Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assumes any liability for any injury and/or damage to persons or property arising out or related to any use of the material contained in this book.

CONTRIBUTORS

Alfred Z. Abuhamad, MD

Mason C. Andrews Professor and Chairman, Department of Obstetrics and Gynecology, Eastern Virginia Medical School; Department of Obstetrics and Gynecology, Sentara Norfolk General Hospital, Norfolk, Virginia

The Role of Doppler Ultrasound in Obstetrics

Fred E. Avni, MD, PhD

Professor of Radiology, Free University of Brussels (ULB); Chief, Department of Medical Imaging, University Clinics of Brussels - Erasme Hospital, Brussels, Belgium

The Fetal Genitourinary Tract

Robert H. Ball, MD

Associate Professor, Departments of Obstetrics, Gynecology and Reproductive Sciences and Radiology, University of California, San Francisco, San Francisco, California; Department of Maternal-Fetal Medicine, St. Mark's Hospital, Salt Lake City, Utah; Director, Fetal Therapy Initiative, Hospital Corporation of America, Nashville, Tennessee

The Prenatal Management of the Fetus With a Correctable Defect

George Bega, MD

Assistant Professor of Obstetrics and Gynecology, and Director, 3D/4D Education and Research Program, Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, Thomas Jefferson University, Philadelphia, Pennsylvania

Ultrasound Evaluation of the Cervix

Beryl R. Benacerraf, MD

Clinical Professor, Departments of Radiology and Obstetrics, Gynecology and Reproductive Sciences, Harvard Medical School; Radiologist, Department of Radiology, Brigham and Women's Hospital; Editor in Chief, Journal of Ultrasound in Medicine, American Institute of Ultrasound in Medicine, Boston, Massachusetts

The Role of Three-Dimensional Ultrasound in the Evaluation of the Fetus

Carol B. Benson, MD

Professor of Radiology, Department of Radiology, Harvard Medical School; Director of Ultrasound, and Co-Director of High Risk Obstetrical Ultrasound, Department of Radiology, Brigham and Women's Hospital, Boston, Massachusetts

Ultrasound Evaluation During the First Trimester of Pregnancy

Vincenzo Berghella, MD

Professor, Obstetrics and Gynecology, and Director, Maternal-Fetal Medicine Division, Department of Obstetrics and Gynecology, Thomas Jefferson University; Department of Obstetrics and Gynecology, Thomas Jefferson University Hospital, Philadelphia, Pennsylvania

Ultrasound Evaluation of the Cervix

Shraga Blazer, MD

Clinical Associate Professor, Department of Pediatrics, Faculty of Medicine, Technion – Israel Institute of Technology; Director of Neonatology, Department of Neonatology, Rambam Medical Center, Haifa, Israel

The Gastrointestinal Tract and Abdominal Wall

Adam F. Borgida, MD

Associate Professor, Department of Obstetrics and Gynecology, University of Connecticut School of Medicine, Farmington; Attending Perinatologist, Department of Obstetrics and Gynecology, Hartford Hospital, Hartford, Connecticut

Ultrasound Evaluation of Multiple Pregnancies

Moshe Bronshtein, MD

Senior Sonologist, Department of Obstetrics and Gynecology, Rambam Medical Center; Director, Alkol Institute of Ultrasound in Obstetrics and Gynecology, Haifa, Israel

The Gastrointestinal Tract and Abdominal Wall

Peter W. Callen, MD

Professor of Radiology, Obstetrics, Gynecology, and Reproductive Sciences, Department of Radiology, University of California School of Medicine, San Francisco, California

The Obstetric Ultrasound Examination; Amniotic Fluid Volume: Its Role in Fetal Health and Disease; Ultrasound Evaluation of the Adnexa (Ovary and Fallopian Tubes); Artifacts, Pitfalls, and Normal Variants

Marie Cassart, MD, PhD

Pediatric Radiologist, Department of Medical Imaging, Erasme Hospital, Brussels, Belgium

The Fetal Genitourinary Tract

Martin R. Chavez, MD

Assistant Professor, Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, University of Medicine and Dentistry of New Jersey – Robert Wood Johnson Medical School, New Brunswick, New Jersey

The Gastrointestinal Tract and Abdominal Wall

PREFACE

This textbook began nearly twenty-six years ago as a Radiologic Clinics of North America edition with the same title. That edition of nearly 400 pages which had state of the art images now *pales* in comparison to the high-resolution images and information presented in the current text of well over 1200 pages. It has been nearly 8 years since the last edition of this textbook. I am often asked why I wait so long to update this book. The answer is quite straightforward. I have waited until technological advances and our knowledge of imaging the obstetric and gynecologic patient had increased sufficiently to warrant a new edition. Nearly two-thirds of the chapters in this textbook are written by new authors and the remaining chapters have been significantly revised. In keeping with previous editions, I have engaged authors who are experts in their respective fields, whose writing style is authoritative and clear. While I have tried to meticulously edit this text, I made no attempt to insure that there was a uniformity of opinion with controversial issues. I believe that it is useful to read differing opinions on a subject and ultimately decide what works best in your practice. Many readers have asked for a more complete textbook in the field of women's imaging rather than a pure ultrasound text. As such, there are chapters on computed tomography, magnetic resonance imaging and for the first time, a chapter on breast ultrasound. I have tried to make sure that the information in each chapter would appeal to both the neophyte in sonographic imaging as well as the *seasoned* expert who uses this textbook as a reference. As such, chapters

can be read in their entirety from beginning to end or used as a reference text. In addition to the numerous tables and figures in each chapter, an extensive appendix is available for reference. Likewise, in addition to the high-quality sonographic images, there are numerous color medical illustrations throughout the text that will help make specific concepts clear.

There are numerous individuals for whom thanks is due. To begin, the authors did a marvelous job of producing authoritative and clear chapters in a timely fashion. The staff at Elsevier, including Martha Limbach and Todd Hummel, in particular, made this a pleasant and painless process. Dr. James Cooper did a wonderful job in providing beautiful and clear medical illustrations for this text. I am thankful to my colleagues, sonographers and trainees who have provided me with helpful suggestions over the years. Importantly, I am grateful for the support of my family who tolerated an endless stream of papers and books scattered throughout the house and a husband and father who was at the computer late at night and early in the morning. My wife Karen was a source of encouragement, support and as a practicing physician herself, aided in my understanding of obstetric and gynecologic issues. Last, I am grateful to you the readers who have given me so much pleasure in your enthusiasm about understanding the field I have come to love.

- Reporting of Ultrasound Results
- Discussing the Examination With the Patient

Evaluating the Obstetric-Gynecologic Ultrasound Literature

Malpractice and the Obstetric Ultrasound Examination

Conclusion

It has now been nearly 4 decades since sonography was first used to evaluate the obstetric patient. At first, the questions this modality sought to answer were basic: Is there a pregnancy? Is the fetus alive? Is there a singleton or a twin gestation? What is the location of the placenta? What is the gestational age? Probably, few envisioned that the day would come when ultrasonography would be used to answer questions as to the presence of subtle anatomic defects such as cleft lip or palate or suggest the presence of a chromosomal abnormality. Likewise, at its inception, it was difficult to convince clinicians as to the usefulness of this new diagnostic modality. Now, it is not unusual for a patient to have one or even several ultrasound examinations during her pregnancy. The recent technologic advances in ultrasound imaging, the use of high frequency transvaginal probes, and the potential for chromosomal screening in early pregnancy (e.g., nuchal translucency) have only magnified the interest in the use of sonographic imaging in the obstetric patient.

Since the last edition of this textbook, there have been dramatic advances in ultrasound technology, including improved spatial and contrast resolution, three-dimensional and four-dimensional imaging, harmonic imaging, new and improved ultrasound scanning probes, and improved digital review workstations, to name a few. Likewise, our knowledge of normal fetal anatomy and pathology, and the pathophysiology of disease have increased substantially. The Internet has made communication among researchers easier. Likewise, there have been many collaborative studies

and refinements of the guidelines for the performance of the obstetric ultrasound examination. However, there are still differences in the approach to the obstetric ultrasound examination from one group to the next. Some very basic issues such as what constitutes a basic ultrasound examination, what structures should be evaluated, the timing of the examination, who should perform and interpret the examination, how safe is ultrasound, how should it be recorded and documented, how should it be reported, and last, how should the patient be told the results of the examination are often hotly debated. These issues are addressed later in the text and some of them discussed here.

SAFETY OF ULTRASOUND EXAMINATION

It was not long after the inception of ultrasound imaging that questions were raised as to the safety of this new modality. Despite numerous claims of the safety of ultrasound to the mother and fetus, there have been a number of studies noting possible adverse effects of diagnostic ultrasound to the developing fetus. These studies have focused primarily on thermal and cavitation mechanisms, leading to possible injuries to the developing fetus.¹⁻⁵

Absorption of the ultrasound wave's energy by soft tissue and bone, and its conversion to heat are measured by the thermal index. A thermal index of 1 means an increase of 1 degree centigrade. Several studies have suggested a general

threshold of temperature elevation of 1.5 to 2° C above maternal core temperature before any evidence of a developmental effect occurs. With modern ultrasound machines, there is only a negligible rise in temperature, usually less than 1° C. The World Federation for Ultrasound in Medicine and Biology⁶ has stated that "a diagnostic exposure that produces a maximum in situ temperature rise of not more than 1.5 degrees C above normal physiological levels may be used without reservation on thermal grounds." In addition, they stated that "a diagnostic exposure that elevates embryonic and fetal in situ temperature above 41 degrees C for 5 minutes should be considered potentially hazardous."⁶ As a result of these conclusions, it is unlikely that there is a deleterious effect of ultrasound in the first trimester during embryogenesis with routine grayscale ultrasound.

However, when Doppler ultrasound is used during the first trimester, it is likely that temperatures above 1.5° C may occur.¹ Studies of the effect of Doppler on soft tissues adjacent to bone and nerve conductance demonstrated a significant rise in temperature when the ultrasound Doppler beam was held for more than 30 seconds.^{1,7} The European Federation for Societies in Medicine and Biology in 1998 concluded that "until further scientific information is available, investigations using pulsed or color Doppler should be carried out with careful control for output levels."^{1,8}

Although the potential for embryonic effects from Doppler imaging exists, there is little evidence that ultrasound is teratogenic. As stated in a recent editorial on the subject, "Many of the studies to date have shown the embryo to be remarkably resilient to ultrasound exposure. Logic would suggest that Doppler techniques should not affect the embryo if the pulses are applied at a low level."⁹ A study of animals by Zhu et al¹⁰ examined the genetic effect of diagnostic color Doppler sonography. The researchers insonated pregnant rats with diagnostic levels of color Doppler ultrasound energy and studied the cell cycles of newborn rats by flow cytometry and factorial analysis. They found that the deoxyribonucleic acid content was not affected in any phase of the cell cycle in newborn rats by any of the different insonation times and frequencies.

Cavitation involves the occurrence of gaseous bubble formation in an air-water interface.¹ The concern is that stress from the fluid adjacent to the gaseous body during the process of cavitation may disrupt cell membranes.^{1,11} Cavitation has been difficult to document in mammalian fetuses, because, for the most part, there is not an air-water interface, which is needed for the cavitation mechanism.¹

A number of studies have evaluated the effect of prenatal ultrasound on neonatal and infant outcome in animal models. Although some studies have documented lower birth weights, shorter heights, and lowered white blood cell counts in neonates that were scanned in utero compared with controls, the size differences disappeared when studied after 3 months. In addition, hematologic parameters normalized by this time.¹² Neurodevelopmental studies revealed no significant differences in motor or cognitive tasks, or in learning skills.^{1,12} Studies evaluating the human fetus and neonate have reached similar conclusions. Studies have found either no difference in birth weights between exposed and nonexposed fetuses, or a difference that although present at birth, was not present at 6 to 7 years of age.^{13,14}

The information on an association between ultrasound and congenital malformations is limited. Studies evaluating chromosomal aberration and ultrasound exposure have demonstrated little or no change.^{1,10,15}

The major difficulties with the studies investigating a possible deleterious effect of diagnostic ultrasound evaluation are threefold: (1) experimental ultrasound exposure levels or time of exposure often far exceeded those that are normally used diagnostically; (2) the systems used to show ultrasound effect (plants, cell culture, laboratory animals) may not be applicable to humans; and (3) many studies that have demonstrated adverse effects in vitro have not been reproducible.¹⁶

A recent study evaluating the effect of diagnostic ultrasound on neuronal migration in mice, once again, raised much attention in the media.¹⁷ Although this is an interesting study in mice, for the reasons stated earlier, it has little to no applicability in humans. There are two major criticisms of this study. Although the study did use commercially available equipment in which only slightly greater ultrasound frequency than normal was used (6.7 MHz versus 3.5–5.0 MHz), the fixed duration of exposure far exceeded what would be normally be used. The study did not demonstrate statistically significant abnormal results until 30 minutes of exposure (2 × 15 minutes). More than 10 years ago, when a sonologist wished to determine that an embryo was nonviable, the recommended evaluation of the embryo was 3 minutes of observation, demonstrating no evidence of embryonic or cardiac activity. Two minutes of evaluation, let alone 3 minutes, seemed like an eternity, and most examiners, in my experience, stopped after 1 minute. In the slightly older embryo and early fetus, greater than 5 to 10 minutes of sustained evaluation of the fetal brain would be excessive. In most cases, the transducer would be moving around the brain rather than being fixed during the examination. The second criticism relates to the timing of embryology and the size of the mouse and human brain. As stated by the authors of this study: "The duration of neuronal production and the migratory phase of cortical neurons in the human fetus lasts approximately 18 times longer than in mice (between 6 and 24 weeks of gestation, with the peak occurring between 11 and 15 weeks), compared with the duration of only approximately 1 week (between E11 and E18) in a mouse."^{17–19} Thus an exposure of 30 minutes represents a much smaller time dedicated to the development of the cerebral cortex in the human than in the mouse, and thus could have a lesser overall effect, making human corticogenesis less vulnerable to ultrasound waves."

The American Institute of Ultrasound in Medicine (AIUM) statement on the clinical safety of diagnostic ultrasound reiterates previous findings that no confirmed bioeffects caused by exposure at intensities typical of present diagnostic instruments have ever been reported in patients or instrument operators.²⁰ This statement acknowledges the possibility that bioeffects may be identified in the future but emphasizes the current data indicating that the benefits of the prudent use of diagnostic sonography outweigh the risks, if any.^{20,21} As stated by Kremkau,²² "even if this risk is so minimal that it is difficult to identify, prudent practice dictates that routine measures be implemented to minimize the risk while obtaining the necessary information to achieve the diagnostic benefit. This is the ALARA (as

low as reasonably achievable) principle of prudent scanning" (Fig. 1-1).

The sonographer's knowledge of ultrasound and its safety is crucial to the safe implementation of this modality. Merritt, in an editorial, summarized it best: "In view of the rapid growth of sonography and its proliferation into the hands of minimally trained clinicians, it is likely that more patients are harmed each day by misdiagnosis resulting from improper indications, poor examination technique, and errors in interpretation than from all bioeffects."²¹

INDICATIONS FOR OBSTETRIC ULTRASOUND EXAMINATION

In some countries, as many as 90% to 100% of women seeking obstetric care have at least one ultrasound examination during pregnancy.^{23,24} In Glasgow, Scotland, where routine scanning is employed, the average number of scans per pregnancy is 2.8.²⁵ In Germany, three ultrasound scans (weeks 9-12, 19-22, and 29-32) are routinely performed during pregnancy.²⁶

If ultrasound evaluation is relatively safe and noninvasive, and has the potential for yielding important diagnostic information, then why not use this modality in every pregnant patient? As one might imagine, there is much controversy over this single issue.

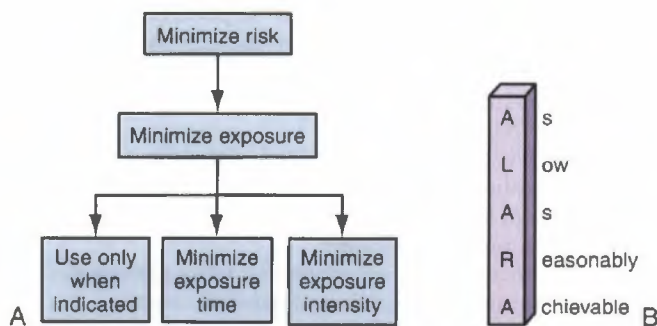

FIGURE 1-1. Minimizing risk by minimizing exposure (A) is the cornerstone of the ALARA principle (B). (From Kremkau FW [ed]: *Diagnostic Ultrasound: Principles and Instruments*, 7th ed. Philadelphia, WB Saunders, 2006.)

In countries where routine prenatal ultrasound examination is practiced, investigators have noted that ultrasound scanning is beneficial in detecting congenital malformations, in diagnosing twins and placenta previa, and in identifying patients at risk for postmaturity and intrauterine growth restriction.^{24,27} Although these observations are clearly important, the major question still unanswered is whether patient outcome is significantly improved by screening ultrasound examinations. In one study in which the routine use of prenatal ultrasound examination was evaluated, researchers found no benefit from the routine use of "office ultrasound."²⁸ Most important errors of gestational age and most twin pregnancies were suspected clinically and diagnosed by an indicated, as opposed to a screening, ultrasound examination.²⁸ In one of the largest studies of its kind, the RADIUS (Routine Antenatal Diagnostic Imaging with Ultrasound) study evaluated over 15,000 low-risk patients in an attempt to determine the efficacy of screening ultrasounds on perinatal outcome.²⁹ Low-risk patients were randomly assigned to have either two screening sonograms (at 15 to 22 weeks and 31 to 35 weeks) or conventional obstetric care with ultrasound used only when believed to be clinically necessary. The conclusion of the study was that screening ultrasound examinations did not improve perinatal outcome and were of no clinically significant benefit. The results of the RADIUS study documented a low detection rate for anomalous fetuses (35% in the screened group versus 11% in the nonscreened group) as well as a low abortion rate (9 abortions for anomalies among 7685 fetuses in the screened group, whereas four pregnancies were terminated for fetal anomalies detected among 7596 control subjects).³⁰ Likewise, many similar studies evaluating the efficacy of screening ultrasound examination have also examined the sensitivity of ultrasound assessment for the detection of congenital anomalies.³¹ These studies have demonstrated that in a low-risk population the sensitivity is low, varying from 17% to 35%, whereas the specificity is quite high at 99%.^{32,33} When targeted examinations of a high-risk population are performed, the sensitivity is significantly improved, to greater than 90%.^{34,35} The major criticisms of the RADIUS and other similar studies have been the low anomaly detection and abortion rates as compared with European studies and those from other countries (Tables 1-1 and 1-2).

Table 1-1 Prevalence of Fetal Anomalies in Published Studies*

From Anderson N, Boswell O, Duff G: Prenatal sonography for the detection of fetal anomalies: Results of a prospective study and comparison with prior series. *AJR Am J Roentgenol* 165:943, 1995.

Possible explanations for the variance in the detection rate of anomalous fetuses may include (1) differences in neonatal assessment, (2) differences in the definition of a major anomaly, (3) a differing risk status of the population, (4) differences in what is considered a routine or standard sonogram, and (5) the expertise of the examiner.³⁶

Even if one concludes that screening ultrasound examinations are a worthwhile endeavor, two major issues must still be addressed. First, the cost of such an undertaking would be large. With approximately 4 million deliveries in the United States annually, the cost of screening every woman, at a conservative estimate of \$200 per examination, would be \$800 million. If one adds the additional cost for multiple examinations, the added health care costs would be more than \$1 billion. Two major arguments are often put forth to counter the concern over cost of screening ultrasound. First, a significant number of patients in public clinics will be found to be at high risk and, thus, will likely require sonographic evaluation in any event. This number may be as high as 40% to 60% of patients. Second, a major criticism of the cost issue relates to the cost of care for nonaborted anomalous fetuses. It has been argued that if the birth of a child with spina bifida, hypoplastic left heart, or trisomy 21 were prevented, the cost savings would pay for the screening of the entire low-risk population in an area.³⁶ In addition to the discussions regarding cost, an argument could be made regarding quality of life and the benefit to the pregnant woman gained from a normal ultrasound.

The second issue involves the persons who perform the screening examinations. Many believe the best solution would be to have virtually any sonologist or sonographer do the screening, as long as he or she would willingly refer all questionable abnormalities to more experienced persons. Although that might conceivably alleviate the problem with the false-positive examination, it would not address the issues of missing an abnormality due to examiner inexperience and a large number of unnecessary "second look" examinations.

As a result of the explosion in the number of ultrasound examinations, several persons and organizations began the process of developing a consensus of indications for the performance of the ultrasound examination. In 1983 to 1984, a panel from the National Institutes of Health convened and, after obtaining input from a number of experienced

sonologists, developed a list of indications for obstetric and gynecologic ultrasound evaluation.³⁷

- Estimation of gestational age by ultrasound evaluation for confirmation of clinical dating for patients who are to undergo elective repeat cesarean delivery, induction of labor, or elective termination of pregnancy.
- Evaluation of fetal growth (when the patient has an identified etiology for uteroplacental insufficiency, such as severe preeclampsia, chronic hypertension, chronic significant renal disease, or severe diabetes mellitus, or for other medical complications of pregnancy when fetal malnutrition, i.e., intrauterine growth restriction or macrosomia, is suspected).
- Vaginal bleeding of undetermined etiology in pregnancy.
- Determination of fetal presentation when the presenting part cannot be adequately assessed in labor.
- Suspected multiple gestation.
- Adjunct to amniocentesis (chorionic villus sampling).
- Significant uterine size/clinical dates discrepancy.
- Pelvic mass detected clinically.
- Suspected hydatidiform mole.
- Adjunct to cervical cerclage.
- Suspected ectopic pregnancy.
- Adjunct to special procedures.
- Suspected fetal death.
- Suspected uterine abnormality.
- Intrauterine contraceptive device localization.
- Ovarian follicle development surveillance.
- Biophysical profile for fetal well-being (after 28 weeks' gestation).
- Observation of intrapartum events (e.g., version/extraction of second twin, manual removal of placenta).
- Suspected polyhydramnios or oligohydramnios.
- Suspected abruptio placentae.
- Adjunct to external version from breech to vertex presentation.
- Estimation of fetal weight and/or presentation in premature rupture of membranes or premature labor.
- Abnormal serum (alpha-fetoprotein [AFP] value for clinical gestational age when drawn).
- Follow-up observation of identified fetal anomaly.
- History of previous congenital anomaly.

- Serial evaluation of fetal growth in multiple gestations.
- Estimation of gestational age in late registrants for prenatal care.

Although there may be some exceptions, this list serves as a useful guideline for referral for ultrasound evaluation in the obstetric and gynecologic patient.

WHO SHOULD PERFORM THE ULTRASOUND EXAMINATION AND HOW SHOULD IT BE PERFORMED?

Theoretically, the answer to who should perform the ultrasound examination should be extremely easy. In fact, it is one of the most controversial issues relating to the ultrasound examination. The answer should be that only those persons who have had adequate training (including didactic as well as supervised "hands-on" experience) should perform and interpret an ultrasound examination.

More than 20 years ago, the Joint Task Group on Training for Diagnosis in Obstetrical and Gynecologic Ultrasound developed guidelines for the postresident physician who completed residency programs in either radiology or obstetrics and gynecology that did not provide formal training in obstetric and gynecologic ultrasound evaluation.³⁸ These guidelines included a recommendation of a minimum of 3 months' experience in obstetric and gynecologic ultrasound evaluation. In addition, it was recommended that this training include 1 month of supervised and documented training in an established ultrasound facility. Such training should include basic physics, technique, performance, and interpretation. In addition, the physician should obtain 2 months of practical experience (at least 200 examinations) before offering services as a physician competent in diagnostic ultrasound examination.³⁸ There is no reason to believe that in the subsequent 20 years, with the increased complexity of this field, that these guidelines should be anything but more stringent.

The "turf" battles between radiologists and obstetricians as to who should perform the examination are unfortunate. As long as the examining physician is adequately trained and performs the minimum standard obstetrical ultrasound examination, as per the guidelines of the American College of Radiology (ACR), AIUM, and American College of Obstetricians and Gynecologists (ACOG), the specialty of the examiner does not matter.^{39,40} I, however, do not believe in the practice of self-referral. Self-referral examinations tend to be performed more and more frequently,⁴¹ and are often less "complete" and of a lower quality than when they are performed by a dedicated ultrasound practitioner. Except in localities where there are no diagnostic ultrasound specialists, patients should be referred to practitioners whose major practice is daily ultrasonography. The potential issues of inconvenience and difficulty in scheduling examinations will undoubtedly always be remedied by practicing sonologists eager for referrals.

Although the previous list of clinical indications addresses the circumstances in which the ultrasound examination should be performed, it does not address the problem of how the examination is performed. In the early 1980s, it became clear that obstetric ultrasound studies were being performed by a variety of persons with disparate levels of training and

that the examinations were different from practitioner to practitioner. There was concern that as the number of examinations was dramatically increasing, their quality was decreasing. In an attempt to address this problem, the ACR Commission on Ultrasound, with minor modification by the AIUM, developed guidelines to serve as a standard for the performance of the obstetric ultrasound examination.⁴² These guidelines have been modified slightly several times, the latest in 2003.⁴³ Although there may be sonologists who exceed these guidelines, the guidelines serve as a minimum standard for all practitioners of obstetric ultrasonography.⁴⁴ In a similar fashion, the ACOG published a technical bulletin in 1988, which was revised in 1993, with very similar standards.^{40,45}

Before discussing the performance of the ultrasound examination, it is necessary to describe the terminology that is used to describe the examination performed in obstetrical ultrasound.

Terminology

The latest classification⁴³ of fetal sonographic examinations by the AIUM, ACR, and ACOG groups the examinations into four major categories: (A) The First Trimester Ultrasound Examination, (B) The Standard Second or Third Trimester Examination, (C) The Limited Examination, and (D) Specialized Examinations. It seems as if the major confusion of what name to call these examinations is centered on categories B and D.

The *standard* second and third trimester obstetric examination is often referred to as a *routine examination*, *basic examination*, *Level 1 examination*, or *complete ultrasound examination*. Although some of these terms are acceptable, some further clarification of the Level 1 and 2 examinations is necessary. These terms, describing sonographic examinations, were developed in the late 1970s to further evaluate patients in whom elevated levels of alpha fetoprotein (AFP) were detected when testing for neural tube defects. Level 1 sonograms were performed largely to detect obstetric problems that result in elevated maternal serum AFP levels (twins, erroneously dated pregnancies, fetal demise). Level 2 sonograms were performed to identify the fetal abnormalities (open neural tube defects, abdominal wall defects) that these programs were designed to detect.⁴⁶ It is important to note that while those individuals performing Level 2 examinations are usually proficient in evaluating patients for congenital anomalies, it does not connote that the level 1 examiner is unskilled.⁴⁶ In an excellent editorial on the subject, Filly⁴⁶ notes that unfortunately some examiners have chosen to use the term "Level 1" as a shield for incompetency. As he states, the Level 1 sonogram is not defined by the technical capability of the examiner, nor by the cost of the sonographic instrumentation employed. In fact, the Level 1 exam "requires a high degree of competency and is for all intents and purposes the standard 2nd or 3rd trimester obstetric sonographic examination as described in the AIUM/ACR/ACOG guidelines" recently published in 2003.⁴³

The *specialized* examination is often referred to as the *Level 2 examination* or *survey examination* or *targeted examination*. As the AIUM/ACR/ACOG guidelines state, this is a detailed anatomic examination that is performed when an anomaly is suspected on the basis of history, biochemical abnormalities,

or the results of either a limited or standard examination previously performed.⁴³

The individuals performing the sonographic examination are referred to as either *sonographers* or *sonologists*. Traditionally, the technical component and initial production of images has been the responsibility of the sonographer (nonphysician), and the professional component and interpretation of images has been the responsibility of the sonologist (physician). The degree of collaboration between the two and their degree of involvement in the ultrasound examination varies from locality to locality. In many parts of the world, examinations are performed predominantly by physicians. Although the contribution of sonographers to the ultrasound examination is invaluable, it should be remembered as stated by the AIUM, "Ultrasound studies shall be supervised and interpreted by a physician with training and experience in the specific area of sonography. Findings must be recorded and results communicated in a timely fashion to the health care provider responsible for care. Although a sonographer may play a critical role in extracting the information essential to deriving a diagnosis, the rendering of the final diagnosis of ultrasound studies represents the practice of medicine, and, therefore, is the responsibility of the supervising physician."⁴⁷

Perhaps the least controversial aspect of this discussion should be who should interpret the ultrasound examination. This, I believe, is straightforward. Only those with adequate training in a conventional training programs (e.g., residency) in which there are didactic lectures, hands-on scanning, and physician supervision in the performance and interpretation of cases should be performing and interpreting ultrasound. Training by manufacturer's training specialists or 1- to 2-week mini courses does not constitute adequate training in ultrasound.

Ultrasound Lexicon

There are undoubtedly hundreds of terms that are used in obstetrics and ultrasonography that are either incorrect or confusing. Many of these terms are addressed later in this chapter and in other chapters in this text. Two areas in which terminology is often either misused or misunderstood in obstetric ultrasonography are fetal life and age. The term *viability* is defined as the ability to survive in the extrauterine environment. Even in cases of very late third trimester examinations, this statement cannot be used with complete certainty. I prefer to state that the embryo or fetus is *living*, if that is the case, and use the term *nonviable* for those embryos or fetuses that either are dead or are not capable of living in the extrauterine environment. Early pregnancy failure is another, perhaps even better, way of communicating this information.

The second often-confusing term is *gestational age*. Taken as it sounds, this term would seem to imply the actual age of the fetus from conception to the present. In fact, this term, which is widely used by obstetricians and sonologists, is most often meant to be synonymous with *menstrual age*. *Menstrual age* refers to the length of time calculated from the first day of the last normal menstrual period to the point at which the pregnancy is being assessed. The true age of the embryo or fetus, *fetal age*, is rarely known accurately unless the patient has had assisted fertilization or has extremely regular menstrual periods and the day of conception is known. Some

examiners subtract 2 weeks from the menstrual age to arrive at the *fetal age*.

In this text, the terms *gestational age* and *menstrual age* are used interchangeably. The important point for any examiner to remember is not which term is necessarily preferable but rather that the person interpreting the examination and the physician who ordered the examination both use the same terminology.

Another often-misused term is *fetal pole*. This is a term that should be abandoned. It is most often used to describe the presence of the *embryo* in the early first trimester sonogram. The embryonic period lasts until the end of the 10th menstrual week; during this time the developing conceptus should be referred to as the embryo.

THE GUIDELINES

In 2003 the *Practice Guideline for the Performance of an Antepartum Obstetric Ultrasound Examination* was developed by the AIUM in collaboration with the ACR and the ACOG.⁴³ These are a modification of previously developed guidelines which first were published in 1986. This guideline is often referred to as the AIUM guidelines or the *guidelines*. The actual ACR/AIUM/ACOG guidelines are presented in Table 1-3. What follows is my own bias as to what constitutes an appropriate ultrasound examination. In some respects, this is an expansion of the guidelines previously mentioned. Because this multi-author text is essentially a detailed review of the obstetric ultrasound examination, I recognize that my viewpoint in this chapter and those of the authors of the subsequent chapters may differ.

ULTRASOUND EQUIPMENT AND DOCUMENTATION

It seems that there will always be differences of opinion as to which ultrasound machines produce the best images. With the present state of ultrasound technology, these differences are often subjective, particularly when discussing state-of-the-art machines. Most ultrasound machines use phased-array real-time technology. Three-dimensional/four-dimensional ultrasound technology is still in its infancy, and its role in the ultrasound examination is increasing but still needs to be evaluated.

An often controversial issue is *which* transducer should be used for the ultrasound examination. The answer is as many transducers as are necessary should be used to answer the question for which the patient is referred. There is a misconception that the newest transducer introduced by a manufacturer may be the only one that is needed. When sector and, ultimately, transvaginal probes were first introduced, many practitioners believed that these transducers alone could be used for the entire examination. Many learned that using only a single transducer restricts the field of view or visualization of detail, making diagnosis more difficult.

The most common transducers, which are the workhorses of the ultrasound laboratory, are a linear array, a sector transducer (3 to 5 MHz), and a transvaginal probe (5 to 10 MHz). The higher frequency transducers are most useful in achieving high-resolution scans, particularly in the near-field, and the lower frequency transducers are useful in

Table 1-3 Guidelines for Performance of the Antepartum Obstetric Ultrasound Examination

The following are proposed guidelines for the antepartum obstetrical ultrasound examination. The document consists of five parts:

Part I: Specification of Examination	Part IV: Fetal Safety
Part II: Documentation	Part V: Quality Control and Improvement, Safety, Infection Control, and Patient Education Concerns
Part III: Equipment Specifications	

The clinical aspects of this guideline (Specifications of the Examination, and Equipment Specifications) were developed collaboratively by the American Institute of Ultrasound in Medicine (AIUM), the American College of Radiology (ACR), and the American College of Obstetricians and Gynecologists (ACOG). Recommendations for physician requirements, procedure documentation, and quality control vary among these organizations and are addressed by each separately.

This guideline has been developed for use by practitioners performing obstetric sonographic studies. Fetal sonography should be performed only when there is a valid medical reason, and the lowest possible ultrasonic exposure settings should be used to gain the necessary diagnostic information. A limited examination may be performed in clinical emergencies or for a limited purpose, such as evaluation. Of fetal or embryonic cardiac activity, fetal position, or amniotic fluid volume. A limited follow-up examination may be appropriate for reevaluation of fetal size or interval growth or to reevaluate abnormalities previously noted if a complete prior examination is on record.

While this guideline describes the key elements of standard sonographic examinations in the first trimester and second and third trimesters, a more detailed anatomic examination of the fetus may be necessary in some cases, such as when an abnormality is found or suspected on the standard examination or in pregnancies at high risk for fetal anomalies. In some cases, other specialized examinations may be necessary as well.

While it is not possible to detect all structural congenital anomalies with diagnostic ultrasound, adherence to the following guidelines will maximize the possibility of detecting many fetal abnormalities.

Part I

Specifications of the Examination

A. First Trimester Ultrasound Examination

1. Indications

A sonographic examination can be of benefit in many circumstances in the first trimester of pregnancy, including, but not limited to, the following indications:

- a. To confirm the presence of an intrauterine pregnancy.
- b. To evaluate a suspected ectopic pregnancy.
- c. To define the cause of vaginal bleeding.
- d. To evaluate pelvic pain.
- e. To estimate gestational (menstrual) age.
- f. To diagnose or evaluate multiple gestations.
- g. To confirm cardiac activity.
- h. As an adjunct to chorionic villus sampling, embryo transfer, and localization and removal of an intrauterine device (IUD).
- i. To evaluate maternal pelvic masses and/or uterine abnormalities.
- j. To evaluate suspected hydatidiform mole.

Comment

A limited examination may be performed to evaluate interval growth, estimate amniotic fluid volume, evaluate the cervix, and assess the presence of cardiac activity.

2. Imaging parameters

Overall Comment

Scanning in the first trimester may be performed either transabdominally or transvaginally. If a transabdominal examination is not definitive, a transvaginal scan or transperineal scan should be performed whenever possible.

- a. The uterus and adnexa should be evaluated for the presence of a gestational sac. If a gestational sac is seen, its location should be documented. The gestational sac should be evaluated for the presence or absence of a yolk sac or embryo, and the crown-rump length should be recorded, when possible.

Comment

The crown rump length is a more accurate indicator of gestational age than is mean gestational sac diameter. However, the mean gestational sac diameter should be recorded when an embryo is not identified.

Caution should be used in making the presumptive diagnosis of a gestational sac in the absence of a definite embryo or yolk sac. Without these findings, an intrauterine fluid collection could represent a pseudogestational sac associated with an ectopic pregnancy.

- b. Presence or absence of cardiac activity should be reported.

Comment

With transvaginal scans, cardiac motion is usually observed when the embryo is 5 mm or greater in length. If an embryo less than 5 mm in length is seen without cardiac activity, an additional scan at a later time may be needed to document cardiac activity.

- c. Fetal number should be reported.

Table 1-3 Guidelines for Performance of the Antepartum Obstetric Ultrasound Examination—cont'd**Comment**

Amnionicity and chorionicity should be documented for all multiple pregnancies when possible.

- d. Evaluation of the uterus, adnexal structures, and cul-de-sac should be performed.

Comment

Presence, location, and size of leiomyomata and adnexal masses should be recorded. The cul-de-sac should be scanned for the presence or absence of fluid.

B. Second- and Third-Trimester Examination

1. Indications

Sonography can be of benefit in many situations in the second and third trimesters, including, but not limited to, the following circumstances: (adapted from National Institutes of Health. Diagnostic Ultrasound Imaging in Pregnancy: Report of a Consensus. NIH Publication 84-667. Washington, DC: US Government Printing Office; 1984).

- a. Estimation of gestational age.
- b. Evaluation of fetal growth.
- c. Vaginal bleeding.
- d. Abdominal/pelvic pain.
- e. Incompetent cervix.
- f. Determination of fetal presentation.
- g. Suspected multiple gestation.
- h. Adjunct to amniocentesis.
- i. Significant discrepancy between uterine size and clinical dates.
- j. Pelvic mass.
- k. Suspected hydatidiform mole.
- l. Adjunct to cervical cerclage placement.
- m. Suspected ectopic pregnancy.
- n. Suspected fetal death.
- o. Suspected uterine abnormality.
- p. Evaluation of fetal well-being.
- q. Suspected amniotic fluid abnormalities.
- r. Suspected placental abruption.
- s. Adjunct to external cephalic version.
- t. Premature rupture of membranes and/or premature labor.
- u. Abnormal biochemical markers.
- v. Follow-up evaluation of a fetal anomaly.
- w. Follow-up evaluation of placental location for suspected placenta previa.
- x. History of previous congenital anomaly.
- y. Evaluation of fetal condition in late registrants for prenatal care.

In certain clinical circumstances, a more detailed examination of fetal anatomy may be indicated.

2. Imaging parameters for a standard fetal examination

- a. Fetal cardiac activity, number, and presentation should be reported.

Comment

Abnormal heart rate and/or rhythm should be reported.

Multiple pregnancies require the documentation of additional information: chorionicity, amnionicity, comparison of fetal sizes, estimation of amniotic fluid volume (increased, decreased, or normal) on each side of the membrane, and fetal genitalia (when visualized).

- b. A qualitative or semiquantitative estimate of amniotic fluid volume should be reported.

Comment

Although it is acceptable for experienced examiners to qualitatively estimate amniotic fluid volume, semiquantitative methods also have been described for this purpose (e.g., amniotic fluid index, single deepest pocket, 2-diameter pocket).

- c. The placental location, appearance, and relationship to the internal cervical os should be recorded. The umbilical cord should be imaged, and the number of vessels in the cord should be evaluated when possible.

Comment

It is recognized that apparent placental position early in pregnancy may not correlate well with its location at the time of delivery.

Transabdominal, transperineal, or transvaginal views may be helpful in visualizing the internal cervical os and its relationship to the placenta.

Transvaginal or transperineal ultrasound may be considered if the cervix appears shortened or if the patient complains of regular uterine contractions.

- d. Gestational age assessment

First trimester crown-rump measurement is the most accurate means for sonographic dating of pregnancy. Beyond this period, a variety of sonographic parameters, such as biparietal diameter, abdominal circumference, and femoral diaphysis

Table 1-3 Guidelines for Performance of the Antepartum Obstetric Ultrasound Examination—cont'd

length, can be used to estimate gestational age. The variability of gestational age estimations, however, increases with advancing pregnancy. Significant discrepancies between gestational age and fetal measurements may suggest the possibility of fetal growth abnormality, intrauterine growth restriction, or macrosomia.

- i. Biparietal diameter is measured at the level of the thalami and cavum septi pellucidi. The cerebellar hemispheres should not be visible in this scanning plane. The measurement is taken from the outer edge of the proximal skull to the inner edge of the distal skull.

Comment

The head shape may be flattened (dolichocephaly) or rounded (brachycephaly) as a normal variant. Under these circumstances, certain variants of normal fetal head development may make measurement of the head circumference more reliable than biparietal diameter for estimating gestational age.

- ii. Head circumference is measured at the same level as the biparietal diameter, around the outer perimeter of the calvarium. This measurement is not affected by head shape.
- iii. Femoral diaphysis length can be reliably used after 14 weeks' gestational age. The long axis of the femur shaft is most accurately measured with the beam of isonation being perpendicular to the shaft, excluding the distal femoral epiphysis.
- iv. Abdominal circumference should be determined at the skin line on a true transverse view at the level of the junction of the umbilical vein, portal sinus, and fetal stomach, when visible.

Comment

Abdominal circumference measurement is used with other biometric parameters to estimate fetal weight and may allow detection of intrauterine growth restriction or macrosomia.

e. Fetal weight estimation

Fetal weight can be estimated by obtaining measurements, such as the biparietal diameter, head circumference, abdominal circumference, and femoral diaphysis length. Results from various prediction models can be compared to fetal weight percentiles from published nomograms.

Comment

If previous studies have been performed, interval measurement changes should also be evaluated for growth. Scans for growth evaluation typically can be performed at least 3 weeks apart. A shorter scan interval may result in confusion as to whether anatomic changes truly are due to growth as opposed to variations in the measurement technique itself. Currently, even the best fetal weight prediction methods can yield errors as high as $\pm 15\%$. This variability can be influenced by factors such as the nature of the patient population, the number and types of anatomic parameters being measured, technical factors that affect the resolution of ultrasound images, and the weight range being studied.

f. Maternal anatomy

Evaluation of the uterus and adnexal structures should be performed.

Comment

This will allow recognition of incidental findings of potential clinical significance. The presence, location, and size of leiomyomata and adnexal masses should be recorded. It is frequently not possible to image the normal maternal ovaries during the second and third trimesters.

g. Fetal anatomic survey

Fetal anatomy, as described in this document, may adequately be assessed by ultrasound after approximately 18 weeks' gestational age. It may be possible to document normal structures before this time, although some structures can be difficult to visualize due to fetal size, position, movement, abdominal scars, and increased maternal wall thickness. A second- or third-trimester scan may pose technical limitations for an anatomic evaluation due to imaging artifacts from acoustic shadowing. When this occurs, the report of the sonographic examination should document the nature of this technical limitation. A follow-up examination may be helpful.

The following areas of assessment represent the essential elements of a standard examination of fetal anatomy. A more detailed fetal anatomic examination may be necessary if an abnormality or suspected abnormality is found on the standard examination.

i. Head and neck

- Cerebellum
- Choroid plexus
- Cisterna magna
- Lateral cerebral ventricles
- Midline falx
- Cavum septi pellucidi

ii. Chest

The basic cardiac examination includes a 4-chamber view of the fetal heart. If technically feasible, an extended basic cardiac examination can also be attempted to evaluate both outflow tracts.

iii. Abdomen

- Stomach (presence, size, and situs)
- Kidneys
- Bladder
- Umbilical cord insertion site into the fetal abdomen
- Umbilical cord vessel number

Table 1-3 Guidelines for Performance of the Antepartum Obstetric Ultrasound Examination—cont'd

- iv. Spine
Cervical, thoracic, lumbar, and sacral spine
- v. Extremities
Legs and arms (presence or absence)
- vi. Gender
Medically indicated in low-risk pregnancies only for evaluation of multiple gestations.

Part II Documentation

Adequate documentation of the study is essential for high-quality patient care. This should include a permanent record of the sonographic images, incorporating whenever possible the measurement parameters and anatomic findings proposed in this document. Images should be appropriately labeled with the examination date, patient identification, and, if appropriate, image orientation. A written report of the sonographic findings should be included in the patient's medical record.

Reporting should be in accordance with the *AIUM Standard for Documentation of an Ultrasound Examination*.

Part III Equipment Specifications

These studies should be conducted with real-time scanners, using a transabdominal and/or transvaginal approach. A transducer of appropriate frequency should be used.

Comment

Real-time sonography is necessary to confirm the presence of fetal life through observation of cardiac activity and active movement.

The choice of transducer frequency is a trade-off between beam penetration and resolution with modern equipment, 3- to 5-MHz abdominal transducers allow sufficient penetration in most patients while providing adequate resolution. A lower-frequency transducer (2 to 2.25 MHz) may be needed to provide adequate penetration for abdominal imaging in an obese patient. During early pregnancy, a 5-MHz abdominal transducer or a 5- to 10-MHz or greater vaginal transducer may provide superior resolution while still allowing adequate penetration.

Part IV Fetal Safety

Diagnostic ultrasound studies of the fetus are generally considered to be safe during pregnancy. This diagnostic procedure should be performed only when there is a valid medical indication, and the lowest possible ultrasonic exposure setting should be used to gain the necessary diagnostic information under the as low as reasonably achievable (ALARA) principle.

The promotion, selling, or leasing of ultrasound equipment for making "keepsake fetal videos" is considered by the US Food and Drug Administration to be an unapproved use of a medical device. Use of a diagnostic ultrasound system for these purposes, without a physician's order, may be in violation of state laws or regulations.

Part V Quality Control and Improvement, Safety, Infection Control, and Patient Education Concerns

Policies and procedures related to quality, patient education, infection control, and safety should be developed and implemented in accordance with the *AIUM Standards and Guidelines for the Accreditation of Ultrasound Practices*. Equipment performance monitoring should be in accordance with the *AIUM Standards and Guidelines for the Accreditation of Ultrasound Practices*.

Modified from Guideline for the antepartum obstetrical ultrasound examination. *J Ultrasound Med* 22:116, 2003.

those circumstances in which increased penetration of the sound beam is necessary. Variations of transducer technology include convex linear transducers and multifrequency probes as well as probes allowing harmonic and three-dimensional imaging and Doppler flow imaging.

Whatever technology is used, the examination should be documented in some form of hard copy. The purpose of documentation is twofold. First, the identification of normal structures is important so they can be viewed retrospectively and compared with later images if pathologic processes are ultimately demonstrated. Second, if a pathologic problem is identified, it can be shown to referring examiners, who will be doing further examinations.

Initially, laboratories used rapid-process film of the Polaroid type for hard copy documentation. The cost and difficulty of mounting these images made this method impractical. Many laboratories then turned to multiformat

cameras that used radiographic film. These cameras added some flexibility but were not without their own problems, including the inconsistency and downtime of these cameras, as well as the added complication of processing time and materials. Some laboratories have chosen videotape as a means of documentation to obviate some of these difficulties. The difficulty with this methodology is the time required to view and compare individual planes of section, particularly when pathologic processes are demonstrated. In the past decade, many imaging centers have implemented picture archiving and communication systems (PACS). These systems allow for the storage of digital ultrasound images on computers and transmission of complete studies to computer workstations for viewing and interpretation. The quality of the images is excellent with these systems. The savings in film costs and development times often compensate for the cost of computer reviewing stations. Likewise, digital images

can be also transmitted to remote locations (telemedicine) for review and consultation.⁴⁸

In addition to the hard copy film, or digitally stored images, a written report of the ultrasound examination should be included in the patient's medical record. When significant pathologic processes are present, the referring physician should be notified immediately before the patient leaves the examination area. This immediate communication should occur not only in cases of fetal malformations but also in cases of oligohydramnios, diminished fetal movement, and macrosomia. Physician notification should be documented.

THE FIRST TRIMESTER ULTRASOUND EXAMINATION

Identification of an Intrauterine Pregnancy

Patients referred for first trimester ultrasound evaluation often have vaginal bleeding, which raises the question of an ectopic pregnancy or a threatened abortion. The primary goal of ultrasound evaluation in the first trimester is to determine whether the pregnancy is intrauterine and whether the embryo is living. With present-day equipment, particularly transvaginal transducers, both of these tasks should be readily accomplished at very early stages of gestation. The same care taken in concluding that a pregnancy in the second or third trimester has a lethal malformation should be applied in deciding that an early pregnancy is nonviable. If there is reasonable doubt about embryonic life, a repeat examination in as few as 7 to 10 days will invariably make the conclusion unequivocal.

Embryonic/Fetal Number

There is no question that, with a careful examination, the true number of embryos can be accurately determined in the first trimester. The literature has emphasized that it is important not to overestimate the number of developing gestations by misinterpreting findings such as a "double sac sign," fluid in the uterine cavity, the yolk sac, or the presence of the amnion as evidence of multiple sacs or embryos and thus multiple gestations. However, the examiner may be just as likely to underestimate the number of developing gestations and embryos if a thorough evaluation of the gestational sac is not made for all embryos.⁴⁹ It is my experience that when multiple gestations are missed using ultrasound assessment, it is usually from a less than optimal first trimester examination. The head (crown) of one embryo may be added to the body (rump) of an adjacent embryo and measured as a singleton. This misdiagnosis, of course, occurs only in monochorionic gestations. It is for these reasons that some investigators prefer that if one ultrasound examination is to be done concentrating on fetal number, it should be done in the early to middle second trimester of pregnancy.

Estimating Gestational Age

The subject of estimating gestational age is covered in detail in Chapter 7. Some estimate of gestational age should be

made when an ultrasound examination is performed in the first trimester. The two most common methods of gestational age estimation are mean gestational sac diameter and crown rump length. For many years, the crown rump length has been acclaimed as the most reliable method of estimating gestational age in utero. The crown rump length is a highly accurate method of estimating gestational age using ultrasound evaluation (accuracy 3 to 7 days). Other measurements, such as the head circumference or femur length, performed in the second trimester, are nearly as accurate and have the added benefit of allowing one to assess fetal morphology to a better advantage in a larger fetus. I believe that the first trimester ultrasound examination should not be done for the sole purpose of obtaining more accurate measurements if there is not a clinical reason why it cannot be done in the second trimester. Clinical indications such as correct estimation of the gestational age to know when to administer other subsequent tests such as maternal serum screening and amniocentesis are examples.

Morphologic Abnormalities

Since the advent of transvaginal ultrasound transducers, there have appeared numerous reports documenting morphologic abnormalities detected in the embryonic stage in the first trimester. Abnormalities involving virtually every organ system have been reported. In light of these reports, I am frequently asked when is the earliest time that a particular abnormality can be detected. My reply is often that although early detection of a morphologic abnormality is useful, the confident unequivocal detection of an abnormality is even more important. Unless one is extremely confident of the existence of an abnormality in the first trimester, a follow-up examination should be performed.

Although there are a number of investigators who advocate earlier scanning of pregnancies for abnormalities, there are few who believe this should occur in the first trimester. One should beware of four potential pitfalls in diagnosis in the first trimester: (1) the normal extra-abdominal position of the embryonic intestine simulating an abdominal wall defect, (2) the prominence of the developing cerebral vesicles (rhombencephalon), (3) the potential false-negative diagnosis of anencephaly, and (4) the false-positive diagnosis of cerebellar vermian and callosal abnormalities due to these structures not being fully developed at an early gestational age.⁵⁰⁻⁵²

Placenta

In very early pregnancies, it may be difficult to ascertain the site of the developing placenta. If, however, the examiner can confidently identify the site of placentation, either anterior or posterior, this information should be documented. There are a number of cases in which the early first trimester ultrasound examination is the only examination obtained during pregnancy. Later in pregnancy, if either an amniocentesis or a cesarean section is planned and no ultrasound equipment is available, it would be helpful to know the location of the placental site from an earlier examination.

Uterus and Adnexa

The maternal uterus should be examined carefully for evidence of uterine abnormalities, particularly in high-risk patients. Late in pregnancy, these anomalies may be extremely difficult to detect. If uterine myomas are detected, their size, site, and relationship to the cervix should be recorded. It should be remembered that transient myometrial contractions may simulate myomas.

The adnexa should be carefully searched for the presence of cysts as well as ovarian neoplasms, both benign and malignant. Again, later in pregnancy, as the adnexal areas are displaced superiorly, they may be extremely difficult to evaluate adequately.

THE SECOND AND THIRD TRIMESTER ULTRASOUND EXAMINATIONS

Fetal Number and Fetal Life

Although evaluating the number of fetuses may be difficult during early pregnancy, it should be extremely easy and accurate in the second and third trimesters. The increased perinatal morbidity and mortality of multiple gestations make it mandatory that a “surprise twin” at delivery be a rare event in any patient who has had a second or third trimester ultrasound examination. The major potential error in determining the number of fetuses is one of underestimation. This mistake, when made, is likely due to either not evaluating the fundal region or not making sure that the fetal head is associated with its body rather than that of a twin. When a multiple gestation is identified, it is important to determine, if possible, the number of placentas and the number of gestational sacs (the chorionicity and amnionicity).

In the ultrasound report, a statement should be made that the fetus was living, if this was the case, by virtue of cardiac motion being identified. In the past, the diagnosis of fetal death was made when there was absence of cardiac motion for at least 2 to 3 minutes, confirmed by more than one examiner. With the improvements in resolution and the availability of transvaginal scanners, this is rarely necessary. However if there is any doubt about fetal life a confirmatory exam at a later date or by another examiner should take place. The lack of fetal motion should not be interpreted as representing fetal death. Slow fetal heart rates often portend a poor prognosis; however, this observation alone should not be considered evidence of a nonviable pregnancy. The author has seen several cases of fetal heart rates less than 80 bpm that have resulted in normal outcomes, followed into childhood.

Fetal Position

Once fetal life and number have been identified, then the fetal lie and presenting part must be determined. Fetal lie refers to the relationship of the long axis of the fetus to the long axis of the uterus. Presentation defines the presenting fetal part closest to the cervix. The most common fetal lie is longitudinal, and the most common presenting part is the fetal head. Fetal lies or presentations other than these are referred to as malpresentations. Their significance lies in increased perinatal morbidity during delivery.

The advent of real-time ultrasound evaluation has placed an additional demand on the sonographer. If the sonologist interpreting the scans has not performed the examination, he or she must be able to deduce the lie and presentation from several images rather than from a single one. This may be done only by understanding the normal fetal anatomy and applying it to the scanning position (Figs. 1–2 and 1–3). Likewise, some congenital anomalies (e.g., dextrocardia, abnormal right-sided abdominal cystic mass) are recognized only fortuitously if a structure is identified as abnormal by virtue of its abnormal position related to the lie and presentation of the fetus.

As mentioned previously, the most common presenting part is the fetal head (cephalic presentation). (I prefer the term *cephalic* rather than *vertex* because the latter term may also be used to describe a location on the fetal head.) When the head is adjacent to the lower uterine segment, it is likely that the fetus is in cephalic presentation; however, one must see all images before coming to that conclusion. The fetal body may also be low in the uterus with the fetal head, and thus, the fetus would be in a transverse lie rather than in a cephalic presentation.

Fetal malpresentations require that the sonographer extend the examination to answer two additional questions important to the referring obstetrician. First, what specifically is the presenting part (i.e., foot, buttocks in the case of a breech presentation, or shoulder in the case of a fetus in transverse lie) (Figs. 1–4 and 1–5)? Second, is there an associated fetal malformation or placental abnormality that may be causally related to the abnormal lie?²³

Assigning Gestational Age and Weight

The assignment of gestational age and weight is covered in detail in Chapter 7. It is important to remember several concepts when assigning gestational age using ultrasonography. First, measurements made early in pregnancy, for the most part, are more accurate than those made near term. In most cases, the measurements of the fetal head, body, and femur will be concordant of one another, within a week in the early to mid second trimester. This is not often true in the late third trimester, when the femur may lag behind the other measurements. In the early to mid second trimester if the femur or the head measurements are greater than one week *less* than the other measurements, this should raise a red flag to alert one to the possibility of either short-limbed bone dysplasia, trisomy 21 or microcephaly. Follow-up in these cases is indicated. Second, pathologic states should be taken into consideration when deciding which body parts to use in assigning gestational age or weight. Most ultrasound machines allow the user to eliminate from the gestational age calculation those body parts that are abnormal. The abdominal circumference measurement is likely to be inaccurate in the presence of fetal ascites, and the femur length measurement is unreliable in fetuses with short-limbed dwarfism. Third, every obstetric ultrasound report should relate the calculated sonographic age to the patient’s menstrual age. Because menstrual histories are frequently inaccurate, there is often a tendency to not believe any woman’s menstrual history in deference to the calculated sonographic age. In doing so, however, one runs the risk of assigning an earlier gestational age to a fetus that

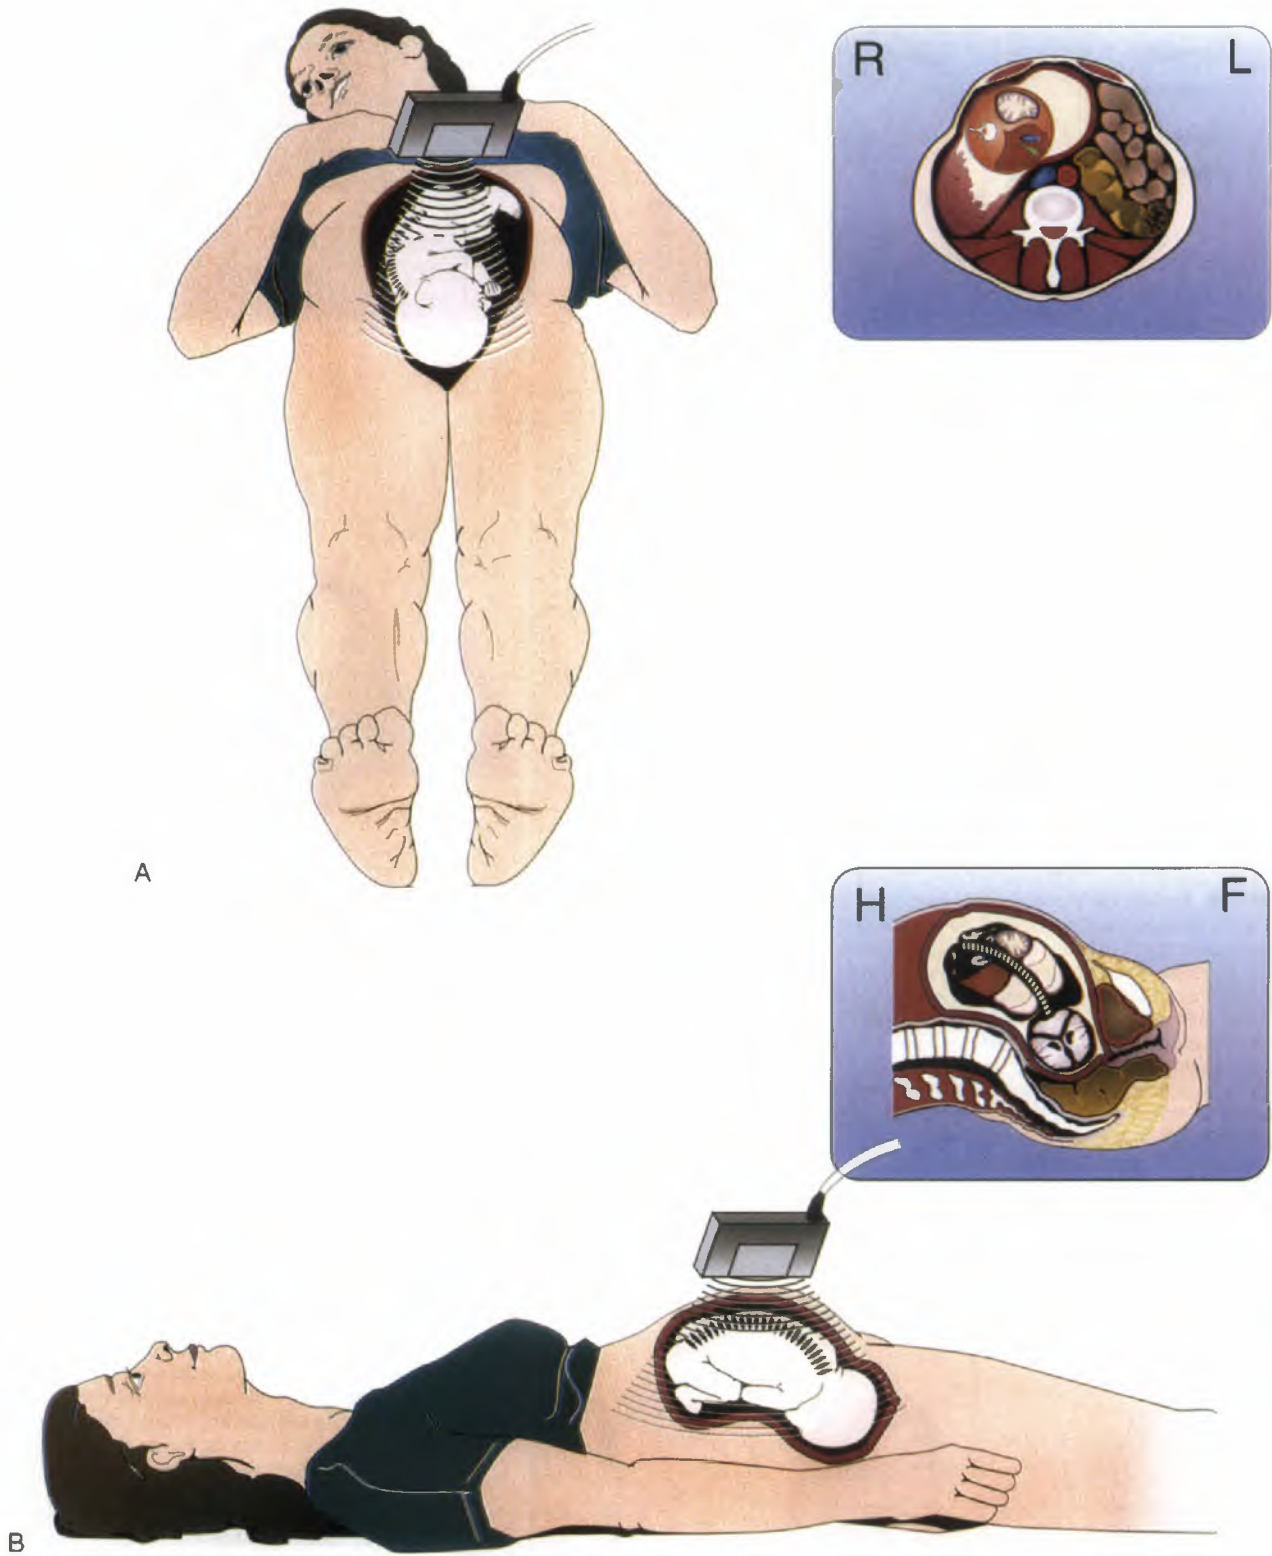

FIGURE 1-2. A. Illustration of a transverse plane of section of the gravid uterus. The fetus is in cephalic presentation, so this scan transects the fetal abdomen transversely. B. Longitudinal plane of section of the same fetus. These images are viewed with the maternal head to the left of the recorded image.

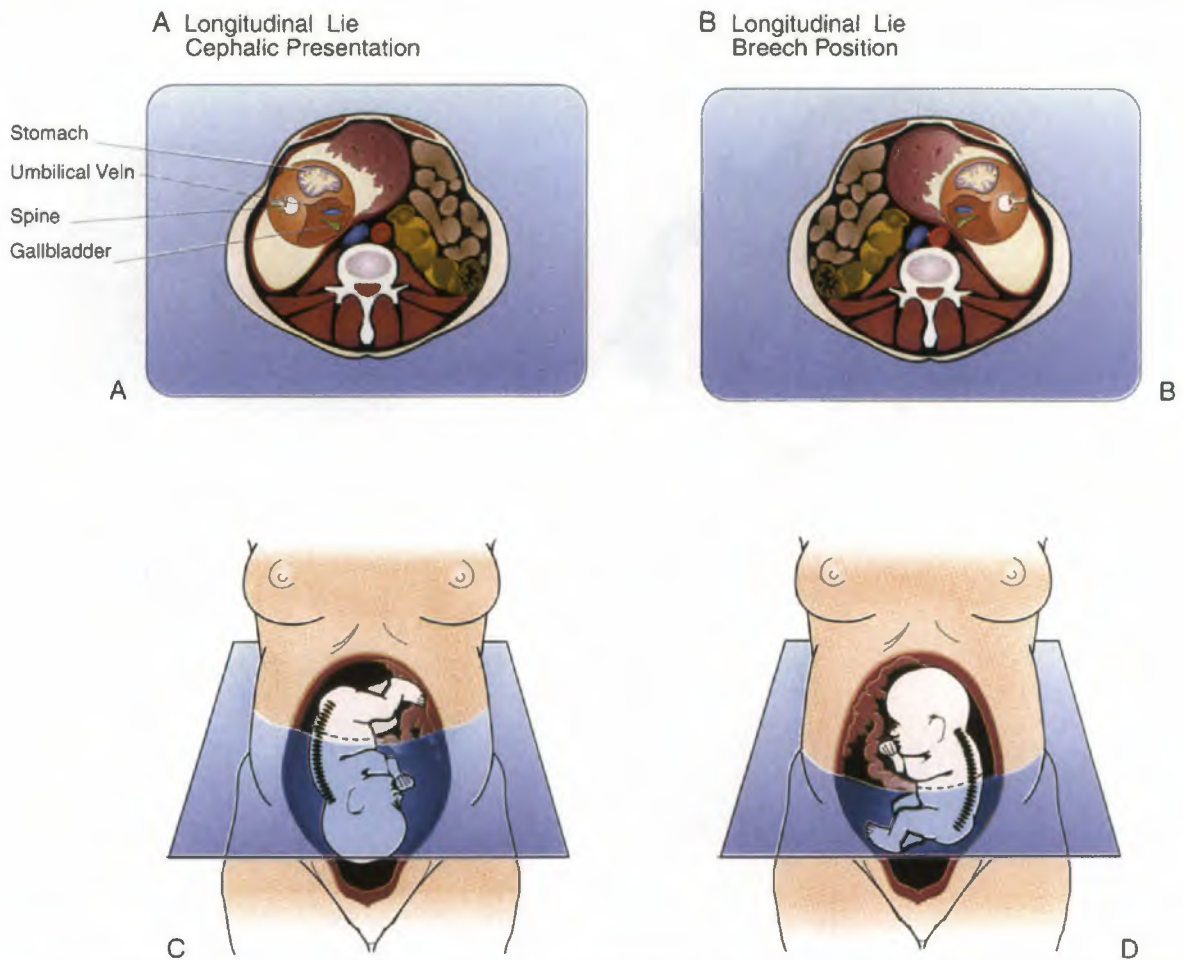

FIGURE 1-3. Knowledge of the plane of section across the maternal abdomen (longitudinal or transverse) as well as the position of the fetal spine and left-sided (stomach) and right-sided (gallbladder) structures can be used to determine the fetal lie and presenting part. *A.* This transverse scan of the gravid uterus demonstrates the fetal spine on the maternal right with the fetus lying with its right side down (stomach anterior, gallbladder posterior). Because these images are viewed looking up from the patient's feet, the fetus must be in a longitudinal lie and cephalic presentation. *B.* When the gravid uterus is scanned transversely and the fetal spine is on the maternal left, with the right side down, the fetus is in a longitudinal lie and breech presentation. *C.* When a longitudinal plane of section demonstrates the fetal body to be transected transversely and the fetal spine is nearest the lower uterine segment with the fetal right-side down, the fetus is in a transverse lie with the fetal head on the maternal left. *D.* When a longitudinal plane of section demonstrates the fetal body to be transected transversely and the fetal spine is nearest the uterine fundus with the fetal right-side down, the fetus is in a longitudinal lie with the fetal head on the maternal right. Although real-time scanning of the gravid uterus quickly allows the observer to determine fetal lie and presentation, this maneuver of identifying specific right- and left-sided structures within the fetal body forces one to determine fetal position accurately and identify normal and pathologic fetal anatomy.

Breech Presentation

FIGURE 1-4. Illustration of the types of breech presentation. In a frank breech presentation (the most common), the thighs are flexed at the hips with the legs and knees extended. In complete breech (the least common), the thighs are flexed at the hips, and there is flexion of the knees as well. One or both hips and knees are extended in the footling breech. The risk of cord prolapse is greatest with a footling breech and least with a frank breech. (Illustration copyright © 2006 Nucleus Medical Art. All rights reserved. www.nucleusinc.com.)

FIGURE 1-5. Longitudinal scan of a footling breech presentation. In this scan, the leg (arrow) and foot extend into the lower uterine segment and cervix.

is in fact older but growth restricted. Likewise, there is the possibility of assigning an earlier gestational age to a pregnancy that is post term, placing the fetus at risk for fetal postmaturity syndrome or in utero death. Fourth, the calculated fetal weight should be stated not only in grams but also as a percentile based on the patient's menstrual age. Again, if the patient's menstrual dates are inaccurate, the obstetrician can make the decision not to become alarmed at a reported low-weight percentile. This is far better than misinterpreting a growth-restricted fetus as normal by relating only the estimated weight to the ultrasound-determined age. (Remember that although the formulas are different for the calculations of fetal age and weight, they are based upon the same biometric measurements and when compared to one another will often be near the 50%.) Fifth, if there has been a previous ultrasound examination, there should be some statement in the report as to whether the fetal growth has been normal or abnormal. Finally, sonograms attempting to assess normal or abnormal interval growth should have an interval of no less than 2 weeks. It may be difficult to determine whether there has been a growth abnormality versus a measurement error if scans are done with a shorter interval.

Amniotic Fluid Volume

During the past several years, there has been tremendous interest in the role of amniotic fluid in fetal development and well-being. Although there is relatively good agreement on the significance of extremes of amniotic fluid volume, there is controversy over the methodology used to make the diagnosis of either too much or too little amniotic fluid. I believe that although the diagnosis of oligohydramnios and polyhydramnios can be learned initially by objective measurements, ultimately the diagnosis of extremes of amniotic fluid volume should best be made subjectively. The difficulty with objective measurements is that they are often too stringent and often do not take gestational age into account. The ability to assess amniotic fluid volume subjectively at different stages of gestation is readily learned and should not be difficult for most examiners. Two points should be remembered

when assessing amniotic fluid volume. First, amniotic fluid volume is large compared with fetal volume at early stages of gestation and should not be misinterpreted as polyhydramnios. Conversely, in term patients, the normal volume of amniotic fluid is quite small so that only small pockets may be seen. Second, patients who are obese often *appear* to have less than normal volumes of amniotic fluid. This may be due in part to scattering of sound with resultant artifactual echoes within the amniotic fluid.

In making the diagnosis of oligohydramnios, one should remember two points. First, because, in most cases, this will imply the likelihood of a fetal renal malformation or severe growth restriction in the absence of ruptured membranes, this diagnosis should only be made when there is almost no amniotic fluid. An exception to this is when there is a small amount of fluid in an early or mid-second trimester examination (when normally large amounts of amniotic fluid would be anticipated). Second, because of the association of severe diminution of amniotic fluid in a compromised fetus and ultimate fetal demise, the obstetrician should be alerted immediately if this diagnosis is made, before the patient leaves the ultrasound evaluation area.

The diagnosis of polyhydramnios, although seeming to be less serious, in many cases may in fact be associated with significant complications to the mother and fetus. In the mother, preterm labor and ruptured membranes may occur as a result of polyhydramnios, and in the fetus, fetal anomalies may be present. Although many cases of polyhydramnios ultimately result in a normal fetus, the high number of anomalous fetuses with this condition reported in the literature should alert the sonographer to perform a thorough evaluation when this diagnosis is suggested.⁵³⁻⁵⁵

Amniotic Fluid Volume in Multiple Gestations

If one looks at a list of causes of polyhydramnios in many obstetric texts, multiple gestations will most likely appear. Although increased amniotic fluid volume may appear in twin gestations, in most cases the cause is some abnormality of pregnancy.⁵⁶ Many of these cases are due to the twin transfusion syndrome.⁵⁷

The Placenta

As mentioned earlier, whenever the placenta is identified in pregnancy, its position and relationship to the cervix should be noted in the interpretation. The literature has emphasized the large number of false-positive diagnoses of placenta previa that are made either early in pregnancy or in the presence of an overdistended urinary bladder.^{58,59} Although this is true, one must not be lulled into a sense of security in thinking that all low-lying placentas will "go away" and be clinically unimportant. If the placenta is low lying during a second trimester examination, every effort should be made to answer the question as to whether there is or is not a placenta previa, often using transvaginal examination. A diagnosis of possible placenta previa may subject the patient to significant life-style restrictions that would not occur if there were not a placenta previa. However, if after a variety of maneuvers and transducers (Trendelenburg position, emptying the bladder, translabial or transvaginal scanning)

one is still unsure about the relationship of the edge of the placenta to the cervical os, the placenta should be interpreted as low lying, and that a placenta previa cannot be excluded. Therefore, these patients will be followed more closely. I prefer to report the distance from the inferior edge of the placenta to the internal cervical os rather than relying on terms that may have differing meanings (e.g., marginal placenta).

Abruptio placentae is a diagnosis that is often difficult to make using ultrasonography. One should remember that the myometrium and its vessels, as well as a transient myometrial contraction, may simulate a hematoma and that these potential false-positive diagnoses should be avoided. Because most clinicians are aware that abruptio placentae is a difficult diagnosis, they often refer patients for ultrasound evaluation to exclude a placenta previa rather than to specifically view the abruption. Patients with a true placental abruption may not ever be seen in the ultrasound laboratory and go straight to labor and delivery.

Vasa previa, which is a variation of umbilical cord anatomy rather than a placental abnormality, is a serious and often overlooked condition. This occurs when fetal vessels cross the internal cervical os in an attempt to reach the main substance of the placenta. This can result in fetal exsanguination during delivery and should be suspected in cases of a velamentous cord insertion or a succenturiate lobe of the placenta.

Fetal Malformations

The subject of fetal malformations is among the most emotionally charged issues that either the parents or diagnostician may have to face. It is of interest that this subject is dominant in parents' minds during the sonographic examination despite the indications or presonographic counseling they might have received. An interesting study by Eurenus et al⁶⁰ evaluated 303 pregnant women and their partners in an attempt to evaluate prescan counseling and the provision of information and their expectations before and experiences during and after a second trimester routine ultrasound scan. Although the information given before the scan clearly stated that the main purposes of the scan were dating and detection of multiple gestations, 89% of the women and 84% of the men thought that the purpose of the scanning was to detect anomalies. "The foremost parental concern is that the baby is healthy and has no malformations, and in spite of the information that 'some serious malformations may be detected,' many think that the scan is a procedure for detection of fetal malformations and a kind of health declaration."⁶⁰

During the past 10 years, ultrasound evaluation has undergone a transformation that has allowed us to answer not only the basic question as to whether the patient is pregnant but also whether a fetal anomaly is present. As smaller and smaller sized abnormalities are identified, the question now becomes what degree of assurance should a patient expect from a report that no anomaly was seen during a routine ultrasound examination. This is a complex issue. The large number of anatomic structures that can be detected by ultrasound studies have necessitated that anomaly detection, by and large, be a *targeted* examination. To examine every patient for all anomalies would be highly impractical.

Fortunately, most *major* anomalies are detected as part of a routine evaluation with several minor modifications.

Major congenital malformations are diagnosed in 4% to 8% of infants during the first year of life.²⁶ Congenital malformations are the single leading cause of infant mortality in the United States, accounting for more than 21% of all infant deaths.²⁶ In the United States, it has been estimated that 100,000 to 150,000 children are born each year with major congenital malformations, and approximately 8000 of these babies die before completing their first year of life.²⁶ Children with congenital malformations account for approximately 30% of pediatric admissions, and the total cost of health care is estimated at more than \$1.4 billion annually.^{26,61,62}

As was mentioned in the discussion of the first trimester ultrasound examination, fetal anomalies have been described in virtually every organ system at almost every gestational age. There is much controversy as to when a comprehensive scan of a pregnancy should occur. There has been a desire from many to accomplish this task at a time just before an amniocentesis (14 to 16 weeks) or even earlier, at the time of nuchal translucency measurement.⁶³ In particular, three advantages have often been cited: (1) transient abnormalities such as an increased nuchal translucency and echogenic bowel (which may serve as markers for chromosomal and structural abnormalities) may disappear if scanning first occurs after 16 weeks⁶⁴; (2) structures such as the fetal hands may be more readily seen, particularly with fingers extended, than later in pregnancy⁶⁴; and (3) if necessary, termination may be easier to accomplish and less dangerous than later in gestation.⁶⁴ Although it is true that many morphologic abnormalities will be detected particularly when using a transvaginal probe, certain abnormalities of the face, heart, and skeleton will not be detected at early gestational ages. Likewise, certain embryologic developmental stages, such as the development of the cerebellar vermis and corpus callosum, are not complete until the mid to late second trimester. If one has the economic luxury of performing several sonographic examinations during pregnancy, a scan at 11 to 16 weeks' gestation, followed by a scan at 22 to 24 weeks' gestation might be ideal. It is certainly not unreasonable to exclude gross and potentially lethal abnormalities during the time of the nuchal translucency scan. This would obviously affect the timing of the next scan. However, it is my recommendation that if a single ultrasound or a targeted (level 2) examination is performed, it should be done at a gestational age of 20 weeks. The reason for this is that the fetus will be of a sufficient size to exclude most abnormalities and still allow time for a follow-up examination, if necessary. I have frequently noted that abnormalities that were not seen at 16 to 18 weeks' gestational age became apparent at 19 to 20 weeks. The slight loss of accuracy in assigning gestational age at this time is well worth the gain in visibility of fetal anatomy and pathology.

The patient and the referring obstetrician should be made aware that during the standard ultrasound examination, although many abnormalities may be detected fortuitously, more subtle lesions are likely to be detected only when the fetus is known to be at risk for a specific malformation. Anatomic malformations are likely to grow during pregnancy just as the fetus does; a defect seen at birth may have been too small to be detected earlier in pregnancy. Some

lesions, such as duodenal atresia and heterozygous achondroplasia may not manifest until late in the second trimester. Finally, it is important for sonologists to know the limits of their expertise. If a malformation is suspected and the examiner has had little experience with the abnormality in question, the case should be referred to a more experienced examiner. Only in this way will patients be served best.

Uterus and Adnexa

Evaluation of the uterus and adnexa becomes more difficult the later in gestation the examination occurs. The most common abnormalities that are likely to be detected are uterine myomas. As stated earlier, it is important to measure the size of the myoma, record the location of the myoma, and define the relationship of the myoma to the cervix. If ovarian abnormalities are suspected and not seen, patients should have a postpartum examination.

Verbiage Used in the AIUM/ACR/ACOG Guidelines

The committees and individual members of the AIUM, ACR, and ACOG who helped develop the guidelines described earlier did a remarkable job. It is not easy producing a document such as this that will be widely applicable to ultrasound practitioners. There are a few areas where I believe the choice of words were not clear and would like to give my own suggestion for interpretation. The reader should read the editorial addressing this subject concerning two of the points raised in the guidelines.⁶⁵

It is understandable that the guidelines attempted to give the practitioner a wide latitude in requirements for the obstetric ultrasound examination. They attempted to take into account the differences in maternal and fetal anatomy from one patient to the next as well as technical limitations at times. There are a number of instances in which the guidelines state that a structure or structures should be imaged. Unfortunately, additional wording is added that states “when possible” or “can also be attempted” or “when technically feasible.” As stated in the editorial mentioned earlier, “One could reasonably state that any of the views defined in the guidelines can only be obtained “if technically feasible.” Indeed, the introduction to “Fetal Anatomic Survey” states that one may anticipate technical limitations: “. . . some structures can be difficult to visualize due to fetal size, position, movement, abdominal scars, and increased maternal wall thickness.”⁶⁵ Adding these additional words, mentioned earlier, gives the examiner a “way out” to not examine important fetal or maternal anatomy. This occurs in discussion of the first trimester, when these modifying statements are made with respect to the cervix and amnionity and chorionicity in multiple gestations. I do not know of a reason why the cervix cannot be assessed in the first trimester in any patient using a variety of methods available. Perhaps the only time that chorionicity and amnionity can best be assessed is actually in the first trimester of pregnancy. Although the differentiation of mono- from diamniotic twins may be difficult, there is no reason I can think of as to why chorionicity cannot be determined at this time. The same holds true for visualizing the cardiac outflow tracts in the second and third trimester. There is no question that demon-

strating the outflow tracts has a definite learning curve that one needs to conquer. However once learned, the outflow tracts should be demonstrated in more than 90% of patients.⁶⁶ In the extremities section, the legs and arms are mentioned. Medically, this would mean only the tibia/fibula and the humerus. I believe the intent was for the femur, humerus, tibia, fibula, radius, and ulna to be evaluated.

The gender was stated as, “Medically indicated in low-risk pregnancies only for evaluation of multiple gestations.” I think I know the intent but I would have stated it differently. I would have said that gender should be demonstrated in singleton gestations when medically indicated for diagnosis and counseling. Examples of this type of indication would include hemophilia or distal urinary obstruction, attempting to differentiate (posterior urethra valves [predominantly male disorder] from a cloacal abnormality [predominantly female disorder]). As for multiple gestations, there are many that would take issue with saying that any multiple pregnancy is low risk. It should have been stated that when chorionicity is difficult to determine in multiple gestation pregnancies, gender determination, when different between the twins, will be helpful in excluding monozygosity.

For weight determination, a statement is made that “Currently, even the best fetal weight prediction methods can yield errors as high as $\pm 15\%$.” Although I agree with this in concept, I would not have put, what appears to be, an upper limit on errors in weight estimation. This seems to imply that numbers greater than this would be below the standard of care. Particularly in macrosomic fetuses, I have seen errors as high as 25% to 30% from what seemed to be reasonable biometry.

A statement regarding technical difficulties reads: “A second- or third-trimester scan may pose technical limitations for an anatomic evaluation due to imaging artifacts from acoustic shadowing. When this occurs, the report of the sonographic examination should document the nature of this technical limitation. A follow-up examination may be helpful.” Although I fully understand this limitation, which all of us have encountered, the recommendation is problematic. There are certain anatomic structures or situations in which the anatomy *has* to be imaged or an abnormality reported. The statement “follow-up examination *may* be helpful” is unacceptable. I have seen far too many cases in which the brain or cardiac anatomy were not well seen due to technical limitations. The referring obstetrician did not read the report until the next patient visit. By the time the patient came back for re-evaluation, it was 25 weeks or beyond, precluding the option for termination of an abnormality, if desired. If the brain, heart, or kidneys and bladder (in the presence of oligohydramnios) are not seen, the patient should be seen later that day or the next morning, and only then should the final report be sent. If the structure is still not seen, the referring obstetrician should be notified and the conversation documented.

Interpretation of the Ultrasound Examination

This is, of course, the focus of the remainder of this book; however, I would like to make several comments. Although the subspecialty of obstetric ultrasound seems to attract new biometric applications daily, I have never been much of an

advocate of the sole use of measurements to achieve a diagnosis. It seems that every day I read in a journal that someone has developed a new chart for the measurement of a fetal anatomic structure. I fully recognize that there are many measurements that are necessary for accurate ultrasound interpretation; fetal biometry for size and weight, cervical length, and fetal ventricular size, to name a few. For many of the abnormalities that can be recognized sonographically, I would prefer that the sonologist give more credence to his or her subjective eye than to a measurement when images or individual structures “just don’t seem right.” Although a measurement may appear to be within normal limits, there are times when subjectivity, in my opinion, wins out. It is acceptable to say that despite an amniotic fluid index of 6, that there is oligohydramnios or that the fetal bowel appears dilated without an objective measurement of the bowel lumen.

Another pitfall is making a measurement of an anatomic structure and not interpreting the significance of the measurement. For example, some ultrasound laboratories believe that adding numerous measurements, for example, transcerebellar, renal, or intraorbital measurements, in addition to standard biometry (biparietal diameter [BPD], head circumference [HC], abdominal circumference [AC], femur length [FL]) will make the examination *more* complete. Although I will not argue the necessity of doing these additional measurements, what is puzzling is that often the interpreter of the examination will not check these measurements against standard tables or nomograms to determine if they are normal or abnormal. In my mind, this is a serious mistake.

Without launching into a discussion of statistics, it is enough to say that no measurement will likely be 100% accurate without false-positive or false-negative results. There are some situations in which false-positive results may be acceptable (e.g., screening examinations for a serious abnormality). Every practitioner abhors the notion of being labeled an “over-reader” of examinations. I have two suggestions: (1) consult with the referring clinician regarding the importance of a specific diagnosis. Ask him or her whether the goal is to not miss any patients with a condition (thus, resulting in more potential false-positive results), which may mean additional testing or intervention, or whether they wish fewer false-positive results and thus risk missing the detection of an abnormality in some patients. With this in mind, one can set the threshold level for the test, either lower or higher. (2) If the sonologist is calling a referring clinician four to six times a week with a suspected abnormality (e.g., pelviectasis, echogenic bowel, and so on), one should perhaps reevaluate the criteria for defining something as abnormal. However, if one calls a referring physician once every 2 to 4 weeks when one is “bothered” by a finding and wishes to call attention to it, one should not feel as if he or she is “over-calling” an abnormality. Likewise, one should not be embarrassed about calling the referring physician about a concern that something might be abnormal even if it ultimately proves to be normal. Only in this way will patients best be served.

Reporting of Ultrasound Results

One would anticipate that this might be the least contentious topic when discussing the obstetric ultrasound examination.

However, it is controversial. In concert with recommendations by various organizations, for example, AIUM, ACR, ACOG, a written report should be produced at the completion of the ultrasound examination and should be placed in the patient’s medical records. As the electronic medical record becomes a reality, this report may of course be digital. A number of reporting packages (technologies) have been developed to make reporting easier: these include but are not limited to: obstetric worksheets or checklists, computer templates or canned reports, computer voice recognition, digital transcription systems accessed by telephone or computer and traditional voice dictation that is typed by transcriptionists (on site or remotely). All of these methods have the potential for producing an accurate and readable report. However, in my own experience, the easier the reporting method, the more likely that observations made during the examination will *not* be conveyed accurately. Too often, I have observed sonographers and sonologists finish an examination and quickly enter checks into boxes on a worksheet indicating that a particular structure was observed or was normal. It is inconceivable to me, watching the speed with which the worksheet is completed, that they ever asked themselves the question, did I *really* see those structures. Although it is becoming antiquated, conventional dictation systems that require the examiner to pick up the recording device and say “the following structures were seen. . .” or some similar device or mechanism, seem to have a better chance of succeeding in conveying accurate information.

