The rationale for the use of FMT as a therapeutic agent has grown from our increasing understanding of the complex interactions between microbes and their human hosts and resulting consequences for human health and disease. The human body is populated by an immense number of microbes, including bacteria, viruses, archaea, and fungi that, in a healthy state, maintain a symbiotic relationship with their human host [5]. Bacterial abundances in the human GI tract alone are estimated to be ten times that of human somatic cells [6]. Deep, culture-independent sequencing techniques utilized in large studies like the Human Microbiome Project (HMP) have recently exposed a vastly more complete and

accurate microbial landscape and detailed community structure on human mucosal surfaces [7, 8].

The microbial composition of the GI tract is perhaps the best characterized among the different human body sites studied. As many as 1500 bacterial species can populate an individual's GI tract at any time, and the vast majority of these species belong to one of four phyla: *Bacteroidetes*, *Firmicutes*, *Actinobacteria*, and *Proteobacteria* [8]. These organisms begin to populate the human neonatal GI tract during childbirth. During the first 2–3 years of life, this microbial community structure is markedly unstable, and colonization patterns are significantly influenced by many variables including mode of delivery (cesarean section vs. vaginal), mode of feeding (breast milk vs. formula), microbial infections, and the early use of antibiotics [9]. While the composition of an individual's gut microbiota seems to stabilize by age 3 or so, variation between individuals continues to be shaped by host genetics, diet, and other environmental factors [8].

Perhaps more important than identifying variations in the gut microbial community structure itself, is elucidating the role of these microbes in the maintenance of human health and disease pathogenesis. For example, it is now well appreciated that gut microorganisms are vital to nutrient processing, metabolic function, and the maturation and function of the host immune system [10, 11]. With these key concepts in mind, recent investigations have revealed a microbial imbalance, or dysbiosis, in the GI tract of individuals with a number of different diseases, including inflammatory bowel diseases (IBDs) and obesity among others, emphasizing a role for intestinal microbes in disease pathogenesis [12–14].

Fecal microbiota transplantation is based on the premise that this dysbiosis is partially and at least temporarily reversible with the introduction of a complete, stable microbial community, and that the changes it induces are sustained, preventing recurrence of the disease state. Patients with CDI may provide the best example of this rationale. In CDI, gut microbial biodiversity is markedly reduced, likely creating an ecosystem where *C. difficile* thrives [15, 16]. The decrease in diversity can persist after antibiotic treatment, which may explain high CDI recurrence rates, but is restored after the engraftment of donor feces post FMT, corresponding to clearance of the bacteria and an improvement in disease-related symptoms [16, 17]. It is important to point out that while FMT has resulted in the successful engraftment of donor fecal flora in the recipient in a number of different diseases, engraftment itself is not sufficient for disease resolution as evidenced by work by Kump et al., who reported donor stool engraftment and a reversal of dysbiosis without clinical improvement in six adults with ulcerative colitis (UC) treated with FMT [18]. Clearly, a better understanding of the mechanisms of how FMT works is needed.

Indications for FMT

FMT is not approved by the US Food and Drug Administration (FDA) however, recognizing the significant morbidity and mortality associated with CDI, the FDA has granted enforcement discretion for the clinical use of FMT in recurrent or refractory CDI [19]. The regulatory status of FMT is further detailed later in this chapter.

Currently, FMT is widely used for recurrent and/or refractory CDI in both clinical practice and research settings with success rates close to 90% worldwide [20–22]. A standard practice guideline from an international FMT working group recommended FMT for recurrent or relapsing CDI (at least three episodes of mild-to-moderate disease including failure of a long vancomycin taper or two episodes of severe disease) and for moderate-and-severe CDI not responding to standard antibiotic treatment for 1 week and 48 h, respectively [23]. FMT has been shown to effectively treat the highly virulent *C. difficile* NAP1/BI/027 strain [24], which is associated with a more severe disease phenotype and is often refractory to standard antibiotic treatment [25].

FMT has been proposed as a treatment for a variety of conditions where dysbiosis is implicated in disease pathogenesis, including IBD, irritable bowel syndrome (IBS), and extraintestinal conditions like obesity, metabolic syndrome, diabetes mellitus, systemic autoimmune disorders, neurologic diseases, and autism spectrum disorders [26–29]. The role of FMT in the treatment of many of these conditions is currently under intense investigation.

Current Evidence for FMT

FMT for *C. difficile* Infection

There is now a sizable body of literature supporting the safety and efficacy of FMT in adults with recurrent/relapsing CDI [1, 20, 21, 23, 30, 31]. Data about FMT in children with CDI are limited, but the existing reports to date suggest similar safety and efficacy [32–34]. A recent systematic review reported the results of FMT in over 500 individuals ranging from 1.5 to 94 years of age [22]; however, it is likely that thousands of patients with recurrent CDI have received FMT. Current estimates from this and other systematic reviews suggest an 87–89% primary cure rate [21] with preliminary work suggestive that lower GI tract delivery (via colonoscopy or enema) is more effective than upper GI tract delivery (via nasogastric/nasojunal tube, gastroscopy, gastrostomy tube), 91.3 versus 80.6% resolution [22]. The majority of our FMT data comes from case reports and series as well as retrospective reviews and as such, specifics about

the ideal donor and most effective protocol remain important questions that future studies should address.

To date, there is only one published prospective randomized controlled trial of FMT in CDI [1]. van Nood and colleagues compared resolution of CDI-associated diarrhea in subjects who received vancomycin alone, vancomycin with bowel lavage, or vancomycin with bowel lavage followed by nasoduodenal infusion of FMT from prescreened volunteer donors. The study was terminated early after an interim analysis revealed unacceptably high rates of relapse in both control groups; 59% in those who received vancomycin alone and 77% who received vancomycin plus bowel lavage, compared to FMT ($p < 0.001$). Although only 16 patients received FMT, 81% achieved the primary outcome of resolution of diarrhea after a single treatment, and 94% achieved the primary outcome after a second treatment. Subjects who received FMT reported mild belching, abdominal cramps, and diarrhea following on the day of infusion following FMT but none reported persistent symptoms. There were no serious adverse events associated with FMT. Interestingly, recipient microbiota analysis post-FMT demonstrated increase in bacterial diversity and profile similar to the healthy donors.

What is striking about FMT as a therapy is its success rates, given the wide variety of protocols, preparations, and delivery methods used. Studies report using both related and unrelated donors, a number of different FMT preparations that may be fresh or frozen, and variable amounts of FMT delivered via different routes including nasogastric tube, upper endoscopy, colonoscopy, or enema. In fact, it is unclear how much donor stool is needed to achieve the desired result. Recipient protocols also vary widely and have included dietary modifications, different antibiotics pre-FMT, the use of a proton pump inhibitors pre-FMT, and the setting in which the FMT was delivered. Future studies and national registries may begin to help define optimal conditions and protocols.

Both authors were among the first pediatric gastroenterologists to describe the use of FMT in children with CDI [32–34]. In our experience, children as young as 1-year-old who have recurrent CDI that has failed standard antibiotic and probiotic therapy, have had successful resolution of their symptoms and clearance of the infection following a single treatment with FMT. Cure rates are 90–100% in children without underlying IBD, and there have been no serious adverse events noted [32–34].

The first reported pediatric FMT was via nasogastric tube to a 2-year-old child with CDI caused by the BI/NAP1/O27 strain [32]. She was unable to clear the infection despite 8 months of repeated courses with metronidazole, vancomycin, rifaximin, nitazoxanide, *Saccharomyces boulardii*, and *Lactobacillus rhamnosus GG*. On therapy, she was asymptomatic, but, off therapy, she experienced abdominal pain and loose stools with mucus. Using a modified protocol

based on the adult experience, she received a single infusion of FMT, with stool donated by her father. Within 36 hours, she had complete resolution of her symptoms and has had no recurrence to date with negative *C. difficile* toxin tests at 2 weeks, 3 months, and 6 months post-FMT.

The second reported use of FMT in a child employed colonoscopic delivery in a toddler who had six documented episodes of recurrent CDI [33]. At 11 months of age, following treatment with azithromycin for a bronchitis infection, he presented with 4–6 foul-smelling watery stools, fever, irritability, vomiting, abdominal pain, a 1–2-lb weight loss, and was found to be *C. difficile* toxin PCR positive. He was then treated with multiple standard and pulsed courses of metronidazole and vancomycin during which his symptoms would be resolved, and his *C. difficile* tests were negative. Shortly after completing the antibiotics, his symptoms would recur, and his stools would test positive for *C. difficile*. At 16 months, he received colonoscopic FMT using his mother as a stool donor. He had complete resolution of his symptoms within 24 hours and has remained clinically well with negative tests.

A case series by Russell et al. just published summarized their experience in ten children with recurrent CDI, three of whom also had underlying IBD who received FMT using their parents as donors [34]. Two children received FMT delivery via nasogastric tube and the remainder by colonoscopic delivery. No serious adverse events were reported. Nine of the ten children had resolution of their symptoms after a single treatment with FMT with a durable response ranging from 1 month to 4 years. Of the three patients with underlying IBD, results were mixed; we may be able to clear the CDI, but the impact of FMT on the IBD remains unclear. In this series, one patient cleared the CDI but then developed acute severe colitis 6-days post-FMT and ultimately underwent colectomy, one patient had a recurrence 8 weeks post FMT that was treated with vancomycin, and one had clearance of the toxin but persistent bloody diarrhea and symptoms resolved following treatment for the underlying Crohn's disease.

Recent systematic reviews also summarize the experience of FMT in adult patients with IBD and recurrent CDI [21, 22]. Similar to the limited pediatric experience, FMT has been highly successful in clearing the CDI; however, the impact of the FMT on the underlying IBD has been mixed with some patients going into remission, some having no change in their disease activity, and a few patients experiencing worsening of their disease [34, 35].

FMT for Inflammatory Bowel Disease

FMT may be a potential therapy for some patients with IBD; however, data are limited, and the regulatory status of FMT

in many countries, including the USA, limits its use for indications other than recurrent CDI, without FDA approval. Several case reports and series have described the outcomes in patients who received FMT for IBD with mixed results and little data in pediatric patients.

In 1989, Bennet, both a physician and a patient with medically refractory UC, treated himself with large-volume FMT enemas with encouraging results. Three months post-transplant, flexible sigmoidoscopy demonstrated chronic but no active inflammation, and, at 6 months, he was symptom-free and off all medications [36]. This was followed by several promising but small series by Borody and colleagues [27, 37, 38]. In 2006, they reported the results of treatment with FMT enemas daily for 5 days in six adults with severely active UC [37]. Clinical improvement was noted as early as 1 week post FMT, and complete symptomatic remission was achieved in all patients by 4 months post-FMT. At the time of follow-up (1–13 years), the patients had no endoscopic or histological evidence of active UC.

Unfortunately, not all of the reports of FMT in patients with IBD have been so positive. Verriere described four patients with Crohn's disease who received nasojejunal FMT who had no clinical response and three of whom developed transient fever and abdominal tenderness [39]. In a similar study out of Austria, examining the effects of nasojejunal and enema-based FMT in five subjects with severely active UC, none achieved clinical remission and only one recipient had a clinical response. All five subjects also had transient post-FMT fever and elevated C-reactive protein that was blood culture negative [40]. Kump and colleagues found that six subjects with chronic active UC who received a single treatment with colonoscopic FMT had a short-term improvement in symptoms but none achieved clinical remission, and one had worsening of disease [18]. Although given the small numbers of subjects, differences in the patient populations and donors, and differences in the protocols used, there are no clear conclusions to be drawn about the potential safety and efficacy of FMT in adults with IBD. Larger randomized controlled trials are needed to further evaluate the therapeutic potential and safety of FMT in IBD.

The first study in pediatric IBD patients treated with FMT was reported by Kunde et al. in 2013. Ten youths, aged 7–21 years, with mildly to moderately active UC were treated with FMT enemas from relatives or close relations, daily for 5 days [23]. Although this small pilot study only followed the subjects for 1 month, nine out of ten subjects tolerated FMT, three out of nine were in clinical remission at 1 week, and six out of nine had a sustained clinical response at 1 month. One patient had had significant hematochezia and a marked increase in the pediatric ulcerative colitis activity index (PUCAI) [41] after having a transient improvement immediately following FMT. No serious adverse events were reported, but two subjects experienced fever following

FMT who responded to antipyretics. Several subjects also noted bloating, abdominal pain, diarrhea, hematochezia, and fatigue though it is unclear if these effects were due to the FMT or the underlying IBD [42].

Vandenplas et al. recently published their experience using repeated FMT infusions to treat a 1-year-old girl with early-onset colitis [43]. Initially, the child's symptoms were responsive to oral and rectal mesalamine, but she relapsed and, at 1 year of age, failed to improve on prednisolone and azathioprine, an amino acid-based formula, and antibiotics. She continued to be quite ill with a PUCAI between 60 and 75 and required intermittent blood transfusions. Following seven treatments with FMT from two donors, she went into clinical and endoscopic remission. Although this report is quite promising, caution is advised as the safety and efficacy of FMT in IBD has yet to be established by rigorous scientific investigation.

FMT Protocols

FMT has been historically performed without regulatory oversight leading to variation in protocols for each step of the process, including donor selection, donor screening, stool preparation and handling, recipient preparation and quantity and method of stool delivery. The international FMT Working Group published guidelines in December of 2011 that have helped to standardize FMT and guide regulation [23]. The importance of standardization, particularly in regard to safety, is underscored by the numerous "How to" guides on the Internet instructing laypeople how to perform FMT at home without important regulation.

Donor selection is an area of particular controversy. FMTs have been successfully performed with stool from related donors (e.g., parents, sexual intimates, etc.) and from healthy, unrelated donors, but characteristics of the "optimal donor" are still under debate. A systematic review of FMT for recurrent CDI found slightly higher success rates when related donors were used (93%) compared to unrelated donors (84%) [20], but more recent studies have found equal if not greater success with unrelated donors [30]. Suggested donor exclusion criteria and screening before transplant from the FMT working group are listed in Table 35.1.

Donor and Recipient Screening

Rigorous evaluation of the stool donor for potentially transmissible infections is of the utmost importance. Optimally, this screening should be performed as close to the time of donor stool collection as possible. The FDA recommends that all tests be performed within 4 weeks of FMT and human immunodeficiency virus (HIV) testing within

Table 35.1 Donor exclusion criteria [23]. (Reprinted from Ref. [23], Copyright 2012, with permission from Elsevier)

<i>1. Absolute</i>
a. For the risk of infectious agent, consider using American Association of Blood Banks Donor history questionnaire: http://www.fda.gov/downloads/BiologicsBloodVaccines/BloodBloodProducts/ApprovedProducts/LicensedProductsBLAs/BloodDonorScreening/UCM213552.pdf
Known human immunodeficiency virus (HIV), hepatitis B or C infections
Known exposure to HIV or viral hepatitis (within the previous 12 months)
High-risk sexual behaviors (e.g., sexual contact with anyone with HIV/acquired immune deficiency syndrome or hepatitis, men who have sex with men, sex for drugs or money)
Use of illicit drugs
Tattoo or body piercing within 6 months
Incarceration or history of incarceration
Known current communicable disease (e.g., upper respiratory tract infection)
Risk factors for variant Creutzfeldt–Jakob disease
Travel (within the last 6 months) to areas of the world where diarrheal illnesses are endemic or risk of traveler’s diarrhea is high
b. Gastrointestinal comorbidities
History of inflammatory bowel disease
History of irritable bowel syndrome, idiopathic chronic constipation, or chronic diarrhea
History of gastrointestinal malignancy or known polyposis
c. Factors that can or do affect the composition of the intestinal microbiota
Antibiotics within the preceding 3 months
Major immunosuppressive medications, for example, calcineurin inhibitors, exogenous glucocorticoids, biologic agents, etc.
Systemic antineoplastic agents
d. Additional recipient-specific considerations
Recent ingestion of a potential allergen (e.g., nuts) where the recipient has a known allergy to this (these) agent(s)
<i>2. Relative exclusion criteria that may be appropriate to consider</i>
History of major gastrointestinal surgery (e.g., gastric bypass)
Metabolic syndrome
Systemic autoimmunity, for example, multiple sclerosis, connective tissue disease
Atopic diseases including asthma and eczema, eosinophilic disorders of the gastrointestinal tract
Chronic pain syndromes, for example, chronic fatigue syndrome, fibromyalgia

2 weeks. Donor screening tests outlined in Table 35.2 have been suggested by the FMT Working Group [23]. Additional screening protocols may be modified based on the recipient and the disease being treated. For example, in the case of FMT for IBD, some have suggested donors be screened for cytomegalovirus (CMV), given its potential to cause colitis. It is also likely that screening protocols and FDA guidelines will continue to evolve. The frequency of screening for repeat donors has not been established.

Similar screening for recipients is not done universally but is being performed by some practitioners and investigators, mostly in an effort to document the recipient’s baseline status at the time of transplant in case of disease transmission.

FMT Preparation

Published methods of donor stool preparation before transplant vary enough that few definite conclusions can be drawn. Historically, fresh donor stool was used, typically within 8 h of passage. More recently, however, the efficacy

of FMT with thawed/previously frozen stool has been shown to be equally effective in recurrent CDI in terms of both clinical improvement [30] and engraftment of the donor flora [44]. In most protocols, a standard kitchen blender is used to homogenize donated stool with a dilutant. Bacteriostatic normal saline, water, and even 4% cow’s milk have been used as dilutants, and although water may give the best results, preservative free saline is most commonly used [20]. Anywhere from 50 to 300 g of stool is blended with 250–500 mL of dilutant to achieve a liquid slurry, which is then filtered to remove particulate matter. Filtration can be performed with simple through gauze or standard coffee filters. Most recommend that, when possible, a fume hood be used during preparation. The optimal dose is unclear in adults but most give at least 250 mL of the final slurry for colonoscopic delivery and at least 50 mL for upper GI tract delivery [45]. Weight- or age-based doses for children have yet to be established. There is limited evidence that supports a trend in higher efficacy and decreased CDI relapse rates when higher doses of donor stool are used and larger volumes of stool slurry are delivered, but this has yet to be adequately studied in a prospective study [20].

Table 35.2 Donor screening tests [23]. (Reprinted from [23], Copyright 2012, with permission from Elsevier)

<i>I. Stool testing</i>
<i>Clostridium difficile</i> toxin B by PCR; if unavailable, then evaluation for toxins A and B by EIA
Routine bacterial culture for enteric pathogens
Fecal <i>Giardia</i> antigen
Fecal <i>Cryptosporidium</i> antigen
Acid-fast stain for <i>Cyclospora</i> , <i>Isospora</i> , and, if antigen testing unavailable, <i>Cryptosporidium</i>
Ova and parasites
<i>Helicobacter pylori</i> fecal antigen (for upper GI routes of FMT administration)
<i>2. Serologic testing (unless otherwise stated, all tests should be performed using FDA-approved test methods)</i>
HIV, type 1 and 2
Hepatitis A virus (HAV) immunoglobulin (Ig) M
Hepatitis B surface antigen, hepatitis B core antibody (both IgG and IgM), and hepatitis B surface antibody
Hepatitis C virus antibody
Rapid plasma reagin and fluorescent treponemal antibody absorbed
PCR polymerase chain reaction, <i>EIA</i> enzyme immunoassay, <i>GI</i> gastrointestinal, <i>FMT</i> fecal microbial transplantation, <i>HIV</i> human immunodeficiency virus

Routes of Administration

Fecal microbiota transplantation using both upper and lower GI tract delivery has been successful in treating recurrent CDI. Upper GI (UGI) tract delivery methods have included gastric and post-pyloric delivery through a gastroscope or flexible naso-enteric tube and more recently by mouth in encapsulated form, while lower GI (LGI) tract delivery is via retention enema or colonoscope. For children, successful nasogastric tube [32] and colonoscopic [33] delivery have both been successful for recurrent CDI. The largest review of cases to date for FMT in CDI showed higher rates of resolution with delivery via the LGI tract (93.6%) compared to UGI tract (76.4%) [20]. A more recent systematic review of CDI cases showed a trend towards better results with LGI tract delivery (91.4%) compared to UGI tract delivery (82.3%) although this did not reach statistical significance [21]. A recently completed, small, randomized trial comparing nasogastric and colonoscopic delivery methods in CDI showed no difference in efficacy [46] but larger trials are certainly needed. If UGI tract delivery does prove to be inferior, one reason may be a lack of stability/survival of donor microbiota in the highly acidic gastric environment. Most investigators have countered this potential problem by treating recipients receiving FMT via the stomach with proton pump inhibitors or delivering the solution post-pylorically. There may be theoretical problems with administering LGI tract flora from the donor into a UGI tract location in terms of engraftment although this has not been extensively studied. This has led some to recommend a bowel lavage for all recipients just before FMT, even for those receiving donor material via the UGI tract [45].

Colonoscopic delivery is more invasive and UGI tract delivery via naso-enteric tube, while somewhat less invasive, still has associated risks and may prove unpalatable for some patients. The logical next step is the encapsulation of donor

fecal material into a pill form that can be taken orally to reduce these procedural risks.

Beyond CDI, little is known about the optimal delivery method for FMT, but it ultimately may depend on the location and other specifics of the condition being treated. Larger, randomized trials comparing delivery method are needed for both CDI and other diseases that might be treated with this therapy.

Ethical, Legal, Social, and Regulatory Issues

There are numerous ethical and regulatory issues surrounding the use of FMT in both the USA and abroad. Given the importance of the ethical, legal, and social issues (ELSIs) related to the microbiome research and technology, the National Institutes of Health (NIH) has specifically solicited research on this topic through the HMP [7]. Unfortunately, research in this area has been slow, and there have only been a few studies addressing the ethical and social issues related to fecal microbiota transplantation [31, 47–49].

The lag in ELSI research on FMT may in part stem from the lack of clarity regarding how FMT is classified. Clearly, it is a biologic substance, but there have been questions about whether or not the microbiome should be classified as an organ or a tissue and whether or not FMT is a drug [50]. In the USA, the FDA has taken an active role in establishing the status of FMT and overseeing its regulation. Although scientists in the field regard the microbiome as an organ [51], the FDA does not recognize stool and the microbiome it contains as an organ or a tissue, but as a drug and a biologic product [50].

Most of the existing ELSI literature explores the social issues related to using stool as a drug and patient and physician perceptions of FMT. Early studies focused on whether patients and parents would be willing to consider or undergo

Table 35.3 Ethical, legal, and social issues in FMT

Ethical, legal, and social issues in FMT
Stigma/“yuck factor”
Discussion of risk
Nonuniform IRB requirements and guidelines
Potential for drug of compassionate use
Protection of vulnerable patients (children)
Impact and coverage of FMT by insurance
Identification of donors
Screening and protection of donors

FMT. Notwithstanding the obvious “yuck” factor associated with FMT, patient and their families were willing and even eager to consider FMT for both IBD and recurrent CDI [47–49]. More recently, investigators have confirmed that although not all physicians are comfortable performing FMT personally, the great majority are comfortable with FMT as a treatment for CDI and/or the creation of specialized centers where FMT can be performed [52].

Beyond physician and patient acceptance, there are numerous ethical issues related to FMT that have yet to be investigated. These ELSIs are outlined in Table 35.3.

Summary and Potential Future of FMT

The excitement over FMT and its potential applications has grown exponentially over the past few years. The success of FMT in CDI has spawned investigations into treatment optimization and also into other microbial-based therapeutics, with growing interest from clinicians, scientists, government health agencies, and commercial entities alike. Ongoing trials of FMT in pediatric diseases will provide much needed data about efficacy, safety, durability, and the long-term impact of FMT in young patients.

Stool Banks and Encapsulation

The use of freshly donated stool for FMT is both time and labor intensive for the practitioner which may limit widespread use. With newer evidence supporting the efficacy of thawed, previously frozen stool, the banking of large amounts of frozen, previously donated stool from healthy donors is underway and should help standardize FMT, ease administration, and improve safety. Since UGI tract delivery seems effective for recurrent CDI and may eventually be a

preferred method for other conditions, the encapsulation of transplant material is the next logical step. The study of such “stool capsules” has been recently published, [53, 54] but raises a host of new questions including dose, optimal capsule material, location of release, and the impact of gastric acid which have not yet been answered.

Bacterial Fingerprinting: Matching Donors and Recipients

Recent investigations have uncovered significant variability in the composition of the human gut microbiome. However, analysis of fecal samples from around the world show that human gut microbial community structures that may also be classified as distinct “enterotypes” based on microbial composition and molecular function [55]. These enterotypes are driven by long-term dietary intake [56], and there is increasing evidence that genetics plays a role in shaping the gut microbiome [57]. This raises important questions for FMT including donor and recipient matching not only in regard to enterotype but also age, gender, and even HLA typing among other factors. Future FMT studies will need to address these questions to better assess optimal matching strategies.

Stool Substitutes: Building Microbial Communities In Vitro

While FMT appears relatively safe in the short term, serious concerns remain in regard to potential pathogen and disease transmission and also in regard to long-term safety. Stool substitutes, combinations of cultured commensal bacteria derived from human stool, have the potential to improve safety by assuring the transfer of only known microbes and thus the absence of transmission of potentially pathogenic microbes such as viruses. Petrof and colleagues reported the successful eradication of recurrent CDI in two adults using a combination of 33 purified bacterial isolates recovered from healthy, unrelated donor stool [58]. Similar results have been reported in animals [59]. While the initial results are promising, it is unknown which components of human stool are mandatory for treatment success. There is also concern that progressive re-culturing of the same strain over time may change bacterial characteristics and affect a microbe’s ability to engraft in the recipient [60]. Efficacy of such “stool substitutes” will have to be compared to more standard FMT using intact donor stool as well as other probiotic mixtures. If they compare favorably, these purified communities of human-derived bacteria grown in vitro will likely improve both the safety and availability of microbiota-based therapeutics.

Commercialization

The recent success of FMT for recurrent CDI has spawned growing attention from commercial entities. Specifically, the encapsulation of donor material and the creation of stool banks lend themselves to commercial interest that would vastly increase the accessibility of FMT to patients and practitioners alike. Although not yet proven to be effective, the creation of “stool substitutes” in vitro may represent the largest opportunity for industry in the future. Commercialization will advance therapeutic standardization and will also lead to more strict oversight by regulatory agencies, likely improving the safety of microbiota-based therapeutics such as FMT for patients.

Unanswered Questions

FMT is an effective therapy for recurrent CDI in both adults and children, but many unanswered questions remain including optimal dosing, delivery route, recipient preparation, and donor characteristics. Short and long-term safety monitoring are of paramount importance, and the long-term outcomes and distant effects on recipient health are essentially unknown. The role of FMT in diseases other than recurrent CDI is unclear and only beginning to be evaluated. Studies in the USA and abroad are beginning to investigate this multitude of questions.

Introduction

Congenital diarrheal disorders (CDD; OMIM 251850) are a group of rare chronic enteropathies characterized by a heterogeneous etiology with a typical onset early in the life. In the first weeks of life, patients affected by CDD usually present with severe diarrhea that within a few hours leads to a life-threatening condition secondary to massive dehydration and metabolic acidosis (or alkalosis in the case of congenital chloride diarrhea, CLD) [1]. The number of conditions included within the CDD group has gradually increased, and many new genes have been identified and functionally related to CDD, opening new diagnostic and therapeutic perspectives [1]. We have proposed a CDDs classification in four groups in relation to main defect:

1. Defects of digestion, absorption, and transport of nutrients and electrolytes
2. Defects of enterocyte differentiation and polarization
3. Defects of enteroendocrine cells differentiation
4. Defects of intestinal immune response modulation

In the context of the first group, congenital disorders of intestinal electrolytes transport are a subset of diseases characterized by early clinical presentation due to autosomal recessive defect. These disorders are challenging clinical conditions for pediatric gastroenterologists because of the

severity of the clinical picture and the broad range of conditions in differential diagnosis. Frequently, abnormal fluid absorption begins in utero, manifesting itself as maternal polyhydramnios. Then soon after birth, patients usually present with severe diarrhea that within few hours leads to a life-threatening condition secondary to massive dehydration and metabolic acidosis [1]. Consequently, these patients require a prompt diagnosis and assistance. Milder forms with subtle clinical signs may remain undiagnosed until adulthood when patients developed irreversible complications. In particular, patients with cystic fibrosis (CF) may have a subtle clinical presentation, with prevalent non-intestinal symptoms.

Different mechanisms are responsible for transepithelial ion transport at intestinal level (Fig. 36.1). In the jejunum, NaHCO_3^- is absorbed via Na^+/H^+ exchange (the secreted H^+ neutralizes an equivalent amount of luminal NaHCO_3^-) and Cl^- movement is purely passive [2]. In the ileum (and, as shown later, also in the proximal colon), NaCl is absorbed via equal rates of Na^+/H^+ and $\text{Cl}^-/\text{NaHCO}_3^-$ exchanges [2]. At least three Na^+/H^+ exchangers (NHEs) have since been localized to intestinal brush border membranes and cloned; NHE2 and NHE3 are found in both small intestine and colon. NHE3 appears to be quantitatively more important, since the NHE2 knockout mouse suffers gastric dysfunction but no intestinal disability, whereas the NHE3 knockout mouse suffers from chronic diarrhea. A third, Cl^- -dependent NHE is found in crypt cells of rat distal colon. The NHE first identified in intestine, NHE1, is present only in the basolateral membrane of enterocytes and is involved in HCO_3^- secretion [3].

Two anion exchangers have also been localized to small-intestinal and colonic brush border membranes and cloned: downregulated in adenoma (DRA) and putative anion transporter 1 (PAT1) [1]. DRA was first cloned from colonic mucosa; it was found to be downregulated in villus adenomas and carcinomas and subsequently was found to incur mutations in the rare diarrheal disorder familial chloride diarrhea (see “Congenital chloride diarrhea” below). Both DRA and PAT1 are abundant in the duodenum and present at higher density there than NHE2 and NHE3, suggesting a role in

Fig. 36.1 Pathophysiological mechanisms of congenital disorders of intestinal electrolytes transport. 1 *Familial diarrhea syndrome* is due to a mutation in intestinal guanylate cyclase receptor (*GC-C*) for the endogenous ligands uroguanylin/guanylin. Ligand binding to *GC-C* increases intracellular levels of cyclic guanosine monophosphate (*cGMP*). The *cGMP* activates *cGMP*-dependent protein kinase II (*PKGII*). *PKGII* phosphorylates the cystic fibrosis transmembrane conductance regulator (*CFTR*), increasing its Cl^- -secreting activity and inhibiting electroneutral NaCl absorption. A missense mutation leads to a gain of function increasing ligand-mediated activation of *GC-C* and intracellular *cGMP* levels resulting in chronic secretive diarrhea. 2 *Congenital chloride diarrhea* is caused by a defect in *DRA* exchanger leading to severe watery diarrhea due to Cl^- malabsorption. The pro-

tein has a C-terminal domain, sulfate transporter and antisigma factor antagonist (*STAS*), that ensures the correct location of the protein on the apical membrane of enterocytes. The *STAS* domain also interacts with the R-domain of the *CFTR*, and it is required for *CFTR* activation. 3 *In cystic fibrosis*, there is an alternated activity of *CFTR*. This membrane protein consists of two membrane-spanning domains, two nucleotide-binding domains (*NBDs*), and a regulatory domain, which controls channel activity. 4 *Congenital sodium diarrhea* probably derives from a defect in apical membrane Na^+/H^+ exchangers leading to severe watery diarrhea due to Na^+ malabsorption. *DRA* downregulated in adenoma, *DTRL* defense terrain research laboratory, *cAMP* cyclic adenosine monophosphate, *AMP* adenosine monophosphate, *GMP* guanosine monophosphate

duodenal alkalization. In the colon, *DRA* appears to predominate over *PAT1*.

More than two brush border ion exchangers are required, of course, for the enterocyte to engage in transcellular salt absorption. Increased turnover of the Na^+/K^+ pump and the opening of Cl^- and K^+ channels are also necessary, the latter to counteract associated cell swelling, to permit serosal exit of Cl^- taken up from the lumen, and to dissipate the added uptake of K^+ through the pump.

Diagnostic Approach

The diagnostic approach to CDDs is a multistep process that includes the careful evaluation of the history and clinical data, results of common laboratory, and instrumental procedures and molecular analysis (Fig. 36.2). Positive family history of early onset chronic diarrhea, polyhydramnios, and/or dilated

bowel loops at ultrasound examination during pregnancy are highly suggestive of CDDs. The main symptom is chronic diarrhea (lasting longer than 30 days). In the diagnostic approach, it is important to take into account that infections and food allergy are the most common cause of diarrhea also at this particular age [4], and that these conditions together with malformations of gastrointestinal tract, should be considered as primary diagnostic hypotheses in a infant with chronic diarrhea [4]. However, in all cases of chronic diarrhea starting in the first weeks of life, the presence of a congenital disorder of intestinal electrolyte transport should be excluded. A fundamental step in the diagnostic process is the identification of an osmotic or secretory mechanism leading to diarrhea. In osmotic diarrhea, unabsorbed luminal substances are responsible for accumulation of fluids in intestinal lumen and diarrhea significantly improves during fasting, whereas in secretory diarrhea, fluids are actively secreted in the intestinal lumen and diarrhea continues dur-

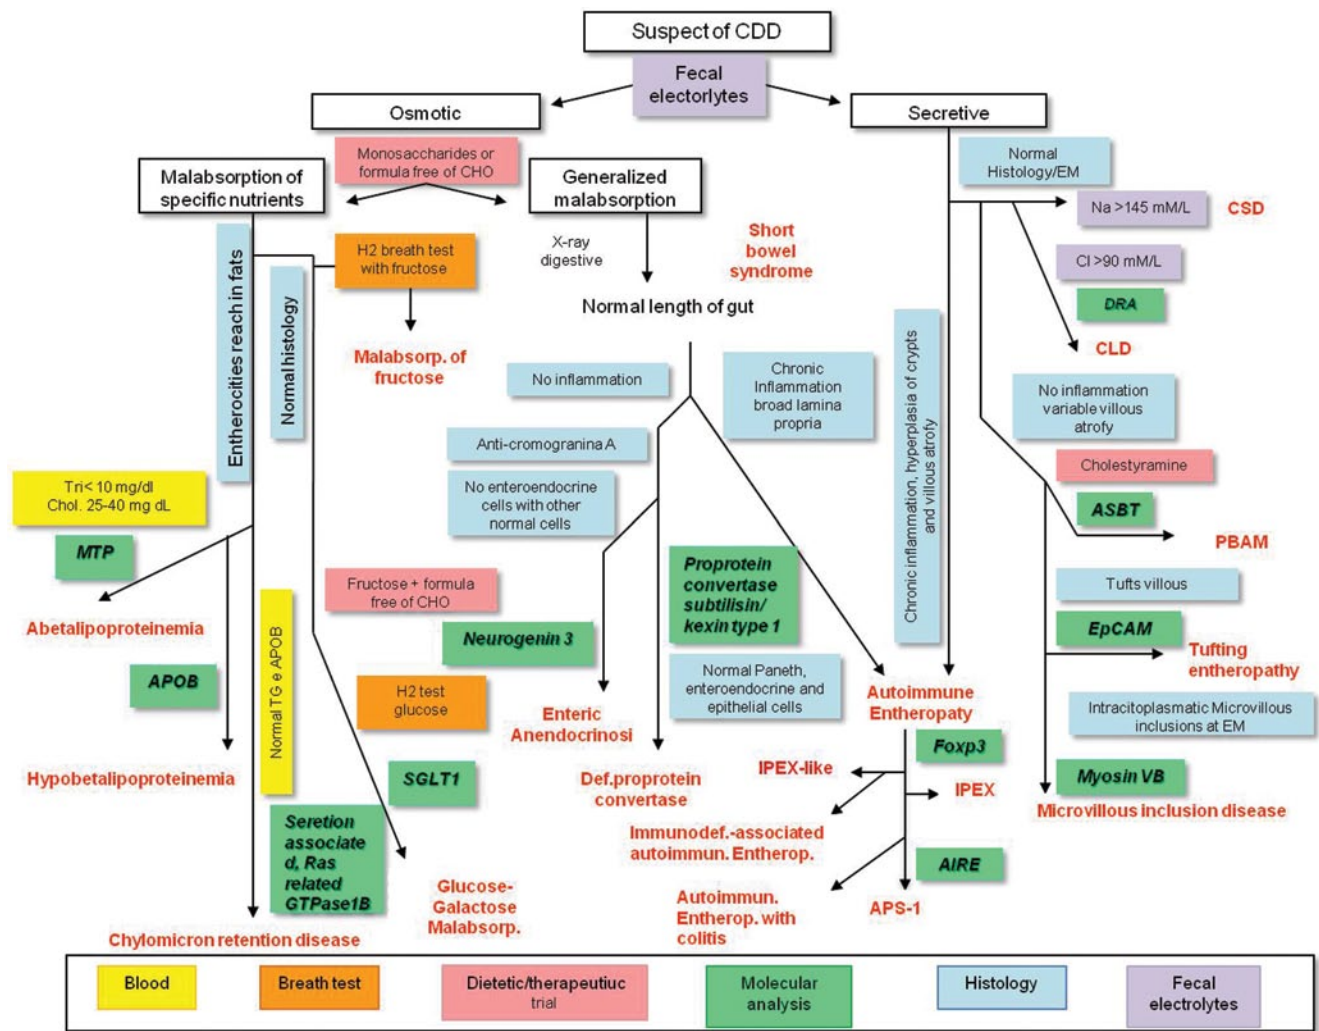

Fig. 36.2 Indications for an integrated diagnostic approach to the main forms of CDDs. The diagnostic approach is a multistep process that includes the evaluation of anamnesis and clinical data, results of common laboratory and instrumental procedures and molecular analysis. The fundamental step in the diagnostic process of CDDs is the identification of an osmotic or secretory mechanism leading to diarrhea. Moreover, the determination of stool electrolyte concentration and fecal ion gap is important to discriminate the two mechanisms responsible for CDDs. The next step is laboratory investigation includes blood gas, blood glucose, ammonium, albumin, triglycerides, and cholesterol, aminoaciduria and the search of reducing substances in the stools, stea-

toic, and sweat test. Finally, intestinal biopsy with histologic examination is crucial for the diagnosis of most CDDs. Molecular analysis, when available, is important and could limit invasive procedures CDD congenital diarrheal disorder, DRA downregulated in adenoma, CLD congenital chloride diarrhea, ASBT apical sodium-dependent bile acid transporter, EpCAM epithelial cell adhesion molecule, PBAM peripheral blood adherent monocyte, IPEX immune dysregulation, polyendocrinopathy, enteropathy, X-linked, MTP media transfer protocol, APOB apolipoprotein B, SGL2 sodium-glucose transport, AIRE autoimmune regulator

ing fasting [5]. Furthermore, the determination of stool electrolyte concentration and fecal ion gap is important to discriminate the two mechanisms responsible for CDDs (Fig. 36.1). If ion gap is >50 fecal, osmolality derived from ingested osmotically active nutrient or not measured ion (i.e., Cl^- , Mg^{2+} ...). In contrast, a low osmotic gap (<50) is typically observed in secretory diarrhea. A direct measurement of Na^+ and Cl^- concentration in the stool may clearly suggest a diagnosis of congenital sodium diarrhea (CSD) or chloride losing diarrhea (CLD), respectively [5]. When an osmotic mechanism is suspected, the next step of laboratory

investigation includes blood gas, blood glucose, ammonium, albumin, triglycerides and cholesterol, aminoaciduria and the search of reducing substances in the stools, steatorrhea, and sweat test (Fig. 36.2). CF is suggested by the presence of steatorrhea and confirmed by a positive sweat test. On the other hand, signs of inflammation in children with secretory diarrhea and familiar history of chronic diarrhea justify the suspect of a familial diarrhea syndrome (FDS). Recent availability of molecular analysis for many of these conditions has progressively limited the need for invasive procedures (Fig. 36.2).

Congenital Chloride Diarrhea

CLD (OMIM 214700) is caused by a mutation in the solute carrier family 26 member 3 (*SLC26A3*) gene, and it is responsible for a life-long watery diarrhea with high fecal Cl^- concentration [6]. The gene, located on chromosome 7.q31, encodes for a transmembrane protein that takes part in gut $\text{Cl}^-/\text{NaHCO}_3^-$ exchange (Fig. 36.2) [7]. The *SLC26A3* is located close to the gene encoding for the cystic fibrosis transmembrane conductance regulator (*CFTR*), raising a possibility of *CFTR* modulation in the pathogenesis of CLD [8]. The protein encoded by *SLC26A3* gene has a C-terminal domain, STAS (sulfate transporter and antisigma factor antagonist), that ensures the correct location of the protein on the apical membrane of enterocytes. Mutations determine transporter mistrafficking and cytosol retention [9]. The STAS domain also interacts with the R-domain of the *CFTR*, and it is required for *CFTR* activation. Studies have shown that deglycosylation of HA-SLC26A3 may contribute to the pathogenesis of diarrhea associated with congenital disorder of glycosylation (CDG) because oligosaccharides protect HA-SLC26A3 from proteolytic digestion enzymes in the intestine [10]. The gene *SLC26A3* has also extraintestinal expression: it is expressed in sweat glands, the male reproductive tract, and kidney, while it is downregulated in human colon adenomas and adenocarcinomas [11–13].

The majority of the *SLC26A3* mutations are single-nucleotide substitutions (nonsense, frameshift, and missense), while additional mutations as deletions/insertions are minor. There is no evidence of a correlation between genotype and phenotype. It has been demonstrated that an identical genetic background of CLD may show different clinical course [14] or different responses to therapy [15].

Countries with a highest incidence are Finland (1:35,000), Poland (1:200,000), Kuwait, and Saudi Arabia [16]. In Arabian countries, the high incidence is mostly due to consanguineous marriages [16]. There is a single mutation in the above-mentioned ethnic groups: in Finns, the p.V317del mutation affects up to 90% of CLD alleles; in Saudi Arabians and Kuwaitis, pG187X is present in more than 90% of altered chromosomes; in Poles, 50% of CLD alleles carry the p.1675dup [6].

The main clinical symptom is lifelong watery diarrhea with high Cl^- content and low pH [1]. If not treated, diarrhea leads to dehydration, metabolic alkalosis, hyponatremia, hypokalemia, hypochloremia, and failure to thrive. Because of the intrauterine onset of diarrhea, CLD pregnancies are characterized by polyhydramnios, and the newborn could be mild premature [16, 17]. Postnatally, CLD patients present prominent abdominal distention and dehydration [16, 18].

Suspect of CLD in pregnant women arises with maternal polyhydramnios, lack of meconium, and images of distended

loops of ileum. These aspects, evidenced by ultrasonography, are an indication of intrauterine onset of diarrhea. The abdomen is usually large and distended, and intestinal contractions are visible. Loops of ileum and colon are dilated with air and fluid, and ascites is often present. Hyperbilirubinemia is common and is caused in part by the dehydration. It is worth remembering that excessive volume and salt depletion reduce the amount of diarrhea and may result in a low fecal Cl^- of even 40 mmol/L such as a stool dilution by urine [16]. After correction of electrolyte homeostasis by salt substitution, the next thing to do is measuring Cl^- on a stool sample, possibly obtained with a soft catheter to avoid urine contamination. A fecal $\text{Cl}^- > 90$ mmol/L confirms the diagnosis in most cases and leads to molecular analysis of *SLC26A3*. Untreated patients show retarded growth and development, with mental and psychomotor delay.

The main therapeutic approach is based on substitutive therapy with NaCl/KCl (see Table 36.1) [19]. Therapy with the short-chain fatty acid butyrate is also beneficial in patients affected by CLD [20, 21]. Butyrate could reduce mistrafficking or misfolding of DRA and may enhance gene expression through the activation of a region crucial for high-level transcription. Butyrate is also able to modulate transepithelial ion transport through the stimulation of Na^+/H^+ exchangers 2 (NHE2) and 3 (NHE3) activity and inhibition of Cl^- secretion by limiting the action of the cotransporter Na–K–2Cl (encoded by NKCC1) on enterocyte basolateral membrane. In fact, treatment with oral butyrate (100 mg/kg/day) allows a progressive reduction to normal in the number of bowel movements and stool volume, an improvement in stool consistency, and a reduction of fecal incontinence episodes [15]. The effect of butyrate on stool pattern is evident within the first 48 h and remains stable during the following days of treatment. Depending on genotype, the response to butyrate may vary, and this explains the different benefits on the basis of ethnicity [15]. Because missense and deletion mutations allow the expression of *SLC26A3* at membrane level, a full response to butyrate (defined by a concomitant significant reduction of Na^+ and Cl^- fecal losses and improvement in stool pattern) is observed only in patients with these types of mutation. On the contrary, a partial response is to be expected in patients with nonsense or splicing mutations [15].

Long-term prognosis of CLD patients is generally favorable. All of the patients treated adequately reach adult life because oral salt substitution with NaCl and KCl allows normal growth and development [17, 19]. Complications such as intestinal inflammation, renal disease, hyperuricemia, inguinal hernias, spermatoceles, and male subfertility are possible [17, 19]. Untreated or poorly treated disease is associated with impaired renal function and nephrocalcinosis, and even with end-stage renal disease [12].

Table 36.1 Therapeutic approach to a child with congenital chloride diarrhea

Treatment of acute dehydration			
1. Initial treatment of fluid depletion (over 6–8 h)			
IV infusion of 0.9% NaCl solution, NO fluids containing bicarbonate			
120–500 mL/day for children under 7 years			
500–1000 mL/day for children over 7 years			
2. Maintenance therapy (over 24 h)			
Intravenous 5% glucose			
100 mL pro kg (children weight 10 kg)			
+50 mL pro kg for each additional kg (children weight between 11 and 20 kg)			
+20 mL pro kg for each additional kg (children weight 20 kg)			
For adult patients: 2000–2500 mL/day			
NaCl 20 mmol/L added			
KCl maintenance need + calculated K ⁺ depletion added (50 mmol/L)			
If severe hypokalemia, higher KCl doses of even 70 (–100) mmol/L			
3. Replacement of ongoing losses for diarrhea (0.9% NaCl and, if necessary, KCl)			
<i>Salt substitutive therapy in stable clinical condition</i>			
	<i>Small children (0–3 years)</i>	<i>Older children</i>	<i>Adolescents and adults</i>
NaCl	0.7% (7 g/L; 120 mmol/L) ^a	1.8% (18 g/L; 308 mmol/L)	Equal molar ratios of NaCl and KCl
KCl	0.3% (3 g/L; 40 mmol/L) ^a	1.9% (19 g/L; 255 mmol/L)	Equal molar ratios of NaCl and KCl
Concentration of Cl [–]	160 mmol/L	563 mmol/L	–
Need for Cl [–]	6–8 mmol/kg/day	3–4 mmol/kg/day	3–4 mmol/kg/day
Administration	Intravenous ^b /Oral	Oral	Oral
Salt dosage	Ready-made solution	Ready-made solution	Dose bags
Doses per day	3–4	2–3	2–3
<i>Pharmacological treatment</i>			
Oral sodium butyrate, 100 mg/kg/day, divided in two doses (particularly useful in patients with missense or deletion mutations)			

^a If a tendency to hyperkalemia: 0.9% NaCl (9 g/L; 154 mmol/L) and 0.2% KCl (2 g/L; 27 mmol/L)

^b Intravenous therapy is used for infants until the shift to peroral fluid is possible. During intravenous therapy, the need for additional fluid is 100–120 mL/day (stool volume) which can be taken orally

Congenital Sodium Diarrhea

CSD (OMIM 270420) is a rare inherited disorder, characterized by severe diarrhea since birth, with metabolic acidosis, dehydration, and hyponatremia due to massive fecal losses of Na⁺ [22]. Gene-inactivating mutations of the apical membrane NHEs are candidates for this disorder, but the pathogenesis of CSD remains elusive. Probably, CSD is not the result of a single mutation in a specific gene.

A diagnosis of CDS is made on the findings of a life-threatening secretory diarrhea, with voluminous alkaline stools (pH > 7.5), containing high concentration of Na⁺ (> 70 mmol/L), hyponatremia (Na⁺ < 130 mmol/L), and metabolic acidosis. There is no evidence of primary structural abnormalities in the intestinal epithelium at light- and/or electron-microscopic examinations, neither of anatomic anomalies in the gastrointestinal tract at radiological examinations. Laboratory parameters for chronic infections or autoimmune disease are by definition negative [22].

The syndromic form of CSD, which differs from classic CSD by loss-of-function mutations in SPINT2, is characterized by choanal or anal atresia, hypertelorism and corneal erosions, double kidney, cleft palate, and digital anomalies [23]. SPINT2, also known as placental bikunin and hepatocyte growth factor activator inhibitor type 2 (HAI-2), has been shown to be a potent inhibitor of a number of serine proteases, such as pancreatic trypsin, plasmin, kallikrein, and hepatocyte growth factor activator in vitro. SPINT2 mutations can affect proteolytic activity in the functional regulation of intestinal epithelial absorption or secretion of sodium. Possible targets include the membrane-bound extracellular serine proteases, the channel-activating proteases (CAP)/prostasin (MIM 600823) and TMPRSS2 (MIM 602060), and the intracellular protease furin, all involved in regulation of epithelial sodium channel (ENaC) activity [23]. The consequences of alterations in SPINT2 function on Na⁺ intestinal absorption and human development in syndromic CSD remain to be elucidated. CSD treatment consists of replacement of lost ions and parenteral nutrition in order to acquire adequate caloric and fluid intake.

Familial Diarrhea Syndrome

A new condition has been described in 32 members of a Norwegian family [24]. FDS is characterized by early onset chronic diarrhea, associated to meteorism, abdominal pain, dysmotility, and inflammatory bowel disease [24]. All affected members show a heterozygous missense mutation in Guanylate cyclase 2C (*GUCY2C*) gene, c.2519G → T (p.Ser840Ile). *GUCY2C* encodes for an intestinal guanylate cyclase receptor for the endogenous peptides uroguanylin/guanylin and for heat-stable enterotoxins that plays an important role in pathogenesis of acute secretory diarrhea (see Chap. 15 “Bacterial Infections”). It has been demonstrated that the basal GC-C enzyme activity, cellular cyclic guanosine monophosphate (cGMP) levels, and affinities of ligands are similar in cells expressing the wild receptor or the mutant one. However, the mutant receptor is activated by heat-stable enterotoxin, uroguanylin, and guanylin to a greater extent than the wild receptor. A missense mutation leads to a gain of function increasing ligand-mediated activation of GC-C and intracellular cGMP levels. cGMP activates protein kinase GII, leading to a phosphorylation of the *CFTR* channel [25]. This activation leads to an efflux of Cl⁻ (or HCO₃⁻ in the duodenum) and water into the intestinal lumen, with a reduced Na⁺ absorption [26] due to inhibition of the Na⁺/H⁺ exchanger 3 (NHE3) [27].

Cystic Fibrosis

CF (CF; OMIM 219700) is an autosomal recessive disorder due to a dysfunction of Cl⁻ channel (*CFTR*) in the apical surface of epithelial cells. Because of the different locations of *CFTR*, CF is characterized by several and various symptoms, and it is the main cause of exocrine pancreatic insufficiency in childhood. Prevalence of CF is 1/3500 and occurs with greater frequency in populations of North America, Northern Europe, Australia, and New Zealand [28]. The pathophysiologic basis of CF is characterized by a mutation of *CFTR* gene, located on chromosome 7, that determines loss of function of *CFTR* (Fig. 36.3). The *CFTR* protein is a member of the ATP-binding cassette (ABC) transporter superfamily. This membrane protein consists of two membrane-spanning domains, two nucleotide-binding domains (NBDs), and a regulatory domain, which controls channel activity, and it functions as a cyclic adenosine monophosphate (cAMP)-dependent chloride channel. *CFTR* is largely expressed in epithelial cells of the airways, in gastrointestinal tract, including the pancreas and the biliary system. More than 1700 different mutations in the *CFTR* gene were identified, but the most frequent mutation is the deletion of a single phenylalanine residue at amino acid 508 ($\Delta F508$) [29]. Because of the large number of mutations, it is very difficult to establish a clear

correlation between genotype and phenotype. The most serious mutations are always associated with pancreatic failure. Some individuals with polymorphisms of both *CFTR* genes have mild CF manifestations [29].

The loss of function of *CFTR* determines the inability to secrete NaCl in the respiratory tract. The small amount of water present on the surface of the mucous membrane is insufficient to hydrate secretions that become more viscous and elastic, resulting in a slowing of mucociliary clearance and airway obstruction. *CFTR* dysfunction can also make PH more acid in respiratory tract. In the normal pancreas, the duct cell chloride secretion via *CFTR* increases duct luminal chloride concentration. Cl lumen levels are important because it will be exchanged with intracellular HCO₃⁻. This mechanism results in more viscous pancreatic secretions. On the contrary, since the function of sweat glands ductal cells is to absorb chloride, rather than secrete it, the salts are not recovered from primitive sweat isotonic, but are transported to the skin surface, and this makes the concentration of chloride and salts in the sweat very high. Primarily, this principle is based on the most important CF diagnostic test.

CF has a wide heterogeneity of clinical manifestations related to the high number of mutations and environmental factors. Pulmonary and gastrointestinal symptoms are the most common. Chronic infection characterized the expression of CF in the airways and is determined by the inability to quickly eliminate microorganisms inhaled, resulting in colonization and inflammatory response in the airway walls. This phenomenon is also determined by the reduction of the secretions antimicrobial activity, resulting in excessive acidity of the fluid surface. Cough is the most common symptom of pulmonary involvement, dry and hacking at first, then loose and productive, usually with purulent expectorated mucus [30]. Gastrointestinal involvement consists in two different clinical entities: meconium ileus and distal intestinal obstruction syndrome (DIOS), both due to an impaired electrolyte and fluid secretion that causes an inspissation of intestinal contents and consequent intestinal obstruction, in combination with the known impaired intestinal motility. Classically, patients present fat maldigestion and malabsorption that can be directly attributable to the reduced secretion of lipase/colipase from the exocrine pancreas. Liver disease secondary to cholestasis is present in 30% of patients, and it is responsible for a variety of biliary tract and hepatic complications. Clinical manifestations of liver involvement are characterized by jaundice, ascites, hematemesis from esophageal varices, and signs of hypersplenism and hepatomegaly with steatosis [31]. Male sterility is a constant feature (Table 36.2).

The diagnosis of CF is based on the positive result of the sweat test, in combination with one or more of the following: (i) typical chronic obstructive pulmonary disease, (ii) documented chronic pancreatic insufficiency, and (iii) posi-

Fig. 36.3 Synthesis of *CFTR* and classes of mutation in cystic fibrosis. *CFTR* gene encodes for a protein that regulate Cl^- transport. *CFTR* is located at membrane level of secretive cells in lungs, gastrointestinal tract, liver, pancreas, and reproductive system. Mutation of class I is related to the production of the protein: Generally, the protein is not produced at all or in very small quantities. Class II mutations prevent the maturation of protein. In class III and IV mutations, protein is pro-

duced, but works incorrectly. Class V mutations allow a slow production of a small quantities of a working protein. Currently, the effects on clinical outcomes are not clear for all mutation, but a correlation between class mutation and pancreatic involvement is known: Classes of mutation I, II, and III are generally associated with pancreatic insufficiency, and classes IV and V are associated with pancreatic sufficiency

tive family history. Sweat test, which is considered the gold standard in the diagnosis of CF, is based on the determination of Na^+ and Cl^- concentration in sweat collected after local stimulation with pilocarpine. Levels of <35 mmol/L and >60 mmol/L are considered normal and pathologic levels, respectively. Between 35 and 60 mmol/L results are considered borderline. Although the sweat test allows to make a diagnosis when associated with at least another condition, some mutations are known that are associated with negative sweat test [32, 33]. Generally, sweat tests are not performed in subjects younger than 2 weeks of age and weighs less than 3 kg. There are often technical problems while performing

the test in very small infants, and there may be a greater risk of complications or obtaining insufficient sweat. The test is contraindicated in babies younger than 48 h of age because high concentrations of sweat electrolytes can be found on the first day of life. If the patient is acutely unwell, dehydrated, oedematous, or receiving corticosteroids, the test should be delayed [32].

Another important diagnostic test is the search for genetic mutations in the *CFTR* gene. Several commercial laboratories test for 30–96 of the most common *CFTR* mutations. This testing identifies $\geq 90\%$ of individuals who carry 2 CF mutations. This test is used to confirm but not to exclude

Table 36.2 Main clinical features of cystic fibrosis

<i>Chronic respiratory disease</i>
Persistent colonization/infection by typical pathogens (<i>Staphylococcus aureus</i> , non-typeable <i>Haemophilus influenzae</i> , <i>Pseudomonas aeruginosa</i> , <i>Burkholderia cepacia</i>)
Chronic cough and sputum production
Persistent abnormalities on chest radiographs (bronchiectasis, atelectasis, infiltrates, hyperexpansion)
Airways obstruction characterized by bronchospasm and air trapping
Nasal polyps and sinus abnormalities evaluable at radiographs or CT
Digital clubbing
<i>Gastrointestinal and nutritional involvement</i>
Intestine: meconium ileus, distal intestinal obstruction syndrome (DIOS), rectal prolapse
Pancreas: pancreatic insufficiency, recurrent pancreatitis
Liver: chronic liver disease characterized by clinical or histological evidence of focal biliary cirrhosis or multilobular cirrhosis
Nutrition: protein-calorie malnutrition, hypoproteinemia and edema, complications secondary to a fat-soluble vitamins deficiency
<i>Salt wasting syndrome:</i>
Acute salt depletion, chronic metabolic alkalosis
<i>Urogenital abnormalities in male determining obstructive azoospermia</i>

dubious diagnosis, because a lot of mutations have not yet been identified.

Measurement of the potential difference across nasal epithelium is also used as a diagnostic test. This test is based on the demonstration of changes in chloride secretion by epithelial cells, after stimulation with amiloride, as based on the measurement of nasal potentials. Patients with CF have different potential values compared to the healthy population, due to the absence of functional *CFTR* channels. Another test is the assessment of pancreatic function. Exocrine pancreatic dysfunction is clinically apparent in many patients. Documentation is desirable if there are questions about the functional status of the pancreas. This assessment is usually made through evaluation of steatorrhea, fecal chymotrypsin, fecal elastase, and the duodenal assay after secretion or pancreozymin stimulation [34].

With newborn screening, diagnosis is often made prior to obvious clinical manifestations such as failure to thrive and chronic cough. Screening consists in a combination of immunoreactive trypsinogen results and limited DNA testing on blood spots, which are then coupled with confirmatory sweat analysis, and it is $\approx 95\%$ sensitive [35].

The treatment of CF is extremely complex and articulate. It is based on the routine symptomatic therapies and new therapies still in the experimental phase: correction of gene mutation, correction of the altered protein, and activation of the alternative channels to *CFTR*.

Respiratory System Therapy of bronchial obstruction is based on physiotherapy which maintains adequate bronchial toilet and on aerosol therapy that has the purpose of

liquefying secretions. Anti-inflammatory therapy has given numerous benefits, despite the contraindications [36]. During exacerbations, an increase of physiotherapy in combination with antibiotic therapy is indicated. Antibiotic therapy should be guided by the results of sputum culture, preferably using intravenous drugs at high doses [37, 38].

Gastrointestinal Tract Pancreatic insufficiency is generally treated with substitution therapy by administration of pancreatic extracts formulated into microspheres gastro-resistant. Therapy of meconium ileus and DIOS should be as conservative as possible, with the use of high-volume enemas and subsequently enema with gastrografin, in association with the rehydration therapy. Surgical therapy is reserved for cases of medical therapy failure.

Introduction

Primary immunodeficiencies are a group of at least 200 disorders, often inherited, that are caused by intrinsic defects in the immune system. The defects can affect humoral (B cell) immunity, cellular (T cell) immunity, both T and B cell immunity, and innate immunity. Gastrointestinal (GI) disorders are present in 5–50% of patients with primary immunodeficiencies. This is in part because the gut is the largest lymphoid organ in the body, containing the majority of lymphocytes and producing large amounts of immunoglobulin (Ig). The mucosal immune system is uniquely equipped to manage its constant exposure to viruses, parasites, and bacterial antigens, all of which are in close proximity to a large reservoir of lymphocytes, macrophages, and dendritic cells. Dysfunction of the regulatory mechanisms maintaining this balance between active immunity and tolerance in the gut may lead to mucosal inflammation and damage and GI diseases. Therefore, it is not surprising that GI disorders are common, and often the initial presenting manifestations, in patients with primary immunodeficiencies (Table 37.1). In pediatric patients, GI manifestations of primary immunodeficiencies are mainly induced by infection, inflammation, or autoimmunity. In adult patients, malignancy could be a frequent additional condition. These manifestations mimic classic forms of disease (in the absence of immunodeficiency) such as celiac disease, food allergy, or inflammatory bowel disease, but they are often unresponsive to conventional therapies.

Evaluation of a Child with Suspected Primary Immunodeficiency

Because GI disease may be the first presentation of an underlying immunodeficiency, it is crucial to consider immunodeficiency in any child with recurrent or chronic severe diarrhea, malabsorption, and failure to thrive that is resistant to conventional treatments. Primary immune deficits are relatively common but likely underdiagnosed. A clinical history of recurrent, opportunistic, or unusual infections, histological features that do not fit the usual pattern of disease, and a poor response to conventional therapy should prompt the pediatrician to pursue further immunologic evaluation. The type of immunodeficiency often influences the nature of infections: bacterial infections indicate B cell deficiencies, fungal or viral infections indicate T cell deficiencies, and T and B cell deficiencies together suggest combined immunodeficiencies. At the same time, routine evaluation of the GI tract is useful for children with immunodeficiency, given the high incidence of GI disease in these patients. Early evaluation and diagnosis can prevent potentially irreversible tissue damage. The child with GI symptoms and suspected immunodeficiency is best approached in stages with the performance of the basic screening tests before continuing on to more advanced testing as necessary. In the majority of cases, a referral to an immunologist is essential. An accurate microbiological analysis of stool samples is mandatory to rule out the presence of common or unusual pathogens. This should be done considering the potential of different diagnostic tools from standard culture to reverse transcription polymerase chain reaction (RT-PCR) analysis. A complete evaluation of quantitative levels of immunoglobulins (IgG, IgA, IgM, and IgE) and blood count should be obtained. Hypogammaglobulinemia can result from protein loss and is excluded by measuring serum albumin and urinary protein levels; enteral loss of protein can be excluded by measurement of stool alpha-1-antitrypsin level (normal values <0.9 mg/g stool). Quantification of IgG subclasses may be helpful in the assessment of an immunodeficiency,

Table 37.1 Main primary immunodeficiencies and associated gastrointestinal features

Immunodeficiency	Main gastrointestinal manifestations
<i>Selective IgA deficiency</i>	Chronic diarrhea Celiac disease Nodular lymphoid hyperplasia
<i>Agammaglobulinemia, X-linked or AR</i>	Chronic diarrhea Malabsorption
<i>Hyper-IgM syndrome</i>	Chronic diarrhea Progressive liver disease Sclerosing cholangitis
<i>Common variable immunodeficiency (CVID)</i>	Chronic diarrhea Nodular lymphoid hyperplasia Flat villous lesions IBD-like disease Atrophic gastritis
<i>Severe combined immunodeficiency (SCID)</i>	Chronic diarrhea Oral candidiasis IBD-like disease
<i>Chronic granulomatous disease (CGD)</i>	Granulomatous colitis Perianal fistulae Hepatic abscess Gastric outlet obstruction Small-bowel obstruction Granulomatous stomatitis Oral ulcers Esophageal dysmotility
<i>Wiskott–Aldrich syndrome (WAS)</i>	Colitis Malabsorption
<i>Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) and IPEX-related disorders</i>	Severe enteropathy with watery often bloody diarrhea associated with eosinophilic inflammation
<i>Interleukin-10 and interleukin-10 receptor defects</i>	IBD-like disease with early onset enterocolitis, perianal disease (multiple abscesses and enterocutaneous fistula)
<i>Hermansky–Pudlak syndrome, type 1</i>	Granulomatous colitis

IBD inflammatory bowel disease

especially in IgA deficiency. Ig values increase through adolescence, so comparison with age-matched controls is necessary for correct interpretation. Further evaluation of a humoral defect includes the qualitative aspect of the antibody response, such as IgG titer to measles, tetanus, *Haemophilus influenzae* type b, pneumococcus, and varicella. If the titer is low, vaccinations may be administered, followed by evaluation of postvaccination titers 4–6 weeks later. It is important to underline that children receiving chronic treatment with steroids may have reduced serum Ig levels; however, the antibody response would be preserved in this case. Especially in the presence of blood cells count abnormalities, it is important to ask for a lymphocyte panel to assess the number of lymphocytes and subpopulations (T cells, B cells, CD4⁺ T cells, and CD8⁺ T cells), because lymphopenia may occur secondary to excessive loss of the cells into the lumen or through the trapping of cells in the inflamed bowel wall. Severe lymphopenia in an infant (<2000/mm³) is a critical finding that, if confirmed, should lead to an immediate immune evaluation for severe combined immunodeficiency

(SCID). Thrombocytopenia and small platelet size suggest a diagnosis of Wiskott–Aldrich syndrome (WAS). In all cases, human immunodeficiency virus testing should be performed if there is clinical suspicion based on history or results of the lymphocyte panel.

Depending on the clinical picture and on the results of these initial tests, further step is the study of cellular immune function. The study of lymphocyte proliferation in response to mitogens and antigens provides more definitive data on T cell function. Failure of lymphocytes to respond to mitogens usually indicates severe impairment of T cell function, as in the case of SCID. These tests may not be possible in patients with significant T cell lymphopenia. Steroid therapy may lead to a reduced number of T cells, making interpretation of these tests difficult during therapy; however, response reappears rapidly with cessation of therapy. Advanced testing can be performed to investigate specific disorders. For example, suspicion of chronic granulomatous disease (CGD) should lead to investigation of neutrophil function; this is accomplished with a dihydrorhodamine assay to determine

a reduction or absence of phagocytic respiratory burst. Flow cytometric analysis of expression of cell surface and intracellular proteins can help in diagnosing X-linked hyper-IgM (through examination of CD40 ligand), WAS (through examination of WAS protein, WASp), and immune dysfunction, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX; through examination of FOXP3). Quantitative, real-time polymerase chain reaction for T cell receptor excision circles is used in neonatal screening assay for SCID. Genetic

testing to identify carrier states or specific mutations can be performed for X-linked agammaglobulinemia (XLA), SCID, and DiGeorge syndrome (Table 37.2). In many cases, the evaluation of GI tract is essential with laboratory tests, radiographic imaging, and intestinal biopsy specimens. It is often helpful to ask the pathologist to review slides when a question of immunodeficiency exists, given some of the unique pathologic findings or lack thereof (e.g., plasma cells) [1].

Table 37.2 Primary immunodeficiencies: main laboratory findings and molecular defects

Immunodeficiency	Laboratory findings	Molecular defect
Selective IgA deficiency	Serum IgA absent or near absent, usually <10 mg/dL	Gene defect unknown
	Normal IgG and IgM levels although IgG2 subclass deficiency may be present	Defective maturation of B cells into IgA secreting plasma cells
	Impaired specific antibody response in some patients	
Agammaglobulinemia, X-linked or AR	Absent IgM, IgG, and IgA	X-linked (BTK)
	B cells <1% of lymphocytes	Autosomal-recessive (μ heavy chain, $\lambda 5$, Ig α , Ig β , BLNK)
	Absent specific antibody response	
Hyper-IgM syndrome	Low IgG and IgA	Mutations in CD40L, CD40, AICDA, UNG
	Normal or increased IgM	
	Normal or increased B cell numbers	
	Impaired specific antibody response	
	Decreased T cell responses in CD40L/CD40 deficiency	
Common variable immunodeficiency (CVID)	Low IgG and IgA and/or IgM	Mutations in ICOS, CD19, CD20, CD81, TNFRSF13B, TNFRSF13C; mostly unknown
	Absent specific antibody response	
	Normal or decreased B cell numbers	
	Variably decreased T cell responses	
Severe combined immunodeficiency (SCID)	Decreased serum immunoglobulins	Multiple defects: RAG1/2, JAK3, CD45, CD3 chain, ZAP70, Artemis, ligase 4, Cernunnos, IL-2RG, IL-7R α , ADA: defects in T and B cells
	Marked diminished/absent T cell, B cell, and NK cell numbers depending on functional deficiency	
	Diminished response to mitogens PHA, ConA, PWM	
Chronic granulomatous Disease (CGD)	Defective oxidative burst in neutrophils by DHR or NBT equivalent	Multiple defects: X linked owing to defects in CYBB encoding the gp91 phox component of NADPH oxidase autosomal recessive owing to defects in NCF1, NCF2, or CYBA defects in components of NADPH oxidase
Interleukin-10 and interleukin-10-receptor defects	Pathological response to functional tests using STAT3 and/or TNF- α assays	Mutations in IL-10, IL-10 receptor
Wiskott–Aldrich syndrome (WAS)	Immunoglobulins variable in concentration secondary to accelerated synthesis and catabolism (decreased IgM; normal or slightly low IgG; often increased IgA and IgE);	Mutations in WAS; cytoskeletal defect affecting hematopoietic stem cell derivatives
	Antibody response to polysaccharides decreased	
	Normal B-cell numbers	
	Progressive decrease in T-cell numbers with abnormal lymphocyte responses to anti-CD3	
	Platelet numbers are reduced and small in size	
Hermansky–Pudlak syndrome, type 1	Normal platelet count	Mutation in the HPS1 gene on chromosome 10q23 that forms part of BLOC-3
	Prolonged bleeding time with abnormal platelet function assays	

ADA adenosine deaminase, AICDA activation-induced cytidine deaminase, AR autosomal recessive, BLNK B cell linker protein, BLOC-3 biogenesis of lysosome-related organelles complex-3, BTK Bruton tyrosine kinase, CYBA cytochrome b α subunit, CYBB cytochrome b β subunit, DHR dihydrorhodamine, ICOS inducible costimulator, JAK3 Janus activating kinase 3, NADPH nicotinamide adenine dinucleotide phosphate, NCF neutrophil cytosolic factor, NF- κ B nuclear factor- κ B, PHA phytohemagglutinin, PWM pokeweed mitogen, RAG recombinase activating gene, TBX1 T-box 1, TNFRSF TNF-receptor superfamily, UNG uracil DNA glycosylase, STAT3 signal transducer and activator of transcription-3, TNF- α tumor necrosis factor- α , NBT nitroblue tetrazolium

Predominant B-Cell (Antibody) Deficiency

Selective Ig A Deficiency

Selective IgA deficiency is the most common primary immunodeficiency; it is defined as decreased serum level of IgA in the presence of other normal Ig isotypes, T-cell immunity, and natural killer activity. The worldwide incidence of IgA deficiency differs by ethnic background, in Caucasians being much higher than that in Asians, with a prevalence of around 1:3000 in US [2]. IgA is the key Ig in the respiratory and GI tracts, which provide the most intimate interface between the environment and self [3]. The manifestations are variable in IgA deficiency patients: from asymptomatic condition (in up to 90% of subjects) to recurrent infections of the respiratory (particularly *H. influenzae* and *Streptococcus pneumoniae*) and GI tracts, autoimmune diseases, allergies, and malignancies. Autoimmune diseases are a frequent finding in IgA deficiency, mainly autoimmune cytopenias, juvenile rheumatoid arthritis, thyroiditis, systemic lupus erythematosus, and celiac disease. IgA deficiency sometimes progress to common variable immunodeficiency (CVID); in fact, the diseases often share a common genetic and familial predisposition (IGAD1) [2]. Other related conditions include anaphylactic transfusion reactions; the patients should be screened for anti-IgA antibodies and treated with low or absent IgA blood products if the need for transfusion arises. GI manifestations are frequent in patients with selective IgA deficiency. *Giardia lamblia* infections can occur in these patients, causing bloating, cramping, excessive flatus, and watery diarrhea. The infection can be chronic, despite treatment with metronidazole, resulting in malabsorption with steatorrhea and villus flattening [4]. The degree of mucosal damage is related to the duration of the infection. Diagnosis is made by examining the stool for cysts or trophozoites of *G. lamblia*, or by examination of duodenal aspirates, which can yield more determinate results. The incidence of selective IgA deficiency has been demonstrated to be higher in celiac disease than in the general population, given shared human leukocyte antigen (HLA) haplotypes. Secretory IgA can bind to wheat gluten and gliadin, and the absence of IgA may lead to abnormal processing of these antigens [4]. The symptoms of celiac disease are similar in patients with or without IgA deficiency, the only differentiating feature is that immunohistochemical staining of small-intestinal biopsies reveals an absence of IgA-secreting plasma cells in IgA-deficient patients. Antigliadin IgA, antitissue transglutaminase IgA, and antiendomysial IgA antibodies cannot be used as screening tests for this population, tissue transglutaminase IgG may be a better screening test [4]. Celiac disease associated with IgA deficiency is responsive to gluten withdrawal, failure to respond to a gluten-free diet should lead one to consider CVID.

Nodular lymphoid hyperplasia also is documented in IgA deficiency. Multiple nodules are found in the lamina propria, superficial submucosa of the small intestine, or both, and occasionally can occur in the stomach, large intestine, or rectum. The lesions can be associated with mucosal flattening, causing malabsorption and even obstruction when large. Diagnosis is made by small-bowel endoscopy sometime with the help of contrast barium or MRI studies. Large amounts of IgM-bearing cells can be found in the immunohistochemical staining, possibly as compensation for the absent IgA. These patients may benefit from oral steroid therapy [4]. Rarely, patients with IgA deficiency can develop pernicious anemia, inflammatory bowel disease, lymphomas (usually B cell origin), and gastric carcinomas. The diagnosis is based on the measurement of IgA concentration in serum; normal levels of IgA are dependent by age, ethnicity, gender, and body habits. The international consensus for diagnosing a selective IgA deficiency is a serum level of below 0.07 g/l in individuals over 4 years of age accompanied by normal levels of IgG and IgM [2]. The threshold of 4 years of age is used to avoid premature diagnosis of IgA deficiency which may be transient in younger children due to delayed ontogeny of IgA system after birth [3]. In IgA deficiency, the mainstay of the therapeutic approach is the treatment of associated diseases. If the patient experiences recurrent infections, daily prophylactic antibiotics on a continuous or seasonal intermittent basis may be beneficial [3]. IL-21 or the combination of CD40 L/anti-CD40, IL-4, and IL-10 are potential targets for new therapeutic modalities [2, 5].

X-Linked-Agammaglobulinemia

XLA results from a maturation arrest of pre-B cells with subsequent B cell generation failure, no plasma cell in lymphoid tissues, virtual absence of all classes of Ig, small tonsils, and lymph nodes. They are typically male infants or young children. The incidence is approximately 1 in 100,000 live births. Female carriers can be detected, and prenatal diagnosis of affected or unaffected male fetuses can be accomplished. XLA results from a defect of Bruton's tyrosine kinase (BTK), a member of Tec family protein. It is an intracellular tyrosine-kinase protein, expressed in most of hematopoietic cells: It presents high levels in all B-cells line, but it is not expressed in T cell precursors and natural killer (NK) cells. BTK gene is located on the proximal part of the long arm of the X chromosome. There are about 554 different mutations of BTK gene, but it seems that there is no correlation between mutation location and clinical phenotype. The abnormal BTK induce a maturational arrest of B lymphocytes at the pre-B cell stage and secondary inability to produce antibody after antigen stimulation. A normal number of pre-B cells are found in the bone marrow, but no

mature B cells. Peripheral CD19, CD20, and CD23 B cells are usually less than 0.1%. IgG, IgA, and IgM levels are virtually absent. There is no production of isohemagglutinins or antibody after vaccinations. There are, also, five different autosomal recessive defects that cause agammaglobulinemia [6]. These include: (1) μ (IgM heavy chain deficiency), (2) Ig- α (CD79a9 deficiency), (3) B cell linker adaptor protein (BLNK) deficiency, (4) surrogate light chain (lambda 5 or CD179b) deficiency, (5) leucine-rich repeat containing 8 (LRRC8). All these forms present similar immunological and clinical phenotypes to XLA but are less common. The majority of males with XLA are asymptomatic during the first 4–6 months of life thanks to mother's transmitted antibodies [7]. Then they present severe and repeated infections caused, mainly, by extracellular pyogenic and encapsulated organisms, often gram-positive (such as *S. pneumoniae*, *Staphylococcus Aureus*, *Neisseria*, *Haemophilus* or *Mycoplasma*). The infections may interest respiratory, GI, and genitourinary tracts. Systemic infections (septicemia or meningitis) are less common but frequent, as well as osteomyelitis, septic arthritis, cellulitis or skin abscesses. In such cases, we can observe chronic fungal infection or *Pneumocystis jirovecii* pneumonia. Viral infections are, usually, self-limiting except hepatitis or enteroviruses despite a good T-cell response. GI manifestations are less common in XLA compared to other antibody-deficiency syndromes and to CVID. The most frequent GI symptom is chronic diarrhea that is often accompanied by secondary malabsorptive syndrome associated with a protein-losing enteropathy [8]. The main pathogens involved in these infectious diarrheas are *G. lamblia*, *Salmonella*, *Campylobacter*, and *Cryptosporidium*; enteroviral infections (such as *Coxsackievirus* and *Echovirus*) are also common and can lead to severe neurologic defects. Sometimes chronic diarrhea is related to small bowel bacterial overgrowth. It is important that GI infection treatments are based on adapted culture methods and adequate prolonged therapy. Cases of malabsorption and bacteremia due to infection of *Helicobacter pylori* and *Campylobacter jejuni* resistant to many antibiotics have been described [9]. Some patients with XLA present small-bowel strictures and transmural intestinal fissures similar to Crohn's disease, without granulomas or plasma cells. XLA patients generally do not develop nodular lymphoid hyperplasia. The disease, occasionally, manifests with different clinical spectrums such as autoimmune diseases or cancer (gastric adenocarcinoma and colorectal cancer). In particular, chronic atrophic gastritis with pernicious anemia is also a common finding that predisposes to gastric adenocarcinoma. In spite of these infections, patients with XLA may not have failure to thrive unless they develop bronchiectasis. The most common cause of death was chronic enteroviral infection [10]. Diagnosis is based on clinical features and typical laboratory results (profound reduction in all classes of Ig and depressed or absent

humoral response to specific antigens, peripheral CD19+ B cell usually <0.1% with preserved T cell number and function) and, it could be confirmed by genetic mutation analysis [11]. An early diagnosis of XLA with immediate initiation of therapy is crucial for ensuring good outcomes for the affected patients. Delayed diagnosis could lead to long-lasting sequelae such as bronchiectasis, hearing loss, or liver cirrhosis due to chronic hepatitis. XLA treatment consists of replacement IgG therapy (intravenous gammaglobulin, IVGG); either intravenous or subcutaneous. Early IVGG replacement therapy decreases the rates of admission and morbidity for chronic complications, such as bronchiectasis and chronic lung disease, and prevents fatal complications like meningoencephalitis. Appropriate IVGG should be started at 6–8 weeks of age because around 25% of the XLA patients show clinical symptoms before 4 months of age. Antibiotics treatment for documented or suspected infections is necessary because commercial preparations of IgG could not have adequate titers against uncommon organisms.

Hyper-IgM Syndrome

Hyper-IgM syndromes are a group of rare inherited immunodeficiencies characterized by impairment of Ig isotype switching resulting from defects in the CD40 ligand/CD40 signaling pathway. They are characterized by high levels of IgM associated with low or absent levels of IgG, IgA, and IgE [12]. This "class switch" is critical to host resistance to bacterial infections. There are several mutations that caused hyper-IgM syndrome:

1. X-linked hyper-IgM syndrome is the most common form. This condition could derive from two different gene mutations: One gene encodes the CD40 ligand (*hyper-IgM syndrome type 1* or *HIGM1*). Because the lack of this ligand on T cells, there is no interaction with CD40 on B cells (this interaction is fundamental for Ig class switching and for the formation of memory B lymphocytes). B cells cultured are able to produce not only IgM, but also IgG, IgA, and IgE, this confirms that the defect interests T cells. Mitogen proliferation may be normal, but NK cell and T cell cytotoxicity is frequently impaired. Antigen-specific responses may be decreased or absent. The male with this syndrome present small tonsils, absence of palpable lymph nodes. Neutropenia, thrombocytopenia, and anemia are common. The other gene, located on X-chromosome, is *NEMO* gene, it encodes for a nuclear factor-kappaB (NF- κ B) nuclear factor. In male, this form is clinically associated with anhidrotic ectodermal dysplasia with immunodeficiency (EDA-ID), in female it causes incontinentia pigmenti.
2. Autosomal recessive hyper-IgM syndrome. The most common form is caused by defects in the CD40-activated

RNA-editing enzyme, activation-induced cytidine deaminase, which is required for isotype switching and somatic hypermutation in B cells. The gene involved is activation-induced cytidine deaminase (AICDA) gene located on chromosome 12 (*Hyper-IgM syndrome type 2* or *HIGM2*). In this case, B cells cultured are not able to produce all class of Ig, this confirm that there is a real defect of B cell. Other two forms interest: uracil DNA glycosylase gene (UNG) and CD40 gene (*hyper-IgM syndrome type 3* or *HIGM3*).

3. *Hyper-IgM syndrome type 4* or *HIGM4* deriving from a yet unidentified gene mutation.

Distinctive clinical features for these patients allow presumptive recognition of mutation, this is important to choose the best therapy. The range of clinical findings varies, even within the same family. Over 50% of males with HIGM1 develop symptoms by the age of 1 year, and more than 90% are symptomatic by the age of 4 years. The clinical presentation of X-linked hyper-IgM is similar to XLA, with recurrent pyogenic infections such as otitis, sinusitis, pneumonia, or tonsillitis that start in the first 2 years of life. These patients are also susceptible to a variety of intracellular pathogens as mycobacterial species, fungi, and viruses; in about 40% of cases, we found pneumonia by *Pneumocystis jirovecii*. Significant neurologic complications are seen in 10–15% of males with HIGM1. However, in at least one half of affected individuals a specific infectious agent cannot be isolated. GI symptoms include mostly chronic diarrhea and liver involvement. The main pathogens that caused diarrhea are *Cryptosporidium parvum* (the most common), *G. lamblia*, *Salmonella*, or *Entameba histolytica*. Chronic diarrhea is a frequent complication of HIGM1, occurring in approximately one third of affected males. Recurrent or protracted diarrhea may result from infection with *C. parvum* or other microorganisms; however, in at least 50% of males with recurrent or protracted diarrhea, no infectious agent can be detected. It can cause failure to thrive and weight loss. Neutropenia often causes oral or rectal ulcers and gingivitis or mucosal abscess. Liver disease, a serious complication of HIGM1, historically was observed in more than 80% of affected males by age 20 years. Hepatic involvement presents: cholangiopathy with *Cryptosporidium* in the biliary tree, B and C hepatitis and cytomegalovirus (CMV) infections with a possible evolution in cirrhosis or hepatocellular carcinoma. It can result in disturbed liver increased gamma-glutamyltransferase levels; this alteration can predict a possible development of sclerosing cholangitis with a risk of cholangiocarcinoma. Tumors of the GI tract (carcinoid of the pancreas, glucagonoma) are common life-threatening complications in adolescents and young adults with HIGM1 [13]. Affected males also have an increased risk for lymphoma, particularly Hodgkin's disease associated with *Epstein-Barr* virus infection. Autosomal recessive forms have usually a later onset and present often

autoimmune disorders (such as diabetes mellitus, autoimmune hepatitis, autoimmune thrombocytopenia, and Crohn's disease). Neutropenia is less common. The reported median survival of males with HIGM1 who do not undergo successful allogeneic bone marrow transplantation is less than 25 years. *P. jirovecii* pneumonia in infancy, liver disease, and carcinomas of the liver and GI tract in adolescence or young adulthood are the major causes of death [14]. Laboratory evaluation is fundamental: These patients have low or absent levels of IgG, IgE, and IgA associated to normal or high level of IgM (very high levels of IgM are typical of autosomal recessive form) and IgD. B and T lymphocyte number are usually normal. The diagnosis of HIGM1 is based on a combination of clinical findings, family history, absent or decreased expression of the CD40 ligand (CD40L) protein on flow cytometry following in vitro stimulation of white cells, and molecular genetic testing of CD40LG (previously known as TNFSF5 or CD154). The only curative treatment currently available is allogeneic hematopoietic cell transplantation, ideally performed prior to the onset of life-threatening complications and organ damage. Other effective therapies are monthly replacement of Ig and antibiotics for specific infectious complications. To reduce the risk of *Cryptosporidium* infection is recommended that patients boil or filter water. In patients with neutropenia is possible use granulocyte colony-stimulating factor (G-CSF).

Common Variable Immunodeficiency

CVID with an estimated prevalence of 1/100,000 to 1/50,000 is the most common symptomatic primary antibody deficient syndrome and is characterized by decreased levels of at least two serum Ig isotypes and recurrent infections particularly of the respiratory tract [15]. The diagnosis is based on significantly reduced levels of IgG, IgA, and/or IgM, with poor or absent antibody production to protein and carbohydrate vaccines with exclusion of other causes of hypogammaglobulinemia [16, 17]. Most patients are diagnosed with CVID between the ages of 20 and 40 years; however, the diagnosis commonly is delayed by 6–8 years, even after the onset of characteristic symptoms [16]. The genetic basis of CVID is unknown in most cases, although defects have been described in four genes: inducible T cell costimulator (*ICOS*), tumor necrosis factor receptor superfamily member 13B (*TNFRSF13B*, also known as *TACI*), tumor necrosis factor receptor superfamily member 13C (*TNFRSF13C*, also known as *BAFFR*), and *CD19* [18–20]. GI symptoms are common in CVID patients, as up to 50% of patients have chronic diarrhea with malabsorption [21]. They may be related to recurrent intestinal infections caused by *G. lamblia*, *C. jejuni*, or *Salmonella*, pathogens frequently associated with profound B cell immunodeficiencies [22, 23]. Diarrhea

and malabsorption have also been ascribed to the onset of inflammatory bowel diseases [24] or to the intestinal villous atrophy mimicking celiac disease, a condition observed in 31% of CVID patients with GI symptoms or anemia [25]. Whether some CVID patients with intestinal villous atrophy can develop an authentic celiac disease remains debated. Some studies concluded to celiac disease responding to gluten-free diet [26], whereas others described histological presentations distinct from celiac disease and resistance to gluten-free diet. An atrophic gastritis, which resembles autoimmune gastritis developing into pernicious anemia, may occur in the absence of demonstrable antiparietal cell antibodies in CVID patients. Treatment of pernicious anemia in CVID patients is similar to that of patients without CVID: monthly replacement of vitamin B12 and careful monitoring of the gastric mucosa for changes associated with malignancy. Gastric adenocarcinoma, in the setting of atrophic gastritis or de novo, has an increased frequency in CVID patients. Patients are treated with monthly infusions of IgG; this treatment alone may not be effective in treating other manifestations of this disorder. Although the inflammatory process responds to steroid therapy, prolonged therapy with steroids is not advisable in CVID patients. Other immune modulators such as 6-mercaptopurine (6-MP) or azathioprine (AZA) can be used in addition to Ig replacement therapy. Careful use of budesonide may be required if unresponsive to 6-MP or AZA until the symptoms are controlled (e.g., reversal of weight loss and dehydration). In severe cases of malabsorption, when significant loss of essential nutrients (e.g., calcium, zinc, and vitamins A, E, and D) lead to bone loss and neurologic deficits, limited use of total parenteral nutrition may be required.

Combined T and B cell Immunodeficiency

SCID

SCID includes a group of disorders characterized by impaired development of cellular and humoral immune function. The overall incidence of all types of SCID is approximately 1 in 75,000 births [27]. This condition is uniformly fatal in the first 2 years of life unless immune reconstitution can be accomplished. The common characteristic of all types of SCID is a severe impairment of T cell development, with a virtual lack of circulating autologous T lymphocytes and absence of functional T-cell responses. SCID can be divided into two main classes: with (B+SCID) and without (B-SCID) B lymphocytes. Presence or absence of NK cells is variable within these groups. The condition results from mutations in known genes that encode components of the immune system crucial for lymphoid cell development (Table 37.2) [28–30].

Affected individuals appear to be normal infants at birth but begin to suffer from excessive infections and failure to thrive coincident with the waning of transplacentally acquired maternal IgG between 2 and 4 months of age [31].

Most males with typical X-SCID come to medical attention between ages three and 6 months. During the first year of life, nearly all untreated males with X-SCID present failure to thrive, oral/diaper candidiasis, absent tonsils and lymph nodes, recurrent infections, infections with opportunistic organisms such as *P. jirovecii*, and persistence of infections despite conventional treatment. Additional features include immune dysregulation and autoimmunity associated with rashes, GI malabsorption, and short stature. Ten to 15% of patients have a “delayed” clinical onset by age 6–24 months and a smaller percentage of patients have “later” onset, diagnosed from ages 4 years to adulthood, showing less severe infections, and gradual immunologic deterioration. All patients with SCID have very small thymuses. The spleen appears depleted of lymphocytes. Lymph nodes, tonsils, adenoids, and Peyer patches are absent or extremely underdeveloped. GI disorders often occur in SCID patients. Oral, esophageal, and perianal candidiasis is common and can affect oral intake. Patients can develop severe diarrhea and malabsorption in the early age. Intractable diarrhea may begin slowly and progressive to massive, watery, bloody, and mucopurulent. Stool should be sent to a laboratory to check for viral and opportunistic infections, especially rotavirus. Chronic infection with rotavirus has been reported in patients who have received the live vaccination. CMV and adenovirus infections also have been identified in GI biopsy specimens. GI biopsy specimens show hypocellular lamina propria, without plasma cells or lymphocytes. Villous atrophy may occur in some infants owing to damage in the intestine after viral or bacterial infections. A hereditary multiple intestinal atresia is described as an unusual and rare form of recurrent intestinal atresia, which can be associated with SCID [32]. Graft versus host disease (GVHD) and a GVHD-like process affecting colon and small intestine can occur in patients with SCID who receive blood transfusions or allogeneic bone marrow transplantation. Early recognition and diagnosis is crucial to these patients. The diagnosis of SCID is established when the absolute lymphocyte count is less than 1500–2000 cells/mm³ (normal 4000–13,500 cells/mm³); CD3+ T cell counts are usually <500 cells/mm³ (normal range 3000–6500 cells/mm³). The number of B and NK cells varies according to the underlying genetic defect. In few rare cases, maternal engraftment of T cells may cause near-normal T cell counts. Serum levels of Ig are usually very low and specific antibody responses are impaired. Diagnosis of infants often is delayed by several months as a result of the protection of maternal antibodies. When there is a prior SCID-affected child with a known specific molecular defect, a prenatal diagnosis can be made through genetic testing.

After diagnosis, treatment relies on prevention of principal complications until allogeneic hematopoietic stem cell transplantation. Replacement Ig therapy is given, as well as prophylaxis for *P. jirovecii* pneumonia. Live vaccinations should not be given to the patient or the patient's caregivers because they can cause life-threatening infections. Blood products are irradiated before administration to prevent GVHD. Definitive treatment is available for SCID predominantly by allogeneic hematopoietic stem cell transplantation but also in specific forms of SCID (SCID-X1 and adenosine deaminase (ADA)-SCID) by gene therapy and by enzyme replacement therapy for ADA SCID [33, 34].

Disorder of Phagocytes Function

Chronic Granulomatous Disease (CGD)

CGD is an uncommon primary immunodeficiency (affecting 1 in 250,000 live births) caused by an inability of the phagocytes to produce adequate reactive oxygen metabolites to kill ingested microorganisms and leads to recurrent or persistent intracellular bacterial and fungal infections and to granuloma formation. This impairment in killing is caused by any of several defects in the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase enzyme complex, which generates the microbicidal respiratory burst. The most common form is X-linked (*gp91phox*); others are autosomal recessive [35]. Patients with CGD are susceptible to severe and recurrent infections due to catalase-positive organisms (e.g., *Staphylococcus aureus*, *Burkholderia cepacia*, *Serratia marcescens*, *Aspergillus* species, *Chromobacterium violaceum*, and *Nocardia* species) at epithelial surfaces (e.g., skin, gut, lungs) as well as in organs with a large number of phagocytes such as the liver. The disease becomes apparent during the first 2 years of life in most patients. GI clinical manifestations are common in patients with CGD, ranging from chronic diarrhea, malabsorption with steatorrhea and vitamin B12 malabsorption, perianal abscesses and fistulae, GI tract infection, liver abscesses, hepatosplenomegaly, oral ulceration, and characteristic obstructive lesions associated with granulomatous infiltration [36]. CGD subjects with colitis often present with signs and symptoms similar to those seen in Crohn's disease and ulcerative colitis. However, in contrast to inflammatory bowel disease, CGD-associated colitis may have distinctive histopathologic findings including more eosinophils, fewer neutrophils, and numerous lipid-laden macrophages. Typically, these cells were located in the lower third of the mucosa near crypt bases. It is critically important for the clinician to consider the possibility of CGD in patients with a "Crohn-like" disease in whom a history of recurrent infections and abscesses is noted [37]. Diagnosis of CGD is made by demonstrating a lack of oxidative

burst by the nitroblue-tetrazolium test or a flow cytometric test using dihydrorhodamine dye, and confirmed by Western blot and mutation analysis. Management of CGD includes antibiotic prophylaxis with trimethoprim-sulfamethoxazole and itraconazole to reduce the incidence of bacterial and fungal infections, although breakthrough infections do occur. Prophylactic administration of subcutaneous interferon- γ also has been used. Hematopoietic stem cell transplantation from an HLA-identical donor can be curative for CGD [38]. CGD-associated colitis typically responds rapidly to treatment with steroids. Other treatment options are based on established inflammatory bowel disease therapies and include interferon- γ , antitumor necrosis factor α (anti-TNF α), and cyclosporine.

Immune Dysregulation Diseases

IPEX and IPEX-Like Disorders

A number of disorders characterized by immune dysregulation and autoimmunity results from defects in T regulatory cells, development and function. The best characterized of these is immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX), resulting from mutations affecting FOXP3. A number of other gene defects that affect T-regulatory cell function also give rise to an IPEX-like phenotype, including loss-of-function mutations in CD25, STAT5b, and ITCH and gain-of-function mutations in STAT1 [39] (Table 37.3). IPEX typically presents during the first 2–3 months of life with severe enteropathy leading to secretory diarrhea (at times mucoid or bloody) unresponsive to fast and failure to thrive, eczema, diabetes mellitus, and hemolytic anemia. Clinical presentation can be similar to that of severe food allergy, although these patients are generally unresponsive to the elemental formula. Histopathology includes loss of normal small-bowel mucosa as a result of total or partial villous atrophy. Involvement of the large intestine is common with lymphocytic and plasma cell infiltration in the lamina propria; eosinophils also may be present. There is mucosal and submucosal destruction, although the muscular layer is preserved. Celiac disease, food allergy, inflammatory bowel disease, and GVHD are often on the differential diagnosis, based on histology. Other autoimmune manifestations, including thyroiditis, thrombocytopenia, and neutropenia, also have been reported. B-cell subsets and CD3+ T cells, including CD4+ and CD8+ subsets, are present in normal numbers and proliferate to mitogens and antigens, although affected patients typically have decreased numbers of regulatory T cell and are unable to suppress T cell proliferation. Serum IgG, IgA, and IgM levels are usually normal but can be slightly reduced from enteric protein loss. IgE usually is increased and eosinophilia is frequently present.

Table 37.3 Clinical and laboratory features of IPEX and IPEX-like disorders

	IPEX	CD25	STAT5b	STAT-1	ITCH
Associated features	None	None	Growth failure	Vascular anomalies	Dysmorphic growth failure
Autoimmunity					
<i>Eczema</i>	+++	+++	++	++	++
<i>Enteropathy</i>	+++	+++	++	++	++
<i>Endocrinopathy</i>	+++	++	+	++	++
<i>Allergic disease</i>	+++	+	+	++	++
<i>Lung disease</i>	+	++	+++	+	+++
Infections					
<i>Yeast</i>	–	++	–	+++	–
<i>Herpes virus</i>	–	+++ (EBV/CMV)	++ (VZV)	++	–
<i>Bacterial</i>	+/-	++	++	++	+
Laboratory findings					
<i>Cytopenias</i>	++	++	++	–	
<i>Serum immunoglobulins</i>	↑	Normal or ↑	Normal or ↑	Normal or ↑/↓	↑
<i>Serum IgE</i>	↑	Normal or ↑	Normal or ↑	Normal or mildly ↑	↑
<i>CD25 expression</i>	Normal	↓	Normal or ↓	Normal	Unknown
<i>CD4 + CD45RO</i>	↑	↑	↑	Normal or ↑	Unknown

<i>Prolactin</i>	Normal	Normal	↑	Normal	Unknown

CMV cytomegalovirus, EBV Epstein Barr virus, VZV varicella zoster virus, IGF insulin-like growth factor binding protein, IGFBP insulin-like growth factor binding protein

The diagnosis is made by showing decreased FOXP3 protein expression and a reduction in the number of regulatory T cells. The diagnosis also can be confirmed by mutation testing of the *FOXP3* gene [1]. Autoantibodies to harmonin and villin are considered specific diagnostic markers of IPEX, and could be of help to differentiate IPEX, including atypical cases, from other early disorders associated with severe enteropathy [40]. Patients are often severely ill by the time a diagnosis of IPEX is made. In absence of aggressive therapy, children usually die before 2–3 years of age as a result of malnutrition, electrolyte imbalance, or infection [41]. Symptomatic treatment includes bowel rest with total parental nutrition and, if necessary, insulin injections and red blood cell and platelet transfusions. Although immunosuppression can be used in the interim, hematopoietic stem cell transplant is curative. Immunosuppressive agents such as cyclosporine A, tacrolimus, sirolimus, and steroids have been used with some success to improve diarrhea; however, these agents do not maintain long-term remission. Chronic therapy may be toxic and may facilitate opportunistic infections [1].

Interleukin-10 and Interleukin-10-Receptor Defects

IL-10 pathway plays a critical role in the control of inflammation by limiting the secretion of pro-inflammatory

cytokines, including TNF- α , IL-1, IL-6, and IL-12. Loss-of-function mutations in IL-10 itself and in IL-10 receptor A (IL-10RA) or IL-10 receptor B (IL-10RB) encoding respectively the α -unit (IL-10R1) and the β -unit (IL-10R2) of the IL-10 receptor have been described in children with severe early-onset enterocolitis [42, 43]. These patients present within the first year of life with enterocolitis and perianal disease, as well as the formation of multiple abscesses and enterocutaneous fistula, requiring several surgical interventions. Histopathology shows ulcerations of the intestinal mucosa with inflammatory infiltrates of the epithelium and the formation of abscesses extending to the muscularis propria. The patients also suffer from chronic folliculitis and recurrent respiratory infections. Although rare, pediatric patients with inflammatory bowel disease and perianal disease should be screened for IL-10 and IL-10R deficiency. Defects in the IL-10R may be evaluated by functional assays. Peripheral blood mononuclear cells from healthy individuals show strong phosphorylation of the signal transducer and activator of transcription-3 (STAT3) upon stimulation with IL-10, whereas peripheral blood mononuclear cells from IL-10R-deficient patients do not. Functional abnormalities can be confirmed by sequencing IL-10RA and IL-10RB [44]. The management of these patients includes various anti-inflammatory drugs, such as steroids, methotrexate, thalidomide, and anti-TNF α monoclonal antibodies, without success of remission or long-term improvement. Both IL-10 and IL-10

receptor deficiency can be successfully treated by hematopoietic stem cell transplantation.

Immunodeficiency Associated with Other Defects

WAS

WAS is a rare X-linked primary immunodeficiency characterized by microthrombocytopenia, eczema, recurrent infections, and an increased incidence of autoimmunity and malignancies. The disease is caused by mutations in the WASp, which is involved in hematopoietic cell differentiation and development [45]. The most severe form of WAS is associated with mutations that lead to absent or truncated protein, and individuals with this class of mutations develop classic WAS. Mutations that lead to full-length, but reduced quantity of WASp typically lead to X-linked thrombocytopenia with minimal, if any, immunodeficiency. Missense mutations that have no effect on WASp expression lead only to intermittent thrombocytopenia. Of note, platelets have reduced size in all three classes of mutation. A fourth class of mutations results in a missense mutation in the WASp Cdc42 binding site. These individuals demonstrate no thrombocytopenia and have normal-sized platelets, but they typically develop a neutropenia (and often a complete loss of this cell line) with infections. Interestingly, the first three classes of mutations in WASp show no tendency toward neutropenia. WAS can also be associated with other immune defects, including abnormalities of humoral and cell-mediated immunity [46]. Patients with WAS usually are male infants present in the first few months of life with the above clinical picture accompanied by bleeding, commonly bloody diarrhea. Although other GI complications are not prominent, malabsorption and nonspecific colitis may be encountered. Serious infections also occur. Encapsulated organisms are frequent pathogens that may cause life-threatening complications, including pneumonia, meningitis, and sepsis. *Pneumocystis jirovecii* and viral infections also may become troublesome. Atopic symptoms are frequently present, and eczema develops in more than 2/3 of these patients. The eczema may improve as the patient gets older, although serious complications such as secondary infection (e.g., cellulitis, abscess) or erythroderma can occur. Laboratory evaluation reveals normal or slightly low IgG levels, high IgA and IgE levels, and low levels of IgM that are secondary to accelerated synthesis and catabolism. Antibody responses to polysaccharide antigens are decreased. Platelet numbers are reduced and small in size. Patients have normal B cell numbers; while their T cells show a progressive decrease in number and function. Diminished lymphocyte proliferation in response to mitogens occurs in approximately 50% of patients. The number

and phagocytic activity of neutrophils are normal, although chemotactic responses are defective. Screening for WASp mutations is performed by flow cytometry; however, this does not identify carriers of, or those patients with, X-linked thrombocytopenia. Sequence analysis of the WAS gene is essential to confirm the diagnosis. Curative therapy for WAS is hematopoietic cell transplantation; however, gene therapy is under investigation [47]. Conventional management includes antibiotic prophylaxis as well as platelet transfusions, to treat major bleeding episodes.

Hermansky–Pudlak Syndrome

Hermansky–Pudlak syndrome (HPS) is a rare autosomal recessive disease that displays genetic heterogeneity, there are nine known subtypes [48]. It is a multisystem disorder characterized by tyrosinase-positive oculocutaneous albinism, a bleeding diathesis resulting from a platelet storage pool deficiency and, in some cases, pulmonary fibrosis or granulomatous colitis. Systemic complications are associated with accumulation of ceroid lipofuscin. The bleeding diathesis can result in easy bruising, frequent epistaxis, gingival bleeding, postpartum hemorrhage, colonic bleeding, and prolonged bleeding with menses or after tooth extraction, circumcision, and other surgical procedures. Pulmonary fibrosis, a restrictive lung disease, typically causes symptoms in the early thirties and can progress to death within a decade. A bleeding granulomatous colitis, which occurs in patients with HPS, has clinical features suggestive of chronic ulcerative colitis and pathological features similar to that of Crohn's disease including non-necrotizing granulomas, fissuring, and transmural inflammation. Colitis usually manifests in the first and second decades of disease; it can be severe and have been reported to be poorly responsive to medical therapies, occasionally requires colectomy [49]. Although the colon is primarily involved in HPS any part of the GI tract, including the gingiva, can be affected. Diagnosis is based on clinical findings of oculocutaneous albinism in combination with a bleeding diathesis, confirmed by an absence of platelet dense bodies and genetic testing. Laboratory findings show normal platelet count, prolonged bleeding time, with abnormal platelet function assays. Recently, treatment with infliximab has been shown to be effective [50].

Nicholas O. Davidson and Emile Levy

Introduction

Congenital disorders of intestinal lipid absorption includes a clinically heterogeneous group of conditions for which the molecular genetic basis has been assigned to a group of gatekeeper genes whose roles are exerted at multiple steps following complex intracellular lipid assembly and the subsequent packaging that eventually form chylomicrons (CMs). The critical steps involve mobilization of membrane-associated complex lipids into vesicular transport vehicles within the lumen of the endoplasmic reticulum (ER) and Golgi and ultimately vectorial delivery to the basolateral membrane of the enterocyte for extrusion and transport into mesenteric collecting lymphatics. The critical role of these gatekeeper genes, particularly MTTP, APOB, and SAR1B has been replicated in preclinical and cell-based models, and we now know much about the function and importance of their cognate proteins. The importance of these genes resides in the recognition that mutations or deletions may give rise to severe fat malabsorption and failure to thrive in early childhood, in association with very low plasma cholesterol and triglyceride (TG) levels. In addition, unrecognized failure to thrive and lipid malabsorption syndromes may lead to progressive ataxic neuropathy and retinal degeneration because of the attendant malabsorption of fat-soluble vitamins, particularly vitamin A and E. With early diagnosis and appropriate nutritional supplementation, these particular complications can be avoided and in general life expectancy should be unaltered.

We review the major genetic syndromes associated with congenital lipid malabsorption, the molecular genetics, and pathophysiologic basis underlying defective lipid absorption and describe the clinical manifestations and management of these patients.

Intestinal Lipid Absorption Overview

The reader is referred to recent comprehensive reviews of intestinal lipid absorption [1, 2] but the essential features are summarized below (Fig. 38.1). Complex lipids (principally long-chain TG and also cholesterol ester (CE) and phospholipids) are enzymatically lipolyzed to yield fatty acid (FA) and monoglycerides (MG), which are then transported through micelle-dependent uptake across the brush border membrane of villi. FA and MG within the enterocyte are used to generate newly synthesized TG droplets through the actions of diacylglycerol acyltransferase 1 (DGAT1) which likely functions in close proximity to the ER (Fig. 38.1). These TG droplets exist in both cytosolic (principally apical) compartments as well as within the ER membrane. Mobilization of TG droplets from within membranous domains requires the integrated actions of two gatekeeper genes, namely the resident endoluminal ER protein microsomal triglyceride transfer protein (MTTP) and a structural acceptor protein that is required for CM formation namely apolipoprotein B (APOB), and its intestine-specific isoform, APOB48. In this scenario, MTTP physically transfers the lipid droplet from the bilayer by mediating a physical interaction with the nascent APOB protein during translation and extrusion into the ER lumen [2]. The fusion of TG droplets with APOB48 within the ER lumen generates a pre-CM particle which then undergoes progressive modification and vesicular transport to the Golgi, a process regulated by several COP (COat Protein)-associated proteins and in particular the Sar1-ADP ribosylation factor, type B (SAR1B). The pre-CM particle then undergoes terminal modifications within the Golgi and is ultimately secreted across the basolateral membrane as a mature CM (Fig. 38.1).

Fig. 38.1 Overview of intestinal lipid absorption: Key genetic regulators. Following digestion of dietary and biliary lipid, the component lipid species including long-chain fatty acid (*FA*), monoglycerides (*MG*), and cholesterol are transported across the brush border membrane into the apical compartment of villus enterocytes. *FA* and *MG* undergo re-esterification into triglyceride (*TG*) which is mediated in a series of enzymatic steps including diacylglycerol acyltransferase 1 (*DGAT1*). The newly synthesized *TG* exists in both cytosolic and intramembranous forms within the endoplasmic reticulum (*ER*) membrane, where *DGAT1* (boxed) also resides. The heterodimeric *ER* pro-

tein *MTP* physically translocates neutral lipid droplets from the *ER* bilayer membrane to an acceptor protein, *APOB*. Mammalian enterocytes synthesize a truncated *APOB* protein referred to as *APOB48*. The fusion of *APOB* and *TG* droplets, mediated by *MTP*, is the critical and rate limiting step in prechylomicron assembly. Following processing in the *ER*, the prechylomicron undergoes vesicular transport to the Golgi, mediated by fusion with *COP* proteins and *SAR1B*. Following further maturation in the Golgi, the CM particle, containing *APOB48* and a cargo of *TG* and cholesterol ester (*CE*) is transported into the lymphatic compartment and delivered into the peripheral circulation

Molecular Genetic Basis for Congenital Defects in Lipid Absorption: Overview

Several rare genetic disorders of lipid absorption have been identified and their molecular basis characterized [3–5]. These include abetalipoproteinemia (ABL), which is an autosomal recessive disorder caused by mutations or deletions in the *MTTP* gene [3]; familial hypobetalipoproteinemia (FHBL), an autosomal codominant disorder which is typical-

ly caused by mutations in the *APOB* gene [4]; chylomicron retention disease (CRD, also known as Anderson's disease), which is an autosomal recessive disorder caused by mutations in *SAR1B* [5]; and one family in which congenital diarrhea was linked to a splice defect in *DGAT1* [6]. The cardinal feature of enterocyte lipid droplet accumulation is common to all the disorders, but the site of lipid droplet accumulation shows subtle distinctions based on the molecular defect. Defects associated with ABL and FHBL result in lipid drop-

let accumulation throughout the cytoplasm but typically do not generate lipid particles within the ER lumen (Fig. 38.2, top panel). Both ABL and FHBL interrupt intestinal lipid absorption at the initiation stage of pre-CM formation and thus completely attenuate CM assembly and the generation of intracellular lipoproteins, particularly large lipoprotein particles that contain neutral lipid (cholesteryl ester and triglycerides). As a result of this block in lipoprotein assembly, neutral lipid droplets accumulate in the apical cytoplasm in ABL and FHBL. These conditions are discussed in more detail below. The defect in CRD, by contrast, is focused at a later stage in CM formation and blocks maturation and exit of CM and pre-CM particles from the ER and Golgi [7, 8]. The accumulation of lipid droplets and pre-CM particles within membranous domains is schematically illustrated in Fig. 38.2, bottom panel. CRD is discussed in a later section.

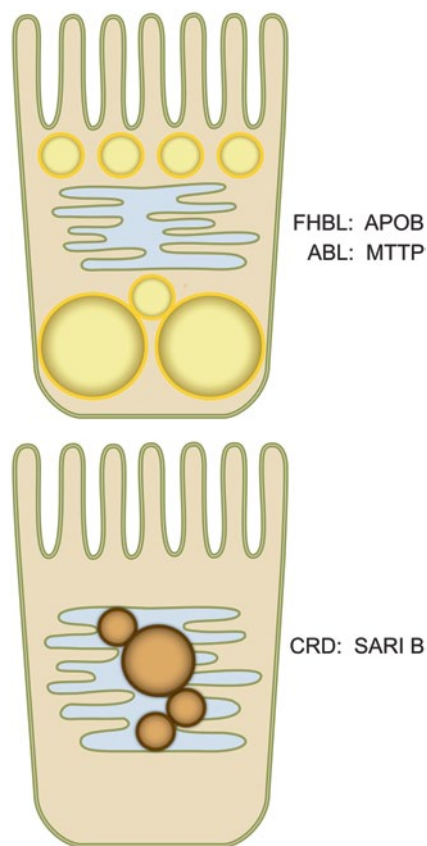

Fig. 38.2 Lipid droplet accumulation in genetic disorders of intestinal lipid absorption. Based upon the pathways outlined in Fig. 38.1, defects or mutations in *APOB* (responsible for familial hypobetalipoproteinemia, *FHBL*) or in *MTTP* (responsible for abetalipoproteinemia, *ABL*) eliminate the earliest steps in chylomicron assembly and thus lead to lipid droplet accumulation with no lipid particles visible within ER profiles (*Top panel*). By contrast, defects in *SAR1B* (responsible for chylomicron retention disease, *CRD*), interrupt the later stages of chylomicron maturation and processing and lead to prechylomicron accumulation (*brown*) within the ER lumen (*Bottom panel*). *APOB* apolipoprotein B, *MTTP* microsomal triglyceride transfer protein *SAR1B* SAR1-ADP ribosylation factor

Congenital Disorders of CM Assembly: Genetics and Clinical Features of ABL and FHBL

Defects in either of the gatekeeper genes that promote CM assembly (i.e., *MTTP* and *APOB*, respectively) each produce congenital lipid malabsorption, which generally presents in infancy as failure to thrive with characteristically low serum lipid levels and other complications (including ataxia and retinitis pigmentosa) that reflect the coincident malabsorption of fat-soluble vitamins [8]. However, the clinical phenotypes in both ABL and homozygous FHBL may be quite variable as discussed below.

Abetalipoproteinemia (ABL, OMIM #200100): Molecular Genetics and Prevalence

ABL is a rare, autosomal recessive disorder with an estimated prevalence in North America of <1 per 100,000 [9] and for which worldwide there were about 50 cases with defined *MTTP* mutations reported as of 2012 [10–15]. There is strong evidence for a founder effect in Ashkenazi Jewish patients, where a conserved haplotype with a common truncating mutation (p.G865X) was discovered in Israel with a carrier frequency of 1:131 and an estimated ABL incidence of 1:69,000 [16]. Some but not all of the reported ABL probands are the offspring of consanguineous marriage, an observation replicated across different national registries [12, 16]. While a range of mutations and deletions have been described in the *MTTP* gene in association with ABL, affected subjects may be either homozygous for a single mutation or compound heterozygous for different mutations and there appears to be no relationship between the site and nature of these mutations and the clinical phenotypes observed [17].

Abetalipoproteinemia (ABL, OMIM #200100): Clinical Features and Management

Although typically ABL presents in infancy with failure to thrive, there is a wide age range of presentation (from infancy to >20 years) suggesting that there are either environmental or other genetic modifiers that influence some of the clinical features. Infants typically present with diarrhea and malabsorption and the hallmark features including extremely low plasma cholesterol and TG levels, very low or undetectable levels of APOB, low to absent levels of fat-soluble vitamins and red blood cell acanthocytosis [9, 11].

The clinical phenotypes of low to undetectable levels of cholesterol and TG and APOB reflect the virtual complete block in lipoprotein secretion from both enterocytes and hepatocytes, which reflects the inability to lipidate the nascent APOB protein as it traverses the ER membrane (Fig. 38.1). The very low levels of fat-soluble vitamins (particularly vitamins A and E) reflect fat malabsorption and defective CM production. Among the neurological sequelae of unrecognized ABL is retinal degeneration, which may be progressive

and result in visual impairment and which is likely a consequence of continued fat-soluble vitamin A and E deficiency [9]. The observation that ABL subjects treated upon diagnosis with long-term high-dose supplementation with vitamins A (10–15,000 IU/day) and E (100 mg/kg/day, equivalent to 150 IU/kg) [18], maintain retinal function and neurological function provides indirect but strong evidence that deficiency of these vitamins is responsible for the phenotypic outcomes, although the exact mechanisms linking ABL to neurologic deficits are yet to be fully elucidated [19]. Importantly, there was no evidence for increased oxidative stress in the plasma of ABL patients receiving long-term vitamin A and E supplementation [19]. For clinical monitoring purposes, it is worth noting that even with high-dose vitamin E supplementation, plasma levels rarely return to the normal range. This is because of the dual defect that exists in vitamin E metabolism, reflecting a block in intestinal absorption of vitamin E and also a defect in hepatic alpha tocopherol transfer to circulating lipoproteins [20]. Because circulating plasma lipid levels are so low in ABL subjects, plasma levels of alpha and gamma tocopherol may not reflect tissue (particularly adipose) concentrations, but nevertheless may be a useful surrogate to monitor long-term compliance [9].

ABL subjects require lifelong maintenance on a low-fat diet (to minimize steatorrhea) and supplementation with fat-soluble vitamins as noted above and in addition supplementation with 1000 IU/day vitamin D (which is available in a water-soluble form). Longer term, ABL subjects should be monitored for development of steatohepatitis (transaminases, liver magnetic resonance spectroscopy) which has been associated with progressive liver disease requiring liver transplantation [21].

FHBL, OMIM #107730: Molecular Genetics and Prevalence

FHBL is an autosomal codominant disorder whose molecular basis (where known) most commonly resides in mutations in the *APOB* gene on chromosome 2 [22]. Unlike ABL, heterozygous FHBL subjects exhibit low circulating levels of plasma cholesterol, triglyceride, and APOB and are generally discovered in routine plasma lipid level screening tests. Heterozygous FHBL, recognized through population-based plasma lipid screening for subjects at or below the fifth percentile, is present in ~1:500–1:1000 [22, 23]. Homozygous FHBL by contrast is extremely rare, with perhaps 20 index cases whose molecular genetic basis is known [24]. FHBL associated with structural defects in the *APOB* gene represent the majority of known cases [22, 23]. The known mutations generally produce truncated forms of APOB (i.e., smaller proteins than APOB100) which are defective in undergoing lipidation despite adequate levels of MTP (Fig. 38.1). These truncated forms of APOB may be detected using denaturing gel electrophoresis and are present at very

low levels in plasma, and notably even in heterozygous subjects are found at lower abundance than those encoded by the wild-type allele. This observation implies that transcription or translation of the mutant allele in FHBL is also defective [25]. In addition, FHBL is genetically heterogeneous with several kindreds described in whom the trait is inherited in an autosomal dominant manner without mutations in the *APOB* gene but rather with linkage to a locus on chromosome 3p21, between D3S2407 and D3S1767 [25]. The molecular basis for the defects in FHBL subjects linking to chromosome three remains unknown.

FHBL, OMIM #107730: Clinical Features and Management

The clinical manifestations of homozygous FHBL are heterogeneous with severely affected individuals presenting in infancy or early childhood with failure to thrive and steatorrhea, while yet other affected homozygous individuals may present in adulthood with incidentally discovered hepatic steatosis and very low levels (<fifth percentile) of plasma lipids and undetectable levels of APOB100 [24]. In general, the clinical manifestations and management of severe homozygous FHBL subjects follows the same principles as alluded to above for ABL subjects, including acanthocytosis, very low levels of plasma lipids and fat-soluble vitamins, and neurologic deficits with macular degeneration and steatorrhea [26]. A more sinister concern longer term for FHBL subjects is the development of cirrhosis [27, 28] and hepatocellular carcinoma [24, 29]. The observations in relation to hepatic lipid accumulation in subjects with FHBL due to APOB truncations were not replicated in homozygous FHBL subjects linked to chromosome 3p21, reinforcing the concept that the clinical phenotypes among FHBL subjects is very variable [30, 31]. Homozygous FHBL subjects should therefore undergo regular evaluation of fat-soluble vitamin sufficiency (as outlined above) and also periodic monitoring for progressive hepatic steatosis and steatohepatitis (transaminases, liver magnetic resonance spectroscopy), again as alluded to above for ABL subjects.

CRD, OMIM #246700: Molecular Genetics and Prevalence

CRD was identified by Roy and colleagues in 1987 [32]. Although this disorder appears to be the same as that described by Anderson in 1961 [33], the term “CRD” is preferred nowadays, as it is more indicative of the pathology. CRD is a very rare, autosomal recessive disorder with fewer than 50 cases described worldwide [7], and whose molecular genetic defect resides in the SAR1-ADP ribosylation factor, type B (SAR1B), which belongs to the Ras superfamily of guanosine triphosphatase (GTPases). SAR1B mutations induce an accumulation of pre-CM transport vesicles [7], as seen on intestinal biopsies and illustrated schematically in Fig. 38.2.

SAR1B is a single polypeptide of 198 amino acids and functions as molecular switch controlled by the exchange of guanosine diphosphate (GDP) and GTP. SAR1 is cytosolic in its GDP form and is recruited to the ER by the exchange of GDP for GTP to initiate COPII-coated vesicle formation. SAR1-GTP forms a coating protein complex (COPII) with two heterodimers SEC23/24 and SEC13/31. COPII initiates budding and captures cargo to eject vesicles from the ER to the Golgi apparatus [34]. The SAR1B GTPase cycle then allows cytosolic COPII proteins to exchange on and off the membrane at specific sites on the ER to regulate cargo exit. As a result, genetic defects in SAR1B affect the transport of pre-CM cargo from the ER to the Golgi apparatus where they usually undergo additional glycosylation before being released from the enterocyte. CMs are transported from the ER to Golgi, probably inside the pre-CM transport vesicle or PCTV [35]. PCTV share several proteins including COPII (SEC13–31, SEC24 and SAR1) [36]. Siddiqi et al. [37] earlier showed that PCTV formation can occur in the absence of SAR1 and later showed that PCTV fusion with Golgi requires the presence of SAR1 [38].

The first investigation of genetic defects in eight families disclosed three frameshift (75–76 delTG, 555–558 dupTTAC, 349–1 G>C) and five missense mutations (109 G>A, 409 G>A, 537 T>A, 536 G>T, 542 T>C) [5]. The second exploration of the genetic abnormalities from eight families identified three new molecular aberrations: a stop codon mutation (364 G>T), a 5946 bp deletion (total exon 2) and a missense mutation (554 G>T) [39]. Thereafter, a new mutation G19T (changing a glutamic acid to a STOP codon) was found in the seventh exon [40] while two additional mutations were detected in exon 2 (G11D) and exon 4 (D75G) [41]. Recently, a novel homozygous deletion at position 142 (c.142delG) led to the replacement of the aspartic acid at position 48 by a threonine and gave rise to a frameshift-derived premature stop codon 17 amino acids further on (p.Asp48ThrfsX17), thereby resulting in a truncated protein (only 32% of the length of the normal protein and 24% of the normal sequence) [7]. Finally, the analysis of *SAR1B* gene mutations in Tunisian children revealed a proband homozygous for a novel nucleotide transition in exon 4 (c.184G>A), resulting in a nonconservative amino acid substitution (p.Glu62Lys) [42]. In order to provide a unifying explanation for the functional impairment of SAR1B mutated proteins, investigators have turned to information gleaned from the SAR1B crystal structure, computational analysis, and sequence alignment [43]. For example, the nonsense mutations and whole deletion of exon 2 in SAR1B yields truncated proteins that are predicted to modify the affinity of SAR1B for GDP and GTP, thereby affecting its interaction with the endoplasmic ER and other components of COPII machinery. In addition, the missense mutations in SAR1B likely yield nonfunctional proteins that alter the con-

formational and/or structural properties of SAR1B. Because SAR1B expression is detected in multiple different tissues, there are frequent clinical manifestations of CRD in organs beyond the gastrointestinal tract. As an example, cardiac abnormalities, myolysis, increased CK levels and cardiac abnormalities were associated with the G19T mutation [40].

Genotype–Phenotype Associations in CRD

Recent studies compared the patients of two cohorts of CRD patients from France and Canada in order to compare the severity and long-term evolution as a function of the *SAR1B* gene mutations [44]. In both series, most of the CRD patients were symptomatic at diagnosis (before the age of 1) and the disease was definitely more severe in infants. This is consistent with the observation that the CRD had profound impact on weight Z scores in Canadian children (1.5 ± 1 years) who were significantly younger at diagnosis than the French subjects (6.4 ± 1.3 years). The catch-up growth and bone mineral density improvement were not as encouraging in the French cohort compared to the Canadian patients, possibly because of the delayed initiation of a low-fat diet with a high polyunsaturated/saturated fatty acid ratio and of supplements of fat-soluble vitamins A, D, and E. In general, the neurophthalmic manifestations detected at the time of diagnosis proved largely reversible with treatment. Although the effect of missense mutations on the protein was considered less deleterious than the those mutations that introduce stop codons or that specified deletions, the clinical phenotype (i.e., growth, neurological impairment, hepatic steatosis, lipid disturbances) was not significantly different in CRD patients based on the underlying genetic mutation [44]. According to the findings of this largest group of CRD patients so far reported, genotype–phenotype correlations are not obvious, suggesting that CRD might represent a more complex trait rather than a simple autosomal recessive disorder [44]. Additional work is required to determine whether modifier genes are involved in the ER-to-Golgi transport.

CRD, OMIM #246700: Clinical Features and Management

CRD presents with failure to thrive probably resulting from fat malabsorption and constant, nonspecific diarrhea that begins shortly after birth. Other digestive symptoms include vomiting or abdominal swelling. Light microscopic examination generally reveals few morphological irregularities in the small intestine of CRD patients; however [7], following an oral fat bolus test meal and ultrastructural examination, numerous CM-size lipid droplets are evident within the cytoplasm of enterocytes. Many of these CM-size lipid droplets are bound by membranes of the smooth ER and clustered mostly in the supranuclear region, whereas only few of them

were visualized within vesicular structures, likely part of the Golgi complex. The larger lipid vacuoles are not membrane bound [8]. Importantly, the intercellular spaces were completely juxtaposed and no CMs were evident in the interstitium between adjacent enterocytes and in the area around the basement membrane. Hepatomegaly and a moderate degree of macrovesicular steatosis have been detected in a few cases [32, 45]. Nonspecific moderate hepatic cytolysis is very frequent but correlates only poorly with steatosis and/or hepatomegaly. Areflexia (combined with proprioceptive abnormalities) and electromyographic abnormalities (reduction in sensory nerve conduction velocity and decreased sensory nerve action potential amplitudes) were among the neurological abnormalities described in CRD children [32, 46, 47], but more severe neurological degeneration, such as ataxia and myopathy and sensory neuropathy, have also been reported in CRD adults [48]. Sometimes muscular pain and cramps are present in CRD children while cardiomyopathy with a decrease in ejection fraction to 40% (normal >60%) has been described in adults [40]. Only minimal ophthalmic complications characterize CRD patients and include micro-nystagmus, mild deficit in the perception of the blue-yellow axis, and delayed dark adaptation [32] while abnormal visual evoked potentials has been evidenced by functional testing [49]. Poor mineralization and delayed bone maturation have also been observed in CRD [46].

Fat malabsorption in CRD impairs the absorption of fat-soluble vitamins, with vitamin E being the most affected, as observed in ABL subjects [50]. Vitamin A levels in plasma are frequently decreased, but generally correctable following oral supplementation. Finally, vitamin D or K insufficiency can be detected in up to half of CRD patients, and can also be corrected with oral vitamin supplementation. In CRD, acanthocytosis is rare, sometimes transient. Acanthocytosis, when it occurs, reflects low plasma vitamin E levels, which is a key to red cell membrane integrity. In association with muscular abnormalities, creatine kinase levels were elevated at diagnosis and have been associated with neurological impairment [49]. As previously noted, hepatic abnormalities may be present.

In contrast to ABL and FHBL, fasting triacylglycerol concentrations are usually normal, but severe hypocholesterolemia is prominent with levels of low-density lipoprotein-cholesterol and APOB100 at the lower limits of normal. Similarly, CRD patients display limited capacity to produce high-density lipoprotein. Importantly, CMs failed to appear in the circulation after a fat meal test explaining the deficiency of fat-soluble vitamins and essential fatty acids. However, patients with CRD express the apolipoprotein species essential for CM synthesis, including APO-AI, APO-AIV, and importantly, APOB48 [7, 51].

Although CRD resembles ABL and FHBL symptomatically with respect to dietary fat malabsorption and its con-

sequences, examination of plasma reveals a key distinction. Plasma from CRD patients contains APOB100 at normal levels but no APOB48 especially after a fat meal. As detailed above, plasma from ABL and FHBL subjects contains virtually no detectable APOB100, because the defect impairs secretion of lipoproteins from both the liver and small intestine [9]. Intestinal transcription of APOB100 messenger RNA (mRNA) and its posttranscriptional editing to APOB48 mRNA was normal in CRD subjects [52]. Both APOB and MTTP along with CM-size lipid droplets were detected in enterocytes from CRD subjects, suggesting that enterocytes can synthesize prechylomicron particles, but fail to process these intravesicular particles into mature CM particles that can be secreted into the lymphatic circulation. Other attempts to identify the underlying mechanisms in CRD confirmed that the primary defect is not in the de novo synthesis of APOB48 protein, although reduced glycosylation of APOB was revealed in intestinal biopsies taken from CRD patients [51].

As with ABL and homozygous FHBL, CRD needs to be recognized early because of its adverse effects on growth and potential for neurological, ocular, hepatic, and other extraintestinal complications. Accurate diagnosis can be readily established using ultrastructural identification of CM-size lipid droplets clustered in the enterocytes, with the absence of fat outside the cells. However, sequencing of the short *SARA2* gene provides a quick, safe, inexpensive, and non-invasive diagnostic tool. Consumption of medium-chain triglycerides can aid in more rapidly correcting malnutrition in infants, but total fat intake and particularly long-chain fatty acid consumption should be limited. The patients must be advised to take adequate intake of essential fatty acids and fat-soluble vitamins. In addition, vitamin E supplementation is critical for the prevention of the progression of neurological findings while vitamin A should be administered at high doses to prevent ophthalmologic complications. Early vitamin D supplementation is also recommended in all patients to avoid bone growth and development abnormalities, and vitamin K should be given in cases of coagulopathies and abnormal clotting parameters.

Introduction

Pancreatic insufficiency, though not very prevalent, must be suspected in every child with failure to thrive of unexplained reasons, as well as in children with recurrent pancreatitis (see Chap. 34). References [1–15] constitute a comprehensive review of all known forms of pancreatic insufficiency. Table 39.1 lists both relatively common as well as rarer genetic causes of this condition.

Pancreatic Insufficiency in Cystic Fibrosis

Cystic fibrosis (CF) is an autosomal recessive condition caused by defects in the CF transmembrane regulator (*CFTR*) gene. About 85% of patients with CF are pancreas insufficient (PI) [16].

Pathophysiology of Pancreatic Insufficiency in Cystic Fibrosis

Mutations of the *CFTR* gene cause impaired chloride transport at the apical surface of epithelial cells [17] and also disturb chloride-coupled bicarbonate transport [18] and sodium channel activity [19]. Pancreatic secretion of chloride, bicarbonate, sodium, and potassium in response to combined cholecystokinin and secretin stimulation is impaired in all patients with CF, regardless of pancreatic function status [16]. Bicarbonate secretion is most impaired, and defective electrolyte secretion leads to reduced fluid secretion [20]. This defective bicarbonate secretion results in impairment in the luminal flow of pancreatic enzymes and proenzymes and impairment in the trafficking of zymogen granules [20]. This

results in a severe block in acinar cell secretion followed by loss of cellular function, cell death, fibrosis, and eventual pancreatic insufficiency which leads to a decline in all the enzymes secreted by the pancreas [17, 20].

In normal people, just 5–10% of the normal post-meal pancreatic enzyme output is adequate for normal digestion, indicating the large reserve capacity of the pancreas [17]. This reserve capacity means that clinically significant malabsorption is not evident until at least 90% of the exocrine cells of the pancreas are destroyed [21]. Again in normal individuals, the presence of free fatty acids in the proximal small bowel causes release of cholecystokinin which in turn stimulates pancreatic secretion [22]. When pancreatic insufficiency begins to develop, this feedback loop is impaired, and the site of maximal digestion shifts to the more distal bowel [17]. This results in larger amounts of nutrients being delivered to the distal bowel with changes in motor and secretory function of the more proximal bowel [23, 24]. These changes, in turn, lead to quicker intestinal transit and worsening of malabsorption [24].

The terms pancreas sufficient (PS) and PI have great clinical and prognostic significance in CF. PS does not mean normal pancreatic function, but that enough pancreatic function is present to avoid the need for pancreatic enzyme replacement therapy (PERT). Patients who are PS are more prone to pancreatitis [25], while PI patients have more severe lung disease, malnutrition, and liver disease [26].

Shwachman–Diamond Syndrome

Shwachman–Diamond syndrome (SDS) is an autosomal recessive disorder characterized by congenital anomalies, pancreatic insufficiency, bone marrow failure, and predisposition to myelodysplasia and acute myeloid leukemia (AML) [27]. Mutations in the Shwachman–Bodian–Diamond syndrome (*SBDS*) gene can be found in approximately 90% of classically presenting patients with SDS [28]. These mutations usually result in reduced, but not absent, protein expression.

Table 39.1 Syndromes and genetic conditions associated with pancreatic insufficiency [1–15]

Condition	Affected gene(s)	Reference
Cystic fibrosis	<i>CFTR</i> gene	[1]
Shwachman–Diamond syndrome	<i>SBDS</i> gene	[2]
Johanson–Blizzard syndrome	<i>UBR1</i> gene	[3]
Pearson marrow–pancreas syndrome	Mitochondrial DNA defects	[4]
Pancreatic agenesis	<i>PDX 1</i> gene	[5]
Pancreatic agenesis and congenital heart defects	Heterozygous mutations in the <i>GATA6</i> gene	[6]
Pancreatic and cerebellar agenesis	<i>PTF1A</i> gene	[7]
Pancreatic lipase deficiency	Unknown	[8]
Pancreatic co-lipase deficiency		
Pancreatic lipase and co-lipase deficiency		
Hereditary pancreatitis	<i>PRSSI</i> gene	[9]
	<i>SPINK 1</i> gene	[10]
	<i>CFTR</i> gene	[11]
	Chymotrypsin C (CTRC) variants	[12]
Pseudohypoparathyroidism Type IA	<i>GNAS 1</i> gene	[13]
CoQ-responsive Oxphos deficiency	Unknown	[14]
Exocrine pancreatic insufficiency, dyserythropoietic anemia, and calvarial hyperostosis	<i>COX 412</i> gene	[15]

In mice, targeted deletion of the gene results in embryonic death suggesting that some expression of this gene is necessary for survival [29]. The *SBDS* gene is involved in ribosomal function [30], and ribosomal subunit assembly is impaired in patients with SDS [31]. The exact mechanism by which this leads to pancreatic insufficiency is unknown. One study found that patients negative for mutations in the *SBDS* gene may have more severe hematological manifestations while having milder pancreatic disease [32].

The incidence of SDS is 1:76,000 individuals with a male to female ratio of 1.7:1 [33, 34].

The classic presentation of SDS is in infancy with failure to thrive, diarrhea, and neutropenia. SDS infants have an average birth weight at the 25th percentile [34]. Table 39.2 details the criteria for the diagnosis of SDS. Growth failure with malnutrition is common in the first year of life, and height falls and remains below the third percentile in 38–56% of patients [35, 36]. After diagnosis, and with appropriate therapy, most children show normal growth velocity, and it appears that with current treatment they attain normal body mass indexes (BMIs) [35]. Steatorrhea is caused by decreased secretion of lipolytic and proteolytic enzymes, while ductular fluid and electrolyte secretion of the pancreas remain normal [37, 38]. Pancreatic insufficiency tends to be diagnosed within the first 6 months of life with 90% of patients being diagnosed in the first year [37]. Spontaneous improvement in pancreatic function can occur in later childhood with 50% of patients having normal fat absorption by age 4 years and no longer requiring pancreatic enzyme supplementation [37]. The pancreas in SDS exhibits a characteristic fatty replacement which can be visualized on ultrasound, CT scanning, and, perhaps, best by MRI scanning [39].

Hepatomegaly and raised serum liver enzymes are common in children with SDS [40]. These resolve by the age of 5 years and no long-term consequences have been observed [40].

Neutropenia is the most common cytopenia and can be persistent or intermittent and mild to severe [34]. Anemia with low reticulocyte counts [34] and elevation in fetal hemoglobin is each seen in 80% of patients [41]. Thrombocytopenia can also be seen. Bone marrow biopsy is usually hypoplastic with increased deposition of fat [41, 42]. Patients with SDS have a propensity to developing infections due to the neutropenia and the occasional functional neutrophil deficits that are seen in SDS [43]. Patients with SDS develop clonal changes in the bone marrow which may or may not be associated with an increased risk of myelodysplasia or AML [23]. Due to the predisposition to myelodysplasia and AML, all patients with SDS should be referred to a pediatric hematologist. Based on data from several registries, the frequency of both myelodysplasia and AML increases with increasing age [32, 44, 45]. In general, early bone marrow transplantation in children with severe cytopenias prior to development of myelodysplasia or AML improves outcome.

The bony dysplasia of SDS manifests as short stature and delayed appearance but subsequent normal development of secondary ossification centers [34]. There is variable metaphyseal widening and irregularity that is most often seen in the ribs in early childhood and femurs later in childhood and adolescence [46]. Rarely, skeletal involvement may be extremely severe and generalized [34]. Usually, these metaphyseal changes become clinically insignificant, but rarely they may lead to limb deformities and fractures [46].

A characteristic pattern of neurocognitive and behavioral difficulties has been described in SDS [47].

<i>Clinical and molecular diagnostic criteria</i>
Diagnostic criteria
Clinical diagnosis
Fulfill the combined presence of hematological cytopenia of any given lineage (most often neutropenia) and exocrine pancreas dysfunction
Hematologic abnormalities may include:
a. Neutropenia $< 1.5 \times 10^9/L$ on at least two occasions over at least 3 months
b. Hypoproliferative cytopenia detected on two occasions over at least 3 months
Tests that support the diagnosis but require corroboration:
a. Persistent elevation of hemoglobin F (on at least two occasions over at least 3 months apart)
b. Persistent red blood cell macrocytosis (on at least two occasions over at least 3 months apart), not caused by other etiologies such as hemolysis or a nutritional deficiency
Pancreatic dysfunction may be diagnosed by the following:
a. Reduced levels of pancreatic enzymes adjusted to age (fecal elastase, serum trypsinogen, serum (iso)amylase, serum lipase)
Tests that support the diagnosis but require corroboration:
a. Abnormal 72-h fecal fat analysis
b. Reduced levels of at least two fat-soluble vitamins (A, D, E, K)
c. Evidence of pancreatic lipomatosis (e.g., ultrasound, CT, MRI, or pathological examination of the pancreas by autopsy)
Additional supportive evidence of SDS may arise from:
a. Bone abnormalities
b. Behavioral problems
c. Presence of a first-degree family member diagnosed before with SDS
Other causes of pancreatic insufficiency should be excluded, in particular when the <i>SBDS</i> gene mutation analysis is negative
Molecular diagnosis: biallelic <i>SBDS</i> gene mutation
Positive genetic testing for <i>SBDS</i> mutations known or predicted to be deleterious, for example, from protein modeling or expression systems for mutant <i>SBDS</i>
<i>Caveats:</i>
Many situations arise when molecular diagnosis is <i>not</i> confirmatory in the presence of clinical symptoms:
No identified mutations (about 10% of cases)
Mutation on one allele only
Gene sequence variations that have unknown or <i>no</i> phenotypic consequence:
A novel mutation, such as a predicted missense alteration, for which it is not yet possible to predict whether it is disease causing
<i>SBDS</i> polymorphisms on one or both alleles. Large population studies may be needed to exclude a sequence polymorphism as a bona fide irrelevant variant

A high degree of suspicion may be needed to diagnose milder cases of SDS. A study of 37 children with SDS found that neutropenia (81%), diarrhea (58%), failure to thrive (73%) lipomatous infiltration of the pancreas (~90%), fecal elastase (82%), skeletal (38%), and congenital and endocrine malformations (65%) were all inconsistently present [48].

Serum immunoreactive trypsinogen (IRT) and pancreatic isoamylase concentrations can be useful markers of the pancreatic phenotype in SDS [49]. In healthy children, serum IRT concentrations are at adult levels at birth, while pancreatic isoamylase concentrations are low at birth and reach adult levels by 3 years of age [49]. In contrast, in SDS, young children have low serum IRT concentrations which then rise with age, while serum pancreatic isoamylase activities are low at all ages. Serum IRT is generally low in PI patients with SDS, while a normal value does not rule out pancreatic insufficiency. Serum isoamylase concentrations

are not useful in determining pancreatic sufficiency or insufficiency. Hence, when SDS is suspected, a serum IRT should be obtained in children < 3 years of age, while serum pancreatic isoamylase should be obtained in children ≥ 3 years of age [34].

The diagnosis of SDS is made using the criteria shown in Table 39.3. The combination of exocrine pancreatic dysfunction and hematological abnormalities when other known causes of exocrine pancreatic dysfunction and bone marrow failure are excluded gives rise to a clinical diagnosis of SDS [34]. CF should be ruled out with a sweat test while Pearson marrow-pancreas syndrome can be differentiated by a bone marrow examination and imaging of the pancreas. Cartilage hair hypoplasia which presents with diarrhea (but not with pancreatic insufficiency), cytopenia, and metaphyseal chondrodysplasia is more common in certain populations such as the Amish.

Table 39.3 FDA-approved pancreatic enzyme products

	Dosages available (lipase/protease/ amylase units)	Bead/microsphere diameter (mm)	Notes
Creon®	3000/9500/15,000	0.7–1.6	Oral, delayed-release capsules
	6000/19,000/30,000		
	12,000/38,000/60,000		
	24,000/76,000/120,000		
Pancreaze®	4200/10,000/17,500	2	Oral, delayed-release capsules
	10,500/25,000/43,750		
	16,800/40,000/70,000		
	21,000/37,000/61,000		
Pertyze®	8000/28,750/30,250	0.8–2.2	Oral, delayed-release capsules with bicarbonate-buffered enteric-coated microspheres
	16,000/57,500/60,500		
Ultreza™	13,800/27,600/27,600	2.0–2.4	Oral, delayed-release capsules
	20,700/41,400/41,400		
	23,000/46,000/46,000		
Viokace™	10,440/39,150/39,150	N/A	Non-enteric-coated tablets Approved only for use in adults Must be given with a proton pump inhibitor
	20,880/78,300/78,300		
Zenpep®	3000/10,000/16,000	1.8–1.9 for 3000 and 5000	Oral, delayed release capsules A generic product is available at the 5000 lipase unit dose
	5000/17,000/27,000	2.2–2.5 for others	
	10,000/34,000/55,000		
	15,000/51,000/82,000		
	20,000/68,000/109,000		
	25,000/85,000/136,000		

Pearson Marrow–Pancreas Syndrome

Pearson described a syndrome of refractory, transfusion-dependent sideroblastic anemia with vacuolization of the bone marrow and exocrine pancreatic insufficiency [4]. Other variable features may include hepatic failure, proximal renal tubulopathy, watery diarrhea, patchy erythematous skin lesions, neutropenia, and thrombocytopenia and high serum lactate/pyruvate ratios [50]. This condition should be considered in the differential diagnosis of Shwachman syndrome. In this syndrome, vacuolization of the marrow is seen, while in Shwachman syndrome the bone marrow is dysplastic; the pancreas is fibrotic in Pearson syndrome, while it is fatty in Shwachman syndrome [51]. Pearson syndrome is caused by mitochondrial DNA alterations which are more abundant in the blood than in other tissues [50]. Diagnosis is suspected based on clinical findings and can be confirmed by Southern blot analysis which detects rearrangements of mitochondrial DNA [52]. This syndrome is usually fatal in infancy, but some children who survive past infancy develop severe neurological symptoms suggestive of another mitochondrial DNA disorder, Kearns–Sayre syndrome [53]. In children without multisystem involvement, bone marrow transplantation or unrelated cord blood cell transplantation has been

suggested as a mechanism to manage the severe hematological manifestations of this syndrome [52].

Johanson–Blizzard Syndrome

Johanson–Blizzard syndrome (JBS) is a rare autosomal recessive disorder caused by mutations in the *UBRI* gene [54, 55]. *UBRI* encodes an E3 ubiquitin ligase that is involved in proteolysis [55]. However, the exact causative mechanism of pancreatic insufficiency in JBS is unknown. A small beak-like nose (due to aplasia or hypoplasia of the alae nasi) and exocrine pancreatic insufficiency are most consistently present while other features in decreasing order of occurrence include dental anomalies, congenital scalp defects, sensorineural hearing loss, growth and psychomotor retardation, hypothyroidism, imperforate anus, and genitourinary anomalies [56].

Clinical Symptoms

The symptoms of fat malabsorption, which have been best described in CF, are abdominal pain, constipation, flatulence, and diarrhea [17]. There is no correlation between dosing of

PERT and symptoms of abdominal pain, constipation, and flatulence [17]. Diarrheal symptoms are not different between PS and PI patients in CF [17]. Hence, these symptoms are not good markers of exocrine pancreatic insufficiency and definitely not measures of adequacy of PERT.

PI can result in significant malnutrition and nutritional deficiencies. Nutritional deficiencies that can potentially be seen in all forms of pancreatic insufficiency include deficiencies of the fat-soluble vitamins—A, D, E, and K—and of the water-soluble vitamin B₁₂ [57]. Zinc, iron, and selenium deficiencies have been described in CF [57]. In CF, the presence of liver disease and enteropathic changes may create further nutritional issues.

Diagnosis of Pancreatic Insufficiency

The ideal test of pancreatic function should be specific, non-invasive, able to quantitate pancreatic function, able to indicate the need and the appropriate dosage of substitutive enzymes even during therapy, cost-effective, and broadly available [58]. No such test is presently available [58].

Fecal elastase-1 is secreted by the pancreas and does not undergo degradation in the gut. It is an inexpensive diagnostic test with good sensitivity and specificity for detection of pancreatic insufficiency in CF. After 2 weeks of age, PS patients can be differentiated from PI patients using a cutoff of 200 µg/g. Fecal elastase-1 can be used in the annual monitoring of CF patients with PS to identify the onset of PI. The monoclonal fecal elastase-1 test only identifies the human form of the enzyme; hence, the test can be done even when the patient is receiving PERT [59]. Falsely low values may be obtained when the stool is dilute as in any diarrheal illness or in the presence of enteropathies.

Fecal chymotrypsin is a less sensitive and specific marker of pancreatic function than fecal elastase-1. However, this test, which does identify porcine enzymes can be used to monitor compliance with PERT in patients who are known to be PI.

In patients with CF, the presence of a low fecal elastase-1 is usually considered diagnostic of PI despite the fact that fecal elastase-1 correlates poorly with fecal fat excretion testing [60]. In other conditions, especially in children who present with poor growth or malabsorption, the next steps after obtaining a fecal elastase-1 level are less clear. The secretin–pancreozymin test is considered the gold standard for the diagnosis of pancreatic insufficiency. However, this test is invasive and time-consuming and rarely performed in clinical practice.

Traditionally, fat absorption is measured using the 72-h fecal fat excretion test. During this time, stool is collected while an estimate of dietary fat intake is made using a detailed food diary [61]. The percentage of fat absorption is calculated using the dietary intake of fat and the stool fat output. Abnormal values are defined as fecal fat excretion

greater than 7% of intake; in other words, less than 93% absorption of ingested fat.

At our institution, we use a secretin and cholecystokinin (CCK) stimulation test done when the patient undergoes an upper endoscopy [62]. Patients receive intravenous secretin (2 U/kg) plus cholecystokinin (0.02 µg/kg). Duodenal fluid is collected at baseline and 5, 10, and 15 min after stimulation and placed on dry ice. Samples are measured for the levels of trypsin (abnormal <55.4 nmol ml⁻¹ min⁻¹), amylase (abnormal <32 nmol ml⁻¹ min⁻¹), lipase (abnormal <146 nmol ml⁻¹ min⁻¹), and chymotrypsin (abnormal <2.5 nmol ml⁻¹ min⁻¹). Unfortunately, the precise sensitivity and specificity of this test is not known.

The ¹³C-labeled mixed triglyceride test is a noninvasive method of assessing lipase activity [63, 64]. However, it is not widely available at the present time.

Management

Much of the data on management of pancreatic insufficiency in children are extrapolated from CF. Infants with CF are usually begun on 2000–5000 lipase units per feeding. In all patients with pancreatic insufficiency, PERT is adjusted to a maximum of 2500 lipase units per kilogram per meal (not to exceed 10,000 lipase units per kilogram per day or 4000 units lipase per gram dietary fat per day) [65]. Higher doses have been associated with fibrosing colonopathy and are not recommended [66]. Other side effects of PERT include soreness in the mouth and perianal irritation [67]. Allergies may occur due to the porcine origin of the enzyme preparations [67]. Hyperuricemia which was seen with older preparations is rarely seen now [53]. A sudden introduction of PERT to patients with uncontrolled fat malabsorption may lead to severe constipation with accompanying abdominal pain [67].

In infants, the enzyme microspheres are mixed with a small amount of breast milk or infant formula or applesauce and given via spoon immediately before the feed. The dose is gradually adjusted based on weight gain and absorption, but the lipase dose is always kept under 10,000 units/kg body weight per day in most children; infants may need higher doses. In older children, the capsules should be swallowed whole at as early an age as possible. When this is not possible, the microspheres should be mixed with a small amount of fluid or applesauce and given via spoon. The child should be encouraged to swallow without crushing or chewing. Enzymes should be given either at the beginning of the meal or half at the beginning and half midway through the meal. Some children with poor growth, particularly with CF, may not respond to high-calorie foods and oral high-calorie beverages. These children may be candidates for supplemental nocturnal gastrostomy tube feeding. These children are given the additional calories needed for growth as a continuous nocturnal infusion of formula. In these patients, pancreatic

enzymes should be given before and after the tube feeding. While a polymeric formula is typically used, some children may require a protein hydrolysate formula due to concerns about uncontrolled malabsorption or continuing concerns about growth despite adequate additional calories. In children receiving the maximum dose of PERT, additional benefit may be obtained by the addition of a proton pump inhibitor when necessary.

In general, the symptoms of pancreatic insufficiency can be more easily controlled in conditions other than CF than in CF.

In children with CF, CF-specific vitamin preparations are recommended and yearly assessment of fat-soluble vitamin status is recommended. These vitamin preparations as well as the regular assessments of vitamin status should be considered in all children with pancreatic insufficiency. It is recommended that these vitamins be taken with a fat-containing meal along with PERT.

Definition

A permanent sensitivity to gluten resulting in a small-intestinal inflammatory disorder occurring in genetically predisposed individuals belonging to human leukocyte antigen (HLA)-class II specific haplotypes, celiac disease (CD) is characterized by a variable combination of elevated titers of celiac-specific autoantibodies, an inflammatory enteropathy with variable degrees of severity, and a wide range of gastrointestinal (GI) and extraintestinal complaints [1, 2].

Described in modern times by Samuel Gee in 1888 [3], it was only in the 1940s that Dicke identified the central role of gluten [4]. The subsequent availability, in the 1960s [5], of a capsule to obtain biopsies from the small intestine allowed the description of the typical changes caused by gluten in the duodenal mucosa of affected individuals. In the following decades, it became clear that CD reached far beyond the intestine as it was associated with many non-GI signs and symptoms, some HLA-associated, some not. Among the best described are: short stature [6, 7], osteoporosis [8, 9], iron-deficiency anemia (IDA) [10–12], arthritis [13–15], headaches [16–18], liver and biliary tract abnormalities [19, 20], myalgia [21, 22], adverse pregnancy outcomes [23–25], dental enamel defects [26, 27], dermatitis herpetiformis [28, 29], and others. In addition, a clear association with other autoimmune conditions such as type 1 diabetes has been well documented [30–32], and its link with some congenital disorders such as IgA deficiency and Down syndrome among others was discovered [33]. Although a genetic-based dis-

ease, CD can have its onset at any age, from infancy to old age, triggered by traumatic events, or in most cases without any obvious precipitating factor.

Epidemiology

The prevalence of CD is increasing at a remarkable pace during the past few decades [34–39]. Once thought to be a rare condition, affecting no more than 1/10,000 people, thanks to the availability and widespread use of specific and sensitive serological markers, CD is now recognized worldwide as a common disorder, with a prevalence varying between 3 and 13 per 1000 [40]. While an increased awareness, especially in North America, is responsible for increased diagnostic rates, reliable epidemiological data document worldwide a true increase in prevalence, of the order of doubling rates every 20 years or so. In Northern Sweden, an epidemiological investigation employing a combined serological/endoscopic approach in an unselected population of 1000 adults found a prevalence of almost 2% [41]. It is assumed that a variety of environmental factors are responsible for such a rapid change [34–39]. Among them: modalities of delivery [42, 43], early-life infections [44], including RSV infections leading to hospitalization [45], exposure to antibiotics [46], infant feeding practices [47, 48], and even socioeconomic status [49, 50]. However, only a limited portion of the expected celiac patients is actually identified, with proportions varying between different countries: in the USA, even though CD overall prevalence should be around 1%, only about 15% of this population (including children and adults) has been diagnosed and can therefore be treated [51]. This phenomenon of underdiagnosis is likely due to a combination of inadequate awareness and a high prevalence of asymptomatic patients and appears to be quite widespread. Recent data suggest that unless a mass screening is implemented, it might be hard to improve substantially our current diagnosis rates, as even strategies based on large-scale case finding have failed to improve diagnostic rates [52].

453

Of interest, CD seems to affect more females than males, with a ratio of about 2:1. However, since studies of prevalence based on screening do not show such clear-cut difference, it is currently thought that the female predominance, while in part due to a true higher prevalence in girls versus boys, could also in part be attributed to the fact that women appear to utilize health-care services more than men [53, 54]. Currently, in most populations, women constitute 60–70% of individuals with diagnosed CD [55, 56].

Etiopathogenesis

Like most multifactorial disorders, CD is the result of a complex interaction between genes, immune status of the host, and environmental triggers.

Genetic Factors

The weight of genetic predisposing factors in CD pathogenesis is relevant, as initially suggested by the observation of a strong familiar aggregation [57], with a prevalence of CD among first-degree relatives of around 10%. The most important and best-characterized susceptibility gene is the HLA class II; in particular, the HLA-DQ2 and HLA-DQ8 alleles are required for CD development. The concordance rate is about 30% among HLA-identical siblings, 80% in monozygotic twins, and 10% in dizygotic twins [58]. The HLA-DQ2 molecules are expressed on the surface of antigen-presenting cells; they contain positively charged pockets that preferentially bind negatively charged epitopes, such as deamidated gliadin peptides (DGP), and present them to cluster of differentiation-4 (CD4)⁺ T cells thereby activating them [59, 60].

The Central Role of HLA-DQ Haplotype

HLA genes are located on chromosome six and are divided into three classes (I–III). HLA-DQ (6p21.3) belongs to class II and is composed of a heterodimer located on antigen-presenting cells and encoded by HLA-DQA1 and HLA-DQB1. Each of the copies of the HLA-DQ gene encodes for a heterodimer, resulting in four proteins (one couple per chromosome). HLA-DQ2 homozygotes (DQB1*02 on both chromosomes) subjects have the highest risk to develop CD, fivefold higher than heterozygotes [61, 62]. Even if more rare in the general population, DQ2 homozygosity is characteristic of 25% of all CD patients and often relates to a more severe clinical outcome, as suggested by its association with earlier disease onset [63, 64] and its higher prevalence in refractory CD patients [65]. In fact, the immune response arising in

homozygous individuals is stronger than the response from heterozygous individuals [57, 66]. The most common configuration (more than 50% of CD patients) is represented by DQ2.5 (DQB1*02/DQA1*05) heterozygotes [62].

HLA-DQ8 is found in 5–10% of CD patients [62, 67], with DQ8 homozygosity conferring increased risk compared to DQ8 heterozygosity [68]. It must be noted that about 5% of CD patients carry only one of the HLA-DQ2 heterodimer alleles (HLA-DQA1*05 or HLA-DQB1*02), therefore encoding for the so-called “half heterodimer.” These patients constitute the overwhelming majority of CD subjects not carrying the full HLA-DQ2 and/or -DQ8 alleles [69]. The highest risk group includes individuals who inherit both DQ8 and DQ2.

Only less than 1% of patients who fulfill clinical criteria for CD do not carry the DQ2 (including half heterodimer) nor the DQ8 alleles [69]. Thus, in the clinical practice CD can be virtually excluded in individuals lacking HLA-DQ2 or -DQ8.

Interestingly, 30% of European descent individuals carry HLA-DQ2 susceptibility allele, however only about 4% of these individuals will develop CD [61]. This suggests that even though those molecules are necessary, they are not sufficient to induce the disease, implying that other genetic and environmental factors must contribute to it.

Non-HLA Genetic Susceptibility Factors

HLA alleles explain only 35% of the disease genetic susceptibility, while the remaining is due to numerous non-HLA genes that singularly contribute to a much lower extent to CD heritability. A recent dense genotyping study [70] identified 13 new CD risk loci reaching genome-wide significance, bringing the number of known CD-associated susceptibility loci (including the HLA locus) to 40. Notably, 64% of the 39 non-HLA loci were shared with at least another autoimmune disease (e.g., type 1 diabetes), reinforcing the idea that autoimmune disorders may share common pathogenic pathways [71].

In those regions, more than 115 non-HLA genes have been associated to CD, individually contributing only modestly to the overall disease risk. Twenty-eight of them encode for molecules involved in the immune response, reinforcing the central role of immune dysregulation in CD pathogenesis. Post-genome-wide association studies (GWAS) will need to focus on elucidating the functional basis of these genetic variants, in particular, the role of regulatory variation. Furthermore, considering multiple gene variants may help refining risk prediction models and identifying high-risk individuals that could benefit of preventive strategies.

Environmental Factors

The high impact of genetic predisposing factors in CD does not exclude a key role of the environment in triggering disease development. In fact, the increased incidence of CD in the past decades cannot be explained by genetic drift and most likely results from faster changes in the environment. In an elegant review, Abadie et al. [72] show that CD prevalence does not perfectly correlate, as it would be predicted, with the levels of wheat consumption and frequencies of HLA-DQ predisposing alleles, thus emphasizing the role of environmental factors in CD pathogenesis.

Infant Feeding Practices and CD Development

Mode of delivery and breast-feeding contributes to shape the infant immune system, thus suggesting that both maternal microbial intestinal flora and early infant feeding practices may have a key role in determining future development of immune-mediated diseases.

As for modalities of delivery, elective cesarean section (C-section) has been associated with a modest increased risk of later CD, possibly related to the profound differences in the intestinal microbiota found between vaginally versus C-section delivered babies [43, 73].

The importance of early infant feeding and timing of first gluten introduction had been highlighted by the so-called “Swedish epidemic.” In the late 1980s in Sweden, a fourfold increase in CD incidence was recorded in children below the age of two that dropped to pre-1985 rates a decade later [74, 75]. This rapid rise in disease incidence correlated with several changes in infant dietary patterns including introduction of gluten after completing breast-feeding and increased amount of gluten in the infant diet. Of interest, such increased incidence declined to pre-epidemic levels only after these changes were reverted [76, 77]. Prolonged breast-feeding too had been thought to have a protective effect on later onset of the disease [78, 79]. On this basis, gradual introduction of small amounts of gluten during breast-feeding has been proposed as strategy to prevent early onset of CD, and breast-feeding is recommended, in infants born in families at risk for CD, for the whole first year of life, with gluten introduction advised between 4 and 6 months of life [80, 81]. While prior studies had suggested, as we have seen, that infant feeding practices and timing of initial gluten exposure are important, two recent multicenter randomized trials that tested strategies of early or delayed gluten introduction in infants, showed that neither strategy appeared to influence celiac disease risk. Additionally, breast-feeding was not shown to protect against the development of CD [82, 83].

Viral Infections

Among environmental factors that contribute to trigger CD, infective agents have been proposed. Higher rates of summer births were described in children with CD, suggesting that exposure of 4–6-month-old infants to winter-linked viral infections such as rotavirus may play a role. The first correlation between viruses and CD dates back to the 1980s when a homology between alpha gliadin and a protein of the human adenovirus [84] had been described and related to increased frequency of adenovirus infection in CD patients [85] compared to controls. More recently, increased rate of rotavirus infections (as measured by anti-rotavirus antibody titers) has been associated with a moderate, but significantly increased risk of CD in HLA-susceptible children [86]. The mechanisms through which viral infections in early life can increase CD occurrence in later years have not been elucidated.

Microbiome

The composition of intestinal microbiota as well as bacterial metabolic products (and especially short-chain fatty acids) can affect intestinal epithelium function and mucosal immune homeostasis. Both quantitative and qualitative differences in the composition of the intestinal microbiome have been observed in patients with autoimmune disorders [87, 88], as well as CD [89–93] when compared to healthy individuals. In the context of CD, an expansion of some pathogenic bacterial populations (*Escherichia coli* and *Staphylococcus*) [93, 94] and a reduction in butyrate-producing bacteria (*Bifidobacterium*) [95, 96] have been described. Currently, it is still unclear whether the observed changes in the microbial composition are the cause or the result of the intestinal inflammatory process. Indeed, epithelial alterations, such as those described in CD, could create a specific environment favoring the selective colonization of some microbial species, thus contributing to the creation of the microenvironmental milieu that favors the disease development. This is clearly a rapidly evolving field, likely to bring important new acquisitions in the near future.

Pathogenesis

CD is a chronic inflammatory disorder with autoimmune features, characterized by a T cell-mediated immune response arising in the small-intestinal mucosa upon gluten ingestion. In genetically susceptible individuals, gliadin peptides activate stress pathways and provide ligands for innate immune

receptors, leading to the release of pro-inflammatory mediators that then sustain the T cell response both in the lamina propria and in the epithelium (Fig. 40.1). This inflammatory reaction typically involves both the innate and the adaptive arms of the immune response. In this model, two hits are required, each one being necessary but not sufficient for the development of CD: one is the activation of stress markers in intestinal epithelial cells and the second is the rise of a gluten-specific proinflammatory CD4 T cell response in the lamina propria [97, 215]. These two events lead to the full activation of mobilization of lymphocytes in the intestinal

epithelium (intraepithelial lymphocytes—IELs), final responsible of tissue destruction [98].

The immunological reaction occurring in CD patients follows the ingestion of gluten-containing cereals: wheat, rye, and barley. Glutenins and gliadins, typical gluten components, are responsible for the viscosity and elasticity of the wheat dough [99, 100]. Their high concentration of glutamine and proline residues (35 and 15% of the total amino acid content) renders them highly resistant to GI enzymes [101]. Indeed, the lack of prolyl-endopeptidase activity in any of the human digestive enzymes prevents enzymatic at-

Fig. 40.1 CD pathogenesis. Celiac disease (CD) is a multifactorial disorder induced by gluten in genetically susceptible subjects. Several environmental factors (i.e., viral infections, alterations in microbiome composition, etc.) can contribute to trigger the disease by inducing epithelial stress in the intestinal mucosa, and the production of innate immune cytokines, such as interleukin 15 (*IL-15*) and type-1 interferon (*type-1 IFN*). Those cytokines contribute to create a pro-inflammatory environment that enhances dendritic cells activation. Undigested gliadin peptides (purple circles) reach the intestinal lamina propria where they are deamidated by tissue-transglutaminase 2 (*TG2*). Deamidation renders gliadin peptides more suitable to be presented by HLA-DQ molecules. Only dendritic cells expressing the CD-associated HLA-DQ2 and/or -DQ8 molecules (orange) can present deamidated gliadin peptides (green circles) to naive CD4⁺ T cells (red cells). Inflammatory

dendritic cells (purple) enhance the arise of a gluten-specific CD4⁺ T cell response, characterized by the production of high levels of pro-inflammatory cytokines such as interferon-gamma (*IFN-γ*) and interleukin 21 (*IL-21*). These cytokines are thought to contribute to induce a full activation of cytotoxic CD8⁺ intraepithelial lymphocytes (*IEL*). The second hit required for the induction of a full activation of IEL is the expression of stress markers (i.e., MIC-A and IL-15) in intestinal epithelial cells. Fully activated CD8⁺ IEL are responsible for the intestinal epithelial destruction and the induction of villous atrophy in CD patients. Furthermore, gluten-reactive CD4⁺ T cells provide the required help to TG2-specific B cells, presenting TG2–gliadin complexes, in a hapten carrier-like manner and drive TG2-specific antibody production. *NKG2D* natural-killer group 2, member D, *MIC* macrophage inhibitory cytokine

tack of proline-rich domains in gluten proteins. Thus, at the end of a normal, full digestive process of gluten, many gliadin peptides remain undigested in the intestinal lumen. The mechanism through which such peptides reach the intestinal lamina propria is not entirely clear. Even though an increase in intestinal permeability has been shown in CD, a retro-transcytosis pathway has been described for secretory antibodies, potentially having a role also for gliadin transport [102].

Tissue-Transglutaminase 2

In the subsequent steps in CD pathogenesis, the enzyme tissue transglutaminase 2 (tTG) has a pivotal role. tTG is a calcium-dependent transamidating enzyme that catalyzes covalent cross-linking of proteins. When located extracellularly in the presence of calcium, tTG is in an open and active form [103]; furthermore, an inflammatory environment leads to its constitutive activation [104]. tTG is the main autoantigen for CD: In addition, it has a crucial role in inducing post-translational modification of gluten peptides. In fact, in the lamina propria, tTG mediates the conversion of glutamine into glutamic acid, introducing negatively charged residues into gliadin peptides that act as immunogenic epitopes binding to HLA-DQ molecules with relatively higher affinity, thus representing a prerequisite for a gluten-specific T cell response [105].

Autoantibodies

Genetic, mechanistic, and epidemiological data relate CD to other autoimmune disorders. One of the key diagnostic features of CD is the presence of serum anti-tTG IgA and IgG autoantibodies. The mechanisms leading to their production in CD are unclear. The upregulation and activation of tTG in inflamed tissues may generate additional antigenic epitopes by cross-linking or deamidating exogenous or endogenous proteins. However, the most accepted hypothesis for their formation, which explains also their dependence on dietary gluten, is that the enzyme cross-links itself to gluten during the substrate–enzyme interaction [106]. Once internalized, those complexes are processed and gluten epitopes bind HLA-DQ molecules of the B cell that may allow gluten-reactive CD4 T cells provide the required help to tTG-specific B cells in a hapten carrier-like manner and drive tTG-specific antibody production.

The Adaptive Immune Response in CD

CD originates as a result of both innate immunity and adaptive immunity activation. Adaptive response, characterized by the activation a gluten-specific CD4 T cell response in the

intestinal lamina propria, is a key event in CD pathogenesis. Gluten contains a large number of peptides capable of stimulating T cells. Dendritic cells present negatively charged gliadin peptides through HLA-DQ2 or HLA-DQ8 molecules to naïve CD4 T cells, thus enhancing a T helper 1 inflammatory response, characterized by the production of high levels of interferon- γ (Fig. 40.1).

The gluten-specific CD4 T cell response is sustained by several cytokines, including IL-15 and IL-21. The expression of IL-21, enhanced by gluten, is very high in active CD patients, while it is downregulated in potential CD [107], supporting its role in the induction of tissue damage. It acts in synergy with IL-15 [108] promoting interferon- γ production and enhancing cytotoxic CD8 T cells proliferation and survival; however, the mechanism initiating its production in CD is unclear.

The Innate Immune Response

As mentioned, innate immune activation is also necessary for the development of CD. There is in fact evidence that in addition to the immunodominant epitopes, which as, discussed, are presented to CD4 naïve T cells, gliadin also contains fragments which are able to enhance epithelial stress and induce an innate immune effect [109–111]. The best-known fragment is the peptide 31–43 (P31–43) of α -gliadin, which is able to upregulate major histocompatibility complex (MHC) class I-related molecules (MICs) [112] to activate the mitogen-activated protein (MAP) kinase pathway and induce apoptosis in intestinal epithelial cells. P31–43 induces cell proliferation and actin cytoskeleton rearrangements in *in vitro* and *ex vivo* models [109–111, 113, 114]. The proliferative response elicited by P31–43 in CD mucosa involves epidermal growth factor (EGF)/IL15 cooperation. Of note, a constitutive activation of the EGF receptor (EGFR)/extracellular signal-regulated kinases (ERK) pathway has been found in celiac patients [110] potentially representing a predisposing condition to the damaging effects of gliadin.

Of interest, P31–43 is able to impair actin cytoskeleton in healthy subjects, suggesting that it can act on similar pathways altered in CD cells. In addition, it enhances the expression of IL-15, a key innate cytokine involved in CD pathogenesis, as it contributes actively to enhance the expression of activating natural killer cells (NK) receptors (i.e., NKG2D) on IELs and impair the T regulatory cells function in celiac patients [115, 116].

IELs Activation and the Induction of Tissue Damage

The tissue damage typical of CD, characterized by villous atrophy and crypt hyperplasia, is due to a profound remodel-

eling of the small intestinal architecture and is mainly mediated by cytotoxic IELs. IELs represent a heterogeneous population including TcR α/β CD8 cells NK-like cells, and TcR γ/δ cells.

As evident in potential CD patients, the gluten-specific T cell adaptive immune response alone can occur even in the absence of villous atrophy, suggesting that other signals are required to induce tissue damage [98]. Indeed, the full activation of IELs and acquisition of their cytotoxic killing phenotype requires also stimuli from the epithelial compartment. Increased expression of stress molecules, such as nonclassical MHC class I molecules (i.e., MIC and HLA-E), has been shown in intestinal epithelial cells of active CD patients, as part of the innate stress response induced by gluten or by other environmental triggers. MIC and HLA-E are ligands for NKG2D and CD94, activating NK receptors that are upregulated on IELs in CD patients and whose expression is enhanced by IL15. Activation of IELs, with increased Fas ligand expression, results in epithelial cell apoptosis and villous atrophy via interactions with Fas on intestinal epithelial cells. Altogether, the end result of these various events is to lead to IEL infiltration and the resulting tissue destruction, characterized by crypt hyperplasia and villous atrophy.

These changes occur in a continuum, going from normal to a complete flattening of the villi in a slow progression. Marsh [117] described in great detail such progression and his description is also utilized in the pathology reports from duodenal biopsies. Thus, the intestinal damage seen in CD is described as follows:

- Type 0 or pre-infiltrative stage (normal);
- Type 1 or infiltrative stage (increased IELs);
- Type 2 or hyperplastic stage (type 1 + hyperplastic crypts);
- Type 3 or destructive stage (type 2 + villous atrophy of progressively more severe degrees, denominated 3a—partial atrophy, 3b—subtotal atrophy, and 3c—total atrophy).

Clinical Presentations

The inflammatory changes described in the previous section, resulting in the most advanced cases in severe villous atrophy, lead to a wide variety of clinical presentations. While GI manifestations are understandably present and in many cases prominent, CD goes well beyond the GI tract, so that basically all systems and organs can be involved. GI signs and symptoms due to malabsorption, such as diarrhea and abdominal pain, are very common and easily lead to evaluation for CD, but they are by no means universally present. In fact, there is evidence [118–122] that CD presentation in children and teenagers has substantially changed over time, moving from a malabsorptive disorder causing GI symptoms and malnutrition to a more subtle condition causing a variety of extraintestinal manifestations (see Table 40.1). Thus, it is understandable that the term “typical,” reserved for the GI

manifestations of CD, is quickly becoming obsolete, as the extraintestinal manifestations are now so prevalent they are no longer to be referred to as “atypical” [123]. It is indeed this variety of presentations, and the fact that CD may also be entirely asymptomatic, that is responsible for the dismal rate of diagnoses around the globe.

Table 40.1 reports the main clinical presentations of CD, with their prevalent age distribution. As it can be seen, the clinical manifestations can be protean, thus making the diagnosis not obvious in most cases. When CD has its onset in infancy and very early childhood, the GI manifestations prevail and can be quite aggressive, resulting in a clinical picture of malnutrition and failure to thrive, often associated with a protein-losing enteropathy. Subsequently, however, the onset may be more subtle, and more extraintestinal manifestations become common.

GI Manifestations

Abdominal pain and distention is probably the most common symptom of patients diagnosed with CD worldwide; in Canadian children, it has been reported in as many as 90% [124]. Chronic or intermitted diarrhea, characterized by bulky, foul-smelling, greasy stool, is a very common symptom in children with CD. Its occurrence, however, is progressively becoming less frequent than in the past. Counterintuitively, long-standing and occasionally severe constipation can be the presenting manifestation in a significant amount of patients, children, as well as adults [125]. Constipation appears to be related to a well-documented delay in oro-cecal transit time [126, 127], possibly caused in part by disturbed upper GI motor function [128]. Other presenting symptoms related to the GI tract are vomiting (especially in infants and toddlers), weight loss, or failure to thrive leading—particularly in cases of delayed diagnosis—to severe malnutrition and cachexia. However, it should be noted that children with CD can also be overweight or obese, as well documented in the literature, (reviewed in [129]) so that the absence of malnutrition should by no means rule out the possibility of CD. More rarely, other disorders such as acute electrolyte disturbances, hypotension, and lethargy can accompany the clinical picture [130]. Recurrent intussusception, an uncommon but important GI sign, was first described in children in 1997 [131], and it is now well recognized as an event occurring more frequently in CD children before their diagnosis than in control populations [132].

Mild elevation of liver transaminases is well described in pediatric CD. A recent meta-analysis [133] revealed that this sign is presented by 36% of children with CD, while 12% of children with mild unexplained hypertransaminasemia have CD. Of note, a gluten-free diet (GFD) normalized transaminase levels in 77–100% of patients with CD within 4–8 months.

Table 40.1 Clinical presentations of celiac disease according to age most commonly involved

Type	Sign or symptom	Age most commonly involved
<i>Gastrointestinal</i>	Abdominal pain, bloating	All ages
	Diarrhea	All ages
	Vomiting	Infancy
	Anorexia	Infancy to early childhood
	Constipation	Child to adolescent
	Failure to thrive	Infancy and early childhood
	Weight loss	Child to adult
	Recurrent intussusception	Infancy to early childhood
	Hypertransaminasemia and other liver issues	All ages
	<i>Extraintestinal</i>	Sad mood
Delayed puberty		Adolescent
Short stature		Child to adolescent
Iron-deficient anemia		Adolescent to adult
Dermatitis herpetiformis		Adolescent to adult
Dental enamel defects		Child to adult
Aphthous ulcers		Child to adult
Fatigue		Adolescent to adult
Arthritis		Adolescent to adult
Osteopenia		Adolescent to adult
Osteoporosis		Adult
Psychiatric disorders		Adolescent to adult
Idiopathic seizures		Child to adult
Headaches, migraines		Adolescent to adult
Numbness/neuropathy		Adult
Cerebellar ataxia		Adult
Unexplained infertility (in women)		Adult

Gastrointestinal presentations are commonly also referred to as “Typical” D while all extraintestinal manifestations are called “Atypical.” Historically, these denominations arose because for decades CD was thought to be restricted to symptoms and signs of malabsorption, and all extraintestinal manifestations were considered rare and not belonging to the classical presentation

Extraintestinal Manifestations

Anemia in celiac children can be the end result of several different, and sometimes combined, causes; however, the single most common type of anemia is due to iron deficiency.

IDA has in fact been reported in between 12 and 69% of newly diagnosed celiac cases [10–12, 122, 134]. Even when asymptomatic, CD can lead to IDA; in a large series of patients with subclinical CD, IDA was indeed found in almost half of the patients, with adults having a higher incidence than children: 46 versus 35% [10]. The pathogenesis of iron deficiency in celiac seems to be straightforward; in fact, iron is absorbed in the duodenum and proximal jejunum, areas that are typically most affected in florid CD. Thus, most cases result from an impaired absorption of iron. The higher prevalence of anemia in celiac patients with an atrophic mucosa (Marsh 3) compared to those with mild enteropathy (Marsh 1 or 2) recently found in a study conducted in Italy on a large number of patients [135] provides indirect support for this.

Dermatitis herpetiformis (DH) is considered the skin presentation of CD. Rare in children, DH affects mostly teen-

agers and adults who present symmetrical, pruritic blisters followed by erosions, excoriations, and hyperpigmentation. The most commonly involved sites are the elbows (90%), knees (30%), shoulders, buttocks, sacral region, and face. Itching of variable intensity, scratching, and burning sensation immediately preceding the development of lesions are common [136, 137]. The diagnosis rests on a combination of clinical, serological (same autoantibodies utilized for CD), and histological criteria showing the typical IgA deposits in skin biopsies [138, 139]. Its treatment is based on a strict GFD. Dapsone and/or other drugs should be used during the period until the GFD is effective [138].

Dental enamel hypoplasia is more common in patients with CD compared to the general population [26], and in CD it has been reported with a prevalence ranging from 10 to 97%. It appears to be more prevalent in children, compared with adults with CD and is thought to be secondary to nutritional deficiencies and immune disturbances during the period of enamel formation in the first 7 years [27].

Aphthous ulcers too can be present in children and adults with CD and they often regress once the patients are on a GFD [28].

Low bone mineral density is found in the vast majority of newly diagnosed patients, and in some cases it is advanced to osteoporosis and can be associated with fractures. The etiology of such bone alterations in CD is multifactorial, thought to be mostly secondary to the combination of intestinal malabsorption and chronic inflammation. At diagnosis, approximately one-third of adult CD patients have osteoporosis, one-third have osteopenia, and one-third have normal bone mineral density [29]. While children with CD, once on a GFD, seem to be able to improve their bone mineral density more fastly, adult patients' bone mineral density was found to be significantly lower than expected for the normal population, not just at diagnosis, but even after 1 or 2 years of GFD [140]. Thus, there is a risk for suboptimal peak bone mass acquisition and a retarded growth in CD children, as the bone density increases until the end of puberty, when it reaches its peak value: if normal peak bone mass is not achieved, the individual is at a higher risk for developing osteoporosis [141].

Joint involvement, though not too common, has been described in children and adults with CD and it is suggested that patients presenting with unexplained articular manifestations be tested for CD [142].

Children with CD have a slightly increased frequency of neurological symptoms compared to controls. These include headache [143], peripheral neuropathy [144], and seizures; ataxia is described only in adult cases [145]. The prevalence of epilepsy in CD children also appears to be slightly higher than expected, around 1% [146]. Seizures are often generalized tonic-clonic, but partial and occasionally absence seizures are also reported [146, 147]. A recent epidemiologic study of nearly 29,000 subjects with CD and 143,000 controls found that CD increased the risk of epilepsy, including in children, by 1.4-fold [148]. In some patients with CD and epilepsy refractory to antiepileptic drugs, seizures have been controlled with a GFD [149, 150].

Relatively common in adolescents are also psychiatric issues: anxiety, often with recurrent panic attacks, hallucinations, depression, leading to a slightly higher prevalence of suicidal behavior in celiac patients [30]. Interestingly, there is some evidence that the GFD may help in alleviating depression in celiac adolescents [31].

Disease Associations

A series of recent large-scale epidemiological investigations, mostly, but not solely, conducted in Sweden, have also revealed a growing number of associated conditions that can occur with CD, although in most cases the reasons for such associations and the clinical relevance of them remain unclear. Among the conditions with increased prevalence in CD, in most cases related to adult patients, are: chronic

obstructive pulmonary disease [151], ischemic heart disease [152], urticaria [153], eosinophilic esophagitis and gastroesophageal reflux disease [154], pancreatitis [155], hemochromatosis [156], cataracts and uveitis [157, 158], idiopathic dilated cardiomyopathy [159], nephrolithiasis [160], end-stage renal disease [161], eating disorders [162], primary hyperparathyroidism [38] (a risk however subsiding on GFD), adrenal insufficiency [33], systemic lupus [163], cataract [40], and endometriosis [39].

In addition, the offspring of celiac mothers appear to also be at an increased risk for a number of adverse events, including congenital malformations [164].

On the other hand, a reduced risk for ovarian and breast cancer has been reported for celiac women [165].

IgA deficiency has also been associated with CD. In fact, about 8% of IgA-deficient children are celiac [166] and about 2% of CD children are IgA-deficient [167]. While clinically not relevant, this association is important in the strategy of screening for CD (see below).

Autoimmune Conditions

A strong association has also been shown between CD and autoimmune disorders, thought to be mostly due to a shared genetic component in the HLA region. The best described association is with type 1 diabetes mellitus (T1DM), where a prevalence of approximately 10% of CD is found [32, 168]. About two-thirds of children diagnosed with CD after T1DM onset have elevated levels of celiac antibodies at the time of T1DM diagnosis or within the first 24 months; however, an additional 40% of patients develop CD a few years after diabetes onset [169], and even adults with a long history of T1DM show a progressively higher prevalence of CD [170]. Thus, it is recommended that T1DM children be repeatedly tested for CD. Of note, it has been shown that the presence or absence of GI symptoms in children with T1DM has no predictable value for biopsy-confirmed CD or not [168]. Clearly, once diagnosed with CD, children with T1DM need to follow a GFD. Its effects on diabetic control are however unclear: In fact, glycemic control, both in children with or without malabsorption, has been found either improved or unaffected [171].

The issue of whether the onset of autoimmune disorders in CD patients is favored by the ingestion of gluten remains controversial. An increased prevalence of autoimmune disorders was found in parallel with the increasing age at diagnosis of CD [172], suggesting that prolonged exposure to gluten may favor the onset of autoimmune conditions; however, these results have not been reproduced by subsequent investigations [173, 174], leaving the question unresolved [175].

Chromosomal Disorders

Down syndrome [176], Turner syndrome [177], and Williams syndrome [178] are conditions where the prevalence of CD has been found to be higher than in the general population, and hence children with such syndromes need to be screened for CD.

Diagnosing CD

Given the many various manifestations of CD, in children as well as adults, clearly the first requisite for diagnosis is a high degree of suspicion. Table 40.2 lists the circumstances that demand testing for CD.

