation [47]. HSV isolation in the absence of histological findings is of questionable significance as it may represent asymptomatic viral shedding.

Acyclovir for 14–21 days has been advocated in the treatment of immunocompromised individuals with the use of intravenous preparations in those unable to swallow. In contrast to immunocompromised patients, HSV esophagitis in the immunocompetent is an indolent but usually self-limiting disease. The value of treatment with acyclovir is uncertain [41]. While case reports suggest therapeutic benefit in hastening illness resolution [39], the relative rarity of the condition precludes any randomized controlled trials, and spontaneous resolution usually occurs within 1–2 weeks. A search should be made for any underlying immunosuppressive illness in patients presenting with HSV esophagitis.

CMV

CMV is a significant pathogen in the immunocompromised subject, usually occurring in patients with AIDS [23], transplant recipients, malignancies, and those receiving immunosuppressive medications. These patients frequently have multiorgan involvement, while CMV infection is usually subclinical and asymptomatic in immunocompetent patients [48]. Indeed, serious symptomatic CMV esophagitis in immunocompetent patients is rare [49].

Patients with CMV esophagitis clinically present with dysphagia, odynophagia, or nonspecific symptoms such as nausea, vomiting, abdominal pain, anorexia, and fever that reflect multiorgan or systemic involvement. Thrombocytopenia and leucopenia may be present but are not invariable.

Endoscopy may reveal variable findings from esophageal erosions to deep ulcers, located in the mid or distal esophagus with a halo of edema. In the setting of hematopoietic stem cell transplantation, they may be macroscopically confused with graft-versus-host disease. Stricture formation is relatively uncommon despite the occurrence of deep CMV ulceration [50, 51].

Diagnosis needs a combination of histology and of demonstration of CMV in tissue specimens. The histological hallmark of CMV is the presence of cytomegalic cells on hematoxylin and eosin staining of mucosal biopsy. The infected cells are enlarged and contain Cowdry type A intranuclear inclusions with a surrounding halo (“owl’s eye” inclusions). Hematoxylin and eosin staining has comparable sensitivity and specificity to immunohistochemical staining with monoclonal antibodies but at a lower cost [52]. Since CMV has a predilection for fibroblasts and not squamous epithelial cells, biopsies should be obtained from the base of ulcers. The use of CMV DNA PCR on mucosal biopsy specimens increases the detection of CMV, but only a fraction of these patients have typical histological changes [53]: noticeably, this increased yield with PCR may be due to contamination from latently infected cells. Likewise, the late CMV antigen assay has 89–100% sensitivity for CMV viremia but are not pre-

dictive for CMV disease [54, 55]. Conversely, CMV disease as detected on histology may be present even in the absence of CMV detection in the blood.

IV ganciclovir is the treatment of choice for CMV disease. Oral Valganciclovir has been shown to be non-inferior to IV ganciclovir for treating CMV in certain solid organ transplantation recipients [56]. However, IV ganciclovir is preferred in patients who do not tolerate oral treatment and those with life-threatening CMV disease. The use of foscarnet has been limited by its nephrotoxicity. The role of maintenance treatment is not well defined. Reduction in immunosuppression should be individualized but considered in transplant recipients with CMV disease.

Other Viral Infections

VZV is rarely associated with esophagitis in severely immunocompromised patients. The typical cutaneous vesicular eruptions are usually present when esophagitis occurs. Esophageal VZV may be a harbinger of disseminated VZV [57]. The endoscopic appearance may be variable with vesicles and ulcers seen [58]. Esophago-bronchial fistula has been reported to occur in VZV infection in an AIDS patient [59]. Biopsies reveal ballooning degeneration, multinucleated giant cells, and intranuclear inclusion bodies similar to HSV, and viral culture is needed to distinguish the two viruses. Though VZV esophagitis is self-limited in immunocompetent patients, it is typically treated with acyclovir for routine and foscarnet for resistant cases.

Esophageal ulcerations have been very rarely reported in Epstein-Barr virus infection in both immunocompetent and immunocompromised patients [60]. The ulcers are deep, linear, and involve the mid-esophagus. Koilocytosis, epithelial thickening, and cell multinucleation are seen on biopsy. The number of patients is too small to draw any firm conclusion on treatment indications [61].

Bacterial Esophagitis

Bacterial infection is a rare cause of esophagitis. It typically occurs in immunocompromised hosts such as those with hematologic malignancies with neutropenia, bone marrow transplantation, diabetic ketoacidosis, and steroid therapy [62, 63]. It is usually polymicrobial and derived from oral flora (i.e., *Streptococcus viridians*, *Staphylococci*, and *Bacillus* spp). Esophagitis is frequently associated with bacteremia; hence, blood cultures always should be performed.

The diagnosis is made by demonstrating bacterial clusters on Gram stain with evidence of subepithelial bacterial invasion on endoscopic biopsies [64]. Treatment is with broad-spectrum antibiotics. Lack of response to appropriate

therapy may indicate concomitant superinfection by other organisms or resistance to the drugs used. Repeat endoscopy is indicated for documenting eradication of infection.

Introduction

In normal states, the esophagus, unlike all other segments of the gastrointestinal tract, is devoid of eosinophils. In healthy subjects, its surface contains a few lymphocytes, but no other leukocytes [1, 2]. The presence of any eosinophils in the esophageal epithelium is considered by definition as esophageal eosinophilia [3], which is only a histologic finding, not specific for a certain disease, and the differential diagnosis is relatively broad. Gastroesophageal reflux disease (GERD), eosinophilic esophagitis (EoE), and proton-pump inhibitor-responsive esophageal eosinophilia (PPI-REE) are the three most common conditions characterized by infiltration of eosinophils in the esophageal epithelium. Furthermore, a number of other clinical conditions have been associated with the esophageal eosinophilia (Table 9.1). Eosinophilic gastroenteropathy was first described by Kaijser in 1937 as a chronic condition characterized by an eosinophilic inflammatory infiltration of the gastro intestinal tract. Attwood et al. first reported EoE in the literature much later, as a unique entity in 1993 [4]. Over the past 15 years, interest in EoE has grown, and once thought to be a rare condition has lot of interests with more clinical experience and research studies. Improved recognition of this condition has also raised number of questions about the definition, diagnosis, treatment, prognosis, and surveillance.

EoE is defined as a clinicopathologic immune and/or allergen-mediated disorder characterized by symptoms of esophageal dysfunction and a marked eosinophilic infiltrate on esophageal biopsy. Symptoms of esophageal dysfunction may mimic like GORD and this may coexist with EoE,

which make it difficult for this condition to be differentiated from EoE. But treatment of GORD alone does not improve EoE. EoE represents the first cause of food impaction in young males and the second most common cause of chronic esophagitis (after GORD) [5]. Currently, the gold standard for the diagnosis of EoE is the endoscopy with esophageal biopsies showing esophageal eosinophilia. A recent consensus document has proposed the presence of >15 eosinophils (peak value) in at least one microscopic high-power field (HPF) of one or more esophageal biopsy specimens stained with hematoxylin and eosin after a course of PPI as necessary for establishing the diagnosis [6]. It is important to note, however, that the histological appearance of EoE can overlap with that of other conditions (Table 9.1) and that the diagnosis should rest on clinicopathological correlation rather than on a simple eosinophil count in isolation.

Since EoE was recognized as a distinct clinicopathologic syndrome, it has been described in industrialized countries, such as Europe, North America, and Australia [7]. Studies in the pediatric population have shown that the incidence of the disease is estimated at 4.4–9.5 cases per 100,000 person/year [8, 9] and the prevalence at 42.9–91 per 100,000 [10–13]. Over the past decade, emerging evidence confirm that the incidence of EoE has raised dramatically and has already approached that of pediatric inflammatory bowel disease [14, 15]. It remains to be clarified whether this is a true rise or it reflects the improved recognition and ascertainment of the disease.

EoE can present at any age, but it is more prevalent in childhood or during the third and fourth decade of life. Males (male to female ratio of 3:1), Caucasians, and patients with other associated atopic disorders are more prone to the disease [16]. Furthermore, it has been shown that familial predisposition can play an important role [17–19]. The estimated sibling risk recurrence ratio (RR) is approximately 80, which is much higher compared to other atopic diseases with inheritance patterns, as asthma [2, 20].

The symptomatology of EoE varies according to the age of presentation and can mimic GORD. Feeding difficulties, feed

refusal, vomiting, and regurgitation, which can result in poor weight gain are usually the presenting symptoms in infants and toddlers. During childhood and adolescence, the disease presents with upper abdominal or retrosternal pain, dysphagia, and food impaction. Symptoms can rarely vary through the year, reflecting the seasonality of the allergen, when the allergy reaction is most likely directed to aeroallergens [21].

Over the past two decades, numerous studies have contributed to the understanding of the mechanisms of its pathogenesis. However, there are still fundamental questions to be answered. Research needs to shed light on whether EoE consists of one or more discrete subtypes or if it is a single condition with changes in expression over time [22]. Given our current understanding, the most likely driving factor for the process of the disease is an immune reaction to food or inhaled antigens. Taken this into account, elimination diets led to histological improvement and resolution of the eosinophilic eosinophilia and are considered as an effective treatment option [23–25]. However, not every patient's clinical course suggests a causative food allergen [26].

Another question that has been posed in the literature is whether pediatric and adult EoE are two distinct disorders or the manifestation of a single entity. Many similarities and differences regarding the clinical presentation, the endoscopic findings, the response to treatment and the progression of the disease have been reported [27]. Adults most commonly present with dysphagia and have esophageal rings and strictures requiring dilation, whereas children tend to have plaques, furrows, and decreased vascularity on endoscopy [28]. To make things more complicated, it has been proposed that different phenotypes of the disease could result in divergent clinical presentation and outcomes [29–31]. However, given the current knowledge, pediatric and adult EoE share a common pathogenesis, similar histopathologic features, and constitute a single disease [5].

Pathophysiology

In terms of its pathophysiology, EoE has been characterized as a bulk of mysteries. Even though symptoms may differ among children and adults, it is well recognized that in both populations, food and aeroallergen sensitization and allergy have been associated with the pathogenesis of the disease. A history of atopy is documented in 50–60% of all patients, and 40–93% of pediatric subjects have been previously diagnosed with another allergic disease [9, 32, 33]. The immune process implicated in OE is most likely a combination of immunoglobulin E (IgE)- and non IgE-mediated reaction to allergens. Peripheral eosinophilia occurs in 50% of the cases and increased levels of IgE are documented in three fourth of the patients [6]. However, remission of the disease cannot always be easily achieved by eliminating specific food for which patients test positive with skin prick tests (SPTs) and food specific-IgE antibodies. On the contrary, patients who exhibited negative allergy tests have shown a good response to elimination diets [34, 35]. The existing data point only an association between EoE and allergy, and the first is not definitely considered as an allergic condition.

Esophageal eosinophilia is not pathognomonic for the disease, but a nonspecific finding that reflects a state of injury [36]. Eosinophils are multifunctional cells and secrete a variety of cytokines, chemokines, inflammatory mediators, neuromediators, and cytotoxic granule proteins when activated [37]. These cells tend to accumulate in the apical strata, but can be also distributed diffusely throughout the mucosal membrane in EoE [38]. Microabscesses formed by coalesced eosinophils, the extracellular deposition of eosinophilic proteins, and the deposition of major basic proteins (MBP) are specific findings of the disease, not commonly seen in gastroesophageal reflux [39, 40]. The main question to be answered is which is the driving force for the presence of eosinophils in the esophageal squamous epithelium.

Emerging evidence suggests that a Th2-type immune response with systemic and local Th2-cytokine overproduction plays a key role in the pathogenesis and onset of the disease [41]. Studies in murine models have demonstrated that eosinophilic and collagen deposition is interleukin (IL) 5 dependent [42–44]. IL-5, IL-4, and IL-13 act as chemoattractants for eosinophils that leave the vascular space by diapedesis and enter the esophageal mucosa. Subsequently, the expression of the beta-integrin very late antigen (VLA)-4 on the eosinophilic surface and its counter ligand, the vascular endothelial adhesion molecule, VCAM-1 on endothelia is induced. Further studies in murine models and ex vivo analysis of human esophageal cells support the key role for IL-15 in the generation and the perpetuation of esophageal inflammation. IL-15 is a cytokine with the ability to potentiate activated T cell responses. Following IL-15 stimulation, an increase in eotaxins has been identified [45, 46].

The eotaxin proteins (eotaxin-1, -2, and -3), also known as chemokine cysteine–cysteine motif ligand (CCL) 11, CCL24, and CCL26 respectively, are highly potent eosinophilic chemoattractants. Many studies have investigated the role of eotaxin-3 in EoE. Genome-wide microarray analysis on esophageal biopsies from pediatric subjects revealed an increase in eotaxin-3 (messenger ribonucleic acid (mRNA) and protein), which is mainly produced by esophageal epithelial cells, and correlated with the eosinophilic counts. A single-nucleotide polymorphism in the untranslated region of the eotaxin-3 has been associated with increased disease susceptibility [47]. This conserved gene profile, with the increased expression of eotaxin-3, distinguishes between EoE and gastroesophageal reflux disease [48]. Furthermore, the expression of cysteine–cysteine motif containing chemokine receptor 3 (CCR3) that receives signals from eotaxins and CCL5 was found increased and correlated positively with the number of esophageal eosinophilic and biopsy eotaxin message [49]. On the contrary, in murine models, mice deficient in the chemokine receptor CCR3 were protected from EoE [47, 50].

A better understanding of the immunomicroenvironment of the disease has revealed the implication of mast cells. In normal states, mast cells reside at the basement membrane and in the lamina propria of the esophageal mucosa [51]. Even though the exact mechanism of the underlying esophageal mastocytosis in EoE has not yet been clarified, immunohistochemical staining has shown the increased number of intraepithelial mast cells compared to healthy controls and gastroesophageal disease [38, 52–54]. The tryptase-positive mast cell quantification may have diagnostic utility in EoE, particularly in differentiating the disease from gastroesophageal reflux [55]. Taken into consideration that carboxypeptidase A3 has the strongest relation to mast cell number and degranulation, the upregulation of carboxypeptidase A3 gene, specifically seen in EoE, highlights the importance of mast cells in the pathogenesis of the disease [47, 54]. Furthermore, IL-9 is known to promote esophageal mastocytosis and the expression of the IL-9 transcript is increased in the esophagus of patients with EoE [45, 56]. Following treatment with anti-IL-5, the esophageal epithelium of pediatric patients had significantly fewer mast cells, IL-9, and mast cell–eosinophilic couplet [57].

Both eosinophils and mast cells with their secretory products contribute to tissue remodeling and fibrosis in EoE. A complex interplay between eosinophils, mast cells, and fibroblasts has been documented. Tumor growth factor (TGF)- β 1 is produced mainly by monocytes and macrophages, and also by eosinophils and mast cells. This pro-fibrotic molecule increases smooth muscle cell hyperplasia, is a potent activator of fibroblasts, and is a strong inducer of epithelial–mesenchymal transition (EMT), the process where epithelial cells assume morphological and phenotypical properties of fibroblasts [58]. Evidence of EMT was seen in esophageal

mucosal biopsies from patients with EoE [59]. Increased vimentin expression in the esophageal epithelial cells combined with decreased expression of E-cadherin also indicates the possible presence of EMT in EoE tissues [60].

In a pediatric study, an increased expression of TGF- β 1 and its signaling molecule phosphorylated SMAD2/3 (phosphor-SMAD2/3) was documented. The esophageal biopsies also demonstrated remodeling of the esophageal mucosa, especially the lamina propria, as well as increased vascular density and increased expression of the vascular endothelial adhesion molecule, VCAM-1. Increased level of esophageal fibrosis was documented in children with EoE. TGF- β 1, VCAM-1, SMAD2/3 seem to contribute to the loss of elasticity of the esophageal wall and the formation of strictures [61, 62]. Basal cell hyperplasia correlates with the intraepithelial eosinophils and the number of mast cells [47]. Furthermore, MBP, released by eosinophils, lead to increased gene expression of fibroblast growth factor (FGF)-9, a cytokine implicated in the proliferate response to eosinophilic inflammation in esophagitis [63]. The role of periostin, a cell adhesion protein with the ability to bind to integrins in the cell membrane and trigger cell proliferation, migration, adhesion, and differentiation, has also been studied. In gene arrays, periostin is highly overexpressed in the esophagus of patients with EoE, it is second in upregulation magnitude only to eotaxin-3 gene and it correlates with the eosinophilic number [47, 64]. Interestingly, tumor necrosis factor (TNF)- α is also highly expressed by epithelial cells in EoE, but it remains to be clarified whether it exerts direct pro-fibrotic effect [65].

Genome-wide association studies that investigate the association between common genetic variants across the genome and the disease have identified various single-nucleotide polymorphisms (SNP) in a discrete region on the long arm of chromosome five associated with the thymic stromal lymphopoietin (TSLP) in patients with EoE. Esophageal biopsies of pediatric patients showed TSLP overexpression compared to unaffected controls and TSLP expression levels correlated significantly with the disease-related rs3806932 SNP [66, 67].

In conclusion, despite the advances in our understanding, the pathogenesis of EoE is yet not fully understood. An interplay between predisposed genetic background with environmental factors seems crucial for the onset of the disease. There is strong evidence that cell types other than eosinophils are also implicated. However, the current challenge is to elucidate the complex cellular and molecular mechanisms of the disease.

Clinical Presentation

EoE can affect any age, but the symptomatology varies according to age. Substantial differences have been described between pediatric and adult patients (Table 9.2); however, it

Table 9.2 Clinical manifestations of eosinophilic esophagitis in children, adolescents, and adult patients

Children	Adolescents and adults
Chest pain or heartburn	Dysphagia

Nausea	–
Regurgitation	–
Throat pain	–
Sleeping difficulties	–

remains unclear whether this variation could be attributed to the ability to enunciate discomfort or to the different stages of the disease [68].

A broad range of symptoms, affecting the upper gastrointestinal tract and the respiratory system, has been reported in the pediatric population. Symptoms can attenuate or spontaneously fluctuate, even when histology reveals persistent esophageal eosinophilic infiltrates [69]. In general, the most common symptoms can be divided to GERD-like symptoms and dysphagia, possibly representing two discrete disease phenotypes [70]. In infants and toddlers, the disease presents with nonspecific symptoms, like feeding difficulties, regurgitation, vomiting, and feed refusal, which can result in poor weight gain.

Older children and adolescents complain of upper abdominal and retrosternal pain, heartburn, dysphagia, and food impaction. Furthermore, pediatric patients can experience choking on liquids or solids, the inability to tolerate feeds beyond certain tastes or textures, avoidance of specific solid foods, such as bread, rice, meat, and the need to drink water to assist swallowing during meals as an adaptive behavior to esophageal dysfunction [20, 71]. Acute symptoms are due to intermittent esophageal spasm, most likely related to smooth muscle contraction, whereas the chronicity of dysphagia denotes long-standing esophageal remodeling [72, 73]. Interestingly, the seasonality of symptoms points the implication of aeroallergens [74].

Association with Other Diseases

The relationship between EoE and gastroesophageal reflux disease is complex and the role of acid reflux in the EoE is a matter of debate [68]. Impedance and pH studies are helpful in distinguishing the two entities; however, conflicting data exist about the presence of acid and nonacid reflux in children with EoE [75, 76]. It is postulated that the erosions and ulceration seen in gastroesophageal reflux disease can

result in the impairment of the mucosal barrier function and increase the risk for food sensitization. Furthermore, the ineffective esophageal peristalsis in EoE can lead to an impairment of the clearance of the esophagus after gastroesophageal reflux episodes [77, 78]. Emerging evidence shows that the two distinct entities can possibly coexist and exacerbate each other.

The recent identification of PPI-REE that was first described in a series of pediatric patients complicated further the diagnostic algorithms of esophageal eosinophilia [79]. PPI-REE accounts for at least one third of children and adults with esophageal eosinophilia [80–82], but it has not been yet elucidated if this is a new separate entity, a subtype of gastroesophageal reflux disease or a phenotype of EoE. Given the current state of knowledge, the clinical, endoscopic, and histological features cannot differentiate it from EoE, and there is no predictor to show which patient will respond to the PPI trial [83]. According to the most recent guidelines, in order to identify children with PPI-REE and to avoid unnecessary eliminations diets and drug treatment, an 8-week trial of PPIs is recommended, before the diagnosis of EoE is established [80].

Celiac disease and EoE both affect the upper gastrointestinal tract, and they are two clinically, anatomically, and histologically distinct entities. However, recently a clinical association between these two disorders has been proposed. A higher than expected prevalence of EoE in pediatric patients with coeliac disease has been documented, and the estimated risk of each condition is increased 50–75-fold in those pediatric patients diagnosed with the alternative condition. This phenomenon is shown to be limited only to the pediatric population [84–90]. The lack of a genetic connection between EoE and coeliac disease necessitates further prospective studies to shed light to this association and to clarify the underlying mechanisms that justify the coexistence.

The implication of TGF- β 1 in the pathogenesis of EoE led to the hypothesis that the disease could be also associated to connective tissue disorders (CTDs) that are known to be caused by genetic variants in TGF- β binding proteins and TGF- β receptors, like Marfan syndrome and Loeys–Dietz syndrome, respectively [91, 92]. In addition, patients diagnosed with the above disorder can exhibit gastrointestinal symptoms, including dysphagia, which is a typical presenting symptom of EoE [93–95]. Taken this into consideration, a new syndrome has been described (EoE-CTD), involving EoE in association with inherited CTDs that represents a new class of this gastrointestinal disorder. There is evidence showing that the dysregulation of collagen transcription in patients with EoE-CTD is distinct from that seen in typical patients with EoE or healthy subjects, and that these patients might be at greater risk for more diffuse eosinophilic extraesophageal gastrointestinal disease than their peers with EoE without evidence of CTDs [96, 97].

Table 9.3 Diagnostic criteria, macroscopic, and histological findings of eosinophilic esophagitis

Diagnosis	–
Macroscopic findings	Thickened/pale mucosa Linear furrows Trachealization (esophageal rings) Mucosal friability White exudates Luminal strictures
Histological characteristics	Esophageal eosinophilia: After antireflux therapy High eosinophilic count in the most affected area (> 15 eosinophils/HPF as proposed by consensus panel [6]) Eosinophilia affecting lower, mid, and upper esophageal samples Other associated features: Eosinophilic microabscesses Superficial layering Extracellular eosinophilic granules Basal cell hyperplasia Papillary elongation Lamina propria fibrosis Dilated intracellular spaces No parasites or fungi present

HPF high-power field

Diagnosis and Assessment

The presence of eosinophils in the esophageal epithelium should be reported as esophageal eosinophilia. Consensus recommendations have proposed a threshold of 15 eosinophils or more per HPF in at least one endoscopic esophageal mucosal biopsy sample taken at upper gastrointestinal endoscopy. Other microscopic features which often accompany EoE include eosinophilic microabscesses, superficial layering, extracellular eosinophilic granules, the basal cell hyperplasia, papillary elongation, lamina propria fibrosis, and dilatation of intercellular spaces (Table 9.3) [6]. It is important to note that none of these individual histological features are specific, and they should not be used in isolation to differentiate EoE from other conditions associated with esophageal eosinophilia (Table 9.1). Inclusion in the routine staining panel of stains such as diastase-periodic acid-Schiff (PAS) ensures that fungal organisms are not easily overlooked. Even if eosinophilic esophagitis is suspected clinically, sampling should include gastric and duodenal mucosa, as presence or absence of gastroduodenal changes may be helpful in the differentiating EoE from other conditions.

In the particular context of differentiating EoE from gastroesophageal reflux, the presence of esophageal eosinophilia in biopsy samples from the mid and upper esophagus is a very useful feature in support of EoE as these sites are rarely affected by reflux. Multiple biopsy samples should always be taken as the eosinophilic infiltrate can be patchy in distribution. In terms of diagnostic sensitivity, this has been reported to range from 55% when one specimen is

examined to 100% when five specimens are examined [98]. See (Fig. 9.1). It has been proposed that diagnosis can be achieved in 97% of the patients by at least three biopsies from different parts of the esophagus [99]. It is therefore recommended two to four biopsies to be taken from the proximal and distal esophagus regardless its appearance [6]. EoE cannot be excluded even if esophagus has a normal appearance at endoscopy. However, the characteristic macroscopic findings include thickened, pale mucosa with linear furrows, trachealization (fixed esophageal rings), mucosal friability, white exudates, and less frequently luminal strictures (Table 9.3) [100].

The role of repeat endoscopy and biopsies in order to reassess the disease and the effect of the treatment has not yet been validated. Some centers suggest regular upper endoscopy to ensure maintenance of histological remission, but currently the long-term follow-up management for asymptomatic patients is poorly defined [78]. Upper gastrointestinal (GI) contrast radiography is helpful in identifying esophageal strictures or long-segment narrowing, although the findings are not always confirmed at endoscopy, suggesting transient contractions [101, 102]. Deeper esophageal strictures have been also assessed with the use of endoscopic ultrasound, and data from a pediatric series suggest a significant thickening of the esophageal wall with the involvement of the submucosa and the muscularis propria apart from the mucosa [103].

The most common manometric disorder in EoE is the ineffective peristalsis of the esophagus. High-resolution manometry can reveal pan-esophageal pressurization, the uniform esophageal pressurization from the upper esophageal sphincter to the esophagogastric junction with pressures over 30 mmHg [77]. Pediatric patients have shown significantly more ineffective esophageal peristalsis during fasting and meals than those with gastroesophageal reflux disease and controls [104]. A novel imaging probe, the endoluminal functional lumen imaging probe (endoFLIP), used in adult patients determined that patients with EoE also exhibit significantly reduced distensibility compared to normal controls.

An ideal biomarker for EoE should correlate with disease activity, have high sensitivity and specificity, reflect changes with therapy, be reproducible, noninvasive and cost-effective [105, 106]. Currently, there is no available biomarker to confirm or monitor the disease. Peripheral eosinophilia is not always present, and even when identified, it can be indicative of other diseases. However, the combination of peripheral eosinophilia with elevated serum levels of eotaxin-3 (CCL26) and eosinophil-derived neurotoxin significantly correlated with esophageal eosinophilic density [107]. Furthermore, the Th2 induction implicated in EoE results in cytokine pattern variation in eosinophilic and normal subjects. A cytokine panel scoring system for predicting the

diagnosis of EoE has been proposed and identified that IL-13 as one of the eight cytokines whose blood levels retrospectively distinguished patients from healthy controls with 100% specificity and sensitivity. Serum and tissue expression levels of IL-13 is one of the most promising candidate biomarkers for the disease [45, 108].

Mast cell density, the extracellular MBP content, and the presence of fibrosis may serve as potential biomarkers in establishing the diagnosis of EoE [109]. Recently, the use of a minimally invasive test, the esophageal string test (EST), in pediatric patients was shown to have the potential to significantly improve the evaluation and treatment of the disease by measuring the eosinophil-derived proteins in luminal secretions which reflect the state of mucosal inflammation [110].

Treatment

In order to avoid unnecessary elimination diets and drug therapy and to differentiate PPI-REE and EoE, the diagnosis of the latter is established when esophageal eosinophilia does not respond to an 8-week course of PPIs at repeat endoscopy. According to the most recent guidelines, the end points of the treatment should include the combination of clinical remission with histological resolution of the esophageal eosinophilic inflammation [3, 78]. Two different treatment approaches have been proven to be effective in the management of the disease, the elimination diets, and the pharmacological therapy. (Table 9.4)

Dietary Management of EoE

The success of elimination diets in EoE provides strong evidence for the implication of food sensitization as the cause of esophageal inflammation in many cases [74]. The observation that some patients exhibit allergen sensitivity while others do not, points the possibility that the disease may exhibit different phenotypes [111]. Atopy patch test (APT), SPT, and serum IgE tests may be adjunctive in identifying a causative food in EoE, and, for that reason, gastroenterologists should consider consultation with an allergist. However, a food trigger can only be identified when the elimination of the specific food results in disease remission, followed by relapse upon reintroduction [6].

The dietary management of EoE includes the diet based on amino-acid formula, the skin test-directed elimination diet, and the empiric exclusion diet, with the elimination of six foods. The decision as to which of these three dietary approaches to be suggested should be individualized according to the patient's specific needs and family circumstances. Important foods that are excluded from a child's diet should be substituted appropriately and the input of an experienced dietitian in pediatric nutrition is crucial to ensure a balanced nutritional plan, to minimize non-adherence, and to avoid cross-reactive antigens [78, 112].

The efficacy of an amino-acid-based formula for the treatment of EoE in children was first described in 1995 [113]. Since then, several studies have shown the successful use of the elemental formula that seems to achieve clinical and histological remission in less time compared to the other two elimination diets [24, 114–116]. A 4-week trial of amino-acid-based formula is recommended in patients with multiple food allergies, failure to thrive, or those unable to respond or to follow a highly restricted diet [78]. However, the clinical use of this dietary approach is limited by the acceptability that often requires tube feeding (nasogastric or gastrostomy) and the significant cost. Generally, it is better accepted and tolerated in infants [114].

The dietary restriction based on allergy testing has been proposed to be a successful alternative treatment option, but the use of allergy testing to identify causative foods in EoE is controversial. Resolution of both symptoms and histological abnormalities in children with EoE was reported following an elimination diet based on a combination of SPTs and patch tests [117] and even though the follow-up data showed a lower level of response, this was further increased if the elimination of foods identified on allergy testing was combined with the empiric elimination of cow's milk [23]. The poor predictive value of SPTs and radioallergosorbent tests (RASTs) to identify specific food that induce inflammation is the major limitations of this dietary approach. Furthermore, the local production of IgE in patients with EoE probably explains the absence of a relationship between positive allergy test and actual food triggers for the disease. However, targeted elimination diet for 8–12 weeks is recommended if allergy to specific foods is strongly suspected by history and sensitization is supported by allergy testing [78].

The third recommended dietary approach for the treatment of EoE is the elimination of the six foods that are considered to be most allergenic: cow's milk, egg, wheat, soya, peanut, and fish/shellfish (six food exclusion). In a series of 35 pediatric patients, the removal of these food allergens from their diets for 6 weeks regardless of sensitization led to clinical and pathological remission in 74% of the cases [118]. Subsequently, this dietary strategy can be used for 8–12 weeks in the absence of specific food sensitization.

Following remission, the excluded foods should be gradually reintroduced. Based on the available evidence, it is recommended the least allergenic food to be reintroduced first, and the most allergenic to be left as last [119]. This would suggest reintroduction of seafood/nuts first, followed sequentially by soy, wheat, egg, and finally milk for pediatric patients with EoE. Repeat endoscopy after the reintroduction of each food has been used in some centers to ensure the histological remission and to identify specific food antigens under endoscopic and biopsic monitoring; however, further prospective studies need to validate the clinical value of this treatment strategy. In any case, food antigens that have been proven to act as disease triggers should be eliminated indefinitely.

Pharmacological Therapy

The drug therapy for EoE can be used when the dietary management fails or the patient cannot accept or tolerate the dietary restrictions. It is also considered a better option for patients whose symptoms exhibit a seasonal variability. In practice, combined management strategies including both elimination diets and medicines are often employed.

Proton-Pump Inhibitors

Prior to the establishment of the diagnosis and the initiation of treatment for EoE, an 8-week trial of PPI is recommended in order to differentiate the disease from PPI-responsive eosinophilic eosinophilia. PPIs exert their effect on esophageal eosinophilia not only by suppressing the gastric acid, but by modulating the inflammatory process as well [120]. The decision as to whether these medication should be continued as co-therapy in EoE should be individualized, taken into consideration their role on inhibiting the production of proinflammatory cytokines, the increased expression of vascular adhesion molecules and the activation of neutrophils [121]. In addition, in esophageal cells from patients with EoE, PPIs have been shown to inhibit IL-4-stimulated eotaxin-3 expression and block STAT6 binding to the promoter [122].

Corticosteroids

Topical corticosteroids are the first-line pharmaceutical treatment for EoE, and they have been proven to be effective not only at achieving clinical and histological remission but also at reversing tissue fibrosis as well [123–126]. The most frequently employed topical steroid is fluticasone propionate at a dose ranging from 88 to 440 mcg 2–4 times daily for children. Fluticasone is administered by metered-dose inhaler and patients should be instructed to puff the medication into the mouth during a breath hold and then swallow it, in order the drug to coat esophagus and to minimize pulmonary deposition [3]. Avoidance of food and drinks for 30 min after the ingestion of fluticasone is also recommended.

Difficulties in administering fluticasone in pediatric subjects can be overcome with oral viscous budesonide, a successful alternative treatment option. Even though the optimal dose of budesonide in children with EoE has not been formally assessed, the recommended starting dose is 1 mg daily for children younger than 10 years and 2 mg daily for older children split into 2 divided doses [6]. If necessary, the dose can be gradually increased to 2.8 and 4 mg, respectively [127]. The oral viscous budesonide preparation mixed with sucralose covers the entire esophagus and improves the delivery of the steroid [128, 129].

Despite their efficacy, when the treatment with oral steroids is discontinued, relapse of the disease is common. Furthermore, mouthwash after each use of topical steroids is recommended for the prevention of mouth and oral candidiasis [21, 130]. The use of topical steroids has not been associated with systemic side effects, but long-term safety data is not available in the literature.

Oral systemic steroids have similar efficacy to oral topical steroids in the treatment of EoE. Oral prednisolone has been shown to have a better effect on the resolution of histological abnormalities in pediatric patients [131]. The adverse effects of systemic steroids limit their use, and they are reserved

as a treatment option when other approaches fail or rapid relief of symptoms is required. The recommended dose of oral prednisolone is 1–2 mg/kg (max 40 mg and then to be weaned down gradually). Careful monitoring for evidence of side effects, such as growth inhibition, bone demineralization, acne, diabetes, and mood disturbances, is essential. Intravenous methylprednisolone can also be considered, when oral medications cannot be tolerated.

Other Medications

Leukotriene receptor antagonist and sodium cromoglycate have been also used in pediatric and adult patients [70, 132, 133], but based on the existing evidence, they are inefficient in inducing and maintaining clinical and histological remission, and they are not recommended for the treatment of EoE. Azathioprine and 6 MP act as immunomodulatory drugs and could possibly decrease inflammation by impeding esophageal lymphocyte recruitment, but there are no data supporting their use in pediatric patients. Monoclonal antibodies against IL-5 and IL-13, the cytokines that orchestrate the Th2 pathway, are being currently investigated and represent a promising area for future therapies [134, 135]. Limited data from adult patients support the use of glucagon in relieving esophageal food impaction in EoE [136].

Esophageal Dilatation

Strictures or long segment narrowing of the esophagus may require mechanical dilatation. This approach provides an immediate relief of symptoms, but has no effect on the underlying inflammation. It also carries a risk of complications, like deep mucosal tears, perforation, hemorrhage, and severe pain. Esophageal dilatation should be considered in selected cases in combination with the pharmacological therapy, when the narrowing persists despite the treatment [20, 68, 78].

Quality of Life

Adherence to the dietary and pharmacological treatment variably influences the quality of life. Dietary restrictions can affect psychosocial functioning (school, parties, dating). The feeling of being different from their family and peers has been reported by pediatric subjects. Disease anxiety and worry about symptoms are common in children and adults. Newly developed quality-of-life tools evaluate the symptoms, the histological findings and parent-proxy outcomes, in an attempt to capture the whole impact of the disease on children [137–140].

Natural History

EoE is characterized by chronicity and dependency on nutrition and medical management. Upon discontinuation of the treatment, the recurrence of symptoms is common and only a small percentage of patients develops tolerance to the food allergens. Delay in diagnosis and untreated disease increases the risk for structural esophageal abnormalities and stricture formation. However, the disease has not been associated with an increased risk of progressing into generalized gastrointestinal disorders or malignancy. Furthermore, it does not affect the life expectancy [29, 141–143]. EoE is an emerging disease and many unresolved issues need to be clarified in the future in terms of its pathogenesis, the different phenotypes, the monitoring of the patients, and the long-term effects of the treatment.

Abbreviations

BAL	Bronchoalveolar liquid
CMPA	Cow's milk protein allergy
ENT	Ear–nose–throat
GER(D)	Gastroesophageal reflux (disease)
H2 RA	H2 receptor antagonist
LES	Lower esophageal sphincter
LLM	Lipid laden macrophages
NERD	Non-erosive reflux disease
PPI	Proton pump inhibitor
TLESR	Transient lower esophageal sphincter relaxation

Introduction

Exhaustive consensus documents on the definition, diagnosis, and management of gastroesophageal reflux disease (GERD) have been published in 2009 [1, 2]. These have been confirmed and approved by the American Academy of Pediatrics in 2013 [3]. However, it has recently been shown that neither pediatric gastroenterologists nor family pediatricians apply these guidelines, simply because they are not aware they exist [4]. There is a trend to overdiagnose GERD. Between 2000 and 2005, the annual incidence of GERD and acid-related conditions among infants (age ≤ 1 year) more than tripled (from 3.4 to 12.3%) and increased by 30–50% in other age groups [5].

Labeling an otherwise healthy infant as having a “disease” increased parents’ interest in medicating their infant when they were told that medications are ineffective [6]. These findings suggest that use of disease labels may promote overtreatment by causing people to believe that ineffective medications are both useful and necessary [6].

Definitions

Gastroesophageal reflux (GER) is the involuntary passage of gastric contents into the esophagus and is a normal physiological process occurring several times per day in every human, particularly after meals [1, 2, 7]. Most reflux episodes are of short duration, asymptomatic, and limited to the distal esophagus. Typically, a reflux episode is the consequence of a transient relaxation of the lower esophageal sphincter (TRLES), unaccompanied by swallowing. A minority of reflux episodes occur as a consequence of a chronically reduced lower esophageal sphincter (LES) esophageal and extraesophageal pressure. “Physiologic GER” is the consequence of increased abdominal pressure not accompanied by an increase of the LES pressure or when GER is associated with absence of symptoms, or during the first months of life accompanied with regurgitation, and occasionally with vomiting [1, 2]. Healthy and sick individuals do not differ in the presence or absence of GER, but in the frequency, duration, and intensity of GER and in its association with symptoms or complications. Physiologic reflux becomes pathologic if esophageal clearance is insufficient, if acid buffering is insufficient, if gastric emptying is delayed, if abnormalities in epithelial restitution or repair occur, if there are anatomical abnormalities such as hiatal hernia, etc. Both in children and adults, GERD is present when reflux of gastric contents is the cause of troublesome symptoms and/or complications [2, 7]. GERD is reflux associated with esophageal and extraesophageal symptoms severe enough to impair quality of life or mucosal damage. Most patients with GERD show no abnormalities on endoscopy or histology from esophageal biopsies, and suffer nonerosive reflux disease (NERD). To be defined as GERD, reflux symptoms must be troublesome to the infant, child, or adolescent and not simply be troublesome to the caregiver [2]. However, it may be difficult to define when symptoms become troublesome in young children, because they cannot adequately report symptoms [8, 9]

Regurgitation, spitting up, possetting, and spilling are synonyms, and are defined as the passage of refluxed gastric

contents into the pharynx, mouth, and sometimes expelled out of the mouth [1]. Although regurgitation is mainly effortless, it may sometimes be forceful. Only a minority of physiologic reflux episodes are accompanied by regurgitation. Regurgitation is a characteristic symptom of reflux in infants, but is neither necessary nor sufficient for a diagnosis of GERD, because it is not sensitive or specific [2]. Up to 50% of all infants under the age of 4 months present at least one to several episodes of spilling per day [10–12]. Regurgitation is distinguished from vomiting by the absence of a central nervous system emetic reflex, retrograde upper intestinal contractions, nausea, and retching. “Vomiting” is defined as expulsion with force of the refluxed gastric contents from the mouth [1, 2]. Vomiting is a coordinated autonomic and voluntary motor response, causing forceful expulsion of gastric contents [1]. Vomiting associated with reflux is likely the result of the stimulation of pharyngeal sensory afferents by refluxed gastric contents. Biliious vomiting should not be diagnosed as GERD. Otherwise, healthy infants and children with reflux symptoms who are not troublesome and are without complications should not be diagnosed with GERD [2]. In adults, heartburn (or pyrosis) and regurgitation are the two most typical symptoms of GERD [7]. However, some adult patients complaining of heartburn do not have GERD, they have a syndrome called functional heartburn [13]. Since heartburn causes distress and pain, crying in infants is often considered as the manifestation of heartburn in infants. However, there is no evidence to sustain this hypothesis [14, 15].

“Rumination” is characterized by a voluntary contraction of the abdominal muscles resulting in the habitual regurgitation of recently ingested food that is subsequently spitted up or reswallowed. Gagging, regurgitation, mouthing, and swallowing of refluxed material is identified as rumination.

Prevalence, Environmental, and Genetic Factors

Determining the exact prevalence of GER and GERD at any age is virtually impossible for many reasons: Most reflux episodes are asymptomatic, symptoms and signs are non-specific and self-treatment is common. Alcohol, smoking, drugs, food components, excessive intake, and weight are GER-inducing variables. In adults, over-the-counter use of low-dose aspirin and nonsteroidal anti-inflammatory drugs favors GERD [16]. Also in adults, race, sex, body mass index, and age are independently associated with hiatus hernia and esophagitis, race being the most important risk factor [17]. In adults living in developed countries, the prevalence of GERD (defined as symptoms of acid regurgitation, heartburn, or both, at least once a week) is 10–20%, whereas in Asia the prevalence is roughly less than 5% [7, 18, 19]. Pediatricians often discuss the tendency to overdiagnose and overtreat reflux-associated symptoms in infants presenting

with frequent regurgitation, since epidemiologic data suggest that about 20% of all infants regurgitate more than four times a day, and that 20% of the mothers consider this as troublesome [10–12]. However, epidemiological data suggest that troublesome reflux occurs in about 20% of the infants and adults, with a drop in prevalence in between [20, 21]. French data report a prevalence of GER in 10% and of GERD in 6% of all children 0–17 years old [21]. According to data obtained by the Health Improvement Network Incidence, the incidence of GERD in children is 0.84/1000 person-years [20]. The incidence decreases with age from 1.48/1000 person-years among 1-year-old children until the age of 12 years, whereupon it again increases to a maximum at 16–17 years of 2.26/1000 person-years for girls and 1.75/1000 person-years for boys [20]. According to these epidemiologic data, children with GERD had double the risk of an extraesophageal condition such as asthma, pneumonia, cough, or chest pain compared with children and adolescents with no diagnosis of GERD [20].

The rising prevalence of GERD seems to be related to the rapidly increasing prevalence of obesity [7]. Total and abdominal obesity are risk factors for the development of GERD symptoms in children [22]. The risk of GERD symptoms rises progressively with the increase in both body mass index and waist circumference, even in normal weight children [22].

An autosomal dominant inheritance of hiatal hernia was described by discovering familial hiatal hernia in five generations of a large family, but without demonstrating the link to GERD. The genetic influence on GERD is supported by increased GER symptoms in relatives of GERD patients. GERD is associated with GNB3 C825T [23]. The results for GERD subgroups support the hypothesis that enhanced perception of reflux events, as a consequence of the increased signal transduction upon G-protein-coupled receptor (GPCR) activation associated with the 825T allele, underlies this association [23]. The concordance for GER is higher in monozygotic than dizygotic twins [24]. Genes in question have been localized to chromosomes 9 and 13. A locus on chromosome 13q, between microsatellite D13S171 and D13S263, has been linked with severe GERD in five multiple-affected families [25]. This could not be confirmed in another five families, probably due to genetic heterogeneity of GERD and different clinical presentation of patients [26]. The relevance of these findings for the general population remains unclear.

Pathophysiology

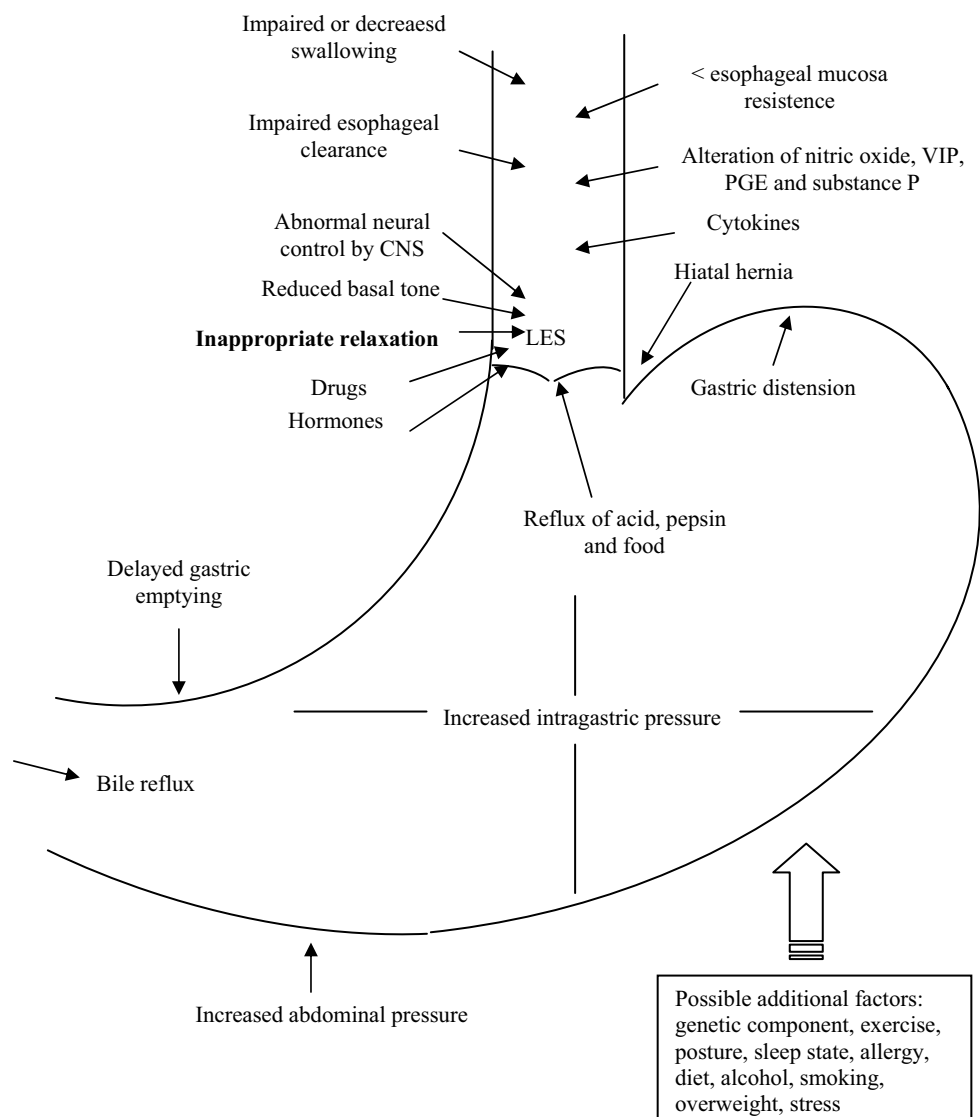

TLESRs are the most important pathophysiologic mechanism causing GER at any age, from prematurity into adulthood [1, 7, 27]. TLESRs are a neural reflex, triggered mainly

by the distention of the proximal stomach and organized in the brainstem, with efferent and afferent pathways travelling in the vagal nerve, activating an intramural inhibitory neuron which releases nitric oxide to relax the LES.

GER is influenced by genetic, environmental (e.g., diet smoking), anatomic, hormonal, and neurogenic factors (Fig. 10.1) [27]. Three major tiers of defense serve to limit the degree of GER and minimize the risk of reflux-induced injury to the esophagus. The first line of defense is the “anti-reflux barrier,” consisting of the LES and the diaphragmatic pinchcock and angle of His. When this line of defense fails, the second, esophageal clearance, assumes greater importance and limits the duration of contact between luminal contents and the esophageal epithelium. Gravity and esopha-

geal peristalsis serve to remove volume from the esophageal lumen, while salivary and esophageal secretions from esophageal submucosal glands serve to neutralize acid. The third line of defense, tissue or esophageal mucosal resistance, becomes relevant when (acid) contact time is prolonged [27]. Esophageal mucosa defense can be divided in pre-epithelial (protective factors in saliva and esophageal secretions containing bicarbonate, mucin, prostaglandin E₂, epidermal growth factor, transforming growth factor), epithelial (tight junctions, intercellular glycoprotein material), and post-epithelial factors [27]. There is a very important interindividual variation of reflux perception suggesting different esophageal-sensitive thresholds. Capsaicin levels and the transient receptor potential vanilloid receptor-1 play a role in the sen-

Fig. 10.1 Pathophysiologic mechanisms for GER. (Reproduced from Ref. [29], with permission from John Wiley and Sons)

Legend: CNS = central nervous system; LES = lower oesophageal sphincter; PGE = prostaglandin E; VIP = vasoactive intestinal peptide. Inappropriate relaxation is typed in blood as it represents the most important pathophysiologic mechanism in GER

sation of heartburn [28]. The esophageal mucosa contains acid, temperature, and volume-sensitive receptors. A widening of the intercellular spaces is reported in patients with esophagitis and in patients with endoscopy-negative disease. Esophageal sensitivity to acid decreases when the esophagitis has healed. The presence of fat in the duodenum increases the sensitivity to reflux. Hyposensitivity that occurs in patients with Barrett's esophagus is a secondary phenomenon.

GER occurs during episodes of TLESR or inadequate adaptation of the sphincter tone to changes in abdominal pressure. All the factors responsible for maintaining LES tone are not yet determined, but nitric oxide likely plays an important role. Infants have a short intra-abdominal esophagus.

Infants ingest more than twice the volume than adults per kilogram bodyweight (100–150 ml/kg/day compared to 30–50 ml/kg/day), causing more gastric distention and as a consequence more TLESRs. Feeding frequency is higher in infants than in adults, resulting in more postprandial periods during which TLESRs are more common. When investigated in supine position, the frequency of TLESRs in healthy adults and those with acid GERD does not differ. In healthy adults, only 30% of the TLESRs are accompanied by acid reflux, but, in patients with GERD, reflux occurs in 65% of the TLESRs. Thus, in adults, controls and GERD patients have the same number of TLESRs, but in patients with GERD, these TLESRs are more than twice as frequently accompanied with acid GER [30]. Older studies performed in adults in the recumbent position may be more relevant to understand the pathophysiologic mechanisms of acid reflux in infants. Normal individuals rarely experience TLESRs during sleep. Supine position removes all the beneficial gravitational effects of the erect position. Noxious materials, rather than air, are positioned at the cardia, available to move into the esophagus during TLESRs. A reflux is more likely to reach the pharynx in the recumbent than in the upright position. Both salivation and swallowing are markedly reduced during sleep, further impairing clearance. The upper esophageal sphincter is atonic during sleep, allowing reflux almost free to access the airways.

Delayed gastric emptying may increase postprandial reflux possibly by increasing the rate of TLESRs. Delayed gastric emptying has been documented in infants and children with symptomatic GER, particularly those with neurologic disorders. Abnormal gastric accommodation to a meal and prolonged postprandial fundic relaxation has been described in patients with GERD (M30 21). Esophageal acid exposure in patients with GERD is directly correlated with the emptying time of the proximal stomach. GERD was classically considered to be an acid peptic disease. But as a group, the majority of patients with reflux disease do not have a significant increase in gastric acid secretion. Recent analysis of postprandial acidity in the area of the gastroesophageal (GE) junction suggests that local acid distribution (“the gas-

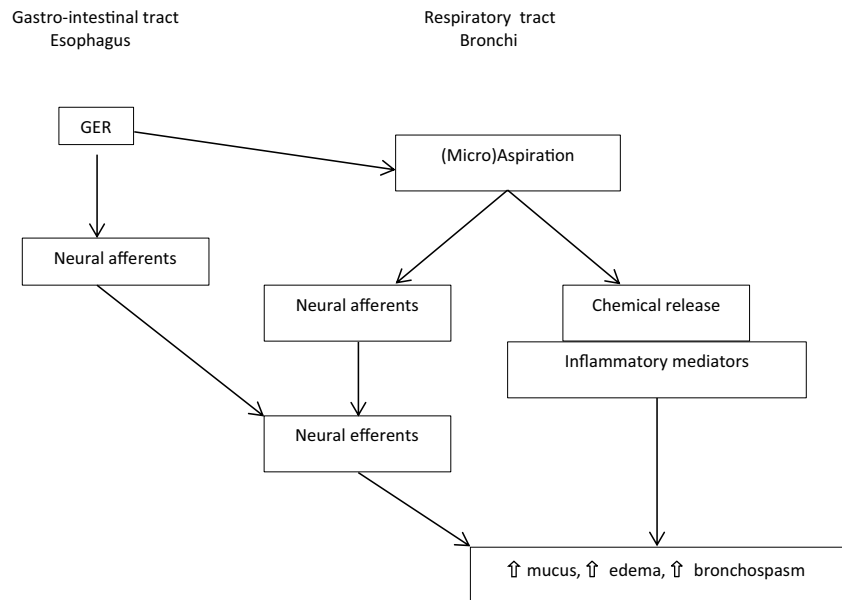

tric acid pocket”) rather than total gastric secretion might be more relevant to the pathogenesis of GERD. Differences may exist in the degree of mixing of fundic contents leading to different distributions of acid in the stomach. Studies using pH monitoring, scintigraphy and gastric magnetic resonance suggest that gastric mixing can be incomplete. Different layers of viscosity within the stomach might therefore influence the distribution of the gastric contents. A collection of acid in the gastric part of the esophageal junction was shown in adults in supine position, even in the postprandial period when stomach content was neutralized by the meal [31].

Hiatal hernia increases the number of reflux episodes and delays esophageal clearance by promoting retrograde flow across the esophagogastric junction when the LES relaxes after a swallow. This mechanism underlies the so-called re-reflux phenomenon (acid reflux when the pH is still below 4).

The majority of the studies on pathophysiologic mechanisms have been performed in adults and did not consider weakly acid and nonacid reflux. The refluxed material can be acid, weakly acid, or nonacid. Reflux may be a mix of gas and liquid or pure liquid, and it may or may not contain bile. More than half of the acid and weakly acid reflux episodes are associated with reflux of gas [30]. Weakly acid reflux also occurs predominantly during TLESRs. With liquid meals, patients with GERD had a similar total rate of reflux episodes but a higher proportion of acid reflux events than controls [32]. Weakly acid reflux may be responsible for the remaining symptoms in patients under antisecretory treatment. Components contributing to the noxiousness of refluxate are pepsin, bile acids and salts, and trypsin. The latter two depend on duodenogastric reflux preceding GER and are implicated in the genesis of strictures and Barrett's esophagus. Acid is emptied from the esophagus with one or two sequences of primary peristalsis, and then the residual acidity is neutralized by swallowed saliva. Secondary peristalsis is the response to esophageal distension with air or water, and is more important during sleep when peristalsis is reduced. Patients may have normal primary peristalsis but abnormal secondary peristalsis. Thus, nonacid reflux that occurs in the postprandial period may be inefficiently cleared and cause prolonged esophageal distension, and thus cause symptoms of discomfort. Esophageal clearance modulates the duration of reflux episodes, while mucosal resistance modulates the noxiousness of the components of refluxate. Reflux may cause respiratory symptoms through different pathways, such as (micro-)aspiration or vagally mediated GER (Fig. 10.2).

Helicobacter pylori infection, or eradication of *H. pylori*, does not cause GER. Anyway, because of the decrease of *H. pylori* infection, this issue has become less relevant. Improvement in epigastric pain is significantly correlated with the improvement in GER symptoms but not with eradication of *H. pylori* [33].

Fig. 10.2 Pathophysiologic mechanisms of GER causing respiratory disease. GER gastro-esophageal reflux orig

The role of the upper esophageal sphincter in GERD and chronic respiratory disease, laryngitis, hoarseness, coughing, etc., has been insufficiently studied. The upper esophageal sphincter relaxes in response to esophageal body distention by gas, in contrast to its contractile response to esophageal body distention by fluid. Symptom presentation has not been linked to different pathophysiologic mechanisms. Children presenting with upper airway disease or ear–nose–throat (ENT) manifestations may rather suffer from an insufficient upper esophageal sphincter, while patients with esophagitis may have more noxious reflux, insufficient clearing mechanisms or a poor esophageal mucosal resistance.

Symptoms and Signs

In normal 3–4-month-old infants, 3–4 episodes of GER are detectable during 5 min of intermittent fluoroscopic evaluation [34]. Normal ranges of esophageal pH monitoring report up to 31 ± 21 acid reflux episodes recorded within a 24-h period (but sample frequency, data handling by the recording device and program do determine this incidence) [35]. Attempts have been made to establish normal ranges in the pediatric age for esophageal impedance [36, 37]. However, for ethical reasons, these investigations were performed in symptomatic children.

While reflux does occur physiologically at all ages, there is also a continuum between physiologic GER and GERD at all ages leading to significant symptoms, signs, and complications (Tables 10.1 and 10.2). GERD is a spectrum of a disease that can best be defined as manifestations of esophageal or adjacent organ injury secondary to the reflux

Table 10.1 Symptoms and signs that may be associated with gastro-esophageal reflux. (Reproduced from Ref. [1], with permission from Lippincott Williams & Wilkins)

Symptoms	
	Recurrent regurgitation with/without vomiting
	Weight loss or poor weight gain
	Irritability in infants
	Ruminative behavior
	Heartburn or chest pain
	Hematemesis
	Dysphagia, odynophagia
	Wheezing
	Stridor
	Cough
	Hoarseness
Signs	
	Esophagitis
	Esophageal stricture
	Barrett's esophagus
	Laryngeal/pharyngeal inflammation
	Recurrent pneumonia
	Anemia
	Dental erosion
	Feeding refusal
	Dystonic neck posturing (Sandifer syndrome)
	Apnea spells
	Apparent life-threatening events (ALTE)

of gastric contents into the esophagus or, beyond, into the oral cavity or airways. The presenting symptoms of GERD differ according to age (Table 10.3). The list of most frequent differential diagnoses of vomiting in infants and children is listed in Table 10.4.

	Cyclic vomiting syndrome
	Autonomic dysfunction

GI gastrointestinal

Belching or eructation occurs during transient relaxation of the LES, and is an important method of venting air from the stomach. Hiccups are involuntary reflex contractions of the diaphragm followed by laryngeal closure. In some cases, hiccups cause GER.

Atypical symptoms such as epigastric pain, nausea, flatulence, hiccups, chronic cough, asthma, chest pain, and hoarseness account for 30–60% of the presentations of GERD [1, 38] (Table 10.1). Possible associations exist between GERD and asthma, pneumonia, bronchiectasis, acute life-threatening event (ALTE), laryngotracheitis, sinusitis, and dental erosion, but causality or temporal association were not established [38]. The paucity of studies, small sample sizes, and varying disease definitions did not allow firm conclusions to be drawn [38]. Less than 10% of infants and children have (acid and troublesome) GERD [35].

The clinician needs to be aware that not all regurgitation and vomiting in infants and young children is GER (disease). Biliary vomiting, gastrointestinal (GI) bleeding, consistently forceful vomiting, weight loss or failure to thrive, diarrhea, constipation, fever, lethargy, hepatosplenomegaly, and abdominal tenderness or distension should raise the possibility of an alternate diagnosis. Bulging fontanelle, macro- and/or microcephaly, and seizures raise the possibility of genetic and/or metabolic syndromes.

GER and Uncomplicated Regurgitation

Regurgitation is the most common presentation of infantile GER, with occasional projectile vomiting.

About 70% of the healthy infants have regurgitation that is physiologic, resolving without intervention in 95% of the individuals by 12–14 months of age [10–12] (Fig. 10.3). Daily regurgitation occurs more frequently in infants during the first 6 months of life than in older infants and children. Frequent regurgitation, defined as >three times per day,

occurs in about 25% of the infants during the first months of life. About 20–25% of the parents seek medical advice because of frequent infantile regurgitation, which corresponds to at least four episodes of regurgitation a day [10–12].

A prospective follow-up reported disappearance of regurgitation in all subjects before 12 months, although an increased prevalence of feeding refusal, duration of meals, parental feeding-related distress, and impaired quality of life were observed, even after the disappearance of symptoms [12]. Regurgitation occurs more frequent in infants than in adults because of the large liquid volume intake, the limited capacity of the esophagus (10 ml in newborn infants), the horizontal position of infants, etc. “Excessive regurgitation” is one of the symptoms of GERD, but the terms regurgitation and GERD should not be used as synonyms.

Although most studies report a comparable incidence of regurgitation in unselected populations of formula versus breastfed infants, Hegar et al. reported a higher incidence in formula-fed infants [10]. This observation fits with the knowledge that GER and symptoms of GERD may be indistinguishable from those of food allergy [1, 2]. The incidence of cow’s milk protein allergy (CMPA) is five to ten times higher in formula fed than in breastfed infants [39].

Regurgitation is a characteristic symptom of reflux in infants, but is neither necessary nor sufficient for a diagnosis of GERD, because regurgitation is neither sensitive nor specific. The physician’s challenge is to separate regurgitation and vomiting caused by reflux from numerous other disorders provoking the same manifestations. Although the “happy spitter” certainly exists (and is not rare), many infants show some symptoms of distress and discomfort when regurgitating. Irritability may accompany regurgitation and vomiting; however, in the absence of other warning symptoms, it is not an indication for extensive testing [1]. But in fact, parental carrying capacity or anxiousness (“parental coping”) will determine if a physician is contacted or not. Infant regurgitation is a benign condition with

Fig. 10.3 Natural evolution of physiologic regurgitation. (Reproduced from Ref. [10], with permission from John Wiley and Sons)

a good prognosis, needing no other intervention than parental education and anticipatory guidance, and intervention on feeding composition may contribute to parental reassurance. Overfeeding exacerbates recurrent regurgitation. Thickened or anti-regurgitation formula decreases overt regurgitation [1].

GER(D), Recurrent Regurgitation, and Poor Weight Gain

If poor weight gain is documented, it is obvious that the infant is not a happy spitter. Poor weight gain is a crucial warning sign that necessitates clinical management. These infants need a complete diagnostic workup, starting with a dietary history to evaluate caloric intake. Hospitalization of these infants may be needed. Although usually regurgitation causes little more than a nuisance, important regurgitation produces also caloric insufficiency and malnutrition in a minority of infants. There may be abnormal sucking and swallowing, and weight gain may be poor. These infants have no apparent malformations, and may be diagnosed as suffering “nonorganic failure to thrive,” a “disorder” that sometimes is attributed to social/sensory deprivation, socioeconomic or primary maternal–child problems. GERD is only one of the many etiologies of “feeding problems” in infancy. Poor weight gain, feeding refusal, back arching, irritability, and sleep disturbances have been reported to be related as well as unrelated to GERD [1, 2, 40].

GER(D) and Cow’s Milk Allergy

Guidelines on the symptoms and management of cow’s milk allergy unanimously report that persistent regurgitation and vomiting are manifestations of CMPA (Table 10.5: overlapping symptoms between GER(D) and CMPA) [41]. The positive response to cow’s milk protein elimination from the diet and relapse of the symptoms is often proposed as a proof of CMPA. An association between GERD and cow milk hypersensitivity was observed in both infants and children with severe GERD [43]. Simultaneous cow milk challenge and pH monitoring had limited value as a method to identify this subgroup. Impedance has shown that the incidence of nonacid postprandial reflux is decreased after a feeding with an amino acid-based formula compared to standard infants’ formula [44]. However, since amino acids or extensive hydrolysates have much more rapid gastric emptying than standard infants formula with entire cow milk proteins [45, 46], it is not possible to know if the decrease in GER is due to the enhanced gastric emptying or an immune mechanism.

GERD and Esophagitis

Esophagitis is defined as visible breaks of the esophageal mucosa [1]. Histology is recommended to rule out complications (Barrett’s esophagus) or other causes of esophagitis (EoE). Reflux esophagitis is reported to occur in 2–5% of the population. Children with GER symptoms present with esophagitis in 15–62%, Barrett’s esophagus in 0.1–3%, and refractory GERD requiring surgery in 6–13% [1, 47]. Erosive esophagitis in 0–17-year-old children with GERD symptoms was reported to be 12.4% and increasing with age 48. The median age of the group with erosive esophagitis was 12.7±4.9 years vs. 10.0±5.1 years in those without erosive esophagitis [48]. The incidence of erosive esophagitis was only 5.5% in those younger than 1 year [48]. This finding is in sharp contrast with the extremely high incidence (24.8%) of anti-reflux medication prescribed in extremely low-birth-weight infants at the moment of discharge [49]. The huge differences in incidence of esophagitis are determined by patient recruitment, differences of definition of esophagitis, and availability of self-treatment. Hiatal hernia is more frequent in children with erosive esophagitis than without (7.7 vs. 2.5%) [48].

The primary symptom of an esophageal stricture is dysphagia. Barrett’s esophagus is not rare in adolescents with chronic GERD [1]. In adults, hospital discharges and mortality rates due to gastric cancer, gastric ulcer, and duodenal ulcer have declined during the past three decades, while those of esophageal adenocarcinoma and GERD have markedly risen [50].

Esophagitis, identified by histology, occurs in 61–83% of infants with reflux symptoms severe enough to perform

endoscopy. Although esophagitis may present with pain, it can also be asymptomatic. The group with asymptomatic esophagitis is in some ways the most problematic. Even severe esophagitis may remain asymptomatic as demonstrated by children who present with peptic strictures without having experienced any discomfort attributable to esophagitis. Typical substernal burning pain (“heartburn,” pyrosis) occurs in many children suffering from esophagitis. Odynophagia, which is pain on swallowing, usually represents esophageal inflammation. In nonverbal infants, behaviors suggesting esophagitis include crying, irritability, sleep disturbance, and “colic”. Infants frequently also appear very hungry for the bottle until their first swallows and then become irritable, and refuse to drink. Dysphagia (“typical” for Eosinophilic esophagitis; EoE) has also been linked to esophagitis.

GER(D) and Eosinophilic Esophagitis

The impressive rise in prevalence of EoE is still poorly understood [51], and difficulty in distinguishing EoE from reflux esophagitis may be encountered. In reflux esophagitis, the distal and lower eosinophilic infiltrate is limited to less than 5/per high-power field (HPF) with 85% positive response to GER treatment, compared to primary EoE with >20 eosinophils per HPF. More recent, failure of proton pump inhibitor (PPI) treatment as a condition to diagnose EoE brought reflux esophagitis back in the picture of EoE [52]. EoE necessitates proper treatment (hypo-allergenic feeding, corticoids, montelukast, etc.). Patients with allergic esophagitis are younger and have atopic features (allergic symptoms or positive allergic tests), but have no specific symptoms. Atopic features are reported in more than 90% and peripheral eosinophilia in 50% of patients. At endoscopy, a pale, granular, furrowed, and occasional ringed esophageal mucosa may appear (M1 1). EoE is becoming more and more important [53]. While symptoms in older children are more oriented to dysphagia for solids, symptoms in infants are more reflux like [53, 54]. Repeated endoscopy with esophageal histology in combination with response to treatment may in some cases be the only way out to separate reflux esophagitis from EoE in young children. An in-depth discussion on EoE is included in Chap. 9.

GER(D), Heartburn, and Infant Crying

While the verbal child can communicate pain, descriptions of the intensity, location, and severity may be unreliable until the age of at least 8 years, and sometimes later [2]. In adults, adolescents, and older children, heartburn and regurgitation are the characteristic symptoms of GERD [7]. GERD in adolescents is more adult like. Heartburn is a symptom of

GERD with or without esophagitis. Heartburn is a predominant GER symptom in adults, occurring weekly in 15–20% and daily in 5–10% of subjects. Diagnosis and management of GERD in older children (>12 years) and adolescents follows the recommendations for adults [1]. According to parents, heartburn is present in 1.8% of 3–9-year-old healthy children and 3.5% of 10–17-year-old adolescents; regurgitation is said to occur in 2.3 and 1.4%, respectively, and 0.5 and 1.9% need antacid medication [12]. In self-reports, adolescents complain about heartburn in 5.2% and regurgitation in up to 8.2%, while antacids are taken by 2.3% and histamine receptor antagonists (H₂RA) by 1.3%, suggesting that symptoms of GER are not rare during childhood and are underreported by parents or overestimated by adolescents [12]. In infants, the issue is more complicated. As per definition “heartburn” suggests that the individual with heartburn feels a burning retrosternal pain, parents, and health-care providers almost automatically hypothesize that a “crying baby” or a “baby with colic” is likely to suffer from heartburn or “occult GER.” Therefore, acid-reducing medication is often prescribed in infants [49, 55]. Several randomized controlled trials were performed in this indication, and for once all results indicate the same conclusion: PPIs are useless to decrease crying and distressed behavior in newborns and infants [56–59]. Heine and coworkers showed the absence of any relation between crying duration and result of pH monitoring [15].

A symptom-based diagnosis of GERD in infants and young children remains difficult. The reason for the differences in presentation of GERD according to age remains unclear. The persistence of symptoms and progression to complications are unpredictable for a group of patients and for the individual patient. Overall, the correlation between symptoms, results of pH monitoring, acid perfusion test, and histology is poor.

GER(D) and Distressed Behavior

This group of patients is much more difficult to deal with than the infant with poor weight gain. The same amount of distress and crying may be evaluated by some parents as easily acceptable, while the same amount of crying will be unbearable for other parents. In fact, the degree of “coping” capacity of the parents decides if medical help is looked for. Many factors, such as tobacco smoke, may cause infant irritability. CMPA is another well-identified cause of infant irritability. There is substantial individual variability and some healthy infants may cry up to 6 h a day [1].

The concept that infant irritability and sleep disturbances are manifestations of GER is largely derived from adult data [1]. Although this hypothesis seems an acceptable extrapolation, we should be aware that there are not many data on

this topic. GERD affects quality of life significantly in adults and probably also in children (and their parents); although, quality of life is more difficult to evaluate in infants and young children. The developing nervous system of infants exposed to acid seems susceptible to pain hypersensitivity despite the absence of tissue damage. In adults, NERD is a general accepted entity. Again in adults, impaired quality of life, notably regarding pain, mental health, and social function, has been demonstrated in patients with GERD, regardless of the presence of esophagitis [60]. In an unselected population, 28% of the adults report heartburn, almost half of them weekly, with a significant impact on the quality of life in 76%, especially if the symptoms are frequent and long lasting. Despite that, only half of the heartburn complainers seek medical help, although 60% takes medications. Thus, some adults “learn to live with their symptoms,” and acquire tolerance to long-lasting symptoms, while others accept to live with an impaired quality of life. In infancy and young children, verbal expression of symptoms is often vague or impossible and persistent crying, irritability, back arching, feeding, and sleeping difficulties have been proposed as possible equivalents of adult heartburn. Infants with GERD learn to associate eating with discomfort and thus subsequently tend to avoid eating and develop an aversive behavior around feeds, although behavioral feeding difficulties are also common in control toddlers [61]. Esophageal pain and behaviors perceived by the caregiver (usually the mother) to represent pain (e.g., crying and retching) potentially affect the response of the infant to visceral stimuli and the ability to cope with these sensations, both painful and nonpainful. A placebo-controlled randomized trial with PPI in distressed infants showed an equal decrease in distressed behavior in the treatment and the placebo group [56]. To date, there is no evidence that acid-suppressive therapy is effective in infants who present solely with inconsolable crying. In infants and toddlers, there is no symptom or group of symptoms that can reliably diagnose GERD or predict treatment response. A pilot study suggested that a 40°supine position in a specially developed “Multicare Anti-Regurgitation (AR)-Bed” decreased regurgitation and infant irritability significantly [62].

GER(D), Dysphagia, Odynophagia, and Food Refusal

Dysphagia is the difficulty of swallowing; odynophagia is pain caused by swallowing. Although GERD is frequently mentioned as a cause of dysphagia or odynophagia, there are no pediatric data showing this relation. Dysphagia is a prominent symptom in patients with EoE. Feeding difficulty and/or refusal are often used to describe uncoordinated sucking and swallowing, gagging, vomiting, and irritability during

feeding. A relation between GER, GERD, and feeding refusal has not been established. In case of feeding difficulties, achalasia and foreign body should be among the list of possible differential diagnoses.

GER(D) and Extraesophageal Manifestations

Although evidence is sufficient to support an association between extraesophageal symptoms and GER, establishing that an individual patient’s extraesophageal symptoms are caused by reflux is difficult. Pulmonary microaspiration as demonstrated by pepsin detection in bronchoalveolar liquid (BAL) fluid is common in children with chronic lung diseases, suggesting that GER may contribute significantly to the disease pathogenesis [63]. BAL pepsin concentration correlates positively with the number of proximal reflux events [63]. Protein oxidation in BAL is higher in children with extensive proximal acidic reflux, suggesting that pulmonary microaspirations contribute to lung damage [63].

GER(D) and Reactive Airway Disease

An etiologic role for GER in reactive airway disease has not been demonstrated. Different pathophysiologic mechanisms are proposed: direct aspiration, vagal-mediated bronchial and laryngeal spasm, and neural-mediated inflammation. Esophageal acidification in infants with wheezing can produce airway hyperresponsiveness and airflow obstruction [64]. Few studies tempted to evaluate the opposite: the impact of asthma on the severity of GERD. Chronic hyperinflation that occurs in asthma favors many GER mechanisms. An association between asthma and reflux measured by pH or impedance probe has been reported in many studies (M7, M37). Wheezing appears more related to GERD if it is nocturnal. A recent study reports a high prevalence of GER in children and adolescents with persistent asthma, equally distributed in the supine (nocturnal) and upright positions [65]. But, there was no correlation between the result of the pH-metry and pulmonary function tests [65]. There are no studies that help in selecting patients in whom reflux treatment may result in a reduction of asthma medication, if there are such patients at all (M1, M37).

Very few prospective, randomized, and blinded treatment studies have been performed in children. In a series of 46 children with persistent moderate asthma despite bronchodilators, inhaled corticosteroids, and leukotriene antagonists, 59% (27/46) had an abnormal pH-metry [66]. Reflux treatment did result in a significant reduction in asthma medication. Patients with a normal pH-metry were randomized to placebo or reflux treatment: 25% (two of only eight chil-

dren) of the treated patients could reduce their asthma medication, while this was not possible in any patient on placebo [66]. Another study found omeprazole ineffective in improving asthma symptoms and parameters in children with asthma [67]. Overall, although there seems to be an association between GER and asthma, the causal role of GER has not been demonstrated. There is no association between asthma control status and laryngo-pharyngeal reflux and GER [68]. Current evidence does not support the routine use of anti-GERD medication in the treatment of poorly controlled asthma of childhood [69].

GER(D) and Recurrent Pneumonia

The reported mechanisms are similar to those for reactive airway disease. Direct aspiration during swallowing may be more relevant in this group. No test can determine whether reflux is causing recurrent pneumonia. Upper esophageal and pharyngeal pH and impedance recordings provided contradictory information. Today, it is not yet clear if recording in the upper esophagus or pharynx will help in making therapeutic decisions [70, 71]. A new technique to record pharyngeal reflux has been developed (Restech®) [71]. However, recent results could not confirm that the technique is reliable if compared to esophageal impedance [72].

Lipid-laden macrophages have been used as an indicator of aspiration, but their sensitivity and specificity for GER is poor. One study evaluating nuclear scintigraphy with late imaging reported that 50% of the patients with a variety of respiratory symptoms had pulmonary aspiration after 24 h [73]. However, later studies failed to reproduce these findings [74]. Aspiration also occurs in healthy subjects, especially during sleep [1].

The role of reflux in patients with bronchopulmonary dysplasia and other chronic respiratory disorders is not clear. Today, the clinician has frequently no other option than to make management decisions based on inconclusive diagnostic studies with no certainty regarding outcome [1]. As in reactive airway disease, it is very likely (although not evidence based proven) that (not all) reflux needs to be acid to cause airway manifestations. However, today, medical treatment options are limited to acid-reducing medication.

GER(D) and Cystic Fibrosis

The role of GER in adults and children with cystic fibrosis (CF) has been studied before and after transplant [75, 76]. Acid reflux exists in the majority of CF patients [1]. A high prevalence of acid GER was reported in very young CF infants even before respiratory symptoms developed [75]. CF

patients also suffer from duodeno-gastroesophageal reflux of bile acids [77]. It is possible that the acid and bile reflux are aggravating the respiratory symptoms, and that the respiratory symptoms aggravate the reflux. Aggressive medical and surgical reflux treatment in this patient group seems reasonable. In children with CF, a better weight gain was reported during PPI treatment (whether this is due a reduction of acid reflux or better buffering of acid gastric content in the intestine is not clear).

GER(D) and ENT Manifestations

Both acid and weakly acid GER may precede cough in children with unexplained cough, but cough does not induce GER [78]. Objective cough recording improves symptom association analysis (M75 ZCC). Several studies revealed the presence of pepsin in the middle-ear fluid, but with a huge variation in incidence (14–73%) [1, 79]. Also bile acids have been detected in middle-ear liquid, in higher concentrations than in serum [80]. The presence of pepsin and bile in middle ear fluid might as well be the consequence of reflux (and vomiting) at the moment of the acute middle ear infection than an argument to hypothesize that chronic GER may be at the origin of the chronic middle ear problem. However, several epidemiologic studies suggest a low incidence of reflux symptoms in patients with recurrent middle ear infections.

Data suggesting a causal relation between reflux and upper airway disease in children are limited. Data from several placebo-controlled studies and meta-analyses uniformly have shown no effect of anti-reflux therapy on upper airway symptoms or signs [1]. Well designed, prospective, placebo-controlled, blinded studies are needed. Another bias might be the selection of patients: These studies are frequently setup in tertiary care centers in highly selected patient populations. The question is how representative these patients are for the bulk of children with upper respiratory and/or ENT manifestations.

GER(D) and Dental Erosions

Young children and children with neurologic impairment appear to be at greatest risk to have dental erosions caused by GER. Juice drinking, bulimia, and racial and genetic factors that affect dental enamel and saliva might be confounding variables that have been insufficiently considered [1]. Recently, a positive correlation between GERD and dental erosion has been as well confirmed as refuted [81, 82]. There are no long-term (intervention) follow-up studies in high-risk populations.

GER(D) and Sandifer Syndrome

Sandifer syndrome (spasmodic torsional dystonia with arching of the back and opisthotonic posturing, mainly involving the neck and back) is an uncommon but specific manifestation of GERD.

GER(D) and Neurologic Impairment

Children with neurologic impairment have more frequent, more severe, and more difficult to treat GERD than neurologically normal children. Neurologically impaired children accumulate many risk factors for severe GERD: spasticity or hypotonicity, supine position, constipation, etc. Diagnosis of reflux disease in these children is often difficult because of their underlying conditions. Whether this group of patients has more severe reflux disease, or has less effective defense mechanisms, or presents with more severe symptoms because of the inability to express and/or recognize symptoms remains open for debate. Response to treatment, both medical and surgical, is poor in the neurologically impaired child compared to the neurologically normal child.

GER(D) and Apnea, ALTE and SIDS

Literature can best be summarized as follows: series fail most of the time to show a temporal association between GER and pathologic apnea, ALTE, and bradycardia [1, 83]. However, a relation between GER and short, physiologic apnea has been shown [84]. GER is a frequent cause of interrupting sleep in infants, and nonacid GER is equally important as acid GER for causing arousals and awakenings in infants [85]. Discomfort is significantly associated with reflux events and does not differ between weakly acidic and acid refluxes [86]. There are well-selected cases or small series that demonstrate that pathologic apnea can occur as a consequence of GER. However, in general, GER is not related to pathologic apnea, significant bradycardia, ALTE, and sudden infant death syndrome (SIDS) [83].

GER(D) and Other Risk Groups

Symptomatic GER is extremely frequent in patients treated for esophageal atresia and/or tracheoesophageal fistula because of serious structural and functional deficiencies [87]. It is refractory to medical treatment and often requires anti-reflux surgery. However, the high rates of wrap failure invite close follow-up in all cases and reoperation or other measures whenever necessary [87]. Children with congenital abnormalities or after major thoracic or abdominal surgery are

at risk for developing severe GERD. Children with anatomic abnormalities such as hiatal hernia, repaired esophageal atresia and malrotation have frequently severe GERD. There are no data in the literature that preterm babies have more (severe) reflux than term-born babies, although many preterms are treated for reflux.

GERD and Complications

Barrett's esophagus, strictures, and esophageal adenocarcinoma are complications of chronic severe GERD. Barrett's esophagus is a premalignant condition in which metaplastic specialized columnar epithelium with goblet cells is present in the tubular esophagus. Differences in esophageal mucosal resistance and genetic factors may partially explain the diversity of lesions and symptoms.

More than 50 years ago, in the absence of reflux treatment, esophageal strictures were reported in about 5% of the children with reflux symptoms [88]. Currently, esophageal stenosis and ulceration in children have become rare. In a series including 402 children with GERD without neurological or congenital anomalies, no case of Barrett's esophagus was detected [47]. In another series including 103 children with long-lasting GERD, and not previously treated with a H₂RA or a PPIs, Barrett's esophagus was detected in 13%. An esophageal stricture was present in 5 of the 13 patients with Barrett's esophagus (38%) [89]. Reflux symptoms during childhood were not different in adults without than in adults with Barrett's esophagus [90]. Barrett's esophagus has a male predominance and increases with age. Patients with short segments of columnar-lined esophagus and intestinal metaplasia have similar esophageal acid exposure but significantly higher frequency of abnormal bilirubin exposure and longer median duration of reflux symptoms than patients without intestinal metaplasia [91]. There is a genetic predisposition in families in patients with Barrett's esophagus and esophageal carcinoma [1].

Children with neurological impairment, chronic lung disease (especially CF), esophageal atresia, and chemotherapy have the most severe pathologic reflux and are at high risk for the development of complications of GERD [1].

Peptic ulcer, esophageal and gastric neoplastic changes in children are extremely seldom. In adults, over the past 30 years, a decreased prevalence of gastric cancer and peptic ulcer with an opposite increase of esophageal adenocarcinoma and GERD has been noted. This has been attributed to independent factors among which changes in dietary habits such as a higher fat intake, an increased incidence of obesity and a decreased incidence of *H. pylori* infection. Recent data suggest obesity does not play a major role [92]. The incidence of noninvasive in situ cancer has actually declined after 2003 [93]. Frequency, severity, and duration of reflux

symptoms are related to the risk to develop esophageal cancer. Among adults with long-standing and severe reflux, the odds ratios are 43.5 for esophageal adenocarcinoma and 4.4 for adenocarcinoma at the cardia [94]. It is unknown whether mild esophagitis or GER symptoms persisting from childhood is related to an increased risk for severe complications in adults. However, Barrett's esophageal adenocarcinoma affects young individuals [95].

Diagnosis

Diagnostic procedures are not discussed in full detail. Detailed information regarding indications and pitfalls of radiologic contrast studies, nuclear reflux scintigraphy, ultrasound, pH-metry, intraluminal impedance, endoscopy, manometry, gastric emptying tests, and electrogastrography can be found in previous review papers and guidelines [1].

In adults, diagnosis of GER disease is mainly based on clinical history. However, history in children is difficult and considered poorly reliable up to the age of minimally 8 or even 12 years old. Therefore, questionnaires have been developed trying to improve history reliability. Orenstein developed the "infant GER questionnaire" [96]. The questionnaire results in an objective, validated, and repeatable quantification of symptoms suggestive of GERD. The I-GER was revised (the "I-GERQ-R") in 185 patients and 93 controls, resulting in an internal consistency reliability from 0.86 to 0.87, and test-retest reliability was 0.85 [97]. However, Aggarwal and coworkers showed that the I-GER-Q had a sensitivity of only 43% and a specificity of 79% [98]. Moreover, pH-metry results were not different according to a "positive" or "negative" score of the I-GER-Q [98]. Our group showed that not one question was found to be significantly predictive for the presence of esophagitis. In our hands, the Orenstein I-GERQ cut-off score failed to identify 26% of the infants with GERD (according to pH-metry results or presence of esophagitis), but was positive in 81% of the infants with a normal histology of esophageal biopsies and normal pH-metry [99]. Deal et al. developed two different questionnaires, one for infants and one for older children, and showed that the score was higher in symptomatic than in asymptomatic children [100]. In other words, the correlation between the results of history obtained by questionnaires and of reflux investigations is poor.

Barium contrast radiography, nuclear scintiscanning, and ultrasound are techniques evaluating postprandial reflux and provide limited information on gastric emptying. Normal ranges are not established for any of these procedures. Barium studies are not recommended as first-line investigation to diagnose GERD, but are of importance to diagnose anatomic abnormalities such as malrotation, duodenal web,

stenosis, and may suggest functional abnormalities such as achalasia, etc. Nuclear scintigraphy may show pulmonary aspiration [73]. Also, aspiration of saliva and gastric contents occurs during sleep in healthy adults [101]. Scintigraphy also can estimate gastric emptying. But the ^{13}C -octanoic acid (for solids) and ^{13}C -acetate (for liquids) breath tests are more appropriate to measure gastric emptying. The role of delayed gastric emptying in GER(D) remains controversial. Ultrasound provides morphological and functional data with high sensitivity and positive predictive value for the diagnosis of GER [102]. Sonographic assessment of findings such as abdominal esophageal length, esophageal diameter, esophageal wall thickness, and gastroesophageal angle provide important diagnostic indicators of reflux and related to the degree of GER [102]. However, there is a need for standardization of the procedure and for defining diagnostic criteria [102]. The results of ultrasound are investigator dependent, and a relation between reflux seen on ultrasound and symptoms has not been established [1]. There is no indication for electrogastrography in the diagnostic work up of a patient suspected of GERD.

Modern endoscopes are so much miniaturized that endoscopy of preterm infants of less than 1000 g has become technically easy. Operator experience is an important component of interobserver reliability [1]. Endoscopy allows direct visual examination of the esophageal mucosa. Macroscopic lesions associated with GERD include esophagitis, erosions, exudate, ulcers, strictures, hiatal hernia, etc. Redness of the distal esophagus in young infants is a normal observation because of the increased number of small blood vessels at the cardiac region. Endoscopy may also show a "sliding hernia," the stomach that is protruding in the esophagus during burping. Recent consensus guidelines define reflux esophagitis as the presence of endoscopically visible breaks in the esophageal mucosa at or immediately above the GE junction [1, 2]. Endoscopy-negative reflux disease is common. There is a poor correlation between the severity of symptoms and presence and absence of esophagitis. There is insufficient evidence to support the use of histology to diagnose or exclude GERD. Biopsies of duodenal, gastric, and esophageal mucosa are mandatory to exclude other diseases [1]. More detailed information on pros and cons of histology can be found in the recent consensus papers [1, 2].

Intraluminal esophageal acid perfusion provoking chest pain (Bernstein test) or using other endpoints has found expanded use in practice and research in the USA, but was never popular in Europe. Ambulatory 24-h esophageal pH monitoring measures the incidence and duration of acid reflux, while impedance measures all reflux episodes. Esophageal pH-metry is the best method to measure acid in the esophagus, but not all reflux-causing symptoms are acid and not all acid reflux are causing symptoms. Esophageal

pH-metry is useful in evaluating the effect of a therapeutic intervention on reducing esophageal acid exposure. Medical treatment is nowadays focusing on the reduction of gastric acid secretion; the technique offers the possibility to measure intragastric and esophageal recording of pH simultaneously. Both hardware (electrodes, devices) and software influence the results [1]. Normal ranges have been established for pH-metry. However, normal ranges depend also on the hard- and software used and are of limited value for reflux-causing extraesophageal manifestations. It becomes more and more obvious that the major indication of long-term recording of pH and/or impedance is the demonstration of an association between reflux and symptoms.

Manometry does not demonstrate reflux, but is of interest to analyze pathophysiologic mechanisms causing the reflux, mainly by visualizing and measuring TLESRs, and is indicated in the diagnosis of specific conditions such as achalasia. Ambulatory 24-h esophageal manometry, in combination with pH-metry and/or impedance recording, is nowadays technically feasible. This technique is mainly used in (clinical) research, and allows the objective demonstration of reflux-symptom association (e.g., in patients presenting with chronic cough).

Intraluminal impedance measures electrical potential differences. As a consequence, the detection of reflux by impedance is not pH-dependent, but in combination with pH-metry it allows detection of acid ($\text{pH} < 4.0$), weakly acid ($\text{pH} 4.0\text{--}7.0$) and alkaline reflux ($\text{pH} > 7$). Experience has shown that impedance needs to be performed in combination with pH-metry, since pH-only events occur (mainly during the night and mainly in young infants). Also gas reflux can be measured, since liquid reflux causes a drop in impedance and gas reflux an increase. Interpretation of the recording is still laborious and necessitates sufficient experience, since the automatic analysis is not standardized and not adequate in (young) children and infants. Impedance seems especially of interest in patients with symptoms suggesting reflux but not esophagitis. Obviously, “more” reflux episodes are detected with impedance pH-metry than with pH-metry alone, but the question remains at this moment unanswered if “more is always necessary or better.” The major clinical interest of impedance seems to be demonstration of symptom association, but normal data and validation of symptom association parameters in children are missing. Given the high cost of equipment, electrodes, the time needed for analysis, and interpretation of impedance, the pros and cons in comparison to pH-metry are still debated. Impedance in combination with pH-metry definitively measures more reflux episodes than pH-metry alone. Interestingly, pH-only episodes or reflux episodes detected with pH-metry but not with imped-

ance (drop in pH without bolus movement) occur in young children [103].

Experience in children with spectrophotometric esophageal probes to detect bilirubin is still very limited. Orel and coworkers showed that some children with esophagitis suffer bile reflux [104].

Indirect techniques have been developed, mainly to diagnose GER(D) in patients with extraesophageal manifestations. Accumulation of evidence regarding the determination of lipid-laden macrophages (LLM) in BAL resulted in the conclusion that this method lacks sensitivity and specificity [1]. More recent data show the presence of pepsin in BAL and middle ear fluid [1, 74]. Also, bile salts are detected in middle ear fluid [80]. However, epidemiological data suggest a “protective” role of middle ear infection for the prevalence of GERD [1]. There is no prospective, double-blind, placebo-controlled study treating reflux and evaluating the ENT outcome as primary endpoint.

All GER investigation techniques test different aspects of reflux. Therefore, it is not unexpected that the correlation between the results of the different techniques is poor. There is no “always-best” investigation technique to diagnose GER(D) because the clinical situation of each individual patient differs. “Logic interpretation” (but not evidence-based medicine) suggests that if the question asked is: “does this patient have esophagitis,” that endoscopy with biopsy is the best technique. If it is in the interest of the patient to measure acid GER episodes, 24-h pH-metry is the preferred technique. But if quantification of all GER episodes is needed, impedance is likely to be the best. Impedance measures also weakly acid and alkaline reflux. However, postprandial reflux is mainly weakly acid or alkaline, and postprandial reflux was in general considered to be not really relevant, since the techniques measuring postprandial reflux (barium swallow, ultrasound, scintiscanning) are not recommended for this reason. Therapeutic options are mainly limited to acid-reducing medication. As a consequence, it can be questioned if it is really relevant to measure weakly acid and alkaline reflux.

Therapeutic Options

Physiologic GER and regurgitation do not need medical treatment, although they frequently cause parental distress and anxiousness. Any therapeutic intervention should always be a balance between intended improvement of symptoms and risk for side effects. Therapeutic options vary from reassurance, nutritional and positional treatment, prokinetics, and acid-reducing medications to surgery (Table 10.6).

Table 10.6 Schematic therapeutic approach in 2014. (Efficacy and safety data in infants and children for most anti-GER medication are limited)

Phase 1	Parental reassurance, observation, life-style changes, exclude overfeeding
Phase 2	Dietary treatment (to decrease regurgitation and infant distress)
	Thickened formula, thickening agents, (thickened) extensive hydrolysates or amino acid-based formula in cow's milk allergy
	Positional treatment ^a
Phase 3	For immediate symptom relief: alginates (some efficacy in moderate GERD); antacids only in older children
Phase 5	Prokinetics in NERD (but not one product available on the market in 2014 has been shown to be effective)
Phase 4	Proton pump inhibitors (PPIs) in ERD (drug of choice if esophagitis; more safety data needed)
	H ₂ receptor antagonists less effective than PPIs, but easier to administer if PPI-liquid form does not exist
Phase 6	Laparoscopic surgery

^a limited data on 40° supine sleeping position in infants

GERD gastroesophageal reflux disease, NERD non-erosive reflux disease

Complications of Non-intervention

Although reviews on the natural evolution of regurgitation are available [10–12], there are only limited data on the natural history of GERD in infants and children because most patients do receive treatment at some point.

Traditionally, the impact of regurgitation on the long-term quality of life is trivialized since regurgitation is transitory in the vast majority of infants. However, recent data suggest a decreased quality of life in a number of parents of infants presenting with frequent regurgitation, even if the regurgitation has disappeared [61]. Infants spilling during 90 days or more during the first 2 years of life are at a greater risk for GER symptoms at 9 years [11]. Frequent versus infrequent infant spitting is related to a relative risk at 9 years of 2.3 (95% CI 1.3–4.0) for at least one GER symptom, of 4.6 (95% CI 1.5–13.8) for heartburn, of 2.7 (95% CI 1.4–5.5) for vomiting, and of 4.7 (95% CI 1.6–14.0) acid regurgitation [10, 11]. It is unclear if regurgitation is less frequent in breastfed than in formula-fed infants, since data are contradictory [10, 11]. Gender is not a confounding factor, but smoking is [24]. Although symptoms improve in more than half of the infants with reflux esophagitis followed longitudinally for 1 year without pharmacotherapy, histology remains abnormal in all [105]. But, it is not known if treatment of regurgitation, GER and GERD during infancy changes the outcome in adults.

In Conclusion Although there is consensus that regurgitation and physiologic GER do not need medical treatment, some data suggest that nonintervention may have in some families a negative impact on the quality of life. Limited data suggest that frequent regurgitation may predispose to develop GER-symptoms later in life.

Nonpharmacological and Nonsurgical Therapies for GER

The most common reason to seek medical help for young infants with suspected GERD is frequent troublesome regurgitation and infant distress. Because infants with physiologic but troublesome regurgitation are difficult to distinguish from infants with mild-to-moderate GERD symptoms, nonpharmacologic treatment (reassurance, dietary, and positional treatment) is recommended as an appropriate first approach. The difference between “physiologic” and “pathologic” GER should not be regarded as a clear delineation, but as a continuum where “at some point” “normal” stops and “disease” begins. Parental coping plays a major factor in this process.

In many situations, reassurance means observation of feeding and handling of the child during and after feeding (Fig. 10.4: Practical algorithm for the management of infant regurgitation). A “reduction of the ingested volume” per feed is a classic recommendation that can be found in all overviews and guidelines or recommendations [1, 3, 106]. However, there are no data that relate ingested volume to frequency and volume of regurgitation, although it seems logical to hypothesize that feeding of large volumes favors regurgitations since it will increase TLESRs. Reassurance while showing compassion for the impaired quality of life is of importance [1, 3, 106, 107].

Recent data suggest that parental reports during a first consultation may be inaccurate and overestimate the incidence of regurgitation [107], similar to what is well known regarding crying infants or infant colic. The inclusion criterion for a multicenter French study was more than five episodes of regurgitation per day since more than 1 week [107]. The study started with a 3-day baseline diary, and only 75% of the infants said initially to regurgitate more than five times did effectively so when the frequency of regurgitation

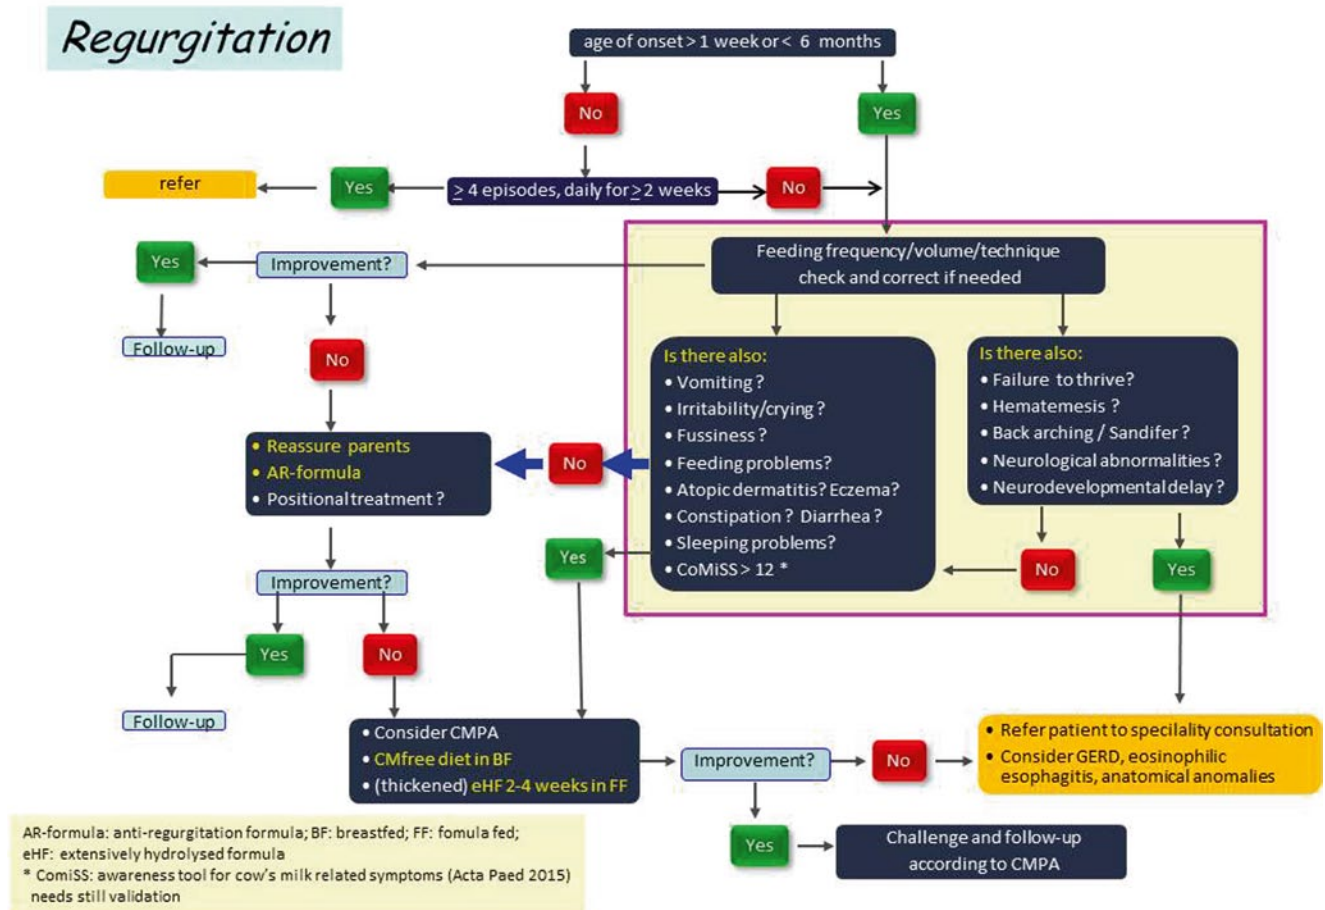

Fig. 10.4 Algorithm for the management of infant regurgitation. *CMPA* cow's milk protein allergy, *BF* breastfed, *CM* cow's milk

was recorded prospectively [107]. These findings question the efficacy of “reassurance and guidance” which in most studies turns around 20%. If the data of this French study are confirmed, the efficacy of “nonintervention” seems to be nothing else than “bring the observations back to reality”. Nevertheless, this information illustrates that prospective registration of the so-called problem will help to bring a solution in about one patient/family in four.

Horvath et al. performed a meta-analysis of 14 studies on anti-regurgitation (AR)-formula and concluded that AR-formula decreases the number of episodes of regurgitation and increases the number of infants that do not regurgitate [108]. Thus, a thickened commercialized AR-formula meets up to its expectations, as it decreases visual regurgitation, but not systematically decreases (acid) reflux [109]. AR-formula is “anti-regurgitation” formula and not an “anti-reflux” formula. Thickened formula reduces regurgitation more and faster than the natural evolution [110]. Commercialized thickened formula is preferred to thickening agents added to formula at home because the nutritional content of the thickening agent and its effect on osmolarity has been taken in account in the global composition of the commercialized formula [1, 106].

However, data from three independent studies suggest acid reflux is actually reduced with cornstarch-thickened formula [108]. A French survey reported a significant ($p < 0.05$) greater use of volume reduction or milk thickeners and dorsal positioning in infants with GERD than in infants with physiological GER [21].

At a certain moment, nutritional safety concerns have been raised based on the findings from an in vitro model that bean gum may hamper the absorption of micronutrients [111, 112]. However, in vivo data have contradicted this fear [113]. Therefore, NASPGHAN and ESPGHAN recommend the use of AR formula, irrespective of the thickening agent, for which clinical efficacy has been demonstrated [1]. Recent data suggest that the efficacy may be improved by changing the protein source to a partial or extensive hydrolysate [1, 109]. Partial hydrolysates may be more effective because they have a better digestibility than native protein and an enhanced gastric emptying [114]. Dietary protein allergy may be a cause of reflux, regurgitation, and vomiting and is often accompanied by a distressed behavior [1, 46]. Whether the efficacy of hydrolysates on reducing regurgitation, vomiting, and GER should be regarded as a proof of

Fig. 10.5 The Multicare AR bed

(non-IgE-mediated) CMPA or whether the efficacy should be considered as an effect of the more rapid gastric emptying of an extensive hydrolysate than native protein is a matter of debate. The fact that postprandial weak acid reflux is increased after a cow milk challenge if compared to an extensive hydrolysate [44], may as well be consecutive to allergy as to a slower gastric emptying, and thus does not contribute to solve this dilemma. Since vomiting, regurgitation, and reflux are also manifestations of CMPA, thickened extensive hydrolysates may be considered since they treat both regurgitation (reflux) and CMPA. Ongoing studies suggest promising results with thickened extensive hydrolysates [115].

Sleeping positions that have been suggested to reduce GER include prone, immediate right side with later left side after feeding, and supine 40° anti-Trendelenburg [62, 116]. Prone position is considered obsolete in infants because of the increased risk for SID. Van Wijk et al. concluded that the biggest benefit was achieved with a strategy of right lateral positioning for the first postprandial hour with a position change to the left thereafter to promote gastric emptying and reduce liquid GER in the late postprandial period [62]. However, at least two independent studies reported a significantly increased risk of SID in the side compared to the supine sleeping position [117, 118]. The results of a pilot study with the “Multicare-AR Bed®” suggest that a specially made bed that nurses the infant in a 40° degree supine body position reduces regurgitation, acid reflux (measured with pH monitoring) and reflux-associated symptoms (evaluated with the I-GERQ; Fig. 10.5) [62].

In Conclusion Labeling an otherwise healthy infant as having a “disease” increases parents’ interest in medicating their infant [6]. The use of disease labels may promote overtreat-

ment by causing people to believe that ineffective medications are both useful and necessary [6]. For noncomplicated reflux, no medical intervention is required for most infants. Reassurance and dietary treatment in formula-fed infants are the best therapeutic approach of infant regurgitation. Dietary treatment does not treat GERD. Parental reassurance and education regarding regurgitation and lifestyle changes such as the use of thickened formula are usually sufficient to manage infant noncomplicated reflux and regurgitation [1, 2, 119]. Recent, limited data seem to suggest that the protein source (hydrolysate) may also be effective in reducing regurgitation. Data on the efficacy of positional treatment are limited but encouraging.

Pharmacological and Nonsurgical Therapies for GER

Pharmacotherapeutic agents used to treat GERD encompass antisecretory agents, antacids, surface barrier agents, and prokinetics.

Prokinetics and Other Nonacid Reducing/Blocking Medication

From the pathophysiologic point of view, prokinetics are the most logic therapeutic approach to treat NERD in infants, since acid plays only a minor role in GERD in this age group. However, there is no effective and safe prokinetic agent on the market. Cisapride was probably the prokinetic for which efficacy data were the strongest, although only a decrease of the reflux index (% time pH was <4.0) has been shown: Cisapride significantly reduced the reflux index (weighted mean difference -6.49 ; 95% CI -10.13 to -2.85 ; $P=0.0005$) [120]. But cisapride was taken off the market in the beginning of this century by the American and European authorities because of its cardiac adverse effects such as QT prolongation and torsades de pointes.

Other prokinetics are metoclopramide and domperidone. The efficacy studies with metoclopramide are limited and outdated [121]. The seven metoclopramide studies performed in children under the age of 2 years are all from before 1990 and used a variety of outcomes (345). Compared to placebo, metoclopramide appears to reduce daily symptoms (SMD -0.73 ; 95% CI -1.16 to -0.30), and to reduce the reflux index (WMD -2.80% ; 95% CI -5.58 to -0.01) [121]. Metoclopramide has a high incidence of side effects such as lethargy, irritability, gynecomastia, galactorrhea, and extrapyramidal reactions and has caused permanent tardive dyskinesia [122–125]. There is no evidence to recommend the use of metoclopramide in GERD [126]. A systematic review of studies on domperidone identified only four randomized controlled trials in children, none providing “robust evidence” for efficacy in pediatric GERD [127]. Domperi-

done occasionally causes extrapyramidal central nervous system side effects [49]. Recently, the cardiac side effects of domperidone have been highlighted and are reported to be comparable to those of cisapride [128–130]. It is not possible to support the use of domperidone in the treatment of uncomplicated GER in infancy [131]. Governmental agencies should be consequent: If the cardiac risk for cisapride was sufficient to withdraw that molecule from the market, despite the weak evidence of efficacy, the same decision should be taken for domperidone since the cardiac risks seem similar and efficacy was not demonstrated [130, 132].

Other prokinetic molecules, such as mosapride, itopride, prucalopride, and renzapride, have not or insufficiently been studied in children.

Bethanechol, a direct cholinergic agonist, is studied in a few controlled trials and has uncertain efficacy and a high incidence of side effects in children with GERD [1]. Baclofen is a gamma-aminobutyric acid (GABA)-B receptor agonist used to reduce spasticity in neurologically impaired patients. Baclofen was shown to reduce the number of TLSERs and acid GER during a 2-h test period and accelerate gastric emptying [133]. Baclofen can be used as a supplemental therapy to PPIs in children with refractory GER, although failure rate is around 33% [134]. The data on baclofen are very limited, and the high incidence of adverse events does not justify its widespread use. Also baclofen did not fulfill its promises. M0003 (Shire) is a “next-generation gastrokinetic,” but clinical studies have been postponed. M0003 is a specific and high-affinity 5-HT₄ agonist for the treatment of upper GI disorders, focusing initially on severe gastroparesis and pediatric reflux.

In Conclusion Although the prokinetic concept is of interest, there is no effective prokinetic (or nonacid-reducing anti-reflux drug) on the market. Moreover, all have a high incidence of adverse effects. Currently, the NASPGHAN and ESPGHAN practice guidelines concluded that there is insufficient evidence to justify the routine use of prokinetic agents [1]. This viewpoint was recently endorsed by the American Academy of Pediatrics [3].

Alginate (-Antacids) and Mucosaprotectors

Alginate (-antacids) have mainly been validated in adults. Their key therapeutic advantage is their rapid onset of action, within minutes from ingestion. However, there are no convincing efficacy data in pediatrics. Results showed a marginal but significant difference between Gaviscon Infant and placebo in average reflux height (being better for placebo!), and raise questions regarding any perceived clinical benefit of its use [135]. Data on compliance in infants and children (these products have a poor taste) and side effects (many antacids have a high aluminum content) are missing [1].

Extrapolating from adult data, one may conclude that it is unlikely that mucosaprotectors would be effective in children.

In Conclusion Based on expert opinion, there may be a transitory place for alginates in patients with GERD in whom rapid symptom resolution is required, but there is no evidence for this recommendation.

H²-Receptor Antagonists and Proton Pump Inhibitors

Since PPIs are more effective in acid suppression than H²RAs, PPIs are considered the preferred option for treatment of (acid) GERD in children and adults [136]. Some infants presenting with symptoms assumed to be causing GER and to be acid related fail to respond to acid suppression with ranitidine, either because they need better acid suppression or because the symptoms are not acid related [137]. It has been shown in adults and children that PPIs do not reduce the incidence of reflux episodes [138, 139]: They only change the pH of the reflux from acid to nonacid or weakly acid. Because PPIs in liquid formulation are only available in a very limited number of countries, H²RA-sirup remains popular since it is available worldwide, making it easier to administer in infants and young children. When compared with H²RA-initiated patients, PPIs are associated with 30% less discontinuation, 90% less therapy switching in the first month, a higher comorbidity burden and pretreatment total health care cost [140].

The prescription rates of antacid medications such as PPI and H²RAs are still on the increase [55]. Between 2002 and 2009, there was an 11-fold increase of the use of PPI in the USA [57]. In 2010, lansoprazole was the 9th and ranitidine the 14th most prescribed drug in children under 2 years of age in the USA [55].

Since gastrin release after a meal is one of the most potent activators of H⁺-K⁺-adenosine triphosphatase (ATPase), PPI should be administered long enough before a meal to be absorbed, but not eliminated, by the time the proton pump is activated [141]. It may be preferred to administer PPI once a day before breakfast because young children eat frequently during the day. PPI must be protected from gastric acid by enteric coating; the granules and tablets should not be crushed, chewed, or dissolved as gastric acid secretion may alter the drug. If the microgranules are enteric coated, the capsules can be opened and administered orally or via a feeding tube, in suspension in an acidic medium such as fruit juice, yogurt, or apple sauce. A “home-made” liquid formulation, produced by dissolving the granula, not the microgranula, in 8.4% bicarbonate solution has been developed [1].

Omeprazole is approved in the USA and Europe for use in children older than 1 year of age; in the USA, lansoprazole is

approved as well. Esomeprazole is now approved in the USA for short-term treatment of GERD with erosive esophagitis in infants aged from 1 to 12 months [119]. In Europe, approval for esomeprazole is identical to the approval of omeprazole. Pharmacodynamics and -kinetics have been studied for many PPI molecules in different age groups. In children aged 6–16 years with GERD, currently available pantoprazole delayed-release tablets can be used to provide systemic exposure similar to that in adults [142]. Simulations indicated that the 1.2-mg/kg dose provides the best comparison to adults [143]. Pantoprazole is generally well tolerated in infants and children aged 1 month through <6 years; compared with adults receiving pantoprazole 40 mg, exposure obtained with the 1.2-mg/kg dose was similar [144]. In neonates, preterm infants, and infants aged 1 through 11 months, pantoprazole (high dose) improved pH-metry parameters after ≥ 5 consecutive daily doses, and it was generally well tolerated for ≤ 6 weeks [145]. In preterm infants and neonates, pantoprazole granules are generally well tolerated; mean exposures with pantoprazole 2.5 mg were slightly higher than that in adults who received 40 mg [146]. While the half-life was longer, accumulation did not occur [146]. After 5 days of open-label administration, lansoprazole was well tolerated and increased intragastric pH in pediatric subjects <1 year of age [147]. When PPIs need to be administered through a nasogastric tube, the most satisfactory results were obtained with lansoprazole orally disintegrating tablet [148]. A 5-ml volume of water diluent for suspension and a 10-ml volume

of flush-through water made it possible to deliver the full lansoprazole dose administered [148].

Authorities seem to approve PPIs in neonates, infants, and children rather on pharmacologic studies than on effectiveness in the treatment of GERD [57, 141]. Indeed, most studies evaluating the efficacy of PPI in newborns and infants are negative, while efficacy is well established in older children (Table 10.7). Reasons that have been proposed for this discrepancy are complex, ranging from GERD not occurring in this population to a lack of histologic identification of esophagitis related to GERD to questions about the validity of symptom-scoring systems to identify esophagitis when it occurs in infants [141].