I have mixed emotions about templates that contain standard paragraphs such as: the following structures were seen: “lateral ventricles, cerebellum, and so on.” Although this information may be necessary for reimbursement purposes I have yet to see a sonologist or referring physician who ever reads these paragraphs. They also have the potential to be confusing when abnormalities are detected, particularly if the paragraph ends with “. . . and these structures were normal.” If one does not alter the paragraph, the referring physician will read in this standard paragraph a sentence that says: “the fetal kidneys were normal” and in the next paragraph a sentence that reads “bilateral fetal hydronephrosis was seen.”

It is my practice and recommendation that when fetal abnormalities are detected, the referring physician should be contacted in person or by telephone and the discussion should be documented in the report.

A question often raised is what to do when a structure normally seen on routine (basic) sonograms (and listed in the guidelines) is not seen. Or, what to do when one identifies a structure that has an unusual appearance that one suspects is probably normal. Often, it is assumed that failure to see a structure or structures are secondary to technical limitations, such as shadowing or poor fetal position or fetal physiology (the fetus just urinated or fluid in the stomach passed into the duodenum). If the examination is performed in the early second trimester, the patient should return within 2 to 4 weeks for another evaluation. As was mentioned earlier, if a structure in question relates to the heart or brain or kidneys and bladder (when oligohydramnios is present), the study should be considered *incomplete* and should *not* be reported until the structure is seen either later that day or the next morning. If a follow-up examination is warranted, the

referring physician should be contacted and the conversation documented. The rationale for these recommendations is the concern that adequate follow-up and evaluation will not occur, or if they do occur, they will not be performed in a timely fashion. Statements indicating "clinical correlation recommended" are appropriate when the abnormality seen needs to be correlated with patient's medical condition, laboratory tests, family history and the patient's age, but not when an isolated abnormality is seen (dilated bowel loop).

Discussing the Examination With the Patient

This topic is also controversial. The patient obviously wants to know that the fetus is healthy and to know the results at the time of the examination. As a general rule, the referring obstetrician knows the patient best and also often has important information about the patient's menstrual history, family history, laboratory values, and emotional state. Thus, the patient's primary physician is often better able to explain the results to the patient and to counsel her effectively. In cases of suspected morphologic or genetic abnormalities, the advice of a reproductive geneticist or perinatologist may prove invaluable. There are situations when the sonologist is asked by the referring obstetrician to explain the results to the patient. As is discussed later, often the first words that are said to the patient are the things that she remembers. Despite what is said later, it may be difficult to undo what was said initially. It is appropriate to say that the interpreter needs to evaluate all of the images together and possibly compare them with old studies. At that time, the final report will be generated.

Counseling is often straightforward if the case is normal or when the diagnosis is unequivocally lethal (anencephaly).⁶⁷ It becomes more complex in cases in which the outcome is less than 100% certain (e.g., mild isolated ventriculomegaly). It is important not to insert our own bias and values about raising children with disabilities. One cannot assume that if a serious malformation is detected that a patient will desire an abortion rather than to deliver a baby with disabilities. In some cases, the person informing the patient of the results is uncertain of the significance of the findings,⁶⁷⁻⁶⁹ and the first information the patient hears may be unclear or misleading. This may color how patients perceive later information and may result in dissatisfaction with the bearer of the news.^{67,69}

It is often assumed that women weigh equally the risk of delivering a baby with a congenital abnormality versus a procedure-related pregnancy loss (amniocentesis). In fact, studies have demonstrated that most women see the long-term consequences of raising a disabled child as *worse* than a miscarriage, although women vary widely in this regard.⁶⁸ It is important to remember that we do not know better than our patients what is best for them. Our challenge is to help them reach a decision that is best for them given their particular background, experience, and values.

Even when precise and correct information is transmitted in a counseling session, it may not be interpreted with the same intended meaning by the patient. Certain words tend to have more serious and worse connotations to the patient than alternative words.⁶⁹ The words *rare* abnormality are often interpreted as serious (even if it is a mild abnormality). The word *abnormality* is often interpreted as worse than a

variation of normal. Likewise, technical genetic words often have a worse connotation. Trisomy sounds worse to most patients than an extra chromosome.⁶⁹ Choroid plexus cysts (CPCs) and echogenic intracardiac foci (EIF) are discussed in Chapter 4. One should be aware that even if the sonologist firmly believes that the finding of an isolated CPC or an EIF is likely a normal variant and of no consequence, the fact that these structures are in the brain and heart are no small matter. The fact that there may not be a significant increased risk in that individual patient based on other findings and the abnormality is of small size may not alleviate the patient's anxiety once she is told of these findings.

There has been much debate regarding whether physicians should disclose that an isolated sonographic *soft marker* for a chromosomal abnormality has been detected in a fetus in the absence of other risk factors for aneuploidy.⁷⁰⁻⁷² A recent study by Lee et al⁷³ found that the detection and communication of isolated aneuploidy markers (choroid plexus cysts, echogenic intracardiac foci, renal pyelectasis, echogenic bowel) is associated with increased maternal anxiety and unnecessary amniocentesis. Their conclusion: "given the amount of maternal anxiety generated with detection of aneuploidy markers, serious consideration should be given to offering pre- and post-ultrasound genetic counseling or otherwise, nothing should be mentioned about ultrasound markers that may be normal variants in patients who have no other risk factors for aneuploidy."⁷³

The likelihood of having a normal child when an abnormality is detected is almost always received more favorably by the family than being told of the small percentage of having an abnormal child when an abnormality is detected. (A 99% chance of normal sounds less worrying than 1% chance of abnormal.) When risk is given as a proportion, it often sounds worse than when it is given as a rate (1/X sounds worse than X%).⁶⁹ One should be aware, that a large portion of the public lacks functional knowledge of fractions, large numbers, or percentages.^{74,75} In one study,⁷⁸ a third of adult women with less than a college education did not recognize that 1/1000 is less than 1%. It is interesting that although in most medical specialties, risk or prognosis is given as a percentage, for example, 10% chance of a cure or bad outcome, in prenatal genetic counseling, risk is often given as a proportion, which most patients do not fully understand. In a study by Grimes et al,⁷⁴ women of varying ages, education, and language were asked to identify which proportion of bladder infection was higher: 1 in 384 or 1 in 112 persons. The same women were then asked to identify which rate of infection was higher: 2.6 per 1000 women or 8.9 per 1000 women. Overall, 73% correctly identified the higher risk in rate format (X/1000), in contrast with 56% who correctly answered the same question framed as proportions (1/X).⁷⁴ Clearly, women understood rates better than proportions.

Perhaps the most important point of this discussion is what to do when a slight variation of normal or an unusual finding is seen. The first answer would be to consult your colleagues. If that does not answer the question, then one should discuss the case further with more experienced experts, for example, perinatologists or geneticists, or refer the patient to a university or specialty center. In some cases, one will simply need to report that there is a finding and that you are

Table 1-4 Evaluating the Literature

Abstract
What are the objectives, findings, and conclusions of the study?
Introduction
What is the purpose of the diagnostic test?
Materials and Methods
How are the patients selected?
Are they representative of those who are ordinarily tested?
How is the test(s) performed and interpreted?
Are the interpretation criteria well defined and reproducible?
What is the gold standard for diagnosis? Is it appropriate?
Are the sonologists blinded from the final diagnosis and is the final diagnostician (pathologist) blinded from sonographic interpretation?
Is the gold standard applied uniformly?
In a comparison study, are the tests evaluated fairly?
Results
How is the accuracy reported?
Are spectrum of disease and important covariates, such as comorbidity, age, sex, and body habitus, accounted for in tabular presentation of data?
Is the statistical analysis clearly described and appropriate?
Discussion
Are the deficiencies in the methodology of accuracy assessment acknowledged and discussed?
Are other relevant factors, such as disease prevalence, therapeutic effectiveness, and cost, adequately accounted for in the clinical recommendations?

From Black WC: How to evaluate the radiology literature. *AJR Am J Roentgenol* 154:17, 1990.

uncertain of the significance. When the physician feels pressure to always give a black and white, or normal or abnormal answer without honest indecisiveness, this approach does a disservice to the patient.

EVALUATING THE OBSTETRIC-GYNECOLOGIC ULTRASOUND LITERATURE

Whereas this text serves as a reference to many, as an aid to ongoing clinical problems, new and useful clinical information is reported constantly in the medical literature. It is appropriate that the reader keep current with new advances. It is also important to be vigilant for poorly constructed studies and conclusions. Although virtually every report will have some mention of the sensitivity and specificity of a new test, this is only a small part of an adequate analysis of the utility of a new technique. There are a number of areas that should be considered when evaluating a new report in the literature; these areas are outlined in Table 1-4.⁷⁷ Perhaps the most common error is that authors do not state the

prevalence of "disease or abnormality" in their population or that readers do not take this into account when applying the report to their own practice. This also holds true for both equipment and techniques used for analysis.

When the authors discuss a new technique or potentially helpful finding, it is invariably depicted in their first figure, "Figure 1." If after looking at Figure 1 in the new publication, as well as its legend and text description, the reader does not understand what is being demonstrated, the publication is likely to be of little value in clinical practice.

MALPRACTICE AND THE OBSTETRIC ULTRASOUND EXAMINATION

It is likely that each person reading this text has been touched in some way by the present malpractice crisis. For most of us, this crisis has resulted in increased costs of goods and services, and for some, it has meant being the defendant in a malpractice suit.

Data on the number of claims of malpractice and their settlements are difficult to obtain. In one report, Sanders⁷⁸ reported malpractice claims in diagnostic ultrasonography in 228 cases. Obstetric ultrasound examinations represented the majority (78%) of the cases.

Some of the more common reasons for the initiation of malpractice suits (whether legitimate or not) include the following:

- Unreasonable expectations of the ultrasound examination on the part of the patient and the referring physician.
- Physician performing the examination has inadequate training or equipment.
- Failure to seek consultation in difficult cases.
- Inadequate or incomplete study.
- Misinterpretation of the ultrasound examination (resulting in the inability to terminate before the legal state limit, a wrongful termination, or pre- or post-term delivery).
- Poor communication with referring clinicians (improper wording, lack of timely communication).
- Failure to maintain ultrasound equipment.
- Failure to supervise personnel adequately.

It is my desire that this text, through the education process of the sonographer and sonologist, will help alleviate errors in diagnosis and thus reduce the number of these cases. Unfortunately, despite the best medical care, some malpractice suits are brought against physicians.

CONCLUSION

The appeal of the ultrasound examination is that it is a noninvasive, safe procedure that has a high degree of patient acceptance and can yield a wealth of information. It is always a delight to examine the obstetric patient and reassure her about her pregnancy, when appropriate.

When a pathologic process is first identified, the role of the sonologist is that of a detective who attempts to piece together all of the information to arrive at the correct diagnosis (Fig. 1-6). Although discovering a pathologic process is always disconcerting, the sonologist can be a counselor to the patient and the clinician, and help guide them to appropriate management decisions. However, there are times when an abnormality is strongly suspected but it may be

FIGURE 1-6. This is an excellent example of how observation of all of the sonographic signs allows one to arrive at the correct diagnosis. The patient was referred because a cyst was seen in the fetal head on initial sonographic scanning. *A*. Slightly angled transverse axial scan of the fetal head demonstrates moderate ventriculomegaly. (The dilated ventricles were what were incorrectly interpreted as a fetal intracranial cyst.) *B*. The ultrasound "worksheet" reveals measurements of the fetal head (biparietal diameter [BPD]), head circumference (HC), abdomen (abdominal circumference [AC]), and femur (femur length [FL]) that are all different from one another. The main differential at this point is that either the head is enlarged and the femur and abdomen more correctly represent the gestational age, or that the head measurements are normal and the fetal abdomen is small from growth restriction. One might assume that the head measurements are abnormally large owing to the ventricular dilation. In fact, the fetal head does not usually enlarge until the ventricular dilation is significantly more pronounced.⁷⁹ *C*. The next step would be to evaluate the epiphyseal ossification centers. In this fetus, both the distal femoral epiphyseal (DFE) and proximal tibial epiphyseal (PTE) centers (arrows) show calcification, indicating a fetus with a likely minimum gestational age of 34 to 35 weeks. *D*. These joined dual images of the long axis of the uterus demonstrate little amniotic fluid. The information from images *C* and *D* would seem to indicate that this fetus is likely of 34 to 35 weeks' gestation with a small abdomen (31 weeks' gestation), little amniotic fluid, and probable growth restriction. *E* and *F*. Transverse and coronal planes of section of the fetal abdomen show an enlarged spleen (*). *G*. A postnatal sonogram confirms the splenomegaly (S). At birth, the neonate was growth restricted, and antibody titers confirmed the diagnosis of cytomegalovirus infection.

equivocal or may not fit into a specific category. Under these circumstances, the best pathway for the sonologist to follow is to do a follow-up examination and seek consultation. If time does not allow a follow-up examination, then the sonologist should communicate to the referring physician and the patient that a definitive answer is not possible and that decisions will have to be made with less-than-perfect information.

I am hopeful that this text will serve two purposes: to educate and to excite. If those reading this text maintain the same enthusiasm for obstetric and gynecologic sonography that I have, I will have fulfilled my goal.

INTRODUCTION

Genetic diseases are often perceived as so rare that the average practitioner will seldom encounter them. However, our increasing knowledge and technologic advances in prenatal diagnosis have demonstrated that this is far from the case. The availability of prenatal diagnosis for a wide range of disorders continues to increase with advances in other areas of genetics. In addition, progress has been made in population screening tests to identify couples who carry a genetic disorder. These improvements in prenatal screening and diagnosis mean that many more at-risk couples are able to have unaffected children. In addition to reproductive choice, carrier screening and fetal diagnostic testing afford the important opportunity for preparation of the family and the delivery site for the birth of a fetus with a known genetic disorder.

Ultrasound plays a central role in the provision of prenatal screening and diagnosis. Not only is ultrasound key to guiding prenatal diagnostic procedures, but integration of a genetics-based prenatal diagnosis program has been shown to increase the accuracy of diagnosis when compared to ultrasound alone.¹ This chapter includes a discussion of genetics, with an emphasis on recent advances relevant to prenatal diagnosis and a description of current strategies for genetic testing, and discusses how genetic screening and sonography together contribute to the provision of accurate and precise prenatal diagnosis.

Genetics and Birth Defects

According to most studies, 2% to 3% of living newborns have a congenital malformation.² When considering birth defects noted in the first years of life, this incidence is nearly doubled. With the decline in infant mortality in the United States from infection and malnutrition, congenital malformations are now a leading cause of infant mortality (>20%) and responsible for greater than 30% of intensive care nursery admissions.³ Congenital defects range from enzyme deficiencies caused by single gene defects to complex associations of structural defects. The continuum between purely biochemical abnormalities and structural birth defects includes disorders of structure, function, metabolism, and behavior.

Birth defects result from the interaction between the genetic makeup of the embryo and the environment in which it develops. The basic developmental information is encoded in genes, but the genotype is subjected to environmental influences that can impact the observed phenotype. In some cases, the genetic information is expressed regardless of environment, whereas in others, environmental causes interfere with normal development despite a normal genotype. Although some processes are primarily environmental and others primarily genetic, the distinctions between the two are not perfect.

Despite considerable advances and research over past several decades, the cause of more than half of human congenital abnormalities remains unknown. Of those with a recognized cause, approximately 15% to 20% are autosomal genetic diseases and 20% are cytogenetic in origin. Less than 1% of anomalies are thought to occur owing to teratogenic medications. Some of the remaining defects are associated

FIGURE 2-1. Prevalence of genetic diseases in the population. (Reproduced with permission from Carlson BM: *Human Embryology and Developmental Biology*, 3rd ed. Philadelphia, Mosby/Elsevier, 2004.)

with other environmental exposures during pregnancy including infectious agents (3%), maternal disease states (4%), mechanical problems (1% to 2%), irradiation, and unknown environmental causes. The remainder are of unknown or complex etiology (multifactorial, polygenic, spontaneous errors of development and synergistic interactions of teratogens) (Fig. 2-1).^{3,4}

Developmental Disorders: Causes, Mechanisms, and Patterns

Errors in morphogenesis are often classified by dysmorphologists according to the underlying pathogenesis (Fig. 2-2). *Malformations* are defects in the structure of an organ resulting from a specific primary abnormality of development, such as a congenital heart or neural tube defect (NTD). A *malformation syndrome* is the occurrence together of several such defects, for example, the presence of a congenital heart defect, central nervous defect, and clefting due to trisomy 13. A *malformation sequence* occurs when the primary malformation results in additional defects, such as a foot deformity and hydrocephalus secondary to spina bifida. *Deformations* are abnormalities of form, shape, or position caused by mechanical forces such as intrauterine molding or constraint. Factors leading to deformations may be extrinsic (for example, oligohydramnios owing to ruptured membranes) or intrinsic (for example, oligohydramnios owing to renal agenesis). Deformations may also occur postnatally; for example, an infant may develop a flat head owing to sleeping in one position. A *disruption* is a morphologic defect that results from breakdown of previously normal tissue. Disruptions can be due to extrinsic forces, internal interferences with a developmental process, or vascular insults. Examples of disruptions include amputations owing to amniotic bands, and gastroschisis and pencephaly, both thought to result from in utero vascular insults.

A *sequence* is a pattern of multiple abnormalities resulting from a single primary anomaly or mechanical factor; it may be a malformation, deformation, or disruption. An example is Potter sequence, in which oligohydramnios from any

cause leads to similar features of fetal compression: characteristic facial features and abnormal positioning of the hands and feet. A *syndrome* is a pattern of multiple abnormalities known to have a common, specific cause. An example is Down syndrome (DS), which is caused by the presence of an extra copy of chromosome 21. Finally, the term *association* is used to identify the occurrence of two or more features more commonly than expected by chance alone but for which no etiology has been demonstrated. A common example is VATER (Vertebral, Anal, Tracheo-Esophageal, and Renal anomalies) association. This term does not imply a specific diagnosis but rather prompts the search for specific other defects when one component of the association is identified.

CHROMOSOMAL DEFECTS

Chromosomal abnormalities occur in approximately 0.9% of newborns (Table 2-1), and it is estimated that at least 10% to 15% of conceptions are chromosomally abnormal. Chromosome abnormalities are the leading cause of pregnancy loss, and at least 95% of chromosomally abnormal conceptions are lost before term. Abnormalities seen in abortuses differ from those seen in liveborn infants. This is because the most severe chromosome abnormalities result in early arrest of development, whereas less severe abnormalities yield more mild phenotypes that allow survival until later in pregnancy or even live birth. The most common abnormalities seen in first trimester spontaneous abortions are 45,X and 47,+16 (trisomy 16). Trisomy 16 is never seen in live births, whereas less than 1% of conceptions with 45,X survive until term.

Chromosome abnormalities can be either numeric or structural. They can involve one or more autosomes, sex chromosomes, or both simultaneously. Aneuploidy refers to the presence of an abnormal number of chromosomes, and is almost always associated with abnormalities of physical and/or cognitive development. Translocations, the exchange of segments between nonhomologous chromosomes, are relatively common, and can be balanced, in which the appropriate amount of chromosomal material is present but rearranged, or unbalanced, in which some chromosomal material is gained or lost. Polyploidy, in which there is one or more entire extra set(s) of chromosomes, occurs but is much less common.

Table 2-2 Risk of Chromosomal Abnormalities in Liveborn Infants

Maternal Age (years)	Risk for Down Syndrome	Total Risk for Chromosomal Abnormalities*

Abnormalities of Chromosome Number

Aneuploidy is the most common clinically significant type of human chromosomal abnormality, and it occurs in 3% to 4% of recognized pregnancies. The risk of trisomy increases with advancing maternal age (Tables 2-2 and 2-3). Both trisomy, the presence of three copies of an individual chromosome, and monosomy, the presence of a single copy of a chromosome, typically have significant phenotypic consequences. Monosomy is seen less frequently than trisomy because this situation is generally not compatible with life. Trisomy or monosomy for any chromosome can theoretically occur, but in practice, some are seen much more frequently than others (Table 2-4). This is because most aneuploidies are incompatible with life, and aneuploid embryos spontaneously abort very early in gestation. Some chromosome abnormalities, for example, trisomy 8, are seen at birth only in mosaic form and the full trisomy is likely lethal.

Table 2-3 Prevalence of Trisomy 21 by Maternal Age and Gestational Age

Maternal Age (years)	Gestational Age (weeks)					
	10	12	14	16	20	40
20	1/983	1/1,068	1/1,140	1/1,200	1/1,295	1/1,527

*Births of appropriate sex only for sex chromosomal abnormalities.

Trisomy 21

The most common aneuploidy detected at birth is trisomy 21, which occurs in approximately 1/700 live births. Trisomy 21 is the basis for 95% of cases of DS (the remainder are owing to translocations involving chromosome 21). Individuals with DS have a characteristic phenotype that includes distinctive facial features, short stature, brachycephaly, a flat occiput, a short neck with redundant skin on the nape, short broad hands, and hypotonia. Other significant problems in individuals with DS include mental retardation, recurrent respiratory infections, and leukemia. Congenital heart defects are present in about 30%, and duodenal atresia and tracheoesophageal fistulas are also common.

The recurrence risk of trisomy 21 (or other autosomal trisomies) is approximately 1% after one such child is born to a couple. Although often requested, there is no indication

for parental chromosomal evaluation after the birth of a child with trisomy 21 (or other straightforward trisomy). The recurrence risk is somewhat higher in younger women, and only slightly increased over the age related risk in women older than 35. A history of DS elsewhere in the family does not increase the risk of having a child with a chromosome abnormality, provided there is no familial translocation.

Trisomy 18

Trisomy 18 occurs in about 1/8000 births but is much more common at conception, with about 95% of such cases resulting in spontaneous abortion or stillbirth. As with trisomy 13, postnatal survival is poor, and the majority of patients die in early infancy. Characteristic findings include cardiac malformations, severe mental retardation, growth restriction, a prominent occiput, small mandible, short sternum, clenched hands, and rocker-bottom feet. Prenatally, about 25% of fetuses with trisomy 18 have choroid plexus cysts. As is discussed later, fetuses with trisomy 18 have a characteristic pattern on biochemical screening, which has a relatively high sensitivity for this disorder.

Trisomy 13

Trisomy 13 syndrome is much less common and more severe than DS. It occurs in about 1/20,000 live births, and most children with this condition die in early infancy. The phenotype includes severe central nervous system malformations, such as holoprosencephaly, severe mental retardation, growth restriction, cleft lip and palate, microphthalmia, polydactyly, clenched hands with overlapping digits, congenital heart defects, and renal abnormalities such as polycystic kidneys.

Table 2-5 Clinical Features of Sex Chromosome Disorders

Features	Klinefelter	XYY	Turner	Triple X
Karyotype	47XXY	47XYY	45X	47XXX
Phenotypic sex	Men	Men	Women	Women
Gonads	Atrophic testes	Normal	Streak ovaries	Normal
Fertility	No	Normal	No	Normal
Intelligence	Normal/slightly low	Usually normal	Usually normal	Usually reduced
Behavioral problems	Sometimes	Sometimes	Minimal	Sometimes
Other features	Hypogonadism	Tall, acne	Short, webbed neck, coarctation	Few

From Harper PS: Practical Genetic Counseling, 6th ed. London, Arnold Publishers, 2004, p 69.

Sex Chromosome Aneuploidy

Among live births, about 1/400 men and 1/650 women have some form of sex chromosome aneuploidy. The consequences of this class of chromosome abnormalities in general are less severe than those of autosomal aneuploidies (Table 2-5).

Turner Syndrome

Although monosomy for an entire chromosome is almost always lethal, an important exception is monosomy X (45,X), which results in Turner syndrome. Turner syndrome is estimated to occur in 1% to 2% of all conceptions, but most are lost prenatally, resulting in a frequency of 1/2000 to 1/3000 live births. Turner syndrome causes a characteristic phenotype, which includes short stature, ovarian dysgenesis with failure to develop secondary sexual characteristics, and infertility, as well as physical features such as a webbed neck, peripheral lymphedema at birth, congenital heart defects, and renal abnormalities. Prenatally, fetuses with Turner syndrome typically have an increased nuchal translucency or cystic hygroma, lymphangiectasia, structural renal abnormalities, and congenital heart defects, particularly left-sided obstructive lesions such as coarctation of the aorta. Women with Turner syndrome usually have normal intelligence, although they may have specific learning disabilities.

The types of specific chromosomal abnormalities seen in women with Turner syndrome are quite variable. Only about 50% of patients have a straightforward 45,X karyotype. Approximately 30% to 40% of cases involve mosaicism, most commonly 45,X/46,XX or 45,X/46,XY. Patients with a Y chromosome may have ambiguous genitalia and are at risk for development of gonadoblastoma in their dysgenetic gonads. Structural abnormalities of the X chromosome are seen in 10% to 20% of cases and also often involve mosaicism. The fact that these patients have more than one cell line can account for variability in phenotype of women affected with Turner syndrome.

Klinefelter Syndrome

Klinefelter syndrome occurs in about 1/1000 male births and is a common cause of primary hypogonadism. Men with Klinefelter syndrome tend to be tall, with long arms and legs. They have small testes and are sterile owing to atrophy of the seminiferous tubules. Gynecomastia occurs in

about 30%. There is an increased risk for learning disabilities, with IQ typically about 10 to 15 points below that of unaffected siblings, although men with Klinefelter syndrome are not typically mentally retarded. Because the disorder is often subtle, men are often first diagnosed in infertility clinics.

47,XXX and 47,XYY

The 47,XXX karyotype occurs in about 1/1000 women. Overt physical abnormalities are not associated with this disorder, but these women can have learning disabilities or mild mental retardation. Men with a 47,XYY karyotype tend to be tall, with mild learning disabilities and IQ 10 to 15 points lower than that of their siblings. The condition is not associated with structural birth defects, but these boys may have behavioral problems. Individuals with increasing numbers of X chromosomes (that is, 48,XXXX or 48,XXXY) have also been described. The degree of mental deficiency and physical abnormalities tend to increase with each additional X chromosome.

Polyploidy

In polyploidy (that is, triploidy and tetraploidy) there are one or more extra sets of chromosomes. A triploid cell has 69 chromosomes (one extra set), and a tetraploid cell has 92 chromosomes (two extra sets). Both triploidy and tetraploidy have been seen in fetuses, although they are lethal and rarely reported in live births. Of those fetuses with triploidy who have been liveborn, there are no reported survivors beyond 10.5 months. Congenital abnormalities seen in triploidy include micrognathia, prominent forehead, dysplastic cranial bones, low-set malformed ears, microphthalmia, hypertelorism, cleft lip and palate, macroglossia, omphalocele, syndactyly, and asymmetric development.

The extra chromosome set in triploid pregnancies can be of either maternal or paternal origin. Maternally derived triploidy results from fertilization of a diploid ovum by a haploid sperm and can result in a XXX or XXY karyotype. Paternally derived triploidy can result from fertilization of a haploid ovum by either a diploid sperm, or by two haploid sperm and can result in a XXX, XXY, or XYY karyotype.

The phenotype of triploid pregnancy has been reported to depend on the parental source of the extra chromosome set. Triploids with an extra set of paternal chromosomes have a well-formed fetus with an abnormal placenta and

Table 2-6 Some Distinctive Cytogenetic Syndromes

Karyotype	Syndrome	Features

often result in partial hydatidiform moles. Those with an extra set of maternal chromosomes usually have a small, growth-restricted fetus and a small, noncystic placenta.⁵⁻⁷

Abnormalities of Chromosome Structure

There are many types of abnormalities of chromosome structure, but all generally result from chromosome breakage, followed by recombination in an abnormal configuration. Overall, structural chromosome abnormalities occur in about 1/375 newborns. *Reciprocal translocations* involve an exchange of segments between nonhomologous chromosomes. These rearrangements are relatively common, and can be balanced (that is, the appropriate amount of chromosomal material is present) typically resulting in a normal outcome, or unbalanced, in which some chromosomal material is gained or lost, therefore resulting in an abnormal outcome. There is an increased risk of unbalanced rearrangements in the offspring of people who carry balanced translocations, thereby leading to decreased fertility and an increased risk of offspring with birth defects.

A *Robertsonian translocation* occurs when the long arms of two acrocentric chromosomes (chromosomes 13, 14, 15, 21, 22) are fused and the corresponding two short arms are lost. Because the short arms of these chromosomes do not contain essential genetic material (they are made up of multiple copies of genes for ribosomal RNA), this does not result in an abnormal phenotype. Offspring of individuals with a Robertsonian translocation can, however, inherit either a missing or extra long arm of the chromosomes involved in the fusion event, resulting in a trisomy for that chromosome arm. The most common Robertsonian translocation involves chromosomes 14 and 21, and is responsible for about 5% of cases of DS. The recurrence of translocation DS depends on whether the translocation was inherited from a carrier parent. In 75% of cases, the translocation is *de novo*, and the recurrence risk is very low (<1%). If the translocation was inherited from a parent who carries a 14;21 balanced translocation, there is a 10% chance of recurrence if the mother is the carrier, and about a 2% chance if the father is the carrier.

When a balanced translocation or other rearrangement is identified in a fetus at the time of prenatal diagnosis, testing of the parents is recommended. If the translocation is inherited from a phenotypically normal parent, the fetus would be predicted to be normal. If a reciprocal translocation occurs as a *de novo* event, there is approximately a

Table 2-7 Common Microdeletion Syndromes

Syndrome	Location	Frequency
Prader Willi	15q	1/25,000
Angelman	15q	1/30,000
Velocardiofacial	22q	1/3,000
Smith-Magenis	17q	1/25,000
Williams	7q	1/10,000
Alagille	20p	1/70,000
Rubenstein-Taybi	16p	1/100,000

Miller Dieker	17p	1/85,000
Wolf-Hirschhorn	4p	1/50,000
Cri-du-chat	5p	1/35,000
Retinoblastoma	13q	1/23,000

doubling of the background risk of phenotypic abnormality. This is thought to be due to subtle, undetected chromosomal imbalance, or disruption of genes at the breakpoint(s).

Other Types of Chromosomal Rearrangements

In addition to translocations, there are several other types of unbalanced chromosomal rearrangements. These include deletions, which occur with the loss of a chromosome segment, resulting in partial monosomy (Table 2-6). Some deletions are too small to be seen through routine karyotyping, and require specialized techniques such as fluorescence in situ hybridization (FISH) to be detected. Such deletions can involve many genes, and are responsible for a number of clinically distinct microdeletion syndromes (often referred to as 'contiguous gene deletion syndromes') (Table 2-7). One of the most common is the 22q microdeletion syndrome, which occurs in about 1/4000 live births. The 22q microdeletion is a relatively common cause of congenital heart defects, particularly conotruncal abnormalities, such as truncus arteriosus and tetralogy of Fallot. It has recently been recognized that small subtelomere deletions are responsible for some cases (approximately 5%) of otherwise unexplained mental retardation. This recognition is important, because a high percentage of such deletions have been demonstrated to be familial.^{8,9} Duplications of a chromosome segment also occur, resulting in partial trisomy. Marker chromosomes are small, additional chromosomes, often unidentified. These

are also known as supernumerary chromosomes or extra structurally abnormal chromosomes (ESACs). Some marker chromosomes contain little more than centromeric heterochromatin and are not significant, whereas others contain material from a chromosome arm and can cause an abnormal phenotype. Other structural rearrangements include ring chromosomes, paracentric and pericentric inversions, and isochromosomes, that are chromosomes that contain two copies of one arm (either the p or q arm) and no copies of the other.

SINGLE GENE DISORDERS

Many important genetic diseases occur as the result of a mutation at a single gene. The 2006 edition of *Online Mendelian Inheritance in Man* (OMIM) lists more than 13,000 known single gene traits in humans. Of these, more than 12,000 are on autosomes and 655 are on the X chromosome.¹⁰ Many have been mapped to specific chromosome locations, cloned, and sequenced.

Gregor Mendel first described the principles of segregation and independent assortment of genes in his well-known experiments with garden peas. This work led to the classic descriptions of autosomal-dominant (AD) and autosomal-recessive (AR) inheritance. Classically, AD inheritance refers to conditions in which one allele asserts its effect in both the homozygous and heterozygous form, whereas AR inheritance requires mutations at both alleles. X-linked inheritance occurs with conditions encoded on the X chromosome, and it may be either recessive or dominant.

The completion of the human genome project in 2003 was an epic chapter in laying the foundation for the study, diagnosis, and treatment of human genes and genetic disease. Although the human genome has now been sequenced, we still do not know how most genes work in either health or disease. We have gained an increased appreciation, however, for the complexity of human genetics. Relevant to clinical genetics, we have greatly increased our understanding of genetic heterogeneity, and the less than clear-cut association of one gene with one disorder. We now understand that mutations at more than one gene locus can lead to the same phenotype, and that multiple different phenotypes can result from mutations in the same locus. Phenotypes also result from the interaction of genotype with the environment (including other genes), and there are numerous phenomena that our advances in genetic technology have uncovered that make genetics far more fascinating, if far more complex.

Autosomal-Dominant Inheritance

In AD inheritance, affected individuals are heterozygous for an abnormal allele, that they transmit to 50% of their offspring, independent of gender. Overall, approximately 1/200 individuals is affected with an AD condition, although any individual condition is typically rare. Matings between two individuals affected with the same AD condition are relatively uncommon, and homozygotes for AD conditions are rare. The exception to this occurs with disorders in which there may be cultural or social reasons that affected individuals may preferentially mate, as with achondroplasia. The homozygous state is often more severe (that is, familial hypercholesterolemia) or lethal (achondroplasia), although

FIGURE 2-3. Paternal age and risk of autosomal-dominant disorders. (Modified from Carlson BM: *Human Embryology and Developmental Biology*, 3rd ed. Philadelphia, Mosby/Elsevier, 2004.)

in some cases homozygotes may have same phenotype as heterozygotes (for example, Huntington disease). In couples with same AD disorder, such as achondroplasia, 25% of pregnancies will be affected with the homozygous, lethal form, 50% with heterozygous achondroplasia, and 25% of offspring will be normal.

In theory, AD inheritance is straightforward, but in actuality, there are numerous factors affecting gene expression that can make evaluation of such cases extremely complex. Counseling of families regarding AD disorders requires consideration of mechanisms such as the rate of new mutation, mosaicism, conditions with late or variable age of onset, incomplete penetrance, and variation in expressivity.

AD disorders may be inherited from an affected parent, or may result from a new mutation. Most cases of achondroplasia result from new mutations, as do about half of cases of neurofibromatosis. Paternal age has a demonstrable effect on the rate of such new mutations (Fig. 2-3). If a disorder occurs owing to a new mutation, the risk of recurrence in a sibling is generally very low. However, an individual may be mosaic for an AD mutation, meaning that there are cells of more than one genetic constitution present. In this case, all or part of a person's germline may be affected, whereas the somatic cells are not and, therefore, the individual is asymptomatic. If germline mosaicism is present, an apparently unaffected individual will have an increased risk of having affected offspring. Germline mosaicism has been demonstrated in as many as 6% of cases of the perinatal lethal disorder osteogenesis imperfecta type II, as well as in X-linked disorders such as Duchenne muscular dystrophy and hemophilia A. For practical purposes, it is reasonable to consider a recurrence risk of about 1% to be likely for any apparent new dominant mutation, unless more specific estimates are available.¹¹

Penetrance and Expression

Further complicating recurrence risk counseling and clinical evaluation of AD disorders are the phenomena of penetrance and variable expression. A given individual may have a disease genotype but may not express the phenotype if a disorder is not 100% penetrant, as is the case with retinoblastoma, which affects only about 90% of individuals who inherit the causative mutation. Age is also an important consideration, because a disorder such as polycystic kidney disease is about 80% to 90% penetrant by 20 years of age and nearly 100% penetrant by 30 years of age but only with careful imaging of the kidneys.¹² A disorder may also demonstrate variable expression between affected individuals. Although disorders such as achondroplasia are expressed with little variation, most AD conditions demonstrate variation in clinical severity, even within a family. Targeted physical examinations, radiologic investigation, and other studies may be required to identify features of a disorder; neurofibromatosis (NF) and tuberous sclerosis are notable examples. Essentially all individuals inheriting the NF gene have some clinical symptoms, although they may range from mild skin manifestations to multiple debilitating neurofibromas. An important consideration is that those individuals who reproduce tend to be the least severely affected, and therefore such a disorder is likely to be more severe, on average, in the child than in the parents. Expression may be affected by environmental effects, modifier genes, somatic mutation (for example, with retinoblastoma), genomic imprinting, anticipation, and allelic heterogeneity. Some of these mechanisms are discussed in more detail later.

Autosomal-Recessive Disorders

AR disorders are classically described as those for which two gene mutations must be present for the disorder to manifest. Such disorders occur most commonly in persons whose healthy parents carry the same recessive gene. The recurrence risk to such carrier parents is 25% in each pregnancy, and these disorders most commonly occur with no prior family history. Carriers are much more common than affected individuals, and the disorders typically cluster in sibships but not in prior generations. Unless there is consanguinity or the disorder is particularly common, the risk to other relatives (for example, half-sibs and children of healthy sibs) is generally low. Consanguinity increases the risk of having offspring with AR disorders. The increased risk to parents who are first cousins to have a child with a major genetic or congenital abnormality is about 6%, or twice the background rate.

Again, with advances in genetics, the exceptions to the traditional rules of AR inheritance are increasingly evident. It is now appreciated that carriers of many of these conditions may have subtle symptoms. Examples of this are cystic fibrosis (CF), in which male carriers may have infertility owing to congenital bilateral absence of the vas deferens (CBAVD). Sickle cell carriers may suffer splenic infarct at high altitudes and are at increased risk for urinary tract infection in pregnancy.

AR disorders demonstrate much less variation in expression, and lack of penetrance is rarely encountered, so counseling is more straightforward with these conditions. Genetic heterogeneity due to more than one causative locus, or multiple alleles at a single locus, is the major cause of

variation in severity of a single disorder. This is important in CF, which is the most common AR condition in the white population and a focus of prenatal screening programs, as described later.

X-Linked Inheritance

X-linked disorders can be recessive, dominant, or dominant with lethality in men. Most X-linked conditions are recessive, and are traditionally thought of as affecting only men, who have unaffected carrier mothers. As with AD inheritance, some cases occur owing to new mutations, and paternal age has been shown to increase the risk of producing daughters who carry X-linked disorders. Because women carry two X chromosomes whereas men carry only one, one X chromosome is randomly inactivated early in embryonic development, thereby allowing women to produce X-linked gene products in the same quantities as men (Lyon hypothesis). The XIST gene in the X inactivation center is responsible, through methylation, for X inactivation. X inactivation is incomplete, however, which is why individuals with abnormal numbers of X chromosomes are abnormal. And because X inactivation is random, some female heterozygote carriers of X-linked disorders will inactivate primarily their X chromosomes carrying the normal allele, and therefore be symptomatic due to skewed X inactivation. This occurs in hemophilia A, in which some carriers can have a mild bleeding disorder owing to reduced levels of factor VIII. Such affected women have symptoms that are usually, but not always, milder than their male counterparts.

X-linked dominant disorders are less common than X-linked recessive diseases, and some such conditions are lethal in men. Examples include Rett syndrome, incontinenti pigmenti, and Aicardi syndrome. Aicardi syndrome is a rare disorder primarily of the CNS, including agenesis of the corpus callosum, microphthalmia, and infantile spasms. Evaluation of gender can be helpful if such a condition is suspected, because identification of female gender would support this diagnosis. When an affected child with such a condition is born to healthy parents, this is likely owing to a new mutation and the recurrence risk is low.

With isolated X-linked recessive disorders, it is important, but often difficult, to determine if an isolated case represents a new mutation or if the mother is a carrier. When molecular diagnosis or other methods of carrier detection are available, the situation can be clarified. However, such tests are not available for all conditions, and risks must often be empirically determined based on pedigree analysis and consideration of other factors such as the number of unaffected men in the pedigree. An example is demonstrated in Figure 2-4, which represents an isolated case of a lethal, X-linked disorder (for example, Duchenne muscular dystrophy) in a family. If the case is due to a new mutation in the affected boy (III-1), there is no increase in recurrence risk for his sister (III-2) or her children. If the case is due to a new mutation in his mother (II-1), then his sister (III-2) has a 50% risk of being a carrier, but his aunt (II-2) does not. Finally, if the grandmother (I-1) is a carrier, then II-2 has a 50% risk of being a carrier, and his female cousin (III-3) has a 25% chance of being a carrier.

Fragile X syndrome, the most common inherited form of mental retardation, is an important disorder that has been

described as X-linked semi-dominant. Fragile X syndrome is characterized by mental retardation, behavioral difficulties, and specific dysmorphic features. The condition affects men (approximately 1/4000) more commonly and more severely than women, and it has a complicated inheritance pattern. Carriers have an intermediate number of trinucleotide (CGG) repeats in the 5' untranslated region of the gene (premutation) that can increase during oogenesis to a larger number of repeats (full mutation) (Fig. 2-5). Full-mutation men have moderate to severe mental retardation and behavior problems, such as autism, whereas women are

affected by a much more variable phenotype, ranging from normal to as severe as affected men. Premutation female carriers have a relatively high rate of premature menopause (15% to 25%), whereas male premutation carriers can have a tremor ataxia condition with an onset later in life.^{13,14}

Imprinting and Other Novel Genetic Mechanisms

Some genetic mutations have been noted to have a very different effect depending on the parent of origin, a phenomenon known as genetic imprinting. Imprinting is probably caused and controlled by differential methylation, with the imprints laid down during very early embryogenesis (Fig. 2-6). A number of genetic disorders, including Prader Willi Syndrome (PWS) and Beckwith Weidemann syndrome (BWS), occur owing to abnormalities of imprinted genes. With PWS, the disorder occurs when both copies of the SNRPN gene, on chromosome 15, are maternally inherited, and no paternal copy is present. Several recent reports have indicated a possible association of imprinting disorders with in vitro fertilization (IVF). An excess number of cases of Beckwith Weidemann syndrome has been reported in the offspring of children conceived with IVF, but the magnitude of this association is, at present, uncertain.¹⁵

Another novel genetic mechanism, long appreciated clinically but only understood on a molecular level in the last

FIGURE 2-4. Pedigree of an isolated case of a lethal X-linked disorder (for example, Duchenne muscular dystrophy). See text for risk estimation discussion.

FIGURE 2-5. Fragile X syndrome. A. Fragile X syndrome is carried on the X sex chromosome. B. In Fragile X syndrome there is an expansion of the CGG trinucleotide repeats. The effect of this expanded trinucleotide repeat is methylation of essential proteins. B

FIGURE 2-6. Genomic imprinting and uniparental disomy (UPD). Schematic of a hypothetical chromosome pair representing genomic imprinting. The maternal chromosome is indicated by the red line, and the paternal copy by the blue line. Genes are represented by circles, colored circles indicate genes that are expressed, and the white circles represent genes that are inactive. The green circles are genes that are not imprinted, whereas red circles indicate genes in which only the maternal copy is active and the blue circles genes in which only the paternal copy is active. *A*, Normal state, with one chromosome inherited from each parent. The non-imprinted gene is expressed from both parents, whereas only one copy of the red or blue (imprinted) gene is expressed. *B*, Paternal UPD. With two copies of the paternal chromosome present, there is a double dose of the paternally expressed (blue) gene, and absence of expression of the maternally expressed gene. *C*, Maternal UPD. There is an absence of paternally expressed gene product (blue) and a double dose of the maternally expressed products (red).

Table 2-8 Mitochondrial Disorders

<p>Leber's optic atrophy MELAS (mitochondrial encephalopathy with lactic acidosis and stroke-like episodes) MERFF (myoclonic epilepsy with ragged red fibers) Kearns-Sayre syndrome Pearson syndrome (lactic acidosis, pancreatic insufficiency, pancytopenia) Deafness (antibiotic-induced and other forms of progressive nerve deafness) Various other central nervous system degenerations Diabetes mellitus (some forms)</p>

Table 2-9 Factors Underlying Variation in Mendelian Disorders

Factor	Effect
Genomic imprinting	Phenotype varies according to parent of origin
Anticipation due to unstable DNA	More severe phenotype with successive generations
Mosaicism	Mild or nonpenetrant phenotype
Modifying alleles	Influence of unaffected parent
Somatic mutation also required	Variable penetrance of familial cancers

decade, is known as anticipation. Anticipation refers to the increasing severity of a genetic disorder in successive generations. This occurs in disorders that result from disruption of genes owing to expansion of trinucleotide repeat number, with increasing numbers of repeats being added on through each subsequent generation. Anticipation had been noted clinically in disorders such as Fragile X syndrome, before the basis was understood, and also occurs in other trinucleotide repeat diseases, including myotonic dystrophy, and Huntington disease.

Mitochondria, which produce adenosine triphosphate (ATP), have their own unique DNA. Our mitochondria are all maternally inherited and have a high mutation rate. Many mitochondrial diseases have now been identified, and they are most commonly maternally inherited. Typical symptoms include neuromuscular abnormalities, such as loss of motor control, muscle weakness and pain, gastrointestinal disorders and swallowing difficulties, poor growth, cardiac disease, liver disease, diabetes, respiratory complications, seizures, visual/hearing problems, lactic acidosis, developmental delays, and susceptibility to infection (Tables 2-8 and 2-9).

Structural Birth Defects with Complex Inheritance

Most common congenital malformations, including NTDs, cleft lip and palate, and congenital heart defects, have an

Table 2-10 Multifactorial Inheritance: Factors Increasing Risk to Relatives

<p>Close relationship to proband High heritability of disorder Proband or more rarely affected gender Severe or early onset disease in proband Multiple family members affected</p>

increased risk of recurrence in families. A small percentage of such defects have a specific cause, such as single gene disorders, chromosomal abnormalities, or teratogens. Most, however, are isolated defects that result from complex interactions between a number of factors, including genotype at one or more loci, and a variety of environmental exposures that trigger, accelerate or exacerbate the disorder. Therefore, occurrence does not match simple mendelian inheritance but is complex and multifactorial. Recurrence risk of such disorders is increased by the presence of more than one affected relative, a severe or early onset form of disease, an affected person of less common sex (in disorders in which persons of one gender are more likely to be affected), high heritability of the disorder, and consanguineous parentage (Table 2-10).

NTDs have long been thought to follow a typical complex inheritance pattern determined by multiple genetic and

environmental factors. Therefore, it was a remarkable discovery that the single greatest factor in causing NTD is a deficiency of maternal serum folic acid, which accounts for about 70% of these birth defects. Antiepileptic agents, such as valproate and carbamazepime are thought to increase the risk of NTD by interfering with folate metabolism. The risk of NTD is inversely correlated with maternal serum folic acid levels in pregnancy, with a threshold of 200 µg/L, below which the risk is very significant.¹⁶ Folic acid levels are strongly influenced by dietary intake and can become depressed during pregnancy even with normal dietary intake. The impact of folic acid deficiency is exacerbated by a genetic variant of the enzyme 5,10-methylenetetrahydrofolate reductase (MTHFR), which catalyzes the conversion of 5,10-methylenetetrahydrofolate into 5-methyltetrahydrofolate, the major circulating form of folate. The C677T allele of the MTHFR gene causes an enzymatic dysfunction that results in mild homocystinemia in people whose folate status is not optimal. Mothers of infants with NTD are twice as likely to be homozygous for the mutant allele, although it is so common in many populations that up to 15% are homozygous. Because MTHFR mutations are not present in the mothers of all children with NTD, it appears that other genetic factors or dietary deficiency alone can also cause NTD. Folic acid supplementation has been shown to decrease the risk of NTD by 80%.¹⁷ Public health initiatives to educate reproductive age women about the importance of folate, and fortification of the food supply (cereals and breads) with folic acid have been instituted in the United States for the purpose of decreasing the incidence of NTD.

Syndromes Due to Disordered Function of Specific Developmental Genes

Identification of the specific genes involved in individual malformation syndromes is a rapidly developing area of medical genetics. Many specific developmental genes have been identified, and they can provide the possibility of early prenatal diagnosis for some of these conditions. Because many developmental genes are conserved between species, discoveries in experimental models have led to important discoveries in human counterparts. Interestingly, many genes involved in developmental defects are proving to be important in neoplasia as well (Table 2-11).

TERATOLOGY

One of the first milestones in human teratology occurred in 1941, when an Australian named Norman Gregg noted the association between first trimester maternal rubella infection and serious birth defects.¹⁸ Twenty years later, the thalidomide disaster sensitized the medical community to the risks of medications in pregnancy. Thalidomide, a very effective sedative, was widely used for several years in West Germany, Australia, and other countries until the association of prenatal exposure with phocomelia and amelia was recognized. Following the recognition of the potent teratogenicity of this drug, intense investigations into the safety of various medications in pregnancy heralded the modern age of teratology.

Embryos are more susceptible to teratogenic agents at specific critical periods of development (Fig. 2-7). The pre-organogenetic phase, from conception until somite formation,

is known as the all or none period, when insults to the embryo are likely to result in either death of the conceptus and miscarriage (or resorption) or in intact survival.¹⁹ At this stage, the embryo is undifferentiated, and repair and recovery are possible through multiplication of the still totipotent cells to replace those that have been lost. Exposure of embryos to teratogens during the presomitic stage usually does not cause congenital malformations,²⁰ unless the agent persists in the body beyond this period.

The embryonic period, between weeks 3 and 8 postconception, is the period when the basic steps in organogenesis occur. This is the period of maximum sensitivity to teratogenicity because tissues are differentiating rapidly and damage to them becomes irreparable. Exposure to teratogenic agents during this period has the greatest likelihood of causing a structural anomaly. Because teratogens are capable of affecting many organ systems, the pattern of anomalies produced depends upon which systems are differentiating at the time of teratogenic exposure. In general, organs that form first tend to be sensitive earlier, and very complex organs tend to have prolonged periods of high susceptibility to disruption.

The fetal phase, from the end of the embryonic stage to term, is the period when growth and functional maturation of organs and already-formed systems occur. Exposure to teratogens in this period will mainly affect fetal growth, or the size or function of a specific organ. The brain in particular may be functionally affected almost throughout the entire pregnancy. Teratogens rarely cause gross structural anomalies during this time.²¹

Recognized Teratogenic Agents

A large number of environmental factors have been reported to be associated with birth defects. These include chemical teratogens, including medications, hormones, maternal infections, and nutritional factors. Although the list of medications suspected of teratogenicity is long, relatively

Table 2-11 The Molecular Basis of Some Congenital Malformations

Disorder	Gene
Apert syndrome	Fibroblast growth factor
Campomelic dysplasia	SOX9 (SRV-related developmental gene)
Hirschsprung's disease	RET oncogene (also involved in MEN2)
Holt-Oram syndrome	Specific gene, 12q (transcription factor)
Opitz syndrome (X-linked)	MID 1 (midline developmental gene)
Rubenstein-Taybi syndrome	CREB binding protein (16p)
Seathre-Chotzen craniosynostosis	TWIST (Drosophila homologue)
Thanatophoric dysplasia	Fibroblast growth factor (FGFR3)
Treacher-Collins syndrome	Specific gene 5q (function unknown)
Waardenburg syndrome	PAX3 (mouse homologue)

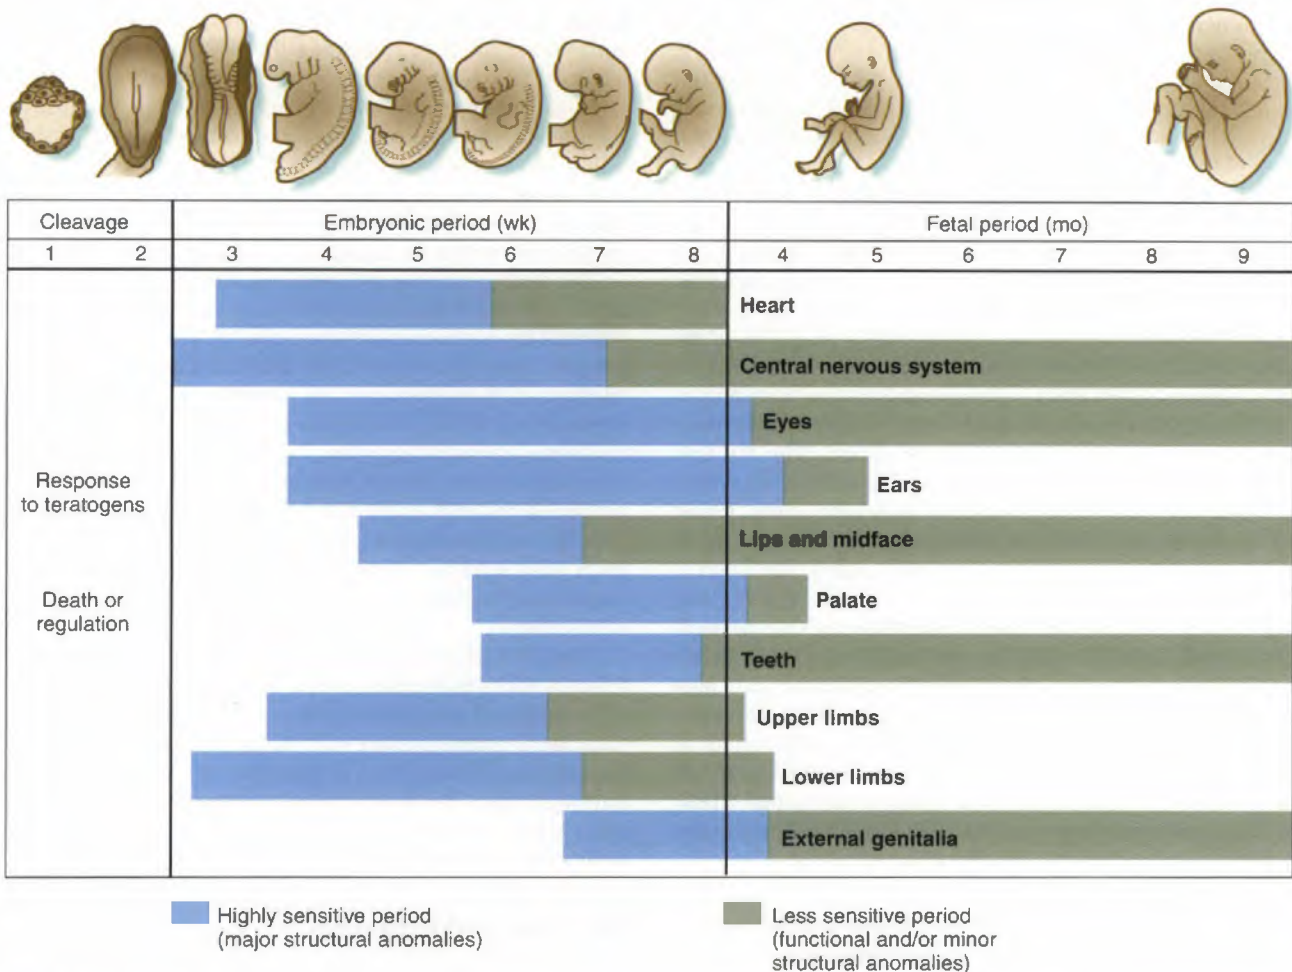

FIGURE 2-7. Periods and degrees of susceptibility of embryonic organs to teratogens. (Reproduced with permission from Carlson BM: *Human Embryology and Developmental Biology*, 3rd ed. Philadelphia, Mosby/Elsevier, 2004.)

few agents have been demonstrated to unquestionably cause birth defects in humans (Table 2-12). There are cases in which these medications must still be used during pregnancy, as the benefit outweighs the risk they impose. Often, maternal uncontrolled diseases are more harmful to the fetus than the administered drug.

Maternal Infections

The incidence of intrauterine infections ranges between 3% and 15%. Rubella was one of the first infectious agents recognized to cause birth defects in humans, and previously one of the most common. Today, because of effective immunization programs against rubella, the most common infection is that apparently caused by cytomegalovirus.

Intrauterine infections with long-term fetal sequelae may be viral, parasitic, or bacterial (see Table 2-12). Most common intrauterine infections are viral, although toxoplasmosis is caused by a protozoan (*Toxoplasma gondii*), and syphilis by a spirochete (*Treponema pallidum*). The timing of maternal infection can influence both the severity and likelihood of fetal infection. Rubella causes a high percentage of malformations in the first trimester, whereas toxoplasmosis

causes fetal infection more commonly in the third trimester, but with more severe consequences if contracted earlier.

Infection of the fetus may occur owing to hematogenous spread through the placental barrier or via ascending infection through the fetal membranes with direct contamination of the amniotic fluid. With intrauterine infections with cytomegalovirus and toxoplasmosis, specific clinical manifestations are seen only rarely in the mother. Cases of suspected intrauterine infections can be evaluated by measuring serum levels of maternal specific antibodies, but the significance of antibody levels is often uncertain. Moreover, a rise in levels of maternal antibodies is diagnostic for maternal, but not necessarily for fetal infection. To diagnose fetal infection, the infective agent should be identified in the amniotic fluid by culture or polymerase chain reaction (PCR), or by specific immunoglobulin M (IgM) in fetal blood. At birth, specific cord blood IgM or typical clinical findings (or both) are the most relevant diagnostic tools.

Medications

Although many medications have been suspected of being human teratogens, there are only a relatively small number

Table 2-12 Proven Teratogenic Agents in Humans

Ace inhibitors	CNS defects, congenital heart defects (first-trimester exposure) Renal failure, skull hypoplasia (second-trimester exposure)
Alcohol	Fetal Alcohol Syndrome: intrauterine growth retardation, microcephaly, developmental delay, characteristic facies, CHD, cleft palate
Carbamazepine	Neural tube defects, similar features to fetal hydantoin syndrome
Chemotherapeutic agents	Miscarriage, various malformations
Cocaine	Abruptio placenta, prematurity, fetal loss, decreased birth weight, microcephaly, limb defects, urinary tract anomalies, and poor neurodevelopmental performance.
Coumarin anticoagulants	Fetal warfarin syndrome: hypoplasia and calcific stippling of the epiphyses, intrauterine growth retardation, developmental delay, central nervous system damage, eye defects, hearing loss
Diethylstilbestrol	Clear cell adenocarcinoma, benign adenosis of the vagina, female genital structural changes (cervix/uterus)
Folic acid antagonists	Fetal aminopterin syndrome: central nervous system defects (hydrocephalus, meningomyelocele), facial anomalies (cleft palate, high-arched palate, micrognathia, ocular hypertelorism, external ear anomalies), abnormal cranial ossification, abnormalities of first branchial arch derivatives, intrauterine growth retardation, mental retardation
Heavy metal (lead, mercury)	
Hydantoin	Fetal hydantoin syndrome: craniofacial dysmorphism (wide anterior fontanelle, ocular hypertelorism, meiotic ridge, broad depressed nasal bridge, short anteverted nose, bowed upper lip, cleft lip, cleft palate), hypoplasia of the distal phalanges, nail hypoplasia growth retardation, mental deficiency, cardiac defects
Isotretinoin	Retinoic acid embryopathy: craniofacial anomalies (microtia or anotia, accessory parietal sutures, narrow sloping forehead, micrognathia, flat nasal bridge, cleft lip and palate, and ocular hypertelorism), cardiac defects (primarily conotruncal malformations), abnormalities in thymic development, and alterations in central nervous system development
Lithium	Cardiac defects, especially Ebstein anomaly
Misoprostol	Limb defects, Moebius sequence
Organic mercury	Mental retardation, cerebral atrophy, spasticity, blindness
Sodium iodide (I131)	Ablation of fetal thyroid gland
Thalidomide	Limb reduction defects, phocomelia, polydactyly, syndactyly, oligodactyly, defects of the external ears, facial capillary hemangiomas, palsies of cranial nerves VI or VII, cardiovascular defects, agenesis of kidneys, spleen, gallbladder and appendix, atresia or stenosis of esophagus, duodenum and anus
Trimethadione	Fetal trimethadione syndrome: characteristic craniofacial anomalies, growth retardation, delayed psychomotor development, clefting and congenital heart defects
Valproate	Neural tube defects, fetal valproate syndrome: narrow bifrontal diameter, high forehead, epicanthal folds, infraorbital creases, telecanthus, low nasal bridge, short nose with anteverted nares, midfacial hypoplasia, long philtrum, thin vermilion border, small mouth, cardiovascular defects, long fingers and toes, hyperconvex fingernails, and cleft lip
Intrauterine infections	
Cytomegalovirus	Cytomegalic inclusion disease: intrauterine growth retardation, microcephaly, chorioretinitis, seizures, blindness, optic atrophy. Neonatal hepatosplenomegaly, jaundice and thrombocytopenia
Rubella	Spontaneous abortion, congenital rubella syndrome: heart disease, deafness, cataracts, intrauterine growth retardation, encephalitis, abnormal long bones. Neonatal hepatosplenomegaly, obstructive jaundice and thrombocytopenic purpura, mental retardation, neurologic deficits, and behavioral abnormalities.
Syphilis	Congenital malformations, prematurity, stillbirth, hepatosplenomegaly, osteochondritis or periostitis, jaundice, petechiae or purpuric skin lesions, lymphadenopathy, hydrops, edema, ascites, rhinitis, pneumonia, myocarditis, nephrosis, and bulbar pseudo paralysis.
Toxoplasmosis	Encephalitis, hydrocephalus, intracranial calcifications, chorioretinitis, erythroblastosis, anemia, jaundice, hepatosplenomegaly, glomerulitis, myocarditis, and myositis. Central nervous system damage, seizures, mental retardation, cerebral palsy, deafness, and blindness.
Varicella-zoster virus	Skin lesions, fetal growth retardation, limb hypoplasia brain and eye defects, cerebral and cerebellar atrophy, seizures, developmental delay, and nerve palsies

CHD, congestive heart disease; CNS, central nervous system.

The above table represents selected medications and their possible associations with fetal structural abnormalities. Many of the listed associations are based on isolated case reports that have appeared in the medical literature for which the association is unproven; or in animal studies where the dosage of medication far exceeded the normal clinical amount normally used. It is likely that in many cases the reported association was coincidental to, rather than resultant from, the medication. *This table is not intended for patient counseling regarding the likelihood of fetal malformations or abnormalities.* This table should be used by the sonologist/sonographer as a guide to evaluate specific organ systems in addition to a thorough sonographic examination. In all cases of suspected teratogenic effects a reproductive geneticist or teratologist and the drug manufacturer should be consulted.

for which there is convincing evidence linking the substance directly to congenital malformations in humans. Testing drugs for teratogenicity is difficult, because agents may cause a high incidence of severe defects in animals but may not cause malformations in other species or in humans (for example, cortisone causes cleft palate in mice but not humans). Conversely, thalidomide is a tragic example of an agent that is highly teratogenic in humans but not in commonly studied laboratory rodents.

Physical Factors

Radiation

Ionizing radiation is a potent teratogen, with the response dependent on the dose as well as the gestational age at which the embryo/fetus is irradiated. Experience with the Japanese atomic bomb survivors as well as women treated with therapeutic radiation in pregnancy provides evidence of the damaging effects of large doses of ionizing radiation in humans. In contrast, there is no evidence that radiation exposure at typical diagnostic levels (a few millirads) poses a significant threat to the embryo, and noncancer health effects are not evident for fetal doses of less than 5 rads. Ionizing radiation at high doses (> 5 to 10 rads) can cause a variety of anomalies in various organ systems. The most prominent radiation-associated abnormalities are defects in the CNS, ranging from NTD to functional disorders, such as mental retardation.²² For fetuses exposed between 8 to 15 weeks' gestation, atomic bomb survivor data indicate that the decline in IQ score is approximately 25 to 31 points per 100 rads, at doses above 10 rads. At 16 to 25 weeks' gestation, the average IQ loss is approximately 13 to 21 points per 100 rads, at doses above 70 rads. After 26 weeks, at doses above 100 rads, the risks for stillbirth and neonatal death increases.^{22,23}

There appears to be a slightly increased risk of childhood cancer with radiation doses to the fetus of greater than 1 rad. There is no evidence that this effect is dependent on gestational age. The absolute risk for fatal cancer at 0 to 15 years of age after prenatal radiation exposure has been estimated to be 0.006% per 100 mrad. For an entire lifespan, this risk is about 0.015% per 100 mrad.²³

Temperature Extremes

In animals, excessive core body temperatures have been documented to cause malformations; NTD are among the most frequently reported. In humans, data are inconclusive and often conflicting. A large review and meta-analysis, published in 2005, reported an odds ratio of 1.9 for NTD associated with maternal hyperthermia, and the authors concluded that maternal hyperthermia in early pregnancy appears to be a human teratogen.²⁴ Other large trials have confirmed the association with NTDs and other birth defects, which has been reported with maternal fever as well as the use of devices such as hot tubs and saunas.^{25,26}

Maternal Factors

A number of maternal illnesses and metabolic disorders have been implicated in the genesis of congenital mal-

formations. Maternal diabetes is strongly associated with congenital malformations, with the risk to the embryo directly related to the degree of maternal glucose control.^{27,28} The most common abnormalities include congenital heart defects and NTD, whereas caudal regression is rare but of greatly increased frequency in infants of diabetic mothers. The phenotype of the infant of diabetic mothers also includes macrosomia, polyhydramnios, and stillbirth, with hypoglycemia and erythroblastosis common neonatal complications. Untreated maternal phenylketonuria is also a potent teratogen and results in microcephaly, mental retardation, congenital heart defects, and low birth weight. Risks to the fetus are related to the level of maternal phenylalanine and almost entirely eliminated with maternal dietary management and avoidance of phenylalanine in the diet of affected women during pregnancy.²⁹

Mechanical Factors

Mechanical disruption can result in a number of recognizable and characteristic sequence disorders. Often, the underlying cause is less important than the common disruption pathway. Potter sequence, for example, results from early, longstanding oligohydramnios of any cause, and consists of pulmonary hypoplasia, clubfeet, congenital hip dislocation, low-set ears, micrognathia, and flattened faces. This same phenotype can result from different causes of absent amniotic fluid, including bilateral renal agenesis and early rupture of the amniotic membrane.

GENETIC SCREENING IN PREGNANCY

Screening is currently recommended in pregnancy for a number of genetic (single gene or Mendelian) disorders, chromosomal abnormalities, and structural birth defects in the fetus. Screening for single gene defects is offered to essentially all patients, although the precise tests offered vary according to ethnic background. Screening for chromosomal abnormalities is also recommended for all patients, with an overwhelming array of sonographic and biochemical options now available for carrying out such screening. Screening for structural birth defects, such as NTD, may involve maternal biochemical screening as well as ultrasound.

Carrier (Heterozygote) Screening

The main purpose of carrier screening in pregnancy is to identify individuals who are themselves healthy, but are at risk of having children with a genetic disorder. The majority of disorders in this category are AR diseases, in which both parents must be carriers of the gene, but typically are unaffected. In the majority of cases, there is no family history of the disorder.

It is generally agreed that the following criteria should be met for heterozygote-screening programs to be effective: (1) disorder of sufficient severity to warrant screening, (2) high frequency of carriers in the screened population, (3) availability of an inexpensive and dependable test with low false-negative and false-positive results, (4) access to genetic counseling for couples identified as heterozygotes, (5) availability of prenatal diagnosis, (6) acceptance and voluntary participation by the population targeted for screening.

Table 2-13**Genetic Screening Tests Currently Recommended by Ethnic Group**

Ethnic Group	Disorders Tested	Test
Ashkenazi Jews	Tay Sachs disease	DNA, enzyme (hexosaminidase-A levels)
	Canavan disease	DNA
	Cystic fibrosis	DNA
	Familial dysautonomia	DNA
Caucasians	Cystic fibrosis	DNA
Africans, African Americans	Sickle-cell anemia	
	Beta thalassemia	MCV, hemoglobin electrophoresis
Southeast Asians	Alpha thalassemia	MCV
Mediterraneans	Beta thalassemia	MCV
Middle Eastern	Hemoglobinopathies	MCV, hemoglobin electrophoresis

MCV, mean corpuscular volume.

Table 2-13 lists the inherited disorders for which carrier screening is currently recommended. There are many other disorders for which screening is available and frequently performed. These include Fragile X syndrome, as well as extensive panels of diseases more common in the Ashkenazi Jewish population. As more genetic tests become available, clinicians and policy groups are faced with the challenge of deciding which tests should be offered for general screening.

Techniques for Carrier Testing

Carrier screening can be performed by biochemical tests that differentiate carriers from noncarriers of a disorder (for example, serum enzyme concentration or activity; low mean corpuscular volume in thalassemia carriers), or by DNA tests that can detect genetic mutations associated with a given disease. In some disorders (for example, Tay-Sachs disease), both biochemical and DNA screening are readily available and either can be used.

Because DNA-based screening tests generally look only at a set of the most common genetic mutations, not all carriers will be detected by a given screening test. Individuals with other mutations not included in the screening panel will not be detected. In some disorders, screening is more effective in a particular ethnic group in which a limited number of disease-causing gene mutations are seen. For example, DNA screening for CF is sensitive in the Ashkenazi Jewish population, in which greater than 95% of carriers can be detected because the majority of disease-causing mutations in this population are known. However, in Asian or black populations, fewer disease-causing mutations are known, therefore fewer carriers of Asian or black descent will be identified by the current CF DNA test. Therefore, it is important to remember that although a negative carrier test lowers the chance that an individual is a carrier, it does not rule it out (Table 2-14).

Tay-Sachs Disease

Carrier screening for Tay-Sachs disease in the Ashkenazi Jewish population has been done on a massive scale since

Table 2-14**Cystic Fibrosis Carrier Frequency and Detection Rates by Ethnic Group**

Group	Incidence	Carrier risk	Detection Rate
Ashkenazi jews	1/3,300	1/29	97%
Europeans	1/3,300	1/29	80%
Hispanics	1/8,464	1/46	57%
African-American	1/17,000	1/62	69%
Asian-American	1/32,400	1/90	~30%

1969. Screening, followed by prenatal diagnosis when indicated, has resulted in a dramatic decrease in the incidence of Tay Sachs disease in the Jewish population.²⁹ A number of practical, social, and ethical complexities have also been identified in this prototypic population-based effort.³⁰ More than 100 mutations in the hexosaminidase A gene (the TSD locus) have been identified to date. Some are associated with later onset or more chronic forms of neuronal storage disease. Two mutations cause a carrier-like pseudodeficiency when enzymatic testing is used (false-positive results). Educational and counseling components must be provided both before and after screening. Issues of privacy and confidentiality of test results must be addressed. In certain cultures, insurability and employment may be involved. The public perception of the biomedical community as advocates for wide-scale testing and screening may be interpreted, in some systems, as conflicts of interest on the part of entrepreneurial scientists, clinicians, and institutions.³¹

In part because of this history of success with TSD screening, and in part because of cultural isolation, an increased number of tests for genetic disorders have been proposed for testing of the Ashkenazi Jewish population. Some of these tests have become routine, whereas others are provided through commercial laboratories that offer an extensive Ashkenazi Jewish panel.

Cystic Fibrosis

CF is the most common severe AR disease affecting white children, with an incidence of 1/2500 to 5000 corresponding to a carrier frequency of 1/25 to 35. The disease is characterized by chronic pulmonary obstruction and infection, and by digestive disorders such as pancreatic insufficiency. It is caused by mutations in the gene that encodes the CF transmembrane receptor protein. Since the gene was cloned in 1989, more than 1000 mutations have been identified. The variety of mutations have ethnic and geographic variation, as well as a wide range of phenotypic variation, from those causing classical, severe CF (such as the common delta F508 mutation) to those that may have subtle or no clinical manifestations. Studies of clinical phenotype in correlation with CFTR genotype have revealed a very complex relationship demonstrating that some phenotypic features are closely determined by the underlying mutations, whereas others are modulated by modifier genes, epigenetic mechanisms, and environment.

Genetic testing is used to confirm a clinical diagnosis of CF and can be used for infants with meconium ileus, for carrier detection in individuals with positive family history and partners of proven CF carriers, and for prenatal

FIGURE 2-8. Hyperechogenic bowel (arrow) in a fetus with cystic fibrosis.

diagnostic testing if both parents are carriers. Since 2001, the American College of Obstetricians and Gynecologists and the American College of Medical Genetics have recommended that screening for CF should be offered to women at higher risk of having children with CF (e.g., Caucasians) and should be made available to couples in other racial and ethnic groups who are at lower risk and in whom the test may be less sensitive. They also recommend that people with a family history of CF or a partner with CF be offered testing.³² Implementing this recommendation is complex and therefore, somewhat controversial. The complexity arises in part because the incidence of CF varies in people of different ethnic groups. It is most common in Ashkenazi Jewish and Northern European populations, in which 1/29 is a carrier, but is far less common in Hispanic, black, and Asian-American persons. Furthermore, as mentioned earlier, the detection rate varies greatly between ethnic groups because not all alleles are known for each population. Most laboratories test for the most common mutations present in the population; in the United States this typically involves screening for the 25 to 32 mutations most common in the European population. Genetic counseling is particularly important in order to explain the limitations of testing (that is, not all carriers will be detected), especially for couples in which one or both partners is a carrier or has a positive family history and/or is of nonwhite ancestry.

Cystic Fibrosis and Echogenic Fetal Bowel

Fetal echogenic bowel (EB), defined as bowel with sonographic density equal to or greater than that of surrounding bone, is diagnosed in 0.2% to 1.8% of fetuses during routine ultrasound examination in the second trimester of pregnancy. This increased echogenicity has been associated with chromosomal abnormalities, congenital infections, intestinal obstruction, and CF (Fig. 2-8).³³ In the case of CF, it is hypothesized that the malfunctioning CFTR protein leads to dehydration of mucous secretions, which become viscous and obstruct the bowel lumen, leading to meconium ileus.

The risk for CF with EB has been extensively studied and reported to have a wide range from 0% to 33%.³⁴ This range could result from differences in ascertainment, CF prevalence, and mutation detection rates.

Because of the complexities and limitations of screening, testing for CF in cases of EB is often not straightforward. In cases of EB and two CF mutations in the fetus, the diagnosis is certain. In cases of EB with no fetal mutations, the risk of CF becomes exceedingly low. However, when the fetus with EB is found to carry one identified CF mutation, the risk of CF is increased but the diagnosis cannot be determined with certainty before birth with current techniques. Given the relatively high CF carrier frequency, this situation is not rare. The precise risk of CF depends on the frequency of CF in EB cases, the frequency of CF in the population studied, and the screening detection rate. It has been estimated at about 9%^{35,36} based on a 2% CF frequency in EB cases, a 4% CF carrier frequency and a 90% mutation detection rate. Therefore, screening of a parent with negative results can decrease, but not eliminate entirely, the risk for CF in the offspring. Depending on the clinical situation (family history, presence or absence of echogenic bowel, and carrier state of the other parent), the interpretation of risk to a given fetus can become quite complex. Various techniques to determine risk in different scenarios have been determined.³⁷

POPULATION-BASED PRENATAL SCREENING FOR BIRTH DEFECTS

Alpha-Fetoprotein

Population-based prenatal screening began in the late 1970s with the use of maternal serum alpha-fetoprotein (AFP) measurements to identify women at increased risk of carrying a fetus with an open NTD. AFP is the major serum protein early in fetal life.³⁸ This oncofetal protein is produced initially by the yolk sac and, after involution of this structure in early pregnancy, by the fetal liver. There are relatively little published data on the biologic activities of AFP during fetal development. AFP is present in amniotic fluid initially through diffusion across immature skin, and later through the kidneys and fetal urination. Amniotic fluid AFP is swallowed by the fetus and recirculates, with eventual degradation by the fetal liver. Minute amounts of AFP are present in maternal serum through diffusion across the placenta and amnion. Nonpregnant women have levels of AFP that are barely detectable (1 u/L), whereas normal median levels at 16 to 18 weeks of gestation range from 18 to 40 u/L. When the fetal serum level is 2 million u/L, the corresponding amniotic fluid AFP (AFAFP) is 20,000 u/L, and the maternal serum level is 20 u/L.³⁹

Fetal plasma and amniotic fluid levels of AFP peak in the midtrimester of pregnancy, whereas maternal serum AFP (MSAFP) continues to increase until 28 to 32 weeks of gestation (Fig. 2-9). The discrepancy between amniotic fluid and maternal serum levels of AFP is not completely understood, but may be due to the rapidly expanding placental and amniotic interfaces.

In the fetus with a defect such as anencephaly or spina bifida, AFP enters the amniotic fluid in increased amounts, leading to higher levels in the maternal serum as well. Levels of AFP are elevated in amniotic fluid and maternal serum

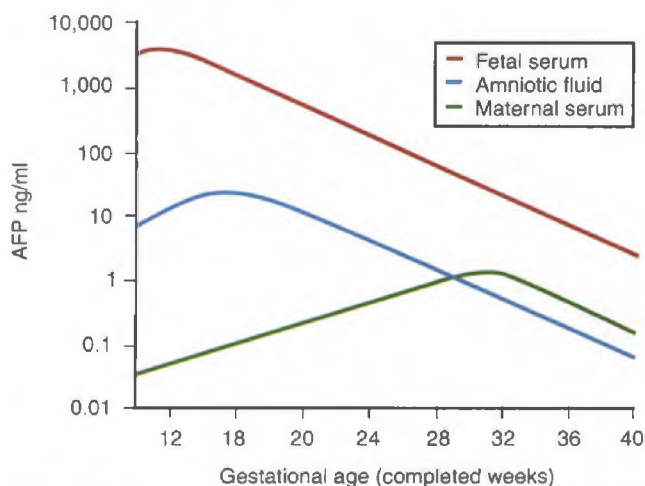

FIGURE 2-9. Mean concentrations of alpha-fetoprotein in maternal serum, amniotic fluid, and fetal serum. (Redrawn from Haddow JE: *Prenatal screening for open neural tube defects, Down's syndrome, and other major fetal disorders.* *Semin Perinatol* 14:488, 1990.)

only when such lesions are open, that is, when the neural tissue is exposed or covered by only a thin membrane. When NTD are skin covered, AFP does not escape from the fetal circulation, and such defects are generally not detected by maternal serum AFP (MSAFP). Whereas essentially 100% of anencephaly lesions are open, approximately 20% of spina bifida cases are skin covered, as are 82% of encephaloceles.³⁹ Discussions of the sensitivity and specificity of AFP testing are generally restricted to open lesions, because it is assumed that closed lesions will not be detected.

Prenatal Screening for Open NTDs

Because more than 80% of infants with NTD are born into families with no prior history of the disorder, MSAFP screening has become an important public health program. In laboratories providing AFP screening, results are expressed as multiples of the median (MoM). This provides less interlaboratory variation, which can be considerable, as well as a way to report results across a range of gestational ages. The distribution of MSAFP is log gaussian, with median values of 1.0 for normal pregnancies, 3.8 for pregnancies with open spina bifida, and 6.5 for pregnancies affected with anencephaly (Fig. 2-10).³⁹ There is significant overlap between affected and unaffected pregnancies, and choosing an MSAFP cutoff requires consideration of both detection rates and false-positive rates. The two most commonly used cutoffs for MSAFP are 2.0 and 2.5 MoM. Using either cutoff level, the detection rate for anencephaly is 95% or higher. The detection rate for spina bifida is between 75% and 90% using a cutoff of 2.0 MoM, and between 65% and 80% using 2.5 MoM. False-positive rates are 2% to 5% and 1% to 3%, respectively.³⁹ Encephaloceles are a less frequent cause of an elevated MSAFP, owing to both a lower incidence and a higher frequency of closed lesions. Given the extent of overlap between affected and unaffected pregnancies, it is not possible to detect all cases of open spina bifida with MSAFP screening and, likewise, most cases reported to be in need of further evaluation will ultimately be determined to be normal.

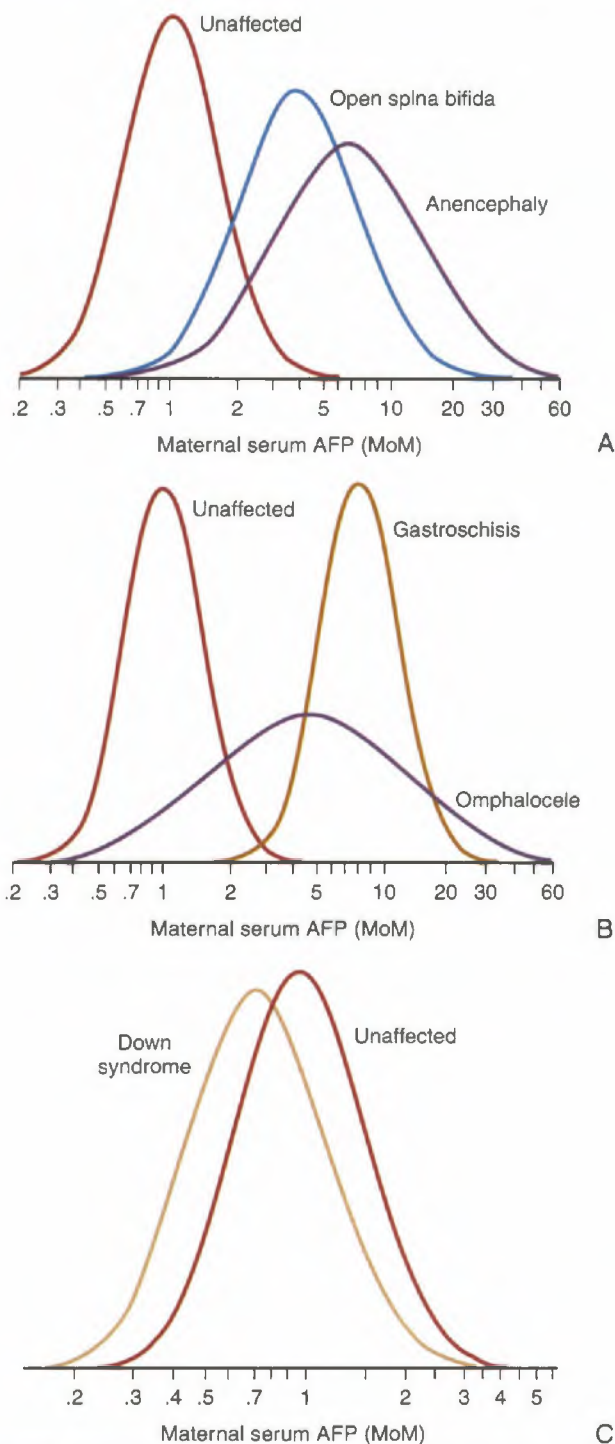

FIGURE 2-10. A. Distribution of second trimester maternal serum alpha-fetoprotein levels (MSAFP) in unaffected pregnancies and those affected by open spina bifida and anencephaly. The median for open spina bifida is 3.8 multiples of the median (MoM) and for anencephaly is 6.5 MoM. B. Distribution of second trimester MSAFP levels in unaffected pregnancies and those affected by gastroschisis and omphalocele. The median for gastroschisis pregnancies is 7.0 MoM and for omphalocele is 4.1 MoM. C. Distribution of second trimester MSAFP levels in unaffected pregnancies and those affected by Down syndrome. The median alpha-fetoprotein value is 0.75 MoM, and extensive overlap occurs between the affected and unaffected populations. (A, B, and C redrawn from Haddow JE: *Prenatal screening for open neural tube defects, Down's syndrome, and other major fetal disorders.* *Semin Perinatol* 14:488, 1990.)

As discussed previously, AFP levels vary with gestational age. The optimal time for serum NTD screening is 16 to 18 weeks of gestation. Before 16 weeks, there is more overlap between affected and unaffected pregnancies. Whereas last menstrual period (LMP) dating is sufficiently accurate for NTD screening, sonographic dating is more accurate and its use improves sensitivity and specificity of screening. In addition, because second trimester biparietal diameter measurements are usually smaller in fetuses with spina bifida, the MSAFP will appear higher, and this artifact improves the detection rate for this lesion. Other sonographic measurements (for example, crownrump length or composite biometry) can reliably date the pregnancy but do not have this unique advantage of BPD dating. Therefore, in the second trimester, ultrasound dating based on BPD alone is recommended for pregnancies at 14 weeks of gestation or later for the purposes of AFP screening. Most laboratories have separate sets of distribution parameters for ultrasound versus LMP-dated pregnancies.

There are several factors other than gestational age that affect MSAFP levels, including maternal weight,⁴⁰ race,^{41,42} insulin-dependent diabetes mellitus (IDDM),^{43,44} and the number of fetuses. Studies have also suggested that second trimester MSAFP is consistently elevated after first trimester transabdominal multifetal pregnancy reduction (MFPR), and should not be performed in this setting.⁴⁵ Because larger maternal size results in greater dilution of fetally derived AFP, obese women have lower levels of MSAFP. Black and Asian women have levels that are 10% to 15% higher than nonblacks, and insulin-dependent diabetic women have levels that are lower than the general population. Whereas the relationship between AFP and IDDM has long been appreciated, the magnitude of the association has been disputed.⁴⁶ Initially, it was felt that AFP levels were 60% to 70% of controls. Later, with correction for age, race, and weight, this was adjusted to 80%.⁴⁷ The physiologic basis for this lower value is unclear. There appears to be an association between the degree of glucose control, as determined by measurements of glycosylated hemoglobin, and MSAFP.^{48,49} Recent data indicates that perhaps the adjustment in IDDM pregnancies is no longer appropriate.⁴⁷ It is possible that better laboratory methods, improved diabetic surveillance and control, and better weight adjusted MoM may have resulted in IDDM values closer to controls. Some correction is still appropriate, although this is less than in the past.