The availability of very sensitive and specific autoantibodies in the IgA subclass, generated in the small intestinal mucosa and detectable in the serum, such as the tTG-IgA or anti-endomysium IgA (EMA-IgA) [179] has given the physician a powerful screening tool. In addition, another class of antibodies has also been found valuable in screening (especially in very young children when tTG-IgA could be negative [180, 181]) and in following up patients with CD: the anti-DGP, both -IgA and -IgG antibodies produced against the gliadin peptides after they have been modified by the tTG [182]. Currently, it is universally recommended [33, 179, 183] that tTG-IgA and total serum IgA be the first line of screening, due to the very elevated sensitivity of this test. Total serum IgA needs to be added in order to ascertain that the individual is able to produce tTG-IgA: In fact, celiac patients who happen to be IgA-deficient may have a false-negative tTG-IgA. In these circumstances, both tTG-IgG [184–186] and DGP-IgG [187] can be usefully checked as markers of CD.

In 1990, the European Society of Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) published diagnostic criteria [188] that have been universally applied for over 20 years, both in pediatric age and in adults. While reducing the number of biopsy procedures needed for a firm

diagnosis from three of the original guidelines (initial one showing typical changes, followed after a year on GFD by a second one documenting healing, and finally by a third one after gluten challenge to show relapse) to only one, they still called for the indispensable role of documenting the flattening of small-intestinal mucosal villi in patients with a consistent history and laboratory findings. In 2012, an ad hoc task force of the same society published revised criteria [1] and produced an evidence-based algorithm that allowed the physician to skip the duodenal biopsy under certain circumstances, namely, in children and teenagers showing a genetic asset and a history compatible with CD, a very elevated titer (more than ten times the upper limit of normal) of tTG-IgA, along with a positive EMA titer. While this simplified approach appears certainly valid, as it possesses a positive predictive value close to 100%, one needs to apply it with great care. In fact, children with GI complaints diagnosed without the endoscopy may have additional disorders that would go undiagnosed by skipping this procedure.

Figure 40.2 is an algorithm (based in part on the ESPGHAN guidelines [1]) that summarizes the diagnostic steps for a child or teenager suspected of CD. Again, Table 40.2 lists the presentations that require screening. The subject with normal serum IgA and normal tTG-IgA do not need to be considered celiac, given the high sensitivity of the test; however, since it would appear that in the infant and toddler tTG-IgA may not be as sensitive as in later ages, DGP-IgA and DGP-IgG can be measured additionally. Furthermore, in the presence of a strong clinical suspicion in the very young child, it would be appropriate to still proceed with an esophago-gastro-duodenoscopy (EGD) with biopsy even if celiac serology is negative.

If the subject has positive tTG-IgA, then the titer becomes important. In fact, as mentioned, with titers that are more than ten times the upper limit of normal range, the EMA titer must be checked and if it too is clearly positive, then the diagnosis of CD can be considered definitive. On the contrary, the EGD would be necessary if the EMA prove negative, or in all cases where the tTG-IgA increase does not reach the threshold of $>10\times$ normal. It is important to notice that it is recommended [1, 183, 189] that at least four biopsies be taken from the distal duodenum, and also one or two from the bulb, otherwise the diagnostic yield may be jeopardized by the occasional patchy duodenal lesions.

The interpretation of the pathology of the duodenal biopsies guides the final diagnosis: while pathology changes showing lesions of Marsh type 2–3, in the presence of positive serology, confirm the diagnosis, caution must be exerted for findings of Marsh type 1, especially when not supported by positive serology. In fact, such increased presence of IELs (“lymphocytic duodenosis”) has been found to be due to celiac in no more than 16–39% of cases [190, 191]. Thus, additional conditions (see Table 40.3) must be carefully looked at before concluding for its association with CD.

Table 40.2 Subjects to be screened for CD

All conditions listed in Table 40.1
First-degree relatives of celiac patients
IgA deficiency
Autoimmune conditions
Type 1 diabetes
Autoimmune thyroiditis
Autoimmune hepatitis
Addison’s disease
Chromosomal disorders
Down syndrome
Turner syndrome
Williams syndrome

Fig. 40.2 Suggested diagnostic algorithm**Table 40.3** Conditions causing lymphocytic duodenitis (Marsh type I changes)

Celiac disease
<i>H. pylori</i> gastritis
Small-bowel bacterial overgrowth
NSAID and other drugs
Immune dysregulation
Crohn's disease
Food protein-induced enteropathy
Infections
NSAID nonsteroidal anti-inflammatory drugs

As for those with a Marsh type 0, the call is even more delicate. In fact, the patient can be defined as “potential” if tTG-IgA are elevated $>10\times$ and/or EMA titer is positive; but with tTG-IgA increased less than ten times and a negative EMA, then the possibility of a false-positive tTG-IgA must be considered. This occurrence is especially common, for unclear reasons, in children with T1DM, where tTG-IgA have also been found to spontaneously normalize [192]. Such patients should therefore remain on a gluten-containing diet and be carefully monitored.

More complex is the decision about the need for a GFD for true “potential” celiac children and adolescents who are asymptomatic. The literature shows in fact variable percentages (between 30 and 60%) of evolution into full-blown CD when they are left on gluten [193–195], including the

possibility of some eventually becoming serologically negative. It seems in fact that potential CD patients show a low grade of inflammation that likely could be due to active regulatory mechanisms preventing the progression toward a mucosal damage [196]. In essence, while research will eventually allow us to predict which patients would develop full-blown CD if left on gluten, currently we do not have this capacity, so that the decision on whether or not to put potential celiac patients on a GFD must be taken with great care, on an individual basis, and be properly agreed upon by the family.

Complications

Refractory CD

Better known by the older terminology as “refractory sprue,” refractory CD is a very severe form of CD that does not respond to a GFD, in spite of normalization of celiac serology [197]. Refractory CD almost exclusively occurs in adults or elderly patients who have been suffering from malabsorptive symptoms for a long time prior to being diagnosed. This condition is further classified into type I and type II on the basis of gamma chain T cell clonal rearrangement and aberrant T cell phenotypes. Type II refractory CD is the most aggressive form, leading to the most feared complication of CD: the

enteropathy-associated T cell lymphoma (EATL). As a consequence, refractory CD results in an increased mortality rate, with a 5-year survival rate of 80–96% for patients with type I refractory CD and 44–58% for type II cases [197]. When examining the survival rate of those patients with type II refractory CD who developed EATL, the survival rate at 5 years was a dismal 8% [198]. New treatment modalities, including autologous stem cell transplant, are becoming available for this aggressive condition [199, 200].

Increased Mortality Rate

Aside from the risks related to refractory CD, evidence is mounting that unrecognized, and hence untreated, CD may carry a risk for increased mortality rate [201]. There appears to be a positive correlation between diagnostic delay and/or insufficient compliance with the diet and decreased life expectancy, which has been documented in a large retrospective study in Italy [202]. More recently, increased mortality has also been reported in undiagnosed patients (based on elevated serum tTG-IgA) in the USA [203] and in Europe [204–206].

All of the evidence therefore strongly emphasizes the importance of an aggressive strategy for early detection and treatment of patients with CD.

Treatment

CD is a lifelong condition and a strict GFD is currently the only available treatment. While the exact amount of gluten that can be tolerated daily by CD patients is unknown and is likely to be subject to a wide interindividual variability, there is evidence that no patient would react to a daily dose of up to 10 mg, while the majority would at 100 mg or above [207]. In practice, many patients, and especially older children and adults, do not present any symptom after inadvertent gluten ingestion or sporadic intentional consumption of gluten-containing products. In addition, dietary compliance assessment is not always an easy task, since serology often fails to reveal slight transgressions. Therefore, a periodical follow-up is needed and the importance of a lifelong diet should be constantly reinforced, especially to asymptomatic patients. The dietary restriction must include wheat, rye, barley, and their derivatives such as triticale, spelt, and kamut. Other cereals such as rice, corn, maize, and buckwheat are perfectly safe for CD patients and can be used as wheat substitutes. Oats were included in the first group of toxic cereals, but later evidence has conclusively shown that they are tolerated by the vast majority of patients, provided the oats-based products are manufactured in plants that can guarantee absence of any possible cross-contamination with flours

based on wheat, rye, or barley. In any case, introducing them with prudence is recommended in order to recognize any adverse effect.

Gluten withdrawal is necessary to shut down the inflammatory response arising in the gut. However, whether a GFD could prevent the development of associated autoimmune conditions or complications, such as malignancies, is still debated [175]. As discussed previously, since the benefits of GFD in terms of prevention of complications and comorbidities in patients with potential CD are still unclear, it remains controversial whether such dietary regimen should be proposed to all of them, particularly those who are asymptomatic.

Future Potential Therapeutic Strategies

Following a lifelong strict dietary regimen is not an easy task for many patients, especially teenagers and young adults who may not easily accept limitations to their social life. On the other hand, there is a subgroup of CD patients (i.e., refractory CD) who fail to respond even to a strict GFD, thus reinforcing the concept that GFD could not be considered a cure for all CD patients. Importantly, a variety of commercial food products and some safe cereals can be cross-contaminated with unsafe cereals as the result of mixing during transportation and processing. Hence, there is a requirement for alternative approaches to treat CD.

A first approach may consist in creating new varieties of wheat that are safe for CD patients. The identification of the full sequences of immune-stimulating peptides may lead to the production of wheat varieties lacking biologically active peptide sequences through breeding programs and/or transgenic technology. Large-scale cultivars where these cereals could replace the current toxic varieties could reduce the risk of possible cross-contamination. However, it is evident that this process will take a long time to be developed and would still require for the patients the need to carefully select such products.

Recent progresses in understanding the cellular and molecular basis of CD have helped in identifying several possible therapeutic targets, from already available molecules that can find a new application in this disease to new drugs that may be developed. Strategies vary from gliadin-degrading enzymes that would allow the occasional consumption of gluten-containing products to the more ambitious attempt to reestablish immunological tolerance toward gluten using a peptide-based “vaccine.”

Given the high content in proline residues, gliadin peptides are highly resistant to proteolysis, thus favoring the accumulation of long fragments within the intestinal lumen. Exogenous proline and/or glutamine-specific proteases-based drugs and/or dietary supplements (i.e., ALV003 (glutenase Alvine 003) and

AN-PEP (alanyl (membrane) aminopeptidase)) facilitate gluten digestion and T cell epitopes destruction [208], thus representing a useful “adjunctive” tool for CD under a GFD, in particular situations where there is a risk of cross-contamination. Another possible gluten detoxifying strategy is represented by gluten-sequestering polymers (i.e., hydroxyethyl methacrylate-co-styrene sulfonate; HEMA-co-SS) that bind gluten fragments, reducing their effects on the intestinal mucosa [209].

A pharmacological reduction of intestinal permeability may contribute to reduce the load of gliadin peptides reaching the intestinal lamina propria. In this perspective, larazotide (AT-1001), a zonulin antagonist, is undergoing clinical trials in CD patients. Furthermore, inhibition of Rho kinase (RhoA or ROCK), two molecules regulating cytoskeleton and tight junction structure, has been proposed as future potential target [210].

Furthermore, the identification of specific epitopes may also provide the basis for immunomodulation by antigenic peptides. In this regard, the most ambitious and promising therapeutic intervention for CD patients is represented by a vaccine based on a set of gliadin immunodominant peptides recognized selectively by HLA-DQ2 and that should promote the induction of tolerance to gluten through a peptide-based desensitization [211].

Other promising approaches include preventing gliadin presentation to T cells by blocking HLA-binding sites [212] or use of tTG inhibitors [213], thus impairing the adaptive immune response activated by gliadin peptides. Any immunomodulatory approach will be required to have a high safety profile to be a valuable substitute to the GFD.

Anti-IL-15 monoclonal antibodies, already tested in rheumatoid arthritis and psoriasis, have been proposed for refractory CD, where the expansion of IELs is dependent on this cytokine. Blocking NKG2D to prevent full activation of IELs has also been proposed as a further potential therapeutic target in CD patients [214]. Again, security profile, side effects, and compliance will need to be taken into account before any of those treatments could replace GFD.

Introduction

This chapter focuses on disease pathobiology of the gastrointestinal, nutritional, and hepatic manifestations of cystic fibrosis (CF) disease.

CF is an autosomal recessive multisystem disease, the highest incidence being in individuals of North European descent. Intense follow-up and treatment have improved the median survival to nearly 40 years, and in many countries, around 50% of individuals are older than 18 years of age. Even though the main cause of death is chronic lung disease, gastroenterological features prominently as 85% of patients have exocrine pancreatic insufficiency (PI), and around 10% suffer from liver disease. The gastroenterological, hepatic, and nutritional aspects of the disease are discussed in this chapter.

Cloned in 1989, the CF transmembrane conductance regulator gene is found on chromosome 7. The CFTR protein has two nucleotide-binding domains, two membrane-spanning domains, and a unique regulatory domain. This protein acts as a cyclic adenosine monophosphate (AMP)-dependent chloride channel and localizes to the apical membrane of secretory and absorptive epithelial cells within the intestine, liver, sweat gland, pancreas, airway, and the vas deferens [1].

An inability of duct lumens to hydrate macromolecules is responsible for a number of CF manifestations. A body of pathologic evidence indicates that organ damage can be traced to ductal or glandular plugging by macromolecules that have precipitated in concentrated secretions. For instance, mucus secretions in the bronchi and the intestine are viscid and inspissated, and the crypts are distended as though

obstructed. A deficit of ductular fluid flow and altered biochemical and physiologic properties of secretions underlie this situation.

The CFTR Gene

There are close to 2000 mutations in the CFTR gene, and they have been divided into six classes [2]. This classification system provides the opportunity to evaluate the effects of genotype on phenotype by considering the effects of CFTR mutations on CFTR protein function. Nevertheless, it should be emphasized that this classification system is limited by the fact that the functional consequences of many rare mutations (particularly missense mutations) are unknown and cannot be predicted.

Class I mutations include mostly nonsense, frameshift, or missense mutations that result in defective protein biosynthesis (truncation, deletion, etc.). The nonfunctional products are efficiently degraded within the cell. Class II mutations, such as F508del, produce a misfolded functional CFTR protein, which is degraded intracellularly preventing trafficking to the apical surface of the cell. Class III mutations affect channel activation by preventing binding and hydrolysis of ATP at one of the two nucleotide-binding domains (NBD1, NBD2). Class IV mutations produce a protein with impaired function due to abnormal anion conduction. Due to a variety of mechanisms including abnormal splicing, promoter mutations, or inefficient trafficking, Class V mutations result in a reduced number of normally functioning CFTR molecules on the apical surface. Class VI mutations result from truncation of the C-terminus of CFTR and produce a functional protein which is unstable at the apical membrane surface. Mutations belonging to classes I–III and VI confer little or no functional CFTR at the apical membrane. As a consequence, inheritance of homozygous or compound heterozygous mutations belonging to these classes are predicted to have severe consequences. Mutations belonging to Classes IV and V on the other hand which confer (or are presumed

to confer) some residual CFTR-mediated channel function would be expected to have milder consequences. In fact, it is patients with at least one mutation belonging to Classes IV or V who generally present with symptoms in late childhood or adulthood.

Animal Models for CF GI Disease

A CF animal model that recapitulates the human findings can provide a powerful tool to study the pathophysiology of disease and design therapies. The first animal model of CF was the mouse model, developed in 1992, 3 years after the CFTR gene was cloned [3, 4]. The porcine [5–10] and ferret models [11–13] were developed recently. The pancreatic, hepatobiliary, and intestinal manifestations of the pig model will be reviewed here.

Pigs

The CF pig model was generated by using homologous recombination. The CFTR gene was disrupted in pig fibroblasts, and somatic cell nuclear transfer was done to generate heterozygous (null or deltaF508). The heterozygous pigs were then crossed to generate the CF pigs [5–8]. CF pigs have multisystem disease that recapitulates the human disease.

Meconium ileus (MI) is present in all CF pigs within the first 24–48 h of life causing intestinal perforation and mortality if untreated surgically. The intestinal pathology in CF pigs is similar to what has been described in human babies with MI (dilated and meconium-filled proximal bowel, a very small-caliber distal bowel, obstruction in distal intestine to proximal colon). Inflammation is insignificant in CF pig intestine unless perforated or necrotic, but most reports are from the neonatal period. Mucus cell hyperplasia is present in small and large intestine at variable levels. A new gut-corrected pig model of CF expresses ~20% of CFTR in the intestine and survives the neonatal period without surgery [14].

From all three animal models, CF pigs exhibit the most severe pancreatic phenotype. The pancreatic lesions start in utero and progress over time in CF pigs, in concordance with the previous autopsy studies of humans with CF [15–17]. The newborn CF pig pancreas has acinar cell loss, duct proliferation, expansion of interlobular connective tissue, and scattered inflammatory cell aggregates [5–10, 14]. Mucous cell metaplasia is a late finding, and some ducts/acini are filled with zymogen-like material. In older animals, the exocrine pancreatic lesions progress, and pancreas is mostly replaced by fat and fibrosis [7, 14]. The islets are morphologically intact [7, 14], but functionally abnormal. As in humans [18–21], the pancreatic fluid is acidic, low in volume, and

high in protein and concentrated in CF pigs at birth [10]. The proinflammatory, complement cascade, proapoptotic, and profibrotic pathways are activated in CF pig pancreas and likely contribute to the destructive process [8, 22].

CF pigs manifest focal biliary cirrhosis, but the lesions are mild and do not progress over time [4, 6, 14]. There is no evidence of cholestasis or fatty infiltration. However, it is not known whether the liver disease would have developed if the pigs lived longer than ~1.5 years. In contrast to mild liver disease, gallbladders are severely diseased in CF pigs. They all have microgallbladder.

Animal models offer a unique opportunity to study the pathogenesis of CF gastrointestinal (GI) disease and various therapeutic approaches.

Diagnosis of CF

The diagnosis is clear if the patient has a sweat chloride concentration >60 mmol/L with at least one recognized phenotypic characteristic which include chronic sinopulmonary disease, salt loss syndromes, and, in males, obstructive azoospermia [23, 24]. The majority of CF patients will have one established CF causing mutation on each CFTR allele. The diagnosis of CF should not be automatically considered if the sweat chloride concentration is >60 mmol/L. There is a list of disorders with high sweat tests which is expanding (Table 41.1).

At the other end of the spectrum, problems arise when there is a CF phenotype in one or more organ systems, and the sweat chloride level is borderline (30–60 mmol/L).

Table 41.1 Conditions other than CF associated with raised sweat electrolyte concentration [25]

Glucose-6-phosphatase
Adrenal insufficiency
Familial hypoparathyroidism
Nephrogenic diabetes insipidus
Mauriac's syndrome
Familial cholestatic syndrome
Anorexia nervosa
Severe malnutrition
Atopic dermatitis
Keratitis-ichthyosis-deafness (KID) syndrome
Fucosidosis
Pseudohypoadosteronism
Patients undergoing prostaglandin infusions
Hyperchlorhidrosis caused by homozygous mutation in CA12, encoding carbonic anhydrase XII. [25]
<i>Accurate references lacking</i>
Glucose-6-phosphate-1-dehydrogenase deficiency
Ectodermal dysplasia
Hypothyroidism

Electrophysiological testing using nasal potential difference (NPD) measurements may aid in the diagnosis of CF patients with normal or borderline sweat tests and negative or uninformative genetic test results [26]. This test measures transepithelial sodium and chloride transport in the nasal epithelium. The function of CFTR in chloride secretion is intimately related to the inwardly directed sodium transport via the epithelial sodium channel (ENaC). The activity of these two channels is the basis for NPD. A catheter is placed under the inferior turbinate and is connected via a series of electrodes to a voltmeter and recorder. The nasal epithelium is perfused with solutions which inhibit sodium transport and activate chloride transport. In CF patients, the readings are markedly dissimilar from controls. Another electrophysiological tool is the intestinal current measurement (ICM) which measures CFTR function *ex vivo* in rectal biopsy using a modified Ussing chamber [27]. Testing should only be carried out by an experienced individual in specialist research center where objective reference values have been established.

CFTR Dysfunction: Gastrointestinal Consequences

Exocrine Pancreatic Abnormalities

Exocrine Pancreatic Function

In pancreatic ductal epithelia, the CFTR protein is highly expressed, allowing fluids and anion to enter the ductal lumen. Thereby, luminal chloride is exchanged for bicarbonate, giving evidence that CFTR is permeable to bicarbonate [28]. According to the Quinton's hypothesis, the defect in bicarbonate transport is indeed the primary defect in CF [29]. This results in an increased volume of alkaline fluid, allowing the acinar cells to remain in a soluble state, due to the highly concentrated proteins secreted. Absent or reduced CFTR channel function impairs chloride and bicarbonate to enter the ducts which results in reduced volume of a more acidic fluid [30]. The acidic milieu within the acinar lumen also leads to impaired reuptake of GP2, the zymogen-granule-associated protein [31]. The consequences of mutations in the CFTR gene have been demonstrated by pancreatic function studies showing that CF patients have low flow secretions with a high protein concentration, presumably which will precipitate in the duct lumina causing obstruction, damage, and atrophy (Fig. 41.1).

These changes begin in utero, and after birth, the process continues with the small duct obstruction leading to a larger duct obstruction. For several months afterwards, there is a release of proteins, originating in the pancreas, into the blood stream. This pathological process forms the basis for the im-

mune reactive trypsinogen (IRT), the neonatal screening test for CF. The reason has yet to be determined, but, interestingly enough, the infant is asymptomatic while this wholesale destruction of the exocrine pancreas is occurring. Eventually, this process results in severe inflammatory changes, obstruction of ducts by mucus and calcium-containing debris, the destruction of acini, and generalized fibrosis. The high IRT does show that some exocrine pancreatic tissue is still present and may have a bearing on possible small molecule therapy targeted at the remainder of the pancreas which may rescue enough tissue to cause viability of the remaining pancreas. This of course contradicts the popular belief that the pancreas is entirely nonfunctioning at birth.

One of the most remarkable observations is that genetic factors exquisitely influence the degree of pancreatic disease and its rate of progression. CF patients are classified as pancreatic insufficient (PI) or pancreatic sufficient (PS). PI patients comprise approximately 85% of all CF patients. PI patients present with maldigestion, as evidenced by steatorrhea (fecal fat greater than 7% of fat intake in infants over 6 months of age and over 15% under 6 months of age), requiring these patients to have pancreatic enzyme replacement therapy (PERT) with meals. PS patients, however, have evidence of pancreatic damage, but retain sufficient endogenous exocrine pancreatic function to sustain normal digestion [33] due to the fact that ductal CFTR in PS patients is partially functional, thereby allowing anions and fluid to enter the ductal lumen. This provides further evidence that mutant CFTR may be acting on other apical anion exchangers to conduct rather than conduct chloride ions itself [34].

The exocrine pancreatic status is directly linked to genotype [35]. Analysis of particular CFTR mutations in patients with pancreatic phenotypes (PI vs. PS) revealed two categories of alleles: "severe" and "mild." Patients homozygous or compound heterozygous for severe alleles belonging to classes I, II, III, or VI confer PI as opposed to patients with a mild class IV or V allele even when the second mutation is severe. These patients are termed "PS." Plausible explanation of this observation finds all known mild alleles belong to class IV or class V all of which are (or predicted to be) associated with some residual chloride channel activity at the epithelial apical membranes. Although these mutations confer sufficient CFTR function to prevent the pancreas to be completely destroyed, many PS patients have reduced exocrine pancreatic capacity and are associated with an increased risk of pancreatitis, as discussed below. A very small number (2–3%) of patients carrying severe mutations on both alleles are PS at diagnosis; however, most patients will experience a gradual transition from PS to PI. A few missense mutations (e.g., G85E) confer a variable pancreatic phenotype.

Many PS patients have reduced exocrine pancreatic capacity and are associated with an increased risk of pancre-

Fig. 41.1 Pathogenesis of pancreatic disease in cystic fibrosis (CF) [32]. Acinar cells secrete large quantities of protein, primarily in the form of digestive enzymes, into the acinar lumen. Under normal circumstances, anions (chloride and bicarbonate) are secreted into the ductal lumen via the cystic fibrosis transmembrane regulator (CFTR) and bicarbonate exchangers. This provides a driving force for the movement of fluid into the lumen of the duct and maintains the solubility of secreted proteins in a dilute, alkaline solution. In CF, impaired

anion transport into the proximal ducts results in decreased secretion of more acidic fluid, which leads to precipitation of secreted proteins. Intraluminal obstruction of the ducts then causes progressive pancreatic damage and atrophy. (Reproduced from Ref. [32], Copyright 2007, with permission from BMJ Publishing Group Ltd) *cAMP* cyclic adenosine monophosphate, *ACh* acetylcholine, *CCK* cholecystokinin, *VIP* vasoactive intestinal peptide

atitis, even though mild mutations confer sufficient CFTR function to prevent the pancreas to be completely destroyed. As first reported by Shwachman in 1975, recurrent acute and chronic pancreatitis are relatively infrequent complications of CF. In this retrospective study, only 0.5% of CF patients had pancreatitis. Durno et al. reported more recently, an incidence of 1.7% in a cohort of over 1000 patients followed over a period of 30 years [36]. All of the pancreatitis patients were classified as PS, but this subgroup of PS patients, in fact, appeared to be highly susceptible to pancreatitis, since almost one in five was affected by this complication. In a seminal paper of the largest study to date of CF PS patients, Ooi et al. determined the association between severity of CFTR genotype and the risk of pancreatitis [37]. They examined a large cohort of 277 PS patients from 2 CF centers of which 62 had well-documented pancreatitis. The mutations were divided into three main groups: severe, moderate-severe, and mild in using a novel pancreatic insufficiency prevalence score. It was found that the proportion of patients who developed pancreatitis was significantly greater for genotypes in the mild group than the moderate-severe group. Thus, the more mild mutations were associated with increased risk of pancreatitis. CFTR mutations may contrib-

ute to the development of pancreatitis along with other genetic and environmental factors [38].

Diagnosis of Pancreatic Phenotype

With the increasing worldwide use of neonatal screening programs, patients may present with symptoms of CF or be entirely asymptomatic. Making a determination in all patients, whether the patient is PI or PS is essential to enable a rational use of oral PERT [39]. When patients have steatorrhea (oil droplets on stool microscopy), hypoalbuminemia, and low fat-soluble vitamin levels, the diagnosis of PI is straightforward. However, the lack of these findings does not exclude PI; therefore, more formal testing is required. In the past, direct exocrine pancreatic stimulation testing was administered. Unfortunately, this was an invasive, time-consuming procedure and not widely used in most centers. Indirect pancreatic testing with 72 h fecal fat measurements should be encouraged and be used as follow up for pancreatic exocrine status and response to therapy. Due to the technical difficulties surrounding the performance of this test, however, most laboratories are utilizing the fecal elastase-1 test instead, as

the main advantage is no need for prolonged stool collection. Pancreatic elastase is secreted into the duodenum and is found at relatively high concentrations in stool ($>500 \mu\text{g/gm}$ stool).

The use of fecal pancreatic elastase-1 has now become a common diagnostic test for assessing exocrine pancreatic status. The advantages and limitations of fecal elastase-1 in CF have been discussed by Kalnins et al. in a review article [40]. The cutoff levels of fecal elastase for PI range between 100 and 200 $\mu\text{g/g}$ stool; a majority of centers use the upper level of 200 $\mu\text{g/g}$ stool. With the use of 200 $\mu\text{g/g}$ stool weight, some patients may be falsely identified as PI. The Toronto group compared stool elastase values to the 72-h fecal fat in both known PI and sufficient patients and found that an elastase value of 100 $\mu\text{g/g}$ stool had a 99% predictive value in ruling out PI based on an abnormal fecal fat. Cade et al. showed that patients with pancreatic sufficiency on the basis of a normal fecal fat balance study were found to have fecal elastase values in the range of 100–200 $\mu\text{g/g}$ stool; elastase levels were compared with the fecal fat test coefficient of fat absorption (CFA) [41]. Whether defining PI as <93 or 90% CFA, cutoff levels of fecal elastase of $<100 \mu\text{g}$ or $<200 \mu\text{g/g}$ stool for either monoclonal or polyclonal methods were positive predictors of insufficient pancreatic function. However, patients with pancreatic sufficiency were not included in this study population. Moreover, these observations question the validity of defining the cutoff for PI as a fecal elastase value below 200 $\mu\text{g/g}$ stool. In a different study of 21 known PS patients, a poor correlation was found between fecal fat excretion and elastase-1 [42]. The fecal elastase result will define clearly whether a patient is PI or sufficient, in a majority of cases, provided the test is done accurately. In situations such as in acute diarrhea, short gut, or stool from an ileostomy, where stool is more watery, fecal elastase levels may be lower than expected; therefore, it would be advisable to wait until the diarrhea resolves, or until a sample that is more formed is available. A definitive answer on pancreatic status may not be provided in those patients with less common genetic variations, where there are no supportive clinical features of PI, and fecal elastase values are often borderline. In such cases, elastase can be used to monitor pancreatic status, in conjunction with ongoing evaluation of clinical and nutritional status [43].

Oral Pancreatic Enzyme Replacement Therapy

Prior to 2010, pancreatic enzyme products were exempt from the Food, Drug, and Cosmetic Act of 1938 and did not require approval of the Food and Drug Administration (FDA). Since then, a plethora of products became available to the public without the need for strict preclinical and clinical studies. The FDA has since mandated that all manufac-

turers of pancreatic enzyme products in the USA must seek approval by April 2010.

Currently, there are six preparations approved and available for use [44–46]: Creon [47–50], Zenpep [51], Pancreaze, Ultresa, Viokace, and Pertzze. During the study on Creon, a fixed dose of 72,000 lipase units with meals and 36,000 with snacks was evaluated. The study was a double-blind, randomized, placebo-controlled trial of 54 adult patients with chronic pancreatitis or post-pancreatic surgery. The treatment arm showed difference in CFA of 19.3% over placebo (85.6 vs. 66.3).

Creon and Zenpep showed a similar nutrient absorption rate between 83 and 87% fat absorption. The dosages of these products are based on the lipase units contained in the product. It is now common for patients to change from one product to another using a 1:1 lipase ratio and then titrating for maximum efficacy. The North American CF Foundation has published guidelines according to the age of the patient and according to the grams of fat ingested per day [52].

The importance of the correct enzyme ingestion in infants and children is a major concern. There is often difficulty in feeding infants capsules or microspheres however small they may be. The continued use of the unprotected powder enzymes for infants until 1 year of age is common in some centers. In infants, these enzymes may have some advantage over the enteric-coated versions in certain situations. The efficacy of unprotected powder enzymes (in tablet or powder form) has not been directly compared to the enteric-coated version in infants, but infants treated with this approach do achieve growth and weight gain, proving their efficacy [53]. In addition to their use for infants, unprotected powder enzymes are often used to help digest enteral tube feedings where oral administration of enzymes is not possible, or when jejunostomy feeds are required.

Breast-feeding mothers should be instructed on proper infant mouth care after enzyme delivery when the unprotected powder enzymes are provided to these infants. It is recommended that soft cotton swabs or a washcloth dipped in sterile water be used to wipe the inside of the infant's mouth and inside the gums. This will prove to be sufficient to prevent gum erosion to the infant and nipple irritation to the mother.

For infants with MI requiring surgery or those with an ileostomy, the powder enzymes may provide the advantage of immediate release in the duodenum. Theoretically, this will improve nutrient digestion compared to the pH sensitive, delayed release enteric-coated microsphere enzyme products. Tablets without a protective coating can be crushed if the powder version in capsules or in bottles is not readily available.

The production of specially designed enzymes for the small child has been a recent advancement. A multicenter cross over study in CF infants who were randomized to receive CfC

(Creon for children) or regular enzyme for 2-week periods was performed; it compared a spoon administration containing 5000 lipase units with the standard Creon 10,000 capsule [54]. The parental preference was the primary end point; over 75% of the parents preferred CfC over the standard preparation.

One study demonstrated that there was no improvement when compared to a standard enzyme preparation [55]; another study showed improvement in fat absorption with the bicarbonate-containing enzyme [56]. However, in both studies, approximately 80% fat absorption was achieved using the bicarbonate-containing enzyme, and Kalnins et al. [55] found the same degree of fat absorption with the conventional enteric-coated enzyme product. Theoretically, the addition of bicarbonate to enteric-coated enzyme preparations might raise the proximal intestinal pH and thereby optimize dissolution of the enteric coating and improve enzyme activity. There were conflicting studies on its efficacy when compared to standard, pH sensitive microsphere enzymes. An enzyme preparation with added bicarbonate had been available in the past, but at time of writing it has not yet received approval by the FDA. Several other enzyme products are in phase 2 or 3 trials. One novel enzyme is lipotamase a non-porcine PERT, containing a biotechnologically derived formulation of crystalline lipase, protease, and amylase [57]. The use of this type of designer drug enzyme has several advantages. The other PERTs are subject to possible viral contamination. In addition, precise dosage standardization had been difficult in the porcine product; the problem of overfill stability has been solved with the new FDA requirements. A preliminary phase 1 study demonstrated good clinical activity, and a multicenter phase 3 study showed that there was significant improvement in the coefficient of fat [56] absorption. A 12-month long-term open-label study [57] of the tolerability and clinical activity in a large number of patients has been published. However, more studies are being carried out on this product. The PERTs currently approved by the FDA have demonstrated efficacy, but new formulations like lipotamase will allow for variety in the type of PERT available.

An important factor for clinicians and families of a CF patient or those with CF to understand and appreciate is that although enzyme therapy for those with PI allows for normal growth and weight gain in most individuals with CF; however, unfortunately, it does not completely correct nutrient malabsorption. There are several reasons for incomplete nutrient digestion with the currently available enzyme products. (1) A proportion of the unprotected powder enzymes or tablets may become inactivated by prolonged exposure to gastric acid. This results in decreased duodenal active enzyme recovery. (2) Enteric-coated microspheres, which dissolve at a pH of >5.5, may only be released in the ileum if duodenal milieu does not reach this pH as occurs in CF. From prior intubation studies, evidence is confirmed that release of enzymes from enteric-coated microspheres is delayed in CF,

and thus, they are delivered beyond the duodenum, even as far distal as the ileum. This results in a nutrient digestion occurring in the more distal small intestine, but not in the duodenum and proximal jejunum as in health. (3) Not only maldigestion but also malabsorption contributes to the insufficient assimilation of nutrients. Fatty acid absorption as well as the digestion of triglycerides is impaired in subjects with CF [58] as suggested by studies done. Other contributing factors to nutrient malabsorption include incomplete lipid solubilization caused by a depleted bile salt pool and thick intestinal mucus. This may affect the unstirred water layer, reducing absorption of fatty acids into the small intestine epithelium. A large center reported <80% fat absorption in approximately 30% of treated patients; therefore, a degree of malabsorption is to be expected for reasons mentioned. Therefore, achieving >90% nutrient digestion as evaluated by 72-h fecal fat studies is not likely to occur in a majority of patients with CF.

Patients should not be automatically encouraged to increase their PERT intake if they experience gastrointestinal symptoms such as abdominal pain, bloating, or loose stools, as there are many other etiologies for these symptoms including compliance. For persistent symptoms, a fat balance study should be performed to titrate dose and proton pump inhibitor (PPI) should be considered. After which, if patient does not experience any improvement, investigations for non-pancreatic disease should be explored (see below). Awareness of these factors by both clinicians and patients will help to guide a rational approach to enzyme therapy in CF; an individualized approach to treatment is recommended.

Hepatobiliary Disease

There are a wide variety of hepatobiliary disorders associated with CF (Table 41.2); almost all patients with CF have evidence of hepatobiliary disease. There are no clinical consequences for the vast majority of patients.

Table 41.2 Hepatobiliary complications of CF

Hepatic	Approximate frequency (%)
Neonatal cholestasis	5
Steatosis	20–60
Focal biliary cirrhosis	11–70
Multilobular cirrhosis	5–7
Liver failure	Rare
<i>Biliary</i>	
Microgallbladder	5–20
Distended gallbladder	3–20
Cholelithiasis and sludge	10–25
Intrahepatic sludge/stones	Unknown
Extrinsic compression of common bile duct	Unknown
Cholangiocarcinoma	Unknown

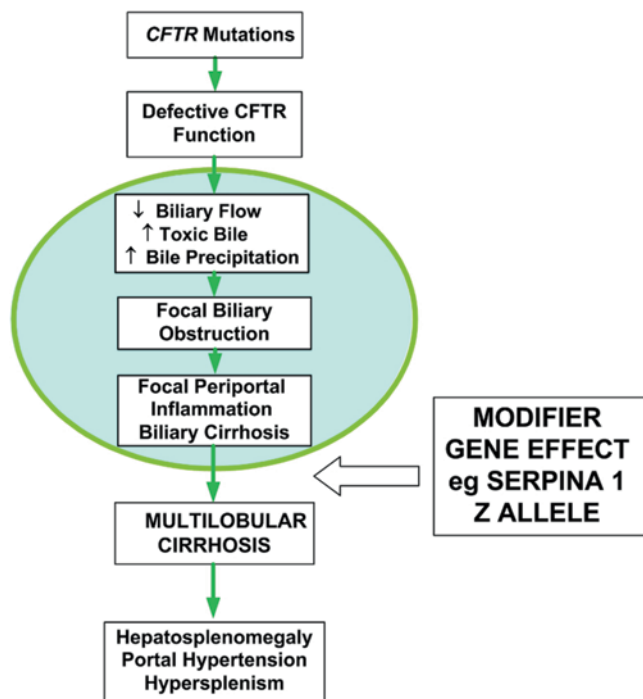

Fig. 41.2 Pathogenesis of cystic fibrosis-related liver disease [32]. Lack of functional CFTR in the biliary ductules causes dehydration, increased concentration, and lack of alkalization of the duct contents. This causes precipitation of biliary secretions and ductular obstruction. In the majority of patients, the pathologic changes are focal and appear to be clinically inconsequential (*circled area*). However, approximately 5–10% of CF patients proceed to develop clinically significant liver disease with evidence of multilobular cirrhosis and portal hypertension. Susceptibility to more severe liver disease may be modulated by other genetic and/or environmental factors. (Reproduced from Ref. [32], Copyright 2007, with permission from BMJ Publishing Group Ltd)

The pathognomonic hepatic feature of CF is focal biliary cirrhosis. Intrahepatic biliary ductal secretion is dependent on CFTR-mediated chloride transport for adequate hydration of the lumen (Fig. 41.2). Loss of CFTR function causes the biliary ductules to become obstructed with thick periodic-acid-Schiff positive material leading to acute and chronic peri-ductal inflammation, bile duct proliferation, and increased fibrosis in scattered portal tracts. Remarkably, adjoining portal tracts are frequently normal. Over 40 years ago, postmortem studies performed show evidence of mild focal disease in 11% of infants, 27% of those dying at 1 year, and in more than 70% of adults. Clinically, significant portal hypertension resulting from severe multilobular cirrhosis develops in only 5–7% of patients. This is termed “CF-associated liver disease” (CFLD). CFLD is the single most important non-pulmonary cause of death, responsible for 2.5% of overall mortality in CF. The average age of diagnosis of CFLD is 10–11 years of age, and 90% are diagnosed before the age of 20 [59]. Following routine examination or by laboratory evidence of hypersplenism, most patients are asymptomatic and

are often identified by the evidence of hepatosplenomegaly. Hepatocellular function remains well preserved for many years, even decades. Splenomegaly is a consistent finding, and the liver edge is often nodular and hard.

About 40–50% of CF patients exhibit intermittent elevations of aspartate aminotransferase (AST), alanine aminotransferase (ALT), or gamma glutamyltransferase (GGT), which are generally 1–2.5 times above the upper reference limits. Biochemical markers of liver disease do not reliably identify patients with multilobular cirrhosis nor do they predict the development of end-stage liver disease. Furthermore, patients with advanced multilobular cirrhosis may have normal liver biochemistry test results. As hyperbilirubinemia is rare, elevated serum gammaglobulin level is more likely to be associated with chronic pulmonary inflammation. CFLD occurs predominantly in PI patients. Thus, severe class I, II, or III mutations on both alleles appear to be a risk factor [60]. A male preponderance of severe CFLD has been shown in most studies.

Why a minority of patients with the same severe CFTR mutations progress to CFLD is unclear. However, it has been hypothesized that non-CF modifier genes, such as polymorphisms in genes that upregulate inflammation, fibrosis, or oxidative stress, confer an increased susceptibility. In a multinational gene modifier study of the different candidate genes, the SERPINA 1 Z allele of alpha-1 antitrypsin deficiency was found to be strongly associated with CFLD. This result is intriguing as the CF patient requires a double-hit to develop CFLD. Hitherto undefined environmental factors are also likely to be involved.

Gallstones develop in 1–10% of patients with CF. There is also an increased incidence of variety of intrahepatic and extrahepatic abnormalities of the biliary tree. Nonfunctioning microgallbladders are common, although it is seen less frequently that patients with CF have distended gallbladders appearing obstructed. Stones may also be commonly visualized within the larger intrahepatic and extrahepatic biliary tree. Debray et al. have proposed using the knockout mouse model that the gallbladder itself, rather than the bile duct epithelia may be the major site for a bile acid shunt, the cholecystohepatic shunt, from the gall bladder back to the liver [61].

The principal cause of CF-associated liver disease remaining controversial; it has been postulated that common duct obstruction resulting from extrinsic compression by fibrosis within the head of the pancreas. Following ERCP or transhepatic cholangiographic imaging, changes resembling primary sclerosing cholangitis (i.e., beading and stricturing of the intrahepatic and extrahepatic ducts) are quite commonly observed [62]. These changes are likely due to accumulation of protein, mucus, or sludge within the biliary lumina.

Diagnosis and Management

Studies are being performed to evaluate early liver disease in CF. Clinical examination is necessary to look for signs of chronic liver disease and organomegaly; routine biochemistry is generally not helpful. The evidence of liver disease is often subclinical until CFLD develops as previously stated. As raised serum liver enzymes in a CF patient may be due to other diseases entirely, it is imperative to consider hepatitis (infectious or autoimmune) Wilson disease and other cause of steatosis (malnutrition, diabetes mellitus) as possible causes when reviewing these patients. A small number of infants may present with neonatal cholestasis, in particular those with MI, usually resolving with no long-term affect [63].

In most centers, ultrasonography of the hepatobiliary system is available, and it includes Doppler measurements of flow in the portal vein; however, the positive predictive value of a normal scan and sensitivity is low. Elastography (Fibroscan R), a new test of liver stiffness (which may be a marker of fibrosis), is used in other chronic liver diseases such as hepatitis C. Early liver disease cannot presently be made on the basis of ultrasound [64].

Recent guidelines by Debray et al. [65] recommend that in order to delay progression of CFLD, ursodeoxycholic acid treatment should be initiated. In a Swedish study, there was evidence that biochemistry is improved in liver histology [66]; however, this treatment and in particular the recommended dose have been challenged after a trial of high-dose ursodeoxycholic acid in another cholestatic liver disease, Primary sclerosing cholangitis, was terminated due to severe side effects [67]; further studies are obviously needed.

Follow up and management of CFLD are the same as for other chronic liver diseases except for (1) the use of beta blockade prophylaxis for variceal bleeding, it needs to be thoroughly examined in CF patients in consultation with the pulmonologists, and (2) selection criteria for liver transplantation have not been established. Apart from the routine indications, there appears to be evidence that earlier liver transplantation, before the development of significant and irreversible nutritional and pulmonary deterioration, may be helpful. However, large, long-term studies have been difficult to perform [68].

Intestinal Complications

Meconium Ileus

Most patients born with MI present within 24–48 h with evidence of intestinal obstruction with abdominal distension, bilious vomiting, and failure to pass meconium. MI occurs in 15–20% of CF patients [69].

Diagnostic aids include a family history of CF and a plain radiograph which may show large distended loops of small bowel and a ground-glass appearance in the right lower quadrant due to inspissated meconium in the ileocecal area.

A diagnostic procedure which may be therapeutic is the performance of a contrast enema. The hypertonic enema may lavage the plug of meconium and provided the infant is stable; this procedure may be repeated several times in order to avoid surgery. Surgery is, of course, necessary for complicated MI.

A small proportion presents with perforation in utero with meconium peritonitis and subsequent intra-abdominal calcification which may only be diagnosed incidentally during third trimester ultrasound examinations. Postnatally, up to 50% of MI patients may have additional problems including malrotation with volvulus or intestinal atresia, termed “complicated MI”.

In a consortium which examined over 3700 cases of MI, several apical transporter genes were found to modify meconium ileu [70], thus appearing that modifier gene(s) together with two severe CFTR alleles confers an increased likelihood of MI. It remains possible that modifier genes with or without environmental factors may explain the variability and severity of other intestinal complications such as distal intestinal obstruction syndrome (DIOS). In a subsequent study, linkage analysis identified a modifier locus for MI on human chromosome 12p13.3 [71].

Distal Intestinal Obstruction Syndrome

Frequently in older children and adults with CF, DIOS a chronic, recurrent form of partial intestinal obstruction occurs. DIOS is frequently confused with other common causes of abdominal pain in patients with CF and almost exclusively in those with PI. Unique to CF, DIOS results from a buildup of adherent, thick intestinal contents in the terminal ileum and proximal colon. The reported frequency is variable, consequently, but a recent study shows a prevalence of 18% in adults [72]. Intestinal inflammation has been shown in the mouse model [73] and is occasionally shown in humans [74]. Patients usually complain of intermittent episodes of pain, which may or may not be localized to the right lower quadrant. Non-tender, or mildly tender, palpable mass can be felt in the right lower quadrant (although it may not always be localized there). Some patients suffer from intractable chronic pain that is difficult to treat, and on rare occasions, there is complete bowel obstruction.

The European Society for Pediatric Gastroenterology Hepatology and Nutrition (ESPGHAN) Cystic Fibrosis and Pancreatic Disease Working Group defines complete DIOS as the combination of (1) complete intestinal obstruction, as

evidenced by bilious vomiting and fluid levels on abdominal radiography with (2) a fecal mass in the ileocecum and (3) abdominal pain and or distension. Incomplete or impending DIOS is defined as (1) a short history of abdominal pain and/or distension (2) a fecal mass in ileocecum but without signs of complete obstruction.

While the exact cause of DIOS is unknown, various precipitating factors have been proposed including abnormal properties of intestinal mucus, dehydration of intraluminal contents, slow intestinal transit, poor compliance with pancreatic enzyme therapy, and a prior history of MI. DIOS should not be confused with simple constipation which is common in CF patients with PI. Although unlike DIOS a right lower quadrant mass is usually not palpable, the rectum will characteristically be full of stool on physical examination, and stooling patterns and consistency are abnormal. Patients undergoing major surgery, such as lung or liver transplant, carry an increased risk of DIOS during the immediate postoperative period.

With other CF-associated or non-CF gastrointestinal disease including appendiceal disease, intussusception, Crohn's disease, fibrosing colonopathy or malignancy, non-specific symptoms and signs may occur; therefore, abdominal ultrasound and CT scans may be necessary.

In complete DIOS, the patient usually requires hospitalization and IV rehydration. Patients with incomplete DIOS respond to oral rehydration combined with mineral oil or polyethylene glycol preparations. Enemas of sodium meglumine diatrizoate (Gastrografin or Telebrix) may be performed by experienced radiologists, but the enema must enter the ileocecal valve to get above the obstruction. Treatment of DIOS is still largely empirical due to few randomized controlled trials. Local instillation of diatrizoate in the cecum via colonoscopy has been described [75]. Surgery is seldom required if early aggressive medical management is performed. Laparoscopy and washout are recommended for consideration before resection. A single episode of DIOS is a risk factor for recurrence; maintenance therapy should be considered along with regular follow up by the gastroenterological service [76].

Appendiceal Disease

The incidence of acute appendicitis in CF is reported to be lower than in the general population. Nevertheless, patients who develop this complication carry a greater risk of a delayed diagnosis and an increased incidence of complications such as appendiceal abscess. The possible factors include luminal obstruction of the appendix with thick mucus, delayed intervention due to mistaken diagnosis of DIOS, or masking of acute symptoms by chronic antibiotic use.

Intussusception

In 1–2% of adult CF patients, intussusception occurs, approximately 10–20 times higher than in the general population. Most cases are ileo-colic, and 25% are associated with small bowel obstruction [77]. Sticky, mucofeculent material which adheres to the intestinal epithelium may act as the lead point in intussusception. Plain abdominal X-rays are often nonspecific, showing fecal loading, or less often a small bowel obstruction. Presentation is usually with intermittent abdominal pain. Classical appearances of intussusception may be seen on barium studies and include a lobulated soft tissue mass and a “coiled spring” usually situated in the right iliac fossa. The “doughnut sign” on transverse scan and “pseudo-kidney” on longitudinal scan are some of the ultrasound examination findings. Intussusception is often intermittent and resolves spontaneously, and it may also be observed in asymptomatic patients as an incidental finding during abdominal imaging [78].

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is a multifactorial problem with contributions from both the severity and treatment of lung disease, physiotherapy, transient inappropriate lower esophageal sphincter relaxation, and delayed gastric emptying. GERD is common in CF patients [79], and there is some evidence that GERD may contribute to the progression of respiratory disease either by pulmonary aspiration of refluxed gastric contents or by neutrally mediated reflex bronchoconstriction secondary to irritation of the esophageal mucosa [80]. This is debatable; however, the GERD may be secondary to the lung disease. Other complications include malnutrition due to increased losses through emesis or reduced energy intake from dysphagia and esophageal strictures. Since silent GERD is common in CF patients, a lack of reported symptoms does not exclude this diagnosis. Bile acids are found in the sputum of children with CF suggesting bile reflux [81]. While esophageal pH or impedance monitoring is helpful, upper endoscopy and biopsy are recommended especially when drug trials have failed in order to define the extent of disease and to rule out other esophageal pathology such as eosinophilic esophagitis.

Fibrosing Colonopathy

A complication of CF involving mainly the colon was reported in young patients with CF in 1994 [82]. The term “fibrosing colonopathy” was coined to describe what became recognized as an iatrogenic complication, resulting in con-

siderable morbidity and some mortality. Many patients were initially diagnosed as having inflammatory bowel disease as their symptoms include worsening abdominal pain, intermittent bowel obstruction, and passage of blood and mucus. The proximal colon developed a concentric ring of fibrosis below the submucosa, but in some patients, the concentric fibrosis extended to the entire colon, producing the shrunken “pipe stem” effect. There is considerable hypertrophy of the muscularis mucosa, and the submucosa shows variable degrees of inflammation with eosinophils and mixed inflammatory cells. In the UK and the USA, case-control studies showed a strong statistical association between this complication and dose of pancreatic enzymes (often in excess of 50,000 U lipase/kg body weight) [52]. This led to a reevaluation of the safety of pancreatic enzymes. Notwithstanding, there was no evidence that excessive doses of enzymes that were used by many clinicians actually improved efficacy or improved abdominal symptoms attributable to maldigestion. Several countries have implemented strict dosing guidelines for PERT. However, a few additional cases of fibrosing colonopathy have been reported in the USA and the UK giving further evidence that “enzyme overdosing” still occurs and also emphasizes the need for close monitoring of enzyme doses in all patients with CF.

Intestinal Infections

The vast majority of patients are asymptomatic, but patients with CF generally demonstrate significantly higher rates of *Clostridium difficile* (32–50%) than the general population (2%), as is the case with healthy neonates. However, on rare occasions severe, potentially fatal cases of pseudomembranous colitis have been reported. Presenting with acute toxic megacolon without diarrhea, the clinical manifestations may be atypical, and absence of diarrhea could be due to lack of intestinal CFTR function. An immunological protection from diarrhea may be due to chronic antibiotic therapy allowing chronic colonization with this pathogen. Alternatively, the unique intestinal environment in CF patients may provide a favorable milieu for this organism. Another hypothesis is due to an abnormality in receptor binding of the toxin, and there is a reduced risk of clinical complications in CF.

CF patients have been reported also to have an increased colonization rate of other bacterial species. This could include *Lactobacillus* spp, *Pseudomonas* spp, *Staphylococcus*, and *Enterococcus*. It has been suggested that CFTR itself acts as a receptor for certain organisms, thereby creating a loss of CFTR affording a form of protection from the consequences of infection. The clinical significance of this is unclear.

In patients with increased diarrhea, abdominal distention, and anorexia, *Giardia lamblia* should be considered as it is

a common intestinal parasite and may be more common in patients with PI from any cause including CF [83].

Small-Intestinal Bacterial Overgrowth

Indirect evidence points to an estimated prevalence up to 50% [84] of CF patients presenting with small-intestinal bacterial overgrowth (SIBO). These risk factors can include abnormal accumulation of surface mucus (which may allow proliferation and adhesion of bacteria), the reduced alkaline flushing of the upper intestine, and the altered intestinal mucins (which may have limited protective functions). Additionally, there is an increased risk of SIBO following intestinal resection due to MI. SIBO may contribute to malabsorption in some patients with CF, although data are limited. The prominent histological feature of the CF mouse small intestine is mucus accumulation, which occludes the crypts and coats the villus surfaces. The mucus obstruction of the crypts is believed to interfere with innate defense mechanisms of the Paneth cells residing at the base of the crypts, secreting a variety of antibacterial products. One may speculate that SIBO of the CF mouse small intestine is similar to that reported in humans [85, 86], as there is evidence of intestinal inflammation characterized by increased mucosal infiltration of mast cells and neutrophils and a 40-fold increase in luminal bacteria, and treatment of the bacterial overgrowth reduces mucus accumulation. CF patients presenting with refractory or unexplained symptoms merit thorough investigation.

Rectal Prolapse

A feature of CF is rectal prolapse, mainly occurring only in PI patients; however, there have been PS patients observed with prolapsed rectums. Children presenting with recurrent rectal prolapse should be referred for a sweat chloride test to exclude CF.

Celiac Disease and Crohn’s Disease in CF

CF was first described as a distinct clinical entity from celiac disease approximately 70 years ago. Reports since then suggest that the prevalence of celiac disease in patients with CF is higher than in the general population; however, definitive studies remain to be done using antibody and HLA testing [87, 88].

The prevalence rate of Crohn’s disease in CF patients is seven times higher than in those reported controls by Lloyd Still et al. [88]. Although there have been many cases reported prior to the description of fibrosing colonopathy, some of them may have been due to the complications of high-dose

enzyme therapy and should be considered in CF patients presenting with suspicious symptoms and signs.

Nutritional Complications

Malnutrition and lung disease are interrelated [83, 89]. Care for CF involves attention to nutritional status to promote the most favorable outcomes. An experienced dietitian in the field of CF would play an essential role in the care of CF patients and should be an integral part of the team.

Nutritional Intake

As an emphasis on a good nutritional diet regime has been to be associated with improved lung function parameters, thus offering parents and patients with CF more motivation to adhere to prescribed therapies such as enzymes, vitamins, and a balanced, high-energy dietary intake [90]. Such studies from the 1980s changed the face of nutritional management of CF and proved that high-fat and high-energy diets were far superior to the old low-fat diet routines. A diet that is composed of 35–40% of calories from fat is recommended in order to meet the energy demands of those with CF.

Thus, this diet regime given to infants from a neonatal screening program has demonstrated that normal growth can be achieved into adolescence. Recommendations by the North American Cystic Fibrosis Foundation Consensus Committee on Nutrition and European Cystic Fibrosis Society include appropriate evaluation of nutritional status at all ages, and a diet that is age appropriate, with sufficient energy to meet needs for normal growth and weight gain [91, 92].

Feeding guidelines for infants with CF recommend breastmilk as the primary source of nutrition for the first year of life [93]. Breast-feeding has been shown to be protective for the infant with CF. Breast-fed CF infants compared to formula had improved lung function with a reduced occurrence of infections during their first 3 years. Breastmilk can provide the complete nutritional support for infants with CF during for the first 4–6 months. It is proven to be more efficient if supplemental energy is added to fortify a portion of the breastmilk feeds with formula or by fortifying formulas to a more concentrated energy level for those infants on a combination of breastmilk and formula or on formula alone. If breast-feeding is not an option or if supplementation is required, regular cow's milk-based infant formulas can be used [53]. In most cases, there is no need for a predigested formula. In warmer climates, sodium supplementation may often be recommended if reported to have a higher degree of loss in sweat [91]. A total of 2–4 mmol/kg supplementation of milk or solids with table salt to provide per day is recom-

mended; however, due to potential for errors in the accuracy of the measurement of the salt, liquid mineral mix solutions prepared by hospital pharmacies are often advised. Breast-milk or formula intake should be supplemented with complementary solids after the first 4–6 months for increased energy. For the exclusively breast-fed infant, meat may be recommended as the first food due to its increased energy content and more importantly for its iron and zinc content. After age one, whole milk is recommended unless breast-milk is continued.

Toddlers and Children

As the dietary intake and degree of physical activity vary with preschool-age toddlers and children, the addition of calorie-rich food is considered important. Self-feeding skills, habits, and food preferences are established at this stage, therefore. Mealtimes should be a positive experience. School activities may conflict limiting snacks and adherence to enzymes; it is recommended that the health-care providers inform parents of appropriate strategies to support compliance with enzyme therapy.

Older children require higher nutrient due to acceleration of their growth; unfortunately, the progression of lung disease may compromise the nutritional status, as it increases the energy demands, interfering with appetite, and resulting in decreased energy intake. If oral intake is not enough to support expected growth or nutritional status, then a more aggressive nutritional intake via enteral tube feeding may be required and is best presented as a positive approach to help improve quality of life and health. However, a thorough evaluation of the nutritional failure must be completed before this type of support is implemented. The following should be considered and addressed as part of the evaluation: Behavioral and emotional issues, compliance, GERD, cystic fibrosis-related diabetes (CFRD), or distal intestinal obstruction syndrome (DIOS). Enteral tube feeding may provide approximately 30–50% of estimated daily energy requirements with appropriate enzyme therapy, generally delivered as overnight feed. The decision varies from individual patients as to when supplemental enteral nutrition is to be commenced. Some centers use intravenous lipids as an adjunct to enteral nutrition particularly in patients with low serum fatty acid concentration [94]. If total parenteral nutrition is used in non-post-surgical situations, weight gain is usually not sustainable once this support ceases.

The importance of the clinical staff being made aware of the overall nutritional status of their patient population allows for more focus on nutritional support. The sharing of these results with patients and families provides for team work and collaboration opportunities.

Fat-Soluble Vitamins

The neonatal diagnosis via screening programs is well documented. In non-screened populations, overt deficiencies are well described including benign intracranial hypertension [95], night blindness [96], rickets [97], hemolytic anemia [98], and coagulopathy due to vitamin A, D, E, and K deficiencies, respectively. Due to ongoing mild to moderate fat malabsorption, fat-soluble vitamin supplements are required for CF PI patients [99]. The European Guidelines are similar to those of North America, with the exception of a higher recommended vitamin A dose (4000–10,000 IU) and a higher starting dose of vitamin E and vitamin K (100 IU and 1 mg) [95, 100]. This discrepancy is due to the lack of controlled studies that aid in defining lower limits of intake that support normal serum levels. For example, those patients who are PS, who do not require pancreatic enzyme supplementation for normal growth, have normal serum vitamin blood levels, and they do not require vitamin supplementation. There is some evidence that supplementation of fat-soluble vitamins in PS patients may be associated with decreased incidence of pulmonary exacerbations possibly due to the antioxidant effect of these compounds [101]. The North American CF Foundation Committee on vitamin D guidelines [102] advise higher supplemental amounts of vitamin D than in the CF vitamin supplements currently available for individuals with suboptimal serum 25-hydroxyvitamin D levels. Therefore, additional vitamin D supplements are recommended, and the annual monitoring of serum vitamin levels for vitamins A, E, and D. Vitamin K may be difficult to monitor as protein induced by vitamin K deficiency (PIVKA) the test used to assess serum levels is not routinely available. However, obtaining serum PIVKA or at least prothrombin levels are advised for those patients with hemoptysis or hematemesis and in patients with liver disease. More studies are needed in order to establish the minimum requirement of vitamin K [103]. The amount of vitamin K in vitamin supplements marketed to CF patients is unlikely to be sufficient. Toxicity of fat-soluble vitamins is very rare in CF; the one exception is post-lung transplantation (see below).

Bone Health

In CF patients, a decrease in bone mineral density (BMD) may begin in early childhood [104]. The nutritional status, calcium, vitamins D and K, pulmonary infection, exercise, glucocorticoids, and class of CFTR mutation are influencing factors of bone health. Poor BMD is a reflection of bone health [105]. Therefore, monitoring of BMD is recommended during routine visits.

Lung Transplant

Patients with CF may present with added nutritional challenges pre- and post-lung transplant. Pretransplant, energy intake is often affected and most likely to be suboptimal, therefore requiring increased nutritional support via enteral tube feeding support [106]. During pre- and post-lung transplantation, reduced BMD is a concern [107]. Posttransplant, patient's appetite usually improves, are usually capable of taking in sufficient energy orally alone, with less and eventually no dependence on enteral tube-feeding support. Posttransplant, it is recommended to leave the enteral tube in place for a period of about 6 months to avoid insufficient oral intake to meet the energy needs and routinely blood monitor the fat-soluble vitamin levels. After transplantation, hypervitaminosis A has been reported, although the etiology of this novel finding is unclear [108]. It may impact drug interactions, altered absorption, increased hepatic synthesis of retinol binding protein, or impaired retinol metabolism. The prescribed amount of vitamin supplements may need to be altered, as vitamin A levels may be elevated in patients with and without CF. Counseling patients that respond well posttransplant regarding lower energy food options is recommended as patients may experience an increased appetite due to the effects of corticosteroids and decreased rate of growth in children. These patients will benefit from an exercise and rehabilitation plan for lung performance and nutritional status [25].

In conclusion, children with CF may have a wide range of gastroenterological manifestations. Gastroenterologists must be involved to improve the quality of life and outcomes of these patients.

Jon A. Vanderhoof and Rosemary Pauley-Hunter

Introduction

The adult human body typically contains at least ten times more microbial cells than human cells because of the high density of microorganisms found in the gastrointestinal (GI) tract [1, 2]. The recent availability of culture-independent molecular methods has significantly changed our understanding of the composition of this GI microbiome. There is tremendous diversity of specific microbial species exceeding 1000 phylotypes, although the fecal microbiome of each individual harbors only about 160 different species. This ecosystem offers protection against pathogens, helps with nutrient processing, and plays a role in many other processes.

The composition of the microbiota differs between different parts of the GI tract. In the stomach and duodenum, there are 10^1 – 10^3 bacteria per gram of liquid with a steady increase to 10^{11} – 10^{12} bacteria per gram of liquid in the colon. The human digestive process has evolved to give the body first priority at the dietary substrates, before the microorganisms. Digestive enzymes from the mouth, stomach acidification, and pancreatic enzymes provide the degradation of the food components for absorption through the small intestine, but most of it occurs in the proximal portion. The microbiota of the small intestine can contribute to the amino acid requirements of the body if they are not provided in the diet itself; however, the microbial biomass in the upper small intestine is so low that it is often not of consequence [3]. Various undigested food components such as fiber, resistant starch, and some lipids are often passed through the small

intestine into the large intestine where they are consumed by microorganisms. It is in the large intestine where the vast majority of our gut flora resides.

During and immediately after parturition, microbes from the mother and surrounding environment colonize the GI tract of the infant. Immediately after vaginal delivery, the microbial populations in the baby closely resemble that of the mother's GI tract, as the vagina normally harbors many of these same organisms [4]. Subsequently, bacteria from other environmental sources including ingested human milk may influence the development of the infant's microbiome. This composition remains relatively constant until shortly before weaning [5]. After weaning, the type and numbers of intestinal flora are greatly influenced by the method and composition of feeding [6]. Early colonization of the infant bowel generally includes lactobacilli and streptococci with successive colonization by anaerobic bacteria, mainly bifidobacteria, bacteroides, clostridia, and eubacteria [7].

There is substantial conflict in the literature regarding the composition of this microenvironment early in life. Some data suggest that breast-fed infants have a much higher composition of bifidobacteria than infants fed with cow milk-based formula; however, the data here are inconsistent. The bulk of available data suggest that biologic mothers are capable of transmitting an initial fecal inoculum of microbiome to their infants during and after birth, but common environmental exposures also shape gut microbiological ecology significantly during subsequent months [8, 9]. After weaning, environmental influences such as cultural/regional variations in diet influence the makeup of the intestinal flora. Differences in fecal microbiota between rural African children who consume high-fiber diets and European children have been identified by DNA sequencing and fecal analysis [10]. 16S ribosomal ribonucleic acid (rRNA) gene sequencing of DNA extracted from duodenal biopsies have also demonstrated differences in intestinal flora in the upper GI tract between children with celiac disease and normal children [11].

In healthy infants, the composition is thought to be relatively unstable until 2–3 years of age at which time it begins

to resemble that of the adult [9, 12] with virtually no coliform bacteria present in the small intestine. Gram-positive bacteria predominate with rare anaerobes present in the upper GI tract. Typical gram-positive bacteria such as *Streptococcus*, *Lactobacillus*, *Prevotella*, *Neisseria*, and *Enterococcus* are often identified by typical culture methods in the stomach and duodenum. In the distal ileum, there is an increase in the numbers of overall bacteria, with a predominance of enterococci and lactobacilli being present in higher numbers than in the jejunum [13]. Once past the ileocecal valve, anaerobic bacteria predominate with Firmicutes including lactobacillus, bacteroidetes, and ac-

tinobacteria including bifidobacteria numbering from 10^{11} to 10^{12} per gram of intestinal liquid. See Fig. 42.1.

Definition

Quantifiable definitions of small bowel bacterial overgrowth (SBBO) have been proposed with the definition being based on increased numbers of bacteria in addition to specific types of bacteria, generally coliform bacteria. Proposed numbers of bacteria range from greater than 10^3 – 10^5 colony-forming

Fig. 42.1 Normal intestinal flora. CFU colony-forming unit. (Adapted with permission from Ref. [14])

* Bacteria are not listed in quantitative order.

units of bacteria per milliliter of luminal fluid of colonic-type bacteria present in the proximal bowel. There are however many GI conditions and symptoms which have been reported at lower levels of bacteria [15, 16]. Previous culture techniques have not identified the true diversity of the intestinal contents that are now being discovered with current molecular DNA processes. Therefore, basing the definition on types of bacteria may not be completely accurate. In a more pathophysiological view, a definition of bacterial overgrowth should include not only the numbers and types of microorganisms present but also evidence that these two factors create pathological signs or symptoms.

Prevalence and Associated Conditions

The true prevalence of bacterial overgrowth is not known due to the lack of a uniform definition and imprecise diagnostic testing. Studies in the general population are lacking, and in those GI symptoms the likelihood is that prevalence would be overestimated if based on noninvasive methods such as breath testing. Estimates have ranged from 0 to 20% of the general population who have SBBO when based on the actual numbers of bacteria [17]. SBBO may exist with greater prevalence in certain acquired conditions, for example, it occurs with intestinal dilatation in patients with short bowel syndrome (SBS). The prevalence of bacterial overgrowth due to unusual intestinal colonization during the first year of life, however, is likely much lower.

Other factors predisposing to SBBO include achlorhydria and old age. Drug-induced hypochlorhydria may result in higher bacterial duodenal counts, especially in the elderly following long-term use [18]. In both adults and children, acid suppression may contribute to the presence of bacterial overgrowth [19–21] although this finding is not consistently seen and may be dependent upon the diagnostic method [22]. It has been estimated that proton pump inhibitors can increase the gastric pH to the point of significantly increasing the colonization of the stomach with gram-positive bacteria and potentially increasing colonization with *Helicobacter pylori* if present [23]. Diabetics more commonly have overgrowth, especially in adulthood [24]. Chronically immunosuppressed patients or patients with HIV may also have an increased incidence of SBBO [25]. Bacterial overgrowth has been reported in children with immunoglobulin A (IgA) deficiency [16, 26]. Patients with small bowel inflammatory diseases such as celiac disease may also have elevated bacterial counts as may patients with pancreatic insufficiency [27, 28]. Autoimmune diseases including scleroderma and rheumatoid arthritis have been associated with increased overgrowth [29].

A primary association with SBBO is a failure of small-bowel clearance due to various motility disorders. Patients

Table 42.1 Conditions associated with bacterial overgrowth

<i>Surgical</i>
Short bowel syndrome
Truncal vagotomy
Gastrectomy
Roux-en-Y
<i>Luminal gastrointestinal and related organ diseases</i>
Celiac disease
Crohn's disease/ulcerative colitis
Radiation enteritis
Pancreatitis
Liver/renal failure
Irritable bowel syndrome
Atrophic gastritis
<i>Neuromuscular</i>
Diabetes mellitus
Connective tissue diseases
Parkinson's disease
Pseudo-obstruction
<i>Miscellaneous</i>
Chronic fatigue syndrome
Medications such as proton pump inhibitors or tricyclic antidepressants
Rosacea
Chronic immunodeficiency states
Obesity
Rheumatoid arthritis

with pseudo-obstruction syndrome, muscular dystrophy, diabetic neuropathy, and other disorders affecting gut motility typically experience symptoms due to increased small bowel bacterial counts particularly with coliform bacteria [15, 24]. Likewise, stricture formation with chronic dilatation is usually associated with overgrowth. This may be seen in Crohn's disease, radiation enteritis, or children with congenital anomalies such as intestinal atresia who have postoperative strictures with some degree of dysmotility [30, 31].

Patients with SBS are characteristically troubled with bacterial overgrowth in the small intestine. Here, the reasons are multifactorial. Patients with SBS often have compensatory dilatation of the small intestine with poor motility. As peristalsis normally rids the small bowel of excessive bacteria, small-bowel dilatation with its associated impairment of normal antegrade peristalsis is a perfect setup for overgrowth. The presence of postoperative strictures may also play a role. Finally, the absence of the ileocecal valve, which functions to prevent reflux of colonic bacteria into the small intestine, further exacerbates the problem. Because of poor gastric emptying and reflux, patients with SBS are also frequently on chronic acid suppression which in many situations promote overgrowth [19, 32]. Table 42.1 lists commonly associated conditions which have been attributed to bacterial overgrowth.

Table 42.2 Symptoms of bacterial overgrowth

Acute	Chronic
Bloating	Vitamin A deficiency: xerophthalmia, night blindness, xerosis of the conjunctiva manifested as Bitot's spots, and follicular hyperkeratosis
Flatulence	Diarrhea → Steatorrhea
Abdominal pain	B12 deficiency: neuropathy with paresthesias and central ataxia
Anorexia	Hypocalcemia with perioral numbness, paresthesias of the hands and feet, and muscle cramps
Vitamin D deficiency → metabolic bone disease	Rosacea
Failure to thrive	Edema due to protein-losing enteropathy

Physiology and Pathophysiology

In the stomach, gastric acidity and normal emptying tend to limit microbial growth. Once in the duodenum, the bile salts provide an unfavorable environment for microorganism proliferation. A prominent gut immunoglobulin, IgA typically can recognize and bind with microbes preventing mucosal penetration, it enhances clearance via peristalsis [33] and may have a more specific role in managing the overall amount and types of microbes in the upper small intestine [34]. The body's natural production of antimicrobial compounds such as defensins has varying abilities to limit or alter the intestinal milieu. The large intestine has a much more favorable environment for microorganisms due to its higher pH, lower level of bile salts, and slower peristalsis. The substantially higher numbers of microbes in the large intestine provide short-chain fatty acids through the fermentation of any dietary components that are not utilized in the small intestine. These short-chain fatty acids, particularly butyrate, provide the primary fuel for the enterocytes in the large intestine. There are small numbers of protozoans and fungi also present in the large intestine [34]. Predominant bacterial populations also act as hosts to a variety of viruses which have an unidentified role in intestinal function [35].

Signs and Symptoms

The clinical manifestations of bacterial overgrowth are quite variable because validated symptom questionnaires do not exist. Symptoms range from very mild to severe. Most commonly, patients experience diarrhea, bloating, and abdominal pain as predominate features. Recently, it has been hypothesized that bacterial overgrowth may mimic the symptoms of irritable bowel syndrome [36, 37]. In these instances, abdominal distention, increased flatus, diarrhea, and even fecal urgency have responded to antibiotic therapy [38–40]. More severe symptoms consistent with malabsorption syndrome, such as weight loss, dehydration, and nutrient deficiencies, have also been reported. See Table 42.2.

Small-bowel bacterial overgrowth is associated with a combination of megaloblastic anemia due to vitamin B12 deficiency and fat-soluble vitamin deficiency due to fat malabsorption [15, 41]. Anaerobic bacteria use vitamin B12 to produce inactive compounds which may compete with vitamin B12 for ileal binding sites, decreasing absorption of the vitamin. Other vitamin deficiencies including thiamine have also been associated with SBBO [42]. Fat-soluble vitamin deficiencies including vitamins A, E, and D are commonly reported. These deficiencies are manifested in night blindness and osteopenia or osteoporosis as evidenced by decreased bone mineral density exist [43, 44]. Vitamin K deficiency is infrequent because of increased luminal production of vitamin K by bacteria. Deconjugation of bile salts by increased intestinal bacteria impairs bile acid reabsorption depleting the bile acid pool and decreasing the intraluminal conjugated bile acids further exacerbating fat and fat-soluble vitamin malabsorption. Bile acids are typically absorbed in the jejunum; however, if they reach that ileum and colon, they may also damage the intestinal mucosa leading to increased diarrhea and malabsorption [45].

Intestinal bacteria may deaminate dietary protein that is malabsorbed and create a situation in which dietary nitrogen is converted to urea and is unavailable for absorption [46]. Low levels of enterokinase may impair activation of pancreatic proteases and thereby reduce protein absorption [47]. Carbohydrate degradation by intestinal bacteria also increases malabsorption, and these malabsorbed carbohydrate by-products significantly contribute to the symptomatology of bloating, cramps, and diarrhea [48]. Neurological symptoms including central or peripheral neuropathy and symptoms of anemia including fatigue may predominate the clinical picture. There is some evidence to suggest that SBBO may be a contributory factor in nonalcoholic steatohepatitis (NASH) [49]. Endogenous ethanol production has also been reported with bacterial overgrowth in association with overgrowth of *Candida albicans* and *Saccharomyces cerevisiae* [50].

In children, abdominal pain, bloating, and diarrhea are more typical symptoms, especially when an underlying disorder is present. Anemia and evidence of gut inflammation including occult-blood-positive stools, and elevated fecal calprotectin levels may be seen in both adults and children

[51, 52]. Systemic inflammatory changes including arthritis may occur. Poor weight gain and decreased appetite are not uncommon. In children, D-lactic acidosis may be a clinical presentation of SBBO [53]. Patients with this disorder develop higher levels of the lactate in the blood because some bacteria produce both D and L stereoisomers of lactate, but only the L form is metabolized well by the human liver. D-lactate accumulates in the blood stream resulting in a variety of neurological symptoms varying from poor school performance to coma. Elevated levels of serum D-lactate and rapid response to oral antibiotic therapy confirm the diagnosis. This disorder appears to be quite uncommon in adults.

Histologically, overgrowth is not uncommonly associated with inflammatory changes in the mucosa [54]. Consequently, reduced brush border disaccharidase levels may result in carbohydrate malabsorption, especially lactose malabsorption. Impaired protein absorption and protein-losing enteropathy may also result. A number of changes in the mucosa have been demonstrated not only by light microscopy but also by electron microscopy, which have identified numerous enterocyte abnormalities including microvillus injury [55].

Diagnosis

The diagnosis of SBBO should be considered in patients with any of the symptoms and findings discussed above particularly when associated with an underlying disease process predisposing the patient to overgrowth. Small-bowel imaging may be helpful in the diagnosis of bacterial overgrowth by identifying areas of bowel dilatation and/or stricture formation which may be the causative factors. This is particularly indicated in conditions where there is a history of intestinal resection.

Aspiration of small intestinal fluid contents for quantitative culture was previously considered the gold standard for diagnosis [17, 56]. Normal values may vary significantly based upon the anatomic location of small bowel aspirate as well as the geographic location of the patient. Tropical patients may have normal values as high as 10^7 microorganisms per milliliter of fluid, whereas 10^4 may be normal in more temperate regions. Even within the same GI disease, such as ulcerative colitis, the intestinal bacteria differ depending on the geographic location of the patient [57].

Aspiration of duodenal versus jejunal fluid will result in different types and species of bacteria. Aspirates from above and below a stricture may also differ. Care must be taken to avoid contamination of the sample with oropharyngeal bacteria, and a number of different techniques have been described [58]. Likewise, appropriate handling of the specimen is very important. Culture of anaerobic bacteria is challenging. Prior to collecting the sample, it is a good idea to have a discussion with the culturing laboratory to make sure the

specimen is handled appropriately. Regardless of the culturing techniques, it is estimated that a great majority of the intestinal microbiota is missed as compared with genomic or DNA sequence-based methods [34].

Significant inflammatory changes may be seen both endoscopically and histologically in patients with severe overgrowth. Occasionally, such changes may be difficult to differentiate from Crohn's disease unless granulomas are present. A typical example of such changes is pouchitis seen after resection for ulcerative colitis. Diffuse nonspecific inflammatory changes occasionally with ulceration can be visualized. Patients with SBS and significant bowel dilatation with poor motility will commonly have similar findings when overgrowth is present. Unfortunately, the chronic inflammatory changes seen histologically are nonspecific, and their use for diagnostic purposes must be considered in clinical context and with other associated laboratory findings.

A number of tests have been devised to predict SBBO noninvasively. Perhaps the most widely used due to the ease and lack of expense is breath hydrogen testing using either glucose or lactulose. These tests are based on the premise that small-bowel bacteria will metabolize the ingested carbohydrate into carbon dioxide and hydrogen or methane gas. Glucose is rapidly and completely absorbed in the small intestine; therefore, an early rise fasting breath hydrogen levels of more than 20 ppm above baseline following an oral load of glucose is considered consistent with the diagnosis of bacterial overgrowth [17, 56]. Glucose is an ideal substrate because it is rapidly absorbed in the small bowel and consequently is not subject to bacterial metabolism in the colon. It is less predictive of ileal bacterial overgrowth for this reason, and likewise can be falsely elevated in patients with SBS who have an extremely short bowel or rapid transit. Patients with chronic overgrowth may have elevated fasting breath hydrogen levels. Lactulose is primarily metabolized in the colon, typically 90 min after ingestion; however, in bacterial overgrowth, there will be an early peak of hydrogen production followed by a later peak when it reaches the colon.

If overgrowth is not associated with large numbers of hydrogen-producing organisms, the breath hydrogen test may not be valid. ^{14}C -xylose- and ^{13}C -xylose-labeled breath tests have also been utilized but are less commonly available. It has been estimated that approximately 10–20% of humans do not have detectable hydrogen production from their GI flora. Some bacteria such as enterococci, *Staphylococcus aureus*, and *Pseudomonas* do not produce hydrogen when metabolized but do produce methane gas [59]. A combination of breath hydrogen and breath methane testing may offer considerable improvement in the diagnosis of bacterial overgrowth [60].

Other screening tests such as serum D-lactate levels may occasionally be helpful if they are elevated. However, care must be taken to make certain that the blood test is ordered

correctly and the laboratory knows exactly what is desired, that is, doing a D-lactate level and not a lactic acid. Urine indican is an indicator of the intestinal overgrowth of anaerobic bacteria. Indican is an indole produced when bacteria in the intestine act on tryptophan. Most indoles are excreted in the feces. The remainder are absorbed, metabolized by the liver, and excreted in the urine. Consequently, excessive bacterial activity on protein in the small bowel will result in excessive indican excretion in the urine.

An empiric trial of antibiotics in patients with symptoms suggestive of bacterial overgrowth may be used diagnostically. Measurement of symptom response of course is hindered by a lack of a validated assessment tool as previously mentioned. However, given the lack of standardized diagnostic testing, short courses of broad-spectrum antibiotics may be the simplest and least expensive method to establish a diagnosis. Future diagnostic testing may include metabolic profiling of the metabolome, the use of electronic nose, and/or field asymmetric ion mobility spectrometry which detects volatile organic compounds from intestinal gases [17].

Treatment

If there is an identifiable structural or functional condition amenable to surgical treatment, then that should be corrected as the first option. Procedures to correct strictures or areas of small bowel dilatation are usually amenable to either endoscopic or surgical revision. Serial transverse tapering enteroplasty is a procedure which lengthens the dilated bowel by stapling it in a zigzag pattern and is particularly efficacious in children whose intestine dilates in the process of adaptation after a major resection [61, 62]. This procedure may add additional more functional intestinal surface as well. Motility disorders may be amenable to therapy with pro-motility agent such as an erythromycin, metoclopramide, cisapride, or domperidone.

Medical treatment of SBBO typically starts with antibiotic therapy [63]. A variety of strategies may be employed. Accurately obtained cultures may reveal a dominant organism and specific sensitivities may be helpful. However, due to the limitations of qualitative and quantitative sampling, empiric trials are typically used to direct therapy. Antibiotic choice generally involves therapy directed at both aerobic and anaerobic organisms. There is no agreement on a standard dosage or duration of treatment. Antibiotics may be given the first 5–7 days of each month, continued for 1 week every other week, or given continuously and rotated depending upon the clinical situation. It is important to remember that the intention is not to sterilize the gut, but simply reduce the enteric population enough to alleviate the symptoms and clear up any inflammatory process. Antibiotic therapy should be individualized and consideration should be given to the high prevalence of the development of bacterial resistance,

Table 42.3 Antibiotic protocols for bacterial overgrowth

Drug	Dose	Considerations
Rifaximin [62]	Adults 1650 mg/day Children 600 mg/day	Nonabsorbable High cost
Amoxicillin–clavulanate [63]	30 mg/kg/day	
Metronidazole [64]	20 mg/kg/day	Peripheral neuropathy
Metronidazole [65–67]	20 mg/kg/day +	Need to check
a. Cephalosporin or cephalexin	30 mg/kg/day	random blood
or	or	gentamicin levels
b. Trimethoprim–sulfamethoxazole	10–12 mg/kg/day	
or	or	
c. Gentamicin (orally)	10 mg/kg/day	
Norfloxacin [63]	Adults 800 mg/day	
Ciprofloxacin [68, 69]	Adults 35–50 mg/kg/day	

the cost of treatment, and potential side effects from long-term usage. A list of antibiotics is shown in the Table 42.3.

When antibiotics fail, a number of strategies can be employed. The first and perhaps most useful is to reduce the carbohydrate intake in the diet [67]. Carbohydrates facilitate SBBO, and replacing them with fat may reduce bacterial populations enough to alleviate the symptoms in many patients. Abdominal bloating and distention may be decreased by removing nonabsorbable sugars, such as sorbitol, and reducing lactose intake may also be helpful. Probiotic therapy has been proposed as one potential treatment option for bacterial overgrowth [17, 70]. A few small pilot studies have demonstrated some suggested benefit; however, there is a lack of a double-blind, randomized, placebo-controlled trials in this setting. Nondigestible fibers, prebiotics, and probiotics may in fact exacerbate SBBO due to their propensity to contribute to gas and bloating.

Medications which delay transit or reduced gut motility such as loperamide may also exacerbate overgrowth and should be discontinued. Acid suppression should be utilized only in cases of medical necessity [71]. In cases of significant inflammation in the mucosa which may occur secondary to bacterial overgrowth, and when initial treatments with antibiotics or diet have not been successful, a trial of anti-inflammatory medications might be considered [67]. 5-aminosalicylate (5-ASA) preparations are usually tried first but if these are unsuccessful, a 2-week trial of corticosteroid therapy may be beneficial [68].

Summary

Small intestinal bacterial overgrowth may result from functional or anatomical alterations in the GI tract. The definition should incorporate both a combination of quantitative

measures of the type and number of bacteria in the presence of symptoms directly attributable to the overgrowth. Current diagnostic techniques have rather poor sensitivity and questionable specificity. As the study of the human intestinal microbiota is advancing, the ability to accurately identify microorganisms and their role in small intestinal function should become clearer. Further studies are needed with better defined end points to more clearly determine ideal treatments for SBBO.

Introduction

Short-bowel syndrome (SBS), like many chronic intestinal disorders, often creates a long-term clinical challenge for a group of health-care practitioners including pediatric gastroenterologists, pediatric surgeons, nutritionists, nurses, and other support personnel. The recent development of multidisciplinary clinics in larger children's hospitals has been very successful in improving the long-term survivability of these patients and significantly reduced the number of complications. Although intestinal transplantation is often integrated into these programs, careful attention to detail in the management of the patient has markedly reduced the need for transplantation. This chapter focuses on a description of the disorder and the various integrated steps of medical and surgical management which often leads to long-term viability and a good quality of life for the infant and/or child with SBS.

Definition

SBS by definition is malabsorption following resection of a significant portion of the small intestine. The actual amount of intestine which may be removed to create a malabsorptive state is highly variable which is why the definition is more of a functional one rather than anatomic. In adults, the normal length of the small intestine is approximately 480, and 50 cm of remaining small intestine is often considered essen-

tial for survival, although this figure is highly variable [1]. In infants, the normal length of the small intestine is approximately 125 cm at the start of the third trimester of gestation and 250 cm at term [2]. Infants with residual small intestine length of less than 75 cm may be at risk for developing SBS however seem to have a greater capacity for adaptation and therefore may be independent of total parenteral nutrition (TPN) with less than 50 cm of remaining small intestine. See Fig. 43.1 for review of normal intestinal absorptive characteristics [3].

A number of variables are important here. For example, areas in the small bowel have inherent adaptability characteristics. The jejunum is responsible for most macronutrient absorption with its long villi, large absorptive surface, highly concentrated digestive enzymes, and many transport carrier proteins. Thus, when the jejunum is resected, a temporary reduction in absorption of most nutrients occurs. The jejunum exhibits modest adaptive changes in response to intestinal resection, and most of these changes are functional with changes in transport and enzyme activity rather than structural or surface absorptive enhancement.

The ileum is the dedicated site of adsorption of vitamin B12 and bile acids, and the capacity of the remaining small intestine to handle these functions is very limited. The ileum is much more adept at water absorption because epithelial junctions in the ileum are tighter/smaller and therefore less permeable to nutrients. This area typically is the site of significant fluid reabsorption as it is subjected to large volumes of water flux in response to osmotic loads delivered from the jejunum. A resection of a significant portion of ileum is often less well tolerated than jejunal resection because patients have a great deal of difficulty with water reabsorption in other areas of the bowel despite the fact that they have been quite capable of handling the macronutrient load. The ileocecal valve is an important barrier to reflux of colonic bacteria and helps regulate the passage of fluid and nutrients from the ileum into the colon (ileal brake).

The colon has an important role in absorption of water, electrolytes, and short-chain fatty acids. Loss of the colon in

Intestinal sites of nutrient absorption

combination with extensive small-bowel resection is poorly tolerated and often leads to dehydration and electrolyte depletion. The colon slows intestinal transit and can absorb a significant percentage of calories, primarily in the form of fermented carbohydrates. The retained colon may adapt after small-bowel resection, with gradual increases in colonocytes and in gut hormone secretion [4].

Another significant factor affecting long-term prognosis in SBS is the process of intestinal proliferation. Following small-bowel resection, the remaining bowel has a rather marked ability to adapt [1, 5]. Lengthening of the villi, and to some degree dilatation of the small-bowel lumen, may result in up to a fourfold increase in mucosal surface area following massive resection. This process has been extensively studied in animal models, and a number of trophic

factors have been identified as having a role in regulating this process [6]. The most recently described compound is glucagon-like peptide-2 (GLP2) [7]. Other factors including enteroglucagon, growth hormone, and peptide YY may also be involved. Most importantly, these trophic factors are heavily dependent upon the presence of enteral nutrition in order to stimulate the adaptation process. The ability of the ileum, normally more trophic than the jejunum, is significantly greater than other parts of the small bowel. SBS in adults usually results from surgical resection for Crohn's disease, malignancy, radiation, or vascular insufficiency. In infants and small children, necrotizing enterocolitis and congenital intestinal anomalies such as atresias or gastroschisis are the most common causes of SBS. Unfortunately, many of the common causes of SBS namely congenital anomalies,

Table 43.1 Common causes of short-bowel syndrome

necrotizing enterocolitis, and Crohn's disease often result in resection of the ileum (see Table 43.1).

Intestinal failure can result from SBS and is defined as a reduction of a critical amount of functional gut mass below the amount needed for adequate digestion and absorption of nutrients and fluid needs or from a poorly functioning absorptive surface secondary to structural abnormalities or chronic inflammation [1]. It is often characterized by macro- and micronutrient malabsorption, electrolyte imbalance with tendency to dehydration, intestinal bacterial overgrowth and poor growth in children, and weight loss in adults [8]. In addition to SBS, diseases or congenital defects that cause severe malabsorption, bowel obstruction, and dysmotility (e.g., pseudo-obstruction) are also causes of intestinal failure. It is intestinal failure, not SBS itself, which leads to intestinal transplantation.

Management

Parenteral Nutrition

The first stage of management and SBS primarily focuses on TPN and managing fluid and electrolyte complications. Parenteral nutrition here differs very little from any disorder necessitating parenteral feeding. Baseline nutrient and energy needs must be met in a standard fashion. In children with SBS, fluid and electrolytes are often a challenge in the immediate postoperative period. Ongoing losses of fluid and substantial quantities of electrolytes are quite variable and highly dependent upon location of any ostomies in addition to losses from nasogastric, gastric, or naso-duodenal tubes. Gastric losses include significant volumes of hydrochloric acid and large quantities of potassium and sodium chloride which can affect acid-base balance as well as electrolyte losses. This hypersecretion of gastric acid and fluids may reduce pH below the optimal level needed for efficient fat absorption by inactivating pancreatic lipase and deconjugating

bile salts requiring use of acid suppression. The gastric hypersecretion typically resolves in the first few months after surgery and is not required indefinitely. In fact, ongoing use, as in those without SBS, may be associated with increased risk of viral infections [9, 10].

Small bowel fluid losses contain much higher concentrations of sodium often approaching that of normal saline. Measurement of these ongoing losses and replacement with a solution separate from the TPN milliliter for milliliter are usually much simpler and preferable to constant reformulation of parenteral nutrition solution. Once ongoing losses stabilize, these volumes can be more easily incorporated into parenteral nutrition solution if desired.

The resting energy expenditure in infants with SBS is similar to healthy controls. However, because of malabsorption, the amount of energy needed will be greater (estimates of 30–70% greater) than that needed parenterally to achieve similar weight gain [11, 12]. In general, growth is monitored by assessing whether increases in weight are proportional to linear growth. Factors such as genetics should also be factored into expectations for growth. Moreover, proportional growth does not necessarily avoid stunting, which appears to be common among children with SBS.

Patients on TPN should initially be monitored daily with electrolytes, blood urea nitrogen (BUN), creatinine, phosphorus, magnesium, albumin, triglycerides, and glucose then weekly until stable and with any subsequent change in TPN formulation or volume. Total and direct bilirubin and aminotransferases (aspartate aminotransferase, AST, and alanine transaminase, ALT) also should be measured regularly to monitor for parenteral-nutrition-associated liver disease. Monitoring of vitamin levels is not essential at this time but becomes of greater importance as the patient becomes solely dependent on enteral nutrition.

Enteral Nutrition

Once gastrointestinal motility resumes and the postoperative ileus has resolved, enteral nutrition can be judiciously initiated. Early initiation of enteral feeding is important for a number of reasons. Enteral nutrition has been shown to strengthen the mucosal barrier and reduce the risk of translocation of bacteria [13]. In addition, the adaptation process which is crucial to long-term survival without parenteral nutrition or at least with minimal parenteral nutrition does not occur in the absence of enteral feeding. Aggressive use of enteral feeding, especially early in the course of treatment, significantly enhances the adaptation process [14]. Much work has been done to understand the role of enteral nutrition, and we do know that certain nutrients appear to be more important than others. Long-chain fats, especially three omega fatty acids, at least eicosapentaenoic acid, appear to

be very important in this process [15]. Consequently, making sure a significant portion of enteral feeding is in the formal long-chain fats is advantageous. More important, however, is the use of aggressive enteral nutrition as early as possible after resection.

Enteral Formula

Selection of the appropriate enteral feeding solution is dependent upon a number of factors. In small infants, hydrolyzed or elemental formulations are commonly utilized. There are substantial data however suggesting that human milk may provide an excellent alternative [16]. Human milk, especially when fresh, contains a number of trophic factors not commonly present in predigested formula. Predigested formulas are commonly used because the nutrients provided are in a form ready for absorption. This avoids wasting part of the absorptive surface while digestion is occurring. Although osmolality is often utilized as a reason to avoid predigested formulas, this is really an issue only when continuous enteral infusion is not being employed. Hyperosmolar formulas of any type when administered via a slow continuous tube feeding are well tolerated. If used, elemental formulas should contain at least 40% of their calories as fat. Some data suggest that more complex formulations may be advantageous for adaptation, due to a greater functional workload demanded from the small-bowel epithelium [16, 17]. In practicality, most clinicians avoid whole protein formulas, as there is an increased risk of non-IgE allergic injury from an intact proteins especially true during the first 2 years of life [17, 18].

The use of medium-chain triglycerides is comparably controversial. While medium-chain triglycerides are better absorbed especially when the supply of pancreatic enzymes or bile acids are limited, they are also less trophic to the small bowel. Medium chain fats also have a lower energy density and exert a greater osmotic load on the epithelium than long chain fats. The optimal ratio between long- and medium-chain fats has not yet been identified, but a majority of the fat delivered early in the course of enteral feeding should probably be supplied in the form of long-chain fats. Pancreatic insufficiency is rarely a problem in these patients, and bile acid deficiency is usually only an issue in infants with liver disease or massive ileal resection.

The ratio of calories provided between fat and carbohydrate is also arguable. The coefficient of absorption of carbohydrate is better, but the caloric density of fat is much higher. Carbohydrate is the preferred nutritional substrate for bacteria and favors the development of small-bowel bacterial overgrowth, another major complication of SBS. Formulations higher in fat and lower in carbohydrate work better in infants with SBS when the risk of injury from small-bowel

bacterial overgrowth is potentially higher [19]. In adults, or older children, colonic salvage of short-chain fatty acids and reduced by bacterial metabolism from malabsorbed carbohydrate is much better which is probably why older children and adults do somewhat better than small infants with a higher proportion of carbohydrate in their enteral feeding. Lactose restriction is not required as most is absorbed in the proximal bowel which is often preserved in many cases of pediatric SBS.

Fiber supplementation may be beneficial not only in absorbing some of the water losses but also provide an additional energy source in patients with a retained colon. In older children, significant malabsorption of fat may lead to oxalate absorption due to the loss of calcium and subsequent development of hyperoxaluria and the formation of kidney stones.

Feeding Techniques

Once initiated, enteral feedings are gradually increased as tolerated. Feeding 24 h a day will optimize absorption through continuous use of the available gut mucosa. The rate of infusion can be gradually increased based on tolerance. Ostomy output in excess of 30–50 mL/kg per day is usually a contraindication to advancing feedings. Measuring reducing substances in the stool or ostomy output will also provide a clue as to whether or not the absorptive threshold has been reached. Once carbohydrate malabsorption begins, advancing feedings usually precipitates more osmotic fluid loss. As the tolerance to enteral feeding increases, parenteral nutrition is reduced in an isocaloric fashion. During this time, the patient has often been weaned to receiving parenteral nutrition during only part of the day or night with the infusion device capped for a certain number of hours each day. The length of the time off of parenteral nutrition can gradually be increased to facilitate care and mobility the patient, rather than simply decreasing the parenteral nutrition rate. Eventually, as enteral nutrition tolerance increases, the patient's parenteral nutrition may be deleted for one night a week, then two, and progressed until the patient is no longer receiving parenteral nutrition.

Enteral nutrition can be provided orally through bolus feedings or by continuous enteral infusion. Oral nutrition has the advantage of including the oral and cephalic processes of digestion and absorption which might perhaps play a role in adaptation. However, especially in small children or infants, continuous enteral infusion is usually employed. Continuous enteral infusion provides constant stimulation for mucosal adaptation. As the nutrients are introduced more slowly and continuously into the gut, optimal saturation of transport carriers is achieved. The enhanced absorption thereby reduces the need of parenteral calories which likewise reduces the

risk of parenteral-nutrition-induced liver disease, one of the most common morbidities seen in SBS.

It is extremely important to initiate small quantities of oral bolus feeding early in the course of therapy. Especially in small infants, if this is not done, oral food aversion becomes a real problem. If only a few milliliters of formula or human milk are given through by mouth four times per day, the risk of oral food aversion can be significantly reduced. Solid foods can be initiated at the usual time (4–6 months of age) in small quantities despite the fact that the child continues to receive most of their enteral nutrition through a continuous infusion. The choice of solid food feeding is also open to controversy. Although it is customary in many cultures to begin oral feedings with carbohydrates such as cereal, there is little logic to this practice. Meat is probably an ideal first food for the short-bowel patient. Meat is high in fat and protein which are both important in stimulating mucosal adaptation and contain little or no carbohydrate which could increase osmotic fluid losses and small bowel bacterial overgrowth.

As feedings are progressed, the short-bowel patient may be receiving solids and oral bolus feedings during the daytime and continuous enteral infusion at night. This also permits optimal use of the gut. Nighttime enteral nutrition however frequently reduces the appetite in the morning and sometimes needs to be reduced to encourage the child to eat. A careful balance among all of these various factors requires clinical experience. This is perhaps one of the reasons why a multidisciplinary approach in SBS has been so successful in major centers [20].

In the management of older children with SBS, oral nutrition is often advanced more quickly. In this instance, the use of small frequent feedings every 2–3 h is beneficial over larger less frequent feedings as it more closely mimics the advantage of continuous enteral infusion [21]. Here, the selection of foods is very important. It is important that each meal contains a balance of carbohydrate, fat, and protein to avoid overloading the small intestinal capacity to absorb micronutrients. An equal balance between carbohydrate and fat, and a significant amount of protein in each of several small meals during the day, will not only facilitate adaptation but also reduce the risk of malabsorption and excessive fluid losses. Involvement of nutritionists who understand this principal and can counsel and educate the patient well is very important at this stage. A nice example is the concept of a small sandwich as the proper size of meal. The bread is the carbohydrate, the meat is the protein, and the butter is the fat. If this counseling is not provided, the patient may well choose to eat small meals but will consume all carbohydrate in one meal and all protein in the next because this is often easier to provide. The major risk in oral feeding is the consumption of large carbohydrate-containing meals. Carbohydrate, even in the form of disaccharides, is rapidly digested

in the small bowel creating an osmotic load which results in fluid rushing into the lumen creating diarrhea or large-volume ostomy losses. Simple carbohydrates are even more problematic. Including fat and protein in each meal while reducing the amount of carbohydrate reduces this risk significantly.

Pharmacologic Therapy

Numerous medications may be useful in the treatment of SBS, but in all instances, they should be considered as adjunctive to the primary treatment, enteral nutrition. Patients with SBS are commonly given H₂ receptor antagonists to suppress acid secretion. Short-bowel patients commonly have delayed gastric emptying which predisposes them to esophagitis and gastritis. These findings are commonly seen endoscopically. Unfortunately, acid suppression results in a greater likelihood of developing small-bowel bacterial overgrowth and allowing both bacterial and viral pathogens a portal of entry for causing disease [22]. One must consider both sides of the equation when prescribing these drugs.

Drugs which reduce small-bowel motility and lengthen transit such as loperamide are also commonly employed. These medications are likewise a double-edged sword. Slowing motility has the advantage of increasing nutrient contact with small-bowel mucosa, perhaps enhancing absorption. Unfortunately, motility is how the bowel rids itself of excess small-bowel bacteria. Patients with SBS already have dilated small bowel in many instances, which predisposes them to poor motility and thereby exacerbates small-bowel bacterial overgrowth [23, 24]. In general, patients with excess fluid losses who do not have overgrowth benefit from these medications and those with malabsorption secondary to overgrowth will probably do worse. Consequently, careful consideration of the clinical situation is needed before proceeding down this path.

Patients with SBS are often given broad-spectrum antibiotics to help control small-bowel bacterial overgrowth [25]. It is very difficult to determine exactly which antibiotics should be used. Attempts have been made to culture the small bowel and base the decision on sensitivity studies, but one can never be certain the organisms causing the symptoms are actually the ones which were cultured [25, 26]. Consequently, trial and error are often employed to make the decision. Determining the presence of overgrowth is also frequently difficult and is the subject of another chapter in this text. Again, trial and error are often utilized to make a decision. Antibiotic regimens which are commonly utilized are shown in Table 43.2.

Recently, a GLP 2 analog has been developed for the treatment of SBS. This followed largely unsuccessful attempt to utilize a combination of glutamine and growth hormone to

stimulate intestinal adaptation. GLP 2 appears to be better suited for this purpose and may have significant antisecretory benefits as well. The drug must be administered parenterally on a daily basis and is extremely expensive which limits its usefulness, but in adults with SBS, it has been shown to be useful in weaning some patients from parenteral nutrition [28, 29].

Complications

Catheter-Related Issues

Patients who require long-term parenteral nutrition may experience complications related to the central venous catheter or implantable infusion device. Most often, mechanical issues include device breakage and occlusion, but infectious complications may also occur. Patients with recurrent complications are at risk for losing central venous access which may be an indication for consideration of intestinal transplant.

The risk of noninfective complications of PN devices can be reduced by use of standardized protocols for insertion and long-term care [30]. Vigorous flushing protocols are important to maintain the patency of the central venous line. If the line becomes occluded, various thrombolytic agents can be used to restore patency [31]. This procedure is usually performed by nurses in the emergency department or from nutrition support or vascular access teams. These efforts to prevent and treat mechanical failure are important to maintain central venous access for those requiring long-term parenteral nutrition.

Damage to external catheters can be minimized by avoidance of over-clamping and limiting the use of scissors near the line. If the catheter is damaged, use of repair kits can help to extend its life although should be performed by those with experience as there is a significant risk of sepsis [32]. Guide wires can be used to change the defective line and help preserve the site of access.

Catheter-related blood stream infections can be life-threatening. Moreover, episodes of sepsis are associated with hyperbilirubinemia and progressive liver disease. Cholestasis in infants is often triggered by a catheter infection [33]. To minimize this risk, the caregivers must be carefully instructed in the care of the catheter and insertion site. Sterile technique, particularly in the initiation and discontinuation of the infusion, is critical to prevent contamination. Bacterial translocation from unhealthy gut epithelium also can contribute to the risk for recurrent sepsis [34, 35]. Antibiotic and ethanol locks may be helpful in treating catheter sepsis but also may increase issues with thrombosis [36, 37]. Although the role of ethanol lock therapy has not been established in the literature in large randomized studies, this technique is

increasingly utilized in intestinal rehabilitation centers in the USA. Catheter exit-site infections can usually be treated with sterile dressing changes and systemic antibiotics if treatment is initiated at the first signs of redness, pain at the site, and drainage.

Hepatobiliary Disease

In patients with extreme SBS, those with SBS beginning in infancy or SBS occurring in premature infants, the development of parenteral-nutrition-associated liver disease is not uncommon. The severity of disease expression is often inversely related to the amount of enteral feedings that can be tolerated. For this reason, even in patients with very short bowel, aggressive enteral nutrition is pursued. An increase in liver enzymes followed by increases in direct bilirubin often suggests that liver injury from parenteral nutrition has occurred. In this instance, steps need to be taken to reduce the risk of progression of liver injury. One of the most important steps is to reduce the amount of soybean-based intravenous lipid to that necessary to prevent essential fatty acid deficiency. This can be done by limiting the amount of lipid administered, utilizing an alternative source such as a fish oil-based solution, or providing a more balanced fatty acid solution [38–40]. Soybean oil is high linoleic acid which acts as a substrate for the synthesis of a variety of pro-inflammatory cytokines. Fish oil on the other hand is rich in eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) which are predominantly anti-inflammatory fats. Whether or not this is the mechanism for the benefits of fish oil intravenous lipid is unknown.

Other maneuvers which are occasionally helpful in reducing the risk of liver injury include cycling of parenteral nutrition so that it is given only for a few hours each day and prevention of catheter-induced sepsis which seems to be associated with an increased incidence of liver injury [41]. Finally, bacterial overgrowth is known to produce toxins in the bowel which can gain access to the liver through the portal circulation so prevention of bacterial overgrowth is also helpful in reducing the risk of liver disease.

Patients with SBS also frequently develop gallstones. The use of continuous enteral nutrition or parenteral nutrition does not stimulate gallbladder emptying to the same degree as eating bolus meals [42, 43]. Consequently, sludge accumulates in the gallbladder predisposing it to the formation of gallstones. Some have even advocated routine removal of the gallbladder in SBS although this practice is not widely utilized. In patients with SBS who develop worsening jaundice or hyperbilirubinemia, an ultrasound to look at the gallbladder for evidence of stones is warranted.

Bacterial Overgrowth

Bacterial overgrowth in the small bowel is said to occur whenever the concentration of normal enteric flora exceeds those observed in the physiologic state. The presence of the excess bacteria may have adverse effects on the mucosa-creating inflammation and the resultant symptoms. This is especially common in SBS, as these patients often have no ileocecal valve which functions to prevent or limit reflux and colonic flora into the small intestine. These patients also experience compensatory dilatation in small bowel diameter often associated with prolonged transit. Both of these processes may be seen as adaptive phenomenon but would certainly place the patient at increased risk of bacterial overgrowth. Finally, patients with SBS may have delayed gastric emptying and some degree of hypergastrinemia; therefore, it is not uncommon for patients with SBS to have inflammation in the esophagus, stomach, and proximal duodenum. The use of aggressive acid suppression is not uncommon in this group of patients and that certainly enhances the risk of development of small-bowel bacterial overgrowth.

Small-bowel bacterial overgrowth can have a significant effect on absorptive capacity for a number of reasons. Perhaps the most significant is by the induction of inflammation in the small bowel, damaging the absorptive surface [44]. Bile salts are conjugated in the lumen by bacteria rendering them nonabsorbable in the ileum which can cause further fat malabsorption and its resultant effects such as the development of kidney stones.

Prevention of the negative effects of small-bowel bacterial overgrowth generally includes dietary management as the first line of therapy, mainly by avoiding excess carbohydrate intake in the susceptible patients. Medications which slow intestinal transit, such as loperamide, should be avoided in patients with overgrowth. Acid suppression should be used judiciously. Antibiotic therapy may be indicated and several protocols have been suggested. One must consider best type of antibiotic (see Table 43.2) as well as the administration frequency. Administration of antibiotics for the first week of each month, on a continuous basis, or on a rotational basis avoids development of antibiotic resistance.

Some patients with small-bowel bacterial overgrowth have other anatomic considerations making them uniquely

susceptible to symptoms. Any anatomic abnormality which adversely affects motility or normal antegrade peristalsis of the small intestine contents is likely to result in the development of overgrowth. Anastomotic strictures in areas of previous atresias or inflammatory strictures from residual necrotizing enterocolitis not uncommonly result in proximal dilatation and dysmotility. Ulceration at the site of anastomosis may also occur and results in chronic blood loss and further exacerbating bacterial overgrowth.

Within these areas of dilated gut, overgrowth and resultant inflammation are not uncommon. In this situation, tailoring the bowel by removing the stricture and reducing the diameter of the dilated bowel frequently results in enhanced motility and reduced overgrowth and despite the fact that some bowel was resected, absorption improves [45]. When there is an extensively dilated segment of small bowel, intestinal lengthening procedures can be performed. Two techniques have been described. The first was the Bianchi procedure which involves isolating the blood supply to each lateral half of the bowel, stapling or sewing the bowel longitudinally to create two segments of equal length but half the diameter, and then attaching the two segments end to end making certain that full segments are attached in such a way to ensure proximal to distal peristalsis. The second operation is known as serial transverse enteroplasty. In this operation, much simpler to perform, opposing transverse incisions are made in the dilated bowel at several intervals and closed longitudinally. The end result is the same, significant lengthening of the bowel and reduction of the diameter with no loss of absorptive surface area [1, 46]. The operation should probably not be performed in children with non-dilated bowel and normal mucosal surface, as this is really a bacterial overgrowth control operation and not an intestinal lengthening procedure as commonly thought. The serial transverse enteroplasty procedure has the advantage of being repeatable, and can be done in a patient who has had dilatation following a previous Bianchi procedure. Decisions regarding the use as well as the performance of these operations should be made by experienced surgeons with extensive knowledge of intestinal failure and bacterial overgrowth.

Micronutrient Abnormalities

Once patients are weaned from parenteral nutrition and must rely on enteral intake, the certainty with which micronutrients can absorb as highly variable. Micronutrient deficiency, either trace metals or vitamins, is fairly unlikely when these are provided in adequate concentrations in the parenteral nutrition solutions. Once enteral intake exceeds about 50% of the total daily caloric needs, the patient begins to depend more on the gut or micronutrients provided in the enteral

nutrition. The risks of deficiency increases significantly when patients are weaned from parenteral nutrition. The fat-soluble vitamins A, D, E and K and certain trace metals and other electrolytes such as calcium and magnesium are the most likely to be deficient. Patient should be monitored for these micronutrients on a routine basis for every 3–6 months (see Table 43.3). Supplementation with high oral replacement doses is often necessary with frequent monitoring to make certain nutritional adequacy is achieved. In patients with ileal resection, vitamin B12 deficiency not uncommonly occurs. Periodic evaluation of B12 levels in such patients is indicated. If levels drop, exogenous administration on a routine basis will be needed throughout life. Patients receiving most of their nutrition parenterally who are receiving limited lipid administration or patients with severe fat malabsorption are at risk for developing essential fatty acid deficiency. In such patients, periodic evaluation of triene/tetrene ratios should be performed to determine if extra intravenous lipid supplementation is needed. Calcium and magnesium are also poorly absorbed in many short-bowel patients, and periodic evaluation of bone density should be done, on a yearly basis [47].

In patients with irreversible parenteral-nutrition-associated liver disease who had not responded to all the measures outlined above, combined liver and intestinal transplantation may be considered. Use of this operation has been declining recently because of the great success of multidisciplinary centers in the management of intestinal failure and the effective use of parenteral and enteral nutrition [48]. Unfortunately, some patients still progress to liver failure and require transplantation. Despite numerous advances and surgical techniques and immunosuppression, 5-year survival is still not much better than 50% [49, 50]. Although some patients do extremely well, recurrent hospitalizations for complications for treatment of rejection are not uncommon. Consequently, transplantation should be considered only when all else is failed. Ideally, these procedures should be performed in an experience transplant center with a multidisciplinary team capable caring for advanced intestinal failure problems.

Background

The State of Food Insecurity (SOFI) estimates that around 870 million people globally have been undernourished (in terms of dietary energy supply) in the period 2010–2012 [1]. The vast majority of these, 852 million, live in developing countries, where the prevalence of undernourishment is around 14.9% [1]. Though many countries are on track in reducing income poverty (Millennium Developmental Goal (MDG) 1a), less than a quarter of developing countries are on track to achieve the goal, of halving undernutrition (MDG 1c) by the year 2015. The global burden of undernutrition remains high with little evidence of change in many countries despite economic growth and still millions of people are faced with starvation and malnutrition with women and children contributing the major share. The progress has also been hampered by the global increase in food and oil prices, climate change, unprecedented draughts and increased number of countries affected by fragility, conflict, and emergencies. According to the World Bank, 33 countries fall in the fragile situations category and in addition, conflict and fragility also occurs at the subnational level within some strongly performing countries. The World Bank further estimated that the food price crisis in 2008 pushed as many as 130–155 million more people globally into extreme poverty with an increase in the

number of children suffering permanent cognitive and physical injury due to malnutrition by 44 million [2].

In the year 2012, almost 6.6 million children under 5 years of age died worldwide [3] and undernutrition was an underlying cause in about 45% of these deaths (representing more than 3 million deaths each year) which includes stunting, severe wasting, deficiencies of vitamin A and zinc, and suboptimum breast-feeding. Fetal growth restriction and suboptimum breast-feeding together cause more than 1.3 million deaths or 19.4% of all deaths of children younger than 5 years. Good nutrition early in life is essential for children to attain their developmental potential; however, globally around 165 million children under the age of five suffer from stunting, 101 million are underweight and 52 million children are wasted [4] and approximately 90% of these live in just 36 countries with the highest prevalence in Southeast Asia and sub-Saharan Africa [3]. Prevalence of malnourished children has reduced and progress has been made in the past two decades but at the current rate of progress, the United Nations regional goals are unlikely to be met in all developing countries, and micronutrient deficiencies remain widespread among women and children globally. In a recent analysis of 79 countries with population-based surveys since the year 2000, stunting prevalence among children under the age of five was higher in the poorest quintile of households than in the richest quintile, higher in boys than in girls, and also higher in rural areas than urban areas [4, 5]. The problems of overweight and obesity among children are also growing and they have delirious consequences in low-income and middle-income countries (LMICs). In 2011, globally, an estimated 43 million (7%) children younger than 5 years were overweight (i.e., weight-for-height Z-scores (WHZ) greater than two Z scores), which is an increase from an estimated 28 million in 1990. This trend is expected to continue and reach a prevalence of 9.9% (64 million) in 2025 [4]. These changes are taking place around the world with prevalence increasing in high-income countries (HIC) and LMIC alike, as around 50% of these overweight children live in LMIC, with 29 million living in Africa and Asia.

In Africa, the prevalence has increased from 4% in 1990 to 7% in 2011, and it is expected to reach 11% in 2025. Many of these countries are said to have the double burden of malnutrition—continued stunting of growth and deficiencies of essential nutrients—along with the emerging issue of obesity. If trends are not reversed, increasing rates of childhood underweight and overweight will have vast implications, not only for future health-care expenditures but also for the overall development of nations.

Trends of Child Nutrition

Causes of childhood growth faltering are multifactorial, but fetal growth restriction might be an important contributor to stunting and wasting in children. A total of 32 million (27%) babies are born small for gestational age (SGA) annually and fetal growth restriction causes more than 800,000 deaths each year in the first month of life [4]. Stunting is a major indicator of childhood undernutrition, because it is highly prevalent in nearly all LMICs, and has important con-

sequences for health and development and there are voices to replace it with underweight as the main anthropometric indicator for children. The prevalence of stunting was 26% in children in LMICs in 2011, a decrease of 14% points since 1990 and the number of stunted children has also decreased globally, from 253 million in 1990 to 165 million in 2011, with an average annual rate of reduction of 2.1% [4] (Fig. 44.1). The World Health Assembly (WHA) called for a 40% reduction in the global number of children younger than 5 years who are stunted by 2025 (compared with the baseline of 2010) [6]. This aim would translate into a 3.9% reduction per year and imply reducing the number of stunted children from 171 million in 2010 to about 100 million in 2025. At the present rate of decline, stunting is expected to reduce to 127 million, a 25% reduction, in 2025. The decrease is substantial in Asia but the figures are not so encouraging for Africa. Wasting has a prevalence of 8% globally in 2011, which amounts to 52 million children; while 101 million children are underweight. There has been an 11% decrease from 58 million in 1990. The prevalence of severe wasting was 2.9%, affecting 19 million children and

Fig. 44.1 Global prevalence of stunting and underweight in children under 5 years of age [3] CEE Central and Eastern Europe, CIS Commonwealth of Independent States

more than two thirds of the world's children with wasting live in Asia.

Deficiencies of essential vitamins and minerals are widespread and have substantial adverse effects on child survival and development. Deficiencies of vitamin A and zinc adversely affect child health and survival, and deficiencies of iodine and iron, together with stunting, contribute to children not reaching their developmental potential. Recent analysis support that all degrees of stunting, wasting, and underweight are associated with higher mortality, while undernutrition can be considered the cause of death in a synergistic association with infectious diseases; all anthropometric measures of under nutrition were associated with increased hazards of death from diarrhea, pneumonia, measles, and other infectious diseases, except for malaria [5]. Besides anthropometric measures, the association between micronutrient deficiencies such as vitamin A deficiency and increased risk of childhood infections and mortality is also well established [7]. Vitamin A deficiency increases the risk of severe diarrhea and thus diarrhea mortality but is not an important risk factor for the incidence of diarrhea or pneumonia, or for pneumonia-related mortality. Other micronutrient deficiencies such as zinc and iron deficiency are also recognized as widespread in developing countries and associated with increased risk of morbidity [8] and mortality [9]. According to World Health Organization (WHO) estimates, globally about 190 million preschool children and 19.1 million pregnant women are vitamin A deficient (that is, have serum retinol $<0.70 \mu\text{mol/l}$) [10]. Globally, 0.9% or 5.17 million preschool age children are estimated to have night blindness and 33.3% or 90 million to have subclinical vitamin A deficiency, defined as serum retinol concentration of less than $0.70 \mu\text{mol/L}$. Vitamin A deficiency using night blindness prevalence can be defined as a global problem of public health importance [10, 11]. Approximately 100 million women of reproductive age (WRA) have iodine deficiency, and an estimated 82% of pregnant women worldwide have inadequate zinc intakes to meet the normal needs of pregnancy [6]. Iron deficiency is widespread and globally about 1.62 billion people are anemic [12], and 18.1% and 1.5% children are anemic and severely anemic, respectively [4]. Suboptimal vitamin B6 and B12 status have also been observed in many developing countries [13].

Risk Factors

Risk factors for undernutrition range from distal broad national scale determinants to proximal individual specific and factors which effect at various age and periods of life. National socioeconomic and political determinants have a bigger impact and include political stability, economics, food security, poverty, and literacy, among others. Natural disas-

ters including famine, floods, and other emergencies have detrimental effects. Maternal education is associated with improved child-care practices related to health and nutrition, and reduced odds of stunting, and better ability to access and benefit from existing facilities. Worrysome food insecurity is obviously critical, but a factor that is potentially even more important (especially for children with marginal intake) is the inability to absorb what they do take in because of repeated or persistent intestinal infections. Severe infectious diseases in early childhood, such as measles, diarrhea, pneumonia, meningitis, and malaria, can cause acute wasting and have long-term effects on linear growth. But the most important of these infections is diarrhea; hence, the need for understanding the impact and mechanisms of malnutrition and diarrhea, which forms a vicious cycle of enteric infections worsening and being worsened by malnutrition. Several recognized processes by which enteric infections cause malnutrition, range from well-recognized anorexia and increased catabolic or caloric demands to direct protein and nutrient loss or impaired absorptive function [14]. Modifiable risk factors for childhood obesity include maternal gestational diabetes; high levels of television viewing; low levels of physical activity; parents' inactivity; and high consumption of dietary fat, carbohydrate, and sweetened drinks, yet few interventions have been rigorously tested [15, 16].

Short- and Long-Term Consequences

Malnutrition leads to early physical growth failure, delayed motor, cognitive, and behavioral development, diminished immunity, and increased morbidity and mortality. These nutritional problems particularly flourish during periods in utero and during the first 3 years of life, and especially affect a large proportion of all children in LMICs. The determination of the child nutrition status starts even before birth, as maternal nutrition and health has a significant impact on child health. Neonates with fetal growth restriction are at substantially increased risk of being stunted at 24 months and of development of some types of noncommunicable diseases in adulthood. Those who survive the initial and direct consequences of malnutrition in early childhood grow up as adults but with disadvantages when compared to those who have been nutritionally adequate and enjoyed healthy environment in the initial crucial years of life. Undernutrition is strongly associated, with shorter adult height, less schooling, reduced economic productivity, and for women with lower offspring birth weight. Low birth weight (LBW) and undernutrition in childhood are risk factors for high glucose concentrations, blood pressure, and harmful lipid profiles [17]. The later consequences of childhood malnutrition include diminished intellectual performance, low work capacity, and increased risk of delivery complications [18]. Short-term

consequences of intrauterine growth retardation (IUGR) involve metabolic, thermal, and hematological disturbances leading to morbidities, while long-term consequences include increased risk of developing metabolic syndrome and cardiovascular disease, systolic hypertension, obesity, insulin resistance, and diabetes type II in adulthood [19, 20]. There are no effective therapies to reverse IUGR and antenatal management is aimed at determining the ideal time and mode of delivery. In order to prevent complications associated with IUGR, it is important to first detect the condition and institute appropriate surveillance to assess fetal well-being coupled with suitable intervention in case of fetal distress. A study carried out in Chile shows that undernutrition at an early age may affect brain development, intellectual quotient, and scholastic achievement in school-age children [21]. This pattern is consistent with increased susceptibility to altered brain growth, particularly with the development of altered frontal lobe structures [22]. A recent review found evidence to support a weak association between LBW and later depression or psychological distress; however, the association may vary according to severity of symptoms or other factors [23]. Hence, the prevention of LBW and the promotion of adequate growth and development during early childhood will result in healthier, more productive adults. These undernourished children also show higher susceptibility to the effects of higher fats diets, lower fat oxidation, higher central fat, and higher body fat gain [24]. Without undermining the importance of the early period of life and even before that, evidence also suggests that improvements in child growth after early faltering may have significant benefits on schooling and cognitive achievement. Hence, interventions to improve the nutrition of preprimary and early primary school-age children also merit consideration [25]. Improvements in height may be obtained through adequate nutrient intake after the child's early years, but the brain is a notable exception because the first 2 years of life represent the period of maximum growth, and 70% of adult brain weight has been attained by the end of the first year [26, 27].

Global Inclination Toward Undernutrition

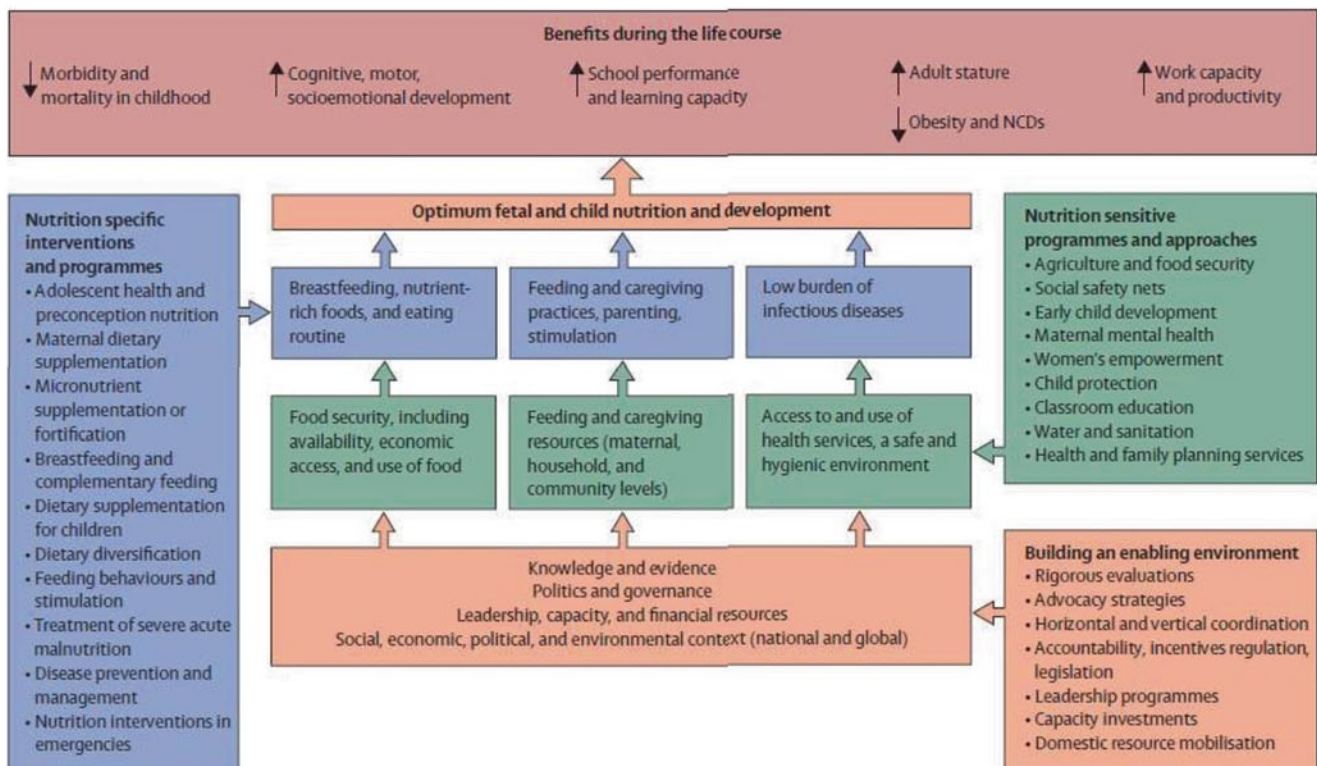

There is growing recognition that interventions designed to improve human nutritional status have instrumental value in terms of economic outcomes. In many cases, productivity gains alone provide sufficient economic returns to justify investments using benefit and cost criteria. The often-held belief that nutrition programs are welfare interventions that divert resources which could be better used in other ways to raise national economies is incorrect. Most development agencies have revised their strategies to address undernutrition. The first Lancet nutrition series in 2008 [28] created a much desired stir and drew attention from relevant quarters.

One of the main drivers of the new international commitment is the Scaling Up Nutrition (SUN) Movement [29] and the second Lancet nutrition series [4]. National commitment in LMICs is growing, donor funding is rising, and civil society and the private sector are increasingly engaged. Nearly every major development agency has published a policy document on undernutrition, and donors have increased official development assistance to basic nutrition. Nutrition is now more prominent on the agendas of the UN, the G8 and G20, and supporting civil society. However, this progress has not yet translated into substantially improved outcomes globally. Improvements in nutrition still represent a massive unfinished agenda. The 165 million children with stunted growth have compromised cognitive, development, and physical capabilities, making yet another generation less productive than they would otherwise be [4]. Countries will not be able to break out of poverty and to sustain economic advances without ensuring their populations are adequately nourished. Undernutrition reduces a nation's economic advancement by at least 8% because of direct productivity losses, losses via poorer cognition, and losses via reduced schooling [30].

Addressing the Burden of Undernutrition

To address this persistent burden of undernutrition in children and to the population at large, various strategies have been employed worldwide (Fig. 44.2). Among these include nutrition education, dietary modification, food provision/supplementation and agricultural interventions including bio-fortification, micronutrient supplementation and fortification. Apart from these direct nutritional interventions, programs to tackle the underlying causes of undernutrition including prevention and management of infections (like diarrhea and malaria) have also been initiated and implemented at various levels of care. Parallel programs have also been pursued to increase coverage and aid uptake of these primary interventions including provision of financial incentives at various levels, home gardening and community-based nutrition education, and mobilization programs. Although all these strategies have shown success and proved to be effective, a coherent, multifaceted, and integrated action which has the global consensus is lacking and several attempts at developing consensus is fraught with controversies and lack of coordination between various academic groups and development agencies.

There is a need for more emphasis on the crucial period from conception to a child's second birthday, the 1000 days in which good nutrition and healthy growth can have lasting benefits throughout life. Early years are important to intervene for various reasons as this is the period of maximum growth, immunological systems develop and mature during this time and they are less able to make their needs known

Fig. 44.2 Conceptual framework for achieving optimal child nutrition. (Reprinted from Ref. [4], with permission from Elsevier) *NCDs* noncommunicable diseases

and are more vulnerable to the effects of poor parenting. Intervening early in pregnancy and even before conception may be beneficial, as many women do not access nutrition-promoting services until later in pregnancy, so it is important to ensure that women enter pregnancy in a state of optimum nutrition. The emerging platforms for adolescent health and nutrition might offer opportunities for enhanced benefits [31]. There is a growing interest in adolescent health as an entry point to improve the health of women and children, especially as an estimated 10 million girls younger than 18 years are married each year [32].

Broader-Scale Interventions

There is a need for building an enabling environment to support interventions and programs to enhance growth and development. Important determinants of undernutrition to address include poverty, food insecurity, illiteracy, and scarcity of access to adequate care which in turn shape economic and social conditions, national and global contexts, capacity, resources, and governance. These could be addressed through investments in agriculture, social safety nets, early child development, and schooling. Social safety nets provide

cash and food transfers to a billion poor people and reduce poverty. They also have an important role in mitigation of the negative effects of global changes, conflicts, and shocks by protecting income, food security, and diet quality [33]. Safety net programs can be more effective, but geographic targeting and other investments to strengthen safety nets are necessary to ensure that fewer people are affected by future crises. Combination of early child development and nutrition interventions makes sense biologically and programmatically, and evidence from mostly small-scale programs suggests additive or synergistic effects on child development and in some cases on nutrition outcomes [33]. Parental schooling is consistently associated with improved nutrition outcomes and schools provide an opportunity, so far largely untapped, to include nutrition in school curricula for prevention and treatment of undernutrition or obesity. School feeding programs is another avenue to improve nutrition at a later life. Recent evidence from in-depth studies argue that while school feeding programs can influence the education of school children and, to a lesser degree, augment nutrition for families of beneficiaries, they are best viewed as transfer programs that can provide a social safety net and help promote human capital investments [34]. Arguably, direct food distribution, including that of ready-to-use therapeutic food

(RUTF), may be part of the overall strategy. Even if such programs are too expensive for sustainable widespread use in the prevention of malnutrition, scalable food distribution programs may be cost-effective to address the heightened risk of malnutrition following weather-related shocks [35]. Community delivery platforms for nutrition education and promotion, integrated management of childhood illness, school-based delivery platforms, and child health days are other possible channels. Innovative delivery strategies, especially community-based delivery platforms are promising for scaling up coverage of nutrition interventions and have the potential to reach poor and difficult to access populations through communication and outreach strategies.

Targeted agricultural programs have an important role in support of livelihoods, food security, diet quality, and women's empowerment, and complement global efforts to stimulate agricultural productivity and thus increase producer incomes while protecting consumers from high food prices [33]. Agricultural interventions including home and school gardening have the potential and a review on agricultural interventions to improve nutritional status of children concluded that home gardening interventions had a positive effect on the production of the agricultural goods and consumption of food rich in protein and micronutrients. However, the impacts on iron absorption and anthropometric indices remained inconclusive [36]. Evidence also suggests that targeted agricultural programs are more successful when they incorporate strong behavior change communications strategies and a gender-equity focus.

Food fortification is one of the strategies that has been used safely and effectively to prevent vitamin and mineral deficiencies. A review of multiple micronutrient (MMN)

fortification in children showed an increase in hemoglobin levels and 57% reduced risk of anemia. Fortification is also associated with increased vitamin A serum levels. A review on mass salt fortification with vitamin A and iodine concluded that the fortified and iodized salt can improve the iodine status [37]. Zinc and Vitamin D fortification have also been effective to varying extent [38]. Micronutrient fortified milk and cereal products have also proven as a complementing strategy to improve health problems of children in developing countries [39]. A recent review has identified it as an effective and potential strategy although more rigorous evidence is required especially from LMIC [40]. Bio-fortification is a relatively new strategy to improve iron, zinc, and vitamin A status in low-income populations. It is the use of conventional breeding techniques and biotechnology to improve the micronutrient quality of staple crops. A review on bio-fortification concluded that it has the potential to contribute to increased micronutrient intakes and improve micronutrient status; however, this domain requires further research [41].

Specific Interventions

Many nutrition interventions have been successfully implemented at scale, and the evidence base for effective interventions and delivery strategies has grown (Table 44.1). At the same time, coverage rates for other interventions are either poor or nonexistent.

Micronutrient supplementation is the most widely practiced intervention to prevent and manage single or MMN deficiencies. Various programs are in place to address these

micronutrient deficiencies through supplementation and evidence from evidence-based systematic reviews suggests that among pregnant women, daily iron supplementation is associated with a 69% reduction in incidence of anemia at term, 66% reduction in iron-deficiency anemia at term, 20% reduction in incidence of LBW and improved birth weight [42]. Calcium supplementation during pregnancy is associated with a 52% reduction in the incidence of preeclampsia and 24% reduction preterm birth with an increase in birth weight of 85 g [43]. MMN supplementation during pregnancy significantly reduces the incidence of LBW infants by 11% and SGA by 13% [44]. A review [45] shows that providing pregnant females with balanced energy and protein (BEP) supplementation results in a significant reduction of 34% in the risk of giving birth to SGA infants and 38% reduction in stillbirth and results in an increased birth weight. These effects were more pronounced in malnourished women when compared to adequately nourished women.

Evidence of micronutrient supplementation in children indicates that vitamin A supplementation (VAS) reduces all-cause mortality and diarrhea specific mortality by 24 and 28% respectively [46]. VAS also reduced incidence of diarrhea by 15% and measles morbidity by 50%; however, there are no significant effects on the incidence of respiratory disease. Iron supplementation in children results in a 49% lower risk of anemia and a 74% lower risk of iron deficiency with higher serum hemoglobin and ferritin concentration, while nonsignificant impacts were observed for height for age and weight for age [47]. Zinc supplementation in a dose of 10 mg zinc/day for 24 weeks could lead to a net gain in height of 0.37 (± 0.25) [48] and reduce the incidence of diarrhea by 13% and pneumonia morbidity by 19% while has nonsignificant effects on mortality [49]. MMN supplementation with three or more micronutrients in children showed small effect sizes for length/height and weight with limited evidence for an impact on outcomes such as morbidity and cognitive function [50].

In children, improved feeding in the early infancy and the initial years of life hold an utmost importance and breast-feeding and complementary feeding are such strategies which ensure optimum nutrition during this vital phase of growth and development. Breast-feeding practices are far from optimum, despite improvements in some countries. Suboptimum breast-feeding results in an increased risk for mortality in the first 2 years of life and results in 800,000 deaths annually [4], poor nutrition often coincides with other developmental risks, in particular inadequate stimulation during early childhood. Breast milk provides numerous immunologic, psychologic, social, economic, and environmental benefits, and it is a natural first food and ideal nutrition for the newborn [51]. Breast-feeding is therefore recommended as the optimal strategy for feeding newborns and young infants. Strategies to improve the uptake of breast-feeding are essential and evi-

dence suggests that breast-feeding education and promotion interventions are effective in improving breast-feeding rates and evidence suggests that these interventions are associated with improved exclusive breast-feeding (EBF) rates of 1 and 6 months with increase in HIC and LMIC [52].

Complementary feeding for infants refers to the timely introduction of safe and nutritional foods in addition to breast-feeding, that is, clean and nutritionally rich additional foods introduced at about 6 months of infant age [53]. These foods are typically provided to children from 6 to 24 months of age [53]. Multiple complementary nutrition interventions targeted to improve nutritional status of children have also been reviewed. These include complementary and supplementary feeding programs with or without nutrition education. Dewey 2008 [54] reviewed the effectiveness and efficacy of complementary feeding interventions in children aged 6–24 months in developing countries. It indicated that provision of complementary food can have a significant impact on growth under well-controlled situations. Complementary food combined with maternal education improved weight and linear growth. A recent review [55], looking at the impact of supplementary feeding that covered energy protein supplementation, found a statistically significant difference of effect for length during the intervention in children aged less than 12 years of age.

WHO recommends that all school children should be treated at regular intervals with deworming drugs in helminthic prevalent areas. A recent review [56] shows that treating children after screening for worms showed that a single dose of deworming drugs may increase weight and hemoglobin. Administration of a single dose of antihelminthics in the second trimester of pregnancy failed to show a statistically significant impact on maternal anemia or LBW, preterm births, and perinatal mortality. Effective interventions to prevent malaria morbidity and mortality include insecticide-treated mosquito nets (ITNs), indoor-residual spraying (IRS) and intermittent preventive therapy (IPTc). A review [57] concludes that antimalarials when given to prevent malaria in pregnant women increased mean birth weight and reduce the incidence of LBW by 43% and severe antenatal anemia by 38% [57]. The impact of therapeutic zinc supplementation for the management of diarrhea reduces all-cause mortality by 46% and diarrhea-related hospitalization by 23% [58].

Most of the interventions previously discussed should be implemented to prevent the development of severe acute malnutrition (SAM). Where markets are fragmented or food access is constrained, appropriate food supplements might be considered. Available evidence shows some positive effects with the use of RUTF compared with standard care for the treatment of SAM in community settings. An emphasis not only on the choice of commodities, but also on the quality of program design and implementation is crucial to improvement of outcomes for children with SAM, as is the

research to fill information gaps, such as optimum treatment methods and approaches for treatment of breast-fed infants younger than 6 months [31].

A recent review using Lives Saved Tool modeled ten nutrition-specific interventions across the lifecycle to address undernutrition [31]. The interventions included: peri-conceptual folic acid supplementation, maternal BEP supplementation, maternal calcium supplementation, MMN supplementation in pregnancy, promotion of breast-feeding, appropriate complementary feeding, vitamin A, and preventive zinc supplementation in children aged 6–59 months, management of SAM and management of moderate acute malnutrition. If these ten proven nutrition-specific interventions were scaled-up from existing population coverage to 90%, an estimated 900,000 lives could be saved in 34 high nutrition-burden countries (where 90% of the world's stunted children live) and the prevalence of stunting could be reduced by 20% and that of severe wasting by 60%. This would reduce the number of children with stunted growth and development by 33 million. On top of existing trends, this improvement would comfortably reach the WHA targets for 2025.

Way Forward

This existing evidence is essential to ensure that future investments are directed toward proven pathways to outcomes. Beyond this evidence, service providers, governments, donors, and the private sector need strong national monitoring and assessment platforms to hold them accountable for the quality and effectiveness of their investments in nutrition [59]. There is a need for the availability of timely and credible nutrition data, presented in accessible ways, can help governments and other actors to be responsive to challenging circumstances, and help civil society organizations to hold them accountable for the effectiveness of their interventions [59]. Advances in health management information systems and the growing availability of newer technologies can help with the real-time monitoring of nutrition outcomes and program coverage and quality, and should be researched.

There is also a need for greater priority for national nutrition programs, stronger integration with health programs, enhanced intersectoral approaches, and more focus and coordination in the global nutrition system of international agencies, donors, academia, civil society, and the private sector. There could also be a potential integration of nutrition with maternal, newborn, and child health interventions, helping to achieve reductions in inequities. Nutrition is crucial to both individual and national development as good nutrition is a fundamental driver of a wide range of development goals. The post-2015 sustainable development agenda must put addressing all forms of malnutrition at the top of its goals.

Introduction

The joint Food and Agriculture Organization (FAO) and World Health Organization (WHO) Expert Consultation on Evaluation of Health and Nutritional Properties of Probiotics in Food including Powder Milk with Live Lactic Acid Bacteria defined probiotics as: “Live microorganisms which when administered in adequate amounts confer a health benefit on the host” (FAO/WHO 2001). In 2002 (London, Canada), a joint FAO/WHO Working Group generated guidelines for the evaluation of probiotics in food. The minimum requirements needed for probiotic status include:

- The assessment of strain identity (genus, species, strain level)
- In vitro tests to screen potential probiotics: e.g., resistance to gastric acidity, bile acid, and digestive enzymes, antimicrobial activity against potentially pathogenic bacteria, etc.
- Assessment of safety: requirements for proof that a probiotic strain is safe and without contamination in its delivery form
- In vivo studies for substantiation of health effects in the target host

Following the FAO/WHO definition, the International Life Science Institute (ILSI 2002) and the European Food and Feed Cultures Association (EFFCA 2003) have launched

similar definitions for a probiotic: “a live microbial food ingredient that, when taken up in adequate amounts, confers health benefits on the consumers” and “live microorganisms which, when ingested or locally applied in sufficient numbers, provide the consumer with one or more proven health benefits.” The definition implies de facto that probiotic ingestion provides benefits for host health.

The science related to probiotics is recent and thus in constant evolution. Probiotics used in food, or supplied as dietary supplement, or when registered as medication should not only be capable of surviving passage through the digestive tract by exhibiting acid and bile survival, but also have the capability to proliferate in the gut. Probiotics must be able to exert their benefits on the host through growth and/or activity in the human body. Topical or local application of probiotics is also proposed in view of the recent evolution of scientific data. Therefore, the ability to remain viable and effective at the target site should be studied and confirmed for each strain, or even better for each commercialized product. Clinical studies should be performed with the commercialized product and not with “the strain.” However, lack of protection contributes to the fact that some companies refuse to deliver information on the specific strains in their product [1]. Recent literature has shown that one of the mechanisms of action of probiotics involves stimulation of the immune system. Whether the probiotics need to be “live” to induce immune modulation can be questioned. Therefore, the definition may have to be revised in the future.

According to the European Community, health claims should only be authorized for use in the European Community after a scientific assessment of the highest possible standard has been carried out by the Panel on Dietetic Products, Nutrition and Allergies (NDA) of the European Food Safety Authority (EFSA; regulation (EC) No. 1924/2006). Key questions which are addressed by the EFSA NDA panel are:

- Is the food/constituent sufficiently defined and characterized?
- Is the claimed effect sufficiently defined, and is it a beneficial physiological effect?
- Have pertinent human studies been presented to substantiate the claim?

The EFSA recommendations are an important step forward in trying to bring claims for probiotics, food supplements and medication closer together. However, companies discovered side-ways to avoid EFSA-restrictions. Some of the food supplements are in the process of registration as “medical device,” which legislation allows claims without providing hard scientific evidence. Moreover, production requirements on quality control and safety still differ substantially between food supplements and medication, putting medication in a disadvantageous situation.

Official controls by national authorities are performed to ensure verification of compliance with food law. Apart from the risk of using unauthorized strains, product mislabeling is a known problem, partly because of the use of phenotyping or genotyping methods with a lack of discriminative power [2]. In addition to official controls, private controls by food producing companies are important in the frame of protection of patented strains and industrial property rights.

In their “Guidelines for the Evaluation of Probiotics in Food” document, the FAO/WHO Working Group (2002) recommends that the following information should be described on the label of probiotic products:

- Genus, species, and strain designation. Strain designation should not mislead consumers about the functionality of the strain
- Minimum viable numbers of each probiotic strain at the end of the shelf-life
- The suggested serving size must deliver the effective dose of probiotics related to the health claim
- Health claim(s)
- Proper storage conditions
- Corporate contact details for consumer information

In most countries, only general health claims are currently allowed on foods containing probiotics. The FAO/WHO Working Group (2002) recommended that specific health claims on foods be allowed relating to the use of probiotics, where sufficient scientific evidence is available. Such specific health claims should be permitted on the label and promotional material. For example, a specific claim that states that a probiotic “reduces the incidence and severity of rotavirus diarrhea in infants” would be more informative to the consumer than a general claim that states “improves gut health.” It is recommended that it be the responsibility of the product manufacturer that an independent third party review

by scientific experts in the field be conducted to establish that health claims are truthful and not misleading.

In line with the suggestions of the FAO/WHO Working Group (2002), on December 20, 2006, the European Parliament and the Council published a novel regulation (No. 1924/2006) on “Nutrition and Health Claims Made on Foods” (<http://eur-lex.europa.eu/LexUriServ/LexUriServ.do?uri=CELEX:32006R1924R%2801%29:EN:NOT>). This regulation applies to all nutritional and health claims relating to all types of food intended for final consumers, thus also including probiotic products brought to the market with a health claim. The regulation aims to harmonize the nutrition and health claims at European level in order to better protect consumers, including commercial communications (labeling, presentation, and promotional campaigns) and trademarks and other brand names which may be construed as nutrition or health claims.

Functional Effect of Probiotics

The definition “probiotics are live microorganisms which when administered in adequate amounts confer a health benefit on the host” only generalizes the probiotic functionality as conferring a health benefit to the host. Hence, this definition basically entails that there must be a measurable physiological benefit to the host who uses the probiotic product. In addition, it is not specified that the probiotic strain must be provided through oral delivery, nor are there specific requirements regarding the mode of action. The latter also entails that survival of the probiotic microorganisms throughout the gastrointestinal (GI) tract is not a prerequisite for recognition of probiotic effects. For example, the delivery of lactase through administration of live *Streptococcus (Strepto.) thermophilus* to the small intestine can be considered as a probiotic activity, although the *Strepto.* strain does not survive the digestive tract [3].

When considering probiotic functionality, the abovementioned definition of probiotics is to be interpreted in a very broad way. This broad functionality definition complicates the process of functional characterization of probiotics. The use of probiotics may target several body sites (mouth, GI tract, respiratory tract, urinary tract, skin, vagina, etc.), and its application can also target specific human subpopulations: healthy individuals, children, elderly people, diseased persons, immune-compromised and genetically predisposed individuals, etc. There is an extremely diverse range of potential biological effects and new functional activities are constantly being explored. While some models are perfectly suited for studying the colonization potency of probiotics, other models need to be applied for assessing their immune-modulating potential, their resilience against pathogen invasion of the GI tract or their anti-inflammatory properties.

Functional Characterization of Probiotics

Target Sites

Probiotic products have been developed to improve physiological conditions at different body sites. While the GI tract is the most important target for the majority of probiotic applications, other body sites such as the mouth, the uro-genital tract, and the skin are also considered. Probiotics may play an important role in oral medicine and dentistry [4, 5].

Probiotics are also considered for abating and preventing infections of the reproductive and urinary tract [6–9]. With regard to skin applications, probiotics may be taken up orally to induce an immune response that has systemic effects, for example, for controlling skin inflammation [10] and dermatological diseases in general [11]. Probiotics have also been applied to protection for respiratory tract infections. *Lactobacillus (L.) rhamnosus* GG prevents respiratory tract infections besides the conventional protection against GI infections [12]. There is a plethora of probiotic strains and applications available with the GI tract as target site. Such applications aim at a wide diversity of health benefits such as decreasing pathogen colonization, synthesis of vitamins, optimizing intestinal transit, alleviation of lactose intolerance, reduction of bloating, immune-modulatory effects and many others.

Delivery Mode

With the aim of obtaining health benefits, probiotic strains often require a specific matrix to guarantee optimal strain survival along the GI tract. For instance, probiotics have recently been formulated in a chocolate matrix, which resulted in a more optimal survival of the probiotic strains in comparison with conventional probiotic formulation methods [13]. Other methods include the introduction of probiotics in more conventional products such as milk [14], kefir [15] and several yoghurts or more specific matrices such as cereals, cheese, even sausages, and cookies. Obviously, many probiotics are introduced for commercial reasons to obtain a better product placement or to integrate the food product into the probiotic market. Examples of these are fruit juices, ice creams, candies, granola bars, etc.

Besides the incorporation of probiotics in food products, probiotic strains are also provided as food supplement, often with the aim of tackling specific health problems. Probiotic food supplements (e.g., *L. rhamnosus* GG, *L. reuteri*) and medication (e.g., *Saccharomyces (S.) boulardii*) have almost become standard in the treatment of pediatric gastroenteritis. Many infant formula milk powders exist in which probiotics have been formulated, both to prevent and alleviate diarrhea.

A special example of designer strains is the application of genetically modified microorganisms as probiotic. *Lactococcus (Lc.) lactis* strains were developed that secrete IL-10

or immunomodulatory *Yersinia* LcrV protein to treat colitis in mouse models [16, 17]. Such approach is currently being considered for the treatment of oral mucositis (high incidence in head/neck cancer patients receiving radiotherapy) with a human trefoil factor 1-secreting *Lc. lactis*. A molecular basis of the therapeutic applications and the chemopreventive activities of certain probiotic metabolites, with emphasis on the interaction between these metabolites and the molecular signaling cascades are considered to be epigenetic targets in preventing colon cancer [18].

Finally, probiotic delivery not only pertains to the food or pharmaceutical environment in which the probiotic is formulated. Specific ointments and nasal sprays are developed [19]. Nowadays, even the introduction of probiotics in mattresses (<http://www.purotex.com>) and cleaning agents (<http://www.naturalhouse.com>; <http://www.optibacprobiotics.co.uk>; <http://www.chrisal.com>) is gaining momentum for an optimized hygienic control. The latter illustrates the necessity to broaden the control on claims larger than food supplements and food. If Europe installs “Authorities” (EFSA) to control claims for foods and food supplements, health-claims for non-food related products should be equally controlled.

Strain Survival

Health benefits are in many cases only obtained when a probiotic strain reaches the target site in a metabolically active state and in sufficient numbers. For oral delivery, probiotic microorganisms must survive the different physicochemical, enzymatic, and microbial stresses throughout the GI transit.

Firstly, microorganisms have to cross the acidic environment from the stomach. In addition, the absence or presence of a food matrix significantly determines the pH profile to which the probiotic strain is subjected. While the initial pH buffering effect from food may subject the probiotic strain to initially less stringent acidic conditions, a longer digestion time in the stomach under fed conditions may expose part of the dosed probiotic to acidic conditions for a longer time. Many probiotic microorganisms have been selected for their higher resilience against such acidic conditions, and new methodologies are available to allow encapsulation of probiotic strains in that purpose [20].

A second stress component is the presence of bile salts that elicit membrane-compromising properties towards microorganisms, due to their amphiphilic character. A particular functional characteristic of microorganisms is their ability to deal with bile salt stress via bile salt hydrolase. Bile salt hydrolase bacteria typically cleave the glycine or taurine moiety from conjugated bile salts, rendering the latter less bacteriostatic. This feature is of particular importance to optimize strain survival during intestinal transit and has been proposed as a mechanism explaining how probiotics could lower serum cholesterol levels [21].

Another feature of probiotic strain survival is the ability to colonize the GI tract. This property can be split up into an ecological component and a mucosal component. Firstly, once a probiotic organism has survived gastric acid and duodenal bile salts and thus reaches the ileum and colon, it has the possibility to develop in a less stringent environment. Yet, it reaches an environment with a highly significant microbial background—the ileum and colon reaching bacterial concentrations of 10^7 and 10^{11} cells/mL chyme, respectively. Obviously, a probiotic strain can be considered as foreign to the residing endogenous microbiota, and unless specific nutrients are provided for the probiotic in the product formulation (e.g., symbiotic), the strain must enter into competition with the residing microbial community for available substrates. In ecological terms, the dosed probiotic must occupy a functional niche in the gut microbial ecosystem. Secondly, an important property for probiotics, for example, with respect to pathogen control, is its ability to adhere to and thrive in the mucus surface that covers the gut epithelium. Mucosal adhesion can rely on cell wall properties. The hydrophobic nature of microbial strains can be assessed with a straightforward bacterial adherence to hydrocarbons (BATH) assay [22], while the unspecific mucus adhesion can be measured using short term adhesion assays with gut-derived mucins (mostly from animal origin) [22, 23]. However, the unspecific adhesion of gut microorganisms to gut mucins is only sufficient for microcolony formation and it does not guarantee a prolonged colonization of the mucus layer. It has been well described that specific microorganisms modulate their gene expression following their incorporation into the mucosal surface. This has not only been described for pathogens [23, 24] but also for probiotic microorganisms such as *L. rhamnosus* GG, which upregulates specific “pilin” structures in the mucosal environment [25].

Human Target Groups

Probiotic products have been developed for a wide variety of health claims. Probiotics can target both healthy and diseased individuals. The expected effects can be of a preventive or curative nature. The goal can be to fight the cause of the disease/metabolic alterations, or to lessen symptoms associated with the occurrence of progression of a disease/metabolic alteration.

With the aim of improving health in the human body, the intake of a probiotic strain by healthy subjects has primarily preventive objectives. Yet, it must be emphasized that the introduction of a foreign strain—even if it is a probiotic—must be approached with care and must be performed after a well-considered evaluation process. More in particular, the gut environment from sensitive human subpopulations such as babies and toddlers is going through a high degree of development or transition. Many studies report on probiotic applications resulting in a positive outcome of markers that

can be of relevance for human health. Probiotic studies have shown beneficial effects in all age-related subgroups such as mother–infants pairs, preterms, newborns, infants and older children, elderly people.

To exemplify, fermented milk drinks with *L. casei* strain Shirota positively stimulate the immune system in healthy human subjects [26]. With respect to different age groups, the effects from long-term consumption of probiotic milk on infections was evaluated in children attending day care centers [27], while *L. delbrueckii* subsp. *bulgaricus* OLL1073R-1 was given to elderly persons with the aim of reducing the risk of infection [28].

In case the microbial community from a specific body region is disturbed (leading to the so-called dysbiosis), functional niches become available in the ecosystem. Examples of dysbiosis are the changes in microbial ecosystem in the mouth, associated with dental caries occurrence, or dysbiosis associated with bacterial vaginosis. The effects from probiotics on oral health in children were recently reviewed [29]. For example, long-term application of probiotic strains such as *L. rhamnosus* GG lowers the risk of dental caries in children [30]; the importance of probiotic supplementation during orthodontic therapy was also reported [31]. Similarly, microbial dysbiosis in the urogenital tract, more in particular bacterial vaginosis, can be tackled by probiotics as well [32]. *L. rhamnosus* GG and specific *L. acidophilus* strains have been used to treat bacterial vaginosis [33, 34]. Probiotics may also be applied orally to abate increased health risks that originate from the gut environment. *Helicobacter pylori*-colonized subjects have been treated with *L. casei* milk drinks [35] and *L. gasseri* OLL2716 (LG21) [36], while specific *Bifidobacterium* (*B.*) strains display anti-*Helicobacter* effects through the production of antimicrobial peptides [37]. However, in Crohn’s disease there is proof that dysbiosis occurs (either as cause or consequence), but probiotic supplementation has always failed to prevent relapse, except in pouchitis. In addition, there is specific attention for developing probiotic concepts for children under modified risks. Preterm babies display an increased risk for developing necrotizing enterocolitis, which is decreased by the application of oral probiotics [38].

Basis of the Biological Effect of Probiotics

The health benefits from probiotic products and applications are extremely diverse and are continuously expanded with new insights and scientific developments.

Microbiological Functionality

Microbiological functionality has a major objective of gaining control over the microbial homeostasis in a body environment and lower pathogen invasion and colonization. The resilience of a microbial community against invasion

by exogenous strains largely depends on the availability of non-occupied functional niches. If not all functional niches are occupied by the endogenous microbial community, there is an increased risk for pathogen invasion in the ecosystem, colonization, and subsequent infection.

Probiotic microorganisms can be applied to improve or restore microbial homeostasis in two scenarios. Firstly, they may occupy functional niches that are left open by the endogenous community, thereby avoiding (opportunistic) pathogens of occupying that niche. Such process is often referred to as competitive exclusion and primarily targets the competition for nutrients, physical sites (e.g., mucus adhesion) or receptors. The second scenario is more of an antagonistic nature as probiotics may actively lower (opportunistic) pathogen invasion or development into the ecosystem. Such approach primarily targets (i) the production of short chain fatty acids and other organic acids (e.g., lactic acid) by probiotics, thereby lowering the pH and increasing the bacteriostatic effect of organic acids towards pathogens, (ii) the production of bacteriocins, which are small microbial peptides with bacteriostatic or bacteriocidal activity, and (iii) production of reactive oxygen species, such as hydrogen peroxide, that are highly reactive and increase oxidative stress for pathogens in microenvironments.

Nutritional Functionality

Specific microbial groups produce vitamins and may thereby contribute to vitamin availability to the human host. Apart from vitamin K [39], vitamin B12 [40], and pyridoxin [41], other vitamins such as biotin, folate, nicotinic acid, and thiamine can be produced by gut microorganisms and thereby affect host health. Such activity from a microbial strain can be considered a probiotic effect.

Besides this, lactase deficiency causes lactose intolerance which results in abdominal cramping, nausea, and bloating. Probiotic strains that are lactase positive have been successfully applied to relieve discomfort from lactose intolerance [42].

Other nutritional functionalities may include the production of health-promoting compounds. The metabolic potency of gut microorganisms is enormous and may rival or even exceed that of the liver [43]. Gut environment harbors a wealth of small chemical factories that produce a plethora of chemical components with putative health-modulating effects [44]. Isolated strains that produce health-promoting products may also be considered as having probiotic potential. To illustrate, production of health-promoting conjugated linoleic acids (CLA) has been reported for *Bifidobacterium* strains [45], *L. plantarum* JCM 1551 [46] and specific *L. acidophilus* strains. Conversion of phytoestrogen precursors to bioactive metabolites by supplemented microorganisms is a potential pathway for future probiotic applications. For example, Decroos et al. previously isolated a microbial

consortium that converts soy-derived daidzein into the bioactive equol [47], while Possemiers et al. performed an in vitro investigation of the probiotic potential of *Eubacterium limosum* strains to convert hop isoxanthohumol into the 8-prenylnaringenin [48].

Physiological Functionality

Probiotic microorganisms have been reported to enhance GI transit. Hamilton–Miller previously reviewed such functionality for the application of probiotic products in elderly persons [49]. Other potential physiological effects may include the reduction by probiotics of bloating or gas production, the enhancement of ion absorption by intestinal epithelial cells [50] and the decrease of bile salt toxicity or the decrease of serum cholesterol levels by bile salt hydrolyase positive probiotics [51, 52].

Lowering Health Detrimental Components in the Gut

Probiotic microorganisms are also applied to reduce the health risks from hazardous components. For example, oral exposure to contaminants, either from a food matrix or from an environmental matrix (soil, dust, water, etc.) is the most dominant scenario by which the human body gets internally exposed to contaminants. These can be (i) mycotoxins, produced from fungi on a wide variety of crops, cereals in particular, (ii) xenobiotics with toxic properties as unwanted residues from environmental contamination of the food chain, or (iii) hazardous compounds from the food production process as such (e.g., polycyclic aromatic hydrocarbons (PAH) production during grilling of meat). The mode of action by which these probiotics lower the risk derived from ingested hazardous components often relates to the sorption of the compound to microbial biomass. This is, for example, the case for aflatoxin B1, which has been shown in vitro to be bound by probiotic strains [53]. Another mode of action may be direct detoxification of the hazardous compound such as the breakdown of fumonisin by *Pediococcus pentosaceus* (L006) that was isolated from corn leaves and that thus has probiotic properties. A final mode of action is more indirect and resembles the above mentioned probiotic modulation of microenvironment in the gut where (food) pathogens produce toxins. For example, the production of organic acids by probiotic microorganisms was reported to negatively affect the production of Shiga-toxin 2 from enterohemorrhagic *E. coli* O157:H7.

Immunological Functionality

The immunological benefits of probiotics can be due to activation of local macrophages and modulation of IgA production locally and systemically, to changes in pro/anti-inflammatory cytokines profile, or to the modulation of response towards food antigens [54, 55].

Probiotic Products in Prevention and Treatment

The following paragraphs are not meant to provide a complete overview of all indications in which probiotics have been studied as possible therapeutic intervention. We focused on the most relevant indications for children with disorders of the GI tract.

Acute Infectious Diarrhea

Probiotics have been largely studied to the prevention of acute infectious diarrhea. Large, randomized controlled trials (RCT) provide evidence of a very modest effect (statistically significant, but of questionable clinical importance) of some probiotic strains (*Lactobacillus GG*, *L. reuteri*, *B. animalis* subsp. *lactis*) on the prevention of community-acquired diarrhea [56–64]. *L. reuteri* protects for the development of diarrhea in Indonesian children with undernutrition [60]. For prevention of diarrhea acquired in day-care centers, many randomized and placebo-controlled trials have been published, conducted in different parts of the world. Probiotics tested were *Lactobacillus GG*, *B. animalis* subsp. *lactis*, alone or in combination with *Strepto. thermophilus*, and *L. reuteri*, *L. rhamnosus* (not GG), and *L. acidophilus*, in various trials either alone or in comparison with each other. The evidence of their efficacy in these settings is only modest for the prevention of diarrhea, although somewhat better for prevention of upper respiratory infections [61]. The number needed to treat (NNT) to prevent one child from developing nosocomial Rota gastroenteritis is seven [62]. However, the protective effect on prevention of diarrhea becomes far less significant if the incidence of diarrhea (episodes per patient-month) rather than the percentage of patients with diarrhea are taken into account [63]. In hospitalized children, the administration of *L. reuteri* DSM 17938 compared with placebo had no effect on the overall incidence of nosocomial diarrhea, including rotavirus infection [65].

The use of the following probiotics (in alphabetical order) may be considered in the management of children with acute gastroenteritis (AGE) in addition to rehydration therapy: *L. rhamnosus* GG (low quality of evidence; strong recommendation) and *S. boulardii* (low quality of evidence; strong recommendation). Less compelling evidence is available for *L. reuteri* DSM 17938 (very low quality of evidence; weak recommendation) and heat-inactivated *L. acidophilus* LB (very low quality of evidence; weak recommendation) [66]. The latter, although traditionally discussed with other probiotics, does not fit with the definition of probiotics. A number of RCTs have evaluated the effect of *Enterococcus faecium* SF68 [66]. A sub-group analysis performed within a Cochrane review (search date: July 2010) found that

Enterococcus SF68 reduced the risk of diarrhea lasting ≥ 4 days (4 RCTs, $n=333$; RR 0.21, 95% CI 0.08–0.52) [66]. However, in vitro studies have documented that the *E. faecium* SF68 strain is a possible recipient of the vancomycin resistance genes [67]. Considering that the risk for in vivo conjugation cannot be ruled out, probiotics with safety issues should not be used [66]. Other strains or combinations of strains have been tested, but evidence of their efficacy is weak or preliminary.

Antibiotic-Associated Diarrhea

The pooled relative risk in a meta-analysis of 63 RCTs, which included 11,811 participants, indicated a statistically significant association of probiotic administration with reduction in antibiotic-associated diarrhea (AAD; relative risk, 0.58; 95% CI, 0.50–0.68; $P<0.001$; I², 54%; (risk difference, -0.07 ; 95% CI, -0.10 to -0.05), (NNT 13; 95% CI, 10.3–19.1)) [68]. Another meta-analysis concluded the NNT was 8 [69]. According to a recent meta-analysis, probiotics reduce the risk of AAD in children significantly [70]. Pre-planned subgroup analysis showed that reduction of the risk of AAD was associated with the use of *Lactobacillus GG* (95% CI 0.15–0.6), *S. boulardii* (95% CI 0.07–0.6), or *B. animalis* subsp. *lactis* and *Strepto. thermophilus* (95% CI 0.3–0.95) [70]. For every seven patients that would develop diarrhea while being treated with antibiotics, one fewer will develop AAD if also receiving probiotics [70]. Only *S. boulardii* was reported to be effective in *Clostridium difficile* (*C. dif.*) disease [71–73]. Recently, a large single-center study showed in elderly that *S. boulardii* was not effective in preventing the development of AAD or in prevention of *C. dif.* infection [74]. In many studies, there is no evidence to support the use of any (other) probiotic to prevent the recurrence of *C. dif.* infection or to treat existing *C. dif.* diarrhea [59]. A new meta-analysis concluded that probiotics significantly reduce the incidence of pediatric AAD (22 trials; RR=0.42; 95% CO 0.33–0.53) and the incidence pediatric *C. dif.* infection (five trials; RR=0.35; 95%CI 0.13–0.92) [75]. *S. boulardii* (RR=0.43; 95% CI 0.32–0.60) and *L. rhamnosus* GG (RR=0.36; 95% CI 0.19–0.69) are the two best-studied strains [75]. In most studies, the probiotic is started together with antibiotic treatment [76].

Traveler's Diarrhea

Traveler's diarrhea is a frequent condition of great socioeconomic impact. It is one of these topics on which there are more reviews than original research published. Different RCTs have been performed evaluating the efficacy of probiotics in the prevention of traveler's diarrhea. One trial

with *L. acidophilus* and two with *L. GG* showed negative results [77–79]. One trial with *S. boulardii* reported a small but significant preventive effect in a subgroup, suggesting geographical differences in efficacy [80]. In a review, McFarland concluded that there is comparable evidence for efficacy for *L. rhamnosus* GG, *L. casei* DN-114001 and *S. boulardii*, and no efficacy for *L. acidophilus* [81]. Since the number of studies in traveler's diarrhea is very limited, a recent meta-analysis concluded that there is no efficacy of probiotics in traveler's diarrhea [82]. There are no data on prebiotics and prevention or treatment of traveler's diarrhea. Overall, the number of studies is too small to allow to formulate recommendations [83].

Irritable Bowel Syndrome

There is a large literature on the effect of probiotics on IBS in adults, but data in children are limited. A Cochrane review from 2009 failed to show an effect of fiber supplements and recorded a limited effect of *Lactobacillus* on symptoms compared to placebo (OR 1.17; 95% CI 0.62, 2.21) [84].

A RCT of 6 weeks with *Lactobacillus* GG versus placebo showed overall negative results in 50 children and young adults, although there was a lower incidence of perceived abdominal distension in *L. GG* group [85]. *Lactobacillus* GG but not placebo caused a significant reduction of both frequency and severity of abdominal pain compared to baseline and influenced intestinal permeability testing [86]. A meta-analysis showed that, compared with placebo, *Lactobacillus* GG supplementation is associated with a significantly higher rate of treatment responders in the overall population with abdominal pain-related functional GI disorders and in the IBS subgroup [87]. However, no difference was found in children with functional abdominal pain or functional dyspepsia who received placebo or *Lactobacillus* GG. A randomized crossover trial with VSL#3 and placebo for 6 weeks, with a 2-week washout period in between in 59 patients showed a superior effect of VSL#3 compared to placebo in symptom relief, as well as in abdominal pain/discomfort, abdominal bloating/gassiness, and family assessment of life disruption [83, 87]. No significant difference was found in the stool pattern [88].

There are no data on prevention or treatment of IBS with prebiotics. Data from one trial suggest that, in infants, a prebiotic-containing whey-based formula provides superior GI comfort than a control formula [89]. A peptide-based formula containing fiber was as well tolerated as a fiber-free formula in a small population of children with GI impairments [90]. Extremes of stool consistency were normalized with the fiber formula. No significant differences were observed in vomiting, abdominal pain, feeding intakes, or weight gain between the two formulas [90]. Synbiotics should be further investigated in this indication [91].

Helicobacter pylori

The use of probiotics in *H. pylori*-colonized subjects with gastric inflammation is supported by many observations. Specific strains of *Lactobacillus* and *Bifidobacterium* exert in vitro bactericidal effects against *H. pylori* through the release of bacteriocins or production of organic acids, and/or inhibit its adhesion to epithelial cells. Such protective effects have been confirmed in animal models. Clinical trials are very important, since in vitro results cannot always be reproduced in patients. Probiotics decrease the bacterial load and improve the immune response [92]. Results of clinical trials indicate that probiotics generally do not eradicate *H. pylori* but decrease the density of colonization, thereby maintaining lower levels of this pathogen in the stomach; in association with antibiotic treatments, some probiotics increased eradication rates and/or decreased adverse effects due to the antibiotics. Many studies show a moderate higher eradication rate (~10%) of *H. pylori* when probiotics are added to the antibiotics and proton pump inhibitor [93]. Although *Lactobacillus* GG seems not to improve eradication [94], most probiotic bacteria and yeasts reduce adverse effects of standard *H. pylori* eradication regimens [95, 96].

Constipation

Constipation is a frequent problem in childhood in which pre- and probiotics could have a positive influence on the intestinal flora with an effect on stool consistency and frequency. Unfortunately, study results are contradictory. In an open trial, *B. breve* was effective in increasing stool frequency in children with functional constipation [97]. Furthermore it had a positive effect with respect to stool consistency, decreasing the number of fecal incontinence episodes and in diminishing abdominal pain [97]. In another open trial, a probiotic mixture (Ecologic Relief®) containing *B. bifidum*, *B. infantis*, *B. longum*, *L. casei*, *L. plantarum* and *L. rhamnosus* showed positive effects on symptoms of constipation [98]. *L. rhamnosus* Lcr35 was effective in treating children with chronic constipation [99]. *B. animalis* subsp. *lactis* was reported to be non effective in constipation [82, 100]. *L. reuteri* DSM 17938 had a positive effect in infants with chronic constipation on bowel frequency, even when there was no improvement in stool consistency and episodes of inconsolable crying episodes [101]. A Brazilian study showed a positive influence of yoghurt on stool frequency with an additional effect of yoghurt supplemented with *B. longum* [102]. In constipated children, the fermented dairy product containing *B. animalis* subsp. *lactis* DN-173 010 did increase stool frequency, but this increase was comparable in the control group [103]. There is currently not sufficient

evidence to recommend fermented dairy products containing *B. animalis* subsp. *lactis* DN-173 010 in this category of patients [103]. No evidence for any effect was found for fluid supplements, prebiotics, probiotics, or behavioral intervention [104]. Until more data are available, probiotics for the treatment of constipation condition should be considered investigational [105].

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is a severe condition occurring especially in preterm babies. Abnormal GI flora development has been hypothesized as one of the possible etiologic factors. The first publication reporting that *L. acidophilus* and *B. infantis* reduced NEC dates back from 1999 [106]. This was followed by a negative study showing that seven days of *Lactobacillus* GG supplementation starting with the first feed was not effective in reducing the incidence of urinary tract infection, NEC and sepsis in preterm infants [107]. Then, several randomized trials with different lactobacilli and bifidobacteria showed a significant reduction in development of NEC [108, 109]. Although *S. boulardii* was shown to ameliorate hypoxia/reoxygenation-induced NECs in young mice [110], it did not protect for NEC in infants [111]. A Cochrane review concluded in 2008 that enteral probiotic supplementation reduced the incidence of NEC stage II or more and mortality [112]. No systemic infections or serious adverse events were directly attributed to the administered probiotic microorganism [112]. According to the published trials, the NNT to prevent one case of NEC is 21 and 27 [112]. However, the centers in which these trials have been performed have a much higher incidence of NEC than most European or North American centers. The recommendation may be different in centers with a high incidence of NEC in which the other measurements to decrease NEC are difficult to apply. The updated Cochrane review from 2011 comes to different conclusions: enteral supplementation of probiotics prevents severe NEC and all cause mortality in preterm infants [113]. The updated review of available evidence supports a change in practice. More studies are needed to assess efficacy in extremely low birth weight (ELBW) infants and assess the most effective formulation and dose to be utilized [113]. The debate to give systematically probiotics to preterms or not is still going on. The American Pediatric Surgical Association Outcomes and Clinical Trials Committee systematic review concluded in 2012 acknowledges that recent Cochrane reviews support the use of prophylactic probiotics in preterm infants less than 2500 g to reduce the incidence of NEC, as well as the use of human breast milk rather than formula when possible. There is no clear evidence to support delayed initiation or slow advance-

ment of feeds [114]. However, an expert group of nutritionists and neonatologists concluded that there is insufficient evidence to recommend routine use of probiotics to decrease NEC [115]. According to this group, there are encouraging data which justify the further investigation regarding the efficacy and safety of specific probiotics in circumstances of high local incidence of severe NEC [115]. According to others, available evidence is still too limited to recommend probiotics to reduced NEC [116]. Other experts suggest that it may become unethical to not give probiotics to preterm babies to decrease NEC [117].

Colic

Colic is a frequent problem in infants and often parents desperate for a solution. In this indication, the effect of *L. reuteri* has been exhaustively studied in breastfed infants [118–120]. However, there are no data with *L. reuteri* in formula fed babies. Dupont et al. reported efficacy of another probiotic strain in formula fed infants [121].

Allergy and Atopic Dermatitis

Simultaneous pro- and prebiotic treatment (a mixture of four strains and galactooligosaccharides, GOS) given to pregnant women during 2–4 weeks before delivery and to the infants during 6 months compared with placebo showed no effect on the cumulative incidence of allergic diseases at the age of 2 years but tended to reduce IgE-associated (atopic) diseases since a significant reduction of (atopic) eczema was noticed [122]. However, Taylor and coworkers challenge the role of probiotics in allergy prevention since they recorded that early probiotic supplementation with *L. acidophilus* did not reduce the risk of atopic dermatitis (AD) in high-risk infants and was even associated with increased allergen sensitization in infants receiving supplements [123]. A Cochrane review from 2007 concluded that there was insufficient evidence to recommend the addition of probiotics to infant feeds for prevention of allergic disease or food hypersensitivity [124]. Although there was a reduction in clinical eczema in infants, this effect was not consistent between studies and caution was advised in view of methodological concerns regarding included studies [124]. However, the efficacy of probiotic intervention to reduce atopic dermatitis and/or allergic disease may depend on the moment of intervention. Preventive administration of probiotics may be only effective if given during pregnancy. Probiotics given to unselected mothers reduced the cumulative incidence of AD, but had no effect on atopic sensitization [125]. A recent meta-analysis showed that the administration of lactobacilli during pregnancy

prevented atopic eczema in children aged from 2 to 7 years [126]. However, a mixture of various bacterial strains does not affect the development of atopic eczema, independent of whether they contain lactobacilli or not [126]. *L. rhamnosus* HN001 was reported effective against eczema in the first 2 years of life persists to age 4 years, while *B. animalis* subsp. *lactis* HN019 had no effect [127]. Therefore, not only timing of administration seems important but also strain specificity. However, timing of administration and strain specificity was then again contradicted by the meta-analysis by Pelucchi and coworkers, being in support of a moderate role of probiotics in the prevention of atopic dermatitis and IgE-associated atopic dermatitis in infants, but regardless of the time of probiotic use (pregnancy or early life) or the subject(s) receiving probiotics (mother, child, or both) [128]. The data on probiotics and allergy need further clarification, because data are somehow contradictory. It might be that geographical or genetic differences play a detrimental role, especially for atopic dermatitis.

Recently, in a double-blind, placebo-controlled multicenter trial, 90 infants with atopic dermatitis, age <7 months, were randomized to receive an infant formula with *B. breve* M-16V and a mixture of short chain GOS and long chain fructooligosaccharides (FOS), or the same formula without synbiotics during 12 weeks [129]. There were no significant differences between the synbiotic and the placebo group [129]. The same group showed that synbiotics prevent asthma-like symptoms in infants with AD [130]. At the same time, another group reported that a synbiotic combination of *L. salivarius* plus FOS is superior to the prebiotic alone for treating moderate to severe childhood AD [131]. While some studies with probiotics as a treatment for AD show a benefit [132], most studies are negative. No benefit was reported from supplementation with *B. animalis* subsp. *lactis* or *L. paracasei* in the treatment of eczema, when given as an adjunct to basic topical treatment, and no effect on the progression of allergic disease from age 1 to 3 years [133]. Most reviews conclude that probiotics are not effective in reducing atopic dermatitis. These contradictory results suggest strain specificity or a genetic influence on the efficacy of probiotics in children with atopic dermatitis. A review of 13 studies of probiotics for treating established eczema did not show convincing evidence of a clinically worthwhile benefit [134].

Extraintestinal Infections and Other Effects

No pediatric studies have demonstrated definite beneficial effects of administering probiotics to treat extraintestinal infections like respiratory tract infections or otitis media [76, 135]. There is no evidence that probiotics decrease

extraintestinal infections. There is some evidence that some lactobacilli might prevent recurrent urinary tract infection in women. However, data in children are lacking. The same is true for recurrent vulvovaginitis. Sazawal and coworkers showed that prebiotic and probiotic fortified milk prevented morbidities among children in a community-based RCT [136].

Candidiasis accounts for 10–20% of bloodstream infections in pediatric intensive care units (PICUs) and a significant increase in morbidity, mortality, and length of hospital stay [137]. A few studies have demonstrated that probiotics are able to prevent *Candida* growth and colonization in neonates, whereas their role in preventing invasive candidiasis in such patients is still unclear [137].

Purified phytases from *B. longum* subsp. *infantis* and *B. pseudocatenulatum* reduced the contents of phytate as compared to control samples (untreated or treated with fungal phytase) and led to increased levels of myo-inositol triphosphate [138]. This is the first example of the application of purified bifidobacterial phytases in food processing and shows the potential of these enzymes to be used in products for human consumption [138]. Lactic acid bacteria improve the synthesis of vitamins B2, B11, and B12 and have the potential strategies to increase B-group vitamin content in cereals-based products [139]. Vitamin-producing *Lactobacillus* have been leading to the elaboration of novel fermented functional foods [139].

Pandemic obesity is now matter of interest in all developed and developing countries. Treatment with probiotics selectively changes the composition of the gut microbiota in favor of specific genera and even strains. Few intervention studies with probiotics in overweight or obese individuals have been published until now, and mostly focus on *Lactobacillus* or *Bifidobacterium*. The administration of a strain of *L. gasseri* in obese and type 2 diabetic patients has been shown to decrease fat mass (visceral and subcutaneous) and body mass index [140]. In addition, Andreasen et al. have demonstrated that the administration of *Lactobacillus* spp. positively impact on insulin sensitivity [141]. Compelling evidence suggest that early gut microbiota modulation with probiotics reduces the body mass index in young children by restraining excessive weight gain during the first years of life (from 0 to 10 years of follow-up) [142]. Only few data are available until now, to have a clear view of the way by which lactobacilli or bifidobacteria can counteract adiposity.

Fecal Microbiota Transplantation

A new approach in the therapeutic applications of bacteria is transplantation of intestinal microflora, especially in difficult to treat condition in which it is known that the fecal

microbiota is abnormal [143, 144]. Observed side effects warrant caution in the ongoing pursuit of this treatment option [144]. There is evidence that many diseases are related to an intestinal dysbiosis. As a consequence, manipulation of the intestinal microbiota is a very attractive therapeutic approach. In spite of the fact that so far results have been often negative [144], and even bacteremia as an adverse event has been reported [145], positive results have also been achieved [146]. To improve safety, clearly the transplanted microbiota should be carefully screened for pathogens [147]. Encouragingly, the first cure of early onset colitis after fecal microbiota transplantation has been reported [148]. Interest should now focus on the reasons of success and failure, (see Chap. 35 “Fecal Microbial Transplant: For Whom, How, and When”).

Safety and Side Effects

Probiotics have a long record of safety, which relates primarily to lactobacilli and bifidobacteria [149]. Experience with other forms of probiotic is more limited. There is no such thing as zero risk, particularly in the context of certain forms of host susceptibility [149]. Probiotics are “generally regarded as safe” and side effects in ambulatory care have almost not been reported. Large-scale epidemiological studies in countries where probiotic use is endemic demonstrate (in adults) low rates of systemic infection, between 0.05 and 0.40% [150]. Administration during pregnancy and early infancy is considered safe [151]. Probiotic compounds may contain hidden allergens of food and may not be safe for subjects with allergy to cow’s milk or hen’s egg [152]. Documented invasive infections have been primarily noted to occur in immunocompromised adults. Invasive infections in infants and children are extremely rare [153–155]. Two cases of bacteremia attributable to *Lactobacillus* supplementation, with identical molecular clinical and supplement isolates, were recently reported in an infant and a child without underlying GI disease or immunocompromised status [156]. Sepsis with probiotic lactobacilli has been reported in children with short gut. Recently, plasmid transfer of antibiotic resistance has been shown to be clinically possible to occur. Long-term use of probiotics under antibiotic selection pressure could cause antibiotic resistance, and the resistance gene could be transferred to other bacteria [157]. Translocation from the gastrointestinal tract in the systemic circulation has not been reported. There is poor public understanding of the concept of risk, in general, and risk/benefit analysis, in particular [149]. Uncertainty persists regarding the potential for transfer of antibiotic resistance with probiotics, but the risk seems to be low with currently available probiotic products [149]. As with other forms of therapeutics, the safety of probiotics should be considered on a strain-by-strain basis [149]. The potential benefits of supplementation should be

weighed against the risk of development of an invasive infection resulting from probiotic therapy.

Conclusion

Probiotics have entered the mainstream of health care. The gastrointestinal microbiota is fundamental for the development of the immune system. Although the main indications of the medical use of probiotics is still in the area of the prevention and treatment of gastrointestinal-related disorders, gradually more evidence is collected on extraintestinal indications such as vaginitis, atopic dermatitis, respiratory tract infections. RCT with the commercialized product in the claimed indications are mandatory before the use of a product can be recommended. Today, *L. rhamnosus* GG and *S. boulardii* are the best studied strains. Although adverse effects have been reported, probiotics are considered as safe. Overuse and use of products that have not been validated constitute potential drawbacks.

Introduction

Enteral nutrition (EN) or enteral tube feeding (ETF) as currently practiced is a technique for nutritional support which delivers a homogeneous, liquid nutrition admixture into the digestive tract by tube, into the stomach, duodenum, or the proximal jejunum. The inception of enteral feeding dates back to 3500 years ago in ancient Egypt, when practitioners used rectal enemas to administer wine, milk, broth, and other nutrients to the ill [1, 2]. The first documented delivery of EN through a tube inserted into the esophagus was by Capi-vavaceus of Venice in 1598, who constructed a device from animal bladder. Recognition of the importance of nutrition therapy during injury and recovery from disease rapidly grew in the 1930s and 1940s, and led to development of specialized commercial enteral feeding products in the 1950s, and modern EN formulas in the 1970s [1, 2]. In 1980, Guaderer and colleagues at Rainbow Babies and Children's Hospital in Cleveland, Ohio, USA, were the first to describe the technique of inserting feeding gastrostomy tubes (GT) without requirement for laparotomy, that is, percutaneous endoscopic gastrostomy (PEG) tube [3]. EN may be administered via oral, nasal, gastrostomy, or jejunal routes (Fig. 46.1).