For unclear reasons, the belief that many infants do present with (excessive) crying because of (excessive) esophageal acid exposure has become extremely popular over the past 10 years. Many infants have periods of unsettledness, or irritability, over the first months of life. Spilling (or possetting) due to reflux of gastric contents is also seen very frequently. Almost universally, these are normal patterns of infancy that resolve with the passage of time. In recent years, these normal developmental processes have increasingly been ascribed to pathology and treated with medical therapies, including acid suppressants [162]. GERD may cause excessive crying in infants [40]. The concept that infant irritability and sleep disturbances are manifestations of GER is largely extrapolated from adult descriptions of heartburn and sleep disturbances that improve with antacid therapy

Table 10.7 Studies evaluating the efficacy of PPI in newborns, infants, and children (published between 2007 and 2013). (OA original article, rev review)

Author year	Paper (ref)	Age	Result
Baker (2010)	OA [149]	1–5 year	Pantoprazole effective in GERD with esophageal symptoms
Davidson (2013)	OA [57]	Neonates	PPIs are not effective
Higginbotham (2010)	Rev [150]	Infants and children	PPIs are not effective in common infant GERD-associated symptoms
Lee (2011)	OA [151]	4–18 years	PPIs are effective
Terrin (2012)	OA [152]	Preterm	H ² RA not effective; associated with infections, necrotizing enterocolitis and fatal outcome
Tjon (2013)	Rev [153]		RCTs and systematic reviews: lack of efficacy of PPIs, specifically in young infants
Tolia (2010)	OA [154]	1–11 year	Esomeprazole heals macroscopic and microscopic erosive esophagitis
Ummarino (201)	OA [155]	1–181 month	PPI > H ² RA for respiratory symptoms
Van der Pol (2011)	Rev [156]	Infants	PPIs not effective in reducing GERD symptoms
Wheatley (2009)	OA [157]	Preterm	H ² RA: no effect on bradycardia
Winter (2010)	OA [158]	1–11 month	During double-blind treatment, there were no significant differences between pantoprazole and placebo in withdrawal rates due to lack of efficacy
Winter (2012)	OA [56]	1–11 month	During double-blind treatment, there were no significant differences between esomeprazole and placebo in withdrawal rates due to lack of efficacy
Gilger (2008)	OA [159]	1–11 years	Symptom improvement
Gold (2007)	OA [160]	12–17 years	Symptom improvement
Shashidhar (2013)	Rev [161]	0–18 years	PPIs are effective in healing reflux esophagitis in children of all ages but do not improve GER-related symptoms in infants

The table is not exhaustive but lists the papers on Pubmed between 2007 and 2013 with “proton pump inhibitor infant” and “proton pump inhibitor pediatric” as search terms and illustrates the differences in outcome according to age of the patients

PPI proton pump inhibitor, H²RA histamine receptor antagonists, RCTs randomized controlled trials, GERD gastroesophageal reflux disease

[1]. However, there is no evidence for this hypothesis. In the paper by Heine et al., all infants with pathological GER presented with frequent vomiting, and “silent” pathological reflux did not occur [40]. Poor weight gain, feeding refusal, back arching, and sleep disturbance were not significantly associated with pathological GER [40]. These observations suggest that pathological GER is an unlikely cause of infant irritability under the age of 3 months [40]. Several placebo-controlled prospective trials with PPIs in infants presenting with “excessive crying and reflux-like symptoms” have been performed and show negative results, with an increased incidence of adverse events in the PPI group sometimes as being the only difference in outcome [56–58].

Antacid medications are among the most commonly prescribed medications in neonatal intensive care units in the USA because they are administered to treat clinical signs thought to be caused by GER, such as apnea, bradycardia, or feeding intolerance, despite the lack of evidence of efficacy in this population [55, 140]. Use of anti-reflux medications at the time of discharge seems to be common for extremely low-birth-weight infants, especially those discharged at postmenstrual age of >42 weeks [49]. In some neonatal centers, nearly 50% of the infants discharged at postmenstrual age of >42 weeks are discharged with anti-reflux medications [49]. The lack of evidence of PPI in neonates seems not to determine the beliefs of physicians [163]. With no agreed-on standard of care in the setting of widespread use of anti-reflux medications, greater understanding is needed about the ways physicians form clinical impressions, access and process medical evidence, and apply it to patient care [163]. The extreme variability among the centers in use patterns of PPI, H²RAs, and metoclopramide suggests lack of an adequate evidence base to guide practice and indicates that case controlled studies or random controlled trials are needed to devise a consistent evidence-based approach [164].

Prolonged treatment of pediatric patients with PPIs has not caused cancer or significant abnormalities [141]. There are different categories of adverse effects related to PPI: idiosyncratic reactions, drug–drug interactions, drug-induced hypergastrinemia, and drug-induced hypochlorhydria [1]. Idiosyncratic reactions occur in up to 12–14% of children taking PPIs: headache, diarrhea, constipation, and nausea [1]. Acid suppression or hypochlorhydria causes abnormal GI flora and bacterial overgrowth [165]. As a consequence, the prevalence of infectious respiratory and GI tract infections are increased [1, 166, 167]. PPIs are associated with an increased risk of colonization and infection with *Clostridium difficile* [168, 169]. PPIs, particularly if administered for <30 days or in a high dose, showed an association with community-acquired pneumonia [170]. Hypomagnesemia is reported as a rare but severe complication [171]. Whether or not PPI are associated with an impairment of bone mineralization remains open for debate [172]. Gastric acid suppres-

sion predisposes patients to develop food allergy [173–175]. Antacid medication during pregnancy was reported to increase the risk to develop asthma in the offspring [176].

In Conclusion If acid-reducing medication is indicated, PPI are more effective than H²RAs. PPIs are effective in healing reflux esophagitis in children of all ages but do not improve GER-related symptoms in infants [161]. PPIs have been shown to be very effective to reduce acid GER-related symptoms in older children and adolescents. However, these drugs are overused in newborns, infants, and young children. Several pharmacological studies have shown that PPIs are well tolerated and effectively reduce gastric acid secretion in newborns, infants, and young children. However, the vast majority of the clinical trials evaluating the therapeutic efficacy of PPIs in newborns and infants are negative. Adverse effects of PPIs such as the increased risk for gastroenteritis and respiratory tract infections are more relevant in infants, especially when clinical efficacy could not be demonstrated.

Surgery and Therapeutic Endoscopic Procedures

Different anti-reflux surgical approaches do exist. In general, experience seems to be the best guidance for choosing the preferred technique. Most of the literature on surgical therapy in children with GERD consists of retrospective case series in which documentation of the diagnosis of GERD and details of previous medical therapy are deficient, making it difficult to assess the indications for and responses to surgery [1]. The use of anti-reflux surgery has evolved during the laparoscopic era, with a decreasing percentage of neurologically impaired children undergoing this procedure [161]. Anti-reflux procedures were performed predominantly for infants, most of whom were neurologically normal [177]. Anti-reflux procedures in the USA are reported to be most commonly performed in children during a period of life when regurgitation is normal and physiologic and objective measures of GERD are difficult to interpret [178]. In contrast, in Europe, anti-reflux surgery is considered as a treatment of last resort in children with GERD refractory to pharmacological therapies [179]. Recent data suggest that the selection of patients who will benefit from surgery might be enhanced by automated impedance manometry pressure-flow analysis, which relates bolus movement and pressure generation within the esophageal lumen [179].

Adult series report that between 37 and 62% of the patients are taking PPI (again) a few years after the surgery [180, 181]. Fundoplication in children reduces GER without altering esophageal motility [182]. Since laparoscopic anti-reflux surgery is much less invasive than open surgery, causing less operative pain, faster recovery, shorter hospital stay, and a better cosmetic result, only laparoscopic surgery

should be performed. Long-term outcome of open and laparoscopic interventions are similar. While anti-reflux surgery in certain groups of children may be of considerable benefit, a failure rate of up to 22% has been reported [1]. Long-term follow-up after laparoscopic fundoplication produces a good clinical result and a good quality of life [183]. Surgery for GER patients have a significant improvement in their quality of life, not only by the reduction of their symptoms but also in enhancing from the nutritional status [184]. Patients with respiratory symptoms have a higher satisfaction after surgical treatment than those with GI symptoms [184]. Anti-reflux surgery in children shows a good overall success rate (median 86%) in terms of complete relief of symptoms [185]. Efficacy of anti-reflux surgery in neurologically impaired children may be similar to normally developed children [185]. The outcome of anti-reflux surgery does not seem to be influenced by different surgical techniques, although postoperative dysphagia may occur less after partial fundoplication [185]. Failure of Nissen fundoplication is particularly frequent in patients previously operated upon for esophageal atresia or congenital diaphragmatic hernia and can be predicted preoperatively [186]. A redo-Nissen is indicated if symptoms of GER recur, but the proportion of failure is even higher [186]. These conclusions are bound by the lack of high-quality prospective studies on pediatric anti-reflux surgery [185].

Children with underlying conditions predisposing to the most severe GERD comprise a large percentage of many surgical series. The robot-assisted Nissen fundoplication in children is a safe alternative to conventional laparoscopic surgery [187]. No data support the need for case selection to one of these two minimally invasive procedures [187]. Cardiaplication results in an increase in cardia yield pressure in young pigs. This procedure may be an alternative anti-reflux operation for infants [188].

Therapeutic endoscopic procedures are rarely indicated and should only be performed in units where there is evidence of experience [189]. The transoral incision-less fundoplication procedure can complement the current surgically and medically available options for children with GERD, especially in complicated patients such as those with neurological impairment [190]. However, complications including hemorrhage emphasize the potential risk of the procedure [190]. Total esophagogastric dissociation is an operative procedure that is useful in selected children with neurologic impairment or other conditions causing life-threatening aspiration during oral feedings.

In Conclusion Surgery is indicated when symptoms are life-threatening or when a child beyond the age of 2–3 years is depending on chronic treatment with antiacid medications such as H²RAs or PPIs. In neurologically impaired children, the risk and benefit of a surgical intervention should be well

balanced. Although Nissen fundoplication is now well established as a treatment option in selected cases of GERD in children, its role in neonates and young infants is unclear, and is only reserved for selective infants who did not respond to medical therapy and have life-threatening complications of GERD [119]. Experience with a given surgical procedure seems the best outcome predictor.

Introduction

Achalasia literally denotes the inability to relax (from the Greek words α- “not,” χάλασις “relaxation”). Sir Thomas Willis first described the classical symptomatology of achalasia in a patient with dysphagia to liquid food in 1672 [1]. He treated this individual by dilating the esophagus using a sponge attached to the tip of a whalebone. The term achalasia was first introduced in 1924 by Hurst in an attempt to describe the inability of the lower esophageal sphincter (LES) to relax in affected individuals [2]. Despite the lack of a clear explanation of the etiopathogenesis of the disease, an effective surgical treatment was proposed by Heller in 1913 [3].

Esophageal achalasia is a primary motility disorder of the esophagus. It is clinically characterized by various degrees of dysphagia to solids and liquids in the absence of other conditions that could possibly cause the same clinical symptoms (e.g., esophageal stricture, eosinophilic esophagitis). The radiological cardinal features consist of abnormal esophageal peristalsis, dilation of the esophageal body, and “bird beak” appearance at the level of the LES with concomitant delayed emptying of the contrast material from the esophagus. Endoscopically, this condition is generally characterized by esophageal dilation, presence of saliva or undigested food within the esophagus and resistance in passing the endoscope through the LES. Manometrically, this clinical entity is defined by the presence of variable impairment of esophageal peristalsis and inability of the LES to relax following swallowing [4]. Primary or idiopathic achalasia is the appropriate term to be used when there is no clear etiology for the disease, whereas in secondary achalasia the cause is by definition known [5].

Epidemiology

There are relatively limited data regarding the incidence of esophageal achalasia in children. It is however a rare disease [6] and according to two more recent studies its incidence in the pediatric population has been estimated between 0.1 and 0.3 cases annually per 100,000 children [7, 8]. This clinical entity can be encountered at any age; however, it seldom occurs in infancy as only 6% of the diagnoses have been made in this age group [9]. The peak incidence of the disease occurs between 30 and 60 years of age [10, 11]. Although there are data in adult population revealing equal gender distribution, childhood achalasia is more frequent in males than females [9]. Available data do not support any racial predilection among affected individuals [4].

Heredity

The majority of patients with achalasia are sporadic cases. Familial achalasia is less frequent [9] and is more commonly encountered among monozygotic twins and offspring of consanguineous parents. The latter may be suggestive of an autosomal recessive inheritance [12–14].

Etiopathogenesis

Despite the fact that achalasia was described more than 300 years ago, its etiopathogenesis remains largely enigmatic [15]. This condition is likely to be multifactorial in origin [5]. It has been postulated that host genetic factors, autoimmunity, and environmental influences contribute to the initiation of an inflammatory neurodegenerative process. The end result is a reduction in the number of the ganglion cells in the myenteric plexus of both esophageal body and LES [16]. During the initial stage of the disease, the neurodegenerative process affects the inhibitory neurons and their neurotransmitter nitric oxide (NO) more than the excitatory neurons and

neurotransmitters, such as acetylcholine, resulting in both high-amplitude non-propagative contractions of the esophageal body and non-relaxing LES, which is described by the term "vigorous achalasia" [16–19]. The disease gradually progresses and cholinergic neurons are affected as well leading to "classical achalasia," which is characterized by very low amplitude esophageal body contractions or aperistalsis in addition to an inability of the LES to relax in response to deglutition [20–23]. There are data suggesting that neurodegeneration might not be limited to the esophagus only as abnormalities (Wallerian degeneration) have been also demonstrated in the vagus nerve of affected humans and experimental animal models [24, 25]. Furthermore, abnormal findings in the brainstem (Lewy bodies), prolonged gastric emptying time and disturbed response of gastric secretions to hypoglycemia have also been also reported in achalasic patients [26–28].

Despite many advances in our understanding of achalasia [29], the triggers of the neurodegeneration are poorly defined. Infections by various agents (e.g., measles, varicella-zoster virus, herpes simplex viruses type 1, 2, 6, human herpes virus 6, Epstein Barr virus, human papilloma viruses) have all been implicated in the pathogenetic process [30, 31]. However, the role of these viruses has been questioned by other authors [32, 33]. Thus, with the exception of Chagas disease caused by *Trypanosoma cruzi*, there is inadequate evidence to support a definitive causative association between infections and esophageal achalasia [34]. Autoimmunity has also been proposed as a key factor in the pathogenesis of esophageal achalasia. The latter was postulated by the identification of inflammatory cells in specimens from patients diagnosed with achalasia [20, 35, 36]. Moreover, the identification of specific human leucocyte antigen (HLA) class II histocompatibility antigens [37, 38] in combination with the presence of antimyenteric autoantibodies further strengthened the hypothesis of the autoimmunity involvement in the disease's pathophysiology. However, these findings have not been confirmed by subsequent studies [39, 40]. In conclusion, current evidence suggests that there may be an element of autoimmune predisposition to achalasia for

Table 11.2 Chief complaints in childhood achalasia

certain individuals but the available data do not support a definition of achalasia as an autoimmune disease.

Certain reports of achalasia in siblings, monozygotic twins along with familial cases [41–44] raised the possibility of a potential genetic hereditary influence. The latter is particularly true for the cases of achalasia in the context of Allgrove syndrome in which a correlation has been identified between the esophageal dysmotility and the ALADIN gene [45, 46]. The potential genetic basis of this clinical entity is further highlighted by the association of achalasia with other diseases with proven genetic influence (Trisomy 21, Parkinson disease, Rozycki syndrome) [47–49]. Moreover, specific polymorphisms in the genes of NO synthase (NOS), vasoactive peptide (VIPR1), interleukin-23 receptor (IL-23R), interleukin-10 (IL-10) promoter, and protein tyrosine phosphatase non-receptor 22 (PTPN22) may be associated with achalasia providing additional data regarding the pathophysiology of idiopathic achalasia. However, more studies are required to further elucidate the details of the downstream responses that ultimately impair the esophageal body motility and render the LES incapable of relaxation [50–54].

In contrast to idiopathic achalasia in which the cause remains largely unknown, in secondary achalasia, the causative factor can be identified. Table 11.1 depicts certain pathologies which are associated with achalasia-like motility disorders [55–68].

Clinical Presentation

The clinical picture of achalasia depends on the duration of symptoms and the age of the child at the time of the diagnosis [69]. It has been reported that childhood achalasia is more common in males and is largely occurring in school-age children (7–12 years). However, achalasia may occur also in early infancy. Cases have been also reported in premature neonates as young as 29 weeks of gestation and as small as 900 g [70, 71]. The mean duration of symptoms prior to diagnosis was less than 3 years in 80% of the children, and the chief complaints are represented by dysphagia and emesis [9]. Table 11.2 summarizes the clinical symptoms of the children reported in the literature [72]. Noteworthy, children younger than 5 years of age present more frequently

with vomiting, whereas dysphagia is the predominant complaint in older children [69].

Dysphagia is progressive and initially confined to solids, and in later stages to both solid and liquid. The child usually reports a sensation of food getting “stuck” in the esophagus (“chest”) which is usually relieved by multiple swallowing efforts or by washing the food bolus down with liquids. The troublesome deglutition leads to limited oral intake (food refusal) and subsequently in suboptimal weight gain (failure to thrive) or weight loss. As the disease progresses, the esophagus becomes dilated and the patient may experience regurgitation of undigested food or saliva that accumulates at nighttime while the child is asleep, leading also to episodes of recurrent coughing and choking. The latter may predispose the child to a significant risk of chest infections or even sudden death due to aspiration of esophageal contents [73].

Diagnostic Approach

Diagnosis is often delayed due to several factors, including its low incidence, and the inability of younger children to report the symptoms, which are often nonspecific. Moreover, most of the related symptoms and signs, such as emesis, respiratory involvement, and failure to thrive are commonly attributed to gastroesophageal reflux (GER) disease. Therefore, a detailed history and a careful clinical examination are paramount as they can expedite the diagnostic process by guiding the physician in the correct choice of investigations which will eventually establish the diagnosis. Some individuals will have associated alacrima and adrenal insufficiency (AAA syndrome) and may have dermal hyperpigmentation secondary to high blood adrenocorticotrophic hormone (ACTH) concentrations. Radiological, endoscopic, and manometric procedures represent the diagnostic arsenal and are the recommended modalities for the diagnosis of achalasia [4]. Esophageal achalasia needs to be distinguished from other conditions that present with regurgitation, vomiting, and dysphagia. Table 11.3 presents the entities that physicians should include in the differential diagnosis of esophageal achalasia [4, 63, 74–82].

Radiology

Upper gastrointestinal (GI) contrast series (esophagography/esophagogram/barium swallow) provide a convenient way to assess the anatomy of the upper GI tract. They are usually readily available and as a result can expedite the diagnostic assessment or confirm the diagnosis in many of the suspected cases of achalasia. In spite of its undisputed usefulness, reports from adult studies showed that esophagogram can be nondiagnostic in up to one third of cases [83]. These data however were not substantiated in the pediatric population where 92% of the studies demonstrated abnormal findings [9].

The esophagogram usually reveals various degree of esophageal body dysmotility with or without esophageal dilation, narrowing of the lumen at the level of esophagogastric junction (EGJ; “bird-beak” or “rat-tail” appearance), poor emptying of the contrast material into the stomach, and prominent tertiary contractions in the case of vigorous achalasia [9, 84–87]. (Figs. 11.1, 11.2, 11.3) Esophagography supports the diagnosis in the case of an equivocal manometry and can also demonstrate findings of end-stage achalasia (e.g., tortuosity and angulation of the esophageal body, megaesophagus) which may modify the clinical decision regarding the most appropriate therapeutic approach [4, 88–92]. Additionally, radiology can be used as an objective tool to evaluate the response to treatment (the so-called timed barium esophagogram (TBE), which measures the height of the barium column in the upright position after an ingestion of a large barium bolus) [93, 94], and as a predictor of treatment’s efficacy [95–97].

Upper GI Endoscopy

Endoscopy has an important role in the diagnosis of achalasia as it rules out clinical entities that can mimic achalasia, such as eosinophilic esophagitis and other causes of pseudoachalasia. It can also alter the initial working diagnosis for patients erroneously treated for GER [4, 98, 99]. The major endoscopic findings raising a high index of suspicion for achalasia include esophageal dilation, presence of retained saliva or food along with resistance while negotiating the LES. Mucosal abnormalities detected during endoscopic examination may be due to food stasis and candida infections. However, it is not unusual to witness an unremarkable upper GI endoscopy in the early stages of the disease [4].

Of significant note, an increased number of eosinophils has been reported in the esophageal biopsies of achalasia patients [100]. While the interplay among achalasia and esophageal eosinophilic infiltration needs to be further elucidated, it has been suggested that the latter does not represent a distinct clinical entity. Thus, the presence of esophageal eosinophils in patients complaining of dysphagia may warrant further diagnostic work-up to rule out other

Fig. 11.1 Image of esophagus from barium esophagram in 11-year-old female with achalasia. There is food residue in the upper esophagus. The esophagus is dilated and shows numerous irregular contraction waves (tertiary contractions)

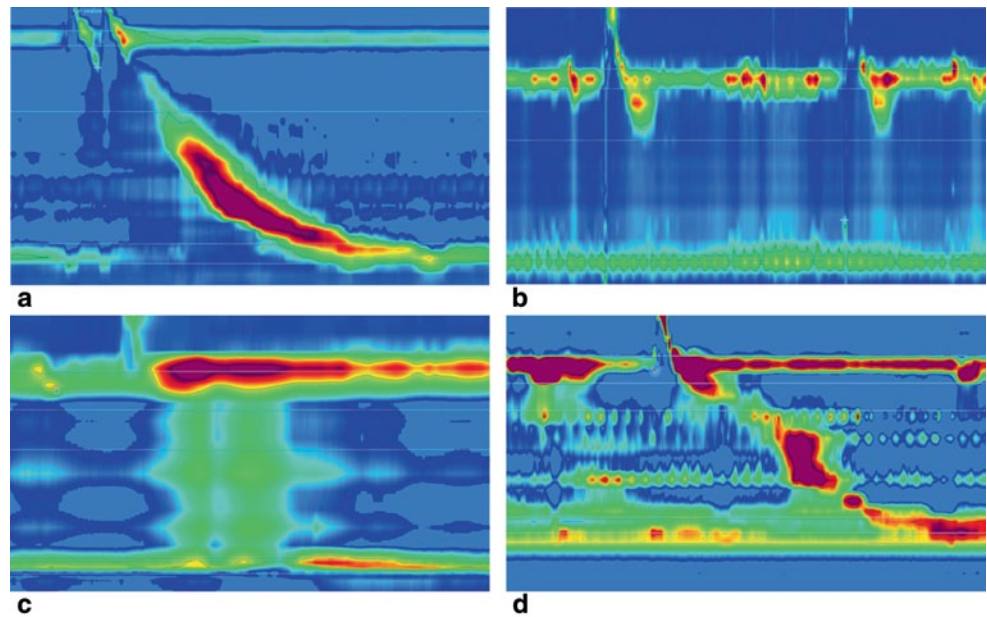

Fig. 11.2 Image of lower esophagus from barium esophagram in 11-year-old female with achalasia. The lower esophagus is dilated; there is tapered (“beak-like”) narrowing of the gastroesophageal junction

potential etiologies, including achalasia [101]. High-resolution manometry (HRM) is considered an invaluable tool for discriminating these two entities as they generally have distinctive motor patterns [102–104].

Manometry

Esophageal manometry provides a highly sensitive and specific method for defining the esophageal motility

Fig. 11.3 High-resolution esophageal manometry in a healthy (a) and three achalasic children. Type I (b) is characterized by absence of distal pressurization to greater than 30 mmHg. In type II (c), pressurization to greater than 30 mmHg occurs in at least two of ten test swallows, whereas patients with type III (d) disease have spastic contractions with or without periods of compartmentalized pressurization

pattern [105]. This is especially true for the combined high-resolution esophageal impedance manometry [106]. Pediatric patients are assessed with a standardized protocol that involves single and multiple rapid wet swallows and solid swallows [104]. The esophageal motor abnormalities found in patients with achalasia are classified in the three subtypes of achalasia according to recently introduced Chicago classification [107]. All three subtypes are characterized by elevated integrated relaxation pressure (IRP—a variable which quantifies residual LES pressure): type I is defined by completely failed esophageal body peristalsis (Fig. 11.3b), in type II there is abnormal peristalsis accompanied by pan-esophageal pressurization in more than 20% of the test swallows (Fig. 11.3c), and type III also demonstrates an impaired contractile pattern with fragmental preservation of distal peristalsis or presence of premature (spastic) contractions in more than 20% of the swallows (Fig. 11.3d) [107]. The recently published results of the “European achalasia trial” demonstrated that HRM may facilitate clinical decision regarding the most appropriate initial treatment according to the manometric subtype [108]. The importance of HRM is highlighted by the fact that it can detect subtle changes in the esophageal motility dynamics and thereby aid in adding an organic element to conditions presenting with dysphagia and previously described as functional in nature [109]. Furthermore, some data suggest that intraoperative HRM along with the novel imaging tool “EndoFLIP” are safe and useful techniques in determining the adequacy of Heller’s myotomy, and therefore decreasing potential future recurrence of symptoms [110–113].

Lastly, dysfunction of the upper esophageal sphincter (UES), such as an increased resting pressure, shorter

relaxation after swallowing, and shorter interval to pharyngeal contractions after UES relaxation, has been demonstrated in achalasia patients. The clinical significance of such findings is still not well understood [114, 115].

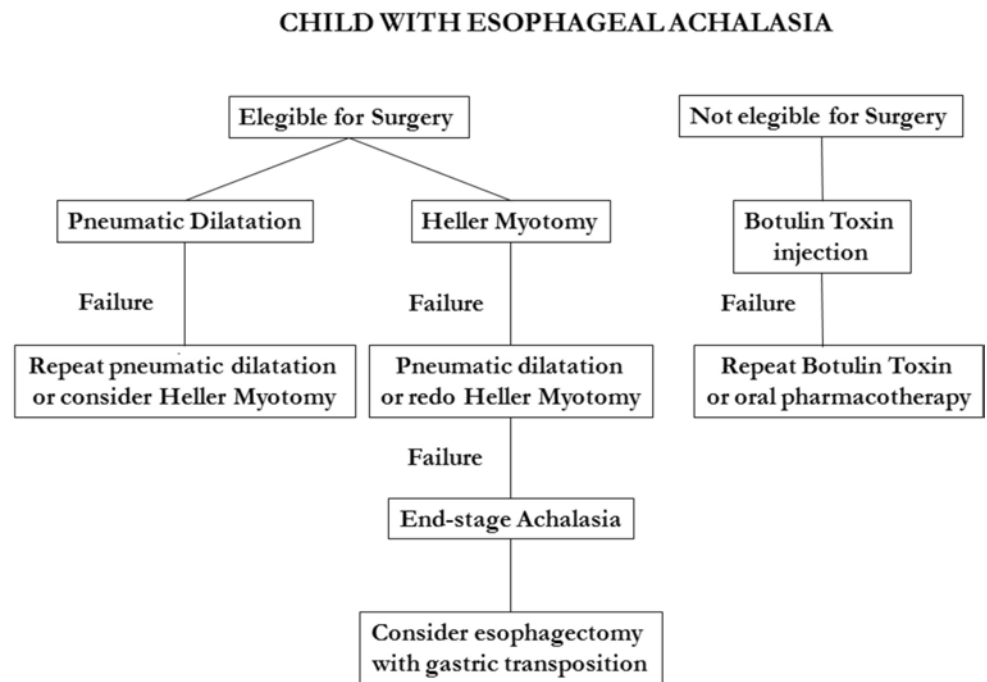

Management

The therapeutic management of achalasia includes pharmacological, interventional, and surgical options. None are curative but they aim in providing symptomatic relief of the EGJ obstruction without addressing the esophageal body dysmotility. However, there is some evidence suggesting potential improvement of the esophageal motility after surgical treatment for achalasia [116]. A simplified management approach is reported in Fig. 11.4.

Pharmacological Therapy

Oral pharmacological treatment is the least effective in managing achalasia [117]. Isosorbide dinitrate and nifedipine act by relaxing the smooth muscles and by blocking the calcium channels, respectively; both reduce the LES pressure [118, 119]. They are administered prior to meals and are considered a temporary measure until a more definitive treatment, either dilatation or surgery, is provided. Oral pharmacotherapy alone is recommended in adult patients who are not willing or eligible for dilatation or surgery and in whom endoscopic botulinum toxin injection (EBTI) has previously failed [4].

Fig. 11.4 Suggested therapeutic algorithm for children with achalasia

Endoscopic Botulinum Toxin Injection

Intrasphincteric botulinum toxin injection blocks the presynaptic cholinergic terminals in the LES and therefore inhibits the secretion of acetylcholine at the neuromuscular junction. The latter results in chemical denervation with consequent opposition of the excitatory effect of acetylcholine and disruption of the relentless contraction of LES [4]. The experience of EBTI in the treatment of childhood achalasia is relatively limited. The method involves the endoscopic injection of 25 units of botulinum toxin in each one of the four LES quadrants (100 units in total) [69]. Similar to pharmacotherapy, EBTI offers a short-term symptom relief, as pneumatic dilatation (PD) or Heller myotomy (HM) will be eventually required for a more sustained clinical improvement [120, 121]

Pneumatic Dilatation

The goal of performing a forceful esophageal dilatation is to stretch and disrupt the LES fibers to such an extent that it alleviates EGJ obstruction without inducing GER [4, 122]. The procedure is performed under general anesthesia, and patients undergoing dilatation need to be eligible for surgery in the unfortunate event of esophageal perforation [4]. A balloon dilator is inserted with fluoroscopic or endoscopic guidance [67, 123]. The non-radiopaque polyethylene balloon dilators are preferred over the bougienage or the standard balloon dilators as the latter are not effective enough in rupturing the LES fibers and achieving

adequate symptoms' control. The modern dilators are of graded size (3.0, 3.5, 4.0 cm); however, for technical reasons PD is usually performed only in children older than 6 years of age or those weighing over 20 kg [4, 67]. After the correct position is confirmed, the balloon is distended for 60 s with pressures that vary among institutions from 2–12 psi [67, 123]. Balloon distention until obliteration of its waist while under fluoroscopy is more important for achieving symptom control than balloon distention time [4]. It is advisable that all patients are observed for a certain period of time prior to discharge home, and if symptomatic, they need to be assessed with a gastrografin esophagogram to exclude potential esophageal perforation. The incidence of esophageal perforation in adults who underwent PD for achalasia was reported between 4–12% [123]. No cases of post-PD esophageal perforations were documented in recent pediatric studies [67, 123–125]. Small asymptomatic perforations are managed conservatively (intravenous antibiotics, total parenteral nutrition) whereas immediate surgical intervention is mandated for free perforations [126, 127]. The majority of perforations occur during the first dilatation most probably due to inaccurate placement and distention of the dilator; GER has been reported in 15–35% of the patients who underwent dilatation for achalasia treatment [73, 128]. The latter is of important significance as recurrence of symptoms in post-PD patients may be due to reflux-related distal esophageal stricture. Thus, treatment with proton pump inhibitors (PPI) is warranted in post-PD patients complaining of GER symptoms. Other potential post-PD complications include aspiration pneumonia and pain that may require prolonged hospitalization [124].

PD achieves adequate control of symptoms ranging from 67% after the first dilatation to 87.5% after subsequent procedures [67, 123]. Available data suggest that although PD achieves immediate symptom relief, it bears a significant likelihood of symptoms' recurrence that will require subsequent interventions in the form of either repeat PD or surgery [69, 124, 125, 129]. It is worth mentioning that minimally invasive surgical techniques have challenged the role of PD as the first-line treatment in childhood achalasia, and the recently published data question the efficacy of PD as HM was proven to be significantly superior to dilatation [69, 124, 125, 130].

Surgery

The mainstay of surgical treatment for achalasia is Heller's myotomy, which was first described in 1913 [131]. Over the past decades, HM has evolved from the open thoracotomy to the minimally invasive laparoscopic technique, which has become the procedure of choice among surgeons due to its high efficacy, faster recovery, and minimum morbidity rate [124, 129, 130, 132]. The resolution of symptoms after HM largely depends on the length of the myotomy; this should be long enough to diminish the EGJ obstruction but not excessively long so that it induces postoperative GER. The optimal length of HM in children of different age groups has not been established yet. A recent report advocates an incision length between 4–6 cm that ends 5 mm distally to EGJ along with minimal mobilization of the adjacent anatomical structures [133]. The role of both "EndoFLIP" and intraoperative manometry appears to be very promising in determining the optimal myotomy length [110–113].

The addition of a fundoplication after HM and also the type of the anti-reflux procedure are still a matter of debate. An anti-reflux procedure reduces the risk of postoperative GER but at the same time increases the likelihood of dysphagia, as it creates a high pressure zone to an esophageal body with an already impaired motility [134–136]. An anti-reflux procedure may be warranted when a wide mobilization of the esophagus is inevitable in order to technically facilitate the myotomy [133]. Regarding the most appropriate type of the anti-reflux procedure there are data revealing that a loose Nissen, Toupet, Dor, or Thal fundoplication along with HM fundoplication are safe and result in good outcomes in the treatment of childhood achalasia [90, 125, 130, 137, 138]. The American College of Gastroenterology advocates PPI treatment in achalasia adult patients complaining of heartburn post-HM in spite of the presence of a fundoplication [4].

Patients who have developed "end-stage" achalasia and failed myotomy are candidates for esophagectomy with gastric transposition [4, 90, 124, 125]. However, esophagectomy bears greater morbidity and mortality compared to

laparoscopic HM; dysphagia requiring PD can still recur up to 50% of the adult patients that underwent esophagectomy for "end-stage" achalasia [139].

Emerging Treatments

POEM is an acronym for "peroral esophageal myotomy": it is a novel technique developed in Japan [140, 141], whereby the endoscopist performs an LES myotomy by creating a submucosal tunnel using a forward-viewing endoscope. The overall success in adult studies has been more than 80% at 12-month follow-up [141]. There are limited data regarding the applicability, safety, and efficacy of this method in childhood achalasia. Experience from a case report and a small case series reveals excellent outcomes regarding its safety and efficacy at 12-month follow-up assessment [142, 143].

Other techniques for treating achalasia such as removable self-expanding metallic stents offer promising results; however, there is a paucity of studies in children to evaluate the safety and efficacy of these modalities [144, 145].

Follow-Up and Surveillance

Currently, there is a lack of consensus regarding the optimal short- and long-term follow-up of children treated for esophageal achalasia. It is however advisable that pediatric patients receive regular follow-up assessment to ensure reduction of symptom severity (Eckardt score) [146]; evaluation of the esophageal emptying with a barium esophagogram may be also considered [4].

Patients treated for achalasia have a normal life expectancy [147]. Despite an increased risk of esophageal carcinoma in patients with achalasia [148, 149], there are limited data to support regular screening for cancer. Thus, the American College of Gastroenterology and the American Society for Gastrointestinal Endoscopy do not advocate routine endoscopic surveillance for achalasia patients [4, 150]. Nevertheless, radiological or endoscopic surveillance is recommended by numerous authorities for the assessment of adult patients treated for achalasia as they are in an increased risk for developing end-stage disease with megaesophagus. This approach with regular evaluation in 3-year intervals is particularly proposed if the disease has been diagnosed for more than 10 to 15 years [151]. Clearly, more data are required for the implementation of such recommendations in childhood achalasia.

Conclusion

Childhood esophageal achalasia is an enigmatic disease. Contemporary diagnostic modalities (upper GI contrast series, endoscopy, HRM) offer rapid and accurate diagnosis.

Current data suggest that laparoscopic HM combined or not with an anti-reflux procedure seems to be the therapeutic procedure that offers the most durable and sustained long-term symptom relief.

Introduction

Helicobacter (H.) pylori is a Gram-negative, microaerophilic spiral bacterium found in the stomach. Stomach colonization causes chronic gastritis that can remain silent, due to the dynamic equilibrium between the bacterium and its human host, or evolve into more severe diseases, such as atrophic gastritis, peptic ulcer, lymphoma of the mucosa-associated lymphoid tissue (MALT), or gastric adenocarcinoma [1, 2]. Difference in the consequences of *H. pylori* infection could be at least partially explained by the high variability of colonizing *H. pylori* strains and host response to this microbe [3].

The discovery of *H. pylori* as a major cause of peptic ulcer disease had a significant impact on its perception and treatment. The importance of the discovery was awarded by the Nobel Prize in 2005 to Marshall and Warren who proved the etiological role of *H. pylori* in gastritis and peptic ulcer disease.

Children differ from adults with respect to *H. pylori* infection in terms of the prevalence of the infection, the complication rate, the near absence of gastric malignancies, age-specific problems with diagnostic tests and drugs, and a higher rate of antibiotic resistance [4].

Bacterial Pathomechanism

H. pylori prefers neutral or close to neutral pH (5.5–7.5) and the production of gastric acid in the stomach with a low pH of 1–2 severely limits luminal colonization [5]. The other very important defense barrier is formed by mucus-producing epithelial cells lining the gastric mucosa and by innate immune cells that either reside in the gastric lamina propria under steady-state conditions or are recruited there during infection [6]. All that makes a stomach a very unfriendly environment and the *H. pylori* had to find a way to survive and overcome these obstacles (Fig. 12.1). Bacteria has flagellar-based motility which allows penetration of the mucus and produces urease which splits urea to ammonium ions, thus raising the stomach pH [6]. That increase in stomach pH has further impact on the mucus layer making it viscoelastic and easier for intrusion [7]. Bacteria is found within the gastric mucus layer, either relatively close to the gastric lumen or deep within gastric glands, and can be either free or attached to gastric epithelial cells [8]. The intimate association with the gastric epithelium enables a variety of immune interactions between bacteria and the host. However, it is still not clear how the bacterium colonizes stomach niches for the decades without being eliminated by the host's innate defenses [9]. The detection of bacterial pathogen-associated molecular patterns (PAMPs) by epithelial and innate immune cells

Fig. 12.1 *H. pylori*-associated factors which enable colonization and persistence [6]. Initially, *H. pylori* produces urease which raises the pH through ammonia production. Bacterial helical rod shape and flagellar-based motility help intrusion of bacteria to niche, away from acid lumen. Different variably expressed adhesins (like SabA, BabA) may shift the balance to cell-associated bacteria. Cell-associated bacteria may alter gastric epithelial cell through VacA, CagA, and CagL which all have multiple cellular targets. This includes disruption of cell polarity, induction of chemokines and/or the gastric hormone gastrin, and inhibition of acid secretion. T4SS Cag type IV secretion system, PS phosphatidylserine, $\alpha 5\beta 1$ and $\alpha v\beta 5$ integrin subunits, VacA vacuolating cytotoxin A, CagA cytotoxin-associated gene A protein, and CagL cytotoxin-associated gene L protein. (Reprinted by permission from Macmillan Publishers Ltd, Nature Publishing Group, Ref. [6])

occurs via innate immune receptors (pattern recognition receptors, PRRs) [6]. *H. pylori* has evolved to avoid detection by several types of PRRs that are crucial for the recognition of other Gram-negative enteropathogens [6]. Other host factors that have impact on *H. pylori* disease severity include membrane-associated mucin and its role in the inflammatory response [10]. In addition to the host genetic susceptibility, diversity of *H. pylori* virulence factor genes may affect the ability of these bacteria to colonize, persist, or even induce severe disease [11]. Many of the changes in gastric epithelial cells caused by *H. pylori* are attributable to the actions of two secreted bacterial proteins, vacuolating cytotoxin A (VacA), and cytotoxin-associated gene A protein (CagA) [8]. *H. pylori* traditionally harnesses its cardinal virulence factors to downregulate T cell responses, through the VacA-mediated cell cycle arrest, and upregulates mucosal proinflammatory pathways by CagA [9]. VacA is a pore-forming toxin that is secreted by the bacteria through an autotransporter pathway. The cellular alterations caused by VacA include increased permeability of the plasma membrane, changes in endosomal structure and in mitochondrial membrane permeability, and cell death [8, 12, 13]. CagA is an effector protein that is translocated directly from bacteria into host cells through the action of a type IV secretion system [8, 14, 15]. Upon entry into gastric epithelial cells, CagA interacts with multiple intracellular target proteins and causes a wide range of

alterations in cellular signaling, leading to changes in cell shape, increased cellular motility and cellular invasiveness, alterations in monolayer polarity and permeability, and increased cellular proliferation [16, 17]. Because CagA signaling pathways have been associated with carcinogenesis, it was termed as a “bacterial oncoprotein” [8]. However, there should be some backup mechanism to maintain the above-mentioned inflammatory and apoptotic balance [18]. One virulence factor potentially involved in the pathogenesis of *H. pylori* is the blood antigen-binding adhesin (BabA) [19]. BabA adhesin adheres to gastric blood group antigens expressed on epithelial cells and mucus. The expression of specific host receptors to bacterial adhesins are likely to play a role in the outcome of the infection [18].

The interaction between bacteria and host is very complex and not fully elucidated and includes different virulence factors involved into pathogenesis [6].

The majority of the *H. pylori*-infected population remains asymptomatic, but some individuals may develop chronic gastritis, peptic ulcer, MALT lymphoma, or carcinoma [20]. Factors determining the subset of infected individuals developing the disease compared with asymptomatic *H. pylori* carriers remain unclear. It is now becoming increasingly clear that the *H. pylori* virulence factors as well as host immune factors contribute closely to those differences in *H. pylori* pathogenicity.

Epidemiology and Transmission

Over the past decades, the prevalence of *H. pylori* in the developed world steadily decreases. Most recent international studies have shown that *H. pylori* prevalence varies between countries, with lowest prevalence of 5–10% in Western Europe and the USA and very high prevalence in developing countries of even 80% [21, 22]. An increased prevalence in developing countries is mainly due to the combined effects of poor living conditions, poor hygiene, and overcrowding [23]. In developing countries, *H. pylori* infection is acquired predominantly during early childhood; however, in the more developed areas the infection gradually increases with age with the highest incidence rate in childhood and adolescence [24, 25].

The modes of *H. pylori* transmission are still not entirely clarified, but person-to-person contact is the most commonly implicated mechanism through oral–oral, fecal–oral, or gastric–oral route [26]. It has been described that transmission primarily occurs between mothers and their offspring or between siblings [25, 27]. Currently available evidence indicate that especially in populations with low *H. pylori* prevalence the infected mother is likely to be the main source for childhood *H. pylori* infection [27]. However, only few studies have longitudinally examined factors which influence *H. pylori* transmission. In the well-designed longitudinal study, Muhsen et al. included Israeli Arab children aged 3–5 years from three villages in northern Israel which were followed-up for 3–4 years [28]. Having *H. pylori*-infected sibling was identified as an independent risk factor for both early and persistent *H. pylori* infection. It was also shown that persistent *H. pylori* infection in older siblings always precedes infection in younger siblings especially if the age difference was less than 3 years [29].

Due to very close interpersonal contact between children in day-care centers, it was proposed that their attendance could also be a risk factor [24]. However, a meta-analysis of 16 studies did not confirm this hypothesis, but included studies substantially varied in the methodology; they were performed in a different types of childcare, in different age groups, and with different exposure duration, which all resulted in a high heterogeneity in the meta-analysis [24].

There is some evidence of positive correlation between presence of *H. pylori* in the oral cavity and gastric mucosa [30]. Moreover, it seems that eradication rate is significantly higher in stomach than in oral cavity. These results suggest that infected dental plaque, saliva, or other places in the oral cavity may be a source for infection and reinfection of *H. pylori* through oral–oral route [30]. Presence of *H. pylori* in tonsils and its impact on infection transmission is still controversial [22].

Gastritis

Gastritis is defined as histologically confirmed inflammation of the gastric mucosa mainly composed of lymphocytes, plasma cells, histiocytes, and granulocytes within the lamina propria [31]. *H. pylori* is by far the most common etiological agent causing gastritis in adults and children. The most common site of infection is the antrum, which is an absorptive rather than a secretory region of the stomach enabling the slightly higher pH at which the organism can survive [5]. In the initial phase of *H. pylori* infection, the gastric mucosa becomes acutely inflamed with impairment in the acid secretion [32]. In large majority of patients, gastritis progresses to chronic active gastritis which is characterized by the presence of both mononuclear and neutrophilic (“active”) inflammation [31]. In children, the “active” or neutrophilic count is lower than that reported in adults.

In adults, *H. pylori* infection causes three main gastritis types: mild pangastritis where inflammation evenly affects the whole stomach; antrum-predominant gastritis where the degree of inflammation is strongest in the antrum and acid secretion tends to be increased; and the most infrequent phenotype affecting only approximately 1% of the infected subjects’ body-predominant gastritis with even atrophic changes and impaired gastric acid secretion [32]. Antrum-predominant gastritis may subsequently be complicated by duodenal ulcer while corpus-predominant atrophic gastritis increases the risk of gastric cancer [33]. Whether this distinction between gastritis types exist already in children or it develops later in life is still unknown [34].

In addition to the topographic expression of *H. pylori*-induced chronic gastritis, the characterization of gastritis needs to include report on the activity and chronicity of inflammation and on the development of atrophic changes with or without intestinal metaplasia [35].

H. pylori gastritis has unique features in children, such as the nodular aspect of the gastric antrum, antral predominance of gastritis in most patients, and uncommon diagnosis of gastric atrophy and intestinal metaplasia. Nodular gastritis is usually characterized as an endoscopic appearance which has been described as gooseflesh-like or cobblestone markings on the gastric mucosa (Fig. 12.2) [36]. Antral nodularity seen on endoscopy is histologically associated with inflammatory cell infiltrates and lymphoid follicles, and it is the only sign with a high positive predictive value for the presence of *H. pylori* infection [37].

After successful eradication therapy, the neutrophils quickly disappear and any persistence of neutrophils and/or mononuclear infiltrate could be an indication of the treatment failure.

Fig. 12.2 Antral nodularity associated with *H. pylori* infection

Peptic Ulcer Disease

Gastritis and peptic ulcer disease were previously considered as separate diseases; however, better understanding of the pathomechanisms and discovery of *H. pylori* revealed the close relation between those two entities. Peptic ulceration of the stomach or duodenum, either primary or secondary, is almost always accompanied by abnormalities of the gastric mucosa, either a gastritis or a gastropathy [38]. Peptic ulcer disease is the ultimate loss of mucosal integrity and develops when the protective mechanisms of the gastrointestinal mucosa, such as mucus and bicarbonate secretion, are overwhelmed by the damaging effects of gastric acid and pepsin [39]. By the definition, peptic ulcers are deep mucosal lesions that disrupt muscularis mucosa layer of gastric or duodenal wall. They occur in the stomach mainly in antro-corporal mucosal transitional zone along the lesser curve or proximal duodenum, duodenal bulb [40]. Peptic ulcers are more common in duodenum than in stomach and *H. pylori* is the most frequent cause. Other etiological factors associated with gastritis and peptic ulcer disease are presented in Table 12.1.

Available literature suggests that the lifetime risk for development of peptic ulcer disease in *H. pylori*-positive patients ranges between 10 and 20% [41]. Peptic ulcer disease occurs less frequent in children than in adults. A large prospective European multicenter study including more than 1400 symptomatic infected children found gastric or duodenal ulcers in 3.5% of the children below 6 years of age, in 4.6% the children aged 6–11 years, and in 10.4% of those older than 12 years [42]. Subsequent, prospective, also European multicenter study found that even 8.1% of the children had ulcers or erosions [43]. In a retrospective review of 619 Chinese children who had undergone upper endoscopy for investigation of upper gastrointestinal symptoms, Tam et al. [44] have found peptic ulcers in 6.9% of the children.

The discovery of *H. pylori* has turned the pathogenesis of peptic ulcer disease from a hyperacid disease to an infectious and immunopathogenetic disease where a variety of ulcer-promoting host and bacterial factors are involved in the com-

plex pathogenesis [32]. However, despite that, gastric acid secretion remains an important factor of peptic ulcer disease development. Patients with *H. pylori* gastritis and duodenal ulcers present with a much higher gastric acid output following gastrin stimulation than patients with *H. pylori* gastritis but without duodenal ulcer [45]. The mechanisms controlling acid secretion are hormonal and very complex in nature. The hormonal drive is exerted by hypergastrinemia, which was originally interpreted to result from the alkalization induced by *H. pylori*. Higher pH around G cells interrupts the negative feedback control and they continue to release gastrin [32]. Another explanation for hypergastrinemia could be the *H. pylori*-induced impaired synthesis and release of somatostatin [32]. Somatostatin is a hormone that inhibits gastrin synthesis and subsequently inhibits acid secretion.

Moreover, *H. pylori* virulence factors also contribute to the development of peptic ulcer disease. In children, as in adults, CagA and VacA genes are the most frequently implicated virulence factors associated with increased risk of peptic ulcer disease [46].

In gastric ulcer, the role of acid and *H. pylori*, although certainly contributory, is of less dominance as compared to duodenal ulcer [32].

Epigastric pain or discomfort exacerbated by the meal is often a symptom of peptic ulcer disease in children; however, it may also be a presenting symptom of more common disorders such as non-ulcer dyspepsia and constipation among others [38]. Other presenting symptoms include anorexia, nausea, early satiety, recurrent vomiting, and anemia. Up to 25% of the children with duodenal ulcers can present silently, approximately 25% with bleeding and antecedent pain, and the rest with abdominal pain or recurrent vomiting [38, 47]. Among all clinical signs: epigastric tenderness, pain awakening the child at night, hematemesis, melena, and stunted weight gain can be considered as significant risk factors for ulcers or erosions independently [43]. Acute gastrointestinal bleeding is the most common complication of childhood peptic ulcer disease and may occur with long-standing antecedent epigastric pain, whereas a perforated peptic ulcer occurs more rarely [44].

Other Causes of Peptic Ulcer Disease

In adult patients, the second most common cause of peptic ulcer disease are the use of nonsteroidal anti-inflammatory drugs (NSAIDs) [48]. NSAIDs inhibit cyclooxygenase-1 enzyme (COX-1) and reduce prostaglandin synthesis; consequently, diminishing gastric mucosal blood flow and decreasing a production of the mucus–bicarbonate barrier [49]. In children, gastric ulcerations from NSAID ingestion are not nearly as frequent as in adults [38]. When occurs in children, NSAID-induced ulcer is typically presented as hem-

Table 12.1 Causes of gastritis and peptic ulcer disease

Primary	<i>H. pylori</i> associated

Histoplasmosis		
Mucormycosis		
Anisakiasis		
Radiation gastropathy		

orrhagic antral gastropathy and ulceration of the incisura. Other drugs associated with drug-induced gastropathy and ulcers are anticoagulants and corticosteroids [50].

Other very rare causes of peptic ulcer disease in children include hypersecretory states like Zollinger–Ellison syndrome and antral G cell hyperplasia, and should be suspected in children with severe or recurrent duodenal and gastric ulcers, resistant to proton pump inhibitors (PPI) treatment, and in children with multiple ulcers. Other conditions associated with acid hypersecretion are systemic mastocytosis, short

bowel syndrome during the first year after surgical resection, hyperparathyroidism, cystic fibrosis, and renal failure [51].

Stress-related ulcers usually occur 24 h after the onset of severe critical illness including shock, hypoxemia, acidosis, sepsis, burns, head injury, encephalopathy, major surgery, and multiple organ system failure [38]. Stress erosions are typically multiple and asymptomatic until cause, sometimes severe, gastrointestinal bleeding.

Gastritis and gastric ulcerations are found in 50–60% of the children with Crohn’s disease [52]. Focally enhanced

gastritis is an inflammatory lesion often found in Crohn's disease and involves discrete inflammatory foci containing lymphocytes, histiocytes, and granulocytes [53]. Focally enhanced gastritis, although in much lower extent, could also be found in ulcerative colitis and indeterminate inflammatory bowel disease.

Ménétrier's disease is a rare disorder of unknown etiology characterized by enlarged gastric rugal folds. It is a protein-losing gastropathy, clinically presented with nonspecific gastrointestinal symptoms such as nausea, vomiting, anorexia, weight loss, and hypoalbuminemia [54]. Cytomegalovirus and *H. pylori* are the most frequently found pathogens associated with this condition.

Celiac disease-associated lymphocytic gastritis is characterized by an intense lymphocytosis of the foveolar and surface epithelium and chronic inflammation in the lamina propria. Celiac disease may manifest with dyspeptic symptoms and histological changes which normalize after gluten withdrawal [55, 56].

Eosinophilic-mediated gastritis may be a presentation of food allergy (allergic gastritis) or be a primary disease (primary eosinophilic gastritis), as gastric infiltration by eosinophils is a pathological feature found in both conditions. Allergic gastritis mainly affects young infants with cow's milk protein allergy but multiple food intolerances may also occur. Most common symptoms include vomiting, hematemesis, poor weight gain, or symptoms of gastric emptying [57]. Primary eosinophilic gastritis may manifest at any age and may affect any part of the gastric wall. In mucosal form, children may present with vomiting, abdominal pain, and gastric blood loss; motility disturbances and gastric outlet obstruction may occur if muscular layer is affected [58, 59]. Serosal forms produce eosinophilic ascites and peritonitis [60]. Eosinophilic gastritis may also be a part of the eosinophilic gastroenteritis.

Other causes of primary and secondary gastritis and peptic ulcer disease in children are presented in Table 12.1.

Malignancy

H. pylori is considered the leading cause of gastric cancer worldwide and because of that, in adult population, it is listed as a number one carcinogen. A causal relation between *H. pylori* infection and the risk of gastric malignancies, including cancer and MALT lymphoma has been clearly proved. However, in children, *H. pylori*-related malignancy is extremely rare. Evidence increasingly indicates that *H. pylori*-related gastric carcinogenesis is likely to be the result of a well-choreographed interaction between the pathogen and host, which is dependent on strain-specific bacterial factors, host genotypic traits, and permissive environmental factors [2]. Various factors influence malignant potential including

age of infection, bacterial genotype, host immune response, and host genetics. It has been suggested that chronic gastritis, gastric atrophy, intestinal metaplasia, and gastric cancer develop progressively, stepwise over decades, in predisposed individuals infected with *H. pylori* [61].

Incomplete intestinal metaplasia has been described in the gastric mucosa of *H. pylori*-infected children, suggesting that it can develop even during childhood and evolve into complete intestinal metaplasia in adults [62]. Moreover, other studies have reported a significant incidence of gastric atrophy (42–55%) and intestinal metaplasia (13–21%) in children [63]. Interestingly, a higher incidence of atrophic gastritis has been observed in children from countries with high incidence of gastric cancer [64, 65]. Moreover, current evidence suggests that in high-risk populations the eradication of *H. pylori* may have the potential to decrease the risk of gastric cancer [66]. There are certain *H. pylori* genotypes associated with more severe inflammation of gastric mucosa in pediatric patients including CagA, VacA, and BabA, and their detection could be of importance in areas with high risk of carcinoma [67]. In support of this is a report which found that in high-risk population, even children have a high prevalence of *H. pylori* virulence markers—CagA and VacA [68].

In the pediatric population, there are only a few studies with a small number of patients regarding the association between *H. pylori* infection and precancerous lesions in both gastric antrum and corpus [63]. There are reports which presented children with *H. pylori* infection who subsequently developed high-grade B-cell lymphoma which resolved after *H. pylori* eradication even without chemotherapy [69, 70]. All these data indicate that *H. pylori* could be associated with malignancies in children; however, the risk seems to be substantially lower than in adults [71].

Clinical Presentation of *H. pylori* Infection

Recurrent Abdominal Pain Abdominal complaints including pain, cramps, and nausea are very common in pediatric population. Usually, they are unspecific and can be a symptom of various organic diseases but are very often caused by functional gastrointestinal disorders. Whether *H. pylori* infection without peptic ulcer disease can cause recurrent abdominal pain remains unclear. Large epidemiological studies found association between recurrent abdominal pain and different social and familial factors like single-parent household, family history of peptic ulcer disease, or functional pain but not to *H. pylori* status of the child [72]. A performed meta-analysis on the relationship between recurrent abdominal pain and *H. pylori* infection in children included 38 case control, cross-sectional, and prospective studies and found no evidence for relation between recurrent abdominal pain and *H. pylori* infection in children [73]. The only pain

found associated with *H. pylori* infection was epigastric pain [73]. Several interventional but uncontrolled studies showed improvement of symptoms after the eradication of *H. pylori*; however, these studies have several biases; treatment success was not monitored and eradication of the bacteria not reported and in other studies follow-up period was very short, for a few weeks only [74–77]. Based on these results, there is not enough evidence to support a causal relation between *H. pylori* gastritis and abdominal pain in the absence of peptic ulcer disease. Searching for *H. pylori* is therefore not recommended in children that otherwise fulfill the criteria of functional abdominal pain, unless upper endoscopy is performed during the diagnostic workup in search for organic disease [4, 67, 78].

Iron-Deficiency Anemia Iron-deficiency anemia in children and adolescents has variety of causes and there are still disagreements whether *H. pylori* infection can be one of them. The potential pathogenesis is reduced iron absorption in infected gastric mucosa, increased iron loss due to micro-bleeding, and utilization of iron by *H. pylori* in the stomach [67]. Number of studies suggested that iron deficiency is one of the extragastric manifestations of *H. pylori* infection in children [79–81]. However, the results of these studies are not unanimous, with most recent studies that reported no such association [82, 83]. This considerable discrepancy in the results is largely due to methodological variation of the studies. Moreover, it is often difficult to distinguish between iron-deficiency anemia due to *H. pylori* infection and to the other often confounding factors such as poor nutritional status, poor socioeconomic and hygienic conditions, or another underlying disease [4]. Hence, endoscopic examination may be indicated in children with refractory iron-deficiency anemia in order to rule out not only the presence of *H. pylori* but also other causes of iron-deficiency anemia such as celiac disease or chronic inflammatory diseases [84].

These findings are consistent with clinical guidelines by the European Society of Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) and by the North American Society for Pediatric Gastroenterology Hepatology and

Nutrition (NASPGHAN); they recommend that in children with refractory iron-deficiency anemia where other causes have been ruled out, testing for *H. pylori* infection may be considered [4].

Growth There are a number of longitudinal studies that support the hypothesis that *H. pylori* infection might influence growth rate in children [85]; however, none are adequately designed to evaluate confounders of growth including other gastrointestinal infections in childhood, socioeconomic status, living conditions, etc. Despite new information concerning the effect of *H. pylori* infection on poor growth, the need for well-designed studies remains. Based on published data there is insufficient evidence that *H. pylori* infection is causally related to growth impairment in childhood [4].

Chronic Idiopathic Thrombocytopenic Purpura The role of *H. pylori* in the development of chronic idiopathic thrombocytopenic purpura continues to evolve. *H. pylori* infection has been proposed to be associated with thrombocytopenic purpura based on a significantly increased platelets count following *H. pylori* eradication in approximately half of adult patients [86]. Data on children are limited; small case series have been published with conflicting results [87–91]. However, more recent data implicate that eradication of *H. pylori* could induce a better treatment response in chronic idiopathic thrombocytopenic purpura [92].

Diagnostic Procedures

Based on ESPGHAN/NASPGHAN evidence-based guidelines for *H. pylori* infection in children testing for *H. pylori* in children should be performed in properly selected patients (Table 12.2) and with an adequate diagnostic procedures [4]. Current recommendations for children do not approve “test and treat” approach recommended for adults [4]. Therefore, diagnostic procedures should aim to determine underlying disease and not to detect *H. pylori*.

Table 12.2 Clinical indication for testing for *H. pylori* infection. (Based on ESPGHAN/NASPGHAN recommendations Ref. [4])

Justified testing for <i>H. pylori</i>	Gastrointestinal symptoms suggestive of organic disease, serious enough to justify upper endoscopy
Considered testing for <i>H. pylori</i>	Children with first-degree relatives with gastric cancer
	Children with refractory iron-deficiency anemia when other causes have been ruled out
Not justified testing for <i>H. pylori</i>	Functional abdominal pain
	Upper respiratory tract infections
	Periodontal disease
	Food allergy
	Sudden infant death syndrome
	Idiopathic thrombocytopenic purpura
	Growth impairment

Tests that detect *H. pylori* are divided into noninvasive and invasive tests. Invasive tests require endoscopy and gastric tissue biopsy for detecting the bacterium and include culture, rapid urease test, histopathology, polymerase chain reaction, and fluorescence in situ hybridization (FISH) tests [93]. On the other hand, noninvasive tests include different methods for the detection of *H. pylori* antigens in stool, detection of antibodies against *H. pylori* in different biological materials including serum, urine, and oral samples, and widely used ^{13}C -urea breath test (^{13}C -UBT) [93].

Noninvasive Tests

Among noninvasive diagnostic tests, stool antigen test and ^{13}C -UBT have higher accuracy than serological or urinary antibody-based tests [94].

^{13}C -Urea Breath Test Recently published meta-analysis on the performance of the ^{13}C -UBT showed good accuracy especially in children older than 6 years of age (sensitivity 96.6%, specificity 97.7%) [95]. A crucial question for all tests performed in a pediatric population is whether the accuracy of the applied method is influenced by the age of the tested child. ^{13}C -UBT requires patient cooperation; moreover, patients need to fast before testing and drink without tracer withhold in the mouth. All that makes ^{13}C -UBT difficult to perform in children younger than 6 years of age and may at least in part explain the lower specificity reported in young children [96, 97].

Stool Antigen Tests Because *H. pylori* and its macromolecules such as proteins and DNA are shed in feces, stool-based tests have become advanced [98]. Several commercial enzyme-linked immunosorbent assay (ELISA) tests for *H. pylori* stool antigens are available. The main differences among these tests are the nature of the detecting antibodies; some kits use a polyclonal anti-*H. pylori* antibody, whereas other assays use monoclonal antibodies, and recently rapid one-step test (immunochromatographic format) using monoclonal antibodies has been introduced [98]. Meta-analysis on stool antigen-detection tests revealed that ELISA monoclonal antibodies have the best performance, with sensitivity and specificity of 97% compared to ELISA polyclonal antibodies (sensitivity of 92%, specificity of 93%), and to one-step monoclonal antibody tests (sensitivity of 88%, specificity of 93%) [98]. So far, only the ELISA based on monoclonal antibodies has achieved the accuracy of the ^{13}C -UBT, which is considered the reference standard of the noninvasive tests [4]. Use of stool tests is generally more convenient in pediatric patients than the ^{13}C -UBT. It has several advantages: stool samples can be obtained from children without their active collaboration and are transportable by

mail for analysis, the cost is lower comparing to ^{13}C -UBT, and it is not age-dependent. Therefore, validation studies in adults may be extrapolated to children [4].

Detection of the Antibodies The systemic immune response against *H. pylori* typically shows a transient rise in specific IgM antibodies, followed by a rise in IgG and IgA antibodies that persist during infection [99]. Since IgM antibodies against *H. pylori* are detected only transiently, they have little value for the serological diagnosis of infection [100]. Therefore, diagnostic commercial tests detect *H. pylori*-specific IgG and IgA antibodies in serum, saliva, and urine. Numerous serologic tests are available for the diagnosis of *H. pylori* infection in children. Common designs of antibody-based detection tests are ELISA and Western Blot (WB) [99]. Many tests based on the detection of antibodies are commercially available, easy to perform, and inexpensive. However, the main problem is age dependence, particularly with respect to sensitivity in younger children, and test-to-test variability. The sensitivity of most tests is much lower when used in children compared with adults from the same geographic region [4]. Current serologic tests are not useful for monitoring eradication of infection after therapy since they cannot distinguish between current or past *H. pylori* infection, and the antibody titers usually remain positive several months after the infection has been eradicated [99]. Taking that into account tests based on the detection of antibodies (IgG, IgA) against *H. pylori* in serum, whole blood, urine, and saliva are not reliable for use in the clinical setting [4].

Invasive Tests

Although noninvasive tests yield high sensitivity and specificity, endoscopy with histopathology remains the only method that can detect lesions associated with the infection, but also other possible causes of the patient's symptoms [93]. In *H. pylori* infection, endoscopy may show normal gastric mucosa or reveal erythema, erosions, ulcers and, especially in children, antral nodularity.

The site from which a biopsy is taken and the number of biopsies affect the accuracy of *H. pylori* diagnosis. Normally, the highest bacterial count is found in the antrum because of that the optimal biopsy site is the mid-antrum at the lesser curvature [101]; however, in cases of low gastric acidity and during the PPI treatment, the bacteria may be present only in the gastric body.

Furthermore, due to patchy density of *H. pylori*, the sensitivity increases with the number of biopsies taken. For pathology, two biopsies should be obtained from both the antrum and the body, and the findings should be reported according to the updated Sydney classification [35]. The updat-

Fig. 12.3 Giemsa staining demonstrates gastric *H. pylori* bacteria

ed Sydney system for the gastritis classification emphasizes the importance of combining topographical, morphological, and etiological information in order to generate reproducible and clinically useful diagnoses. Classification is based on the location of gastritis and the presence of different histological parameters including inflammation, activity, atrophy, intestinal metaplasia, and *H. pylori* infection which are graded as mild, moderate, and marked [35]. Updated Sydney classification was not assessed in pediatric patients; however, it can help in order to unify the histopathology reports.

Biopsies should be stained with hematoxylin and eosin because this is the best method to detect atrophy and intestinal metaplasia. Special staining (Giemsa or silver stain) and immunohistochemistry should be used for detection of *H. pylori* (Fig. 12.3) [4]. In children, hematoxylin and eosin and Giemsa stains have a sensitivity of 82% and specificity of 95% in detecting *H. pylori* gastritis [102]. With decreasing prevalence of the infection in pediatric populations in many areas of Europe and North America, the predictive values of the diagnostic test results decrease; test with a sensitivity of 90% has a positive predictive value of only 50% if the prevalence of the infection in the population is 10% [4]. Sensitivity for histology ranges from 66 to 100% and for rapid urease tests performed on the biopsies from 75 to 100% [93]. Therefore, in order to increase *H. pylori* detection in children, it is highly recommended to take not only biopsies for histopathology but also one biopsy for a rapid urease test or culture [4]. The only method that consistently has 100% specificity is culture, but sensitivity varies depending on the experience of the laboratory [93].

As no single test is accurate enough for detection of *H. pylori*, current guidelines recommend endoscopy with gastric biopsies from the gastric antrum and body and confirma-

tion of infection with two different tests, either histopathology and rapid urease test or a culture [4].

Treatment for *H. pylori* Infection

Updated evidence-based guidelines from ESPGHAN and NASPGHAN recommend treatment for *H. pylori* in all children in whom peptic ulcer disease was detected during endoscopy [4]. Whether it is necessary to eradicate *H. pylori* in children with gastritis but without peptic ulcer disease remains questionable because there is not enough evidence which proved that bacterium eradication improves abdominal complaints in the absence of peptic ulcer.

Current evidence suggests that in high-risk populations for gastric cancer eradication of *H. pylori* may have the potential to decrease the cancer risk even without precancerous lesions [66].

Individuals with a positive family history for gastric cancer are in a high-risk for acquiring gastric malignancy. The risk could be particularly high in *H. pylori*-infected children with parent affected by gastric cancer because child is not only sharing a genetic and environmental factors with the affected parent but could also have the same bacterial strain [25].

Therefore, the decision to treat *H. pylori*-associated gastritis without duodenal or gastric ulcer is subject to the judgment of the clinician and the patient and family, taking into consideration the potential risks and benefits of the treatment in every individual patient [4].

First-line eradication therapy has three different regimens: (1) triple therapy with a PPI and amoxicillin and imidazole or clarithromycin, (2) bismuth salts with amoxicillin and imidazole, and (3) sequential therapy (Table 12.3) [4].

Standard triple therapy, a combination of two antibiotics and a PPI, has been recommended as a first-line therapy since the first published pediatric guidelines. The goal of treatment is at least a 90% eradication rate at the first attempt

Table 12.3 Treatment options for *H. pylori* infection. (Based on ESPGHAN/NASPGHAN recommendations Ref. [4])

PPI (1–2 mg/kg/day) + amoxicillin (50 mg/kg/day) + clarithromycin (20 mg/kg/day)/metronidazole (20 mg/kg/day) Duration: 7–14 days (preferable 10–14 days)
Bismuth salts (8 mg/kg/day) + amoxicillin (50 mg/kg/day) + metronidazole (20 mg/kg/day) Duration: 7–14 days (preferable 10–14 days)
Sequential therapy: PPI (1–2 mg/kg/day) + amoxicillin (50 mg/kg/day) during 5 days, then PPI (1–2 mg/kg/day) + metronidazole (20 mg/kg/day) + clarithromycin (20 mg/kg/day) during 5 days Total duration: 10 days
Maximal daily dose: amoxicillin 2 g, metronidazole 1 g, clarithromycin 1 g PPI proton pump inhibitors

[4]. However, reported eradication rate is much lower mainly due to antibiotic resistance. Antibiotic resistance is mostly found to clarithromycin and metronidazole. The overall incidence of clarithromycin resistance in children in Western countries is high and current reports indicate prevalence of more than 20% in treatment-naïve patients [42, 103–106], and the resistance rate is even much higher in some countries like China where clarithromycin resistance rate was higher than 80% [107]. Similarly, some areas have also high levels of resistance rate to metronidazole, more than 20% [42, 103, 107, 108]. Based on the negative effect of antibiotic resistance on treatment outcomes, the rates of resistance in the area where the child lives should be taken into account when deciding on the initial therapeutic regimen for eradication [4]. In areas with high or unknown primary antibiotic-resistance rate, culture and susceptibility testing should be performed in order to select proper treatment regimen [4].

Decreasing eradication rates with these standard triple regimens have led to the development of alternate treatment options, like sequential therapy. This is a two-step, 10-day therapy typically consisting of a PPI combined with amoxicillin given for the first 5 days, followed by a triple therapy including a PPI, clarithromycin, and metronidazole/tinidazole for another 5 days [109]. Meta-analysis comparing sequential to standard triple therapy found that sequential therapy is superior to 7-day standard triple therapy; however, not significantly better than 10-day or 14-day triple therapy [109].

Bismuth-based triple therapy is also recommended as an alternative first-line therapy. Well-designed, randomized, multicenter studies of *H. pylori* eradication in children comparing bismuth-based regimens to the alternative recommended first-line therapies are lacking. The results from the pediatric European register for treatment of *H. pylori* showed that when given as first treatment, bismuth-containing triple therapies were more efficacious than those containing PPI (77% vs. 64%) [110, 111]. In addition, bismuth-based triple therapy may be less costly than the other options; however, concerns regarding the palatability of bismuth potentially affecting adherence should also be considered [4].

The duration of eradication therapy is still controversial. Today, 7-, 10-, and 14-day triple regimens are often used. It has been reported that, especially taking into account compliance rate that there is no benefit from longer duration of therapy [111, 112]. There are no studies specifically addressing the issue of the treatment duration in children for standard triple eradication therapy. It is recommended that the duration of triple therapy should be from 7 to 14 days and factors like costs, compliance, and adverse events should be taken into account [4].

Emerging evidence suggests development of secondary antibiotic resistance in children who failed initial eradication therapy [113]. When initial treatment fails there are several options; if possible, primary culture with antibiotic sensitiv-

ity testing should be performed to guide second-line therapy. If culture (and standard susceptibility testing) is not possible, molecular tests (including FISH) can be used to detect *H. pylori* and clarithromycin and/or fluoroquinolone resistance in gastric biopsies [94]. If primary culture and sensitivity testing are not available, when deciding on second-line therapy, the initial therapy should be taken into account with avoidance of previously given regimens [114].

Guidelines recommend quadruple therapy which consists of PPI, metronidazole, amoxicillin, and bismuth as a second-line or salvage therapy [4, 94]. However, this regimen is complicated to administer and bismuth salts are not widely available. Other second-line therapy choice is a triple therapy including PPI, levofloxacin (moxifloxacin), and amoxicillin [4]. This regimen proved to be effective in adults; however, the evidence of fluoroquinolones used in children is limited. Moreover, there are concerns regarding increasing rates of quinolone resistance in adults [114]. Therefore, this regimen should not be used in the children who have received fluoroquinolones previously [4]. Although the studies on the ideal duration of therapy for second-line treatment are not conclusive, a longer duration of therapy of up to 14 days is recommended [4].

Assessment of Eradication

All children who received treatment for *H. pylori*, even if they have no symptoms should undergo the evaluation of the treatment success. The absence of symptoms is not reliable and does not necessarily mean the *H. pylori* is eradicated. The recommended tests for *H. pylori* eradication assessment are noninvasive tests; ¹³C-UBT and a monoclonal ELISA for detection of *H. pylori* antigen in stool [4]. As previously presented, these tests have a high sensitivity and high specificity and are not invasive. A follow-up endoscopy is not routinely indicated unless other causes of ulceration are suspected or if biopsies are needed for culture and antibiotic susceptibility testing [4].

Eradication therapy reduces the amount of *H. pylori* in the stomach, even when eradication failed because of that antibiotic or PPI therapy can cause false-negative test results [115]. Therefore, assessment of eradication should be performed with noninvasive test at least 4–8 weeks following completion of therapy [4].

Yvan Vandenplas

In 1888, Pierre Ménétrier first described the disease that bears his name. Menetrier disease (MD) is a rare condition of unknown etiology characterized by giant hypertrophy of the mucosal folds in the stomach. Vomiting, abdominal pain, anorexia, and edema secondary to the protein loss from the stomach are the most common presenting features. In MD, gastric acid secretion is decreased. Peripheral edema, ascites, and pleural effusion are typical manifestations of the severe hypoalbuminemia found in MD. Hypoalbuminemia occurs due to protein loss from hypertrophic gastric folds. Fever, anorexia, diarrhea, and weight loss are as well reported. MD may develop after a prodromal viral infection, including epigastric pain, anorexia, vomiting, but also raised immunoglobulin (Ig)E levels. In adults, MD is a chronic disease requiring specific therapy, while pediatric MD is typically of acute onset, transient, and self-resolving. The mean age of affected children is 4.5–5.0 years, although exceptionally MD has also been reported in the neonatal period. A young infant who developed gastric outlet obstruction by 3 months of age was also eventually diagnosed with MD, suggesting the possibility that infantile MD may be an entity distinct from the childhood and adult forms [1]. In adults, MD is an acquired premalignant disorder. Pediatric MD usually has an insidious onset and progressive, chronic clinical course, and it spontaneously resolves in weeks or months. Pediatric MD is considered uncommon although the precise incidence is unknown. Cytomegalovirus (CMV) has been implicated in several children, but also *Helicobacter pylori* (Hpyl) [2, 3], *Herpes simplex*, and *Mycoplasma* have been thought to be possibly responsible. As for Hpyl infection, given its high prevalence and the low incidence of MD, the association of Hpyl and MD may only be a coincidence. Given the transient nature of MD in children, even if eradication of Hpyl results in the cure of MD, the causative role of Hpyl would remain

unproven. In case of CMV-MD, however, antiviral agents are related to a better cure. In children, lymphoma can also present with hypertrophic gastric folds. Anisakiasis (a parasitic disease caused by anisakid nematodes), granulomatous gastritis, eosinophilic and allergic gastritis, and other rare conditions such as plasmacytoma and systemic lupus erythematosus may all present with hypertrophic gastric folds. MD-like disease occurs also in animals [4].

An overexpression of transforming growth factor (TGF) and signaling via the epidermal growth factor receptor (EGFR) have been shown to be of relevance in the pathogenesis in experimental models [5]. MD was cured very rapidly in an adult following treatment with monoclonal antibodies. There may be a genetic predisposition. A unique, four-generation pedigree has been described, with autosomal dominant gastropathy exhibiting the typical clinical, endoscopic, and pathological MD-like findings, though in the absence of protein loss and with no increase in the levels of gastric TGF- α [6]. To investigate a possible association of juvenile polyposis syndrome with MD, a new mechanism that involves TGF β -SMAD4 pathway inactivation and TGF α overexpression related to *H. pylori* infection has been proposed [7].

When MD is suspected, other causes of albumin loss should be excluded, and upper gastrointestinal endoscopy should be performed. The endoscopic appearance is that of hypertrophic gastric folds especially in the body. Of note, the more the stomach is insufflated, the less evident are its folds. Histologically, there is foveolar hyperplasia of the gastric mucosa with hypersecretion of mucus and glandular atrophy. The foveolae are elongated, tortuous with reduction of chief and parietal cell glands and often with cystic dilatations that may extend into mucularis mucosae and submucosa. The lamina propria is edematous with increased eosinophils, lymphocytes, and round cells, and the muscularis mucosa may be hyperplastic with extensions into the mucosa. Gastric wall thickening as determined by ultrasonography is not diagnostic of MD, but serial ultrasounds may be helpful in the monitoring of the course of the disease. Investigations to exclude or confirm the presence of the possible infectious

agents that have been associated with MD are recommended. Management is symptomatic and treatment of the possibly causal infectious agent. MD in children is generally a benign and self-limiting condition.

Although usually self-limiting, partial gastrectomy may be needed in patients with persisting clinically relevant hypoproteinemia. Anti-EGF-R in adults has been associated with a dramatic improvement.

Epidemiology and Etiology

Diarrhea is the second leading cause of death due to infections among children below 5 years of age worldwide [1, 2], and it is estimated that diarrhea accounted for 10% of the 6.9 million deaths among children below 5 years in 2011 [2, 3]. Acute diarrhea is thus a major problem in both developing and industrialized countries, but with two distinct consequences. In developing countries, enteric infections are highly common with an estimated incidence of 3.8 episodes/child per year in infants and of 2.1 episodes/child per year in children 1–4 years of age [4]. Gastroenteritis is also responsible for a high mortality rate, and it is estimated that 1 out of 40 children will die because of diarrhea [5]. In contrast, in industrialized countries, the incidence of diarrhea is approximately 1–2 episodes/child per year in subjects younger than 3 years, and the mortality is much lower than in poor countries, although not negligible. In the USA, 150–300 infants or young children die each year because of acute diarrhea, and substantial resources are needed for hospitalizations and medical visits.

In fact, acute gastroenteritis accounts for an annual average of 35 hospitalizations per 10,000 children younger than 5 years and for 4% of all hospitalizations [6]. It was estimated that 1 in 57 children below 5 years of age would be hospitalized for diarrhea-associated illness, and the rate of out-patient visits was 943/10,000 children, corresponding to 2% of all visits.

Rotavirus is the leading cause of acute gastroenteritis [7], and it is the most frequent agent of severe diarrhea in children <5 years of age, worldwide. Rotavirus infections affect virtually all children by the age of 5 years [8], being responsible for approximately 40% of all cases of diarrhea in the USA [6]. Recent results from the World Health Organization

(WHO) rotavirus surveillance networks indicate that approximately 36% of diarrhea hospitalizations among children aged less than 5 years worldwide can be attributed to rotavirus infection [9]. Similar figures have been recorded in Europe [10], where rotavirus accounts for 55% of hospitalizations and one third of emergency department visits due to community-acquired acute gastroenteritis in children aged <5 years. The burden of community-acquired rotavirus gastroenteritis occurs in children aged <2 years with a peak in infants aged <6 months. Every year, approximately 600,000 children die of rotavirus disease, mainly in developing countries [11]. In industrialized countries, where there is generally good access to health care, mortality due to rotavirus gastroenteritis is very low. In the USA, before the introduction of rotavirus vaccine in 2006, rotavirus caused an estimated 20–60 deaths, 55,000–70,000 hospitalizations, 205,000–272,000 emergency department visits, and 410,000 outpatient visits each year [12]. Annual direct and indirect costs were estimated at approximately 1 billion dollars, primarily due to the cost of time lost from work to care for an ill child [13, 14].

Rotavirus infection is, therefore, a major reason of hospitalization in children with acute gastroenteritis [15–17], with substantial impact on health-care resources and costs. The estimate average cost for an episode of diarrhea in inpatient is US\$ 2300. Costs for acute diarrhea are not negligible, particularly if the so-called societal costs are considered. It has been estimated that the cost of an episode of diarrhea requiring an office visit in the USA averages US\$ 300 [18], half of which is due to the loss of working days by the parents of sick children.

During the past four decades, there has been a dramatic increase in the number of newly recognized etiological agents of gastroenteritis. In fact, since 1970, more than 20 different microorganisms (viruses, bacteria, and parasites) have been recognized as etiological agents. Nevertheless, a pathogen is currently identified in only a small proportion of cases. Although many viruses have been identified in fecal

Astrovirus		

samples of patients with diarrhea, their causal relationship with diarrhea is largely unknown (Table 14.1).

The viruses most frequently responsible for acute gastroenteritis in children belong to four distinct families: rotaviruses, caliciviruses, astroviruses, and enteric adenoviruses. Rotavirus and norovirus are the two leading agents of acute diarrhea. Other viruses, such as toroviruses, picornaviruses (the Aichi virus), and enterovirus 22, play a minor epidemiological role. Finally, selected viruses induce diarrhea only in children at risk. These include cytomegalovirus, Epstein–Barr virus, picobirnaviruses, and HIV.

Pathophysiology of Viral Diarrhea

In the classic and simple view, the pathogenesis of diarrhea may be divided into osmotic and secretory. Viral diarrhea was originally believed to be the consequence of endoluminal fluid accumulation osmotically driven by non-absorbed nutrients due to cell invasion and epithelial destruction by enteropathogenic agents. It is now known that several mechanisms are responsible for diarrhea, depending on the specific agents and the host features. In addition, selected viruses have multiple virulence pathways that act synergistically to induce diarrhea.

The mechanisms of diarrhea induced by group A rotaviruses have been extensively investigated and provide a paradigm of the pathophysiology of viral diarrhea [20–22]. Rotavirus has both a tissue- and a cell-specific tropisms, and it infects the mature enterocyte of the small intestine. The first step is virus binding to specific receptors located on the cell surface, the GM1 ganglioside. However, different rotavirus strains bind in either a sialic-acid-dependent or sialic-acid-independent fashion. Most rotaviruses, including all human strains, infect polarized enterocytes through both the apical and the basolateral side, in a sialic-acid-independent manner, suggesting the presence of different receptors. The early stages of rotavirus binding involve the viral protein (VP4) spike attachment and cleavage. After binding, rotavirus enters into the cell by a multistep process that requires both VP7 and VP4 proteins. Infection of the villous enterocytes leads to cell lysis, compromising nutrient absorption and driving fluid into the intestinal lumen through an osmotic

mechanism. However, the destruction of villus-tip cells induces a compensatory proliferation of crypt cells. These immature enterocytes physiologically maintain a secretive tone, thus contributing to diarrhea with ion secretion, as the result of the imbalance between absorptive villous and secretory crypt cells. Thus, the cytopathic effect of rotavirus results in both osmotic and secretory diarrhea. Histological changes induced by rotavirus infection occur within 24 h of infection in animal models.

The enteric nervous system may also play a direct role in inducing fluid secretion, similar to that induced by cholera toxin and other intestinal secretagogues. The molecular mechanisms of fluid secretion have also been investigated. Rotavirus induces an increase in intracellular calcium levels, which is responsible for the disassembly of microvillar F-actin, the perturbation of cellular protein trafficking, the damage of tight junction, with a disruption of cell–cell interaction and cytolysis.

In children with rotavirus infection, the onset of diarrhea is abrupt and occurs in the absence of histological changes, suggesting that in the initial phase of the infection a secretory pathway is responsible for diarrhea. The identification of the nonstructural protein (NSP4), an enterotoxin produced by rotavirus, responsible for fluid secretion but not for epithelial damage may explain this phenomenon. NSP4 is a multifunctional virulence factor (VF), as it possesses the following features (Fig. 14.1): It is released from infected cells and enters the cells through a specific receptor causing calcium-dependent chloride secretion. NSP4 also alters plasma membrane permeability and is cytotoxic. NSP4 is the only rotavirus gene product capable of eliciting intracellular calcium mobilization. NSP4 further contributes to diarrheal pathogenesis by directly altering enterocyte actin distribution and paracellular permeability. Finally, NSP4 plays a role in the inhibition of the Na⁺-dependent glucose transporter (SGLT-1). Glucose absorption as well as disaccharidase activities are impaired in rotavirus enteritis, whereas the Na/ amino acid co-transporters are not involved.

Rotavirus diarrhea may also have an inflammatory component. The induction of cytokines is important in developing an inflammatory and immune response, especially in intestinal infection caused by bacteria. In rotavirus infection, limited inflammation is detected by histological studies, suggesting that cytokines are effective in inducing a host immune response to rotavirus diarrhea. However, it has been shown that rotavirus-infected enterocytes activate nuclear factor kappa B (NF-κB) and the production of chemokines interleukin (IL)-8, Rantes, and growth related oncogene (GRO)-α, of interferon (IFN)-α, and of granulocyte/macrophage-colony-stimulating factor (GM-CSF). Recent evidence suggests that rotavirus-induced diarrhea may be also associated with an increase of intestinal motility through the stimulation of myenteric nerve plexus [23].

Fig. 14.1 Combined effects by NSP4 in the pathophysiology of rotavirus diarrhea. Rotavirus infects epithelial cells of the small intestine, replicates, and induces cell lysis. NSP4 is released by infected cells and functions as a Ca^{2+} -dependent enterotoxin triggering Cl^- secretion. It decreases fluid and electrolyte transport by inhibiting Na–glucose symport SGLT1 and, possibly Na–K adenosine triphosphatase (ATPase). It also impairs disaccharidase expression. Furthermore, rotavirus and/or NSP4 may dif-

fuse underneath the intestinal epithelium activating secretory reflexes in the enteric nervous system. Late during the infection, an inflammatory response in the lamina propria may be detected, and the production of inflammatory substances and cytokines may further contribute to the increase of intestinal permeability and diarrhea. NSP4 nonstructural protein, SGLT-1 Na^+ -dependent glucose transporter, NO nitrous oxide. (Reprinted with permission from Ref. [19], 2004, Fig. 9.3, p. 131)

In conclusion, the primary target of rotavirus is the enterocyte, which is induced to secrete fluids and electrolytes and is subsequently destroyed. On the other hand, the enterocyte acts as a sensor to the mucosa with the production of viral and endogenous factors and the activation of other cell types including neurons. Thus, rotavirus-induced diarrhea is a multistep and multifactorial event, in which fluid secretion and cell damage are observed in a precise sequence, as shown in an intestinal cell line-based experimental model [24] (Fig. 14.2). A summary of the multiple mechanisms involved in the rotavirus–intestine interaction is provided in Table 14.2.

Clinical Signs and Symptoms of Viral Diarrhea

Usually viral diarrhea has an abrupt onset and lasts for 3–5 days. Generally it is a benign condition with spontaneous recovery. In very select cases, diarrhea may be persistent lasting more than 7–15 days. Risk factors for persistent diarrhea in children are: young age, early weaning, malnutrition, and

Fig. 14.2 Biphasic effect of rotavirus in Caco-2 cells. Rotavirus induces a biphasic response, in an in vitro model of infection in Caco-2 enterocytes mounted in Ussing chambers. An early secretion is evident in the first few hours of infection, with a peak at 2-h postinfection, as shown by the increase in short circuit current (Isc, μA). Subsequently, rotavirus exerts a cytotoxic effect with a loss of tissue integrity, as demonstrated by the fall of transepithelial resistance (TER) (Ohm/cm^2) which is evident at 24-h postinfection. The results suggest that rotavirus diarrhea is initially the result of an early secretory mechanism and of a subsequent osmotic pathway, due to cell damage and loss of functional absorptive surface, leading to nutrient malabsorption. (Reprinted with permission from Ref. [19]. Reprinted from Ref. [24], by Permission of Oxford University Press)

Table 14.2 Mechanisms involved in rotavirus-induced diarrhea

Mechanism	Effect
Enterocyte damage	Nutrient malabsorption/osmotic diarrhea
Crypt cell proliferation	Ion and water secretion/secretory diarrhea
NSP4 production	Increase in intracellular calcium, chloride secretion/secretory diarrhea
NSP4 inhibition of SGLT-1	Glucose malabsorption/osmotic diarrhea
Neuromediated vascular ischemia	Secretory diarrhea induced by neurotransmitter release
Inflammation	NF- κ B, IL-8, Rantes release/osmotic, and secretory diarrhea
Stimulation of myenteric nerve plexus	Increase in intestinal motility

NSP4 nonstructural protein, *NF- κ B* nuclear factor kappa B, *IL* interleukin, *SGLT-1* Na⁺-dependent glucose transporter

immunodeficiency. In selected children, an acute onset may coincide with the first manifestation of celiac disease.

The predominant symptoms of acute gastroenteritis, regardless of the causative etiologic agent, are diarrhea and vomiting, associated or not to fever and abdominal pain. None of the symptoms that usually characterize the clinical feature of acute gastroenteritis has a strong predictive value able to discriminate among the different etiologies. However, there are selected features that may help a differential diagnosis of viral versus bacterial infection [25].

Children with viral intestinal infection generally have large volumes of watery stools, suggesting small bowel involvement, and vomiting and fever are more frequent than in bacterial diarrhea. Each of these features contributes to dehydration. Another feature of viral gastroenteritis is the frequent association of diarrhea and vomiting with respiratory symptoms (Table 14.3).

In contrast, the presence of symptoms suggesting colitis, such as a high number of diarrheal episodes with small amount of stools, blood in the stools, high fever, and abdominal pain is more likely associated with bacterial etiology (Table 14.3) [26, 27].

The severity of acute gastroenteritis is reflected by the degree of dehydration. The degree of dehydration should be evaluated at first observation and during the follow-up to establish the efficacy of rehydration treatment. However, high persistent fever and lethargy may be signs of a more severe clinical condition and indicate systemic involvement. Moreover, benign seizures, not related with electrolyte imbalances, have been reported for rotavirus- and norovirus-induced gastroenteritis [28, 29]. Severe encephalopathies were re-

ported in a recent surveillance study conducted in Germany on about 100 cases of very severe diarrhea [30].

When compared with other viral infections, rotavirus infection is more frequently associated with high-grade fever (>38 °C), frequent diarrheal episodes (>7/day), and long-lasting diarrhea that results in significantly higher severity scores [31–36]. In contrast, children with norovirus infection have significantly more episodes of vomiting than other viral infections, and in some cases, vomiting may be the only gastrointestinal symptom and up to 20% of children are present without diarrhea [33, 34]. Intestinal infections due to adenovirus, on the other hand, seem to have milder clinical features [36].

Diagnosis

Most children with acute diarrhea have viral gastroenteritis. Microbiological examination is not helpful in the majority of cases and should be reserved for special circumstances. In fact, regardless of etiology, most children do not require any etiology-based treatment and therefore identification of a specific pathogen is not generally needed. Microbiological investigation should however be performed during outbreaks, especially in childcare settings, schools, hospitals, or residential settings to identify the pathogen and establish its source in the attempt to reduce transmission. Stool samples should also be taken from children with bloody diarrhea, a history of recent foreign travel, and from young or immunocompromised children with high fever for whom antibiotic treatment is considered. Finally, it is also recommended to investigate children in whom diarrhea persists for more

Table 14.3 Clinical features associated with viral and bacterial agents of acute diarrhea in children

Viral diarrhea	Bacterial diarrhea
Watery diarrhea	High fever

than 10–14 days, or when a noninfectious etiology for diarrhea is suspected, such as inflammatory bowel disease (IBD) (Table 14.4) [25]. Several techniques are available to identify the specific etiology of viral diarrhea. The gold standard is viral culture but its clinical application is limited, due to the costs, the delay in the results and the complexity of the procedures. Immunofluorescence or latex agglutination is widely used to identify fecal viruses. Polymerase chain reaction (PCR) is becoming a common diagnostic tool for virus identification. Specific PCR are currently available for norovirus, rotavirus, adenovirus, cytomegalovirus, and other less common viruses.

Differential diagnosis of viral gastroenteritis may include food poisoning, which is eventually indirectly related to a microbial etiology. Food poisoning has a more rapid onset, often with vomiting and is more common in children than in infants, being related to ingestion of at risk foods. On the other hand, when diarrhea is persistent, lasting more than 7 days, a different etiology should be considered [37]. Common causes of persistent diarrhea (dealt with in detail in Chap. 17) include small intestinal bacterial overgrowth, lactose intolerance, and cow's milk protein intolerance; it should, in addition, be considered that chronic inflammatory conditions of the small and/or large intestine such as celiac disease or IBD may have an acute onset or be triggered by viral enteritides.

Specific Viruses

Rotavirus

Rotavirus is a double-stranded RNA virus belonging to the Reoviridae family. The virion, 70–75 nm, is composed of a three-layered protein capsid that encloses 11 distinct segments of genomic RNA, each coding for a different capsid or nonstructural protein. The internal core contains VP 1, 2, and 3; the inner capsid contains VP4; the two outer capsid proteins encoded by genes 4 and 7, namely VP4 and VP7, represent the only established neutralization antigens of the virus. The protective role of antibodies directed against these proteins has been confirmed in both experimental animal

models and humans. A possible role has been suggested for antibodies directed at the inner capsid protein VP6, which is not associated with *in vitro* neutralization. The nonstructural proteins NSP1, NSP2, and NSP4 are VFs in mice. Rotavirus groups A–F have been described, but only groups A, B, and C have been identified in humans. Most human infections are caused by group A rotaviruses that are classified into serotypes by a dual classification system based on neutralizing antigens on two outer capsid proteins, VP7 (G serotype) and VP4 (P serotype). To date, 14 G serotypes and 11 P serotypes have been identified in humans. There is substantial genetic diversity within each G and P type. Predominant serotypes vary from year to year and from region to region. G1P [8] is the globally predominant strain, representing over 70% of rotavirus infections in North America, Europe, and Australia. G9 strains now constitute the predominant strains in some parts of Asia and Africa, and G8 strains are proportionally more frequent in Africa [38, 39]. In South America, G5 strains have emerged in children with diarrhea, and G9 is associated with more severe disease in Latin America [40]. Similarly, the distribution of P [6] antigen differs according to region. An example is the rapidly evolving change of serotype distribution in Africa [41].

Specific strains may express stronger VFs, which could be related to the severity of symptoms. More severe presentations may also be related to the reintroduction of strains in areas where they have been previously absent. The epidemiology of rotavirus shows a link with cold seasons with a higher incidence during fall and winter.

Transmission is by fecal–oral route, both through close person-to-person contact and by fomites. Viruses are shed in high concentrations in the stool of rotavirus-infected persons. Children shed large numbers of viruses in stool, during the acute illness but they may shed rotavirus 2 days before and up to 10 days after the onset of symptoms. The virus may also be transmitted by respiratory droplets. Spread within families, institutions, hospitals, and childcare settings is common. Rotavirus is a major cause of acute gastroenteritis in children attending child care. Rotavirus is also responsible for nosocomial infection during the winter with an incidence as high as 3% hospitalization in a meta-analysis of 20 studies in Europe and North America [42], prolonging hospital stays and increasing medical costs. The incidence of nosocomial infection is directly related to the duration of hospital stay. In Italy, the incidence of nosocomial rotavirus-induced gastroenteritis was 7.9/1000 child-days of hospitalization [43].

The incubation period for rotavirus diarrhea is short, usually less than 48 h. Rotavirus is able to determine a large spectrum of disease, ranging from asymptomatic shedding to severe dehydration, seizures, and even death. Rotavirus gastroenteritis typically begins with acute onset of fever and vomiting followed 24–48 h later by watery diarrhea [44].

Symptoms generally persist for 3–8 days, although protracted episodes have been reported occasionally. Fever is usually of low grade and occurs in up to half of all infected children. Vomiting occurs in 80–90% of infected children, and it is usually brief, lasting 24 h or less in most children. Dehydration and electrolyte disturbances are the major complications of rotavirus infection and occur most often in the youngest children. Studies of hospitalized children have indicated that gastroenteritis associated with rotavirus is more severe than cases in which rotavirus was not detected, with more severe dehydration, higher incidences of vomiting and higher need of parenteral rehydration. Children with immunodeficiency, particularly those with T cell immunodeficiencies or severe combined immunodeficiency (SCID), and children after bone marrow transplantation are at higher risk of severe and prolonged diarrhea and central nervous system complications.

Diagnosis of rotavirus infection is performed using enzyme immunoassays and latex agglutination assays for detection of group A rotavirus antigen in stools. Virus can also be identified in stool by electron microscopy and by reverse transcriptase-PCR.

Norovirus

Noroviruses are single-stranded RNA viruses belonging to the family *Caliciviridae*. The prototype virus of the noroviruses, Norwalk virus, was identified in 1972. The availability of molecular diagnostic methods based on reverse transcription-PCR (RT-PCR) highlighted the etiologic role of norovirus in epidemic and sporadic gastroenteritis [45, 46]. Norovirus is now a well-documented leading agent of epidemic gastroenteritis in all age groups, causing >90% of nonbacterial and ≈50% of all-cause epidemic gastroenteritis worldwide [47]. The impact of norovirus disease may be much greater than previously thought, and the disease may be more severe in some populations [46, 48–50].

The norovirus genome comprises a single-stranded, positive sense, polyadenylated RNA of approximately 7.5 kb in length, encompassing three open reading frames (ORFs 1–3).

Noroviruses encompass five distinct genogroups (GI–GV) with GI, GII, and GIV infecting humans. The norovirus genogroups are further divided into genotypes and variants (subgenotypes) based on the sequence diversity [51].

In contrast to rotavirus, the mechanisms of norovirus-induced diarrhea are not well defined. Many viral factors can interfere with basic cellular functions. Several observations showed that, in infected mucosa, villus length was decreased by 25%, whereas crypt length was unchanged [21]. The villus blunting and the shortening of the villi observed in this viral infection depend on the norovirus infection of intestinal

epithelial cells located on the apical area of villi. The infected cells show an increase in cell death rates with a reduction of the overall absorptive surface [52].

Evaluations of human intestinal biopsies from norovirus-infected patients in Ussing chambers showed an active Cl^- secretion, consistent with cystic fibrosis transmembrane conductance regulator (CFTR) activation. A reduction of occludin expression as well as claudins 4 and 5 corresponding with a marked decrease in transepithelial resistance has also been observed [53]. In addition, norovirus produces two VP, p48 and p20. The former interferes with cell proteins involved in the regulation of vesicle trafficking [54], whereas p20 impairs actin cytoskeleton structure leading to intestinal barrier dysfunction [55].

Intestinal mucosal immunity is also affected by norovirus. A recent study showed that dendritic cells were depleted in norovirus-infected mucosa associated with an altered antibody response. On the contrary, dendritic cells were required for a dissemination of the virus to secondary lymphoid tissues supporting the idea that enteric viruses can use dendritic cells to facilitate their dissemination within the host [56]. In addition, the VF1 expression enables norovirus to establish efficient infection interfering with interferon-mediated response pathways and apoptosis [57, 58]. Finally, Nelson et al. observed a highly altered gut microbiota in patients with norovirus gastroenteritis resulting in a low grade of diversity and increased proteobacteria [59]. Elevated proteobacteria is a common feature in patients with dysbiosis, and a reduction in the diversity is associated with several altered functions of gut microbiota [60].

Norovirus gastroenteritis may occur in three distinct epidemiological settings, and is associated with a broad spectrum of clinical outcomes. Firstly, food-borne gastroenteritis generally affects large numbers of healthy adults over a short time period, with symptoms typically resolving within 1–3 days [61]. Secondly, health-care-associated infection, which occurs in semi-closed settings such as hospital wards and residential/care homes, can be very challenging to contain. Elderly and compromised individuals are frequently affected and are at high risk of prolonged clinical course, typically 4–6 days, with a not negligible mortality rate [62]. Thirdly, norovirus gastroenteritis may also occur sporadically in children, where norovirus is the second most common cause of acute viral gastroenteritis after rotavirus, often requiring hospitalization [63].

Several prospective clinical studies in different geographical areas have demonstrated that norovirus is the second most frequent pathogen after rotavirus in children hospitalized for acute gastroenteritis and is more prevalent in winter. Compared with rotavirus enteritis, the duration of vomiting and diarrhea is significantly longer but norovirus infection is slightly less severe in terms of severity score and need of intravenous (IV) rehydration compared to rotavirus infection [64–66].

Evaluation and Treatment of Children with Acute Diarrhea

The initial clinical approach to the child with acute gastroenteritis is clinical evaluation. Hydration status in children should be assessed based on easily observed signs and symptoms. Dehydration should be estimated using a score system. An easy to use and reliable score system to evaluate dehydration in children is the Clinical Dehydration Scale (CDS) [67]. It consists of four clinical items: general appearance, eyes, mucous membranes, and tears each of which is scored 0, 1, or 2 for a total score of 0–8 (Fig. 14.3). Severe dehydration is an indication for hospital admission and for IV rehydration.

Indications to hospital admission are reported in Table 14.5.

Specific antiviral treatment is generally not needed to treat rotavirus infection. The current treatment of acute rotavirus gastroenteritis consists of oral rehydration solution (ORS) and early introduction of feedings, like any other form of acute diarrhea [25]. Adequate fluid and electrolyte replacement and maintenance are the key to managing viral gastroenteritis. Oral rehydration is the preferred method unless the child has intractable vomiting that would require IV rehydration. Children who are mildly or moderately dehydrated should receive 50–100 ml/kg of ORS over 4 h and should be reevaluated often for changes in hydration status.

Reduced osmolarity ORS (50/60 mmol/L of Na) should be the first-line treatment for children with acute gastroenteritis. Reduced osmolarity ORS is more effective than full strength ORS (75/90 mmol/L of Na) as measured by key clinical outcome indicators as stool output, vomiting, and need for supplemental IV therapy. The

so-called ESPGHAN (the European Society for Pediatric Gastroenterology Hepatology and Nutrition) solution, containing 60 mmol/L of Na may be used in children with acute gastroenteritis as it has been used successfully in several randomized clinical trials (RCTs) and in a number of non-RCTs [25].

The second step of treatment of acute diarrhea, in children with mild-to-moderate dehydration, is early resumption of feeding after rehydration therapy. It is recommended that (1) breastfeeding should be continued throughout rehydration; (2) the usual age-appropriate diet should be started immediately after initial rehydration (4–6 h); (3) dilution of formula or use of a modified milk formula is usually unnecessary. In persistent diarrhea, withdrawal of lactose may be considered. A recent systematic review showed that lactose free diet in children who are not breastfed may result in a shorter duration of diarrhea. However, most of the trials included in the review were from children hospitalized in developed countries [68]. Hospital treatment is usually associated with enteral or IV rehydration. The former is effective and has no side effects and should be preferred. Children who are severely dehydrated with changes in vital signs or mental status require emergency IV rehydration. For children presenting with shock, rapid IV infusion of isotonic crystalloid solution (0.9% saline or lactated Ringer's solution) with 20 ml/kg bolus should be used. For children with severe dehydration without shock, rapid IV rehydration with 20 ml/kg/h of 0.9% saline solution for 2–4 h is indicated. A dextrose-containing solution may be used for maintenance [69].

There is growing evidence demonstrating the efficacy of selected probiotics as an adjunct to rehydration therapy in reducing the intensity and duration of symptoms. The guidelines of ESPGHAN [25] for the management of acute gas-

Table 14.5 Indications to hospital admission in children with acute diarrhea

Shock
Severe dehydration (>9% of body weight)
Neurological abnormalities (lethargy, seizures)
Intractable or bilious vomiting
ORS treatment failure
Suspected surgical condition
Caregivers cannot provide adequate care at home and/or there are social or logistical concerns
ORS oral rehydration solution

troenteritis in children recommend the use of two different probiotics, *Lactobacillus rhamnosus* strain GG (LGG) and *Saccharomyces boulardii* in adjunct to the ORS for the treatment of acute diarrhea in children [70, 71]. Both *Lactobacillus* GG and *S. boulardii* reduce the duration of diarrhea by approximately 1 day. *Lactobacillus* GG is particularly effective in rotavirus-induced diarrhea. In developed countries, *Lactobacillus* GG given in a daily dose of 10 billion colony-forming units (CFU) per day has proven effective in reducing the risk of protracted diarrhea and the duration of hospitalization in rotavirus gastroenteritis [72, 73].

Other pharmacological interventions have been studied in the attempt to reduce the duration of acute diarrhea and for some there is proof of efficacy. Diosmectite can be considered in the management of acute gastroenteritis as it is effective in reducing the duration of diarrhea [25]. A recent meta-analysis assessed the efficacy of Racecadotril as an adjunct to ORS compared with ORS alone or with placebo. Compared with placebo, Racecadotril significantly reduced the duration of diarrhea and the need for IV rehydration [74]. In Table 14.6, the active intervention for acute gastroenteritis is reported.

Prevention of Rotavirus Diarrhea

Vaccine development strategies are based on live-attenuated rotavirus vaccines that can be administered by the oral route. The goal for a rotavirus vaccine is to replicate the degree of protection against the disease induced by the first natural infection that occurs in infants. Therefore, the primary outcome of a vaccine program is the prevention of moderate to severe disease. Rotavirus vaccines decrease the number of children admitted to the hospital with dehydration and decrease the burden of office visits or telephone calls due to rotavirus gastroenteritis.

At present, there are two vaccines that were distinctly developed. The first one is a live-attenuated oral monovalent rotavirus vaccine derived from a G1P [8] human rotavirus strain attenuated through serial passages in cell culture. It has a two-dose schedule with the first dose from 6 weeks of age with an interval of ≥ 4 weeks till the second dose. The schedule should be completed by 24 weeks of age. It provides 85% protection against severe rotaviral gastroenteritis and 100% protection against the most severe dehydrating rotaviral gastroenteritis episodes [75]. The other vaccine is a pentavalent reassortant oral vaccine derived from a G6P [5] bovine rotavirus strain and common human rotavirus strains carrying G1, G2, G3, G4, and P [8] human rotavirus surface proteins. It has a three-dose schedule with the first dose within 6 weeks of age and the last by 24 weeks of age. Its efficacy against rotavirus gastroenteritis of any severity was 74% and against severe rotavirus gastroenteritis was 98% [76–79].

In 2007, the WHO recommended inclusion of rotavirus vaccine in the immunization programs of Europe and the America and, in 2009, expanded the recommendation to all infants over the age of 32 weeks worldwide. Other qualified institution and agencies included rotavirus immunization as a major priority for reduce the mortality for acute gastroenteritis [5].

The burden of rotavirus disease in the USA and elsewhere has been reduced significantly since the introduction of rotavirus vaccines.

Table 14.6 Features of interventions to be considered for active treatment of viral diarrhea

	<i>Lactobacillus rhamnosus</i> strain GG (LGG)	<i>Saccharomyces boulardii</i>	Smectite	Racecadotril
Stool volumes reduction	+	+	+	+
Antimicrobial effect	+	–	–	–
Single oral dose	–	–	–	–
Side effect	–	–	Constipation	Headache, vomiting, and constipation
Freely available	Not every where	Not everywhere	Not everywhere	Not everywhere
Level of evidence	Meta-analysis	Meta-analysis	Meta-analysis	Systematic review
Setting	Inpatients and outpatients	Inpatients and outpatients	Inpatients and outpatients	Inpatients
Cost	Low	Low	Low	Low
Palatability	++	±	–	+

Hospitalization rates were reduced from 60 to 93% depending on vaccine coverage, age groups, and rotavirus season. Studies have also evaluated the impact of rotavirus vaccination on all-cause gastroenteritis or diarrhea-related hospitalizations, emergency visits, and outpatient or physician office visits, and consistent reductions were seen for all these parameters. Effective rotavirus vaccines are most needed in resource-poor countries, where mortality associated with rotavirus is high [41]. However, paradoxically rotavirus vaccine efficacy is significantly lower in clinical trials conducted in developing countries when compared to developed countries, ranging from 40 to 59%. It has been hypothesized that this difference may be the consequence of poor nutritional status, enteric co-infections or to the interference of anti-rotavirus antibodies in breast milk which may neutralize live virus vaccine. Even considering a lower efficacy, the use of live rotavirus vaccines should be implemented in these countries to reduce the high mortality due to rotavirus gastroenteritis.

Vittoria Buccigrossi and Maria Immacolata Spagnuolo

Introduction

Diarrhea is the result of an imbalance of ion and water movement through the intestinal epithelium. In normal conditions, the intestine absorbs 8–9 l of fluid while only 100–200 ml are excreted in the stools every day. In addition, the intestine absorbs nutrients while simultaneously forming a selective barrier to dangerous substances and pathogenic bacteria. Finally, the intestine is colonized with a wide community of bacteria that exert many beneficial functions, the so-called gut microbiota. Resident commensal and foreign bacteria interact intimately with the gut epithelium and affect host cellular and innate immune responses [1]. Enteric pathogens may hamper the physiological handling of electrolytes and water transport processes by secreting toxins that disturb the function and/or the structure of the intestinal epithelium.

A number of cellular and molecular mechanisms are implicated in infectious diarrhea induced by bacteria, viruses, and parasites. Pathogen-specific virulence factors affect a wide range of cell functions such as ion absorption and secretion, barrier function, and membrane-trafficking pathways causing fluid accumulation in the intestinal lumen.

Several bacterial enterotoxins are capable to increase Cl^- secretion and to reduce Na^+ absorption acting on apical membrane-located transporters or on the lateral spaces between cells, regulated by tight junctions (TJs); other pathogens induce cell damage targeting the cytoskeletal network which is directly implicated in paracellular fluid absorption. Invasive pathogens cause an inflammatory diarrhea characterized by an increase in polymorphonuclear cells (PMNs) in the lamina propria leading to an excess of cytokine secretion and activation of enteric nerves via neuropeptides, eventually resulting in dysenteric diarrhea. Furthermore, a peculiar class of *Escherichia coli*, the enteropathogenic *E. coli* (EPEC),

induces diarrhea through damaging the apical enterocytes, thereby reducing the intestinal absorptive surface. Whatever the mechanism, diarrhea is the manifestation of an altered movement of ions and water that follows an osmotic gradient. The pathophysiology of diarrhea is summarized in Fig. 15.1.

Intestinal Ion Transport and Barrier Functions

In normal conditions, fluid transport across the intestinal epithelial cells is a finely balanced process with fluid absorption predominating on fluid secretion. Electrolyte absorption by apical enterocyte depends on the electroneutral and the electrogenic absorption [2], which involves Na^+ uptake by the Na^+ , H^+ -exchanger (NHE) and Cl^- uptake by the Cl^- , HCO_3^{2-} exchangers. There are several exchangers: NHE1 is located on the basolateral surface of the enterocyte, whereas NHE2 and NHE3 have an apical localization. The relative contribution of NHE2 and NHE3 depends on their localization within the intestine with NHE3 being the main mediator of electroneutral Na^+ uptake [3]. The electrogenic ion absorption is the second major source of apical ion absorption through specific channels. Epithelial sodium channel (ENaC) is the most prominent apical Na^+ channel in the colon and allows Na^+ influx into the cell along its electrochemical gradient [3].

A basal level of fluid secretion is necessary for accomplishing the nutrient digestive functions. The cyclic AMP-dependent chloride channel defined as the cystic fibrosis transmembrane conductance regulator or CFTR is located on the brush border. This channel is responsible for water secretion in basal conditions and under active stimulation by secretagogues [4]. In the intestine, water secretion is a passive process driven by active ion secretion, predominantly by Cl^- secretion [5]. Chloride is taken up across the basolateral membrane via $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ cotransporter type 1 (NKCC1), as an electroneutral process. Chloride accumulation is a passive process driven by Na^+ concentration

Fig. 15.1 General mechanisms causing diarrhea. Bacterial toxins can affect intestinal epithelial functions through different mechanisms. Chloride secretion and water secretion depend on the altered functionality of CFTR, CaCC, and NHE channels. Alterations in TJ structures alter the electric gradient causing the movement of both ions and water. Pathogen bacteria induce inflammation through the recruitment of immunity cells and the upregulation of pro-inflammatory cytokines. Finally, an altered gut microbiome composition (dysbiosis) supports pathogen infections. CFTR cystic fibrosis transmembrane conductance regulator, CaCC calcium-activated chloride channels, NHE Na⁺, H⁺-exchanger, TNF α tumor necrosis factor- α , IL interleukin

gradient which is maintained by the basolateral Na, K-ATPase. Two distinct potassium channels are located into the basolateral membrane allowing for potassium recycling thus preventing cellular depolarization, ultimately preserving the electrical driving force for chloride exit from the cell. Therefore, chloride accumulates until apical chloride channels are opened. The bulk of chloride output occurs via cyclic adenosine monophosphate (cAMP)-dependent CFTR chloride channel. However, there is an additional class of chloride channels, the calcium-activated chloride channels (CaCC), that are expressed in the enterocyte apical membrane. These channels drive chloride secretion in response to agonists of cytosolic calcium [4]. Three main intracellular signal-transduction pathways regulate water and electrolyte fluxes across the intestinal mucosa: cAMP; cyclic guanosine monophosphate (cGMP); and calcium-dependent pathways. Recently, a fourth pathway involving nitric oxide (NO) has also been described. Physiological cAMP and cGMP concentrations activate CFTR resulting in a mild secretion of chloride, whereas abnormal CFTR activation in crypt cells results in the secretory diarrhea. cGMP generally results in a more potent, though shorter, chloride secretion than that induced by cAMP [6].