Each of these factors is taken into account in the calculation of risk. Although other factors, such as maternal smoking,^{50,51} and IVF^{52,53} have a small impact on levels of MSAFP and other biochemical markers, these differences are not of sufficient magnitude to warrant correction.

Follow-Up When MSAFP Is Elevated

When the MSAFP level is near the cutoff (either 2.0 or 2.5 MoM), the accuracy of dating is assessed. If dating based on LMP was used for the original calculation, an ultrasound should be performed to confirm dating and rule out multiple gestations and fetal demise, both of which can cause an elevated MSAFP. Each program determines the discrepancy in dating at which recalculation is performed, generally between 7 and 14 days.

If the screening ultrasound does not identify an etiology for the increased MSAFP, further assessment with more sophisticated sonography and amniocentesis is indicated. The sensitivity of ultrasound for the detection of NTD and other significant structural abnormalities associated with increased MSAFP has been reported to be as high as 94% to 100%.⁵⁴ A recent study in fact indicated that ultrasound alone is more sensitive than MSAFP for the initial detection of NTD; this varies with the experience and expertise of the ultrasound examiner.⁵⁵ Ultrasound is less expensive than amniocentesis and does not carry the risk of pregnancy loss.

Amniocentesis allows for measurement of both AFP and acetylcholinesterase (AChE) in the amniotic fluid. In some programs, AChE is only measured when the AFAFP is greater than 2.0 MoM, an approach that provides the best balance between sensitivity and specificity.⁵⁶ Occasionally, AChE is done when there is an increased prior risk (for example, elevated MSAFP, abnormal ultrasound, or a positive family history). Measurement of AFAFP and AChE has a 97% detection rate for NTD, with a false positive rate of 0.5%.⁵⁷ Although there are many disorders that can result in an elevated AFAFP, AChE is more specific to neural tissue. Detection of AChE in the amniotic fluid generally indicates that an open NTD is present, although a positive AChE has also been reported with omphalocele, gastroschisis, cystic hygroma, fetal skin lesions, and fetal hydrops.^{58,59}

A major cause of borderline amniotic fluid AFP elevations and false-positive AChE results is contamination of the sample with fetal blood. Fetal blood AFP levels are more than 100 times higher than AF levels. False-positive AChE results occur in about 2% of visibly blood-stained samples and 0.2% of samples that are not visibly blood stained. Testing for the presence of fetal hemoglobin is indicated for samples with elevated AFAFP, visible red blood cell contamination, and certain other indications (for example, unexplained elevated MSAFP, reddish AF). The false-positive rate of AChE when early amniocentesis is performed (between 10 and 15 weeks), is four times higher than with amniocentesis at 15 weeks or beyond.⁶⁰

One study comparing strategies for evaluation of elevated MSAFP indicated that a program using targeted ultrasound and an MSAFP cutoff of 2.0 MoM would detect 90/110 structurally abnormal fetuses in a cohort of 100,000 hypothetical singleton pregnancies, without iatrogenic fetal loss, at a cost of \$5700 per anomalous fetus. The authors contrast this with a strategy of amniocentesis with karyotyping for MSAFP of 2.5 MoM or greater, which would detect 15 additional abnormal fetuses (including some chromosome abnormalities), but with nine iatrogenic fetal losses and an incremental cost of \$46,100 per anomalous fetus.⁶¹

Several investigators have reported an association between elevated MSAFP and an increased risk of fetal aneuploidy, an additional argument for amniocentesis. These studies have estimated the prevalence of clinically significant aneuploidy in this setting at 1%, with approximately 55% of these being autosomal aneuploidies and 45% sex chromosomal abnormalities.^{62,63}

Other Abnormalities and Elevated AFP

An elevated MSAFP can be associated with fetal defects other than NTDs (see Fig. 2-10, Table 2-15). Such disorders

Table 2-15 Causes of an Elevated MSAFP

Multiple gestation
Fetal demise
Fetal-maternal hemorrhage
Placental abnormalities
Uterine abnormalities
Maternal ovarian or hepatic tumors
Fetal congenital defects
Neural tube defects
Spina bifida

Encephalocele
Open ventral wall defects
Omphalocele
Gastroschisis
Congenital nephrosis
Triploidy
Bilateral renal agenesis
Congenital skin disorders
Epidemolysis bullosa
Aplasia cutis
Autosomal recessive polycystic kidney disease
Sacroccygeal teratoma
Cystic adenomatoid malformation of the lung

MSAFP, maternal serum alpha-fetoprotein.

include other open fetal defects, such as omphalocele and gastroschisis. In addition, some fetal skin disorders allow increased diffusion of AFP into the amniotic fluid, resulting in an elevated MSAFP. Congenital nephrosis can cause extremely high levels of AFP owing to fetal proteinuria and is suspected with a normal ultrasound and markedly elevated MSAFP (often >10 MoM). This AR disorder results in renal failure early in life, and children often die in infancy or early childhood. It is relatively rare except in Finland, where the reported incidence of 1/2600 live births makes the disease a primary focus of AFP screening program. DNA testing for Finnish nephrosis is now available, although it is of less use in families not of Finnish descent.^{39,64,65}

Elevated AFAFP

A number of studies have addressed the risk of an abnormality when an elevated AFAFP is detected. In one study of 85,000 consecutive samples from the California state screening program, 2.2% had an AFAFP greater than 2.0 MoM. One half measured 2.0 to 2.4 MoM, and 93% of these had a normal outcome. Sixty-seven percent of those with higher levels had abnormalities. With a positive AChE, the chance of an abnormal fetus was 67% for levels between 2.0 and 2.4 MoM and 99% at greater than 5.0 MoM. After a normal ultrasound and karyotype, the risk for a fetal abnormality was 1% for AFAFP measuring 2.0 to 2.4 MoM and 3% for higher levels.⁶⁶ Like MSAFP, an unexplained AFAFP has also been associated with preeclampsia and preterm delivery.⁶⁷

Table 2-16 Pattern of Results Seen with Expanded AFP Screening in Fetal Disorders

	AFP	uE ₃	hCG	Inhibin A
Open NTD	↑	No Change	No Change	No Change
Down syndrome	↓	↓	↑	↑
Trisomy 18	↑	↓	↓	No Change

AFP, alpha-fetoprotein; hCG, human chorionic gonadotropin; NTD, neural tube disorders; uE₃, unconjugated estriol.

Biochemical Markers and Fetal Chromosomal Abnormalities

Shortly after the introduction of MSAFP screening for NTD, it was recognized that fetuses with DS had a lower mean MSAFP in the second trimester, estimated at 0.74 MoM.^{68,69} Subsequent investigations have reported that maternal serum, amniotic fluid,⁶⁹ and fetal cord serum⁷⁰ levels of AFP are all lower in pregnancies in which the fetus has DS. This may be owing to either decreased production of AFP by the fetal liver or more rapid removal of AFP from the fetal circulation.⁷¹

A number of other biochemical markers have also been studied for use in aneuploidy screening. Although some of these markers have not been found to be useful, unconjugated estriol (uE₃),⁷² human chorionic gonadotropin (hCG)⁷³ and dimeric inhibin A⁷⁴⁻⁷⁶ all add sensitivity and specificity to second trimester biochemical screening for DS. Like AFP, uE₃ is 25 to 30% lower in DS pregnancy, whereas hCG and inhibin A are both increased with a median value about twice that of normal controls (Table 2-16).⁷¹

E₃ is a steroid hormone that is produced by the syncytiotrophoblast. Biosynthesis of estriol requires dehydroepiandrosterone sulfate (DHEAS) production by the fetal adrenal gland and subsequent conversion of DHEAS to 16 α -OH-DHEAS in the fetal liver. In the placenta, 16 α -OH-DHEAS is then deconjugated by a sulfatase and the resulting molecule aromatized to yield unconjugated estriol. Fetal disorders that affect the precursors or enzymes involved in this pathway may impact uE₃ levels in maternal screening and can be detected with second trimester multiple marker screening (see later).

HCG is secreted by the syncytiotrophoblast. Other placental secretory products such as progesterone, human placental lactogen (hPL) and pregnancy-specific beta-glycoprotein are higher in maternal samples from DS pregnancies. This finding suggests a hypersecretory or immature placenta as a characteristic of fetal DS.^{73,77}

Screening Programs for Fetal Aneuploidy

Because AFP, uE₃, hCG, and inhibin A are all independent of maternal age and only weakly correlated with each other, they can be used in combination to estimate fetal DS risk. In the second trimester, screening for DS now most commonly involves either triple marker screening with MSAFP, uE₃ and hCG, or quad screening with those three markers plus inhibin A.^{76,78}

Table 2-17 Screen-Positive Rate of Down Syndrome Screening Test at Different Risk Cutoff

Down Syndrome Test	Dating Method	1/190	1/270
Triple	US	3.8%	5.7%
	LMP	5.3%	7.4%
	Combined	4.4%	6.3%
Quad	US	3.2%	4.7%
	LMP	4.6%	6.2%
	Combined	3.7%	5.3%

LMP, last menstrual period.

From Knight GJ, Palomaki GE: Epidemiologic monitoring of prenatal screening for neural tube defects and Down syndrome. *Clin Lab Med* 23:531, 2003

In addition to using different combinations of markers for screening, laboratories use different risk cutoff levels. As with many screening tests, a trade-off is made between detection of the disorder and the number of individuals with a screen positive result. Table 2-17 summarizes the relationship between DS risk cutoff, triple marker versus quad screening, and method of dating. In the United States, many laboratories use the triple test, and a cutoff equal to the risk of a 35-year-old. At this risk cutoff, the triple test yields a screen positive rate of 7.4% with LMP dating, with a detection rate (DR) of 70% to 75% (all ages). Some laboratories choose a risk cutoff to provide a false positive rate (FPR) of 5%. This rate occurs at a screening cutoff of 1/190 and is associated with a DR of 60% to 65%. With the addition of inhibin A and use of quad screening, at a cutoff of 1/270, the DR increases to 80% and the positive rate decreases to 6.2% with LMP dating.⁷⁹

Trisomy 18 Detection

In pregnancies in which the fetus is affected with trisomy 18, the levels of AFP, uE₃, and hCG are all decreased, with median values of 0.6, 0.5, and 0.3 MoM, respectively. Inhibin A does not contribute to the detection of trisomy 18 and is not included in the screening algorithm. Use of a protocol evaluating this characteristic pattern is associated with an 80% detection rate for trisomy 18, while identifying only 0.5% of women as high risk.⁸⁰

Prenatal Screening in Multiple Gestations

A number of complexities arise in the screening of twin pregnancies. First, serum markers are approximately, but not exactly, twice those found in singleton pregnancies. Second, a single maternal serum value is used to provide information about multiple fetuses. In discordant cases, the normal cotwin will mask the abnormal marker production associated with the affected twin. Third, with monozygotic twins, both are most commonly either affected or unaffected, whereas with dizygous twins, the risk of DS is independent. Although ultrasound determination of monochorionicity is diagnostic of monozygosity, with same-gender dichorionic pregnancies, zygoty is uncertain. Because nuchal trans-

lucency screening in the first trimester is able to evaluate each fetus individually, this may be the most useful screen for multiple pregnancies.

Although some data are available on serum screening with twins, the distributions of serum markers in twins with DS are not known with any degree of certainty.^{81,82} Risk estimates in twins are calculated to classify twins as screen positive or screen negative in a way that ensures a false-positive rate similar to that in singletons. It is generally assumed that the detection rate for chromosomal abnormalities in twin pregnancies is lower than that in singletons, and the predicted detection rate for a 5% false-positive rate is only 47%.⁸³ However, these assumptions are theoretical rather than based on reliable observations. In high-order multiple gestations, biochemical screening is generally not possible, and again, nuchal translucency is the most useful (or only) option in such cases. Large studies are needed to determine the optimum screening method in multiple pregnancies.

Controversy of Maternal Age Screening

Maternal age has historically been the most frequent method for identifying women at increased risk for fetal chromosome abnormalities, and determining who should be offered prenatal diagnostic testing. Risk is commonly expressed in two ways, either as risk of delivering a child with DS, or the risk of diagnosing DS in midtrimester, at the time of amniocentesis. This distinction is important, because 25% of affected fetuses are spontaneously lost between midtrimester and term. Thus, the risk of carrying a fetus with DS at 35 years of age is 1/270 in the second trimester, but 1/384 at term. On average, the risk of DS in women older than 35 years of age is about 1/150 in the midtrimester. As maternal age increases, the chance of delivering a child with DS increases from about 1/1000 at 30 years of age, to almost 1/400 at 35 years of age, and 1/100 at 40 years of age (see Table 2-4).⁸⁴ Paternal age does not affect aneuploidy risk. This clinical observation is consistent with studies demonstrating that greater than 90% of trisomy 21 results from nondisjunction in the oocyte, most commonly during meiosis I.⁸⁵

Because of the association of advancing maternal age with DS (and other chromosome abnormalities), prenatal diagnosis has been offered to women 35 years of age or older for many years. At 35 years of age, the chance of identifying a fetus with DS approximately equals the chance of miscarriage due to the amniocentesis procedure. It is in part for this reason that testing has traditionally been offered at this point. With advances in screening, a risk threshold comparable to the risk of an unscreened woman 35 years of age continues to be used as the cutoff to recommend diagnostic testing. For many women, however, the decision to undergo amniocentesis is difficult, because not all women weigh the risks equally. For some, the possibility of miscarriage is far more of a concern than the possibility of having a child with DS. For others, concerns over caring for a child with disabilities may be more serious.⁸⁶

Age-based guidelines for offering of prenatal diagnosis have remained largely unaltered despite improvements and availability of second trimester maternal serum screening, the widespread use of ultrasound to identify findings associated

with fetal aneuploidy, demonstrated performance of first trimester screening and the potential for combinations of these approaches.⁸⁷ As improvements in screening have provided much better risk estimates than are available using age alone, more and more women 35 years of age and older are electing to have screening prior to making a decision regarding amniocentesis. However, numerous recent editorials have questioned whether the use of maternal age as a sole criterion for aneuploidy risk assessment remains justified.⁸⁸

All patients considering prenatal diagnosis should undergo genetic counseling to discuss the options available and the risks, benefits, and limitations of each testing choice.

Third-Trimester Pregnancy Complications after Abnormal Serum Screening

Extreme marker levels, both low and high, have also been associated with third-trimester pregnancy complications such as hypertensive disorders, intrauterine growth restriction, and preterm birth. Most cases, however, are not due to fetal or maternal pathology and ultimately result in a normal outcome.

Numerous studies have demonstrated that women with elevated levels of MSAFP have an increased risk of complications, such as spontaneous abortion, small-for-gestational age infants, pregnancy-associated hypertensive disorders, and preterm delivery. The magnitude of risk increases with increasing maternal serum levels, from a risk of 19% with levels of 2.5 to 2.9 MoM, to 67% with an MSAFP of greater than 6.0 MoM.⁸⁹

In cases of unexplained increased MSAFP, increased transplacental transfer is responsible for the elevated value. Such increased transfer occurs with various placental abnormalities, and these same placental abnormalities later result in perinatal complications. Abnormalities such as placental accreta, increta, and percreta have also been reported with an elevated AFP,⁹⁰ and uterine anomalies have been reported to be 22 times more common in these patients, as well.⁹¹ Because of the very large concentration gradient between fetal and maternal serum levels of AFP, even a slight compromise in uteroplacental integrity will allow detectably increased transport of AFP across the placenta.

Other biochemical markers and combinations of markers have also been studied with respect to adverse outcome in late pregnancy. Elevated hCG in particular has been associated with an increased risk of intrauterine growth restriction, hypertension/preeclampsia, fetal malformations, chromosomal abnormalities, and adverse perinatal outcome. As with MSAFP, the highest levels of hCG are associated with the highest risk of poor outcome.⁹² Both singleton and twin pregnancies with elevated hCG and AFP have been associated with adverse obstetric outcomes.⁹³⁻⁹⁵

The recently completed FASTER trial was a large prospective trial of biochemical screening for chromosomal abnormalities that included comprehensive pregnancy outcome data. This study of over 38,000 women identified numerous associations between serum markers and adverse outcomes. There was a relatively low, but often significant

risk of having an obstetric complication if a patient had a single abnormal marker. However, the risk of having an adverse outcome increased significantly if a patient had two or more abnormal markers.⁹⁶

Another study compared the risks of adverse outcome in women with unexplained elevated hCG or AFP, and whether these risks vary by prepregnancy risk status (medical or previous obstetric complications). These investigators found that abnormal serum screening was independently associated with preeclampsia, intrauterine growth restriction, fetal death, and preterm birth in both high- and low-risk women.⁹⁷ In patients with intrauterine growth restriction (IUGR), those who also had elevated hCG or decreased uE₃ were associated with an increased risk of adverse outcome as compared with patients with IUGR and normal markers.⁹⁸

Optimal management of the patients with unexplained abnormal biochemical screening, however, remains controversial. Overall, many experts have concluded that, apart from the six- to seven-fold increased risk when both AFP and hCG are elevated, the clinical utility of differences in one marker are probably poor.⁹⁹

Low Estriol

Women with low estriol (<0.75 MoM) have also been found to have an increased risk of adverse outcome, including IUGR, oligohydramnios, and delivery of small-for-gestational-age infants, a risk that seems independent of elevated hCG or AFP.¹⁰⁰ About 0.27% of women will have a very low uE₃ (<0.15 MoM), a finding that has been associated with a number of metabolic and genetic disorders including Smith-Lemli-Opitz syndrome (SLO), steroid sulfatase deficiency, Kallman syndrome, congenital adrenal hyperplasia, and other disorders associated with adrenal dysfunction. SLO is an AR disorder that results in multiple malformations, including congenital heart defects, mental retardation, and ambiguous genitalia in men. Because the primary abnormality involves cholesterol biosynthesis, a lack of cholesterol precursors from the fetus render the placenta unable to produce uE₃.¹⁰¹ Prenatal diagnosis is possible through detection of elevated levels of 7-OH-dehydrocholesterol in amniotic fluid or maternal urine.¹⁰² Some screening programs, including the expanded AFP program in the state of California, provide evaluation of risk for SLO.¹⁰³⁻¹⁰⁶ Although detection of SLO has proved rare in such programs, patients identified at increased risk for SLO have been found to have a very high risk of various adverse perinatal outcomes of greater than 50%.¹⁰⁴

The other, more common cause of very low estriol is the presence of X-linked steroid sulfatase in the fetus. Lack of this enzyme in the placenta also results in the inability to produce unconjugated estriol. This disorder is an X-linked condition leading to ichthyosis as the primary symptom in offspring, and a careful family history will often reveal symptoms in a previously undiagnosed male relative (grandfather or brother). The diagnosis can be confirmed through molecular testing for the causative microdeletion on amniotic fluid. Although the disorder is relatively mild, prenatal diagnosis can reassure the family and physician that another, more serious condition is not present.¹⁰⁶⁻¹⁰⁸

<p>Previous child with multiple congenital abnormalities, mental retardation, or isolated birth defect</p> <p>Family history of a hereditary condition, such as cystic fibrosis</p> <p>Prenatal diagnosis for maternal 35 years of age or older</p> <p>Follow up of abnormal prenatal screening tests (triple screen, nuchal translucency, etc.)</p> <p>Ultrasound detection of fetal structural abnormalities</p> <p>Consanguinity</p> <p>Teratogen exposure, such as medications, alcohol, occupational chemicals</p> <p>Recurrent pregnancy loss or infertility</p> <p>Parent with structural chromosome abnormality</p> <p>Previous child with chromosome abnormality</p> <p>Newly diagnosed abnormality or genetic condition</p> <p>Referral for genetic testing, including testing for cancer susceptibility and late onset disorders</p> <p>Follow up for a positive screening test, such as the phenylketonuria test in a newborn or the Tay-Sachs carrier test in an adult of reproductive age</p>

GENETIC COUNSELING AND PRENATAL DIAGNOSTIC TESTING

Genetic Counseling

Clinical genetics is the discipline that is concerned with the diagnosis and management of the medical, social, and psychological aspects of hereditary disease. Often, people seeking genetic counseling are parents of a child with a potential or known genetic condition. Others who seek genetic counseling include adults with an abnormality or a family history of an abnormality. Genetic counseling is also an integral part of genetic testing and screening programs, including prenatal testing. (Table 2-18).

The process of genetic evaluation involves several components: validation of the diagnosis, obtaining the family history, estimation of the risk of recurrence, helping the family to reach decisions and take appropriate action, and followup. An important part of genetic counseling involves understanding of the family history. Couples referred for prenatal testing for one indication will frequently have other risk factors identified. Generally, patients are not told what decisions to make with regard to testing and management options but, instead, are provided information and support. This approach, referred to as *nondirective counseling*, has been adopted widely as the standard in this field.

A family may be referred to the medical genetics unit for diagnosis, if this has not been made previously, or for prenatal testing if a diagnosis is known in the family and the pregnant woman may be at risk. The precise diagnosis must be certain in order to provide accurate prenatal diagnostic testing. The inheritance pattern must be known to provide correct risk figures, as some disorders may have different patterns of inheritance in different families.

Making a precise diagnosis may have enormous implications for counseling a family. For example, if a prior male fetus was diagnosed with hydrocephalus and the pregnancy terminated, a recurrence risk of 5% in future pregnancies

would generally be quoted. Ultrasound would be offered for prenatal diagnosis, although in some cases, ventriculomegaly may not manifest until late in pregnancy. On the other hand, more thorough evaluation of the prior fetus may have resulted in a diagnosis of X-linked aqueductal stenosis with identification of a mutation in the *L1CAM* (cell-adhesion molecule) gene. In such cases, testing of the mother is possible to determine if she is a carrier. If so, the recurrence risk is 50% for male offspring and very small for female offspring (although 50% of her daughters would also be carriers). CVS at 10 weeks would be possible for prenatal diagnosis if a molecular mutation were identified. The spectrum of the disorder includes boys with mental retardation but without hydrocephalus, so ultrasound would not be adequate for ruling out a recurrence of this condition.

PRENATAL DIAGNOSIS

For many families seeking genetic counseling, a major goal is learning the risk for heritable disease in their children and the options that are available for avoiding having an affected child. The principal goal of prenatal diagnosis is to supply at-risk families with information so they can make informed choices during pregnancy. The potential benefits of prenatal diagnosis include: (1) providing reassurance to at-risk families when the results are normal, (2) providing risk information to couples who would not have a child without such reassurance, (3) allowing couples to prepare for the birth of an affected child, (4) allowing medical providers to plan for the delivery and postnatal care of an affected infant, (5) providing risk information to couples for whom termination of an affected pregnancy is an option.

Prenatal diagnosis is typically performed early in pregnancy, at a time when termination of an affected fetus can be performed safely. For many families, even if termination of pregnancy is not an acceptable option, prenatal diagnosis can help them prepare mentally, emotionally, and financially, and seek support systems before the baby arrives. For most disorders, the chance of a normal, unaffected child outweighs the risk of birth defects, and prenatal genetic tests will reassure couples they will *not* have a child with a specific disease. In counseling patients, it is important to remember that in many cases, genetic testing of the parents will indicate that there is little or no genetic risk to their offspring, and prenatal diagnosis is not necessary.

Although prenatal diagnosis with termination of affected fetuses is one option for preventing the recurrence of a genetic disorder in a family, it is by no means a universal solution. There are many disorders for which prenatal diagnosis is not possible, and for many parents termination is not an acceptable option, even if prenatal diagnosis is available. Other measures for avoiding recurrence of a genetic disorder include avoiding childbirth through contraception or sterilization; adoption; sperm or ovum donation; or preimplantation genetic diagnosis (PGD) on embryos obtained through IVF (see below).

Genetic Counseling Before Prenatal Diagnostic Procedures

Parents considering prenatal diagnosis need information that will allow them to understand their situation and give

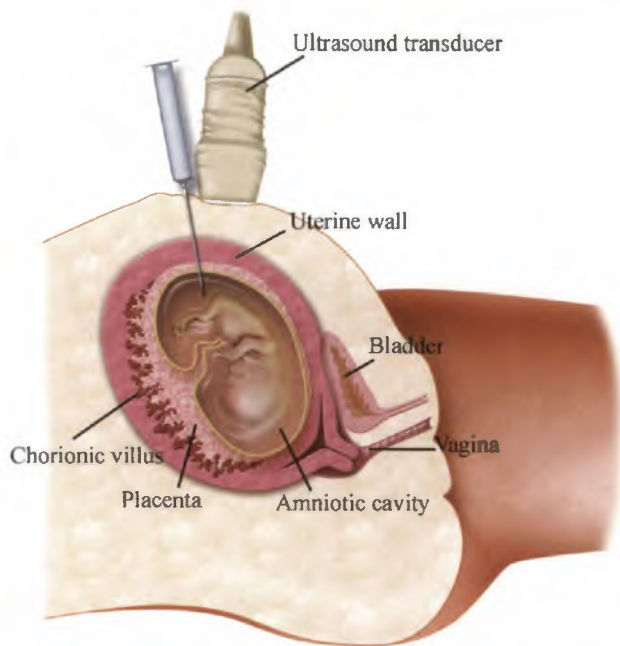

FIGURE 2-11. Amniocentesis needle is positioned in the amniotic cavity under ultrasound guidance. (Illustration by James A. Cooper, MD, San Diego, CA.)

(or withhold) consent for the prenatal diagnostic procedures. Genetic counseling before such procedures usually addresses the following: (1) the chance that the fetus will be affected, (2) the nature and consequences of the disorder, (3) the risks and limitations of the procedures being performed, (4) the time required before a report of the test results can be issued, (5) the possibility of complications of the procedures such as a failed attempt to obtain a sufficient, testable sample, or inconclusive results. Options for dealing with abnormal results are usually discussed, and it is emphasized that undertaking prenatal diagnosis in no way obligates the parents to terminate a pregnancy if an abnormality is discovered.

Techniques for Prenatal Diagnosis

Amniocentesis

In amniocentesis, a sample of amniotic fluid (typically 20 mL) is removed by inserting a 20- or 22-gauge spinal needle through the maternal abdomen and uterine wall into the amniotic cavity under ultrasound guidance (Fig. 2-11). Amniotic fluid contains desquamated fetal cells that can be cultured and karyotyped, or used for a variety of metabolic assays or DNA extraction if a specific indication is present. Amniotic fluid AFP levels are also routinely measured.

The major complication of amniocentesis is the risk of miscarriage (above the 2% to 3% risk for any pregnancy at this gestational age). Miscarriage risk of midtrimester amniocentesis at 15 to 20 weeks gestation is typically quoted at 0.5%, or 1/200, although the origin of this commonly quote number is obscure. The only randomized trial that has been performed in low-risk patients was in the United Kingdom in 1986; this study demonstrated a 1% procedure

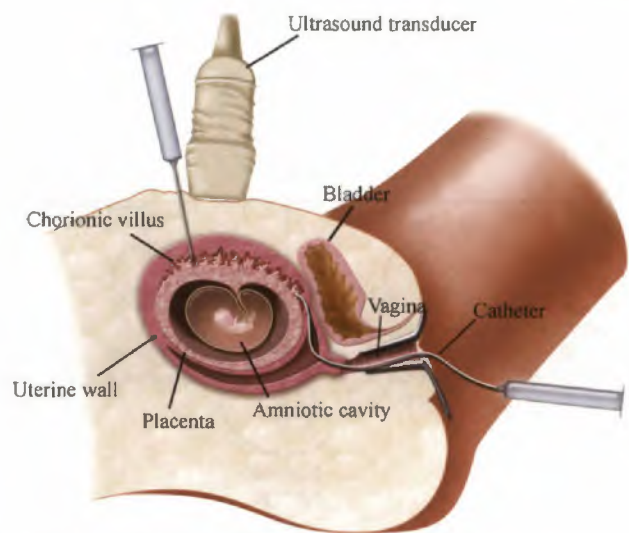

FIGURE 2-12. Chorionic villus sampling. Either chorionic villus catheter or sampling needle is placed into the developing placenta under continuous ultrasound guidance. (Illustration by James A. Cooper, MD, San Diego, CA.)

related loss rate.^{109,110} More recent data indicate that the risk may be substantially lower.^{111,112} Leakage of amniotic fluid following amniocentesis is not uncommon but typically resolves without long-term sequelae. Needle-associated injury to the fetus is rare.

Amniocentesis is typically performed at 15 to 20 weeks' gestation. The volume of amniotic fluid at 15 menstrual weeks is 125 mL, and increases 50 mL/wk for the next 13 weeks.¹¹³ In an attempt to provide earlier results, the feasibility and safety of amniocentesis as early as 11 weeks' gestation has also been investigated. Results of a large, multicenter randomized trial of early (11 0/7 to 13 6/7 weeks) versus midtrimester (15 0/7 to 16 6/7 weeks) amniocentesis revealed a significantly increased loss rate in the early amniocentesis group (7.6% versus 5.9%). In addition, there was a significantly increased incidence of talipes equinovarus in the early amniocentesis group (1.3% versus 0.1%). Thus, it appears that early amniocentesis does carry an increased risk compared with midtrimester amniocentesis, and this procedure is infrequently performed.¹¹⁴

Chorionic Villus Sampling

In chorionic villus sampling (CVS), a biopsy of the developing placenta is performed at 10-13 weeks' gestation (Fig. 2-12). The primary advantage of CVS is that it can be performed earlier in gestation, which allows a decreased period of anxiety for patients at risk. Early results also permit first trimester termination, a safer and more readily available procedure than abortion in the second trimester. Indications for CVS are generally the same as for amniocentesis, although AFP levels cannot be assessed on chorionic villi. Therefore, women who undergo CVS require NTD screening with either maternal serum AFP measurement or ultrasound later in pregnancy.

There are two commonly used approaches to CVS, transcervical and transabdominal. Both are performed under ultrasound guidance, which is used to document fetal life,

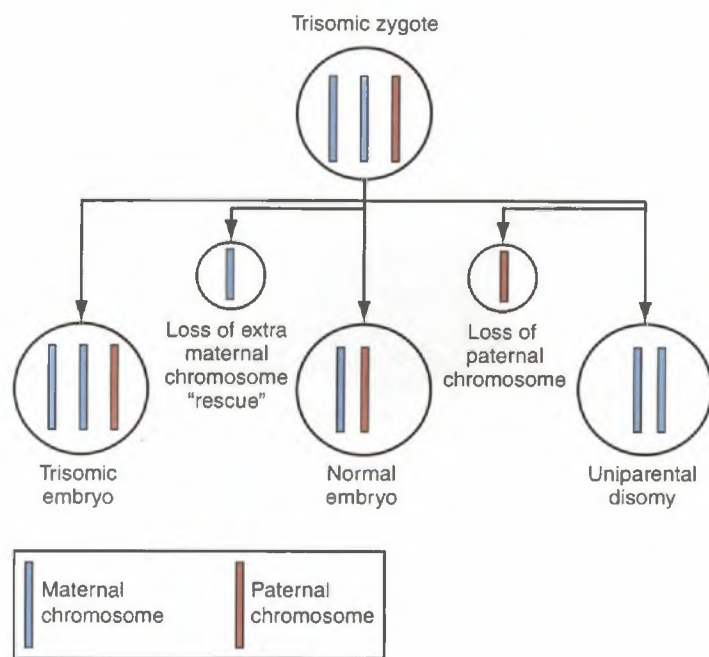

FIGURE 2-13. Trisomy rescue and uniparental disomy. Diploid ovum is fertilized by a normal, haploid sperm, resulting in a trisomic zygote. The cells multiple and divide, and one cell reverts to a diploid state owing to anaphase lag. This may happen owing to loss of either of the maternal chromosomes, or of the paternal chromosome. If one of the maternal chromosomes is lost, the resulting cell or cells will be normal. If the paternal chromosome is lost, the cells will be diploid but uniparental disomy will result.

gestational age, fetal number, localization of the trophoblast, and determination of the best approach and sampling path. With transcervical CVS, the patient is placed in the dorsal lithotomy position, a speculum inserted, and the vagina and cervix prepared with iodine antiseptic. A 16 g polyethylene catheter with a flexible, stainless steel obturator is inserted through the cervix and into the developing placenta. With a transabdominal approach, a 20-gauge needle is inserted into the placenta in a fashion similar to amniocentesis. In either approach, a 20-mL syringe is used to apply negative pressure and obtain a sample.

The risks of CVS were compared with those of amniocentesis in several trials performed shortly after introduction of the technique in the 1980s. A U.S. collaborative study demonstrated a loss rate 0.8% higher than that of mid-trimester amniocentesis, a difference that was not statistically significant.¹¹⁵ A Canadian trial also demonstrated a non-significant increase in losses of 0.6% above amniocentesis (Canadian).¹¹⁶ Since the completion of these trials over 20 years ago, experience has resulted in a decrease in the loss rates of both procedures. A recent study completed at the University of California San Francisco concluded that the decrease in risk of CVS-related losses has been greater than with amniocentesis. This has resulted in closing of the gap in risk and we now quote comparable rates of miscarriage following CVS or amniocentesis in our center.¹¹² However, CVS has a long learning curve and the risks are very provider dependent, therefore this equivalent loss rate may not be generalizable to all centers and providers.¹¹⁷

One important characteristic of CVS is the risk of confined placental mosaicism, which occurs in 1% to 2% of cases. Confined placental mosaicism (CPM) represents a discrepancy between the chromosomal makeup of the placenta and the fetus, and is diagnosed when a mixture of trisomic and normal cells are detected by CVS, whereas only normal cells are found on a subsequent amniocentesis or in the infant at birth. Most commonly, CPM represents a

trisomic cell line present only in the placenta with a normal diploid chromosome complement in the fetus.¹¹⁸ However, the fetus is truly mosaic in about 10% of cases,¹¹⁹ although the risk is somewhat dependent on the specific trisomy identified.¹²⁰ Although some cases of CPM are associated with poor placental function and perinatal complications such as IUGR and maternal hypertension, most commonly the outcome is normal.

CPM can arise following so-called trisomy rescue of an originally trisomic conception (Fig. 2-13). When this occurs, the fetus may be disomic but have uniparental disomy (UPD), a condition in which both chromosomes were inherited from the same parent. For example, if an embryo has trisomy 15 due to maternal nondisjunction, one or more cells in the inner cell mass, destined to become the fetus, may be 'rescued' by loss of one chromosome 15. If by chance the paternal copy is lost, there will be a normal chromosome number in the fetus, but maternal UPD 15. Trisomy rescue and UPD can potentially involve any chromosome, but if imprinted genes are present on the particular chromosome involved, this may have consequences for the fetus. Maternal UPD 15 is a cause of PWS, a condition characterized by mental retardation, obesity, and hypogonadism. Therefore, testing for UPD is indicated as a follow up to CPM detected by CVS when a chromosome containing known imprinted genes is involved (chromosomes 7, 11, 14, and 15). If the chromosome involved in the original trisomy does not contain imprinted genes, no phenotypic outcome for the fetus is suspected.

In the early 1990s, there were a number of reports of fetal limb reduction defects following CVS.^{121,122} The procedures in the affected infants were largely performed between 55 and 66 days of gestation, and subsequent studies indicated that early gestational age (<10 completed weeks) at sampling increased the risk for this complication. After much investigation, including a large study of more than 140,000 cases of CVS submitted to the World Health Organization

registry, it was concluded that there is no increased risk of limb reduction defects following CVS performed at greater than 10 weeks gestation.¹²³

Multiple Gestations

If a twin gestation is present, the risk of a chromosome abnormality is increased as compared with a singleton pregnancy. The chance that one or both fetuses will have a chromosome abnormality is dependent on the zygosity. There are three possibilities that would result in either one or both twins being affected: (1) dizygotic twins with one fetus affected, (2) dizygotic twins with both fetuses affected, and (3) monozygotic twins with both fetuses affected. Postzygotic errors can also result in discordant karyotypes in monozygotic twins, although this is rare. Using existing tables of estimated risks of chromosomal abnormalities in singleton gestations and mathematically derived formulas, age-related risks of chromosomal abnormalities in twin gestations have been determined. According to these calculations, a patient 31 years of age or older with a twin gestation has a risk of a chromosome abnormality in at least one of her twins equivalent to that of a 35-year-old woman with a singleton.¹²⁴ Prenatal genetic testing should therefore be offered to women with twins at a younger age than the traditional 35 years of age.

Knowledge of chorionicity is critical when performing invasive procedures in multiple gestations. This is best determined by ultrasound in the first trimester, at which time the determination of chorionicity is highly accurate.¹²⁵ Prenatal diagnosis in monochorionic pregnancies theoretically requires only one sample, because the fetuses should be chromosomally identical. However, there is a small chance of postzygotic mutations leading to discordant karyotype, or of incorrect assignment of chorionicity. For this reason, both twins are typically sampled.

Both CVS and amniocentesis are used in sampling multiple gestations. The technique for amniocentesis involves visualizing the dividing membrane and identifying an amniotic fluid pocket in each sac. In order to be certain that each amniotic sac is sampled, 0.5 mL of indigo carmine dye is instilled after removal of fluid from the first sac. Aspiration of clear fluid from the second sac ensures proper placement. Indigo carmine has not been associated with risks to the fetus, whereas methylene blue dye should not be used owing to reports of fetal hemolysis, bowel atresias, and fetal demise when injected intraamniotically.¹²⁶⁻¹²⁸ A single-needle insertion technique for amniocentesis has also been reported, with puncture of the dividing membrane to access the second sac.¹²⁹ This raises potential for admixture of samples with mosaic results, as well as disruption of the intertwin membrane. Reports of fetal abnormalities in twin gestations following rupture of the membrane,¹³⁰ and concern for creating an iatrogenic monoamniotic twin pregnancy with potential for umbilical cord entanglement, are also concerns.

With CVS, the procedure requires careful sonographic determination of placentation, because dye studies to mark the sample are not possible. Placing the tip of the aspiration device (catheter or needle) near the cord insertion can minimize the possibility of sampling the same fetus twice. A risk of less than 2% of sampling error has been reported with CVS in multiple gestations.¹³¹

With either CVS or amniocentesis, detailed description of the relative locations of the fetuses and placentas is important, particularly if discordant karyotypes are present and selective termination is to be considered. Noting any structural abnormalities or other findings that can differentiate the fetuses is also helpful.

Postprocedural Loss Rates in Multiple Gestations

Although genetic amniocentesis is frequently performed in multiple gestations, smaller numbers limit the availability of data regarding postprocedural losses in multiple gestations following either amniocentesis or CVS. A number of studies have been performed to assess fetal loss rate following amniocentesis in twins. The quoted range of loss rates of 2.7% to 8.1% is comparable to the 6% background loss rate of twins reported by Yaron et al.^{131,132} Whereas some studies do suggest a higher postprocedural loss rate in twin pregnancies when compared with singletons, not all account for the higher background loss rate of twins. Further study is needed to evaluate the risk associated with multifetal amniocentesis.

With CVS, even more limited data are available to determine the safety and accuracy of this procedure in multiple gestations. Reported pregnancy loss rates in the largest recent trials reported in the literature range from 0.6% to 4.0%, again comparing favorably with the 6% background loss rate reported for twin pregnancies.¹³¹⁻¹³⁵

The choice as to whether to perform amniocentesis or CVS in a multiple pregnancy depends on many factors, such as the likelihood of proceeding to multifetal pregnancy reduction, the gestational age at presentation, the experience of the operator, and the technical difficulties of the specific case, including maternal body habitus and relative positions of the gestational sacs and placentas. Several studies have shown that CVS, in the hands of experienced operators, is at least as safe as second trimester amniocentesis for prenatal diagnosis in multiple pregnancies with loss rates comparable to control twins.¹³¹⁻¹³⁵

Selective Termination of Multifetal Pregnancies

The finding of a single affected fetus in a multiple gestation can present a complex counseling situation. Management options include termination of the entire pregnancy, continuation of the pregnancy, or selective termination. Selective termination in a dichorionic twin pregnancy can be performed with fetal intracardiac injection of potassium chloride. Such an approach is effective, but carries a loss rate of 4% to 12% for the remaining fetus or fetuses, depending on the gestational age of the pregnancy, starting number of fetuses and location of the affected fetus.^{136,137} If the pregnancy is monochorionic, but discordant for a chromosomal or structural abnormality, the ubiquitous presence of intertwin anastomoses makes intracardiac injection unsafe for the normal twin. If selective termination is desired in this situation, umbilical cord occlusion using laser, ligation, or bipolar coagulation is the only option. Little data exist as to risks to the pregnancy and the remaining twin if this approach is chosen.

Fetal Blood Sampling and Other Fetal Tissue Biopsy

Although there are theoretically many indications for accessing the fetal circulation directly, advances in molecular genetic technology have greatly decreased the need for percutaneous umbilical blood sampling (PUBS) as well as for performing biopsy of tissues such as fetal muscle, skin or liver. PUBS has also frequently been used to obtain fetal blood for rapid karyotyping but again, the availability of FISH to detect the most common trisomies has decreased the need for this technique. Disorders such as hemophilia, hemoglobinopathies, immunodeficiencies, and diseases expressed in muscle, skin, and liver that have, in the past, required direct biochemical evaluation of fetal tissue can now commonly be detected through DNA mutation analysis on amniocytes or chorionic villi.

At present, PUBS is most commonly used in the evaluation and treatment of fetal isoimmunization, when a need for in utero transfusion is suspected. When this procedure is performed, it is done under continuous ultrasound guidance. The umbilical cord insertion into the placenta is identified; this is the optimal area for sampling because the cord is fixed at this location. The cord insertion into the fetus, or a free loop of cord can also be accessed, however, this may be more difficult owing to movement of the cord and fetus. The mother may be given parenteral sedation both for her

comfort and to decrease fetal movement. Intramuscular or intravascular injection of curare or Pavulon is also occasionally used to eliminate fetal movement, although the long-term effects of fetal paralysis are unknown.^{138,139}

Once the optimal site for accessing the cord has been identified, the maternal abdomen is prepped and draped, and the insertion site is infiltrated with a local anesthetic. Under ultrasound guidance, a 20- or 22-gauge spinal needle is advanced into the umbilical vein. Samples of fetal blood are aspirated into heparinized syringes.

PGD is a prenatal testing technique whereby early embryos, conceived through IVF, undergo genetic testing while being cultured in vitro, before reimplantation in the uterus (Fig. 2-14). Only those embryos with normal results are transferred. This technique can be used to test for most genetic disorders in which a mutation has been identified, and can be helpful for couples at high risk of having a fetus affected by a genetic disease for whom termination of a fetus after CVS or amniocentesis is not an option. PGD is also used to select aneuploid embryos in couples with recurrent pregnancy failure suspected to be owing to recurrent aneuploidy, carriers of balanced translocations, and to optimize IVF efficiency especially in cases of recurrent IVF failure.¹⁴⁰ A surprisingly high percentage of embryos have been found to be aneuploid and/or mosaic in such cases, and it is not clear that biopsy of one or even two cells is

FIGURE 2-15. G-banded male karyotype.

indicative of the chromosomal make up of the entire embryo.¹⁴¹ The utility of PGD for such cases has not been demonstrated in large controlled series.

Because the genetic testing done in cases of PGD must be performed using just one or two cells from these early embryos, with a very rapid turnaround time (generally less than 24 hours), the technique is complex and errors can occur. The rate of error is generally quoted as less than 5%,¹⁴² and it is recommended that CVS or amniocentesis be used to confirm results from PGD. Again, large studies to determine the accuracy and efficacy of PGD are clearly needed.¹⁴³

PRENATAL TESTING FOR CONGENITAL MALFORMATIONS

Anomalies such as NTD, cleft lip and palate, and congenital heart defects usually occur as multifactorial traits, caused by an interaction of multiple genes with environmental factors. Because these disorders have an elevated risk of recurrence in families, prenatal testing is often requested. Owing to their complex genetic causes, congenital malformations cannot be identified by amniocentesis or CVS. In most cases, prenatal testing consists of detailed ultrasound evaluation aimed at the detection or elucidation of specific fetal birth defects.

As in all other areas of medicine, providing appropriate information and treatment relies on a correct diagnosis. In the prenatal diagnosis of congenital disorders, providing prognostic information or evaluating a possible recurrence in a future pregnancy relies first and foremost on ensuring the correct diagnosis of the original affected child (or other relative). Whereas many congenital malformations are isolated traits, they can also occur as part of a syndrome, in

which a pattern of malformations and features result from a single etiology. The etiology of a syndrome can involve an entire chromosome (that is, trisomy), deletion of a small chromosome region, or a single gene mutation. Often the other features of the syndrome cannot be detected by ultrasound, and therefore careful counseling of the family, as well as consideration of other testing, is important.

As an example, a congenital heart defect (CHD) identified on prenatal ultrasound is commonly an isolated finding. However, it may occur as part of a syndrome in which other abnormalities, such as mental retardation, are present. CHDs are heterogeneous in etiology, caused in some cases by a single gene or chromosomal mechanism, and in others by teratogens such as rubella infection or poorly controlled maternal diabetes. The cause in most cases is unknown, and the majority are believed to be multifactorial in origin. First-degree relatives have an increased recurrence risk of 2% to 4%. Prenatal ultrasound (echocardiography) is typically offered to couples with a strong family history or a previous fetus with CHD. In cases in which a CHD is unexpectedly detected by ultrasound, amniocentesis is offered to test for chromosome abnormalities, which underlie 10% to 15% of fetal CHD. Amniocentesis can also test for genetic abnormalities that increase the risk of CHD. For example, CHD is associated with a relatively common microdeletion on chromosome 22 (22q.11) that can be detected through the use of FISH on fetal tissue obtained by amniocentesis (Fig. 2-15). This microdeletion is associated with a spectrum of outcomes, including DiGeorge sequence and velocardiofacial syndrome. Chromosome abnormalities or deletions have important genetic counseling implications, because a child with such an abnormality typically has other physical and developmental problems, in addition to the heart defect.

FIGURE 2-16. A. Fluorescence in situ hybridization in interphase cells. Probes to chromosome 21 (test) are red, and to chromosome 13 (control) are green. Presence of three red signals indicates the presence of trisomy 21. B. Fluorescence in situ hybridization in metaphase cell. Probes to chromosome 22q11 (test) are red, and to 22q13 (control) are green. Presence of a single red signal indicates a 22q11 deletion and the presence of DiGeorge syndrome.

Techniques of Genetic Analysis

Over the past 2 decades, advances in genetics have included increases in our understanding of novel genetic mechanisms. Much of this increased understanding has come about because of improvements in genetic technology, allowing more detailed investigation of genes, mechanisms of mutation and genetic variation in the population. As these techniques are used and investigated, an increasing number of clinically available tests are offered, with more and more being applicable to and useful for evaluation of the fetus.

Chromosome Identification

Standard prenatal diagnosis involves evaluation of the individual chromosomes making up the fetal karyotype. Giemsa staining, which produces a specific banding pattern called G banding, is the technique most widely used in clinical cytogenetics laboratories for chromosome analysis. Each chromosome stains in a characteristic pattern of light and dark bands (see Fig. 2-15). In an internationally accepted system of chromosome classification, the dark and light bands on each chromosome are numbered. This numbering system allows the location of any particular band and its involvement in any chromosome abnormality to be described unambiguously and precisely.

Fluorescence In Situ Hybridization

FISH is a technique that allows visualization of a small chromosomal region, generally too small to be seen with karyotyping. FISH can also be used for rapid chromosome identification, because it can be performed on interphase

cells and, therefore, culturing is not required for analysis. FISH is carried out by using a small fragment of DNA (called a DNA probe) with the same nucleotide sequence as the stretch of chromosomal DNA of interest. The DNA probe is covalently attached to a fluorescent label, hybridized with metaphase, prophase or interphase chromosomes and then visualized under a fluorescence microscope. FISH is used to determine whether a small portion of a chromosome (too small to be seen on the karyotype) is deleted and to identify translocations and marker chromosomes. It is also used to identify pieces of chromosomal material that are too small or too ambiguous to be localized by banding techniques. Normally, a probe will hybridize in two places, reflecting the presence of two homologous chromosomes. If a probe from the chromosome segment in question hybridizes to only one of the patient's chromosomes, then the patient is likely to have a deletion on the other. Excess chromosomal material can also be detected with FISH, in which case the probe will hybridize in more than two places. As a rapid assessment for trisomy (or other aneuploidy), interphase cells can be analyzed with FISH probes that hybridize to centromeric regions of specific chromosomes, thereby allowing a fast count of the copy number of a specific chromosome (for example, 21 to rule out DS) (Fig. 2-16).

Molecular Techniques for DNA Analysis

It is surprisingly easy to isolate pure DNA, which is generally very stable when compared with enzymes and other molecules. DNA can be extracted from any cell type that has a nucleus, including white blood cells, buccal cells, amniocytes, chorionic villi, and skin fibroblasts. The DNA is

essentially the same regardless of the tissue of origin. PCR can be used to amplify very small quantities of DNA, allowing small samples to be used for the detection of specific mutations.

Genetic mutations generally occur due to point mutations, deletions, or duplications. PCR and southern blotting are commonly used techniques for identification of genetic mutations in DNA samples. Automated techniques of DNA sequencing are also available; such sequencing was used to complete the human genome project in 2003. Use of sequencing in clinical practice is complicated by the potential for identification of previously undescribed mutations of uncertain clinical significance.

Whether a defect is a deletion or a point mutation, its identification allows a specific test to be applied to at-risk relatives or for prenatal diagnosis. In cases in which the condition has been mapped but the gene itself remains unknown, or a specific mutation has not been identified, linked DNA markers can be used in some cases to follow the gene through the family and compare affected and unaffected individuals. Such analysis is limited in its accuracy by the potential for recombination between the marker and the mutation, the potential for genetic heterogeneity, and the possibility that informative markers will not be identified in the family. With either direct mutation analysis or linkage, it is critical that firm proof of the diagnosis exists, and that the mutation identified is known to be causative. In addition, detection of a mutation in a person (or fetus) at risk does not make a diagnosis of a clinical disorder and all the previously described caveats are critical to accurate diagnosis and management of genetic disorders, particularly in the prenatal setting.

FUTURE DIRECTIONS IN GENETIC ANALYSIS

Quantitative Fluorescent PCR and Comparative Genomic Hybridization

Other new techniques for molecular evaluation of the genome, such as quantitative fluorescent PCR and comparative genomic hybridization (CGH), have been recently developed and introduced into clinical use. Such techniques are being increasingly used for prenatal evaluation of chromosomes and chromosome abnormalities in the fetus.^{145,146} Quantitative fluorescent PCR (QF-PCR) assays are based on the amplification of DNA sequences unique for each chromosome pair and have been developed to establish the number of specific chromosomes present in a cell. These tests amplify small tandem repeat or microsatellite markers with quantification of the products. QF-PCR can quickly identify aneuploidy and is used in some centers as an alternative to FISH for the rapid prenatal detection of aneuploidies involving chromosomes 21, 18, and 13, and the sex chromosomes.^{147,148}

CGH is a technique whereby DNA from a test subject is hybridized together with control DNA. Differential labeling of the test versus control DNA allows comparative analysis of copy number, thus screening for decrease or increase in copy number across the genome. CGH is now most commonly performed using microarrays, or slides to which

FIGURE 2-17. Array CGH technique. CGH, comparative genomic hybridization. DNA to be tested is labeled green, and control, reference DNA red. Labeled DNA is hybridized to a microarray contained hundreds to thousands of DNA clones, and copy number analyzed for each clone. The ratio of test to reference DNA at each clone is indicated on the graph. Increase in ratio of test DNA indicates duplication or trisomy, and decrease in ratio indicates deletion or monosomy for each clone.

the labeled control DNA has been applied. Test DNA is then hybridized and computer analysis done to identify ratios at each individual probe. In simplistic terms, array CGH provides the ability to perform multiple FISH analyses simultaneously. Originally developed primarily for use in cancer, array CGH has great utility in constitutional and prenatal cases, in which features suggest a chromosomal abnormality but are not specific enough to indicate a single FISH analysis (Figs. 2-17 and 2-18).¹⁴⁹

Free Fetal DNA

Whereas methods for analysis of intact fetal cells continue to improve, approaches to noninvasive methods of obtaining fetal samples continue to be pursued.¹⁵⁰ In 1998, Lo et al demonstrated that cell-free fetal DNA is present in plasma from healthy pregnant women.¹⁵¹ Surprisingly high concentrations of fetal DNA, nearly 5% of total maternal DNA, were detected in plasma of pregnant women, using quantification through PCR. That cell-free fetal DNA is consistently detected in maternal blood during pregnancy raises diagnostic potential.^{152,153}

Initial diagnostic application of cell-free DNA involved detection of fetuses that had inherited a mutant allele from an affected father. If the father has a DNA sequence that the mother lacks, presence of that sequence in maternal blood must be of fetal origin; thus, the fetus has inherited the mutant paternal allele. Detection of a paternally transmitted AD trait (that is, a fetus with hemoglobin Lepore disease) was reported initially by Camaschella et al.¹⁵⁴ Analysis of cell-free DNA has also been applied to managing Rh(D) isoimmunization. Presence of the *D* allele in maternal blood of Rh-negative women can be detected and has been used to

FIGURE 2-18. Array comparative genomic hybridization result demonstrating a deletion in chromosome 16q. A decrease in ratio indicated by the arrow is diagnostic of a deletion corresponding to several clones. The most distal clones are present, indicating that this is an interstitial deletion. Karyotype has reported a terminal deletion, and array comparative genomic hybridization was able to clarify the precise deletion more accurately.

determine whether the fetus has inherited the *D* allele from its father and is at risk for hemolytic disease.¹⁵⁵⁻¹⁵⁷

Analysis of cell-free fetal DNA has other clinical applications. Total cell-free fetal DNA levels are increased two-fold when the fetus has trisomy 21, even though the fetal DNA need not be derived from a gene locus on chromosome 21.¹⁵⁸ Cell-free fetal DNA could thus serve as an additional (and perhaps independent) maternal serum analyte for aneuploidy screening. Active investigation is ongoing into these and other noninvasive strategies for diagnosis and management of fetal disorders.¹⁵⁵

Availability of Early Prenatal Diagnosis

Choosing the Correct Combination of Screening Tests

At present, the ideal time to screen for fetal aneuploidy is during the first trimester of pregnancy. This is a marked change in screening policy due to the significant advances which have been made in antenatal screening for fetal chromosomal abnormalities over the past 20 years. In the past, invasive prenatal diagnosis for Down syndrome with amniocentesis or chorionic villus sampling (CVS) was offered only to women of advanced maternal age (older than 35 years of age at delivery) or those who previously had an affected child. Subsequently, invasive diagnosis was offered to women younger than 35 years of age who had abnormal second trimester multiple-marker serum screening and also to those with abnormal second trimester sonographic signs—so-called soft-markers—of Down syndrome. It should be noted that the most efficient multiple-marker screening test in the second trimester is the “quad” screen, comprising alpha-fetoprotein (AFP), human chorionic gonadotropin (hCG), unconjugated estriol (E₃), and inhibin-A (Table 3-1). This approach yields sensitivity for Down syndrome of up to 81%, when sonographic dating is used, for a 5% false-positive rate.^{1,2}

However, since the early 1990s, great interest has been directed toward first trimester screening with the use of sonographic and serum screening markers. In a recent survey of perinatologists in the United States, 46% used nuchal translucency sonography and 27% used the serum markers PAPP-A and hCG during the first trimester to screen for Down syndrome (Table 3-2).³ With the advent of national training programs for nuchal translucency sonography and with the endorsement of many national professional bodies, it is likely that first trimester based screening programs for Down syndrome will become dominant, with only those patients presenting too late for this form of screening being offered second trimester tests.

FETAL NUCHAL TRANSLUCENCY

The single most powerful marker available today for differentiating Down syndrome from euploid pregnancies is the first trimester sonographic measurement of the fetal

Table 3-1

Pattern of Results Seen With Expanded AFP Screening in Fetal Disorders Used in the Second Trimester

	AFP	uE ₃	hCG	Inhibin A
Open NTD	↑	No Change	No Change	No Change
Down syndrome	↓	↓	↑	↑
Trisomy 18	↓	↓	↓	No Change

AFP, alpha-fetoprotein; hCG, human chorionic gonadotropin; NTD, neural tube defect; uE₃, unconjugated estriol.

Table 3-2

Nuchal Translucency and Serum Markers Used in First Trimester Screening and their Associations

Possible Condition	First Trimester Marker		
	NT	PAPP-A	f-βhCG
Trisomy 21	Increased	Low	High
Trisomy 18	Increased	Low	Low
Pregnancy loss <24 weeks	Increased	Very Low	Very Low
Congenital heart defect	Increased	Normal	Normal

NT, nuchal translucency; PAPP-A, pregnancy-associated plasma protein A; f-βhCG, free β human chorionic gonadotropin.

A

Conventional Measurement

B

FIGURE 3-1. A. Conventional measurement for determining the nuchal translucency. Although this illustration demonstrates the recommended placement of the measurement calipers, many investigators use an 'inner to inner' measurement. (Illustration by James A. Cooper, MD, San Diego, CA.) B. Optimizing the technique for first trimester nuchal translucency sonography: Nuchal translucency measurement in a normal fetus at 12 weeks' gestation. Components of a good sonographic screening protocol are evident, including adequate image magnification, mid-sagittal plane, neutral fetal neck position, correct caliper placement. Arrow, amnion.

nuchal translucency space. Nuchal translucency refers to the normal subcutaneous fluid-filled space between the back of the fetal neck and the overlying skin (Fig. 3-1). Normally, this space is small; however, in many fetuses with Down syndrome, this space can be significantly increased (Fig. 3-2). By adhering to a standard ultrasonographic technique, it is

possible to obtain accurate measurements of this area in the vast majority of fetuses between 10 and 14 weeks' gestation (CRL of 36–84 mm). When performing nuchal translucency sonography, it is absolutely essential to ensure optimal technique, which can be attained by focusing on the following criteria⁴:

FIGURE 3-2. Increased nuchal translucency measurement of 3.7 mm in a fetus at 12 weeks' gestation with Down syndrome.

- The fetus should be imaged in the midsagittal plane, ideally with the fetal spine down.
- The image should be adequately magnified so that only the fetal head, neck, and upper thorax fill the viewable area.
- The fetal neck should be neutral, with care being taken to avoid measurements in the hyperflexed or hyperextended positions.
- The skin at the fetal back should be clearly differentiated from the underlying amniotic membrane, either by visualizing separate echogenic lines or by noting that the skin line moves with the fetus.
- Measurement calipers should be placed on the inner borders of the echolucent space and should be perpendicular to the long axis of the fetus (see Fig. 3-1).
- Ultrasound and transducer settings should be optimized to ensure clarity of the image and of the borders of the nuchal space in particular. This may require transvaginal sonography in certain situations.

There is a direct correlation between increasing nuchal translucency measurement and risk for Down syndrome, other aneuploidies, major structural malformations, and adverse pregnancy outcome.^{1,2,7} Possible causes for the development of this increased fluid-filled space include cardiac failure secondary to structural malformation, abnormalities in the extracellular matrix, and abnormal or delayed development of the lymphatic system.^{6,7}

NUCHAL TRANSLUCENCY SCREENING FOR DOWN SYNDROME

Nuchal translucency sonography is the most powerful marker for general population screening for Down syndrome.⁸ The largest study of this form of screening was performed by the Fetal Medicine Foundation based in London.⁹ This prospective study of 96,127 unselected patients at 22 centers required nuchal translucency sonography to be performed between 10 and 14 weeks' gestation by specially trained sonographers who used a standardized technique.

The overall Down syndrome detection rate was 77% detection rate, for a 5% false-positive rate.⁹ Another large prospective study from the United Kingdom that evaluated the role of nuchal translucency sonography in general population screening was the SURUSS Trial.² A total of 39,983 patients had nuchal translucency sonography obtained between 10 and 14 weeks' gestation, and the Down syndrome detection rate was 63%, for a 5% false-positive rate. A large US-based screening program which focused on a more high-risk group of patients (The BUN Trial) revealed a Down syndrome detection rate of 69%, for a 5% false-positive rate, after screening 8216 patients.¹⁰

The largest prospective trial of all forms of Down syndrome screening yet performed, the FASTER Trial, has also validated the important role of nuchal translucency sonography. This was a multicenter prospective study from 15 centers in the United States in which 36,306 patients from the general population had first trimester nuchal translucency sonography performed.¹ The detection rate for nuchal translucency with maternal age ranged from 70% to 64% at 11 and 13 weeks' gestation respectively, for a 5% false-positive rate.¹ These large studies from varied centers and geographic locations confirm that nuchal translucency sonography must be a key component of first trimester screening programs for fetal Down syndrome.

COMBINED FIRST TRIMESTER TESTING: NUCHAL TRANSLUCENCY WITH SERUM MARKERS

Together with the clear role of nuchal translucency sonography, research in first trimester screening has consistently shown that pregnancies with fetal Down syndrome are associated with altered levels of certain maternal serum markers, including elevated levels of total hCG and of the free β subunit of hCG (with a median multiple of the median [MoM] of 1.83 in affected cases) and lower levels of pregnancy-associated plasma protein A (with a median MoM of 0.38 in affected cases) (Table 3-2).^{11,12} Studies of the combination of free β subunit of hCG, pregnancy-associated plasma protein A, and maternal age uniformly demonstrate a sensitivity for Down syndrome of approximately 60% with a 5% false-positive rate.¹²

These first trimester serum markers are largely independent of nuchal translucency, which has resulted in the development of a combined serum and sonographic screening protocol which would be more effective for screening than either alone. Two large prospective studies have now been published from the United States validating the performance of such combined first trimester screening. The BUN study evaluated 8216 patients and demonstrated a Down syndrome detection rate of 79%, at a 5% false-positive rate, or 64% at a 1% false-positive rate.¹⁰ The FASTER study evaluated 38,033 patients and demonstrated even better Down syndrome detection rates, and showed that performance varied significantly by gestational age.¹ For a 5% false-positive rate, the Down syndrome detection rates using combined serum and sonographic screening were 87%, 85%, and 82% at 11, 12, and 13 weeks' gestation, respectively. For a 1% false-positive rate, the Down syndrome detection rates were 73%, 72%, and 67% at 11, 12, and 13 weeks' gestation respectively.¹

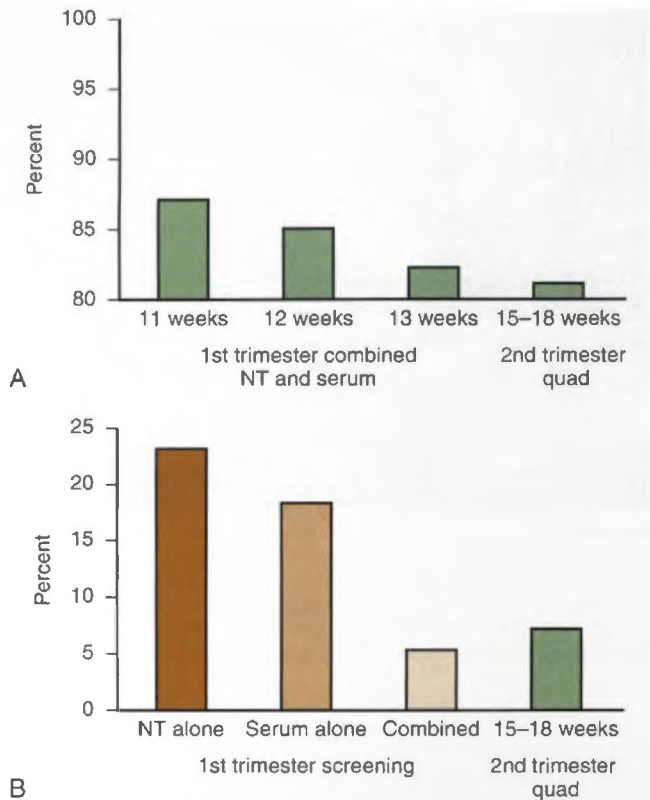

FIGURE 3-3. A. Comparison of first- and second trimester screening for Down syndrome: Detection rates of combined first trimester screening at 11, 12, and 13 weeks' gestation, compared with first trimester quad marker serum screening performed at 15 to 18 weeks' gestation (each at 5% false-positive rate). B. Comparison of first- and second trimester screening for Down syndrome: False-positive rates of first trimester nuchal translucency alone, PAPP-A and fβhCG alone, and first trimester combined screening at 12 weeks' gestation, compared with second trimester quad marker serum screening performed at 15 to 18 weeks' gestation (each for 85% detection rate). (Data from Malone FD, Canick JA, Ball RH, et al: A comparison of first-trimester screening, second-trimester screening, and the combination of both for evaluation of risk for Down syndrome. *N Engl J Med* 353:2001, 2005.)

Recently, much debate has occurred regarding the relative performance of these newer first trimester screening programs, compared with the more traditional second trimester serum screening approaches. Previously it has been difficult for clinicians to objectively compare screening programs that occur at different gestational ages because of the differences in aneuploidy prevalence. It is now possible to evaluate objective comparative data upon which the range of screening tests currently available can be directly compared.^{1,2} Figure 3-3 summarizes the comparative performance of the various screening options from the FASTER Trial, and demonstrates that first trimester combined screening has very similar performance to second trimester quad marker serum screening.¹ Only when performed at 11 weeks' gestation does first-trimester combined screening have a significantly better performance than second trimester Quad marker serum screening (87% versus 81% Down syndrome detection, respectively, at a 5% false-positive rate). Additionally, the combined first trimester screening test has the lowest false-positive rate, compared with either first trimester component used alone or compared with second trimester serum

FIGURE 3-4. A. Septated cystic hygroma at 12 weeks' gestation: midsagittal sonographic view of a fetus with septated cystic hygroma, demonstrating increased nuchal translucency space (calipers) extending along the entire length of the fetus. B. Septated cystic hygroma at 12 weeks' gestation: transverse view through the fetal neck of the same fetus demonstrating obvious septations (arrows).

screening. It is also important to realize that only the combination of first trimester nuchal translucency sonography with first trimester serum markers comes close to the performance of second trimester quad marker serum screening. Nuchal translucency alone, without being combined with serum markers, has significantly inferior performance characteristics.¹

ENLARGED NUCHAL TRANSLUCENCY AND CYSTIC HYGROMA IN THE FIRST TRIMESTER

It is now clear that a subset of fetuses with very large nuchal translucency measurements that have an extremely high risk of fetal aneuploidy or other adverse pregnancy outcomes can be effectively identified in the first trimester. This finding has been described as septated cystic hygroma, and is present when the nuchal translucency space is enlarged extending along the entire length of the fetus, and in which septations are clearly visible (Fig. 3-4).¹² Septated cystic hygroma is

seen in more than one in 300 first trimester pregnancies. In a recent prospective study of routine first trimester sonographic screening, septated cystic hygroma was shown to have a 50% chance of being associated with fetal aneuploidy, with most cases being Down syndrome, as well as cases of Turner syndrome and Trisomy 18.¹² Additionally, among cystic hygroma cases confirmed as being euploid, approximately 50% had a major structural fetal malformation, with most cases including cardiac malformations, as well as other malformations such as skeletal dysplasias. When compared with simple increased nuchal translucency, septated cystic hygroma cases were five times more likely to be aneuploid, 12 times more likely to have cardiac malformations, and six times more likely to result in fetal or neonatal demise.¹²

The practical benefit of being able to counsel patients in the first trimester following the identification of septated cystic hygroma is that there is no need to delay decision making while awaiting serum marker results or using computerized risk calculation algorithms. When faced with a 50% chance of fetal aneuploidy, it is reasonable to offer such patients the immediate option of CVS, and if fetal aneuploidy has been excluded, a detailed fetal anatomic evaluation, including fetal echocardiography, should be performed at 18 to 20 weeks' gestation.¹²

Debate has also occurred regarding the differentiation between septated cystic hygroma and simple enlarged nuchal translucency, with some investigators believing that they are both part of a spectrum of a similar sonographic feature.¹³ However, the FASTER Trial, a prospective study of over 38,000 pregnancies, has also now demonstrated that whenever a simple nuchal translucency measurement of 3.0 mm or greater is noted, CVS should be offered immediately because of a minimum risk of aneuploidy of 1 in 6.¹⁴ With such nuchal translucency measurements, there is no role for delaying decision making while awaiting serum marker results, because such additional information does not meaningfully alter the original aneuploidy risk. This finding, therefore, suggests that debating the presence or absence of septations in cases of enlarged nuchal translucency is a moot point, because the risk of aneuploidy either when a nuchal translucency measurement of 3.0 mm or greater is noted, or when a septated cystic hygroma is noted, is sufficiently high to warrant immediate diagnostic testing.¹⁴

NASAL BONE SONOGRAPHY IN THE FIRST TRIMESTER

There appears to be a clear association between the absence of the fetal nasal bones on first trimester ultrasound examination and Down syndrome.¹⁵ In a study conducted by Cicero et al,¹⁵ 701 fetuses with increased nuchal translucency were evaluated for the presence or absence of the nose bones during first trimester ultrasonography. The fetal nasal bones could not be visualized in 73% of Down syndrome fetuses (43 of 59) and in only 0.5% of unaffected fetuses (three of 603). The authors also felt that the absence of the fetal nose bone was not related to nuchal translucency thickness and therefore could be combined into a single ultrasound screening modality, with a predicted sensitivity of 85% for a 1% false-positive rate.¹⁵ This study was subsequently expanded to a larger series of 3829 high-risk

FIGURE 3-5. First trimester ultrasound examination of a fetus at 13 weeks' gestation, with normal nasal bones. Features of good nasal bone imaging technique are evident, including midsagittal plane, fetal profile facing upward, adequate magnification, and visualization of two parallel lines at the level of the fetal nose, one representing fetal skin (*small arrow*) and the deeper line representing nasal bones (*large arrow*).

first trimester pregnancies, in which the detection rate for Down syndrome using absent nasal bones was 67%, for a 2.8% false-positive rate.¹⁶

Adequate imaging of the fetal nasal bones can be technically challenging in the first trimester, and careful attention to correct technique should, therefore, be paid to ensure consistency in technique. The nasal bones should be visualized on ultrasound along the midsagittal plane with a perfect fetal profile. The fetal spine should be posterior, with slight neck flexion. Two echogenic lines at the fetal nose profile should be visualized; the superficial echogenic line is the nasal skin, and the deeper echogenic line represents the nasal bones. This deeper echogenic line representing the nasal bones should be more echolucent at its distal end (Fig. 3-5). Care should be taken not to perform this evaluation with the ultrasound beam parallel to the plane of the nasal bones, because this might erroneously lead to the conclusion of absent nasal bones.

Although several other studies evaluating the role of first trimester nasal bone sonography as a screening test for fetal Down syndrome have also been published, all were limited by being derived from high-risk patient populations or lacking adequate pregnancy outcome ascertainment.¹⁷ The largest study of first trimester fetal nasal bone sonography published to date, and in which an unselected general patient population has been evaluated, did not confirm a useful role for this form of screening.¹⁷ In a prospective study of 6324 patients having nasal bone sonography by trained and experienced sonographers, adequate views of the fetal profile were obtained in only 76% of cases, and none of the 11 cases of fetal Down syndrome were found to have absent nasal bones.¹⁷ Two further studies of the role of first trimester nasal bone sonography as a screening tool in the general population have also recently been published, and have confirmed these findings that there is only a limited role of this form of screening.^{18,19} One study screened 7116 unselected patients from the general population including 12 cases of

FIGURE 3-6. Pulsed-Doppler sonography image of a normal ductus venosus waveform at 12 weeks' gestation. Of note, the ductus venosus can be identified using color flow as a small vessel with turbulent flow. The nadir of flow during the "a" wave remains forward flowing (arrow).

Down syndrome, and screened a further 510 high risk patients including 23 cases of Down syndrome.¹⁸ Absent nasal bones in the first trimester was noted in only 17% of cases in the general population and in 48% of cases in the high-risk population. A further study screened 1800 consecutive patients from the general population, and absent nasal bones was noted in only two of seven (29%) of Down syndrome cases.¹⁹

Although it is possible that there may be a role for first trimester fetal nasal bone sonography in the hands of select experts as a second-line screening tool in high risk patients, current data would suggest that this form of sonography should not be used as a general population screening tool.

FIRST TRIMESTER DUCTUS VENOSUS SONOGRAPHY

First trimester Doppler sonographic evaluation of ductus venosus blood flow has been described as an adjunctive test for fetal aneuploidy screening. Forward triphasic pulsatile ductus venosus flow, as illustrated in Figure 3-6, is normal, whereas reversed flow at the time of the atrial contraction has been associated with aneuploidy and fetal cardiac malformations.²⁰ In a series of early studies date evaluating this association, between 59% and 93% of aneuploid fetuses had abnormal first trimester ductus venosus flow velocities.⁸ Abnormal ductus venosus flow velocities were also found in as few as 3% or as many as 21% of normal fetuses. It may, therefore, be possible that fetal ductus venosus flow velocity waveform analysis may be useful to modify a patient's final risk for aneuploidy following completion of the nuchal translucency measurement. This could be used to either improve the detection rate or alternatively to reduce the false-positive rate.

FIGURE 3-7. First trimester sonographic evaluation for tricuspid regurgitation in a fetus at 11 weeks' gestation. Note the pulsed-Doppler gate placed across the tricuspid valve, with the angle to the direction of flow close to zero. There is no regurgitation greater than 60 cm/sec.

Although it appears that there is some association between abnormal ductus venosus flow studies and aneuploidy in the first trimester, there are several pitfalls that must be considered. The ductus venosus vessel itself may be as small as 2 mm at 10 to 14 weeks, making it difficult to obtain accurate flow velocity waveforms from such a tiny vessel without contamination of the waveform from neighboring vessels. For example, if the Doppler gate is placed too proximally near the umbilical sinus, the normal continuous venous flow from the umbilical vein may obscure absence of flow during the atrial contraction in the ductus venosus. Alternatively, placement of the Doppler gate too far distally, near the insertion of the ductus venosus into the inferior vena cava, may lead to the erroneous diagnosis of reversal of flow at the atrial contraction, as such reversal of flow is commonly seen in the inferior vena cava. The current consensus appears to be that first trimester ductus venosus Doppler flow studies should be performed only as a secondary screening test in the hands of experienced sonologists at referral centers, either to modify the final risk for aneuploidy or to help predict the prognosis of fetuses with normal chromosomes and an increased nuchal translucency measurement.^{21,22}

FIRST TRIMESTER TRICUSPID REGURGITATION EVALUATION

An association has been suggested between fetal aneuploidy and abnormal tricuspid regurgitation noted during first trimester sonography.²² To perform this assessment, the fetus should be oriented so that the chest wall is anterior and the fetal heart should be insonated parallel to the ventricular septum. A pulsed-Doppler gate of approximately 3-mm is then placed across the tricuspid valve, with care to ensure that the angle to the direction of flow is as close to zero as possible (Fig. 3-7). Significant tricuspid regurgitation is

considered to be present if a regurgitant jet of at least 60 cm/sec is noted extending to over half of systole.²³

In a series of 1557 high-risk pregnancies at 11 to 13 weeks' gestation, significant tricuspid regurgitation was noted in only 4% of chromosomally normal fetuses, but was present in 77 of 114 cases (68%) of Down syndrome and 14 of 42 cases (33%) of trisomy 18.²³ These investigators were able to obtain adequate Doppler waveforms of the tricuspid valve in 99% of cases and there was low interobserver variability of measurements.

Although these data are encouraging regarding an association between first trimester tricuspid regurgitation and chromosomal abnormalities, like ductus venosus assessment, it is unclear whether this form of screening will have any role in general population screening. Extrapolation of the results of a screening test from a high-risk population, performed in the hands of experts, to implementation in the general population will likely overstate the true performance of the test. It is likely that first trimester sonography for tricuspid regurgitation may have a role as a second line test, following an initial high-risk nuchal translucency and serum screen. In this setting, it may have a role in reducing the false-positive rate of screening. In one series of 75,821 first trimester pregnancies, addition of tricuspid regurgitation as a second line screening test following nuchal translucency and serum screening resulted in a Down syndrome detection rate of 92% for a false-positive rate of only 2.7%.²²

NUCHAL TRANSLUCENCY SCREENING IN MULTIPLE GESTATIONS

The prenatal risk assessment of Down syndrome in multiple gestation pregnancies has been limited before the advent of nuchal translucency-based screening. Maternal serum screening has not been widely used in the setting of multiple gestations because of the potential for discordancy between twins and the impact of different placentas on the various analytes. Nuchal translucency measurements are broadly similar between singleton and twin pregnancies, implying that the Down syndrome detection rates should be similar. The false-positive rate of nuchal translucency screening might be higher in monozygotic twins because some complications unique to monozygotic gestations, such as twin-to-twin transfusion syndrome, might present with increased nuchal translucency measurement.²⁴

Options for first trimester screening for Down syndrome therefore include providing either a fetus-specific risk based on nuchal translucency alone, or providing an overall pregnancy risk based on combined serum and sonographic markers. In one series of 448 twin pregnancies, nuchal translucency yielded an 88% detection rate for a 7% false-positive rate.²⁴ In another series of 206 twin pregnancies screened using nuchal translucency and first trimester serum markers, the Down syndrome detection rate was estimated to be approximately 75% for a 5% false-positive rate.²⁵ To provide a pregnancy specific risk in twins, a likelihood ratio is calculated for each fetus' nuchal translucency measurement, these two likelihood ratios are then added together, and this is then multiplied by the biochemistry likelihood ratio to provide a final "pseudorisk" calculation.²⁶ Although additional research on the efficacy of this combined first-trimester screening in multiple gestations is still needed,

nuchal translucency measurement should at least represent an improvement over serum screening in multiple gestations. At present, some centers use nuchal translucency sonography to assist in selecting fetuses for reduction in higher-order multiple gestations.

IMPLEMENTING NUCHAL TRANSLUCENCY-BASED SCREENING INTO GENERAL CLINICAL PRACTICE

Nuchal translucency sonography has pushed prenatal screening for Down syndrome and other aneuploidies into the first trimester. This has the potential of providing major advantages for patients, such as earlier reassurance when results are normal or safer pregnancy termination if abnormal results are found. However, there are several practical issues that must be resolved before all obstetric providers should consider implementing this form of screening into routine obstetric practice.²⁷

Nuchal Translucency Quality Control

The extent of quality control measures among earlier studies of nuchal translucency screening likely accounts for the large inconsistencies in quoted Down syndrome detection rates.⁸ Nuchal translucency ultrasound is extremely operator dependent and will be a poor technique for general population screening if strict guidelines and ongoing quality control systems are not maintained.²⁸ In one multicenter study in which adequate training and quality control were not addressed, the overall sensitivity for Down syndrome was only 31%.²⁸ Appropriate training, adherence to a standard technique, and experience are key to its success as a reliable screening tool.

Initial training in nuchal translucency sonography, however, is only one element of the quality control needed to optimize this technique. Systems must also be put in place at each local ultrasound practice to ensure that ongoing quality assurance is maintained. The optimal method of ensuring adequate nuchal translucency quality control at a population level will likely be to track individual sonographers' median nuchal translucency measurements and standard deviations over time. This quality assurance technique has the advantage of being easier to standardize and automate, thereby being more practical for national screening. In the United Kingdom and other countries internationally, the Fetal Medicine Foundation (www.fetalmedicine.com) has an established system of credentialing of sonologists, together with ongoing audit of measurements. In the United States, the Society for Maternal Fetal Medicine (www.nfq.org) has developed a similar system for initial training and interacts with sonologists and laboratory providers to maintain an ongoing nuchal translucency quality review program.

Nuchal Translucency Interpretation

Mean nuchal translucency measurements increase by approximately 15% to 20% each week from 10 to 14 weeks' gestation.^{1,2,29} Therefore, it is inappropriate to use a single millimeter cutoff to define a normal nuchal translucency or a pregnancy that is normal. More appropriate options include using the 95th percentile for a particular gestational age or

multiples of the median (MoMs). Unfortunately, calculation of such cutoff values require a software program to adequately integrate other background data, such as maternal age and maternal serum marker results, into the risk assessment.

Additionally, it is still unclear whether it is valid to use generic population medians to interpret nuchal translucency measurements or whether such medians for risk calculations should be center-specific or sonographer-specific. In the recently completed SURUSS trial from the United Kingdom, the use of sonographer-specific medians resulted in an improvement of 5% in overall Down syndrome detection rates, compared with use of center-specific medians.² In another study that addressed the importance of differences in center-specific medians, a Scottish trial of 15 centers evaluating 17,229 patients had individual center nuchal translucency median MoMs ranging from 0.7 to 1.4 MoMs.³⁰ Ideally, the median MoM should be 1.0. The consequences of such large variability in MoMs between centers on the actual risks quoted to individual patients could be dramatic.

Implications for Second Trimester Serum Screening

Implementing a national nuchal translucency screening program in isolation will likely have a negative impact on current second trimester serum screening programs, because the positive predictive value of second trimester screening might be reduced as much as sixfold after first trimester screening.²⁷ The number of fetuses with Down syndrome still alive during the second trimester will be significantly reduced because many such fetuses will have already been diagnosed in the first trimester. Sequential screening without appropriate modifications of second trimester serum marker cutoffs will increase the overall false-positive rate, resulting in an increased number of amniocenteses and procedure-related pregnancy losses.¹

Implications for Second Trimester Ultrasound

Nuchal translucency screening will not obviate the need for second trimester ultrasound for the detection of structural fetal abnormalities. The "genetic sonogram," which evaluates for structural malformations and a range of second trimester soft markers for aneuploidy, such as short femurs, echogenic bowel, echogenic intracardiac foci, and increased nuchal fold, has gained widespread acceptability. A national policy of first trimester screening will likely have a negative impact on the performance of the "genetic sonogram." The positive predictive value of these ultrasonographic soft markers for aneuploidy will decrease because the number of aneuploid fetuses entering the second trimester will be reduced. At present, it is not known what the relevance of these soft markers will be in a population of fetuses that has already undergone nuchal translucency-based screening. If the "genetic sonogram" continues without allowance for the lower prevalence of second trimester aneuploid fetuses, it is likely that more unnecessary amniocenteses will be performed without significant improvement in detection rates. The best way to incorporate the "genetic sonogram" into a

practice in which first trimester screening has already been performed is to rely on likelihood ratios. If a soft marker for Down syndrome is seen at a second trimester ultrasound examination, the appropriate likelihood ratio for that marker should be multiplied by the final Down syndrome risk quoted from first trimester screening, rather than multiplying by the maternal age-related risk.

Availability of Early Prenatal Diagnosis

One of the most compelling arguments in favor of nuchal translucency-based screening for Down syndrome is the shift to earlier diagnosis through CVS at 10 to 13 weeks' gestation. CVS is not as widely available as amniocentesis on a national basis.³ Early amniocentesis in the first trimester is no longer considered an acceptable alternative to CVS owing to its higher association with fetal loss, fetal clubfoot, and procedure failure.³¹ If first trimester screen-positive patients do not have ready access to CVS, they might experience increased anxiety, waiting 3 to 4 weeks for an opportunity to undergo amniocentesis at 15 weeks. Therefore, a policy of first trimester screening for aneuploidy should not be implemented unless first trimester diagnosis with CVS is locally available. If a patient desires the benefit of first trimester screening but CVS is not easily available, then the optimal approach might be to provide the first trimester result at 16 weeks as part of a single integrated screening result in combination with second trimester serum markers.^{2,27}

Choosing the Correct Combination of Screening Tests

With the increasing range of Down syndrome screening tests available to obstetric providers today, there is a need for accurate comparative data to evaluate the best combination of tests to implement into practice. The comparative performance of each type of Down syndrome screening has recently been described in the FASTER Trial.¹ These results have shown that the most inefficient test, associated with the highest screen-positive rate, is nuchal translucency sonography performed on its own. First trimester screening seems to derive much of its efficiency by combining nuchal translucency with pregnancy-associated plasma protein A and free β subunit of hCG evaluation. An integrated screen, incorporating nuchal translucency and pregnancy-associated plasma protein A in the first trimester, together with AFP, hCG, unconjugated E₃, and inhibin-A in the second trimester, seems to be the single most efficient test. In a center without easy access to high-quality nuchal translucency sonography, another reasonable alternative might be a serum-only test, incorporating pregnancy-associated plasma protein A in the first trimester with AFP, hCG, unconjugated E₃, and inhibin-A in the second trimester, with a single risk being quoted.