EN is used to preserve nutritional status, support normal growth, and treat malnutrition when oral feeding is inadequate or not possible. EN is more physiologic, usually safer, easier to administer, and less costly compared to parenteral nutrition (PN). Therefore, EN should be preferred to PN in infants and children with malnutrition and/or nutritional risk,

when the intestinal tract is usable to provide sufficient nutrients for achieving optimal growth or catch-up growth [4]. EN may be administered rapidly as a bolus into the stomach, or more slowly over several hours as a continuous infusion into the stomach, duodenum, or jejunum. The underlying disease and patient tolerance are what determines whether to use bolus or continuous feeds. The physiological basis of continuous EN makes it of great interest in pediatric patients with feeding intolerance and other gastrointestinal (GI) disorders [4]. EN may be used as the sole source of nutrition or to just supplement a patient's oral and/or PN intake. Also, depending on the indication, EN may be used daily or just on a periodic basis. While EN is normally initiated in the hospital, continuing it at home has become a common option. Home EN may be used long term or just as a temporary bridge until children achieve oral food intakes that support adequate growth and nutritional status. Even though home EN is an effective method of meeting a child's growth and nutritional requirements, health practitioners should not disregard the mixed acceptance by families and sometimes negative impact on quality of life [5–7].

Physiological Basis of Continuous Enteral Feeding

Gastrointestinal Motility

The rate of gastric emptying, and secretion of pancreatic biliary fluids, is regulated by the infusion rate, calorie density, and osmolality of the enteral feeds [8]. In case of gastric administration of continuous feeds, a rate of continuous gastric emptying related to the infusion rate can be achieved if the infusion rate, calorie density, and osmolality of the mixture are not excessive. Steady-state gastric emptying of 1 kcal/mL formula can be maintained at infusion rates of ≤ 3 mL/min. When the infusion rate is excessive and higher than the gastric emptying rate, the risk of vomiting increases. As caloric load and/or osmolality of the formula increase, the

gastric emptying rate is reduced to maintain a constant calorie load delivered into the duodenum. Thus, EN consisting of very calorie-dense formulas should initially be administered very cautiously. The individual nutrient composition of the formula has a lesser effect on gastric emptying function than the caloric density, except for the type of triglyceride: In fact, long-chain triglycerides (LCTs) cause greater delays in gastric emptying than medium-chain triglycerides (MCTs)

Gastric emptying is dependent on duodenal function. The effects of continuous enteral nutrition (CEN) on intestinal motility can be analyzed by manometry. Motor migrating complexes are observed in adults during CEN, as during fasting state [9]. In small preterm infants, duodenal motor activity is higher following slower infusion of gastric feeds than with rapid boluses, and this is associated with lower postprandial gastric contents [10]. During administration of jejunal feeds, energy loads at rates within the physiologic range of gastric emptying (≤ 4 kcal/min) initiate normal-motor small-bowel motor responses; however, increasing the osmolality (> 600 mosmol) has a significant inhibitory effect on small bowel contractile and propagative activity [11] and thus greater likelihood for intolerance. Very few data are available about the changes of colonic motility induced by CEN; the continuous gastric infusion of nutritive formula modifies the gastrocolic reflex. Gallbladder motility is maintained during CEN as assessed by increased serum cholecystokinin (CCK) and ultrasonography [11, 12]. Emulsified LCTs delivered to the duodenum have a potent stimu-

lating effect on CCK release and gall bladder contraction [13]. Conversely, whereas dietary MCTs are more efficiently absorbed and rapidly metabolized compared to LCT's [14], they are very weak stimulants for CCK release, gall bladder contractility, and hence luminal postprandial bile acid concentrations. Biliary complications such as sludge or cholelithiasis are rare during long-term CEN.

Digestive Secretion and Hormonal Response

Gastric secretion depends mostly on protein intake, and, in case of elemental diet, on amino-acids composition; secretory response is not influenced by carbohydrates but reduced by lipids. It has not been demonstrated whether or not the type of diet (i.e., elemental, semi-elemental, or polymeric) modifies gastric acid secretion [15]. Secretion of CCK and pancreatic polypeptide (PP) are maintained during CEN [12]. All forms of oral and enteral feeding stimulate pancreatic synthesis and secretion through CCK and PP. Pancreatic secretions can be reduced by 50% if a low-fat elemental formula is used for duodenal feeding. Stimulation of pancreatic trypsin synthesis or secretion can be inhibited by delivering EN into the mid-distal jejunum [16]. The mechanism involves increased secretion of the 'ileal-brake' hormones glucagon-like peptide-1 (GLP-1) and peptide YY (PYY) [17, 18] which inhibit production of pancreatic secretions and motility in the proximal GI tract. Gastrin secretion

is also maintained during CEN, but its response to protein load is decreased. Gastric or duodenal CEN stimulate insulin secretion depending on the type of infused nutrients. The glycemic and insulinemic response induced by EN parallels that of oral feeds and significantly lower than PN [16]; therefore, less risk for steatosis.

Effects of CEN on Mucosal Trophicity

The effects of elemental formulas (totally absorbed in the upper GI tract and providing minimal residue to the distal bowel) on small bowel mucosal trophism remain controversial. In studies, comparing intestinal trophicity and function in animals fed elemental diets versus regular chow, there was similar digestive function but significantly decreased mucosal mass in the distal bowel of animals-fed elemental diets. These changes could be the consequence of the almost complete absorption of nutrients within the proximal part of the small bowel, leading to lack of stimulation of the distal segment. This suggests an ability of EN to achieve bowel rest in the distal part of the bowel, providing efficient treatment for ileocolic inflammatory diseases.

Effects of CEN on Energy Expenditure and Feeding Tolerance

Thermogenic effect of feeding is related to the increase of energy expenditure for synthesis and secretion of digestive

enzymes following ingestion of food. The increase in energy expenditure induced by CEN in normal subjects is lower than when the same nutrients are administered by bolus feed [19]. Finally, the slow and continuous administration of nutrients into the GI tract through CEN allows the achievement of optimal utilization despite intestinal illness. In fact, by changing the conditions of flow and of contact between the nutritive formula and the digestive tract, CEN may increase the capacity for intraluminal digestion and intestinal absorption. This feeding technique does not appear to provide benefit in patients without intestinal disease [20, 21]; however, it seems logical and efficient when the absorptive surface is reduced, for example, short bowel syndrome (SBS), villous atrophy, enterocutaneous fistula, or proximal enterostomy. CEN has been associated with better feeding tolerance, nutrient absorption, and growth than boluses or oral feeds in infants and adult patients with intestinal disease [22, 23].

Indications

Indications for EN are different from indications for PN, since the use of EN as nutritional support is based on normal or at least partially preserved gut functions. The decision tree for the route of feeding is determined based on aspiration risk, motility function of the stomach, and anticipated duration of need for EN support. See Fig. 46.2. EN can be used on any patient with normal GI absorptive function but unable to adequately be fed by mouth. The conditions commonly encountered are listed in Table 46.1.

Fig. 46.2 Decision tree for the route of EN. *GER* gastroesophageal reflux, *PN* parenteral nutrition, *GI* gastrointestinal, *PEG* percutaneous endoscopic gastrostomy, *PEG/J* percutaneous endoscopic gastrostomy/jejunostomy, *G-tube* gastrostomy tube

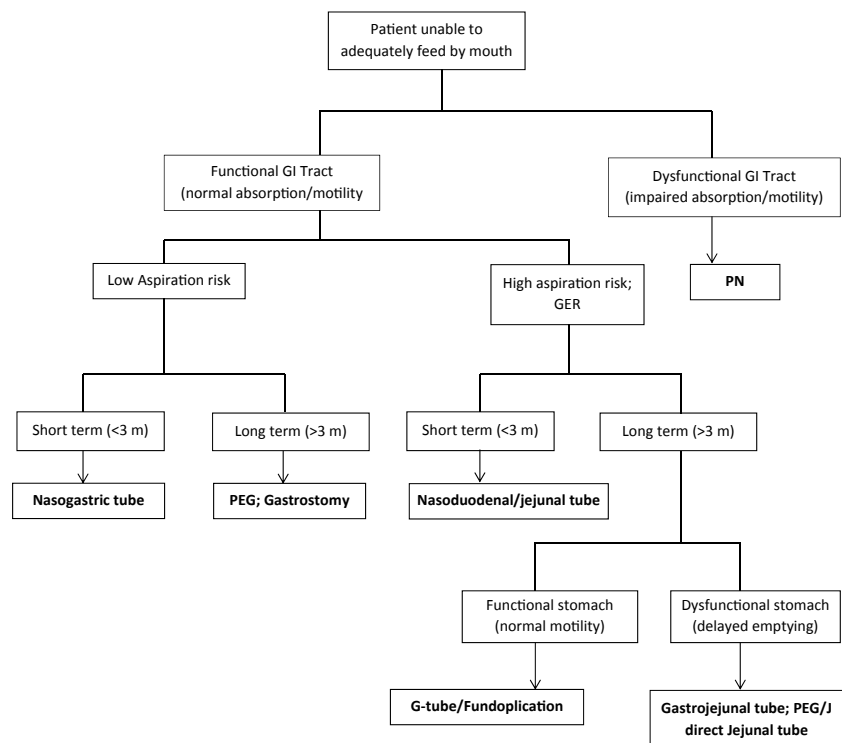

Table 46.1 Conditions commonly managed with EN

<i>Conditions with normal intestinal absorptive function</i>
Preterm infants
Critically ill patients
Nonorganic FTT
Anorexia
Inborn errors of metabolism
Glycogen storage diseases, urea cycle defects
Chylothorax
<i>Hypermetabolic states</i>
Head injury, graft versus host disease (GVHD), renal failure, congenital heart disease
<i>Digestive disorders</i>
Protracted diarrhea of infancy/childhood
Short bowel syndrome
Intestinal pseudo-obstruction
Crohn's disease
<i>Malabsorption disorders</i>
Cystic fibrosis
Chronic liver disease
FTT failure to thrive

Conditions with Normal Intestinal Absorptive Function

EN is required in cases of inability to eat normally, that is, in those situations that are secondary to structural or functional abnormalities of the upper GI tract or neurological impairment of the processes involved in sucking and/or swallowing (see also Chap. 20 on “Disorders of Sucking and Swallowing”). Esophageal diseases including esophageal atresia, fistula, or stenosis, often resulting from sequel of epidermolysis bullosa, are among the conditions that can benefit from EN, usually through gastrostomy or duodenal tubes [24, 25]. The choice of feeding through gastrostomy versus transpyloric tube must be assessed according to the patient age, disease, and condition (Fig. 46.2). Children with chronic diseases inducing immaturity or inability to feed orally, especially with sucking and swallowing troubles as seen in neurologically impaired children, with neuromuscular chronic diseases or cerebral palsy also require EN, using GTs.

Premature Infants

EN via nasogastric or orogastric tube is routinely used in premature infants younger than 32 weeks' gestation because of uncoordinated suck, swallow, and breathing related to immaturity [26]. Human milk is the preferred feed because of its immunological benefits. Preterm infant formulas come fortified with protein, calcium/phosphorous, and a calorie density of 22–24 kcal/oz. to meet the high nutritional requirements of infants. A Cochrane systematic review of treatment trials did not provide evidence of any beneficial effect from transpyloric feeding over gastric feeding on feeding tolerance, growth, and development in preterm infants

[27]. Therefore, gastric feedings administered by bolus or continuously is the preferred approach for EN in preterm infants, where its use appears to also have a role in preventing necrotizing enterocolitis [28] (see also Chap. 6 on “Enteral Nutrition in Preterm Neonates” and Chap. 7 on “Parenteral Nutrition in Premature Infants”).

Eating Disorders: Anorexia

Anorexia nervosa (AN) is a life-threatening psychiatric condition characterized by disordered eating behaviors, significantly lower than expected body weight, intense fear of becoming overweight, and a distorted body image. It is managed by a multidisciplinary team of health providers including psychiatrists, adolescent medicine pediatricians, nutritionists, and social workers. Indications for inpatient therapy include presence of suicidal or aggressive behaviors; severe bradycardia, hypotension, electrolyte imbalance, dehydration, and hypothermia; and medical complications, for example, seizures and pancreatitis [29]. Weight restoration is one of the major predictors for favorable short- and long-term outcomes in patients with AN [30]. Also, restoration of body weight is associated with improvements in malnutrition-induced cognitive impairments thus facilitating psychological and psychiatric therapy [31].

Nutritional support in AN remains very controversial. The oral feeding route is preferred; however, patients are given the option of voluntary or forced EN if resistant to therapy and/or severe malnutrition, that is, body mass index (BMI) < 13 kg/m² in adolescents [32] and weight-for-height z score < -3 in younger children [33]. Other options like GT and PN are considered in young children or severe and chronic cases [29]. Follow-up of adults treated with EN during adolescence did not show any long-term benefits or adverse outcomes on growth, recovery, or persistence of AN or risk for development of psychiatric comorbidities [34]. The initial range of prescribed energy intake varies from 10–60 kcal/day to 1000 kcal/day and > 1900 kcal/day with progressive increase during the course of hospitalization [29, 30]. The main complication of nutritional management is risk for developing re-feeding syndrome: hypophosphatemia, hypokalemia, edema, and increased hepatic transaminases. The risk factors associated with re-feeding syndrome include greater severity of malnutrition, abnormal electrolytes prior to re-feeding, use of EN or PN, and weight loss > 15% within the preceding 3 months [29, 30]. Patients may be preemptively treated with phosphate supplements during the early phases of nutritional management.

Inborn Errors of Metabolism

EN is part of the standard therapy used to prevent biochemical abnormalities, metabolic decompensation, and catabolism in patients with inherited disorders of metabolism, for example, hepatic glycogen storage disease (GSD) and

enzyme deficiencies of the urea cycle. Patients with GSD type 1 (glucose-6-phosphatase deficiency) develop hypoglycemia and compensatory biochemical abnormalities of lactic acidosis, hyperuricemia, hyperlipidemia, and platelet dysfunction all stemming from the primary defect of inability to dephosphorylate glucose-6-phosphate to free glucose. Managing GSD type 1 involves overnight continuous high-carbohydrate feedings and frequent daytime feedings supplemented with uncooked cornstarch [35, 36]. EN consisting of a glucose/glucose polymer solution or a sucrose-free, lactose-free/low formula enriched with maltodextrin may be used. EN should be started within 1 h after the last meal. Likewise, an oral or EN should be given within 15 min after discontinuation of the continuous EN because of the risk for hypoglycemia. Gastrostomy is contraindicated in patients with GSD type 1b because of complications in case development of inflammatory bowel disease or local infections [36]. Continuous EN should provide a glucose infusion rate of 7–9 mg/kg/min in children younger than 6 years, 5–6 mg/kg/min in children aged 6–12 years, and 5 mg/kg/min in adolescents [36]. Intermittent feedings of uncooked cornstarch may be used if continuous nighttime EN is not an option. No significant differences in biochemical parameters or growth have been found between patients with GSD type 1 receiving overnight continuous EN compared to scheduled feeds of uncooked cornstarch [37, 38]. The starting dose for uncooked cornstarch is 0.25 g/kg and optimal dose is 1.75–2.5 g/kg of ideal body weight every 6 h [36, 37, 39]. Patients with GSD type 3 (debrancher enzyme deficiency) have impeded glycogenolysis; however, gluconeogenesis is endogenously enhanced to maintain adequate glucose production. Therefore, nutritional management of patients with GSD type 3 involves frequent high-protein feedings during the day and a high-protein snack at night. Patients with GSD IV (brancher enzyme deficiency), GSD VI (phosphorylase deficiency), and GSD IX (phosphorylase kinase deficiency) respond to the high-protein diets similar to what is recommended for patients with GSD type 3 [40].

Inherited defects in urea synthesis are inborn errors of nitrogen detoxification and arginine synthesis due to defects in the urea cycle enzymes namely carbamylphosphate synthetase 1, ornithine transcarbamylase, arginosuccinate synthetase, arginosuccinate lyase, and arginase [41]. They may present at any age with symptoms ranging from poor feeding to coma shock and death. Other clinical symptoms may include lethargy, vomiting, ataxia, confusion, behavior changes, hypotonia or spasticity, hyperventilation (leading to respiratory alkalosis), and seizures. The main biochemical abnormalities are hyperammonemia and increased plasma concentrations of glutamine [42]. The symptoms of metabolic crisis are usually precipitated by protein intake in excess of what the patient can metabolize, catabolism of lean body mass resulting from intercurrent infection, trauma, in-

adequate energy intake, or inadequate intake of protein or essential amino acids. Management of patients with urea cycle defects involves a combination of carefully restricting protein intake and therapy with nitrogen-scavenging drugs, for example, sodium benzoate, sodium phenyl acetate, or sodium phenyl butyrate [41]. The nutritional management includes: (1) administration of sufficient energy to support anabolism, (2) restriction of protein intake to that tolerated by the patient without producing excess NH₃, (3) provision of essential amino acids in adequate amounts to support growth, (4) supplementation of “conditionally” essential arginine or citrulline in all except arginase deficiency, and (5) provision of all required minerals and vitamins in adequate amounts for age [43]. During hyperammonemic metabolic crisis, the nutritional management consists of providing high-energy low-protein intakes [44]. Successful long-term management requires a dedicated metabolic dietician and physician to make dietary adjustments and closely monitor progress. Patients with neurological handicaps or developmental delays, feeding difficulties, poor appetite/refusal of food, compliance problems with the diet, and/or medications will require use of nasogastric or gastrostomy feeding tubes to ensure adequate intake [41, 45]. Patients in metabolic crisis with symptomatic hyperammonemia (>500 μM/L) and/or lack of response despite 4 h of medical treatment should have management escalated to dialysis [41].

Hyper Metabolic States

Hypermetabolic states include patients with burns, cancer, and head injury. Much of the morbidity and mortality in severely burned patients is connected to the prolonged hypermetabolism and catabolism, impaired wound healing, and sepsis. Whenever, GI function permits, EN is superior to PN in patients with burns [46]. EN results in better regulation of the postburn catabolic hormones and inflammatory cytokine responses than PN [46, 47]. Furthermore, early EN support of patients with severe burns helps maintain gut mucosal integrity, which has the beneficial effect on reducing risk for enterogenic infections [48].

Graft Versus Host Disease

Traditionally, PN is given as the first option for nutrition support in children undergoing chemotherapy and/or bone marrow/stem cell transplant. The reasons cited range from intestinal injury and poor GI tolerance secondary to conditioning and myeloablative therapy; intestinal graft versus host disease (GVHD), oral mucositis, epistaxis, and parental refusal of EN. However, whenever GI function permits, EN is equally as effective as PN, associated with lower risk for infection, and more cost-effective [49–52]. A prospective study comparing EN and PN in children with bone marrow

transplants had poor enrolment into the EN group. Initiation of EN prior to transplant was associated with better overall tolerance. The EN group was also less likely to develop cholestasis [51]. A more recent Cochrane database review of nutrition support in patients of all ages with bone marrow or stem cell transplants failed to find evaluable data that properly compared efficacy and superiority of EN versus PN. However, the overall findings suggested that in patients without GI symptoms, intravenous fluids and oral diet should be considered as preference to PN [53].

Renal Failure

Supplemental nutrition should be given to children with renal failure to promote positive nitrogen balance and meet energy needs [4]. Children with chronic renal failure are at risk for malnutrition and growth retardation from persistent anorexia, inadequate protein calorie intake, chronic metabolic acidosis, azotemia, hormonal and metabolic disturbances, and catabolic diseases associated with uremia, for example, infections. Long-term EN is effective in preventing growth retardation in children with chronic renal disease and persistent anorexia, especially if started before the age of 2 years [54, 55] but singly may not lead to catch-up growth [56]. There is a positive correlation between efficacy of dialysis and linear of children with chronic renal failure [57]. Therefore, the combination of aggressive nutrition support with whey protein-based formulas in children age <2 years, whole protein enteral formula (1–1.5 kcal/mL) in older children [58], and enhanced dialysis is necessary for inducing growth in children with chronic renal failure [59]. Growth hormone therapy is recommended if there is persistent growth retardation despite adequate nutrition support [58, 60]. Ultimately, catch-up growth in height is mainly seen in children who undergo renal transplant before the age of 6 years [61].

Congenital Heart Disease

Inadequate calorie intake is the predominant cause of growth failure in infants and children with congenital heart disease. Different approaches for nutrition intervention are utilized during the preoperative, postoperative, and post-discharge periods, respectively [62]. Infants with cyanotic congenital heart disease and complex ventricular lesions are particularly susceptible to malnutrition and growth failure [63]. Approximately, 50% of infants with surgically treated uni-ventricular lesions get discharged home on EN via nasogastric or GT [64]. The causes of malnutrition include an imbalance between energy intake and increased expenditure particularly in children with congestive heart failure. Infants with severe congenital heart disease have normal resting energy expenditure [65, 66] but increased total energy expenditure [67], thus indicating that they expend large amounts of energy above basal requirements, which places them at risk

for inadequate calorie intake when feeding at normal rates. Perioperative injury to the recurrent laryngeal nerve may lead to feeding difficulties from swallowing dysfunction and vocal cord paralysis [68]. Other contributing factors include pulmonary hypertension, tachypnea and fatigue interfering with oral feeding, medications associated with anorexia, for example, diuretics, prescription of fat-restricted diets in patients who develop chylous effusions, and GI nutrient loss in patients who develop post-Fontan protein-losing enteropathy. Post-Fontan protein-losing enteropathy is managed with therapies directed at improving cardiac hemodynamics and controlling inflammation [69].

Digestive Indications

Since EN has a trophic effect on the intestinal mucosa, and helps maintain mucosal integrity, it plays an important role in the treatment of many digestive diseases, either replacing or complementing oral feeding. Digestive diseases leading to an anatomical or functional reduction of the absorption capacity of the small bowel represent the first group; they include SBS, protracted diarrhea with villous atrophy, and inflammatory bowel disease.

Severe Protracted Diarrhea of Infancy

A syndrome of intractable diarrhea of infancy was first described by Avery et al in 1968. Its definition, presentation, and outcome have considerably changed during the past two decades [70]. This syndrome could now be defined as persistent diarrhea despite prolonged bowel rest requiring long term-total parenteral nutrition (TPN) in children when no effective treatment is available [71, 72]. According to that definition, EN in this circumstance is indicated and often effective [73]. In fact, the reduction of digestive secretions, villous atrophy, and acquired brush border disaccharidase deficiency lead to malabsorption and malnutrition. Most of the time, a short course of PN followed by protracted CEN provides control of the disease within 6–8 weeks [74, 75]. In a prospective study of CEN versus PN, Orenstein showed that the resolution of diarrhea was faster in the enterally fed group [75]. The use of CEN in children and mainly infants with protracted diarrhea presenting also severe malnutrition may prove difficult. If the response to CEN is not good enough to provide rapidly adequate caloric supplies with resolution of diarrhea, PN should be started. Such decisions must be taken by experienced teams in specialized and well-staffed units. Severely malnourished infants with some types of particularly severe celiac disease, intolerance to cow milk proteins, protein hydrolysates, or with specific malabsorption syndromes, such as Anderson's disease may also benefit from CEN [76].

Short Bowel Syndrome

SBS is the leading cause of intestinal failure in newborns as well as infants and young children, and it is most commonly the result of an extensive intestinal resection during the neonatal period. EN is often used in these circumstances, although several controversies over the ideal nutritional treatment of children with SBS remain [77]. Of note, intestinal failure may also lead to liver disease [78] (see also Chap. 43 on “Short Bowel Syndrome”).

Congenital and Newborn Intestinal Disorders and Pseudo-obstruction

In neonatal abdominal surgery for congenital or acquired disease, CEN, usually combined with PN, offers prolonged nutritional support which has transformed the prognosis in many conditions and is particularly important in the following situations: (1) reduction of the absorptive surface with enterocutaneous fistulae or extensive intestinal resection; (2) functional disorders of gut motility, such as malfunctions of duodenojejunal anastomosis, “plastic” peritonitis after repeated interventions, gastroschisis, and omphalocele.

Chronic intestinal pseudo-obstruction syndrome is a disabling disorder of enteral feeding characterized by repetitive episodes or continuous symptoms and signs of bowel obstruction, including radiographic documentation of dilated bowel with air–fluid levels, in the absence of fixed-lumen-occluding condition [79]. Pseudo-obstruction is classified as “congenital” if newborn infants present with symptoms persisting for the first 2 months of life. “Acquired” pseudo-obstruction applies when previously well patients present with feeding intolerance from pseudo-obstruction symptoms persisting longer than 6 months [79]. Most patients with intestinal pseudo-obstruction require decompression stomas, ileostomies, and colostomies to relieve the recurring obstruction symptoms. Long-term PN is required in a significant proportion of children with pseudo-obstruction [80–82], and even then, administration of at least small volumes of CEN is essential and encouraged for prevention of PN-associated liver disease [83] and maintenance of bowel mucosal integrity [84].

Crohn’s Disease

Enteral feeding has been used for many years, particularly in Europe, not only to improve nutritional status and growth but also to influence disease activity in patients with Crohn’s disease [85–94]. It was shown that CEN diet is as effective as high-dose corticosteroids in inducing remission in pediatric patients with Crohn’s disease and has the added benefit of improved growth and development without the steroid side effects [95, 96]. However, serial meta-analysis conducted by Griffiths et al. in 1995, 2001, and 2007 suggested that therapy with EN was inferior to corticosteroids for inducing clinical response in patients with active Crohn’s disease [97–99]. All

three analyses largely included adult studies, and several pediatric studies showing striking efficacy were excluded owing to methodological weakness. A more recent meta-analysis that focused on 11 randomized controlled pediatric studies still reported similar efficacy for EN and corticosteroids for inducing remission in Crohn’s disease but also cited limited data [100]. The benefits of EN appear to be more favorable in children than adults including correction of impaired growth. Thus, EN is an underused therapy with the advantage of preserving growth while remission is achieved and therefore must be promoted [101]. There is no relevant data showing any significant difference in clinical outcome based on composition of the EN, that is, elemental, protein hydrolysates, or polymeric formula. Indeed, the beneficial effect in achieving remission appears not to be related to the mode of delivery or to the type of diet (no beneficial effect of elemental versus polymeric or semi-elemental) but rather to the reduced antigen load and mostly to changes in the intestinal microbiota [95]. Removal of antigenic material, alteration in intestinal micro flora, changes in gut hormone levels, and the presence of bioactive transforming growth factor- β (TGF β -1) in casein-based formulas may all play a role in the clinical success of EN [102, 103]. Glutamine-enriched polymeric diet offered no advantage over a standard low-glutamine polymeric diet in the treatment of active Crohn’s disease [104]. EN may be also helpful in correction or maintenance of the nutritional state, especially during a relapse of Crohn’s disease [96]. EN is part of the preparation for surgical procedure and may be useful during recovery, especially after intestinal resections or enterostomies. In case of severe digestive involvement during Schönlein–Henoch purpura, CEN can be used as nutritional support in the absence of occlusion [105]. More on the treatment of Crohn’s disease can be found in Chap. 28.

Other Malabsorption Syndromes

Cystic Fibrosis

Malnutrition and impaired growth affects approximately 23% of children with cystic fibrosis (CF) [106], and growth within the normal range of weight-for-length and BMI is associated with better pulmonary function and long-term survival. In 2008, the CF Foundation recommended that growth assessment using percent ideal body weight (%IBW) be discontinued, and instead rely on age-appropriate weight-for-length percentiles in children aged <2 years, and BMI percentiles in children aged 2–20 years. The nutritional goals in children with CF are to maintain and support growth at weight-for-length or BMI at or above the 50th percentile [106]. Growth abnormalities in patients with CF have a multifactorial etiology including active CF-pulmonary or sinus disease, inadequate or ineffective pancreatic enzyme

therapy, inadequate calorie intake, anorexia, presence of CF-related hepatobiliary disease, CF-related diabetes, infectious enteritis, small bowel bacterial overgrowth, and other comorbid intestinal conditions including, for example, celiac disease, inflammatory bowel disease and SBS [107]. Whereas these disorders require specific therapy, nutrition monitoring and intervention in patients with CF should always be implemented regardless of comorbid disease. Improved weight status in patients with CF often requires energy and protein intakes ranging from 110 to 200% of normal needs in healthy people [108, 109]. However, even with an optimal approach to oral feeding, some patients respond poorly to nutritional counseling alone. Therefore, use of EN to supplement dietary intake is recommended to help restore and maintain nutritional status, especially in children aged 13 years and older who present with persistent growth deficits despite nutrition counseling [106]. The utilization of supplemental EN by patients with CF increased from 8.5% in 2001 to 11.1% in 2011 [110] thus indicating greater engagement of nutritional therapy. EN is generally performed during the night over 8–10 h with the initial goal of providing 30–50% of the estimated requirements [107]. Patients with CF are then asked to eat and drink as much as possible during the daytime. Standard formulas containing intact protein, long-chain fat and calorie densities of 1.5–2.0 kcal/mL are generally well tolerated with appropriate dosing and administration of pancreatic enzymes [107, 111]. Semi-elemental formulas may be tolerated better in patients with excessive anorexia, bloating, or nausea. The data are unclear whether formulas with medium-chain triglycerides are advantageous over regular formula in patients with CF [107].

Nasogastric tube (NGT) feeding is generally used as a first step. The tube is passed every night, 1–2 h after dinner, and removed in the early morning before physical therapy so that patients are not disturbed during the daytime for school attendance. In some children, NGT becomes increasingly uncomfortable because of nausea, vomiting, nasal discomfort as a result of nasal polyposis, or dislodgement during coughing in cases of pulmonary exacerbation. PEG is the preferred modality for administering home nocturnal EN when long-term EN is anticipated. Generally, PEGs are perceived well by patients with CF who rely on EN therapy for poor weight gain or weight loss. On the contrary, patients and families without PEGs were found to be apathetic towards their value, citing fear of interference with activities, embarrassment, pain, and discomfort [112]. Therefore, there is need for more accurate information about benefits and lifestyle in patients with PEGs. Good early childhood nutritional status is associated with better pulmonary function and long-term survival in patients with CF [113]. However, poor growth and advanced lung disease have been associated with poor outcomes regardless of adherence to EN [114]. There is also currently insufficient evidence to determine whether nutritional rehabilitation after onset of malnutrition improves

pulmonary function in patients with advanced CF-related lung disease. Therefore, the importance of a proactive approach of growth monitoring and early nutritional intervention to optimize growth in children and adolescents with CF. It is important to assess for gastroesophageal reflux before starting EN. Patients should also be monitored for glucose intolerance during administration of EN, especially during illness, therapy with steroids, and if not gaining weight. Insulin therapy should be administered as needed in patients with glucose intolerance [107].

Chronic Liver Disease

Mechanisms leading to protein-energy malnutrition and requirement for EN in infants and children with chronic liver disease are multifactorial and dependent on the type of liver injury [115]. Malnutrition in cholestatic liver disorders is from reduced biliary secretion and intraluminal bile concentrations resulting in malabsorption of lipids and fat-soluble vitamins [116]. Protein and energy requirements are increased by different mechanisms including hypermetabolism [117], portosystemic shunting and ascites, futile metabolic pathways [118], and the energy demands from complications such as sepsis or variceal bleeding [119]. Liver disease from inborn errors of metabolism, for example, galactosemia, tyrosinemia, GSD, and Wilson's disease requires specific dietary restrictions and EN feeding protocols to prevent hypoglycemia and other forms of metabolic decompensation. Patients with fulminant hepatic failure may be well nourished and nutritionally independent at clinical presentation but later require EN because of impaired mental status. Anorexia is common in children with chronic liver disease resulting from organomegaly, abdominal pressure effects of ascites, congested gastric mucosa, reduced motility from portal hypertension, central effects of unidentified toxins, dietary manipulations such as fluid restriction, or use of unpalatable feeds. Several factors contribute to long-chain polyunsaturated fatty acids (PUFAs) deficiency including low PUFAs intake, malabsorption, and disturbed metabolism of long-chain PUFAs. Finally, the interaction of growth hormone with insulin-like growth factor 1 (IGF-1) and its binding proteins constitute an important mechanism linking nutrition and growth.

The most common cause of cirrhosis in children is biliary atresia, and the only definitive therapy is liver transplantation [120]. A total of 60–80% of affected children are moderately to severely malnourished prior to transplantation [116], and poor nutritional status prior to transplantation is associated with prolonged hospital stay, increased risk for death at high cost of medical care [119, 121, 122]. Supplemental EN or PN to improve nutritional status is the one intervention known to improve pre- and posttransplant growth and clinical outcomes in children with end-stage liver disease [123–127].

Anorexia, inadequate calorie intake, and failure to thrive are prevalent in children with chronic liver disease [116];

therefore, EN is recommended to supplement per oral food intake [119]. NGT feeding may be safely used without increased risk for bleeding in patients with portal hypertension varices [128, 129]. PEGs should be avoided in children with chronic liver disease and portal hypertension because of likely portal-hypertensive gastropathy with increased bleeding risk from gastric varices [119]. MCTs are nutritionally advantageous in patients with cholestasis because of no bile requirement for digestion and rapidly absorbed into the portal circulation. MCTs may be administered separately as supplements; however, the selected EN should not contain more than 80% of fat as MCT because of risk for inducing essential fatty acid deficiency [130]. Children with weight-for-length z scores < -3 fall into the category of severe malnutrition and > 9 -fold risk for mortality [131] therefore should be prioritized for nutritional intervention. Patients with chronic cholestatic liver disease have increased metabolism [117], futile metabolic pathways [118], and malabsorption; therefore, the goal for supplemental EN to enable a daily calorie intake of 140–200% of estimated requirements [116]. Children with chronic cholestatic liver disease should continue receiving fat-soluble vitamins (A, D, E and K) regardless of amounts listed in EN [132]. Protein intake of infants and children should not be restricted except in cases of intractable encephalopathy [132], and, even in these cases, protein intake should remain within the adequate intake range of 1–2 g/kg/day [133] and accompanied by sufficient intake of nonprotein calories to prevent inappropriate utilization of protein for energy synthesis [134]. Children with cholestatic liver disease have increased requirements for branched-chain amino acids (BCAA) compared to healthy controls [135]. However, nutritional outcome studies using either BCAA-enriched or standard formulas reported growth benefits in all recipients of EN [123, 124]. Furthermore, a Cochrane review did not find BCAA-enriched formula protective against encephalopathy when compared to iso-nitrogenous non-BCAA enriched formulas [136]. Therefore, there is currently insufficient evidence to recommend the use of BCAA-enriched formulas over standard non-BCAA enriched formula.

Chylothorax

Nutritional management of chylothorax involves adherence to EN or an oral diet enriched with medium-chain triglycerides and restricted in long-chain triglycerides and supplementation with essential fatty acids and fat-soluble vitamins [137]. Nutrition support during the preoperative period utilizes EN in infants who are hemodynamically stable and early use of PN if otherwise. The immediate postoperative period is characterized by fluid restrictions and hemodynamic instability and therefore requires active involvement of a dietician and reliance on PN to meet goal calories. Once hemodynamic stability is established, enteral feeding is introduced while following standardized protocols that include screening for swallowing dysfunction and management of

GI symptoms, for example, reflux. Nutrition surveillance should be performed continually pre- and post discharge to guide further interventions including use of calorie-dense formula and home tube feeds [62].

Techniques of Delivering Enteral Nutrition

The route of EN administration should be individually tailored, depending on the underlying condition (Fig. 46.1). Enteral feeding is preferable to PN, and therefore it should be immediately implemented in children with functional GI but unable to feed per oral. The absolute contraindication to EN includes mechanical obstruction of the GI tract (unless indicated for decompression), active peritonitis, uncorrectable coagulopathy, or bowel ischemia [138, 139]. The intragastric route of administration is the most commonly used in children, since it is the more physiologic route which permits the action of salivary and gastric enzymes, the bactericidal action of gastric acid, and the better mixing with biliary and pancreatic juice. Therefore, the duodenal or jejunal route is used in very few circumstances in children. For intragastric EN, NGT, or GT may be used. NGT feeding is the best initial approach to EN, to evaluate the tolerance of EN before placing a permanent GT, and/or when a brief period of EN support is anticipated.

NGT are made of polyvinylchloride (PVC), polyurethane, or silicone. Modern feeding tubes are made of either silicone or polyurethane [140]. Polyurethane tubes come externally and internally impregnated with a water-activated lubricant to ease insertion through the nasopharynx and facilitate removal of introducer wires [141]. They are also more resistant to degradation and deterioration when compared to silicone tubes. Tube size (outer diameter) is described in French Gauge (Fr) units. The millimeter conversion can be derived by dividing each Fr by π (3.14). The length of insertion for a nasal- or oral-gastric feeding tube to be in a child is determined by using either the morphological markers of “nose–ear–mid-xiphoid–umbilicus” span or age-specific prediction equations. Length predictions based on just a “nose–ear–xiphoid” span are likely to result in a placement that is too proximal [142]. At the time of NGT placement, aspirating fluid and measuring a $\text{pH} \leq 5$ is the most reliable bedside test confirming gastric placement in children [143]. However, the usefulness of this test may be limited in patients being treated with gastric acid suppressants. Simple auscultation is not a reliable method for assessing position because injection of air into the tracheobronchial tree or pleural space can produce an indistinguishable sound. Therefore, an abdominal X-ray is the gold standard for establishing location of the NGT tip [143].

Duodenal or jejunal tube placement is more difficult; the patient should be placed in the right lateral position, and if necessary, after an intravenous injection of erythromycin. The position of the distal end of the tube is then checked by

abdominal X-ray. Careful nasal fixation of the tube is used to avoid displacement; it is taped to the upper lip, the ipsilateral cheek, and the external ear. In some particular indications for EN, the feeding tube may also be introduced through the mouth, especially in patients with congenital or acquired nasal obstruction and premature infants on respiratory therapy with continuous positive air pressure (CPAP). The placement of NGT made of PVC is easier, but these tubes should be changed more frequently as they become more rigid. Silicone or polyurethane NGT may be used over 3-week periods or more. However, silicone and polyurethane are generally more flexible and easily displaced by vomiting. They are preferentially used for transpyloric and long-term EN. Individualized goals for growth, nutrition, and when to discontinue EN should be established prior to insertion of a feeding tube. Use of EN may only be temporary in acutely ill but previously healthy children, or as a long-term source of supplemental nutrition in children with chronic inadequate per oral food intake, and the sole source of nutrition in children with severe disability in per oral feeding.

When a child's duration on EN is longer than 30 days and feeds well tolerated yet low anticipation for timely acquisition of adequate per oral feeding skills, transition to a feeding gastrostomy should be considered [138, 140]. Percutaneous approach to placement of gastrostomy has revolutionized the placement of enteric feeding tubes in children. The standard approach involves use of a gastroscope for gastric transillumination and stoma site identification. This is followed by percutaneous introduction of a guide wire that gets grasped using the gastroscope and then orally withdrawn. Thereafter, the gastrostomy catheter is attached to the oral end of the guide wire, and then pulled in an antegrade manner through the oropharynx, esophagus, and stomach, and then across the gastric and abdominal walls [144]. It may be placed using GI endoscopy, surgical laparoscopy, or by interventional radiology [140]. Following placement, postoperative care mostly involves pain management, and most providers permit the use of GT within 12–24 h. The initial PEG tube is changed after 2–3 months, by which time a good tract has formed. Button-replacement gastrostomy devices provide patients a cosmetic advantage in case of long-term EN.

Percutaneous placement of gastrostomy or jejunostomy is contraindicated in patients with previous abdominal surgery, abnormal abdominal anatomy, or severe deformities of the chest and spine which modify the position of the stomach and other intra-abdominal viscera. In such cases, a surgical GT should be placed. The implantation of a jejunal feeding tube, via PEG, is a possible method for the treatment of inadequate oral feeding in patients who are affected by gastroesophageal reflux (GER) and is thus an alternative to fundoplication and drugs [144, 145]. However, gastrojejunal feeding tubes are also prone to technical complications requiring replacement because of clogging and recoil of the jejunal catheter back into the stomach [145]. EN may be delivered

as boluses or prolonged continuous feeding using a feeding pump, syringe, or controlled delivery by gravity. Pumps recommended for pediatric use have to provide clear flow rate display and alarms. Miniaturized and battery-powered pumps are specially designed for home and ambulatory EN.

Nutrients

Nitrogen The absorption of amino acids is more rapid and efficient when given in the form of short peptides than free amino acids [146, 147]. Therefore, in order to maximize nitrogen assimilation in patients with marked impairment of gut absorptive capacity, the ideal EN should consist of di- and tripeptides and free amino acids [147]. In addition, the quality, in term of digestion and intestinal absorption of protein hydrolysates, depends on the type of hydrolysate, for example, lactalbumin is superior to casein [148]. However, in patients with normal GI function, EN with formulas consisting of protein hydrolysates offers no nutritional or absorptive advantage over EN based on formula consisting of free amino acids or intact protein [149]. Thus, the initial formula in patients with normal GI function should be based on intact protein or polypeptides, with a lower osmolality, rather than on a mixture of free amino acids and short polypeptides.

Carbohydrates Disaccharidase enzymatic activities are depressed in disease involving the small intestine mucosa. Lactase appears to be the most sensitive to injury and the last of the disaccharidases to recover. In addition, certain drugs such as neomycin or colchicine depress the intestinal disaccharidases. Thus, it is important to avoid dietary sources of lactose. Other disaccharides should also be omitted from the solution used for initial feeding as their corresponding brush border enzymatic activities are reduced. The carbohydrate source allowed during the EN in patients with normal GI function can be lactose. However, patients with impaired GI function should be fed an EN containing lacto-free glucose polymer as the carbohydrate source.

Lipids The main dietary lipids are triglycerides structurally made up of three fatty acids linked to glycerol molecule. The fatty acids contain between 2 and 24 carbon atoms (C: 2 and C: 24). Classification of the triglycerides is based on length of the fatty acid chain, that is, short-chain triglycerides (SCT) contain fatty acids that range in length from 2 to 4 carbons (C: 2 to C: 4); the MCT contain fatty acid chains ranging from 6 to 12 carbons (C: 6 to C: 12) and; LCT have >12 carbons. In contrast to the LCTs, dietary MCTs are hydrophilic and do not require bile salts or micelle formation, and their free fatty acids are directly absorbed into the portal systems without requirement for re-esterification into chylomicrons [14, 150]. MCTs are hydrolyzed faster than LCTs in the small intestine by pancreatic lipase; they are converted almost exclusively

into free fatty acids and glycerol and reach directly the portal circulation and the liver. Nevertheless, in case of pancreatic insufficiency, MCTs may also be absorbed intact. The excessive use of MCTs-containing diet can lead to osmotic diarrhea as a result of their rapid hydrolysis. Dicarboxylic aciduria has been described in infants supplemented with MCTs-rich formulas without any proof of deleterious effect [151]. The provision of essential fatty acids (EFA) must be considered since MCTs contain no EFA. Furthermore, MCTs decrease the LCTs absorption; thus, supplementation with linoleic acid must be done. However, its addition to a formula based on MCTs may be insufficient to prevent EFA deficiency, thus making necessary to provide EFA parenterally. Nevertheless, most of formulas containing MCTs include also up to 50% of lipid as LCTs. LCTs in excess in the intestinal lumen, especially if they are hydroxylated by bacteria, reverse the rate of water and electrolyte absorption and increase malabsorption. In those conditions, the addition of cholestyramine an EFA supplement may be appropriate. Finally, a lipid intake of 3–4 g/kg/day may be achieved, depending on absorption capacity and digestive tolerance.

Other Components Recommendations concerning energy, water, and electrolytes supplies in premature and full-term

infants are provided in the chapter on PN in the premature infant. In older children, the recommended energy intake is based on recommended daily intake (RDI) values or may be estimated using World Health Organization (WHO) weight, age, and gender prediction equations or directly measured using an indirect calorimeter [133]. The minimum daily fluid requirements with some exceptions may be estimated using the “Holliday–Segar” calculation, which is an extrapolation based on daily calorie expenditure. For weights ranging from 0 to 10 kg, the estimation is 100 mL/kg/d; from 10 to 20 kg, 1000 mL plus 50 mL/kg for each kilogram of body weight more than 10; and over 20 kg, the estimation is 1500 mL plus 20 mL/kg for each kilogram more than 20 [152].

Choice of a Formula

Enteral feeding formulas are divided into several families. The choice of a formula is made according to numerous parameters like protein–calorie needs, digestive function, protein sensitivity, motility status, tolerance to fluid intake, all obviously dependent on the age and on the underlying disease (Fig. 46.3). In preterm, newborns, and young infants with normal intestinal function, human milk or standard in-

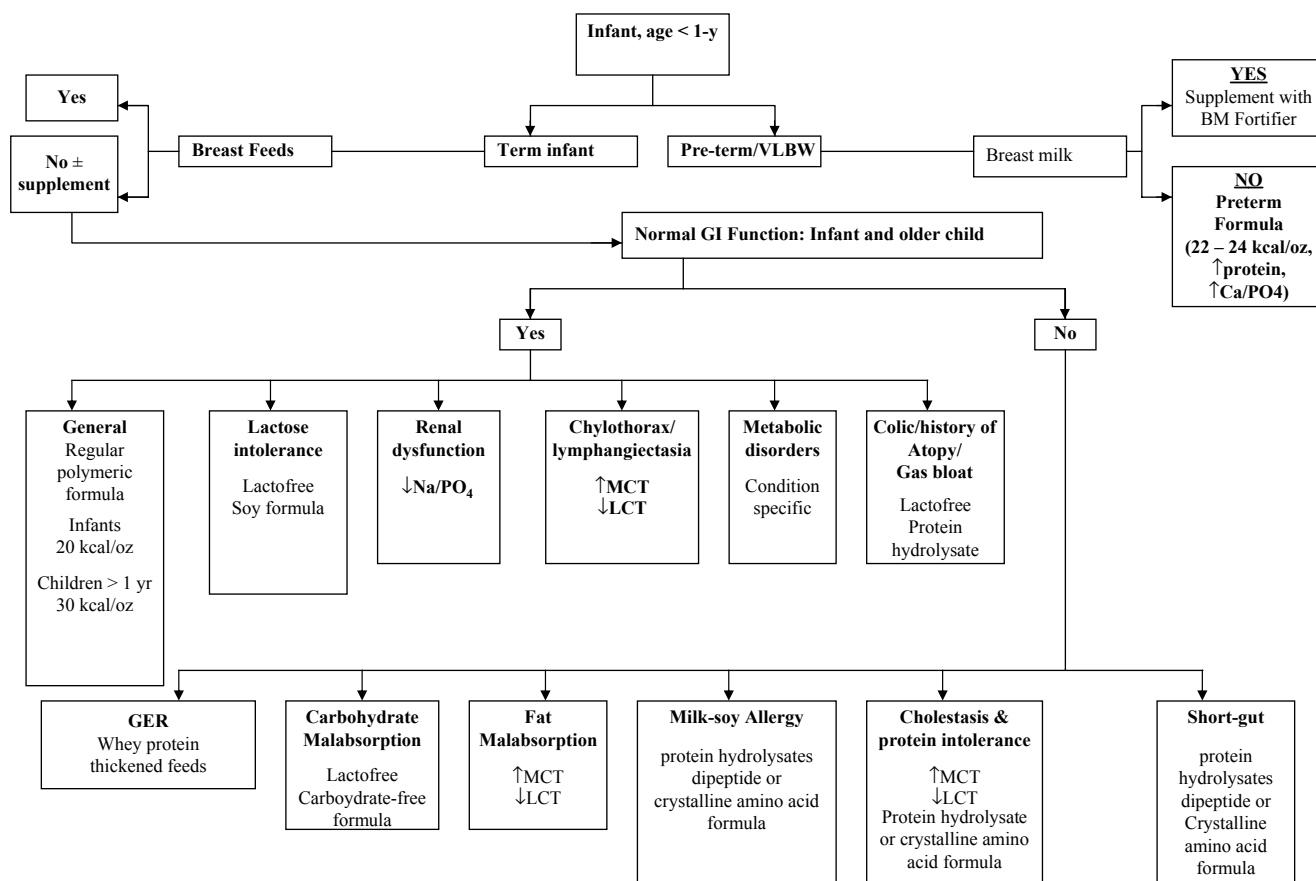

Fig. 46.3 Algorithm for selection of formula. GER gastroesophageal reflux, MCT medium-chain triglycerides, LCT long-chain triglycerides, EN enteral nutrition

fants formulas supplemented with long-chain polyunsaturated fatty acids (LCPUFA) may be used. Formulas for preterm infants are unique in being more calorically dense (72–90 kcal/100 mL) with increased protein (1.8–2.3 g/100 mL), calcium (70–108 mg/100 mL), and phosphorous [153]. The preterm formulas are continued after hospital discharge in preterm or small for gestation-age infants with discharge growth parameters are below appropriate post-conception growth, and continued until achievement of catch-up growth [153]. Breast milk and standard infant formulas have a calorie density of 0.67 kcal/mL with lactose as the carbohydrate source and fat source compromised of LCTs and LCPUFA (DHA and EPA). Commercial polymeric formulas are available for older children (age > 1 year), and blenderized diets can be prepared using food from the kitchen may be used in the nonstressed patients, with normal gut function. The calorie density of formulas used in older children (age > 1 year) ranges from 1 kcal/mL (standard) to 1.5–2.0 kcal/mL (calorically dense).

In case of GI disease, the choice of the nutritive solution must take into account not only the child's age and nutritional status but also the underlying digestive disease, for example, the presence of anatomical and functional changes in the intestine, whether due to an extensive reduction of the absorptive surface, to enteropathy or to pancreatic insufficiency. Limiting factors in such cases are impairment of gastric, biliary, and pancreatic secretions, disturbances of the intestinal flora, and malabsorption. Most standard (1 kcal/mL) polymeric formulas have osmolality within the range of 300–360 mosmol/kg. Oligomeric (hydrolysate/semi-elemental) and elemental (crystalline amino acid based) enteral formulas are designed for use in patients with malabsorption such as in short bowel syndrome, CF, cholestasis, food allergy or intolerances. These diets include dipeptides, tripeptides and a few free amino acids, combined with LCTs and MCTs, and carbohydrates including glucose polymers and maltodextrins.

The osmolality of a solution is determined by the number of particles within it. Likewise, the osmolality of enteral formulas is directly influenced by the calorie density and whether made up of intact protein, peptides or amino acids. Therefore, free amino acid-based formulas tend to have a higher osmolality. Children with severe malabsorption or short bowel syndrome unable to tolerate peptide-based formulas (protein hydrolysates) might benefit from the free amino acid-based formulas [154, 155]. Nutritional formulas in which each of the constituents is modified independently are mostly used in special conditions, for example, selective malabsorption. In that case, glucose may be given initially as calorie source, the amount being increased progressively and controlled according to the stool volume, pH, and absence of reducing substances in the stools. In the first days of feeding, at least a molar ratio of glucose and sodium is

maintained. Then, protein hydrolysates are gradually introduced according to digestive tolerance. The caloric enteral intake usually increases from 10–15 to 70–80 kcal/kg/day over the first week. In a second step, qualitative and quantitative changes are gradually carried out: Fructose is added to the glucose, and then disaccharides are introduced, starting with maltose. Nitrogen and lipids are simultaneously increased. During this period, the introduction of oligosaccharides precedes that of a commercially available semi-elemental diet.

Regulation of Intakes and Rhythm of EN Delivery

EN should be progressively introduced depending on the child's nutritional status and the indications for EN. In case of digestive disease, CEN can be used after a brief or prolonged period of PN. The first step includes the progressive reduction of the parenteral intake and the stepwise increase of EN according to the digestive tolerance. Semi-elemental diet (protein hydrolysates) can be used early, by progressively increasing volume as well as concentration according to digestive tolerance and up to achieve optimal energy and nitrogen intakes. The water and sodium supply should be increased to compensate for the intestinal losses generally induced by the start of EN; the tolerance is estimated from the weight of the child, the volume and osmolality of urine samples, and from the plasma osmolality. The tolerance and needs are estimated from 24-h urine analysis, while attempting to maintain a natriuresis of 2–3 mmol/kg/day. At the same time, potassium intake is adjusted as a function of the nitrogen and energy intake.

The rhythm of EN delivery depends on the underlying disease. Intermittent feeding using bolus is more physiological and well tolerated when the digestive function is normal. Continuous cyclic nocturnal EN is better tolerated in some patients who do not tolerate bolus feeding and provides less interference with daytime oral intake. On the other hand, continuous 24/24 h rhythm of delivery is indicated in case of impaired digestive function. The weaning period varies from few days to several weeks or months. Eating disorders can be avoided by the maintenance of sucking and swallowing functions during the period of CEN. On the other hand, it has been demonstrated that nonnutritive sucking intervention during CEN in preterm infants resulted in faster transition from feeding tube to oral feeds, better bottle feeding performance, enhanced growth and intestinal maturation, and decreased duration of hospital stay compared to preterm infants without the intervention [156, 157]. In older children, weaning from EN may include a period of continuous nighttime feeding supplemented by several meals in the daytime until the latter account for 50% of the total intake. Oral feeding must be carefully increased because of the relatively low intestinal activity due to long-term CEN.

Complications of Enteral Nutrition Therapy

Although complications occur rarely, they can be quite serious. Strict adherence to the procedure is indicated and careful supervision is essential to prevent them. See Table 46.2.

Functional Complications of Feeding Tubes

The functional complications of enteral feeding tubes include tendency to clog, which occurs 18–45% of the times [158]. The risk is higher in smaller-diameter tubes, and the cause of occlusion includes interaction of protein-based formulas with an acidic environment and medications, and complete obstruction from knotting of the feeding tube [158–160]. Clogged NGTs should be readily replaced with no need to apply extraneous efforts to unclog. However, a good effort should be made to unclog blocked nasojejunal and gastrojejunal tubes because they are more difficult to insert. Clogging and occlusion can be minimized by frequently flushing the tube before and after administration of feeds. Water is more effective than carbonated beverages for flushing and unclogging occlusions. Sterile water is preferred for flushing because several published cases of infection were traced to tap water [139]. Persistently clogged tubes despite water flushes may respond to installation of one crushed tablet of Viokase (pancreatic enzyme) in 5 mL water and pH raised to

7.9 using NaOH instilled into the tube using a 50 mL syringe under manual pressure for 1 min, then the tube clamped for 5 min [159]. Other options include trial of meat tenderizer or use of mechanical devices such as Fogarty balloon and biopsy brush. Failure to unclog the tube requires replacement of the tube [139].

Gastrointestinal Complications

Risks and complications start with passage of NGTs, which can be hazardous in any patient, especially those with poor or impaired gag reflex, absent cough reflex, or altered consciousness. Furthermore, presence of a cuffed endotracheal tube is not guaranteed protection against pulmonary intubation. Therefore, feeding should not begin until proper placement of the tube is verified [138]. The bedside assessment tools of visually inspecting for color and testing for pH of aspirates may be inaccurate because small bore tubes may collapse resulting in failure to drawback aspirates, and therapy with gastric acid suppressants may affect the measured pH. The auscultation method is also problematic because sounds may be transmitted to the epigastrium regardless of tube placement in the lung, esophagus, or stomach. Some protocols call for the first feed to be water to ensure tolerance [138]. Overall, abdominal X-ray is the gold standard for establishing location of the NGT tip [143].

Table 46.2 Complications of enteral feeding tubes and therapy

Nasogastric	PEG/gastrostomy
<i>Complications during tube insertion</i>	
Arrhythmias	Aspiration
Pyriiform sinus perforation	Hemorrhage
Esophagus perforation	Peritonitis
Tube in pulmonary tree/pulmonary intubation	Necrotizing fasciitis (rare)
Pneumothorax	Ileus
Empyema	Fistulous tracts
Gastric perforation	Perforation of viscera
Duodenal perforation	—
<i>Complications when in situ</i>	
Otitis media	Peristomal infection
Sinusitis	Stomal leakage
Epistaxis	Buried bumper
Nasal mucosal ulceration	Gastric ulcer
Pulmonary aspiration	Inadvertent removal
Gastroesophageal reflux	—
Tube dislodgement	—
<i>Functional complications</i>	
Diarrhea	
Clogging	
Knotted tubes	
Contaminated feeds: <i>Coronbacter</i> spp (formally <i>Enterobacter sakazakii</i>), <i>E. Cloacae</i>	
Re-feeding syndrome	
Feeding aversions	

Aspiration pneumonia is the most threatening complication associated with NGT feeding [138]. Irregular flow rate of infusion, delayed gastric emptying due to the underlying disease or to the drugs, GER, tube placement or migration into the distal esophagus, behavioral vomiting, and formula intolerance are risk factors for vomiting and aspiration. The general prevalence of feeding-tube-related aspiration pneumonia is unknown; however, the incidence in critically ill patients ranges from 25 to 40% [161] with both oropharyngeal and gastropharyngeal contents implicated. The risk factors in critically ill patients include decreased level of consciousness, vomiting, malpositioned feeding tube, larger-diameter NGT, and bolus feeding. The preventative measures include keeping the patient in a semi-recumbent position, continuous aspiration of subglottic secretions, and change from bolus/intermittent to continuous EN [161, 162]. Tubes placed past the third portion of the duodenum are associated with decreased risk of aspiration [138].

Diarrhea is the most common complication of EN and is reported in up to 68% of patients [138]. Increased stool losses occur when the combined absorptive capacity of the small bowel and the salvaging capacity of the colon are exceeded (see ref. [163]) for a review of the role of colon in short bowel syndrome) and may result in dehydration and hypoglycemia. The causes include inappropriate composition of the formula for the underlying disease, high formula osmolality and rate of infusion, intraduodenal infusion, hypoalbuminemia, and bacterial contamination of the formula. The volume of endogenous fluid flux into the jejunum is directly proportional to the osmolality and rate of infusion of the EN [164]. Therefore, since higher osmolality (>300 mosmol/kg) feeds will induce greater endogenous fluid flux into the bowel, their rates of infusion should be increased cautiously.

Mechanical, Infectious, and Metabolic Complications

NGT-related mechanical complications include nasal trauma, laryngeal ulceration, or stenosis and esophageal or gastric perforations. Duodenal perforations have been reported in association with transpyloric feeding tubes in preterm infants, neonates, and critically ill children regardless of whether polyvinyl, silicone, or polyurethane feeding tubes [165–167]. In one series of 526 critically ill children receiving transpyloric EN, the prevalence of GI complications was 11.5%. These included abdominal distension and/or excessive gastric residue (6.2%), diarrhea (6.4%), and GI bleeding, necrotizing enterocolitis, and duodenal perforation (0.9%). The major factors associated with risk for developing the complications were shock, epinephrine dose >0.3 µg/kg/min, and hypophosphatemia [168]. Therefore, frequent reevaluation and a high index of suspicion are required in

this patient population. Complications from PEG placement may occur during the immediate postoperative period and or late onset/delayed. The postoperative complications include aspiration, hemorrhage, peritonitis, necrotizing fasciitis, peristomal infections, prolonged ileus, fistulous tracts, and inadvertent removal. The delayed complications include site infections, persistent peristomal leakage/irritation, buried bumper syndrome, gastric ulcer, fistulous tracts, inadvertent tube removal, and fungal tube infections, especially affecting silicone tubes leading to tube degradation and malfunction [139]. Children without fundoplication may go through a period of worsened reflux symptoms [169–171] that may respond to slower advancement of EN or necessitate a brief period of change to continuous feeding schedule.

Patients with PEGs placed too close to the pylorus, and 24–30% of children with fundoplication, may develop metabolic dumping characterized by postprandial tachycardia, diaphoresis, lethargy, refusal to eat, gas bloat, and water diarrhea in association with bolus feeds [172–175]. Establishing a screening protocol for postprandial hypoglycemia in patients with history of fundoplication is important because approximately 46% of affected children fail to exhibit symptoms [175]. The diagnosis of dumping is confirmed by a glucose tolerance test showing postprandial hypoglycemia preceded by postprandial hyperglycemia. The management options include initial avoidance of boluses, change to continuous feeding schedule, modification of the EN to avoid lactose, change to a complex carbohydrate source, supplementation of bolus feedings with uncooked cornstarch [176–179], and in refractory cases, therapy with ascorbase (disaccharidase inhibitor) [180].

Infectious Complications

EN has been associated with outbreaks of antimicrobial-resistant organisms. *Coronabacter spp* (formally *Enterobacter sakazakii*) is a rare but one of the most important worldwide causes of outbreaks of neonatal sepsis and meningitis associated with non-sterile powdered infant formula or human milk fortifier, has a mortality of 40% [181]. Ninety-nine percent of affected patients are infants <2 months. The infection may be acquired in hospital or at home and the predominant risk factor is use of powdered infant formula or human milk fortifier [181, 182]. Therefore, the US Food and Drug Administration has issued the recommendation that use of powdered infant formulas and human milk fortifiers should be minimized in hospitalized preterm or immunocompromised neonates [183]. Ready-to-use commercial formulas are sterile therefore recommended for EN in hospitals.

Other sources of organisms include post-manufacturer microbial contamination exogenously introduced during manipulation of the formula, and through retrograde contamina-

tion of the feeding tube system by the patient's endogenous flora. The enteral feed administration sets become colonized externally by microbes grown from the enteral tube hub, and may serve as a reservoir of organisms that can be cross transmitted [184–186]. Commercial liquid formulas received from the manufacturer are required by regulatory agencies to be shelf-stable and free of enteric pathogens. The more common sources of organisms may be exogenous the patient through contamination of locally prepared and manipulated formula [184]. Microbial contamination of the enteral tube hub may result from retrograde growth of endogenous bacteria along the tubing system [187] following which nosocomial cross-transmission to other patients may occur when care providers handling the enteral tube hub and fail to practice strict infection control procedure [188, 189]. Therefore, adherence to standard precautions is critical when handling enteral feeding apparatuses. The bacterial contamination of the nutritive solution with enterotoxin-producing bacteria like coliforms or *E. cloacae* [186], at the time of preparation, storage or delivery to the patient has been associated with gastroenteritis and/or septicemia [185, 190]. The relationship between bacterial contamination of enteral formula and diarrhea may be a matter of debate. When EN is delivered into the stomach there is a protective effect from gastric acid. Therefore, the risk of bowel contamination is theoretically higher when EN is delivered below the pylorus. Since necrotizing enterocolitis (NEC) may occur in premature infants and neonates suffering from hypoxia and infections, the abdomen must be checked daily very carefully. Because of the risk of infectious complications and NEC, use gastric route as far as possible, strictly limit duodenal infusions and to use ready to ready-to-use preterm formulas is recommended in preterm infants.

Refeeding Syndrome

This is a metabolic syndrome induced by feeding that occurs in previously starved or chronically malnourished patients. The syndrome is characterized by hypophosphatemia, hypokalemia, hypomagnesemia, arrhythmia, edema, congestive heart failure and increased risk for death. The incidence of re-feeding syndrome in children is not known; however, it is reported in up to 50% of hospitalized adults documented to be malnourished [191]. It results from rapid anabolism induced by increased insulin secretion in response to provision of nutrients. The increased glucose load, with corresponding increase in the release of insulin leads to cellular uptake of glucose, potassium, magnesium and phosphate. This rapid shift in electrolytes from the extracellular to intracellular space results in hypokalemia, hypomagnesemia and hypophosphatemia. Insulin also exerts a natriuretic effect on the kidneys resulting in sodium and fluid retention. The

anabolism may unveil or cause other nutrient deficiencies, for example, thiamine deficiency and Beriberi, further leading to life threatening circumstances [192]. The pre-nutrition therapy determinants of risk for developing re-feeding syndrome include patients underfed or not fed for at least 10–14 days (regardless of therapy with crystalloid intravenous fluids), acute weight loss of >10% in the preceding 1–2 months, severe malnutrition as defined by <80% ideal body weight or weight-for-age z-score <−3 [33], decreased pre-albumin [193] AN, marasmus, edematous protein-energy malnutrition (kwashiorkor), children of neglect, cerebral palsy and other conditions causing dysphagia [192]. The risk for developing re-feeding syndrome is higher during the first 5–7 days of implementing nutritional therapy. The metabolic derangements can be avoided by initiating feeds at a calorie intake of 50–75% of the measured or estimated resting energy expenditure with appropriate supplementation of phosphorus. The calorie intake is then increased by 10–20% per day with close monitoring and correction of biochemical parameters until the calorie goal is met [194].

Home Enteral Nutrition (HEN)

Indications

HEN is a logical alternative to long-term hospitalization when a long-term enteral nutritional support is necessary (more than 1 month) in a patient in stable clinical condition. HEN has been proven to be an effective and safe method, compatible with the best possible quality of life [195–197]. Major costs savings induced by home EN as compared to hospitalization have been demonstrated. The importance of families' teaching and medical follow-up to prevent somatic and psychological complications should not be underestimated [198].

Prevalence-Incidence

The origins of home EN are much older than those of home PN. In North America, 20,000 patients received HEN in 1985 and it was estimated that 150,000 individuals received HEN in 1992 (about 500 per million population) [199]. Based on an estimate growth rate of 25% per year, about 500,000 patients may have been on HEN in the USA in 1997 [200]. However, whereas HEN is more extensively used the PN, because there is no national registry in the United States for patients on HEN to verify these projections or compared outcomes data [201]. The British Association of Enteral and Parenteral Nutrition estimated that the number of patients on HEN was about 40 per million population, about 10 fold the number of HPN patients in the same country at the same

time. Children accounted for 30–40% of HEN patients in Britain, compared to about 20% in USA [200, 202]. The Spanish national registry for Pediatric home enteral nutrition (NEPAD) is a web based registry of exclusively Pediatric data established in 2003 with the goal of gathering more comprehensive information on indications, modes of administration, types of diets and duration of nutrition support [197]. The number of entrants has steadily increased; however, enrolment is voluntary therefore, prevalence and incidence data cannot be derived. Therefore, the lack of national registers in most European countries makes estimation very difficult.

Organization

The quality of home EN programs depends on the organization of multidisciplinary nutrition support teams based on a tight collaboration between the different professionals including physicians, home care nurses, dieticians, pharmacists and social workers. In some countries, pumps, disposable equipment and nutrients for HEN are mainly delivered by hospitals, while in others, such as in the USA where they are the most developed, home care companies participate to patients' training and provide a delivery service and a 24 h emergency phone contact. With expansion of the home care industry, it is important to ensure that adequate standards of care are provided. The American Society of Parenteral and Enteral Nutrition and the British Association of Parenteral and Enteral Nutrition have produced such standards [4, 202].

Parents' Teaching

Tolerance and efficacy of EN have to be proven at the hospital before to organize HEN. As for HPN, HEN in children is feasible only when the family is highly motivated and able to deal with technical aspects. Parent's teaching is based on a nutrition multidisciplinary hospital team including physician, nurse, dietician and pharmacist. Parents are taught not only about technical aspects but also about risks, complications and their prevention. The hospital team ensures a 24/24 h phone contact and regular follow up, in tight cooperation with the general practitioner. The help of a community nurse may be required, especially in case of placement of a nasogastric tube.

Results

Quality of Life Although HEN, like HPN, is usually considered by children and families as an improvement of their quality of life, psychological consequences of this technique have to be carefully estimated and prevented. The placement

of a NGT is distressing to parents and children. A NGT in situ for continuous 24/24 h infusion is a major problem, particularly in oldest children and adolescents, because it induces an unwelcome public interest. These problems are solved by the use of gastrostomy. Children and families may also suffer from the suppression of meals taken together, which are usually considered as an important moment of the family life. Adequate psychological preparation and follow-up improve tolerance of children and parents to HEN [203, 204].

Outcomes Outcome studies on HEN patients have been fewer than those on patients on HPN. Improvement of the nutritional status and low mortality rate (always related to major underlying diseases) are usually described in children on HEN [205].

Cost and Funding HEN is far from being as expensive as HPN. The total cost per day HEN was about \$ 35 in the USA in 1992, when the cost per day HPN was about \$ 300 [199]. The cost-savings associated with providing HEN estimated by the British Association for Parenteral and Enteral Nutrition in 1994 were about 70% [202]. In most countries, patients on HEN are funded by the National Health Service, although in the USA they are mostly paid for by insurance companies [200, 202].

Susan Hill

Introduction

Parenteral nutrition (PN) is a lifesaving supportive treatment in intestinal failure (IF) that should be considered one of the major medical advances of the last century. IF has been defined as the inability to absorb sufficient fluid and nutrients from the intestine to maintain homeostasis and to grow and develop even when the most suitable enteral nutrition is given via the most appropriate artificial feeding device for the individual patient [1]. The use of PN has enabled even the sickest child to survive including the most premature of infants. However, PN should be prescribed and administered in an appropriate clinical setting to minimize the possibility of complications that could harm rather than benefit the child's health and can be life-threatening. In other words, PN is not just another drug to be prescribed. The support needed includes a comprehensive laboratory service and pharmacy and dietetics in addition to specialist medical and nursing skills.

While PN is essential for survival in patients with severe IF the aim of treatment is to stabilize the child, and at the same time to diagnose, investigate, and treat the underlying cause of the IF in order to wean the patient back on to enteral feed at the earliest opportunity.

PN can be defined as the infusion of nutrients directly into the bloodstream and by-passing the gastrointestinal tract.

“Total” PN (TPN) is the term used for infusion of all the individual's nutritional requirements into the bloodstream. “Partial” PN is the infusion of some nutrients into the bloodstream while a portion of the daily nutritional requirements is derived from enteral nutrients

Treatment with PN has been defined as “long-term” by the British Society of Pediatric Gastroenterology, Hepatology and Nutrition (BSPGHAN) when it is given for > 27 days

[2]. “Home” PN is considered when a hospitalized patient is stable on PN and expected to require treatment for at least two further months. Parents are usually formally trained to administer the PN and administer it to the child overnight at home. Table 47.1 lists indications for parenteral nutrition.

History and Development of PN

Attempts to feed directly into the bloodstream have been made ever since the circulatory system was first described by William Harvey in 1628. For example, Sir Christopher Wren infused ale and opium into dogs in 1656 using a bladder and sharpened quill.

In order for PN to be safely used in the clinical setting, suitable carbohydrate, protein, and lipid sources were required in a form that was stable in solution, nontoxic, and suitable to be infused directly into the bloodstream.

The first suitable protein source was developed in 1937 when a casein hydrolysate was successfully infused in adults and in 1940 a crystalline L-amino acid solution was first used clinically in children. Technical difficulties and high commercial costs were sufficiently overcome for the solutions to be used routinely from the 1960s.

Carbohydrate energy sources trialed included fructose, sorbitol, ethanol, and glucose. Although glucose was metabolically the most suitable energy source, it was associated with venous thrombosis. It was only when Dudrick et al. in 1968 infused glucose into a large central vein that thrombophlebitis was avoided [3]. PN was first provided on a commercial basis from the late 1960s after a suitable lipid source was developed. The lipid was required in order to provide adequate calories without an excessive osmotic load as well as a source of essential fatty acids (EFA). An artificial “chylomicron” composed of soybean oil and egg phosphatides was developed by Wretling and Schuberth in 1963 that is still in use today [4].

Table 47.1 Indications for parenteral nutrition

Primary digestive disorder	Primary non-digestive disorder
Short bowel syndrome	Prematurity
–	Acute pancreatitis (enteral feeds usually recommended)
Protracted diarrhea with faltering growth	Radiotherapy
Necrotizing enterocolitis	Chemotherapy
Chronic intestinal pseudo-obstruction	Acute liver failure
Postoperative abdominal surgery	Acute renal failure
–	Extensive burns
–	Severe trauma

Constituents of PN

PN is a complex mixture of sterile nutrients in a suitable form to be safely infused directly into the bloodstream. It consists of carbohydrate lipid and amino acids with added vitamins and minerals.

Lipid is usually supplied as a separate infusion that also contains the fat soluble vitamins, that is, vitamins A, D, E, and K.

The standard carbohydrate source is dextrose. The amino acid formulation is usually based on egg protein and in the neonate, on breast milk.

Until the last few years soybean has been the only lipid source. However, more recently olive oil, fish oil, coconut oil, and an artificially structured lipid have been developed. See Table 47.2.

The lipid emulsion provides an energy-dense source of nonprotein calories and if includes soybean oil contains EFA, alpha-linolenic acid and linoleic acid.

Lipid should represent about 30% of nonprotein energy and linoleic acid should be 1–2% of total energy. The maximum lipid utilization rate is about 3.3–3.6 g/kg/day.

Minerals and vitamins are available in mixed formulations or can be added individually.

Iron is not routinely included since iron-associated liver cirrhosis can develop. However, it is often added when iron-deficiency anemia develops in children on prolonged treatment.

Table 47.2 Parenteral nutrition lipid solutions

Parenteral nutrition lipid solutions
Clinoleic 20% (Baxter): 20% soybean oil, 80% olive oil
Intralipid: 20% (Baxter) pure soybean oil
Lipidem (B-Braun): fish oil, olive oil, soybean oil
Lipofundin (B-Braun): medium-chain and long-chain triglycerides MCT/LCT) MCT/LCT 20%® a physical mixture, 1:1 by weight, of soybean and coconut oil
Omegaven 20% (Fresenius Kabi): pure fish oil
SMOF lipid® 20% (Fresenius Kabi) physical mixture of 30% soybean, 30% MCT, 25% olive, and 15% fish oil; SMOF

Additional substances that can be directly added to the formulation include the nonessential amino acid glutamine and certain medication, such as the H-2 receptor antagonist, ranitidine.

PN should be formulated in a licensed compounding unit. The unit should have access both to their own stability data and that available in specialist PN units elsewhere in the UK and Europe. An automated system in a specialized sterile unit is usually used to mix the PN ingredients according to international pharmaceutical standards. The final formulation is supplied in a sealed plastic bag. In most cases, the nutrients for a 24-h period are contained within two bags; one with the amino-acids, dextrose, electrolytes, trace elements, and water soluble vitamins, and the other with lipid and fat-soluble vitamins, that is, vitamins A, D, E, and K.

Stability of the PN formulation can be a major problem in children when compared to adults since they have relatively high calcium and phosphate requirements: two salts that readily precipitate.

PN can be sourced in three different ways:

1. Individually formulated/bespoke PN bags usually prescribed and manufactured on a daily basis according to the patient's requirements. It is usually the most appropriate treatment for hospitalized children (but may not be appropriate for premature newborn infants) with varying daily needs. The "shelf life" of these bags is approximately 48–72 h. The PN pharmacy is usually within the hospital.
2. Second, standard prepared commercially available bags with a longer shelf life of several days or weeks that can sometimes be stored at room temperature are increasingly used in premature neonates and adult patients. Vitamins, trace elements and, if needed, extra electrolytes (that would not remain stable in the solution for more than a few days) should be added immediately prior to infusion in a sterile compounding unit, preferably in the hospital pharmacy. Standard bags are increasingly being used in neonatal units since they are readily available and more appropriate for the nonsurgical premature infant.
3. Third, certain pharmacies have sufficient expertise and stability data to manufacture individually prescribed PN

with prolonged stability for 1–4 weeks. There will be a gradual breakdown of certain vitamins during storage. These pharmacies usually supply PN to patients with chronic IF on long-term treatment with PN who are usually at home.

How to Start PN

It is essential that all attempts are made to feed a child enterally (unless contraindicated, e.g., intestinal obstruction, post-gastrointestinal surgery) before commencing PN. Once the need for PN has been established it usually needs to be commenced with some urgency.

The severity and complications of a chronic disease are worse in undernourished patients. Nutritional support should be begun early, for example, within 1–5 days if a child is unable to tolerate any enteral nutrition since nutritional reserves are limited. Age, nutritional state, and intestinal losses should be taken into account. It has been estimated that a small premature baby (1 kg) has sufficient reserves to survive only 4 days and a term infant up to 12 days [5]. When enteral nutrition is not tolerated or contraindicated, PN should be begun within 1–2 days of the intake/absorption becoming inadequate in the newborn infant, but can be delayed for up to 5–7 days in a well-nourished adolescent. Other than in the premature neonate, it is usually best practice to stabilize the patient and start PN during normal working hours. See Table 47.3 for the steps that need to be taken when commencing PN.

Venous Access

In order to safely administer PN with a sufficiently high concentration of nutrients for a child to thrive, it needs to be infused into a central vein. For example, a glucose concentration of 12.5% or more should *only* be administered through

Table 47.3 How to start parenteral nutrition

	How to start parenteral nutrition
1.	Obtain secure central venous access
2.	Assess maintenance fluid and electrolyte requirements from patients length/height and weight
3.	Add extra requirements for excessive intestinal losses
4.	Prescribe PN
5.	Obtain appropriate equipment for infusing PN: a giving set to connect to the central venous catheter and the bag of PN and an infusion pump
6.	Gradually increase PN over 4–6 days from 60% to full requirements
7.	Monitor weight and blood electrolyte levels on a daily (or twice daily) basis for first 5–7 days

PN parenteral nutrition

a CVC. The optimal position is for the tip of the catheter to be high in the right atrium or low in the superior vena cava. A silicone rubber (Silastic) catheter should be used, preferably with a subcutaneous cuff to hold the catheter in place and a single rather than double lumen in order to reduce the risk of infection. A peripherally inserted catheter with the tip centrally placed (PICC) line can also be used, particularly if it is likely to only be needed for a few days/weeks. The major advantage of a PICC line over a cuffed catheter is that since a PICC can be removed without general anaesthetic.

A subcutaneous implantable port should be avoided if at all possible, since accessing the port can be traumatic for the child and it can be difficult to eradicate infection. However, a port maybe suitable for short-term PN in certain circumstances. A short peripheral cannula should not be used to administer PN since the high osmolality of the PN solution readily causes thrombophlebitis and tissue necrosis should it leak from the vein. If in exceptional circumstances PN had to be given peripherally, the glucose concentration must be less than 12.5% and the osmolality should not exceed 600–900 mOsmol/l.

In the neonate, the catheter is usually inserted via a peripheral vein with the tip placed centrally in the superior vena cava. Insertion in the older child is usually via the subclavian (or occasionally the internal jugular) vein with the tip positioned high in the right atrium. The femoral veins can be used, but are less suitable, unless the catheter is tunneled under the skin, since the exit site is in the nappy area so susceptible to fecal contamination.

In patients requiring long-term PN, that is, >27 days the catheter should be placed under radiological control in order to minimize damage to the blood vessel during insertion.

It is of utmost importance to use radiological control in patients with chronic IF who may require repeated CVC insertions in order to avoid loss of venous access.

A catheter with a subcutaneous cuff to fix the line in place and prevent movement is usually used in children. Alternatively, a PICC line can be used. Although use of a PICC is only recommended for a few weeks, they can function successfully for many months and in some children at home on PN have been kept in situ for over 12 months. The major advantage of a PICC line over a cuffed catheter is that the PICC line can be removed without the need for a general anaesthetic.

In children on long-term home treatment, the CVC can remain in situ for as long as 8–10 years (personal observation). It may eventually need to be changed when the child has grown sufficiently for the line tip to become displaced from the right atrium.

If at all possible, the catheter should be dedicated to the infusion of PN in order to preserve patency and minimize risk of infection. In children who have had frequent cannulation of blood vessels and/or excessive anxiety associated

Table 47.4 Monitoring when commencing parenteral nutrition

Monitoring when commencing parenteral nutrition
Clinical observation: temperature, heart rate, respiratory rate, blood pressure
Daily ward urine analysis for glucose and ketones until stable
Blood glucose level 4-hourly until stable in the older child or according to the unit's glucose monitoring policy for neonates
The maximum infusion rate of glucose through a central vein should be 1.0–1.5 g/kg/h; if greater than this glycosuria is highly likely
Weigh daily for 5 days (twice daily if excessive fluid losses/difficult fluid balance)
Twice weekly once stable, then weekly
Weigh on the same scales and at the same time everyday
Urine analysis for glucose and ketones if PN glucose concentration increased
Blood sodium, potassium, urea, creatinine, calcium, magnesium phosphate, and liver function tests analysis on a daily basis over the first 4 days when introducing PN
The child's urine sodium and potassium should initially be monitored twice weekly, and once stable on a weekly basis
Check blood glucose when start to "cycle" PN—initially at 30 min intervals after stopping the infusion
Other nutritional blood tests that should be monitored when starting PN, zinc, copper, selenium, vitamins A and E, and ferritin, then 4–6 weekly
Vitamin D, 6 monthly and if normal, 12 monthly
B group vitamins, T4, TSH annually
<i>PN</i> parenteral nutrition, <i>TSH</i> thyroid stimulating hormone

with venepuncture, it may be extremely difficult to obtain blood samples from a peripheral vein. The distress and/or time attempting peripheral vein access may outweigh the potential complications of using the CVC for other infusions and/or blood sampling.

Administration of PN

The PN should be infused via a pump attached to an infusion stand. The pump should be positioned within 30 cm of the heart and should have a pressure alarm set. The pump should be set to the correct infusion rate and volume to be infused. The infusion should pass through a 1.2 µm filter [6].

Children on long-term home PN treatment should have the use of a portable pump with rucksack for the PN bag itself.

Parenteral fluid and electrolyte requirements are prescribed according to the child's weight [7].

Children in intensive care often have restricted total fluid intake and require other intravenous infusions in addition to PN. It may not be possible to give required nutrients in the volume available for the PN infusion.

Monitoring on PN Treatment

When commencing PN treatment, observations should be performed regularly as shown in Table 47.4.

In addition, the child's length should be measured monthly using appropriate equipment and plotted on the child's centile chart. Head circumference should also be charted in children under 2 years of age.

In certain conditions when fluid balance is altered, weight may not be a useful measure. For example, children in renal

failure or with low blood albumin may retain fluid within the body tissues and those with intestinal pseudobstruction may "pool" fluid within dilated intestinal loops.

Neonatal PN

It is important to commence PN at the earliest opportunity and within 6 h of birth in the "high risk" premature neonate. Initially, PN at 60–90 ml/kg/day that includes both amino acids and lipid. See Table 47.5 for guidelines. Infusion can be commenced via an umbilical venous catheter UVC or peripherally inserted long line. If the child is clinically stable, trophic feeds of expressed breast milk (EBM) should also be commenced. "High-risk" neonates include those born prematurely at less than 32 weeks gestation, very low birth weight (VLBW) of under 1.5 kg, less than 35 weeks gestation with intrauterine growth retardation (IUGR) with weight <9th centile and absent/reversed end-diastolic flow and those with congenital gastrointestinal malformations, such as gastroschisis. Other neonates at nutritional risk who may need PN are those with necrotising enterocolitis, gastrointestinal obstruction, those who need inotropic support, perinatal hypoxia/ischaemia, cyanotic or duct-dependent cardiac lesions or persistent pulmonary hypertension of the newborn (PPHN).

Management on PN

The four major stages in the use of PN are as follows: (1) stabilize the patient, (2) aim for appropriate weight gain—usually "catch up" weight gain required (3) maintain weight centile appropriate for patients length/height (4) withdraw/wean PN and institute enteral nutrition.

Table 47.5 Recommended parenteral nutrient requirements for preterm and term infants [7, 8] *Courtesy of Walsh O, Larmour K, Curry J, Hill S, Huertas A. UCLH, UK Neonatal Nutrition team*

	Parenteral nutritional requirements

ESPGHAN European Society for Clinical Nutrition and Metabolism, European Society of Pediatric Gastroenterology, Hepatology and Nutrition, ELBW extremely low birth weight, VLBW very low birth weight

Enteral nutrition should be continued alongside PN if at all possible. The major benefits of enteral nutrition are prevention of intestinal mucosal atrophy, maintenance of the enterohepatic circulation and if given orally, retention of feeding skills. Full use of any residual intestinal function should be made in order to maximize absorptive ability unless there are significant adverse consequences such as excessive fluid losses or pain. A continuous enteral feed can play an essential role, first in weaning the child off PN by maximizing use of the remaining intestinal function, then in the longer term management at home.

Nutrition Support Team

It is important to bring all professionals contributing to the management of the PN together to work as a nutrition support team (NST) [9].

All children receiving PN treatment should be reviewed on a regular basis and at least weekly by the NST. The multidisciplinary team usually includes a doctor specializing in nutrition, dietitian, pharmacist, and specialist nurse. Other potential members of the team include a biochemist, speech and language therapist, and microbiologist.

The team may either prescribe or advise the medical team caring for the patient.

Complications of Short-Term PN

The most frequent complications associated with PN are the refeeding syndrome and other metabolic disorders, inadequate weight gain, septicemia, liver disease and venous catheter problems, and thrombosis. Each of these problems will be discussed below.

Refeeding Syndrome and Metabolic Disorders

Initial PN complications are most commonly related to fluid and electrolyte imbalance [9]. Refeeding syndrome is a common problem that develops in a previously undernourished child when full nutrition is commenced too rapidly. As the body changes from catabolism to anabolism potassium, phosphate, and magnesium are taken up into the cells and there can be a rapid drop in blood levels known as “refeeding syndrome.” If severe, refeeding syndrome can be life-threatening. The maximum possible phosphate will be needed in the PN. An oral or peripheral blood infusion of phosphate and/or potassium may be required alongside the PN if the amount required exceeds the concentration that is stable within the PN formulation. Low total body sodium is another frequent longer-term problem when sodium losses have not been adequately replaced. Measurement of urine sodium is

one of the most helpful investigations in the absence of diuretic treatment or renal failure. Patients with a low urinary sodium level (<20–50 mmol/l) may have a low total body sodium and are unlikely to gain weight appropriately. Extra sodium infusion in the PN is required. If a patient is weaning from the PN, the extra sodium may best be given enterally.

Inadequate Weight Gain

One of the major complications is inadequate nutrition. The four main reasons are fluid restriction, infusing a lower volume of PN than that prescribed, under-prescribing and negative sodium balance.

It may not be possible to infuse sufficient volume of PN to supply adequate calories and protein in the critically ill child with other major organ failure. The child may only tolerate limited fluid volume and a proportion of the fluid tolerated may be taken up with infusion of medications and as a result the child will fail to gain weight adequately. It is important to infuse any medications in the minimum possible volume and ensure that whenever possible medications are prepared in 10% dextrose to maximize calorie intake. Secondly, children are often given less PN than the volume prescribed. If other infusions are given through the same CVC lumen, the length of time taken for those infusions needs to be taken into account and the total PN volume required prescribed in the hours available.

The PN prescription is based on body weight. It is important that the prescriber uses the patient's expected weight for length/height rather than the actual weight when the weight centile is lower or higher than the length/height centile. The only exception is in the child with stunted growth who may benefit from feeding to a higher length centile in order to improve growth.

Septicemia

Catheter-related sepsis is a common complication. It is important to have a policy for management. If a patient has a fever >38.5°C or symptoms suggestive of septicemia, a blood culture should be taken via the CVC and at least two broad-spectrum antibiotics need to be commenced to treat potential gram-positive and gram-negative bacterial infection. Antibiotics must be given via the CVC. If there is more than one lumen then treatment needs to be rotated between the lumens in order to eradicate the infection. Once cultures are available the antibiotic regime should be tailored according to the bacteria detected. For example, if the organism is only cultured from one lumen then treatment should only be given via that lumen. In older children, but not neonates or children with a major immunodeficiency, the antibiotics

can be stopped if cultures are negative after 48 h. It is usual practice in neonates and immunodeficient patients to give a full 5–7 day course of antibiotics even when the culture is negative.

PN should be continued while treating the infection unless the child develops multiorgan failure or severe cardiovascular compromise when the infusion is commenced. A “Y” connector needs to be attached to the “giving set”/infusion tubing for antibiotic administration.

Risk of septicemia is minimized by cleaning the CVC hub with 2% chlorhexidine when connecting/disconnecting [10] the CVC. Nursing practices when handling the catheter should be regularly reviewed and updated as necessary in order to minimize the risk of infection.

Liver Disease

A common and potentially life-threatening complication is IF-associated liver disease (IFALD). Major risk factors for IFALD include prematurity, lack of enteral intake, recurrent sepsis, length of time on PN treatment, over-feeding, small intestinal bacterial overgrowth, and certain components of PN [11]. Constituents of PN solutions implicated include a high carbohydrate load and the soya component of lipid. Soybean contains phytosterols that have been associated with liver disease by inhibiting bile acid secretion [12]. When affected patients have changed to pure Ω -3 fish oil-based lipid (Omegaven10%, Fresenius Kabi) infusions, severe cholestasis may resolve [13]. Use of newer mixed lipid emulsions including olive oil, MCT as well as fish oil and soybean have also been associated with less IFALD [14]. Safety data using mixed lipid types have been published for premature infants and children [15].

In the neonate, cholestasis commonly develops within 2 weeks of bacterial infection; this could relate to a breakdown in the gut mucosal barrier. Enteral feeding even if less than 10% of the total energy intake is the most important factor in preventing/reversing cholestasis. Ursodeoxycholic acid may be beneficial since it reduces bile synthesis and secretion, solubilizes cholesterol, and increases bile flow. Small-bowel stasis causes bacterial overgrowth and production of the less soluble more hepatotoxic secondary bile acid lithocholate. Oral metronidazole may be used to treat the overgrowth. A deficiency of taurine, a conditionally essential amino acid, results in less of the more soluble taurine conjugated bile acids being made; this can be prevented/reversed by giving a taurine enriched feed. Copper and manganese are usually excreted in bile but become hepatotoxic in cholestatic patients.

In addition, reducing the hours of lipid infusion and the limiting lipid to alternate days appear to improve liver function [16]. See Table 47.6 below for management strategies.

Table 47.6 Management of intestinal failure-associated liver disease (IFALD)

Management of intestinal failure-associated liver disease (IFALD)
1. Treat any underlying infection
2. Introduce enteral feed at the earliest opportunity, even if only minimal amount tolerated
3. Reduce the amount of lipid infused or stop completely if patient is tolerating some enteral nutrition/unlikely to need the PN for more than a further 14 days
4. Reduce the number of lipid infusions/week
5. If totally dependent on PN will require about 0.5 g/kg/day lipid to ensure adequate essential fatty acids
6. If patient is not already on a mixed lipid emulsion change to such a solution
7. Consider reducing frequency of lipid infusions to 2–3 times/week
8. Treat small intestinal bacterial overgrowth with, e.g., metronidazole
9. Consider ursodexoycholic acid at 10 mg/kg TDS
10. Aim to cycle PN, i.e., allow a period of time free of the infusion each day if the child is stable without it

PN parenteral nutrition

CVC Occlusion and Venous Thrombosis

Central venous catheter (CVC) occlusion may occur with deposition of lipid and/or calcium and phosphate precipitates within the lumen. Obstruction may also be positional with the tip resting against the wall of a blood vessel. Occlusion may be cleared with alteplase or alcohol line lock [17]. Limiting lipid infusions helps prevent CVC occlusion related to fat deposition. High concentrations of polyunsaturated fats may impair platelet adhesion; consider reducing lipids to 1–2 g/kg/day if platelets are $<50 \times 10^9/l$.

Home Parenteral Nutrition

Children should be considered for discharge home on treatment with PN if after extensive investigation and treatment in a specialist gastroenterology referral center, it is not possible to significantly improve the underlying disease and symptoms are expected to persist for at least two further months. Every attempt should have been made to wean the child from PN using most appropriate type of feed given via the most suitable enteral route for the child, that is, oral or infused directly into the stomach or duodenum/jejunum. It is usually possible to discharge an infant home from about 4 months of age. Most infants are able to tolerate a 10-h period without PN from about 4.5 kg, although in some cases weight may need to be 6 kg.

The etiology of chronic IF requiring long-term/home PN is most commonly short bowel syndrome, usually with <30 cm small intestine remaining. Other conditions include severe intractable Crohn's disease that has failed to respond to even the most aggressive immunological treatment, congenital enteropathies, for example, microvillous atrophy and tufting enteropathy, and motility disorders including neuropathic or myopathic intestinal pseudoobstruction and intestinal dysmotility. Home PN may be requested for IF secondary

to other organ disease such as life-limiting severe immunodeficiency or malignancy.

Children with severe neurological impairment may develop intestinal dysmotility and hyperaesthesia as their disease progresses. Ethical issues should be addressed when considering long-term/home PN in children with other major organ failure, particularly since PN is unlikely to benefit a child who has progressive disease and will never be capable of an independent life. The aim of treatment is to relieve rather than prolong suffering and improve quality of life. Support from a palliative care team is important.

The aim of PN at home should be to incorporate the child's care into the family's lifestyle and not to have a "hospital at home." Major advantages of going home are that the family is reunited, there is a significantly lower risk of septicemia [18], the child's psychosocial environment improves and s/he can return to usual school and participate in other childhood activities including swimming. It is also possible to enjoy family holidays again.

In most cases, it would not be reasonable to expect a family to function with a child on treatment for more than 14 h. Many parents will continue to have a regular job and care for other children as well.

Organization of PN at Home

The steps that need to be taken when discharging a child home on PN are as follows:

- Nutrition team meets with the parents/carers to explain what is involved and ensure that they are prepared to go ahead with treatment at home.
- The specialist nurse needs to ensure the home is adequate with regard to space to connect and disconnect the PN and to infuse it in the bedroom, ease of access to running water and for the older child, toilet facilities, space for

a dedicated fridge, and reliable electricity supply for the infusion pump.

- Social worker should meet with parents/carers to ensure any social problems are addressed, the employer(s) are informed of need for parents to have time to train and relevant financial benefits are applied for.
- If the patient has a more local hospital that they could be admitted to in an emergency, shared care with that hospital needs to be set up.
- To plan a formal training period for the parents/carers to be taught how to administer the PN. The training is usually undertaken by the specialist nurse. It can take about 30 h to complete and may need to be spread over a 2-week period.
- The simplest possible management regime should be used, for example, a one-person aseptic non-touch technique (ANNT) in order to enable flexibility at home.
- Every effort should be made to train both parents to ensure that they are both fully aware of their child's long-term needs and a second parent is available should the main carer be unwell.
- Funding will need to be secured and a pharmacy to agree to manufacture and if possible, deliver the PN to the child's home.
- Arrangements vary from country to country. Currently, in the UK, there is a national framework for home PN with central government funding.
- Arrange a discharge meeting with all professionals who will be involved in the child's care and parents present. In the UK, the specialist pediatric gastroenterologist, local hospital pediatrician, community nurse, and specialist nutrition nurse are essential participants. The meeting will often need to be held via video-link or teleconference.

Specific Features of PN at Home

PN at home should be infused over 12–14 h overnight thus enabling the child and family to lead a normal daytime life. It is unreasonable to expect a family to have a child attached to a pump for any longer than 12 h and would be difficult for a school age child to pursue a reasonably normal lifestyle (even with a portable pump).

Every effort should be made to supply all PN requirements in a single bag for each infusion night. Most children will need two separate formulations since the lipid-containing infusion should be limited to 2 or 3 nights/week, that is, dextrose and amino acid preparation without lipid should be given on intervening nights.

The PN bag should be made up with extra volume/"overage" in case the child's requirements increase. In smaller infants, the rate of infusion should be reduced for

the final hour in order to minimize the risk of rebound hypoglycemia when the infusion is stopped.

At the earliest opportunity the PN should be reduced to the minimum possible number of nights/week for the child to thrive. It is better to give a larger volume on fewer nights in order to minimize complications such as septicemia. Enteral sodium supplements maybe needed as well as adequate enteral fluid intake after a night off.

As soon as an infant can tolerate about 50% of requirements enterally, PN can be reduced to a maximum of five nights and possibly less.

When discharged, the child should be sufficiently stable to cope with the same PN formulation being given for a week, in order to give the homecare pharmacy a reasonable time to make changes to the formulation. If changes to the PN are required more frequently, the volume should be increased/reduced. The aims should be to obtain PN stability for about 21 days for a single, individualized PN bag. All nutrients should be included in order to minimize infection and nutritional risk of adding to the bag at home. Patients need a reliable source of equipment.

A portable pump should be supplied. Unlike in hospital pressure reading is not essential.

In certain circumstances, for example, when using a commercially available standard bag the vitamins may be added at home. When patients have residual intestinal function, most vitamins (especially water soluble) can be adequately absorbed from the gastrointestinal tract. However, carers may omit enteral vitamin doses, belittling their importance and put the child at risk of thiamine deficiency exacerbated by the high PN carbohydrate infusion.

In patients unable to tolerate lipid, for example, with severe IFALD, enteral walnut oil (<5 ml) may be tolerated. In neonates, EFA can be absorbed from the skin if sunflower or safflower oil is applied daily. Stability of PN formulation can be a major problem in children, particularly due to high calcium and phosphate requirements, two salts that readily precipitate. The pharmacy specializing in homecare should have access both to their own stability data and that available in specialist PN units elsewhere in the UK/Europe. The specialist hospital team should regularly audit the home-care service. From the patient's perspective, it is important to remain with one company, in order to establish a good relationship with the company and delivery drivers.

Complications of PN at Home

Children at home are susceptible to the same complications as children on short-term PN. Prophylactic taurolidine line locks have been associated with a significant reduction in septicemic episodes in children with recurrent infections [19]. Additional complications of long-term treatment are

poor bone mineralization [20], abnormal body composition [21], gallstones, renal abnormalities, and thrombotic complications such as pulmonary emboli.

Venous thrombosis may develop in as many as 67% of children with a central feeding line at home catheter occlusion can be due to a calcium phosphate precipitate or due to fibrin or lipid. One possible mechanism is the formation of antiphospholipid antibodies and a resulting hypercoagulable state with a form of antiphospholipid syndrome. Intralipid contains phospholipids that can be immunogenic. Children with evidence of pulmonary emboli detected on radio-isotopic ventilation–perfusion scan should be treated with long-term prophylactic anticoagulant treatment [22]

Long-Term Management

Parents are expected to connect and disconnect the CVC themselves every evening and morning to minimize the risk of septicemia. Direct access to the closest hospital to the home for acute emergencies should be organized prior to discharge, for example, suspected septicemia or CVC problems such as displacement, obstruction, or exit site infection. The patient can be stabilized there and if necessary transferred to the specialist unit for care, for example, repair of a fractured CVC or radiologically guided insertion of a replacement CVC.

If a child develops recurrent episodes of septicemia, for example, >2/12 months taurolidine or alcohol line lock, should be substituted for heparin [19].

Managing home PN is both physically and psychologically demanding. Practical support should be sought ranging from, for example, doing housework during the day to the carer staying in the home overnight to help with infants by changing nappies/attending to the pump alarms.

The family should have ease of access to contact the specialist center by e-mail/phone. Review in a specialist clinic is usually only necessary on a 3-month basis when the child is stable. Growth and development should be monitored and PN adjusted as necessary. Dietetic input is essential to ensure earliest possible introduction of enteral nutrition. Laboratory investigations/monitoring are also only needed 3-monthly when stable. Appropriate investigations include blood urea, electrolytes, urine sodium, full blood count, vitamin A and E, ferritin, copper, zinc, and selenium. Vitamin D and thyroid function should be checked annually. If iodine-deficient hypothyroidism develops, sea kelp capsules can be given or betadine applied to the skin. Manganese level should be measured annually in view of risk of manganese deposition in the cerebral basal ganglia. Children aged over 5 years should have annual measurement of bone age and bone density [20].

The underlying intestinal disease predisposing the child to IF should be reviewed regularly and treatment appropri-

ately adjusted. Investigations including upper and lower intestinal endoscopy may need to be repeated annually.

Outcome

Management of PN is now so successful that a child can grow and develop normally on PN treatment throughout childhood and into adult life even when unable to tolerate little/no enteral nutrition.

In children with a primary digestive disorder, life expectancy is good with a reported 2-year survival rate of 97%, 5-year survival rate of 89%, and 10-year rate of 81% [23]. Children grow and develop normally on PN. IFALD usually improves in children discharged home.

Weaning/Withdrawing PN Treatment

Weaning a child from PN to oral/enteral nutrition can be one of the most complex aspects of management. Even with extensive investigation and assessment of intestinal function, it is only certain whether a child has adequate intestinal function by reducing the PN and increasing the enteral nutrition appropriately. Most patients have been weaned off treatment from 6 months to 3 years (mean 2.5 years) after discharge. Weaning from parenteral to enteral nutrition is gradual and usually takes place at home with good dietetic support from the specialist unit.

Transition to Adult Care

Children are now being transferred from pediatric to adult care on PN. Transition needs to be arranged on an individual basis since there are a limited number of patients on long-term care into adult life. Although issues relating to transition are the same as for other chronic conditions, transfer needs to be performed between specialist IF units with the experience and resources to ensure the child complies with the process.

The two major changes are (1) the adolescent takes on “ownership” of the condition and (2) the parent(s) relinquishes responsibility. The experienced units have the ability to provide a bespoke service for each patient with a professional (usually a specialist nurse) to provide support.

Transplant

Small intestine often with/without liver/other organ transplant may be appropriate treatment for some patients with long-term dependence on PN when complications develop.

Current indications include limited venous access, severe/progressive IFALD, life-threatening sepsis episode, and poor quality of life for the child and/or family.

Summary

A good nutritional state is a prerequisite for normal growth and development in childhood and a sense of well-being. The effects of inadequate nutrition in childhood may have lifelong consequences (poor growth and intellectual development) in addition to worsening any systemic illness. Children with even severe IF can now survive and grow and develop normally on treatment with PN with the support of a multidisciplinary professional team.

History and Introduction

First described by Dutch physician Paul Barbette in 1674, intussusception is the full-thickness telescoping or invagination of a proximal portion of the intestine into an adjacent, more distal portion. The term derives from the Latin words “intus” (“within”) and “suscipere” (“to receive”). Ladd published the first radiograph with contrast enema demonstrating intussusception in 1913. While he considered contrast enema a useful diagnostic tool, Ladd did not appreciate its therapeutic potential in reducing intussusception. Diagnosis of intussusception was later expedited with the use of ultrasound. Burke and Clarke first described the distinctive ultrasonographic pattern of intussusception, including the pathognomonic “target sign” and “pseudo kidney,” in 1977 [1].

Before reduction techniques were developed and refined, infant intussusception was almost universally fatal in the early nineteenth century. Samuel Mitchell reported the first successful reduction of childhood intussusception by air enema using an enema tube and “common pair of bellows” in 1836. Hirschsprung first described controlled hydrostatic reduction in 1876. Successful reduction by hydrostatic pressure using saline or contrast solutions was reported by Hipsley in Australia in 1926 and by Retan and Stephens in America, Pouliquien in France, and Olsson in Scandinavia in 1927. Despite these reported successes, many surgeons remained skeptical of the potential benefits of hydrostatic reduction in the mid-twentieth century. Reduction by barium enema under fluoroscopy was popularized in the 1950s by Ravitch at Johns Hopkins, but has since fallen out of favor in the UK due to the risk of leakage and subsequent barium peritonitis. In 1959, Fiorito and colleagues reintroduced pneumatic

reduction with pressure control, and this remains the method of choice in the UK today [1].

Although Barbette had suggested the possibility of surgical reduction in his early description of intussusception, the first successful operation for intussusception in an infant after failed hydrostatic reduction did not take place until 1873 under British surgeon Jonathan Hutchinson. As has been the way with many other surgical procedures, it is now possible to reduce intussusceptions laparoscopically. This approach is of particular use in recurrent cases to avoid repeat laparotomy and as a prelude to possible laparotomy in cases of failed conservative treatment [1].

Intussusception represents the most common cause of gastrointestinal obstruction in children aged between 3 months and 3 years [2]. It is the second most frequent acute abdominal surgical emergency in pediatrics after acute appendicitis [3]. Left untreated, intussusception can have serious, potentially life-threatening sequelae.

Pathogenesis and Natural History

The drawing up of the proximal portion of the intestine (the “intussusceptum”) into the lumen of the distal portion of the intestine (the “intussusceptiens”) is driven by peristalsis. As the mesentery becomes progressively incorporated into the intussusception, it is compressed, resulting first in impaired lymphatic return and, second, poor venous drainage, culminating in congestion and edema. This builds pressure on the mesenteric vasculature, eventually causing arterial compromise, infarction, ischemia and necrosis. The mucous membrane lining the lumen is highly sensitive to ischemia and therefore begins to slough off and bleed. Mucous, shed blood, and sloughed mucosa combine and are expelled as “red currant jelly stools.” If the built-up pressure is not relieved, it will result in the complete obstruction of the bowel and transmural gangrene of the intussusceptum. This can produce fluid sequestration, perforation of the bowel, leakage of intestinal contents into the peritoneal cavity, and

peritonitis [2]. If the associated mesentery is lax, the intussusceptum can be drawn up as far as the distal colon or sigmoid (Fig. 48.1) and eventually prolapse through the anus. The later intussusception presents, the more manifest the natural history of the disease will become. Timely diagnosis and management is therefore extremely important.

Spontaneous reduction is another possible outcome and reportedly occurs in almost 20% of intussusceptions [4].

Etiology

The pathogenesis of intussusception is possibly caused by an imbalance in the longitudinal forces acting along the intestinal wall.

The majority of intussusceptions (~95%) are idiopathic as no obvious etiology can be identified. In these so-called idiopathic cases, it is thought that Peyer's patches, hypertrophied in response to a respiratory or gastrointestinal infection, function as a lead point. Peyer's patches are oval masses of aggregated lymphoid follicles on the mucous membrane lining the small intestine. Peyer's patches are distributed irregularly along the anti-mesenteric wall, becoming more numerous and forming a lymphoid ring in the distal ileum. These structures have been labeled the 'immune sensors of the intestine' owing to their role in "sampling" the contents of the gut lumen, taking up antigens and microorganisms and, if appropriate, stimulating a protective mucosal immune response [5]. This probably explains why an antecedent viral infection is present in as many as 20% of intussusceptions. Specifically, adenovirus [6], cytomegalovirus, and live rotavirus vaccines [7] have been variably associated with intussusception. Bacterial enteritis involving, for example, *Salmonella*, *E. coli*, *Shigella*, and *Campylobacter*, also increases the risk of intussusception in children [8].

This imbalance may be caused by a mass protruding into the intestinal lumen, which represents a "lead point" upon which peristalsis acts in an attempt to clear it as if it were a bolus of food. A pathological lead point has been defined as "a recognizable intraperitoneal anomaly or abnormality

that tethers or obstructs the bowel, initiating the process of intussusception" [4]. Pathological lead points are identified in 2–12% of intussusceptions. While a lead point is rarely identified in patients <2 years, 20% of patients >2 years are found to have a lead point [2]. Pathological lead points are more commonly identified in ileoileal or colocolic intussusceptions.

Meckel's diverticulum [9], benign and malignant intestinal or mesenteric tumors including lipomas [10], lymphomas [11], and polyps associated with Peutz–Jeghers syndrome [12], duplication cysts [13, 14], intestinal abnormalities associated with cystic fibrosis (e.g., hypertrophied mucosal glands or thickened feces) [15], hematomas secondary to abdominal trauma [16] or—Henoch–Schönlein purpura and other vascular/coagulation disorders [17], foreign bodies [18], intestinal hemangiomas [19], Kaposi sarcoma [20], abnormalities associated with posttransplantation lymphoproliferative disorder [21], and anastomotic sutures and staples and indwelling tubes [22] have all been reported as providing pathological lead points.

A small percentage of intussusceptions (typically ileoileal) arise postoperatively, usually after laparotomy with extensive bowel manipulation, although it has been reported following other abdominal and non-abdominal procedures. The precise mechanism underlying postoperative intussusception is unknown, but disorganized peristalsis, early postoperative adhesions, electrolyte disturbances, anesthetic drugs, and/or neurogenic factors may be implicated [23].

Epidemiology

In the UK, the reported incidence of intussusception stands at around 1.6–4 cases per 1000 live births [2]. Males are affected more frequently than females, with an incidence ratio of 3:2. The male preponderance becomes more evident after 9 months of age.

Ninety percent of intussusceptions will occur within the first 3 years of life, 65% of cases arising within the first year of life and 50% between 3 and 10 months [2]. Incidence peaks between 5 and 7 months [24]. Intussusception in utero is rarely reported [25, 26], and perinatal intussusception in newborns accounts for only 0.3% of all cases. Several reasons for the increase in incidence from around 3 months of age have been advanced, including changes in feeding practices that affect the gut, maturation of lymphoid tissue, fattening of the mesentery which increases the likelihood of it becoming trapped, or a decline in the protection afforded by maternal antibodies against microorganisms that might precipitate intussusception [2, 27].

Adult intussusception is rare, representing around 5% of all cases. Unlike in the pediatric population, where intussusception is the most common cause of acute intestinal obstruction

tion and is usually idiopathic, intussusception only accounts for 1–5% of cases of intestinal obstruction in adults, often presents atypically and subacutely [28], and it is attributable to a pathological process in 90% of cases. A more definitive, surgical approach (often resection) is warranted when managing adult intussusception compared to pediatric intussusception, due to the significant risk of associated malignancy (~65% cases) [29] and high risk of perforation and leakage of microorganisms [30].

Evidence suggests that the relative risk of intussusception may vary according to race or ethnicity. For example, in their review of pediatric hospitalization data in the USA between 1993 and 2004, Tate et al. [31] found that in infants over 16 weeks of age, non-Hispanic black and Hispanic infants had higher rates of hospitalization for intussusception compared with non-Hispanic white infants. In line with the USA findings, research from the UK and Republic of Ireland suggests that Black Caribbean and African infants have higher incidence rates of intussusception than in White British and Asian groups [27]. Justice et al. [32] and Webby et al. [33] have identified a lower risk of intussusception among indigenous Australian children compared to nonindigenous children. However, as these studies rely on data gathered from hospitals, the differences they identify may reflect differences in admission and access rather than any actual ethnic variation in intussusception incidence [34].

Incidence of intussusception is also thought to vary by geographic region. Compared to other regions, it has been observed that incidence is higher than average in populations in Australia, Hong Kong, Vietnam, South Korea, and Japan and lower than average in populations in Finland, India, Malaysia, and Bangladesh [24, 35]. However, data upon which the assertion of geographic variability is based is problematic [27].

Finally, it is suggested that incidence of intussusception varies by season. Incidence has been found to peak during winter (Dec–Feb) and spring (March–May) in the UK and Republic of Ireland [27], although no such trend has been demonstrated in studies in equatorial regions [36] or indeed in those performed on a global scale [24]. Absence of any significant seasonal variation in incidence of intussusception goes against there being any strong association between intussusception and natural rotavirus, which has a highly seasonal pattern [37].

Classification

Intussusception is classified anatomically, with the proximal portion of the intestine (the “intussusceptum”) first, followed by the more distal portion (the “intussusceptiens”). The majority of intussusceptions (~80%) involve the terminal ileum telescoping into the cecum or ascending colon and

are thus termed ileocecal or ileocolic intussusceptions. Less frequently, segments of ileum invaginate into ileum (ileoileal) or segments of colon invaginate into colon (colocolic) or a combination arises (ileo-ileo-colic).

Clinical Presentation

Sudden onset of severe, colicky abdominal pain is the most common presenting feature of intussusception [38], present in around 85% of cases [39]. Infants will typically present with episodes of inconsolable crying while drawing up their legs in conjunction with spasms of peristalsis. These episodes occur every 10–15 min and last around 2–3 min. The pain becomes more constant after around 12 h. Between episodes, the infant may appear normal or increasingly pale, clammy, quiet, and lethargic. It is hypothesized that lethargy may be induced by the release of endogenous opioids or endotoxins from the ischemic bowel [40].

Vomiting (non-bilious, undigested gastric contents becoming bilious) can be an early indication of intestinal obstruction. Evacuation of small, loose stools from the colon distal to the obstruction will occur early in the course of the disease in some patients. Around 50% of patients pass “red currant jelly” stool [39]. Overall, 1/3 patients will have the classic triad of abdominal pain, vomiting, and bloody stool [2].

The combination of reduced fluid intake, increased fluid loss through vomiting, anticipated losses into the obstructed bowel, and perhaps some reactive vasodilation can culminate in dehydration and hypovolemic shock. If the bowel perforates resulting in bacteremia, the child will become febrile, tachycardic, and hypotensive.

Examination can be unremarkable in between “attacks.” A “sausage-shaped” mass is palpable in around 65% of cases, usually in the right upper quadrant extending to the left along the line of the transverse colon (Fig. 48.2). The mass can be tender and is sometimes seen on clinical inspection. It can become harder to detect this mass as the disease progresses and the abdomen distends [39]. The right lower quadrant can become flat or empty due to the absence of bowel (“Dance” sign). In around 5% of cases, the apex of the intussusceptum

Fig. 48.2 Typical right abdominal mass

Table 48.1 Features of intussusception [39]

Differential diagnosis	Supporting	Excluding
Infantile colic due to wind in the intestine associated with feeding difficulties	Common in first 3 months	Rarely lasts 1 h Usually no vomiting
Gastroenteritis	Severe cases can present with colic and passage of blood and mucus	Greater volume of diarrhea
Strangulated inguinal hernia	Abdominal pain and distension Vomiting	On examination - irreducible lump in the groin

can be palpated on rectal examination. It rarely prolapses out of the anus.

Differential Diagnosis

Conditions that mimic features of intussusception are shown below. These differential diagnoses should be excluded on the basis of careful history taking and examination (Table 48.1).

Investigation

Diagnostic work up of a patient with clinically suspected intussusception might include a plain abdominal radiograph, abdominal ultrasound, contrast enema, and CT scan. Laboratory tests are not specifically diagnostic but may show leukocytosis, acidosis, and electrolyte disturbance associated with bowel ischemia.

A plain radiograph is usually only performed if the diagnosis on presentation is unclear [3]. Suggestive signs of intussusception on a plain radiograph include an elongated soft tissue mass typically in the right upper quadrant, abnormal distribution of gas and fecal contents, dilated bowel loops, no gas in the transverse or descending colon, and air–fluid levels in the presence of bowel obstruction. Although plain radiographs can aid diagnosis of intussusception, they may appear normal in the early stages and they lack sensitivity (i.e., high incidence of false positives) [41].

Ultrasonography is an extremely effective imaging modality for diagnosing intussusception. It has a sensitivity over 98% and a specificity of 100% when diagnosing ileocolic or colocolic intussusceptions. These parameters are slightly reduced for ileoileal intussusceptions [2]. The “doughnut” or “target” sign on transverse section (concentric rings created by the telescoping bowel) and a “pseudo-kidney” (bowel wall and mesentery mimic renal structures) are characteristic signs of intussusception on ultrasound [2].

If the diagnosis is still in doubt, a contrast enema is the gold standard for diagnosing intussusception. Barium or (more commonly) air is introduced via a catheter inserted into the rectum. When the contrast substance enters the lumen of the intussusceptum and the intraluminal space, this

creates the “coiled-spring” sign. This test is contraindicated if there is evidence of perforation on plain radiograph. Enemas can be therapeutic as well as diagnostic [41].

Finally, CT scans are more commonly used in adults with suspected intussusception. Transversely, concentric rings of telescoping bowel will form the equivalent of an ultrasonographic “target” sign. Longitudinally, a soft tissue sausage-shaped mass may be observed. Hyper-dense rings at the proximal end of the intussusception formed by the intussusceptum and the folded edge of the intussusciptens might also be visualized. Occasionally, a lead point may be picked up on CT [41].

Management

Initial management focuses on stabilizing the child. This includes fluid resuscitation using normal saline—20 mL/kg intravenous (IV) bolus to start. Nasogastric (NG) tube should be placed. It should be regularly aspirated and free draining. Prophylactic broad-spectrum antibiotics (e.g., cefuroxime and metronidazole) should be administered.

Focus then shifts to reducing the intussusception nonsurgically or surgically. The majority of cases of intussusception are reduced nonsurgically with sustained intra-colonic pressure delivered by enema using various different substances [42]. Some centers have reported successful reduction of intussusceptions with saline [43].

A catheter, often with an inflatable balloon and attached pressure gauge, is inserted into the rectum, and the child's buttocks are held together to create a tight seal. Air is then passed through the catheter at carefully monitored pressures up to 120 mmHg. Up to three attempts at reduction can be made, each lasting up to 3 min [2]. If the first three attempts fail but the child is clinically well, the air enema can be repeated after 4–6 h (Fig. 48.3a, b). A radiologist usually performs the procedure, but a surgeon must be present in case complications arise, the most serious of which is an acute tension pneumoperitoneum. This compromises venous return from the lower body and causes cardiovascular collapse. Decompression of the abdominal cavity is achieved by inserting a large-bore cannula into the peritoneum. A total

Fig. 48.3 **a** Ileocolic intussusception. **b** Same patient as **a**: After three attempts at reduction

of 75–90% of intussusceptions are successfully reduced by air enema [2].

In the remaining cases, laparotomy can be performed. A transverse incision is made in the right lower quadrant, although occasionally can be transumbilical or in the right upper quadrant. Once the intussusception is located and delivered through the incision, the intussusciptiens is gently squeezed or milked so that the intussusceptum is pushed distally and the telescoping is reduced (Fig. 48.4). The reduced bowel should be carefully examined for signs of ischemic damage and signs of a pathological lead point. Resection with anastomosis may be necessitated by presence of nonviable ischemic bowel or an obvious lead point after manual reduction. Indications for laparotomy include perforation, peritonism, and unsuccessful nonsurgical reduction. Many centers will bypass attempts at nonsurgical reduction in atypical cases or if intussusception is recurrent or related to a pathological lead point [2].

Minimally invasive laparoscopic surgery is becoming increasingly popular for reduction of intussusception [44]. Gentle pressure is applied distally using atraumatic graspers inserted through the ports. A recent systematic review reported a 71% success rate for laparoscopic reduction of intussusception [44]. Compared to open reduction, laparoscopic reductions are associated with shorter operating times, shorter time to first postoperative feed, reduced use of IV narcotics, and earlier discharge [45]. It has therefore been suggested that tertiary centers with adequate facilities should use laparoscopy as the primary surgical approach to reduc-

Fig. 48.4 Intraoperative picture of manual reduction

ing intussusceptions. The major disadvantage to using laparoscopy is that it reduces a surgeon's tactile acuity, meaning that extra care should be taken to search for pathological lead points.

Complications and Prognosis

Complications of pneumatic reduction include perforation causing tension pneumothorax and failure to reduce the intussusception.

Complications associated with surgical reduction of intussusception include perforation, systemic infection (e.g., sepsis and meningitis), bleeding, wound infection, leak or breakdown of an anastomosis, incisional hernia, adhesions, and bowel obstruction [4]. Resection rarely has any long-term consequences, although removal of the ileocecal valve may cause increased stool frequency [2].

Recurrence of intussusception following reduction is not uncommon. Recurrence usually arises within 2–3 days of the first reduction (~60% within 6 months), presents early, and is treated in the same way as the initial episode. Recurrence is more likely in the presence of a pathological lead point.

Death is a rare outcome, usually associated with late presentation. Prognosis varies globally as diagnosis and treatment usually occur earlier in developed countries compared to the developing world [36].

Conclusion

Intussusception is a common emergency in pediatric surgery, which must be diagnosed and managed swiftly to avoid life-threatening complications. It should be suspected in children presenting between 3 months and 3 years with colicky abdominal pain, vomiting, and bloody stools and reduced as soon as possible to avoid irreversible ischemic damage to the bowel. Therapeutic pneumatic air enema forms the main form of treatment modality. Surgical reduction of intussusceptions, when required, is becoming less invasive.

Ashish P. Desai

Introduction and History

Meckel's diverticulum (MD) is one of the commonest diverticulum in human beings. It occurs in 2% of the population. As Charles Mayo described—"Meckel's diverticulum is frequently suspected, often looked for, and seldom found".

Heladnus first described it in 1598 [1]. Ruysch and Levater described the diverticulum much before Meckel's description [2]. However, Johann Friedrich Meckel described the diverticulum in detail in 1809 and is credited with the first detailed description [3].

In 1962, Harper et al. suggested that as ^{99m}Tc pertechnetate is concentrated by gastric mucosa, the MD containing the gastric mucosa should be identifiable scintigraphically using ^{99m}Tc pertechnetate [4]. However, most MD may be identified intra-operatively due to its varying presentation of intestinal obstruction caused by either band with volvulus or intussusception, umbilical discharge and diverticulitis.

Embryology

During the first few weeks of gestation, primitive yolk sac divides into primitive midgut and yolk sac. Omphalo-mesenteric duct or vitello-intestinal duct connects the two. This structure usually regresses between 5th and 7th week of intrauterine life. Failure of regression leads to various presentations of patent vitello-intestinal duct (VI duct). Persistence of the tube proximally causes MD.

Incidence

MD is usually described by rule of 2. Common dictum is that it is present in around 2% of the population. It is 2 in. long and found around 2 ft from the ileo-caecal (I/C) valve. It may contain two types of heterotopic mucosa—gastric or pancreatic.

However, these are more generalisations than fact. Incidence of symptomatic MD is thought to be around 4% in the first 3 years of life. Following that, the incidence decreases. Prevalence of MD during postnatal autopsies is 1.23% [5].

Associated Anomalies

MD is usually an isolated condition. However, patients with Hirschsprung's disease, Down syndrome, oesophageal atresia, duodenal atresia, malrotation and congenital cardiac abnormalities show increased incidence [6].

Gross and Microscopic Anatomy

MD arises on the anti-mesenteric border of the ileum. Its distance from I/C valve is variable and is thought to be anywhere from 30 to 120 cm. Hence, during surgery, it is advisable to inspect at least 150 cm of terminal ileum. It has its own blood supply from persistent vitelline artery which is a branch of superior mesenteric artery.

On histology, it usually resembles the ileum. As it is a true diverticulum, it contains all layers of a normal intestine, that is, mucosa, submucosa, muscularis propria and serosa. However, it may contain heterotopic mucosa—either gastric or pancreatic tissue. Incidence of gastric mucosa occurs in around 9% of the patients. Pancreatic mucosa is seen in 2.5% of patients [7]. Various studies have also showed presence of carcinoid, lipoma, leiomyoma or enterolith.

Variations of Patent VI Duct Anomalies

VI duct anomalies occur due to variation of persistence of VI duct remnant and its attachment to the umbilicus.

Various anomalies are

1. MD—persistent proximal part of the VI duct
2. Isolated fibrous band—persistent remnant of whole VI duct
3. Omphalo-mesenteric fistula—presents as stoma at the umbilicus [8] or prolapse through the umbilicus [9]
4. Enterocyst—persistent middle part of the fistula.
5. Meckel's diverticulum may also have attached fibrous band.

Clinical Features

Most MDs are asymptomatic throughout life. In symptomatic cases, presentation varies with age.

Neonatal

In neonates, the presentation is usually due to persistent VI duct presenting as either a discharging sinus at the umbilicus [8] or a prolapsing VI duct remnant [10, 11]. Other presentations may be due to a band with associated volvulus causing partial or complete obstruction. Perforation is rare.

Pediatric Age Group

In pediatric age group, presentation varies between gastrointestinal (GI) bleeding, Intestinal obstruction and inflammation.

GI Bleeding

GI bleeding is the commonest presentation in children below 2 years of age. It is usually the major lower GI bleed, which is painless or associated with minimal pain. The bleeding is associated with gastric heterotopia in majority of cases [12]. Bleeding is due to peptic ulcer in the surrounding normal ileal tissue.

In cases where the gastric mucosa is absent, bleeding is usually attributable to other causes like intussusception or gastritis.

Management of major GI bleed should include—assessment of hemodynamic stability, differentiation between upper and lower GI bleeding and then to determine the diagnosis and site of the bleeding.

In children suspected to have MD, after adequate fluid resuscitation, they should be started on H2 blockers like raniti-

dine or famotidine. Currently, proton pump inhibitors like omeprazole or lansoprazole are routinely used. Once bleeding is controlled, 99 m technetium-pertechnetate scan should be done to look for the diagnosis of MD. If diagnosed, they should be resected.

Diverticulitis

Inflammation of the MD may be the presenting sign in 10–20% of children. Children are usually older. They are often mistaken as acute appendicitis. During surgery, inflamed MD is identified and should be excised.

Obstruction

Obstruction is a common presentation in children as well as adults. Obstruction could be due to multiple reasons like volvulus around the MD with fibrous band, intussusception [13], enterolith or incarceration in Littre's hernia [14] or within umbilical hernia [15].

Other Presentations

Other rare presentations can be due to development of bezoar in the diverticulum [16] or malignancy. The commonest tumour affecting the MD is carcinoid tumour [17, 18]. However, villous adenoma [19] or GI stromal tumour [20] has also been reported.

Investigations

As MD has very varied presentation, it is not always possible to diagnose it prior to surgery. The surgeon needs to have high index of suspicion.

However, the investigations, which might raise the possibility of MD, are as follows:

1. *Plain X-ray abdomen*: Plain X-ray may show evidence of intestinal obstruction. If enterolith is present, it may be visible. If MD has perforated, pneumoperitoneum may be visible.
2. *GI Contrast study*: It is unusual to identify MD by barium meal. However, it may be visible in 0.7% cases by small bowel enema.
3. *Fistulogram*: Patent VI duct may be identified by fistulogram from umbilical fistula.
4. *Angiography*: In adults and older children, bleeding MD may be identified by selective superior mesenteric artery angiography. If the patient is very unstable, it may be possible to temporarily occlude the bleeder by embolising the vessel. However, the patient should have laparotomy as soon as he is stabilised as embolisation may lead to gangrene and perforation of MD in a few hours' span.
5. *Scintigraphy*: Harden demonstrated that technetium-99m was concentrated in the gastric mucosa. Hence, it can

demonstrate the presence of heterotopic gastric mucosa in MD when present. The isotope is selectively taken into gastric, salivary and thyroid tissue. It is excreted in urine. Hence, sometimes, false-negative scans may be reported if the diverticulum is overlapped by urinary bladder. Sensitivity of the scan can be increased by using either pentagastrin or glycogen [21]. Scan has specificity of more than 95% and sensitivity of more than 85%.

Surgical Technique

Resection of the diverticulum is the final aim. Whole diverticulum with heterotopic mucosa, if present, should be excised. After the excision, the bowel needs to be anastomosed without causing luminal obstruction. This can be achieved either by diverticulectomy alone if the base is narrow or by resection of the ileum containing the diverticulum with end-to-end anastomosis.

Decision about diverticulectomy or segmental resection is usually on individual surgeons. MD Resection Index (MDRI) has been proposed which calculates the index using the length and width of the diverticulum [22].

This procedure was routinely performed by laparotomy but, with changing practice, laparoscopy is playing an increasing role. During diagnostic laparoscopy performed whether for GI bleeding or acute appendicitis, routine examination of the terminal ileum should be carried out for at least 150 cm from the I/C valve to look for MD. Surgeon should start inspecting the ileum systemically from I/C valve. Two bowel graspers at anti-mesenteric border should grasp intestinal loops, and both sides should be examined. When MD is identified, it can either be excised in situ or the same can be delivered outside the abdominal cavity and the resection and anastomosis performed. The intestine can then be repositioned inside.

With advances in the minimal access techniques, now the same can be performed either using single-port technique [23] or natural orifice trans-luminal surgery (NOTES) [24].

Outcome/Conclusion

Meckel's diverticulectomy has low morbidity and mortality. However, its first presentation may be at any age and is varied with obstruction, diverticulitis, haemorrhage or neoplasm [25]. Hence, the clinician needs to show high degree of suspicion and look out for this. It is seldom found easily, and early diagnosis and proper treatment is essential to manage its varied clinical symptoms. Surgical or laparoscopic techniques have developed over time, and today laparoscopy has found its increasing use in the management of MD.

Background

The appendix is considered as a vestigial organ and does not seem to have a function in human beings.

Appendicitis was first described accurately by Reginald Fitz in 1886, who described the clinical history, physical findings, and pathology. He was also the first to advocate appendectomy for appendicitis. In 1887, Thomas Morton performed the first successful appendectomy in the USA. In 1889, Nicholas Senn from Chicago (the USA) was one of the first surgeons to diagnose acute appendicitis correctly and perform an appendectomy. In this same year, Charles McBurney described the clinical findings of acute appendicitis and the point of maximal tenderness.

Inflammation of appendix or appendicitis is the most common pediatric surgical emergency. In spite of being a common condition, it is often misdiagnosed or diagnosed late.

Incidence

Males are more commonly affected with male to female ratio of 1.4:1. The incidence between birth and the age of 4 years is 1–2 cases per 10,000 children per year, which increases to 25 cases per 10,000 children per year between 10 and 17 years of age. Thereafter, the incidence continues to decline, although appendicitis does occur in adulthood and into old age.

Overall, 7% of the population in the USA will have their appendix removed during their lifetime.

Appendicitis is 1.4 times more common in whites than in nonwhites [1]. It is also much more common in developed countries. Although the reason for this discrepancy is unknown, potential risk factors include a diet low in fiber and high in sugar, family history, and infection [2].

Anatomy

The appendix is a blind-ending tube arising from the cecum where the three taenia meet. It roughly lies at the lower 1/3 junction of a line joining the anterior superior iliac spine and umbilicus. This junction is also called the McBurney's point.

Although the base of the appendix is fixed to the cecum, the tip can be located in various positions around the cecum and presents with different symptoms and different sites of tenderness causing diagnostic dilemma.

Cecum develops as a dilatation of the hindgut by 5 weeks of gestation with the appendix appearing from it by 8 weeks of gestation. The appendix has all the three layers of colon and is lined by colonic epithelium.

The submucosa contains lymphoid follicles, which are very few at birth and gradually increase to a maximum of 200 between 10 and 20 years of age. Their numbers then declines throughout adulthood and are half the number by 30 years.

Etiopathogenesis

Acute appendicitis is the end result of a primary obstruction of the appendix lumen. Most common cause of luminal obstruction is fecal deposits known as appendicoliths or fecoliths, which are hardened fecal deposits. In children, obstruction by submucosal hyperplasia of lymphoid follicles is also common. The cause of this hyperplasia is controversial, but dehydration and viral infection have been proposed.

Fecal stasis may play a role in development of appendicitis, as patients of appendicitis tend to have a significantly

lower number of bowel movements when compared with normal controls. Many studies have shown a direct correlation between a low-fiber diet and the incidence of appendicitis [2].

Rare causes of appendicular obstruction include worms, foreign body, strictures, and neoplasm especially carcinoids [3, 4].

Following the obstruction, the appendix gets filled with mucus and distends. The bacteria trapped within the appendicular lumen begin to multiply increasing the distension. This causes a progressive rise in the intraluminal pressures leading to occlusion to lymphatics and blood vessels. The appendix becomes edematous, congested, and later ischemic. Occlusion of the blood flow and stagnation of blood causes thrombosis within these small vessels.

The combination of bacterial infection and ischemia produce inflammation, which progresses to necrosis and gangrene. When the appendix becomes gangrenous, it may perforate. Perforation is caused by ischemic weakening of appendicular wall, increased intraluminal pressure, and erosion by fecolith.

The progression from obstruction to perforation usually takes place over 72 h. Appendiceal perforation is more common in children, specifically younger children, than in adults. Perforation is directly related to the duration of symptoms before surgery [1, 5–7].

Staging

As the condition progresses, the appendix passes through the stages of ischemia, necrosis, gangrene, and perforation. This progression is arbitrarily divided into three stages namely: acute (non-gangrenous), suppurative, or gangrenous (non-perforated), and perforated appendicitis.

Clinical staging of appendicitis is important for planning postoperative management and prognosticating the child.

The first stage is acute appendicitis also called as early appendicitis with absence of mural necrosis or gangrene. Rarely, spontaneous recovery may occur in this stage.

Suppurative or gangrenous (non-perforated) appendicitis is the second stage, which involves mural gangrene with microperforations and transmigration of intramural bacteria. This frequently causes intra-abdominal or wound infections.

Perforated appendix is the third stage with perforation of the appendiceal wall and release of intraluminal contents in the peritoneal cavity leading to peritonitis. Perforated appendicitis can be further divided into cases with localized or dif-fused peritonitis. The omentum and adjacent bowel loops try to contain the spillage of luminal contents. If the perforation is contained it forms an appendicular abscess otherwise it leads to a generalized peritonitis.

If untreated, the infective process may continue and cause septicemia and death.

Presentation

Presentation in children varies with age and location of the appendix.

Classical symptoms of acute appendicitis, usually seen in older children, are abdominal pain, vomiting, and fever, occurring in that order. It is also called Murphy's triad. This is present in only 2/3 causing diagnostic problems.

A neonate may present only with irritability and refusal of feeds. Younger children are uncomfortable, withdrawn, and listless and prefer to lie still because of peritoneal irritation [8, 9].

Pain

Almost all (99%) patients with appendicitis have abdominal pain [7].

The classical presentation is of an initial gradual onset, diffuse periumbilical pain leading to pain which is more intense, continuous, and localized in the right iliac fossa (RIF).

The migration of pain to RIF is highly specific, but occurs in only half of the patients [7].

Initial pain is due to innervation of visceral peritoneum and stretch receptors of the appendicular wall by T10 nerve roots. While, later there is involvement of the parietal peritoneum, which is supplied by the pain sensitive receptors.

Localization of pain depends on the location of the tip of appendix and the collection of exudate. Hence, pain may also localize to flank, right upper abdomen, pelvic region, or to psoas muscle if the appendix is retrocecal.

Atypical presentations are common in children who are neurologically impaired, immune compromised, or are already on antibiotics for another illness leading to delay in diagnosis. Perforation of appendix with reduction of intraluminal pressure may cause a period of relief of pain, which is soon followed by development of generalized abdominal pain and peritonitis.

Nausea and Vomiting

Many patients develop nausea (81.7%), anorexia (72.4%), and vomiting (67.7%). This usually follows pain [7].

Diarrhea

Diarrhea is rare in appendicitis, but may occur in pelvic appendicitis or perforated appendix with a pelvic abscess.

Inflammation of the rectum and perirectal tissue causes irritative hypermotility and excessive secretion of excessive mucous presenting as diarrhea. Characteristically, diarrhea in appendicitis is frequent, small in volume, with soft stools rather than watery diarrhea associated with infection. Occasionally, there may be blood in stools with tenesmus.

Fever

Most children with appendicitis are afebrile or have a low-grade fever, with characteristic flushing of cheeks (44.9%) [7]. High fever is uncommon and may be present if perforation has occurred. Children with generalized abdominal pain, tachycardia, and a temperature higher than 38°C are likely to have perforated appendicitis [10].

General Examination

Patients' general state should be observed before interacting with them. The patient's state of activity or withdrawal may lend information into their condition.

General examination should include examination of chest to look for pneumonia, an ear, nose, and throat (ENT) examination to look for tonsillitis that may be suggestive of mesenteric adenitis as the cause of pain. The child's gait may be observed to look for any abnormalities.

Abdominal Examination

Abdomen should be fully exposed and examination should be gentle to cause minimal distress.

All patients of suspected appendicitis should have adequate and early relief of pain. Giving morphine for pain relief does not interfere with diagnostic findings, but may improve diagnostic yield and make the child more cooperative [11]. Observation of facial expressions during palpation gives vital clues.

Tenderness is present in early, a stage which is followed by guarding, rebound tenderness, and rigidity. Usually, maximal tenderness is present at the McBurney point but may vary depending on the location of the appendix.

Younger children have a more diffuse abdominal pain.

A child with peritonitis lies still and sudden movements may cause pain. Gentle percussion of the abdomen may elicit rebound tenderness. An appendicular mass may be palpable in late cases.

Acute scrotum should be looked for in boys as it may present with abdominal pain, nausea, and vomiting.

There are various signs described for diagnosing appendicitis.

- Pain in the RIF when pressed in left iliac fossa (LIF) is called Rovsing sign and indicates peritoneal irritation.
- Rebound tenderness over McBurney's point is called Bloomberg sign.
- Pain on hyperextension of right hip is called Psoas (Cope's psoas) sign and suggests an inflammation of psoas muscle due to an inflamed retrocecal appendicitis overlying it.
- Pain on internally rotating the flexed right thigh indicates an inflamed pelvic appendix overlying the obturator muscle and is called the obturator (Cope's obturator) sign.
- Sherren triangle hyperesthesia is increased tactile sensation in the triangle formed by joining anterior superior iliac spine, the pubic symphysis, and umbilicus.
- Dieulafoy's triad is hyperesthesia, marked tenderness, and guarding over McBurney's point and is an important finding.

Per Rectal Examination

A rectal examination is usually not done in children, but can be helpful in doubtful cases of pelvic appendicitis and in sexually active adolescent girls to check for pelvic inflammatory disease (PID) [12].

Differential Diagnosis

Various abdominal and extra-abdominal conditions mimic appendicitis.

Abdominal Conditions Mimicking Appendicitis

GI Tract Meckel's diverticulitis, pancreatitis, gastroenteritis, intussusception, neutropenic typhlitis, epiploic appendagitis, volvulus, typhlitis, omental torsion, constipation, hemolytic-uremic syndrome, Henoch–Schoenlein purpura.

Other Abdominal Organs Urinary tract infections, pelvic inflammatory disease, ovarian cyst, pyelonephritis, renal calculi, testicular torsion, ovarian torsion. PID, pregnancy, ectopic pregnancy, renal calculi, mittelschmerz, and paratubal cysts.

Extra Abdominal Organs Presenting with Abdominal Signs Mesenteric lymphadenitis, pneumonia (right lower lobe), lymphoma.

Differential Diagnosis for Acute Appendiceal Abscess or Mass Includes Inflammatory bowel disease including Crohn's disease and malignancy.

Investigations

Urine

Urine should be tested to rule out urinary tract infection as well as for pregnancy test in adolescent female patients.

Full Blood Count

White blood cell (WBC) count is usually normal in first 24 h and becomes raised with disease progression. In first 24 h, raised neutrophil count or band count may aid in diagnosis. Leukocytosis is found in approximately 70–90% of patients with progression of appendicitis. Leukocytosis is a nonspecific marker of inflammation with low specificity [7, 13].

In the immunocompromised patient, especially those on chemotherapy, a neutrophil count lower than 800 may suggest neutropenic enterocolitis or typhlitis.

C-Reactive Protein

C-reactive protein (CRP) is an acute phase reactant and is raised in 85% of the cases of appendicitis. Following inflammation, CRP rises within 12 h of inflammation.

CRP with raised WBC can be used in tandem to increase the diagnostic accuracy [13].

Abdominal X-Rays

Plain abdominal X-rays has a low sensitivity and specificity [7]. Nonspecific signs of appendicitis are appendicolith, lumbar scoliosis due to psoas spasm, obliteration of the right psoas margin due to inflammatory edema, localized ileus in RIF, RIF mass, air in the appendix, and rarely intraperitoneal free gas.

Abdomen X-ray is normal in many patients with appendicitis. Appendicolith is present in many normal controls [8].

Ultrasonography

A normal appendix is sometimes visualized on ultrasonograph (US), especially in thin patients with a wall thickness of less than 3 and 6 mm in diameter. An inflamed appendix is more easily seen as it is much larger than 6 mm in diameter

and wall thickness greater than 3 mm. It appears as a non-peristaltic, noncompressible, blind-ended, tubular structure which is tender. Graded compression technique described by Puylaert in 1986 requires visualization of appendix and eliciting tenderness by compressing it with the probe. The point of maximum tenderness is also called sonographic McBurney point [14].

In the transverse plane, the inflamed appendix has a target appearance. In approximately 1/3 of patients, an appendicolith is seen as an intraluminal echogenic material with post-acoustic shadowing. Peri-appendiceal fluid collection, localized ileus and hyperechogenic pericecal fat, and increased blood flow on Doppler scan are some of the other findings of appendicitis.

Abdominal US has proved to be valuable for diagnosing appendicitis in children, with many published reports indicating a sensitivity, specificity, and accuracy of at least 90–95% [15]. Factors that add difficulty to the examination include obesity and gaseous distension of the intestines overlying the appendix [7, 16].

US is also used extensively to monitor or perform percutaneous appendicular abscess drainage [15].

US is useful in diagnosing other causes of abdominal pain, for example, tubo-ovarian pathology, mesenteric adenitis, etc.

CT

CT scan has a high sensitivity and specificity when compared with those of other imaging techniques. Appendicitis is suggested by a non-filling of appendix with contrast, distended appendix, hyper enhancement of the appendiceal wall, appendiceal wall thickening (>3 mm), appendicolith within the appendix, and fat streaking around the appendix. Other signs being thickening of the cecal wall, enlarged mesenteric nodes, peri appendicular inflammation or fluid, extraluminal air, marked ileocecal thickening, localized lymphadenopathy, peritonitis, and small-bowel obstruction. Arrowhead sign indicates contrast outlining the cecum and funneling into the origin of the appendix, with obstruction of the lumen preventing retrograde flow of barium into the distal appendix. Signs of perforated appendicitis include abscess, phlegmon, appendicolith within an inflammatory mass or in a fluid collection and extensive free fluid. Air in periappendiceal, pericecal, retroperitoneal region, or in the abscess cavity is suggestive of perforation. Rarely, gas under the diaphragm may also be seen.

CT scan has an accuracy of more than 97% in diagnosing appendicitis. It is readily available, noninvasiveness, and can diagnose the other causes of abdominal pain [15].

Disadvantages include radiation exposure, the need for oral and intravenous (IV) contrast and its related disadvan-

tages, and the need for the patient to be still, which is often difficult for small children.

CT scan is very helpful in diagnosing and managing perforated appendix. CT scan defines the extent of the abscess and is useful in performing an open surgical or percutaneous drainage of an abscess.

Magnetic Resonance Imaging

MRI is rarely used in diagnosing appendicitis, although it has the advantage of avoiding radiation. Diagnosis involves findings of enhancement of the inflamed appendix and surrounding fat.

Two different techniques have been described one being gadolinium-enhanced, fat-suppressed, and T1-weighted, spin-echo images, the other being unenhanced, axial, and T2-weighted, spin-echo imaging which avoids the use of nephrotoxic gadolinium and is apparently the preferred method.

MRI has an accuracy of nearly 100%. Ileal diverticulitis/abscess and Crohn's disease may lead to false-positive results on MRI [16, 17].

Nuclear Imaging

WBC tagged scans have been developed to diagnose appendicitis with 91–95% accuracy. The scans are time consuming, costly, not freely available, and hence are of no practical use.

Diagnosis

Many scoring systems, protocols, diagnostic pathways algorithms have been devised to aid in diagnosis, however, none of them are foolproof, and clinical judgment and experience is required to reduce errors. Probably the most common scoring system used is the Alvarado (MANTRELS) score. Other common scoring systems being Samuel score, Kharbanda, Eskelinen, Lintula, and Ohmann score [18–20].

Fluid Resuscitation

Children with appendicitis are dehydrated. Even in early acute appendicitis, children frequently have a poor oral intake and vomiting contributing to intravascular depletion caused by third space losses.

It is essential to adequately hydrate patients who present with suspected appendicitis.

Patients with advanced appendicitis will require fluid boluses prior to operation. Urine output should not be lower

than 0.5 mL/kg/h. If urine output needs to be determined accurately and frequently, then Foley catheter should be inserted.

Management

The definitive treatment for appendicitis is appendectomy, which can be performed by open or laparoscopic method. Meta-analysis has shown both the methods to have similar results and none to be better than the other. Laparoscopy obviously has a better cosmetic appearance; some studies report a lesser pain, early resolution of ileus, early mobilization, and discharge [21–23].

Contraindications

Almost no contraindications exist to the surgical treatment of appendicitis. However, in patients with septic shock at the time of presentation, surgery should be delayed to ensure adequate fluid resuscitation and appropriate broad-spectrum antibiotics administration.

Conservative Management

Appendectomy is an established treatment for appendicitis, since the time of Fitz 100 years back; many researchers have now questioned the role of appendectomy in the era of new and improved antibiotics. Some surgeons advocate nonoperative treatment with antibiotics for early appendicitis, more so, if the diagnosis is in doubt [20, 24].

The most commonly encountered organisms in appendicitis are *Escherichia coli*, *Klebsiella*, *Enterococcus*, *Bacteroides fragilis*, *Pseudomonas*, *Clostridium*, etc. [25–27]. Antibiotic regimens should provide wide coverage for Gram negative and anaerobic organisms. The common antibiotic used is a second-generation cephalosporin or amoxicillin-clavulanate.

Oschner was the first one to recommend conservative management in patients with an appendicular mass [28].

A patient with perforated appendicitis is kept nil by mouth, given adequate analgesia, broad spectrum antibiotics, and administered IV fluids. Oral intake is allowed gradually and increased as tolerated. Fluid and electrolyte balance are managed carefully. In the presence of appendicular abscess, percutaneous drainage is performed if it can be safely approached. Child can be discharged once afebrile, pain free on oral medications, and is on adequate oral intake.

Patients who do not improve or deteriorate on conservative management should have drainage of abscess with or without an appendectomy. Indications of failure of conser-

vative management being—hemodynamic instability, increasing WBC count with toxic granules and shift to the left, persistent hyperthermia greater than 38 °C. Lack of clinical progress within 3 days is deemed as failure. Conservative management fails in as many as 38% of children with perforated appendicitis [6, 10, 29, 30].

The ideal management in pediatric patients with a perforated appendix is unclear and could be treated by emergency appendectomy or conservative management. Interval appendectomy may be performed 2–3 months later following a successful conservative management.

The necessity of interval appendectomy following conservative management is being questioned since conservative management was first recommended. Proponents of interval appendectomy believe that there is a high rate of recurrent appendicitis if appendectomy is not performed. The possibility of a missed pathologic diagnoses coupled with a low complication of interval appendectomy strengthen their case. Some surgeons perform interval appendectomy only if a fecolith is confirmed on imaging studies as presence of appendicolith increases recurrence rate to 72 from 20% in other cases [7, 29, 31, 32].

The opponents argue that the incidence of recurrent appendicitis following conservative management is low and the residual appendix is shriveled or may be having a pathology other than appendicitis like a neoplasm, Meckel's diverticulitis, etc. [4, 31, 32]. There is also a worry regarding a finite operative morbidity of a procedure which is probably not required. Conservative management with interval appendectomy requires extra resources due to increased hospital stay, repeated imaging, and prolonged antibiotics [20, 32, 33].

A large meta-analysis done by Anderson et al. showed a significantly greater morbidity for emergency appendectomy than for conservative treatment with interval appendectomy (35.6 vs. 13.5%). Laparoscopic interval appendectomy has a low morbidity, better visualization of the abdomen, and can be performed as a day case procedure. Hence, it is the procedure of choice for most surgeons [6, 34, 35].

Appendectomy

Patients should be adequately resuscitated with fluids prior to surgery and should receive preoperative prophylactic antibiotics.

Open Appendectomy

Under general anesthesia, the abdomen is palpated and if a mass is felt some surgeons would manage the patient con-

servatively and may perform interval appendectomy (read conservative management).

A transverse right lower quadrant incision is made, usually at the McBurney's point. If an abdominal mass is palpable after the induction of anesthesia, the exact location of the incision can be shifted so that it is centered over the mass.

After identifying and delivering appendix, it is devascularized and the stump is ligated before amputating the appendix. Appendicular stump may or may not be buried.

If a normal-appearing appendix is identified, other pathologic conditions should be sought like evidence of Crohn's disease, mesenteric lymph nodes, and Meckel's diverticulum. In females, ovarian pathology should be excluded.

If no other pathology is identified, most surgeons will remove the appendix. In case of peritoneal contamination, peritoneal wash with warm 0.9% saline is given to reduce the contamination. A few surgeons have questioned the usefulness of the intra-abdominal wash [36].

Laparoscopic Appendectomy

Many surgeons have reported superior results with laparoscopic method compared to open method. Although, no studies have conclusively proved superiority of one over the other, laparoscopic technique has the obvious advantage of better cosmesis and is frequently used for diagnostic purposes [10, 22, 37, 38].

Single-incision multiport laparoscopic surgery has gained popularity in recent years. Multiple prospective, randomized studies comparing single-incision versus standard three-port laparoscopic appendectomy have shown no advantages of one technique over the other with respect to complications, but they differ in their cosmetic satisfaction scores [10, 39, 40].

Management of Appendicular Abscess

Patients discovered to have perforated appendicitis should have appendectomy. In perforated appendix, there is a high incidence of wound infection.

If an abscess cavity is found, the cavity is cleaned and a drain may be placed.

In rare cases where appendix cannot be safely identified and removed, the appendix is left in place, the abscess cavity is drained, and a subsequent interval appendectomy is planned [41].

Monitoring and Follow-up

The postoperative course is dictated by the status of the appendix at operation. Postoperatively, pain control, mobilization, and chest physiotherapy are very important.

Children with uncomplicated appendicitis can be established on oral intake soon after surgery. It should be possible to discharge these patients within 24–36 h after the operation.

Patients with complicated appendicitis and ileus may take time to return to oral feeds. Those with prolonged ileus will require a period of nasogastric drainage and a few would benefit from parenteral nutrition.

Histology

Histological findings range from acute inflammatory infiltrate in the lumen or submucosa level in early appendicitis. Gangrenous appendicitis may show area of necrosis and thrombosis. Evidence of transmural infarction is seen in perforated appendicitis.

A “normal” appendix found at surgery may show signs of early appendicitis (7.7%) like intraluminal or submucosal inflammatory cells on histological findings of intestinal parasites which require antihelminthic treatment [3, 7]. Chronic inflammation or fibrosis of the tip of the appendix may be seen in the so-called resolving appendicitis.

Most centers would accept a 10–20% of removal of normal appendix rather than risk the morbidity of perforated appendix [7]. Widespread use of imaging studies and diagnostic protocols has reduced this rate [9, 16, 17, 42].

Complications

Wound infection (0–84%) is among the most common complications, more so if there is complicated appendicitis [25, 43]. Rarely there is a complete or incomplete wound dehiscence.

There has been lot of debate regarding reduced fertility in females due to intra-abdominal adhesions following perforated appendicitis. Urbach et al. in 2001 convincingly demonstrated that there was no reduced fertility following appendicitis.

Postoperative ileus is common with peritonitis or following extensive dissection and handling of bowel as in appendicular abscess.

Postoperative adhesions are also a known complication and majority resolve spontaneously with the above management.

Post Appendectomy Abscess

Some patients especially those with complicated appendicitis like gangrenous or perforated appendicitis develop intra-abdominal abscesses (0–12%) [25]. These may be present at the time of presentation or may develop postoperatively.

A post-appendectomy patient with prolonged ileus, swinging temperature for more than 3 days postoperatively, increasing neutrophils, and persistently raised inflammatory markers should be suspected to have an intra-abdominal abscess. Sometimes the wound becomes erythematous, painful, and drainage of large quantity of pus, raising suspicion of intra-abdominal collection.

US is very sensitive in diagnosing a collection.

The majority is small and resolve with an extended course of antibiotics. Larger intra-abdominal abscess may require drainage of the collection, usually performed under ultrasound guidance.

Prognosis

The prognosis is good in timely managed child. Morbidity and mortality in appendicitis is related to the time since initial presentation and treatment. Appendix is perforated in 20–30% of cases at the time of diagnosis. Intra-abdominal abscesses, most commonly pelvic, occur postoperatively in about 10% of cases of perforated appendicitis [25].

The perforation rate rises dramatically to 80–100% in children younger than 3 years, whereas the rate is 10–20% in children above 10 years [7]. Children with ruptured appendicitis are more likely to have wound infection, prolonged ileus, delayed feeding, intra-abdominal abscess formation or adhesive intestinal obstruction leading to an extended hospital stay [7].

The mortality rate for children with appendicitis is 0.1–1%. Death from appendicitis is most common in neonates and infants. Mortality rate in neonatal age group is around 28% [8].

Indre Zaparackaite and Ashish P. Desai

Introduction

Vascular abnormalities are either present at birth or appear soon after. They are more commonly seen as cutaneous lesions.

The first scientific reports of vascular malformations appeared in literature in the sixteenth century. In 1628, *William Harvey* published his major work, *On the Motion of the Heart and Blood in Animals*, where he explained blood circulation. Since then, there was a continuous scientific urge to explore the secrets of abnormal circulation and aberrant vascular communications.

In the eighteenth century, a German scientist, *Rudolf Virchow* (1821–1902), the founder of cellular pathology, was the first to suggest that hemangioma is formed of new vessels rather than by passive dilatation of preexisting channels. He also speculated that these tumors appeared antenatally and continued to grow postnatally.

Embryology

The vascular system arises from mesodermal blood islands in the wall of yolk sack. These blood islands are composed of progenitors of blood cells and endothelial progenitor cells. Further development encompasses vasculogenesis (formation of embryonic vessels), migration of angioblasts to the organs, and angiogenesis (the process of growing new vessels). Angiogenesis is regulated by local factors maintaining the subtle balance between the inhibitors (e.g., thrombospondins, endostatin) and stimulators (e.g., vascular endo-

thelial growth factor (VEGF), basic fibroblast growth factor (bFGF), and angiopoetins). VEGF is a key regulator in angiogenesis and has been found to be responsible for inducing penetration of the capillary vessels in to avascular epidermis [1]. As an end product, the vessels are composed of a single layer of endothelial cells surrounded by variable number of layers of vascular smooth muscle cells.

The precise pathogenesis of development of vascular lesions is not fully understood. Nevertheless, there is evidence that signaling aberrations at the molecular level may result in abnormal proliferation, differentiation, maturation, and apoptosis of vascular cells [2].

Vascular Tumors Vascular tumors are characterized by increased endothelial proliferation. The precise origin of the hemangioma endothelial cells remains uncertain. Immunophenotypic similarities with placental endothelium suggest a placental origin [3]. The mechanism is believed to be embolization of placental endothelial cells, which enter the fetus from chorionic villi through right-to-left shunts (normal in fetal circulation). This theory was checked in different laboratories, though the results could not be universally confirmed.

In summary, hemangiomas express abnormal proliferation with increased endothelial cell turnover and increased surface markers (VEGF, bFGF). Conversely, vascular malformations are a product of abnormal morphogenesis. Their endothelial lining is flat, smooth muscle architecture is abnormal and the expression of surface markers is minimal.

Classification of Vascular Lesions

In the past, the terminology used in association with such abnormalities has been rather confusing, being mainly descriptive and dismissive of the histological origin of the lesions. A binary classification, into *vascular tumors* and *vascular malformations*, was proposed by Mulliken and Glowacki in 1982 [4] and has since been adopted by the International

Vascular (or vasoproliferative) neoplasms	Vascular malformations
Infantile hemangioma	Slow-flow vascular malformations
Congenital hemangiomas (Rapidly involuting congenital hemangioma (RICH) Non-involuting congenital hemangioma (NICH)	Capillary malformation Venous malformation Lymphatic malformation
Kaposiform hemangioendothelioma and tufted angiomas (with or without Kasabach–Merritt syndrome)	Fast-flow vascular malformations
Spindle cell hemangioendothelioma	Arterial malformation
Epithelioid hemangioendothelioma	Arteriovenous malformation
Other rare hemangioendotheliomas (i.e., composite, retiform, and others)	Arteriovenous fistula
Angiosarcoma	Combined vascular malformations (various combinations of the above)
Dermatologic acquired vascular tumors (i.e., pyogenic granuloma)	–

Society for the Study of Vascular Anomalies (ISSVA), established in 1992 (Table 51.1).

Classification into either of these groups is determined by clinical appearance, by radiological and pathological features, and by biological behavior. In rare cases, vascular tumors and vascular malformations can coexist [6].

In order to understand different modalities of investigation and treatment, it is important to appreciate the different origin and behavior of vascular anomalies irrespective of their site. We describe the lesions with special emphasis on gastrointestinal (GI) lesions.

Group I: Vascular Tumors

Congenital vascular tumors can be divided into the following major groups:

- Infantile hemangiomas
- Congenital hemangiomas
- Kaposiform hemangioendotheliomas
- Other rare tumors (tufted angiomas, angiosarcomas)

Hemangioma is the most common tumor of infancy and childhood with recorded 1.0–2.6% incidence among Caucasian neonates. By the age of 1 year, some 4–12% of Caucasian children have a hemangioma. The female-to-male ratio is 3:1. Hemangiomas are more common in premature babies [7].

Infantile Hemangiomas

Infantile hemangiomas are proliferating endothelial tumors. They are strongly characterized by endothelial expression of glucose transporter protein-1 (GLU-1). GLU-1 is not observed in other vascular malformations and vascular tumors, except for some focal areas in cases of RICH [7]. Infantile hemangiomas, usually apparent in the early neonatal period, proliferate until 1 year of age then slowly regress until the age of 7, when they end in the involution phase.

Congenital Hemangiomas

Congenital hemangiomas are fully formed at birth and can follow two patterns of biological behavior: either rapidly involuting congenital hemangiomas (RICH) or non-involuting congenital hemangiomas (NICH). They often have a large feeding vessel and sometimes can cause shunting and cardiac overload.

Kaposiform Endotheliomas

Kaposiform endotheliomas and tufted angiomas can result in Kasabach–Merritt-type coagulopathy, characteristic of which is platelet trapping by abnormal endothelium and the consumption of fibrinogen. Thrombocytopenia can be life-threatening, especially when resulting in disseminated intravascular coagulation. The Kasabach–Merritt phenomenon is associated with a mortality rate of 14–24% [8, 9].

If patients present with five or more cutaneous hemangiomas, the abdominal ultrasound scan is indicated looking for visceral lesions, more commonly situated in the liver.

The hemangiomas of the GI tract are rare and only account for approximately 0.3% of all GI tumors. They have a tendency towards multiplicity (intestinal hemangiomatosis) and solitary tumors are uncommon. Patients may present with GI hemorrhage, anemia, or symptoms of obstruction. Interestingly, 11–30% of GI hemangiomas may remain asymptomatic [10, 11].

Group II: Vascular Malformations

Vascular malformations are localized defects of vascular development, which occur in the process of vascular morphogenesis.

Although most vascular lesions are sporadic, inheritance has been observed and has thus provided a route to genetic analysis. Sporadic forms usually present as single lesions, but multiple lesions have been observed in familial cases.

Ninety percent of vascular malformations are present at birth. Estimated incidence of vascular anomalies in the general population is approximately 1.5% [12].

Female-to-male ratio is 1:1. These malformations infiltrate the surrounding tissue, never regress and can worsen over time if not treated. Changes in hemodynamic factors such as arteriovenous shunting or venous stasis can accelerate growth and morbidity.

The “vascular malformations” group can also be subdivided into fast flow (arterial or arteriovenous) and slow flow (capillary, lymphatic, or venous). If fast-flow lesions are localized subcutaneously, they may become more erythematous, and may develop a palpable thrill and a bruit.

Vascular malformations of the GI tract are rare in children but they can be diagnosed at any age, including newborns [13]. They may appear anywhere in the GI tract from mouth to anus and may coexist with similar lesions on the skin.

Patients may present with recurrent abdominal pain, GI bleeding, acute or, more often, chronic anemia, intestinal obstruction, volvulus, intussusception, and palpable mass lesion. Sometimes, because of mucosal edema, nodularity, and vascular congestion, these lesions might be mistaken for inflammatory bowel disease. Bleeding per rectum may also be misleading towards the diagnosis of symptomatic Meckel’s diverticulum. Intestinal lesions often represent a diagnostic challenge requiring sophisticated methods of investigation.

Group II: Vascular Malformations: Associated Syndromes

Certain syndromes are associated with GI vascular malformations, including:

1. Osler–Weber–Rendu disease (hereditary hemorrhagic telangiectasia)
2. Klippel–Trenaunay syndrome
3. Blue rubber bleb nevus (BRNB) syndrome

Osler–Weber–Rendu Disease (Hereditary Hemorrhagic Telangiectasia)

This is a genetic disorder inherited in autosomal dominant manner occurring in 1:5000 of the general population. Genetic diagnosis is difficult but tests are available for the *ENG*, *ACVRL1*, and *MADH4* mutations [14].

The condition typically presents with distinctive small skin and mucosal vascular malformations (telangiectasias), and may appear in the nose, lips, fingers, and along the GI tract. Larger arteriovenous malformations are usually localized in the lungs, liver, brain and, occasionally, the spine. Though the main clinical problem is usually epistaxis, GI bleeding may also occur, but it is rare in pediatric population. The malformations developing in the liver may eventually

lead to portal hypertension, high-output cardiac failure, or encephalopathy. The clinical diagnosis is based on the Curaçao criteria [15], which are:

- Spontaneous recurrent epistaxis
- Multiple telangiectasia in typical locations
- Proven visceral arteriovenous malformations (lung, liver, brain, spine)
- First-degree family member with hereditary hemorrhagic telangiectasia

Treatment of anemia due to GI bleeding is mainly symptomatic but in severe cases argon plasma coagulation or laser therapy may be applied.

Klippel–Trenaunay Syndrome

This is a relatively rare condition with approximate incidence of 1:30,000 live births [16]. Historically, it is characterized by a triad of symptoms: capillary skin malformation (port wine stain), varicose veins (especially persistent embryonic lateral vein of Servelle), and bony/soft tissue hypertrophy of the extremity. This hypertrophy is caused by venous and lymphatic malformations localized in the soft tissue but often involving the bony structures. Most commonly, one extremity is affected, usually the leg, but multiple involvement is also possible.

The etiology of the syndrome is not entirely clear but it is believed that most cases happen due to sporadic gene mutation, though some autosomal dominant inheritance cases are also reported. Mutations in PI3K–AKT gene pathway may play a role in development of the condition [17].

In association with the classical triad of clinical symptoms, the GI tract may also be affected by vascular malformations. Though intestinal involvement is rare (1–12% of all patients affected by the syndrome)—the risk of bleeding should always be considered [18].

BRNB Syndrome (Bean Syndrome)

This syndrome is characterized by cutaneous and visceral venous malformations. These malformations can occur in any tissue but are most prominent in the skin and in the GI tract, the small bowel being the most frequently affected part. Their number can range between several to hundreds, such as the 557 in one patient reported by Fishman in 2005 [19]. Cutaneous lesions are generally small (about 1–2 cm or even smaller), rubbery, compressible, blue to purple nipple-like nodules often found on the face, the upper limbs, and the soles of the feet.

Most cases are sporadic, but some autosomal dominant transmission has also been reported.

A common problem is GI bleeding presenting at early age and continuing throughout life, resulting in chronic anemia requiring repeated blood transfusions. A broad spectrum of treatment options is available, from conservative and endoscopic treatment to an aggressive surgical approach.

Group III: Lymphatic Malformations

Lymphatic malformations are relatively rare in the GI tract, especially in children.

The majority of intra-abdominal lymphatic malformations are identified within the mesentery and retroperitoneum. Lesions affecting the bowel are uncommon and account for less than 1% of all lymphatic malformations. Approximately, 70% of those are detected in the small bowel and 30% in the colon [20].

Patients may present with abdominal pain, failure to thrive, palpable cystic mass, intestinal volvulus, bowel obstruction, or intussusception. Differential diagnosis includes intestinal duplication cyst, ovarian cyst, teratoma, Wilm's tumor, and neuroblastoma. In the case of a small-bowel lesion, the differential diagnosis of lymphangiomyoma and benign multicystic mesothelioma could be considered. Immunohistochemical analysis can give a clear indication if the lesion was derived from the lymphatic vessels (expected focal positivity of D2-40, a lymphatic endothelial marker).

Primary Intestinal Lymphangiectasia (Waldmann's Disease)

Dilated intestinal channels resulting in lymph leakage into the small-bowel lumen and responsible for protein-losing enteropathy leading to lymphopenia, hypoalbuminemia, and hypogammaglobulinemia characterize this disorder. The exact etiology of this condition is unknown and it is generally diagnosed before 3 years of age. Patients often present with bilateral lower limb lymphoedema, inability to gain weight, steatorrhea, and later develop pleural effusions or ascites. This may be accompanied by abdominal pain. Sometimes the abdominal mass may be palpable or patients may develop intussusception. Mechanical obstruction of the small intestine may be caused by localized oedema leading to intestinal wall-thickening and lumen diminution.

Diagnostic process can be helped by ultrasound scan, capsule endoscopy, CT, albumin scintigraphy, and sometimes by lymphoscintigraphy.

The condition requires long-term medical treatment in form of reduced dietary fat, medium-chain triglycerides, elemental diet, corticosteroids, and vitamin supplements [21]. In some localized cases, surgical resection may provide satisfactory results. In chronic recurrent conditions, fibrin glue application has been used.

Investigations and Treatment

Several imaging modalities can be employed to establish more precisely the type and the location of vascular anomalies. MRI imaging, selective angiography, color Doppler sonography, multiphase CT enterography, and 99 m Tc-red

blood cell (RBC) scintigraphy can all be useful for this purpose [22–25]. The slow flow veno-lymphatic malformations on MRI scan are typically multispacial, multicystic, and may have a partially solid component. Fast-flow arteriovenous malformations demonstrate turbulence, flow voids, and hyperintense signal.

From the imaging point of view, it is important to remember that while young the hemangiomas may behave like arteriovenous malformations and may exhibit the features of fast flow. The slow flow is being established in involution phase. Currently, ultrasonography and MRI with contrast (T1- and T2-weighted sequences) are the most widely used modalities of initial diagnostic choice.

At endoscopy, the whole GI tract should be visualized, if possible, by using different approaches, including rigid or flexible endoscopy, single- or double-balloon enteroscopy, wireless capsule endoscopy, laparotomy/laparoscopy, and enterotomies.

Each method has its advantages and limitations. Capsule endoscopy, for example, transmits a radio-frequency signal, which allows estimation of the location of the capsule and tracking of it in real time inside the GI tract. Nevertheless, unlike endoscopy it cannot treat pathologies it discovers. Another limitation, specific to the pediatric population, can be the age and size of the patient; these factors can affect tolerance of certain procedures and the accuracy of imaging.

Once the lesions are localized there is a choice of surgical methods of treatment, including segmental or wedge bowel resection, band or suture ligation and argon plasma coagulation or electrocoagulation [26].

Even though both hemangiomas and vascular lesions often present with bleeding, principal treatment options are entirely different. Visceral hemangiomas are at risk of bleeding in the proliferation phase and the risk diminishes after they enter the involuting phase. In many cases this could be achieved by using the inhibitors of angiogenesis. For example, extensive intestinal hemangiomatosis can be successfully managed with propranolol, corticosteroids, α -interferon, vincristine, and also with thalidomide and somatostatin analog [27].

The antiangiogenic treatment is ineffective for vascular malformations. If amenable, especially if the vascular malformations are located in the anorectal region, direct injection and sclerotherapy can be performed [28].

The principal method of sclerotherapy is injection of water-based or oleous substances into abnormally dilated vessels that can inflict damage to endothelial lining and cause thrombosis, fibrosis, stenosis and—eventually—scarring. Sclerotherapy for treatment of lymphatic and venous malformations employs a variety of agents, including absolute ethanol, bleomycin, OK-432 (picibanil), and doxycycline [3]. Each agent has a risk profile: Ethanol injections are painful, requiring general anesthesia even in adults, and may

cause cardiovascular shock. Bleomycin may cause interstitial pneumonia or pulmonary fibrosis and treatment with doxycycline may result in tooth discoloration or electrolyte abnormalities.

Some complicated vascular anomalies resistant to other treatments can be conservatively treated with sirolimus (especially if they have a lymphatic component), bevacizumab, and estrogen–progesterone combination therapy [15, 29].

Conclusion

GI vascular lesions are rare. Vascular malformations are more common than vascular neoplasms. They require extensive investigations to identify the type and location. Different modalities need to be used to treat the lesions by limited resection or sclerotherapy. Many lesions require lifelong supportive therapy to treat chronic anemia and nutritional deficiencies.

Introduction

Children and adolescents with gastrointestinal polyps may present symptomatic with rectal bleeding, abdominal pain, or intussusception, or alternatively, they may be asymptomatic, having been referred, either because an adult family member has been affected with early onset colorectal cancer (CRC) or there is a known family history of a polyposis syndrome. Many children fall under the latter category. Managing these children and families requires knowledge of the different polyposis syndromes, their inheritance and genetics, potential for malignant change and pediatric complications.

Gastrointestinal polyps in children fall into two major categories: hamartomas and adenomas (Table 52.1). Solitary polyps in children are most commonly hamartomas, predominantly of the juvenile type, and such polyps are benign. Of the familial syndromes, familial adenomatous polyposis (FAP) is more common than juvenile polyposis or Peutz–Jeghers polyposis.

Clinical Presentation of Gastrointestinal Polyps

The most common clinical manifestation of a large bowel polyp is painless rectal bleeding. Other symptoms attributed to polyps include abdominal pain, altered bowel habit, and prolapse of polyp or rectum. Diagnosis will be made upon full colonoscopy with polypectomy. The clinical presentation, endoscopic appearance, pathological findings, histological description of the polyp, and genetic investigations are all

necessary to establish the correct diagnosis of a polyposis syndrome. Once a polyp has been identified at endoscopy, a carefully targeted family history must be taken to enquire if there are family members who have or have had cancer, the site of the cancers, and age of onset (see Table 52.2). Taking such a history to develop a detailed family cancer pedigree may require the expertise of a multidisciplinary familial cancer clinic or polyposis registry [1].

JPS juvenile polyposis syndrome, PTEN phosphatase and tensin, PJS Peutz–Jeghers syndrome, FAP familial adenomatous polyposis, HHT hereditary hemorrhagic telangiectasia The Single Hamartomatous Polyp (the Juvenile Polyp)

With a prevalence of up to 3% of children, the commonest presentation of a single hamartomatous (or juvenile) polyp is painless bright red rectal bleeding with blood seen on wiping or mixed in the stool. Seventy percent of juvenile polyps are found in the rectum or rectosigmoid. The rest however are found more proximally, hence the need for pancolonoscopy. Single or solitary juvenile polyps are benign and confer no future risk of malignancy. Presently, it is unknown whether children who present with a single polyp in childhood may continue to form polyps over time [2].

If a polyp is found to be solitary after full colonoscopy, and there is no relevant family history, endoscopic polypectomy should be sufficient treatment. After polypectomy, parents should be advised that juvenile polyps may be the first feature of a hamartomatous polyposis syndrome, and if new symptoms arise, the child should be reinvestigated. If multiple juvenile polyps are found (>3–5) or there is a positive family history (e.g., colonic polyps or early onset CRC), a hamartomatous polyposis syndrome should be considered and an alternative approach should be taken.

Hamartomatous Polyposis Syndromes

Hamartomatous polyposis syndromes are a rare group of hereditary autosomal dominant disorders. The polyps themselves are benign but the polyposis syndromes confer significant potential for developing CRC and extra colonic cancers. The hamartomatous polyposis syndromes include juvenile polyposis syndrome (JPS), Peutz–Jeghers syndrome (PJS), and phosphatase and tensin (PTEN) hamartoma tumor syndrome, which includes Cowden (CS) and Bannayan–Riley–Ruvalcaba syndrome (BRRS).

Juvenile Polyposis Syndrome

JPS is rare, with an estimated prevalence of 1 in 100,000 individuals presenting with multiple hamartomatous polyps and an increased risk of gastrointestinal malignancies. Affected individuals develop multiple gastrointestinal polyps which are predominantly in the colon, though other areas of the gastrointestinal tract can also be involved. The condition should be considered in any patient with more than five juvenile polyps in the colon, any juvenile polyps found

in other parts of the gastrointestinal tract, or if any juvenile polyp is found in a child with a positive family history. Patients present with chronic and acute gastrointestinal bleeding, anemia, prolapsed rectal polyps, abdominal pain and diarrhea and can develop up to 50–200 polyps in the colon, while in some patients, with generalized juvenile polyposis, polyps can affect the colon, stomach, and small bowel. The total number of polyps needed to make the diagnosis remains controversial, between 3 and 5 [3]. A significant proportion of patients with juvenile polyposis have been reported to have other morphological abnormalities including digital clubbing, polydactyly, macrocephaly, alopecia, cleft lip or palate, congenital heart disease, and mental retardation. A specific variant of JPS called juvenile polyposis of infancy has an onset in infancy presenting with anemia and hemorrhage, diarrhea, protein-losing enteropathy, intussusception, and rectal bleeding. The course in such infants is fulminant and, even despite colectomy, in severe cases, death occurs before the age of 2 years.

There is little doubt that juvenile polyposis is a premalignant condition. There is a 15% incidence of colorectal carcinoma occurring in patients under the age of 35 years, leading to a cumulative lifetime risk of CRC of 38–68% with a mean age of colonic neoplasia onset between 38 and 44 years [4].

Genetics of Juvenile Polyposis

JPS is a fully penetrant condition with variable expression. Sixty percent of cases are familial and the others occur sporadically. Germline mutations in *SMAD4*, *BMPRIA*, and *ENG1* cause JPS. Approximately 54% of JPS cases will have a detectable mutation [5].

Patients with the *SMAD4* mutation on chromosome 18q21.2 appear to have a higher risk of gastric polyps and hereditary hemorrhagic telangiectasia (HHT). The latter condition is characterized by cutaneous telangiectasia and risk of arteriovenous malformations. Patients found to have the *SMAD4* mutation should be screened for cerebral and pulmonary arteriovenous malformations associated with HHT [6]. *BMPRIA* is located on chromosome 10q22.3 and accounts for another 20% of JPS patients. *ENG1* mutation on gene 9q34.1 has recently been described in JPS patients without HHT.

Screening and Follow-Up

Once the gene mutation has been identified in the index patient, other at risk family members should be tested. All children of an affected adult will have a 50% chance of inheriting the mutation, and if the family mutation is known, children should undergo genetic screening.

Proposed guidelines suggest affected children should undergo colonoscopic surveillance every 2 years or earlier if symptoms arise [7]. In those families where the gene mu-

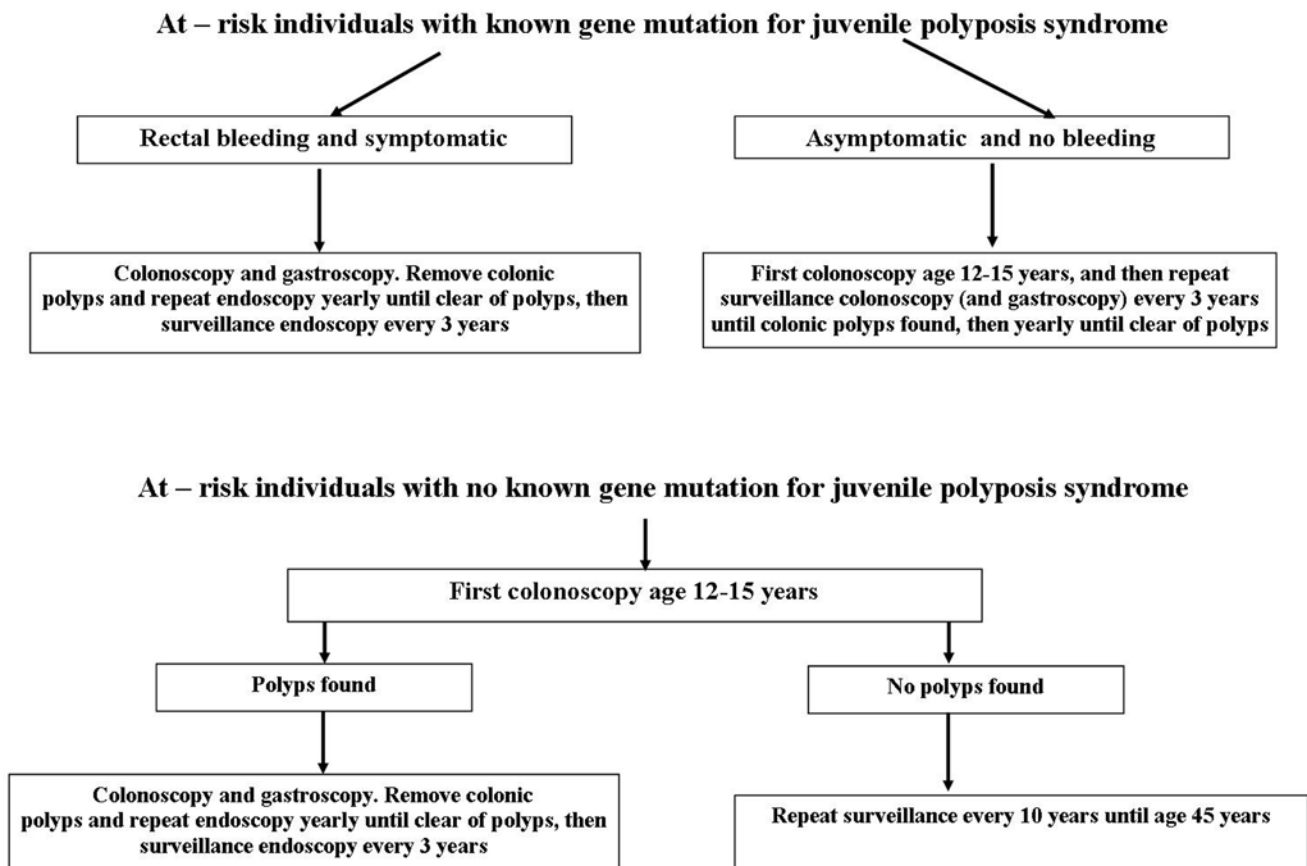

Fig. 52.1 Screening and surveillance algorithm for juvenile polyposis syndrome

tation is not known, first-degree relatives of patients with JPS should be screened by a single colonoscopy starting at age 12–15 years, even when the subject is asymptomatic (Fig. 52.1).

Full colonoscopy is necessary as right-sided polyps are the most common. All polyps should be resected. Annual colonoscopy is performed until all polyps have been resected after which the screening interval is stretched to every 2–3 years. Gastroscopy is commenced from mid-teens. Colectomy is warranted for patients with cancer, dysplasia, or high polyp burden with symptoms that cannot be controlled endoscopically.

PTEN Hamartoma Tumor Syndrome

This group comprises three rare genetic syndromes: Cowden syndrome, BRRS syndrome, and Proteus syndrome (the latter has very few intestinal features). All are associated with a mutation in the PTEN gene located at 10q23.3 [8]. All three syndromes are characterized more by extraintestinal manifestations than intestinal polyposis. The PTEN mutation can be detected in 80% of patients with Cowden, 60% with BRRS, and 50% with Proteus syndrome.

Cowden syndrome rarely presents in childhood. Clinical manifestations include macrocephaly, papillomatous papules, mucocutaneous lesions, facial trichilemmoma, and acral keratosis. It carries a 50% risk of breast cancer in adult women and a 10% lifetime risk of epithelial thyroid cancer. Guidelines presently recommend screening for breast, thyroid, endometrial, and kidney cancer from the age of 18–25 years.

BRRS presents in childhood with gastrointestinal hamartomas, particularly in the ileum and colon, which cause intussusception, rectal bleeding, and hypoalbuminemia. There are additional characteristics including macrocephaly, developmental delay, abnormal metacarpal and phalanges, pectus excavatum, scoliosis, genital pigmentation, and hemangiomas. BRRS presents prior to adolescence, and there is value in genetic testing in early childhood in a family where the mutation has been identified. Patients with BRRS need regular colonoscopy and small-bowel surveillance as they are at risk of anemia, intussusception, and hypoalbuminemia from the polyposis. They carry a probable lifetime increased risk of cancer, and surveillance is recommended from age 18–25 years focusing on renal, thyroid, and breast cancer [9].

Peutz–Jeghers Syndrome

Clinical Features and Diagnosis

PJS is a rare autosomal dominant condition with a prevalence of 1 in 50,000 to 1 in 200,000 live births. It is characterized by mucocutaneous pigmentation and the presence of hamartomatous polyps throughout the gastrointestinal tract. Polyps arise primarily in the small bowel and to a lesser extent in the stomach and colon. Polyps are most commonly found in the jejunum and cause bleeding and anemia, or intussusception and obstruction from an early age. Presumptive diagnosis can be made in those with a positive family history and typical PJS freckling.

Pigmentation tends to arise in infancy, occurring around the mouth, nostrils, perianal area, fingers, toes, and the dorsal and volar aspects of hands and feet. The primary concern to the pediatrician is the risk of small-bowel intussusception causing intestinal obstruction, vomiting, and pain (Fig. 52.2). In addition, intestinal bleeding—with melena, hematemesis, and rectal bleeding—can occur, leading to anemia.