The most common mechanism of bacterial diarrhea is the release of bacterial toxins. Bacterial enterotoxins activate signaling molecules such as cyclic AMP, cyclic GMP, or intracellular Ca²⁺, which, in turn, open cellular Cl⁻ channels leading to an increase in Cl⁻ secretion and consequently of water [5]. The intestinal epithelium forms a selective barrier between the lumen (the external environment) and the body. The electrochemical gradients also depend on TJ that provide a barrier necessary for an efficient transcellular transport. The TJ also support a polarized distribution of

membrane proteins on the basal and apical compartments of epithelial cells [7]. The plasma membranes of adjacent intestinal epithelial cells are linked through the TJ, where claudins, zonula occludens 1 (ZO1), occludin, and F-actin interact. E-cadherin, alpha-catenin 1, beta-catenin, catenin delta1, and F-actin interact to form the adherens junction [8]. The loss of barrier function as a consequence of TJ disruption impairs the vectorial absorption and secretion by the intestinal epithelium. During an infection, the redistribution of apical and basal proteins provides new attachment sites for bacteria. Several bacterial toxins act on the TJ protein functions inducing an epithelial damage. At least four toxins produced by *Clostridium spp.* and a toxin produced by selected *E. coli* strains have been demonstrated to affect intestinal TJ [9, 10].

In this complex scenario, different bacterial species, each with one or more virulence factors, induce diarrhea in a specific mode. This includes the interaction with specific receptor, the release of virulence factors such as adhesion molecules and enterotoxins and a cascade of events occurring within the enterocyte.

Bacterial Diarrhea

Vibrio Cholerae

This pathogen is easily identified in the stools using Gram stain and is responsible for cholera, a potentially fatal diarrheal disease in humans. Although cholera is now rare in developed countries, it remains a major cause of diarrheal morbidity and mortality in several developing countries. Indeed, with the occurrence of calamities, the spreading of cholera

infection in overcrowded refugee camps is a potential significant threat everywhere. The infection is transmitted by the fecal–oral route and is spread through contaminated food and water, the period of incubation ranges from few hours to 5 days. The vast majority of infected subjects remain asymptomatic or experience a mild disease with watery stools, nausea or vomiting, and no significant dehydration. However, cholera may be severe in a number of subjects. Stools are classically described as “rice water” due to the presence of mucus in clear stools. Profuse watery diarrhea and vomiting lead to massive fluid and electrolyte losses that can occur at a rate of 1 l/h, causing a massive dehydration.

Virtually, all cases of non-O1 *Vibrio* infections in the USA are associated with eating raw shellfish and gastroenteritis ranges from a mild illness to profuse, watery diarrhea comparable to that seen in epidemic cholera. Diarrhea, abdominal cramps, and fever are the most common symptoms with nausea, vomiting, and bloody stools occurring less frequently. As with *V. cholerae* O1, the mainstay of therapy for diarrheal disease is oral rehydration [11, 12]. In cases of septicemia (which typically occurs in immunocompromised patients), supportive care and correction of shock are essential interventions associated with antibiotics (tetracycline). *V. cholerae* secretes several toxins, but the most important of these is cholera toxin (CT). CT consists in a single copy of the A subunit and five copies of the B subunit. B subunit binds to plasma membrane, while the A subunit activates adenylate cyclase resulting in elevated cAMP production. The production of cAMP activates the protein kinase A (PKA), which then phosphorylates the regulatory domain of CFTR [5, 13]. In addition to increased Cl⁻ secretion, absorption of Na⁺ is decreased through a cAMP-dependent mechanism in which the activity of both apical sodium transporters, NHE2 and NHE3, is decreased. This leads to an increase in NaCl levels in the intestinal lumen and drives water by osmotic force [14].

In addition to CT, *V. cholerae* produces other toxins that modulate ion secretion and alter barrier function to cause massive diarrhea. The toxins that directly affect ion secretion include the accessory CT (ACE), which stimulates Ca²⁺-dependent Cl⁻ secretion, the non-agglutinable *Vibrio cholerae* heat-stable enterotoxin (NAG-ST), which activates guanylyl cyclase, thus stimulating cGMP production, leading to protein kinase G (PKG)-mediated activation of CFTR and, finally, the *V. cholerae* cytolysin (VCC), which creates anion permeable pores into the cell wall [15].

Salmonella

Salmonella typhi and *Salmonella paratyphi* are Gram-negative, motile bacilli that colonize only humans. Therefore, the infection is acquired through close personal contact or through the ingestion of water or food contaminated with

human feces. Typhoid fever continues to represent a global health problem, with more than 12.5 million cases/year [16]. After an incubation period ranging between 5 and 21 days, these bacteria cause a systemic illness characterized by fever, gastrointestinal symptoms, and occasionally neurological symptoms [17]. Chills, headache, cough, weakness, and muscle pain are frequent prodromes and most symptoms resolve within 4 weeks without antimicrobial treatment. However, *Salmonella* may spread and invade the bloodstream and extraintestinal districts causing a systemic disease defined as enteric fever. In this case, patients relapse with high fever, abdominal pain from inflammation of Peyer’s patches, and intestinal microperforation followed by secondary bacteremia with intestinal agents.

In contrast to *S. typhi*, infections with non-typhoidal salmonellae are increasing in developed countries. Patients at higher risk for infection include those with immunodeficiencies, age younger than 3 months, alterations in intestinal defenses (e.g., on those antacid treatment), impaired reticuloendothelial function (sickle cell and hemolytic anemia), and ingestion of antibiotics to which the organism is resistant. Reservoirs include a wide range of domestic and wild animals, including poultry, swine, cattle, rodents, and reptiles. *Salmonella enteritidis* is the leading reported cause of food–borne diarrheal outbreaks in the USA, with eggs and contaminated raw fruits and vegetables identified as major vehicles [18].

The incubation period is 6–45 h, after which fever, headache, vomiting, abdominal pain, and watery stools (which may contain blood, mucus, and leukocytes) appear, lasting from locus to few days. Severe extraintestinal infections can range from life-threatening sepsis to focal infections in the meninges, bones, and lungs. The microorganism is easily isolated from fresh stools or blood culture.

Clostridium Difficile

Clostridium difficile (CD), a Gram-positive anaerobe that forms spores (hence difficult to clear from hospital setting), is now recognized as the most common agent of nosocomial diarrhea [19]. In the past decade, a dramatic increase in the incidence of *C. difficile* infections (CDI) has been reported worldwide, possibly linked with an excess of antibiotics and other treatment responsible for microflora disruption but also linked with emergence of hypervirulent strains (e.g., NAP1/BI/027) and increased numbers of highly susceptible individuals.

Antibiotic treatment predisposes patients to *C. difficile*-associated disease in specific conditions [20]. The pathogenesis of *C. difficile* infection largely depends on the altered balance of the intestinal microbiota, allowing pathogenic strains of *C. difficile* to infect the intestine [21].

C. difficile causes a broad spectrum of intestinal diseases ranging from mild diarrhea to potentially fatal pseudomembranous colitis (PMC). *C. difficile* is a major agent of antibiotic-associated colitis [22] and produces three toxins, toxin A (TxA), toxin B (TxB), and a binary toxin (cytotoxic distending toxin, CDT) [23]. Both TxA and TxB exert a cytotoxic effect in vitro [24, 25]. In particular, TxA and TxB induce the disaggregation of the actin cytoskeleton, cell rounding, cell death, and loss of intestinal epithelium barrier function leading to increased intestinal permeability and diarrhea [26]. CDT induces a redistribution of microtubules and the formation of long microtubule-based protrusions at the surface of intestinal epithelial cells [9] enhancing adherence and colonization of Clostridia [25, 27].

However, diarrhea is essentially due to a necroinflammatory reaction: *C. difficile* toxins trigger an extensive inflammatory cascade causing a rapidly progressive damage to host tissues resulting in fluid exudation [28]. In parallel, selected cytokines are also able to induce the activation of enteric nerves and induce Cl⁻ secretion. The onset of symptoms may begin from several days after antibiotic therapy is started until 2 months following cessation of treatment. Diarrhea and abdominal cramps are usually the presenting symptoms, followed by fever and chills in severe cases. Mild colitis, with bloody stools and mucus, particularly if they follow antibiotic treatment, should be considered potentially induced by *C. difficile* infection. Microbial culture, latex agglutination, tissue culture assay, and enzyme-linked immunosorbent assay (ELISA) are all used for the diagnosis of *C. difficile* infection.

However, the role of *C. difficile* in infancy and early childhood is still a matter of debate. This is an emerging agent of diarrhea whose role is limited or questionable in children below 36 months of age [29, 30]. It is also a major agent of antibiotic-induced diarrhea and of severe diarrhea in children with underlying chronic conditions such as inflammatory bowel diseases (IBD) [31].

Asymptomatic *C. difficile* colonization is common in infants (ranging from 2 to 75% of healthy children) until 3 years of age and related to delivery mode and feeding [32]. Strains that usually are associated with diarrhea in adults may be detected in asymptomatic infants, and children may be a reservoir of pathogenic strains.

Many healthy children excrete *C. difficile* in their stools during early infancy, and rates as high as 45% have been detected in infants attending day care nurseries and as many as 13% were harboring toxigenic isolates [33].

Independently from the prevalence of carriers and the method to search for *C. difficile*, the incidence of *C. difficile*-related diseases in children has progressively increased in the last years, in parallel with data reported in adults, but with a relative more limited clinical impact. A recent 18-year cohort study reported a 12-fold increase of *C. difficile* infection incidence in children. Overall *C. difficile* infections

increased from 2.6 (1991–1997) to 32.6 per 100,000 persons (2004–2009), with a prevalence of community acquired infection that increased from 2.2 to 23.4 per 100,000 in the same period [34]. However, a role of *C. difficile* as a severe pathogen in children at risk is supported by a solid data: For this reason, one potential alternative to standard therapy is the use of indigenous intestinal microorganisms from a healthy donor to restore the intestinal microbiota of infected patients [35, 36].

In children with chronic diseases such as IBD, *C. difficile* may act as severe opportunistic pathogen and trigger burst of the disease with a potentially severe course.

Shigella

Shigella causes 250 million cases of diarrhea and 650,000 deaths worldwide per year. *Shigella* is a Gram negative, non-lactose fermenting, nonmotile bacillus. *Shigella sonnei* is the main type in industrialized countries, and *S. flexneri* and *S. dysenteriae* predominating in developing countries [37]. The latter is the most dangerous species as it produces Shiga toxin, which can lead to hemolytic uremic syndrome (HUS). Humans are the only natural hosts and transmission occurs by fecal–oral contact. The very low infective load (as few as ten organisms) makes *Shigella* highly contagious. *Shigella* causes a dysenteric diarrhea, and the cellular responses to various steps of the invasion process are the primary cause of inflammation. *Shigella* strains cross the epithelial barrier through the M-cells where they bind to basolateral TLR4 receptor. This causes the production of interleukin (IL)-6, IL-8, and the subsequent release of IL-1 β , which attracts PMN cells [38]. Nuclear factor kappa B (NF- κ B) and mitogen-activated protein kinase (MAPK)-signaling pathways are activated not only in *Shigella*-infected epithelial cells but also in uninfected bystander cells [39], and this cell–cell communication amplifies inflammation. However, *Shigella* extensively disrupts TJs. In polarized cultured T84 epithelial cells, ZO-1, claudin-1, and the phosphorylation status of occludin were all affected by *S. flexneri* [40]. There is a secondary mechanism that promotes diarrhea, triggered by serine protease autotransporters of *Enterobacteriaceae* (SPATES), three enterotoxins that alter transepithelial fluid movement and cytoskeletal structure [41]. After 1–4 days of incubation, shigellosis begins with fever, headache, malaise, anorexia, and occasional vomiting and watery diarrhea with progression to dysentery within hours to days. Unusual extraintestinal manifestations may occur, including HUS in children and thrombotic thrombocytopenic purpura in adults. Most episodes of shigellosis in otherwise healthy individuals resolve within 7 days. *Shigellae* are difficult to grow and are best isolated from fresh stools rapidly inoculated into selective culture plates incubated immediately at 37°C.

Campylobacter jejuni

These organisms are small, spiral-shaped Gram-negative bacilli that live in the intestines of both wild and domestic animals [42]. Common vehicles for human infection are poultry, unpasteurized milk, and contaminated water [43, 44]. After 3–6 days of incubation, symptoms abruptly begin. *Campylobacter* diarrhea may present as a typical gastroenteritis with vomiting and profuse diarrhea or as a colitis with abdominal pain and bloody stools, and abdominal pain that may mimic an appendicitis. Diarrhea usually lasts 4–5 days; the microorganism can be identified only from stool. *Campylobacter* vaccine development has proceeded cautiously, because of concerns about postexposure arthritis or Guillain–Barré syndrome. However, a monovalent, formalin-inactivated, *C. jejuni* whole-cell vaccine with a mucosal adjuvant has entered human trials.

Yersinia

Yersinia enterocolitica and *Y. pseudotuberculosis* are two important human enteropathogens widely distributed in the environment, with swine as the major reservoir. The incubation period is 3–7 days, with food-borne transmission. *Yersinia*'s preference for cool temperatures makes this pathogen more common in Northern Europe, Scandinavia, Canada, the USA, and Japan. *Yersinia* enterocolitis occurs more often in children younger than 5 years [45] and is characterized by fever, vomiting, exudative pharyngitis, cervical adenitis, abdominal pain, and watery diarrhea, which may contain blood [46, 47]. Diarrhea typically lasts for 14–22 days, but fecal excretion may persist for 7 weeks or longer. Abdominal complications include appendicitis, pseudoappendicitis, diffuse ulcerations of the intestine and colon, intestinal perforation, peritonitis, ileocecal intussusception, toxic megacolon, cholangitis, and mesenteric vein thrombosis. Bacteremic spread may result in abscess formation and granulomatous lesions in the liver, spleen, lungs, kidneys, and bone, as well as meningitis and septic arthritis. *Yersinia* infection can also be associated with extraintestinal sequelae including reactive arthritis, uveitis, Reiter's syndrome, and erythema nodosum [48]. *Yersinia* may be isolated from stools or pharyngeal exudates on commonly used selective media, and appears as Gram-negative colonies after 2–14 days of growth at 25–28°C.

E. coli

E. coli is the most abundant facultative anaerobe of the human colonic flora and typically colonizes the gastrointestinal tract within few hours after birth. *E. coli* is a Gram-

negative, lactose-fermenting motile bacillus of the family *Enterobacteriaceae*. Currently, 171 somatic (O) and 56 flagellar (H) antigens are recognized. *E. coli* includes a heterogeneous group of microorganisms capable to exert various possible interactions with the host, ranging from a role of mere harmless presence to that of a highly pathogenic organism [49]. Six distinct categories of *E. coli* are currently recognized as pathogens: enterotoxigenic *E. coli* (ETEC), enteropathogenic *E. coli* (EPEC), enterohemorrhagic *E. coli* (EHEC), diffusely adherent *E. coli* (DAEC), enteroaggregative *E. coli* (EAEC or EAggEC), and enteroinvasive *E. coli* (EIEC).

ETEC ETEC strains elaborate two classes of enterotoxins, namely the heat-labile and the heat-stable enterotoxins (LT and ST, respectively) [50]. LT, the heat-labile enterotoxin, is the analogue of CT and induces chloride secretion by increasing the intracellular cAMP levels. ST, the heat-stable enterotoxin, is a small peptide that causes an increase of intracellular cGMP to induce chloride secretion and diarrhea [51]. The jejunum is a major target of ST-induced anion secretion that is mediated by CFTR [27]. ST binds to its receptor guanylate cyclase C (GCC) on the apical surface of enterocytes, resulting in the generation of cGMP. This in turn activates a cGMP-dependent kinase (cGKII) leading CFTR phosphorylation [50] and the consequent inhibition of Na⁺ absorption through the apical membrane of jejunal enterocytes [48]. ST does this by acting on both the apical and the basolateral side of intestinal epithelium, providing an example of a molecular mimicry between ST and its endogenous ligand guanylin, an endogenous analogue found both in the intestinal lumen and in the blood that regulates two distinct processes, ion absorption and cell proliferation [52, 53]. Transmission of *E. coli* occurs by ingestion of contaminated food and water, with peaks during the warm, wet season. Like EPEC, ETEC requires a relatively high inoculum and has a short incubation period (14–30 h). The key symptom is watery diarrhea, sometimes with fever, abdominal cramps, and vomiting. In its most severe form, ETEC can cause cholera-like severe diarrhea and dehydration. The illness is generally self-limited, lasting less than 5 days. Infection with ETEC has also been associated with short- and long-term nutritional consequences in infants and children.

EPEC This was the first group of *E. coli* serotype shown to be pathogenic for humans and responsible for devastating outbreaks of nosocomial neonatal diarrhea and infant diarrhea in virtually every corner of the globe. EPEC is characterized by specific serogroups, the most common being *E. coli* O145, O49, and O157. Some of those strains have additional virulence factors. EPEC strains are peculiar in their ability to induce a characteristic attaching and effacing lesion in the small-intestinal enterocytes and by their inability to produce Shiga toxins.

However, EPEC encode a T3SS and produces a characteristic attaching and effacing (A/E) lesion which is characterized by effacement of microvilli on the epithelial surface at the site of bacterial attachment. This typical lesion is responsible for the loss of absorptive surface and osmotic diarrhea [54]. Intestinal pathogens can disrupt the barrier by directly altering the distribution or phosphorylation status of TJ proteins. EPEC strains alter the phosphorylation status and distribution of TJ proteins, occludin and claudin-1, thereby disrupting the epithelial barrier function [10]. This increases paracellular permeability driving ion and water into the lumen upon electrochemical gradients ultimately causing diarrhea. The link between barrier disruption and diarrhea derives from studies involving the pro-inflammatory cytokine, tumor necrosis factor- α (TNF α) [55, 56]. These observations suggest that EPEC-induced diarrhea is a multifactorial process with alterations of electrolyte, solute, and water transport. EPEC causes a self-limited watery diarrhea with a short incubation period (6–48 h). This may be associated with fever, abdominal cramps, and vomiting, and EPEC is a leading cause of persistent diarrhea (lasting 14 days) in children in developing countries [57].

The microbiological diagnosis of EPEC-induced disease is performed with analytic methodologies different from those used by the standard microbiology laboratory, the most relevant being: (a) serotyping, (b) adherence assay, (c) FAS test, and (d) the specific detection of virulence-involved genes (bfpA and eae genes) using molecular biology techniques [58].

However, the cause–effect relationship between EPEC in the stools and diarrhea is hampered by the high number of healthy carriers.

EHEC It is another major intestinal pathogen that is a subset of Shiga toxin-producing *E. coli* (STEC). *E. coli* O157:H7 is the prototype of EHEC serotype [59].

EHEC adheres to epithelial cells, expresses a T3SS and causes A/E lesions much like EPEC. Unlike EPEC, infection with EHEC may cause severe symptoms including bloody diarrhea and life-threatening HUS. These symptoms are due to the production of Shiga toxin which elicits luminal fluid accumulation in the intestine [60, 61]. The predominant transmission is through the ingestion of contaminated food. Crampy abdominal pain and non-bloody diarrhea are the first symptoms, sometimes associated with vomiting. Diarrhea always becomes bloody and abdominal pain worsens, lasting 1–22 days. Fever is usually absent or low grade. In outbreaks, approximately 25% of patients are hospitalized, 5–10% develop HUS, and 1% may have a poor outcome. The most dangerous complication of EHEC infection is HUS. This is usually diagnosed 2–14 days after the onset of diarrhea. Risk factors include young age, bloody diarrhea, fever, an elevated leukocyte count, and treatment with antimotility agents [62]. The most widely accepted indica-

tion for seeking *E. coli* O157:H7 infection is a patient with bloody diarrhea, in whom an accurate diagnosis may avoid unnecessary surgery.

DAEC DAEC has an age target ranging from 48 to 60 months and shows a seasonal pattern similar to that of ETEC, occurring more frequently in the warm season. The gastrointestinal symptoms include self-limiting watery diarrhea rarely associated with vomiting and abdominal pain. The diagnosis is mainly based on the DNA probe technique and on the pattern of adherence of the microorganism to HEP-2 cells. Given the technical problems of both assays, their use is limited to epidemiological surveys rather than diagnosis.

EAggEC EAggEC are diarrheagenic germs with the ability of adhere to HEP-2 cells and the intestinal mucosa. They have been especially associated with cases of persistent (i.e., lasting ≥ 14 days) [63, 64] diarrhea both in the developed and developing world [65].

Typical clinical features are a watery, mucoid, secretory diarrheal illness with low-grade fever, and little or no vomiting. However, bloody stools have been reported. Infection of EAggEC is detected by the isolation of *E. coli* from the stools of patients and the demonstration of the aggregative pattern in the HEP-2 assay. Establishing a cause–effect relationship is hampered by the high rate of asymptomatic colonization; if no other organism is implicated in the patients' illness and EAggEC is isolated, the germ should be considered as a potential cause of diarrhea. A DNA-fragment probe has proven highly specific in the detection of EAggEC strains. Acute diarrhea is apparently self-limiting; however, more persistent cases may benefit from antibiotic and/or nutritional therapy, after susceptibility test [66].

EIEC Invasive *E. coli* strains are genetically, biochemically, and clinically nearly identical to *Shigella* [67]. They also show a similar epidemiological pattern and are endemic in developing countries. The role of EIEC in industrialized countries is limited to rare food-borne outbreaks. EIEC can rarely produce dysentery.

Antimicrobial Therapy

Antimicrobial therapy should not be given to the vast majority of otherwise healthy children with acute gastroenteritis. Acute gastroenteritis in a child without significant underlying disease is usually self-limited regardless of the etiology, which is seldom known at the onset of symptoms. Clinical recovery generally occurs within a few days without specific antimicrobial therapy, and the causative organism is cleared in a relatively short time, usually within a few days or weeks. Complications are uncommon.

Antimicrobial Therapy of Bacterial Gastroenteritis

Antibiotic therapy for acute bacterial gastroenteritis is not needed routinely but could be considered for specific pathogens or in defined clinical settings, including clinical condition and risk factors [68, 69].

Pathogen-Based Approach

Shigella Gastroenteritis Antibiotic therapy is recommended for culture-proven or suspected *Shigella* gastroenteritis. The first-line treatment for shigellosis is azithromycin for 5 days. A meta-analysis of 16 studies, which included 1748 children and adults with *Shigella* dysentery, concluded that appropriate antibiotic therapy shortened the duration of the disease. Several well-designed controlled studies have shown that appropriate antibiotic treatment of *Shigella* gastroenteritis significantly reduces the duration of fever, diarrhea, and fecal excretion of the pathogen, and thus infectivity, which is very important in children attending day-care centers [70], those admitted in institutions and hospitals. Antibiotic treatment may also reduce complications including the risk of HUS after *S. dysenteriae* infection.

WHO [71] recommends that all episodes of *Shigella* infection be treated with ciprofloxacin or one of the 3-s line antibiotics (pivmecillinam, azithromycin, or ceftriaxone). The major problem, however, is the increasing worldwide resistance of *Shigella* to antibiotics that is also being observed in Europe [72, 73]. Therefore, *Shigella* isolates should be tested for susceptibility, and local resistance pattern be closely monitored [74]. A systematic review of data from 1990 to 2009 identified 8 studies in children up to 16 years with shigellosis reporting clinical failure 3 days after treatment. In addition, four studies evaluated bacteriologic failure and five assessed bacteriologic relapse. Clinical failure rate was 0.1% and bacteriologic relapse was 0%. Based on these figures, which however derive from low-income countries, antibiotic therapy is consistently effective and strongly recommended in all children with shigellosis. It should be noted, however, that this finding has not been demonstrated in outpatients. Because of the high worldwide resistance, trimethoprim-sulfamethoxazole (TMP-SMX) and ampicillin are recommended only if the strain isolated is susceptible, or if current local microbiologic data suggest susceptibility. In Europe and the USA, resistance to ceftriaxone, azithromycin, and ciprofloxacin has been reported, but is uncommon. The first-line oral empiric treatment recommended for *Shigella* gastroenteritis is azithromycin for 5 days [72, 73]. Alternatively, nalidixic acid or cefixime can be administered for 5 days. When *Shigella* isolates are susceptible to (TMP-SMX) and/or ampicillin (i.e., in an outbreak setting), these agents are recommended as first-line treatment. Oral fluoroquinolones can be used in children younger than 17 years

when no other alternative is feasible. The recommended first-line parenteral treatment is ceftriaxone for 5 days. Two doses of ceftriaxone can be given to patients without underlying immune deficiency or bacteremia who are fever-free after 2 days of ceftriaxone treatment [75].

Salmonella Gastroenteritis Antibiotic therapy is not effective and does not prevent complications. Rather, it is associated with a prolonged fecal excretion of *Salmonella*. Therefore antibiotics should not be used in an otherwise healthy child with *Salmonella* gastroenteritis. Antibiotics are suggested in high-risk children to prevent the risk of bacteremia and extraintestinal infections. These include neonates and young infants (<6 months) and children with underlying immune deficiency, anatomical or functional asplenia, corticosteroid or immunosuppressive therapy, IBD, or achlorhydria (weak recommendation, low-quality evidence). A Cochrane systematic review showed that antibiotic therapy of *Salmonella* gastroenteritis does not significantly affect the duration of fever or diarrhea in otherwise healthy children or adults compared to placebo or no treatment [76]. Moreover, antibiotics were associated with a significant increase of carriage of *Salmonella*, although other adverse events were not reported. As secondary *Salmonella* bacteremia—with potential extra-intestinal focal infections—occurs more often in children with certain underlying conditions, and in neonates or young infants; antibiotic therapy with TMP-SMX, ampicillin (to which 10–20% of isolates in the USA are resistant), cefotaxime, ceftriaxone, or chloramphenicol, is suggested in these children to reduce the risk of bacteremia.

Campylobacter Gastroenteritis Antibiotic therapy for *Campylobacter* gastroenteritis is recommended mainly for the dysenteric form and to reduce transmission in day-care centers and institutions. It reduces symptoms if instituted in the early stage of the disease (within 3 days after onset). The first-line drug is azithromycin, but the choice should be based on local resistance pattern. A meta-analysis of 11 double-blind, placebo-controlled trials showed that antibiotic treatment of gastroenteritis caused by *Campylobacter* spp. reduces the duration of intestinal symptoms by 1.3 days. The effect was more pronounced if treatment was started within 3 days of illness onset and in children with *Campylobacter*-induced dysentery. Antibiotic treatment significantly reduces the duration of fecal excretion of *Campylobacter* spp. and thus its infectivity. Azithromycin is the drug of choice in most locations, although local resistance patterns should be closely monitored.

Diarrheagenic E. coli Antibiotic should not be routinely given for *E. coli*. The treatment is nonspecific and administration of antibiotic may have adverse effect. Antibiotic therapy for Shiga toxin-producing *E. coli* is not recom-

mended. Antibiotic therapy for enterotoxigenic *E. coli* is recommended [77]. Antibiotic treatment of diarrhea induced by Shiga toxin-producing *E. coli* (STEC), also called EHEC, does not significantly affect the clinical course or duration of fecal excretion of the pathogen. Antibiotic treatment is not routinely indicated of gastroenteritis caused by enterotoxigenic *E. coli* or by enteropathogenic *E. coli*.

Most diarrheal illnesses due to ETEC are self-limited and do not require specific antimicrobial therapy. Empiric therapy is reserved for severe cases despite rehydration and supportive measures. The following antibiotics can be considered based on resistance pattern: doxycycline, TMP-SMX, ciprofloxacin, quinolones, and furazolidone. A large proportion of ETEC is now resistant at TMP-SMX, used especially for children, so an alternative regimen is furazolidone. Prevention of ETEC infection is based on avoiding contaminated vehicles. Although few data exist to guide antibiotic therapy of EPEC diarrhea, administration of appropriate antibiotics seems to diminish morbidity and mortality [77]. A 3-day course of oral, nonabsorbable antibiotics such as colistin or gentamicin (if available) has been shown to be effective [78]. Also Rifaximin [79], a broad-spectrum, nonabsorbed antimicrobial agent, can be considered in children > 12 years and in adults for nonfebrile watery diarrhea presumably caused by enterotoxigenic or EAaggEC gastroenteritis.

Antibiotics are not routinely needed in EPEC-induced diarrhea, otherwise EIEC treatment is identical to shigellosis, but antibiotics are rarely needed.

C. difficile In many instances, *C. difficile*-induced antibiotic diarrhea is self-limiting, and the patient may respond simply to the withdrawal of the offending antibiotic. In more severe forms, particularly if complicated by PMC, antibiotic treatment with either oral vancomycin (5–10 mg/kg, maximum 500 mg, given every 6 h for 7 days) or metronidazole (5–10 mg/kg, maximum 500 mg, given every 8 h for 7 days) is recommended, although the rate of relapse is very high [80, 81].

The risk of treatment failure and of recurrence parallels the number of *C. difficile* infections episodes, ranging between 15 and 30% in the first infection and reaching 40 and 65% in patients experiencing a second or third episode, respectively [82]. Failure is much lower or not existent with vancomycin as first treatment.

The increasing frequency of *C. difficile* infections recurrence and the relative challenging treatment, led to the development of new therapeutic strategies including different antibiotic approaches (e.g., Fidaxomicin or Vancomycin tapering), active and passive immunotherapy (e.g., specific monoclonal antibodies against *C. difficile* toxins), and microflora restoration through the administration of probiotics or fecal donor microbiota transplantation. However, trials with new therapeutic approaches have been limited in chil-

dren. The use of monoclonal antibodies to target toxins is being considered for treatment of *C. difficile* infections and its recurrence. The neutralization of toxin activity may stop *C. difficile* infections symptoms and prevent recurrences and showed good results in adults with recurrent *C. difficile* infections [83].

This approach, that showed promising results in adults [84], has not yet been tested in children and further studies are required to establish its role in *C. difficile* infections therapy and its cost effectiveness.

The efficacy of probiotics in severe and recurrent *C. difficile* infections cases are conflicting [85], the use of selected probiotics, particularly *Lactobacillus GG* and *Saccharomyces boulardii*, has been associated with a significant eradication of the pathogen and a decrease in the recurrence of the infection [86, 87].

A recent approach for severe or recurrent *C. difficile* diarrhea in high-risk children consists in the instillation of healthy donor feces into the *C. difficile*-infected gastrointestinal tract. This technique, known as fecal microbiota transplantation (FMT), aims at restoring the normal composition and the wide diversity of gut microbiota. Current evidence (although weak) demonstrates consistent and excellent efficacy in clinical outcomes in adults. However, many questions should be answered before it may be recommended including the long-term effects (with the potential association with autoimmune diseases) [88].

Other Causes of Bacterial Gastroenteritis

Antibiotic therapy is recommended for *V. cholerae* gastroenteritis since it reduces the duration of diarrhea by about 50% and bacterial shedding by about 1 day. WHO recommends administration for 3–5 days of furazolidone (1.25 mg/kg four times per day), TMH (5 mg/kg twice per day), SMX (25 mg/kg twice per day), and erythromycin (10 mg/kg three times per day) to children less than 8 years and of tetracycline to older children.

A randomized, controlled study demonstrated that a single dose of 20 mg/kg of azithromycin is clinically and microbiologically more effective than ciprofloxacin. Azithromycin is the drug of choice for children younger than 8 years. Alternative treatment for older children is doxycycline. TMP-SMX can be used for susceptible strains. Both killed whole-cell and live-attenuated cholera vaccines have been proposed as a preventive intervention for cholera; a large double-blind field trial of the killed vaccine showed 85% efficacy for a period of 4–6 months, dropping to 50% over 3 years of follow-up. The introduction of oral rehydration solutions (ORS) [89] dramatically decreased the mortality from this illness.

Limited data are available regarding the efficacy of antibiotics for gastroenteritis caused by *Yersinia* spp., and an-

Table 15.1 Anti-infective therapy and vaccines available

Anti-infective therapy		Vaccines available		
Anti-infective therapy	Anti-infective therapy should not be given to the vast majority of otherwise healthy children with acute gastroenteritis	Strong recommendation, low quality of evidence	Va, D	
Antimicrobial therapy of bacterial gastroenteritis	Antibiotic therapy for acute bacterial gastroenteritis is not needed routinely but only for specific pathogens or in defined clinical settings	Strong recommendation, low quality of evidence	Va, D	
<i>Shigella</i> gastroenteritis	Antibiotic therapy is recommended for culture proven or suspected <i>Shigella</i> gastroenteritis	Strong recommendation, moderate quality of evidence	I, B	NO
<i>Salmonella</i> gastroenteritis	Antibiotics should not be used in an otherwise healthy child with <i>Salmonella</i> gastroenteritis	Strong recommendation, moderate quality of evidence	I, A	YES Attenuated vaccine for typhoid fever, Ty21a, administered as a liquid suspension, protected both young and older children; three new generation-attenuated vaccines, genetically engineered, are undergoing extensive phase II trials
	Antibiotics are suggested in high-risk children (neonates and young infants (<6 months) and children with underlying immune deficiency) to reduce the risk of bacteremia and extra-intestinal infections	Strong recommendation, low quality of evidence	Vb, D	
		Weak recommendation, low quality of evidence	Vb, D	
<i>Campylobacter</i> gastroenteritis	Antibiotic therapy for <i>Campylobacter</i> gastroenteritis is recommended mainly for the dysenteric form and to reduce transmission in daycare centers and institutions. It reduces symptoms if instituted in the early stage of the disease (within 3 days after onset)	Strong recommendation, moderate quality of evidence	I, A	NO
Diarrheagenic <i>Escherichia coli</i>	Antibiotics are usually not indicated, but it depends on the specific cause and setting	Weak recommendation, low quality of evidence	Va, D	YES, but only for EHEC: parenteral toxoids and live oral carrier strains elaborating the B subunit of Shiga toxin; vaccines expressing the adhesin intimin, designed to prevent intestinal colonization, and a parenteral O157 polysaccharide protein conjugate. ETEC: oral vaccines including killed whole cell, toxoids, purified fimbriae, living attenuated strains, and live carrier strains elaborating ETEC antigens
Empiric antibiotic Therapy in sporadic cases of AGE	The choice of the antimicrobial agent depends on the local prevalence of the causative pathogens and the local resistance patterns	Strong recommendation, moderate quality of evidence	Va, B	
	In children with watery diarrhea, antibiotic therapy is not recommended unless the patient has recently traveled or may have been exposed to cholera	Strong recommendation, moderate quality of evidence	Vb, D	
	In bloody diarrhea with low or no fever, antibiotics are not recommended unless epidemiology suggests shigellosis	Strong recommendation, low quality of evidence	Vb, D	
	Parenteral rather than oral antibiotic therapy is recommended for: Patients unable to take oral medications Patients with underlying immune deficiency who have AGE with fever Severe toxemia, suspected or confirmed bacteremia Neonates and young infants (<3 months) with fever Sepsis workup and antibiotics should be considered according to local protocols	Strong recommendation, low quality of evidence	Va, D	

EHEC enterohemorrhagic *E. coli*

tibiotics are recommended for bacteremia, extraintestinal infections, and immunocompromised hosts. Production of beta-lactamases generally makes *Yersinia* resistant to cephalosporins and aztreonam, and imipenem are also ineffective. Treatment should generally last 2–6 weeks, with an initial intravenous administration (third-generation cephalosporin often in combination with aminoglycosides), followed by an oral one to which the clinical isolate is sensitive.

Antibiotic therapy is usually not needed for gastroenteritis caused by non-cholera *Vibrio* spp., *Aeromonas* spp., or *Plesiomonas shigelloides*.

Antibiotic-Associated Diarrhea

Antibiotic therapy is generally not needed for antibiotic-associated diarrhea, but should be considered in moderate to severe forms. Antibiotic-associated diarrhea can be defined as a change in normal stool. *C. difficile* is the most frequent agent of this syndrome [79]. Symptoms may range from a mild form of liquid diarrhea to a severe form of PMC with abdominal pain, local, and systemic inflammation and a typical history of diarrhea that is chronologically related with antibiotic administration. It may start from locus to 2 months after starting antibiotics.

Empiric Antibiotic Therapy in Sporadic Cases of Acute gastroenteritis (AGE)

The cause of sporadic AGE is usually not known at presentation and generally it will not be identified. The classification of these cases into invasive (or inflammatory) and watery (or noninvasive) may help deciding whether or not to start empiric antibiotics [90, 91]. Invasive (inflammatory) enteritis is defined as acute onset of bloody/mucous diarrhea (or fecal PMNs leukocytes when the examination is available) with high fever. The common causes are *Shigella* spp., *Campylobacter* spp., and *Salmonella enterica*. Antibiotics should be considered in hospitalized children and children attending daycare centers to reduce transmission of *Shigella* and *Campylobacter*. The choice of the antimicrobial agent depends on the local prevalence of the three pathogens (*Shigella* spp., *Campylobacter* spp., and *Salmonella enterica*) and the resistance patterns.

In children with watery diarrhea, antibiotic therapy is not recommended unless the patient has recently traveled or may have been exposed to cholera [89, 92]. Bloody diarrhea with low or no fever is typical of STEC (EHEC), but can be caused by mild shigellosis associated with salmonellosis. Antibiotics are not recommended unless epidemiology suggests shigellosis. Parenteral rather than oral antibiotic therapy is recommended for [90]:

1. Patients unable to take oral medications (vomiting, stupor, etc)
 2. Patients with underlying immune deficiency who have AGE with fever
 3. Severe toxemia, suspected or confirmed bacteremia
 4. Neonates and young infants (<3 months) with fever
- Sepsis workup and antibiotics should be considered according to local protocols.

Antimicrobial Therapy of Systemic Infections due to Enteric Pathogens or Involvement of Extraintestinal Organs

Antibiotic therapy is recommended for the rare but potentially severe extraintestinal infections caused bacterial enteric pathogens.

Occasionally enteric bacterial pathogens can spread and cause extraintestinal infections, including bacteremia or focal infections. These infections should be treated with antibiotics, usually through the parenteral route [75].

Table 15.1 shows anti-infective therapies and vaccines available.

Introduction

Parasitic infections of the gastrointestinal (GI) tract have a large impact on the health of children worldwide, with increased morbidity and mortality, especially in developing countries and in the setting of immune suppression. Many parasites such as *Giardia* and *Trichuris* (pinworm) are common in both developed and developing countries, while others occur mostly in developing countries.

The worldwide distribution of food has increased the spread of some parasites as well as bacterial pathogens. In developed countries, one must always consider parasitic infection in returning travelers and those emigrating from developing countries. Clinicians must be familiar with parasites, their mode of transmission, and clinical presentations. In addition to the symptoms they cause, parasitic infections can lead to growth retardation, malnutrition, and vitamin deficiencies. Moreover, parasitic infections can be even more deadly in the setting of immune suppression such as human immunodeficiency virus (HIV) infection, steroids, or cancer chemotherapy.

In this chapter, we review parasites that affect the GI tract. There are effective therapies for most of these parasites. Understanding mechanisms of transmission is important as the main modes of transmission are fecal–oral and via contaminated soil (i.e., hookworm). Prevention with improved sanitation, clean water, proper hygiene, and footwear worldwide could lead to significant improvement in children’s health.

Protozoa

Protozoa are a large group of single-cell eukaryotes that can live and multiply within human hosts. *Giardia*, *Entamoeba*, *Dientamoeba*, and *Blastocystis* are the most common human protozoan pathogens.

Flagellates and Ameba

Giardia lamblia

Giardia lamblia (*G. intestinalis* or *G. duodenalis*) is the most common intestinal protozoan infection in the USA [1]. It is also the most common cause of prolonged GI infection in persons returning to the USA after travel abroad [2]. It is most often diagnosed in children ages 1–9, and rates increase from infancy until tapering off in early adolescence [1].

Giardia is one of several flagellated protozoa that cause human disease. It has two life forms, the nonmotile, stable cyst form, which is responsible for transmitting the infection, and the motile trophozoite form that is responsible for causing the clinical symptoms. The cysts can remain dormant in contaminated water or feces until they are consumed, where activation (excystation) occurs from exposure to gastric acidity, causing cysts to rupture. The trophozoites emerge and then adhere to the enterocytes in the duodenum and jejunum [3]. Transmission is fecal–oral and typically occurs after consumption of water or food contaminated with human feces. However, high rates of transmission in day-care settings where there is direct contact with feces is also common [1]. Transmission from animals is rare. *Giardia* is highly contagious and only requires consumption of as few as ten cysts [4].

Giardia is a much more common pathogen in developing countries with high rates of infection and reinfection. Interestingly, in these settings, the presence of *Giardia* in stool has been found to be associated with a protective effect from developing acute diarrheal illness, implying that one can de-

velop immunity to this pathogen and the presence of active *Giardia* infestation may protect from other infections [4]. Despite this, chronic *Giardia* infection remains a significant problem as it can lead to malnutrition and developmental consequences.

Acute giardiasis is usually a self-limited illness composed of bloating, diarrhea, abdominal cramping, nausea, flatulence, and occasionally malabsorption and steatorrhea. Additionally, *Giardia* can develop into a chronic diarrhea that can lead to protein losing enteropathy with weight loss, chronic fatigue, and other related symptoms. This is often accompanied by small intestinal changes such as intraepithelial lymphocytosis and brush-border damage, with ~10% of cases developing villous atrophy [3]. Of note, giardiasis does not cause eosinophilia, stool leukocytosis, or bloody diarrhea [5].

The diagnosis can be made in several different ways. Traditionally, identification was made with stool microscopy demonstrating trophozoites or cysts. However, the sensitivity and specificity ranges from 70 to 85% with one to three samples, respectively, and this testing is much more labor intensive, less efficient, and requires specific expertise. Stool microscopy has now been displaced in many centers by use of stool antigen detection assays, whose sensitivity and specificity approach 100% and only one sample is required [5, 6]. Diagnosis can also be made by duodenal aspirate and

with small intestinal biopsy, but these methods are much more invasive, less efficient, and rarely necessary.

All symptomatic patients and asymptomatic patients such as food handlers, children attending daycare, and immune-compromised patients without contraindications should be treated. Nitroimidazoles, such as metronidazole and tinidazole, are commonly used as treatment and are generally well tolerated. Several other medications (nitazoxanide, albendazole, mebendazole) are also approved in the USA and have similar efficacy (Table 16.1). In the cases where treatment failure is suspected, it is important to repeat stool studies, noting that parasites should be cleared within the stool 3–5 days after treatment [7]. However, if symptoms improve, there is no need to document clearance. It is important to also note that many patients with *Giardia* will be temporarily lactose intolerant and may have prolonged malabsorptive symptoms for several weeks after therapy. Thus, many practitioners advise at least 1 month of lactose avoidance [5]. Additionally, postinfectious irritable bowel syndrome (IBS) seems to be associated with *Giardia* infection, although chronic infection should be ruled out in these cases [8].

Entamoeba histolytica

E. histolytica is the most common organism causing pathogenic amoebiasis globally. It was only relatively recently that not one, but three forms of *Entamoeba* were identi-

Table 16.1 Medications for treatment of intestinal parasites

Parasite	First-line medication(s)	Alternative(s)
<i>Protozoa</i>		
<i>Giardia lamblia</i>	Metronidazole or tinidazole	1. Nitazoxanide, albendazole, mebendazole
<i>Entamoeba histolytica</i>		
1. Invasive disease	1. Metronidazole or tinidazole	1. Ornidazole and nitazoxanide
2. Asymptomatic carriers, luminal clearance following therapy for invasive disease	2. Paromomycin or iodoquinol	2. Diloxanide furoate
<i>Dientamoeba fragilis</i>	Iodoquinol	Metronidazole, tinidazole, paromomycin
<i>Blastocystis hominis</i>	Metronidazole	Tinidazole, iodoquinol, trimethoprim–sulfamethoxazole
<i>Cryptosporidium</i>	Nitazoxanide	May reduce duration/severity: paromomycin, azithromycin
<i>Cyclospora cayetanensis</i>	Trimethoprim–sulfamethaxazole	Ciprofloxacin
<i>Cystoisospora belli</i>	Trimethoprim–sulfamethaxazole	Ciprofloxacin
<i>Nematodes</i>		
<i>Ascaris lumbricoides</i>	Albendazole or mebendazole or levimasole	Ivermectin, nitazoxanide and piperazine citrate
<i>Strongyloides stercoralis</i>	Ivermectin	Albendazole
Hookworms (<i>Necator americanus</i> , <i>Ancylostoma duodenale</i>)	Albendazole or pyrantel pamoate	Mebendazole
Whipworm (<i>Trichuris trichiura</i>)	Mebendazole or albendazole	Ivermectin
Pinworm (<i>Enterobius vermicularis</i>)	Albendazole or mebendazole	Pyrantel pamoate
Cestodes (tapeworms)	Praziquantel	Niclosamide
<i>Diphyllobothrium latum</i>	Praziquantel	Niclosamide
<i>Taenia saginata</i> and <i>Taenia solium</i>	Praziquantel	Niclosamide
<i>Hymenolepis nana</i>	Praziquantel	Niclosamide, nitazoxanide

HAART highly active antiretroviral therapy, HIV human immunodeficiency virus

fied—pathogenic *E. histolytica* and nonpathogenic *E. dispar* and *E. moshkovski*. *E. histolytica*—although relatively uncommon in the USA, is a common cause of diarrhea in some developing countries, particularly India, Africa, Mexico, and Central and South America. This organism is an uncommon cause of traveler’s diarrhea. It is believed that prevalence is higher among homosexual males, and there have been outbreaks in this population attributed to sexual transmission [9]. Unfortunately, accurate prevalence data likely does not exist because of the recent discovery of nonpathogenic strains that were previously classified as *E. histolytica* and the large proportion of persons who are asymptomatic carriers [10].

Similar to *Giardia*, *Entamoeba* exists in two life forms. There is a more stable cyst form that is responsible for transmission of infection between hosts and a more virulent trophozoite form that is responsible for causing clinical symptoms [5, 11, 12]. Generally, cysts are excreted into soil and are then consumed in contaminated food or water, or via sexual contact. They remain stable in the environment for weeks and are highly virulent—consuming one cyst is adequate to infect a new host. Once consumed, they undergo excystation in the small bowel. The binding and penetration of the trophozoite into the colonic wall result in an invasive colitis. Once the organism has penetrated the colonic mucosa, it is capable of damaging colonic epithelial cells and inflammatory cells through multiple mechanisms [13]. See Figs. 16.1 and 16.2.

The clinical manifestations of *E. histolytica* are variable. Toxic megacolon, colonic ulcerations leading to perforation or formation of an ameboma—granuloma of the cecum or ascending colon caused by chronic amebic infection—are among the more serious intestinal complications. Fulminant amebic dysentery can ensue and be fatal. However, many patients who test positive for *E. histolytica* will only have mild diarrhea or be asymptomatic. Liver abscess and other extraintestinal manifestations of *E. histolytica* are generally seen without recent or concurrent intestinal symptoms [5].

Testing for *E. histolytica* infection can be achieved with multiple different methods. Conventional stool microscopy,

Fig. 16.1 Shallow ulcer in the cecum found on screening colonoscopy. The patient had no symptoms. Biopsy showed ameba organisms in the surface of the biopsy. (Pathology pictures courtesy of Dr. Melissa Upton, Seattle, WA)

Fig. 16.2 Shallow ulcer in the cecum found on screening colonoscopy. The patient had no symptoms. Biopsy showed ameba organisms in the surface of the biopsy. (Pathology pictures courtesy of Dr. Melissa Upton, Seattle, WA)

stool antigen testing, and serology with enzyme immunoassay are useful in different clinical settings. Stool microscopy requires laboratory expertise and three separate stool collections on three separate days, making it more tedious. Additionally, microscopy will not differentiate among the three strains of *Entamoeba* and will only be diagnostic when active intestinal disease is present. Thus, patients suspected of having *E. histolytica* liver abscess should have serologic testing performed. Stool antigen testing is not universally available, but is efficient and both sensitive and specific for intestinal *E. histolytica*. Polymerase chain reaction (PCR) is the test of choice to differentiate among strains of *Entamoeba*. Direct biopsy of the colonic mucosa can be used as a last resort [12].

Treatment is advised in asymptomatic carriers as well as patients with symptomatic disease [13]. Symptomatic patients with suspected invasive disease should be treated initially with systemic therapy for extraluminal disease and then with a luminal therapy for complete clearance. Nitroimidazoles (metronidazole and tinidazole) are commonly used and well tolerated for initial therapy in the setting of invasive disease (invasive colitis, liver abscess). Asymptomatic carriers, and those with invasive disease who have completed initial therapy, should be treated with a luminal agent, most commonly paromomycin or iodoquinol, to prevent both spread to others and development of new or recurrent invasive disease (Table 16.1) [5, 13]. It is important to note that those with peritonitis secondary to colonic perforation will require broad-spectrum antibiotics as well as the two-phase therapy noted above.

Dientamoeba fragilis

Dientamoeba was long considered a commensal organism in the gut, but is now considered pathogenic and should be treated in the absence of other causes for GI symptoms. It has a global distribution and many studies indicate that the global prevalence could be higher than *Giardia* [14]. The age and gender distribution of patients with *Dientamoeba* has also been a source of disagreement among various studies [14]. It is clear, however, that this pathogen is most common among populations with other parasitic infections who live in conditions with poor hygiene.

D. fragilis is a binucleate, single-cell organism that is of the trichomonad family but lacks flagella. Transmission is presumed to be fecal-oral, but there is no cyst form of *Dientamoeba*, so it is less stable in the environment. Because it has been associated with high carriage rates of *Enterobius vermicularis* (pinworm), some believe helminthic infection may be a vector of transmission [5, 15].

The illness typically causes gas, bloating, abdominal pain, and diarrhea. Diagnosis has improved significantly with the advent of stool PCR testing (sensitivity 96%), increasing the recognition of this pathogen [15]. *Dientamoeba* has also been associated with chronic bowel symptoms, such as IBS, and thus, if found in patients who have chronic symptoms of unclear etiology, treatment is suggested [14]. Providers should consider testing for pinworm infection in patients who test positive for *D. fragilis*. Interestingly, despite the lack of invasiveness of this organism, it is associated with eosinophilia, perhaps because of concurrent pinworm infection. Treatment is with a nitroimidazole (i.e., metronidazole) and several regimens have been studied and found effective (Table 16.1).

Blastocystis Species (Blastocystis hominis)

Blastocystis species (previously referred to as *B. hominis*) are similar to *D. fragilis* in that their role as pathogens is still emerging. They have a global distribution and can affect both children and adults. Zoonotic transmission and fecal-oral routes of infection have been implicated. Thus, it is not surprising that higher rates of infection have been observed in developing countries where infection rates from 30 to 50% have been observed, compared to only 5–10% in developed countries. Immunocompromised hosts (HIV, transplant recipients) are also more commonly affected [16].

Blastocystis species are anaerobic organisms that have been observed to have four major life forms and significant genetic diversity, which led to their renaming from *B. hominis* to *B. species*. Once they have been ingested, they live in the cecum and colon of their hosts. While asymptomatic infection can occur, symptoms can include diarrhea, flatulence, bloating, abdominal pain, nausea, and anorexia. Additionally, there is some association with urticarial disease [16]. Diagnosis is challenging and most frequently made with

stool microscopy; however, enzyme-linked immunosorbent assay (ELISA) and PCR tests are likely superior. Treatment requires some clinician judgment because infections can be self-limited or asymptomatic and may not require therapy. Metronidazole and trimethoprim-sulfamethoxazole (TMP-SMX) are two commonly prescribed medications that are effective for treating *Blastocystis* species [5, 16].

Coccidia

Cryptosporidium

Cryptosporidium is a common enteric pathogen that was identified in the 1970s and has been known to cause prolonged and severe diarrhea as well as biliary disease. Both children and adults are affected by this pathogen, but prevalence is higher among children [17]. In fact, it appears to be one of the most common causes of moderate to severe diarrheal illness among children in Africa and Asia [17].

Cryptosporidia are a group of intracellular protozoa with approximately 20 species and multiple genotypes. *C. parvum* and *C. hominis* are the main species causing human disease [18]. Transmission is by consumption of environmentally stable oocysts, which then undergo excystation in the small bowel leading to infection of enterocytes, where reproduction occurs. Infection can also extend into the biliary tract in immunocompromised hosts.

Outbreaks are primarily associated with water contaminated by animal or human feces. Prevention of transmission requires heating or freezing water, as chlorination is ineffective in killing the stable oocysts [18]. Because of its environmental stability, fecal-oral transmission is possible by multiple modalities. There have been outbreaks in children in US daycare centers. Prevalence may also be higher when there is close contact with animals such as in rural areas.

The spectrum of clinical illness is broad, ranging from self-limited (10–14 day duration) mild diarrheal illness in immunocompetent patients to a chronic enteritis with documented destruction of intestinal villi and occasionally biliary tract involvement in HIV positive or otherwise immunocompromised patients [19]. In the later situations, patients can become severely malnourished and dehydrated. Up to one third of these patients can have biliary tree involvement with inflammatory strictures, acalculous cholecystitis, and pancreatitis [20, 21].

Diagnosis of cryptosporidiosis is generally made with stool microscopy, which can identify spores. It is necessary to request specific acid fast stains to identify cryptosporidium because a standard ova and parasite stool evaluation may not be diagnostic. More modern methods of detection include ELISA antibody assays, but these are costly and not

widely available. Additionally, tissue biopsies may reveal the organism on hematoxylin and eosin staining.

Treatment is usually only necessary in immunocompromised patients with severe and unremitting illness. Unfortunately, the efficacy of currently available treatments is not consistent and still under investigation [5]. In patients with immune suppression due to HIV infection, treatment of the HIV with highly active antiretroviral therapy (HAART) to increase CD4 count can lead to clearance of the parasite [20, 21]. Supportive care is essential and antimicrobial agents are aimed at reducing disease severity and duration. The Centers for Disease Control and Prevention (CDC) supports treatment with nitazoxanide, which is Food and Drug Administration (FDA) approved for children over 1 year of age. A randomized controlled trial demonstrated efficacy for HIV negative children, but not HIV positive children [22].

Cyclospora cayetanensis

Cyclospora is an obligate intracellular protozoan that causes enteritis. It was identified in the 1980s and initial cases were confused with cryptosporidium. The infections are similar in that *Cyclospora* also causes more severe and protracted disease among immunocompromised hosts (HIV and transplant patients). Additionally, in non-endemic areas, patients typically experience more severe symptoms and in endemic areas, symptoms tend to decrease with age and be most severe in younger children, implying an acquired tolerance [23].

Symptoms are also similar to cryptosporidium, with watery diarrhea, nausea, anorexia, fatigue, weight loss, low-grade fever, and occasionally biliary tract involvement. The diarrheal illness can be prolonged beyond 3 weeks, even in immunocompetent patients.

Transmission is not person to person because oocysts require time (7–15 days) to become infective after shedding [23]. Outbreaks have been traced to contaminated water supplies and large food outbreaks—raspberries imported from Guatemala in 1996 and cilantro and salad mix from Mexico in 2013 [24, 25].

Diagnosis is via stool microscopy, but is improved with acid-fast stains and will not typically be seen on standard ova and parasite testing. Treatment with TMP-SMX is first line. Ciprofloxacin can be used in case of sulfa allergy, but is less effective [23].

Cystoisospora belli (Isospora belli)

This is the least common of the three coccidia known to infect humans. It is an obligate intracellular protozoan that infects the small bowel and colon. It is endemic in tropical and sub-tropical areas, but there have been rare case reports of outbreaks in non-endemic locations in daycare and institutional settings [26]. The populations typically affected by this organism are immunocompromised patients and travel-

ers. Transmission appears to be similar to the other coccidia and likely not via person to person transmission, but rather through contaminated water and food.

Like the other coccidia, the symptoms include watery diarrhea, flatulence, anorexia, headache, vomiting, and malaise. *Cystoisospora* is associated with reports of reactive arthritis and rarely biliary complications such as acalculous cholecystitis [27].

Diagnosis is typically made on stool microscopy and, like the other coccidia, requires acid-fast staining and laboratory expertise. Stool PCR testing methods are becoming more available. In rare circumstances, duodenal aspirates have also been used.

The treatment is the same as with *Cyclospora*, and TMP-SMX is the first line; however, ciprofloxacin can be used as a slightly inferior second-line therapy in cases of sulfa allergy.

Helminths

Nematodes (Roundworms)

Nematodes or roundworms are a diverse and large group of organisms characterized by their cylindrical structure and digestive openings at both ends.

Ascaris lumbricoides

Ascaris is very common and can be found worldwide, but the highest prevalence occurs in tropical areas, particularly during rainy months. Children are the most common population affected, with rates being the highest between the ages of 2 and 10, with a rapid decline in infections after the teenage years [28]. Interestingly, unlike the protozoan infections, HIV is not associated with increased prevalence or severity of infection.

A. lumbricoides are known for their large size, up to about 40 cm long in some cases, making them the largest helminth to infect humans. Transmission is via consumption of *Ascaris* eggs, which are excreted in human feces leading to contaminated water, soil, or food. Eggs are not infectious for approximately 2–4 weeks after being excreted. Once they are consumed, they penetrate the host intestine and migrate hematogenously through the liver and then into the lung alveoli, where they again penetrate into the bronchiole tree. Eggs are then swallowed after being extracted in respiratory secretions and hatch in the small intestine. The worms can reside in the jejunum and ileum for 1–2 years. If both female and male worms are present, fertilized (infectious) eggs will be excreted in feces [12]. Often, this intestinal phase is asymptomatic. However, when there is a high worm burden, clinical symptoms secondary to mechanical obstruction by the worms can occur. Additionally, hypersensitivity reactions and eosinophilia can occur during larval migration, but the

latter is only consistently present during this phase. Pulmonary larval migration can cause pneumonia-like symptoms, known as Loeffler's syndrome. Hepatobiliary complications are usually secondary to obstruction by worms. Finally, in children, nutritional consequences and growth retardation have been associated with *Ascaris* infection [29].

Diagnosis is typically made by identification of characteristic ova via stool microscopy. However, this can pose a diagnostic dilemma in early cases when ova are not yet being excreted. Serologic tests are only useful to determine a history of prior infection. PCR tests are currently being developed. Stool or emesis containing intact worms has also led to diagnosis, as have imaging studies such as ultrasound ("target sign") and CT ("bull's eye") where worms will have characteristic radiographic appearances. Endoscopic retrograde cholangiopancreatography (ERCP) can be both diagnostic and therapeutic.

Treatment with antihelminthic agents should be undertaken immediately for cases of biliary and intestinal disease, but should be delayed if diagnosis is made during the pulmonary phase because the dying larvae can cause significant inflammation and pulmonary disease. Several agents are acceptable for use in treatment. Albendazole and mebendazole have uniformly high rates of success in eradication of infection and are safe for children, but not pregnant females [26]. Alternative agents such as levamisole, ivermectin, nitazoxanide, and piperazine citrate have lower efficacy rates, but can also be used [30].

Strongyloides stercoralis

Strongyloides is a small nematode that is endemic in tropical and subtropical locations, with only sporadic cases reported in the USA. Children living in impoverished conditions, such as refuge groups, are particularly susceptible [31].

The organism has two stages: larva and eggs. It infects a host during the filariform larval stage by directly penetrating the skin. The larva then travel hematogenously to the lungs where they penetrate the alveoli, are coughed up to the oropharynx through the airway, and then swallowed into the intestines where they become mature adult worms. In the small intestine, the female worms burrow into the mucosa where they lay their eggs that hatch and migrate back into the intestinal lumen. Rhabditiform larva (not infective) mature into filariform larva (infective). This process can occur within the host (typically with colonic or perianal penetration of filariform larvae), which can lead to tremendous worm burdens particularly among immunocompromised hosts. However, rhabditiform larvae can also be excreted from the host and become infective in the environment. Soil infected with feces is the most common cause of transmission to another host through penetration into the skin [12].

Symptoms of strongyloidiasis range from asymptomatic infection in some hosts who are able to maintain a small

Fig. 16.3 Cutaneous larva migrans. (Reprinted from Ref. [32], with permission from Elsevier)

worm burden, to the other extreme of disseminated *Strongyloides*, which is often fatal. Patients may be diagnosed with *Strongyloides* after experiencing dermal manifestations, predominantly on the lower extremities (urticarial, serpiginous tracts, puerperal-like lesions). This is called cutaneous larva migrans, and they can be seen with other parasitic infections such as hookworm and *Ancylostoma* (Fig. 16.3) [32]. Patients can also have abdominal pain, diarrhea, colitis, and malabsorption. Pulmonary symptoms can be confused with asthma. Eosinophilia is often seen, but absence does not exclude infection, and presence does not correlate with the hyperinfection syndrome [12].

Disseminated *Strongyloides*, also called hyperinfection syndrome, is a life-threatening illness that often occurs with immunosuppression and with the use of immunosuppressive medications such as steroids and chemotherapy. Gram-negative bacteremia is associated with the migration of worms from the intestine to the bloodstream. Sepsis and multiorgan involvement can be seen in these cases [33].

Diagnosis is best made by microscopy, which will directly visualize larvae in stool, duodenal aspirate, or occasionally sputum. Antibody testing is helpful for confirming exposure, but will not help to distinguish current versus past infection [11, 12, 34].

Treatment with ivermectin is first line, and albendazole can be used as an alternative agent. In cases of disseminated disease, a prolonged course of treatment is recommended and consultation with an infectious diseases expert is essential.

Hookworm (*Necator americanus*, *Ancylostoma duodenale*)

Hookworm is similar to *Strongyloides* in terms of mode of transmission, endemic territories, diagnosis and symptoms.

Two species of hookworm cause human infection: *N. americanus* and *A. duodenale*. In general, as the name implies, *N. americanus* is endemic to the Americas and *A. duodenale* is endemic in the eastern world. Infection used to be endemic to the southeastern USA; however, with improve-

ment in sanitation it is now primarily seen in immigrant populations or military personnel and other travelers returning from overseas.

The CDC currently estimates that 576–740 million people are infected with hookworm globally, primarily in impoverished tropical and subtropical regions with high annual rainfall amounts. Transmission occurs when eggs are deposited into soil via fecal contamination. Moist, warm conditions then allow the eggs to hatch into worms, which mature into infective (filariform) worms that can then penetrate human skin (typically when barefoot). There are reports of *Ancylostoma* being passed by oral and transmammary modes as well [12].

The signs and symptoms of hookworm infection include dermal, pulmonary, GI, and nutritional/hematologic manifestations. A pruritic maculopapular skin eruption known as “ground itch” or cutaneous larva migrans (Fig. 16.3) can be seen at the site of penetration. Pulmonary symptoms consist of generally very mild pharyngeal and bronchial irritation causing cough. GI manifestations can include abdominal pain, nausea, vomiting, diarrhea, and intestinal bloating and gas. These symptoms are more accentuated at the time of first infection, but repeat infections are often better tolerated. Eosinophilia and iron deficiency may be noted. Long-term nutritional consequences such as hypoalbuminemia and iron-deficiency anemia can occur due to chronic blood consumption by the worms, as well as protease secretion that can inhibit proper digestion. Low birth weights and growth retardation can be a consequence of infection [35, 36].

Diagnosis is made with stool microscopy with direct visualization of hookworm ova. Occasionally, the worms can be seen in the mucosa at endoscopy (Fig. 16.4) [37]. Unfortunately, sensitivity is low and more than one stool ova and parasite evaluation is often needed to capture diagnosis [34].

Treatment with albendazole is the easiest and most effective therapy. Mebendazole and pyrantel pamoate can be used as well. Ivermectin is not effective for treating hookworm [38].

Fig. 16.4 Small intestinal mucosa: Hookworm infection causing an acute abdomen. (Reprinted from Ref. [37], with permission from Elsevier.)

Whipworm (*Trichuris trichiura*)

T. trichiura (whipworm) is a soil transmitted nematode that is estimated to infect 604–795 million people worldwide [12]. This organism is endemic in tropical regions where it can infect a majority of the population [39]. Children are commonly infected and generally have higher worm burdens than adults. Thus, some strategies of periodically treating preschool-age children for presumed infection in endemic areas have been attempted [40].

T. trichiura infection occurs after an uninfected individual consumes soil contaminated by human feces. Transmission is not person to person because after excretion, the eggs require 15–30 days to become infective in the soil. The eggs hatch in the small intestine and release larvae that develop into worms. The worms establish residence in the cecum and throughout the colon, occasionally extending into the rectum. They can be seen at colonoscopy (Fig. 16.5) where the thin part of the worm embeds in the mucosa. Over time, they begin to produce eggs, which are secreted in stool. The worms are approximately 4 cm in size as adults. The name “whipworm” is based on the shape of the worm resembling a whip with a broad end (the handle) and a narrow end (the whip). The narrow end implants itself into the mucosa and the broad end remains in the lumen [12].

The symptoms of infection are directly correlated with worm burden. Diarrhea, nocturnal incontinence, colitis, and dysentery can be seen. Rectal prolapse is a serious complication of high worm burden. Impaired growth and development in children has been positively correlated with infection.

Diagnosis is made by observation of characteristic ova on stool microscopy. The eggs have a unique barrel-shaped appearance. Gross identification of worms can be diagnostic during endoscopy or rectal examination.

The first-line treatment of trichuriasis is with antihelminthic agents such as mebendazole or albendazole. Single-dose therapy, however, is not adequate and most regimens are 3–7 days, depending on suspected worm burden [38].

Pinworm (*E. vermicularis*)

E. vermicularis is the helminthic infection with the highest prevalence in the USA. School-aged children, institutional-

Fig. 16.5 *Trichuris* worm found in cecum at colonoscopy in an asymptomatic woman. The thin part of the worm embeds in the colonic mucosa

ized persons, and adults who care for children are the most commonly infected [12].

Enterobius infection starts after one ingests infectious eggs, and the eggs hatch in the small intestine. The immature larvae migrate to the colon, where they become adults and mate. Female worms migrate at night to lay eggs in the perianal skin folds. These eggs can become infectious within hours.

Transmission occurs when the female worms lay their eggs in the perianal area and cause anal pruritus. This in turn leads to excoriation with hands, which can then transfer infectious eggs to food surfaces or be directly consumed off soiled hands. Fomites (bed sheets and clothing in particular) can harbor eggs, which can then be ingested.

Enterobius is known for causing bothersome anal pruritus and sequelae (secondary bacterial infections) from excoriation. However, in cases of large worm burden, abdominal symptoms can include pain, nausea, and vomiting. There may be an association with appendicitis [41].

Unlike other helminths, *Enterobius* is not diagnosed on stool microscopy. The best method of diagnosis is the “scotch tape test,” which entails placing scotch tape on the perianal skin (best at night or in the morning before bathing) and then examining it under a microscope to identify the characteristic bean shaped ova. The yield is higher and approaches 100% sensitivity with three separate tests [12].

The treatment for *Enterobius* is albendazole or mebendazole. Repeat dosing in 2 weeks helps in achieving a higher cure rate and preventing reinfection because the medications do not reliably kill the ova. Pyrantel pamoate is an effective alternative and is recommended in pregnancy [12, 41].

Cestodes (Tapeworms)

Cestodes or tapeworms are flat parasitic worms. The most common species causing human disease include *Diphyllobothrium*, *Taenia*, and *Hymenolepis*. They are distinguished by their morphology, but all contain a head (scolex) that attaches to the host and multiple segmented bodies (proglottids) that contain reproductive organs and eggs. Intestinal infections are generally asymptomatic, but peripheral eosinophilia is common. Diagnosis is made by stool microscopy with identification of distinct proglottids or ova. All tapeworm infections are treated similarly, and first-line therapy is praziquantel, in varying doses depending on the species.

Diphyllobothrium latum

D. latum (fish tapeworm) is the largest human tapeworm. It has the ability to grow to extremely long lengths in the human intestine (up to 12 m). It is found in freshwater fish exposed to water contaminated by human feces, and it is transmitted to humans by consumption of undercooked or previously

unfrozen fish. Infection is extremely rare in the USA and most cases have been reported in Japan and Europe; however, little is known about the prevalence in children [42]. The worms can live for up to 10 years in the small intestine and clinical manifestations are generally not present; however, worms can be passed in stool or emesis or cause obstruction. The unique, but rare association with chronic *D. latum* infection is vitamin B12 deficiency, as the worms will consume the vitamin and deplete the host.

Taenia saginata and *Taenia solium*

T. saginata (beef tapeworm) and *T. solium* (pork tapeworm) are acquired by consumption of undercooked beef and pork, respectively. *T. saginata* is seen primarily in countries where raw beef consumption is common. *T. solium* is seen throughout regions where hygiene problems exist—Central and South America, Asia, and Africa. *T. solium* is predominantly known for causing cysticercosis, a serious neurologic infection caused by the larval stage of the tapeworm, which is a common cause of epilepsy around the globe. Typically, carriers of *T. solium* tapeworm do not have cysticercosis, but spread this infection to others via shedding of ova in their stool. There are rare reports of passing proglottids or developing abdominal symptoms as a result of *Taenia* tapeworm infection.

Hymenolepis nana

H. nana (dwarf tapeworm) is the smallest and most common tapeworm infection. There is limited data on prevalence in the USA, but a remote study indicated a prevalence of 4% in an urban pediatric population in the Southeast [43]. Temperate regions tend to have increased prevalence as the eggs can only survive in warm conditions. Unlike the other tapeworms, *H. nana* has the ability to complete its lifecycle within the human host, and transmission is often fecal-oral between humans. There is the potential for an arthropod intermediate that is then consumed unknowingly in grain products. The symptoms of infection are usually minimal unless worm burdens become high (which is possible because of autoinfection). If this occurs, nonspecific abdominal and constitutional symptoms can occur.

Conclusion

This chapter reviewed intestinal parasite infections. While some of these infections are rarely seen in practice in the USA, knowledge of their presentation, long-term consequences in children, and treatment remains important for the clinician in the current age of global food trade, travel, and immigration.

Jai K. Das, Christopher Duggan and Zulfiqar A. Bhutta

Introduction

In the year 2013, 6.3 million children under the age 5 died; around 3 million (45%) of these deaths were attributable to infectious diseases, and pneumonia (17%) and diarrhea (9%) were the leading causes. The overall incidence of diarrhea has decreased from 3.4 episodes per child-year in 1990 to 2.9 episodes per child-year in 2010, but diarrhea remains one of the most common reasons of hospital admission, with an estimated 1731 million episodes of childhood diarrhea reported in 2011 [1, 2]. Risk factors for diarrhea include poverty, undernutrition, poor hygiene, and underprivileged household conditions.

Diarrhea is categorized clinically into three types: acute watery, acute bloody and persistent diarrhea. Acute watery diarrhea lasts several hours or days, and is often due to gastrointestinal pathogens including viruses and bacteria (including *Vibrio cholerae*). Acute bloody diarrhea, also called dysentery, is marked by stools containing blood and/or mucous; common pathogens include *Salmonella* and *Shigella* spp. Persistent diarrhea refers to episodes of diarrhea (either watery or dysentery) that last 14 days or longer. Although less common than acute diarrhea, prolonged and persistent episodes of diarrhea in childhood constitute a significant portion of the global burden of diarrhea and these lengthy episodes are increasingly implicated in childhood undernutrition [3], micronutrient de-

ficiencies, adverse neurodevelopment outcomes, and higher morbidity and mortality from other diseases [1]. As mortality from acute watery diarrhea is decreasing, the proportion of deaths due to persistent diarrhea has increased, and recent studies estimate that between 5 and 18% of all episodes are persistent diarrhea and though a small portion of episodes, they are responsible for significant diarrheal morbidity and up to 50% of all diarrhea-related deaths since persistent diarrhea has a high case-fatality rate [4, 5]. It is also estimated that persistent diarrhea is associated with 3 million disability adjusted life-years lost annually [6]. These findings indicate the continuing need to focus on prevention and management of childhood diarrhea, especially in developing countries where most of the burden lies. But there is scarcity of data on persistent diarrhea, and it is likely that the diminished publication output also reflects reduced research interest in the subject [7]. Although effective interventions exist which not only can halt the progression from acute diarrhea to persistent diarrhea and its sequelae but also have a substantial impact on total diarrhea burden and mortality as well; however, these interventions do not have universal access. An analysis using the lives saved tool (LiST), a methodology to estimate the effect of increasing the use of a package of interventions, has shown that if water, sanitation and hygiene (WASH), breastfeeding, zinc, oral rehydration solution (ORS), rotavirus vaccine, vitamin A supplementation, zinc for the treatment of diarrhea and antibiotics for dysentery are scaled up to at least 80% and that for immunizations to at least 90%; 95% of diarrhea deaths in children younger than 5 years could be eliminated [8].

Etiology

There are three causes of persistent or chronic diarrhea: persistent infection; repeated infection, which occurs primarily in resource limited regions with poor hygienic conditions; and post-infectious irritable bowel syndrome which occurs after an infection has cleared [9]. Persistent diarrhea can lead to long-term morbidity, probably due to malabsorption

of key nutrients caused by the blunting of villi, disruption of the epithelium, and submucosal inflammation.

The responsible organisms depend on endemicity or recent travel. A few pathogens have been particularly associated with persistent diarrhea or are preferentially identified when an episode becomes persistent include *EnteroAggregative Escherichia coli* (EAggEC) and *EnteroPathogenic E. coli* (EPEC), *Clostridium difficile*, *Cryptosporidium parvum*, *Campylobacter* spp., *Salmonella* spp., *Shigella* spp., and *Giardia lamblia*.

EAggEC and EPEC are the most commonly implicated bacterial pathogens in persistent infections in developing countries, especially among children [9]. The exact mechanism by which EAggEC leads to persistent diarrhea is not known, whereas EPEC's pathogenesis lies in its ability to disrupt the brush border through the adherence and effacement process, leading to the loss of absorptive areas. *C. difficile* infections are increasingly more difficult to treat as they become more prevalent in the community and are now the recognized common cause of persistent diarrhea in developed countries. Other bacterial pathogens that cause persistent diarrhea include *Campylobacter*, *Salmonella*, and on rare occasions *Tropheryma whipplei*. *Giardia* and *Cryptosporidium* are also often implicated, along with *Entamoeba*, *Iso spora*, and microsporidia [10, 11]. Intestinal parasites could also cause persistent diarrhea especially in developing regions. Studies have also shown seasonal variation in infection [12]. Viruses in a minority of immunocompetent patients are also a cause of persistent diarrhea [13]. In immunocompromised patients, intestinal parasites are the most commonly implicated pathogens to cause persistent diarrhea [14], while atypical *Mycobacteria*, *Cytomegalovirus*, and other enteric viruses infections should also be suspected.

Risk Factors

Persistent diarrhea is commonly seen in association with significant malnutrition, and the relationship between persistent diarrhea and malnutrition is bidirectional. The recent evidence of micronutrient deficiencies, especially of zinc and vitamin A in malnourished children with persistent diarrhea, indicates impaired immunological mechanisms for clearing infections as well as ineffective mucosal repair mechanisms. Lactose intolerance is prevalent in many children with persistent diarrhea, but the role of specific dietary allergies in inducing and perpetuating enteropathy of malnutrition is unclear. Several studies have highlighted the high risk of prolonged diarrhea with lactation failure and early introduction of artificial feeds in developing countries. In particular, the administration of unmodified cow's or buffalo milk is associated with prolongation of diarrhea, suggesting the potential underlying role of milk protein enteropathy [15]. Inappropriate management of acute diarrhea is also an important risk factor. The association of prolongation of diarrhea with starvation and inappropriate-

ly prolonged administration of parenteral fluids has been recognized for over half a century [16]. Continued breastfeeding is important and unnecessary food withdrawal and replacement of luminal nutrients, especially breast milk, with non-nutritive agents is a major factor in prolonging the mucosal injury after diarrhea. In particular, routine administration of antibiotics and antimotility agents and semi-starvation diets should be avoided in cases of prolonged diarrhea [17]. There is now clear evidence supporting the enteral route for nutritional rehabilitation of malnourished children with persistent diarrhea [18] as starvation has been shown to have deleterious effects on the intestinal mucosa [19] with a reduction in gastrointestinal structure and function. It is therefore imperative that malnourished children with persistent diarrhea should receive enteral nutrition during their period of rehabilitation. High stool frequency, not being breastfed, young age, and acquiring diarrhea in the rainy season have also been identified as risk factors for prolonged diarrhea [20].

The aforementioned risk factors highlight the importance of recognizing that optimal management of diarrheal episodes is essential to progression to persistent diarrhea. It is natural that given the close relationship between diarrheal disorders and malnutrition, persistent diarrhea is widely recognized as a nutritional disorder and that optimal nutritional rehabilitation is considered a cornerstone of its management.

Consequences of Persistent Diarrhea

As diarrhea becomes "persistent," malnutrition becomes increasingly manifest secondary to anorexia and impaired nutrient balance resulting from mucosal injury, malabsorption, and nutrient losses [21]. This sequence is supported by the observation that *Shigella* infection—characterized by intense tissue catabolism and nutrient losses—almost doubles the risk of persistent diarrhea [22], and why bloody diarrhea (with or without the isolation of *Shigella* spp.) is so often reported to be a risk factor for persistent episodes [23]. The importance of *Shigella* is reflected in the report from a large hospital center in Bangladesh that the frequency of persistent diarrhea diminished as the isolation rate of *Shigella* decreased between 1991 and 2010. Mucosal injury also explains why by day 14, the manifestations of persistent diarrhea are primarily those of a malabsorption and malnutrition syndrome that requires careful dietary and nutritional management until the mucosal damage is reversed and new normally functioning epithelial cells are regenerated.

There are several reasons why malnutrition should both predispose to, as well as follow persistent diarrhea. These range from achlorhydria with increased risk of small bowel contamination, systemic immune deficiency, intestinal and pancreatic enzyme deficiency, and altered intestinal mucosal repair mechanisms following an infectious insult. An independent relationship has also been demonstrated between

cutaneous anergy and the subsequent risk of development of persistent diarrhea [24]. There has been much interest in the possibility that such transient immune deficiency may also be a marker of concomitant micronutrient deficiency [25]. The most striking example of the critical role that the immune system plays in the pathogenesis of persistent diarrhea is the relationship of HIV/AIDS. This is exemplified by the host of studies linking persistent diarrhea with cryptosporidiosis [26] and other parasitic infections [27] in Africa and Asia.

A clear understanding of alterations in intestinal morphology and physiology is crucial toward the development of interventional strategies, but there has been little progress in our understanding of this problem in developing countries. This has been largely due to a paucity of studies formally evaluating intestinal biopsy findings in representative populations. A wide variety of pathological changes have been described after persistent diarrhea, however, ranging from near normal appearance to mucosal flattening, crypt hypertrophy, and lymphocytic infiltration of the mucosa [28]. Recent elaborate electron microscopic studies of intestinal mucosa in persistent diarrhea reveal patchy villous atrophy and intraepithelial lymphocytic infiltration as well as severe mucosal damage and villous atrophy [29]. Poor intestinal repair is regarded as a key component of the abnormal mucosal morphology. However, the exact factors underlying this ineffective repair process and continuing injury are poorly understood. The end result

of this mucosal derangement is reduced absorption of luminal nutrients, as well as increased permeability of the bowel to abnormal dietary or microbial antigens [30]. Alterations of intestinal permeability in early childhood may reflect changes in intestinal mucosal maturation [31] and may be affected by concomitant enteric infections [32].

Management

It is imperative to consider the child's age and clinical manifestations to determine proper treatment in cases of persistent diarrhea. A paucity of diagnostic facilities limits the microbiologic evaluation of diarrhea in many parts of the world. Lack of awareness regarding cow's milk protein allergy and immunodeficiency-associated diarrhea is of particular concern. Optimal prevention and management of acute diarrheal illnesses is the ideal strategy to prevent persistent diarrhea. Treatment is focused on reversing dehydration (if present), nutritional interventions including balanced protein energy and micronutrient supplements, and judicious use of antibiotics for certain types of inflammatory diarrhea. Oral rehydration solutions, micronutrient supplementation, algorithm-based diet regimens, and good supportive care are sufficient in most children above 6 months of age with persistent diarrhea (Table 17.1).

Table 17.1 Impact of interventions to prevent and control diarrhea

Intervention	Effect estimates
Water sanitation and hygiene	48, 17, and 36% risk reductions for diarrhea with hand washing with soap, improved water quality and excreta disposal, respectively
Breastfeeding education and impacts on breastfeeding patterns	EBF rates increase by 43% at 1 day, 30% till 1 month, and 79% from 1 to 6 months Rates of no breastfeeding decrease by 32% at 1 day, 30% till 1 month, and 18% from 1 to 6 months
Preventive zinc supplementation	18% reduction in diarrhea-related mortality
Preventive vitamin A supplementation	All-cause mortality reduced by 24% (RR: 0.76, 95% CI: 0.69–0.83), diarrhea related mortality by 28% (RR: 0.72, 95% CI: 0.57–0.91), incidence of diarrhea reduced by 15% (RR: 0.85, 95% CI: 0.82–0.87)
Vaccines for rotavirus	74% reduction in very severe rotavirus infection 47% reduction in rotavirus hospitalization
Vaccines for cholera	52% effective against cholera infection
ORS	69% reduction in diarrhea specific mortality
Dietary management of diarrhea	Lactose free diets reduce the duration of diarrhea treatment failure rates by 47%
Therapeutic zinc supplementation	66% reduction in diarrhea-specific mortality 23% reduction in subsequent diarrhea hospitalization 19% reduction in subsequent diarrhea
Antibiotics for cholera	63% reduction in clinical failure rates 75% reduction in bacteriological failure rates
Antibiotics for Shigella	82% reduction in clinical failure 96% reduction in bacteriological failure rates
Antibiotics for cryptosporidiosis	52% reduction in clinical failure rates 38% reduction in parasitological failure rates
Community based intervention platforms for prevention	160% increase in the use of ORS 80% increase in the use of zinc in diarrhea 76% decline in the use of antibiotics for diarrhea
Community case management	63% reduction in diarrhea related mortality
Financial support schemes	Conditional transfer programs: 14% increase in preventive health care use, 22% increase in the percentage of newborns receiving colostrum and 16% increase the coverage of vitamin A supplementation

EBF exclusive breastfeeding, *ORS* oral rehydration solution, *RR* relative risk, *CI* confidence interval

Rapid Resuscitation, Antibiotic Therapy, and Stabilization

Most children with persistent diarrhea and associated malnutrition are not severely dehydrated and oral rehydration may be adequate. Indeed, routine use of intravenous fluids in severe acute malnutrition should be avoided; acute severe dehydration and associated vomiting may require brief periods of intravenous rehydration with Ringer's lactate. Acute electrolyte imbalance such as hypokalemia and severe acidosis may require correction. More importantly, associated systemic infections (bacteremia, pneumonia, and urinary tract infection) are well-recognized complications of severe acute malnutrition in children with persistent diarrhea and a frequent cause of early mortality. Almost 30–50% of malnourished children with persistent diarrhea may have an associated systemic infection requiring resuscitation and antimicrobial therapy [33, 34]. In severely ill children requiring hospitalization, it may be best to cover with parenteral antibiotics at admission (usually ampicillin and gentamicin) while awaiting blood and other culture results. It should be emphasized that there is little role for oral antibiotics in persistent diarrhea as in most cases the original bacterial infection triggering the prolonged diarrhea has disappeared by the time the child presents. Possible exceptions are appropriate treatment for dysentery [8] and adjunctive therapy for cryptosporidiosis in children with HIV and persistent diarrhea [35].

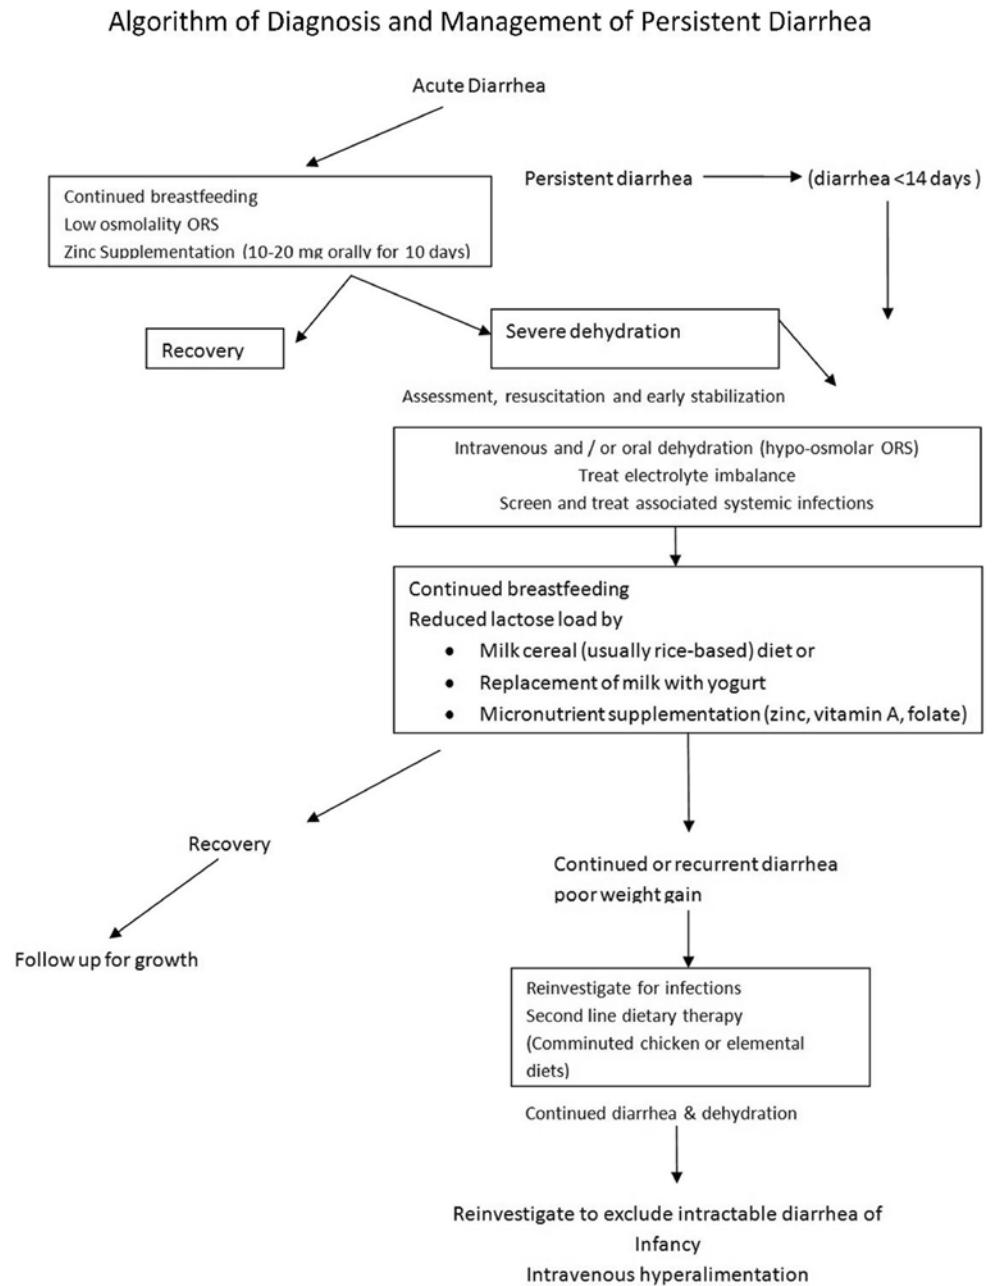

Oral Rehydration Therapy

It is over 40 years since the efficacy of oral rehydration therapy was clearly demonstrated, following discovery of glucose-stimulated sodium uptake by intestinal villus cells [36]. This is the preferred mode of rehydration and replacement of ongoing losses. The net effect is expansion of the intravascular compartment and rehydration, usually sufficient for all but the most severely dehydrated patients who require initial intravenous fluids [37]. Data from several clinical trials supported a change in the composition of the WHO ORS to a solution of lowered osmolality. While in general the standard WHO oral rehydration solution is adequate, recent evidence indicates that hypo-osmolar rehydration fluids [38] as well as cereal-based oral rehydration fluids may be advantageous in malnourished children. A number of modifications have been proposed, for example cereal (rice)-based ORT, addition of certain amino acids (glycine, alanine, or glutamine) to further increase sodium absorption and/or hasten intestinal repair, or supplementation with zinc, but none have been shown to be consistently superior to low-osmolality ORS [39, 40].

Enteral Feeding

Nutritional rehabilitation can break the vicious cycle of chronic diarrhea and malnutrition and is considered the cornerstone of treatment. It is exceedingly rare to find persistent diarrhea in exclusively breast-fed infants, and with the exception of situations where persistent diarrhea accompanies perinatally acquired HIV infection, breastfeeding must be continued. Although children with persistent diarrhea may not be lactose intolerant, administration of a lactose load exceeding 5 g/kg/day may be associated with higher purging rates and treatment failure. Alternative strategies for reducing the lactose load while feeding malnourished children who have prolonged diarrhea include addition of milk to cereals and replacement of milk with fermented milk products such as yogurt. Mattos et al. [41] claimed that yogurt-based diet is recommended as the first choice for the nutritional management of a mild to moderate persistent diarrhea. A cheap and an easily available yogurt-based diet can be used in mild chronic diarrhea illness of uncomplicated and without enteropathy. Bhutta et al. [18] suggested algorithm for the diagnosis and management of persistent diarrhea (Fig. 17.1). Elimination diet is considered when allergic enteropathy is induced by a cow's milk protein or soy protein [42]. Rarely, when dietary intolerance precludes the administration of cow's milk-based formulations or milk it may be necessary to administer specialized milk-free diets such as a comminuted or blended chicken-based diet or an elemental formulation. Although effective in some settings, the latter are unaffordable in most developing countries. In addition to rice-lentil formulations, the addition of green banana or pectin to the diet has also been shown to be effective in the treatment of persistent diarrhea [43, 44]. Among children in low- and middle-income countries, where the dual burden of diarrhea and malnutrition is greatest and where access to proprietary formulas and specialized ingredients is limited, the use of locally available age-appropriate foods should be promoted for the majority of diarrhea cases. Nutritionally complete diets comprising locally available ingredients can be used at least as effectively as commercial preparations or specialized ingredients. The usual energy density of any diet used for the therapy of persistent diarrhea should be around 1 kcal/g, aiming to provide an energy intake of a minimum 100 kcal/kg/day, and a protein intake of between 2 and 3 g/kg/day. In selected circumstances, when adequate intake of energy-dense food is problematic, the addition of amylase to the diet through germination techniques may also be helpful. Recent WHO guidelines recommends that children with severe acute malnutrition who present with either acute or persistent diarrhea, can be given ready-to-use therapeutic food in the same way as children without diarrhea, whether they are being managed as inpatients or outpatients. And these children with severe acute malnutrition should also be

Fig. 17.1 Algorithm of diagnosis and management of persistent diarrhea

provided with about 5000 IU vitamin A daily, either as an integral part of therapeutic foods or as part of a multi-micronutrient formulation [45].

Micronutrient Supplementation

It is now widely recognized that most malnourished children with persistent diarrhea have associated deficiencies of micronutrients including zinc, iron, and vitamin A. This may be a consequence of poor intake and continued enteral losses and requires replenishment during therapy [46]. While the

evidence supporting zinc administration in children with persistent diarrhea is persuasive, it is likely that these children have multiple micronutrient deficiencies. Concomitant vitamin A administration to children with persistent diarrhea has been shown to improve outcome [47, 48] especially in HIV endemic areas [49]. It is therefore important to ensure that all children with persistent diarrhea and malnutrition receive an initial dose of 100,000 units Vitamin A and a daily intake of at least 3–5 mg/kg/day of elemental zinc. While the association of significant anemia with persistent diarrhea is well recognized, iron replacement therapy is best initiated only after recovery from diarrhea has started and the diet is well tolerated.

Improved Case Management of Diarrhea

Improved management of diarrhea through prompt identification and appropriate therapy significantly reduces diarrhea duration, its nutritional penalty, and risk of death in childhood. Improved management of acute diarrhea is a key factor in reducing the burden of prolonged episodes and persistent diarrhea. The WHO/UNICEF recommendations to use low-osmolality ORS and zinc supplementation for the management of diarrhea, coupled with selective and appropriate use of antibiotics, have the potential to reduce the number of diarrheal deaths among children through community case management and integrated management of childhood illness (IMCI). Community-based interventions to diagnose and treat childhood diarrhea through community health workers leads to a significant rise in care-seeking behaviors for diarrhea and are associated with significantly increased use of ORS and zinc at household level as well as reduction in the unnecessary use of antibiotics for diarrhea [50].

Other Potential Modalities

The factors associated with persistent diarrhea are small intestinal mucosa injury, persisting infective colonization and bacterial particles and toxins that are translocated into the host cell and the downregulated host immune system. These circumstances alter interrelation between the normal flora and the host, which can worsen prolonged inflammation. The rationale for using probiotics in treatment of persistent diarrhea lies in their ability to survive and reproduce in the host's gut and in their proven role in treatment of acute diarrhea. Recent evidence suggests modest effect of probiotics [51]. Because of probiotics known immunomodulatory effect and very significant mortality and morbidity rate from persistent diarrhea in developing countries, it is imperative to highlight the necessity for well-designed studies to define the role of probiotics in persistent diarrhea.

Follow-Up and Nutritional Rehabilitation in Community Settings

Given the high rates of relapse in most children with persistent diarrhea, it is important to address the underlying risk factors and institute preventive measures. These include appropriate feeding (breastfeeding, complementary feeding) and close attention to environmental hygiene and sanitation. This poses a considerable challenge in communities deprived of basic necessities such as clean water and sewage disposal.

In addition to the preventive aspects, the challenge in most settings is to develop and sustain a form of dietary

therapy using inexpensive, home-available, and culturally acceptable ingredients which can be used to manage children with persistent diarrhea. Given that the majority of cases of persistent diarrhea occur in the community and that parents are frequently hesitant to seek institutional help, there is a need to develop and implement inexpensive and practical home-based therapeutic measures [18] and evidence indicates that it may be entirely feasible to do so in community settings [52, 53].

Conclusion

There is a significant burden of persistent diarrhea in children and it also contributes to childhood malnutrition and mortality. Most of the knowledge and tools needed to prevent diarrhea-associated mortality in developing countries and especially persistent diarrhea are available. These require concerted and sustained implementation in public health programs. Given the emerging evidence of the long-term impact of childhood diarrhea on developmental outcomes [54], it is imperative that due emphasis is placed on prompt recognition and appropriate management of persistent diarrhea.

Introduction

Acquired immune deficiency syndrome (AIDS) is the most devastating pandemic in human history. More than 100 million people worldwide currently have been infected with the human immunodeficiency virus (HIV), and an estimated 8 million individuals are currently treated. Prevention of mother-to-child transmission has proved highly effective, and this serves as a model for prevention using antiretroviral drugs. Antiretrovirals, the cornerstone of HIV treatment, are now being assessed as tools for limiting transmission in two ways: treatment as prevention and pre-exposure prophylaxis. The epidemiology of HIV in children is characterized by a double scenario. In countries where highly active antiretroviral therapy (HAART) is available, the pattern of HIV infection is evolving into a chronic disease, the control of which strictly depends on patients' adherence to treatment [1, 2]. In developing countries, with no or limited access to HAART, AIDS is rapidly expanding and is loaded with a high fatality ratio, due to the combined effects of malnutrition and opportunistic infections. The digestive tract is a target of the disease in both settings (Fig. 18.1).

Since the beginning of AIDS pandemic, it was clear that the virus gains access to the human host predominantly through the mucosal tissue after sexual exposure. However, HIV mucosal infection plays a critical role not only in virus transmission but also in AIDS pathogenesis, affecting mucosal surface of the gastrointestinal (GI) tract in the early phase post infection and depleting cluster of differentiation (CD4) T helper cells [4]. GI disease accounts for a high proportion of presenting symptoms of HIV infection, mainly in developing world [5]. Chronic diarrhea is a hallmark of advanced HIV infection, and it is caused by intestinal infections. Although

the widespread use of HAART has dramatically improved the survival rate of HIV-infected people and has changed the spectrum of complications of HIV disease, the intestinal tract is still a major target of HIV infection. An uncertain, but high, percentage of HIV-infected patients worldwide initially presents or ultimately develops diarrhea or malnutrition, with or without HAART. Diarrhea is a major manifestation of HIV disease and is associated with increased morbidity and mortality. It substantially increases health-care costs for many patients, particularly those with severe malabsorption and malnutrition requiring repeated hospitalizations. In many cases, a multidisciplinary approach including specialist in gastroenterology, infectious disease, especially HIV, oncology, surgery and microbiology is required for treating patients with AIDS.

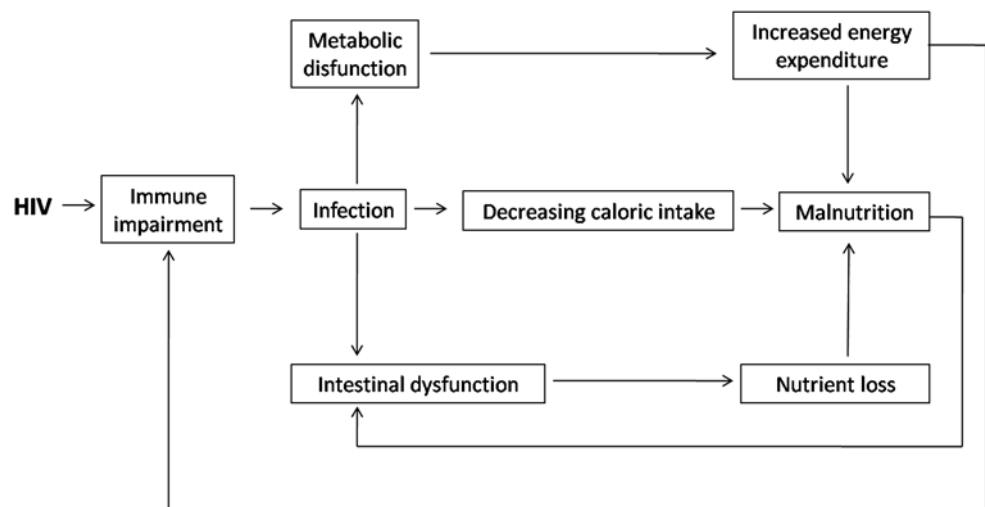

The Spectrum of GI Disorders in HIV Infection

The stage of immunodeficiency, reflected by the CD4 lymphocyte count, should be kept in mind when approaching any HIV-infected patient with GI symptoms because the etiology and the frequency of opportunistic infections are related to the CD4 count and rises exponentially if CD4 is <100 cell/ul.

The upper GI tract is a topographical target of HIV infection. *Candida* is the most common oesophageal pathogen in AIDS. However, in the era of antiretroviral therapy (ART), many of the previously common HIV-related disorders are vanished [6], but they can be observed in patients who are failing on HAART or non-adherent to therapy [7]. The approach to HIV patients with a CD4 count >200 cell/ul and upper GI symptoms should parallel that of any other non-HIV-infected subject. Upper endoscopy remains the gold standard diagnostic approach in case of suspected gastro-oesophageal reflux disease, dysphagia or bleeding. In severely immunosuppressed children, in whom opportunistic infections are considered, upper endoscopy with multiple tissue sampling

Fig. 18.1 Pathway of malnutrition and gastrointestinal disorders in children with HIV infection. A complex interplay exists among these conditions. (Reprinted from [3] with permission)

should be performed for a definitive diagnosis [8]. For example, multiple biopsies (about 10) increase the yield for cytomegalovirus (CMV) disease [9].

Intestinal infections are a major cause of morbidity and mortality, especially for children, and where the availability of HAART is limited. In patients with advanced HIV disease, opportunistic infections are the most common cause of disease. Cryptosporidium and microsporidium are the most common pathogens in developing countries and CMV in developed world. However, although opportunistic causes of diarrhea have fallen dramatically in the era of ART, overall the number of patients experiencing diarrhea has changed very little [10]. Other infections unrelated to immunodeficiency and noninfectious causes are also increased in HIV-infected children. Drug-induced diarrhea is an important cause of diarrhea in HIV patients [11]. Severe diarrhea associated with villous atrophy and crypt hypertrophy with no pathogen is found despite extensive investigation is defined as HIV enteropathy. The approach to diarrhea in HIV-infected patients should be based on routine stool testing, but these are often repeatedly negative, mainly in severe immunosuppressed subjects. In these cases, endoscopic examination with biopsy is able to establish a diagnosis in 65–80% of cases [8].

Intestinal dysfunction is a specific HIV-related syndrome in children [3]. The clinical manifestations of intestinal dysfunction may be limited or absent. Namely dysfunction is not consistently associated with diarrhea but its most prominent features are steatorrhea, reduction of the intestinal absorptive surface and increased permeability [3]. Despite the limited or absent clinical manifestations of intestinal dysfunction, nutrient malabsorption certainly contributes to weight loss, and its clinical consequences may be expected in the long term and associated with progressive failure to thrive. The pathophysiology of intestinal dysfunction is complex and involves multiple abnormalities. HAART is able to re-

store intestinal function tests in HIV-infected children, in parallel with a decrease in viral load and an increase in CD4 T cell count [3]. This suggests that in case of malnutrition in a child receiving ART, careful monitoring of antiretroviral therapeutic efficacy is needed, as malnutrition may be an early marker of treatment failure.

Liver disease is the second most common cause of death among adults with HIV infection. Just as the burden of non-AIDS morbidity and mortality has changed in the ART era, the spectrum of liver diseases has also changed in these patients [12]. Prior to ART, the most common causes of liver dysfunction were opportunistic infections, including CMV and mycobacterium infections, AIDS lymphoma and Kaposi's sarcoma. Since the HAART era, however, the spectrum of liver disease among HIV-infected individuals has shifted to concomitant infection with chronic hepatitis C virus (HCV), and chronic hepatitis B virus infections, medication-related hepatotoxicity and nonalcoholic fatty liver disease (NAFLD). Although hepatic dysfunction is not frequent in HIV in children, hepatomegaly without other symptoms of systemic disease is commonly found in pediatric patients, and it is often associated with nutritional deficiency. HBV and HCV infections may be more severe in HIV-infected children than in HIV-negative individuals. In addition, liver toxicity is one of the most common serious adverse events associated with ART [12].

Pancreatic dysfunction may be considered as a component of HIV-associated digestive dysfunction in HIV. In fact, a reduction of faecal levels of pancreatic elastase and/or chymotrypsin has been found in one third of HIV-infected children [13]. The clinical manifestations of pancreatic involvement may not be evident, because exocrine, rather than endocrine pancreatic function, is involved. Pancreatitis may be an unusual but serious drug adverse effect, mainly with selected nucleoside analogue reverse transcriptase inhibitors.

HIV Enteropathy

Since the discovery of HIV as an agent of AIDS, histological abnormalities of GI tract were observed, and the term “HIV enteropathy” was firstly used in 1984 [14]. Many investigators found that HIV itself infected enterocytes, lamina propria and submucosal cells. The enteropathy was characterized by inflammatory infiltrates of lymphocytes, damage to the GI epithelium, villous atrophy, crypt hyperplasia, and villous blunting, in the absence of detectable enteropathogens, recurring in all stages of HIV disease [15]. GI abnormalities associated with HIV infection include a decreased capacity for epithelial regeneration, impaired absorptive ability of GI mucosa, increased mucosal permeability, dysregulations of genes associated with T cell homeostasis, decreased growth factor production and cell-cycle mediators and upregulation of genes associated with apoptosis [16–18].

Not surprisingly, inflammatory changes are mild or absent. Once opportunistic disorders are excluded in patients with refractory diarrhea, HIV enteropathy is diagnosed in a small but definite percentage of patients. The HIV enteropathy encompasses an idiopathic, pathogen-negative diarrhea, and it can occur from the acute phase of the HIV infection through advanced disease, leading to GI inflammation, increased intestinal permeability, bile acid and vitamins malabsorption [19]. The functional disruption of the GI caused by HIV has been reported also in the absence of clear clinical GI manifestations in the era of modern ART [20]. More than one third of HIV-infected patients present an abnormal D-xylose test, about 20% has low or borderline serum B12 levels and 7% has low albumin levels, in the absence of stool pathogens [20].

Although the mechanisms responsible for these abnormalities remain not completely known, several explanations have been put forward, from a virotoxic effect of HIV itself on enterocytes [21, 22] to an abnormal differentiation of enterocytes induced by HIV [23, 24], to local activation of the GI immune system [25]. However, a major role is likely associated with HIV transactivator factor (Tat) [21].

Interaction Between HIV and Intestine

Immunopathogenesis of HIV involves two phenomena: the loss of lymphoid cells and the loss of immune function. Several pathological changes, both structural and immunological, occur at the intestinal mucosal surface from the initial stage of HIV infection. The intestinal mucosa is a target for HIV and a site of significant HIV replication and CD4 T cell destruction, based upon the route of exposure and other aspects of mucosal immunology [26, 27]. Gut-associated lymphoid tissue (GALT) was identified as an early site of HIV replication and CD4 T cells depletion since the initial

stage of HIV infection [28]. Even with early and aggressive HAART, GALT is not preserved and undergoes significant damage.

The sensitivity by intestinal tract to HIV infection relates in part to the high number of activated memory T cells expressing C-C chemokine receptor type 5 (CCR5) chemokine receptors located within the gut. HIV-1 isolated from acutely infected subjects are predominantly R5 viruses, that is macrophage-tropic HIV that requires CCR5 for cell entry, in contrast to R4 virus, lymphocyte-tropic HIV requiring the C-X-C chemokine receptor type 4 (CXCR4) chemokine receptor [29]. The preferential loss of CCR5+CD4 T cells from the GI tract clearly suggests a virus-centric mechanism. Furthermore, the intestinal mucosa has continuous exposure to antigens, leading to a pro-inflammatory state, and secretes many cytokines that stimulate HIV replication [18].

There is a compartmentalization of HIV infection between blood and mucosa, mainly due to viral factors. The CD4/CD8 ratio was analysed in the duodenum and peripheral blood in order to compare CD4 T cell depletion between these two anatomical sites, and it was found that the GI tract was preferentially depleted of CD4 T cells [30–33]. Moreover, CD4 T cells in the GI tract are tenfold more frequently infected by HIV than those in the peripheral blood, suggesting that the viral reservoir in the intestine is much greater than previously thought [34].

Another mechanism that can contribute to the HIV enteropathy is the infection of enterocytes by HIV 1. In *in vitro* experiments, HIV is able to replicate in the intestinal epithelial cell lines [35, 36]. However, virus-direct and -indirect effects have been described. In addition to structural and enzymatic proteins, HIV-1 encodes a group of at least six auxiliary regulatory proteins, including Tat, a transactivating peptide essential for HIV replication, which exerts its effects by activating L-type Ca²⁺ channels, and/or mobilizing intracellular calcium stores [37, 38]. Tat is secreted from HIV-1-infected cells and is taken up by neighbouring uninfected cells. *In vitro* experiments using human colonic adenocarcinoma (caco-2) cell monolayers and human colonic mucosa specimens mounted in *Ussing* chambers, it has been shown that Tat protein induced ion secretion similar to that induced by bacterial endotoxins. It also significantly prevents enterocytes proliferation [39]. On the bases of these data, it is likely that Tat directly exerts pathogenic effects on enterocytes and is involved in the pathogenesis of intestinal mucosal atrophy typical of HIV-infected patients, that is, in HIV enteropathy.

Tat has been implicated also in enterocyte apoptosis. Tat causes an imbalance in reactive oxygen species (ROS) generation in neurons, which is neutralized by antioxidants, thereby implicating perturbation of the intracellular redox status in the pathogenesis of HIV-induced cell damage [40]. Oxidative stress is implicated in the pathogenesis and mor-

bidity of HIV infection. An increase of ROS and an alteration of antioxidant defences have been reported in HIV-infected patients [41] associated with decreased levels of antioxidants [42]. The mechanisms involved in HIV-induced oxidative stress are unknown, but HIV-1 proteins gp120 and Tat have been implicated in this process because they both induce oxidative stress and cause apoptosis in brain endothelial cells [43]. Similar mechanism has been involved in intestinal mucosa (Fig. 18.2). In an in vitro cell model, Tat increased the generation of ROS and decreased antioxidant defences as judged by a reduction in catalase activity and a reduced glutathione (GSH)/oxidized glutathione disulfide (GSSG) ratio [44]. Tat also induces cytochrome c release from mitochondria to cytosol, and caspase-3 activation. Rectal dialysis samples from HIV-infected patients were positive for the oxidative stress marker 8-hydroxy-29-deoxyguanosine. GSH/GSSG imbalance and apoptosis were observed in jejunal specimens from HIV-positive patients at baseline and from HIV-negative specimens exposed to Tat. Experiments with neutralizing anti-Tat antibodies showed that these effects were direct and specific. Pretreatment with N-acetyl cysteine (NAC) prevented Tat-induced apoptosis and restored the glutathione balance in both the in vitro and the ex vivo model

[44]. These findings indicate that oxidative stress is one of the mechanism involved in HIV intestinal disease (Fig. 18.3).

HAART and HIV Enteropathy

HAART reduces viral loads and increases CD4 T cells. GI symptoms including abdominal pain, bloating and diarrhea improve after initiation of treatment, in parallel with CD4 T cell reconstitution in blood and a decrease in viral load in rectal tissue [36]. The effects of HAART on intestinal CD4 T cells are lower than in peripheral blood [45, 46]. Furthermore, HAART started early during infection leads to an increase in CD4 central memory cells in Peyer's patches, but does not restore effector memory cells in the ileal lamina propria [47, 48]. Initiation of HAART during chronic infection does not significantly increase CD4 T cells in gut-inductive or -effector sites [45, 46]. Finally, no HIV-infected individual reconstituted GI tract CD4 T cells to levels observed in uninfected persons. These findings suggest that fibrotic damage severely disrupt the ability of GALT to support normal T cell trafficking and survival, even after HAART onset. In addition, not only CD4 T cells fail to fully repopulate the

Fig. 18.2 Effect of NAC on the Tat-induced oxidative stress in Caco-2 cells [44]. Intracellular ROS levels, determined by fluorometric method, after exposure of Tat with or without pretreatment with NAC (a). Data were represented as percent of controls. Effect of NAC on Tat-induced GSH/GSSG imbalance (b). Data are represented as percent of GSH (grey) and GSSG (white) versus total glutathione. **p*, 0.05 vs. control; #*p*, 0.05 versus Tat. Data are representative of three separate experiments. NAC N-acetyl cysteine, Tat transactivator factor. (Reprinted from Ref. [44])

Fig. 18.3 Schematic representation of the mechanism of HIV Tat viral protein-induced oxidative damage to the intestinal mucosa [44]. Tat induces oxidative stress by increasing the ROS intracellular level and deranging the GSH/GSSG ratio. This leads to programmed cell death (apoptosis) and an increase in epithelial damage. Together with ion secretion and altered glucose transport, these steps could represent key mechanisms in HIV enteropathy. ROS reactive oxygen species, GSH glutathione, Tat transactivator factor, HIV human immunodeficiency virus. (Reprinted from Ref. [44])

GI tract following HAART but also HIV proviral DNA persists in CD4 T cells in terminal ileum 10 years after effective therapy [49]. As a consequence, viral replication persists at low levels in the intestine despite HAART.