It is unlikely that a single screening test will be suitable for all practitioners and their patients. The decision as to which screening test to incorporate into local clinical practice will be based on factors such as gestational age at presentation, availability of high-quality nuchal translucency sonography, and availability of first trimester invasive testing with CVS (Fig. 3–8). Some patients might be most interested in the

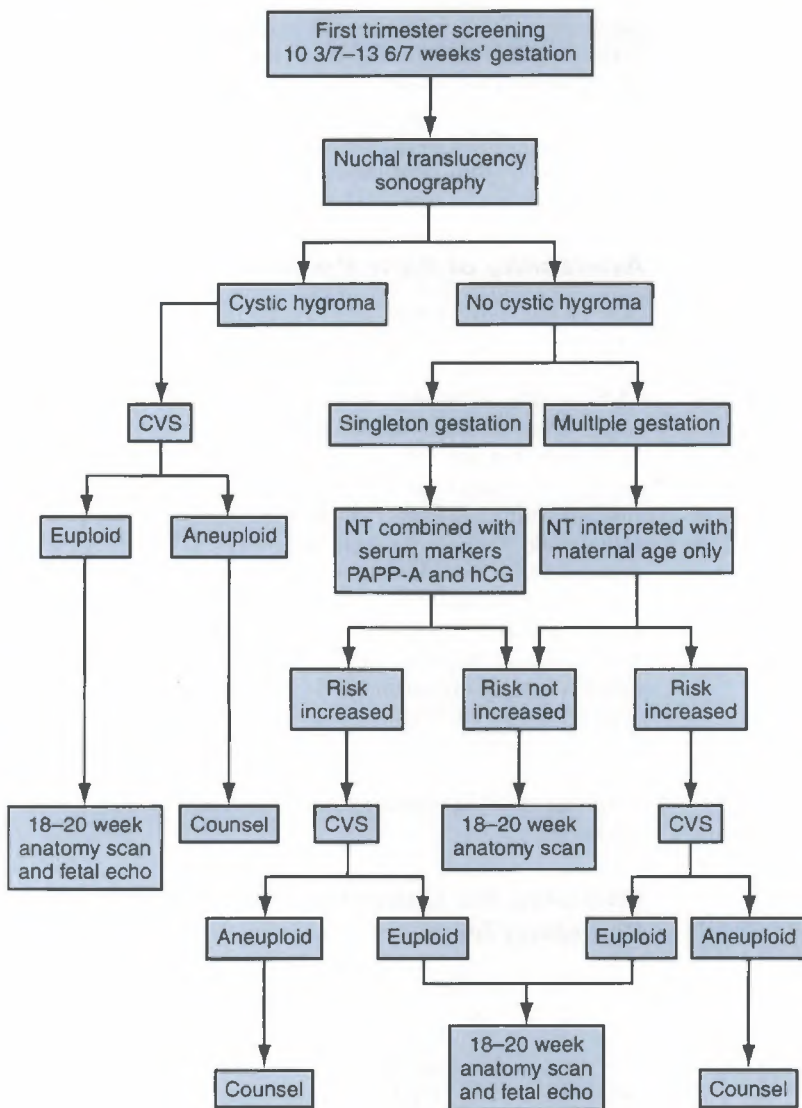

FIGURE 3-8. Flow diagram demonstrating screening decision options during the first trimester.

earliest possible screening result; for such patients, combined first trimester nuchal translucency and serum screening might be desired. Other patients might be more interested in the most efficient test, maximizing their detection rate and minimizing the need for amniocentesis; for such patients, a single integrated screen result combining first- and second trimester approaches might be desired. Still other patients might not present for care sufficiently early to take advantage of first trimester screening; for these patients, there should be the option of second trimester serum screening and genetic sonography.

Future directions in Down syndrome screening may also use more sophisticated combinations of tests.²⁷ Stepwise sequential screening involves providing a risk result after first trimester combined screening. High-risk patients undergo diagnostic testing using CVS, whereas lower risk patients return at 15 weeks' gestation for further screening, such as the second trimester quad serum markers, and have the option of then undergoing amniocentesis. These latter tests however are interpreted using the first trimester marker results to ensure the most accurate risk estimation and to

minimize the overall false-positive rate. Another option may be contingency screening, which involves categorizing patients into three groups after first trimester combined screening. Patients with very high-risk results, such as one in 30 or higher for example, undergo diagnostic testing using CVS, whereas patients with very low-risk results, such as one in 1500 or lower, are reassured and have no further testing. Intermediate patients with risks between these two cutoffs return at 15 weeks' gestation for second trimester quad serum markers. Again, these latter tests however must be interpreted using the first trimester marker results to ensure accuracy of risk estimation and to minimize the overall false-positive rate. Initial models have suggested that such a contingency screening program could yield detection rates as high as 95% for a 5% false-positive rate, but with only 15% of patients needing to return in the second trimester for further tests.³²

Informed consent regarding this large variety of prenatal screening options for aneuploidy should be an integral part of the screening process itself. Because of the complexity of choices regarding the different screening options, and

because of the range of abnormal outcomes associated with increased nuchal translucency, it will be vital to provide all patients with pretest genetic counseling before embarking on screening.

Introduction

Biochemical Serum Marker Screening in the Second Trimester

Sonographic Features of Fetal Aneuploidy

- Structural Abnormalities
- Nuchal Fold
- Short Long Bones
- Pyelectasis
- Echogenic Intracardiac Focus
- Hyperechoic Bowel
- Choroid Plexus Cysts
- Nasal Bone

- Iliac Wing Angle
- Ear Length
- Extremity Abnormalities
- Single Umbilical Artery
- Other Sonographic Aneuploidy Markers

Trisomy 21 (Down Syndrome)

Second Trimester Genetic Sonography

Trisomy 18 (Edwards Syndrome)

Trisomy 13 (Patau Syndrome)

Conclusion

INTRODUCTION

Unfortunately, aneuploidy occurs in human development. Its frequency varies, depending on the maternal age and also the gestational age of the fetus. With earlier gestational ages and in nonviable gestations, the prevalence of aneuploidy increases. Chromosome abnormalities are the leading cause of pregnancy loss, and at least 95% of chromosomally abnormal conceptions are lost before term. A minimum of 10% to 15% of conceptions are chromosomally abnormal. Aneuploid fetuses account for approximately 6% to 11% of all stillbirths and neonatal deaths.¹ One large study reported that among newborn children, 0.8% had a chromosomal abnormality at birth.² It has been common and widespread practice to offer genetic amniocentesis to all women who have increased risks for fetal chromosomal abnormalities, such as advanced maternal age, family history of aneuploidy, or abnormal second trimester serum screening. However, the practice of offering routine invasive testing to all high-risk pregnant women has been challenged, owing to its invasive nature and associated risks such as pregnancy loss.

Over the last several years, it became apparent that many chromosomal abnormalities are associated with fetal structural abnormalities or aneuploidy markers that are capable of being detected during second trimester ultrasonography. This is due to the fact that over the years, there has been an improvement and evolution of high-quality resolution in fetal imaging, such that detailed examination of the fetus is possible. Today, ultrasound provides a very important noninvasive method for the prenatal detection of fetuses with chromosomal abnormalities. In addition, an ultrasound examination provides a tangible and realistic modality because patients can visibly see for

themselves, as compared with relying solely on biochemical screening. Fetuses with trisomies 18 and 13 have many major structural anomalies and, therefore, ultrasound has a high sensitivity in detecting them (up to 83%–100% for trisomy 18)^{3,4} and 91% for trisomy 13.⁵ However, this may not necessarily apply to Down syndrome cases. Because only 25% of second trimester fetuses with Down syndrome have ultrasonically detectable major congenital anomalies,⁶ investigators have been searching for other sonographic markers to increase the sensitivity of detection. This has formed the basis for the emergence and practice of second trimester genetic sonography.

This chapter focuses on second trimester ultrasonography as a means of detecting fetal aneuploidy and specific patterns of malformations associated with the most common autosomal trisomies (Down syndrome, trisomy 18, trisomy 13), and also discusses the significance of individual aneuploidy markers. Because biochemical serum screening in the second trimester is often incorporated into risk calculations with genetic sonography, this also is reviewed.

BIOCHEMICAL SERUM MARKER SCREENING IN THE SECOND TRIMESTER

Biochemical screening during the second trimester has made a major impact on screening for fetal trisomy 21, although simultaneously, maternal age alone as a screening method has become less important. Screening for Down syndrome in low-risk patients (women <35 years of age) was begun when researchers discovered in the mid-1980s that the mean level of maternal serum alpha-fetoprotein (MSAFP) in Down syndrome pregnancies was 0.7 multiples

of the normal median (MoM).⁷⁻⁹ Subsequently, it was also realized that in Down syndrome pregnancies, unconjugated estriol levels were lower (0.79 MoM) and human chorionic gonadotropin (hCG) levels were higher (2.04 MoM).¹⁰⁻¹³ AFP, unconjugated estriol, and hCG are independent of maternal age and only weakly correlated with each other. Therefore, they can be used in combination to estimate fetal Down syndrome risks. By using the relative risks derived from maternal serum levels of these three analytes, the maternal age-related risk can be modified, and for each individual patient a "triple screen" risk can then be derived.

Triple marker screening has been the preferred screening test for fetal Down syndrome in women younger than 35 years of age, and it is routinely offered in pregnancy over the past several years.¹³⁻¹⁶ Multiple marker screening has a significantly higher sensitivity than MSAFP screening alone. In the population of women younger than 35 years of age, the triple marker screen identifies approximately 60% of all Down syndrome pregnancies, for an approximately 5% screen-positive rate. In women 35 years of age and older, it will detect 75% or more of all Down syndrome cases, and also some other aneuploidies.¹⁷ Because maternal age is the basis of the serum screening protocol, both the Down syndrome detection rate and the screen-positive rate increase with maternal age.¹⁸ Different screen-positive cutoffs may be used, depending on the laboratory. For instance, some will use the midtrimester Down syndrome risk of a 35-year-old woman as the screen-positive cutoff (1/270), whereas others select a screen-positive cutoff that results in an acceptable balance between detection rate and screen-positive rate (usually 1/190 or 1/200).

Maternal serum sampling can be done between 15 and 20 weeks of gestation; however, it is most accurate when performed between 16 and 18 weeks. Dating of the pregnancy must be accurate, because incorrect dates will affect the assigned triple-screen risk, and may lead to false-positive or false-negative results. When there is wrong dating (for example, after sonography has been performed), it is essential to either recalculate the results, or have a new blood sample drawn if the original specimen was drawn at less than 15 weeks of gestation. Maternal weight, race, diabetes, and the number of fetuses present are all incorporated into the risk calculation.

Although serum screening is used primarily for the detection of Down syndrome, it may detect other types of fetal aneuploidy, such as trisomy 18. Some other types of aneuploidy that are likely to be missed by serum screening may be lethal (for example, trisomy 13) or sex chromosome abnormalities that have not been found to be associated with profound mental retardation or severe physical or developmental limitations.

Some believe that the free beta subunits of hCG (β -hCG) are superior to the intact hCG molecule, but neither has definitively been proven to be superior. Recently, there has also been the testing and emergence of a new analyte, dimeric inhibin A. This has been the most promising new second trimester analyte and is currently used by many commercial laboratories in combination with the more traditional three analytes. This new four-analyte combination, or "quadruple screen," appears to detect 67% to 76% cases of fetal Down syndrome in women younger than 35 years of age, with a screen-positive rate of 5% or less.^{19,20}

For multiple gestations, diagnostic options are somewhat limited. With twins, the risk of Down syndrome should be calculated by considering the maternal age-related risk of Down syndrome and the probability that either or both fetuses could be affected. The midtrimester risk for at least one fetus to have Down syndrome in a twin gestation in women 33 years of age is approximately the same as the risk for a singleton pregnancy in women 35 years of age, therefore justifying discussion regarding invasive testing under these circumstances.²¹

SONOGRAPHIC FEATURES OF FETAL ANEUPLOIDY

All pregnancies are theoretically at risk for fetal aneuploidy. Additional risk factors include advanced maternal age, abnormal biochemical screening results, history of fetal aneuploidy, known balanced translocation, or other structural rearrangements in one of the parents, and abnormalities visualized on prenatal ultrasound. In aneuploid fetuses, sonography may reveal structural abnormalities, other findings (such as intrauterine growth restriction, polyhydramnios), or aneuploidy markers. "Soft" sonographic markers are variations in normal anatomy that, except for their relationship to aneuploidy (especially trisomy 21), are unlikely to be clinically significant. Compared with structural anomalies, markers are often transient and nonspecific findings which can also occur frequently in euploid fetuses.

Some of the most common sonographic markers seen in the second trimester include nuchal fold thickening, echogenic intracardiac focus, shortened long bones, hyperechoic bowel, renal pyelectasis, choroid plexus cysts (CPCs), clinodactyly, and hypoplastic or absent nasal bone. As a general statement, as the number of identified markers increases, the risk for aneuploidy in the fetus increases as well. Among aneuploid fetuses, although the features may be highly variable from one fetus to the next, certain patterns of anomalies and common features exist (Tables 4-1, 4-2, and 4-3).

Discovering features of fetal aneuploidy on prenatal sonography and detection rates depend on various factors. These include indications for the scan, gestational age, the population examined (high risk versus low risk), quality of imaging, criteria for an abnormal scan, the type of chromosomal abnormality, and experience of the examiner. For instance, although high sensitivities of detection have been reported by experienced examiners in high-risk populations, low sensitivities can be expected from less experienced sonographers in low-risk populations.²²

Structural Abnormalities

Structural or major anomalies that may be seen in aneuploid fetuses include central nervous system anomalies, facial abnormalities, cystic hygroma, diaphragmatic hernia, cardiac defects, gastrointestinal abnormalities, genitourinary anomalies, nonimmune hydrops, and extremity abnormalities. Many fetuses with trisomies 18 and 13 have multiple major structural anomalies; however, this may not necessarily apply to Down syndrome cases. Only 25% of second trimester fetuses with Down syndrome have ultrasonographically detectable major congenital anomalies.⁶ In two prenatal series

Other findings	Brachycephaly Flat profile Protruding tongue Hydrops Hydrothorax Pericardial effusion Unfused amnion and chorion after 14 weeks

before 20 weeks, structural anomalies were detected by sonography in only 16% to 17% of trisomy 21 fetuses.^{23,24}

Infants with Down syndrome have a 50% incidence of cardiac defects, most commonly ventricular septal defects (Fig. 4-1) and common atrioventricular canal defects (Fig. 4-2). Unfortunately, ventricular septal defects can be quite difficult to identify on prenatal sonography and the detection rate may be variable. One group was able to detect heart defects in just over one half of fetuses with Down syndrome.²⁵ By using nonspecific cardiac findings (such as tricupsid regurgitation, pericardial effusion, and right-left disproportion), DeVore reported abnormal cardiac findings in 76% of fetuses with Down syndrome; however, only 9% showed an atrioventricular septal defect.²⁶ Cardiac malformations are also found in more than 90% of trisomy 18 and 13 fetuses. In our own recent study of 38 fetuses with trisomy 18, we found that the majority (84%) had major congenital heart disease on ultrasound.⁴ Another study also found structural heart defects to be present sonographically in 80% of their cohort of fetuses with trisomy 18.²⁷

Identification of cardiac abnormalities on prenatal sonography may increase the risk for fetal aneuploidy. As compared with postnatal studies, a much higher frequency of aneuploidy (22% to 32%) has been found in fetuses with

sonographically detectable cardiac malformations.^{28,29} One factor that also contributes to the frequency of aneuploidy is the type of cardiac defect present. For instance, the aneuploidy risk is much higher for hypoplastic heart (Fig. 4-3), atrioventricular canal defects, tetralogy of Fallot, or double-outlet right ventricle as compared with isolated ventricular septal defects or valvular stenosis.³⁰ In particular, atrioventricular canal defects have a high risk of aneuploidy. In one series of 38 atrioventricular septal defects, the authors found aneuploidy in 58% (n = 22): Down syndrome (n = 19), trisomy 18 (n = 1), trisomy 13 (n = 1), and mosaicism (n = 1).³¹

Other findings	Microcephaly
	Intrauterine growth restriction
	Polyhydramnios

Duodenal atresia (Fig. 4-4) is usually recognized after 20 to 24 weeks of pregnancy by the documentation of the “double bubble” sign (dilated fluid-filled stomach and proximal duodenum) and evidence of polyhydramnios. This is the leading cause of intestinal obstruction among newborns. Among cases of duodenal atresia detected prenatally, trisomy 21 is present in approximately one third of cases.³⁰ Therefore, invasive testing for karyotype has been offered when duodenal atresia is prenatally identified (even if this occurs in the third trimester, as it still provides vital information in counseling patients).

Cystic hygromas are abnormal cystic masses of lymphatic origin that usually occur in the posterolateral area of the neck (Figs. 4-5 and 4-6). They have a high predisposition to aneuploidy. In fact, aneuploidy is found in more than 60% of fetuses with cystic hygroma. The frequency of aneuploidy varies with the gestational age, and the size and appearance of the hygroma. Large cystic hygromas (typically seen after 14 weeks) tend to have septations (see Fig. 4-5) and carry a high risk of aneuploidy. In the second trimester, about 75% are associated with aneuploidy, and Turner syndrome (45X) accounts for 80% of these.³⁰ In addition, trisomies 18, 13,

**FIGURE 4-1.** Apical four-chamber view of the fetal heart showing an inlet ventricular septal defect.**FIGURE 4-2.** Transverse axial view of the fetal chest, showing a complete atrioventricular canal defect of the heart in a Down syndrome fetus. Note the primium atrial septal defect and inlet ventricular septal defect at the crux of the heart, along with a single atrioventricular valve.

and 21 are also found. Because hygromas may occur in fetuses with Down syndrome, they may represent a “severe” form of the spectrum of increased nuchal fold thickening. However, for hygromas seen in the first trimester, the aneuploidy rate is different (lower), and there is a higher proportion of Down syndrome and other chromosomal abnormalities. Therefore, whenever a cervical cystic hygroma is identified on prenatal sonography, invasive testing should be offered.

In a study comparing septated with nonseptated cystic hygromas in the early second trimester, it was found that septated hygromas were more likely (than nonseptated hygromas) to be associated with aneuploidy (72% versus 6%), and other anomalies (52% versus 15%).³² Isolated cystic

FIGURE 4-7. Transverse axial section of fetal chest, showing evidence of hydrops. Note the bilateral pleural effusions and significant skin edema.

hygromas that occur in an atypical location (noncervical) also do not appear to carry a significant risk of aneuploidy.³⁰

In general, *nonimmune hydrops* (Fig. 4-7) can result from a variety of both maternal and fetal causes. It is recognized sonographically by ascites, pericardial effusions, pleural effusions, polyhydramnios, thickened placenta, and skin

FIGURE 4-8. Large unilateral pleural effusion (*asterisk*) pushing the heart into the right side of the chest.

edema. Aneuploidy is also a common cause of nonimmune hydrops, accounting for up to 16% of cases.³³ The pathophysiology of hydrops is not clear, but involves congestive heart failure or lymphatic dysplasia. The most common types of karyotype abnormalities that are associated with hydrops include Turner syndrome, trisomies 21, 18, and 13, and triploidy. When we studied the prenatal sonographic features of trisomy 18 fetuses, we found that 13% had evidence of hydrops/pleural effusions.⁴ In addition, when nonimmune hydrops is diagnosed before 18 weeks, there is a higher incidence of aneuploidy, as compared with hydrops diagnosed in the latter half of pregnancy.³⁴ Therefore, when hydrops is diagnosed sonographically and appears to be unexplained, invasive testing should be offered. The combination of generalized hydrops and cystic hygroma, which is referred to as lymphangiectasia, is lethal in prognosis. Lymphangiectasia is associated with aneuploidy in approximately two thirds of cases, especially Turner syndrome. Thus, it should be separated from hydrops without cystic hygroma.

Hydrothorax (pleural effusion, chylothorax) has been linked to aneuploidy, especially Turner syndrome, Down syndrome, and trisomy 13. Among 82 cases of isolated fetal pleural effusion (Fig. 4-8) reported in the literature, Down syndrome was present in 4.9%.³⁵ Therefore, fetal karyotype analysis should be offered whenever hydrothorax is identified on prenatal sonography. It should be noted that *ascites* (Fig. 4-9) may occur in isolation and without other signs of hydrops. This has also been associated with aneuploidy, as reported in an evaluation of 18 fetuses with ascites where 5.6% ($n = 1$) had Down syndrome.³⁶

Diaphragmatic hernia (Fig. 4-10) is due to a congenital defect in the fetal diaphragm, with herniation of abdominal viscera into the fetal chest. This abnormality carries an increased risk for chromosomal abnormalities, such as trisomy 18 (most common), trisomy 13, Down syndrome, Turner syndrome, and other chromosomal abnormalities. It appears that the aneuploid frequency has been reported to be from 8% to 34%, most commonly 10% to 20%.³⁷⁻³⁹ Therefore, karyotype testing should be offered whenever this defect is identified prenatally.

FIGURE 4-9. Transverse axial view of the fetal abdomen, demonstrating ascites and significant skin edema.

FIGURE 4-10. Transverse view through the fetal chest, showing a left-sided diaphragmatic hernia. Note the stomach (*S*), bowel (*Bo*), and liver (*Li*) within the chest cavity, displacing the heart to the right side.

An *omphalocele* (Figs. 4-11 and 4-12) occurs when there is a central abdominal wall defect that results in herniation of intra-abdominal structures into the base of the umbilical cord, which is covered by a membrane. Omphaloceles are associated with other fetal anomalies and aneuploidy in more than one half of the prenatally diagnosed cases. They carry a high risk of aneuploidy, such as trisomies 18 and 13 (most often), Down syndrome, Turner syndrome, and triploidy. Similarly to other fetal malformations, there appears to be a higher frequency of aneuploidy in most prenatal studies (30%–40%) as compared with neonatal studies (with

FIGURE 4-11. Large liver containing omphalocele (arrows) in a second trimester patient. The omphalocele is larger than the native fetal abdomen.

FIGURE 4-12. Second trimester fetus with trisomy 18 with large omphalocele containing both liver (Li) and echogenic bowel. The umbilical cord insertion can be seen by color Doppler on the apex of the herniated sac. Also note the umbilical cord cyst (arrow).

a combined rate of 12%), owing to the presence of more severely anomalous fetuses who die in utero or in the immediate neonatal period.³⁰ In one study, of 35 cases of omphalocele diagnosed by sonography, 54% had aneuploidy: trisomy 18 ($n = 17$), triploidy ($n = 1$), and Klinefelter syndrome ($n = 1$).⁴⁰ In a recent study by our group, we found that of all trisomy 18 fetuses, 18% had an omphalocele identified on prenatal sonography.⁴ Patients should be offered invasive testing for karyotype whenever an omphalocele is identified. Omphaloceles with intracorporeal liver (containing bowel only) have a higher aneuploidy risk than those with extracorporeal liver (containing liver) (see Fig. 4-11).⁴¹ One group found an aneuploidy rate of 87% in omphaloceles with intracorporeal liver, versus 9% in extracorporeal liver.⁴¹ When the omphalocele is extracorporeal and no other anomalies are identified, the risk for aneuploidy is low. Chromosomally normal fetuses with omphaloceles and no

FIGURE 4-13. Transverse axial scan at midgestation showing ventriculomegaly with a markedly dilated ventricle (arrows).

life-threatening abnormalities may have an excellent outcome after surgery.

Many *central nervous system* abnormalities carry an increased risk for fetal aneuploidy. *Cerebral ventriculomegaly* (Fig. 4-13), which is diagnosed when the atrial diameter of the cranial lateral ventricle reaches 10 mm or more, is a frequent finding. This is often associated with a relative “shrinkage” (inability to fill entirely the width of the lateral ventricle) or “dangling” of the choroid plexus. Ventriculomegaly (even mild) is associated with an increased risk for aneuploidy such as Down syndrome. However, it may also be seen as a normal variant later in the second trimester (after 20 weeks’ gestation) and in male fetuses, in the absence of “dangling” of the choroid plexus.³⁰ In one study, there were 31 fetuses with isolated borderline ventriculomegaly (10 to 15 mm) and 9.7% ($n = 3$) were found to have aneuploidy (2 Down syndrome, 1 trisomy 13).⁴² By reviewing the literature and including their cases, from a total of 234 patients, aneuploidy (mostly Down syndrome) was found in 3.8%. In another large (2743) series of cases, 3.8% were found to be karyotypically abnormal and Down syndrome was present in 2% of all the cases.²³ In chromosomally normal, aneuploid, and Down syndrome fetuses, mild ventriculomegaly was observed in 0.5%, 6.8%, and 5.5%, respectively.²³ Although the odds ratio of mild ventriculomegaly for aneuploidy was 4.4 (95% confidence interval (CI), 1.3 to 93.4), the ventriculomegaly was never isolated in these cases.

Hydrocephalus (Fig. 4-14) and *spina bifida* (Fig. 4-15), both together and each alone, have been reported to be associated with various types of karyotypic abnormalities, mainly trisomy 18, 13, and triploidy.⁴³ In a review of 107 fetuses with central nervous system abnormalities, aneuploidy was found in 3%, 8%, and 33% of fetuses with hydrocephalus, hydrocephalus and spina bifida, and spina bifida alone, respectively.⁴³ In our study of 38 trisomy 18 fetuses, we found that 19% had neural tube defects, whereas 8% had ventriculomegaly/hydrocephalus.⁴ Therefore, if spina bifida is diagnosed prenatally, fetal karyotype testing should be offered.

FIGURE 4-14. Marked dilation of both lateral ventricles with dangling choroid plexuses (arrows) in a fetus with hydrocephalus.

FIGURE 4-15. Three-dimensional sonogram showing the fetal back affected by a neural tube defect (arrow) in the lumbosacral area.

When *cerebellar* abnormalities are detected on prenatal sonography, there is an increased risk for aneuploidy and associated abnormalities.⁴⁴ Cerebellar abnormalities include Dandy-Walker malformation (Figs. 4-16 and 4-17), Dandy-Walker variant, and cerebellar hypoplasia with enlargement of the cisterna magna. In both Dandy-Walker malformation and variant, the enlarged fourth ventricle expands through a defect in the cerebellar vermis. With the variant type, there is incomplete vermian agenesis. Trisomy 18 is the most common aneuploidy, but other chromosomal abnormalities may also be observed. It is important to know that subtelomeric rearrangements have been seen related to brain abnormalities, including hypoplastic cerebellum and hydrocephalus³⁰; this should be considered when karyotype

FIGURE 4-16. Dandy-Walker malformation in a trisomy 13 fetus. In a transverse axial plane, an enlarged fourth ventricle (arrows) is seen along with a defect in the cerebellar vermis. Note that the cerebellar hemispheres are splayed.

FIGURE 4-17. Pathologic specimen of brain shows cerebellar hemispheres bilaterally, but with complete absence of the vermis, consistent with Dandy-Walker malformation.

testing is performed. The Dandy-Walker variant is more strongly associated with aneuploidy (as compared with the malformation type), which is counterintuitive because the variant type is a more subtle anomaly.^{45,46} Among those tested, one group found karyotypic anomalies in 53% fetuses with Dandy-Walker variant, as compared with 32% in those with Dandy-Walker malformation.⁴⁶

Although it may be seen in normal fetuses, an enlarged cisterna magna may be indicative of chromosomal abnormalities (especially trisomy 18). This is most commonly visualized in the third trimester, and is less likely in the

FIGURE 4-18. A. Fetus with agenesis of corpus callosum. Widely separated frontal horns (arrows) are seen with absence of the cavum septum pellucidum. B. Transverse axial scan through the lateral ventricle shows the characteristic "teardrop" shape of lateral ventricles or disproportionate enlargement of the occipital horns (colpocephaly) (asterisk), which is indicative of agenesis of corpus callosum.

second trimester.^{47,48} One study examined fetuses with vermian agenesis or enlarged cisterna magna, and found that 55% had aneuploidy, most commonly trisomy 18 or trisomy 18 variant.⁴⁵ However, it appears that when there is an isolated enlarged cisterna magna (especially after 26 weeks) without other structural anomalies, this is usually associated with a normal karyotype and outcome.⁴⁹

Agenesis of the corpus callosum (Fig. 4-18) can be complete or partial. The diagnosis is made by showing absence of the

FIGURE 4-19. Transaxial view through the head of a trisomy 13 fetus, showing alobar holoprosencephaly. Note the fused thalami (T) surrounded by a single monoventricle (asterisk).

complex formed by the corpus callosum and cavum septum pellucidum, along with various other sonographic findings such as colpocephaly (or disproportionate enlargement of the occipital horns) (see Fig. 4-18). Aneuploidy is found in approximately 20% of cases, and mostly include trisomies 18, 8, and 13.⁵⁰ However, a variety of other types of chromosomal abnormalities are also reported. A recent study examined cases of agenesis of the corpus callosum diagnosed prenatally and postnatally.⁵¹ Among the prenatally diagnosed cases, aneuploidy was present in 8%, as compared with 4% in postnatal cases.

Holoprosencephaly (Figs. 4-19 and 4-20) is a midline abnormality of the brain, resulting from absent or incomplete division of the prosencephalon (embryonic forebrain), and formation of the midline structures. It is embryologically related to development of the midface, hence, the common association with median facial anomalies (Fig. 4-21) involving the forehead, interorbital structures, nose, premaxilla, and upper lip. There are three major types of holoprosencephaly, depending on the degree of anatomic abnormality: alobar, semilobar, and lobar type. Aneuploidy is present overall in 50% to 60% of fetuses with alobar or semilobar holoprosencephaly. Of the various types of chromosomal abnormalities, trisomy 13 or a variant of trisomy 13 is the most common (found in 50%–75% of those with abnormal karyotype); however, there is a wide variety of other aneuploid types reported. Among fetuses with trisomy 13, holoprosencephaly has been reported in 39%.⁵ In the presence of facial or extrafacial abnormalities in addition to holoprosencephaly, the risk for aneuploidy is increased.

Facial anomalies are commonly seen in fetuses or neonates with karyotypic abnormalities. Some karyotypically abnormal fetuses or neonates may demonstrate micrognathia (Figs. 4-22 and 4-23), sloping forehead (see Fig. 4-23),

FIGURE 4-20. Pathologic specimen of alobar holoprosencephaly in neonate affected with trisomy 13.

FIGURE 4-22. Abnormal facial profile, showing severe micrognathia (arrow).

FIGURE 4-23. Gross pathologic features seen in the face of a neonate with trisomy 9. Note the sloping forehead, flat profile, small nose, and micrognathia (arrow).

FIGURE 4-21. Gross pathologic features seen in the face of a neonate with alobar holoprosencephaly. A single eye globe (cyclopia) and a proboscis located above the median eye are present. Also note the clenched hands bilaterally.

flattened profile (Fig. 4-24), or retrognathia. In examining the sonographic features of 38 fetuses with trisomy 18, we found that approximately one half (53%) had facial anomalies visualized.⁴ Twenty-nine percent had an abnormal profile (excluding micrognathia), 21% had micrognathia, and 18% had hypotelorism.

The presence of *cleft lip/palate* (Figs. 4-25 and 4-26) is associated with aneuploidy (such as trisomies 13 and 18), especially when found together with central nervous system malformations or other abnormalities. A recent study examined fetuses with cleft lip and palate and reported aneuploidy in 0%, 32%, 59%, and 82% in unilateral cleft lip, unilateral cleft lip and palate, bilateral cleft lip and palate, and median cleft lip and palate, respectively.³⁰ Although some would argue that cleft lip alone has a low risk of aneuploidy and invasive testing is not always necessary, occasionally it is difficult to diagnose cleft palate prenatally and therefore this may represent a false-negative examination for cleft palate. Therefore, amniocentesis should probably be offered to all patients with fetal cleft lip and/or palate diagnosed on ultrasound.

FIGURE 4-24. Facial profile of fetus with trisomy 18. The profile is flattened and there is a hypoplastic nasal bone.

FIGURE 4-26. Three-dimensional image of the fetal face showing bilateral cleft lip.

FIGURE 4-25. Three-dimensional image of the fetal face showing unilateral cleft lip (arrow).

FIGURE 4-27. Marked hypotelorism in a fetus with trisomy 13.

Ocular anomalies, such as hypotelorism (Fig. 4-27), hypertelorism, microphthalmia, anophthalmia, and cyclopia (see Fig. 4-21) can be associated with fetal karyotype abnormalities. Most importantly, when they are seen along with other malformations (especially holoprosencephaly), the risk of aneuploidy is particularly increased.

Genitourinary abnormalities can be associated with fetal chromosomal abnormalities. The highest frequency of aneuploidy has been reported in those fetuses with urethrovesical obstruction (bladder outlet obstruction), most commonly trisomy 18 or 13.³⁰ In a cohort of 39 fetuses having obstruction at or distal to the urethrovesical junction,

chromosomal abnormalities were reported in 23%.⁵² For urinary tract abnormalities occurring more proximally, aneuploidy has been reported with less frequency. For unilateral renal abnormalities including ureteropelvic junction obstruction and multicystic dysplastic kidneys, the risk of aneuploidy is considered to be low.⁵³ However, amniocentesis for karyotype may still be offered in all cases of multicystic dysplastic kidney (Fig. 4-28) because of the potential for associated chromosomal abnormalities.

In general, although the majority of congenital malformations may increase the risk for fetal aneuploidy, there are still some exceptions. These involve disorders that result from tissue or vascular disruption, such as gastroschisis, tumors, limb-body wall complex, hydranencephaly, and amniotic band syndrome.

FIGURE 4-28. Parasagittal scan through the fetal lower abdomen shows large multicystic dysplastic kidney with multiple cysts of varying sizes.

FIGURE 4-29. View through the posterior fossa shows normal nuchal fold thickness (0.41 cm) in the second trimester.

Nuchal Fold

In 80% of newborns with Down syndrome, redundant nuchal skin folds or excess soft tissue in the posterior neck area are present.⁵⁴ Nuchal thickening is also present in other chromosomal abnormalities, such as trisomy 18, 13, and Turner syndrome. In some cases, it may even result from cystic hygroma resolution. In 1985, Benacerraf was the first to report thickened soft tissue at the fetal occiput between 15 and 20 weeks of gestation as a sonographic sign for trisomy 21.⁵⁵ The authors showed that 33% of fetuses with Down syndrome had a nuchal fold thickening of greater than or equal to 6 mm. By directing a transaxial plane through the fetal head and angled posteriorly to include the cerebellum and occipital bone, the nuchal skin fold thickness can be obtained (Fig. 4-29). Internal anatomic landmarks include

FIGURE 4-30. Transaxial plane through the posterior fossa of the fetal head, revealing an increased nuchal skin fold thickness (10 mm) in a 21-week fetus with Down syndrome.

the cavum septum pellucidum, cerebral peduncles, cerebellar hemispheres, and cisterna magna. Measurements are typically performed between 15 and 21 gestational weeks, and are measured by calipers from the outer skull table (or outside the occipital bone) to the outer skin edge. Values of greater than or equal to 5 or 6 mm are considered abnormal or increased (Fig. 4-30). The mean intraobserver and interobserver errors for this measurement are only 0.63 mm and 0.53 mm, respectively, thus making this marker highly reproducible.⁵⁶ However, it should be noted that when obtaining the nuchal fold thickness in breech fetuses, fetuses with an extended head on the neck or when increased pressure is placed on the transducer over the fetal head, a false-positive increased thickness may be obtained.

The sensitivity and false-positive rates for nuchal fold thickening (Fig. 4-31) vary with gestational age and the definition of a positive examination. Two large prospective clinical trials have shown the sensitivity of nuchal fold thickness for fetal Down syndrome detection to be 43% and 42%, with positive screening rates of 0.1% and 1.3%, respectively.^{56,57} Another group found that by using a cutoff value of greater than or equal to 6 mm, 33% of trisomy 21 fetuses could be detected, with only a 0.1% false-positive rate.⁵⁸ They suggested lowering this cutoff to greater than or equal to 5 mm in order to achieve a sensitivity of 77.8% with a 2% false-positive rate. Benacerraf observed that in 303 normal fetal cases, none showed nuchal thickening greater than 5 mm up to 20 weeks' gestation.⁵⁷ Therefore, other studies have suggested that using 5 mm is a better cutoff, leading to improved sensitivity with only a slight increase in the false-positive rate.^{58,59} At our institution, we use 6 mm or more as the threshold value for abnormal. Multiple other studies have also confirmed the finding that thickened nuchal fold on second trimester sonography is associated

FIGURE 4-31. A. Longitudinal image of second trimester fetus with trisomy 21. Increased soft tissue is seen at the back of the head (arrow). Note that the fetal head is in a neutral position with respect to the cervical spine. B. Longitudinal image of a third trimester fetus with known Down syndrome. Note the redundant nuchal skin (arrow). In this case the prominent soft tissue is abnormal. However, extension of the fetal head on the neck, as in this case, may cause normal soft tissue to appear prominent and abnormal.

with a high risk for fetal Down syndrome.^{56,60-62} The thickened nuchal fold is one of the most important markers, and the most sensitive and specific single marker for the midtrimester detection of Down syndrome,⁵⁵ although absent nasal bone has also recently been shown to have 41% sensitivity and 100% specificity for fetal Down syndrome.⁶³ Even as an isolated finding, abnormal nuchal fold has been reported to carry a likelihood ratio of at least 11 for Down syndrome.^{64,65} Even among women who are not at risk for having a Down syndrome fetus, the thickened nuchal fold is helpful in detecting these affected fetuses.⁶⁶ Therefore, nuchal fold as a marker is a powerful tool, even in low-risk patients. Given these results, genetic amniocentesis should be offered when an abnormal nuchal fold measurement is observed, even in a low-risk population.

A very important fact is that although the nuchal thickness may persist throughout the second trimester in some fetuses with trisomy 21, other fetuses will have complete

Table 4-4

Biparietal Diameter/Femur Length Ratio for Detection of Down Syndrome

Study	Number of Down Syndrome Fetuses	Sensitivity	Positive Screen Rate
Dicke et al ⁷²	33	18%	4%
Hadlock et al ⁷³	16	19%	12%
Perella et al ⁷⁴	19	26%	23%
Hill et al ⁷⁵	22	36%	7%
Brumfield et al ⁷⁶	15	40%	2%
Lockwood et al ⁷⁰	35	51%	7%
Venacerraf et al ⁵⁷	20	70%	5%

resolution.⁶⁷ Thus, regression may occur whether or not the fetus has Down syndrome; therefore, once an abnormal nuchal skin measurement is obtained, an amniocentesis should be offered, regardless of whether the nuchal skin thickness resolves.⁶⁸

Short Long Bones

Because trisomy 21 individuals often have short stature, it is not surprising that the second trimester Down syndrome fetus may have a tendency for short humerus and femur bone lengths. In fact, the somatic and visceral growth profiles of midgestation trisomy 21 fetuses have been described, and it has been shown that the most striking deviations from normal are the short limbs (which are discordant with the head circumference).⁶⁹ When measuring long bone lengths, it is important to obtain the measurement with the diaphysis located horizontally in the image, because vertical measurements can falsely "shorten" the length. The most commonly used method for determining short long bone length is to compare the actual with the expected measurement based on biparietal diameter (BPD), rather than using gestational age.

In 1987, it was first shown that a short femur was associated with an increased risk for fetal Down syndrome.^{57,70} The femur length can be assessed between 15 and 23 weeks using either a BPD/femur length ratio, or the observed-to-expected femur length ratio.^{57,70} By choosing an upper limit of 1.5 standard deviations above the mean in the BPD/femur length ratio, Lockwood found that the sensitivity and false-positive rate was 51% and 7%, respectively, for detecting Down syndrome fetuses (Table 4-4).⁷⁰ Benacerraf demonstrated that 68% of trisomy 21 fetuses had ratios of the observed-to-expected femur length of less than 0.91, based on the BPD (Table 4-5).⁵⁷ Some investigators have found differences in the diagnostic accuracy of the BPD/femur length ratio, depending upon the gestational age of the fetus.⁷¹ Most specifically, a short femur was most helpful in detecting trisomy 21 between 17 and 19 weeks gestation.

The efficacies of the BPD/femur length ratio and the observed-to-expected femur length ratio for trisomy 21 detection are depicted in Tables 4-4^{57,70,72-76} and 4-5.^{57,72,75,77-80} As seen, there is a wide range of sensitivities reported, with some studies failing to show a clinically meaningful association between short femur length and Down syndrome. This may be a reflection of the differences

in the populations examined in each of the studies. Because there is variation in fetal femur length with respect to maternal race,⁸¹ it is advisable that in order to optimize sensitivity and specificity, each center should establish its own normal reference data, because mean values and standard deviations may significantly vary from one site to another.

Most data show that trisomy 21 fetuses have slightly shorter femurs (as compared with normal fetuses); however, the reduction in femur length in these fetuses is only minimal and it may not be useful as an isolated marker in screening for Down syndrome. Therefore, as with other sonographic aneuploidy markers, using a combination of markers (versus in isolation) to detect fetal Down syndrome is more useful.

In a 1989 study based on postmortem measurements in trisomy 21 fetuses, it was reported that humeral lengths were shorter than expected.⁸² Subsequently, Benacerraf examined the role of humerus length in detecting trisomy 21 fetuses in the second trimester by using the measured-to-expected humerus length ratio of less than 0.90 as a cutoff; 50% of Down syndrome fetuses were identified with a 6.25% false-positive rate.⁸³ In the same year, our group found that short humerus length had a 54% sensitivity for the ultrasonographic detection of second trimester Down syndrome fetuses (versus 18% for femur length).⁸⁴ However, other investigators have found short humeral length to be less useful as a screening marker for trisomy 21 (28% sensitivity and positive screen rate of 9%).⁸⁵

By combining both humerus and femur length assessments, a remarkable reduction in false-positive rates can be achieved.⁸⁶ Fetuses with both a short humerus and short femur carry an 11-fold higher risk of having trisomy 21, when compared with the age-based risk.⁸⁷ Gender may appear to have a role in influencing long bone lengths. In 1993, one study found that affected male fetuses with Down syndrome had more short femur and humerus measurements than affected female fetuses did, when compared with their normal counterparts.⁸⁸ A subsequent study by our group found that affected Down syndrome male fetuses had a greater proportion of short femur and humerus measurements at any given BPD, than did affected female fetuses.⁸⁹ However, when another group studied the impact of gender on the sonographic detection of fetal trisomy 21, they did not find statistical significance in the incidences of any of the sonographic markers, including short long bones.⁹⁰

FIGURE 4-32. A transverse scan in the second trimester shows bilateral pyelectasis (arrows) in a fetus with Down syndrome.

Pyelectasis

Renal pyelectasis (or renal pelvic dilation) (Fig. 4-32) is measured in an anteroposterior dimension as the fluid-filled renal pelvis. It should be measured only when the kidneys and spine are positioned directly toward or away from the transducer (versus to the side). Among various centers, the abnormal cutoff varies, but the most common value used is 3 to 4 mm. At our unit, we use a threshold measurement of 4 mm or more in the second trimester. Pyelectasis has been associated with an increased risk for aneuploidy,⁹¹⁻⁹⁴ especially for trisomy 21. Its prevalence varies with gestational age, with many cases resolving as the pregnancy advances. However, pyelectasis (especially mild) is a relatively common finding on prenatal sonography and may be seen in 2% to 2.8% of normal fetuses.⁹²

In 1990, it was first shown that mild fetal pyelectasis was associated with an increased risk for trisomy 21.⁹¹ By using a cutoff of greater than 4 mm, it was found that 25% of Down syndrome fetuses had pyelectasis.⁹¹ Similarly, one group found that 18.7% of their Down syndrome fetuses had pyelectasis,⁵⁶ whereas another showed a 17% incidence of pyelectasis among fetuses with Down syndrome, with a 2% false-positive rate.⁹² Among 210 fetuses overall with pyelectasis, 3.3% had Down syndrome.⁹¹ Snijders⁹⁵ estimated that mild pyelectasis increased the risk for Down syndrome by 1.6-fold over the baseline risk. Some studies have focused on isolated pyelectasis as a marker for aneuploidy. Of 99 fetuses with isolated pyelectasis, two fetuses had aneuploidy (one of which had Down syndrome).⁹⁶ However, in a population of women with advanced maternal age, among the 2.9% of second trimester fetuses with isolated pyelectasis, the authors did not find an increased incidence of aneuploidy.⁹⁷

Overall, although isolated fetal pyelectasis is a sonographic marker that carries a slightly increased risk for trisomy 21, the risk is probably not enough to justify amniocentesis in a low-risk population. However, in a high-risk population, pyelectasis may be used sonographically in combination with other aneuploidy markers, such as nuchal fold, short long bones, and so forth. When present in high-

FIGURE 4-33. Apical four-chamber view of the fetal heart, showing an echogenic intracardiac focus (arrow) in the left ventricle. Note the similar brightness to surrounding bone.

risk women, even as an isolated marker, the identification of pylectasis may increase the a-priori risk for fetal trisomy 21.

Echogenic Intracardiac Focus

An echogenic intracardiac focus (EIF) is commonly seen on second trimester sonography, and it is present in 3% to 4% of normal fetuses.⁹⁸ It is a discrete, brightly echogenic spot with brightness similar to bone (Fig. 4-33), and appears to be caused by reflection from the papillary muscles and chordae tendinae. Pathologic correlation suggests that EIF correlates with papillary muscle mineralization that may be seen histologically.⁹⁹ It may also represent coarse intramyocardial calcifications surrounded by myocardial fibrosis.¹⁰⁰ In low-risk patients, presence of an EIF is not associated with cardiac anomalies.¹⁰¹⁻¹⁰³ The prevalence of EIF appears to be significantly higher among the Asian population, with EIF found three times more often among Asian patients, as compared with whites.¹⁰⁴ Because EIF could be a subjective finding, its detection depends on various factors such as fetal positioning, maternal scanning characteristics, experience of the sonologist, quality and resolution of the ultrasound machine, completeness of the examination, and sonographic technique. Importantly, it is best visualized in an apical four-chamber view, with the apex of the heart pointing either toward or away from the transducer,¹⁰⁵ because it may “disappear” when examining the heart from a subcostal four-chamber view (apex pointing to the side). Although it has been reported that it typically resolves by the third trimester,¹⁰³ we have found that with careful sonographic examination, an EIF can still be visualized even in the third trimester.

EIF was considered a normal variant until 1992.⁹⁸ In a pathologic study, Roberts was the first to suggest an associ-

ation between mineralization of the papillary muscle and aneuploidy.¹⁰⁶ Microcalcification of the papillary muscle was seen in 2%, 16%, and 39% of normal fetuses, trisomy 21 fetuses, and trisomy 13 fetuses, respectively.¹⁰⁶ Subsequently in 1995, Bromley reported on a series of 1334 second trimester fetuses undergoing amniocentesis, and found that 4.9% had an EIF.¹⁰¹ Eighteen percent (4/22) of Down syndrome fetuses had an EIF, compared with 4.7% (62/1312) of normal fetuses. They found that in this high-risk population, the sonographic identification of an EIF was associated with a fourfold increase in the risk for trisomy 21.¹⁰¹ Recently, the same authors found that as an isolated finding, EIF carries a likelihood ratio of 1.4 for fetal trisomy 21.¹⁰⁷ Subsequently, many studies have confirmed an association between Down syndrome and EIF.¹⁰⁸⁻¹¹¹ The likelihood ratio of EIF for Down syndrome is estimated to fall in the range of 1.8 to 4.2.³⁰ However, some investigators have failed to show an association between Down syndrome and EIF.^{102,112} An association between EIF and trisomy 13 has also been reported.⁵ The authors found EIF in 39% of trisomy 13 fetuses earlier than 20 weeks.

Although an EIF may occur in either or both cardiac ventricles, it is most frequently seen in the left ventricle. One study found EIF in the left ventricle, combined left and right ventricles, and isolated to the right ventricle in 96%, 4.3%, and 0.7% of cases, respectively.¹¹³ It appears that multiple or large EIF (Fig. 4-34) may also further increase the risk for aneuploidy. In other words, when the right ventricle or both ventricles show an echogenic intracardiac focus, the incidence of aneuploidy may be higher than it is for a single, left-sided focus.¹⁰⁹ One group of investigators found that right-sided (Fig. 4-35) and bilateral EIF combined had approximately a twofold greater risk for aneuploidy, as compared with left-sided foci.¹⁰⁹ Among fetuses with an EIF

FIGURE 4-35. Echogenic intracardiac focus seen the right ventricle of the heart (arrow).

FIGURE 4-36. Hyperechogenic bowel (arrows) in the abdomen (Grade 3) of a Down syndrome fetus. The echogenicity is similar to that of the vertebral bodies.

in the right ventricle, there appeared to be a higher incidence of Down syndrome, as compared with fetuses with EIF isolated to the left ventricle only. Another study found that of 15 fetuses having multiple EIF, 67% ($n = 10$) had abnormal karyotypes, and only two of these had other sonographic abnormalities.¹¹⁴ Others have also found that EIF involving both cardiac ventricles (see Fig. 4-34) are more often associated with aneuploidy. One group reported that chromosomal abnormalities was more common when EIF involved both ventricles, as compared with either ventricle alone.¹¹¹

In summary, the relationship between an echogenic intracardiac focus and trisomies 21 and 13 has been confirmed in the literature. Therefore, in the high-risk population even when an echogenic intracardiac focus is isolated, this will increase the a priori risk for fetal Down syndrome. However, in low-risk populations when the EIF is isolated and no other sonographic major or minor anomalies are identified, it is considered a "normal variant," and no further evaluation (including fetal karyotyping) is generally recommended.

Hyperechoic Bowel

As with many other aneuploidy markers, hyperechogenic bowel is nonspecific and it can be seen in normal fetuses. Overall, it is not a very frequent finding, as it is found in approximately 0.5% of normal fetuses. Normally in the second trimester, the bowel is homogeneous and has the same echogenicity as the rest of the fetal abdomen, thus appearing nondiscreet and normally unnoticeable. However, in the presence of hyperechoic bowel, one will have a subjective impression of unusually echogenic bowel. Its clinical significance varies with the degree of echogenicity. It has also been shown that the echogenicity of normal bowel increases with transducer frequency, although this effect is uniform (although true hyperechoic bowel tends to be focal).¹¹⁵ Especially with current ultrasound technology and better sonographic resolution, one should remember that using

high-frequency transducers can highlight or exaggerate the echogenicity of fetal bowel, even in the normal fetus. Because the clinical detection of hyperechoic bowel still requires subjective interpretation, some have used a grading system to reduce subjectivity as much as possible.¹¹⁶ Some will only acknowledge bowel that is markedly echogenic on sonography, whereas others will recognize both moderate and markedly echogenic bowel. A grading system for hyperechoic bowel which has been proposed includes grade 1 (mildly echogenic and typically diffuse), grade 2 (moderately echogenic and typically focal), and grade 3 (very echogenic, similar to that of bone structures).¹¹⁶ In our unit, we diagnose hyperechoic bowel only if it has sonographic echogenicity similar to the iliac bones.

Hyperechoic bowel is seen with increased frequency in aneuploid fetuses (Fig. 4-36), especially trisomy 21.^{24,117-119} In 1990, Nyberg reported an association between chromosomal abnormalities and hyperechoic bowel; of 94 fetuses with Down syndrome, 7% had hyperechoic bowel.²⁴ Another group examined 50 fetuses with hyperechoic bowel (defined as echogenicity comparable to bone) and found that 16% had aneuploidy, most of whom had Down syndrome.¹¹⁷ The same group of investigators reported that 12.5% of all second trimester Down syndrome fetuses in their unit had hyperechoic bowel. Hyperechoic bowel appears to increase the risk of trisomy 21 by six- to sevenfold.⁶⁴ However, the risk will vary depending on maternal age, presence of other abnormalities, and a variety of other risk factors. The risk of Down syndrome in fetuses with isolated hyperechoic bowel is approximately 1.4% in the general population.⁶⁸ Others have reported that isolated hyperechoic bowel would be expected to be associated with a risk of trisomy 21 of approximately 1% to 2% in the general population.³⁰

The differential diagnosis of hyperechoic bowel includes congenital infections (such as cytomegalovirus, herpes simplex virus, and parvovirus), meconium ileus (due to cystic fibrosis), and bowel obstruction/atresias/malformations. It may also be associated with prenatal vaginal bleeding and fetal swallowing of blood from intraamniotic hemorrhage.¹²⁰ With hyperechoic bowel, there is also an increased risk of

FIGURE 4-37. Three patients with choroid plexus cysts. *A.* Transverse axial scan of the head shows a single choroid plexus cyst. Normal chromosomes. *B.* Transverse axial scan of the fetal head in another patient. Several choroid plexus cysts were seen. Normal chromosomes. *C.* Bilateral large choroid plexus cysts. The patient had trisomy 18. There were multiple other sonographic abnormalities also visualized.

poor perinatal outcome, such as fetal demise, intrauterine growth restriction, and placenta-related complications.¹²⁰ It has been shown that the risk of both cystic fibrosis and aneuploidy increases with the degree of echogenicity of the fetal bowel.^{116,121} From 145 cases of second trimester hyperechoic bowel, one study showed that cystic fibrosis was found in 0%, 2.5%, and 20.8% of fetuses with grades 1, 2, and 3 bowel, respectively.¹²¹ They also found Down syndrome in 0%, 2.5%, and 25% of fetuses with grades 1, 2, and 3 bowel, respectively.

It is important to distinguish hyperechoic bowel from meconium peritonitis, in which the most common and characteristic finding on prenatal sonography is peritoneal calcification. Hyperechoic bowel is also different from hyperechoic meconium seen during the third trimester, which can be normal but is usually confined to the colon.

From a summary of the largest studies of hyperechoic bowel and their outcomes, Nyberg reported that the data indicated an increased risk for fetal or neonatal demise (3%–4%), aneuploidy (about 3%), other anomalies (3%), bowel complication (1%–2%), cystic fibrosis (1%–2%), and congenital infection (1%–2%).¹²² Therefore, when hyperechoic bowel is visualized, one should consider maternal

studies for congenital infection, cystic fibrosis carrier status, invasive testing for fetal karyotype, and serial scans throughout the pregnancy to rule out intrauterine growth restriction and bowel malformations/atresias (which may not be evident until the third trimester). In general, the prognosis is favorable once aneuploidy, structural anomalies, infection, cystic fibrosis, and intrauterine growth restriction have been ruled out.

Choroid Plexus Cysts

The cranial lateral ventricles contain sonolucent cerebrospinal fluid. Within the lateral ventricles lies the brightly echogenic choroid plexus that normally fills the atrium, and may contain cysts (Fig. 4–37). CPCs are a relatively common finding during the second trimester, especially with current improved sonographic technology and resolution. The reported prevalence among normal fetuses is variable and ranges anywhere from 0.3% to 3.6%.^{123,124} This variability can be accounted for by various factors, such as indications for referral, completeness of the scan, size criteria for diagnosing cysts, and gestational age. CPCs themselves have no known effect on fetal development and are essentially benign.

In addition, unlike other aneuploidy markers (for example, hyperechoic bowel), there is no known association with other adverse outcomes if the karyotype is normal.

CPCs are seen almost exclusively in fetuses between 16 to 21 weeks of gestational age, and appear to be transient. By the 23rd week of gestation, they are usually undergoing regression and it is uncommon to see them sonographically after 25 to 26 weeks. Cysts may be unilateral or bilateral, single or multiple, and small or large. Commonly, they are multilocular in appearance, and the cysts typically range from between 0.5 cm and 2 cm in size. Occasionally, they may be so large as to fill almost the entire lateral ventricle and expand its walls, giving the false appearance of ventriculomegaly (Fig. 4-37B).

CPCs can be a significant finding because there have been reports in the literature over the years describing the association of CPCs with fetal aneuploidy, specifically with trisomy 18.¹²⁵⁻¹²⁷ CPCs appear to be present in approximately one third of trisomy 18 fetuses.¹²⁶ Because of this association, there is much debate as to whether fetuses having CPCs on ultrasound should undergo karyotyping. It is clearly recommended that when fetuses with CPCs have other sonographic findings, invasive testing should be offered. However, when prenatal sonography by experienced personnel reveals that the CPCs are *isolated*, management should be conservative. However, some investigators believe that fetuses having isolated CPCs and no other anomalies may still carry a risk of aneuploidy high enough to justify amniocentesis. However, the critical component lies in whether an "isolated" CPC is, in fact, truly isolated. This can only be presumed once a detailed fetal survey by experienced examiners has failed to reveal other structural abnormalities/markers. Therefore, it is imperative that all fetuses with CPCs undergo a detailed fetal sonographic anatomic survey by someone who is skilled and experienced in prenatal diagnosis.

Several meta-analyses have been reported in the literature with regard to fetuses with isolated CPCs. One report revealed that 13 of the largest studies had a 0.27% incidence (or 1/374 risk) of trisomy 18 among fetuses with isolated CPCs, thus suggesting that invasive testing is not warranted.¹²⁷ Another report found that among 1346 fetuses with isolated CPCs, seven had trisomy 18 and five had Down syndrome.¹²⁸ Their study suggested a likelihood ratio of 13.8 (CI 7.7 to 25.0) for trisomy 18, and 1.87 (CI 0.78 to 4.46) for Down syndrome. Table 4-6 contains a summary of reported studies examining the incidence of aneuploidy in fetuses with isolated CPCs. Only one of the large studies (274 fetuses) shows the presence of chromosomal anomalies in cases of isolated CPCs.¹²⁹ As seen from the table, of 24 studies, the majority had no cases of aneuploidy, whereas eight studies found an association of isolated CPCs with chromosomal anomalies.

Snijders et al¹³⁰ found CPCs in 50% of their fetuses with trisomy 18, and in 1% of chromosomally normal fetuses. However, because the vast majority of affected fetuses showed other sonographic anomalies, the risk (for trisomy 18) of isolated CPCs was only marginally increased, with a likelihood ratio less than 2; however, the presence of just one other abnormality increased the risk 20 times.¹³⁰ Recently, we examined the prenatal sonographic features of 38 fetuses with trisomy 18, and found that 50% had CPC identified, but they were always associated with multiple other

sonographic abnormalities (never isolated).⁴ Recently, DeVore also found the prevalence of CPCs in trisomy 18 fetuses to be 53%, and when these cysts were isolated, they were not associated with trisomy 18.²⁷ In another study by our group, we found that of 98 fetuses with isolated CPCs, none had aneuploidy, whereas of the 13 fetuses with CPCs and major anatomic abnormalities, 100% had trisomy 18.¹³¹ Subsequently, one group of investigators found that all 131 fetuses with isolated CPC had normal karyotypes, and all fetuses with aneuploidy had additional anomalies.¹³² In addition, we have shown that from a cost-benefit point of view, invasive testing based on the presence of isolated CPCs is not justified.¹³³

Previously, it has also been believed that large cysts (> 1 cm) or bilateral cysts increased the risk for aneuploidy. Some evidence suggests that these larger cysts further increase the risk for trisomy 18 (compared with smaller cysts)¹³⁴⁻¹³⁸; however, this should still be regarded within the context of whether other abnormalities are also present or not. Although CPCs always resolve, larger cysts may take longer to undergo this process, lending support to the observation that delayed resolution of CPCs may carry an increased risk for trisomy 18.³⁰ One must also remember that it has been shown that small, unilateral lesions may be seen in chromosomally abnormal fetuses.¹³⁹ Whether CPCs are unilateral or bilateral is probably not significant, although it is probably the case that larger cysts also tend to be bilateral.³⁰ In our study, of the 19 trisomy 18 fetuses with CPCs, 79% (n = 15) had bilateral cysts; of these, six had a "moth-eaten" appearance of the choroid plexus.⁴ On the

other hand, four fetuses had unilateral CPC(s), of whom three had only a single cyst.

Unlike for trisomy 18, a possible relationship between CPC and trisomy 21 is somewhat controversial. Some studies have suggested that CPCs are associated with Down syndrome in the second trimester.^{127,134,139–141} However, Bromley showed that the incidence of CPCs in the normal population (1.4%) was the same as the incidence of cysts among fetuses with Down syndrome.¹⁴² Thus, they concluded that the presence of CPCs did not increase a patient's risk for fetal Down syndrome. In a meta-analysis, the authors reported that isolated CPCs were associated with a fetal Down syndrome risk of 1/880, which is the same as that of the general population.¹⁴³

Therefore, in order to increase or decrease one's suspicion of aneuploidy, when CPCs are visualized sonographically, we believe a thorough, detailed examination needs to be performed of the remaining fetal anatomy to rule out other abnormalities. In our experience, if no other anomalies are found (especially when hands are open and ear length is normal), the risk of aneuploidy remains very low (even in a high-risk patient), and invasive testing is not warranted. As described in a recent editorial, it is recommended that when CPC is the only detected sonographic abnormality, it should be emphasized that as an isolated finding in a patient otherwise considered at low risk for fetal aneuploidy, a CPC is not considered clinically significant and does not change the patient from low- to high-risk status.¹⁴⁴ Therefore, although CPCs have been reported to be associated with fetal aneuploidy, if no other major or minor sonographic anomalies are identified in the fetus, and in the absence of other risk factors, this is considered a "normal variant," and no further evaluation is recommended.¹⁴⁴

Many recommend that if fetal karyotyping is not performed when CPC are identified, follow-up sonograms should be performed to follow the cysts. However, because they always resolve, repeat scans add no value to decision making, with the possible exception of detecting other sonographic anomalies that were previously missed.

Nasal Bone

In 1866, when Langdon Down first described the features of patients with trisomy 21, he noted that the face was flat and the nose small.¹⁵⁷ This is a common feature of the Down syndrome facies (Fig. 4–38). As a more objective confirmation, absent ossification, hypoplastic or short, and agenesis of the nasal bone have also been described in radiographs of Down syndrome fetuses.^{158,159} Keeling et al¹⁵⁸ examined 31 Down syndrome fetuses (12–24 weeks) with radiographs, and found that 61% had hypoplasia or agenesis of the nasal bone. Recently, nasal bone hypoplasia or absence of nasal bone on ultrasonography has been described as a sign of fetal Down syndrome. One of the first ultrasound papers was published in 2001, when Cicero noted that among 59 cases of Down syndrome in the first trimester, 73% had an absent nasal bone with a false-positive rate of only 0.5%.¹⁶⁰ Subsequently, this was followed by a case report series in 2002 that described three second trimester Down syndrome fetuses of high-risk women, in which 66% ($n = 2$) had an absent nasal bone, and the third had a nasal bone length less than 2.5% for gestational age.¹⁶¹

FIGURE 4–38. Characteristic Down syndrome facies on three-dimensional imaging, with a small nose and the tongue protruding outwards.

When evaluating the facial profile for the nasal bone, the correct technique and angle of insonation should be used. The profile should be viewed in the midsagittal plane, with care taken to keep the angle of insonation close to 45 degrees or 135 degrees.¹⁶¹ This technique is recommended in order to avoid artificially causing false nasal bone measurements. With angles less than 45 degrees or greater than 135 degrees, the nasal bone may artificially appear *absent*. On the other hand, as the angle approaches 90 degrees, edges of the bone may become difficult to delineate precisely because of echo scatter, and the measurement may become artificially large. The nasal bone should be visualized as a linear echogenic structure if the correct technique described above is used (Fig. 4–39).

Many studies have examined the sensitivity and false-positive rates in the second trimester, for sonographically absent (Fig. 4–40 and Table 4–7) or hypoplastic/short fetal nasal bone (Fig. 4–41) as a sonographic marker for the detection of Down syndrome. The sensitivities for absent nasal bone have ranged from 28% to 66%, and false-positive rates from 0 to 20%. However, many studies show sensitivities and false-positive rates ranging from 34.6% to 57% and 0% to 3.7%, respectively (see Table 4–7). Importantly, it appears that the sensitivity and false-positive rate of absent nasal bone in detecting Down syndrome approximates that of nuchal fold thickening (40% sensitivity, 0.1% false-positive rate).¹⁷² Recently, through a matched case-control study we examined the usefulness of absent nasal bone by ultrasound in the prenatal detection of second trimester fetuses with Down syndrome.⁶³ There were 40 fetuses identified with Down syndrome, and in 72.5%

*Mean ± standard deviation.

($n = 29$), an adequate facial profile was obtained. Of these 29 fetuses, 12 had an absent nasal bone for a sensitivity of 41%, with a specificity of 100% (or false-positive rate 0%). More importantly, the sensitivity of genetic sonography was increased from 83% to 90% by adding absent nasal bone to the other sonographic aneuploidy markers.⁶³ Since 2003, we have therefore added this marker to the list of other sonographic aneuploidy markers evaluated during a genetic ultrasound examination. With regard to absent nasal bone, because the specificity is very high (with correspondingly low false-positive rates), it is an ideal marker to add to other more "traditional" markers evaluated during genetic sonography because it does not increase the false-positive rate. Others also have suggested that the association of NBLs to other sonographic markers may further improve sensitivity and reduce the false-positive rate for fetal trisomy 21, allowing the avoidance of unnecessary invasive procedures.¹⁷³

In 2005, we reported that the addition of absent nasal bone as an aneuploidy marker increased the sensitivity of second trimester genetic sonography for Down syndrome from 87% (before including absent nasal bone as a marker) to 92.8%, without increasing the false-positive rate.¹⁷⁴ This significant increase in the detection of trisomy 21 with the addition of absent nasal bone as a marker emphasizes the need to include this marker in the list of aneuploidy markers evaluated during a genetic sonogram. Similarly to our finding, Goncalves found that three of their 26 Down syndrome fetuses had no sonographic markers for this condition at the time of examination.¹⁶⁶ However, among these fetuses, two had absent nasal bone, although one had a normal nasal bone. Bromley et al¹⁶² also found that among their 16 Down syndrome cases, although 13 had other sonographic markers suggesting aneuploidy, three had no other markers. Nevertheless, of these three Down syndrome fetuses that possessed no other sonographic markers, two had absent nasal bone.

We currently use the presence or absence of nasal bone as a sonographic marker for aneuploidy, and we have shown 100% agreement between examiners with respect to presence or absence of nasal bone. However, we believe that if short or hypoplastic nasal bone is going to be used as a marker in detecting Down syndrome, each unit should establish their own sonographic nomograms of NBL in the second trimester which are specific to their respective patient populations. It is only then, that examination of various cutoffs and evaluating their respective efficacies can establish what degree of hypoplastic nasal bone (or NBL) has the most appropriate efficacy for detecting fetal Down syndrome and aneuploidy. This has already been performed by some groups.^{175,175} Through normative data of NBLs which have been created, it has been shown that the fetal NBL increases linearly with advancing gestational age.^{173,175} There also appears to be some ethnic/racial differences in NBLs. A pilot study examining the fetal nasal bone in the Chinese population found the length to be shorter than that of whites and blacks.¹⁷⁶

Mean NBLs are shorter and BPD/NBL ratios are greater in fetuses with trisomy 21, as compared with euploid fetuses.¹⁷⁷ In one study examining 16 fetuses with Down syndrome, 37% had no detectable nasal bone, compared with 0.5% of euploid fetuses. An absent nasal bone was found to confer a likelihood ratio of 83 for fetal Down syndrome.¹⁶² In addition,

although absent nasal bone was a powerful marker for trisomy 21, a short nasal bone was also associated with an increased likelihood for trisomy 21 in a high-risk population. By using a BPD/NBL ratio of greater than 10, there was an 81% sensitivity for Down syndrome, with an 11% false-positive rate.¹⁶² Another recent study in 2005 found that of 18 Down syndrome fetuses, 55.5% had an absent nasal bone and an additional 22.2% had hypoplastic nasal bone, with the false-positive rate being only 0.47%.¹⁶⁹ In addition, the BPD/NBL was 10 or greater in 62.5% of fetuses affected by Down syndrome, and in 9.8% of euploid fetuses. They concluded that inclusion of NBL into the second trimester screening protocol could potentially obviate the false-negative cases from other screening tests. Therefore, the measurement of NBL in the second trimester seemed to provide additional benefits beyond the assessment of the presence or absence of the nasal bone.¹⁶⁹

Recently, three-dimensional (3-D) ultrasonography has been used in the second trimester to allow more accurate visualization of the fetal bony face and the nasal bones.^{164,166,170} One group has found that unilateral absence or hypoplasia of the nasal bone is an important observation in Down syndrome fetuses, and that this differentiation may be best demonstrated on 3-D imaging.¹⁷⁰ Although many trisomy 21 fetuses had absent nasal bones concordantly on both two-dimensional (2-D) and subsequent 3-D imaging, there were three fetuses with a discrepancy between the imaging modalities. In these three Down syndrome fetuses, all had absent nasal bones by 2-D imaging, however 3-D sonography showed absence of a unilateral nasal bone in all three, and either hypoplasia ($n = 2$) or normal nasal bone ($n = 1$) on the other side. The authors point out that the finding of unilateral hypoplasia of the nasal bone has not been previously described in studies of 2-D imaging, because the nasal bone is normally viewed in a single parasagittal section.¹⁷⁰ The findings could explain some discrepant findings where there is "absence" of the nasal bone on 2-D imaging, but presence on postmortem x-rays. This new information suggests that when 3-D sonographic equipment is available, suspicious findings of hypoplastic/absent nasal bone should be examined via this modality, and volumes can be stored for later evaluation and rendering.¹⁷⁰ The hope and anticipation is that this may improve the accuracy of sonographic prenatal findings and accordingly, the sensitivity for Down syndrome.

Finally, when absent nasal bone is visualized, this is not necessarily a marker solely for fetal Down syndrome. Lee reported that at least 58 genetic syndromes (including trisomy 18) may be associated with absence of the nasal bone.¹⁶⁴ Another study has found that in 41% of all aneuploid fetuses, the nasal bone was either absent or hypoplastic (see Fig. 4-41).¹⁶⁵

Iliac Wing Angle

Children with trisomy 21 have pelvic dysplasia and a wider lateral span of the iliac wing as compared with normal children, thus causing a widened iliac angle. Accordingly, attempts have been made to use this as a possible sonographer marker in the second trimester for fetal Down syndrome. By examining a transverse view of the fetal pelvis, the iliac angle made by the two iliac crests at the pivot point

FIGURE 4-42. Iliac wing angle on a transverse view through the fetal pelvis, showing a 90-degree angle made by the two iliac crests (arrows) at the sacrum.

of the sacral spine can be measured (Fig. 4-42). One study examined 19 fetuses with trisomy 21, and found that the mean iliac angle was 80 ± 19.7 degrees, as compared with 63.1 ± 20.3 degrees for those with normal karyotypes ($P = 0.0004$).¹⁷⁸ By using an iliac angle of 90 degrees as a cutoff, 36.8% fetuses with Down syndrome were identified, as well as 12.8% of normal fetuses ($P = 0.003$). Other studies have assessed the iliac angle and also found a difference between normal and trisomy 21 fetuses.^{179,180} For example, one group found that in their high-risk population, by using a cutoff of greater than or equal to 90 degrees as abnormal, they could detect 90% of Down syndrome fetuses (positive predictive value 33%).¹⁷⁹ Some have also reported using iliac length measurements in screening for trisomy 21.¹⁸¹ They found that the observed-to-expected iliac length measurement gave a sensitivity of 40% (false-positive rate 2%) for the detection of trisomy 21 fetuses.¹⁸¹

However, unlike other aneuploidy markers, which are very reproducible and consistent (such as pyelectasis, single umbilical artery), there is considerable variation in the measurement of the iliac wing angle. The angle may vary, depending on the actual transverse level at which the measurement is taken, and there is also significant intra- and interobserver variability. Several factors affect this measurement, including orientation of spine, axial level, and gestational age.¹⁸² One group found that the iliac angle decreased by 15.7 degrees from the superior to inferior portion of the pelvis, and decreased by as much as 15.6 degrees when the spine is directed to the side.¹⁸² Thus, despite studies toting the utility of this sonographic marker in the second trimester for detecting fetal Down syndrome, if one has a known Down syndrome fetus, depending on which level the angle is measured, the angle can be greater or less than 90 degrees. Therefore, similar to others,¹⁸³ because obtaining a standard measurement is difficult and due to variation in the angle measured depending on the various factors described, we have not incorporated this particular

FIGURE 4-43. Second trimester fetus with low-set ear (arrow).

marker into our second trimester genetic sonogram. Most experts believe that a widened pelvic angle is not a useful marker, especially when used as part of a screening ultrasound.¹⁸⁴

Ear Length

Abnormally small ears have previously been described to be one of the most consistent clinical findings in newborns and infants with aneuploidy, including Down syndrome.¹⁸⁵ As a matter of fact, it has been described by Thelander and Pryor¹⁸⁶ that one of the most striking and consistent growth discrepancies documented in children with Down syndrome is in the development of the external ear. They found that of all the anthropomorphic measurements examined, the longitudinal dimension of the pinna fell the furthest below the expected norm in all age levels studied. In addition, as many as 60% of newborns with Down syndrome and more than 80% to 90% of those with trisomy 18 and 13 have ear anomalies described as a characteristic feature.¹⁸⁷ Low-set ears (Fig. 4-43) with abnormal helix have also been found to be one of the most frequent anomalies (77%) in autopsy cases of trisomy 18.¹⁸⁸

Therefore, short ear length on prenatal ultrasound has been examined as a potential sonographic marker for the detection of fetal aneuploidy. Several prenatal sonographic studies have noted an association between fetal ear length and aneuploidy. One group found that short ears (≥ 1.5 standard deviations below gestational age average) were associated with fetal chromosomal disorders, with a sensitivity of 73.3%.¹⁸⁹ However, although short ears were always found sonographically in cases with trisomy 18 and 13, it occurred only in about half of the cases with trisomy 21.¹⁸⁹ Lettieri et al¹⁹⁰ prospectively measured second trimester fetal ear lengths and found that most aneuploid fetuses had short ear lengths (≤ 10 th percentile), with a sensitivity of 71%. Another study calculated measured-to-expected ear length ratios and

found that these ratios were significantly lower in fetuses with aneuploidy. They found that a ratio of less than 0.8 had a 75% sensitivity for detecting Down syndrome fetuses and 83.3% sensitivity for detecting trisomy 18.¹⁹¹ Subsequently, in 1997 another group found the sensitivity of ear length below the 5th percentile for the detection of chromosomal abnormalities to be 80%.¹⁹² Chitkara et al¹⁹³ measured sonographic ear lengths in normal fetuses to create a nomogram, and then found that short ear lengths were a useful parameter in predicting fetal aneuploidy.¹⁹⁴ Thirty-two percent (11/34) of fetuses with significant chromosomal abnormalities had short ear lengths, and in six cases, this was the only sonographic finding.¹⁹⁴

We recently examined the sensitivity of ear length in detecting fetal aneuploidy. First, we established a nomogram for ear length (14–41 weeks) prospectively.¹⁹⁵ Ninety-six fetuses with aneuploidy were identified: trisomy 21 (n = 51), trisomy 18 (n = 24), trisomy 13 (n = 6), Turner syndrome (n = 4), and others (n = 11). Sixty-three of these aneuploid fetuses had ear lengths less than or equal to 10th percentile for gestational age, for a sensitivity of 66%. We found that of all the Down syndrome fetuses, 41% had an ear length less than or equal to 10th percentile. Twenty-three out of the 24 fetuses with trisomy 18 had ear lengths less than or equal to 10th percentile for gestational age, for a sensitivity of 96%, whereas all six fetuses with trisomy 13 had ear lengths less than or equal to 10th percentile for gestational age, for a sensitivity of 100%.¹⁹⁵ Therefore, short ear length was not as sensitive a marker for trisomy 21 as it was for trisomies 18 (96%) and 13 (100%). Aneuploid ear lengths were also plotted against the nomogram curves for BPD, divided according to the type of aneuploidy. When using ear length against BPD, the sensitivity of all aneuploid fetuses less than or equal to 10th percentile was 43%. When examining the individual aneuploidies, the sensitivities of ear length less than or equal to 10th percentile for BPD for trisomies 21, 18, 13, and other types of aneuploidy were 28%, 87%, 60%, and 27%, respectively. Therefore, we found that the small ears were not related entirely to overall small fetal size, but in almost one half the cases (43%), the fetal ear lengths were disproportionately smaller than their BPDs (especially in trisomy 18 and 13), indicating “true” smaller ears.

In another study, we examined the prenatal detection of fetal trisomy 18 through abnormal sonographic features.⁴ Twenty-seven fetuses with trisomy 18 had prenatal ear length measurements available and were defined as short if the ear length was less than 10th percentile for gestational age. We found short ear length to be overall the most sensitive marker for trisomy 18 (96%). It is important to note, however, that this finding was always seen with multiple other abnormalities and never in isolation. Chitkara et al¹⁹⁴ found that from their four cases of trisomy 18, 75% had short ear length, as well as other sonographic abnormalities.

When performing second trimester genetic sonography, we routinely obtain the ear length measurement and incorporate evaluation of fetal ear length as an aneuploidy marker. In addition, when trying to rule out trisomy 18 on prenatal sonography, an attempt should always be made to evaluate the ear length. Although a normal ear length cannot rule out trisomy 18 completely, it should markedly decrease the risk for this condition.

FIGURE 4-44. Long-axis view of fetal lower extremity in the second trimester, showing a clubbed foot. Note that the plantar surface of the foot is seen in the same plane as the entire lengths of the tibia and fibula.

FIGURE 4-45. Gross pathologic image of neonate demonstrating bilateral clubbed feet.

Extremity Abnormalities

In addition to being seen frequently in association with spina bifida, clubfoot (Figs. 4-44 and 4-45) has been also associated with various types of aneuploidy, including trisomies 18 and 13.¹⁹⁶ In our experience, 32% of trisomy 18 fetuses have clubfeet.⁴ In a postmortem study, clubfeet were also present in 23% of trisomy 18 cases.¹⁹⁷ In another study of 26 fetuses with trisomy 18, 38% had evidence of clubfeet on ultrasound.¹²⁶ In general, however, most of these aneuploid fetuses will show other sonographic anomalies. Therefore, it is somewhat controversial as to whether an isolated clubfoot justifies invasive testing for karyotype analysis. In one study examining 68 cases of fetuses with apparently isolated clubfoot on ultrasound and having available follow-up, approximately

FIGURE 4-46. Gross pathologic image of neonate with trisomy 9, showing a rocker-bottom foot.

6% had aneuploidy (trisomy 21, trisomy 18, 47XXX, 47XXY).¹⁹⁸ However, there were other anomalies some of which were detected only after birth, including mild posterior urethral valves, early renal dysplasia, ventricular septal defects, and hip or other limb abnormalities. Accordingly, the authors recommended that because other subtle associated malformations may not be detected on early second trimester sonography, fetal karyotyping should be offered when isolated clubfoot is visualized on prenatal sonography.¹⁹⁸ On the other hand, in a recent study reviewing 51 cases of isolated clubfoot, other investigators found no additional malformations detected at birth or cases of aneuploidy.¹⁹⁹ Accordingly, the study concluded that provided a thorough fetal sonogram is performed (and is normal), and the patient is considered low risk, an isolated unilateral/bilateral clubfoot does not appear to be an indication for fetal karyotyping.¹⁹⁹

Rocker-bottom foot (Fig. 4-46) occurs when one or both feet appear to have a “rocker-bottom” appearance on sonography (similar to the bottom of a rocking chair), instead of the normal inward arch of the plantar surface of the foot. This finding may be seen in some aneuploidies, such as trisomies 18 and 13. In our series of fetuses with trisomy 18, we found that 29% had evidence of rocker-bottom feet.⁴ In a post-mortem study, rocker-bottom feet were present in 10% of trisomy 18 cases.¹⁹⁷ Another group found that of 12 fetuses with trisomy 18, 70% had clubfeet or rocker-bottom feet seen on prenatal sonography.²⁰⁰

Clinodactyly (or hypoplasia of the middle phalanx of the 5th digit) (Figs. 4-47 and 4-48) is visualized as a curving inward or deviation of the 5th digit of the fetal hand toward the other fingers. It may be seen with Down syndrome, and in a radiographic postmortem study, was seen in about one third of cases.¹⁵⁹ Of infants with trisomy 21, it appears that

FIGURE 4-47. Second trimester fetus with Down syndrome showing a hypoplastic middle phalanx of the fifth digit (arrow) and clinodactyly.

FIGURE 4-48. Sonographic view of fetal fingers, showing complete absence of the middle phalanx of the fifth digit (arrow).

60% have this feature.⁶⁸ Subsequently, clinodactyly has been examined in both normal and Down syndrome fetuses on second trimester prenatal sonography.²⁰¹ By using a ratio (length middle phalanx 5th digit/length middle phalanx 4th digit), some investigators found that the mean ratio for normal and Down syndrome fetuses was 0.85 and 0.59 ($P = 0.04$), respectively. When a cutoff ratio of 0.70 was used, there was a 75% sensitivity for fetal Down syndrome, with an 18% false-positive rate.²⁰¹

FIGURE 4-49. Plantar view of the foot in a second trimester fetus with Down syndrome, showing a sandal-gap deformity with wide space between first and second toes (*arrow*).

Although clinodactyly is often used as an aneuploidy marker for fetal Down syndrome, it should be kept in mind that this is a feature seen in many normal fetuses. In addition, unlike thickened nuchal fold or pyelectasis, the interpretation and impression of clinodactyly is often susceptible to more subjective variability. It can also be a feature that is generally difficult to assess on second trimester sonography and is dependent on fetal positioning. Therefore, whereas evaluation of this marker may be appropriate in the high-risk patient, it should probably not be used in a screening environment, due to its high false-positive rate.

In 1994, the *sandal gap* deformity was described in a fetus with Down syndrome.²⁰² This occurs when there is separation of the great toe from the second toe (Fig. 4-49), causing a wide space or gap to be visualized on prenatal sonography. Like clinodactyly, sandal gap is also commonly seen among normal fetuses and can therefore be difficult to use in a screening setting. However, in our experience, although many normal fetuses may exhibit this feature, in these cases, it is usually transient, and careful observation will reveal closing of this space during the time of the sonogram. We have noticed that in fetuses with trisomy 21, the sandal gap deformity often remains persistent throughout the observation period, even despite fetal movement. Another point to keep in mind is that the sonographic appearance of the fetal toes may be very similar or even identical to that of the parents (who can show a wide normal variation in appearances), and may therefore be familial and not necessarily indicative of an abnormality or malformation.

Limb reduction malformations (such as *radial aplasia*) (Fig. 4-50) are associated with aneuploidy, especially trisomy 18.²⁰³ In fact, when radial aplasia is identified, trisomy 18 should be in the differential diagnosis.

FIGURE 4-50. Scan of the arm in a trisomy 18 fetus shows the characteristic appearance of radial aplasia. The hand is turned inwards, and the forearm is shortened. The long humerus bone is also visualized.

FIGURE 4-51. Sonogram of fetus with trisomy 18 shows bilateral clenched hands, which persisted throughout the sonographic examination.

Flexion deformities and movement disorders are also commonly seen with trisomy 18. In particular, a very characteristic finding of this chromosomal abnormality is fixed flexion of the hands (*or clenched hands*), often having overlapping digits (Figs. 4-51 and 4-52). In fact, some trisomy 18 fetuses even show generalized arthrogryposis or contractures. When examining the prenatal sonographic features of trisomy 18, we found contractures in 18%.⁴ We also found bilateral clenched hands and overlapping digits to be highly sensitive (95%) and the second most common sonographic abnormality in fetuses with trisomy 18.⁴ Importantly, this feature was seen even at early gestational ages (between 14.6 and 17.6 weeks). This has been documented on fetoscopic observation as early as 14 weeks, suggesting that malpositioning of the fingers in trisomy 18 occurs some time between 12 and

FIGURE 4-52. Three-dimensional image of fetus with trisomy 18 shows persistently bilateral clenched hands in front of the face. These hand findings are a characteristic finding of this aneuploidy.

14 weeks of gestation.²⁰⁴ Another case series has reported overlapping fingers sonographically at 13 weeks.²⁰⁵ Our sensitivity of 95% is similar to the experience of Shields et al,²⁰⁶ in which they found the most common sonographic abnormality seen in trisomy 18 fetuses was persistent abnormal positioning of fingers or clenched fist (89%), and to that of Kinoshita et al,²⁰⁷ who found overlapping fingers and flexion to be the most common external anomaly (84%) on autopsy.²⁰⁷ Shields et al²⁰⁶ also state that because the most common sonographic abnormality found in their population of fetuses with trisomy 18 was abnormal positioning of the hands, it is likely that documentation of an open hand, along with use of maternal triple screen, should reduce the number of patients with CPCs who need invasive testing.

Many other studies have also found abnormal hands to be their most common fetal sonographic abnormality in trisomy 18.^{126,200,208} In a postmortem study of aneuploid cases, clenched fists were seen in 35% of cases of trisomy 18 at autopsy.¹⁹⁷ Another study of ultrasonographically diagnosed fetal wrist position abnormalities showed 32% to have trisomy 18.²⁰⁹ We have never sonographically visualized open hands (full extension of all fingers in the same plane as the metacarpals) in fetuses that ultimately prove to have trisomy 18. Our sensitivity of hand abnormalities was not 100%. However, because one fetus was 36 weeks at the time of sonographic examination (the hands were difficult to visualize), and in the other case, the hands were not examined sonographically owing to the patient's request to

FIGURE 4-53. Plantar surface of the foot of a trisomy 18 fetus. Note the very abnormal appearance of the dysplastic toes. The fourth and fifth toes (*arrow*) are also smaller than the rest.

stop the examination. In both cases, however, delivery and autopsy ultimately showed bilateral clenched hands.

When examining the prenatal sonographic features of trisomy 18, we also found almost two thirds (63%) of our fetuses with trisomy 18 to have lower extremity/feet abnormalities overall.⁴ Thirteen percent had evidence of contractures on prenatal sonography, although 16% had an abnormal position/appearance of the toes (Fig. 4-53). In Nyberg's study of 47 fetuses with trisomy 18, he found extremity abnormalities by pathologic examination, sonography, or both, in 93% of fetuses, suggesting that when trisomy 18 is suspected on the basis of other sonographic findings, the hands and feet should be specifically evaluated.³ Another study found that of 15 fetuses with trisomy 18, the most common sonographic abnormality was abnormal hands or feet (73%).²⁰⁸

Polydactyly occurs when there is the presence of more than five digits. It is classified as preaxial if the extra digits are located on the radial or tibial side, or postaxial if they are located on the ulnar or fibular side. Most commonly, this extra digit is a simple skin tag (which can be difficult to see sonographically), but bones or a completely duplicated and nonfunctional digit may also be present. Polydactyly is frequently present in fetuses with trisomy 13 (Fig. 4-54).³⁰

Single Umbilical Artery

The normal umbilical cord contains three vessels (two arteries and one vein) that are surrounded by Wharton's jelly. The absence of one of the umbilical arteries (SUA or two-vessel cord) is the most common pathologic condition of the umbilicus in humans and one of the most common malformations in humans, with an incidence of 1% in singleton births, and 4.6% in twin births.²¹⁰

The prenatal diagnosis of SUA (Fig. 4-55) on sonography is not difficult with current, modern sonographic equipment. The basic prenatal screening technique involves an

FIGURE 4-54. View of the hand of a trisomy 13 fetus, showing postaxial polydactyly (arrow). Both hands were affected similarly.

examination of transverse views of a free loop of cord with adequate magnification (see Fig. 4-55). In this view, when there is an SUA, only two vessels are visualized, where the larger vessel is the vein and the smaller vessel is the umbilical artery. Another method that can be used in the prenatal detection of SUA is demonstrating the absent intra-abdominal segment of the missing umbilical artery. This can be detected prenatally by examining the umbilical arteries running alongside and around the fetal bladder in a transverse view of the pelvis (Fig. 4-55B). Examination is greatly enhanced by using color flow Doppler or power Doppler imaging, and appears to be the best screening technique for SUA.