Genetics of PJS

As with other hamartomatous syndromes, PJS has an autosomal dominant pattern of inheritance, and many cases may be sporadic new mutations. The mutated gene *STK11(LKB1)*, located on chromosome 19p 13.3, can be identified in up to 90% of PJS patients [10]. After appropriate genetic counseling and informed consent, testing at-risk family members may be performed early in childhood so that gastrointestinal surveillance can commence before gastrointestinal complications arise.

Screening, Management, and Complications

Individuals at risk of PJS should be evaluated in infancy for pigmented lesions and gastrointestinal symptoms. Asymp-

Fig. 52.2 Large obstructing duodenal PJS polyp seen at gastroscopy

Fig. 52.3 Intraoperative enteroscopy performed at laparotomy for intussusceptions in a patient with PJS

tomatic at risk children should undergo genetic testing for the family proband mutation in the *STK11/LKB1* mutation if known, soon after infancy, so the family can access medical care early if the child develops symptoms consistent with small-bowel obstruction.

The management of a young child with mid-gut PJS polyps is controversial, but recommended guidelines have been published [11]. Children who present with mid-gut complications need polypectomy either by laparotomy and intraoperative enteroscopy (IOE; Fig. 52.3) or double balloon enteroscopy (DBE). An IOE is recommended in any patient with PJS undergoing laparotomy, as careful endoscopy via an enterotomy in the small bowel allows identification and removal of polyps, thus avoiding multiple enterotomies and the risk of short bowel syndrome associated with resection. This technique is superior to palpation and transillumination in identifying polyps, and removal of all detected polyps (“clean sweep”) reduces re-laparotomy rate significantly [12].

DBE with polypectomy of PJS polyps in the small bowel carries a significant risk of perforation and should be performed only by those who are expert in polypectomy. Muscularis mucosa commonly invaginates into the large pedunculated stalk increasing the risk of perforation at electrocautery (Fig. 52.4). DBE can be combined with laparoscopy to assess perforations that may arise at polypectomy.

Endoscopic evaluation of the upper and lower gastrointestinal tract and imaging of the small bowel should be performed from the age of 8 years. Screening should start earlier if symptoms are present before this. The development of video capsule endoscopy (VCE) has replaced barium enterography as the preferred technique for assessing the small bowel [13]. VCE is more sensitive, preferred by patients, and reduces the lifetime risk from cumulative radiation exposure. An acceptable alternative to VCE is MRI enterography with a close correlation between the two modalities, especially with polyps > 15 mm [14]. The advantages and disadvantages of prophylactic polypectomy for asymptomatic patients should be discussed with the family (Fig. 52.5). Prophylactic

Fig. 52.4 Indentation of the serosal surface of the ileum from intussuscepting PJS polyp

polypectomy of larger small-bowel polyps (> 1.5 cm) by intraoperative or DBE should be performed in order to reduce the incidence of subsequent complications and the requirement for emergency laparotomy.

The risk of neoplasia is well documented in young adults. A meta-analysis to assess the risk of cancer in PJS identified a relative risk for all cancers in PJS patients (aged 15–64) of 15.2 compared to the normal population, with tumors. Clinicians caring for adolescents with PJS should be aware of unusual symptoms and have a low threshold for investigating potential malignancies. A recommended screening program for PJS patients after adolescence is shown in Table 52.3.

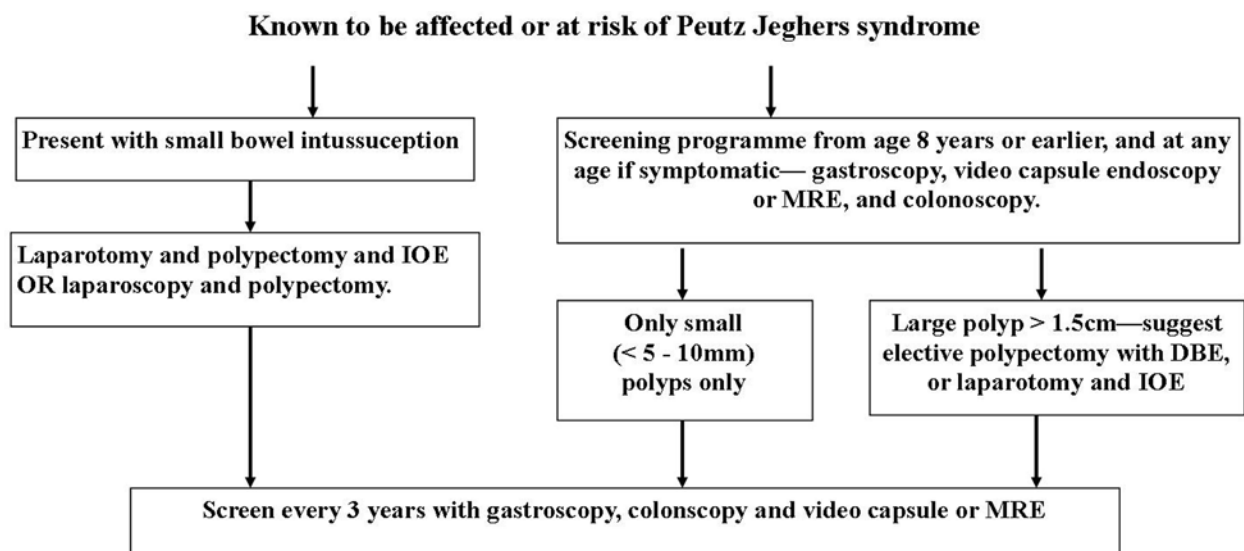

Table 52.3 Suggested program for screening for malignancies in Peutz–Jeghers syndrome after adolescence

<i>General</i>
Annual hemoglobin and liver function tests
Annual clinical examination
<i>Genital tract</i>
Annual examination and testicular US biennial from birth until 12 years

<i>Gastrointestinal</i>
Baseline EGD/colonoscopy age 8
Polyps detected, continue 3 yearly until 50 years
No polyps detected, repeat age 18 years, then every 3 years until 50 years
VCE every 3 years from age 8 years
<i>Breast</i>
Monthly self examination from age 18 years
Annual breast MRI from age 25–50, thereafter annual mammography

EGD esophagogastroduodenoscopy, VCE video capsule endoscopy, MRI magnetic resonance imaging Adenomatous Polyposis Syndromes

Familial Adenomatous Polyposis

In children, GI adenomas are almost always associated with hereditary adenomatous polyposis syndromes. FAP is characterized by the development of hundreds of adenomas in the colon and rectum as well as several extra colonic mani-

DBE = double balloon enteroscopy
IOE = intraoperative enteroscopy
MRE = magnetic resonance enterography

Fig. 52.6 Endoscopic appearance of large adenomatous polyps seen in advanced FAP

festations. Almost all affected patients will develop aCRC if not detected and treated at an early stage.

Clinical Features

Patients with FAP typically develop multiple adenomas throughout the large bowel—usually more than 100 and sometimes more than 1000 (Fig. 52.6). Polyps begin to appear in childhood or adolescence and increase in number with age. The standard clinical diagnosis of typical/classical FAP is based on the identification of >100 colorectal adenomatous polyps. By the fifth decade, CRC is almost inevitable if colectomy is not performed. Attenuated FAP (AFAP) is a milder form of the disease which is observed in

8% of cases. It is characterized by fewer adenomas and later presentation [15].

Gastric fundic gland polyps occur in the antrum in 50% of FAP-affected adults, and small-bowel adenomas also occur and neither requires intervention. Children under 5 years of age may develop hepatoblastoma, with an increased risk in boys [16]. Adult patients are at increased risk of malignancies of the duodenum and ampulla of Vater, with a lifetime risk of duodenal adenomas of 100%. Duodenal adenomas will progress to malignancy if untreated in 5% of adults and are the second most common malignancy in FAP and AFAP. In addition, FAP is associated with an increased risk of cancers of the thyroid, brain, and pancreas while papillary carcinoma of the thyroid has been reported in adolescence.

Extraintestinal manifestations are common (see Table 52.4). Pigmented ocular lesions (previously termed congenital hypertrophy of the retinal epithelium or CHRPE) are found in some but not all cases.

Genetics of FAP

FAP is an autosomal dominant inherited condition caused by a mutation in the adenomatous polyposis coli (APC) gene occurring in 1:10,000 births. In 20–30% of cases, the condition is caused by a spontaneous mutation with no clinical or genetic evidence of FAP in the parents or family.

The gene responsible for FAP, *APC*, is located on chromosome 5q21 and appears to be a tumor-suppressor gene [17]. Most mutations are small deletions or insertions which result in the production of a truncated APC protein which then predisposes to adenoma formation. Many mutations have been identified on this large gene, and there is a correlation

between the genetic site and severity of clinical manifestation. Mutations between codons 1250 and 1464 (Fig. 52.7), and especially those with a mutation at codon 1309, are associated with a severe form of FAP. Mutations localized at the extreme ends of the gene and in the alternatively spliced part of exon 9 are associated with a mild form of FAP, and an intermediate expression of disease is found in patients with mutations in the remaining parts of the gene. Other phenotype-genotype correlations have been observed [18]. These correlations are not absolute, and there may be considerable intrafamilial variation suggesting that there are other factors involved in the pathogenesis of the disease. Families need to be aware that the mutation may only be detected in 70–90% of cases.

Diagnosis: Interpretation of the Genetic Test and Clinical Screening in FAP

In order to determine the appropriate screening protocol for a given family, the first step would be to seek which mutation is present in the FAP affected index case. If a mutation cannot be found, the genetic testing is non-informative, and it will not be possible to offer predictive testing to asymptomatic at-risk relatives.

When family-specific mutation is identified, directed DNA diagnostic techniques can be readily used to predict FAP in other family members. The absence of the gene mutation in other family members is considered accurate in excluding FAP, and the subject should be considered to hold an average population risk for the subsequent development of adenomas and cancer. Such genotype negative individuals can be discharged from follow-up.

The presence of the family-specific gene mutation confirms the diagnosis of FAP, and such patients should undergo

endoscopic assessment. The diagnosis is confirmed by finding polyps upon sigmoidoscopy or colonoscopy which are histologically confirmed as adenomas (see Fig. 52.2). Teenagers predicted at gene testing to be affected will require a full colonoscopy by the age of 14–16, preferably beginning at age 10–12 years [19], to determine polyp density and location, and degree of dysplasia. Upper endoscopic surveillance of the stomach, duodenum, and periampullary region with a side-viewing endoscope is recommended after the age 20 years, unless the patient has symptoms such as upper abdominal pain which warrant earlier investigation.

For families in which the genotype is not known, protocols vary. It is necessary to perform annual sigmoidoscopy on all first-degree relatives until adenomas are found.

No patient should undergo screening for FAP without detailed counseling. The individual being screened must understand the nature of the test and its possible outcomes. Many authorities feel that the child should be involved in the decision-making process, and the diagnosis be delayed until the child is old enough to contribute to the screening program, for example, from the age of 11 years onwards [20]. Although parents might request testing of a child or infant at a young age, there is value in deferring a test until the child or adolescent can participate in the discussion [21]. Well-informed consent, as a mature minor, prior to predictive testing is the most desirable outcome. There are psychological issues, as well as family, insurance, and employment implications, which may arise in the case of a positive result. These should be discussed prior to testing, and there should be a clear protocol for posttest management [22].

The current advice is to commence endoscopic surveillance from the early teens. Some patients, especially those

with a mutation located at codon 1309 in the APC gene, may develop severe polyposis of the colorectum before the age of 10, and therefore, attention must be paid to FAP-related symptoms. These symptoms may include increasing bowel movements, looser stools, mucous discharge, rectal bleeding, abdominal, or back pain. In symptomatic patients, endoscopic investigation may be indicated at any age. Severe dysplasia and even malignancy have been documented in children with FAP under the age of 12 years. Consequently, those children from families in which severe dysplasia or carcinomas have been found at a young age should undergo screening at an earlier age [23]. Some clinicians advocate annual screening for hepatoblastoma with liver palpation, ultrasound, and serum α -fetoprotein levels in at-risk children between the ages of 0–6 years.

Management of FAP

Internationally agreed guidelines are currently in place for the management of patients with FAP [24]. If adenomas are detected, colonoscopic investigations should be performed annually until colectomy is planned [25]. Colectomy is currently the only effective therapy that eliminates the inevitable risk of CRC. In the absence of severe dysplasia, colectomy is usually performed in mid- to late teens or early 1920s to accommodate work and school schedules. Almost all screen-detected adolescents are asymptomatic and therefore may not be willing to contemplate interruptions in their schooling or effects on relationships. The surgical option, therefore, must not only be carefully timed but also have low morbidity and excellent functional result.

Colectomy is indicated as soon as there are more than 100 adenomas (measuring up to 5 mm) or adenomas showing a high degree of dysplasia. The timing of primary preventative surgery may be influenced by knowledge of the mutation site and the likely severity of the polyposis. For example, patients with a deletion at codon 1309 should be offered earlier surgery since this phenotype is characterized by a large number of polyps and a higher risk of cancer [26].

Surgical options are either subtotal colectomy with ileorectal anastomosis (IRA), or restorative proctocolectomy with ileal pouch anal anastomosis (IPAA or pouch procedure). The IRA is a low risk operation with good functional results and can be performed laparoscopically. There is no pelvic dissection, and therefore, attendant risks of hemorrhage, loss of fertility in women, and damage to adjacent organs such as the ureters are avoided. Complication rates after IRA are low, and postoperative bowel function is almost always good, averaging four semi-formed stools daily. After the IRA, the rectum remains at risk of cancer. Therefore, postoperative six-monthly surveillance of the rectum is mandatory.

An IPAA procedure removes the CRC risk almost completely, but is more complicated than an IRA. It carries a

higher morbidity and risk of complications. It often requires a temporary loop ileostomy, reoperations and longer hospital stays, night evacuation and decreased fertility in women [27]. Bowel frequency is generally higher than that for an IRA. The risk of cancer does exist after IPAA as they may develop at the anastomosis or below. The pouch should be examined regularly postoperatively for adenomas [28].

The advantages of an IPAA with a lower risk of cancer must be balanced against the higher operative morbidity. Conversion after an IRA to an ileoanal pouch can be carried out when the patient is older [29]. An IPAA is the treatment of choice if the patient has a large number of rectal adenomas, for example, >15–20 adenomas, if there is presence of adenoma with severe dysplasia, a colon with >1000 adenomas or those with high-risk genotypes (e.g., codon 1309) [30, 31]. In patients with only a few rectal adenomas or with a polyp-free rectum, both options are possible although an IRA may be preferable. The decision can be made on an individual basis, considering preoperative sphincter function, patient compliance, and risk of desmoid.

Desmoid Disease

Desmoids are locally aggressive but non-metastasizing myofibroblastic lesions which occur with disproportionately high frequency in patients with FAP. Putative risk factors include abdominal surgery, positive family history for desmoids, and site of the mutation (mutations beyond codon 1444). In contrast to sporadic desmoid tumors, the majority of the tumors associated with FAP are located in the abdominal wall or intra-abdominally. The tumors can be diagnosed by CT scanning or MRI. Desmoids occur most commonly in the peritoneal cavity (Fig. 52.8) and may infiltrate locally leading to small bowel, ureteric, or vascular obstruction. These lesions may progress rapidly or may resolve spontaneously, their unpredictable nature making them difficult to treat [32]. Attempted surgical resection carries a high morbidity and mortality and usually stimulates further growth. The options for treatment are pharmacological (nonsteroidal anti-inflammatory drugs (NSAIDs) [33] and/or anti-estrogens), chemotherapy, surgical excision, or radiotherapy. Pediatricians treating children with extraintestinal desmoid tumors should consider the possibility of FAP in the family.

Chemoprevention

NSAIDs may be protective against colon cancer by inhibiting prostaglandin synthesis via their effects on cyclooxygenase (COX). Publications have shown a significant reduction in the number of rectal polyps in those patients taking the NSAID sulindac after colectomy. However, despite protracted drug use, the adenomas still progressed with case reports of rectal cancer. Sulindac administered before the development of polyps in genotype-positive adolescents did not prevent the development of adenomas.

Fig. 52.8 Intra-abdominal mass from a desmoid tumor seen in a teenager with FAP

Cyclo-oxygenase-2 (COX-2) enzyme is induced in inflammatory and neoplastic tissue. Selective COX-2 inhibitors generate fewer gastrointestinal-related side effects compared to the classical non-selective NSAIDs. One of these drugs (celecoxib) was found to reduce the number of colorectal adenomas by 28% [34] and also to reduce the number of duodenal adenomas [35]. Unfortunately, cardiovascular side effects have been reported in patients using selective COX-2 inhibitors [36]. Although NSAIDs cannot replace surgical treatment for colonic FAP, they may play a role in postponing surgery in patients with mild colonic polyposis, or patients with rectal polyposis after prior colectomy. Other agents investigated but with so far inconclusive effect on polyp burden include: vitamin C, oral calcium, and ornithine decarboxylase inhibitor difluoromethylornithine (DFMO) and eicosapentaenoic acid present in fish oil [37, 38].

Prognosis

Genetic investigations, colonic surveillance, and prophylactic colectomy have impacted favorably on mortality in FAP-affected patients. Studies that evaluated the mortality of patients with FAP reported that surveillance policies and prophylactic colectomy have resulted in a reduction in the number of FAP patients that died from CRC. Currently, a greater proportion

of deaths are attributable to extracolonic manifestations of the disease (desmoid tumors, duodenal cancer). Central registration in a family cancer registry and prophylactic examination lead to a reduction of CRC-associated mortality and ensure appropriate follow up and patient support.

MYH-Associated Polyposis and Lynch Syndrome

MYH-associated polyposis (MAP) is characterized by the presence of adenomatous polyposis of the colorectum and an increased risk of CRC. Patients present with a variable number of polyps but no apparent extra-colonic features. This autosomal recessive condition results from a compound heterozygote of the *mutY* human homologue (MYH) gene located on chromosome 1p. MYH polyposis should have no pediatric implications as colonic polyposis typically occurs in patients in their 40s, although cancer and polyps can occur at earlier ages. Surveillance colonoscopy in affected individuals should commence at age 25 years.

Lynch syndrome is an inherited condition with a high penetrance for the development of early CRC caused by an alteration in DNA mismatch repair genes (*MLH1*, *MSH2*, *MSH6*, *PMS2*). With no described pediatric complications, the syndrome is associated with colorectal, endometrial, ovarian, gastric, renal tract, and other cancers. The median age for the development of CRC in Lynch syndrome is approximately 44 years and is uncommon below the age of 25 years. Revised criteria (Amsterdam II or Bethesda criteria) exist to help identify affected families and enable genetic testing for the DNA mismatch repair genes in early adulthood. Once identified as at risk, colonoscopic surveillance should be undertaken from the age of 20–25 years.

Other Polyposis Syndromes

Gorlin syndrome is an autosomal dominant condition comprising upper gastrointestinal hamartomas and pink or brown macules in exposed areas such as the face and hands.

Turcot's syndrome (also referred to as brain tumor-polypoid syndrome) is characterized by concurrence of a primary brain tumor (most often glioblastoma multiforme) and multiple colorectal adenomas. The number of adenomas is often not high, but many of the reported patients have been adolescents. Patients with a polyposis syndrome and neurological symptoms should undergo thorough neurological examination and investigation for possible brain tumor.

In patients with long-standing inflammatory colitis, inflammatory polyps (pseudopolyps) may develop. Inflammatory polyps are of no significance and have no malignant potential.

The Role of a Polyposis Registry

There are numerous advantages to integrating a family into a cancer/polyposis registry. Polyposis registries are established across the world. A polyposis registry enables registration of polyposis patients and family members accessing counseling and genetic testing and initiation and coordination of screening of family members at risk of a polyposis syndrome. By increasing the rate of diagnosis of FAP and other polyposis syndromes, and enabling earlier diagnosis, there is proven improved survival of patients registered, almost certainly attributable to the improvement in organization and coordination of patient screening [39].

Other Tumors of the GI Tract (Excluding the Stomach and Hepato-biliary)

Gastrointestinal Stromal Tumors

Gastrointestinal stromal tumors (GISTs) are a unique variety of mesenchymal tumors that have recently been described. They are very uncommon among children and adolescents, and their true incidence is not well known due to the small number of described cases.

The overall incidence rates of GIST are reported to range between 6.5 and 14.5 per million per year [40–42]. The UK National Registry of Childhood Tumours showed an annual incidence of 0.02 per million children below the age of 14 years [43].

GISTs were described for the first time in 1990 and probably arise from neural interstitial cells of Cajal. Its molecular oncogenetics derives from mutations in the KIT oncogene (*v-kit* Hardy-Zuckerman 4 feline sarcoma viral **oncogene** homolog) that encode for class III receptor tyrosine kinases and platelet-derived growth factor receptor alpha (PDGFRA), which are expressed in GIST patients. About 0–10% of pediatric GISTs have an oncogenic KIT mutation [44–46], and only two patients were reported with a PDGFRA mutation to date [47, 48] which reflects probably other downstream activation pathway other than c-Kit mutation. A small subgroup of syndromic GISTs were found to have common germline mutations encoding the succinate dehydrogenase (SDH) gene [48, 49]. Recently, another molecule, IGF1R (insulin growth factor receptor 1), was found to be significantly expressed in a series of 17 GIST including one pediatric GIST, both by Western blot analysis and immunohistochemistry, and that it seems to be a new attractive pathway for this complex oncogenetic process [50].

Immunohistochemically, these tumors stain positive for vimentin (CD-117, a *c-kit* proto-oncogene protein) and CD-34—and stain negatively for smooth muscle actin [51]. Since the use of CD117 staining in 2002, 82% of mesenchymal tumors were considered to be GISTs, so its' true inci-

dence rose since there, with a proportional decline of smooth muscle tumors cases [52]. Histologically, GISTs are composed either of spindle-shaped cells, epithelioid cells, or a combination of both, being spindle-shaped type slightly more frequent in a large analysis of 99 of 113 pediatric cases [53].

GISTs can present as sporadic or inherited cases, and the latter can be inherited through familial autosomal dominant fashion or as syndromic tumors, named as the Carney triad.

Carney Triad

GIST can occur rarely in association with other tumor syndromes. The association of gastric leiomyosarcoma, extra-adrenal paraganglioma and pulmonary chondroma was first described in 1977 and subsequently named the Carney triad [54]. It affects predominantly females, and it has been described as a chronic benign-course tumor that comprises recently also adrenocortical tumors and esophageal leiomyoma [55–57]. Neither KIT, PDGFRA, nor SDH mutations were found in patients with the Carney triad. In 2002, Carney and Stratakis distinguished an inherited tumor syndrome comprising GIST and paragangliomas which have common germline mutations encoding SDH subunits B, C, D, and it was termed Carney–Stratakis diad [58].

Familial

Familial GIST cases are very rare, and they are autosomal dominant inherited. They differ from Carney dyad as they are heritable germline KIT mutations tumors. Occurrence of multiple tumors can be observed both in syndromic [59–64] and in sporadic GIST. Familial GISTs do not have female predominance, and the main location is small intestine, in contrast to sporadic GIST where the stomach is the main affected place [61, 65]. Other phenotypic characteristics associated with familial GIST include mastocytosis [66], dysphagia [67, 68], cutaneous hyperpigmentation or urticaria pigmentosa [59, 61, 64, 69, 70], and recurrent small intestinal diverticular perforation [68]. Familial GIST does not develop early in life, as the youngest patient in a GIST family described to this date had symptoms at 18 years old [70].

Sporadic

A considerable number of articles describing children and adolescents with sporadic GIST have been published [71–73]. Sporadic GISTs have been described in newborns [72–75], but the majority of cases become symptomatic in the second decade of life. There is a strong female predominance with a male-to-female ratio of 1:2.5.

The majority of pediatric GISTs are located in the stomach (mainly in the antrum) [45, 72–74, 76–80], but it can be found virtually in every digestive tube segment as well as mesentery, omentum, and abdominal wall [81–84].

Clinical presentations vary from upper gastrointestinal bleeding with anemia and anemia-related symptoms to non-

Fig. 52.9 GIST in the stomach *GIST* gastrointestinal stromal tumors

specific symptoms such as loss of appetite, poor feeding, abdominal pain, abdominal distension, nausea, vomiting, constipation, epigastric discomfort, diarrhea, and intestinal obstruction [53]. Sometimes they are incidentally discovered in a routine abdominal examination as a palpable mass, suggestive for a more advanced stage of the disease, or at ultrasound [53].

GISTs generally have a nodular growth pattern, with frequent submucosal spreading. Surface ulceration may result in acute or chronic bleeding which promotes clinical investigation (Fig. 52.9). Gastrointestinal contrast series denote solitary or multiple nodular round filling defects. Even without metastases on presentation, submucosal spreading can occur, so endosonography can be a very useful diagnostic resource [44, 80, 85–87]. Other image tools include abdominal and thoracic CT or MRI to perform disease staging. Metastases on diagnosis are not frequent, but they may occur in the liver (most commonly), lymph nodes, peritoneum, and mesentery. Even without metastasis on diagnosis, these are very frequent places for recurrent disease [47, 72, 76, 77, 87].

Fluorodeoxyglucose-positron emission tomography (FDG-PET) seems to be a sensitive diagnostic tool, particularly to monitor treatment response. The final diagnosis is based on histology and immunohistochemistry. Tissue samples can be obtained either by biopsy or by tumor resection, which in many cases of small localized disease, is usually the only procedure needed [88].

There are no algorithms for children GIST workup as well as for the treatment. As in adults, total resection with microscopic free margins is the gold standard treatment. Adjuvantive therapy from conventional cytotoxic chemotherapy had no positive results. Localized disease is usually cured by surgery, and it can be performed more than once in recurrent disease or in incomplete primary resection. Metastases should undergo surgical treatment as lymph node dissection and resection of hepatic-affected areas [88].

Recently, there are increasing cases of children treated with RTK inhibitors (imatinib and sunitinib), based on adult

experience. They may be considered in high-risk patient such as metastatic diffuse disease or when the primary tumor cannot be fully resected. Despite the fact that there is no randomized trials in children or consensus on imatinib dosage, a starting dose of 400 mg/m² once daily might be suggested with a maximum dose of 400 mg bid = 2 times daily [53].

In children, prognosis depends on the results from surgery of the main tumor lesion and the presence of metastatic lesions, especially if they are not amenable to complete resection [44, 76, 77, 89–91]. Recurrences are frequent and may occur many years following diagnosis, but it seems that mortality from GIST is low, despite tumor recurrence and development of metastases.

In summary, the pathogenesis, clinical course and prognosis of GIST in children are currently insufficient due to the small number of reported cases. Future research based upon controlled randomized trials should be encouraged to inform about optimal management in this particular population.

Gastrointestinal Autonomic Nerve Tumors

Gastrointestinal autonomic nerve tumors GANT are variants of GIST. Diagnosis is based on electron microscopic studies showing neural differentiation in contrast to GIST, and the number of pediatric patients with GANT is limited to a few cases [92–97].

Inflammatory Pseudotumors

Inflammatory pseudotumors are solid tumors composed by spindle cells, myofibroblasts, plasma cells, and histiocytes that can occur in every organ system during childhood [51, 98, 99]. Lung is the most common location, whereas occurrence in the gastrointestinal tract is rare, the majority involving the stomach [100] (Fig. 52.10). They are commonly described as plasma cell granulomas or inflammatory myofibroblastic tumors. Abdominal pain is the most common presenting symptom, but may also present with dysphagia,

Fig. 52.10 Inflammatory pseudotumor

intestinal obstruction, and iron-deficient anemia. It affects mostly girls, as reported in the literature [98].

Like the majority of gastrointestinal tract tumors in childhood, complete surgical resection is the treatment of choice. Sporadic trials of nonsteroidal and steroidal antiinflammatory medications have been reported for the treatment of large and unresectable masses. Its success rate seems to be variable [101]. Recurrence rates are reported between 18 and 40% and are more common in extrapulmonary lesions. Multiple recurrences are associated with a higher rate of malignant transformation with an overall mortality of 5–7% [51, 102, 103].

Sarcomas

Soft tissue sarcomas account for 7% of all childhood malignancies, and only 2% of this group have digestive involvement [104, 105]. Sarcomas are smooth muscle-derived neoplasms that occur anywhere along the gastrointestinal tract, more often involving the stomach and small intestine (leiomyomas) (Fig. 52.11). In the stomach, these can be confused with the appearance of an umbilicated lesion typical of an ectopic pancreas. The malignant form (leiomyosarcoma) is more common in the jejunum [106, 107]. The definition of malignancy usually is based on mitotic index at histologic examination (more than 10 mitosis per high-powered field), but in children, it is not common to see a high mitotic index that enables the adult classification of leiomyosarcoma [51]. Nearly 40% of these present with less than 5 mitoses per high-powered field, so pathologic features must also include tumor size, cellular atypia, tumor necrosis, and myxoid change [108].

Clinical presentation occurs early on life, with over half of the leiomyosarcomas occurring in the newborn period, but they can present throughout childhood and adolescence. The

Fig. 52.11 Leiomyoma of the stomach

clinical signs vary from an incidental mass finding to active GI bleeding with associated anemia signs or acute perforation. They can also be the cause of recurrent intussusception [109–112]. Rare presentations include cough and dysphagia (if esophageal location) and oral cavity swelling [113, 114].

Symptomatic lesions may also present concurrently in patients with neurofibromatosis and in children with human immunodeficiency virus (HIV-AIDS) [115–117]. The goal of treatment is complete resection as pediatric leiomyosarcomas are less likely to be found with metastases at diagnosis [118], and the use of adjuvant chemotherapy and radiotherapy remains experimental. Long-term outcomes for leiomyosarcomas are related with the histologic type of the tumor and with successful surgical excision.

Carcinoid Tumors

Carcinoid tumors in children are quite rare, and their true incidence is unknown. The occurrence of carcinoid tumors in children was recently reported as approximately 0.1% of all pediatric cancers [71, 119]. These tumors are more prevalent in school-aged children, but younger patients have been reported. An overall female-to-male ratio of 3:1 has been noted [119]. Despite their rarity, carcinoid tumors have been described in all portions of the gastrointestinal tract from the stomach to the rectum. The most common location is the appendix, followed by involvement of the small intestine and rarely the colon and rectum [120]. Reports have also documented the presence of carcinoid tumors in gastrointestinal duplication cysts and Meckel's diverticulum [121–123]. The diagnosis is often made through the incidental pathologic findings within an appendectomy specimen. However, these tumors may present with clinical signs of hematochezia or anemia from chronic gastrointestinal blood loss, right-lower quadrant abdominal pain, and small-bowel obstruction associated signs [119, 121, 124]. The vast majority of carcinoid tumors are benign. Occasionally, they may be locally invasive, especially if originating from the colon or small intestine. Few reports have noted their malignant transformation in children, with metastasis to the liver, lung, and bone [119]. Serotonin hypersecretion signs known as carcinoid syndrome with cutaneous flushing, diarrhea, asthma-like respiratory distress, and right-sided cardiac failure are quite rare [121, 124, 125].

Incidental gastrointestinal carcinoid tumors which are less than 2.0 cm diameter and without evidence of metastasis are successfully treated with complete resection, which should include tumor-free margins. For those with evidence of serosal penetration or local extension, a bowel resection with associated mesenteric resection is required, along with abdominal surveillance for metastatic disease [51]. Patients with tumors exceeding 2.0 cm in size should undergo thor-

ough evaluation for possible metastases to the liver, lung, and bone. Serum 5-hydroxyindolacetic acid (5-HIAA) levels may act as a serologic marker of disease, but are not present in all metastatic cases. Serum chromogranin A is more reliable as a marker and does not require metastases for this to be an abnormal result. Abdominal and thoracic CT or MRI and 99m-technetium bone scan should be considered in patients with metastatic disease and/or bone pain. Children with metastatic disease often respond poorly to cytotoxic chemotherapy, but they can benefit from the administration of octreotide for symptomatic relief [119].

Gastroenteropancreatic Neuroendocrine Tumors

Pediatric gastroenteropancreatic neuroendocrine tumors (GEP-NETs) have traditionally been classified into two groups: carcinoids, which are subdivided by their origin into tumors of the *foregut* (lung, thymus, stomach, duodenum), *midgut* (jejunum, ileum, appendix, right colon), and *hindgut* (left colon, rectum), which were previously discussed, and pancreatic tumors [126]. A more useful classification was proposed by the World Health Organization in 2000: well-differentiated NETs, which show benign behavior and well-differentiated neuroendocrine carcinomas, which are characterized by low-grade malignancy and poorly differentiated NEC of high-grade malignancy [127].

These tumors can be *functional* or *nonfunctional*. Functional tumors have clinical symptoms caused by hypersecretion of hormones such as gastrin, while nonfunctional tumors can produce clinically silent hormones such as pancreatic polypeptide. The functional tumors are named according to the hormone responsible for the clinical syndrome, such as gastrinoma causing Zollinger–Ellison syndrome and insulinoma causing hypoglycemic syndrome. NETs can either be sporadic or occur as part of familial syndromes such as multiple endocrine neoplasia (MEN) I and II, von Hippel–Lindau (VHL) syndrome, and neurofibromatosis type I (NF-I) [128].

GEP-NETs are very rare in children. Tumors with gastroenteropancreatic hormone production include amine precursor uptake and decarboxylation tumors (APUDomas), extrapancreatic gastrinomas, and vasoactive intestinal polypeptide tumors [129, 130]. Pancreatic NETs account for approximately 30% of pancreatic tumors in patients younger than 20 years. While insulinomas are the most common in adults, gastrinomas are more common in children and affect more frequently the stomach. Hypersecretion of gastrin by gastrinomas causes recurrent or ectopic peptic ulcers (Zollinger–Ellison syndrome), or malabsorption diarrhea [128]. Non-gastrinoma neuroendocrine tumors can occur in any part of the pancreas [131]. Metastases are present in

60–80% of patients at initial diagnosis of gastrinoma, with the liver and lymph nodes being the most common sites of metastatic disease [132]. There is limited information in the pediatric literature regarding the imaging findings of NETs as well as treatment options. PET scan with octreotide labeling may help in diagnosis. Prognosis of this rare entity depends of disease extension and presence of metastatic disease. A recent study from a European registry showed an overall survival of 100% when complete surgical resection was performed in patients with localized neuroendocrine neoplasm (NEN) in contrast to poor survival rate associated to metastatic disease [133].

Adenocarcinoma

Progression to adenocarcinoma from polyposis syndromes such as FAP and the HNPCC is dealt with above.

Colorectal cancer's prevalence in children is very low with fewer than 500 pediatric cases reported in the literature and a few articles dealing with this as reviews [134–138]. Compared to adults who have no predetermining diseases, in children, there is usually preexisting polyposis or, rarely, colitis.

Pathogenesis

Colorectal carcinoma is due to sequential genetic mutations, commonly known as the adenoma–carcinoma sequence. Progress to malignancy happens due to the coexistence of four or more genetic problems which can include mutational activation of oncogenes and inactivation of tumor-suppressor genes.

Pathology

Colonic carcinoma in children is usually cecal or right-side colonic disease, with 50% in the ascending and transverse colon. If colonic cancer penetrates the bowel wall, it can spread to regional lymphatics and subsequently to distant lymph nodes, and metastasize to the liver, lungs, and vertebrae. Cases are staged according to the degree of local spread and presence or absence of transmural penetration, the degree of lymph node involvement, and the presence of distant metastases. In a review of younger cases with colonic cancer, 82% of these cases had either distant metastases, lymph node involvement, or transmural penetrating disease, significantly higher than adults cases.

In adults, the CRC is that of a moderate to well-differentiated adenocarcinoma. In children, this is a more aggressive type, with more proportion of tumors with mucinous (30%) and signet-ring (10%) histological appearances, hence with a poorer prognosis—this probably leads to the poorer prognosis at presentation in children (Fig. 52.12).

Fig. 52.12 Histological appearance of signet-ring adenocarcinoma

Fig. 52.13 Colonoscopic appearance of recto-sigmoid adenocarcinoma

Clinical Presentation

Abdominal pain is the main presenting symptom in the majority of cases—other symptoms include: weight loss, intussusception, vomiting, rectal bleeding, and altered bowel habit. The site of the lesion is important with constipation, obstruction, and bleeding more common with left-sided disease, and more commonly in childhood, right-sided disease which may not present with obstruction until the cancer is larger and a mass is palpable.

Diagnosis is by most usefully achieved by ileo-colonoscopy in the majority (Fig. 52.13), although the lesion can also be identified by other diagnostic techniques including wireless capsule endoscopy, ultrasound, CT colonography, or MRI. Although serological markers such as carcinoembryonic antigen (CEA) are available, their role in establishing this rare diagnosis in children has not been fully evaluated.

Treatment/Prognosis

Surgery is the most effective treatment for colonic carcinoma, with complete resection of the primary lesion and regional lymph nodes being the main aim; however, total

clearance and resection are often not possible in children due to the advanced stage at presentation. Chemotherapy for metastatic disease has poor results, and the role of radiotherapy or combination therapies grouping childhood cases is hampered by limited numbers presenting precluding viable randomized studies.

Sadly the prognosis for children with colon cancer is poor with five-year survival rates of 10–20% [134–141]. These poor results are due to a combination of aggressive phenotype and delayed presentation.

Lymphoma

Epidemiology and Classification

In the developed world, lymphoma accounts for 10% of all cancers in children under 15 years of age—however, it is an unusual GI condition and would need a predisposing condition in most cases, for example, celiac disease or isolation by distance (IBD). Nevertheless, cases occur without these prerequisites [142, 143].

Etiology

Non-Hodgkin's lymphoma (NHL) usually presents in association with immunodeficiency syndromes—inherited (e.g., ataxic-telangiectasia, severe combined immunodeficiency, SCID) and acquired (e.g., HIV infection), and also with immunosuppressive drug regimens such as those encountered after liver transplant [144]. Epstein-Barr virus (EBV) may play a role in disease pathogenesis especially in Burkitt's lymphoma, although malaria coinfection may be important in promoting B-cell activation as part of the process. Other conditions that give rise to chronic mucosal inflammation have also been linked to lymphoma including *Helicobacter pylori*. T cell NHL is associated with celiac disease, while both lymphoma and adenocarcinoma are associated with both Crohn's disease where the lesion is typically in the small bowel and with ulcerative colitis [142, 143].

Pathology

Intra-abdominal NHL in children typically is of an undifferentiated histological type—only around 50% have a primary intestinal origin—most common intestinal primary sites are the distal ileum, cecum, and appendix. Bone marrow involvement occurs in up to 40% of undifferentiated lymphoma while central nervous system involvement is uncommon. In Burkitt's lymphoma, 60% can have abdominal disease.

Clinical Presentation

Disease may present with nonspecific symptoms such as abdominal distension, nausea, vomiting, altered bowel habit, and abdominal pain. Lymphoma in the GI tract is typically localized to the distal ileum and cecum and would present

Fig. 52.14 Endoscopic appearance of small bowel lymphoma

as a mass or occasionally as an ileo-cecal intussusception manifesting with obstructive symptoms or bleeding.

Endoscopy is important in diagnosis (Fig. 52.14), and when the tumor is suspected but is outside the reach of conventional endoscopes, then wireless capsule endoscopy (Fig. 52.15) and balloon enteroscopy can be useful tools in identifying lesions, and then if necessary biopsy of these lesions and tattooing, thereby accurately localizing them in case of absence of serosal abnormality for future surgical resection (Fig. 52.16). The diagnosis of NHL depends on histological examination with immunophenotyping and cytogenetics. Staging of disease with chest and abdominal imaging, lumbar puncture, and bone marrow examination is also required and may allow treatment to start if there is a delay in undertaking a laparotomy.

Fig. 52.15 Lymphoma in the mid-small bowel identified by wireless capsule endoscopy

Fig. 52.16 Biopsy and then tattooing for identification of the exact site of a small bowel tumor by double-balloon enteroscopy prior to surgery

Treatment and Outcome

Surgical resection of local disease is indicated where it is possible, although such fully resectable disease accounts for only 60–75% of cases [144]. The high mortality associated with intestinal perforation in more advanced disease has led to debate as to the role of partial resection as opposed to simple biopsy to establish histological type. Subsequent chemotherapy is required in all cases. For more localized disease, the overall outcome is relatively good. In the 30% of childhood, NHL cases with localized disease cure rates as high as 95% have been reported following combined surgical resection and combination chemotherapy [144].

Part II
Hepatology

Corina Gabriela Cotoi and Alberto Quaglia

Short Introduction

The liver is mentioned in various ancient medical manuscripts such as the Edwin Smith Papyrus, an ancient Egyptian medical text from 1600 BC. It was seen as the site of origin of veins by Praxagoras of Cox in ancient Greece (340 BC), as the source of blood by Empedocles from Sicily (fifth century), as the ‘seat’ of life in Mesopotamia [1] and as the site of emotions and the symbol of life by other ancestors [2].

The Development of the Liver

The liver develops from the embryonic liver bud or liver diverticulum, which appears in the human embryo between the 3rd and the 4th week of gestation (4-mm embryo), arising from the ventral endodermal layer of the distal foregut (future duodenum) [3]. The mesenchymal tissue in which the liver further grows is developed from the septum transversus [4]. The forming primitive hepatocytes (or hepatoblasts) cords seem to surround mesenchymal spaces [5], and as they grow towards the septum transversus, they are penetrated by the capillary plexus that arises from the vitelline veins, forming the primitive hepatic sinusoids [6]. The mesenchymal cells interposed between the endothelial cells and the hepatoblasts will form the liver connective tissue and the liver capsule [6].

The liver haematopoietic activity starts from the 6th week, and by the 12th week, the liver is the main site of haematopoiesis, until the third trimester of intrauterine life [4, 6, 7], which fades slowly after birth [5] (see Fig. 53.1).

A caudal part of the liver bud becomes the gallbladder and its stalk, the cystic duct [7]. The intrahepatic bile ducts develop from the limiting plates of the forming hepatoblast

cords in the mesenchyme adjacent to the portal vein branches, forming the ductal plates, double-layer cylindrical structures, which by remodelling will evolve into the intrahepatic bile duct system. This process starts around the hepatic hilum [6, 8].

Disorders such as Caroli disease and Caroli syndrome, congenital hepatic fibrosis, autosomal recessive and autosomal dominant polycystic kidney disease and von Meyenburg complexes are considered the result of abnormalities of ductal plate development [9].

Bile formation begins in the 12th week, but the excretion into the duodenum does not happen until the 16th week of intrauterine life [6], and maybe at low levels until after birth, due to the lack of enteral nutrition. This would explain why liver injury, in cases of biliary atresia, is not present at birth but develops in the next following weeks [10].

The opening of the common bile duct into the posterior side of the duodenum is the result of the ventral pancreatic bud rotation around the duodenum [11].

In the early stages, the blood flow into the sinusoids of the developing liver is sustained through the two vitelline veins and the right and left umbilical veins, until the 5th week when the left umbilical vein becomes the main blood supply from the placenta [4]. The umbilical vein gives branches to the left liver and drains into the ductus venosus, a structure that connects it to the inferior vena cava [12]. In the 7th week, the portal vein is already formed from the anastomosing channels of the initial two vitelline veins. The hepatic artery originates from the celiac axis and the arterial system of the liver spreads from the hilum to the periphery, through the branching of the main artery [4].

Within a week after birth, the umbilical vein is obliterated and the ductus venosus is closed, forming the round ligament and the ligamentum venosum, respectively. The hepatic arterial and biliary systems are not completely mature until around 15 years of age [13].

Fig. 53.1 Liver haematopoiesis

Liver Anatomy

The liver is situated in the right hypochondrium and epigastric region, reaching often the left hypochondrium, and is almost entirely protected by the ribcage. It is the largest internal organ in the human body. Its size when compared to the total body size is greater in the foetus than in the adult, constituting, in the former, about one eighteenth, and in the latter about one thirty-sixth of the entire body weight.

Classically, the liver is divided into two large lobes (right and left) and two small central ones (quadrate and caudate lobes). Its external surfaces can be divided into superior, inferior and posterior. The superior surface lies under the diaphragm. The diaphragm separates it from the ribs and the costal cartilages on the lateral and posterior sides and the lungs with pleurae and the heart with the pericardium on the superior side. The superior and inferior surfaces are demarcated on the anterior side of the liver by a well-defined margin, the anterior border. This border is marked by two notches: the umbilical notch and the one where the gallbladder fundus lies. In children and women, this border projects below the ribs unlike in adult males where it generally corresponds with the lower margin of the thorax in the right mammillary line. Both intercostal and subcostal approaches for percutaneous liver biopsy are possible in children [14].

Most of the liver is covered by the visceral peritoneum, except for the 'bare area' on the posterior surface, which is in direct contact with the diaphragm and delimited by the coronary ligament. The porta hepatis is the entry point of the hepatic artery (to the left) and the portal vein (behind and between the duct and artery) and the exit point of the common hepatic duct (to the right). Nerves and lymphatic vessels can also be found in this region.

A few ligaments help keeping the liver in place or limit its lateral movements. The organ is connected to the diaphragm

and to the anterior wall of the abdomen by five ligaments, four of which are peritoneal folds: the falciform, the coronary and two lateral (triangular) ligaments, the fifth being a fibrous cord (the round ligament) corresponding to the obliterated umbilical vein.

The subdivision of the liver into segments as proposed by Couinaud in 1957, is based on the intrahepatic distribution of the portal and hepatic veins, and is used in clinical practice, particularly in planning surgical resections. Couinaud divided the liver into two functional lobes of similar sizes, separated on the liver surface by an imaginary line going through the inferior vena cava sulcus and the middle of the gallbladder fossa. The right lobe is further divided into posterior and anterior sectors and the left lobe into medial and lateral part. Each of the two segments is separated into inferior and superior segments. Thus, eight total segments, with almost independent blood supply are formed, as follows: (I) caudate lobe, (II) superior subsegment of the left lateral segment, (III) inferior subsegment of the left lateral segment, (IV) left medial segment, (V) inferior subsegment of the right anterior segment, (VI) inferior subsegment of the right posterior segment, (VII) superior subsegment of the right posterior segment, (VIII) superior subsegment of the right anterior segment [15].

Liver Vascularisation and Innervation

The liver receives a dual blood supply through the portal vein and the hepatic artery. The hepatic artery in the foetal and early postnatal life is the largest branch of the celiac axis, its calibre decreasing with age to an intermediate size artery in adults. At the porta hepatis, it divides into a right and a left hepatic artery. They branch out progressively to terminal hepatic arterioles, which communicate with the hepatic sinusoids. The hepatic artery provides the blood supply to the biliary tree through a peribiliary plexus and forms a perivenous plexus around the portal vein branches. Hepatic artery thrombosis can cause ischemic necrosis of the biliary tree due to its dependence on the arterial supply. The portal vein drains the blood from most of the gut, and it is formed at the level of the second lumbar vertebra by the confluence of the superior mesenteric vein, inferior mesenteric vein and splenic vein. It enters the liver through the porta hepatis and subdivides into right and left branches and then progressively down to the terminal portal venules and inlet venules to open into the sinusoids. The sinusoidal blood drains into the centrilobular venules, and eventually through the hepatic veins into the inferior vena cava. Segments II, III and IV are drained by the left hepatic vein, the middle hepatic vein gathering blood from segments IV, V and VIII, while the right hepatic vein serves segments V–VIII. One small inferior

hepatic vein drains the caudate lobe (segment I) directly into the inferior vena cava. Liver biopsy through the transjugular route is an established procedure to sample liver parenchyma via the hepatic veins [16].

The lymphatic drainage of the liver parenchyma occurs in two directions. One is through the porta hepatis into the celiac nodes. The other is through the falciform ligament and the bare area into the parasternal and mediastinal nodes.

The liver innervation seems to appear in the late stages of embryonic development, continues to mature postpartum, and comprises sympathetic and parasympathetic fibres [17], which enter through the porta hepatis. The capsule is supplied by a few branches of the lower intercostal nerves.

Liver Microarchitecture and Basics of Liver Histology

Various models have been proposed to define the structural and functional unit of the liver. The hexagonal lobule of Kierman, described in 1833 places the hepatic venule in the centre of the lobule and the portal tract, which contain one of each ramification of the hepatic artery, portal vein and bile duct [18]. In 1954, Rappaport proposed the concept of the hepatic acinus, which has a triangular shape, with the portal venule at the apex and the portal tracts at the base. According to the Rappaport model, the acinus is divided into three zones: zone 1, which is located in the vicinity

of the portal venule, and is well oxygenated; the mid-zone (zone 2); and zone 3, situated close to the hepatic venule [19]. These two classical models are still in common usage (see Fig. 53.2).

The liver parenchyma is composed mostly of hepatocytes, arranged in a tridimensional spongiform pattern, in plates that vary in thickness, from the foetal liver to about 5 months after birth, when they form two-cell-thick trabeculae. At approximately 5 years of age, they adopt the adult pattern of one-cell-thick plates [12]. Under light microscopy, hepatocytes have a well-defined polygonal shape of approximately 25 μm in diameter. The cellular membrane can be divided into three aspects, with different characteristics: a *basolateral* aspect facing the sinusoidal lumen, a *canalicular* aspect, which delimitates the canalicular space and the *lateral* aspect between the other two. The nucleus is centrally located, and most hepatocytes are mononuclear, although binuclear hepatocytes are often found. The cytoplasm is abundant and eosinophilic, and the glycogen accumulation can be highlighted with periodic acid-Schiff stain. Periportal hepatocytes in children and adolescent show physiological vacuolated nuclei.

Stainable iron and copper accumulation are abundant in the first weeks of life, but they diminish and slowly disappear at 3–6 months of age approximately [6]. Lipofuscin is usually absent in children.

The bile canaliculi are found between two adjacent hepatocytes and they are not easily demonstrated on routine

histological stains with haematoxylin–eosin (H&E). They connect to the bile ducts through the canals of Hering.

The hepatic sinusoids are lined by fenestrated endothelium. Kupffer cells rest on the internal sinusoidal surface and are a part of the reticuloendothelial system [6].

The space between the endothelial cells and the hepatocytes is defined as the space of Disse, which contains the hepatic stellate cells (Ito cells). They store retinoids, can contract affecting the sinusoidal calibre and can produce extracellular matrix participating to fibrogenesis when activated. A reticulin (silver impregnation stain) highlights the scaffolding of the liver, which is mainly composed of type III collagen [6] (see Fig. 53.3).

Imaging of Cholestatic Jaundice

Neonatal

Neonatal jaundice that persists longer than 2–3 weeks demands clinical, laboratory, and radiological investigation, as early diagnosis of surgically treatable conditions leads to favorable outcomes. The role of radiology in the workup of conjugated hyperbilirubinemia is to make a distinction between obstructive cholestasis due to structural biliary anomalies and nonobstructive conditions such as genetic, metabolic, endocrinal, or infective disorders, in which imaging investigations are often normal at presentation.

High-resolution ultrasonography (US) is the imaging modality of choice in the screening of these patients and provides the radiologist with a noninvasive, nonionizing tool, independent of liver function tests.

The ultrasound approach to these patients needs to be systematic, with thorough examination of the liver parenchyma, gallbladder, bile ducts, portal venous system, spleen, and pancreas. In particular, the examiner should concentrate on the intra- and extrahepatic bile ducts, in order to detect dilatation. The common bile duct (CBD) should not exceed a caliber of 1 mm in neonates, 2 mm in infants up to 1 year of age, 4 mm in older children, and 7 mm in adolescents [1, 2]. The gallbladder needs to be evaluated in its length (normal range between 1.5 and 3 cm) and shape and for presence of gallstones, inspissated bile and irregular, thickened walls. Evaluation of portal vein patency and direction of flow, presence of collaterals as well as splenic length and ascites is needed to assess signs of portal hypertension. Finally, the size and echogenicity of the pancreas and the caliber of the pancreatic duct (which needs to be <1–2 mm) should also be recorded [3].

Absence of dilated ducts, a small, abnormal gallbladder with irregular walls and hyperechoic fibrous tissue at the porta hepatis (triangular cord sign), are suggestive but not pathognomonic features of extrahepatic biliary atresia. Signs of biliary atresia splenic malformation (BASM) syndrome also need to be sought, such as polysplenia, situs ambiguous, interrupted inferior vena cava (IVC), pre-duodenal portal vein, anomalous hepatic artery supply, and intestinal malrotation (Fig. 54.1); these patients require MRI supplemented by angiographic sequences for detailed vascular delineation, crucial for preoperative planning. Infants with biliary atresia can present with end-stage liver disease, and therefore initial US can detect coarse nodular liver parenchyma, retrograde flow in the portal vein, ascites, varices, and splenomegaly. In biliary atresia, hepatic scintigraphy will show failure of biliary excretion after 24 h; however, neonatal hepatitis could also show absent bowel activity due to poor hepatocellular function, therefore, phenobarbital is administered prior to the procedure to enhance hepatocellular function. Confirmation of diagnosis is normally achieved with liver biopsy, which will differentiate between biliary atresia and neonatal hepatitis, which is a diagnosis of exclusion.

When dilated ducts are detected, the differential will include choledochal malformation, inspissated bile syndrome and Caroli with congenital hepatic fibrosis. In these instances, the patient needs further evaluation to define the anatomy; historically, this was achieved by means of direct percutaneous cholangiography (PTC) or endoscopic retrograde cholangiopancreatography (ERCP), but the implementation of magnetic resonance imaging (MRI) with heavily T2-weighted cholangiography sequences has allowed the radiologist to achieve the diagnosis confidently and in a non-invasive way [4].

Magnetic resonance cholangiopancreatography (MRCP) can in fact classify the different types of choledochal malformations and reveal anomalies of the pancreatico-biliary junction (more often associated with type I cysts) with possible complications, such as calculi within a long common channel (Fig. 54.2).

Fig. 54.1 T2W MRI image of a patient with BASM. The liver is cirrhotic with a large central regenerative nodule and atrophied left lobe and posterior segments of the right lobe. There is polysplenia and interrupted IVC with hemi-azygous continuation (*arrow*)

Fig. 54.2 MRCP MIP reconstruction of the biliary tree showing a type of choledocal malformation with an impacted calculus within a long common channel (*arrow*)

In case of Caroli, MRCP will show multifocal cystic dilatation of the intrahepatic bile ducts, possibly containing

Fig. 54.3 MRI T1W (a) and T2W (b) images of a cirrhotic liver with markedly abnormal contour and varying size-regenerative nodules throughout. The portal vein is occluded and there are numerous short gastric and splenic varices (*arrows*)

filling defects, representing calculi; these cysts communicate with the biliary tree, thus excluding autosomal dominant cystic liver disease and biliary hamartomas. A specific MR finding of Caroli is the “central dot sign,” a portal vein branch protruding into the lumen of a dilated duct, which enhances with gadolinium [5].

ERCP is not routinely indicated but may still be required in doubtful cases or as a therapeutic option in those patients where MRCP has identified an obstructed biliary system due to inspissated bile or choledocholithiasis (shown as signal voids).

Older Children

Jaundice in older children can be caused by hepatocellular disease (acute or chronic) and obstructive causes and imaging investigations can distinguish these entities and often establish the etiology of many chronic conditions and acquired or developmental biliary disorders.

Ultrasound findings in acute hepatitis are normally non-specific, with US demonstrating hypoechoic parenchyma, increased periportal reflectivity due to edema, and thickened gallbladder walls.

In the context of chronic liver disease, radiology can confirm the clinical diagnosis demonstrating coarse, heterogeneous liver parenchyma and abnormal liver architecture as well as signs of portal hypertension (Fig. 54.3).

Medical causes of jaundice in older children include Wilson’s disease, cystic fibrosis, glycogen storage disorder, tyrosinemia, and alpha1 antitripsin deficiency. In all these conditions, US will show nonspecific changes with hyperechoic liver parenchyma; however, these patients are prone to develop focal liver lesions (such as adenomas and, importantly, hepatocellular carcinomas) and in this instance, US is extremely useful as a noninvasive, radiation-free surveillance test. In addition, some of these conditions have specific imaging features, such as multiple small nodules with low signal intensity in T2 on MR in Wilson’s disease and focal biliary cirrhosis with periportal fibrosis seen on US and MR in cystic fibrosis.

Calculi, benign strictures (as seen in primary sclerosing cholangitis, PSC), and neoplasms (which will be discussed separately) are all obstructive causes of jaundice in older children.

Calculi are seen in US as hyperechoic foci with posterior acoustic shadowing, mobile when detected within the gallbladder; these are seen as signal voids on MR. Inspissated bile is again hyperechoic in US but does not cause posterior shadowing.

Primary sclerosing cholangitis (PSC) is characterized by inflammation and fibrosis of the biliary tree, which results in cholestasis with progression to secondary biliary cirrhosis and hepatic failure. Histologically, the intrahepatic bile ducts are surrounded by cuffs of inflammatory cells and fibrosis, which results in segmental dilatation of the peripheral ducts alternated with narrow or obliterated segments, reflected in the imaging findings. The radiological diagnosis of PSC is often challenging, and needs confirmatory clinical, biochemical, and histologic findings. Traditionally, ERCP and PTC have been used as standard imaging procedures for the radiological diagnosis of PSC, however, MRCP has nowadays replaced these techniques.

Ultrasound remains the first-line investigation in these patients and shows segmental duct dilatation, irregular thickened walls of the CBD (Fig. 54.4), lymph nodes at the porta hepatis and heterogeneous reflectivity of the liver parenchyma (depending on the stage of disease). In established chronic liver disease, there is coarse echotexture with nodularity and relative atrophy of the right lobe with hypertrophy of the caudate and lateral segment of the left lobe.

MRCP can depict ductal irregularity, stricturing, focal dilatation, beading, and pruning affecting the intra- or extrahepatic biliary tree (Fig. 54.5). Post-contrast dynamic MR sequences should also be included to look for enhancement

Fig. 54.4 US of the liver of a patient with PSC shows thickened wall of the common bile duct (arrow). PV portal vein, GB gallbladder

Fig. 54.5 MRCP MIP reconstruction of the biliary tree showing irregularity of the walls of the intra- and extrahepatic bile ducts, with focal structuring, in keeping with PSC. MIP maximum-intensity projection

of thickened walls of the extrahepatic ducts and cholangiocarcinoma.

Congenital and Acquired Vascular Disorders

Portal Hypertension

The etiology of portal hypertension can be classified as cirrhotic and non-cirrhotic. The latter can be prehepatic (portal vein thrombosis), intrahepatic (portal vein sclerosis, congenital hepatic fibrosis, steatosis, nodular regenerative hyperplasia, veno-occlusive disease), or suprahepatic (Budd–Chiari). Depending on the etiology, different radiological findings will be present. Liver function tests may be normal, and the diagnosis of portal hypertension often relies on demonstration of splenomegaly and formation of portosystemic collaterals.

In cirrhosis, prehepatic and pre-sinusoidal portal hypertension, the role of radiology is to determine the extent of involvement of the portal venous system, as this would influence the therapeutic options, which include surgical portosystemic shunt, Rex bypass, transjugular intrahepatic portosystemic shunt (TIPS), and ultimately liver transplantation.

The radiological approach to children with portal hypertension starts again from US with Doppler, which can detect low velocity, retrograde, or absent flow in the main portal vein and intrahepatic divisions. A patent umbilical vein, splenomegaly with varices, and ascites can also be easily seen on US; however, cross-sectional imaging is used as a “road-map” for the evaluation of the portal system and collaterals pathways; CT and MR venography (MRV) can also demon-

strate cavernous transformation of the portal vein, seen as a typical “beaded” appearance at the porta hepatis, which consists of venous channels within and around a previously stenosed or occluded portal vein [6]. This can occur within a few weeks after a thrombotic event, even in case of partial recanalization of the thrombosed segment, and can extend to the intrahepatic branches. Cystic and pericholecystic dilated veins can also be seen. A computed tomography (CT) performed in the arterial phase often shows patchy areas of high density at the periphery of the liver parenchyma, and this is due to a peripheral increase of the arterial inflow to supply the areas not reached by the cavernous portal vein.

Intra- and Extrahepatic Vascular Shunts

Intrahepatic communications between portal vein, hepatic artery, and hepatic veins are rare, and the most common, although often difficult to demonstrate, are small arteriportal shunts seen in cirrhotic livers. Large connections include portosystemic shunts (intra- and extrahepatic), arteriportal shunts, and arteriovenous shunts/malformations.

The origin of portosystemic shunts is still controversial and congenital, genetic, (such as trisomy 21) and acquired causes (such as in cirrhosis and post-traumatic) have been postulated [7]. These shunts have been historically classified into intrahepatic and extrahepatic, however, some authors discourage this classification and suggest to use an anatomical classification, which is aimed to establish the origin of the shunt (main portal vein, its tributaries or intrahepatic branches) and its systemic termination, the type of communication (end-to-end or side-to-side) and the number of connections. A distinction should be made between these shunts and a persistence of the ductus venosus [8].

The aim of radiology is to detect the shunts, delineate the anatomy, assist planning, and monitoring of interventional/surgical corrections and follow-up. Doppler US is the modality of choice to achieve this: direct communication between a portal branch and hepatic vein or the ductus venosus can be readily demonstrated, often due to enlargement and tortuosity of the vessels involved; the flow is usually continuous but triphasic flow can be seen in the portal branch. In case of main portal vein IVC connections, there is low velocity flow or non-visible intrahepatic portal vein, and the liver is usually decreased in size. Cross-sectional imaging is performed routinely to confirm the diagnosis and define the anatomy prior to intervention or surgery; in addition, shunts between the splenic vein or superior mesenteric vein and the IVC may be easily missed on US. CT and MR are also useful to characterize focal liver lesions, often found in associations with these shunts.

Angiography is often part of the workup of these children, either as a therapeutic option or prior to surgery to detect non-visible intrahepatic portal vein branches; a balloon occlusion catheter is placed in the shunt and pressures are measured before and after occlusion to evaluate how closure will be tolerated.

Arteriportal shunts may be congenital (in Rendu–Osler disease) or acquired (posttraumatic, post-liver biopsy, cirrhosis).

On CT, small arteriportal shunts in cirrhosis appear as small, wedge-shaped, peripheral areas of increased attenuation with early portal venous filling in the arterial phase and uniform attenuation in the portal venous phase. In presence of large arteriportal shunts or fistulas, there is early and marked enhancement of the main portal vein or segmental branches during the arterial phase. At Doppler US, large shunts will manifest with pulsatility of the portal vein flow [9].

Connections between the hepatic artery and systemic veins are rare, and can be seen in congenital arteriovenous malformations (AVM), hepatocellular carcinoma (HCC) and large hemangioendotheliomas; on Doppler US, altered waveforms of the hepatic vein can be seen in severe AVM, whereas CT will show asymmetrical, early filling of the hepatic vein.

Budd–Chiari Syndrome

Budd–Chiari syndrome is the clinical manifestation of hepatic venous outflow obstruction at any level of the hepatic veins, IVC or right atrium; this could be primary, caused by an endoluminal thrombus or membrane or secondary, when the occlusion is due to nonvascular material or from extrinsic compression. On US, there is narrowing, lack of visualization or thrombosis of the hepatic veins/IVC, with absent or monophasic flow at color Doppler. There is enlargement of the caudate lobe, ascites, and signs of portal hypertension with retrograde flow in the portal vein and splenomegaly.

On cross-sectional imaging, in the acute setting, occlusion of the hepatic veins with severe ascites is the typical finding. There is patchy, decreased peripheral enhancement of the liver due to portal and sinusoidal stasis and higher enhancement of the central parenchyma and caudate lobe, which compresses the IVC (Fig. 54.6). In subacute Budd–Chiari syndrome, portal vein thrombosis can develop as the result of reduced portal flow caused by blockage of the outflow. Finally, in chronic stages, multiple regenerative nodules can be seen, and on MR, these are bright on T1-weighted images and strongly hypervascular on post-gadolinium sequences. The nodules are predominantly isointense or hypointense relative to the liver on T2-weighted images [10].

Fig. 54.6 MRI post-gadolinium T1W images of a patient with Budd-Chiari. In the acute phase **a**, there is significant enlargement of the caudate lobe (*black arrows*), which enhances normally versus the poorly

vascularized peripheral parenchyma. The IVC is compressed by the caudate lobe. In the subacute phase **b**, there are signs of paraseptal necrosis (*white arrow*) with preserved central enhancement

Imaging of Transplant Liver

Liver transplantation is the treatment of choice for children with end-stage acute or chronic liver failure in which other therapies have failed or are not available. The successful development of novel surgical techniques of segmental, split, auxiliary, and living donor transplantation, together with advances in organ preservation, immunosuppressive therapy and adequate choice of donor organ, have led to a reduced rate of complications. However, these new surgical techniques have also brought with them new potential complications: in living-related transplants, for example, when the vascular pedicle may be too short, an autologous iliac artery conduit can be used, leading to potential higher risk of vascular complications.

Early recognition is crucial to the successful management of these complications, and a multimodality imaging approach is most effective to achieve the diagnosis, except in case of graft rejection, in which radiology has no role.

Serial ultrasound is the screening modality of choice immediately postoperatively and can be easily performed at the patient's bedside; however, ultrasound has inherent limitations and, even though the use of ultrasound contrast agents can improve its sensitivity, it depends on the expertise of the operator, and cross-sectional imaging is often necessary in inconclusive cases. Conventional angiography is now limited to those cases in which endovascular treatment is required.

We will illustrate the imaging appearances of the main, commonest complications following liver transplant.

Hepatic Artery

A normal hepatic artery waveform shows a rapid systolic peak followed by a continuous diastolic flow; the resistive index (RI) should range between 0.5 and 0.8, except in the immediate postoperative period (<72 h), in which the RI can

be higher. An increased RI is associated with older donor age and prolonged ischemia time.

Hepatic artery thrombosis is a feared complication and a major cause of graft loss due to fulminant hepatic necrosis; in the long term, this complication can also lead to ischemic cholangiopathy, as the hepatic artery is the only arterial supply to the bile ducts in liver grafts. Children are particularly at risk, due to hepatic artery size discrepancy between recipient and donor.

On color and Doppler US, complete loss of arterial signal at the porta hepatis and within the liver suggests hepatic artery thrombosis. A tardus parvus waveform (prolonged systolic acceleration time and low-flow velocity with $RI < 0.5$) at the porta hepatis or in the intrahepatic arteries indicates significant impairment of hepatic arterial perfusion, usually as a result of either arterial stenosis (uncommon) or thrombosis with collateral arteries (Fig. 54.7): collateral vessels from the Roux loop may form rapidly following hepatic artery thrombosis, therefore surveillance with Doppler US in the immediate postoperative days is vital. Conversely, false positive results can be found in case of hepatic edema or systemic hypotension [11]. In case of inconclusive findings on US but still high clinical suspicion of hepatic arterial insufficiency, a CT angiogram with thin-slices acquisition should be performed, which will show abrupt interruption of the hepatic artery and ischemic/necrotic parenchyma in case of thrombosis, and focal narrowing with decreased hepatic perfusion in case of stenosis. Ischemic lesions can liquefy and complicate with infection and abscess formation.

The role of conventional angiography is mostly therapeutic rather than diagnostic, with thrombolysis, angioplasty, or stenting (depending on the findings) to allow early revascularization.

Portal Vein

Portal vein complications are relatively rare and normally result from technical problems, such as difference in caliber

Fig. 54.7 **a** Doppler US scan of a left lateral segment transplant liver. There is a pulsus tardus parvus in a collateral of the hepatic artery with a prolonged acceleration time and reduced peak systolic velocity (17.9 cm/s). **b** CT angiogram confirms the finding of a thrombosed hepatic artery (red arrow). **c** A follow-up CT scan performed 1 month later shows low-attenuation lesions within the parenchyma, in keeping with bile lakes (black arrows)

between donor and recipient, narrow native portal vein (e.g., in biliary atresia) and stretching at the anastomotic site, or other factors including previous thrombosis, hypercoagulable states, and increased resistance due to IVC strictures.

On US, a normal portal vein has smooth walls, anechoic lumen and on color and Doppler images shows antegrade/hepatopetal monophasic flow, except from the early post-operative period, where it can show high-velocity, turbulent flow.

Portal vein thrombosis manifests with echogenic intraluminal thrombus and lack of flow on color and Doppler trace, in which case either thrombolysis, or, more frequently, surgery with thrombectomy or venous graft is performed.

Portal vein stenosis has a later onset and can present with signs of portal hypertension. B-mode US shows focal severe narrowing of the portal vein at the anastomotic site with post-stenotic dilatation; on color and Doppler images, there is focal aliasing at the stenotic site with an increase of the velocity of three to fourfold compared to the pre-stenotic segment [11, 12]. Symptomatic patients are normally treated with balloon angioplasty or stenting.

These findings can be confirmed with CT or, usually for the late onset complications, with MR angiography.

IVC

Venous outflow obstruction is a rare complication secondary to either stenosis, thrombosis of the suprahepatic IVC or caval kinking from organ rotation.

The normal Doppler trace of the hepatic vein and IVC is triphasic due to pressure variations during the cardiac cycle; a monophasic waveform is a sensitive but nonspecific sign of stenosis, and a triphasic or biphasic waveform can exclude a substantial stenosis [11, 12]. As for the portal vein, stenosis can be seen on US as a focal stricture with impaired flow and pre-stenotic dilatation of the hepatic vein, whereas echogenic thrombus and complete absence of flow are direct signs of thrombosis. CT or MR is normally needed to confirm US findings or make the diagnosis where US is inconclusive. Cross-sectional imaging can also show signs of Budd–Chiari syndrome with the typical mosaic pattern of perfusion.

Biliary Disorders

Biliary complications are relatively frequent and are a common cause of graft dysfunction; these can often present with ischemic liver injury as well as cholestasis and cholangitis,

Fig. 54.8 **a** MRCP MIP reconstruction of the biliary tree in a left lateral segment transplant liver shows signs of cholangiopathy with an anas-

tomotic stricture of the biliary enterostomy. **b** PTC image confirming the MRCP findings of a stricture (*white arrow*). The patient underwent balloon dilatation of the stricture. *MIP* maximum-intensity projection

and include anastomotic strictures, fistulas, stone formation with obstruction, diffuse cholangiopathy, and bile leaks.

A Roux-en-Y choledochojejunostomy is the most commonly performed anastomosis to achieve biliary drainage, although an end-to-end choledochal anastomosis may be performed in older children recipient of a whole graft.

US serves as a surveillance test to detect bile duct dilatation, although this is a variable feature, as mild dilatation can be present in the absence of significant obstruction and therefore clinical and laboratory correlation is needed.

MRCP is the modality of choice to investigate cholangiopathy and biliary strictures, the commonest biliary complication (Fig. 54.8). This can be due to either fibrotic proliferation and narrowing of the lumen or ischemic cholangiopathy; multiplanar MR provides anatomical details and helps planning percutaneous, endoscopic or surgical treatments.

Bile leaks normally occur early and can form perihepatic collections, which are drained percutaneously; treatment options include placement of a stent or biliary reconstruction. Intra-hepatic bile leaks are normally secondary to ductal ischemia.

Liver Masses

Radiological Approach to the Child with a Focal Liver Lesion

The diagnostic approach to children with chronic liver disease or a suspected liver mass should be tailored to the clinical scenario, including the age of the child and serum alpha-fetoprotein (AFP) levels; not all malignancies produce AFP, however, if serum AFP is elevated, a benign lesion is unlikely. US is the modality of choice in the screening of these children, because of its lack of ionizing radiation and no need for sedation. Some tumors, such as hemangioendothelioma have typical features on US and Doppler scan and may not require further characterization; however, the vast majority of liver masses need cross-sectional investigation [13, 14].

When performing a CT in children, efforts should be made to minimize radiation exposure, and unnecessary phases should be avoided (such as non-contrast scans); when the aim of the scan is surgical planning, a single post-contrast phase should be performed.

If multiphase post-contrast imaging is required, then MRI should be performed instead of CT. The limiting factor here is the need for sedation in young children and therefore, each scan should be performed starting from the most valuable sequences to achieve a definitive diagnosis.

If, at the end of the diagnostic pathway, there is still uncertainty on the nature of a lesion, then imaging guided (either US or CT) biopsy should be performed.

Benign Tumors

Hemangioendotheliomas

Hemangioendothelioma is a vascular neoplasm and represents the most common benign tumor in children; the lesions can be either single or multifocal and its margins may be sharp or ill-defined. In the first 6 months of life, these tumors show progressive growth, followed by spontaneous involution.

On antenatal US scan, a hypoechoic liver mass can be detected, sometimes together with fetal hydrops and cardiomegaly, which correlate with worse prognosis.

Multifocal lesions are small and uniform in appearance, usually hypoechoic on US within a markedly enlarged liver. Large lesions can have heterogeneous appearance in all modalities, due to central hemorrhage, necrosis, fibrosis, and calcifications.

At cross-sectional imaging, there are signs of high flow, with enlargement of the hepatic artery and veins and possibly tapering of the aorta below the origin of the coeliac axis. On post-contrast images, the tumor shows peripheral nodular enhancement with “filling in” on the delayed phase. On MR, the lesions have characteristic hyperintense signal on T2-weighted images (Fig. 54.9).

Fig. 54.9 **a** CT scan performed in the arterial phase in a newborn baby shows a large haemangioma-endothelioma in the right lobe of the liver with peripheral enhancement. **b** In the portal venous phase, there is centripetal enhancement of the mass. **c** A T2W MR image shows the lesion as hyperintense compared to normal liver parenchyma

Angiography is now reserved for those cases in which arteriovenous shunts require embolization of the feeding arteries.

Mesenchymal Hamartoma

Mesenchymal hamartomas typically present as solitary tumors of the liver in infants and small children; most commonly, they involve the right lobe of the liver and the vast majority of these contain cysts, even though they can be either predominantly cystic or solid. The gross pathologic appearance will influence imaging findings: cystic portions are avascular with thin or thick septa, and solid components are hypovascular compared to the normal liver parenchyma. The cysts will be anechoic on US and have high signal on T2-weighted MRI and either low signal (clear cyst contents) or high signal (mucoid contents) on T1-weighted images.

Focal Nodular Hyperplasia

Focal nodular hyperplasia (FNH) is a benign epithelial liver tumor, uncommonly seen in young children. The tumor is composed of well-differentiated hepatocytes forming nodules divided by fibrous septa, which form a characteristic vascular central scar with a stellate shape. It is usually a solitary, well-circumscribed, encapsulated mass but can be multifocal. On US, it appears as a homogeneous lesion of variable echogenicity, usually isoechoic compared to a normal liver. Central vascularity can be detected at color Doppler

and contrast-enhanced ultrasound (CEUS) will show a typical pattern of centrifugal, spoke-wheel arterial enhancement followed by uniform enhancement with the rest of the parenchyma in the portal venous and late phases. This can be confirmed at post-contrast cross-sectional imaging; on MR, the central scar is normally bright in T2-weighted images. In equivocal cases, tissue-specific agents (such as Teslascan or Primovist) show tumor uptake that persists for hours or even several days.

Hepatocellular Adenoma

Hepatocellular adenoma (or hepatic adenoma) is a rare benign neoplasm composed of hepatocytes with increased intracellular fat and glycogen, often prone to intralesional hemorrhage and necrosis. The majority of hepatic adenomas present as solitary well-circumscribed lesions, although in children with glycogen storage disease, they can be multifocal.

Hepatic adenomas without hemorrhage will be homogeneous with the rest of the liver in all imaging modalities. Following administration of contrast in CT or MR, the lesions typically display increased enhancement in the arterial phase and uniform enhancement with the rest of the liver in the portal venous and delayed phases; if there is hemorrhage, the lesion will enhance heterogeneously. Lesions with high fat content will show on MR high signal intensity on T1- and T2-weighted images, with signal dropout on opposed-phase or fat-suppressed sequences.

Nodular Regenerative Hyperplasia

Nodular regenerative hyperplasia (NRH) is characterized by regenerative nodules surrounded by atrophic liver without a fibrotic component. Various types of small-vessel blood-flow alterations are seen in association with NRH, including lymphoproliferative disorders, autoimmune disorders and Budd–Chiari syndrome and with the use of various medications (steroids, chemotherapeutic agents). The nodules, usually multiple with the tendency to coalesce, are composed of hepatocytes like the surrounding liver, therefore they can be difficult to distinguish from the adjacent parenchyma in all modalities, even after contrast administration.

Malignant Tumors

Hepatoblastoma

Hepatoblastoma is the most common primary hepatic tumor in children, occurring predominantly in children below the age of 5 years.

These tumors normally present as large masses often containing hemorrhagic and necrotic areas and speckled or amorphous calcifications; in 90% of the cases, AFP serum levels are elevated. At imaging, hepatoblastomas present as large, well-circumscribed masses with septa; epithelial tumors have a homogeneous appearance, whereas mixed epithelial and mesenchymal tumors are more heterogeneous with variable osteoid, cartilaginous, and fibrous components. The primary role of radiology is to assess the tumor for operability (sections involved, involvement of the caudate, vessel invasion) and staging (the lung being the most common site for metastases): hepatoblastoma should be evaluated using the pretreatment extent of disease (PRETEXT) classification as this will establish treatment regimen [15].

On post-contrast cross-sectional imaging, hepatoblastomas show poor, inhomogeneous enhancement (Fig. 54.10); vascular invasion is better demonstrated on contrast-enhanced scans.

Hepatocellular Carcinoma

The main differential diagnosis of hepatoblastoma is hepatocellular carcinoma; HCC however is rare under the age of 5 years and 50% of cases have a preexisting liver disease, such as biliary atresia, familial intrahepatic cholestasis, glycogen storage disease type I, tyrosinemia, Wilson disease, and alpha1-antitrypsin deficiency.

Unlike in adults, small HCCs are unusual in children and lesions can have variable appearance on US, with a

Fig. 54.10 A CT scan performed on the portal venous phase shows a large, poorly enhancing hepatoblastoma involving the whole of the liver; note intralésional calcification (*arrow*)

hypochoic halo if the tumor has a capsule. Large tumors may contain areas of hemorrhage and necrosis.

On post-contrast cross-sectional imaging, HCC typically shows early arterial enhancement with wash out in the portal venous and delayed phases; portal and hepatic venous invasion may be identified.

Fibrolamellar Carcinoma

Fibrolamellar carcinoma is a slow-growing tumor that occurs in adolescents and young adults. The tumors are normally well demarcated and contain numerous fibrous septa which may separate the tumor into lobules and form a central scar-like structure; hemorrhage and necrosis are rare but calcifications can be observed. US shows a solitary heterogeneous mass; post-contrast CT and MR show avid enhancement in the arterial phase with often lack of enhancement of the central scar; on MR, the scar is typically hypointense in T1- and T2-weighted images, in contrast with the scar seen in FNH, which is normally hyperintense in T2.

Undifferentiated Embryonal Sarcoma

Undifferentiated embryonal sarcoma (UES) is a rare tumor that usually present between 6 and 10 years of age; AFP levels are usually normal and the presentation is nonspecific.

The tumors show very aggressive local growth with invasion of the diaphragm and lung. These tumors typically show a predominantly solid appearance on US but cystic appearance on CT and MR, due to its prominent myxoid stroma, which contains water. These tumors are usually well demarcated by a fibrous pseudocapsule, which generally show marked enhancement on post-contrast images.

Angiosarcoma

Angiosarcoma is a rare vascular tumor that can occur in young girls and in children with a previous diagnosis of hemangioendothelioma.

US can show either multiple nodules or a large mass of variable echogenicity. On post-contrast imaging, the lesion often shows decreased, heterogeneous enhancement compared to the normal liver with occasionally central or ring enhancement. Hemorrhage or necrosis can be observed.

Embryonal Rhabdomyosarcoma

Rhabdomyosarcoma can rarely arise from the biliary tree and this form is almost exclusively seen in young children; it spreads by intraluminal extension and causes significant cholestasis. At imaging, a mass can be seen usually at the porta hepatis, with intrahepatic biliary duct dilatation and normal-sized extrahepatic duct. Portal vein displacement without invasion is common.

Imaging of Liver Trauma in Children

CT remains the gold standard in the evaluation of blunt abdominal traumas in children; however, due to the risks related to radiation exposure, CT must be reserved for those children in whom there is a high index of suspicion, and should be performed following IV injection of contrast, possibly with split-bolus technique. When indicated, CT can provide rapid information regarding intra-abdominal injuries and can guide patient's management towards operative or conservative. Even though US would be preferable to CT giving its noninvasive nature and the lack of radiation, published data regarding the use of focused abdominal sonography for trauma (FAST) in children are not supportive of its use. Conversely, there are encouraging data regarding the use of CEUS in the setting of pediatric trauma, and in many centers, this imaging modality is routinely used, if not at presentation, certainly as the main follow-up examination [16].

The liver is the second most commonly injured organ in pediatric abdominal trauma (the spleen being the commonest site of injury); the role of the radiologist in this setting is to establish the extent of the injury (in terms of lobes and segments involved and vascular injury) and possible associated complications, such as ongoing hemorrhage. When active bleeding is demonstrated on CT, the patient will proceed to have an angiography with selective embolization of the bleeding vessel. At follow-up, normally between days 5 and 7 of trauma, potentially dangerous complications like pseudoaneurysm of the hepatic artery, hematomas, and bile leaks should be actively sought.

Imaging of Pancreas

Acute and chronic pancreatitis are a significant cause of morbidity and mortality in children; the most common causes of pancreatitis in children are trauma, structural anomalies, multisystem and metabolic disease, drugs, and autoimmune disease.

US is the first-line examination of the pancreas, and can exclude extra-pancreatic disease; change in pancreatic parenchyma echogenicity is a variable feature, as well as swelling of the gland. US can easily detect dilatation of the pancreatic duct and peripancreatic fatty infiltration, free fluid, and collections. In chronic pancreatitis, calcifications can be demonstrated.

MRI with MRCP is the most useful imaging modality to evaluate the severity of pancreatitis and establish further management; in addition, underlying structural anomalies such as abnormal pancreatico-biliary junction and choledochal cysts can also be diagnosed.

Autoimmune pancreatitis shows some specific features: the enlarged pancreas is in fact associated with irregular narrowing of the pancreatic duct, delayed contrast enhancement and a capsule-like rim which is more evident in the early post-contrast images on CT or MR; this corresponds to a fibrosing process extending to the peripancreatic fat.

Pancreatic involvement in children with CF is more frequent than liver disease, with plugging of pancreatic ducts due to inspissated secretions resulting in exocrine insufficiency. US shows an enlarged or atrophied pancreas with increased echogenicity due to fat deposition; cysts can be present, probably related to the obstruction of ducts.

Sona Young and Ruba K. Azzam

Introduction

Jaundice in the first 2 weeks of life can be a common clinical finding, occurring in 2.4–15% of newborns [1]. Most often, this jaundice is due to an unconjugated hyperbilirubinemia and resolves spontaneously. However, persistent jaundice past the 2 week point is abnormal, and the serum bilirubin should be checked in its fractionated forms of conjugated/direct and unconjugated/indirect bilirubin to evaluate for cholestasis.

Definition

Cholestasis is a central key manifestation of hepatobiliary disease in all age groups. Cholestasis is defined physiologically as a measurable decrease in bile flow, pathologically as the histological presence of bile pigment in hepatocytes and bile ducts, and clinically as the accumulation in blood and extrahepatic tissues of substances normally excreted in bile [2]. This is usually the resultant of either reduced bile formation (hepatocellular cholestasis) or decreased bile flow (obstructive cholestasis).

Obstructive cholestasis results from either anatomic or functional obstruction of the biliary system at any level of the biliary system: intra- or extrahepatically. Principal examples are biliary atresia (BA), anatomic biliary anomalies, and Alagille syndrome. On the other hand, hepatocellular cholestasis results from defective mechanisms of bile formation, which once established may be amplified by several

mechanisms. Examples include idiopathic neonatal hepatitis (INH), viral infections, and bacterial sepsis.

Incidence

The incidence of neonatal cholestasis is 1 in 2500–5000 live births. It usually manifests as conjugated hyperbilirubinemia with direct or conjugated hyperbilirubinemia of more than 1 mg/dl if total serum bilirubin is at or below 5 mg/dl, or direct bilirubin fraction >20% of total bilirubin when the latter is higher than 5 mg/dl. In general, direct bilirubin and conjugated bilirubin are not interchangeable exactly, since most methods report the combination of conjugated and δ -bilirubin as direct bilirubin.

The most commonly identifiable cause of cholestasis in the neonatal period is BA. There is a wide range of incidence reported internationally of BA [3]. It accounts for approximately 20–35% of infantile cholestasis [4]. Genetic disorders, metabolic disease, and alpha1-antitrypsin deficiency are also among common etiologies. In older studies, INH was reported to be the most common cause, with an incidence ranging from 1 in 4800 to 1 in 9000 births [5]. However, in these cases, the term neonatal hepatitis was used to describe the histologic appearance of widespread giant-cell transformation, which is nonspecific and may be attributed to infectious, metabolic, and syndromic disorders. Therefore, with this realization and the advancement of diagnostic methods, the actual incidence of INH is now realized to be significantly lower [4, 6, 7]. Congenital infections including toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex (TORCH) infections account for about 5% of cases.

Susceptibility of the Neonatal Liver to Cholestasis

The neonatal liver is more susceptible to cholestasis as compared to livers of older children and adults.

While the physiologic development of normal hepatic function matures in the later stages of gestation, many other processes are developmentally regulated over the first few months after birth. This physiologic immaturity limits the capacity to synthesize and transport bile acids and affects the metabolism, detoxification and excretion of drugs, and xenobiotics [8, 9]. Reports on newborn animals have shown that their enterohepatic circulation is characterized by decreased bile salt secretion, flow, and synthesis; a smaller bile acid pool size; a decreased hepatic uptake of portal bile salts; and an inefficient uptake of bile salts in the ileum [10]. This then leads to high levels of circulating bile salt levels [11].

Differential Diagnosis

Although there is a long list of disorders that could potentially induce cholestasis, fewer than 15 of these account for greater than 95% of neonatal cholestasis [10]. Table 55.1 illustrates these differential diagnoses. Some of these diagnoses are briefly outlined below.

Obstructive

BA is a destructive, inflammatory process that causes fibrosis of the intra- and extrahepatic biliary tree. It is the most common cause of chronic cholestasis in infants and children, and it is the most common indication for liver transplant in the pediatric population. It is estimated to affect 1 in 8000–12,000 live births worldwide with a slight female predominance. There are two types of BA: congenital/embryonic which accounts for 15–20% of cases and perinatal or acquired which is the majority of cases. The etiology of BA remains deeply researched. Typically, the presentation of direct hyperbilirubinemia with acholic stools in infants a few weeks old should prompt the expedient evaluation for BA. There is a tremendous amount of evidence that suggests earlier diagnosis and surgical repair with a Kasai portoenterostomy will lead to a better outcome when performed before the age of 45–60 days [12–14].

A choledochal cyst is a congenital condition involving cystic dilation of the bile ducts. There are five different types, classified based on site of the dilation. The most common are types 1 (saccular dilation of only the extrahepatic bile duct) and 4 (saccular dilations of the intra- and extrahepatic biliary tree). The majority of cases present within the first year of life.

Table 55.1 Causes of infantile cholestasis

<i>Obstructive</i>	<i>Infectious</i>
Biliary atresia	Congenital TORCH infection:
Choledochal cyst	Toxoplasmosis
Syndromic and nonsyndromic paucity of interlobular bile ducts	Cytomegalovirus
	Rubella
Inspissated bile syndrome	Herpes virus
Caroli's disease/congenital hepatic fibrosis	HIV
Neonatal sclerosing cholangitis	Bacterial sepsis
	Urinary tract infection
<i>Idiopathic neonatal hepatitis</i>	<i>Metabolic</i>
	Bile acid synthesis defects
	Gestational alloimmune liver disease/neonatal hemochromatosis
	Galactosemia
	Hereditary tyrosinemia
	Hypothyroidism
	Panhypopituitarism
	Storage diseases
<i>Genetic</i>	<i>Toxic</i>
Alpha-1-antitrypsin deficiency	Parenteral nutrition
Alagille syndrome	Drugs
Progressive familial intrahepatic cholestasis	
Cystic fibrosis	
Arthrogryposis–renal dysfunction–cholestasis syndrome (ARC)	

HIV human immunodeficiency virus, *TORCH* Toxoplasmosis, Other Agents, Rubella, Cytomegalovirus, Herpes Simplex

Hepatocellular

INH is defined as a prolonged conjugated hyperbilirubinemia with no known etiology after a thorough evaluation has ruled out identifiable infectious and metabolic/genetic causes. Histologically, the typical findings would include widespread transformation of multinucleated giant cells. As discussed above, with the advancement of diagnostic techniques, the incidence of INH has sharply declined [7].

Bacterial, viral, and fungal infections can all cause cholestasis. Congenitally acquired pathogens capable of doing so include rubella, toxoplasmosis, cytomegalovirus, herpes, human immunodeficiency virus, and syphilis. Bacterial infections with either gram-negative or gram-positive organisms have also been implicated; in fact, jaundice may be one of the presenting symptoms of urinary tract infections in infants.

Genetic/Metabolic

Alpha-1-antitrypsin (α 1-AT) deficiency is an autosomal recessive disorder caused by a misfolded protein that prohibits its secretion, leading to intracellular accumulation of the protein. This accumulation leads to liver injury, cirrhosis, and increased risk for hepatocellular carcinoma through the formation of protein polymers, activation of autophagy, mitochondrial injury, and caspase activation [15]. Its incidence is approximately 1 in 1600–2000 live births, and it is extremely rare in the non-Caucasian population. Diagnosis is made based on the serum levels of α 1-AT and the phenotype. Individuals homozygous for the mutant Z allele are at risk for the development of liver disease and emphysema, while the heterozygous carrier state for the mutant Z gene may be a modifier gene for liver disease. In infancy, the typical presentation is one of neonatal cholestasis, but the presentation of patients can be highly varied. In fact, only 8–10% of individuals born with the homozygous Z allele develop any clinically significant liver disease over the first 20 years of life. Liver biopsy may show globular, eosinophilic inclusions in hepatocytes, representing dilated endoplasmic reticulum membranes and the accumulated Z protein. It stains positive with periodic acid–Schiff and is diastase resistant [15]. Prospective studies indicate that 80% of patients with the homozygous Z allele and presenting with neonatal cholestasis are healthy and free of chronic disease by the age of 18 years [16].

Alagille syndrome is an autosomal dominant multisystemic disease that results from mutation usually involving the *Jagged 1* or *NOTCH2* gene. Jagged-1 is a member of the Jagged family of genes that encode cell surface proteins that interact with Notch receptors; this interaction regulates cell fate during embryogenesis. The syndrome is characterized by paucity of interlobular bile ducts. The variable pen-

etrance of the mutation leads to different characteristics of the disease including: abnormal facies, chronic cholestasis, posterior embryotoxon, butterfly-like vertebral arch defects, and cardiovascular malformations. Associated vascular abnormalities have been noted in Alagille patients including decreased intrahepatic portal vein radicals and cerebrovascular abnormalities similar to Moyamoya disease. Infantile presentation follows a variable course with some developing gradual improvement as they get older, whereas others progress into cirrhosis. Medical management emphasizes on the supplementation of medium-chain triglycerides, essential fatty acids, and fat-soluble vitamins. Liver transplantation may be needed in cases of cirrhosis, portal hypertension, or severe pruritus [17].

Progressive familial intrahepatic cholestasis (PFIC) refers to a heterogeneous group of autosomal recessive disorders that disrupt bile formation [18]. It is divided into three subtypes. Type I, also known as Byler disease or familial intrahepatic cholestasis (FIC)1 disease, is caused by a mutation in the P-type ATPase FIC gene. FIC1 is expressed in several epithelial tissues, including the small intestine, pancreas, and liver, and thus patients express extrahepatic manifestations as well like recurrent pancreatitis, diarrhea, wheezing and cough, sensorineural hearing loss, and posttransplant steatosis. A benign form of recurrent intrahepatic cholestasis (BRIC) with symptom-free intervals in between the attacks could be seen in patients with mutations in the same gene.

PFIC type II is caused by a defect in the bile salt export pump (BSEP/ABCB11) gene, which leads to impaired bile acid transport from the hepatocytes into the bile canaliculus. The gene is liver specific, and thus mutations result in no extrahepatic manifestations. Similar to FIC1 disease, genetic mutations in BSEP could manifest in a more benign recurrent disease called BRIC2. Both type I and II have normal serum γ -glutamyltranspeptidase (γ -GTP) levels, unlike type III.

PFIC type III is due to a defect in MDR3 which is a member of the adenosine triphosphate (ATP)-binding cassette family of transporters that serve as phospholipid flippases. Its impairment leads to defective biliary phospholipid secretion, impairing the balance in cholesterol saturation index and leading to crystallization of cholesterol, and lithogenicity of bile, and bile duct injury.

Galactosemia is an autosomal recessive disorder that can result from deficiencies of three different enzymes; the most common and severe form is caused by a complete deficiency of galactose-1-phosphate uridylyltransferase (GALT). Most states in the USA include testing in the newborn screening, but infants may become symptomatic prior to the availability of these test results. The gold standard for diagnosis is the demonstration of nearly complete absence of GALT activity in red blood cells. It is important to remember that blood transfusions from a donor may interfere with the diagnosis.

Physical exam and history will typically reveal a jaundiced infant that may be lethargic, hypotonic, with poor feeding, and displays hepatomegaly. Dietary restriction of galactose in the newborn period reverses the hepatic dysfunction. However, chronic and progressive neurologic impairments may occur even in patients with dietary compliance [19].

Tyrosinemia is an inborn error of metabolism that results from deficiencies in specific enzymes in the tyrosine catabolic pathway, leading to the accumulation of toxic metabolites such as succinylacetone, maleylacetoacetate, and fumarylacetoacetate. It is characterized by acute liver failure in the first weeks or months of life. It is detected by quantitative measurement of plasma amino acids and urine succinylacetone levels. The treatment is dietary restriction of tyrosine and phenylalanine as well as early initiation of the medication nitosine, a potent inhibitor of the enzyme 4-hydroxyphenylpyruvate dioxygenase. This decreases the concentration of succinylacetone.

There are numerous other inborn errors of metabolism that can be screened for with serum amino acid and urine organic acid concentrations. The remainder will not be discussed in detail at this time.

Evaluation

Distinguishing between jaundice caused by cholestasis from non-cholestatic causes is critical since the former need prompt evaluation and management, given that the most common causes of cholestatic jaundice in the first few months of age, especially in the non-sickly-looking babies, are BA and INH. Guidelines for the evaluation of cholestatic jaundice in infants were published by North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) in 2004 and recommended that any infant noted to be jaundiced at 2 weeks of age be evaluated for cholestasis with measurement of total and direct serum bilirubin. However, breast-fed infants who can be reliably monitored and have an otherwise normal history (no dark urine or light stools) and physical examination may be asked to return at 3 weeks of age and, if jaundice persists, have measurement of total and direct serum bilirubin at that time [20]. This is in line with the fact that early diagnosis of the different possible etiologies of cholestasis will lead to better outcomes, especially in BA where the successful establishment of biliary flow is more likely when the Kasai portoenterostomy is performed between 45 and 60 days of age.

An algorithm for the evaluation of cholestatic infants is presented in Fig. 55.1.

History and physical examination are the initial steps in the evaluation and usually guide the diagnostic process. The report of acholic stools is a strong indicator of cholestasis, though parents do not seem to reliably differentiate the

abnormal hue of stools from normal. Dark urine is another nonspecific indicator of abnormal conjugated hyperbilirubin levels. Mass screening with a stool color card in Taiwan proved its efficacy in early diagnosis of BA patients [21]. In addition, some infants may present with bleeding or bruising due to a coagulopathy from vitamin K malabsorption and/or liver failure. Family history may suggest a genetic disorder with an autosomal dominant inheritance pattern such as Alagille's, cystic fibrosis, alpha-1-antitrypsin deficiency, PFIC. Consanguinity may raise suspicion for rarer, autosomal recessive disorders. A maternal pregnancy history is important to evaluate for possible congenital infections, such as cytomegalovirus or hepatitis B. In addition, prenatal ultrasounds may have detected anatomic abnormalities such as a biliary cyst. A history of severe ABO incompatibility may explain a conjugated hyperbilirubinemia; in about 3% of infants, this is a benign complication which resolves on its own accord within a month [22].

A careful physical examination may reveal clinical features that will serve as clues about the diagnosis. BA is more common in females of normal birth weight, while INH is more common in males with low birth weight or who were born prematurely, and who may have had a sibling with similar presentation. Abnormal facies can point towards Alagille, as can a cardiac murmur (also seen in congenital BA).

Other possible clinical findings may include splenomegaly in cases of portal hypertension, storage disorders, or hemolytic disease.

Infants with cholestasis due to congenital infections are usually small for their gestational age, may have microcephaly, pupuric rash, or chorioretinitis. Infants who appear acutely ill in the setting of cholestasis are likely suffering from a potentially life-threatening disorder such as sepsis or metabolic diseases that need to be ruled out.

Confirmation of the presence of cholestasis by measuring a fractionated serum bilirubin level along with baseline assessment of the severity of hepatic dysfunction forms (albumin, serum glucose level, ammonia and prothrombin time/international normalized ratio; INR) is the basis for the tests that follow. If INR is abnormal, the administration of parenteral vitamin K should normalize the coagulation study if the hepatic synthetic function is preserved.

Serum transaminases (alanine transaminase, ALT; aspartate transaminase, AST) are indicators of hepatocellular injury but lack prognostic value.

The elevation in alkaline phosphatase is indicative of biliary obstruction, but it is nonspecific as it is also produced by other organs like the bones, small bowel, and kidneys. On the other hand, the level of γ GTP is more sensitive to biliary disease and more importantly directs the evaluation towards certain pathologies. Low γ -glutamyl transpeptidase (GGT) cholestatic diseases make a short list of diseases and include PFIC1, PFIC2, arthrogyrosis–renal dysfunction–cholestasis

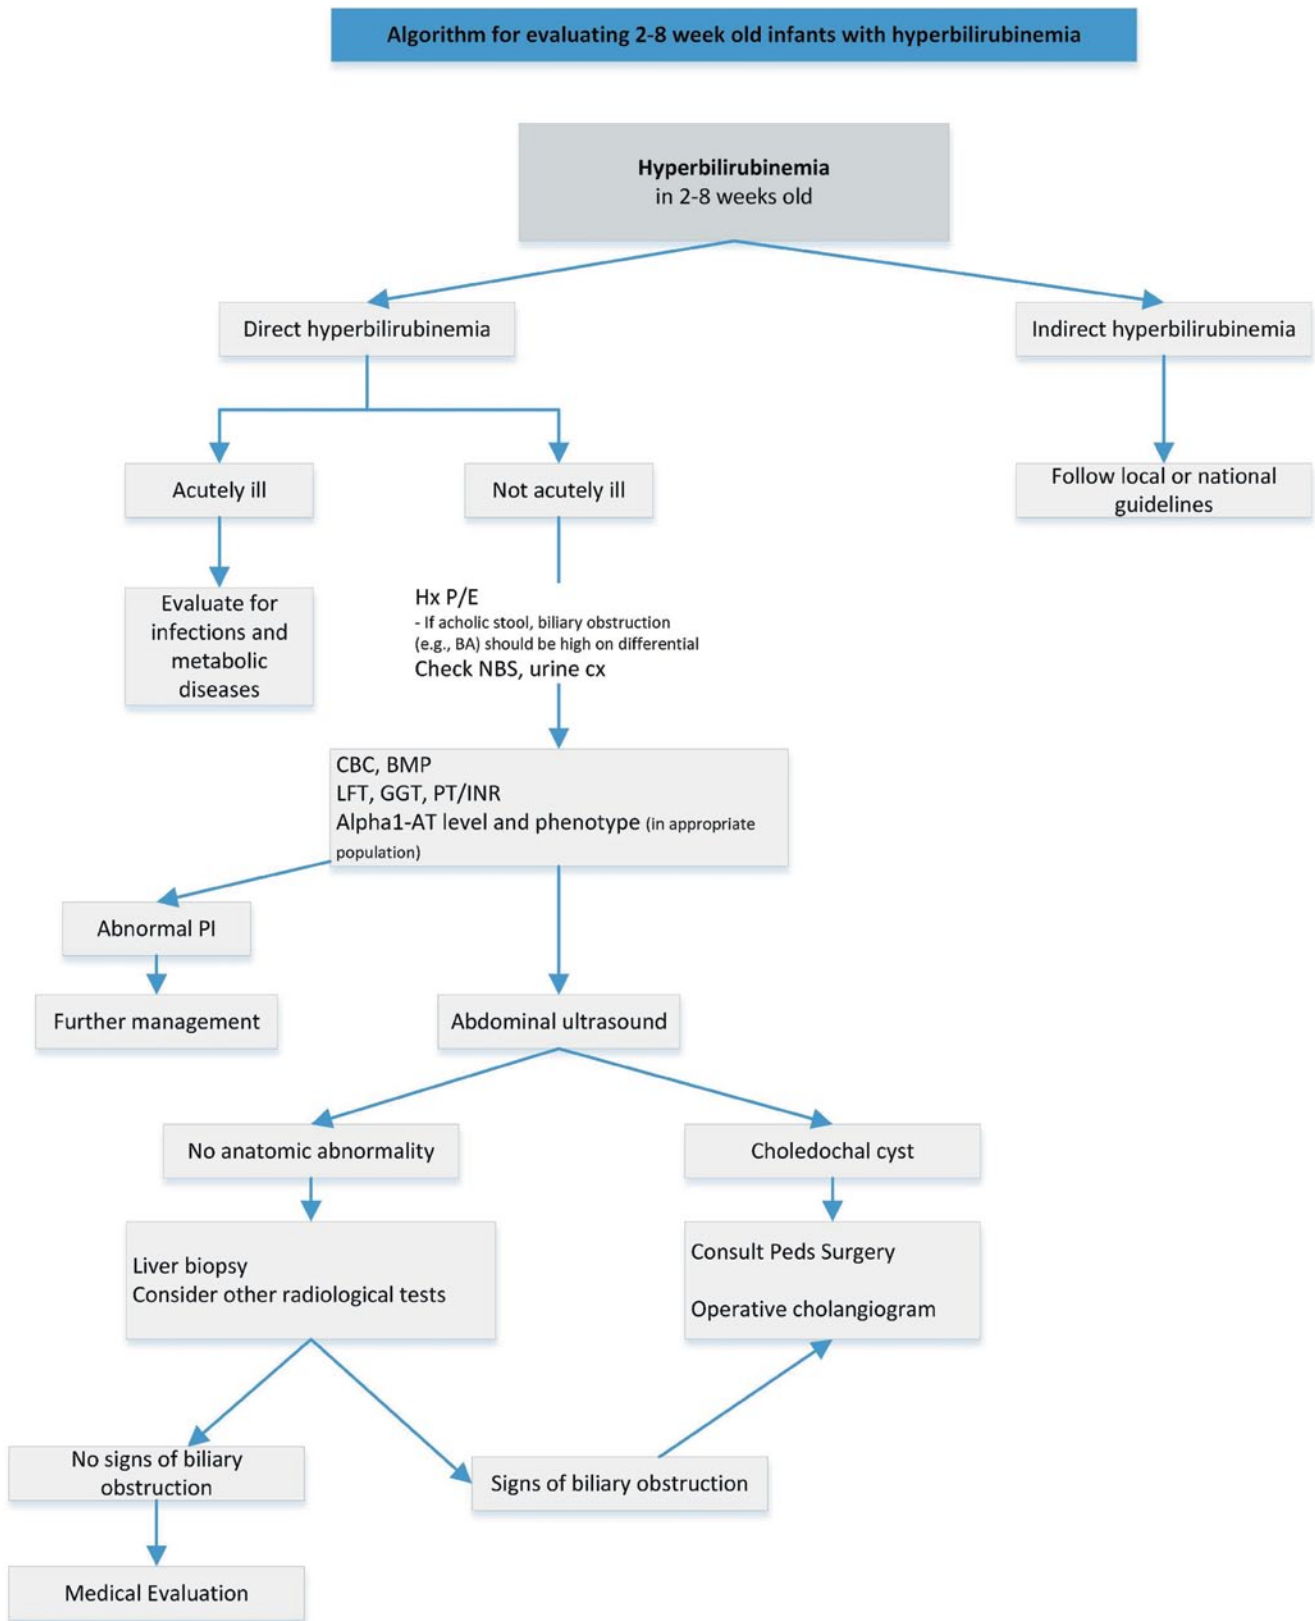

Fig. 55.1 An algorithm for the evaluation of cholestatic infants. Hx P/E history and physical examination, *CBC* complete blood count,

BMP basic metabolic profile, *LFT* liver function test, *GGT* gamma glutamyl transpeptidase, *PT/INR* prothrombin time/international normalized ratio, *Alpha1-AT* alpha-1-antitrypsin

syndrome (ARC), lymphedema–cholestasis syndrome (LCS or Aagaens syndrome) and inborn errors of bile acid synthesis.

Cholestatic liver diseases are associated with elevated total serum bile acid concentrations, but levels that are normal or inappropriately low for the degree of cholestasis should lead to further evaluation for inborn errors of bile acid synthesis.

Bacterial blood and urine cultures are indicated as clinically appropriate. Hepatobiliary dysfunction with cholestasis is common in the early course of neonatal septicemia. Circulating endotoxins are believed to cause down regulation of biliary transporters, biliary stasis, and hepatic parenchymal injury.

Alpha1-antitrypsin level and phenotype need to be checked early on, especially that the histologic differentiation between BA and α 1-antitrypsin deficiency is very difficult in the few-week-old infants.

Radiologic Evaluation

Ultrasonography is usually the initial imaging study that provides information about the size and echotexture of the liver, as well as the assessment for anatomic biliary anomalies such as biliary cysts. It also evaluates the size of the gall bladder and the presence of stones or sludge. It detects signs of obstructive dilatation of the biliary tree. It may detect extrahepatic anomalies like polysplenia or asplenia, situs inversus, and the different positional variants of the portal vein and hepatic artery. Certain findings can also suggest the presence of BA, such as a small or absent gallbladder. A “triangular cord sign,” or triangular echogenicity of the anterior wall of the right portal vein on transverse or longitudinal view, has specificity and sensitivity reported as high as 80 and 98% and can be a useful finding for diagnosis on ultrasound [21, 23, 24]. Limitations of the ultrasound include operator dependence. However, it is recommended for evaluation of the infant with cholestasis of unknown etiology.

Computed tomography is used less often, given that almost the same information is provided by ultrasonography without the risk of exposure to radiation.

Magnetic resonance cholangiography (MRCP), performed with T_2 -weighted turbo spin-echo sequences, is noninvasive, and not operator dependent, though requires sedation. It can evaluate detailed structural anomalies including anomalous pancreatobiliary duct union. Delineating the small common bile duct in small infants could be challenging, using gadolinium enhancement for its T_2 -shortening effect may allow a more definitive determination of the presence or absence of the common bile duct (CBD) in infants with cholestasis, especially when conventional magnetic resonance cholangiopancreatography (MRCP) is indeterminate [21].

Hepatobiliary scintigraphy using technetium Tc99m iminodiacetic acid analogues has been used to differentiate extra-hepatic biliary obstruction from nonobstructive causes. Using phenobarbital for 3–5 days before performing the test increases its yield, but obviously is time consuming, especially in cases where presentation is not timely.

ERCP use in cholestatic neonates and infants is a safe and reliable diagnostic method, when performed by a skilled and experienced endoscopist in a high-volume tertiary care center. Its sensitivity and specificity in the diagnosis of extrahepatic causes of cholestasis is superior to other available diagnostic methods including cholescintigraphy and MRCP. Of particular significance is the high negative predictive value (NPV) and specificity of ERCP in diagnosing structural abnormalities of the bile ducts, namely all types of BA and choledochal cysts [25].

Liver biopsy continues to be the diagnostic test with the highest usefulness even in the smallest infants, and its use is inevitable in most cases on infantile cholestasis. It is accurate in diagnosing BA in 90–95% of cases as reported by several studies. Attention should always be paid to timing for the development of the typical features of histopathology changes of BA, as liver biopsies in the first few weeks of age will not have all the features and will miss the diagnosis of BA. Serial investigations and possibly a follow-up liver biopsy at around 6 weeks of age will be needed. Liver biopsy can be diagnostic for other diseases as well, and it could navigate the evaluation process in a more specific path. The addition of electron microscopic exam and/or immunohistochemical, biochemical, or biological evaluation of the tissue may be required to identify specific pathologies.

Intraoperative cholangiogram is the gold standard test to study the patency of the biliary system and establish the diagnosis of BA. It is also the procedure that surgeons rely on to demystify the small number of cases where the diagnosis stays doubtful after reviewing the different imaging studies and liver biopsy.

Biliary Atresia

Introduction

In 1891, John Thompson, a physician from Edinburgh, described in detail the clinical features and postmortem findings of an infant with what he termed as “congenital biliary obstruction” [1]. His drawings clearly show an absence of a common hepatic duct (CHD) and a collapsed empty gallbladder. Further reports during the early part of the twentieth century prompted surgeons to explore the biliary tree to try and identify a blockage and perhaps a proximal bile-containing duct to anastomose to. This led to the concept that biliary atresia (BA) was either “correctable” or “uncorrectable” depending on operative findings. With increasing experience, it became evident that the latter was much more common and hence survivors were exceptional. Although the use of these terms is nowadays anachronistic (because you can “correct” the uncorrectable!), it perhaps illustrates the hopeless prognosis of these unfortunate infants.

Figure 56.1 illustrates the various types of BA and is based upon the most proximal level of obstruction. Thus, over 95% are type 3 where there is no visible bile duct in the porta hepatis (hence “uncorrectable”). It does not imply anything about causation (described later in the chapter).

A more radical approach to the technique was pioneered in Sendai, Japan, during the 1950s and 1960s by Morio Kasai (1922–2008) to the problem of “uncorrectability” [2, 3]. He advocated a more radical approach to the biliary dissection and simply transected at the most proximal point in the porta hepatis. The porta, even if there were no visible ducts, was then anastomosed to a Roux loop (portoenterostomy). Transection exposes residual microscopic bile duct remnants within the fibrous tissue which retain communica-

tion with the intrahepatic duct system (still often very abnormal). Hence, bile flow actually occurs to a varying degree, but in perhaps the majority, enough to lose their jaundice (see later for results and outcome), postoperative outcome significantly improved.

For the first time, Kasai portoenterostomy (KPE) enabled a much larger cohort of long-term survivors, initially in Japan [3] but later from the 1970s in Europe and North America. It was not a cure though, and even survivors displayed many complications related to liver fibrosis and cirrhosis.

Thomas Starzl, in 1963, attempted the first liver transplant in humans in a child born with BA [4]. Sadly, the child died of operative bleeding related to severe portal hypertension. This prompted a number of units around the world to set up transplantation programmes, but, in the absence of effective immunosuppression, they were all terminated by the end of the 1960s. With the discovery of cyclosporine at the beginning of the 1980s, transplantation once more became a viable option, and from this the current strategy of an initial attempt to restore (some might say resurrect) bile flow with a KPE followed by liver transplantation if this fails evolved.

Variants of Biliary Atresia

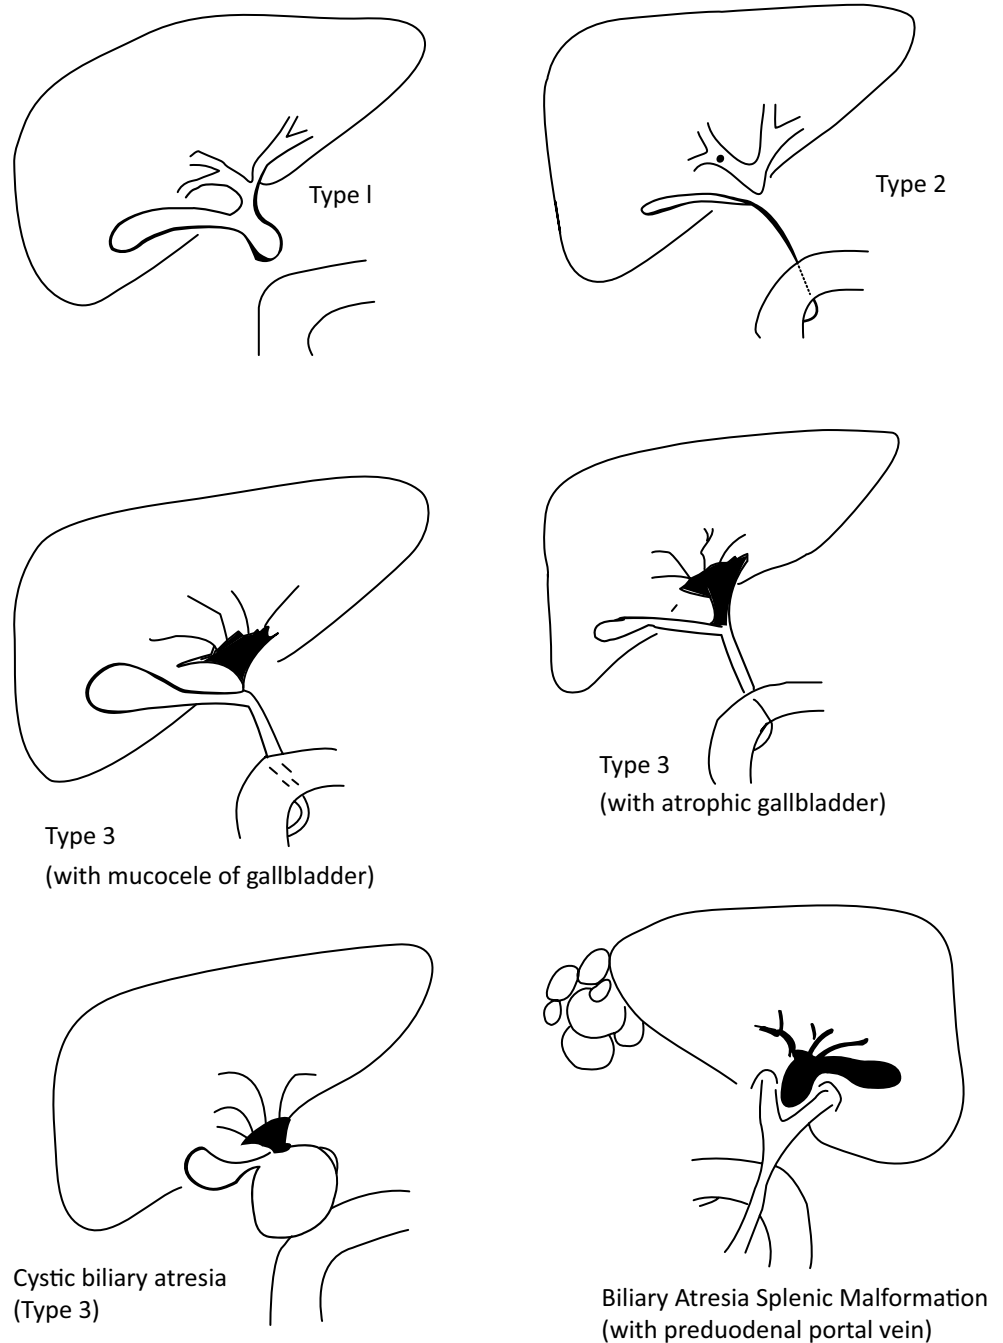

BA is not a single disease rather it should be thought of as a phenotype resulting from a number of different and entirely separate aetiologies leading to the final common phenotype of biliary inflammation, luminal obliteration and fibrosis [5].

We are able to define clinically four broad groups (Fig. 56.2):

1. Syndromic biliary atresia. While BA is usually an isolated abnormality found in otherwise normal-term infants, there are a group of infants (about 10–15% in European and North American series, but <2% in Asian series) with other non-biliary anomalies and a poorer prognosis. We have termed this specific constellation of anomalies the biliary atresia splenic malformation (BASM) syndrome [6, 7]. All will have a splenic malformation, usually

polysplenia but occasionally asplenia and about half will have situs inversus and congenital heart abnormalities. Other anomalies are evident at laparotomy including preduodenal portal vein, absence of the inferior vena cava and malrotation. Most infants with this syndromic form of BA are female. It is speculated that such cases may result from some fundamental derangement of extrahepatic bile duct (and other systems) development within the embryological phase (<6 weeks gestation). A genetic aetiology has not been convincingly shown clinically, though several candidate genes exist (e.g. CFC-1). There is some evidence that affected infants have been exposed to an

abnormal first-trimester intrauterine environment such as that found in maternal diabetes and thyrotoxicosis.

2. Cystic biliary atresia (CBA). In about 5% of cases, there is obvious cyst (sometimes containing bile) formation within an otherwise obliterated biliary tree. In recent years, it has been possible to detect this cystic change on antenatal ultrasound (US) scans as early as the 18th week of gestation [8, 9]. CBA should not be confused with cystic choledochal malformation (CM), which can be indistinguishable on US [10]. Discrimination may be made clinically as CBA will invariably have conjugated jaundice, pale stools, etc., and at laparotomy as the chol-

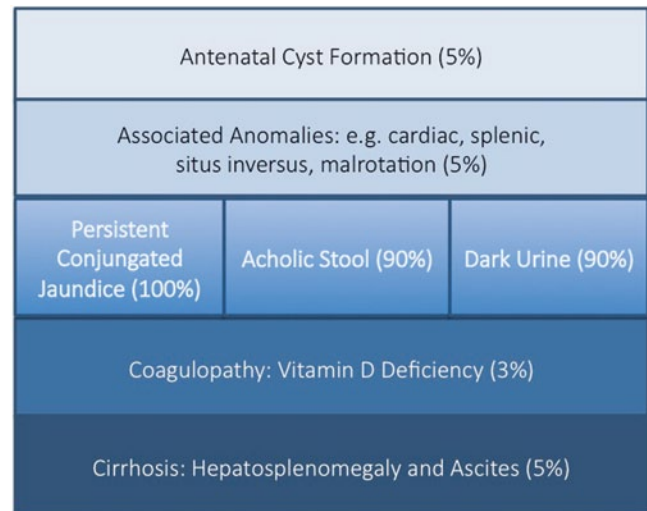

Fig. 56.3 Modes of presentation of biliary atresia

angiogram will show the abnormal and primitive intrahepatic duct structure. Both CBA and the syndromic BA can clearly be termed “developmental” as whatever caused their pathology occurred during prenatal life.

3. Isolated biliary atresia (IBA). This is the typical BA variant accounting for about 70–80% of cases [11]. They have no other significant features and usually display an obliterated biliary tree at laparotomy (usually type 3). In the absence of any clinical or laboratory evidence, we do not actually know the aetiology in this group.
4. Cytomegalovirus IgM +ve biliary atresia. Although there is a range of possible hepatotropic cholangiopathic viruses (e.g. reovirus type 3, rotavirus) it has been difficult to definitively ascribe clinical consequences to infection. We have recently discriminated infants with CMV IgM +ve antibodies from their IgM –ve fellows clinically, histologically and in their response to treatment (unpublished results). This is still controversial and other European series have not shown any such differences; however, the focus in these has been on a group of viruses rather than specifically CMV [12].

Epidemiology

Population-based studies reporting incidence and outcomes of BA are scarce. There is marked variation in incidence across the globe with the highest rates found in East Asian countries compared to Europe and North America [13]. The place with the highest reported incidence appears to be Taiwan at an incidence of 1 in 6622 [14].

The incidence in the UK is about 1 in 17,000–18,000 live births [11], and this appears to be similar to reports from France [15], Sweden [16], Germany [17] and Switzerland

[18]. Most large series show an equal gender split although by variant there is marked female predominance in the developmental forms of BA [7, 9, 11, and 15].

A number of small series suggested seasonality for BA [13, 19], though these were far from definitive and larger national series failed to observe any predilection for a particular season [11, 15, 20].

Clinical Features

The key features of BA are persistent conjugated jaundice, acholic stools and dark urine in an otherwise healthy term infant (Fig. 56.3). The latter feature is caused by excess conjugated (i.e. water-soluble) bilirubin passing into the urine causing its colour to darken. Such alternative pathways of bilirubin excretion are more developed or at least preserved in the newborn, and very high levels of bilirubin (>300 μmol/L or >17 mg/dl) are exceptional. Sometimes jaundice will be difficult to discern in infants of Asian or Afro-Caribbean origin leading to delays in diagnosis and treatment. The median time to referral was 47 days in non-white versus 52 days in white infants in one UK study [21]. Furthermore, all of those “missed” and referred beyond 100 days were non-white.

Sometimes the antenatal US scan will be abnormal showing a sub-hepatic cyst, and one should be suspicious of CBA [8]. There is no difference in gestational age or birth weight between those with developmental BA compared to isolated BA, but both groups show a failure to thrive by the time they are admitted. Fat malabsorption is the presumed mechanism and will also cause deficiency of the fat-soluble vitamins D, A, E and K. Low vitamin D levels are common even in those infants presenting early, and this is exacerbated in those of Asian family origin, presumably reflecting low maternal stores (Fig. 56.4). Vitamin K deficiency is possible and a

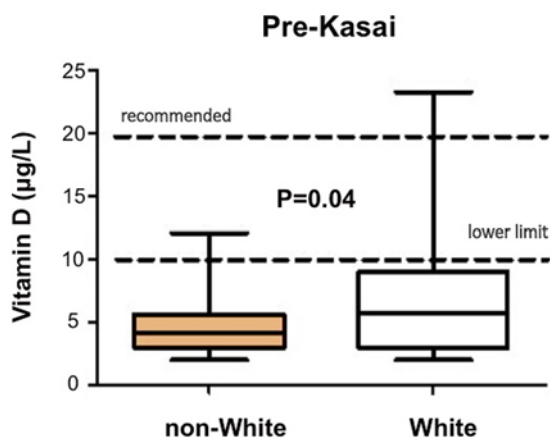

Fig. 56.4 Decreased preoperative vitamin D-levels in non-white compared to white infants with biliary atresia. (Courtesy of Ms. Anu Paul)

proportion will present with a bleeding tendency, perhaps from the umbilical stump or more catastrophically with an intracranial haemorrhage. Marked elevation of the international normalised ratio (INR) or prothrombin time will be seen. Some syndromic cases will present early because of other abnormalities associated with BASM (e.g. cardiac anomalies, malrotation or situs inversus).

Diagnosis

The diagnostic work up in our institution includes a detailed US of the liver, liver biochemistry and a percutaneous liver biopsy [10]. Using this, more than 90% will have an accurate diagnosis before laparotomy.

Ultrasonography

The US examination is a key part of the diagnostic protocol as it usually excludes other surgical diagnoses (e.g. CM, inspissated bile syndrome, etc.). All of these are characterised by intrahepatic or common bile duct (CBD) dilatation. US may be suggestive of BA as a diagnosis—by showing a shrunken, atrophic gallbladder with no evidence of filling between feeds. In about 20% of cases, a “normal gallbladder” is described—which turns out to be a mucocele of the gallbladder together with a relatively preserved CBD and an absent CHD; Fig. 56.1).

Laboratory Findings

Liver biochemistry will show a conjugated jaundice (typically >100 µmol/L), modestly raised transaminases (>100 µmol/L) as well as significantly raised γ -glutamyl transpeptidase (GGT >200 IU/L). Serum protein and albumin levels should be normal. However, none of this is specific.

Percutaneous Liver Biopsy

In the authors' unit, the pre-laparotomy diagnosis of BA is usually made by percutaneous liver biopsy showing histological features characteristic of large duct obstructions such as bile duct proliferation, portal oedema and absence of sinusoidal fibrosis. It is less accurate the younger the infant, and it does require an experienced and confident liver pathologist.

Aspartate Aminotransferase-to-Platelet Ratio Index

The aspartate aminotransferase-to-platelet ratio index (APRI) can be used as a surrogate of liver fibrosis in many liver diseases, including BA. We have recently reported that this correlates significantly with age at surgery and was much higher in CMV-associated BA. Macroscopic cirrhosis evident at laparotomy could also be predicted using a cut-off value of 1.2, with reasonable sensitivity (75%) and specificity (84%) in a large cohort of infants from our unit [22].

The usual differential diagnoses of conjugated jaundice include TORCH infections (e.g. toxoplasma, rubella, CMV, hepatitis, etc.), genetic conditions (e.g. α -1-antitrypsin deficiency, Alagille's syndrome (abnormal “elfin” facies, butterfly vertebrae, pulmonary stenosis), progressive familial intrahepatic cholestasis (PFIC) disorders, metabolic conditions (e.g. cystic fibrosis, galactosemia), and parenteral nutrition and neonatal hepatitis.

Miscellaneous Diagnostic Techniques

Other techniques which have been used include endoscopic retrograde cholangiopancreatography (ERCP), percutaneous cholangiography, duodenal intubation and measurement of intraluminal bile. Unfortunately, magnetic resonance cholangiopancreatography (MRCP) is not detailed enough as yet to confidently diagnose BA and radioisotope hepatobiliary imaging (e.g. using iminodiacetic acid derivatives), that shows absence of bile excretion lacks specificity—many being simply “neonatal hepatitis”.

The surgical differential is less common and includes obstructed CM, which usually shows obvious dilated intra- and extrahepatic biliary dilatation; inspissated bile syndrome which usually occurs in the preterm with a precipitating event such as dehydration or haemolysis and spontaneous perforation of the bile duct which usually shows US evidence of bile ascites and a sub-hepatic collection evident on US [10].

Screening

Some countries have adopted a population screening programme for BA. The most well-developed has been that of Taiwan [23], where mothers are issued with colour-coded cards and asked to compare it with their infant's stool. Recognition of pale stool prompts further investigation and re-

Fig. 56.5 Close-up of porta hepatis during Kasai portoenterostomy. **a** Hypertrophied proximal biliary remnant (BR) being separated from vascular structures of liver. **b** Same view following resection of BR, showing denuded portal plate

ferral. This has certainly shortened their time to surgery—the median age at KPE is now <50 days and is currently the best achieved anywhere in national terms. The key achievement, we believe, has been the marked reduction in late-presenting infants who have already developed obvious cirrhosis [24].

In a recent study from our institution, skills of health-care professionals in recognising pale stools were assessed. Sadly, the study showed that one third of the abnormal stools were not correctly identified by physicians and nurses who were apparently regularly in contact with jaundiced infants. The authors suggested that distribution of standardised stool colour cards throughout community clinics and outpatient departments might rectify this problem [25].

The simplest solution to early diagnosis remains education, however. It is clear from so many histories that it is often the parents who recognise that persistent jaundice in their infants is not normal but then are falsely reassured by health visitors and their community doctors who fail to inquire about pale stools or dark urine (nevermind looking at them) and fail to do the appropriate blood test (split bilirubin for conjugated and unconjugated fractions). The statutory community check in the UK occurs at 6 weeks of age and is far too late to make a difference in when these affected infants come to surgery.

Kasai Portoenterostomy

The aim of surgery is to excise all extrahepatic biliary remnants allowing a wide portoenterostomy onto a portal plate, denuded of all such tissue (Fig. 56.5). In most cases, this will expose sufficient transected microscopic bile ductules which retain connections with the primitive intrahepatic bile ductule system to allow restoration of at least a degree of biliary drainage. This should be the object of all three types of BA.

Fig. 56.6 Schematic illustration of retrocolic Roux-en-Y loop, typically measured at 40 cm from portoenterostomy to jejunojunction

A short right upper quadrant muscle-cutting incision should be performed initially to confirm the suspected diagnosis or, if the gallbladder is shown to contain bile, to proceed to on-table cholangiography.

There are then two surgical strategies to expose the porta hepatis: One involving division of at least the left-sided suspensory ligaments and then eversion of the liver onto the abdominal wall. The other retains the liver in the abdominal cavity but usually requires dissection and slinging of the right and left portal veins to allow full exposure of the biliary remnants. A simple portoenterostomy using a retrocolic Roux loop (about 40 cm) completes the reconstruction (Fig. 56.6). Older techniques involving stomas in the Roux loop have been abandoned by virtually all centres.

The KPE can be replicated laparoscopically. However, most centres which explored and pioneered this technique have subsequently reverted to open KPE [26, 27]. The portal dissection, the key to wide excisional surgery, is not improved by being performed laparoscopically and the reconstruction remains technically challenging. There is obviously a better scar, though the infants remain in hospital for the same length of time and an adhesion-free abdominal cavity for the transplant surgeon, although even the latter has been challenged by a study from Germany [28]. Surgeons in Juntendo, Tokyo, have adopted a different approach to these issues by limiting the scale of the portal dissection, and consciously limiting the transection to a basic oval shape—allowing at least some remnant to remain [29].

Postoperative Management

Intravenous fluids and nasogastric aspiration are continued until return of bowel function (about 3–4 days). Careful monitoring of blood glucose, electrolytes and INR is important in the early phase. Liver biochemistry (including bilirubin) may well worsen in the first week, but, by about

the 4th week, there should be a definite fall in bilirubin and consistently pigmented stools in those who will do well. Strict attention to nutritional needs is important and all infants need regular vitamin supplementation. Medium-chain triglyceride formula milk (e.g. Caprilon®; SHS, Liverpool, UK) is advocated to maximise calorie input and facilitate lipid absorption.

Adjuvant Therapy for Biliary Atresia

Although a number of drugs have the potential to improve the outcome of KPE surgery, there has been little published in the way of scientific data to provide credible support for any [30]. Postoperative steroids remain popular: A recent study from the USA, including 516 patients from 42 children's hospitals reported about a usage rate of 46% [31]; however, there is only a single prospective, double-blind, randomised, placebo-controlled trial using a low dose (2 mg/kg/day) [32]. This showed a significant reduction in early bilirubin levels (especially in young livers) in the steroid group but did not translate to a reduced need for transplant or improved overall survival. A further follow-up study using a higher starting dose of prednisolone (5 mg/kg/day) confirmed biochemical benefit and also reported a 15% improvement in jaundice clearance when infants <70 days were selected out [33]. There does not seem to be significant side effects from the high-dose regimens.

Ursodeoxycholic acid (UDCA) also remains popular and may be beneficial, but only if surgery has already restored bile flow to a real degree. Willot et al. from Lille in France assessed the effect of UDCA on liver function in children >1 year post-KPE and showed that it improved biochemical liver function in stable children [34]. It may also have an extra-beneficial effect in BA because of its immunosuppressive properties as it has been shown to decrease proliferation of and cytokine production by mononuclear cells in vitro [35].

Complications

About 20–30% of infants will have no effect from KPE, their stools will remain pale; their bilirubin levels will continue to rise. These infants will inexorably continue to develop cirrhosis and end-stage liver disease with severe failure to thrive, ascites, splenomegaly, deepening jaundice and often bleeding from variceal formation. Such infants need expedited liver transplantation, often before their first birthday. It is important to recognise these infants early and not offer false hope that they will somehow turn a corner—they will not.

Other specific complications deserve a more detailed coverage.

Cholangitis

Re-establishment of bile drainage exposes the child to the risk of ascending cholangitis, which occurs most commonly in the year following primary surgery in about 40–50% of children. Paradoxically, it only occurs in children with some degree of bile flow, not in those with early failure as described above. The usual organisms are enteric in origin (e.g. *Escherichia coli*, *Pseudomonas*, *Klebsiella* spp.).

Clinically, an episode is characterised by fever, acholic stools and a change in biochemical liver function (rising bilirubin and aspartate aminotransferase; AST levels). The diagnosis may uncommonly be confirmed by blood culture or rarely by percutaneous liver biopsy, but, the key component is antibiotic treatment on suspicion and not confirmation. Intravenous broad-spectrum antibiotics effective against Gram-negative organisms (e.g. piperacillin and tazobactam, gentamicin). Most will respond within 24 h and liver function is usually restored fairly quickly. Some children sustain repeated cholangitis, and they should be treated by prolonged courses of intravenous antibiotics via an indwelling vascular device. If, however, it is clear that there are other features of end-stage liver disease, then they too should be considered for transplant.

Occasionally, cholangitis occurs as a late event in otherwise normal children or adolescents, who have good liver function and have cleared their jaundice [36]. The Roux loop may be at fault here with partial obstruction leading to bile stasis. A combination of radioisotope scans and percutaneous cholangiography may aid the diagnostic process and operative Roux loop revision may be required. Recently, we have used an enteroscope to investigate these patients and provide radiological and endoscopic visualisation of the proximal Roux loop [37].

Portal Hypertension

Increased portal venous pressure has been shown in about 70% of all infants at the time of Kasai operation [38]. However, subsequent portal hypertension depends on both the degree of established fibrosis and, most importantly, the response to surgery. There is a relationship with biochemical liver function and variceal development and in those who fail and need early transplantation; about 30% will have had a significant variceal bleed.

Infants and children with bleeding oesophageal varices need rapid access to high-quality paediatric facilities with the resources and expertise to manage them appropriately. Injection and/or banding is not a technique for the occasional paediatric endoscopist. Restoration of circulating blood volume and pharmacotherapy (e.g. 2 ml/h of 500 µg octreotide in 40 ml of saline) should precede endoscopy and achieve a measure of stabilisation. Sometimes a modified Sengstaken tube needs to be placed to achieve control of bleeding. Invariably, in children, this can only be done under general

anaesthesia but can be life saving. The definitive treatment in older children is endoscopic variceal banding, although injection sclerotherapy retains a role in treating the varices in infants.

In common with other large centres, we therefore recommend that for each child with BA there is the opportunity to enter a programme of endoscopic surveillance to try and pre-empt variceal bleeding [39]. In this respect, there may be a role for selection based on haematological, biochemical or US variables to assign risk. Our recent work has suggested that APRi and clinical prediction rule (CPR) [40] appear to be superior in this respect to simple univariate indices (e.g. platelets, bilirubin) or US dimensions (e.g. spleen size or resistance index).

The key variceal signs that should prompt *prophylactic* endoscopic treatment are the presence of significant red *wales* in grade II/III oesophageal varices and obvious (usually lesser curve) gastric varices [39]. Liver transplantation needs to be actively considered as definitive treatment for portal hypertension where liver function is poor and the child is already significantly jaundiced.

Ascites

This is related to portal hypertension in part, but there are other contributory factors including hypoalbuminaemia and hyponatraemia. It also predisposes to spontaneous, bacterial peritonitis. Conventional treatment includes a low-salt diet, fluid restriction and the use of diuretics particularly spironolactone. It is often seen in settings of malnutrition and end-stage liver disease, and a nutritional supplementation is important to try and increase calorie and protein intake.

Outcome Following Kasai Portoenterostomy

There are many factors, which will influence surgical outcome in BA. Some are unalterable (e.g. degree of cirrhosis at presentation, absence of, or paucity of bile ductules at the level of section) and some are subject to change (e.g. efficacy of the KPE due to surgical inexperience, poor choice of technique, complications postoperatively due to inexperienced unit, untreated cholangitis, etc.). In large centres with experienced surgeons, about 50% of all infants should clear their jaundice and achieve a normal (<20 $\mu\text{mol/L}$ or <1.5 mg/dL) bilirubin [41]. These should do well and have a good quality of long-term survival with their native liver.

There is no doubt that increasing age at KPE is associated with increasing liver fibrosis and cirrhosis although the actual rates of progression differ according to underlying cause [42]. There is a marked relationship with age at surgery for instance with cystic BA and BASM but it is not that evident in isolated BA. So, it is not really possible to use age as a simplistic predictor in individual cases as even in those

coming to surgery at >100 days may still have a response to KPE [43]. Still there may be a role for those with the signs of evident cirrhosis (e.g. ascites, heterogeneity of the liver appearance on US) for consideration of transplantation as the primary procedure. It remains an uncommon choice though, perhaps <5% in our experience [41].

In the England and Wales, we have adopted a policy of centralisation of surgeons and resources. So for a country of 56 million, there are only three recognised centres to treat this condition. All surgical facilities including transplantation are available. This policy was adopted because previous audits of outcome had shown a significant difference depending on centre experience with the less experienced centres showing poor outcomes [44]. Subsequent studies confirmed an improvement in overall national outcome [41, 45]. This policy has been replicated by some European countries again with demonstrable benefit [46, 47].

Choledochal Malformation

Introduction

The German anatomist Abraham Vater recognised the ampullary nature of the junction of biliary and pancreatic ducts which since then has carried his name. Subsequently, he also described what appeared to be a choledochal cyst in a pamphlet published in 1723 [48].

Further examples of this, the classical choledochal cyst, were described, but still barely 90 cases had been recorded by 1959, when Alonso-Lej et al. attempted a simple classification into three types [49]. Even as recently as 1975, Flanagan could only identify details of 955 cases from the literature [50].

CM (of which some can be described as choledochal “cysts”) may be characterised as, . “an abnormal dilatation of the biliary tract, in the absence of any acute obstruction”. This allows us to exclude the dilated CBD secondary to choledocholithiasis and strictures secondary to chronic pancreatitis for instance. Similarly, while many CMs present with jaundice and biliary obstruction, it is obvious that previously their function was unimpaired for much of the subject’s life in the presence of clear morphological change.

Aetiology

Most CMs appear in some way to be of congenital origin though the actual mechanism itself is obscure.

There are two competing hypotheses:

1. *Pancreatic reflux*. An intrinsic part of most examples of CM complex is an abnormal pancreatobiliary junction. Normally, the pancreatic and bile ducts open separately

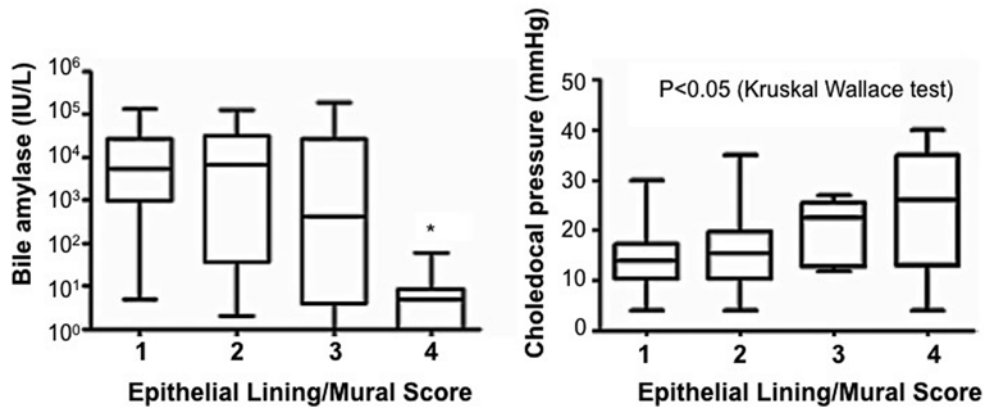

Fig. 56.7 Relationship between biliary amylase, choledochal pressure and epithelial histology. Levels of biliary amylase (a) (as a surrogate of pancreatic reflux) and in-situ choledochal pressure (b) in 73 children with choledochal malformation. The Y axis (Epithelial lining/mural score) uses a semi-quantitative score for biliary epithelium where 0

normal; 1 minimal focal hyperplasia and chronic inflammation; 2 mild chronic inflammation; 3 pronounced hyperplasia and moderate chronic inflammation and 4 epithelial loss, bile impregnation and biliary necrosis. ([59], with permission from Wiley)

within the wall of the duodenum at the ampulla of Vater achieving biological separation of bile and pancreatic juice. In most patients with CM, duct confluence occurs within the head of the pancreas, outside the duodenal wall resulting in a common channel that allows free intraductal mixing of both types of secretion [51–53].

Donald Babbitt, an American radiologist, proposed that this reflux of presumably activated pancreatic juice could damage the wall of bile duct causing weakness and dilatation [54]. There are a number of experimental animal models which have tried to replicate the effects of pancreatic enzymes on bile ducts [55, 56], but there has been little actual documented change in the dimensions of the biliary system.

2. *Distal bile duct stenosis.* Almost 15% of CM can now be detected antenatally on the maternal US scan. Most of the infants are not actually jaundiced at birth—though some are. In all of these, the morphological type is a cystic malformation and in these, though there might be a common channel, there is minimal amylase in bile (implying no reflux) and often a very definite abrupt change and distal bile duct stenotic segment. Furthermore, animal models involving ligation of the distal bile duct [57] produce obvious cystic change.

To try and resolve some of these questions, we have looked into a series of studies at the relationship between age at presentation, modes of clinical presentation, bile duct pressure (as measured at operation), levels of amylase in bile (as a marker of reflux) and the histological appearance of the resected choledochus [53, 58, 59]. This showed that there is a remarkable inverse relationship between pressure and amylase—the higher the pressure, the lower the amylase and that increasing histological epithelial injury and damage are found in those with higher pressures and very obviously not with high amylase levels (Fig. 56.7).

Classification

The original Alonso-Lej classification (types 1, 2 and 3) [49] has been modified most notably by Takuji Todani, a Japanese surgeon, by adding the concept of multiple dilatation (type 4) and isolated intrahepatic dilatation (Type 5) [60]. Our own classification has been in clinical use for over 20 years and is illustrated in Fig. 56.8 [59, 61].

We prefer to use the generic term *choledochal malformation*, rather than the very specific term choledochal cyst, since

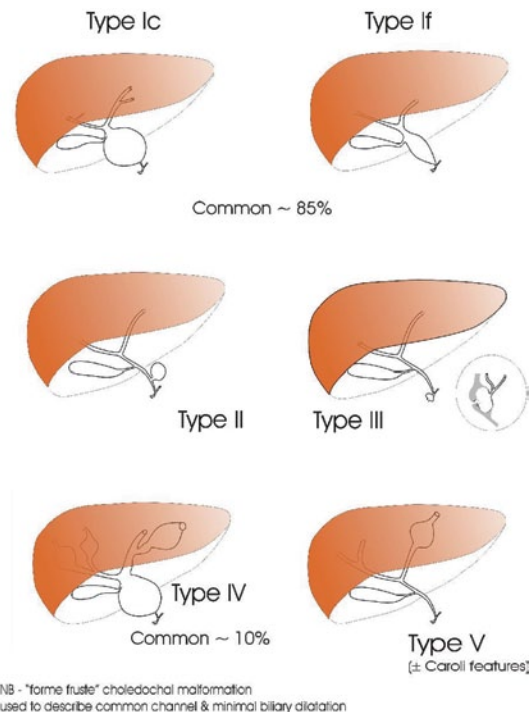

Fig. 56.8 King's College Hospital classification for choledochal malformation

Fig. 56.9 Types of choledochal malformation. **a** Operative cholangiogram showing classical type 1c choledochal malformation (CM). Note the demarcation both proximally and distally, together with long common channel. **b** Percutaneous transhepatic cholangiogram of type 1f CM. Note the generalised dilatation down to a common channel which is dilated and filled with debris (the child presented with acute pancreatitis)

not many of the described dilatation appears as “cystic” (i.e. spherical). The principle variants of extrahepatic dilatation (type 1) making up about 80% of all cases are either *cystic CM (type 1c)* or *fusiform CM (type 1f)*. The former typically has a natural demarcation at either end (Fig. 56.9a), while the latter is much smaller in diameter but merges imperceptibly with a common channel distally or the bifurcation proximally. The only other common variant (*type 4*) is either of the foregoing extrahepatic dilatation together with significant intrahepatic biliary dilatation—sometimes this is because of actual obstruction (with a swift return to normal calibre after surgery) but in others it may appear as an intrinsic feature of the condition (Fig. 56.9b) [62]. Of the remaining variants, *types 2* and *3* are rarely seen in children. The former can be likened to a diverticulum of the CBD, the latter a localised dilatation of the CBD as it transits the wall of the duodenum (aka choledochocoele). *Type 5 CM* refers to usually solitary intrahepatic biliary cystic lesions. Most of these are detected incidentally and can be left alone.

Jacques Caroli, a French gastroenterologist and prolific author, described a number of intrahepatic biliary pathologies which carry his name [63, 64]. The term Caroli disease is usually applied to ectasia or segmental dilatation of the larger intrahepatic ducts (typically the left hepatic duct system) without any other extrahepatic manifestation and is usually sporadic. Caroli syndrome describes a condition in which there are multiple, discrete small yet saccular dilations of the intrahepatic bile ducts with almost invariably hepatic fibrosis and usually renal disease. This is generally inherited in an autosomal recessive manner [65–67], and there is a large overlap with congenital hepatic fibrosis, polycystic kidney disease (both autosomal dominant and recessive types) *et alia*.

Epidemiology

CM is a relatively rare abnormality in the West and far more common in the East although the actual prevalence remains uncalculated [68, 69]. Virtually, all of the large series of this has been reported from Japan [68, 69] and now increasingly China [70], with very little substantial series from North America [71] or Europe [72]. There is a marked female predominance [72], but not much in the way of an identifiable hereditary element. However, isolated examples of familial occurrence in siblings and twins have been reported [73–75].

Clinical Features

CM can present at any age, but more than 90% will present within the first decade [72]. Clinical manifestations do differ according to the age of onset. Typical presenting symptoms in the newborn mimic biliary atresia and specifically cystic biliary atresia with obstructive jaundice, acholic stools and hepatomegaly, depending on the degree of obstruction. These sometimes have advanced liver fibrosis depending on the length of the period of obstruction.

Older infants and toddlers then tend to present with jaundice and may well be found to have an upper abdominal mass, and most turn out to have a type 1c CM. If obstructive features are ignored, then chronic liver disease may result and cirrhosis is possible though seemingly not as common as in some older series [72].

Recurrent abdominal pain becomes a feature later on and may be due to an obstructed high-pressure system or actual recurrent pancreatitis. This is usually pathologically mild, oedematous and short-lived and associated with hyperamylasemia. This scenario is usually associated with the type 1f CM. Sometimes investigation shows a common channel, presenting features of pancreatitis but not much in the way of biliary dilatation. This has been termed a *forme fruste* CM or more simply common channel syndrome (Fig. 56.10).

Perforation of a high-pressure system is uncommon (5%), and in these the clinical scenario may mimic spontaneous biliary perforation in infancy [76] or appendicitis in the older child. Bile leakage is usually confined to the retroperitoneum and tracks down the paracolic gutter.

There is a risk of carcinomatous change in long-standing CM which will manifest later in adulthood, exceptionally rarely in adolescence. Up to 10% of adult series have established malignant change at laparotomy [61, 77, 78]. In a Japanese series of 94 patient (adults and children) with excised choledochal malformation, four later developed malignancy. The age at detection ranged from 27 to 65 years with the malignancy arising both in the liver and the head of pancreas [77]. Similarly, Lee et al. described 80 patients with biliary

Fig. 56.10 Common channel syndrome. An 8-year-old girl with long history of recurrent acute pancreatitis requiring an ERCP to diagnose a common channel, with presumed reflux of bile into the pancreatic duct. She was cured by disconnection of biliary and pancreatic ducts and Roux loop hepaticojejunostomy biliary reconstruction

malignancies from a large Korean multicentre series of 808 adults [78]. Of these, most ($n=74$) were evident at initial presentation and laparotomy, while six presented 4 years after their previous choledochal excision. What is not known is what the real long-term risk is in those who have had their definitive excisional surgery in childhood.

Diagnosis

A choledochal cyst was first diagnosed antenatally using US by Dewbury et al. from Southampton, UK, in 1980 [79]. Since then, up to 15% of CMs (in the UK at least) are diagnosed antenatally from as early as 15 weeks' gestation and these are almost invariably types 1c or 5 CM [80]. CM may be confused with duodenal atresia, cystic biliary atresia, ovarian cyst, duplication cyst and mesenteric cyst. In this scenario, it is most important to exclude the possibility of cystic BA who requires urgent KPE [9]. If there is clinical doubt, then a dynamic radioisotope scan (e.g. technetium⁹⁹ labelled iminodiacetic acid, HIDA-scan) will confirm the non-obstructing CM, where surgery can be deferred to about 3–4 months.

Postnatally, US is the initial diagnostic modality of choice, allowing for precise measurements of intra-/extrahepatic duct dilatation and identification of stones/sludge. MRCP has superseded the use of CT and for the most part ERCP for preoperative anatomical delineation of the pancreatobiliary tract. Three-dimensional reconstructions images are easily obtained, although sedation may be required in infants and small children.

Functional assessment of CM may be shown using a dynamic radioisotope scan which can show baseline parenchymal hepatocyte uptake together with the pattern and degree

of bile excretion—important if not considering surgery. This may also be useful in diagnosing choledochal perforation. ERCP is still required when there is diagnostic uncertainty over the nature of the pancreatobiliary junction and common channel, particularly in those with minimal biliary dilatation and often with a presenting feature of pancreatitis. Notwithstanding these, a detailed US scan supplemented by MRCP or intraoperative cholangiography provides sufficient anatomical information in most cases.

Biochemical liver function tests may be normal or show evidence of biliary obstruction. Amylase levels may be elevated during episodes of abdominal pain suggestive of actual pancreatitis. A prolonged INR secondary to cholestasis should be corrected with intravenous vitamin K.

Surgical Management

Open surgery is still very much the standard in most centres. For the common types (type 1c, 1f and type 4), this consists of excision of the dilated part of the extrahepatic biliary tree; clearance of debris and stones from any dilated intrahepatic ducts (best achieved with on-table cholangioscopy); clearance of any common channel debris (\pm transduodenal sphincteroplasty) and a reconstruction end-to-side hepaticojejunostomy using a long (40–50 cm) Roux loop. Despite often quite alarming intrahepatic dilatation, the usual best course is excision of the extrahepatic segment with a fastidious approach to segmental drainage and cautious follow-up. Most ducts will reduce in size, particularly in children which in itself suggests the primary aetiological role of elevated intrabiliary pressure [62].

The first laparoscopic cystectomy and reconstruction of a 6-year-old female with a type 1c malformation was reported by Farello et al. in 1995 from Schio, Italy [81], and this has become an option in some parts of the world. The largest series are from either China or Vietnam and now number over 200 children in each [70, 82]. The technical skills required are high and a large throughput is important in minimising complications. The standard Roux loop reconstruction is usually carried out by extracting the small bowel through an enlarged umbilical incision though the hepaticojejunostomy is performed intracorporeally. A controversial innovation has been to discard the hepaticojejunostomy because it is difficult and perform a hepaticoduodenostomy instead [83]. This short cut may be expedient but the long-term effects of this may be poorer. Cholangitis and biliary gastritis are both significantly more common using this so-called physiological alternative [84].

Excision of the diverticulum is probably all that is needed in the rare type 2 CM as long as normal unobstructed distal bile flow can be demonstrated radiologically [85]. Large choledochoceles (type 3 CM) can be removed transduodenally, whereas smaller choledochoceles can be treated by

sphincteroplasty or endoscopic sphincterotomy, although admittedly most reported experience is in adults [86].

Most type 5 CMs are isolated, asymptomatic and picked up incidentally with US. They can probably best be treated conservatively with serial US to try and detect any complications such as stone formation [80]. In those with symptomatic or complicated Caroli-like intrahepatic dilatation, resection should be considered particularly if unilobar. The treatment of Caroli's syndrome may be complicated and occasionally liver transplantation may be considered.

Postoperative Management

Intravenous fluids and nasogastric aspiration are continued until return of bowel function, usually on day 2 or 3 after the operation. Oral feeding is recommenced after the fluid from the nasogastric tube becomes clear.

Complications

Complications are uncommon, but may include bleeding, adhesive small bowel obstruction, anastomotic leakage and leakage from the pancreatic duct. Anastomotic leakage may be treated conservatively particularly if this has followed a difficult and challenging anastomosis. Abdominal drainage is key and if there is no obstruction to a functioning Roux loop, then it will settle. Pancreatic leaks are less common but more challenging, particularly if the ampullary sphincter is still intact. Consideration should be given to endoscopic ERCP and stenting if a conservative trial of abdominal drainage, intravenous antibiotics, nasogastric decompression and parenteral nutrition fails.

Anastomotic stricture usually followed by recurrent cholangitis and intrahepatic stone formation are late complications [87]. Cholangitis implies a mechanical problem and should be aggressively investigated. Strictures or persistent intrahepatic dilatation can be treated by radiological intervention with surgery reserved for failure. Recurrent pancreatitis implies obstructive problems with the retained common channel. MRCP, but more likely ERCP should be diagnostic and in the latter's case, may be therapeutic with endoscopic channel clearing or stenting.

Terms and Definitions

The term “fibrocystic liver diseases” is used to describe a group of congenital disorders most often presenting in childhood. Their common feature is the abnormal embryologic development of the ductal plate that leads to dilatation and cyst formation within the intrahepatic or extrahepatic biliary tree. Two major disorders are discussed in this chapter: congenital hepatic fibrosis (CHF) and Caroli's disease (CD). Caroli's syndrome (CS) combines the features of both CHF and CD. Differences and overlap between these clinical entities are thoroughly discussed.

Pathophysiology of CHF and CD

CHF and CD are closely related to each other, because they both result from a ductal plate malformation (DPM) due to abnormalities in primary cilia.

Liver Development Overview

In vertebrates, the early liver bud develops when a few cells from the endoderm delaminate into the adjacent mesenchyme. The early liver cells are called hepatoblasts. They are bipotential precursors which eventually adopt either a hepatocyte fate or a cholangiocyte fate (Fig. 57.1) [1]. As such, they express markers of both lineages during development, some of which can be reactivated in certain disease states [2]. Hepatoblasts contribute to intrahepatic biliary development at the ductal plate, a process which is orchestrated by intrahepatic vascular development and which will be of importance in understanding the fibrocystic liver diseases [3].

The Ductal Plate

The ductal plate is the embryonic precursor of the intrahepatic bile ducts. It is first detected by 6–7 gestational weeks and consists of a double layer of cuboidal, biliary-type epithelium that surrounds the developing portal veins. This layer develops from the transformation of hepatoblasts and yields an anastomosing tubular network of biliary ducts through a process called ductal plate remodeling (Fig. 57.1) [4–7].

Ductal plate remodeling begins by 11 weeks of gestation, and in normal conditions it is complete in early postnatal life. It is a process of negative selection of nonfunctional ductal plate elements which involute in a centripetal fashion from the hilum toward the liver periphery [4, 6, 8]. The remodeling phase is characterized by a high rate of mesenchymal proliferation, resulting in the separation of the developing bile ducts from the liver parenchyma (Fig. 57.1) [4, 8]. Meanwhile, hepatocytes and intrahepatic biliary epithelial cells undergo apoptosis at a higher rate than normal under the control of apoptosis-related proteins: C-myc protein and fas antigen stimulate cell-death while Bcl-2 protein inhibits apoptosis [5]. It is possible that an imbalance between proliferation and apoptosis impedes normal ductal plate remodeling, thereby yielding the DPM [4, 5]. Remodeling is under the control of a number of genetic and molecular factors that make it vulnerable to maldevelopment. Among these factors are signaling molecules from the portal venous mesenchyme, from adjacent hepatoblasts, from involuting bile ducts, and hormones such as estrogens.

The Ductal Plate Malformation

The term “ductal plate malformation” was first used by Mogens Jorgen Jorgensen in 1977 to describe an unusual histologic configuration of the liver of children with polycystic disease. He first described extensive fibrosis and increased number of bile ducts within the fibrotic regions, now recognized as the cardinal features of the DPM [9]. It is now understood that the DPM occurs when excessive ductal plate remnants fail to disappear. What is not understood is why

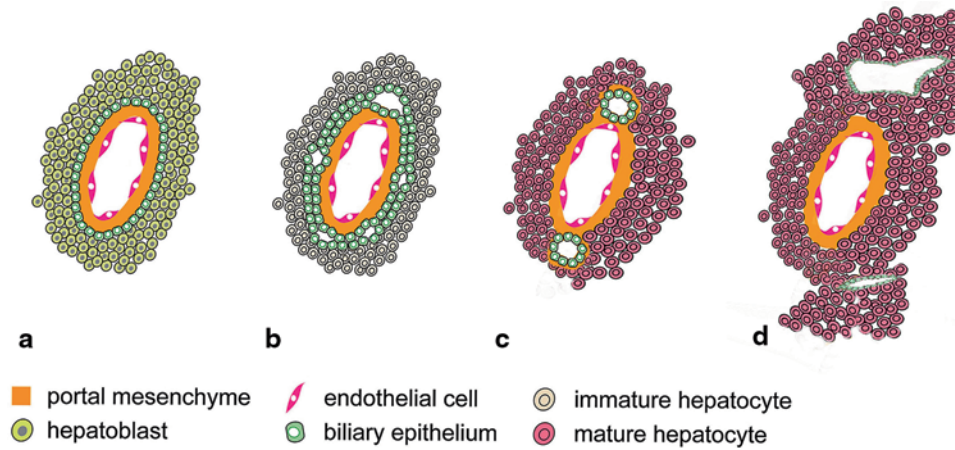

Fig. 57.1 Biliary development and the ductal plate malformation (modified from [1]). **a** At 14 weeks of gestation, hepatoblasts in contact with portal vein mesenchyme adopt a biliary epithelial fate. **b** At 17 weeks of gestation, biliary layer duplicates and focal dilatation within the layer leads to bile ducts formation. **c** At birth, bile duct development is nearly completed, and the bilayer has involuted. Liver cells are either hepatocytes or hepatoblasts. **d** Ductal plate malformation: abnormal ductal plate remodeling leads to saccular, biliary dilatations

the size of the bile ducts affected by the DPM varies between diseases: Small ducts are affected in CHF while larger ducts are dysmorphic in CD. Figure 57.2 [10] illustrates the DPM and related diseases along what might be considered a centrifugal axis from the hilum to the subcapsular region. In the case of complete lack of remodeling of the ductal plate, the DPM appears like a circular lumen surrounding a central fibrovascular axis. Alternatively, incomplete remodeling results either in a ring of interrupted ducts around a fibrovascular axis or a polypoid projection of biliary epithelium in a dilated duct [10, 11].

There are two groups of diseases in which the DPM is a dominant feature. The first is characterized by inflammation and destruction of intrahepatic bile ducts with some degree of fibrosis, as seen in biliary atresia. The second is the pattern typically seen in fibrocystic diseases: extensive fibrosis with ectasia and hyperplasia of intrahepatic bile ducts (Fig. 57.2) [7]. Our purpose is to focus on the latter group.

Cavernous Transformation of the Portal Vein

The DPM is often associated with abnormalities in portal vein branching. During normal development, the portal

Fig. 57.2 Schematic of intrahepatic biliary tree and level of DPM [10]. For reasons still unknown, defects in ductal plate remodeling impact the biliary tree at different levels. In addition, the remodeling defect yields one of two phenotypes: predominantly fibrotic lesions or dilated biliary structures. Caroli’s syndrome is an example of how the two phenotypes might overlap. *DPM* ductal plate malformation, *CHF* congenital hepatic fibrosis, *ARPKD* autosomal recessive polycystic kidney disease, *ADPKD* autosomal dominant polycystic kidney disease, *PLD* polycystic liver disease

vein invades the early liver parenchyma in a centrifugal branching pattern from the hilum to the periphery. This branching pattern determines the lobular architecture of the liver. Therefore, it follows that alterations of vascular development and intrahepatic bile ducts go hand in hand [7, 12, 13]. In the case of DPM, branching is abnormal, thereby leading to the “pollard willow formation,” characterized by clusters of unseparated venous tracts [7, 10, 12]. Extrahepatic cavernous transformation of the portal vein occurs in 50–70% of patients with CHF and CD and contributes to portal hypertension, one of the main clinical features of CHF patients [12, 13]. Congenital absence of the portal vein has rarely been reported in association with CHF [14, 15].

Fibrosis

CHF is a developmental disorder due to DPM of the small, interlobular bile ducts, during which persistence of embryonic remnants stimulates the development of fibrosis. Portal fibrosis is the major histological finding in CHF. The development of fibrosis is a multifactorial process involving hepatic stellate cells (HSC), myofibroblasts, and macrophages. Known molecular mediators include transforming growth factor- β 1 (TGF- β 1) and connective tissue growth factor (CTGF) [16]. CTGF is known to promote fibrosis [16]. In CHF, CTGF is retained in the extracellular matrix (ECM), thereby maintaining a local stimulus for fibrosis. How fibrosis develops in ciliopathies is further explained in the section below on animal models.

HSC constitute approximately 5–8% of liver cells. They are located in the space of Disse, between sinusoidal endothelial cells and liver parenchymal cells [17, 18]. Activated stellate cells express tissue inhibitors of metalloproteinases 1 and 2 (TIMP 1 and 2) [19–21]. These factors have two roles in fibrogenesis: they exert a direct inhibitory action on metalloproteinases which leads to ECM accumulation, and they confer antiapoptotic proliferative signals to activated stellate cells [19, 22]. Finally, stellate cells respond to nearby injury by transforming into myofibroblasts [17] which secrete ECM components leading to scarring [17, 18].

Myofibroblasts are only present in the injured liver, and are classically believed to derive from portal fibroblasts or HSC. They are responsible for producing the ECM which leads to fibrosis [18, 23]. In CHF, parenchymal fibrosis is minimal compared to portal fibrosis. Therefore, it is possible that, in CHF, myofibroblasts derive from periductal fibroblasts rather than from parenchymal stellate cells [16].

Finally, *macrophages* have also been recognized as important regulators of liver fibrosis. They are located close to myofibroblasts and interact with the latter and with HSCs [24–27]. They also act independently, by producing their

own metalloproteinases and TIMP. They contribute to the phagocytosis of cellular debris and to the secretion of cytokines and immunoregulatory mediators [24, 27, 28].

In summary, portal fibrosis is a major feature of CHF. In response to abnormal ductal plate remodeling, portal fibroblasts transform into myofibroblasts and interact with macrophages which secrete the inflammatory cytokines that trigger fibrosis. At this time, however, the underlying molecular and cellular mechanisms are not clear.

Ciliopathies

Abnormal primary cilia are now understood to be one of the main mechanisms causing DPM. The term *ciliopathies* refers to a heterogeneous group of disorders involving anomalies in primary cilia. Primary cilia are highly conserved organelles used to detect various extracellular stimuli [29]. Although their existence has been known since the nineteenth century, their role in disease is still incompletely understood.

In the liver, cholangiocytes are the only cells with primary cilia [30, 31]. Normal ciliary function is necessary for biliary development. Cholangiocyte cilia are important receptors of mechanical and osmotic signals. They respond by modulating intracellular levels of cyclic adenosine monophosphate (cAMP) and calcium in response to bile flow. This function depends on polycystin 1 and 2 (PC-1 and PC-2) that form a functional complex. PC-1 is a ciliary protein with a large extracellular domain that senses cilia bending. It then transfers this signal to PC-2 which triggers a rise in intracellular calcium which in turn regulates cellular proliferation. PC-1 exerts a regulatory role on growth, such that when its function is impaired or its level of expression diminished, the break is lifted and excess proliferation ensues [32]. Cholangiocyte cilia also detect osmotic changes in bile via the transient receptor potential cation channel subfamily V member 4 (TRPV4) protein which participates in the regulation of bicarbonate-dependent bile secretion (Fig. 57.3) [30, 31, 33–36].

Structural and functional defects of primary cilia result in decreased intracellular calcium and increased cAMP, causing cholangiocyte hyperproliferation and abnormal cell–matrix interactions [30, 34, 37–39]. Excessive cholangiocyte proliferation leads to the development of cysts. Estrogens and insulin-like growth factor 1 (IGF-1) also contribute to cholangiocyte proliferation, and cystic cells have been shown to overexpress estrogen and IGF-1 receptors [38, 40]. Furthermore, cell cycle dysregulation also contributes to cholangiocyte proliferation [38]. Finally, cystic cholangiocytes also display an abnormal ion transporter pattern leading to increased fluid secretion in the cysts [38, 41]. As summarized in Fig. 57.3, cyst expansion in ciliopathies is related

to structural and functional defects of the cilia, leading to cholangiocyte proliferation and cyst formation. This process is enhanced by other factors, such as abnormal cell–matrix interactions, cell cycle dysregulation, overexpression of estrogen and IGF-1 and increased fluid secretion in the cysts.

Evidence suggests that biliary precursors are vulnerable to second hits that can suffice to impair remodeling, for example, somatic mutations occurring during development [42, 43]. A mutation in a single allele of a developmentally key transcription factor such as hepatocyte nuclear factor-6 (HNF6) may lead to impaired ciliogenesis and thus cyst development. This can be a very early event that precedes the formation of the ductal plate by days or weeks and may involve genetic modification leading to the loss of heterozygosity, but may also involve other cellular events such as glycosylation and posttranslational modification leading to faulty transcription factor binding [44]. Among other developmental steps prone to anomalies the local growth-factor milieu is another variable in a complex web of events. It is probably because the number of genes and signaling pathways are so numerous and the possible combinations of developmental accidents almost infinite, that biliary development is so vulnerable to malformations and that there is so much overlap between phenotypes among the ciliopathies and fibrocystic diseases. To help make sense of this wide range of phenotypes, it has been suggested that DPMs can be categorized in one of three ways: perturbations in differentiation of biliary precursors, impaired maturation of radially asymmetrical primitive ductules and abnormal (excessive) ductular expansion.

Animal Models of Ciliopathies

Much of what is understood today about cystogenesis, fibrosis, and ciliopathies is through animal studies. Although different parameters have been identified leading to cholangiocyte proliferation and cyst development, until recently there were no clear mechanistic studies to explain the link between cyst formation and fibrosis. Recent studies in rats have shown that abnormal cystic cholangiocytes can undergo an epithelial to mesenchymal transition and secrete ECM molecules contributing to the development of fibrosis (Fig. 57.3) [45].

The PCK rat carries a splicing mutation in polycystic kidney and hepatic disease 1 gene (*Pkhd1*) an ortholog of polycystic kidney and hepatic disease 1 (*PKHD1*). Defects in ciliary structure of cholangiocytes lead to abnormalities of biliary tree differentiation and bile duct dilatation, mimicking CD. Besides the histological findings described above, macroscopic findings include cholangitis with intestinal metaplasia and hepatic fibrosis [28, 45, 46]. Therefore, this animal model will likely be pivotal in understanding the disease process and developing novel therapies.

Fig. 57.3 Schematic description of molecular and cellular mechanisms in the hepatic manifestations of ciliopathies. Mutations in polycystin (*PC*) lead to impaired calcium transport into cilia, and thus impaired movement. In case of *TRPV4* mutation, osmotic changes in bile cannot be sensed, and a dysregulation of bicarbonate-dependant bile secretion occurs. Structural and functional defects of the cilia lead to ductal plate malformation. Cholangiocytes undergo an epithelial to mesenchymal transition and proliferate in the mesenchyme contributing to fibrosis. *PC* polycystin, *TRPV4* transient receptor potential cation channel subfamily V member 4, *EC* extracellular, *C* cytosol, *EMT* epithelial-to-mesenchymal transition

Clinical Features

CHF and CD/CS are ciliopathies associated with ductal plate malformation. The liver findings are rarely an isolated finding. Rather, they are most often associated with polycystic kidney disease (PKD), part of the wider family of ciliopathies. When the phenotype combines hepatic and renal manifestations, these conditions are also referred to as the hepatorenal fibrocystic disorders (HRFCD).

CHF usually presents between 5 and 7 years of age. Familial cases exist, highlighting the importance of a thorough family history [47–50]. CHF can present in one of four ways [33, 50–52]. The most frequent presentation is portal hypertension with firm hepatomegaly and splenomegaly [47, 48, 50, 53, 54]. Thrombocytopenia and hypersplenism are often present. Occasionally anemia reveals occult variceal bleeding. The presenting complaint is often an acute gastrointestinal bleed in a previously healthy child. In 30–70% of patients who present within the first decade of life, recurrent hematemesis or melena caused by variceal bleeding is frequent, whereas ascites is uncommon [52]. In most patients without an associated syndrome, growth and development are normal. Serum aminotransferase- and bilirubin levels are generally within the normal range at diagnosis and remain normal throughout follow-up. No progression to liver failure has been reported [49]. Complications of portal hypertension such as hepatopulmonary syndrome and porto-pulmonary hypertension have been described [49, 52].

The second presentation, frequently associated with CD/CS, is recurrent bacterial cholangitis. Symptoms include intermittent abdominal pain and pruritus from chronic cholestasis. In this case, serum levels of gamma-glutamyl transferase (gGT), alkaline phosphatase, and bilirubin are elevated. Bacterial cholangitis can progress to septicemia and lead to the development of hepatic abscesses. Recurrent cholangitis may lead to liver failure and failure to thrive [52].

Occasionally, patients can present with both portal hypertension and cholangitis. Finally, the disease can be latent and revealed by an incidental, clinical, biological, or radiological finding such as hepatomegaly or cytopenias [55–57]. When CHF or CD is associated with other extrahepatic signs, clinicians should think of associated syndromes, which are described in the following section.

In the long run, CD and CS are associated with an increased risk of cholangiocarcinoma, due to bile stasis and chronic inflammation. Cholangiocarcinoma, which can be the presenting feature, has been reported to occur in 5–10% of patients with CD and CS. It has also been reported in patients with isolated CHF, albeit rarely. The average age at appearance is >40 years (range of 33–75 years), and the risk increases with age. It occurs more often in the monolobar form of the disease, and has very poor 1-year survival rates [58–61].

Associated Syndromes and Ciliopathies

CHF and CD are often features of a multisystem disorder. Ciliopathies with a prevalence of more than 1:150,000 are described below and ciliopathies with low prevalence are outlined in Table 57.1 [62–73].

Autosomal Recessive Polycystic Kidney Disease

Autosomal recessive polycystic kidney disease (ARPKD) is the most frequent ciliopathy in childhood, affecting 1:20,000 live births. It is characterized by progressive cystic degeneration of the kidneys and CHF. As its name suggests, transmission is recessive. All patients diagnosed with ARPKD have CHF from birth on microscopic examination, but only 50% have hepatomegaly. Most of the patients are born with nephromegaly from dilated collecting ducts which can present as a palpable flank mass. Thirty percent of patients die at birth from pulmonary hypoplasia (Potter's syndrome). There is a marked variability of phenotypes even among siblings. The course and the severity of renal disease and liver disease are unrelated. In the infant or neonate, presentation is usually renal, while CHF is typically asymptomatic early in life. Renal disease can present as a simple urinary concentration defect or more often as severe cystic kidney disease leading to hypertension and renal failure. End-stage renal disease affects about 30% of children under 10 years. For neonates surviving the first month of life, the 5-year survival rate is about 90%. Children who present later in life will show one of the CHF presentations described earlier. Diagnosis is clinical and by ultrasonography (US). Kidneys appear hyperechoic on ultrasound, and the liver is either normal or hyperechoic. Rarely, macroscopic liver cysts are visible on ultrasound. Annual follow-up should include a full blood count and ultrasound. MR cholangiography should be performed once to understand biliary morphology. Ultrasound examination of the parents' kidneys is important because autosomal dominant disease can mimic the recessive form in neonates. Management is supportive, both for the renal and liver complications. Most patients presenting as neonates will require kidney transplantation before 20 years of age. Improvement in the management of renal complications has led to an increased awareness of liver-related morbidity and mortality. Liver-related mortality following kidney transplantation has been reported. Liver transplantation is performed in about 3% of cases of ARPKD, usually during adolescence. Combined liver and kidney transplantation are indicated in renal failure with recurrent cholangitis or refractory complications of portal hypertension [74–79].

Autosomal Dominant Polycystic Kidney Disease

Across all age groups, the most common hepatorenal fibrocystic disease is autosomal dominant polycystic kidney disease (ADPKD), with an incidence of 1:1000. Liver involvement usually presents as polycystic liver disease, while CHF and CD or CS are rarely described. As its name suggests, transmission is dominant. Kidney cysts develop progressively from the whole tubule. Onset is slow such that diagnosis is usually made in adulthood. Other organs may also develop cysts: pancreas, intestinal epithelium, arachnoid mater, and seminal vesicles. Cardiac valvular disease and cerebral aneurysms have also been described. Affected patients are usually asymptomatic in childhood. On occasion, an incidental finding of cysts in the fetus, young child, or adolescent can lead to the misleading suspicion of ARPKD. Most often, in childhood, the incidental finding of a cyst should orient toward ADPKD, especially if hypertension is present. Some very rare cases of end-stage renal disease are described in childhood [80, 81].

Nephronophthisis

Nephronophthisis is the most frequent genetic cause of end-stage kidney disease in children and may be associated with liver disease. Nephronophthisis is classified according to age at presentation: infantile, juvenile, and adolescent. In all cases renal involvement leads to end-stage renal disease requiring kidney transplantation. Most commonly, it is the adolescent form caused by mutations in NPHP3 which presents with liver disease characterized by bile duct proliferation and portal fibrosis [82–85]. This characteristic histology should encourage clinicians to search for NPHP3 mutations and examine renal function. Tapeto-retinal abnormalities constitute another sign favoring the diagnosis [86]. Mutations in eight other genes have been identified in the adolescent and juvenile form (NPHP1, NPHP3–NPHP8) but have not been associated with liver abnormalities except for an occasional biochemical abnormality. In NPHP2 and NPHP3, both presenting in infancy, liver involvement varies from mild to CHF [87].

Meckel–Gruber Syndrome

Meckel syndrome is a rare autosomal recessive lethal ciliopathy composed of four cardinal features: occipital encephalocele, bilateral cystic kidneys, CHF (100%), and polydactyly. In addition, CHF is present in 100% cases. The incidence is 1:140,000 and is increased in the Finnish population (1:1000) [88–90].

COACH Syndrome Related to Joubert Syndrome

Joubert syndrome (JS) is a recessive disorder with occurrence of 1:100,000 and characterized by brainstem and cerebellar malformation, ataxia, developmental impairment, alternance of hyperpnea and hypopnea, abnormal eye and tongue movements, and hypotonia and by an array of neurological, retinal, renal, or skeletal anomalies. The key feature of JS is the molar tooth sign (cerebellar peduncles and deep interpeduncular fossa on cerebral MRI). COACH syndrome includes cerebellar vermis hypoplasia/aplasia, oligophrenia, ataxia, coloboma, and hepatic fibrosis. This very rare syndrome combines the presence of CHF and the classical neurologic signs of JS. Mutations in transmembrane protein meckelin (MKS3), a centriole protein necessary for ciliary function and for primary cilium formation, are present in more than 50% of COACH syndrome cases and are uncommon in JS patient without liver involvement [91, 92].

Diagnosis

Radiology

Diagnosis should first be suspected on clinical findings. US is a useful, first-line tool for the diagnosis of CHF. Findings typically include heterogeneous liver parenchyma, foci of hyperechogenicity, and images compatible with biliary cysts. The left lobe may appear enlarged and the right lobe atrophic. Splenomegaly and Doppler are suggestive of portal hypertension and cavernous transformation of the portal vein, although esophagogastroduodenoscopy is the gold standard in the assessment of portal hypertensive complications. Dilatations of the proximal bile ducts and the presence of intrahepatic stones suggest CS [51, 52, 93]. Since the risk of endoscopic retrograde cholangiopancreatography (ERCP)-related complications is high, MR cholangiography (MRCP) is best to evaluate biliary disease using 3D reconstructions (Fig. 57.4). Likewise, MR angiography or CT angiography can further characterize vascular findings. US and MR elastography are increasingly used to evaluate fibrosis [94, 95].

Histology

Liver biopsy is the gold standard to confirm diagnosis. CHF is characterized by the presence of persistent ductal plate structures of the interlobular bile ducts. Large bands of fibrous tissues link enlarged portal tracts with mild inflammatory cell infiltrates (Fig. 57.4). Within the fibrous bands, branching small interlobar bile ducts lined by normal, cuboidal epithelium are irregularly dilated and may contain bile. The hepatic parenchyma and architecture between portal tracts

portal tracts with adjacent normal lobular architecture. **d** Hematoxylin-eosin staining of a ductal plate malformation. **e** Characteristic biliary saccular dilatation in Caroli's disease

and centrilobular veins remain normal. There is hypoplasia of portal vein branches and compensatory increased arterial profiles. CD is characterized by saccular or fusiform cystic dilatation of larger and proximal, intrahepatic, and extrahepatic ducts without signs of fibrosis. CS combines the histological features of CHF and CD [47, 48, 50, 51, 54, 96–98].

Practical Approach

All patients with known cystic renal disease should be evaluated for liver involvement. Liver fibrosis begins early in life in patients with ARPKD and ADPKD. In the absence of signs or symptoms, it is not recommended to perform a liver biopsy. Clinicians should look for signs of portal hypertension at each visit. Annual liver function tests and annual liver US are recommended. An MR cholangiogram may give an idea about biliary disease, but only if the US is consistent with cysts or biliary dilatation. Although liver biopsy is the gold standard for diagnosis, it is not always indicated if it does not immediately alter management. Conversely, since the association between renal and liver disease is so frequent, all patients diagnosed with CHF or CD/CS should be evaluated for renal cystic disease. Screening for malignant transformation is not indicated in children, because onset occurs generally in the fifth decade. Improved management of children with chronic liver disease means that more patients with fibrocystic liver diseases are reaching adulthood with their native livers, and therefore that adult gastroenterologists will be the ones to diagnose malignancy in these patients [99].

Genetics

Genetic testing is recommended for diagnosis, management, and prognosis [***]. If the clinical picture is suggestive of a given phenotype and the differential diagnosis narrow, known candidate genes can be tested to provide a definitive diagnosis, and genetic counseling should be offered to patients and relatives. When the differential diagnosis is broad, there is a need to cast a wider net to identify the ciliopathy, something now achievable through Next Generation Sequencing (NGS). Given the complexity of these analyses and the inherent difficulty of interpretation, clinical genetic expertise should be sought. According to the identified variant and the specific mode of inheritance familial segregation analysis may be indicated.

Other Fibrocystic Liver Disease and Differential Diagnosis

Perturbations in ductal plate remodeling exist in other conditions than CHF and CD/CS. These conditions are summarized in Table 57.2 [101–105]. Choledochal cysts may be considered part of the “fibrocystic liver disease” spectrum, because extensive fibrosis and other signs of CHF may be seen on biopsy [98]. In general, it is important to consider that there can be extensive phenotypic overlap between fibrocystic liver diseases [98].

Table 57.2 Fibrocystic liver diseases with ductal plate malformation [101–105]

Disease	Characteristics	Symptoms	Diagnosis	Associated syndromes	Treatment
<i>Caroli's disease</i>	No signs of CHF	Cholestasis	US	Extrahepatic bile duct dilatation	Antibiotics for cholangitis
	Saccular or fusiform cystic dilatation to 5 cm of larger and proximal intrahepatic biliary ducts	Cholangitis	MRCP	Choledochal cyst	Partial hepatectomy
	Inheritance unclear but familial cases	No portal hypertension	Liver biopsy		Liver transplantation
<i>Autosomal dominant polycystic liver disease (PCLD)</i>	>20 round and smooth cysts	Asymptomatic	US	Distinct form associated with ADPKD	Somatostatin analogues
	Non communicating	Abdominal mass Pain	MRCP		(Inhibition of cAMP pathway)
	Development of cyst associated with hormonal features	Cyst infection, bleeding	Liver biopsy		Surgical resection
	Woman > men	Biliary obstruction			Rarely liver transplantation
	Gene: <i>SEC63, PRKCSH</i> → <i>Abnormalities of cAMP pathway</i> [101, 102]	No portal hypertension Rare liver failure			
<i>Von Meyenberg complex</i> [103, 105]	Bile ducts hamartomas	Asymptomatic, usually found in liver biopsy for other indication	Incidental	ADPKD	None
	Benign pathology	Rare portal hypertension	MRCP	ARPKD	
	Multiple/unique round uniform cysts 0.1–0.3 cm		Liver biopsy	Risk of CCA	
	Localized close to portal tracts				
<i>Choledochal cyst</i> [104]	Dilatation of common bile duct ± intrahepatic and extrahepatic biliary tree	Conjugated hyperbilirubinemia	US	CHF	Surgical resection
	Classification based on location	Jaundice abdominal pain	MRCP	Risk of CCA	Choledo-enterostomy
	Type I–IV: No parenchyma hepatic involvement	Acute complication: perforation, bleeding, infection lithiasis			
	Type V: Multiple cyst dilatation intrahepatic → Caroli's disease 8–53% cases	Long-term complication: biliary cirrhosis and hypertension			

CCA cholangiocarcinoma, US ultrasonography, MRCP magnetic resonance cholangiopancreatography, ADPKD autosomal dominant polycystic kidney disease, ARPKD autosomal recessive polycystic kidney disease, CHF congenital hepatic fibrosis, CCA chromated copper arsenate, cAMP cyclic adenosine monophosphate

Table 57.3 Other causes of liver cysts [106–108]

Disease	Characteristics	Symptoms	Diagnosis	Treatment
<i>Solitary hepatic cyst, non-communicating</i>	<p>Delimited</p> <p>No communication with biliary duct</p> <p>Right lobe</p> <p>No associated cysts in viscera</p>	<p>Asymptomatic</p> <p>Complications: infection; perforation, obstruction, neoplastic degeneration</p>	<p>Clinical and MRCP</p> <p>Avoid biopsy → infectious risk</p>	<p>Surgery: [106] laparoscopic fenestration or total resection or hepatectomy; [107, 108]</p>
<i>Obstructive bile duct dilatation</i>	<p>Stones inside ducts or stricture of ducts from extrabiliary cause (neoplasia; pancreatitis)</p>	<p>Asymptomatic</p> <p>Complication: Cholestasis; cholangitis, perforation</p> <p>Signs of primary disease causing obstruction</p>	<p>Clinical</p> <p>MRCP</p> <p>US</p> <p>Signs of primary disease</p>	<p>Surgery</p> <p>Treatment of primary disease</p>
<i>Parasitic</i>	<p>Acute symptoms</p>	<p>Acute</p>	<p>Hyper eosinophilia MRI, US</p>	<p>Antimicrobials</p>

US ultrasonography, MRCP magnetic resonance cholangiopancreatography

Since fibrosis is the hallmark of most liver diseases, the differential diagnosis is wide and includes both congenital and acquired diseases. As for the presence of intrahepatic cysts, the differential diagnosis is more narrow and summarized in Table 57.3 [106–108].