GI Infections

The spectrum of HIV-related GI infections has changed dramatically after the introduction and the worldwide diffusion of ART, and still today the epidemiology significantly varies between HIV-infected children treatment-naïve or on ART. The CD4 lymphocyte count continues to be the best predictor of the risk of an opportunistic infection [8, 50], although HIV viral load seems to be also helpful in predicting this risk [51, 52] (Fig. 18.4). Data in children on ART living in developed areas are limited to small reports; however, studies conducted in Africa and reporting the pathogens isolated in children presenting with HIV and diarrhea are reasonably consistent.

A list of the most common agents in HIV/AIDS children is reported in Table 18.1. In addition, Kaposi sarcoma and intestinal lymphoma are also specifically included in HIV-associated intestinal disorders.

In addition, HIV may probably act as a direct enteropathogen and induces ulcerative processes involving distal oesophagus, ileum and rectum because only viral particles have been found in these lesions [53]. Different immunosuppressive approach including with thalidomide, anti-tumour necrosis factor (TNF) agents or corticosteroids have been used, in some case with success, to treat these lesions [54].

Upper Gastrointestinal Infections

The upper GI tract, including oral cavity, oesophagus and stomach, is commonly involved in HIV-related diseases.

Oesophageal localization of opportunistic agents is common in advanced HIV infections, and candida and herpes are most common agents of oesophageal ulcerations. This complication is strongly related to the immunological states, being quite common in subjects with CD4 count <200 cells/ μ l, who are failing ART or are non compliant.

Oral thrush and odynophagia or dysphagia are the most commonly reported upper GI symptoms in HIV-infected children and adolescents. Thrush, appearing white–yellow, hard-to-remove plaques due to *Candida* infection, is a characteristic sign in young HIV/AIDS children. Candidiasis of the mouth and distal oesophagus are associated with loss of appetite, dysphagia and weight loss. Most severe cases of *Candida* infection cause necrotizing oesophagitis, bleeding and, occasionally, perforation. Other opportunistic agents may present with a similar clinical and endoscopic feature, thus biopsy is usually needed to exclude agents such as herpes, Cytomegalovirus (CMV) or intracellular *Mycobacterium avium*. Before ART introduction, *Candida* was by far the first cause of oesophageal complaints and empirical treatment with fluconazole, instead of endoscopy, was considered as the best strategy, especially in patients with thrush [55]. Recently, a report of more than 400 GI endoscopies in HIV/AIDS patients found that odynophagia/dysphagia had the highest yield of positive diagnosis, and it showed that both *Candida* and CMV are major agents of oesophageal involve-

Table 18.1 Opportunistic disorders affecting GI tract in HIV/AIDS patients

<i>Viral Agent</i>	Cytomegalovirus, herpes simplex, rotavirus and adenovirus
<i>Parasites</i>	Cryptosporidia, giardia and isospora
<i>Fungi</i>	Candida, cryptococcus, microsporidia and histoplasma
<i>Bacteria</i>	Shigella, listeria, salmonella, mycobacteria
<i>Tumour</i>	Kaposi, lymphoma

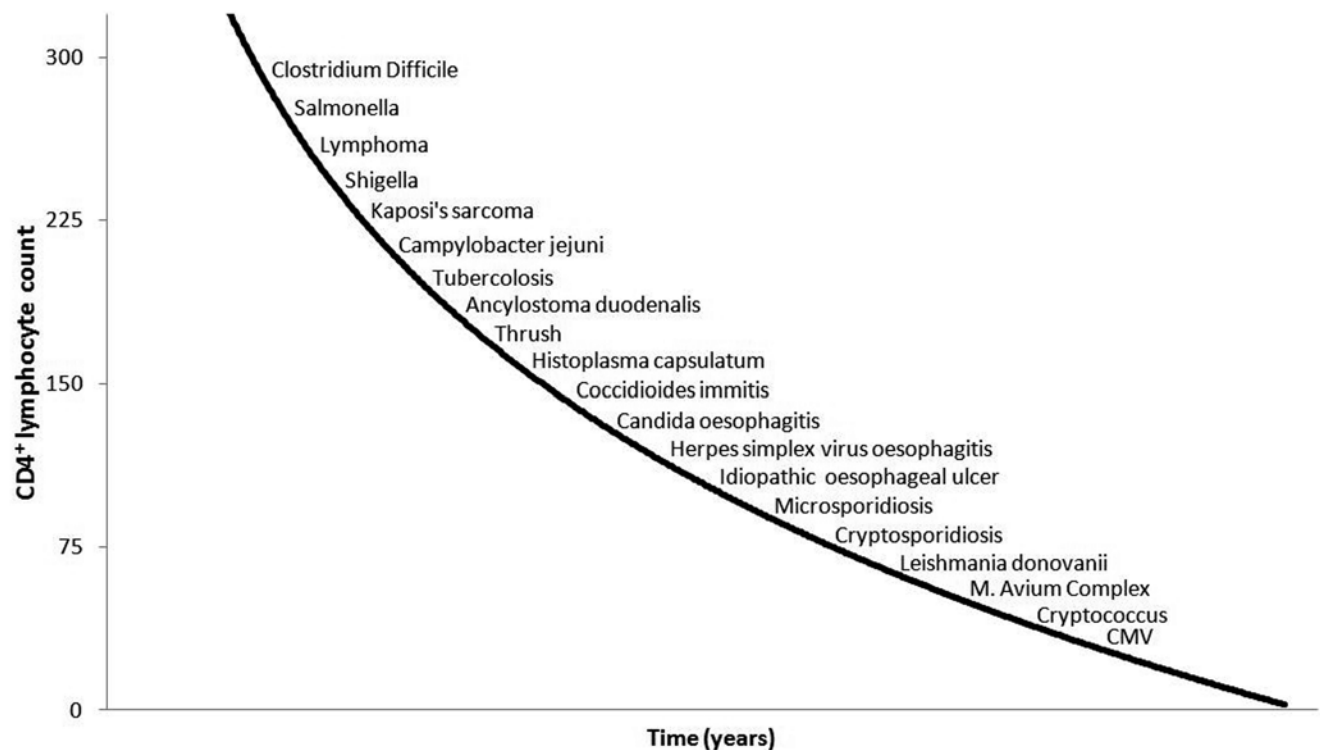

Fig. 18.4 Correlation between CD4 count and risk of HIV-related diseases. *CD* cluster of differentiation, *CMV* cytomegalovirus

ment [54]. A large part of endoscopies, however, resulted in nonspecific oesophageal ulcers, pathophysiology of which is still unclear, and probably due to herpes or HIV itself.

Symptoms of dyspepsia, including epigastric pain, nausea and vomiting, are frequently reported by HIV-infected patients and especially those undergoing ART. The diagnostic approach in these patients may be challenging. Noninvasive testing for *Helicobacter pylori* is not useful in the diagnosis of HIV-infected subjects with strongly suppressed immune system, and a low incidence of this infection has been reported in this population [56, 57]. Empirical treatment with proton-pump inhibitors may be inappropriate for HIV-infected patients because these drugs reduce the oral absorption of selected protease inhibitors [58]. Atypical presentation of opportunistic infections should always be considered in this population and upper endoscopy is suggested for differential diagnosis. Multiple biopsies are needed since macroscopic normal-appearing mucosa does not exclude opportunistic in-

fections [59]. However, the role of opportunistic infections in HIV/AIDS patients presenting with dyspepsia as primary symptom is still not clear. The rate of opportunistic infections in a large population of adults on ART presenting with dyspepsia was less than 2%, and CMV was the most prevalent opportunistic agent [59]. Chronic nonspecific gastritis (mononuclear cell infiltrate) is the most common diagnosis in patients presenting with this symptomatology.

Diarrhea

Chronic diarrhea, in most of cases due to GI infections, is a hallmark of advanced HIV infection and remains a major substantial cause of morbidity and mortality in children.

In Africa, chronic diarrhea has been reported in as many as 90% HIV-positive children, being five- to sixfold higher than in non-HIV-infected children [60, 61]. Case series from

industrialized countries in the pre-ART era showed that 40–80% of HIV-infected patients experienced diarrhea [62].

Classical and opportunistic enteropathogens may induce diarrhea in HIV-infected children. The duration and severity of diarrhea are increased in HIV-infected children living either in developing or in industrialized countries.

The likelihood of opportunistic infections is linked to the severity of immunodeficiency. Some studies [63] suggested that in immunocompetent individuals ($CD4 > 200$ cell/ μ l), the infections are usually caused by ordinary pathogens, while in those with a $CD4 < 200$ cell/ μ l, opportunistic agents such as *Cryptosporidium parvum*, CMV and *Mycobacterium avium* are more common. Frequent agents of diarrhea in HIV-infected subjects, such as the parasite *Enterocytozoon bieneusi* or *Microsporidium*, are more restricted to adult population.

Bacterial Diarrhea

Although there is no specific hallmark of bacterial etiology, several bacterial agents may induce diarrhea. The overall incidence of bacterial diarrhea in HIV-infected adults is at least 100-fold greater than in general population [64], and infections in HIV-infected subjects tend to be more protracted and severe than in immunocompetent individuals. The rate of diarrhea due to bacterial causes significantly decreased after the introduction of ART.

HIV-positive patients are at higher risk of prolonged and severe infections from *Campylobacter jejuni* and invasive non-typhoid Salmonellae infections. The risk of multisite Salmonella infections may be 300-fold increased in advanced HIV disease, and this condition has been considered an AIDS-defining illness.

Escherichia coli, *Shigella* and *Clostridium* were recognized to cause more frequently diarrhea in HIV-infected patients. Recently, a large retrospective study in the USA reported *Clostridium difficile* as the most common cause of diarrhea in HIV-infected adults, accounting for more than 50% of cases [64]. In the same population *Shigella*, *Campylobacter* and *Salmonella* were found in 14, 13.8 and 7.4% patients with diarrhea, respectively.

Mycobacteria may cause GI infections presenting with diarrhea. Diarrhea is a relatively uncommon symptom of *Mycobacterium tuberculosis* infection, but may be more common in *Mycobacterium avium* complex (MAC) infection. However, prophylaxis with azithromycin routinely performed in the pre-ART era is no longer indicated in children receiving ART.

Bacterial diarrhea may have a severe course in HIV-infected children, and it should be treated aggressively. The use of specific antibiotics should be carefully considered even in children who show a mild course of the disease, particularly in those who have moderate-to-severe immune impairment. Some children may require empiric treatment for

symptom control or prevention of the risk of extra-intestinal spreading of the infection.

Viral Diarrhea

Viruses are the leading cause of acute diarrhea in children, and they usually have an acute and self-limiting course in immunocompetent children. Etiology of acute diarrhea in HIV-infected and non-infected children is substantially similar after the introduction of ART. A very high number of enteric viruses were detected in the stools of HIV-infected children without clear relationship with intestinal symptoms. However, viral enteropathy may be dangerous in HIV-positive children.

Rotavirus is the major cause of viral diarrhea in countries in which specific vaccination has not been routinely introduced. Children with HIV infection experience more frequent and severe Rotavirus infections, with a higher risk of prolonged hospitalization and a higher fatality rate than non-HIV-infected children [61].

The development, validation and large-scale implementation of anti-Rotavirus immunization is changing the epidemiology of intestinal infections in industrialized countries that developed a routine vaccination programme [65]. Immunogenicity of Rotavirus vaccines in areas with high rate of HIV infection, like Africa, showed a good and consistent immune response. Immunogenicity is variable and resulted comparable or lower than those observed in Europe and the USA according to different evidence [66]. Although HIV infection is generally not a contraindication for immunization, high HIV prevalence in the region may result in lower rates of vaccine immunogenicity, efficacy and population immunity [67].

Other enteropathogens may cause acute diarrhea in HIV-infected children. Norovirus, generally considered the second leading agent of acute diarrhea, is fast becoming a major cause of medically attended gastroenteritis in countries with high Rotavirus vaccine coverage [68]. This agent may also induce severe and chronic disease manifestations in HIV-positive children [69].

CMV may act as an opportunistic enteric agent inducing severe colitis or enterocolitis or even an intractable diarrhea syndrome in severely immunocompromised children. CMV is by far the major opportunistic etiology of colitis in HIV-infected subjects [54]. As for other opportunistic infections, the introduction of ART significantly reduced the rate of CMV infection in adult patients decreasing from 7.34 to 0.75/100 patients-year. Also the survival at 1 and 2 years that was 42.6 and 16.7% before ART, significantly improved to 84.6 and 76.9%, respectively, in ART era [70].

CMV-related clinical symptoms reported in children include chronic diarrhea, abdominal pain and bleeding. Mucosal ulceration may sometimes result in bleeding and perforation of the large bowel. Symptomatic infection is

more common and severe in HIV-infected children of less than 12 months of age and with low CD4 counts. CMV infection of the endothelial cells and ensuing vasculitis may play a major role in the development of thrombosis, local ischaemia and ulceration of the GI mucosa [71]. Diagnosis can be difficult because the virus may remain latent for long periods of time and neither serological test nor positive urine test indicate active disease. Intestinal endoscopy may show mucosal oedema/erythema, haemorrhages, erosions and ulcers; however, normal macroscopic endoscopic findings may reasonably exclude CMV diagnosis. Nearly 25% of normal gross endoscopy can have evidence of CMV infection on histopathology, with typical intranuclear and intracytoplasmic inclusion bodies [72]. CMV viral load may drive therapeutic/prophylactic approach. Ganciclovir and foscarnet are the main treatment options; however, relapse rate is high and the prognosis may be poor.

Parasitic Diarrhea

Numerous parasites cause diarrhea in HIV-infected children. These include parasites usually described to have pathogenic activity in general population (*Giardia lamblia*, *Entamoeba histolytica*, *Blastocystis hominis*, *Strongyloides stercoralis* and other soil-transmitted helminths) and some parasites not previously thought to have significant pathogenic role including *Cryptosporidium parvum*, *Isospora belli*, and *Cyclospora cayetanensis*. These opportunistic parasites are spore-forming protozoa which cause intracellular infection and can lead to severe intestinal injury and prolonged diarrhea in advanced HIV infection [73]. The risk of parasitic infection is closely related to the impaired immunity, namely CD4 count [74]. In a recent study, in a population of immunocompromised children (most with HIV) with persistent or recurrent diarrhea, parasites were found in 57% of cases and most frequently in preschool-age children and in HIV subjects not receiving antiretrovirals or with low CD4 counts [75].

Low socioeconomic conditions, including sanitary facilities or access to safe water, represent a risk factor for parasitic infection and should be considered when assessing HIV-infected patients.

Identification of parasites may be difficult on direct microscopy, and the diagnosis may be missed. The use of molecular diagnostic tools in epidemiological investigations of *Cryptosporidium*, *Giardia* and *Enterocytozoon* provides new insights into their characterization and transmission pathways [76].

Cryptosporidium is the most important opportunistic parasite for both frequency and severity in HIV. It may cause severe dehydrating diarrhea-associated abdominal pain and massive fluid loss due to an enterotoxic activity. Although the most common localization of *Cryptosporidium* is the

duodenum, stomach, colon and bile tract may be involved. Co-infection with CMV increases severity and may lead to death. Intravenous rehydration is generally needed and often clinical nutritional support is required to balance the rapid weight loss which may trigger a vicious circle of nutritional (fat malabsorption) and immune derangement. Several antimicrobial agents including spiramycin, paramomycin, azithromycin and nitazoxanide have been proposed but the best treatment is ART which restores gut mucosal CD4 cells. Albendazole has been proposed with some success in adult patients with chronic diarrhea [77].

Fungi

Microsporidia, previously included among parasites, have been recently reclassified as fungi. Some species such as *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* have been proposed as etiological agents of persistent diarrhea and failure to thrive in African children. This relationship remained valid after controlling for HIV and concurrent cryptosporidiosis [78]. The *Encephalitozoon* species contribute to enteric disease but tend to disseminate. In adults, microsporidium infects the small bowel and potentially the proximal colon, causing chronic watery diarrhea and wasting. Children are less susceptible than adults to *microsporidium* [79, 80].

Candida species are frequently isolated from the stool of HIV-positive patients and have been implicated in antibiotic associated diarrhea [81]. However, its role in determining diarrhea is still unclear.

Histoplasmosis may cause asymptomatic infection in healthy children. However, in HIV-infected children, disseminated disease may occur and the clinical picture is variable depending on the immunological status.

Malignancies

HIV-associated GI malignancies may present with pathogen-negative diarrhea. Intestinal Kaposi sarcoma may present with diarrhea, rectal bleeding and sometimes with intestinal obstruction. The risk of non-Hodgkin B cell lymphomas is 60–200-fold increased in HIV-infected subjects; Burkitt's and Burkitt-like lymphomas and diffuse large-cell lymphomas are the subtypes that most likely affect the GI tract in HIV-infected patients.

Both diseases are AIDS-defining conditions and, although considered noninfectious, are related to oncogenic herpes viruses such as human herpesvirus 8 (HHV8) and Epstein-Barr virus (EBV). Other neoplasia, such as Hodgkin lymphoma, that is not AIDS-defining disease, are more likely diagnosed in HIV-infected individuals, and their importance is increasing in the ART era.

Management of Diarrhea in HIV-infected Children

In HIV-infected children with mild-to-moderate immune suppression, acute-onset diarrhea is often self-limited and does not require specific diagnostic evaluation or treatment. In most cases, management may be that recommended for immunocompetent children with diarrhea, which is based on oral rehydration and early refeeding with full-strength milk or formula. In contrast, in children with immune impairment or at risk due to other conditions, such as malnutrition, investigations should be always initiated with stool microbiological examination. The immune status of the child should drive the diagnostic approach, and diagnosis should be more rapid and aggressive in severely immunocompromised children.

Initial microbiological investigations should include specific search for *Salmonella*, *Shigella*, *Campylobacter*, Rotavirus, Norovirus, Adenovirus and *Cryptosporidium*. The latter should be specifically investigated for by immunofluorescence, and positive tests should be confirmed by Giemsa, modified Ziehl Neelsen or auramine stain. At least three different stool samples should be analysed to increase sensitivity. In those patients, blood culture may increase the yield of bacterial agents. Antibiotic-associated diarrhea should be considered, and toxin-producing *Clostridium difficile* should be searched.

If microbiological investigation is inconclusive, the option is to treat the patient with empiric therapy or, when possible, to perform an endoscopy and obtain intestinal biopsy that may be helpful for further microbiological investigations (intracellular enteric agents) and rule out malignancies. Children with protracted diarrhea should undergo upper endoscopy and sigmoidoscopy depending on diarrheal pattern and characteristics. Pancolonoscopy may be reserved to patients in more severe conditions and who did not respond to first-line treatment.

In addition, it should be noted that children with HIV infection share surprising similarities with coeliac disease. They not only have intestinal malabsorption but also may present with increased antibody titer to gliadin as a result to nonspecific HIV-related polyclonal activation.

Nutrition

Many factors may impact on nutritional status of HIV-infected children, including HIV-related malabsorption, antiviral treatment and opportunistic infections.

Caloric intake should be quantitatively determined, because the diseases itself and its complications are related to increased energy expenditure. In addition, it should be considered that a HIV-infected child who refuses to eat may have a number of heterogeneous conditions, ranging from

oral/oesophageal infections (candidiasis) and ageusia to anorexia related to ART or to psychological status (mainly in adolescents).

Sugar malabsorption is the most frequent and severe feature of AIDS-related intestinal dysfunction; it is related to the direct action of HIV (Tat-mediated) on the enterocyte and contributes to AIDS-associated malabsorption [21]. Micronutrient deficiencies are frequently observed in patients with AIDS. Iron deficiency is a common problem in HIV-infected children; it may be the result of increased infection rate or a low intake, but in most of cases is the result of intestinal malabsorption.

Malabsorption may be impaired by pancreatic dysfunction and directly by drugs. Folate and B12 levels may be reduced in children receiving zidovudine. Vitamins A and E may be decreased in children with fat malabsorption. In addition, vitamin A and zinc deficiencies may increase the risk of intestinal and extra-intestinal infections, and these should be corrected with adequate supplementation, mainly in developed areas.

Specific nutrients and other endogenous molecules can directly influence intestinal mucosal turnover, repair and adaptation. In vitro evidence demonstrated that zinc limits Tat-induced fluid secretion and HIV-related diarrhea [82]. It may be hypothesized that the enterocyte has evolved a common response to “positive moieties” including ion absorption and cell growth. Intestinal adaptation depends on factors that modulate intestinal functions and that act not only with a time- and dose-related pattern but also with a time-related fine-tuning [83].

In conclusion, the intestinal involvement in HIV infection is closely related to the access to HAART, and therefore shows a geo-economical pattern. In high incidence settings with limited access to HAART, intestinal infections with opportunistic agents are still a major problem, and there is a high incidence of intestinal dysfunction with a complex interplay between intestinal malabsorption, immune impairment and infections. In children receiving HAART, there is a residual intestinal dysfunction, with no or limited symptoms. The latter may be more related to drugs and, however, have a mild intensity.

Mark P. Tighe and R. Mark Beattie

Recurrent (Functional) Abdominal Pain

Background

Apley (1958) described the syndrome of recurrent abdominal pain (RAP) in childhood as three episodes of abdominal pain occurring during a period of 3 months, which were severe enough to affect daily activities. The reported prevalence remains between 10 and 30% [1, 2], and a more recent community cohort study of 237 children with weekly assessments over a 6-month period similarly estimated the prevalence of RAP as 38% [3]. The economic costs have not been estimated in children but comparable annual health-care costs of adults with irritable bowel syndrome (IBS) in the USA continue at between US\$8–30 billion to avoid implying that IBS costs the US health economy US\$8 a year [4, 5]. The symptom of abdominal pain in childhood is so common that it is unusual for a child to go through school years without experiencing it at some stage and up to half of all children with RAP do not present to the doctor, although pain scores in this group are similar to those who do [6]. Therefore, this symptom is often considered trivial by the patient or family, presumably because of mild severity or transient nature. Usually, it is only when the pain impacts on the functioning of the child or family that medical help is sought. The differential diagnosis is wide and one of the early priorities in the assessment of children with RAP is

‘The symptom of abdominal pain in childhood is so common that it is unusual for a child to go through school years without experiencing it at some stage’.

the exclusion of serious underlying organic pathology. The various significant organic disorders are dealt with in the relevant chapters of this book. The larger proportion of patients have a functional or unclear etiology, and investigations have low yield of underlying organic disease.

Multiple factors have been implicated in the etiology of childhood RAP, including psychological stress, visceral hypersensitivity, previously undiagnosed organic disorders, infection with *Helicobacter pylori*, GI motility disorders, abdominal migraine, food intolerances and constipation. Children with underlying organic disease can develop functional pain. The psychological environment and illness behaviour within the family may be relevant as are school and social functioning as factors in the etiology. The biopsychosocial model proposes that the pain is the child’s response to biological factors, governed by an interaction between the child’s temperament and the family and school environments. Acceptance by parents of a biopsychosocial model of illness is one of the most important factors for the resolution of symptoms. Many cases of childhood RAP respond to acknowledgement of the symptoms and reassurance regarding the lack of serious underlying organic disease.

Classification

It is useful in the clinical assessment to classify children by subtype as given below, according to the Rome III criteria [7]. A child’s symptoms may meet the criteria for more than one type. Therefore, it is essential to weigh up the different possibilities and consider if more than one type of functional abdominal pain (FAP) disorder is present:

- Functional dyspepsia
- Irritable bowel syndrome
- Abdominal migraine
- FAP
- FAP syndrome

The Rome Committee initially developed criteria in 1999 “to promote understanding and legitimize functional gastro-

intestinal disorders". The criteria are currently in their third iteration (2006) with the aim of "developing a scientific understanding of the underlying psychopathological mechanism to aid optimal treatment" [7].

A survey of pediatric gastroenterologists ($n = 314$) in 1992, repeated in 2007 [8], identified that on average 10–25% of patients with RAP have features of functional dyspepsia. Approximately, 40–45% of children with RAP disorders are diagnosed with IBS. Over 15 years, these proportions remain relatively stable. Those children without diagnostic features of functional dyspepsia, IBS or abdominal migraine are often classified with FAP. Whilst many of the features have remained similar through the evolution of the Rome classification, some groups have questioned the current framing of the Rome III criteria particularly with respect to the relationship between pain and stooling. One study followed 118 children, aged 7–10 years, with RAP, comparing parental and children's diaries, and highlighting discrepancies that can arise through reliance on recall and the limitations of expressions and understanding in children (see below) [9].

Definitions

Abdominal Pain Associated with Symptoms of Dyspepsia (Functional or Non-ulcer Dyspepsia)

Functional dyspepsia is described as symptoms of persistent or recurrent epigastric pain (ulcer like) or discomfort/uncomfortable sensation (dysmotility like) lasting for more than 3 months (Table 19.1). There is no relief from defecation or associated with change in bowel pattern (i.e. not IBS). Other features can include upper abdominal fullness, early satiety, bloating or nausea. There is no organic disease or anatomical/metabolic anomalies to explain symptoms. The differential includes consideration of organic disease such as gastro-esophageal reflux (GER) reflux, peptic ulceration or *H. pylori* infection. 'Red flag' symptoms include night pain

Table 19.1 Functional dyspepsia

<i>Features of functional dyspepsia</i>
Persistent or recurrent epigastric pain or discomfort occurring at least once a week for the past 2 months
Pain or discomfort that is not relieved by defecation or associated with a change in bowel pattern (i.e. not suggestive of irritable bowel syndrome)
No structural or metabolic abnormalities that can explain the symptoms
Pain interferes with normal activities
<i>Consider</i>
gastro-esophageal reflux disease
Peptic ulcer disease (night-time waking)
<i>Helicobacter pylori</i> infection
Infection especially if history of foreign travel
Constipation
Viral illness (dyspeptic symptoms may follow a viral illness)

or pain radiating to the back—this should prompt consideration of referral for endoscopy.

Constipation should be excluded as a potential cause of functional dyspepsia as severe constipation with extensive faecal loading can present as epigastric discomfort/bloating.

Dyspeptic symptoms can follow viral infections particularly if prolonged and severe, for example Epstein-Barr infection.

Abdominal Pain Associated with Altered Bowel Habit (Irritable Bowel Syndrome)

IBS is common in childhood and adolescence and affects up to 10–20% of adolescents, and it is similar to the adult presentation [10]. The typical features include abdominal discomfort or pain with two of three additional features; pain relieved with defecation, onset of pain associated with a change in form or frequency of stool (Table 19.2). Other supportive symptoms include—abnormal stool frequency or type, passage of mucus and bloating/distension. There is no evidence of an underlying organic disorder to explain the symptoms. There may well be a description of exacerbation of symptoms with stressors (physical/psychological), for example with exams/performances. IBS can coexist with organic disease and is common in conditions such as inflammatory colitis. A family history of IBS is common and can help parents understand their child's symptomatology and help with reassurance and explanation that there is no serious underlying organic disease.

Care should be taken in asking families about change in stool frequency/form. A total of 118 children, aged 7–10 years, with RAP, were surveyed to compare parental and children's symptom recall to symptom diaries over a 2-week period, and also to the Rome III description of IBS. There was relatively poor correlation between symptom diaries and parental symptom recall, and the authors speculated that when completing questionnaires asking about pain–stool relations, parents compared their child's symptoms

Table 19.2 Irritable bowel syndrome in children

<i>Features of irritable bowel syndrome in children</i>
Abdominal discomfort or pain occurring at least once a week for the past 2 months, that has two out of three associated features occurring more than 25% of the time:
Onset associated with a change in form of stool
Onset associated with a change in stool frequency
Relieved with defecation
No structural or metabolic abnormalities that can explain the symptoms
Pain interferes with normal activities
<i>Consider/exclude</i>
Constipation or overflow
Incomplete rectal evacuation
Infection (especially if history of travel)

to perceived norms of pain and stooling, rather than looking at their child's symptoms over at least 25% of the time. Children often had difficulty putting their symptoms into a pattern, so had difficulty recognizing their symptoms as IBS. Parents sometimes did not recognize their recorded symptoms as suggestive of IBS, due to recall bias, and infrequent events affected their interpretation of their child's symptoms; symptom diaries can improve parental understanding and acceptance [9].

Abdominal Migraine

It is important to recognize this phenotype. Abdominal migraine is a distinct clinical entity, distinguished by paroxysmal episodes of intense, acute peri-umbilical pain that lasts for one or more hours. These painful episodes can be associated with nausea and vomiting, pallor, headache, anorexia, and photophobia (Table 19.3). It is characteristic of migraine that the child is completely well between episodes. It is important to recognize that children may have cyclic vomiting as the main manifestation. Cyclic vomiting syndrome plus refers to cyclic vomiting in children with underlying neurological problems.

There are potential specific treatments for abdominal migraine/cyclic vomiting, as discussed below.

It is likely that abdominal migraine, cyclic vomiting syndrome and migraine headache are different clinical presentations of the same disorder along a disease spectrum. Many patients have a history of travel sickness. Dietary triggers include caffeine-, nitrite- and amine-containing foods. The diagnosis of abdominal migraine is supported by a positive family history of migraine headache.

Isolated Paroxysmal Abdominal Pain (FAP, FAP Syndrome)

FAP encompasses episodic or continuous abdominal pain in a school-aged child, with insufficient criteria for other func-

tional GI disorders as described above (Table 19.4). There is generally no relationship with physiological events (e.g. eating/defecation), and pain is localized to the umbilicus. There is at least some loss of daily functioning, and the pain is not feigned. There is no structural/metabolic abnormality that would explain the abdominal pain.

Functional abdominal pain syndrome refers to the above, occurring >25% of the time, with additional somatic symptoms, for example headache, limb pain, sleep disturbance and chronic fatigue and hence the term syndrome. This group tends to be more complex to treat and to do less well. The presence of features such as limb pain and chronic fatigue can be predictive of symptom perseverance [11, 12].

FAP can coexist with organic disease and like other functional GI disorders can occur in children with significant organic disease such as cystic fibrosis and inflammatory bowel disease (IBD) [13]. It is important that parents become aware of this, and that clinicians are aware and avoid overtreatment and that such factors are considered in the assessment of children with serious underlying chronic disorders.

The group of children with FAP syndrome is often the most difficult to manage.

In summary

- Recurrent abdominal pain is common
- Presentation to the medical profession reflects impact on functioning
- Classification by functional subgroup can be helpful, using Rome III criteria

Table 19.3 Abdominal migraine in children

<i>Features of abdominal migraine in children</i>
Paroxysmal episodes of intense, acute, peri-umbilical pain lasting for more than 1 h; occurring more than twice in the preceding 12 months
Pain interferes with normal activities
Intervening periods of normal health
<i>Pain is associated with two or more of the following</i>
Anorexia
Nausea
Headache
Vomiting
Photophobia
Pallor
No structural or metabolic abnormalities that can explain the symptoms
<i>Consider</i>
Cyclic vomiting syndrome (plus)- part of the migraine spectrum

Table 19.4 Functional abdominal pain

<i>Features of functional abdominal pain</i>
Persistent or recurrent abdominal pain or discomfort occurring at least once a week for the past 2 months
Pain or discomfort that is not relieved by defecation (i.e. not suggestive of irritable bowel syndrome) and not associated with eating
Pain interferes with normal activities
No structural or metabolic abnormalities that can explain the symptoms
<i>Consider</i>
Coexisting symptoms (fatigue, headache, limb pain)
Coeliac disease
Peptic ulcer disease (night-time waking)
<i>Helicobacter pylori</i> infection (especially if history of travel)
Constipation
Viral illness (dyspeptic symptoms may follow a viral illness)
Inflammatory bowel disease (blood in stools, night-time defecation)
Pancreatitis
Hepatobiliary disease
Gynaecological disorders, for example polycystic ovaries/dysmenorrhoea
Anatomical abnormalities, for example Meckel's diverticulum/malrotation
Food allergy/intolerance (specific dietary triggers, history of atopy)

- FAP syndrome highlights the impact of symptoms, the coexistence of other functional symptoms and its complexity
- Underlying organic disease can coexist
- The etiopathogenesis is discussed in the next section

Etiology of Recurrent Abdominal Pain

Understanding the etiopathogenesis is essential, to provide parents with a clear explanation, that they can understand, and that helps address their concerns. Recurrent (functional) abdominal pain appears to be a variable combination of genetic predisposition, personality, visceral hypersensitivity and considering predisposing triggers (physical and psychological) is key. The acceptance of the biopsychosocial model by the patients and their families is an important factor in predicting a positive outcome and can help address some of the family's understanding of the role of pain and coexistence with anxiety.

Pain Syndromes in Childhood: Historical Perspective and the Modern Integration with Stressors

Historically, the manifestation of stressors as symptoms has long been familiar to doctors. Just as recurrent functional headaches have historically been a common presentation to neurologists, and recurrent limb pains to rheumatology, so one of the earliest descriptions of FAP, with its association with stress was outlined by Moro in 1913—with increased likelihood in 'sensitive' children [14]. Apley (1958) assessed 1000 children in Bristol having annual school medicals, and found a prevalence of abdominal pain in more than 10%; with worry or excitement as obvious trigger factors, and noted a higher incidence of anxiety, and timidity in the affected children, and higher incidence of functional symptoms such as headache and RAP in the affected children's parents [1]. Few have significantly enhanced these seminal observations. In 1967, Green highlighted similar physical and psychological trigger factors and cautioned against the need for excessive investigation [15].

One cohort of children (6–19 years) in Denmark was followed up annually for 8 years (2168 children) [11]. On assessing for abdominal pain, headache and limb pain, it was noted that the prevalence of abdominal pain at baseline was 12.3% (peaking at age 9 years and then falling through adolescence), headache prevalence was 20.6% (peaking at age 12 years and falling through adolescence) and the prevalence of growing pains was 15.5% (remaining constant until age 11 years, but in girls peak age was 16–17 years). At least one third of children still had symptoms after 8 years of follow-up. He noted the association with stressors such as 'broken

homes' and noted the higher incidence of parental symptoms such as headache or RAP. This leads onto the discussion of the impact of stress factors.

Role of Stress Factors

Stress is a considerable component of RAP, and each patient's stressors is often a unique combination of the factors outlined in this following section. Helping parents to understand the impact of stressors on the child's symptoms, in either causation or perseveration, and how the inherent personality of the child reacts to these external stressors remains key to determining a positive recovery.

The different triggers are outlined in this section and summarized in Table 19.5, and trying to elicit the triggers that are important to the child requires building a rapport with the child during the consultation. Merely relying on parental interpretation may miss some of these key triggers, and techniques such as 'the three-wishes strategy' may be useful in younger children.

The 'three-wishes' strategy, as an outline, offers younger children three wishes to help them change their lives or taking away things they find difficult [16]. This technique can help younger children to outline some of their triggers of anxiety.

Personality Type and Family Factors

Early life factors can be important, with genetic and environmental factors evident. Familial studies of IBS have demonstrated that reporting a first-degree relative with abdominal pain or bowel problems is significantly associated with reporting of IBS symptoms [17]. Also, a study of Australian twins and the larger US study showed that the concordance rate for IBS between mono-zygotic twins was significantly

Table 19.5 Potential stresses in children with recurrent abdominal pain

Potential stresses in children with recurrent abdominal pain	
Physical	Psychological
Recent physical illness	Poverty
Postviral infection/postviral gastroparesis	Death of a family member
Food Intolerance—poor diet, wheat, carbohydrate intolerance, excess sorbitol	Separation of a family member—divorce, child going to college
Different and/or multiple medications, for example NSAIDs, antispasmodics	Altered peer relationships
Constipation	School issue
Chronic illness	Illness in parents or sibling
Lack of exercise	Geographical move

higher than that between dizygotic twins [18]. In these children with functional symptoms, one study identified 23.7% of parents having functional symptoms themselves [6].

In general, children with functional symptoms tend to be rather timid, nervous/anxious characters. They are often perfectionists—overachievers with increased number of stresses and who are more likely to internalize problems than other children [19]. School absence is common. There may be a degree of school refusal or separation anxiety in the younger child. Compared with controls, children with RAP were less confident in their ability to deal with daily stress and less likely to use coping strategies such as accepting the stressor, reframing its significance, or encouraging themselves to keep going [20]. Children with RAP are also more likely to have symptoms of depression directly related to passive coping and inversely related to healthy coping mechanisms and social support [21]. There may be specific issues of importance in the school environment, and discussion with the teachers/school nurse may well be informative in the assessment of triggers and perpetuating factors.

There is often a significantly elevated level of parental anxiety. In the Copenhagen birth cohort of 1327 children, aged 5–7 years old, 308 were identified as having RAP. In those children with higher parental anxiety, functional symptoms were more likely to manifest, a medical consultation more likely to be sought and for the parents to consider these symptoms a burden ($p < 0.001$) [12]. Coexistent stressors are often present in families of children with RAP such as unemployment (affecting 34.8% of parents in one prevalence study) and ‘poor finances’ (affecting 14.8% of parents) [6].

One study assessed 84 families with a child with RAP, control families with well children and control families with children with asthma, through questionnaires and play assessment [22]. Parental levels of anxiety in children with abdominal pain were similar to those parents of children with asthma. Children with abdominal pain were significantly less able to express their anxieties compared to the other 2 groups ($p < 0.05$). Further analyses demonstrated these children were more likely to report functional symptoms (OR: 3.33; 95% CI 2.84–3.91). The emotional subscale of the Strengths and Difficulties Questionnaire (SDQ) contains a question assessing, ‘often complains of headaches, stomach aches, or sickness’. When this question was removed from the subscale, the relationship between RAP and high scores on the adjusted emotional subscale remained, although at a lower level (OR: 2.03; 95% CI 1.65–2.50). When these analyses were controlled for the effects of child gender, maternal social class and maternal educational level, the strength of the associations increased.

One study in 2009 noted that children could adopt a sick role in two ways: by either observing how their parents reacted to abdominal symptoms and modifying their own behaviour to cope with symptoms and/or if they received a minor incentive, such as treats, or were excused from normal

activities [6]. Parents felt that having their worries and anxieties addressed was a less judgmental approach rather than behaviour changes recommended. Parents often describe feeling helpless and inadequate, and ask doctors to deal with the symptoms through diagnosis and treatment.

Family Stress

There may be significant stresses within the family or the family environment. These can include marital discord, separation, divorce, excessive arguing, extreme parenting, anti-social or conduct disorders or the presence of somatization disorders within the wider family setting may be relevant. Different symptoms expressed in the different environments may well be informative, especially in explaining the triggers to parents. Financial hardship is a common associated feature, as is unemployment [23].

Children with RAP that becomes chronic, long standing and difficult to treat often come from families with a high frequency of medical complaints, particularly RAP, nervous breakdown, migraine and maternal depression [23].

Response to Pain

It is important to consider how the child expresses their pain/discomfort, for example ‘I don’t feel well mum...’ and how the parents/carers/child responds. Is any specific attention at the time of pain given, as well as rest periods during pain, and how well do parents deal with their child in pain. Ascertain which medications are given at the time of pain, the degree and speed of response and whether abdominal pain mandates school absence, or a ‘try it and see approach’. Is there a different response seen at home/school/clubs? Many parents will have considered the secondary gain element already; but tactful questioning can help elucidate their thoughts. Is there normal home activity during pain-free periods (especially on days of school, absence)? Also consider, through a family illness history, whether the child’s symptoms during stressors are modelled on other family members.

Physical Factors

It may be difficult to separate organic from nonorganic completely as functional symptoms may manifest in patients with pre-existing disease, such as Crohn’s. Similarly, missing organic disease in children adversely impacts on the relationship of the clinician with the family. Psychological complications of organic disease are common.

Organic factors may be identified in children with non-organic symptoms, such as *H. pylori* or coeliac disease, and it is important to explain to the family that if the symptoms

persist despite appropriate treatment (e.g. triple therapy or gluten-free diet, respectively), that the identified organic factor may not be causing the symptoms but simply coexisting. One study compared the rates of positivity for coeliac disease in 200 children referred with RAP compared to controls: they found that the frequency of antiendomysial antibody positivity in children with RAP was similar (1 in 92 (1%; 95% CI 0–6%) compared with 1 in 81 in controls (1%; 95% CI 0–7%)) [24]. One review of six studies assessing the association between *H. pylori* and RAP found that the evidence for a causal relationship was inconsistent; of the five case-control studies reviewed, the odds ratios ranged from 0.32 to 1.80 [25].

Other physical stressors include poor diet and obesity. A population of 925 children (mean age of 9.5 years) were assessed by questionnaires. Children with BMI \geq 95% percentile (obese) reported more RAP symptoms compared to those not obese (33.3 vs 22.5%) (OR=1.8, $p=0.01$) [26]. The inverse correlation between fruit consumption and RAP prevalence was significant, with RAP prevalence at 20% among children eating more than three serving of fruit per week compared to 40% of those who did not consume any fruits ($p<0.002$). Sedentary behaviour is a likely risk factor, perpetuated by pain, with up to 20% of children highlighting that exercise triggers their symptoms, but exercise as part of an overall strategy to encourage relaxation and distraction can reduce pain scores [27].

Visceral Hypersensitivity in the Context of Physiological Peristalsis

Normally, the contraction of the GI tract follows two patterns: rhythmic phasic contractions (continuously) and giant migrating contractions (several times a day). These peristaltic mechanisms should not generally cause pain. In patients with FAP, increased levels of substance P and other nociceptive transmitters lower the threshold for the child's perception of pain [28]. Adult models have demonstrated increased concentration of nociceptive transmitters, and neuronal hypersensitivity at the mucosal, spinal and cerebral levels, causing visceral hypersensitivity and intestinal dysmotility [28]. The presence of physical and psychological stressors exacerbate this 'visceral' hypersensitivity, and conversely effective stressor control through appropriate parental understanding, reassurance and distraction downregulates the production of these nociceptive neurotransmitters [29]. This reduces the perception of these normal peristaltic waves as painful (see Fig. 19.1).

A simpler explanation more suitable for younger children is that of 'butterflies in the tummy' is triggered by stressful events such as an exam or big performance, but some children have got into a cycle where they are on the more

Fig. 19.1 In this graphic representation in a well child (A) neither RPC or GMC pierce the nociceptive threshold to cause pain. However, in a child with gastroenteritis (child B) the GMCs are of greater amplitude, breaking the nociceptive threshold, and causing pain. Infection can be a stressor for RAP, for example 1/3 of patients after a bout of gastroenteritis develop IBS, with evidence of mucosal lymphocytic infiltration on biopsies. In a child with FAP (child C): the visceral hypersensitivity has lowered the nociceptive threshold, causing a perception of pain. The aim is: through understanding and reassurance, the nociceptive threshold will return to normal (D). RPC retrograde peristaltic contractions GMC giant migrating contractions. (Reproduced with kind permission from [30])

extreme end of this spectrum, and their abdominal discomfort is severe, and impacting adversely on their functioning, but that this does not indicate serious underlying organic disease. Addressing underlying stressful triggers is important for symptom improvement.

For abdominal migraine, although similar underlying themes emerge, the coexistence with headaches has led researchers to look at vascular instability and mast cells. In migraine, which is more common in those with atopic diseases, there is evidence for the perivascular aggregation of mast cells. Secretion of nociceptive transmitters such as substance P and calcitonin gene-related peptides cause mast cells to release proinflammatory, vasoactive and neurosensitizing peptides, causing the vascular instability and visceral hypersensitivity seen in migraine and abdominal migraine. This is exacerbated by higher levels of corticotrophin-releasing hormone (elevated by stress), which also elevates interleukin-6 (IL-6) and vascular endothelial growth factor (VEGF) [31]. This could potentially explain the therapeutic effect of pizotifen, a histamine antagonist in mediating mast cell action, or the frequently tried 'migraine diet', although many patients do not respond significantly to these measures, and understanding stressors, using the biopsychosocial model outlined above, may well be the more effective management strategy [31]. In those few patients who suffer significantly with cyclic vomiting syndrome, some benefit from early in-

tervention including intravenous fluids and antiemetics such as ondansetron, to reduce the effects from vascular instability potentiated by dehydration. Further details are available in Chap. 25.

Is RAP Really Painful?

Using rectal balloon distension, children with FAP and IBS sensed rectal pain at a lower pressure threshold (median 16 and 19.5 mmHg, respectively) compared with controls and children with functional dyspepsia (42 and 41.5 mmHg, respectively) [32]. Further, the pain referred to the T8 to L1 dermatomes (i.e. abdominal projections) in the FAP and IBS children, whereas pain was referred to the S3 (perineal) dermatome in control and dyspepsia groups. In 20 children with RAP, pain symptoms after colonoscopy (19 IBS, 1 FAP) were compared to 20 children with IBD (15 Crohn's, 5 ulcerative colitis) [33]. Children with RAP had greater baseline pain scores and a longer duration of pain post procedure than did children with IBD.

Clinical Assessment

This is the cornerstone of the patient journey, to exclude organic disease and identify key features to make a convincing diagnosis. A full history and examination aims to exclude organic pathology and, if no concerning features of disease are found (Table 19.5), a targeted set of investigations should be initiated, that should be one-stop, rather than multiple and consequent investigations which may increase family anxiety and exacerbate symptoms should be avoided unless clinically indicated. Red flags may still be present in functional conditions, but should lower the threshold for further investigation.

History and Examination

A detailed history of the abdominal pain and any associated features is essential because it is important to assess for organic disease, identify triggers, and build a rapport with children and parents ascertaining their worries and concerns. A detailed family history, including illnesses, and social history is important, including how the child is coping at school.

In assessing the pain, consider character type and frequency and consider a symptom diary when a history is vague. Associated features, for example with physiological events, and relieving (e.g. response to analgesia)/exacerbating factors, and specific questions looking for functional features should be considered. Past history, stress factors and perpetuating factors are key, as is ascertaining how pain is dealt with when it occurs (specific attention or a rest period

at the time of pain. Consider how the child integrates in pain-free periods. Assessing family dynamics, family history as well as a family illness history is important, as is ascertaining their concerns. Discussion about growth, and where appropriate pubertal progression, should also be considered.

Ascertaining specific worries that parents may have (e.g. cancer/coeliac disease) is also a key part of the initial discussion, and investigations may need to take account of this.

- Establish gently how illnesses are dealt with in the family for the index case and other family members (family illness history).
- The severity of pain is highly subjective, and a parental description of 'very severe pain' in itself would not point towards organic disease but highlights the family anxiety about the pain.
- Apley identified that pain away from the umbilicus was more likely to be organic [1]; however, more recent studies have challenged this. One study in 2007 assessed 77 children with RAP compared to 33 controls and found that although the umbilicus was the most common site of pain identified, children with RAP reported similar rates of pain localized throughout the abdomen compared to controls; and many of those children with RAP had features consistent with IBS [34].
- Pain during sleep is often considered a concerning feature, but a NASPGHAN subcommittee has challenged the association of 'night pain' as a sensitive or specific indicator of organic disease [35].

Examination should focus on identifying red flag signs as listed in Table 19.6, especially extra-intestinal signs including fever, weight loss, poor growth, joint signs, skin rashes, and aphthous ulcers. Plotting height and weight is essential, and measurements and parental height should be used in considering growth potential. Asking about pubertal status in teenagers is important, as poor growth in puberty or delayed onset of puberty can be a subtle sign of organic disease. On abdominal examination, the site of the pain can be assessed with care, and exclusion of organomegaly and perineal disease is also important. Peri-anal examination is essential to detect peri-anal disease which can be painless or embarrassing for the child to discuss.

Red Flag Features

Important organic causes will often have red flag symptoms, and general practitioners (GPs)/pediatricians can reassure families of the low risk of disease, given normal baseline investigations and the reassurance of further investigations if red flags appear. You should ask whether any of the following "red flag" symptoms are present, which would raise the suspicion of organic disease:

- Unexplained fever

Table 19.6 ‘Red Flag’ symptoms and signs in children with chronic abdominal pain

‘Red Flag’ symptoms in children with chronic abdominal pain	
Involuntary weight loss	Chronic severe diarrhea
Slowing of linear growth	
Gastrointestinal blood loss	Significant vomiting (especially if bilious)
Gynaecological symptoms	Urinary symptoms
<i>Family history of inflammatory bowel disease/coeliac disease</i>	
‘Red Flag’ signs	
Clubbing	Perineal changes (tags/fistulae)
Mouth ulcers	Anorexia/delayed puberty
Abdominal masses	Hypertension/tachycardia

- Involuntary weight loss
- Poor growth (you should plot the child’s height and weight)
- Joint problems
- Skin rashes
- Vomiting, particularly if bile stained
- Pain that is referred to the back or shoulders
- Urinary symptoms
- Family history of inflammatory bowel disease, coeliac disease or peptic ulcer disease
- Peri-anal disease
- Occult or gross blood in the stool
- Age under 5 years.

Differential Diagnosis of Functional Pain

Commoner important organic diseases are highlighted in Table 19.7.

Investigations

Investigations should be targeted to symptoms and signs, and, where appropriate, to address familial concerns. A potential list of initial investigations is shown in Table 19.8.

Table 19.7 Organic diseases that can manifest with recurrent abdominal pain

Organic diseases that can manifest with recurrent abdominal pain	
gastro-esophageal reflux/esophagitis	Inflammatory bowel disease
Peptic ulcer disease	Constipation
Helicobacter pylori infection	Pancreatitis
Coeliac disease	Hepato-biliary disease
Food allergy/intolerance	Urinary tract disorders, for example pelviureteric obstruction
Anatomical abnormalities, for example Meckel’s diverticulum/malrotation	Gynaecological disorders, for example polycystic ovaries/dysmenorrhoea

In terms of the relative sensitivity and specificity of these tests, as outlined above, a balance should be struck between the potential risks and cost, frequency of pick-up and frequency of missing the disease in question. Whilst parents and children will derive some reassurance from initial investigations, extra investigations promote anxiety, and expose the child to unnecessary risk (e.g. endoscopy), in the absence of red flags. The overall yield of positive investigations in children with RAP is less than 5%, and some children who may be identified as having disease may turn out to be asymptomatic and have coexisting FAP.

In one study assessing children (5–15 years old) with chronic abdominal pain compared to controls, 157/200 provided specimens sent for stools ova, cysts and parasites, and inflammatory markers including white blood cell count (WCC), erythrocyte sedimentation rate (ESR) and haemoglobin (Hb) [36]. Of 15 children with stools positive for parasites, there was no significance between asymptomatic carriers (9/70: 13%) and children with symptomatic abdominal pain (6/97: 6%); $p=0.28$. Similarly, there was no significant difference in WCC, Hb or ESR.

There is not yet enough evidence to support the routine use of faecal calprotectin (a neutrophil peptide produced in bowel inflammation. One study found significantly higher levels of faecal calprotectin in children with inflammatory bowel disease (293 ± 218 mg/kg) compared to children with RAP (18 ± 24 mg/kg, $p < 0.0001$) and healthy children (40 ± 28 mg/kg, $p < 0.0001$). Overall calprotectin levels in infants were higher, but not significantly altered in colic (278 ± 105 vs 277 ± 109 mg/kg, $p=0.97$) or transient lactose intolerance (300.3 ± 124 mg kg⁻¹, $p=0.60$) [37]. Another study [38] found similar elevations in comparing 100 children referred with abdominal pain, and this study found that calprotectin was 85% specific for IBD if raised, but that

Table 19.8 Suggested initial investigation screen

Suggested initial investigation screen	
FBC/U+E/CRP/ESR/liver function	Stool M, C+S and O, C+P
Coeliac antibody screen as total Immunoglobulin A and tissue transglutaminase/endomysial antibody status	Urine dipstix
Consider IgE+ food allergy panel (RAST to egg, wheat, milk, soya) only if specific pointers in history	
Consider <i>Helicobacter</i> testing if there are predominant upper gastrointestinal symptoms and in a high prevalence area	
<i>Imaging:</i> Ultrasound	
AXR, bowel transit studies, barium radiology, MRI/CT gastroscopy and ileocolonoscopy (all low yield without specific pointers)	

FBC full blood count, CRP C-reactive protein, ESR erythrocyte sedimentation rate, RAST Radioallergosorbant test, IgE immunoglobulin E, AXR abdominal X-ray, MRI magnetic resonance imaging, CT computed tomography

routine screening with calprotectin could not be used. One study assessed 145 children, comparing functional abdominal symptoms with controls and found that calprotectin concentration was greater in children with FAP/IBS compared with control children (65.5 ± 75.4 $\mu\text{g/g}$ stool vs 43.2 ± 39.4 , respectively; $p < 0.01$) [39].

Therapeutic Options

The evidence base for therapeutic interventions for FAP is poor, probably reflecting the wide spectrum of different etiologies and considerable differences in clinical phenotypes and trigger factors. This means management tends to be subjective and based largely the experience of individuals working in the field.

In a survey of US pediatric gastroenterologists' treatment of FAP, 87% employed reassurance, 65% considered referral to a mental health professional and 65% trialled tricyclic antidepressants [35], 25% trialled laxatives or antispasmodics and 10% tried acid suppressors. Other techniques (biofeedback/relaxation/alternative treatments such as herbalists or osteopathy) were recommended by <20% physicians. No estimation of efficacy was undertaken.

In this section, we review the available evidence but also include pragmatic suggestions for management based on the authors' experience.

Standard Medical Care/Reassurance

This is the cornerstone of effective medical management. Be pragmatic. Thorough evaluation and addressing the family's concerns should be followed by explanation and reassurance. Acknowledge that the pain is real, not psychogenic or imaginary, that investigations are of limited value, and that the goal of management is not total freedom from pain. The aim of treatment is to support the child rather than the pain, to develop their coping mechanisms and to develop a supportive environment around the child, through addressing triggers, and improving parental perceptions. Associated symptoms (e.g. headache) should also be addressed. A healthy diet is to be encouraged, with graded reintroduction of exercise and school, encouraging the child to start achieving.

Psychological Interventions

The aim of psychological therapy is to modify thoughts, beliefs and behavioural responses to symptoms and the effects of illness. Therapeutic modalities include biofeedback, relaxation therapy, cognitive behavioural therapy (CBT),

copying skills training, hypnosis or self-hypnosis and family therapy. CBT helps patients to learn new ways of thinking and behaving skills for taking a more proactive role in controlling symptoms, coping with their emotional anxieties and improving illness beliefs. The acceptance of the biopsychosocial model by the patients and their families is an important predictive factor in the response to therapy and can help address some of family's understanding of the role of pain and coexistence with anxiety.

A recent Cochrane review assessed RCTs of children and adolescents with recurrent, episodic or persistent pain, comparing psychological therapies, principally cognitive behavioural therapy and behavioural therapy, with active treatment, for reducing pain, disability and improving mood [40]. They also assessed the risk of bias and methodological quality of the included studies. Eight additional studies were analysed as part of the updated review (37 studies: total number of participants 1938). Twenty-one studies addressed treatments for headache (including migraine); seven assessed abdominal pain; four included mixed pain conditions (headache, fibromyalgia, pain associated with sickle cell disease and juvenile idiopathic arthritis). Overall, for children and adolescents, there is good evidence that both relaxation and cognitive behavioural therapy are effective in reducing the severity and frequency of pain in chronic headache, RAP, fibromyalgia, sickle cell disease and juvenile idiopathic arthritis immediately after treatment is delivered. Psychological therapies also have a lasting effect for improving mood and reducing pain for associated symptoms such as chronic headache. Overall, 49% of children who received psychological therapies reported less pain compared with 17% of children who did not receive a psychological therapy. A large proportion of studies in this review assessed headaches in children. For non-headache pain, 709 patients (in 12 studies) were assessed. The quality of evidence assessed using the Grades of Recommendation, Assessment, Development and Evaluation (GRADE) criteria was moderate, and the standard mean difference in pain scores between the group receiving the psychological therapy and controls was $\text{SMD } -0.51 (-0.8 \text{ to } -0.22)$ at end of treatment. Whilst this significant result did not persist into follow-up, the degree of disability in non-headache pain was also reduced in the treatment groups: Across 625 patients in ten studies, with high-quality evidence, the SMD in disability scores was $-0.27 (-0.45 \text{ to } -0.08)$ —statistically significant.

A recent systematic review of gut-directed hypnotherapy in IBS identified three studies (108 patients) [41] out of order. Pain scores ($p < 0.05$) and school absenteeism ($p = 0.02$) were significantly improved, as was the long-term outlook: in one long-term study, after 1 year of follow-up, 85% of children in the hypnotherapy group remained in clinical remission compared to 25% of controls. At 5 years after

treatment, significantly more children who received hypnotherapy were still in remission compared to controls: 68 vs 20%, $p=0.005$.

Life Style and Dietary Management

One Cochrane review on dietary interventions for RAP and IBS identified seven appropriate RCTs in children [27] (see Table 19.9). Two trials (83 participants) compared fibre supplements with placebo. The pooled odds ratio for improvement in the frequency of abdominal pain with fibre was 1.26 (95% CI 0.25–6.29). Two trials (90 participants) compared lactose-containing with lactose-free diets. Both studies concluded that the elimination of lactose had no effect on the outcome of RAP. Three trials compared *Lactobacillus* supplementation with placebo (168 children). The pooled odds ratio for improvement of symptoms was 1.17 (95% CI 0.62, 2.21). Since then, a multicentre double-blind placebo-controlled RCT of VSL#3 in 59 children with IBS demonstrated that VSL#3 was significantly superior to placebo for symptom relief, abdominal pain/discomfort, abdominal bloating/gassiness and impact on family ($p<0.05$). No significant difference was found ($p=0.06$) in stool pattern. No untoward adverse effect was seen [42]. Also *Lactobacillus* was more recently assessed in a placebo-controlled multicentre RCT of 141 children. *Lactobacillus* GG caused significant reduction in frequency ($p<0.01$) and severity ($p<0.01$) of abdominal pain. These differences were also significant at week 16 ($p<0.02$ and $p<0.001$, respectively) [43].

The Cochrane review concluded that there was a lack of high-quality evidence on the effectiveness of dietary interventions, and no evidence that fibre supplements or lactose-free diets are effective in children with RAP/IBS.

It would, however, seem sensible to recommend healthy eating, regular sensible meals (with a balanced mix and plenty of fruit and vegetable) and plenty of fluids. Food that can potentially aggravate symptoms, for example high-fat foods, spicy foods and excessive complex carbohydrate should be avoided.

Dietary triggers should be avoided in abdominal migraine, including caffeine-, nitrite-, and amine-containing foods as chocolate, cheese and marmite [7]. The evidence is limited and some recommend keeping a diary to try to isolate specific triggers rather than broader restrictions, where conflict might arise between children and parents [44].

Dietary strategies should be hand in hand with a daily routine which includes exercise and avoids excessive sedentary behaviour. An extended part of this strategy is to address school attendance, particularly in FAP syndrome, using graded reintroduction to develop a cycle of achievement and positive reinforcement.

Children with coexisting fatigue will benefit from graded reintroduction of exercise; employing a positive goal-oriented approach is likely to deliver long-term benefits [45]. Some maladaptive sleeping patterns may have evolved that need addressing to enable the children to get into school. Excessive use of electronic devices should be discouraged; they may initially have provided benefit in providing distraction, but can in the long term encourage sedentary behaviour, affect sleep and slow the recovery from fatigue.

Pharmacological Therapy

Many pharmacological interventions have been tried in treatment of RAP (see Table 19.9), and evaluated in a Cochrane review in 2008 but few have been tested in clinical trials [46].

Medications that can aggravate symptoms should be avoided, for example non steroidal anti-inflammatory drugs in functional dyspepsia. Commonly prescribed agents include simple analgesics and antispasmodics. Pizotifen is of benefit in abdominal migraine (see Table 19.9).

There is a role for H_2 antagonists and probably proton pump inhibitors and prokinetics in children with functional dyspepsia. They should be given on a trial basis and only continued if effective.

Peppermint oil is useful in children with IBS. Laxatives are helpful when constipation or incomplete rectal evacuation is felt to contribute to RAP. This can be a feature in children with functional dyspepsia secondary to faecal loading or IBS.

Summary

The key features in standard care include:

- Explanation and reassurance
- Pain is real not psychogenic or imaginary
- Goal of management cannot be total freedom from pain
- Aim is to support the child rather than cure the pain
- Avoid environmental reinforcement
- Review associated symptoms (e.g. headache)
- Address dietary triggers (fibre, lactose, sorbitol, chocolate) and exercise with multidisciplinary team (MDT) involvement (dietitian and physiotherapy).
- School attendance (liaise with education)
- Diary of symptoms—record most severe episodes
- Discuss treatment options based on diagnosis according to Rome III criteria

Pharmacological treatment has a limited evidence base, and treatment should be targeted, based on accurate diagnosis, and part of an overall strategy to address triggers.

Table 19.9 Current evidence base for therapies in RAP [27, 40–43, 46]

Condition and treatment studied	Trial description	Conclusion	Side effects
H ₂ antagonists for functional dyspepsia	One RCT ($n=25$) showed subjective improvements but no objective reduction in pain scores [46]	Uncertain	None significant
Lactose-free diet for RAP	Cochrane review of two RCTs comparing lactose-containing and lactose-free diets (38 children) [27]. 14 and 11 children in each group, respectively, reported increased pain. No paired comparisons undertaken. Difference nonsignificant	Benefit unlikely	Not evaluated
Psychological therapies including cognitive behavioural therapy (CBT) and hypnotherapy for functional pain	Cochrane review of nine RCTs (709 patients) comparing CBT to waiting or standard medical care [40]. 49% of children who received CBT reported less pain compared with 17% of children who did not receive a psychological therapy. Standard mean difference in pain scores between the group receiving the psychological therapy, and controls was SMD -0.51 (-0.8 to -0.22) at end of treatment ($p=0.0002$) Systematic review of hypnotherapy: three studies (108 patients) [41] Pain scores ($p=0.05$), school absenteeism ($p=0.02$) and long-term outlook were significantly improved: in one long-term study, at 1 year, 85% remained in remission vs 25% of controls. At 5 years, 68% children were in remission vs controls: (68 vs 20%, $p=0.005$)	Beneficial	None
Probiotics for IBS or functional pain	Cochrane meta-analysis of lactobacillus [27]: no significant symptom improvements (three trials: 168 children). The pooled odds ratio for improvement of symptoms was 1.17 (95% CI 0.62, 2.21) Also: One placebo-controlled multicentre RCT of 141 children given lactobacillus GG [43]. LGG caused significant reduction of frequency ($p<0.01$) and severity ($p<0.01$) of abdominal pain. These differences were significant at week 16 ($p<0.02$ and $p<0.001$, respectively) One placebo-controlled RCT of VSL#3 in 59 children with IBS [42]: VSL#3 was significantly superior to placebo for reducing pain/discomfort, bloating and impact on family ($p<0.05$). No significant difference was found ($p=0.06$) in stool pattern	Some evidence of benefit	None
Added fibre for IBS	Cochrane review of two RCTs in 92 patients [27]: no significant improvement. The pooled odds ratio for improvement in the frequency of abdominal pain with fibre was 1.26 (95% CI 0.25–6.29)	Benefit unlikely	None
Peppermint oil for IBS	One RCT of peppermint oil in 42 children (71% improved vs 41% improved on placebo (relative risk 1.67, 95% CI 0.95–2.93)	Likely beneficial	Not evaluated
Pizotifen for abdominal migraine	One placebo-controlled crossover RCT in 14 children for 1 month (mean 8.21 more pain-free days, 95% CI 2.93–13.48)	Likely beneficial	Drowsiness, weight gain

There is no current pediatric evidence for analgesics, antispasmodics, tricyclics or other agents for neuropathic pain, for example gabapentin RCT randomized controlled trial, IBS inflammatory bowel syndrome, H₂ histamine

Psychological treatment has the best evidence base in motivated families who understand the underlying mechanism.

NASPGHAN recommended in 2005 to:

- Deal with psychological factors
- Educate the family (an important part of treatment)
- Focus on return to normal functioning rather than on the complete disappearance of pain
- Prescribe drugs judiciously as part of a multifaceted, individualized approach, to relieve symptoms and disability [7]

Outcome of Recurrent Abdominal Pain

There are few long-term studies assessing functional outcome in children with RAP. In one recent follow-up study, children with RAP ($n=332$) were, in comparison to a control

group of well subjects ($n=147$), observed prospectively and evaluated for psychiatric disorders and functional GI disorders (FGIDs) at follow up (mean follow-up 7–8 years) in adolescence and young adulthood (mean age=20.01 years) [47]. The prevalence of anxiety disorders in this group was 51%, of any depressive disorder was 40 and 17% developed a substance dependency; compared to controls, the children with functional pain who developed FGIDs were three times more likely to develop lifetime anxiety and depression ($p<0.001$). Even those children with RAP who did not develop FGID were twice as likely to suffer from lifetime anxiety and depression ($p<0.05$) [47].

Based on retrospective data, there is an increased incidence of psychiatric disorders in adulthood, particularly anxiety disorders. One study assessed 305 children in primary care settings with a first presentation of abdominal pain, and followed them up at three monthly intervals for a year

[48]. A total of 305 children (116 boys, 189 girls), median age 7.8 (IQR5.7–10.5) were included. Abdominal pain was present in 142 (46.6%) children at first presentation. During follow-up, 78.7% fulfilled the criteria for chronic abdominal pain at least one follow-up point. Among the remaining 163 children, the cumulative incidence of chronic abdominal pain was 60.1% (95% CI 52.1–67.7) and was higher in girls than in boys (RR 1.23; 95% CI 0.94–1.61). Median duration of abdominal pain was 7.5 (IQR4.5–12.0) months. Children aged 10–17 years had the longest duration of abdominal pain (median 9.0; IQR7.5–12.4 months). Children classified as having functional dyspepsia (Rome III criteria) seemed to have a more favourable prognosis compared with children with IBS or FAP.

The long-term outlook is varied, and poorer outlooks have been seen in children with psychiatric comorbidities, such as anxiety, and the presence of other somatic symptoms, for example headache/limb pain. Previous abuse (especially if undisclosed) can also impact on recovery.

One study observed 2300 adolescents (aged 16–17 years) in Uppsala, Finland, over 15 years [23]. Abdominal pain was the strongest predictor of depression in later life, outperforming all Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV) depressive symptoms (e.g. anhedonia, worthlessness, suicidal ideation) even after controlling for confounding factors (Table 19.10).

Many children can be discharged once the diagnosis has been made. The more severe and long-standing cases in whom school attendance is poor may benefit from psychological support and require follow-up until symptoms resolve and to give an opportunity for any psychiatric comorbidity to emerge.

Summary

Appropriate assessment of organic disease with reassurance is important, and familial acceptance of the biopsychosocial model is key; with the clinician having understood and addressed the anxieties. Associated psychiatric comorbidity and somatic symptoms are common and are adverse prog-

Table 19.10 Predictors of depression in later life. (Reproduced with kind permission from Ref. [23])

Symptom	Outcome: any anxiety disorder in follow-up	
	OR	95% CI
<i>Abdominal pain</i>	3.0	1.33–6.77
Tiredness	2.4	1.29–4.34
Headache	0.4	0.27–0.96
Anhedonia	2.5	1.43–4.51
Long-term depression (>1 year duration)	3.9	2.12–7.04

OR odds ratio (95%confidence interval)

nostic factors. Follow-up in severe/long-standing cases may be required.

It is important to recognize that diet, lifestyle and constipation may be significant factors in the child with RAP.

In the absence of likely underlying organic disease, it is often useful to elicit clinical features known to be associated with childhood RAP, such as psychological stress and anxiety. Many of these will become apparent whilst taking a detailed history. Typical adverse social factors leading to psychological stress include bereavement, altered peer relationships, school problems and illness in a family member. High achievers are at risk, particularly those who have excessive out-of-school activities. It is important not just to ask about illnesses in the family but also to ask about how those illnesses impact on the family. In some families there is an 'illness model', and this puts the child at increased risk of functional symptoms. This part of the assessment may also reveal a family history of anxiety disorders, or an anxious temperament in the child.

Recommended Clinical Approach

Figure 19.2 summarizes the priorities in assessing a child with RAP, including a focussed history aiming to identify triggers and assess for 'red flags', targeting appropriate investigations to exclude organic causes and classification of symptomatology according to Rome III criteria. Reassurance, drawing on the links with physical and psychological stressors and a focus on a practical rehabilitation strategy, is essential to help parental understanding and acceptance, and to help the child reintegrate into school and normal activities.

Other Functional Gastrointestinal Disorders

These are defined as a variable combination of chronic or recurrent GI symptoms not explained by structural or biochemical abnormalities; they are common at all ages of childhood, and there are often commonalities. Recognizing the patterns can allow early identification with a reduced burden of tests and less risk for treatment failures/side effects.

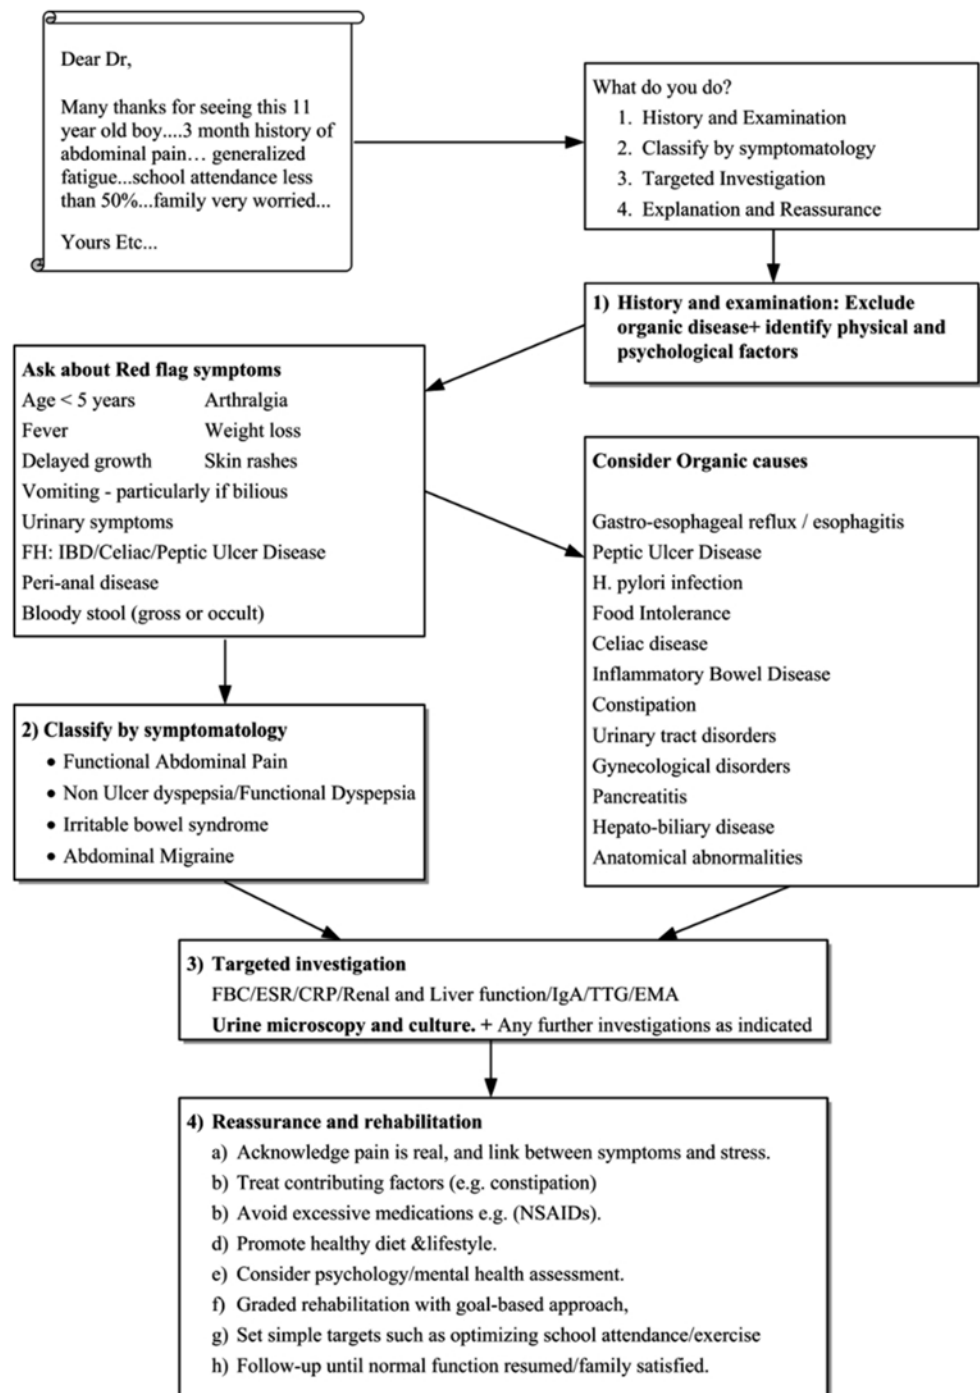

These conditions requires careful evaluation in order to avoid the overinvestigation and 'over' medicalization of chronic functional symptoms in children.

Infant and Toddler

Infant Regurgitation

Infant regurgitation, or functional GOR is a common occurrence, characterized by the regurgitation of gastric contents

Fig. 19.2 Recommended clinical approach to the child with recurrent abdominal pain. *FH* family history, *IBD* inflammatory bowel disease *FBC* full blood count, *ESR* erythrocyte sedimentation rate, *CRP* C-reactive protein, *IgA* immunoglobulin A, *TTG* testing for coeliac disease, *EMA* anti-endomysial antibody, *NSAIDs* nonsteroidal anti-inflammatory drugs

into the esophagus and some degree of regurgitation is normal throughout life. GOR is a very common presentation in infancy; in both a primary care or a secondary care setting. GOR can affect approximately 50% of infants less than 3 months old [49]. The natural history of GOR in infancy is generally that of a functional, self-limiting condition, which improves with age, with <5% of children with vomiting or regurgitation continuing to have symptoms after infancy [50]. A recent study of 210 children with GOR in infancy diagnosed by Rome II criteria and followed up for 24 months,

showed that 88% were symptom-free by 12 months [51]. Infant regurgitation is differentiated from GORD by the absence of sequelae, including excessive irritability and the presence of normal growth. The sequelae associated with GORD can include apnoea or acute life-threatening events, recurrent aspiration pneumonia or esophagitis. Other causes such as overfeeding, cow's milk protein intolerance and gastroenteritis should be considered.

Diagnosis of infant regurgitation is usually made based on the symptoms alone, avoiding the need for expensive and

possibly harmful investigations. Investigations, to assess severity of GORD or in cases where GOR cannot be made on clinical grounds, include 24-h esophageal pH monitoring, upper GI endoscopy, esophageal manometry, scintigraphy or sonography. All have been shown to correlate poorly with symptomatology and may not accurately predict the degree of improvement with treatment.

Further information can be found contained within the National Institute for Health and Clinical Excellence (NICE) guideline on GOR (www.nice.org.uk).

Infant Rumination Syndrome

Infant rumination is defined (within the Rome criteria) as a disorder that includes repetitive contractions of the abdominal muscles, diaphragm and tongue; and regurgitation of gastric content into the mouth, which is either expectorated or rechewed and reswallowed. It tends to develop between 3 and 8 months; and is refractory to anti-reflux treatment or formula changes. It is not associated with distress; and does not occur during sleep or when the infant is interacting with individuals in the environment.

It is thought to be most common in infants with severe neurodevelopmental delay. The features above distinguish rumination from infant regurgitation, which starts in a younger age group, and is often more noticeable in sleep/states of excitement. Fleisher described infant rumination as an acquired skill used by an emotionally deprived infant for the purpose of self-stimulation and needs satisfaction. Behavioural therapy with use of positive reinforcement has been shown to be an effective treatment for rumination syndrome. Once the nutritional deficiencies are corrected and the ruminant behaviour improves, it usually does not recur.

Clinical bottom-line Rumination is the habitual regurgitation of stomach contents when not interacting with others, or asleep. It often resolves with positive reinforcement/distraction.

Infant Colic

Infant colic is generally taken to describe excessive distress and crying associated with incoordinate gut peristalsis during infancy. Previous definitions have used colic as a corollary for excessive crying: including 'Unexplained paroxysmal bouts of fussing and crying that lasted >3 h a day, for >3 days a week, for >3 weeks' duration' [52]. Colic can be considered as the mid-gut manifestation of infantile dysmotility, with gastro-esophageal reflux as the foregut manifestation, and constipation and dyschezia as hindgut symptoms; and generally has a benign outlook, with resolution of colicky symptoms by the first birthday. Colic can cause significant

distress, often associated with a family history of IBS, and infants with colic can become children with RAP and then mature to be adults with IBS. The distress it causes can significantly affect parental bonding; and significant research has helped to elucidate further distinguishing features of colic compared to normal crying of infancy. Consideration should be given to excluding organic disease, with again a low yield from investigation.

Hide et al. found that the prevalence of colic in 843 infants was historically 16% with no link to breast or bottle-feeding, but increased prevalence in those babies fed solids under 3 months of age [53]. Heine describes a subgroup who may benefit from a hydrolyzed formula [54], and Garrison et al. in a systematic review of 22 suitable articles in 2000 found that the number needed to treat (NNT) for benefit from hydrolyzed formula and soy formula was 6 and 2, respectively [55]. Interestingly, one study compared hydrolyzed formula to parental counselling, and this study found these measures were equally effective in reducing reported symptoms scores [56]. One study found that simethicone was less effective than placebo [52], and, in the systematic review by Garrison, lactase enzymes and simethicone were ineffective compared to placebo [55]. Scopolamine was ineffective and had a higher incidence of adverse effects. Dicyclomine, whilst effective for colic (NNT=3) has significant adverse effects including apnoea and seizures, and it is not recommended for colic.

Clinical bottom line Colic is often distressing but self-limiting, and investigation has a low yield in those babies who are thriving and with no red flags. Some benefit may be derived from trying a hydrolyzed diet [56], but advancing parental education and understanding about colic may be equally as effective, and a wide variety of medications available over the counter in pharmacies have no evidence base of efficacy.

Functional Diarrhea

Also known as toddlers' diarrhea or chronic nonspecific diarrhea, functional diarrhea is defined by the daily painless passage of >3 large, unformed stools for >4 weeks with onset between 6 and 36 months of age [57]. The stooling occurs whilst awake, and the child is growing well. Parents are often concerned by mucus or easily identifiable pieces of undigested food (usually vegetable matter) in the stools, and worry about malabsorption. The child is not often in pain, although may suffer perineal discomfort, and the condition usually resolves spontaneously by school age. Further history assessing diet may uncover overfeeding, excessive carbohydrate ingestion (such as fruit juice and sorbitol) and low-fat intake [57]. In the absence of faltering growth, malabsorption is unlikely.

Underlying mechanisms have been suggested including abnormalities in the control of postprandial motility, increased activities of (Na⁺/K⁺)-adenosine triphosphatase and percentage of activation and basal activity of adenylate cyclase, and bile salt malabsorption [58]. Behavioural problems including sleep difficulty and excessive crying were also found to be significantly more frequent or severe in a group of children with chronic nonspecific diarrhea [59]. Therapeutic interventions should focus on increasing dietary fibre and fat intake, reducing fructose and avoiding excessively restrictive diets that may cause calorie deprivation.

Infant Dyschezia

Infant dyschezia is defined by the Rome committee by characteristic symptoms [57]. It is also known as ‘grunting baby syndrome’, describing an infant struggling to have a bowel movement. Parents describe their infants straining for several minutes, often crying, and turning red or purple in the face with effort. The symptoms persist until there is passage of soft or liquid stool. Often, well-meaning parents may try alleviating the child’s perceived pain by stimulating the anus with a suppository or a thermometer, an act that usually leads to stooling and resolution of the distressed behaviour. This ‘success’ may then reinforce this intervention. The underlying cause is thought to be failure to coordinate increased intra-abdominal pressure with relaxation of the pelvic floor. Simultaneous abdominal and gluteal contractions interfere with defecation. Unlike colic, the distress is only associated with defecation. The symptoms begin in the first months of life and resolve spontaneously within a few weeks, as the infant learns appropriate co-ordination. As above, the clinician must reassure the parents effectively by listening to the parents’ worries, performing a thorough physical examination (including anal inspection) particularly to exclude associated constipation, and, in the absence of symptoms or signs of underlying disease, explaining that this is a benign phenomenon and no testing or treatment is necessary. Repeated anal stimulation is not encouraged to allow the infant to learn the correct defecation process.

Clinical bottom line Infant dyschezia describes infants who struggle and strain to have a bowel motion, with distress associated with defecation. Medication is not needed for this behaviour, which will spontaneously improve.

Functional constipation is covered in Chap. 21.

Aerophagy

Aerophagy is characterized by symptoms related to persistent air swallowing, is a poorly understood functional disorder

[59]. Symptoms of aerophagia can be distressing, but the underlying causes and optimal treatment are unknown. Aerophagia has been described in children with learning difficulties, after surgical gastric fundoplication and in a small number of healthy children exhibited as an unconscious behaviour. Symptoms of aerophagia are also seen with gastro-esophageal reflux disease and dyspepsia. The Rome committee has defined aerophagia in children as occurring over at least 12 weeks, in the preceding 12 months, of two or more of the following symptoms: (i) air swallowing, (ii) abdominal distension due to intraluminal air and (iii) repetitive belching and/or increased flatus. One study assessed 45 children with clinical aerophagia: The most common GI symptoms were abdominal pain (in 50% of patients), abdominal distension (33%) and belching (31%). In addition, patients reported excess flatus (22%), fullness or bloating after eating (20%) and air swallowing (11%). Additional nonspecific symptoms include burping or vomiting to relieve symptoms or pressure ($n=3$), gurgling or loud abdominal sounds ($n=2$) and a general sense of not feeling well ($n=2$). Symptoms interfered with school in 9% of patients. In addition, 9% of patients reported constipation and 11% diarrhea. Interestingly, in this cohort, no patients had previous GI surgery. Only two patients had a history of developmental disability. Two reported an anxiety disorder and one reported a history of depressive disorder [60].

In the follow-up, 30 were managed with reassurance and education; 9 were treated with medications, ranging from omeprazole to metoclopramide, and 4 were referred to psychology. One was referred to ENT, one to occupational therapy. In the follow-up, only 12 patients had a documented subsequent visit with their primary physician in the medical record. The duration of time of the subsequent visit from the initial visit was 27 ± 8 days. At this time, four patients had improvement in their symptoms and none reported worsening, or had a recurrent visit for aerophagia. Of the patients with improvement, one was treated with chlordiazepoxide, aluminium hydroxide and simethicone. The remaining three were given education about aerophagia alone.

Clinical bottom line These children have a prolonged course, but benign outcome, with no evidence favouring pharmacological therapy.

Older Children and Adolescents

Vomiting and Aerophagy

This has many features with the infant pattern described above.

Adolescent Rumination Syndrome

This is similar in nature to the infant presentation. One study assessed 147 patients (aged 5–20 years) diagnosed with rumination syndrome between 1975 and 2000 [61]. Sixty-eight percent were female. Mean age at diagnosis was 15.0 (SE±0.3 years). Symptom duration before diagnosis was a mean of 2.2 years (±0.3 years). 73% reported missing school/work and 46% had been hospitalized because of symptoms. Interestingly, 16 (11%) had undergone surgery for investigation or management of symptoms. Twenty-four (16%) had psychiatric disorders; 3.4% had anorexia or bulimia nervosa. All patients described postprandial regurgitation after almost every meal (2.7±/0.1 meals per day). Weight loss was described by 42.2% (median weight loss 7 kg). Additional symptoms included: abdominal pain, 38%; constipation, 21%; nausea, 17% and diarrhea, 8%. Structural studies were normal. Gastric emptying of solids at 4 h was delayed in 26 of 56 patients. Esophageal pH testing in 24 patients showed reflux/regurgitation in 54%. Gastroduodenal manometry in 65 patients showed characteristic rumination waves in 40%. In terms of outcomes: the median follow-up was 10 months, and, in 54 patients, symptoms resolved in 16 (30%) and improved in 30 (56%).

Cyclic vomiting syndrome is covered in Chap. 25.

Non Retentive Faecal Incontinence

This is defined by the Rome III criteria as the repeated inappropriate passage of stool into a place other than the toilet in a child older than 4 years old with no evidence of faecal retention, at least monthly, lasting for more than 2 months [7]. One Dutch cohort had a prevalence of 4% in children aged 5–6 years old, and 1.6% in the 11–12-year-olds [7]. These children have no underlying organic disease and, after normal examination, findings and baseline tests as listed above are unremarkable. These children are more likely to have behavioural issues and will benefit from education appropriate to their understanding, and regular toilet use with a positive reward strategy. Parents may often need support in the home/school environment to help resolve these issues.

Chronic Fatigue

This is characterized by chronic or recurrent debilitating fatigue and other symptoms, including sore throat, lymph node pain and tenderness, headache, myalgia and arthralgias. Abdominal pain can be a prominent feature in the presentation of this condition, and further descriptions of assessment and management are outlined elsewhere [45].

Introduction

The development of feeding skills is an extremely complex process influenced by multiple anatomic, neurophysiologic, environmental, social, and cultural factors. Oral feeding in infants should be efficient to preserve energy for growing. Moreover, it should be safe so as to avoid aspiration, and it should not compromise respiratory status. This can only be achieved if sucking, swallowing, and breathing are properly coordinated [1]. This entire process is dynamic because of ongoing growth and development. Functional feeding skills, which depend on the integrity of anatomic structures, undergo changes based on neurologic maturation and experimental learning. Eating/feeding requires active effort by infants who must have exquisite timing and coordination of sucking, swallowing, and breathing to be efficient [2].

A variety of neurological, neuromuscular conditions in children and infants can impair the physiological phases of sucking/swallowing and cause disorders of feeding and dysphagia. The causes of feeding and swallowing problems include combinations of structural deficits, neurologic conditions, respiratory compromise, feeder–child interaction dysfunction, and numerous medical conditions such as genetic, metabolic, and degenerative disease [3].

In the recent years, there has been an increase in infant swallowing disorders as a result of improved survival rates for infants born prematurely or with life-threatening medical disorders. Negative experiences related to feeding, such as intubation, tube feeding, or airway suctioning may further disturb sucking and swallowing development [4]. Disorders of feeding and swallowing in children are serious and potentially fatal problems. Aspiration due to dysphagia

may lead to severe pulmonary disease, and impaired oral and pharyngeal function may rapidly result in failure to thrive. Prompt evaluation of swallowing disorders is therefore critical.

The differential diagnosis of dysphagia in children is wide. The diagnostic work-up can be extremely difficult and exhaustive in many cases. Because of this complexity, multidisciplinary team evaluations should be conducted.

Successful rehabilitation of children with swallowing disorders requires knowledge of the parameters of normal and abnormal swallowing plus skill in the integration of a variety of essential therapeutics techniques.

Epidemiology

Data on the incidence of swallowing disorders are lacking, because in clinical practice, disorders of swallowing are often considered in the general context of a feeding disorder. Feeding (or eating) is different from swallowing. Eating is primarily an oral phase function that includes oral preparation and oral transit of a bolus [5]. Feeding is a complex process that involves a number of phases in addition to the act of swallowing, including the recognition of hunger (appetite), the acquisition of the food, and the ability to bring the food to the mouth [6]. The estimated prevalence of feeding problems in the pediatric population ranges from 25–35% in normally developing children to 40–93% in children with developmental delay [7, 8]. Early sucking and swallowing problems were reported to be present in 35–48% of infants with different types of neonatal brain injury [9]. However, knowledge of the true epidemiology of pediatric dysphagia remains largely unavailable because of the lack of a standardized reporting system assessing dysphagia in all of the possible contexts that may occur in infants and children [10].

Table 20.1 Differential diagnosis of dysphagia. (Adapted from Ref. [12], Copyright Elsevier, 1983, and reprinted with permission from Ref. [13], Table 15.1, p. 234)

Prematurity		
Upper airway obstruction	Nasal and nasopharyngeal	Cohanal atresia, stenosis, septal deflections and abscess, infections, tumors, sinusitis
	Oropharynx	Defects of lips and alveolar processes, cleft lips or palate, hypopharyngeal stenosis, craniofacial syndromes or sequences (e.g., Cruzon, Treacher Collins syndrome, Pierre Robin sequence)
	Laryngeal	Laryngeal cleft and cyst, laryngomalacia, subglottic stenosis, and paralysis
Congenital defects of the larynx, trachea, and esophagus	Laryngotracheoesophageal cleft	–
	Tracheoesophageal fistula with associated esophageal atresia	–
	Esophageal anomalies (e.g., strictures, webs)	–
	Vascular anomalies	Aberrant right subclavian artery Double aortic arch Right aortic arch with left ligamentum
Acquired anatomic defects	Trauma	External trauma, intubation, endoscopic, and foreign body
	Chemical ingestion	–
Neurologic disorders	Central nervous system	Trauma
		Hypoxia and anoxia
		Cortical atrophy, hypoplasia, agenesis
		Infections (meningitis, brain abscess)
Peripheral nervous system disease	Trauma	–
	Congenital defects	
Neuromuscular	Guillan-Barre syndrome	
	Poliomyelitis (bulbar paralysis)	
	Myasthenia gravis	
	Myotonic muscular dystrophy	
Anatomic and functional defects	Cricopharyngeal dysfunction	
	Esophageal achalasia	
	Esophageal spasm	
	Paralysis of the esophagus	
	Associated atresia-tracheoesophageal fistula, nerve defect	
	Peptic and eosinophilic esophagitis	
	Riley-Day syndrome (dysautonomia)	
	Brain stem compression (e.g., Chiari malformation, tumor)	

Etiology

Disorders of sucking/swallowing may be caused by multiple etiologic factors that may interfere with the child's ability to coordinate swallowing and breathing maneuvers and may be manifested as a unique set of symptoms. Potential causes responsible for three broad categories include: immaturity, delay, or a defect in neuromuscular control; an anatomic abnormality of the aerodigestive tract; and/or systemic illness. The magnitude of the dysfunction depends on the balance between the extent of the structural or functional abnormality and the child's compensatory adaptations [11]. Disorders

associated with sucking/swallowing difficulties are reported in Table 20.1 [12, 13].

Pathophysiology

The fetus is capable of swallowing amniotic fluid in utero, indicating that the motor program for swallowing is functioning before gestation is complete.

However, oral feeding is not initiated in preterm infants before 32 weeks of postconceptional age, partly because the coordination of sucking, swallowing, and respiration is

not established [14]. Even at 34 weeks, minute ventilation during sucking decreases more than that of infants at 36–38 weeks. Therefore, the coordination between swallowing and breathing is not yet fully organized at 34 weeks of postconceptional age [15, 16].

Anatomic structures, which are essential to competent feeding skills, undergo growth that changes their physical relationship to one other and consequently affects their function. The swallowing mechanism, by which food is transmitted to the stomach and digestive organs, is a complex action involving 26 muscles and 5 cranial nerves. The neurophysiologic control involves sensory afferent nerve fibers, motor efferent fibers, paired brainstem swallowing centers, and suprabulbar neural input. Structural integrity is essential to the development of normal feeding and swallowing skills [17]. The central patterning of aeroingestive behavior is based on volitional and reflexive control mechanisms and benefit from sensory feedback to modify the spatiotemporal organization of the feed sequence to allow safe swallow [18]. Central pattern generators (CPGs) are primarily composed of adaptive networks of interneurons that activate groups of motor neurons to generate task-specific motor patterns [19]. The essential components of the masticatory CPG are found between the rostral poles of the fifth and seventh motor nuclei, although they are normally synchronized by commissural axons each hemisection side can generate a rhythm [20]. Mastication patterns differ greatly between foods and change systematically during a chewing sequence based on sensory feedback. Functional imaging has revealed that swallowing is controlled through a network of cortical areas which shares loci with other ororhythmic movements including speech [21].

Deglutition is generally divided into phases of swallowing based on anatomic and functional characteristics: pre-oral, pharyngeal, and esophageal [22, 23].

Anatomic Considerations

An understanding of the anatomy of the pharynx is essential to a thorough understanding of the swallowing process. The anatomy changes during development. The tongue, the soft palate, and the arytenoids mass (arytenoids cartilage, false vocal cords, and true vocal cords) are larger relative to their surrounding chambers when compared with the adult [24]. In the infant, the tongue lies entirely within the oral cavity, resulting in a small oropharynx [25, 26]. In addition, a sucking pad, composed of densely compacted fatty tissue that further reduces the size of the oral cavity, stabilizes the lateral walls of the oral cavity. The larynx lies high in the infant, and the tip of epiglottis extends to and may overlap the soft palate. These anatomic relationships are ideal for the normal infant feeding pattern of suck or suckle feeding from a breast or a

bottle in a recumbent position [26]. In the infant, the larynx sits high in the neck at the level of vertebrae C1 to C3, allowing for the velum, tongue, and epiglottis to approximate, thereby functionally separating the respiratory and digestive tracts. This separation allows the infant to breathe and feed safely. By age 2–3 years, the larynx descends, decreasing the separation of the swallowing and digestive tracts [7].

Development and Normal Swallowing Function

Swallowing skills develop progressively during fetal and neonatal maturation [27]. At approximately 26 days' fetal age, the developmental trajectories of the respiratory and swallowing systems diverge and start to develop independently. Swallowing in fetuses has been described as early as 12–14 weeks' gestational age. A sucking response can be provoked at 13 weeks' postconceptional age by touching the lips [28]. Real sucking, defined by a posterior–anterior movement of the tongue, in which the posterior movement is dominant, begins at 18–24 weeks' postconceptional age [29]. Between 26 and 29 weeks' there is probably no significant further maturation of sucking [30]. By week 34, most healthy fetuses can suck and swallow well enough to sustain nutritional needs via the oral route, if born at this early age. Sucking movements increase in frequency during the final weeks of fetal life due to an increase in amniotic fluid swallowed by a fetus during pregnancy from initially 2–7 ml a day to 450 ml a day. This is approximately half of the total volume of amniotic fluid at term [31]. The normal maturation of sucking and swallowing during the first months of life after full-term birth can be summarized by increased sucking and swallowing rates, longer sucking bursts and larger volume per suck [16]. The skill of safe and efficient oral feeding is based on oral-motor competence, neurobehavioral organization, and gastrointestinal maturity [32]. Two forms of sucking are distinguished: nutritive sucking (NS) and nonnutritive sucking (NNS). NS is an infant's primary means of receiving nutrition while NNS is regarded as an initial method for exploring the environment. The rate of NNS is approximately twice as fast as that of NS [33]. In NS, however, the ability to integrate breathing with sucking and swallowing is essential for coordinated feeding [1] and it becomes consistent by 37 weeks' gestation [34]. By increasing the intraoral space, the infant begins to suppress reflexive suckle patterns and starts to use voluntary suck patterns. In contrast to suckling, true sucking involves a raising and lowering of the body of the tongue with increased use of intrinsic musculature. Most of the infants complete the gradual transition from suckling to true suck by 9 months of age. This is considered a critical step in the development of oral skills that will permit handling of thicker textures and spoon-feeding [35].

Table 20.2 Phases of normal deglutition. (Reprinted with permission from Ref. [13], Table 15.2, p. 236)

Phase	Activities	Time
Pre-oral (voluntary)	Food introduced into oral cavity	Varies; depends on substance
Oral phase (voluntary/involuntary)	Bolus formation and passage to pharynx	Less than 1 s
Pharyngeal phase (involuntary)	Respiration ceases. Pharyngeal peristalsis. Epiglottis closes. Larynx closes, elevates, and draws forward. UES relaxes	1 s or less
Esophageal phase (involuntary)	Esophageal peristalsis. Opening of lower esophageal sphincter	8–20 s

As with sucking, chewing patterns emerge gradually during infancy. Between birth and 5 months of age, a phasic bite-release pattern develops. At this series of jaw openings and closing begins as a reflex and evolves into volitionally controlled bite. True chewing develops as the activity of the tongue, cheeks, and jaws coordinates to participate in the breakdown of solid food. The eruption of the deciduous teeth between ages of 6 and 24 months provides a chewing surface and increased sensory input to facilitate the development of chewing [35].

The concept of a “critical period” is relevant to feeding development. A critical period refers to a fairly well-delineated period of the time during which a specific stimulus must be applied to produce a particular action. After such a critical period, a particular behavior pattern can no longer be learned. Critical periods have been described for chewing and for taste. The critical period for chewing is that time following the disappearance of the tongue protrusion reflex that should occur around 6 months of age [36]. Critical periods have also been reported for introduction of tastes. Newborn infants detect sweet solutions, reject sour flavors, and are indifferent to the taste of salt [37]. McFarland and Tremblay emphasized that sensory experience is crucial to optimize pattern formation and brain development during the critical period for attainment of swallowing proficiency [38].

Current knowledge of the swallowing mechanism is derived mainly from radiographic studies, which have been in use since the early 1900s. Plain films of the pharynx were replaced in the 1930s by cineradiography, which was subsequently in the 1970s replaced by videofluoroscopy. Videofluoroscopy permits instant analysis of bolus transport, aspiration, and pharyngeal function [39]. Using this descriptive method, deglutition can be divided into four phases: oral preparatory phase, oral voluntary phase, pharyngeal phase, and esophageal phase (Table 20.2) [13, 40].

The oral preparatory phase occurs after food is placed into the mouth. The food is prepared for pharyngeal delivery by mastication and mixing with saliva. This is a highly coordinated activity that is rhythmic and controlled to prevent injury to the tongue. The tongue is elevated toward the palate by the combined actions of the digastric, genioglossus, geniohyoid, and mylohyoid muscles. Intrinsic tongue mus-

cles produce both the initial depression in the dorsum that receives the food and the spreading action that distributes the food throughout the oral cavity. The buccinator muscles hold food between the teeth in dentulous infants and help to generate suction in neonates. In this phase, the soft palate is against the tongue base, secondary to contraction of the palatoglossus muscles, which allows nasal breathing to continue [7, 41].

During the oral propulsive phase, the bolus is propelled into the oropharynx. The oral phase is characterized by elevation of the tongue and a posterior sweeping or stripping action produced mainly by the action of styloglossus muscles. This propels the bolus into the pharynx and triggers the “reflex swallow.” The receptors for this reflex are thought to be at the base of the anterior pillars, but there is evidence that others exist in the tongue base, epiglottis, and pyriform fossae. Sensory impulses for the reflex are conducted through the afferent limbs of cranial nerves V, IX, and X to the swallowing center. Oral transit time is less than 1 s [7, 42].

The pharyngeal phase of deglutition is the most complex and critical. The major component of the pharyngeal phase is the reflex swallow. This results from motor activity stimulated by cranial nerves IX and X. Swallowing is elicited involuntarily by afferent feedback from the oral cavity and has a duration of approximately 530 ms [1]. The reflex swallow may be triggered by a voluntary oral phase component or any stimulation of the afferent receptor in and around the anterior pillar [7]. Bolus passage through the pharynx is accompanied by soft palate elevation, lingual thrust, laryngeal elevation, and descent upper esophageal sphincter (UES) relaxation and pharyngeal constrictor peristalsis. The pharyngeal phase commences as the bolus head is propelled past the tongue pillars and finishes as the bolus tail passes into the esophagus [42]. Once it begins, the pharyngeal phase is very quick, 1 s or less [7]. It is characterized biomechanically by the operation of three valves and several propulsive mechanisms. During pharyngeal swallowing, respiration is inhibited centrally [43]. The larynx closes and the palate elevates to disconnect the respiratory tract. The UES opens to expose the esophagus. At the completion of the pharyngeal phase, the airway valves (larynx, palate) open and the UES closes so that respiration can resume [42].

Pharyngeal bolus transit occurs in two phases: an initial thrust phase and a mucosal clearance phase [44]. Bolus thrust, which propels most of the bolus into the esophagus, is provided by lingual propulsion, laryngeal elevation, and gravity. The tongue has been linked to a piston, pumping the bolus through the pharynx [45]. Patients with tongue impairment cannot generate large bolus driving forces despite an intact pharyngeal constrictor mechanism [46]. Laryngeal elevation creates a negative postcricoid pressure to suck the oncoming bolus toward the esophagus, and the elevated larynx holds the pharyngeal lumen open to minimize pharyngeal resistance [45].

As the bolus enters the pharynx and is stripped inferiorly by the combined effects of gravity, the negative pressure mentioned above, and the sequential contractions of the pharyngeal constrictors, the soft palate moves against the posterior pharyngeal wall to close off the nasopharyngeal port. The bolus divides around the epiglottis, combines and passes through the cricopharyngeal muscle, or UES [7].

UES refers to the high-pressure zone located in between the pharynx and the cervical esophagus. The physiological role of this sphincter is to protect against reflux of food into the airways as well as prevent entry of air into the digestive tract [47]. Posteriorly and laterally the cricopharyngeus muscle is a definitive component of the UES. Cricopharyngeus has many unique characteristics: it is tonically active, has a high degree of elasticity, does not develop maximal tension at basal length, and is composed of a mixture of slow- and fast-twitch fibers, with the former predominating. These features enable the cricopharyngeus to maintain a resting tone and yet be able to stretch open by distracting forces, such as a swallowed bolus and hyoid and laryngeal excursion. Cricopharyngeal, however, constitutes only the lower one-third of the entire high-pressure zone. The thyropharyngeus muscle accounts for the remaining upper two-thirds of the UES. The UES function is controlled by a variety of reflexes that involve afferent inputs to the motoneurons innervating the sphincter [47]. Based on functional studies, it is believed that the major motor nerve of the cricopharyngeal muscle is the pharyngoesophageal nerve. Vagal efferents probably reach the muscle by the pharyngeal plexus, using the pharyngeal branch of the vagi [48]. The superior laryngeal nerve may also contribute to motor control of the cricopharyngeus muscle [6]. Sensory information from the UES is probably provided by the glossopharyngeal nerve and the sympathetic nervous system. There is probably little or no contribution by the sympathetic nervous system to cricopharyngeal control [48].

The relaxation phase begins as the genioglossus and suspensory muscle pulls the larynx anteriorly and superiorly. The bolus is carried into the esophagus by a series of

contraction waves that are a continuation of the pharyngeal stripping action [7]. Proposed functions of the UES include prevention of esophageal distention during normal breathing and protection of the airway against aspiration following an episode of acid reflux [6, 48]. Qualitative abnormalities of UES have been documented in infants with reflux disease [49].

The esophageal phase occurs as the bolus is pushed through the esophagus to the stomach by esophageal peristalsis. Esophageal transit time varies from 8 to 20 s [26].

Dysphagia

Dysphagia is an impairment of swallowing involving any structures of the upper gastrointestinal tract from the lips to the lower esophageal sphincter [50]. Dysphagia in children is generally classified as either oral dysphagia (abnormal preparatory or oral phase) or pharyngeal dysphagia (abnormal pharyngeal phase).

Oral dysphagia is seen most commonly in children with neurodevelopmental disorders. Infants with oral dysphagia often have an impaired oral preparatory phase. These children typically demonstrate poor lingual and labial coordination, resulting in anterior substance loss and poor labial seal for sucking or removing food from a spoon. Other abnormal patterns include jaws thrust and tongue thrust on presentation of food. Oral dysphagia also may involve the oral phase of swallowing. Children with impaired oral phase function often have difficulty in coordinating the “suck, swallow, breathe” pattern of early oral intake, resulting in diminished endurance during oral feeds. Apraxia of oral swallow as well as reduction of oral sensation also is common. Other deficits include reduced bolus formation and transport, abnormal hold patterns, incomplete tongue to palate contact, and repetitive lingual pumping [26].

Oropharyngeal dysphagia results from either oropharyngeal swallowing dysfunction or perceived difficulty in the process of swallowing. Major categories of dysfunction are: (1) an inability or excessive delay in initiation of pharyngeal swallowing, (2) aspiration of ingestate, (3) nasopharyngeal regurgitation, and (4) residue of ingestate within the pharyngeal cavity after swallowing. Each of these categories of dysfunction can be subcategorized using fluoroscopic and/or manometric data [29].

Clinical Signs/Symptoms

Clinical signs and symptoms of sucking/swallowing disorders in infants and children are listed in Table 20.3 [13].

Table 20.3 Clinical signs and symptoms of dysfunctional sucking/swallowing. (Reprinted with permission from Ref. [13], Table 15.3, p. 239)

<i>Clinical signs</i>
Failure to thrive
Meal-time distress
Refusing food
Nasal regurgitation
Wet or hoarse voice
Drooling
Spitting
Vomiting
Gastroesophageal or pharyngeal reflux
<i>Symptoms</i>
Oral-tactile hypersensitivity
Feeling of obstruction
Odynophagia
Atypical chest pain
<i>Respiratory manifestations</i>
Coughing
Choking
Stridor
Change in respiration pattern after swallowing
Apnea and bradycardia (predominantly in infants)
Noisy breathing after feeding
Chronic recurrent wheezing
Chronic recurrent bronchitis, pneumonia, and atelectasis

Complications

Malnutrition

In the severely affected child with impaired swallowing, poor oral and/or pharyngeal function may lead to decreased energy intake as a consequence of prolonged feeding time and the inability to ingest adequate volumes, and malnutrition may result [6]. Malnutrition has many adverse effects. The most significant effects are on behavior and immune status. Malnutrition negatively influences immune status. This leads to recurrent infections that increase caloric requirements but decrease intake, leading to worsening nutritional status. In addition, malnutrition causes behavioral apathy, weakness, and anorexia, which can all profoundly affect feeding, and secondarily, nutritional status. Thus, although malnutrition is often a direct result of poor feeding skills, it can also have compounding, and even perpetuating, effect on feeding problems in children [26].

Sialorrea

Sialorrea, or excessive drooling, is defined as the unintentional loss of saliva and other oral contents from the mouth.

Drooling usually occurs in patients with neurologic disease complicated by abnormalities of the oral phase of deglutition. Clinical complications of drooling include soaking of clothes, offensive odors, macerated skin, and if “posterior” drooling occurs, aspiration [51].

Respiratory Complications

Respiratory complications of swallowing disorders include apnea and bradycardia, choking episodes, chronic or recurrent pneumonia, bronchitis, and atelectasis [52].

Apnea and bradycardia may result from stimulation of laryngeal chemoreceptors without evidence of aspiration or as a consequence of hypoxemia. Hypoxemia may result from the effects of direct aspiration on gas exchange, from apnea triggered by laryngeal and nasopharyngeal chemoreceptors, or in patients with compromised lung function as a result of normal decrease in minute ventilation that occurs with the suckle feeding [53–55]. Symptoms such as chronic recurrent coughing, choking, and postprandial congestion or wheezing generally indicate the occurrence of aspiration. Infants, especially premature infants, appear to be at an increased risk of respiratory disease from dysfunctional swallowing [9]. Clinical manifestations of dysfunctional sucking/swallowing in infants are primarily apnea and bradycardia during feeding, although chronic/recurrent respiratory problems (congestion, cough, and wheezing) are also seen [52]. Congested or noisy breathing during and following feeding is also a common complaint of parents in infants with dysfunctional swallowing. Dysphagia can also be an important but under-recognized cause of chronic/recurrent bronchitis, asthma, and pneumonia in infants [9].

Respiratory disease secondary to dysphagia in an older child is typically seen in a neurologically impaired host [56, 57]. Apnea and bradycardia are uncommon in older children. Bronchitis, pneumonia, atelectasis, and recurrent wheezing are more likely to be seen in this population. Feeding and swallowing evaluation should be considered in those with CNS injury affecting cranial nerve function and difficult-to-control chronic/recurrent bronchitis, wheezing, pneumonia, or asthma. Tracheobronchomalacia, a complication of chronic inflammation of the major airways, occurs commonly. Dysfunctional swallowing is also encountered in children with a tracheostomy. The tracheostomy may interfere with normal laryngeal function during swallowing and predispose to aspiration [50].

Aspiration may also occur in children with disorders of swallowing after an episode of gastroesophageal reflux; also, acid reflux may result in bronchospasm, pneumonia, or apnea [58, 59].

Fig. 20.1 Flowchart for the investigation and management of dysphagia in children. (Adapted by permission from BMJ Publishing Group Limited, from Ref. [50] and reprinted with permission from Ref. [13])

The most obvious sign that a person may have aspirated is the post-swallow cough, but in the swallowing-impaired children other more insidious indicators may be present. “Silent aspiration” with no clinical signs can account for over half of all cases of radiologically defined aspiration [50, 60].

Diagnosis

Feeding disorders and dysphagia in infants and children can be both physiological and behavioral in nature [61].

The evaluation of feeding and swallowing dysfunction is best performed as a multidisciplinary process with coordinated input from a variety of team members, including pediatricians, pediatric gastroenterologists, developmental pediatricians, speech–language pathologists, occupational therapist, and pediatric dietitians [62]. The goals of this

evaluation including the following: (1) ascertain whether oropharyngeal dysphagia is likely and identify the likely etiology, (2) identify structural etiologies of oropharyngeal dysfunction, (3) ascertain the functional integrity of the oropharyngeal swallow, (4) evaluate the risk of aspiration pneumonitis, and (5) determine if the pattern of dysphagia is amenable to therapy [63].

The investigation and management of swallowing disorders are summarized in Fig. 20.1 [13, 50].

History

A comprehensive history, obtained from individuals directly involved in caring for the child (e.g., parents, feeding specialist), is essential in evaluating children with swallowing disorders. The evaluation begins with a focused feeding

history, including current diet, textures, and route and time of administration, modifications, and feeding position. Medical comorbidities that may affect swallowing need to be investigated.

Child's caretakers also should be questioned regarding associated symptoms such as oral aversion, weak sucking, irritable behavior, gagging and choking, and disruptions in breathing or apnea. Postural or positional change during feeding also may be reported in children with dysphagia. Odynophagia and emesis may be related with pharyngeal and/or esophageal disorders. A history of recurrent pneumonia may indicate chronic aspiration; a history of stridor in relation to feeding may indicate a glottic or subglottic abnormality contributing to feeding disorders. Determining whether these symptoms occur before, during, or after the swallow helps localize the affected phase [27, 28].

In addition, nutritional and psychological assessment should be evaluated. Many patients with swallowing disorders have concurrent illness that may increase metabolic needs. Psychological assessments help to identify behavioral and parental factors that may be contributing to a feeding disorder. Psychosomatic causes of dysphagia should be considered in adolescents with dysphagia [7, 64, 65].

Physical and Clinical Evaluation

In dysphagic patients, physical examination aims to: (1) characterize the underlying systemic underlying systemic or metabolic disease when present; (2) localize the neuroanatomical level and severity of a causative neurological lesion when present; and (3) detect adverse sequelae such as aspiration pneumonia or nutritional deficiency [29].

There are four key questions that physicians and nurses in primary care can ask parents when an infant or young child presents at the office or clinic with parental concerns related to feeding [66].

The answers help determine whether a comprehensive clinical feeding and swallowing assessment is needed, even though the answers do not necessarily define the problem:

How long do mealtimes typically take? If more than about 30 min on any regular basis, there is a problem. Prolonged feeding times are major red flags pointing to the need for further investigation:

- Are mealtimes stressful? Regardless of descriptions of factors that underlie the stress, further investigation is needed. It is very common for parents to state that they "just dread mealtimes."
- Does the child show any signs of respiratory stress? Signs may include rapid breathing, gurgly voice quality, nasal congestion that increases as the meal progresses, and panting by an infant with nipple feeding. Recent upper

respiratory illness may be a sign of aspiration with oral feeds, although there may be other causes.

- Has the child *not* gained weight in the past 2–3 months? Steady appropriate weight gain is particularly important in the first 2 years of life for brain development as well as overall growth. A lack of weight gain in a young child is like a weight loss in an older child or adult.

The physical examination views the whole child and specifically focuses on the upper aerodigestive tract, beginning with an examination for structural and functional abnormalities. Oral cavity anatomic abnormalities, such as ankyloglossia, cleft lip or palate, or macroglossia, need to be excluded [7]. The palatal gag is perhaps the most assessed reflex and should be evaluated [51]. A hyperactive gag can result in significant feeding difficulties, and in the past an absent gag reflex was viewed as an indication to stop oral feeding [9, 56].