There is a well-known association between SUA and cytogenetic abnormalities. The incidence of cytogenetic abnormalities among fetuses demonstrating SUA has been 17%, with nearly one half of these fetuses having major anomalies.^{211,212} Trisomy 18 is the most common aneuploidy associated with SUA.²¹⁵ The next most common types of abnormal karyotypes associated with SUA are trisomy 13, Turner syndrome (45X), and triploidy.²¹³ SUA has an incidence of 11.3% among cytogenetically abnormal pregnancies, and it can be found in 10% to 50% of trisomy 18 fetuses.²¹⁴ Of trisomy 13 fetuses, 10% to 50% also have an SUA.³⁰ In one of our recent studies examining the abnormal sonographic features of trisomy 18, we found that 21% had a single umbilical artery.⁴ On the other hand, Down syndrome does not appear to be commonly associated with SUA,²¹² although it has been reported. It is important to keep in mind, however, that although SUA has been included as an aneuploidy marker, it is nonspecific and is most commonly seen in normal fetuses.

SUA has also been reported to be associated with an increased risk of congenital anomalies, fetal growth restriction,

FIGURE 4-55. A. Multiple short axis sections through the umbilical cord in a patient with a single umbilical artery. The larger structure in each case is the vein, the smaller, the artery. B. Transverse axial plane of section through the fetal abdomen in a patient with a single umbilical artery. The single umbilical artery is seen adjacent to the urinary bladder.

prematurity, and an increased perinatal mortality rate.²¹⁵ The incidence of congenital anomalies has been reported to be 20% in infants with SUA.²¹¹ The risk for congenital anomalies in infants with SUA depends on the ascertainment method (being highest at autopsy), but cases diagnosed sonographically or at term deliveries still have an increased risk of anomalies. The rate of associated fetal anomalies with SUA ranges, in various studies, from 18.4% to more than 47%, with the highest rates of associated malformations reported in pathologic rather than clinical studies.²¹⁶

Neonates with SUA may have anomalies involving a wide variety of organ systems, including central nervous, musculo-skeletal, cardiovascular, gastrointestinal, and genitourinary systems.²¹⁷ However, no consistent pattern of anomalies has been recognized in association with SUA, and virtually any malformation may be present. SUA also occurs in various genetic syndromes, such as VATER association, Jarcho-Levin syndrome, Meckel-Gruber syndrome, as well as others.²¹⁸ Therefore, it is imperative that when a SUA is identified, a targeted and detailed fetal anatomic survey should be performed to rule out concurrent malformations. In addition, given the common association of single umbilical artery with congenital cardiac disease, even in the presence of a normal fetal karyotype, a detailed evaluation of the heart should also be performed in fetuses with SUA.²¹⁹

In a large study of 167 fetuses with SUA, among those cases with postnatal information, 31% had structural abnormalities, often involving multiple organs.²¹⁷ The most common organ systems involved were the heart, the gastrointestinal system, and central nervous system, in that order. Importantly, among 85 cases with apparently isolated single umbilical artery at sonography and known fetal outcome, 7% proved to be anomalous at birth, which is considerable.²¹⁷ Therefore, although invasive testing in the neonatal period may not be necessary in an uncomplicated infant, a careful and thorough physical examination of the neonate is required to exclude other anomalies.

In fetuses with isolated SUA, there is usually no increased incidence for a chromosome abnormality.²¹¹ However, as with isolated CPCs, this stipulates that a detailed sonogram by experienced personnel should rule out other anomalies. Once the single umbilical artery is believed to be genuinely isolated, in the absence of high-risk factors, invasive prenatal diagnostic procedures for chromosomal analysis may not be routinely indicated, because most fetuses with isolated SUA are karyotypically normal. However, when intrauterine growth restriction or multiple malformations are detected in association with SUA, prenatal karyotyping should be offered. In summary, once SUA is identified sonographically, this should trigger a search for additional abnormalities, but by itself, the finding may not be an indication for chromosome analysis in the low-risk patient. However, patients should be informed that their neonates may be at risk for subtle anomalies which may be found only at the time of birth.

Other Sonographic Aneuploidy Markers

Brachycephaly (anteroposterior shortening) (Fig. 4–56) and frontal lobe shortening can be seen in infants with Down syndrome. Therefore, investigators have tried to evaluate the use of these characteristics in detecting fetuses with trisomy 21.^{220,221} In 1998, a report showed that frontal lobe shortening had a sensitivity of 16%, with a false-positive rate of 3%.²²¹ They suggested that this marker could be used in conjunction with other aneuploidy markers. In examining the frontothalamic distance in 19 fetuses with Down syndrome in the second trimester, another group found that 52% of Down syndrome fetuses had a distance that was less than 10th percentile.²²⁰ By setting the false-positive rate at approximately 5%, the sensitivity of this measurement was 21%.

FIGURE 4–56. Transaxial image of the fetal head showing brachycephaly in a fetus with trisomy 21.

FIGURE 4–57. Transverse view of the head of a second trimester fetus with trisomy 18, showing a strawberry-shaped skull.

In 1992, Nicolaides first described the *strawberry-shaped* skull (Fig. 4–57) seen in fetuses with trisomy 18.²²² They reported this feature in 52% of fetuses with trisomy 18 who, however, had other anomalies seen sonographically, too. Subsequently, another group reported a strawberry-shaped head in 34% of fetuses with trisomy 18.²⁰⁶ It is believed that although the false-positive rate in normal fetuses is unknown, it is probably about 1%.²²³ Once head shape abnormalities are identified, a careful search of the rest of the fetus for abnormal sonographic findings is warranted.

TRISOMY 21 (DOWN SYNDROME)

Autosomal trisomies are primarily the result of meiotic nondisjunction, which increases with maternal age. The most common autosomal trisomy in live-born infants is Down syndrome, or trisomy 21. The clinical features of Down syndrome were first described by Dr. John Langdon Down in 1866.¹⁵⁷ It was not until almost a century later that the chromosome abnormality was discovered in 1959. Overall, 1 child in 800 is born with Down syndrome.²²⁴ In the United States, it occurs in 1/504 pregnancies during the second trimester,²²⁵ with the prevalence significantly varying with maternal age. The specific risk of trisomy 21 at the time of second trimester amniocentesis varies from 1/274 for women 35 years of age, to 1/10 for women 48 years of age.²²⁶ Many other chromosomal abnormalities are also associated with increasing maternal age, including trisomies 13 and 18. The risk for fetal Down syndrome also changes depending on the gestational age at the time of the examination, due to intrauterine losses of chromosomally abnormal conceptuses. Thus, at birth, the maternal age-specific incidence of Down syndrome is 33% lower than it is at 15 to 20 weeks, and it is 54% lower at birth than it is at 9 to 14 weeks.²²⁶

The significance of trisomy 21 lies in the fact that it is the single, most common genetic cause of mental retardation. Trisomy 21 is due to the addition of all or a critical portion of chromosome 21, leading to a triplicate or trisomic state. The critical zone for producing the typical phenotypic characteristics of Down syndrome appears to be 21q22.3. Studies examining the parental origins of chromosome 21 in Down syndrome have shown that 95% of cases of trisomy 21 are due to maternal nondisjunction, and only about 5% of cases contain an extra paternal 21. Ninety-five percent of individuals with trisomy 21 have three copies of chromosome 21, whereas the remaining are due to mosaicism or Robertsonian translocation (most involving chromosome 14 or 21). In general, the recurrence risk for Down syndrome is approximately 1%.

The mean survival is approximately 55 years of age, with the early mortality due to the severity of anomalies (especially cardiac). Invariably, mental retardation is present in adults, with mean IQs of 50 to 60.³⁰ Persons affected with Down syndrome also have increased risks for premature onset of Alzheimer's disease, hearing loss, strabismus, hypothyroidism, leukemia, and premature aging.

Persons with Down syndrome often exhibit characteristic clinical features, such as: short stature, redundant nuchal skin, flat and small nose, small ears, clinodactyly or curving inward of the 5th finger (midphalanx hypoplasia), Simian crease (single palmar crease), brachycephaly, flat occiput, epicanthal folds, protruding tongue, sandal gap (wide space between first and second toes), cardiac defects, ventricular dilation/hydrocephalus, and gastrointestinal abnormalities. Accordingly, with careful examination, it has been shown that many of these dysmorphic features may also be visualized on second trimester sonography (see Fig. 4-38). Therefore, this knowledge has therefore led to the development of the genetic sonogram, which is essentially a noninvasive evaluation tool for Down syndrome.

SECOND TRIMESTER GENETIC SONOGRAPHY

Over the past years, with the emergence of sophisticated and high-resolution ultrasonography, and a greater proportion of the maternal population achieving pregnancies at an advanced maternal age, the ability to screen for fetal aneuploidy and other fetal abnormalities has achieved monumental importance in the management of obstetric patients. This task can be accomplished through various testing modalities in the second trimester, such as biochemical serum marker screening as previously discussed, detailed ultrasonography, and if indicated, invasive testing. Invasive forms of testing, such as amniocentesis, chorionic villus sampling, and cordocentesis are diagnostic tests that provide almost a 100% diagnostic accuracy of the presence or absence of aneuploidy. Genetic amniocentesis testing has traditionally been offered to patients who are considered to be at high risk for fetal Down syndrome. These are women whose age at the time of delivery is at least 35 years of age have an abnormal serum marker screen, or both. Biochemical screening and ultrasonography, for the purpose of aneuploidy detection, are screening tests associated with a high number of false-positive results. Nevertheless, owing to the potential significant risks of invasive testing such as pregnancy loss, rupture of membranes, bleeding, and infection, many patients choose to undergo screening surveillance initially and then decide upon further, more invasive forms of diagnosis, if necessary.

The first method of screening for fetal Down syndrome was introduced in the early 1970s and was based on maternal age; amniocentesis was offered to women age 35 years of age or more. This is because at 35 years of age, the midtrimester risk for fetal Down syndrome approximates the risk of pregnancy loss due to amniocentesis (1/270). Over the last three decades, there has been a fundamental shift in birth trends observed, with more births occurring in women 35 years of age or older.²²⁵ Women in the group of 35 to 49 years of age made up 4.7% of live births in 1974, as compared with 12.6% in 1997.²²⁵ As a result, the prevalence of fetal Down syndrome during the second trimester has increased from 1/740 in 1974 to 1/504 in 1997. However, although maternal age is strongly correlated with the risk for fetal Down syndrome, most children with Down syndrome are actually born to women younger than 35 years, because most children are born to women in this younger age group.

A wealth of information has been published in the literature regarding the specific use of second trimester genetic ultrasonography for detecting Down syndrome prenatally by examining multiple aneuploidy markers, and it has now gained widespread use. We currently offer second trimester genetic sonography to all (and only) high-risk patients (advanced maternal age at the time of delivery, abnormal second trimester serum screening results, or abnormal first trimester screening results). Many women use the information derived from this sonogram to obtain an adjusted risk for Down syndrome to guide their decision regarding genetic amniocentesis, rather than choosing traditional, invasive testing as a first option. In fact, we have found over the years that genetic sonography has been a patient-driven service. In high-risk patients when the genetic sonogram is normal, the amniocentesis rate is only 3%.²²⁷

We have also found that the amniocentesis rate increases in direct proportion to the number of abnormal sonographic markers identified, with 100% of patients selecting invasive testing when four or more markers are seen. Since the initiation of our genetic sonography service over a 10-year period, approximately 5000 patients have avoided amniocentesis testing. If the fetal loss rate directly related to amniocentesis is estimated to be between 1/100 and 1/300, then this amounts to between 17 and 50 fetal lives saved, thus attesting to the power of normal genetic sonography.

Maternal age as a screening method may currently identify only 47% of Down syndrome cases, with a false-positive rate that has been increasing in recent years (13%–14%).²²⁵ When advanced maternal age alone is used to screen for Down syndrome, about 140 amniocenteses are needed to discover one trisomy 21 fetus,⁶ implying that one normal fetus may be lost for every two fetuses identified with DS. Although combining maternal age and second trimester serum screen identifies approximately 60% to 65% of fetuses with DS,²²⁸ this approach would still require approximately 60 to 70 amniocenteses to detect one fetus with DS.⁶ As a result, one normal fetus may be lost as a complication of amniocentesis for every three to four fetuses detected with trisomy 21. Therefore, owing to these reasons, the practice of routinely offering invasive testing to all high-risk pregnant women has been challenged.²²⁸ Genetic sonography reduces the invasive testing rate, and can optimize the selection of candidates for invasive testing in order to decrease procedure-related losses of normal fetuses without significantly decreasing detection rates. Accordingly, the genetic sonogram evolved from a patient's perspective with the purpose of possibly avoiding invasive testing, and many patients use the information derived from genetic ultrasound to guide their decision regarding amniocentesis.

Genetic sonography, which is performed in the second trimester, is a specific targeted examination for fetal aneuploidy, most specifically for trisomy 21, that searches for the presence of fetal structural anomalies, as well as other aneuploidy markers and abnormal fetal biometry.²²⁷ Ideally, it is performed between 18 and 20 weeks of gestation. Because only 25% of Down syndrome fetuses in the second trimester have sonographically detectable major anomalies,⁶ the search must involve some of the aforementioned markers in order to increase sensitivity. The sonographic aneuploidy markers that are used may include short long bones, increased nuchal fold thickness (see Figs. 4–30 and 4–31), pyelectasis (see Fig. 4–32), CPCs (see Fig. 4–37), short ear length (see Fig. 4–43), wide iliac wing angle (see Fig. 4–42), hyperechoic bowel (see Fig. 4–36), echogenic intracardiac focus (see Figs. 4–33, 4–34, and 4–35), sandal gap toes (see Fig. 4–49), hypoplastic mid-phalanx of 5th digit (see Figs. 4–47 and 4–48), clinodactyly (see Fig. 4–47), and more recently, absent nasal bone (see Figs. 4–40 and 4–41).

Each marker by itself has only a low to moderate sensitivity for Down syndrome. However, there is no question that the risk of fetal trisomy 21 increases with the number of markers present. One should also keep in mind that many of these prenatal sonographic markers, when found in isolation, may not necessarily increase the risk for aneuploidy and can commonly be seen in euploid fetuses. However, when they are found in the context of multiple other sonographic abnormalities or markers, or in high-risk patients, the risk

Abnormal test was defined as the presence of ≥ 1 abnormal ultrasound markers.

for fetal aneuploidy is increased. A meta-analysis by Smith-Bindman examined more than 50 trials dating back to 1984, and demonstrated that isolated markers (other than increased nuchal fold thickness and structural anomalies) do not have a significant prediction for fetal Down syndrome.²²⁹ However, their sensitivity for multiple (one or more) markers visualized on sonography reached 69%, with a false-positive rate of 8% for detecting Down syndrome. By combining multiple aneuploidy markers, the sensitivity for trisomy 21 can be increased to greater than 80% with false-positive rates of 10% to 15% (by defining as abnormal any ultrasound examination with at least one abnormal marker present).^{230,231} The use of multiple sonographic markers improves the sensitivity of sonography for the detection of Down syndrome, but also results in higher false-positive rates. The sensitivity of genetic sonography depends on a variety of factors, such as gestational age, indications for referral, markers examined, experience of the sonologist, and quality of the examination. Benacerraf's group in 1992 first established a sonographic scoring index for fetal aneuploidy by examining multiple markers.²³¹ Subsequently, many more studies have been published that examine the accuracy of genetic sonography for detecting fetal Down syndrome in high-risk populations (Table 4–8). By defining as abnormal the ultrasound with at least 1 abnormal marker, the overall sensitivity is 77% (50% to 93%) and the false-positive rate is 13% (7% to 17%).

In 1998, a large multicenter collaborative study involving 11 institutions (including our own) examined the sensitivity of sonography in detecting fetal Down syndrome.²⁴³ They found that 85% of Down syndrome fetuses ($n = 241$) had at least one abnormal finding on ultrasound. Recently in 2003, an eight-center study (including our own) evaluated the use of second trimester genetic sonography among high-risk pregnancies, including 176 Down syndrome fetuses.²⁴⁴ The sensitivity for Down syndrome was 72%, with a range from 64% to 80% at the various centers. Of significance, about

one half (47%) of Down syndrome fetuses had a thickened nuchal fold of 5 mm or more, making this marker the one with the highest sensitivity.

In 1996, our group was the first to publish data on using second trimester genetic sonography to guide clinical management of women at high risk for fetal Down syndrome.²³⁵ In this study, when one or more abnormal ultrasound markers were present, the sensitivity for trisomy 21 was 93%. Subsequently, once we analyzed our 1999 data, in the presence of a normal genetic ultrasound, we counseled high-risk patients that the likelihood for fetal Down syndrome was reduced by at least 80% from the a priori risk.²²⁷ Over almost a 10-year period (since November 1992) we have evaluated over 5000 fetuses by using genetic sonography; the overwhelming majority (85%) had no markers seen (normal scan), 12% had one abnormal marker present, and 3% had two or more markers present. Eighty-seven percent of fetuses with Down syndrome, 100% of fetuses with trisomy 18, 80% of fetuses with trisomy 13, and 88% of fetuses with other chromosomal abnormalities had abnormal genetic sonograms (one or more abnormal sonographic markers present). When one or more abnormal sonographic markers were present, the sensitivity, specificity, positive and negative predictive values for Down syndrome were 87%, 91%, 11% and 99.8%, respectively. Approximately two thirds of fetuses with trisomy 21 had two or more abnormal sonographic markers seen. Because the greatest sensitivity is provided by using greater than or equal to one markers present, we use this as the abnormal test because the greatest risk reduction for high-risk women will occur in this situation after a normal genetic sonogram.

Currently, at our institution, we target for many specific aneuploidy markers when performing the genetic ultrasound (Table 4-9). These include structural anomalies including cardiac, short femur, short humerus, pyelectasis, nuchal fold thickening, echogenic bowel, CPCs, hypoplastic middle phalanx of the fifth digit, sandal gap, two-vessel

umbilical cord, echogenic intracardiac focus, short tibia, short fibula, and short ear length. Recently in 2003, we have added absent fetal nasal bone to the list.

Over the years, we have found there is an ever-increasing proportion of high-risk women who prefer to have genetic sonography as the first option rather than amniocentesis (Table 4-10). In 1997, we retrospectively examined the use rates of genetic sonography from 1993 to 1996 and its role in influencing the decision for amniocentesis in women at increased risk for fetal Down syndrome.²⁴⁵ Over this time period, there was an increasing use trend found, and the most important factors associated with the patient's decision to undergo genetic amniocentesis were (relative risk [RR]; 95% CI): three or more sonographic markers present (RR 189.5; 37.1, 980.0), two sonographic markers present (RR 47.2; 9.8, 267.8), one sonographic marker present (RR 12.7; 5.5, 29.7) and abnormal serum biochemistry (RR 3.0; 1.0, 8.9).²⁴⁵ Table 4-10 shows the overall increasing use rates of genetic sonography as a first option among high-risk women and the corresponding decreases in the total number of amniocentesis procedures performed since we began offering genetic sonography services in 1993. Since 1998, more than 70% of women chose to undergo genetic sonography as a first option rather than amniocentesis. Accordingly, there has been a decrease in the number of amniocenteses performed. The total amniocentesis rate (sum of amniocentesis as first option plus amniocentesis after genetic sonography) decreased from 99.6% in 1993 to 32% in 2002. This is a 68% reduction rate in the total number of genetic amniocenteses since 1993.

Many other studies have shown that normal second trimester genetic sonography, in effect, reduces the risk for fetal Down syndrome, and therefore reduces the need for

amniocentesis in high-risk patients.^{246,248} In 2001, one group studied 1556 high-risk patients (advanced maternal age and/or abnormal triple screen) between 1993 and 1998.²⁴⁸ They found genetic ultrasound's sensitivity for Down syndrome to be 87% (27/31) with a reduction in the need for amniocentesis by 61%.

In 1999, we examined whether there were any clinically significant indication-specific variations in the accuracy of genetic sonography for trisomy 21.²⁴⁹ The indications for genetic ultrasound were grouped into four categories: (1) advanced maternal age (regardless of triple screen results), (2) abnormal triple screen results (regardless of maternal age), (3) abnormal triple screen results in women younger than 35 years of age, and (4) abnormal triple screen results in women older than 35 years of age. We found no significant indication-specific variations to be present.

In looking at updated data with a higher number of patients (Table 4–11), the likelihood of fetal trisomy 21 is reduced by 82% to 88% after a normal genetic ultrasound, depending on the indication for testing.²⁵⁰ Thus, the degree of risk adjustment after a normal genetic sonogram seems to be independent on the indication for testing, including advanced maternal age, abnormal triple screen, or some combination of the two. We have found that the sensitivity of genetic sonography ranges from 84% among women with advanced maternal age to 90% among women younger than 35 years of age having an abnormal triple screen. Again, there were no significant indication-specific variations in the accuracy of genetic sonography.

Recently, we targeted the value of genetic sonography in the specific population of women with advanced maternal age and normal triple screen.²⁵¹ Among 768 patients meeting these criteria, we found the risk for Down syndrome was 0% (0/673) with a normal genetic ultrasound, and the risk was 4.2% (4/95) when the genetic ultrasound was abnormal. There were four fetuses with Down syndrome in this population, and all had abnormal genetic sonography. The maternal triple screen risks in these four Down syndrome fetuses ranged between 1/319 and 1/833. Thus, genetic sonography may indeed increase the detection rate of fetal Down syndrome in women with advanced maternal age and moderate triple screen risks (between 1/275 and 1/1000).

Although second trimester genetic sonography has been advocated for screening the general population, it is our opinion that this should be performed and applied only to the high-risk population, for various reasons. First, considerable expertise is necessary to rule out sonographic fetal malformations (especially subtle cardiac defects) and such expertise is not widely available. Application of genetic sonography to the low-risk population may be inappropriate and even dangerous, due to the high false-positive rates of 12% to 15% in the high-risk population (which is probably higher in low-risk populations). If the presence of any one marker is considered a positive screen in the low-risk patient, the high false-positive rate will lead to considerable anxiety among these patients. In low-risk patients, the a priori risk for fetal Down syndrome may be so low that the presence of only one aneuploidy marker (for example, pyelectasis) does not usually elevate the risk enough to justify amniocentesis. Therefore, it is expected that the positive predictive value, and perhaps even the sensitivity of genetic ultrasound for fetal Down syndrome, may be decreased in the low-risk patient. It is also important to realize that the accuracy of second trimester aneuploidy markers has been mainly studied in high-risk populations and extrapolation of such accuracy to the low-risk patient is not appropriate. In the low-risk population, isolated markers (other than increased nuchal fold thickness, absent nasal bone, or structural anomalies) should not be used as an indication for amniocentesis testing. However, often one may incidentally discover one or more abnormal sonographic markers in the low-risk population. Figure 4–58 reveals the algorithm that we follow at our institution as a clinical practice guideline. It is vital to remember that because the sensitivity of an isolated marker (with the possible exception of increased nuchal fold thickness or absent nasal bone) is so low, clinicians should not recommend amniocentesis in low-risk patients.²⁵² All sonographic abnormalities involving a major organ/structural anomalies (with a few exceptions), thickened nuchal fold, absent nasal bone, or the presence of two or more aneuploidy markers (or minor structural abnormalities) indicate a high risk for fetal aneuploidy, and invasive testing should be offered, even in the low-risk patient. Certain isolated sonographic fetal abnormalities (for example, gastroschisis) that

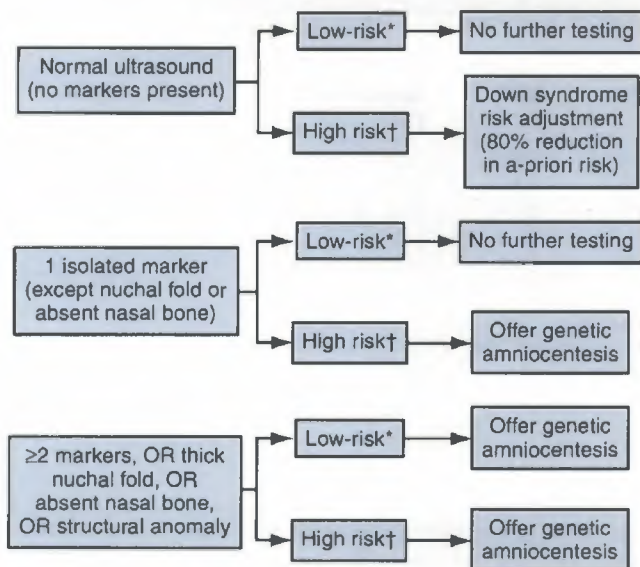

SECOND TRIMESTER ULTRASOUND MARKERS
PRACTICE GUIDELINES

FIGURE 4-58. Algorithm for clinical management based on the results of second trimester ultrasound (presence or absence of sonographic markers). Maternal age younger than 35 years of age, serum screen result less than 1/274, or both (*asterisk*). Maternal age 35 years of age and older, serum screen result 1/274 and greater, or both (*dagger*). are not usually associated with aneuploidy may not require further invasive testing.

In high-risk patients, we use genetic sonography as an adjunct to maternal age and serum screening to adjust the risk for fetal Down syndrome for each individual patient, based on our accuracy. The a priori risk may be based on first trimester combined screening, triple/quadruple screen, or on maternal age (if first or second trimester screen results are not available or were not performed). We then multiply the a priori risk with the negative likelihood ratio, if the examination is normal. For instance, if the risk for fetal Down syndrome by maternal age is 1/274 and the genetic scan is normal, the new adjusted risk for fetal Down syndrome will be 1/274 times 0.20 (or 1/1370) (at least 80% reduction). If only one marker is present (except structural anomaly, thick nuchal fold, or absent nasal bone), we recommend invasive testing only if the patient is high risk. On the other hand, once two or more markers are visualized, we offer invasive testing, regardless of risk status. One should keep in mind and counsel patients that the genetic scan can never reduce their risk of having a Down syndrome fetus to 0%. Either a triple or quadruple screen is acceptable as an a priori risk because most of our findings are based on high-risk patients who underwent serum testing.

We believe that in high-risk patients, a normal ultrasound can *reduce* considerably the risk of Down syndrome. Hobbins et al²⁵² supported the position that the most important application of genetic sonography is that when it is normal, it diminishes the possibility of Down syndrome, and consequently, reduces the number of invasive procedures in

Table 4-12 Likelihood Ratios of Isolated Markers in Four Large Studies

From Benacerraf BR: The role of the second trimester genetic sonogram in screening for fetal Down syndrome. *Semin Perinatol* 29:391, 2005.

high-risk patients. The degree of risk reduction depends on several factors, such as the criteria and number of aneuploidy markers sought, and the sensitivity of the ultrasound. Most recent studies use a negative likelihood ratio ranging somewhere between 0.2 to 0.4 after a normal genetic sonogram, corresponding to a 60% to 80% reduction in risk.

Other centers have used a scoring index system to optimize the clinical management of sonographic markers.²⁵³ The main advantage of this particular method is the ease of use and comprehension. This index is based on the assumption that individual aneuploidy markers are not equally important. In this system, two points are given when structural abnormalities or nuchal thickening is identified, although one point is given for other markers. For those patients having a score of two or more, amniocentesis is then offered. By using a score of two or more, it allowed the authors to detect 81% of fetuses with Down syndrome, with a 4.4% false-positive rate.²⁵¹ Subsequently, the scoring index system was modified to incorporate maternal age, by giving one point for age older than or equal to 35 years of age, and two points for age older than or equal to 40 years of age.²⁵⁴ The authors emphasize that the single most clinically important use of second trimester genetic sonography lies in the risk reduction that is conferred by a normal sonogram (0 score), because it allows the opportunity for many high-risk women to avoid amniocentesis.

Another method which has been used is to integrate the risk of sonographic markers with the a priori risk based on maternal age.²⁵⁵ This is called age-adjusted ultrasound risk adjustment (AAURA) for fetal Down syndrome and are used for women of *all* ages. In using this method, sonographic markers are "weighted" by the strength of individual findings, expressed as likelihood ratios. The authors base the individual risk assessment of fetal Down syndrome on maternal age and the presence or absence of each of the ultrasound markers in terms of likelihood ratios. Likelihood ratios of isolated markers have been reported in several studies (Table 4-12). By using likelihood ratios, the post priori risk is then estimated. We do not use these likelihood ratios because in our experience, the overwhelming majority of trisomy 21 fetuses have multiple markers in combination, not in isolation. Therefore, we have been unable to generate stable and reliable positive likelihood ratios of isolated markers. Yet, some investigators are using AAURA, and

report that both the sensitivity of fetal Down syndrome detection and the false-positive rate increase with maternal age. This is believed to be appropriate because older women desire a high sensitivity, and the alternative clinically is amniocentesis for all women age 35 years or older (100% false-positive rate).³⁰ At the same time, AAURA also minimizes the false-positive rate for younger women (4% false-positive rate) with a satisfactory sensitivity (61.5%).³⁰ The authors also believe that because sonographic findings are largely independent of both maternal age and biochemical analytes, the risk from biochemical screening (serum markers plus maternal age risk) can be substituted for maternal age risk alone, when known.³⁰

It is imperative that every center that performs genetic sonography monitor its sensitivity in detecting fetal Down syndrome in order to provide patients accurate, detailed, and updated counseling regarding their degree of risk reduction when the scan is normal. We continuously monitor our accuracy in detecting fetal Down syndrome in high-risk women. We and other investigators believe that risk adjustment for Down syndrome is institution-specific and that data may not apply to other centers.²⁵⁶ Some believe also that the use of genetic sonography should be limited to specialized centers.²⁵⁷

Another issue to address is whether second trimester genetic sonography is cost effective. We recently analyzed the cost between universal amniocentesis and genetic sonography and found that genetic sonography was cost effective if the sensitivity for detecting Down syndrome was greater than 74%.²⁵⁸ We also found that genetic sonography resulted in savings to the health care system of 9%, and decreased the loss rate of normal fetuses following amniocentesis by 87%.²⁵⁸ Genetic sonography is also cost effective in women younger than 35 years of age who are at moderate risk for Down syndrome based on triple screen results, as well as in advanced maternal age patients, who decline amniocentesis after second trimester genetic counseling.²⁵⁹ Offering genetic sonography to these patients is associated with cost savings for most acceptable genetic ultrasound accuracies. Finally, recent data indicate that combining second trimester genetic sonography with traditional serum markers may significantly improve the diagnostic accuracy of Down syndrome fetuses.²⁶⁰ Various integrated algorithms combining serum analytes and sonographic markers have been generated (for example, nuchal thickness, humerus length, serum AFP, hCG). However, these algorithms have not been prospectively validated.

TRISOMY 18 (EDWARDS SYNDROME)

Trisomy 18 (Edwards syndrome, or trisomy E) occurs in approximately 1/8000 births. Trisomy 18 is much more common at conception because 95% of these cases result in spontaneous abortion or stillbirth. Trisomy 18 is the second most common autosomal trisomy and has a uniformly dismal prognosis. Intrauterine demise is common, and it is estimated that of those fetuses alive at 16 weeks, 50% to 90% do not survive to live birth.²⁶¹ Survival postnatally is very poor, with the majority dying in early infancy. Those who survive are profoundly mentally and physically retarded, and common problems include failure to thrive, hypotonia, and feeding difficulties.

Pregnancies affected with fetal trisomy 18 have a characteristic pattern on biochemical maternal serum screening in the second trimester. All three serum markers are lower than normal, with median values as follows: AFP, 0.6 MoM; unconjugated estriol, 0.5 MoM; and hCG, 0.3 MoM. The triple marker screen can identify approximately 60% to 75% of fetuses with trisomy 18 when a separate analysis is performed that seeks low levels of all three analytes, with or without consideration of maternal age.^{262,263} However, because of the low prevalence of trisomy 18, ultrasound is still recommended following a positive screen for trisomy 18. One study suggested that ultrasound was superior to biochemistry in detecting trisomy 18, although both tests identified affected fetuses missed by the other.²⁶⁴

It is well established that those affected with trisomy 18 have many major structural anomalies. In fact, more than 100 different abnormalities involving virtually every organ system has been noted in association with trisomy 18.²⁶⁵ Neonates with trisomy 18 have many characteristic clinical features, such as cardiac defects, growth restriction, prominent occiput, small mouth, micrognathia, low and pointed ears, mental retardation, clenched hands with overlapping fingers, short sternum, and rocker-bottom feet. Overlapping of fingers most frequently occurs with the index finger overlapping the middle finger, and the 5th finger curving inward. As a result, there is a multitude of sonographic abnormalities/malformations that can be visualized prenatally (see Table 4-2). These include cystic hygroma, cardiac defects, omphalocele, extremity abnormalities, craniofacial defects, spina bifida, diaphragmatic hernia, genitourinary abnormalities, amniotic fluid abnormalities, CPCs, single umbilical artery, umbilical cord cysts and short ear length. An important point is that trisomy 18 fetuses can show an onset of intrauterine growth restriction as early as the second or even first trimester. By the third trimester, almost all are significantly growth restricted; unfortunately, some fetuses with trisomy 18 are delivered by cesarean section before any discovery or knowledge of aneuploidy.²⁶⁶ Nyberg found that intrauterine growth restriction was present in one half of the fetuses less than 24 weeks gestation, and in 89% of those greater than 24 weeks' gestation.³ When growth restriction, polyhydramnios, and abnormal hand posturing is visualized, this is highly predictive of trisomy 18 in the third trimester.

Sonography has been shown to have variable but high sensitivity in detecting trisomy 18 (64% to 100%) (Table 4-13), particularly when performing a thorough, anatomic survey. One group found 100% sensitivity of ultrasonography to detect fetuses with trisomy 18; however, this was not restricted to fetal structural anomalies, but also included abnormal measurements.²⁶⁸ In a sample of 15 fetuses with trisomy 18, Benacerraf et al²⁶⁸ found that 80% had one or more sonographic abnormalities (range 0-5). Three of the fetuses had no sonographic findings at all; however, these examinations were performed between 16 and 17 weeks. In examining fetuses with trisomy 18 during the early second trimester only, Shields et al²⁷⁰ found that most, but not all (86%) fetuses had one or more detected abnormalities on ultrasound, with the mean number of abnormalities per fetus being three (range zero to six). In 1993, Nyberg found that when excluding CPCs, 83% (39/47) of fetuses with trisomy 18 had more than one ultrasound abnormalities (range zero to six) identified.³ DeVore²⁷ found

Table 4-13 Sensitivity of Prenatal Sonography in Fetuses with Trisomy 18

Author/Year	Number	Gestational Age in Weeks (Range)*	Sensitivity of U/S in Detecting Trisomy 18	Most Common U/S Abnormality
Bundy 1986 ²⁶⁷	12	18 (12-40)	75%	IUGR (42%)
Benacerraf 1988 ²⁰⁸	15	22.7 ± 7.9 (15-35)	80%	Abnormal hands or feet (73%)
Benacerraf 1990 ¹²⁶	26	19.4 ± 7.0 (13.5-36)	77%	Abnormal hands (38%) Clubfeet (38%)
Nyberg 1993 ³	47	14-24 weeks (29 fetuses) >24 weeks (18 fetuses)	83%	IUGR (51%)
Scoud 1994 ²⁶⁸	12	22.1 ± 5.3	100%†	Flexion hands (70%) Clubfeet or rocker bottom feet (70%)
Salihu 1997 ²⁶⁹	11	≤24 weeks (7 fetuses) >24 weeks (4 fetuses)	64%	Polyhydramnios (36%)
Shields 1998 ²⁷⁰	35	17.5 ± 2.0 (14-22)	86%	Abnormal position fingers (89%)
DeVore 2000 ²⁷	30	17.5 ± 1.5 (14-23)	97%	Structural cardiac defects (80%)
Feuchtbaum 2000 ²⁷¹	23	N/A	65%	CPC (43%)
	142	N/A	66%	N/A
Brumfield 2000 ²⁶⁴	30	14-22	70%	CPC (43%)
Yeo 2003 ⁴	38	20.1 (14.6-36.3)	100%	Shortened ear length < 10th percentile (96%)

CPC, choroid plexus cyst; IUGR, intrauterine growth restriction; N/A, not available; U/S, ultrasound.

*Mean + standard deviation or median given when available

†However, also includes >1 abnormal measurements; not just structural anomalies

that of 30 fetuses with trisomy 18 between 14 to 23 weeks, ultrasound had a very high sensitivity of 97%. The most frequent sonographic abnormality was structural cardiac defects (80%). Others have found a lower sensitivity of ultrasound in detecting trisomy 18.²⁷¹ In this study, ultrasound was reportedly normal in 35% of 23 affected fetuses with trisomy 18.

In a recent study, we found that by performing a complete sonographic survey, all trisomy 18 fetuses had four or more sonographic anomalies (one patient had 19 individual fetal anomalies).⁴ We found that the sonographic presence of short ear length (96%), bilateral clenched or closed hands or overlapping digits (95%), and central nervous abnormalities (87%) were the most sensitive markers for fetal trisomy 18. We also found that 92% of trisomy 18 fetuses had at least two of four minor sonographic abnormalities (upper extremities/hands, lower extremities/feet, face, ear).⁴ This fact emphasizes the importance of thorough prenatal sonographic examination of fetuses, with attention to fine detail in addition to examination of all organ systems after 18 weeks gestation.

For those fetuses at risk for fetal trisomy 18, a complete and detailed prenatal sonogram is indicated. Being aware of the types of malformations that are associated with this aneuploidy is imperative in order to target the sonographic examination appropriately. Similarly to the concept of genetic sonography in screening for fetal Down syndrome, we believe that normal findings from a complete anatomic survey in experienced hands should "decrease" a patient's risk of trisomy 18 (regardless of the presence/absence of CPC or abnormal serum screen results) to an extremely low level sufficient to avoid genetic amniocentesis after appropriate patient counseling.⁴ On the other hand, when sono-

graphic findings are visualized that are consistent with trisomy 18, fetal karyotyping should be offered, along with appropriate counseling.

As with trisomy 13, there is little information regarding the recurrence risk for trisomy 18. In general, an empiric risk of approximately 1% is usually given to patients.²⁷²

TRISOMY 13 (PATAU SYNDROME)

Trisomy 13 and its congenital abnormalities was first described by Patau in 1960.²⁶⁵ The birth prevalence is estimated at between 1/5000 and 1/20,000 births.²⁷³ It accounts for approximately 1% of spontaneous first trimester miscarriages and has an extremely poor prognosis. Most children with this chromosomal abnormality die in infancy; the median survival is 2.5 days.²⁶⁵ Of newborns with trisomy 13, 82% die in the first month and only 5% survive the first 6 months.²⁶⁵ Survivors have severe mental defects, often have seizures, apnea, feeding difficulties, and failure to thrive. The phenotype is often so characteristic that a diagnosis can be made frequently based on clinical features alone. The features include microcephaly, serious central nervous system abnormalities (such as abnormal posterior fossa, ventriculomegaly, agenesis of corpus callosum), cardiac defects (> 80%), growth restriction, receding forehead, ocular anomalies, cleft lip and palate (60% to 70%), limb deficiencies, rocker-bottom feet or clubfeet, clenched hands with overlapping digits, postaxial polydactyly (75%), omphalocele, and renal abnormalities (such as polycystic kidneys). In particular, alobar holoprosencephaly is a common finding that is often associated with severe midline facial defects, such as midline clefts, microphthalmia, hypotelorism, cyclopia, and absence of the nose.

Table 4-14 Sensitivity of Prenatal Sonography in Fetuses with Trisomy 13

Author/Year	N	Gestational Age (Weeks)	Sensitivity of U/S in Detecting Trisomy 13	Most Common U/S Abnormalities
Nicolaides 1992 ²⁷⁴	31	15-39	100%	Abnormal extremities 68% Renal 65% Facial cleft 48% Growth restriction 48% Cardiac 45% Holoprosencephaly 35%
Lehman 199 ⁵⁵	33	12-32	91%	Central nervous system 58% Cardiac 48% Facial 48% Growth restriction 48% Holoprosencephaly 39% Renal 33% Extremity 33% Echogenic intracardiac foci 30%
DeVigan 2001 ²⁷⁶	85	All gestational ages	68.2%	Cardiac 20% Cleft 18% Holoprosencephaly 18% Holoprosencephaly 47% Hypotelorism/cyclopia 40% Abnormal hands/feet 40% Facial cleft 33% Cardiac 33%
Tongsong 2002 ²⁷⁵	15	16-22	93%	Central nervous system 64% Facial 64% Cardiac 54% Renal 43%
Papp 2006 ²⁷⁷	28	13-25	89.3%	

U/S, ultrasound.

Because fetuses with trisomy 13 have severe abnormalities, the sensitivity of prenatal sonography for the detection of this aneuploidy is very high (Table 4-14), with most studies reporting sensitivities greater than 90%.^{5,274,275} One large study examining data from 11 European countries reported a sensitivity of only 68.2% in 85 cases of trisomy 13.²⁷⁶ However, the study focused on the detection of major malformations because not all registries recorded soft markers. In addition, the study was performed via routine scanning, and the authors believed that when detailed scanning is undertaken, the performance would be better.²⁷⁶ In order to achieve a high degree of sensitivity, a detailed and systematic sonographic survey should be performed. Characteristic features of trisomy 13 that can be visualized on prenatal sonography are described in Table 4-3. In one of the largest series of 33 fetuses with trisomy 13, one or more prenatal sonographic findings were found in 91% overall.⁵ Some of the most common findings included central nervous system anomalies (58%), cardiac defects (48%), facial anomalies (48%), growth restriction (48%), holoprosencephaly (39%), renal abnormalities (33%) (Fig. 4-59), and extremity abnormalities (33%). Importantly, EIF, which is an aneuploidy marker, were also seen in 30% of cases.

It is important to distinguish trisomy 13 from Meckel-Gruber syndrome, which is an autosomal-recessive disorder that shares some common characteristic features with trisomy 13. This has implications in counseling because this autosomal-recessive disorder, unlike trisomy 13, has a 25% recurrence risk. Meckel-Gruber syndrome is characterized by polycystic kidneys, polydactyly, midline central nervous

FIGURE 4-59. Coronal view of the fetal abdomen showing bilateral echogenic kidneys.

system malformations (such as occipital encephalocele, Dandy-Walker malformation), and other features.

There is little information regarding the recurrence risk for trisomy 13. In general, an empiric risk of approximately 1% is usually given to patients.²⁷²

CONCLUSION

At present, there is no uniformity in population-based screening for fetal Down syndrome in the United States.

There are many variations, including first trimester screening and/or second trimester serum markers. Regardless of the method used, high sensitivity is important for those women who are high risk, although low false-positive rates are most desirable among low-risk women. Genetic sonography has enabled us to detect fetal aneuploidy, and also diagnose many fetal congenital anomalies in all trimesters of pregnancy. We have come a long way with regard to the potential options that high-risk patients can be given. According to many pregnant women, advanced maternal age alone or abnormal maternal serum screening alone may no longer be indications for invasive testing, and it is clear that for such patients, prenatal sonography is of paramount importance. With the emergence of first trimester screening (both ultrasound and serum), this will also add additional information that in the future may be incorporated into genetic sonography to give individualized risks for Down syndrome to patients. The most appropriate application of genetic sonography pertains to those high-risk women who seek reassurance, and, therefore, risk reduction by a normal genetic sonogram. The power of normal genetic sonography lies in its ability to save fetal lives by avoiding many unnecessary amniocentesis procedures. We have found that although many clinicians may refer patients for genetic sonography, in our experience, it has been over the years mainly a patient-driven service. There are many women who will no longer undergo amniocentesis automatically as a first option, but rather, will choose to use the information from genetic sonography to help guide their decision about invasive testing.

Wolf-Hirschhorn Syndrome

Congenital anomalies are typically organized by organ system. This is an excellent organization in that similar disorders are grouped together. However, multisystem syndromes do not fit neatly in the organ category organization.

Usually, the most striking finding or the most unusual finding is the one that leads to the inclusion in one or another group. Yet with the more precise information that one can now acquire, it is time to organize syndromes as a separate subject.

Congenital anomalies, which represent structural abnormalities of the developing embryo or fetus, are often classified into four different types: (1) malformation, (2) deformation, (3) disruption, and (4) dysplasia.

Malformation. A morphologic defect of an organ, part of an organ, or larger region of the body that results from an intrinsically abnormal developmental process. The term intrinsic implies that the developmental potential of the primordium or anlage is abnormal from the beginning. Malformations may be single or multiple.

Deformation. Deformation refers to an abnormal form, shape, or position of part of the body caused by mechanical forces antenatally, often as a result of intrauterine molding or constraint. The forces that cause deformations may be extrinsic, such as uterine abnormalities, or intrinsic factors, such as oligohydramnios.

Disruption. A morphologic defect of an organ, part of an organ, or larger region of the body resulting from the breakdown of previously normal tissue. It is caused by an extrinsic force or internal interference with a developmental process or a vascular insult. Extrinsic factors such as infection, teratogen, or trauma are considered disruptive. Intrauterine vascular accidents are a major cause of disruptions.

Dysplasia. An abnormal organization of cells into tissues and its morphologic results. Dysplasia is the process and consequence of abnormal tissue formation. It is casually nonspecific and often affects several organs because of the nature of the underlying cellular disturbances.

When more than one fetal abnormality is identified, several terms are used to describe the causation and pathogenesis.

Sequence. A pattern of multiple anomalies that results from a single anomaly or mechanical factor. Also referred to as an anomalad. The resultant secondary problems may be due to a malformation, disruption, or deformation.

Association. A nonrandom occurrence in two or more individuals of multiple anomalies not known to be a sequence or syndrome.

Syndrome. A pattern of multiple anomalies thought to be pathogenetically related and not known to represent a single sequence.

In the following pages we review several syndromes that should be familiar to sonographers and sonologists either because they are fairly characteristic or common, or because their recognition will affect the management of the pregnancy. The selection of the syndromes included is somewhat artificial, but all can be detected prenatally or will affect the pregnancy. Clearly, this review cannot be exhaustive. The Birth Defect Encyclopedia contained approximately 2000 syndromes, and the Online Mendelian Inheritance in Man (OMIM) recently passed the 10,000-syndrome landmark. Even for physicians dedicated to the subject, this is an unmanageable amount of information to grasp. Rather than attempt to read (let alone memorize) such a large body of knowledge, it is more important to learn how to investigate unusual cases. What are the most noticeable and major of findings? And almost as important, what are the minor or more subtle findings? Once the observations are made, is

there other clinical information of importance? Before rushing to do an amniocentesis, some review of the large database is usually indicated to suggest differential diagnoses and further tests (call the laboratory to see what test tube they want). The London Dysmorphology Database used to be the standard, but OMIM is clearly the easier one to use presently. Even Medline, with the use of Boolean operators (advanced search) is an excellent tool to identify rare conditions. These tools should be readily available.

Another aspect of the prenatal diagnosis of syndrome that must be kept in mind is the progress of molecular genetics. Since the recognition of the disorders of the fibroblast growth receptor factor (FGFR), the classification of the skeletal dysplasias (see Achondroplasia later) has been completely reorganized. These sources should be consulted because it is likely that a genetic or a biochemical test (see Smith-Lemli-Opitz syndrome later) can be made for these disorders that will establish the diagnosis with certainty.

Finally an important aspect of the prenatal diagnosis is the assistance to the parents in making management decisions. This is best done by providing them with contacts with support groups, and here again the Internet has revolutionized the communication between parents formally isolated in small pocket all around the world. A good resource is **NORD (National Organization for Rare Disorders)**, but often a good search with an internet search engine will identify many more sites of interest.

Over the last 5 years, the function of the sonologist has changed significantly from simply identifying some findings to being much more proactive in the making of the differential diagnosis and the establishment of management plans. Often, the sonologist is the first one to identify the disorder, and is the one to establish contacts with the genetics department, dysmorphology specialists, and various cardiologists and surgeons. The ability to provide clear directions to the parents is important, and in this time of turmoil for the family, being the reference point to which they can come back is important. We routinely provide searches and references to our patients and attempt to identify support group so they can get the other parent's information, which is often more realistic than the information provided within the health care system.

ACHONDROGENESIS

Definition. This group of lethal neonatal chondrodysplasia with short-limb dysplasia contains several entities.

Synonyms. Type IA is the Houston-Harris type; type IB is the Parenti-Fraccaro type; and type II is the Langer-Saldino type and is also called chondrogenesis imperfecta, achondrogenesis-hypochondrogenesis type II, and was the type IB achondrogenesis. There are two less common types, III and IV. Types II and IV were isolated by Whiteley and Gorlin on femoral measurement. The validity of these two last types is questioned, with type III probably representing type II and type IV probably representing hypochondrogenesis. These essentially radiologic categories have been modified several times and are being replaced by genetic classification (see later) and thus are mainly of historical interest.

Prevalence. Rare, with probably less than 100 cases reported. Birth prevalence is 0.9 to 0.23 per 10,000 births.

Etiology. Autosomal recessive (type IB) and dominant (type II).

FIGURE 5-1. Achondrogenesis. Almost absent mineralization of the spine (note the spinal cord).

FIGURE 5-2. The appearance of transparent bones in which both cortices can be seen.

Diagnosis. Type I achondrogenesis is a severe chondrodystrophy characterized radiographically by poor ossification of the spine and pelvic bones, which results in stillbirth or early death. The ultrasound manifestation includes very short limbs and short thin ribs that may have fractures. The short ribs are responsible for the lethal pulmonary hypoplasia and the polyhydramnios from esophageal compression. The abnormal mineralization may or may not be manifested sonographically as bones that are either very echogenic, or in which both cortical can be imaged. Normally, only the proximal cortical side is imaged and the distal side is shadowed by the proximal side. Type II also presents with the same findings but the mineralization deficit is less severe.

FIGURE 5-3. Micromelia with the arms not joining in front of the chest.

FIGURE 5-4. Achondrogenesis. The appearance of the fetus at 19 weeks.

and the long bones less short. Two cases of large cystic hygromas in association with achondrogenesis have been reported.

Genetic Anomalies. Type IA: unknown. Type IB: mutation in the gene for diastrophic dysplasia sulfate transporter gene (*DTDST*) on the long arm (locus 32–33) of chromosome 5. The diastrophic dysplasia sulfate transporter gene is recessively transmitted and is an allele of the diastrophic dysplasia gene. This is important because the type II (see below) is an autosomal-dominant mutation (and thus involves a new mutation for each case since the disease is lethal) and, therefore, has a much lower likelihood of recurrence than the 25% risk of the type IB. The diagnosis can be made by chorionic villus sampling in at-risk couples. Type II achondrogenesis is the Langer-Saldino type and is caused by new dominant mutation in the type II collagen gene (*COL2A1* gene) on chromosome 12. Therefore, it is more related to hypochondroplasia, spondyloepiphyseal dysplasia, and the Kniest-Stückler syndrome. These may be allelic variants, with hypochondroplasia related to achondrogenesis as hypochondroplasia is related to achondroplasia.

Differential Diagnosis. Osteogenesis imperfecta (type II and occasionally type IIIc) and hypophosphatasia also

present with demineralization, but the limb shortening is not usually as severe. Abnormal mineralization and shortened trunk length distinguish it from thanatophoric dysplasia in which these are normal.

Prognosis. Lethal.

Management. Termination of pregnancy can be offered before viability. Standard prenatal care is not altered when continuation of the pregnancy is opted for. Confirmation of diagnosis after birth is important for genetic counseling.

ACHONDROPLASIA

Definition. Rhizomelic micromelia associated with frontal bossing and low nasal bridge.

Synonyms. None.

Prevalence. Common: 0.5 to 1.5:10,000

Etiology. Defective cartilaginous molding of the bone precursor.

Diagnosis. This skeletal dysplasia may manifest as homozygous and heterozygous achondroplasia. Patel and Filly have described the methodology for distinguishing the two genetic manifestations of this dysplasia. Their results indicated that those fetuses with femoral lengths that are below the 3rd percentile standard compared with the biparietal diameter (BPD) at 17.0 weeks BPD age and that demonstrate progressive shortening at 20.0 and 23.0 weeks BPD age have homozygous achondroplasia, whereas those fetuses in whom a decrease in femoral length is seen at 17.0 to 23.0 weeks BPD age have heterozygous achondroplasia. In addition, fetuses with heterozygous achondroplasia are expected, and those with homozygous achondroplasia are

not expected, to have a femoral length that exceeds 34 mm at 26.0 weeks BPD age. Fetuses with normal interval growth in femoral length during the second trimester are expected to be unaffected, and an ultrasound scan obtained after 26.0 weeks should help confirm this prediction. The frontal bossing and depressed nasal bridge can also be recognized. Occasionally more subtle anomalies such as the trident hand (an increased interspace between the third and fourth digit) or the lack of widening of the lumbar canal can also be identified.

Genetic Anomalies. Achondroplasia is an autosomal-dominant skeletal dysplasia caused by mutation in the

FIGURE 5-5. Short femur in a patient with homozygous achondroplasia.

FIGURE 5-6. Achondroplasia. Frontal bossing.

FIGURE 5-7. Achondroplasia. Lack of widening of the spinal canal.

fibroblast growth factor receptor-3 gene, which is located on the short arm of chromosome 4 at the 16.3 locus. Bellus has demonstrated that the anomaly was due to a glycine to arginine substitution at codon 380. These papers are landmarks in our knowledge about skeletal dysplasias. Before these papers, skeletal dysplasias were almost strictly classified by radiologic criteria. These papers marked the beginning of an intense and successful search for gene mapping of skeletal dysplasia, many of which were subsequently recognized to result from alterations of the fibroblast growth factors (I–III).

Differential Diagnosis. The differential diagnosis is with multiple conditions, such as

- Thanatophoric dysplasia (narrower chest, platyspondyly, more severe micromelia, no trident hand, more severe polyhydramnios).
- Achondrogenesis (very poor mineralization, with lack of echogenicity of the bones, more severe micromelia, and more severe polyhydramnios).
- Osteogenesis imperfecta type II (poor mineralization (often the proximal aspect of the brain is well seen through the “transparent” skull), variable micromelia, sometimes visible bone angulations from fractures, bell-shaped chest).

AICARDI SYNDROME

Definition. Neurodegenerative disorder was first described in 1965, including cerebral atrophy, intracerebral calcification of the basal ganglia, a chronic cerebrospinal fluid lymphocytosis, and negative serologic investigations for common prenatal infections. It is associated with a developmental arrest, agenesis of the corpus callosum, chorioretinal lacunae, infantile spasm, and physical handicaps.

Synonyms. None

Incidence. More than 100 cases reported.

Etiology. Autosomal-recessive inheritance or possibly an X-linked dominant disorder that occurs de novo in women, and it is lethal in the hemizygous man. It is genetically heterogeneous, with almost 50% of families mapping to the first known locus at 3p21 (AGS1). Another linkage to a

- Diastrophic dysplasias in which the micromelia is associated with joint contractures, in particular, abnormal finger and toe positions.

Prognosis. Children with achondroplasia have normal intellectual achievements. The major problems are orthopedic (narrow spinal canal and foramen magnum). There is a vibrant support group (The Little People of America) that is very active in resolving the problems of affected individuals.

Management. Although termination of pregnancy can be offered before viability, the majority of these children adapt well in society and lead productive lives.

second AGS locus (AGS2) at chromosome 13q14-21 exists, as well as at least one further locus.

Pathogenesis.

May result from a perturbation of interferon-alpha metabolism.

Sonographic Findings.

Micro-ophthalmia, choroid plexus cysts, choroid plexus papilloma, Dandy Walker malformation, and dysgenesis of the corpus callosum can be recognized prenatally. Agenesis of the corpus callosum is complete in 72% and partial in 28% of the cases. Infrequently, this syndrome has been associated with cleft lip and palate.

Implications for Targeted Examinations

- Cerebral anomalies (like calcifications, cerebral cyst, and a high-riding third ventricle characteristic of agenesis of

the corpus callosum) with ultrasound and cerebral magnetic resonance imaging.

- Female fetus.
- Investigate the possibility of parental consanguinity.
- Increase of interferon-alpha level in the fetal blood and cerebrospinal fluid.
- Exclude an infectious etiology.
- Assess the newborn shortly after birth.

Differential Diagnosis. Dysgenesis of the corpus callosum.

Prognosis. Poor, with most infants dying during the first few years. Those that survive are profoundly mentally retarded later.

Recurrence Risk. It is sporadic in nature and affects only female fetuses.

ALAGILLE SYNDROME

Definition. This is a disorder characterized by the association of biliary hypoplasia (manifesting as neonatal cholestasis), pulmonary stenosis, vertebral abnormalities, characteristic facies, ocular and cardiovascular anomalies.

Synonyms. Alagille-Watson syndrome, cholestasis with peripheral pulmonary stenosis, arteriohepatic dysplasia, hepatic ductular hypoplasia, jagged I syndrome.

Etiology.

This is a multisystem autosomal dominant disorder with variable penetrance. The *JAG1* gene on chromosome 20p12.1-p11.23 is currently the only gene known to be implicated in Alagille syndrome.

Sonographic Findings. Fetal sonography can reveal facial alterations such as a broad forehead, pointed mandible, and bulbous tip of the nose; cardiac and vascular anomalies such as pulmonary valvular stenosis, peripheral arterial stenosis; skeletal abnormalities such as abnormal vertebrae ("butterfly" vertebrae), a decrease in interpediculate distance in the lumbar spine and in the fingers, varying degrees of foreshortening, and progressive severe intrauterine growth restriction.

Differential Diagnosis. Cystic kidney disorders associated with cholestatic liver disease and all the familial intrahepatic

Management. Termination of pregnancy can be offered before viability. Standard prenatal care is not altered when continuation of the pregnancy is opted for. Confirmation of diagnosis after birth is important for genetic counseling.

cholestasis: Zellweger syndrome, cholestasis-lymphedema syndrome, Byler disease, and cholestasis with defective formation of cholic acid. Alpha-1-antitrypsin deficiency may present as neonatal cholestasis with a paucity of intrahepatic bile ducts.

Associated Anomalies. It is frequently associated with growth failure, attributed to concurrent congenital anomalies, cholestasis, malabsorption or malnutrition, renal abnormalities, and also unilateral cystic kidney disease with or without renal dysplasia.

Prognosis. The vascular anomalies such as basilar artery aneurysms, internal carotid artery anomalies, middle cerebral artery aneurysm, aortic aneurysms and coarctations, internal carotid artery anomaly, and renal artery stenosis are the major cause of morbidity and mortality in the affected children. They account for 34% of the mortality because of the elevated risk of intracranial bleeding. Absent deep tendon reflexes are frequent in the infants as well as elevated

transaminases and alkaline phosphatase, posterior embryotoxon in the eye examination, generalized xanthomas, including oral xanthomas, and marked hypodontia. The degree of biliary hypoplasia is variable. Some patients may have severe cholestasis, progress to cirrhosis, and require liver transplantation.

Management. This disorder should be suspected in all the infants with cholestasis. It is important to evaluate the newborn also with a renal ultrasound examination.

AMNIOTIC BAND SYNDROME

Definition. Amniotic band syndrome is a set of congenital malformations ranging from minor constriction rings and lymphedema of the digits to complex, bizarre multiple congenital anomalies that are attributed to amniotic bands that stick, entangle, and disrupt fetal parts.

Synonyms. ADAM complex (amniotic deformities, adhesion, mutilation), amniotic band sequence, amniotic disruption complex, annular grooves, congenital amputation, congenital constricting bands, Streeter's bands, transverse terminal defects of limb, aberrant tissue bands, amniochorionic mesoblastic fibrous strings, amniotic bands.

Prevalence. The prevalence is 7.7/10,000 live births, but it can be as high as 178/10,000 for spontaneous abortions. The male-to-female ratio is 1:1.

Etiology. Not precisely known. Some theories have been suggested teratogenic, multifactorial, and genetic factors that cause a rupture of the amnion. Teratogenic effect of drugs such as methadone and lysergic acid diethylamide may play an important role in many cases.

Pathogenesis. Rupture of the amnion in early pregnancy leads to entrapment of fetal structures by "sticky" mesodermic bands that originate from the chorionic side of the amnion, followed by disruption. It has been suggested that the bands lead to a decreased blood flow in the constricted limb and subsequent natural amputation. This exogenous mechanistic theory does not explain several features of this syndrome, such as why there are reported cases of amniotic band syndrome with histologically normal and intact amniotic lining; why internal abnormalities such as holoprosencephaly,

FIGURE 5-10. Pathophysiology of amniotic band syndrome. Amniotic band wrapping around the extremity and head resulting in nonembryologic abnormalities such as amputation of the distal limb and a noncentral encephalocele. (Illustration by James A. Cooper, MD, San Diego, CA.)

FIGURE 5-11. Amniotic band attached to the fetal head. (Courtesy, Vicente Ruiz, 2005, *thefetus.net*.)

cerebellar dysplasia, heterotopia, cardiac, and renal abnormalities can be seen; and why monozygotic twins are more often affected than dizygotic twins.

Diagnosis. The syndrome results in structural anomalies that vary from minor to lethal forms. The most common findings are constriction rings around the digits, arms, and legs; swelling of the extremities distal to the point of constriction; amputation of digits, arms, and legs; asymmetric face; facial clefts; cephalocele; anencephaly; acrania; multiple joint contractures; pterygium; clubfeet, clubhands, and pseudosyndactyly; microphthalmia, uveal coloboma, corneal metaplasia, and unilateral chorioretinal lacunae.

A detailed view of the fetus' face, digits and body with 3-dimensional ultrasound exams, may contribute to the diagnosis.

Differential Diagnosis. A uterine synechia or septation can simulate an amniotic band. The amniotic folds can be differentiated because they are not “sticking” to the body.

Prognosis. The more severe forms are lethal. Mild manifestations sometimes are found just at birth and do not have impact on survival.

Recurrence Risk. No recurrence is expected, except in rare sporadic familial cases, which have been reported in association with epidermolysis bullosa and Ehler-Danlos syndrome.

Management. It depends on the extent of the anomalies. Termination of pregnancy can be offered for the severe

FIGURE 5-12. Postnatal image showing the amniotic band attached to the skull and the exencephaly. (Courtesy, Vicente Ruiz, 2005, *thefetus.net*.)

forms. Recently, endoscopic release has been reported and may prove beneficial in releasing the constriction band in threatened limb amputation. Endoscopic fetal therapy with lysis of the constriction ring in utero is an option, but intervention is probably not always warranted. Spontaneous lysis of an amniotic band attached to a fetal elbow has been shown.

APERT SYNDROME

Definition. Apert syndrome is a rare developmental deformity characterized by craniofacial and limb malformations accompanied by variable degrees of mental retardation in 50% of the cases. In 1894, Wheaton provided the first description and subsequently, in 1906, Apert summarized the disorder, presenting nine cases.

Incidence. The occurrence of Apert syndrome is estimated at 0.0625 to 0.1:10,000 live births. The male-to-female ratio is 1:1.

Synonyms. Acrocephalosyndactyly type 1, Apert-Crouzon disease.

Etiology. Apert syndrome is an autosomal disorder with dominant inheritance. Most of the cases are sporadic,

FIGURE 5-13. Facial abnormality; short and broad head, high cranial vault (acrocephaly), frontal bossing, depressed nasal bridge with prognathism and “mitten hand” deformity (bilateral symmetric syndactyly) of Apert syndrome. (Illustration by James A. Cooper, M.D., San Diego, CA.)

resulting from new mutations. Association with advanced paternal age has been described.

Sonographic Findings. Brachycephaly and acrocephaly, high forehead, flat occiput, *craniostenosis* usually involving the coronal sutures, flat face, and hypertelorism. Other ultrasound findings that are present are agenesis of the corpus callosum, mild ventriculomegaly, and fusion of the cervical vertebrae at the level of C5-C6. In the extremities, we can find syndactyly (“mitten hand”) (osseous and cutaneous), usually involving the second, third, and fourth fingers. There is a broad thumb and hallux. Polyhydramnios (caused by the decreased fetal swallowing) and variable degrees of mental retardation have also been found, and their occurrence and intensity seem to correlate with the severity of central nervous system anomalies. The prenatal diagnosis by ultrasound and fetoscopy has been reported in all trimesters of pregnancy. Increased nuchal translucency at the first trimester might be a sonographic marker for the disorder.

Diagnosis. The most typical findings in Apert syndrome are craniostenosis (by synostosis of the coronal sutures), bilateral symmetric syndactyly of the limbs (mitten-like hands and feet), and midfacial hypoplasia. Additional features, which appear with variable frequency, include

- Skeletal anomalies: short and broad head, high cranial vault (acrocephaly), prominent forehead (frontal bossing) hypertelorism and proptosis, depressed nasal bridge with parrot-beaked nose, hypoplastic maxilla, prognathism.
- Cardiac anomalies: pulmonic stenosis, overriding aorta, ventricular septal defects.
- Central nervous system anomalies: hydrocephaly, malformation of the corpus callosum and limbic structures, gyral abnormalities, hypoplasia of the white matter, and heterotopic gray matter.

Genetic Anomalies. The most common mutations associated with Apert syndrome are substitution S252W and P253R, which occur in the fibroblast growth factor receptor 2 genes. Genetic molecular studies are recommended for the fetus (by chorionic villus sampling or amniocentesis) and for parents when Apert syndrome is suspected, in particular in those families affected for the first time. The development of molecular techniques for the definitive diagnosis of this

FIGURE 5-14. Apert syndrome. Sonogram demonstrating frontal bossing (three-dimensional view). (Courtesy of Luis Izquierdo, 2000, *thefetus.net*.)

condition in prenatal cases was made possible by the finding of the *FGFR2* gene mutations.

Differential Diagnosis. Genetic syndromes also characterized by the presence of craniostenosis such as Crouzon, Pfeiffer, Carpenter, and Saethre-Chotzen may be included in the differential diagnosis. Molecular genetic studies can exclude these disorders.

Recurrence Risk. When resulting from a new mutation, the recurrence risk is improbable. If one of the parents carries the disorder, the recurrence risk is 50%.

Management. If diagnosed before viability, termination of pregnancy can be offered. After viability, standard obstetric management is not altered. Delivery in a tertiary center is recommended.

ARNOLD-CHIARI MALFORMATION

Definition. The Arnold-Chiari malformation was first identified in 1883 by Cleland. It is characterized by the prolapse of hindbrain structures below the level of the foramen magnum. It can be associated with skeletal abnormalities and neurologic dysfunction. There are three types of Arnold-Chiari malformation (see also Table 5-1):

- Type I: Downward displacement of the cerebellar tonsils beneath the foramen magnum of greater than 4 mm. The fourth ventricle remains in the posterior fossa. This is mainly an incidental computed tomographic discovery.
- Type II: Invariably seen prenatally as a congenital deformity characterized by displacement of cerebellar tonsils, parts of the cerebellum, fourth ventricle, pons, and medulla oblongata through the foramen magnum into the spinal canal. In 95% percent of the cases, it is accompanied by a myelomeningocele and often hydrocephalus.
- Type III: In its most severe form, the condition is associated with large herniation of the posterior fossa contents with myelomeningocele and hydrocephalus.

Synonym. The nickname "banana sign" has been applied to the deformity of the cerebellum.

Incidence. Commonly associated with spina bifida; rare outside of spina bifida. There is a higher preponderance of Arnold-Chiari type I in female fetuses versus male fetuses (3:2).

FIGURE 5-16. The banana sign: the lobes of the cerebellum have lost their lumpy appearance and the vermian incisures are not as marked as normal (arrows).

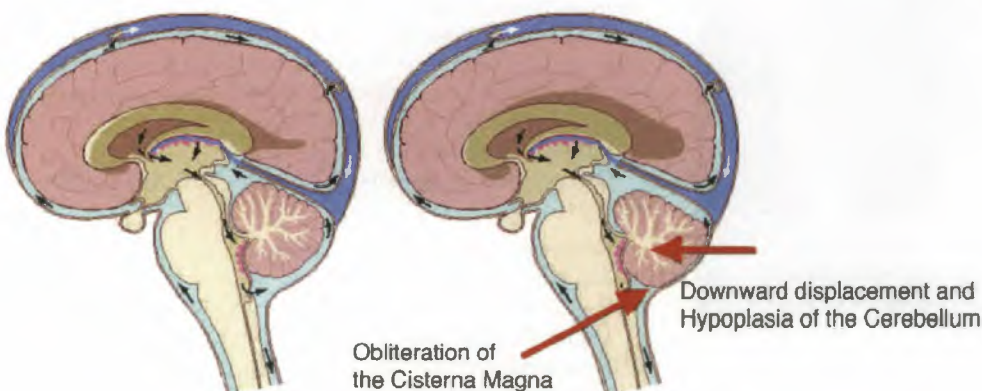

FIGURE 5-15. Schematic changes in Arnold-Chiari type II.

Table 5-1 Intrauterine Visualization of Alterations of Chiari Malformation

Findings	Chiari I	Chiari II	Chiari III
Posterior fossa	Displacement of cerebellar tonsils toward the superior cervical canal	Small posterior fossa with inferior displacement of vermis and superoanterior of cerebellum.	High cervical encephalocele with herniation of content of posterior fossa and/or occipital lobe
Brain	Usually normal	Pointed quadrigeminal plate Dysgenesis of corpus callosum, heterotopia and polymicrogyria	There might be similarity to Chiari II findings
Ventricles	Hydrocephalus (mild to moderate in 20% of cases) Fourth ventricle is small, elongated, and with inferior displacement	Hydrocephalus (90% of cases)	There might be similarity to Chiari II findings
Spinal cord	Hydrosyringomyelia (in 30%–60% of cases)	Myelomeningocele (approximately 100% of cases) Hydrosyringomyelia (in 50%–60% of cases) Diastematomyelia	There might be similarity to Chiari II findings
Associative malformations	Difficult prenatal evaluation Bone anomalies of base of skull	Difficult prenatal evaluation	Posterior bifida spine in topography on C1 and C2

FIGURE 5-17. Sagittal T2-weighted (29 weeks) showing marked hydrocephalus (*H*) and a myelomeningocele (*M*). Note the increased volume of the bladder (*B*). (Courtesy of Heron Werner, 2005, *thefetus.net*.)

Etiology. Autosomal-recessive inheritance for some forms.

Pathogenesis. The abundance of theories regarding the pathogenesis of Chiari malformation reflects the present lack of consensus on the subject. An understanding of the pathogenesis of Chiari malformations must be aimed at examining the pathophysiology at the craniocervical junction. A defect during embryonic development causes underdevelopment of the posterior fossa and blockage of the normal outlets of the fourth ventricle (foramina of Magendie and Luschka), resulting in increased pressure and causing the cerebellar tonsils to descend into the foramen magnum. Accumulated cerebrospinal fluid is then forced caudally through the entrance into the central canal of the spinal cord at the caudal-most portion of the fourth ventricle, because of a pressure gradient.

Diagnosis. The displacement of the cerebellum deforms the lateral lobes (which lose their “round shape”) and the vermicular notch to appear more continuous (thus, the banana sign). The diagnosis has been made as early as the first trimester. D’Addario et al have evaluated the angle between the clivus and supra occiput and found it a useful parameter to diagnose Chiari II malformation.

Genetic Anomalies. Unknown.

Differential Diagnosis. Nonobstructive hydrocephalus, such as

- Dysgenesis of the corpus callosum.
- Aqueductal stenosis.
- Borderline ventriculomegaly.
- Dandy-Walker malformation.
- Porencephaly.
- Schizencephaly.

Associated Anomalies. Hydrocephaly from obstruction of the foramina of Magendie, syringomyelia, diastematomyelia.

Prognosis. Variable. Poor if other brain abnormalities (migrational abnormalities) are present and if associated with a large or high myelomeningocele.

Management. Termination of pregnancy can be offered before viability. For those affected by spina bifida, an experimental intrauterine repair performed between 23 and 30 weeks' gestation has been proposed in a few centers in the United States. Standard prenatal care is not altered when continuation of the pregnancy is chosen. Confirmation of diagnosis after birth is important for genetic counseling.

ARTHROGRYPOSIS MULTIPLEX CONGENITA

Definition. This heterogeneous set of conditions shares limitation of movements and joint ankylosis as main findings.

Synonyms. Congenital contractures, fetal akinesia sequence, Pena-Shokeir syndrome.

Incidence. 1 to 3:10,000

Etiology. Possibly autosomal dominant.

Pathogenesis. Arthrogyrosis results from decreased in utero motion, either from neural, muscular, connective tissue, infectious origin.

Diagnosis. Although the anomalies are obvious when recognized, when the baby is born, the prenatal diagnosis may be challenging when fluid is decreased, and the abnormal limb position appears attributable to the oligohydramnios. Some forms are associated with polyhydramnios and the abnormal limb position (knocked knee), genu recurvatum,

FIGURE 5-18. Arthrogyrosis multiplex. Fixed flexion deformity of the hips. Also noted is bilateral congenital talipes equino varus. (Courtesy of S. Manohar, MD, 2004, *thefetus.net*.)

FIGURE 5-19. The postnatal image of a fetus with arthrogyrosis multiplex. (Courtesy of S. Manohar, MD, 2004, *thefetus.net*.)

clubfeet, and clubhand) make the diagnosis easy. Polyhydramnios is often a manifestation of decreased swallowing, which may be part of the same pathogenesis as the arthrogyrosis itself (muscular or neuronal deficit). An increase in nuchal lucency as well as the characteristic decreased movement can also be seen in the first trimester.

Genetic Anomalies. Several anomalies have been linked to the following site 5q35, 9p21-q21, 11p15.5.

Differential Diagnosis. Trisomy 18, renal agenesis, and myotonic dystrophy may present with some similar findings.

Associated Anomalies. Because of the heterogeneity of the condition, numerous associated anomalies have been described including scoliosis, central nervous system anomalies, and even seizures.

Prognosis. The prognosis depends on associated anomalies (respiratory limitations, scoliosis.)

Management. Termination of pregnancy can be offered before viability. Standard prenatal care is not altered when continuation the pregnancy is opted for. Confirmation of diagnosis after birth is important for genetic counseling.

ASPHYXIATING THORACIC DYSPLASIA

Definition. Autosomal-recessive chondrodysplasia characterized by a small thorax, varying degrees of rhizomelic brachymelia, polydactyly, pelvic abnormalities, and renal anomalies.

Synonyms. Jeune syndrome

Incidence. Unknown, usually affecting white babies.

Pathogenesis and Etiology. Autosomal-recessive disorder.

Diagnosis. The most striking ultrasound finding is a very narrow chest with short limbs. The limbs, however, are not as short as those of other lethal conditions such as thanatophoric dysplasia, achondrogenesis, OI type 2, and the short-rib polydactyly syndromes. The increased iliac wing angle, reported in the radiographic literature, has not been reported yet with ultrasound. Pancreatic cysts have been recognized in one case.

Genetic Anomalies. The defect is probably located on the short arm of chromosome 12.

Differential Diagnosis. Ellis van Creveld syndrome (short arm of chromosome 4) that presents mainly with cardiac anomalies instead of renal anomalies.

Prognosis. In spite of the dreadful name, not all newborns are asphyxiated, and with corrective surgery of the chest, some patients have had a fairly normal outcome.

Management. Termination of pregnancy can be offered before viability. Standard prenatal care is not altered when

FIGURE 5-20. Coronal view of the chest and abdomen of a fetus with asphyxiating thoracic dysplasia. Note the constriction of the chest (arrows). (Courtesy of Adrian Clavelli, 2001, *thefetus.net*.)

continuation the pregnancy is opted for. Confirmation of diagnosis after birth is important for genetic counseling.

Reference

ASPLENIA-POLYSPLENIA SYNDROMES

Definition. This set of syndromes is due to errors of lateralization of the primary field. It results (with simplifi-

cations) in either a fetus with a predominant right-sidedness and an isomeric left side (asplenia: a fetus whose left side is a mirror image of its right side) or left-sidedness and an

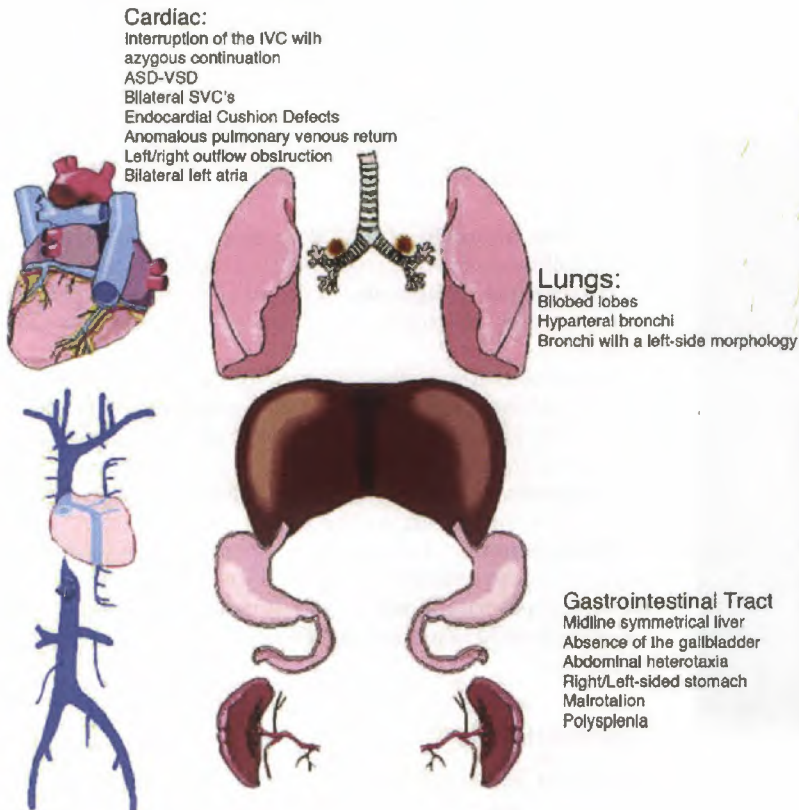

FIGURE 5-21. Schematic drawing of the findings in polysplenia. (Courtesy of P. Jeanty, 1999, *thefetus.net*.)

Table 5-2 Anomalies Associated With Asplenia-Polysplenia Syndromes

	Asplenia	Polysplenia
Cardiovascular	Bilateral superior vena cava, anomalous pulmonary venous connections, absence of the coronary sinus, endocardial cushion defect, right ventricular outflow tract obstructions, transpositions of the great arteries, isomerism of the atria (both resemble a right atrium), atrial septal defects; the apex of the heart can be in either direction	Anomalous pulmonary venous return, interrupted IVC with (hemi)azygos continuation, atrial and ventricular septal defects, pulmonic stenosis, endocardial cushion defects (less severe than in asplenia)
Spleen	Splenic agenesis or more commonly hypotrophy	Multiple splenules
Lungs	Trilobate lungs with eparterial bronchus	Bilobated lungs with hyperarterial bronchus
Liver	Decrease in the normal difference of size between the right and left lobe, independent hepatic vein on the opposite side of the IVC	
Stomach	Right sided or midline	
Bowel	Malrotation (the colon is posterior to the small bowel)	
Complications	Infections	

IVC, inferior vena cava.

isomeric right side (polysplenia: a fetus whose right side is a mirror image of its left side). These fetuses are usually recognized because of the associated cardiac anomalies.

Synonym. Ivemark syndrome, heterotaxia, cardiosplenic syndrome.

Incidence. The incidence is very low, estimated at 1 in 10,000 to 20,000 live births.

Etiology. Autosomal-recessive inheritance with male preponderance in the most of the cases, but there are reports of autosomal-dominant and X-linked inheritance, too. Heterotaxy syndromes could also occur in chromosomal translocation or deletion in sporadic cases.

Diagnosis. The diagnosis is usually made by the recognition of the cardiac anomalies, in particular, the presence of atrioventricular septal defect, mesocardia (the axis of the interventricular septum being almost anteroposterior) with an endocardial cushion defect, an intrahepatic segment of the umbilical vein that is also oriented anteroposteriorly, and an odd-looking stomach. The abnormal lobation of the lungs is difficult to recognize, and the only instance when it can be done is when a sliver of pleural fluid is infiltrated between the lobes. Another typical finding is the interruption of the inferior vena cava with azygos continuation. The typical findings include an inferior vena cava that is posterior in the upper abdomen (instead of curving anteriorly to enter the right atrium) and the abrupt decrease in size of the inferior vena cava near the diaphragm. An enlarged azygos arch joining the superior vena cava can also be recognized. The presence of a persistent left superior vena cava is rarely recognized, not because it is a challenging finding, but because it is not sought. Color and pulsed Doppler of the splenic artery has been suggested as an aid in the prenatal diagnosis of the syndrome. Other findings include agenesis of the corpus callosum with pachygyria and hydrocephalus.

Genetic Anomalies. Although it was thought that the syndrome resulted from a possible mutation in the gene encoding connexin 43 (CX43), this was not supported by further studies.

Differential Diagnosis. The cardiac anomalies (in particular, endocardial cushion defect) without the syndrome and trisomy 18 may be included in the differential diagnosis.

Associated Anomalies. Anomalies are listed in Table 5-2.

Prognosis. Asplenia tends to be a more severe disease because of the cyanotic heart lesions and the superimposed infections. Although morbidity and mortality in the neonatal period are determined mainly by the cardinal cardiac defects, the visceral anomalies may strongly affect the long-term outcome of these patients.

Management. Termination of pregnancy can be offered before viability. Standard prenatal care is not altered when continuation of the pregnancy is chosen. Confirmation of diagnosis after birth is important for genetic counseling. The treatment of the infant is dictated by the cardiac defects.

BECKWITH-WIEDEMANN SYNDROME

Definition. Beckwith-Wiedemann syndrome is a disorder first described by Beckwith in 1963 and Wiedemann in 1964. It is characterized by the classic triad of macrosomia, omphalocele, and macroglossia.

Synonym. Exomphalos-macroglossia-gigantism syndrome.

Incidence. The incidence has been estimated to be 0.72:10,000 births, and more than 500 cases are reported in the literature.

Etiology. The condition is sporadic in most cases. Beckwith-Wiedemann syndrome has an autosomal-dominant inheritance, with incomplete penetrance and variable expressivity. Rearrangements involving the chromosome

FIGURE 5-22. Beckwith-Wiedemann syndrome. The ear-lobe groove (arrow) can be recognized when searched for clinically.

FIGURE 5-23. Typical omphalocele (arrow). (Courtesy of Luis Machado, MD, 2000, thefetus.net.)

FIGURE 5-24. Coronal plane of section from a fetus at 26 weeks' gestation with subsequently proven Beckwith-Wiedemann syndrome. Bilateral fetal nephromegaly is demonstrated.

11p15 region seem to be the mutation responsible for this disorder.

Diagnosis. The detection of macrosomia, omphalocele, and macroglossia associated with normal karyotype makes the diagnosis of Beckwith-Wiedemann syndrome. Other features occurring in variable incidence include nephromegaly, hepatomegaly, small groove earlobe creases, diaphragmatic hernia, hemihypertrophy, exophthalmos, enlargement of the testis, enlarged kidneys, adrenocortical macrocyst, single umbilical artery, and cardiac defects. The most typical findings include macrosomia, polyhydramnios, enlarged placenta, and a distended abdomen. Because most described signs developed after 22 weeks of gestation, a careful follow-up should be carried on until late stages of pregnancy.

Genetic Anomalies. Structural anomalies of the chromosome including paternal isodisomy of the 11p15.5 region, isodisomy of 11q, and uniparental disomy may be detected by cytogenetic studies. Thus, aside from a conventional cytogenetic analysis, some authors recommend using polymerase chain reaction of polymorphic loci on 11p15.5, to detect possible maternal deletions or inversions, paternal duplications, and uniparental disomy. These may account for 25% of cases of Beckwith-Wiedemann syndrome.

Differential Diagnosis. Down syndrome must be excluded by chromosomal analysis owing to the occurrence of macroglossia in both conditions. Diabetic fetopathy is another cause of macrosomia and, thus, is a differential

FIGURE 5-25. Profile of the fetal face in a patient with macroglossia (arrow) and Beckwith-Wiedemann syndrome.

diagnosis. Zellweger syndrome can also combine liver and kidney enlargement, and may be diagnosed prenatally by measuring fatty acid concentration and activity of marker enzymes. Perlman syndrome, a rare entity characterized by hypotonia, facial dysmorphism, gigantism, and visceromegaly including nephromegaly, is another differential diagnosis.

Complications. Pancreatic cell hyperplasia may affect 30% to 50% of patients, causing hyperinsulinism and neonatal hypoglycemia on the second or third day of life. Untreated neonatal hypoglycemia is an important complication and may result in further cerebral dysfunction, such as seizures, mild to moderate mental retardation, or neonatal death in more severe cases. Macroglossia can cause variable complications ranging from feeding difficulties to airway obstruction and death. Long-term complications include high risk for abdominal tumors, in particular Wilms tumor (3.7% incidence); hepatoblastoma; neuroblastoma, and adrenal cortical carcinoma. The risk of developing malignant tumors increases when hemihypertrophy is present. Beckwith-Wiedemann syndrome is a favorable biologic marker for survival in children who have intra-abdominal tumors. Benign tumors are associated with this disease.