Management

Treatment of CHF and CD/CS is mostly symptomatic and is mainly directed toward the management of complications, such as recurrent episodes of cholangitis and portal hypertension. The management of portal hypertension is reviewed elsewhere in this volume.

Intrahepatic cholelithiasis is managed with ursodeoxycholic acid and with ERCP and sphincterotomy. Partial hepatectomy for recurrent cholelithiasis has yielded satisfactory results [109–111]. In the case of monolobar CD, partial hepatectomy has also been shown to prevent recurrent, life-threatening cholangitis, with acceptable morbidity [58, 59, 112].

Liver Transplantation

Liver transplantation is the only definite cure for CHF and CD/CS. It is indicated in refractory portal hypertension, severe growth failure, recurrent cholangitis, decompensated cirrhosis and liver failure.

The short- and long-term outcome of liver transplantation in patients with CHF and CD is satisfactory overall. Outcomes for CD/CS reach the current average outcomes of liver transplantation for other indications [51, 58, 59, 112–114].

In patients with PKD requiring renal transplantation, combined liver and kidney transplantation yields better results compared to kidney transplantation alone. It has been shown that the outcome of patients with PKD mostly depends on the severity of liver disease and that major complications, such as sepsis, are more frequent in patients with advanced liver disease. Combined liver and kidney transplantation seems to be the treatment of choice for these patients, since nephrotoxic drugs for isolated liver transplantation prior to kidney transplantation can accelerate renal demise [52, 115–117].

Antifibrotic Agents

Although the prospect of antifibrotic agents is attractive and may prove life-saving or at least postpone liver transplantation for some indications, there is no data to show an effect on the fibrosis of fibrocystic diseases. Fibrocystic diseases differ from other secondary causes of fibrosis in several ways: (1) destruction of abnormal cholangiocytes trigger an inflammatory cascade and (2) peribiliary fibroblasts rather

than contribute to the ECM deposition. Therefore, no extrapolation can be made from evidence garnered in other causes of cirrhosis.

Conclusion and Future Perspectives

Ciliopathies with associated DPM often present with liver disease and portal hypertension. Associated renal disease is frequent and should be sought. An increasing number of disease causing mutations are identified, and sequencing is part of the diagnostic work up of these diseases. However, there is no clear genotype–phenotype correlation. In particular, it is unclear why some ciliopathies present with distal DPM while others show abnormalities of the large, proximal bile ducts. Cholangiocarcinoma is a rare complication with poor outcome. Combined liver and kidney transplantation yields excellent outcomes and is usually the treatment of choice in case of life-threatening complications.

Acknowledgments We gratefully acknowledge Mrs. Sylvia Udry-Moulin and Dr. Véronique Raies-Dauve for their helpful assistance with illustrations, Dr Makrythanasis for his help with genetics, Dr. Anooshiravani-Dumont for providing illustrative imaging, and Dr. Rougemont for sharing examples of histology.

List of Abbreviations

BSEP	bile salt export pump
CLDN1	Claudin-1
CLDN2	Claudin-2
FHC	familial hypercholanaemia
FIC	familial intrahepatic cholestasis syndrome
FXR	farnesoid X receptor
GGT	gamma-glutamyltransferase
HCC	hepatocellular carcinoma
IE	ileal exclusion
LT	liver transplantation
MDR3	Multi-drug Resistance Protein 3
PEBD	partial external biliary diversion
SPAD	single pass albumin dialysis
TJP2	Tight Junction Protein 2
UDCA	Ursodeoxycholic acid
ZO	zona occludens

Introduction

Two main mechanisms of cholestasis have been so far identified, which can be either hepatocellular or obstructive in origin affecting the biliary structures. Hepatocellular cholestasis is considered to be due to alterations in bile formation and transportation of bile salts and other components of bile at the cellular level involving multiple mechanisms. Obstructive cholestasis on the other hand is due to bile duct injury at either extra and/or intrahepatic level.

To date, four major types of familial intrahepatic cholestasis (FIC) have been identified; associated with mutations in genes encoding proteins involved in the hepatocellular

transport and structure. These are FIC1 deficiency, bile salt export pump (BSEP) deficiency, multidrug resistance protein 3 (MDR3) deficiency, and most recently tight junction protein 2 (TJP2) deficiency. The inheritance pattern in each case is autosomal recessive. Presentation is usually within the first year of life for the more severe forms in either recurrent, such as FIC1, or progressive form such as BSEP, TJP2, and MDR3 deficiency. Irregularities in bile formation and transportation can lead to disturbance in the enterohepatic circulation with bile salt retention and cholestasis. Cholestatic syndromes can affect solely the liver but can also have multiorgan involvement (Table 58.1).

FIC1 Deficiency

Familial intrahepatic cholestasis protein 1 (FIC1) deficiency is an autosomal recessive condition with a wide phenotypic spectrum extending from mild recurrent to severe liver disease. FIC1 deficiency was initially called Byler's disease, after the Amish family in which it was first described. Furthermore, the term Byler bile has been used as the description of coarsely granular canalicular bile seen in FIC1 deficiency on transmission electron microscopy.

It is characterized by hepatocellular cholestasis with low serum levels of γ -glutamyltransferase (GGT) activity and normal cholesterol levels. Presentation can be early on in life with recurrent cholestatic episodes and eventually progress to cirrhosis [1, 2]. Less severe disease can, however, present in adulthood. Presenting features consist of cholestasis, low serum albumin, epistaxis, and splenomegaly.

FIC1 is the protein encoded by the gene *ATP8B1* [3–5], which is located at chromosome 18q21-q22. FIC1 (or ATP8B1) is a P-type ATPase, which is one of several aminophospholipid flippases present in different membranes. Its role in the liver, largely based on a mouse model, is in maintaining the gradient of phosphatidylethanolamine and phosphatidylserine towards the inner leaflet of the cell membrane. A transmembrane balance of lipids appears to be required in

the presence of the high bile salt concentration in the canaliculus [6]. The normal canalicular membrane requires a high degree of detergent resistance in order to prevent damage from the detergent effect of bile itself. Paulusma et al. showed that by ex vivo infusion of bile acids in the knockout mouse, the extraction of aminophospholipids was greatly increased. In the human liver, several proteins are not present, or are in reduced quantities, in the canalicular membrane of patients with FIC1 deficiency. This observation still does not account for the cholestasis, as no transporter critical to bile formation has been identified to be absent. It appears more likely that these proteins are malfunctioning in an altered lipid environment of the canalicular membrane. As FIC1 deficiency is primarily characterized by cholestasis, studies have attributed this phenotype to a defective farnesoid X receptor (FXR) signalling pathway [7, 8]. Other groups, however, suggested that impaired FXR activity is secondary to cholestasis and not responsible for the phenotype [9]. The activity of FXR and its target genes remained uninterrupted in FIC1-depleted Caco-2 cells, created using small hairpin RNA and small interfering RNA, respectively, suggestive of an unimpaired FXR signalling mechanism in FIC1-deficient patients [10, 11]. In view of a proportion of phenotypically FIC1-like patients in whom no mutations were identified, a study looked into promoter and 5' untranslated (5'-UTR) regions affecting gene regulation in human liver and small intestine tissue by 5' rapid amplification of cDNA ends. Expression levels of *ATP8B1* transcripts were determined by quantitative reverse-transcription polymerase chain reaction (qRT_PCR) and compared with the non-variable part of *ATP8B1*. Twelve different splicing variants and four novel untranslated exons located up to 71 kb upstream of the previously published exon 1 were identified in both tissue types. A number of transcription start sites were identified and the proximal promoter upstream of the major transcription start sites was also proven to be an essential regulatory element responsible for 70% of total *ATP8B1* transcriptional activity. In vitro, the main promoter was shown to drive constitutive *ATP8B1* gene expression independent of bile acids [12].

Altered gene expression demonstrated in extrahepatic sites may be contributory to the multisystemic nature of this

cholestatic syndrome. Other disease features include diarrhea, malabsorption of fat-soluble vitamins, hearing loss, pancreatitis, renal tubular acidosis, delayed puberty, and growth failure. The multisystemic nature of the disease is supported by the widespread expression of the *ATP8B1* gene including the liver, pancreas, kidney, and more widely in the small intestine [5].

Liver histology changes consist of cholestasis with bile plugs, periportal biliary metaplasia of hepatocytes in the absence of ductular proliferation in the portal tracks (Figs. 58.1, 58.2, and 58.3).

Early-onset patients, without treatment, usually progress to end-stage liver disease by early adulthood. First-line treatment includes antipruritic agents such as ursodeoxycholic acid (UDCA) [13], fat-soluble vitamin supplementation, and nutritional support. Failure of medical treatment would lead to first-line surgical treatment, which is currently partial external biliary diversion (PEBD), a technique that diverts an unknown proportion of bile externally. The consequences of

Fig. 58.1 Liver biopsy from a 20-year-old patient with *ATP8B1* disease/FIC1. Hepatocytes are small and without anisocytosis. There is canalicular cholestasis. Of note, there is pale-staining bile within the canaliculi (H&E x400 magnification)

Fig. 58.3 Evident canalicular expression of CD10 (x400 magnification)

this procedure certainly include interruption of the enterohepatic circulation of bile acids [14–17]. An external stoma can also be formed by using the appendix creating a cholecystoappendicectomy as reported by Rebhandl et al. [18]. Another alternative is ileal exclusion (IE), which has also been performed in cases with previous cholecystectomy or as rescue treatment [2, 15, 19, 20].

Liver transplantation (LT) is the next treatment option for these patients [16] but some extrahepatic symptoms will not improve, such as growth, and some may even become aggravated, such as diarrhea [14], liver steatosis, or kidney disease. Some of these patients may end up requiring multi-organ transplantation including liver, small bowel, kidneys, and pancreas (personal data).

BSEP Deficiency

The major bile salt transporter of the canalicular membrane level is the BSEP, which is encoded by the gene *ABCB11* [21]. The clinical condition associated with bile salt transport deficiency was previously known as “Byler’s syndrome”. The phenotype of BSEP-deficient patients can also vary from a mild benign recurrent intrahepatic cholestasis (BRIC) to a more severe type requiring LT [22–24]. *ABCB11*, expressed only in the liver, encodes BSEP; a member of the adenosine triphosphate (ATP)-binding cassette (ABC) family of transporters responsible for the transport of bile acids across the canalicular membrane. The locus for *ABCB11* is at chromosome 2q24 with the most common European mutations being D482G (c.1445A>G) and E297G (c.890A>G) [21, 23]. BSEP deficiency leads to accumulation of bile salts within hepatocytes and has a subsequent effect on hepatocellular function. As anticipated, it has also been shown to have significant affinity for some of the main bile salts in human bile, such as glycocholate, taurocholate, and chenodeoxycholate [25].

Severe BSEP deficiency presents within the first year of life and although variable, it is usually a non-relapsing severe progressive cholestasis and pruritus leading to fibrosis. Birth weight can be below normal range, especially in the non-D482G>E patients [22]. Serum bilirubin levels are not necessarily reflective of the degree of cholestasis as bilirubin is transported separately from bile salts. Like FIC1 deficiency, BSEP-deficient patients demonstrate low GGT activity but with a trend to higher cholesterol, significantly raised transaminases (>threefold higher compared to FIC1 deficiency), alpha-fetoprotein, and serum bile acid concentrations. Other biochemical indices include fat-soluble vitamin deficiencies manifesting with coagulopathy and rickets. Gallstones have been reported in up to 32% of patients [22]. Serum bile acid profiles demonstrate a high cholic acid to chenodeoxycholic acid ratio as reported in FIC1 patients. Reduced biliary bile salt concentration in BSEP patients is similar to that in progressive familial cholestasis (PFIC1) and in direct contrast to MDR3-deficient patients [3, 26, 27].

Severe phenotypes have been associated with mutations leading to protein truncation or failure of protein production. In a series by Strautnieks et al., missense mutations were identified in 79% of patients, many affecting protein processing and trafficking or protein structure [28]. Previous reports of *ABCB11* missense mutations and single-nucleotide polymorphisms showed pre-messenger RNA (mRNA) splicing subsequently causing reduction in mRNA levels in a significant number of cases. These defects at the protein or mRNA level can have a detrimental impact in BSEP function [28].

Liver histology features consist of increased lobular inflammation and portal fibrosis, giant cell transformation of

Fig. 58.4 Liver biopsy from a 7-month-old patient with *ABCB11* disease/BSEP deficiency. There is bridging fibrosis and partial nodular transformation of the parenchyma (not shown). Hepatocytes show giant cell change and canalicular cholestasis. Lobular inflammation is present. BSEP immunostaining shows absence of canalicular expression, whilst canalicular GGT expression is preserved (not shown) (H&E stained slide at x200 magnification)

hepatocytes, and neonatal hepatitis with finely filamentous bile. Absence of liver immunohistochemistry for BSEP can assist in the diagnostic process [23, 29] (Fig. 58.4). Immunohistochemically detectable BSEP expression does not exclude functional BSEP deficiency [30]. In a previous series, 28% of BSEP patients analysed exhibited some degree of BSEP staining and, in a small minority, expression was even considered normal [23].

Hepatocellular carcinoma (HCC) or cholangiocarcinoma have been reported in a number of children on the background of severe neonatal hepatitis [31, 32] or proven BSEP deficiency [23, 32]. The risk appears to be higher in patients with two protein-truncating mutations (38 vs 10%) compared to other genotypes. The exact mechanism of malignancy remains unclear, though further insight to the development of these tumours has been gained recently [33].

Treatment options for BSEP deficiency include antipruritic agents such as UDCA, rifampicin; liver enzyme inducers (phenobarbitone), nutritional support, and fat-soluble vitamin supplementation, where indicated. Partial external biliary diversion, ileal exclusion (IE) and LT are all recommended surgical treatment options [16, 20, 34, 35]. Hepatocellular malignancy remains an indication for early LT in BSEP patients. Patients with biallelic truncating mutations warrant close monitoring with liver ultrasonography and serum alpha-fetoprotein levels. Overall in terms of prognosis, patients with D482G mutation developed portal hypertension less frequently, developed fibrosis at an older age, and underwent LT at an older age as well [22].

Recurrence of symptoms after LT has been described in BSEP-deficient patients, in contrast to other FIC syndromes. Jara et al. reported recurrence of cholestasis and pruritus following LT in BSEP patients with no evidence of cellular rejection on liver biopsy in 2009 [36]. In the same year, BSEP antibodies in the serum and at the hepatocyte canalicular membrane of a single patient who underwent two liver transplants were described [37]. The mechanism of action is thought to be that anti-BSEP antibodies form, which bind to an epitope in the intracanalicular domain of BSEP and subsequently block the function of the bile acid transporter. A multicentre series of six patients with recurrence of disease [38] was reported in 2010. In all of these patients, treatment was extremely problematic, four underwent a repeat LT, and various management protocols were suggested. All reports have identified mutations (splice site, missense, truncating) leading to absence of BSEP protein expression on immunostaining. Modifications in immunosuppression, plasmapheresis, intravenous immunoglobulin courses, and single-pass albumin dialysis were used in isolation or jointly with limited effect in patients' symptoms. Following the identification of BSEP antibodies in post-LT BSEP deficiency patients with cholestasis in the absence of rejection, an antibody-based treatment was suggested as potentially beneficial. Two cases of patients with BSEP deficiency following LT, had demonstrated evidence of functional BSEP deficiency treated successfully with two repeated 4-week courses of anti-cluster of differentiation CD20 monoclonal antibodies were subsequently reported [39, 40].

TJP2 Deficiency

Since in one third of patients with normal GGT cholestasis mutations in either *ABCB11* or *ATP8B1* have not been identified [26], a cohort of 33 cholestatic children with relatively low-serum GGT levels were studied recently [41]. Twelve patients from eight consanguineous families with novel protein truncating mutations in the *TJP2* gene were identified. The phenotype of these patients consists of early presentation within the first couple of months of life with low-serum GGT and nine of them underwent LT by their first decade of life. Patients can develop portal hypertension, persistent pruritus, and malabsorption. A single patient died at 13 months. Liver immunohistochemical findings consist of lack of TJP2, reduced staining of Claudin-1 (CLDN1) with normal distribution of Claudin-2 (CLDN2), both proteins essential to cellular tight junctions (Figs. 58.5, 58.6, and 58.7). On transmission electron microscopy, elongation of the tight junctions with sparsity of the zona occludens (ZO) is also seen. Extrahepatic involvement is present in some cases and

Fig. 58.5 Liver biopsy from a 4-year-old patient with TJP2 disease. There is extensive bridging fibrosis (not shown). Hepatocytes are oedematous and show rosetting. Canalicular cholestasis is present (H&E x200 magnification)

Fig. 58.7 Absence of canalicular TJP2 expression with expression of canalicular BSEP (x400 magnification)

Fig. 58.6 Absence of canalicular TJP2 expression (x400 magnification)

consists of chronic respiratory disease or neurological complications such as subdural haematomas. Mutations in the *TJP2* gene have been previously associated with familial hypercholanemia (FHC), a non progressive cholestatic disorder, described in the Amish population [42]. In that report, out of all 17 individuals with FHC, screened 11 patients in eight families were found homozygous for an incompletely penetrant missense mutation in *TJP2*, with alterations in the cellular bile acid concentration gradient.

Treatment consists of supportive choleric agents, fat-soluble vitamin supplementation, nutritional support, PEBD,

and subsequently LT. No liver malignancy has been so far described in this newly defined PFIC group.

MDR3 Deficiency

This type of FIC is caused by a variety of mutations in the ATP-binding cassette subfamily B member 4 (*ABCB4*); the gene encoding MDR3 [43]. It is also inherited in an autosomal recessive pattern. *ABCB4* has been mapped to the 7q21–36 region, and it codes for a floppase responsible for phosphatidylcholine (PC) [44] translocation across the canalicular membrane. Defective PC translocation leads to a lack of PC in bile. The absence of PC inhibits the chaperoning of bile acids through micelle formation, leading to damage to the biliary epithelium and cholangiopathy. Biliary phospholipid levels are significantly reduced and biliary bile salt-to-phospholipid and cholesterol-to-phospholipid ratios are significantly higher in affected individuals when compared with wild-type bile [45].

MDR3 deficiency causes a spectrum of liver diseases such as cholesterol cholelithiasis, adult biliary cirrhosis, low phospholipid-associated cholelithiasis syndrome (LPAC), transient neonatal cholestasis, intrahepatic cholestasis of pregnancy (ICP) and drug-induced cholestasis [46–52]. In severe MDR3 deficiency, symptoms can manifest within the first year, but not usually as neonatal jaundice, and gradually progress towards liver cirrhosis and end-stage liver disease within the first few years of life [1, 53, 54]. Patients with a single affected copy of the gene can develop symptoms under particular circumstances, such as pregnancy, while otherwise they may remain asymptomatic [55, 56].

Fig. 58.8 Liver biopsy from a 1-year old child with MDR3 deficiency/ABCB4 disease. There is a cholangiopathy manifested by cholangiocyte disarray and vacuolation. Immunohistochemistry demonstrated an absence of canalicular MDR3 expression (not shown) (H&E x200 magnification)

Liver histology demonstrates expansion of portal tracts, bile duct proliferation, bile plugs, and portal fibrosis with mixed inflammatory infiltrate (Fig. 58.8). Cytokeratin immunostaining can be confirmatory of the ductular proliferation, and MDR3 immunohistochemistry can be absent or markedly reduced at the canalicular membrane in affected individuals [57].

MDR3 deficiency is differentiated from the other three FIC types at a biochemical level by an elevated serum of GGT. Biochemical profile also consists of normal serum cholesterol and moderately raised concentration of serum primary bile salts [27].

First-line management, as in the other FIC types, is with UDCA and other antipruritic and choloretic agents. UDCA seems to be very effective in milder cases and it may also prevent disease progression in these cases. LT remains the treatment of choice for the nonresponders.

Conclusion

Over the past few years, our understanding of pediatric cholestatic disorders has significantly improved. Through the latest gene-sequencing techniques (targeted re-sequencing and/or whole exome sequencing) and careful patient selection, we have managed to identify causative genes for cholestatic syndromes in most patients and highlight the mechanism of action of the encoded proteins at a cellular level. This enables physicians to characterize and treat these patients more efficiently although new challenges keep appearing such as recurrence of BSEP deficiency after LT.

Binita Maya Kamath

Introduction

Alagille syndrome (ALGS) is an autosomal dominant disorder that affects the liver, heart, face, eyes, skeleton, kidneys, and vasculature [1–6]. ALGS is primarily caused by mutations in the gene *JAGGED1* (*JAG1*) and in a second gene *NOTCH2*, in a minority of cases. Previously, ALGS was estimated to have a frequency of 1 in 70,000 live births; however, the advent of molecular testing has proven this to be an underestimate, and this figure is closer to 1 in 30,000 [7]. There is significant variability in the extent to which each of the aforementioned organ systems is affected in an individual, if at all [8, 9]. This variability in organ involvement requires the managing physician to have an understanding of the breadth and interplay of the variable manifestations. Due to the original descriptions of ALGS as a hepatic disease, with cholestasis as a central feature, the condition has been primarily managed by gastroenterologists and hepatologists, but frequently requires a multidisciplinary approach.

Clinical Manifestations of Alagille Syndrome

The hallmark clinical feature of ALGS is extreme variability. There is variability in the severity of organ system involvement in an individual, and also between those sharing the same disease-causing mutation. Typical patterns of organ involvement in ALGS are described below, but clearly not all individuals have manifestations in all systems.

Hepatic

The majority of ALGS patients who are symptomatic with liver disease present in the first year of life with cholestasis, classically with neonatal conjugated hyperbilirubinemia and high γ -glutamyltransferase (GGT). During childhood, elevations of serum bilirubin up to 30 times normal and serum bile salt elevations of 100 times normal are common. Cholesterol levels can be staggering and may exceed 1000–2000 mg/dL. However, this high level of plasma cholesterol is largely associated with lipoprotein-X [10]. Lipoprotein-X is in the low-density lipid range and resists oxidation, thereby protecting against atherosclerosis. Thus, the hypercholesterolemia of ALGS does not appear to carry an increased risk of cardiovascular disease [11, 12]. Hepatic synthetic function is usually well preserved in ALGS.

Physical examination findings in children with ALGS and liver disease include hepatomegaly early on and splenomegaly in the majority over time. The pruritus seen is among the most severe of any liver disease. It rarely is present before 3–5 months of age but is seen in most children by the second year of life, even in some who are anicteric. Multiple xanthomas are a common sequelae of severe cholestasis associated with ALGS and correlate with a serum cholesterol level greater than 500 mg/dL. Xanthomas typically form on the extensor surfaces of the fingers, the palmar creases, the nape of the neck, the ears, the buttocks, and around the inguinal creases (Fig. 59.1a, b). Xanthomas are disfiguring and occasionally interfere with fine motor function when they occur on the fingers.

The natural history of the liver disease in ALGS has a unique course. For those children with significant cholestasis in infancy, the hepatic involvement generally follows a more severe course in the first 5 years of life after which it appears to improve for most patients. This spontaneous improvement is poorly understood, but well documented. In approximately 10–20%, the cholestasis persists unabated or progresses to end-stage liver disease (ESLD). For those children with mild cholestasis or hepatitis in early childhood, there is no

Fig. 59.1 a, b Xanthomas on the hands of a child with Alagille syndrome

progression of liver disease in later life. It is difficult to predict early on, which ALGS children with cholestasis in early childhood will eventually require liver transplantation and which will spontaneously improve. There are no known genotypic or radiologic predictors of liver disease progression in ALGS. A review of laboratory data of ALGS patients showed that bilirubin and cholesterol levels before the age of 5 may aid in distinguishing patients at high and low risk of problematic cholestasis in later childhood. More specifically, mean levels of total bilirubin (TB) > 6.5 mg/dL (111 μ mol/L), conjugated bilirubin (CB) > 4.5 mg/dL (77 μ mol/L), and cholesterol > 520 mg/dL (13.3 mmol/L) are strongly associated with severe liver disease in later life, whereas levels lower than this are associated with a good hepatic outcome [13]. These data may assist the clinician in predicting which children might go on to resolve their cholestasis, and thereby avoid unnecessary liver transplantation in young children with ALGS.

Of note, there have been several case reports of hepatocellular carcinoma in patients with ALGS, including as young as 4 years of age [14–16]. Most but not all patients who developed hepatocellular carcinoma also had progressed to cirrhosis.

Bile duct paucity is the hallmark histopathologic feature of ALGS. The normal bile duct to portal space ratio is between 0.9 and 1.8. Bile duct paucity is defined as a ratio of bile duct to portal tract that is less than 0.9. Bile duct paucity, however, is not present in infancy in many patients ultimately shown to have ALGS. Several studies of serial liver biopsies have demonstrated that paucity is more common later in infancy and childhood [4, 17, 18]. Emerick et al. found that paucity was present in 60% of 48 infants younger than 6 months of age but in 95% of 40 who underwent biopsy after 6 months [4].

Cardiac

In a comprehensive evaluation of 200 ALGS subjects, cardiovascular involvement was present in 94% [19], with right-sided lesions being the most prevalent. Pulmonary artery anomalies are the most common abnormality identified (76%) and may occur in isolation or in combination with structural intracardiac disease [19]. The most common congenital defect is tetralogy of Fallot (TOF), which occurs in 7–12% [4, 19]. Approximately, 40% of patients with ALGS demonstrating TOF have pulmonary atresia, representing a more severe phenotype. Cardiac disease accounts for nearly all of the early deaths in ALGS. Patients with intracardiac disease have approximately a 40% rate of survival to 6 years of life, compared with a 95% survival rate in patients with ALGS without intracardiac lesions [4].

Facial Features

A characteristic facial appearance is one of the most penetrant features of ALGS (for *JAG1*-associated disease). These features include a prominent forehead, deep-set eyes with moderate hypertelorism, a pointed chin, and a saddle or straight nose with a bulbous tip. The combination of these features gives the face a triangular appearance (Fig. 59.2). The facies may be present early in infancy but in general becomes more apparent with increasing age. In adults, the forehead is much less prominent, and the protruding chin is more noticeable so that the face loses the triangular appearance.

It should be noted that among the few patients reported to date, there appears to be a lower penetrance of characteristic ALGS facial features in patients with *NOTCH2* mutations, and it is therefore a less valuable diagnostic tool in this group [20].

Fig. 59.2 Facial features of Alagille syndrome

Ophthalmologic

The ocular abnormalities of patients with ALGS do not generally affect vision but are important as diagnostic tools. A large and varied number of ocular abnormalities have been described, though posterior embryotoxon is the most important diagnostically. Posterior embryotoxon is a prominent, centrally positioned Schwalbe's ring (or line) at the point at which the corneal endothelium and the uveal trabecular meshwork join and is visible on slit-lamp examination. Posterior embryotoxon occurs in 56–88% of patients with ALGS and was also detected in 22% of children evaluated in a general ophthalmology clinic [21]. Posterior embryotoxon is seen in other multisystem disorders such as chromosome 22q deletion, as well. The Axenfeld anomaly, seen in 13% of patients with ALGS, is a prominent Schwalbe's ring with attached iris strands and is associated with glaucoma. Optic disk drusen identified using ocular ultrasonography has been described in ALGS patients with high prevalence but this test is not routinely performed [22, 23].

Skeletal Involvement

The most characteristic skeletal finding is the sagittal cleft or butterfly vertebrae, which is found in 33–87% of patients with ALGS [4, 24–26]. This relatively uncommon anomaly may occur in normal individuals and is also seen in other multisystem abnormalities, such as 22q deletion syndrome and vertebral defects, anal atresia, tracheoesophageal fistula, and radial and renal defect (VATER) syndrome. The affected vertebral bodies are split sagittally into paired hemivertebrae because of a failure of the fusion of the anterior arches of the vertebrae. Generally, these are asymptomatic and of no structural significance.

Other associated skeletal abnormalities include an abnormal narrowing of the adjusted interpedicular space in the lumbar spine, a pointed anterior process of C1, spina bifida occulta, fusion of the adjacent vertebrae, hemivertebrae, the absence of the 12th rib, and the presence of a bony connection between ribs. In addition, supernumerary digital flexion creases have been described in one third of patients [27].

Severe metabolic bone disease with osteoporosis and pathologic fractures is common in patients with ALGS. Recurrent fractures, particularly of the femur, have been cited as an indication for liver transplantation. Preliminary survey data suggest that there is a propensity towards pathologic lower extremity long bone fractures in ALGS [28]. A number of factors may contribute to osteopenia and fractures, including severe chronic malnutrition, vitamin D and vitamin K deficiency, chronic hepatic and renal disease, and magnesium deficiency. It is not yet known whether there is an intrinsic defect in cortical or trabecular structure of the bones

in patients with ALGS. Olsen evaluated bone status in prepubertal children with ALGS and identified significant deficits in bone size and bone mass that were related to fat absorption but not dietary intake [29].

ALGS patients are frequently found to have short stature; this is likely multifactorial in origin resulting from cholestasis and malabsorption, congenital heart disease, and genetic predisposition. A validated growth curve for ALGS individuals is not yet available.

Renal Involvement

Renal involvement in ALGS has been widely reported on an individual case basis or as part of a larger report on general features of ALGS. The prevalence of renal involvement in larger series ranges from 40 to 70% such that it has been proposed that renal anomalies now be considered a disease-defining criterion in ALGS. In a large retrospective study, there was a prevalence of 39% of renal anomalies or disease. The most common renal involvement was renal dysplasia (58.9%), followed by renal tubular acidosis (9.5%), vesicoureteric reflux (8.2%), and urinary obstruction (8.2%) [30]. Hypertension in patients with ALGS can be of cardiac, vascular, or renal etiology.

Functional and structural evaluation of the kidneys should be undertaken in all patients. Renal function should be reassessed during the evaluation for liver transplantation.

Vascular Involvement

Unexplained intracranial bleeding is a recognized complication and cause of mortality in ALGS. Intracranial bleeds occur in approximately 15% of patients; in 30–50% of these events, the hemorrhage is fatal [4, 25]. There does not seem to be any pattern to the location and/or severity of the intracranial bleeding, which ranges from massive fatal events to asymptomatic cerebral infarcts. Epidural, subdural, subarachnoid, and intraparenchymal bleeding have been reported. The majority of this bleeding has occurred in the absence of significant coagulopathy or trauma. Lykavieris studied a cohort of 174 individuals with ALGS and identified 38 patients (22%) who had 49 bleeding episodes [31]. All these hemorrhages occurred in the absence of liver failure, with normal median platelet counts and prothrombin times, suggesting that ALGS patients may be at particular risk for bleeding.

Underlying vessel abnormalities in the central nervous system that could explain the occurrence of bleeding and stroke in ALGS have been described in some of these patients [5, 25, 32]. Aneurysms of the basilar and middle cerebral arteries and various internal carotid artery anomalies have

been described. Moyamoya disease (progressive intracranial arterial occlusive disease) also has been previously described in several children with ALGS. Emerick et al. prospectively studied 26 patients with ALGS using magnetic resonance imaging (MRI) with angiography of the head. Cerebrovascular abnormalities were detected in 10 of 26 patients (38%). One hundred percent of symptomatic patients had detected abnormalities, and 23% of screened, asymptomatic patients had detected anomalies [32]. These results suggest that MRI with angiography is useful in detecting these lesions and may have a valuable role in screening for treatable lesions such as aneurysms. The current recommendation is for all asymptomatic ALGS patients to have a screening MRI/magnetic resonance (MR) angiography as a baseline and for physicians to have a low threshold for reimaging ALGS patients in the event of any symptoms, head trauma, or suspicious neurologic signs and prior to major surgical interventions.

Systemic vascular abnormalities have also been well documented in ALGS. Aortic aneurysms and coarctations, renal artery, celiac artery, superior mesenteric artery, and subclavian artery anomalies have all been described. In the evaluation of a large cohort of ALGS patients, 9% (25 of 268) with noncardiac vascular anomalies or events were identified [5]. In addition, vascular accidents accounted for 34% of the mortality in this cohort. These findings suggest that vascular abnormalities have been under-recognized as a potentially devastating complication of ALGS.

Genetics of Alagille Syndrome

ALGS is inherited in an autosomal dominant manner, with highly variable expressivity. It is a genetically heterogeneous disorder and may be caused by mutations in either *JAG1* (seen in 94% of clinically defined probands) or *NOTCH2* (seen in approximately 1%) [33–35]. Jagged1 is a cell surface protein that serves as a ligand for the four Notch receptors (Notch1, 2, 3, and 4), and together these proteins begin the cascade of events that turn on the Notch signaling pathway. The Notch signaling pathway is involved in the determination of cell fate and as such plays a crucial role in normal development.

Gene Identification and Mutation Analysis

JAG1 was identified as the cause of ALGS in 1997 [33, 35]. To date, more than 430 *JAG1* mutations have been identified in patients with ALGS. Utilizing current screening techniques, the mutation detection rate is 94% [36]. The frequency of sporadic mutations (i.e., new in the proband) is approximately 60–70%. Approximately, 75% of ALGS patients have *JAG1* protein-truncating (frameshift or nonsense or splice-site) mutations [8, 36–38]. Approximately,

7% have gene deletions. Missense mutations are identified in 15%. Haploinsufficiency, a decrease in the amount of the normal protein, is hypothesized to be the mechanism causing ALGS.

ALGS associated with *NOTCH2* mutations was described in 2006. Thus far, ten patients with unique *NOTCH2* mutations have been described [20, 34].

A small fraction (3–5%) of ALGS individuals have deletions of chromosome 20p. Genome-wide single-nucleotide polymorphism (SNP) analysis of 25 patients with ALGS revealed 21 deletions ranging from 95 kb to 14.62 Mb [39]. Patients with deletions greater than a critical 5.4 Mb region had additional phenotypic features not usually associated with ALGS such as developmental delay and hearing loss.

Genotype–Phenotype Correlations

JAG1 Mutations

Although the ALGS phenotype is highly variable, there is no apparent correlation with *JAG1* genotype in the majority of patients. A study of 53 *JAG1* mutation-positive relatives of a cohort of ALGS probands demonstrated that only 53% met the clinical criteria for a diagnosis of ALGS, including 11 of 53 with obvious clinical features that would easily have led to a diagnosis of ALGS and 17 of 53 (32%) who had mild features that would have only been apparent on targeted evaluation following the diagnosis of a proband in their family (i.e., discovery of elevation of liver enzymes or posterior embryotoxon in an asymptomatic individual) [7]. This underscores the variable clinical consequences associated with a *JAG1* mutation and suggests the presence of genetic modifiers.

NOTCH2 Mutations

To date ten individuals with complete or partial features of classical ALGS have been found to have *NOTCH2* mutations [20, 34]. From a phenotypic standpoint, individuals with *NOTCH2*-related ALGS appear to have less penetrance of the characteristic facial features and less skeletal involvement.

Diagnostic Considerations

Clinical Diagnostics

The majority of infants with ALGS are evaluated for conjugated hyperbilirubinemia in the first weeks or months of life. ALGS is occasionally misdiagnosed as biliary atresia because of the overlap of biochemical, scintigraphic, histologic, and cholangiographic features. Serum bilirubin, bile acid, and GGT levels typically are elevated in both of these

disorders. Ultrasound findings in both conditions may reveal small or apparently absent gallbladders. Excretion of nuclear tracer (diisopropylacetanilido iminodiacetic acid; DISIDA) into the duodenum excludes biliary atresia, but non-excretion of tracer is also possible in ALGS. There was no excretion of scintiscan in 61% of 36 infants with ALGS [4].

Although a liver biopsy is not mandatory to diagnose ALGS, it remains an important step in differentiating between ALGS and biliary atresia. In biliary atresia, bile duct proliferation is the typical histologic lesion. In ALGS, paucity is evident in 60% of infants younger than 6 months but in 95% of older patients [4]. Unfortunately, there may be a normal number of ducts early in the course of biliary atresia and also in some patients with ALGS, and bile duct proliferation occasionally occurs in infants with ALGS. Giant cell hepatitis is also seen in both disorders. Finally, it should be noted that bile duct paucity, if present, is not diagnostic of ALGS and other diagnoses should be considered (e.g., alpha-1-antitrypsin deficiency, cystic fibrosis, cytomegalovirus infection, etc.).

An operative cholangiogram is the gold standard procedure to evaluate the extrahepatic and intrahepatic biliary tree; however, this can also be misleading in ALGS. The extra- and intrahepatic ducts are extremely small in patients with ALGS, and the cholangiogram commonly does not demonstrate communication proximally. In 37% of 19 cholangiograms in infants with ALGS, there was no opacification of the proximal extrahepatic ducts, and, in another 37%, the proximal extrahepatic tree was abnormally small [4]. The intrahepatic ducts were normal in only 10% of 19 infants with ALGS, small or hypoplastic in 16%, and not visualized in 74%. Therefore, even the apparent gold standard test to differentiate ALGS and biliary atresia can be misleading.

Clinical features in extrahepatic organ systems may also help in the diagnostic evaluation. The list of abnormalities identified in the “major” organ systems and the list of other affected organs have grown appreciably. Thus, an echocardiogram, slit-lamp examination, renal ultrasound, and spinal X-ray are essential diagnostic tests when ALGS is suspected. It should be noted that several of the ALGS-defining features are present in normal individuals or other conditions. Heart murmurs are present in 6% of all newborns, posterior embryotoxon appears in 22% of the general population, and butterfly vertebrae are seen in 11% of patients with 22q11 deletion. Furthermore, the facial features of ALGS patients are subtle during the first months of life making this an unreliable diagnostic tool in infancy.

With the advent of molecular testing for ALGS and the broader appreciation of the phenotypic variability, the diagnostic criteria for ALGS have been modified. To make a clinical diagnosis for an index case (proband) in the family, the original Alagille criteria hold, modified only so as no longer to require histology. Thus ALGS can be diagnosed clinically on the basis of cholestasis with at least three features from

the list of characteristic Alagille facies, consistent cardiac disease, posterior embryotoxon, butterfly vertebrae, typical ALGS renal disease, and a structural vascular anomaly. In families with one definite clinically defined proband, other members with only two features should be considered as having ALGS.

Molecular Diagnostics

Molecular sequencing is now widely commercially available for *JAG1* and *NOTCH2* on a limited basis. An evaluation by fluorescence in situ hybridization (FISH) for deletions including the *JAG1* gene will identify these deletions in less than 7% of patients. A molecular diagnosis can assist in an atypical ALGS case and is also useful for genetic counseling and prenatal diagnosis. *JAG1* sequencing identifies mutations in individuals with clinically defined ALGS in the majority of cases (>90%). Individuals that have clinical features of ALGS but are not found to be carrying *JAG1* mutations should have sequence analysis of *NOTCH2* [34].

Once a *JAG1* mutation is identified in a proband, it is simple to test parents and other relatives for the identified mutation. Mutations are inherited from an affected parent in 30–50% of patients, whereas the mutations appear de novo in 60–70% [8, 37]. If a parental mutation is identified, there is a 50% risk for each future offspring to inherit the *JAG1* mutation. However, it should be emphasized that expressivity of the disorder is highly variable, and it is not currently possible to predict disease severity. If no parental mutation is identified, then the recurrence risk is limited to the chance of germ-line mosaicism, which for multiple different disorders is estimated at from 1 to 3%.

Prenatal genetic testing for ALGS is possible if a parental mutation has been identified. This requires amniocentesis or chorionic villous sampling and assessment for a known *JAG1* mutation. Pre-implantation genetic diagnosis has also been successfully performed in ALGS. It is imperative to carefully counsel parents undergoing any type of prenatal testing since there are no genotype–phenotype correlations in ALGS, so it is not possible to make predictions about a child’s clinical course based on the type or presence of a mutation.

Management of Alagille Syndrome

Cholestasis Management

Patients with ALGS present significant management challenges due to profound cholestasis and complex multisystem disease [40, 41]. A sequential and additive approach to medical cholestasis therapy in ALGS is most appropriate. The most commonly used agents are listed in Table 59.1 with common side effects and described below.

Table 59.1 Medications for cholestasis in Alagille syndrome

Medication	Dose	Most frequent side effects
<i>Choleretics</i>		
Ursodiol (Actigall)	10–30 mg/kg/day, divided in 2 doses	Diarrhea, abdominal pain
Phenobarbital; rarely used	5–10 mg/kg/day, divided in 2 doses	Sedation
<i>Other</i>		
Rifampin	10 mg/kg/day, divided in 2 doses (maximum dose 600 mg/day)	Red discoloration of urine, idiosyncratic hypersensitivity reactions, hepatitis
<i>Bile-salt binding agents</i>		
Cholestyramine	240 mg/kg/day, divided into 3 doses; maximum dose of 8 g/day	Constipation, abdominal pain
Colesevelam	Limited pediatric data 625 mg once daily (adult dose)	Constipation
<i>Antihistamines</i>		
Diphenhydramine	5 mg/kg/day, divided into 3–4 doses; maximum 300 mg/day	Drowsiness
Hydroxyzine	2 mg/kg/day, divided in 3–4 doses	Drowsiness
<i>Opioid antagonists</i>		
Naltrexone	Limited pediatric data 0.25–0.5 mg/kg once daily, up to 50 mg daily (adult dose)	Symptoms of opioid withdrawal

The pruritus associated with ALGS cholestatic liver disease can be severe and may occur even without jaundice. Pruritus is often debilitating, disturbing sleep, daily activities, and cognitive development. Conservative management of pruritus entails taking care to keep the skin hydrated with emollients, trimming the fingernails, and taking short baths or showers to limit drying of the skin. Bile flow may be stimulated with choleretics, and ursodiol is the most commonly used agent. The use of ursodiol has been studied in ALGS children with improvement in pruritus, xanthomas, and biochemical markers of cholestasis [42–45]. Therapy with antihistamines may provide some symptomatic relief but are rarely effective alone. Bile-acid-binding resins, such as cholestyramine, are often effective but sometimes not palatable. They are also difficult to administer since they must be given 2 h apart from other medications. Colesevelam may be better tolerated but has not been studied in pediatrics. It should be noted that colesevelam is a very potent bile-acid-binding resin and may severely deplete the concentration of free luminal bile acids resulting in risk of fat-soluble vitamin deficiency, and these levels should therefore be monitored. Rifampin has been comparatively well studied in ALGS [38, 46, 47]. Yerushalmi et al. studied 24 children with severe cholestasis, of whom 6 had AGS, and 92% of the cohort showed a response in improving pruritus [31]. Although rifampin is associated with elevation of serum transaminases, none of these studies reported clinical or biochemical adverse events. Naltrexone has been shown to be effective against pruritus in cholestatic adults. Based on anecdotal experience, it can be useful in the pruritus of ALGS children as well. Newer agents that inhibit apical sodium-dependent transport of bile acids at the enterocyte and interrupt the enterohepatic circulation are currently in clinical trials and offer hope for a new therapy for pruritus.

Biliary diversion has been successful in a number of patients, though it does not appear to be as effective for ALGS

as it does for progressive familial intrahepatic cholestasis [48, 49]. Emerick studied nine ALGS patients with severe mutilating pruritus who underwent partial external biliary diversion (PEBD). Mean pruritus scores were significantly lower 1 year after the procedure, and eight of the nine had only mild scratching when not distracted. Three of the nine also had complete resolution of extensive xanthomas. Biliary diversion should be considered in all ALGS children when medical management of pruritus fails and external diversion appears to be more effective than internal approaches. It should be noted, however, that the outcome of PEBD is poor in the setting of hepatic fibrosis, and therefore a liver biopsy should be considered prior to offering this therapy.

Xanthomas do not require specific treatment unless they interfere with vision, feeding or motor development which is exceptionally rare. As the hypercholesterolemia of ALGS is not atherogenic, dietary modifications or medical therapy are not necessary.

Hepatoportoenterostomy is inappropriate in ALGS and may increase the amount of liver injury and progression to hepatic fibrosis. In a limited retrospective study comparing ALGS patients to matched biliary atresia patients after Kasai procedures, the ALGS cohort had a significantly higher rate of liver transplantation (47 vs. 14%) and sustained higher mortality [50]. These data suggest that the Kasai procedure is not a marker for severe underlying liver disease but that the Kasai procedure itself has a detrimental effect on outcome.

Liver Transplantation

Liver transplantation is required in 21–31% of patients with ALGS based on case series [41]. Several of these series are older, and with current therapies this frequency is likely to

be lower. Indications for transplant in ALGS are ESLD secondary to chronic cholestasis, severe complications of cholestasis such as failure to thrive, portal hypertension, and recurrent fractures.

Liver transplantation in patients with ALGS is complicated by the associated comorbidities, particularly cardiac, renal, and vascular involvement. A detailed renal evaluation is warranted in any ALGS patient prior to liver transplantation including urinalysis, blood pressure, renal ultrasonography, glomerular filtration rate, serum cystatin C and blood gas measurement. If renal impairment is documented, renal-sparing immunosuppressive protocols should be considered. Vascular involvement should be assessed with computed tomography (CT) or MR angiography of the head, neck, and abdomen. Cardiac pre-transplant workup is based on information acquired with echocardiography and electrocardiography. However, the peripheral branches of the pulmonary arteries and the degree of right ventricular hypertrophy are underappreciated using these modalities. Investigators at King's College have suggested a pre-transplant dynamic stress test with dobutamine to stimulate perioperative conditions with concomitant cardiac catheterization [51]. If the patient achieves >40% increase in the cardiac output, then the cardiac reserve is considered adequate for liver transplantation.

Living-related transplantation (LRT) in ALGS requires careful consideration. In general, in North America, LRT has not been offered to donors with a known disease-causing mutation as they may have subclinical liver disease. In Japan, the outcomes from LRT in ALGS in 20 children have been reported and are good with a 1-year survival rate of 80% [52]. On a cautionary note, Gurkan reported two instances in which apparently unaffected parents underwent donor operations that were unsuccessful because of a paucity of duct structures discovered intraoperatively [53]. Therefore, the recommendation in North America is for potential donors to undergo screening for the known mutation in the proband and for them generally not to be used as donors if positive for the mutation.

The survival rate of patients with ALGS undergoing liver transplantation has significantly improved in recent years with careful selection of transplant candidates and better management of concomitant cardiac disease. Combined case series show a 1-year posttransplantation patient survival rate of 79%. A recent report by Arnon et al. from the United Network for Organ Sharing dataset of 461 ALGS who underwent liver transplantation from 1987 to 2008, revealed 1 and 5-year patient survival of 83 and 78%, respectively [54]. Early death in the first 30 days was significantly higher in ALGS patients as compared to biliary atresia patients. Death from graft failure, neurologic, and cardiac complications were also significantly higher in the ALGS cohort.

Nutritional

Failure to thrive and malnutrition need to be addressed aggressively and early on in life. There is significant malabsorption of long-chain fat; therefore, formulas supplemented with medium-chain triglycerides have some nutritional advantage. Many patients are unable to eat enough to provide the substantial quantities of energy required for growth and development, and nasogastric or gastrostomy tube feedings can provide necessary supplementation.

Fat-soluble vitamin deficiency is present in most patients with significant ALGS cholestasis. Oral or parenteral supplementation is necessary for prevention of vitamin deficiencies and their sequelae. Multivitamin preparations may not provide the correct ratio of fat-soluble vitamins; vitamins are best administered as individual supplements tailored to the specific needs of the patient. Close monitoring (every 3–6 months) of fat-soluble vitamin levels is crucial to avoid complications of vitamin deficiencies, particularly in the first years of life.

Cardiac Anomalies

Management of the cardiac involvement in ALGS is clearly lesion specific. In a large ALGS series, cardiac surgery was performed in infancy in 11% [4]. The mortality rates were 33% for those with TOF and 75% for those with TOF with pulmonary atresia. The survival of patients with ALGS with these lesions is markedly lower than for patients (with these lesions) without ALGS. This may be a result, in part, of the common presence of significant stenoses in the distal pulmonary artery or other systemic manifestations of the syndrome. Nonsurgical invasive techniques have been used successfully for patients with ALGS, including valvuloplasty, balloon dilatation, and stent implantation [55, 56]. Heart-lung transplantation has been performed in combination with liver transplantation in a child with ALGS [57].

Other Extrahepatic Disease

As with the cardiac involvement in ALGS, other extrahepatic disease must be managed according to the specific lesion. For the vasculopathy, no ALGS-specific treatments exist for intra- or extracerebral vessel anomalies, and consultation with a vascular surgeon or neurosurgeon must be sought if an anomaly is found. Without longitudinal data available, the risks and benefits of surgery in an isolated intracranial vascular anomaly should be carefully balanced. In the case of known progressive disease, such as Moyamoya, the risk of recurrent stroke usually mandates surgical intervention, and outcomes of this neurosurgery appears to be favourable in Alagille syndrome [58].

Prognosis of Alagille Syndrome

Cardiac, hepatic, and vascular disease account for the majority of deaths in ALGS. The presence of a complex intracardiac anomaly is the only predictor of an excessive early mortality rate, and cardiac anomalies account for the majority of deaths in early childhood. Overall, vascular events account for most of the mortality in ALGS; 34% in a large series [5]. Quiros-Tejeira reported a 72% survival rate in 43 patients at a mean follow-up of 8.9 years in a population in which 47% underwent liver transplantation [26]. Emerick estimated the 20-year survival rate in 92 patients to be 75% overall, 80% for those not requiring liver transplantation, and 60% for those requiring transplantation [4]. For patients with structural intracardiac disease, however, the survival rate was only 40% at 7 years.

Conclusion

To conclude, ALGS is a complex condition in which the molecular basis is well understood but the absence of identified genotype–phenotype correlations and the broad variability poses management challenges. Renal and vascular involvement should likely be included in the diagnostic criteria. As molecular testing becomes more readily available, it is likely that patients with isolated or subtle manifestations will be diagnosed as having ALGS. The discovery of two disease genes and a broader phenotype, which includes individuals with *no* liver disease, suggests that a redefinition of this syndrome is warranted based on molecular defects, possibly reserving the term ALGS for those with liver disease and associated features, as Daniel Alagille originally intended.

RNA	ribonucleic acid
SVR	sustained viral response
TNF- α	tumor necrosis factor alpha

Chronic Hepatitis B**Introduction**

Hepatitis B virus (HBV) infection remains a global health burden with estimated 300–350 million people chronically infected worldwide. Nevertheless, since HBV vaccine has become available for more than 20 years and many countries introduced vaccination programs as a prevention strategy on a regularly basis for young infants, significant reduction of the incidence of acute hepatitis B in children and adolescents has been observed. Unprotected, approximately 90% of HBV-infected infants and 20–25% of those infected in preschool age will develop chronic infection decreasing to a chronicity rate of around 5% for adolescents and adults [1–3]. Despite of a rather benign spontaneous course of the disease during childhood and adolescence, there is a considerable lifetime risk of progressive liver disease, liver cirrhosis, and the development of a hepatocellular carcinoma (HCC), which may eventually reduce life expectancy. Thus, careful long-term monitoring has to be performed, and appropriate treatment options, which unfortunately are not entirely curative at present, have to be considered.

Pathogenesis of Chronic HBV Infection

HBV belongs to a DNA virus family called hepadna viruses. It contains a partially double-stranded DNA genome with about 3200 nucleotides. The minus strand covers four overlapping open reading frames (ORFs): S, for the surface gene encoding three envelope proteins (hepatitis B surface antigen, HBsAg); C, for the core gene encoding the core protein (hepatitis B core antigen, HBcAg); X, for the regulatory X gene; and P, for the polymerase gene encoding the viral DNA polymerase. By using multiple start codons, HBV is able to encode more than one protein from an ORF. After hepatocyte entry by an unknown receptor, the viral envelope is removed, and the nucleocapsid reaches the nucleus,

where the double strand will be completed and converted into a covalently closed circular DNA (cccDNA). This is an important step, because the majority of cccDNA is then organized into nucleosomes forming the viral minichromosome, which is serving as template for the synthesis of the viral mRNA. The transcripts are translated into the viral proteins, and simultaneously reverse transcription leads to the synthesis of a complete minus strand of HBV DNA. The plus strand can then be synthesized again, and the molecule circularizes. Thus, the replication of HBV is similar to that of a retrovirus. The proteins are synthesized and assembled at the endoplasmic reticulum and eventually discharged by vesicular transport as a Dane particle which contains the complete virus. The cccDNA plays a key role in viral persistence, viral reactivation after treatment withdrawal, and drug resistance. It accumulates in the nucleus of the hepatocyte as a stable minichromosome organized by histone and nonhistone viral and cellular proteins [4, 5]. Persistent HBV replication is associated with a high frequency of integration of HBV sequences into the human host liver cell genome. Enhanced DNA replication and DNA damage occurring during chronic inflammation with cycles of cell death and regeneration increase the availability of DNA ends in host genomic DNA and promote the process of viral integration [6]. Furthermore, it is presumed that certain altered cells are susceptible to the development of additional genetic and epigenetic changes that may lead to the development of malignant cell transformation and HCC.

For the understanding of the different phases during the course of the chronic disease, it is important to realize that the virus itself is not primarily pathogenic to the hepatocyte. The mechanism of cell death is generally accepted to be the result of a cytotoxic T-lymphocyte-mediated immune response of the host to the virus. Additionally, it has been shown that some HBV proteins may be able to induce apoptosis. During the transition from the immune tolerant to the immune active phase, a shift from the hepatitis e antigen (HBeAg)-specific Th2 cell tolerance to Th1 cell activation may recognize HBV-related epitopes on hepatocytes resulting in secretion of cytokines such as interleukin (IL)-2 and tumor necrosis factor alpha (TNF- α) and thus activating inflammation [7].

Epidemiology

There are still high endemic countries in Asia, Africa, and some parts of South America with an HBsAg prevalence of more than 8%. The Arabian region, parts of the Eastern hemisphere, and Greenland show a HBV prevalence of 2–7%, and in the Western countries the rate is below 2% [8]. Global immunization programs have been established in many countries, and the HBV infection rate has declined

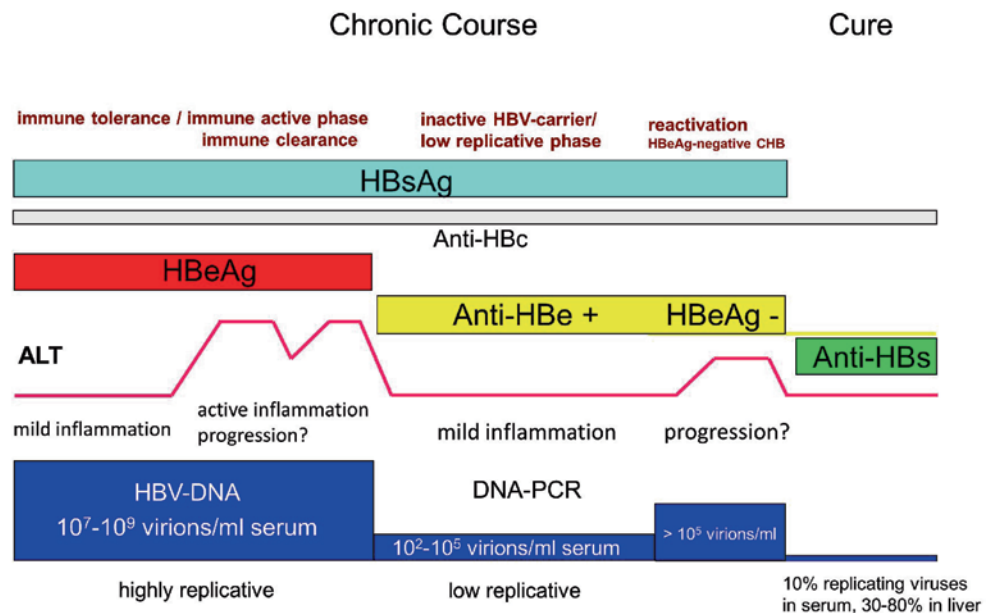

worldwide. Vertical transmission has become the main route of infection; nevertheless, in some areas, HBV may also be a predominant disease in adolescents and adults due to high-risk sexual behavior and drug abuse [9]. Unfortunately, up to 2–15% of perinatal HBV infection of antibody against HBeAg (anti-HBe)- and HBeAg-positive mothers cannot be prevented by active and passive immunization due to intra-uterine infection, vaccine failure, or HBsAg escape mutants [10–12]. Thus, passive and active immunization has to be started immediately after birth in all newborns from HBsAg-positive mothers. HBeAg-positive mothers can be considered to receive treatment with the nucleoside analogues lamivudine or telbivudine in late pregnancy to decrease viral load [13, 14]. After complete immunization, there are no objections against breast feeding. In countries with blood donor screening and serum testing, parenteral transmission does no longer play a significant role. The HBsAg prevalence in children is estimated between 0.02 and 0.03% in Western countries and the USA, in Brazil 0.14% and 0.5% in Taiwan after immunization [1, 15]. Given HBsAg prevalence in pregnant women of 0.4% in Western Europe and an HBV transmission rate of 5–10% despite complete vaccination, 20–40 newborns in 100,000 births may be infected and become a chronic carrier state.

Ten HBV genotypes (A–J) have been documented showing a distinct distribution. Genotypes A and D are predominant in North America, Europe, and India, and genotypes B and C are mostly found in Asian countries. To date, routine determination of genotype is not yet recommended because treatment options are not adjusted to genotypes. Nevertheless, since there is line of evidence that genotypes C and D may be associated with more aggressive liver disease, this might become significant during the long-term follow-up [16].

Diagnostics

Chronic hepatitis B infection is defined as a repeatedly positive HBsAg test result within 6 months. Apart from the aminotransferases, HBeAg, anti-HBe, anti-HBcIgG, and quantitative HBV DNA have to be determined to confirm chronic hepatitis B and to classify the present stage. Additionally, antibody against delta virus (anti-HDV) should be tested to exclude concomitant hepatitis D. It is recommended to perform an ultrasound examination including liver stiffness assessment for baseline findings. Since chronic hepatitis B usually is a mild disease in terms of inflammation in childhood, histological examination by liver biopsy is not mandatory. However, in subjects, who are suspicious of progressive liver disease or cirrhosis or if an impact on therapeutic decisions is identifiable, liver biopsy may be a reasonable completion.

Natural History

There are four natural stages of chronic hepatitis B infection: immune tolerance stage, immune reactive or immune clearance stage, inactive HBsAg carrier stage, and reactivation stage. As fifth and last stage, viral elimination with antibody against HBsAg (anti-HBs) seroconversion, which is a rather rare event occurring not more than 0.5% annually in children, could be denominated [7, 17]. Figure 60.1 illustrates the different phases of chronic hepatitis B.

Children who have HBV infection acquired perinatally or in the first months have an initial tolerance stage which is characterized by the presence of HBsAg, HBeAg, and extremely high HBV DNA levels (10^{7-9} virions/ml) and normal aminotransferases. The duration of the immune tolerant phase is not predictable and may last 1–4 decades. Asian patients seem to have a longer immune tolerant stage. T helper (Th) cell immune tolerance is generated by HBeAg functioning as an immunoregulatory protein mostly already transplacentally transmitted. This kind of induced immune tolerance may explain the high chronicity rate, and the younger the individuals are when they get infected. Usually, only minimal inflammatory activity is detectable in the liver tissue in this phase. Even in adult patients, no severe progression is expected during the immune tolerant stage [18]. Although antiviral therapy is still not recommended for immune tolerant subjects, they should be carefully monitored to duly recognize progression to immune active phase.

With time, a nonspecific increase of inflammatory activity or a decrease of HBeAg serum concentration, which may be due to emerging mutants in the core promoter or precore region resulting in a lower HBeAg production, may activate HBeAg-specific T cell clones. In this immune reactive

phase, HBeAg remains positive, and aminotransferases rise. HBV DNA remains high or stays at a little lower level. During this time, progression to liver fibrosis or cirrhosis may occur. However, liver cirrhosis rate is not expected to exceed 3–5% until reaching adulthood [19–21]. In the immune reactive, phase treatment has to be considered.

A key event in the natural course of chronic hepatitis B is the HBeAg/anti-HBe seroconversion which occurs unpredictably for the single individual during the immune active phase. Anti-HBe seroconversion is associated with a significant decrease of viral replication and normalization of aminotransferases reflecting the biochemical and histological remission of inflammatory activity. In some studies, the annual seroconversion rate depends on the route of infection and the ethnic origin. Whereas the mean seroconversion rate in non-Asian children ranges between 8 and 15%, seroconversion in Asian children was considerably lower with approximately 5% per year [7, 20]. Anti-HBe seroconversion is followed by the inactive HBsAg carrier state with persistently normal aminotransferases and a low viral load. Viral replication is considered low when HBV DNA serum concentrations remain below 2000 IU/ml. Some carriers may be lucky and develop anti-HBs antibodies indicating viral elimination and cure of the disease. The estimated incidence of this rare event in children is 0.05–0.8% per year in endemic areas with predominantly perinatal HBV transmission [7, 15].

Approximately, 20–30% of inactive HBsAg carriers will experience spontaneous reactivation during long-term follow-up. Those episodes may cause progressive liver damage. The reactivation phase is characterized by the presence of anti-HBe and elevated aminotransferases. HBV DNA levels rise over 2000 IU/ml. This status is also named HBeAg-

negative hepatitis B. However, reactivation rarely occurs during childhood and adolescents.

Another particular condition warrants mention: occult HBV infection. It is defined as the existence of HBV DNA in serum among HBsAg-negative patients and can be classified into seropositive and seronegative with respect to the presence of anti-HBs or antibody against HBcAg (anti-HBc) antibodies. Possible explanations are low levels of viral replication activity or the emergence of HBV variants in the a-determinant of the S-gene. Occult hepatitis B is most common in endemic regions and seems rare with 1.4% [22]. However, prevalence may rise considerably in immunized children from HBsAg-positive mothers. One study reported a prevalence of 28% in this special group [23].

Long-Term Prognosis

Individuals with chronic HBV infection are at risk to develop long-term sequelae such as end-stage liver disease including liver cirrhosis, hepatic failure, and HCC. Progression strongly correlates with the disease activity in terms of viral replication level, inflammatory activity, HBsAg levels, HBV genotypes, and HBeAg/anti-HBe status. Strong risk factors for developing liver cirrhosis and HCC are higher age, male, presence of HBeAg, HBV DNA levels $> 10^4$ copies/ml, HBsAg serum concentrations $> 10^3$ IU/ml, and alanine aminotransferase (ALT) > 45 IU/l [24, 25]. Progression to liver cirrhosis in children is under 5% until adulthood and data of the Asian region report 0.01–0.003% of individuals with chronic hepatitis B to be expected developing HCC in childhood [26, 27]. In general, anti-HBe seroconversion significantly reduces the risk of developing HCC. The time at which anti-HBe seroconversion occurs is important. A study in adults investigating the 15-year cumulative incidences of HBeAg-negative hepatitis demonstrated that cirrhosis and HCC increased with increasing age of HBeAg seroconversion [28]. The lowest risk was observed in patients with anti-HBe seroconversion under the age of 30 (cirrhosis 7%, HCC 2.1%) and highest in individuals older than 40 years (cirrhosis 42.9%, HCC 7.7%). The hazard ratio for HBeAg-negative hepatitis, cirrhosis, and HCC was 2.95, 17.6, and 5.22, respectively, in the older compared with the younger group. The authors conclude that patients with HBeAg seroconversion before age 30 have an excellent prognosis, whereas patients with delayed HBeAg seroconversion after age 40 have significantly higher incidences of HBeAg-negative hepatitis, cirrhosis, and HCC. An additional precondition is persistently normal ALT levels [29]. Since children have a high probability to experience anti-HBe seroconversion until adulthood, the overall risk of developing severe liver disease in later life seems limited. Nevertheless, there remain a considerable number of patients with immune tolerance or inflammatory activity that needs careful and professional monitoring.

Relevance of Genotypes and Mutants

During the replication cycle, HBV polymerase is acting as a reverse transcriptase without proof-reading function. Therefore, mutant viral genomes are regularly emerging in a considerable number particularly during the high replicative status. Peculiar requirements such as replication modalities, selection pressure, and changing immunological conditions may select variants and strongly influence the predominant HBV quasispecies in an infected individual. Generally, a change of the primarily determined genotype is possible during long-term course and ranges between 2.8 and 19% usually associated with anti-HBe seroconversion [26, 30]. It is not yet known, if there is any clinical impact at all. In adults, genotype C infection is rather than genotype B associated with a delayed anti-HBe seroconversion and a higher risk of developing HCC. Genotype D trends to proceed more severely and shows delayed anti-HBe seroconversion compared with genotype A. Precore and basic core promoter (BCP) mutants are frequently associated with HBeAg-negative hepatitis, and HBsAg escape mutants are now increasingly observed in association with primarily vaccinated children. The typical precore point mutant is the G1896A stop codon preventing the production of HBeAg. It emerges typically around the time of anti-HBe seroconversion and may be associated with a decreased risk of developing HCC compared with the wild type. But it can also be found in patients with HBeAg-negative hepatitis. Depending on European or Asian regions, precore mutants have been detected between 8 and 50% in HBeAg-negative children. The BCP mutants A1762T/G1764A prevail to be associated with an increased risk for HCC. But finally, the data remain controversial [7, 16, 31, 32].

Treatment

Since there is no definitely curative medical treatment available to date, it has to be defined what the aim of antiviral treatment should be in dependence on age group and phase of chronic hepatitis B. There is no doubt that one major goal is to reduce the risk of progressive liver disease and long-term sequelae such as liver cirrhosis, hepatic decompensation, and HCC and eventually to achieve the same life expectancy compared with healthy individuals of the same age. Unfortunately, anti-HBs seroconversion can only be reached in 5–10% at the most under current medical treatment strategies. Thus, the most important task in the treatment of children and adolescents is to achieve anti-HBe seroconversion at the earliest possible time associated with suppressed viral replication and decreased liver inflammation followed by persistent presence of anti-HBe, undetectable HBV DNA, and preferably aminotransferases values less than half of the upper limit of normal. Children with HBeAg-positive

hepatitis should be monitored every 6 months with physical examination, measurement of laboratory parameters such as aminotransferases, hepatitis B serology, alpha-fetoprotein, and ultrasound of the liver. After anti-HBe seroconversion follow-up visits can be performed for lifetime on an annual basis [15, 17, 33].

The decision to treat should be based on age, phase of HBV infection determined by ALT level, HBeAg/anti-HBe status, liver histology, coexisting diseases, and expectable compliance. The response rate in patients in the immune tolerant phase is very low. Thus, treatment of children with normal aminotransferases has not been recommended to date. At present, clinical trials in immune tolerant children combining a nucleoside analogue and peg-alpha-interferon are being performed. Treatment should be considered when aminotransferases rise and transition to the immune active phase is recognized. Children and adolescents who have persistently elevated ALT levels for more than 6 months should be offered treatment. Currently, seven treatment options are approved for hepatitis B in adults, including two formulations of conventional and pegylated interferon as an immunomodulatory therapy and five nucleos(t)ide analogues (lamivudine, adefovir dipivoxil, entecavir, telbivudine, and tenofovir disoproxil) with strong reduction of viral replication. Approval for children and adolescents depends on the region. Large trials have been performed in children for lamivudine, adefovir, entecavir, and tenofovir. Entecavir has been authorized from 6 years onwards, and Adefovir and tenofovir have been approved for subjects older than 12 years of age in the USA and Europe [34–36]. Predictors of response may be increased ALT levels, relatively low HBV DNA levels, and infection with genotype A or B. The main problem of all clinical trials with nucleos(t)ide analogues is the duration of medical treatment of not more than 96 weeks. Although a high proportion of treated patients will experience a significant decrease of viral load, the anti-HBe seroconversion rate cannot be expected to exceed 25%. After ceasing treatment, a reactivation of viral replication to baseline levels can be observed. A 24-week course of alpha interferon yields an approximately 10% higher anti-HBe seroconversion rate. Anti-HBs seroconversion rate is limited to single cases with nucleos(t)ide analogues and may range between 6 and 10% in patients with alpha interferon. There is no doubt that these results are dissatisfying with respect to our primary goal of anti-HBe seroconversion. Another interesting fact is that alpha interferon treatment only accelerates anti-HBe seroconversion in successfully treated individuals, but does not enhance the absolute number of responders [37]. Extending the treatment with nucleos(t)ide analogues for several years will result in an anti-HBe seroconversion rate of 40–50% [33]. However, there are no long-term data in children with regard to side effects. In the case of anti-HBe seroconversion, treatment should be maintained for 12 months, because

the treatment-induced anti-HBe-positive status may be unstable and reactivation may occur [38, 39].

In view of the present data and experience, there is a remarkable counseling conflict between the choice of drug and the duration of treatment, given that anti-HBe seroconversion remains the essential goal. Antiviral drug resistance is a major limitation to the long-term success of antiviral treatment. For this reason, lamivudine with a 5-year resistance rate of 70% has been considered obsolete just as adefovir which does often not sufficiently suppress viral replication. Nevertheless, at least for smaller children, lamivudine can be used as an approved drug for a limited time. Telbivudine has also a considerable resistance risk. Entecavir and tenofovir do not show significant resistances after years of treatment. Tenofovir may be associated with an increase in serum creatinine levels after 3–5 years of therapy. Decrease of bone mineral density has also been reported. Oral treatment with nucleos(t)ide analogues is quite comfortable but needs a real true commitment to the treatment, and alpha interferon may have sometimes restrictive side effects but with the advantage of a defined duration.

Thus, the decision which treatment option to choose is not that easy and has to be achieved in agreement with the patient and the parents. Alpha interferon is particularly appropriate for those children and adolescents who are reluctant to commit to a long duration of treatment and are not in the pubertal growth spurt. Nowadays, peg-alpha-interferon should be recommended for 48 weeks. Nucleos(t)ide analogues are most appropriate for patients with contraindications to interferon, after liver transplantation with an anti-HBe-positive donor or under immune suppressive treatment. It is most important that they are willing to commit to a treatment for several, probably 3–5 years, may be longer. Entecavir and tenofovir have the best profile in terms of safety, efficacy, and drug resistance. For younger patients, entecavir seems actually the preferable option.

Children and adolescents with a HBeAg-negative hepatitis should be treated with a nucleos(t)ide analogue if ALT levels are elevated and HBV DNA concentration is above 20,000 IU/ml to prevent progressive liver disease [40]. During long-term treatment with nucleos(t)ide analogues, HBV DNA, HBeAg/anti-HBe status, and aminotransferase levels should be monitored every 3 months. Very low or negative HBV DNA concentrations are important preconditions to avoid drug resistance.

Prevention

Vaccination is the most effective procedure in order to prevent infection with the HBV. Active and passive immunization is well established in newborns of HBsAg-positive mothers. The first injections have to be administered within 12–24 h after birth to achieve a seroprotective response in

90–95% when two monthly follow-up active vaccinations are completed. Very low birth weight preterm infants should receive a total of four doses. HBeAg-positive mothers can be treated with a nucleoside analogue (lamivudine, telbivudine) during the last trimester of pregnancy to reduce the risk of vertical transmission.

In many countries, routine active HBV vaccination is implemented in the vaccination schedule of all infants. Post-vaccination testing for a protective anti-HBs concentration (>100 IU/l) is not routinely recommended. If indicated, the best time would be approximately 2–3 months after the last vaccination. Revaccination is indicated in subjects with an anti-HBs titer <10 IU/l. In the majority of nonresponders, three more vaccinations will induce protective response. According to present experiences, protective anti-HBs response will be maintained for more than 15 years [13, 39].

Chronic Hepatitis C

Introduction

Hepatitis C virus (HCV) infection is a frequent course of chronic liver disease, and approximately 150–200 million people are estimated to be chronically infected worldwide. Unfortunately, to date, no preventive vaccination could be developed. Despite of a normally benign course of the disease during childhood and adolescence, there is a considerable lifetime risk of progressive liver disease, liver cirrhosis, and the development of a HCC, which may eventually reduce life expectancy. Remarkable advances have been made in therapeutic approaches during the last 10 years, and considerable rates of cure have been yielded with the current standard of care. Nevertheless, careful long-term monitoring has to be performed, and appropriate improved treatment options have to be discussed, always considering that the development of novel treatment regimen is going fast and may continuously further improve the response rate [41].

Pathogenesis of Chronic Hepatitis C Infection

HCV is a positive-stranded RNA virus within the Flaviviridae family. It forms its own genus Hepacivirus, and there are six main genotypes. The viral genome encodes nine proteins including its own RNA polymerase. Because of the high error rate of the virus-specific RNA polymerase, many variants may be produced. So-called quasispecies represent the high variability of the virus which allows a survival advantage to the virus. Replication of HCV starts with the binding to hepatocytes and entry which is a rather complex procedure. RNA is released into the cytoplasm and translated in the rough endoplasmic reticulum. A 3000-amino-acid-long polyprotein arises and is then cleaved into ten different prod-

ucts. Membranous replication vesicles are induced, and HCV assembly is accomplished and released with the help of very low density lipoprotein (VLDL) synthesis. Chronic hepatitis C in children is associated with a variety of histological patterns, mostly considered as mild and slow progressive. Nevertheless, significant fibrosis or cirrhosis may occur, but is not expected to exceed 4% until reaching adulthood. Need for liver transplantation is very rare as is the development of HCC [42]. Little information is available about the host response to the virus. Cluster of differentiation 4 (CD4)+lymphocytes seem to be involved. Infants with the rs 12979860 CC genotype for the IL28B polymorphism trend to experience a higher spontaneous viral elimination [43–45].

Epidemiology

The prevalence of HCV infection in children in developed countries ranges between 0.1 and 0.4%. For adults, prevalence rates are 0.4–3% in North America and Western Europe and higher in Eastern Europe and Middle East. Egypt has the highest prevalence with 9%, almost exclusively genotype 4 [41, 46, 47]. Central and East Asia and North Africa are estimated to have a prevalence between 3.6 and 3.8% [48]. During the last 15 years, the predominant route of viral hepatitis C transmission has become vertical infection. Contamination through blood products is exceedingly rare in developed countries, but may remain an issue in developing countries. The rate of perinatal transmission from an HCV-RNA-positive mother ranges from 2 to 5%. Out of this group, a considerable number of infants received the infection probably already in utero [49]. Concomitant HIV infection may increase the risk of HCV transmission. Breast feeding does not promote viral transmission and is allowed. The HCV prevalence in pregnant women from North America and Central Europe was reported between 0.16 and 0.53%. Assumed a perinatal transmission rate of 2–4%, 8–10 newborns in 100,000 births per year may be infected and become chronically infected during the first year of life. Viral clearance in vertically infected children seems to be dependent on the genotype and was reported to range from 2.4 to 25%. In contrast, children infected with genotype 3 had a higher spontaneous clearance rate compared to individuals with genotype 1. Beyond the age of 5 years, spontaneous viral elimination becomes less likely [50, 51].

Diagnosis

Serologic testing for anti-HCV antibodies is the appropriate screening test for HCV. The next diagnostic step is the determination of quantitative HCV RNA and the genotype. The most prevalent genotype in pediatric trials performed in Western countries was genotype 1 (ca. 74%) followed by

genotype 3 (ca. 14%) and 2 (ca. 9%). Genotype 4 had the lowest prevalence (ca. 3%) [52]. It is useful to perform an ultrasound examination including liver stiffness assessment for the baseline report. As chronic hepatitis C usually is a histologically mild disease with low inflammatory activity in childhood, liver biopsy is not mandatory. However, in subjects, who are suspicious of progressive liver disease or cirrhosis or if there is an impact on therapeutic decisions, liver biopsy may be a reasonable measure [41, 52].

Several studies have demonstrated that certain host polymorphisms (e.g., CC) located upstream of the IL28B (interferon lambda 3) gene are associated with a higher sustained viral response rate to combination treatment with peg-alpha-interferon and ribavirin. There is also an association with spontaneous clearance of HCV. To date, determination of IL28B polymorphisms is not routinely used, but might be of interest to identify the individual patients' likelihood of response particularly in future therapy options [41].

Natural History

Normally, HCV infection is asymptomatic. Histological findings are usually mild, and the risk of severe complications until the infected individuals are reaching adulthood is low. Not more than 5% of children and adolescents will have evidence of advanced liver fibrosis or cirrhosis. Liver transplantation units from the USA have reported on 133 transplanted children due to chronic hepatitis C during a time span of 13 years. In a lifetime, the risk of developing liver cirrhosis is about 20%, and the risk of HCC based on liver cirrhosis is estimated 2–5% [44]. These data are from adults, and there are no long-term follow-up studies in vertically infected patients. Natural history is also affected by other medical and social factors. Overweight children with liver steatosis are at greater risk for progressive liver disease. Risky behaviors and alcohol misuse worsen the long-term prognosis. Similar course and progression of hepatitis C were reported in former pediatric patients with successfully treated malignant disease after three decades of observation with about 20% spontaneous clearance and up to 5% liver cirrhosis. During the chronic course, ALT levels may be normal or intermittently elevated. Only few patients show persistent markedly elevated aminotransferases. Also the HCV RNA serum concentration may considerably fluctuate, but without immediate prognostic relevance. Spontaneous resolution beyond the preschool age is quite rare and may occur in up to 10% of adolescents [44, 47, 53]. Some extrahepatic manifestations may be associated with chronic hepatitis C such as glomerulonephritis and possibly cognitive deficits or developmental delay [54]. However, in adult patients, the clinical effects of reported symptoms such as fatigue, depression, or marginal poorer learning efficiency were rather limited [55]. In conclusion, early acquired chronic hepatitis C is a clinically and

histologically silent and hidden condition. Nevertheless, it may become insidious. Although the rate developing liver cirrhosis until adulthood is low, activation beyond the second decade of life is likely. A large Danish study in adults revealed that in patients with chronic HCV infection, the 8-year risk of liver-related death was 5.5% compared with 2.0% in individuals who cleared the infection [56]. However, patients who have eventually proceeded to compensated liver cirrhosis have a dubious prognosis. In a follow-up study of cirrhotic patients over more than 10 years, HCC developed in 32% and the annual mortality rate was 4% [57]. Thus, the literal aim of therapeutic interventions in children and adolescents is not the treatment of an ongoing liver disease, but the prevention of a future one by early eradication of the infection.

Treatment

The primary goal of HCV therapy is to cure the infection which is reflected by persistently negative HCV RNA in serum and normalized aminotransferases. Sustained viral response (SVR) is defined as an undetectable HCV RNA level 24 weeks after cessation of treatment. The combination of pegylated alpha interferon with ribavirin and a protease inhibitor, either telaprevir or boceprevir for the treatment of genotype-1-infected patients for 48 weeks was the approved and established standard of care in adults. Non-genotype 1 patients are treated with peg-alpha-interferon in combination with ribavirin, for example, genotype 2 and 3 for 24 weeks. With these regimens, considerable sustained viral response rates can be achieved ranging from more than 65% for genotype 1 to over 80% for genotype 2 and 3 patients [58]. Two pegylated alpha-interferon molecules can be used, that is, alpha-interferon-2a and alpha-interferon-2b. The pharmacokinetics of these drugs differ, but there is currently no conclusive evidence that one peg-alpha-interferon should be preferred to the other one. Currently, approved interferon-free treatment options and more protease inhibitors such as sofosbuvir and ledipasvir are changing the treatment regimen.

Treatment management of children with chronic hepatitis C infection is formed by the attitude of the medical attendant regarding the need of therapeutic intervention with respect to a generally slow progressive disease. Thus, delay of treatment seems common with barely a quarter of patients being treated [51]. Adverse events during treatment are frequent, and due to age, adolescents may have a lack of compliance. On the other side, mostly treatment is better tolerated in younger patients, and in case of success, the benefit of socio-economic aspects is not to disregard. Under the aspect of health prevention for a long lifetime, all children with a measureable level of HCV RNA should be considered for treatment. Neither the level of aminotransferases nor of

HCV RNA predicts the long-term outcome of the disease. Also liver histology is not a helpful entry criterion for indicating treatment, because children generally do not have severe lesions. Nevertheless, new direct-acting antivirals (DAA) against the HCV have been developed, and interferon-free oral treatment regimen is an important goal for the next years. Toward this aim, several clinical trials combining only oral antiviral compounds have begun to show promising results in some subgroups. It will take a couple of years to have approved substances available for children. However, with the present knowledge, well-balanced counseling is particularly important for the individual patient and his parents when indicating treatment or advising deferral.

Experiences with the treatment of children with chronic hepatitis C started in the early 1990s. Nineteen studies using recombinant alpha interferon were published between 1992 and 2003. A meta-analysis of trials with alpha-interferon monotherapy showed a wide range of viral response (0–76%). Based on an increasing number of trials in adults, ribavirin was also added to alpha-interferon treatment trials for children. Between the years 2000 and 2005, six studies were published showing a sustained viral response rate from 27 to 64% [52]. It became clear that genotype-2- and genotype-3-infected individuals responded much better. Alpha-interferon-2b in combination with ribavirin was then approved by the FDA. Interestingly, the only controlled randomized trial, comparing a pegylated alpha interferon (-2a) with and without ribavirin, was only published in 2011, definitely showing that the addition of ribavirin was necessary to obtain significantly better treatment results than without [52, 59]. Trials with peg-alpha-interferon and ribavirin followed in the next years and both peg-alpha-interferon-2b and peg-alpha-interferon-2a have been approved by FDA and EMA 2008/2009 and 2011/2012 in combination with ribavirin for children. Peg-alpha-interferon-2b can be used in children from 3 years and peg-alpha-interferon-2a from 5 years onwards. A meta-analysis with eight trials to examine the efficacy and safety of peg-alpha-interferon treatment in combination with ribavirin was recently published, confirming that combination therapy is effective and safe in this age group [60]. Most subjects who achieved an early viral response (70%) also achieved a sustained viral response (58%). Relapse rate was rare with only 7%, as were discontinuations due to adverse events (4%). Two trials stratified the results in genotype 1 patients according to the baseline viral load. In both studies, patients with a lower viral load before treatment (<600,000 IU/ml and <500,000 IU/ml, respectively) had a better sustained viral response rate (73 and 62%) [61, 62]. Mode of infection and baseline levels of aminotransferases do not significantly correlate with the outcome. Representative trials with peg-alpha-interferon and ribavirin with more than 20 treated patients are summarized in Table 60.1 [59, 61–65].

Most adverse events are mild to moderate. Apart from flue like symptoms, which are very common, the most frequent side effects were in 32% neutropenia and in 52% leukopenia, whereas anemia and thrombocytopenia were documented in only 11 and 5%, respectively. Injection site erythema, pruritus, alopecia, and growth inhibition, which was reversible in the majority of patients, were also observed. Severe psychiatric side effects were rare in prepubertal individuals. Up to 20% of patients with 48-week treatment may have abnormal thyroid-stimulating hormone levels or other signs of thyroid dysfunction [52].

In summary, there is sufficient evidence to recommend antiviral therapy in chronic hepatitis C [66]. Peg-alpha-interferon and ribavirin therapies in treatment naïve children and adolescents yield a sustained viral response rate in approximately 50% of adequately treated genotype-1-infected patients. Thus, this option can be offered to all interested individuals. In patients infected with genotype 2 or 3, treatment for 24 weeks should absolutely be performed because the response rate is more than 90%. According to the approvals of the drugs, treatment start is possible beyond the age of 3 and 5 years, respectively. However, since spontaneous viral elimination in vertically infected subjects may occur within the first years until preschool age, watchful waiting is a justified alternative to an early treatment start. Additionally, various individual and family variables may influence the appropriate time to initiate treatment. Mid-childhood age before pubertal growth spurt is preferable. Re-therapy in previously treated genotype-1- and genotype-4-infected individuals produces sustained viral response in roughly one third, so deferral until availability of better treatment options seems reasonable [63].

In adults, triple therapy is still an approved current standard of care. However, oral interferon-free treatment regimens have been started. It could be expected that triple therapy would also increase the sustained viral response rate in children. Therefore, clinical trials in combination with boceprevir and telaprevir have been launched for children and adolescents. Most interestingly, the FDA stopped the boceprevir study for ethical reasons. One essential was the rapidly upcoming of numerous DAA with the perspective of interferon-free oral treatment options in the foreseeable future also for children [58]. For example, sofosbuvir is a new promising nucleotide analogue which has been tried with good results in combination with ribavirin in genotypes 2 and 3 infected and combined with peg-alpha-interferon in genotype-1-infected adults [67, 68]. The protease inhibitor faldaprevir was tested in combination with the polymerase inhibitor Deleobuvir as interferon-free regimen in genotype 1 patients [69]. This new way with a couple of upcoming further compounds will allow a shortened and more individual response-guided therapy. As of the beginning of the year 2015, a panel of new substances has been licensed

for adults: sofosbuvir, simeprevir, daclatasvir, ledispavir in combination with sofosbuvir and the combination of paritaprevir, ritonavir, ombitasvir, dasabuvir, and ribavirin. Thus, it is clearly conceivable that the current adult triple therapy will never routinely be used in children even with a pediatric approval, because the rapid development of new treatment options significantly accelerates the timeline. DAA trial in children have now been started. Therefore, we have to consider well balanced, if it would be better for the individual patient, to wait some time until oral treatment options for children, particularly infected with genotype 1, are available. Another issue is the question, if we actually have enough patients to perform appropriate trials for approval for the best drug combination. Thus, experts should carefully discuss, if waivers for pediatric investigation plans for some substances would be useful, when it becomes foreseeable that advanced concepts will get ahead of previous one.

Introduction

Primary nonviral infections of the liver parenchyma itself are uncommon; presumably the phagocytic Kupffer cells play a key role in preventing the infection. The liver's dual blood supply renders it uniquely susceptible to infection, receives blood from the intestinal tract via the hepatic portal system and is sustained by systemic circulation via the hepatic artery. Because of this unique perfusion, the liver is frequently exposed to systemic or intestinal infections or the mediators of toxemia. The biliary tree provides a further conduit for gut bacteria or parasites to access the liver parenchyma.

Infections of the liver with a wide range of organisms present variously from asymptomatic biochemical abnormalities to symptomatic hepatitis or space occupying lesions, for example, abscesses or granulomas producing biochemical changes of cholestasis but rarely significant jaundice. Some of these infections have a high mortality if not treated promptly. We describe nonviral infectious diseases affecting the liver caused by bacteria, mycobacteria, spirochetes, rickettsia, fungi and parasites.

Bacterial, Spirochaetal and Rickettsial Infections

Bacterial Sepsis

Bacterial sepsis precipitating jaundice is a well-recognized phenomenon particularly in the newborn and young infants [1]. The exact pathogenesis of hepatic insult is not known, but may be multifactorial, including direct invasion of liver parenchyma by blood-borne pathogens and nonspecific injury due to hypoxia or endotoxin-mediated paralysis of biliary

canaliculi inducing cholestasis. Implicated bacteria include 'coliforms', pseudomonads, *Salmonella* spp., anaerobes, *Haemophilus influenzae*, streptococci and *Staphylococcus aureus*. In patients with jaundice, serum bilirubin is usually between 5 and 10 mg/dl. Hepatomegaly is found in 50% of cases, and liver enzymes usually mildly elevated. Clinical evaluation and microbiological investigation may identify the source of sepsis and antimicrobial therapy usually results in complete resolution.

Liver Abscess

Pyogenic liver abscess (PLA) in infancy and childhood is uncommon, with incidence ranging from 3 to 25 per 100,000, but carries a high mortality [2–4]. The aetiology of PLA is variable. Though PLA in healthy children is a rare entity, up to 40–50% has occurred among immunocompromised children [2]. Pyogenic bacteria can reach the liver through various routes: (i) portal: secondary to gut pathologies such as appendicitis, inflammatory bowel disease or diverticulitis, sometimes complicated by portal pyelophlebitis and portal vein system thrombosis; (ii) biliary: caused by extrahepatic biliary tract disease such as stricture, calculus or malignancy; (iii) blood borne from an infected focus anywhere in the body via hepatic artery; (iv) contiguous extension from gallbladder or perinephric abscess; (v) following penetrating wounds of liver and (vi) cryptogenic [2, 5].

PLA may present as single large lesion or multiple abscesses, the latter often secondary to biliary tract infection. The importance of the portal venous route has fallen with better diagnosis and management of appendicitis. In most reviews, more than 60% abscesses are in the right lobe, 20–25% bilateral, and less than 15% in the left lobe [4, 5]. Predisposing factors include immunosuppression, quantitative or qualitative granulocyte abnormalities like chronic granulomatous disease, trauma, umbilical vein catheterization, omphalitis, sickle-cell disease, biliary tract surgery, hepatic artery thrombosis (post liver transplantation), liver

biopsy, percutaneous or endoscopic biliary drainage, diabetes, worm infestation and protein-energy malnutrition especially in developing countries [4, 5].

Multiple abscesses complicate biliary diseases such as bacterial cholangitis, sclerosing cholangitis, congenital biliary anomalies (Caroli's disease) and gallstones with higher mortality. *S. aureus* is the most common isolate in children, but Gram-negative aerobes, anaerobes and microaerophilic streptococci are also common [2, 4, 5]. Less frequent causes include *Pseudomonas* spp., *Clostridium* spp., *Salmonella typhi*, *Yersinia enterocolitica* and *Pasteurella multocida*. The classic presentation is pyrexia, chills, right upper quadrant (RUQ) tenderness, abdominal pain, hepatomegaly and leucocytosis but may be nonspecific. The diagnosis must be entertained in any pyrexia of unknown origin (PUO). Unusual presentations include an abdominal mass or acute abdomen secondary to rupture in to the peritoneal cavity or portal hypertension secondary to portal pyemia and portal vein thrombosis. Liver function tests may be unhelpful with nonspecific changes. Ultrasonography (USS), computerized tomography (CT) and magnetic resonance imaging (MRI) are all sensitive but cannot always differentiate abscesses from other lesions such as cysts, tumours or haemorrhage. USS or CT-guided drainage of as much pus as possible (from as many abscesses as possible) confirms diagnosis, and is central to the management. Initial treatment is conservative with broad-spectrum antibiotics (e.g. cefotaxime plus metronidazole or clindamycin) and should be adjusted when culture results are available [5, 6]. Duration of treatment is usually 3–6 weeks. Patients with multiple abscesses have to be on conservative treatment after a diagnostic tap, and up to 3–4 months of antibiotic therapy has been recommended to prevent relapses [5, 7]. Prognosis is worse in multiple abscesses. Most reports emphasize the good outcome after percutaneous drainage, which should be USS or CT guided. Contraindications to drainage include ascites and inaccessible lesions. Complications of aspiration include haemorrhage, hepatic laceration, fistula formation, peritonitis and additional abscess formation. Indications for open drainage procedure are biliary obstruction, loculated or highly viscous abscesses, persistence of fever for more than 2 weeks despite percutaneous catheter drainage and appropriate antimicrobial therapy. Predisposing immunodeficiency conditions should be managed with appropriate expert opinion from immunologists or infectious diseases experts.

Cholangitis

The normal biliary tract is sterile and, in children, acute cholangitis rarely occurs in the absence of congenital abnormalities or interventions in the biliary tract [8]. The children at highest risk include those with portoenterostomy or choledochal cyst, and those who have nonoperative biliary

manipulations such as transhepatic cholangiography or endoscopic retrograde cholangiography with stent placement. Risk of cholangitis in children after Kasai operation has been reported to be 40–50% [8]. Partial biliary obstruction encourages bacterial growth, with increased intraductal pressure and reflux of bacteria into blood vessels and perihepatic lymphatics leading to bacteremia. Infection may ascend from the duodenum or an infected gallbladder, or via lymphatics or bloodstream [9].

Cholangitis is a clinical diagnosis based on fever, abdominal pain, jaundice, pale stools or hepatic tenderness. However, the spectrum encompasses mild disease to severe sepsis, or shock, with bacteraemia [8]. Although *Escherichia coli*, *Klebsiella* spp., *Enterobacter* spp. and *Pseudomonas* spp. are usually implicated, infection may be polymicrobial and include anaerobes [8]. Leucocytosis is common, but changes in liver function tests are nonspecific; the serum bilirubin may be normal. In recurrent cholangitis, liver biopsy may be indicated for confirmation and microbiological examination. Treatment requires supportive care and an urgent USS or CT will help establish whether obstruction requires drainage. Broad-spectrum antibiotics should be administered—such as an acylureidopenicillin (piperacillin, mezlocillin or piperacillin-tazobactam) or a late generation cephalosporin (e.g. ceftazidime), plus an aminoglycoside [10]. Single agents, such as piperacillin, piperacillin-tazobactam, ciprofloxacin and imipenem or meropenem, appear safe and effective if an aminoglycosides is contraindicated. Duration of treatment is generally 3 weeks for acute cholangitis, but prolonged therapy may be necessary for recurrent cholangitis and multiply resistant bacteria [11]. Three months of intravenous antibiotics through central line has been helpful in treating recurrent cholangitis in biliary atresia children with portoenterostomy. Prolonged antimicrobial therapy in recurrent cholangitis only helps in preventing the bacteraemia by preventing bacterial overgrowth in biliary tract. There is always risk of development of resistant organisms and therefore more serious infection.

Tuberculosis

Tuberculosis (TB) of the liver is almost invariably a complication of miliary disease and occurs in 50 and 75% of patients with pulmonary or extrapulmonary TB, respectively. The site of primary focus usually dictates presentation. Rarely the liver appears to be the sole site of infection such as in congenital TB acquired via the ductus venosus [12, 13]. Congenital TB may present in first few weeks of life with failure to thrive, hepatosplenomegaly and jaundice. In older children, hepatic TB presents with PUO, weight loss, abdominal discomfort and hepatomegaly [12, 13]. In areas of low incidence a positive tuberculin skin test is diagnostically useful. However, confirmation requires liver biopsy, histology and culture confirmation. Caseating granulomata on liver biopsy

are highly suggestive of TB, but may be absent; a granulomatous hepatitis can complicate Bacille Calmette–Guerin (BCG) administration. The diagnosis of TB should be sought by specific staining and culture of material from other sites, including bronchoalveolar lavage, lymph node or pleural biopsy, marrow aspirate, lumbar puncture or early morning gastric aspirates, as clinically indicated. Polymerase chain reaction (PCR)-based tests may be helpful but require further evaluation. Standard antituberculous therapy is effective, but expert advice should be sought in areas with a high incidence of drug resistant TB or in compromised patients, including those with concurrent HIV infection.

Brucellosis

It is a multisystem infection caused by *Brucella melitensis*, *B. suis*, *B. abortus* and *B. canis*; *B. melitensis* causes more severe disease with a higher risk of chronicity. In endemic areas, transmission is often by ingestion of unpasteurized dairy products or raw meat. Granulomatous hepatitis may occur in acute or chronic disease and manifests as nonspecific changes in liver function tests [14]. Diagnosis requires clinical suspicion, blood and bone marrow cultures, serology and histopathological examination. PCR-based tests for brucellosis are available. The recommended treatment for children under 9 years of age with uncomplicated brucellosis is trimethoprim–sulphamethoxazole. For the treatment of serious infection, the addition of gentamicin or streptomycin is recommended for the first 1–2 weeks. Older children should receive doxycycline (6 weeks) plus rifampicin or streptomycin (2 weeks).

Listeriosis

Listeria monocytogenes may cause liver disease as part of systemic intrauterine infection of the foetus—granulomatous infantiseptica at birth or later in the neonatal period—and in older immunocompromised children after ingestion of contaminated food or water. The major hepatic manifestation is granuloma; jaundice is rare. Diagnosis is achieved by recovering the bacterium from blood culture, cerebrospinal fluid or liver aspirates. Treatment is with high dose ampicillin, with or without gentamicin.

Tularemia

Francisella tularensis has been isolated from many wild mammals, domestic animals and birds. Human infection usually follows bites from parasites of these animals or direct contact with animals. In some cases, a hepatitis-like picture follows with raised aminotransferases. Hepatomegaly is rare and biopsy may show necrosis. Diagnosis is usually serologi-

cal as the bacterium is difficult to recover in culture. Treatment with streptomycin or gentamicin is effective; the fluoroquinolones appear promising but require further evaluation.

Leptospirosis

Human infection follows exposure to leptospire excreted in the urine of chronically infected animals—including rats, cattle and dogs—or water contaminated with urine. Children are usually infected when swimming in contaminated rivers, ponds or lakes, or by canine exposure [15]. Leptospire gain entry via skin abrasions, conjunctivae or mucosae and an initial leptospiremia presages a multisystem infection. The incubation period is 5–15 days, and in 90% of patients there is a self-limiting anicteric disease but 5–10% develop jaundice (Weil's disease) [16]. Classically, the anicteric leptospirosis runs a biphasic course, with a leptospiremic phase lasting for 3–7 days and a second phase associated with leptospiruria and rising antibody titres lasting for 4–30 days. Predominant manifestations are fever, headache, myalgia, abdominal pain, nausea, vomiting, meningism, conjunctival suffusion, maculopapular rash, impaired renal function, lymphadenopathy and hepatosplenomegaly. Weil's disease is characterized by hepatic, renal and vascular dysfunction with persistent fever, profound jaundice, abdominal pain, renal failure, confusion, epistaxis, haematuria, gastrointestinal bleeding and other haemorrhagic phenomenon. Death may follow cardiovascular collapse, renal failure and gastrointestinal or pulmonary haemorrhage, though with supportive therapy mortality should be less than 10%. Liver histology reveals swollen perivenular hepatocytes with increased mitoses indicative of regeneration and disorganized liver cell plates. Leptospire may be recovered from blood, urine or cerebrospinal fluid (CSF) during the first week of illness, and from urine thereafter, and may be seen by dark ground microscopy of blood in the early stage of disease and in urine thereafter. Diagnosis, however, is usually serological using complement fixation tests (CFTs), enzyme-linked immunosorbent assay (ELISA) or a microagglutination test. PCR can detect leptospiral DNA in blood, serum, CSF, urine or aqueous humour. Penicillin or doxycycline is recommended and most beneficial if started early in the disease. The benefits of commencing antimicrobials later in Weil's disease are less clear.

Borreliosis

Borrelia burgdorferi, is a tick-borne spirochaete which causes systemic infection in humans (Lyme disease) following exposure to these vectors in forest or parkland. Predominant manifestations of acute disease are fever, malaise, extending erythematous rash, meningism, arthralgia, hepatitis and lymphadenopathy. Abnormal liver function tests

occur in up to 20% of patients and, rarely, hepatomegaly and RUQ tenderness [17]. Diagnosis requires clinical suspicion, positive serology and histopathology. Spirochetes may be seen in liver biopsy with a mixed inflammatory infiltrates in sinusoids, mitotic activity and ballooning degeneration of hepatocytes with hyperplastic Kupffer cells. Ampicillin or amoxicillin is administered for 3 weeks in early disease in children less than 9 years of age; tetracycline for older children. In late disease, intravenous cefotaxime or ceftriaxone for 2–4 weeks is recommended followed by oral ampicillin plus probenidicid for a further 4–8 weeks.

Syphilis

Treponema pallidum may infect the foetus at any stage of maternal syphilis, causing disseminated infection. Congenital syphilis may result in mucocutaneous lesions, a diffuse rash, pneumonitis, myocarditis, hepatosplenomegaly, jaundice, lymphadenopathy, haemolytic anemia, thrombocytopenia, perichondritis and osteochondritis; the infant is usually small for age. Late stigmata include arthropathy with bilateral knee effusions, notched upper incisors and frontal bossing of the skull and poorly developed maxillae. Neonatal death usually results from liver failure, severe pneumonia or pulmonary haemorrhage. Diagnosis requires detection of spirochetes by dark-field examination (skin rash, nasal secretions) or serology, including detection of specific IgM antibodies; long bone radiography at 1–3 months of age may contribute to diagnosis. Benzylpenicillin (10–14 days) remains the drug of choice.

Q Fever

Q fever is a systemic infection caused by the rickettsia *Coxiella burnetii* following exposure to infectious dust or aerosols from farm or domestic animals, or consumption of raw milk. Illness is usually a self-limiting ‘flu-like illness’ with an incubation period of 1–2 weeks. However, acute Q fever can present with atypical pneumonia and hepatitis with jaundice, hepatomegaly and abnormal liver function tests [18]. The characteristic histopathological finding is granulomata with dense fibrin rings around central lipid vacuoles. Diagnosis is by detecting immunoglobulin G (IgG) and immunoglobulin M (IgM) to phase II antigens of *C. burnetii*, usually by indirect fluorescent antibody test or ELISA. Seroconversion occurs at 7–15 days after the onset of symptoms with 90% patients having detectable antibodies by the third week. Titres of antibodies to phase I antigens exceed those to phase II antigens in chronic disease. Treatment is recommended for all cases to prevent chronicity; tetracycline or chloramphenicol is effective.

Parasitic Infections

Amoebiasis

Entamoeba histolytica is most commonly encountered in the tropics and subtropics. Hepatic abscess is a major complication of invasive amoebiasis and seen in 3–9% of adult cases but is less common in children [19]. Amoebic trophozoites reach the liver via the portal vein and induce hepatocyte apoptosis and a leucocyte response resulting in abscesses containing viscous brown pus. Hepatic abscesses, can be demonstrated by USS or CT scanning, are usually single and most frequent in the right lobe. Multiple abscesses may be associated with more severe disease. A typical presentation is with pyrexia (75%) and RUQ pain radiating to the right shoulder. In left lobe disease, there may be epigastric or left shoulder pain. Tenderness in the hypochondrium (85%), tender hepatomegaly (80%) and localized swelling over the liver (10%) may be elicited [20]. Less specific symptoms include nausea, vomiting, concurrent diarrhea or dysentery (10%) and loss of weight. Jaundice is present in up to 8% of cases. The white blood cell count is usually elevated. Demonstrating cysts in stool may contribute to diagnosis, but serum antibodies are present in more than 95% of patients. Aspiration under USS guidance may yield ‘anchovy sauce’ pus; rarely amoebas are seen in necrotic abscess wall or adjacent parenchyma. Abscesses may rupture in to the peritoneal cavity, pleural cavity or lungs, pericardium, portal vein or biliary tract, intraperitoneal rupture being more common than intrathoracic. Extraintestinal amoebiasis should be treated with metronidazole or dehydroemetine for at least 2 weeks [21]. The cure rate with both the drugs are same, but metronidazole has the advantage of being less toxic and being effective for both hepatic and intestinal phases of the disease. To prevent continued intraluminal infection, luminal amoebicide, such as paromomycin or diloxanide furoate should be given. Occasionally, amoebic abscess do not respond to metronidazole and addition of daily chloroquine may be considered for 2–3 weeks. Chloroquine has an additive effect to metronidazole and better penetration of the abscess wall. Percutaneous needle aspiration is recommended for large abscesses, failure to respond or if there is imminent risk of rupture, particularly in to the pericardium.

Schistosomiasis

Schistosomiasis affects 200 million people worldwide, the majority children aged 5–15 years [22]. Transmission occurs in endemic areas (Middle East, Brazil, West Indies, Far East and Southeast Asia) after exposure to water inhabited by infected snails. The intermediate hosts: larvae (cercariae) released from snails can penetrate intact skin and disseminate.

S. japonicum, *S. mansoni* and *S. mekongi* cause hepatosplenic disease subsequent upon portal venous system obstruction by a granulomatous response to eggs and subsequent periportal fibrosis and portal hypertension. Granulomata consist of eosinophils, epithelioid cells, plasma cells and lymphocytes encircling an ovum. Patients present with pyrexia, urticaria, eosinophilia, hepatosplenomegaly or upper gastrointestinal tract bleeding from oesophageal varices. Dilated abdominal wall veins and ascites reflect portal venous hypertension and USS may reveal thickening of the portal vein. Ova should be sought in stool and urine and may be identified in liver or rectal mucosal biopsy. Serological tests cannot distinguish past from active infection but a negative ELISA excludes the diagnosis. Praziquantel is the drug of choice; oxamniquine an alternative for *S. mansoni*.

Hydatid Disease

Echinococcus granulosus is the dog tapeworm. Typically dogs are infected by being fed offal from infected livestock—such as sheep—which contain hydatid cysts. Humans become infected by close exposure to domestic dogs and the eggs passed in their faeces. The liver is most frequent site for cyst formation, usually in the right lobe (60–80%). Presentation is with hepatic enlargement, with or without palpable mass, epigastric pain, nausea and vomiting; secondary cyst pressure effects include portal hypertension, inferior vena cava compression or thrombosis and biliary cirrhosis. USS of the liver reveals round solitary or multiple cysts of variable size with multiple internal daughter cysts; calcification may be noted. Diagnosis requires demonstration of specific antibody by ELISA, CFT, indirect agglutination or latex agglutination tests. Closed aspiration should not be undertaken: definitive therapy requires surgical removal which may be complicated by spillage of contents, anaphylaxis and seeding of new cysts. To avoid this, cysts can be injected with chlorhexidine or hydrogen peroxide prior to surgery. Both mebendazole and albendazole may successfully treat small uncomplicated cysts.

Ascariasis

Adult *Ascaris lumbricoides* worms cause disease by migrating into the pancreatic ducts, gallbladder and biliary tract. Biliary ascariasis is more common in children than in adults. Children with a heavy worm burden may be malnourished. Presentation of biliary involvement includes fever, RUQ pain, vomiting and passing of worms in stool or vomitus. Mechanical obstruction by worms can cause acute cholecystitis, cholangitis and biliary colic. Adult worms in the biliary tract may be demonstrated by USS, cholangiography or endoscopic retrograde cholangiography (ERCP); eggs

should be sought in the faeces [23]. Treatment is usually with mebendazole or albendazole—though endoscopic removal of adult worms may be necessary if there are persisting biliary symptoms.

Toxocariasis

Toxocariasis is caused by infection with the dog roundworm *Toxocara canis*. Ingested eggs hatch in the small intestine and larvae penetrate the mucosa before migrating to the liver, lungs and many other tissues. Visceral larva migrans (VLM) refers to a syndrome of eosinophilia, pyrexia, leucocytosis, hepatosplenomegaly, lymphadenopathy and hyperglobulinemia as the larva migrate. Ocular disease may also occur. A history of exposure to puppies should be sought. Humans are a ‘dead-end’ host: adult worms do not develop so eggs are not passed. Serodiagnosis is with an ELISA. In massive infection liver biopsy may reveal eosinophils surrounding larvae or granulomata formation with epithelioid giant cells and lymphocytes. VLM is treated with thiabendazole. Severe disseminated disease or ocular infection may warrant concomitant steroids.

Liver Fluke Infestation

Fasciola hepatica infection follows ingestion of aquatic plants—such as watercress—contaminated with eggs passed by infected sheep or cattle. After hatching, larvae penetrate the gut wall; enter the peritoneum and having breached the liver capsule pass through the parenchyma to the bile ducts. The flukes mature and lay eggs in the biliary tract, causing cholangitis and hepatomegaly. Diagnosis is made by demonstrating ova in stool and positive serology. ERCP may show filling defects due to inflammation and worms can be aspirated. Liver biopsy shows infiltration with eosinophils, histiocytes and polymorphs; granulomas may or may not be present. Treatment is with bithionol.

Clonorchis sinensis is endemic in the Far East. Infection follows ingestion of cysts in uncooked freshwater fish or crabs. Metacercariae excyst in the small intestine and invade the bile ducts in which the flukes mature, producing eggs which may be demonstrated in the faeces. Infection is usually asymptomatic, but bile duct fibrosis with liver impairment, strictures and pancreatitis may ensue. Praziquantel is the treatment of choice.

Toxoplasmosis

In the immunocompetent patient, acute acquired *Toxoplasma gondii* infection usually presents as self-limiting lymphadenopathy, though hepatosplenomegaly and hepatitis can

occur. The risk and severity of congenital toxoplasmosis vary according to the trimester in which maternal infection with the protozoan occurs. The likelihood of foetal infection increases through pregnancy, whilst disease severity decreases. The spectrum of disease in infected neonates includes: retinochoroiditis, meningoencephalitis, hydrocephalus, intracranial calcification, pneumonitis, myocarditis, purpura, hepatitis, hepatosplenomegaly and hydrops fetalis. Congenital toxoplasmosis must be differentiated from the other major causes of congenital infection: rubella virus, cytomegalovirus, herpes simplex virus, *T. pallidum* and *L. monocytogenes*.

Diagnosis of congenital infection requires full clinical evaluation and exclusion of other infections, with recovery of *T. gondii*, histology or serological investigation. Reference laboratory tests include culture (blood, body fluids, placenta), the dye test (for serum and CSF) and ELISAs for IgG, IgM, IgA and IgE detection in both neonate and mother. *T. gondii* DNA may be detected in body fluids (blood, urine and CSF) by PCR.

Treatment is with pyrimethamine plus sulphadiazine, though expert advice should be sought. Toxoplasmosis in the immunocompromised may follow reactivation or new acquisition and usually presents as central nervous system disease though other organs, including the liver, may be affected. *T. gondii* may be transmitted in the graft at liver transplantation and cause liver and severe systemic disease thereafter.

Fungal Infections

Fungal infections of the liver are usually seen in the immunocompromised—including those with acute liver failure. Although *Candida albicans* predominates, other *Candida* spp. and *Aspergillus* spp. infections are increasingly reported.

Candidiasis

Severely immunocompromised patients are prone to disseminated candida infections with the liver (and often spleen) affected in 50–70%. Typically, hepatosplenic candidiasis presents in haemato-oncology patients rendered neutropenic at the time of recovery of the neutrophil count. The hallmark is multiple small lesions in the liver and spleen on USS or CT scan with raised alkaline phosphatase. Yeasts may be visible on fine needle aspiration or liver biopsy and cultures may be positive; blood cultures are usually negative. Hepatic or hepatosplenic candidiasis is treated with fluconazole or amphotericin B. Although prolonged therapy may be required, the immune status of the patient is the key determinant of outcome.

Aspergillosis

Disseminated aspergillosis is an increasingly recognized problem in the severely immunocompromised. Increased incidence is seen in hospital with building constructions. Hepatic aspergillosis may manifest as an aspergilloma or granulomata formation, with hepatomegaly, elevated bilirubin, alkaline phosphatase and aminotransferases. Confident diagnosis requires both histopathological demonstration of invading hyphae and isolation of *Aspergillus* spp. (usually *A. fumigatus*) from liver biopsy. To date, serology has been unhelpful, but detection of circulating cell wall galactomannan by ELISA- and PCR-based tests show promise. Treatment with voriconazole and liposomal amphotericin B should be commenced immediately—on clinical suspicion alone—in immunocompromised patients.

Other Rare Fungal Infections

Other rare fungal infections of the liver include cryptococcosis, mucormycosis, histoplasmosis, blastomycosis, coccidioidomycosis and paracoccidioidomycosis.

Introduction

Primary immunodeficiencies (PIDs) are heritable disorders of innate and/or acquired immunity, often complicated by severe, recurrent or unusual infections, chronic diarrhea with failure to thrive and malignancies of lymphoid tissue in long-term survivors [1, 2].

Many of the problems children with these conditions face have been successfully addressed; for the early-presenting, life-threatening PIDs such as variants of severe combined immune deficiency (SCID) or hyper immunoglobulin E (IgE) syndrome, elective hematopoietic stem cell transplantation (HSCT), preferably from haploidentical donors, has become a treatment of choice [3]. In contrast, many milder forms of PIDs can be successfully managed for short-to-medium term by regular anti-infectious prophylaxis with antibiotics and/or antifungals and replacement immunoglobulins.

Liver disease occurs in approximately 25% of children with PIDs [4]. The proportion of adult patients developing this complication is unknown, but likely to be underdiagnosed and overall higher. Their number and liver pathology potentially could be affected by exposure to alcohol and propensity to develop diabetes mellitus and obesity-related liver problems such as nonalcoholic fatty liver disease later in life.

Pathophysiology

Many of the liver-related problems in PIDs stem from the fact that compromised first line anti-infectious barrier in gastrointestinal tract allows low-grade chronic infection which could ascend proximally into the biliary system and the liver. The infections are frequently caused by unusual pathogens, escaping routine anti-infectious strategies, such

as *Cryptosporidium* (CS) or *Microsporidium* [4]. The main form of liver disease in PIDs is chronic cholangiopathy, seen in around 65% of affected children [4]. This condition has a well-documented potential to develop biliary cirrhosis and full-blown clinical features of end-stage chronic liver disease, such as portal hypertension, bleeding from oesophageal varices and hypoalbuminemia with jaundice. In a small proportion of PID patients with the liver involvement, milder and more nonspecific histological features, such as fatty change, mild portal inflammation or development of small non-caseating intrahepatic granulomas, could be observed [4].

A considerable role in the chronic cholangiopathy of PIDs is attributed to protozoal infections, unaffected by the standard anti-infectious regimens. Chronic cryptosporidial infection has been implicated in chronic inflammatory and dysplastic biliary changes in the context of chronic cholangiopathy and superimposed complications such as biliary cirrhosis and cholangiocarcinoma. The pathogenic role of CS in immune deficiency is likely, albeit incompletely understood. Animal models of the CS-related cholangiopathy have been described. For example, interferon-gamma knockout mice appear to be particularly susceptible to CS infection, suggesting important role for this cytokine in pathogenesis of the cholangiopathy in PIDs [5]. The biliary injury in humans appears to be caused by direct cytopathic effects of this protozoan, mediated by apoptosis [6]. In addition, CS is known to cause cholangiopathy in human immunodeficiency virus (HIV) infection [7] and after organ transplantation [8]. Several additional intracellular parasites such as *Microsporidium*, *Mycobacterium avium intracellulare* and cytomegalovirus (CMV) have also been implicated in development of the chronic cholangiopathies in adult HIV-positive patients [7]. The accelerated evolution of the cholangiopathy in this setting is often interpreted by probable synergistic effects of multiple biliary infections [7].

A classical paradigm for development of the cholangiopathy of PIDs is hyper-IgM syndrome. This condition is caused by mutations in cluster of differentiation (CD)40

ligand (CD154) gene, known to control interaction between CD40 molecules from B-cells and CD40 ligand on activated lymphocytes in its X-linked form (CD40 ligand deficiency). Alternative mechanism for hyper-IgM syndrome is defective expression of immune activation-induced cytidine deaminase (AID) on B cells in the autosomal recessive form of the disease [9]. As a consequence, in both forms, B cells could not facilitate physiologic IgM class switching to other immunoglobulin types, which renders total serum IgM levels high and distal components of the immune response arm ineffective. However, the IgM levels may not always be elevated, and chronic neutropenia is often observed [10, 11]. Several series have described development of chronic biliary disease occasionally complicated by cholangiocarcinoma in older patients with hyper-IgM syndrome.

Although there are more than 100 described PIDs, a majority now characterised by mutations in different genes responsible for various facets of the immune response, frequent lack of genotype/phenotype correlation makes general recommendations for detecting liver disease difficult. On occasion, an adult patient could be diagnosed with PIDs and exceptionally some children with conditions known to confer susceptibility for chronic cholangiopathy, such as hyper-IgM syndrome, could remain completely asymptomatic, on anti-infectious prophylaxis, well into the adulthood. However, the lifelong risk of the liver disease and its complications remains undisputable.

Diagnosis

Increased awareness of immunologists is a key to early detection of liver involvement. Routine biochemical blood tests and occasional but regular expert ultrasonography with stool screening for CS is recommended. Of note, standard stool microscopy could often miss protozoan infections, and therefore PCR-based techniques are preferable.

When CS is detected with whatever technique available, aggressive treatment is required. In immunodeficient patients, therapeutic options include nitazoxanide, paromomycin and azithromycin, often required in combination, in repeated courses, or indefinitely [8, 12]. This clearly indicates that they are not very effective and that avoidance of this ubiquitous pathogen is recommended if possible. Thus, preventative measures such as drinking boiled water or azithromycin three times a week may be more appropriate in children diagnosed with conditions known to confer susceptibility to cholangiopathies such as hyper-IgM syndrome.

If prominence or dilatation of bile ducts is noted on ultrasound scan (USS), further imaging with magnetic resonance cholangio-pancreatography (MRCP) is indicated. If MRCP is suggestive of dominant biliary stricture, endoscopic ret-

rograde cholangio-pancreatography (ERCP) is required in order to attempt balloon dilatation, sample the bile for microbiology and biopsy the suspected lesion to rule out cholangiocarcinoma. Percutaneous liver biopsy under intravenous antibiotic cover is indicated in presence of consistent biochemical abnormality in patients with PIDs (see Fig. 62.1).

ERCP demonstrating diffuse CS-positive cholangiopathy in a 7-year-old immunodeficient patient with dedicator of cytokinesis 8 protein (DOCK8) deficiency (a form of hyper IgE syndrome)

Management

Liver replacement will not work for the patients with PIDs until their immune defect is also rectified. There are many reports describing recurrence of cholangiopathy in the liver grafts within months after successful liver transplantation. Patients with less advanced liver disease can survive isolated non-myeloablative HSCT, but generally children with established cholangiopathies secondary to hyper-IgM syndrome or any other PIDs should be identified and screened for a matched donor for HSCT early [13]. When the liver injury becomes clinically more severe, the children with PIDs are unlikely to tolerate conventional HSCT protocols, which often include potentially hepatotoxic medications. Thus, they should be transplanted while their liver involvement remains minimal, mild or absent if a good donor is available

Fig. 62.1 Endoscopic retrograde cholangio-pancreatogram showing diffuse bilateral intra- and extrahepatic cholangiopathy in a child with a form of hyper IgE syndrome (DOCK8 deficiency)

[14]. A sequential approach with combined liver and non-meloablative (“mini”) HSCT may be required for the ones with decompensated biliary cirrhosis and complications of advanced liver disease [15].

Effective HSCT not only prevents progression of established cholangiopathy but also could revert the histological abnormalities. We have observed four children with significant improvement of their histological features of cholangiopathy within couple of years after HSCT. However, there was no short-term change in the calibre of their bile ducts on ultrasonography [16].

Over the past decade, we have observed a reducing number of patients with PIDs and advanced chronic liver disease. There are two possible explanations for that: (1) these patients are referred earlier due to increased awareness of possible liver problems among immunologists and (2) they receive their HSCT earlier, before serious liver disease develops. It is hoped that this strategy will continue to work and that the hepatologists would only exceptionally be required to see the patients with PIDs.

Haemophagocytic Lymphohistiocytosis

Haemophagocytic lymphohistiocytosis (HLH) is a condition which probably still remains underdiagnosed due to specific diagnostic tools and the clinical features mimicking acute septicaemia of early infancy and relatively atypical diagnostic approach. Majority of primary or familial HLH cases could be regarded as a form of PID. Secondary or nonfamilial forms can be associated with any infectious pathogen or presence of malignancy. Some use the term macrophage activation syndrome to highlight ubiquitous nature of this systemic reaction. A subgroup of patients with primary perforin deficiency presents acutely, often in infancy, with acute liver failure, but also in respiratory distress, fever, pancytopenia, rash and renal impairment, all indicative of systemic involvement. Perforin is a 60 kDa polypeptide, produced by cytoplasmic granules of activated natural killer (NK) cells and cytotoxic lymphocytes. Perforin then assists in primary immune response by forming perforations/“pores” on membrane of the invading cells, facilitating entry of mediators such as granzyme, which lead to osmotic cell lysis and consequent cell death [17]. There are at least five different loci where mutations for familial forms of HLH can be detected [17].

The liver involvement is frequently so severe to warrant consideration for liver transplantation. In addition to classical signs of acute liver failure such as hyperbilirubinemia, coagulopathy and hypoalbuminemia with ascites, those patients have hyperferritinaemia, hypertriglyceridaemia, hypofibrinogenaemia and signs of activated T lymphocytes, in particular interleukin (IL)-2R positive cells in circulation.

Patients often exhibit fever, splenomegaly and pancytopenia. Bone marrow aspirate reveals haemophagocytosis—a phenomenon defined by macrophages engulfing other cells and cellular debris. This urgent situation requires prompt identification of immune defect if it underlies the clinical situation, as liver transplantation would only be a palliative measure; the underlying ongoing immune overactivity continues. Potential cure is control of the immune reaction by combination of steroids and chemotherapy (HLH protocol) [18]. The mortality is high and surviving patients should be worked up for HSCT as each new exposure to an infectious agent could trigger another life-threatening episode of haemophagocytosis [18].

Therefore, any child who presents in acute liver failure with fever, splenomegaly and pancytopenia should, in addition to standard treatment of this condition, be urgently investigated for primary immunodeficiency by performing bone marrow aspirate and flow cytometry for expression of IL-2R and perforin on activated lymphocytes. Suggestion that the child could be immune deficient may indicate that consideration for emergency liver transplantation may not be justified.

Introduction

Autoimmune liver disorders are inflammatory diseases characterized histologically by a dense mononuclear cell infiltrate in the portal tract that invades the surrounding parenchyma (interface hepatitis, Fig. 63.1a), biochemically by increased levels of transaminases, and serologically by the presence of circulating autoantibodies and high levels of immunoglobulin G (IgG). These disorders usually respond to immunosuppressive treatment, which should be instituted as soon as a diagnosis is made. These conditions can present insidiously or with a picture of acute hepatitis. Best results are obtained with early institution of immunosuppression [1–3].

There are three liver disorders in which liver damage is likely to arise from an autoimmune attack: autoimmune hepatitis (AIH), autoimmune sclerosing cholangitis (ASC), and de novo AIH after liver transplant.

Autoimmune Hepatitis

Clinical Features

Two forms of AIH are recognized according to the type of autoantibody present in the serum (Table 63.1). Type 1 AIH (AIH-1) is positive for smooth muscle antibody (SMA) and/or antinuclear antibody (ANA), while type 2 AIH (AIH-2) for anti-liver/kidney microsomal type 1 (anti LKM-1) and/or anti-liver cytosol type 1 (anti-LC-1) antibody (Fig. 63.2).

AIH-1 accounts for two thirds of the cases and presents often around puberty, while AIH-2 tends to present at a younger age and also during infancy. IgG is usually raised at disease onset in both types, though 15% of children with AIH-1 and 25% of those with AIH-2 have normal levels. IgA deficiency is common in AIH-2 [4]. Severity of disease is similar in the two types [4, 5], but anti-LKM1-positive children have higher levels of bilirubin and transaminases at onset than those who are ANA/SMA positive and present significantly more frequently with fulminant hepatic failure [4]. Excluding children with the fulminant presentation, a severely impaired hepatic synthetic function, as indicated by the presence of prolonged prothrombin time and hypoalbuminemia, is more common in AIH-1 than in AIH-2. The severity of interface hepatitis at diagnosis is similar in both types, but cirrhosis on initial biopsy is more frequent in AIH-1 than in AIH-2, suggesting a more chronic course of disease in the former. Progression to cirrhosis during treatment is more frequent in AIH-1.

In both types of AIH, a more severe disease course and a higher tendency to relapse are associated with the possession of antibodies to soluble liver antigen (SLA) [6, 7]. In both types, some 20% of patients have associated autoimmune disorders—including thyroiditis, vitiligo, type 1 diabetes, inflammatory bowel disease (IBD), and nephrotic syndrome—and some 40% have a family history of autoimmune disease (Table 63.1) [4].

There are three clinical patterns of AIH presentation (Table 63.1) [4]:

- a. In at least 40% of patients, the presentation is indistinguishable from that of an acute viral hepatitis (nonspecific symptoms of malaise, nausea/vomiting, anorexia, and abdominal pain, followed by jaundice, dark urine, and pale stools). Some children, particularly those who are anti-LKM1-positive, develop acute hepatic failure with grade II to IV hepatic encephalopathy (fulminant hepatitis) within 2–8 weeks from onset of symptoms.

AIH autoimmune hepatitis, ANA antinuclear antibodies, ASC autoimmune sclerosing cholangitis, SMA anti-smooth muscle antibodies, anti-LKM-1 anti-liver kidney microsomal type 1 antibody, pANNA peripheral anti-nuclear neutrophil antibodies, anti-SLA anti-soluble liver antigen, IgG immunoglobulin G, C4 C4 component of complement, HLA human leukocyte antigen

^a Measured by radioligand assay [6]

^b But increased in HLA DR*0701 negative patients [10]

- b. In 25–40% of patients, the onset is insidious, with an illness characterized by progressive fatigue, relapsing jaundice, headache, anorexia, amenorrhea, and weight loss, lasting for several months and even years before diagnosis.
- c. In about 10% of patients, there is no history of jaundice, and the diagnosis follows presentation with complications of portal hypertension, such as splenomegaly, haematemesis from oesophageal varices, bleeding diathesis, chronic diarrhea, and weight loss.

The mode of presentation of AIH in childhood is therefore variable, and the disease should be suspected and excluded in all children presenting with symptoms and signs of liver disease not ascribable to more common pathologies. The course of the disease can be fluctuating, with flares and spontaneous remissions, a pattern that may result in delayed referral and diagnosis. The majority of children, however, on physical examination have clinical signs of an underlying chronic liver disease, including cutaneous stigmata (spider nevi, palmar erythema, leukonychia, striae), firm liver, and

splenomegaly. At ultrasound, the liver parenchyma of these patients is often nodular and heterogeneous.

Epidemiology and Genetic Predisposition

The epidemiology of childhood AIH has not been studied. Data collected at the King's College Hospital Pediatric Hepatology tertiary referral centre show an increase in the yearly incidence of juvenile autoimmune liver disease, only partially explained by a referral bias: In the 1990s, it represented 2.3% of some 400 children older than 4 months who were newly referred yearly; since 2000, the yearly incidence has increased to 12%.

In northern Europe, pediatric AIH-1, similar to adult AIH, is associated with the possession of the human leukocyte antigen (HLA) DRB1*03 (Table 63.1) [4, 8]. In contrast to adult patients, possession of DRB1*04 does not predispose to AIH in childhood, and this can even exert a protective

role [4]. AIH-2 is associated with possession of DRB1*07, and, in DR7-negative patients, with possession of DRB1*03 (Table 63.1) [9, 10]. In Egypt, AIH-2 appears to be associated also with possession of HLA-DRB1*15 [11]. In Brazil and Egypt, the primary susceptibility allele for AIH-1 is DRB1*1301, but a secondary association with DRB1*0301 has also been identified [11, 12]. Interestingly, in South America, possession of the HLA-DRB1*1301 allele not only predisposes to pediatric AIH-1 but is also associated with persistent infection with the endemic hepatitis A virus [13, 14]. Pediatric patients with AIH, whether anti-LKM-1 or ANA/SMA positive, have isolated partial deficiency of the HLA class III complement component C4, which is genetically determined [15].

AIH-2 can be a part of the autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) syndrome, an autosomal-recessive monogenic disorder [16, 17] in which the liver disease is reportedly present in over 20% of cases [18, 19].

Diagnosis

The diagnosis of AIH is based on a series of inclusion and exclusion criteria [1–3].

Liver biopsy is necessary to establish the diagnosis; the typical histological picture including a dense mononuclear and plasma cell infiltration of the portal areas, which expands into the liver lobule, destruction of the hepatocytes at the periphery of the lobule with erosion of the limiting plate ('interface hepatitis'; Fig. 63.1a), connective tissue collapse resulting from hepatocyte death and expanding from the portal area into the lobule ('bridging collapse'; Fig. 63.1b), and hepatic regeneration with 'rosette' formation. In addition to the typical histology, other positive criteria include elevated serum transaminase and IgG levels and presence of ANA, SMA, anti-LKM-1, or anti-LC-1.

The diagnosis of AIH has been advanced by the scoring systems developed by the International Autoimmune Hepatitis Group (IAIHG) for adult patients [1, 2] where negative criteria, such as evidence of infection with hepatitis B or C virus, Wilson disease, or alcohol, among others, are taken into account in addition to the positive criteria mentioned above. The IAIHG scoring system was devised mainly for research purposes to allow ready comparison between series from different centres, but it has also been used clinically, including in pediatric series. More recently, the IAIHG has published a simplified scoring system based on autoantibodies, IgG, histology, and exclusion of viral hepatitis that is better suited to clinical application [20]. However, neither scoring system is suitable to the juvenile form of the disease, where diagnostically relevant autoantibodies often have titers lower than the cut-off value considered positive in adults [21–23]. In addition, neither system can distinguish between

AIH and ASC (see below) [24, 25], which can only be differentiated if a cholangiogram is performed at presentation.

A key diagnostic criterion for all AIH scoring systems is the detection of autoantibodies (ANA, SMA, anti-LKM-1, and anti-LC-1), which not only assists in the diagnosis but also allows differentiation of AIH types. ANA and SMA that characterize AIH-1 and anti-LKM-1 and anti-LC-1 that define AIH-2 are usually mutually exclusive; in those instances when they are present simultaneously, the clinical course is similar to that of AIH-2 [26]. A major target of SMA is the actin of smooth muscle, whereas the molecular target of anti-LKM-1 is cytochrome P-4502D6 (CYP2D6) [27] and of anti-LC-1 is formiminotransferase cyclodeaminase [28]. ANA, SMA, anti-LKM-1, and anti-LC-1 should be sought by indirect immunofluorescence using rodent stomach, kidney, and liver as substrate, as other techniques, for example commercially available enzyme-linked immunosorbent assay (ELISA), remain to be fully validated (Fig. 63.2) [26]. In contrast to adults, in healthy children, autoantibody reactivity is infrequent, so that titers of 1/20 for ANA and SMA and 1/10 for anti-LKM-1 are clinically relevant. Anti-LC-1, also detectable by indirect immunofluorescence, can be present on its own, but frequently occurs in association with anti-LKM-1. This co-occurrence can go unnoticed because anti-LKM-1 obscures the anti-LC-1 pattern. Anti-LC-1 can also be detected by commercial ELISA. Positivity for autoantibodies is not sufficient for the diagnosis of AIH since they can be present, usually at low titer, in other liver disorders such as viral hepatitis [29, 30], Wilson disease [31], and nonalcoholic steatohepatitis [32].

Other autoantibodies less commonly tested but of diagnostic importance include peripheral antinuclear neutrophil antibody (atypical perinuclear anti-neutrophil cytoplasmic antibodies, pANCA or peripheral anti-nuclear neutrophil antibodies, pANNA) and anti-SLA. pANNA is frequently found in AIH-1 and ASC, and it is also common in IBD, while it is virtually absent in AIH-2. Anti-SLA, originally described as the hallmark of a third type of AIH [33], is also found in up to 50% of patients with AIH-1, AIH-2, or ASC, where it defines a more severe course [6, 7]. Anti-SLA is not detectable by immunofluorescence, but the definition of its molecular target as Sep (O-phosphoserine) tRNA:Sec (selenocysteine) tRNA synthase (SepSecS) [34, 35] has enabled the establishment of molecularly based diagnostic assays. However, it should be noted that ELISAs are less sensitive than radioligand assays available in research laboratories [34, 35].

There are a small proportion of patients with AIH without detectable autoantibodies. This condition, which responds to immunosuppression like the seropositive form, represents seronegative AIH [36], a rare type of AIH in adults, whose prevalence and clinical characteristics remain to be defined in children.

Pathophysiology

The typical histologic picture of AIH, which is characterized by a dense mononuclear cell infiltrate eroding the limiting plate and invading the parenchyma (interface hepatitis, Fig. 63.1a), first suggested that auto-aggressive cellular immunity might be involved in its causation [37]. Immunocytochemical studies have identified the phenotype of the infiltrating cells. T lymphocytes mounting the alpha/beta T cell receptor predominate. Among the T cells, a majority is positive for the cluster of differentiation (CD)4 helper/inducer phenotype, and a sizable minority is positive for the CD8 cytotoxic phenotype. Lymphocytes of non-T cell lineage are fewer and include (in decreasing order of frequency) natural killer cells (CD16/CD56 positive), macrophages, and B lymphocytes [38]. Natural killer T cells, which express simultaneously markers of both natural killer (CD56) and T cells (CD3), are involved in liver damage in an animal model of AIH [39].

A powerful stimulus must be promoting the formation of the massive inflammatory cell infiltrate present at diagnosis. Whatever the initial trigger, it is most probable that such a high number of activated inflammatory cells cause liver damage. There are different possible pathways that an immune attack can follow to inflict damage on the hepatocyte (Fig. 63.3). Liver damage is believed to be orchestrated by CD4-positive T lymphocytes recognizing a self-antigenic peptide. To trigger an autoimmune response, the peptide must be embraced by an HLA class II molecule and presented to uncommitted T helper (Th0) cells by professional antigen-presenting cells (APCs), with the co-stimulation of ligand–ligand (CD28 on Th0, CD80 on APC) interaction between the two cells. The Th0 cells become activated, differentiate into functional phenotypes according to the cytokines prevailing in the microenvironment and the nature of the antigen, and initiate a cascade of immune reactions determined by the cytokines they produce. Arising in the presence of the macrophage-produced interleukin-12 (IL-12), Th1 cells secrete mainly IL-2 and interferon- γ , which activate macrophages, enhance expression of HLA class I (increasing the vulnerability of liver cells to cytotoxic attack), and induce expression of HLA class II molecules on hepatocytes, which then become able to present the autoantigenic peptide to Th cells, thus perpetuating the immune recognition cycle. Th2 cells, which differentiate from Th0 if the microenvironment is rich in IL-4, produce mainly IL-4, -5, and -10, which induce autoantibody production by B lymphocytes. Physiologically, Th1 and Th2 cells antagonize each other. The process of autoantigen recognition is strictly controlled by regulatory mechanisms. If these regulatory mechanisms fail, the autoimmune attack is perpetuated. Over the past three decades, different aspects of the above pathogenic scenario have been investigated.

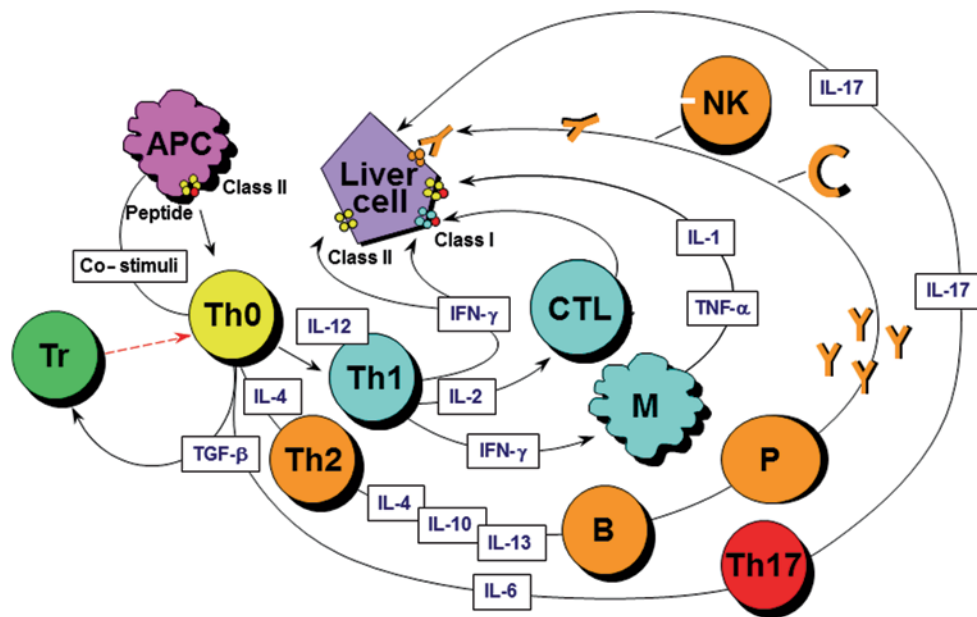

Fig. 63.3 An autoantigen is presented to uncommitted T helper (Th0) lymphocytes within the HLA class II molecule of an antigen-presenting cell (APC) in either the regional lymph nodes or within the liver itself. Activated Th0 cells differentiate into Th1 or Th2 cells in the presence of interleukin (IL)-12 or IL-4 and according to the nature of the antigen, and trigger a series of immune reactions determined by the cytokines they produce: Th1 cells secrete IL-2 and interferon-gamma (IFN- γ), cytokines that stimulate cytotoxic T-lymphocytes (CTL), enhance expression of class I and induce expression of class II HLA molecules on the liver cells and activate macrophages. The latter release IL-1 and tumour

necrosis factor-alpha (TNF- α). Th2 cells secrete mainly IL-4, IL-10, and IL-13, and stimulate autoantibody production by B lymphocytes. In the presence of defective regulatory T cells (Treg), hepatocyte destruction ensues from the engagement of damaging effector mechanisms, including CTL, cytokines released by Th1, and by activated macrophages, complement activation, or adhesion of natural killer (NK) cells to autoantibody-coated hepatocytes through their Fc receptors. Th17 cells, a recently described proinflammatory population that derives from Th0 cells in the presence of transforming growth factor beta (TGF- β) and IL-6, are the focus of current investigation. (Adapted with permission from Ref. [40], with permission from Wiley-Blackwell)

An impairment of immunoregulatory mechanisms has been described in AIH. Both children and young adults with this condition have low levels of T cells expressing the CD8 marker and impaired suppressor cell function [41, 42] which segregate with the possession of the HLA haplotype B*08/DRB1*03 (formerly B8/DR3), and can be corrected by therapeutic doses of corticosteroids [43]. Furthermore, patients with AIH have been reported to have a specific defect in a subpopulation of T cells controlling the immune response to liver-specific membrane antigens [44]. Further evidence for an impairment of immunoregulatory function in AIH has been obtained in the past decade [45–47]. Among T cell subsets with potential immunosuppression function, CD4+ T cells constitutively expressing the IL-2R alpha chain (CD25; regulatory T cells, T-regs) have emerged as the dominant immunoregulatory population [48]. These cells, which represent 5–10% of the total population of peripheral CD4+ T lymphocytes, control the innate and the adaptive immune responses by preventing the proliferation and effector function of autoreactive T cells. Their mechanism of action involves mainly a direct contact with the target cells, and, to a lesser extent, the release of immunoregulatory cytokines, such as IL 10 and tissue growth factor beta 1.

A numerical T-reg impairment affects both children and adults with AIH. This defect is more evident at diagnosis than during drug-induced remission, although even then circulating T-reg frequencies fail to reach the levels seen in health [45, 49, 50]. The percentage of T-regs inversely correlates with biomarkers of disease severity, suggesting that a reduction in regulatory T cells favours autoimmune liver disease. Importantly, T-regs from AIH patients at diagnosis are impaired in their ability to control the proliferation of CD4 and CD8 effector cells compared to T-regs isolated from AIH patients at remission or healthy subjects [49].

Recently, it was reported that effector CD4 T cells isolated from patients with AIH are less susceptible to the regulatory control exerted by T-regs. This defect is linked to reduced expression of the inhibitory receptor T cell immunoglobulin- and mucin-domain-containing-molecule-3 (Tim-3), which upon ligation of galectin-9 expressed by T-regs, induces effector cell death [51].

Hepatocytes from patients with AIH, in contrast to normal hepatocytes, express HLA class II molecules [52], and, although lacking the antigen-processing machinery typical of APCs, they may present peptides through a bystander mechanism. Given the impaired regulatory function and the

inappropriate expression of HLA class II antigens on the hepatocytes, it is conceivable that an autoantigenic peptide is presented to the helper/inducer cells, leading to their activation. Although there is no direct evidence as yet that an autoantigenic peptide is presented and recognized, activation of helper cells has been documented in AIH [38, 53]. These activated cells possess the CD4 phenotype, and their numbers are highest when the disease is most active.

Most advances in the study of T cells have occurred in AIH-2, since the knowledge that CYP2D6 is the main autoantigen has enabled the characterization of both CD4 and CD8 T cells targeting this cytochrome. One study has shown that CD4 T cells from patients with AIH-2 positive for the predisposing HLA allele DRB1*0701 recognize seven regions of CYP2D6 [9], five of which have later been shown to be also recognized by CD8 T cells [54]. A high number of interferon-gamma-producing CD4 T cells and CD8 T cells are associated with biochemical evidence of liver damage, suggesting a combined cellular immune attack.

What triggers the immune system to react to an autoantigen is unknown. A lesson may be learned by the study of humoral autoimmune responses during viral infections. Thus, studies aimed at determining the specificity of the LKM-1 antibody, present in both the juvenile form of AIH and some patients with chronic hepatitis C virus (HCV) infection, have shown a high amino acid sequence homology between the HCV polyprotein and CYP2D6, the molecular target of anti-LKM-1, thus implicating a mechanism of molecular mimicry as a trigger for the production of anti LKM-1 in HCV infection [27, 55, 56]. It is therefore conceivable that an as-yet unknown virus infection may be at the origin of the autoimmune attack in AIH.

Titers of antibodies to liver-specific lipoprotein, a macromolecular complex present on the hepatocyte membrane, and its well-characterized component asialoglycoprotein receptor, correlate with the biochemical and histologic severity of AIH [57, 58]. Antibodies to alcohol dehydrogenase, a second well-defined component of liver-specific lipoprotein, have been described in patients with AIH [59]. Immunofluorescence studies on monodispersed suspensions of liver cells obtained from patients with AIH showed that these cells are coated with antibodies *in vivo* [60]. A pathogenic role for these autoantibodies has been indicated by cytotoxicity assays showing that autoantibody-coated hepatocytes from patients with AIH are killed when incubated with autologous lymphocytes. The effector cell was identified as an Fc receptor-positive mononuclear cell [61]. T cell clones obtained from liver biopsies of children with AIH and expressing the gamma/delta T cell receptor have been shown to be cytotoxic to a variety of targets but preferentially kill liver-derived cells as opposed to cell lines derived from other organs [62].

The establishment of cell lines and clones has shown that the majority of T cell clones obtained from the peripheral blood and a proportion of those from the liver of patients with AIH are CD4 positive and use the conventional alpha/beta T cell receptor [62–65]. Some of these CD4-positive clones were further characterized and were found to react with partially purified antigens, such as crude preparations of liver cell membrane or liver-specific lipoprotein [63], and with purified asialoglycoprotein receptor [63, 65] or recombinant CYP2D6 [64] and to be restricted by HLA class II molecules in their response. Because CD4 is the phenotype of Th cells, T cell clones were investigated for their ability to help autologous B lymphocytes in the production of immunoglobulin *in vitro* [63, 65]. Indeed, their coculture with B lymphocytes resulted in a dramatic increase in autoantibody production.

The possible role of Th17 cells in the pathogenesis of AIH is under investigation. Th17 cells contribute to autoimmunity by producing the proinflammatory cytokines IL-17, IL-22, and TNF- α and inducing hepatocytes to secrete IL-6 [66], which further enhances Th17 activation. Th17 cells have been shown to be elevated in the circulation and liver of patients with AIH [66].

Treatment

Unless it presents with fulminant hepatic failure (i.e. acute liver failure and encephalopathy, which usually requires urgent transplantation), AIH responds satisfactorily to immunosuppression, even in the presence of poor synthetic function and/or established cirrhosis. Treatment should be started with prednisolone 2 mg/g/day (maximum 60 mg/day), which is gradually decreased over a period of 4–8 weeks if there is progressive normalization of the transaminases, and then the patient is maintained on the minimal dose able to sustain normal transaminase levels, usually 5 mg/day. During the first 6–8 weeks of treatment, liver function tests should be checked weekly to allow a frequent fine-tuning of the treatment, avoiding severe steroid side effects. The initial goal is to obtain at least 80% of reduction of the transaminase levels by 8 weeks of treatment. During this period of time, if progressive normalization of the liver function is not observed at weekly blood tests, azathioprine is added at a starting dose of 0.5 mg/g/day, which, in the absence of signs of toxicity, is increased up to a maximum of 2–2.5 mg/g/day until remission (i.e. normal transaminase levels) is achieved. Azathioprine is not recommended as first-line treatment because of its potential hepatotoxicity, particularly in severely jaundiced patients. Interestingly, it has been shown that neither thiopurine methyltransferase genotype nor activity predicts azathioprine hepatotoxicity in AIH, which appears instead to be related to the degree of liver fibrosis [67]. A prelimi-

nary report in a cohort of 30 children with AIH suggests that the measurements of the azathioprine metabolites 6-thioguanine and 6-methylmercaptopurine are useful in identifying drug toxicity and non-adherence and in achieving a level of 6-thioguanine considered therapeutic for IBD [68]. However, it has been reported that patients with AIH can achieve remission with azathioprine metabolite levels lower than those needed for IBD [69].

Although an 80% decrease of initial transaminase levels is usually obtained within 6–8 weeks from starting treatment in most patients, complete normalization of liver function may take several months. In our own series, normalization of transaminase levels occurred at medians of 0.5 years (range 0.2–7 years) in ANA/SMA-positive children and 0.8 years (range 0.02–3.2 years) in anti-LKM-1-positive children [4]. Relapse while on treatment is common, affecting about 40% of the patients and requiring a temporary increase of the steroid dose. An important role in relapse is played by non-adherence, particularly in adolescents [70]. The risk of relapse is higher if steroids are administered on an alternate-day schedule, often instituted in the unsubstantiated belief that it has a less negative effect on the child's growth. Small daily doses should be used because they are more effective in maintaining disease control and minimize the need for high-dose steroid pulses during relapses (with attendant more severe side effects). Side effects of steroid treatment are usually mild, the only serious complication being psychosis during induction of remission in 4%, which resolves after prednisolone withdrawal [4]. All patients develop a transient increase in appetite and mild cushingoid features during the first few weeks of treatment. After 5 years of treatment, 56% of our patients maintained their baseline centile for height or went up across a centile line, 38% dropped across one centile line, and only 6% dropped across two centile lines [71]. Moreover, all patients achieved their expected final height after a median steroid treatment of 8.9 years [72].

Treatment should be continued for at least 3 years before considering its cessation, after which period stopping treatment can be attempted but only if liver function tests and IgG levels have been persistently normal, and autoantibodies are either undetectable or detectable at very low titre (ANA/SMA < 1:10; anti-LKM-1 should be negative) over at least 12 months, and a follow up liver biopsy shows no inflammatory changes. However, it is advisable not to attempt treatment withdrawal during or immediately before puberty, when relapses are more common. Treatment withdrawal is reportedly successful in 20% of children with AIH-1, but is rarely achieved in AIH-2 [4]. An important role in monitoring the response to treatment is the measurement of autoantibody titers and IgG levels, the fluctuation of which is correlated with disease activity [73]. The prognosis of those children with AIH who respond to immunosuppressive treat-

ment is generally good, with most patients surviving long term with excellent quality of life on low-dose medication. Development of end-stage liver disease requiring liver transplantation despite treatment, however, has been reported 8–14 years after diagnosis in 8.5% of children with AIH [4].

Maintenance with azathioprine monotherapy has been advocated once remission is achieved [74], but whether this is effective long term and whether it offers any benefit on possible side effects compared to low-dose prednisolone/azathioprine maintenance is unclear.

Induction of remission has been obtained in 72% treatment-naïve children with AIH-1 using cyclosporine A alone for 6 months, followed by maintenance with low-dose prednisone and azathioprine [75]. A 5-year follow-up of this study shows that 94% of the patients eventually achieved remission, with minor side effects [76]. Whether this mode of induction has any advantage over the standard treatment remains to be evaluated in controlled studies in specialized centres.

Tacrolimus is a more potent immunosuppressive agent than cyclosporine, but it also has significant toxicity. There is limited evidence supporting its role as initial treatment of AIH apart from anecdotal reports in adults.

Budesonide has a hepatic first-pass clearance of >90% of oral dose and fewer side effects than prednisolone, but cannot be used in the presence of cirrhosis, which affects at least two thirds of AIH patients. In a large European study, including adults and children with AIH, a combination of budesonide and azathioprine had fewer adverse effects compared to medium-dose standard prednisone and azathioprine [77]. In this study, budesonide at a dose of 3 mg three times daily, decreased upon response, was compared with prednisone 40 mg once daily reduced per protocol irrespective of response. After 6 months of treatment, remission was achieved in 60% of the budesonide group but in only 39% of the prednisone group, both percentages being worse than those achieved with standard treatment [4]. The results among the children recruited into this study were particularly disappointing, with a similarly low remission rate of 16% for budesonide and 15% for prednisone after 6 months of treatment and of 50 and 42%, respectively, after 12 months of treatment, with similar steroid side effects in both groups, apart from higher frequency of weight gain in children on prednisone [78]. Large controlled studies are needed to establish the appropriate dose for children [79]. Nevertheless, budesonide could be a valid alternative in selected non-cirrhotic patients who are at risk of adverse effects from steroids.

In those patients (up to 10%) in whom standard immunosuppression is unable to induce stable remission, or who are intolerant to azathioprine, mycophenolate mofetil at a dose of 20 mg/kg twice daily has been successfully used [80]. In case of persistent no response or of intolerance to mycophen-

nolate mofetil (headache, diarrhea, nausea, dizziness, hair loss and neutropenia), the use of calcineurin inhibitors (cyclosporine A or tacrolimus) should be considered.

Children who present with fulminant hepatic failure, that is with grade 3–4 encephalopathy and international normalized ratio (INR) ≥ 2 , pose a particularly difficult therapeutic problem. Although it has been reported that they may benefit from conventional immunosuppressive therapy [81, 82], most require liver transplantation [4]. Encouraging results have been reported using cyclosporine A in anti-LKM-1-positive patients presenting with fulminant hepatitis [81]. These should be evaluated on a larger number of patients because our own experience has not confirmed the value of this therapeutic approach.

Autoimmune Polyendocrinopathy–Candidiasis–Ectodermal Dystrophy (APECED)

APECED is a monogenic disorder due to mutations of the *AIRE1* gene [16, 17]. Its phenotype is variable and includes AIH in about 20% of the cases [19]. This resembles AIH-2 and responds to standard immunosuppressive treatment [18], though the anti-LKM-1-like antibody detected by immunofluorescence targets a cytochrome (P4502A6) different from that of classical AIH-2. APECED, also known as autoimmune polyendocrine syndrome 1, is an autosomal recessive disorder caused by homozygous mutations in the *AIRE1* gene and characterized by a variety of organ-specific autoimmune diseases, the most common of which are hypoparathyroidism and primary adrenocortical failure, accompanied by chronic mucocutaneous candidiasis.

AIRE1 sequence consists of 14 exons containing 45 different mutations, with a 13-base-pair deletion at nucleotide 964 in exon 8 accounting for more than 70% of APECED alleles in the UK [17]. The protein encoded by *AIRE1* is a transcription factor. *AIRE1* is highly expressed in medullary epithelial cells and other stromal cells in the thymus involved in clonal deletion of self-reactive T cells. Studies in a murine model indicate that the gene inhibits organ-specific autoimmunity by inducing thymic expression of peripheral antigens in the medulla leading to central deletion of auto-reactive T cells. Carriers of a single *AIRE* mutation do not develop APECED. However, although the inheritance pattern of APECED indicates a strictly recessive disorder, there are anecdotal data of mutations in a single copy of *AIRE* being associated with human autoimmunity of a less severe form than classically defined APECED [16, 17]. The role of *AIRE1* heterozygote state in the development of AIH remains to be established. *AIRE1* mutations have been reported in three children with severe AIH type 2 and extrahepatic autoimmune manifestations [83].

Autoimmune Sclerosing Cholangitis

Clinical Features

Sclerosing cholangitis is an uncommon disorder, characterized by chronic inflammation and fibrosis of the intrahepatic and/or extrahepatic bile ducts. When bile duct damage is detectable histologically, but cholangiography is normal, a diagnosis of ‘small-duct disease’ is made. In childhood, sclerosing cholangitis may occur as an individual disease or may develop in association with a wide variety of disorders. The term primary sclerosing cholangitis (PSC), used in adult patients, is not accurate to describe pediatric sclerosing cholangitis: ‘Primary’ denotes ignorance about etiology and pathogenesis, while in pediatrics there are well-defined forms of sclerosing cholangitis [25, 84–87]. In the neonatal period, pathological features of severe sclerosing cholangitis characterize biliary atresia as well as neonatal sclerosing cholangitis, a condition inherited in an autosomal recessive manner [88]. Some other inherited diseases and immunological defects may produce a clinical picture similar to adult PSC. For example, mild-to-moderate defects in the *ABCB4* (*MDR3*) gene are a likely cause of a number of cases of small-duct PSC in children and adults [89, 90], and sclerosing cholangitis may complicate a wide variety of disorders, including primary and secondary immunodeficiencies, Langerhans cell histiocytosis, psoriasis, cystic fibrosis, reticulum cell sarcoma and sickle cell anaemia. Moreover, an overlap syndrome between AIH and sclerosing cholangitis (ASC), is significantly more common in children than in adults [25]. In only a relatively small number of pediatric patients, sclerosing cholangitis occurs without any of the above defining features. The term of PSC would be better confined to the latter, as different types of sclerosing cholangitis respond to different therapeutic managements.

ASC is characterized by florid autoimmune features, positive autoantibodies, especially ANA and SMA, hypergammaglobulinaemia, and interface hepatitis on liver biopsy [25, 91]. Since these features are shared with AIH, and alkaline phosphatase (AP) or gamma-glutamyl transpeptidase (GGT) levels are often not elevated at disease onset, the diagnosis of ASC relies on cholangiographic studies. In a 16-year prospective study, during which all children with serological and histological features of autoimmune liver disease underwent liver biopsy, sigmoidoscopy, and cholangiography at presentation [25], approximately half were found to have bile duct changes characteristic of sclerosing cholangitis (Fig. 63.4) and were therefore diagnosed with ASC. Importantly, a quarter of children with ASC had no histological features pointing to bile duct involvement, despite abnormal cholangiograms. Virtually, all ASC patients were seropositive for ANA and/or SMA. In contrast to AIH, which is pre-

Fig. 63.4 Magnetic resonance cholangiography of a child with autoimmune sclerosing cholangitis showing a diffuse cholangiopathy with strictures and dilations affecting the intra-hepatic bile ducts

dominantly a disease of females, ASC affects similarly boys and girls [25].

The mode of presentation of ASC is similar to that of AIH-1, although an association with IBD is more common in ASC (45%) than AIH-1 (20%) [25]. Of note, in the prospective study, only one third of the children with IBD had bowel symptoms, while the others were diagnosed because of surveillance sigmoidoscopy. At presentation, liver function tests—including GGT levels, which are a more reliable indicator of cholestasis than (AP) in growing children/adolescents, in whom AP often reflects bone growth—do not discriminate between AIH and ASC, though the AP/AST ratio is significantly higher in ASC (Table 63.2). Notably, atypical pANCA (also termed pANNA) positivity is present in 74% of children with ASC but only 45% of those with AIH-1 and 11% of those with AIH-2 [25]. Anti-SLA by a sensitive radioligand assay was found in some 50% of patients with ASC, and, also in this condition, it defines a more severe disease course [6].

Table 63.2 Biochemical findings at presentation in childhood autoimmune liver disease. (King's College Hospital experience [4, 25]. Results expressed as median (range))

	AIH	ASC
<i>Bilirubin</i> (<i>nv</i> <20 μmol/L)	35 (4–306)	20 (4–179)
<i>Albumin</i> (<i>nv</i> >35 g/L)	35 (25–47)	39 (27–54)
<i>AST</i> (<i>nv</i> <50 IU/L)	333 (24–4830)	102 (18–1215)
<i>INR</i> (<i>nv</i> <1.2)	1.2 (0.96–2.5)	1.1 (0.9–1.6)
<i>GGT</i> (<i>nv</i> <50 IU/L)	76 (29–383)	129 (13–948)
<i>AP</i> (<i>nv</i> <350 IU/L)	356 (131–878)	303 (104–1710)
<i>AP/AST ratio</i>	1.14 (0.05–14.75)	3.96 (0.20–14.20)

AIH autoimmune hepatitis, ASC autoimmune sclerosing cholangitis, AST aspartate aminotransferase, INR international normalised ratio, GGT gamma glutamyltranspeptidase, AP alkaline phosphatase, *nv* normal values

HLA studies have shown that in the UK susceptibility to ASC is conferred by the possession of HLA DRB1*1301 [10].

Evolution from AIH to ASC was documented in one patient during the published prospective series [25] and has been observed in two further patients during follow up [92], suggesting that AIH and ASC are part of the same pathologic process.

Clinical, laboratory, and histological features of type 1 and 2 AIH and ASC are compared in Tables 63.1 and 63.2.

Though 'small-duct disease' is reported rarely in pediatric series, in a study [86], where cholangiography was mainly performed by magnetic resonance cholangiopancreatography (MRCP), no radiological biliary involvement was detected despite histological evidence of sclerosing cholangitis in a high proportion (36%) of patients, some of whom had autoimmune features. Whether this finding is due to a lower sensitivity of the MRCP compared to retrograde cholangiopancreatography in detecting biliary changes remains to be verified.

Currently, in our centre, imaging of the biliary system by MRCP, followed by ERCP if MRCP is not informative, as well as colonoscopy, are part of the evaluation of all children with liver disease associated with autoimmune features.

The IAIHG scoring systems for the diagnosis of AIH, as currently formulated, do not allow distinguishing AIH from ASC [24, 25] as they do not include cholangiographic investigations at presentation. Table 63.3 summarizes diagnostic criteria for juvenile autoimmune liver disease.

Treatment

Children with ASC respond usually well to the same immunosuppressive treatment described above for AIH [25,

Table 63.3 Diagnostic criteria of juvenile autoimmune liver disease

Elevated transaminases
Positivity for circulating autoantibodies
ANA and/or SMA (titre ≥ 1:20)=AIH-1 or ASC
Anti-LKM-1 (titre ≥ 1:10)=AIH-2
Anti-LC-1=AIH-2
Elevated immunoglobulin G (in 80% of cases)
Liver biopsy:
Interface hepatitis
Multilobular collapse
Exclusion of viral hepatitis, Wilson disease and non-alcoholic steatohepatitis
Cholangiogram:
Normal=AIH or 'small duct disease'
Abnormal=ASC

AIH autoimmune hepatitis, ASC autoimmune sclerosing cholangitis, ANA anti-nuclear antibodies, SMA anti-smooth muscle antibodies, anti-LKM-1 anti-liver kidney microsomal type 1 antibody, anti-LC-1 anti-liver cytosol type 1 antibody

87] with resolution of liver test abnormalities within a few months in most patients. Response to immunosuppressive drugs is less satisfactory if the disease is long standing before starting treatment [85, 86].

The medium- to long-term prognosis of ASC is worse than that of AIH because of progression of bile duct disease despite treatment in some 50% of patients, with 20% of them eventually requiring liver transplantation [25, 87, 92].

Based on a reported beneficial effect in adult PSC, ursodeoxycholic acid (UDCA) is added to the treatment of ASC, but whether it is helpful in arresting the progression of the bile duct disease remains to be established. In adults with PSC, high-dose UDCA was reported as more beneficial than standard doses [93], but a randomized double-blind controlled study from the Mayo Clinic shows that high-dose UDCA has a negative effect [94]. It is prudent, therefore, to use doses not higher than 15–20 mg/kg/day.

Reactivation of the liver disease often follows flares of the intestinal disease in sclerosing cholangitis patients with IBD. It is therefore essential to control the bowel pathology to avoid progression of liver disease. A beneficial effect of oral vancomycin (500 mg tds) has been reported in 14 patients with sclerosing cholangitis and IBD [95]. All patients showed improvement of liver function tests and erythrocyte sedimentation rate, which was more marked in those without cirrhosis. These results await confirmation in a larger number of patients. Whether vancomycin acts through its antibiotic or immunomodulatory [96] properties remains to be elucidated.

Pathophysiology

It is unclear if the juvenile autoimmune form of sclerosing cholangitis and AIH are two distinct entities or different aspects of the same condition. Akin to AIH, in addition to positivity for ANA and/or SMA, liver-specific autoantibodies, including antibodies to liver-specific lipoprotein, asialoglycoprotein receptor, alcohol dehydrogenase, and SLA, can be found in ASC [6, 59, 97]. Susceptibility to ASC in children is conferred by the possession of HLA DRB1*1301, while possession of HLA DRB1*0401 appears to be protective. HLA DRB1*1301 has also been associated with susceptibility to PSC in adults [98]. An association with HLA DRB1*1301 has been reported in children with ANA/SMA-positive AIH in Argentina, but no cholangiographic studies were performed, and therefore not excluding the possibility that the cohort comprised also children with ASC [99].

Liver Transplant and Autoimmune Liver Disease

Liver transplantation is indicated in patients with AIH who present with fulminant hepatic failure (with encephalopathy) and patients with AIH or sclerosing cholangitis who develop end-stage liver disease despite treatment. The latter is more likely when established cirrhosis is present at diagnosis, or if there is a long history of liver disease before the start of treatment. Approximately, 10% of children with AIH and 20% of those with sclerosing cholangitis require liver transplantation. After transplantation, recurrent AIH has been described in about 20% of cases [100] and recurrent sclerosing cholangitis in 27–67% of transplanted patients [92, 86]. Diagnosis of recurrence is based on biochemical abnormalities, presence of autoantibodies, interface hepatitis on liver histology, steroid dependence, and, for sclerosing cholangitis, presence of cholangiopathy. Recurrence may occur even years after transplantation, and consequently maintenance of steroid-based immunosuppression at a higher dose than that used for patients not transplanted for autoimmune liver disease is recommended. While recurrence of AIH does not usually affect post-transplant outcome, recurrence of ASC leads to retransplantation in a high proportion of patients [92]. Recurrence of sclerosing cholangitis after transplantation is often associated to uncontrolled IBD [100, 101]. In this context, it is of interest that PSC recurrence in adults with IBD can be prevented by pre-liver transplant colectomy [102–104].

De novo AIH After Liver Transplantation

In the late 1990s, it was observed that AIH can arise de novo after liver transplantation in children who had not been transplanted for autoimmune liver disease. Characteristic of this condition is a histological picture of interface hepatitis and multilobular collapse associated with increased IgG levels and positive autoantibodies. These include not only ANA, SMA, and classical anti-LKM-1 but also atypical anti-LKM-1, staining the renal tubules but not the liver. After the original report [105], de novo AIH following liver transplant has been confirmed by several studies in both adult and pediatric patients [106–109] and has been reported to be more frequent in steroid-free antirejection regimens [110, 111]. Importantly, treatment with prednisolone and azathioprine using the same schedule for classical AIH, concomitant with reduction of the calcineurin inhibitor dose, is highly effective in de novo AIH, leading to excellent graft and patient survival. It is of interest that these patients do not respond satisfactorily to the standard antirejection treatment schedule, making it essential to reach an early diagnosis to avoid graft loss. Rapamycin has been reported to be effective in difficult-to-treat patients [112].

Pathophysiology of De Novo AIH after Liver Transplant

Whether the liver damage observed in these patients is a form of rejection or the consequence of an autoimmune injury, possibly triggered by drugs or viral infection, remains to be established.

Several reports have investigated whether the development of de novo AIH is associated to the possession of specific major histocompatibility complex (MHC) antigens either by the recipient or by the donor. In the original report, five of seven children with de novo AIH received livers from donors who were HLA DR3 or DR4 positive [105]. In adults, Heneghan et al. found HLA DR3 or DR4 in either donors or recipients in all cases [113], and Salcedo et al. noted an overrepresentation of DR3 in recipients [114].

There are several nonmutually exclusive explanations as to why autoimmunity and AIH may arise de novo in patients transplanted for non-autoimmune conditions. Besides autoantigen release from the damaged tissue, molecular mimicry might be involved, where immune responses to external pathogens become directed towards structurally similar self-components [115]. In Salcedo et al.'s series, all patients developed de novo AIH in relation to infection with Cytomegalovirus, Epstein–Barr virus, or Parvovirus [114]. Viral infections, which are frequent after liver transplant, may lead to autoimmunity also through other mechanisms, including polyclonal stimulation, enhancement, and induction of membrane expression of MHC class I and II antigens, and/or interference with immunoregulatory cells [106, 116].

Moreover, calcineurin inhibitors may interfere with the maturation of T cells and/or with the function of T-regs, with consequent emergence and activation of auto-aggressive T cell clones [116–121]. In the experimental context, calcineurin inhibitor-associated autoimmunity arises in animals treated during the neonatal period or rendered immunocompromised by irradiation, reinforcing the concept that patients treated with immunosuppressants, like prednisolone, after liver transplant, may be predisposed to developing autoimmunity through the influence of calcineurin inhibitors. Cyclosporine blocks activation-induced cell death of effector T cells, and it interferes with tolerance induction by co-stimulation blockade [121]. Calcineurin inhibitors also act by reducing IL-2 production [122]. As IL-2 is an indispensable survival and growth factor for T-regs [123], absence of IL-2 leads to impaired suppressor function [124]. De novo AIH occurs more frequently in patients who develop repeated episodes of acute cellular rejection [110, 113, 125–130], which is also associated to a decreased number of circulating T-regs [129]. T-reg impairment, as a consequence of calcineurin inhibitors and/or acute cellular rejection, may contribute to the

perpetuation of an autoreactive immune response, and to the development of de novo AIH.

Since children have an immature immune system—therefore an active thymus and an immature T cell receptor repertoire—and are exposed to numerous primary infections, they may be more vulnerable to autoimmunity under calcineurin inhibitors' influence [130]. This would account for the reportedly higher incidence of de novo AIH in pediatric age.

Hugh Lemonde and Mike Champion

Introduction

The liver plays a central role for many of the body's metabolic processes and so understandably inherited metabolic disorders (IMDs) may present with liver dysfunction. Most IMDs are monogenic conditions and the faulty protein is an enzyme, but others involve structural proteins, receptors, hormones or transport proteins. Presentation may be restricted to the liver, involve multiple organ systems or although expressed in liver cells, symptoms may be exclusively extrahepatic. Securing the diagnosis is important to direct specific treatment, inform prognosis and facilitate genetic counseling, but may be complicated by secondary metabolic disturbance from liver dysfunction generating metabolites falsely indicating a primary IMD. Although these conditions are inherited and presentation in the newborn period is common, some present later in childhood or not until adult life.

Presentation

Liver presentations may result from the making or breaking of complex molecules; the former often presenting at birth with dysmorphic features as these molecules are important in embryogenesis and patterning, for example, peroxisomal biogenesis defects, congenital disorders of glycosylation (CDGs) and the latter developing features of storage over time such as coarsening of the features and the development of organomegaly as these molecules accumulate, for example, lysosomal storage disorders (LSDs). I-cell disease is an exception in that dysmorphic features may be present at birth. Classical intoxications are signified by a symptom-free

period prior to toxic metabolites accumulating, for example, tyrosinemia type 1, galactosaemia and urea cycle defects (UCDs). Defects of energy metabolism may only manifest if feeding is interrupted or compromised such as in glycogen storage disorders (GSDs) and fat oxidation defects (FAOs). Primary blocks in energy production, for example, mitochondrial disorders and disorders of pyruvate metabolism will be present from birth, but their effects may not at first be obvious.

Specific liver presentations include cholestasis, acute liver failure, hepatomegaly and encephalopathy (see Table 64.1). Cholestasis commonly presents in the newborn period. The cholestasis may herald progressive liver disease. In Niemann–Pick type C (NPC) and cerebrotendinous xanthomatosis (CTX), cholestasis may be transient and no further symptoms may be noted until presenting with a progressive neurological deterioration later in childhood. Citrin deficiency may present with prolonged cholestasis which resolves prior to presentation usually as an adult with hyperammonemic encephalopathy. Intermediary metabolic blocks may present with acute liver failure and commonly present in the newborn period often after a symptom-free period. Hepatomegaly may be isolated without splenomegaly as seen in GSDs; glycogen is not stored in the spleen. Firm hepatomegaly is more commonly associated with tyrosinemia type 1, galactosaemia, Niemann–Pick and Gaucher disease. Encephalopathy results from hyperammonemia, hypoglycaemia or other specific toxic metabolites.

Diagnosis

History

Diagnosis is hampered by the rarity of these conditions, non-specific presentation and the requirement for specific investigations. Diagnostic clues are therefore sought from history and examination to suggest the potential for an IMD (see Table 64.2) and remain the foundation of diagnosis [1].

Table 64.1 Specific liver presentations and underlying IMDs

<i>Cholestasis</i>	α_1 -antitrypsin deficiency	
	Arginase deficiency (UCD)	
	Bile acid metabolism defects, e.g. CTX	
	Byler disease	
	CDGs	
	Cholesterol synthesis defects	
	Citrin deficiency	
	Galactosaemia	
	LCHAD	
	Mevalonic aciduria	
	Niemann–Pick C (LSD)	
	Peroxisomal defects	
	Tyrosinemia type 1	
	Transaldolase deficiency	
	Wolman disease (LSD)	
	<i>Acute liver failure</i>	α_1 -Antitrypsin deficiency
CDGs		
Galactosaemia		
Hereditary fructose intolerance		
Fat oxidation defects (FAOs)		
Mitochondrial disorders including Alpers disease		
Neonatal hemochromatosis		
Organic acidemias (OAs)		
Tyrosinemia type 1		
Urea cycle defects (UCDs)		
Wilson disease		
<i>Hepatomegaly (main or isolated symptom)</i>		α_1 -antitrypsin deficiency
		Cholesterol ester storage disease and Wolman disease
	Galactosaemia	
	Fanconi–Bickel syndrome	
	Glycogen storage disorders (GSD I, III, IV, VI, and IX)	
	Lysosomal storage disorders (LSDs)	
	Farber disease	
	Gaucher disease	
	Mucopolidoses	
	Mucopolysaccharidoses (MPS)	
	Niemann–Pick B&C	
	Neonatal haemochromatosis	
	Peroxisomal disorders	
	Tyrosinemia type 1	
	Wilson disease	
<i>Encephalopathy</i>	FAOs	
	Fructose 1,6 bisphosphatase deficiency	
	Mitochondrial disorders	
	OAs	
	UCDs	

CTX cerebrotendinous xanthomatosis, CDG congenital disorders of glycosylation, LCHAD long-chain hydroxy acyl-CoA dehydrogenase

The family history is particularly important searching for evidence for other affected family members such as previous sudden infant deaths, previous miscarriages or known relatives with the same condition or similar presentation. Potential mode of inheritance must be considered and is best

facilitated by a three-generation history. Some conditions, such as FAOs, are associated with maternal symptoms in pregnancy including hyperemesis or frank liver dysfunction such as acute fatty liver of pregnancy. Self-imposed dietary restriction is seen in some conditions; especially the avoid-

Table 64.2 Clues from the history suggestive of an underlying IMD

<i>Family history</i>	Consanguinity
	Previous sudden infant death
	Positive family history and inheritance pattern
	Only males affected suggests X-linked
<i>Maternal obstetric history (if an infant or childhood presentation)</i>	Matrilineal inheritance suggests mitochondrial DNA point mutation
	Multiple miscarriages (may signify previously affected pregnancies)
	Hyperemesis extending beyond the first trimester
<i>Past medical history</i>	Acute fatty liver of pregnancy (AFLP) and hemolysis, elevated liver enzymes and low platelets (HELLP) syndrome association with carrying foetus with long-chain fat oxidation defect
	Recurrent episodes, especially relating to intercurrent infections (catabolic stress)
	Specific food avoidance, e.g., fructose, protein

ance of sweet foods in hereditary fructose intolerance (HFI) and protein in UCDs. HFI will not present prior to weaning as fructose is not present in breast milk or formula milk.

Examination

IMDs associated with obvious dysmorphic features include peroxisomal disorders, CDGs and LSDs; however, many IMDs have no specific diagnostic features on examination. It is essential to look for extrahepatic manifestations to confirm the multi-organ involvement in some conditions. Developmental concerns are a feature of many IMDs and a full neurological examination should be undertaken to look for neurological signs.

Careful ophthalmic examination is required [2]. Cataracts are nearly always present at birth in galactosaemia but are easily missed in the non-dilated eye due to their transparent (oil drop) appearance. If the diagnosis is missed, the cataract will become more obvious as it matures. Cataracts are also seen in peroxisomal disorders, CTX, Wilson disease and some mitochondrial disorders. A cherry-red spot may be visible due to the accumulation of sphingolipid around the fovea in Niemann–Pick B. Pigmentary retinopathy is a feature of long-chain hydroxy acyl-CoA dehydrogenase (LCHAD) and mitochondrial disorders. Eye movement disorders are a feature of CDG-Ia (squint), NPC (vertical supranuclear gaze palsy), Gaucher disease (horizontal supranuclear palsy) and mitochondrial disorders (external ophthalmoplegia—limited gaze in all directions). Ptosis is found in many conditions including peroxisomal and mitochondrial disorders.

Investigation

Investigations may be divided between the general and the specific. Renal and cardiac assessment including ECG and echocardiography is important to exclude multi-organ involvement. Mitochondrial disorders are characterised by ‘illegitimate associations’, that is, signs and symptoms which may not be obviously linked until one considers the central requirement for energy production. Cardiac involvement

may be subtle such as mild compensatory myocardial hypertrophy. Liver imaging may glean further information such as increased reflectivity secondary to fatty steatosis in FAOs and liver biopsy is indicated to help further diagnosis when initial investigations have proven inconclusive. Enzymology and genotyping are often required to secure a diagnosis (see Table 64.3).

Newborn screening offers the opportunity for therapeutic intervention prior to developing clinical symptoms. In the UK, this is limited to a few metabolic conditions including medium-chain acyl-CoA dehydrogenase deficiency (MCADD) which presents with encephalopathy, hypoglycemia and liver dysfunction. Phenylketonuria (PKU), a neurodevelopmental disorder, is screened by detecting elevated phenylalanine; however, a generalised amino acidemia occurs in liver dysfunction and so a positive screen may indicate a liver disorder such as galactosaemia [3]. The clue is phenylalanine to tyrosine ratio which is elevated in PKU due to the block in the conversion of phenylalanine to tyrosine by phenylalanine hydroxylase but normal or decreased in liver disorders. Following an expanded newborn screening pilot, the number of conditions screened is increasing to include isovaleric acidemia and maple syrup urine disease which can both present with decompensation including liver dysfunction in the newborn period. In the other parts of Europe, North America and Australia, many more conditions are covered by newborn screening.

Next-generation sequencing is another technology increasingly used to screen patients to secure a diagnosis. This can either be targeted such as a gene chip, for example, causes of cholestasis or be for a specific group of conditions, for example, GSDs screening all the associated genes simultaneously [4, 5] or screening all coding regions for disease causing mutations (exome sequencing) [6, 7]. This is likely to identify new conditions and broaden the phenotype of known disorders, but is not without risk, ensuring that variations detected are indeed disease causing and responsible for the clinical presentation [8].

Table 64.3 Examples of metabolic investigations and associated pathological findings

Investigation	Condition	Metabolite/finding	Presentation
Amino acids	Tyrosinemia type 1	Raised tyrosine, methionine	C, LF, H
	Urea cycle defects	Raised glutamine, low arginine	LF, E
		Raised citrulline (citrullinemia)	
		Raised arginine (arginase deficiency)	
	Citrin deficiency	Raised citrulline	C, H
Galactosaemia	Amino acidemia	C, H, LF	
Organic acids	Lysinuric protein intolerance	Low lysine, ornithine and arginine	H, E
	Organic acidemias	Specific organic acids	C, LF, H, E
	Tyrosinemia type 1	Succinylacetone	C, LF, H
Ammonia	Argininosuccinic aciduria (urea cycle defects, UCD)	Argininosuccinic acid	LF, E
	UCD		LF, E
	Organic Acidemias		C, LF, H, E
Acylcarnitines	Fat oxidation defects	Specific acylcarnitine and often low Free carnitine	LF, H, E
	Organic acidemias	Specific acylcarnitine and often low Free carnitine	C, LF, H, E
Lactate	Mitochondrial disorders	Raised and exacerbated postprandially	C, LF, E
	Gluconeogenesis defects	Rapid resolution with treatment	H, E
	Fat oxidation defects		LF, H, E
	GSD I	Elevated on fasting	H
	GSD III	Elevated postprandially	H
CK	Fat oxidation defects	Elevated	LF, H, E
	GSD III	Elevated	H
Very long-chain fatty acids (VLCFAs)	Peroxisomal disorders		C, LF, H
Gal-1-PUT activity	Galactosaemia	Parental if infant already transfused to confirm carrier levels of activity	C, H, LF
α_1 -antitrypsin	α_1 -antitrypsin deficiency		C, H
Lipid profile	Wolman and CESD	Raised lipids	C, H, LF
	Glycogen storage disorders	Raised triglycerides	H
Urate	Glycogen storage disorders	Raised	H
Bile acids	PFIC	Raised normal bile acids	
	Bile acid defects	Specific abnormal bile acids present	
Transferrin isoelectric focusing	Congenital disorders of glycosylation		C, H, LF
Vacuolated lymphocytes	Lysosomal storage disorders		C, H
Glycosaminoglycans (GAGs) and oligosaccharides	Lysosomal storage disorders		C, H
Bone marrow aspirate	Lysosomal storage disorders	Storage cells	C, H
Abdominal X-ray	Wolman	Adrenal calcification	C, H, LF

C cholestasis, H hepatomegaly, LF liver failure, E encephalopathy, CESD cholesterol ester storage disease, CK creatine kinase, GSD glycogen storage disorders, PFIC Progressive familial intrahepatic cholestasis

Inherited Disorders of Carbohydrate Metabolism

Galactosaemia

Classical galactosaemia (galactose-1-phosphate uridyl transferase deficiency) typically manifests within the first week of life and sometimes within days of starting milk feeds. These feeds introduce galactose that in turn leads to the ac-

cumulation of the abnormal and putative toxic metabolite galactose-1-phosphate (see Fig. 64.1). Vomiting and jaundice typically ensue accompanied by hepatomegaly, ascites, deranged liver function, coagulopathy and renal tubulopathy. There is a marked failure to thrive. Careful examination of the eyes reveals oil drop cataracts that are easily missed as the red reflex is present. Classical lentiform cataracts can take many weeks to become apparent and although hypoglycemia is much quoted, it is not a major feature. Neonatal

Fig. 64.1 Metabolism of galactose and associated disorders. UDP uridine diphosphate

sepsis (typically *Escherichia coli*) is another mode of presentation and the threshold for antibiotic use in the acute phase should be low. Raised intracranial pressure is also a recognised feature. Occasionally, a more indolent course is followed with symptoms occurring beyond the first month with failure to thrive, renal tubulopathy or the development of cataracts or very rarely developmental delay. However, mild prolongation of the prothrombin time is almost always present.

The incidence in the UK is approximately 1 in 45,000 live births, and the gene is located on chromosome 9 and inherited in a recessive fashion. There is a common mutation Q188R identified in 72% of cases with classical galactosaemia. Genotype–phenotype correlations are unclear; however, the Duarte variant (N314D) has 50% residual enzyme activity and is a benign variant [9].

Diagnosis is by measurement of galactose-1-phosphate uridylyl transferase activity in erythrocytes. Care must be taken in neonates that have received a red cell transfusion as false negative results can be obtained within 3 months of the transfusion. In this circumstance, galactosaemia can be excluded by testing enzyme activity in the parents and comparing to well-defined heterozygote ranges. Testing urine for the presence of reducing substances is rarely performed as it is neither sensitive nor specific.

Uridine diphosphate galactose 4'-epimerase (UDP-galactose epimerase) deficiency is a rare condition that presents in similar fashion to classical galactosaemia. It should be considered if there is a strong suspicion of galactosaemia when galactose-1-phosphate uridylyl transferase activity is normal. It is characterised by elevated galactose-1-phosphate in red cells. Galactokinase deficiency is the third disorder of galactose metabolism, but its phenotype is restricted to ophthal-

mic symptoms. Galactosaemia screening is available; however, the majority of patients have presented clinically by the time the result would be available and presymptomatic treatment of known sibling cases appears to afford no benefit regarding avoidance of the long-term complications.