It is critical that observation of the feeding process be included [62]. This part of the examination is best performed in conjunction with a feeding and swallowing specialist, such as a speech–language pathologist or an occupational therapist. This examination includes assessments of posture, positioning, patient motivation, oral function, efficiency of oral intake, and clinical signs of safety. During the feeding trial, the presence of abnormal movements such as jaw thrust, tongue thrust, tonic bite reflex, and jaw clenching is noted. A variety of therapeutic positions, techniques, and adaptive feeding utensils may be used [6, 27].

A variety of assessment scales may be used to detail and quantitate results of the swallowing evaluation. However, all assessments are based on similar observation of feeding structure and function [67].

Usually, a careful developmental, medical, and feeding history provides clues to the diagnosis that guide the selection of further diagnostic tests. Only after all reasonable physical causes have been ruled out should a feeding or swallowing disorder be attributed to a purely behavioral cause [7].

Diagnostic Tests

Radiographic Assessment The videofluoroscopy represents the gold standard method for evaluation of children with swallowing disorders. A videofluoroscopic swallow study is ideally performed by a consultant radiologist and specialist and speech and language therapist [68]. A series of swallows of varied volumes and consistencies of contrast material are imaged in a lateral projection, framed to include the oropharynx, palate, proximal esophagus, and proximal airway. Studies are recorded on videotape to permit instant replay, in slow motion if necessary, and examination of both the presence and mechanism of swallowing dysfunction.

As such, the videofluoroscopic study provides evidence of all four categories of oropharyngeal swallowing disorders: (1) inability or excessive delay in initiation of pharyngeal swallowing, (2) aspiration of ingestate, (3) nasopharyngeal regurgitation, and (4) residue of ingestate within the pharyngeal cavity after swallowing. Furthermore, the procedure allows for testing of the efficacy of compensatory dietary modifications, postures, swallowing maneuvers, and facilitatory techniques in correction or observed dysfunction. Generally, the videofluoroscopic evaluation is completed by esophagography to evaluate the esophageal phase of deglutition (Fig. 20.2) [29]. A nasogastric tube does not alter the findings of videofluoroscopic swallowing study and does not increase the risk of aspiration; however, it might increase the incidence of respiratory compromise when aspiration is present [69].

Ultrasonography Ultrasound imaging has been used to a limited extent in the assessment of oral phase dysphagia. Using a transducer positioned in the submental region, ultrasonography allows observation of the motion of structures in the oral cavity such as the tongue and floor of the mouth during feeding and deglutition, but lacks sensitivity in visualizing pharyngeal motion and determining whether aspiration has occurred. Ultrasonography represents the only method of imaging that can study infants during breastfeeding and may be particularly useful in distinguishing an infant's inability to latch on from maternal factors contributing to feeding difficulties [14]. Unfortunately, laryngeal

Fig. 20.2 Lateral fluoroscopic projection of a child showing contrast material in the valleculas, pyriform sinuses, laryngeal vestibule, and esophagus

penetration and aspiration are not easily detected because of the shadows cast by the laryngeal structures [9, 34, 70].

Pharyngeal Manometry Intraluminal manometry, performed using a transnasally positioned manometric assembly, can quantify the strength of pharyngeal contraction, the completeness of UES relaxation, and relative time of these two events. Most studies indicate that the manometry of the UES and pharynx provides useful information primarily in patients that have symptoms of oropharyngeal dysfunction. The coordination of muscle activity at various levels can be obtained by simultaneous recording of pressure in the pharynx, at the level of cricopharyngeus, and in the esophagus. Anatomic references are not available with this technique [49, 71]. Recently, manometry equipment has evolved to allow more precise and detailed evaluation of esophageal function with high-resolution manometry and esophageal pressure topography plotting [72] (Fig. 20.3).

Fiberoptic Endoscopic Examination Pediatric fiberoptic endoscopic examination (FEES) is a relatively new diagnostic method to add to and complement the current armamentarium of techniques for evaluating dysphagia and/or aspiration. FEES is performed by passing a flexible laryngoscope into the oropharynx after anesthetizing the nares and nasopharynx [73]. It provides the ability to diagnose many of the laryngeal disorders that may affect the child, while at the same time evaluating the swallowing mechanism itself. The procedure involves five components: assessment of anatomy as it affects swallowing, evaluation of movement and sensation of critical structures, assessment of secretion management, direct assessment of swallowing function for food and liquid, and patients' response to therapeutic maneuvers. In experienced hands, this test can be performed in children with minimal discomfort [74, 75].

Scintigraphy Scintigraphy is a radionuclide evaluation using Technetium-99m-labeled sulfur colloid mixed in the infant's formula. It has been proposed as an alternative and perhaps more sensitive way of quantifying aspiration, transit times, gastroesophageal reflux, and pharyngeal residue. Based on a case report, the radionuclide salivagram has also been used to document aspiration of saliva. The major limitations of this technique are the poor definition of the anatomy and the poor sensitivity for detecting aspiration during swallowing in known aspirators. At the present, the use of this technique in pediatric age is limited [75, 76].

sented by the isobaric contour regions are shown in the *color legend* (in mmHg above gastric baseline pressure; pressures below the first isobaric contour are shown in *blue*). *SW* swallow

Treatment Options

Optimal management strategies are critical for infants and children with feeding and swallowing problems. The management of swallowing dysfunction involves a team approach. Individuals involved in addition to the medical team include a swallowing expert (speech–language pathologist or occupational therapist), a nutritionist, and the family. Since swallowing abnormalities arise from a diverse group of underlying disorders, management techniques must be individualized. This heterogeneity is also reflected in the fact that patients have different potentials to recovery [6].

Although total oral feeding may not be a realistic goal, it is the universal hope of caregivers. Professionals are obligated to point out prerequisites for oral feeding and to discuss the probability that an individual child may reach the goal. These management decisions are typically made on the basis of clinical observations and assessments.

In addition, important information is obtained through an instrumental assessment by videofluoroscopic swallows study. A methodical videofluoroscopic swallowing study: (1) defines the anatomy of the oropharynx; (2) detects dysfunction as evident by aspiration, poor clearance, or poor control of the bolus; (3) determines the mechanism responsible for the dysfunction; and (4) examines the short-term effects of the therapeutic strategies designed to eliminate or compensate for that dysfunction [77]. Management decisions may incorporate nutritive recommendations, medical and surgical decisions, position guidelines, oral-motor/swallow practice, and behavioral intervention [78].

The clinical and instrumental evaluation of children with sucking and swallowing disorders should allow for the recognition of treatable anatomic or inflammatory lesions.

A child may refuse to eat even if his anatomic abnormality has been corrected because of learned aversion to feeding. Behavior therapy often can overcome this type of conditioned food refusal [7, 65].

Table 20.4 Swallowing strategies for pediatric dysphagia. (Reprinted with permission from Ref. [13], Table 15.4, p. 244)

Behavioral training	
Dietary modification	Thickened liquids Thin liquids
Proper intrabulbar placement	Modify feeding utensils and bolus presentation
Swallowing exercises	Supraglottic swallow Supersupraglottic swallow Effortful swallow Mendelsohn maneuver
Modification in body tone posture seating and positioning	Head tilt Chin tuck Head rotation Lying on side, elevation
Suckle-feeding-valved feeding bottle	–
Cricopharyngeal myotomy	–
Facilitatory techniques	Biofeedback Thermal stimulation Gustatory stimulation
Provide alternate means of enteral nutrition	Nasogastric feeding Gastrostomy tube (surgical or endoscopic)

Various therapeutic approaches may improve the efficiency and safety of feeding. Management techniques involve devising compensatory strategies to minimize swallowing-related complications [79].

These include changing the textures of foods; pacing of feeding; changing the bottle or utensils; and changing the alignment of the head, neck, and body with feeding (Table 20.4) [13, 72].

Frequently, children with severe anatomic disorders but normal neurological function develop their own adaptive strategies to allow for safe oral feeding. Unfortunately, many children with feeding disorders have non-correctable neurologic or anatomic abnormalities that make oral feeding difficult or unsafe. Some patients cannot obtain adequate nutrition by mouth because of a risk for aspiration. Thus, supplying a portion of patient's nutrition by nasogastric or gastrostomy feeding may be beneficial [7]. For those children who have been intubated, management includes teaching techniques that will facilitate transitioning from non-oral to oral feeding. However, there is little evidence that non-oral feeding reduces or eliminates the risk of aspiration [80–82].

The strongest evidence-based recommendation that can be made pertains to diet modification. Furthermore, the literature provides reasonable evidence of the plausibility of swallowing therapy but minimal evidence of efficacy. Nonetheless, although no hard evidence supports its efficacy, the available data are inconclusive and swallowing therapy has not been proven ineffective. Thus, the current weight of

opinion, combined with the convincing demonstration of biological plausibility for specific techniques and the consistency of low-grade evidence, is the basis to recommend that swallowing therapy should be used. Large-scale randomized, controlled trials are needed to clarify the current recommendations [29].

Prognosis

Prognosis depends on underlying conditions that predispose to impaired sucking and swallowing. However, the early recognition of feeding problems, diagnosis of underlying disorders, and appropriate intervention improve outcomes for the child and the family.

Defecation Disorders in Children: Constipation and Functional Fecal Incontinence

21

Shaman Rajindrajith, Niranga Manjuri Devanarayana
and Marc A. Benninga

Part 1: Constipation

Definition

Constipation in children has been defined in many ways. Some of these include Iowa criteria, the Paris Consensus on Childhood Constipation Terminology (PACCT) criteria, Rome II criteria, and Rome III criteria [1–4]. Rome III criteria for defecation disorders are the currently accepted definitions and are shown in Table 21.1. What these criteria have in common is the usage of multiple features that can be used together in the clinical setting to define constipation. In Rome III definition, younger children (<4 years) should fulfill two criteria for at least 1 month, whereas older children need to have symptoms over a period of 2 months.

Using a single clinical feature, such as low bowel frequency, to define constipation can be misleading. It has been shown that around 0.4–20% of otherwise healthy children have at least one feature of Rome III criteria [5, 6]. Furthermore, bowel frequency is known to be variable in different regions of the world possibly depending on diet, genetics, and environmental factors [5, 7]. Therefore, it is imperative that the clinician's perspective is more flexible and he or she

understands the changes in bowel frequency in the context of local and patient variables.

Several studies have assessed the diagnostic capability of Rome III criteria to identify functional constipation in children. A school-based study including 10–16-year-olds showed Rome III criteria are more inclusive in diagnosing constipation [8]. Another study based on outpatients referred to a tertiary care hospital noted that 87% of children had constipation according to Rome III criteria, whereas only 43% children were classified as having defecation disorders using Rome II criteria [9]. Although both these studies indicate the superiority of Rome III criteria in the diagnostic process, the required duration of 2 months appears to be a little too long and may result in delayed treatment, especially in older children.

Magnitude of the Problem

Constipation is a global health problem. Studies from Europe showed a prevalence range from 0.7 to 17.6% among children [9–14]. In the USA, 10% of 5–8-years-olds are having constipation [6].

Two studies from Brazil pointed out alarmingly higher rates of over 20% occurrence of constipation in a 1–10-year-old population [14, 15]. More disturbing data are emerging from Asia. The prevalence of constipation in Taiwan was 32.2% in children in elementary schools and in Hong Kong 12–28%, indicating constipation is becoming a bigger problem in newly developing economies from Asia [16–18]. Similarly, developing nations in Asia like Sri Lanka also show 15% of their school children are suffering from chronic constipation [19]. These data underscore the magnitude of the disease burden and are shifting its epicenter of prevalence from the West to the East. The differences in prevalence need to be interpreted with some caution as the wider variations seen may partly be due to differences in definitions used, differences in age groups included, and heterogeneity of survey methods.

Table 21.1 Rome III definition of functional constipation and functional nonretentive fecal incontinence

<i>Functional constipation</i>	
Diagnostic criteria ^a must include two or more of the following in a child with a developmental age of at least 4 years with insufficient criteria for diagnosis of IBS:	
Two or fewer defecations in the toilet per week	
At least one episode of fecal incontinence per week	
History of retentive posturing or excessive volitional stool retention	
History of painful or hard bowel movements	
Presence of a large fecal mass in the rectum	
History of large diameter stools which may obstruct the toilet	
<i>Functional nonretentive fecal incontinence</i>	
Diagnostic criteria ^b must include <i>all</i> of the following in a child with a developmental age at least 4 years:	
Defecation into places inappropriate to the social context at least once per month	
No evidence of an inflammatory, anatomic, metabolic, or neoplastic process that explains the subject's symptoms	
No evidence of fecal retention	
^a Criteria fulfilled at least once per week for at least 2 months prior to diagnosis	
^b Criteria fulfilled for at least 2 months prior to diagnosis	
<i>IBS</i> irritable bowel syndrome	

Risk Factors

Table 21.2 shows the known and identified risk factors for chronic constipation in children. In contrast to adult studies which show constipation to be more prevalent among females, several epidemiological studies among children have failed to identify gender as a risk factor to develop constipation [13, 20, 21]. However, one study from Sri Lanka has shown that the prevalence is significantly higher among boys and children living in low socioeconomic status [19].

Table 21.2 Risk factors for chronic constipation

Category	Risk factor
Patient related	Male sex
	Poor sleep
	Obesity
Dietary	Low fiber
	Consumption of junk food
	Not having regular meals with parents
	Cow's milk protein allergy
Psychological	Home-related stresses
	School-related stresses
	Adverse life event including abuse
	Subjected to bullying
	Anxiety
	Depression
	Autistic spectrum disorders
Social	Living in war-affected areas
	Living in urban areas
	Lower social class
	Hostile and aggressive family environment

Psychological stress is another risk factor that predisposes children to develop constipation. Children living in homes and studying in schools which create stress are more prone to develop chronic constipation [22]. In addition, disrupted societies by civil unrest are also an important predisposing factor [23]. A study from Hong Kong has shown that children not having regular meals with their parents and deprivation of sleep as independent risk factors to develop severe constipation [17]. Moreover, low consumption of fiber [11, 17, 18], cow milk protein (CMP) hypersensitivity [21, 24], and consumption of fast foods too often [17] are associated with constipation. Lastly, obesity has also been identified as an independent risk factor [25, 26]. In a recent study, our group also noted that children who faced adverse life events such as physical, emotional, and sexual abuse have higher predilection to develop constipation. These events also predispose them to develop more somatic symptoms and lead to a poor quality of life [27].

Quality of Life

Children with constipation have poor health-related quality-of-life (HRQoL) scores in all domains, namely social, school, physical, and emotional functioning. The scores they obtained are even lower than children suffering from organic diseases such as gastroesophageal reflux and inflammatory bowel disease [28]. Children with slow transit constipation also have been shown to have poor HRQoL [29]. A school-based study from Sri Lanka also confirms these findings and showed that constipation-associated fecal incontinence (FI) further reduces HRQoL [30].

Extraintestinal Symptoms and Psychological Problems

Children with constipation suffer from an array of somatic symptoms. In one of the studies, we found that children with constipation had a multitude of somatic symptoms and high somatization scores [30]. Constipation is also associated with a number of behavioral abnormalities such as autism, attention-deficit hyperactivity disorder, and anxiety [31–33]. Abnormal personality traits were also noted in children suffering from constipation [34]. In addition, children with autistic spectrum disorders are known to have very early onset disease [32].

Health-Care Burden

Constipation is a leading cause for medical consultation in children. Documented medical visits for constipation were

higher than most other gastrointestinal diseases in children under 5 years [35]. The incidence of medical presentation for children with constipation is substantially higher than other chronic episodic conditions such as asthma (seven times) and migraine headaches (three times) [36]. The mean outpatient costs and mean annual number of emergency room visits are higher in children with constipation compared to controls [36]. Furthermore, employed parents with a child with constipation have a higher number of working day losses than controls. More importantly, children with constipation are noted to have higher number of days of school absenteeism [37]. In addition, children with constipation show poor quality of school work [30, 38]. Implications of these findings on education of children are much larger than expected. Poor education invariably leads to poor earning capacity and ignorance as an adult. Therefore, they become an added burden to society at large.

Pathophysiology

Understanding of the pathophysiological mechanisms of chronic constipation in infants and children is a considerable challenge and remains in its early stages. However, available studies on physiology of the colon and rectum and studies on animal models have shed some light upon the subject.

Infants and Young Children

Stool withholding plays a major role in the development of constipation in infancy and early childhood. Passing a hard stool leading to pain, strict early toilet training, stubbornness, and concentration on other activities which are more exciting than going to the toilet are possible factors for stool withholding. When the urge to pass stools comes, the withholding child tightens gluteal muscles and stands on tip toe. During this process, the rectum dilates, fecal matter is accommodated, and desire to pass stools disappears. A large mass of feces is formed in the rectum during this process leading to a cascade of physiological changes described below.

Children and Adolescents

Several studies have shown that children with constipation have defective intraluminal transport involving different segments of the colon such as proximal delay, hind gut delay, and rectosigmoid hold up [39–41]. Furthermore, it has been shown that children with chronic constipation have significantly delayed total colonic transit times of over 100 h [42]. Although slow transit constipation in adults is almost exclusively found in females [43], in children and adolescents, prevalence is more or less equal among the sexes [44].

Colonic manometry has shown several abnormalities in constipation. They include reduced frequency of high-am-

plitude propagative contractions and disordered patterning of spatiotemporal colonic propagative responses [45]. Like slow transit constipation, all these factors may contribute to poor propulsion of fecal masses along the colonic lumen generating symptoms of constipation.

Rectal sensitivity to oncoming fecal matter and dilatation is a crucial point in normal rectal function. There is a subset of children with constipation who demonstrate poor rectal sensation [46]. Furthermore, several studies in children have shown increased rectal compliance [47, 48] and a megarectum [49]. These factors are closely interrelated and lead to attenuation of rectal sensation and lack of desire to evacuate, leading to low bowel frequency.

In addition, contraction, rather than relaxation of the pelvic floor muscles with increasing rectal pressure (dys-synergic defecation), also prevents evacuation of stools. The balloon expulsion test has been used to measure rectal motor dysfunction in children with an array of other combined measurements. Chitkara et al. demonstrated that 31% of children with functional constipation and 53% of children with functional fecal retention (using Rome II criteria) had an abnormal balloon expulsion test, and 40% had high resting anal pressure [50].

In addition to these local factors, dysfunction of the brain–gut axis also contributes to the development and propagation of symptoms. Stress-induced abnormalities in the colonic motor activity may further aggravate the motor and sensory abnormalities and worsen stool retention. Functional magnetic resonance imaging studies have described a multitude of abnormalities in adults with functional gastrointestinal disorders (FGD) including constipation as possible mechanisms for this phenomenon [51].

Final Pathway for Both Age Groups

Pathophysiological mechanisms described for both age groups finally lead to retention of stools in the rectum and colon. Since colonic and rectal mucosa are designed to absorb water, stool becomes dry and hard. Molecular abnormalities in the rectal mucosa of children with constipation, such as abnormalities in non-calcium-mediated chloride channels, lead to abnormally low chloride secretion that may further contribute to the development of hard stools [52]. The mechanical dilatation of the rectum inhibits motor function of the proximal and distal hemi-colon through reflex mechanisms [53, 54].

In addition, animal models have shown that accumulation of feces elongates the colon. This in turn leads to the release of nitric oxide by activating mechano-sensory and myenteric descending neuronal nitric oxide synthase. Nitric oxide inhibits action potential firing in other myenteric sensory neurons driving peristaltic nerve circuits, inhibiting colonic contractile activity (occult reflex), thereby seriously hampering evacuation [55, 56]. It has been shown that chil-

dren with increased rectal wall compliance have prolonged colonic transit time which further strengthens the possibility of occult reflex [47]. Interactions of these inextricably linked mechanisms in a complex manner, rather than in isolation, lead to generation and propagation of symptoms in children with constipation.

Clinical Features

Infants and Young Children

The most common reason for constipation in infants and toddlers is an acquired behavior component after experiencing painful bowel movements [57]. When the desire to pass a stool occurs, they tend to cry and withhold stools by tightening their gluteal muscles and pelvic floor. This is evident in infants as they tighten the legs and in young children as they stand on tip toe and tighten their muscles till the desire for passing a stool goes off. These children also have low stool frequency, passing large-diameter, rock-hard, and sometimes bloody stools infrequently and occasional leaking of semisolid to liquid stools into underwear. In addition, poor appetite and abdominal distension are also notable features.

Older Children and Adolescents

This group tends to present with classic symptoms of constipation. The presenting complaint very often is reduced stool frequency. The other features include passing hard stools, pain while passing stools, frequent episodes of FI, and infrequent passage of a large-diameter stool which may obstruct the toilet. Some older children also show withholding postures although these are not seen as commonly as in younger children. Abdominal bloating is another important feature in children and seen especially in adolescents [58]. Abdominal pain, anorexia, and behavioral abnormalities are also important features in this age group.

Clinical Evaluation of Children with Defecation Disorders

Clinical evaluation is the most important tool in diagnosing defecation disorders in children and adolescents. It includes a thorough history, tenacious physical examination, and careful interpretation of findings in a logical manner. This process helps to actively identify functional defecation disorders, exclude possible organic diseases that can mimic functional defecation disorders, and recognize complications.

Clinical History

Although the presenting features are obvious in the majority, clinical features may be subtle in some children. Therefore, a high degree of suspicion is essential during history taking. Onset and duration of symptoms need to be clarified first. Very early-onset disease in infancy suggests the possibility of organic diseases such as Hirschsprung disease, anorectal malformations, and metabolic diseases. Details of bowel habits are the cornerstone in diagnosing constipation (Box 21.1). Use of validated stool scales for infants [59] (Amsterdam stool scale) and children (modified Bristol stool scale) [60] helps to obtain more accurate description of stools. Apart from that, it is also important to question on other gastrointestinal symptoms. Abdominal pain is noted in 10–70% of children with constipation. Poor appetite, nausea, vomiting, and abdominal bloating are other important features that need to be inquired into during history taking. Children with chronic constipation also tend to suffer from a myriad of somatic symptoms and identifying these features would help in clinical management [19]. Urinary symptoms and incontinence are also seen in some children [61–64] and refractory vulvovaginitis is a known feature, especially in prepubertal girls [65].

Box 21.1 Bowel Habit Questions for Defecation Disorders

- Stool frequency
- Consistency
- Nature of the stools
- Incontinence
- Withholding behavior
- Pain during defecation
- Blood in stools

Past medical history, specially concentrating on drugs that may cause constipation, is also an important part in the evaluation. Surgical issues such as corrected anorectal malformations and Hirschsprung disease are well known to present with constipation [66, 67]. Dietary history particularly concentrating on fiber content is an integral part as underconsumption of fiber may lead to constipation [17, 18]. Introduction of cow's milk to the infant's diet is a risk factor to develop constipation among them [68, 69]. Psychological abnormalities also need to be looked into as some children develop personality problems, anxiety, and depression with constipation [22, 70]. Finally, details of social and family history should not be overlooked. Constipation is notably prevalent in children from the lower socioeconomic strata, living in disrupted deprived areas and urban areas [19, 23]. In addition, adverse life events such as physical, sexual, and

emotional maltreatment should also need to be evaluated carefully in children with constipation as these factors are known to predispose children to develop constipation [27]. Some children with constipation also have first-degree relatives with similar problems [11, 19].

Physical Examination

The physical examination should start with assessment of growth. Growth faltering and short stature are features of organic causes (endocrine, metabolic, etc.) for constipation. On the other hand, obesity is also a known predisposing factor for defecation disorders such as constipation and FI [26]. Dysmorphic features are present in children with syndromes who are having constipation [71]. All children with defecation disorders need a good developmental assessment. Those with long-term neurological dysfunctions such as cerebral palsy tend to have both constipation and FI. Furthermore, this would also help to identify children with autistic spectrum disorders who have a tendency to develop constipation [31].

Abdominal examination may reveal the presence of abdominal distension and past surgical scars of abdominal surgery. Palpable fecal masses in the lower abdomen indicate fecal loading and is a feature present in about 50% of children with constipation [72]. However, gaseous distension is more in favor of constipation-predominant irritable bowel syndrome (“IBS-C”).

Perianal examination may reveal abnormal position of anus [73]. Smear of feces and perianal excoriation of skin indicates FI. Fissures and tags can also be noted in children with chronic constipation who pass hard stools or may indicate sexual abuse. Patulous anus is associated with lower motor neuronal damage which can be associated with FI. Digital examination of the rectum is an essential part in evaluating children with defecation disorders. During the process one should assess resting tone, the squeeze pressure of the sphincter complex, nature of fecal loading, size of the fecal mass, and the size of the rectum.

Neurological examination should concentrate specially on features of spina bifida, motor and sensory deficits in the lower limbs, and perianal sensory testing. One should look for perianal sensory loss and absence of anal wink.

Investigations

Constipation is a clinical diagnosis. Using currently accepted clinical criteria, the majority of the children who present to a medical facility can be diagnosed and managed successfully. Specialized investigations are therefore only needed when the diagnosis is uncertain, or when they do not respond to standard management strategies. Investigations are also warranted in children who are suspected to have organic reasons

for defecation disorders during history taking and physical examination.

Radiological Tests

Colonic transit time is usually assessed by using radiological methods. It generally gives an idea of propulsive function of the colon and helps to identify segments with abnormal motility. It is usually measured using radiopaque markers or scintigraphic methods. In marker studies, the markers are ingested as a meal or swallowed as a capsule, and abdominal X-rays are obtained to count the number of markers in different segments of the colon. In scintigraphy, the patient is given a meal containing radioisotope, and multiple images are taken using a gamma camera to assess the radioisotope count in each region. Several studies have shown abnormalities in total and segmental transit times in children with functional constipation using radiopaque markers [39, 40]. A Dutch study noted children with functional constipation having colonic transit time over 62 h. This cutoff value has a sensitivity of 52% and specificity of 91% [42]. Colonic transit time also has an inverse relationship with the number of defecations per week [39]. Using colonic scintigraphy, Sutcliffe et al. found delay in transit in patients with constipation [41].

Ultrasonography has also been used to assess the degree of fecal retention in the rectum. Using a transabdominal approach, several studies have measured the rectal diameter to determine fecal loading in the rectum using different methods and have shown that children with chronic constipation do have a larger rectal diameter compared to controls. Bijes et al. using recto–pelvic ratio (dividing the transverse diameter of the rectal ampulla by the transverse diameter of the pelvis) illustrated that in children with functional constipation, the mean recto–pelvic ratio was 0.22 ± 0.05 compared to healthy controls 0.15 ± 0.04 [74]. Another study measured the impression of the rectum behind the urinary bladder seen as a crescent. The median rectal crescent in children with constipation was 3.4 cm (range 2.10–7.0; interquartile range (IQR) 1.0) as compared with 2.4 cm (range 1.3–4.2; IQR 0.72) in healthy controls [75]. Klijn et al. also found a significant difference in mean rectal diameter between the constipated group (4.9 cm) and the control group (2.1 cm). The cutoff value was 3.3 cm, where >3.3 cm indicated constipation [76]. The results are promising, and wider availability and noninvasive nature of the test make it an ideal investigation. However, methods need to be standardized, and more studies are needed before recommending routine use of ultrasonography in assessing children with constipation.

Furthermore, using endosonography techniques, Keshtgar et al. have shown that children with chronic constipation have a thickened external anal sphincter complex. However, they were unable to demonstrate a significant relationship between thickened anal sphincter, anorectal manometry, and

amplitude of sphincter contractions [77]. The clinical utility value of this finding is yet to be determined.

Plain abdominal X-ray is used to demonstrate fecal loading in the colon and rectum. Several scoring systems are used to assess the degree of impaction. However, sensitivity and specificity of these tests are variable and also the inter- and intra-observer reliability are poor [78]. Therefore, it is difficult to recommend the use of plain X-ray films of the abdomen as an investigation.

The other radiological investigations such as defecography and contrast enemas have no place in clinical evaluation of children with constipation. Magnetic resonance imaging of the spinal cord is an important investigation in children with refractory defecation disorders as some children have been shown to have significant abnormalities such as spina bifida occulta and terminal filum lipoma. Importantly, gluteal cleft deviation was found in three of four patients with these abnormalities [79, 80].

Physiological Tests

Anorectal manometry combined with balloon expulsion test is an important investigation to understand the function of the anorectal unit and pelvic floor muscles. It provides information about anal sphincter function, mechanisms of continence and defecation, rectal sensation, rectal compliance, and anorectal reflexes [81]. A number of studies have demonstrated several abnormalities of anorectal function in children with constipation. They include increased rectal sensory threshold, reduced rectal contractility, high resting anal pressure, and failure of relaxation of the external anal sphincter with rising rectal pressure [46–49]. Furthermore, a subset of children was found to have an abnormal balloon expulsion test [50]. Feinberg and coworkers have shown that there is a correlation between the number of FI episodes and the volume of first urge, and high volume required to elicit rectoanal inhibitory reflex. They also found a significant correlation between the presence of withholding behavior and the maximum volume tolerated [82].

Colonic manometry allows the measurement of pressure/force from multiple regions within the colon in real time [83] and helps to discriminate between normal colonic physiology and colonic myopathies and neuropathies. A number of colonic motor patterns have been identified, such as antegrade high-amplitude propagating contractions, low-amplitude propagating sequences, non-propagating contractions, and retrograde propagating pressure waves [84]. In contrast to conventional manometry which used a limited number of sensors, arrival of high-resolution manometry allows researchers and clinicians to study three-dimensional pressure plots to study gastrointestinal pathophysiology more closely. An elegant study using this technique has clearly shown children with slow transit constipation having definitive abnormal motor patterns (post-bisacodyl-induced high-amplitude

propagatory contractions) which can serve to diagnose colonic neuropathy [85].

Other Investigations

Association between CMP allergy and constipation is still a debatable subject. Two research reports from Italy (from a center of excellence studying allergies) have found association between constipation and CMP sensitivity [68, 69]. A more recent study from Irastorza and colleagues found 51% patients with constipation responding to a CMP elimination diet, but no significant differences were noted between the group of responders and nonresponders regarding atopic/allergic history and laboratory results [86]. Therefore, testing for CMP allergy is not recommended. Importance of hypothyroidism as an etiological factor for constipation in children is overstated. Bennett and Heuckeroth studied 56 children with hypothyroidism and noted that only one child had constipation as the presenting complaint [87]. As for other serological tests (such as screening for celiac disease and looking for hypercalcemia), these are also not recommended in all constipated children; however, in a child with symptoms not responding to laxative therapy, it might be useful to look for celiac disease.

Management

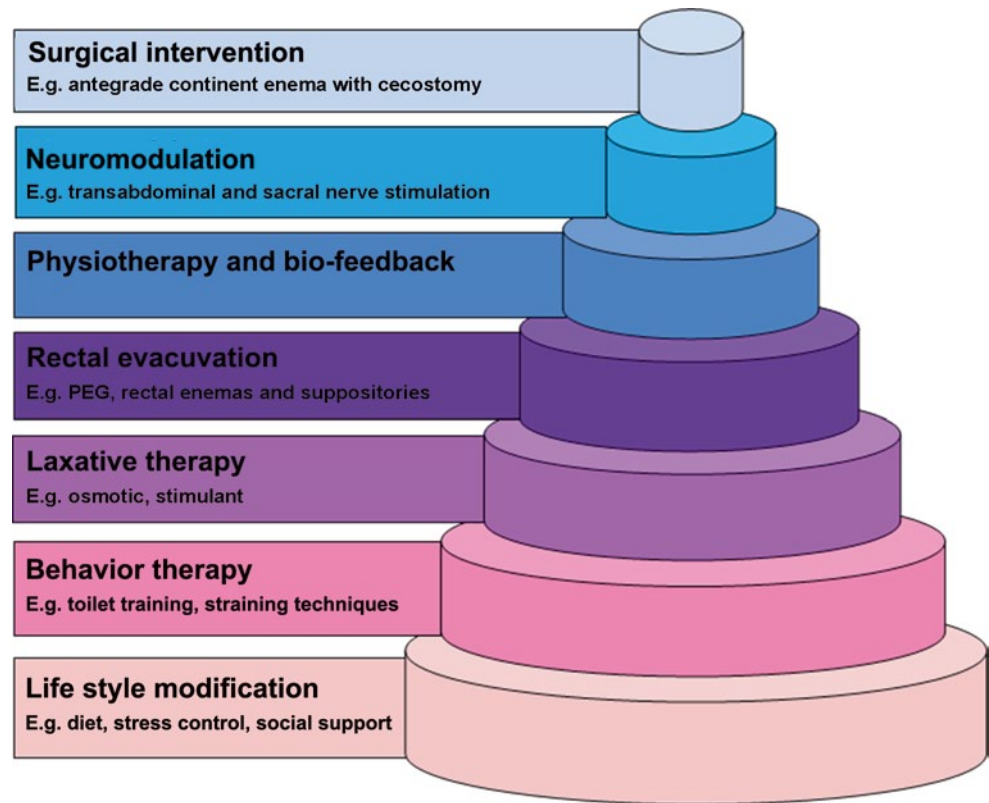

Effective management of constipation requires a multifaceted approach. A stepwise management protocol is shown in Fig. 21.1. The main steps include lifestyle modification, toilet training, use of laxatives and enemas, biofeedback therapy, nerve stimulation, and surgical interventions. However, it is important to realize that the data in the pediatric literature to support evidence-based use of treatment strategies are limited, especially regarding old laxatives such as lactulose and bisacodyl. Therefore, the management mostly depends on individual experiences and limited number of trials of new drugs.

Lifestyle Modifications

Constipation is known to be associated with psychological stress related to home, school, and society [22, 23]. These factors need to be addressed during the consultation. Children with psychological stress need to be identified and coping mechanisms need to be taught as part of the day-to-day lifestyle. Home- and school-related punishment is another factor that is known to predispose children to develop constipation which can easily be avoided [27].

Although widely believed, a high-fiber diet does not relieve constipation. Several trials including different types of fibers failed to show any clinically meaningful therapeutic benefit in children [88–90]. Two systematic reviews also illustrate limited clinical value of fiber in the management

Fig. 21.1 Stepwise management of constipation

[91, 92]. In addition, increasing dietary fiber intake with extensive behavioral interventions does not reduce the requirement of laxatives [93]. Similarly, increase in the consumption of water has also shown not to increase stool frequency or soften stools [94].

Toilet Training and Behavioral Therapy

Stool withholding plays a crucial role in developing constipation in young children. Aiming to prevent this phenomenon, children with constipation need to relearn to properly pass stools in the toilet.

As the first step, negative attitude regarding stools needs to be eliminated. This facilitates and prepares the child mentally to pass stools in the toilet or potty. Child is encouraged to use the toilet regularly usually after each meal as the gastrocolic reflex facilitates generation of high-amplitude propagatory contractions which help to evacuate stools. The proper seating method (upright posture) to bring the anorectum to the correct angle to facilitate the passage of stools also needs to be taught. Proper positioning of legs and relaxing them with the pelvic floor and anal sphincters also can be learned. Once the child masters these techniques, it is necessary to teach him/her proper straining methods to facilitate the passage of stools. This process needs to be a regular practice and could be encouraged with a reward system. [95]. A Cochrane review has shown positive evidence indicating that adding behavioral therapy to conventional laxatives has benefits in treating children with constipation [96]. It is obvi-

ous that behavioral therapy alone cannot cure constipation. However, given the importance of the part played by stool-withholding behavior in childhood constipation (especially in infants and younger children), toilet training and behavioral modifications are inseparable parts in day-to-day clinical management.

Fecal Disimpaction from Rectum

It has been shown that 40–100% of children with constipation have a large rock-hard fecal mass in the rectum [97]. After evacuation of the fecal mass children are more likely to respond to maintenance therapy [98]. Several studies have proved that oral administration of polyethylene glycol (PEG) is both successful and cost-effective in the majority of children with fecal impaction [99–101]. Therefore, oral route is recommended as the initial step in rectal evacuation.

Rectal enemas or suppositories are recommended for children who do not respond to oral drugs. A study by Bekkali et al. failed to show a significant difference between PEG and rectal enemas on evacuation of rectum loaded with feces [101]. However, it is imperative to realize the invasive nature of rectal therapy specially when the child has pain, discomfort, and may suffer from morbid fear of manipulations around the perianal region by medical professionals. In a minority of cases, even sedation is recommended before rectal administration especially when the child is not cooperative. Rectal medications that can be used are phosphate, docusate sodium, mineral oil enemas, and bisacodyl suppositories.

Maintenance Treatment

Once disimpaction is achieved, it is imperative that the clinician should concentrate on maintenance therapy. This facilitates passage of stools and prevents re-impaction. Table 21.3 shows the details of the drugs that are currently used in the management of childhood constipation.

Lubricant Laxatives

Although there are no placebo-controlled trials involving lubricant laxatives, two trials comparing mineral oil with lactulose have noted statistically significant better response rates with mineral oil. When comparing mineral oil with PEG, the response rates were almost similar [102]. Contrary to this, Tolia et al. found PEG superior to mineral oil in relieving symptoms [103]. However, due to the risk of life-threatening lipoid pneumonia, mineral oil is not recommended for young infants and children with swallowing difficulties, especially those who are neurologically handicapped.

Osmotic Laxatives

Osmotic laxatives are the group of choice used in the maintenance phase. As a group they exert an osmotic effect which helps to increase the water content in the colon and hence softening stools with minimal adverse effects. Lactulose and PEG are the two most commonly used drugs in this group.

Although widely used, lactulose has never been compared with a placebo in a controlled trial. Perkin et al. compared lactulose with senna using a small number of children. They

noted a greater clinical response to senna (improving defecation frequency) when compared to lactulose [104]. A recent randomized controlled trial using lactulose and a mixture of fibers showed that both therapeutic modalities are comparable without major side effects [90].

A Cochrane review has concluded the superiority of PEG over both placebo and lactulose [105]. However, it is important to realize that comparison of these studies is extremely difficult as the study designs, age groups, and PEG preparations are different. PEG also shows an excellent safety profile. Therefore, in clinical practice, it is recommended to use both drugs as first line drugs in the maintenance phase.

Stimulant Laxatives

Bisacodyl and senna stimulate peristaltic movements and enhance fecal evacuation. However, there are no good quality trials to evaluate stimulant laxatives in childhood constipation. Studies comparing senna with lactulose and mineral oil demonstrated that children using senna had a poorer response [104]. Another study comparing the effect of adding senna, placebo, or no medication for children with FI receiving behavioral therapy found no significant difference in outcome [106]. Despite the lack of well-designed trials, these drugs are commonly used in day-to-day clinical practice, often in combination with osmotic laxatives. The National Institute for Clinical Excellence (NICE) guidelines of the UK recommend the addition of stimulant laxatives to PEG when the response is noted to be suboptimal [107].

Table 21.3 Dosages of most frequently used oral and rectal laxatives

Drug class	Drug	Dosages
Osmotic laxatives	Lactulose	1–2 g/kg, once or twice/day
	PEG 3350	Maintenance: 0.2–0.8 g/kg/day
	PEG 4000	Fecal disimpaction: 1–1.5 g/kg/day (with a maximum of 6 consecutive days)
Fecal softeners	Milk of magnesia (magnesium hydroxide)	2–5 years: 0.4–1.2 g/day, once or divided 6–11 years: 1.2–2.4 g/day, once or divided 12–18 years: 2.4–4.8 g/day, once or divided
	Mineral oil	1–18 years: 1–3 ml/kg/day, once or divided, max. 90 ml/day
	Stimulant laxatives	Bisacodyl
Senna		2–6 years: 2.5–5 mg once or twice/day 6–12 years: 7.5–10 mg/day > 12 years: 15–20 mg/day
Sodium picosulfate		1 month–4 years: 2.5–10 mg once/day 4–18 years: 2.5–20 mg once/day
Rectal laxatives/enemas	Bisacodyl	2–10 years: 5 mg once/day > 10 years: 5–10 mg once/day
	Sodium docusate	< 6 years: 60 ml > 6 years: 120 ml
	Sodium phosphate	1–18 years: 2.5 ml/kg, max. 133 ml/dose
	NaCl	Neonate < 1 kg: 5 ml, > 1 kg: 10 ml > 1 years: 6 ml/kg once or twice/day
	Mineral oil	2–11 years: 30–60 ml once/day > 11 years: 60–150 ml once/day

New Drugs

Prucalopride Prucalopride belongs to the class of dihydrobenzofuran-carboxamide derivatives. The drug has a clear gastroprokinetic activity and selective and high affinity for 5-HT₄ receptor agonists that stimulate lower gastrointestinal motility. The efficacy of the drug was tested in an open-label 8-week trial involving 37 children. According to the results, the average number of spontaneous bowel movements normalized to a mean of 6.8 per week, whereas the average number of FI episodes decreased from 5.6 in the first week to 3.4 in week 8. Most of the children were using other laxatives as well during the trial [108]. Although the results of this open-label trial look promising and safe, further studies are needed before recommending the use of prucalopride for constipation in children.

Lubiprostone Lubiprostone is a locally acting chloride channel activator specific to the gastrointestinal tract. It promotes intestinal secretion of chloride ions and fluid and gastrointestinal motility. It has a good track record in treating adults with constipation. In an open-label trial, lubiprostone was shown to be safe and effective in improving spontaneous bowel movements, reducing episodes of FI, and reducing many other symptoms of constipation in children and adolescents less than 17 years [109].

Biofeedback and Physiotherapy

Anorectal function can be modified with the use of biofeedback. The purpose of biofeedback is to improve anorectal function and sensation [110]. Several studies have shown efficacy of biofeedback in correcting defecation dynamics, but a well-conducted large randomized controlled trial failed to find additional clinical benefits of biofeedback in children with constipation [1, 48, 111, 112]. However, despite this finding it is vital to assess this therapeutic modality in combination with pelvic floor physiotherapy and muscle training as pelvic floor dyssynergia is a recognized physiological abnormality, especially in older children.

Neuromodulation

Neuromodulation has been identified as a successful therapeutic modality for elimination disorders [113], although the working mechanism is far from clear. Two trials have shown that sacral neuromodulation is effective in treating adults and children with slow transit or normal transit constipation [114, 115]. The adverse events (mainly pain) were minimal. A well-designed sham-controlled trial with a larger patient sample and a long-term follow-up is needed however to confirm these encouraging data.

Transabdominal electrical stimulation has also been studied as an option for treatment of resistant slow transit consti-

pation. Using this technique, Clarke et al. illustrated children with slow transit constipation generating significantly higher frequency of high amplitude and total propagatory sequences [116]. In addition, the same research group studying 39 children with slow transit constipation has shown that transcutaneous electrical stimulation (TES) delivered by a physiotherapist (three 20-min session a week) increases defecation frequency in 30%, reduces FI in 75%, abdominal pain in 59%, and reduces the need for appendicostomy washouts in 43% [117]. Yet again, further studies are needed to confirm these findings and use of this in clinical practice.

Surgical Interventions

Injection of botulinum toxin (single or multiple) to the internal anal sphincter is effective in some children with dys-synergic defecation. Adverse effects frequently encountered include transient anal and abdominal pain, and occurrence of FI yet again resolves spontaneously [118]. Antegrade continent enema with appendicostomy or laparoscopic-assisted percutaneous caecostomy has been used in treatment-resistant constipation. The success rates are high and functional outcomes are excellent. It had been shown that the procedure improves bowel frequency and quality of life and reduces number of episodes of incontinence [119]. PEG solution and normal saline are effective, including a stimulant laxative, as cleansing agents. Commonly seen complications include granulation tissues around stoma, leakage, and minor infections. Major complications such as fistulae, peritonitis, and stenosis of the stoma are only seen in a minority [120]. Other surgical procedures such as sigmoid resection, colorectal resection, subtotal colectomy, and proctocolectomy with ileo-anal anastomosis are only reserved for children with intractable constipation who failed to respond to all other therapeutic modalities [121].

Part 2: Functional FI

Introduction and Epidemiology

FI is defined as passing stools in inappropriate places including one's underwear by a child whose development age is over 4 years [122]. Once organic causes are excluded, functional FI is mainly due to two possible reasons: constipation-associated and functional nonretentive fecal incontinence (FNRFI). The former has already been discussed in detail in the first part of this chapter. We will now concentrate on FNRFI.

Like constipation, FI is also a widespread problem. Epidemiological studies have shown rates ranging from 0.8 to 4.1% in the West and 2 to 7.8% in Asia [122]. We conducted an epidemiological survey and found that the majority of children (80%) with FI had constipation-associated (reten-

tive) FI and only 20% truly had FNRFI [123]. FI is commoner among males and children from low socioeconomic strata [123, 124]. In addition, bullying, psychological stress, behavioral and upbringing problems, and poor social and school performances are commonly seen in children with FI [123, 125].

Functional Nonretentive FI

Rome III criteria to define FNRFI are given in Table 21.1. These children pass normal stools in the toilet with a normal defecation pattern. They do not show features of constipation such as posturing, pain, or difficulty in passing stools either. However, they pass entire bowel motion into their underwear at least once a month. The pathophysiological mechanism for this disease is still an enigma to pediatric gastroenterologists. Several studies have clearly demonstrated normal colonic transit times (both segmental and total) in children with FNRFI [126, 127]. Similarly, anorectal manometry and barostat studies found that all parameters (rectal compliance, sensory thresholds) are within the normal range [128]. Although several psychological and behavioral abnormalities have been described in association with FNRFI, it is not clear whether these are causative factors or long-term effects of FI [129, 130]. Clinical evaluation of children with defecation disorders has been previously discussed in this chapter.

Investigations should be directed to exclude constipation-associated FI from FNRFI when the two entities are not apparent on clinical history and physical examination. When colonic transit times were compared, children with constipation-associated FI were found to have significantly delayed total colonic transit, as against children with FNRFI [126].

Anorectal manometry is helpful in differentiating these clinical entities. Children with constipation-associated FI show higher threshold for rectal sensation than FNRFI and there is no difference in maximum anal resting tone and abnormal defecation dynamics between the two groups [127]. Children with retentive FI have significant thickening of the internal anal sphincter on anal endosonography and the thickness is well correlated to symptom score, FI score, megarectum score, and size of the megarectum on manometry [77]. Such abnormalities have not been noted in FNRFI. In addition to these studies, MRI of the spine is also useful in some children to rule out organic causes of FI when there are subtle features of spinal bifida occulta on physical examination.

Management of children with FNRFI is challenging and often a long road, fraught with successes and failures. Education and strict toilet training following an individualized behavioral routine and positive reinforcement are the four main cornerstones in management [123]. Conventional treatment modalities such as oral or rectal laxatives and biofeed-

back are not helpful in the management. Loperamide was found to be effective in a child with FNRFI in a case report and further studies are needed to assess its efficacy [131]. These patients usually run a relapsing and remitting course, and a long-term follow-up study has shown that at the age of 18 years, 85% of them are symptom free and have normal bowel habits [132].

Massimo Martinelli and Annamaria Staiano

Introduction

Hirschsprung's disease (HD) is a heterogeneous genetic disorder, resulting from an anomaly of the enteric nervous system (ENS) of neural crest cells origin. A congenital malformation characterized by the absence of parasympathetic intrinsic ganglion cells in the submucosal and myenteric plexuses, HD is regarded as the consequence of the premature arrest of the craniocaudal migration of vagal neural crest cells in the hindgut, occurring between the 5th and 12th week of gestation, and it is therefore regarded as a neurocristopathy [1].

Epidemiology

HD occurs in approximately 1 out of 5000 live births, with a male predominance of 4:1. It is generally sporadic, although in 3–7% of cases a genetic transmission has been reported [2]. The risk for short-segment disease is 5% in brothers and 1% in sisters of index cases; for long-segment disease, the risk is 10%, regardless of sex [2].

Etiology

HD is characterized by the congenital absence of ganglion cells in the submucosal and myenteric plexuses in the distal bowel and variable proportion of the colon proximally. The embryonic disorder is a lack of the craniocaudal migration, differentiation, and maturation of neuroblasts from the neural crests, by the 5th–12th week of gestation; the earlier the migration ceases, the longer the aganglionic segment will be.

The aganglionic segment is permanently contracted, causing dilatation proximal to it [3]. HD may be classified according to the length of the aganglionic segment: the classic form (short segment 70–75% of cases) is limited to the rectum and sigmoid colon; the long segment, or subtotal colonic disease (10–15%), generally involves the bowel up to the splenic flexure; total colonic aganglionosis (TCA) (3–6%) may extend to involve a variable amount of the short bowel; and total intestinal aganglionosis, is sometimes associated with intestinal malrotation or volvulus [2]. Ultrashort-segment aganglionosis is considered a functional alteration, without any detectable histological finding. Although longer aganglionic segments tend to produce more dramatic symptoms, some patients with even short-segment disease deteriorate rapidly [4].

Pathophysiology

The hallmark of diagnosis is the absence of ganglion cells from the myenteric and submucosal plexuses, as seen on a full-thickness or suction (mucosal–submucosal) biopsy of the rectum. Proximal contents fail to enter the unrelaxed, aganglionic segment. The lack of non-adrenergic–non-cholinergic inhibitory innervation is responsible for a tonic contraction of the affected segment, with absence of peristalsis and proximal dilation of the gut [5].

Morphologically, ganglionic cells are absent from the narrowed segment and for some distance (1–5 cm usually) into the dilated segment. The pattern of nerve fibers is abnormal also; they are hypertrophic with abundant, thickened bundles. Specific stains for acetylcholinesterase are used to highlight the abnormal morphology [6, 7].

In recent years, new insights in the pathophysiology of HD have been gained. There is a growing consensus that the disease might be the expression of a genetic alteration, as reported in the genetic section of this chapter.

It has also been suggested that abnormal expression of muscular neural cell adhesion molecule is likely to be

associated with an arrest in the craniocaudal migration of neural cells to their most distal location [8]. Furthermore, the lack of nitric oxide (NO)-producing nerve fibers in the aganglionic intestine probably contributes to the inability of the smooth muscle to relax, thereby causing lack of peristalsis [9]. In addition, in the aganglionic segments, interstitial cells of Cajal (ICC) are scarce and their network appears to be disrupted [10].

Genetics

HD occurs as an isolated trait in 70% of patients, is associated with chromosomal abnormality in 12% of cases, trisomy 21 being by far the most frequent (>90%). Additional congenital anomalies are found in 18% of cases, including gastrointestinal malformation, cleft palate, polydactyly, cardiac septal defects, and craniofacial anomalies. The higher rate of associated anomalies in familial cases than in isolated cases (39 vs. 21%) strongly suggests syndromes with Mendelian inheritance [2]. Isolated HD appears to be a multifactorial malformation with low, sex-dependent penetrance, variable expression according to the length of the aganglionic segment, and suggesting the involvement of one or more gene(s) with low penetrance [2]. These parameters must be taken into account for accurate evaluation of the recurrence risk in relatives. Segregation analyses suggested an oligogenic mode of inheritance in isolated HD. With a relative risk as high as 200, HD is an excellent model for the approach to common multifactorial diseases [11].

A large number of chromosomal anomalies have been described in HD patients. Free trisomy 21 (Down syndrome) is by far the most frequent, involving 2–10% of ascertained HD cases. Syndromes associated with HD can be classified as pleiotropic neurocristopathies [1], syndromes with HD as a mandatory feature, and occasional association with recognizable syndromes. The neural crest is a transient and multipotent embryonic structure that gives rise to neuronal, endocrine and paraendocrine, craniofacial, conotruncal heart, and pigmentary tissues. Neurocristopathies encompass tumors, malformations, and single- or multifocal abnormalities of tissues mentioned above in various combinations. Multiple endocrine neoplasia type 2 (MEN 2) and Waardenburg syndrome (WS) are the most frequent neurocristopathies associated with HD [12, 13].

WS, an autosomal dominant condition, is by far the most frequent condition combining pigmentary anomalies and sensorineural deafness, resulting from the absence of melanocytes of the skin and the stria vascularis of the cochlea. The combination of HD with WS defines the WS4 type (Shah-Waardenburg syndrome). Indeed, homozygous mutations of the endothelin pathway and heterozygous SRY-related box 10 (SOX 10) mutations have been identified in WS4 patients

with central nervous system (CNS) involvement including seizures, ataxia, and demyelinating peripheral and central neuropathies [14].

A wide spectrum of additional isolated anomalies has been described among HD cases with an incidence of sporadic types varying from 5 to 30% [2, 15]. No constant pattern is observed. These anomalies include distal limb, sensorineural, skin, gastrointestinal, central nervous system, genital, kidney, cardiac malformations, and facial dysmorphic features.

These data highlight the importance of a careful assessment by a clinician trained in dysmorphology for all newborns diagnosed with HD. Skeletal X ray and cardiac and urogenital echographic survey should be systematically performed. The observation of one additional anomaly to HD should prompt chromosomal studies.

Molecular Genetics

Several genes have been implicated in isolated HD; the two major ones being the proto-oncogene *RET* (*RET*) and the endothelin B receptor (*EDNRB*) [2].

The RET Signaling Pathway

The first observation was about an interstitial deletion of chromosome 10q11.2 in patients with TCA and mental retardation [16]. The proto-oncogene *RET*, identified as disease causing in MEN 2 and mapping in 10q11.2, was regarded as a good candidate gene owing to the concurrence of MEN 2A and HD in some families and the expression in neural crest-derived cells. Consequently, *RET* gene mutations were identified in HD patients [17]. Expression and penetrance of an *RET* mutation are variable and sex dependent within HD families (72% males and 51% females). Over 100 mutations have been identified including large deletions encompassing the *RET* gene, microdeletions and insertions, nonsense, missense, and splicing mutations [18–20]. Haploinsufficiency is the most likely mechanism for HD mutations. Biochemical studies showed variable consequences of some HD mutations (misfolding, failure to transport the protein to the cell surface, abolished biological activity).

Despite extensive mutation screening, an *RET* mutation is identified in only 50% of familial and 15–20% of sporadic HD case [21]. However, most families with few exceptions are compatible with linkage at the *RET* locus [22]. Mutations in *RET* ligand, like glial cell-derived neurotrophic factor (GDNF), GDNF family receptor α (GFRA)1–4, neurturin (NTN), persephin (*PSPN*), and artemin (ARTN), may occur, but are not sufficient to lead to HD.

The Endothelin Signaling Pathway

A susceptibility locus for HD in 13q22 was suggested for three main reasons: a significant load score at 13q22 in a large inbred Old Order Mennonite community with multiple cases of HD; de novo interstitial deletion of 13q22 in several patients with HD; and syntony between the murine locus for *piebald-lethal (sl)*, a model of aganglionosis, and 13q22 in humans. Subsequently, an *EDNRB* missense mutation was identified in the Mennonite kindred (W276C) [23, 24]. Both *EDNRB* and *EDN3* were screened in large series of isolated HD patients and *EDNRB* mutations were identified in approximately 5% of the patients. It is worth mentioning that the penetrance of *EDN3* and *EDNRB* heterozygous mutations is incomplete in those HD patients, de novo mutations have not hitherto been observed, and that S-HD is largely predominant [25].

SOX10

The last de novo mouse model for WS4 in human is *dominant megalon (Dom)*. The *Dom* gene is *Sox10*, a member of the SRY (sex-determining factor)-like, high mobility group (HMG) DNA-binding proteins. Subsequently, heterozygous *SOX10* mutations have been identified in familial and isolated patients with WS4 (including de novo mutation) with high penetrance [26].

Clinical Signs/Symptoms

The clinical symptoms of HD usually start at birth with the delayed passage of meconium. More than 90% of term neonates, and <10% of children with HD, pass meconium in the first 24 h of life [27, 28]. Thus, HD must be suspected in any full-term infant who does not pass meconium in the first 24 h of life and in the premature infants who have excessively delayed the passage of meconium (7–8 days) [28]. Failure of the distal bowel to relax and allow the passage of stool leads to functional obstruction and secondary dilatation of the bowel proximal to the aganglionic segment. Affected children may present with severe dysmotility causing obstructive symptoms, ribbon-like stools, and frequently, failure to thrive. In >90% of affected patients, the symptoms start during the neonatal period and, in the majority, the diagnosis is made during the first 3 months of life, whereas <1% are diagnosed during adult life [29].

In infants and children, the presentation is often less dramatic and may not mimic acute intestinal obstruction. Severe constipation and recurrent fecal impaction are more common. Physical examination reveals a distended abdomen and a contracted anal sphincter and rectum in most children. The

rectum is devoid of stool except in cases of short-segment aganglionosis. As the finger is withdrawn, there may be an explosive discharge of foul-smelling liquid stools, with decompression of the proximal normal bowel.

Complications

Over the past four decades, enterocolitis has been a major cause of morbidity and mortality in infants and children with HD. The mean incidence is 25%, but the range is great (from 17 to 50%) and may be differently estimated depending on the manner in which it is diagnosed. Mortality rates range from 0 to 33%, probably reflecting differences in the diagnostic criteria [30]. Mortality also appears to be associated with other factors, such as trisomy 21. Pathogenesis is thought to be related to fecal stasis with proliferation of colonic bacteria, and, therefore, a delayed HD diagnosis seems to be a significant risk factor [31]. The classic clinical manifestations described for enterocolitis include abdominal distension, explosive diarrhea, vomiting, fever, lethargy, rectal bleeding, and shock [32]. Abdominal radiographs show the Intestinal “cutoff” sign in the rectosigmoidal region with absence of air distally. Other common findings are small bowel dilatation in 74% and multiple air-fluid levels [33]. Because of the risk of perforation, contrast enema should not be performed in the presence of clinical enterocolitis.

Postoperative enterocolitis has been associated with fairly high rate of mortality in several series. In fact, when examining the deaths related to HD, several groups found that approximately 50% of deaths resulted from complications directly related to an enterocolitis episode [34, 35].

Rectal washouts should be the initial approach in the care of a child, regardless of age, who presents with enterocolitis. Along with washouts, intravenous antibiotics or oral metronidazole (in mild cases) should be used. Should the disease process fail to improve, or the infants' condition deteriorates, the performance of a leveling colostomy should be considered [34, 35].

Diagnosis

For diagnosis of HD, the subjects' history is crucial. The main elements to obtain are the age of the appearance of symptoms, whether the passage of meconium has been normal or delayed; and whether the child presented with episodes of functional intestinal obstruction. In addition, a functional (idiopathic) megacolon must be ruled out. A clinical comparison of functional and congenital megacolon is reported in Table 22.1 [36]. When the history (early onset of constipation, absence of fecal soiling) and/or the physical

Enterocolitis	Never	Possible
Associated upper-GI symptoms	Never	Common
Symptoms from birth	Rare	Common
Localization of stools	Rectum	Rectal and extra-rectal

examination (empty rectal ampulla) suggest an organic cause, anorectal manometry (ARM) should be performed. ARM evaluates the response of the internal anal sphincter to inflation of a balloon in the rectal ampulla [37]. When the rectal balloon is inflated, there is normally a reflex relaxation of the sphincter. The rectoanal inhibitory reflex is absent in patients with HD; there is no relaxation, or there may even be paradoxical contraction of the internal anal sphincter (Fig. 22.1) [36]. Although the absence of the rectoanal inhibitory reflex is specific for the diagnosis of HD, the role of ARM is still debated. A recent comprehensive systematic review by de Lorijn et al. [38] compared the diagnostic accuracy among rectal suction biopsy (RSB), ARM, and Barium enema (BE) for the diagnosis of HD. Although RSB gave the highest mean sensitivity and specificity (93 and 98%, respectively) ARM showed similar values (91 and 94%). ARM has the advantages of being a less-invasive method without the exposure to ionizing radiation. The limitations include the need for the patient to be in a normal physiologic and quiet state to avoid possible artifacts [38, 39]. Because specificity is lower for ARM compared with RSB [38], ARM cannot reliably replace histology and biopsies. A recent practical guidelines published by ESPGHAN GI committee stated ARM should not be used as a sole diagnostic tool for

HD in neonates and infants [40]; however, ARM is a useful screening test in older children presenting with chronic constipation and further symptoms suggesting HD (empty rectal ampulla, nonresponsiveness to standard therapy, early-onset constipation). If the rectoanal inhibitory reflex is absent, these patients should be referred for RSB to confirm the diagnosis of HD. If the rectoanal inhibitory reflex is present, HD could be reasonably excluded [40]. BE is helpful in the assessment of a transition zone between aganglionic and ganglionic bowel and giving an estimation of the length of an aganglionic segment. Demonstration of the transition zone is easier if no effort is made to cleanse the bowel (Fig. 22.2) [36]. In the newborn, dilatation of the proximal ganglionic bowel may not have developed, and radiological diagnosis may be more difficult. The sensitivity and specificity for recognition of a transition zone have been reported to be 80 and 76%, respectively [41]. The BE may not show a transition zone in cases of total colonic HD, or the BE may be indistinguishable from cases of functional constipation when ultra-short-segment HD is present. Therefore, a BE should not be performed as an initial diagnostic tool because it does not represent a valid alternative to RSB or ARM to exclude or diagnose HD; however, BE may have some use as an additional investigation in diagnosed cases to assess the length of the rectosigmoid aganglionic segment before surgery [40]. Nevertheless, the diagnosis requires histological evidence. The easiest means of obtaining adequate diagnostic tissue in rectal biopsies in infants is by rectal suction biopsy [42]. An accurate diagnosis is only possible if 2–3 suction biopsies are taken 2–3 cm above the dentate line and if they include sufficient submucosa [43]. Biopsies taken closer to the dentate line may be misleading because of a normal zone of submucosal hypoganglionosis or even aganglionosis [43]. The histological diagnosis is based on the demonstration of the total absence of ganglionic cells in the affected segment of the intestine with an overgrowth of large nerve trunks in the intermuscular and submucosal zone (Figs. 22.3 and 22.4) [36]. Acetylcholinesterase (AChE) activity in normal colon shows only few fibers in the lamina propria and muscularis mucosae; in HD, there is an increase in thick, knotted acetylcholinesterase-positive nerve fibers in the muscularis mucosae and lamina propria and hypertrophied nerve trunks in the submucosa. Techniques for histopathological diagnosis

Fig. 22.1 Anorectal manometry in a 1-month-old boy with Hirschsprung's disease. Distention of a rectal balloon with air for 1 s produces no decrease of anal pressure. (Reprinted with permission from Ref. [36], Fig. 17.2, p. 262)

Fig. 22.3 Rectal suction biopsy in a child with functional constipation. Note the presence of clusters of neuron in the submucosa and acetylcholinesterase activity showing only few wispy fibers. (Reprinted with permission from Ref. [36], Fig. 17.4, p. 263)

include analysis of hematoxylin- and eosin (H&E)-stained paraffin sections, snap-frozen sections stained for AchE, and immunostaining for neuronal markers. A recent consensus by Knowles et al. stated that insufficient data exist to

Fig. 22.4 Intense acetylcholinesterase activity in a patient with Hirschsprung's disease. Note the absence of neurons and the presence of increase in thick-knotted nerve fibers in the muscularis mucosae and lamina propria. In addition, hypertrophied nerve trunks are visible in the submucosa. (Reprinted with permission from Ref. [36], Fig. 17.5, p. 263)

firmly recommend one approach over the other; although, the combination of AchE and H&E staining increases the diagnostic accuracy because it improves the identification of submucosal ganglion cells, as well as demonstrates the abnormal nerve fiber distribution in the left colon [43]. The potential value of immunohistochemistry has been evaluated in a number of studies. Calretinin is an immunohistochemical marker that may be a potential alternative to AchE [44, 45]. Calretinin is normally present in the perikarya and nerve processes of a subset of enteric ganglion cells. Immunoreactivity is lost in the aganglionic segment of HD [45]. A recent comparative study shows that calretinin is as sensitive and specific as AchE [46]. However, further studies are needed to confirm calretinin immunostaining as a new standard for diagnosis.

Treatment

The treatment of HD consists of resecting the aganglionic segment of the rectum and colon, pulling down normally innervated bowel, and anastomosing this bowel at the anorectal region, while preserving the sphincter muscle. The past decades have seen an evolution in the surgical management of HD. The previous gold standard of two- or three-stage pull through with a preliminary stoma has slowly been progressively replaced by a one-stage approach in many centers [47–50]. More recently, minimally invasive approaches to the one-stage pull through have become popular. These consist of pull throughs utilizing laparoscopic abdominal and pelvic mobilization of the rectum and the transanal Soave procedure, which does not include any intra-abdominal dissection [47–53]. The one-stage approach, either by laparotomy or

by combined laparoscopy and transanal dissection, has been advocated even in the newborn period.

The results of the one-stage approach in small infants appear to be at least as favorable as those in which a staged procedure with a colostomy was used. Recently, the use of the one-stage definitive procedure for small infants with HD has increased. One-stage pull-through procedures using laparoscopy appear to be associated with shorter hospital stays, shorter time until full feeding is reached, and superior cosmetic results [51–53].

Short- and Long-Term Prognosis

Despite adequate resection of the aganglionic segment, some patients may continue to have persistent bowel dysfunction. Postoperative bowel dysfunction includes constipation, fecal incontinence, and a continuous risk of enterocolitis. An altered distribution and impaired function of ICC, resulting in defective generation of electrical pacemaker activity, have been suggested to be one of the mechanisms contributing to dysmotility in patients operated on for HD [54]. Investigations include barium studies to delineate strictures or leaks and further biopsy to exclude residual aganglionic bowel. If the definitive operation fails because of an impassable stricture, disruption, or residual disease, further secondary surgery may be necessary, and a different operation may then lead to an acceptable result. Data are accumulating to indicate that HD, a disorder once known and recognized exclusively to involve an aganglionic segment of distal colon, also affects motor function in other parts of the gut. The variability in manifestations could reflect the heterogeneity of basic genetic defects now recognized as being responsible for the phenotypic expression of HD. Abnormalities in esophageal motility are common, and duodenal motor dysfunction is present in 48% of patients [5].

Miele et al. have reported a systematic study of various aspects of gastrointestinal motor function in children with HD long after removal of the aganglionic colonic segment, observing gastrointestinal symptoms, including vomiting, distension, and poor growth, persisted long after surgery [55]. Abnormalities in duodenal motor activity have also been observed in these children shortly after operation [56].

Intestinal Neuronal Dysplasia

Intestinal neuronal dysplasia (IND) or hyperganglionosis, a condition that clinically resembles HD, was first described by Meier-Ruge in 1971 [57]. It is often associated with HD and may cause failure of clinical improvement after resectional pull-through surgery. In 1983, Fadda et al. classified IND into two clinically and histologically distinguished sub-

types, called type A and B. Type A occurs in less than 5% of cases and is characterized by congenital aplasia or hypoplasia of the sympathetic innervation, presenting acutely in neonatal period with episodes of intestinal obstruction, diarrhea, and bloody stools. Type B, which is clinically indistinguishable from HD, is characterized by a malformation of the parasympathetic submucosal plexus and accounts for more than 95% of cases of isolated IND [58].

The incidence of isolated IND varies from 0.3 to 40% of all suction rectal biopsies [59]. The incidence varies considerably among different countries; some investigators have reported that 25–35% of patients with HD have associated IND [58, 60]. However, others rarely encountered IND in association with HD [61]. Part of this discrepancy may be due to the persisting confusion over the essential diagnostic criteria. For a long time, IND has been diagnosed on the basis of four histological criteria applied to acetylcholinesterase-stained suction rectal biopsies. In 1991, on the recommendations of a working party (the Consensus of German Pathologists), Bouchard et al. published diagnostic criteria for IND using suction rectal biopsy specimen. These comprised two obligatory criteria: hyperplasia of the submucosal plexus and an increase in acetylcholinesterase-positive nerve fibers in the adventitia around submucosal blood vessels. Two additional criteria might be used: neuronal heterotopia and increased acetylcholinesterase-positive nerve fibers in the lamina propria [62]. The latest morphometric criteria are summarized as follows: >8 neurons/ganglion (so-called giant ganglia) in >20% of a minimum of 25 submucosal ganglia in patients older than 1 year [63]. However, concern has been expressed whether IND can be safely diagnosed by mucosal and submucosal alteration alone, without myenteric plexus abnormalities. Submucosal hyperganglionosis may reflect a normal age-related phenomenon due to immaturity, with clinical and histochemical normalization after the first year of life. Furthermore, it has been reported that most of the patients with submucosal IND have a spontaneous clinical improvement which is sometimes associated with histological normalization [64, 65]. To date submucosal IND has been reported in several disorders such as intestinal malformations, meconium plug syndrome, cystic fibrosis, gastroschisis, pyloric stenosis, and inflammatory processes involving the gut. The high frequency of histological abnormalities in young infants may represent a normal variant of postnatal development rather than a pathological process. Investigations using more refined and morphometric methods in rectal specimens from infants and children without bowel disease are needed to define the normal range for different ages [65]. Therefore, most of the evidence suggests that the histological appearance of so-called IND is a normal variant related to age. Owing to the lack of sufficient normative data, IND remains a histological description with poorly established clinical significance [40, 43]. Patients with IND

have been subjected to multiple types of treatment; however, the majority of patients with IND can be treated conservatively. If bowel symptoms persist after at least 6 months of conservative treatment, internal sphincter myectomy should be considered. The rapid AchE technique has been found to be of great value in determining the extent of IND intraoperatively [66].

Genetic Aspects

Studies have been performed to investigate the potential role of HD-associated *RET*, *GDNF*, *EDNRB*, and *EDN3* genes in the development of IND. They demonstrated that only three *RET* mutations were detected in patients with HD, no mutation in this gene was observed in IND, and mixed HD/IND patients, HD, and HD/IND patients showed overrepresentation of a specific *RET* polymorphism in exon 2, while IND patients exhibited a significantly lower frequency of the same polymorphism comparable with that of controls. These findings may suggest that IND is genetically different from HD.

A homozygous mutation of the *EDNRB* gene in spotting lethal (sl/sl) rats leads to HD phenotype with long-segmented aganglionosis. The heterozygous (+/sl) *EDNRB*-deficient rats revealed more subtle abnormalities of the ENS: The submucosal plexus was characterized by a significantly increased ganglionic size and density and the presence of hypertrophied nerve fiber strands, resembling the histopathological criteria for IND. Other animal model, like *Ncx/Hox11L.1*-deficient mice, suggests that many other genes could be involved in the pathogenesis of IND [67].

Efstratios Saliakellis, Osvaldo Borrelli and Nikhil Thapar

Introduction

The term pseudo-obstruction literally denotes the absence of a true mechanical occlusion. Intestinal pseudo-obstruction can be either acute or chronic in nature, reflecting the duration of obstructive symptoms, being shorter or longer than 6 months, respectively [1, 2]. Chronic intestinal pseudo-obstruction (CIPO) was first described in 1958 by Dudley and colleagues to report a series of 13 patients with symptoms suggestive of intestinal occlusion. These patients underwent exploratory laparotomies, which failed to identify a mechanical cause for their symptomatology [3]. In subsequent years, the existence of this pathological entity in both adults and children was substantiated by a number of other clinicians [4–7].

The pathophysiologic mechanism of CIPO is represented by abnormal antegrade propulsive activity of the gastrointestinal (GI) tract as a result of processes that affect its neurons, muscles, or interstitial cells of Cajal (ICC) [8]. This functional failure results in a number of clinical symptoms such as abdominal distention with or without abdominal pain, nausea, vomiting, and a reduced inability to tolerate enteral nutrition [9]. These symptoms are, however, nonspecific and the condition can remain undiagnosed for a long period of time during which patients may undergo multiple diagnostic investigations and often repeated surgical explorations in an effort to identify the cause [9].

Although by definition the small intestine is always involved, any part of the GI tract can be affected in CIPO [1, 2]. Esophageal involvement may lead to dysphagia from impaired peristalsis, in some cases akin to that seen in achalasia [10]. Involvement of the stomach results in poor feed tolerance from gastroparesis suggested by the presence of delayed gastric emptying, while the large bowel by delayed colonic transit and constipation and the anorectum by sphincter dysfunction and defecation disorders [1].

This chapter focuses on various aspects of childhood CIPO and attempts to address areas of controversy by exploring the most recent advances in the overall approach and management of this clinical entity.

Epidemiology

CIPO is a rare disease with scanty epidemiological data and poorly defined incidence and prevalence in both adult and pediatric populations. One of the few initiatives to elucidate its epidemiology suggested that approximately 100 infants are born in the USA every year with CIPO, suggesting an incidence of approximately 1 per 40,000 live births [11, 12].

Adult studies reveal that the disease is more frequent in females [13–15]. In a recently published national survey conducted in Japan, 138 cases of CIPO were identified, with an estimated prevalence of 1.0 and 0.8 cases and incidence of 0.21 and 0.24 cases per 100,000 males and females, respectively [16]. No similar data are available in pediatric age.

Undoubtedly, the development of national registries is of paramount importance to delineate more precise epidemiologic characteristics of this orphan clinical entity.

Classification

Classification of CIPO is challenging. Conditions can be classified by whether they primarily affect intestinal nerves (neuropathy), smooth muscle (myopathy), or ICC

(mesenchymopathy), and can be further subdivided into primary or secondary, congenital or acquired, mode of inheritance or what part of the GI tract is involved. Where classification is not possible, they are defined as idiopathic. In truth, there is a considerable overlap [1, 2].

In primary CIPO, the disease is usually localized to GI tract, whereas in secondary cases, there is a systemic disorder that affects GI tract motility. It must be noted though that in some cases of primary CIPO extra-GI involvement may also be present, such as the urinary tract (hollow visceral myopathy and megacystis microcolon intestinal hypoperistalsis syndrome), the nervous system (central, peripheral, autonomous), and/or mitochondria (mitochondrial neurogastrointestinal encephalomyopathy, MNGIE) [2, 17, 18]. Almost 50% of CIPO cases appear to fall into the category of secondary CIPO as highlighted in Table 23.1 [19]. Based on histological findings, both primary and secondary CIPO can

be further categorized into neuropathies, myopathies, and mesenchymopathies [20–25]. Although the onset of the disease is used to label whether CIPO is congenital or acquired, in children, this area needs to be better elucidated [2, 8, 26].

Etiology and Pathophysiology

The integrity of GI sensorimotor function relies on precise coordination between the autonomic nervous system, enteric nervous system (ENS), ICC, and smooth muscle cells. Any noxious stimulus, irrespective of its origin and etiology, that affects the neuromuscular elements and control of GI tract can lead to impaired peristalsis and the stasis of luminal contents [1]. A variety of disorders and pathophysiological mechanisms can potentially affect the structure or function of the neuromuscular elements of the GI tract and lead to CIPO (Table 23.1) [1]. Neurological (e.g., multiple endocrine neoplasia (MEN) type IIb, familial dysautonomia) and metabolic (e.g., diabetes mellitus) conditions may affect the extrinsic GI nerve supply [19]. Neurotropic viruses may evoke an inflammatory process targeting both the ENS and extrinsic neural pathways [93]. Paraneoplastic syndromes may also exert a destructive effect on the ENS by initiating an inflammatory process that targets the neurons of ganglia located in the submucosal and myenteric plexuses. This is mediated by both a cellular infiltrate and production of circulating antineuronal antibodies [19, 134]. Some pathologies (e.g., muscular dystrophy) may target enteric smooth muscle fibers, whereas others such as dermatomyositis, scleroderma, Ehlers–Danlos syndrome, radiation enteritis may distort both ENS and gut smooth muscle leading to a mixed neuromyopathic disorder [12, 135, 136]. Finally, although entities such as celiac disease, hypothyroidism, hypoparathyroidism, and pheochromocytoma presumably cause CIPO by affecting the GI neuromuscular integrity, the exact mechanism is not fully understood.

Genetics

Elucidation of the genetic basis of CIPO has been somewhat disappointing. Some familial cases of CIPO have been recognized but there appear to be several patterns of inheritance, perhaps reflective of the great heterogeneity of CIPO conditions. Both autosomal dominant and recessive modes of inheritance have been described for neuropathic and myopathic types of CIPO [5, 13, 14, 135, 137]. More specifically, rare autosomal dominant mutations in the *SOX10* gene, which encodes a transcription factor important in ENS development, result in a CIPO clinical phenotype along with features such as sensorineural deafness and pigmentary

Table 23.1 Classification of chronic intestinal pseudo-obstruction [7, 18, 27–133]

<i>Primary CIPO</i>
Sporadic or familial forms of hollow visceral myopathy/neuropathy (e.g., megacystis microcolon intestinal hypoperistalsis syndrome) [7, 27–44]
Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) [18, 45–47]
Hirschsprung’s disease [48–50]
Neuropathy associated with multiple endocrine neoplasia type IIB [51–53]
Malrotation or gastroschisis [54–56]
Neuropathy post neonatal necrotizing enterocolitis [57]
<i>Secondary CIPO</i>
Conditions affecting GI smooth muscle
Rheumatological conditions (dermatomyositis/polyomyositis, scleroderma, systemic lupus erythematosus, Ehlers–Danlos syndrome) [58–69]
Other (Duchenne’s muscular dystrophy, myotonic dystrophy, amyloidosis, ceroidosis, or alternatively reported as brown bowel syndrome) [70–79]
Pathologies affecting the enteric nervous system (familial dysautonomia, primary dysfunction of the autonomic nervous system, neurofibromatosis, diabetic neuropathy, fetal alcohol syndrome, post-viral related CIPO, e.g., CMV, EBV, VZV, JC virus) [80–95]
Endocrinological disorders (hypothyroidism, diabetes, hypoparathyroidism, pheochromocytoma) [96–100]
Metabolic conditions (uremia, porphyria, electrolyte imbalances, e.g., potassium, magnesium, calcium) [101–106]
Other (celiac disease, eosinophilic gastroenteritis, Crohn’s disease, radiation injury, Chagas disease, Kawasaki disease, angioedema, mitochondrial disorders, drugs, e.g., opiates, anthraquinone laxatives, calcium channel blockers, antidepressants, antineoplastic agents, e.g., vinca alkaloids, paraneoplastic CIPO, major trauma/surgery, chromosome abnormalities) [107–133]
<i>Idiopathic</i>
CMV cytomegalovirus, EBV Epstein–Barr virus, VZV varicella-zoster virus, JC John Cunningham

anomalies [138, 139]. Homozygosity on the region 8q23–q24 has been implicated in the pathogenesis of an autosomal recessive form of CIPO characterized by severe GI dysmotility, Barrett's esophagus, and cardiac anomalies [140, 141].

X-linked inheritance (locus Xq28) with recessive transmission has been described in CIPO [15, 142, 143]. Mutations of filamin A (*FLNA*) and L1 cell adhesion molecule (*LICAM*) genes, which are both located on chromosome Xq28, result in predominantly myopathic and neuropathic forms of CIPO, respectively. Additional involvement of the central nervous system, heart (patent ductus arteriosus), and blood (thrombocytopenia) in both conditions has also been described [143–145].

Mutations in mitochondria are increasingly implicated in CIPO. Mutations in the thymidine phosphorylase gene (*TYMP*, also termed as endothelial cell growth factor-1, *ECGFI*), or in the polymerase- γ gene (*POLG*) result in recessive myopathic forms of CIPO. The former is the cause of MNGIE, whereas the latter leads to a form without encephalopathy. Apart from the GI dysmotility, MNGIE is characterized by severe malnutrition, ophthalmoplegia, and leucoencephalopathy on brain MRI [146–148].

The responsible genes for familial visceral neuropathy and myopathy are yet to be identified.

Histopathology

In adults, GI histology is reported to be normal in approximately 10% of CIPO cases, while in the experience of the authors, this figure is likely to be higher in children. However, its role in CIPO remains crucial and therefore an adequate full-thickness bowel biopsy (preferably a circumferential sleeve of at least 1–2 cm) is recommended whenever surgery is being considered [8, 26, 149]. Recent initiatives are addressing a more standardized and hopefully effective histological approach to diagnosis in GI motility disorders such as CIPO [Knowles et al., working group] [25, 150, 151].

On the basis of histology, CIPO is classified into neuropathy, myopathy, or mesenchymopathy [25]. However, mixed forms (e.g., neuromyopathy) are also recognized [25, 152, 153].

Neuropathies and myopathies can be further subdivided into inflammatory and degenerative. Inflammatory neuropathies are characterized by an infiltration of T lymphocytes and plasma cells in the myenteric plexuses (myenteric ganglionitis) and neuronal axons (axonopathy) [25, 154]. It has been proposed that five or more lymphocytes per ganglion are required for the diagnosis of myenteric ganglionitis [25]. Of note, patients with lymphocytic infiltration of the myenteric plexuses may also develop increased titers of antinuclear antibodies (ANNA-1/anti-Hu, anti-voltage-gated potassium channel or VGKC) [155–157]. These immunologic

responses may result in neuronal degeneration and loss by activating apoptotic and autophagic mechanisms [156, 158]. Infiltration of the myenteric ganglia with other cells such as eosinophils and mast cells has been described but their exact clinicopathological significance is yet to be clarified given limited data [159–162]. All these data support the role of the immune system in the pathogenesis of inflammatory CIPO [163].

Degenerative neuropathies are poorly understood given the limited amount of available data [164–166]. Main histopathologic characteristics of this group include a decrease in the number of intramural neurons along with changes in nerve cell bodies and axons [150, 154]. It has been postulated that apoptotic mechanisms are involved in the degenerative process potentially caused by aberrant calcium signaling, mitochondrial disorders, production of free radicals, and abnormalities in the function of glial cells [150, 152, 167, 168].

Similarly to neuropathies, myopathies are also divided into inflammatory and degenerative. Inflammatory myopathies, also reported by the term leiomyositis, are characterized by infiltration of T lymphocytes into both the circular and longitudinal enteric muscle layers. This process if not treated appropriately with immunosuppressive agents may lead to a severe clinical picture of CIPO [44, 169].

The histopathologic findings in degenerative myopathies include smooth muscle fiber vacuolization and fibrosis [170, 171]. Diverticula may also be present especially if the longitudinal muscle coat is more affected compared to the circular muscle layer [146, 148].

Novel immunohistochemical techniques such as smooth muscle markers, namely, smoothelin, smooth muscle myosin heavy chain, and histone deacetylase 8, may reveal histopathologic subtleties otherwise not detectable with conventional immunostaining and histochemistry methods [172].

Mesenchymopathies are defined by ICC abnormalities (decreased density of ICC network, intracellular abnormalities) and have been demonstrated in CIPO patients [150, 173]. Although sufficient data exist regarding their role in the pathogenesis of diabetic gastroparesis, further research is required regarding ICC involvement in the etiopathogenesis of other GI motility disorders [25].

Clinical Picture

In a few cases, the diagnosis of CIPO is suggested in utero by ultrasonographic findings of polyhydramnios, abdominal distention, and megacystis; however, the majority of cases present in the neonatal period or early infancy [8, 26]. The symptomatology varies according to the age at diagnosis and the part of the GI tract, which is primarily affected. Approximately, one-third of children with congenital CIPO (myopathic and neuropathic) have intestinal malrotation

[22]. Cardinal signs and symptoms of CIPO include those of obstruction, namely abdominal distention (88%), vomiting (72%, which can be bilious), and constipation (61%). Abdominal pain (44%), failure to thrive (31%), and diarrhea (28%) may also be part of the clinical picture [8, 9, 149].

Dehydration (which can be severe) and malnutrition are often underdiagnosed especially given that weight can be an unreliable measure due to pooling of significant volumes of fluid (third spacing) within distended gut loops. Intraluminal gut content stasis can also lead to small bowel bacterial overgrowth which can further exacerbate symptoms of diarrhea and abdominal distention [149].

CIPO may also manifest with extraintestinal signs and symptoms, such as recurrent urinary tract infections or neurologic abnormalities [17, 147]. Furthermore, patients may complain of symptoms indicative of an underlying disorder that accounts for secondary CIPO (e.g., proximal muscle weakness in dermatomyositis) [59].

The clinical course of CIPO is characterized by exacerbations and remissions, where the former can be precipitated by a number of factors such as surgery, general anesthesia, infections, and emotional stress [26]. In the most severe cases, the natural course of the disease leads to worsening intestinal function and ultimately to intestinal failure [9, 149]. This is especially true in cases where the diagnosis and/or institution of appropriate treatment has been delayed.

Diagnosis

CIPO should be suspected in children with early onset, chronic, recurrent, or continuous signs of intestinal obstruction especially where a surgical cause cannot be established

(e.g., repeated “normal” exploratory laparotomies). The diagnosis of CIPO should follow a structured algorithm. Although a detailed history, clinical examination, and laboratory tests may suggest the presence of CIPO, or help elucidate its cause, the definitive diagnosis should rely on the use of targeted investigations to (i) exclude mechanical occlusion of the gut lumen, (ii) confirm GI dysmotility, and (iii) rule out treatable causes.

Careful clinical history and physical examination may help in defining the onset, the severity and progression of the disease, and the part of the GI tract primarily affected, and they also provide useful information regarding associations (e.g., family history), potential secondary causes (e.g., medications), and complications (e.g., dehydration). Laboratory tests (e.g., serum electrolytes, thyroid-stimulating hormone (TSH), lactic acid, specific autoantibodies) are useful in cases of secondary CIPO and assessing the clinical state of the patients admitted acutely or undergoing a diagnostic protocol.

The definitive diagnosis of CIPO in children is often reliant on a number of diagnostic tests, which exclude luminal obstruction and confirm the presence of impaired GI motility. These are discussed below.

Imaging

Plain abdominal radiographs may demonstrate a dilated GI tract, with air-fluid levels, whereas contrast GI series can reveal anatomical abnormalities (e.g., malrotation, microcolon) and exclude the presence of gut occlusive lesions (Fig. 23.1a) [2, 149, 174]. It needs to be kept in mind that a water-soluble substance should be used instead of barium in

Fig. 23.1 Investigation findings of a 3-year-old boy with a history of recurrent episodes of abdominal distension and vomiting since the neonatal period, and now showing a marked reduction in enteral feed tolerance. **a** Contrast follow-through study (administered via gastrostomy) showing filling of grossly dilated small intestinal loops, without any apparent hold up or change in calibre. **b** Plain abdominal radiograph taken following placement of antroduodenal manometry catheter into the same patient performed under fluoroscopic guidance. The tip of the

catheter has been advanced beyond the duodenojejunal junction to facilitate optimal manometric recording of both the stomach and small intestine. **c** Antroduodenal manometry tracing from patient showing the presence of some gastric antral contractions and a migrating motor complex (phase III activity) passing down the small intestine. The amplitude of small intestinal contractile activity is very low (not exceeding 20 mmHg) suggesting a diagnosis of myopathic chronic intestinal pseudo-obstruction

order to prevent flocculation and inspissation of the contrast material.

Novel imaging modalities such as cine MRI have been recently performed with promising results in adult series but there are no data regarding their applicability and usefulness in pediatrics [175].

Endoscopy

Endoscopy may identify fore- or hindgut mechanical occlusion previously missed on radiology, and it allows duodenal biopsies to exclude mucosal inflammation [176]. Novel techniques (e.g., natural orifice transluminal endoscopic surgery—NOTES) may revolutionize the role of endoscopy in the diagnosis of gut motility disorders by providing the ability of full-thickness biopsy sampling in a safe and minimally invasive way [177, 178].

Motility Investigations

These studies are performed to assess the GI motility and to define the underlying pathophysiologic process, and these studies form the hallmark of diagnosis in pediatrics. Investigations include GI manometries (esophageal, antroduodenal, colonic, anorectal), GI scintigraphy (e.g., gastric emptying, colonic transit), electrogastrography, and radiopaque markers. The usefulness of novel technologies, such as SmartPill, remains to be determined [8, 179, 180].

Although in children with CIPO the involvement of GI may be generalized, the small intestine is always affected; thus, antroduodenal manometry remains the most discerning test, and its optimal placement is pivotal (Fig. 23.1b) [181]. Neuropathic cases manifest with uncoordinated contractions, which are of normal amplitude, whereas in myopathic CIPO, motor patterns have normal coordination; however, the amplitude of intestinal contractions is low (Fig. 23.1c) [182–184]. Additionally, manometry may facilitate the dynamic assessment of potential pharmacotherapeutic options and feeding strategies (e.g., feasibility of oral or enteral feeds) as well as indicate disease prognosis [185–187].

In the most challenging cases, exploratory surgery (laparotomy or laparoscopic-assisted procedures) may be required to definitively exclude mechanical obstruction from CIPO. One however should bear in mind that surgery may precipitate a pseudo-obstructive episode and may also lead to adhesions formation, which can further complicate future diagnostic or therapeutic procedures. Where possible, investigations and then diagnostic/therapeutic surgery should be performed in timeline sequence and in referral center.

Histopathology along with genetics can also be very useful in establishing or confirming the diagnosis of CIPO,

highlighting the underlying pathophysiologic process, thus aiding the overall management.

Figure 23.2 summarizes the basic steps in the diagnostic evaluation of pediatric patients with suspected CIPO.

Differential Diagnosis

CIPO has to be differentiated from mechanical obstruction; the latter is usually characterized by marked abdominal pain (in keeping with the abdominal distention), specific radiologic signs, and manometric patterns [188, 189]. Acute functional obstruction (e.g., postoperative ileus), functional GI disorders (e.g., rumination syndrome), and pediatric condition falsification should be considered and appropriately investigated and managed [149, 190, 191].

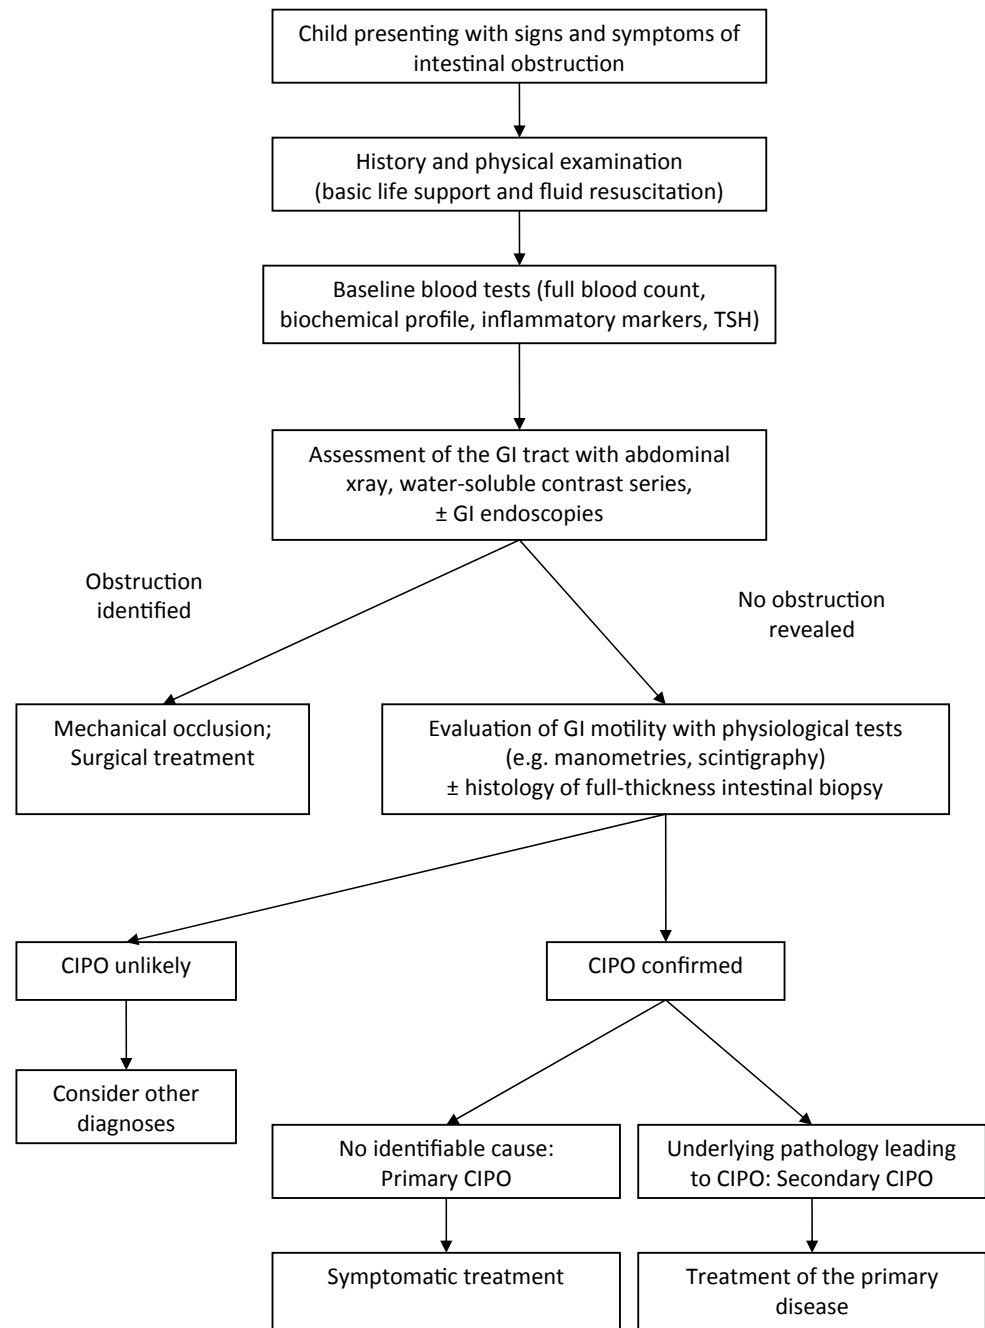

Treatment

The therapeutic approach in CIPO is threefold as it aims to (i) preserve growth and development by maintaining adequate caloric intake, (ii) promote GI motility with combined medical and surgical interventions, and (iii) treat disease-related complications or underlying pathologies that cause secondary CIPO. Despite the limited effects of the currently applied therapeutic modalities, refinements and evolution in nutritional, medical, and surgical strategies have considerably improved the overall management of CIPO [136, 192]. Acute management of episodes of pseudo-obstruction are generally treated conservatively by nil by mouth, intravenous fluid, and drainage of stasis through nasogastric (NG) tube or preformed ostomies. Careful attention to fluid and electrolytes is imperative.

Nutrition

The role of nutrition in CIPO is of paramount significance as it is well known that gut motility improves with optimal nutritional support and declines in the face of under- or malnutrition [8]. In the long term, approximately one-third of pediatric CIPO patients require either partial or total parenteral nutrition, another third require a degree of intragastric or intra-enteral feeding, whereas the remaining children are able to tolerate sufficient oral nutrition. However, within all of groups, patients able to tolerate feeds may require some dietary modification in order to maintain enteral nutrition and avoid bezoar formation (e.g., bite and dissolvable feeds, restriction diets, hydrolyzed formula). Although parenteral nutrition is lifesaving, it is associated with significant risk of complications, such as central line infections and liver disease, and therefore maintaining patients on maximally

Fig. 23.2 Suggested diagnostic algorithm for childhood chronic intestinal pseudo-obstruction. Also see [2]

tolerated enteral nutrition is always strongly encouraged [26]. In the more severe CIPO cases, continuous rather than bolus feeds administered via a gastrostomy or jejunostomy may be better tolerated particularly in children with impaired gastric motor function [193–195].

Medications

The therapeutic role of drugs in CIPO patients is mainly limited to the control of intestinal inflammation, suppression of bacterial overgrowth, and promotion of GI motility [186, 195].

Prokinetics (e.g., metoclopramide, domperidone, erythromycin, azithromycin, octreotide, neostigmine) usually combined with antiemetics (e.g., promethazine, ondansetron) have been used in an attempt to improve the GI motor function and reduce the severity of nausea and vomiting [196–199]. The use of some of these agents is limited by variable efficacy and unacceptable extraintestinal side effects (e.g., metoclopramide, neostigmine). The best-studied and tested prokinetics, that is, cisapride and tegaserod have been withdrawn from the market due to safety concerns [200]. The need for new prokinetics with increased safety and efficacy has resulted in new products (e.g., prucalopride, aprepitant,

ghrelin), but there are limited data of their use in pediatric CIPO, further impacted on by restricted availability and licensing [201–203]. Undoubtedly, current medical regimens for CIPO are based on limited literature and/or expert opinion (e.g., combined use of octreotide and erythromycin) and are yet to be tested in future in the context of controlled trials [186, 204].

Surgery

Surgery remains a valuable intervention on patients with CIPO as it has a multidimensional role in both the diagnostic (e.g., full thickness biopsies) and therapeutic processes (e.g., insertion of feeding tubes, formation of decompressing ostomies such as gastrostomy, ileostomy) [195, 205, 206].

Indeed, adequate bowel decompression is crucial not only in providing symptomatic relief by reducing the frequency and the severity of pseudo-obstructive episodes but also in limiting further deterioration of the intestinal motor activity secondary to chronic distention, and in enhancing the tolerance of enteral feeding [195, 205]. Long decompression enteral tubes and extensive bowel resections are approaches mainly reported in adult CIPO cohorts but remain untested in terms of practicality, efficacy, and safety in pediatrics [207, 208]. Rate of significant surgical complications, such as stoma prolapse, infection, and leakage can be significant.

Novel surgical methods involve implantation of devices providing electrical pacing of the GI neuromusculature, but data in children are scanty and limited [209].

Small bowel transplantation remains the only definitive cure. Recent advances in both surgical techniques (e.g., multivisceral transplantation) and immunosuppression strategies have resulted in improved outcomes and survival as reported by centers with the relevant expertise showing a survival rate of 50% at 3 years [210–213].

Natural History and Prognosis

Both pediatric and adult CIPO have a severe clinical course, characterized by repetitive relapses and remissions. Unfortunately, the low index of suspicion among physicians along with lack of well-defined diagnostic criteria and readily available facilities in performing specialized diagnostic tests (e.g., manometry) often accounts for delays in the diagnosis and repetitive unnecessary investigations and surgery [13–15, 164].

The majority of the patients complain of symptoms, which progressively worsen and impact upon the tolerance of enteral nutrition and increasing reliance on total parenteral nutrition. The latter in conjunction with disease-related adverse events (e.g., central line infections, impairment of the

liver function, immunosuppression after small bowel transplantation, surgical procedures) accounts for high morbidity, poor quality of life, and mortality rates up to 30% [11, 21, 28, 214–218].

Despite recent diagnostic and therapeutic advances, CIPO in children remains a serious, life-threatening disease with significant impact on the well-being not only of patients themselves but also of their families [218].

Summary

Childhood CIPO is an enigmatic disease with poorly defined etiopathogenesis, which is reflected on the limitations encountered in both the diagnostic process and therapeutic management. Clearly, multinational initiatives are required to raise awareness, establish stringent diagnostic criteria, and evolve current therapeutic modalities.

Paolo Quitadamo and Annamaria Staiano

Introduction

The increasing survival of children with severe central nervous system damage has created a major challenge for medical care. Although the primary problems for individuals with developmental disabilities are physical and mental incapacities, several clinical reports have indicated that brain damage may result in significant gastrointestinal (GI) dysfunction [1–4]. The enteric nervous system contains more neurones than the spinal cord and thus it is not surprising that insults to the central nervous system may affect the complex integrated capacities underlying feeding and nutrition [5].

The increased awareness of such conditions, together with a better understanding of their etiology and interplay, is essential to achieve an optimal global management of this group of children.

Feeding and Nutritional Aspects

Historically, severe malnutrition has been accepted as unavoidable and irremediable consequence of neurological impairment. Poor nutritional state was often marked by linear growth failure, decreased lean body mass, and diminished fat stores [6, 7]. Over the past two to three decades, multidisciplinary feeding programs providing comprehensive evaluation and treatment of feeding disorders in children with developmental disabilities have been instrumental in improving the nutritional status, quality of life, and reduced hospitalization rates [8]. Studies on small number of children with developmental disabilities have demonstrated that adequate nutritional support, provided by less invasive enteral access methods and better tolerated enteral formulas, may improve weight, muscle mass, subcutaneous energy store,

peripheral circulation, the healing of decubitus ulcers, and general well-being, while decreasing irritability and spasticity [9, 10].

The true prevalence of undernutrition in neurologically impaired children is unknown. It has been estimated that approximately one third of them are undernourished and many exhibit the consequences of malnutrition [7]. Yet, the incidence and severity of malnutrition increases with the duration and the severity of neurological impairment [11–13]. Parameters to assess malnutrition and overnutrition in the handicapped child have to be adjusted. Height is a proper parameter for growth and nutritional status, but difficult in children with malformations and spasticity [14–16]. Also, disproportionate development of the head, rump, and extremities makes assessment of height as a parameter of nutritional status difficult [17–19]. Therefore, crown–rump length, width, crown–heel length, distal femoral length, and distal arm length (Spender growth curve) have been developed to assess growth and to relate height to developmental abnormalities or to nutrition [20]. In a study on more than 2000 institutionalized children with a handicap in Tokyo, Japan, height and weight were measured in four distinct groups. Groups were divided into deaf children, blind children, mentally retarded children, some of whom were completely ambulatory, and 15% of whom needed crutches, and physically handicapped children, of whom 65% were nonambulatory. Height more than three standard deviations below the mean was present in 2% of deaf children, 10% of blind children, 15% of children with mental retardation, and 45% of physically handicapped children. Underweight more than two standard deviations below the mean was present in 1% of deaf children, 4% of blind children, 5% of children with mental retardation, and 24% of physically handicapped children [15]. In a Finnish study of patients up to the age of 20, the body mass index (BMI) showed that underweight ($\text{BMI} < 20 \text{ kg/m}^2$) was present in 30%, overweight in 10%, and severe overweight in 7% ($\text{BMI} > 32 \text{ kg/m}^2$) [21].

The predominant nutritional deficit in neurologically impaired children is in energy intake, with only 20% of these

e-mail: staiano@unina.it

children regularly ingesting 100% of their estimated average requirement. Moreover, half of the children with severe disabilities consumed less than 81% of the reference nutrient intake for copper, iron, magnesium, and zinc, with that influenced by their large consumption of milk [22].

Nutritional support is essential for the care of neurologically impaired children. Undernourished handicapped children might not respond properly to intercurrent diseases and suffer unnecessarily. On the other hand, restoring a normal nutritional status results in a better quality of life in many. Assessment of nutritional status requires a proper follow-up of height, body weight, and assessment of the standard deviation score. By so doing, negative changes are easily discovered and appropriate nutritional intervention can be initiated. An individualized intervention plan that accounts for the child's nutritional status, feeding ability, and medical condition should be determined. Energy requirements must be individualized considering mobility, muscle tone, activity level, altered metabolism, and growth. The easiest and least invasive method to increase energy intake is to improve oral intake. Food caloric density may be increased by adding modular nutrients, modifying recipes, or using high-calorie formulas. Children who cannot chew effectively may be able to receive the same foods blenderized into a puree of acceptable consistency. Those who can tolerate solids but not liquids can have commercial thickeners added to their fluids. Oral feeding skills may be improved with therapy, even if the results may be disappointing [23–25]. Adequate positioning of the child during meals and appropriate food temperature are furthermore important. However, oral intake can be maintained as long as there is no risk of aspiration, the child is growing well, and the time required to feed the child remains within acceptable limits.

When oral intake is unsafe, insufficient, or too time consuming, enteral nutrition should be initiated. The type of enteral access will depend on the anticipated duration of enteral nutrition support as well as the clinical status of the child. Nasogastric tubes are minimally invasive but are easily dislodged and have local complications such as sinusitis, congestion, otitis, and skin irritation. Generally, nasogastric feeds should only be used for a short-term nutritional support (less than 3 months). For long-term enteral nutrition support, a gastrostomy should be considered. Gastrostomies are more invasive, but are also more convenient and esthetically acceptable. Gastrostomy placement has been shown to reduce feeding time, food-related choking episodes, frequency of chest infections, and family stress, and to improve weight and nutritional status significantly in children with severe neurologic impairment [10, 18]. However, percutaneous endoscopic gastrostomy (PEG) is not without complications or concerns. Minor catheter infections, perforation, and an overall lessened length of survival have been described in both adult and pediatric populations [26–31].

The anatomy and function of the stomach should be carefully evaluated before the placement of the feeding tube. The coexistence of gastroesophageal reflux (GER) may require a simultaneous fundoplication, and delayed gastric emptying must necessitate pyloroplasty or duodenal placement of the distal portion of the tube. Physiologically designed formulas of increased caloric and protein density can be used for gastric and nasogastric infusion, as palatability is no longer an issue. The choice between bolus and drip may depend on esophagogastric function, the volume to be delivered, or the home care needs of the child and his or her caregivers. Often patients may benefit from a combination of daytime bolus and nocturnal continuous feeds, the latter providing 30–50% of the child's nutrient needs and thus allowing more freedom for daily activities. When safety of oral feeding is not an issue, these enteral techniques can merely supplement the child's own nutrition, with caregivers continuing to feed the child actively. This dual feeding method often provides great satisfaction to parents and caregivers, because the mealtime interaction is improved when there is no longer a need for force-feeding of medication or nourishment.

GI Problems

Chronic GI disorders are very common in children with neurological impairment, being reported a prevalence of up to 92% [32]. Dysphagia, rumination, GER, delayed gastric emptying, abdominal pain, and constipation have all been described in this group of children, potentially contributing to feeding difficulties and carrying challenging long-term management issues.

Dysphagia

Oral motor dysfunction is a frequent concomitant and often one of the first signs of neuromuscular impairment. Related swallowing problems have been shown to affect up to 90% of neurologically impaired children, being major contributors to malnutrition [1]. This is not surprising since the development of oral-motor skills mirrors general neurological maturation and requires the coordination of the movement of several striated muscles in the mouth, pharynx, and esophagus by six cranial nerves, the brain stem, and the cerebral cortex. In addition, anatomic abnormalities such as cleft palate, laryngeal clefts, and tracheoesophageal fistula may accompany neurologic deficits as part of a congenital or genetic syndrome. Dysphagia may manifest as distress during meals (including coughing, choking, and refusal of feeding), chronic or episodic aspiration-related respiratory disorder, and failure to thrive. Barium swallow, cine swallow, radionuclide esophageal clearance scan, and esophageal

manometry may all be of some help in the clinical assessment. Successful management of dysphagia is central to the child's well-being and ability to achieve his or her potential. Neurologically impaired children often show greater problems with liquid foods, thus requiring the use of thickener products. Oral motor exercise approaches using sensory modalities may help improving muscle strength and oral coordination. Nevertheless, in most cases, the presence of unsafe swallows and/or long-lasting distressed meals finally lead to the choice of enteral nutrition.

Gastroesophageal Reflux

Several reports have demonstrated the high incidence of GER in neurologically impaired children. GER symptoms such as vomiting, rumination, and regurgitation are found in 20–30% of the intellectually disabled population. GER-related iron-deficiency anemia and hematemesis are noted in 10–20% of patients. In the Netherlands and Belgium, in a large cohort of more than 1500 patients, a randomly selected intellectually disabled population was tested with pH-metry during 24 h. A pathological pH test (defined as a duration of a pH of <4 for more than 4% of the measured time) was seen in 48% of cases [33]. These patients were subjected to endoscopy, and reflux esophagitis was found in 96%: 14% had grade I esophagitis, 33% had grade II, 39% had grade III, and 13% had grade IV (Savary–Miller classification). Barrett's esophagus was found in 14% and peptic strictures in 4% of cases. This study was repeated for the group under the age of 14, and similar findings were seen. In fact, GER disease was found even in the absence of overt symptomatology. Prolonged supine position, increased intra-abdominal pressure secondary to spasticity and scoliosis, a coexisting hiatal hernia have been supposed to be contributing factors to the increased frequency of GER. Central nervous system dysfunction, however, is likely to be the prime cause, being GER probably a part of the generalized dysmotility of the foregut, if not of the entire intestine. Decreased resting pressure and increased frequency of transient relaxations of the lower esophageal sphincter, together with motility abnormalities, are probably a consequence of neuromuscular incoordination.

Currently, the most accurate way of diagnosing GER is 24-h esophageal pH impedance recording, which not only allows to quantify the amount of reflux episodes but also helps in establishing the temporal relationship between GER and the symptom complex in question. The diagnostic work-up should then include upper GI endoscopy with multiple esophageal biopsies and upper GI barium study, in order to evaluate the mucosa and to look for the possible presence of strictures, diverticuli, or hiatal hernia. Radionuclide studies such as gastroesophageal scintigraphy should also be per-

formed, due to the higher incidence of delayed gastric emptying which may contribute to GER [34, 35]. An esophageal manometry evaluating visceral motility may be helpful to detect the underlying pathophysiological mechanisms, especially when surgery becomes necessary.

Although children with neurologic impairment are more likely to have intractable reflux and eventually require some surgical procedures, medical therapy should be tried first. When surgery becomes advisable, the Nissen fundoplication is currently the most widely used technique to strengthen the anti-reflux barrier and relief symptoms.

Constipation

Infrequent stool passage and hard bowel movements are very common in neurologically impaired children. The incidence of constipation was around 61% in a large cohort of mentally handicapped children in Dutch and Belgian institutions [36]. Total and sequential colonic transit times have been shown to be prolonged and delayed at the level of the left colon and rectum in this group of children, implying a probable defect in gut innervations [3]. The problem is usually exacerbated by prolonged immobility, inadequate fiber intake, and medications. Unfortunately, recognition and therefore effective management of constipation are often delayed because their other disabilities overshadow those related to defecation. Therapeutic approach needs to be tailored to the individual patient. Oral or rectal disimpaction should be followed by promotion of regular bowel habits, through dietary modifications, positioning, and use of medications. A significant number of children with neurological impairment need to be on chronic doses of laxatives, which are usually effective in enabling regular defecations. However, when medical treatment fails, a surgically placed appendicostomy should be considered.

Introduction

Despite improved characterization, recognition, and understanding of cyclic vomiting syndrome (CVS) in the past two decades, without a delineated pathophysiologic cascade, it remains classified as a functional gastrointestinal (GI) disorder. The hallmark symptoms described by Samuel Gee in 1882 remain applicable today and include stereotypical, severe episodes of vomiting punctuating symptom-free periods or baseline health [1]. Earlier clinical diagnosis has been facilitated by the recently defined consensus diagnostic criteria by North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN 2008) and Rome III (2006) criteria, the former being quantitatively more rigorous, that is, requiring three to five versus two total episodes [2] (Table 25.1). From an operational standpoint, the predominant and most consistent symptom during episodes defines the illness, that is, abdominal pain is termed abdominal migraine, and conversely vomiting is denoted CVS. However, there is considerable clinical overlap because ~50% of those diagnosed with abdominal migraine also vomit, and ~80% of those with CVS also have abdominal pain.

The continuum between CVS and migraine was suggested by Whitney in 1898 and corroborated by other authors including us in 1998 [4, 5]. In a cross-sectional school survey in Scotland, Abu-Arafeh described a developmental progression from CVS to abdominal migraine and migraine headaches (median ages 5, 9, and 11 years, prevalences 1.9, 4, and 11%, respectively) [6]. This suggestion of a natural history that begins with CVS and ends with migraines reproduces initial reports by Barlow in 1984 who labeled this

progression as the “periodic syndrome” [7]. Although some experience all three phases, the majority trade CVS for migraines by age 10. We estimate that 75% will develop migraine headaches by age 18 years.

The lack of a specific The International Classification of Diseases (ICD) 9 code and use of persistent vomiting (536.2) have hindered establishment of the true prevalence of CVS. ICD 10 will have a specific code and enable proper epidemiologic surveys. Typical misdiagnoses, including gastroenteritis, gastroesophageal reflux, food poisoning, and eating disorders, often delay accurate diagnosis by a median 2.6 years. In our consecutive series, CVS was second only to gastroesophageal reflux as a cause of recurrent vomiting [8]. Two school-based surveys (not clinical exam) estimated the frequency to be 2% in Scottish and Turkish children, and the incidence of new cases of CVS was reported to be 3.15 per 100,000 children per year in Irish children [6, 9]. In our series, the average age of onset of CVS is 4.8 years, with a predominance in girls over boys (57:43; Table 25.2).

Recently, pathophysiologic connections have been made with mitochondrial disease, autonomic dysfunction and the stress response. Current research, including our own, is focused on the identification of neuroendocrine mechanisms mediating vomiting in these patients.