Prognosis. Neonatal mortality rate is approximately 21%, due mainly to congestive heart failure. Among those who survive, the prognosis is in general favorable, depending on the severity of the associated anomalies and long-term complications. Preterm delivery is a complication due to the polyhydramnios and gestational hypertension.

Management. When diagnosed before viability, termination can be offered. After viability, sonographic evaluation of fetal growth is suggested. When macrosomia is suspected, cesarean section may be offered owing to the risk of shoulder dystocia. An early diagnosis of Beckwith-Wiedemann syndrome is important for counseling the parents concerning potential risk for developing embryonic tumors, selection of the mode of delivery due to potential adrenal cysts that might bleed during labor, and prevention of neonatal hypoglycemia. Serum alpha-fetoprotein screening, usually in combination with abdominal ultrasound, can lead to early detection of hepatoblastoma. Delivery in a tertiary center is recommended for early abdominal wall defect repair and treatment of the hypoglycemia. Sonographic screening for abdominal tumors is recommended during the first 6 years of life. Aggressive follow-up is warranted in cases of association with hemihypertrophy and nephromegaly with or without evidence of a Wilms tumor precursor.

CAMPOMELIC DYSPLASIA

Definition. Campomelic dysplasia is a congenital disorder characterized by the development of abnormal curvature of the long bones, particularly the lower extremities, such as femur and tibiae. Some authors have classified the disease into two varieties—"long limbed" and "short limbed"—

depending on the type of limbs involved in the pathologic process.

Synonyms. Campomelic dysplasia, campomelic syndrome, campomelic dwarfism, congenital bowing of the limbs.

Prevalence. The disorder affects 0.02:10,000 live births. Sex reversal occurs in some genotypic male fetuses who lack

FIGURE 5-26. Campomelic dysplasia. Bowing of the femur (arrows). Note the gentle curve that differentiates this entity from the more acute angles seen in osteogenesis imperfecta fetuses.

the H-Y antigen. Phenotypic sex ratio is approximately M1:F2.3, karyotypic sex ratio is approximately M2:F1.

Etiology. The transmission of campomelic dysplasia is still debated. Autosomal-recessive inheritance is thought to be the most common pattern, although it may also be due to sporadic autosomal-dominant mutation.

Recurrence Risk. Depends on the etiology. If transmitted by autosomal-recessive pattern, it has a 25% recurrence risk. When transmitted by autosomal-dominant pattern, it has 50% recurrence risk, but in fact, most are new mutations.

Diagnosis. The most characteristic sign of campomelic dysplasia is the marked anterior bowing of the long bones, particularly of the femur and tibia. Severe angulation may mimic fractures. Other sonographic features that are commonly present include growth restriction; bell-shaped narrow chest; 11 pair of ribs; hypoplasia of the midthoracic vertebral bodies, fibula, and scapula; scoliosis; shortness of the limbs; talipes equinovarus; tracheobronchomalacia; flat and small face; high forehead with prominent occiput; low nasal bridge; micrognathia; cleft of the soft palate; hypertelorism; low-set and malformed ears; hydrocephalus; and ambiguous genitalia.

CAUDAL REGRESSION SYNDROME

Definition. Caudal regression syndrome is a rare congenital defect, characterized by the absence of the sacrum, and defects of variable portions of lumbar spine, associated with anomalies from different systems.

Synonyms. Caudal dysplasia sequence, sacral agenesis.

Prevalence. 1 to 0.25:10,000 in normal pregnancies and 200 to 250 times higher in diabetic pregnancies.

Etiology. Unknown, but associated with maternal diabetes in 16% of the affected.

Recurrent Risk. This anomaly is not thought to be hereditary, and the recurrent risk is very small, although it is higher in diabetics.

Diagnosis. The sonographic findings are variable, and depend on the extent and severity of the defect. It ranges from complete absence of the sacrum associated with abnor-

Genetic Anomaly. A mutation in SOX9, a sex-determining region of Y (SRY)-related gene, located at 17q24 seems to be associated with the occurrence of both campomelic dysplasia and sex reversal.

Pathogenesis. Although many theories have been proposed to explain the development of the anomalies present in this syndrome, (in particular the bowing of the bones), the precise mechanism is not known. Some of the theories are

1. Mechanical stress due to faulty fetal position within the uterus.
2. Primary muscle imbalance and shortening, particularly of the calf muscles causing secondary bending of the tibia.
3. Intrauterine fracture with subsequent healing.
4. Abnormal vascular and cellular elements of perichondrium.
5. Developmental disturbance in the cartilaginous phase of bone formation.

Associated Anomalies. Polyhydramnios, and anomalies from the central nervous, cardiac, and renal systems have been described antenatally. After birth, hearing loss may occur.

Differential Diagnosis. Osteogenesis imperfecta types I and II, hypophosphatasia, unclassifiable varieties of congenital bowing of the long bones, thanatophoric dysplasia, mesomelic dysplasia (Reinhart variety), Roberts syndrome, and diastrophic dysplasia.

Prognosis. Almost all result in neonatal or infant death owing to respiratory complications. Some survivors, including a boy alive at 17 years, have been reported.

Management. Before viability, the option of pregnancy termination should be offered. After viability, standard obstetric management is not altered, and respiratory function in the newborn must be supported.

malities of the lumbar spine and lower extremities (such as clubfeet and contractions of the knees and hips) to abnormalities of the sacrum, without associated defects. The most typical findings are the absence of a few vertebrae, the shield-like appearance of the fused or approximated iliac wings and the decrease interspace between the femoral heads. Some sonographic planes of section will intersect the fetus at such an angle that no spine is visible, a very striking and probably pathognomonic finding. Decreased movement of the legs is frequently observed. First trimester diagnosis may be difficult to accomplish because of the incomplete ossification of the sacrum at that time. A short crown rump length and abnormal appearance of the yolk sac have been proposed as early sonographic signs of caudal regression syndromes.

Genetic Anomaly. Unknown.

FIGURE 5-27. Caudal regression syndrome. Although on superficial examination, this image might pass for normal, note that on the caudal side of the image (on the right, because the ribs can be seen on the left side of the image) the spine terminates (*arrow*) without the usual landmark of the iliac wings and sacrum.

FIGURE 5-29. Caudal regression syndrome. The lack of sacrum allows the iliac wings to be approximated, giving them a shield-like appearance (*arrow*).

FIGURE 5-28. This same finding is even more striking on the sagittal view of the spine, where the distal end (*arrow*) appears to have been "erased." This is actually the finding that caught the eye of one of my astute sonographers: she was puzzled by the spine "looking too short."

FIGURE 5-30. The spinal cord of this fetus is about at 2:00 (compare with the position of the iliac wing on Fig. 5-29). I do not know of any other condition that can provide this same image of a cross-section through a fetal abdomen with no visible spine. All of the other differential diagnoses such as achondrogenesis and the severest forms of osteogenesis imperfecta would not present with the localized anomaly seen here.

Pathogenesis. Disruption of the maturation of the caudal portion of the spinal cord complex before 4 weeks' gestation, leading to motricity deficits and neurologic impairment, varying from incontinence of urine and feces to complete neurologic loss.

Associated Anomalies. Anomalies of the central nervous, musculoskeletal, genitourinary, cardiac, respiratory, and gastrointestinal systems may be found in association with caudal regression syndrome.

Differential Diagnosis. Sirenomelia, which was thought to be the most severe form of caudal regression syndrome (today it is considered a different entity), is the main

differential diagnosis. Fusion of the lower extremities is a typical finding of sirenomelia.

Prognosis. Depends on the severity of the spinal defect and associated anomalies, but the vast majority of survivals requires urologic and orthopedic interventions. Severe forms are commonly associated with cardiac, renal, and respiratory problems, which are responsible for early neonatal death.

Management. If detected early, pregnancy termination can be offered. Standard prenatal care is not altered if continuation of pregnancy is opted. If born alive, extensive surgery in tertiary center is usually needed to repair the defects.

CEREBROHEPATORENAL SYNDROME

Definition. One of the four syndromes of the “peroxisome biogenesis disorders” or heterogeneous group of human neurodegenerative diseases that results in impairment of many metabolic pathways, especially of the beta-oxidation of very-long-chain fatty acids (VLCFAs), due to deficiency of peroxisomes in liver and kidneys.

Synonym. Zellweger syndrome.

Incidence. 0.2 to 0.25:10,000. The proportion between male and female fetuses is 1:1. The probable locus is on the long arm of chromosome 7 in the 21-22 regions.

Etiology. Autosomal-recessive inheritance with variable expression.

Pathogenesis. Peroxisomes are single membrane-bound cell organelles that perform numerous metabolic functions. The inherited peroxisomal disorders appear when these organelles lack one or more of their functions and become impaired. Although multiple organs are affected, the nervous system is affected most.

Sonographic Findings. The fetuses demonstrate growth restriction, hypotonicity with decreased movements, and increased nuchal translucency. Abnormal head shape (bulging forehead, wide metopic suture), facial dysmorphism (micrognathia, and buphthalmos), central nervous system (hydrocephalus) periventricular cysts, ventriculomegaly, hepatomegaly with dysgenesis, cardiac anomalies, clinodactyly, and simian creases can also be detected prenatally.

Differential Diagnosis. Many aneuploidies may present with similar findings. Down syndrome is commonly misdiagnosed owing to the overlapping of several structural findings.

Implications for Targeted Examinations. The initial laboratory diagnosis is suspected by demonstration of elevated very-long-chain fatty acids in plasma and with a detailed

FIGURE 5-31. Cerebrohepatorenal syndrome. Buphthalmos. Note the enlarged size of the eye (arrow).

ultrasound scanning. Cultured chorionic villus sampling and amniocentesis with a detection of reduced peroxisomes and abnormal lipid metabolism are essential for a complete classification and to confirm the presumed diagnosis. Some recent studies report also a low estriol level and low concentrations of human chorionic gonadotropin in the maternal serum screening.

Prognosis. Most infants with this disorder die within the first year.

Management. Termination of pregnancy can be offered before viability. Standard prenatal care is not altered when continuation of the pregnancy is chosen. Confirmation of diagnosis after birth is important for genetic counseling.

CHARGE ASSOCIATION

Definition. Coloboma of the eye, heart defects, atresia of the choanae, retarded mental and growth development, genital anomalies, and ear anomalies with or without deafness (Table 5-3).

Diagnosis. Hall (1979) first reported a constellation of nonrandomly associated malformations occurring with choanal atresia. Subsequent authors have validated the CHARGE association and suggested the inclusion of orofacial clefts and esophageal atresia as main features. Tetralogy of Fallot is the most frequent heart defect reported in the CHARGE association. Tellier et al (1998) evaluated 47 CHARGE patients for the frequency of major anomalies, namely, coloboma (79%), heart malformation (85%), choanal atresia (57%), growth and mental retardation (100%), genital anomalies (34%), ear anomalies (91%), and deafness (62%). In addition, they commented on anomalies observed frequently in neonates and infants with the CHARGE syndrome, including minor facial anomalies, neonatal brain stem dysfunction with cranial nerve palsy, and internal ear anomalies such as semicircular canal hypoplasia, which was found in each patient that could be tested. Criteria for poor survival were thought to include male gender, central nervous system and esophageal malformations, and bilateral choanal atresia. A significantly higher mean paternal age at conception, together with concordance in monozygotic twins and the existence of rare familial cases, supported the role of genetic factors such as de novo dominant mutation or subtle submicroscopic chromosome rearrangement.

Genetics. A large percentage of children with CHARGE syndrome have a mutation in the *CHD7* gene on chromosome 8. Mutations in this gene can confirm the diagnosis of CHARGE in those cases. Not finding a mutation does NOT rule out the CHARGE syndrome.

Etiology. Unclear.

Recurrence. Recurrence risk is low. Empiric risk of recurrence is at most 1% to 2%.

Differential Diagnosis. 22q11 deletion spectrum/VCF (velocardiofacial) syndrome (sometimes called DiGeorge syndrome) has different facial and ear features; VACTERL association, *PAXα* mutation (coloboma, hearing loss, and renal abnormalities); retinoic embryopathy.

Prognosis. Mortality in the first 2 years of life is 20% to 25%. Choanal atresia is a threat to life because young infants cannot establish the habit of mouth breathing.

Table 5-3 Major Characteristics of CHARGE*

Finding	Includes	Frequency
Coloboma of the eye	Coloboma of the iris, retina, choroids, disc, not including colobomas of the eyelid; microphthalmos (small eyes) or cryptophthalmos (absent eye)	80%–90%
Choanal atresia or stenosis	Unilateral or bilateral: bony or membranous. Unilateral atresia or stenosis may be difficult to diagnose	50%–60%
Cranial nerve dysfunction or anomaly	I–Lack of smell (anosmia) IX/X–Swallowing difficulties VII–Facial palsy–(unilateral or bilateral)	Frequent 70%–90% 40%
Characteristic CHARGE ear	Short, wide ear with little or no lobe, “snipped off” helix, prominent anti-helix that is discontinuous with the tragus, triangular concha, decreased cartilage, often stick out, usually asymmetric Middle ear: ossicular malformations seen on MRI Malformed inner ear (Mondini defect) with deformed cochlea and vestibules seen on MRI	Frequent Frequent 80%–90%

MRI, magnetic resonance imaging scan.

*These are very common in CHARGE and relatively rare in other conditions.

FETAL ALCOHOL SYNDROME, FETAL ALCOHOL EFFECTS

Alcohol use during pregnancy results in a spectrum of adverse outcomes known as fetal alcohol spectrum disorders. Fetal alcohol syndrome (FAS) is one of these disorders. FAS is characterized by specific facial abnormalities and significant impairments in neurodevelopment and physical growth. Children exposed to alcohol (approximately 45 to

50 g of ethanol per day or equivalent) in utero suffer from growth and mental retardation, physical abnormalities, and immune dysfunction. There is no “threshold,” so some fetuses exhibit signs of fetal alcohol effects at lower exposure. Recommendations for clinicians regarding assessment of thresholds published by the National Institute on Alcohol Abuse and Alcoholism recommend that any woman who reports drinking more than seven drinks per week or more

FIGURE 5-33. Characteristic facial features in a child with fetal alcohol spectrum disorders. Findings may include a smooth philtrum, thin upper lip, upturned nose, flat nasal bridge and midface, epicanthal folds, small palpebral fissures, and small head circumference. (Reproduced with permission from Darryl Leja, NHGRI, National Institutes of Health; Wattendorf DJ, Muenke M: *Fetal alcohol spectrum disorders*. *Am Fam Physician* 72:279, 2005.)

FIGURE 5-35. Characteristic features of a hand of a child with fetal alcohol spectrum disorders. Note the curved fifth finger (clinodactyly) (small arrow) and the upper palmar crease (large arrow) that widens and ends between the second and third fingers ("hockey stick" crease). (Reproduced with permission from Darryl Leja, NHGRI, National Institutes of Health; Wattendorf DJ, Muenke M: *Fetal alcohol spectrum disorders*. *Am Fam Physician* 72:279, 2005.)

FIGURE 5-34. Characteristic features of an ear of a child with fetal alcohol spectrum disorders. Note the underdeveloped upper part of the ear parallel to the ear crease below ("railroad track" appearance). (Reproduced with permission from Darryl Leja, NHGRI, National Institutes of Health; Wattendorf DJ, Muenke M: *Fetal alcohol spectrum disorders*. *Am Fam Physician* 72:279, 2005.)

than three drinks on any given day be further assessed for risk of developing alcohol-related problems.

Synonyms. None.

Incidence. The incidence of FAS ranges from 2 to 30:10,000 live births. This represents the most common form of mental retardation in the United States. In the United States, the prevalence of FAS has been estimated to fall between 0.5 and 2.0 cases per 1000 births. It has been long recognized that the true extent of teratogenic injury from alcohol exposure exceeds the clinically recognized prevalence of FAS, because behavioral and physical teratogenesis may be present in the absence of full expression of the syndrome.

Etiology. Direct toxicity of alcohol and its metabolites that cross the placenta and are not detoxified by the fetal liver.

Diagnosis. The findings include microcephaly, long round philtrum, small micrognathia, cleft palate, suppression of the Cupid arch, microphthalmia, microcephaly, dysgenesis of the corpus callosum, malformed ears, atrial septal defect, ventricular septal defect, and growth restriction predominantly involving the limbs and occurring early without oligoamnios. This lack of specificity suggests that the FAS facies may be a

common teratogenic expression of exposure to a variety of substances occurring during a defined period of fetal development.

Differential Diagnosis. Other conditions that involve growth restriction and microcephaly such as toxoplasmosis, rubella, cytomegalovirus, herpes simplex (TORCH) and chromosomal anomalies.

Prognosis. Mental retardation and delay in growth that persists postnatally. Most children with FAS are mildly to moderately retarded, but intellectual ability varies widely. The severity of mental retardation appears related to the severity of growth deficits and dysmorphogenesis, such that the more phenotypically affected individuals have lower IQ scores. Hyperactivity is frequently observed. As adults, mental illness is highly prevalent with FAS, affecting more than 70% in one series in which 60% had alcohol or drug dependence, 44% depression, and 40% psychosis.

FETAL CYTOMEGALOVIRUS INFECTION

Definition. Fetal cytomegalovirus infection is a congenital disorder characterized by hydrops, ascites, ventriculomegaly, and other findings caused by transplacental transmission of cytomegalovirus to the fetus. The double-stranded DNA herpes group virus causes a mild infection or a mononucleosis-type illness in young healthy adults, chronic disease in older adults, and mild to severe congenital infection.

Synonym. Congenital cytomegalovirus infection.

Etiology. Cytomegalovirus (a double-stranded DNA herpes group virus).

Incidence. Congenital cytomegalovirus infection occurs in 0.2% to 2.2% of deliveries. Intrauterine transmission of cytomegalovirus takes place in approximately 40% of infections, and approximately 10% of live-born infants have symptomatic disease at the time of birth and later. Few cases may have isolated findings such as ascites.

Diagnosis. Cytomegalovirus infection as well as other congenital infections should be suspected whenever non-immune hydrops is found. Other suggestive findings that may be present are intracranial calcifications and intracranial hemorrhage, microcephaly, brain atrophy, abnormal periventricular echogenicities, intraparenchymal foci, ventriculomegaly, intraventricular adhesions, periventricular pseudocysts, sulcation and gyral abnormal patterns, hypoplastic corpus callosum, cerebellar and cisterna magna abnormalities, signs of striatal artery vasculopathy, splenomegaly, chorioretinitis (an echogenic lining to the vitreous body), occlusion of the foramen ovale (marked by decreased motion of the foramen ovale flap and thickening of the flap), signs of right-sided heart overload from the premature closure, ascites, hyper-echoic bowel, intrauterine growth restriction, and oligohydramnios. Most features are found by ultrasound examinations, at approximately 20 weeks' gestation.

Whenever maternal infection is confirmed, culture and polymerase chain reaction testing of amniotic fluid and cordocentesis is required for serologic studies (search for fetal-specific IgM antibody), although it does not have 100% reliability. Polymerase chain reaction on amniocentesis samples can be made after 21 weeks' pregnancy, after a 7-week interval between diagnosis of maternal infection and antenatal procedure. The diagnosis can also be made by

Management. The management of these pregnancies should be aimed at reducing the alcohol consumption; few programs have had much efficacy.

FIGURE 5-36. Sonogram of a second trimester fetus with proven cytomegalovirus infection. Hepatic calcifications (arrows) are seen as well as fetal ascites (asterisk).

histologic study of typical inclusion bodies in biopsy or autopsy specimens.

Focal sonographic periventricular increased echogenicity associated with mild ventriculomegaly, without any abnormalities of the cerebral and cerebellar organogenesis or cephalic biometry alteration in the third trimester of pregnancy, should be considered as a marker of encephalitis following cytomegalovirus infection of the fetal brain. Fetal magnetic resonance imaging is a useful adjunct in the evaluation of intrauterine infection with cytomegalovirus.

Pathogenesis. The exact mode of transplacental passage is uncertain. The virus replicates in fetal tissues, producing inflammation, tissue necrosis, and organ dysfunction. Cytomegalovirus hepatitis in the neonate can present with an intense inflammatory response involving the portal triads. In these cases, lobular disarray, degeneration of hepatocytes, and cholestasis are also seen. The cause of ascites in congenital cytomegalovirus infection is not certain. Contributing factors may include low serum protein levels due to

hepatic dysfunction and portal obstruction resulting from periportal inflammation.

Associated Anomalies. Isolated ascites is an uncommon finding in fetuses with cytomegalovirus infection but may occur. Cardiovascular, gastrointestinal, musculoskeletal, and ocular lesions may be found in association with the classic features. Petechiae, neurosensory hearing loss, and poor intellectual development may also occur after birth.

Differential Diagnosis. Because ascites is often the first manifestation of hydrops, the differential diagnosis for fetal ascites is essentially the same as with generalized hydrops, which includes mainly all congenital infections. Conditions that present with intracranial calcifications (such as tuberous sclerosis), hyperechoic bowel (cystic fibrosis and Down syndrome), and hepatomegaly (primary liver disease or extramedullary hematopoiesis) should be considered.

Prognosis. In general, neonates with symptomatic cytomegalovirus infection do poorly, with a neonatal mortality rate as high as 30% and a high rate of neurologic handicap in survivors. Cytomegalovirus hepatitis is reversible in survivors, but mental retardation, motor handicaps, and hearing loss are expected long-term sequelae. Late sequelae such as sensorineural hearing loss and neurodevelopmental disorders occur in 10% to 15% of infants lacking symptoms at birth. Pediatric neurologic morbidity is related to the degree of antenatal ventriculomegaly and, when it is greater than 15 mm, it is associated with an increase in abnormal neurologic development.

Recurrence Risk. Considering that viral infection confers immunity in the majority, there is just a small theoretical risk of reinfection in another pregnancy.

FETAL RUBELLA SYNDROME

Definition. Fetal rubella syndrome is a congenital disorder resulting from primary maternal infection with the rubella virus. It is characterized mainly by deafness, mental retardation, congenital cataract, heart defects, and other structural anomalies that may be found with variable severity and frequency. During acute rubella in pregnancy, the rate of congenital infection is higher than 90% in the 12 first weeks of pregnancy, approximately 60% in weeks 13 to 17, 25% in weeks 18 to 24, and then increases again during the last month of pregnancy.

Synonym. Fetal rubella effects.

Etiology. It is caused by a RNA togavirus, which is the only member of the genus Rubivirus. The fetus is infected by transplacental transmission.

Recurrence Risk. None.

Incidence.

Not precisely known. Administration of rubella vaccine has significantly reduced the incidence of maternal infection, although reinfection after vaccination is possible. The development of fetal infection reaches 50% among those exposed during the first trimester and 20% during the second trimester.

Diagnosis. The most frequent sonographic findings are cardiac malformations (in particular, septal defects), eye defects (cataracts, microphthalmia, and retinopathy), microcephaly, hepatomegaly, splenomegaly and growth restriction. Deafness and mental retardation are expected after birth. The confirmation of fetal infection can be made by isolating

Management. Termination of pregnancy can be offered before viability. If continuation of the pregnancy is chosen, monthly follow-up with ultrasound is recommended to monitor growth restriction, hydrops, and the other fetal manifestations. Decompression with paracentesis to remove fetal ascites may prevent pulmonary hypoplasia and improve the circulatory system in those cases severely affected.

rubella viral RNA from amniotic fluid samples and applying polymerase chain reaction.

Associated Anomalies. Occasionally, the following anomalies can be associated with the classic findings of fetal rubella syndrome: renal disorders, hypospadias, cryptorchidism, meningocele, glaucoma, patent ductus arteriosus, and peripheral pulmonary stenosis.

Differential Diagnosis. All of the conditions that can be associated with congenital hepatomegaly and cataracts should be excluded. This includes congenital infections (TORCH), fetal anemia, fetal liver tumor, chondrodysplasia punctata, Neu-Laxova syndrome, Smith-Lemli-Opitz syndrome, and Walker-Warburg syndrome.

Prognosis. Intrauterine death may occur. Postnatal impact of the intrauterine infection varies from absence of any defect to all the anomalies mentioned earlier with variable severity. The agent may remain for years in the tissues, causing chronic infection and its complications (such as diabetes mellitus due to chronic viropathy of the pancreas).

Management. Termination of pregnancy should be considered every time fetal infection is detected during the first trimester, owing to the severity of the condition in this group. After viability, monthly sonographic monitoring for growth and follow-up of the anomalies is recommended.

Prevention. Women found to be susceptible during pregnancy should be offered vaccination postpartum and before discharge from the hospital. Breastfeeding is not a contraindication to receiving the rubella vaccine.

FETAL TOXOPLASMOSIS SYNDROME

Definition. Toxoplasmosis is caused by infection with the protozoan parasite *Toxoplasma gondii*. Toxoplasmosis is normally asymptomatic in immunocompetent individuals. Acute infections in pregnant women can be transmitted to the fetus and cause severe illness (mental retardation, blindness and epilepsy). The risk of maternal fetal transmission increases with gestational age at the time of exposure, whereas the incidence of severe disease decreases.

Synonyms. None.

Incidence. An estimated 400 to 4,000 cases of congenital toxoplasmosis occur each year in the United States. Of the 750 deaths attributed to toxoplasmosis each year, 375 (50%) are believed to be caused by eating contaminated meat, making toxoplasmosis the third leading cause of food-borne deaths in this country. The incidence of toxoplasmosis acquisition during pregnancy ranges from 1 to 4 per 10,000. Half of the fetuses escape from the infection, one third has a subclinical infection, and only one tenth has a severe infection.

Etiology. Infectious. Women infected with *Toxoplasma* before conception, with rare exceptions, do not transmit the infection to their fetuses. Women infected with *Toxoplasma* after conception can transmit the infection across the placenta to their fetuses. Fetal involvement results from acute infection in the mother; however, those mothers with chronic infection can transmit the disease by reactivation, which is caused by an immunologic dysfunction. The rate of fetal transmission during primary infection is 25%, 54%, and 65%, in the first, second, and third trimesters, respectively.

Pathogenesis. The fetus is infected hematogenously through the placenta during parasitemia in the mother.

FIGURE 5-37. Severe dilatation of posterior horns of the lateral ventricles in a fetus with toxoplasmosis infection. (Courtesy of Julio Cesar Coub, 2006.)

FIGURE 5-38. Intracranial calcifications (arrows). (Courtesy of Julio Cesar Coub, 2006.)

Ocular toxoplasmosis causes irreversible damage to the retina in utero. The fetus and infant mount inflammatory responses that may contribute to ocular damage.

Diagnosis. The classic triad of signs suggestive of congenital toxoplasmosis includes chorioretinitis, intracranial calcifications, and hydrocephalus. However, most infants infected in utero are born with no obvious signs of toxoplasmosis on routine examination, but many develop learning and visual disabilities later in life. If left untreated, congenital toxoplasmosis can be associated with severe and even fatal disease. Other findings include microcephaly, encephalomyelitis, seizures, mental retardation, ascites, and hepatosplenomegaly. Although the diagnosis used to be made by serologic techniques and cultures, it can now be done with polymerase chain reaction detection of *Toxoplasma gondii* in fetal tissues.

Differential Diagnosis. The other TORCH infections.

Prognosis. Approximately 75% of congenitally infected newborns are asymptomatic.

Recurrence Risk. Typically none.

Management. Depending on gestational age and whether the fetus is known to be infected, pregnant women have been treated with the antibiotic spiramycin or with sulfadiazine alone or the combination of pyrimethamine and sulfadiazine. Treatment of acute infection during pregnancy has been associated with an approximately 50% reduction in fetal infection.

Prevention. Toxoplasmosis infection can be prevented in large part by cooking meat to a safe temperature, and peeling or thoroughly washing fruits and vegetables before eating; pregnant women should avoid changing cat litter or,

if no one else is available to change the cat litter, use gloves, then wash their hands thoroughly.

FETAL VALPROIC ACID EXPOSURE SYNDROME

Definition. Fetal valproic acid exposure syndrome is a syndrome resulting from maternal valproate (anticonvulsant) use during pregnancy and it is characterized by a cluster of minor and major anomalies, including central nervous system dysfunction, spina bifida, developmental delay, intrauterine growth restriction, and cardiac anomalies.

Synonym. Depakene exposure.

Incidence. Unknown, rare. Any epileptic pregnant mother has two to three times increased risk for congenital anomalies compared with the general population. If the exposure to valproic acid takes place between the 17th and 30th days after fertilization, the incidence of neural tube defects reaches 1% to 2%. In general, the teratogenic risks rise with increasing doses of valproic acid, with a significantly higher malformation risk in doses up to 1000 mg/day.

Etiology. Exposure to valproic acid.

Pathogenesis. Unknown.

Diagnosis. The findings include cardiovascular abnormalities, hypotonia, spina bifida, hypospadias, and limb reductions. The facial appearance can be characterized by an oral cleft, small broad nose, small ears, flat philtrum, a long upper lip with shallow philtrum, and micrognathia/retrognathia. Intrauterine growth restriction, microcephaly, generalized hypertrichosis sparing palms and soles, coarse face, gum hypertrophy, clubfeet and clubhands, musculoskeletal abnormalities, genital abnormalities, and urogenital defects may also be present. Heart defects have also been reported. In 26% of patients with fetal valproic acid exposure syndrome, cardiovascular abnormalities, most frequently ventricular septal defects, aortic or pulmonary stenosis, and persistent ductus arteriosus also occur. Pulmonary hypoplasia is also reported. Epilepsy and mental retardation may develop after birth.

Genetic Anomalies. None.

Associated Anomalies. Anomalies from different systems have been reported in association with this syndrome, such

Roberts F, Mets MB, Ferguson DJ, et al: Histopathological features of ocular toxoplasmosis in the fetus and infant. *Arch Ophthalmol* 119:51, 2001.

as omphalocele, inguinal hernia, duodenal atresia, and scoliosis. Hyperbilirubinemia, hepatotoxicity, transient hyperglycemia, afibrinogenemia, and fetal or neonatal distress may be found.

Differential Diagnosis. Other neural tube defects. However, the clinical history in the presence of an association of spina bifida and cardiac anomaly should suggest the diagnosis.

Prognosis. Fetuses that present major anomalies have a poor prognosis. Metabolic disturbances may also complicate the neonatal period. These affected children can die in infancy, and the surviving patients can develop mental retardation.

Recurrence Risk. If the mother is exposed to valproic acid in a second pregnancy, the teratogenic effect will be the same.

Management. When detected in the second trimester, termination of the pregnancy can be offered. If the pregnancy is allowed to continue, no alteration of the management is needed. Many new antiepileptic drugs have been introduced over the past few years, and switching the mother to one of those is recommended. Because of the increased risk of malformations, pregnant women using valproic acid should be informed about the option of prenatal diagnosis by structural ultrasound examination and alpha-1-fetoprotein analysis of maternal serum.

FETAL VARICELLA ZOSTER

Definition. Fetal varicella zoster is a combination of abnormalities of multiple organs, caused by fetal contamination with maternal chickenpox infection.

Synonyms. Congenital varicella syndrome, varicella embryopathy, chickenpox, herpes zoster.

Incidence. The incidence of maternal infection with herpes virus varicella is 7:10,000 pregnancies. The risk of fetal involvement among all pregnant women infected with varicella during their gestation varies from 1% to 20%. First trimester varicella infections have been associated with an increased risk of spontaneous abortion. Second trimester

varicella infections have been associated with 2% risk of a congenital syndrome characterized by limb hypoplasia, cutaneous scars, cataracts, microcephaly, and cortical atrophy.

Etiology. Herpes virus.

Recurrence Risk. Less than 1%.

Diagnosis. Maternal infection at any time in pregnancy exposes the fetus to a high risk of transplacental contamination and is indicative of fetal follow-up. The risk of fetal anomalies, however, is higher during the first and second trimesters. Sonographic signs of fetal disease include fetal demise, growth restriction, musculoskeletal abnormalities such as clubfeet and abnormal position of the hands (caused

FIGURE 5-39. Varicella zoster infection. The fetal face at autopsy (26 weeks). Note the collapsed cranium, intact skin (very little maceration), disproportionate necrosis of the ocular globes, and flattened midface. (Courtesy of R.R. Lebel, 1992.)

by both necrosis and denervation of the affected tissue), limitation of limb extension due to cicatrices formation, cutaneous scars, limb hypoplasia, chorioretinitis, congenital cataracts, microphthalmia, hydrops, polyhydramnios, hyperechogenic hepatic foci, cerebral anomalies such as ventriculomegaly or atrophy, and microcephaly, disseminated foci of necrosis and microcalcifications, encephalitis, echogenic bowel in the second trimester. The placenta can show a multifocal chronic villitis with multinucleated giant cells. Fetal infection can be demonstrated by detection of varicella-zoster virus DNA by polymerase chain reaction in fetal blood and amniotic fluid or by detection of the specific IgM antibody, in the same fluids.

Pathogenesis. Direct damage to fetal tissues by neurotropic virus.

Associated Anomalies. Congenital anomalies from multiple organs with variable severity can be associated with varicella embryopathy. Among survivors, development of mental retardation, seizures, and limitation of movements may develop after birth. The virus may cause serious infections, particularly pneumonia, in adult women.

Differential Diagnosis. Other viral infections, vascular accidents, amniotic band syndrome.

FRASER SYNDROME

Definition. Fraser syndrome is a rare genetic syndrome with abnormalities of the head, lungs, kidneys, and limbs. It combines acrofacial and urogenital malformations with or without cryptophthalmos.

Synonym. Cryptophthalmos-syndactyly syndrome

Incidence. 0.043:10,000 live-born infants and 1.1:10,000 stillbirths.

Prognosis. The severity of fetal involvement varies from dermatologic lesions to lethal disseminated disease. Limited scarring tends to have an excellent prognosis. Fetal brain disruptions, or severe maternal varicella with development of lethal maternal pneumonia and encephalitis, are indicators of an extremely high risk for fetal demise. The mortality rate varies from 39% to 61%. Early maternal infection (first and early second trimester) has a higher association with fetal anomalies, and third trimester infections have a higher risk for varicella-zoster development at the neonatal period. A life-threatening illness may occur when a newborn is delivered within 5 days of the onset of maternal illness.

Management. Termination of pregnancy can be offered before viability. If continuation of the pregnancy is chosen, periodic sonographic evaluation is recommended to search for fetal anomalies, limb contractures, and other signs of fetal compromise. If maternal seroconversion is suspected for the varicella-zoster virus, combining prenatal ultrasound and magnetic resonance imaging may document the extent of tissue damage and assist in the counseling. After a therapeutic abortion, fetal infection can be confirmed by detection of varicella zoster viral DNA in several fetal tissues and placenta, and by histopathologic findings such as miliary calcified necroses in fetal organs.

Prevention. Serologic testing and vaccination should be offered to women of childbearing age, and women should be questioned about immunity to varicella preconceptionally. Susceptible pregnancy patients should be counseled to avoid contact with individuals who have chickenpox. If exposure occurs, varicella-zoster immunoglobulin should be administered within 96 hours in an attempt to prevent maternal infection. Also susceptible neonates should receive varicella-zoster immunoglobulin. Acyclovir is active against the varicella-zoster virus, and treatment is indicated in seriously ill adults and neonates.

- Hartung J, Enders G, Chaoui R, et al: Prenatal diagnosis of congenital varicella syndrome and detection of Varicella-Zoster virus in the fetus: a case report. *Prenat Diagn* 19:163, 1999.
- Chapman SJ: Varicella in pregnancy. *Semin Perinatol* 22:339, 1998.

Etiology. Probably autosomal-recessive transmission because an unusual proportion of infants are born to consanguineous parents.

Recurrence Risk. Fraser syndrome has a recurrence risk of 25% among siblings, and therefore, prenatal diagnosis and counseling of the affected families is important.

Diagnosis. The diagnosis has been suggested prenatally by the combination of the major and minor characteristics.

FIGURE 5-40. A case of Fraser syndrome diagnosed at 16 weeks' gestation. Megacystis, syndactyly, and oligohydramnios were seen. A. Sonogram demonstrating megacystis (BI) and ascites (asterisk). (B) Neonatal image. Note the distention of the abdominal wall. C. Picture of the postmortem feet showing syndactyly between I, II, and III digits. (A, B, C courtesy of Fabrice Cuillier, 2005, *thefetus.net*.)

Cases are diagnosed on the basis of at least two major criteria and one minor criterion or at least four minor criteria.

The major characteristics are

- Cryptophthalmos.
- Syndactyly.
- Genital anomalies.
- Sibling with Fraser syndrome.

The minor characteristics are

- Alterations of the nose.
- Alterations of the ears.
- Alterations of the larynx.
- Oral clefts (cleft lip and/or palate).
- Umbilical hernia.
- Renal agenesis (unilateral or bilateral).
- Skeletal anomalies.

The prenatal diagnosis of Fraser syndrome can be suspected, but because of the great variety of malformations, the diagnosis will remain doubtful unless a previous child is affected.

Sonographic Findings. Hyperechogenic lungs, laryngeal stenosis/atresia, oligohydramnios, ascites, renal agenesis/dysplasia, microphthalmia/hypertelorism, hydrocephalus, syndactyly, ear defects, ambiguous genitalia.

Pathogenesis. A defect of apoptosis has been suggested because several of the anomalies result from failure of

FIGURE 5-41. Sonogram of another fetus with laryngeal atresia and Fraser syndrome. Bilateral enlarged hyperechogenic lungs and fluid-filled bronchi (arrows) are seen. Ascites (asterisk) was present.

programmed cell death (fusion of eyelids, digits, larynx, and vagina).

Genetic Anomalies. The Fraser syndrome gene is located to 4q21.

Associated Anomalies. Cryptophthalmos, absent or malformed lacrimal ducts, middle and outer ear malformations, high palate, cleavage along the midplane of nares and tongue, hypertelorism, laryngeal stenosis, syndactyly, wide separation of symphysis pubis, displacement of umbilicus and nipples, primitive mesentery of small bowel, maldeveloped kidneys, fusion of labia and enlargement of clitoris, and bicornuate uterus and malformed fallopian tubes.

Differential Diagnosis. The differential diagnosis of hyperechogenic lungs includes congenital diaphragmatic hernia, cystic adenomatoid malformation (type III), sequestered lung, and tracheal or bronchial atresia. The differential diagnosis of the cryptophthalmos includes alobar holoprosencephaly, which should be easy to recognize from the simple hydrocephalus of the Fraser fetuses.

Prognosis. Fatal if laryngeal atresia or renal agenesis is present. If cryptophthalmos is the main sign, even surgical

repair will yield very poor vision (20/200 and 20/360) in the rare correctable cases.

Management. Depends on the predominant associated anomalies. Termination of the pregnancy can be recommended when renal agenesis or laryngeal atresia is present.

FRYNS SYNDROME

Definition. Fryns syndrome is a rare congenital disorder characterized by dysmorphic facial features (coarse face with microphthalmia, hypertelorism, facial hair growth, cloudy corneas, broad and flat nasal bridge, cleft lip and palate, microretrognathia, and low-set ears), diaphragmatic hernia, distal limb hypoplasia, and pulmonary hypoplasia. The first description was provided by Fryns in 1979.

Incidence. Unknown. Ayme and coworkers reported a prevalence of 0.7:10,000 births in France.

Etiology. Autosomal recessive inheritance.

Recurrence Risk. 25%.

Diagnosis. The phenotypic variability makes the sonographic diagnosis of Fryns syndrome a challenge. The detection of typical facial dysmorphism associated with diaphragmatic hernia (which is a leading sonographic criterion), hypoplastic thorax with widely spaced nipples, hypoplasia or absence of the lobulation of the lungs, distal limb deficiencies with hypoplasia of the terminal phalanges and nails, and postaxial oligodactyly should suggest Fryns syndrome. Development of polyhydramnios late in the second trimester and normal growth or overgrowth of the fetus are also expected. The use of three-dimensional ultrasound may be helpful to precisely define the facial anomalies. Although the frequency of cystic hygroma is not as high as the features mentioned earlier, this defect has been proposed as a sonographic first trimester marker for recurrent cases. Other findings that can be detected are persistent truncus arteriosus, interrupted aortic

arch, left isomerism, complex central nervous system midline malformations, and multiple pterygias. Maternal and amniotic fluid alpha-fetoprotein levels may be elevated, in particular in fetuses that carry open defects.

Genetic Anomalies. No specific DNA defect has been identified.

Differential Diagnosis. The differential diagnosis includes trisomy 18 (which can be excluded by karyotype), Killian/Teschler-Nicole syndrome (mosaic tetrasomy 12p), Zellweger syndrome (deficiency of peroxisomal enzyme), and Brachman-DeLange syndrome (usually associated with severe growth restriction).

Associated Anomalies. Anomalies from skeletal, cardiac, central nervous, gastrointestinal, and genitourinary systems can be associated with Fryns syndrome.

Prognosis. The majority of affected infants are stillborn or die in early neonatal period. A few reported infants who survive have severe mental and developmental retardation.

Management. When the syndrome is detected before viability, termination of pregnancy can be offered. After viability, standard prenatal care is not altered.

GOLDENHAR SYNDROME

Definition. Hemifacial microsomia, epibulbar dermoids, preauricular appendages, ear hypoplasia, transverse facial clefts, asymmetry of skull, and spinal anomalies (vertebral segmentation errors).

Incidence. This syndrome has an estimated frequency of 1/3000 to 1/5000 newborns, with a minor male-to-female (3/2) predominance.

Synonyms. Oculo-auriculo-vertebral spectrum, Goldenhar-Gorlin's syndrome, facio-auriculo-vertebral dysplasia.

Etiology. Probably sporadic, with rare cases suggesting an autosomal-recessive or autosomal-dominant inheritance.

Diagnosis. The diagnosis is usually made by observing the facial asymmetry (likely to become more common with three-dimensional ultrasound) or a maxillary cleft in association with unilateral microphthalmia. Other findings include anophthalmos, cardiac, or urinary anomalies and lipoma of the corpus callosum.

Pathogenesis. Possible fetal hemorrhage in the region of the first and second branchial arches at the time when the blood supply of these arches switches from the stapedia artery to the external carotid artery.

Genetic Anomalies. Unknown.

Associated Anomalies. Tracheoesophageal fistula, epibulbar dermoids, syringohydromyelia, neurodevelopment

FIGURE 5-42. Asymmetry of the face with hypoplasia of the left side and cleft in a fetus with Goldenhar syndrome. (Courtesy of Luc de Catte, 1999, *thefetus.net*.)

delay, occipital meningoencephalocele, tetralogy of Fallot, ventricular septal defects, asplenia syndrome, ventricular

inversion associated with double-outlet right ventricle, pulmonary atresia with ventricular septal defect, double-outlet right ventricle, infradiaphragmatic total anomalous pulmonary venous connection, ectopic and fused kidneys, renal agenesis, vesicoureteral reflux, ureteropelvic junction obstruction, ureteral duplication, multicystic kidney, and single umbilical artery.

Differential Diagnosis. Kaufman syndrome (oculo-cerebro-facial syndrome), acrofacial dysostosis, and CHARGE association.

Prognosis. Aside from the mental handicaps these patients may have, many complications result from upper airway problems as well as vertebral complications.

Recurrence Risk. Probably none unless in an autosomal-dominant/autosomal-recessive inheritance.

Management. When the diagnosis is recognized in the early stages of gestation, termination of pregnancy may be offered. In the prenatal period, the management will attempt cosmetic improvements.

HELLP SYNDROME

Definition. HELLP syndrome is an acronym for a severe variant of preeclampsia, characterized by **h**emolysis, **e**levated **l**iver enzymes, and **l**ow **p**latelets. This condition is life threatening for both mother and fetus. Sonographic signs of fetal compromise include intrauterine growth restriction, decreased tonus, decreased movement, and abnormal Doppler of the umbilical and cerebral arteries.

Incidence. HELLP syndrome affects 2% to 12% of the patients who develop preeclampsia, and white women seem to be more affected than black women.

Etiology. HELLP syndrome is a situation specific of pregnancies complicated by severe preeclampsia.

Recurrence Risk. Although the risk of recurrence is not precisely known, every patient affected by HELLP syndrome should be followed in a subsequent pregnancy as a patient at increased risk.

Diagnosis. The maternal diagnosis is made by laboratory studies (hemolysis, elevated liver enzymes, and thrombocytopenia—platelets below 100,000, which is the most consistent finding) and clinical signs and symptoms (which includes edema, hypertension, nausea, and abdominal pain due to hepatic hemorrhage and rupture). Although it is agreed that hemolysis, liver dysfunction, and thrombocytopenia must be present to make a diagnosis of HELLP syndrome, there is disagreement over the specific biochemical and

hematologic criteria to be used. The criteria specified by Sibai and Martin are often used. Sibai's criteria include hemolysis as evidenced by an abnormal peripheral smear, lactate dehydrogenase greater than 600 IU/L or total bilirubin greater than 1.2 mg/dl; elevated liver enzymes as evidenced by an aspartate transaminase greater than 70 IU/L and platelets less than 100 000/mm³. Martin's criteria include hemolysis as evidenced by a falling hematocrit, lactate dehydrogenase greater than 164 IU/L or a bleeding diathesis; elevated liver enzymes as evidenced an aspartate transaminase greater than 48 IU/L and alanine transaminase greater than 24 IU/L and platelets less than 100 000 mm³. The fetal findings include intrauterine growth restriction and reduced amniotic fluid volume, which are fetal responses to the chronic process of decreased placental blood supply, resulting from the maternal hypertension. In a more severe situation, with diminished fetal oxygen reserve, signs of distress may be found, such as decreased tonus, movement, respiratory movement, and abnormal Doppler velocimetry. Fetal demise and neonatal death are not uncommon in severe cases.

Associated Anomalies. A very important and dangerous condition that may associates with HELLP syndrome is disseminated intravascular coagulation.

Differential Diagnosis. Disorders that can result in liver dysfunction or anemia, such as thrombocytopenic purpura,

thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, gallbladder disease, viral hepatitis, and acute fatty liver of pregnancy.

Prognosis. The prognosis is variable, according to the severity of both maternal and fetal status. Maternal morbidity and mortality rates are proportionate to the severity of systemic disease, whereas fetal morbidity and mortality rates are gestational-age dependent in the majority of cases.

Management. Patients with HELLP should be considered as having severe preeclampsia. Referral to a tertiary center as well as delivery of term pregnancies is recommended. Cases remote from term of pregnancy should be managed conservatively, with intensive monitoring of both maternal and fetal well-being. Delivery should be accomplished as soon as pulmonary maturity is reached.

HEREDITARY LYMPHEDEMA I

Definition. Hereditary lymphedema is a rare disease characterized by a firm edema of the lower extremities that can be generalized to the whole leg or limited to feet or toes. It was first described by Milroy in 1828. In general, it is considered to be a benign disorder with mainly cosmetic importance.

Synonyms. Nonne-Milroy lymphedema, early-onset lymphedema, primary congenital lymphedema.

True congenital lymphedema, or hereditary lymphedema type I (OMIM 153100), usually presents either at, or soon after, birth and may be associated with other congenital malformations.

Onset of clinical symptoms in hereditary lymphedema type II (OMIM 153200) usually occurs during or near either puberty or the menopause.

In 1962, a case was reported of congenital chylous ascites in an affected infant, whose father had recurrent swelling of the scrotum beginning at the age of 20 years. In 1964, pleural effusion was observed. In 1965, Esterly described one child with a congenital type, which implies an intrinsic abnormality of the lymph-conducting pathways, or a secondary type, which implies that external factors such as radiotherapy, severe infection, or surgical excision have damaged lymph drainage routes. Most forms of primary lymphedema are thought to be caused by a congenital abnormality of the lymphatic system.

Incidence. It is estimated to occur with an incidence of approximately 1 in 6,000 newborn. The male-to-female ratio is 1:2 to 3.

Etiology. The disease has autosomal-dominant inheritance with incomplete penetrance (80%–84%), variable expressivity

FIGURE 5-43. A and B. Two-dimensional and three-dimensional sonograms of a fetus with primary lymphedema demonstrating edema of the lower extremities and feet. (Courtesy of Montse Alegre, 2005, *thefetus.net*.)

FIGURE 5-44. Photograph of neonate in Figure 5-43, demonstrating lower extremity edema. (Courtesy of Montse Alegre, 2005, *thefetus.net*.)

and variable age of onset. These features tend to appear at birth or in infancy.

Pathogenesis. All of the anomalies found are due to dysgenesis of lymphatic microvessels. This dysgenesis ranges from mild to severe and even to aplasia of both the lymphatic capillaries and collectors. This condition results from impaired lymph drainage in the presence of normal capillary filtration. It may be either primary in type, which implies an intrinsic abnormality of the lymph-conducting pathways, or secondary in type, which implies that external factors such as radiotherapy, severe infection, or surgical excision have damaged lymph drainage routes. Most forms of primary lymphedema are thought to be caused by a congenital abnormality of the lymphatic system.

Diagnosis. This condition is suggested by the finding of isolated edema of the dorsum of feet in the fetus, a normal karyotype, and absence of other significant malformations. The disease has variable expressivity and must be suspected in those fetuses with distal subcutaneous edema of the extremities, most frequently of the lower limbs, but the hands can also be involved. Findings can be present in one extremity or in all of them, and there is no concordance in the time of appearance and degree of involvement of each extremity. Occasionally, persistent or transient pleural effusion and ascites can be found. The rest of the examination is normal. The prenatal diagnosis has been suggested in fetus from 15 weeks of gestation. Chylothorax, ascites, and pericardial effusion have been described in association with the lymphedema.

Clinical Characteristics. Lymphedema is present in one or both legs at birth and is painless, nonpitting, with no tendency to ulceration, and no associated varicosities. In the majority of the cases, the lymphedema persists throughout life.

Genetic Anomalies. The exact location of the genetic alteration causing the hereditary lymphedema has not been described. However, it has recently been demonstrated that the gene is located to the region 5q34-q35. There is also

evidence that the disorder might be associated with mutations in the *FLT4* that encodes the vascular endothelial growth factor receptor-3.

Differential Diagnosis. The following dysmorphic syndromes must be considered:

- Turner syndrome.
- Noonan syndrome.
- Lymphedema-distichiasis syndrome (double row of eyelashes).
- Lymphedema and ptosis syndrome.
- Meige lymphedema (hereditary lymphedema type II).
- Congenital recessive type lymphedema.

Associated Anomalies. There are reports of associations with distichiasis, hydroceles, atrial septal defect, and characteristic facial changes.

Prognosis. Edema, particularly severe below the waist, sometimes complicated with papillomatosis and nail changes. Present in one or both legs, the lymphedema persists throughout life but does not seem to affect longevity. As the patient matures, the overlying skin displays a slightly rosy hue, while the size of the edematous parts remains proportional to the remainder of the body. The morbidity is due to infections. There are few significant complications associated with this disorder. There are case reports of intestinal lymphangiectasia, recurrent septic arthritis, angiosarcoma, and lymphangiosarcoma.

Management. If other fetal anomalies are ruled out and fetal karyotype is normal, parental counseling concerning etiology, management, and possible complications is advisable. Several individuals wear compression stockings, which are effective in containing the edema, whereas those who are more severely affected attend hospital for compression pumping to reduce limb size.

HERPES SIMPLEX INFECTION

Definition. Prenatal infection by the herpes simplex virus type II, rarely the type I.

Synonyms. None.

Incidence. Unknown.

Etiology/Pathogenesis. Transplacental or transcervical passage of the virus. Almost all neonatal herpes simplex virus infections are the results of a first-episode maternal infection near the time of labor, when the birth occurs before the development of protective maternal antibodies. It is clear that the majority of newborns acquire the virus by contact with infected genital secretions. Because the majority of cases of first episode genital herpes during pregnancy are asymptomatic or unrecognized in 60% to 80% of women, the prevention of neonatal transmission depends on the identification of the herpes simplex virus serologically discordant couple. Herpes simplex type I transforms the HB-1 human cell line by association with the human gene for adenylate kinase-1 (on chromosome 9). Women with primary genital herpes simplex infection lesions (symptomatic or asymptomatic) who deliver vaginally have a high risk (33%–50%) of transmitting infection to their neonates. With recurrent disease, the risk of transmission during a vaginal delivery is much lower (<2%–5%).

Diagnosis. Growth restriction, microcephaly, hydranencephaly, cerebellar necrosis, chorioretinitis, cataract, and microphthalmia. Hepatosplenomegaly can also be present.

Genetic Anomalies. None.

Associated Anomalies. Inguinal hernias, aplasia cutis.

Differential Diagnosis. Other TORCH infections.

Recurrence Risk. Unknown; no siblings have been reported to have been infected.

Prognosis. A majority of these babies are born prematurely. Mortality and morbidity rates are high, even though an effective antiviral therapy is now available.

Management. Isolation of the virus in amniotic fluid culture does not necessarily mean infection of the fetus. Treatment with acyclovir and vidarabine may be attempted. Studies of acyclovir use among pregnant women suggest that acyclovir treatment orally, near term, reduces the rate of abdominal delivery in women who have frequent recurrences because of a decrease on the incidence of active lesions at delivery. Cesarean delivery is indicated for all women with active genital lesions at the time of the delivery.

Prevention. Couples should be educated about the natural history of genital herpes simplex infection. Susceptible pregnant women should avoid sexual contact during the last 6 to 8 weeks of gestation if they partners have active genital infection.

HOLOPROSENCEPHALY

Definition. Holoprosencephaly is a heterogeneous entity of central nervous system anomalies caused by the impaired midline cleavage of the embryonic forebrain. In the most cases, it is associated with midfacial anomalies. Holoprosencephaly is graded according to the severity of the brain's anomaly as alobar, semilobar, and lobar (Table 5–4). In the most severe alobar form, the ventricle is continuous, whereas in the lobar form, an attempt to form occipital horns and abnormal frontal horns is present. Because of a mechanism of reciprocal induction between the brain and the skull, the facial structures are also abnormal. The severity of the facial malformation reflects the severity of the intracranial anomalies.

Synonyms. The following are part of the holoprosencephaly complex: arhinencephaly, cebocephaly, ethmocephaly, and cyclopia.

Incidence. The incidence is about 6 to 12:10,000 among live-born infants but 40:10,000 in embryos. Half of these are associated with trisomy 13. The sex distribution shows a female predominance.

Etiology. Autosomal-dominant, autosomal-recessive, and monogenic inheritance as well as infectious (cytomegalovirus, toxoplasmosis), toxic (hydantoin), and maternal conditions such as gestational diabetes have been reported.

Pathogenesis. Failure of sagittal cleavage of the telencephalon that results in the presence of a midline single ventricle with variable degrees of separation. This is probably

due to mutations in the gene for the sonic hedgehog morphogen and genes that encode its downstream intracellular signaling pathway. There is also some evidence for a defect in the cholesterol biosynthesis.

Diagnosis. The diagnosis is suggested by numerous findings such as cyclopia, cebocephaly, ethmocephaly, hypotelorism, proboscis; median cleft lip, single ventricular cavity, thalami fusion, absence of median structures, and microcephaly.

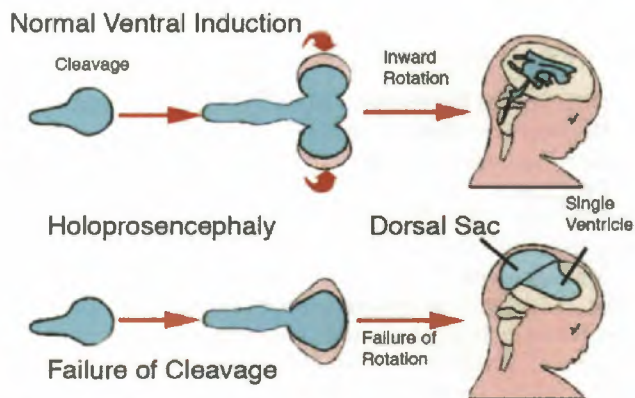

FIGURE 5-45. Normal and abnormal brain development leading to holoprosencephaly.

FIGURE 5-46. Note the proboscis above the fused eye. (Courtesy of Lenin Montilla, 2004, *thefetus.net*.)

Recurrence Risk. The risk of recurrence depends of the basis for the actual condition, such as chromosome defect or syndrome. Both autosomal-dominant and autosomal-recessive conditions have been described, but incomplete penetrance or an incomplete form or microform can make the interpretations of familial occurrence difficult. The proportion of sporadic cases is estimated to be 68%, with a 6% recurrence rate for sporadic, nonchromosomal forms. In the autosomal-dominant form, the penetrance is estimated as 82% for major types (alobar, semilobar, lobar) and 88% when major and minor types (atypical) were included. Thus, the recurrence risk after an isolated case is 13% for major types and 14% when minor types are included.

Genetic Anomaly. Possibly located on the short arm of chromosome 3, the long arm of chromosome 7 or the long arm of chromosome 14.

Associated Anomalies. Median cleft lip, proboscis, arhinencephaly, cebocephaly, ethmocephaly, and cyclopia.

Differential Diagnosis. The associated aneuploidies (trisomy 13 and 18) should be excluded by karyotype.

Prognosis. Depends on the form. The severe forms are usually associated with neonatal death. Some of the mildest form (single front incisor) may have mild to moderate mental retardation and are at risk for pituitary dysfunction.

FIGURE 5-47. Axial T2 magnetic resonance imaging view of a fetus with alobar holoprosencephaly demonstrating the single common ventricle (arrow). (Courtesy of Heron Werner, 2005, *thefetus.net*.)

Table 5-4 Classification of Holoprosencephaly

Findings	Alobar	Semilobar	Lobar
Craniofacial anomaly	Severe	Variable	Mild or absent
Ventricles	Monoventricle	Rudimentary occipital horns	Frontal horns with a rectangular aspect
Septum pellucidum	Absent	Absent	Absent
Falx cerebri	Absent	Partial	Well developed
Interhemispheric fissure	Absent	Partial	Present; some anteroinferior fusion
Thalamus, basal ganglia	Fused	Partially separated	Separated

Management. Termination of pregnancy can be offered for the severe cases (semilobar, alobar).

HOLT-ORAM SYNDROME

Definition. The Holt-Oram syndrome consists of congenital heart disease and anomalies of the upper limb (phocomelia (4.5%), radial ray aplasia, triphalangeal thumb, clinodactyly).

Synonyms. Heart-hand syndrome. (This syndrome appears genetically distinct from the Heart-hand syndrome types II and III).

Incidence. Uncommon.

Etiology. Autosomal-dominant inheritance with 100% penetrance and no evidence of reduced fitness. Increasing severity occurs in succeeding generations consistent with anticipation.

Recurrence Risk. 50%.

Diagnosis. The cardiac lesions include atrial (30%–60%) and ventricular septal defects, patent ductus arteriosus, endocardial cushion defect, hypoplasia of the left ventricle, and conduction disturbances. Seventeen percent have complex cardiac anomalies. The radial ray aplasia varies from a difficult to diagnose triphalangeal thumb to more obvious club hand. The absence of the thumb can also be recognized.

FIGURE 5-49. Scan of the left forearm at 24 weeks of gestation. The scan showed the ulna alone. (Courtesy of Fabrice Cullier, 2003, *thefetus.net*.)

FIGURE 5-48. Holt-Oram syndrome. Scan of the right forearm made at 22 weeks of gestation. The scan showed a ulna alone with clubbed arm. (Courtesy of Fabrice Cullier, 2003, *thefetus.net*.)

FIGURE 5-50. Profile of the left forearm of the fetus at 24 weeks of amenorrhea. The thumb is on the same plane as the fingers and is triphalangeal. (Courtesy of Fabrice Cullier, 2003, *thefetus.net*.)

Pathogenesis. Probable cardiomeelic developmental field.

Genetic Anomaly. Mutations in two of the T-box genes (TBX5 and TBX3) on chromosome 12q24.1 have been shown to be responsible for the congenital abnormalities associated with Holt-Oram syndrome. TBX5 is only involved in anterior limb development.

Associated Anomalies. See definition. A few inconstant anomalies such as renal anomalies have been reported.

Differential Diagnosis. The differential diagnosis is usually that of the radial ray aplasia and could include the TAR syndrome, Fanconi anemia, VACTERL association, and the radial ray-choanal atresia.

HYDROLETHALUS SYNDROME

Definition. This syndrome is characterized by multiple developmental defects of fetus such as polydactyly (postaxial in the hands and preaxial in the feet), central nervous system malformations such as hydrocephalus and absent midline structures of the brain, micrognathia, limb anomalies, and several other abnormalities, mostly in the midline structures.

Synonym. Salonen-Herva-Norio syndrome.

Incidence. Approximately 1 in 20,000. Parents often have some ancestry in an eastern region of Finland, where the syndrome was described for the first time in 1981. Outside of this subgroup, the incidence is very rare.

Etiology. Autosomal-recessive lethal malformation syndrome.

Diagnosis. The findings of massive hydrocephalus, encephalocele, micrognathia, polydactyly (in particular, a

FIGURE 5-51. Profile of the fetus at 24 weeks of amenorrhea. The angulated forearm is seen with the radial ray limb deformation. (Courtesy of Fabrice Cullier, 2003, *thefetus.net*.)

Prognosis. Mainly related to the severity of the cardiac and orthopedic handicap.

Management. Usually, no alteration of the prenatal care is needed. Great orthopedic progress at pollicization of the index finger to provide opposition have decreased the handicap of some of these children.

duplicated big toe), syndactyly, cardiac malformation, clubfeet, and polyhydramnios are very suggestive of the diagnosis. Other findings include cleft lip/palate, lung hypoplasia, and endocardial cushion defects. In families in which there has been a previously affected fetus, ultrasound diagnosis can be made in the 11th week of gestation.

Genetic Anomalies. It is caused by a missense mutation in a novel gene *HYLS1*.

Differential Diagnosis. Other midline malformation syndromes including: Pallister-Hall, Smith-Lemli-Opitz, pseudo-trisomy 13, oro-facial-digital syndrome, some skeletal dysplasias such as the short rib-polydactyly syndromes, and campomelic dysplasia are difficult to distinguish from hydrolethalus. Others include Meckel syndrome, characterized by polydactyly, central nervous system anomalies (cephalocele instead of hydrocephaly), and cystic kidneys;

acrocallosal syndrome, which shows severe mental retardation, agenesis, or hypoplasia of the corpus callosum, polydactyly of fingers and toes, and anencephaly besides other midline defects.

Prognosis. Aside from an anecdotal survival of more than a few months, neonatal death is the rule.

Management. Termination of pregnancy can be offered before viability. Standard prenatal care is not altered when continuation of the pregnancy is chosen.

HYPOPLASTIC LEFT HEART SYNDROME

Definition. Hypoplastic left heart syndrome is a congenital cardiac anomaly characterized by the association of a small left ventricle with aortic atresia and mitral hypoplasia or atresia.

Synonyms. Aortic atresia.

Incidence. Hypoplastic left heart syndrome comprises 10% to 15% of prenatally detected congenital heart diseases, and affects 1.6 per 10,000 live births.

Etiology. The etiology of hypoplastic left heart syndrome is not precisely known. Autosomal-recessive, autosomal-dominant, and polygenic inheritance have been suggested. Multifactorial is the more likely form of transmission.

Recurrence Risk. The recurrence risk depends on the etiology and varies from 0.5% to 25%, being quoted at around 2% in most of the cases. According to Norwood, the recurrence risk is 4% for those families with one affected child and 25% for those with two or more affected children.

Diagnosis. The typical findings seen on four-chamber view include a small, thick-walled and hyperechoic left

ventricle, with weak contractility. Aortic valve atresia, variable degree of hypoplasia of the ascending aorta and poor mitral valve motion are also expected. The presence of an echogenic bundle where the atrioventricular valve should have been is a typical finding of the mitral or tricuspid atresias. In hypoplastic left hearts, the aorta is small or not visible, whereas in hypoplastic right heart the pulmonary artery is hypoplastic or missing. The identification of a small amount of flow (usually only feasible with color Doppler) is important. If the flow is retrograde, the septum is usually intact and the prognosis poor. The presence of antegrade flow signals the presence of a ventricular septal defect.

Pathogenesis. Unknown.

Genetic Anomaly. A defect at 11q23.3 has been suggested.

Associated Anomalies. Aside from the cardiac anomalies (mentioned earlier), extracardiac defects are frequently seen associated with hypoplastic left heart, and the most common are two-vessel cord, craniofacial, gastrointestinal, genitourinary, and central nervous system abnormalities.

FIGURE 5-52. Hypoplastic left heart. Four-chamber view. The left ventricle is posterior and to the right of the image. Note how much smaller it is than the right ventricle. There is also a small pericardial effusion in the atrioventricular groove on the right side of the heart.

FIGURE 5-53. In the "three-vessel" view the "line-dot-dot" configuration of the pulmonary artery, the ascending aorta and the superior vena cava is incomplete. The hypoplastic ascending aorta is missing between the pulmonary artery and the superior vena cava.

Differential Diagnosis. The single ventricles, hypoplastic right ventricles and the severe forms of endocardial cushion defect may all appear similar in the four-chamber view. A careful observation of the position of the atria, atrio-ventricular valves, and great vessels often allows the correct diagnosis.

Prognosis. Hypoplastic left heart syndrome is responsible for 25% of cardiac deaths in the first week of life. Almost all of the affected infants die within 6 weeks if they are not treated. Several palliative procedures, including atrial septectomy, banding of the pulmonary artery, and creation of aortopulmonary shunt have been used. Patients undergoing these procedures either died at some time after the operation or have been followed for a very limited period. Thus far, Norwood reconstruction and cardiac transplantation are the most successful techniques, but the success rate is still very limited.

KLIPPEL-FEIL SYNDROME

Definition. Klippel-Feil syndrome first was described by Klippel and Feil in 1975. It is a congenital anomaly characterized by a classic triad including short neck, low posterior hairline, and limited range of motion due to fusion of cervical vertebrae. It now is known that fewer than 50% of patients with congenital defects of the cervical spine have all three signs of this classic triad. Patients with Klippel-Feil syndrome were assigned to one of three types:

- Type I comprises fusion of many cervical and upper thoracic vertebrae into bony blocks.
- Type II has fusion at only one or two vertebrae, and may associate hemivertebrae and fusion of the occipito-atlantoic joint.
- Type III has both cervical fusion and lower thoracic or lumbar fusion.

Synonyms. Segmentation syndrome 1.

Incidence. It has been estimated that it occurs in approximately 1:40,000 TO 42,000 births, which may be an

FIGURE 5-54. Second trimester sonogram of a fetus with Klippel-Feil syndrome. Persistent retroflexion of the head on the neck should raise suspicion.

Management. When the diagnosis is made before viability, the option of pregnancy termination can be offered. After viability, delivery in a tertiary center should be recommended where a cardiovascular team is prepared to undertake surgical care of the infant.

underestimate because some mild forms may be underreported. A slight female predominance of approximately 3:2 has been reported.

Etiopathology. Anomalies of segmentation of the somites in the 4th to 8th week.

Diagnosis. The short neck may be associated with opisthotonos (retroflexion of the head), and the disorganization of the cervical vertebrae is potentially recognizable. It is sometimes associated with ocular malformations, cleft lip and palate and occasional oligodontia in both the primary and permanent dentition, craniofacial asymmetry, maxillary constriction and velopharyngeal insufficiency, persistent trigeminal artery, congenital heart defects and renal (renal agenesis, and genital anomalies. An interesting case of an intramedullary mass thought to be due to this syndrome has also been reported, perhaps due to a maldevelopment of the cervical spine.

Genetic Anomalies. Dominant inheritance with reduced penetrance and variable expression of a defective gene on the long arm of chromosome 8 at locus 22.2. Possible role of PAX1 in the pathogenesis of KFS is object of studies. It has

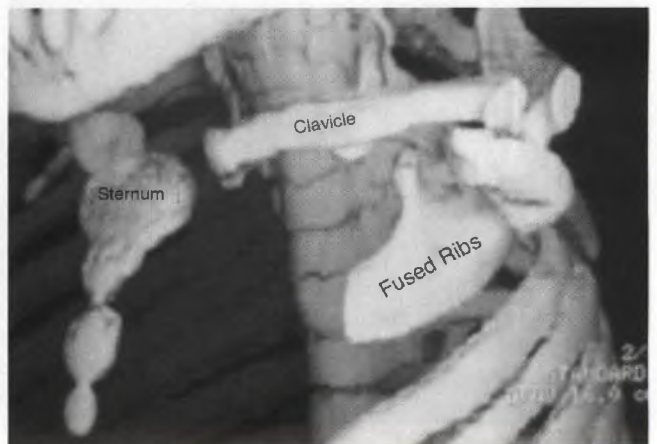

FIGURE 5-55. Reformated computer tomographic scan of a 2-year-old child with Klippel-Feil syndrome. Note the fused ribs. (Courtesy of Ian Suchet, 2002, *thefetus.net*.)

FIGURE 5-56. A child with Klippel-Feil syndrome. Note the opisthotonic position, low-set ears, and micrognathia.

been shown that a PAX1 mutant mouse is characterized by vertebral segmentation defects, reminiscent of the human disorder Klippel-Feil syndrome.

Differential Diagnosis. Iniencephaly presents with similar opisthotonos but appears more severe (cervical spina

KLIPPEL-TRENAUNAY-WEBER SYNDROME

Definition. In 1900, Klippel and Trenaunay originally described the entity of limb overgrowth, multiple cutaneous angiomas, and varicose veins, which was confirmed by Parkes-Weber in 1918 and extended by the infrequent finding of arteriovenous fistulae. This syndrome is a rare congenital soft tissue anomaly, with sporadic occurrence, characterized by a triad of multiple hemangiomas, arteriovenous fistulas, and unilateral limb hypertrophy, due to bony and soft tissue overgrowth.

Synonyms. Klippel-Trenaunay syndrome; angio-osteohypertrophy syndrome, Parkes-Weber syndrome.

Incidence. Rare.

Etiology. Happle suggested a predominant inheritance that most satisfactorily explains the findings. Heterozygous individuals for a single gene defect are phenotypically normal. The trait is expressed only when a somatic mutation occurs in the normal allele at an early stage of embryogenesis. The embryo is then a mosaic of homozygous or

bifida); dyssegmental dysplasia presents with similar vertebral findings but adds short limbs and cephaloceles. It is unclear whether Klippel-Feil syndrome is a discrete entity, or if it is one point on a spectrum of congenital spinal deformities. Only by identifying the link between the genetic etiology and the phenotypic pathological anatomy of the syndrome we'll be able to rationalize the heterogeneity of it.

Prognosis. The complications result from the vertebral fusion and include cord compression syndrome, cervical instability, and motility impairment.

Management. Termination of pregnancy can be offered before viability. Standard prenatal care is not altered when continuation of the pregnancy is chosen. Confirmation of diagnosis after birth is important for genetic counseling.

heterozygous cell lines for the mutation. This explains the patchy distribution of the defect.

Pathogenesis. The exact mechanism causing Klippel-Trenaunay-Weber syndrome is not known. A mesodermal

FIGURE 5-57. Klippel-Trenaunay-Weber syndrome. Sonogram of the leg of a fetus at 20 weeks' gestation with marked edema. (Courtesy of Carlos Alberto Mejia Escobar, 2000, *thefetus.net*.)

defect affecting angiogenesis and associated with persistence of the embryonic vascular network might explain the vascular anomalies. Others have suggested that a disturbance in the regulation of tissue growth factors is the underlying mechanism.

Recurrence Risk. Probably none, although some cases have raised the possibility of autosomal dominance.

Diagnosis. May include hydrops fetalis (from high-output cardiac failure) with limbs edema and hypertrophy (more girth than length), ascites, abnormal abdominal hemangiomas, and hepatomegaly. A three-dimensional diagnosis was made recently.

Genetic Anomaly. This may be due to a single gene defect on either chromosome 5q or p11.

Associated Anomalies. Kasabach-Merritt syndrome of thrombocytopenia due to platelet consumption within the hemangioma, and high-output cardiac failure may complicate the outcome. It is reported also an association with an umbilical cord hemangioma.

Differential Diagnosis. Lymphangioma, Proteus syndrome, and fetal thoracic mass (even if color-flow Doppler studies of the mass are negative).

LARSEN SYNDROME

Definition. This syndrome consists of skeletal dysplasia with multiple joint dislocations and short stature and abnormal facial features. There are two forms of the syndrome: a lethal and a nonlethal form. The lethal form is usually fatal due to pulmonary hypoplasia.

Synonyms. None.

Incidence. It is a rare anomaly with an estimated incidence of 1/100,000 births.

Etiology. Both autosomal-dominant and autosomal-recessive patterns of inheritance have been reported.

Pathogenesis. Generalized mesenchymal disorder involving connective tissues due to a decreased α -1/ α -2 chain ratio in type I collagen.

Diagnosis. Prenatal diagnosis of Larsen syndrome is difficult and a review of the literature revealed only five previous cases. The abnormal joint with dislocations (hip dislocation, genu recurvatum, clubhands from accessory carpal bones, clubfeet) can be associated with rhizomelic shortening of the upper extremities and with hypoplastic fibula. A coronal cleft in the vertebral body can also be recognized. At the level of the face, a low nasal bridge, frontal bossing, micrognathia, and hypertelorism can be observed. The neurologic defects associated with Larsen syndrome include agenesis of the corpus callosum, hydrocephaly, and hearing defects.

Associated Anomalies. Some associated anomalies have also been reported including cleft palate, cervical spine instability, cardiac defects, and pulmonary hypoplasia.

Genetic Anomalies. The gene locus is at 3p21.1-p14.1.

Differential Diagnosis. It has to be differentiated from the congenital genu recurvatum, arthrogryposis multiplex congenita, Pena-Shokeir phenotype, and cerebro-oculo-facio-skeletal syndrome. In the absence of familial history, these patients are usually identified as having arthrogryposis.

Prognosis. When recognized, the tracheomalacia, pulmonary insufficiency, and vertebral instability (cervical kyphosis from marked hypoplasia of one or two vertebral

Prognosis. When detected prenatally, the disorder is usually more severe and the prognosis poor when associated with cardiac insufficiency.

Management. Termination of pregnancy can be offered in the severe forms; otherwise, no alteration of management is expected. Given the rarity of the disease, there is not enough information available to counsel patients regarding obstetric outcome.

bodies—usually the fourth or fifth cervical vertebra) can be managed to improve the prognosis but probably only for the nonlethal form.

Management. Termination of pregnancy can be offered before viability. Standard prenatal care is not altered when continuation of the pregnancy is chosen. Confirmation of diagnosis after birth is important for genetic counseling.

LETHAL MULTIPLE PTERYGIUM SYNDROME

Definition. Massive and early hydrops with cystic hygroma and joint contractions. Pterygium is used to describe webbing of the skin across the joint. The term means “wing-like.” Limb pterygia at birth indicate an abnormal developmental process probably occurring in the first trimester and involving reduced mobility of the webbed limb. The severity of the web appears to correlate directly with the degree of hypomobility of the affected joint and with the time in development at which the movement reduction began. This syndrome consists of a constellation of multiple anomalies associated with fetal akinesia sequence and fixation and hypomobility of the joints.

Incidence. Unknown but not rare in the first trimester.

Synonyms. Lethal contractural syndromes.

Etiology. Autosomal-recessive syndrome, with a few cases suggesting an X-linked transmission or a glycogen storage disease type IV.

Pathogenesis. The data suggest that the syndrome combines the manifestations of a jugular lymphatic obstruction sequence with those of an early severe fetal akinesia sequence with two possible mechanisms: an abnormally fragile collagen constitution or an early fetal muscular “dystrophy.”

Diagnosis. In the first trimester, the appearance of a thickened nuchal lucency extending around the whole body and, to a lesser extent, the limbs is characteristic. These fetuses have hydrops and bob along in the fluid when shaken. Occasionally, the diagnosis is not made until later in the pregnancy, at a time when the hypokinesia, the joint contractions, and the multiple pterygia are more visible. Other possible findings are polyhydramnios, craniofacial/ocular anomalies, short forearms of the fetus, pulmonary hypoplasia, diaphragmatic hernia, scoliosis, and fractures.

Genetic Anomalies. Unknown.

Differential Diagnosis. Some of the severe aneuploidies may also present with hydrops. The arthrogryposes (fetal akinesia sequence), the cerebro-oculo-facio-skeletal syndrome and the Pena-Shokeir syndrome show joint contractions, too, so they should be considered in the differential diagnosis. But the most obvious ultrasound finding in lethal multiple pterygium syndrome is not the contractions but the hydrops. Limited pterygia of the popliteal regions can also be seen in fetuses with caudal regression syndrome. Noonan syndrome also presents with cystic hygroma.

FIGURE 5-59. Lethal multiple pterygium syndrome. Photograph of the fetus showing evidence of contracted joints and cystic hygroma.

Associated Anomalies. Some vertebral and other bony anomalies may be present.

Prognosis. Lethal.

Management. Termination of pregnancy can be offered before viability. Standard prenatal care is not altered when continuation of the pregnancy is chosen. Confirmation of diagnosis after birth is important for genetic counseling.

LISSENCEPHALY

Definition. Lissencephaly is a cerebral developmental disorder, with agyria of the brain, which may be accompanied by pachygyria, minimal or no hydrocephalus, a wide cortical mantle, and characteristic dysmorphic features. Miller in 1963 and Dieker in 1969 provided the first descriptions. Lissencephaly is a cerebral developmental disorder with reduced or absent brain gyri, which is caused by disturbed neuronal migration in the neocortex. Two main distinctive types (type I and type II) exist, both with subconditions. Lissencephaly is differentiated in two main groups with subtypes and a third distinctive type:

LISSENCEPHALY TYPE I. Characterized by agyria with or without pachygyria, a wide cortical mantle and minimal or no hydrocephalus. Both agyric and pachygyric regions have a four-layer cortex: (1) a molecular layer, (2) an outer cellular layer (true cortex), (3) a cell sparse layer, and (4) a deep cellular layer composed of heterotopic incompletely migrated neurons.

- Miller-Dieker syndrome.
- Norman Roberts syndrome.
- Isolated lissencephaly.

LISSENCEPHALY TYPE II. The thickened cortex is disorganized without layering. Vascular bundles and

FIGURE 5-80. Abnormal Sylvian fissure/insula at 26 weeks. *A*, Axial ultrasound image at 26 weeks in a fetus with lissencephaly associated with Miller-Dieker syndrome shows a shallow, flat Sylvian fissure/insula (arrow) with absence of angularity at the insular margins. Image in the inset shows the expected appearance of the Sylvian fissure/insula in a 26-week normal fetus. Infolding of the operculum should be seen with acute angles (black arrows in inset) at the margins of the insula (white arrowhead in inset) at 24.5 weeks' gestation. *(B)* Axial and *(C)* coronal T2-weighted magnetic resonance images at 28 weeks in the same fetus with Miller-Dieker syndrome showing a shallow Sylvian fissure (arrow). The brain has an hourglass or figure-of-eight appearance on the axial image. Also note the agyria, large subarachnoid space, and mildly dilated occipital horns. (Reproduced with permission from Fong KW, Ghai S, Toi A, et al: Prenatal ultrasound findings of lissencephaly associated with Miller-Dieker syndrome and comparison with pre- and postnatal magnetic resonance imaging. *Ultrasound Obstet Gynecol* 24:716, 2004.)

fibroglial tissue are present in the cortex and subarachnoid space. Lissencephaly type II typically is characterized by hydrocephalus and additional serious central nervous system defects. It is usually part of a syndrome.

- HARD+/-E syndrome.
- COM syndrome.
- Other subtypes.

NEU-LAXOVA SYNDROME. Lethal autosomal-recessively inherited disorder consisting of growth restriction, microcephaly, lissencephaly, corpus callosum agenesis, intracranial calcifications, cerebellar hypoplasia, facial dysmorphism, microphthalmia, exophthalmos, cataracts, absent eyelids, hydrops, ichthyosis, contractures of extremities, and syndactyly. A prenatal ultrasound diagnosis was published in 1987, but the sonographic evaluation of central nervous system features was not mentioned.

Synonyms. Lissencephaly type I, Miller-Dieker syndrome, chromosome 17p13 syndrome, chromosomal deletion 17p13.

Prevalence. Unknown but rare; the male-to-female ratio is 1:2.25.

Etiology. Monosomy for the terminal segment of the short arm of chromosome 17, especially band 17p13. It may be discrete.

Recurrence Risk. If de novo deletion or translocation occurs, the recurrence risk is low. If the translocation is inherited from one parent (who has a balanced trans-

location), the recurrence risk may be as high as 25%. Affected children will not grow to reproductive age.

Diagnosis. Sonographic diagnosis in general is not accomplished earlier than the late second trimester, when the characteristic cerebral anomalies can be noted. The progressive microcephaly and failure of development of both sulci and gyri (which in normal conditions is well defined from 26 to 28 weeks) are suggestive of lissencephaly. The occurrence of polyhydramnios associated with intra-uterine growth restriction is an expected finding for the third trimester. If the condition is severe, polyhydramnios may complicate the diagnosis. Facial dysmorphism is characterized by prominent forehead, short nose, broad and flat nasal bridge, and protuberant upper lip.

Genetic Anomalies. Deletion at the 17p13.3 locus.

Pathogenesis. Defective neuronal migration with four rather than six layers in the cortex.

Associated Anomalies. Duodenal atresia, urinary tract abnormalities, congenital heart defects, cryptorchidism, inguinal hernia, clinodactyly, polydactyly, and ear anomalies may be found.

Differential Diagnosis. Isolated lissencephaly sequence, Norman-Roberts syndrome, lissencephaly syndromes type II such as HARD+/-E (Walker-Warburg) syndrome and COM syndrome, and Neu-Laxova syndrome as a third lissencephaly type. All syndromes that may develop microcephaly should be suspected.

Prognosis. Usually severe mental retardation affects these patients. Failure to thrive, infantile spasms, and seizures are also expected. The prognosis is poor, and death occurs usually within the first 2 years of life.

Management. Karyotyping is recommended to detect the chromosomal defect. Differentiation from lissencephaly type II is important for genetic counseling purposes, considering that type II has an autosomal-recessive pattern of transmission. No causal treatment is available at this time.

MECKEL SYNDROME

Definition. Meckel syndrome is a rare and lethal syndrome characterized by occipital cephalocele, postaxial polydactyly, and dysplastic cystic kidneys. It can be associ-

FIGURE 5-61. Occipital encephalocele. (Courtesy of Marcos V Sanchez, 2005, *thefetus.net*.)

FIGURE 5-62. Meckel's syndrome. Cystic dysplastic kidneys. (Courtesy of Marcos V Sanchez, 2005, *thefetus.net*.)

Usually, the ultrasound diagnosis is made during the third trimester, and termination is not an option. Standard prenatal care is not altered.

Ghai S, Fong KW, Toi A, et al: Prenatal US and MR imaging findings of lissencephaly: review of fetal cerebral sulcal development. *Radiographics* 26:389, 2006.

FIGURE 5-63. Polydactyly. (Courtesy of Marcos V Sanchez, 2005, *thefetus.net*.)

FIGURE 5-64. Photograph of another fetus with Meckel syndrome. Note the small posterior cephalocele, the large abdominal distention due to the bilateral cystic kidneys, and the postaxial polydactyly.

ated with many other conditions, and hepatic fibrosis is one of the most common associations.

Synonyms. Dysencephalia splanchnocystica, Meckel syndrome (used in English literature)-this is the preferred appellation and is used by both Medline's Medical Subject Heading and *The Birth Defects Encyclopedia*; Gruber syndrome (used in European literature), Meckel-Gruber syndrome.

Incidence. Not precisely known, but authors agree that this is a very rare condition. According to Bergsma, the incidence of Meckel syndrome is 0.2:10,000 live births. Salonen stated that the incidence of Meckel syndrome at birth varies from 0.07 to 0.7:10,000 births. In Finland, the disorder is unusually frequent and reaches 1.1:10,000 births. It is also estimated that this syndrome corresponds to 5% of all neural tube defects.

Etiology. Autosomal-recessive inheritance.

Recurrence Risk. 25% recurrence risk is involved.

Genetic Anomalies. The locus for Meckel syndrome is on chromosome 17, long arm, region 2, bands 1-4. Phenotypic variability and cases that did not have confirmed linkage to 17q suggest that there is some degree of locus heterogeneity.

Diagnosis. In 1981, Fraser and Lytwyn suggested that the cystic dysplastic kidneys are a constant anomaly in Meckel syndrome and, therefore, must be present in addition to at least two minor defects to make the diagnosis. This concept is still discussed, and the reported incidence of renal disorder in this syndrome varies from 95% to 100%. Initially, the kidneys develop microscopic cysts that destroy the parenchyma and enlarge the organ up to 10 or 20 times. The syndrome can be confidently detected and diagnosed by sonography at the 11th to 14th gestational week. Unfortunately, the first sonographic finding is often oligohydramnios, which makes the diagnosis more difficult to establish. It is caused by renal dysfunction, and it develops early in the second trimester when the kidneys replace extracellular diffusion as the main source of amniotic fluid. However, some cases of Meckel syndrome have normal amniotic fluid, and thus the presence of normal fluid does not exclude the diagnosis. Sometimes, absence of the bladder can also be recognized. An early sonogram, with normal kidneys, in a family at risk for recurrence, does not exclude Meckel syndrome, and a follow-up at 20 weeks of gestation is recommended.

Occipital cephalocele is present in 60% to 80%. Maternal serum or amniotic fluid-fetoprotein level may be normal, as a membrane may cover the cephalocele. Post-axial polydactyly is present in 55% to 75% of fetuses. Other limb anomalies, such as bowing and shortening, may also be present.

Finding at least two of the three features of the classic triad, in the presence of normal karyotype, makes the diagnosis. There is also a "variant" form of this syndrome that joins the posterior fossa malformation and multicystic kidneys with hepatic fibrosis.