If the diagnosis is suspected, galactose must be promptly removed from the diet until the condition has been excluded. Conversion to a soya-based formula, or casein-based protein hydrolysate-based formula (such as Pregestamil) if hepatic impairment is severe, brings rapid improvement. A lifelong dietary restriction of galactose is generally recommended, although practices vary widely and there is much debate regarding the severity of restriction and the necessity of restriction in later life [10]. Many centres will allow a slight relaxation of diet in later life, such as galactose-containing fruit and vegetables while still avoiding sources of lactose, such as dairy products, as this keeps dietary intake well below the level of endogenous galactose production. Calcium intake needs to be regularly assessed to ensure adequate intake, especially in childhood. Long-term complications are not abolished by dietary management, and they include neurodevelopmental problems, osteoporosis and hypergonadotrophic hypergonadism/infertility in females [11]. Careful management of puberty is essential to ensure adequate uterine growth to allow successful pregnancy following ovum donation.

Hereditary Fructose Intolerance

HFI is an autosomal recessive condition due to a deficiency of aldolase B. The key to diagnosis is establishing a clear history of fructose intake prior to the onset of symptoms.

Table 64.4 Nomenclature of hepatic glycogen storage disorders

Type (Alternate name)	Enzyme	Gene	Inheritance
Ia (Von Gierke)	Glucose-6-phosphatase	<i>G6PC</i>	Recessive
Ib	Glucose-6-phosphate translocase	<i>G6PT1/SLC37A4</i>	Recessive
IIIa (Cori/Forbes)	Glycogen debrancher (liver and muscle)	<i>AGL</i>	Recessive
IIIb (Cori/Forbes)	Glycogen debrancher (liver)	<i>AGL</i>	Recessive
IV (Andersen)	Glycogen branching enzyme	<i>GBE1</i>	Recessive
VI (Hers)	Liver glycogen phosphorylase	<i>PYGL</i>	Recessive
IXa (XLG)	α -Subunit phosphorylase b kinase (liver)	<i>PHKA2</i>	X-linked
IXb	β -Subunit phosphorylase b kinase (liver/muscle)	<i>PHKB</i>	Recessive
IXc	γ -Subunit phosphorylase b kinase (liver)	<i>PHKG2</i>	X-linked
0a	Liver Glycogen synthase	<i>GYS2</i>	Recessive

Fructose is a monosaccharide that is found in many food sources, notably sucrose (glucose–fructose disaccharide), fruits, vegetables and honey. Sorbitol is an artificial sweetener that is metabolised to fructose. The classical presentation is that of healthy milk-fed infant that develops symptoms when it is first exposed to fructose upon weaning. Gastrointestinal (GI) upset progresses to persistent vomiting, sweating, lethargy and coma if intake continues. These symptoms are accompanied by liver failure and evidence of renal proximal tubulopathy. Hypoglycemia is common but can be masked by glucose administration.

There is a considerable spectrum of disease severity; infants can present with a chronic course of failure to thrive, hepatomegaly and liver impairment. School-age children may present with avoidance of sweet foods and hepatomegaly, with dentition that is unusually free of caries. Patients may develop specific food aversion to avoid sources of fructose that allow them to remain quite well.

Biochemical associations include lactic acidosis, hyperuricemia, marked liver dysfunction and renal tubulopathy. The enzyme deficiency results in accumulation of fructose-1-phosphate, an inhibitor of both glycogenolysis and gluconeogenesis that depletes inorganic phosphate, thus restricting adenosine triphosphate (ATP) production. Cellular depletion of ATP is postulated to be a significant mechanism of hepatocellular toxicity.

There is no rapid test that can exclude HFI. If it is suspected on historical or clinical grounds, then fructose should be immediately excluded. A rapid correction of biochemistry and liver function can be expected over a number of days. Hepatomegaly may take several months to resolve. Direct enzyme assay is restricted to liver tissue, and liver biopsy is likely to be contraindicated in the acute phase. Genotyping of the *ALDOB* gene is likely to provide a definitive diagnosis.

Treatment is the lifelong restriction of fructose from the diet and is a challenge due to its restrictive nature. Care must be taken to avoid inadvertent consumption of fructose in medicines and processed foods.

Glycogen Storage Disorders

Glycogen is a glucose polymer found primarily in the liver and muscle that is an important source of rapidly accessible stored energy. Hepatic glycogen is ultimately released as free glucose, whereas glycogen in the muscle is utilised directly by the muscle itself. The GSDs are inherited disorders of glycogen breakdown with the exception of GSD type 0 (glycogen synthase deficiency), which is a block in glycogen synthesis causing patients to present with hypoglycemia due to a short fasting tolerance in the absence of hepatomegaly. The clinical manifestation of GSDs reflects the different utilisation of glycogen and can be hepatic (hepatomegaly/hypoglycemia), myopathic or a combination of both. The hepatic forms of GSDs include types I, III, IV, VI and IX (see Table 64.4). Massive hepatomegaly is a feature common to all hepatic GSDs, usually in the absence of splenomegaly although this may be present in a minority of patients in association with hepatic fibrosis and cirrhosis. Hepatomegaly is also a feature of the LSD infantile Pompe disease, also known as GSD type II, although this condition is dominated by hypotonia and cardiomyopathy and is not considered in this chapter.

A simplified scheme for liver glycogen metabolism can be seen in Fig. 64.2.

GSD type 1 differs from the other GSDs as it disrupts the release of glucose rather than the breakdown of glycogen itself, effecting both glycogenolysis and gluconeogenesis. Thus, hypoglycemia associated with raised lactate is a hallmark of GSD type 1, in addition to raised urate and triglyceride. It typically presents with hypoglycemia and hepatomegaly in the first 6 months of life when feed frequency is reduced, although a neonatal presentation with hypoglycemia is occasionally seen. Abnormal distribution of fat gives the ‘doll-like’ facies and nephromegaly is a prominent feature. Failure to thrive is common with catch-up growth only occurring with dietary treatment while platelet dysfunction leads to bruising and nose bleeds. GSD type 1b is also associated with neutropenia and abnormal neutrophil function that leads to skin infections, mucosal ulceration and inflamma-

Fig. 64.2 Glycogen metabolism in the Hepatocyte. *GSD* glycogen storage disorders, *Glc* glucose, *Glc-6-P* glucose-6-phosphate, *Glc-1-P* glucose-1-phosphate

0	↑ Postprandial	N	N	N	N	N	↓ Liver

CK creatine kinase, *ALT* alanine transaminase, *GSD* glycogen storage disorders

tory bowel disease. Long-term complications are numerous including osteoporosis, gout (hyperuricemia), pancreatitis (hypertriglyceridemia), polycystic ovaries, anemia, Fanconi syndrome and renal impairment. Hepatic adenoma occur in 75% of patients peri- and postpubertally that have the potential for malignant change [12–15] (see Table 64.5).

GSD type III is caused by a deficiency of the glycogen debrancher enzyme that results in the accumulation of abnormal glycogen. It may be clinically indistinguishable from type I but fasting tolerance/tendency for hypoglycemia is typically not as severe as type I and nephromegaly is not a feature. Lactate characteristically increases postprandially and creatine kinase is commonly raised. Symptoms gradually improve, particularly around puberty, including spontaneous catch-up of growth and marked reduction in hepatomegaly. The mixed hepatic and muscle form is the commonest (type IIIa). Muscle weakness is not common in childhood and becomes more prominent in adults, although motor milestones may be delayed and activity can be impaired. Cramps at night are common. Long-term outcome in the purely hepatic form (type IIIb) appears excellent. Hepatic adenoma are rare, and reports of cirrhosis and progression to liver failure are

infrequent. In type IIIa complications include progressive myopathy and cardiomyopathy although the latter is rarely clinically symptomatic [16, 17].

GSD type IV is an extremely rare condition that classically presents with hepatomegaly and progressive cirrhosis. The deficiency of the branching enzyme produces abnormal glycogen resembling amylopectin. Glucose release from the abnormal glycogen is also impaired and fasting hypoglycemia may occur. Recently, however, the clinical spectrum of this disorder has widened considerably. Different presentations with varying overlap have been reported including foetal akinesia, infantile neuromuscular, cardiomyopathic and adult polyglycosan body disease [18–21]. In neonatal and infantile forms, death within infancy is usual.

Phosphorylase (GSD type VI) and its activator phosphorylase b kinase (GSD IX) are required for the removal of glycosyl molecules from the straight chains of glycogen. GSD type VI presents with pronounced hepatomegaly and a mild tendency to hypoglycemia in early childhood. Growth failure may be marked but catch-up growth occurs spontaneously and normal adult height is achieved. The disorder may be so mild that it remains undiagnosed. Long-term outlook is gen-

erally excellent, although hepatic adenomas have rarely been described. GSD type IX has a number of subtypes including three that have a hepatic component (see Table 64.4). Type IXa is by far the most common and has a relatively mild isolated hepatic phenotype similar to type VI. Type IXb is very rare and has a mild mixed liver/muscle phenotype. Type IXc has more severe phenotype often associated with significant hypoglycemia and progression to cirrhosis [22–24].

Confirmation of a suspected diagnosis of GSDs ultimately requires assessment of individual enzyme activity or genetic characterisation. Liver biopsy is not required for the diagnosis but commonly is the mode of diagnosis when patients being investigated for hepatomegaly are found to have significant amounts of glycogen in the liver. Periodic acid–Schiff (PAS) staining reveals cytoplasmic glycogen deposition often accompanied with increased lipid content. The glycogen is of normal structure in GSD types I, VI and IX while types III and IV have abnormal glycogen structure. Type III accumulates glycogen with shortened outer branches and type IV has an amylopectin-like structure [17]. Enzyme analysis requires targeted testing of individual enzymes, with enzymology of type I being limited to liver tissue. With the advent of high-throughput genetic techniques, simultaneous sequencing of all GSD genes is now available and is superseding enzyme assays, although the enzyme assay remains a valuable tool to evaluate genetic changes whose pathogenicity is uncertain.

Treatment for GSD type I includes strict dietary management. Hypoglycemic episodes are avoided by instituting frequent high-carbohydrate feeds during the day and continuous overnight tube feeds. This may be supplemented with uncooked or modified cornstarch to prolong normoglycemia [25], acting as a slow release form of glucose. Prophylactic trimethoprim is beneficial in GSD Ib for oral ulceration and granulocyte colony stimulating factor (GCSF) is reserved for resistant cases or those with recurrent infection. Regular assessment is required to monitor for long-term complications such as renal disease, hepatic adenoma/malignant transformation, osteopenia, hyperuricemia and hyperlipidemia [15]. Dietary management in type III depends on the severity [17]. Patients with early-onset hypoglycemia are managed as type I. A high protein intake has been advocated as gluconeogenesis is intact [26]. Dietary treatment in types IV, VI and IX is often unnecessary, but there is evidence that dietary management may improve fibrosis and long-term outcome in type IX [27].

Liver transplant is rarely considered but has been used in cases of hepatic failure, adenoma or malignancy or in cases refractory to dietary manipulation in patient with GSD types I and III [28, 29]. The only significant therapeutic intervention for type IV is liver transplant, although the extrahepatic progression of neuromuscular and cardiac disease post transplant has been documented in a number of patients [30].

Fanconi–Bickel Syndrome

The Fanconi–Bickel syndrome, previously classified as type GSD XI, presents with marked hepatomegaly secondary to glycogen storage and fasting hypoglycemia. Other features include postprandial hyperglycemia, hypergalactosaemia and renal Fanconi syndrome. The primary defect is a deficiency of the glucose 2 (Glut2) transporter important in the uptake and release of glucose from the liver. Glut2 is also expressed in pancreas, gut and kidney. Defects impair glucose sensing within islet β -cells compounding hyperglycemia in the fed state, due to decreased liver uptake, by blunting the insulin response. Hypoglycemia, in the fasting state, is secondary to impaired glucose release from the liver. Increased intrahepatic glucose inhibits glycogen degradation facilitating storage, and glycogen deposition may be noted on liver biopsy. Diagnosis relies on recognition of abnormal glucose homeostasis and renal tubulopathy while transaminitis, hyperlipidemia and hyperuricemia may be present. Treatment focuses on dietary support of glucose homeostasis with regular feed and also active replacement of renal losses.

Fructose-1,6-Bisphosphatase Deficiency

Fructose-1,6-bisphosphatase (FDP) deficiency is a defect in gluconeogenesis, the pathway that generates endogenous glucose and is a crucial mechanism to maintain glucose homeostasis when dietary glucose is depleted. It is also required for the metabolism of exogenous fructose. The classical features of FDP are hypoglycemia, lactic acidosis and prominent hepatomegaly. Approximately, 50% of cases present within the first 4 days of life and the majority by 6 months of age. Acute acidosis causes hyperventilation and irritability that progress to coma, apnoea and cardiac arrest. Acute hepatomegaly is commonly found, and a urinary ketosis can be evident (an unusual finding in neonates). Diagnosis relies on clinical suspicion that is confirmed by enzyme analysis of FDP in leukocytes (or liver) or genetic analysis of the *FBP1* gene. It is an autosomal recessive condition and a family history of neonatal death/acidosis is not uncommon.

Treatment of the acute presentation involves vigorous supplementation of glucose to inhibit gluconeogenesis. The acidosis and hepatomegaly generally respond promptly to this therapy. The acidosis may be severe enough to warrant use of bicarbonate to correct acid–base balance. If the sequelae of acute hypoglycemia and acidosis are avoided, prognosis is excellent. Mild hepatomegaly may persist during infancy but is not associated with signs of liver disease. Chronic treatment involves strict avoidance of fasting and adequate supply of energy during intercurrent illness. Dietary sources containing significant amounts of fructose

(includes sucrose/sorbitol) should be avoided but fructose does not have to be rigorously excluded as in HFI.

Transaldolase Deficiency

Transaldolase deficiency is a very rare single enzyme defect of the pentose phosphate pathway. There seems to be a wide phenotype but the few cases described presented uniformly in the neonatal period with hepatosplenomegaly and liver impairment [31]. Associated features included dysmorphism (including cutis laxa), cardiac anomalies, oedema, renal abnormalities, hemolytic anemia and thrombocytopenia.

Prognosis is poor with developmental delay and commonly death within the first year of life associated with liver failure. Diagnosis relies on clinical suspicion followed by analysis of urine polyols (showing amongst others raised sedoheptulose-7P). Confirmation of diagnosis can be achieved by enzyme assay in lymphocytes, erythrocytes, fibroblasts or liver tissue and by analysis of the *TALDO1* gene.

Congenital Disorders of Glycosylation

The CDGs are a large group of disorders that present a considerable diagnostic challenge. Over the past decade, their number has rapidly expanded to nearly 70 discrete conditions. Individually, they are rare disorders with a very broad phenotype whose biochemical diagnosis relies on complex and often non-specific methods (i.e. transferrin isoelectric focusing). Glycosylation is the addition and modification of complex carbohydrate molecules (glycans) to proteins and lipids. The majority of extracellular, membrane bound and some intracellular proteins are glycosylated and the glycans perform a wide variety of functions from structural roles to cell–cell signalling. The process of glycosylation is a highly complex intracellular mechanism, the understanding of which is constantly being updated as new disorders are discovered [32].

The majority of CDGs are multisystem disorders. Developmental, skeletal and neurological problems dominate many of these conditions while hepatic involvement is not uncommon. Typical of this is by far the most common CDG, phospho-mannomutase 2 deficiency (PMM2-CDG). Even within this single condition, the phenotypic spectrum is very wide, but patients classically present in the neonatal period with dysmorphism, abnormal fat pads, inverted nipples and hepatomegaly. Significant development delay becomes evident with hypotonia, ataxia and failure to thrive. Transaminitis is typical and liver histology is characterised by steatosis and fibrosis with myelin-like lysosomal inclusions within hepatocytes on electron microscopy

Phosphomannose isomerase deficiency (MPI-CDG) is a rare CDG that presents primarily with hepatic and GI phenotype, but is remarkable as the sole CDG with an effective treatment. Typical presentation is within the first year to life with vomiting, abdominal distension, protein losing enteropathy, GI bleeding and liver dysfunction. Hypoglycemia may also be apparent. Dysmorphic features and a significant neurological phenotype are not associated with this condition. Transferrin isoelectric focusing is abnormal (see below) and diagnosis can be confirmed by enzymology in leukocytes or by gene sequencing (*MPI* gene). Treatment is by dietary supplementation of mannose [33].

Diagnostic testing for CDGs starts by analysing the glycan structures on a well-characterised glycoprotein such as transferrin (transferring isoelectric focusing). An abnormal pattern can then undergo further biochemical testing, or if the clinical picture permits, a specific genetic diagnosis can be sought. It should be noted that other liver pathology can result in an abnormal transferrin isoelectric focusing pattern, namely alcoholism, classical galactosaemia and HFI. When liver disease is present as part of an undefined systemic disorder, a congenital disorder of glycosylation should be considered [34].

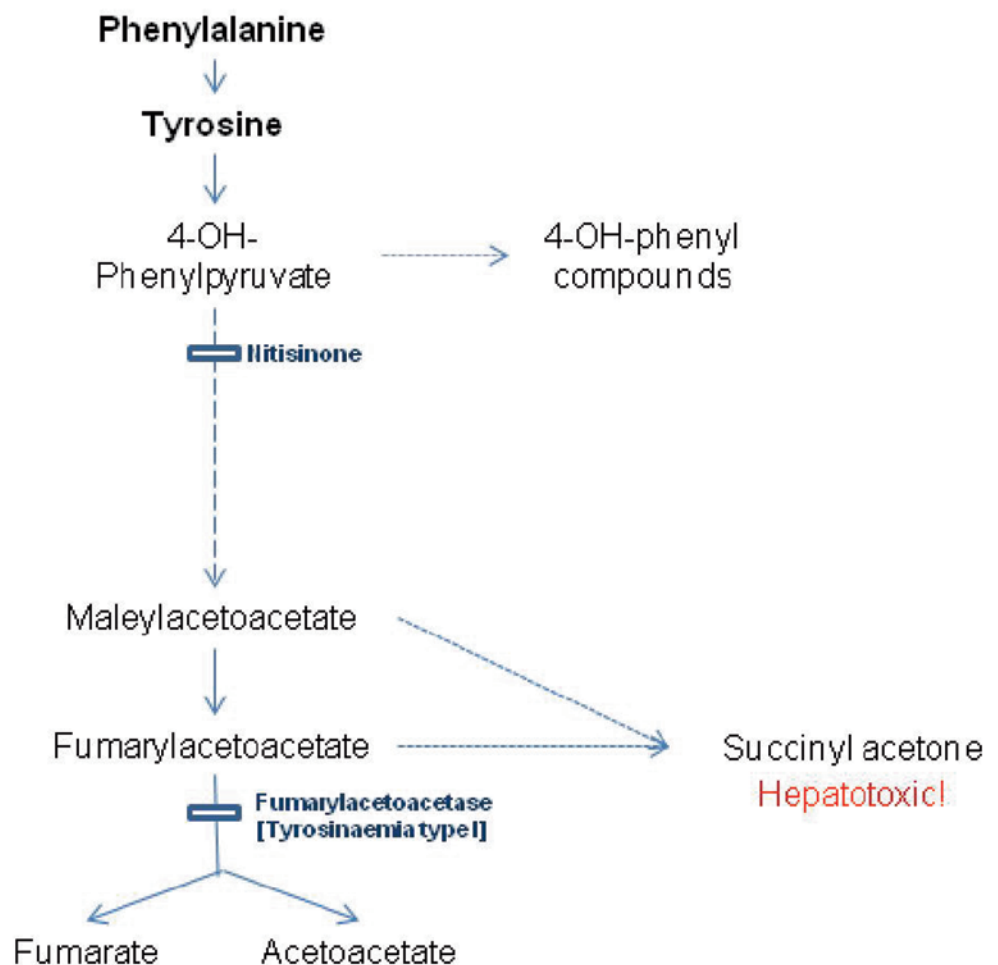

Inherited Disorders of Protein Metabolism

Tyrosinemia Type 1

The metabolic defect responsible for tyrosinemia type 1, fumarylacetoacetase deficiency, arises late in the catabolic pathway of tyrosine (see Fig. 64.3). The immediate precursors to the block fumarylacetoacetate and maleylacetoacetate damage the liver and kidney, with their reduced derivatives including succinylacetone. The early onset form presents with liver failure, coagulopathy, jaundice and ascites in the first 6 months of life. Hypoglycemia may result from liver dysfunction or hyperinsulinism secondary to islet cell hyperplasia [35]. Milder forms may present with hypophosphatemic rickets secondary to a renal Fanconi syndrome. Occasionally, children present with neurological crises which resemble acute porphyria with abdominal pain, hypertension, peripheral neuropathy and muscle weakness.

Liver function reveals mild elevation of bilirubin, transaminemia, elevated alkaline phosphatase and deranged coagulation. Tyrosine, phenylalanine and methionine are raised on plasma amino acids in acutely ill patients. The presence of succinylacetone on urinary organic acids is pathognomonic, and the diagnosis is confirmed on genotyping although enzymology in lymphocytes or fibroblasts can be performed. α -Fetoprotein is raised acutely and falls with treatment. Urinary Δ -aminolevulinic acid is raised. Biochemical evidence

Fig. 64.3 Diagram showing biochemical pathway of tyrosine catabolism, defective step causing tyrosinemia type I and the action of the substrate reduction therapy nitisinone

of a renal Fanconi syndrome is common. Hypertrophic cardiomyopathy is described.

The management of tyrosinemia type 1 has been revolutionised by nitisinone, originally developed as a herbicide, with rapid resolution of liver and renal dysfunction [36]. Treatment with a phenylalanine- and tyrosine-restricted diet is still required with home fingerprick monitoring of tyrosine and phenylalanine levels, but the risk of hepatocellular carcinoma is markedly reduced in patients treated early (<6 months). α -Fetoprotein monitoring in clinic should therefore continue with annual imaging of the liver. Current management combines oral nitisinone 1 mg/kg/day with a tyrosine- and phenylalanine-restricted diet supplemented with a tailored amino acid supplement. Methionine should be restricted in addition in the acute phase while still elevated. Target tyrosine levels are below 500 $\mu\text{mol/l}$.

Indications for liver transplant include: failure of response (no significant improvement in prothrombin time within 14 days of commencing treatment, or a bilirubin >100 mMol/l inspite of increased dose 2 mg/kg/day), development of hepatocellular carcinoma and chronic liver disease with risk of developing hepatocellular carcinoma (development of liver nodule or persistently elevated or rising α -fetoprotein). Para-

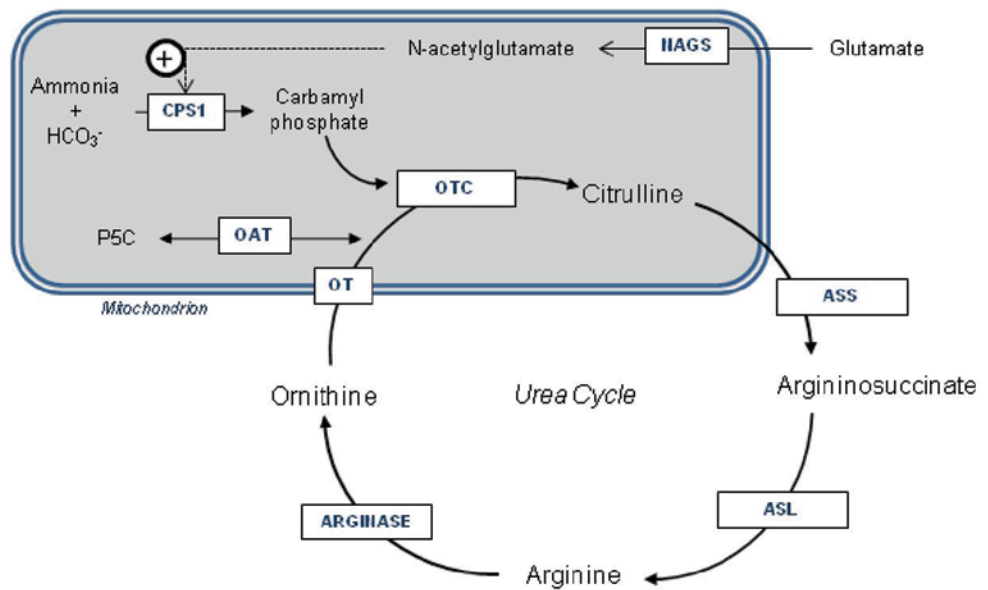

doxically, patients with milder disease presenting later may do less well in the longer term as the liver has been subjected to chronic exposure to the toxic metabolites and therefore is more likely to have cirrhotic changes. Concerns remain as to the cognitive outcomes of treated patients, and further work is needed to delineate whether this is due to the condition or a long-term nitisinone effect [37].

Tyrosinemia type I is inherited in an autosomal recessive manner. Prenatal diagnosis is available.

Urea Cycle Disorders

The urea cycle converts waste nitrogen to urea for excretion via the kidney and is the site of synthesis of the non-essential amino acid arginine. Enzyme defects within the pathway result in hyperammonemia and encephalopathy (see Fig. 64.4). Inheritance is autosomal recessive with the exception of ornithine transcarbamylase (OTC) deficiency which is X-linked recessive. Females can present with symptoms due to the effects of lyonisation if sufficient wildtype OTC genes are inactivated in the liver. OTC is the commonest UCD.

Fig. 64.4 Urea cycle disorders. *CPS1* carbamylphosphate synthase 1, *OAT* ornithine aminotransferase, *OT* ornithine transferase (hyperornithinemia, hyperammonemia, homocitrullinuria or HHH syndrome), *OTC* ornithine transcarbamylase, *NAGS* *N*-acetylglutamate synthase, *ASS* argininosuccinate synthase, *ASL* argininosuccinate lyase, *P5C* pyrroline-5-carboxylate

Neonatal presentation is a classical intoxication with lethargy/irritability, poor feeding, and vomiting progressing to overt encephalopathy. Tachypnoea secondary to the respiratory stimulant effect of ammonia initially produces a mild respiratory alkalosis. Apnoea and fits are also common. First presentation may occur later with a variety of non-specific features including failure to thrive, developmental delay, anorexia and vomiting. Investigation of cyclical vomiting should include assessment of ammonia during at least one of the episodes. Children may appear fussy eaters self-electing a low-protein diet. Episodes of acute metabolic decompensation may be precipitated by intercurrent infections. Long-term neurological sequelae relate to the severity of encephalopathic episodes (peak ammonia and duration), with peak ammonias as low as 360 $\mu\text{mol/l}$ being associated with poorer outcome [38].

Diagnosis is suggested by marked hyperammonemia and low urea. Assessment of amino acids and urinary orotic acid reveals the level of the block (see Table 64.6) and can be

analysed on a single sample by tandem mass spectrometry. Glutamine tends to be elevated as it forms part of the hepatic nitrogen pool that feeds into the urea cycle, and arginine low as it becomes an essential amino acid in UCDs due to reduced flux through the cycle, with the exception of arginase deficiency. Liver dysfunction and coagulopathy are often features in the acute stage. The main differential diagnosis for hyperammonemia includes spurious (poor sampling technique), organic acidemia, acute liver dysfunction and FAOs. Diagnosis is confirmed by liver enzymology and mutation analysis and prenatal diagnosis is available.

Acute management requires cessation of feeds, promotion of anabolism with 10% dextrose-based fluids with the addition of an insulin infusion if hyperglycemia appears and removal of ammonia. Initial management of hyperammonemia includes loading with alternate pathway drugs: Sodium benzoate (250 mg/kg) conjugates with glycine from the hepatic nitrogen pool allowing excretion in the urine bypassing the urea cycle and sodium phenylbutyrate (250 mg/kg) con-

Table 64.6 Diagnosis of urea cycle defects

Condition	Enzyme	Key amino acids	Orotic acid	Tissue for enzymology
NAGS deficiency	<i>N</i> -acetyl glutamate synthase	Glutamine \uparrow Arginine-normal	Normal	Liver
CPS deficiency	Carbamyl phosphate synthase	Glutamine \uparrow Arginine \downarrow	Normal	Liver
OTC deficiency	Ornithine transcarbamylase	Glutamine \uparrow Arginine \downarrow	$\uparrow\uparrow\uparrow$	Liver
Citrullinemia	Argininosuccinate synthase	Glutamine \uparrow Citrulline $\uparrow\uparrow\uparrow$	\uparrow	Liver
Argininosuccinic aciduria	Argininosuccinate lyase	Glutamine \uparrow Argininosuccinate \uparrow	\uparrow	Red blood cell Liver
Argininase deficiency	Arginase	Glutamine \uparrow Arginine $\uparrow\uparrow\uparrow$	$\uparrow\uparrow$	Red blood cell Liver

jugates with glutamine. This helps reduce the nitrogen load on the cycle and can be followed by a continuous infusion. Arginine becomes an essential amino acid with the exception of arginase deficiency and should be supplemented (150 mg/kg load) followed by a continuous infusion. Higher doses are required in citrullinemia and arginosuccinic aciduria (500 mg/kg/day). Carglumic acid, an *N*-acetylglutamate synthetic analogue is the specific treatment for *N*-acetylglutamate synthase (NAGS) deficiency [39]. A trial of carglumic acid has been proposed for use in all undiagnosed hyperammonemic crises. If ammonia levels are $>300 \mu\text{mol/l}$ and rising, dialysis is indicated for rapid control and to avoid the long-term neurological sequelae of prolonged hyperammonemia. The latter can be achieved with hemofiltration, but may be limited by the size of the baby ($>2.5 \text{ kg}$) where peritoneal dialysis (PD) is used. Crossflow PD using two catheters may be used in the smallest babies to improve ammonia clearance [40].

Long-term management requires dietary protein restriction, titrating growth with ammonia ($<70 \mu\text{mol/l}$) and glutamine ($<1000 \mu\text{mol/l}$) concentration. Essential amino acids are monitored to ensure the adequacy of the diet. Essential amino acid supplements can be used as part of the protein intake having the advantage that nitrogen waste will be reduced as non-essential amino acids will need to be synthesised. Sodium benzoate and/or sodium phenylbutyrate, and arginine continue as part of long term management; carglumic acid in NAGS deficiency. Citrulline can be substituted for arginine in severe OTC and CPS deficiency.

Prognosis is related to the peak ammonia and duration; a rapid reversal of hyperammonemia reduces the risk of neurological injury [41]. Neonatal presenting OTC has the poorest prognosis, and early liver transplantation in the first 6 months is indicated to offer the best long-term outcomes [42]. Liver transplantation in UCDs is reserved for brittle patients with good neurology and has a 5-year survival of approximately 90% [43]. Hepatocyte transplant has been used as a bridge to transplant in a few cases [44]. Liver fibrosis may develop in argininosuccinic aciduria, but the exact pathophysiology is not known.

Hyperornithinemia, Hyperammonemia, Homocitrillinuria Syndrome and Ornithine Aminotransferase Deficiency

Hyperammonemia is a feature of hyperornithinemia, hyperammonemia, homocitrillinuria (HHH) syndrome, a defect of ornithine transport into the mitochondrion. Severity is variable, but may present in a similar fashion to OTC deficiency. The diagnosis is suggested by an elevated ornithine, and it is confirmed on fibroblast uptake studies and genotyping.

Inheritance is autosomal recessive. Management follows UCD guidelines.

The differential for hyperornithinemia includes ornithine aminotransferase (OAT) deficiency (gyrate atrophy). Progressive retinal disease was thought to be the only manifestation; however, a number of OAT cases have now been observed where classical UCD presentation was a feature. At such times, ornithine levels are actually low rather than elevated, as the flux through the pathway in the first months of life is in the direction of ornithine synthesis rather than breakdown which then reverses during the first year of life [45].

Citrin Deficiency

Citrin deficiency results from a deficiency of the glutamate-aspartate transporter which has a role in gluconeogenesis from lactate and transporting cytosolic nicotinamide adenine dinucleotide (NADH)-reducing equivalents into mitochondria as part of the malate aspartate shuttle. Citrin deficiency causes two age specific phenotypes: neonatal intrahepatic cholestasis associated with citrin deficiency (NICCD) and citrullinemia type 2 (CTLN2) in adults that is more common in Japan and the Far East. The clinical features of NICCD are a transient intrahepatic cholestasis and poor weight gain. Liver dysfunction is variable and usually resolves in the first year of life. Some infants succumb to infection and liver cirrhosis. Transaminases are modestly elevated with hypoproteinemia and reduced coagulation factors. Complications include hemolytic anemia and hypoglycemia. Ammonia is only mildly elevated, but citrulline and methionine are significantly elevated with milder elevations in threonine, tyrosine, lysine and arginine [46]. Diagnosis is confirmed by SLC25A13 genotyping. Management includes the supplementation of fat soluble vitamins and the use of lactose-free or formulas containing medium-chain triglyceride (MCT). Many children subsequently develop aversion to carbohydrate-rich food and prefer protein-rich or fat-rich foods developing hyperlipidemia and the risk of fatty liver and pancreatitis. Some will develop CTLN2.

CTLN2 is characterised by acute onset recurrent hyperammonemia with neuropsychiatric symptoms. Hepatic argininosuccinate synthetase protein is reduced but without any mutations in the argininosuccinate (ASS) gene as seen in citrullinemia. Precipitants include alcohol, sugar intake, medicines such as anti-inflammatories or analgesics, or surgery. Not all patients have a preceding history of NICCD. Liver transplantation is the most effective treatment, preventing hyperammonemic crises and reversing the biochemistry [47]. Arginine supplementation reduces ammonia and careful dietary management is needed to provide appropriate carbohydrate (low) and protein (high) intake as the standard

hyperammonemic treatment of low protein, high carbohydrate can precipitate crises in these patients. This is because carbohydrate suppresses ureagenesis in citrin deficiency. Sodium pyruvate may have a role in treatment by reducing oxidative stress, reducing NADH and reducing inhibition of ureagenesis [48].

Lysinuric Protein Intolerance

Lysinuric protein intolerance results from impaired transport of dibasic amino acids: lysine, arginine and ornithine. There is both defective intestinal absorption and increased renal losses. Hyperammonemia, with associated symptoms, develops postprandially as protein intake increases on weaning. High-protein food aversion, failure to thrive and hepatosplenomegaly ensue. Some patients have anemia, leukopenia and thrombocytopenia; the reticulocyte count may be elevated. Pulmonary fibrosis may develop. Severe osteopenia with fractures is common. Immune disturbance with raised immunoglobulin (IgG), lymphocyte subsets and antibody response is recognised with hemophagocytic lymphohistiocytosis as a known complication.

Urinary lysine, arginine and ornithine excretion is increased with a corresponding reduction in plasma levels. Plasma glutamine, alanine and glycine are raised. Ammonia rises postprandially secondary to poor urea cycle function due to arginine depletion. Lactate dehydrogenase, ferritin and zinc are all increased with normal serum iron and transferrin. Combined hyperlipidemia is common in adults. Citrulline supplementation improves urea cycle function and protein tolerance while some patients require alternate pathway medication. Moderate protein restriction further reduces the likelihood of hyperammonemia. Lysine supplementation is complicated by poor absorption and diarrhea but small doses can improve deficiency. Carnitine is given to patients with low free carnitine. Crises are managed as UCDs above.

Organic Acidemias

Organic acidemias result from inherited blocks in the catabolic pathways of amino acids provoking the accumulation of organic acids prior to the block. There are many disorders, but the commonest are propionic acidemia (PA), methylmalonic acidemia (MMA) and isovaleric acidemia (IVA). Acute presentations, either severe neonatal or intermittent late onset forms are associated with encephalopathy, marked metabolic acidosis, raised anion gap, ketosis, elevated lactate and variable hyperammonemia, the latter resulting from secondary inhibition of the urea cycle. Hepatomegaly and liver dysfunction are frequent. Neutropenia, or frank pancytopenia, is a sign of marrow depression and may lag behind the

initial presentation and will recover as the decompensation is controlled. Blood glucose may be low, high or normal. Hypocalcemia is a frequent finding in the acute stage. IVA has an associated pungent odour of sweaty feet.

Diagnosis relies on urinary organic acid analysis to identify the key urinary metabolites and acylcarnitine analysis to identify abnormal plasma metabolites. Free carnitine may be depleted and glycine is often raised on plasma amino acid analysis. Complications include pancreatitis, cardiomyopathy and renal failure. Amylase should be measured during metabolic crises. Liver histology may show macro- or microvesicular fatty infiltration. Definitive diagnosis requires enzymology of the specific enzyme in fibroblasts.

Acute management is focused in promoting anabolism while removing toxic metabolites—intravenous fluids containing 10% dextrose are used in conjunction with protein restriction. Carnitine supplementation is used to facilitate organic acid excretion. Glycine is used in IVA for conjugation and increased clearance. Alternate pathway medication is used to manage acute hyperammonemia, and recently carglumic acid has been shown to be of use in some patients [49, 50]. Theoretically, this should work well as the site of urea cycle inhibition is at the level of NAGS and carginic acid is a synthetic analogue of *N*-acetylglutamate. Acute toxin removal during crises may require dialysis.

General management consists of protein restriction to a level that prevents overload of the pathway while providing sufficient for growth and repair, with or without amino acid supplementation, and cofactor supplementation. A trial of vitamin B₁₂ should be given to assess responsiveness in all patients with MMA. Metronidazole in low dose either continuously or episodically may be used to alter bowel flora to reduce propionate production from the gut. Constipation in itself may precipitate decompensation due to increased gut propionate production.

Patients remain at risk of decompensation most commonly precipitated by intercurrent infection and for patients with neonatal presentations the outlook is poor [51, 52]. Neurological and cognitive defects are common and progressive renal impairment is a feature of MMA leading to renal failure in the second to third decade. MMA patients who are B₁₂ responsive have a better prognosis, but the poor outcomes for most organic acidemias has led to serious consideration of transplantation. Liver transplant in PA has been successful with a marked reduction in risk of decompensation [53], but the risk of metabolic stroke persists and so a degree of protein restriction may still be required. The value of liver transplantation in MMA is less certain with significant continued risk of metabolic stroke and renal involvement [54]. Combined liver and renal transplantation has been performed, but is high risk [55], whereas isolated renal transplant appears to have a role in MMA patients with chronic kidney disease and may help reduce the frequency of decompensation [56].

Inherited Defects of Lipid Metabolism

Fat Oxidation Defects

The FAOs form a large group of conditions that commonly present with hepatic symptoms. Fatty acids are a major fuel source in the fasted state, the preferred substrate for cardiac muscle, and a vital energy source for skeletal muscle during prolonged exercise. Fatty acids are mobilised from stores and are oxidised by most tissues except the brain, which is reliant on hepatic β -oxidation for ketone production that can be utilised within the central nervous system reducing the demand for glucose.

Fatty acids are predominantly oxidised within mitochondria (see Fig. 64.5 and Table 64.7). The carnitine cycle is required for passage of fatty acyl-coenzyme A (CoA) across the mitochondrial membrane with the exception of medium chain fatty acids. The fatty acyl-CoAs then enter the β -oxidation cycle with shortening of the fatty acid by two carbons with each passage through the cycle yielding acetyl-CoA for entry into the TCA cycle or ketone production (liver), and reduced cofactors for entry into the respiratory chain for ATP production. The acyl-CoA dehydrogenases central to the β -oxidation cycle are chain length specific, for example, short-chain acyl-CoA dehydrogenase (SCAD), medium-chain acyl-CoA dehydrogenase (MCAD), and very long-chain acyl-CoA dehydrogenase (VLCAD) for saturated straight chain fatty acids. Unsaturated fatty acids require additional enzymes for oxidation, while branched-chain fatty acids require initial α -oxidation in peroxisomes before they can enter β -oxidation. This is why very long-chain fatty acids (VLCFA, that include the branched-chain fatty acids) are used as a screening test for peroxisomal disorders. Deficiencies of the electron transfer flavoprotein and its dehydrogenase (multiple acyl-CoA dehydrogenase (MAD) deficiency or glutaric aciduria type 2) block the transfer of electrons from β -oxidation to the respiratory chain, and also block the oxidation of branched chain amino acids, lysine and glutaric acid.

Clinical features are predominantly hypoketotic hypoglycemia, encephalopathy including a Reye-like syndrome, hepatomegaly, cardiomyopathy and rhabdomyolysis with the majority presenting within the first year, often precipitated by intercurrent infection. Fasting tolerance increases with age as hepatic glycogen stores increase and relative glucose requirement decreases. Hepatic symptoms are common with associated raised lactate and ammonia. Acute hepatomegaly can occur due to fatty acid mobilisation. Liver failure is rare. Hepatic symptoms may also occur in carrier mothers carrying an affected foetus. Cardiac involvement, either cardiomyopathy and/or arrhythmias may be seen in all FAOs except carnitine palmitoyl transferase 1 (CPT 1). Episodic muscle pain, rhabdomyolysis and myoglobinuria may be pre-

cipitated by metabolic stress such as exercise or intercurrent infections. Creatine kinase is elevated during muscle crises. Proximal muscle weakness may have a more chronic progressive course. Neuropathy and pigmentary retinopathy are long-term complications LCHAD deficiency. Neurological deficits may remain following acute encephalopathic insults in many of the FAOs.

Inappropriately low ketones in the presence of hypoglycemia always raises the possibility of an underlying FAO. Plasma acylcarnitine analysis by tandem mass spectrometry is the investigation of choice to diagnose the specific defect. Plasma free-carnitine may be depleted thereby masking the diagnostic acylcarnitine profile. Very low free-carnitine levels are found in a carnitine transport defect and are significantly elevated in CPT I deficiency. Full characterisation may require fat oxidation studies on cultured fibroblasts. Urinary organic acids at the time of decompensation may reveal characteristic dicarboxylic acids; however, the urine between bouts may be normal. Further confirmation may be gained from genotype analysis screening for the common A985G mutation in MCAD and G1528C in LCHAD. FAOs are inherited in an autosomal recessive fashion, and therefore siblings should be screened.

The acute management consists of glucose either orally or if not tolerated, intravenously as 10% dextrose saline to switch off lipolysis. Hypoglycemia is a late sign and so normoglycemia does not exclude significant decompensation and therefore management should not be delayed. Resolution of encephalopathy may take some hours. Long-term management consists of avoiding prolonged fasting. An emergency regime consisting of giving frequent high-calorie glucose polymer drinks every 2 h day and night is adopted during intercurrent infections. Failure to improve or to tolerate the drinks requires admission to hospital for intravenous dextrose.

In the long-chain defects, fat mobilisation is suppressed to avoid the production of toxic long-chain acylcarnitines by frequent feeds, the use of uncooked cornstarch and overnight nasogastric feeds. Long-chain fat in the diet is restricted, and essential fatty acids supplemented as walnut oil. MCT bypass the carnitine cycle and enter the mid-portion of the β -oxidation cycle and therefore may be of benefit in carnitine cycle and long-chain defects.

Carnitine replacement is essential in the carnitine transport defects (100–200 mg/kg/day). Low levels of carnitine are seen in many FAOs due to accumulation of acylcarnitines. The use of carnitine in long-chain FAOs remains controversial with the theoretical risk of compounding mitochondrial toxicity with the accumulation of long-chain acylcarnitines. A trial of riboflavin should be started in all patients with MAD. Triheptanoin is currently under investigation for use in FAOs to help replenish tricarboxylic acid intermediates and thereby increase flux and ATP production [57].

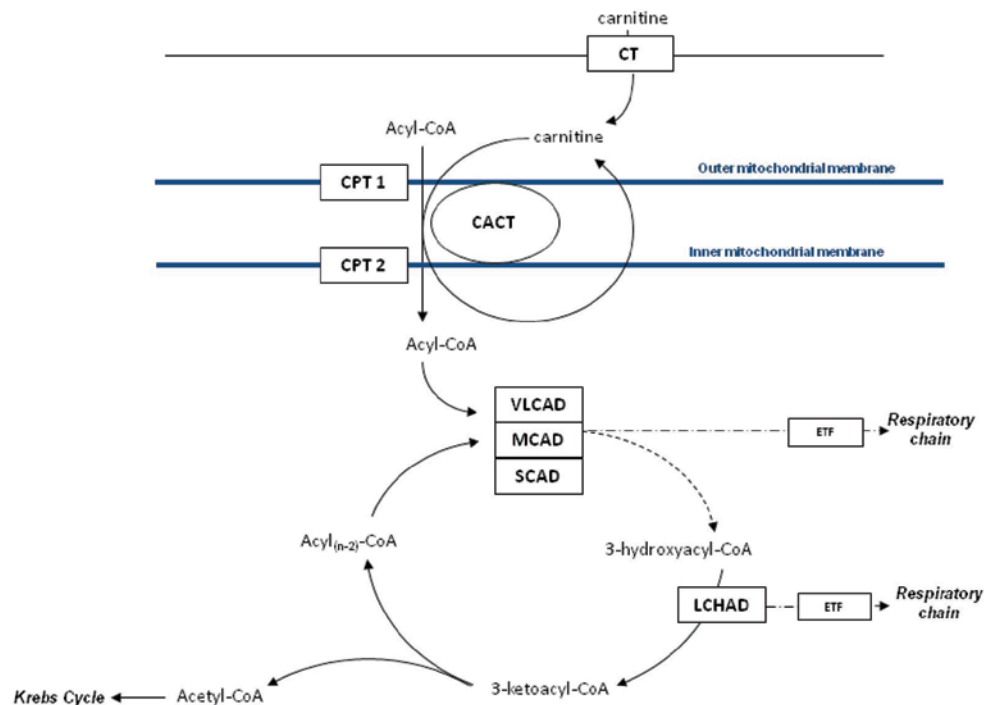

Fig. 64.5 Schematic of mitochondrial fatty acid β -oxidation. The carnitine shuttle facilitates fatty acid entry into the mitochondrial matrix where the β -oxidation spiral chain shortens fatty acids releasing energy in the form of acetyl-CoA that enters the Krebs cycle and electrons that are transferred via electron transfer flavoproteins (*dash-dot line*) to the respiratory chain. Disease causing enzymes are boxed: *CT* carnitine transporter, *CPT1*

carnitine palmitoyltransferase 1, *CPT2* carnitine palmitoyltransferase 2, *CACT* carnitine acylcarnitine translocase, *VLCAD* very long-chain acyl-CoA dehydrogenase, *MCAD* medium-chain acyl-CoA dehydrogenase, *SCAD* short-chain acyl-CoA dehydrogenase, *ETF* electron transfer flavoproteins (causing multiple acyl-CoA dehydrogenase deficiency (MADD)), *LCHAD* long-chain hydroxyacyl CoA dehydrogenase

Table 64.7 Clinical features of fat oxidation defects

Enzyme/transporter defect	Hypoketotic hypoglycemia/liver dysfunction	Cardiomyopathy	Rhabdomyolysis	Other features
<i>Carnitine cycle</i>				
Carnitine transporter (CTD)	+	+		
Carnitine palmitoyl transferase-1 (CPT1)	+	+	+	Renal tubular acidosis
Carnitine/acylcarnitine translocase (CACT)	+	+		
Carnitine palmitoyl transferase-2 (CPT2)	+	+ (CPT2 and cardiomyopathy)	+ (CPT2 and rhabdomyolysis)	
<i>β-oxidation cycle</i>				
Very long-chain acyl-CoA dehydrogenase (VLCAD)	+	+	+	
Long-chain hydroxy acyl-CoA dehydrogenase (LCHAD) and trifunctional protein (MTP)	+	+	+	Retinopathy, neuropathy
Medium-chain acyl-CoA dehydrogenase (MCAD)	+	+	+	
Short-chain hydroxyacyl-CoA dehydrogenase (SCHAD)	+			
<i>Electron transfer</i>				
Multiple acyl-CoA dehydrogenase (glutaric acidurias type II)	+	+		

The prognosis in many FAOs depends on the avoidance of acute decompensations. The outcome in MCADD is much improved once the diagnosis is made and future crises avoid-

ed [58]. Neonatal screening for detection of MCADD in the UK and other FAOs overseas on blood spot acylcarnitines by tandem mass spectrometry has greatly reduced morbidity

ity and mortality [59], but cannot eliminate early neonatal deaths prior to the screening result being available. Siblings with milder phenotypes with the same genotype have been recognised since screening, particularly with regard to VLCAD. Recurrent rhabdomyolysis remains a problem in patients with CPT 2, VLCAD and LCHAD, the latter also developing retinopathy and neuropathy which are not prevented by current management strategies.

Acyl-CoA Dehydrogenase 9 (ACAD 9)

ACAD9 is an unsaturated acyl-CoA dehydrogenase with weak overlapping activity with VLCAD but is non-compensatory in VLCAD deficiency and has a very different physiological role in that it is crucial for complex I biogenesis in the respiratory chain [60]. ACAD9 deficiency is therefore not an FAO but a mitochondrial disorder. The clinical, phenotype continues to expand and includes liver dysfunction including liver failure, hypoglycemia, muscle hypotonia, cardiomyopathy, lactic acidosis and neurological symptoms [61–63]. Patients may be responsive to riboflavin supplementation.

Other Inherited Metabolic Disorders

Lysosomal Storage Disorders

The lysosome is an intracellular organelle that is a key component in cellular recycling and homeostasis. The LSDs are a large group comprising of over 50 disorders with an estimated combined prevalence of approximately 1 in 8000 [64]. The fundamental pathological mechanism of these disorders is of a single enzyme deficiency leading to defective degradation or transport of a complex molecule such as a mucopolysaccharide or sphingolipid. The consequence is a

build-up of ‘storage’ material that impacts on normal cellular function and homeostasis. These conditions are commonly progressive and multisystemic, effecting systems to a highly variable degree. Musculoskeletal involvement can include hypotonia, dysostosis multiplex, cardiomyopathy and the classically course features of the mucopolysaccharidosis. Endothelial reticular involvement can include hepatosplenomegaly and bone marrow dysfunction. Neurological involvement is common and is the most devastating feature of LSDs, causing severe neurological regression.

Hepatomegaly, usually associated with splenomegaly, is a common feature of LSDs. A list of LSDs that are associated with hepatosplenomegaly is listed Table 64.8 along with other common associated features. Of all the LSDs, the lipid storage diseases (NPC and Wolman (cholesterol ester storage) disease) are most commonly associated with liver dysfunction, and are considered in more detail below.

Niemann–Pick Type C

NPC is a disorder of cholesterol trafficking that leads to accumulation of unesterified cholesterol within the lysosome. The classical presentation is of neonatal jaundice and liver impairment that resolves with subsequent onset of a progressive neurological deterioration (between 3 and 13 years). However, the presentation is highly variable making the diagnosis notoriously difficult [65, 66]. Patients may have no hepatic involvement prior to the onset of neurological symptoms. Conversely, neonatal hepatic failure has been described in the absence of neurological symptoms, while a diagnosis has been made on the basis of isolated splenomegaly in adulthood alone. Persistent splenomegaly is a common finding. The neurological presentation is also varied and classically involves vertical gaze palsy. Another unusual feature that has been described in association with NPC is gelastic cataplexy. The other neurological manifestations are typically progressive with initial hypotonia leading to dysto-

Table 64.8 LSDs commonly associated with hepatosplenomegaly

Disorder	Associated features
GM1/GM2 gangliosidosis	Neurological regression, coarse facies, cherry-red spot
Mucopolysaccharidoses	Coarse facial features, +/- skeletal dysplasia, neurological regression, cardiomyopathy
Fucosidosis	Neurological regression, seizures, coarse facies
Mannosidosis	Neurological regression, corneal clouding, coarse facies
Sialidosis type II	Neurological regression, coarse facies, cherry-red spot, cardiomyopathy
Galactosialidosis	Coarse facies, neurological regression, skeletal dysplasia, spasticity, corneal clouding, cherry-red spot
Niemann–Pick A	Neurological regression, failure to thrive, cherry-red spot
Niemann–Pick B	Growth restriction, interstitial lung disease, normal intelligence
Niemann–Pick C	Neonatal liver disease, neurological regression, seizures, cherry-red spot
Farber	Contractures, skin nodules, neurodegeneration
Multiple sulphatase deficiency	Coarse facies, skeletal dysplasia, neurodegeneration, spasticity
I-cell disease	Neonatal coarse features, skeletal dysplasia, neurodegeneration, cardiomyopathy
Pompe	Hypotonia, cardiomyopathy, macroglossia
Wolman	Failure to thrive, abdominal distension, diarrhea, calcification of adrenal glands

nia, spasticity, dysphagia and psychiatric disturbances commonly leading to death in the first or second decade. Early onset of neurological symptoms is generally associated with a poor prognosis.

Diagnosis has been hampered by the lack of simple biomarker for the disease. Traditionally, diagnosis was made on a histological basis using stains such as filipin to detect the presence of unesterified cholesterol from fibroblasts or the presence of foam cells/sea blue histiocytes in bone marrow. Chitotriosidase is also significantly raised in NPC, as it is in a number of LSDs including Gauchers disease (it should be noted approximately 6% of the European population have no chitotriosidase activity [67]). However, these tests are not sensitive and may produce equivocal results. Further confirmation can be achieved by genetic characterisation of the two causative genes *NPC1* (accounting for approximately 95% cases) and *NPC2*. However, a new rapid test measuring oxysterols in plasma promises to be both a sensitive and specific test for this condition [68].

Treatment for NPC is generally restricted to symptomatic support of either hepatic or neurological manifestations, although some novel medical therapies are emerging as possible disease modifiers. Liver transplant has been used but failed to prevent neurological deterioration [69] while the evidence available to support bone marrow transplant does not demonstrate efficacy in improving neurology outcome [70, 71]. Migustat is a substrate reduction therapy that was originally developed to treat the sphingolipioses, but it has shown some efficacy in stabilising the progression of neurological disease, especially in the later onset forms of the disease [72]. Another medical therapy undergoing phase I clinical trial is cyclodextrin, an agent capable of sequestering cholesterol and that is postulated to facilitate its transport from the lysosome [73, 74].

Wolman/Cholesterol Ester Storage Disease

Both Wolman disease and cholesterol ester storage disease (CESD) are caused by a deficiency of lysosomal acid lipase that leads to accumulation of cholesterol esters and triglycerides. Wolman disease represents the severe phenotype with massive hepatosplenomegaly and death in infancy while patients with CESD have a different and attenuated phenotype involving more benign hepatomegaly in later childhood or adulthood. The genotypes observed in CESD are generally associated with residual enzyme activity (commonly associated with a c.894G>A mutation) [75].

Patients with Wolman disease usually have a short period of normal progress for the first month or two of life before developing diarrhea (steatorrhoea), vomiting, abdominal distension and severe failure to thrive. Massive hepatosplenomegaly is prominent and can be associated with ascites, jaundice and transaminitis while anemia is common. Survival beyond the first year is unusual. Calcification of the

adrenals is a hallmark of this disorder and can be identified on abdominal films, ultrasound and more reliably computed tomography (CT). Plasma cholesterol and triglyceride levels are commonly raised but may be normal. Further diagnostic clues can be found by histological examination; vacuolated lymphocytes can be seen on peripheral blood film and foamy histiocytes on bone marrow aspirate. Liver biopsy reveals foamy macrophages and Kupffer cells with large vacuolated hepatocytes. Periportal fibrosis develops and portal cirrhosis may be present [76].

Definitive diagnosis relies on assay of enzyme activity in leucocytes or characterisation of the *LIPA* gene. Treatment has historically been symptomatic. Bone marrow transplant has been implemented in early diagnoses with limited success [76, 77]. The development of enzyme replacement therapy potentially represents the first effective treatment for Wolman disease. In principle, enzyme replacement therapy shows promise as the severely affected organs (liver, spleen and gut) are highly accessible to enzyme given intravenously. Clinical trials for sebelipase alfa are currently ongoing (ClinicalTrials.gov identifier NCT017574).

Patients with CESD may present in childhood or adulthood with asymptomatic hepatomegaly or hepatosplenomegaly. Progression to cirrhosis and chronic liver failure is uncommon. Hyperlipidemia is prominent and premature atherosclerosis is common. Treatment with 3-hydroxy-3-methyl-glutaryl-CoA (HMG-CoA) reductase inhibitor provides the mainstay of treatment.

Peroxisomal Disorders

Peroxisomes are subcellular organelles present in all cells except mature erythrocytes, and are especially abundant within the liver. Key functions include β -oxidation of chain fatty acids and fatty acid derivatives, pipecolic acid and glyoxylate degradation, phytanate α -oxidation, plasmalogen, cholesterol, and bile acid biosynthesis [78]. Biochemically, peroxisomal disorders are characterised by the extent of peroxisomal dysfunction from complete absence of peroxisomes (biogenesis disorders), to multiple enzyme defects and single enzyme defects. However, there is much overlap within the phenotypes of these groups; hence, a more useful categorization is made by considering clinical features and age of presentation.

In the most severe peroxisomal phenotype, Zellweger spectrum disorder (ZSD—includes previous classifications of Zellweger syndrome, neonatal adrenoleukodystrophy and infantile Refsum disease), hepatic involvement is a prominent feature. ZSD presents in the neonatal period or early infancy with severe neurological impairment including marked hypotonia, seizures and retardation, jaundice, hepatomegaly, cholestasis, hepatic dysfunction and classical dys-

morphic features that are often the key to diagnosis. Liver histology shows fibrosis usually leading to micronodular cirrhosis. Renal cysts are common; however, they may not be easily demonstrable on ultrasonography. Ocular features are common including retinopathy, cataracts and optic nerve dysplasia. Failure to thrive evolves and little developmental progress is made. Death usually occurs within the first 12 months although the more attenuated forms may involve survival well into the first decade.

Defects in a large number of genes have been described as causing ZSD (mostly *PEX* genes). Initial investigations should include plasma VLCFAs. These are typically elevated, but it should be noted that in some peroxisomal phenotypes other than ZSD VLCFAs may be normal. Further delineation of the biochemical block may be gained by measuring plasma bile acid intermediates and plasmalogens. Definition of the precise molecular defect requires skin biopsy and complementation studies followed by enzymology or molecular genetic techniques. Other investigations that may be considered to support a diagnosis of ZSD are electroretinogram (ERG), visual evoked potentials (VEPs) and brain auditory-evoked responses (BSAERs) that are abnormal in most cases. Neuroimaging may delineate neuronal migrational defects and demyelination. Plain films of the knees may reveal calcific stippling.

Treatment remains supportive and can be challenging. Seizures are typically difficult to control and hypotonia often results in requirement for assisted feeding. Progressive liver impairment often contributes to morbidity and mortality. Docosahexanoic acid (DHA) supplementation has been attempted as it is believed to play an important role in brain development, but most recent evidence does not support therapeutic benefit [79]. Ursodeoxycholic acid is commonly used to improve bile flow in cholestatic patients, but the primary bile acids cholic and chenodeoxycholic acids have also been reported to improve hepatic outcome in a single patient with ZSD [80]. The primary bile acids are postulated to improve bile flow but also inhibit, by negative feedback, the production of abnormal bile acid metabolites formed in the absence of functioning peroxisomes. Currently, a clinical trial of cholic acid is in progress (ClinicalTrials.gov NCT00007020). The authors experience in one patient was increasing transaminitis upon commencement of cholic acid that was subsequently stopped. It should be noted that cholic acid is a biological detergent and increased hepatic concentration via enterohepatic circulation could at least in theory contribute to hepatotoxicity.

α -Methyl-CoA racemase (AMACR) deficiency is a rare peroxisomal disorder that is associated with an adult onset sensorimotor neuropathy, but has been described causing neonatal cholestasis. Treatment of the neuropathy is with a phytanate restricted diet while the neonatal cholestasis may respond to cholic acid therapy. It should be noted VLCFAs

will be normal with elevated pristanic and bile acid intermediates dihydroxycholestanic acid (DHCA)/ trihydroxycholestanic acid (THCA) [81].

Mitochondrial Disorders

Mitochondria are central to metabolism, producing the energy required to drive the cell via oxidative phosphorylation with the generation of ATP. Mitochondrial disease can affect any organ. However, those that have a high metabolic demand are more likely to produce symptoms, particularly the brain, muscle, kidney and liver. Mitochondrial involvement may be patchy throughout the body leading to a constellation of problems that at first may appear unrelated, so-called illegitimate associations that may be considered the hallmark of mitochondrial disease. Diagnostic clues such as lactic acidemia may be present but are often absent and further evidence of mitochondrial dysfunction is often sort by biochemical assay of respiratory chain enzymes that requires invasive muscle biopsy. If mitochondrial disorders are to be successfully identified, evidence of multisystem involvement must be actively sort. Treatment for the vast majority of mitochondrial disorders remains symptomatic. Most are progressive disorders, while examples of self-resolving conditions have recently been described.

There is a rapidly increasing number of mitochondrial disorders being described whose pathophysiology is becoming clear and that present with well-defined clinical syndromes. Examples of these that include the hepatic/GI system are included in Table 64.9, and the reader should be directed to several recent reviews of hepatic/GI mitochondrial disease [82, 83]. Any review of mitochondrial disease warrants a text all to itself, but this section outlines a few of the mitochondrial conditions whose primary features are hepatic/GI in nature.

Hepatic dysfunction is common in mitochondrial DNA depletion syndromes (MDDS). These conditions may present with early-onset liver failure, hepatomegaly and hypoglycemia and are usually associated with significant neurological symptoms such as seizures, encephalopathy, neuroregression and nystagmus. Alpers (Alpers–Huttenlocher) syndrome typifies this presentation and is caused by mutations in the nuclear gene *POLG* that encodes a DNA polymerase that is responsible for mitochondrial replication. Seizures are often the herald of disease onset, usually before the age of 2 years. Liver failure may then ensue and can be triggered by valproate therapy. Hepatic dysfunction has also been associated with disorders of mitochondrial DNA translation. A particularly interesting example of this is seen in mutations of the *TRMU* gene. These are associated with a syndrome of acute liver failure in early infancy that, if surviving the initial presentation, has spontaneous recovery of liver func-

Table 64.9 Mitochondrial syndromes affecting hepatic/gastrointestinal systems

System affected	Disorder	Mitochondrial pathology	Associated features	Gene(s)
Liver	Alpers–Huttenlocher	MDDS	Seizures, liver dysfunction, failure	<i>POLG, PEO1, FARS2</i>
	Hepatocerebral mitochondrial cytopathy	MDDS	Development arrest, seizures, liver dysfunction/failure, peripheral neuropathy	<i>DGUOK (elevated tyrosine)</i> <i>MPV17</i> <i>SUCLG1 (raised MMA)</i>
	Navajo neurohepatopathy	MDDS	Liver disease, sensorimotor neuropathy, acral mutilation, corneal scarring	<i>MPV17</i>
	‘Benign’ reversible mitochondrial hepatopathy	mtDNA translation defect	Liver failure with spontaneous recovery	<i>TRMU</i>
	GRACILE syndrome	Complex III assembly	Growth restriction, aminoaciduria, cholestasis, iron overload, lactic acidosis	<i>BCS1L</i>
	MEGDEL syndrome	Mitochondrial membrane defect	Liver dysfunction, 3-methylglutaconic aciduria, deafness, leigh-like encephalopathy	<i>SERAC1</i>
Gastrointestinal	MNGIE	MDDS	Pseudo-obstruction, encephalopathy, ophthalmoplegia, peripheral neuropathy	<i>TYMP</i>
	Pearson syndrome	Large scale mtDNA rearrangement	Pancreatic exocrine dysfunction, sideroblastic anaemia	
	Ethylmalonic encephalopathy	Inhibition of complex IV	Diarrhea, encephalopathy, acrocyanosis, petechiae	<i>ETHE1</i>

MDDS mitochondrial DNA depletion syndrome, *mtDNA* mitochondrial DNA, *MMA* methylmalonic acid, *GRACILE* growth retardation, aminoaciduria, cholestasis, iron overload, lactacidosis and early death, *MEGDEL* methylglutaconic aciduria with deafness, encephalopathy, and Leigh-like syndrome, *MNGIE* mitochondrial neurogastrointestinal encephalomyopathy

tion and subsequent normal development with favourable prognosis. Identification and intensive support of these patients is paramount. Defects of individual respiratory chain complexes can also give rise to hepatic disease. An example of this is GRACILE syndrome (growth restriction associated with aminoaciduria, cholestasis, iron overload, lactic acidosis and early death) caused by mutations in *BCS1L*, although this has been linked to a variety of other phenotypes many of which include liver impairment.

Examples of mitochondrial disorders that present with GI upset include mitochondrial neurogastrointestinal encephalopathy (MNGIE) and ethylmalonic encephalopathy (EME). MNGIE is caused by an autosomal recessive deficiency of thymidine phosphorylase that classically presents in the first three decades of life. Initial symptoms are often related to GI dysmotility and can present as frank pseudobstruction and failure to thrive/cachexia. However, neurological symptoms develop that include peripheral neuropathy, ptosis, ophthalmoplegia, hearing loss and a progressive leukoencephalopathy. Lactic acidemia may be present. Unusually for a mitochondrial disorder, a diagnostic metabolic profile of raised urinary/plasma thymidine and deoxyuridine will confirm the diagnosis. EME also has a characteristic metabolic profile

with large amounts of ethylmalonic acid found in urine (ethylmalonic acid is commonly found in small amounts in urine as a non-specific marker of mitochondrial dysfunction). It is caused by mutations in *ETHE1* that encodes a mitochondrial sulphur dioxygenase, which has a role in sulphur detoxification. Accumulation of hydrogen sulphide potentially inhibits complex IV of the respiratory chain. Affected infants classically have persistent diarrhea and the unusual finding of petechiae and acrocyanosis. Associated neurological findings include seizures, encephalopathy and developmental regression. This condition is usually lethal in infancy.

Investigation of suspected mitochondrial disease includes assessment of potentially affected organ systems—important to consider are markers of renal tubular dysfunction, liver function, echocardiogram/ECG and neuroimaging. Non-specific biochemical evidence of mitochondrial dysfunction can be demonstrated by elevated lactate levels, but further biochemical evaluation requires invasive testing such as muscle biopsy to assess individual components of the respiratory chain. Ultimately, the clinical and biochemical picture may enable selected molecular testing to come to a diagnosis.

Mitochondrial conditions have a vast array of presentations that can include hepatic dysfunction and GI symptoms.

These are multisystem disorders and should always be on the differential list of the gastroenterologist faced with a child with multisystem disease, especially a child with unexplained neurological symptoms.

Concluding Remarks

Inherited disorders of metabolism are individually rare but as a group of conditions are commonplace. The group is rapidly expanding as clinicians and scientists have access to technologies that allow comprehensive analytical screening of metabolites and high-throughput gene/genome sequencing. Inherited disorders of metabolism rarely display isolated hepatic or GI disease, but it is not unusual for these to be presenting features. In order to recognise these conditions promptly, clinicians should be aware of the different modes of presentation that inherited metabolic disease can manifest and also to actively search for clues to the presence of metabolic disease, such as a thorough family history and the presence of multisystem disease.

Introduction

Wilson's disease (WD) was first described as the new disease in 1912 by Samuel Kinnier Wilson: "it was characterized as progressive lenticular degeneration, a familial nervous disease associated with cirrhosis of the liver" [1]. After 100 years we know a lot about the disease—molecular defects have been identified, there is some agreement on diagnostic tests, and we have effective therapies. Still, there are many questions that arise with the growing knowledge on the disease. Moreover, diagnostic and therapeutic practices differ among countries which could be shown when collecting information in a large European database of new Wilsonian cases within the "Eurowilson" project. We do not have a clear answer to variability of clinical presentations of WD and mutation analysis does not explain variable course and onset of the disease. The most effective therapies are still discussed. There are a few position statements coming with proposals of diagnostic and therapeutic standards, but they also raise many opened questions. Also specific problems of pediatric age are not analyzed in detail [2].

Definition

WD is an autosomal recessive disorder of copper metabolism, which leads to copper accumulation in the liver and other organs and tissues including brain. The clinical presentation was first described by Wilson in 1912, who also indicated inheritance of the disease showing familial nature. The disease

gene encodes adenosine triphosphatase 7B (ATPase7B)—a protein responsible for transporting copper into the secretory pathway for incorporation into apoceruloplasmin and excretion into the bile. It is located on chromosome 13. Prevalence of different mutations differs among populations. Clinical presentation is variable—the disease commonly affects liver and central nervous system. The prevalence of the disease is estimated to be 1:40,000 up to 1:30,000.

Pathophysiology

Copper is an essential dietary nutrient which is present in most of dietary products. The daily requirement is about 0.9 mg and the excess must be excreted. Copper facilitates electron transfer reactions and is needed for mitochondrial respiration, melanin biosynthesis, dopamine metabolism, iron homeostasis, antioxidant defense, connective tissue formation, and peptide amidation. Still, it can be potentially toxic to the cells which may be explained partly by the Fenton reaction in which Cu^{1+} causes production of the highly reactive hydroxyl radical which may cause lipid peroxidation of macromolecules:

Biliary excretion is the only mechanism for copper elimination under physiological conditions, and it increases with increasing size of the hepatic copper pool. Trafficking of copper in and through the hepatocytes involves several transport proteins: *Copper transporter 1* (Ctr1) responsible for the copper uptake at the hepatocyte plasma membrane; *metallothioneins* (MT), intracellular proteins capable of binding metalions, including copper; and *metallochaperones* that mediate the delivery of copper to specific proteins, and they are responsible for transfer of copper from metallothionein to the site of synthesis of copper containing proteins. Trafficking of copper is essential for further binding with ATP7B protein.

The WD protein, ATP7B has got several functions that finally allow effective copper excretion from the hepatocyte and binding with ceruloplasmin which protects from potential copper toxicity. Copper transport into the trans-Golgi is initiated by ATP binding to the “nucleotide binding domain” of ATP7B. ATP hydrolysis and subsequent dephosphorylation allows the movement of copper associated with two binding sites on one of the transmembrane domains into the lumen of the trans-Golgi. Entering trans-Golgi is essential for the further transport of copper—it is incorporated into apo-ceruloplasmin and other apoproteins and then excreted to sinusoids or after saturation of six copper-binding sites at the N-terminal cytoplasmic tail of ATP7B and phosphorylation of serine residues it migrates in vesicles to the biliary canaliculus [1].

Mutations of the WD gene coding ATP7B protein impair its function and lead to accumulation of copper in the hepatocyte and in other organs. There are more than 500 mutations in the WD gene identified which affect the catalytic and export functions of the protein (according to the database: <http://www.wilsondisease.med.ualberta.ca/database.asp> [3]). The most common are missense mutations. The functional consequences of most mutations are not described. Usually two different mutations can be found on two different alleles of a gene (heterozygous composition). The most common mutation in Caucasian patients is H1069Q in the nucleotide-binding domain. This mutant binds ATP in an incorrect orientation with a reduced affinity, causing instability due to temperature-dependent unfolding and retention of ATP7B_{H1069Q} within the endoplasmic reticulum [4]. For better understanding the role of different mutation of functionality of ATP7B, a yeast strain that lacks its endogenous copper transporter was used to segregate ATP7B mutants into severe and mild categories based on their ability to restore growth. Studies in mammalian cells have shown decreased protein levels and mislocalization for several mutants, and copper transport has been studied in vesicles derived from cell lines with various ATP7B mutations [5]. The functional studies can help to understand why some mutations are pathogenic and lead to copper accumulation, but do not yet explain the

Fig. 65.1 Copper transport within a hepatocyte involving ATPase7B protein

phenotypic variability of WD. Liver disease seems to result from a direct copper accumulation in hepatocytes, and consequently mitochondrial damage and disturbance of lipid oxidation. Hepatic steatosis is an early pathologic feature of the disease and may be explained by this mechanism. Injury of other tissues seems to be a consequence of copper accumulation outside the liver and usually appears at later age. Once capacity of the liver to store copper is exhausted, copper is released into the circulation. It can be taken by different organs but the central nervous system is most vulnerable [6].

Specific pathways that allow the intracellular trafficking and compartmentalization of copper within the hepatocyte showing the role of ATPase7B are shown on Fig. 65.1.

Liver Histology and Ultrastructural Changes

Histological abnormalities observed in liver biopsy are not specific for WD and cannot be regarded as a valuable diagnostic tool. In the early phase, microvesicular and macrovesicular fatty deposition can be observed (Fig. 65.2), with glycogen-containing vacuoles in the nuclei of periportal hepatocytes. Liver disease may then progress to portal fibrosis and

Fig. 65.2 Histopathological findings on liver biopsy from patients with Wilson’s disease: **a** steatosis (HE staining) and **b** advanced fibrosis (Azan staining). (Courtesy of Dr Joanna Kuszyk, Department of Pathology of the Children’s Memorial Health Institute, Warsaw)

inflammation. It should be noticed that histological changes in WD may resemble those observed in autoimmune hepatitis (AIH) with interportal fibrous bridging or cirrhosis.

Ultrastructural changes are also not regarded to have a significant diagnostic value— one of the typical features are pleomorphic mitochondria with increased matrix density and widening of intercrystal spaces.

Copper staining can be used for diagnostic purposes— using rhodanine or rubeanic acid staining. The absence of histochemically demonstrable copper does not exclude a diagnosis of WD. Liver copper content is used as one of major diagnostic criteria—therefore in suspected WD, a piece of the liver biopsy should be placed in a dry plastic copper-free container for subsequent analysis by atomic absorption analysis.

Clinical Symptoms

WD may present with liver, neurological, or psychiatric symptoms. It seems that liver involvement can be observed in most of the neurological presentations but it is not always looked for. Due to high index of suspicion in many countries WD is diagnosed very early in the presymptomatic phase. WD may present at any age from early childhood (with raised transaminases, measured for some unrelated reason) to the eighth decade (often with surprisingly mild neurological features). Still, the clear liver symptoms (like hepatomegaly, clotting disturbances) have not been observed before the age of 3 years.

Hepatic Symptoms

There is a wide spectrum of hepatic involvement from asymptomatic to hepatomegaly, fatty liver disease, hepatitis, jaundice, cirrhosis, and liver failure at the end. As indicated earlier, the liver damage and liver symptoms are not characteristic and making diagnosis required biochemical and/or molecular tests. AIH can be easily misdiagnosed as specific for this condition autoantibodies are commonly found in WD. Therefore final diagnosis of AIH requires exclusion of WD.

Acute liver failure is a severe presentation of WD and requires fast diagnosis which may be difficult to obtain. It is usually found in a previously healthy child who suddenly presents with jaundice, hepatomegaly, rapidly progressing coagulopathy, and, in some cases, encephalopathy. The case history of a child may reveal important clinical problems in the past: episodes of jaundice, hemolytic anemia, or increased transaminases. Even if acute liver failure is not a chronic condition, liver biopsies taken at transplantation or

postmortem show cirrhosis which indicates that it is acute on chronic liver disease. Acute liver failure is defined according to the Pediatric Acute Liver Failure (PALF) study group—in a child with biochemical evidence of acute liver injury, international normalized ratio (INR) exceeds/equals 1.0, in the presence of clinical hepatic encephalopathy (HE), or exceeds/equals 2.0 regardless of encephalopathy (HE). WD makes a significant proportion of ALF etiologies—in 703 ALF patients in the PALF registry, 23 had a diagnosis of WD. However, among 329 patients without a final diagnosis, WD had been tested for in only 81 % so there may be some underdiagnosis [7]. WD comprised 4% of the King's College Hospital pediatric ALF series [8].

Some clinical and lab features may indicate WD in acute liver failure like KF ring, family history of WD, neurologic features of WD, jaundice and relatively moderately increased transaminases (100–500 IU/l) and alkaline phosphatase (<600 IU/l), hemolysis, and high bilirubin (>300 $\mu\text{mol/l}$) [9].

Presence of encephalopathy is a bad prognostic feature [10].

Chronic liver disease is more common among Wilsonian patients. Again, AIH may be falsely diagnosed because of the presence of low-titre autoantibodies. The differential diagnosis requires also testing for viral hepatitis and alpha-1-antitrypsin deficiency.

Acute hepatitis is not commonly observed, and it can be rather looked for in the past history of the patient with WD who could have had an episode of jaundice and malaise from which he recovered.

Neurological Symptoms

Neurological symptoms are extremely rare in children with WD as they usually develop in the third decade of life and are the presenting symptoms of WD in about half of all patients. Some initial symptoms can be difficult to be diagnosed like difficulty with speech. Otherwise the neurological symptoms seem to be typical and can be described as:

1. A dystonic syndrome with dystonic postures and choreo-athetosis
2. An ataxic syndrome presenting as postural and intentional tremor and ataxia of the limbs
3. A parkinsonian syndrome with hypokinesia, rigidity, and resting tremor

To improve diagnostic approach and evaluate therapy, Czlonkowska and coworkers developed a scoring system for neurologic symptoms in adult patients with WD based on the Eurowilson project [11, 12]. The limited data on neurological presentations in children does not allow describing the frequency of neurological symptoms at this age. However, dysarthria, salivation, gait disturbances, and postural tremor

should be looked for. The presence of Kayser–Fleischer ring is usually associated with neurological involvement.

Other Symptoms

Psychiatric symptoms are described to be the predominant presentation of WD recognized in adults in later age but usually are associated with other clinical symptoms. The most common seems to be depression which can lead to attempted suicide (also from author's experience in children). Psychiatric problems are not easy to detect as some of them can be attributed to the teenage such as mood change, aggressiveness, and irritability. These symptoms may also be a reason for noncompliance with therapy once WD is diagnosed.

Kayser–Fleischer ring is very typical for WD and should be always looked for with a slit lamp—it is a gold or gray-brown opacity in the peripheral cornea which represents a deposit of copper and sulfur-rich granules in Descemet's membrane. Although very characteristic, Kayser–Fleischer ring is uncommon in children (observed in less than 5% of children with WD).

Hemolysis with negative Coombs test is another typical feature of WD even if not commonly described in children with WD—usually it associated with fulminant liver failure.

Dermatological findings are also described in children with WD such as xerosis, keratosis pilaris, spider angioma, papulopustular lesions, and hyperpigmentation [13].

Fanconi syndrome (renal tubular abnormality presenting as glycosuria, aminoaciduria, renal tubular acidosis, impaired phosphate reabsorption) can be observed in the course of WD. Proteinuria may also be detected pointing to glomerular damage in the course of WD but it is usually associated with penicillamine therapy.

Skeletal manifestations appear rarely and include arthritis, rickets, or osteoporosis.

Asymptomatic WD

Asymptomatic liver disease seems to be the most common presentation due to increasing awareness of WD manifestation with slightly increased transaminases. Abnormalities at physical examination like hepatomegaly and splenomegaly and abnormal liver tests raise a suspicion of WD. In some countries, liver tests are checked at many occasions and any abnormalities lead to further differential diagnosis of liver problems [14]. Siblings of Wilsonian patients should be also diagnosed as early as possible usually in the preclinical phase.

Diagnostic Approach

As WD can mimic any kind of liver disease in childhood other than neonatal cholestasis, the diagnosis rests upon lab findings (Table 65.1) [15]. Ensure that the lab you are relying upon participates in an external quality assurance scheme. Each of the tests has limitations, and particular tests vary in usefulness in different clinical situations.

Plasma Ceruloplasmin

Plasma ceruloplasmin (CP) may be measured immunologically or by enzymatic activity; the latter is more accurate in WD, where apoceruloplasmin may contribute to the level measured immunologically. Be aware that CP is an acute phase reactant, so may be elevated into the normal range in WD with active liver inflammation, is produced in the liver so may be reduced in cirrhosis of other causes, may be reduced in WD or aceruloplasminemia heterozygotes, may be low in protein losing enteropathy, and is a glycoprotein so may be reduced in some disorders of glycosylation. Twenty

Table 65.1 Diagnostic biochemical tests for WD [15]

Test	Comments
Serum ceruloplasmin	<20 mg/dl (in >80% of WD patients)
Urinary copper excretion	24 h copper excretion >100 µg in 65% of WD patients
Urinary copper penicillamine challenge with two dosages of 500 mg 12 h apart and measure urine copper	24 h copper excretion >1600 µg in patients with active liver disease
Serum copper	Serum copper may be low in asymptomatic cases (because ceruloplasmin is low) or high in cases with active liver disease (because free copper is raised)
Serum "free" copper calculated on the basis that ceruloplasmin contains 0.3% copper	Free copper >25 µg/dl
Liver copper	>250 µg/g of dry weight liver

WD Wilson's disease

percent of WD patients may present with normal ceruloplasmin levels. Values exceeding 30 mg/dl are rare in WD.

Twenty-Four-Hour Urinary Copper Excretion

Accuracy of 24 h urinary copper estimations depends on the collection, the container, and the lab. Values greater than 40 $\mu\text{g}/24\text{ h}$ raise the suspicion of WD; values greater than 100 $\mu\text{g}/24\text{ h}$ make it very likely.

In the originally described penicillamine challenge test using a cut-off value of 25 $\mu\text{mol}/24\text{ h}$ (1600 $\text{mcg}/24\text{ h}$), the test was abnormal in 15 of 17 Wilsonian patients with active disease and 1 of 58 non-Wilsonian patients. The test was again evaluated by Muller et al. who showed sensitivity to be 76% and specificity—93% in the whole cohort of patients. However, and most importantly, the sensitivity was as high as 92% in symptomatic patients and only 46% in asymptomatic patients [16]. Others have found a cut-off value five times the upper limit of normal gives good differentiation. The test has not been evaluated in adult neurologically presenting cases.

Serum Copper

Serum copper is largely CP bound, so will be low in mild or presymptomatic disease but sometimes raised (e.g. in acute liver failure) if serum-“free” copper is raised. Calculated free serum copper according to the formula (total copper – 0.3% ceruloplasmin) is in practice a disappointingly inaccurate parameter, but the recently described direct measurement of “relatively exchangeable copper” holds more promise [17].

Liver Copper

When a liver biopsy is performed in suspected WD patients, a specimen for measurement of liver copper should always be obtained. Values equal to or higher than 250 $\mu\text{g}/\text{gm}$ of dry weight are considered to be typical for WD. In chronic cholestatic conditions, the liver copper content will also be elevated, but this should not be a source of diagnostic confusion. Values less than 250 $\mu\text{g}/\text{g}$ may be found in WD cirrhosis, where the centers of large regenerating nodules and tracts of fibrous tissue will both have lower Cu concentrations. Thus, Ferenci et al. assessed the hepatic copper content of 106 patients at the time of diagnosis of WD of whom 19 Wilsonian patients had a liver copper concentration below 250 $\mu\text{g}/\text{g}$ dry weight. The sensitivity analysis based on comparison of these 106 patients to 244 other patients without WD showed that the upper limit of diagnosis ($>250\text{ }\mu\text{g}/\text{g}$ dry weight) has a poor sensitivity (82%) and very good specific-

ity. The low range (50 $\mu\text{g}/\text{g}$ dry weight) has a higher sensitivity, but lower specificity as well as a positive predictive value [18].

Liver biopsy is rarely performed in adult neurological patients so the value of liver copper quantification in neurological presentation is not established.

Mutations in the WD ATP7B Gene, Locus 13q14.3 and Genetic Testing Strategy

The WD gene comprises 80,000 base pairs on 21 protein coding exons and a poorly characterized promoter. More than 500 mutations are recorded in the WD Mutation Database [3]. H1069Q (hist1069glu) is the commonest worldwide and by far the commonest WD mutation in Central Europe. By contrast, H1069Q is rare in Asian, Japanese, and Chinese patients, where other mutations predominate. In Western Europe, many different mutations are found and patients are often compound heterozygotes. A total of 116 different mutations, including 32 novel mutations, were identified on 356 alleles from 179 individuals in the coding region or adjacent splice sites of *ATP7B* in the NHS lab serving the UK [19]. Only 40 of these patients were homozygotes, the rest being compound heterozygotes.

Testing Strategy

Mutation detection by direct sequencing is now widely available but bear in mind the following. First, the testing strategy should be appropriate to the population served. In Central Europe a rapid detection method for H1069Q should be available, and it will be very valuable in the newly presenting acute case. For heterogeneous populations, it may be known which exons have the highest mutation frequency. For the UK, these are exons 14 (24%), 8 (20%), and 2 (12%). Analysis of these three exons would detect 56% of mutations while analysis of exons 2, 5, 8, 13, 14, 18, 19, 20 would detect 82% of the mutations in this population. Second, some patients have been found to have three mutations, two on one chromosome (“in cis”). Therefore finding two mutations does not necessarily mean the patient has WD; they might be in cis so that s/he is actually a carrier, that is, has one normal allele on the other chromosome. This mistake is avoided by proving that one of each of the patient’s mutations is present in each parent. Third, though large deletions are rare they can occur and may be missed and the patient may be wrongly described as just having the one-point mutation on the other chromosome. Fourth, apparent parent to-child transmission of WD occurs, the unaffected parent turning out to be a Wilsonian patient. Therefore, family screening must extend to the children of known parents with WD. Mutation testing

Table 65.2 Diagnostic score in WD [15, 21]

Symptom/test	Score	
Kayser–Fleischer rings	Absent-0	
	Present-2	
Neuropsychiatric symptoms suggestive of WD (or typical brain MRI)	Absent-0	
	Present-2	
Coombs negative hemolytic anemia+ high serum copper	Absent-0	
	Present-1	
Urinary copper (in the absence of acute hepatitis)	Normal-0	
	1–2 × ULN-1	
	> 2 × ULN, or	
	> 5 × ULN-1 day after 2 × 0.5 g D-penicillamine-2	
Liver copper quantitative	Normal- minus 1	
	< 5 × ULN-1	
	> 5 × ULN-2	
Rhodanine positive hepatocytes (only if quantitative Cu measurement is not available)	Absent-0	
	Present-1	
Serum ceruloplasmin	> 0.2 g/l-0	
	0.1–0.2 g/l-1	
	< 0.1 g/l-2	
Disease-causing mutations detected	None-0	
	One-1	
	Two-4	
<i>Assesment of the Wilson's disease diagnostic score</i>		
<i>0–1: unlikely</i>	<i>2–3: probable</i>	<i>4 or more: highly likely</i>
<i>ULN upper limit of normal, WD Wilson's disease</i>		

for WD should be restricted to labs which participate in the European Molecular Quality Network.

Diagnosis in Different Clinical Scenarios

In Central Europe a rapid H1069Q test may be the most cost-effective first-line test in any suspected WD patient. Otherwise one is reliant on biochemistry. One needs to tailor the testing to the clinical scenario. In acute liver failure, suspect WD if there is Coombs' negative hemolysis, a high bilirubin (>300 μmol/l) and a relatively low transaminases (100–500 IU/l) and alkaline phosphatase (<600 IU/l) and alkaline phosphatase IU/l per total bilirubin mg/dl ratio <2. Urine copper and a penicillamine challenge are probably the most valuable copper tests. In active but non-fulminant disease, the penicillamine challenge test is useful whereas in presymptomatic siblings it will be useless, but ceruloplasmin should be discriminatory and there is of course time to get a mutational analysis.

Making diagnosis in infants is also difficult. Healthy neonates and young infants present with naturally low levels of ceruloplasmin and liver copper is increased in infancy so these tests cannot be used directly for making diagnosis of WD.

However, the value of biochemical tests for making early diagnosis should not be completely excluded. Early screening for WD may be possible if new cut-off values for ceruloplasmin are established as indicated by Kroll and coworkers who analyzed blood spots for ceruloplasmin concentration from 1045 anonymous newborn screening specimens and from two Wilsonian patients. Ceruloplasmin levels were extremely low in Wilsonian patients (2.8 and 2.6 mg/dl) compared to healthy infants (6.5 to >60 mg/dl) [20] (see Table 65.1) [15].

Scoring System for Diagnosis of WD

As making diagnosis of WD based on clinical symptoms or single biochemical test is difficult, several parameters need to be taken into account all together. In 2001, a scoring system was proposed and further evaluated by Ferenci et al. [21] (Table 65.2) [15].

The patients with a total score of at least four are diagnosed to have WD. The patients with a total score of two to three are considered as “likely to have Wilson's disease, yet more investigations had to be performed.” The diagnosis of WD was judged to be improbable for scores between zero and one [21].

In order to test this scoring system, Dhawan et al. investigated records of 143 children with chronic liver disease,

aged at least 5 years. Among the patients studied, 53 children were diagnosed to have WD (median observation time 11 years) and 90 children had other liver diseases. Fifty patients with WD had a score ≥ 4 (true positives). A total of 85 true negatives with a score of either 2–3 (40 children) or < 1 (45 children) were observed. Both sensitivity and specificity of this scoring system was higher than 94% [22].

Genotype–Phenotype

It would be prognostically useful if there were a clear mutation/phenotype relationship, but there is not.

It is common to find differing phenotypes among siblings even for identical twins. Two statements may be made. First, patients homozygous for H1069Q tend to present later and with neurological disease. Second, there is a suggestion that fulminant hepatic failure is more likely in patients with truncating mutations.

Treatment

The aim of therapy is to decrease copper absorption and accumulation in the liver and central nervous system. For all WD patients, lifelong medical therapy is required. Conventional medical therapies are based on either copper chelators (penicillamine, trientine, tetrathiomolybdate) or zinc. Chelators mobilize intracellular copper into the circulation which is then excreted with the urine. Zinc decreases copper content mainly by reducing intestinal absorption. It induces copper-binding metallothionein in both enterocytes and hepatocytes, reducing the damaging effects of free liver copper.

Definite treatment is liver transplantation which is however indicated only in selected cases where rapidly progressing liver failure cannot be reversed by medical therapy.

Evidence from observational studies shows very good long-term prognosis on medical therapy with a survival comparable to the general population, even if some of them do not normalize completely aminotransferase activity [23, 14]. Poor compliance is regarded to be the major problem and the major reason of poor outcome.

Copper Chelators

Penicillamine and trientine are chelating agents regarded to be the first-line therapy in severe liver disease, but also effectively used in neurological symptoms and in asymptomatic cases. The major limitations for their use (mainly penicillamine) are side effects and toxic reactions reported in almost 10% of adult patients. Still, the experience in children seems to be better than in adults like ours (Socha–Warsaw),

and experience of King's College, London (Dhawan) shows that these reactions are less frequent in children and usually do not require discontinuation of the therapy. The major risk of chelating therapy is worsening of neurological symptoms (in neurological presentation) after therapy is started and for this reason the doses are usually increased gradually (within a few weeks). Penicillamine therapy is more common in Europe (according to data from Eurowilson project—unpublished). Trientine can replace penicillamine in patients presenting with penicillamine intolerance (trientine is regarded to be safer). In some European countries trientine is not licensed. Tetrathiomolybdate is another copper chelator which was mainly investigated in neurologic presentation of the disease. It seems to be more powerful decoppering agent than trientine and penicillamine but there is limited experience in pediatric practice. According to Brewer et al., it showed very strong control of free copper levels over the 8 weeks of treatment in adults and it was better than trientine in the tetrathiomolybdate/trientine double blind study [24].

The full dose of penicillamine is 20 mg/kg/day, given in three doses. Adults receive 1 g per day up to 2 g if there is a poor response. Side effects include hypersensitivity reactions (usually transient and at the beginning of therapy), proteinuria, fever, lymphadenopathy, and bone marrow suppression. Patients should be monitored for side effects with blood count, urine analysis, as well as with liver and renal tests.

Trientine should be given 300 mg twice a day in younger children or 600 mg twice a day in older children and adults.

Zinc

Zinc can be alternatively given to the patients with WD but it is not recommended in severe liver disease with abnormal synthetic function as chelating agents are believed to be more effective in producing negative copper balance. Zinc seems to be safe and it was the reason for its preferential or alternative use in neurological and asymptomatic cases. It is not associated with neurological deterioration which could be the main reason for its common use in neurological patients. Zinc is also used for maintenance therapy after the induction phase with chelators.

Zinc is given in the dose of 25 mg of elemental zinc three times in younger children (< 50 kg) a day or 50 mg three times a day in older children. In very young children under 5 years of age the dose is not well defined. Patients should be fasted so zinc should not be given between meals. Monitoring of the therapy is based on measuring serum zinc levels, 24-h urinary copper and zinc excretion. Brewer et al. advise to test zinc serum and urine copper levels during therapy. A zinc serum level less than 125 $\mu\text{g/dL}$ generally indicates poor compliance. Urine copper levels should not exceed 50–75 $\mu\text{g}/24$ h.

There are two different chemical zinc preparations used, zinc sulphate and zinc acetate. Zinc acetate is more commonly used and has a better tolerance profile but is also more expensive. Zinc sulphate is also commonly used but may cause more significant side effects like nausea, vomiting and epigastric pain, mild gastric irritation, decreased blood iron levels, and anemia. We have also recently reported gastric/duodenal mucosal ulceration or erosion [25]. These side effects may lead to discontinuation of the therapy and it could be the reason for slightly elevated transaminases observed on this treatment.

Different Clinical Presentations and Choice of Medical Therapy

The choice of medical therapy is related to clinical presentation of WD and there is an agreement to use chelators for acute liver failure as first-line treatment. However, there are still many controversies on preferential use of chelators or zinc for other clinical situations. In severe liver insufficiency due to WD penicillamine or trientine therapy should be started immediately after diagnosis is made. Improvement does not appear soon after therapy was started and usually first after one or several months liver function tests improve. For other hepatic presentations of WD, chelators seem to be more effective as indicated by the review of 288 patients with a median follow-up time of 17.1 years presented by Weiss et al. who showed that increase in activity of liver enzymes occurred more frequently from zinc therapy (14/88 treatments) than from chelator therapy (4/313 treatments; $P < .001$). Similarly, the survival without transplantation was better for chelating agents. Patients who did not respond to zinc therapy showed hepatic improvement after reintroduction of a chelating agent [26].

Zinc is commonly used in neurological presentation where it seems to be as effective as chelators [27].

Still, it is difficult to compare both therapies as most of the evidence comes from observational trials. Wiggelinkhuizen et al. performed a systematic review of zinc and penicillamine therapies for WD. They found 1 randomized controlled trial and 12 observational trials. Patients with liver presentation seemed to respond better to penicillamine. Zinc

appeared to be better option in presymptomatic and neurological cases [28].

It is also difficult to compare trientine and penicillamine; however, trientine appears to be a safer option but due to high costs its use is limited in many countries. From the published experience of King's College in London (16 out of 96 cases were treated with trientine), trientine was as effective as penicillamine [29].

For asymptomatic cases, it is not clear at what age therapy should be started but there is an agreement not to start in the first year of life.

Diet in Therapy of WD

The role of the avoidance of copper rich food products (nuts, chocolate, liver, shellfish) is not well established, but they are traditionally excluded from the diet.

Liver Transplantation

Liver transplantation is indicated for acute liver failure with fatal prognosis. Acute liver failure with encephalopathy does not respond to medical therapy and requires immediate listing for liver transplantation. The indications for liver transplantation in acute liver failure without encephalopathy are less clear as many patients recover with chelation therapy. It is advised to use the scoring system developed at King's College Hospital (Table 65.3) [30], which should be applied daily. A score ≥ 11 indicates the need to list urgently for liver transplantation. A deteriorating score similarly raises the need to list. A stable or improving score is an indication to continue with medical therapy [30].

The indications for liver transplantation are less clear in patients with predominant neurological symptoms. In general, neurological symptoms are not an indication for liver transplantation but there are some reports of neurological improvement after liver transplantation (however, some patients deteriorated).

Table 65.3 Prognostic score in acute liver failure due to WD. A score ≥ 11 indicates the need to list for urgent liver transplantation. A sensitivity and specificity of 93 and 97%, and positive predictive value and negative predictive values of 92 and 97%, respectively, are reported [30]

Score	Bilirubin ($\mu\text{mol/L}$)	INR	AST (IU/L)	WCC ($\times 10^9/\text{L}$)	Albumin (g/L)
0	0–100	0–1.29	0–100	0–6.7	>45
1	101–150	1.3–1.6	101–150	6.8–8.3	34–44
2	151–200	1.7–1.9	151–300	8.4–10.3	25–33
3	201–300	2.0–2.4	301–400	10.4–15.3	21–24
4	>301	>2.5	>401	>15.4	<20

WCC white blood cell count, INR international normalized ratio, AST aspartate aminotransferase

Therapy in Pregnancy

Treatment should be continued throughout the pregnancy to avoid exacerbation of symptoms. Zinc is commonly used in this period as it appears to be safer but according to some practices penicillamine can be used in decreased doses even if safety of this therapy is not well proven.

Novel Therapies

Present medical therapy is effective enough but recent progress in gene therapy may be also used for treatment of WD. Novel strategies aim at enhancing the protein expression of mutant ATP7B with residual copper export activity. Some therapies were tested in animal models like hepatocyte transplantation, lentiviral gene transfer or adenovirus-mediated transfer.

Compliance

Life-long compliance to drug therapy seems to be major problem in WD which decides about prognosis. Stopping medication may lead to severe organ damage, or even death, within a time period that can be as short as a couple of months. There are several reasons for poor compliance: nausea on zinc therapy, fear for numerous side effects of penicillamine, revolting age (teenagers) as well as psychiatric problems seen in Wilsonian patients. Urine copper excretion and free copper concentration are also good indicators of compliance during penicillamine therapy.

Conclusions

Even if prevalence of WD is not high it should be included into differential diagnosis of chronic liver disease and acute liver failure in children >3 years of age. Disease can be diagnosed early in children with increased transaminase activity and/or hepatomegaly. The scoring system for diagnosis of WD may be helpful and it is highly specific. Except for molecular diagnosis no single test can be used to establish diagnosis or for screening.

It is difficult to compare effectiveness of different therapies but penicillamine or trientine appear to be drugs of choice for severe liver damage. Zinc is regarded to be safer and is mainly used in mild liver, neurological, or asymptomatic disease.

Emer Fitzpatrick

Introduction

Nonalcoholic fatty liver disease (NAFLD) was first described in 1980 in obese adults who had a pattern of injury similar to alcoholic hepatitis but who denied alcohol consumption [1]. The disease was subsequently described in children in 1983 [2]. Nonalcoholic steatohepatitis (NASH) is part of the spectrum of NAFLD, which ranges from simple steatosis to inflammation and fibrosis. The importance of this disease is borne out by the dramatic increase in its prevalence, now with an estimated 30% of adults and 10% of children affected in the USA [3–5].

It is likely that a significant number of those affected by NASH will go onto end-stage liver disease and/or hepatocellular carcinoma (HCC) within decades [6]. As NAFLD is predicted to become the most common chronic liver disease in the next decade, this will put a huge burden on an already overstretched liver transplantation service [3]. Both genetic predisposition and lifestyle factors influence the disease process, the pathophysiology of which is not yet fully understood. In view of the startling prevalence of the disorder and the potential to progress to serious liver disease, understanding the pathogenesis of the condition and the ability to recognize and manage the condition in children is of great importance.

Epidemiology and Predisposing Factors

The increase in prevalence of NAFLD is directly associated with the epidemic rise of obesity. Prevalence of childhood obesity in the UK has increased dramatically over the past three decades. The National Study of Health and Growth and the Health Survey for England demonstrated an increase in

prevalence of overweight/obesity in boys aged 5–10 years from 11.3/1.8% in 1974 to 17.9/5.7% in 2006/2007 and in girls aged 5–10 years from 9.6/1.3% in 1974 to 21.8/6.1% in 2006/2007 [7, 8]. The Health Survey for England 2012 reported that 14% of 2–15 year olds are obese and 28% are overweight. The National Health and Nutrition Examination Survey (NHANES) report from the USA also describes a dramatic rise in childhood obesity from 5% in 1960 to 15% in 2000 and 17.1% of children in 2003–2004 [9, 10] and 16.9% in 2007–2008 [11]. The definition most widely used for obesity in childhood is body mass index (BMI) >95th percentile and overweight as a BMI between 85 and 95th percentile. The ‘normal’ BMI varies with age and sex and different percentile charts are available for different populations.

The lack of clarity regarding the definition of the disorder is one of the main issues affecting the study of incidence and prevalence of NAFLD. Liver biopsy is the criterion standard for diagnosis of NAFLD, clearly this is not feasible as an epidemiological tool and proxy markers such as abnormal transaminases and/or the presence of an echogenic liver on ultrasound (US) are often used to define the disorder. The true sensitivity, specificity and predictive value of these proxy markers are unknown and it is well recognized that an elevation of transaminases may only occur in 60% of cases of NAFLD [12]. As the reference range for aspartate aminotransferase (AST) and alanine transaminase (ALT) is derived from population data including those with undiagnosed NAFLD, the use of these markers as a proxy for NAFLD is fundamentally flawed [3, 13]. In addition, there is considerable variation in normal ranges for laboratory values across different institutions.

Nevertheless, in the absence of a more robust noninvasive diagnostic test, population studies have used an elevated ALT (in the absence of other diagnoses) as definition of the disorder. In one US-based study, an elevated ALT was found in 8% of the 5586 adolescents aged 12–19 years [14]. Park et al. reported a prevalence of 3.2% in 1543 Korean teenagers using ALT >40 [15]. In Japan, a population-based

753

study found 2.6% of the children had NAFLD based on US [16]. In a study from Italy of 268 obese children, 44% had NAFLD using US and elevated ALT [17]. Studies of liver biopsy findings give a more accurate reflection of prevalence as NAFLD is a histological diagnosis. An autopsy study from San Diego of almost 800 children who died an unnatural death described fatty liver in 9.3%, with NASH present in 3% [4].

The prevalence of NAFLD appears to increase with age and in general, boys are more at risk [4, 18, 19]. Ethnic variations also exist; Hispanic children and adolescents have a greater risk of NAFLD compared to Caucasian children. Black, non-Hispanic children are less susceptible despite a higher incidence of insulin resistance (IR) [4, 19, 20]. This mirrors findings in adults [5, 21, 22]. Both genetic and environmental factors are likely to be involved in ethnic distribution. Familial clustering is also seen [23, 24] with a strong heritability in first degree relatives [25].

The advent of genome-wide association studies (GWAS) has significantly advanced our understanding of genetic susceptibility to NAFLD. Single nucleotide polymorphisms (SNPs) in DNA resulting in the altered expression of a gene or altered protein function in addition to other epigenetic modification have been investigated in NAFLD. It is likely that multiple SNPs influence the phenotype of this polygenic disease [26]. Three large GWAS studies have identified a common SNP in patatin-like phospholipase domain-containing protein (PNPLA3; adiponutrin) rs738409 (1148M) to have a strong association with NAFLD [27–29]. PNPLA3 is a 481-amino acid transmembrane protein which is thought to have both lipolytic and lipogenic activity. The 1148M SNP may promote hepatic accumulation of triglycerides (TG) and cholesterol by inhibition of TG hydrolysis [30]. The histological severity of disease is also associated with the presence of the SNP [31], but IR is not [32]. A recent pediatric study has shown an association between the SNP and severity of NAFLD in Italian children [33].

A SNP in the gene encoding apolipoprotein C III (APOC III) has also been implicated in NAFLD [34]. Increased levels of APOC III production that occur in the presence of this polymorphism leads to increased TG uptake and production. Polymorphisms in the adiponectin gene and receptor are implicated in both NAFLD and IR [35–37]. Adiponectin is a 244-amino acid adipocytokine with an important role in modulation of inflammation, glucose tolerance and fatty acid (FA) catabolism. Low levels are associated with type 2 diabetes and increasing severity of NAFLD.

Other polymorphisms associated with oxidative stress and immune function have a potential role in susceptibility to NAFLD. These polymorphisms may be associated with the inflammatory component of NASH rather than with steatosis per se; for example, polymorphisms in interleukin 6 (IL6; 174G/C) [38] and tumor necrosis factor α (TNF α) [39].

Liver fibrosis in NAFLD was found to be associated with a splice mutation in a tumor suppressor gene; Kruppel-like factor (KLF6) in a genome-wide study [40]. The presence of Gilbert syndrome caused by the uridine 5'-diphospho (UDP)-glucuronyltransferase1A1*6 polymorphism seems to have a protective effect against development of NAFLD possibly due to the antioxidant properties of bilirubin [41].

Other epigenetic factors, particularly microribonucleic acids (miRNAs) have been implicated in pathogenesis of NAFLD. Epigenetic modification is unrelated to changes in DNA sequence. MicroRNAs are small soluble RNAs which influence the translation of certain genes. The relative underexpression of microRNA-122 has been described in NAFLD [42].

Nutrition and physical activity are important environmental factors determining the risk of NAFLD, with lifestyle modification as the primary recommendation in the prevention and management of the disease [43, 44] (Fig. 66.1). Excess food intake and lack of exercise contribute to weight gain and contribute to the progression of liver fibrosis and inflammation in patients with NAFLD [45, 46].

Specific dietary factors either protect against or exacerbate the development and progression of NAFLD. Musso et al. analyzed 7-day diet records from 25 biopsy-proven adults with NAFLD and 25 controls, finding that saturated fat and cholesterol intakes were higher in cases than controls, whilst intakes of polyunsaturated FAs (PUFA), fibre and the antioxidant vitamins C and E were lower [47]. A Japanese study reviewed the 3-day food diaries of 28 adults with NASH and 18 with simple steatosis and identified a significantly lower zinc intake in patients with NASH [48]. Food-based analyses have suggested that higher meat and fructose [49–51], and higher consumption of low-nutrient, high-calorie, and high-salt food [52] are associated with

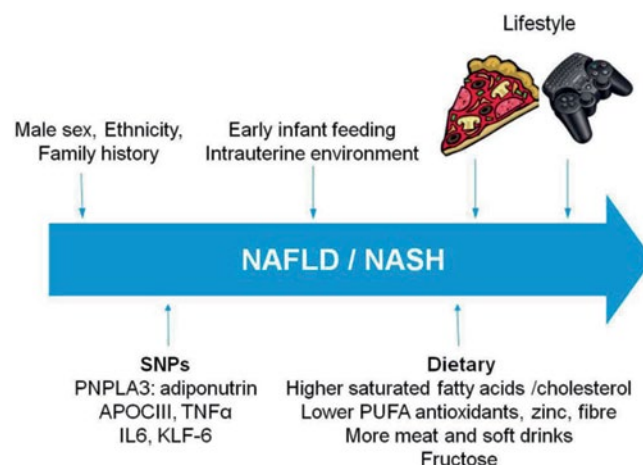

Fig. 66.1 Factors associated with the pathogenesis of NAFLD. *PNPLA* pectin lyase, *APOC* apolipoprotein C, *TNF* tumor necrosis factor, *KLF* Kruppel-like factor, *PUFA* polyunsaturated fatty acids, *NAFLD* non-alcoholic fatty liver disease, *NASH* nonalcoholic steatohepatitis

NAFLD. Fructose has been identified as a particular culprit in increasing fat, inflammation and fibrosis [53, 54]. Few pediatric studies of dietary composition have been undertaken in NAFLD; however, a recent large study from Australia compared a Western diet in 993 14-year-olds to later development of NAFLD on US and found a significant association of Western diet and development of steatosis at 17 years [55]. A study in 82 obese Greek children revealed that a diet higher in carbohydrates, saturated FAs and lower in omega-3 was associated with NAFLD [56].

Dietary chemical composition of FAs may be critical factors in lipotoxicity observed in IR. Palmitic acid rather than oleic acid results in lower steatosis but in higher cell death and impaired insulin signaling [57]. A study of fish intake and omega-3 FA intake in children with NAFLD revealed a dietary deficiency of both was associated with increased portal and lobular inflammation [58].

Vos et al. described an association of dietary vitamin E insufficiency and increased steatosis in children with NAFLD [59].

The importance of the intrauterine environment and early infant feeding on development and progression of NAFLD has been a focus of interest. Offspring of obese mice were found to have a dysmetabolic, insulin-resistant and NAFLD phenotype compared to offspring of lean dams [60]. Offspring of lean dams suckled by obese dams developed an exaggerated phenotype suggesting that development of NAFLD and the metabolic syndrome is significantly influenced by early postnatal nutrition. Nobili and colleagues have studied breast-feeding habits in a cohort of children with NAFLD and concluded that breast-feeding is protective against progression of the disease from simple steatosis to steatohepatitis and fibrosis [61]. Figure 66.1 shows the factors associated with the pathogenesis of NAFLD.

Pathophysiology

NAFLD can be thought of as the hepatic manifestation of the metabolic syndrome (linking obesity, IR, hypertension and hyperlipidaemia). The pathogenesis of the condition is still incompletely understood.

IR is found in up to 80% the children with NAFLD and has a similarly high prevalence in adults with the condition [20, 22, 62, 63]. It is widely accepted that IR and the resulting hyperinsulinemia seem to play a major role in the development of hepatic steatosis and steatohepatitis. The molecular mechanism leading to the involvement of IR in the development of NAFLD is complex, however, and has not yet been fully elucidated.

The 'two hit hypothesis' proposed in 1998 consists of a first hit of liver fat accumulation which is caused by an imbalance in uptake and synthesis of hepatic lipids on the

one hand and export and oxidation on the other in the context of IR [64]. The steatotic liver is then thought to be more vulnerable to a 'second hit'. This may be oxidative stress, small-bowel bacterial overgrowth [65, 66], adipocytokines from a high visceral fat mass or saturated free FAs (FFA) [67]. A more recent hypothesis suggests that fat accumulation in the liver is a manifestation of stress and a protective mechanism in itself [68, 69]. This protective effect was demonstrated by Yamaguchi et al. in db/db mice fed a methionine–choline-deficient (MCD) diet [68]. Knockdown of TG synthesis increased the amount of potentially damaging FFA (i.e. blocked detoxification) in the hepatocyte and led to increased necro-inflammation and fibrosis despite decreased steatosis. Thus, in some individuals, the capacity for compensation via detoxification is exceeded and apoptosis and inflammation result.

Steatosis

Macrovesicular steatosis is characterized by the accumulation of TG (formed of glycerol esterified to three FAs) in the hepatocyte. Steatosis is conventionally thought to arise from increased hepatic supply of FFA as a result of obesity and associated extrahepatic IR.

Normally, adipocytes store fat after meals and release fat during fasting by lipolysis. In the liver, carbohydrate is stored as glycogen and when liver is saturated, de novo lipogenesis occurs via acetyl coenzyme A and FA synthetase. The third source of FAs as a substrate for the liver is dietary.

In the setting of normal insulin sensitivity, FAs undergo esterification to TG in the hepatocyte and are then exported from the cell as very low-density lipoproteins (VLDL) via apolipoprotein B enzyme activity [70]. Alternatively, they may undergo beta oxidation in the mitochondria or oxidation in the peroxisomes or microsomes. Uptake of FFA into the mitochondria requires carnitine palmitoyl acyltransferase which is inhibited by insulin and malonyl coenzyme A.

The net retention of lipids is the primary problem in steatosis. The most consistent predisposing factor to hepatic FA accumulation is IR, though other factors may be involved.

In normal physiological circumstances, the role of insulin includes glycogen synthesis, glycolysis and protein and lipid synthesis. In the postprandial state, insulin promotes lipogenesis and suppresses lipolysis and gluconeogenesis. The normal fall in insulin with the fasting state, which is accompanied by an increase in glucagon and catecholamines, mediates glycogenolysis and gluconeogenesis. These processes are accompanied by lipolysis and increased lipid oxidation. Sensitivity to insulin is increased by adiponectin and decreased by TNF α [71].

In the setting of IR, fat-laden and insulin-resistant adipocytes continue to release glycerol and FFA into the circula-

lation, and deliver increased free FFA to the liver [72–74]. This in itself may then induce hepatic IR [75]. Hyperinsulinemia and hyperglycaemia promote de novo lipogenesis via upregulation of the transcription factors sterol regulatory element-binding protein 1c (SREBP1c) and peroxisome proliferator-activated receptor γ (PPAR γ) [72]. In addition, insulin increases malonyl coenzyme A (an intermediate of FA synthesis) and inhibits carnitine palmitoyl transferase thereby inhibiting the passage of long-chain FAs (LCFA) into mitochondria for β -oxidation [76]. SREBP1c can also be upregulated by glucose and saturated fats, whereas polyunsaturated FAs (PUFA) lead to decreased expression [77]. Increased glucose levels also stimulate lipogenesis through the activation of carbohydrate response element-binding protein (ChREBP), a transcription factor activating the expression of key enzymes of glycolysis and lipogenesis [78, 79].

Hyperinsulinemia also results in decreased TG secretion as VLDL by lowering apolipoprotein B synthesis and stability [80, 81]. Hence, hepatic FFA uptake and lipogenesis outweigh FA oxidation and TG secretion leading to hepatic fat accumulation [82]. In the setting of peripheral IR some hepatic insulin sensitivity may be preserved with continuing de novo lipogenesis as a consequence. This is mixed and thought to be medicated through a functioning insulin receptor substrate 1 (IRS-1) which blocks lipid oxidation, but aberrant IRS-2 serine phosphorylation which fails to suppress gluconeogenesis [70].

Thus, in summary, the first concept in development of NAFLD is the net increase in circulating free FAs in the setting of IR. The adipocyte continues to release FAs even in the fed state as the insulin-mediated switch-off of lipogenesis is not triggered. The hepatocyte itself continues to produce free FAs via de novo lipogenesis. Activation of transcription factors such as SREBP1c, PPAR γ and ChREB occurs in the presence of hyperinsulinemia and hyperglycaemia. Impaired free fatty oxidation and VLDL production ensue, both mechanisms which normally neutralize the toxic effects of free FAs.

Oxidative Stress

Mitochondrial FA oxidation and ketogenesis are increased and the transcription factor PPAR α is activated as a result of FA accumulation [83]. This results in reactive oxygen species (ROS) which lead to oxidative stress and lipid peroxidation. Cell membranes are damaged and cytochrome c is released from the mitochondrial intermembrane space. In turn, this leads to an imbalance in the flow of electrons over the respiratory chain (RC) creating over reduction of RC complexes which can react with oxygen to form further ROS [84]. ROS may act as a ‘second hit’ in the development of NASH.

Mitochondrial function has been shown to be impaired in patients with severe steatosis and steatohepatitis [85]. Ultrastructural abnormalities of mitochondria have been demonstrated in patients with NASH [86, 87]. It is not clear if this is a primary or secondary phenomenon however. Mitochondrial abnormalities could be a pre-existing condition enabling the excessive production of ROS in the setting of enhanced FFA β -oxidation [86]. This could explain why for the same amount of obesity, or for the same degree of IR, certain patients just have steatosis, whilst others develop NASH and cirrhosis. Genetic polymorphisms could also at least partially explain this difference in susceptibility as some could favour mitochondrial dysfunction [88]. Alternatively, the overload of the mitochondrial RC, the resulting formation of ROS and subsequent lipid peroxidation products may give rise to mitochondrial damage. There is an inverse correlation of peripheral TNF α levels and measures of IR with RC enzyme levels suggesting that IR and cytokine activity may be important in impairment of the mitochondrial RC [89]. Enhanced ROS formation in the vulnerable steatotic liver subsequently triggers lipid peroxidation and the formation of reactive aldehydes such as 4-hydroxynonenal (4-HNE) and malondialdehyde (MDA). These give rise to further mitochondrial damage and ROS formation, resulting in a vicious cycle [84]. Hepatic stellate cells may be activated by these molecules thus leading to fibrosis [90].

Cytokines and Inflammation

Much of the progression from simple steatosis to steatohepatitis is characterized by an inflammatory response [91]. It is clear from both rodent and human studies that hepatic steatosis is associated with a state of chronic inflammation [92–94]. More specifically, hepatic steatosis in this context is associated with nuclear factor κ B (NF κ B) activation. FFA can directly activate the pathway via a lysosomal cathepsin B-dependent mechanism [95], as can mitochondrial and endoplasmic reticulum (ER) stress [93, 96]. NF κ B is a sequence-specific transcription factor that functions as a pro-inflammatory master switch during inflammation. It upregulates the transcription of a wide range of inflammatory mediators including TNF α , IL6 and IL1 β . Increased production of inflammatory cytokines by hepatocytes leads to Kupffer cell activation with subsequent inflammatory mediator release and hepatic and systemic IR [97].

Animal studies have shown that translocation of bacteria from the gut to the liver via the mesenteric circulation can activate Kupffer cells (via CD14/Toll-like receptor 4 (TLR4) binding) and induce a local and systemic inflammatory response [98]. There has been a great deal of interest in gut microbiota and the innate immune response in the context of obesity and IR [36]. There is evidence that intestinal bacte-

rial overgrowth exacerbates NAFLD and that the prevalence of bacterial overgrowth is higher in those who are obese [37], the portal circulation providing a direct route from gut to liver. Manipulation of gut microbiota and elimination of intestinal bacterial overgrowth may thus be a promising way to halt the progression of steatosis to steatohepatitis and fibrosis.

Finally, visceral fat is a highly inflammatory tissue and the source of many inflammatory mediators known as adipocytokines which have an important role in IR and, most likely, in NAFLD [99, 100]. These adipocytokines, including leptin, adiponectin, TNF α and IL6, are polypeptides produced by both adipocytes and macrophages which infiltrate adipose tissue [101]. Adipokines are involved in the various injury patterns in NASH such as cell death, inflammation and fibrosis [84].

Leptin is a 16-kDa protein, a product of the *ob* gene and has important roles in appetite suppression and regulation of energy metabolism [102], with high levels in obese individuals though this is thought to be a result of leptin resistance. The role of leptin in NAFLD is not yet clear though it is thought to contribute as a proinflammatory, profibrogenic mediator [103, 104].

Adiponectin is a polypeptide adipokine with a collagen-like domain and globular domain produced in white adipose tissue. It has an important role in insulin sensitivity, as part of their action, thiazolidinediones (TZDs) are known to increase levels of adiponectin [105]. It is also hepatoprotective with anti-inflammatory and anti-fibrogenic properties [106–108].

Hepatocyte Apoptosis

Hepatocyte apoptosis is recognized as an important event in the development of chronic liver disease and has particular prominence in NAFLD [109]. The initiating event in apoptosis may be extrinsically mediated hepatocyte injury (e.g. in autoimmune liver disease, viral hepatitis and ischaemia perfusion injury). This is usually directed through pathways involving Fas ligand, TNF α , and TNF-related apoptosis-inducing ligand (TRAIL). Alternatively, intrinsic injury and death may occur via organelle dysfunction when cells are subjected to excessive oxidative stress (ER or mitochondrial), for example, with drugs/toxins, FAs, and iron. This results in altered membrane permeability and RNA damage with cytochrome *c* release [110, 110]. The injurious mechanism in NAFLD/NASH appears to be due to a combination of extrinsic and intrinsic insults [111, 112].

Though apoptosis is classically thought to be a silent event without provoking an inflammatory response, this is not the case in the liver [111]. Apoptotic bodies can activate stellate cells and Kupffer cells inducing an inflammatory re-

sponse and leading to the progression of steatohepatitis and fibrosis [113, 114].

Fibrosis

The final common pathway of inflammation, oxidative stress and hepatocellular damage is the development and progression of fibrosis in NAFLD. The process of fibrosis involves the deposition of extracellular matrix within the parenchyma. Cirrhosis, the end stage of the fibrotic process, is characterized by septum and nodule formation. Several different injurious processes will result in fibrosis. Hepatocyte injury, inflammation, apoptosis and death initiates the process which involves a cascade of inflammatory cells, the release of cytokines and the activation of fibrogenic effector cells (mainly stellate cells) [115].

Thus, a number of different processes and mechanisms are involved in the progression of steatosis to NASH: oxidative stress, inflammation, apoptosis and fibrosis. The exact sequence of development of obesity, fatty liver and NAFLD remains unclear. Whether IR causes hepatic steatosis or whether the accumulation of fat in the liver is the primary event leading to hepatic and peripheral IR is also yet to be elucidated [116]. Figure 66.2 shows the interplay of oxidative stress, inflammation, apoptosis and fibrosis in the pathogenesis of NASH [117].

Diagnosis and Histology

Children with NAFLD are often asymptomatic or may present with vague nonspecific symptoms such as abdominal pain and/or fatigue. The majority are overweight (gender-

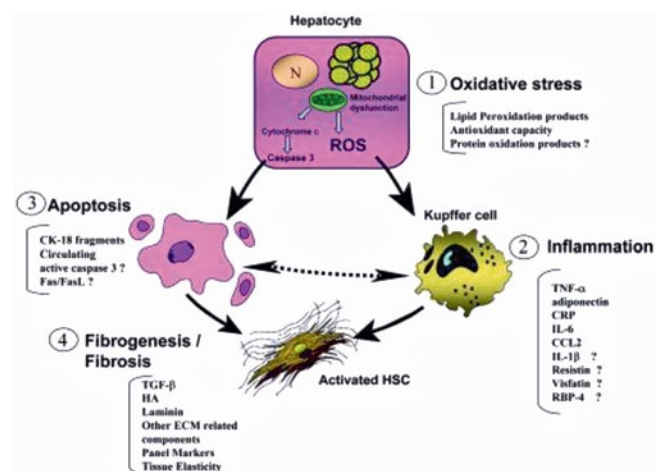

Fig. 66.2 The interplay of oxidative stress, inflammation, apoptosis and fibrosis in the pathogenesis of NASH. (ROS reactive oxidative species, HSC hepatic stellate cell. Reprinted with permission from [117], with permission from John Wiley and Sons)

and age-specific BMI > 85th percentile) or obese (>95th percentile) [118]. Hepatomegaly may be present and acanthosis nigricans (a black pigmentation of the skin folds, axillae and neck), often seen in children with IR, is found in 30–50% of children with NAFLD [20, 119]. The majority of children with NAFLD have IR as measured by homeostasis model assessment-IR (HOMA-IR is (fasting glucose (mmol/l) × fasting insulin (IU/l))/22.5) [20]. A normal HOMA-IR (<90th percentile) is generally less than 2.5 but varies with sex and pubertal stage [120]. Children will often have a positive family history for the metabolic syndrome [19].

In the diagnostic workup of NAFLD, alternative causes of chronic liver disease should be excluded including chronic hepatitis B and C infection, Wilson disease, α 1-antitrypsin deficiency, autoimmune hepatitis and drug toxicity (including steroids, amiodarone, oestrogens and antiretroviral treatment). Conditions such as cystic fibrosis, malnutrition and parenteral nutrition-associated liver disease may also present with a fatty liver on US and can be excluded on clinical

or biochemical grounds. In addition, mitochondrial/ metabolic disease and cholesterol ester storage disease may also look very similar on liver biopsy and need to be considered. Table 66.1 gives differential diagnoses that must be excluded.

Recommendations for undertaking biopsy in children with suspected NAFLD are made by a consensus document published by the American Association for the Study of Liver Diseases (AASLD), American College of Cardiology (ACG) and American Gastroenterological Association (AGA) [121]. These are to perform liver biopsy where the diagnosis is unclear there is a possibility of multiple diagnoses, before starting therapy with potentially hepatotoxic medications or prior to starting children on pharmacologic therapy for NASH. An ESPGHAN guideline was published the same year suggesting that liver biopsy should be performed in children with suspected NASH according to the following criteria; to exclude other treatable disease, in cases of clinically suspected advanced disease, as part of an interventional protocol or research trial [122]. Table 66.1 shows

Table 66.1 Conditions which need to be excluded before a diagnosis of NAFLD is made

Clinical condition	Clinical features	Biochemical/ other features which help distinguish from NAFLD
Wilson disease	May present with chronic liver disease, hemolytic anaemia or more rarely neurological disease in childhood. Look for Kaiser Fleisher rings	Low serum ceruloplasmin, high urinary copper pre and post penicillamine, high liver copper, genetics may be positive
Alpha 1 antitrypsin deficiency	–	Alpha 1 anti-trypsin phenotype ZZ (or ZS) more rarely SS
Drugs—steroids, amiodarone, alcohol, methotrexate, ecstasy, l-asparaginase, vitamin E, valproate, tamoxifen, antiretrovirals	History of drug ingestion	–
Cystic Fibrosis-associated liver disease	History/examination	Positive sweat test/genetics positive
Malnutrition	Clinical examination	–
Coeliac disease	May have failure to thrive	Tissue transglutaminase positive/positive jejuna biopsies
Hepatitis C	–	Positive serology
Parenteral nutrition-associated liver disease	Compatible history	–
Mitochondrial disease/fatty acid oxidase deficiency	May be history of neuro-developmental problems or other system involvement	Abnormal respiratory chain enzymes liver/muscle, abnormal acyl-carnitines./skin fibroblast studies, mitochondrial depletion demonstrated, genetics for mitochondrial disease
Metabolic disease: Lysosomal acid lipase deficiency (cholesterol ester storage disease)	–	Positive enzymology or genetics
Galactosaemia	Age of presentation	Abnormal Gal-1-PUT result
Fructosemia	May be history of avoiding sweets	Enzymology on liver biopsy
Glycogen storage disease	Hepatomegaly, may be short, history of fasting hypoglycaemia	Positive enzymology/genetics, glycogen not fat on biopsy
Peroxisomal disorders	May be hypotonic/have wide anterior fontanelle, neurological problems	Abnormal very long-chain fatty acids
Mauriac syndrome	History type 1 diabetes	Glycogen on liver biopsy
Hypobetalipoproteinaemia/abetalipoproteinaemia	Low serum triglycerides, may be history of fat malabsorption, may be failure to thrive	Low or absent Apo1B levels
Lipodystrophies	Examination	Genetics
Schwachman syndrome	FTT pancreatic insufficiency, bony changes, cyclical neutropenia	Genetics

conditions which need to be excluded before a diagnosis of NAFLD is made.

Tools commonly used in the workup and diagnosis of NAFLD include serum transaminases and imaging techniques (US, computerized tomography, magnetic resonance imaging/spectroscopy). The sensitivity, specificity and predictive values of these techniques are variable [3]. Franzese et al. studied the incidence of liver involvement in 72 obese children using both US and transaminases [123]. Fifty-three percent of the children had a bright liver on US consistent with liver steatosis whilst only 25% had elevated transaminases. Molleston and colleagues reported histological abnormalities in 91 children with NAFLD and normal or only mildly elevated ALT. Forty-six percent of the group had some fibrosis with 38% mild to moderate fibrosis and 8% bridging fibrosis [124]. Neither US nor transaminases are good discriminators of histological severity [125]. Ultrasound will detect >20–30% steatosis as increased echogenicity, though this is not specific for fat [126]. Magnetic resonance imaging/spectroscopy (MRI/MRS) is more sensitive and can detect >5% steatosis [127]. However, neither technique can assess presence of inflammation or fibrosis.

Liver biopsy remains the gold standard in differentiation of steatosis from steatohepatitis. The diagnosis of NASH is based on a specific pattern of histopathological findings including macrovesicular steatosis, mixed or polymorphonuclear lobular inflammation, ballooning degeneration with Mallory hyaline, a perivenular distribution of fibrosis in adults (type 1 NASH) [128] (Fig. 66.3). Children may have a different pattern of disease with greater degree of steatosis, less prominent ballooning and portal rather than pericentral accentuation of inflammation and fibrosis (type 2 NASH) [129] (Fig. 66.4). Schwimmer et al. reviewed the histological findings in a cohort of 100 children (2–18 years) with biopsy-proven NAFLD [125]. Type 1 NASH was present in 17% and type 2 NASH in 51% of the children. Sixteen percent of

Fig. 66.4 Liver biopsies showing **a** type 1 NASH with pericentral disease and **b** type 2 NASH with periportal disease. Type 2 NASH is more common in children and type 1 in adults. Pictures kindly provided by Department of Liver Histopathology, King's College Hospital

biopsies had overlapping features of type 1 and 2 disease and the remaining 16% showed simple steatosis. Children with type 2 NASH were younger and had greater severity of obesity than in type 1 NASH. Boys and those of Asian, Native American and Hispanic ethnicity were more likely to have type 2 NASH. In contrast, in a study from Italy of 57 children with NASH, only 2.4% had type 1 NASH, 28.6% were classified as type 2 NASH, whereas the majority (52.4%) had an overlap between the two (17% had simple steatosis) [130]. Takahashi reports the presence of type 2 NASH in 9% of adult patients and 21% of pediatric patients studied in Japan [131]. The mechanism leading to the different phenotypes of NAFLD is not yet understood.

The occurrence of portal inflammation was reviewed as a distinct entity in NASH by the NASH Clinical Research Network (CRN) [132]. A study of biopsies from 728 adults and 205 children found that the presence of portal inflammation in adults was associated with older, female patients with a higher BMI and IR. There was a clear association with amount and location of steatosis, ballooning and advanced fibrosis. In the pediatric group, portal inflammation was associated with younger age, azonal location of steatosis and more advanced fibrosis (bridging). In both groups, it was associated with diagnosis of definitive NASH. There was no association with lobular inflammation in either group. It is not clear if this pattern is due to a separate pathophysiological mechanism, though it certainly seems to be a marker of more advanced NASH. The periportal pattern mirrors that of the ductular reaction which has been reported in NAFLD. The possible epithelial-mesenchymal transition of biliary cells in this process may relate to the pattern of fibrosis seen [133].

Though the classic description of fat in NAFLD is macrovesicular, the presence of microvesicular steatosis has recently been described in 102 of 1022 biopsies in patients with the condition [134]. In this study, the presence of microvesicular steatosis was strongly associated with cellular injury and cytoskeletal damage. Microvesicular steatosis has the appearance of distended hepatocytes with foamy cytoplasm; the nucleus is usually central rather than pushed peripherally as in macrovesicular steatosis. Oil red O staining

is sometimes needed to identify microvesicular steatosis if it is not visible in haematoxylin and eosin staining. Classically, this type of steatosis has been associated with mitochondrial disease, acute fatty liver of pregnancy and some drug effects (e.g. steroids and valproate) which can cause β -oxidation impairment [135]. Taken together, microvesicular steatosis in NAFLD is a likely indicator of mitochondrial damage. It is not yet understood if this is a feature of advanced disease per se or if the pathogenesis of disease in those with microvesicular steatosis is different.

Caldwell et al. reported on the significance of ballooning in NAFLD [136]. These are classically enlarged cells with rarefied cytoplasm. Using ultrastructural analysis, this group reported on the multiple small fat lipid droplets seen in with degree of ER dilatation and Mallory Denk bodies and cytoskeletal disarray. Fugii et al. have demonstrated altered expression of FFA-associated protein on the surface of fat droplets which also stain for oxidized phosphatidylcholine (a marker of oxidative damage) [137]. They concluded that oxidative injury to the fat droplet surface may impair its safe disposal and contribute to lipotoxicity.

The Pathology Committee of the NASH CRN proposed a histological scoring system that could be useful in studies of NAFLD [138]. The scoring system includes the evaluation of steatosis (0–3), lobular inflammation (0–2), hepatocellular ballooning (0–2) and fibrosis (0–4). The NAFLD activity score (NAS) is the unweighted sum of steatosis, lobular inflammation and hepatocellular ballooning scores. NAS of 5 or more correlates with the diagnosis of NASH, whilst NAS less than 3 is defined as ‘not NASH’. As this system is typically developed for adult type 1 NASH, the interobserver agreement for pediatric NASH is not as strong (only 18 children were included in the study cohort used for development of the score). The CRN also emphasize that the scoring system was developed as a tool for use in trials and is not a surrogate for a histological diagnosis of NASH [139]. Despite these shortcomings, this is the best available tool to standardize the description of the entire spectrum of NAFLD in both adults and children across different centres for research purposes.

It is important, however, to consider the pediatric pattern of disease as a separate entity, particularly when investigating the pathophysiological mechanisms or putative biomarkers of disease severity/progression. Figure 66.3a and b shows an example of histology of NAFLD. Figure 66.4 shows showing type 1 NASH with pericentral disease (a) and type 2 NASH with more periportal disease (b).

Natural History and Management

The natural history of NAFLD varies according to the histological pattern of the disease. Simple steatosis without evidence of inflammation or fibrosis appears to have a benign course whilst NASH is a potentially serious condition which can progress to cirrhosis. In a 10-year follow-up of 132 individuals with NAFLD, 22% of those with NASH versus 4% of those with simple steatosis went onto develop cirrhosis [46]. There was also a significantly higher liver-related mortality in the time period in the NASH group. Ekstead et al. followed 129 patients over a mean period of 13.7 years and found progression of liver fibrosis in 44% [140]. All-cause mortality was higher in the NASH group versus those with simple steatosis, particularly from cardiovascular and liver-related deaths. Four hundred and twenty patients with NAFLD were followed in the Rochester Epidemiology project, a population-based study. Liver-related mortality was the third leading cause of death in those with NAFLD [6]. Cirrhosis was present at follow-up in 5% of cohort. Adams et al. reported a series of 103 patients with NAFLD with follow-up biopsy at a mean interval of 3.2 years and found that fibrosis progressed in 37%, remained stable in 34% and regressed in 29% [141]. A higher BMI and diabetes were associated with fibrosis progression. A systematic review of 10 studies including 221 patients with a mean follow-up of 5.6 years concluded that fibrosis progressed in 37.6% of those with NASH [142]. Musso reported a further systematic review of 40 cohort studies examining the natural history of NAFLD in adults [143]. The authors found an overall and cause-specific pooled increase in mortality in those with NAFLD (odds ratio (OR) 1.57 (1.18–2.1)) versus the general population. In those with a steatotic liver on US, the risk of mortality from cardiovascular disease was increased by an OR of 2.05, with an OR of 3.5 for the development of type 2 diabetes. With subgroup analysis, patients with simple steatosis were found to have a similar mortality as the general population and those with NASH had an OR of 1.81 for overall mortality. The excess cause of death in this subgroup was mainly liver related with an incidence of 11–17 versus 1.7–2.7% in those with simple steatosis.

Steatosis is often no longer present in end-stage NASH and is replaced by cirrhotic change. NAFLD is thought to be the underlying etiology in the majority of cases of cryptogenic cirrhosis in many parts of the world [144, 145]. Evidence of this includes the finding that the prevalence of obesity and type 2 diabetes in cryptogenic cirrhosis mirrors that of those with NAFLD [146]. There is also an increased frequency of NASH occurrence post transplant in those with cryptogenic cirrhosis [147].

The development of HCC remains a major concern in patients with NAFLD [148]. Multiple case series and reviews have reported the association of HCC with the condition,

even in the absence of NASH-related cirrhosis [149–154]. Diabetes and obesity are known to be risk factors for HCC and other malignancies [150]. In the setting of NASH the inflammatory cascade, oxidative stress and IR may all contribute to hepatocyte hyperplasia [150].

Cirrhosis secondary to NASH has been reported in children as young as 10 years [119, 155]. A recent study by Feldstein et al. describes the long-term outcome of 66 children with NAFLD followed-up for up to 20 years [156]. Of the five children who underwent follow-up biopsy, four showed progression of fibrosis. During the study period, two patients required liver transplantation for decompensated end-stage disease. Both had recurrence of NASH in the allograft and one required retransplantation.

In adult studies, the variables most commonly associated with fibrosis are the presence of diabetes, increasing age and high BMI [157]. Similarly in children, severity of obesity and IR seem to be predictors of advanced fibrosis [20]. The difference between the natural history of type 1 and type 2 NASH has not yet been characterized and is an important subject for future research.

Management of NAFLD encompasses lifestyle modification, medication or both. NAFLD is largely the consequence of imbalanced nutrition and sedentary behaviour on the background of genetic predisposition. Primary prevention is the ideal. In adults, weight reduction of 5–10% body weight often leads to normalization or improvement of serum transaminases and reduced hepatic steatosis, inflammation and fibrosis [158–160]. In children, weight maintenance as the child crosses the height percentiles may achieve the same effect.

Several case series and uncontrolled trials have demonstrated the effect of weight loss on improvement of transaminases or US abnormalities [123, 161, 162]. A prospective study carried out in 84 children (3–18.8 years) with NAFLD demonstrated a significant decrease in BMI, levels of fasting glucose, insulin, lipids, transaminases and liver echogenicity on US following a 12-month program of lifestyle advice consisting of diet and physical exercise [130]. Another study of 53 children comparing lifestyle intervention plus antioxidant or lifestyle intervention plus placebo demonstrated similar improvements in both groups in terms of steatosis, inflammation, ballooning and NAS score [163].

Control of both quality and quantity of dietary components may be important. As above, nutritional data to date have suggested that a high intake of simple carbohydrates such as fructose with a low intake of polyunsaturated FAs correlate with pathogenesis and progression of disease [47, 53].

The type of fat consumed is possibly more relevant than quantity with higher saturated fat and lower PUFA intake associated with IR and NAFLD in some studies [47, 52]. Palmitic acid rather than oleic acid results in lower steatosis but in higher cell death and impaired insulin signalling in

vitro [57]. Several small studies of PUFAs in adults and one in children have demonstrated improved liver enzymes and histology in the treatment group [164–167].

Insulin Sensitizers

Insulin sensitizers have been investigated extensively and in view of the strong association of IR and the progression of NAFLD. Metformin is an important insulin sensitizer, reducing hyperglycaemia through a number of different mechanisms including inhibition of hepatic output and increasing peripheral uptake [168]. Thiazolidiones are PPAR γ agonists which stimulate FFA uptake by adipocytes and allow the redistribution of fat from the liver to peripheral tissue [105].

A Cochrane review examined the evidence for insulin sensitizers in NAFLD. Only three randomised controlled trials (RCT) met search criteria (RCT comparing insulin sensitizer to placebo in nondiabetic adults with NAFLD) [169]. Though there was some histological and biochemical improvement with both metformin and rosiglitazone versus placebo, the results of the meta-analysis are inconclusive [170–174]. A large RCT (the PIVENS (pioglitazone, vitamin E or placebo for the treatment of NAFLD) trial) found favourable results for vitamin E but not for pioglitazone [175].

Metformin has the side effect of gastrointestinal intolerance but weight loss is an advantage of this medication. The TZDs have the unfortunate side effect of weight gain. There have also been concerns about cardiovascular events and diminished bone mass with their use [169]. There is no available data on the safe use of TZDs in children.

Only metformin has been investigated in pediatric patients with NAFLD. A large randomized, double-blind, placebo controlled trial has recently been reported by the NASH CRN in which both vitamin E and metformin were used [176]. The purpose of this study was to determine if therapeutic modification of IR or oxidative stress leads to improvement in serum or histological indicators of liver injury and quality of life (treatment of nonalcoholic fatty liver disease in children (TONIC) trial). The results demonstrate that there was a significant histological improvement in the vitamin E treatment group versus placebo with resolution of NASH ($p < 0.006$), though there was not a significant difference in resolution of transaminases (the primary outcome measure) in either treatment group. Other studies of metformin in children include an open-label pilot study of metformin (500 mg twice daily for 24 weeks) which was conducted in 10 nondiabetic children with biopsy-proven NASH and elevated ALT level [177]. Significant improvement was observed in serum ALT and hepatic steatosis as assessed with MR spectroscopy. A subsequent study conducted in children did not show any benefit of Metformin compared to lifestyle advice [178]. A third study of metformin in insulin-resistant

adolescents resulted in lower severity scores of fatty liver on US and a decrease in prevalence of fatty liver disease in the metformin group [179].

Antioxidants

The oxidation of FFA leads to the production of reactive oxygen species. Normally, hepatocytes have enough antioxidants such as glutathione to keep this process under control. The increased oxidative stress in NASH is in part due to increased FFA which overwhelm a presumably impaired normal oxidation pathway leading to the abundant production of reactive oxygen species. As this may have a major pathophysiological role in development and progression of the disease, antioxidants and hepato-protectants may be useful in management of the condition. Antioxidants such as ursodeoxycholic acid, vitamin E, *S*-adenosylmethionine, betaine, N-acetyl cysteine and pentoxifyline have all been investigated in this context. Newer drugs such as caspase inhibitors and inhibitor of kappa B kinase (IKK) inhibitors are under development. The TONIC trial demonstrated some encouraging histological improvement with vitamin E; however, there was no difference to outcome measures as defined [180].

An open-label pilot study with vitamin E (400–1200 IU/day) in 11 children with NASH, showed improvement of serum transaminases despite no major changes in BMI or US appearance of the liver [181]. Other studies using vitamin E in children refute these findings [178, 182].

The recent PIVENS trial demonstrated that in a multi-centre, double-blind, RCT of vitamin E versus pioglitazone versus placebo in 248 nondiabetic adults with NAFLD, there was a significant improvement in histology in the vitamin E group (43%) versus the pioglitazone group (19%) [175].

Ursodeoxycholic acid (UDCA) has multiple cytoprotective properties [183]. Using a combination of UDCA and vitamin E, Balmer et al. demonstrated an improvement in transaminases and liver histology together with increased adiponectin levels and decreased hepatocyte apoptosis [184]. There was no significant change in the amount of fibrosis present following 96 weeks of treatment, however. UDCA has also been studied in pediatric NAFLD. A small study which evaluated the efficacy of UDCA in 31 obese children with abnormal transaminases did not show any effect of UDCA treatment [185]. A Cochrane review found insufficient evidence that UDCA was an effective treatment for NAFLD [186].

Bariatric Surgery

The role of bariatric surgery (both Roux-en-Y bypass and gastric band) in management of NAFLD was examined in

adults as a Cochrane review. Though RCT exist to date, 21 observational studies were included. The majority of these studies demonstrated improvement in steatosis or inflammation post surgery though with improvement in fibrosis in only 6 studies and deterioration in 4 [187]. No data are available for children.

Orlistat

Orlistat is a gastrointestinal lipase inhibitor which has beneficial effects in terms of weight reduction and reduction of free FAs. The effect of Orlistat with calorie-controlled diet on liver enzymes and histological features of NAFLD has been tested in three RCTs. These RCTs had conflicting results, and though Orlistat appears to be a safe adjunct to dietary counselling, the net effect is uncertain [188–190]. No pediatric data are available.

Probiotics

There has been recent interest in the role that gut microbiota play in obesity, IR and NAFLD [36]. There is evidence that intestinal bacterial overgrowth exacerbates NAFLD and that the prevalence of bacterial overgrowth is higher in those who are obese [37]. Manipulation of gut microbiota with probiotics is a promising way to halt the progression of steatosis to steatohepatitis and fibrosis. Both animal experiments and small human studies have investigated the use of probiotic agents to reverse the progression of steatohepatitis and fibrosis in NAFLD [191, 192]. Two recent double-blind RCTs—one in adults and one in children were reported [193, 194]. Treatment with probiotics in both studies resulted in improvement in transaminases.

Fibrates

Fibrates are PPAR α ligands which can decrease TG levels and increase high-density lipoprotein (HDL) by stimulating lipoprotein lipase and regulating apolipoprotein [195]. Fibrates have been shown to ameliorate IR and inflammation, stimulate β -oxidation and improve transaminase levels but not histology in patients with NAFLD [196]. There have been no RCT in children.

Noninvasive Biomarkers in NAFLD

Though the criterion standard for diagnosis and assessing progression of disease is liver histology, the decision ‘if or when’ to perform a liver biopsy in children with suspected

NAFLD remains controversial. Liver biopsy in children requires admission to hospital and sedation. Risks include bleeding and very rarely death [197]. Repeated biopsy is not a suitable tool for regularly monitoring progression of disease or response to treatment. In addition, biopsy samples only 1/50,000 of the liver, raising the possibility of sampling error [198].

There has been much focus on the development and validation of noninvasive biomarkers of NAFLD in recent years. There is an urgent need for a less invasive method than biopsy of screening the population, stratifying disease severity and following disease progression.

The pathophysiology and evolution of the condition under scrutiny is an important consideration in the development and evaluation of biomarkers. In the case of NAFLD, there are two potential targets. The first is the differentiation of simple steatosis from steatohepatitis. This is important as the prognosis of those with simple steatosis is different from those with NASH [199]. The second issue is the identification of fibrosis stage. This is the main determinant of prognosis and knowing the extent of fibrosis is useful in making treatment decisions, in patient selection for treatment studies and in monitoring progression/regression. Most longitudinal cohort studies in NAFLD have shown that prognosis is determined by stage and rate of progression of fibrosis rather than the presence of necro-inflammation [46, 140, 200]. Clinical importance lies with being able to differentiate between no/minimal fibrosis (F0/F1), significant fibrosis (F2), severe fibrosis (F3) and cirrhosis (F4).

Serum Biomarkers and NASH

Large adult series have suggested scoring systems using age, BMI, IR, AST/ALT, platelet count and albumin to differentiate mild from severe disease [157, 201–203]. These simple markers are neither sensitive nor specific enough in isolation [5, 12]. A growing understanding of the pathophysiology of the disease has allowed the investigation of more specific, mechanism-based biomarkers [117, 204, 205].

Markers of apoptosis/cell death have been shown to be very useful in differentiating simple steatosis from NASH [109]. CK18-M30 fragments have been shown by a number of studies including pediatric studies to correlate well with severity of NASH [206–209].

A number of predictive models to differentiate either NAFLD from obese controls or simple steatosis from NASH have been developed and validated. Tools include the hypertension, ALT, IR (HAIR) score which gives an area under the curve (AUROC) of 0.9 [210], and the NASH test (consisting of 13 variables including weight, TG, glucose, α 2-macroglobulin and apolipoprotein A) which has an AUROC of 0.79 for differentiation of NASH from simple steatosis

[211]. When the NASH test is combined with the Steatostest (10 variables including simple blood tests, age, gender and BMI) [212] and the Fibrotest into what is known as the Fibromax panel, the diagnostic accuracy improves further [212].

The following studies report predictors of NAFLD using routine clinical parameters in cohorts of obese children. Sartorio et al. reported a multivariate analysis of 267 obese children and found that BMI z score, ALT, uric acid, glucose and insulin were useful predictors of NAFLD [17]. Mandato reported IR, ferritin, CRP and glutathione peroxidase as good discriminators of those with NAFLD from those without in a cohort of obese children [205]. Neither of these studies used a histological diagnosis of NAFLD.

Adipocytokines have been investigated in a number of studies in children including TNF α and leptin [213–215], retinal-binding protein-4 (RBP-4) [216], Fetuin A [217] and plasminogen activator inhibitor 1 (PAI-1) [218, 219].

Noninvasive Markers of Fibrosis in NAFLD

Simple tests derived from regression analysis of large series of patients include the AST to platelet ratio index [220], the AST to ALT ratio [221], which have been validated in the NAFLD population with AUROC between 0.67 and 0.86 for differentiation of severity of fibrosis [222–224]. Algorithms specifically derived from NAFLD cohorts include the BAAT score (consisting of BMI, ALT, age and TG levels) [225], the BARD score (BMI, AST/ALT ratio, diabetes) [202, 226] and the NAFLD fibrosis score (incorporating age, glucose, AST, ALT, BMI, platelets and albumin) [201, 222, 223, 227, 228]. In a recent meta-analysis the AUROC for the NAFLD fibrosis score was found to be 0.85 with a pooled sensitivity of 90% and specificity of 97% [143].

Fibrometer has been validated in a NAFLD population [224]. The test incorporates age, weight, fasting glucose, AST, ALT, ferritin and platelets and demonstrates an AUROC of 0.94 for significant fibrosis, 0.9 for severe fibrosis and 0.9 for cirrhosis.

Other biomarkers measure the degree of ECM turnover. Using such ECM markers is a more direct method of assessing fibrogenic activity, and it will tend to measure a dynamic process rather than a static one.

Combinations of both clinical markers and ECM turnover include the Fibrotest [229, 230] which is an algorithm of 13 markers derived from regression analysis including haptoglobin, α 2-macroglobulin, apolipoprotein A1, bilirubin, γ GT, age and gender. It has an AUROC of 0.84 for advanced fibrosis in NAFLD [231].

The European liver fibrosis (ELF) test combining hyaluronic acid, procollagen III N-terminal peptide (P3NP) and TIMP1 was first derived by Rosenberg et al. in a cohort of over 1000 patients with chronic liver disease including

NAFLD [232] and has since been validated in other NAFLD cohorts with the addition of several simple markers to improve accuracy [233]. Importantly, this test has been shown to correlate well with outcome [234]. In 112 children with NAFLD, ELF had an AUROC of 0.92, 0.98 and 0.99 in distinguishing any, significant and advanced fibrosis respectively [235].

As with adult studies, the noninvasive diagnosis of fibrosis (rather than necro-inflammatory change) in NAFLD is considered separately in children. It is important to acknowledge that the different distribution of fibrosis in pediatric patients may affect the validity of applying measures derived from adult cohorts to this population.

Iacobellis et al. reported a cohort of 69 children with NAFLD, 60% of whom had fibrosis [203]. They found that BMI was the only significant predictor of fibrosis with multivariable analysis of simple clinical parameters. BMI had an OR of 5.85 for predicting presence of fibrosis. Manco et al. found waist circumference as a significant predictor of fibrosis in a cohort of 197 children with NAFLD (OR 2.4 (1.04–5.54)) [236]. In both these studies the number of children in the F2–F4 groups was small.

Nobili et al. developed and internally validated the paediatric NAFLD fibrosis index (PNFI) in 136 children with NAFLD [237]. Logistic regression analysis of gender, age, BMI, waist circumference, ALT, AST, γ GT, albumin, prothrombin time, glucose, insulin, cholesterol and triglycerides gave a predictive model with an AUROC for detection of fibrosis was 0.85. Again this study was limited in view of small numbers in fibrosis groups F2–F4.

Hyaluronic acid (HA) level > 1200 ng/ml in 100 children (65% with fibrosis) was a reliable discriminant of fibrosis in NAFLD in one study [203]. The ELF test was evaluated by Nobili et al. in 122 children with NAFLD [238]. Simple markers including age, waist circumference and TG were added to improve diagnostic accuracy. Excellent AUROC for any (0.92), significant (0.98) and advanced (0.99) disease were achieved. In this cohort, 37 (30%) had no fibrosis, 58 (48%) scored as F1, 9 (7%) as F2, and 8 (6.5%) as F3–F4. Alkhoury et al. developed this further and validated both the PNFI and ELF in a cohort of 111 children with NAFLD (69% with fibrosis) [239]. The area under the curve for presence of fibrosis was 0.76 for PNFI, 0.92 for ELF and when the two indices were combined: 0.94. The major issue in both studies was the skew towards no or minimal disease, potentially overestimating the accuracy of the test.

Noninvasive Biomarkers and Imaging

US, CT and MRI

US has a high sensitivity and specificity for diagnosis of steatosis > 30%, but is not good at detecting fibrosis. Because of the low cost, the absence of radiation exposure and the wide availability, US is often used in screening for NAFLD. The accumulation of fat causes the liver to appear hyperechoic compared with the kidney. This finding is nonspecific and does not differentiate fat from other substances such as glycogen. When compared with histological findings, the sensitivity of US to detect fat infiltration below 30% of the liver is low [240]. Computed tomography (CT) is rarely used for the assessment of NAFLD in children because of its ionizing radiation exposure. Magnetic resonance imaging (MRI) and spectroscopy are the imaging techniques with the greatest accuracy to determine hepatic fat content in studies of both adults and children [127, 241–243]. Aside from liver fat, however, other features of NASH cannot be assessed. Other methods include MR elastography which visualizes and measures propagating shear waves and has a high sensitivity (> 85%) and specificity (> 90%) for fibrosis [244]. Cost of this technique may be preclusive however.

For diagnosis of NASH, Iijima et al. have reported on the use of contrast US with Levovist with an AUC of 1.0 [245]. The decreased accumulation of micro-bubbles with advancing degree of fibrosis is unique to NAFLD.

There is an emerging literature examining the use of acoustic radiation force-based shear stiffness in NAFLD, an US-based investigation which correlates well with the stage of fibrosis in the condition [246, 247].

Transient Elastography

Transient elastography (Fibroscan®) has been shown to be a useful method for detection of liver fibrosis. In NAFLD, a small number of studies have demonstrated the efficacy of TE in distinguishing severity of fibrosis. In a study of 246 adults with NAFLD, TE had an AUROC of 0.84, 0.93 and 0.95 in distinguishing significant fibrosis, severe fibrosis and cirrhosis, respectively [248]. A Japanese study demonstrated similar results [249]. A recent report of 52 children with NAFLD has shown an AUROC of 0.977, 0.992 and 1 for distinguishing any, significant and severe fibrosis [250]. Feasibility and reproducibility of transient elastography is an issue when patients have a BMI > 30 [251]. An XL probe is now available for better accuracy in this scenario [252].

Non-hypothesis Driven Search for Novel Biomarkers Using New Technologies

The use of relatively new techniques such as proteomics [253–256], glycomics [257, 258], and microarray studies in the derivation of panels of biomarkers associated with a disease may also give an insight into pathophysiology of the condition.

Future Areas for Research

The pathophysiology of NAFLD in both adults and children is still incompletely understood. The reason for different patterns of disease in children, particularly with reference to the occurrence of periportal inflammation and fibrosis rather than the typical type 1 pattern of pericentral disease remains elusive. Determining susceptibility to the disease using genetic analysis for SNPs may become standard practice, particularly in screening the high number of overweight and obese pediatric patients. Further investigation into specific dietary patterns in children may also yield valuable information in this multifactorial disease.

The determination of the most effective management of the condition—both in terms of achieving lifestyle change and pharmacological treatments—will be a major focus going forward. Further areas of interest include the role of intestinal microbiota and the possible use of probiotics in the condition and dietary manipulation with PUFA.

Finally, the long-term outcome of children with NAFLD remains unknown and well designed, long-term prospective studies using networks, such as the NASH clinical research network in the US, are vital to achieving this.

In conclusion, NAFLD in children is a very real, very prevalent condition and, should current trends continue, is likely to become the most common indication for liver transplantation in coming decades. It is important that the condition is recognized in children as there is the potential to reverse the process and to avoid the morbidity and mortality associated in later years.

Portal Vein Anomalies

The portal vein (PV), originating at the union of the splenic vein (SV) and superior mesenteric vein (SMV), drains the blood from the gastrointestinal tract, the spleen, pancreas, and biliary apparatus [1]. Between the 4th and 10th week of embryonic life, the PV develops from an anastomotic network formed by the vitelline veins around the duodenum [1, 2]. Congenital anomalies of the PV are rare and can often be explained by persistence of portions of the vitelline veins [3].

Congenital Anomalies of the Portal Vein

The most common congenital anomaly of the PV is a *pre-duodenal portal vein (PDPV)* [3] in which the PV passes anteriorly to the duodenum rather than posteriorly [3–6]. The embryogenesis of this anomaly, described by Gray and Skandalakis [7], consists of the persistence of a preduodenal vitelline communicating vein [8, 9]. Although PDPV can occur as an isolated defect, it is typically associated with other congenital anomalies, including heterotaxia or polysplenia syndrome, situs inversus, cardiac defects, malrotation, biliary or duodenal atresia, and annular pancreas [4, 6, 10]. Clinically, PDPV can cause a duodenal obstruction by itself or in combination with the typically coexisting anomalies. Approximately, 50% of patients remain asymptomatic, with PDPV being a radiologic or peroperative incidental finding [4, 6].

Congenital PV atresia or hypoplasia may involve the whole extent of the vein or may be localized to the portion just proximal to its division into its two main branches in the

porta hepatis. The foetal umbilical vein and ductus venosus which empty into the left PV undergo a spontaneous obliterative process at birth. If this obliterative process proves to be excessive, the involvement of the PV may lead to PV atresia or stenosis [11]. Hypoplasia of the PV often occurs in patients with biliary atresia [12, 13]. Children with small or hypoplastic PV represent a challenge for liver transplantation with higher complication rates (thrombosis, stenosis, liver graft ischemia, and dysfunction) [13].

The PV is the most common site of visceral venous aneurysms [14, 15]. Nevertheless, *PV aneurysms (PVAs)* are rare, representing fewer than 3% of all venous aneurysms [14, 16, 17]. The major location of PVA is the main extrahepatic PV at the confluence of the SV–SMV [16, 17]. Some PVAs are thought to be congenital. It has been proposed that incomplete regression of the distal right primitive vitelline vein leads to a vascular diverticulum that ultimately develops into an aneurysm [14, 16, 17]. Portal hypertension, related to chronic liver disease, is the most common acquired etiology of PVA [14, 15, 17, 18]. Other causes are inflammatory processes such as pancreatitis, trauma, and invasive malignancy [15]. The most common clinical presentation is nonspecific abdominal pain, followed by incidental finding and gastrointestinal bleeding [17, 19]. Complications of PVA include thrombosis, biliary tract obstruction, inferior caval vein obstruction, and duodenal compression [14, 17, 18].

Anomalous pulmonary venous return is a congenital cardiac malformation in which the pulmonary veins fail to connect with the left atrium during cardiac development [20, 21]. In the infradiaphragmatic type of this anomaly, the pulmonary veins drain through a large channel into the portal venous system or the ductus venosus [21, 22]. This anomaly is frequently seen in association with complex cardiac anomalies, especially with right atrial isomerism syndrome [20]. Clinical symptoms of a total anomalous pulmonary venous drainage develop early (within 24–36 h of life) and include respiratory distress with cyanosis, tachypnea, and tachycardia. Liver enlargement is common [21].

Abnormal connections between the portal and hepatic veins (portosystemic shunts) and between the hepatic artery with the PV (arteriportal shunts) are discussed in the “Hepatic Vascular Shunts” section.

Extrahepatic Portal Vein Obstruction

Definition and Etiology

Extrahepatic PV obstruction (EHPVO) is a major cause of portal hypertension in children and adolescents [23–29]. In EHPVO, the portal inflow is impeded by congenital or postnatal obstruction of the PV [30, 31]. This results in cavernomatous replacement of the PV [16, 31], which consists of formation of venous channels within and around a previously stenosed or occluded PV that act as portoportal collateral vessels. The cavernoma is composed of dilated biliary (cystic and pericholecystic veins) and gastric branches (left and right gastric veins) of the PV and the partially recanalized thrombus. These collaterals are usually insufficient to bypass the entire splenomesenteric inflow resulting in signs of prehepatic portal hypertension [16].

Thrombosis of the PV is usually associated with the presence of a hypercoagulable state, vascular injury, or stasis [3]. Prothrombotic conditions should be excluded in children presenting with an EHPVO. Few studies have evaluated the prevalence of thrombophilic disorders in children and adolescents with portal vein thrombosis (PVT). Genetic abnormalities affecting the physiologic anticoagulant system, such as hereditary deficiency of protein C (PC), protein S (PS), and antithrombin (AT) as well as factor V Leiden (FVL), methylenetetrahydrofolate reductase (MTHFR) C677T and prothrombin (PTHR) G20210A mutations have been well established as risk factors of venous thrombosis in adults and should be excluded in children and adolescents with PVT [24, 28, 30, 32].

Direct damage to the PV in about 25% of cases can be inferred with a history of umbilical vein catheterization during the neonatal period [27]. Umbilical venous catheters may cause thrombosis by damage to vessel walls, disruption of blood flow, damage to endothelial cells by the infusion of substances such as total parenteral nutrition, and thrombotic catheter material [29, 30, 33]. Portal hypertension appears to be rather uncommon following neonatal PVT. This may in part be due to the predominant left PV involvement. Liver lobe atrophy is more common than portal hypertension following neonatal PVT [29, 30].

Clinical Presentation

Acute PV thrombosis can be assumed when patients present with symptoms such as abdominal pain, ascites, or fever in the absence of portal cavernoma and portosystemic collaterals. Patients also can be asymptomatic [32]. Most children with *chronic EHPVO* develop hypersplenism that triggers a more detailed medical assessment. One third to one half of the children present with acute upper gastrointestinal bleeding with no prior history of gastrointestinal disorders or symptoms of hypersplenism. Morbidity is mainly related to variceal bleeding, hypersplenism, portal biliopathy [34], limitations of quality of life (e.g. limited ability to participate in sports owing to extreme thrombocytopenia and/or splenomegaly), growth retardation, neurocognitive impairment, portopulmonary hypertension, and hepatopulmonary syndrome [32, 35, 36].

Diagnosis

EHPVO is diagnosed by Doppler ultrasound (US), computed tomography (CT), or magnetic resonance (MR) angiography [27, 32] which demonstrate PV obstruction, presence of intraluminal material, or PV cavernoma (Fig. 67.1). CT or MRI, in addition, allow to evaluate the patency of the other abdominal veins facilitating planning for potential future in-

tervention. When uncertainty persists regarding the patency of the intrahepatic PV, transjugular retrograde or percutaneous transhepatic portal venography should be undertaken in case meso-Rex bypass is considered. Further diagnostic work up consists of full hypercoagulability panel, liver biopsy in case of suspicion of intrinsic liver disease, and echocardiography to rule out congenital heart disease and to look for evidence of associated hepatopulmonary syndrome or portopulmonary hypertension [32].

Management

Anticoagulation therapy can be considered for patients with a well-documented prothrombotic condition. In patients with idiopathic chronic EHPVO, there is no role for anticoagulant therapy. Insufficient evidence exists in favour of interventional therapy such as local thrombolysis [32].

For the management of portal hypertension caused by EHPVO refer to Chap. 68 “Portal Hypertension in Children”.

Hepatic Artery Anomalies

Ischaemic Cholangiopathy

Ischaemic cholangiopathy has been defined as focal or extensive damage to bile ducts due to impaired blood supply [37]. Unlike the hepatic parenchyma which has a dual blood supply from the hepatic artery and PV, the biliary system depends only on the arterial blood supply [3, 37]. Ischaemic bile duct injury may occur when small hepatic arteries or the peribiliary plexus are injured, or when all possible arterial blood supply is interrupted as in the case of hepatic artery thrombosis after liver transplantation [37]. Conditions associated with ischaemic cholangiopathy are iatrogenic factors (hepatic arterial chemotherapy [38, 39], abdominal radiation [40], liver transplantation [41]) and systemic diseases (panarteritis nodosa [42, 43], paroxysmal nocturnal haemoglobinuria [44]). In the acute stage, patients can present with pain, fever, and jaundice, with or without bacterial cholangitis. In the further course, localized or diffuse bile duct stenosis can occur with variable presentation going from no clinical signs to progressive or fluctuating jaundice, itching, fatigue, or bacterial cholangitis and eventual development of portal hypertension [37].

Pseudoaneurysm of the Hepatic Artery

Hepatic artery pseudoaneurysm (HAP) accounts for 12–20% of all visceral aneurysms [45, 46]. HAPs can be found incidentally, but rupture of the aneurysm can be the first clinical manifestation with abdominal pain, gastrointestinal haemorrhage, or haemobilia [47]. Although HAPs can resolve

spontaneously by thrombosis, the reported risk of rupture ranges from 14 to 80% [45, 48]. Hence, once the diagnosis is confirmed, the aneurysm should be treated regardless of the symptoms. This is done by direct percutaneous injection with thrombin or glue, transarterial embolization or stent placement, or surgical approach [45].

Abnormalities of the Sinusoidal Blood Flow

Pericellular Fibrosis

The hepatic sinusoids comprise one of the largest-calibre vascular beds in the body. Impairment of blood flow through this vascular bed results in a major loss of physiologic function, with profound influence on homeostasis for the entire human organism [49]. The most common cause of sinusoidal blood flow obstruction is cirrhosis leading to a decrease in sinusoidal fenestrations, deposition of subendothelial basement membrane and collagen, loss of hepatocellular microvilli, increased expression of endothelial factor VIII and binding of ulex europaeus agglutinin (UEA)-1 lectin to endothelial cells [50, 51]. Pericellular fibrosis is commonly seen in alcoholic liver disease, chronic passive congestion, nonalcoholic fatty liver disease, Gaucher’s disease, congenital syphilis, and vitamin A toxicity [3].

Physical Occlusion of the Sinusoids

In sickle cell disease, sinusoids can become packed with sickled red cells and erythrophagocytes leading to parenchymal necrosis [52]. In disseminated intravascular coagulation and eclampsia, fibrin deposits may occlude the sinusoids. When these lesions are severe, widespread infarction might occur. Furthermore, the sinusoids might become infiltrated by mast cells in mastocytosis, Gaucher’s cells, metastatic tumour cells, and leukaemia or lymphoma cells [3].

Peliosis Hepatis

Peliosis hepatis is a rare condition in which the sinusoidal dilatation is primary [53]. The liver contains blood-filled cystic spaces, either non-lined or lined with sinusoidal endothelial cells [54]. The pathogenesis of peliosis hepatis is unknown [49]. In adults, peliosis hepatis can be induced by anabolic steroids, azathioprine, oral contraceptives, 6-thioguanine and 6-mercaptopurine, or presents in the context of chronic underlying disorders such as malnutrition [55], leukaemia [56], tuberculosis [57], vasculitis [58], cystic fibrosis, or human immunodeficiency virus (HIV) infection [59]. Peliotic lesions found in acquired immunodeficiency

syndrome (AIDS) and other immunosuppressed patients are caused by bacterial organisms (*Bartonella* species) [56, 60]. In children, peliosis hepatis also occurs most frequently in association with chronic underlying conditions such as cystic fibrosis [61], malnutrition [62], Fanconi anaemia [63], adrenal tumours [64], Marfan syndrome [65], congenital cardiopathy [66], myotubular myopathy [67], or renal transplantation [68]. Four pediatric cases have been published without underlying systemic disorder. In these cases, there seemed to be an association with *Escherichia coli* infection suggesting a direct role of *E. coli* toxins in causing endothelial damage [69–71]. The definitive diagnosis of peliosis hepatis is based on histological findings but should be suspected when ultrasonography reveals hypoechogenic areas involving the whole liver in association with intraperitoneal fluid and normal Doppler signals [70].

Hepatic Vein Anomalies

Budd–Chiari Syndrome (BCS)

BCS is defined as hepatic venous outflow obstruction at any level from the small hepatic veins to the junction of the inferior vena cava and the right atrium, regardless of the cause of obstruction. Outflow obstruction caused by hepatic veno-occlusive disease and cardiac disorders is excluded from this definition. BCS can be classified as primary due to an endoluminal venous lesion (thrombosis or webs) or secondary due to intraluminal invasion by a parasite or malignant tumour or extraluminal compression by an abscess, cyst, or solid tumour [72]. In primary BCS, an underlying prothrombotic disorder or established risk factor for venous thrombosis is often present. In adults, myeloproliferative diseases account for half of the cases of BCS [73, 74]. Table 67.1 gives an overview of predisposing conditions for BCS. The role of

hyperhomocysteinaemia and primary protein C, protein S, or antithrombin deficiency is unclear because liver disease obscures recognition of these disorders [75]. BCS is uncommon with an estimated incidence of 1 in 2.5 million persons per year [76]. It is very rare in children and has a wide variety of predisposing causes. Young children (<10 years of age) account for 1–7% of all cases of BCS [77], whereas in endemic areas, children younger than 10 years may compose 16% of the total cases [78]. Hepatic venous outflow tract obstruction leads to increased sinusoidal pressure, sinusoidal congestion, hepatomegaly, hepatic pain, portal hypertension, and ascites. Elevated sinusoidal pressure leads to perisinusoidal necrosis of hepatocytes in the centrilobular region and eventually to irreversible liver damage, cirrhosis, or liver failure [79].

A diagnosis of BCS should be considered in any patient who presents with acute or chronic liver disease as the clinical manifestations can be extremely diverse. The majority of patients present with the typical triad described by George Budd in 1845: right upper quadrant pain, hepatomegaly, and ascites. Oedema of the lower extremities is also a common finding [72]. Asymptomatic BCS accounts for 15–20% of cases [80]. Jaundice, gastrointestinal bleeding, and hepatic encephalopathy are less common [75]. The diagnosis of BCS is established upon demonstration of obstruction of the hepatic venous outflow tract. US combined with Doppler imaging has a diagnostic sensitivity of more than 75% and should be the first line of investigation [81, 82]. Hepatic veins devoid of flow signal, collateral hepatic venous circulation, a spider web appearance usually located in the vicinity of the hepatic vein ostia and stagnant, reversed, or turbulent flow can all be indicative of BCS [83, 84]. When adequate ultrasonography is technically difficult or when diagnostic features cannot be demonstrated, CT or MRI should be performed. The latter is preferred in children due to absence of radiation exposure. Only in a minority of cases, retrograde cannulation of the hepatic veins for X-ray venography will be ultimately necessary for diagnosis. This technique allows the assessment of the extent of venous outflow obstruction and allows for pressure measurements (Fig. 67.2). Concurrent liver biopsy can contribute in confirming the diagnosis and ruling out other causes such as veno-occlusive disease and cirrhosis of other etiologies [85]. Once the diagnosis of BCS is established, the patient should be investigated for underlying prothrombotic conditions and a haematologic work up for myeloproliferative disorder should be performed. The rarity of BCS in children often means that the disease is diagnosed in its later stages by which time irreversible pathology may be present [77].

The management of BCS in adults consists of anticoagulation, thrombolytic therapy, and angioplasty with or without stenting, transjugular intrahepatic portosystemic shunts (TIPSSs), and surgically fashioned portosystemic shunts [77, 86]. These approaches have, to variable degrees, been

extrapolated for use in pediatric BCS. Early referral has the best possible outcome by creating the opportunity of re-establishing native hepatic venous outflow tract without surgery. Thrombolytic therapy might be successful in dissolving fresh thrombi and can be combined by transjugular balloon angioplasty. Local infusion of thrombolytic therapy in a partially recanalized vein with appreciable flow in a patient who presents earlier than 4 weeks has been associated with a consistently successful outcome in adult patients [87]. Maintenance of flow can be ensured by long-term anticoagulation and treatment of the underlying haematologic disorder if one is identified. TIPSSs have been successfully used in children with favourable long-term results [88, 89]. Percutaneous stent placement has also played a role in the management of pediatric BCS [90, 91] (Fig. 67.2). In a late presentation with established hepatic cirrhosis and complications of portal hypertension, liver transplantation is the only option that can offer an excellent chance of long-term survival. Reports on the long-term outcomes for orthotopic liver transplantation (OLT) specifically for BCS in children are scarce and limited to a few sporadic case reports [92, 93].

Veno-Occlusive Disease (VOD)

VOD, also known as sinusoidal obstruction syndrome, is a severe and potentially fatal liver disease originally described in Jamaican drinkers of pyrrolizidine alkaloid-containing bush tea. It is now seen predominantly, but not exclusively, in patients undergoing haematopoietic stem cell transplantation (HSCT) [94]. The incidence of VOD after HSCT varies between 10 and 60% in different series [95]. VOD usually presents in the first 30 days after HSCT [96, 97]. The clinical course is characterized by rapid weight gain, jaundice, abdominal pain, hepatomegaly, and ascites. Encephalopathy may develop. The most commonly used diagnostic criteria for VOD are the (modified) Seattle criteria [97] and the Baltimore criteria [96] illustrated in Table 67.2. Doppler ultrasound can further support the diagnosis by showing evidence of decreased or reversed portal venous flow. The pathogenesis of VOD is most likely due to a primary injury to the endothelial cells of sinusoids and small venules by chemotherapy and radiation. Many of the cytotoxic agents used in HSCT are metabolized in the liver, including cyclophosphamide and busulfan. It is thought that depletion of glutathione in zone 3 hepatocytes and sinusoidal cells plays an important role in the initiation of the damage [98]. A number of markers of endothelial injury and adhesion molecules are upregulated in patients with VOD. These include plasma thrombomodulin, P- and E-selectins, tissue factor pathway inhibitor, soluble tissue factor and plasminogen activator inhibitor (PAI-1). Increased serum levels of PAI-1 is both a diagnostic and prognostic marker for VOD [99–102]. Histopathologically, the early lesion is subintimal oedema and haemorrhage involving the hepatic venules with fibrin deposits. This leads to sinusoidal congestion and dilatation with (mainly centrilobular) hepatocellular necrosis. In the further course, fibrous obliteration occurs of the venular walls with atrophy of

Table 67.2 Clinical criteria for the diagnosis of hepatic VOD during HSCT [96, 97]

<i>Seattle criteria (modified)</i> [97]
Presence of at least two of the following before day 20 after HSCT
Bilirubin > 35 $\mu\text{mol/l}$
Hepatomegaly or right upper quadrant pain
Ascites or unexplained weight gain of 2% above baseline
<i>Baltimore criteria</i> [96]
Bilirubin > 35 $\mu\text{mol/l}$ in the first 20 days after HSCT and at least two of the following:
Hepatomegaly
Ascites
Weight gain (> 5% compared to pre-transplant)

perivenular hepatocytes and development of sinusoidal fibrosis potentially leading to venocentric cirrhosis [3, 103]. Risk factors for VOD include advanced malignancy and pre-existing liver disease which might be the consequence of previous hepatotoxic chemotherapy, previous abdominal irradiation, or iron overload due to repeated blood transfusions [96, 97, 104]. Busulfan, especially in combination with cyclophosphamide increases the risk of VOD [104, 105]. Targeted dosing of busulfan and pharmacokinetic monitoring of cyclophosphamide and its metabolites could be effective in reducing the risk of VOD [106]. The risk of VOD is higher in allogeneic compared to autologous transplants, with a higher incidence in unrelated and mismatched donors versus sibling donors [96, 97, 104]. High-level evidence from randomized controlled trials supporting prophylaxis for hepatic VOD is scarce [107]. Ursodeoxycholic acid might reduce the incidence of hepatic VOD, but trial results are conflicting and did not show any survival benefit [108–111]. The same holds true for trials on low-dose heparin infusion for VOD prophylaxis [112, 113]. Furthermore, trials on enoxaparin, glutamine, and fresh frozen plasma (FFP) all failed to demonstrate efficacy on reduction of VOD or overall mortality. Supportive treatment of VOD focusses on maintaining intravascular volume and renal perfusion without increasing extravascular fluid accumulation. Avoidance of exposure to hepatotoxic drugs, fluid and sodium restriction, and diuretics are important in the care of a patient with VOD. Again, high-level evidence is lacking on treatment options. There is substantial evidence for the efficacy of defibrotide, a poly-disperse mixture of single-stranded oligonucleotide with anti-thrombotic and fibrinolytic effects on microvascular endothelium, in the treatment of VOD [114, 115]. Defibrotide can be used safely in pediatric patients [116]. Despite emerging therapies such as defibrotide, VOD remains a much feared transplant complication with unfavourable prognosis. Therefore, risk stratification of patients before HSCT is essential to minimize severe VOD and improve transplant outcome. Improved understanding of risk factors will enable to offer high-risk patients a reduced intensity conditioning regimen or T cell depletion to minimize their risk for transplant mortality. As PAI-1 is now recognized to be associated with the pathogenesis of VOD, serial monitoring of blood PAI-1 levels could offer a new diagnostic and potential prognostic tool for this disease [117].

Congestive Cardiac Failure

Congestive cardiac failure is associated with dilatation of sinusoids and atrophy of perivenular hepatocytes which can lead to fibrosis and occasionally nodular regenerative hyperplasia (NRH) [118].

Hepatic Vascular Shunts

Arteriovenous Malformations

Arteriportal shunts may be congenital (in hereditary haemorrhagic telangiectasia) or acquired (blunt or penetrating trauma, percutaneous liver biopsy, cirrhosis) and consist of a communication between the hepatic artery and the portal venous system [3, 16, 21]. Most congenital arteriportal fistulas are symptomatic within the first year of life. Hepatofugal flow develops in the arterialized PV which can lead to portal hypertension, hypersplenism, varices, ascites, and hypertensive enteropathy resulting in malabsorption and diarrhea [21].

Hepatic arteriosystemic shunts are the rarest form of intrahepatic shunts connecting the hepatic artery (or other systemic arteries) and the hepatic veins. These shunts may be congenital or associated with hereditary haemorrhagic telangiectasia, hepatocellular carcinoma, or large haemangiomas [16]. Hepatic arteriosystemic shunts are usually localized in one lobe of the liver [21]. Arteriovenous fistulas can not only present clinically in neonates with congestive heart failure, anaemia, hepatomegaly, and portal hypertension but can also manifest later in childhood in the clinical setting of hereditary haemorrhagic telangiectasia with congestive heart failure, hepatic ischaemia, and portal hypertension [21].

Portosystemic Shunts

The complicated development of the inferior caval vein and the close relationship of its development with that of the vitelline veins may explain the occurrence of congenital portosystemic anastomoses. Portosystemic venous shunting causes elevated levels of galactose, bile acids, ammonia, and other nitrogenous substances in the plasma, some of which can affect the brain [16, 119]. The age of onset of encephalopathy is variable but related in part to the volume and duration of the shunt and the presence of concomitant liver disease [119]. Both extrahepatic and intrahepatic portosystemic shunts have been described [21, 120].

Extrahepatic portosystemic venous shunts are also known as Abernethy malformations described in 1793 [1, 121–124]. Morgan and Superina classified extrahepatic portosystemic shunts into two types [121, 124]. In type I, there is a complete diversion of the portal blood flow in the caval vein, with congenital absence of the PV. Type Ia has absent PV, with the SV and SMV entering in systemic veins separately. These patients are usually girls with cardiac or other congenital anomalies including biliary atresia, oculoauriculovertebral dysplasia, situs inversus, and polysplenia. Hepatic masses are frequent, usually described as focal

Fig. 67.3 A 5-month-old child with multiple intrahepatic portosystemic shunts. **a** Indirect mesentericography with visualization of multiple intrahepatic portosystemic shunts. **b** Direct portography in the same patient with guiding into the right hepatic vein. (Courtesy of Dr. P. Van Langenhove and Prof. Defreyne, Department of Interventional Radiology, Ghent University Hospital, Belgium)

nodular hyperplasia (FNH), but sometimes hepatoblastoma, hepatocellular carcinoma, and adenoma. In type Ib, the SV and SPV join into a PV which then drains into a systemic vein. This form usually occurs in boys without the associated anomalies or hepatic masses [1, 3]. In type II, the PV is intact, but some of the portal flow is diverted into the caval vein through a side-to-side extrahepatic communication, which is congenital, usually isolated, and mostly seen in boys (type IIa) or acquired, most often induced by portal hypertension (type IIb) [21].

Congenital *intrahepatic portosystemic shunts* are abnormal intrahepatic connections between branches of the PV and the hepatic veins [3, 125] (Fig. 67.3). Intrahepatic portosystemic shunts which are acquired are most often associated with hepatic trauma or portal hypertension.

Hereditary Haemorrhagic Telangiectasia

Hereditary haemorrhagic telangiectasia (HHT) or Rendu–Osler–Weber disease is an autosomal dominant vascular disorder with variable penetrance with an estimated prevalence

around 1 in 5000–8000 [126]. HHT is characterized by mucocutaneous telangiectases, recurrent epistaxis, and visceral arteriovenous malformations. Hepatic vascular malformations have been reported in 47% of pediatric patients with HHT ranging from small telangiectases to discrete arteriovenous malformations [127].

Parenchymal Response to Vascular Injury

Nodular Regenerative Hyperplasia (NRH)

NRH is the major cause of non-cirrhotic portal hypertension in the Western world. It is a benign condition characterized by diffuse transformation of the liver parenchyma into small regenerative nodules distributed evenly throughout the liver with minimal or no fibrosis in the perisinusoidal or periportal areas [118]. NRH results from abnormalities in the portal hepatic and occasionally small hepatic blood flow giving rise to ischaemic atrophy and a secondary adaptive hyperplastic reaction of hepatocytes in regions with favourable blood flow [128, 129]. NRH occurs predominantly in older patients

and is rather uncommon in children [130]. In a large series of 716 pediatric liver tumours, NRH was demonstrated in 4.5% of the cases [131]. NRH is seen in conditions affecting the hepatic blood flow including solid-organ transplantation, bone marrow transplantation, vasculitic conditions, and can be associated with underlying autoimmune, inflammatory, and neoplastic diseases or HIV [49]. Immunosuppressive medications such as azathioprine, 6-mercaptopurine, and 6-thioguanine may induce NRH by damaging endothelial cells of small hepatic veins [132–134]. NRH presenting with progressive portal hypertension was described in six children treated with 6-thioguanine as maintenance therapy for childhood acute lymphoblastic leukaemia [135]. Imaging findings are relatively poor in sensitivity and specificity for NRH. A diffusely heterogeneous hepatic parenchyma may be the only imaging abnormality. Regenerative nodules are usually not visible on ultrasound [129]. On CT, regenerative nodules remain isodense or hypodense in both arterial and portal venous phases, distinguishing NRH from FNH and adenomas [130]. The significance of MRI in the diagnosis of NRH is still controversial with only few reports in the literature. Lesions appear hyperintense on T_1 -weighted images and iso- or hypointense on T_2 -weighted images [136]. The gold standard for diagnosis is histopathology demonstrating regenerative nodules consisting of hypertrophied hepatocytes centrally surrounded by atrophic hepatocytes peripherally. There is no or minimal perisinusoidal or portal fibrosis on reticulin staining and compression of the central veins by the regenerating nodules may be seen [137, 138]. The management of NRH mainly relates to the prevention and treatment of complications of portal hypertension.