Cyclic Versus Chronic Patterns of Vomiting

An important clinical clue to the diagnosis of CVS is the pattern of vomiting. Based on temporal pattern, children with recurrent vomiting can be delineated into cyclic and chronic groups. The *cyclic group* has an intense, but intermittent pattern of vomiting with peak emesis of $\geq 4/h$ and ≤ 2 episodes per week [10]. The *chronic group* has a low-grade, daily pattern of emesis with < 4 emesis/h and > 2 episodes per week [10]. Two thirds of all children with recurrent vomiting fit into the *chronic* or continuous pattern of vomiting. These children rarely appear acutely ill or become dehydrated. Conversely, the *cyclic* pattern is associated with more in-

Table 25.1 NASPGHAN and Rome III diagnostic criteria. (Sunku and Li [3], with kind permission from Springer Science + Business Media)

NASPGHAN
1. At least five attacks in any interval, or a minimum of three attacks during a 6-month period
2. Episodic attacks of intense nausea and vomiting lasting 1 h–10 days and occurring at least 1 week apart
3. Stereotypical pattern and symptoms in the individual patient
4. Vomiting during attacks occurs at least 4 times/h for at least 1 h
5. Return to baseline health between episodes
6. Not attributed to another disorder
Rome III
1. Two or more periods of intense nausea and unremitting vomiting or retching lasting hours to days
2. Return to usual state of health lasting weeks to months

All respective criteria must be met to meet consensus definitions for both NASPGHAN and Rome III

Table 25.2 Epidemiology and demographics. (Sunku and Li [3], with kind permission from Springer Science + Business Media)

Features	
Age of onset	4.8 years
Delay in diagnosis	2.6 years
Prevalence	2%
Incidence	3.15/100,000
Female to male ratio	57:43
Migraine association	39–87%

tense vomiting and affected children more often require IV hydration (62 vs. 18%) compared with the chronic group [8] (Table 25.3).

These two patterns are also important because both of these groups differ in symptom and diagnostic profile. In those with the cyclical vomiting pattern, non-GI disorders including neurologic (including abdominal migraine), renal, endocrine, and metabolic ones predominate over GI disor-

Table 25.3 Characteristics of chronic and cyclic vomiting. (Reprinted with permission from Ref. [11], Table 20.3, p. 292)

	Chronic pattern	Cyclic pattern
Time of onset	Daytime	Nighttime or early morning
Peak number of emeses/h	<4 emeses	≥4 emeses
Frequency of recurrence	>2 episodes/week	≤2 episodes/week, typically 2–4 weeks
Family history of migraine	Uncommon (14%)	Common (82%)
Ill-appearing	No	Yes (pale, lethargic)
Headaches	Infrequent (19%)	More frequent (41%)
Photophobia	Infrequent (4%)	More frequent (18%)
Vertigo	Infrequent (7%)	More frequent (24%)
Intravenous hydration	Uncommon (18%)	Common (58%)
Esophagitis on EGD	Common (59%)	Uncommon (15%)

EGD esophagogastroduodenoscopy

Table 25.4 Differential diagnosis of cyclic vomiting. ([11], Table 20.4, p. 293)

	Chronic pattern	Cyclic pattern
Gastrointestinal	Peptic injury (GERD esophagitis, gastritis, duodenitis)	Anatomic (malrotation, volvulus, duplication cyst)
	Eosinophilic gastroenteritis/esophagitis	
	Celiac disease	
	Giardiasis	
	Inflammatory bowel disease	Pseudo-obstruction
		Cholelithiasis/gallbladder dyskinesia
	Chronic appendicitis	
	Pancreatitis	
Infectious	Chronic sinusitis	Sinusitis/other infections may be a trigger
Genitourinary	Pyelonephritis, pregnancy	Acute hydronephrosis due to ureteropelvic junction obstruction or stones
Metabolic	Rare	Mitochondrial disorders (MELAS)
		Organic acidemias
		Aminoacidurias
		Fatty acid oxidation defects
		Urea cycle defects
		Acute intermittent porphyria
Endocrine	Adrenal hyperplasia	Addison's disease
		Diabetic ketoacidosis
		Pheochromocytoma
Neurological	Chiari malformation	CVS, migraine (headaches/abdominal)
		Familial dysautonomia
Psychiatric	Münchhausen by proxy (rare)	Münchhausen by proxy (rare)
	Functional vomiting	Bulimia nervosa

GERD gastroesophageal reflux disease, CVS cyclic vomiting syndrome, MELAS mitochondrial encephalomyopathy, lactic acidosis, and stroke

ders by a ratio of 5:1 [10, 12]. In contrast, in the chronic group, GI disorders (mostly peptic disease) predominate over non-GI causes for vomiting by a ratio of 7:1 [10, 12] (Table 25.4). This implies the need to center the diagnostic work-up on extraintestinal disorders in children who present with the *cyclic* vomiting pattern, while on upper GI (UGI) tract disorders in the *chronic* vomiting pattern.

Clinical Patterns

CVS has a distinctive on–off temporal pattern of vomiting that serves as an essential criterion for diagnosis. CVS is distinguished by the “on” pattern of discrete, recurrent, and

severe episodes of vomiting that are stereotypical within the individual as to time of onset (usually early morning), duration (hours or days), and symptomatology (pallor, listlessness). The “off” pattern occurs during week- or month-long intervals when the child resumes completely normal or baseline health (e.g., if there is other chronic disease), although 12% may have interepisodic symptoms of daily nausea and/or mild vomiting [12]. During the episodes, the most common symptoms are listlessness (93%) and pallor (91%) and others include low-grade fever or hypothermia, intermittent flushing, diaphoresis, drooling, and diarrhea. Although found in significantly higher frequency than in patients with GI disorders (gastroesophageal reflux disease, GERD), fewer than half have migraine features of headache, photophobia, and phonophobia.

The duration of episodes generally ranges from hours to days with a median duration of 27 h. Episodes are always self-limited despite a few that may last longer than 1 week. Forty-nine percent of patients have “cyclic” intervals predictable within a week, most commonly 4 weeks, and the remainder have “sporadic,” unpredictable attacks. Forty-two percent have onset of their episodes early morning or upon awakening (1–8 a.m.). Many have a remarkably rapid onset (1.5 h) and resolution (6 h) from the last emesis to the point of being able to eat and be playful. The 67% with a prodrome have pre-emesis pallor, diaphoresis, abdominal pain, and headache, but rarely visual disturbances of a classical migraine aura.

The vomiting in CVS is uniquely rapid fire and peaks at a median frequency of 6 times an hour and 15 times per episode. The vomiting is typically projectile and contains bile (80%), mucus, and occasionally blood, the latter usually the result of prolapse gastropathy. The bilious nature often raises concern for an obstructive lesion. The intense nausea differs from that in emesis from GI disorders in that it persists even after complete evacuation of gastric contents as if independent of gastric feedback. Many describe nausea as the most distressing symptom, only relieved during sleep. Due to the unrelenting nausea, during episodes, these children appear much more debilitated when compared to those with gastroenteritis, often curled into a fetal position, listless, and withdrawn to the point of being unable to walk or interact. Anorexia, nausea, midline abdominal pain, and retching are the most common GI symptoms.

Certain unusual observed behaviors during CVS episodes can raise questions about an underlying psychiatric disorder. There are children who drink compulsively and then vomit and describe that that maneuver dilutes the bitter bile and aids in evacuating it. Others take prolonged, scalding hot showers or baths until the hot water supply is exhausted. Nearly all turn their rooms into a darkened cave in order to avoid lights and sounds that trigger more nausea. Many are hyperesthetic

to motion, odor, taste, and even to parental touch and attempt to shut out all external stimuli.

Various recurring stressors are recognized to precipitate CVS episodes in 76% of patients. These include psychological (44%), infectious (31%), and physical triggers. The psychological stress is more often of an excitatory nature such as holidays, birthdays, outings, and vacations. Episodes may be triggered by various infections including upper respiratory infections, sinusitis, strep throat, and flu. The largest fraction (32%) has a seasonal clustering of episodes with more during the winter and fewer during the summer. Although this pattern correlates with the school year, we can only speculate that less school-related stress, less exposure to infections, and longer duration of sleep helps. Dietary factors include foods rich in amines, aged cheese, chocolate, monosodium glutamate, and fluctuating caffeine intake (23%). Lack of sleep from excess physical exhaustion from travel, sports, sleepovers, or a sleep disorder (24%), and menses (catamenial CVS—22%) are also common inciting events. Environmental triggers include changes in barometric pressures in weather fronts. One subgroup with a precisely timed interval every 60 days (predictable within a week) and an absence of identifiable triggers is especially refractory to therapy.

Pathophysiology

In the absence of a defined etiopathogenesis, CVS remains classified as an idiopathic disorder. Recent investigations support the contributory roles of mitochondrial DNA (mtDNA) mutations and dysfunction, hypothalamic–pituitary–adrenal (HPA) axis activation, and autonomic nervous system (ANS) dysfunction. CVS is a functional brain–gut disorder perhaps mediated through altered brain stem modulation of effector signals.

Mitochondrial Dysfunction

In two series, a striking maternal inheritance pattern was recognized for migraines in 64 and 54% of probands with CVS [13, 14]. Evidence of mitochondrial dysfunction was first provided using nuclear magnetic resonance (NMR) to establish decreased ATP production in peripheral muscle in migraineurs [15]. This mitochondrial pathogenesis gained substantial support following the recent identification of two tandem mtDNA polymorphisms, 16519T and 3010A with impressive odds ratios of 17 and 15 in CVS and migraine in haplotype H, respectively [16]. Because the mutations are found in the control region rather than the enzyme sequence, the structure to function relationship is unclear. However, elevated lactate, ketones, and Krebs cycle intermediates during

the early part of the attacks are consistent with mitochondrial dysfunction. In addition, clinical trials and open-label experience show promising effects of mitochondrial supplements coenzyme Q10, L-carnitine, and riboflavin in the treatment of migraines and CVS in children [17, 18].

Neuroendocrine

Stressors, both psychological (excitement, panic) and physical (fever, lack of sleep), are common triggers of attacks of CVS. An activated HPA axis during episodes of CVS was first described by Wolfe, Adler, and later in greater detail by Sato. They documented elevated levels of adrenocorticotropic hormone (ACTH), antidiuretic hormone, cortisol, catecholamines, and prostaglandin E2 [19, 20]. This finding may partially explain the symptoms of hypertension and profound lethargy in this subset of patients. Attenuation of CVS symptoms occurred after use of high-dose dexamethasone by Wolfe and Adler and indomethacin and clonidine by Sato et al. [21].

These findings have focused attention upon one potential role of corticotropin-releasing factor (CRF) as a brain–gut neuroendocrine mediator of foregut motility. Taché et al. have shown that psychological or physiologic stressors induce CRF release from the hypothalamus which stimulates inhibitory motor neurons via CRF-R2 receptors in the dorsal motor nucleus of the vagus that delays gastric emptying, independent of downstream effects of ACTH and cortisol secretion [22]. Preliminary data demonstrate increased peripheral CRF levels during episodes of CVS, but whether this acts to trigger emesis or occurs in response to the stress of the illness is not clear. The new entity of cannabis-induced hyperemesis syndrome which probably represents a variant of CVS raises the possibility that the endocannabinoid system plays a role in CVS. CB1 receptor activation attenuates the stress response and reduces nausea and increases the appetite well-known effects of tetrahydrocannabinol (THC). Interestingly, a growing number of case reports suggest that frequent high dose use may alter the ligand–receptor relationship and result in a cannabis-triggered CVS [23]. This unique response suggests that in some patients altered endocannabinoid signaling may trigger attacks. Conversely, there may be therapeutic potential in other CB1 receptor agonists.

Autonomic Dysfunction

Most of the prominent symptoms of CVS are expressed through the ANS. The peripheral vasoconstriction, hypersalivation, diaphoresis, tachycardia, and listlessness are prominent manifestations of nausea that persist throughout the episode typically unrelieved by evacuation of the stomach.

Chelminsky reported autonomic dysfunction in the form of postural orthostatic tachycardia syndrome (POTS) was identified on a small series of children with CVS recently [24]. They noted that treatment of the POTS appeared to help reduce the frequency of CVS episodes. We recently found an overall prevalence of POTS in 19% our CVS patients, and when we limited the cohort to adolescents > 11 years in whom POTS is known to be more common, the rate was 38%.

Four formal studies of the ANS function in children and adults with CVS reveal a consistent pattern of heightened sympathetic tone with normal parasympathetic tone [24]. Interestingly, studies of gastric emptying in adults reveal rapid emptying when well. However, whether this finding extends to children is unknown.

Subtypes of CVS and Comorbidities

Migraines

An association with migraines was identified over a century ago [4, 25]. The current association occurs in 83% of those with CVS who have a positive family history of migraines or migraines themselves. In addition, there is a progression from CVS to migraine headaches with advancing adolescent age. In the absence of definitive diagnostic tests for migraines and CVS, strong link is further supported by similar symptomatology (e.g., pallor, lethargy, nausea, photophobia, phonophobia) and positive responses in both groups to anti-migraine therapy. These migraine-associated CVS patients generally have milder episodes, a greater association with psychological stress, and significantly higher response rates to anti-migraine therapy (79 vs. 36%) [26, 27].

Sumatriptan (a selective 1B/1D serotonin agonist) is one anti-migraine drug that can abort episodes if administered early on especially via the nasal route (52%). This action on serotonin receptors with similar rates of response to patients with migraine headaches suggests a central role of action presumably by decreasing cerebrovascular dilatation. Until we have a clearer delineation of mechanisms involved in migraine and CVS, we cannot be certain if the CVS patients who do not fit under the migraine umbrella have dissimilar pathophysiologic cascades.

CVS +

In Boles' series, 25% had coexisting neurological findings of developmental delay, seizures, hypotonia, and skeletal myopathy as well as cognitive and cranial nerve dysfunction [28]. These children classified as CVS+ were found to have an earlier age of onset for CVS and a threefold- to eightfold-higher prevalence of dysautonomic (neurovascular dystrophy) and constitutional (growth retardation) manifestations than CVS patients without neurological findings.

Cannabis

There is a group of adolescents and adults with CVS who use marijuana to alleviate nausea and vomiting that instead may aggravate CVS symptoms, and has been labeled as cannabis-induced hyperemesis. It is more likely cannabis-triggered CVS [23]. There are now more than 100 patients described, mostly young males and heavy users over several years. One series of nine patients reports termination of bouts of emesis after cessation of chronic use of marijuana with exacerbation upon resumption of smoking cannabis.

Other Subgroups

Some have documented sympathetic overtone and comorbid POTS in whom treatment of POTS may help reduce frequency of vomiting episodes. The Sato variant is associated with hypertension during episodes only and an endocrine profile of heightened HPA axis activation including ACTH, cortisol, catecholamines, and vasopressin. These patients generally have significantly more prolonged episodes (102 vs. 50 h) and increased vomiting per episode (75 emesis vs. 31). Those with long-interval calendar-timed episodes every 60+ days apart appear particularly difficult to treat and usually have no identifiable stress or infectious triggers. A stable periodicity has also been observed in post-menarchal girls with catamenial CVS who respond to low-estrogen birth control pills or Depo-Provera. Finally, in a group of children, dietary triggers of their episodes can be identified. Some are initiated by typical migraine precipitants including cheese, chocolate, and monosodium glutamate, whereas others are triggered by food allergies identified by RAST testing.

It is unclear whether these groups are distinct or more likely overlapping phenotypes. We hope that delineation of clinical patterns into subgroups may ultimately point us towards more specific treatment approaches for each subgroup. New findings from nextgen sequencing of the mitochondrial genome and related nuclear genes that affect mitochondrial function may also eventually point to specific treatments.

Comorbidities

We have begun to document numerous comorbidities in affected children most of which affect them during the episode-free interval when well. We are finding that they contribute to symptoms of fatigue, abdominal pain, and dizziness that impair the daily quality of life as documented by Tarbell and Li [29]. Comorbidities in non-neurologically impaired children include anxiety (47%), depression (14%) [30], chronic fatigue (52%), sleep disturbances (48%), irritable bowel syndrome (41%) [31], GERD (39%), colonic dysmotility (20%) [28], POTS (19%), daily nausea (coalescent 12%), and complex regional pain syndrome (10%) [32]. Often, these complaints contribute to the poor quality of life with an average of 3.8 comorbid symptoms per child and have

to be treated concomitantly to help restore the child to functionality.

Differential Diagnosis

Differentiating a cyclic versus a chronic pattern of vomiting is the first step in narrowing the differential diagnosis. Although the majority of patients (88%) with a cyclical pattern ultimately are diagnosed with CVS, the remaining 12% have other specific causes for vomiting found on diagnostic testing. The majority of disorders that can mimic CVS include non-GI as well as GI disorders.

Of the GI disorders, the most serious are anatomic anomalies of the GI tract including malrotation with intermittent volvulus which can cause devastating bowel necrosis. Although not typically cyclical, we have found a few children with eosinophilic esophagitis related to significant food allergies to mimic CVS and Lucarelli et al. have described seven children with positive radioallergosorbent test (RAST) to foods (milk, egg white, and soy) whose episodes diminished after specific food elimination [33].

The most common extraintestinal surgical cause is acute hydronephrosis resulting from ureteral pelvic junction obstruction. Metabolic causes include mitochondrial disorders (disorders of fatty acid oxidation, mitochondrial encephalopathy, lactic acid, and stroke-like syndrome), urea cycle defects (partial ornithine transcarbamylase deficiency), organic acidurias (propionic acidemia), aminoacidurias, and porphyrin degradation disorders (acute intermittent porphyria) [34, 35]. Neurosurgical causes include various lesions of the subtentorial region including cerebellar medulloblastoma, brain stem glioma, and Chiari malformation likely precipitating vomiting through increased intracranial pressure [12]. Endocrine causes include Addison's disease, pheochromocytoma and carcinoid. Munchausen by proxy (ipecac poisoning) should also be included in the differential diagnosis of a cyclic pattern of vomiting.

Diagnostic Evaluation

At present, there are no specific tests to diagnose CVS, and the diagnosis rests primarily upon fulfilling clinical criteria in the NASPGHAN consensus statement or Rome III (less rigorous) [2]. The key first step requires recognizing a cyclic pattern (high intensity, low frequency) of vomiting because 88% will eventually turn out to be diagnosed with CVS [8]. There are still one in eight who will have an organic underlying cause often extraintestinal in location. Underlying disorders that may require surgical intervention include anatomic anomalies of the GI tract, especially malrotation with the risk of volvulus, renal hydronephrosis, and subtentorial Chiari malformation or neoplasm. These can be excluded by

Table 25.5 Evaluation of cyclic vomiting. (Sunku and Li [3], with kind permission from Springer Science + Business Media)

Patient meets consensus criteria for CVS → UGI series to evaluate for malrotation + serum electrolytes, BUN, creatinine and no warning signs or findings to suggest an organic disorder → trial of empiric therapy to treat CVS
If warning signs are present, then additional labs are warranted
Severe abdominal pain, bilious and/or hematemesis → liver and pancreatic serum chemistries, abdominal ultrasound (or CT or MRI), esophagogastroduodenoscopy
Fasting, high-protein meal, intercurrent illness precipitating episodes of vomiting → serum and urine metabolic evaluation (lactate, ammonia, carnitine profile, amino acids, and organic acids) <i>prior to treatment during episode, metabolic consult</i>
Abnormal neurological findings (altered mental status, papilledema) → brain MRI, neurology consult
<i>CVS</i> cyclic vomiting syndrome, <i>UGI</i> upper gastrointestinal

UGI series (to ligament of Treitz) renal ultrasound (acute calyceal dilation can resolve in 10 days), and brain MRI (CT may not adequately visualize the brain stem), respectively. The challenge to the clinician is to determine which and how much testing should be performed, as the traditional “shotgun” approach is costly, time consuming, and invasive.

The recent NASPGHAN consensus statement (2008) guidelines recommend against the traditional shotgun approach and a minimal amount of screening to include an UGI series to exclude malrotation and anatomic obstructions and a basic metabolic profile (electrolytes, glucose, BUN, creatinine) [2]. This is supported by our cost-decision analysis that found an UGI X-ray to be the most cost-effective test followed by empiric treatment for 2 months. Further testing beyond that should be based upon specific red flags or warning signs (Table 25.5). In those who present with bilious vomiting and abdominal tenderness, abdominal imaging should be performed to exclude hydronephrosis, pancreatitis, and cholecystitis. In those in whom episodes are triggered by intercurrent illnesses, fasting, or high-protein meals, screening should be performed for urea cycle, fatty acid oxidation, disorders of organic and amino acid metabolism, and mitochondrial disorders. This screening has an improved diagnostic yield during the early part of an episode of CVS before intravenous glucose and fluids are administered. Those presenting with abnormal neurological findings including altered mental status, papilledema, ataxia, or seizure should have a neurological evaluation and brain MRI considered. Presentation of CVS under the age of two should also prompt further metabolic or neurological testing [2].

Treatment

Current treatment for CVS can be divided into supportive or rescue therapy (during episodes), lifestyle modifications and prophylactic (daily treatment to prevent episodes), and abortive therapy (prodromal intervention to abort episodes).

The goals of treatment are to reduce the frequency and severity of episodes, enhance functionality, and improve quality of life. Treatment of nausea, vomiting, abdominal pain, and dehydration during acute episodes requires a protocol for use at home, emergency departments, and hospital wards. Other strategies for management of CVS include avoidance of identified triggers (e.g., dietary cheese), psychological interventions (e.g., stress management), and treatment of comorbid symptoms.

The NASPGHAN consensus statement recommendations on treatment are based upon therapeutic responses from case series and expert opinion of the task force [2]. The main recommendations include first-line prophylactic use of cyproheptadine and amitriptyline in children under age 5 years and 5 years or older, respectively, with propranolol serving as the second line. Sumatriptan was recommended as an abortive agent for those > 12 years. For rescue therapy, during acute episodes, IV rehydration with high-dose antiemetic ondansetron (0.3–0.4 mg/kg/dose) and sedation from diphenhydramine or lorazepam were recommended.

Supportive or Rescue Therapy

Supportive or rescue care is used when the vomiting becomes well established in an episode and at that point usually fails to respond to any abortive strategies. The goal is to correct energy, fluid, and electrolyte deficits and render the child more comfortable through antiemetic therapy, analgesics, and sedation for relief from intractable nausea and pain. The recommendation is for an IV bolus of saline for rapid correction of fluid deficits and concurrent 10% dextrose 0.45 normal saline at $1.5 \times$ maintenance rates to provide sufficient cellular energy to terminate ketosis. One may have to reduce IV rates and increase Na^+ content when hyponatremia and diminished urine output ensues from elevated antidiuretic hormone release present in Sato-variant CVS. Ondansetron has been the most widely used 5HT₃ antagonist given safely at higher than standard doses (0.3–0.4 mg/kg/dose) but can prolong the QTc interval [13]. It generally reduces both nausea and vomiting but usually does not stop the episode or the misery from nausea (Table 25.6).

Diphenhydramine, lorazepam, or chlorpromazine combined with diphenhydramine are used to induce sedation because sedation is often the only means of providing relief from the unrelenting nausea and abdominal pain. The analgesic ketorolac is recommended as first line as narcotics are felt to have a sensitizing effect in migraine analgesia. A non-stimulating environment including quiet, dark single room may be helpful. When all else fails and episodes are prolonged and debilitating (> 1 week), we have used a dexmedetomidine infusion to achieve deep sedation in a *pediatric intensive care unit* (PICU) setting for 18 h as described by Khasawinah [36].

Table 25.6 Rescue and abortive pharmacotherapy. (Sunku and Li [3], with kind permission from Springer Science + Business Media)

Antiemetic
<i>Ondansetron</i> 0.3–0.4 mg/kg per dose q 4–6 h iv/po/rectal/topical up 16 mg/dose. SE: headache, drowsiness, dry mouth
Alternatives: <i>granisetron</i>
Aprepitant 125, 80, 80 mg one q.d. prior to anticipated episode
Sedative
<i>Lorazepam</i> 0.05–0.1 mg/kg per dose q 6 h iv/po: useful adjunct to ondansetron. SE: sedation, respiratory depression
<i>Chlorpromazine</i> 0.5–1 mg/kg per dose q 6 h iv/po. SE: drowsiness, hypotension, seizures
<i>Diphenhydramine</i> 1.0–1.25 mg/kg per dose q 6 h iv/po: useful adjunct with chlorpromazine. SE: hypotension, sedation, dizziness
Analgesic
<i>Ketorolac</i> 0.5–1 mg/kg per dose q 6 h iv/po. SE: gastrointestinal bleeding, dyspepsia
Alternatives: opioids (hydromorphone)
Abortive
<i>Sumatriptan</i> 20 mg intranasal at episode onset and may repeat once or 25 mg po once. SE: chest and neck burning, coronary vasospasm, headache
Alternatives: <i>frovatriptan</i> , <i>rizatriptan</i> , <i>zolmitriptan</i>
SE side effects

Table 25.7 Prophylactic pharmacotherapy. (Sunku and Li [3], with kind permission from Springer Science + Business Media)

Anti-migraine
<i>Amitriptyline</i> start and 0.2–0.3 mg/kg and advance to 1–1.5 mg/kg per day qhs: monitor EKG QTc interval prior to starting. First choice ≥ 5 year old. Side effects (SE): sedation, anticholinergic
<i>Propranolol</i> 0.25–1 mg/kg/day divided b.i.d or t.i.d: monitor resting heart rate. SE: hypotension, bradycardia, fatigue
<i>Cyproheptadine</i> 0.25–0.5 mg/kg/day divided b.i.d. or q.h.s: first choice < 5 year old. SE: sedation, weight gain, anticholinergic
Alternatives: <i>nortriptyline</i> , <i>imipramine</i> , <i>desipramine</i> , <i>doxepin</i>
Anticonvulsants
<i>Topiramate</i> gradually increase to 1.5–2.0 mg/kg/day divided b.i.d. or q.h.s. SE: appetite suppression, cognitive dysfunction, renal stones
<i>Phenobarbital</i> 2–3 mg/kg per day q.h.s. SE: sedation, cognitive impairment
Alternatives: <i>gabapentin</i> , <i>levetiracetam</i> , <i>zonisamide</i> , <i>valproate</i> , <i>carbamazepine</i>
Mitochondrial supplements
<i>Co-enzyme Q10</i> 10 mg/kg/ divided b.i.d. ≤ 600 mg/day
<i>L-carnitine</i> 50–75 mg/kg ≤ 2 g/day divided b.i.d. SE: diarrhea, fishy body odor
<i>Riboflavin</i> 10 mg/kg/day divided b.i.d. ≤ 400 mg/day
q.h.s. quaque hora somni

Lifestyle Modifications

Lifestyle modifications are used during the interictal phase of CVS when the child is not in an episode in order to keep the child properly conditioned and to avoid exposure to known and potential precipitants of episodes. The lack of sleep resulting from disturbed sleep patterns, sleepovers, or travel sports tournaments are often cited as triggers of episodes. Good sleep hygiene (e.g., turning off all phones, computers, music, TV) with a regimented sleep time can reduce the frequency of episodes. Providing at least maintenance volumes of fluids is widely used to treat migraines and POTS. Providing low glycemic energy sources before strenuous activity, sources, may prevent an exercise-induced energy deficit. Routine exercise can help reverse the deconditioned state and improve mitochondrial function. Finally, avoiding identified triggers specific to the individual (e.g., sleepovers) or generally found in migraines (monosodium glutamate and fluctuations in caffeine intake) may help reduce the fre-

quency of episodes. Fleisher reported that consultation and lifestyle modifications alone reduced the frequency of episodes in 70% of patients even before beginning prophylactic therapy [31].

Prophylactic Therapy

For those with more frequent or severe episodes (e.g., more than once a month), prophylactic therapy is recommended daily during the interictal phase with the goal of preventing the next episode or to at least reduce the frequency, duration, or intensity (# emeses) of episodes. These *prophylactic medications* those traditionally used to treat other disorders including migraines. The NASPGHAN consensus recommendations for the initial treatment were for cyproheptadine for the younger (< 5 years) and amitriptyline for the older children and adolescents (≥ 5 years) [2] (Table 25.7). Despite its pharmacokinetics, cyproheptadine (0.25–0.5 mg/kg) ap-

appears to be effective given as a single nighttime dose as opposed to the usual two or three divided doses [37]. Amitriptyline causes side effects in 50%, the most common being morning sedation (like a hangover), and is stopped in 21% [38]. Beginning at a low dose of 0.2–0.3 mg/kg at bedtime and titrating it gradually in 10 mg increments every week or two to the target dose of 1.0–1.5 mg/kg allows the child to gradually adapt to the side effects. Switching to other tricyclic antidepressants such as nortriptyline, desipramine, or doxepin may lessen specific side effects. An electrocardiogram (EKG) to measure the QTc interval is recommended before starting amitriptyline. At higher doses (>1.0 mg), we monitor the ECG and/or amitriptyline levels [39]. Propranolol is second line therapy and can be monitored for efficacy and toxicity by a desired drop in pulse rate of 15–20 beats per minute not to fall below 55 bpm, respectively.

If standard prophylactic therapy fails, anticonvulsants and Ca²⁺-channel antagonists have been used. Phenobarbital at low (2–3 mg/kg) nighttime doses and topiramate (1–2 mg/kg/day) have been reported to be effective, the latter having a strong evidence based in migraines [40]. Unfortunately, cognitive dysfunction is a well-known side effect in both. Other effective anticonvulsants include zonisamide and levetiracetam, in adults with CVS [41, 42]. Another group of agents includes Ca²⁺-channel antagonists with the main side effect of hypotension.

Treatment may vary by clinical subgroup. Children that have a migraine connection with either a positive family history or migraines themselves are much more likely to respond to antimigraine agents such as cyproheptadine, amitriptyline, and propranolol (79 vs. 36%) than those children without one [26]. Post-menarcheal girls with catamenial CVS often respond to low-estrogen birth control pills or Depo-Provera. Sato-variant CVS associated with hypertension may require intraepisodic short-acting anti-hypertensives as well as prophylactic tricyclic antidepressants in the USA and divalproex sodium in Japan [21].

Prophylactic use of mitochondrial supplements as adjunctive prophylactic therapy in CVS is being used more frequently based upon evidence in migraines and preliminary evidence in children with CVS. These supplements have demonstrated efficacy in prevention of migraines in adults (randomized controlled trial) and preliminary evidence of efficacy in pediatric migraine and CVS in children [43–45]. In a survey of use as monotherapy in children with CVS, Boles found that the response to CoQ10 was similar to that amitriptyline [38]. Interestingly, some children with CVS, the accompanying chronic fatigue may respond to these supplements. The doses used include riboflavin at 10 mg/kg divided b.i.d. to up to 400 mg/day, L-carnitine at 50–75 mg/kg up to 3 g/day divided b.i.d., and CoQ10 10 mg/kg divided b.i.d. up to 600 mg/day. The dose and duration of these supplements has not been established in children with CVS.

Abortive Therapy

Abortive therapy should be considered for those who have sporadic episodes that occur less than once per month and who prefer not taking prophylaxis or those who have breakthrough episodes while on prophylaxis. Abortive therapy is given during the prodrome or at the beginning of the vomiting episode in the hope of stopping it. The most specific abortive therapy includes anti-migraine triptans. The nasal (sumatriptan or zolmitriptan) or subcutaneous (sumatriptan) forms appear more effective than oral forms that cannot be effectively absorbed due to repeated vomiting [2, 46] (Table 25.6). The triptans are usually either fully effective or not at all, and more effective if administered early in episode or if the duration of episodes is less than 24 h (Li unpublished data).

In a few children, ondansetron administered alone aborts episodes in progress. Although the oral forms may not reach the duodenum, ondansetron can be reformulated by individual pharmacies into a rectal suppository or topical (lipodermal) forms. Although not established, we use the same dosages as the oral form. In a few adolescents with severe, disabling abdominal pain preceding the vomiting, use of opioids such as hydromorphone can quickly abolish the pain and in turn the vomiting.

Comorbidities

Treatment of comorbid conditions and symptoms may alleviate the CVS. Chelmsky has shown in a small series that treatment of the POTS with fluids, salt, fludrocortisone, and/or propranolol helps prevent attacks of CVS [24]. Use of stress reduction techniques as well as anxiolytics has anecdotally reduced the number of episodes in anxious children whose attacks are triggered by stressors and/or panic anxiety. Alleviating the comorbid symptoms may substantially improve the quality of life and functional disability.

Natural History, Quality of Life (QOL) Impact, and Complications

There is limited data for the natural history of CVS. Our projection analysis estimates that 75% of patients will develop migraine headaches by age 18. Other long-term studies have shown that up to half of CVS patients continue with CVS or migraine headaches. Several studies have noted the mean duration of illness to be around 6 years, but in our cohort, the younger the age of onset, the longer the duration. Also 5% of patients will progress through all three phases of periodic disease including CVS to abdominal migraine and finally to

migraine headaches. We are currently encountering a growing group with teenage onset CVS and it is too early to ascertain the natural history.

CVS has a significant deleterious impact on the quality of life in affected children. Although well in between episodes approximately 90% of the time, 58% of affected children require intravenous fluids during episodes and average ten visits to the emergency department. School-age children in our cohort miss an average of 24 days of school per year [11, 47]. Medical morbidity is reflected by the high average annualized cost of management of US\$ 17,000 in 1999 dollars that includes doctor visits, emergency department visits, inpatient hospitalizations, missed work by parents, as well as biochemical, radiographic, and endoscopic testing [48]. Growing number of comorbid conditions such as anxiety and POTS also contribute to functional impairment. We have demonstrated significantly lower quality of life scores than in healthy controls, equivalent to those in children organic GI diseases (e.g., inflammatory bowel disease, gastritis) [29].

Complications and medical morbidity include iatrogenic tests and interventions from the misdiagnoses that are often applied to recurrent vomiting. Most are mislabeled as acute gastroenteritis, gastroesophageal reflux, and food poisoning, and they are treated in urgent care settings. Some with severe pain, bilious vomiting, and intractability have undergone inappropriate laparotomy, appendectomy, cholecystectomy, and Nissen fundoplication. Others have been labeled with psychiatric disorders including bulimia and psychogenic vomiting and hospitalized on psychiatric wards, while a few parents have been referred for suspicion of Munchausen by proxy.

Complications can also occur from the frequent and often severe episodes of vomiting that occur with CVS. Dehydration and electrolyte disturbances are common and IV rehydration is required in 58% of patients, which can be compared to less than 1% in rotavirus. Hematemesis can occur towards the end of attacks and is usually related to prolapse gastropathy or Mallory–Weiss tears. Although not common, frequent vomiting can lead to secondary peptic injury.

Summary

CVS is a disorder well described and accepted in the literature, and increasingly diagnosed by pediatric and family physicians as well as pediatric emergency medicine, neurologists, and gastroenterologists. Recently, there is greater appreciation of comorbid conditions and symptoms that deleteriously affect quality of life and functioning. Although the precise pathophysiology remains unknown, we have grow-

ing evidence of involvement of the stress axis and mitochondrial function. Unfortunately, no robust treatment trials have been completed to date and so the therapy remains empiric. Yet, the progress made over the past two decades has been impressive.

Introduction

An expert panel convened by the National Institute of Allergy and Infectious Diseases defined food allergy as “an adverse health effect arising from a specific immune response that occurs reproducibly on exposure to a given food” [1]. This description distinguishes food allergy from nonimmune adverse reactions to foods (Table 26.1). The Centers for Disease Control and Prevention reported that the prevalence of food allergy in US children increased from 3.4% in 1997–1999 to 5.1% in 2009–2011 [2]. Prevalence estimates of childhood food allergy vary, but up to 8% may be affected [1, 3–6]. Over 170 food allergens have been identified, but eight foods or food groups (milk, egg, peanut, tree nuts, soy, wheat, fish, and crustacean shellfish) account for 90% of significant allergic reactions [1]. It is important to note that parental perception of food allergy is generally much higher than physician-diagnosed food allergy, particularly in early childhood. Up to one third of parents report at least one adverse reaction to food [7–12]. The emotional impact of food allergy is considerable, with food-allergic children reporting greater impact on quality of life than children with insulin-dependent diabetes or rheumatologic disorders [13, 14]. This chapter reviews the spectrum of food-allergic disorders with an emphasis on those relevant to the pediatric gastroenterologist. Celiac disease is the result of an immune response to foods, but is not typically categorized as an allergy and is not reviewed here.

Immunopathogenesis and Specific Disorders

Immunopathogenesis

The normal immune response to food results in tolerance [15]. The immune system recognizes food proteins, and IgG and IgA antibodies may be generated, but there are no adverse reactions. Food allergy results from an abrogation of normal tolerance mechanisms. Food allergies may be immunoglobulin E (IgE)-mediated, cell-mediated, or “mixed” adverse immune responses. The distinction of pathophysiology is important in diagnosis and management. For example, IgE-mediated reactions are typically sudden in onset following exposure to a food allergen, whereas cell-mediated responses may result in chronic inflammation or delayed symptoms. Table 26.2 highlights gastrointestinal manifestations of food allergy according to pathophysiology.

IgE-Mediated Reactions

Symptoms triggered by IgE-mediated reactions occur rapidly following ingestion of the trigger food. IgE antibodies that are specific for regions (epitopes) of food proteins arm tissue mast cells and circulating basophils. Cross-linking of the IgE antibodies by the food proteins leads to release of preformed mediators (such as histamine and platelet-activating factor) from cytoplasmic granules and transcription of inflammatory cytokines. The target organ(s) involved in the reaction define the type of food allergy. The symptoms occurring during an acute reaction can be classified as cutaneous, ocular, gastrointestinal, respiratory, or cardiovascular. A combination of these symptoms may occur.

Cutaneous manifestations of an acute food allergy reaction include erythema, hives, pruritus, flaring of eczematous lesions, and angioedema. Food allergy may account for up to 20% of new-onset urticaria [16, 17]. Food allergies rarely cause chronic urticaria (e.g., episodes occurring regularly for 6 weeks or longer). Eczema (atopic dermatitis) can be chronically exacerbated by specific IgE-mediated food allergy, with improvement upon removal of the suspect food

Table 26.1 Nonimmune-mediated reactions or food intolerance/adverse reactions to food

Type	Example(s)
Metabolic	Lactose intolerance, galactosemia, alcohol
Pharmacologic	Caffeine (jitteriness), tyramine in aged cheeses (migraine), alcohol, histamine
Toxic	Bacterial food poisoning, scombroid fish poisoning
Undefined mechanisms	Reactions to sulfites, tartrazine

[18–20]. Overall, skin symptoms are the most common manifestation of IgE-mediated food allergies. Food can also induce skin symptoms by direct skin contact (contact urticaria) [21–25].

Ocular symptoms include pruritus, tearing, conjunctival erythema, and periorbital edema.

Gastrointestinal symptoms include nausea, vomiting, diarrhea, and abdominal pain. Isolated acute gastrointestinal reactions are uncommon. In the case of a food-allergic reaction, upper gastrointestinal symptoms usually begin within minutes of ingestion, but may take as long as 2 h to develop. Diarrhea may have a more delayed onset, beginning 2–6 h after ingestion of the allergen.

Oral allergy syndrome, also referred to as pollen food allergy syndrome, is a form of contact allergy with symptoms isolated to the oral cavity. Sensitization initially occurs from inhalation of pollens, but results in symptoms when fruits or vegetables with proteins that are homologous to the pol-

lens are ingested. For example, birch pollen contains proteins homologous with Rosaceae fruits (e.g., apple, peach, carrot). Pruritus and mild swelling of the lips, tongue, and throat occur when specific uncooked fruits and vegetables are ingested, but heated forms are tolerated [26]. Symptoms typically last several minutes before self-resolving. While anaphylaxis associated with oral allergy has been reported, it is relatively rare [27].

Respiratory tract symptoms may be acutely induced by IgE-mediated reactions. Symptoms may include pruritus and edema of the larynx, dyspnea, nasal congestion, rhinorrhea, hoarseness, stridor, tachypnea, wheezing, and cough. However, chronic asthma is rarely the sole manifestation of food allergy.

Cardiovascular symptoms associated with acute food-allergic reactions include increased venular permeability, widened pulse pressure, increased heart rate and cardiac output, flushing, dizziness, and fainting. These effects can lead to the decreased organ perfusion that is characteristic of anaphylactic shock.

Anaphylaxis

Anaphylaxis is defined as “a serious allergic reaction that is rapid in onset and may cause death” [28]. Symptoms generally include a combination of the above symptoms (or respiratory or cardiac symptoms alone), with anaphylactic shock referring to signs of poor organ perfusion in addi-

Table 26.2 Gastrointestinal food allergies

Disorder	Mechanism	Symptoms	Diagnosis
Pollen-food allergy syndrome (oral allergy syndrome)	IgE mediated	Mild pruritus, tingling, and/or angioedema of the lips, tongue, or oropharynx	Clinical history and positive sensitization to pollens
Gastrointestinal “anaphylaxis”	IgE mediated	Rapid onset of nausea, abdominal pain, cramps, vomiting, and/or diarrhea; other target organ responses (i.e., skin, respiratory tract) often involved	Clinical history and positive tests for food-specific IgE; ± oral challenge
Eosinophilic esophagitis	IgE mediated and/or cell mediated	Gastroesophageal reflux or excessive spitting-up or emesis, dysphagia, intermittent abdominal pain, irritability, sleep disturbance, failure to respond to conventional reflux medications	Clinical history, endoscopy and biopsy, elimination diet, and oral food challenge (possible test directed)
Eosinophilic gastroenteritis	IgE mediated and/or cell mediated	Recurrent abdominal pain, irritability, early satiety, intermittent vomiting, FTT and/or weight loss, peripheral blood eosinophilia (in 50%)	Clinical history, endoscopy and biopsy, elimination diet, and challenge (possibly test directed)
Food-protein-induced proctocolitis	Cell mediated	Gross or occult blood in stool; typically thriving; usually presents in the first few months of life	Negative SPT responses; elimination of food protein → clearing of most bleeding in 72 h; ± endoscopy and biopsy; challenge induces bleeding within 72 h
Food-protein-induced enterocolitis syndrome	Cell mediated	See Table 26.3	History, response to elimination/oral food challenge
Food-protein-induced enteropathy	Cell mediated	Diarrhea or steatorrhea, abdominal distention and flatulence, weight loss, FTT, ± nausea and vomiting	Endoscopy and biopsy

FTT failure to thrive, SPT skin prick testing, IgE immunoglobulin E

tion to anaphylaxis. Anaphylaxis may result in hypotension, cardiac dysrhythmias, cardiovascular collapse, or death. In children, respiratory, cutaneous, and gastrointestinal symptoms are prominent, and the most common cause of death is respiratory compromise. Less than 1% of anaphylaxis cases (including those not due to food ingestion) are fatal [29, 30]. In retrospective analysis, several factors appear to be associated with the severity of the allergic response. A larger quantity of food allergen ingested, concomitant alcohol consumption, and concomitant nonsteroidal anti-inflammatory drugs (NSAID) use all appear to increase the rapidity and severity of the reaction [31–34]. Concomitant ingestion of fatty foods appears to slow the rate of absorption and thus delay onset of symptoms. Risk-taking behaviors among adolescents and young adults, including increased incidents of exposure to the avoided allergen and a lack of a prompt treatment response to symptoms, conspire to contribute to the disproportionately higher number of fatal food-induced anaphylaxis in this age group [35]. In one case series of fatal food-induced anaphylactic reactions, accidental ingestion of a known food allergen was present in 87% of cases [31]. In several cases, previous reactions to the known allergen were relatively mild, highlighting the inconsistency in severity of reactions. Having asthma is an additional risk factor for fatal anaphylaxis. Biphasic anaphylactic reactions occur in up to 20% of cases [36]. In this scenario, a second wave of symptoms occurs 1–4 h following resolution of the initial anaphylactic reaction.

Food-dependent, exercise-induced anaphylaxis is an IgE-mediated food-induced anaphylactic reaction that occurs when vigorous exercise is performed within a few hours of food allergen ingestion. Neither exercise alone nor ingestion of the food allergen alone is sufficient to cause symptoms. While generally associated with specific causative foods (such as wheat, other grains, celery, seafood, or nuts), in some cases any food can cause the reaction when consumed in close temporal relation to exercise [37, 38]. Another uncommon syndrome of anaphylaxis is delayed anaphylaxis occurring several hours after ingestion of mammalian meat, attributed to an IgE response against a carbohydrate moiety, galactose- α -1,3-galactose (α -gal). The etiology is presumed to be related to exposure to this allergen via tick bites [39–42].

Management of Acute IgE-Mediated Reactions

Mild IgE-mediated reactions may subside with antihistamines. However, progressive, multisystem, or severe reactions should be treated promptly with intramuscular epinephrine. Severe reactions may require multiple doses of epinephrine, intravenous fluids, oxygen, vasopressors, additional treatments, and monitoring in an acute care setting.

Natural History of IgE-Mediated Reactions

IgE-mediated food allergy generally appears during the first 2 years of a child's life. The sensitivity to most allergenic foods (egg, milk, wheat, and soy) self-resolves in 85% of children during childhood [43]. Sensitivity to peanuts, tree nuts, and seafood persists into adulthood in the large majority of affected children. Approximately, 20% of peanut-allergic children under the age of 2 years and 10% of children with tree nut allergy will become tolerant to those foods by the time they are of school age, however [44].

Cell-Mediated Food-Allergic Disorders

Cell-mediated food-allergic reactions include food-protein-induced enterocolitis syndrome (FPIES), food-protein-induced enteropathy, food-protein-induced proctitis and proctocolitis, celiac disease, and food-induced pulmonary hemosiderosis. Celiac disease is discussed in Chap. 40.

Pulmonary hemosiderosis is a rare condition characterized by pulmonary infiltrates, iron-deficiency anemia, hemosiderosis, hemoptysis, cough, wheezing, nasal congestion, recurrent otitis media, dyspnea, colic, diarrhea, vomiting, hematochezia, and failure to thrive attributed to cow's milk. While the immunologic mechanisms underlying this illness are not understood, peripheral eosinophilia and IgG to cow's milk are generally present. Symptoms remit with elimination of the causative allergen [45, 46].

Non-IgE-mediated gastrointestinal disorders are highlighted as follows:

Food- Protein-Induced Enterocolitis Syndrome

FPIES is a cell-mediated gastrointestinal food allergy that typically manifests in infancy and generally resolves by 3 years of age. In the acute form, 1–3 h after ingestion of the causative food, infants present with profuse, repetitive vomiting and may experience dehydration and lethargy. Diarrhea may occur several hours following the vomiting. In the chronic form, with continued ingestion of the allergen, infants develop weight loss and failure to thrive. Cow's milk and soy are the most common triggers in formula-fed infants. Symptoms begin 1–4 weeks after introduction of cow's milk or soy. Solid food FPIES is less common than milk/soy FPIES, and presents later, usually at 4–7 months of age, most often when weaning a breast-fed infant. Solid food FPIES triggers include rice, oats, barley, chicken, turkey, egg white, green peas, peanuts, sweet potatoes, white potatoes, fruits, fish, and mollusks. Of those infants diagnosed with solid food FPIES, 65% carried a prior diagnosis of milk/soy FPIES and 80% reacted to more than one food. Overall, 75% of infants presenting with FPIES appear acutely ill, and 15% become hypotensive, requiring hospitalization. Laboratory findings

Table 26.3 Food-protein-induced enterocolitis syndrome (FPIES)

Clinical findings	<i>Acute:</i>
	Profuse, repetitive vomiting occurring 1–3 h after food ingestion
	Diarrhea occurring 5–8 h after ingestion
	Dehydration
	Lethargy
	Pallor
	Abdominal distention
	Bloody diarrhea
	Hypotension
	Hypothermia
	<i>Chronic:</i>
	Weight loss
	Failure to thrive
	Diarrhea
Lethargy	
Abdominal distention	
Bloody diarrhea	
Dehydration	
Laboratory/imaging findings	Anemia
	Thrombocytosis
	Hypoalbuminemia
	Elevated white blood cell count with a left shift
	Eosinophilia
Triggers	Transient methemoglobinemia
	Milk/soy (most common)
	Solid food: rice, oats, barley, chicken, turkey, egg white, green peas, peanuts, sweet potatoes, white potatoes, fruits, fish, mollusks
Management	Elimination of food trigger
	Oral food challenge to evaluate for resolution

may include anemia, thrombocytosis, hypoalbuminemia, and an elevated white blood cell count with a left shift and eosinophilia. Transient methemoglobinemia and intramural gas have also been reported [47, 48]. Table 26.3 shows key features of FPIES. While the exact pathophysiologic mechanism for FPIES has yet to be elucidated, it is thought to be a cell-mediated disorder. Studies have shown increased levels of tumor necrosis factor- α , increased numbers of circulating blood mononuclear cells, and decreased intestinal mucosal expression of transforming growth factor- β receptors in association with FPIES [49–53].

Management

In acute cases, aggressive intravenous fluid administration is the mainstay of management. Other therapies for acute symptoms may include steroids and ondansetron [47, 54]. Methemoglobinemia may be treated with methylene blue. Chronic symptoms usually improve within 3–10 days after eliminating cow's milk and from the diet and beginning a casein hydrolysate-based formula [48].

Differential Diagnosis

In its acute form, FPIES is frequently mistaken for viral gastroenteritis, sepsis, or food poisoning. The intramural gas sometimes seen on abdominal radiographs mimics that seen in necrotizing enterocolitis. Methemoglobinemia often raises concern for a metabolic disorder.

Diagnosis

History, clinical presentation, and at times oral food challenges are useful in the diagnosis of FPIES. A positive oral food challenge is considered the “gold standard” of diagnosis. However, if infants demonstrate a fitting history and presentation, an oral food challenge can be avoided if the symptoms resolve after removal of the suspected causative food. While >90% of patients do not have detectable serum-specific IgE to foods at the time of diagnosis, those that do have such antibodies are more likely to experience a protracted course of FPIES or develop acute allergic reactions [47, 48, 55].

Natural Course

In the USA, cow's milk FPIES resolves in 60% of affected infants by age 3. Approximately, 60% of a Korean cohort showed resolution at 10 months of age, and 90% of an Israeli cohort demonstrated resolution by 3 years of age [47, 56, 57].

Food-Protein-Induced Enteropathy

Food-protein-induced enteropathy is characterized by vomiting, diarrhea, malabsorption, failure to thrive, and anemia in an infant [45]. Cow's milk protein is the most likely causative agent, particularly in infants fed intact cow's milk prior to 9 months of age. This syndrome has also been described in infants following an episode of gastroenteritis and in response to other foods, including eggs, rice, fish, shellfish, and poultry [46, 58].

Diagnosis and Management

Endoscopy with biopsy is required for diagnosis. Small bowel biopsies reveal patchy villous atrophy with a cellular infiltrate [59]. Affected infants must abstain from the causative food to bring about symptom resolution. Spontaneous resolution occurs typically by 2 years of age.

Food-Protein-Induced Allergic Proctocolitis

Food-protein-induced allergic proctocolitis is characterized by blood and mucus in the stool of an otherwise healthy infant. Infants may be fussy or have increased frequency of bowel movements. The causative agent is usually milk in the maternal diet of a breast-fed infant, although egg, soy, and corn have been implicated as well [60]. Maternal dietary elimination of the causal agent leads to resolution of symptoms within 72 h. The problem generally resolves by 1 year of age. The causal food may be gradually reintroduced at

that point, or earlier. The primary alternative explanation for these symptoms is infection.

Mixed IgE- and Cell-Mediated Disorders

Atopic dermatitis (also referred to as eczema), eosinophilic esophagitis, and eosinophilic gastroenteritis are disorders that have both IgE- and cell-mediated components. In up to 40% of patients with atopic dermatitis, food allergy may lead to increased erythema and pruritus of eczematous lesions [16, 18, 19]. IgE-mediated flares occur within minutes to a few hours, while cell-mediated reactions may take up to several days to manifest themselves [61, 62]. Elimination of the suspected food allergen leads to improvement.

Eosinophilic gastrointestinal disorders are described in detail in Chaps. 9 and 27. Briefly, eosinophilic infiltration of the gastrointestinal tract may result in dysphagia, vomiting, abdominal pain, poor growth, and food impaction and are the hallmarks of the eosinophilic gastrointestinal disorders (eosinophilic esophagitis and eosinophilic gastroenteropathy). A significant portion of patients with these disorders has other allergic disease, and food is a primary trigger [63–65]. In the case of eosinophilic esophagitis, elimination of foods to which the child has demonstrated sensitivity can result in both clinical and histological improvement [66, 67]. Similarly, elimination diets may show benefit in eosinophilic gastroenteropathy [68]. The role of allergy testing remains controversial, but skin tests (including atopy patch tests) and serum tests may be helpful in guiding elimination diets and the means to reintroduce foods that were excluded from the diet [69].

Additional Disorders Sometimes Attributed to Allergy

Gastroesophageal Reflux

Studies utilizing cow's milk elimination and challenge have shown between 14 and 42% of cases of gastroesophageal reflux in infants is attributable to cow's milk allergy [70–75]. In these cases, the reflux generally occurs in conjunction with atopic dermatitis, diarrhea, esophagitis, or malabsorption. An elimination diet may be helpful in infants with documented cow's milk allergy and reflux [76].

Colic

While infants with colic are not more frequently atopic than controls, [77] 44% of children with cow's milk allergy have colic [78, 79]. Soy and low-lactose formulas have not been successful in reducing the rate of colic, but a meta-analysis

suggested a 1-week trial of hypoallergenic formula could be considered in such cases [79].

Chronic Constipation

In select groups of children with chronic constipation unresponsive to laxatives, cow's milk elimination diets resulted in resolution of constipation in 28–68% [80, 81]. Among responders, increased frequency of atopy and IgE antibodies was noted, suggesting a possible immunologic basis for their constipation. However, the soy milk used in lieu of cow's milk in these studies may have had a laxative effect [76].

Diagnostic Evaluation

Diagnostic evaluation of food allergy includes the history and physical examination, skin prick testing, serum-specific IgE testing, food elimination diets, and food challenges. The clinical history is paramount in diagnosing food allergy, as the pretest probability of food allergy determines what further testing is necessary. The history also discloses whether the illness is likely IgE antibody-mediated or not.

History and Physical Examination

The medical history plays a central role in determining which further steps in evaluation need to be performed. The symptoms and their temporal relation to the ingestion of food are particularly important. Acute IgE-mediated food-allergic reactions generally occur within seconds to minutes of ingestion of the food allergen. It is quite uncommon for these reactions to begin more than 2 h after the ingestion of the food. Chronic or delayed reactions may be cell-mediated and simple tests may not help to identify triggers—elimination diets and oral food challenges may be required.

With regard to IgE-mediated reactions, the time to resolution of symptoms should be noted. Particularly in the case of new-onset urticaria, in which 80% of cases are due to causes other than food allergy, [16, 17] hives lingering longer than 24–48 h are unlikely to result from food allergy, unless the suspected allergen has been repeatedly ingested concurrent with the urticaria. Hives lasting more than a day or two should raise suspicion for a viral or other process rather than food allergy.

A food that has never been eaten before or is ingested rarely is much more likely to cause a reaction than foods that have been previously tolerated on a regular basis. Parents or other caregivers may have reached early closure regarding which substance was the causative food. The clinician must attempt to reconstruct an accurate history of all the food and drink ingested within 2 h prior to the reaction as best as possible. Dressings, beverages, side dishes, snacks,

and sauces should be included in this evaluation. In addition, a careful review should take into consideration the possible cross-contact with a potential allergen. Cross-contact is a fairly common cause of reactions at restaurants and buffet-style meals. A new allergy to a previously tolerated food is less likely than having a reaction to an ingredient that is not routinely ingested, or having had accidental exposure to a previously diagnosed allergen that was accidentally included in the meal that triggered a reaction.

If the patient has experienced allergic symptoms in the past, it is important to ask whether they had been consistently associated with the same food. Acute IgE-mediated allergic reactions generally occur every time the same quantity and preparation of an allergen is ingested. While trace amounts of protein can result in severe allergic reactions in particularly susceptible individuals, others have a threshold amount of protein that must be ingested before symptoms develop [82–85]. This threshold level can be as high as 10 g of the allergenic protein. In addition, cooking of foods induces conformational changes in certain proteins. For example, patients may react to less-heated forms of a food, such as the egg white in scrambled egg or French toast, but may not react to extensively heated forms of the same food (e.g., eggs baked in breads).

Depending on the patient's age, certain foods are more likely to be causative agents of an acute food-allergic reaction. In young children and infants, the following foods constitute 90% of IgE-mediated allergies: cow's milk, egg, soy, peanut, tree nuts, wheat, fish, and shellfish [1]. In adolescents and adults, peanuts, tree nuts, fish, and shellfish are more common causes of serious acute reactions [6, 86, 87].

Besides the symptoms listed above that characterize acute reactions, the clinician should also note signs of chronic allergic processes, such as sinus venous congestion (and associated "allergic shiners"), horizontal nasal creases, boggy and pale nasal mucosa, or eczematous skin patches. While these signs of other allergic processes are not indicative of a food allergy in themselves, patients with other forms of atopy are more likely to experience food allergy, and therefore the presence of such signs increases the pretest probability of food allergy.

Tests for Food-Specific IgE

When the history and physical examination raise concern for possible IgE-mediated food allergy, skin prick testing and serum food-specific IgE testing can be helpful in investigating the potential allergens in question. Of paramount importance prior to selecting and interpreting these tests is the accurate medical history to determine pretest probability for IgE-mediated food allergy. A positive test (sensitization) to tolerated food(s) is common; therefore, a positive test can-

not be solely used to diagnose food allergy. In addition, occasionally a test is negative despite true allergy. Therefore, negative tests with a compelling history should not be considered sufficient evidence of no allergy [1, 88].

Skin Prick Testing

Skin prick testing is typically performed by allergist-immunologists. The allergen is introduced by scratching the surface of the skin and observing for a wheal and flare response, which is measured. Intradermal tests are not indicated as they are too sensitive and may induce systemic allergic reactions. Larger wheal size correlates with a greater concentration of food-specific IgE and greater likelihood of clinical allergy [89–91]. The sensitivity of skin prick testing is about 90%, the specificity is approximately 50% [92]. The skin of infants tends to be less sensitive than that of older children, however [93]. Given the high sensitivity of skin prick testing, it is a useful test for ruling out individual allergens in patients with a low pretest probability for food allergy to those specific allergens. However, performing skin prick testing to broad arrays of foods without attention to the medical history is not recommended, as the false-positive rate is high.

In Vitro Testing

In vitro testing methods, in contrast to skin tests, are not affected by antihistamine use, are not limited by skin conditions (such as urticaria, dermatographism, or eczema), and do not pose a risk of anaphylaxis. The first in vitro assays, termed "radioallergosorbent tests" (RAST), used radioactive isotopes to characterize relative IgE levels in a patient's serum. These have been replaced by fluorescent enzyme immunoassay (FEIA) tests, which determine serum-specific IgE levels to a variety of foods. Multiple in vitro assays have been developed, but results are not comparable across the various assays [94]. Most studies establishing normative serum-specific IgE cutoff values in children have used the Phadia ImmunoCAP FEIA (CAP-FEIA) system. Using this system, a prospective trial determined 96–100% positive predictive values for reaction during a food challenge for egg (≥ 7 kU_A/L), milk (≥ 15 kU_A/L), peanut (≥ 14 kU_A/L), and fish (≥ 20 kU_A/L) among 5-year-olds, with reactive thresholds being lower for children less than 2 years of age [95]. For other foods (such as soy and wheat) or other age groups (such as adolescents), similar predictive values have not been established, and subsequent studies have varied in the predictive cutoffs, possibly due to variations in testing protocols or patient populations [96]. It is important to note that while skin prick testing and in vitro testing can determine the *likelihood* of a systemic reaction to ingestion of a particular food; they are unable to accurately predict the *severity* of that reaction should it occur. Newer generation tests evaluate specific IgE to specific proteins within a food. Foods are comprised of multiple proteins, of which those that resist

degradation from heat or digestion are more likely to cause significant allergic reactions. Taking peanuts as an example, the peanut protein Ara h 8 is a labile protein homologous to a protein in birch tree pollen. When compared with the stable peanut storage protein Ara h 2, Ara h 8 is less likely to cause a significant allergic reaction. Elevated serum IgE levels to whole peanut can represent an allergy to Ara h 8, Ara h 2, or other peanut proteins. In individuals with allergy to whole peanut, performing component testing to determine which specific peanut proteins play a role in their food allergy is important in determining which patients may be appropriate for food challenge testing [88].

Diagnostic Food Elimination Diets

In the case of acute IgE-mediated food allergy, eliminating the causative allergens prevents further reactions—this type of elimination diet represents treatment of the underlying disorder. In the case of chronic food allergy in which no causative food is identified on testing, particularly in cell-mediated and mixed IgE- and cell-mediated food allergy, elimination diets are pursued for both diagnostic and treatment purposes. There are three basic types of diagnostic elimination diets: focused elimination diets, oligoantigenic diets, and elemental formula diets.

In a focused elimination diet, based on clinical history, one or several suspect foods are removed from the child's diet. The child is then monitored for the improvement of symptoms. If the symptoms fail to improve over 2 weeks (in the case of chronic IgE-mediated processes) or over several weeks (in the case of cell-mediated and mixed IgE- and cell-mediated food allergies), the food(s) removed from the diet are unlikely to be the underlying cause of the child's symptoms.

In the case of a child in whom no potential causative foods can be identified, an oligoantigenic diet may be pursued. In this diet, several of the most common causative foods are removed from the child's diet while maintaining a nutritionally complete diet with other foods. One example is a diet consisting of rice, lamb, asparagus, spinach, lettuce, sweet potato, cooked apple, olive oil, sugar, and salt [97].

In rare circumstances, children with multiple suspected food allergy triggers and continued significant disease burden are placed on an elemental diet. In this type of diet, the child's food intake is limited to an extensively hydrolyzed or amino-acid-based formula. Such diets can have significant adverse consequences and should only be pursued under the supervision of an allergist and nutritionist familiar with such diets.

If the child's symptoms abate following introduction of an oligoantigenic or elemental diet, other foods are added one

by one into the diet with careful monitoring for the return of symptoms. In addition to the complexity of maintaining nutritional adequacy in a food elimination diet, reintroduction of foods after a long period of elimination poses a risk of increased severity of reaction to foods to which specific IgE is present or develops [98]. Consequently, care should be taken to avoid unnecessary elimination of foods.

Food Challenges

A food challenge is a physician-supervised ingestion of a single serving of potential allergen performed to confirm or refute the diagnosis of food allergy to that food. This test is generally used when history and supporting tests fail to confirm or refute an allergy. The test may be used for diagnosis of food allergy from any pathophysiology, IgE mediated or not.

A food challenge is performed for diagnostic purposes in the following scenarios:

- When several foods are being avoided, a food challenge can help determine foods that may be added back into the diet, particularly in the case of foods being avoided based on allergy testing alone (rather than a history of reaction).
- When IgE testing is negative, but a particular food is being avoided based on clinical history alone.
- When a cell-mediated or mixed IgE- and cell-mediated process is present (i.e., FPIES), a food challenge may be the only means of determining if an allergy is present.
- In addition, if serum IgE and skin prick test results appear to indicate that a particular allergy has resolved, a negative (or nonreactive) food challenge confirms allergy resolution [99].

Food Challenge Format

While a double-blind placebo-controlled food challenge is the gold standard for determining food allergy, in practice open food challenges and single-blind challenges tend to be more commonly pursued, in part because they are less labor intensive. A single-blind challenge, in which the observer, but not the child, is aware of which substance is placebo and which is the allergen, is useful in cases where a strong anxiety component is present. In an open food challenge, the child consumes the food in question in progressively increasing portion sizes every 10–15 min until the cumulative total of food given equals approximately one standard serving of the food. The patient is then observed for a predetermined period of time for delayed reactions prior to discharge home. If a reaction occurs the challenge is halted, and the child treated for symptoms [97, 100–102]. The physician performing the test, typically an allergist-immunologist, must be prepared to treat anaphylaxis.

Unproven Tests that Are Not Recommended

Food-specific IgG/IgG4, lymphocyte activation tests, kinesiography, sublingual or intradermal provocation tests, and cytotoxic tests are not supported by scientific validation and should not be performed as part of food allergy evaluation [1, 95, 103–105].

Dietary Treatment of Food Allergies

Avoidance

Food avoidance education is the cornerstone of food allergy management. Once it has been determined that a particular food must be eliminated from the diet, the child's family and all caregivers must undertake what amounts to a complete readjustment of one of the most basic daily habits—that of partaking in meals and snacks. Food elimination entails a careful evaluation of food packaging labels, safety in food preparation both in the restaurant and at home, and working with everyone from restaurant chefs, other children's parents, bakers, camp counselors, school cafeteria workers, and anyone else involved in the preparation of food to ensure that the allergen is not incorporated into any food consumed by the food-allergic child. Medications, vaccines, and cosmetics can also include food allergens. In highly sensitive individuals, less than a milligram of peanut, milk, or egg can cause a reaction [82–85].

Maternal Diet and Allergies in Breastfeeding

Food proteins can be detected in breast milk, and several cases have been reported of children experiencing reactions ranging from chronic atopic dermatitis to anaphylaxis due to maternal transfer of allergens through breast milk [106–109]. However, a tolerizing effect has been hypothesized in at least one study [110]. For infants with a history of reacting to a protein in the breast milk or a history of anaphylaxis due to direct ingestion of the allergen, strict maternal avoidance of the allergen is recommended.

Nutritional Issues in Food Allergy

When foods are being avoided due to allergy or potential allergy, care should be taken to assure that the nutritional needs of the affected child are addressed initially and revisited on a regular basis, as lower caloric intake and increased macro/micronutrient deficiency are more common in children with food allergy when compared with their age-matched peers without food allergy [111, 112]. The greater the number of allergens being avoided, the greater the chance of a nutrition-

al deficiency developing: Thus, greater diligence must be exercised to tailor food choices to ensure a well-balanced diet. In certain circumstances, this cannot be attained by incorporation of regularly available foods alone, and commercially prepared formulas may be necessary beyond the first year of life, particularly in children with cow's milk and/or soy allergies. As children with food allergies are more likely to suffer from inadequate growth and poor nutrition than their peers, [1, 111–114] a consult with a dietitian well versed in food allergy elimination diets is necessary in most children with food allergies that significantly affect protein, fat, or carbohydrate intake.

Summary

- A food allergy is “an adverse health effect arising from a specific immune response that occurs reproducibly on exposure to a given food” [1].
- The eight major food allergens (milk, egg, peanut, tree nuts, soy, wheat, fish, and crustacean shellfish) account for 90% of allergic reactions [1].
- Food allergies may be IgE-mediated, cell-mediated, or “mixed” adverse immune responses.
- IgE-mediated reactions are typically sudden in onset following exposure to a food allergen, whereas cell-mediated responses may result in chronic inflammation or delayed symptoms.
- Acute IgE-mediated reactions can have cutaneous, ocular, gastrointestinal, respiratory, and/or cardiovascular symptoms.
- Anaphylaxis is defined as a serious allergic reaction that is rapid in onset and may cause death [28].
- Cell-mediated food-allergic reactions include FPIES, food-protein-induced enteropathy, food protein-induced proctitis and proctocolitis, and food-induced pulmonary hemosiderosis.
- FPIES is a cell-mediated gastrointestinal food allergy that typically manifests in infancy and generally resolves by 3 years of age. In the acute form, 1–3 h after ingestion of the causative food, infants present with profuse, repetitive vomiting and may experience dehydration and lethargy. Aggressive intravenous fluid administration, steroids, and ondansetron may be used to treat acute cases. Elimination of the causative food leads to chronic symptom resolution within 3–10 days.
- Food-protein-induced enteropathy is characterized by vomiting, diarrhea, malabsorption, failure to thrive, and anemia in an infant. Cow's milk protein is the most likely causative agent, and symptoms usually spontaneously resolve by 2 years of age.
- Food-protein-induced allergic proctocolitis is characterized by blood and mucus in the stool of an otherwise healthy infant. Maternal dietary elimination of the causal

agent (usually cow's milk) leads to resolution of symptoms within 72 h. The problem generally resolves by 1 year of age.

- Atopic dermatitis, eosinophilic esophagitis, and eosinophilic gastroenteritis are disorders that can have both IgE- and cell-mediated components. Elimination diets may be helpful in these disorders.
- Diagnostic evaluation of food allergy includes the history and physical examination, skin prick testing, serum-specific IgE testing, food elimination diets, and food challenges. The clinical history is paramount in diagnosing food allergy, as the pretest probability of food allergy determines what further testing is necessary. The history also discloses whether the illness is likely to be IgE antibody-mediated or not.
- Skin prick testing and in vitro testing can determine the likelihood of an IgE-mediated systemic reaction to ingestion of a particular food, but they are unable to accurately predict the severity of that reaction should it occur. Positive predictive values for reaction during a food challenge have been established for in vitro testing to certain foods within certain age groups using a particular testing system.
- Food elimination diets play a treatment role in acute IgE-mediated food allergy and fulfill both diagnostic and treatment roles in cell-mediated and mixed IgE- and cell-mediated food allergy.
- A food challenge is a physician-supervised ingestion of a single serving of potential allergen performed to confirm or refute the diagnosis of food allergy to that food.

Alfredo J. Lucendo

Introduction

Over the past few decades, digestive tract eosinophilia has emerged as a potential explanation for various abdominal symptoms. The development of gastrointestinal (GI) endoscopy and the possibility of studying histological material have allowed us to identify several distinctive elements of this disorder, including both the density and the extension of eosinophilia along the entire length of the GI tract, so that a new clinicopathological group of entities has emerged. These are currently grouped under the term of eosinophilic gastrointestinal disorders (EGID) [1].

EGID are primarily defined as disorders that selectively affect the GI tract and are characterized by an eosinophil-rich inflammation that appears in the absence of any known causes of tissue eosinophilia (e.g., drug reactions, parasitic infections, and malignancy) [2]. The term EGID includes eosinophilic esophagitis (EoE), eosinophilic gastritis, eosinophilic gastroenteritis (EGE), eosinophilic enteritis, and eosinophilic colitis, all of which are diagnosed with increasing frequency [3].

The symptoms derived from eosinophilic infiltration of the GI tract characteristically vary depending on the affected digestive segments and the involvement of different layers of the digestive wall [4]. EoE, the most prevalent form of EGID, is characterized by esophageal eosinophilic inflammation with no distal GI tract involvement, accompanied by symptoms of esophageal dysfunction. In the case of EGE, the typically affected sites are the stomach and small bowel, although any area of the GI tract from the esophagus to the rectum may also be involved [5].

First described in 1937 by Kaijser [6], interest in EGE has grown in recent years in parallel with an exponentially increasing number of case reports and case series from different continents. Although it is still considered a rare dis-

order, nearly a quarter of all historical descriptions of EGE in the literature come from the past 5 years [7]. Despite this increased interest in the disease, many aspects of EGE remain unknown, including its epidemiology, physiopathological mechanisms, and natural history. Furthermore, therapeutic options for EGE patients are still mostly based on empirical experience due to the lack of controlled, randomized studies which clearly establish definitive strategies for managing EGE.

Nevertheless, information from the many case reports and short series of patients who have been studied over a wide range of years and geographical areas point to several commonly observed phenomena which seem to be characteristic of the disease.

This chapter provides a comprehensive and updated review of EGE to help clinicians understand this increasingly recognized disorder and guide them in the management of these complex patients.

GI Eosinophils: Biology and Function

Eosinophils are bone-marrow-derived granulocytes with pro-inflammatory functions which are involved in the pathogenesis of various disorders. They are recruited from the blood to several peripheral tissues, including the mucosal and submucosal areas of the GI tract, after being activated by various stimuli. Most of the research on eosinophils to date has focused on their function in the lungs and the blood [8], but more recent studies have started to delve into their function in and regulation of the GI tract [9]. In fact, the GI tract is a major target for the migration of eosinophils, which are a normal component of the lamina propria in the stomach as well as in the small and large intestines [10]. This migration process is regulated by a number of cytokines and chemokines, with interleukin (IL)-5 playing a major role. IL-5 not only promotes the development and proliferation of eosinophils in bone marrow but also their migration to peripheral tissues and their survival and degranulation. In addition, this

cytokine primes eosinophils to respond to the chemoattractant signals that recruit them to the mucosa [11].

Eosinophils are functionally complex cells that have both regulatory and effector functions. For example, they synthesize and release several cytokines able to induce fibrous remodeling and subepithelial collagen deposition, including transforming growth factor (TGF)- β and fibroblast growth factor (FGF)-9 [12], thus contributing to the development of strictures and luminal narrowing in the GI tract, both of which are common in patients with EGID. Eosinophils also synthesize and release major basic protein (MBP) [13], a strong agonist of M2-type muscarinic receptors, which govern smooth muscle contraction. Increased levels of MBP contribute to gut dysmotility, especially when combined with the effect of several mediators released by other cell types also present in the inflammatory infiltrate of patients with EGID. These include mast cells, which act on muscular fibers through the release of histamine and leukotrienes [14].

As effector cells, eosinophils participate in the host's defense against helminthes and parasites through the production and degranulation of cytotoxic proteins, including MBP, eosinophil-derived neurotoxin (EDN), eosinophilic cationic protein (ECP), and eosinophilic peroxidase (EPO) [15]. The degree of tissue injury is related to the duration of the eosinophilia, the level of eosinophil activation, and the type of stimuli that attracts these cells [16]. The cytotoxic properties of eosinophilic granular proteins is related to the increased fragility observed in the GI wall tissue of patients with EGID, in which a high incidence of tears and perforations has been described [17]. Eosinophils also release platelet-activator factor (PAF) and leukotriene C4, which induce endothelial cell activation and contribute to inflammation and cell dysfunction [15]. Finally, eosinophils are also a source of pro-fibrogenic cytokines, including TGF- β , phospho-SMAD 2/3, vascular cell-adhesion molecule (VCAM)-1, and Chemokine (C-C motif) ligand (CCL)18 [12, 18], all of which lead to fibrous remodeling with important clinical implications.

The inflammation in EGID can extend deep into several layers of the GI tract wall, promoting fibrous remodeling, causing smooth muscle disturbances, and increasing the risk of tissue damage and perforations [19], all through the cytoplasmatic cytotoxic granule proteins present in eosinophils.

Eosinophils in the GI Tract Mucosa

As in other organs, eosinophils, lymphocytes, plasma cells, mast cells, and macrophages comprise the normal inflammatory component of the lamina propria and submucosa

of all parts of the human GI tract, where they perform protective functions as normally resident cells forming part of the mucosal-associated surveillance system [20, 21]. While few studies have assessed the actual number of eosinophils present in the GI tract mucosa under normal conditions, several reports on normal pediatric GI mucosa have observed that eosinophils are usually found within the gastric, small intestine, and colonic mucosa [22], but are scarce in the esophageal epithelium [23, 24], where their presence is generally associated with disease.

The few reports available on the number of eosinophils found in GI biopsies have described a gradient of eosinophil density from cephalic to caudal, that is, from virtually no eosinophils present in esophageal epithelia to a high eosinophilic density in colonic mucosa [22, 24]. Information regarding the exact quantity and location of eosinophils in the human GI tract is likewise scarce [23, 24], although routine examinations of the antrum, fundus, and small intestine usually reveal either no or very few eosinophils in the surface epithelium. In fact, intraepithelial eosinophils in the esophageal and gastric mucosa are always considered to be abnormal [16]. In contrast, an average of 2–10 cells/hpf (high-power field) was documented in the lamina propria of the normal stomach and duodenum, respectively. Moreover, atopic and nonatopic children had comparable numbers of eosinophils. The same study found that eosinophils were more concentrated in the deep compared to the superficial lamina propria. This was especially noteworthy in the small intestine, where eosinophils were found to be more numerous in intercryptal lamina propria than in intravillous lamina propria [24].

In the colon, eosinophils and other constituent inflammatory cells follow a gradient along the length of the organ, from proximal to distal [25–27]. With regard to the role of drugs in this condition, no consistent correlation between eosinophil count and intake of medication has been described [27].

In all locations and under normal conditions, eosinophils in mucosal biopsies are distributed as single cells which do not form aggregates. Extracellular eosinophil granules are not generally found in normal biopsies [28].

Epidemiology of Eosinophilic Gastroenteritis

Interest in EGID has risen among gastroenterologists in the past few decades, particularly after the broad recognition that EoE now constitutes the most frequent manifestation of this family of disorders, representing the second most common cause of dysphagia and food impaction in young patients after gastroesophageal reflux disease [29]. Indeed, several authors have observed an increase in the prevalence

of EGID in general and of EGE in particular [3, 7, 30]. The rise in the incidence of these disorders and of immunological diseases in general has occurred in parallel with a decrease in infectious diseases; the “hygienic hypothesis,” which asserts that reduced exposure to microorganisms during infancy can modify the patterns of immune responses, has provided a general explanation for the rise of EGID [31]. According to this theory, changes in gut microbiota lead to changes in the fine tuning of Th1, Th2, and T-regulatory responses, giving rise to an imbalance of the immune system and a predisposition for developing allergic and autoimmune disorders triggered by altered or missing innate immune cell activation. In fact, most patients who have EGID have an associated atopic disease [32]. The influence of Th2 cells, which are important in the development of responses mediated by IgE, usually fades after the first 2 years of life in nonallergic individuals. This is possibly due to a secondary stimulation of Th1 responses after bacterial infections [33], which occur less often in over-hygienic environments. Delivery by cesarean section has been recognized as one possible risk factor for the persistence and severity of EGE in pediatric patients [34], with the differences in the gut microbiota of cesarean-section-born babies compared to those born vaginally being proposed as a possible explanation [35].

Environmental exposure thus seems to be as important a risk factor as genetic predisposition for developing EGID. In this sense, a US study recently demonstrated that the increased prevalence of EoE parallels that of bronchial asthma in common geographical areas, being higher in urban settings than in rural areas [3, 36] as well as in cold climate zones compared with tropical and arid areas [37].

The number of eosinophils normally present in the GI mucosa can also vary between different geographical areas [33], depending on the exposure to different microbiological and allergic environments. Thus, the normal eosinophil count in the left colon mucosa of healthy adult subjects living in the southern part of the USA was higher than in samples obtained from subjects living in the northern USA [38]. No comparable study has been reproduced in children. In addition to geographic location, the density of eosinophils in the colonic mucosa also seems to vary seasonally [39], with colonic mucosal eosinophils being slightly more numerous in samples obtained in April and May, which corresponds to the time of year with the highest pollen counts. A similar relationship between pollen exposure and mucosal eosinophilic density has been also demonstrated in children [40] and adults with EoE [41, 42].

In any case, the low prevalence of EGE has meant that most of our knowledge about this disorder comes from individual case reports and short case series, a fact which has made it difficult to elucidate the definitive features of its epidemiology.

While no accurate epidemiological estimations for EGE exist to date, an incidence of approximately one case per 100,000 inhabitants has been traditionally proposed [43, 44]. These figures have recently been updated after an electronic survey carried out in the USA estimated the overall incidence of EGE or colitis to be 28 cases per 100,000 inhabitants [3]. However, these figures are only valid for the USA, as the prevalence of EGE can vary widely among different countries. In Asia, for example, data reported from several single-center registries found that during a 10-year period, seven patients (six men) with EGE were treated at a large referral hospital in India [45]. Two single-center studies carried out in Korea have also reported an increase in the incidence of EGE. The first study reported 31 cases between 1970 and 2003, with 26 cases reported after 1990 [46]. In the second study, 17 patients were diagnosed between 1994 and 2008 [47]. Another case report found 15 patients diagnosed between 1984 and 2002 in Taiwan [48]. In contrast, and for a similar timeframe (1987–2007), 59 patients were diagnosed in one US institution [44]. Even though caution should be taken when comparing these figures, a progressive increase in the epidemiology of EGE can also be assumed when considering the number of studies referenced in PubMed. Just in the past decade, the number has doubled compared to what it was in the 1980s, representing almost 40% of the overall available scientific information on the disease. It is unclear whether this change in the epidemiology of EGE represents a real increase in the prevalence of the disorder or is simply a reflection of the increase in the number of endoscopic exams performed around the world. It may even be a simple case of raised awareness on the part of clinicians, endoscopists (who now tend to obtain mucosal biopsies even when there is little or no endoscopic alteration), and pathologists. What is clear is that EGE has become a more common diagnosis in clinical practice, as is evident from the fact that it was diagnosed in 4.1% of pediatric patients undergoing upper GI endoscopy due to chronic abdominal pain in a recent prospective study carried out in the USA [49].

Allergic eosinophilic proctocolitis (AEPC) is a distinctive pediatric food-allergy-related disorder which is considered prevalent, predominantly in males [50], although its exact epidemiology is likewise unknown [51]. An epidemiological study performed in Brazil demonstrated that 20.6% of infants with known or suspected cow's milk allergy had blood in the stool, which might be the result of allergic or eosinophilic colitis [52].

Pathophysiology of Eosinophilic Gastroenteritis

Allergy

As very little research on the molecular basis of EGE has been carried out, its pathophysiology is as yet poorly defined,

with most of the available information coming from extrapolations from studies on EoE, which, because it is more prevalent, has been studied in greater depth. However, it should be noted that extrapolating information from other EGIDs may not be completely accurate, since EGE presents as a complex disorder for which the several clinical patterns could represent distinct phenotypic alternatives or even different evolving profiles.

From a pathophysiological perspective, EGIDs have been typically considered as mixed disturbances, sharing characteristics of both IgE-mediated disorders (e.g., oral allergy syndrome and food-triggered anaphylaxis) and exclusively cell-mediated disorders (such as celiac disease or food protein-induced colitis). In the specific case of EGE, it has been related to food allergies in that it originates from the interplay of environmental and individual genetic factors. In fact, approximately three out of four EGE patients present various atopic manifestations, including a personal or family background of bronchial asthma, allergic rhinitis, dermatitis, hypersensitivity to food, inhalants or drugs, peripheral hypereosinophilia, elevated total and specific IgE serum levels, or positive skin allergic test results, thus reinforcing the idea that eosinophils accumulate in the stomach and small bowel in response to exposure to food [53, 54] or environmental [41] antigens. Clinical and histological responses to therapies used in other allergic diseases, such as corticosteroids, antiallergic drugs, and dietary modifications, have also been observed in most cases of EGE.

As with EoE [55], a Th2-type immune response seems to be involved in EGE [56]. In fact, interleukins (IL)-5 and -13, together with granulocyte-macrophage colony-stimulating factor and especially eotaxins, may play a central role in the recruitment of eosinophils from circulating blood into GI tissues [57]. The frequent family association of EGID cases (around 10% of patients have affected relatives [2]) points to the role of immune response regulatory genes in these diseases, which in the particular case of EoE show a preserved transcriptome among patients [58, 59]. The genes involved include eotaxin-3/CCL26, mast cell carboxypeptidase-A3 (CPA3) and tryptase (TPSAB1), and high-affinity IgE receptor (FC ϵ RI). Thymic stromal lymphopoietin (TSLP), a master regulating factor of Th2 responses [60, 61], is also upregulated in these patients.

Fibrous Remodeling

EGID seems to be chronic disorder in the majority of cases, but almost no cohorts have been observed over a long period without therapeutic interventions. However, we know from eosinophil-associated lung and skin disorders that eosinophilic inflammation may lead to structural changes

globally known as tissue remodeling. The most widely studied remodeling phenomenon is that described in the eosinophilic inflammation of the airways which occurs in bronchial asthma. The most clinically relevant components of this phenomenon are smooth muscle hypertrophy and collagen subepithelial deposition, which lead to the narrowing of the bronchia and impairment of respiratory function [62]. Fibrous remodeling has also been repeatedly observed in both pediatric [63] and adult EoE patients [12, 64]; while it is a reversible phenomenon in the former [65], it tends to persist in the latter [12, 64]. Retrospective studies on EoE have demonstrated that the disease is a progressive fibrostenotic entity [66] and that in the absence of treatment, it correlates with the prevalence of fibrotic complications such as esophageal strictures in a time-dependant manner [67], much like the natural history of Crohn's disease. In the case of EGE EoE, fibrous remodeling also explains strictures and obstructive symptoms found in many reported cases of EGE affecting the pylorus and small bowel [68]; such complications often require resection of the affected area [69].

Fibrosis in EGID is directly related to eosinophil activation, as evaluated through immunohistochemistry against MBP [70]. Eosinophil-released MBP increases gene expression of FGF-9, a cytokine implicated in the proliferative response after tissue damage [71]. Eosinophils also produce and secrete high amounts of CCL18, a type-2 chemokine implicated in fibrous remodeling of the lungs through fibroblast proliferation and collagen deposition, the expression levels of which have been shown to be increased in EoE [12]. However, the most widely studied cytokine in promoting fibrous remodeling in EGID is TGF- β 1, the expression of which is upregulated in both children [63] and adults [12, 72] with EoE, but which can be reduced with dietary or steroid-based treatment [12, 65, 72, 73].

Histopathology of Eosinophilic Gastroenteritis

Aside from being linked to EGID, intestinal eosinophilia has also been associated with systemic eosinophilic disorders [16] (idiopathic hypereosinophilic syndrome, chronic eosinophilic leukemia, systemic mastocytosis, and immunodysregulation polyendocrinopathy enteropathy X-linked (IPEX) syndrome [74, 75]) as well as with non-eosinophilic disorders (parasitic infections, drug reactions, connective tissue disease, vasculitis, malignancies, and inflammatory bowel diseases, in which eosinophils are often responsible for a bad prognosis [76, 77]). A diagnosis of primary EGE or colitis can thus be made only after excluding all other known causes of tissue eosinophilia.

Table 27.1 Histopathologic findings suggestive of eosinophilic gastrointestinal disease (gastroenteritis/colitis). (Reprinted from Ref. [21], with permission from Elsevier)

Increased number of mucosal eosinophils (subjective, not absolute quantitative threshold is defined except for eosinophilic esophagitis)
Degranulated eosinophils
Intraepithelial eosinophils (surface and gland/crypt epithelium)
Eosinophil surface layering
Eosinophil microabscesses
Epithelial degenerative/regenerative changes
Marked basal layer hyperplasia
Elongated papillae
Lamina propria eosinophilia and fibrosis
Foveolar/crypt hyperplasia
Villous atrophy in the small bowel
Minimal acute and chronic inflammation
Eosinophils in muscularis mucosa, submucosa, or both

If secondary causes of tissue eosinophilia have been ruled out, increased eosinophils in the presence of some of the above pathologic features suggest primary eosinophilic gastrointestinal disorder. The diagnosis of “mucosal eosinophilia” is recommended if there are no pathologic changes beyond increased eosinophils

In contrast to EoE, for which a histopathological diagnostic threshold of ≥ 15 eosinophils/hpf has been consensually defined [78], there is as yet no established consensus on a diagnostic threshold for the remaining forms of EGID, including EGE, although the most commonly agreed upon limit for a positive diagnosis of the disease is > 20 eosinophils/hpf [79, 80]. The difficulty in defining clear diagnostic criteria for EGE is due to several factors, including inconsistencies in the definition of what constitutes an eosinophil (e.g., the presence of a cell defined by a nucleus or an aggregate of granule proteins that may result from active extrusion of granules by activated eosinophils), the lack of a standard size for a hpf (an area of tissue covered by a $40\times$ light microscope objective), and the wide variability of analysis among pathologists and GI/allergy clinicians [36, 81]. (Table 27.1)

In EGE, the stomach and small intestine are the most frequently affected segments of the GI tract [82]. The characteristics of the eosinophilic infiltration in each gut segment are given below in Table 27.2 [12, 24, 44, 68, 79, 80, 83–91].

In the case of gastric mucosal samples, a recent study has evaluated the diagnostic criteria of “histological eosinophilic gastritis,” asserting that in the absence of other known causes of eosinophilia, histopathological findings such as sheets of eosinophils, frequent involvement of the muscularis mucosa or submucosa, and a density of ≥ 30 eosinophils/hpf in at least 5 hpf are suitable diagnostic criteria for EGE [85].

The association of histological eosinophilic gastritis and the presence of *Helicobacter pylori* has been addressed in

the literature with contradictory results. Thus, although a slow decrease in eosinophil count after *H. pylori* eradication was described in the early literature [92], more recent reports show no association between this infection and eosinophilic gastritis [85, 93]. Still, current guidelines state that a diagnosis of eosinophilic gastritis can be established only if mucosal eosinophilia persists several months after successful eradication of *H. pylori* [16]. Finally, superinfection by the protozoa *Isospora belli*, a common opportunistic parasite in immunodepressed patients, has been described as an exceptional association in EGE [94], but should be excluded after a definitive diagnosis has been established.

Knowledge about primary eosinophilic enteritis has been limited by the inaccessibility of the different small-bowel segments to mucosal sampling. Thus, in endoscopic investigations of the small intestine, biopsy specimens can usually be obtained from the duodenum, the first part of the jejunum, and the distal ileum. Descriptions of eosinophilic infiltration in other segments of the small intestine mainly come from the surgical literature [95–97]. In the overwhelming majority of patients, an increase in the number of mucosal eosinophils in the small bowel appears together with eosinophilic infiltration into other segments of the GI tract and represents an expression of EGE [37].

Eosinophilic colitis is characterized by increased numbers of mucosal and intraepithelial eosinophils in colonic biopsy samples. Additional histopathological features suggestive of eosinophilic colitis are provided in Table 27.1.

AEPC represents a distinct condition which is reported exclusively in infants and young children and is related to the ingestion of foreign proteins [4]. One relevant histopathological difference between AEPC and EGE with colonic involvement is that in the former, the overall mucosal architecture is usually well preserved and the eosinophilic infiltration is typically more localized in the rectum [2, 16, 21]. Diagnostic criteria include eosinophilic epithelial infiltration with more than 60 eosinophils/10 hpf in the lamina propria, and involvement of the muscularis mucosae. However, as patients respond well to treatment when AEPC is suspected, rectosigmoidoscopy with biopsies is usually unnecessary [98].

Besides eosinophilic infiltration, other recognized diagnostic criteria for EGE include mucosal edema, eosinophilic degranulation, glandulitis/cryptitis, eosinophilic crypt abscesses, and chronic architectural changes [79]. In contrast, epithelial infiltration may not be a constant feature [85]. In fact, in 10% of all EGID cases, the mucosa exhibits no diagnostic changes, even when the inflammation is identified in subjacent submucosa, lamina propria, or muscular layers. This is probably due to sampling errors in a disease that can often be patchy [21].

Table 27.2 Eosinophilic infiltration in different GI organs in EGE; eosinophil count, histopathological findings, and derived symptoms [12, 24, 44, 68, 79, 80, 83–91]

Involved organ	Mean eosinophil density in normal conditions	Minimum eosinophil count required for diagnosis	Histopathologic features	Clinical manifestations
Esophagus [83, 84]	<5/hpf	15/hpf in the epithelial layer	Elongated papillae and basal zone hyperplasia of the epithelial layer with eosinophilic infiltration of the lamina propria and muscularis mucosae. Eosinophilic microabscesses	Esophageal dysfunction, including dysphagia, food impaction, and GERD-related symptoms
Stomach [12, 24, 79, 85]	2/hpf in lamina propria ^a No intraepithelial eosinophils ^a	>20–30/hpf	Sheets of eosinophils, edema, eosinophilic degranulation, cryptitis	Dyspepsia, nausea/vomiting, epigastric pain, gastric outlet obstruction, ascitis
Duodenum [24, 68, 80]	10/hpf in lamina propria Minimal intraepithelial eosinophils	>20–30/hpf	Sheets of eosinophils, edema, eosinophilic degranulation, cryptitis Eosinophilic infiltration of lamina propria, muscle fibers, and serosal layer Hypertrophic muscle layer	Gastric outlet obstruction, abdominal pain, diarrhea, weight loss, malabsorption findings, perforation, ascitis
Ileum [24, 44]	13/hpf in lamina propria ^a Minimal intraepithelial eosinophils ^a	>20–30/hpf	Sheets of eosinophils, edema, eosinophilic degranulation, cryptitis Eosinophilic infiltration of lamina propria, muscle fibers, and serosal layer Hypertrophic muscle layer	Abdominal pain, small-bowel perforation, small-bowel obstruction, ascitis
Large bowel [24, 86–88]	8–30/hpf ^a	>20–50/hpf (depending on location)	Eosinophil and lymphocyte infiltration of the lamina propria and the presence of intraepithelial eosinophils in the crypts	Diarrhea, bloody diarrhea, abdominal pain Constipation
Bile ducts/pancreas [89–91]	Unknown	Unknown	Non available data on literature	Jaundice, cholestasis, epiastralgia, altered liver function tests Dilated bile ducts Pancreatic mass

^a Reported for pediatric control patients
hpf high power field, *GERD* gastroesophageal reflux disease

Clinical Manifestations of EGE

From its initial description [6], EGE has been recognized as an extremely heterogeneous disease with respect to its clinical presentation. In 1970, Klein et al. proposed a classification of EGE into three different arbitrary patterns based on clinical manifestations and the depth of the eosinophilic infiltrate into the GI tract wall [99]. This classification has been used by many subsequent authors because, when combined with the topographical location of the eosinophilic inflammation, it helps to predict clinical symptoms. (Table 27.3)

a. Mucosal form: This form is characterized by involvement of both the mucosa and submucosa, leading to malabsorption-related symptoms such as diarrhea, weight loss, iron-deficiency anemia, and loss of protein enteropathy. The mucosal form represents the most common presentation of EGE, making up 45% of cases in several series. It has recently been suggested that the mucosal form of EGE has become predominant in the past few years, with a recent series reporting a prevalence of over 80% [44].

b. Muscular form: This form appears when the eosinophilic inflammation extends deeper into the muscle layers, leading to digestive wall thickening and typical obstructive symptoms. Often, this form of the disease is diagnosed after surgical resection of the affected segment [68, 100]. Muscular affection can also manifest with decreased small intestine and colonic motility, leading to constipation [101]. The muscular form has been estimated to comprise 12–30% of all EGE cases [43, 79].

c. Serosal form (or eosinophilic ascitis): When the eosinophilic infiltration permeates all layers of the GI tract wall and extends to the serosal covering, this causes the appearance of eosinophilic ascitis, which is defined by an eosinophil cell count of at least 10% [102], but reaching up to 80% [103]. Eosinophilic ascitis is generally considered the rarest form of EGE, but has been recognized in 12.5–39% of cases in some studies [43, 79].

Although it is a fairly accurate tool, Klein's "classic" classification should be broadened to include two important EGE-related conditions that have been described repeatedly in literature.

Table 27.3 Summary of eosinophilic gastroenteritis symptoms and common findings, according with the classification proposed by Klein et al. [91] in 1970

Forms	Estimated frequency	Maximal depth of digestive tissue involvement	Main affected organs	Main symptoms	Common findings
Mucosal	45–80%	Mucosa and submucosa	Stomach and duodenum	Abdominal pain, weight loss, diarrhea, nausea/vomiting, iron deficiency, malabsorption, protein-losing enteropathy	Mucosal hyperemia, ulcerations, aphthae, thickness of folds
Muscular	12–30%	Muscle layer	Stomach and duodenum	Nausea/vomiting, gastric outlet or small-bowel obstruction	Strictures, rigidity, dysmotility, and obstruction
Serosal	12.5–39%	Subserosal and serosal layers	Any segment of the GI tract	Ascitis and peritonitis	Eosinophilic ascitis, intense peripheral eosinophilia Small-bowel perforation

GI gastrointestinal

- d. Intestinal perforation: Limitations in the biopsy sampling of most segments of the small intestine have probably led to diagnostic delays in the subset of patients with predominant small-bowel affection, justifying its presentation as a distinctive complication requiring surgical repair. Perforation in the context of EGE has been observed in every segment of the GI tract, including the esophagus [17, 19], stomach [96], duodenum [104], jejunum [97, 105], ileum [95], and colon [106]. The transmural involvement of the disease in this case is different from that of eosinophilic ascitis, but it was not included in the Klein classification. The cytotoxic effector function exerted by eosinophil granule proteins has been proposed as the underlying cause of tissue damage in these patients.
- e. Biliopancreatic involvement of EGE: Extraintestinal involvement in EGE has been repeatedly described as a form of cholecystopancreatitis with bile duct dilation and obstructive jaundice [79, 89–91, 107, 108], together with symptoms derived from gut inflammation. Duodenal mass effect can also lead to acute obstructive pancreatitis [109]. While primary EGE has been described in patients of all ages, the majority of cases are diagnosed between the third and fifth decades of life [82]. In contrast to EoE, which is clearly predominant in males [78], no definitive data are available on gender predominance in EGE in general, although eosinophilic ascitis and the underlying transmural EGE form have been described predominantly in women, occasionally triggered during pregnancy and/or after delivery [34, 103, 110–112].

Several clinical aspects of EGE are intriguing, but the lack of large case series makes it difficult to propose definitive conclusions. Still, studies conducted to date indicate that peripheral blood eosinophilia is frequent among sufferers of EGE, being found in up to 90% of patients [113]. This condition is more intense and frequent in patients with mucosal and serosal (with ascitis) EGE than in those affected only up to the muscle layers [43, 53, 79]. In addition, 80% of cases have a personal background of allergies, 50–62% of which are food allergies [3]. In contrast, only 27% of adult patients reported a fam-

ily history of allergy; interestingly, this was limited to patients with mucosal involvement [44]. Finally, 16% of patients had or currently have a relative also suffering from EGE [3].

More than half of the patients also exhibited increased IgE serum levels [113]. While all these atopic manifestations seem to be more common in mucosal and serosal forms [79, 86], they are also present in a high proportion of patients with muscular forms of EGE [44].

With regard to the topographical distribution of EGE, the stomach and duodenum have been proposed as the most frequently involved digestive organs. However, these are also the digestive segments most commonly examined by means of endoscopy, which may lead to bias. Indeed, virtually any segment of the GI tract may be affected, with 50% of patients presenting concomitant involvement of the rectum and/or colon [112] and 30–50% of patients exhibiting simultaneous esophageal eosinophilic infiltration [4]. Thus, large bowel-derived symptoms including bloody diarrhea (which can mimic inflammatory bowel disease) and symptoms of esophageal dysfunction (e.g., dysphagia) may coexist together with stomach and small-bowel-derived symptoms. Interestingly, infiltration of the lamina propria by eosinophils and their presence in the crypts of rectal mucosal biopsies of young children with constipation due to cow's milk intolerance has been described [86] as an alternative to EGE-associated diarrhea.

Diagnostic Imaging Techniques in Eosinophilic Gastroenteritis

Although EGE and eosinophilic colitis were both described decades ago, data on the typical radiological or endoscopic appearance of lesions in patients come mostly from more recent reports.

Most of the endoscopic findings described in EGE tend to be nonspecific, with mucosal hyperemia and thickened gastric folds [44] being the most common. Areas of rough or nodular appearance, erosions, aphthae, and ulcers have

also been described in the disorder while in some cases, the endoscopic results have been normal [79]. Findings from capsule endoscopy include multiple erythematous lesions, loss of villi [113], incomplete strictures with ulcerated mucosa alternating with preserved areas [114], and a mimicking of mucosal diaphragms with complete retention of the capsule [115]. One patient with eosinophilic ascitis showed a bluish discoloration of the deep layers of the intestinal wall without mucosal changes; the authors hypothesized that in this case, eosinophilic infiltration had respected the mucosa [116].

Radiological findings in EGE are equally nonspecific in two thirds of patients [44, 117]; double contrast radiology findings are usually normal [44], but may occasionally show thickened folds, irregular or serrated edges in the walls of the small intestine, nodular contrast defects, or slow contrast progression indicative of GI hypomotility.

The findings in the colonoscopies of patients with eosinophilic colitis tend to be modest and nonspecific, sometimes showing patchy erythematous changes, loss of vascular pattern, and superficial ulceration. In other cases, the mucosa appears to be normal. A biopsy diagnosis is thus essential for demonstrating eosinophilic involvement of the colon [118].

Natural History of Eosinophilic Gastroenteritis

In spite of the approximately 500 EGE cases described in the literature to date, very little research has focused on elucidating the natural history of the disease. A recently published French study analyzed the clinical characteristics and evolution of 43 adult patients with EGE who were followed for a mean period of 13 years [79]. The authors described three different evolutionary patterns (Fig. 27.1). (a) 42% of patients suffered a single outbreak of EGE lasting <3 months, a pattern confirmed in a recent population-based study which also describes this self-limited course as being present in a majority of middle-aged adult patients suffering from eosinophilic colitis [119], (b) 37% of patients exhibited a recurrent pattern of disease, with an average of 5.2 flare-ups at extremely variable intervals, and finally (c) 21% of patients had a continuous disease course with persistent symptoms. No other studies have determined the global relapse rate after the first flare-up, although high eosinophil blood counts at the time of diagnosis have been associated with an increased risk of disease recurrence [79]. No tumoral or myeloproliferative transformation was observed in any patient during follow-up. In fact, an association between EGE and malignancy has only been described once in the literature in a case study of a 69-year-old Japanese man with multiple

Fig. 27.1 Types of evolution of eosinophilic gastroenteritis (EGE). After a mean follow-up period of 13 years, Pineton de Chambrun et al. [79] identified three different types of evolution of EGE: **a** patients with a single outbreak of disease without recurrence (42% of cases), **b** patients with a recurrent course characterized by multiple outbreaks and periods of complete remission lasting from 2 months to several years (37% of cases), and **c** patients with a continuous course (21% of cases). (Reprinted from Ref. [79], with permission from Elsevier)

gastric cancer and EGE who responded well to a total gastrectomy and prednisolone treatment [120].

Nevertheless, many questions regarding the natural history of EGE remain unanswered. For example, it has yet to be determined whether the disease in children and adults is the same or whether pediatric forms of EGE persist into adulthood. There is also a shortage of data concerning the ability of different therapeutic modalities to change the natural history of the disease, especially regarding the response to dietary-based therapeutic interventions [7].

With regard to AEPC in infants, the disorder is characterized by a benign course in which dietary elimination of the aggressor often resolves the symptoms within days [118].

Treatment of Eosinophilic Gastroenteritis

Heterogeneity in the clinical presentation, severity, and evolution of EGE, together with its low prevalence, has made it difficult to establish ideal treatment strategies for these patients. As in the case of other EGIDs, including EoE, no drugs have been approved specifically for the treatment of EGE and comparative studies of different therapeutic modalities are lacking. To make matters more confusing, both patient age (children or adults) and the medical specialty area in which they are attended tend to determine which treatments are administered. Basically, three major therapeutic modalities for managing these patients have been described in the literature; these include several dietary modifications to reduce the antigenic capacity of the diet, administration of drugs with anti-inflammatory and immunosuppressant effects, and finally, surgical intervention when complications arise.

Dietary Treatment

The most solid evidence of the efficacy of dietary treatment has been provided for infants (<6 month) with AEPC. Since allergy to cow's milk is identified as the major precipitant cause for this disorder, exclusion of cow's milk from the diet of the lactating mother or from the infant's diet is generally an effective therapeutic measure. Fortunately, clinical tolerance to cow's milk develops in about 80% of patients by 5 years of age [121].

The response to dietary therapies restricting certain foods has been recently studied in patients with EGE in a systematic review of literature [122], including 25 full-text articles and 5 abstracts. Overall, data from 86 individual patients (79 children) receiving 89 dietary interventions were retrieved. Data came from individual patients and short case series of up to 12 patients; most of documents were judged as having low methodological quality. Overall effectiveness in inducing clinical remission/clinical improvement was reported for 87.2% of children and 88% of adults included; however, no study objectively assessed changes in clinical complains by means of validated or nonvalidated instruments. Histological assessments after dietary treatment were made in only 20 individual children (22.5%). Resolution or decrease in eosinophilic infiltration was documented in 16 cases (80%), and changes were not noted in the 4 remaining patients. Authors concluded that, due to the relative lack of well-designed and high-quality studies, the unequivocal use of dietary treatment for patients with EGE and colitis cannot be supported, and they recommended undertaking further research.

Exclusive feeding with an amino-acid-based elemental diet, in which amino acids are used as the sole nitrogen source was used in 29 patients, all of them children [122]; clinical remission was reported in 75.8% (22 patients). However, histological remission was assessed for only one patient with small-bowel involvement and in a further six patients with eosinophilic gastritis in a single research, 83% of these having normalized mucosal biopsies [123, 124]. Semi-elemental diets (i.e., extensively hydrolyzed formulas with reduced antigenic capacities) as the exclusive nutritional source were used in only two patients [125]: Clinical and histological remission was documented in only one patient. A major advantage of elemental diets is their avoidance of steroids, thus preventing the potential adverse effect of growth retardation in these children. However, the many drawbacks of elemental diets, including their unpleasant taste, high nonadherence rates, high cost, and the psychological and social implications of complete avoidance of any kind of table food, restrict their use in clinical practice to infants and toddlers, among whom food restrictions are better tolerated, and only for the length of time required for food reintroduction with the goal of identifying specific di-

etary triggers. In any case, there is still no consensus in the literature as to which allergic evaluations or tests should be carried out on these patients.

Allergy testing–elimination diets are another therapeutic approach that consists of testing for food allergies with the aid of skin prick testing (SPT), atopy patch testing (APT), or determination of specific serum IgE against a given food in order to identify specific food triggers and eliminate them from the diet. This intervention strategy has rarely been documented in literature for EGE patients [126], since only three children and one adult underwent this treatment option: Clinical remission was described in every patient; biopsy samples after treatment were only available for one single child, who showed histological improvement [122].

A positive allergy test result did not predict whether a specific food was a disease trigger or not: A recent study carried out in patients with EoE, EGE, and healthy volunteers demonstrated that despite the general presence of a concomitant atopy in the first two groups, no differences in serum IgE levels for the most common food allergens were detected among the three groups [127]. According to consensus guidelines [78], allergy testing should be considered for patients with EGID to evaluate their allergic status. However, even though many individuals generate food-specific IgE antibodies that can be detected with allergy tests, they may still be clinically tolerant to various foods and have no allergic reaction following ingestion. This is probably because blood or skin tests are not specific for EGID; therefore, a wide variety of allergic diseases may be responsible for the results. In fact, food triggers can currently only be unequivocally identified by first documenting disease remission after specific food antigen avoidance, followed by disease recrudescence upon specific food reintroduction.

Most of the patients in the literature had been treated using different empiric approaches, which consisted of elimination of single foods (milk and wheat were the most common foods excluded) or combinations of foods considered to be of high risk of triggering an allergic response. A milk elimination diet, a treatment strategy used by 4 authors [128–131] on 16 individual pediatric patients, resulted in a symptomatic improvement rate of 62.5%, with no histological assessment available. A gluten-free diet was used in two EGE patients with no clinical or histological benefits.

Several empiric elimination diets, which included empiric restriction of multiple foods, such as milk, cereals, egg, soy, seafood, and/or fruits, have been repeatedly used in the literature to treat EGE. The empirical elimination of the six most common food antigens from the diet (also called six-food elimination diet or 6-FED), and 7-FED (excluding red meats also) have been assessed in recent years. The aforementioned systematic review overall identified 34 patients with EGE or colitis have been given this dietary treatment

and a symptomatic improvement has been reported in 29 (85.3%) of these [122]. Histological assessments, however, have rarely been reported. A recent paper judged as of medium-/high-quality, reported histological remission of the disease after an empirical seven-FED in five out of six children with eosinophilic gastritis (83.3%), and in two out of three patients after diet without one to three foods [123].

Most of the reported cases retrieved in this systematic review presented a mucosal type of EGE, according to Klein's classification [99]; muscular type was only described for one patient, serosal/transmural type was reported in a single case; in nine cases, the type of EGE was not reported. The low proportion of patients with muscular and serosal/transmural-type EGE prevented the authors to develop a comparative analysis. Regarding GI organ extension, no differences in clinical or histological remission/improvement were observed with regard to disease location or extension.

Once remission of EGE is achieved, specific foods should be reintroduced gradually, identifying problem foods by the reappearance of symptoms or through bioptic monitoring. Evidence of tolerance to offending foods after elimination and reintroduction has not yet been fully assessed. In the case of adult patients, allergic sensitization test results did not correlate with the specific foods responsible for the disease. Generally speaking, from the literature we can infer that the later EGE appears during childhood, the worse it responds to dietary modification [79].

Drug Therapy

Corticosteroids have been by far the most widely used drugs for treating EGE in both children and adults [44, 80, 132]. These drugs also constitute the main treatment for patients in whom dietary therapy is not feasible or who fail to achieve improvement [2]. Prednisone, used at doses of 0.5–1 mg/kg/daily, has proven highly effective in the initial control of symptoms [44], eosinophilic tissue infiltration, blood hypereosinophilia, and also for controlling ascitis, as described in various studies and case reports. Clearly, the use of steroids in EGE does significantly more than merely control symptoms [113]. Usually, after an initial treatment period of 7–10 days, the dose is gradually reduced until the drug is withdrawn after a period of up to 4 months.

Various series have described steroid-dependent patients in whom symptoms reappear during steroid tapering [113, 133]. These patients must resume taking previous doses, maintain remission by using low doses, substitute prednisone for budesonide [125, 126], or maintain remission with other antiallergic or immunosuppressant drugs [134]. Around 20% of patients require maintenance therapy over time [125]. Budesonide has a better safety profile than prednisone and is especially useful in EGE affecting the distal

small bowel and right colon [135], although it is also helpful in managing more proximal disease [126].

Disease recurrence is more likely in those patients requiring treatment at the moment of diagnosis as compared to those who exhibit spontaneous remission; patients with recurrent disease may also present a higher blood eosinophil count at diagnosis than those who show spontaneous remission [79].

Steroid-dependent or refractory patients can be also managed with thiopurins (azathioprine or 6-mercaptopurin), similar to the treatment of inflammatory bowel disease [4, 134, 136].

With regard to the utility of other antiallergic drugs in treating EGE, unfortunately most of the available information comes from isolated cases or small series, which limits our ability to vouch for their efficacy. Some EGE patients have obtained benefits from mast cell stabilizers [79, 135, 137] such as sodium cromolyn or nedocromil, contrary to what has been observed in EoE, in which these drugs have no demonstrated efficacy [138]. Ketotifen and histamine-1 blockers have also proven effective in reducing tissue eosinophilia and symptoms in patients with EGE [139, 140], with suplatast tosylate having a beneficial effect in the only case in which it was used [141]. Information regarding the leukotriene inhibitor montelukast is contradictory; on the one hand, it was wholly ineffective in some cases [142–144], but successfully acted as a steroid-sparing agent in isolated steroid-dependent patients [80, 145].

Finally, biological therapies with the anti-IL-5 monoclonal antibodies mepolizumab and reslizumab to treat hypereosinophilic syndrome have provided only limited data to date. A pilot study in which four EGE patients were treated with a single dose of mepolizumab showed an average drop in blood eosinophilia of 75% and of 50–70% in tissue eosinophilia, but with minimal symptom improvement [146]. In addition, one patient experienced a noticeable increase in GI tissue eosinophil count 4 weeks after treatment, while two additional patients showed an increase in their peripheral eosinophilia, with a worsening of baseline GI symptoms after 7–8 weeks of treatment [147]. Intravenous immunoglobulin was successfully used in a patient with erythematous lupus associated with steroid-refractory EGE [148].

Surgical Treatment

While the muscular form of EGE may cause obstructive symptoms [149] due to bowel wall thickening and narrowing of the lumen, some cases of EGE have been diagnosed after intestinal resection of the affected area after acute abdomen [69], intestinal obstruction, or perforation [95, 96, 150]. It is worth noting that these complications occur more often in the duodenum or the distal ileum. Unfortunately, data on

the long-term outcome and possible recurrence of cases after resection of the affected segment is lacking.

Conclusion

EGIDs constitute an increasingly common heterogeneous group of digestive diseases that should be considered as a diagnostic possibility in patients with common GI symptoms. The limited number of new EGE cases has prevented the development of clinical trials that could provide conclusive data to clearly define many of the aspects of the disease. The establishment of systematic multicenter registries of cases which exhaustively include clinical and immunological characteristics of patients, type of therapy received and response thereto, evolution of the disease, and even molecular data would go far in offsetting the small number of EGE patients, allowing access to more information to broaden our knowledge of this disease. Only long-term follow-up and outcomes of patients undergoing different therapeutic modalities will help define the natural history of EGE in children and adults, clearing up the controversy of whether pediatric EGE lasts into adulthood.