Differential Diagnosis. The differential diagnosis will depend on the type of the associated anomalies. Owing to several sonographic similarities between these conditions, trisomy 13 must be excluded by karyotype. Another possible differential diagnosis is autosomal-dominant polycystic kidney disease.

Associated Anomalies. The constellation of possible anomalies associated with this syndrome is extensive. In some situations, such a wide phenotypic variation makes the recognition of the disease more difficult.

Prognosis. Meckel syndrome is a lethal disorder. Most infants are stillborn or die hours or days after birth. A few sometimes survive a few months with poor quality of life. According to Ramadani, there is one report of a long survivor who died at the age of 28 months. In 1997 Paavola reported another atypical case of a long survivor who died at 18 months of life.

Management. A karyotype study should be obtained when Meckel syndrome is suspected in order to exclude chromosomal disorders. If the diagnosis is made before viability, termination can be offered. When the family decides to continue the pregnancy, or if the diagnosis is made after viability, the standard obstetrical management is not altered.

MONOSOMY X (TURNER) SYNDROME

Definition. Chromosomal disorder of female patients, described by Turner in 1938, characterized by the absence of one X sex chromosome (45, XO).

Synonyms. Monosomy X, Ullrich-Turner syndrome.

Incidence. 2.5 to 5.5:10,000 live-born female infants in the white population. In the Japanese population, it has been estimated to be 7 to 21:10,000 live-born female infants. The incidence in all pregnancies, however, is considered much higher because Turner syndrome accounts for one fourth of the spontaneous abortions caused by chromosomal anomalies.

Etiology. The absence of one sex chromosome, in general the paternal chromosome, which occurs sporadically in most cases. Eight to sixteen percent of all cases are

mosaic. Advanced maternal age is not associated with this aneuploidy.

Pathogenesis. In general, the cystic hygroma is a large septated cystic mass posterior to the neck, due to a dilatation of the jugular lymphatic sacs. It is caused by a developmental delay in the connection with the venous system, or a primary abnormal dilatation or proliferation of the lymphatic channels interfering with a normal flow between the lymphatic and venous systems.

Diagnosis. Cystic hygroma is the most characteristic prenatal feature in this syndrome. Spontaneous remission of the cyst may occur, often resulting in webbing of the neck. Other common findings include lymphedema, in particular of the dorsum of hands and feet, or, in the more severe cases, anasarca, hydrops, short cervical spine, intrauterine growth

FIGURE 5-65. Monosomy X. Transverse axial view of the neck demonstrates large septated masses. (Courtesy of P. Jeanty, 1999, *thefetus.net*.)

restriction, short neck, prominent auricles, horseshoe kidney, heart defects (coarctation and bicuspid aortic valve), fetal tachycardia, bone dysplasia, and short stature. Dysgenesis of the ovaries occurs in 90% of cases, causing absent menses and infertility in adult life. Variable degrees of mental and developmental retardation are also frequently seen. Elevated maternal serum β hCG has been reported in association with Turner syndrome.

Differential Diagnosis. Head and neck cystic mass, such as cephalocele and meningocele, must be excluded. Often, the angle of junction of the cystic mass with skin can be used in the differential diagnosis. Cystic hygromas that elevate the subcutaneous tissues tend to have a smooth junction angle, whereas cephaloceles that herniate through the skin tend to have an acute angle at their junction. Cystic hygromas may occasionally be present in Robert syndrome, and other autosomal recessive disorders. Chromosomal analysis can exclude these conditions.

Genetic Anomalies. Absence or structural abnormalities of one X chromosome, such as deletion of the sex-determining region (XY Yp deletion) or mosaicism (45, X1 46, XX or 45XI 46XY), can also be responsible for this condition.

Prognosis. Intrauterine demise occurs in many cases and is generally caused by hydrops, which is the major intra-

FIGURE 5-66. The fetus at autopsy. (Courtesy of P. Jeanty, 1999, *thefetus.net*.)

uterine complication. Among survivors, the prognosis depends on the severity of the associated anomalies. Cases of mosaicism tend to have a better prognosis, and in some cases with discrete manifestations, the syndrome remains undiagnosed for years.

Recurrence Risk. Considering that Turner syndrome is a sporadic event in the majority of cases, chances of recurrence are extremely low, although not precisely known.

Management. A karyotype is recommended when Turner syndrome is suspected. Termination of pregnancy can be offered before viability. After viability, standard prenatal care is not altered.

NOONAN SYNDROME

Definition. In 1968, Jacqueline A. Noonan described 19 cases of a syndrome very similar to the disorder described by Turner. Among her patients, 17 had pulmonary stenosis and 2 had patent ductus arteriosus (12 boys and 7 girls). Other anomalies included lymphedema, pterygium coli, deformity of the sternum with precocious closure of sutures resulting in a pectus carinatum superiorly and a pectus excavatum inferiorly, coarctation of the aorta, cryptorchidism, and thrombocytopenia. Aside from this syndrome occurring

in both genders, there is a large phenotypic overlap with Turner syndrome.

Synonyms. Turner syndrome with normal XX, pseudo-Turner syndrome, male Turner syndrome, Ullrich syndrome.

Incidence. Its prevalence is 4 to 10:10,000 births.

Etiology. Autosomal-dominant inheritance with sporadic new mutations.

Diagnosis. The initial anomaly most likely to be observed is a posterior nuchal cystic hygroma, which may regress later in the gestation into a nuchal fold redundancy and

pterygium coli. Other fetuses have been suspected because of special facial features (low-set ears, depressed nasal bridge, and large head), congenital heart disease, pleural effusions, renal abnormalities, polyhydramnios, short stature, hydrops and familiar history. Some fetuses have been identified by triple marker screening, too. Congenital heart disease may appear in up to 60% of Noonan syndrome patients. In fact, a cardiac abnormality associated with cervical lymphatic abnormalities may provide the only clues to diagnoses of Noonan syndrome. In the literature, three cases of persistent right umbilical vein with no intrahepatic portion are described associated with Noonan syndrome. In these cases drainage was possible directly into the right atrium, inferior vena cava or inferior vena cava through the iliac vein. Amelioration of early nuchal region findings in a fetus with a normal karyotype and late onset of the more "typical" ultrasonographic changes may limit early prenatal detection. Noonan syndrome is yet diagnosed at birth or during childhood.

Genetic Anomalies. X-linked dominant inheritance of either a single mutant gene or a submicroscopic deletion was originally suspected, but now it is recognized that one of the genes for Noonan syndrome is located on chromosome 12 in the 12q24.2-q24.31 region.

Differential Diagnosis. Turner syndrome (excluded in boys or otherwise by karyotype) is also unlikely to be

familial, whereas Noonan syndrome has a strong familial predilection; trisomy 21; Escobar syndrome.

Prognosis. Fairly normal life expectancy for those without major complications of heart disease. After thoracoamniotic shunting, pleural effusion with hydrops has a 57% survival rate; premature delivery is the leading source of morbidity.

Management. Termination of pregnancy can be offered before viability. Standard prenatal care is not altered when continuation of the pregnancy is chosen.

OSTEOGENESIS IMPERFECTA

Definition. Heterogeneous group of genetic disorders (classically divided in four types assessed by Sillence: I, II or congenital, III, and IV) characterized by severe bone fragility, leading to abnormal ossification and multiple fractures. The four types are

- *Type I:* does not present prenatal deformities, and the diagnosis is made after birth, when the limb deformities start to develop.
- *Type II:* the most severe form; presents with multiple skeletal malformations, such as bone shortening and angulation due to multiple fractures, demineralization of

FIGURE 6-67. Osteogenesis imperfecta. A and B. Note the fractured femur. (Courtesy of Annette Reuss, 2005, *thefetus.net*.)

FIGURE 5-68. The skull demonstrates markedly decreased echogenicity and is readily compressible even with moderate transducer pressure (*left*).

FIGURE 5-69. Frontal x-ray scans of the fetus. Note the poor mineralization and the numerous fractures.

the skull, narrow and bell-shaped chest caused by fractures of the ribs, decreased fetal movement, wrinkling of the surface of the bones due to multiple fractures.

- *Type III*: less severe form than type II, usually presents multiple fractures at birth, with development of progressive bone deformities from neonatal period to adolescence. Detectable as early as second trimester in *type IIIc*.
- *Type IV*: this is the mildest presentation of the disorder, not detectable prenatally. It usually involved premature osteoporosis in the 4th to 5th decades of life.

Synonyms. Osteogenesis imperfecta congenital, Van der Hoeve syndrome, Lobstein disease, trias fragilitas osseum, brittle bone disease, and Vrolik disease.

Incidence. 0.4:10,000 live births and about half of it (0.19:10,000) represent type II.

Etiology. In the majority of the cases of both types I and IV, an autosomal-dominant pattern is involved. Type II is a *de novo* dominant mutation (with a few reports of autosomal recessive pattern), and type III is either autosomal recessive or dominant.

Recurrence Risk. Depends on the form of transmission. In general, it ranges from 2% to 5% for type II, if it is not caused by a spontaneous mutation.

Diagnosis. The sonographic findings that may be present (in particular in type II) include broad, short, fractured long bones, with a wrinkled appearance caused by callus formation, decreased ossification of the skull, with increased visualization of the intracranial structures, small bell-shaped chest, abnormal skull shape, broad irregular ribs, angulation of the long bones, abnormal face. A typical finding of osteogenesis imperfecta type II is the ability to see both cortices of a bone. Normally, the distal cortex is shadowed by the proximal, but not in the severe demineralization of osteogenesis imperfecta (achondrogenesis and hypophosphatasia may present the same finding). Most of the anomalies can be detected in utero by ultrasound early in the second trimester. A normal ultrasound for a high-risk patient does not exclude the disorder. In general, if the fractures do not occur in utero, the diagnosis is made only after birth.

Genetic Anomaly. A disorder in one of the two genes responsible for the type I collagen production (*COL1A1* and *COL1A2*) is the cause of the disease.

Pathogenesis. A defect of formation, organization, and chemical composition in type I collagen (which is found in skin, ligaments, tendons, demineralized bone, and dentine) is responsible for decreased mineralization and bone fragility.

Associated Anomalies. Kyphoscoliosis, deafness, hypotonia, inguinal hernias, hydrocephalus, hydrops, prenatal grown deficiency.

Differential Diagnosis. Hypophosphatasia (infantile form), achondrogenesis, and other short-limbed dwarfisms.

Prognosis. Type II osteogenesis imperfecta is uniformly lethal, and the most frequent causes are cerebral hemorrhage and respiratory failure. The other forms develop after birth, progressive deformities of the long bones, and short stature.

Management. Owing to the uniformly fatal outcome, termination of pregnancy could be offered at any stage of the gestation when type II is diagnosed. For the other forms, termination could be offered before viability. If continuing the pregnancy is opted for, standard prenatal care should not be altered.

PALLISTER-KILLIAN SYNDROME

Definition. Rare polymalformative complex syndrome characterized by facial dysmorphism, severe mental retardation, and epilepsy.

Synonyms. Pallister-Killian syndrome, tetrasomy 12p, Teschler-Nicola/Killian syndrome.

Incidence. Human autosomal tetrasomies are rare. Among them, tetrasomy 12p is undoubtedly the least unusual. It is more common in woman of advanced age.

Etiology. Tissue-specific mosaic distribution of an additional isochromosome 12p. The chromosomal abnormality is observed in either a mosaic or a non-mosaic state on selected tissues, such as bone marrow and skin fibroblast. It generally occurs as a mosaic and the pattern intensity varies from one tissue to another. The reference tissue for isochromosome 12p is the skin fibroblast, where the abnormality is most common and clear. All of the cases are sporadic, with only a single preliminary report of recurrence.

Pathogenesis. The mechanism of the increased nuchal translucency is unclear. Tetrasomy 12p is not always diagnosed, because the tissues are affected differently. Although it is present in a high percentage of fibroblasts, it is practically absent from the blood. Individuals with Pallister-Killian syndrome are often mosaic of isochromosome 12p, but in some cases, the degree of mosaicism in the chorion villus sample is much lower than that in the fetal tissues subsequently examined. Confined placental mosaicism is a well-recognized phenomenon in a number of chromosomal abnormalities and is said to contribute to their intrauterine survival.

Diagnosis. Sonographic findings include facial anomalies as eye defects (hypertelorism), prefrontal edema, flat profile with a small nose and thin lips, but never micrognathia or clefting; fetal hydrops in the first trimester or a thick nuchal fold, pulmonary abnormalities, heart defect, diaphragmatic defects, rhizomelic limb shortening, acral hypoplasia, square hands, syndactyly, polydactyly, urogenital abnormalities, rare acral hypoplasia. Therefore, Palladini thought that the diagnosis of Pallister-Killian syndrome should be considered whenever diaphragmatic hernia and short limbs are detected. In such cases, the detection of the typical profile may contribute to establishing a diagnosis.

Differential Diagnosis. It has to be differentiated from Fryns syndrome, chondrodysplasia of Robinow (facial dysmorphism, short limbs and vertebral dysostosis), metabolic disorder (macrosomia, macroglossia), acrocallosal syndrome (preaxial polydactyly along with corpus callosum agenesis), VATER anomaly (with anal imperforation and cardiac malformations).

FIGURE 5-70. Pallister-Killian syndrome. Postmortem examination demonstrates a flat facial appearance with dysmorphic low-set ears. (Courtesy of Fabrice Cuillier, 2003, *thefetus.net*.)

Prognosis. Phenotypic expression has varied from multiple anomalies resulting in perinatal death to the more characteristic situation of profound mental retardation, coarse facial appearance, pigmentary anomalies, localized alopecia in the temporofrontal area, hypertelorism, and long philtrum. The prognosis is poor. At birth, up-slanting palpebral fissures, a broad nasal bridge, dysmorphic low-set ears, cutaneous edema on the neck and the trunk, and a long philtrum were noted. Tetrasomy 12p is not always diagnosed, because the tissues are differently affected. Although it is present in a high percentage of fibroblasts, it is practically absent from the blood. Less severely affected individuals may present in postnatal life with profound mental retardation, seizures, abnormal skin pigmentation, facial anomalies, and short necks. The psychomotor retardation is extremely severe, and is accompanied by vertebral and joint deformities, with muscular atrophy in older subjects. The blood karyotype is normal. In fibroblast

cultures, the extra chromosome resembles chromosome 20. The appearance of R bands suggests the fusion of two 12p chromosomes.

Recurrence Risk. All of the cases of Pallister-Killian syndrome described up to 1997 are sporadic.

Management. The diagnosis of Pallister syndrome based on clinical appearance alone is often difficult owing to the broad spectrum of clinical anomalies not specific to this syndrome. When highly suspected on ultrasound examination, prenatal cytogenetic studies are suggested, because survivors are severely mentally retarded. Owing to mosaicism, it is altogether necessary to examine several tissues for the presence of tetrasomy 12p, including circulating lymphocytes in which mosaicism can be low as 1% to 3%, amniocytes, chorionic cells and skin fibroblasts in which mosaicism ranges from 6% to 100%. Fluorescence in situ hybridization is the only accurate way to determine the real distribution of the isochromosome in various tissues. The occurrence of 12p tetrasomy cells decreases with age of the fetus, the mitotic index, and the time the tissues has been in culture.

PENA-SHOKAIR SYNDROME

Definition. Pena-Shokeir syndrome is an inherited disorder characterized by neurogenic arthrogryposis, facial anomalies, pulmonary hypoplasia, and dysmorphic features resulting from fetal akinesia. It was first described by Pena and Shokeir in 1974, and was subsequently included among the phenotypes associated with fetal akinesia deformation sequence.

Synonyms. Fetal akinesia/hypokinesia sequence, fetal akinesia deformation sequence, arthrogryposis multiplex congenita with pulmonary hypoplasia.

Etiology. Autosomal-recessive inheritance is the most common pattern of transmission. Several descriptions of unusual presentations suggest a heterogenic etiology.

Recurrence Risk. The prediction of the recurrence risk is imprecise due to the multifactorial etiology. In most cases, it varies from 0% to 25%.

Incidence. Unknown.

Pathophysiology. Active fetal movement starts in mid-first trimester and is of major importance for the normal development of the joints and contiguous tissues. Absent or reduced fetal movement leads to stiff joints, pterygia, and abnormal neuromuscular function with decreased fetal swallowing, which causes pulmonary hypoplasia and polyhydramnios.

Diagnosis. The combination of abnormal limb position, restrictive fetal movement with reduced or absent response

PENTALOGY OF CANTRELL

Definition. This congenital disorder described by Cantrell is characterized by two major defects: ectopia cordis and an abdominal wall defect (most commonly an omphalocele, but gastroschisis can also be present). The other three defects of the pentalogy are disruption of all the interposing structures: the distal sternum, anterior diaphragm, and diaphragmatic pericardium. Variants of the classic form, such as incomplete expressions, have also been reported. It was first described by Cantrell in 1958, and the syndrome occurs sporadically, with variable degrees of expression.

to acoustic stimulation, growth restriction, polyhydramnios, and pulmonary hypoplasia makes the diagnosis. Low-set malformed ears, hypertelorism, short neck, cleft palate, scalp edema, thoracic deformities, camptodactyly, and micrognathia may also be found. Anomalies less frequently described in association with Pena-Shokeir syndrome include diaphragmatic hernia, gastroschisis, and microcephaly.

Differential Diagnosis. Trisomy 18 may present features that overlap with Pena-Shokeir syndrome, in particular craniofacial, limb, and intrathoracic abnormalities. Karyotype analysis makes the differential diagnosis. Nonlethal forms of arthrogryposis present the same set of findings, except for the pulmonary hypoplasia.

Prognosis. Pena-Shokeir is a lethal condition. A significant number of the affected fetuses are born prematurely. Of those born at term, 30% are stillborn. Among the survivors, the majority die within a few weeks of life. Pulmonary complication is the main cause of death.

Management. Termination of pregnancy can be offered before viability. Standard prenatal care should be changed throughout the pregnancy only for maternal indications.

Reference

- Paladini D, Tartaglione A, Agangi A, et al: Pena-Shokeir phenotype with variable onset in three consecutive pregnancies. *Ultrasound Obstet Gynecol* 17:163, 2001.

Synonyms. Thoracoabdominal ectopia cordis, ectopia cordis; Cantrell-Heller-Ravitch syndrome; pentalogy syndrome; peritoneopericardial diaphragmatic hernia.

Incidence. Very rare. Approximately 90 cases have been reported in the literature, and even fewer have had the complete syndrome confirmed.

Etiology. Unknown. Sometimes it can be associated with chromosomal abnormalities.

Diagnosis. Presence of complete disruption of the anterior chest and abdominal wall, causing the five defects described by Cantrell, is the classic form and may be

FIGURE 5-71. Sonogram of an embryo at 10 weeks' gestation with pentalogy of Cantrell. (Courtesy of Fernando Maia, 2005, *thefetus.net*.)

FIGURE 5-72. Color Doppler sonogram in the same patient with pentalogy of Cantrell. (Courtesy of Fernando Maia, 2005, *thefetus.net*.)

detected as early as mid-second trimester. The typical finding of cardiac activity outside the chest in association with an omphalocele makes the diagnosis. Karyotype analysis is recommended to exclude chromosomal anomalies. Ascites and pleural effusion may occur due to compression of the contents of both chest and abdomen.

Genetic Anomalies. Unknown.

Pathogenesis. Developmental failure of a segment of the lateral mesoderm between 14 and 18 days after conception, resulting in failure of ventral wall closure and incomplete external primordial bands fusion.

Associated Anomalies. Intracardiac anomalies (i.e., tetralogy of Fallot, ventricular septal defect) are the rule. Others include cranial and facial anomalies, hydrocephalus, anencephaly, chromosomal abnormalities, malrotation of the colon, cystic hygroma, dysplastic kidney, and clubfeet.

FIGURE 5-73. Postmortem view of a fetus with pentalogy of Cantrell. (Courtesy of Heron Werner, 2005, *thefetus.net*.)

Differential Diagnosis. Isolated thoracic cardiac ectopy, ectopia cordis associated with amniotic band syndrome, body-stalk abnormality, isolated omphalocele, Beckwith-Wiedemann syndrome, chromosomal abnormalities.

Prognosis. Survival is rare and depends on the size of the abdominal wall defect, extent of the cardiac defect, and presence of associated anomalies. Rare milder forms may be corrected surgically. Cases presenting a complete extrusion of heart and abdominal contents have an extremely poor prognosis.

Recurrence Risk. Unknown. No recurrence has been recorded. One set of monozygotic twins concordant for the syndrome has been reported.

Management. Termination of pregnancy can be offered before viability. After viability, periodic ultrasonographic evaluation of the lesions, fetal growth, and delivery in a tertiary center are recommended. After delivery, repair of the omphalocele should not be delayed. Repair of the sternal, diaphragmatic, and pericardial defects can be attempted at the same time. Surgical correction is often difficult secondary to hypoplasia of the thoracic cage and inability to enclose the ectopic heart. Some affected infants have respiratory insufficiency secondary to pulmonary hypoplasia. Recognition and treatment of any intracardiac anomaly is important because congenital heart disease is a source of major morbidity in infants surviving the neonatal period.

PFEIFFER SYNDROME

Definition. The Pfeiffer syndrome is characterized by bilateral coronal craniosynostosis, midface hypoplasia and syndactyly of hands and feet, and congenitally enlarged thumbs. It was originally described in eight persons from three generations by Pfeiffer in 1964. It is divided in three clinical subtypes, with diagnostic and prognostic implications:

- Type I. Classic appearance with craniosynostosis, broad thumbs, syndactyly, and normal intelligence. This form is compatible with life. It has generally good outcome.
- Type II. Cloverleaf skull, ocular proptosis, broad thumbs, variable visceral anomalies, elbow ankylosis, and severe compromise of the central nervous system. Usually results in early death.
- Type III. Craniosynostosis, severe ocular proptosis without cloverleaf skull, elbow ankylosis, and variable visceral anomalies. Affected fetuses have severe neurologic compromise, with poor prognosis and early death.

Synonyms. Acrocephalosyndactyly type 5

Incidence. Unknown. Since the first description was done, approximately 30 cases have been reported.

Etiology. Type I: autosomal-dominant or fresh mutations. Types II and III: sporadic

Recurrence Risk. Variable, depending on the etiology. When the transmission has an autosomal-dominant pattern, the recurrence risk is 50%. If caused by fresh mutations, the risk of recurrence is very low.

Diagnosis. Sonographic signs of Pfeiffer syndrome include craniofacial anomalies (brachycephaly, acrocephaly, craniosynostosis of the coronal suture, hypertelorism, small nose, and low nasal bridge) and hands and feet anomalies

(partial syndactyly of second and third fingers and second, third, and fourth toes, broad thumb, and big toe).

Genetic Anomalies. Pfeiffer syndrome is genetically heterogeneous. Some cases are linked to mutations at the fibroblastic growth factor receptor 1 (*FGFR1*) gene at chromosome 8p11.22-p12. Mutations at the *FGFR2* gene, which map at chromosome 10q25-q26, were also reported. An exclusive paternal origin of a de novo mutation, associated with advanced paternal age, has been described in Pfeiffer syndrome.

Associated Anomalies. Choanal atresia, tracheomalacia and bronchomalacia, cloverleaf skull, fused vertebra, Arnold-Chiari malformation, hydrocephalus, and imperforate anus. After birth, seizures and mental retardation may develop.

Differential Diagnosis. The main differential diagnosis includes the syndromes that are characterized by craniosynostosis (Apert, Carpenter, Crouzon, kleeblattschädel anomaly, and thanatophoric dysplasia).

Prognosis. The prognosis depends on the severity of associated anomalies, mainly on the severity of the central nervous system compromise. Type I has in general a good prognosis. Types II and III are not compatible with life, and death occurs early.

Management. Termination of pregnancy can be offered before viability. If continuation of the pregnancy is chosen, periodic sonographic evaluation of the anomalies (central nervous system anomalies in particular) is recommended.

PIERRE ROBIN SYNDROME

Definition. The Pierre Robin syndrome is a rare malformation that consists of micrognathia, glossoptosis, and a cleft palate.

Synonyms. Cleft palate-micrognathia-glossoptosis, Pierre Robin sequence, Robin anomalad.

Incidence. 1:8500 live births.

Etiology. Autosomal-recessive inheritance, with a few X-linked cases. Some authors suggested a prenatal and neonatal brain stem dysfunction as a neuroembryological hypothesis to explain the onset of some cases of Pierre Robin sequence.

FIGURE 5-74. Pierre Robin syndrome. A. Normal autopsy. The tongue (arrow) occupies the anterior part of the mouth and free airway as compared with (B). B. Glossoptosis (arrow) and "no tongue" in the anterior space of the mouth.

Diagnosis. The easiest method to establish the diagnosis is to obtain a sagittal section of the face, in which the micrognathia is most visible. Three-dimensional multiplanar imaging increases the likelihood to analyze a true midline sagittal view of the facial profile. Another important clue is often the polyhydramnios resulting from the failure to swallow properly due to the macro-retroglossia. Other findings can be oro-digestive and cardiorespiratory functional disorders.

Genetic Anomalies. Unknown (this is a heterogeneous group of conditions).

Differential Diagnosis. The agnathia-microstomiasynotia syndrome (otocephaly) resembles a severe form of Pierre Robin syndrome. Other causes of micrognathia include trisomy 13, trisomy 18 and the cerebro-costo-mandibular syndrome characterized by Pierre-Robin anomaly, multiple rib defects and occasional occurrence of intellectual impairment.

Associated Anomalies. May be associated with trisomy 18, Stickler syndrome, and other syndromes. Cardiac abnormalities were also commonly detected with an incidence approaching 20%.

POLAND SYNDROME

Definition. Poland syndrome consists of a congenital unilateral absence or hypoplasia of the pectoralis muscle, most frequently involving the sternocostal portion of the pectoralis major muscle, and a variable degree of ipsilateral hand and digit anomalies, including symbrachydactyly. Ipsilateral aplasia of the breast exists in females. Dextrocardia has been reported in several cases.

Synonyms. Poland-Moebius syndrome, subclavian artery supply disruption sequence.

Incidence. The incidence, reported by different authors, ranges from 1:10,000 to 1:100,000. It is observed more frequently in males than in females; the right side of the body is affected more often than the left.

Etiology. The etiology of this syndrome is still discussed. Most of the cases are sporadic, but a familial incidence is described, too. Genetic causes, vascular compromise in the subclavian arteries during early stages of embryogenesis, and teratogenic effects of environmental xenobiotics (cigarette smoking by pregnant women) are different etiologic factors considered.

Diagnosis. The chest asymmetry and symbrachydactyly can be recognized, but the long bones are probably too normal to be recognized.

PRADER-WILLI SYNDROME

Definition. Complex, multisystem disorder that affects the central nervous system, with a predilection for the hypothalamus.

Synonyms. Prader-Labhart-Willi syndrome.

Etiology. It can be considered an autosomal-dominant disorder and is caused by deletion or disruption of a gene or several genes on the paternal chromosomal 15q11-q13 region, or a maternal uniparental disomy (maternal UPD15/mUPD15) of chromosome 15 with normal karyotype (because the genes on the maternal chromosome 15 are virtually

Prognosis. Upper airway obstruction, neonatal respiratory distress and feeding problems.

Management. Termination of pregnancy can be offered before viability. Standard prenatal care is not altered when continuation of the pregnancy is chosen. Antenatal recognition is important because it allows the pediatrician to provide immediate assistance for the infant. It is a neonatal emergency because the tongue may obstruct the airways and lead to suffocation. Confirmation of diagnosis after birth is important for genetic counseling.

- Hsieh YY, Chang, CC, Tsai HD, et al: The prenatal diagnosis of Pierre-Robin sequence. *Prenat Diagn* 19:567, 1999.

Genetic Anomalies. Not established.

Differential Diagnosis. Differential diagnosis in the fetus is limited to those conditions characterized by body asymmetry, such as congenital hemidysplasia with ichthyosiform erythroderma and limb defects (CHILD) syndrome, and to the cluster of anomalies caused by the occurrence of thoracic hemivertebrae, such as chest asymmetry and rib hypoplasia. However, in cases of isolated thoracic hemivertebrae, upper limb malformations are usually absent. The real problem is represented by CHILD syndrome.

Prognosis. Aside from the anomalies of the extremity, the prognosis is excellent.

Management. Standard prenatal care is not altered. Confirmation of diagnosis after birth is important for genetic counseling.

inactive through imprinting), or an imprinting center mutation. A small cytogenetic subset of these patients have a so-called small supernumerary marker chromosome (sSMC). The vast majority of fetuses with Prader-Willi syndrome occur sporadically. Deletions account for 70% to 80% of cases; the majority are interstitial deletions, many of which can be visualized by prometaphase banding examination. A minority consist of unbalanced translocations, mostly de novo, which are easily detected by routine chromosome examination. The remainder of cases are the result of maternal uniparental disomy. In most of these latter cases,

cytogenetic examinations yield normal results. However, in a few cases, either balanced translocations, familial or de novo, or supernumerary small marker chromosomes, are observed.

Diagnosis. Ultrasound examination may reveal polyhydramnios, decreased fetal movements, malpresentation, characteristic craniofacial features, large biparietal diameter of the fetus, slightly enlarged lateral ventricles, hypoplasia of the corpus callosum, abnormal fetal heart rhythm with prolonged inactive periods and diurnal variation of the incidence of heart rate accelerations, and hypoplastic male external genitalia without intrauterine growth restriction.

Differential Diagnosis. Angelman syndrome.

Prognosis. The clinical picture manifestation in Prader-Willi syndrome is variable, and depends on the age of the affected child. It is characterized by diminished fetal activity, obesity, muscular hypotonia, mental retardation, short stature, small hands and feet, and hypogonadotropic hypogonadism. The neonate is often profoundly hypotonic, can often present with asphyxia and absence of crying. In addition, there is mild prenatal growth restriction, hyporeflexia, poor feeding due to diminished swallowing and sucking reflexes. Cryptorchidism occurs with hypoplastic penis and scrotum in boys and hypoplastic labiae in girls. Often, the most prominent features such as obesity, mental retardation and behavioral disorders do not become evident until later childhood, which can lead to underdiagnosis or late diagnosis in early childhood. Generally the feeding difficulties improve by the age of 6 months. From 12 to 18 months onward, hyperphagia causes major somatic and psychologic problems. Diminished growth is observed in the majority of infants. Small hands with delicate and tapering fingers and small feet (acromicria) are seen in most infants and adolescents; hand and foot sizes correlate well with length, but not with age, and foot size tends to be smaller than hand size. The face is characterized by a narrow bifrontal diameter, almond-shaped eyes (often in mild upslanted position), strabismus, full cheeks, and diminished mimic activity due to muscular hypotonia. Plethoric obesity becomes the most striking feature. From the age of about 6 years onward, many children present scars from scratching due to itching, and later, almost all show abdominal striae. Depigmentation relative to the familial background is a feature in about three quarters of the patients.

Recurrence Risk. Kennerknecht (1992) estimated an overall recurrence risk of 0.4%. However, if two or more siblings are affected, he estimated that the risk to the next sibling would be 50%. This syndrome usually occurs de novo with a very low recurrence risk. However, in rare cases, familial translocations are observed, giving rise to a high recurrence risk.

Management. In a karyotypically normal fetus with ambiguous male external genitalia and cerebral anomalies, extensive cytogenetic and molecular biology studies are strongly recommended because of risk of this syndrome. Candidates for prenatal diagnosis of Prader-Willi syndrome are fetuses of pregnancies in which a reduced activity is observed. Because of the long-term implications of this

syndrome, it is important to recognize its features as soon as possible so that early counseling of parents and the affected child is possible and also a prevention of the complications in both pregnancy and labour.

PRUNE-BELLY SYNDROME

Definition. Prune-belly syndrome is a rare congenital disorder, more common in boys, consisting of deficiency of abdominal wall muscles (absent or hypoplastic), cryptorchidism, and genitourinary malformations.

Synonym. Eagle-Barrett syndrome.

Etiology. Many theories have been proposed to explain the pathogenesis of this anomaly. The first one proposes that prune-belly syndrome occurs as an abnormal mesodermal development. The developmental arrest of the mesodermal elements would lead to severe abdominal laxity and defective development of the urinary tract. The second theory is that this condition is a result of the urethral obstruction malformation complex. It proposes that pressure atrophy of the abdominal wall muscles occurs when urethral obstruction leads to massive distention of the bladder and ureters. Bladder distention would also interfere with descent of the testes and, thus, be responsible for the bilateral cryptorchidism. The mechanism responsible for the urinary tract dilatation and distention is a flap valve mechanism that results from a hypoplasia of the stromal and epithelial elements of the prostatic urethra. The hypoplasia of these elements leads to an underlying weakness and subsequent sacculation of the prostatic urethra. The last theory is that this is a genetic defect on the basis of the predominance in male fetuses and few familial cases.

Incidence. 0.25 to 0.3:10,000 live births, almost exclusively in male fetuses (male-to-female ratio 20:1). The higher incidence of this syndrome in male fetuses has been explained on the basis of the more complex morphogenesis of the male urethra, possibly resulting in obstructive anomalies at several levels.

Diagnosis. The diagnosis should be suspected in fetuses with very large abdominal masses. These are, most typically, bladder obstruction caused by urethral valves, urethral agenesis, but also other abdominal masses such as an ovarian cyst. When the etiology is urethral obstruction, oligo-

hydramnios with consequent pulmonary hypoplasia and urinary ascites may result. Usually, the oligohydramnios makes the detection of cryptorchidism impossible. Other findings may be Potter facies, pulmonary hypoplasia, gastric dilatation, short bowel, microileum, microcolon, malrotation of the intestines, imperforate anus, arthrogryposis and club-foot. Additional information can be gained by addition three-dimensional ultrasonography scanning and could be useful for more efficient counseling and therapeutic planning.

Differential Diagnosis. Urinary tract anomalies such as megacystis, megaureter, urethral obstruction, and primary vesicourethral reflux are differential diagnoses. Neurogenic bladder and megacystis, microcolon, intestinal hypoperistalsis syndrome may also be considered, although the latter presents with normal amniotic fluid.

Prognosis. The prognosis depends on the degree of renal function compromise. Outcome is typically good in cases of prune-belly syndrome with normal amniotic fluid volume. The early urinary obstruction, present in the majority of cases, leads to renal failure, pulmonary hypoplasia, and death in the neonatal period. More than 60% of infants die in the first week of life. Early decompression of severe bladder obstruction improves the prognosis. Fetuses that develop mild urinary tract distention have better prognosis. Mild hydronephrosis and megalourethra may be the only manifestations in these cases.

Recurrence Risk. Unknown, but low. A familial occurrence has been seen in some affected patients, suggestive of an X-linked inheritance. A multifactorial, or polygenic, inheritance has also been proposed.

Management. Sonographic monitoring of the urinary tract and amniotic fluid volume is required throughout the pregnancy. When early or severe distention of the urinary tract is observed, a vesicoamniotic shunts with vesical decompression and correction of the amniotic fluid levels has been proposed to improve renal and pulmonary function. Anatomic abnormalities that warrant consideration

FIGURE 5-75. Prune-belly syndrome. Ultrasound demonstrating a markedly dilated urinary bladder (25 weeks). (Courtesy of Heron Werner, 2005, *thefetus.net*.)

A

B

FIGURE 5-76. A. Sagittal T2 magnetic resonance imaging scan demonstrating high signal from a markedly dilated urinary bladder (*black arrow*). (*A and B courtesy of Heron Werner, 2005, thefetus.net.*)

of correction are those that interfere with critical fetal organ development. Experimental evidence suggests that fetal urinary tract obstruction, whether intermittent or persistent, can lead to renal dysplasia, which is often irreversible, even

FIGURE 5-77. Postmortem neonatal photograph demonstrating a markedly enlarged abdomen with redundant skin. (*Courtesy of Heron Werner, 2005, thefetus.net.*)

if the obstruction is relieved immediately after birth. The percutaneous placement of an indwelling catheter for urinary diversion is one possible therapy. Urinary tract decompression in the early second trimester is desirable to reduce the potential for ongoing damage to the developing kidneys. The benefits of such therapy remain controversial and are yet to be evaluated in a prospective, randomized fashion. As such, urinary diversion should be considered on a case-by-case basis. Additionally, correction of severe oligohydramnios as early as possible should reduce the possibility of pulmonary hypoplasia. Abdominal wall reconstruction for both aesthetics and function is often necessary. Because 75% of individuals with prune-belly syndrome have extra-urinary anomalies, a thorough evaluation, especially cardiac, should be performed.

ROBERTS SYNDROME

Definition. Roberts syndrome is a rare genetic developmental disorder, characterized by multiple malformations, in particular symmetrical limb abnormality, craniofacial anomalies, and severe mental and growth restriction. It was initially described by Appelt. Herrmann described in 1974, cases of a very similar entity called pseudothalidomide or SC syndrome (SC were the initials of the two families that were originally described). Presently Roberts syndrome and SC phocomelia are considered a single genetic entity, with a wide phenotypic variation.

Synonyms. Pseudothalidomide syndrome, tetraamelia syndrome.

Prevalence. Unknown.

Etiology. This disorder has an autosomal-recessive transmission with marked variability of phenotypic expression. The disease locus was assigned to chromosome 17q21. The unique cytogenetic abnormality, called premature centromere separation, which disrupts the process of chromatid pairing, is responsible for the development of multiple structural anomalies found in Roberts syndrome.

Recurrence Risk. The recurrence risk for couples with positive family history is 25%.

Diagnosis. The presence of craniofacial anomalies such as midfacial clefts (lip and palate), hypertelorism with prominent eyes and corneal clouding, nose and ear anomalies, prominent premaxilla, micrognathia, midfacial capillary hemangiomas, microcephaly, curly silvery blond hair, symmetric limb abnormality (that range from tetraphocomelia to less serious limb reduction and affect more severely the upper limbs than the lower, and severe mental and growth retardation are very suggestive of Roberts syndrome. Less common findings include oligodactyly, oligohydramnios, heart defects (in particular atrial septal defect and patent ductus arteriosus), diaphragmatic defect, agenesis of the spleen, and adrenal glands, gastrointestinal abnormalities (obstructions), renal anomalies (polycystic or dysplastic kidneys), cryptorchidism, enlarged phallus (compared to rest of the body), hypoplasia of the pelvis, malformed uterus, atresia of the urethra, vagina, and anus.

Sonographic detection of those features is highly indicative of Roberts syndrome. Clinical findings and cytogenetic studies make the diagnosis after birth.

Genetic Anomaly. Cytogenic analysis of fetal cells, obtained from chorionic villus sampling in the the first trimester, or amniocentesis or cordocentesis during the second and third trimesters, is required to confirm the diagnosis prenatally. The presence of premature centromere separation makes the diagnosis. One negative cytogenetic analysis does not exclude Roberts syndrome. A second analysis using a different type of fetal tissue is required.

Prognosis. Most patients born at term with less than 37 cm of birth length and severe facial and limb defects have been stillborn or have died early in childhood. Patients born with more than 37 cm of birth length and less severe defects have better prognosis but the survivors have grown abnormalities and severe mental deficiency. However, survival beyond the infancy is infrequent.

Management. When detected before viability, termination of pregnancy can be offered. After viability, standard obstetrical management is not altered. For those families previously affected, chorionic villi sample for cytogenetic studies during the first trimester must be offered.

SEPTO-OPTIC DYSPLASIA

Definition. Septo-optic dysplasia is a syndrome characterized by anomalies of cerebral midline structures, such as absence of the septum pellucidum, congenital optic nerve dysplasia, and panhypopituitarism, leading to multiple endocrine defects (diabetes insipidus, hypogonadotropic hypogonadism, hypothyroidism, adrenal insufficiency, abnormal thyrotropin releasing hormone test, gonadotropin releasing hormone test, and gonadotropin hormone-releasing hormone). Septo-optic dysplasia may represent a mild form of holoprosencephaly.

Synonym. Morsier syndrome

Incidence. Unknown but rare.

Etiopathology. Although a vascular disruption sequence has been postulated, more recent genetic anomalies seem to explain the findings (see genetic anomalies later). A possible mendelian (autosomal-recessive) inheritance has also been

postulated. Also, illicit drug use may play a causative role in brain development anomalies. In addition, intrauterine exposure to valproic acid has been associated with an increased risk of central nervous system abnormalities, primarily neural tube defects.

Clinical Findings.

- Central nervous system: seizures, mental retardation, atrophy of the optic nerve, dilatation of the suprasellar cistern, empty sella, cortical atrophy and dystrophic corpus callosum, and anterior cephalocele have also been described.
- Face: hypotelorism, microphthalmia, visual impairment with nystagmus, unilateral or bilateral optic disk hypoplasia with double rim appearance (choroidal pigment in the outer margin and pale nerve tissue in the inner), variable visual loss, coloboma, strabismus, astigmatism, bilateral cleft lip and palate, high arched palate and flat nasal bridge.

FIGURE 5-78. Second trimester sonogram of the fetal head in a patient with septo-optic dysplasia. Absence of the septum pellucidum and communication of the frontal horns of the lateral ventricles (arrows) is seen.

- Endocrine system: low growth rate and short stature. The most common problem is growth hormone deficiency (93%), followed by adrenocorticotropic hormone deficiency (57%), hypothyroidism (53%), and diabetes, and gonadotropin deficiency. Hypothalamic dysfunction is the basic origin of these endocrine abnormalities. Septo-optic dysplasia is responsible for approximately 4% of all growth hormone deficiencies in children.

Diagnosis. Absence of the septum pellucidum is probably the most typical finding. Sometimes, the standard sonographic views of the brain, obtained along the axial planes at midgestation, can fail to identify this absence. It can be explained by the close proximity of the walls of the lateral ventricles, normal in size that could generate an

artifact resembling a normal cavum septum pellucidum. The magnetic resonance demonstration of hypoplastic optic tracts can allow one to make the diagnosis definitively. Hypotelorism, enlarged cerebral ventricles, communicating lateral ventricles, and bilateral cleft lip and palate have also been recognized prenatally.

Genetic Anomalies. Mutations of the homeobox gene *HESX1* is suggested as the etiologic cause at least in a subset of patients. An Arg53Cys missense mutation was found in two children within the *HESX1* homeodomain, which destroyed its ability to bind target DNA. Mice that are deficient of the *HESX1* homeobox gene present with neural defects similar to those of septo-optic dysplasia.

Differential Diagnosis. Several variants with associated schizencephaly, dysgenesis of the corpus callosum, or microphthalmos, as well as incomplete forms, have been described. Lobar holoprosencephaly may also resemble septo-optic dysplasia.

Recurrence Risk. Unknown.

Prognosis. The variable degree of mental deficit (from minimal to severe) as well as the presence of multiple endocrine dysfunctions affects the prognosis for each infant. Prevention of hyperthermia (in case of fever), dehydration (fever and diabetes insipidus), and other endocrine dysfunctions should be searched and corrected.

Management. Termination of pregnancy can be offered before viability. Standard prenatal care is not altered when continuation of the pregnancy is chosen. Confirmation of diagnosis after birth is important for genetic counseling. Prevention of recurrent hypoglycemic episodes, seizures, and hormonal imbalances may improve the overall prognosis.

SIMPSON-GOLABI-BEHMEL SYNDROME

Definition. Simpson-Golabi-Behmel syndrome is characterized by a pre- and postnatal overgrowth, a characteristic facial appearance, a high risk for the development of embryonal tumors, and a spectrum of congenital malformations (visceral and skeletal) that overlap those of other overgrowth syndromes.

Synonyms. Bulldog syndrome, dysplasia gigantism syndrome, X-linked, Dgsx Golabi-Rosen syndrome, Simpson dysmorphism syndrome, encephalo-tropho-schisis syndrome.

Etiology. By Simpson (in 1975) and Behmel (in 1984) who first described this condition.

Prevalence. Unknown.

Etiology. X-linked syndrome characterized by either deletions or point mutations within the glypican-3 (*GPC3*) gene at Xq26, one member of a multigene family encoding for at least six distinct glycosylphosphatidylinositol-linked cell surface heparan sulfate proteoglycans. Occasionally, these deletions also include the glypican-4 gene (*GPC4*). Not

all individuals with SGBS have demonstrated disruptions of the *GPC3* locus, which raises the possibility that other loci on the X chromosome could be responsible for some cases of this syndrome.

Diagnosis. An ultrasound screening can find.

- Characteristic “coarse” face with hypertelorism, a short broad upturned nose, a wide mouth, a straight facial profile with incompetence of the lips, midline groove of tongue, macroglossia, malposition of teeth, submucous cleft, malocclusion, cleft palate, a large maxilla and mandible, a large inferior face height, large anterior cranial base, sometimes also odontogenic keratocysts.
- Macrosomia.
- Skeletal anomalies such as finger hypoplasia, a congenital abnormality of the proximal phalanx, postaxial polydactyly, broad hands, hypoplastic index finger nails.
- Visceral and congenital anomalies such as pulmonic stenosis, heart defects, and severe tachyarrhythmias.

- Diaphragmatic hernia, gastrointestinal malformations, visceromegaly, pyloric stenosis, splenomegaly, large dysplastic kidneys;
- Congenital midline defects such as agenesis of the corpus callosum

Elevated maternal serum alpha-fetoprotein is also present.

Differential Diagnosis. Beckwith-Wiedemann syndrome, Sotos' syndrome, Lysosomal diseases, and other syndromes with overgrowth.

Associated Anomalies. Wilms tumor, nephroblastomatosis, hepatoblastoma, hepatocellular carcinoma, neuroblastoma, hemangioma.

Prognosis. The clinical manifestations of the syndrome are broad, varying from very mild forms in carrier women to infantile lethal forms in affected men. The affected newborns may manifest, besides the findings reported earlier and already revealed by ultrasound, an obstructive sleep apnea syndrome, mental retardation ranging from normal to mildly retarded, tall stature, generalized muscular hypotonia, increased risk for cardiac arrhythmias and for development of embryonal tumors such as neuroblastoma and Wilms' tumor in early childhood. Ambiguous genitalia (micropenis and perineoscrotal hypospadias with cryptorchidism) and supernumerary nipples are also reported. Cardiac defects and conduction disturbances are major components of the syndrome and can be responsible for death in early infancy and perhaps for cardiac arrest in the adult.

Recurrence Risk. Unknown.

Management. Depends on the predominant associated anomalies. Termination of pregnancy can be offered before viability. If continuation of the pregnancy is chosen, periodic monitoring of fetal growth and evaluation of the structural defects are recommended.

SIRENOMELIA

Definition. A congenital anomaly, caused by a disruptive vascular defect, characterized by fusion of the lower extremities, associated with renal agenesis, absence of the sacrum, rectum, and bladder. It was considered in the past to represent a severe form of caudal regression syndrome.

Synonyms. Mermaid syndrome, sirenomelia sequence.

Etiology. Although the etiology is unknown, sirenomelia is not believed to be hereditary.

Recurrence Risk. Unknown.

Diagnosis. The diagnosis of sirenomelia is based on the presence of fusion of the lower extremities associated with other skeletal and lumbar spine deformities, bilateral renal agenesis (which leads to severe oligohydramnios and pulmonary hypoplasia), and heart and abdominal wall

FIGURE 5-79. Sirenomelia. The fused extremity and the flipper-like deformity of the foot are characteristic of sirenomelia.

defects. The defect varies from simple cutaneous fusion of the limbs to absence of all long bones but one femur. The defect of the feet is proportional with the defect of the long bones, with a cutaneous defect commonly presenting with a double fused foot with 10 toes, and more severe defects presenting with a more rudimentary foot and ectromelia. Because the legs are fused, the rotation of the legs does not occur and they remain in their fetal position. Thus, the fibulae when present, are between the tibia and the sole of the foot is oriented "ventrally" instead of "dorsally."

Pathogenesis. An alteration in early vascular development, leads to a "vitelline arterial steal," in which blood flow is diverted from the caudal region of the embryo to the placenta, resulting in multiple defects of the lower extremities. Many of these fetuses have an aberrant vasculature, with the umbilical arteries connected to the old vitelline arteries (the superior mesenteric arteries).

Genetic Anomaly. Unknown.

SMITH-LEMLI-OPITZ SYNDROME

Definition. Smith-Lemli-Opitz syndrome (SLO) is a common autosomal-recessive disorder described in 1964 by Smith et al, characterized by multiple anomalies including typical facial appearance, mental and growth retardation, syndactyly of the second and third toes, genital and other abnormalities of the internal organs. Depending on the severity of the malformations, the prognosis can range from mild intellectual impairment to lethal. The diagnosis was based on clinical features found after birth or in autopsy until 1993, when Irons described the reduced plasma cholesterol levels and elevated levels of cholesterol precursor 7-dehydrocholesterol (7-DHC) in association with SLO. The confirmation of these biochemical findings by many

Table 5-5 Anomalies Associated With Sirenomelia

Abnormality	Frequency
Abnormal genitalia	Very frequent sign
Agenesis/hypoplasia of kidneys	Very frequent sign
Ambiguous genitalia	Very frequent sign
Bladder anomalies	Very frequent sign
Imperforate anus/anal stenosis	Very frequent sign
Sacrococcyx agenesis	Very frequent sign
Cardiac anomalies	Frequent sign
Radius absent/abnormal	Frequent sign
Spina bifida	Frequent sign
Tracheo-oesophageal fistula	Frequent sign

Reproduced with permission from Orphanet:
<http://www.orpha.net/consor/cgi-bin/home.php?Lng=GB>.

Associated Anomalies. Anomalies are listed in Table 5-5. Cardiac, renal, abdominal wall, chest, and lower spine defects are frequently seen. Single umbilical artery, imperforate anus, and absence of the genitals are commonly found.

Differential Diagnosis. Caudal regression syndrome is the main differential diagnosis, and it usually presents with milder deformities compared to sirenomelia and normal amniotic fluid volume. Owing to the bilateral renal agenesis, fetuses affected by sirenomelia frequently have Potter facies. The fusion of the lower extremities, present in sirenomelia, makes the differential diagnosis. Other conditions that should be excluded are Fraser and VATER.

Prognosis. This is a lethal condition due to the associated renal agenesis and its complications. Exceptional cases present without renal agenesis and may survive.

Management. Termination of pregnancy can be offered before viability. Standard prenatal care is not altered throughout the pregnancy if continuation is opted for.

other researchers proved that cholesterol and its precursors plasma levels could be reliable markers for the prenatal diagnosis. Currently, the cholesterol analysis can be made prenatally using amniotic fluid or, in the first trimester, by chorionic villus sampling. The introduction of biochemical testing for Smith-Lemli-Opitz syndrome has improved the prenatal detection of this syndrome. However, the recognition of ultrasonographic features suggestive of Smith-Lemli-Opitz syndrome is necessary to raise the suspicion, especially in patients who are not aware of their carrier condition and are having their first affected pregnancy. The ultrasonographic examination also evaluates the severity of the anomalies, and thus assists in predicting the outcome. In 1987, Curry proposed the division of the entity

into two classes: type I (the classical syndrome described by Smith) and type II (the most severe cases).

Synonyms. Acrodysgenital dwarfism, Lowry-Miller-MacLean syndrome.

Incidence. Some authors suggest that Smith-Lemli-Opitz syndrome is the second most common autosomal recessive disorder in North American whites, after cystic fibrosis. The prevalence of this syndrome has been estimated between 0.25:10,000 and 0.5:10,000, but an incidence of 1:10,000 was mentioned in 1997, in a population in Middle Bohemia. Furthermore, with the identification of a metabolic defect, a re-evaluation of these data has been suggested.

Etiology-Pathogenesis. Dellaire observed in 1966, the autosomal-recessive pattern of transmission. In 1994, Wallace reported a case of balanced translocation in an affected patient and suggested that the gene locus might be at 7q32. Caused by a defect in the cholesterol biosynthesis, Smith-Lemli-Opitz syndrome is the first known genetic syndrome with a metabolic etiology.

Diagnosis. The detection of an extremely reduced concentration of cholesterol and abnormal accumulation of 7-dehydrocholesterol in the plasma make the diagnosis in infants and adults. Elevated concentration of 7-dehydrocholesterol at amniotic fluid in the second trimester or at chorionic villus sampling in the first trimester, normally undetectable in both specimens, is a reliable marker for prenatal diagnosis of Smith-Lemli-Opitz syndrome. Cases of Smith-Lemli-Opitz syndrome with normal cholesterol and abnormal 7DHC have been reported and, thus, normal levels of isolated cholesterol do not completely exclude the disorder. Estriol levels in maternal urine late in pregnancy may be reduced, as well as estriol levels in maternal circulation. Half of the fetuses that suffered intrauterine fetal demise with Smith-Lemli-Opitz syndrome were found to have low or undetectable maternal serum estriol levels, raising the speculation that this finding might become a maternal serum screening for this syndrome. The gene for Smith-Lemli-Opitz syndrome has been mapped and mutations have been isolated, but only on experimental basis now.

Sonographic Findings. Ultrasonographic findings during prenatal examination may raise the suspicion in patients who do not have familial or past histories of Smith-Lemli-Opitz syndrome and thus, are not aware of their condition of carriers. Ultrasonographic detection of multiple anomalies such as facial anomalies, polydactyly, syndactyly (more common between the second and third toes), single palmar crease, hypospadias and cryptorchidism in the male fetus, ambiguous genitalia, cardiac defects, lung malformations and many others in association with normal karyotype is suggestive of Smith-Lemli-Opitz syndrome. The detection of major anomalies is important to evaluate the severity of the disorder. Detection of increased nuchal translucency, or persisting nuchal edema with nonimmune hydrops are other findings reported in fetuses with Smith-Lemli-Opitz syndrome 8.

Differential Diagnosis. The pattern of multisystemic anomalies is characteristic of trisomies 21, 18, and 13, and thus, karyotype is recommended to exclude these disorders. Overlap of Smith-Lemli-Opitz syndrome with disorders such as Meckel syndrome has been reported, due to variability of phenotype in both conditions. The presence of occipital encephalocele as well as dysplastic kidneys favors

Table 5-6 Associated Anomalies and Peculiarities of Smith-Lemli-Opitz Syndrome

Anatomic Area	Anomaly	
Limbs	Syndactyly (of the second and third toes in particular)	
	Postaxial polydactyly	
	Short limbs	
	Clinodactyly	
	Dislocated hips	
	Valgus deformity

CNS, central nervous system.

Meckel syndrome. Genital anomalies and syndactyly support the diagnosis of Smith-Lemli-Opitz syndrome.

Associated Anomalies. Although Smith-Lemli-Opitz syndrome more often presents features such as facial, limbs, and genital anomalies associated with growth and mental retardation, the wide phenotype variation is the most important aspect of this disorder. Anomalies from all the systems have been described, and the most common are mentioned in Table 5-6.

THANATOPHORIC DYSPLASIA

Definition. Thanatophoric dysplasia is a lethal congenital form of short-limbed chondrodysplasia, which is divided into two subtypes:

- *Type I* is characterized by extreme rhizomelia, bowed long bones, narrow thorax, a relatively large head, normal trunk length, and absent cloverleaf skull. The spine shows platyspondyly, the cranium has a short base, and frequently, the foramen magnum is decreased in size. The forehead is prominent, and hypertelorism and a saddle nose may be present. The hands and feet are normal, but the fingers are short.
- *Type II* is characterized by short, straight long bones and cloverleaf skull.

Synonyms. Thanatophoric dwarfism.

Incidence. 0.69:10,000; the male-to-female ratio is 2:1.

Etiology. Possibly autosomal-dominant inheritance, but the majority of cases result from new mutations of the fibroblast growth factor receptor 3.

Recurrence Risk. A general empiric risk was estimated in 2%.

Diagnosis. The sonographic diagnosis can be made in the presence of short-limbed dwarfism, hypoplastic thorax, cloverleaf skull, frontal bossing and simian crease. Femur bowing, narrow thorax, large head size even without ventriculomegaly, and redundant soft tissues are features that become more pronounced with advancing gestation but may not be present in midtrimester. In 70% of cases, thanatophoric dysplasia is associated with polyhydramnios, which may be massive and lead to premature labor. Fetal movements do not seem to be affected by the disease, but a decrease in motion during the third trimester has been reported. Decreased hand flexure is probably responsible for the presence of simian crease. In the absence of cloverleaf

FIGURE 5-81. Further three-dimensional surface rendering mode image shows more details. (Courtesy of Ana Bircher, 2002, thefetus.net.)

FIGURE 5-82. The upper limbs were short, mostly rhizomelic and maintain a right angle throughout all examinations. (Courtesy of Ana Bircher, 2002, *thefetus.net*.)

skull, the disease should be suspected when severe rhizomelic dwarfism and a narrow thorax are detected. Sonographic measurement of fetal femur length, especially when correlated with biparietal diameter, is a reliable method in the identification of certain forms of short-limbed skeletal dysplasias, as well as thanatophoric dysplasia.

Pathogenesis. Characteristic generalized disruption of the growth plate with persistent mesenchyme-like tissue.

Associated Anomalies. “Cloverleaf skull” (in type II), horseshoe kidney, hydronephrosis, atrial septal defect, defective tricuspid valve, imperforate anus, and radioulnar synostosis.

Differential Diagnosis. Chondroectodermal dysplasia (Ellis-van Creveld syndrome), asphyxiating thoracic dysplasia, short rib–polydactyly syndrome, and homozygous achondroplasia. All short-limbed dwarfism should be considered. If type II is suspected, conditions that have association with craniosynostosis and cloverleaf skull should be excluded (Apert, Crouzon, Pfeiffer, Carpenter, and Kleeblattschadel syndromes).

Prognosis. This is a uniformly lethal condition, and in general, affected infants die shortly after birth. The cause of death is respiratory failure due to hypoplastic lungs.

Management. The option of pregnancy termination should be offered before viability. Sonographic evaluation of hydrocephalus is recommended, considering that it may cause malpresentation and difficult delivery. If massive hydrocephalus has developed, cephalocentesis or elective cesarean section should be considered to avoid maternal trauma.

TUBEROUS SCLEROSIS

Definition. This syndrome is associated with facial angiofibroma (often incorrectly called adenoma sebaceum), epilepsy, mental retardation, renal cysts, multiple and bilateral angiofibroma of the kidney, and rhabdomyoma of the heart. Diverse cutaneous manifestations such as hypochromic patches (visible under Wood light) and café-au-lait patches (light brown areas) are also typical of the syndrome. Brain tumors such as ependymoma of the third ventricle and astrocytoma may also be present.

Synonym. Bourneville sclerosis and Brissaud.

Incidence. 0.3 to 1:10,000. The age of onset is in the first decade of life.

FIGURE 5-84. Tuberosclerosis. Several rhabdomyomas are seen in this four-chamber view of the heart. (Courtesy of Luc Gourand, 2002, *thefetus.net*.)

Table 5-7 Main Aspects of Tuberous Sclerosis

Classic triad (<50% of cases):
Facial lesions,
Convulsions and
Mental retardation
Central Nervous System
Cortical hamartomas
Lesion of white substance*
Subependymal hamartomas (95%)
Typical localization: alongside lateral ventricle walls
Astrocytoma of subependymal giant cells*
Localization: foramen of Monro
Obstructive hydrocephaly
Kidney:
Cysts
Angiolipoma
Cardiovascular:
Rhabdomyoma
Aneurysm, stenosis, and vascular ectopia
Liver:
Leiomyoma
Adenoma

*No reports of intrauterine visualization.

Etiology. Autosomal-dominant inheritance with a large proportion of fresh mutations (sporadic cases). The expression is highly variable.

Pathogenesis. Tubers are the expression of an early disorder of the embryogenesis. The greater the number of tubers, the greater the number of neurologic impairments. They can be found everywhere within the cerebral hemispheres, such as in the subependymal region located in the walls of lateral ventricles and on the surface of the basal ganglia. They may extend into the ventricles in the foramen of Monro area, and they can cause obstruction and hydrocephalus. They may also appear in the cortical gyri and sulcus terminalis. Tuberous sclerosis induces a reduction of the number of neurons, which are substituted by "monster" multinucleated giant neurons. The overgrowth of the fibrillary astrocytes can result in malignant astrocytomas. The sclerosis induces a demyelization, as well as calcium deposition in the glia and the blood vessels, which go through hyaline degeneration.

Clinical Findings. Tuberous sclerosis can show a wide variety of signs that involve many organs as a consequence of the multifactorial origin of this genetic disorder (Table 5-7).

Diagnosis. The diagnosis is usually suggested by the discovery of cardiac tumors, which resemble small uterine fibroids (round, usually well-delineated homogeneous masses). Between 51% and 86% of cardiac rhabdomyomas are associated with tuberous sclerosis. Occasionally, the finding of a rhabdomyoma during routine second trimester ultrasound examination may lead to the recognition that the

mother is affected. Cardiac rhabdomyomas increase prenatally, may regress in early infancy, remain unchanged during childhood, and regress in adolescence. The rhabdomyomas may cause rhythm disruptions (Wolff-Parkinson-White syndrome, supraventricular tachycardia, paroxysmal arrhythmias) as well as obstructions or regurgitation. Renal angiofibromas have not been recognized prenatally, although this may simply be a matter of time. Some recent unpublished reports have demonstrated that the periventricular subependymal nodules may also be detected.

Two-dimensional Doppler echocardiography is a useful, noninvasive method to diagnose fetal cardiac rhabdomyomas and to monitor their influence on fetal cardiac function. However, it does not help to determine which fetuses affected by rhabdomyomas will develop tuberous sclerosis. Some studies report that 39% of prenatal suspected cardiac rhabdomyomas will be diagnosed at birth as a tuberous sclerosis syndrome. Family history remains the strongest predictor of the syndrome in prenatal counseling, whereas size of the cardiac tumor can not reliably be used. Magnetic resonance imaging can be performed to assess all of the associated malformations.

Genetic Anomalies. Tuberous sclerosis C is caused by defects or mutations on two genes, tuberous sclerosis C1 and tuberous sclerosis C2. Only one of the genes needs to be affected for tuberous sclerosis C to be present. The tuberous sclerosis C1 gene, discovered in 1997, is on chromosome 9 and produces a protein called hamartin. The tuberous sclerosis C2 gene, discovered in 1993, is on chromosome 16 and produces a protein called tuberin. These proteins act as tumor suppressors, agents that regulate cell proliferation and differentiation.

Differential Diagnosis. The predominant prenatal finding is that of the rhabdomyomas. Other cardiac tumors, such as a fibroma, should also be considered.

Recurrence Risk. Low in cases of new mutation; higher in cases of gonadal mosaicism; 50% in cases of parental involvement.

Prognosis. When no hydrops results from the presence of the rhabdomyomas, the prognosis depends on the other complications of the disorder. Because of the great variability of expression, an accurate prediction of the status of the child is difficult to infer from the status of the parent. Furthermore, new genetic evidence seems to indicate that the mental prognosis varies with the locus of the defective gene; thus, this may influence the decision about the pregnancy in the future.

Management. Termination of the pregnancy may be offered before viability.

TWIN-TO-TWIN TRANSFUSION SYNDROME

Definition. Twin-to-twin transfusion syndrome is a congenital entity unique to monochorionic diamniotic twin pregnancies, characterized by an imbalanced blood exchange between the twins' circulation, which occur through interplacental anastomosis and may cause fetal compromise varying from growth discordance to death of both fetuses. The first description was made by Schatz in late 1800s.

Synonym. Stuck twin.

Etiology. Vascular anastomosis.

Recurrence Risk. Unknown, but very low, considering the small chance to develop a second monochorionic diamniotic twin pregnancy.

Incidence. Twin-to-twin transfusion complicates about 15% of monochorionic twin gestations and is responsible for 17% of the perinatal mortality in multiple pregnancies.

Diagnosis. Ultrasonographic criteria for the diagnosis of twin-to-twin transfusion syndrome include monochorionic placentation, with visualization of a separating membrane, fetuses of the same sex, mid-pregnancy polyhydramnios-oligohydramnios sequence (polyhydramnios at the recipient's sac and oligohydramnios at the donor's sac), in the absence of other causes of abnormal amniotic fluid volume, and marked growth discordance. Significant weight discordance is considered a difference between the twin's size equal or greater to 20%. Other findings that might be observed include nonvisualization of the donor's bladder with enlarged recipient's bladder, abnormal Doppler systolic/diastolic (S/D) ratio at the umbilical cord, hydrops or evidence of congestive heart failure of either twin (more commonly found at the recipient twin). Milder forms of the disease are more difficult to diagnose owing to the lack of

uniform criteria; however, one should suspect twin-to-twin transfusion syndrome in the presence of amniotic fluid discrepancy between the cavities.

Pathogenesis. If embryonic splitting occurs before day 3 after fertilization, two independent fetuses with separate placentas will result. A single placenta with two amniotic cavities occurs if splitting takes place between days 4 and 7. If division of the embryoblast occurs after about 8 days, the twins share a single placenta and amniotic cavity (monochorionic-monoamniotic twins). Division beyond day 12 results in conjoined twins.

When two fetuses share the same placenta, vascular anastomoses develop between their circulations. These anastomoses can be of three types: vein to vein, artery to artery, and artery to vein. Even when there are multiple vascular connections within a single placenta, no transfusion should occur provided the anastomoses are balanced. Placentas from pregnancies with twin-to-twin transfusion syndrome have fewer anastomoses, which are more likely to be solitary and of the deep arteriovenous type than those without twin-to-twin transfusion syndrome. Provided transfusion occurs, the donor or "pump" twin becomes hypovolemic owing to blood loss. Hypoxia develops because of placental insufficiency, which is also responsible for intrauterine growth restriction. Poor renal perfusion leads to oligohydramnios. This latter feature, when severe, is responsible for the classic appearance of the stuck twin: the amniotic sac becomes too small, the amniotic membrane

FIGURE 5-87. Twin-to-twin transfusion syndrome. The fetuses are visibly discordant in size with the larger fetus on the left (the recipient) demonstrating ascites.

FIGURE 5-88. A different case of twin-to-twin transfusion syndrome. The fetus on the maternal right (*left side of the image*) is held up against the anterior uterus by the dividing membrane (*arrows*).

FIGURE 5-89. Postmortem photograph of twins. The twins are discordant with the larger, recipient twin on the left.

comes in close contact with the body of the “pump” twin, and the fetus appears trapped to the uterine wall. Hypervolemia with increased renal perfusion leads to polyhydramnios in the sac of the recipient twin. Because there is no loss of protein or cellular components from its circulation, colloid osmotic pressure draws water from the maternal compartment across the placenta, establishing a vicious circle of hypervolemia, polyuria, and hyperosmolarity, leading to high-output cardiac failure, hydrops, and polyhydramnios.

In the most severe forms, the diagnosis should not be difficult: a single placenta, massive polyhydramnios in the sac of the recipient twin, a stuck donor twin attached to the uterine wall with poor mobility, and obvious growth discordance. Milder forms of the disease are more difficult to diagnose owing to the lack of uniform criteria. However, one should suspect twin-to-twin transfusion in the presence of amniotic fluid discrepancy between the cavities, regardless of the amount of weight discordance between the twins. An intertwin hemoglobin difference greater than 2.4 g/dl in fetal blood obtained by cordocentesis has been shown to be consistent with stuck twin syndrome.

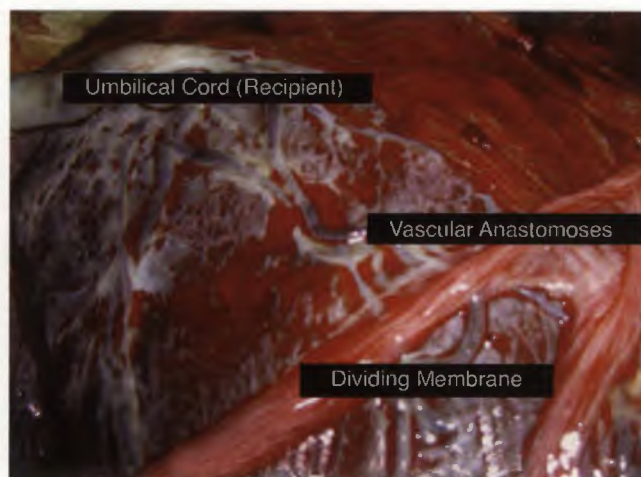

FIGURE 5-90. This is another case of twin-to-twin transfusion. Fetal surface of the placenta showing two sacs, a dividing membrane and the vascular anastomoses.

Associated Anomalies. The overdistention of the uterus caused by the polyhydramnios can cause preterm labor, amniorrhexis, abruptio placentae, respiratory, and abdominal discomfort. Death of one twin can cause embolic phenomena (twin embolization syndrome) and coagulation problems in the remaining twin, and sequelae such as neurologic, cardiac, and renal diseases are common among survivors.

Differential Diagnosis. The differential diagnosis should be mainly concerned with twins of discordant size without transfusion as the underlying pathophysiologic mechanism for the problem. Some authors have proposed a new entity called twin oligohydramnios-polyhydramnios sequence, in which twin-to-twin transfusion is included. Histopathologic studies of the placenta are required to differentiate twin-to-twin transfusion from the other conditions included in twin oligohydramnios-polyhydramnios sequence. Isolated intrauterine growth restriction can be considered if the growth discrepancy is minimal (less than 15%) and the other features of the syndrome are not present. Dichorionic twin pregnancy with fused placentas and growth restriction of one of the fetuses is another condition that can lead to misdiagnosis. This can be excluded if the twins have different sexes or, after birth, by histopathologic analysis of the placenta.

Prognosis. When the disease manifests during the second trimester, there is a higher risk of perinatal morbidity and mortality. Intrauterine hypoxia, preterm delivery, and death of one fetus (usually the donor) with subsequent death or hypoxic-ischemic sequelae (see twin embolization syndrome earlier) in the surviving twin are the most common complications to watch for in these pregnancies. The absent end-diastolic flow in the donor’s umbilical artery, accompanied by venous pulsation in the recipient’s umbilical vein, is usually associated with a poor prognosis. Hydrops or evidence of congestive heart failure of either twin is also associated with ominous prognosis. These signs are found more commonly at the recipient twin.

Management. Although efficacy of the therapies available is still controversial, the elevated mortality rate

(which can be as high as 100%) when expectant management is opted for, imposes the necessity of invasive therapy. Treatment includes serial amniocentesis to drain polyhydramnios in the sac of the recipient twin and, more recently, ablation of communicating vessels on the placental surface by neodymium: YAG laser guided by fetoscopy and umbilical cord ligation. Intensive monitoring with weekly nonstress testing, alternating with biophysical profiles, is recommended from the time of diagnosis to delivery.

VACTERL ASSOCIATION

Definition. Initially described in 1973, the vertebral, anal, tracheoesophageal, renal and radial abnormalities (VATER) association represents a defect in mesodermal development at the primitive streak level. More recently, this association has been expanded to include these abnormalities as well as cardiac features and a broader description of limb anomalies (VACTERL). VACTERL is a mnemonically useful acronym for a nonrandom association of malformations including **V** (vertebral anomalies), **A** (anal atresia), **C** (cardiac anomalies), **TE** (tracheoesophageal fistula or esophageal atresia), **R** (renal/urinary anomalies), and **L** (limb defect). Patients are considered to have the VACTERL association when three or more organ systems are involved. The most frequent defects described are tracheoesophageal fistula and anal or vertebral anomalies.

Synonyms. VATER sequence, VATER association, VACTEL syndrome.

Incidence. Uncommon. Approximately 300 cases have been reported.

Etiology. Although VACTERL occurs as a sporadic event in the majority of cases, a high frequency among offspring of diabetic mothers has been observed. Some authors report that prenatal rats exposed to doxorubicin (Adriamycin) demonstrated a similar series of anomalies.

Recurrence Risk. Varies from 1% to 50%.

Pathogenesis. Defective mesodermal development of unknown origin, possibly a mitochondrial disorder.

FIGURE 5-91. VACTERL association. Sonogram of a fetus with anal atresia and a dilated segment of large intestine.

Reference

Bruner JP, Anderson TL, Rosemond RL: Placental pathophysiology of the twin oligohydramnios-polyhydramnios sequence and the twin-twin transfusion syndrome. *Placenta* 19:81, 1998.

Diagnosis. The association of vertebral anomalies (in particular at the lumbosacral level) and renal, heart, and radial defects constitutes the classic manifestation of VACTERL syndrome. It is well known, however that some people who are affected will not present all typical findings. The diagnosis can also be suspected because of polyhydramnios in the presence of a small or absent fetal stomach (the tracheoesophageal fistula), hemivertebrae or scoliosis, or limb (in particular, radius anomalies, club hand, reduction defects, and polydactylies), renal, and cardiac defects. The presence of a supernumerary rib (13 and 14 pairs thoracic, 6 to 7 lumbar) may be recognized, especially with three-dimensional rendering. The ultrasound diagnosis of VACTERL syndrome may be accomplished early in the second trimester, if the fetus is severely affected.

Genetic Anomalies. X-linked and autosomal-recessive inheritance.

Differential Diagnosis. Nearly half of patients with tracheoesophageal fistula will exhibit other VACTERL malformations. Townes syndrome has many similar features. Because VACTERL syndrome consists of anomalies of multiple systems, chromosomal disorders such as trisomy 18 and trisomy 13 must be excluded by karyotype study. Disorders characterized by the presence of vertebral, renal, and/or radial defects (such as thrombocytopenia absent radius syndrome, Fanconi anemia, Robert's syndrome, Holt-Oram syndrome, Nager syndrome, caudal regression syndrome, sirenomelia, müllerian duct, renal agenesis, upper limb, and rib abnormalities association, electroductylectodermal dysplasia syndrome, and Jarcho-Levin syndrome) should be considered.

FIGURE 5-92. Abnormal vertebrae (arrow) in association with the above-mentioned finding and a radial abnormality (not shown) should arouse suspicion of VACTER association.

Associated Anomalies. Numerous. Hydrocephalus is commonly associated.

Prognosis. Poor overall but depends on the particular association of anomalies. During the last several decades, the literature has reflected a steady increase in the survival of infants with the VACTERL association. Today most children with the VACTERL association survive.

Management. Termination of pregnancy can be offered before viability. Monthly sonographic monitoring of fetal growth and evaluation of the structural defects are recommended. Delivery in a tertiary center is required for prompt surgical repair and rehabilitation. The most common organ system involved is the urinary system with an upper urinary tract anomaly in more than 90% of cases. After birth, patients with the VACTERL association should remain on

antibiotic prophylaxis for urinary tract infection while awaiting the completion of screening. Urologic follow-up is crucial because the majority of patients eventually require genitourinary intervention. Today, surgeons are more apt to correct cardiac and intestinal problems in these cases.

WALKER-WARBURG SYNDROME

Definition. Walker-Warburg syndrome is a genetic disorder characterized by retinal detachment, cataracts, microphthalmia, and musculoskeletal and central nervous system anomalies (hydrocephalus, lissencephaly type II, cephalocele) associated with mental retardation. It was first reported by Walker in 1942 and reviewed by Warburg in 1971.

Synonyms. Lissencephaly type II, HARDE syndrome (hydrocephalus, agyria, retinal dysplasia, and encephalocele), muscle-eye-brain disease, cerebro-oculomuscular syndrome, cerebro-ocular dysplasia-muscular dystrophy, Warburg syndrome, Walker lissencephaly, encephalo-ophthalmic dysplasia, and oculocerebral malformation.

Incidence. Unknown.

Etiology. Autosomal-recessive inheritance.

Diagnosis. Dobyns reviewed 63 cases in 1989 and established the diagnostic criteria, which include lissencephaly type II, cerebellar malformations, retinal malformation (in general, retinal nonattachment), and congenital muscular dystrophy. Indeed, congenital muscular dystrophy is present in 100% of the cases. However, a wide variety of eye and cerebral manifestations have been reported, in addition to the main anomalies including: microphthalmia, buphthalmos, congenital glaucoma, cataract, optic nerve hypoplasia, persistent hyaloid artery, Dandy-Walker malformation, hydrocephalus, cephalocele, microcephaly, and agenesis of the corpus callosum. Based on this wide spectrum of defects, the association of any type of eye with cerebral malformations should raise the suspicion of Walker-Warburg syndrome. The finding of a concentric ring inside the vitreous body (the detached retina) or the presence of lipoma of the corpus callosum is very suggestive of the diagnosis. When prenatal sonographic findings are inconclusive, magnetic resonance imaging, computed tomography, electromyography, and autopsy studies are indicated after birth to provide accurate genetic counseling to the family.

Genetic Anomalies. Defect of 9q31.

Associated Anomalies. Cleft lip and genital malformations may occasionally be found.

Differential Diagnosis. Anomalies associated with lissencephaly such as Miller-Dieker and Neu-Laxova are major differential diagnoses. Other disorders that should be excluded are Meckel syndrome, Fryns syndrome, trisomies

FIGURE 5-93. Small cephalocele (arrow) in a fetus with Walker-Warburg syndrome. The previous child of this family was similarly affected.

18 and 13, severe Fukuyama-type congenital muscular dystrophy, and maternal viral infections.

Recurrence Risk. The recurrence risk for couples with previously affected children is 25%.

Prognosis. Most of the newborns affected by Walker-Warburg syndrome die within the first year of life. Of those few who survive until 5 years of age, the majority have severe mental and developmental retardation.

Management. When detected before viability, termination of pregnancy can be offered. After viability, standard prenatal care is not altered.

WOLF-HIRSCHHORN SYNDROME

Definition. Chromosomal disorder caused by loss of material from the distal aspect of the short arm of chromosome 41.

Synonyms. 4p-deletion syndrome, Wolf-Hirschhorn syndrome, Wolf-Hirschhorn chromosome region.

Incidence. Approximately 120 cases reported in the world literature, but several times that many are registered in support group.

Etiology. Abnormal chromosome breakage during synapsis and recombination. Although it was first thought that the deletion was paternal in origin, it has been found recently that it can be of both maternal and paternal origin. Paternal age is not a causal factor.

Diagnosis. The prenatal diagnosis is suggested by the presence of severe intrauterine growth restriction associated

with no Doppler anomaly, normal amniotic fluid, midline defects, and a “downturned mouth.”

Genetic Diagnosis. Although there may be some difficulty in detecting some small deletions by cytogenetics, the standard cytogenetics (regular-G-banding, high-resolution banding, polymerase chain reaction typing, Southern blot hybridization, and fluorescence in situ hybridization technique) can provide the diagnosis. The gene map locus is 4p16.3.

Associated Anomalies. Anomalies are listed in Table 5-8. Differential diagnosis,

- *PITT syndrome*: is very closely related to 4p-. PITT syndrome, or Pitt-Rogers-Danks syndrome (PRDS), is a rare presumed autosomal-recessive syndrome with pre- and postnatal growth retardation, microcephaly, characteristic facial appearance, seizures, unusual palmar creases, and

Table 5-8 Anomalies Associated with Wolf-Hirschhorn Syndrome

Area	Features
Growth	Severe growth restriction is the rule
Achievements	Psychomotor delay Mental retardation
Central nervous system	Dysgenesis of the corpus callosum Abnormal EEG pattern characterized by generalized or unilateral myoclonic seizures followed by brief atypical absences. Seizure disorders tend to disappear with age
Skull	Microcephaly Dolichocephaly Scalp defects
Face	Greek helmet facial appearance Earlobe anomalies Large rectangular nose continuing to the eyebrows Low-set ears Anterior eye segment anomalies (extropia, blepharoptosis) Coloboma of the eyes Hypertelorism High forehead Downward-slanting palpebral fissures Some ophthalmic features of 4p- syndrome are similar to those of 5p- (cri-du-chat syndrome) Coracoid nose Microretrognathia Facial dysmorphism Cleft lip and palate Down-turned mouth Taurodontism, which is a dental trait characterized by teeth with elongated pulp chambers and apical displacement of the bifurcation and trifurcation of roots. It causes eruption delay and congenitally lost teeth
Heart	Ventricular septal defect Right ventricular hypoplasia
Lungs	Pulmonary isomerism Diaphragmatic hernia Hypoplastic thorax
Urinary system	Renal hypoplasia Polycystic dysplasia Oligomeganephronia (a rare renal hypoplasia characterized by a reduction in the number of reniculi with compensatory hypertrophy of the glomeruli and proximal renal tubules)
Genital	Hypospadias Undescended testes with an irregular distal penis
Spine	Sacral dimples Sacral sinus
Others	Skeletal anomalies

Continued

Table 5-8 Anomalies Associated with Wolf-Hirschhorn Syndrome—Cont'd

Area	Features
Midline fusion defects	Antibody deficiencies (IgA and IgG2) are mentioned in some cases. The association of antibody defects with 4p- suggests a regulatory gene with the deleted chromosome region that effects the B cell system
	One 8-months-old baby girl developed malignant hyperthermia after cheiloplasty
	Esophageal atresia
	Cystic hygroma
	Large placental chorioangioma
	Hypotrophic placenta, with possible vascular lesions, also without maternal hypertension
	Ranging from minor abnormalities such as
	Scalp defect
	Hypertelorism
	Pulmonary isomerism
	Common mesentery
	Hypospadias, that is one of the most prominent and characteristic midline defects in male infants with this syndrome
	Sacral dimple
	to:
	Cleft palate
	Corpus callosum agenesis
Ventricular septal defect	
Diaphragmatic hernia	

EEG, electroencephalography; IgA, immunoglobulin A; IgG2, immunoglobulin G2.

developmental delay. It is also a microdeletion in 4p16.3.

- *Zink finger syndrome*: is considered as a subfamily of 4p-; however signs and symptoms are different.
- *Trisomy 13*: caused by trisomy for some or all regions of chromosome 13, share several features including pre- and postnatal growth retardation, microcephaly, cleft lip and palate, and cardiac anomalies.
- *Other aneuploidies*: Although 4p- is similar to 5p-, 4p- individuals do not have the distinct cry. The ocular features, which distinguish 4p- from other deletions, include normal tearing, some degree of blepharoptosis, and the preponderance of anterior segment signs.

Prognosis. Usually lethal; however, four cases have been followed up to 16 years.

Recurrence Risk. Unknown.

Management. The diagnosis of a growth-restricted fetus with normal amniotic fluid, normal Doppler, and negative infection screen suggest a detailed examination of the fetal brain and heart and a karyotype. Standard cytogenetics cannot always demonstrate a microdeletion; thus, high-resolution banding and molecular analysis should be performed. A three-dimensional ultrasonographic examination is also useful to observe the face of fetuses. An autopsy can reveal delayed bone age.

Conclusion

During the first trimester of pregnancy, a unique and dramatic sequence of events occurs, defining the most critical and tenuous period of human development: the remarkable transformation of a single cell into a recognizable human being. The time span for the first trimester is based on menstrual dates; in a patient with a 28-day cycle, it begins 2 weeks before fertilization (on the first day of the last normal menstrual period) and concludes 12 weeks later. In this chapter, gestational age (GA) is used exclusively and is synonymous with menstrual age (MA). This terminology is chosen because menstruation is a visible event that establishes the date of the last normal menstrual period, and because it is consistent with radiologic and obstetric usage. In contrast, embryologic dating begins with conception and is, therefore, 2 weeks later than the first day of the last normal menstrual period. Although embryologic age is scientifically more precise, there is no visible landmark to announce conception, and so, radiologists and obstetricians continue to use MA or GA for pregnancy dating.

Transvaginal sonography is the optimal way to image a patient during the first trimester of pregnancy (Fig. 6-1).

Indications and the need to do this examination are many and include¹: (1) to identify the location and number of gestational sacs; (2) to assign a GA to the pregnancy; (3) to determine whether an early pregnancy has a normal appearance or whether sonographic indicators are present that predict failure; (4) to evaluate maternal symptoms such as pain or bleeding; (5) to evaluate uterine contents before pregnancy termination; and (6) to guide diagnostic or therapeutic procedures that require visual guidance (that is, chorionic villus sampling, amniocentesis). As ultrasound technology continues to evolve and improve, there is increasing emphasis for early screening of fetal complications. For example, early detection of Down syndrome and other chromosomal abnormalities can now be achieved by measuring the fetal nuchal translucency between 11 and 14 weeks' gestation, and combining this information with maternal age and maternal serum biochemistry levels (pregnancy-associated plasma protein A [PAPP-A], and the free beta subunit of human chorionic gonadotropin).^{2,3} Some investigators also suggest that it is possible to examine cardiac and noncardiac fetal anatomy in a low-risk population in the

FIGURE 6-1. Sagittal transabdominal scan (A) reveals a normal-appearing retroverted uterus. A transvaginal scan (B) done immediately after the transabdominal study shows the yolk sac within an intrauterine gestational sac.

setting of a routine 11 to 14 week ultrasound scan.⁴ Indeed, at this GA, a wide range of congenital anomalies that can affect the central nervous system, heart, ventral wall, urinary tract, and skeleton have been reported.⁵ What role three-dimensional (3D) ultrasound will play at this time of development is still unclear, but preliminary work suggests that it can potentially minimize scanning time and provide an excellent way to store scanned data.⁶

To comprehend normal and abnormal sonographic findings in early pregnancy, it is important to understand normal development and to appreciate the rapid and critical sequential changes that are occurring. The first trimester can be divided into preovulation and periovulation, conceptus, embryonic, and fetal phases of development (Table 6-1).⁷

Table 6-1 Embryology of Early Pregnancy

Period of Development	Weeks	Features
Pre- and periovulation	1-2	Ovarian follicle matures ↑
Ovulation		↑

The following discussion highlights physiologic, embryologic, and anatomic changes that occur during this time and emphasizes developmental changes as they relate to sonographic images obtained with high-resolution transvaginal transducers. A 28-day cycle is used in this discussion, although a normal cycle may vary in length from 25 to 35 days. For those interested in a more detailed explanation of these events, an excellent source for this material is *The Developing Human: Clinically Oriented Embryology* by Moore and Persaud.⁸⁻¹⁸

MATERNAL PHYSIOLOGY AND EMBRYO DEVELOPMENT

During the first 2 weeks of pre- and periovulation, cyclic changes occur within both the ovaries and endometrium as a result of the influence of pituitary gonadotropic follicle-stimulating hormone (FSH) and luteinizing hormone (LH) (Fig. 6-2).¹⁷ Initially, under the influence of FSH, a mature ovarian follicle develops. Estrogen elaborated by the follicle causes the functional layer of endometrium to proliferate and become thicker, as the spiral arteries elongate and the uterine glands increase in number and length. As a result of an abrupt surge in LH, ovulation occurs, and an oocyte is extruded, typically on day 14 of the cycle. After ovulation, the follicle collapses and transforms into the glandular corpus luteum, which produces progesterone and a small amount of estrogen. This hormonal activity is responsible for additional histologic changes of the endometrium as it enters the secretory phase, so named because the uterine glands now secrete material rich in glycogen. The glands

FIGURE 6-2. Diagrammatic representation of the relationships between gonadotropic hormones and changes in the endometrium and ovary during a normal menstrual cycle. Ovarian changes are induced by follicle-stimulating hormone (FSH) and luteinizing hormone (LH). As a result, ovarian hormones are produced (estrogen and progesterone), which promote cyclic changes in the structure and function of the endometrium. (From Moore KL, Persaud TVN: *The Developing Human: Clinically Oriented Embryology*, 7th ed. Philadelphia, WB Saunders, 2003.)