Focal Nodular Hyperplasia (FNH)

FNH is a localized hyperplastic lesion in response to locally augmented arterial blood flow. The diagnosis of FNH

is rarely made in the pediatric population [139]. It most often affects females between the age of 30 and 50 years [140, 141]. Most cases are found incidentally on abdominal imaging. Large subcapsular lesions might lead to vague abdominal pain. Complications such as rupture and intratumoral haemorrhage are extremely rare. Most lesions remain stable with a likelihood to regress with age, and there is no malignant potential [139]. On imaging, FNH should be differentiated from liver cell adenoma [142] or hepatocellular carcinoma [143]. The typical ultrasound finding in FNH is a well-demarcated homogeneous hypo- or isoechoic lesion with a central scar which can be seen in less than 20% of cases. On colour Doppler, there is a central arterial structure with a spoke-wheel pattern of radiating smaller aberrant vessels [144]. CT shows typically a well-circumscribed iso- or hypodense lesion with rapid homogeneous intense enhancement in the arterial phase and gradual enhancement of the central scar in the portal venous phase [145]. On MR, a homogeneous lesion is seen that is isointense or slightly hypointense on T_1 - and isointense or slightly hyperintense on T_2 - weighted images. During the arterial phase, the typical FNH lesion becomes homogeneously hyperintense apart from the central scar which often exhibits avid enhancement in the delayed phase [146] (Fig. 67.4). In the presence of typical radiological findings there is usually no indication for liver biopsy. When performed, histopathology (Fig. 67.5) shows a non-encapsulated nodule with a central stellate fibrous region containing large vessels from which there are radiating septa. The parenchyma between the septa exhibits essentially normal hepatocytes but with a thickened plate architecture characteristic of regeneration [140]. Patients with asymptomatic FNH are treated conservatively without need for further imaging if there is a typical radiological appearance of FNH. In case of symptoms, which are usually seen in large subcapsular lesions, or in case of atypical radiological features which do not allow to rule out malignancy, surgical resection can be indicated [139].

Fig. 67.4 MRI showing focal nodular hyperplasia (FNH) in a 16-year-old girl. This lesion is discretely hyperintense on T_2 weighted images (a, b), hypointense on T_1 weighted images (c), with intense early arterial phase enhancement (d) and isointense aspect compared to normal liver parenchyma in the portovenous phase (e). (Courtesy of Dr. N. Herregods, Department of Radiology, Ghent University Hospital, Belgium)

ductular reaction and cholate stasis in the lesion. **c** Typical ‘map-like’ pattern of FNH lesion on glutamine synthetase staining (40 \times). (Courtesy of Prof. L. Libbrecht, Department of Pathology, Ghent University Hospital, Belgium)

Benign and Malignant Vascular Tumors

Vascular tumours of the liver comprise a substantial portion (13%) of all hepatic neoplasms in children [147]. Most of these lesions are benign. Infantile hepatic haemangioma (HH) is the most common benign tumour of the liver in infancy [148]. The terminology used in the literature is quite confusing and infantile HH is also called infantile haemangioma-endothelioma. Most of these haemangiomas remain asymptomatic and probably a substantial part remains undiagnosed [149]. An increasing number of hepatic haemangiomas is being identified on antenatal ultrasound [150]. Almost all patients with HH present before 6 months of age with most being diagnosed within the first 2 months [150–153]. The main symptoms are abdominal mass or distension. Other potential presentations include failure to thrive, high-output congestive heart failure, anaemia, thrombocytopenia (Kasabach–Merritt syndrome), respiratory distress, pulmonary hypertension, liver failure, and jaundice. In rare cases, spontaneous rupture has been described. Infantile HH express type 3 iodothyronine deiodinase that converts thyroid hormone to its inactive form. This can result in acquired hypothyroidism which is often seen in larger multifocal and diffuse HH and resolves with tumour involution [154–156]. Based on data from the Liver Haemangioma Registry, a division into three principal categories has been proposed: focal, multifocal, and diffuse lesions [149, 156]. Focal lesions could be considered as the hepatic variant of the cutaneous rapidly involuting congenital haemangioma which typically evolves during foetal life and is fully grown at birth. These lesions do not expand postnatally and are less commonly associated with accompanying cutaneous infantile haemangioma [152, 157, 158]. Because they develop antenatally, focal HH can be diagnosed prenatally [159–161]. Most focal HH are discovered as an abdominal mass in an otherwise healthy child [156]. Ultrasonography reveals a well-circumscribed mass with large feeding and draining vessels. On CT or gadolinium MRI, a well-defined, solitary, spherical tumour with centripetal enhancement and central sparing because of thrombosis, necrosis, or intralesional haemorrhage can

be seen [149, 150, 162] (Fig. 67.6). Multifocal and diffuse HH are considered as true infantile haemangiomas [156]. They are associated with cutaneous infantile haemangiomas in the majority of cases and characterized by the immun-expression of glucose transporter (GLUT)-1 in liver tissue [156]. These lesions appear within the first weeks of life and are therefore not antenatally detected. The typical course in these lesions is one of rapid postnatal growth (0–12 months) followed by slow involution (1–5 years) [156]. Multiple well-defined spherical lesions are observed on CT, MRI, or ultrasound with intervening areas of normal hepatic parenchyma in multifocal HH, whereas the lesions in diffuse HH nearly totally replace the liver [156] (Fig. 67.7). Biopsy can be avoided in typical haemangioma (i.e. multifocal haemangiomas with cutaneous involvement or solitary haemangiomas, presenting in the first few months of life, with typical imaging findings) but should not be delayed in the face of diagnostic uncertainty or when children present with vascular tumours after infancy [150, 156]. Two histological subtypes have been described (Fig. 67.8). Type 1 HH are composed of capillary, sinusoidal and cavernous parts lined by plump endothelial cells with a bland cytological appearance [163]. Type 2 HH have areas composed of papillate tufting vascular channels that are lined by larger pleomorphic and hyperchromatic endothelial cells which exhibit more extensive cell proliferation and active mitosis [147]. The treatment of HH is controversial and the effects of the various forms of therapy are diverse and inconclusive [164]. Asymptomatic HH should be observed. Imaging studies of the brain and chest radiography are appropriate for patients with multifocal and diffuse HH [150] and thyroid function should be checked. In case of symptoms, medical treatment is indicated. Corticosteroids are most frequently used as pharmacological therapy. Early evidence suggests that propranolol, a nonselective β -blocker, may be as efficacious as corticosteroids in the treatment of infantile HH [165, 166]. Other pharmacological treatments which have also been reported to be effective are α -interferon therapy, chemotherapeutic agents, such as vincristine [167, 168], actinomycin D, and cyclophosphamide [169]. When there is no response

Fig. 67.6 MRI findings in a 2-week-old infant with infantile hepatic haemangioma. Large, relatively well-demarcated exophytic mass in *right* lobe of the liver ($81 \times 49 \times 87$ mm). There is heterogeneous hyperintensity on T_2 -weighted images with prominent flowvoids (a, b). On non contrast-enhanced T_1 -weighted images, the spontaneous hyperintense zones in the lesion are compatible with haemorrhagic components (c). After intravenous contrast administration there is peripheral nodular enhancement of the lesion in the arterial phase (d) with progressive, centripetal filling in the portovenous phase (e). (Courtesy of Dr. N. Herregods, Department of Radiology, Ghent University Hospital, Belgium)

Fig. 67.7 MRI of multifocal infantile hepatic haemangioma in a 3-month-old boy. Multiple well-defined T_2 -hyperintense (a, b), T_1 -hypointense (c) nodular lesions spread throughout the liver. After intravenous contrast administration there is nodular enhancement in the arterial phase (d) with nearly isointense aspect of the lesions in the portovenous phase compared to unaffected liver (e). US findings in the same child (f). (Courtesy of Dr. N. Herregods, Department of Radiology, Ghent University Hospital, Belgium)

to pharmacological treatment, arterial embolization, hepatic artery ligation, or surgical resection should be considered. Hepatic transplantation may be indicated in extremis when other treatment options are impossible or fail [156]. Infantile hepatic haemangiomas differ from *cavernous haemangiomas* which are usually asymptomatic in children. Being devoid of malignant potential, they are usually discovered as an incidental finding during abdominal imaging, most frequently between the fourth and the fifth decades of life. They are multiple in more than 50% of cases and show a clear female predominance. Pathological examination reveals a focal tender mass formed by multiple vascular channels limited by a single layer of endothelial cells with thin fibrous stroma. In general, the blood circulation within these tumour vessels is slow. Morphologically, it is a well-defined lesion,

possessing round or lobulated margins. Their size usually remains stable and can vary from a few millimetres to more than 20 cm [143] (Fig. 67.9). *Pediatric angiosarcoma*, in contrast to HH, is a very rare but highly malignant tumour. It usually presents with a rapidly growing hepatic mass. The precise diagnosis may be difficult, even on a biopsy specimen [170]. Open biopsy of the tumour is therefore advisable. Most angiosarcomas develop after the first year of life. Chemotherapy and radiotherapy are notably inefficient in achieving tumour control, and the prognosis remains very poor. Radical resection or even liver transplantation should therefore be attempted if possible. *Hepatic haemangioendothelioma* is a rare neoplasm of endothelial origin having a clinical behaviour intermediate between haemangioma and angiosarcoma [171, 172]. Patients generally present from the

Fig. 67.8 Infantile hepatic haemangioma in a 6-month-old girl (a, b) and a 2-month-old boy (c). **a** H&E (100 \times) and **b** CD 34 (100 \times) staining showing fragment of subcapsular liver parenchyma containing a focal, clearly demarcated vascular lesion consisting of multiple, small capillary to slit-like vessels composed of a single layer of endothelial

cells with plump nuclei. **c** H&E (40 \times) IHH lesion containing capillary-like structures with plump endothelial cells. Towards the centre of the lesion, there is increasing cell paucity with haemorrhagic and myxoid stroma. (Courtesy of Prof. L. Libbrecht, Department of Pathology, Ghent University Hospital, Belgium)

Fig. 67.9 MRI findings in a 4-month-old girl with cavernous haemangioma. Well-demarcated T_2 hyperintense (a) and T_1 hypointense (b) lesion (1.6 \times 1.4 cm) in segment 4 with rapid, intense centripetal enhancement in the early phase after contrast injection (c) and progressive enhancement and fill-in in portovenous phase (VIBE contrast enhanced images) (d). VIBE volumetric imaging breath-hold examination (Courtesy of Dr. N. Herregods, Department of Radiology, Ghent University Hospital, Belgium)

second decade, and the tumour commonly affects liver, lung, skin, or bone but also other presentations are reported [173].

Introduction

Portal hypertension (PH) is the commonest complication of chronic liver disease in children as in adults [1]. Children with PH are at risk of severe complications. Children with PH and their parents may be frightened by the most severe complication of PH, gastrointestinal hemorrhage (GH), often referred to as a terrifying experience and giving the impression of impending death; nevertheless, only few pediatric patients die from variceal bleeding, especially if they have a non-cirrhotic cause of PH [2]. Unfortunately, there are very few robust data published in the past few decades in children with PH [3]. Conversely, in adults, many treatments have been challenged, and a plethora of studies have been carried out and summarized periodically in the Baveno Consensus Conference [4]. A panel of experts sporadically provides a pediatric opinion on the Baveno Conference trying to translate the experience gained from treating adults into children [5].

Therefore, most children are treated simply extrapolating the data from adults and applying the same protocols adapted according to body size [6, 7]. Nevertheless, there are several important differences between PH in children and adults. One is represented by the early onset and rapid progression of pediatric liver diseases causing cirrhotic PH, together with a relatively larger availability of split organ donations allowing us to solve most of the severe cases by organ replacement. Thus, the length of the follow-up of children with severe cirrhotic PH is short. Second, a large proportion of children with PH have presinusoidal disease, having different implications as far as management and outcome are concerned [8]. These points explain why most of the children

with large varices and bleeding that we manage in the long term usually have non-cirrhotic PH, clearly a scenario different to that in adult practice.

Anatomy of the Portal Venous System

The liver receives blood from two main vessels: the proper hepatic artery and the portal vein. The former is a branch of the common hepatic artery, which arises from celiac trunk, and supplies oxygenated blood accounting for 25% of the blood entering the liver. The latter, which drains deoxygenated blood accounting for 75% of the liver blood flow, is the largest vessel of the portal venous system. In adults, the total hepatic blood flow ranges between 800 and 1200 mL/min, which is equivalent to approximately 100 mL/min per 100 g of wet liver. Although the liver mass constitutes only 2.5% of the total body weight, this organ receives nearly 25% of the cardiac output.

This huge portal venous flow is driven through the liver across a minute pressure gradient. The pressure gradient between the portal inflow and the hepatic venous outflow is usually no more than 5 mmHg. The resistance to blood flow through the portal vein is so low because of the unique hepatic vasculature, with conducting blood vessels terminating in each of the microvascular units of the acinus and flowing past only approximately 20 hepatocytes before exiting into the wide hepatic venules. Thus, at least 50% of the entire blood content of the liver can be expelled without significant vascular resistance [9].

The portal venous system extends from the intestinal capillaries to the hepatic sinusoids. It carries the blood from the abdominal gastrointestinal (GI) tract, pancreas, gallbladder, and spleen back to the heart flowing through the liver (Fig. 68.1).

In this system, the central vessel is the portal vein, which is formed by the union of the splenic vein (SV) and the superior mesenteric vein (SMV), but receiving blood also

Fig. 68.1 Anatomy of the portal system

from the inferior mesenteric vein (IMV), the gastric, and the cystic veins. The SMV is formed by tributaries from the small intestine, colon, and head of the pancreas, and irregularly from the stomach via the right gastroepiploic vein. The SVs originate at the splenic hilum and join near the tail of the pancreas with the short gastric vessels to form the main SV. The IMV carries blood from the left part of the colon and rectum and reaches the SV in its medial third. Anatomical variations include the IMV draining into the confluence of the SMV and the SV, and the IMV draining in the SMV (Fig. 68.1).

Immediately before reaching the liver, the portal vein divides into right and left main branches, and then ramifies further, forming smaller venous branches, and ultimately the portal venules. Each portal venule runs alongside a hepatic arteriole and the two vessels form the vascular components of the portal triad. These vessels ultimately merge into the hepatic sinusoids to supply blood to the liver. Three hepatic veins (right, middle, and left) drain the blood from the liver into the inferior vena cava (IVC) [10].

Pathophysiology of Portal Hypertension

The portal venous pressure is directly proportional to the portal blood flow and the hepatic resistance, according to Ohm's law ($\Delta P = Q \times R$, where ΔP is the variation of pressure along the vessel, Q is the blood flow, and R is the resistance to flow). Since portal vascular resistance is inversely proportional to the fourth power of the radius (Poiseuille's

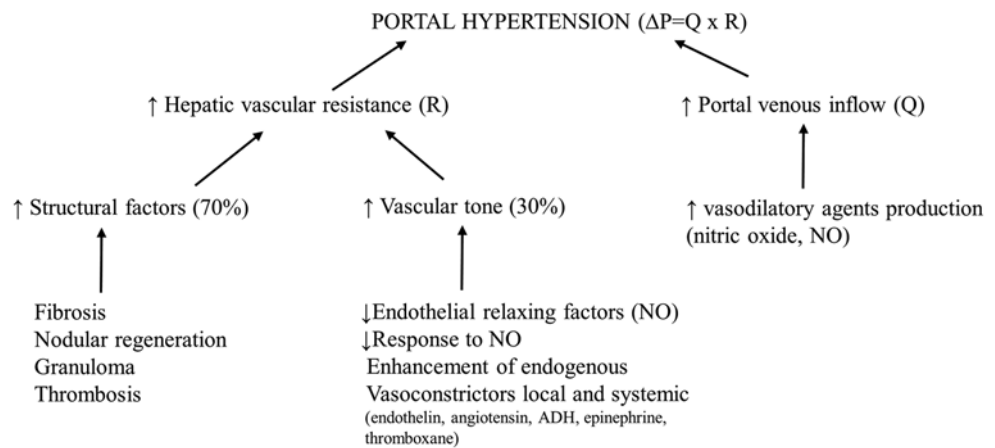

equation), a small decrease in the vessel diameter produces a large increase in the portal vascular resistance and, in turn, in portal blood pressure. In the healthy liver, the intrahepatic resistance changes according to the variation of portal blood flow to keep portal pressure within normal limits. In fact, under physiological conditions, a rise in portal pressure is counteracted by sinusoidal dilatation, even in the presence of increased blood flow as can happen after meal ingestion [10, 11]. Most of the following statements made on PH come from experiments on animal models, such as the rat with a ligated portal vein or bile duct or with carbon tetrachloride-induced cirrhosis, and then confirmed in clinical studies carried out mainly in adults [11–13].

Increase of Vascular Resistance

The portal venous system has a baseline portal pressure of 7–10 mmHg, and the hepatic venous pressure gradient (HVPG) ranges from 1 to 4 mmHg. PH is defined as a portal pressure greater than 10 mmHg or a gradient greater than 4 mmHg. In adults, a pressure gradient above 10 mmHg has been associated with esophageal varices (EV) formation, and with ascites and variceal bleeding if above 12 mmHg [14, 15].

The main pathogenetic factor in the development of PH is an increased vascular resistance (Fig. 68.2). Depending on the site in which it occurs, PH can be classified as extrahepatic (prehepatic and posthepatic) and intrahepatic. The latter may be further subdivided into three forms including

Fig. 68.2 Portal hypertension development according to Ohm's law

presinusoidal (portal venules), sinusoidal (sinusoids), and postsinusoidal (terminal hepatic venules; central veins; Table 68.1).

In patients affected by chronic liver disease, though, increased vascular resistance is located at various intrahepatic levels.

The pathogenetic mechanism explaining the increased resistance in extrahepatic PH, where the blood flow is blocked by a mechanical obstruction, is quite obvious. Conversely, the pathogenesis is more complicated in intrahepatic PH, in which many factors, both mechanical and dynamic, may occur simultaneously [15].

Increase of Portal Blood Flow

The second factor contributing to the development of PH is an increase in blood flow, established through splanchnic arteriolar vasodilatation caused by an excessive release of endogenous vasodilators including nitric oxide (NO), glucagon, endothelin (activated by the vasoactive intestinal peptide), as well as by the activation of the sympathetic and the renin–angiotensin systems. These changes cause sodium and water retention, hypervolemia, renal hypoperfusion, and increase in cardiac output and splanchnic blood inflow, resulting in a hyperdynamic vascular status which characterizes the advanced stages of PH (Fig. 68.2).

Extra-hepatic Causes of PH

Prehepatic causes of increased resistance to flow include SV thrombosis, congenital atresia or stenosis of the portal vein, extrinsic compression (tumors), and portal vein thrombosis (PVT). In these disorders, the obstruction in the prehepatic portal venous system leads to an increased portal venous pressure [16].

Table 68.1 Classification and etiology of portal hypertension

<i>Prehepatic</i>
Portal vein thrombosis
Congenital stenosis or extrinsic compression of the portal vein
Splenic vein thrombosis
Artero-venous fistulae
<i>Intrahepatic presinusoidal</i>
Congenital hepatic fibrosis
Chronic viral hepatitis (HBV and HCV)
Primary biliary cirrhosis
Myeloproliferative diseases (Hodgkin's disease, leukemia)
Focal nodular hyperplasia
Idiopathic portal hypertension (IPH)/non-cirrhotic portal fibrosis (NCFP)/hepatoportal sclerosis
Granulomatous diseases (schistosomiasis, sarcoidosis, tuberculosis)
Amyloidosis
Gaucher's disease
Polycystic liver disease
Infiltration of liver hilum (independent of cause)
Benign and malignant neoplasms
Toxins and drugs (arsenic, vinyl chloride monomer poisoning, methotrexate, 6-mercaptopurine)
Peliosis hepatis
Reidu–Osler–Weber syndrome
Chronic hepatitis
<i>Intrahepatic sinusoidal</i>
Liver cirrhosis (independent of cause)
Wilson's disease
Hemochromatosis
Storage diseases (fatty liver, glycogenosis type III, Niemann–Pick disease, α 1-antitrypsin deficiency)
Acute Hepatitis (viral and autoimmune)
Hypervitaminosis A
<i>Intrahepatic postsinusoidal</i>
Veno-occlusive disease (VOD)
Hepatic vein thrombosis (Budd–Chiari syndrome)
<i>Posthepatic</i>
Inferior vena cava obstruction (thrombosis, neoplasms)
Right heart failure
Constrictive pericarditis
Tricuspid valve diseases

HBV hepatitis B virus, HCV hepatitis C virus

The isolated obstruction of the SV (mainly due to thrombosis) usually results in left-sided PH (sparing the superior mesenteric district). In this rare clinical condition, the blood flows retrogradely through the short and posterior gastric veins and the gastroepiploic veins, leading to the formation of isolated gastric varices. The most common causes of SV occlusion are pancreatic diseases, such as pancreatic cancer, pancreatitis, or a pseudocyst. Although very rare in children, it should be considered in the presence of isolated gastric bleeding with normal liver function and unexplained splenomegaly. The diagnosis may be difficult, and splenectomy represents the treatment of choice in symptomatic patients [17–19].

PVT is the most prevalent cause of extrahepatic portal vein obstruction (EHPVO), and is the major cause of non-cirrhotic PH in children. Conversely, congenital abnormalities, such as portal vein stenosis, atresia, or agenesis, are relatively uncommon.

The etiology of PVT remains obscure in approximately 50% of the cases whereas known etiologies include umbilical vein catheterization, omphalitis/umbilical sepsis, thrombophilia (acquired, hereditary), myeloproliferative disorders, surgery (splenectomy, liver transplantation), dehydration, and multiple exchange transfusions in the neonatal period [20–22].

In a multicenter Italian study including 187 pediatric patients diagnosed with EHPVO, it was shown that the condition is strictly associated with a neonatal disorder. The mean age at diagnosis was 4 years; 59% were born preterm; 65% had a history of umbilical catheterization; 82% had associated illnesses, such as complications of prematurity (43.5%), cardiac malformations (7.5%), noncardiac malformations (8.5%), deep infections (7%), and hematological disorders (5.5%). The patients were diagnosed upon detection of splenomegaly (39.5%), after an episode of GI bleeding (36.6%), because of hypersplenism (5.2%), by chance in the context of other investigations (16.3%; personal data, unpublished).

The pathogenesis of PH in EHPVO is closely related to the portal vein obstruction, which causes an increased vascular resistance in the portal venous system. Initially, the occlusion of the portal vein by thrombus formation is followed by compensatory vasodilation of the hepatic artery buffering the need for blood supply to the liver. Eventually, collateral venous vessels bypassing the thrombus develop and constitute the so-called “cavernomatous transformation” or “portal cavernoma.” Part of these collaterals may reperfuse the liver, whereas the majority contributes to the porto-systemic shunting developing at various levels in the portal system. Liver tests are usually normal since there is no parenchymal disease apart from mild vascular changes, such as portal venous dilatation and sclerosis.

The management of EHPVO is mainly directed to the treatment of PH complications through medical and endo-

scopic means. Despite their efficacy in obliterating EV, endoscopic methods have no effect on portal pressure. Conversely, surgical procedures may decompress the portal venous system and normalize the portal vein pressure. Possible indications for surgical treatment include acute variceal bleeding that cannot be controlled by endoscopic means, persistent EV formation, massive symptomatic splenomegaly, growth retardation, and symptomatic portal biliopathy [23, 24]. EHPVO is dealt with more extensively in the non-cirrhotic PH section.

Posthepatic causes of increased resistance to flow are those related to vascular and/or cardiac diseases, including thrombosis/stenosis of the hepatic veins or the atrio-caval junction, any condition increasing the right atrial pressure, such as constrictive pericarditis, severe tricuspidal regurgitation, and right side cardiac failure. The postsurgical status of some congenital cardiac malformations, such as the Fontan circulation, result in increased central venous pressure and increased resistance to liver outflow [25]. Unlike prehepatic PH, in which liver function remains often normal overtime, in posthepatic PH, the liver blood stagnation may compromise liver function leading to cirrhosis [26].

Budd–Chiari syndrome (BCS) is one of the most common causes of post-hepatic PH both in adults and children. BCS is characterized by hepatic venous outflow obstruction at any level from the small hepatic veins to the atrio-caval junction, regardless of the cause of obstruction. The acute increase of vascular resistance secondary to the hepatic venous outflow obstruction causes the sudden appearance of PH, whereas the chronic status may lead to cirrhosis [27].

A wide variety of predisposing causes may determine the onset of the BCS, including congenital or acquired webs of the IVC and thrombotic, inflammatory, or neoplastic processes.

BCS is relatively rare in children. In studies including patients younger than 10 years with PH, the percentage of cases of BCS accounted for 1–7% of all, although in some areas such as Africa, India, and China, the rate of pediatric BCS may raise up to 16% [28, 29].

The presentation of BCS can be acute, chronic, or fulminant. In the early course of the disease, it may be asymptomatic and accompanied by normal liver tests. Eventually, the hepatic venous outflow obstruction may lead to hepatic dysfunction associated with abdominal pain, ascites, and hepatosplenomegaly.

Due to its rarity, BCS in children is often diagnosed with some delay. The stage of the disease at diagnosis influences the management strategy and an early diagnosis offers the best chance of cure without major surgery [30].

The management of BCS in pediatric patients may include the use of anticoagulation, thrombolytic therapy and angioplasty with or without stenting, transjugular intrahepatic porto-systemic shunts (TIPS), and, rarely, surgical

Table 68.2 Hepatic venous pressures according to the pathophysiology of portal hypertension

Etiology of PH	ISP	PVP	RAP	WHVP	FHVP	HVPG
<i>Prehepatic</i>	↑↑	↑↑	N	N	N	N
<i>Intrahepatic</i>	Presinusoidal	↑↑	↑↑	N	N or ↑	N or ↑
	Sinusoidal	↑↑	↑↑	N	↑↑	↑↑
	Postsinusoidal	↑↑	↑↑	N	↑↑	↑↑
<i>Posthepatic</i>	↑↑	↑↑	N or ↑	↑↑	↑↑	N or ↑

ISP intrasplenic pressure, PVP portal vein pressure, RAP right atrial pressure, WHVP wedged hepatic venous pressure, FHVP free hepatic venous pressure, HVPG hepatic venous pressure gradient (difference between WHVP and FHVP), ↑↑ severe increase, ↑ mild increase, N normal

portosystemic shunts, the latter carrying high risk of thrombotic obstruction. Some patients may end up with end-stage liver disease and require transplantation.

Intrahepatic Causes of PH

Intrahepatic causes of increased vascular resistance have a more various and complicated pathogenesis compared to the extrahepatic forms, and can be further subdivided, according to the relation with the sinusoidal bed, into three subgroups: presinusoidal, sinusoidal, and postsinusoidal.

Presinusoidal venous block can be caused by many conditions, as detailed in Table 68.1. These disorders cause an elevated portal venous pressure, which cannot be detected by the hepatic vein catheter study, since wedge hepatic venous pressure (WHVP) reflects that of the sinusoids that are distal to the lesion, and therefore have normal blood pressure in this condition. Thus, the only useful technique to gather information on the degree of presinusoidal PH is that of the direct measurement of portal or splenic pulp pressure (Table 68.2).

Schistosomiasis is one of the leading causes of PH in the developing countries. Liver involvement due to schistosomiasis is caused by one of the two trematode flukes *schistosoma mansoni* and *japonicum*. While the former is seen predominantly in Africa and South America, the latter is common in eastern Asia, especially mainland China [31]. The pathogenesis of liver disease here is secondary to entrapment of eggs in the portal venules that cause granulomatous inflammation leading to fibrosis and, in 4–8% of cases, presinusoidal PH. Portal tract inflammation results from the host response to the parasitic egg in the hepatic venule. The natural history of PH in this condition is closely related to the number of eggs deposited in the liver [32, 33].

Sinusoidal obstruction is mainly due to cirrhosis. It is marked by an increase of HVPG, normal free hepatic venous pressure (FHVP), and raised WHVP (Table 68.2). In sinusoidal PH, WHVP is equal to portal venous pressure because disrupted intersinusoidal communications diminish compressibility and compliance of the sinusoids, allowing direct transmission of portal pressure to the WHVP [34, 35]. In cirrhosis, the increase of vascular resistance occurs at the level of the hepatic microcirculation (sinusoids), and

it is secondary to both a *mechanical* and a *dynamic factor*. The *mechanical factor* is represented by the hepatic architectural derangement, and is characterized by hepatocyte swelling, hyperplasia, portal tract inflammation, and fibrosis in response to liver injury. Besides, collagen deposition in the space of Disse may contribute to increased intrahepatic resistance [36]. The *dynamic factor* is represented by the active contraction of myofibroblasts and vascular smooth-muscle cells of the intrahepatic veins, and it may be modified by endogenous molecules and pharmacological agents, which affect the intrahepatic vascular resistance. Factors that increase the hepatic vascular resistance include endothelin-1 (ET-1), the alpha-adrenergic stimulus, and angiotensin II. Those decreasing hepatic vascular resistance include NO, prostacyclin, and vasodilating drugs (e.g., organic nitrates, adrenolytics, calcium channel blockers) [15, 37, 38].

Among these endogenous factors, ET-1 and NO play a key role in regulating the hepatic vascular resistance. ET-1 is a powerful vasoconstrictor synthesized by sinusoidal endothelial cells that has been implicated in the increased hepatic vascular resistance of cirrhosis, and in the development of liver fibrosis. NO is a powerful vasodilator substance that is also synthesized by sinusoidal endothelial cells. In the cirrhotic liver, the production of NO is decreased, whereas that of ET-1 is increased. The result of these changes is a net vasoconstrictive effect that, in cirrhosis, accounts for approximately 20–30% of the increased intrahepatic resistance [39–41].

Another dynamic factor that can lead to an increase of intrahepatic vascular resistance is mediated by stellate cells. Hepatic stellate cells (HSCs) are located in the perisinusoidal space of Disse, behind the endothelial barrier, resulting in 5–8% of all human liver cells and 13% of sinusoidal cells. HSCs are involved in vitamin A storage and the synthesis of extracellular matrix components, matrix degrading metalloproteinase, cytokines, and growth factors [42].

HSCs have the capacity to contract or relax in response to vasoactive mediators, such as ET-1 and NO, therefore having a crucial role in controlling intrahepatic vascular resistance and blood flow at sinusoidal level. Indeed, stellate cells become “activated” in response to acute or chronic noxae damaging the liver parenchyma, acquiring a myofibroblast-like phenotype. During HSCs activation, their production of extracellular matrix changes qualitatively and

quantitatively, leading to an increase of intravascular resistance.

In summary, in cirrhosis, the increased intrahepatic vascular resistance consists of two main components. The “mechanical factor” is fixed and caused by the structural changes, which occur in patients with chronic liver disease mainly in the form of fibrosis and nodule formation [43, 44]. The “dynamic factor” is variable and caused by endogenous mediators (ET-1 and NO) as well as HSCs activation. The main target of the management of PH is represented by medical therapy directed against the “dynamic factor” to decrease the intrahepatic vascular resistance [45, 46].

Postsinusoidal obstruction includes right-sided heart failure, IVC obstruction, small venules BCS, veno-occlusive disease (VOD). In this setting, WHVP is elevated, whereas HVPG and FHVP can be either normal or elevated, depending on the site of obstruction, intrahepatic postsinusoidal or posthepatic, respectively (Table 68.2). Hepatic VOD is a clinical syndrome occurring early after bone marrow transplantation (BMT) as a result of liver damage by pretransplant conditioning, or chemotherapy for solid tumors. Its incidence in the pediatric BMT population is between 22 and 28%, with an associated mortality of up to 47% [47, 48]. The pathologic injury initiates in zone 3 of the liver acinum with subendothelial edema of hepatic venules, fibrin deposition, microthrombosis, venular narrowing, and sclerosis, followed by hepatocyte necrosis [49]. The result is a postsinusoidal increased resistance to hepatic venous outflow resulting in acute PH and, in some cases, multiorgan failure [50–52].

Other Pathogenetic Mechanisms of PH

In some conditions, PH can be caused by the increase of portal venous inflow itself. In patients with an artero-venous communications between the splanchnic arteries and the portal venous system, an *artero-portal fistula* (APF), the portal flow is markedly increased and arterialized, with the consequent development of presinusoidal PH. APF can be acquired or congenital, but the most common causes are hepatic trauma and liver biopsy, and can be asymptomatic or manifest with PH. Long-standing APF can lead to severe PH characterized by arterial Doppler signal in the portal vein, reversal of the portal flow, and thickening/narrowing of the extrahepatic portal vein. In this setting, radiological procedures represent the best treatment option to close the artero-venous fistula and restore a normal portal vein flow; although, in the congenital forms, the fistula often reappears through the development of new spontaneous shunt formation [53].

In 1898 Banti described a disorder characterized by splenomegaly and hypersplenism, resulting in PH and anemia in the absence of hematological and liver disease. The actual

existence of the condition has been questioned for a long time due to the lack of explanation for the development of splenomegaly, hypersplenism, and PH in these patients. Nowadays, Banti's syndrome is considered the result of microscopic changes of the portal tract that were not detected at the early stages of its clinical description and corresponding to a group of diseases causing non-cirrhotic PH. *Hepatoportal sclerosis* (HS) is one of the rare disorder characterized by sclerosis of the intrahepatic portal veins resulting in non-cirrhotic PH. HS in children is uncommon but probably underestimated, and only few case reports have been published so far. The cornerstone of the diagnosis of HS is the histology, characterized by portal fibrosis without evidence of either cirrhosis or nodule formation; portal fibrosis is responsible for the increase in the intrahepatic vascular resistance and PH. Nevertheless, the mechanism leading to portal fibrosis and, in general, the entire phenotype of HS are still not well known [54]. Yilmaz reported on 12 pediatric patients with non-cirrhotic PH. On histology, all patients had HS or intimal fibrous thickening of portal vein and periportal fibrosis, acinar transformation, and regenerative nodules not surrounded by fibrous septa. In some of them, there were also signs compatible with cholestatic disease, including neoductular reaction in seven, mild cholangitis in one, and canalicular bile pigment in one [55].

Systemic Hemodynamic Changes in Portal Hypertension

Increased resistance to portal blood flow is likely to be the “*primum movens*” in the development of PH; however, a variety of hemodynamic changes contribute to amplify the increased portal venous pressure observed in patients with chronic liver disease.

The hyperdynamic syndrome was first described in the 1950s, when some physicians observed that patients with cirrhosis often showed “warm extremities, cutaneous vascular spiders, wide pulse pressure and capillary pulsations in the nail beds.” In 1953, Kowalski and Abelmann published the first study which demonstrated an increase in cardiac output and a decrease in peripheral vascular resistance in patients with alcohol-induced cirrhosis [56]. The recognition of the dangerous effect of this syndrome on multiple organs, though, was achieved only several years later [57].

Vasodilatation plays a key role in the development of the hemodynamic changes. The hyperdynamic syndrome should be better called “progressive vasodilatory syndrome,” because vasodilatation is the main factor that brings about all the vascular changes and finally the multiorgan involvement seen in cirrhosis [58]. A major step ahead in this field was accomplished in the 1990s, when researchers discovered that

NO was responsible for the vasodilatation and, in turn, of the multiple organ malfunctions characterizing the hyperdynamic circulation [59].

Both clinical studies and animal models have demonstrated and explained the hemodynamic events that occur in PH but, since they have not been performed in children, the findings should be interpreted with caution (Fig. 68.2).

Splanchnic Circulation Vasodilation of the splanchnic circulation is a process mediated by humoral vasodilatory agents, and it is probably the initial signal triggering the hyperdynamic systemic circulation. Splanchnic vasodilation causes, as a consequence, an increased portal venous blood inflow, contributing to the maintenance and the aggravation of PH [57, 60]. The result of this significant vasodilation is that a large proportion of circulating blood volume remains confined to the splanchnic system, with a subsequent reduction of central blood volume. This process is called the “forward flow” theory and provides a rationale for the use of vasoconstrictors in adult patients with PH [12].

Systemic Circulation Splanchnic vasodilation is associated with changes in the systemic circulation, such as a decrease of arterial pressure, that is consequence of the decreased central blood volume and peripheral resistance in various organs [61]. Compensatory mechanisms include the activation of baro- and volume receptors as well as the production of neurohormonal substances leading to sodium and water retention, with plasma volume expansion and increase in cardiac output [62].

The cardiac response is directly related to splanchnic vasodilatation and plasma volume expansion, together with an increased venous return that is mostly due to the formation of porto-systemic shunts. Although vasodilatation is essential as the initiating factor, no hyperdynamic circulation occurs without expansion of plasma volume and porto-systemic shunting [63]. The former is due to renal sodium retention, which has been shown to precede the increase in cardiac output, and can be prevented or reversed by sodium restriction and administration of spironolactone. The latter is characterized by the development of new veins (called collateral vessels) bypassing the liver and decompressing the portal venous system. These veins directly connect the portal blood vessels to veins that divert the blood away from the liver into the systemic circulation. The drawback in this compensatory process is that substances (such as ammonia and toxins) that are normally removed from the blood by the liver, pass directly into the systemic circulation, and have adverse effects in other organs [64].

Collateral vessels tend to develop at the lower end of the esophagus and at the upper part of the stomach (Fig. 68.1).

Here, the vessels enlarge and become full of twists and turns, becoming varicose veins in the esophagus (EV) or stomach (gastric varices). Other collateral vessels may develop on the abdominal wall and in the rectum. These vessels are prone to rupture, leading to GI bleeding.

Lung Circulation PH and liver shunting may also affect the lungs, resulting in the development of hepatopulmonary syndrome (HPS) and porto-pulmonary hypertension (PPH); these conditions are characterized by hypoxia due to pulmonary artero-venous shunts and pulmonary hypertension, respectively [65]. Although the intrinsic mechanism triggering these complications is not fully known, the major role seems to be played by molecules active on the pulmonary endothelium (including NO and carbon monoxide) that can cause either condition [66, 67].

Renal Circulation Renal circulation is affected indirectly by the hyperdynamic state. To balance the progressive systemic vasodilation, the kidney responds to a perceived hypovolemia by retaining sodium and water. The relative hypovolemia results from an increase of the vascular compartment caused by vasodilatation, leading to the activation of vasoconstrictive and volume-retaining neurohumoral substances that perpetuate sodium and water retention [68]. These compensatory mechanisms include the activation of renin–angiotensin–aldosterone system and antidiuretic hormone secretion. In the early course of the disease, the intravascular volume and the cardiac output increase to maintain the arterial perfusion pressure [69]. With the progression of the disease, vasodilatation worsens, and the cardiac output continues to increase up to a maximum, and then it is not enough to maintain the perfusion pressure. At this point, the renal blood flow drops and renal failure develops [70, 71].

The hyperdynamic circulation should not be considered a complication of cirrhosis but a complication of PH. In fact, it was observed also in non-cirrhotic subjects and confirmed in different experimental models of PH [57, 59].

Clinical Manifestation of Portal Hypertension

PH in children has a broad spectrum of clinical manifestations, varying from the occasional finding of splenomegaly discovered during a routine follow-up visit in absence of any symptom, to hematemesis and melena due to the rupture of EV (Table 68.3). The main manifestations of PH are GH, ascites, and splenomegaly, but, in a minority of patients, other complications may arise including hepatic encephalopathy (HE), pulmonary vascular disorders, and kidney disease [72].

Table 68.3 Clinical evaluation and investigations useful to recognize patients with suspected portal hypertension

Step	Aim
Clinical history	Ask for neonatal umbilical catheterization, episodes of gastrointestinal bleeding, results of previous blood tests, investigations for an undefined splenomegaly
Physical examination	Assess liver size and consistency, look for splenomegaly, abdominal venous patterning (site and direction of venous flow), spider naevi and telangiectasias, palmar erythema, ascites, limbs edema
Liver function tests	Assess liver function and full blood count for hypersplenism
Ultrasonography and Doppler of the liver	Evaluate liver parenchyma, patency of portal vein and direction of venous blood flow, hepatic veins patency, venous anatomical abnormalities, hepatic artery (patency and abnormalities), porto-systemic shunts, ascites, splenomegaly, renal abnormalities
Upper endoscopy	Assess varices and hypertensive gastropathy
CT scan of the abdomen	Assess liver parenchyma, biliary tree conformation, vascular anatomy, Rex recessus patency and signs of portal hypertensive biliopathy
Measure portal venous pressure (HVPG, WHVP, FHVP)	Evaluate the degree of portal hypertension. Diagnose prehepatic, intrahepatic, posthepatic causes
Liver biopsy	Assess fibrosis/cirrhosis, inflammation, histological pattern

CT computed tomography, *HVPG* hepatic venous pressure gradient, *WHVP* wedge hepatic venous pressure, *FHVP* free hepatic venous pressure

**Fig. 68.3** Endoscopic appearance of large esophageal varices with red signs in two children with portal hypertension. (Reprinted from Ref. [73], with permission from Elsevier)

Gastrointestinal Hemorrhage

GH is defined as bleeding in the digestive tract, and it can be classified as proximal or distal, acute or chronic. Bleeding from the upper digestive tract (esophagus, stomach, and upper portion of the small intestine) causes hematemesis and melena, whereas bleeding from the lower digestive tract (lower portion of the small intestine, large intestine, and rectum) causes dark blood or bright red blood mixed with stool, depending on the proximity to the anal sphincter. GH is mainly related to bleeding from EV and also, in a minority of cases, from portal hypertensive gastropathy, gastric antral vascular ectasia, or gastric, duodenal, peristomal, or rectal varices (Fig. 68.3).

Acute GH is often the first symptom of a long-standing silent liver disease, and therefore it is regarded by patients and carers as a frightening event, giving the impression of imminent death. Although the mortality from GI bleeding in children is lower than in adults, acute GH remains a life-threatening event and requires prompt medical intervention. Chronic bleeding is usually mild and can be discovered since the patient has refractory iron-deficiency anemia and positive fecal occult blood test [73].

The formation of varices and their rupture result from the increased pressure within the vessel as a consequence of PH. When the wall tension exceeds the variceal wall strength,

the rupture of the varix occurs, and the patient develops hematemesis and/or melena [74].

Variceal bleeding in children with chronic liver disease often follows an acute upper respiratory tract infection, with the contribution of several factors such as the increased abdominal pressure during coughing or sneezing, the increased cardiac output due to fever, and the erosive effect of nonsteroidal anti-inflammatory drugs used to treat the fever. Gastroesophageal reflux is another factor which may contribute to erosions of varices leading to its rupture and bleeding [75–77].

Hematemesis and melena are the most common presenting symptoms in children with both intrahepatic and extrahepatic PH, and the first episode can be as early as 2 months of age [2, 22, 78–80].

The age at the first bleeding episode is related to the underlying etiology. In children with biliary atresia, the first bleed was described at a mean age of 3 years, while in children with cirrhosis due to cystic fibrosis it occurred at 11.5 years [74, 81]. In a recent study, 65 children with EHPVO were followed for a median period of time of 8.4 years. Thirty-two (49%) patients presented with bleeding at a median age of 3.8 years (0.5–15.5) and, during the follow-up period, 43 of them (66%) had at least one bleeding episode [2]. Triger et al. followed 44 children with EHPVO for a mean follow-up of 8 years. The actuarial probability of bleeding was 49% at age 16 years and 76% at 24 years of age. If the child bled before 12 years of age, the probability of bleeding was higher than in those who had not bled before 12 years of age. Further, there was no evidence of variceal regression over time. These studies do not support the previous hypothesis that variceal bleeding decreased in adolescence due to the development of spontaneous porto-systemic collaterals [2, 82]. In a multicenter Italian study on 187 children with EHPVO, the mean age at diagnosis was 4 years, and the most common symptoms at onset were splenomegaly (39.5%) and bleeding (36.6%). In 71 patients with an available

endoscopy at presentation, 62 (87.3%) had already developed EV. Development of EHPVO was strictly associated with a neonatal disorder including history of prematurity, neonatal illness, and umbilical venous catheter. Authors concluded that a liver Doppler ultrasound should be performed before discharge from the neonatal unit and at the follow-up to allow an early recognition of the disease and avoid bleeding from EV that are present from the early stages (personal, unpublished data). Since splenomegaly is a very common sign detected in children with PH at the time of GI bleeding, the association between GI bleeding and splenomegaly should be suggestive of PH until proven otherwise [74].

There is no strong evidence supporting the efficacy of any treatment for the prevention of variceal bleeding in children. The administration of nonselective β -blockers (NSBBs), the endoscopic treatment of varices, and the surgical (meso-*rex* bypass, porto-systemic shunts) and radiological (TIPS) measures to decompress the portal system represent the main therapeutic options for the primary and secondary prophylaxis of bleeding in children with PH [73, 83].

Splenomegaly

Splenomegaly indicates an enlargement of the spleen usually associated with an overactivity of the spleen, defined hypersplenism, which leads to premature destruction of blood cells. Splenomegaly is due to PH which causes at the beginning only spleen congestion and eventually tissue hyperplasia and fibrosis. The increase in spleen size is followed by an increase in splenic blood flow, which participates in PH actively congesting the portal system [84]. Together with EV, splenomegaly represents the most common finding in children with PH even though, in asymptomatic children, it is often discovered accidentally during a routine physical examination.

Despite a big spleen is highly suggestive for PH, many children with liver disease and isolated splenomegaly have often a delayed diagnosis. In clinical practice, splenomegaly accompanied by hypersplenism is considered a sign of hematological disorders, leading to a long hematological follow-up (including bone marrow aspiration and biopsy) before asking consultation to a hepatologist. Due to the large spleen, children with PVT often receive a diagnosis of infectious mononucleosis every time they come to clinical attention because of a viral illness, and PH is disclosed only after a bleeding episode.

Liver function tests and Doppler ultrasound are mandatory in healthy children with splenomegaly and hypersplenism to exclude the presence of EHPVO and avoid worthless procedures [74, 85].

Some studies have tried to identify the best noninvasive method to diagnose the presence of EV in children with PH.

Platelet count and splenomegaly are usually considered the most reliable parameter to predict the presence di EV. The clinical prediction rule proposed by Gana has high predictive value (area under the receiver operating characteristic; ROC curve 0.80) and is calculated according to the following formula: $(0.75 \times \text{platelets}) / (\text{spleen } z \text{ score} + 5) + 2.5 \times \text{albumin}$ [86].

Once liver transplantation (LTX) or porto-systemic shunting is performed, splenomegaly and hypersplenism may improve significantly, but sometimes they persist for long, depending on the grade of splenic hyperplasia and fibrosis developed over time [87, 88].

Ascites

Ascites is the accumulation of serous fluid in the peritoneal cavity, and is usually seen in patients with PH due to cirrhosis. Ascites appears when the hydrostatic pressure goes above the osmotic pressure within the hepatic and mesenteric capillaries, and the transfer of fluids from blood vessels to lymphatics overcomes the drainage capacity of the lymphatic system [89].

Ascites should be analyzed to obtain information on its cause and possible complications. The serum ascites albumin gradient (SAAG) is used to classify ascites into portal and non-portal hypertensive etiologies. The SAAG is calculated by subtracting the ascitic fluid albumin level value from the serum albumin value, and the result correlates directly with portal pressure. This phenomenon is the effect of Starling's forces between the fluid of the circulatory system and ascitic fluid, as albumin does not move across membranes easily, because it is a large molecule. Under normal circumstances, the SAAG is ≤ 1.1 g/dl because serum oncotic pressure (pulling fluid back into circulation) is exactly compensated by the serum hydrostatic pressure (which pushes fluid out of the circulatory system). In presence of PH, there is an increase in the hydrostatic pressure causing more fluid and more albumin to move from the circulation into the peritoneal space with ascites formation. As a consequence, the SAAG increases (≥ 1.1 g/dl). Thus, a high gradient (SAAG ≥ 1.1 g/dl) indicates that the ascites is due to PH, whereas a low gradient (SAAG ≤ 1.1 g/dl) indicates that ascites is not associated with increased portal pressure (Table 68.4). In clinical practice, some conditions may influence the proper value of the SAAG including the sampling of ascites and serum in different states of hydration or the impact of serum globulin concentration [90, 91].

Ascites should also be evaluated for spontaneous bacterial peritonitis (SBP), an ascitic fluid infection without an evident intra-abdominal surgically treatable source. The diagnosis is made by ascitic fluid cell count. The absolute polymorphonuclear cell (PMN) count in the ascitic fluid is

Table 68.4 Causes of ascites based on serum ascites albumin gradient (SAAG)

SAAG ≥ 1.1 g/dl=portal hypertension	SAAG ≤ 1.1 g/dl=other causes of ascites
Cirrhosis	Peritoneal lymphoma
Non-cirrhotic liver disease	Serositis
Fulminant hepatic failure	Chronic peritoneal infection
	Tuberculosis
	Other (bacteria, viruses, fungi)
Vascular/heart disease	Low serum colloid osmotic pressure
Portal vein thrombosis	Nephrotic syndrome
Veno-occlusive disease	Protein-losing gastroenteropathy
Budd–Chiari syndrome	Kwashiorkor
IVC obstruction/right heart failure	Hollow organ leak
Benign and malignant neoplasms	Lymphatic
Mixedema	Other (pancreatic, biliary, intestinal)

IVC inferior vena cava, TBC tuberculosis

calculated by multiplying the total white blood cell count (or total “nucleated cell” count) by the percentage of PMNs in the differential. The diagnosis of SBP is established by an elevated ascitic fluid absolute PMN count (≥ 250 cells/mm³), a positive ascitic fluid bacterial culture, and absence of secondary causes of peritonitis [92]. Patients with SBP should receive antibiotic therapy, such as intravenous third-generation cephalosporin, and be considered for liver transplantation.

Treatment of ascites includes salt and fluid restriction and use of diuretics. Spironolactone is the diuretic of choice as it is an aldosterone antagonist counteracting the endocrine changes of the hyperdynamic circulation, but often there is the need to add a loop diuretic, such as furosemide, that can improve diuresis and counteract hyperkalemia. In children with normal liver synthetic and biliary function, ascites can often be managed with diuretics and occasional paracentesis (Fig. 68.4). Paracentesis has been utilized safely in children and is indicated when ascites is large and not responding to diuretics [93, 94]. When ascites does not recede, recurs shortly after paracentesis, or when children do not tolerate diuretic therapy due to side effects, the management can take advantage of more aggressive treatment including regular large-volume paracentesis and, if feasible, TIPS. TIPS procedure, although uncommon in children, provided good results in term of resolution of refractory ascites in both native and transplanted livers [88].

When ascites is accompanied by signs of end-stage liver disease, such as hypoalbuminemia, jaundice, clotting derangement, or SBP, the only effective treatment is liver transplantation. In these cases, albumin infusions can be used along with diuretics, in order to increase the osmotic pressure and facilitate the passage of fluid from the extravascular to the intravascular

**Fig. 68.4** Tense ascites and abdominal venous patterning in a child with biliary atresia, failed Kasai, and end-stage liver disease

compartment. In children with end-stage liver disease, ascites can be associated with hyponatremia, which is a risk factor for severe complications and death. Pugliese et al. evaluated the association of pretransplant variables with the mortality within 90 days following the inclusion on the waiting list of 520 children with cirrhosis. On multivariate analysis, the presence of ascites and serum sodium levels were associated with decreased patient survival while awaiting a liver graft [95].

Chylous ascites is a rare clinical condition marked by an extravasation into the peritoneal cavity of a milky fluid deriving from the mesenteric lymphatic vessels. Usually, it results from major abdominal surgical interventions, such as liver transplantation, during which several lymphatic vessels are inadvertently resected and PH has not yet resolved; nevertheless, chylous ascites can present also in patients with PH due to PVT or congenital portal venous malformation. In this setting, in spite of the absence of strong evidences, the management includes fat-free diet and somatostatin analogues [96].

Pulmonary Complications

Children with PH may develop two rare pulmonary complications: hepatopulmonary syndrome (HPS) and portopulmonary hypertension (PPH). Their relative frequency and risk factors have not been defined, and only isolated cases or small series have been published so far.

The pathogenesis of HPS and PPH remains unclear, but the two conditions arise only in patients with porto-systemic shunting, and therefore the pathogenesis must be related to it. The proposed theories suggest that these disorders result from a combination of the hyperdynamic circulation, the increased cardiac output, the sheer injury to the vascular walls, and an imbalance of circulating vasoactive peptides. Abnormal hepatic synthesis of vasoactive peptides, such as EN-1, or impaired hepatic metabolism of intestinally derived endotoxins, cytokines, and neurohormones may result in these substances reaching the pulmonary vascular bed via

porto-systemic shunting, directly altering the vessel tone or leading to pulmonary vascular inflammation and remodeling. The resulting pathology is strikingly different in these two disorders, with vasodilation of pulmonary arterioles and capillaries causing artero-venous shunting in HPS, and intimal fibrosis with endothelial and smooth-muscle cell proliferation leading to increased pulmonary vascular resistance in PPH [97–99].

HPS is defined as intrapulmonary vascular shunting (IPVS), ventilation–perfusion mismatch and chronic hypoxemia in a setting of liver disease and/or PH. The mechanisms implicated in the development of HPS are likely to include many of the vasoactive substances involved in the genesis of the hyperdynamic circulation, including NO and EN-1 [100–102]. Porto-systemic shunting plays a key role in the pathogenesis of the HPS; in fact, HPS has been described also in patients with congenital porto-systemic shunting and no liver disease (i.e., the Abernethy malformation).

From the clinical point of view, HPS is characterized by shortness of breath, exercise intolerance, and digital clubbing. Since the disease is often subtle and progresses slowly, in the early stages it can be easily overlooked and become overt only when advanced. Patients with PH should be screened for HPS by measuring the transcutaneous oxygen saturation and, if <96%, by performing further investigations to assess the real presence of IPVS. The two main procedures to confirm the presence of IPVS are the echocardiography with agitated saline and the macroaggregated albumin scan. The former is simple and sensitive in both symptomatic and asymptomatic children. The latter may be used to quantify the degree of shunting, which can be useful in clinical decision-making and to test the progression of HPS over time [103–105].

Liver transplantation represents the only effective treatment option for children with HPS. Al-Hussaini et al. reported a study on 18 children with HPS over 14 years. Fourteen underwent LTX with resolution of HPS in 13. Six developed vascular or biliary complications and four died (two before transplantation) [106].

PPH is defined as an elevation of the mean pulmonary arterial pressure and increased vascular resistance caused by a pulmonary arteriopathy, in the setting of PH and in the absence of underlying cardiopulmonary disease [105]. The pathophysiology of this disorder is still unclear; however, it seems to be related to a decreased hepatic clearance and porto-systemic shunting of biochemical mediators in the setting of liver dysfunction and PH. PPH produces characteristic histological changes in the pulmonary vasculature that have been well documented on autoptic samples [107].

Although there are scant data in children, it has been shown that PPH can develop in patients with cirrhotic and non-cirrhotic causes of PH such as biliary atresia, PVT, focal nodular hyperplasia, and congenital hepatic fibrosis [108].

From the clinical point of view, PPH presents most commonly with exertional dyspnea, fatigue, palpitations, and syncope or chest pain. The symptoms are often subtle at onset, so that a high index of suspicion is required to diagnose PPH in asymptomatic patients before they develop severe and irreversible pulmonary hypertension [107]. Echocardiography with Doppler flow is considered the most useful screening modality in patients with suspected pulmonary hypertension, although limited by the fact that it relies on the presence of tricuspidal regurgitation, it measures systolic rather than mean pressure in the right ventricle and the measurement is approximate. Chest X-ray and electrocardiogram (ECG) definitely lack sensitivity. If there are indirect signs of pulmonary hypertension at ECG, further evaluation should include a right heart catheter study and, in some cases, high-resolution computed tomography (CT) of the chest and ventilation-perfusion lung scanning [104].

If the diagnosis of PPH is made early before the development of irreversible pulmonary vasculopathy, LTX can be successfully performed and may reverse the process. Conversely, once PPH is advanced (with a mean pulmonary pressure >35 mmHg) and associated with right-sided heart failure, LTX becomes unfeasible because of the functionally obstructed liver outflow that leads to graft failure and death in at least 50% of cases. More recently, it has been shown that the perioperative use of inhaled and intravenous pulmonary vasodilators (NO and epoprostenol) as well as oral drugs (sildenafil and bosentan) can remarkably reduce the pulmonary pressure to a safe level, allowing to perform LTX [108]. The goal of treatment is, therefore, lowering the mean pulmonary arterial pressure and move the patient from high risk to a safer ground for transplantation. However, if there is no response or the pressures remain very high, the only viable option is a combined lung–liver transplant.

Other Major Complications of Portal Hypertension

An abnormal *abdominal venous patterning* can be seen in children with PH, in whom a prominent subcutaneous vascular pattern develops as part of spontaneous porto-collateral shunting (Fig. 68.4). This is the result of the attempt at decompressing the portal venous system through the umbilical vein recanalization that leads to periumbilical collaterals. Although less common than in adults, both umbilical venous shunts and rectal varices can be observed in children with long-standing PH, whereas in children with PH and an intestinal stoma (i.e., in short bowel syndrome associated with liver disease), stomal varices often occur and represent a site of low resistance and bleeding [109].

Hepatorenal syndrome (HRS) is defined as a functional renal failure in patients with liver disease and PH, and it

constitutes the climax of the systemic circulatory changes associated with PH [91]. In pediatric patients, HRS is rare, probably due to the relatively short time that cirrhotic children spend on the transplantation waiting list. Two types of HRS have been identified. Type 1 HRS is an acute and rapidly progressive form that often develops after a precipitating factor such as GI bleeding or SBP. Type 2 HRS is a slowly progressive form of renal failure that often occurs without a sudden trigger in the setting of chronic and refractory ascites. HRS arises from severe vasoconstriction of the renal circulation to compensate for the characteristic circulatory imbalance of advanced cirrhosis. This leads to an increased renal arterial resistance which in turn causes renal hypoperfusion and arterial hypotension. The small volume of the produced ultrafiltrate is then reabsorbed almost completely in the proximal tubule, whereas no solutes (such as sodium) flow to the Henle's loop with nearly no hyperosmolar natriuresis, activation of adiuretin-vasopressin and reduced urine output. As a result, standard diuretic treatment has little effect on diuresis [110]. The criteria to diagnose HRS are difficult to be applied in young children because of the lack of pediatric data. HRS is a potentially reversible condition, but its natural prognosis is poor. Various vasoconstrictors are useful in the treatment of HRS, and terlipressin is the first choice [111]. In the pediatric setting, the experience is little. In a report, four children with end-stage liver disease received terlipressin treatment for renal failure compatible with HRS type 1 in three and type 2 in one. All four responded well and no side effects were reported [112]. Liver transplantation is the ultimate treatment for HRS, ensuring full recovery and long-term survival, and thus it remains the principal tool both in adults and children.

Hepatic encephalopathy (HE) refers to a variety of reversible neurological abnormalities reported in patients with cirrhosis and PH associated with anatomical and functional porto-systemic shunting. In children, HE can be subtle, and the condition seems to appear at a later stage of liver disease and be difficult to diagnose, especially in ill infants. Disturbed consciousness (including coma), personality changes, intellectual deterioration, and speech and motor dysfunction are common in older children with HE. These symptoms usually have a sudden onset and a rapid reversibility suggesting they are of metabolic origin [113].

Protein diet restriction, cleansing enemas, oral antibiotic, and lactulose are the most effective medical options to prevent and treat HE [114, 115].

Non-cirrhotic Portal Hypertension

Non-cirrhotic PH (NCPH) is a heterogeneous group of liver disorders characterized by PH in absence of cirrhosis and with normal or only mildly elevated HVPG values [116].

They are of crucial importance in pediatric hepatology since, while the majority of children with cirrhotic PH are treated with liver transplantation successfully in the early years of the life, those with NCPH do not have any indication for LTX and are managed and followed up for a long time up to adult age [73].

In relation to the site of increased vascular resistance to blood flow, such disorders may be classified as prehepatic, hepatic, and posthepatic. Among presinusoidal NCPH disorders, non-cirrhotic portal fibrosis (NCPF) and EHPVO represent two different entities in whom features of PH are not associated to significant parenchymal dysfunction [116].

NCPF is mostly a disorder of young adults or middle-aged women, whereas non-cirrhotic EHPVO is reported both in infancy and in older children. Recently, it has been proposed the so-called unifying hypothesis, providing a common explanation to the pathogenesis of both NCPF and EHPVO, and focusing on thrombotic events affecting the portal branches. The authors hypothesize that a major thrombotic event occurring at early ages and involving the portal trunk results in EHPVO, whereas repeated microthrombotic events occurring later in life and affecting the small or medium branches of the portal vein would lead to NCPF [117]. In this session, we focus on such two disorders. NCPF is a rather unknown liver disorder in children, whereas EHPVO represents the most common cause of NCPH in the pediatric population.

Non-cirrhotic Portal Fibrosis (NCPF)

The clinical pattern of presentation of NCPF is that of PH in the absence of an evident cause, such as liver fibrosis/cirrhosis or vascular obstruction. NCPF is also named idiopathic PH (IPH), idiopathic non-cirrhotic portal hypertension (INCPH), hepatportal sclerosis (HS), and obliterative venopathy [116].

On histology, the main features include phlebosclerosis, fibroelastosis, periportal and perisinusoidal fibrosis, aberrant vessels in portal tract (portal angiomatosis) with preserved lobular architecture, and differential atrophy. The main portal vein branch is dilated, with thick sclerosed walls, along with thrombosis in the medium and small portal vein branches, giving a picture of "obliterative portal venopathy" [118, 119]. However, in children, these features are often subtle and the condition may be overlooked.

The etiology of NCPF is undefined, but the attention has been brought to various factors that may trigger autoimmunity or endotoxin-mediated injury leading to vascular abnormalities, which cause presinusoidal block to the portal venous flow. The interest has been pointed particularly on lack of hygienic conditions, that would support the role of infections as trigger of the disease, and prothrombotic disorders, that would support the association with an underlying prothrombotic state [120].

The diagnosis of NCPF is based on clinical evidence of PH without liver dysfunction and a histology with no significant fibrosis. The Asian Pacific Association for the study of the liver (APASL) has proposed some criteria for the diagnosis of NCPF in adults [121]. Recently, Schouten et al. redefined five criteria including:

1. Any one of the following clinical signs of PH: splenomegaly, EV, ascites, raised HVPG, and evidence of porto-systemic collaterals
2. Exclusion of cirrhosis on liver biopsy
3. Exclusion of known causes of chronic liver disease causing cirrhotic or non-cirrhotic PH
4. Exclusion of common conditions causing NCPF
5. Patent portal and hepatic veins

All five criteria must be fulfilled to diagnose NCPF [122].

In adults, the most common symptoms at onset include bleeding from varix rupture, splenomegaly with or without hypersplenism, and ascites in 10–34% of the cases. On physical examination, the liver may be normal, enlarged, or slightly shrunken, whereas the clinical signs of chronic liver disease are absent [123]. Liver function tests are usually normal in NCPF, but derangements in liver enzymes, prothrombin time, and albumin are seen in a small proportion of adult patients [124].

Hemodynamic studies showed that the increased vascular resistance in NCPF is pre- and perisinusoidal. HVPG is normal or slightly elevated (median 7 mmHg) in this condition [125].

In adults, the natural history of NCPF seems benign, with an overall good outcome. However, in the long term, 30–33% of the adults develop liver atrophy and possible decompensation, development of PVT, HPS, and, sometimes, need for LTX [126, 127].

In childhood, NCPF is an uncommon cause of PH but, since the awareness among pediatric specialists is still low, this condition is probably underdiagnosed. The published experiences in this disease are scarce, and they come mainly from Asiatic regions.

There are no standardized criteria to make the diagnosis of NCPF in children. Although the Schouten criteria may be utilized also in the pediatric population, in children, in the early phase of the disease, the first criterion may not be satisfied due to the delayed onset of clinical signs of PH.

Girard et al. reported a child with Adams–Oliver syndrome and HS. They hypothesized that a vascular anomaly and thrombosis may be the etiology for this condition based on the fact that the patient had PVT and Factor V Leiden mutation. However, the same association has not been described in other children so far [128].

Prolonged exposure to several medications and toxins has also been proposed as possible causes. Indian studies on children with PH showed that, among 134 cases, 29 (22%) were due to NCPF. The authors carried out a sociodemographic

study that found a significant association with residency in arsenic-affected areas [129]. Toxins can surely lead to liver injury but a strong association between arsenic intoxication and development of NCPF has not been proven.

Poddar published the experience on 388 Indian children with PH (median age 11 years). Eleven of them (3%) were diagnosed with NCPF. Variceal bleeding, splenomegaly, and a lump in the left upper abdomen were the most common symptoms at onset [130]. Cantez described 12 children (median age 13.5 years) with a histological diagnosis of HS. Four patients had splenomegaly, three had EV, one had developed HPS and had been transplanted, whereas the others did not show symptoms of PH [131]. Yilmaz reported on 12 children who had a diagnosis of HS, but some of them had also cholestatic features on histology. The authors concluded that cholestatic features noticed in histopathological evaluation may represent a variant group in the spectrum of this disease [55]. A special mention is needed for HIV-related NCPF. The condition occurs predominantly in males (50–100%), homosexuals (50–75%), with a prolonged infection (median 11.5 years, range 7–15 years). It is not known whether the development of NCPF is related to the infection or rather to the antiretroviral treatment. A recent study described a 10-year-old HIV-infected girl who was on antiretroviral therapy. She had splenomegaly and presented with a massive bleeding from EV rupture. The liver biopsy showed features compatible with NCPF. HVPG was normal. She was managed successfully by treatment with β -blockers and endoscopic variceal eradication [132]. Further studies are warranted to best define the real frequency of NCPF in children, and to understand the underlying pathogenetic mechanisms leading to PH, in order to define the best therapeutic strategy.

Extrahepatic Portal Vein Obstruction

EHPVO is defined by the obstruction of the extrahepatic portal vein with or without the involvement of the intrahepatic portal veins. It may include occlusion of the splenic, superior mesenteric, and coronary veins, but excludes the isolated thrombosis of the SV. It is the most common cause of non-cirrhotic, presinusoidal, and prehepatic PH in children [72].

EHPVO represents also the most common disease on long-term care of PH, since these patients do not progress to end-stage liver disease and have no indication for liver transplantation. As a consequence, they represent the group of pediatric patients in whom there is the largest experience with long-term complications and care of PH [78, 133]. EHPVO is primarily a childhood disorder but can present at any age from few months to adulthood.

The etiology of EHPVO is not yet well defined, but various factors including umbilical vascular catheterization,

sepsis, and an underlying hypercoagulable states (or thrombophilia) play a key role in the pathogenesis of the thrombus formation. Due to that a full hypercoagulability panel, including genetic factors, has to be performed whenever the diagnosis is made [22]. Pathogenetic mechanisms which lead to PH are mainly related to the increased vascular resistance in the portal venous system due to thrombus formation. The formation of the portal cavernoma represents a tentative to bypass the thrombus and replace a physiological portal venous flow.

Studies on adult patients with EHPVO have been performed to assess the role of PH in producing changes in splanchnic and systemic circulation in the absence of liver dysfunction. They demonstrated an increase in the cardiac index and a decrease in the total peripheral resistance in patients with EHPVO compared to control patients, suggesting the presence of a hyperdynamic circulation also in patients with a normal liver function. Systemic and pulmonary hemodynamic changes have been evaluated in adults with EHPVO and compared with a group of controls represented by patients with compensated cirrhosis. The authors considered the measurements of cardiac index (by Fick's oxygen method), and systemic and pulmonary vascular resistance indices. Both patients with EHPVO and cirrhosis had similar values, confirming that patients with EHPVO have a hyperdynamic circulation similarly to cirrhotic compensated patients who have the same degree of PH [78, 134, 135]. These studies suggest a predominant role of PH *per se* in the genesis of systemic and pulmonary hemodynamic alterations [136].

Expanded plasma volume, development of porto-systemic venous collaterals and increased venous return to the heart seem to be the main factors which cause and maintain hyperdynamic circulation in patients with EHPVO [133, 137–140].

There are no studies evaluating the presence of a hyperdynamic circulation in children with EHPVO. Radiological procedures to assess hemodynamic changes (i.e., HVPG, right atrial pressure, pulmonary arterial pressure, pulmonary wedge pressure, and mean arterial pressure) are considered too invasive and are not routinely performed in children except in selected cases [125].

Nevertheless, children with EHPVO usually do not show symptoms compatible with the hyperdynamic circulation such as warm extremities, cutaneous vascular spiders, wide pulse pressure, and capillary pulsations in the nail beds. Even major complications of the hyperdynamic circulation of cirrhosis (high cardiac output, HRS, SBP), described in animal models and adult patients, are not common in children with EHPVO. The symptoms are rather those related to PH complications including GI bleeding, splenomegaly with or without hypersplenism, and ascites. Abdominal pain, ascites, or fever in the absence of portal cavernoma and porto-systemic collaterals are suspected for PVT with

an acute presentation (pylephlebitis). On physical examination, the liver is normal or shrunken. Liver function tests are usually normal, at least in the early phases, whereas they can be deranged in the long term [141]; in fact, the increase of γ -glutamyl transpeptidase, total bilirubin, and bile salts in this setting should raise the suspicion of the development of portal hypertensive biliopathy (PHB) [142–144].

In clinical practice, EHPVO is considered a less severe form of PH. The patients may be asymptomatic for many years, and the mortality from bleeding appeared to be negligible in this group of patients [145, 146]. The diagnosis is based on Doppler ultrasound, CT scan, or nuclear magnetic resonance (NMR), which demonstrate portal vein obstruction, presence of intraluminal material, or portal vein cavernoma [72, 147].

Invasive procedures, such as transjugular retrograde or percutaneous transhepatic portal venography, should be undertaken when uncertainty persists. Liver biopsy is not essential for the diagnosis unless an underlying chronic liver disease is suspected, but, when performed, has shown a picture similar to what is described in NCPF. Echocardiography may rule out associated congenital heart disease, and look for HPS or PPH. Children with EHPVO are usually diagnosed years after the event. Anticoagulation therapy is not indicated outside of the acute phase, unless a hypercoagulable state has been documented [11].

Growth Retardation

Incidence and natural history of EHPVO in children is not well defined. The morbidity is mainly related to variceal bleeding, hypersplenism, and overall limitation of quality of life. The management of variceal bleeding in non-cirrhotic PH does not differ from what we described in cirrhotic patients. However, other complications, in both the short and the long term, need to be further elucidated. Growth retardation represents an important complication in this setting. Failure to thrive in children with EHPVO depends on duration of PH and declines further with age despite appropriate energy intake. The pathogenetic mechanisms may include the reduced portal blood supply to the liver and the consequent deprivation of hepatotropic factors, the poor substrate utilization associated with the malabsorption due to portal hypertensive enteropathy, as well as growth hormone resistance. Restoration of portal blood flow to the liver that follows a successful meso-portal bypass (MPB) results in improved growth in these patients [148–150] (Fig. 68.5).

Portal Hypertensive Biliopathy

Patients with EHPVO occurring in infancy almost invariably develop radiological evidence of PHB as young adults; nevertheless, only 20–30% develop clinical signs of cholestasis [151]. PHB is a disorder characterized by anatomical and functional abnormalities of the intrahepatic, extrahepatic,

Fig. 68.5 Dizygotic twins born preterm. One developed portal vein thrombosis and shows evident growth retardation

and pancreatic ducts occurring most commonly in patients with non-cirrhotic PH [142]. Abnormalities of the biliary tree include intrahepatic biliary radicles dilatation, caliber irregularities, displacements, ectasias, strictures, and common bile duct stones [144]. The pathogenesis is mainly related to long-standing portal cavernoma in the biliary and peribiliary region, causing compressive and ischemic changes of the biliary tree, and more frequently in the left hepatic duct [143]. When symptomatic, PHB presents with jaundice, biliary colic, abdominal pain, and recurrent cholangitis. Magnetic resonance cholangiopancreatography (MRCP) is the first-choice tool to diagnose PHB in children. [152]. The decision to treat biliary obstruction in these patients depends on the presence of symptoms. In asymptomatic patients no intervention is recommended. In symptomatic children, biliary stenting (by endoscopic retrograde cholangiopancreatography, ERCP, or percutaneous transhepatic colangiography, PTC) may temporarily improve the symptoms restoring a normal bile flow. Nevertheless, some patients may require shunt or bypass surgery to decompress the biliary varices and resolve the obstruction [151].

Minimal Hepatic Encephalopathy

HE is a brain dysfunction caused by liver insufficiency and/or porto-systemic shunting; it manifests as a wide spectrum of neurological/psychiatric abnormalities ranging from subclinical alterations to coma. The subclinical manifestation of HE, which is called minimal HE (MHE), is detectable by the alteration of at least two specific psychometric tests or electrophysiological techniques [114]. Nowadays, the term covert HE is also used to refer to all the spectrum of manifestations of HE that do not produce disorientation in time or space [153].

HE can occur not only in patients with liver cirrhosis but also in those with non-cirrhotic PH and porto-systemic shunting [154, 155]. MHE has been reported in about one

third of children with EHPVO and normal liver function [156, 157]. The diagnosis is made by psychometric tests, critical flicker frequency, and MR spectroscopy [158]. Hyperammonemia seems to play a key role in the pathogenesis of this complication [159].

According to this research, MHE would compromise attention, processing speed, and psychomotor performance, in some cases affecting the academic performance of the patients. MHE seems solved by restoring blood flow to the liver by the meso-portal bypass (MPB), while surgical porto-systemic shunts may eventually worsen it [114, 156].

Management of EHPVO

Management of children with EHPVO is primarily focused on treatment of PH complications. However, the use of medical therapy, endoscopic procedures, and surgery are still questionable because there are no evidence on efficacy of NSBBs, endoscopic varices obliteration (EVO), and different types of surgical operations [72]. In clinical practice, EHPVO is managed according to what is proposed for cirrhotic children with PH. As far as surgery is concerned, special attention should be paid to the possibility of curing these patients by a successful MPB. MPB represents a physiologic repair of EHPVO, restoring the normal hepatic physiology, and therefore it should always be considered in this setting [160]. However, there is no wide agreement on feasibility, indications, timing, and success of this procedure [161, 162]. Due to the absence of standardized guidelines, the management of EHPVO needs to be individualized depending on the age of presentation, site and nature of obstruction, and clinical manifestations. In a retrospective study, we reviewed 65 children with EHPVO (median age at diagnosis 3.5 years) and proposed a stepwise approach to manage such a cohort of patients. After retrograde portogram, MPB resulted feasible only in 44% of the cases. Children were treated with endoscopic procedures and NSBB as first-line therapy. Those who had varices not well controlled by medical/endoscopic treatment underwent MPB in 13 (38.2%), a proximal spleno-renal shunt in 13 (38.2%), a meso-caval shunt in 3 (8.8%), a TIPS in 2 (5.9%), a distal spleno-renal shunt in 2 (5.9%), and a LTX because of HPS in 1 (3%). Such a stepwise approach, consisting of medical, endoscopic, and surgical options, provided excellent survival and bleeding control in more than 90% of the patients [2].

A lively debate is ongoing as to whether MPB should be considered as a preemptive technique or as a second-line option after failure of medical and endoscopic management [162, 163]. Although MPB may turn up not to be feasible in children who developed EHPVO following neonatal umbilical catheterization, it seems reasonable to consider restoring the normal liver flow in the early phase of the disease, when possible [2, 164].

Diagnosis of Portal Hypertension

The diagnostic workup in patients with PH includes actions aiming at diagnosing the underlying liver disease, quantifying the degree and severity of PH, and identifying the presence of clinical complications. In the clinical history, it is important to collect information on prematurity, neonatal jaundice, umbilical catheterization, and presence of signs or symptoms highly suspicious for PH (e.g., history of unexplained splenomegaly) (Table 68.3).

Physical examination is directed to assess liver size and consistency, splenomegaly, abdominal venous pattering (site and direction of venous flow), ascites, skin signs of chronic liver disease (e.g., spider nevi, telangiectasias, palmar erythema), bruises, and edema.

Laboratory tests should include liver function, blood cell and platelet count, and clotting.

A variety of radiological and endoscopic procedures are routinely utilized in children to diagnose PH. However, the majority of them have been well studied in adults but not in the pediatric population. Such procedures include abdominal Doppler ultrasound, upper GI endoscopy, CT scan of the abdomen, invasive measurements of portal venous pressure, and liver biopsy.

Doppler Ultrasound

Doppler ultrasound is a noninvasive and inexpensive technique that is widely used in children to study liver vessels and parenchyma. Although operator dependent and related to the experience and skill of the radiologist, Doppler ultrasound is a valuable tool to screen patients with suspected PH both at the time of the diagnosis and during the follow-up. In a few minutes, this test can provide information on liver size and texture, patency of portal and hepatic veins, hepatic artery patency and flow pattern (including the resistance index), porto-systemic shunting, ascites, splenomegaly, and associated intra-abdominal abnormalities [165].

The liver is usually enlarged in the hepatic (e.g., biliary atresia, ciliopathies, genetic cholestasis) and posthepatic forms of PH (e.g., Budd–Chiari syndrome), whereas it is of normal size in prehepatic PH. The echogenicity of the parenchyma may be increased in cirrhosis and in some diseases in which steatosis is a histological feature (i.e., Wilson's disease and α 1-antitrypsin deficiency) [166]. Gross abnormalities of the bile ducts, such as biliary dilatation, the presence of gallstones, or other morphological abnormalities, can be easily visualized by ultrasound, whereas small irregularities require more powerful imaging studies to be detected.

In patients with prehepatic PH, it is crucial to detect the presence of a portal cavernoma and rule out a dilatation of the biliary tree possibly due to PHB. The splenic size is easily

measured and compared to normal values for age, although it does not correlate strictly with the severity of PH [165]. In children with liver disease, it is important to evaluate also the renal parenchyma to exclude the presence of renal cysts that can accompany several genetic liver disorders and provide a further hint to the diagnosis [166].

Bi-dimensional ultrasonography can easily detect and confirm the presence of ascites suspected clinically, and the color Doppler technique provides information on blood flow in the portal venous system, the hepatic artery, and the hepatic veins, where it is possible to calculate the flow velocity, although it is not possible to estimate pressures [167, 168]. When PH worsens, the portal blood flow may become hepatofugal towards the left gastric, paraduodenal, or paraumbilical veins. Reversal of flow in the SMV or SV may be suggestive of spontaneous mesentericocaval or splenorenal shunts, respectively [169].

The hepatic veins are straight, anechoic, tubular structures that converge towards the IVC approximately 1 cm below its confluence with the right atrium. The normal hepatic vein waveform is triphasic as a result of transmitted cardiac activity [170].

Varices are formed in the lower esophagus by portosystemic shunting via the left gastric vein through the lesser omentum (Fig. 68.1). As a consequence, the lesser omentum gets thickened in PH [171, 172]. Patriquin H et al. measured the lesser omental thickness in 150 children without systemic, liver, or renal disease. They suggested that, in the absence of obesity or lymphadenopathy, a lesser omentum measuring more than 1.7 times the aortic diameter should raise the possibility of PH [173].

Although the “gold-standard” method for liver fibrosis assessment is liver biopsy, in the past years, noninvasive methods have increasingly been used in adult hepatology. The best validated tool is transient elastography (TE) [174, 175]. Data on its use in children are still scarce, and the influence of technical aspects such as probe choice and site of measurement on results is not clear. In one study TE was performed in 527 children (229 girls, ages 0.1–17.8 (median 6.0) years, including 400 healthy controls). The feasibility rate was 90%, but it decreased to 83% in children younger than 24 months even in ideal conditions. General anesthesia significantly increased liver stiffness in healthy children. The authors concluded that In one study TE is feasible even in extremely young children, but confounding influences on test results such as probe choice, sedation, or food intake need to be taken into account when interpreting the results [176].

Endoscopy

Unlike adults, in the pediatric population, there are few reports on the prevalence of varices in children with PH, and

it is therefore difficult to predict how many children would benefit from endoscopic screening [177]. In children, the endoscopic procedures to diagnose and treat EV are routinely performed under general anesthesia.

There is no recommendation to routinely undertake tests to screen for the presence of varices in children with PH. Despite that, many pediatric hepatologists prefer their patients to undergo endoscopic surveillance to best define and prevent the risk of bleeding from varix rupture. In fact, when pediatric hepatologists were asked if they would offer screening endoscopy for varices to a child with biliary atresia and evidence of PH, most of them answered they would, both in Europe and in North America [3, 73, 160].

Data on diagnosis and grading of EV in children are scant. The scoring systems adopted in adults have not been validated in children, but such information is mandatory to determine the effectiveness of prophylaxis of variceal bleeding by either NSBBs or endoscopic treatment (Fig. 68.3). Studies on the interobserver agreement on pediatric varices grading are underway, and the preliminary results suggest that accordance in the recognition of large varices is satisfactory [86, 178].

Another major issue is how to grade varices in this setting. Varices have been defined into 3 grades according to the size, and red marks have been shown to predict bleeding. Recently, the classification has been simplified, and the proposed description of small or large varices, with or without red marks, appears to be more practical [76]. Large varices, varices of any size but with red marks, and gastric varices are likely at higher risk of bleeding in the short term, but again this has not been proven in children so far [179].

Endoscopy in children with PH is only indicated for the treatment of acute bleeding and in the secondary prophylaxis of further bleeding episodes. The usefulness of diagnostic endoscopy and primary prophylaxis of bleeding by endoscopic obliteration is still unproven [72].

Measurement of Hepatic Venous Pressure Gradient

PH is defined by an increased pressure in the portal venous system. Such an increased venous pressure may be detected by a direct measurement of the pressure into the portal vein or by the measurement of a portal pressure gradient (PPG) resulting from the difference, in pressure, between the portal vein and the IVC. Direct measurements of portal pressure can be performed through transhepatic or transvenous catheterization of the portal vein but, since they have high risk of major complications (e.g., intraperitoneal bleeding), these tools are rarely used, apart from those cases in which WHVP is unreliable, such as presinusoidal PH [180].

HVPG measures the PPG as the difference between “wedged” hepatic vein pressure (WHVP) and “free” hepatic

vein pressure (FHVP). The WHVP is measured by occluding the hepatic vein by inflating a balloon at the tip of the catheter. The injection of 5 ml of contrast dye into the vein with the balloon inflated can confirm an adequate occlusion of the hepatic vein. The WHVP reflects the portal vein pressure basing on the concept that when the blood flow in a hepatic vein is blocked by a “wedged” catheter, the static column of blood transmits the pressure from the preceding vascular territory, in this case, the hepatic sinusoids. As in cirrhosis the intersinusoidal communications are lost due to fibrosis, septa, and nodule formation, the sinusoidal pressure equilibrates with portal pressure. Thus, the WHVP correlates closely with portal vein pressure but, in fact, it is a measurement of the hepatic sinusoidal pressure and not of portal pressure itself [35].

The difference between WHPV and FHPV provides HVPG values ($HVPG = WHVP - FHVP$).

Normal HVPG ranges from 1 to 5 mmHg in adults. Subclinical PH is defined when HVPG ranges from 6 to 10 mmHg, whereas complications of PH are expected when HVPG is greater than 10 mmHg. An HVPG greater than 12 mmHg correlates with variceal bleeding, rebleeding, and increased mortality [181].

HVPG values allow to classify different forms of PH. Presinusoidal PH is characterized by normal or slightly increased HVPG values, with normal or slightly increased WHVP and normal FHVP. Sinusoidal PH is found in most chronic liver diseases and is characterized by an increase in WHVP with normal FHVP, resulting in high HVPG (cirrhosis is the most common cause). In postsinusoidal PH, HVPG is normal and both WHVP and FHVP are increased, such as in the Budd–Chiari syndrome (Table 68.2).

The HVPG is considered the gold standard technique to measure portal venous pressure and, in cirrhotic adults, is widely utilized to quantify the severity of PH, predict the outcome, and guide the therapeutic decisions [4, 182, 183].

In children, the diagnosis of PH is essentially based on clinical evidence of PH complications (i.e., splenomegaly, upper varices, ascites) in a setting of an underlying liver disease. Unfortunately, so far the measurement of HVPG in children has been considered an invasive procedure that has to be performed only in limited cases. Due to that, we have only few published data on HVPG measurements in the pediatric setting [184]. Wolfsson reported on 49 children, with acute and chronic liver disease, who underwent 52 HVPG measurements. The procedure resulted feasible in all patients and no complications were documented. HVPG values ranged between 0 and 28 mmHg, and they were greater than 6 mmHg in 30 patients. The Authors concluded that, despite the small sample size, HVPG measurements were feasible and safe in their cohort of patients [185]. Further studies on large cohorts of pediatric patients are necessary to obtain strong evidences on the utility of the HVPG measurements in the management of children with PH.

Other Investigations

CT scanning with intravenous contrast and MR angiography may be used to study children with PH. These investigations provide information on focal liver lesions, portal vein and hepatic vein patency, presence of collateral circulation and arteriovenous shunts. CT has a sensitivity of 85% in the detection of EV compared to endoscopy, but has the advantage of demonstrating splenorenal, gastrosplenic, peripancreatic, pericholecystic, retroperitoneal and omental collaterals, as well as spontaneous large portosystemic shunts [186]. In a study performed on adult patients, MR angiography proved more reliable than Doppler ultrasound for evaluating the portal venous system in patients with PH caused by cirrhosis [187].

Management of Portal Hypertension

Prophylaxis of Bleeding

Currently, there are no data supporting the role of any type of prophylaxis to prevent variceal bleeding in children [3]; nevertheless, many clinicians would consider a cirrhotic child with large varices at risk of mortality from the first bleed, and therefore a definite candidate for primary prophylaxis [73]. Conversely, a reasonable, and somehow evidence-based, consensus on indication to perform endoscopic secondary prophylaxis (prevention of rebleeding) in cirrhotic children appears to be wide [72].

Nonselective β -Blockers

The rationale of NSBBs in PH stands on its ability to decrease the portal flow by reduction of cardiac output (via β_1 -receptor antagonism) and splanchnic vasodilatation (via β_2 -receptor antagonism) [188]. Studies in adults have shown that a dose reducing the heart rate by 25% (or the HVPG by 20%) does decrease the bleeding rate in cirrhosis [183]. There are no randomized trials assessing the efficacy of propranolol as prophylaxis of variceal bleeding in children, and the few cohort studies carried out did not include the measurement of HVPG before and after treatment start [6, 189, 190]. Moreover, these studies showed that in children the evaluation of heart rate at rest is problematic, and the range of drug dosage required to reduce it by 25% is very wide, making achievement of adequate NSBBs dosage impractical and time consuming. Whether pediatric patients with presinusoidal PH, having no classical features of the hyperdynamic circulation, may benefit from treatment with NSBBs has yet to be demonstrated [140].

A further difficulty in carrying out trials with NSBBs in this setting is that propranolol is not licensed for use in children. However, from the clinical experience made, as well as from the previously published studies, it appears that propranolol is safe for children, even at high doses [191].

Endoscopy for Screening and Management of Esophageal Varices

There are few reports on the prevalence of varices in children with PH, and it is therefore difficult to predict how many would benefit from endoscopic screening. Besides, the uncertainty regarding the impact of any prophylaxis in this setting makes endoscopic screening questionable.

Despite this, the mortality of cirrhotic children at the time of first bleeding episode has been reported to be as high as 5–15% and supports screening endoscopy in all children with advanced liver disease and clinical signs of PH [80].

Unlike past decades when endoscopic obliteration of varices was done using sclerosing agents (such as ethanolamine or polidocanol) injected inside or around the varix, currently variceal band ligation (EVL) has become more popular and has been shown to be superior to sclerotherapy as far as efficacy, safety, and degree of standardization are concerned, in both adults and children [192–194]. Nevertheless, in small children, in whom the banding devices available on the market cannot be used with small pediatric endoscopes, sclerotherapy remains the only feasible treatment option to manage large varices [194].

A real challenge in this setting is the presence of large gastric varices; there are no published data on experience of management of gastric varices in children, and probably most centers would treat this scenario according to the experience in adults. Large gastric varices are a threat because they are difficult to obliterate prophylactically, and even more so if actively bleeding; in this situation, balloon tamponade is often ineffective and the only option is to perform sclerotherapy with tissue glue (such as *N*-butyl-cyanoacrylate). In general, a child with large gastric varices should be considered for TIPS, shunt surgery, or liver transplantation, based on the degree of liver disease.

Management of Acute Variceal Bleeding

The main goal of the management of a child with acute esophageal bleeding is well-balanced blood volume restitution. It is therefore mandatory to monitor vital signs, obtain venous access to perform blood tests (full blood count, international normalized ratio, liver function and electrolytes, C-reactive protein, and a blood crossmatch) and start blood

volume correction [195]. Packed red blood cells (PRC) should be provided with the aim to maintain the hemoglobin >7 g/dl, carefully avoiding a rebound overload of fluids that favor the increase of portal pressure and rebleeding [196]. In the presence of coagulopathy, it might be wise to support the patient with plasma, also in view of the fact that esophageal bleeding implies loss of whole blood that, if large, will not be efficiently replaced by PRC. Children with upper GI bleeding may benefit from nasogastric tube placement, with the primary goal being to monitor persistence of active bleeding. Vasoactive drugs, such as octreotide, are effective in stopping bleeding from varices and should be started immediately to bridge the child to endoscopy, and continued thereafter for a total of 4–5 days [197].

In adults, it has been proven that infectious complications commonly follow an episode of variceal bleeding in cirrhotic patients [198]. Although in children there is no such evidence it is recommended to monitor them for any sign of infection and, if present, to start antibiotic treatment promptly, especially in cirrhotic children with advanced disease.

After the initial step, the child should be managed according to hemodynamic stability and the control of bleeding. If unstable, the child should be managed in an intensive care setting, possibly with a central venous catheter providing information on circulating blood volume and preload (Fig. 68.6). Usually, bleeding stops spontaneously after the ruptured varix empties. After cessation, it is usually

acceptable to schedule an elective endoscopy in the following 24–72 h because rebleeding is uncommon during this time frame. If bleeding does not stop despite appropriate fluid replacement and correction of coagulopathy, the child may require urgent endoscopy, and rarely, the placement of a Sengstaken balloon as a bridge to TIPS or urgent shunt surgery (Fig. 68.7). Endoscopic sclerotherapy around the vessel may be the only option to treat an acutely bleeding varix that is underfilled, and therefore difficult to be strangulated by a rubber band placed by endoscopic variceal ligation devices.

Surgical Procedures

When medical and endoscopic treatment of bleeding varices fails, the only option is to consider decompression of the portal system by a shunt or a bypass [199]. Children with EHPVO can be managed effectively by MPB (Fig. 68.8) [23]; however, in our experience of children who had an umbilical venous catheter placed at birth, only about half had a patent Rex recessus at retrograde portogram [2]. If the MPB is not feasible, these patients can usually be treated by other forms of shunt surgery [200]. One recently suggested approach is to perform the MPB preemptively, regardless of complications of PH, in view of its beneficial effects on growth and neurocognitive outcome [162, 164 & 165]. Other patients with presinusoidal PH, but not

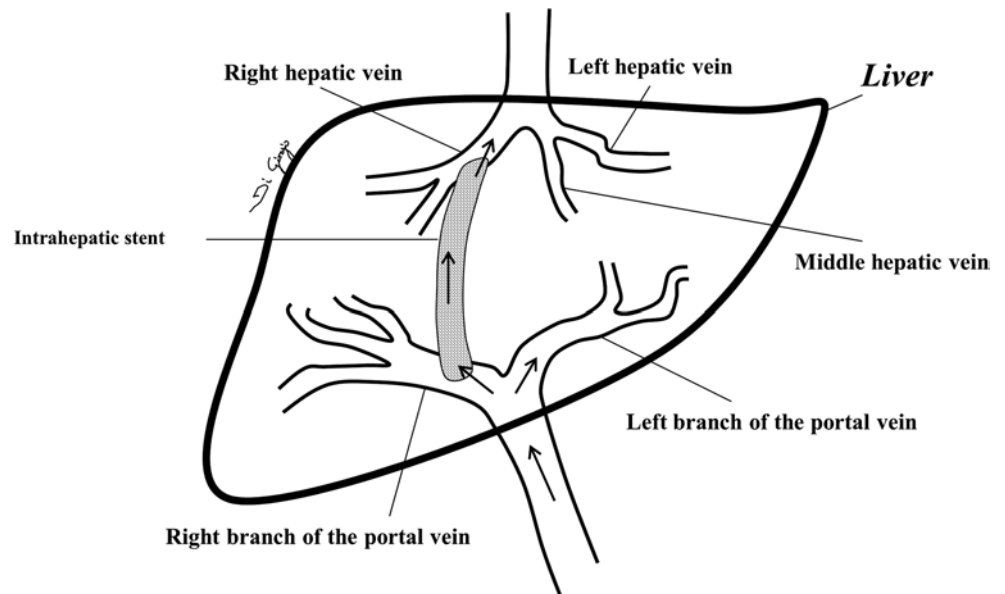

Fig. 68.8 Portal circulation after the operation of meso-portal bypass that reestablishes the hepatopetal flow to the liver

amenable to MPB, can be managed by TIPS or by shunt surgery [201].

Cirrhotic children with PH usually have a rapidly progressive biliary type of cirrhosis (such as biliary atresia, intrahepatic cholestasis, and Alagille syndrome), are young, and have a short transplant-free survival. In our institution, the median age at transplantation is 1.4 years. Therefore, shunt surgery or TIPS is rarely indicated in this cohort of patients in whom PH is usually accompanied by liver decompensation and is an indication for LT. However, cirrhotic

children with a compensated long-standing noncholestatic liver disease complicated by severe PH may be considered for TIPS.

Transjugular Intrahepatic Portosystemic Shunt

TIPS is a well-established tool to manage severe complications of PH in adults, but its experience in children is limited. In our institution, 13 children affected by PH unresponsive

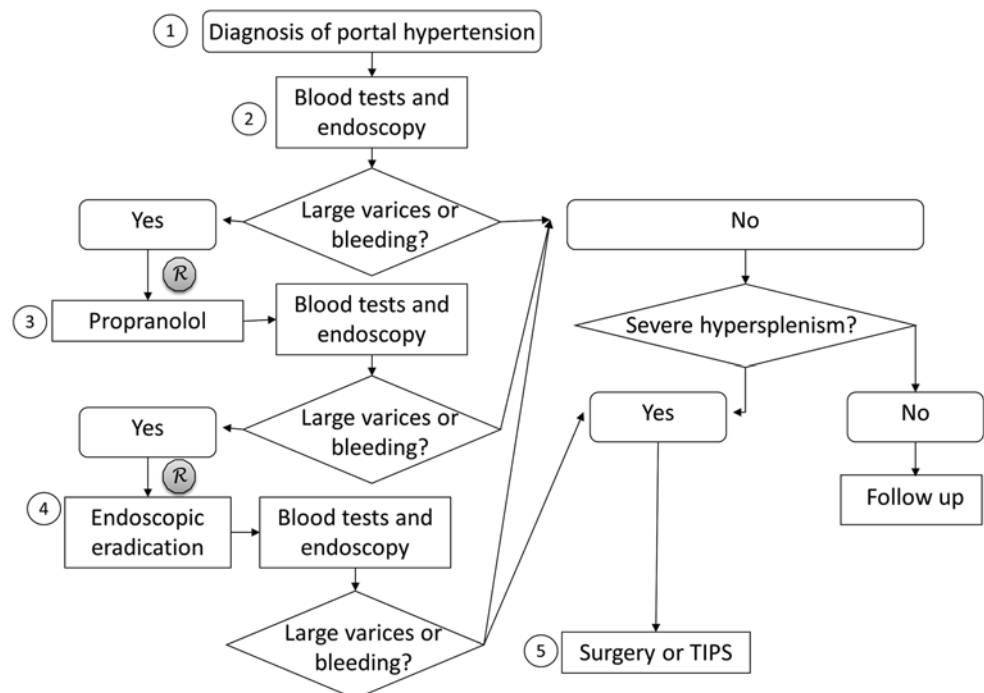

to NSBBs and endoscopic treatment were considered candidate for TIPS. Eleven underwent a successful expanded-polytetrafluoroethylene-covered stent placement, including three who had a split LTX. The shunt led to significant decrease of the portosystemic gradient and resolution of PH complications in all but one. No patient developed overt HE. All shunts were patent at the last follow-up (median of 20 months) or transplantation [88]. TIPS appears to be feasible and effective in children as it is in adults and should become part of the armamentarium used to manage PH complications in pediatric patients.

A Protocol for Screening, Prophylaxis, and Treatment of Esophageal Varices

The need for large sample sizes, the difficulties in recruiting patients into multicenter studies, and the lack of official approval and knowledge on drug dosing make it quite unlikely that there will be robust data on the use of NSBBs in children with PH in the coming years. The same applies to endoscopy because there is no single center able to recruit enough patients to answer questions regarding screening and primary prophylaxis of varices, and multicenter trials require diagnosis and treatment standardization. Besides, such studies can probably only be carried out in non-cirrhotic children having sufficient follow-up time to test the given hypothesis. Alternatively, many centers are already using these tools empirically in both cirrhotic and non-cirrhotic

children, with uncertain and inconsistently measurable results. Is it then possible to gather more information on the utility of NSBBs and endoscopic treatment of varices in children? A proper trial on this matter should be randomized and have variceal bleeding as the primary end point; however, many clinicians and families would consider permitting a GI bleed as unacceptable to test the hypothesis of effectiveness of NSBBs or endoscopic treatment. One possibility to overcome this could come from considering the development of large varices as the end point, because children with large varices or red marks have failed treatment and will eventually bleed. At least two studies have shown that most children with cirrhosis or PVT and grade 2–3 varices will bleed within a few years of follow-up [202, 203]. Therefore, it is possible to hypothesize a randomized, nonblinded multicenter trial of development of large varices in children and their response to treatment. Because of the large sample size needed, such study would first require a solid proof that there is sufficient agreement among endoscopists to recognize large varices in the different pediatric centers involved in the trial [179]. Figure 68.9 illustrates an algorithm of a stepwise approach to manage EV, which considers the formation of large varices as the end point and could offer the chance to test the hypothesis that NSBBs and endoscopy can improve the outcome of children with PH, avoiding the risk of not offering the best of practice currently available. Nevertheless, an extraordinary effort will be required to produce such evidence on the best management of PH in children.

Introduction

Liver tumors are uncommon in the pediatric age group and constitute 1–2% of all solid tumors in children. About 60% of all liver tumors in children are malignant [1]. Hepatoblastoma (HB) is by far the most common constituting over 50–60% of all liver tumors in this age group. Hepatocellular carcinoma (HCC), undifferentiated embryonal carcinoma and biliary rhabdomyosarcoma are other malignant liver tumors in children. Benign tumors include hemangiomas (HMGs), mesenchymal hamartoma, and focal nodular hyperplasia (FNH). Secondary tumors to the liver can spread from a host of primary tumors including lymphomas, Wilms' tumor, neuroblastoma, osteosarcoma, etc. (Table 69.1). Several congenital and environmental risk factors have been reported to increase the predilection for liver tumors (Table 69.2).

There is a striking age-related variation in the frequency of different tumor types (Table 69.3). Over 90% of liver tumors in children below 5 years are HB, while 87% of tumors in the 15–19-year age group are HCC. A gradual increase in the incidence of liver tumors in children over the past 3–4 decades has been reported. This is particularly evident in the case of HB where the incidence has increased from 0.6 to 1.2 per million population between 1973–1977 and 1993–1997. On the contrary, incidence of HCC has decreased from 0.45 to 0.29 per million population during the same period [2].

Tumor Markers in Childhood Liver Tumors

Alpha-fetoprotein (AFP) is the most recognized tumor marker in liver tumors. AFP is a glycoprotein similar in physical and chemical characteristics to albumin. It is secreted by the fetal liver and yolk sac until 13 weeks' gestation and then primarily by the fetal liver [3]. AFP levels at birth are very high with Bader et al. reporting a median level of over 40,000 ng/ml in cord blood samples [4]. These levels rapidly drop during the first year of life at a rate primarily dictated by the half-life of AFP of 5–6 days [5]. AFP levels at birth in the preterm babies are higher than full-term babies. Similarly, a decrease in at-birth AFP for every week of prolonged gestation has been reported [4]. The high levels of AFP in the infant should be kept in mind by the clinician when AFP levels are used for the diagnosis and monitoring of pediatric liver tumors.

Several tumors are associated with elevated AFP. HB is the commonest cause in infants though HCCs and germ cell tumors are also associated with elevated AFP. Nonneoplastic conditions, such as tyrosinemia and neonatal hepatitis, can also cause elevated AFP levels.

Malignant Tumors

Hepatoblastoma

HB is the most common liver tumor in children. It is almost always seen in the first 4 years of life with median age at diagnosis of 18 months. It can present at birth and has been diagnosed in the intrauterine period on antenatal scans. Prematurity and very small birth weight have been identified as risk factors. HB developing in these children is also reported to have a worse prognosis [6, 7].

HB is a tumor of immature hepatocyte progenitor cells. It is an embryonal tumor, which recapitulates various stages of liver development. Histologically, these tumors are heterogeneous and comprise combinations of epithelial, mes-

<i>Benign</i>	Hemangioma: focal, multiple, diffuse
	Mesenchymal hamartoma
	Hepatic adenoma
	Focal nodular hyperplasia
	Inflammatory myofibroblastic tumor (may be locally invasive)
<i>Malignant</i>	
Primary	Hepatoblastoma
	Hepatocellular carcinoma, fibrolamellar HCC
	Transitional tumors
	Embryonal sarcoma
	Biliary rhabdomyosarcoma
	Calcifying nested stromal–epithelial tumor
Secondary	Angiosarcoma
	Lymphomas, leukemia, Wilms' tumor, neuroblastoma, osteosarcoma, colon cancer

Table 69.2 Risk factors and premalignant conditions for childhood liver tumors

Tumor	Risk factors	Premalignant lesions
Hepatoblastoma	Beckwith–Wiedemann syndrome, familial adenomatous polyposis, Li–Fraumeni syndrome, trisomy 18, preterm birth and very low birth weight	–
Hepatocellular carcinoma	Glycogen storage disease, tyrosinemia, Alagille syndrome, biliary atresia, PFIC, Ataxia-telangiectasia, hepatitis B infection, hepatitis C infection	Hepatic adenoma
Embryonal sarcoma	–	Mesenchymal hamartoma
Angiosarcoma	–	Hemangioma
<i>PFIC</i> progressive familial intrahepatic cholestasis		

Table 69.3 Age-wise distribution of childhood liver tumors

Age group	Benign tumors	Malignant tumors
Neonatal period	Hemangioma, mesenchymal hamartoma	Hepatoblastoma
0–5 years	–	Hepatoblastoma, biliary rhabdomyosarcoma
5–15 years	–	Hepatocellular carcinoma, embryonal sarcoma
>15 years	Hepatic adenoma	Fibrolamellar carcinoma

enchymal, and occasionally teratoid components in varying proportions (Table 69.4, Fig. 69.1). Majority of tumors have a primarily epithelial component containing hepatoblasts at varying stages of differentiation. The histological type has an impact on behavior with well-differentiated fetal epithelial type having the best prognosis. The small-cell undifferentiated type of HB has the worst prognosis with very poor survival. Mixed tumors contain both epithelial and mesenchymal components, are more resistant to chemotherapy, and have a worse prognosis. Post-chemotherapy residual tumors and metastatic tumors may demonstrate a pleomorphic pattern with pleomorphic nuclei having coarse chromatin and prominent nucleoli. This pattern may resemble HCC.

Diagnosis

The usual presentation is with an abdominal lump identified by the parent or the clinician. Pain, failure to thrive, or jaundice are uncommon modes of presentation. Investigations reveal an elevated AFP level in over 90% of cases. The AFP

levels are extremely high (in the order of 10^5 ng/ml) and are usually a log higher than those seen with HCC. AFP level has been identified as a prognostic marker in HB with both very high levels and low levels (<100 ng/ml) predicting poor biology [8]. Thrombocytosis is a recognized laboratory finding in HB and is probably related to production of thrombopoietic cytokines including thrombopoietin in the tumor tissues.

Imaging with computed tomography (CT) is necessary to confirm the diagnosis, stage the extent of liver disease, identify vascular invasion, extrahepatic disease, and lung metastases. HB appears as a heterogeneously enhancing well-circumscribed lesion with occasional calcifications. A biopsy is usually required to confirm diagnosis before start of neoadjuvant chemotherapy and for prognostication.

Staging and Prognostication

Several staging systems have been developed to tailor treatment for HB. The preoperative extent of tumor (PRETEXT) system based on preoperative imaging, which was devel-

Table 69.4 Histological types of hepatoblastoma

Histological type	Description
<i>Epithelial</i>	Primarily containing immature hepatocytes
Fetal	Commonest variant of epithelial HB. Composed of polygonal cells resembling fetal hepatocytes arranged in one- to two-cell thick cords, trabeculae or sheets
Embryonal, well differentiated	Tumor resembles the liver at 6–8 weeks of gestation. Demonstrates organized tubular or acinar formation. Hematopoietic elements are commonly admixed with epithelial component
Cholangioblastic	Tumour cells differentiate as cholangiocytes and form small ducts. This component expresses cholangiocyte lineage markers (cytokeratins 7 and 19)
Macrotrabecular	Cells arranged in thick trabecular pattern (>5 cells thick)
Small cell undifferentiated	Sheets of small cells with large hyperchromatic nuclei similar to neuroblastoma
<i>Mixed epithelial–mesenchymal type</i>	Mixture of epithelial and mesenchymal cell types
Teratoid	Contains heterologous components such as stratified squamous epithelium, mucus-producing cells, neuroectodermal derivatives
Non-teratoid	Contains stromal derivatives including spindle fibroblastic cells, osteoid, skeletal muscle, and cartilage

**Fig. 69.1** Hepatoblastoma, epithelial type with fetal and embryonal epithelium.

oped and popularized by the International Childhood Liver Tumors Strategy (SIOPEL) Group, is commonly used in Europe (Table 69.5, Fig. 69.2). This is an anatomical classification focusing on the extent of tumor and the amount of liver that can be spared during resection [9]. Modifications to the PRETEXT scoring system have included additional subclassifications to identify high-risk factors such as vascular involvement, caudate lobe involvement, etc. (Table 69.6) [10].

SIOPEL also classifies HB into standard risk, high risk, and very-high-risk groups based on the PRETEXT staging and additional factors to tailor management (Table 69.7) [11].

Table 69.5 PRETEXT staging and frequency of various PRETEXT stages at initial presentation [8]. Refer to Fig. 69.2

PRETEXT staging	Definition	Frequency at presentation (%)
I	One section is involved and three adjoining sections are free	4.8
II	One or two sections are involved, but two adjoining sections are free	36.6
III	Two or three sections are involved and no two adjoining sections are free	38.8
IV	All four sections are involved	19.8

Other staging systems include the Children's Oncology Group (COG) classification, which is based on intraoperative findings, and presence of residual tumor have been used more commonly in the USA.

Management

Early results of HB with surgical resection alone were poor due to the advanced stage at which these tumors usually present. Only 5% of all tumors at presentation can be staged as PRETEXT I, and over 50% are unresectable at initial presentation (Table 69.5). Metastatic disease in the lungs at presentation is not uncommon. However, this should not dissuade the clinician from aiming for cure as resection of lung metastases along with treatment of primary has been shown to improve long-term survival [12].

HB are highly chemosensitive tumors and respond well to platinum-compound-based chemotherapy. Use of chemotherapy in conjunction with surgery has radically altered the outcomes of these tumors. Today, multimodality treatment with surgery and chemotherapy is the mainstay of treatment for HB.

Ideal treatment strategy for PRETEXT I tumors is controversial. Some authors have suggested complete resection alone without chemotherapy as an option. This is especially true for the low-risk tumors with fetal histology where complete surgical resection with follow-up has been shown to be effective in providing long-term disease control [13]. Ad-

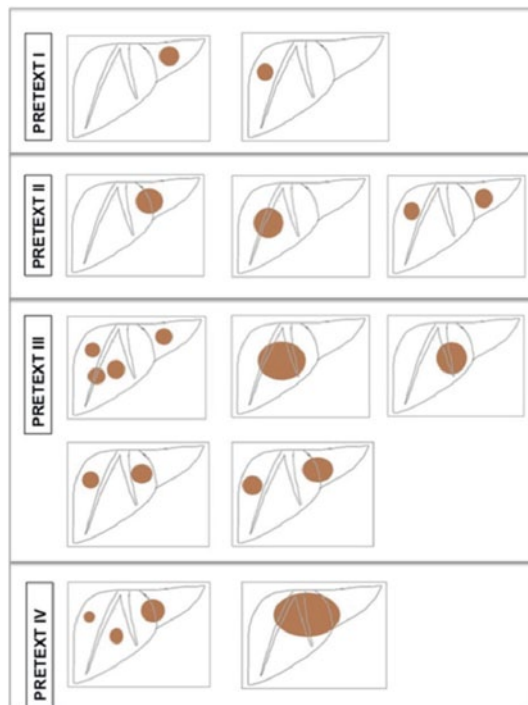

Fig. 69.2 PRETEXT staging: The PRETEXT system is based on the preoperative imaging and is an assessment of the liver that is free of tumor. The liver is divided into four sectors by the right and middle hepatic veins and the falciform ligament. The four sectors are the left lateral, left medial, right medial, and right lateral sectors. The number of contiguous sectors that are free of tumor is the key to the staging. Tumor may be single or multiple. **a** PRETEXT 1, three contiguous sectors are tumor free, **b** PRETEXT 2, two contiguous sectors are free of disease, **c** PRETEXT 3, only one sector is free, **d** PRETEXT 4, all four sectors are involved

vocates for this approach highlight the fact that these children are spared the adverse effects of chemotherapy such as ototoxicity [14]. The SIOPEL group advocates neoadjuvant chemotherapy for all HB. The purported advantages of this approach are that it shrinks the tumor, and clearly demarcates the tumors making resection more straightforward. Tumors also become more fibrotic and hence intraoperative handling is easier.

The current protocol for PRETEXT II and III is to give up to four cycles of neoadjuvant chemotherapy, followed by assessment for resection (Fig. 69.3).

If the tumor becomes resectable, then surgery is followed by two more cycles of chemotherapy. If the tumor remains unresectable, two further cycles of chemotherapy may be considered before a decision is made regarding attempted resection or primary transplantation. Monitoring the fall in AFP level after beginning chemotherapy and after surgery is an excellent means of predicting tumor response. The chemotherapy regimen advised by the SIOPEL group varies for the standard risk and high-risk HB (Table 69.7)[11].

Surgical resection for HB should be carefully planned and is best carried out in units with expertise in pediatric hepatobiliary surgery and liver transplantation (LT). This is particularly true in children with large tumors and borderline resectability. Children can tolerate extensive liver resections better than adults, and up to 85% of liver can be resected safely. More aggressive liver resection techniques such as total vascular exclusion and caval resection may be required to achieve complete disease clearance.

LT for unresectable HB is a well-defined indication [15]. These could be PRETEXT IV tumors (solitary or multifo-

Table 69.6 Additional criteria for PRETEXT staging [10]

Caudate lobe involvement	C1—tumor involving caudate lobe C0—all other patients	—
Extrahepatic abdominal disease	E0—no evidence of tumor spread in abdomen (except M or N) E1—direct extension of tumor into adjacent organs or diaphragm E2—peritoneal nodules	Add suffix “a” if ascites is present
Tumor focality	F0—solitary tumor F1—two or more discrete tumors	—
Tumor rupture	H1	—
Distant metastases	M1	—
Lymph node metastasis	N0—no nodal metastases N1—abdominal lymph node metastases only N2—extra-abdominal lymph node metastases	—
Portal vein involvement	P1—involvement of left or right branch of portal vein P2—involvement of main portal vein	Add suffix “a” if intravascular tumor present
IVC or hepatic vein involvement	V1—involvement of one hepatic vein, IVC free V2—involvement of two hepatic veins, IVC free V3—involvement of all three hepatic veins and/or IVC	Add suffix “a” if intravascular tumor present

IVC inferior vena cava

Table 69.7 Risk stratification and treatment of hepatoblastoma (SIOPEL guidelines). (Available at www.siopep.org [11])

Risk status	Definition	SIOPEL guideline for treatment
Standard risk	PRETEXT I, II, III without any other risk factors as defined below ^a	<i>SIOPEL 3, Cisplatin alone arm</i> Cisplatin X 4 cycles Surgical resection Cisplatin X 2cycles
High risk	PRETEXT IV or any PRETEXT stage with vascular involvement (P2 or V3), extrahepatic disease (E1, E2), tumor rupture (H1)	<i>SIOPEL 3, SUPERPLADO arm</i> Alternating cycles of Cisplatin and carboplatin+doxorubicin X 7 cycles Resection/Transplantation Alternating cycles of Cisplatin and carboplatin+doxorubicin X 3 cycles
Very high risk	Any tumor with metastases or very low AFP (<100 ng/ml)	SIOPEL 4, dose-dense cisplatin-based chemotherapy or enrolment in clinical trial

^a PRETEXT I with fetal histology may be considered for surgical resection alone and observation
 AFP alpha-fetoprotein, PRETEXT preoperative extent of tumor

Fig. 69.3 CT images of Hepatoblastoma in a 1-year-child. **a** CT at presentation showed a PRETEXT 2 disease with tumor involving the two left sectors. **b** CT following four cycles of chemotherapy prior to resection. Note the significant shrinkage in tumor size. The CT appearance of the tumor has also changed and the demarcation between the tumor and healthy liver tissue is much more clear

Fig. 69.4 CT image of a hepatoblastoma in a 6-year child. This child had persistent PRETEXT III tumor after six cycles of chemotherapy. The tumor was closely approximated to the cava. She underwent primary living donor liver transplantation

cal), centrally located PRETEXT II or III, or tumors with portal or caval involvement (Fig. 69.4). In children where surgical resection is not feasible, early referral for LT assessment is the best approach. Primary LT in high-risk cases has better outcomes than rescue transplantation after resection, and the latter should be considered a relative contraindication [16]. A recent US study reported that over the past 20 years, the percentage of HB receiving transplantation has increased from 5 to 20%, and the number of transplantations for HB has increased almost 20-fold [17]. This could be a reflection of the increasing confidence among clinicians for this radical modality of treatment.

The options are either split-liver deceased donor LT (DDLT) or living donor LT (LDLT) and both have comparable results. Children planned for DDLT usually complete neoadjuvant chemotherapy and are placed on the waiting list with some form of prioritization to enable timely transplantation. Where LDLT is an option, transplantation can be planned to follow the planned course of neoadjuvant chemotherapy. Transplantation should be followed by adjuvant chemotherapy. Presence of lung metastases increases the risk

of posttransplant recurrence but is not a contraindication for LT as long as they can be resected [18]. Close follow-up in the posttransplantation period is essential and usually involves periodic AFP estimation and imaging studies.

Results of HB have significantly improved over the past 2–3 decades. Overall disease-free survival has improved to over 70% for all HB. Low-risk tumors have a 90% 5-year survival, while high-risk tumors have a survival of around 50%. Histological subtype has an impact on survival. Fetal types of HB have the best outcomes, while the small-cell undifferentiated type of tumors have worse prognosis. Relapse after initial complete response occurs in 11% of children. Liver and lungs are the commonest sites of relapse. Positron emission tomography/computed tomography (PET/CT) has been reported to be better at identifying relapse when compared to CT or MRI [19]. Combination of surgery and chemotherapy provide the best chance of achieving a second complete response in these children with reported 3-year overall survival of over 40% [20].

Hepatocellular Carcinoma

HCC is the second commonest liver tumor in children. It forms 15% of all malignant liver tumors in children but constitutes over 75% of all liver tumors in adolescents. HCC in children can occur in a background of chronic liver disease secondary to hepatitis B or metabolic disorders though non-cirrhotic HCC is more common than in adults. With increasing use of universal hepatitis B immunization, the incidence of HCC in children has decreased [2, 21]. HCC in children may be the standard type as seen in adults or the fibrolamellar variant seen in children and young adults.

HCC usually presents as an abdominal lump. Occasional presentation may be with abdominal pain or jaundice due to biliary compression or tumor ingrowth into the biliary tree. Rarely, these tumors may present as an emergency due to bleeding or rupture. HCCs are usually associated with an elevated AFP level though the elevation is not as high as that seen in HB. Liver function tests should be evaluated to assess the severity of any underlying liver disease. Metabolic screen is important to identify underlying liver disease which may impact management. Triphasic CT or MRI with contrast can help in characterizing the lesion, presence of chronic liver disease, any vascular involvement, and the presence of metastases.

HCC are chemoresistant tumors. Complete surgical excision provides these children with the best chance of long-term cure. However, the feasibility of resection depends on the size and extent of the tumor and the presence of underlying liver disease. In patients with underlying chronic liver disease, LT has the benefit of treating the underlying liver disease and providing adequate tumor clearance.

In the adult setting, the option of LT is available only for HCC within strict size and number criteria [22]. It is unclear if these criteria are appropriate in the pediatric setting, as most children will present with large tumors. Studies have shown good results in children transplanted for HCC beyond Milan criteria [23]. Hence, unless there is major vascular invasion or extrahepatic disease, unresectable HCC in children should be considered for LT. Presence of lung metastases is a contraindication for LT in pediatric HCC unlike HB due to the high risk of posttransplant progression of metastatic disease. Use of sorafenib in combination with cisplatin-based chemotherapy has also been reported in the management of pediatric HCC [24].

Outcomes of pediatric HCC are inferior to HB. The average 5-year survival is around 70%. Recurrent disease is the most common cause of death in these children and usually occurs in the lungs or bones.

Fibrolamellar Hepatocellular Carcinoma

This is an uncommon form of primary liver tumor seen in children greater than 5 years and young adults. The median age at presentation is 21 years. It is less common than standard HCC and occurs on a background of a non-cirrhotic liver. An elevated AFP is only seen in around 10% of these tumors. They are detected incidentally when they become symptomatic and are hence large at presentation. In a systematic review of available literature of fibrolamellar HCC (FL-HCC), the mean size of tumor at surgery was 12 cm [25]. On CT imaging, they appear as large well-circumscribed lesions which enhance strongly in arterial and portal venous phases becoming isodense in delayed scans. A poorly enhancing central scar may be seen. These tumors spread by both lymph node and blood borne systemic metastases.

Management of these tumors is primarily surgical. If resectable, surgical resection offers the best chance of cure for these tumors with a 5-year survival of 70% in adults [25, 26]. However, within the pediatric age group, results of FL-HCC do not appear to be superior to standard HCC probably because of late presentation and local recurrence after resection [27]. LT for FL-HCC has been reported though the long-term results are not encouraging possibly because of large tumor size at presentation and presence of lymph nodal metastases.

Transitional Tumors

These are a special group of tumors initially described by Prokurat et al. that share characteristics of both HB and HCC [28]. They usually develop in older children and are large in size at presentation. AFP levels are elevated. Histologically, they have features intermediate between the macrotrabecular variant of HB and trabecular HCC. Most of these were initially diagnosed as HB and treated as such. However, they have been reported to have much poorer outcome.

Embryonal Sarcoma (Undifferentiated Sarcoma of Liver)

This is a rare mesenchymal tumor constituting 5% of all liver tumors in children. The median age of presentation is between 6 and 10 years and is more common in males. There have been several reports of development of embryonal sarcoma from mesenchymal hamartomas [29]. Studies have also shown similar karyotypic abnormalities in both tumors. Presentation is with an abdominal lump. This tumor has characteristic radiological appearance. Ultrasonography

Fig. 69.5 Histology of embryonal sarcoma. Tumor shows large areas of necrosis with islands of spindle-shaped tumor cells in a myxoid matrix

(USG) shows a solid isoechoic clearly demarcated tumor. CT shows a well-circumscribed hypoattenuating lesion with multiple enhancing septations. An enhancing pseudocapsule may be present. The tumors are usually large at presentation and may be associated with lung metastases. Histologically, these tumors demonstrate large areas of necrosis with patches of viable tumor. Stellate or spindle-shaped tumor cells are loosely arranged in a myxoid matrix (Fig. 69.5).

Initial reports of this tumor described poor prognosis [30]. However, recent reports have shown that multimodality approach combining resectional surgery, chemotherapy, and transplantation can provide survival rate of up to 90% [31, 32].

Biliary Rhabdomyosarcoma

This is the most common cause of malignant biliary obstruction in the pediatric age group. These tumors arise from any part of the intrahepatic and extrahepatic biliary tree including the gall bladder and ampulla of Vater. The median age at presentation is 3 years, and children commonly present with jaundice and abdominal pain. Preoperative diagnosis is usually a choledochal cyst [33, 34]. CT scan shows a dilated biliary tract with a hypoattenuating tumor in the bile duct [35]. Surgery helps in confirming diagnosis and enables resection of the tumor and biliary drainage in the form of a hepaticojejunostomy. Surgical excision with negative microscopic margins is rarely possible. These tumors have been found to respond well to adjuvant multi-agent chemotherapy. Spunt et al reported 25 cases of biliary rhabdomyosarcoma with a 5-year survival of 66% for all cases and 78% for children without systemic metastases. Death was primarily due to recurrent disease or complications of aggressive resection and/or chemotherapy [36].

Calcifying Nested Stromal-Epithelial Tumor

These are rare primary liver tumors of uncertain histogenesis that typically occur in children and young adults [37, 38]. Histologically, they have a characteristic appearance with circumscribed nests and islands of bland-appearing epithelioid cells. Focal psammoma-like calcifications with or without ossification may be present. The tumors typically have an indolent course and are considered as low-grade malignancies. Surgical resection is the treatment of choice. Some of these tumors have been reported to be associated with Cushing's syndrome which improved on resection.

Angiosarcoma

These are highly malignant tumors with poor prognosis. Malignant transformation from HMGs has been reported. Resection, if possible, should be carried out. Survival is poor due to development of systemic metastases [39, 40].

Benign Liver Tumors

Hemangioma

HMGs are the most common benign tumors in the pediatric setting. They constitute over half of all liver tumors in the neonatal period. The Liver Hemangioma Registry of the Vascular Anomalies Center at the Children's Hospital of Boston recognizes three clinical subgroups of infantile hepatic HMG—focal, multifocal, and diffuse [41]. Focal HMGs are usually single and indolent. Their clinical presentation is based entirely on their size and usually present as a large abdominal mass. Smaller focal lesions are diagnosed only on routine imaging studies in the antenatal period or after birth and usually have no clinical relevance. Associated extrahepatic lesions are uncommon with focal HMGs.

Multifocal HMGs present as multiple lesions in one or both lobes of the liver or may involve the liver diffusely. Histologically, they may be classified as capillary or cavernous HMG and may rarely show pleomorphism, intravascular spread, necrosis, and hemorrhage. The term hemangioendothelioma has also been used to describe these lesions. Over half of these children have extrahepatic vascular lesions, most commonly in the skin but also in the brain, eye, etc. Hemangioendotheliomas have the tendency to grow in the first year of life and then involute. Status of the cutaneous lesions has been used as a marker for monitoring the involution of the liver lesions [42].

Clinical presentation is commonly as an abdominal mass. High-output cardiac failure and consumptive coagulopathy due to trapping and destruction of platelets within the lesions

are serious problems with these tumors [43]. Abnormalities in thyroid function have been reported in these children [42, 44]. A small percentage of these tumors (<5%) may be pre-malignant and progress to angiosarcoma if left untreated [45].

Treatment of these lesions should be tailored to individual presentation [42]. Small, asymptomatic lesions are best left alone. Symptomatic lesions have been treated with a variety of pharmacological and interventional approaches. Steroids, chemotherapeutic agents, β -blockers, hepatic artery ligation, or hepatic artery embolization have all been reported by various authors to be useful. Large symptomatic lesions are best treated by liver resection and are best managed in centers with advanced hepatobiliary and LT expertise. Liver transplantation has been reported in large symptomatic lesions not amenable to resection [42].

Mesenchymal Hamartomas

These rank second in frequency among benign liver neoplasms in children. They usually present as a large abdominal mass in the first 2 years of life. Some of these tumors may be detected incidentally or because of symptoms of abdominal pain, vomiting, or failure to thrive. Rare presentations are with respiratory distress, high output cardiac failure in the newborn and with jaundice, hemorrhage, or rupture [29, 46].

Imaging usually shows a single tumor in the right lobe with solid and cystic components. Occasionally, one cyst may be large giving it the appearance of a single cystic lesion.

Microscopic examination shows varying proportions of epithelial and loose connective tissue components arranged in a disorganized pattern. The epithelial element consists of bile ducts and hepatic parenchyma without acinar pattern. Numerous arteries and veins are scattered in the loose myxoid stroma. Cystic degeneration and foci of extramedullary hematopoiesis are also identified. Some authors have classified it as a neoplasm rather than a hamartoma. Reports that these tumors are associated with karyotype abnormalities such as aneuploidy and balanced translocations suggest a malignant potential [29].

Natural history of these tumors is variable, but the majority grows in size. There have been occasional reports of spontaneous regression or malignant transformation into undifferentiated embryonal sarcoma [47].

Treatment is primarily surgical. Complete excision is recommended and, where not possible, LT has been reported.

Hepatic Adenomas

These are diagnosed in older child and adolescents. In adults, there is a correlation between the use of oral contraception and hepatic adenomas. They are usually identified on routine

screening, though bleeding and rupture of superficial adenomas may lead to a more acute presentation. Small adenomas are best followed up by serial imaging because of the small risk of malignant transformation. Larger adenomas or superficial adenomas presenting with pain are better resected to avoid complications.

Focal Nodular Hyperplasia

FNH is uncommon in children and constitutes about 5% of all pediatric liver tumors. There has been some reported association between previous liver or bone marrow cancers or the presence of congenital or surgical portosystemic shunts and the development of FNH. A possible response of the liver tissue to the cytotoxic chemotherapy has been postulated. Similarly, borderline ischemia of the liver due to the shunting has also been postulated as a possible explanation of their coexistence with shunts.

FNH is usually diagnosed on routine imaging and is identified as a slightly hypodense, discrete lesion on plain CT. On contrast images, it enhances homogeneously in the arterial phase with the lesion becoming isodense in delayed scans. A central scar is noted in 50% of cases with delayed enhancement of the central scar a characteristic finding in FNH.

Macroscopically, it appears as a well circumscribed mass with a central depression (Fig. 69.6). Cut surface shows small nodules divided by fibrous septa leading to a central scar. Microscopically, the nodules contain hyperplastic hepatocytes supported by a well-developed reticulin framework. The septa contains abundant vessels, consisting of both arteries and veins. Variable eccentric intimal fibroplasia and disruption of the elastic lamina is noted in the arteries. Inflammatory cells and numerous proliferating ductules are also identified in the septa. Chronic cholestatic features are also identified in the cells adjacent to septa.

The most common presenting symptom is pain. These lesions may be small and multiple or may be single and large. If imaging is suggestive of FNH, then close follow-up with

Fig. 69.6 Cut section of focal nodular hyperplasia. Note the well-circumscribed lesion with multiple nodules separated by fibrous septa joining at a central scar

Fig. 69.7 **a** Section of an Inflammatory myofibroblastic tumor displaying interlacing bundles of fibroblasts admixed with inflammatory cells. **b** CT showing an inflammatory myofibroblastic tumor involving the hepatic hilum in a 4-year-old child. The child presented

with constitutional symptoms, obstructive jaundice, and recurrent episodes of cholangitis. He underwent endoscopic stenting with no relief of symptoms. Surgical resection (extended right hepatectomy with excision of extrahepatic biliary tract) was carried out

serial imaging to detect any increase in size is recommended. Biopsy may be necessary in doubtful cases. Resection is only appropriate for large tumors or tumors with significant symptoms. Closure of the predisposing portosystemic shunts has been reported to cause shrinkage of the tumors.

Inflammatory Myofibroblastic Tumor

Inflammatory myofibroblastic tumors (IMFT) are predominantly benign lesions of unknown origin. These tumors can occur anywhere in the body and have occasionally been reported in the liver where they may mimic liver tumors.

These lesions have a characteristic histological picture comprising a spindle-cell proliferation admixed with chronic inflammatory cell infiltrate of plasma cells, lymphocytes, and histiocytes (Fig 69.7a). Anaplastic lymphoma kinase gene rearrangements have been noticed in about half of IMFT, further supporting its neoplastic nature. Expression of anaplastic lymphoma kinase is associated with localized disease at presentation and an improved prognosis.

Presentation may be with constitutional symptoms such as fever, jaundice, and weight loss [48]. Their natural history is variable with some reports of spontaneous regression, while some children may develop recurrent episodes. Local invasion has been reported in some cases (Fig. 69.7b). Surgical resection is indicated if the lesion persists or progresses after a trial of conservative therapy, or manifests evidence of local infiltration into vital structures, or of malignant transformation. Complete resection is curative in most patients [49].

Secondary Liver Lesions

Primary tumors such as neuroblastoma and Wilms' tumor can spread to the liver and present as liver metastases. These are usually multiple and are best managed with chemotherapy. Surgical resection is rarely an option in these cases.

Conclusion

Liver tumors in children are uncommon. Most present as an abdominal lump and are usually advanced at initial presentation. HB is the most common childhood liver tumor. Evidence-based multimodality therapy using improved liver resection techniques, LT, and use of effective chemotherapeutic agents has improved outcomes in these tumors.

Introduction

Acute liver failure (ALF) used synonymously with fulminant hepatic failure is a blanket term used to describe severe and sudden onset of liver cell dysfunction leading on to synthetic and detoxification failure across all age groups. Pathogenesis of hepatocyte cell injury is multifactorial (Fig. 70.1) and liver failure is the outcome of a complex equation between hepatocyte death and regeneration, as suggested by the US Acute Liver Failure Study Group [1]. Injured liver cells secrete several bioactive substances and toxins that initiate cascade of events leading on to multiorgan failure (Fig. 70.2).

Definition

“Fulminant liver failure” was coined by Trey and Davidson 40 years ago to define onset of hepatic encephalopathy (HE) within 8 weeks of appearance of symptoms of liver dysfunction in an otherwise healthy individual with no prior history of liver disease. O’Grady and colleagues categorized ALF as “hyperacute (1 week), acute (1–4 weeks) and subacute failure (5–12 weeks)” depending on the interval between jaundice and onset of encephalopathy, for prognostication purpose [2]. It is difficult to use adult-based definitions in children, as encephalopathy is a late sign and sometimes ALF has in utero onset and so time quantification would be difficult [3]. Acknowledging the fact that diagnosing encephalopathy in children is difficult and often a late and terminal event, Bhaduri and Vergani proposed the definition of ALF

as “A rare multisystem disorder in which severe impairment of liver function with or without encephalopathy, occurs in association with hepatocellular necrosis in a patient with no recognized underlying chronic liver disease” [4]. Even this definition does not seem to be clear as the term “severe impairment of liver function” in the definition did not have any objective quantification values of liver function and so there was a lot of subjective variation in diagnosing ALF.

The pediatric acute liver failure study group (PALFSG) developed a working definition to identify ALF in children without interobserver variation. PALFSG used international normalized ratio (INR) in the background of acute liver disease as an objective measurement to demarcate acute hepatitis and ALF. As per PALFSG, ALF is defined as (i) hepatic-based coagulopathy defined as a prothrombin time (PT) 15 s or INR 1.5 not corrected by vitamin K in the presence of clinical HE or a PT 20 s or INR 2.0 regardless of the presence or absence of clinical HE, [5] (ii) biochemical evidence of acute liver injury, and (iii) no known evidence of chronic liver disease [6]. Asymptomatic preexisting liver disease, which manifests acutely, should be considered as ALF, if they fulfill the diagnostic criteria, as in acute fulminant Wilson’s disease.

Coagulopathy is not only a key criterion in diagnosing pediatric ALF but also acts as a prognostic marker. Due to short half of several liver-based clotting factors, PT/INR functions as a dynamic marker of synthetic inadequacy due to loss of liver cells in ALF. Factors II, VII, IX, and X depends on vitamin K to convert them into active form. Correction of coagulopathy by intravenous vitamin K differentiates between vitamin K deficiency due to decreased absorption from liver synthetic failure. Isolated prolonged APTR is not due to liver disease, as factor VII in extrinsic pathway (Fig. 70.3) has the shortest half-life (4–6 h) of the vitamin K-dependent factors, therefore is the first factor depleted in ALF and invariably affects INR. Coagulopathy secondary to disseminated intravascular coagulation (DIC) precipitated by infection is common in acute liver injury and so it is essential to rule out DIC before making a diagnosis of ALF based on INR.

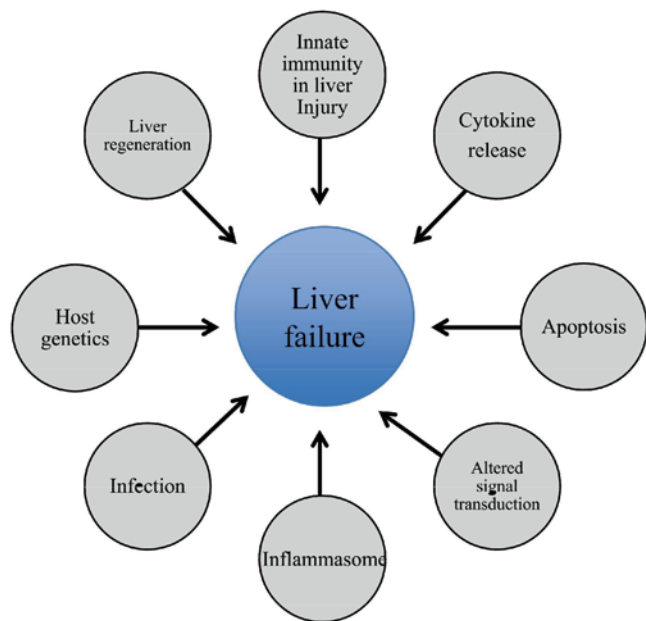

Fig. 70.1 Pathogenesis of liver cell injury is multifactorial with several factors influencing liver cell death and regeneration. When the net result is liver cell loss beyond a critical mass required maintain normal body function, liver failure sets in

Etiology

The etiologies of ALF differ with age groups and geographic location. In Southeast Asia and Latin America, viral hepatitis A and E are the most common cause of ALF in children while in Northern America and Europe etiology remains elusive (indeterminate) in majority of children [7]. Certain disorders, such as neonatal hemochromatosis, are very unique to pediatric population. The exact incidence of ALF in pedi-

atric age group is not known but probably the overall annual incidence of ALF in USA is around 5.5/million population among all ages [8].

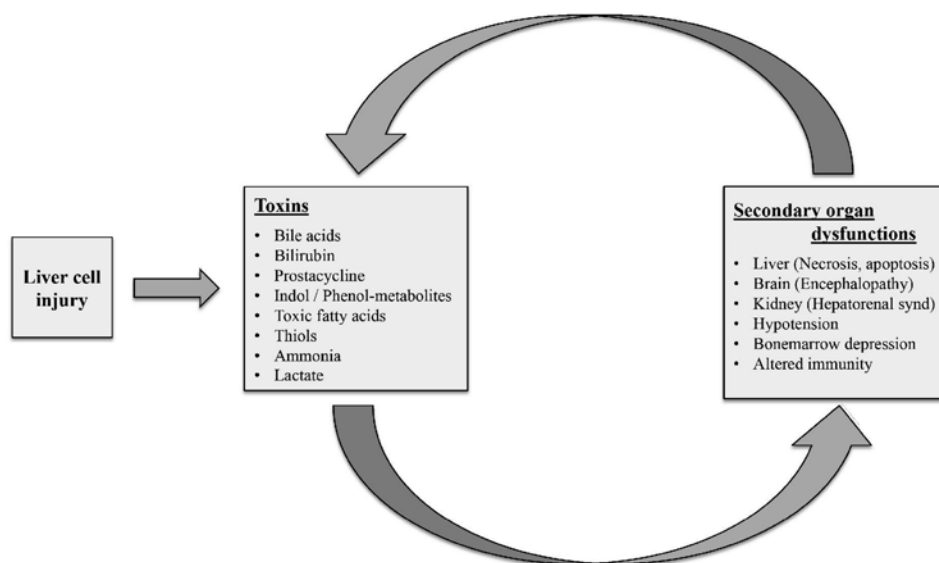

Infection

Hepatitis A and E viral (HAV and HEV) infections are the common cause of ALF in developing countries with poor sanitation and overcrowding, as these viruses are spread by contaminated water and food. The risk of liver failure is 0.1–0.4% following symptomatic HAV infection and it increases with a preexisting liver disease. Specific diagnosis is established by detecting HAV immunoglobulin (Ig)M antibodies in the blood at presentation. The infection is most often self-limiting with subsequent recovery and only in few it might be severe enough requiring liver transplantation [9]. The risk of developing ALF in adults following HEV infection is 0.6–2.8%, with higher risk if contracted during pregnancy [10]. Bhatia et al. showed that the case-fatality associated with HEV-induced ALF in pregnancy is similar to that of age-matched general population [11].

The ALF due to hepatitis B virus (HBV) can occur at the time of acute infection, reactivation of chronic HBV infection or seroconversion from a hepatitis Be antigen–positive to a hepatitis Be antibody (HBeAb)-positive state. Infants born to HBeAb-positive mothers are at special risk and could present with ALF around 6 weeks to 9 months [12]. Super infection or coinfection of hepatitis delta virus (HDV) in HBV-infected patients can cause liver failure. Hepatitis C viral (HCV) infection has not been reported as a cause of ALF.

Herpes simplex virus 1 and 2 (HSV) is the predominant cause of viral-induced ALF during first month of life. Neonatal ALF due to HSV carries a high mortality of about 85%

Fig. 70.2 Except for Von Willebrand factor and tissue plasminogen activator, liver is the major site for synthesis of clotting factors. Factors V synthesis is first to be affected and factor VII have the shortest half-lives and are theoretically more sensitive markers than INR of hepatic synthetic function. *INR* international normalized ratio

Fig. 70.3 Liver cell injury leads on to release several toxic substances that causes secondary organ dysfunction, this leads on to a vicious cycle of autointoxication. *APTT* Activated Partial Thromboplastin Time, *APTR* Activated Partial Thromboplastin Ratio, *PT* prothrombin time, *INR* international normalized ratio

and should be suspected in any neonate with or without vesicular rash who is unwell with dramatically high transaminases and coagulopathy. Treatment with high doses of aciclovir should be initiated in all infants with ALF, while awaiting serology results as the associated liver failure is rapidly fatal. Liver transplantation has a good outcome when considered in a hemodynamically stable neonate with ALF due to HSV [13]. Other members of herpes virus family such as cytomegalovirus, Epstein–Barr virus, and varicella-zoster virus can cause ALF. Rarely, viruses such as Dengue, Lassa, Ebola, Marburg, and Toga and bacteria such as *Leptospira* and *Salmonella* are implicated as a cause for ALF.

Drugs and Toxins

In developed countries, drug-induced liver failure is the most common identifiable cause of ALF in adults and children. Drug hepatotoxicity could be an idiosyncratic reaction, a dose-dependent response, or a synergistic reaction due of several drugs. It is essential to include details of complementary therapies and herbal medications as some are potential hepatotoxics [14]. Acetaminophen is the most common drug associated with ALF, probably due to the easy availability without the need for a prescription. It is safe when used in recommended doses and toxicity is usually dose dependent. Acetaminophen is detoxified mainly by glucuronidation (40%), sulfation (20–40%), and *N*-hydroxylation (15%). A small fraction is metabolized via cytochrome P450 to yield *N*-acetyl-para-benzoquinone-imide (NAPQI), a toxic intermediate compound which irreversibly conjugates with the sulfhydryl group of glutathione and causes hepatocyte necrosis [15]. Genetic polymorphism of

cytochrome P450 isoenzymes predisposes affected people to acetaminophen toxicity due to increased NAPQI production. Bound NAPQI forms acetaminophen–protein adducts, which acts as a specific biomarker for chronic acetaminophen toxicity. Hepatotoxicity of acetaminophen is dose dependent and liver injury results either because of acute higher doses ingestion or cumulative over doses taken over a few days. In acute acetaminophen overdose plotting serum levels after 4 h against time on the Rumack nomogram will guide towards potential toxicity. However, it may not be useful in situations of cumulative over doses. In such cases, bound NAPQI forms of acetaminophen–protein adducts in blood would aid the diagnosis. The mechanism of toxicity of anti-tuberculosis drugs, particularly isoniazid is similar to acetaminophen, oxidation via cytochrome P450 pathway results in toxic metabolites.

Most common cause of idiosyncratic drug-induced liver injury (DILI) are due to antibiotics and NSAIDs [14]. The reported incidence of idiosyncratic DILI was around 14 new cases/100,000/year, of which 8% would progress to ALF [16, 17]. Genetic susceptibility of an individual, unmasking of underlying mitochondrial cytopathies by certain drugs are some of the proposed causes of DILI [18]. Drugs such as diclofenac, mefenamic acid, valproic acid, amiodarone, isoniazid, etc. can unmask mitochondrial cytopathy and cause ALF. Chemotherapy drugs are known to produce veno-occlusive disease leading on to ALF due to endothelial damage.

Councils for International Organizations of Medical Sciences/Roussel Uclaf Causality Assessment Method (CIOMS/RUCAM) scale are helpful in establishing causal relationship between offending drug and liver damage. Using the scoring system, suspected drug could be categorized into “definite or highly probable” (score >8), “probable” (score 6–8), “possible” (score 3–5), “unlikely” (score 1–2), and “excluded” (score 0) [19]. This scale is helpful in identifying drug-induced hepatotoxicity even in newly marketed drugs and for a previously unreported older drug.

Metabolic Disorders

Metabolic disorders presenting as ALF is common in young children. Galactosemia and tyrosinemia 1 are the most common cause of neonatal liver failure, presenting with hepatomegaly, jaundice, and coagulopathy. Classical galactosemia is an autosomal recessive condition resulting because of mutation in galactose-1-phosphate uridyl transferase gene located on chromosome 9p13. Liver failure in this condition is thought to be due to accumulation on galactitol. Neonates presenting with hepatitis or ALF should be started on a galactose-free formula until galactosemia. Galactose-free diet coupled with supportive management helps the liver to

recover, but some may still progress and need a liver transplant. Despite strict galactose-free diet, patients could develop complications like developmental delay, motor disorders and hypergonadotrophic hypogonadism due to endogenous galactose production on a long-term follow-up [20]. Tyrosinemia 1 is an autosomal recessive condition due to defect in the enzyme fumarylacetoacetate hydroxylase. This causes accumulation of intermediate compounds, maleylacetoacetic acid, and fumarylacetoacetic acid, which are then converted to succinylacetone, a toxin that damages the liver and kidneys. Tyrosinemia should be suspected when a coagulopathy and modest rise of transaminases is associated with elevated alpha-fetoprotein levels. Fructosinemia, inborn errors of bile acid synthesis are a few other rare cause of ALF during infantile period.

Medium-chain acyl-coenzyme A dehydrogenases (MCAD) are group of enzymes involved in β -oxidation of 6–12 carbon chain fatty acids in mitochondria. They help in ketone production from fatty acids when hepatic glycogen stores become depleted during prolonged fasting and periods of higher energy demands. Affected children could present with hypoketotic hypoglycemia, recurrent liver failure, precipitated by otherwise minor illness. Unless treated with dextrose supplementation, these episodes may quickly progress to coma and death.

Wilson's disease, an autosomal recessive disorder could present as ALF. The acute hepatic presentation is usually characterized by the presence of liver failure, Coombs-negative hemolytic anemia and low serum alkaline phosphatase. Diagnosis might be difficult as blood test might show weakly positive autoantibodies and tissue copper estimation might not be possible due to coagulopathy. Demonstration of Kayser–Fleischer rings is diagnostic of Wilson's disease in a patient who presents with ALF. Wilson's disease presenting with ALF has high mortality without transplantation.

Mitochondrial disorders are group of spontaneous or inherited disorders of mitochondrial proteins resulting in defective oxidative phosphorylation, fatty acid oxidation, urea cycle, and other mitochondrial pathways [21]. This can affect the function of various cell types, such as neurons, myocytes, etc., where the need for energy requirement is high. Deficiencies of complex I, III and IV, multiple complex deficiencies and mitochondrial DNA (mtDNA) depletion syndrome is associated with liver failure. Diagnosis might be difficult due to particularly in (mtDNA) depletion syndrome where there is tissue specific mitochondrial enzyme deficiency. The infants usually presents with hypotonia, hypoglycemia, feeding difficulties, seizures, and deranged liver function. Liver transplantation could be offered in isolated liver-based mitochondrial disorders, while in multisystemic involvement it should be deferred, hence it is utmost important to perform thorough investigation to rule out neuromuscular involvement [22].

Gestational Alloimmune Liver Disease

Neonatal hemochromatosis (NH) is the single most common cause of ALF during first month of life, where there is massive iron deposition in liver and extrahepatic tissues, but with sparing of the reticuloendothelial system. The pattern of iron overloading is similar to hereditary hemochromatosis, but NH affects only newborn and so far no specific genetic mutation has been identified. NH was considered to be a primary disease of iron overload of liver leading on to liver failure. Under current concept, iron accumulation in NH is considered to be a secondary phenomenon due to immune-related severe fetal liver injury resulting in impaired regulation of maternofetal iron flux [23]. NH is now referred as gestational alloimmune liver disease (GALD), as maternal antibody is directed towards fetal liver antigen resulting in activation of fetal complement leading to the formation of membrane attack complex (MAC) resulting in hepatocyte loss [24, 25]. This hypothesis is supported by successful prevention of severe disease by antenatal and postnatal treatment with intravenous Ig. GALD presents with jaundice, coagulopathy, moderately elevated alanine aminotransferase, high ferritin, and raised iron saturation levels. High ferritin is seen in other cause of neonatal liver failure and no single biochemical test is diagnostic of NH. The diagnosis can only be confirmed by demonstration of extra hepatic iron deposits sparing the reticuloendothelial system. Labial salivary gland biopsy is safe and effective way of demonstrating this [26]. The disease varies in severity; at one end of spectrum it is associated with fetal death while at the other end spontaneous recovery is reported.

Malignancies

Hemophagocytic lymphohistiocytosis (HLH) is a malignant disorder of hemopoietic system where there is uncontrolled proliferation of activated lymphocytes and macrophages and could present as ALF, particularly during infancy. HLH could be inherited or acquired following infection due to over activation of natural killer cells and of CD8+ T cell lymphocytes, invariably leading to clinical and hematologic alterations. It is associated with defective apoptosis and reduced cytotoxic activity. Familial HLH is an autosomal recessive disease seen mostly in infancy and early childhood. The mutations result in reduced or defective production of cytoplasmic granules such as perforin in cytotoxic cells resulting in paradoxical over activation. Familial HLH is classified into four types based on mutation analysis. Secondary HLH usually occurs after systemic infection or immunodeficiency, which can affect people at any age and may subside spontaneously. HLH presents with fever, cutaneous rash, hepatosplenomegaly, pancyto-

penia and, in severe cases, with ALF [27]. ALF might be the presenting feature of hematologic malignancies such as leukemia or lymphoma [28]. Usual associated features would be fever, hepatosplenomegaly, high alkaline phosphatase, high lactate dehydrogenase, and abnormalities on peripheral blood film. Bone marrow examination confirms the diagnosis.

Autoimmune Hepatitis

Autoimmune hepatitis (AIH) can present as ALF, most of these children have positive liver–kidney microsomal (LKM) antibody (type 2 AIH). Diagnosis might be difficult, as some may not show specific antibodies at initial presentation. ALF due to AIH without encephalopathy could be benefited by immunosuppression, while ALF along with encephalopathy do not respond to any form of immunosuppression and need urgent liver transplant [29]. In our experience, of the six AIH children presenting with ALF and encephalopathy, four required liver transplantation, one died while awaiting transplantation, and one recovered with steroids [30]. The steroid responder was antinuclear/smooth muscle antibody positive (type 1 AIH) while rest five were LKM positive (Type 2 AIH).

Other Causes

In spite of extensive investigation, the diagnosis could not be found in many children (indeterminate). Indeterminate ALF is probably due to unidentified infectious agent as suggested by presentation with severe hepatitis, liver failure and bone marrow failure mimicking viral-induced disease or presentation with minimal jaundice and centrilobular necrosis on histology suggesting drug induced. There is wide variation in reporting of indeterminate etiology among various centers. This is probably due to incomplete investigations in ALF, which has been highlighted by Narkewicz et al., and labeling them as indeterminate etiology [31]. Hypoxia, bacterial infections, underlying cardiac problem, venous outflow obstruction are few other causes of ALF.

Investigations

As the etiology of ALF is so diverse that it is practically impossible to do all the tests during initial evaluation. A detailed clinical history and thorough general examination could give valuable clue of underlying problem and could help in directing management while awaiting confirmatory results. The first-line investigations should include complete blood count, liver function tests, serum electrolytes,

Table 70.1 Disease specific investigations in acute liver failure

<i>Infective:</i>
Serologic/quantitative tests
Hepatitis A: anti-HAV IgM antibody
Hepatitis B: HBsAg, HBcAb(IgM), HBcAg
Hepatitis C: anti-hep C antibody, hep C PCR
Hepatitis D: anti-hep D antibody
Hepatitis E: anti-HEV antibody(IgM)
Human immunodeficiency virus (HIV)
Herpes simplex virus (neonates)
Cytomegalovirus, Epstein–Barr virus
If indicated: measles/varicella/adenovirus/echovirus/leptospirosis/
Cultures
Bacterial cultures: blood, urine, stool, throat swab, sputum
Skin lesion if present, ascitic fluid if present
Viral culture of urine and skin lesion if present
<i>Metabolic:</i>
Galactosemia: galactose-1-phosphate uridyl transferase
Tyrosinemia: urinary succinylacetone
Fructose intolerance: quantitative enzyme assay, q22.3 band mutation in chr 9
Mitochondrial disorders: quantitative mitochondrial DNA assay, mutation analysis
Congenital disorders of glycosylation: transferrin isoelectrophoresis
MCAD deficiency: plasma acylcarnitine
Wilson’s disease: serum copper and ceruloplasmin
24-h urinary copper pre and post penicillamine
<i>Type 1 and 2 autoimmune hepatitis:</i>
Immunoglobulins
Antinuclear antibodies
Smooth muscle antibody
Liver cytosol antibodies
Soluble liver antigen
Liver–kidney microsomal antibody
Antineutrophil cytoplasmic antibodies
<i>Hematological malignancy:</i>
Bone marrow examination
Ascitic or cerebrospinal fluid cytospin
Genetics for HLH
<i>Drugs and toxins:</i> drug levels in serum/urine
<i>Budd–Chiari syndrome:</i> ultrasound, echocardiography, computer tomography
<i>Neonatal hemochromatosis:</i> lip biopsy
<i>HAV</i> hepatitis A virus, <i>HEV</i> hepatitis E virus, <i>HBcAg</i> hepatitis B core antigen, <i>HBsAg</i> hepatitis B surface antigen, <i>HLH</i> hemophagocytic lymphohistiocytosis, <i>IgM</i> immunoglobulin M

uric acid, lactate, cholesterol/triglyceride, amylase, coagulation studies (INR), and blood glucose. Surveillance blood and urine cultures should be collected prior to starting antibiotics. The clinical presentation along with the results of first-line investigations will guide further specialized tests. Investigations to establish etiological diagnosis are outlined in Table 70.1. Supportive management along with anticipatory management of possible complications associated with liver failure would help in favorable outcome.

Table 70.2 King's College Hospital criteria for liver transplantation

<i>Non-acetaminophen acute liver failure</i>
INR greater than 6.5 or
Three of the following five criteria:
Patient age <11 or >40
Serum bilirubin >300 µmol/L;
Time from onset of jaundice to the development of coma >7 days;
INR greater than 3.5
Drug toxicity
<i>Acetaminophen-induced acute liver failure</i>
Arterial pH <7.3 (after fluid resuscitation) or
All three of the following criteria
INR >6.5
Serum creatinine >300 µmol/L
Encephalopathy (grade III or IV).
INR international normalized ratio

Prognosis

Categorical demarcation between spontaneous liver recovery and irreversible ALF is difficult. In adults with non-acetaminophen-induced ALF, King's College Hospital criteria (KCHC; Table 70.2) is used for prognostication and the need for liver transplantation. Fulfillment of KCHC is usually associated with death unless transplanted [32]. But in children KCHC does not reliably predict death with a poor positive predictive value of 33% [33]. Of the several prognostic markers that has been proposed to predict outcomes in ALF in children, INR and factor V concentration remains the best indicators. In children with ALF, INR 4, bilirubin 235 µmol/L, age <2 years, and WBC >9 × 10⁹/L are associated with poor outcome without liver transplantation [34]. Bhaduri and Mieli-Vergani have shown that the maximum INR reached during the course of illness was the most sensitive predictor of the outcome, with 73% of children with an INR less than 4 surviving compared with only 4 of 24 (16.6%) with an INR greater than 4 [35]. French centers use factor V concentration for prognostication and a value of less than 20% of normal (Clichy criteria) suggests a poor outcome. New Wilson index proposed by Dhawan et al. based on serum bilirubin, serum albumin, INR, aspartate aminotransferase (AST), and white cell count (WCC) at presentation identified a cutoff score of 11 for death and proved to be 93% sensitive and 98% specific, with a positive predictive value of 88% (Table 70.3) [36]. In acetamino-

phen overdose, metabolic acidosis with arterial pH less than 7.3, after the second day of overdose in adequately hydrated patients, is associated with 90% mortality. In acetaminophen overdose, KCHC could be used in children for selecting candidates requiring liver transplantation (Table 70.2).

Table 70.3 showing Wilson's disease index, which has five parameters and a score of 11 or more indicates the need for liver transplant.

Management

Due to unpredictable course of liver failure, management has to be carried out along side of investigation. Early liaison and transfer to a specialist center with transplantation facilities is crucial for better outcome.

General Measures

Children with ALF should be monitored in a quiet setting. Vital parameters, such as pulse, blood pressure, oxygen saturation, neurologic observations, should be done on regular basis. Prophylactic broad-spectrum antibiotics and antifungals should be started in all children and acyclovir should be added in infants and neonates. Children with encephalopathy or an INR greater than four should be admitted to an intensive care unit for close monitoring. Hypoglycemia should be avoided by use of intravenous glucose infusion or by ensuring adequate enteral intake. The idea of protein restriction to limit the possibility of HE has now been disregarded and adequate calories should be provided. A plant protein-based diet which has more of branched chain amino acid (BCAA) is preferred over animal protein which has more of aromatic amino acid (AAA). Oral or nasogastric feeding is usually well tolerated. Prophylactic histamine 2 blockers or proton pump inhibitors should be started to all patients requiring mechanical ventilation as stress ulcers can cause bleed [37].

N-Acetylcysteine (NAC)

N-acetylcysteine (NAC) is being increasingly used in non-acetaminophen-induced ALF as it enhances circulation and improves oxygen delivery. Retrospective study from King's

Table 70.3 Wilson's disease index

Bilirubin (µMol/L)	INR	AST (IU/L)	WBC (10 ⁹ /L)	Albumin (G/L)	Score
0–100	0–1.2	0–100	0–6.7	>45	0
101–150	1.3–1.6	101–150	6.8–8.3	34–44	1
151–200	1.7–1.9	151–200	8.4–10.3	25–33	2
201–300	2.0–2.4	201–300	10.4–15.3	21–24	3
>300	>2.5	>300	>15.4	0–20	4

AST aspartate transaminase, INR international normalized ratio, WBC white blood cell count

College Hospital has shown that NAC infusion in non-acetaminophen-induced ALF was associated with a shorter length of hospital stay, higher incidence of native liver recovery without transplantation, and better survival after transplantation [38]. In a prospective, double-blind trial in adults with non-acetaminophen ALF, NAC usage is associated with significant improvement in transplant-free survival in patients with early (stage I–II) coma, indicating the necessity for early initiation of treatment [39]. But a more recent prospective study on NAC usage in children with non-acetaminophen ALF, failed to show any significant benefit when compared to placebo [40].

Airway and Ventilation

Elective intubation and mechanical ventilation should be considered in patients with grade 1 or 2 encephalopathy that are agitated or planned to transfer and in all patients with grade 3/4 encephalopathy. Apart from providing secure airway, mechanical ventilation helps in reducing sudden variation of intracranial pressure (ICP). Sedation could be maintained with a combination of an opiate such as morphine or fentanyl and a hypnotic such as midazolam. Peak end-expiratory pressure above 8 cm of water should be avoided because it may increase ICP.

Fluid Management and Renal Failure

Intravenous fluids should be restricted to two thirds maintenance, with the idea of decreasing the possibility of development of cerebral edema. Ultrasonic cardiac output monitor (USCOM), which is a noninvasive method to measure cardiac parameters, helps in decision making regarding appropriate fluid regimens/ionotropes even in small infants. In ALF, there would be hyperdynamic circulation with decreased systemic vascular resistance, and in the presence of persistent hypotension, first-line inotropic agent of choice would be noradrenaline followed by vasopressin analogues. Continuous filtration or dialysis should be considered when the urine output is less than 1 mL/kg/h to prevent acidosis and volume overload.

Neurologic Complications

Encephalopathy is not always recognizable in children and usually is a late feature. The most serious complications of ALF are cerebral edema with resultant intracranial hypertension and HE. Encephalopathy that occurs in ALF is categorized as type A, according to the suggested nomenclature by Working Party at the 11th World Congress of

Table 70.4 West Haven criteria for grading of mental state

Grade 0	Normal
Grade 1	Euphoria or anxiety
	Shortened attention span
	Impaired performance of addition
	Trivial lack of awareness
	Inverted sleep pattern
Grade 2	Subtle personality change
	Minimal disorientation for time or place
	Impaired performance of subtraction
	Lethargy or slow response
Grade 3	Tremor and hypoactive reflexes
	Somnolence to semi stupor, but responds to verbal stimuli
	Confusion, gross disorientation
	Inappropriate behavior
	Brisk reflexes and Babinski's sign
Grade 4	Muscle rigidity
	Deep coma (unresponsive to verbal or noxious stimuli)

Gastroenterology. HE could be clinically graded from 1 to 4 using West Haven criteria (Table 70.4) and conscious levels could be assessed using Glasgow coma scale, which has lesser interobserver variability [41] (Table 70.5).

Clinical features of raised ICP would include systemic hypertension, bradycardia, hypertonia, and hyperreflexia and in extreme cases decerebrate or decorticate posturing. Electroencephalographic (EEG) changes occur very early in HE, even before the onset of psychological or biochemical disturbances. Ammonia-lowering measures such as dietary protein restriction, bowel decontamination, or lactulose are of limited or no value in rapidly advancing encephalopathy. Mannitol is an osmotic diuretic commonly used to treat intracranial hypertension. A rapid bolus of 0.5 g/kg as a 20% solution over a 15-min period is recommended and the dose can be repeated if the serum osmolarity is less than 320 mOsm/L. In ventilated patients, prophylactic hyperventilation provides no role as hypocapnia could decrease cerebral perfusion and PaCO₂ should be kept between 4 and 4.5 kPa. In case of clinical features of acute rise in ICP, hyperventilation could be done for a brief period of time until there is symptomatic improvement. Invasive ICP monitoring using special catheters helps in objective measurement of ICP. This helps to maintain optimal cerebral perfusion pressure (mean arterial blood pressure—ICP) of more than 50 mm Hg. Inotropic agents could be used to increase mean arterial blood pressure to achieve the optimal cerebral perfusion pressure. Studies have shown sodium thiopental, mild cerebral hypothermia (32–35 °C) and hypernatremia (serum sodium >145 mmol/L) improves cerebral perfusion. Table 70.6 shows some of pathophysiological changes that lead on to multiorgan dysfunction associated with ALF.

Table 70.5 Glasgow coma scale

	Infants	Children	Score
<i>Eye opening</i>	Open spontaneously	Open spontaneously	4
	Open in response to verbal stimuli	Open in response to verbal stimuli	3
	Open in response to pain only	Open in response to pain only	2
	No response	No response	1
<i>Verbal response</i>	Coos and babbles	Oriented, appropriate	5
	Irritable cries	Confused	4
	Cries in response to pain	Inappropriate words	3
	Moans in response to pain	Incomprehensible words or nonspecific sounds	2
	No response	No response	1
<i>Motor response</i>	Moves spontaneously and purposefully	Obeys commands	6
	Withdraws to touch	Localizes painful stimulus	5
	Withdraws in response to pain	Withdraws in response to pain	4
	Responds to pain with decorticate posturing (abnormal flexion)	Responds to pain with flexion	3
	Responds to pain with decerebrate posturing (abnormal extension)	Responds to pain with extension	2
	No response	No response	1

Table 70.6 Pathophysiology of complications in ALF

Coagulopathy:
Decreased levels of coagulation factors, decreased protein C, protein S, and antithrombin associated with dysfunctional platelets and fibrinogen
Encephalopathy and intracranial hypertension:
Inhibitory effect of ammonia and gamma-aminobutyric acid on neuronal cell membranes and synapses. The direct toxicity of toxins on neuronal cells and vasogenic imbalance leading onto intracellular fluid shifts resulting in cerebral edema
Renal failure:
Acute tubular necrosis secondary to complications of ALF such as sepsis, bleeding, and/or hypotension
Hepatorenal syndrome because of renal vasoconstriction probably due to release of vasoactive mediators
Hypotension:
Decreased systemic vascular resistance and hypovolemia secondary to shift of fluids into interstitial space. Adrenal insufficiency due to decreased liver synthesis of apolipoprotein A-1, the major protein component of HDL leading on to decreased HDL and thereby decreased cortisol production
Metabolic derangement:
Hypoglycemia due to increased plasma insulin levels owing to reduced hepatic uptake, reduced glycogen stores, impaired gluconeogenesis. Lactic acidosis is related to inadequate tissue perfusion due to hypotension and also due to decreased detoxification by the liver
Infection:
Impaired Kupffer cell and polymorphonuclear function along with reduced levels of factors such as fibronectin, opsonins, chemo attractants, and components of the complement system
HDL high-density lipoprotein

Coagulopathy

As INR is a dynamic indicator of disease progression, coagulopathy should be corrected only if the patient is having a bleed or prior to an invasive procedure. Bleeding

manifestation is very unusual in ALF as there would be proportional reduction in plasma levels of both procoagulant and anticoagulant proteins [42]. Thromboelastography would be an appropriate tool in diagnosing risk of bleeding. To correct coagulopathy, fresh frozen plasma could be given at a dose of 10 ml/kg and cryoprecipitate at 5 ml/kg (if fibrinogen is < 1 g/l). In resistant cases, factor seven concentrates improve the coagulopathy for a short period. Platelet count should be maintained above $50 \times 10^9/\text{dL}$, as thrombocytopenia is an important risk factor for hemorrhage.

Disease Specific Management

Antioxidant cocktail (*NAC*, *selenium*, *desferrioxamine*, *prostaglandin E1*, *vitamin E*) has been used in NH, based on the concept that iron chelation and free radical scavenging would prevent liver damage, with no proven benefit. As GALD is the common cause of NH, evidence is accumulating towards the usefulness of high-dose intravenous immunoglobulin (IVIG; 1 g/kg), in combination with exchange transfusion resulting in significant decrease in the need for liver transplantation in NH [43]. IVIG when given as prophylaxis to mothers whose previous pregnancy/child was affected with NH at a dose of 1 g/kg bodyweight, weekly from the 18th week until the end of gestation has been associated with milder phenotypic expression of the disease and 100% survival of babies [44]. The management of HLH consists of liver supportive therapy, chemotherapy, and hematopoietic stem cell transplantation (for genetically verified/ familial disease and persistent/reactivation of secondary disease) [27]. Dietary intervention with restriction of phenylalanine and tyrosine together with oral medication, 2 (2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexenedione

(NTBC), helps in normalization of liver function in tyrosinemia type 1, but does not prevent long-term risk for development of hepatocellular carcinoma [45]. In amanita phalloides (death cap) poisoning, benzylpenicillin given at a dose of 1,000,000 U/kg/d followed by 500,000 IU/kg for the next 2 days prevents toxin uptake by liver cells. In all the abovementioned conditions (excluding hematological malignancy), liver transplantation has to be considered in case of failed medical management.

Liver Assist Devices

Release of toxins and inflammatory mediators from the necrosed hepatocytes initiates cascade of events which could ultimately lead onto to multiorgan failure and this elicits a vicious cycle of autointoxication (Fig. 70.3). Liver assist devices are developed to interrupt the cycle of autointoxication by removing toxins there by providing an opportunity for the liver to regenerate. An ideal extracorporeal liver support system has to perform complex synthetic, detoxifying, and biotransformatory functions of hepatocytes and Kupffer cells. Creating such a perfect device with possibility of providing an extracorporeal liver support system for short periods while the native liver regenerates or a liver transplant becomes available is still experimental. Currently available liver support devices could be broadly classified into cell-free cleansing devices and bioartificial liver support system, which contains human or animal liver cells. Cleansing devices perform only the detoxifying function of the liver, whereas bioartificial liver support systems have a theoretic advantage of providing the synthetic and detoxifying properties. These devices have shown to decrease the toxins (ammonia, bilirubin, cytokines, etc.) but have no effect on mortality. Successful use of these devices in ALF as a bridge, supporting liver function while the native liver regenerates still remains elusive and not recommended outside research setting.

Liver Transplantation

Liver transplant remains the only proven treatment that has improved the outcome of ALF. Improved surgical techniques such as split liver grafts, reduced grafts and living related donors have increased the timely availability of donor organs. The donor organs are usually blood group matched. In emergency situations ABO-incompatible liver transplantation could be done, but is associated with lower graft survival. Careful patient selection is essential, as it would minimize patients from being listed for liver transplantation and then being removed due to spontaneous recovery. Patients, who were removed from the list due to spontaneous recovery, could have potentially ended up with liver transplantation if

the organ becomes available before overt clinical improvement is appreciated. Absolute contraindications for liver transplant are fixed and dilated pupils, uncontrolled sepsis, systemic mitochondrial/metabolic disorders, and severe respiratory failure [46, 47]. Relative contraindications are increasing inotropic requirements, infection under treatment, cerebral perfusion pressure of less than 40 mmHg for more than 2 h, and a history of progressive or severe neurologic problems.

Auxiliary Liver Transplantation

Auxiliary liver transplant is surgical procedure where a healthy donor liver graft is implanted with native liver in situ. Auxiliary liver transplant could be orthotopic (part of the native liver is resected and replaced with a reduced-size graft) or heterotopic (the donor graft is placed alongside the native liver in the right upper quadrant). Due to higher incidence of complications associated with heterotopic auxiliary liver transplant, it is no more used in clinical practice. Now the standard surgical technique is auxiliary partial orthotopic liver transplantation (APOLT). The rationale behind the use of this technique in ALF is that the allograft supports liver function while the native liver regenerates and then immunosuppression could be weaned and eventually stopped. It has been shown that complete native liver recovery could happen even when there is more than 90% hepatocyte loss [48, 49]. In a series from King's College Hospital, of the 20 children who received auxiliary liver transplantation for ALF, 10-year patient survival was 85% [50]. Among the 17 survivors, 14 (82%) have successfully regenerated their native liver of which immunosuppression was withdrawn successfully in 11 patients at a median time of 23 months after transplantation. This would be an ideal option in ALF due to indeterminate etiology, as spontaneous regeneration of native liver remains a possibility. Caution should be exercised while selecting patients with hemodynamic instability and cerebral edema as deterioration might happen during postoperative period due to "toxic necrotic liver" left behind.

Hepatocyte Transplantation

Hepatocyte transplantation is a procedure where hepatocytes are infused intraportally into the patient's liver, where a proportion of cells will engraft and would support liver function. This technique has been tried with variable success in certain liver-based metabolic disorders. Its use in ALF still remains experimental. Lack of surrogate markers of rejection poses an important problem, as it is difficult to titrate the immunosuppression. A novel technique, where alginate-encapsulated hepatocytes could be injected intraperitoneally is under trial.

This technique avoids the complications of coagulopathy, portosystemic shunting of infused cells and protects the cells from direct immune attack, allowing immunosuppression-free transplantation.

Conclusions

ALF in children is a medical emergency as it leads on to multiorgan failure and has to be approached systematically. Newer definition for ALF obviates the need for encephalopathy to make the diagnosis. Expert intensive care facility is essential to stabilize and make this children fit for transplantation. Etiological diagnosis aids in disease-specific management. Acyclovir should be started in all neonates with ALF until results of herpes virology are available. Liver transplantation is the only definitive treatment that improves survival in pediatric ALF, while liver assist devices and hepatocyte transplantation are potential emerging therapies.

Introduction

Cirrhosis is the end result of progressive fibrosis irrespective of the insult to the parenchyma or biliary tree. Unlike adults, there is no time duration of illness that defines chronic liver disease (CLD). All the inherited metabolic and genetic conditions even when diagnosed at birth could have advanced fibrosis or cirrhosis. Cirrhosis is a histological diagnosis but is liberally used in clinical practice without histological evidence. Liver cell death leads to a cascade of immunological reactions leading to activation of stellate cells with subsequent excessive collagen production and ultimately fibrosis. Bridging of the portal tracts (porto-portal) or the central vein to the portal tracts with nodule formation and disruption of the liver architecture is defined as cirrhosis. The disruption of the liver architecture leads on to disturbance in hemodynamics of blood flow into the liver and homeostasis of synthetic and detoxification functions of the liver, resulting in complications such as portal hypertension (PHT), ascites, and encephalopathy. This can lead to a secondary cascade of events affecting the function of several end organs such as brain, kidney, and lungs [1]. Understanding the pathophysiology of the complications in CLD helps in anticipation and initiation of treatment at appropriate time. This chapter deals with the common complication associated with CLD.

Cirrhosis

The hallmark of CLD is fibrosis of the liver. Cirrhosis is a histopathological term used to describe microscopic and

or macroscopic changes in liver characterized by aberrant nodule formation, vascular changes, and totally disturbed architecture associated with fibrosis. The degree to which the abovementioned changes progress depends on the nature and duration of the insult. Cirrhosis/fibrosis leads to complications such as PHT, ascites, encephalopathy, hepatorenal syndrome (HRS), hepatopulmonary syndrome (HPS), and eventually resulting in end-stage liver disease.

Etiology of Cirrhosis

Common diseases that cause chronic injury to the liver in children leading to cirrhosis are outlined in Table 71.1. Cell death or injury, as in hepatotropic viral infections or accumulation of toxic by-products such as hydrophobic bile acids in hepatocytes, is associated with release of several proinflammatory mediators (e.g., tumor necrosis factor, TNF) that lead on to progressive fibrosis and eventually liver cirrhosis. As with any other multifactorial disease, both genetic and environmental factors play role in cirrhosis. The pattern and type of proinflammatory mediator released depend on the underlying etiology of hepatocyte death [2]. These mediators act on Kupffer cells, hepatocytes, and cholangiocytes that release secondary mediators, which then activate hepatic stellate cells (HSC) to produce extracellular matrix (ECM). Thus, etiology of liver insult influences the pattern of fibrosis, as fibrosis is first observed in periportal area in viral hepatitis, perivenular region in toxic damage, while in developmental malformations such as biliary atresia fibrosis starts around bile duct. Liver fibrosis is considered to be a wound-healing process, similar to any injured tissue in body, but when the response is exaggerated and persistent, it progresses to cirrhosis.

Table 71.1 Some of the common causes of liver cirrhosis in children

Etiology of liver cirrhosis
Metabolic liver disease
α1-Antitrypsin deficiency
Wilson disease
Progressive familial intrahepatic cholestasis
Glycogen storage diseases (especially types IV, VI, IX, and X)
Lipid abnormalities (e.g., Gaucher disease)
Peroxisomal disorders (e.g., Zellweger syndrome)
Tyrosinemia
Cystic fibrosis
Developmental/ genetic:
Biliary atresia
Congenital hepatic fibrosis
Alagille syndrome
Infections:
Viral (e.g., chronic hepatitis B or C)
Parasitic (e.g., echinococcosis)
Immune related:
Autoimmune hepatitis
Sclerosing cholangitis
Vascular:
Budd–Chiari syndrome
Hepatic veno-occlusive disease
Portal vein thrombosis
Miscellaneous:
Nonalcoholic steatohepatitis (NASH)
Drugs

Pathogenesis of Liver Fibrosis

Persistent insult to either hepatocytes or cholangiocytes acts as a stimulus for fibrosis to set in. Hepatotropic viruses, toxins, and diseases that cause chronic cholestasis (tyrosinemia, progressive familial intrahepatic cholestasis, etc.), damage liver cells, either by apoptosis or necrosis leading on to activation of a cascade of events causing fibrosis/cirrhosis (Fig. 71.1). The damaged liver cells secrete inflammatory mediators such as transforming growth factor (TGF)-β1, TNF-α, epidermal growth factor (EGF), insulin-like growth factor (IGF), endothelin (ET), and platelet-derived growth factor (PDGF) that activate HSC. These damaged hepatocytes/cholangiocytes also recruit and activate T cells and Kupffer cells which secrete interleukin 6 (IL-6), interferon (IFN)-α, CD40, CCL21, and IGF which in turn activates HSC via a different pathway. The ECM such as type IV collagen, fibrinogen, and urokinase-type plasminogen activator that is secreted during the process of fibrosis could act as a stimulus for further activation of HSC starting a vicious cycle [3].

Under normal condition, HSC are quiescent cells that store lipids and vitamin A in liver that resides in space of Disse. When activated, HSC transdifferentiate to myofibro-

blast-like cells, acquiring fibrogenic and secretory properties. Apart from HSC, myofibroblasts that are derived from small portal blood vessels and bone marrow play a role in ECM formation during fibrosis of liver [4–6]. The source of fibroblast that is involved in fibrosis of liver depends on the etiology of insult to the liver [6]. With biliary pathology such as biliary atresia, portal tract fibroblasts, and in hypoxic insults, bone marrow fibroblasts play an important role [7, 8].

The ECM laid during this process of fibrosis differs in structure and composition, when compared to the ECM laid during routine remodeling. Mitogenic stimuli such as TGF-β upregulate several precollagenous genes and increase the secretion of collagen by myofibroblasts, particularly type 1 and 3. Activated HSC also enhance the secretion of ECM-digesting enzymes like interstitial collagenase, gelatinase A, and stromelysin-1 which degrade specific components of ECM such as type 4 collagen and laminin, paving way for increased composition of type 1 and 3 collagen in fibrosis [9]. Increased tissue inhibitors of matrix metalloproteinases (TIMPs), which inhibit collagenase, result in gross imbalance between production and degradation of ECM. The fibrous tissue thus formed could interconnect portal tracts, portal tracts and central venules, or a mixture of both patterns and progress to cirrhosis. Contrary to the initial belief, it is shown that liver fibrosis even cirrhosis could regress to some extent on successful treatment of underlying cause [10].

Diagnosis of Liver Fibrosis

Fibrosis of liver covers an entire spectrum of microscopically detectable fibrosis during initial stages to macroscopically gross fibrosis as in advanced stages of CLD. There is no validated biochemical test or scoring system based on biochemical tests that would grade the severity of fibrosis [11]. Synthetic liver function or cholestasis has no correlation with the degree of fibrosis, as these parameters may be normal even in advanced fibrosis as in congenital hepatic fibrosis. Imaging techniques such as ultrasonography, computer tomography, and magnetic resonance imaging (MRI) can identify liver fibrosis though quantification is difficult. Liver biopsy is considered to be the gold standard method for the assessment of liver fibrosis as it provides necroinflammatory and the fibrosis grade. Figure 71.2a shows complete nodule formation, and Fig. 71.2b shows extensive collagen, when stained by trichrome in a cirrhotic liver. Scoring of degree of fibrosis could be done using Metavir (stages I–IV) and Ishak score (stages I–V). Due to invasive nature of the procedure, it is practically difficult to monitor fibrosis progression using liver biopsy. To overcome this problem, transient elastography (FibroScan®), a noninvasive technique is used in serial

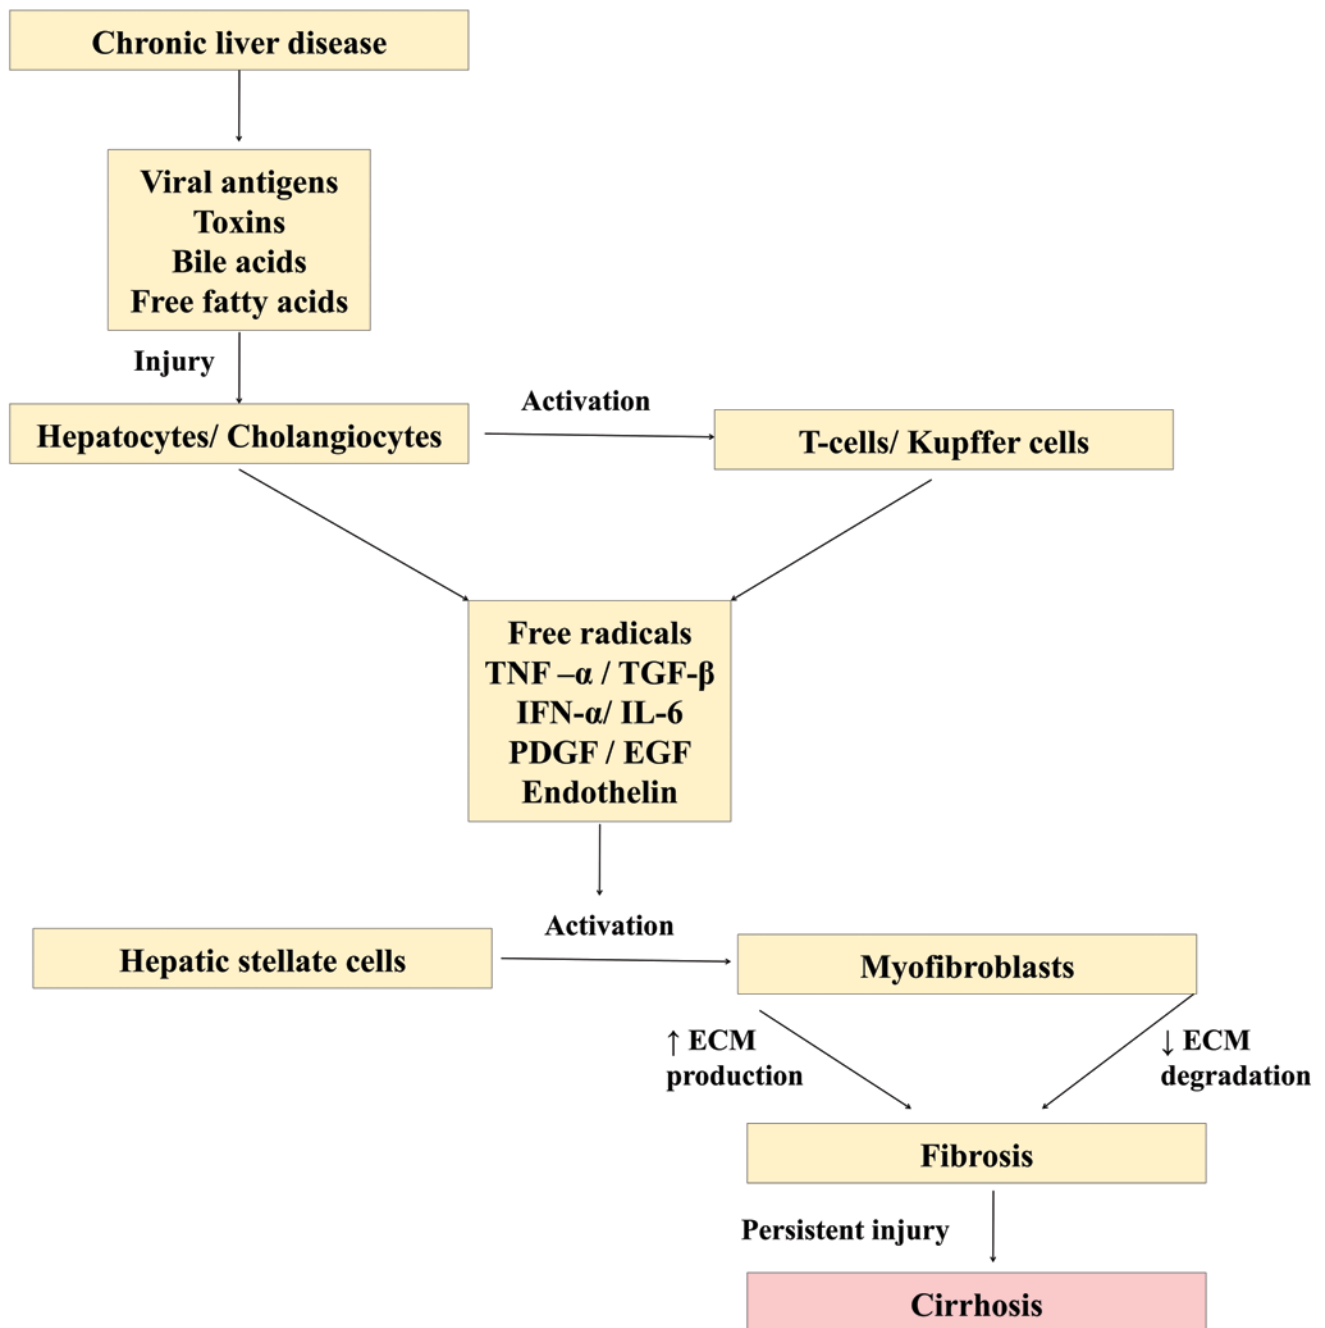

Fig. 71.1 Diagram showing cascade of events leading on to liver cirrhosis

monitoring of progress of fibrosis with good accuracy and has been validated even in children [12].