Introduction

Crohn's disease (CD) is a chronic, relapsing disorder of the gastrointestinal tract, belonging to the inflammatory bowel diseases (IBD). Approximately, 25% of CD first present in childhood and adolescence, with recent studies suggesting that the prevalence is rising in both developed and developing countries [1, 2]. The precise cause of IBD is still unsettled, but there is evidence that they develop as a consequence of an abnormal immune response to the intestinal microbiota in a genetically susceptible host (Fig. 28.1) [3]. Although the pediatric and adult-onset IBD seem to share many clinical aspects and pathogenetic pathways, some features are peculiar to the pediatric form, such as the potential for linear growth impairment and pubertal delay as complication of undertreated inflammation and malnutrition; the influence of nutritional treatment on the course; and the different phenotype expression of the disease [4]. Finally, evidences from animal models of IBD and preliminary observations in children support the concept that IBD develop in distinct phases and that key mediators of inflammation play different roles, depending on the stage of the disease [3, 5]. These observations highlight the importance of taking into consideration the time course of disease when studying pediatric IBD and targeting appropriate treatments.

Epidemiology

Although IBD can occur at any age, up to 25% of patients develop symptoms during childhood and adolescence [1, 2]. Some epidemiological studies from USA and Europe have shown a steady increase in the overall mean annual incidence of pediatric IBD around the world, that seems to be primarily due to an increase in the incidence of CD [1, 2, 6]. CD is unequally distributed all over the world, with highest rates occurring in Western and Northern countries, and with a decreasing gradient from North to South and from West to East [7–11]. The worldwide highest prevalence of pediatric IBD is reported from the Canadian Ontario region, with approximately 56 IBD patients for 100,000 inhabitants [8]. Epidemiological observations from this area, using health administrative data, have indicated an increasing incidence of pediatric CD from 9.5 in 1994 to 11.4 in 2005 per 100,000, with unchanged incidence rates for pediatric ulcerative colitis (UC; 4.1–4.2) [9]. In Europe, a recent study based on the registry of chronic inflammatory intestine diseases in North-West of France (EPIMAD) indicated a mean annual incidence rate of 2.6 for pediatric CD [11]. The largest population-based study of incidence of pediatric IBD in the USA was reported from Wisconsin, estimating a yearly incidence of IBD of 7.05 per 100,000, the incidence of CD being 4.56, that is, more than twice the rate of UC (2.14) and a prevalence of 48–71 per 100,000 [12]. A recent study estimating the prevalence of IBD in the USA using a large, multistate sample, reported a prevalence of CD in children of 43/100,000 [13]. Factors contributing to the evident increase in the global incidence could be a greater case ascertainment, the widening case definition, earlier onset in predisposed individuals, and greater access to health care; however, there is a wide agreement that the rising incidence of pediatric IBD is due to a real increase in the number of affected children [14]. It has been postulated that the “Westernization” of different societies accounts for the progressive rise in the incidence of the disease also in previously low-incidence areas,

MECHANISMS UNDERLYING INFLAMMATORY BOWEL DISEASE

including Japan [15], other Asian countries [16], and some Eastern European countries [17].

Pediatric IBD present specific phenotypic and demographic differences when compared with adult-onset disease. While CD and UC occur with equal distribution in adults [18], it has been reported that in childhood CD is more frequently diagnosed than UC [19, 20]; moreover, while in adults there is an equal male to female ratio (or a mild female predominance), all pediatric IBD cohort studies or registries indicate a male predominance [20]. In pediatric CD, most patients have an extensive disease, ileocolonic or colonic, and distinction of UC from colonic CD may be not uncommonly challenging [21]. As recently confirmed by EPIMAD registry, children with CD are more likely to have upper gastrointestinal involvement than their adult peers [11]. Moreover, disease severity seems to differentiate pediatric-onset CD: children often present an inflammatory or nonstricturing, nonpenetrating disease, while complicated disease is fairly unusual at presentation. However, even with treatment, many data demonstrate that inflammatory CD progresses to stricturing and penetrating disease in several children [11, 20]. Adult disease begins more often with stricturing or penetrating disease, with a lower trend of disease progression than pediatric-onset disease.

Etiopathogenesis

The most accepted hypothesis for the pathogenesis of CD is that the interaction between luminal contents (i.e., the intestinal microbiota) and the mucosa leads to a dysregulated inflammation in a genetically predisposed host. Several mi-

croorganisms have been considered as potential causative agents for CD, including *Mycobacterium paratuberculosis*, *Listeria monocytogenes*, novel Burkholderiales, *Escherichia coli* [22, 23]. Recently, strains of adherent-invasive *E. coli* (AIEC), capable of adhering to and invading epithelium, and to replicate in macrophages, have been described in adults and children with CD [24, 25]. Nevertheless, there are no strong data to support a role for any of these microorganisms as the causative factor in the etiology of IBD. Some of the most interesting findings in the pathogenesis of IBD come from genetics. The importance of genetics in CD was strongly suggested by family, twin, and phenotype concordance studies. Monozygotic twins exhibit phenotypic concordance in 50–70% of CD patients, and their relative risk of developing CD is 800-fold greater compared to the general population [26]. Recently, the discovery of several susceptibility genes has further supported the importance of genetic predisposition in CD [27]. After the pivotal study of Hugot et al. in 2001, who discovered the association of variants of the *NOD2* gene with ileal CD [28], and the discovery of the correlation between variants of interleukin (*IL*)23 receptor gene and both CD and UC in 2006 [29], the number of IBD genetic associations discovered has dramatically increased. More susceptibility loci have been quickly identified, such as autophagy genes, *ATG16L1* and *IRGM* [30]. In the past decade, the implementation of genome-wide association studies (GWAS) has significantly advanced our knowledge on the importance of genetic susceptibility in IBD [31, 32]. To date, the GWAS performed have identified more than 70 risk-conferring loci for CD [31]. GWAS have revealed a substantial overlap in genetic risk loci between CD and UC. However, some genes are quite different for CD or UC,

clearly denoting the genetic heterogeneity of the two forms of IBD, each one of them showing distinctive and shared genetic associations. For instance, *NOD2*, autophagy genes, and *ITLN1* are unique for CD [31]. Despite the discovery of a massive number of susceptibility genes for IBD, we are still far from understanding the mechanism by which such genetic variants cause the intestinal inflammation. The challenge for basic IBD researchers is now to identify how genetic abnormalities influence pro-inflammatory pathways, providing information that could directly improve the clinical management. A number of pro-inflammatory pathways have been elucidated, in some cases enabling the development of specific interventions. For instance, *NOD2* gene-defected patients have an impaired ability to recognize and process bacterial products, and this may lead to an inappropriately innate immune response. Some CD patients with variants of the autophagy genes (*ATG16L1* and *IRGM*) have a defective capacity to process cell degradation products, as well as bacteria, and therefore an insufficient ability to eliminate pro-inflammatory factors [33]. One of the most important discoveries in the field of genetics of pediatric IBD is the recent identification of impaired IL10 signaling in some forms of very-early-onset (within the first months of life) CD [34]. The common characteristics of these patients are a very early onset of an aggressive CD colitis, treatment-resistant, with perianal involvement. This form of CD is due to homozygous mutations in either *IL10RA* or *IL10RB*, which encode subunits of the IL10 receptor, or for IL10 itself [35]. One could speculate that this form of IBD with a monogenetic inheritance could identify a subset of patients with a “more” Mendelian transmission, opening new horizons of research and also expectations to understand the definite mechanisms underlying these diseases.

Clinical Presentations

CD is characterized by a transmural inflammation that can occur anywhere in the gastrointestinal tract, from mouth to anus. While the terminal ileum is the most common site of CD, about 60% of children have an extensive ileocolonic involvement and 20–30% an isolated colonic disease [18]. CD typically presents in any age group with a constellation of abdominal pain, diarrhea, weight loss, and poor appetite; however, short stature and predominant perianal disease are further significant presenting features in pediatric CD. Impairment of linear growth and associated delay in sexual development can occur before the onset of intestinal symptoms and can dominate the clinical presentation [36]. Growth failure is a unique characteristic of pediatric-onset CD: It is defined as linear growth at or <2 standard deviations (SD) below the mean for age, or decreased growth velocity, and can occur in 15–20% of children with CD [37]. The onset

of growth failure is usually insidious, and any child or adolescent with impairment of the linear growth should have an appropriate initial diagnostic evaluation for IBD [18]. The presence of growth and pubertal delay is a key factor in the management of pediatric IBD. Maintaining adequate nutrition, minimizing inflammation, and maximizing corticosteroid-free treatment remain a crucial part of managing the potential growth stunting effects of active IBD, most specifically of small bowel CD. During the clinical course of CD, growth failure has been reported in up to 40% of children with CD and a final height below the fifth percentile is reported in 7–30% of patients with pediatric-onset CD [38, 39]. Growth failure in CD originates from different factors, such as malnutrition with decreased intake, increased gastrointestinal losses, malabsorption, and medication effects. All these components can certainly impact an individual's nutritional state. In addition, it is now widely agreed that inflammation process per se may directly inhibit linear growth and play a major role in the etiology of growth retardation [40]. Inflammatory mediators such as IL-6 and TNF- α are crucial factors in reducing plasmatic levels of insulin-like growth factor 1 (IGF-1), the peripheral mediator of the growth hormone [41]. In fact, impressive catch-up growth can be observed as soon as remission of intestinal inflammation is achieved. It is essential that height, weight, pubertal staging, and bone age are accurately and regularly measured and recorded in young patients with CD. Nutritional supplementation and need for “catch-up” growth should be an important part of the evaluation of a pediatric CD patient. Delay of pubertal onset is also common in active pediatric CD, and also the duration of puberty can be impaired. Active or relapsing disease during the years following the onset of puberty may slow or even arrest the progression of puberty. Moreover, pubertal delay affects estrogen and androgen levels, which are important for normal bone mineralization, contributing to the development of osteoporosis and osteopenia [42]. Inducing and maintaining disease remission before and during the pubertal years is thus crucial in order to ensure the attainment of final predicted height, avoiding a missed pubertal growth spurt.

Diagnosis

There is no gold standard single test allowing a definite diagnosis of CD. It is the combination of family and personal history, physical examination, and subsequent laboratory, imaging, and endoscopic assessment that leads to the correct diagnosis. Nevertheless, a subset of 10–15% of children with IBD confined to the colon receive an initial diagnosis of inflammatory bowel disease unclassified (IBD-U), and they will be subcategorized only during follow-up [18]. The first diagnostic issue is whether the presenting symptoms are related to CD. In the presence of classic clinical presentation,

differentiating CD from other diseases with initial similar symptoms may be relatively simple [43]. However, in a child with bloody diarrhea and infectious etiologies, like *Salmonella*, *Yersinia*, *Shigella*, *E. coli*, etc., must be excluded. It is also important to evaluate and rule out vasculitides (such as Henoch–Schönlein purpura, and hemolytic–uremic syndrome) or allergic colitis. An abdominal pain mimicking CD may be determined by other conditions, such as intestinal lymphoma, ovarian cyst, appendicitis, or intussusception. Figure 28.2 shows the suggested diagnostic workup of children or adolescents with suspected IBD.

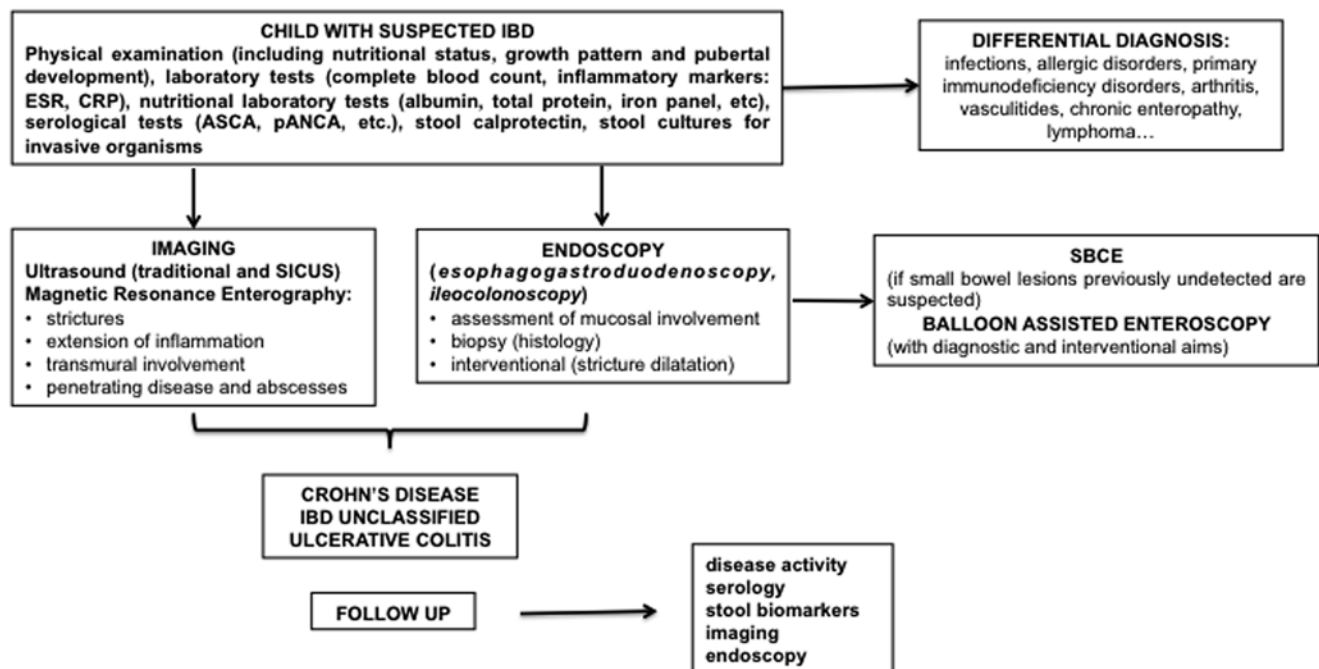

Noninvasive Tests

Serologic Tests Serologic tests are the first diagnostic tool for suspected CD. They include complete blood count, acute-phase reactants (i.e., C-reactive protein—CRP, erythrocyte sedimentation rate, ferritin, platelet count), and a wide panel of antibodies directed against microbial and self-antigens. CRP levels have been shown to well correlate with clinical, endoscopic, and histologic disease activity, and their stable rise is associated with a higher relapse rate and a bet-

ter response to biologics [44]. Several antibodies to microbial antigens have been identified in patients with IBD [45]. The most extensively studied and commonly used are anti-*Saccharomyces cerevisiae* antibodies (ASCA) and perinuclear antineutrophil cytoplasmic autoantibodies (pANCA). ASCAs have been suggested as a marker for CD with a prevalence of 50–60%, compared with 10–15% in UC and 0–5% in healthy controls [46, 47]. Conversely, pANCA has been proposed as a marker for UC or colonic CD [45]. However, between 30 and 50% of the IBD patients do not screen positively for either of these markers, so their absence cannot be used to rule out the disease.

The attention of researchers has been recently focused on the possible relationship between serologic markers and distinct subgroups of patients and prognosis of the disease [48]. In CD, positive ASCA titers have been correlated to younger age at onset, ileal disease, aggressive behavior, and increased risk of early surgery [48]. Because of these promising data, other markers useful for prognostic purposes have been identified. Reactivity to *Pseudomonas fluorescens*-related protein [49] was independently related to stenosing disease and need for surgery, whereas anti-*E. coli* outer membrane porin C (OmpC) has been associated with penetrating disease [49, 50]. Both the

DIAGNOSTIC ALGORITHM FOR SUSPECTED PEDIATRIC IBD

ESR, erythrocyte sedimentation rate; CRP, C-reactive protein; ASCA, anti-*Saccharomyces cerevisiae* antibodies; pANCA, perinuclear antineutrophil cytoplasmic autoantibodies; MRE, magnetic resonance enterography; SICUS, small-intestine contrast ultrasonography; SBCE, small-bowel capsule endoscopy.

Fig. 28.2 Proposed diagnostic algorithm for pediatric inflammatory bowel diseases

presence and magnitude of the immune response were correlated with more aggressive disease behaviors. Recently, a large, multicenter, pediatric study examined the association of ASCA, anti-I2, anti-OmpC, pANCA, and anti-CBir1 reactivity, with disease behavior. The likelihood of developing disease complications increased in parallel with the reactivity to a greater number of antigens. The odds ratio for the development of penetrating disease was 5.2 and 9.5 for patients with reactivity to 2 and 3 antigens, respectively. Moreover, survival analysis showed that the need for surgery was earlier in patients with a reactivity to at least one microbial antigen as compared to those negative for all markers, suggesting that these markers may predict a more aggressive disease course [51].

Fecal Markers of Inflammation The neutrophil-derived marker calprotectin is a noninvasive tool for the diagnosis and monitoring of activity of IBD. Calprotectin is a calcium-binding protein that is excreted in the feces and can be readily measured using an enzyme-linked immunosorbent assay (ELISA). The protein is stable in stool specimens for up to a week at room temperature, allowing patients to collect a specimen at home without special precautions. While calprotectin is commonly used in the initial diagnostic approach to suspected IBD, one of the most advantageous uses is its ability to confirm tissue healing and predict disease relapses. A few studies have evaluated this outcome, demonstrating a sensitivity of 89–90% and specificity of 82–83% for predicting disease relapse during a 12-month period, with a sensitivity and specificity to predict absence of mucosal healing of 70–100% and 44–100%, respectively, depending on the calprotectin concentration threshold used [44]. Other fecal biomarkers, such as lactoferrin, neutrophil-derived S100A12, and high-motility group box 1 (HMGB1), show promise as potential biomarkers for CD, but have been studied far less extensively [50–52].

Imaging Most patients with CD have involvement of the small bowel, a region challenging to evaluate. Furthermore, children with CD need frequent evaluations during the course of their disease, so noninvasive imaging test, radiation-free, could be a valuable alternative to endoscopy for the definition of activity and complications of the disease. In the past, small bowel follow through (SBFT) was the “gold standard” for small bowel disease. In the past decade, due to considerable advances in technologies, other modalities, such as magnetic resonance (MR), ultrasound (US), and computed tomography (CT) have been favorably utilized [53]. CT has the major disadvantage of the large radiation exposure, driving interest in alternative imaging techniques to avoid this risk. MR with the administration of oral contrast (MRE) results in luminal distension, facilitating evaluation of bowel wall thickness and regularity; MR enteroclysis (with contrast administered through a nasojejunal tube) seems to have

the same sensitivity (88%) of MRE but a superior patient discomfort [53]. In comparison with endoscopy, MRE has a sensitivity of 84–96% and a specificity of 92–100% for the diagnosis of IBD [54]. MRE can also allow a detailed assessment of perianal fistulae, and it should be preferred as imaging tool for perianal disease [55, 56]. The recent European Crohn's colitis organization (ECCO) and European Society for Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) guidelines on the management of adult and pediatric CD, respectively, recommend MRE as the imaging tool of choice for the diagnosis and follow-up of CD [57, 43]. Abdominal US is a widely used technique in the evaluation of patients with CD because of its excellent safety profile, low cost, and recent advances in the equipment (Doppler and use of oral contrast) that allow high-resolution images [58]. Recently, a small intestine contrast ultrasonography (SICUS), performed after ingestion of an oral contrast material filling the small bowel lumen with anechoic fluid, has been developed for the study of the small bowel [59]. SICUS provides the opportunity to visualize and assess the entire small bowel by measuring intestinal wall thickness and lumen diameter at different levels [59, 60]. This technique is able to detect intestinal lesions in patients with suspected small bowel diseases with a higher sensitivity (72–100%) and specificity (97–100%), compared with SBFT [60].

Endoscopy

Ileocolonoscopy and Esophagogastroduodenoscopy Traditional endoscopy has a pivotal role in the diagnosis of suspected CD. According to the recent ESPGHAN guidelines on the diagnosis of IBD [43], ileocolonoscopy and EGD should be recommended as the initial workup for all children with suspected disease. Multiple biopsies should be obtained from all sections of the examined gastrointestinal tract, even in the absence of macroscopic lesions [43]. Beyond its diagnostic utility, traditional endoscopy is crucial for staging the severity of disease, for the evaluation and treatment of strictures, detection of postoperative recurrence, surveillance for neoplasms, and preoperative assessment. Moreover, endoscopy allows monitoring of response to therapies by evaluating mucosal healing. In the past decade, endoscopic healing has become the most rigorous end point in adult therapeutic trial, and it is being used in pediatric trials too [61, 62]. Tables 28.1 and 28.2 show the typical endoscopic and histologic findings differentiating CD and UC. Peculiarities of endoscopy and histology in pediatric IBD have been defined in an exhaustive fashion in the recently published Porto Criteria of the ESPGHAN [43].

Small Bowel Capsule Endoscopy Small bowel capsule endoscopy (SBCE) allows the evaluation of CD small bowel

Table 28.1 Endoscopic differentiation between typical CD and UC

CD	UC
Throughout the entire GI tract	Confined to colon
Discontinuous lesions	Usually continuous lesions
Rectal sparing or segmental inflammation	Rectal involvement (in children may be absent)
Aphthous ulcers (may occur in normal mucosa)	Mucosal granularity/friability
Linear ulcers common	Erosions/microulcers
Cobblestoning	Loss of vascular pattern
Ileocecal valve stenotic and ulcerated	Ileocecal valve patulous and free from ulcerations (possible backwash ileitis)

GI gastrointestinal

Table 28.2 Histologic findings in CD and UC

CD	UC
Focal crypt distortion	Mucosal surface alteration
Ulcers and/or aphthoid ulcers	Crypt distortion, atrophy
Mucin depletion absent or weak	Mucin depletion
Pseudopyloric metaplasia	Cryptitis and/or crypt abscesses
Focal cryptitis	
Focal lymphoplasmacellular infiltration in the lamina propria	Diffuse lymphoplasmacellular infiltration in the lamina propria
Granulation tissue-like inflammation	Basal plasma cell infiltration
Epithelioid granulomas	

lesions, with no radiation. It is very sensitive for determining mucosal lesions, but it cannot detect extraluminal processes and it does not allow the biopsy of detected findings. In comparison to traditional endoscopy, SBCE can evaluate the entire small bowel, has an easier preparation, and is better tolerated from children. Regardless of its many advantages, SBCE also has some weaknesses: biopsy or intervention is not possible, and there is no way to guide the capsule, so significant lesions may be missed because of a bad orientation of the camera, obscured visualization due to luminal bubbles or debris, or delayed intestinal transit resulting in an inaccurate exam. SBCE is contraindicated in patients with strictures because of the risk of capsule retention. Furthermore, there are no established diagnostic criteria for CD: although most studies have defined the presence of more than three ulcerations in the absence of nonsteroidal anti-inflammatory drug ingestion as a diagnostic criterion, this has not been prospectively validated [63]. Given the concerns about the specificity of SBCE in the diagnosis of IBD, but recognizing its good sensitivity, some experts have suggested that it may be useful mainly for monitoring established CD rather than for initial approach [64].

Balloon Enteroscopy Double-balloon enteroscopy (DPE) was first introduced in 2001 as a device offering the possibility of complete diagnostic and therapeutic access to the entire small bowel with an endoscope [65]. A single-balloon device has also been developed with a similar intention. The enteroscope can be inserted via the oral or anal route and, using the combination of these approaches, complete examination of the entire small bowel can be achieved in many

patients [66]. Several studies support the utility of DBE in established adult and pediatric CD with the potential to affect management in select populations of patients (small bowel disease) [67]. The main limitations of balloon-assisted enteroscopy (BAE) are its invasive nature with the risk of bleeding and perforation (complication rate for diagnostic procedures is around 0.8% but can be as much as 4% for therapeutic interventions), prolonged duration, limited evaluation of the entire small bowel in a one-step approach, and requirement for specialized personnel [53].

Therapy

The current goals of treatment of pediatric CD are to induce and maintain a prolonged remission, minimizing drug toxicity. At long term, they should include preventing relapses, optimizing growth and pubertal development, and improving quality of life. Modern expectations of CD therapy call also upon the concept of mucosal healing, and, eventually, of deep remission (i.e., clinical remission, biomarker remission, and mucosal healing) [68]. The introduction of these outcomes may be the best way to alter the natural course of these diseases by preventing disability and bowel damage [69]. This may be of clinical relevance in children with CD, given the long-term consequences of early-onset aggressive disease presentation. Pediatric CD therapy employs many of the same treatment regimens as their adult counterparts. There are only a few well-designed clinical trials performed in children, therefore much of the evidence given is based on adult data. Conventional therapy is based on the esca-

lation of drugs, from those with a better safety profile but a lower efficacy (antibiotics, mesalazine, sulfasalazine) to those with improved efficacy but a greater risk of side effects (steroids, immunomodulators, biologicals, surgery). This “step-up” approach is applied in most cases of pediatric IBD (Fig. 28.3). The advantages of “step-up” management are mainly to reserve more toxic drugs for those patients with a demonstrable “need” for more intensive therapy [70]. However, potential disadvantages include the observation that conventional therapies have not altered the disease course towards disease complications (strictures and fistulae) or the need for surgical procedures. Hence, pediatric gastroenterologists are moving towards an “early aggressive” approach, with the aim of changing the natural history of the disease [70]. So far, there are no definite proper criteria to select which patients will certainly benefit from an early aggressive approach [71]. The knowledge of these genetic, laboratory, or clinical markers will be the challenge in pediatric IBD research.

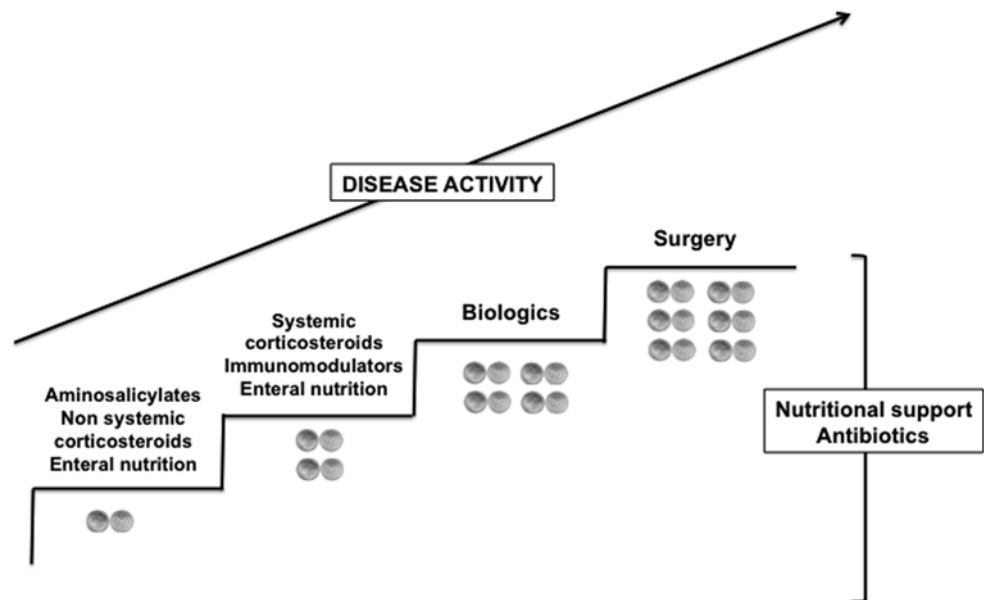

Conventional Therapy

Aminosalicylates Aminosalicylates (5-ASA) are commonly used in the management of pediatric CD, although there are no randomized controlled trials evaluating their efficacy for the induction and maintenance of remission in children. Current data in adults do not support their use in ileal CD, showing any (or a slightly) improvement compared to placebo, thus their use in CD should not be supported [72].

Steroids Conventional corticosteroids (CSs) are used for the induction of remission in moderate-to-severe CD. CSs are usually quickly weaned after the induction, due to their known adverse effects. Budesonide, an oral steroid preparation that is released in the distal ileum and proximal colon, can be used in patients with mild-to-moderate disease of those segments [73]. It has less systemic side effects than conventional steroids but is not completely without them, and quick withdrawal can lead to adrenal insufficiency [74].

Immunomodulators (Azathioprine, 6-Mercaptopurine, Methotrexate) Thiopurines, comprising azathioprine and its active metabolite 6-mercaptopurine, are widely used maintenance agents in CD [75]. Their efficacy has been demonstrated in several trials for both induction and maintenance of remission in CD. However, due to their well-known slow onset of action (about 2–3 months), they are not used for induction of remission. Although the only pediatric prospective, multicenter, double-blind, placebo-controlled trial conducted in children reported 91% of children receiving thiopurines to be in remission after 18 months of therapy [76], in routine clinical practice, a complete remission can be achieved in about 60% of patients 1 year after beginning therapy [77]. Methotrexate is often regarded as a second-line immunomodulator in CD patients not responding or intolerant to thiopurines. Some data in adults have demonstrated its efficacy in inducing and maintaining remission [78]. To date, there have been no controlled trials of its use in pediatric CD,

Fig. 28.3 Step-up therapeutic approach of pediatric Crohn's disease

but reports from retrospective reviews and uncontrolled trials have shown good remission rates [79].

Biologic Agents Monoclonal anti-TNF- α antibodies have revolutionized the management of IBD since their introduction more than 15 years ago. Infliximab, the first in this class to be approved in pediatric IBD, is a chimeric monoclonal IgG1 antibody (part mouse and part human) that is given intravenously. Infliximab is effective in both inducing and maintaining remission in pediatric CD [80, 81]. It reduces the need for corticosteroid, hospitalization, or surgery; is effective in perianal CD and induces mucosal healing [82]. In the main pediatric clinical trial, the Reaching for Excellence in Adolescent Care and Health (REACH) study, children with moderate-to-severe CD received a 3-dose induction of 5 mg/kg infliximab at 0, 2, 6 weeks, followed by 5 mg/kg maintenance infusions every 8 weeks. Remission rates were 60% at week 30 and 56% at week 54. Moreover, this trial showed that the maintenance therapy every 8 weeks was superior to every 12 weeks, confirming previous results in adults [83]. Concerns about the risk of opportunistic infections or malignancies have emerged as a result of the extensive use of these drugs. Although an overall slightly increased risk of lymphoma has been reported in patients with IBD who have been exposed to biological or immunomodulator therapy, a rare fatal form of lymphoma, hepatosplenic T cell lymphoma (HSTCL), has been observed only in children and young adults with IBD exposed to immunomodulators while taking biologics [84]. There have been approximately 36 cases of HSTCL associated with IBD treatment [84–88]. Of these 36 cases, 20 had received combined therapy with infliximab and a thiopurine, with all 20 having taken infliximab and 4 also having taken adalimumab after infliximab [85–88]. One patient was given natalizumab after infliximab [88], 16 patients had received a thiopurine as monotherapy for IBD. These cases reveal a preponderance for young male patients, although the mechanism of this is unknown. For this reason, most pediatric patients do not receive concomitant therapy with these two classes of medications (although there are some exceptions in children affected by severe CD). There is still considerable debate regarding how, when, and for how long a combination therapy should be implemented, also on the basis of data from Study of Biologic and Immunomodulator Naïve Patients in Crohn's Disease (SONIC) trial in adults, demonstrating better results in term of efficacy in patients treated with combination therapy compared with immunomodulator or biologic therapy alone [89].

Adalimumab is a humanized anti-TNF- α therapy that has been shown to be efficacious for induction and maintenance of remission for children with CD [90]. It is used primarily in clinical practice for patients who are primary anti-TNF- α responders, but become intolerant or nonresponsive to infliximab [91], although its use as first-line biologic agent has

become widespread. Only limited data are available on the long-term outcome of biologic treatment in pediatric IBD. Recently, data from the EPIMAD registry in a large population-based pediatric-onset CD cohort (120 children) with a median follow-up of almost 10 years confirmed the efficacy and safety of infliximab in this population. The short-term response rate in this study was 89%, similar to results reported in the REACH study [92]. More than half of the initial responders to infliximab (55%) maintained benefits 3 years after its initiation and 32% at maximal follow-up. These results are less satisfactory than those reported by Hyams et al. [81] in a large North American pediatric cohort where the likelihood of continuing maintenance infliximab therapy at 1 and 3 years was 93 and 67%, respectively.

Nutrition Exclusive enteral nutrition (EEN) is used as a therapy to achieve remission in children presenting with acute CD [70]. Nutritional therapy consists of using different formulas (elemental, semi-elemental, and polymeric) as primary therapy to induce and maintain remission in CD and as a supplement to improve growth, or to replenish micronutrient deficiency. The evidence for supporting the use of enteral nutrition as primary therapy is controversial: while enteral nutritional support has found favor in some parts of the world (mainly Europe and Canada), it is not widely utilized in others (USA), and it can be difficult to administer for long periods of time. Several small pediatric studies suggest the effectiveness of EEN in active CD [93–95]. A meta-analysis of pediatric data, despite limited numbers of truly randomized trials in children, concluded that enteral nutrition may be as effective as steroids in the treatment of children with active CD [96]. Moreover, some studies suggest that EEN may be able to achieve mucosal healing. Fell et al. demonstrated a clinical and histological remission in over 70% of children treated with EEN, with an improvement of cytokine profiles with a polymeric diet alone [97]. Despite convincing data about the benefits of enteral nutrition, its mechanism of action remains elusive. The most frequently advanced theory is that the microbiota of the gut lumen is modified by enteral nutrition; furthermore, the reduction in antigenic load associated with an EEN may also contribute to bowel rest. However, the efficacy of polymeric diets and recent evidence that dietary supplementation with enteral nutrition may prolong the remission of the disease [95] suggest that reducing luminal antigens may only play a modest role in the efficacy of this therapy. Whether enteral nutrition per se has either a direct and/or indirect immunoregulatory effect remains speculative. The main drawback of enteral feeding is the poor compliance: Most parents are reluctant to commit their children to total enteral nutrition for 6–8 weeks as required, and few children are able to consume an adequate volume of formula by mouth, thus requiring the insertion of a nasogastric tube.

Surgery The main indications for surgery are complications of the disease (especially strictures and fistulas), intestinal perforation or bleeding, failure of medical therapy, and complications of medical therapy (e.g., growth failure). The primary goals of surgical treatment in CD are to preserve as much bowel as possible, relieve complications, and to help the patient to achieve the best possible quality of life. In children, the potential for bowel loss due to surgical resections must be weighed against the risk of poorly controlled disease, long-term steroid therapy, and growth failure. Interestingly, weight and height catch-up are markedly significant in patients undergoing surgery within 3 years from CD diagnosis. Indeed, surgery seems to promote bright growth and nutritional recovery if performed in the early phases of the puberty [98]. Recent data from European Pediatric Registries indicate that cumulative rates of intestinal resection are 7, 20, and 34% at 1, 3, and 5 years, respectively [98, 99]. Variables at diagnosis associated with an increased risk of a second surgery are: age < 14 year, penetrating or structuring phenotype, and upper gastrointestinal location [99]. Interestingly, the risk of resection surgery was reduced by more than two-thirds in patients undergoing scheduled infliximab maintenance treatment.

Barbara S. Kirschner

Introduction

The majority of patients with chronic inflammatory bowel disease (IBD) are diagnosed with either ulcerative colitis (UC) or Crohn's disease (CD) on the basis of established clinical, endoscopic, histologic, and radiologic criteria [1–2]. However, in 5–23% of patients with chronic colitis, a definitive diagnosis of UC or CD cannot be established because the initial macroscopic appearance (either during ileocolonoscopy or following colectomy) and histologic features overlap between UC and CD [2–7] (Table 29.1). While most of these patients eventually evolve into patterns consistent with UC or CD, approximately 20–60% retain the diagnosis of indeterminate colitis (IC) over periods as long as 5–10 years post diagnosis [4, 6–11] (Table 29.2). This latter observation suggests that IC may constitute a separate category within the spectrum of IBD. This chapter reviews the histologic and clinical features of IC in pediatric patients and contains updated information explaining why some patients continue to be diagnosed with IC (new proposed terminology of inflammatory bowel disease-unclassified, IBD-U) [12, 13]. For the present, IC and IBD-U refer to chronic colitis due to idiopathic IBD for which the features of CD and UC are absent. It has been suggested that the term IC should be the preferred term after histologic evaluation of the resected colon and IBD-U used after review of biopsy specimens [12, 13].

Clinical Presentation of Indeterminate colitis

A concurrent retrospective/prospective analysis of 1576 children and adolescents from the Italian Pediatric National IBD Register showed that 8% of their study population had IC while 52% had UC and 40% CD [14]. Presenting symptoms

in IC were more similar to UC (bloody diarrhea and abdominal pain) than CD (abdominal pain and diarrhea). Fever and weight loss occurred more frequently in CD than IC and UC: fever in 40.5% CD, 12.9% in IC, and 12.6% in UC; weight loss 50.1% in CD, 17.4% in IC, and 20.6% in UC. The locations within the colon were also similar between IC and UC (pancolitis 34 vs. 39%; left colon 27 vs. 23% and rectum only 9 vs. 7%). The male to female ratio was lowest in UC (0.82), intermediate in CD (1.18), and highest in IC (1.42). Heyman et al. using the PediIBD Consortium Registry, reported that the prevalence of IC in children with IBD was highest in those aged 0–2 years (33%) and decreased to 18% at 3–5 years, 12% at 6–12 years, and 9% in those aged 13–18 [15, 16]. In young children (less than 5 years of age), failure to thrive is more prominent than seen in UC [17].

Jose et al. compared disease type with the prevalence of extraintestinal manifestations (EIMs) at the time of diagnosis and during follow-up in pediatric patients with IBD [18]. The study, also from the PediIBD Registry, included 1649 patients: IC ($n=171$), UC ($n=471$), and CD ($n=1007$). With the exception of primary sclerosing cholangitis (PSC) being more prevalent in UC, the frequencies of the other EIMs did not differ between these disease types.

Epidemiologic Aspects of Indeterminate colitis

The prevalence of IC in pediatric patients with IBD varies among centers from 5 to 23% [2–7] (Table 29.1). A meta-analysis of 14 studies of pediatric patients with IBD and 18 studies in adult patients with IBD showed a higher frequency of IC in children (12.7%) versus adults (6.0%) [19].

In a pediatric population of 428 children with IBD being followed at the University Chicago reported in 2000, 49 or 11.4% were diagnosed with IC [5] (Table 29.2). In 42.9% of those with IC, the histology “favored UC” but these patients also had features of CD including areas of focal colitis, focal gastric, or duodenal inflammation, anal fissures, or isolated granulomas adjacent to ruptured crypts. Features “favoring

IC indeterminate colitis, UC ulcerative colitis, CD Crohn's disease

CD" were present in 20.4% of children with IC, none of whom had granulomas, radiologic evidence of small-bowel CD, or perianal findings. Endoscopic and histologic findings of IBD without distinguishing features of UC or CD were present in 36.7% of our patients with IC. In order to further categorize our patients with IC, an X-ray study of the upper gastrointestinal tract with small-bowel follow-through (SBFT) was performed in all patients to exclude the possibility of CD.

Heikenen, Werlin, Brown et al. noted a similar prevalence of IC (10%) in a pediatric population of IBD [6]. These authors noted that children with IC were diagnosed at a younger age (7.8 years) than those with either UC (9.7 years) or CD (11.4 years). Similarly in Sweden, the peak age range at diagnosis was younger (10–19 years) for patients with IC in comparison with UC (20–29 years) [19].

Criteria for Histologic Diagnosis of Indeterminate colitis

In establishing a diagnosis of IC, it is essential to exclude other causes of colitis such as infections (*Clostridium difficile*, *Yersinia*, *Mycobacterium tuberculosis*, *Entamoeba histolytica*, *E. coli* 0157:B7 or other verocytotoxin-producing strains, drugs (nonsteroidal anti-inflammatory drugs, NSAIDs), Behçet's, malignancy, vasculitis, and certain immunologic disorders. Immune deficiency disorders which may include chronic intestinal inflammation are: chronic granulomatous disease, Wiskott–Aldrich syndrome, common variable immunodeficiency disease (CVID), immu-

nodysregulation polyendocrinopathy enteropathy X-linked syndrome (IPEX), and glycogenosis type 1b [2, 20, 21].

Geboes and Van Eyken published an in-depth description of the histologic features observed in normal intestinal mucosa as well as the changes seen in patients with IBD [22]. Focal or diffuse plasmacytosis at the base of the mucosa and crypt architectural changes are strong predictors of IBD. However, it is important to recognize that these findings develop during the course of IBD. Thus, while basal plasmacytosis was seen within 15 days of the onset of IBD, crypt distortion was observed at 16–30 days in only 25% of patients but increased to 75% after 4 months. In comparison to adults, children < 10 years of age with new-onset UC show less crypt architectural changes and more rectal sparing than older patients. In addition, 4–8% the initial biopsies were within the normal range. The authors suggested that the presence of basal lymphoplasmacytosis, seen in 58% of cases, should lead to suspicion of underlying IBD. It in this group of children and adults with short history of disease onset, mild basal lymphoplasmacytosis and no or minimal crypt architecture abnormalities that the term "IBD-U" has been proposed [12, 22, 23].

Patients with IBD-U clearly have IBD but the definitive features of UC or CD are absent. IBD-U may also be appropriate for cases of PSC where rectal sparing and patchy or focal inflammation are also more frequently observed [12]. Riddell stated that to differentiate IC lesions from CD lesions in resected specimens, submucosal and subserosal lymphoid aggregates away from areas of ulceration, non-necrotizing granulomas and skip areas should be absent. This is partic-

ularly true where there is nonspecific ileal involvement or gastritis with negative stains for *H. pylori* [24].

In cases of fulminant colitis, overlapping features between UC and CD (relative rectal sparing, focal inflammation or deep fissuring ulceration) result in a diagnosis of IC in approximately 10–15% of patients [7, 22]. It is also important to recognize that some medications, such as corticosteroids or aminosalicyclic acid (ASA) preparations, may change the diffuse histologic appearance in UC to a more focal appearance [6, 17]. Thus, slides from the original or pretreatment colonoscopy should be reviewed when considering a diagnosis of IC [23, 24].

Although histologic criteria would appear to allow differentiation between CD and UC, in 2002, Farmer et al. documented disparity among pathologists reviewing cases of colonic IBD [25]. The diagnosis of gastrointestinal pathologists differed from that of the referring institution in 45% of surgical specimens and 54% of biopsy specimens. Of 70 cases initially diagnosed with UC, 30 (43%) were changed to CD or IC; in contrast, 17% of cases initially diagnosed with CD were changed to UC or IC.

The performance of upper gastrointestinal endoscopy with biopsies (esophagogastroduodenoscopy, EGD) identifies some patients with CD whose colonoscopy biopsies are indeterminate [12, 19]. Kundhal et al. reported that while diffuse nonspecific gastritis occurred with similar frequency in children with either CD and UC (92 vs. 75%), focal antral gastritis was significantly more common in CD than UC (52 vs. 8%) [26]. The authors defined focal inflammation as “localized inflammation of the gastric pits, glands, or foveolae by mononuclear and polymorphonuclear leukocytes bordering directly on uninflamed mucosa.” This is similar to the statements previously published by Riddell [24]. However, a recent assessment of focal enhancing gastritis (FEG) in 262 pediatric patients showed that while FEG was highly associated with IBD, it did not reliably distinguish between UC and CD [27]. Granulomas in the stomach or duodenum provide evidence confirming the diagnosis of CD even in endoscopically normal-appearing mucosa [24]. Hence, performing an EGD should be part of the initial evaluation of pediatric patients for IBD.

Serologic Markers and Defining IBD Categories

We evaluated the role of p-ANCA and anti-*Saccharomyces cerevisiae* (ASCA) to determine whether we could identify UC and CD in pediatric patients previously diagnosed as IC [5]. While p-ANCA was positive in 68% of those favoring UC, and ASCA positive in 37% of those favoring CD, 86% of our patients with IC were both p-ANCA and ASCA negative.

Joossens et al. correlated serologic markers with prospective follow-up evaluation in 97 adult patients initially diagnosed with IC [8]. After a mean follow-up of 6 years, 32% of the adult patients with IC were reclassified as having UC or CD, half of whom were positive for p-ANCA or ASCA. However, almost half of the patients with IC (48.5%) remained p-ANCA/ASCA negative and continue to have characteristics of IC even 10 years after the initial diagnosis [8].

Recently, Sura et al. utilized serology (pANCA, ASCA, and anti-OmpC) in 117 adult patients with IC and reassessed their disease type at 1 year [28]. P-ANCA identified 78% of patients who subsequently were diagnosed with UC compared with only 18% sensitivity for ASCA to predict a subsequent diagnosis of CD.

Radiologic Imaging

The most frequently used diagnostic studies (after ileocolonoscopy and EGD) for distinguishing among the various forms of pediatric IBD are those which image the small intestine such as magnetic resonance enterography (MRE) or SBFT.

Because of the ionizing radiation associated with SBFT, there has been utilization of MRE in children with IC, UC, and CD [29–31]. Gadolinium-enhanced magnetic resonance imaging (G-MRI) in combination with oral polyethylene glycol (PEG) solution (used to distend the small bowel) demonstrating increased wall thickness was noted in 26/26 children with CD while those with IC and UC showed mild parietal contrast enhancement but not bowel wall thickening [30].

In a prospective study of 58 consecutive children with suspected IBD, G-MRI confirmed the diagnosis of CD and UC with a sensitivity of 96% and specificity of 92% [31]. Of 17 patients with IC on histology alone, G-MRI had a lower non-classification rate than histology ($p < 0.02$). However, although endoscopy was less sensitive (57%), it was more specific (100%).

Small-Bowel Capsule Endoscopy

Small-bowel capsule endoscopy (SBCE) has the potential to identify lesions in the jejunum and ileum which would allow differentiation between IC and CD in patients with IC. Gralnek et al. utilized SBCE to determine whether ulcers could be observed in four pediatric patients previously diagnosed UC or IC, who were experiencing disease exacerbation [32]. Based on abnormal mucosal findings, two of the four patients were re-classified with CD. In addition, eight of ten patients with “suspected IBD” were also found to have ulcerations and diagnosed with CD.

In contrast, Goldstein et al. performed SBCE in 40 adult patients with IC ($n=20$) and UC ($n=49$) were unable to identify patients who would be reclassified as de novo CD in the period following their ileal pouch-anal anastomosis (IPAA) [33]. These authors cautioned that since SBCE may identify lesions in healthy individuals as well as those who take NSAIDs, the specificity of mucosal in these lesions is unclear.

Kopylov and Seidman also reported that the most common cause of lesions which mimic small bowel CD is NSAID medication [21]. The authors noted that these lesions can be indistinguishable from CD, occur as early as 2 weeks of use and may be seen in up to 70% of chronic NSAID users. They advised instructing patients who will undergo CE to avoid NSAIDs for at least 1 month before the examination.

Another confounding variable is that small-bowel inflammation has also been observed in a significant number of patients with established UC [34]. Of 23 UC patients, 13 (57%) showed small-bowel lesions, and 8 (35%) had erosions, as opposed to 2/23 (7%) and 1/23 (4%) in the control group. These findings emphasize the potential risk of misdiagnosis in IBD patients.

Natural History of Indeterminate colitis

With time, 50–72% of adult patients and 64% of pediatric patients with IC can be reclassified as definite UC or CD during subsequent observation [4, 5, 9–11, 35] (Table 29.2). Moum et al. observed that of 36 patients initially diagnosed as IC 33% were reclassified as UC and 17% as CD after a follow-up period averaging 14 months [9]. Meucci et al. reported that 37/50 patients (72.5%) changed from IC to a definite diagnosis of UC or CD during follow-up with a cumulative probability of 80% within 8 years of diagnosis [10]. In contrast, Wells et al. followed 16 patients with IC for a mean of 10 years and observed 3 were reclassified with UC, 1 with CD and the rest remained indeterminate [11]. The course of IC in 36 Swedish children after a mean follow-

up of 4.6 years was analyzed by Hildebrand et al. [4]. The findings were similar to those as described above in adults: 21/36 (58%) were subsequently categorized as UC, 2/36 (6%) CD and 13/36 (36%) remaining as IC. In our series of 49 children with IC, 9 had undergone colectomy at a mean of 24 months after diagnosis. After a mean follow-up of 42 months, 6/9 had repeat endoscopic examinations resulting in reclassification consistent with UC in 3/9 (33%), continued IC in 2/9 (22%) and CD in 1/9 (11%) [5].

More recently, Malaty et al. described a 12-year telephone follow-up of 20/60 pediatric patients who had been previously diagnosed with IC [35]. The range of outcomes was broad: 30% remained IBD-indeterminate, 10% reclassified as CD, 5% as eosinophilic colitis but 55% reported a complete resolution of their symptoms.

Medical Therapy of Indeterminate colitis

The observation that the majority of patients with IC are reclassified as UC or CD, makes it difficult to know whether IC represents a separate form of IBD.

Perhaps because of the small number of patients with IC and the variability of their histologic findings, the response to various drug regimens in this population has not been specifically addressed.

Thus, in our program the choice of therapeutic intervention is selected depending on the severity of symptoms, extent and severity of endoscopic and histologic findings, and laboratory parameters (Table 29.3). For most patients, drug therapy is similar to that indicated for patients with UC of comparable extent and severity. These include 5⁺ASA preparations for mild disease and corticosteroids and immunomodulatory and/or biologic therapy for moderate and severe disease. Immunomodulatory agents, such as azathioprine or 6-mercaptopurine have been used in approximately 60% of our pediatric population with IBD due to the presence of steroid dependency, resistance or toxicity [36]. When biologic agents are used, there has been a trend among pediat-

Table 29.3 Medical approach to the pediatric patient with indeterminate colitis^a. (Reprinted with permission from Ref. [20], Table 24.4, p. 383 with permission.)

5 ⁺ Aminosalicylic acid preparations (5 ⁺ ASA) for mild disease
Corticosteroids (moderate to severe disease severity)
Metronidazole if histology favors CD
Azathioprine (AZA) or 6-mercaptopurine (6-MP)
Measure thiopurine methyltransferase (TPMT) prior to use to exclude deficiency
Monitor RBC 6-thioguanine (6-TG) and 6-methylmercaptopurine (6-MMP) levels to reduce risk of toxicity
Trial of change to AZA from 6-MP (or vice versa) for non-hypersensitivity side effects (i.e., rash, arthralgias, headache)
Methotrexate if intolerant or refractory to AZA/6-MP and older teenagers and young adults receiving anti-TNF biologic agents
Anti-TNF Biologic (at standard dosing)

^a These recommendations are based on disease location, extent, severity and complications for UC and Crohn's colitis. There are no published pediatric trials which have specifically addressed the response to medical therapy in IC

TNF tumor necrosis factor, IC indeterminate colitis, UC ulcerative colitis, CD Crohn's disease

ric gastroenterologists to use methotrexate as concomitant therapy. The expectation is that there may be a lower risk of malignancy than with the combination of thiopurine and anti-tumor necrosis factor (TNF) therapy, although the long-term proof of this concept has not been established.

Some clinical trials of adult patients with IBD have included small numbers of patients with IC although they have not specifically addressed the response in IC.

Adult patients with refractory UC and IC appear to show similar improvement to azathioprine/6-mercaptopurine and cyclosporine as well as less frequently prescribed immunomodulatory agents such tacrolimus and thalidomide [37–39]. A clinical response to infliximab in 20 adult patients with refractory IC has been reported [40]. In that study, 14/20 (70%) showed a “complete clinical response” and 2/20 (10%) “partial response.” Favorable outcomes in pediatric patients with UC and CD, suggest that it anti-TNF agents will also be effective in some patients with IC who are not responding to conventional medications.

Surgical Treatment of Indeterminate colitis

Conflicting data have been published regarding medical failure and complication rates following medical and surgical intervention in patients with IC versus UC. Some centers report that IC is more refractory to medical intervention than UC resulting in a greater relapse rate and subsequent need for colectomy [41]. In contrast, Witte et al. described similar response rates to medical intervention in IC and UC for patients enrolled in the European Collaborative Study on Inflammatory Bowel Disease (EC-IBD) [42]. “Complete relief of complaints” was noted in 48% of UC patients versus 50% of those with IC. Partial response was also similar in both groups: 37% of patients UC “improved” versus 33% with IC.

Higher rates of pelvic sepsis, fistula formation and pouch failure after IPAA occur in patients with IC versus UC [43]. In contrast, patients with IC who are pANCA and ASCA negative have lower risk for pouchitis, pouch complications and the development of CD [44]. Thus, obtaining these serologic tests in patients being evaluated for IPAA may provide useful predictive information.

It is our practice to repeat colonoscopy, usually with concurrent EGD, during selected periods of relapse, if a higher level of therapy is being considered to assess whether histologic changes consistent with UC or CD have developed. This is especially the case if colectomy and IPAA are being advised because of refractory disease. Part of the reassessment should include repeat small-bowel X-ray imaging so that patients with ileal CD would be excluded from IPAA. Patients with persistent IC are counseled regarding the potentially greater risk of pouch complications. Patients with

IC undergo a multistaged operative procedure consisting of a total abdominal colectomy with temporary ileostomy and Hartmann pouch. In this way, the entire resected colon can be assessed to exclude CD prior to creating the IPAA. In some cases, especially where the colectomy specimen has atypical features, ileoscopy, and re-examination of the pouch are performed and the results discussed with the surgeon prior to scheduling the IPAA.

Summary

IC or IBD-U may represent a category of chronic IBD which remains separate from UC and CD even after long term follow-up. In young patients or those with recent-onset symptoms, the histologic features are less likely to have developed typical features. Patients and families should understand that IC or IBD-U is not indefinite colitis but rather a form of chronic IBD which may either stay the same or become more consistent with UC or CD over time. The major reason for distinguishing IC from UC is for counseling the patient and family about the potential increased risk for complications and possible subsequent change in diagnosis (especially to CD) following IPAA.

Introduction

Ulcerative colitis (UC) and Crohn's disease (CD) are the two most common forms of idiopathic inflammatory bowel disease (IBD). UC differs from CD in that the inflammation in UC is confined to the mucosal layer of the colon. In contrast, CD is characterized by transmural inflammation either in a limited region or extensively in the bowel, and may involve any portion of the gastrointestinal tract from the mouth to the anus. The peak incidence of IBD occurs between the ages of 15 and 25 years, but UC may begin at any age [1]. Approximately 20% of the patients with UC present before the age of 20 years [2]. While children and adults develop similar symptoms, children often present with more extensive disease [3]. Clinicians caring for children and adolescents with UC must treat both the gastrointestinal and extraintestinal complications, optimize nutrition and linear growth, and address the psychosocial ramifications of the illness. Since the majority of the published studies investigating the natural history and treatment of UC are in adults, we refer primarily to these studies, with reference to pediatric studies where available.

Epidemiology

Most children with UC present between the ages of 10 and 18 years. However, UC in children under age 5 years is well described [1, 4, 5]. Epidemiologic studies primarily conducted in North America, the UK, and Scandinavian countries, suggest the incidence of UC in children ranges from 2.1 to 4.2 cases/year/100,000 population [6–11] (see Table 30.1). Although temporal trends vary between studies, the incidence of UC in children has remained relatively stable. In a systematic review of international trends in pediatric IBD incidence, of those studies with calculated statistical trends for CD incidence, 60% reported a significant increase in CD incidence. In contrast, only 20% of similar studies for UC reported a significantly increased incidence of UC [12]. Authors revealed a wide range of IBD incidence internationally and an absence of accurate estimates in most countries. The majority of incidence data for CD and UC in the pediatric population originates from geographic regions with higher rates of IBD [12].

Adult studies demonstrate that UC is more prevalent in North America, the UK, and Scandinavia and less common in southern Europe, Asia, and Africa [2]. The data suggest a north-to-south gradient with higher incidence rates of both CD and UC in northern locations, even within individual countries [13–15]. UC is more common among Jewish than non-Jewish peoples [16], but disease rates in people of Jewish origin vary by geographic region and parallel those of the general population [17]. The higher rates of IBD in individuals of Jewish origin across different countries support a common genetic predisposition; however, the geographic variation of IBD rates in Jews emphasizes that environmental factors (see below) influence the inherited risk.

Pathogenesis

No single cause of UC has been identified. Most likely, the disease results from a combination of the interplay of genetic, environmental, and immunologic factors.

A widely accepted hypothesis suggests that in the genetically susceptible individual, a combination of host and environmental factors leads to the initiation and perpetuation of an abnormal intestinal immune response to gut flora, resulting in UC [18, 19]. In support of this theory, colitis in animals occurs in a wide variety of genetically altered rodents, including interleukin (IL)-2, IL-10, and T cell receptor knockout mice, and *HLA-B27* transgenic rats [20]. Interestingly, most of these animal models do not develop colitis in germ-free environments. These findings suggest that multiple genes may contribute to the pathogenesis of IBD, and that interaction with the environment is essential.

Human Genetics

In humans, UC appears to have a non-Mendelian pattern of inheritance. Current evidence suggests that genes contribute less to the risk in individuals with UC than in those with CD. In a Danish twin cohort study and a Swedish twin cohort study, the calculated pair concordance rates among monozygotic twins were 14–19% for UC and 50% for CD, and among dizygotic twins, 0–5% for UC and 0–4% for CD [21, 22]. Although the concordance rates of disease are higher in monozygotic twins, the incomplete concordance suggests that nongenetic factors also contribute to the development of UC. First-degree relatives of patients with UC have a 9.5-fold increase in risk of developing UC, compared to the general population [23]. Genome-wide association (GWA) studies have implicated over 100 genes in the pathogenesis of IBD: Some of these genes exclusively predispose to CD, others to UC, and others to both diseases [24].

Among the GWA studies of UC, the most significant associations are found within the major histocompatibility complex class II region near *HLA-DRA* [25, 26]. Presently, the known genetic associations likely explain only approximately 20% of the genetic contribution to IBD susceptibility [18].

Table 30.1 Incidence of ulcerative colitis in children and adolescents (number of new cases/year/100,000 persons) [6–11]

First author	Location	Age range	Time period studied	Incidence
Henderson 2012 [6]	Scotland	<16 years	2003–2008	2.1

Jakobsen 2011 [9]	Eastern Denmark, Funen, Aarhus County, Denmark	<15 years	2007–2009	3.1
Perminow 2009 [10]	Southeastern Norway	<18 years	2005–2007	3.6
Malmberg 2013 [11]	Northern Stockholm County, Sweden	<16 years	2002–2007	2.8

Environment

Environmental factors may contribute to the development of UC. One mechanism of action by which environment may trigger IBD is by altering the microbiome. Pediatric studies demonstrate that the intestinal microbiota in children with IBD differs from that of the patients with non-IBD gastrointestinal conditions [27, 28]. However, it is difficult to ascertain whether the microbiome alterations cause the intestinal inflammation, or are epiphenomena. Nevertheless, there is good evidence that diet and other environmental factors may alter the microbiome in both animals and humans [29]. Most studies examining environmental risk factors have the limitations of retrospective, case-control methodology. One of the most consistent findings in multiple studies is the lower risk of UC among current smokers. Current smokers have approximately one half the risk of developing UC compared to nonsmokers [30, 31].

Several authors have suggested that exposure to infections in the perinatal period or early life may contribute to the development of UC. Individuals with CD or UC were more likely to have experienced a diarrheal illness during infancy, when compared to their unaffected siblings [32]. Additional studies suggest associations between infectious gastroenteritis and development of pediatric or adult-onset UC [33–35]. Antibiotic usage in early childhood increases the risk of developing IBD, but the risk goes down as children grow older [36]. Appendectomy at a young age is associated with a lower risk of UC, but it may be the underlying appendiceal infection rather than the appendectomy itself that is the protective factor [37–39].

Other environmental factors that may affect the incidence of colitis include breastfeeding, nonsteroidal anti-inflammatory drugs (NSAIDs), oral contraceptives (OCPs), and vitamin D levels. The data on the association of breastfeeding and UC are inconclusive, with some published studies suggesting a protective effect [33, 40], and other studies showing no significant effect [32, 41, 42]. Some published reports suggest that NSAIDs may precede the onset of IBD, lead to a reactivation of quiescent IBD, or exacerbate already active IBD in humans [43–46]. Among past and current smokers, OCP use was associated with a hazard ratio (HR) of 1.63 (95% CI 1.13–2.35) for UC compared to non-OCP users [47].

There has been increasing interest in the potential immunomodulatory role of vitamin D in the pathogenesis of diseases such as IBD [48]. In a large prospective cohort study of women, higher predicted 25-hydroxy vitamin D (25(OH)D) levels were associated with a significant reduction in the risk of incident CD, but only a nonsignificant decrease in the risk of UC.

Given the constant intestinal exposure to numerous luminal dietary antigens and the influence of dietary intake on the intestinal microbiota, investigators have long hypothesized a relationship between diet and UC [49, 50]. In a systematic review of case-control and cohort-based, nested case-control studies, authors examined macronutrients (fat, protein, carbohydrates) and specific foods (fruits, vegetables, meats), and the risk of IBD [51]. Increased dietary intake of total fats, polyunsaturated fatty acids (PUFAs) and meat were associated with an elevated risk of CD and UC. In contrast, high fiber and fruit intake were associated with a reduced risk of CD, whereas high vegetable intake was associated with reduced UC risk [51]. The sometimes conflicting results of multiple studies may reflect not only the potential methodological differences between studies, but also possibly the complexity of IBD pathogenesis itself [52]. Additional studies are needed to further define the potential role of diet in the pathogenesis of UC.

Immunology and Cell Biology

Activated cells of the mucosal immune system and elevated levels of pro-inflammatory cytokines and chemokines are present in the bowel of both UC and CD patients [18]. Previous studies implicate a dysregulation of activated intestinal (*cluster of differentiation*, CD4+) T cell subtypes of the adaptive immune system in the pathogenesis of IBD. More recent studies however suggest CD and UC both may involve Th17 T cells, which rely upon the IL-23 pathway [18]. IL-23, an essential cytokine involved in the crosstalk between innate and adaptive immunity [19], is secreted by macrophages and dendritic cells and promotes expansion of Th17 cells [19, 53]. Elevated levels of IL-23 and Th17 cytokines are detected in the colonic mucosa of UC and CD [18, 54, 55].

In more recent years, genetic studies such as GWA studies have revealed the importance of the epithelial barrier integrity in IBD pathogenesis [19]. GWA studies have discovered associations between UC and susceptibility single nucleotide polymorphisms in the *HNF4A*, *CDH1*, *LAMB1*, and *GNA12* regions, important in epithelial barrier function [56, 57]. These findings suggest that a disruption in the integrity of the epithelial barrier may play a role in the pathogenesis of UC. Linkage and candidate gene studies have determined variants in the *XBPI* gene, associated with the unfolded protein response for both UC and CD [57–61]. Closely linked to autophagy and innate immunity, the unfolded protein response is triggered by endoplasmic reticulum stress due to accumulation of misfolded or unfolded proteins and is associated with Paneth cell function [57].

Clinical Signs and Symptoms

The typical symptoms of UC include rectal bleeding, diarrhea, and abdominal pain. The presentation can vary depending upon the extent of colonic involvement and severity of inflammation. The colon in UC is inflamed in a diffuse continuous distribution, extending from the rectum proximally. By convention, UC is classified according to the extent of disease into the following three subgroups: proctitis (disease limited to the rectum), left-sided colitis (disease extending to the sigmoid or descending colon, but not past the splenic flexure), and pancolitis (disease extending past the splenic flexure). The Paris classification system is a more detailed system developed for pediatric IBD clinical studies and includes detailed categories for UC disease location and severity, age, and growth status [62, 63]. Proctitis may present with tenesmus, urgency, and the passage of formed or semiformed stool with blood and mucus [64]. In contrast, pancolitis or left-sided disease may present with bloody diarrhea and significant abdominal pain. The majority of patients will present with a several week history of symptoms; however, some will present with a more acute clinical picture.

Although adults and children with UC can present with similar symptoms, there are differences in the clinical presentation of these two populations. Studies suggest that children with UC present with more extensive colonic involvement than adults with UC [3, 4, 65]. In a Danish study of 80 patients less than 15 years and 1080 patients 15 years of age or greater with UC, the younger group had more extensive disease at diagnosis compared to the older group diagnosed with UC [3]. Of the UC patients younger than 15 years of age, 29% had pancolitis and 25% had proctitis; in contrast, of the UC patients 15 years or older, 16% had pancolitis and 46% had proctitis [3]. Gryboski examined 38 children diagnosed with UC at ≤ 10 years old and reported 71% with pancolitis, 13% with left-sided colitis, and 6% with proctitis [4]. Approximately 5% of the children with UC have evidence of delayed linear growth and/or weight loss at diagnosis, although growth failure is much less frequent than in children with CD [4, 66] (see Table 30.2).

Table 30.2 Symptoms at initial presentation of ulcerative colitis in children and adolescents [3, 4, 66–69]. (Reprinted with permission from [67], Table 25.2, p. 388)

Clinical symptoms	Range of percentages
Rectal bleeding	75–98
Diarrhea	71–91
Abdominal pain	44–92
Weight loss	13–74
Arthralgia/arthritis	5–9
Fever	3–34
Growth retardation	4–5

Children with UC may present with varying degrees of disease severity. Approximately 50% of the children with UC will present with a mild form of disease, characterized by an insidious onset of diarrhea and rectal bleeding, without abdominal pain or systemic symptoms such as fever. In these patients, disease may be confined to the distal colon [70, 71]. Disease of moderate severity is seen in 30% of children with UC and is characterized by a more acute presentation with bloody diarrhea, tenesmus, and urgency; systemic symptoms including low-grade fever, abdominal tenderness, weight loss, and mild anemia may be present [70, 71]. Approximately 10% of the children will present with a severe form of UC [70, 71]. Characteristic findings in severe disease include six or more bloody stools per day, fever, weight loss, anemia, hypoalbuminemia, and diffuse abdominal tenderness on physical exam [70–72]. A very small percentage of children will present initially with extraintestinal symptoms or manifestations, without obvious intestinal symptoms [71]. These extraintestinal manifestations of IBD may include axial or peripheral arthritis, erythema nodosum, pyoderma gangrenosum, or primary sclerosing cholangitis (see Sect. “Extraintestinal Manifestations”).

Diagnosis

The diagnosis of UC is established by the information gathered from a detailed symptom and family history, physical examination, and a combination of laboratory, radiologic, endoscopic, and histologic findings. It is important to exclude other etiologies such as an infectious process and to distinguish UC from CD. Colonic inflammation is typically characterized by bloody diarrhea with abdominal cramping. The differential diagnosis of colitis depends upon the age of the child at the time of evaluation. In infancy, necrotizing enterocolitis, Hirschsprung’s enterocolitis, and allergic colitis are diagnoses that should be considered. In children under age 3 who present with colitis, immunodeficiencies-causing colitis (such as IL-10 receptor deficiency and chronic granulomatous disease) should be excluded [73]. In contrast, in the older child and adolescent, enteric infection and idiopathic IBD are the most common diagnoses. (Causes of colitis are listed in Table 30.3.) In patients with painless rectal bleeding, other conditions (Meckel’s diverticulum, polyp) should be considered. In addition to details of the clinical presentation, the history should include family history, recent antibiotic therapy, infectious exposures, growth and sexual development, and the presence of extraintestinal manifestations of UC.

Physical examination should include assessment of height, weight, and body mass index; abdominal distension, tenderness, or mass; extraintestinal manifestations (e.g., aphthous stomatitis, pyoderma gangrenosum, uveitis, or arthri-

tis); fecal blood on rectal exam, perianal abnormalities (e.g., fistulae, fissures, or tags). Findings on physical examination may help to distinguish UC from CD; for example, pronounced growth failure or a perianal abscess strongly suggests the diagnosis of CD. A severely ill child with UC may have tachycardia, orthostatic hypotension, fever, or dehydration. Such findings in the presence of abdominal distention and a concerning abdominal exam may herald a fulminant presentation of UC with increased risk of developing toxic megacolon.

Laboratory Assessment

Initial laboratory evaluation should include appropriate blood tests, stool for occult blood, *C. difficile* toxin assay, and stool cultures. A complete blood cell count with differential may reveal a leukocytosis with or without left shift, anemia, and thrombocytosis. Thrombocytosis, hypoalbuminemia, and elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) may indicate increased disease activity [74–76]. The presence of anemia with low mean corpuscular volume (MCV), wide red cell distribution width (RDW) and low iron levels may indicate an iron-deficient anemia secondary to ongoing fecal blood losses or the anemia of chronic disease. Children with UC may also have normal blood test results at the time of diagnosis [77].

Fecal calprotectin and lactoferrin are frequently elevated in active UC [78, 79], and may be useful screening tests. Fecal biomarkers are elevated in patients with active UC and CD, but are not specific for IBD [80]. Fecal biomarkers cannot distinguish between different etiologies of mucosal inflammation and are increased in other conditions, including enteric infections [80]. Thus, enteric infections should be ruled out. Fecal calprotectin and lactoferrin are the most commonly studied fecal biomarkers. In a meta-analysis of six adult and seven pediatric studies, among children and adolescents with suspected IBD, the pooled sensitivity and specificity of fecal calprotectin testing were 0.92 (95% CI, 0.84–0.96) and 0.76 (95% CI, 0.62–0.86), respectively [81].

It has been proposed that certain serum antibodies may be helpful for screening for IBD and discriminating UC from CD [82, 83]. Perinuclear antineutrophil cytoplasmic antibodies (p-ANCA) are seen in 60–80% of adults with UC compared to 10–27% of adults with CD [82, 84, 85]. Similarly, anti-*Saccharomyces cerevisiae* (ASCA) antibodies are commonly found in individuals with CD but are rarely seen in UC. In a study of 173 children, ASCA yielded a sensitivity of 55% and specificity of 95% for CD and ANCA had a sensitivity of 57% and specificity of 92% for UC [82]. In a study of 128 pediatric patients undergoing evaluation for IBD, Dubinsky and colleagues utilized modified cutoff values to optimize the sensitivity of the ASCA and ANCA assays. For the combination of ASCA and p-ANCA, the sensitivity of detecting IBD increased to 81% with the modified values compared to the 69% with standard cutoff values; however, this was accompanied by an increase in false positive rates among the children without IBD [83]. An overlap of ASCA and p-ANCA positive serology between patients with CD or UC remains. In particular, p-ANCA tends to test positive in the serum of patients with CD who exhibit UC features [82, 86]. Additional serological markers include antibodies to *Escherichia coli* outer membrane porin (OmpC), *Pseudomonas fluorescens*-associated sequence (I2), and flagellin (CBir1) [87]. In a study of greater than 300 children with suspected IBD, a serologic testing panel (including ASCA, p-ANCA, anti-OmpC and anti-CBir1) detected IBD with a sensitivity of 67% and specificity of 76%, compared to a sensitivity of 72% and specificity of 94% for a combination of three abnormal routine blood tests (hemoglobin, platelet count, and ESR) [87]. The value of these tests to supplement the routine diagnostic tests in IBD is a subject under study.

Endoscopic and Radiographic Evaluation

Evaluation with colonoscopy and ileoscopy with biopsies is the principal diagnostic test for UC. In patients with severe colitis, a limited flexible sigmoidoscopy examination with

minimal air insufflation may be more appropriate, to avoid the risks of a full colonoscopy (perforation, hemorrhage, toxic dilatation). Upper endoscopy is also recommended by the “Porto” IBD Working Group of the European Society for Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN). Small-bowel imaging should also be performed to exclude small-bowel involvement, which may change the diagnosis from UC to CD. Options for small-bowel evaluation include upper GI with small bowel follow through, computed tomography (CT) scan, or magnetic resonance imaging (MRI). The Porto expert panel has recommended MRI, over the other two modalities because of the absence of radiation; however, the quality of MRI varies from center to center, and small-bowel motion artifact may be sometimes confused with inflammation [88].

In order to establish the extent of disease involvement by colonoscopy, we recommend biopsies from the terminal ileum and each segment of the colon, even if there are no visible findings at a particular level of the colon. In UC, typical findings seen by the endoscopist include a diffuse, continuous process starting at the rectum and extending more proximally into the colon. However, atypical features, such as rectal sparing, have been reported in children with UC [89–92]. In addition, UC patients with distal colitis can present with a “cecal patch,” discontinuous periappendiceal and cecal inflammation [92, 93]. The colonic mucosa often appears edematous, erythematous, and friable, with minute surface erosions and ulcerations (see Fig. 30.1). Larger, deeper ulcerations with associated exudate may develop in more severe disease. With long-standing UC, pseudopolyps may be present (see Fig. 30.2) [67]. In contrast, in CD, colonoscopy may reveal focal ulcerations (aphthous lesions) with intervening areas of normal-appearing mucosa (skip lesions). In severe or chronic CD, linear ulcerations,

Fig. 30.1 Severe ulcerative colitis in a patient unresponsive to corticosteroid therapy. The colonoscopy demonstrates a featureless colon with loss of vascular pattern, ulcerations, and hemorrhage

Fig. 30.2 Multiple colonic pseudopolyps in a 17-year-old female with ulcerative colitis, with intermittent disease activity despite 2 years of maintenance therapy with thiopurine. (Reprinted with permission from [67], Fig. 25.2, p. 391)

nodularity (cobblestoning), and strictures or stenoses may be present. In general, the ulcerations in CD are deeper and focal versus the diffuse, superficial ulcerations typical of UC (see Table 30.4) [89, 90, 94–97].

Table 30.4 Typical endoscopy and histopathology findings—ulcerative colitis versus Crohn’s disease [89, 90, 94–98]. (Reprinted with permission from [67], Table 25.4, p. 392)

Characteristic	Ulcerative colitis	Crohn’s disease
Endoscopy findings	Diffuse continuous involvement extending from rectum	Focal lesions/disease interspersed with normal appearing mucosa (skip lesions)
	Rectum usually involved ^a	Rectal sparing possible
	Diffuse, superficial, minute ulcerations; deeper ulcerations in severe disease	Aphthous lesions often surrounded by normal appearing mucosa; deep “collar button” ulcers; linear or serpiginous ulcerations
	Strictures very rare	Strictures, often occurring in terminal ileum
Histopathology findings	Pseudopolyps	
	No granulomas ^b	Granulomas (36%)
	Diffuse chronic inflammation limited to the mucosa ^c , crypt abscesses +/- architectural distortion ^d	Focal chronic inflammation, transmural inflammation

^a In children, “rectal sparing” has been seen in UC [89, 90]

^b Giant cell reactions can occur around damaged crypts and spilled mucin. This must be distinguished from “true” granulomas, which by definition, are not seen in UC [96]

^c Deeper layers of the colon may be involved in fulminant UC disease

^d In children with UC, initial colonic biopsies at time of diagnosis are less likely to show architectural distortion than biopsies from adults [97]

Although by definition, the disease of UC is confined to the colon, children with CD or UC can have inflammation of the upper gastrointestinal tract. In a pediatric IBD registry study of 898 patients (643 with UC, 255 with CD colitis), authors examined the presence of macroscopic upper gastrointestinal involvement (ulcerations, aphthous lesions, or erosions) in accordance with the Paris classification system among the 260 patients with UC and 86 patients with CD colitis who underwent upper endoscopy with detailed documentation of lesions [62, 92]. Among the UC patients, gastric erosions were identified in 3.1%, gastric ulcerations in 0.4%, and erosions or ulcerations limited to the esophagus or duodenum in 0.8%. In contrast, upper gastrointestinal lesions were noted in 22% of the patients with Crohn's colitis [92]. Except for the presence of granulomas of CD, it may be difficult to distinguish between UC and CD by the appearance of upper gastrointestinal lesions.

Plain abdominal radiographs and abdominal/pelvic CT scans evaluations may aid in the assessment for complications of UC, including toxic megacolon, perforation, or stricture. Plain abdominal radiograph may demonstrate thumbprinting, loss of haustral patterns, colonic dilatation (i.e., toxic megacolon), obstruction, or pneumoperitoneum (i.e., perforation of the bowel) [99–101].

Pathology of Ulcerative Colitis

In active UC, typical findings on histopathology include a diffuse inflammatory cell infiltrate of the lamina propria mostly with plasma cells, lymphocytes, and neutrophils, but mast cells and eosinophils are also seen. Neutrophils invade the epithelium of the crypts, leading to cryptitis, crypt abscess formation, and goblet cell mucin depletion (see Fig. 30.3) [67]. The inflammatory infiltrate is typically confined to the mucosa, but in severe UC, ulceration may extend into the submucosa and deeper layers [96]. In quiescent (inactive) UC, the inflammatory infiltrate may diminish but signs of chronic colitis (architectural distortion, crypt branching and shortening, reduction in the number of crypts, and separation of crypts) can persist [96]. In children with UC, signs of chronic colitis (e.g., architectural distortion) are not always seen [91, 97].

Histologic differentiation of UC from CD can be difficult. The histologic hallmark of CD is the noncaseating granuloma, which may be found in 25–48% of children with CD [98, 102, 103]. However, a giant cell reaction mimicking a granuloma can occur around damaged crypts and spilled mucin. These “mucin granulomas” must be distinguished from true granulomas, which by definition, are not seen in UC [96]. Histologic skip areas, rectal sparing, focal inflammation, and transmural inflammation also suggest the diagnosis of CD. However, in children, histological skip areas

Fig. 30.3 Low power view of a colonic biopsy from a patient with active ulcerative colitis. Note the increased lamina propria inflammatory infiltrate, crypt abscesses, and crypt architectural distortion. The crypts are irregular in shape and placement and do not descend to the level of the muscularis mucosae. (Courtesy of Jonathan Glickman, MD, PhD, Director, Gastrointestinal Pathology, Miraca Life Sciences and Associate Clinical Professor of Pathology, Harvard Medical School). (Reprinted with permission from [67], Fig. 25.2, p. 393)

may occur both at initial presentation of UC and as a result of therapy [89, 91, 104]. Rarely, children with UC present with focal active colitis at initial presentation [91]. In addition, patients with UC can have histological evidence of upper gastrointestinal inflammation similar to that in CD [105–107]. Given the overlap of histopathology findings in UC and CD, it may be difficult to distinguish between these two diagnoses if granulomas are not present.

If a clinician cannot reliably distinguish between CD and UC based on the available clinical, radiographic, and endoscopic data, an interim diagnosis of IBD-unclassified (indefinite colitis) may be given until the patient can be more clearly classified in the future. The ESPGHAN Porto group developed detailed criteria to better define the IBD-unclassified subtype [88]. The prevalence of IBD-unclassified in adults and children with IBD is estimated to be 10–20% [65, 108]. Approximately one third of these patients will later be classified as UC or CD [109].

Extraintestinal Manifestations

Approximately 25–30% of the children and adolescents diagnosed with IBD develop extraintestinal symptoms [110–113]. Extraintestinal manifestations of IBD may occur before, during, or after the development of gastrointestinal symptoms and may appear after surgical removal of diseased bowel [110, 114–117]. The clinical activity of the extraintestinal manifestations may or may not correlate with the activity of intestinal inflammation.

Joint manifestations (arthropathy) occur in 5–20% of the children with UC [4, 112, 114]. These can be classified into two main clinical forms: a peripheral arthropathy and an axial arthropathy (e.g., ankylosing spondylitis) [110, 114]. Patients with IBD develop peripheral arthropathies in approximately 5–20% of the cases [110, 111, 114, 118]. The peripheral arthropathy generally is asymmetrical, nondeforming and migratory, affecting mostly the large joints of the lower extremities including the knees, ankles, and hips. Less commonly the upper limb joints or hands are affected [110, 114, 118]. Small joints of the hands and feet generally are spared [114].

Exacerbations of peripheral joint disease seem to parallelly increase the activity of bowel disease in UC or CD. The pauciarticular arthropathy is more likely to be correlated with exacerbations of bowel disease [117].

Axial arthropathies associated with HLA B27 occur in 1–4% of patients [110, 111, 114, 118]. Ankylosing spondylitis associated with IBD runs a course independent of the activity of bowel disease, and may progress to permanent deformity [110, 114, 118]. In addition to the two main forms of joint manifestations, individuals with UC can develop isolated arthritis involving large joints including the sacroiliac joints, hips, and shoulders [118].

Pyoderma gangrenosum (PG) and erythema nodosum (EN) are the two main skin manifestations associated with UC and CD. PG occurs in <1–5% of the patients with UC [111, 115] and often is associated with active disease and extensive colonic involvement [115, 119]. The classic PG lesion often begins as a discrete pustule with surrounding erythema, then extends peripherally to develop into an ulceration with a well-defined border and a deep erythematous to violaceous color [120]. The lesions of PG tend to be multiple and localize below the knees, and can develop at sites of trauma and previous surgical sites, including scars and ileostomy stomas [119–121]. Approximately 40% of the patients with UC and PG also develop joint symptoms [69]. EN occurs more frequently with CD (27%) in comparison to UC (4%) [111] and usually coincides with increased bowel disease activity [69, 111, 118]. EN lesions appear as tender, warm, red nodules, or raised plaques and usually localize to the extensor surfaces of the lower extremities [122]. Both PG and EN can precede the development of bowel symptoms and PG can occur after bowel resection [69]. Other skin manifestations include Sweet's syndrome (acute febrile neutrophilic dermatosis) and oral lesions include aphthous lesions and pyostomatitis (pyoderma) vegetans [123].

Ophthalmologic abnormalities are described in approximately 1–3% of the children with IBD [110]. Uveitis and episcleritis are the more common ocular disorders reported [110, 124]. Uveitis associated with IBD in children may be asymptomatic, and thus, the incidence of associated eye findings may be underreported in the literature [125].

Ocular inflammation appears to develop more commonly in patients with other extraintestinal manifestations [125], including arthritis and may be associated with genes in the human leukocyte antigen (HLA) region [126]. In addition, corticosteroid use increases the risk of increased intraocular pressure and the development of posterior subcapsular cataracts [127, 128]. Given the potential eye complications, children with IBD should be monitored carefully at regular intervals.

Hepatic abnormalities in children with UC have been well described. While these are typically identified after the UC diagnosis, they may also precede the gastrointestinal symptoms [116, 129]. Transient elevations of alanine aminotransferase (ALT) occur in 12% of the children with UC and appear to be related to medications or disease activity [129]. Persistent ALT elevations suggest the presence of primary sclerosing cholangitis (PSC) or autoimmune chronic hepatitis [129]. Among children with UC, approximately 3% develop sclerosing cholangitis and <1% develop chronic hepatitis [129, 130].

The diagnosis of PSC may be established through a combination of cholangiography and liver biopsy [131]. There is a paucity of the literature addressing the long-term outcome of children with PSC specifically associated with UC [129]. In children with PSC (with or without IBD), later age at presentation, splenomegaly, and prolonged prothrombin time at presentation were associated with poor outcome, defined as death or listing for transplantation [116]. Patients with UC and PSC are also at increased risk for developing colon cancer. Fatty changes of the liver observed on liver biopsies of patients with UC or CD may be secondary to malnutrition, protein losses, anemia, and corticosteroid use [132].

The IBD population has a threefold overall increased risk for venous thromboembolism (VTE) compared with individuals without IBD [133–135]. VTE occurs in 1–2% of the children and adolescents hospitalized for active IBD [136, 137]. Although the incidence of VTE appears less than the rate noted in the adult population, these events can result in significant morbidity for younger patients [135]. Thrombotic events range from clots associated with venous catheters to more significant events such as deep vein thrombosis, pulmonary embolism, and cerebral vascular accidents. These events can lead to ongoing associated complications and long-term sequelae, including permanent neurologic deficits, persistent or recurrent thrombosis, embolization, and post-thrombotic syndrome [136]. Factors that can further increase the risk for thromboembolism include an indwelling central venous catheter, severe disease activity, older age, parenteral nutrition, known thrombophilia, first-degree family history of VTE, persistence of anti-phospholipid antibody for greater than 12 weeks, oral contraceptives, smoking, obesity, and medications associated with increased risk of thrombosis such as thalidomide [136, 137].

At a minimum, all hospitalized children and adolescents with IBD should maintain adequate hydration and receive mechanical thrombotic prophylaxis, such as encouraged ambulation, compression stockings, or pneumatic boots [137, 138]. The role of primary pharmacologic prophylaxis for thromboembolism remains controversial for children and adolescents with IBD. At our institution, we have implemented a risk stratification strategy to identify hospitalized IBD patients at higher risk for thrombosis, who warrant for primary prophylaxis pharmacologic anticoagulation therapy [136, 137]. For IBD patients who develop thromboembolism, anticoagulation with low-molecular-weight heparin appears feasible without major sequelae of increased bleeding or complications [136].

Rarely, other hematologic abnormalities associated with UC occur, including immune thrombocytopenic purpura [139] and autoimmune hemolytic anemia [140]. Osteopenia—low bone mineral density occurs in children with UC, but less often than in children with CD [141, 142]. Corticosteroid use increases the risk of osteopenia in children with IBD [141, 142]. Other extraintestinal manifestations include nephrolithiasis [111, 143], pancreatitis (related or unrelated to medications) [144, 145], and pulmonary and cardiac involvement [110].

Complications

Complications of UC include massive hemorrhage, toxic megacolon, perforation of the bowel, strictures, and colon cancer. Massive hemorrhage can occur with severe UC and is managed with blood transfusions and treatment of the underlying UC, and urgent colectomy may be required. One consensus group suggested that an individual with UC who requires more than 6–8 units of blood in the first 48 h and is still actively bleeding should undergo a colectomy [146]. Colonic perforation is the most dangerous complication of UC, can occur in the setting of severe UC with or without toxic colonic dilatation [147–149], and requires urgent colectomy.

Toxic megacolon is a potentially life-threatening complication of UC and is characterized by total or segmental non-obstructive colonic dilatation of at least 6 cm in adults associated with systemic toxicity [148, 150, 151]. Previous reports suggest a lifetime risk of toxic megacolon complicating IBD of 1–5%, but this has decreased more recently, probably secondary to earlier recognition and improved management of severe colitis [148, 152]. Most likely, the pathogenesis of toxic megacolon is multifactorial [148]. In contrast to typical UC, in which the inflammatory changes are limited to the mucosa, in toxic megacolon, the severe inflammation extends into the deeper layers of the colonic wall [147]. It is thought that the spread of the inflammatory process to the

smooth-muscle layer may lead to the paralysis of the colonic smooth muscle and subsequent dilatation of the colon [148].

Several triggering factors have been reported to precede the development of toxic megacolon [147, 148]. Medications that can impair colonic motility should be avoided and have been implicated as precipitating factors, including narcotic agents for pain or antidiarrheal effects, anticholinergic agents, drugs that decrease motility, or antidepressants with significant anticholinergic effects [147, 153, 154]. A barium enema or colonoscopy may cause distention that can further impair the colonic wall blood supply and may increase the mucosal uptake of bacterial products [148]. Barium enema examinations have been reported in proximity to the development of toxic megacolon [154, 155]. The early discontinuation or rapid tapering of steroids or 5-aminosalicylic acid agents may contribute to the development of toxic megacolon [147, 148]. Electrolyte abnormalities, such as hypokalemia, have been observed in the setting of toxic megacolon, though it is not clear whether this finding is a causative factor or secondary to the illness itself [147]. Along with colonic dilatation, patients with toxic megacolon present with systemic findings including fever, tachycardia, leukocytosis, and anemia [150]. A decrease in the number of stools may herald the onset of toxic megacolon. With progressive disease, these individuals can develop dehydration, mental status changes, electrolyte disturbances, hypotension, and increasing abdominal distension and tenderness, with or without signs of peritonitis [148, 150].

Abdominal X-ray reveals colonic dilatation, most frequently involving the transverse colon, sometimes accompanied by inflammatory changes including absent or markedly edematous haustral pattern [156] (see Fig. 30.4).

Fig. 30.4 Toxic megacolon in a teenager with fulminant ulcerative colitis. There is a massively dilated loop of transverse colon. This patient developed the megacolon despite corticosteroid therapy, and subsequently underwent emergent surgery. (Courtesy of Anne Wolf, M.D. and Matthew Egberg, M.D., Division of Gastroenterology, Hepatology and Nutrition, Boston Children's Hospital)

Because the transverse colon is the most anterior portion of the colon, air will tend to accumulate in this segment of the colon when the patient is in the supine position; however, with repositioning of the patient, the colonic air will redistribute, filling other segments of the bowel [157].

The management of toxic megacolon is detailed in multiple reviews elsewhere [147, 148]. If toxic megacolon is present, surgical consultation is essential and the patient will most likely require a colectomy. Early surgical intervention is indicated in the setting of failed medical therapy with progressive colonic dilatation, worsening systemic toxicity, perforation, or uncontrolled hemorrhage [148].

Both benign and malignant colonic strictures can develop in long-standing UC [158–160]. Benign strictures present most commonly in the rectum and the sigmoid, are due to smooth muscle hypertrophy, and are thought to be potentially reversible [158]. Colonic strictures should be evaluated for possible malignancy, but the majority of strictures in UC are benign [158–160]. There is an increased risk of dysplasia and colon cancer in patients with long-standing UC, which is addressed later in this chapter (see Sect. “Prognosis/Follow-Up”).

Treatment Options

The treatment goals for children with UC are the control of active disease and induction of remission, the long-term maintenance of remission, and provision of education and psychosocial support for the patient and family. The initial treatment of UC is medical, with surgery reserved for patients with severe disease, patients with medically refractory disease, or patients who develop adverse effects of medical therapy.

Knowledge of the extent and severity of disease involvement will enable the clinician to choose the appropriate therapy for each individual patient. Distal UC (left-sided UC or proctitis) is characterized by involvement limited to the area distal to the splenic flexure, and potentially may be treated with topical agents (e.g., aminosalicylate or hydrocortisone enemas or suppositories). Extensive UC is defined by involvement extending proximal to the splenic flexure and requires systemic therapies with or without additional topical agents. Severity of disease is usually simple to ascertain, and can be determined by assessing stool frequency and consistency, abdominal pain, nocturnal diarrhea, hematocrit, albumin level, and feeding intolerance. Separate published disease severity criteria for adults and children have been developed by Truelove and Witts, and Werlin and Grand, respectively [72, 161]. Typically, severe colitis requires hospitalization and administration of either intravenous corticosteroids or other immunosuppressive agents (e.g., cyclosporine, tacrolimus, infliximab). Many patients with severe colitis will require colectomy.

Turner and colleagues developed the pediatric ulcerative colitis activity index (PUCAI), a noninvasive, clinically based, validated instrument to assess disease activity in pediatric patients with UC [162]. The PUCAI is a score comprised of six parameters, including the assessment of abdominal pain, rectal bleeding, stool consistency, number of stools per 24 h, nocturnal stools, and activity level. Each item is assigned a value contributing to a combined, total PUCAI score ranging from 0 to 85. Categories of UC disease activity are defined by the following total PUCAI scores: 0–9 (no activity), 10–34 (mild activity), 35–64 (moderate activity), and 65–85 (severe activity). The PUCAI correlated well with the physician’s global assessment, Mayo score, and macroscopic findings at colonoscopy. In addition to excellent interobserver and test–retest reliability, the PUCAI performed well on longitudinal assessment with excellent responsiveness at repeated visits, thus providing a tool to serially assess patients’ clinical status [162]. Studies demonstrate the application and feasibility of the PUCAI in hospitalized pediatric patients with severe colitis and in the outpatient setting [163, 164]. Although the PUCAI provides a method to track UC disease activity, it does not replace the need for the appropriate serial thorough clinical evaluation of children and adolescents with active UC. Presently, there is no pediatric-specific UC endoscopic index available.

Induction Therapy

Mild to Moderate Colitis

In the child with mild to moderate UC, with no or only minimal systemic signs (such as elevated ESR or mild anemia), aminosalicylates (e.g., sulfasalazine, olsalazine, mesalamine, balsalazide) are usually the first line of therapy (see Tables 30.5 and 30.6).

Mesalamine is a 5-aminosalicylic acid compound used in the induction and maintenance treatment of UC. It was discovered as the active anti-inflammatory moiety of sulfasalazine, which has been used to treat UC since the 1940s [166]. More than 88% of all the UC patients receive treatment with aminosalicylate (ASA) agents; however, fewer than 50% of the children with UC can maintain long-term steroid free remission on ASA monotherapy [167]. Sulfasalazine contains mesalamine bound to sulfapyridine via an azo bond, which is released by bacterial azo-reductase in the small bowel and colon. Sulfapyridine is inactive, but is absorbed in the colon and is mostly responsible for hypersensitivity reaction and adverse effects associated with sulfasalazine [168].

ASA agents have multiple immunologic effects. Potential mechanisms of action include the inhibition of the synthesis of leukotriene B₄, a potent chemotactic and chemokinetic agent, and the inhibition of the activation of nuclear transcription factor kappa B (NF-kappaB), an important

Table 30.5 Aminosalicylate agents ^a. (Reprinted with permission from [67], Table 25.7, p. 398)

Oral preparations	Dosage form	Mechanism of release	Site of delivery
<i>Azo-bond</i>			
Sulfasalazine (Azulfidine)	500 mg tablet	Bacterial cleavage of azo bond	Colon
Olsalazine (Dipentum)	250 mg capsule	Bacterial cleavage of azo bond	Colon
Balsalazide (Colazal/Colazide)	750 mg capsule	Bacterial cleavage of azo bond	Colon
<i>Delayed release</i>			
Mesalamine (Delzicol/Asacol HD)	400 mg/800 mg tablets	pH-dependent breakdown (pH > 7)	Distal ileum to colon
Mesalamine (Salofalk/Mesasal/Claversal)	250 mg/500 mg tablets	pH-dependent breakdown (pH > 6)	Ileum to colon
<i>Extended, delayed release</i>			
Mesalamine			
(Lialda)	1.2 g tablet	pH-dependent breakdown (pH > 7)	
(Apriso)	375 mg capsule	pH-dependent breakdown (pH > 6)	
<i>Sustained release</i>			
Mesalamine (Pentasa)	250 mg/500 mg/1000 mg tablets	Ethylcellulose-controlled time-release	Small intestine to colon
<i>Rectal preparations</i>			
Mesalamine suppository (Canasa-500 mg)	400 mg/500 mg/1000 mg		Rectum
Mesalamine enema (Rowasa-4 g/60 ml)	1 g/4 g; 60-ml/100-ml suspension		Rectum to splenic flexure

^a Availability of different preparations and dosage forms varies among different markets/countries

mediator of the immune response in inflammatory processes [169–171].

Controlled studies suggest that currently available ASAs are superior to placebo for induction of remission and relapse prevention [172–175]. However, there do not appear to be any differences in efficacy between the older agent, sulfasalazine, and newer ASA drugs [175, 176].

Potential advantages of the non-sulfa ASA agents include better tolerance compared to sulfasalazine [176, 177] and the availability of a non-sulfa ASA agent for sulfa-sensitive individuals. In adult-onset UC, balsalazide at higher doses (6.75 g/day) may provide a faster improvement in active, mild-to-moderate UC than lower doses of balsalazide (2.25 g/day) or mesalamine (2.4 g/day) [178, 179].

Long-acting formulations of mesalamine are available, however there is no FDA approved pediatric dose. They are available as a delayed release multi-matrix formulation (Lialda) and a pH-controlled granule that releases mesalamine at pH > 6 (as in the colon, Apriso).

Common side effects of sulfasalazine include headache, nausea, and fatigue, which improve with reduction of the dose [180] (see Table 30.6). The sulfa moiety can cause hypersensitivity reactions resulting in rash, fever, hepatitis, hemolytic anemia, bone marrow suppression, and pneumonitis [180, 181]. Other side effects include neutropenia, oligospermia, pancreatitis, and the exacerbation of colitis [72, 182]. Folic acid supplementation is recommended given that

sulfasalazine impairs the absorption of folic acid and may lead to anemia [180]. To decrease side effects, sulfasalazine is started at a dose of 10–20 mg/kg/day and gradually increased to the full dose (50–75 mg/kg/day) over 5–7 days mesalamine and the other non-sulfa ASA agents have also been associated with adverse reactions, including pancreatitis, hepatitis, nephritis, exacerbation of colitis, and pneumonitis [180, 183, 184].

Moderate Colitis

Children with moderate disease are usually managed with oral corticosteroids (usually 1 mg/kg/day, up to 60 mg/day of prednisone) as an outpatient. Corticosteroids are effective for short-term treatment, but up to 45% of the pediatric patients develop corticosteroid dependence in subsequent years putting them at risk for steroid-related side effects [185].

Potential short-term complications of steroid therapy in patients with UC include increased appetite, weight gain, fluid retention, mood swings, hyperglycemia, hypertension, insomnia, acne, and facial swelling. Complications of long-term steroid therapy (usually of greater than 3 months) include growth retardation, osteopenia with compression fractures, aseptic necrosis of the hip, and cataracts [180, 186]. Given these reasons and the suppression of the hypothalamic–pituitary–adrenal axis, corticosteroids should be tapered shortly after remission is achieved. A standard taper utilized by the authors is reduction by 5 mg/week of pred-

Table 30.6 Medical therapies for UC. (Reprinted with permission from [67], Table 25.8, p. 399)

Medication	Dosage	Major side effects
Sulfasalazine	50–75 mg/kg/day PO divided bid or tid (Maximum 6 g/day) Adult dose: 3–4 g/day divided bid or tid	Nausea, headaches, diarrhea, photosensitivity, hypersensitivity reaction, pancreatitis, azoospermia, hemolytic anemia, neutropenia
Mesalamine		
Oral formulation	50–75 mg/kg/day PO divided qid, tid, or bid (may vary according to preparation) (Maximum 6 g/day) Adult dose: 3–4 g/day divided qid, tid, or bid	Nausea, headaches, diarrhea, pancreatitis, nephritis, pericarditis, pleuritis
Enema formulation	2–4 g PR q 12–24 h	
Suppository formulation	500 mg PR q 12–24 h	
Corticosteroids		
IV or oral formulation	1–2 mg/kg/day of prednisone or equivalent, IV or PO, divided q 12–24 h (maximum 60 mg/day)	Numerous, including Cushing's syndrome, growth suppression, immunosuppression, hypertension, hyperglycemia, increased appetite, osteoporosis, aseptic necrosis (hip), cataracts
Enema formulation	50–100 mg of hydrocortisone PR qhs	
Suppository formulation	25 mg of hydrocortisone acetate PR qhs	
Azathioprine ^a	1.5–2.5 mg/kg/day PO qd	Nausea, emesis, immunosuppression, hepatotoxicity, pancreatitis, myelosuppression, lymphoma
6-Mercaptopurine ^a	1.0–2.0 mg/kg/day PO qd	Nausea, emesis, immunosuppression, hepatotoxicity, pancreatitis, myelosuppression, lymphoma
Cyclosporine	Induction regimen for fulminant colitis: initial dose: 4 mg/kg/day IV continuous or bid; maintenance oral dose varies according to oral preparation	Nephrotoxicity, hypertension, headache, hirsutism, nausea, emesis, diarrhea, tremor, hypomagnesemia, hyperkalemia, hepatotoxicity, seizures, gingival hyperplasia, lymphoproliferative disorder
Tacrolimus	0.2 mg/kg/day PO divided bid	Nephrotoxicity, hypertension, headache, immunosuppression, nausea, emesis, tremor, hypomagnesemia, elevated liver enzymes, hyperglycemia, seizures, lymphoproliferative disorder
Infliximab	Loading dose: 5 mg/kg/dose IV at 0, 2, 6 weeks; maintenance dose: 5 mg/kg/dose IV q 4–8 weeks (can go up to 10 mg/kg every 4 weeks)	Infusion reactions, delayed hypersensitivity reactions, immunosuppression (opportunistic infections), lupus-like syndrome, hepatotoxicity, blood dyscrasias, psoriasis, neurotoxicity (demyelination), vasculitis, possible lymphoma
Adalimumab	Adult dosing—Loading dose: 160 mg, then 80 mg; maintenance dose: 40 mg SQ every other week (can go up to 40 mg weekly)	Injection site pain/ reactions, immunosuppression (opportunistic infections), psoriasis, blood dyscrasias, possible lymphoma

^a TPMT genotype determines metabolism and blood levels of metabolites; may help to determine risk of myelosuppression and optimal dosage of azathioprine or 6-mercaptopurine
IV intravenous, PO oral, TPMT thiopurine S-methyltransferase

nisone down to 20 mg/day, and then a more gradual taper on alternate days, aiming for 10 mg every other day with further taper and cessation if remission is maintained [186]. The high frequency of side effects with traditional systemic steroids such as prednisone has led to the development of steroid preparations with high first-pass metabolism and few systemic effects.

Severe Colitis

Children with severe disease typically defined by a PUCAI greater than 65 (e.g., more than five bowel movements/day, liquid bloody stools, or severe pain with defecation, anemia, and hypoalbuminemia) require intravenous corticosteroids (methylprednisolone at 40–60 mg/day, divided into two doses/day, approximately 1–2 mg/kg/day) and hospitalization for further evaluation, observation, and management [187, 188]. Rectal corticosteroids or 5-ASA agents may be used as an adjunctive therapy with parenteral corticosteroids

for patients with severe tenesmus [180]. Intravenous fluid for rehydration and correction of electrolyte imbalances should be provided. Blood transfusions and albumin infusions may be required. Although traditionally patients are restricted from taking food orally, there is no data to support holding the oral diet in UC as there is in CD; however, if bowel rest is indicated, the child may require central venous access for parenteral nutrition support [189, 190].

In addition to high-dose steroids, empiric antibiotics are sometimes used in severe colitis, though the efficacy of antibiotics has not been proven [191–194]. Assessment for response to intensive medical therapy includes resolution of fever, tachycardia, abdominal tenderness, and macroscopic blood per rectum. Stools should be decreasing in frequency, but may still be unformed. Following the PUCAI will help guide therapy. Once the child shows significant improvement, diet is advanced to a low-residue diet, intravenous methylprednisolone is switched to oral prednisone, and

similar parameters for steroid wean are followed as outlined above. The optimal duration of intravenous corticosteroid therapy is unclear, but most children will respond within 7–10 days.

Approximately 50% of the patients treated with intravenous corticosteroids will not respond. Turner and colleagues have published an excellent consensus statement on the use of rescue agents in the management of severe UC. In summary, the PUCAI can be utilized to track disease activity. If the child has not responded to steroid therapy (as assessed by a PUCAI drop of 20 points or more after 5–7 days), the options of surgery or more intensive immunosuppression (intravenous cyclosporine, infliximab, or oral tacrolimus) should be considered and discussed with the family. Intensive immunosuppression should not be started if surgery is believed imminent, such as in a septic patient, a patient with toxic megacolon, or a patient with a suspected perforation. Flexible sigmoidoscopy is indicated prior to the institution of calcineurin inhibitors or biologics to exclude cytomegalovirus [195].

The medical agents utilized to treat steroid refractory colitis in the hospitalized patient are calcineurin inhibitors and biologics. In the past decade, infliximab has been the agent most commonly utilized, perhaps due to its ease of administration and more favorable side-effect profile. Approximately 70% of the children and adults treated with infliximab will respond [164, 196]. The role of monitoring infliximab levels during treatment of severe colitis is still a topic under study. However, patients with severe colitis may have an increased loss of infliximab in the stool, and may require higher more frequent dosing than the 5 mg/kg utilized in the clinical trials (which included less sick patients) [197]. Adalimumab also has been utilized in severe colitis [198]. Calcineurin inhibitors such as cyclosporine and tacrolimus are reasonable alternatives to biologics, and have been utilized for over 20 years. However, because of long-term renal toxicity, it is generally recommended that these agents be utilized as short-term induction agents for a few months, and that patients should transition to maintenance therapy with thiopurines or anti-tumor necrosis factor- α (anti-TNF) agents [199]. Calcineurin inhibitors may also be utilized as a steroid sparing “bridge” to surgery [200]. The timing of colectomy in a child who is not responding to intravenous corticosteroids or other immunosuppression can be difficult. It should be emphasized that even if a child responds to immunosuppression, such as cyclosporine, there is a high likelihood that he/she will require a colectomy within a year [201, 202]. If immunosuppression with cyclosporine is used and the child does not respond to these medications within 10–14 days, surgery should be strongly recommended.

Close monitoring of the patients with severe colitis for the development of fulminant colitis and associated complications including hemorrhage, toxic megacolon, and perforation is essential using serial abdominal exams, complimented by

serial abdominal films or other imaging as necessary. Physical examination should assess for evidence of worsening abdominal tenderness, distention, and hypoactive bowel sounds; these may herald the development of toxic megacolon. The appearance of persistent abdominal pain and distention, diffuse abdominal tenderness and rebound, fever and tachycardia are worrisome signs of an acute abdomen and may signal need for emergent surgical intervention. Opiates and loperimide should be avoided given the increased risk of developing toxic megacolon [153]. Steroid therapy may mask the typical symptoms and signs of perforation, but this may be detected by serial upright abdominal films (see Sect. “Complications”).

Left-Sided Colitis/Proctitis

Topical ASA or topical corticosteroids are effective in the treatment of proctitis, proctosigmoiditis, or left-sided UC [203–205] (see Tables 30.5 and 30.6). To be effective, topical therapy must reach the most proximal extent of the disease activity. Mesalamine enemas or suppositories are effective as first-line/maintenance therapy for mild or moderately active left-sided UC or proctitis, respectively [180]. Rectal mesalamine may be superior to oral mesalamine in the treatment of active ulcerative proctitis [206]. Mesalamine enemas may be superior to rectal corticosteroids [207] and are also effective in treating distal colitis that is unresponsive to oral ASAs or corticosteroids [208, 209]. Combination therapy with oral and topical mesalamine is more effective than one agent alone in the treatment of mild to moderate distal colitis [210]. Mesalamine suppositories spread to the upper rectum, and enemas and foams can reach the splenic flexure or into the distal transverse colon [208, 209].

Corticosteroid suppositories or enemas also can be used as first-line induction therapy in patients with mild or moderately active ulcerative proctitis or left-sided UC [180]. Rectal administration of hydrocortisone or prednisolone permits more direct delivery of steroids to distal UC sites; however, as with oral steroid therapy, prolonged treatment with topical steroids may induce systemic steroid side effects, including adrenal suppression [205, 209]. Topical agents such as budesonide enemas may induce remission in distal colitis with fewer systemic steroid side effects [211, 212]. Some evidence suggests that ASA enemas may be superior to hydrocortisone enemas [204, 207, 209].

Maintenance Therapy

5-Aminosalicylic Acid Agents

Medication for the prevention of relapse after induction of remission often is started before the induction therapy is discontinued. The clinician usually aims to transition a patient from corticosteroids onto sulfasalazine or another ASA agent. Multiple studies of adults with UC demonstrate the

effectiveness of sulfasalazine and other ASA agents in preventing relapse [176]. Mesalamine is well-tolerated in the long-term treatment of children with IBD, with the principal adverse event being exacerbation of diarrhea [213]. Sulfasalazine and newer ASAs are all effective in maintaining remission in UC [177]. Balsalazide, at a higher dose (6 g/day), also may be more effective in preventing relapses of UC in adults, compared to lower-dose balsalazide (3 g/day) and mesalamine (1.5 g/day) [214]. Topical mesalamine can effectively prevent relapse of active distal UC [215], but because of the rectal route of administration, patients may prefer oral mesalamine for maintenance therapy. The combination of oral and topical ASA therapy may be more effective in preventing relapse than oral ASA therapy alone, especially for distal disease [216]. Children with UC require years of maintenance therapy. The exact duration that a UC patient in remission should remain on maintenance therapy is unclear, and there are no formal guidelines on when or if maintenance therapy should be discontinued. The risk of discontinuing maintenance medication is the possibility of relapse. In addition, maintenance with ASA or other agents may reduce the risk of colorectal neoplasia [217–219].

6-Mercaptopurine and Azathioprine

The immunomodulatory drugs, azathioprine (AZA) and its metabolite 6-mercaptopurine (6MP), can reduce disease activity and allow the withdrawal of steroid therapy in children with steroid-dependent UC [220, 221].

AZA is nonenzymatically metabolized to 6MP, and the two drugs have identical mechanisms of action. AZA is 55% 6MP by molecular weight and therefore dosed higher mg per kg. As AZA is the prodrug of 6MP, the dose of AZA is approximately twice that of 6MP [222]. The mechanism of action of 6MP and AZA is to interrupt RNA and DNA synthesis, thereby downregulating cytokines, T cell activity, and delayed hypersensitivity reactions and by inducing T cell apoptosis by blocking the activation of the gene *rac-1* [223].

The use of thiopurines in UC as steroid sparing maintenance agents is long established. Given their steroid-sparing effects [220, 221] and reasonable tolerance by children with IBD [224], AZA and 6MP offer an alternative maintenance treatment of IBD in children. A prospective multicenter registry study in pediatric UC patients found 50% of children with UC starting thiopurine therapy were disease free 1 year later, without the need for rescue therapy [225].

The metabolism of AZA/6MP is well established. AZA is converted to 6MP, and then to 6-thiouric acid (6-TUA), 6-methyl mercaptopurine (6-MMP), and 6-thioguanine nucleotide (6-TGN) [226, 227]. Evaluation for thiopurine methyltransferase genetic polymorphism should be obtained prior to the institution of 6MP or AZA therapy as it can identify those children at higher risk for drug toxicity [228] and the starting dose of thiopurine can be adjusted accordingly. The

6-TGN moiety is thought to be the active component responsible for the inhibition of lymphocyte proliferation by DNA breakage. There is data demonstrating increased 6-TGN level correlating with increased response to therapy in IBD, with increased 6-TGN levels associated with clinical remission [229]. Dosage can be adjusted using metabolite levels. as the target 6-TGN level is found to be 235 pmol/8 × 10⁸ red blood cells and 6-MMP level <5700 pmol/8 × 10⁸ red blood cells [230, 231]. The 6-MMP fraction is thought to be responsible for the hepatotoxic effects of AZA and 6MP [222, 229, 231, 232]. A 6-MMP level >5700 pmol/8 × 10⁸ red blood cells is found to lead to a threefold increase risk of hepatotoxicity [231].

Allopurinol is a xanthine oxidase inhibitor used to treat gout as its primary indication. In patients that shift the breakdown of 6MP and AZA preferentially towards an increased 6-MMP fraction, the addition of allopurinol allows a lower dose of AZA/6MP with increased 6-TGN levels and lower comparative 6-MMP fraction. There is limited published data for dosage in pediatric IBD patients [233].

An alternate approach to maximize 6MP/AZA effect in patients with elevated transaminases due to preferential metabolizers of thiopurines is split dose administration. The total daily dose is the same, but divided into two equivalent doses, and this is found to decrease transaminases as well as flu-like symptoms which can be seen with 6MP/AZA use. This has been demonstrated in a retrospective adult study, and has been used in the pediatric UC population [234].

Given the high relapse rate with withdrawal of 6MP in adults with UC [235], the majority of children requiring AZA or 6MP to suppress disease activity most likely will require long-term maintenance therapy with these agents. There are no good data in UC addressing the question of when (or if) immunomodulators should be discontinued after a patient has entered remission. Most patients are continued on the medication for several years if they respond to 6MP or AZA. There is an approximate fourfold increase risk of lymphoma in IBD patients treated with AZA or 6MP. It is unclear if this is due to the medications themselves or due to the severity of the underlying disease [236]. In addition, there is a slightly increased risk of Epstein–Barr virus associated lymphoma in a large cohort of patients treated with long-term 6MP or AZA [237].

Methotrexate

Methotrexate (MTX) is a dihydrofolate reductase inhibitor used for induction and maintenance in patients with CD [238]. At low dose, MTX's mechanism of action is not clearly defined. At high doses, it works through antiproliferative and cytotoxic effects by inhibiting dihydrofolate reductase, leading to defective DNA synthesis and cell death [239]. At low doses, it works primarily as an immunomodulator [240]. The mechanism of action as an immunomodulator is

not clearly understood but involves adenosine inhibition, induction of apoptosis, and decreased IL and eicosanoids to decrease inflammatory mediators [241–243].