Complications and Management of Cirrhosis

CLD and the term “cirrhosis” have been used interchangeably in literature as cirrhosis is a manifestation of CLD, and most of the complications in CLD are secondary to cirrhosis. With progressive fibrosis, there is distortion of blood

vessels and bile leading on to increased resistance to blood flow resulting in increased portal pressure on afferent side and tissue hypoxia due to reduced blood supply on efferent side. Cirrhosis also leads to increase in hepatic artery resistance, and in the case of hypotension secondary to an infection or variceal bleed, the liver could suffer hypoxic insult and could decompensate. Over a period of time, the fibrous tissue coalesces to form a tight capsule and restricts hepatocyte regeneration and worsen cholestasis. Synthetic/detoxification failure, cholestasis, and fibrosis individually or in

Fig. 71.2 **a** Microscopic image of cirrhotic liver showing a nodular formation. Hepatic lobule (*arrow head*) completely encased by fibrous tissue. **b** Microscopic image of trichrome-stained liver, where collagen is stained *blue*, while the cytoplasm of hepatocytes is stained *red* and nuclei as black structures within cells

combination contribute towards complication of CLD, some of which are highlighted in Table 71.2. There is an increased risk of hepatocellular carcinoma (HCC) in cirrhotic liver, and the generalized nodular transformation of liver makes it difficult to diagnose HCC at early stages. Ultimately, these patients would succumb either to liver failure or to its complication unless treated appropriately. Fibrosis is a reversible phenomenon, but the extent to which the distorted liver architecture would revert back to its original state still remains an unanswered question. Disease-specific treatment, for example, chelation for Wilson's disease and steroids for autoimmune liver diseases, halts the progress of fibrosis and could reverse cirrhosis. At present, there is no approved drug that would inhibit or reverse fibrosis.

Complications of Cirrhosis

Portal Hypertension

Liver is a unique organ with dual blood supply, via the hepatic artery and portal vein. The portal vein, formed by the

splenic vein and superior mesenteric vein, supplies nutrient-rich blood from the intestine to the liver. The usual pressure is less than 5 mmHg, and this blood traverses hepatic sinusoids reaching hepatic venules having much lower pressures and enters systemic venous circulation. PHT develops when there is increased resistance anywhere along the portal system, and thus PHT could be extrahepatic (portal vein thrombosis), intrahepatic (cirrhosis), or posthepatic (hepatic venous thrombosis). PHT leads on to opening up of porto-systemic collaterals causing varices, which could rupture and cause bleed.

Direct measurement of portal pressure is difficult, and so hepatic venous pressure gradient (HVPG) is measured via hepatic venous catheterization. HVPG is pressure difference between wedged hepatic venous pressure (WHVP) and free hepatic venous pressure, which is reflective of portal pressure. HVPG of more than 10 mmHg is associated with the development of varices, and pressures more than 12 mmHg is associated with variceal bleed. In clinical practice, accurate measurement of portal pressure by invasive methods is of little relevance as esophageal varices and splenomegaly hint towards the development of PHT, and this needs to be managed appropriately.

Table 71.2 Signs and symptoms of cirrhosis and probable mechanism causing it

Complications of cirrhosis		
Symptoms	Signs	Underlying mechanism ^a
Jaundice, pruritus	Elevated bilirubin and bile acids	Detoxification failure of liver
Altered mental status	Encephalopathy	Detoxification failure of liver
Distended abdominal veins, vomiting blood	Caput medusae	Portal hypertension
Abdominal distension Swelling of legs	Ascites/edema	Hypoalbuminemia, portal hypertension
Muscle wasting	Malnutrition	Decreased absorption of nutrients due to defective bile flow and increased demand
Telangiectasia	Spider nevi	Detoxification failure of certain hormones
Easy fractures	Osteoporosis and osteomalacia	Hepatic osteodystrophy
Decreased urine output	Oliguria	Hepatorenal syndrome
Bluish discoloration and swelling of fingers	Cyanosis and clubbing	Hepatopulmonary syndrome, portopulmonary hypertension
Difficulty in breathing	Dyspnea	Hepatopulmonary syndrome, portopulmonary hypertension

^a More than one mechanism could be involved

Pathogenesis of PHT in Cirrhosis

Like any other tubular organ, resistance and flow govern the pressure in portal venous system. In CLD, there is a substantial increase in both flow and resistance of portal vein leading on to net increase in portal pressure.

Increased Resistance to Portal Flow

In cirrhosis, dynamic contractile elements within sinusoids and portal venules contribute up to 40% of increased vascular resistance, while the rest is attributed to fibrosis. Wrapping of HSC and myofibroblasts can wrap around sinusoids, and the portal venular smooth muscle contraction can increase vascular resistance [13]. ETs are a group of peptides, which cause vasoconstriction and stimulation of cell proliferation in tissue. ET-1 and ET-3 are found to be increased in cirrhotics when compared to controls, probably due to increased production [14]. Angiotensin II, norepinephrine, and thromboxane A₂ (TXA₂) are other vasopressors which are found to be increased in cirrhosis of the liver and cause increased vascular resistance of portal venules [15]. There is an associated endothelial dysfunction, which further increases the vascular resistance instead of decreasing it. This is probably due to increased levels of TXA₂ impairing the response to endothelium-dependent vasodilator acetylcholine, and thus the resultant increased vascular resistance is probably due to imbalance between increased vasoconstrictors and decreased vasodilators in CLD [16].

Increased Portal Circulation

Splanchnic vasodilatation combined with hyperdynamic circulation contributes to increased portal circulation. Nitric oxide (NO) [17] increases the production of cyclic guanosine monophosphate, which directly relaxes the smooth muscle. Increased NO due to enhanced endothelial NO synthase (eNOS) activity in splanchnic circulation is suggested to play an important role in splanchnic vasodilatation. Increased levels of glucagon found in cirrhosis cause direct vascular smooth muscle relaxation and decrease the sensitivity of vascular smooth muscle to endogenous vasoconstrictors. Other vasodilators such as capsaicin–calcitonin gene-related peptide, neuropeptides, and adenosine have a doubtful role. Plasma volume expansion due to sodium retention in cirrhosis also plays a role in increased portal flow.

Variceal Bleed in Portal Hypertension

Apart from ascites and hypersplenism, the major complication of PHT is variceal bleed. HVPG of more than 10 mmHg results in opening up of porto-systemic collaterals, which are situated at the lower end of esophagus, rectum, paraumbilical, and retroperitoneal regions. Life-threatening bleeds are

usually from esophageal and gastric varices that arise from a collateral network through the coronary and short gastric veins draining into the systemic azygous vein. Miga et al. showed that 20% of children had esophageal variceal hemorrhage (EVH) within 2 years after Kasai portoenterostomy, and the risk of death or need for liver transplantation was 50% at 6 years after the initial episode of EVH in a cohort of children with biliary atresia [18]. Etiology plays an important role in the survival outcome after variceal bleed, with varices due to portal vein thrombosis has better prognosis when compared with those due to intrinsic hepatobiliary disease [19].

Management of Variceal Bleed

Variceal bleed is a life-threatening emergency, and the patient needs to be stabilized before shifting for emergency endoscopy. In the event of hypovolemic shock, fluid resuscitation has to be initiated while awaiting whole blood, and in addition, fresh frozen plasma/platelets/cryoprecipitate/factor VIIa might be required, as these patients would be coagulopathic secondary to liver disease. Nasogastric tube placement and gastric lavage help to quantify the blood loss as well as to remove blood from the stomach that could precipitate encephalopathy. Vasoactive drugs that decrease portal pressure (Table 71.3) should be started along with proton pump inhibitors/H₂ blockers and antibiotics. Once stable, endoscopic variceal ligation (EVL) or endoscopic sclerotherapy could be done [20]. In the case of continuous bleed and hemodynamic instability, balloon tamponade with a Minnesota or Sengstaken–Blakemore tube should be attempted. Both these tubes have esophageal and gastric balloon, but Minnesota tube has esophageal aspiration port in addition to gastric aspiration port while Sengstaken–Blakemore tube has only gastric aspiration port. These tubes need to be placed by an experienced person as improper placement or overinflation of the balloon can result in esophageal rupture and/or ischemia [21]. Once bleeding is controlled, endoscopic sclerotherapy (ESL) and endoscopic variceal ligation (EVL) has to be performed, as conservative management (medication and balloon tamponade) without endoscopic intervention was associated with 3.6 times higher risk of rebleed [22].

ESL is a procedure where sclerosant such as ethanolamine oleate or sodium tetradecyl sulfate is injected into a varix under direct vision, thereby obliterating the vessel. Cyanoacrylates are synthetic glues used in gastric varices that rapidly solidify on contact with water and blood. Usually, cyanoacrylates are mixed with ethanolamine oleate at 1:1 ratio to decrease the rate of solidification, as it minimizes the inadvertent adherence to catheters and endoscope. EVL is a procedure where an elastic O-ring is applied over a small area of esophageal mucosa and submucosa, causing strangulation

Table 71.3 Various drugs used in portal hypertension and its mechanism of action

Medications used in portal hypertension		
<i>Drugs used in acute variceal bleed</i>		
Drug	Dosage	Mechanism of action
Vasopressin	Initial IV bolus 0.3 U/kg (maximum: 20 U) over 20 min followed by infusion: 0.002–0.01 U/kg/min	Acts via V1 receptors, reduces portal blood flow, portal systemic collateral blood flow, and variceal pressure
Octreotide	1 µg/kg/h IV Infusion or 2–4 µg/kg/dose/8 h s.c.	Analogue of somatostatin Reduce portal flow and pressures
Terlipressin	8–20 µg/kg of body weight given at intervals of 4–8 h	Terlipressin, a prodrug of vasopressin
<i>Drugs used to prevent rebleed</i>		
Propranolol	1–5 mg/kg/day in three divided doses	Reduces portal hypertension by decreasing cardiac output and inducing splanchnic vasoconstriction by blocking β-1 and β-2 receptors
Atenolol	1 mg/kg/day in two doses (Dose has to be adjusted to decrease heart rate by 25%)	
Carvedilol	0.3 mg/kg/day	Nonselective β-blocker with additional α-1 blocking action

IV intravenous, s.c. subcutaneous

of the tissue (varix) caught in-between the ring, eventually leading to fibrosis and obliteration. Randomized trial of endoscopic sclerotherapy versus variceal band ligation for esophageal varices showed that while both are equally effective in controlling acute bleed; EVL achieved variceal obliteration in fewer treatment sessions along with significantly lower rate of the development of portal gastropathy and rebleeding [23]. Meta-analysis suggests that pharmacotherapy coupled with either EVL or ESL showed better initial bleeding control and 5-day hemostasis, but no effect on mortality [24]. Occasionally, bleeding from gastric varices and Roux en Y jejunal loop varices might be difficult to control and might require interventional measures such as transjugular intrahepatic portosystemic shunt (TIPSS), surgical shunts, esophagogastric devascularization±splenectomy [25]. Liver transplantation has to be offered to those with CLD, after control of the acute bleeding episode.

Prophylactic Therapy for Variceal Bleed

The American Association for the Study of Liver Diseases (AASLD) practice guidelines recommend β-blockers as first-line therapy in adults with medium/large esophageal varices and EVL for patients in whom β-blockers are contraindicated or poorly tolerated [26]. Trials on children showed that β-blockers and EVL/ESL are relatively safe to be used, but so far, there are no robust data to suggest that its use as primary prophylaxis decreases the incidence of first episode variceal bleed in children [27, 28]. Variceal eradication and nonselective beta-blocker are recommended in adults after an episode of bleed as secondary prophylaxis, while in children, small studies have shown usefulness of

EVL/EST to prevent rebleed, but role of beta-blocker is still unclear [29, 30].

Neurological Complications in Cirrhosis

CLD predisposes to a variety of neurological complications such as intracranial hemorrhage due to the presence of coagulopathy, increased risk of cerebral infection due to decreased immune function, and hepatic encephalopathy (HE) [31].

Hepatic Encephalopathy

HE is defined as a metabolically induced, potentially reversible, functional disturbance of the brain that may occur in acute or CLD[32]. Though HE is considered to be a potentially reversible condition, some patients might not recover to their previous level of cognitive function after a severe episode of HE.

Factors such as infection, trauma, and electrolyte imbalance in the background of CLD could cause sudden liver decompensation and lead to HE. Encephalopathy that occurs in acute liver failure (ALF) is categorized as type A, HE in portosystemic shunt without any intrinsic hepatocellular disease as type B, and in CLD as type C. Type C could be further subclassified into minimal, episodic, or persistent. HE is called minimal hepatic encephalopathy (MHE), when diagnosis could be made only on psychometric analysis in an apparently normal person with CLD. Episodic encephalopathy in CLD coincides with episodes of high protein intake, gastrointestinal bleed, infection, etc. Usually, these episodes resolve with the treatment of the precipitating factors, but sometimes they persist and termed as persistent HE.

Clinical Features

HE could be clinically graded from 1 to 4 using West Haven criteria, and Glasgow coma scale which has lesser interobserver variability could be used in assessing conscious levels [33]. MHE is associated with mild intellectual impairment, where verbal ability is preserved and apparently normal personality [34]. Worsening of HE leads on to asterix (flapping tremor), hypertonia and hyperreflexia, hypotonia, and areflexia may be seen with subsequent progression to coma. Features similar to Parkinsonism such as muscular rigidity, bradykinesia, hypokinesia, monotony of speech, and tremors could be seen in HE.

Pathogenesis of Hepatic Encephalopathy

The pathogenesis of HE is thought to be multifactorial, with neurotoxins and altered neurotransmitters acting on the neurons. Ammonia is considered to be an important factor involved in pathogenesis, while mercaptans, short- and medium-chain fatty acids, phenols, methionine derivatives, etc. play a minor role. altered ratio of excitatory (\downarrow dopamine and noradrenaline) and inhibitory (\uparrow gamma-aminobutyric acid (GABA) and serotonin) neurotransmitters resulting in abnormal cerebral function. Apart from these, there is an increased formation of false neurotransmitters such as octopamine, phenyl methionine from accumulation of phenylalanine, and tyrosine. There are other proposed mechanisms of HE such as increase in false neurotransmitters (octopamine, phenyl methionine), altered ratios of branched-chain amino acids (BCAA) and aromatic amino acids (AAA), changes in postsynaptic receptor activity, increased permeability of blood–brain barrier, etc.

Role of Ammonia in HE

Ammonia is produced from a variety of sources such as small intestine enterocytes, gut flora, muscle, and kidney. Under healthy condition, around 80–90% of ammonia is either converted to urea by periportal hepatocytes or glutamine by perivenous hepatocytes. Though ammonia is implicated in HE, the exact mechanism is still elusive. Few of the suggested mechanisms are: (1) Excess ammonia is converted to glutamine by glial cells. This glutamine increases intracellular osmotic pressure, leading on to swelling of astrocytes, cerebral edema and can competitively bind to glutamate receptors and inhibit them. (2) Oxidative stress triggered by ammonia toxicity in the astrocyte resulting in mitochondrial dysfunction. (3) Enhanced cytokine activity and impaired intracellular signaling [35].

It was thought that ammonia in portal circulation was exclusively produced by the gut flora, but current hypothesis

suggests that small gut enterocytes produce ammonia in excess of gut flora, and gut decontamination alone has minimal effect on ammonia levels [36]. Kidney is involved in both production and elimination of ammonia. Kidney can metabolize glutamine to produce ammonia and bicarbonate and can excrete ammonia as ammonium ion and urea in urine [35]. Alkalosis can decrease the conversion of ammonia to ammonium, as there is no need to excrete the hydrogen ion resulting in elevated free ammonia that can cross blood–brain barrier and precipitate HE. Myocytes can act as buffer by converting ammonia to nontoxic glutamine via glutamine synthetase, and thus poor muscle mass is an important risk factor for HE [37].

Role of Neurotoxins and Inflammatory Mediators in HE

The ratio of BCAA/AAA phenylalanine, tyrosine, and tryptophan is called the Fischer ratio [38, 39]. There is decrease in Fischer ratio in liver failure, due to preferential usage of BCAA by muscles and decreased clearance of AAA by liver. Elevated serum AAA can cross the blood–brain barrier into the brain and results in synthesis of false neurotransmitter such as octopamine and synephrine [40].

Several short-chain fatty acids such as propionate, butyrate, and valerate are produced in small intestine by breakdown of proteins by fecal flora [41]. These short-chain fatty acids competitively inhibit urea cycle enzymes and can bind to albumin and displacing albumin-bound toxins, thus precipitating HE. Indole, oxindole, endozepines, neuronal acetylcholinesterase, TNF- α , and allopregnanolone are few of the other bioactive substances that could play a role in HE [42–46].

Diagnosis

Diagnosis of encephalopathy is mainly based on clinical history and examination [47]. Clinical diagnosis of mild-to-moderate HE is difficult in children as it requires their cooperation to perform psychometric tests. Neuroimaging and electrophysiological studies of brain would give supportive evidence rather than to confirm the diagnosis of HE. Though arterial ammonia level correlates with the severity of HE, it could not be used to grade encephalopathy [33]. HE could be clinically graded using West Haven criteria, and conscious level is graded using Glasgow coma scale [33].

Neuropsychological Assessment

In children, neuropsychological assessment should be made using tests such as Wechsler intelligence tests and Dutch child intelligence test (Revisie Amsterdamse Kinder Intelli-

gentie test), where validated nomogram exists for the selected age, sex, racial, and ethnical subgroup. The Psychometric Hepatic Encephalopathy Score (PHES) and number connect test (NCT) A and B could be used to diagnose MHE in adults while these tests are not validated in children [48, 49].

Critical Flicker Frequency

Critical flicker-frequency threshold is a simple and reliable test for the quantification of low-grade HE [50]. The principle of the test is to identify the point of switch over from a steady red light to a flickering light. A normal human eye perceives flicker rate of 60 Hz as a steady light. The frequency of the light is gradually decreased to a point where the patient starts to perceive the light as flicker. Using this technique, it was found that patients with HE can pick up flickering only when the flicker rate comes below 39 Hz, while cirrhotic counterparts without encephalopathy and normal individual could identify flickering at higher rate [47]. The need for understanding (and being able to follow instructions) the test limits is used only in children more than 8 years [51].

Electroencephalogram

Using electroencephalogram (EEG), HE could be graded into 5 grades (0–4). Grade 0 is a normal EEG with regular alpha rhythm. Grade 1 encephalopathy is characterized by irregular background alpha rhythm and appearance of theta rhythm. Theta activity becomes continuous with occasional delta wave in grade 2 HE, and theta activity becomes prevalent with transient polyphasic complexes of spikes and slow waves in grade 3. Grade 4 is deep coma, having continuous delta waves with abundant complexes of spikes and slow waves [47]. With the availability of newer complex EEG analytical softwares, EEG can be analyzed in specific regions of the brain.

Neuroimaging in HE

Computer tomography (CT) of brain is not a useful tool in diagnosis of HE, apart from excluding organic causes such as bleed, tumors, or gross edema that can cause encephalopathy [52]. MRI is a better modality to diagnose cerebral edema and demyelination associated with HE. Conventional MRI lacks sensitivity in diagnosing milder forms of edema, and newer techniques such as magnetization transfer imaging (MTI), fast fluid-attenuated inversion recovery (FLAIR) imaging, and diffusion-weighted imaging are more sensitive in picking up brain tissue water content [53]. Proton MR

spectroscopy could measure different levels of metabolites in brain such as myo-inositol, choline, and glutamine. These specialized neuroimaging is more of research interest and provides little benefit in routine clinical practice.

Management of Hepatic Encephalopathy

Management should be directed towards stabilization of the patient and treating the precipitating factors such as bleeding, electrolyte imbalance, and infection. In HE of grade 3 or 4, elective intubation has to be considered to protect the airways. Despite increased total body water, these patients would be intravascularly fluid depleted. Hydration is best monitored by central venous pressure (CVP) and ideally should be 6–8 cm of H₂O. Though their serum sodium is low, they will have high total body sodium, and any attempt to normalize the sodium will lead on to worsening of edema. Supplementation of extra sodium is required if the sodium level falls below 120 mEq/l [54].

Lactulose decreases the colonic pH to around 5, and thereby decreasing the bacterial fermentation and production of short-chain fatty acids [55, 56]. In acidic environment, the ammonia produced in colon is converted to ammonium ion, reducing its diffusibility back into circulation and thereby removed along with stools. The amount of lactulose dose has to be titrated to produce three soft stools/day. Long-term lactulose in CLD helps to prevent HE, but will not change the ultimate requirement of a liver transplantation. Lactitol (B galactosido-sorbitol) is a nonabsorbable sugar which has similar action to lactulose, but less sweeter and more palatable [57].

Neomycin, vancomycin, and rifaximin are few of the antibiotics that are used to eliminate ammoniagenic bacteria from the gut, thereby decreasing the ammonia production in the intestine. Of all the antibiotics, rifaximin has been shown to be very effective in decreasing ammonia production and highest risk benefit ratio [58]. Rifaximin and lactulose given together was found to be more beneficial than either of them given alone [59]. Use of probiotics has shown to reduce plasma ammonia, but there was no change in final outcome [60].

L-ornithine-L-aspartate (LOLA) enhances the action of ornithine and aspartate transaminases in brain and peripheral tissues to produce nontoxic glutamate. There is no standard dosing in children, up to 20 g/day could be given at an infusion rate not exceeding 5 g/h as suggested by drug monogram and not recommended in children less than 8 years old [54]. Sodium benzoate (250 mg/kg/day) along with intravenous sodium phenylacetate (250 mg/kg/day) or oral sodium phenylbutyrate (250 mg/kg/day) could be used to eliminate ammonia by alternate pathways, thereby decreasing serum ammonia levels. Water-soluble hippuric acid and phenylacetyl-glutamine are formed by conjugation of benzoate with

glycine and phenyl acetate with glutamine, respectively. Hippuric acid and phenylacetyl-glutamine are then excreted by kidneys, thereby reducing ammonia load [61]. Though all these medications are more useful in hyperammonia due to urea cycle defects, they are used off-label in hyperammonemia due to liver failure [35].

There has been increasing interest in the possibility of providing an extracorporeal liver support system for short periods while liver allograft becomes available. High cost, nonavailability of small filters, and lack of safety data in children limit the usage of these devices to clinical trial setting. Liver transplantation has shown to be the definitive treatment, which has improved survival outcome both in adults and children. Elective liver transplantation offers 5-year survival of more than 85% in children. Synthetic liver failure with encephalopathy is one of the indications for liver transplantation in CLD, which has to be done before permanent neurological damage sets in.

Ascites

Fluid retention and low albumin in CLD result in accumulation of fluid in extravascular space leading to edema, ascites, and plural effusion. Presence of ascites is one of the variables that increase the mortality in children with CLD [62]. Onset of ascites indicates decompensation of liver disease and the need for liver transplantation. Ascites increases the risk of bacterial peritonitis and HRS, which potentially adds on to the already increased mortality associated with liver decompensation (see Fig. 71.3).

Pathophysiology of Ascites

There are several theories based on the triggering factor of the vicious cycle that leads to fluid retention and ascites. The “overflow” theory suggests hepatorenal reflex to be the primary event that leading on to sodium and fluid retention and subsequently ascites. The “underfill” theory suggests that the increased pressure in portal sinusoids results in increased hydrostatic pressure leading on to excessive lymph production. When lymph production exceeds absorption, the net result is ascites and contraction of intravascular volume (underfill). “Peripheral arterial vasodilation hypothesis” which was proposed in 1988 suggests that splanchnic and peripheral arterial vasodilatation secondary to PHT and cirrhosis is the initial triggering event [63]. This causes decreased intravascular volume, leading on to baroreceptor-mediated activation of renin angiotensin aldosterone system and release of antidiuretic hormone, resulting in hypervolemic stage due to renal sodium and water retention [63–65]. Splanchnic vasodilatation along with hypervolemia results in increased hydrostatic pressure that ultimately results in passage of fluid to peritoneal space [66]. It is difficult to ex-

Fig. 71.3 Image of a child with failed Kasai portoenterostomy showing gross ascites, dilated abdominal veins, and edema of legs

plain the complex cascade of events leading on to ascites based on one theory, and it is possible that mechanisms as suggested by different theories could contribute to various stages of ascites formation.

Biochemical Diagnosis

Ascitic tap should be carried out in any new onset ascites. Estimating serum-ascites albumin gradient (SAAG) is considered to be superior in making differential diagnosis of probable cause of ascites, compared to quantifying it as exudate or transudate. SAAG ≥ 1.1 g/dL is associated with cirrhosis, portal or hepatic venous occlusion, congestive cardiac failure, etc., while SAAG < 1.1 g/dL is associated with nephrotic syndrome, peritoneal infection, or malignancy [67]. Spontaneous bacterial peritonitis is an important complication of ascites and has to be differentiated from surgical cause of peritonitis such as perforation which accounts for 5% of cases [68]. Polymorphonuclear neutrophils (PMNs) of $> 250 \text{ mm}^3$ in ascitic fluid are suggestive of the presence of bacterial infection while predominant lymphocytic cells

in ascites (>20% of the total leukocyte count) along with ascites–blood glucose quotient of <0.7 is suggestive of tuberculous infection. In the case of high PMNs in ascitic fluid with symptoms of fever and abdominal tenderness, antibiotics need to be continued even if the cultures are negative as 34.5% turn culture positive on repeated samples.

Management

Optimizing caloric and protein intake helps improving serum albumin and thus oncotic pressure. Diuretic therapy remains the first line of treatment in ascites. Aldosterone antagonist, spironolactone, is the initial drug of choice. It is usually started at 3 mg/kg/day in three to four divided doses and could be gradually increased to 6 mg/kg/day (maximum dose 400 mg/day). Potent loop diuretics such as Furosemide (1–2 mg/kg) could be added if there is no effective diuresis on monotherapy. Spironolactone causes hyperkalemia while frusemide causes hyponatremia and hypokalemia, which has to be monitored on regular basis. Sometimes dual therapy with these drugs is beneficial as potassium loss by frusemide is counteracted by potassium conservation by spironolactone. The suggested optimal drug dosage ratio to achieve this is 2 (frusemide):5 (spironolactone). Tolvaptan is an oral vasopressin receptor antagonist that helps in free water excretion and corrects hyponatremia, and it has been approved by the US Food and Drug Administration (FDA) for use in adults with cirrhosis. It is currently under phase three trials for its safety in children.

Paracentesis is indicated in the case of tense ascites causing respiratory distress. Usually, 20% albumin at a dose of 5 ml/kg is given slowly over 2 h during the procedure as plasma expander as well as to prevent rapid reaccumulation of ascites. It is shown that children tolerate large volume paracentesis (>50 ml/kg) well, and the noticed side effect such as reduced urine output responded well to volume expanders [69]. It is advisable to taut the skin at the point of needle entry to create “Z,” so that normal skin covers the muscle puncture site, preventing post-procedure leak.

Pulmonary Complications in Cirrhosis

The common pulmonary complications of CLD are HPS, portopulmonary hypertension (PoPH), and pulmonary hydrothorax. Care should be taken to exclude intrinsic lung diseases such as alpha-1-antitrypsin (AIAT) deficiency and cystic fibrosis that could coexist with liver disease and contribute towards hypoxia.

Hepatopulmonary Syndrome

Kennedy and Knudson coined the term “HPS” in 1977 to describe the association of cirrhosis with cyanosis and club-

bing. The diagnostic criteria for HPS is the presence of CLD along with $\text{PaO}_2 < 70$ mmHg or alveolar-arterial oxygen gradient >15 mmHg and intrapulmonary vascular dilatation [70]. The overall prevalence of HPS ranges from 4 to 30% in cirrhotics. Suggested prevalence of HPS in pediatric population with CLD is around 8–20% [71, 72].

Pathogenesis

Higher prevalence of HPS in disorders where there is intrinsic liver disease along with PHT such as biliary atresia rather than in condition with PHT alone such as portal vein thrombosis led to the hypothesis that PHT along with intrinsic liver disease is essential for the development of HPS [52, 73, 74]. HPS is probably due to the effect of several vasoactive substances such as NO [17], carbon monoxide (CO), prostaglandins, vasoactive intestinal peptide, calcitonin, and glucagon, which escapes liver metabolism due to PHT and acts on pulmonary vasculature. NO is a potent vasodilator, and its nitrates and nitrite metabolites are found to be high in exhaled air of patients with HPS, which normalizes after liver transplantation. NO synthase is an enzyme that helps in production of NO from L-arginine. It has several isoforms of which eNOS was found to be increased in pulmonary small alveolar vessels, in small animal models of HPS. Elevated levels of ET-1 in blood and increased expression of its receptor ET B (ETB) expression in the pulmonary vasculature result in increased eNOS synthesis and thus vasodilatation [75]. Apart from eNOS, TNF- α , IL-1 β , carbon monoxide, etc. are some of the other vasoactive substances implicated in pathogenesis of HPS [76–78]. These substances were thought to be involved in angiogenesis and vasodilatation of pulmonary vasculature leading on to portopulmonary and hepatopulmonary shunts. In lung areas where there are capillary dilations, there would be more of perfusion compared to ventilation while in areas with shunting effect, the blood is diverted away from alveoli resulting in less perfusion, leading on to ventilation perfusion mismatch. Due to this, 100% oxygen inhalation might improve PaO_2 in cases of HPS with predominant intrapulmonary vascular dilatation, while there won't be any change in those with predominant shunt.

Clinical Manifestation

Dyspnea, clubbing, cyanosis, spider nevi are some of the clinical manifestations of HPS. In HPS, dyspnea is more on upright position, due to increased congestion because of gravity exaggerating the ventilation—perfusion mismatch. PaO_2 decrease of 5% or more or 4 mmHg or more from the supine to upright position is defined as orthodeoxia, which is the hall mark of HPS [79]. Clubbing, also described as drumstick fingers (Fig. 71.4) seen in HPS, is due to the release

Fig. 71.4 Shows clubbing of fingers in a 10-month-old child with chronic liver disease due to missed biliary atresia

of PDGF in nail beds that acts as growth factor and causes bulbous swelling of nails beds [80].

Diagnosis

In cirrhotic patients with hypoxia, chest X-ray has to be taken as first line to rule out other causes of hypoxia such as pulmonary atelectasis, pneumonia, pulmonary edema, or hepatic hydrothorax. X-ray would be normal in majority of patients with HPS, but few might show interstitial infiltrate in the lung bases [81]. Contrast enhanced echocardiography is the preferred screening test for HPS [75]. Saline or indocyanine green is agitated to produce microbubbles at least 15 μm in diameter and then injected intravenously. These microbubbles act as contrast and could be visualized in echocardiography on right side of the heart. When these microbubbles traverse the lung, they get trapped in alveolar microvasculature and gradually absorbed. In individuals with either intracardiac or intrapulmonary shunts, these microbubbles could be seen in the left heart. Differentiation between intracardiac or intrapulmonary shunts depends on the timing of appearance of microbubbles in left heart. With intracardiac shunts, the microbubbles appear in three heartbeats, while with intrapulmonary shunts, it takes 4–6 heart beats for the contrast to appear in left side of heart. Though contrast echocardiography is sensitive, it lacks specificity, as some cirrhotic patients with positive results on contrast echocardiography might not fulfill the diagnostic criteria for HPS [75].

If the initial screening raises the possibility of HPS, technetium-99 m macroaggregated albumin (Tc-99 m MAA) lung perfusion scan has to be considered, which is more

sensitive and specific [70, 82]. Macroaggregated albumin, which is of 20 μm in size, is tagged with radioisotope technetium. In normal individuals, macroaggregated albumin gets trapped in lung, and less than 5% of tracer activity can be quantified in the brain. In HPS patients, the fraction is more than 6%. Using this technique, the magnitude of shunt can be quantified which is inversely proportional to arterial oxygen saturation [70]. The drawback of this procedure is that correlation between shunt fraction and response of PaO_2 after 100% oxygen supplement remains unpredictable. High-resolution CT could show increased ratio of segmental arterial diameter to adjacent bronchial diameter, but published data were quite scarce [83]. Selective pulmonary angiography along with possible embolotherapy has to be considered in patients with HPS who fail to respond to 100% oxygen and particularly in those whom liver transplantation has to be considered. Angiography could reveal two types of vascular pattern, diffuse (type 1) and focal (type 2). In type 1 HPS, diffuse speckled, spidery, or sponge-like appearance of vasodilated vessels may be demonstrated. Type 1 was considered to be of better prognosis with liver transplantation as there is high possibility of resolution of HPS [84]. In type 2 HPS, vascular changes resembling arteriovenous (AV) shunts or vascular malformations could be seen. If amicable, embolization of feeding vessel could be done before considering liver transplantation [85, 86].

Management

Oxygen supplementation remains the main stay in HPS patients when $\text{PaO}_2 < 60$, and it improves the quality of life and exercise tolerance [87]. Several medications such as indomethacin, tamoxifen, somatostatin analogues, sympathomimetics, beta-blockers, methylene blue, and plasma exchange have been tried in HPS with abysmal results. Martinez-Palli et al. showed that decreasing PHT using TIPSS had no effect on pulmonary gas exchange and thus not recommended [88]. Severity of HPS correlates with mortality, and so it should be combined with the model for end-stage liver disease (MELD) score as to prioritize these patients in organ allocation [89, 90]. Liver transplantation is considered to be the definitive treatment in selective group of HPS patients as it reverts the pulmonary capillary abnormality and normalizes oxygenation [91]. Overall, postoperative complications in patients with HPS are higher than those without HPS. Embolic cerebral hemorrhage, worsening of hypoxia, and failure of AV shunts to resolve (particularly type 2) are a few of the unique complications of HPS [85, 92].

Careful patient selection is essential as severe preoperative hypoxemia ($\text{PaO}_2 < 50$ mmHg in room air) and significant intrapulmonary shunting (Tc-99 m MAA shunt fraction $> 20\%$) are associated with high mortality after liver transplantation [93].

Portopulmonary Hypertension

PoPH is defined as the presence of mean pulmonary artery pressure (MPAP) >25 mmHg along with pulmonary vascular resistance (PVR) >240 dynes s cm^{-5} with normal capillary wedge pressure (PCWP) <15 mmHg, in the presence of PHT [94]. It is postulated that the toxins and bioactive substances that bypasses liver metabolism via varices in PHT could lead on to pulmonary vasoconstriction, structural remodeling of the pulmonary arteries, formation of microthrombi, etc. along with high flow state [95]. PHT seems to be a prerequisite as PoPH is seen in disorders with no intrinsic liver disease such as extrahepatic portal vein thrombosis [96]. The histopathological changes in PoPH consist of medial hypertrophy with nonspecific intimal fibrous thickening along with fibrous mural pads, occlusive fibrous tissue in vascular lumens, which is similar to that of primary pulmonary hypertension [53].

Clinical Features

The most common presenting symptom is dyspnea on exertion followed by syncope, chest pain, and fatigue [97]. Sometimes it is associated with hemoptysis. In mild-to-moderate PoPH, the symptoms are mild or absent. The time interval between diagnosis of PHT and symptoms due to PoPH is around 5 years [98]. Clinical examination would reveal systolic murmur with loud pulmonary component of second heart sound indicating tricuspid regurgitation. Edema and ascites (features of right heart failure) are other clinical features.

Diagnosis

Diagnosis of PoPH is made based on the presence of pulmonary hypertension in the background liver disease. Chest X-ray might show prominent central pulmonary arteries and cardiomegaly, and electrocardiogram might show right ventricular strain pattern. Estimated right ventricular systolic pressure >50 mmHg (normal <30 mmHg) is strongly suggestive of PoPH, when assessed by Doppler echocardiography, but has a false-positive rate of around 15% [94]. Right-heart catheterization study remains the gold standard test for accurately diagnosing pulmonary hypertension and could be classified into mild, moderate, and severe based on MPAP, PVR, and cardiac index [94].

Management

Three groups of drugs, namely prostacyclin analogues (epoprostenol, iloprost), ET receptor antagonists (bosentan), and

phosphodiesterase inhibitors (sildenafil) have been used with good response in children with primary pulmonary hypertension, and the data on its usage in children PoPH are sparse [99]. Continuous intravenous infusion of epoprostenol (30–90 ng/kg/min) improves circulatory hemodynamics and exercise capacity in children with PoPH [99]. Treprostinil is another prostacyclin analogue, which could be given either subcutaneously or intravenously [100]. Bosentan is an ET receptor antagonist which when used in children has shown to decrease MPAP and pulmonary vascular resistance index and improve cardiac index [101]. Sildenafil is a phosphodiesterase-5 inhibitors and causes vasodilatation of pulmonary arteries and thereby decreases pulmonary hypertension when given at a dose of 0.5–1 mg/kg/dose given three to four times [99]. Mild-to-moderate PoPH frequently resolves after liver transplantation while severe PoPH is associated with the persistence of pulmonary hypertension and increased mortality [94].

Renal Involvement in Cirrhosis

Renal decompensation in liver disease is an important complication of both acute and CLD. Kidneys could be affected as a part of generalized circulatory changes associated liver disease (e.g., hypovolemia after variceal bleed) or as a specific phenomenon that occurs only in liver disease (e.g., hepatorenal syndrome). Renal involvement in liver disease has to be identified at the earliest and treated appropriately as progressive renal failure in liver disease is an adverse prognostic factor [102].

Hepatorenal Syndrome

HRS is a progressive, reversible functional renal impairment that occurs in patients with advanced liver cirrhosis or those with fulminant hepatic failure. Diagnostic criteria of HRS are outlined in Table 71.4. Type 1 HRS is characterized by rapid progression of renal failure and has a precipitating factor in most cases. It is associated with rapidly declining urine output and increasing creatinine in less than 2 weeks duration. Type 1 HRS occurs in the setting of an acute deterioration of circulatory function (arterial hypotension and activation of the endogenous vasoconstrictor systems) and is frequently associated with rapid impairment in liver function and encephalopathy, carrying a poor prognosis. Type 2 HRS is characterized by a moderate renal failure, which follows a steady or slowly progressive course. It appears spontaneously in most cases and frequently associated with refractory ascites.

Pathophysiology

The hallmark of HRS is renal vasoconstriction, which progresses with worsening liver disease. The renal cortical

Table 71.4 Six major criteria, all of which are necessary for the diagnosis of hepatorenal syndrome and five additional criteria, which are usually associated with hepatorenal syndrome but are not required for diagnosis

Diagnostic criteria for hepatorenal syndrome	
The six major criteria are as follows:	
1.	Presence of cirrhosis and ascites
2.	Serum creatinine > 1.5 mg/dL (133 μmol/L) or 24-h creatinine clearance of less than 40 mL/min
3.	No improvement of serum creatinine (creatinine level \leq 1.5 mg/dL or clearance > 40 mL/min) after at least 48 h of diuretic withdrawal and volume expansion with albumin
4.	Absence of shock, ongoing bacterial infection, fluid loss, or current or recent treatment with nephrotoxic medications
5.	Absence of parenchymal kidney disease as indicated by proteinuria > 500 mg/day,
6.	Absence of any evidence of obstructive uropathy on renal ultrasound scanning
The five additional criteria are as follows:	
	Urine volume of less than 500 mL/d
	Urine sodium concentration of less than 10 mEq/L
	Urine osmolality greater than plasma osmolality
	Urine RBC count of less than 50 per high-power field
	Serum sodium concentration of less than 130 mEq/L

^a As defined by the International Ascites Club

blood flow has been documented to be reduced in HRS using selective renal arteriography and xenon-113 studies, but the underlying mechanisms involved in HRS are incompletely understood [103, 104]. Four pathways have been implicated in the pathophysiology of HRS.

1. Peripheral and splanchnic vasodilation secondary to increased production of vasodilatory amines in the leading on to activation of renin angiotensin system in the kidneys, thereby reducing urine output.
2. Sympathetic nervous system activation leading to possible hepatorenal reflex.
3. Cardiac dysfunction contributing to renal hypoperfusion.
4. Action of cytokines and vasoactive mediators on renal circulation leading to the loss of renal autoregulation mechanisms may also play a role in the development of HRS.

Clinical presentation: The incidence of HRS in patients with cirrhosis and ascites is 20% in the 1st year and 39% within

5 years. The rapidity and severity of renal failure at presentation depend on the type of HRS. Type 1 HRS is preceded by a precipitating factor in 70% of cases. The most common precipitating events are spontaneous bacterial peritonitis, large volume paracentesis without volume replacement, gastrointestinal hemorrhage, and sepsis. These patients have many of the features present with advanced liver disease, in addition to renal dysfunction. These patients may also have underlying ascites, which are refractory to diuretic therapy. The findings in acute azotemia in patients with liver disease are given in Table 71.5.

Management

There is no proven effective therapy for HRS except liver transplantation. The general principles include treating precipitating factors and avoiding agents and factors, which can precipitate HRS. In cases of tense ascites, abdominal paracentesis done in conjunction with albumin replacement to avoid circulatory dysfunction has been proved to be safe [105]. Systemic vasoconstrictors include vasopressin analogues (terlipressin and ornipressin), somatostatin analogue (octreotide), and alpha-adrenergic agonists (midodrine and norepinephrine) are helpful in managing HRS. Studies have shown in adults that terlipressin when used alone or with albumin has higher efficacy in reversing the renal function in patients with HRS [106].

Portosystemic shunts such as TIPSS placement in adults have been shown to improve renal function. The mechanism by which TIPSS exerts this effect is still speculative but could be the result of reduction of portal pressure, suppression of a putative hepatorenal reflex, improvement of the circulating volume, or amelioration of cardiac function. Renal replacement therapy is indicated for those who failed to respond to vasoconstrictors, TIPSS, intractable metabolic acidosis, hyperkalemia, volume overload, and those who are waiting for a liver transplant.

Liver transplantation is the definitive treatment for patients with HRS, as it corrects liver dysfunction and eliminates PHT [30, 107]. Shusterman et al. showed that in 77% of those with HRS, serum creatinine levels decreased to less

Table 71.5 Features to differentiate prerenal azotemia, acute tubular necrosis, and hepatorenal syndrome

Differentiating hepatorenal syndrome from other causes of renal failure	Hepatorenal syndrome	Prerenal azotemia	Acute tubular necrosis
Urinary sodium concentration	< 10 mEq/L	< 10 mEq/L	< 10 mEq/L
Urine plasma creatinine	> 30:1	> 30:1	< 20:1
Urine osmolality	> Plasma osmolality	> Plasma osmolality	Equal to plasma osmolality
Fractional excretion of sodium	< 1%	< 1%	> 2%
Urinary sediment	Normal	Normal	Casts, debris
Response to volume expansion	Brief or No diuresis	Sustained diuresis	No diuresis

than 1.5 mg/dL after liver transplantation, and at 3 months post liver transplantation, none of the patients required dialysis [30, 107].

Other System Involvement in Cirrhosis

Pruritus is one of the most debilitating complications of CLD that affects the quality of life. Grading of pruritus and medical management is outlined in Table 71.6. Severe pruritus that does not respond to medical management per se is an indication for liver transplantation. Cardiac dysfunction in CLD is a discrete phenomenon called as cirrhotic cardiomyopathy, and it is associated with all or some of following changes: (1) baseline increased cardiac output but blunted ventricular response to stimuli, (2) systolic and/or diastolic dysfunction, (3) the absence of overt left ventricular failure at rest, and (4) electrophysiological abnormalities including prolonged QT interval on electrocardiography and chronotropic incompetence [108]. Altered cardiac muscle membrane properties, impairment of stimulatory β -adrenergic receptor signaling pathways, and over active negative-inotropic factors are some of the factors implicated in pathogenesis of cirrhotic cardiomyopathy [109]. In a cohort of 40 children with median age of 8 months awaiting liver transplantation, Desai et al. showed that 27 (74%) had cirrhotic cardiomyopathy [110]. Liver transplantation remains the only curative therapy in most of the patients [110].

Increased caloric needs, decreased absorption due to cholestasis, and poor appetite contribute to undernutrition in CLD. Bone disease with both the components of osteoporosis and osteomalacia in CLD is termed as hepatic osteodystrophy (HO) [111]. The pathogenesis of HO is considered to be multifactorial due to complex interaction of IGF-1 deficiency, vitamin D and K deficiency, hypogonadism, etc., on growth and differentiation of bones in the back ground of hyperbilirubinemia [112]. The reported prevalence of fractures due to HO in children is around

10–13% [112]. Regular bone mineral density by dual-energy X-ray absorptiometry scan (DEXA) and monitoring serum 25-hydroxy vitamin D (25OHD) levels help in early detection and treatment of deficiency states. Routine supplementation of vitamin D at a dose of 3–10 times the recommended daily allowance has been suggested [60]. The recommended form of vitamin D for both prophylaxis and treatment is either ergocalciferol (vitamin D2) or cholecalciferol (vitamin D3) targeting a 25OHD level of more than 50 nmol/L. Bisphosphonate therapy is indicated only in the presence of low-impact fractures (≥ 1 vertebral, or ≥ 1 lower limb, or ≥ 2 upper limb) along with low bone mineral density (BMD) [113].

Prognosis

MELD is a scoring system developed to predict death within 3 months of surgery in patients who had undergone a TIPSS procedure and was subsequently found to be useful in determining prognosis in patients with CLD due to other etiologies. MELD is calculated using serum bilirubin, serum creatinine, and international normalized ratio (INR). A value of 40 or more is associated with 71% mortality in 3 months, while a value of less than nine is associated mere 1.9% mortality. MELD is used in US and European countries in prioritizing CLD patients for liver transplantation. In children under 12 years of age, pediatric end-stage liver disease (PELD) score is used for prognostication where age less than 1 year and growth failure are also taken into consideration. Though many countries use PELD to prioritize children in waiting list, it has its own limitations. PELD score does not take into consideration complications such as cholangitis, severe PHT, pulmonary hypertension, and HPS and could underestimate the risk of death [17].

Table 71.6 Though grading is very subjective, it helps in comparing the symptomatic improvement to therapy

Grading and medical management of pruritus
Grade 1: no pruritus
Grade 2: mild scratching, but can be distracted
Grade 3: active scratching without abrasion
Grade 4: active scratching with abrasions
Grade 5: taneous mutilation with bleeding/scarring
Ursodeoxycholic acid (10 mg/kg twice a day)
Rifampicin (4–10 mg/kg/day)
Phenobarbitone (15–45 mg/day)
Naltrexone (0.1–0.5 mg/kg)
Ondansetron (0.1 mg/kg/three times a day to max 4 mg/dose)
Cholestyramine (1/3 to 1 sachet three times a day)

Conclusions

Cirrhosis secondarily affects nearly every system in the body, where the correlation might or might not be proportional to the severity of liver disease. Apart from managing complications of cirrhosis, it is essential to take care of general well-being of these children such as growth monitoring, immunization, vitamin supplementation, and their education. Though the functionality of end organs (brain, kidney, lungs, etc.) could revert back to normal or near normal after liver transplantation, advanced end organ damage might render a patient unfit to undergo liver transplantation. Anticipation of the complication and timely intervention would help in better outcome in these children.

Sara Mancell and Deepa Kamat

Introduction

The liver is the key organ in the production and distribution of nutrients, playing a central role in glucose homeostasis, protein synthesis, bile salt production, lipid metabolism, and vitamin storage. Chronic liver disease can disrupt these processes leading to malnutrition. Malnutrition is highly prevalent in children with liver disease and is associated with increased morbidity and mortality [2]. Potential causes of malnutrition include insufficient nutrient intake, increased nutritional requirements, impaired nutrient absorption, and altered metabolism. Nutrition strategies in children with liver disease are centered on managing these factors while promoting normal growth and development. Maintaining optimal nutrition in children with chronic liver disease may prevent further liver damage and improve outcomes post transplant [1].

In acute liver disease, if the presentation is rapid, children may be well nourished initially. The aim is to preserve nutritional status and manage complications such as hypoglycemia and hyperammonemia.

The nutrition management of liver disease caused by in-born errors of metabolism does not form part of this chapter.

Nutritional Management of Chronic Liver Disease

Causes of Malnutrition

The following table outlines the mechanisms of malnutrition (see Table 72.1).

Insufficient Nutrient Intake

Poor intake of nutrients may be due to nausea and vomiting, pruritis, taste changes associated with medications, unpalatable feeds, reduced gastric capacity, and discomfort due to ascites and organomegaly. With ascites, some degree of fluid and sodium restriction is usually required, and this can further reduce oral intake. In the hospital environment, intake may be affected by investigations or procedures or unpalatable hospital meals. There is some evidence that anorexia may be due to increased tumor necrosis factor or leptin [3].

Malabsorption

Malabsorption may be due to reduced bile flow, pancreatic enzyme deficiency, or mucosal edema. The result can be faltering growth and fat-soluble vitamin deficiency. Long-chain triglycerides (LCT) require emulsification by bile in the intestine, and therefore, the absence or reduction of bile flow leads to fat malabsorption. In some types of liver disease such as Alagille's syndrome, malabsorption may also be due to pancreatic enzyme insufficiency [4]. Finally, inflammation and mucosal edema in the small bowel due to portal hypertension may cause protein malabsorption [5].

Altered Metabolism

As liver failure progresses, the metabolism of carbohydrate, protein, and fat may be altered. There is a reduction in glycogen storage and an increased breakdown of fat and protein to meet energy demands alongside inefficient use of the substrates which are available [6]. The result is wasting of fat and lean body mass, hypoglycemia, hypoproteinemia, and hyperammonemia [7].

Increased Energy Expenditure

Children with end-stage liver disease have been shown to have a resting energy expenditure almost 30 % higher than controls [8, 9]. Increased requirements may be due to inefficient energy production due to altered metabolism, catabolic stresses such as infection or increased respiratory effort from ascites or organomegaly [6]. Greer et al. [9] suggest

Table 72.1 Causes of malnutrition

Causes of malnutrition	Contributing factors
Decreased nutrient intake	Nausea and vomiting
	Pruritis
	Taste changes
	Unpalatable diets/specialist feeds
	Reduced gastric capacity and discomfort from ascites or organomegaly
	Fluid and sodium restriction due to ascites
	Investigations and procedures interrupting meals or feeds
Malabsorption	Anorexia
	Absence or reduction of bile flow
	Pancreatic insufficiency
Altered metabolism	Mucosal edema due to portal hypertension
	Reduced glycogen storage
	Impaired gluconeogenesis
Increased energy expenditure	Increased fat and protein oxidation
	Stress factors such as infection
	Increased respiratory effort from ascites or organomegaly
	Increased metabolically active cells mass

that increased requirements may also be due to differences in body composition, with children with end-stage liver disease having less body fat and a higher relative proportion of metabolically active cells.

Management

Insufficient Nutrient Intake

Feeding strategies should take into account the often multifactorial causes of poor nutrient intake. When oral intake is significantly reduced because of persistent nausea or vomiting or the discomfort of pruritis or unpalatable feeds, supplemental tube feeding may be required. This can be given during the day as bolus feeds and/or as a continuous overnight infusion. Where there is ascites or organomegaly, high-energy, low-volume feeds may help with the problem of reduced gastric capacity. With ascites, a rigid sodium restriction is not recommended, but rather a general reduction in salty foods. In hospital, extended periods of nil by mouth and feeding interruptions due to investigations and procedures should be kept to a minimum, and every effort should be made to make meal times enjoyable.

Malabsorption

Where there is fat malabsorption, an energy dense diet is given combined with medium-chain triglyceride (MCT) supplementation. MCTs do not require emulsification with bile, diffusing easily into the intestinal cells, where they are absorbed directly into the bloodstream. There is little evidence regarding how much dietary fat should be MCT. MCTs are not a source of essential fatty acids (EFAs), and as the percentage of MCT increases it is more difficult to meet

requirements for EFAs. The European Society for Gastroenterology, Hepatology and Nutrition (ESPGHAN) guidelines are that infant formula should contain 4.5–10.8% energy as linoleic acid, and the ratio of alpha-linoleic:linolenic should be 5–15:1 [10]. The majority of feeds which are currently available in the UK provide approximately 50 % of the fat as MCT and meet requirements for EFAs (refer to Table 72.2). If an MCT feed with a particularly high MCT content, for example, Emsogen®, is used for a prolonged period of time, supplementing with a source of EFAs is warranted, for example, walnut oil supplemented at 1 ml/100 kcal. In cases where mucosal edema due to portal hypertension may be contributing to malabsorption, it may also be beneficial to give hydrolyzed protein to maximize absorption. Where there is a low stool elastase indicating pancreatic insufficiency, supplementation with pancreatic enzymes may be beneficial.

Altered Metabolism

Dietary strategies are centered on trying to preserve lean body mass, avoid hypoglycemia, and minimize hyperammonemia.

Preserving Lean Body Mass

To minimize catabolism, periods of fasting should be reduced so that an exogenous supply of nutrients is used in preference to body fat and muscle stores. This can be achieved by giving feeds or meals more frequently or using a feeding pump for continuous feeding. Studies have shown that supplementation with branched-chain amino acids (valine, leucine, and isoleucine) may help to improve nutritional status in liver disease [11]. As branched-chain amino acids are metabolized extrahepatically, they continue to be available for protein synthesis and as an energy substrate in liver fail-

MCT medium-chain triglyceride, BCAA branched-chain amino acids

ure. This may help to preserve muscle and fat mass. Mager et al. [12] showed that there is an increased requirement for BCAA even in children with relatively mild liver disease.

Avoiding Hypoglycemia

In addition to the above strategies, it may be necessary to increase the carbohydrate content of the feed to maintain blood sugars. This can be done by increasing the concentration of powdered formulas, using a high-energy feed or adding glucose polymers (refer to section “Achieving Increased Nutritional Requirements”). In older children, the inclusion of starchy carbohydrates and bedtime snacks may be necessary. Intravenous dextrose and close monitoring of blood sugars may be required, especially during periods of fasting or illness.

Managing Hyperammonemia

A major site of ammonia production is the large intestine, where protein is broken down by bacteria to produce ammonia. Ammonia is converted to urea in the liver, which is then excreted by the kidneys. In liver failure, this process is disrupted resulting in accumulation of ammonia in the blood. Exposure of brain tissue to toxic levels of ammonia leads to hepatic encephalopathy. A dietary protein restriction (2 g/kg protein) is often used initially as a way of reducing ammonia production in the gut [13]. A prolonged protein restriction is counterproductive as this leads to increased muscle breakdown, the by-product of which is ammonia [13, 14]. Furthermore, a severe protein restriction can worsen malnutrition in a group of patients whose baseline protein requirements are already higher than normal [15–17]. A randomized controlled trial comparing protein-restricted diets to normal

protein diets in a small group of adults found no difference in the course of encephalopathy between the two groups [18]. The main difference was increased muscle breakdown in the protein-restricted group. For these reasons, a protein restriction may be used initially but is not recommended long term as it may worsen encephalopathy and nutritional status [19].

Increased Energy Expenditure

Due to increased resting energy expenditure and nutrient malabsorption, energy and protein requirements for children with chronic liver disease are generally well above the estimated average requirement (EAR). Table 72.3 shows that children may need up to 160% of the EAR for energy and between 3 and 4 g/kg protein for adequate growth [15–17, 20, 21].

Estimations of energy and protein requirements are used only as a guide; requirements are calculated based on the individual, taking into account age, gender, nutritional status, disease state, and growth. Calculated requirements are not static and should be recalculated as part of monitoring procedures.

Achieving Increased Nutritional Requirements

In order to achieve nutritional requirements, it is usually necessary to increase the nutrient density of the diet. This can be done by increasing the concentration of powder-based feeds, supplementing the diet with high-energy sip or tube feeds, adding energy supplements to the diet, and increasing the nutrient density of meals and snacks.

Table 72.3 Energy and protein requirements for children with chronic liver disease [15–17, 20, 21]

	Infants	Older children
Energy	120–150 kcal/kg [15, 20]	120–160% of the EAR for age [15, 17, 20, 21]
Protein	3–4 g/kg [15, 16]	3–4 g/kg [17]

Concentrating Feeds

To increase the nutrient density of a powder-based formula, the concentration can be increased beyond the standard recommended dilution, usually in 2 % increments. For example, the concentration of Heparon Junior® could be increased in two stages from 18 to 22 % which would increase the energy from 86.4 to 105.6 kcal/100 ml. Feeds should be concentrated cautiously given that as the concentration increases so too do all the micronutrients and macronutrients, the renal solute load, osmolality, and the risk of osmotic diarrhea. When concentrating feeds, explicit instructions should be provided to the carers to avoid errors when making up feeds.

Supplementation with High-Energy Sip or Tube Feeds

Nutrient dense feeds can be given orally or via feeding tube. Not all of the feeds provide complete nutrition; some supplements contain no fat (e.g., Fortijuce®) or incomplete micronutrients (e.g., Scandishake®) and should be given alongside a balanced diet. See Table 72.4 for examples of standard high-energy sip and tube feeds.

Energy Supplementation

The addition of nonprotein energy to the diet can affect the overall balance of a feed or meal. When adding energy, it is important to maintain a protein:energy ratio of between 7.5 and 12 % for infants and between 5 and 15 % for older chil-

dren [22]. Energy can be added in the form of glucose polymers, fats, or a combination of the two (refer to Table 72.5). These supplements are usually added in 1 % increments and increased daily depending on tolerance. As a guide, the total carbohydrate concentrations recommended are 10–15 % for infants and up to 30 % in older children. For fat, recommendations are 5–6 % for infants and 7 % for older children [22].

Increasing the Nutrient Density of Meals and Snacks

In order to increase the nutrient density of the diet, foods which are high in energy and protein should be recommended, but without compromising the overall balance of the diet. The energy density of meals can be further increased by adding high-energy products such as cheese, butter, oil, and cream.

Fat-Soluble Vitamin Supplementation

Due to the effects of cholestatic liver disease and resulting malabsorption, the requirements for fat-soluble vitamins are higher than the standard recommended nutrient intake (RNI) for age and should be supplemented. Table 72.6 shows how fat-soluble vitamins are supplemented at the authors' institution. It should be noted, however, that these are suggested starting doses, and prescribed amounts should be adjusted

Table 72.4 Examples of high-energy sip and tube feeds

Feed per 100 ml	Age (years)	Weight (kg)	Complete nutrition?	Energy (kcal)	Protein (g)	Fat (g)

MCT Duocal®	497	72	23.2	0	75% medium-chain triglycerides

Table 72.6 Fat-soluble vitamin supplementation

Vitamins	Infants	Children over 1 year
A and D	Abidec or Dalivit 0.6 ml/day May have additional oral or intramuscular vitamin D	Abidec or Dalivit 1.2 ml/day Forceval 1 capsule/day (if over 12 years of age) May have additional oral or intramuscular vitamin D
E	10 mg/kg (up to maximum starting dose of 100 mg/day)	100 mg/day
K	1 mg/day	2 mg up to 10 mg/day

according to serum levels of fat-soluble vitamins. If serum vitamin levels are particularly low, then they may be given intramuscularly.

Nutritional Assessment and Monitoring

The nutritional assessment and monitoring of patients with liver disease is essential, in order to assess requirements as well as to evaluate progress. A dietetic assessment should include not just the current situation but any relevant history. It should be carried out at regular intervals to take account of changes in clinical status, anthropometry, nutrient intake, activity levels and social factors.

Dietary Assessment

A full assessment of dietary intake should be undertaken at baseline, including current and previous intake, and should indicate quantity and quality of the diet. Current intake can be ascertained by way of a 24-h dietary recall which will provide a retrospective snapshot of recent intake. Other methods include requesting parents or carers to complete a food diary at home prospectively over several days. However, as this is not always practical a 24–48-h dietary recall is preferentially used; it is straightforward and can be carried out instantaneously in both the inpatient and outpatient setting. Dietary software to calculate macro- and micronutrient provision is available, allowing values to be compared to requirements. As part of the assessment, cultural and social factors should be taken into account; for example, dietary restrictions for religious reasons or financial constraints impacting on food choice. It is important to also take into account any problems which may impact on intake such as nausea and vomiting, diarrhea, pruritus, and issues such as early satiety arising from ascites and organomegaly. The patient's clinical picture should also be considered as part of the assessment, namely the diagnosis as well as the progression of liver disease which may thus involve a change in dietetic intervention.

Anthropometry

Monitoring of anthropometry is vital. Measurements should be done at baseline, and then regular and ongoing monitoring should be carried out, with the frequency dependent on the severity and degree of liver disease.

Height/Length Faltering length/height may indicate problems with long-term chronic malnutrition. Lengths should be measured in children under 2 years using a length board and over 2 years using a stadiometer. These should be plotted on age/gender appropriate growth charts. Certain liver conditions (e.g., Alagille's syndrome) predispose the child to short stature, with height-for-age *z* scores often being low.

Weight Regular weights are useful. However, caution must be exercised when interpreting weights in those patients with organomegaly and/or ascites. Abdominal girth can be useful to indicate the presence of ascites especially where weights are fluctuating. Infants should be weighed naked and older children with no shoes and light clothing. Weights should be plotted on age and gender appropriate growth charts.

Head Circumference Serial measurements of head circumference in patients under 2 years are useful indicators of long-term nutritional status. Measurements should be plotted on age and gender appropriate growth charts. Measurements should be made with a non-stretchable tape measure and taken around the forehead and above the ears.

Mid-Upper Arm Circumference Serial measurements of mid-upper arm circumference (MUAC) are a good indication of fat and muscle stores and are a sensitive marker of malnutrition. Measurements should be plotted on appropriate growth charts available for children between 3 months and 5 years [23]. In children over 5 years, assessment of nutritional status is made by way of regular, serial measurements due to the current lack of age-appropriate growth charts. The measurement should be conducted on the same arm, with the patient preferably standing (or seated in a lap). The midway point from the acromion process to the olecranon process should be marked and the circumference measurement taken around the point with a non-stretchable tape measure (to the nearest 0.1 cm). Serial measurements taken by a single observer are important to avoid interobserver errors.

Triceps Skinfold Thickness This differentiates fat from muscle stores and is a good marker of medium to long-term nutritional status. Measurements are taken by way of callipers which are used to measure subcutaneous adipose tissue at the triceps commonly (though other sites can also be accessed e.g., subscapular). When measuring the triceps,

the midway point from the acromion process to the olecranon process should be marked. At this point, a fold of skin and subcutaneous tissue should be picked up and grasped away from the underlying muscle, and the jaws of the caliper applied at the marked spot [24]. Serial measurements taken by a single observer are important to avoid interobserver errors. Practically, skinfold thickness can be challenging to measure unless the child is cooperative.

Methods of Feeding

Oral Feeding

All children should be encouraged to feed orally where possible, particularly in infancy when infants need to learn to suck, swallow, and chew as part of normal feeding development. Several factors can predispose children to behavioral feeding problems including vomiting, tube feeding [25] and extended periods with no oral feeding, all of which may occur with chronic liver disease. With infants, particularly those with end stage liver disease awaiting transplant, it is especially important to encourage age-appropriate weaning practices, to avoid missing the 'window of opportunity' to introduce tastes and textures. This can be especially difficult when there is ascites or organomegaly or when the child is being tube fed. The emotional and social benefits of eating and drinking for the child and family should not be overlooked and should be encouraged, even if only a fraction of nutritional requirements are taken orally.

Tube Feeding

Tube feeding may be required in children who are unable to take sufficient nutrition orally. Nasogastric (NG) tube feeding has been associated with improved body composition in children with liver disease [26, 27]. Tube feeding may have a positive impact on quality of life as it can remove the pressure on both the child and family to meet requirements orally. The tube can be used to administer unpalatable feeds and medicines, and continuous or frequent feeds can minimize periods of fasting, thus helping to maintain blood sugars and preserve body stores. Where possible, some degree of oral feeding should be continued, as discussed above, even if full nutritional requirements are being met by tube feeding.

Gastrostomy feeding is preferred in children with long-term feeding problems but is rarely possible in children with chronic liver disease. Portal hypertension and intra-abdominal varices increase the risk of bleeding during placement of the tube [28] while ascites may prevent adequate tract formation around the gastrostomy [28]. Gastrostomy feeding has

been used successfully in children with no portal hypertension, varices, or ascites [29]. Where gastrostomy placement is indicated, it should be a decision undertaken by the multidisciplinary team.

Parenteral Nutrition

Due to the risks of parenteral nutrition (PN) worsening liver function, PN should only be used when it is not possible or effective to feed enterally [13]. For example, PN may be used when NG placement is not possible (e.g., due to large, bleeding varices) or where there is significant and persistent malabsorption impacting on growth. Sullivan et al. [30] found that PN improved nutritional status in malnourished biliary atresia patients awaiting liver transplant, although there was a more rapid progression of cholestasis. It was thought that this progression may have been reduced by the use of omega-3 lipid sources rather than the soy-based lipids used in this study.

The Management of Common Liver Conditions

Conjugated Hyperbilirubinemia

Infants presenting with conjugated jaundice will generally require a formula containing a proportion of the fat as MCT. If galactosemia is suspected or has not been excluded, breast feeding should be stopped and replaced with an MCT-rich feed containing only trace amounts of galactose (e.g., Pregestimil®). The mother should be encouraged to express breast milk as it is usually possible to restart breast feeding once galactosemia is excluded. It should be noted that if Pregestimil® is used in preterm infants, additional iron and folate may be required.

If cholestasis persists with accompanying symptoms of malabsorption and suboptimal growth, supplementation with MCT will continue to be required. This can be given as the fat emulsion, Liquigen® (2–5 ml with every breast-feed) or as an MCT-rich formula (e.g., Pregestimil®, Heparon Junior®) alongside breast feeding. If jaundice is persistent and growth is poor, the latter option is preferred, and the percentage of specialist formula compared to breast milk will need to be increased. At the authors' institution, the initial target is generally two-third specialist formula to one-third breast milk. Parents should be given the option of how they would like to administer feeds, taking into consideration practicalities and home life. The specialist formula can, for example, be given prior to each breast-feed, or formula feeds can be alternated with breast-feeds.

Extrahepatic Biliary Atresia

Infants often present feeding excessively, due to malabsorption but with satisfactory weight gain initially. The nutritional intervention at the authors' institution is as described above for conjugated jaundice. Following the Kasai procedure, an MCT-rich feed is introduced at around day 3 and then slowly increased to meet requirements by day 5. The infant may be able to start some breast feeding additionally, but the majority of the infant's nutrition provision should come from the MCT formula. Satisfactory feeding should be established whilst in hospital and the infant discharged with a regime that is practical and manageable at home. Following discharge, growth should be carefully monitored (as described above), and the volume and concentration of the feed should be altered accordingly. Close monitoring is particularly important for infants with biliary atresia given that at least 50 % are likely to receive a transplant in the first 2 years of life [31] with a further 20–30 % likely to eventually require a transplant later in life [30]. When the infant is ready to be weaned, standard weaning practices are advised, with age-appropriate solids. At the authors' institution, infants generally remain on an MCT formula until at least 6 months post Kasai. A review by Davenport et al. [32] showed that 57% of infants had cleared their jaundice by this time. If jaundice has cleared at this milestone, the MCT formula can be discontinued and replaced with a standard or high-energy formula. If jaundice persists, the infant should continue on an MCT-containing formula.

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) exists as a spectrum ranging from benign hepatic steatosis to more aggressive forms that can potentially progress to cirrhosis in childhood [33]. It is the most common liver abnormality in the pediatric population [34]. The aims of management are to correct the associated metabolic abnormalities, for example treating insulin resistance, reducing visceral obesity, and treating oxidative stress [35]. Treatment of NAFLD remains largely challenging. At present, weight reduction and, in particular, reduction in central obesity through dietary modifications and physical activity are the cornerstone of management. A prospective study involving 84 pediatric patients (aged 3–18.8 years) with raised transaminases and biopsy-proven NAFLD, who underwent a 12-month diet and lifestyle program, demonstrated a significant reduction in BMI, fasting glucose levels, insulin, lipids and liver enzyme activity, and a reduction in liver echogenicity on ultrasound [33]. Several trials have been conducted using pharmacologic approaches such as vitamin E to reduce oxidative stress; ursodeoxycholic acid which has cytoprotective, immunomodula-

tory, and antioxidant properties, and metformin which counters insulin resistance [36, 37]. At present, however, lifestyle changes remain the mainstay of treatment.

Wilson's Disease

Wilson's disease is an autosomal disorder of copper metabolism and may present at almost any age. Copper accumulates in the liver during childhood but may also deposit in other parts of the body such as the brain, eyes, joints, and kidneys. Treatment is primarily through chelating agents that bind dietary copper for excretion. Foods with very high concentrations of copper such as offal, shellfish, nuts, dried fruit, chocolate, and mushrooms may also need to be avoided [38].

Progressive Familial Intrahepatic Cholestasis

Progressive familial intrahepatic cholestasis (PFIC) refers to a group of autosomal recessive disorders that interfere with the secretion of bile and often present in infancy with cholestasis of hepatocellular origin [39, 40]. The major problem from a nutritional point of view is fat malabsorption, necessitating MCT supplementation. Poor intake and appetite may also occur as a result of intractable pruritis. Short stature is also characteristic of the disease, though can improve following liver transplantation [41]. If oral intake is suboptimal, nutrition support via NG tube should be initiated, and if long-term feeding is required, gastrostomy insertion should be considered.

Alagille's Syndrome

Alagille's syndrome can be particularly challenging with regard to nutrition. It is characterized by cholestasis and malabsorption, poor growth, with low height-for-age *z* scores and low weight-for-age *z* scores, fussy eating, intractable itching, and renal acidosis [42, 43]. As mentioned previously, it has generally been thought that a certain proportion of patients with Alagille's syndrome are affected by pancreatic insufficiency [4] although data from a recent study suggested that pancreatic insufficiency is not a clinically significant issue in Alagille's syndrome [44]. The nutritional management is aimed at treating the symptoms of cholestasis, as described above for conjugated jaundice. When the infant is ready to be weaned, standard weaning practices are advised. Intervention through specialist feeding clinics may be beneficial to address fussy eating. As described with PFIC, supplementary nutrition support via NG tube or gastrostomy is often the only means for optimal nutrition provision. Oral nutrition support in older children may be instigated through

optimizing the energy and protein content of the diet or the use of nutritional supplement drinks.

Parenteral-nutrition-associated Liver Disease

Parenteral-nutrition-associated liver disease (PNALD) is a risk of long-term PN and can progress from cholestasis to fibrosis and cirrhosis. Other risk factors include prematurity, short bowel syndrome, sepsis, intestinal bacterial overgrowth, and a lack of enteral nutrition [45]. Strategies to reduce the risk of PNALD include early implementation of enteral feeding, a specialized, multidisciplinary approach, and techniques focused on avoiding sepsis [46]. The use of the lipid formulation SMOF (soybean oil, MCT, olive oil, fish oil) in place of soybean oil has been a significant advance and has been shown to reduce PN-related cholestasis [47, 48].

Liver Transplantation

Feeding post transplant usually starts within the first 3–5 days. As many children have moderate-to-severe faltering growth at the time of transplant [49], high-energy feeds are usually started and gradually increased over 1–2 days. The aim is to achieve catch-up growth. Catch-up growth is usually seen in the 2 years following transplant, although children may achieve a final height below their genetic potential [50]. Where a child may have been well nourished prior to transplant and was eating and drinking normally, high-calorie milk feeds may not be necessary and foods may be gradually increased over the next few days. Where there are gastrointestinal complications (e.g., bowel perforation) or severe undernutrition at the time of transplant, PN may be commenced. In most cases, children are fed via NG tube until oral feeds can be established. Preexisting behavioral feeding difficulties are common and may mean that tube feeding continues for an extended period. In cases where children are fed via gastrostomy and are likely to require tube feeding post transplant, the aim may be to keep the gastrostomy in situ. This is, however, often not possible due to the increased risk of complications described previously. If oral intake prior to transplant was established, a normal diet for age is often achieved relatively quickly.

Following liver transplant, Seville oranges and grapefruit should be avoided as they interfere with immunosuppressant medication [51]. Where infants are breast-fed post transplant, the breast-feeding mother should also exclude these items from the diet. It is important to adhere to food safety guidelines and avoid foods that may contain bacteria such as listeria, *Escherichia coli*, or salmonella as there is an increased vulnerability to food poisoning when on high-dose

immunosuppressant medication. The following foods should be avoided: unpasteurized milk and cheese, soft cheese such as feta, Brie and Camembert, live yoghurt, pâté, foods containing raw egg, raw fish, shellfish, unwashed salads, and deli meats.

Chylous Ascites

Chylous ascites is a potential complication post liver transplant. It occurs as a result of damage to the lymph vessels during surgery and results in a loss of chyle, a milky, triglyceride-rich fluid, into the peritoneal cavity. Posttransplant, this is often evident in the intra-abdominal drain. Current treatment for chylous ascites is the dietary restriction of LCT, the aim of which is to reduce the flow of lymph in the disrupted lymphatic system. Dietary restriction generally lasts for no more than 3 weeks. For infants solely formula fed, Monogen® containing 80% MCT is the feed of choice. This should be supplemented with walnut oil to meet EFA requirements. If solids are given, they should be low in LCT. For older children, if supplementation is indicated alongside the low LCT diet, MCT fat emulsions such as Liquigen® or MCT Oil® can be used to provide extra calories or fat-free supplements such as Fortijuce® or Paediasure Plus Juce® can be given.

The Nutritional Management of Acute Liver Failure

As with chronic liver failure, acute liver failure (ALF) can result in impaired glycogen storage and gluconeogenesis with protein and fat stores broken down to meet energy demands. The catabolic effect is increased by a rise in insulin and glucagon, driving the need for gluconeogenesis to maintain blood sugars [52]. A further problem, particularly in infants, is that there can be a delay in determining the diagnosis. Metabolic disorders are a frequent cause of ALF and require specific dietary therapy to prevent accumulation of toxic by-products. The ideal dietary therapy cannot begin until the diagnosis is determined. Management is based on preventing hypoglycemia (as discussed previously), managing metabolic disturbances such as hyperammonemia (as discussed for CLD) and maintaining nutritional status.

Summary

Optimal nutrition support which is tailored to the individual and responsive to the changing clinical picture is essential for children with liver disease. Nutrition therapy should focus not only on correcting nutritional deficits and man-

aging the complications of liver disease but also promoting normal growth, development, and quality of life.

Introduction

Liver transplantation (LT) continues to be the only effective treatment for children with end-stage liver disease. Thomas Starzl performed the first liver transplant in a child in March 1963 [1]; however, it was not until 1967 that he reported the first recipient with significant survival. Following his early series of seven children aged between 13 months and 16 years [2], more than 15,000 pediatric liver transplants have been carried out in the USA and 10,000 in Europe, with 3- and 5-year survival of 80 and 75%, respectively. There have been continued improvements in all aspects of care of the child with liver disease coming to LT including surgical, anesthetic, intensive care, and postoperative management. The large numbers of recipients currently surviving beyond 15 years are informing clinical practice and providing more information for families currently facing transplantation. As the majority of children are transplanted at a young age and have little memory of the events surrounding their transplant continuing patient and family education are increasingly recognized as important. There has been a change of emphasis in care from a focus on survival to long-term outcomes centered on well-being, psychosocial and physical development, and educational attainment. It is clear that adolescence and transition to adulthood and follow-up within an adult environment pose further significant challenges, and late death due to non-adherence to medication and follow-up are significant problems. The emergence of models of care to manage these challenges will hopefully help lead to further improvement in long-term outcomes. In addition, the timing of transplant and its influence on subsequent development and outcome is coming under increasing scrutiny.

Pre-transplant

Historically, children have been listed for LT based on criteria adopted from adult experience. However, children present with a different spectrum of diseases, with two thirds of children coming to LT in the first 5 years of life, and consideration has to be given to emotional, social, intellectual, and physical development. The timing of LT has to be considered with the long-term development of the child in mind, and there remains a lack of data regarding this topic.

Indications for LT

LT should be considered for any child with end-stage liver disease with a predicted prognosis of less than 18 months. Indications for LT are in general derived from adult liver transplant experience, but are modified for children and include:

- Liver decompensation (prolonged international normalized ratio (INR), low serum albumin, ascites)
- Disordered metabolism (jaundice, loss of muscle mass, osteoporosis)
- Portal hypertension (variceal bleeding, intractable ascites)
- Encephalopathy
- Spontaneous bacterial peritonitis
- Hepatopulmonary syndrome
- Pulmonary hypertension
- Recurrent cholangitis and intractable pruritus
- Quality of life (failure to growth, poor concentration, lethargy)
- Tumors

Extrahepatic biliary atresia (BA) is the most common indication for LT and accounts for 40–50% of cases listed worldwide. Other common causes include metabolic disorders, tumors, and acute liver failure (ALF). The majority of pediatric recipients under 2 years old have cholestatic diseases, particularly BA, which accounts for 74% of cases

Hospital FT NHS Trust, Denmark Hill, London SE5 9RS, UK
e-mail: nigel.heaton@nhs.net

in this age group. Metabolic disorders and ALF are less common indications and account for 9% each of the overall number [3].

Chronic Liver Diseases

Biliary Atresia

Extrahepatic BA is a destructive inflammatory obliterative cholangiopathy that affects the intrahepatic and extrahepatic bile tree. Type 3 BA is the most frequent form of the disease accounting for 90% of cases and is the most severe form with a solid porta hepatis, microscopic ductules, and a solid gallbladder or mucocele [4]. The majority of children coming to transplant have undergone Kasai portoenterostomy (KP) within the first 3 months of life. Early portoenterostomy and expertise of the multidisciplinary team have a significant impact on outcome and the need for LT in early life [5, 6]. The results of concentrating expertise in a small number of centers each performing more than five cases per year have led to a 4-year survival with the native liver intact of 41–51% and an overall survival of 87–89%. More recently, survival of 96% at 10 years has been reported for the UK with an integrated program of KP and LT [4]. Mortality is distributed equally between deaths on waiting list for liver transplant and in the post-transplant period. By the age of 18 years, approximately 80% of children with BA will have been treated by LT. Outcomes have been reported for 5- and 10-year actuarial graft and patient survival of 76.2 and 72.7% and 87.2 and 85.5% for cadaveric [7] and 84.9 and 76.6 and 86.7 and 80.8% for living donor LT (LDLT) [8], respectively.

The majority of young children (under 5 years of age) with BA will come to transplant with jaundice and synthetic failure. In a small number of children (6% of cases), acute decompensation secondary to ischemic hepatitis may occur following a viral illness or infection. Children at risk of ischemic hepatitis and liver decompensation are those with a hepatic artery resistance index of greater than one on Doppler ultrasound who are dependent on arterial inflow [9]. Children older than 5 years of age may present with failure to grow and a falling serum albumin (synthetic failure), but without jaundice. Adolescents coming to transplantation will invariably have portal hypertension as a dominating feature, which in association with adhesions from previous surgery can make for a difficult surgical challenge.

Congenital anomalies associated with “syndromic” BA (15% of all cases) include polysplenia/asplenia, absent inferior vena cava (IVC), portal hypoplasia, preduodenal portal vein (PV), malrotation, and situs inversus and may complicate surgery and influence graft choice.

Cholestatic and Metabolic Disorders

Cholestatic liver diseases excluding BA account for 10% of liver transplants in children. These include Alagille syndrome, progressive familial intrahepatic cholestasis

(PFIC), and sclerosing cholangitis. LT is often used to treat symptoms, such as severe pruritus. Children with Alagille syndrome are at risk of growth failure and morbidity from pruritus, xanthomas, and complications of vitamin deficiency. PFIC defines a group of disorders characterized by chronic, unremitting cholestasis and autosomal recessive inheritance with a shared pattern of biochemical, clinical, and histological features. LT is reserved for those with severe symptoms including pruritus or progressive liver disease. Earlier transplant may lessen future growth and developmental impairment in some, but not all of these conditions [10]. In Alagille syndrome, the biliary hypoplasia is associated with other congenital malformations, the most important of which is pulmonary artery stenosis. This needs to be assessed preoperatively due to the risk of mortality post reperfusion if cardiac output is limited by the pulmonary stenosis. Dobutamine stress testing has been used to identify at-risk children who are unable to increase their cardiac index by 50%.

Inborn errors of metabolism, collectively as a group, form a relatively common indication for LT accounting for 9 and 26% of children under and over 2 years of age at the time of transplant, respectively. Metabolic diseases resulting in cirrhosis include alpha-1-antitrypsin deficiency, tyrosinemia, Wilson’s disease, neonatal hemochromatosis, respiratory chain disorders, fatty acid oxidation defect, glycogen storage disease type IV, among many others. Metabolic diseases without structural liver disease include Crigler–Najjar syndrome type 1, glycogen storage disease type 1, propionic acidemia, primary hyperoxaluria type 1, hereditary tyrosinemia, factor VII deficiency, ornithine transcarbamylase deficiency, familial hypercholesterolemia, and protein C deficiency. Two series from the USA from the Scientific Registry of Transplant Recipients (SRTR) of 551 transplants [11] and Europe from King’s College Hospital of 112 transplants reported excellent outcomes for this group [10]. Although the presence of cirrhosis did not appear to be a risk factor for worse outcomes, recipient black race, simultaneous organ transplantation, ALF, hospitalization before transplant, and age less than or equal to 1 year were predictors. The study from Sze et al. reported 11 auxiliary liver transplants (ALTs) with similar outcomes to whole liver replacement for noncirrhotic liver disease with an absent enzyme/gene product such as Crigler–Najjar type 1 [10].

Tumors

LT for liver tumors in children accounts for 2–6% of all cases in European and American series. The most common indication is unresectable hepatoblastoma (following appropriate chemotherapy). Other tumors treated by LT include hepatocellular carcinoma (HCC), hemangioma, infantile hemangioendothelioma, and epithelioid hemangioendothelioma. Angiosarcomas should not be transplanted as they invariably recur early. However, differentiation from more benign vascular tumors can be difficult. Clinical fea-

tures such as pain, rapid deterioration, or disease progression indicate sarcoma. The outcome of LT for unresectable hepatoblastoma is excellent with long-term patient and graft survival rates for cadaveric transplantation of 91, 77.6, and 77.6% at 1, 5, and 10 years, respectively [12]. Patient and graft survival for children undergoing LDLT is 100, 83.3, and 83.3% at 1, 5, and 10 years, respectively. Two North American series of 25 (HCC, 10 cases; hepatoblastoma, 15 cases) and 12 patients (HCC, 6 cases; hepatoblastoma, 6 cases) reported similar medium- and long-term survival rates for both tumors [13, 14]. Salvage transplantation for recurrent hepatoblastoma after conventional liver resection is less satisfactory with 5-year survival of 40% with a high rate of further recurrence. An analysis of the United Network for Organ Sharing (UNOS) data of 336 patients with liver tumors which included 237 hepatoblastomas, 58 HCC, and 35 hemangioendotheliomas noted that patient survival for the latter was inferior to that of hepatoblastoma (5-year survival of 72%) and rare liver tumors (5-year survival of 78.9%), but better than HCC (5-year survival of 53.5%) [15]. Tumor recurrence was the major cause of death in hepatoblastoma and HCC, but not in hemangioendothelioma.

The development of HCC has been reported in BA, Alagille syndrome, and progressive intrahepatic cholestasis. Children with tyrosinemia have a high risk of HCC before 2 years of age which appears to be markedly reduced by the use of 2-(2-nitro-4-(3-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NBTC) therapy [16]. For HCC, there are no criteria for selection comparable to the Milan criteria in adult patients. Macrovascular invasion continues to be a contraindication.

Acute Liver Failure

ALF is defined by the onset of severe impairment of liver function in the absence of previous liver disease. Coagulopathy is always present, but in young children hepatic encephalopathy may be absent and is a late feature associated with a poor outcome. ALF is an indication for LT in 9% of under and 16% of over 2 years old in Europe and 15% of children in the USA. The cause of ALF cannot be determined in the majority of children (49% of all children and 54% of those aged 1 year) [17]. Other causes include metabolic, paracetamol intoxication, autoimmune hepatitis (AIH), viral hepatitis, drugs, Wilson's disease, and vascular and Amanita phalloides poisoning. The risk of death or LT is highest in children under 3 years of age. Logistic regression analysis has identified total serum bilirubin > 5 mg/dL, INR > 2.55 , and hepatic encephalopathy as risk factors for death or LT. Of note, grade IV hepatic encephalopathy on admission was associated with higher rate of spontaneous recovery than those children who progressed to grade IV during the course of admission (50 vs. 20%). Indications for LT are different from adults and an INR > 4 (in the absence of dis-

seminated intravascular coagulopathy) identifies the at-risk population.

Two recent series reported 5-year patient survival of 70% in children with ALF [18, 19]. Farmer et al. identified four factors which predicted graft or patient survival in 122 children with ALF which included creatinine clearance (cCrCl) < 60 mL/min/1.73 m (graft and patient), pediatric end-stage liver disease (PELD) > 25 (graft), recipient age < 24 months (graft), and time from the onset of jaundice to encephalopathy < 7 days (patient) [18]. The presence of two or more of these factors was associated with a significant reduction in graft and patient survival to about 25–40%. Other series have also noted lower graft survival in children aged less than 2 years with ALF possibly reflecting technical challenges in small babies [20]. This population is the most challenging group, and further improvements in perioperative surgical and intensive care are needed to make progress.

ALF in neonates is a rare but often fatal event characterized by a failure of synthetic function with coagulopathy. Hepatic encephalopathy is a late event and difficult to diagnose in infants [21]. Causes of ALF in neonates include metabolic, infectious and hematological disorders, congenital vascular/heart abnormalities, and drugs. Congenital hemochromatosis is the commonest indication and the challenge is to provide a graft in time. Neonates and young children with ALF should only be treated in specialized pediatric hepatology centers with facilities for LT which continues to be the only therapeutic option with a long-term survival of over 60%.

Timing of Transplantation

The timing of LT in children has been based on criteria established in adults and thus is focused on graft and patient survival. Optimal timing was viewed as listing for LT when expected survival was less than 2 years. Children with liver disease may not develop physically, intellectually, and socially at a time of deteriorating liver function, and the timing of transplant needs to take this into account. There is general agreement that KP should be performed for BA and that LT is reserved for those who develop progressive liver disease (apart from rare cases of late presentation > 4 months).

The model for end-stage liver disease (MELD) was introduced in 2002 as a response to increasing waiting list mortality. It provides a means of allocating livers based on likelihood of dying while on the waiting list. PELD was a similar mathematical tool based on data derived from the Studies of Pediatric Liver Transplantation (SPLIT) research group using bilirubin, INR, serum albumin, age > 1 year, and growth [22]. The introduction of MELD (and subsequently PELD) significantly decreased death or removal from the waiting list for being too sick within 2 years for both adults and children [23]. Cowles et al. [24] in reviewing a cohort

of 71 children transplanted for BA (61, KP before LT; 10, primary LT) considered that PELD monitoring identified those in need of transplantation. Children with a PELD greater than 12 ($n=47$) had a higher rate of post-LT mortality and retransplantation than those with a PELD of 10 or less. The authors suggested that a PELD score approaching 10 should trigger discussion of LT. PELD is the only scoring system currently used in children and although helpful in advanced liver dysfunction; it is of limited value in the very young (under 1 year of age) and in older recipients, particularly with complications such as recurrent cholangitis, severe portal hypertension, pulmonary hypertension, and hepatopulmonary syndrome [25–29]. Because of these limitations, PELD use has been largely restricted to North America. More research is needed to define optimal timing of transplantation in children to gain most benefit in terms of survival, growth, and intellectual and social development.

Intraoperative

Whole LT

Whole liver replacement is relatively uncommon in children under 5 years of age at the present time. Above the age of 5 years, it is more common. The transplant involves excision of the diseased liver, by division of the common bile duct (or Roux loop if there has been previous biliary surgery), hepatic artery, PV, and IVC above and below the liver. Orthotopic liver replacement is accomplished by anastomosis of the corresponding structures with the donor liver and achieving hemostasis; the alternative is the use of the piggyback technique. Management of intraoperative coagulopathy is an essential component of the operation. The technique is very similar to adult LT, but the smaller size of the vascular structures demands a more refined surgical technique, especially for arterial reconstruction. The use of cell salvage has led to bloodless surgery becoming a practical proposition. Closure of the abdomen should only be performed if there is no risk of graft compression.

Partial Liver Grafts

The use of partial grafts was the solution to both organ shortage and size restriction in children. In Europe, more than 10,000 LT have been performed in recipients under 16 years old. Of these, approximately 38% have been performed with whole organs. Partial grafts account for 80 and 52% of all LT performed among patients aged 0–2 and 2–15 years old, respectively. Early experience was with reduced-size grafts, either left lobe or left-lateral segment (LLS) which then led onto to split and LDLT with both techniques being incor-

porated into routine clinical practice from 1991 onwards. Roberts et al. analyzed the data of 6467 LTs performed in patients under 30 years old from the SRTR–Organ Procurement and Transplantation Network (OPTN) database [30]. It was noted that patient and graft survival during the first year after transplant for each donor graft type varied according to the recipient age group. For children of 2 years and under, living donor (LD) grafts had a 51 and 30% lower relative risk (RR) of graft failure than deceased donor split (DD-S) and deceased donor full (DD-F), respectively. A similar difference in mortality risk in the same group of age favored recipients of LD grafts over DD-S (RR=0.71, $p=0.08$). Recipients in the 0–2-year age group had higher risk of mortality and graft failure with DD-S livers than DD-F livers (RR=1.31, $p=0.04$ for mortality; RR=1.42, $p<0.001$ for graft failure). For patients aged 2–10 years, the RRs of mortality and graft loss were higher after LD than after DD-F (RR=1.78, $p=0.02$ for mortality; RR=1.53, $p=0.02$ for graft loss) but not after DD-S. In the 11–16-year age group, a significantly higher RR of graft failure was observed after LD than after DD-F transplant (RR=3.63, $p=0.0001$) or DD-S transplant (RR=2.87, $p=0.02$), although mortality risks were similar for all three donor graft types. Subsequent publications have confirmed the excellent outcomes with LDLT in young children, but published experience with children over 12 years of age remains limited outside of India and the Far East.

Publications of outcomes of LLS reduced-size LT tend to be from the early 1990s, and there are few direct comparisons with those observed after split LT (SLT). SLT has become an established technique which has successfully addressed organ shortage in children while preserving the pool of liver grafts for adults. A recent study of 251 LTs, which included 138 reduced and 30 split, reported 1-year patient and graft survivals that were comparable at 73 and 67%, respectively [31]. In addition, no differences in vascular complications were observed. Of note, biliary complications were significantly more common after split when compared with reduced-size grafts (21 vs. 4%, $p<0.0001$). The most common biliary complication after SLT was late stricture, in contrast to reduced-size LT (RLT), which was a cut-surface bile leak. Patients undergoing SLT had a 6.7-fold increased risk of biliary complications compared to those receiving an RLT; however, these complications did not appear to impact on graft or patient survival. A further series from the University of California Los Angeles (UCLA) has compared the outcome of whole and partial grafts in both adult and pediatric recipients [31]. Of 442 LTs, 284 were whole, 109 were split-LLS (SL-LLS), and 49 were LD-LLS. The 10-year patient survival for children was similar for all graft types. Multivariate analysis confirmed that history of previous LT and SL-LLS was independent predictors of reduced survival. Chronic rejection and hepatic artery thrombosis were the most common reasons for graft loss. The largest

study from Hong et al. of outcomes after partial liver grafting in children analyzed data from the SPLIT registry and compared the outcome of each variants with that of whole organ transplantation (1183 whole, 261 split, 388 reduced, and 360 live donor (LDLT)) [32]. There was a clear difference in outcomes at 1 year (W, 93%; R, 82%; S, 87%; L, 89%) and 4 years (whole liver transplantation (WLT), 89%; RLT, 79%; SLT, 85%; LDLT, 85%) after transplant. However, the groups were not strictly comparable in terms of era of transplant, recipient selection, and center. Children receiving a technical variant waited on average 2.3 months less than those receiving a whole liver and tended to be younger. Complications were significantly higher after partial grafts: At 24 months, the incidence of biliary complications was WLT, 17.3%; SLT, 28.5%; RLT, 25.3%; LDLT, 40.1% and vascular complications were WLT, 16.5%; SLT, 23.8%; RLT, 23.5%; LDLT, 24.4% [33].

Trying to understand and balance the increased opportunity of being transplanted against the higher incidence of complications and potential graft loss associated with SLT is difficult. Merion et al. tried to address this issue by comparing the predicted lifetimes for SLT for an adult and a child recipient with WLT for an adult to determine the best use of this limited supply of organs [34]. They analyzed mortality risk for 48,888 patients on the waiting list: 907 SLT and 21,913 WLT recipients (between 1995 and 2002). Of 23,996 donor livers used for transplantation, 533 were split. Donors aged 10–39 years comprised 81.6% of split livers and 48.5% of livers used for WLT. Only 11.8% of livers that were split were from donors older than 40 years. They analyzed years gained per SLT performed against the waiting list death ratio and concluded that “the potential annual net gain in life years could be as high as 169 patient-years in the first 2 post-transplant years, if all livers meeting accepted criteria were used for splitting.” For every 100 donor livers, an extra 11 years of life were predicted over the first 2 years of follow-up if organs were split rather than transplanted whole. In addition, they identified a significant survival benefit for pediatric recipients of SLT compared with children continuing on the waiting list and concluded that it could provide enough organs to satisfy the entire current demand for pediatric donor livers.

Living Donor Liver Transplantation

LDLT has become an important source of grafts for children worldwide. Following on from the first description by Raia et al. in 1988 [35], the first long-term survivor from Strong et al. in 1989 [36], and the early series published by Broelsch et al. [37], the technique has become established with excellent short- and long-term survival. The LLS is the most commonly used graft [38]. Full left or right lobe grafts are used

less commonly and tend to be in young adults. Donation is most commonly from parents, although other family members and altruistic donation have been well reported. The ethics and understanding of the desire to donate are easily understood, and the risks appear to be low, but not negligible. Donor mortality for LSS grafts is of the order of 1:1500. The incidence of other significant donor complications which include bile leak (1–2%), bleeding and the need for transfusion (1–2%), deep vein thrombosis and pulmonary embolus, and incisional hernia (5%) are considered acceptable. Risks of donor mortality are similar for left liver and rise to 0.5% for right lobe donation. The risks of bile leak are also higher for the donor, particularly with the right lobe grafts where the incidence may be as high as 5%. Donor age above 55 years has become generally accepted as a contraindication (especially for the right lobe) due to the slower regeneration and the increased risk in this population.

The LLS segment graft accounts for approximately 20–25% of the adult liver, but provides a full-sized “liver” for the child. Assessment of the donor is designed to ensure that the liver segment is anatomically and functionally suitable for transplantation and to identify additional risk factors such as procoagulant abnormalities, smoking, and steatosis within the liver. Many centers continue to follow the two-stage assessment and consent model reported by Broelsch et al. which includes psychiatric/psychological assessment of the donor and family [37]. Depending on the availability of cadaveric transplantation, suitability for living donation will vary from 50 to 90% when assessing families. The techniques of surgery have been standardized and outcomes are excellent for all liver diseases. The advantages of living related LT (LRLT) include the ability to perform surgery electively with an excellent quality graft, dry cut surface (minimal blood loss), and excellent outcome. The incidence of early rejection is similar to that of cadaveric transplantation, but long term it is considered, although the supporting evidence is limited, that these recipients may be tolerant of their grafts and that immunosuppression (IS) withdrawal may be more likely.

Morioka et al. reported the long-term outcome of LRLT in 46 children who underwent LDLT for metabolic disorders [39]. Mean age at diagnosis and LDLT was 48.6 (0–196) and 86.5 (1.4–199) months, respectively with survival rates of 86.9 and 81.2% at 1 year and 5 and 10 years post-transplant. Patient survival was significantly better in children with liver-centered disease which included Wilson disease, ornithine transcarbamylase deficiency, tyrosinemia type 1, Crigler–Najjar syndrome type 1, and bile acid synthetic defect than in those with non-liver centered disease (glycogen storage disease, propionic acidemia, methylmalonic acidemia, and erythropoietic protoporphyria; $p=0.003$). Statistical analysis showed that cumulative survival of patients with normal or slightly delayed physical growth at the time of

DLT was significantly better than for those with delayed physical growth ($p=0.012$).

DLT is an excellent option in the management of ALF in children. The workup can be performed rapidly if the unit is regularly performing elective DLT. Ethical concern has been expressed regarding the ability of the donor to appreciate the risk in these circumstances [40]. The lower risk of LLS donation has led to the use of DLT as an accepted therapy. Greater debate surrounds the use of right lobe living donation for ALF particularly in countries with effective cadaveric organ donation.

Recent Developments in Transplant Surgery

Over the past 30 years, surgical techniques have become standardized worldwide. LLS and left and right liver LT are used to overcome size discrepancy and to engraft the majority of children. Split and LRLT have been key to sustaining the reduction in deaths on the waiting list. Auxiliary LT offers scope for native liver regeneration in children presenting with ALF and is able to withdraw from IS in the majority. Hepatocyte transplants remain experimental and have been used to bridge young children with metabolic liver disease through the liver replacement. The current challenge is to minimize technical complications that impact on graft survival, such as hepatic artery thrombosis and biliary strictures, and continue to improve outcomes. New technologies are emerging that are currently under evaluation and will impact on practice, and normothermic organ perfusion is perhaps the most prominent.

Auxiliary LT

ALT was first described in a dog by Welch in 1955 [41]. The auxiliary liver was placed in a heterotopic position in the right paravertebral gutter, with portal venous inflow from the iliac vein. The idea of heterotopic ALT was attractive as it avoided the need for native hepatectomy with the idea that it would improve hemodynamic stability during surgery. The first experience of ALT in a human was reported in 1964, using a heterotopic graft, with the aim of avoiding obstacles presented by whole liver replacement. Chenard-Neu et al. reported long-term survival of 2 out of 47 patients who underwent heterotopic ALT between 1964 and 1980 [42]. From 1986 onwards, outcomes of ALT began to improve, although only small numbers were performed [43]. The technique of ALT proved to be more difficult than that of LT with a higher rate of technical complications and inferior graft function and outcome. The development of HCC in the cirrhotic liver remnant of one long-term survivor led to the abandonment of ALT as a treatment for chronic liver disease.

The technique has become an established indication, however, for ALF especially in children. ALT has also been

used to treat noncirrhotic inborn errors of metabolism based in the liver [44]. For ALF, the aim is to treat children satisfying established criteria for transplantation, with survival equivalent to that obtained with whole liver replacement with subsequent native liver regeneration and IS withdrawal. Children have the most to gain from avoiding the complications of lifelong IS. An early multicenter European experience identified that recipients under 40 years of age and particularly children were most likely to survive, have successful liver regeneration and withdraw from IS [43]. In addition, patients with hyperacute liver failure were more likely to regenerate than those with subacute liver failure and that orthotopic rather than heterotopic ALT had a better outcome. IS withdrawal has been possible in more than 70% of survivors [45–47].

ALT has included the use of whole liver, right lobe, left lobe, or LLS grafts. A proportion of the native liver is resected to make room for the graft. The graft is piggy-backed onto the cava, portal inflow is established by end-to-side anastomosis, and arterial inflow is established using either a donor iliac conduit or a branch of the native hepatic artery. Biliary drainage is achieved with either a short Roux-en-Y hepatico-jejunostomy or by anastomosis to the native bile duct. In children, the majority of ALTs are performed using LLS grafts to overcome donor–recipient size discrepancy. Selection of the recipient includes satisfying existing criteria for LT for ALF, no neurological or cardiovascular contraindication and a suitable graft. The donor liver should be of excellent quality to ensure that good early function is achieved. Marginal livers are difficult to use as partial grafts and provide inferior function and should be avoided.

Postoperatively, patients are managed with conventional IS. Early graft dysfunction is due to technical complications, particularly inadequate venous inflow or outflow, and poor quality or small for size grafts. The serum aspartate aminotransferase (AST) and INR may be slower to settle than with conventional transplantation. Persistent elevation of the serum bilirubin indicates complications with the graft. Postoperative bleeding with the need for relaparotomy is more common due to the presence of two cut surfaces.

Patients are followed with CT or MR imaging with guided biopsies of both graft and native livers in the early postoperative period and at 6-month intervals to assess liver recovery. Hepatobiliary dimethyl iminodiacetic acid (HIDA) scintigraphy is also of value in assessing the differential function of the two livers and documenting native liver recovery. The decision to begin IS withdrawal is usually made at 6 months or when signs of regeneration are observed on biopsy. Gradual weaning is necessary to avoid severe graft rejection and infarction. The graft will usually atrophy and disappear completely. IS withdrawal may need to be started to stimulate native liver regrowth. Even after massive hepatic necrosis the liver regenerates fully. However, the larger

the graft transplanted the slower the regeneration of the native liver is without reduction in IS. In the subacute group, regeneration is less rapid, as observed by sequential imaging. Successful IS has been reported up to 4 years after auxiliary partial orthotopic LT (APOLT). Histopathological assessment of the native liver at the time of ALT has identified patterns of hepatocyte cell loss which insight into the likelihood of regeneration. A diffuse pattern with uniform cell loss throughout was associated with hyperacute liver failure and with excellent regeneration with restoration of normal histology in over 70% of patients [48]. A map-like pattern was associated with seronegative hepatitis and adults had a mixed outcome; however, in children the results were excellent. In a small number of cases, no viable hepatocytes could be identified and this group did not regenerate effectively. Of five cases in our series of over 60 adults and children with this pattern, three died and two were retransplanted. ALT has become the gold standard for the treatment of children with ALF requiring transplantation.

Donation After Circulatory Death Donation

The use of donation after circulatory death (DCD) liver grafts has become common in Western countries over the past 10 years. The majority have been from controlled donation (within the hospital intensive care environment) and usually have unrecoverable brain injury. Withdrawal of support occurs, and death is pronounced clinically and with ECG. There follows a 5-min standoff before surgical retrieval is initiated. Warm ischemia is calculated from the onset of systolic blood pressure (BP) <50 mmHg or PaO_2 <70% to cold perfusion of the liver. The organs have been used successfully in children, either as whole or reduced-size grafts with excellent outcomes. Selection criteria for liver reduction include donor age <40 years, warm ischemic time of <30 min, good liver function, and no steatosis with the cold ischemic time being kept under 8 h. Several centers including our own have reported significant numbers of RLT with excellent early and late graft and patient survival and no biliary complications such as cholangiopathy [49].

Post-transplant

Postoperative IS

Over the 30 years, pediatric LT has seen serial improvements in morbidity and mortality. These improvements are related to IS, donor selection and maintenance, surgical technique, and complex team working. The focus of IS has been on the prevention of acute rejection and graft loss; however, in children, morbidity and mortality rates from infections exceed those from rejection and can also impair growth and renal function and increase the risk of some cancers. Getting the

balance of IS right in the short and long term is key to a successful LT program. Evidence is also accumulating that children may be more likely to develop graft tolerance and to wean from IS in the long term [50].

Early post-transplant IS has been associated with increasing use of induction therapy (26%), particularly with interleukin (IL)-2 receptor antibodies either to supplement IS or as a renal sparing regimen. For maintenance IS, calcineurin inhibitors (CNI) remain the cornerstone; but cyclosporin has been largely replaced by tacrolimus. Children often receive an anti-proliferative agent such as azathioprine or mycophenolate mofetil to supplement IS or for CNI/renal sparing. Tacrolimus trough levels of 8–10 ng/l in the first 3 months and 5–8 ng/l thereafter are usually sufficient. Longer-term tacrolimus levels can be further weaned to low levels, if graft function is normal with no rejection episodes. Moderate-to-severe acute rejection is treated with steroid boluses and if unresponsive antithymocyte globulin can be given.

Over-IS is associated with long-term side effects including renal impairment, hypertension, lymphoproliferative disease, and cancer and may hinder the process of immune engagement and the development of immune tolerance. There has been a move toward progressive minimization of IS, including steroid withdrawal which is associated with a growth advantage without any significant rejection-related complications [51, 52]. Many units discontinue steroids during the first or second post-transplant year and more than 50% of children are on monotherapy tacrolimus by 18 months post LT [53]. It has been suggested that early steroid withdrawal may be associated with a higher risk of acute and chronic rejection and the development of de novo AIH [54]. The pathogenic mechanisms behind de novo AIH remain unclear, but it appears to be related to under IS and affects 2–5% of pediatric LT recipients [55, 56].

CNI share a number of side effects in common including nephrotoxicity, neurotoxicity, and hyperlipidemia [57]. There are, however, some differences between tacrolimus and cyclosporin. Cyclosporin is associated with hirsutism and gum hyperplasia while tacrolimus is associated with diabetes and hair loss. For teenagers, especially in females, tacrolimus is often the CNI of choice because of the lower incidence of gum hyperplasia and hirsutism. Tacrolimus has greater water solubility and less dependence on bile salt absorption, thus resulting in improved bioavailability over cyclosporin. However, it has larger interindividual variations. The introduction of once-daily preparations of CNI may help reduce variations in drug levels and improve adherence to medication [58]. Tacrolimus may be superior to cationic steroid antibiotic (CsA) with regard to steroid withdrawal and the incidence of acute and chronic graft rejection. CNI sparing or substitution with mammalian target of rapamycin (mTOR) inhibitors such as sirolimus or everolimus is used for patients with nephrotoxicity, but their efficacy requires validation in long-term studies in large cohorts.

Children surviving more than 1 year post LT also appear to improve adherence. Non-adherence is one of the commonest causes of late mortality and is the leading cause in adolescents and young adults [59]. Non-adherence has been linked to a number of factors including traumatic stress disorder from the time of transplant, a lack of knowledge and understanding of their medical history, and an absence of continuing medical education. Psychological intervention and ongoing education can provide effective intervention and reduce the likelihood of graft and patient loss. Once-daily CNI formulations, particularly taken in the morning, also improve adherence without increasing the incidence of acute rejection, graft loss, or death [58].

Surgery-Related Complications

Early surgical post-LT complications are primarily related to the vascular and biliary reconstructions. Outcomes after pediatric LT are influenced by transplant volume and available expertise. It has been reported that 1-year patient death ratios were significantly lower for high-volume centers (> 16 procedures per year; 0.77) than for low-volume centers (<7 procedures per year; 1.23, $p=0.027$). Co-location of adult and pediatric LT may also contribute to better outcomes [60].

Primary Graft Nonfunction or Dysfunction

Early failure of the graft is relatively rare (1–2%), and retransplantation is the only life-saving therapy. Underlying causes may be due to the mode of death of the donor, problems with retrieval, preservation, or implantation. Signs of poor graft function include hemodynamic instability requiring continuing inotrope support, persistent or increasing acidosis and lactatemia, and bleeding due to persistent coagulopathy. INR greater than four and first-day AST levels of greater than 2000 IU/l reflect major cell damage, but even levels of more than 5000 IU/l may settle with good long-term graft function.

Bleeding

Postoperative intra-abdominal hemorrhage is a common complication in the first 48 h after transplant occurring in 5–10% of patients. Risk factors include renal failure, perioperative dialysis, and ALF. Re-exploration may be necessary, but a definite bleeding point is identified in only half the cases. Bleeding from coagulopathy associated with graft dysfunction needs to be resolved rapidly to avoid hypotension and further graft injury.

Caval Complications

The reported incidence of hepatic vein–IVC anastomotic complications is low and occurs either as a result of technical failure or as a consequence of graft hypertrophy and distor-

tion. Caval complications are rare in size matched and full left liver graft with caval replacement LT with an estimated incidence of less than 1%. The use of interrupted anterior sutures in all venous anastomoses may help to avoid stenosis and kinking in the short and long term. The incidence of hepatic venous obstruction is higher after LLS LT and is of the order of 2–4%. It is always considered to be hepatic vein outflow obstruction; it is often associated with caval stenosis at the inferior aspect of the anastomosis or with twisting. It is a risk at retransplantation particularly if the native cava is small. The most important technical development was the triangulation technique for left hepatic vein (LHV)/caval anastomosis which significantly reduced the incidence of complications. Fixing the graft at the end of the procedure also helps to avoid rotation of the liver and kinking of hepatic vein anastomosis. Clinical manifestations of venous outflow obstruction include hepatomegaly, persistent ascites, unexplained renal impairment, and peripheral edema (if there is caval stenosis) [61]. It may start insidiously 2 or more weeks after the transplant. The characteristic features of venous outflow can usually be seen on CT angiography and confirmed by pressure measurements across the cava and anastomosis. Balloon angioplasty is usually effective, but occasional hepatic venous and/or caval stents may need to be inserted [62]. Long-term patency rates have not been reported and long-term anticoagulation may help further complications.

PV Thrombosis and Stenosis

PV thrombosis (PVT) and stenosis occur in 3.2 and 4% of LT, with a higher incidence after LLS LT particularly for BA and usually involving the extrahepatic PV trunk. Early PVT may be asymptomatic for the first day or two but develop gastrointestinal bleeding from the jejuno-jejunal anastomosis, rising INR and increasing ascites (occasionally chylous). If it extends into the liver, hepatic dysfunction may become evident, with rising transaminases which may progress to liver failure. If the extrahepatic PV is involved, collaterals may develop with normalization of liver function. With clinical stabilization, the INR does not fall below 1.4, the platelet count is low, and signs of portal hypertension persist. Risk factors for PVT include discrepancy in caliber between donor and recipient PV (atrophic or pre-duodenal PV associated with BA), the length of PV, twisting, technical failure, and graft rotation [63]. Doppler ultrasound and/or CT angiography will identify the problem. Early diagnosis and surgical correction will rescue the situation. Care must be taken to remove all the clot in the native PV and SMV. If PVT is recognized late, when collateralization has developed and liver function is normal then intervention can be avoided. If there are late complications from persistent portal hypertension then a Rex or systemic shunt should be attempted. Liver biopsy should be performed prior to surgery to identify any changes such as nodular regenerative hyperplasia which may

influence the surgical decision. A recent analysis of PV complications in 521 pediatric LDLTs identified thrombosis or stenosis in 9% with six graft losses with early complications [63]. The incidence of PV complications within 3 months of LT was 1.7% and body weight of less than 6 kg was the main risk factor on multivariate analysis. In this series, early PV complications had to be recognized early and corrected surgically to avoid graft loss. The platelet count was a valuable indicator of portal hypertension and late PV complications.

Porto-mesenteric venous occlusion is a relative contraindication to LT. If there is a large varix or an isolated vein then a jump graft may be sufficient to revascularize the liver. Many of these patients are young adults with the Janus kinase 2 (JAK-2) mutation, the risk of further thrombosis is high and coagulation post-transplant is essential. JAK-2 mutation is a rare cause of venous thrombosis in children. Portocaval hemitransposition has been utilized in predominantly adult recipients for extensive porto-mesenteric thrombosis; however, the incidence of primary graft nonfunction and retransplantation is high. Survival of 62% has been reported in 34 cases with relatively modest long-term follow-up [64]. Portocaval hemitransposition must be considered as a salvage option in selected cases due to the high rate of primary nonfunction and the lack of a proper experience in all the reported cases.

Arterial Complications

Hepatic artery stenosis (HAS) and thrombosis (HAT) occur in up to 14 and 7% of pediatric LTs, respectively [65]. The mean incidence of early HAT has been reported to be 8.3%. A higher incidence of HAT after adult LT has been reported from lower-volume centers (5.8% with <30 LT cases/year vs. 3.2% with >30 LT cases/year). No data are available for the performance of individual surgeons with respect to the number of LT procedures performed or center activity.

Early HAT is silent and can be identified by daily postoperative Doppler ultrasound before the development of complications. HAT should be suspected if there is a fever or a positive blood culture for a gram-negative organism in the first month after LT [66]. If HAT is unrecognized, then the subsequent clinical course will depend on the potential for and the efficiency of developing a collateral arterial circulation and supervening infection within the compromised biliary tree. Liver dysfunction may occur with modest transaminitis and subsequent cholestasis. The clinical picture can mimic early rejection. With the development of parenchymal ischemia, the transaminitis becomes more pronounced. Increasing cholestasis and the onset of cholangitis mark the development of significant biliary ischemia and cholangiolitic abscesses with associated parenchymal necrosis; if untreated, it progresses to liver failure and death. A more protracted course of recurrent cholangitis and chronic ill health is less common. The pathognomonic sign of HAT

is the development of a nonanastomotic/complex biliary stricture, most commonly at the hilum. The ischemic biliary tree sheds damaged biliary epithelium, and densely adherent casts form on the ulcerated surfaces. These casts and duct ischemia predispose the patient to recurrent cholangitis and obstructions with the development of biliary abscesses and liver infarction.

Factors influencing collateralization are poorly understood, but include the site of the arterial thrombosis (the closer it is to the hilum, the more likely), the graft type (split/reduced grafts may be more likely to collateralize than whole livers), Roux-en-Y hepatico-jejunostomy, multiple arteries, and the timing after LT (patients with a later occurrence are more likely to survive). The overall mortality rate for patients with early HAT has been estimated to be as high as 33%. Just more than half of the recipients with early HAT lose their grafts [67]. The clinical burden of retransplantation and the use of precious grafts to salvage these patients are high and are mirrored by the escalating financial costs.

The surgical causes of early HAT include retrieval injuries (e.g., intimal tears, dissection, and hematoma), technical problems with anastomotic stenosis or kinking and small or multiple arteries requiring arterial reconstruction, and use of arterial conduits [68]. Other reported risk factors have included split liver grafts, DCD and neonatal donors, cytomegalovirus (CMV)-negative recipient, long cold ischemia, large liver (graft-to-recipient body weight ratio >3–4%), small-for-size liver (graft-to-recipient body weight ratio <0.8%), and blood group ABO incompatibility. Retransplantation is also associated with a higher incidence of HAT from both surgical and nonsurgical complications. Nonsurgical factors contributing to HAT include procoagulant states such as JAK-2, anticardiolipin antibodies, factor V Leiden deficiency, and a high hematocrit during the early postoperative course. Procoagulant states may also be associated with particular liver diseases such as autoimmune disease and sclerosing cholangitis, high ascitic drain loss, and use of drugs such as aprotinin and tranexamic acid. Vessel fragility associated with alpha-1-antitrypsin deficiency also increases the risk of HAT.

Interventions for early HAT include urgent revascularization with thrombectomy, vascular anastomosis revision, and thrombolytic drug therapy. Traditionally, the choice was urgent retransplantation or conservative management. In a comprehensive review of HAT, Bekker et al. looked at outcomes after various interventions in adults and children [65]. Revascularization was attempted in 54% of children with an overall success rate of 56%. A correlation was noted between early intervention and successful outcome. Daily ultrasound examinations for the first week were associated with early recognition and better outcomes (66 vs. 45%). Children were more likely than adults to have a successful outcome after early revascularization (61% of adults and 92% of children). Retransplantation was performed for res-

cue in up to 62% of children with a mortality rate of at least 30%.

Early HAS has also been recognized as a predisposing risk for both HAT and graft ischemia/loss. Risk factors include clamp injury, intimal trauma caused by perfusion catheters, technical, intimal hyperplasia, and severe rejection. In a recent study by Sommacale et al., in adults, of 37 patients treated by transluminal radiological intervention, hepatic artery patency was 94.6% with 5-year graft and patient survival rates of 82 and 87%, respectively, at median follow-up of 66 months. Repeat interventions were helpful in 20% of treated recipients with an overall incidence of HAT of 11% [69]. The use of Doppler ultrasound to identify HAS with a tardus parvus waveform (defined as a waveform with a resistive index <0.5 and a systolic acceleration time <0.08 s) has been associated with a low positive predictive value and a high false-positive rate [70]. When combined with an optimal peak systolic velocity of 48 cm/s, it has an improved specificity of 99% and a positive predictive rate of 88% with a false-positive rate of 1%. The early identification of tardus parvus with appropriate interventions may reduce the incidence of subsequent thrombosis. Further data are needed for children with HAS.

The management of early HAT is based on the appearance of the liver on CT angiography which will confirm thrombosis and reveal the presence of parenchymal ischemia. If the serum transaminases are normal and there is no parenchymal ischemia, then revascularization should be attempted with or without accompanying thrombolysis [71]. If there is significant transaminitis or definite parenchymal ischemia on CT, then revascularization may produce a significant reperfusion injury that may endanger the child. Late recognition should be managed conservatively with rescue retransplantation for those developing ischemic complications. The routine performance of retransplantation for all cases of early HAT is not indicated in an era of organ shortages. Further research is required to understand and reduce the incidence of early HAT and to improve outcomes.

Biliary Complications

Biliary complications remain a significant problem after LT with an incidence of 11–38% [72]. Factors associated with biliary complications include anatomical variations of biliary anatomy, ischemia, technical failure, DCD grafts, ABO incompatibility, and CMV infection. The commonest early complication is biliary leak which may be anastomotic or nonanastomotic. Anastomotic leaks are usually due to technical failure, but aberrant right posterior sectoral ducts may be missed. Nonanastomotic leaks are only seen with segmental grafts and usually represent missed segment IV or segment I ducts. Strictures may be early or late and occur at anastomotic or nonanastomotic sites [72]. Most anastomotic strictures are secondary to technical failure or scar tissue causing

retraction and narrowing of the CBD at the suture site, although ischemia may also be a factor. Anastomotic strictures will require surgical or radiologic intervention. Strictures occurring within the first year after LT will usually respond to percutaneous dilatation. Nonanastomotic strictures are probably caused by bile duct ischemia due to arterial insufficiency. This ischemic phenomenon is responsible for the loss of the biliary epithelium, producing multiple focal areas of intrahepatic biliary duct strictures separated by dilatations. These strictures may occur anywhere in the biliary tree and if extensive inevitably lead to retransplantation. A recent report of 126 LT in 108 children identified biliary complications in 30 cases, including leak (14), stricture (14), necrosis (9), and biliary occlusion caused by a drain (1) [72]. Fifty-six percent of those with complications required surgery. Serum gamma-glutamyl transferase (GGT) peak value in the first week (358.8 ± 283.7 vs. 251.3 ± 194 U/L) was considered a good early noninvasive marker to identify recipients at risk of biliary complications. In contrast, Anderson et al. reported 66 LT, of whom 17 (26%) developed biliary complications that required intervention [73]. The stricture rate was 16% for whole, 27% for split, and 43% for LDLT and none after reduced-size grafts. Sixteen patients were treated with percutaneous biliary dilatation, and one was treated with endoscopic stenting with complete resolution in 12 (71%). The remainder underwent surgical correction. Nonanastomotic or diffuse biliary strictures are associated with hepatic artery thrombosis, preservation injury and transplantation with ABO-incompatible grafts, and invariably come to retransplantation.

Other Surgical Complications

Bowel perforation is a rare complication except in children with BA who have undergone previous surgery when the incidence is 15%. Division of adhesions, portal hypertension, use of diathermy, CMV enteritis, sepsis, use of inotropes, steroids, and malnutrition have all been implicated. Paralysis of the right diaphragm due to a phrenic nerve injury at surgery may occasionally be the cause of failure to wean from the ventilator despite excellent gas exchange and a “normal” chest X-ray. Diaphragmatic hernia has been reported in up to 2% of LTs and has been associated with the use of LLS grafts, young children, ascites, and large for size grafts. The hernias may contain small and large bowel and should be repaired promptly to avoid ischemic complications.

Retransplantation

Retransplantation is needed in 15% of children, although the incidence has fallen consistently over 20 years. Hepatic artery thrombosis accounts for 50% of cases, and patient survival of 82% has been reported with elective versus 46%

emergency retransplantation. Retransplantation for primary nonfunction or in the setting of multiorgan failure has a survival of less than 30%. However, retransplantation has made a significant contribution to overall survival in children undergoing LT [74].

Nonsurgical Complications

Infections

Infection is a common complication of LT. The majority of transplant recipients will have at least one episode of infection in the postoperative recovery period, particularly if transplanted for ALF, if there is persistence of graft dysfunction or following steroid therapy for acute rejection. Bacterial pneumonia is the most common infection in the first week. Gram-positive line infections occur from 5 days onwards, and venous access must be changed regularly. Gram-negative sepsis is often associated with biliary leak, bowel perforation, or graft ischemia. Immunosuppressive therapy may minimize clinical signs of sepsis. Late opportunistic bacterial infections including legionellosis, nocardiosis, and tuberculosis may also occur particularly in those children who have received higher levels of IS. Of 2291 children (<18 years) reported by Shepherd et al., infection was the primary cause of death in 3.1% of all recipients, primarily due to bacterial sepsis (56%), with viral and fungal infection accounting for 19 and 10%, respectively, of infection deaths [75]. Infection contributed to death in patients dying from multiorgan and cardiopulmonary failure. Infection directly or indirectly contributed to 46% of all deaths. Viral infections tend to occur later than bacterial, and the overall incidence of CMV disease was 6%, Epstein–Barr virus (EBV) disease 8.6%, and lymphoproliferative disease (PTLD) 2.7%. Multivariate analysis showed that risk factors for bacterial infection included age (infants vs. adolescents), race (black and Hispanic vs. white), IS (cyclosporin vs. tacrolimus), year of LT (before 2001 vs. after 2001), serum bilirubin level, and organ donor type (DD-S or reduced-size). Risk factors for viral infection were treated acute rejection, era of transplant (before 2001), and organ donor variants (split or reduced-size, i.e., older donors). The risk from infection exceeds that of rejection, particularly in infants, who have three times the rate of bacterial or fungal infection than adolescents. Infection was the most common cause of death with a tenfold greater risk of death from infection than from rejection (3.1 vs. 0.2% of patients; 46 vs. 4.7% of deaths, $p < 0.001$).

Fungal infections particularly *Candida* respond to treatment with fluconazole or amphotericin B, but invasive aspergillosis may be fatal. Fungal sepsis is particularly common in children with ALF or bowel perforation and they must receive appropriate prophylaxis. Atypical pneumonia due to *Pneumocystis carinii* should be considered if hypoxia

is present and treated with high-dose septrin. Central nervous system infection with toxoplasmosis is rare and should be treated with pyrimethamine/sulfadiazine or high-dose penicillin.

Herpes viruses form the most important viral pathogens post-transplant. Herpes simplex and varicella-zoster infections occur within 1 and 3 months, respectively post-transplant and both respond to early treatment with acyclovir. CMV infection occurs between 2 and 6 weeks post-transplant and should be treated by a reduction of IS and ganciclovir. High-risk cases, for example, CMV-positive donor and recipient are routinely given prophylactic ganciclovir. CMV hepatitis presents with flu-like symptoms, high fever, and relative neutropenia with a mild rise in serum transaminases. Serology is of limited value and has been replaced by diagnostic tests which monitor levels of antigenemia or CMV DNA.

Lymphoproliferative Disease and Epstein–Barr Infection

EBV infection may occur as a primary infection from a positive donor or reactivation of a previous infection [76]. It presents with a spectrum ranging from a mononucleosis-like illness to a malignant lymphoma. The presence of unexplained persistent fever, anemia, and positive fecal occult bloods is suggestive of PTLD and should prompt endoscopy and CT examinations. Young, previously EBV-negative children appear to be particularly at risk of developing EBV-related PTLD. The overall incidence is 2%, but may be as high as 5–10% in children less than 1 year. It is a life-threatening complication with 35% mortality [77]. Risk factors include primary EBV infection, age at LT, type and intensity of IS, and CMV infection [78]. Because most children have not been exposed to EBV, they are particularly susceptible to acute infection, and in combination with IS they are at high risk of developing PTLD. Infants have ten times the rate of PTLD of adolescents presumably because they are EBV and CMV naïve and have an immature immune system. Some PTLD will regress with IS reduction and steroid therapy; however, rituximab has become the main stay of therapy with systemic chemotherapy being reserved for children not responding to therapy.

An individualized approach to the prevention of EBV disease and PTLD is helpful in infants, given their risk. EBV polymerase chain reaction (PCR) monitoring identifies children with increasing viral load and allows for IS reduction, but this is not specific for PTLD. The therapeutic value of preventive use of antiviral therapies (e.g., ganciclovir or acyclovir) remains unproven. However, the improved awareness of PTLD and EBV monitoring has led to earlier diagnosis with less systemic involvement resulting in a more favorable outcomes [79].

Graft and Patient Survival

Over the past four decades, there has been progressive improvement in outcome after LT. According to data from UNOS, adjusted graft survival for both deceased and LDLT programs have achieved excellent survival rates in children. Patient survival at 1 year after elective LT should be in excess of 95% and for ALF approximately 80% and of the order of 80 and 70% at 10 years, respectively. Graft survival has been improving with lower rates of retransplantation due to fewer technical complications and a lower incidence of chronic rejection. Concerns over the finding of significant graft fibrosis in many children at 10 years post LT have raised concerns over the longer term outlook and question whether IS levels are appropriate [80]. It has been shown that increasing IS in the presence of fibrosis does lead to improvement in the liver fibrosis. Long-term outcomes are similar for all children except for the very young <3 months and adolescents. The reasons for the poorer outcomes for adolescents are not clear and require further research.

Quality of Life

The improved long-term outcomes are turning attention to quality of life of survivors. Quality of life is difficult to measure, especially in children. Studies show that most children surviving more than 1 year post LT were able to return to school [31]. Quality of life is dependent on good graft function and an absence of recurring medical complications requiring repeated hospital admission.

Overall quality of life seems to be satisfactory in children with good graft function. Growth and social and physical development is normal in the absence of liver diseases such as Alagille. Alonso et al. on behalf of the (SPLIT group studied 873 children surviving at least 12 months, mean age of 8.17 ± 4.43 years (from 22 centers) [81]. Using a 23-item PedsQL 4.0 (Mapi Research Institute, Lyon, France) generic core scales, which encompasses physical, emotional, social, and school functioning, they demonstrated that these children had moderately diminished health-related quality of life (HRQOL) as compared with healthy peers. The largest difference was noted in the area of school functioning, with days missed from school being important from the perspective of children and their parents. Comparisons in HRQOL in this study with children with cancer revealed that both populations shared similar struggles in social and school functioning areas.

Some effect has been noted on cognitive function; however, motor developmental delay may be due to chronic illness. Parents often comment that their child is active and plays well and is able to do physical activities. Overall family interactions and school behavior also improve. Parents

may view themselves as more relaxed and being able to be more balanced and consistent in applying discipline. Siblings behave more appropriately, but may remain resentful toward the recipient. For many families, there is difficulty in adjusting to the new situation of having a well rather than ill child. There remain long-term anxieties about the child's prognosis and well-being over. The child is used to taking a disproportionate amount of the parents' time and attention at the expense of other siblings and trying to restore "fairness" can cause problems. Behavioral immaturity may persist, and acts of defiance or aggression are sometimes seen particularly in teenage years. There is continuing parental concern over rejection, side effects of IS, of being overprotective, continuing medical and "social" expenses, and changes to family dynamics. Parents who have devoted their energies into the care of a chronically ill child sometimes interrupting their professional life may find it difficult to adjust to their new role within the family with a "well" child [82]. Anxieties about children going to school and being separated from their parents after many years of dependence can also cause problems [83]. However, these challenges can be addressed with continuing follow-up and support from health-care professionals within the transplant network.

Transition to Adolescence and Young Adult Life: Adulthood

The most difficult step in long-term follow-up is the transition from childhood, and LT recipients require specific care, attention, and support. Life cannot be considered to be normal because of the need to take IS and lifestyle restrictions regarding alcohol. The appearance of conflict between recipient and their parents may become problematic. Maintaining a healthy relationship will improve adherence and the quality of life of the recipient. Adolescent and young adults are concerned about their appearance and complications such as acne, hirsutism and gum hypertrophy may lead to non-adherence unless IS is changed to help. Nephrotoxicity is a significant problem and by 10 years post LT, up to 5% of recipients may have developed end-stage renal failure which has a major bearing on long-term follow-up.

An increased incidence of graft loss in adolescence has consistently been linked to non-adherence and has become a leading cause of late death in this population. Annunziato et al. [84] examined adherence during transition and compared it with pediatric and adult cohorts. Adherence was significantly poorer in the adolescent cohort versus pediatric, and adult cohorts. The increase in non-adherence was due to a number of factors: Pediatric clinics have a more "hands-on" approach to treatment; changes in insurance status may be associated with a lapse in attendance and IS usage; and the stress of transitioning to less familiar providers may exacerbate

bate existing individual and familial risk factors compromise adherence. Subsequently, the same group tested a pilot intervention of facilitating transition [85]. Twenty-two patients were enrolled in a two-session educational program providing details of their underlying liver disease and treatment. A second component focused on educating families regarding the transition of health-care responsibility to the recipient facilitated by a clinical psychologist. This structured intervention significantly improved adherence with improvement in liver function and greater consistency of tacrolimus trough levels. Fredericks et al. also confirmed in a review that rates of non-adherence among adolescents are high, and adherence to IS is a critical factor in transition with an increased risk of poor long-term health outcomes [86]. Further research is needed to identify factors and interventions that affect long-term health outcomes in this population.

Long-Term Outlooks and Trends

Long-term survival is now achieved by large numbers of children following LT. The initial obstacles to survival, such as getting to transplant and managing IS, are being tackled, but the challenges raised by psychological, social, and health problems produced by successful transplantation are belatedly being addressed by specialist transition and adult “pediatric” services [87]. The overall life expectancy of a child undergoing LT is still to be determined. The goal remains transplantation without long-term IS, but until donor-specific tolerance can be safely produced, there will continue to be complications from IS therapy. As the majority of children are under 5 years of age at the time of transplant, continuing specialist care and education must be provided, particularly during adolescence and young adult life, when life’s challenges may threaten well-being and non-adherence to medication. It is important that pediatric liver transplant recipients are able complete their education, have employment and families of their own and in the future these factors may influence the timing of transplantation. The challenge is to ensure children undergoing LT can be restored to a normal life expectancy with the potential to enjoy life to the full.

Marianne Samyn and Anna Hames

Introduction

As the survival of children with liver disease has significantly changed over the past few decades, with the development of pediatric liver transplantation and improved medical and nutritional management, a large cohort of patients is now moving into adolescence and adulthood with a liver condition. This has brought its own challenges related to the condition and the management of it, combined with the challenges young people face during adolescence. Due to the unique challenges that this growing population face for both pediatric and adult services, our centre has a specialist multidisciplinary approach to managing young people with liver disease as they transition into adulthood. In this chapter, we, as physician and clinical psychologist, will give an overview of the interaction of physical development during puberty and liver disease, as well as the psychosocial and health behaviour aspects of adolescence. Transition of medical care from pediatric to an adult-based setting will have a significant impact on the patient and their support network, especially in patients with special health needs. This is also discussed.

Young People

The World Health Organization recognizes that ‘young people’ aged between 10 and 24 years are a population who require dedicated care [1]. Having a chronic condition or disability has multiple effects on adolescent development including biological, psychosocial and social effects that can

in turn contribute to poor adherence and risk-taking behaviours [2]. Non-adherence to medication is a particular challenge in the adolescent population as it is difficult to measure, often multifactorial; however, relatively developmentally appropriate. Its prevalence is reported to exceed 50% in the post-transplant population [3] and effects long-term outcome in this patient population. Adolescence coincides with transfer of medical care from pediatric to adult-centred services, hence the importance of defining a dedicated, individualized transition care pathway for young people. This will be discussed in more detail further in the chapter.

Medical Aspects of Growing Up with Liver Disease

Within pediatrics, liver disease is a relatively new specialty within which the past few decades have seen a significant change in the diagnosis and management of conditions. Patients tend to present in infancy or later childhood with a variety of genetic and incidental conditions, either in an acute, often life threatening, or more chronic setting. Life-long specialist follow-up and treatment is usually required. The development of pediatric liver transplantation has had a significant impact on the outcome and prognosis of children developing end-stage liver disease or presenting with acute liver failure, and the majority of the patients are now moving into adolescence and adulthood. This emerging population is a challenge for both pediatric and adult hepatology teams.

Information on the long-term outcome of patients with liver disease presenting in infancy, such as biliary atresia and Alagille syndrome, is becoming available but is still scarce and more focused on survival data. It is estimated that 23–52% of patients with biliary atresia now survive into adulthood without needing liver transplantation. This was confirmed in our recent series [4]; 34% of our patient cohort is alive with their native liver at a median age of 20.6 years (range 16–32 years), with 9% showing no evidence of chronic liver disease. Indication criteria and timing for trans-

plantation in this population might differ from standard adult liver transplant criteria and is important to keep in mind. In Alagille syndrome, extrahepatic aspects of the syndrome related to vascular or renal involvement are becoming more relevant and can impact the long-term prognosis [5, 6].

Other conditions such as autoimmune liver disease, Wilson disease and non-alcoholic fatty liver disease tend to present more frequently during adolescence and patients will have to come in terms with their condition and management during an already challenging time in their life.

The advances in molecular genetics are now enabling us to diagnose genetic liver conditions such as familial intrahepatic cholestasis and other rarer metabolic conditions such as mitochondrial cytopathies, etc. The implications of dealing with a genetically based condition can have an additional impact on coming to terms with the diagnosis for both patients and families and have further long-term implications on adult life and prognosis.

Outcome Data

The majority of outcome data on patients with childhood liver disease are available from the liver transplant population. Survival rates are fairly similar for different age groups until 5 years following liver transplant, but show poorer patient and graft survival after 10 years for those transplanted between the ages of 12 and 17 years (74 and 62%, respectively) compared to the younger patients (1–5 years; 84 and 72%, respectively) [7]. Young people constitute a unique and vulnerable cohort who deserves special attention by health professionals focusing on better outcome and survival. In the non-transplant setting, a recent report on predictors of poor outcome in a cohort of 133 patients with autoimmune hepatitis aged 14 and over found that presentation between the ages of 14 and 20 years was a significant independent predictor of liver-related death or requirement for liver transplantation, suggesting that their condition was more challenging to manage compared to the older population [8]. Data from the renal transplant community support this, with patients receiving their first kidney transplant between the ages of 14 and 16 years being at the highest risk of graft loss with inferior outcomes at 1, 3, 5 and 10 years post-transplant. The risk was higher in black adolescents, in patients with deceased donors compared to living donors and governance insurance versus private insurance [9].

Impact of Liver Disease on Physical Development

Growth retardation is common in children with chronic liver conditions and more common in cholestatic liver disease, where some degree of catch up growth is noted after liver transplantation. In an analysis of growth following liver

transplantation, risk factors for poor linear growth were prolonged steroid exposure, lower weight percentiles at time of transplantation, linear growth impairment pre-transplantation and metabolic disease as primary diagnosis [10]. More recently, out of a total of 892 liver transplant patients between 8 and 18 years, 20% had linear growth impairment at their last follow-up and, where available, height z scores were significantly lower than the calculated mid-parental height z scores. Linear growth impairment at transplant, re-transplantation, non-white race and primary diagnosis other than biliary atresia were found to be independent predictors of growth impairment. In the same study, the authors reported on the pubertal development of 353 children and found that 61% of girls and 58% of boys aged 16–18 years reached Tanner 5 compared to 100% of a normative population with growth impairment occurring in 11% of Tanner 5 subjects [11]. Growth impairment has also been described in genetic conditions such as Alagille syndrome. Further data are needed to establish the prevalence of growth failure and pubertal delay in chronic liver disease, but is already available in other chronic conditions such as inflammatory bowel disease, nephrotic syndrome, asthma and cystic fibrosis. Growth failure and pubertal delay can have a significant psychosocial effect on quality of life and long-term outcomes; hence, treatment of recombinant human growth hormone in this population has been reported to be associated with improvement in psychosocial functioning as well as linear growth [12]. Larger studies are needed to assess its safety in this patient population.

In girls with chronic liver disease, menstrual cycles can be irregular and amenorrhea and anovulation are common. Menorrhagia can occur in patients with advanced liver disease with portal hypertension. Estrogens, and typically the synthetically produced ethinylestradiol used in the combined hormonal preparations, are more potent with a potential effect on the liver irrespective of the route of administration. Progestogens do not have receptors on the liver cells and are commonly given at a lower dose and well tolerated.

Although not contraindicated in patients with compensated cirrhosis, in both pre- and post-liver transplant settings the current contraceptive recommendation is with progesterone-only preparations such as minipill (e.g. Cerazette), medroxyprogesterone injection or etonogestrol implants and, if sexually active, levonogestrol releasing intrauterine system [13]. Successful pregnancy outcomes have been reported in both chronic liver disease and liver transplantation settings, although with an increased risk for both mother and baby. Treatment with calcineurin inhibitors, steroids and azathioprine is recommended to be continued during pregnancy to avoid graft dysfunction or relapse in autoimmune liver disease; mycophenolic acid and rapamycin are contraindicated because of the increased risk of birth defects. In patients with portal hypertension an upper gastrointestinal (GI) endoscopy during the second half of the second trimester is indicated

to assess the degree of portal hypertension and the need for further management to avoid GI bleeding during the course of pregnancy [14]. Obstetric follow-up by an experienced team in a hospital setting is required. Adolescent girls should be informed timely of the various contraceptive options, the potential complications of pregnancy and childbirth as well as the possible genetic implications of their underlying condition.

Cosmetic side effects of medical treatment, such as steroids and currently less commonly used, cyclosporine, can have an impact on body image and adherence to treatment in the adolescent population (described later in the chapter) and health professionals should keep this in mind when prescribing treatment.

In order to effectively manage young people's care, it is crucial to successfully address their wider 'medical, psychosocial and educational/vocational needs' [15]. To do this, professionals need to be familiar with the unique developmental stage of adolescence and recognize that young people are neither just 'big children' nor 'small adults'. This developmental perspective is discussed in the next section, along with the psychosocial elements of growing up with liver disease.

Adolescent Development and Its Interaction with Liver Disease

The biopsychosocial changes associated with adolescence interact with how young people manage their illness and treatments, and accordingly how their healthcare should be approached. For an excellent review of this area, see Suris et al. [2].

Although most of the literature focuses on adolescence, research demonstrates that structural and functional changes continue to take place in the brain into young adulthood [16]. This is mirrored by changing societal norms with young people increasingly delaying many of the traditional 'tasks' of adulthood, such as financial independence and starting a family. Furthermore, health outcomes are poorer for young adults into their mid-20s [17], so it is more helpful to think about young adult development more broadly.

Adolescence is traditionally defined by the onset of puberty. Delayed puberty, reported in young people with liver disease, can impact on how the young person views themselves, their illness and their wider world. For example, an adolescent who looks younger may be treated differently by people and have reduced social opportunities. Common stories from patients include being asked by adult clinic staff whether they are there with their mum, being stopped by the police when driving to check their age and being refused entry to 18 rated films or pubs.

Alongside the physical changes are changes in how young people think and feel, and in the nature and importance of their social world. In order to become an independent adult,

the adolescent needs to separate from their parents. They start to develop a more independent sense of identity, and their peer group typically takes over from family as being their main social world [18]. Peer acceptance becomes key, with a strong desire to feel normal. Self-consciousness increases. The typical adolescent has an increased sense of invincibility, poorer abstract thinking and reduced thoughts of the future [19]. An increasing body of research demonstrates ways in which the structure and function of the adolescent's social brain is distinctly different from that of children or adults [20].

As part of this adolescent profile, risk-taking behaviours peak, with high levels of alcohol and drug use, smoking and unsafe sex [21]. In the UK, 'binge drinking' is widespread and synonymous with certain rites of passage for young people, such as the introductory 'freshers' week' at university. Young people growing up with liver disease have the same needs as other young people, with the additional challenge of trying to balance their health needs against their social and psychological needs. The way to meet these can often seem to be opposition. Indeed, research suggests that alcohol and drug use is similarly prevalent in young people with chronic illnesses as compared to their healthy peers [22], and they are equally as likely to be sexually active [23]. This adolescent profile and tendency to take risks helps young people to develop independence, but can present significant challenges for successfully managing a chronic illness. This is discussed further below under adherence.

Impact of Family

All of the above changes happen within a family context. To enable the young person to develop into an adult, their family also need to adapt their roles, for example, by giving their child more freedom and privacy [24]. Parents/carers of children with chronic illness have often dedicated much of their lives to caring for their sick child and have their own relationships with the illness and hospital teams. They might also have had to change other roles in their lives, such as giving up work, to successfully care for them. This can result in some parents seeming to be more overprotective, for example, worrying about their adolescent taking their medication, abstaining from alcohol at parties, monitoring for symptoms or appropriately seeking help [25].

There are also significant challenges for families of young people who are diagnosed with a liver disease during their adolescent years, as is common, for example, in autoimmune liver disease or Wilson disease. At a time when adolescents should be becoming more independent, the acute stage of illness forces them into a state of dependence on others. This can present challenges for the whole family that may not be expected at this stage of development [26], such

as parents needing to take time off work, physically caring for their child and spending concentrated time together that might not otherwise have been expected from being the parent of a teenager or be normal amongst their peers.

Wider Influences

The above processes occur within a wider set of systems still, such as schools, workplaces, friendships and other relationships; how the liver disease is managed in any of these contexts will interact with the young person's adjustment and management of it. Furthermore, this is within a societal context in which the general public hold certain beliefs, assumptions and prejudices. As public perception of people with liver disease and transplant is most commonly associated with drug and alcohol use, young people struggle to develop a positive self-identity if they associate (or other people associate them) with this stigmatized group. Our patients often grapple with the dilemmas about whom to tell about their condition and how to tell, as many have experienced bullying or prejudiced comments in the past. It can be beneficial to discuss these dilemmas with patients and help support them in communicating their needs to schools and workplaces.

Given the importance of peer relationships during this period, it is worrying that peer networks are often disrupted in young people with chronic illness [27]. Amongst young people, post-transplant peer support has been found to be an effective means of engaging young people in services and improving their health outcomes and well being [28]. In a small recent study in which young people were trained to act as mentors for younger post-transplant patients, the mentors themselves benefited from improved adherence [29]. As part of the liver transition service at King's College Hospital, we run peer support days and peer mentoring for young people with chronic liver disease and post transplant. Preliminary feedback suggests numerous benefits of this for both young people and their mentors, including feeling more positive about having a liver condition due to increased hope and feeling less alone, as well as feeling more prepared for transition [30].

Most of the developmental models are based upon Western notions of adolescence. It is unclear how this may differ in other cultures, for example, where adolescence may not exist as a construct or notions such as independence from family are not expected or endorsed. How culture interacts with chronic illness management and transition is an under-researched area that demands further attention [31]. It is important for professionals to be curious about what the adolescence and their family expect at this stage of development rather than making assumptions about how these constructs may or may not apply.

Psychological Aspects of Growing Up with Liver Disease

Adolescence is a period of rapid change, full of opportunities and challenges. Young people growing up with chronic liver disease have the same aspirations in life as their healthy peers, but have additional stresses and restrictions to manage, including hospital visits, time off school, medication and lifestyle restrictions. Rather than focusing purely on the presence of psychological distress, it is important to consider how all young people and families adapt to their changing health needs at different stages of development. Most young people, with or without liver disease, strive to be normal [32]. Those who have difficulties adjusting to their illness/treatment and integrating it into a positive self-identity are at increased risk of developing psychological difficulties and are less likely to manage their physical health needs effectively. Routine questions about the adolescent's wider world are crucial for engagement and in order to assess how they are adjusting to the demands of their condition and areas that may require intervention [33].

There has been relatively little research into the psychological needs of young people growing up with liver disease, and most of this limited research has focused on those post transplant. Research conducted with adults with liver disease is unlikely to be generalizable as the populations are different on multiple levels, including age and developmental stage, age at diagnosis, type of liver disease and/or reason for transplant. A brief overview of some key areas is given below, citing research specific to liver disease where it exists and otherwise extrapolating from other chronic childhood diseases.

Quality of Life

Quality of life is a broad term that encompasses a range of physical, psychological and social factors. Health-related quality of life is found to be poorer in children and young people post-liver transplant as compared with the general population, but similar to young people with other chronic conditions [25, 34, 35]. A recent study of children and adolescents with autoimmune liver disease found a similar trend, with poorer quality of life being associated with the presence of symptoms such as ascites, abdominal pain and fatigue [36].

In a qualitative study aiming to understand how liver transplant affects young people's quality of life, adolescent participants spoke about the impact of transplant on their relationships, schooling, fatigue, burden of medication, communication with health-care professionals and thinking about the future [25]. These are key areas to explore when working with young people, and demonstrate the importance of fostering good collaborative relationships with young

people, in which they feel listened to, valued and their wider needs and hopes are respected.

School Achievement

A young person growing up with a chronic liver disease or transplant is more likely than healthy peers to take time off from school for hospital appointments and ill health. This can have a significant impact on their school attainment and subsequent employment opportunities in adulthood.

Data available on cognitive development in the context of pediatric liver conditions, and mainly in the post-liver transplantation setting, confirms an increased incidence of learning difficulties in this population. Out of 144 patients from the Studies of Pediatric Liver Transplantation (SPLIT) registry, children aged between 5 and 7 years and more than 2 years post-transplant, 26% were found to have a mild to moderate, and 4% a serious, cognitive delay with 25% having learning difficulties with reading and maths skills, and a relevant executive functioning deficit which would potentially affect independent management of their health condition in adult life [37]. Further research identified height centile at transplantation and genetic–metabolic conditions as having a high impact on long-term cognitive functioning [38].

There is limited information on developmental assessment and cognitive function in patients with liver disease who have not been transplanted and further multicentre studies are required in these populations. The longer-term impact of these childhood difficulties also needs to be further researched, as in clinical practice we frequently see the long-term consequences such as in Case Study 74.1.

Case Study 74.1

Harry was diagnosed with biliary atresia shortly after he was born. Following a Kasai procedure, he required regular visits to hospital for appointments and sometimes needed admission for treatment with antibiotics or endoscopy procedures as he developed portal hypertension. He was a bright, sociable child who was well liked by patients and staff. Aged 11, his health deteriorated and the decision was made to list him for liver transplantation. A year later Harry was transplanted and he recovered well after surgery. Due to time spent in hospital, he missed most of his formal education and left school without any qualifications. Harry is now 22 years old. He lives with his parents and is unemployed. He has held a number of casual jobs, but struggles to find permanent employment due to his lack of qualifications and relevant experience. Harry feels left behind by his friends, most of whom who have now been to university and started good jobs.

Mood Difficulties

Research investigating psychological well being in adolescents with chronic illness more broadly suggest that there are higher rates of depressive and anxiety symptoms relative to healthy controls, but the rates varies across studies and illness group (see metaanalysis by Pinquart and Shen [39]). Two recent studies conducted with adolescents with non-alcoholic fatty liver disease reported higher rates of depressive symptoms as compared to healthy overweight controls [40] and higher depressive and anxiety symptoms relative to healthy normal weight controls [41]. In keeping with this, a recent study we conducted with 80 young people (aged 1–24 years old) with a range of chronic liver conditions found elevated rates of self-reported difficulties with anxiety, depression and anger [42]. In this study, young people with chronic liver disease or transplant reported higher levels of body image dissatisfaction; contrary to intuition, this dissatisfaction was not associated with whether the young person had an abdominal transplant scar or was on high doses of steroids.

Post-Traumatic Stress Disorder

Young people with chronic liver disease are likely to have had some unpleasant experiences in hospital, and times which may have been felt confusing, scary or upsetting. High rates of post-traumatic stress disorder (PTSD) have been found in adolescents who have had transplants. For example, in 104 adolescents (aged 12–20 years) post-solid organ transplant, 16% met full criteria for PTSD, with an additional 14% reporting two of the three necessary symptom clusters at a level that was causing them clinically significant distress [43, 44] reported similar prevalence rates of PTSD (13%) in 76 children post transplant; these PTSD symptoms were significantly under-reported by parents.

In addition to the distress associated with PTSD, in a small study of 19 adolescents post-liver transplant [45], a significant association was found between presence of PTSD symptoms and non-adherence (as measures by blood levels and clinician judgement). This is likely to be due to medication serving as a reminder of the transplant and non-adherence therefore being a form of avoidance. Functional outcomes are also found to be lower, for example, adult survivors of childhood cancer who had PTSD were found to have lower functioning in areas such as school, work and personal relationship [46].

Failure to identify PTSD compromises the young person's well being, impacts on their functioning as adults and is associated with non-adherence. As parents tend to underestimate rates of PTSD and there is no relationship between the objective characteristics of the trauma and the risk of PTSD [47], it is impossible to predict who will have diffi-

culties. Detection therefore relies upon directly asking the young person. Research has not addressed rates of PTSD in young people with chronic liver disease more generally, but as these young people also encounter situations where they perceive their life to be threatened then it is reasonable to assume that their rates of PTSD may also be elevated.

One of the most significant challenges of caring for adolescents is the high rates of non-adherence. This is outlined below.

Adherence

As highlighted earlier, rates of non-adherence to medication are found to be as high as 50% in adolescents post-transplant, with significant negative implications for their health.

It is easy to see that a typically developing adolescent as described in the earlier section might not take all their medications or attend appointments correctly. Adherence in liver disease or transplant requires the patient to trust their doctor that the treatment is required, buy into the notion that the status of their liver disease may not correspond with symptoms, be motivated by a long-term outcome of improved health, and be able to plan and organize themselves to maintain a good routine. This directly contrasts with the developmental profile of young people, as illustrated in Case Study 74.2.

Case Study 74.2

Jake is 18 years old. He was well throughout his childhood until being diagnosed with autoimmune liver disease when he was 14 years old. When he was first diagnosed, Jake felt quite unwell and spent a week in hospital, but since then he has been well and only has to go to an outpatient clinic appointment every few months. Jake does not think of himself as being sick and does not really think about it except for when he goes to hospital. He is most bothered about the way he looks, in particular about his acne, which started when he was commenced on steroid treatment and lack of muscle tone. He feels very self-conscious around other people his age and often feels quite down about his appearance. Jake is told to take daily medications to prevent him from getting ill again in the future—but when he stops taking his medications, nothing bad happens; he actually feels better because he is not bothered by side effects, his skin gets better and his face looks more defined. Jake feels happier because he feels more similar to his friends, and does not feel so self-conscious about having to remember to take his medicines or risk having to explain his condition to others. Jake has been told that he should not drink

alcohol, but all of his friends do and it is really hard to explain why he cannot. When he started drinking recently at a party, it was really fun and nothing bad happened, so he thinks it must be alright. Jake does not really get on very well with his parents and teachers at the moment, so does not tell them because he knows they will nag him about it. When he goes to hospital, his mum does most of the talking. Jake's doctor tells his mum about some blood tests numbers that he does not really understand, and then he gets to go home.

A full review of the factors associated with non-adherence is outside the scope of this chapter, but a number of comprehensive reviews exist (e.g. [48–50]). Many of the characteristics known to make adherence more difficult are present for young people with liver disease, for example, the treatment is seemingly preventative rather than curative, does not have any immediate tangible benefits and needs to be taken for life. Knowledge is generally necessary, but not sufficient for adherence (e.g. [51]) and requires particular attention as young people grow up and each with different understandings. Individual education, which is tailored to the young person's needs, and repeated and checked regularly is important, to ensure the young person has a good understanding of their condition and rationale for treatment recommendations. It is important to understand the young person's priorities and encourage them to have open conversations about the barriers to adherence for them, for example, discussions may enable medication regimes to be simplified or altered to fit in with the person's routine, encouraging use of alarms and reminders, taking medication on sleepovers and more broadly how to manage the handing over of responsibility from parents to their child. Simplifying medical treatment and conversion to once daily preparations of immunosuppression have been reported to improve adherence and treatment satisfaction [52]. An overview of strategies for improving adherence can be found in Table 74.1.

Non-adherence has also been found to be associated with psychosocial distress, such as PTSD [45] and other psychosocial stressors [53]. Social difficulties such as financial restrictions should not be overlooked. For example, in the UK at the age of 18 years, young people have to start paying for their prescriptions and travel to hospital; when money is limited, these can be very real barriers to adherence for which support is available. Within our service, we adopt a multi-disciplinary approach to identifying and managing adherence, which begins with a stance of assumed non-adherence and reinforcing disclosures; as rates are known to be around 50%, we normalize that most young people will struggle to take all of their medication all of their time. See Table 74.2

Table 74.1 Adherence management strategies

Barrier to adherence	Strategies
Naive about the risks of non-adherence	Individualized education about illness and medication
Burden of medication regime: too many tablets or too many times a day	Simplify medication regimes Ensure young person understands rationale for each medication and anticipated course
Non-intentional non-adherence: forgetting or organizational difficulties	Pill boxes, blister packs Medication charts and apps Alarm reminders Visual reminders Pairing medication with a daily activity
Intentional non-adherence: not taking medication due to the meaning of it/psychological benefits of non-adherence	Explore beliefs about illness and medication, including the benefits of non-adherence for the young person. Assess mood Referral to psychologist
Intentional adherence: practical barriers	Assess barriers such as housing, finances, parental support Referral to social worker

Table 74.2 Routine assessment and management of adherence

Task	Rationale	Example questions
Engage the young person	Young people are more likely to be actively involved in their health care and more adherent if they have a good relationship with their health-care provider Screen for psychosocial difficulties Gather information about how the illness and treatment fits into the young person's life	See HEADSS [33]: ask about home, school/college, friendships, activities and interests
Assess who is responsible for medication	Responsibility needs to be handed over from parents to young person: difficulties often arise during this transition	'Who is in charge of medication at home? How long have you been taking charge of your medication? Who organizes the prescriptions?'
Assume non-adherence and routinely assess with every patient in a non-judgemental manner	Rates of non-adherence exceed 50%—most young people will be non-adherent some of the time Impossible to predict who will be non-adherent so need to ask everyone Asking questions in a non-judgemental way that assumed some non-adherence is more likely to increase disclosure	'In a normal week, how often do you tend to miss your medication? How often do you take it at a different time?'
Normalize: full adherence is difficult; very few people are adherent all of the time	More likely to increase honest disclosure and willingness to discuss the barriers to their adherence Trying to scare or tell off your patient is unlikely to improve their adherence, but will ensure that they do not disclose it to you again!	'Most young people we see struggle to take all of their medication all of the time. We know that it can be a really hard thing to have to take medication every day.'
Check understanding of illness and risks of non-adherence	Knowledge is necessary (but not sufficient) for adherence Need to ensure that the young person understands why they need to take medication and fully understand the risks of not taking it	'How would you explain your condition to someone who hadn't heard of it before? What do you think the medications do? What do you think would happen if you didn't take your medication? How many doses of medication do you think you could get away without taking?'
Assess intentionality of non-adherence	Different determinants of non-adherence require different interventions	'Are there times that you remember your medication, but choose not to take it for some other reason? How often do you forget your medication compared to choosing not to take it? When you miss it, do you always miss all of your medication or just some of them?'
Identify barriers	Different determinants of non-adherence require different interventions	'What gets in the way of taking medication? What is the worst/hardest thing about (having to take) medication?'

HEADSS home, education/employment, peer group activities, drugs, sexuality, and suicide/depression

for details of our approach for routinely assessing in this age group. From conducting a case-note review of the more complex cases seen by our clinical psychologist and specialist social worker, we found that a significant minority had entrenched relational difficulties and had experienced childhood abuse [54]. We hypothesized that non-adherence can be related to attachment difficulties and in some cases can require long-term specialist input to treat. Effective identification of non-adherence and the factors contributing to it are essential to ensure access to the appropriate services.

Non-adherence is thought to be related to both the adolescent stage of development (e.g. [17]) and the process of transitioning into adult services at this risky period (e.g. [53]). It is therefore crucial for every centre to carefully consider how to transition their young people. This is reviewed below.

Transition from Pediatric to Adult-Centred Health Services

The adolescent health society defined transition in 1993 as a ‘Purposeful, planned process that addresses the medical, psychosocial and educational/vocational needs of adolescents and young adults with chronic physical and medical conditions from child-centred to adult-orientated healthcare systems’.

In 2002, American Academy of Pediatrics published the following consensus: ‘The goal of transition in health care for young adults with special health care needs is to maximize lifelong functioning and potential through the provision of high-quality developmentally appropriate health care services that continue uninterrupted as the individual moves from adolescence to adulthood’ [55]. Several reports, mainly in the transplant setting, have since been published, with worse outcomes for patients transplanted during adolescence but a decrease in 1 year mortality in renal transplant recipients as patients age from 20 to 30 years. This supports the concept that maturation and complete development occur after the age of 18 years [9]. It seems that to date the development of dedicated programs to optimize transition from pediatric to adult-centred care has mainly been driven by pediatric specialists, with currently no consensus as to how to implement or measure this, or even define what a successful outcome is. Different models of transition programs have been described and will need to be developed depending on the set up and needs of the individual centres. Pediatric teams should focus on developing strategies to overcome barriers to an adequate transition including learning difficulties, social factors, patients in care and patients with mental health problems and aim for an integrative process. With regards to congenital and rare conditions typically presenting in childhood, where adult teams might be less familiar in managing these conditions, management in specialized centres with pediatric expertise is recommended. In cardiology, for example, it is

recommended for ‘grown up adults with congenital heart disease’ also known as GUCH to be followed up in specialized centres with multidisciplinary input [56].

Patients and their families should be given realistic expectations of the adult health-care systems where the patient is expected to advocate for themselves and therefore self-management skills should be included in the transition process.

Experience in the renal transplant setting demonstrated that the introduction of an integrated pediatric/young adult joint transition clinic and care pathway improved outcome over a 4-year period, with no episodes of late acute rejection or graft loss compared to 35% graft loss in a group of patients who did not benefit from this service [28]. A transition service should aim to manage young people with a chronic condition in a comprehensive and holistic way and should include parents/caregivers whose role will change during the process as one of the main aspects of transition is shifting from caregiver-provided to parent-provided care and the self-management of one’s own illness [57]. It has been shown that incorporation and promotion of disease self-management within chronic care models have improved outcomes in conditions as asthma, diabetes mellitus and rheumatoid arthritis [58]. In this respect, it is important to use transition readiness tools to define a patient’s individual needs and for a multi-professional team to address these.

A recent small pilot study in a group of 20 liver transplant recipients whose care was coordinated by a transition coordinator showed, compared to a historic group of 14 patients, improved adherence to treatment during the year before transfer to adult services. After transfer, tacrolimus standard deviation (SD) scores remained stable in the group supported by the transition coordinator compared to the historic group where the tacrolimus SD increased, suggesting poorer adherence [59].

Ideally, the timing of the transition process should be flexible and aimed at the patient’s needs and readiness; however, in practice, lack of age-appropriate inpatient facilities or pediatric and adult setting being on different sites often means that patients over 18 years cannot be admitted to pediatric inpatient facilities, raising the importance of starting the transition process early enough. This is particularly relevant in patients with special health-care needs where the transition process becomes more complicated as the patient might not be able to advocate for their care, consent for procedures and manage an inpatient stay on an adult ward independently. In these cases, the multi-professional team should ensure a well-documented care; pathway is discussed prior to transition to adult services [60, 61].

Summary and Conclusions

- With advances in medicine, more patients with liver conditions are growing in to adulthood.

- Adolescence is a period of biological, psychological and social changes and the impact of a chronic condition on this process can be significant.
- Outcome data suggest that young people are a unique and vulnerable cohort who deserves special attention by health professionals, focusing on better outcome and survival.
- Growth failure and pubertal delay are prevalent and sexual health advice should be offered standard during the consultation with the young person.
- Psychological aspects of growing up with liver disease are increasingly being recognized and identified and require management by specialized health-care professionals.
- Non-adherence to all aspects of care is common, multifactorial and often underestimated, however, impacts on outcome and survival. A non-judgemental approach aimed at identifying barriers to adherence and developing an individualized strategy is recommended.
- Successful transition programs have shown improvement in outcome and quality of life and should be developed according to the facilities of the individual centre and focus on self-management, keeping in mind the special needs patients might have.

Emer Fitzpatrick and Anil Dhawan

Introduction

Pediatric hepatology as a distinct subspecialty has emerged gradually over the past 40 years [1], indeed, though one of the first two liver transplants undertaken was performed in a child with biliary atresia in 1964 [2]. The division from adult hepatology and the distinction from pediatric gastroenterology have taken time to evolve. The UK became the first country to introduce 3 years' training programme in pediatric hepatology, while advanced fellowships are being introduced in the countries like the USA. Over the past half century, massive advances have been made, with liver transplantation outcomes for children surpassing 90% survival. Now pediatric hepatology is poised at the brink of a hugely exciting era with the potential of advances in technology, particularly in genetics, bioengineering and small molecules, bringing real advantages to diagnostics and therapeutics. In addition, there is a renewed focus not just on survival and medical outcomes but on improving the quality of life for patients and minimising the side effects of each treatment.

As a speciality of rare diseases, in general, a lot of the research and development to date in pediatric hepatology, particularly in transplantation, comes adapted from adult practice. In the twenty-first century, however, with focus on genetics and metabolic disease, pediatric hepatology research is set to take the lead as regards innovative practice.

Genes, cells and molecules are cross-cutting themes across diagnostics, the better understanding of pathophysiology and thus therapeutic options. Each of these is explored in more detail within this chapter. In addition, there will need to be a biopsychosocial emphasis on research and development within the subspecialty: The focus is now on long-term outcomes for children with liver disease and a shift away from survival alone to holistic wellbeing. New challenges face us

in the twenty-first century, particularly the massive increase in the prevalence of obesity across both the adult and pediatric population. This has consequences in terms of both lifestyle-related liver disease and the decline in healthy livers suitable for transplantation due to the frequent occurrence of steatosis.

Genetics

Diagnostics

Our understanding of single-gene and polygenetic/multifactorial disorders has undergone major advancement over the past number of years and continues to do so. Many of the rare disorders described in pediatric hepatology have found explanation in genetic alteration, thanks to collaboration of pediatric hepatologists and geneticists internationally. The major technological advances of next-generation sequencing, whether in whole-genome analysis or targeted studies, have allowed analysis and elucidation of huge amounts of data. Over the past two decades or so, the genetics of Wilson's disease [3, 4], Alagille disease [5, 6], arthrogyrosis, renal dysplasia and cholestasis (ARC), microvillus inclusion disorder, familial intrahepatic cholestasis (FIC)1 disease, bile salt export pump (BSEP) deficiency, multidrug resistance (MDR)3 deficiency and most recently tight junction protein-2 (TJP2) disease have been described [7–10]. In addition to this, the genetic basis of many metabolic diseases affecting the liver, such as glycogen storage disease and mitochondrial depletion disorders [11, 12], has been discovered leading to more rapid and less invasive diagnostic measures.

Gene 'chips' now exist for the diagnosis of cholestatic conditions in neonates and certain metabolic diseases (glycogen storage disease).

The interaction of genetic susceptibility and the environment has also come to the fore with an understanding of genetic variation in man due to epigenetics. Single-nucleotide polymorphisms (SNPs) can not only explain variation in susceptibility to disease processed, for example, patatin-like

phospholipase domain-containing protein 3 (PNPLA3) in nonalcoholic fatty liver disease (NAFLD) [13], autoimmune liver disease [14] but also in hepatocellular carcinoma and response to treatment in hepatitis C. Next on the agenda are determining the genetic modifiers for multifactorial conditions, for example, biliary atresia, idiopathic acute liver failure. Cystic fibrosis-associated liver disease and liver disease in alpha-1-antitrypsin deficiency will also benefit from this approach.

Gene Therapy

Genetic modification has still promise as a therapy. Liver-based metabolic disease has the particular advantage of the liver as a target organ for gene therapy. Preclinical studies and clinical trials to date have yet to overcome safety concerns in terms of stability and the potential for carcinogenesis.

The potential of using induced pluripotent stem (iPS) cells has become a hot topic and the use of genetically modified iPS cells from adults with alpha-1-antitrypsin deficiency that may be a useful approach without the need for immunosuppression [15, 16].

The delivery of gene therapy involves use of a vector at present which may be viral or nonviral. This, in addition to the major issue of genomic instability, is the major safety concern limiting the current clinical applicability of the therapy.

Other approaches to genetic therapy targeting liver disease include using interfering RNA, with some success, including the use of this technique to treat transthyretin-mediated amyloidosis, a liver-centric disease [17]. Small interfering RNAs bind to the RNA-induced silencing complex-mediated cleavage of target messenger RNA. This has been exploited by developing tools to enable delivery to target organ in stable formulation, for example, lipid nanoparticles which are stable and robust. When delivered intravenously, they home in to the liver.

MicroRNAs (miRNAs) are small noncoding RNAs, 18–24 nucleotides in length that regulate gene expression by binding to mRNAs to interfere with the process of translation. They are regulated during or after transcription and SNPs in miRNA genes may also modify their activity and function. Approximately, 1400 mammalian miRNAs are known and each can influence hundreds of gene transcripts. These molecules are involved in all biological processes in all cell types. In the liver, there has been much interest in the role of miRNA in glucose and lipid metabolism, inflammation, apoptosis and cell death, cell cycle and proliferation and fibrosis. miRNAs have been investigated as both biomarkers of disease processes in the liver and potential therapeutic targets by both inhibition and over-expression. Clinical trials

are currently ongoing using an anti-miRNA 122 locked nucleic acid (LNA) inhibitor in hepatitis C—early results have shown a prolonged dose-dependent reduction of hepatitis C virus (HCV) RNA levels without conveying resistance.

Regenerative Medicine and Cell Therapy of Liver Disease

Liver transplantation is undoubtedly the standard of care for end-stage liver disease and many liver-based metabolic conditions and developments in surgical technique, peritransplant care and immunosuppressive medication means that outcomes are improving. However, the unfortunate fact is that organs are in short supply, and the growing tendency towards obesity in the general population means that fewer and fewer non-steatotic, healthy livers are available through donation and are particularly unsuitable for split-organ transplantation (which is the main source of transplanted livers in children). Thus, deaths inevitably occur while awaiting a suitable organ. Hepatocyte transplantation is becoming more established as an alternative to orthotopic or auxiliary liver transplantation in the management of liver-based metabolic conditions and in acute liver failure [18–24]. As with auxiliary transplantation, the native liver remains in place; in the case of acute liver failure, this allows the possibility of native liver regeneration over time; in metabolic liver disease, the native liver serves as a back-up in case of graft failure and remains available for the future possibility of gene therapy. The procedure is significantly less invasive than organ transplantation and previously isolated and cryopreserved cells are available on demand.

Hepatocytes are derived from organs that would otherwise be rejected for transplantation. In general, these often compromised livers may be steatotic, from non-heartbeating donors [25], or unused segments [26]. Innovative methods to improve cell quality from these poor grafts and cryopreservation methods have been a focus of research. Challenges also remain in the effective engraftment of hepatocytes into the host liver. The optimal immunosuppression approach is also as yet unknown. Therapeutic effect is often lost after 6–9 months, perhaps due to rejection, apoptosis or other causes. The single most important obstacle to the widespread application of hepatocyte transplantation is the limited availability of hepatocytes. This has encouraged investigation into alternative sources of cell, including stem cells, immortalised cells and xenotransplantation, each with its own challenges.

In all, there have been over 80 case reports of clinical human hepatocyte transplantation from 13 centres for liver-based metabolic disease, acute liver failure (ALF) or chronic liver disease. Table 75.1 depicts the conditions where human hepatocyte transplantation has been attempted. Cells are infused into the liver via the portal vein/hepatic artery or into

Table 75.1 Conditions where human hepatocyte transplantation has been attempted in children

Inborn errors of metabolism
Crigler–Najjar syndrome type 1
Familial hypercholesterolaemia
FVII deficiency
Glycogen storage disease type I
Infantile Refsum’s disease
Progressive familial intra-hepatic cholestasis type 2 (PFIC2)
Urea cycle defects
Ornithine transcarbamylase deficiency
Arginosuccinate lyase deficiency
Carbamoyl phosphate synthase type 1 deficiency
Citrullinemia
Acute liver failure
Drug
Viral
Idiopathic

the spleen. In ALF, intraperitoneal transplantation may be optimal.

The aim of hepatocyte transplantation in metabolic disease is to replace the missing function without the need to replace the whole organ. In animal model of Crigler–Najjar syndrome, approximately 12% of liver mass is needed to normalise the bilirubin levels [27]; however, fewer cells may be enough to change the phenotype in other conditions.

In acute liver failure, hepatocyte transplantation may act as a bridge to recovery and regeneration of the injured native liver or alternatively to orthotopic liver transplantation once an organ becomes available. The procedure may also be used in patients who are not candidates for organ transplantation. A major advantage of hepatocyte transplantation is the immediate availability of cryopreserved cells. Sufficient cell mass (approximately 10–15% of liver cell mass) is needed to provide enough function to sustain metabolic function [27]. Hepatocyte transplantation in patients with ALF has resulted in a reduction in ammonia and bilirubin with improvements in hepatic encephalopathy and cardiovascular instability [19, 28, 29]. The advantages of intraperitoneal transplantation of hepatocytes encapsulated in alginate microbeads are currently being evaluated. Alginate serves as an anchorage point for cells and protects the hepatocytes from immune attack.

In metabolic liver diseases, the aim of hepatocyte transplantation is to replace function by the engrafted cells. Attempts at improving engraftment include temporary embolisation of the portal vein [30], liver irradiation [31] and the administration of growth factors [32].

The supply of good quality livers for hepatocyte isolation is a major issue. There is a pressing need for an easily available alternative cell source. Stem or progenitor cells have many advantages as an alternative source of cell for hepatocyte transplantation. They are readily available and may be effectively expanded *in vitro* or *in vivo*. Autologous cells (iPS cells) eliminate the need for immunosuppression; how-

ever, they may need to undergo corrective genetic manipulation prior to use to correct the underlying defect [33].

Early experimental evidence for progenitor cells/stem cells was demonstrated by Petersen [34], since that time there have been numerous studies showing expression of liver-specific genes by differentiated stem cells *in vitro* and *in vivo* summarised by a number of excellent reviews [33, 35, 36]. Proof of true functionality of these cells has been less frequent. It is not clear as yet whether transdifferentiation or fusion is responsible for the change in phenotype of the cells. For example, with severe selection pressure, such as in the fumarylacetoacetate hydrolase (FAH)^{-/-} mouse (model for tyrosinemia type 1), successful repopulation occurs mainly because of hepatocyte fusion with host hepatocytes [37]. The tumorigenic potential of modifications to the genome needs to be considered.

Embryonic Stem Cells

Human embryonic stem cells (hESCs), isolated in 1998 [38], have generated great interest and controversy over the past decade. Despite their undoubted therapeutic promise, their effective clinical application has remained elusive to date. hESC lines have been effectively differentiated to hepatocyte lineage with evidence of repopulation of immunosuppressed mouse model of liver injury [39, 40]. Undifferentiated ESC transplanted into immunodeficient mice resulted in teratoma formation [41, 42]. Safety concerns are thus a major obstacle to clinical translation. hESCs are thought to be less susceptible to immune rejection than more mature cells due to their low immunostimulatory potential [43], though the true capacity of hESC to evade the immune response remains unknown.

Hepatoblasts and Foetal Liver Progenitor Cells

The foetal liver is a source of more committed progenitor cells in the form of hepatoblasts. These cells retain their proliferative capacity but are ‘directed’ specifically towards development of hepatocytes and cholangiocytes. There has been success in using progenitor cells from foetal liver in animal models [44] and clinical case reports in ALF [45] and Crigler–Najjar syndrome [46]. Again there is some concern regarding the ability of progenitor cells to differentiate into functionally mature hepatocytes [47]. The most appropriate microenvironmental conditions for this have not yet been fully defined. An ‘adult’ microenvironment may be conducive to differentiation. Problems with this source include difficulty accessing tissue with uncertainty around the most appropriate gestational age to target. There are also some ethical concerns surrounding the harvesting of foetal tissue.

In contrast, 'adult' stem cells combine the ability to differentiate into liver cells with proliferative capacity. Use of this source is less ethically complex and closer to the clinic than embryonic or foetal liver stem cells.

Endogenous Liver Stem Cells

It is well known that the liver has the ability to regenerate by division of mature hepatocytes as demonstrated to good effect following partial hepatectomy [48]. Usually, hepatocytes turn over once or twice a year [36]. A second compartment of facultative stem cells become active in the presence of long-standing injury or impaired proliferation of mature hepatocytes. This occurs when replicative senescence is reached. These cells are located in the intrahepatic biliary tree within the canals of Herring [49], giving rise to bipotent cells which have the potential to become both cholangiocytes and hepatocytes. Adult-derived human liver stem cells have also been isolated by outgrowing cultures of primary hepatocytes and are thought to have advantages over other pluripotent cells. In particular, they are already 'directed' towards hepatocyte differentiation and thus are theoretically more likely to provide the required function without the problems of teratogenicity. A major advantage of these cells is their ability to expand *in vitro*. The functionality of these cells once differentiated has been documented [50].

Mesenchymal Stromal Cells

Mesenchymal stromal cells have also been shown to have promise in the cell therapy of liver disease [51]. These are multipotent, adherently growing cells which provide support for haematopoietic cells within the bone marrow [52]. They are a readily available source of stem cell also isolated from umbilical cord blood and matrix, placental tissue and adipose tissue [53–55]. Mesenchymal stem cells (MSCs) have beneficial effects in animal models of ALF. They can transdifferentiate into hepatocyte-like cells both *in vitro* and *in vivo* [56, 57]. MSCs play a major role in tissue repair both through localised immunosuppressive effects and through the release of soluble trophic factors to affect neighbouring cells, properties which make them excellent candidates for improving the survival of transplanted cells [58, 59]. Improved survival has been shown in animal models of liver disease and pilot clinical studies of liver failure [60, 61]. It is not clear, however, whether the transdifferentiation of MSCs into hepatocyte-like cells or an anti-inflammatory, anti-apoptotic effect induced by the MSCs result in the desired outcome. Soluble factors such as growth factors, cytokines, extracellular matrix glycoproteins and other small molecules produced by MSCs likely mediate these effects in ALF rather

than transdifferentiation [58]. Candidate molecules include interleukin (IL)-1 α , IL6, IL8, granulocyte-colony-stimulating factor, nerve growth factor and hepatocyte growth factor [60, 62]. MSC-conditioned medium conferred a significant improvement in mortality and biochemical indices of liver damage in a galactosamine-injured rat with evidence of inhibition of apoptosis and promotion of liver regeneration in the treated liver [63]. This anti-apoptotic, pro-regenerative effect of MSCs has also been seen in the setting of myocardial infarction [64] and stroke [65]. In addition to the beneficial effects on liver inflammation and regeneration, other studies have recognised the supportive effects of bone-marrow-derived cells in coculture with hepatocytes [66]. Co-encapsulated hepatocytes and bone marrow stem cells resulted in prolonged maintenance of function in the co-encapsulated group *in vitro* and *in vivo* in a rodent model of ALF [67, 68]. Thus, not only are MSCs anticipated to improve the viability and functionality of co-transplanted hepatocytes but transplanted mesenchymal stem cells may also be a source of anti-inflammatory/anti-apoptotic mediators in the setting of the failing liver and the subsequent cytokine storm. MSCs are already used clinically in the treatment of graft versus host disease, and these have safety and logistical advantages over hESC and alcoholic liver disease/hepatic stellate cell ALD/HSC.

Induced Pluripotent Stem Cells

The description by Takahashi and Yamanaka [69, 70] of the induction of somatic cells back to their pluripotent state by over-expressing certain transcription factors, and the subsequent differentiation of the cells along alternative lineages, has opened massive possibilities for cell therapy in liver disease. The differentiation of autologous dermal cells into hepatocytes following induction of pluripotency may have significant advantages, avoiding the need for immunosuppression in cell transplantation and providing an accurate model of disease to investigate pathophysiological mechanisms and test therapies. Of course, the transplantation of autologous cells in a disease state would require the need for genetic manipulation to correct that defect in the first instance. Thus, potential genomic instability may be a problem; however, new techniques are emerging which may minimise this risk and allow genomic stability. One such approach is using a piggyBac technique which enables removal of transgenes without residual sequences. This technique was used to good effect in a study by Yusa et al. which differentiated iPS cells from dermal cells of a patient with alpha-1-antitrypsin deficiency, corrected the genetic abnormality and demonstrated the function of the hepatocyte-like cells when transplanted into a mouse [15]. iPS-derived hepatocyte cells have also been used in the successful formation of 'liver buds' together

with endothelial cells from umbilical cord and mesenchymal stromal cells. When transplanted into a mouse, this human liver bud rapidly vascularised and demonstrated liver-specific function [71].

Immortalisation

In order to establish a sustainable source of cells for transplantation, immortalisation of hepatocytes has also been described. Clonal cell lines of human and rat hepatocytes have been transduced with retroviral vector expressing the immortalising simian virus 40 large T antigen gene [72]. Despite control mechanisms for switching immortalisation on and off, concerns regarding safety remain.

Thus, the potential of cell therapy for liver disease is promising, though cell source is an issue, the emergence of mesenchymal stromal cells and iPS cells into the clinical field is particularly relevant and may provide an alternative source for successful translation. Pediatric liver disease, especially liver-based metabolic disease, remains a priority for this approach.

Small Molecules and Chaperones

As a reduction in protein stability is often a common outcome of monogenic disease, for example, alpha-1-antitrypsin deficiency or cystic fibrosis, focus on the stabilisation of such proteins and provision of an increase in intracellular function is the remit of pharmacological chaperones and other small molecules.

The work of Lomas group and others have focused on the use of small molecules to block the abnormal polymerisation of alpha-1-antitrypsin in the Z state [73]. At present, however, this work is proof of principle and not yet at translation point, though in the future may offer real therapeutic promise. A pediatric group in Pittsburgh investigated the use of carbamazepine as an autophagy enhancer to clear the intracellular load of abnormally formed alpha-1-antitrypsin in the disease state and reduced liver fibrosis in mice [74], using a well-established pharmacological substance as a molecular manipulator. Similarly, lysosomal storage disease and phenylketonuria have also been a focus for the development of protein chaperones [75, 76].

Targeting other nuclear receptors with pharmacological agents is a focus for polygenic or multifactorial disease such as NAFLD and primary biliary cirrhosis. Farnesoid X receptor (FXR) is a nuclear receptor that binds extensively to genomic DNA. FXR undergoes conformational change and alters gene expression following binding by bile acids or other pharmacological compounds. This results in the regulation of bile acid levels in the liver and in addition glucose

and lipid homeostasis. Thus, modulation of FXR binding and function using a semi-synthetic bile acid may be a useful approach to therapy of nonalcoholic steatohepatitis (NASH) [77] and certain cholestatic liver diseases for which there are early clinical studies ongoing at present [78].

Conclusions

Pediatric hepatology is increasingly becoming an independent speciality. Success of liver transplantation has been crucial to the success of this speciality. A majority of chronic liver diseases are of perinatal onset with large number due to genetic or metabolic defects. Rapid advances in the field of genetics and molecular medicine will help unravel the mechanisms underlying these disorders and molecular diagnostic approaches. Understanding the underlying mechanism will help us to use newer treatments like gene therapy and small molecules. In parallel, the field of cellular therapy using human hepatocytes continues to gain momentum with proof-of-concept clinical applications in liver-based metabolic disorders and ALF. Stem cell sources of liver cells from embryonic stem cells, induced pluripotent cells and production of liver organoids from stem cells with use of growth factors appear to hold great promise to replace whole liver replacement in future.