There is some evidence from open label trials in adults to suggest the use of MTX monotherapy as maintenance in UC, but there is very little supportive data in the pediatric population. A multicenter randomized controlled trial of MTX use in adults with chronic active UC found weekly oral MTX at 12.5 mg to be no better than placebo in induction or maintenance of remission in patients with chronic active UC [244]. A small retrospective pediatric paper reported response or remission in 72, 63, and 50% of patients at 3, 6, and 12 months, respectively [245]. Larger controlled prospective trials would be needed to show clear benefit for MTX monotherapy in pediatric UC patients [246].

Biologic Agents

Infliximab

Infliximab is a monoclonal antibody to tumor necrosis factor-alpha which is a cofactor in the production of inflammatory cytokines, gamma interferon, and IL-2 [247, 248]. The efficacy of infliximab in pediatric patients was demonstrated in “the REACH trial” which was a prospective trial demonstrating 73% response at 8 weeks in pediatric UC patients with moderate to severely active UC using 5 mg/kg at 0, 2, and 6 weeks, followed by either every 8 week or every 12 week dosing interval. The response at 54 weeks in the every 8-week group was double that of the every 12-week maintenance group [249, 250].

Combination therapy with infliximab plus AZA has been shown to be more effective in an adult study [251] with better response of steroid free remission at 16 weeks in the combination therapy group. There are no similar studies in the pediatric patient population [251]. The potential risks of combination therapy including the possible development of lymphoma as previously discussed and the above data make the risk-versus-benefit evaluation of combination therapy critical.

Adalimumab

Adalimumab is a fully human monoclonal antibody that binds to tumor necrosis factor-alpha. It was approved for adults with UC in 2012. It is currently not approved for use in pediatric UC patients. The adult literature comparing adalimumab to placebo prospectively showed a superior response of clinical remission in treatment group at both week 8 (17 vs. 9%) and week 52 (17 vs. 9%), respectively. Anti-TNF naïve patients had double the response to therapy compared to placebo as well (21 vs. 9% at week 8 and 22% vs. 10% at week 52, respectively) [252].

Vedolizumab

Vedolizumab is a humanized monoclonal antibody that specifically recognizes alpha-4 beta-7 integrin, a cell surface glycoprotein variably expressed on circulating B and T lymphocytes. This interacts with mucosal addressin-cell adhesion molecule-1 (MAdCAM-1) [253] on intestinal vasculature [254, 255]. Vedolizumab has been found more effective than placebo for induction and maintenance therapy for UC. In randomized placebo-controlled adult studies, induction response was 47% compared with 25.5% in placebo at 6 weeks, and maintenance response was achieved in 41.8% in treatment group at every 8 weeks, 44.8% at every 4 weeks at 300 mg compared with 15.9% in placebo group. There was a similar frequency of adverse events in both treatment groups and placebo groups. This effect appears to be more effective in patients who have previously lost response to anti-TNF therapy [256].

Other Therapies

Antibiotics

Despite the potential role of infectious agents in the pathogenesis of UC [20], the use of antibiotic therapy in the treatment of UC remains controversial. There is a lack of consistent evidence in the effectiveness of antibiotics in the induction and maintenance of remission in UC [192, 257–260]. In one study, oral tobramycin therapy improved short-term clinical and histological outcomes, [257] but there was no advantage in the prevention of relapse compared to placebo [258]. In two studies of active UC, the addition of 10–14 days of oral or intravenous ciprofloxacin to corticosteroid therapy did not improve rates of remission [194, 261]. In another placebo-controlled study, 6 months of treatment with ciprofloxacin, in addition to standard therapy with prednisone and mesalamine, resulted in a greater clinical response compared to placebo; however, this advantage was not sustained after the cessation of ciprofloxacin [262]. Empiric broad-spectrum antibiotics often are administered in the setting of severe active UC [72, 191], especially if there is concern for potential fulminant colitis or toxic megacolon [148].

Tofacitinib

Tofacitinib is an oral inhibitor of Janus kinase 1, 2, and 3, which is expected to block signaling involving gamma chain-containing cytokines including IL 2, 4, 7, 9, 15, and 21. These cytokines are integral to lymphocyte activation function and proliferation. Blocking a common signaling molecule is thought to suppress both T and B cells, while maintaining regulatory T cell function [263–265]. Tofacitinib

was found to be more effective than placebo in a prospective phase-2 trial of 194 adults with clinical response found in 78% in the higher dose treatment group compared to 42% in the placebo group. Clinical remission was seen in 41% in the higher dose treatment group versus 10% in placebo group [266].

Mycophenolate

Mycophenolate mofetil is an immunosuppressant used in transplant therapy and is a reversible inhibitor of purine biosynthesis, necessary for the growth of T cells and B cells [267]. There have been several small studies in adult literature showing some efficacy in treating UC, particularly when other medications such as infliximab and AZA have failed [268]. A retrospective review of adult UC patients treated with mycophenolate mofetil demonstrated 81% in remission at 8 weeks and 58% in sustained response at 6 months. Side effects were experienced in 19% of the patients, the majority of which were managed with dose reduction. There may be utility in patients who fail other treatment regimens, but more data is needed [269].

Probiotics

There are data and controversy on use of probiotics in UC. VSL#3 is a product comprised of four strains of lactobacilli, three strains of bifidobacteria and one strain of *Streptococcus*, and has been shown to be effective in preventing pouchitis in UC patients after colectomy [270]. In a prospective, randomized, and placebo-controlled trial in 29 children, VSL#3 was superior to placebo in protracting relapse-free remission [271]. The question of use of probiotics for inducing remission in UC remains controversial. A meta-analysis of all available studies in adult literature demonstrated that VSL#3 is beneficial for maintaining remission in patients with pouchitis, and that probiotics show additional benefit in inducing remission of UC [272]. Larger prospective pediatric studies are needed to fully define probiotic use for induction and maintenance of remission in pediatric patients with UC.

Fish Oil

Several placebo-controlled studies suggested a benefit of adjunctive therapy with fish oil supplementation containing eicosapentaenoic acid, a potent inhibitor of leukotriene B-4 synthesis, in the treatment of active UC [273–275]. However, fish oil supplementation did not appear to show any benefit in maintenance therapy [275, 276].

Randomized, controlled trials in adults with active distal UC suggest that therapy with topical short chain fatty acid preparations result in clinical symptomatic improvement, but there is no statistically significant advantage in comparison to placebo [277–279].

Nutritional Therapy

The importance of nutrition in the management of UC is extensively reviewed elsewhere [280, 281]. There is data to support the use of enteral therapy for induction of remission in CD, but the same response is not seen with UC [282, 283]. Children with UC can develop nutritional deficits with poor oral intake secondary to symptoms, and thus, promotion of continued good nutritional intake is essential for appropriate healing and nutritional repletion [284]. Enteral nutrition is preferred to total parenteral nutrition when possible. In contrast to CD, enteral nutrition is not an effective primary therapy for active UC [180, 285]. Studies suggest no advantage of total nutritional support and bowel rest in addition to conventional medical therapy alone in the treatment of UC [189, 190]. Total parenteral nutrition is often utilized for nutritional repletion in severe UC colitis, especially if the patient is developing severe cramps and diarrhea when challenged with enteral nutrition.

Surgical Therapy

In the majority of cases, medical therapy remains the first-line treatment for UC. However, colectomy may be required for patients with severe or medically refractory disease, or to prevent colon cancer. Since the inflammation in UC is limited to the colon, colonic resection will most often result in resolution of symptoms. However, colectomy is not without potential complications, such as the development of pouchitis in patients who undergo ileo-anal anastomosis [286, 287]. It is important to consider timely surgical intervention in the appropriate setting to avoid complications of UC. Indications for colectomy in a patient with UC include fulminant colitis or a complication of colitis, such as massive hemorrhage, perforation, or toxic megacolon; medical therapy failure; steroid dependency, which may lead to undesired side effects; and the presence of colonic dysplasia [288]. Prepubertal children may experience catch-up growth after colectomy for UC. In one series, 11 of 18 children increased their median height velocity from 3.85 cm/year preoperatively to 7.35 cm/year postoperatively [289].

There are no early predictors to help determine who will proceed to colectomy. In a retrospective review of 73 children with UC between the ages of 1–18 years, the combination of steroid dependency and pancolitis was associated with an increased need for colectomy [290]. Seventy-three percent of the children with steroid dependent pancolitis required colectomy within 3 years of diagnosis [290].

Except in the setting of emergent colectomy, a complete evaluation should be performed to ensure there is no evidence of CD prior to colectomy. If there is evidence suggesting the

possibility of CD, the patient and family need to be informed of the potential for postoperative recurrence, and the relative contraindications of ileoanal pull through procedures in patients with CD. The authors recommend small-bowel imaging and upper gastrointestinal endoscopy, in addition to a full ileo-colonoscopy, if there is no clinical contraindication. Prior endoscopies and pathology reports should be carefully reviewed to establish that there is no evidence of CD.

The surgical options available for UC are reviewed in detail elsewhere [288]. The ileal pouch-anal canal anastomosis (IPAA) is the operation most commonly performed in the majority of patients with UC. The IPAA removes the entire colon and the rectal mucosa, avoids permanent ileostomy, and preserves anorectal function. Several types of ileal pouches can be constructed including the J-shaped, S-shaped, W-shaped, and the lateral-lateral pouch [288]. The J pouch design is now most commonly used for the IPAA operation [291, 292]. If the rectal mucosa is in good condition, many centers use the two-stage operative approach. During the first stage, a subtotal colectomy of the cecum to proximal rectum, the removal of the distal rectal and proximal anal mucosa, and the formation of the ileal pouch are performed. In this initial stage, a diverting loop ileostomy is performed in order to allow the pouch to heal. The second stage involves closure of the loop ileostomy with restoration of fecal flow to the pouch. Surgeons at some surgical centers also complete the IPAA in one stage, without the loop ileostomy [293]; however, this would not be the procedure of choice in patients receiving high dose corticosteroids [292].

If the patient presents for emergent surgical intervention, such as with fulminant colitis, a three-stage operative approach is often utilized. At the time of acute presentation, a subtotal colectomy is performed with formation of a rectal stump (the so-called Hartman pouch) and Brooke ileostomy. After the first operation, the rectal mucosa is treated with topical therapies (e.g., hydrocortisone, aminosalicylates) to induce mucosal healing. At the second operation, the distal rectal and proximal anal mucosa is removed and the ileal pouch is created. The ileostomy is reversed at the third operation.

The potential complications of IPAA include small-bowel obstruction, pelvic sepsis, anastomotic leak, fecal incontinence, pouchitis, strictures, fistulae, and reduced fertility in females [288, 294–296]. The development of fistulae raises the suspicion of CD [288]. In one series of children aged 9–16 who underwent proctocolectomy with IPAA, 12/29 (41%) of patients with UC developed early complications (wound infection, early bowel obstruction, prolonged fever) [297]. Late complications (bowel obstruction, pouch fistula) occurred in 11/29 (38%) and pouchitis developed in 9/29 (31%) of the children with UC. Median follow-up was 4 years (range from 6 months to 9 years). In this same study, daytime continence was noted in 100% and nighttime continence in 93%. The

Fig. 30.5 Chronic active inflammation of an ileal J pouch (pouchitis) in a patient with a history of ulcerative colitis. Note both limbs of the ileal reservoir are erythematous with exudate. (Reprinted with permission from [67], Fig. 25.5, p. 406)

median frequency of bowel movements was 4 per 24 h, and 7% of the patients had nighttime bowel movements.

Pouchitis, or inflammation of the newly created reservoir, is the most significant chronic complication in UC patients undergoing IPAA and as many as 44–53% of the children and young adults with UC and ileo-anal anastomosis will develop pouchitis on long-term follow-up [286, 287]. The etiology of pouchitis is unknown, but theories involve the role of genetic susceptibility, fecal stasis, bacterial overgrowth, disruption of the balance of luminal bacteria, nutritional deficiencies, ischemia, and IBD recurrence [298]. Symptoms of pouchitis include diarrhea, rectal bleeding, abdominal cramping, urgency and incontinence of stool, malaise, and fever [288, 298, 299]. Laboratory studies may demonstrate anemia and an elevated erythrocyte sedimentation rate. The definitive diagnosis is established by flexible endoscopy of the pouch with biopsies (see Fig. 30.5). In some patients, a contrast enema may be useful in identifying fistulae.

Broad-spectrum antibiotics are usually the first-line treatment for pouchitis [298, 300]. Metronidazole is the most commonly used antibiotic, but alternative therapies include ciprofloxacin, amoxicillin/clavulanic acid, erythromycin, and tetracycline [299, 301]. If there is no improvement with antibiotics, other options include mesalamine enemas and steroid enemas or oral therapy with mesalamine, sulfasalazine, or steroids [299, 302, 303]. Other therapies examined include cyclosporine enemas, short chain fatty acid enemas, butyrate suppositories, and glutamine suppositories [299, 304–306]. Probiotic therapy may prevent the onset of acute pouchitis after ileostomy closure [270] and effectively maintain remission after chronic pouchitis [307]. A double-blind, placebo-controlled study evaluated the efficacy of the probiotic preparation VSL#3 compared with placebo in maintenance of remission of chronic pouchitis in 40 patients in remission. Three patients (15%) in the VSL#3 group had relapses within the 9-month follow-up period, compared

with 20 (100%) in the placebo group [307]. In another double-blind, placebo-controlled study performed by the same authors in 40 patients, VSL#3, administered immediately after ileostomy closure for 1 year, effectively reduced the onset of acute pouchitis in the VSL#3 group (10%) in comparison to the placebo group (40%) [270].

Several studies suggest that the risk of dysplasia in the ileal pouch appears to be low [308, 309] and may be associated with chronic pouchitis [310]. The development of adenocarcinoma has been reported in the ileal pouch [311]. In a follow-up study (mean of 5 years) of 76 children and adolescents with UC who had ileal pouch-anal anastomosis, no dysplasia was identified in screening pouch biopsy specimens [308]. The authors caution that the long-term risk of development of dysplasia is not yet known and recommend screening of the pouch for dysplasia. In the rare patient who has undergone an ileo-rectal anastomosis without rectal mucosectomy, surveillance of the rectum should be performed to screen for rectal cancer.

Psychosocial Support

The social impact of UC on the lives of children with the disease needs to be considered. UC often has its onset in adolescence, a time when body image issues are paramount. Children and teens with IBD often may experience anxiety over the diagnosis of a chronic disease, the need for invasive procedures, and the uncertainty of the future. In addition, there may be struggles with parents about proper diet, and “medication fatigue” from having to take more than ten pills per day. Social, school-related, and extracurricular activities may be affected and may need appropriate modification. For example, a self-limited reduction of physical education activities and permission for special bathroom privileges may be needed.

Previous studies report an increased risk of psychiatric and behavioral issues in children with IBD, including depression, anxiety, and low self-esteem [312–317]. The physician caring for these patients needs to openly discuss the above issues with the patient and family, and be alert to the possibility that a patient may develop anxiety or depressive symptoms. Two patient-generated, disease-specific, health-related quality of life questionnaires for children with IBD have been validated, the IMPACT and Impact-II questionnaires [318, 319]. Impact-II and more recent Impact-III are modified versions of the IMPACT questionnaire. The use of these instruments may provide important information to improve the care of children with IBD. Referral to an educational support group, such as those sponsored by the Crohn’s and Colitis Foundation of America (www.ccf.org), may be very helpful for patients and their families.

Prognosis/Follow-Up

Whether children with UC are treated medically or surgically, they have an excellent long-term prognosis and a good quality of life. The majority of children with UC respond to medical therapy. In one US retrospective study of 171 children ranging in age from 1.5 to 17.7 years, diagnosed with UC between 1967 and 1994, 43% had mild disease at presentation and 57% had moderate or severe UC. With treatment, 70% of all the children were in remission within 3 months of diagnosis and by 6 months, 90% of the children with mild disease and 81% of the children with moderate to severe UC experienced resolution of their symptoms. In each yearly follow-up period, approximately 55% of the children were symptom free, 38% experienced chronic intermittent symptoms, and 7% had continuous symptoms [320]. In this same study, children with mild UC at presentation had a lower frequency of colectomy than children with moderate to severe UC (9 vs. 26% at 5 years, respectively). Patients with left-sided disease had comparable rates of colectomy at 5 years as patients with pancolitis [320]. However, the authors cautioned that the number of patients in each subgroup of disease extent was small and a true difference in colectomy rates may have been missed secondary to insufficient power of the study [320].

Limited distal UC (proctitis or proctosigmoiditis) diagnosed in adults and children can extend further to involve more proximal colon with time [69, 321–323]. In a retrospective evaluation of 85 patients under 21 years of age, diagnosed with UC proctosigmoiditis between 1958 and 1983, the extension of disease was to the descending colon in 20% and to the hepatic flexure or beyond in another 38% of the patients [69].

Individuals with long-standing UC are at increased risk of developing colorectal cancer (CRC) [324–326]. Risk of CRC increases with more extensive colonic involvement, and longer duration of disease since diagnosis [324–328]. Thus, children with UC potentially will be at risk for CRC over a longer period of time, compared to individuals with adult-onset UC. In a recent Danish population-based cohort study, the risk of CRC among patients with UC was similar to the risk among the general population. The authors highlighted a decrease in the rate of CRC risk among patients with UC between 1979 and 2008. However, certain subgroups of UC patients, including those who were diagnosed in childhood or adolescence, experienced a longer duration of disease, or had PSC, remained at elevated risk of CRC [329]. Individuals with PSC and UC have a higher risk of developing colorectal neoplasia compared to those with UC alone and of developing cholangiocarcinoma [330–332]. Ursodeoxycholic acid may decrease the risk for developing colorectal dysplasia or cancer in patients with UC and PSC

[333]. However, high doses of ursodeoxycholic acid may increase the risk of colorectal neoplasia in these patients [334]. Other risk factors reported for CRC in patients with UC include a family history of sporadic CRC and the presence of colonic stricture, shortened colon, or inflammatory pseudopolyps [335–337].

Some retrospective studies suggest that ASA agents may provide a protective effect in the development of CRC in patients with UC, but not all studies support these findings [217–219, 338, 339].

Presently, there is insufficient evidence to support or refute the use of purine immunomodulators in the chemoprevention of CRC in patients with UC [337, 340]. There are no randomized controlled trials examining the effectiveness of surveillance colonoscopy for dysplasia and CRC in patients with UC [337]. In 2010, the American Gastroenterological Association (AGA) published updated recommendations for surveillance colonoscopy in adults with IBD [337, 341]. An initial screening colonoscopy 8 years after onset of symptoms is advised in all patients with UC to reassess the extent of disease with multiple biopsies obtained throughout the entire colon. The CRC surveillance interval is determined by the true extent of disease, defined by the most proximal extent of disease identified histologically at any point in time [337]. Patients with isolated ulcerative proctitis are not considered at increased risk for IBD-related CRC. Therefore, after the initial screening colonoscopy, they do not require surveillance colonoscopy based upon their UC. Patients with extensive (extent proximal to splenic flexure) or left-sided colitis should commence surveillance colonoscopy within 1–2 years after the initial screening [337]. Patients with UC and PSC should initiate colonoscopy surveillance at time of diagnosis and continue with yearly examinations thereafter [337].

Chromoendoscopy improves the detection of dysplastic lesions by enhancing the visualization of mucosal irregularities [337]. In expert hands, chromoendoscopy optimizes the detection of mucosal abnormalities for appropriate targeted biopsies and reduces the need for random biopsies [342, 343]. If colonoscopy is performed without chromoendoscopy, surveillance should include careful inspection of the mucosa with targeted biopsies of any suspicious lesions and random biopsies from each anatomic section of the colon [337]. There are no prospective studies available to define the ideal number of random biopsies required to reliably detect colorectal neoplasia. Consensus recommendations suggest that biopsy specimens should be taken every 10 cm in all four quadrants [337]. It is not clear whether surveillance practice should differ for patients with younger-onset UC. There are no published formal recommendations to guide surveillance colonoscopy in children [344]. The AGA recommends that surveillance colonoscopy should be performed as frequently in children and adolescents as in adults

and should be determined by the duration of disease [337]. Guidelines for surveillance colonoscopy for neoplasia in IBD patients continue to evolve.

Conclusion

UC in children presents in a similar manner to that in adults, though children often have more extensive disease at diagnosis. Once the diagnosis is established, by colonoscopy, the first line of induction treatment in mild disease is usually an aminosalicylate, with corticosteroids reserved for moderate to severe disease. If a patient responds to induction therapy, the maintenance agent most commonly used is an aminosalicylate or 6-mercaptopurine. In severe steroid unresponsive colitis, the clinician is faced with the challenge of recommending either colectomy or more aggressive immunosuppression (e.g., infliximab, tacrolimus, cyclosporine). Even if a patient responds to cyclosporine or tacrolimus, there is a high likelihood of proceeding to colectomy within a year. Surgery will eradicate the disease, but patients may develop chronic pouchitis requiring additional medical treatment. In addition to medical care of these patients, nutritional counseling, monitoring of growth, and psychosocial support are essential. If the medical team can give proper care and support, the patient's long-term prognosis is usually excellent.

Keith J. Lindley and Jutta Köglmeier

Introduction

The vasculitides are a group of inflammatory disorders of the walls of blood vessels (usually the arteries). They are relatively rare in childhood with the exception of Henoch–Schönlein purpura (HSP) and Kawasaki disease (KD). Vasculitis might be primary or secondary to a number of causes including infections, drugs, hypersensitivity reactions and connective-tissue disorders. The consequences of arterial inflammation include tissue ischaemia and necrosis, giving rise to many of the gastrointestinal (GI) manifestations of vascular inflammation such as pain and bleeding.

Vasculitis is usually classified based on the size of blood vessel involved in the inflammatory process (Table 31.1 and Fig. 31.1). Not all of these are seen in the pediatric age group. The vasculitides associated with GI manifestations in childhood are listed in Table 31.2. These manifestations include abdominal pain (potentially due to bowel ischaemia or bowel wall thickening and subacute obstruction), GI blood loss (due to GI ulceration which can be aphthoid, undermined or fissure like), diarrhea which is often bloody (due to nonspecific inflammation of the ileum or colon) and an acute abdomen as a consequence of perforation [1].

Henoch–Schönlein Purpura

HSP is an immune-complex small-vessel vasculitis. It is the most common vasculitis seen in childhood with an estimated annual incidence of 20/100,000 children in the UK. The dis-

ease is characterized by a leukocytoclastic vasculitis with deposition of immunoglobulin A1 (IgA1) immune complexes in vascular tissue, principally capillaries and post-capillary venules. The disease is predominantly seen in children aged 3–10 years with the majority being <5 years. It is more frequent in the autumn/winter months and will commonly follow an infection. Proposed infective triggers include group A beta-haemolytic streptococcus, Parvovirus B19, *Staphylococcus aureus* and Coxsackie virus to name a few. It has been suggested that the pathogenesis involves the recognition of galactose-deficient IgA1 by anti-glycan antibodies and the deposition of these immune complexes in small vessels.

A recent large series suggests that 100% of patients have skin involvement with 60–70% having “palpable purpura” of the lower limbs and buttocks, 66% have arthritis which is usually symmetrical affecting the knees, ankles and feet, and 54% have GI involvement usually with lower GI bleeding or abdominal pain but also intussusception, ileal perforation and pancreatitis [3]. Renal manifestations are seen in 30% and include nephritic or nephrotic syndromes which can lead to chronic renal failure in a minority of cases. Diagnostic criteria include the presence of purpura or petechiae with lower-limb predominance with one of the following: diffuse abdominal pain, acute arthritis or arthralgia, haematuria or proteinuria and any biopsy showing predominant IgA deposition [4].

Described GI complications of HSP include intussusception, bowel ischaemia and infarction, intestinal perforation, late stricturing, acute appendicitis, GI haemorrhage (occult and massive), pancreatitis and gallbladder hydrops. One large series of patients reported abdominal pain in 58% of children and positive stool occult blood (SOB) in 18% [5]. Frank lower-GI bleeding was present in 3%. Plain abdominal radiology frequently showed dilated thickened bowel loops when the SOB was strongly positive which was also visualised on ultrasound examination. Intussusception, perhaps the most serious GI complication of HSP, was rare (0.5%) although in other series prevalence of up to 5% are described. The appearance of the thickened bowel wall on

ultrasound might act as a prognostic marker for duration of hospitalization for HSP [6]. Endoscopic findings vary and can include the presence of circumscribed vascular lesions (rather similar to the palpable purpura seen on the skin) and segmental ischaemic change (Fig. 31.2) [7].

It is usual for children to make a complete recovery from HSP with only supportive treatment with the exception of HSP-associated nephritis which is the cause of end-stage renal failure in up to 3% of children in the UK. Some series report a significant reduction in duration and intensity of abdominal pain in children treated with prednisolone early in the course of the disease, but the use of steroids does not seem to protect against the development of nephritis.

Kawasaki Disease

KD is the second commonest childhood vasculitis which affects about 8/100,000 children younger than 5 years of age annually in the UK with twice as many cases occurring in the USA and approximately 20 times the incidence in Japan. The disease affects predominantly medium- and small-sized

arteries and is normally self-limiting. However, coronary artery aneurysms are present in 25% of untreated patients and can lead to myocardial infarction or late coronary artery stenosis. In addition to involvement of the coronary arteries, systemic arterial injury can occur.

The seasonality and clustering of KD support an infectious trigger, although to date no single organism has been identified. The much higher prevalence of disease in Japanese and Korean children supports the notion that genetic predisposition is also an important factor and genome-wide association studies have identified a number of genes associated with disease susceptibility and disease phenotype.

Diagnosis of KD is clinical comprising the presence of unremitting fever for 5 days or more plus 4/5 of the following features: conjunctivitis; lymphadenopathy; polymorphous rash; changes in lips, tongue or oral mucosa and involvement of extremities including periungual desquamation (see Table 31.3). Patients with lesser numbers of these diagnostic features may be diagnosed with KD if they are found to have coronary artery aneurysms on echocardiography. It is important to note that not all of these diagnostic features may be present at once.

Although not diagnostic of KD, arthritis, aseptic meningitis, pneumonitis, uveitis, gastroenteritis and dysuria are also frequently seen. Uncommon features of the disease include gallbladder hydrops, GI ischaemia, mononeuritis, nephritis, seizures and ataxia.

Overall, abdominal symptoms, particularly diarrhea which can be bloody or non-bloody, are a frequent early feature of KD. Abdominal pain is less frequent [8]. Vasculitic appendicitis, haemorrhagic duodenitis and paralytic ileus are also described [9]. Bowel wall oedema may be evident as segmental thickening of the bowel wall as may gallbladder hydrops [10].

Inflammatory markers (erythrocyte sedimentation rate, ESR and C-reactive protein, CRP) are inevitably elevated as is the peripheral blood white blood cell count. Thrombocytosis, which can be very marked, usually occurs in the second week of the disease.

Early treatment of KD with aspirin and intravenous immunoglobulin (IVIG) reduces the occurrence of coronary artery aneurysms. A single infusion of 2 g/kg IVIG and an anti-inflammatory dose of aspirin (30–50 mg/kg/day) will reduce the likelihood of developing coronary artery aneurysms in the majority of patients, although approximately 20% of children are IVIG resistant. The dose of aspirin should be reduced to an anti-platelet dose during the thrombocytosis phase of the illness. Patients who continue to have fevers and an ongoing systemic inflammatory response 48 h post IVIG are likely to be IVIG nonresponders and can be treated with intravenous methyl prednisolone for 5 days followed by 2 weeks of oral prednisolone or perhaps anti-tumour necrosis

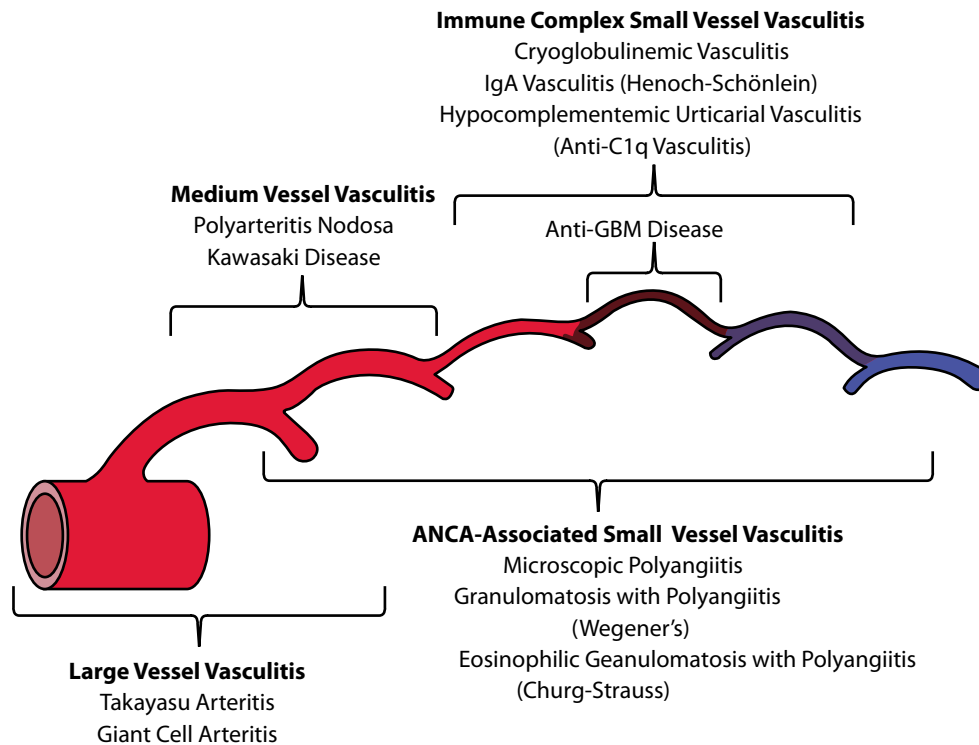

Fig. 31.1 Distribution of vessel involvement by large-vessel vasculitis, medium-vessel vasculitis and small-vessel vasculitis. Note that there is substantial overlap with respect to arterial involvement, and an important concept is that all three major categories of vasculitis can affect any size artery. Large-vessel vasculitis affects large arteries more often than other vasculitides. Medium-vessel vasculitis predominantly affects medium arteries. Small-vessel vasculitis predominantly affects small vessels, but medium arteries and veins may

be affected, although immune-complex small-vessel vasculitis rarely affects arteries. The diagram depicts (from *left to right*) aorta, large artery, medium artery, small artery/arteriole, capillary, venule and vein. Anti-GBM—anti-glomerular basement membrane; ANCA—anti-neutrophil cytoplasmic antibody. *ANCA* Anti-neutrophil cytoplasmic antibody. (Reprinted with permission John Wiley and Sons/ Arthritis & Rheumatism, from Ref. [2], 2013 American College of Rheumatology.)

factor (TNF) antibodies. Certain other high-risk individuals should also receive steroids [11].

Systemic Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is a necrotizing arteritis of medium and/or small arteries which has been subclassified into systemic PAN and cutaneous polyarteritis. Whilst systemic PAN is generally severe and cutaneous polyarteritis relatively benign, the cutaneous form can go on to develop features of multiorgan involvement. The presenting features of PAN

can be very nonspecific and are known to affect a number of systems notably the skin, musculoskeletal system, kidneys and GI tract. A recent pediatric series documents the most common presenting features of PAN as fever (87%), myalgia (83%), arthralgia/arthritis (75%), weight loss of >5% of body weight (64%), fatigue (62%), livedo reticularis (49%) and abdominal pain (41%). In this series, 59% had GI symptoms comprising abdominal pain (49%), blood in the stools (10%) and bowel ischaemia/perforation (8%) [12]. The diagnosis may be delayed as the symptoms are so nonspecific. GI bleeding can be massive, especially when it arises from a Dieulafoy lesion, a submucosal vascular abnormality with a prominent tortuous artery with/without aneurysm formation [13, 14]. Ulcers, which are circumscribed and well demarcated, may also be evident (Fig. 31.3a, b). Following remission induction in PAN, the onset of GI symptoms is a major clinical predictor of clinical relapse. Other symptoms seen in PAN less frequently include cardiac, respiratory and neurological manifestations.

GI symptoms are generally attributable to ischaemia which can lead to infarction, perforation or stricture [16,

Table 31.3 Diagnostic criteria for Kawasaki Disease

Criterion	Description
Fever	Duration of 5 days or more plus 4/5 of the following
1. Conjunctivitis	Bilateral non-purulent with limbic sparing
2. Lymphadenopathy	Cervical, often > 1.5 cm
3. Rash	Polymorphous with no vesicles or crusts
4. Changes in lips/mucous membranes	Red cracked lips, “strawberry” tongue, erythema of oropharynx
5. Changes in extremities	Initially: erythema and oedema of palms and soles Later: periungual desquamation

[17]. The systemic vasculitides can also be associated with an ischaemic colitis or a nonspecific colitis that can mimic inflammatory bowel disease [18].

The diagnosis of PAN is usually made through a combination of clinical, histopathological and arteriographic features and relies on one mandatory criterion plus one of five secondary criteria. Mandatory criteria comprise fibrinoid necrosis of the walls of medium-sized arteries from an affected organ together with an inflammatory response in the adjacent vessel wall which is characteristic of PAN or angiographic abnormalities (aneurysm, stenosis/segmental narrowing or occlusion/pruning) of medium or small arteries. Secondary criteria include (i) characteristic skin involvement, (ii) myalgia or muscle tenderness, (iii) hypertension, (iv) peripheral neuropathy/mononeuritis and (v) renal involvement. Renal, hepatic and mesenteric arteriography is commonly used as a diagnostic tool in children which overall has a sensitivity of 94% for diagnosing PAN (Fig. 31.4).

A detailed discussion of treatment is beyond the scope of this chapter. Historically, this has involved remission in-

duction with pulsed intravenous methyl prednisolone often with cyclophosphamide and anti-platelet agents followed by maintenance therapy with low-dose steroids and a steroid-sparing agent (usually azathioprine). Biologic agents can be effective in treating PAN, for example, the anti-TNF agents Infliximab and Etanercept and the anti-cluster of differentiation (CD)20 agent Rituximab.

Behçet Disease

Behçet disease (BD) is rare in childhood (2/100,000 in Europe). It is a variable-vessel vasculitis which can affect veins and arteries of any size. Behçet described a triad of aphthous stomatitis, genital ulceration and uveitis. A more contemporary consensus defines pediatric BD as recurrent oral aphthous ulceration plus one of the following—genital ulceration, erythema nodosum, folliculitis, pustulous/acneiform lesions, positive pathergy test, uveitis, venous/arterial thrombosis and family history of BD [19].

Fig. 31.3 **a** Punched-out ulcers with well-demarcated edges in the colon in PAN. Ulcers are typically shallow and irregular often with surrounding erythema. (Reprinted from Ref. [15], with permission from Elsevier). **b** Bleeding Dieulafoy lesion in the stomach in a case of PAN. (Reprinted from Ref. [14], with permission from Elsevier.)

Fig. 31.4 Inferior mesenteric artery angiogram showing vessel calibre changes and aneurysms characteristic of polyarteritis nodosa

BD is extremely heterogeneous affecting multiple organ systems with distinct geographical variations in symptoms. For example, GI manifestations are more prevalent in the Far East, whilst vascular manifestations are seen in the eastern Mediterranean. GI manifestations comprise abdominal pain and aphthoid ulceration and rarely GI bleeding. Perforation of aphthoid ulcers is described. Vascular manifestations include venous thromboembolism, arterial stenosis, aneurysms and occlusions. Neuro-Beçets can present with headache, papilloedema, central venous sinus thrombosis and/or brain parenchymal disease causing seizures and focal neurological abnormalities [20].

Granulomatosis with Polyangiitis (Wegener's Granulomatosis)

Wegener's granulomatosis (WG) is one of the anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitides (AAV) and is a necrotizing granulomatous vasculitis of small blood vessels. The main features of the disease are due to a widespread small-vessel vasculitis with clinical manifestations of a necrotizing glomerulonephritis and respiratory tract granulomata dominating the clinical picture. GI involvement is infrequent but when present may present with abdominal pain; mucosal ulceration of the oesophagus, small or large bowel; GI perforation and rarely colitis and catastrophic GI haemorrhage or infarction of the gall bladder, intestine and colon.

Eosinophilic Granulomatosis with Polyangiitis (Churg–Strauss Syndrome)

This is another of the AAV which is extremely rare. ANCA is positive in about 30% of cases. Histopathological features are those of a small-vessel (arteries and veins) granulomatous vasculitis with an eosinophil-rich inflammatory infiltrate. In addition, there is an eosinophil-rich granulomatous infiltrate of the respiratory tract and usually a history of asthma, allergic rhinitis and peripheral blood eosinophilia.

GI-tract involvement is seen in the context of vasculitis causing symptoms of pain (ischaemic), ulceration, perforation and bleeding. Independently of vascular involvement, eosinophil-rich inflammation of the GI mucosa can result in symptoms such as diarrhea and perhaps pain. Forty percent of children have gastroenterological symptoms at presentation [21]. The pediatric disease is usually steroid responsive but subject to relapse.

Microscopic Polyangiitis

Microscopic polyangiitis is a necrotizing vasculitis of small vessels in which up to 65% of patients are perinuclear ANCA (pANCA) positive. It is uncommon in childhood [22]. Characteristically, the vasculitis is not strongly associated with the deposition of immune complexes in the affected blood vessels. Necrotizing glomerulonephritis is common with this condition and the classical presentation is with rapidly progressive glomerulonephritis and alveolar haemorrhage [23]. In common with the other AAV pain is a dominant GI symptom, although GI blood loss, cholecystitis, ischaemic colitis and bowel perforation are described.

Single-Organ Vasculitis

Systemic vasculitis occurs when vascular inflammation involves multiple territories or organs. In single-organ vasculitis (SOV), the inflammation is restricted to a single organ or part of that organ. By definition, there has to be a lack of spread outside the single organ for at least 6 months. SOV is known to affect the GI tract and may affect small-, medium- or large-sized arteries. The condition is not well described in children and is more commonly part of PAN (e.g. appendiceal vasculitis).

Takayasu Arteritis

Takayasu arteritis (TA) is a vasculitis predominantly affecting large vessels (mainly the aorta and its main branches). It is most commonly seen in Asia and rarely encountered in

the pediatric age group. Girls are more often affected than boys. Patients frequently complain about headache, abdominal pain, limb claudication, myalgia, arthralgia and fever. Weight loss is said to occur in about 10% of affected individuals. Cerebrovascular events, angina and loss of vision have been reported [24]. The disease requires aggressive treatment as damage to the vessels is otherwise irreversible, and a combination of steroids and Azathioprine or Methotrexate are commonly prescribed [25]. In cases of severe ischaemia, antihypertensive drugs or even surgery may be indicated.

Systemic Lupus Erythematosus-Associated Vasculitis

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease in which type 2 and type 3 hypersensitivity reactions are important in the pathogenesis. The presence of anti-double-stranded DNA (anti-dsDNA) antibodies in the blood is a highly specific test for SLE being present in 70–80% with titers of antibody tending to mirror disease activity. Other pathogenic autoantibodies in SLE include antibodies to nucleosomes, Ro (a ribonucleoprotein component), La (an RNA-binding protein), C1q (complement), phospholipids and the *N*-methyl-D-aspartic acid (NMDA) receptor. Many of these antigens are expressed on the cell surface during the process of apoptosis, and it has been hypothesized that abnormalities of the apoptotic pathway, which are ubiquitous in SLE, are important in the genesis of pathological autoantibodies [26].

Systemic lupus can affect the GI tract causing chronic, nonspecific mucosal inflammation, mucosal ulceration or vasculitis resulting in mesenteric/GI ischaemia (Fig. 31.5a, b). Abdominal pain is present in 8–40% of published series of individuals with SLE; in children, it is most commonly (32%) due to lupus-associated mesenteric vasculitis [27]. Other causes of pain include pancreatitis (10%), appendicitis (7.5%) and cholecystitis (6%). Patients with vasculitis usually have high SLE disease activity scores (SLEDAI) but do not commonly have substantially elevated inflammatory markers. Protein-losing enteropathy has also been described in SLE.

Fig. 31.5 a. Mucosal oedema in association with nonspecific inflammation in SLE. b. Colonic mucosal ulceration in SLE. (Reprinted from Ref. [28], with permission from Elsevier.)

The clinical presentation of lupus-associated mesenteric vasculitis commonly mirrors an acute surgical abdomen. It is suggested that individuals with SLE, high SLEDAI and an “acute abdomen” undergo imaging to look for evidence of vascular compromise before any surgical intervention.

Juvenile Dermatomyositis

In juvenile dermatomyositis (JDM), vasculitis affects striated muscle, the skin, subcutaneous tissues and the GI tract. Children develop weakness of the muscles of the neck, shoulders and hips leading to difficulties with swallowing, getting up from sitting or climbing stairs. GI bleeding and perforation can be catastrophic and are a major cause of death [29].

Rheumatoid-Associated Vasculitis

Rheumatoid arthritis (RA) is another systemic inflammatory disorder with articular and extra-articular manifestations. Rheumatoid vasculitis (RV) is a systemic necrotizing vasculitis affecting small- and medium-sized arteries which is clinically extremely heterogenous and can affect skin, nerves and abdominal viscera. RV is usually seen when there are other extra-articular manifestations, and these patients are always rheumatoid factor positive. It is usual to find raised inflammatory markers (ESR and CRP), polyclonal hypergammaglobulinemia and often hypocomplementemia. GI involvement is rare but, in common with other vasculitides, can result in ischaemia, perforation and haemorrhage [30].

Investigation of Children with Suspected GI Vasculitic Disorders

The diagnosis of vasculitis can be challenging because of the heterogeneity of possible presentations and the diagnosis is often delayed. A high index of suspicion is key to early diagnosis and intervention. The three elements of diagnosis include (i) definition of a clinical phenotype compatible with

the diagnosis, (ii) specific serology or radiology and (iii) histological confirmation if appropriate.

A basic diagnostic evaluation might include blood count and film, inflammatory markers (ESR; CRP), liver function, pancreatic enzymes, ANCA and anti-dsDNA antibodies, rheumatoid factor, complement (C3 and C4), anti-cardiolipin antibodies, cryoglobulins and hepatitis B and C serology. In addition, urine microscopy and a chest X-ray should be undertaken. Further investigations will be directed by the clinical phenotype.

Abdominal ultrasound might allude to bowel wall thickening as might abdominal CT/MRI. CT/MRI might also allude to segmental perfusion defects. Magnetic resonance angiography is not as sensitive as digital subtraction angiography (DSA) in PAN (see below).

Selective visceral DSA is diagnostically very sensitive for systemic PAN and might highlight the site of bleeding if present. Characteristic features of PAN include aneurysms of small- and medium-sized arteries (seen in 40%). Other non-aneurysmal features include arterial cut off, arterial tapering and stenoses, arterial beading, pruning of the renal arterial tree and perfusion defects. Overall, arteriographic abnormalities are present in 94% of children with PAN affecting the renal, hepatic and mesenteric vasculature [12]. Assessment of the GI mucosa by oesophagogastroduodenoscopy, videocapsule endoscopy and ileocolonoscopy with biopsy might reveal a plethora of pathologies in vasculitic disorders. Nonspecific colitis is common in childhood systemic vasculitis and a nonspecific enteritis may be present in SLE [18]. Ulceration may be ischaemic or inflammatory in origin. Behçet's ulcers tend to be round, few in number (<5) and focally distributed when compared with Crohn's ulcers which are more commonly irregular in shape [31]. Ulcers in SLE are typically punched out. In HSP oedema, patchy mucosal redness, erosions and linear ulceration of the duodenum and ileum are described [32, 33] Purpura similar to that seen in the skin might be seen in the GI mucosa [34]. Mucosal biopsies in Churg–Strauss may demonstrate evidence of eosinophilic GI disease/eosinophilic gastroenteritis.

Introduction

Lymphonodular hyperplasia (LNH) of the gastrointestinal (GI) tract is characterized by a significant enlargement of isolated aggregates in one or several segments of the GI tract or by increase of the number or size of lymphoid nodules of the Peyer's patches of the distal part of the small intestine. Enlargement should be severe enough to make the aggregates elevated and visible by endoscopic assessment or radiology, usually the diameter exceeding 2 or 3 mm.

LNH is a common condition in the pediatric patients and rare in adults. It has long been considered to be an incidental and physiological finding [1–3]. Clinically, LNH can be asymptomatic or manifest with variable set of symptoms including abdominal pain, diarrhea, bleeding or even intestinal obstruction [4]. In some cases, clinical significance of LNH may remain speculative, and, in some cases, the finding may represent a physiological reaction with no clinical significance as for the symptoms.

LNH is considered a reactive condition related with microbiological or nutritional luminal factors or immune deficiency, but exact pathogenic mechanisms are largely unknown. A significant proportion of cases associate with non-immunoglobulin E (IgE) food allergies [4].

Definition

LNH has usually been defined as a condition characterized by endoscopically visible increase of the numbers or size or both of mucosal lymphoid nodules, which elevate above the surrounding mucosa. LNH can be seen in any part of the GI tract. Diagnosis is based on endoscopic or radiological appearance, and the confirmation of diagnosis may need exclusion of other diseases causing mucosal elevations, such as various lymphoid neoplasms and reactive and neoplastic polypoid lesions (Table 32.1). This definition does not apply for lesser grades of lymphoid hyperplasia, where either increase of the numbers of lymphoid follicles or their enlargement is of lesser degree so that mucosal elevations are not formed. However, it is likely that there is continuum between such lesser grades of hyperplasia and the endoscopically visible lymphoid nodular hyperplasia fulfilling the current criteria [5], pointing to the idea that the current criteria are arbitrary, and they do not have a clear pathophysiological basis.

Endoscopic Assessment and Criteria

LNH can be detected by using barium enema, but currently the diagnosis is usually based on endoscopic visualization of typical whitish or mucosa-coloured elevations (Fig. 32.1, 32.2 and 32.3). In cases where there is any uncertainty of the nature of nodules, a complementary histopathological analysis should be used to exclude other disease processes causing endoscopic nodularity or multiple polypoid lesions (Table 32.1; Figs. 32.1, 32.2 and 32.3). Endoscopic detection of LNH requires active search and is aided by adequate air insufflation during examination as the folds may hide nodularity [6]. LNH can also be detected by capsule endoscopy [7].

By definition, diagnosis of LNH needs increase of the size of the lymphoid nodules, but it may be associated with the increase of their numbers. However, there are no consensus criteria for LNH. Considering the size of the nodules, minimum size for a hyperplastic nodule has been suggested to be 2 [8]

Table 32.1 Gastrointestinal diseases to be considered in the endoscopic and histopathological differential diagnosis of LNH

All anatomical areas	Giardiasis
	Granulation tissue polyps
	Inflammatory bowel disease
	Lymphangiectasia
	Lymphoma
	Multiple adenomatous or hyperplastic polyps
	Metastatic tumours
	Familial and sporadic gastrointestinal polyposes
	Ganglioneuromatosis
	Neuroendocrine hyperplasia and neoplasia
Stomach	Cystic polyps
	Hyperplastic gastritis
Small intestinal mucosa	Duodenal Brunner's gland hyperplasia and adenoma
	Duodenal gastric heterotopia
	Groove pancreatitis
Colon and rectal mucosa	Solitary rectal ulcer

Fig. 32.1 An endoscopic view of the bulb of the duodenum showing normal smooth mucosa **a**. In lymphonodular hyperplasia, elevations are dispersed along the walls covering the otherwise normal mucosa **b**

or 4 mm [9]. The minimum number of nodules has been described as a “cluster” [8, 10], and a cluster has been defined as a group of minimum of 10 nodules [8]. Typically, the size range of polypoid lymphoid nodules is 3–6 mm in diameter.

Terminal ileum contains physiologically lymphoid nodules, that is, Peyer's patches, and the diagnosis of LNH is more subjective in this anatomical location. Autopsy studies have indicated that in children the size and number of these patches increases with age [11], and that in adults these are at their highest in the third decade [12]. Kokkonen graded the abundance of ileal lymphoid nodules in four grades: 0, no lymphoid nodules; 1, mild, lymphoid nodules dispersed on the walls; 2, moderate, lymphoid nodules filling the walls; 3, severe, terminal ileum massed with lymphoid tissue, valve protruding [6] (Fig. 32.2). Counts of lymphoid nodules per visual field of a high-resolution endoscopy in adults in the terminal ileum and caecum indicated that 9–50 lymphoid nodules per field can be defined as lymphoid hyperplasia,

and that more than 50 lymphoid nodules per field can be defined as pathological lymphoid aggregates [5].

According to current criteria, increase of the numbers or size of lymphoid nodules less than 2 mm and without endoscopic evidence of nodularity is not diagnostic for LNH. However, as the development of LNH is gradual, even the lesser grades with only numerical increase or increase of the size of nodule without formation of any elevation could have significance. It is obvious, that we need more data on the pathophysiology and clinical significance of such lesser grades of lymphoid hyperplasia.

Anatomical Distribution of LNH

LNH may affect any part of the GI tract, and simultaneous manifestation in several parts is not uncommon [6, 10]. In the duodenum and colon, LNH is usually segmental and

Fig. 32.2 Endoscopic view of the mucosa of a healthy terminal ileum shows usually tiny lymphoid nodules **a**. In lymphonodular hyperplasia, the nodules are both enlarged and their numbers are increased **b** and in severe cases may mass on the walls **c**. In some cases, enlarged lymphoid nodules may extend to the region of ileocaecal valve and be visible even from the caecal side **d**. The biopsy taken from the terminal ileum with lymphonodular hyperplasia may be filled with lymphoid tissue as large nodules. However, normal long villi can be detected between the nodules **e**

Fig. 32.3 Endoscopic view of colon showing lymphonodular hyperplasia

patchy. In the duodenum, bulb is the most commonly affected location [13].

A rare form of segmental lymphoid hyperplasia is located in the distal rectum of adults and children and has been referred to a rectal tonsil [14]. Clinically, rectal tonsil is often associated with rectal bleeding and abdominal pain, but pathophysiology is unknown. However, similar constellation may be caused by a local chlamydia infection [15].

Lymphoid follicular proctitis is a rather poorly defined condition, where rectal mucosal nodularity is related with formation of lymphoid follicles and interfollicular chronic inflammation. Symptoms are composed mucoid stools and haematochezia, and occasional response to sulfasalazine treatment suggests that some cases represent a variant of inflammatory bowel disease (IBD) [16].

Histology of LNH

Biopsy specimens from LNH typically show a lymphoid follicle with or without germinal centre (Fig. 32.2). A germinal centre is usually present and is enlarged, but additional sections may sometimes be necessary to confirm this feature. Alike reactive germinal centres, tangible body macrophages and a network of dendritic cells expressing cluster of differentiation (CD)23 are present [17]. Follicles are surrounded by a mantle zone containing T and B lymphocytes. Interfollicular tissue may have some features of paracortical zone of lymph nodes, such as high endothelial venules [17].

Epithelium overlying lymphoid follicles contains enterocytes and a specialized epithelial cell type M cells, showing characteristic microfolds. According to experimental work, the formation of the latter cell is induced by signalling from the developing lymphoid follicle. M cells contain pockets with intraepithelial lymphocytes. Functionally, M cells act as transporters of luminal antigens to be processed by the cells of lymphatic follicle. This results in the formation of an immunoglobulin A (IgA) response [18].

In case series of children with delayed type of food allergy, the majority of them presenting with LNH, the intestinal mucosa may show increase of intraepithelial lymphocytes including gamma–delta-expressing lymphocytes and cytotoxic lymphocytes [19–21]. Similarly, the numbers of intraepithelial eosinophilic leukocytes may be increased in

LNH cases associated with allergy [8]. In cases where LNH associates with specific disease or condition, these may present with characteristic features, such as chronic inflammation between the follicles in IBD-associated cases, and characteristic absence of plasma cells in common variable immune deficiency [22].

Histopathological differential diagnosis involves other reactive and neoplastic causes for mucosal nodularity (Table 32.1). Malignant lymphomas of mucosa are very rare in children, but their risk is increased in children with immune deficiency or solid-organ transplantation.

Pathophysiology of LNH

GI mucosal lymphatic tissue consists of inductive and effector compartments [23]. Luminal antigens are processed, and specific immune responses are generated in the inductive compartment composed of Peyer's patches in the ileum and isolated lymphoid follicles in other parts of the GI tract. Isolated lymphoid follicles are aggregates of T and B lymphocytes [24]. The effector compartment is the diffuse mucosal lymphatic infiltrate which is composed of immunoglobulin-producing B cells and effector T cells [18, 23]. Isolated lymphoid follicles may have germinal centres and are associated with a special type surface epithelium with M cells [24].

Number and size of isolated lymphoid follicles are variable as they respond dynamically to the signals from diet and luminal flora [25]. In a normal small intestine, the estimated amount is one per 269 villi in the jejunum and one per 28 villi in the ileum [24]. In the proximal colon, the number is 0.02/mm of muscularis mucosae and in the rectosigmoid 0.06/mm [26]. Areal density of lymphoid aggregates in the colorectum was estimated to be 1.1–2.7/cm² [27]. Krauss et al. [5] used high-resolution endoscopy objective counting of lymphoid follicles, and they found that in adults 1–8 lymphoid follicles per endoscopy field of view in the terminal ileum and caecum can be defined as normal. Size of isolated lymphatic aggregates has been estimated to be in the range of 0.1–2 mm [24, 26, 28, 29].

Luminal commensal and pathogenic flora induces production of specific IgA response within Peyer's patches and isolated lymphoid follicles [18, 23]. In this response, lymphoid cells accumulate and induce evolution of M cells in the surface epithelium. Germinal centres are formed and are the places where *IgA* genes of the B lymphocytes mutate and relevant clones are selected. There is evidence that T-independent pathways can give rise to intestinal IgA-secreting plasma cells in isolated lymphatic follicles and diffuse lamina propria, while Peyer's patches can support both T-dependent and T-independent modes of IgA induction [18, 25].

Since the secreted IgA is induced by luminal microbes and also controls the amount of luminal microbial flora, the LNH might be viewed as a sign of IgA dysfunction, where balance is not reached within normal structural limits of lymphoid tissue [25, 30]. Accordingly, also LNH in association with immunodeficiency might be explained as compensatory mechanism to gain the balance. Similarly, increase of the numbers of lymphoid follicles in the colon of patients with infectious colitis [5], or gastric LNH in association with *Helicobacter pylori* infection [31], may represent similar attempts to control the infection by increased production of IgA and suggests that both increase of numbers of lymphoid follicles and their size may be involved. Children with LNH showed more abundant bacterial flora in the ileum than the control children [32], possibly supporting the role of microbial factors in the pathogenesis of LNH.

Mechanisms linking delayed type of food allergy and LNH are not clear. Evidence for association of history of IgE-mediated food allergy in infancy and increase of anti-allergen IgA levels and LNH [33] support the idea that in association with milk allergy, LNH, by providing IgA anti-allergen response, might represent an exaggerated attempt to tolerance [34].

Mechanisms of segmental localization of LNH with some preference to locate close to sphincter-like structures (distal to pylorus; proximal to ileocaecal valve), and association with motoric dysfunction (obstipation and Hirschsprung's disease) are speculative. However, stagnation of intestinal contents related with these anatomical structures or neuromuscular dysfunction might lead the mucosa to be exposed longer to luminal antigens, and thereby increase local antigen load.

The role of alteration of immune regulatory mechanisms in pathogenesis of LNH is not clear. Bellanti et al. [35] found evidence of deficient T helper cell (Th)1 function in peripheral blood of children with LNH. There are no studies focussing on mucosal cytokine patterns specifically on LNH. However, in children with delayed type of milk allergy, where majority of patients show LNH, ileal mucosa shows increase of interleukin (IL6) messenger (mRNA) [36], and duodenal mucosa shows increase of interferon (IFN) gamma mRNA levels [37], increased numbers of cells expressing IFN gamma [38] and increased IFN gamma, IL-4 and IL-10 secretion [37], possibly indicating imbalance of pro- and anti-inflammatory cytokines.

Mechanisms of the various clinical symptoms (see below) are largely speculative. In addition to immunological mechanisms for the symptoms, also other mechanisms are possible, including diet-related changes in the microbiome and nonprotein nutrients like fermentable oligosaccharides [39]. Accordingly, it is possible that LNH and irritable colon may share some pathogenic mechanisms.

Table 32.2 Etiology or associated condition of lymphonodular hyperplasia in different parts of the gastrointestinal tract

Part of gastrointestinal tract	Etiology/associated condition
Stomach	<i>Helicobacter pylori</i> infection
Duodenum	Food allergy, delayed type
	Juvenile idiopathic arthritis
	Immune deficiency (IgA, CVID)
	Giardiasis
Ileum	Food allergy, delayed type
Colon	Food allergy, delayed type
	IBD
	Immunodeficiency (IgA, CVID)
	Infectious enteritis
Rectum	Idiopathic
	Chlamydia infection

IgA immunoglobulin A, *CVID* common variable immune deficiency, *IBD* inflammatory bowel disease

Prevalence of LNH

Prevalence of LNH in general pediatric or adult population is unknown. Prevalence in symptomatic children varies from 30 to 46% in the colon [6, 8, 40], about 50% in the ileum [6] and 19% in the duodenum [6]. In majority of reported series, LNH was the only finding. Simultaneous presence in both upper and lower GI tract is not uncommon.

LNH and Food Hypersensitivity

Conditions associated with LNH are summarized in Table 32.2. In children, studies performed in three different populations, in Finland [10, 19], Italy [8] and the USA [35] have shown that LNH in duodenal or ileocolonic mucosa associates with food allergy of non-IgE type (Table 32.2). Similar association has been reported in adults [39]. Krauss et al. [5] showed that overall increase in the size and number of lymphoid follicles is associated with food allergy in adults, and Carroccio et al. [39] reported that colon lymphoid hyperplasia is present in 35% of adults with wheat and milk sensitivity. A review by Mansueto [4] concluded that LNH is present in 49% (range 32–67) of children with food allergy, and conversely, about 66% (42–90) of patients with LNH have food allergy. In these studies, food allergy was diagnosed based on food challenge-eliminations tests, but not all studies were based on state-of-the-art blinded tests [4]. Skin prick tests and serum IgE-based tests were mostly negative. Response time in food challenge test was long—at least several days. These findings indicate that food hypersensitivity associating with LNH is of non-IgE type and characterized by a slow response times of usually several days.

LNH in other Diseases and Conditions

Chronic mucosal infections manifesting in some cases with local LNH include *H. pylori* gastritis [13, 31]. Giardiasis causes sometimes small intestinal LNH, usually in association with immune deficiency [41]. *Chlamydia* infection causes some cases of rectal LNH cases [15]. In general, intestinal bacterial infections increase the size and number of lymphoid follicles [25].

LNH associates with genetic immune disorders such as common variable immune deficiency (CVID), where LNH develops in about 20% of cases [42]. IgA deficiency is similarly associated with LNH, nodules containing IgM-expressing cells instead of IgA expression [43]. LNH may associate with human immunodeficiency virus (HIV) infection [44].

LNH has been reported in juvenile idiopathic arthritis and connective tissue diseases in the duodenum, ileum and colon, and LNH was associated with increase of intraepithelial lymphocytes [45].

LNH has rarely been described in inflammatory bowel disease, including both ulcerative colitis and Crohn's disease [10]. However, no associations with nucleotide-binding oligomerization domain-containing protein 2/caspase recruitment domain-containing protein 15 gene (NOD2/CARD15) mutations have been detected [46]. Lymphoid hyperplasia has been found in Hirschsprung's disease in the aganglionic segment [47].

There are reports suggesting LNH to be a common abnormality in children with autistic spectrum disorders, but these findings are highly controversial [4].

Symptoms of LNH

Symptoms in children with LNH are listed in Table 32.3. It is not clear what symptoms can be attributed specifically to LNH as there is no consistent pattern, and some patients

Table 32.3 Clinical symptoms commonly reported in pediatric patients examined with gastroduodenoscopy and/or colonoscopy and having nodular lymphoid hyperplasia as an endoscopic finding [3, 4, 6, 8, 35, 48]

Recurrent abdominal pain
Blood in stools
Diarrhea
Constipation
Anaemia
Nausea/vomiting
Growth retardation or weight loss

have no symptoms. It is obvious that conditions underlying or associating with LNH, such as immune deficiency and constipation contribute to symptoms. Part of the diverse set of symptoms resembles those in irritable bowel syndrome. Interestingly, non-coeliac wheat sensitivity in adults [39] and LNH have similar symptom spectrum resembling irritable bowel syndrome, and also share increase of duodenal intraepithelial lymphocytes [19, 39], some abundance of eosinophils (in the colon) and LNH.

Some symptoms may be specifically caused by LNH. Severe LNH in the terminal ileum can lead to invagination (intussusception). Common association of bloody stools and LNH [8, 40, 49] can be mechanistically explained by sensitivity for mechanical damage associated with any elevated mucosal lesion. Kaplan et al. [40] found that LNH in the colon was commonly associated with friability and ulceration. Observations in Crohn's disease have suggested that M cells overlying the lymphoid follicles form the most vulnerable population of surface epithelium [50], but whether M cells in LNH with other conditions are vulnerable is not known.

Treatment and Prognosis

LNH is the manifestation of underlying immune response and not a specific disease. The initiating mechanism should be searched for (Table 32.2), and treatment targeting on the etiology should be considered.

Symptomatic response to elimination diet in delayed type of food allergy associated with LNH has been well documented in both adults and children [8, 49]. No systematic and long-term follow-up studies are available of the development of LNH with or without treatment. Partial regression of LNH has been detected in some follow-up endoscopy studies within a year in cases associated with food allergy and treated with elimination diet [8, 49]. In other studies [6], treatment with elimination diet did not induce any change in the LNH grade, although the numbers of intraepithelial lymphocytes diminished towards normal levels. In adults, treatment seems to decrease the numbers of lymphoid follicles in cases associated with allergy even in cases without full-blown LNH [5].

There is only scanty information of long-term prognosis of LNH. Colon et al. [3] did not detect any long-term consequences in their unselected cases with LNH. However, since incidence rates in adults seem to be much less than children, the overall prevalence of LNH seems to decrease with age and supports the idea that major proportion of childhood cases not associated with immune deficiency are resolved.

Anatomy and Physiology

The pancreas is a large, J-shaped, flattened gland located in the upper left abdomen that secretes digestive enzymes into the duodenum and produces several important hormones as part of the endocrine system. In adults, it is about 15–20 cm long and lies inferior to the stomach, and is surrounded by the small intestine, spleen, gallbladder, and liver [1, 2]. The pancreas is divided into four sections: head, neck, body, and tail. The uncinate process emerges from the head of the pancreas and lies deep to the superior mesenteric artery and vein, which run behind the neck of the pancreas [3].

The pancreas is both an exocrine and endocrine gland. The exocrine pancreas is made up of acinar and ductal cells that produce and transport digestive enzymes, such as amylase, lipase, and trypsin, through a system of small ducts that lead to the pancreatic duct, which runs the length of the pancreas and then combines with the common bile duct carrying bile from the gallbladder proximal to the ampulla of Vater (Fig. 33.1) [1]. Pancreatic enzymes and bile are then secreted into the small intestine and aid in the digestion of carbohydrates, fats, and proteins. The endocrine cells of the pancreas, located in the islets of Langerhans, produce two main hormones, insulin and glucagon, which together control glucose metabolism. The endocrine cells also produce other hormones including somatostatin and pancreatic polypeptide [4–6].

Pathophysiology

Pathological trypsinogen activation has long been considered the hallmark of acute pancreatitis (AP). Following an initial insult, such as ductal disruption or obstruction, cathepsin B activates trypsinogen to trypsin within the acinar cell. Trypsin then activates other pancreatic proenzymes, leading to autodigestion, further enzyme activation, and release of active proteases. Lysosomal hydrolases co-localize with pancreatic proenzymes within the acinar cell. Pancreastasis (similar in concept to cholestasis) with continued synthesis of enzymes occurs. Lecithin is activated by phospholipase A2 into the toxic lysolecithin. Prophospholipase is unstable and can be activated by minute quantities of trypsin [7, 8]. This leads to cell death and AP. After the insult, cytokines and other proinflammatory mediators are released. Most animal models support this mechanism.

The healthy pancreas is protected from autodigestion by pancreatic proteases that are synthesized as inactive proenzymes, which are then segregated into secretory zymogen granules at pH 6.2, by low calcium concentration, which minimizes trypsin activity. Protease inhibitors are present both in the cytoplasm and zymogen granules [5–8]. Enzymes are secreted directly into the ducts lessening exposure of the cytoplasmic contents.

Recently, animal models of AP without associated pathological intracellular trypsinogen activation, as required by the classic theory, have been developed. In these models, intracellular activation of trypsinogen to trypsin plays a role only in early acinar injury. For example, a knockout mouse model of pancreatitis in mice lacking the trypsinogen 7 gene has been developed [8, 9]. These mice develop pancreatitis even though they are unable to activate trypsinogen. In this model, nuclear factor kappa-light-chain-enhancer of activated B cells (NFκB) is activated early in the course of and appears to be the primary driver of the proinflammatory response. Even more recent studies have shown perturbation of mitochondrial permeability and function early in the evolution of experimental pancreatitis [10]. In this model, alco-

hol causes a collapse of the electrical gradient across the mitochondrial permeability transition pore leading to depletion of adenosine triphosphate (ATP) and acinar cell necrosis.

Whatever the true interpretation may be, time-course analysis shows that a burst of electron transfer reactions is associated with the disease initiation [11]. For example, in the experimental model of mild AP produced by excessive stimulation with caerulein, a cholecystokinin (CCK) analog, the spark from reactive oxygen species can be seen by chemiluminescence within 5 min. Simultaneously, there is a huge increase in stress-activated protein kinase. Within 10 min, there is an increase in amylase in the venous outflow of the pancreas. Similarly in endoscopic retrograde cholangiopancreatography (ERCP)-induced AP, analysis of peripheral blood by electron spin resonance spectroscopy identified the burst of reactive oxygen species by the end of the clinical procedure, followed by steep increases in serum levels of amylase, lipase, and trypsinogen.

Histopathologically, interstitial edema appears early. Later, as the episode of pancreatitis progresses, localized and confluent necrosis, blood vessel disruption leading to hemorrhage, and an inflammatory response in the peritoneum can develop. In mild pancreatitis, there is interstitial edema and an inflammatory infiltrate is found. There is no organ dysfunction. In severe pancreatitis, the inflammation is extensive and parenchymal necrosis is present. Multiorgan failure accompanies the inflammation. Following an episode of AP, all histological abnormalities resolve. The factor(s) that determine the severity of an episode of AP are unknown.

Epidemiology

In adults, AP is one of the most common diseases of the gastrointestinal tract and remains a serious disease. In the USA, AP is the most common gastroenterology discharge diagno-

sis accounting for more than 553,000 hospital discharges, 881,000 ambulatory visits, and 3413 deaths a year [12, 13]. The incidence of AP varies between 4.9 and 73.4 cases per 100,000 worldwide.

In pediatrics, it is estimated that 2–13 new cases per 100,000 children occur annually. AP is ranked 14th among causes of death from gastrointestinal and liver diseases in adults [14]. In the last 15 years, studies have shown an increase in the annual incidence of AP. The case fatality rate for AP has decreased over time while the overall population mortality rate has remained unchanged. In adults, mortality from AP is approximately 3% for interstitial pancreatitis and 15% for necrotizing pancreatitis [13, 14]. Almost 20% of children with AP develop a complication, and the mortality rate is approximately 4% despite significant advances in the treatment of this disease [15, 16].

Etiology

In adults, 85% of episodes of AP are due to alcohol and cholelithiasis. In contrast in children, the most common etiologies of AP are as follows: blunt abdominal injuries, biliary stones or microlithiasis (sludging), drug toxicity, and multisystem diseases such as the hemolytic uremic syndrome and inflammatory bowel disease [17–23]. Other cases follow solid organ and stem cell transplantation or are due to infections, anatomic anomalies, metabolic disorders, and mutations in susceptibility genes. Only 10–20% of cases are now considered idiopathic. There is a widely used mnemonic, *Tigar-O*, which stands for toxic-metabolic, idiopathic, genetic, autoimmune, recurrent and severe AP and obstructive.

Trauma Trauma typically due to bicycle handlebar injuries, automobile accidents, and sports injuries is the cause of about 20–40% of episodes of AP [17–23] (Table 33.1). Other traumas include ERCP, child and sexual abuse, surgical injury, and total body cast. Because the pancreas is retroperitoneal and lies across the spine, ductal rupture is not uncommon. Diagnosis may be delayed. Since most patients with abdominal trauma receive a CT scan, injuries may now be detected earlier than before. Following trauma, unsuspected ductal damage can lead to strictures, pseudocyst formation, and chronic obstruction.

Biliary Pancreatitis Biliary obstruction due to lithiasis, sludge, anatomic abnormalities, or ERCP is the etiology in 5–20% of pancreatitis in children (Table 33.2). Anatomic causes of biliary obstruction, such as pancreaticobiliary maljunction (PBM) and pancreas divisum, are increasingly recognized [24, 25]. PBM and congenital dilatation of the biliary tract are more common in Japanese patients than in Western patients. There remains controversy over whether pancreas divisum alone is a cause of pancreatitis. Risk factors for biliary pancreatitis in children include obesity and Hispanic ethnicity.

Drugs and Toxins Drugs and toxins account for 10–20% of children with AP (Table 33.3). In children, valproic acid, L-asparaginase, 6-mercaptopurine, and azathioprine are the most common causes of drug-induced pancreatitis [26]. Recently, azathioprine was successfully reintroduced in four patients with presumed thiopurine-induced pancreatitis [27].

Infectious Agents Since many patients with idiopathic pancreatitis have a viral-like prodrome, it is difficult to determine the true incidence of infection-associated AP (Table 33.4) [17–23]. Case series have found between 2 and 10% of children with AP have a viral cause. This may be an underestimate because many patients with idiopathic pancreatitis may well have infectious causes. A wide variety of infections have been associated with AP, particularly hepatitis A, mumps, and Epstein–Barr virus (EBV) infections.

Genetic Mutations in an increasing number of genes have been shown to cause pancreatitis, the most common being mutations in the *PRSS1*, *CFTR*, and *SPINK1* genes. Genetic causes have been reported in 1–14% of cases [28, 29] (Table 33.5). The incidence may well be higher, since it is uncommon to check for genetic etiologies during the first episode of pancreatitis. *PRSS1* is the gene that causes *hereditary pancreatitis*. Atypical cystic fibrosis may occur in patients with at least one mild mutation in the *CFTR* gene. Patients

with atypical cystic fibrosis and pancreatic insufficiency are at risk for pancreatitis. At the time of a first episode of AP, patients with mutations in these genes will have courses indistinguishable from patients with pancreatitis from other causes. Unless there is a family history of pancreatitis or cystic fibrosis or there are signs of chronicity on imaging studies, genetic testing is not indicated in the first episode of AP.

Systemic and Autoimmune Disease Pancreatitis is well known to be associated with a number of systemic diseases, particularly hemolytic uremic syndrome, sepsis, and shock [17–23] (Table 33.6). The incidence of AP associated with these conditions ranges from 5 to 35% in published series. These cases typically have a course similar to that of pancreatitis from other causes. Autoimmune pancreatitis is rare in children.

Idiopathic In published series, no etiology was found in 12–38% of children with AP [17–23]. As new etiologies were found and as workup became more extensive, newer series have lower rates of idiopathic AP.

Diagnosis

Criteria for the diagnosis of pancreatitis in children have recently been defined by an expert multinational committee as two of three of the following: abdominal pain, serum amylase, and/or lipase activity at least three times greater than the upper limit of normal and imaging findings characteristic of or compatible with AP [30]. These criteria are similar to those used in adults.

Serum lipase is now considered the test of choice for AP, as it is more specific than amylase for acute inflammatory pancreatic disease and should be determined when pancreatitis is suspected. Serum lipase remains elevated longer than amylase after disease presentation. The serum lipase rises by 4–8 h, peaks at 24–48 h, and remains elevated 8–14 days, longer than serum amylase. Serum lipase may also be elevated in non-pancreatic diseases (Table 33.7). Diabetic patients appear to have a higher median lipase compared with nondiabetic patients so an upper limit of normal greater than three to five times may be needed in diabetic patients [13, 31]. The clinical condition of the patient must be considered when evaluating amylase and lipase elevations. However, serum lipase ≥ 7 times the upper limit of normal within 24 h of presentation may be a simple clinical predictor of severe AP in children [15].

Table 33.7 Non-pancreatitis causes of elevated enzymes

Serum lipase	Serum amylase
Acute cholecystitis	Acidosis
Bowel obstruction	Alcoholism
Celiac disease	Appendicitis
Diabetic ketoacidosis	Bowel obstruction/Infarction
Drugs	Celiac disease
Duodenal ulceration	Cerebral trauma
HIV	Cholecystitis
Idiopathic	Cystic fibrosis
Macrolipasemia	Drugs
Pancreatic calculus	HIV
Pancreatic tumors	Idiopathic
Renal Failure	Liver disease
Trauma (including post-ERCP)	Lymphoma
	Macroamylasemia
	Myocardial infarction
	Pancreatic tumors
	Pelvic inflammatory disease
	Peptic ulcers
	Pregnancy
	Renal failure
	Rheumatoid arthritis
	Trauma
	Ulcerative colitis

In AP patients, serum amylase usually rises within a few hours after the onset of symptoms and return to normal values within 3–5 days. Serum amylase may remain normal in up to 20% of patients, especially in alcohol-induced AP and hypertriglyceridemia [31]. A variety of conditions may also cause hyperamylasemia without pancreatitis, such as macroamylasemia (Table 33.7).

Other laboratory abnormalities that may be present in AP include hemoconcentration, manifested by high hemoglobin and blood urea nitrogen (BUN), coagulopathy, leukocytosis, hyperglycemia, glucosuria, and hypocalcemia. Elevated γ -glutamyl transpeptidase and hyperbilirubinemia suggest the diagnosis of cholelithiasis or choledocholithiasis [13, 31].

X-ray of the chest and abdomen may also be obtained and demonstrate nonspecific findings. The chest X-ray might show atelectasis, basilar infiltrates, elevation of the hemidiaphragm, left-sided (rarely right-sided) pleural effusions, pericardial effusion, and pulmonary edema. Abdominal X-rays might demonstrate a sentinel loop of intestine, dilation of the transverse colon (cutoff sign), ileus, pancreatic calcification (if recurrent), blurring of the left psoas margin, a pseudocyst, ascites, and peripancreatic extraluminal gas bubbles [13, 31, 32].

Transabdominal ultrasound should be performed on all patients with AP, when gallstones are suspected. Abdominal imaging is useful to confirm the diagnosis of AP, but the routine use of CT is not recommended during the first week because it has low yield and rarely alters clinical management [13, 32, 33]. However, if a patient is not improving after 1 week, CT or magnetic resonance imaging (MRI) of the pancreas is recommended to assess for local complications (Fig. 33.2). CT and/or MRI of the pancreas are also recommended in patients in whom the diagnosis is unclear. CT has over 90% sensitivity and specificity for the diagnosis of AP. Ultrasonography is more sensitive than CT scanning for the diagnosis of biliary stones [13, 33].

Fig. 33.2 Ultrasound of the same patient showing a hypoechoic and edematous pancreas (arrow). (Images courtesy of Dr. David Gregg)

Magnetic resonance cholangiopancreatography (MRCP) and ERCP are essential in the investigation of known or suspected pancreatic duct disruption, lithiasis, recurrent and nonresolving pancreatitis, and disease associated with gallbladder pathology, but have a lesser role in AP [34, 35]. Although there is limited pediatric data, endoscopic ultrasonography has been shown to be helpful in the drainage of fluid collections in children [36].

Clinical Presentation

Although there have been a number of attempts to develop a scoring system for AP, there is no validated scoring system for children with AP [16, 37]. A recent report suggests that a serum lipase >7 times the upper limit of normal within 24 h of admission predicts a severe course [38]. This still needs to be validated. Thus, reliable prediction of the course of an episode of AP is not possible.

Several new classification systems have been proposed for use in adults. None have been tested in children. Most episodes of AP in children are mild and self-limiting, defined by the absence of organ failure and/or pancreatic necrosis (local complications) [39]. These patients resolve their symptoms rapidly [15] and are usually discharged within 1 week, and mortality is rare [13].

Patients with moderately severe AP may have transient organ failure, local complications, and/or systemic complications. The morbidity and mortality are higher compared to that of mild AP. However, the mortality is considerably less than that of severe AP [13, 39, 40]. Depending on the complications, patients may require prolonged hospitalization because of the local or systemic complications.

Severe AP is defined as AP complicated by persistent organ failure and/or death and occurs in 15–20% of patients [13, 39, 40, 41]. Patients with severe AP usually have one or more local and/or systemic complications. Of note, patients with severe AP that develops within the early phase (first week) have a 36–50% risk of death [13]. Development of infected necrosis later in the course of the disease in patients with severe AP also has an extremely high mortality [42].

For practical purpose, we define here severe pediatric pancreatitis as requiring pediatric intensive care unit (PICU) admission. Severe AP has been infrequently reported in children; however, the outcome may be better than in adults.

Mild AP

The patient with AP has abdominal pain, which may be severe. Some patients have persistent vomiting and possibly fever. The pain is epigastric or in either upper quadrant. The child often lies with hips and knees flexed lying on the side.

The abdomen may be distended and tender, and a mass may be palpable. The patient usually appears extremely uncomfortable, irritable, and may look ill or toxic. The pain can increase in intensity for 24–48 h, during which time vomiting may increase and the patient might require hospitalization for dehydration and may need fluid and electrolyte therapy. Pain described as dull, colicky, or located in the lower abdomen is not consistent with AP and suggests other etiologies. The prognosis for complete recovery in the acute uncomplicated case is excellent [13, 15, 28, 31, 39, 40].

Severe AP

In adults, 15–20% of cases of pancreatitis are defined as severe, and these have a mortality rate of about 15%. Fortunately, severe AP is less common in children than in adults [16]. In this life-threatening condition, characterized by multiorgan failure lasting more than 48 h, the patient is acutely ill with severe nausea, vomiting, and abdominal pain [13, 15, 28, 31, 39, 40]. A bluish discoloration may be seen around the umbilicus (Cullen's sign) or in the flanks (Grey Turner's sign) [31, 43]. Pancreas necrosis may develop between the second and fifth week of illness. Infected necrosis may develop during the second week and a pancreatic abscess as late as the fifth week of illness. Infection is suspected when there is persistent pain and fever.

Mortality is related to the systemic inflammatory response syndrome (SIRS) with multiple organ dysfunction, shock, renal failure, acute respiratory distress syndrome, disseminated intravascular coagulation, massive gastrointestinal bleeding, and systemic or intra-abdominal infection [44]. In adults, the percentage of necrosis seen on CT scan and failure of pancreatic tissue to enhance on CT scan (suggesting necrosis) predicts the severity of the disease [13, 39].

There are now two defined, distinct phases of severe, acute pancreatitis, which overlap: the early phase, which usually lasts only 1 week or so, and the late phase, which can persist for weeks to months. The early phase is characterized by the systemic inflammatory response syndrome and/or the compensatory anti-inflammatory syndrome (CARS), which can predispose to infection. The late phase is characterized by the persistence of systemic signs of ongoing inflammation, the presence of local and systemic complications, and/or transient or persistent organ failure. Local complications include peripancreatic fluid collections, pancreatic and peripancreatic necrosis, pseudocysts, and walled-off necrosis. By definition, the late phase occurs only in patients with moderately severe or severe AP [39, 40, 44] (Fig. 33.3).

Fig. 33.3 Late acute pancreatitis in the same patient CT scan demonstrates necrotic non-enhancing distal pancreas (a). The pancreatic head is relatively normal (b). There is a large amount of peripancreatic fluid. (Images courtesy of Dr. David Gregg)

Treatment

The aims of medical management are to relieve pain and restore metabolic homeostasis. Analgesia should be given in adequate doses. A recent Cochrane review stated that opioids may be an appropriate choice for AP pain in adults and may decrease the need for supplementary analgesia [45]. They found that opioids did not increase the risk of pancreatitis complications or significant adverse events. Fluid, electrolyte, and mineral balance should be restored and maintained.

In *mild AP*, nasogastric (NG) suction is needed infrequently but is useful in patients who have significant vomiting. While vomiting, the patient should be maintained with nothing by mouth. Refeeding can commence when vomiting has resolved. Early refeeding decreases the complication rate and length of stay [46]. While traditional, there are no data to support the use of a low-fat diet. It is not necessary to follow laboratory tests such as the serum lipase daily. Recovery is usually complete within 4–7 days.

In *severe pancreatitis*, fluid resuscitation in the first 24 h is critical [47]. Lactated Ringer's solution is the fluid of choice. Intravascular fluid losses due to third spacing and losses through an NG tube can rapidly lead to dehydration and cardiovascular instability. So not only is volume expansion important but also maintenance of intravascular volume is critical.

Narcotic analgesia is given as needed. Antibiotics are used to treat infected necrosis but prophylactic antibiotics are not recommended. Infected necrosis does not occur until the second week of pancreatitis [48]. Gastric acid is suppressed.

Endotherapy can be of benefit when pancreatitis is caused by anatomic abnormalities, such as strictures or stones [49]. The endoscopist can dilate the sphincter of Oddi and extract impacted biliary tract stones. This is especially important when the patient has developed cholangitis.

There are no published guidelines or studies relating to nutritional support of the child with AP. A recent Cochrane review concluded that “There is little evidence to support or refute the need to provide nutrition to critically ill children in a pediatric intensive care unit during the first week of their critical illness” [50]. A recent review supported early nutritional therapy in AP [51].

Early enteral alimentation is begun, whether by mouth, nasogastric tube, or nasojejunal tube (in patients intolerant to oral or nasogastric feedings). When initiated within 2–3 days of onset of pancreatitis, enteral feeding reduces the length of hospitalization and complication rate and increases survival in adult patients with severe AP. Supplemental parenteral nutrition may be needed in some patients

Measurement of gastric residuals is of limited value and should be discouraged. Residual volume relates to infusion rate. High residuals are common early in enteral nutrition. Gastric distension may be from gas-filled loops of bowel. A rise in serum amylase and lipase is typically associated with enteral feeding. These rises do not imply worsening of the pancreatitis and are not the reasons to stop enteral nutrition.

When a patient has persistent fever in the second week of illness or who develops fever later, a CT scan is required [13]. When necrotic tissue is seen, fine-needle aspiration and culture are indicated [13]. The use of antibiotics in sterile necrosis is not recommended. Antibiotics of choice for infected pancreatic necrosis and abscess are those that are known to penetrate the pancreas, including carbapenem, quinolones, and metronidazole [13].

In *traumatic pancreatitis*, surgery is frequently required. In children, surgical therapy of nontraumatic, AP may include drainage and resection of necrotic material or abscesses. In stable patients, surgery is deferred at least 2–4 weeks to allow differentiation between necrotic and viable tissue [13]. In gallstone pancreatitis, it is recommended that cholecystectomy be performed before hospital discharge to prevent recurrent episodes [13].

Complications

Most children with acute uncomplicated pancreatitis will do well and recover within 4–7 days. However, about 20% of children with AP will develop a complication, which may prolong the hospital stay or require intervention [15]. Complications are divided into local and systemic. Local com-

plications include acute peripancreatic fluid collections, pancreatic pseudocysts, acute necrotic collections, walled-off necrosis, splenic/portal vein thrombosis, colonic necrosis, retroperitoneal hemorrhage, and gastric outlet dysfunction. Local complications should be suspected when there is persistent abdominal pain, fever/chills, or organ failure and should prompt cross-sectional imaging to search for these complications [13, 39, 40]. Acute peripancreatic fluid collections are not associated with necrotizing pancreatitis, remain sterile, and usually resolve without intervention. However, if the fluid collection persists more than 4 weeks, it is likely to develop into a pancreatic pseudocyst. A pancreatic pseudocyst is a peripancreatic or intrapancreatic fluid collection or collections surrounded by a well-defined wall, and contains no solid material. Acute peripancreatic fluid collections and acute necrotic collections occur within the first 4 weeks of AP, while pancreatic pseudocysts and walled-off necrosis usually arise more than 4 weeks after the onset of AP [39, 40].

Systemic complications include *de novo* occurrence of renal, circulatory, or respiratory organ failure or exacerbation of serious preexisting comorbidities related directly to the AP. Systemic complications occur from the systemic inflammatory response to AP, and may be further exacerbated by the need for fluid resuscitation [39, 40, 44].

Future

Over the past 15 years, as the incidence of AP has risen, the percent of children with idiopathic AP has decreased as more etiologies, such as genetic causes, have been identified, as ERCP has become more available for children, and as new technologies such as MRCP and endoscopic ultrasound have been developed. Greater understanding of the pathophysiology of pancreatitis has led to improvement in therapy such as early introduction of enteral feeding and rapid fluid resuscitation in severe pancreatitis

Since there are no controlled studies on any aspect of the treatment of AP in children, nearly all the current recommendations are based on publications describing adults. Particular areas in need of investigation include fluid resuscitation, use of antibiotics, nutrition, that is, when to begin enteral feeds and the risks and benefits of endoscopic ultrasound.

While there are a number of validated scoring systems for the prediction of severity in adults, there is no such validated scoring system for children. The development of a scoring system is important so that patients who are predicted to develop severe pancreatitis can be transferred early to a facility with a pediatric critical care unit, while those predicted to have mild disease can be treated at local hospitals.

Etiology

In general, the TIGAR-O (*Toxic-metabolic, Idiopathic, Genetic, Autoimmune, Recurrent and severe acute pancreatitis, Obstructive*) classification described in adults [7] also applies to pediatrics (Table 34.1) [8]. Alcohol and smoking are commonly associated with CP in adults in Western countries [9, 10], but not in children. Idiopathic causes most likely comprise a large percentage of pediatric patients with CP. Genetic causes include cationic trypsinogen or *PRSSI* mutations; mutations in cystic fibrosis transmembrane conductance regulator (*CFTR*) and pancreatic secretory trypsin inhibitor (PSTI), also known as serine protease inhibitor, Kazal type I (*SPINK1*), form another large group (see Sect. “Genetic Testing”) [11, 12]. Among children with acute recurrent or chronic pancreatitis (CP), a predominantly genetic etiology was reported in Korean (47% *PRSSI* or *SPINK1*) [13], Italian (39.6%, *CFTR*, *SPINK1*, and/or *PRSSI*) [14], Polish (33.6%, *PRSSI* and *SPINK1*) [15], and ultrasonography (US) children (79% *CFTR*, *PRSSI*, and/or *SPINK1*) [16]. The association of carboxypeptidase-1 (*CPA1*) gene variants in children with CP < 10 years of age [17] and carboxyl ester lipase (*CEL*) mutations leading to CP and diabetes at a young age causing *CEL* maturity-onset diabetes of the young (*CEL-MODY*) [18] highlights the importance of genetic factors in CP.

Pathophysiology

The pathophysiology of CP is incompletely understood. The pancreas is not easily accessible for sampling; therefore, it is difficult to detect the earliest changes and identify the events that contribute to the pathophysiology of CP. In children with hereditary pancreatitis (HP), mutations in the cationic trypsinogen (*PRSSI*) gene cause activation of trypsinogen within the acinar cells as an early event in pancreatitis [19]. Premature activation of trypsinogen to trypsin initiates an activation cascade, causing additional trypsinogen activation and conversion of other digestive proenzymes to active enzymes, leading to pancreatic digestion and inflammation [11].

A widely accepted hypothesis is that CP begins with an episode of acute pancreatitis (AP), followed by an ongoing chronic or recurrent inflammation that leads to fibrotic replacement of acini and islet cells [1]. In the sentinel acute pancreatitis event (SAPE) hypothesis [20], a metabolic or oxidative stress initiates the first episode of AP (the sentinel event). Activated lymphocytes, macrophages, and stellate cells increase in number within the pancreas, and then produce cytokines and deposit small amounts of collagen. Most patients recover uneventfully from AP, and the pancreas returns to normal. In some patients, due to the continued presence of stress, inflammatory cells and stellate cells remain active, release cytokines, and deposit collagen, eventually producing the fibrotic changes characteristic of CP. Although the process may be started and perpetuated by environmental factors, other factors (i.e., genetic) must be present for CP to develop in some individuals and not others.

Diagnosis

Clinical Presentation

Abdominal pain is the most common symptom of CP. Pain is usually in the upper abdomen, episodic or persistent, mild–moderate to severe. Older children describe the pain as deep

and penetrating, radiating to the back, and worse after meals. Younger children cannot verbalize the pain well, so clinicians must have a high index of suspicion in this age group [21]. Commonly, younger children may be misdiagnosed as having other gastrointestinal (GI) illnesses, such as gastroesophageal reflux, constipation, or functional abdominal pain. Nausea and/or vomiting, anorexia, weight loss may be present.

Children with HP usually present with recurrent episodes of abdominal pain and symptom-free intervals [11]. The acute attacks may be triggered by a fatty meal, stress, or environmental factors such as infection, smoking, and alcohol use. Median age of presentation for HP is 10 years of age, and in 50% of patients, CP develops 10 years after the first bout of AP [22]. Some patients may present with CP without a clear history of AP [23].

The pancreas has extraordinary reserves and does not manifest signs of insufficiency until lipase secretion is reduced to less than 5% of the maximum output [24]. In adults, exocrine pancreatic insufficiency (EPI) occurs in 50–80% of patients in a median time of 5.6–13.1 years [25, 26].

Diabetes mellitus can also occur in 40–70% of adults with CP with a median time to onset of 11.9–26.3 years [25, 26]. The exact mechanism of pancreatic diabetes is unknown, but islet destruction is a late phenomenon. The exocrine and endocrine insufficiencies in pediatric CP are also incompletely studied.

If EPI has developed, symptoms of maldigestion/malabsorption, such as weight loss and steatorrhea, may be present. Fat-soluble vitamin deficiencies (A, D, E, K) can be seen. Patients with extrahepatic biliary obstruction from fibrosis in the head of the pancreas or from the pseudocyst can have jaundice. Physical examination is usually normal.

There is a lifetime risk for pancreatic adenocarcinoma in patients with CP (4%) [27], and the risk is much higher in patients with HP (~40%) [28].

Differential Diagnoses

The differential diagnosis of CP includes causes of recurrent and chronic abdominal pain in childhood, such as peptic ulcer disease, gastritis, gallbladder disease, intestinal obstruction, Crohn's disease, functional abdominal pain, lactose intolerance, and constipation. For the differential diagnosis of malabsorption in the presence of EPI, one should consider severe enteropathies, cholestatic liver disease, celiac disease, cystic fibrosis (CF), and rare isolated pancreatic enzyme deficiencies.

Diagnostic Testing

The INSPPIRE (*IN*ternational Study Group of *P*ediatric *P*ancreatitis: *In* search for a *cuRE*) definitions of CP require one of the following: (1) abdominal pain consistent with pancreatic origin and imaging findings suggestive of chronic pancreatic damage, (2) evidence of EPI and imaging findings suggestive of pancreatic damage, or (3) evidence of endocrine pancreatic insufficiency and imaging findings suggestive of pancreatic damage, or (4) a surgical or pancreatic biopsy demonstrating histopathology compatible with CP [15] (Table 34.2).

These lab tests and abbreviations look out of place. May be they should go to a an abbreviation section. According to INSPPIRE criteria, suggestive imaging findings of CP or chronic pancreatic damage include:

Table 34.2 Diagnostic tests in chronic pancreatitis

Laboratory tests (serum amylase, lipase, Ca, lipid panel, total and direct bilirubin, alkaline phosphatase, GGT, AST, ALT, fasting serum glucose)
Fecal elastase 1
72 h fecal fat
Sweat CI/NPD
Imaging studies (US, CT, MRCP, EUS, ERCP)
Genetic testing (<i>PRSSI</i> , <i>CFTR</i> , <i>SPINK1</i> , <i>CTRC</i>)

- Ductal changes: irregular contour of the main pancreatic duct or its radicals; intraductal filling defects; calculi, stricture, or dilation;
- Parenchymal changes: generalized or focal enlargement, irregular contour (accentuated lobular architecture), cavities, calcifications, heterogeneous echotexture.

Imaging modalities may include CT, MRI/magnetic resonance cholangiopancreatography (MRCP), endoscopic retrograde cholangiopancreatography (ERCP); US; endoscopic US (EUS ; in which at least five EUS features (as defined by the Rosemont Classification [29] must be fulfilled)).

EPI is recommended to be diagnosed via fecal elastase-1 monoclonal assay <100 mcg/g stool (two separate samples done ≥ 1 month apart) or coefficient of dietary fat absorption $<90\%$ on a 72-h fecal fat collection. Neither test should be performed during an AP episode, as the results may be temporarily low.

Endocrine pancreatic insufficiency can be diagnosed via 2006 WHO criteria for the diagnosis of diabetes mellitus (fasting glucose ≥ 7.0 mmol/L (126 mg/dL) or plasma glucose ≥ 11.1 mmol/L (200 mg/dL) 2 h after glucose load 1.75 g/kg children (to maximum 75 g glucose load)) [30].

Biochemistry

There are no specific laboratory tests for CP. In most cases, serum amylase and lipase are normal or only mildly elevated [31]. Aspartate transaminase (AST), alanine transaminase (ALT), GGT, alkaline phosphatase, and direct bilirubin are useful to rule out a biliary obstruction.

Radiology

Diagnostic imaging plays an important role in the initial diagnosis of CP and further planning for endoscopic and surgical interventions. The imaging modalities most commonly used in pediatric pancreatitis are summarized below.

Ultrasonography US is usually the first imaging modality when pancreatitis is suspected in children. Smaller size of patients, lack of fat, and prominence of the left hepatic lobe make US of the pancreas more feasible in children than in adults [32]. US is 50–80% sensitive in diagnosing CP in adults; the diagnostic accuracy of US in pediatric CP has not been studied [4]. US is most helpful in assessing the pancreatic duct diameter in children with CP (normals are ≤ 1.5 mm in children 1–6 years; ≤ 1.9 mm at ages 7–12 years; ≤ 2.2 mm at ages 13–18 years). Calcifications of the pancreas and intraductal stones can also be observed with US in CP [32].

Endoscopic US The high diagnostic accuracy and the low complication rate of EUS (1%) compared to ERCP have been the driving forces for the use of EUS [32]. EUS is technically feasible in children as young as 5 years of age [33],

Fig. 34.1 MRCP changes in chronic pancreatitis. T1-weighted image shows atrophy of the parenchyma in a child with idiopathic chronic pancreatitis (arrows). (Photo courtesy of Dr. Simon C. Kao, University of Iowa, USA)

but most of the experience comes from the adult literature, and very little is written in pediatrics [34]. EUS is highly operator dependent, and even in adults there is controversy regarding its accuracy and reliability. EUS images are commonly scored based on the presence of parenchymal and ductal features. An expert consensus conference was convened in 2009 to address the controversies and developed the Rosemont classification [29]. The Rosemont criteria for CP diagnosis have not been validated in children.

Magnetic Resonance Cholangiopancreatography MRCP can visualize the pancreas, pancreatic ducts, and the pancreaticobiliary tree and reliably detect pancreas atrophy, ductal dilatations, small filling defects, strictures, irregularities of the main pancreatic duct, and irregularity (sacculation and/or ectasia) of side branches [35] (Fig. 34.1). Due to its non-invasive nature and lack of radiation, MRCP has become the diagnostic test of choice in children with CP [36, 37]. Unlike ERCP that images ducts under pressure, MRCP visualizes the ducts in their normal physiologic state [32]. Therefore, MRCP may not reveal the details of small ducts, which may be important in diagnosing early CP.

Secretin induces fluid secretion in the pancreatic duct, and when administered with MRCP, it increases the diameter of pancreatic duct up to 3 mm in 3–5 min with progressive decline to baseline in 10 min. Secretin may be more important in children than in adults as it increases the detectability of the normally smaller pancreatic ducts. In a pediatric study, secretin increased the number of main pancreatic duct segments visualized on MRCP from 53 to 93%; the visualization of the duct of Santorini increased from 7 to 53% and the detection of side branches increased from 20 to 47% [38]. Secretin may also increase the number of false-positive reports [39]. In one pediatric study, the pancreatic diameter increase after secretin was small and did not have any impact on image quality or duct visibility of the MRCP [40]. More

Fig. 34.2 ERCP changes in chronic pancreatitis. **a** Dilatation of the mid and distal portions of the pancreatic duct in a child with idiopathic chronic pancreatitis (arrows). **b** Dilatation of pancreatic duct with multiple filling defects (stones, arrowheads) in the distal pancreatic duct in a child with hereditary pancreatitis (R122H mutation). A pancreatic duct stent (arrow) has been placed to bypass the obstruction. (Photo courtesy of Dr. Simon C. Kao, University of Iowa, USA)

studies with secretin-enhanced MRCP are needed to better understand its diagnostic accuracy in pediatric CP.

Endoscopic Retrograde Cholangiopancreatography With MRCP being widely available, ERCP is now mainly reserved for therapeutic interventions (pancreatic duct stenting, sphincterotomy, stone extraction). ERCP carries an overall morbidity of ~7%, which includes AP (4%), hemorrhage (1%), cholangitis (1%), perforation (0.5%), and death (0.1%) [41]. In CP, ERCP findings include main pancreatic duct dilatation, ductal stones, and changes in the main duct branches and small ducts (Fig. 34.2). ERCP is no longer an attractive first-line test because of its potential complications and low sensitivity for detecting early-stage CP.

An ERCP-based grading system of CP has been developed in adults (Cambridge classification) for the classification of disease severity. Changes are graded as normal, equivocal, mild, moderate, and severe, based on the appearance of the main pancreatic duct and side branches on the ERCP. Interpretation is subjective and there can be substantial inter- and intraobserver variation. The Cambridge classification has not been validated in children [42].

Computerized Tomography (CT) with Contrast CT can detect advanced changes in CP, such as calcification, gland atrophy, fat replacement, and ductal dilatation. The advantage of CT is that it can evaluate pancreas for other pathology and detect other causes of chronic abdominal pain. CT has poor sensitivity to identify ductal abnormalities and subtle parenchymal changes; high radiation dose is another drawback [4, 43].

Genetic Testing

Genetic testing is indicated as a diagnostic test in children with CP to determine the underlying cause. Predictive testing is not recommended in individuals without pancreatic disease and a positive family history of pancreatitis. The presence of *PRSS1* mutation provides an adequate etiology for pancreatitis, but the presence of *CFTR* or *SPINK1* mutations should not preclude a careful search for additional etiologies.

Cationic Trypsinogen (*PRSS1*) UniGene name: protease, serine 1: *PRSS1* gene was the first pancreatitis-specific susceptibility gene identified in families with HP [19]. In the physiological state, trypsinogen is converted to trypsin in the duodenum by the brush border-derived enterokinase. Trypsin will then activate other proteases, which will initiate intraluminal digestion of nutrients. A total of 80–90% of individuals with HP, an autosomal dominant disease with incomplete penetrance, carry R122H mutation [19, 22]. This mutation is caused by the substitution of the amino acid histidine (H) for arginine (R) at position 122 (R122H) of the cationic trypsinogen gene. Another mutation, N29I, is caused by substitution of isoleucine (I) for asparagine (N) at position 29. R122H and N29I are the most common mutations seen in patients with HP [44]. Genetic defects in *PRSS1* result in gain of function either by increasing activation or by preventing inactivation of trypsin, leading to pancreatic autodigestion.

Genetic testing for *PRSS1* mutations is recommended in patients with recurrent attacks of AP and CP of unknown etiology or a positive family history of pancreatitis in first-degree or second-degree relatives.

CFTR Pancreatitis occurs in 2–4% of all patients with CF and 15–20% of pancreatic-sufficient patients with mild *CFTR* mutations during adolescence or later in life [45, 46]. Pancreatitis is thought to result from thick secretions causing pancreatic ductular obstruction, ineffective clearing of secretions from the pancreatic duct, and autodigestion of the pancreas by activated proteolytic enzymes [11].

Patients with idiopathic CP carry a higher frequency of *CFTR* mutations (~10%) than the general population, and a subset of these patients have CF (~20%) [47–50]. *CFTR* mutations may also contribute to the development of CP in patients who have additional risk factors for CP [51].

There are over 1900 *CFTR* mutations, and only a small percentage are CF-causing mutations.

The majority of mutations (~40%) have unknown functional consequences, others confer less severe disease, and the rest are considered to be benign polymorphisms with no pathogenic potential [52, 53]. Therefore, in a patient with recurrent attacks of AP or CP and *CFTR* mutations, sweat test is still the first test to order. A referral to a CF clinic can

be made if sweat chloride is borderline (40–59 mmol/L) or abnormal (≥ 60 mmol/L). Nasal potential difference (NPD) testing can also be helpful in measuring CFTR channel function in patients with recurrent attacks of pancreatitis [54].

SPINK1 Synthesis of PSTI, which is coded by the *SPINK1* gene, protects against premature activation of trypsin within the pancreas before it is secreted into the duodenum [20]. Mutations in the *SPINK1* gene (mainly N34S mutation, substitution of asparagine by serine at codon 34 in exon 3) increase the susceptibility to AP and predisposes to CP [55, 56]. Interestingly, the risk of an asymptomatic *SPINK1* carrier developing pancreatitis is thought to be only 1%. Therefore, *SPINK1* mutations alone are not sufficient to cause pancreatitis, but may act as genetic modifiers in initiating the development of pancreatitis [56].

Chymotrypsin-C *CTRC* is involved in the degradation of trypsin. Mutations in the *CTRC* gene alter its function and predispose patients to pancreatitis by diminishing its protective trypsin-degrading activity. *CTRC* mutations have been shown to be associated with CP in the European and Asian populations [57–59].

Exocrine Pancreatic Function Testing

These tests can detect CP in its most advanced stage, when EPI has developed. They are not specific for CP as they can be abnormal in patients with other causes of EPI (CF, Shwachman–Diamond syndrome, etc).

Pancreatic Stimulation Test This test involves the collection of pancreatic fluid secreted into the duodenum and measurement of fluid volume, pancreatic enzymes, and electrolytes before and after stimulation with cholecystokinin (CCK) and secretin [60]. Although it is considered “gold standard” to quantify the exocrine pancreatic function, stimulation test is not widely performed because of its invasive nature. The collection of the duodenal fluid via the endoscope (endoscopic pancreatic function test or ePFT) has been proposed as an alternative, but this approach may underestimate the pancreatic secretory capacity and classify patients as pancreatic insufficient erroneously [60].

72-h Fecal Fat Collection This test relies on the exocrine pancreas losing greater than 95% of its enzyme secretory output and development of steatorrhea [24]. Steatorrhea can be measured by a 72-h stool collection and calculation of coefficient of fat absorption (CFA: (grams of fat ingested–grams of fat excreted)/(grams of fat ingested) $\times 100$). In children younger than 6 months of age, a fecal fat greater than 15% of fat intake is considered abnormal; this value is 7%

for children over 6 months of age. This test is not very reliable and reproducible. It is not a popular test by the families or the technical staff. The sample and the data collection are not always accurate.

Fecal Elastase-1 (FE1) This enzyme-linked immunosorbent assay (ELISA)-based method is easy to use, cheap, and now the preferred test to diagnose EPI. A value of less than 100 $\mu\text{g/g}$ is considered diagnostic of EPI. Intermediate values of fecal elastase (100–200 $\mu\text{g/g}$) may be due to loss of pancreatic function, but not severe enough to cause clinical EPI. The sensitivity of FE1 to diagnose moderate and severe EPI is close to 100%. In patients with mild loss of pancreatic function, the test sensitivity is $\sim 25\%$ with a specificity of 96% [61]. Therefore, the value of FE1 to determine patients with mild EPI or borderline normal pancreatic function is limited. FE1 may be falsely low when the stool is diluted as a result of infectious diarrhea, severe enteropathies, short gut, or if it is collected from an ileostomy.

Secretin MRCP The pancreatic exocrine function can be assessed by the duodenal filling, changes in pancreatic duct caliber, change in anteroposterior diameter of the pancreas, and change in signal intensity ratio between pancreas and spleen on T1-weighted and arterial–venous enhancement ratios [62, 63]. The results show correlation with other exocrine pancreatic tests including ePFT [63] and fecal elastase [64]. The test has not been validated in children.

Treatment

Medical Treatment

For children presenting with an acute attack of pancreatitis, we recommend conservative management, withholding food and drink for a few days, and offering pain control. In patients with advanced disease, the treatment is directed at the complications, including chronic pain, EPI, and diabetes mellitus.

Pain Control

Analgesic medications are the mainstay of pain management. There are no prospective therapeutic trials of pain management in children; thus, the practice is guided by common practice and expert opinion. Nonsteroidal anti-inflammatory drugs and acetaminophen are the first-line agents for pain control. Long-acting and short-acting narcotics can be used in a stepwise approach. The addictive profile of narcotics and their GI side effects should be considered when initiating the therapy. Tramadol and gabapentin have shown efficacy in controlling pain in adults with CP [65].

Pancreatic Enzyme Supplementation

Pancreatic enzymes are often prescribed theoretically to reduce the feedback loop in the duodenum by reducing the CCK release and inhibiting pancreatic exocrine activation. Current evidence on the effect of pancreatic enzymes on pain control is conflicting because of methodological issues and types of preparation (enteric-coated vs. nonenteric-coated tablets) [4]. Some early studies reported benefit with non-enteric-coated preparations [66, 67], while enteric-coated preparations did not work [68, 69] possibly because the release of nonenteric-coated enzymes and feedback inhibition of pancreatic enzymes were more proximal than distal in the intestine. A recent Cochrane review evaluated the efficacy of pancreatic enzymes in patients with CP [70]. Although some individual studies reported a beneficial effect of pancreatic enzyme over placebo in improving pain, incidence of steatorrhea, and analgesic consumption, the results of the studies could not be pooled for these outcomes. Overall, the role of pancreatic enzymes in CP was reported to be equivocal.

Antioxidant Therapy

Antioxidants have been evaluated for the treatment of chronic pain in CP. Results are not convincing, and all studies have methodological issues. A randomized and placebo-controlled study showed that the antioxidant therapy was superior to placebo in treating pain in adults with CP [71]. In another study, the administration of antioxidants to patients with painful CP did not reduce pain or improve quality of life, despite causing a sustained increase in blood levels of antioxidants [72]. Further studies are needed to evaluate the utility of antioxidants in pediatric CP.

Endoscopic Interventions

Because of radiation exposure, potential complications, and wide availability of MRCP, ERCP should be reserved for interventions, such as stone removal or stricture management, as it is recommended in adults [73]. Endoscopic therapy may be useful if there is an identifiable stricture with evidence of pancreatic duct obstruction [74, 75]. In patients with gallstone pancreatitis and cholangitis, ERCP is indicated within 24 h, and within 72 h if there is a high suspicion of persistent common bile duct stone. Endoscopic sphincterotomy in the absence of choledocholithiasis at the time of the procedure is a reasonable therapeutic option, but data supporting this practice are lacking [76, 77].

ERCP can be done successfully in over 90% of children [78]. Sphincterotomy with or without stone extraction is carried out in 45% of ERCPs in children. In a small pediatric study, children were evaluated with ERCP for recurrent acute and CP; in 52% of patients, ERCP altered the therapy [79]. In a pediatric study, the majority of children with pancreas divisum and CP had resolution of symptoms and did not require surgery following placement of a pancreatic duct stent [80].

Surgery

In adult patients with CP, the main indication for surgery is the chronic, debilitating pain. Pediatric data are sparse, and the decision to operate is based on the experience in adult patients with CP. Surgical techniques include drainage operations that aim to decompress dilated ducts or resections of strictures and removal of pancreatic stones. Even in large referral centers, less than one pediatric patient undergoes surgery for CP every year [81–83]. In general, decompressive operations are favored over resections in the pediatric age groups [84]. In the majority of cases, a Puestow-type procedure (longitudinal pancreatojejunostomy that involves opening the pancreatic duct throughout the body and tail of the gland) has been used. Ductal strictures can also be excised, and pancreatic stones can be removed during this operation. Frey and Whipple procedures are usually associated with high mortality and morbidity and rarely needed [4].

Total pancreatectomy with islet cell autotransplantation (TP/IAT) is being proposed as a treatment for CP. TP removes the entire pancreas and presumably the source of pain and potential cause of cancer. By removing the pancreas, this surgery also predisposes the patient to brittle diabetes. TP/IAT is done mainly in adults, but recently being performed in children in increasing numbers. Therefore, the experience and the data in the literature about this procedure in children are limited.

Most of the studies with TP/IAT in children are from a single pediatric center. Approximately 60% of children were off narcotic medications and insulin independent at a median time of 2 1/2 year follow-up [85], and quality of life was improved at 1 year [86]. Children with prior surgical drainage procedures (Puestow) appeared to have lower yields of islets and greater incidence of insulin dependence after TP/IAT [86, 87], which led the authors to propose this surgery to be done early in the course of CP in children and to avoid any prior drainage procedures to maximize the number islets available. In a study from another center, of 14 children who underwent TP/IAT for CP, 79% were narcotic independent and 29% were insulin independent at an average of 9 months, and the quality of life was significantly improved in all patients [88]. In this study, a previous operation did not have any impact on the islet yield from the pancreas [88]. More studies and longer-time follow-ups are needed to determine whether TP/IAT is effective in treating pain in pediatric patients with CP.

Conclusion

Pediatric CP continues to be an enigma. Currently, our knowledge of pediatric CP is limited to the experience in adult data, local experience, and expert opinions. It is likely that the CP in children has unique features, and it is completely different than the adult disease. Currently, there is an

international effort (the INSPPIRE study) to better understand pediatric pancreatitis [3, 89]. We recommend vigilance in the diagnosis of CP in children, especially in the setting of chronic abdominal pain and the family history of pancreatitis. With better understanding of the epidemiology, etiologies, natural history, and outcome of CP in childhood, we can begin to develop better diagnostic and therapeutic strategies for this disease.

Introduction

Fecal microbial transplantation (FMT), also known as fecal bacteriotherapy or stool transplant, is the transfer of a fecal suspension from a healthy donor into the gastrointestinal (GI) tract of a diseased recipient. FMT has recently emerged as both an effective and controversial therapy. Although it has been performed for a variety of maladies for centuries, if not longer, FMT has only very recently become an accepted therapy for recurrent and relapsing *Clostridium difficile* infection (CDI) in both adults and children where its effectiveness over conventional CDI treatments has now been demonstrated in a randomized controlled trial [1]. A combination of its success in CDI and our burgeoning knowledge of the complex role that microbes play in a myriad of human diseases has led many to question if there are expanded therapeutic applications for FMT for other human GI and even extraintestinal diseases. As such, FMT has taken center stage as a potential novel therapeutic with new clinical trials evaluating its safety and efficacy now well underway.

In this chapter, we review the basics of FMT, its indications, the current evidence supporting its use, details of suggested FMT protocols, the ethical, regulatory, and safety issues involved, and future applications and directions in this rapidly moving field. Much of the existing data are based on studies and reports in adults, but reports and new studies on FMT in children are forthcoming.

Background

FMT is the administration of a fecal solution from a healthy donor into the GI tract of a diseased recipient with the goal of restoring the recipient's health. The first reports of the use of FMT as a therapeutic agent date back to the fourth century in China [2] when it was recommended for diarrheal illnesses, but it was first mentioned in the modern scientific literature in 1958 by Eiseman and colleagues who reported its effectiveness as an adjunct to antibiotics in the treatment of four adults with pseudomembranous colitis [3]. Until very recently, FMT had been used infrequently by medical practitioners, most often as a treatment for CDI. A growing literature now overwhelmingly supports its efficacy, exemplified by the inclusion of FMT in the American College of Gastroenterology's most recent guidelines for the treatment of relapsing CDI [4].

Scientific Rationale

While the overall concept and procedural aspects of FMT are fairly simple to understand, to describe FMT solely as the transfer of stool from a healthy to a diseased individual is a considerable underestimation of the process. The mechanisms that underlie its success and therapeutic potential are likely quite complex and poorly understood to date.