FIGURE 6-3. Diagram demonstrating the sequence of ovulation, fertilization, and early development of the embryo. Soon after the morula enters the endometrial cavity, fluid penetrates the cell mass to create the blastocyst. The blastocyst begins to implant into the decidualized endometrium by the end of the 3rd gestational week. (From Moore KL, Persaud TVN: *The Developing Human: Clinically Oriented Embryology*, 7th ed. Philadelphia, WB Saunders, 2003.)

become increasingly wide, tortuous, and saccular, and the uterine spiral arteries become increasingly coiled as they invade the superficial compact layer of endometrium. The endometrium continues to thicken as a result of glandular and vascular growth and increased stromal fluid.

During the 3rd to 5th weeks of the cycle (the conceptus period), fertilization occurs, with subsequent development of the morula, blastocyst, and bilaminar and ultimately trilaminar, or flat, embryo.^{7,8,10,16} Fertilization most often occurs within 1 day of ovulation (day 15 of the 28-day cycle), typically in the ampulla, the longest and widest portion of the fallopian tube (Fig. 6-3). At fertilization, fusion of the egg and sperm, each haploid gamete with 23 individual chromosomes, results in a zygote, a diploid cell with 23 pairs, or 46 chromosomes. Over the next 2 days, the cell mass transgresses the tube while dividing repeatedly to form a solid ball of 12 or more cells, called the morula. As the

morula enters the uterine cavity on day 18 or 19 of the cycle, endometrial fluid penetrates the cell mass to create a central cavity. When this occurs, the morula is transformed into a blastocyst, and its tissue is divided into two important layers. The outer cell layer, or trophoblast, ultimately creates the chorionic membranes and the fetal contribution to the placenta. The inner cell layer develops into the embryo, amnion, umbilical cord, and the primary and secondary yolk sacs. By the end of the 3rd week, the blastocyst begins to implant into the decidualized endometrium, a term applied to the functional layer of the thickened and edematous gravid endometrium (Fig. 6-4).

During the 4th week, the blastocyst, measuring only 1 mm in diameter, becomes fully imbedded into endometrial tissue. Not surprisingly, during this process, as trophoblastic tissue invades the endometrium, vaginal bleeding may occur and be confused clinically with an atypical menstrual cycle.

FIGURE 6-4. Diagrammatic illustration of blastocyst implanting into the decidua. Note the extent of the invading syncytiotrophoblastic tissue, which contributes to the placenta. The amniotic cavity is slitlike at this early stage of development. The exocoelomic cavity becomes the primary yolk sac, and the epiblastic and hypoblastic layers of cells develop into the bilaminar embryonic disk. Despite these ongoing events, sonographic examination cannot yet detect the presence of a pregnancy. (From Moore KL, Persaud TVN: *The Developing Human: Clinically Oriented Embryology*, 7th ed. Philadelphia, WB Saunders, 2003.)

The 4th week is a time of rapid cell proliferation and differentiation, affecting multiple primordial structures. The primary yolk sac shrinks and disappears gradually while the secondary yolk sac forms. The latter structure plays a critical role by providing nutrients for the embryo, serving as the site for initial hematopoiesis, and contributing to the developing gut and reproductive systems.⁹ A tiny bilaminar embryo also forms between the secondary yolk sac and developing amnion, and a primitive uteroplacental circulation is established.⁸ By the end of this week, the products of conception have attained a diameter of 2 to 3 mm and are at the threshold of detection by state-of-the-art transvaginal ultrasound transducers. In addition, the pregnancy test becomes positive because a measurable quantity of human chorionic gonadotropin (hCG) is produced by trophoblastic tissue.

During the final week of the conceptus stage (5 weeks' GA), normal menstrual flow is absent, and the woman may suspect pregnancy. The products of conception continue to enlarge primarily as a result of expansion of the chorionic cavity, which attains a diameter of 5 mm (Fig. 6-5). This cavity is identified by sonologists as fluid within the "gestational sac." The secondary yolk sac is variably identified by sonographic examination, and the developing bilaminar embryonic disk undergoes the process of gastrulation, which transforms it into a trilaminar disk with three germ layers (endoderm, mesoderm, and ectoderm). Despite these transformations, the embryo remains undetectable by sonography.

Weeks 6 through 10 constitute the embryonic phase, during which time all major internal and external structures begin to form (Table 6-2).¹¹ Although most organ function remains minimal, the cardiovascular system develops rapidly, and the primordial heart starts to beat at the beginning of the 6th week.¹² The appearance of the embryo changes dramatically as it is transformed from its flat disk-like configuration to a C-shaped structure, and it develops a human-

like appearance (Fig. 6-6). During embryogenesis, crown rump length (CRL) grows rapidly, measuring 30 mm by the end of the 10th week.

The final 2 weeks of the first trimester (11th and 12th weeks GA) begin the fetal period, during which there is continued rapid growth and ongoing organ development.¹³ During the initial phase of fetal development, the head is disproportionately large and constitutes one half of the CRL. As body growth subsequently accelerates, relative proportionality becomes apparent.

DEVELOPMENT OF THE PLACENTA AND FETAL MEMBRANES

Development of the Placenta

The placenta contains both maternal and fetal tissue. The maternal component is derived from a portion of decidualized endometrium, whereas the fetal component is derived from a portion of chorionic tissue that surrounds the blastocyst.¹⁴

Endometrium deep to the implanted conceptus, the decidua basalis, forms the maternal component of the placenta. The superficial portion of decidua, which covers the invading conceptus, is the decidua capsularis; the remaining endometrium is the decidua parietalis (also called decidua vera) (Fig. 6-7).

The fetal component of the placenta is derived from trophoblastic tissue, which by 5 weeks' GA develops into chorionic villi that completely encircle the conceptus (see Fig. 6-7A).¹⁵ Initially, these villi are uniform in thickness and are in intimate contact with adjacent decidual tissue. Subsequently, the most superficial two thirds of villi, located immediately beneath the decidua capsularis, degenerate to form the smooth chorion (also called chorion laeve) (see Fig. 6-7B). The remaining villi are in contact with the decidua basalis and are located adjacent to the most deeply

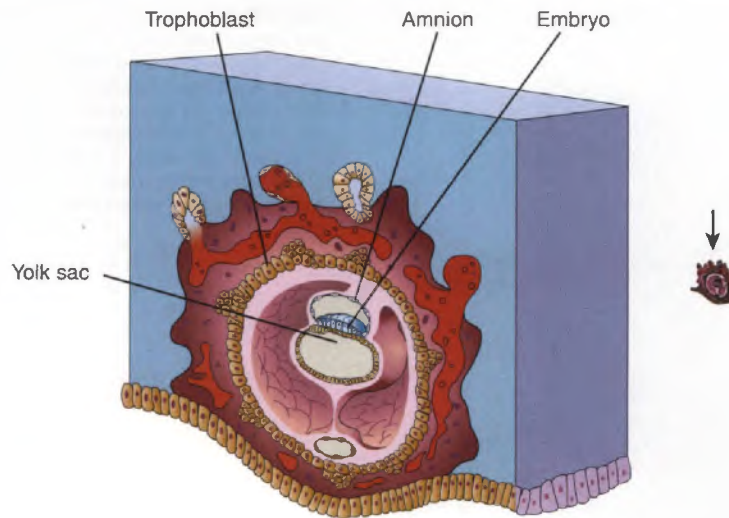

FIGURE 6-5. Diagram of the blastocyst at the end of the conceptus stage of development. The gestational sac, which is now visible by sonography, measures approximately 5 mm in diameter and contains the secondary yolk sac lying opposite the amniotic cavity. A developing embryo is interposed between these two fluid-filled cavities. Sonography variably identifies the secondary yolk sac, although the embryo cannot yet be seen. (From Moore KL, Persaud TVN: *The Developing Human: Clinically Oriented Embryology*, 7th ed. Philadelphia, WB Saunders, 2003.)

Table 6-2 Criteria for Estimating Developmental Stages in Human Embryos

GA (days)	Length (mm)	Main External Characteristics
34-35	1.5-3.0	Flat embryonic disk.
36-37	2.0-3.5	Embryo straight or slightly curved.
38-39	2.5-4.5	Embryo curved owing to head and tail folds.
40-41	3.0-5.0	Upper limb buds appear.
42-44	4.0-6.0	Embryo has C-shaped curve.
45-46	5.0-7.0	Upper limbs are paddle shaped.
47-50	7.0-9.0	Hand plates formed; digital rays present. Lower limbs are paddle shaped.
51-54	8.0-11.0	Foot plates formed.
55-57	11.0-14.0	Digital rays visible in hand plates.
58-60	13.0-17.0	Digital rays clearly visible in foot plates.
61-62	16.0-18.0	Limbs extend ventrally. Trunk elongating and straightening. Midgut herniation prominent.
63-65	18.0-22.0	Upper limbs longer and bent at elbows. Fingers webbed.
66-67	22.0-28.0	Hands and feet approach each other. Fingers are free and longer. Toes webbed. Stubby tail present.
68-69	23.0-28.0	Toes free and longer. Eyelids and external ears more developed.
70	27.0-31.0	Head more rounded and shows human characteristics. External genitalia still have sexless appearance. Distinct bulge still present in umbilical cord, caused by herniation of intestines. Tail has disappeared.

GA, gestational age.

Adapted from Moore KL, Persaud TVN: Organogenic period: The fourth to eighth weeks. In Moore KL, Persaud TVN (eds): *The Developing Human: Clinically Oriented Embryology*, 7th ed. Philadelphia, WB Saunders, 2003, pp 78-93.

imbedded portion of the blastocyst. These villi rapidly increase in number, branch profusely, and enlarge as they become the chorion frondosum, the fetal contribution to the definitive placenta.

Development of the Uteroplacental Circulation

To understand developing uteroplacental circulation, a basic knowledge of the anatomy and physiology of uterine blood flow is helpful. Blood to the uterus is from the paired

uterine arteries, which are branches of the anterior division of the internal iliac artery. As each uterine artery enters the uterus at the uterocervical junction, it ascends along the lateral uterine wall and produces multiple penetrating arcuate branches. When these branches pierce the endometrium, they become the spiral arteries.

With early embryonic development, the spiral arteries located within the decidua basalis become increasingly prominent. Side-by-side maternal and embryonic circulations are established initially as trophoblastic cells form chorionic villi that invade into portions of the decidualized endo-

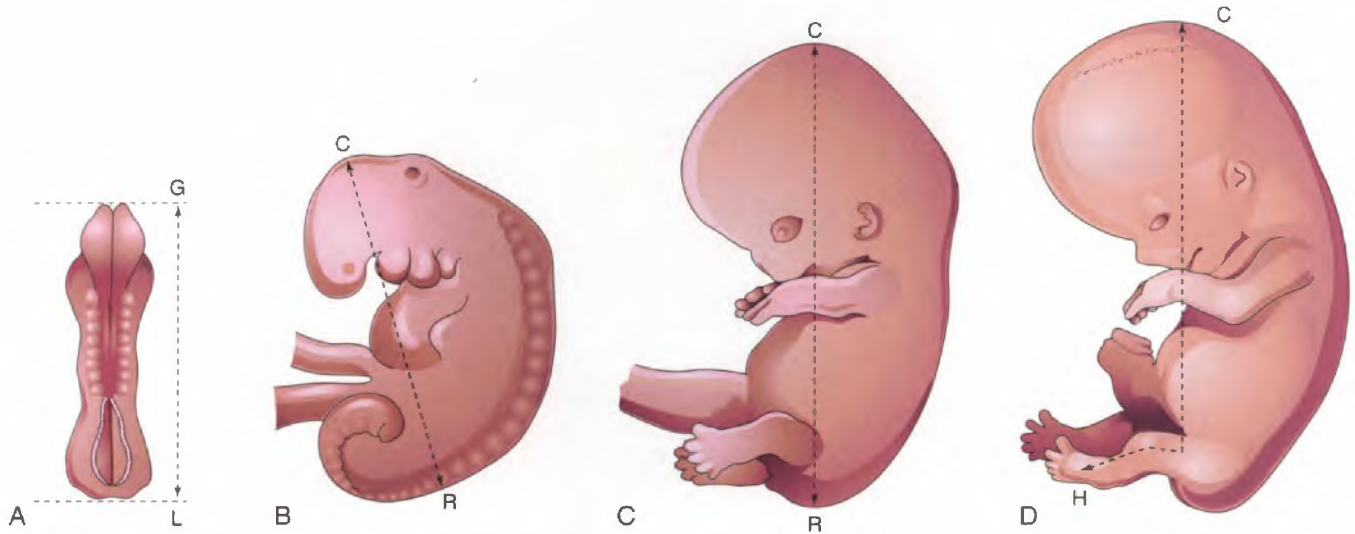

FIGURE 6-6. A-D. Sketches during the embryonic phase of development (6 to 10 weeks gestational age) reveal dramatic changes in both the size and shape of the embryo. Initially, the embryo has a flat, disklike configuration (A) without a clearly defined crown or rump. Soon thereafter, it becomes C-shaped (B), and by the end of the embryonic phase of development it has a human-like appearance. (B, C) Methods used to measure crown-rump length and (D) crown-heel length. (From Moore KL, Persaud TVN: *The Developing Human: Clinically Oriented Embryology*, 7th ed. Philadelphia, WB Saunders, 2003.)

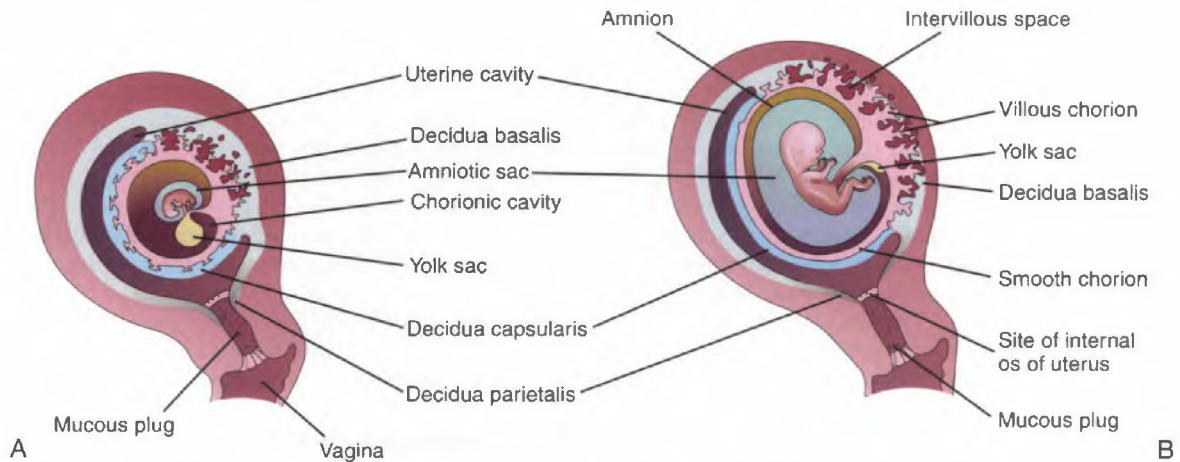

FIGURE 6-7. A. At 7 weeks' gestational age, chorionic villi completely surround the gestational sac and are relatively thick where they contact underlying endometrial tissue (decidua basalis). As the sac enlarges, the chorion and overlying decidual tissue (decidua capsularis) protrude into the compressed uterine cavity and come into contact with the decidua parietalis. This anatomic configuration gives rise to the double decidual sac sign. B. The compressed and avascular chorionic tissue becomes smooth and is defined by sonologists as the chorionic "membrane." Because of its fixed anatomic relationship to the developing placenta, in the event of placental bleeding, blood can dissect between the chorionic membrane and overlying decidual tissue, giving rise to a subchorionic hematoma. (From Moore KL, Persaud TVN: *The Developing Human: Clinically Oriented Embryology*, 7th ed. Philadelphia, WB Saunders, 2003.)

FIGURE 6-8. Maternal and embryonic circulations develop side by side as trophoblastic cells form chorionic villi, which invade and erode portions of the decidualized endometrium. The result of this process is development of vascular intervillous spaces that ultimately receive maternal blood from the spiral arteries. This anatomic relationship allows villi containing fetal blood to be surrounded and perfused by maternal blood. (From Moore KL, Persaud TVN: *The Developing Human: Clinically Oriented Embryology*, 7th ed. Philadelphia, WB Saunders, 2003.)

metrium (Fig. 6-8).¹⁴ Before actual maternal-fetal circulation is established, however, the invading trophoblastic cells create plugs within the maternal spiral arteries. The villi simultaneously erode tiny portions of the decidua, which subsequently enlarge to form the intervillous spaces. The intervillous spaces will ultimately receive maternal blood from the spiral arteries, and thus the villi containing fetal blood will be surrounded and perfused by maternal blood by the end of the first trimester.¹⁹ There is some controversy as to how and when in the first trimester the perfusion of villi begins and when actual maternal fetal circulation is initiated. Two hypotheses have been proposed to explain these events.

The first hypothesis is based on studies of first trimester gravid hysterectomy specimens and postulates that until the end of the first trimester there is no communication between maternal and fetal circulations, and intervillous blood flow is absent.²⁰⁻²⁸ Early studies suggested that the intervillous spaces are initially filled with clear fluid, possibly filtered maternal plasma.²⁰ These fluid-filled spaces may create a hypoxic and protective environment for the developing embryo.²⁹ As the trophoblastic plugs within the spiral arteries dissolve or dislodge by the end of the first trimester, maternal blood begins to circulate into the intervillous spaces. Concurrent with this event is a marked increase in uterine blood flow, which can be documented by sonography.²⁶

An alternative hypothesis suggests that transformation of the intervillous space from fluid filled to blood filled occurs gradually throughout the entire first trimester.^{30,31} According to this theory, the trophoblastic plugs are incomplete and venous flow is normally present in the intervillous space. The flow is low velocity and has low pulsatility, presumably to prevent the implanting trophoblast from becoming detached from the decidua. This slow flow can be detected by sensitive Doppler techniques by as early as 5.5 gestational weeks.³²⁻³⁶ Which of these theories best approximates actual physiologic development remains to be determined.

Development of the Chorionic "Membrane"

The chorion is derived from the superficial two thirds of chorionic villi that, at approximately 10 weeks' GA, become compressed and avascular, and subsequently degenerate into a membrane-like structure (see Fig. 6-7B).¹⁴ Embryologists identify this as the smooth chorion or chorion laeve, whereas ultrasonologists refer to it as the chorionic "membrane." Because the chorionic membrane and chorion frondosum each originate from chorionic villi, these two structures remain in intimate contact throughout gestation. For this reason, the chorionic membrane always extends up to and merges with the edge of the placenta. As is described

later, understanding this anatomic relationship is important for comprehending sonographic findings that accompany placental bleeding.

As the gestational sac grows, it begins to protrude into the compressed uterine cavity (see Fig. 6–7). As a result, the overlying decidua capsularis and smooth chorion come into contact with the decidua parietalis, which is located on the opposite side of the uterine cavity. During the second trimester, the capsularis and parietalis actually fuse and obliterate the uterine cavity. This allows the chorionic membrane to become loosely attached to the decidua parietalis. These anatomic relationships have clinical import because, in the event of placental bleeding, blood can easily dissect into the space between the chorionic membrane and decidua parietalis (see later discussion).¹⁴

Development of the Amnion

At 3 to 4 weeks' GA, concurrent with implantation and development of trophoblastic tissue, the amniotic membrane begins to form from cells that originate from the inner blastocyst (see Figs. 6–4, 6–5, and 6–9).⁸ This membrane initially surrounds the newly formed amniotic cavity, opposite the newly formed secondary yolk sac, and is attached to the bilaminar embryonic disk, which is contiguous to and lies between the amnion and chorion. As the amnion and its cavity rapidly expand, they surround the growing embryo. The amniotic membrane remains attached to the embryo at the umbilical cord insertion site; as the embryo flexes, its dorsal surface pushes into the amniotic sac. As the umbilical cord elongates, the secondary yolk sac, having completed its functions, is displaced away from the embryo and is readily visible within the shrinking chorionic cavity. Whereas the amniotic cavity continues to expand, the chorionic cavity shrinks and is ultimately obliterated between 12 and 16 weeks.

NORMAL SONOGRAPHIC ANATOMY AND LANDMARKS

Despite considering the pre- and periovulation period as part of the “first trimester of pregnancy,” pregnancy has not yet occurred. However, each month the functional layer of endometrium undergoes anticipatory changes in the event of conception. During menstruation, sonographic images depict the endometrium as a thin central echogenic line because of the opposed endometrial surfaces. Over the next 10 days, before ovulation, the functional layer proliferates, and at sonography a hypoechoic area is perceived surrounding the central linear echo. The total anteroposterior thickness of this multilayered endometrium is approximately 8 mm. Correlation with histologic specimens suggests that this appearance is due to relative homogeneity of endometrial tissue, with the glandular elements remaining straight and orderly.^{37,38}

During the conceptus phase of pregnancy (weeks 3 to 5), despite rapid and dramatic changes involving the products of conception, the endometrial appearance is identical to that observed during a nonconceptual cycle. After ovulation, it enters the secretory phase of the cycle, becoming dramatically hyperechogenic, and approaching 14 mm in total thickness. Histologically, the increased echogenicity results not only from new acoustic interfaces that originate

as a result of glandular and vascular tortuosity but also from reflections from glandular secretions, glycogen, and mucus.³⁷ As the 4th week concludes, despite complete implantation, the blastocyst remains undetectable to even high-resolution vaginal imaging because of its small size (1 mm). During the final week of the conceptus phase, however, just as the patient becomes aware that she may be pregnant, sonography can often identify changes that signal intrauterine implantation.

Identifying the Gestational Sac

The first definitive sonographic finding to suggest early pregnancy is visualization of the gestational sac. Using vaginal transducers with frequencies of at least 5 MHz, the size threshold for sac detection is 2 to 3 mm, corresponding to between 4 weeks' and 1 day GA and 4 weeks' and 3 days GA (Fig. 6–10).^{39–41} At sonography, the earliest appearance of a gestational sac is a small round fluid collection surrounded completely by a hyperechogenic rim of tissue. The central fluid collection is the chorionic cavity, and the surrounding echoes are due to developing chorionic villi and adjacent decidual tissue. As the sac enlarges, the hyperechogenic rim should be at least 2 mm thick, and its echogenicity should exceed the level of myometrial echoes.⁴²

To maintain uniformity, gestational sac size should be determined by calculating the mean sac diameter (MSD). This value is obtained by adding the three orthogonal dimensions of the chorionic cavity (excluding the surrounding echogenic rim of tissue) and dividing by 3 (Fig. 6–11).

The position of a normal gestational sac is in the mid- to upper uterus. As the sac implants into the decidualized endometrium, it should be adjacent to the linear central cavity echo complex, without initially displacing or deforming this hyperechogenic anatomic landmark (Fig. 6–12). On the basis of the physiology of sac implantation, Yeh et al,⁴³ in 1986, described the intradecidual sign. Using this sign with a transabdominal approach, these investigators reported a sensitivity of 92%, specificity of 100%, and accuracy of 93% for diagnosing an early intrauterine pregnancy (IUP). Two subsequent studies, each using a vaginal approach, have been published in an attempt to validate the effectiveness of this sign. The initial report by Laing et al⁴⁴ had disappointing results, with a sensitivity of 34% to 66%, specificity of 55% to 73%, and accuracy of 38% to 65%. A subsequent investigation by Chiang et al,⁴⁵ had more favorable results, with a sensitivity of 60% to 68%, specificity of 97% to 100%, and accuracy of 67% to 73%. The reason for the disparate results of these two reports is uncertain, but may relate to different criteria used to precisely and confidently identify the thin echogenic line (central uterine stripe) that represents the potential uterine cavity.

Also confounding the problem of identifying an early intrauterine gestational sac with certainty, is that with continued growth, it often changes shape from round to elliptical, and it may develop an irregular contour as a result of adjacent uterine contractions, myomas, implantation bleeds, or a distended maternal urinary bladder. Because even the most favorable reported statistics are not highly sensitive or accurate for documenting the intradecidual sac sign, and because occasionally a pseudogestational sac of an

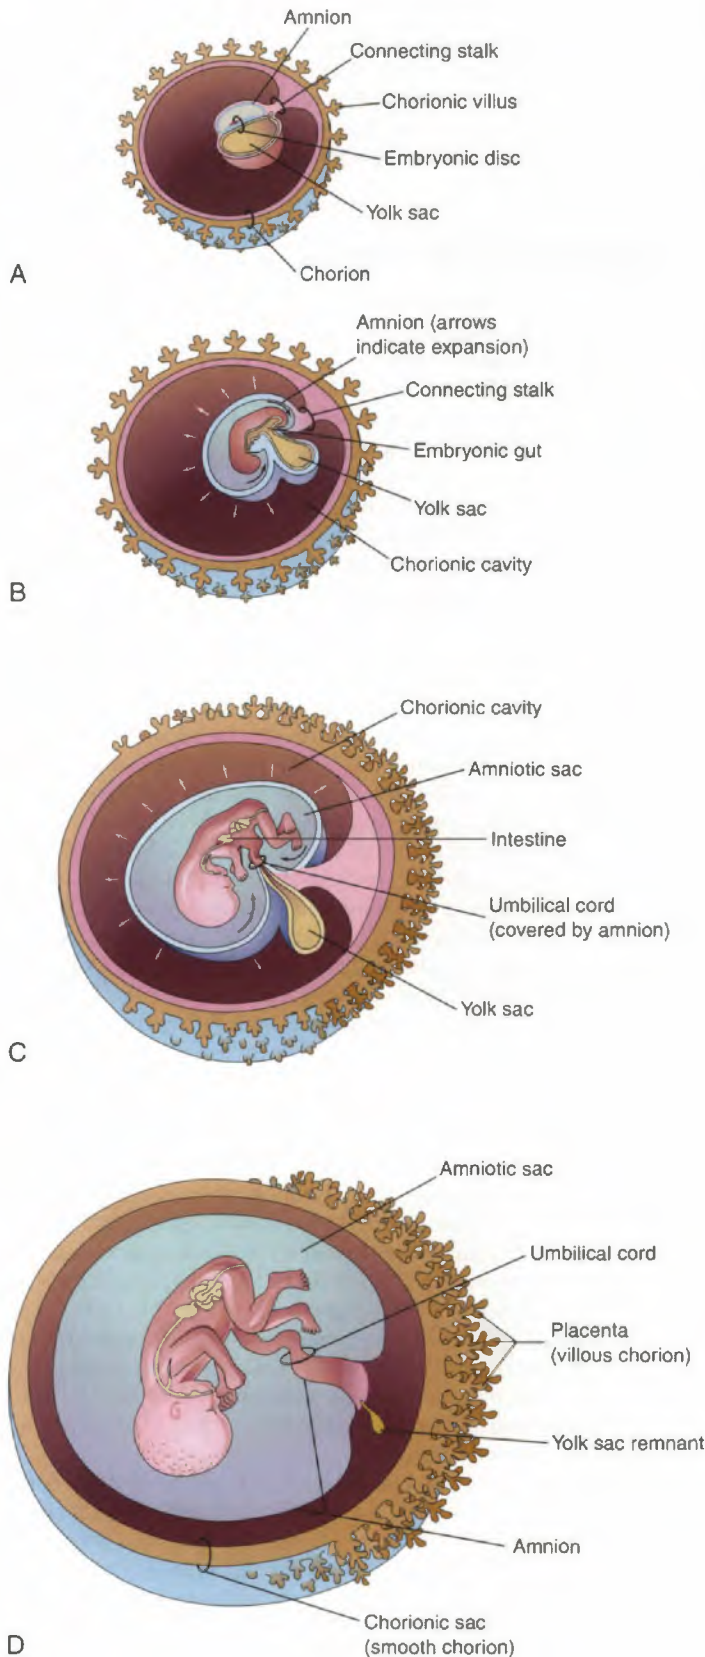

FIGURE 6-9. *A.* At 5 weeks' gestational age, the amniotic membrane surrounds the newly formed amniotic cavity and is opposite the newly formed secondary yolk sac. Interposed between these two cavities is the bilaminar embryonic disc. *B.* By 6 weeks' gestational age, the rapidly expanding amniotic cavity surrounds the enlarging embryo. Note how the dorsal surface of the embryo pushes into the amniotic sac and how the yolk sac is extruded into the chorionic cavity. At this stage of development, chorionic villi completely encircle the sac. *C.* At 12 weeks, the amniotic cavity continues to enlarge, whereas the chorionic cavity becomes relatively small but still contains a visible yolk sac. With degeneration of the smooth chorion over the surface of the sac that protrudes into the uterine cavity, the chorionic "membrane" is formed. *D.* By 22 weeks' gestational age, complete fusion of the amnion and chorionic membranes has occurred, with obliteration of the chorionic cavity. (From Moore KL, Persaud TVN: *The Developing Human: Clinically Oriented Embryology*, 7th ed. Philadelphia, WB Saunders, 2003.)

FIGURE 6-10. An early gestational sac, measuring 4 mm in diameter, is visible as a small fluid-filled structure (the chorionic cavity) surrounded by an echogenic rim of tissue (chorionic villi and adjacent decidual tissue) (arrows).

FIGURE 6-11. Mean gestational sac diameter is determined by adding the three orthogonal dimensions of the chorionic cavity and dividing by 3. Correct caliper placement is illustrated between calipers one and two. Note that the echogenic choriodecidual reaction is not included in the measurement.

ectopic pregnancy and a gestational sac can have a very similar appearance (Fig. 6-13), the value of this sign appears limited. In cases of very early pregnancy, follow-up sonography should be obtained to document the appearance of the yolk sac or embryo.^{44,45}

As the sac enlarges, it gradually impresses and deforms the central cavity echo complex, giving rise to the characteristic sonographic appearance referred to as the double decidual sac sign (see Figs. 6-7 and 6-14).^{46,47} This sign, which is universally present when the MSD is 10 mm or greater, consists of two concentric echogenic lines surrounding a portion of the gestational sac. The line closest to the sac represents the combined smooth chorion-decidua capsularis, whereas the adjacent, more peripherally located line represents the decidua parietalis. The uterine cavity is the potential space between these two lines and often contains a trace of fluid. The double decidual sac sign is most effective with transabdominal sonography performed at 5 to 6 weeks' GA because, using this approach, sonographers can confirm the presence of an IUP before a yolk sac is visualized. With the advent of nearly universal transvaginal sonography, the double decidual sac sign has been relegated to a lesser role. The sign may still be useful, however, in patients in whom transvaginal sonography is not possible.

Blood Flow in Early Pregnancy

The characteristic first trimester main uterine artery waveform obtained at the uterocervical junction consists of high-resistance flow with a prominent diastolic notch, although the notch will occasionally be absent in a normal patient (Fig. 6-15). The diastolic notch typically disappears during the second trimester and in some cases as early as

13 weeks' gestation.²¹ Persistence of the diastolic notch into the third trimester correlates with umbilical cord and placental abnormalities.⁴⁸

Doppler signals can also be obtained from the spiral arteries or subchorionic vessels, located at the junction of the myometrium and hyperechogenic choriodecidual tissues. Flow in these vessels is typically pulsatile, with a low-resistance pattern (Fig. 6-16). Deep to the subchorionic vasculature is the intervillous space (Fig. 6-17). In the first trimester, Doppler interrogation at this level reveals a more venouslike flow pattern, which may be difficult to detect (even in a more developed placenta) because of its extremely low velocity.²²

Over the course of the first trimester, vascular impedance decreases and blood flow velocity increases, and the uteroplacental hemodynamics change from high resistance low volume to the low resistance high velocity state that will continue for the remainder of the pregnancy.³¹

During first trimester sonography, prominent hypochoic areas with visible venous flow are occasionally seen around the margins of a gestational sac (Fig. 6-18). These have been termed venous lakes. Unlike true intervillous flow, which is difficult to localize without sensitive Doppler settings, slow flow within these vascular spaces can often be appreciated with gray-scale sonography alone if high-gain settings are used. Because of its extremely low velocity, the flow is difficult to document with color or pulsed Doppler. If no attempt is made to evaluate for the presence of flow, these spaces may be incorrectly considered subchorionic hematomas. Whether these vascular spaces have any significance with regard to pregnancy outcome is uncertain; opinions range from benign to ominous.^{49,50} Therefore, when multiple lakes are seen, close sonographic follow-up is probably indicated.

The white area represents thickened decidual tissue. (From Laing FC, Brown DL, Price JF, et al: *Intradecidual sign: Is it effective in diagnosis of an early intrauterine pregnancy?* Radiology 204:655, 1997) B. Transvaginal sonogram demonstrates the double decidual sac sign. Two concentric lines are due to the echogenic decidua capsularis-smooth chorion (DC) and the peripherally located decidua parietalis (DP). In this patient, the uterine cavity contains a small amount of fluid. The decidua basalis (DB) is slightly more echogenic as a result of developing placental tissue.

FIGURE 6-15. Uterine artery waveforms. *A.* Tracing of the left uterine artery at 8.4 weeks gestational age shows high systolic velocity and an early diastolic notch. *B.* In another patient at 6.0 weeks gestational age, the uterine artery tracing lacks a diastolic notch. The outcome was normal.

Identifying the Yolk Sac

The yolk sac is the first anatomic structure identified within the gestational sac. Embryologically, this is the secondary yolk sac, but because the primary yolk sac cannot be detected by sonography, sonologists refer to this structure simply as the yolk sac. Using a transvaginal approach, it may be visible as early as the beginning of the 5th gestational week (MSD, 5 mm), and it is almost always seen by 5.5 weeks' GA (MSD, 8 mm).⁵¹ Using a transabdominal approach, the yolk sac should be evident by 7 weeks' GA, when the MSD is 20 mm.⁵² Because detecting a yolk sac unequivocally confirms that an intrauterine fluid collection represents an early IUP as opposed to a pseudosac associated with an ectopic pregnancy, it is important to optimize scanning parameters to ensure its visualization.⁵³ Given a choice, the highest possible transducer frequency as well as harmonic imaging should be selected (Fig. 6-19). Detecting the yolk sac is also important for purposes of assigning GA, and to

FIGURE 6-16. Subchorionic artery Doppler tracing at 7.5 weeks' gestational age is obtained at the junction of the echogenic trophoblast and myometrium and shows a low velocity waveform with prominent diastolic flow.

FIGURE 6-17. Doppler flow obtained from the intervillous spaces reveals a venouslike waveform with extremely low velocity.

locate the contiguous embryonic disk and early cardiac activity.^{51,52,54,55}

The yolk sac is spherical in shape, with a well-defined echogenic periphery and a sonolucent center. Its diameter increases steadily between 5 and 10 weeks' GA to a maximal diameter of 5 to 6 mm⁵⁶⁻⁵⁸; this corresponds to a CRL of 30 to 45 mm (Fig. 6-20 and Table 6-3).⁵⁸ As the GA advances, the yolk sac separates and ultimately detaches from the

FIGURE 6-18. With gray scale imaging, visible flow was obvious within a crescentic area contiguous to the gestational sac (arrows). In this patient, follow-up examination confirmed embryonic demise.

embryo but remains visible within the shrinking chorionic cavity. Subsequently, its diameter decreases,^{57,58} and it may occasionally become somewhat irregular in contour.⁵⁶ By the end of the first trimester, it is no longer detected by sonography, although, if searched for, it can be found at delivery.⁵⁹

Identifying the Embryo and Cardiac Activity

Using state-of-the-art vaginal transducers, the embryonic disk is detected initially as a subtle area of focal thickening along the periphery of the yolk sac (Fig. 6-21). Most authorities agree that the threshold for embryo detection is when the disk measures 1 to 2 mm in length. Depending on the investigator, this corresponds to between 5 and 6 weeks' GA⁶⁰⁻⁶³ and a MSD of between 5 and 12 mm.⁶⁴⁻⁶⁶

Embryologic investigation suggests that cardiac contractions begin at 36 to 37 days GA.¹² Support for this is found in a series of patients who conceived with assisted reproduction. In these patients, transvaginal sonography detected embryonic cardiac activity at 34 gestational days, with a simultaneous embryonic length of 1.6 mm.⁶⁷ Because the human eye is exquisitely sensitive to motion, very early cardiac pulsations can occasionally be appreciated by real-time sonography before the embryo itself is identified. For practical purposes, many sonologists consider the identification of cardiac activity in an embryo with a CRL of less than 5 mm as 6 weeks' GA.⁶⁸ Cardiac activity should be detected routinely when the embryo attains a length of 4 to 5 mm.^{67,69,70} This corresponds to a GA of 6.0 to 6.5 weeks, at which time the MSD is 13 to 18 mm.^{51,65,67,71,72} Using a transabdominal approach, cardiac activity should be evident by 8 weeks' GA, when the MSD is 25 mm.⁵²

A

B

FIGURE 6-19. 5.3-week intrauterine gestational sac. A. A transvaginal scan using a 5MHz transducer failed to detect a yolk sac. B. With a 75 MHz transducer, a yolk sac is easily seen.

During the first trimester, cardiac rates, which should be recorded using M-mode, vary with GA, but not with the sex of the embryo (Table 6-4 and Fig. 6-22).⁷²⁻⁷⁷ When activity is obtained before 6 weeks, the rate is relatively slow, typically between 100 and 115 beats per minute (BPM) (Fig. 6-23).^{72,78-80} Thereafter, it increases rapidly, and by 8 weeks is between 144 and 170 BPM.⁷²⁻⁷⁴ After 9 weeks' GA, the rate plateaus at 137 to 144 BPM.⁷² Examining an individual embryo for 15 to 60 minutes reveals almost no

variation in cardiac rate⁷⁵; in contrast, comparing embryonic heart rates at different GAs reveals progressively more variation in heart rate with increasing GA.⁷⁶

Sonographic observation throughout the embryonic period (weeks 6 to 10) reveals dramatic transformation of anatomic structures (see Figs. 6-6, 6-24, and 6-25 and Table 6-2). CRL length increases by approximately 1 mm/day.^{66,81} During the 6th week of development, with ventral folding of the cranial and caudal ends of the embryo, it changes rapidly from a flat disk into a 3D C-shaped structure.¹¹ The rapidly developing brain and head become prominent as the rostral neuropore closes, and the caudal neuropore elongates and curves into a tail. Soon thereafter, as the amniotic sac surrounds the developing embryo, the yolk sac, and embryo diverge from one another. Despite the extra-amniotic location of the yolk sac, initially it remains attached to the embryo via the sonographically visible vitelline duct (also called the omphalomesenteric duct) (Fig. 6-26).⁸² This structure contains an artery and vein that transport blood elements, nutrients, and primordial sex cells

FIGURE 6-21. The embryonic disk is initially seen as a focal thickening along the periphery of the yolk sac (arrow). In this case, its length is approximately 2 mm, corresponding to 6 weeks' gestational age.

from the yolk sac to the embryo. Between 7 and 8 weeks, limb buds evolve into paddle-shaped upper and lower limbs, with early development of the hands and feet. By the 9th week, the extremities protrude ventrally, the trunk begins to elongate and straighten, and midgut herniation into the umbilical cord is prominent. The 10th week (embryo length, 30 to 35 mm) reveals a distinctly human-appearing embryo, with visible and relatively opposed hands and feet and the tail no longer present (Fig. 6-27). Although a prominent embryologic textbook suggests return of the midgut to the abdomen during the 12th gestational week,¹⁸ sonographic

FIGURE 6-23. Before 6 weeks, the fetal heart rate is relatively slow. In this case, it was determined as 94 beats per minute.

analysis suggests this event is completed by the end of the 11th week.⁸³⁻⁸⁵

The combination of higher frequency and technologically improved transducers in concert with multiplanar endovaginal 3D image acquisition have heralded a new and exciting method to advance “sonoembryology,” such that it is now possible to visually observe, study, and better understand the rapid growth and dramatic anatomic changes that occur during the first trimester.⁸⁶⁻⁹⁰ As four-dimensional sonographic technology improves, it has the potential to evaluate early fetal movement and behavior patterns.^{91,92} The goal for these types of observations is to improve first

trimester assessment of normal anatomic structures, improve evaluation of selected patients at risk for embryologic-fetal malformations, and improve pregnancy dating by basing it on the chronologic and sequential appearance of normal anatomic structures.

Identifying Fetal Membranes and the Placenta

Recall that, in a normal pregnancy, the first intrasac structure identified by sonography is the yolk sac, visible by 5.5 weeks’ GA. A few days later, the embryonic disk can be detected. Although the amniotic membrane develops concurrently, because it is so thin (0.02 to 0.5 mm),⁹³ and possibly because it is closely applied to the embryo,⁹⁴ it is not normally identified until 6.7 weeks’ at which time the CRL is 7 mm (Fig. 6-28).⁹⁵ Rarely, however, it can be seen as a small membranous structure contiguous with the embryo but on the side opposite the yolk sac; the term double bleb sign has been used to describe this anatomic relationship (see Figs. 6-5, 6-9A, and 6-29).⁸²

Using vaginal transducers and relatively high-gain settings, the thin amniotic membrane becomes apparent surrounding the embryo, which is now located within the sphere-shaped amniotic cavity or sac. With continued first trimester growth, an interesting linear relationship is apparent with respect to CRL and amniotic sac diameter. Not only do each increase by 1 mm per day but their measurements are equivalent (that is, in a normal pregnancy, a CRL of 12 mm should have an amniotic cavity with a mean diameter of 12 mm).⁹⁶

FIGURE 6-25. Two-dimensional sonographic images that depict changes during the first trimester in embryonic size and shape. *A.* At 6.5 weeks' gestational age (GA), it is not possible to differentiate the crown from the rump (embryo is measured between calipers) (compare with Fig. 6-6A). *B.* At 8 weeks' GA, the embryo has a C-shaped configuration (compare with Fig. 6-6B). The cephalic end becomes prominent and contains an easily visible sonolucent structure: the developing rhombencephalon. The rump may reveal a tail-like appendage. Because of embryonic curvature, length measurement is often a neck-rump length (between calipers) rather than a crown-rump length. *C.* By 10 weeks GA (CRL of 30 mm between calipers), the limbs are becoming visible (*open arrow*), and the gut is herniating into the base of the umbilical cord (*arrow*) (compare with Fig. 6-6C). Note that the head is disproportionately large relative to body length. *D.* At the end of the first trimester, the fetus has a human-like appearance (compare with Fig. 6-6D). Note the relative proportionality between the head size and overall body length.

FIGURE 6-26. As the developing embryo and yolk sac diverge, they remain attached via the vitelline (omphalomesenteric) duct (arrow).

In many cases, only the portion of amnion located perpendicular to the ultrasound beam may be visible (Fig. 6-30). Importantly, in some normal cases, it may not be visible at all, and the inability to visualize the amnion does not predict pregnancy failure (Fig. 6-31). Detection of the amnion and its cavity confirms the presence of an intrauterine gestational sac. Its size and appearance help determine whether an early pregnancy is progressing normally.

Because the amniotic cavity enlarges more rapidly than the chorionic cavity, the latter structure is obliterated as the amniotic membrane reaches the chorion (see Fig. 6-30). The process of apposition begins in the middle of the first trimester but is often incomplete until 12 to 16 weeks' GA.⁵⁹ Once apposed, the amniotic membrane is no longer visible.

In most patients, the chorionic cavity is identified by knowledge of its peripheral anatomic relationship to the amnion. Unless a separate amnion is visible, however, the chorionic cavity cannot be identified with confidence. Occasionally, diffuse low-level echogenic material fills the chorionic cavity, and by virtue of acoustic contrast, this anatomic space is "labeled" (Fig. 6-32).^{59,82} The precise nature of these echoes is unknown, but they most likely relate to the relatively thick, proteinaceous material contained within this cavity.⁹⁷

As placental development begins during the 8th gestational week, the hyperechogenic ring surrounding the sac becomes asymmetric, with focal peripheral thickening of the most deeply imbedded portion of the sac. This is due primarily to combined developmental changes occurring within the embryonic and, to a lesser degree, the maternal contributions to the placenta.

DETERMINING GESTATIONAL AGE

Calculating GA on the basis of menstrual history is often risky. Many women are uncertain of their dates, and even when the menstrual history is known to be correct, individual variations in the time of ovulation can alter the length of a cycle from 25 to 35 days. Despite these variables, experts agree that the most accurate time to date a pregnancy is during the first trimester, when biologic variation is relatively

FIGURE 6-27. A. Three-dimensional image of embryo at 10.4 weeks' gestational age demonstrates proportionally large head, 4 visible extremities, and mild prominence at the base of umbilical cord, consistent with physiologic herniation of the gut into the cord. Comparison with gray scale image of the same embryo (B) shows crown-rump length of 34.8 mm, without discernable anatomic detail.

minimal (Table 6-5).^{68,98} Accurate dating is a critical prerequisite for subsequent reliability in fetal growth studies.

The first structure that can be measured for the purpose of calculating GA is the gestational sac. Sac measurements should be obtained if there is no visible yolk sac or embryo. Various methods and formulas have been developed for this

FIGURE 6-28. Transvaginal scan of a 6.7-week gestational age embryo (crown rump length of 7 mm) demonstrates a thin echogenic line (*arrow*) close to the embryo that is due to the amnion. The yolk sac (YS) is visible in the chorionic cavity.

FIGURE 6-30. Because it is so thin, it is not unusual to visualize only the portion of amnion located perpendicular to the ultrasound beam. In this 13.5-week gestational age pregnancy, note that the yolk sac is more visible than the amnion and is located in the relatively small chorionic cavity.

FIGURE 6-29. Transvaginal scan of a 5.8-week gestational age embryo (crown rump length, between calipers, measured 2.6 mm) demonstrates the uncommonly observed double bleb sign. Because it is thicker and more echogenic, the outer covering of the yolk sac (YS) is more easily seen than the amniotic membrane (A). In this image, an embryo is difficult to identify, but cardiac activity (118 beats per minute) was recorded.

FIGURE 6-31. In this normal 8.3-week intrauterine pregnancy, the embryo and yolk sac are clearly seen. Despite relatively high gain settings, the amnion is not visible.

purpose, including sac volumes and mean diameters.^{52,64} Because of the ease with which it can be obtained, many authorities use the MSD (see Fig. 6-11). Between 5 and 11 weeks' GA, a simple and convenient method to calculate GA (in days) using sac size is to add 30 to the MSD (in millimeters).^{52,99} With this formula, a sac with a mean diameter of 5 mm corresponds to 35 days GA. Whether 3D

ultrasound determination of sac volume will prove superior to conventional methods remains to be shown. Of two published comparative studies, one suggested 3D was superior to conventional two-dimensional volumetry,¹⁰⁰ whereas the other showed equivalent results.¹⁰¹ Neither study demonstrated prognostic superiority of volumetric measurements with respect to gestational outcome.

FIGURE 6-32. Occasionally, in a normal first-trimester pregnancy, the chorionic cavity contains low-level echogenic material. In this example, the amniotic cavity is relatively sonolucent compared with the chorionic cavity.

The next visible landmark that can be used for pregnancy dating is the presence of a yolk sac. A yolk sac without an embryo or cardiac activity, detected by transvaginal scan, corresponds to 5.5 weeks' GA.⁶⁸ With normal development, in accordance with the formula noted previously, the MSD should be 8 mm. If cardiac activity is detected but the CRL is too small to measure, the GA is reported as 6 weeks.⁶⁸ Between 6 and 12 weeks' GA, determining the CRL measurement is generally considered the most accurate method of dating a pregnancy.^{62,63,102-105} When the embryonic disk is detected initially at 6 weeks' GA, it may be too small to actually measure, although cardiac pulsations are frequently visible (see Fig. 6-29). Within days, the length of the linear embryonic disk can be measured, although it is not possible to actually distinguish the crown from the rump (see Figs. 6-6A and 6-25A). As the embryo grows and it assumes a C shape, the cranial end becomes relatively prominent and identifiable (see Figs. 6-6B, 6-25B, and 6-27A). Before 8 weeks' GA, because of rather dramatic flexion of the head, the greatest length along the longest axis is actually a neck-rump measurement.¹⁰⁶ Toward the end of the embryonic phase of development, with gradual extension of the head and regression of the tail, a true crown rump measurement is possible (see Figs. 6-6C and 6-25C).

Robinson,¹⁰⁷ in 1973, initially reported use of the CRL for pregnancy dating. Over the next 2 years, he and Fleming refined their methodology and, in their 1975 landmark article, stated that "a single CRL measure could estimate maturity to within ± 4.7 days with 95% confidence on the basis of a single measurement."¹⁰² Despite relatively crude equipment, their tables have, quite remarkably, withstood the test of time, although more recent tables (some based on transvaginal studies or pregnancies conceived through assisted reproduction) modified the original numbers to reflect more accurately GA determination in very early pregnancy (Table 6-6).^{59,62,63,66,68}

Because normal embryonic growth is almost linear at 1 mm/d,^{52,61-63,95} GA in days can also be estimated by adding 42 to the embryonic length (in millimeters). For

Table 6-5 Guidelines for Dating a Pregnancy During First Trimester

Stage of Development	Gestational Age (weeks)
Gestational sac (no yolk sac, embryo, heartbeat)	5.0
Gestational sac and yolk sac (no embryo, no heartbeat)	5.5
Gestational sac and yolk sac (living embryo, CRL <5 mm) too small to measure	6.0
Embryo/fetus ≥ 5 mm in length	Age based on CRL (see Table 6-6)

Formulas: mean sac diameter (mm) + 30 = gestation age (days) (between 5 and 11 weeks).

CRL, Crown rump length (mm) + 42 = gestation age (days) (between 6 and 9.5 weeks).

From Benson CB, Doubilet PM: Fetal measurements-normal and abnormal growth. In Rumack CM, Wilson S, Charboneau JW, et al (eds): Diagnostic Ultrasound, 3rd ed. St Louis, Elsevier Mosby, 2005, pp 1493-1512.

pregnancies between 43 and 67 days, this determination has a 95% confidence limit of ± 3 days.⁶¹

Toward the end of the first trimester, with rapid fetal development and flexion/extension positional changes limiting accurate CRL determination, measurements of the biparietal diameter and femur length become the preferred biometric parameters for calculating GA.^{68,108} The primary factor that negatively influences the reliability of first trimester GA determination is measurement error.

FIRST TRIMESTER COMPLICATIONS

Because of the complex sequence of events that accompany first trimester development, it is not unusual for complications to occur. Approximately 15% of clinically recognized pregnancies are spontaneously miscarried; the loss rate is estimated at two to three times higher with very early and often clinically unrecognized pregnancy.^{109,110}

Vaginal spotting or frank bleeding is very common and is experienced by approximately 25% of patients during the first few weeks of pregnancy.¹⁰⁹ Often the bleeding is temporary and self-limited, and is likely due to implantation of the conceptus into the decidualized endometrium. If ultrasound is performed in these patients, the results are usually normal.

In a setting of severe pain, uterine contractions, and a dilated cervix, the pregnancy is doomed to failure. In these cases, ultrasound is not usually indicated but may be used selectively to determine whether retained products of conception are present, which could require curettage.

If the cervix is long and closed in a patient with vaginal bleeding, the diagnosis is *threatened abortion*. This term, applicable in approximately 25% of clinically apparent pregnancies of 20 weeks or less, is used when the patient is clinically considered to have a potentially living embryo. Threatened abortion encompasses a broad range of conditions that are named based on the stage of development

and the sonographic appearance of the products of conception (Table 6-7).¹¹¹ Analysis of these pregnancies suggests that 50% eventually abort; the remaining 50% have a normal outcome.¹⁰⁹ The term *missed abortion*, still common in clinical parlance, does not adequately describe pathophysiologic changes and should be abandoned.¹¹² Instead, *embryonic demise* should apply when there is clear evidence of a nonliving embryo, and *blighted ovum* should be used to describe an abnormal pregnancy with a gestational sac but no visible embryo. To simplify matters without adversely affecting clinical management, consideration should be given to describing any abnormal intrauterine first trimester pregnancy as one that is *unsuccessful*, or *failed*.

Other entities that can present clinically as threatened abortion are ectopic pregnancy and gestational trophoblastic disease. The findings at ultrasound examination in patients with threatened abortion are often both crucial and pivotal because, in most cases, the sonographic findings not only can determine the precise diagnosis but can also be used to guide therapy. Occasionally, to interpret the ultrasound images correctly, it is also necessary to know the quantitative level of serum hCG (see Usefulness of hCG in First Trimester Pregnancy).

The following section reviews the ultrasound findings in threatened abortion (with the exception of gestational trophoblastic disease and ectopic pregnancy, discussed separately in Chapters 29 and 32). Emphasis is on transvaginal criteria that can be used to differentiate a normal from an abnormal first trimester pregnancy reliably and confidently. As a practical point for discussion, and with regard to the uterus, the sonographic findings are divided into those that reveal an absent intrauterine sac, a sac lacking an embryo, and a sac containing an embryo.

Absent Intrauterine Sac

If the uterus appears normal on sonographic examination, or if the endometrial echoes appear prominent and no sac is visible, the differential diagnosis includes absence of pregnancy, a very early IUP (normal or abnormal), or an ectopic pregnancy. Assuming a positive pregnancy test, most often the outcome is unfavorable. This is because most patients with threatened abortion present after 6 weeks' GA, when sonographic examination normally reveals intrauterine products of conception.¹¹⁰

Table 6-7 Typical Clinical and Sonographic Findings of Threatened Abortion and Abnormal Intrauterine Pregnancy

Term	Clinical Signs	Serial hCG Levels	Ultrasound Findings
Normal Outcome			
Threatened abortion	Vaginal bleeding, clots (rarely), closed cervical os	Normal exponential rise	Embryo with cardiac activity Empty gestational sac (5–6.5 weeks) that subsequently develops with embryo Empty uterus (3–5 weeks)
Abnormal Outcome			
Complete abortion	Complete passage of embryo and gestational tissue	Rapid fall	Empty uterus
Incomplete abortion	Incomplete passage of gestational tissue	Slow fall or plateau	Typical thickened and irregular endometrium or fluid within endometrial cavity
Abortion in progress	Bleeding, often with clots and uterine cramps	Variable; usually plateau	Gestational sac in the process of expulsion
Embryonic (fetal) demise	Lack of uterine growth, absent fetal heart tones when expected	Variable; initial normal rise, then plateau or fall	Discrete embryo lacking cardiac activity
Blighted ovum (anembryonic Pregnancy)	Lack of uterine growth, absent fetal heart tones when expected	Variable; initial normal rise, then plateau or fall	Discrepancy in gestational sac development and embryonic development with little or no embryonic remnant

hCG, human chorionic gonadotropin.

From Nyberg DA, Laing FC: Threatened abortion and abnormal first-trimester intrauterine pregnancy. In Nyberg DA, Hill LM, Bóhm-Velez M, et al (eds): Transvaginal Ultrasound. St. Louis, Mosby-Year book, 1992.

When the endometrium is abnormally thick or irregularly echogenic, the differential diagnosis includes intrauterine blood or retained products of conception after an incomplete spontaneous abortion, a decidual reaction associated with an ectopic pregnancy, or decidual changes resulting from an early but not yet visible IUP. Patient history in conjunction with the quantitative level of hCG can often pinpoint the specific cause for the sonographic findings. Failure to detect an intrauterine sac when the hCG level exceeds a specific discriminatory number* excludes a normal early IUP (see Usefulness of hCG in First Trimester Pregnancy). In the absence of heavy bleeding, the likelihood of an ectopic pregnancy increases.

With heavy vaginal bleeding, retained products of conception or intrauterine blood are likely, although ectopic pregnancy is not completely excluded. Under these circumstances, Doppler evaluation may be useful to detect the presence of retained tissue (Fig. 6-33). When tissue is present, available therapeutic options include surgical intervention (cervical dilatation and curettage), medical management (with a vaginal prostaglandin analog such as misoprostol), or expectant management. Several studies suggest that ultrasound may be useful to predict which patients can be managed expectantly. For example, with detectable blood flow in the presumed intervillous space, Schwärzler et al¹¹³ reported an 80% success rate with spontaneous abortion occurring within 7 days, whereas this happened only 23% of

the time when flow was not detected. Two additional investigations each suggest that expectant management has a better outcome when sonography reveals an incomplete miscarriage (that is, retained products), as opposed to an intact gestational sac (with or without a visible embryo).^{114,115}

If the sonographic examination fails to reveal an intrauterine sac and the quantitative hCG level is less than the discriminatory number for sac detection, diagnostic considerations include an early IUP (normal or abnormal) or an ectopic pregnancy. Under these circumstances, the patient's clinical status and her desire to either maintain or terminate the pregnancy should determine whether serial tests (serum hCG or ultrasound or both) should be performed or whether intervention is required. On the basis of clinical considerations, the latter includes laparoscopy, laparotomy, uterine curettage, or administration of methotrexate, or a combination of these.

DETECTING A SAC WITHOUT AN EMBRYO OR YOLK SAC

When ultrasound examination reveals a sac without an embryo or yolk sac, the diagnosis is limited to one of three entities: (1) a normal early IUP; (2) an abnormal IUP; or (3) a pseudogestational sac in a patient with an ectopic pregnancy.

In theory, an intrauterine sac can be distinguished from a pseudogestational sac because the former is located within the decidua, whereas the latter is within the uterine cavity (see Fig. 6-12).⁴³ In practice, this distinction is often difficult to make with certainty (see Fig. 6-13). Therefore, a follow-up ultrasound should be obtained to document subsequent appearance of the yolk sac or embryo.^{44,45}

*In this context, a discriminatory number or level refers to the lowest value for which a certain observation should always be detected; in contrast, a threshold number or level refers to the lowest value for which a certain observation can be detected by sonography.

FIGURE 6-33. Heavy bleeding occurred in this patient who was reported to be 8.5 weeks pregnant. *A.* Gray scale imaging reveals echogenic material in the endometrial cavity (between calipers). *B.* Color Doppler confirms vascular flow within this material, consistent with retained products of conception. This was surgically confirmed.

ABNORMAL SAC CRITERIA

Size

Recall that the threshold for detecting a normal intrauterine sac by transvaginal ultrasound examination is when the sac diameter is only 2 to 3 mm; this corresponds to a GA of slightly more than 4 weeks.³⁹⁻⁴¹ A sac should be detected consistently by both transabdominal and transvaginal sonography when its mean diameter is 5 mm; this corresponds to a GA of 5 weeks.^{52,54}

Specific size criteria can be used to differentiate a normal from an abnormal intrauterine gestational sac. Using a *transabdominal* approach, discriminatory size criteria that suggest an abnormal sac include failure to detect a double

FIGURE 6-34. Despite a mean sac diameter of 22 mm, transvaginal sonography failed to reveal either a yolk sac or embryo. This appearance is diagnostic of a failed pregnancy. Note the double decidual sac sign (between *arrows*), confirming an intrauterine gestational sac and not a pseudogestational sac resulting from an ectopic pregnancy.

decidual sac when the MSD is 10 mm or greater, failure to detect a yolk sac when the MSD is 20 mm or greater, and failure to detect an embryo with cardiac activity when the MSD is 25 mm or greater.^{42,47}

Because of superior resolution, a transvaginal approach should be used preferentially to evaluate any intrauterine fluid collection that lacks an embryo. Also, because yolk sac and embryo detection in early pregnancy is critically dependent on transducer frequency, the highest possible transducer frequency should be used to detect these subtle, but critically important anatomic structures (see Fig. 6-19).⁵³ Generally accepted *transvaginal* discriminatory criteria for determining an abnormal sac include failure to detect a yolk sac when the MSD is 8 mm or greater and failure to detect cardiac activity when the MSD exceeds 16 mm (Fig. 6-34).^{51,116}

It is important to understand that these discriminatory criteria should be used as guidelines and that exceptions to these numbers have been reported.¹¹⁷ If certain findings are not observed at the appropriate time, the results of an ultrasound examination are equivocal, the examination is technically difficult, or the sonographer is inexperienced, caution is warranted. Follow-up ultrasound examination should be obtained in these cases to obviate the risk of terminating a normal IUP.

Growth Rate

The terms *blighted ovum* and *anembryonic pregnancy* imply that developmental arrest occurred either before formation of the embryo or before it is detectable using currently available equipment. In a series of 3500 consecutive first trimester abortuses, Byrne et al¹¹⁸ determined that the embryo failed

FIGURE 6-35. This sac-like structure had a mean diameter of 28 mm, did not contain a yolk sac or embryo, and lacked a double decidual sac sign. The surrounding tissue was abnormally thin and only weakly echogenic. These findings suggest a failed pregnancy, although a pseudogestational sac is not excluded. Doppler may be useful to distinguish between these two entities.

FIGURE 6-36. This gestational sac has an unusual echogenic convex bulge (arrow). Accurate dating based on in vitro fertilization was 6.0 weeks; a tiny living embryo (not shown) was small for dates, and measured 1.3 mm. Follow up scan 2 weeks later confirmed demise. In very early pregnancies this convex bulge (referred to recently as the “chorionic bump”) should not be mistaken for an embryo without a heartbeat.

to develop in greater than 60% of cases. Despite an anembryonic state, trophoblastic tissue often continues to function, resulting in continued gestational sac growth, albeit at a diminished rate. Whereas the MSD increases by 1.13 mm/d in a normal gestation, the growth rate of an abnormal sac is only 0.70 mm/d.⁵² On the basis of these observations, abnormal sac growth can be diagnosed confidently when the MSD fails to increase by at least 0.6 mm/d.

In possibly abnormal cases and in those with sacs that are less than the discriminatory size for visualizing the yolk sac or cardiac activity, knowledge of normal developmental and sac growth parameters allows sonologists to gauge an appropriate time interval between the initial and follow-up ultrasound examinations. Ideally, the repeat study should aim to identify both the yolk sac and cardiac activity. For example, if the initial MSD is 4 mm, a follow-up study should be done to detect cardiac activity when the sac achieves a diameter of 16 mm. Because normal sac diameter increases by approximately 1 mm/d, an appropriate time interval between the two sonographic examinations is at least 12 days. In contrast, if the initial sonographic examination reveals an MSD of 12 mm (without cardiac activity), the follow-up study should be done approximately 4 days later to determine whether the pregnancy is developing normally.

Trophoblastic Appearance

Initially described on the basis of transabdominal sonography, an abnormal-appearing choriodecidual or trophoblastic reaction consists of a distorted sac shape; thin (< 2 mm), weakly echogenic, or irregular choriodecidual reaction; and absence of a double decidual sac when the MSD exceeds 10 mm.⁴² Often the sac associated with a failing or failed pregnancy has multiple abnormal trophoblastic changes (Fig. 6-35).

Recently, subtle trophoblastic abnormalities have been reported using a vaginal approach. In their investigation of asymptomatic women between 5 and 12 weeks' GA, Bajo et al¹⁹ measured trophoblastic thickness at the embryonic implantation site and noted that in 15% of cases, the difference between the GA (in weeks) and the trophoblastic thickness exceeded 3 mm. This was associated with a 64% miscarriage rate within 7 days of the ultrasound study. A much less common first trimester observation, also associated with a guarded prognosis, consists of an irregular convex bulge that arises from the choriodecidual surface and protrudes into the gestational sac (Fig. 6-36). In a report of 15 patients (prevalence 0.7%) with this so-called chorionic bump, Harris et al¹²⁰ reported subsequent miscarriage in 8 (53%) patients. One should be cautious when making this observation, as this protrusion of tissue into the gestational sac may simulate a nonviable embryo adjacent to the developing placenta. The pathophysiology for both of these observations is speculative, but the respective authors suggest early placental insufficiency and a hematoma bulging into the sac. Clearly, the take home message is that “the harder we look, the more we see.”

ROLE OF DOPPLER

Doppler sonography may also be useful for determining whether an intrauterine sac-like structure that lacks an embryo is a true gestational sac. When a nonspecific-appearing intrauterine fluid collection is identified, Doppler may help differentiate a pseudogestational sac associated with an ectopic pregnancy from an intrauterine gestational sac, either normal or abnormal. Flow around a pseudogestational sac may be either absent or show only a minimal amount of low-velocity flow (< 8 cm/s peak systolic velocity).¹²¹ In contrast, flow around an intrauterine gestational sac typically is high velocity with a low-resistance

FIGURE 6-37. Color Doppler interrogation of an intrauterine fluid collection without a yolk sac or embryo shows extensive myometrial and endometrial blood flow with high peak systolic velocity. Pathology confirmed a failed pregnancy.

pattern (Fig. 6-37). Our personal experience, as well as others, confirms that low-resistance arterial flow may occasionally be detected with pseudogestational sacs.¹²² This finding limits the usefulness of Doppler for making this important distinction. Therefore, patients whose initial sonogram demonstrates an intrauterine fluid collection but no adnexal mass or definite IUP should undergo sonographic and clinical follow-up rather than Doppler interrogation. Also, because Doppler sonography delivers more energy than gray-scale ultrasound, its use should be minimized to prevent unnecessary and potentially harmful exposure of an early embryo.¹²³ Within 1 to 2 weeks, both normal and abnormal IUPs will become more apparent clinically and sonographically. If there is an ectopic pregnancy, follow-up studies will reveal the diagnosis in most patients.

DETECTING A SAC WITH AN EMBRYO

Cardiac Activity Absent

When an embryo is visible during a transabdominal ultrasound examination but cardiac activity is absent, the prognosis is usually poor. Occasionally, however, cardiac activity is not detected in a very small embryo because of its size. On the basis of work by Pennell et al,¹²⁴ the discriminatory embryonic size for detecting cardiac motion transabdominally has been determined as being 9 mm. In their experience, cardiac activity was absent in 21% of normal pregnancies with a CRL of less than 9 mm.

Not surprisingly, a vaginal approach lowers the discriminatory CRL for detecting cardiac activity. Levi et al⁶⁹ suggested a 4-mm CRL cutoff because, in their experience, all normal pregnancies had cardiac activity when embryos achieved this length, whereas cardiac activity was absent in 18% of embryos with a CRL measurement of less than

4 mm. Other investigators used 5 mm as the discriminatory embryonic length for detecting cardiac motion.^{70,124} If the length of the embryo is less than the discriminatory value, the patient should be managed expectantly and a repeat ultrasound examination done when the expected CR length exceeds the discriminatory value. Alternatively, or additionally, the level of serum hCG may be useful for determining whether or not a normal IUP is present.

When embryonic length exceeds the discriminatory length and cardiac activity is absent, a nonviable gestation is highly likely. Because this negative observation (failure to perceive a heartbeat) has such important clinical ramifications, caution and certainty are required before reaching this conclusion. To ensure that the measured structure is indeed the embryo, it is useful to note its relationship to the yolk sac. Between 6 and 7 weeks' GA, the embryo and yolk sac are closely applied and contiguous structures (see Fig. 6-21); after 7 weeks' GA, they diverge from one another (see Fig. 6-26). The scan should be performed using the highest transducer frequency available,⁵³ M-mode and if possible a real-time clip or videotape should be obtained to document absent cardiac activity, and also if possible, a second independent observer should be present to confirm the findings (Fig. 6-38). Interpretive caution must always be exercised whenever a question is raised with regard to either the technical adequacy of the study (maternal or equipment related) or the experience of the examiner. In most cases, embryonic demise is due to a chromosome abnormality that leads to arrested embryonic development.^{109,118}

Cardiac Activity Present

Sonographic detection of cardiac activity not only confirms a living embryo but is also considered a favorable prognostic finding.^{69,80,125,126} In general, if cardiac activity is found in an asymptomatic woman examined after 8 weeks' GA, the risk of loss is only 2% to 3%.¹²⁷⁻¹²⁹ Despite optimism associated with cardiac activity, however, multiple risk factors have been described that increase the possibility of subsequent embryonic-fetal demise.

RISK FACTORS FOR EARLY PREGNANCY FAILURE

Gestational Age

An inverse relationship exists between GA and an adverse outcome. When asymptomatic women are examined before 6.5 weeks' GA, the incidence for subsequent demise ranges from 7% to 24%.^{66,74,130} This loss rate declines to approximately 2% after 8 weeks.¹²⁷⁻¹²⁹ Increased early loss most likely reflects a well-recognized high background demise rate as a result of lethal chromosome mutations during this phase of pregnancy.

Intrauterine Blood

Intrauterine collections of blood are found in many women with first trimester threatened abortion as well as some asymptomatic patients. During early pregnancy, as implantation occurs, the genesis for these collections most likely relates to the erosive effects of the chorion frondosum (the

FIGURE 6-38. A. Demise of a 9.1-week gestational age embryo can be documented by an M-mode tracing that shows lack of cardiac activity. Color Doppler (B) can also confirm this diagnosis by documenting lack of embryonic blood flow.

fetal contribution to the definitive placenta) as it penetrates into the decidua basalis (the maternal contribution to the definitive placenta). Later it is likely due to venous bleeding associated with separation or abruption of the placental margin or marginal sinus.¹³¹ A range of descriptive words, including intrauterine, perigestational, implantational, or subchorionic, can be used to characterize these maternal hemorrhages. When this occurs, blood dissects along paths of least resistance and ultimately can be located in a variety of positions relative to the developing sac and placenta (Fig. 6-39). As blood tracks away, and becomes remote from the placenta, it often elevates the attached chorionic membrane (smooth chorion), dissecting it and the attached decidua vera. In this manner, it comes to surround the gestational sac. If the collection penetrates into the adjacent endometrial cavity, bleeding becomes clinically apparent. Similar to hematomas throughout the body, the echogenicity of the blood depends on its age and the amount of associated clot (Fig. 6-40). In general, acute hemorrhage is hyperechoic or isoechoic relative to placental tissue. With evolution, liquefaction occurs, and the collection becomes more sonolucent but often contains residual low-level echoes.

The literature reveals widely disparate findings regarding pregnancy outcome in women with first trimester vaginal bleeding. Several studies suggested a two- to threefold increased risk of spontaneous abortion,^{126,132-135} whereas others reported no increase in miscarriage rate despite a visible intrauterine hematoma.^{136,137} One explanation for the varied opinions may relate to the location as opposed to

the size of the hematoma. For example, a small retroplacental hematoma may be associated with a relatively worse prognosis than a larger hematoma situated within the endometrial cavity and away from the placenta.¹³⁸ To further confuse this issue, there is also evidence that suggests that first trimester bleeding is associated with an adverse outcome, but this is statistically independent of the presence or absence of a hematoma.^{134,139} Other confounding variables either alone or in combination may also play a role in determining pregnancy outcome. These include an increased risk for spontaneous abortion with a progressively larger hematoma, advancing maternal age, earlier GA, bradycardia, smoking, and small sac size.^{132,134,135,140} Despite these negative prognostic features, a well-designed study that prospectively evaluated pregnancies between 6 and 13 weeks' GA noted that both symptomatic and asymptomatic women can be assured that their pregnancy has a high likelihood of a favorable outcome if sonography confirms fetal cardiac activity and the scan results are normal.¹²⁵ Fortunately, despite vaginal bleeding, the majority of patients with this complication will have a successful pregnancy outcome.

Heart Rate

When embryonic cardiac activity is first detected between 5 and 6 weeks' GA, the rate is relatively slow (see Figs. 6-22 and 6-23, and Table 6-4). Although mean heart rates of 82 BPM at 5 weeks' GA and 96 BPM at 6 weeks' GA have been reported,¹⁴¹ most investigators reported a normal

FIGURE 6-39. Three patients with intrauterine blood in various locations. *A.* A moderately large subchorionic hematoma (SCH) developed as a result of blood dissecting the chorion (arrow) and its decidual attachment. Note that the chorion remains attached to the placenta (P) and that the margin of the placenta is separated from the uterine wall (curved arrow). *B.* In another patient, the hematoma covers the cervix (CX) and elevates the chorionic membrane (arrows) from the posterior uterine wall. Because the echogenicity of blood (asterisk) is similar to placental tissue (P), they may be difficult to discriminate from one another. *C.* A small retroplacental hypoechoic collection of blood (asterisk) indicates placental (P) abruption. This is unusual during the first trimester, as most collections are subchorionic in location.

range of 100 to 115 BPM between 5 and 6 weeks' GA.^{72,78-80} The mean heart rate increases to approximately 140 BPM by 9 weeks' GA.⁷² Because of the relatively slow initial heart rate, one report defines bradycardia as less than 100 BPM before 6.2 weeks' GA and less than 120 BPM between 6.3 and 7.0 weeks.⁷³ Multiple investigations document an adverse outcome with embryonic bradycardia, and this is especially worrisome when vaginal bleeding is also present.^{134,135} Close and continued follow up of embryos with early bradycardia (at 6 to 7 weeks' GA) is warranted, because even if the rate normalizes by 8 weeks' GA, there still is a 25% demise rate by the end of the first trimester (Fig. 6-41).¹⁴² A few case reports document first trimester bradycardia associated with both atrial and ventricular arrhythmias; typically, the outcome is dismal (Fig. 6-42).^{143,144} Analysis of first trimester bradycardia also confirms an association with structural and chromosome abnormalities, especially trisomy 18 and triploidy.^{145,146} In contrast, other chromosome defects, including trisomy 21, and especially trisomy 13 and Turner syndrome, have an association with first trimester tachycardia (determined at 10-14 weeks' GA).¹⁴⁶ In another investigation, however, that evaluated embryonic heart rates at or before 7 weeks' GA, a rapid early heart rate had a good prognosis, with a high likelihood of a normal outcome.¹⁴⁷

Nonetheless, because of reported risks associated with cardiac rate abnormalities, consideration should be given

to follow-up ultrasound examinations if the embryonic heart rate is either less than or exceeds the limits of normal for a given GA, or if an irregular rhythm is detected.

SMALL SAC SIZE-GROWTH DELAY

During the first trimester, the volume of fluid within the gestational sac is not routinely reported because most first trimester sacs contain relatively similar small amounts of fluid. Occasionally, however, the amount of fluid in a first trimester sac is noticeably diminished, resulting in a sac that is small for dates. In two reports evaluating pregnancy outcome in the presence of first trimester oligohydramnios, the incidence of spontaneous abortion was between 80% and 94% despite normal cardiac activity (Fig. 6-43).^{148,149} In these studies, oligohydramnios was diagnosed when the difference between the MSD and CRL was less than 5 mm. Even less severe discrepancies, in the range of 5 to 8 mm, are at increased risk for miscarriage, with a reported rate of approximately 25%.¹⁴⁸ This is not surprising when a small sac is present; other adverse prognostic indicators such as embryonic bradycardia, maternal bleeding, and delay in embryonic growth may also be present.^{135,138} Although a small sac size is relatively uncommon (observed in 1.9% of fertility patients),¹⁴⁸ this observation can be used to counsel women who present with this finding.

FIGURE 6-40. Three patients with intrauterine blood of varying echogenicity. *A.* A large amount of echogenic blood surrounds a very small embryo (*arrow*). Because the echogenicity of the hematoma is identical to that of placental tissue, they may be very difficult to distinguish from one another. Color Doppler may be helpful to show intraplacental blood flow. *B.* Despite its moderate size, this hematoma (between calipers) is difficult to identify because its echogenicity is similar to adjacent tissue. *C.* On this image, the prominent sonolucent crescent-shaped structure (between calipers) could be misconstrued for a gestational sac. It is, in fact, a subchorionic hematoma, that partially surrounds an adjacent gestational sac (*arrow*).

Occasionally, a live embryo is seen that is smaller than expected on the basis of accurate dating or prior ultrasound examination. Studies suggest that a smaller-than-expected first trimester CRL measurement reflects early growth restriction that persists throughout pregnancy and is associated with low birthweight, low birthweight percentile, and premature delivery.¹⁵⁰⁻¹⁵² The origin of fetal growth impairment may reflect a defect in early placentation.¹⁵³ In these women, first trimester circulating concentration of PAPP-A is decreased; because this trophoblast derived protein is part of a complex system that among other things, controls trophoblastic invasion of the decidua, a paucity of this substance may negatively impact placental development and result in chronic placental dysfunction.

YOLK SAC EVALUATION

Both the size and appearance of the yolk sac should be considered in early pregnancy, although once cardiac activity is documented, the yolk sac is relegated to secondary status. A normal yolk sac has a maximal diameter of 5 to 6 mm at approximately 10 weeks' GA. Although abnormal yolk sac diameters are generally reported to be associated with subsequent pregnancy failure,^{56,57,154,155} one study of 14 cases with yolk sac diameters greater than the 95th percentile for GA reported normal pregnancy outcomes.¹⁵⁶ An interesting observation, recently reported in a group of 18 women with insulin-dependent diabetes, revealed that during their first trimester, the diameter of their yolk sacs

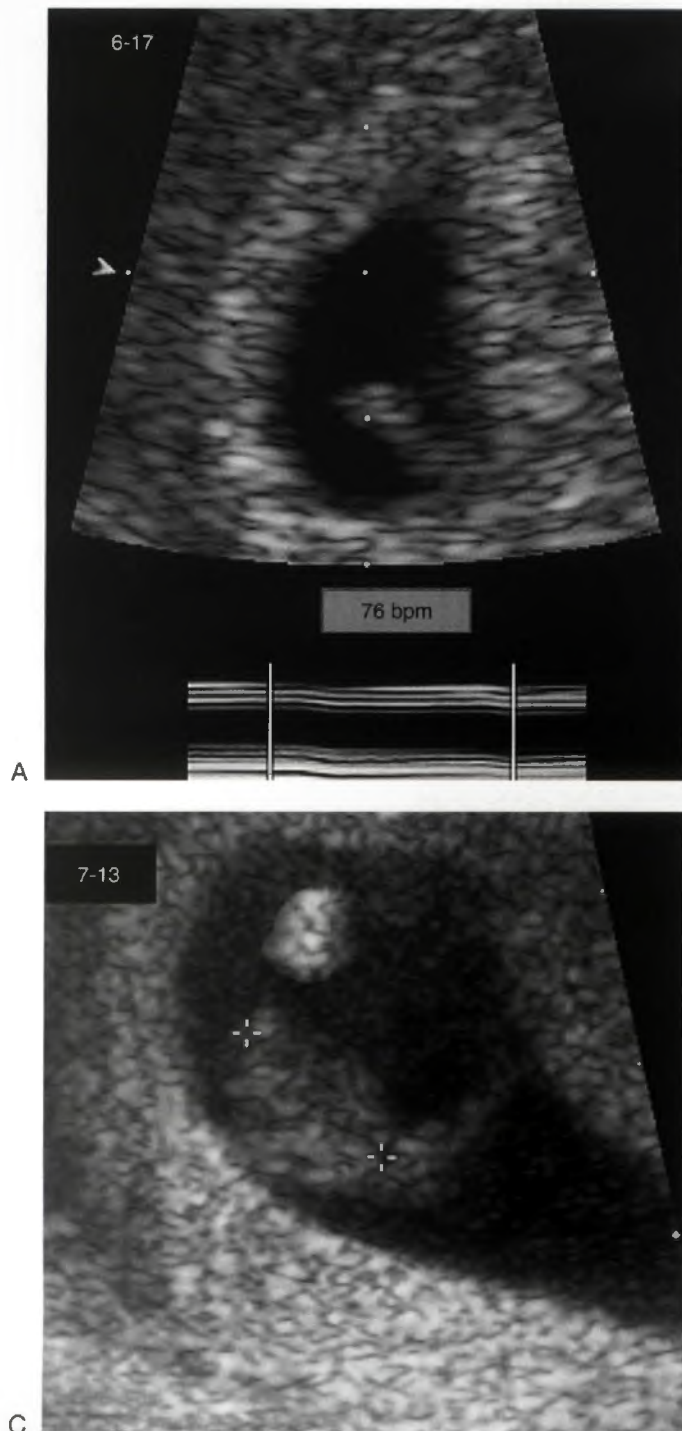

FIGURE 6-41. A. An initial scan, done at 6 weeks' gestational age (GA) demonstrates embryonic bradycardia at 76 beats per minute. B. A follow-up scan 12 days later (7.7 weeks GA) demonstrates normal embryonic growth and a normal heart rate at 136 beats per minute. C. Follow-up, at 10 weeks GA, however, revealed embryonic demise. Note the abnormally echogenic yolk sac, which appeared normal on the 2 prior examinations.

was significantly larger when compared with a control group. Unfortunately, the outcome of these pregnancies was not reported, so the diagnostic implication of this observation is unknown.¹⁵⁷

A practical approach to this issue is to consider any patient with a large yolk sac to be at increased risk for spontaneous abortion. In our experience, follow-up scans reveal that many, but not all, of these patients have subsequent embryonic demise (Fig. 6-44).

An abnormal-appearing yolk sac is also associated with early pregnancy failure.¹⁵⁴ Sporadic case reports suggest that yolk sacs that are abnormally shaped, calcified, echogenic, or double (vitelline duct cyst) are associated with either antecedent or subsequent embryonic demise (Fig. 6-41C).^{158,159} Despite an abnormal-appearing yolk sac, whenever cardiac activity is present, follow-up imaging is recommended because, in rare and exceptional cases, the pregnancy may continue to term (Fig. 6-45).

FIGURE 6-42. At 7.4 weeks' gestational age, this embryo was noted to have an irregular heart rate, that varied between 76 beats per minute (A), and 120 beats per minute (B). A scan done 2 weeks after this examination revealed demise of the embryo.

FIGURE 6-43. First trimester oligohydramnios is obvious in this sac that contained a living embryo with a normal cardiac rate. Follow-up examination, however, confirmed demise.

FIGURE 6-44. Based on in vitro fertilization, this pregnancy was 7.6 weeks' gestational age. The embryonic length, however, was lagging by more than a week, the heart rate was slow (83 beats per minute), and the yolk sac was large (diameter of 6.7 mm). Follow-up scan confirmed embryonic demise.

FIGURE 6-45. This embryo (between calipers), which was 6.5 weeks' gestational age, had an abnormally echogenic yolk sac (arrow). Despite this predictor for a poor outcome, follow-up examination revealed normal growth and development.

AMNION EVALUATION

Because it is such a thin membrane or perhaps because it initially lies in close proximity to the embryo,⁹⁴ the normal amnion may be difficult or impossible to perceive at sonography during the first trimester, and it is not seen normally until the CRL is 7 mm or greater (6.7 weeks' GA) (see Fig. 6-28).⁹⁵ In a study of 169 normal and 169 failed pregnancies, the amnion was visible in 34 embryos with a CRL less than 7 mm. In each case, these pregnancies had already failed or subsequently failed.⁹⁵ Another investigation that determined amniotic fluid volume in normal first trimester pregnancies could only do so at or after 7 weeks' GA, when the amnion became visible.¹⁶⁰ In 1988, using a transabdominal approach, Yeh et al⁸² described the double bleb sign, which was transiently visible between 5 and 7 weeks' GA, and was owing to the contiguously positioned amniotic sac-embryo-yolk sac complex. In our laboratory, despite extensive experience with vaginal sonography during this gestational period, a double bleb appearance is rarely seen in a normal 5- to 7-week GA pregnancy (see Fig. 6-29). When the double bleb appearance is obvious, it is typically associated with impending or frank pregnancy failure. In some cases, it represents two contiguous yolk sacs associated with monozygotic twinning; rarely, it is due to an anomaly such as an umbilical cord cyst (Fig. 6-46).

Abnormal amnion development is suggested when the membrane is easy to see or if its thickness and echogenicity approach that of the yolk sac. Another worrisome finding is an enlarged amniotic cavity relative to the CRL (Fig. 6-47). Recall that in a normal first trimester pregnancy, the mean amniotic sac diameter is approximately equal to the CRL. In Horrow's evaluation of 10 first trimester embryos that subsequently died, each displayed an abnormally large amniotic cavity relative to the size of the embryo and its chorionic cavity (Fig. 6-48).⁹⁶ In this report, the difference between the CRL and amniotic cavity diameter was approximately 1 mm in normal pregnancies but almost 9 mm in abnormal pregnancies. As with other adverse prognostic indicators, patients with enlarged or suspicious-

appearing amniotic sacs should be advised to undergo a follow-up ultrasound examination (Fig. 6-49).

Because ultrasound imaging normally detects an embryo before the amnion, a finding that has been reported as highly suggestive of an abnormal pregnancy is visualization of this membrane without detection of an embryo (Fig. 6-50).¹⁶¹ The majority of cases with an "empty amnion" sign also have an MSD greater than 16 mm, which, in and of itself, is consistent with a failed pregnancy. When this sign is apparent but the sac diameter is less than 16 mm, confirmation of failed pregnancy should be corroborated with the serum hGC level or follow-up ultrasound examination.

If an otherwise empty sac contains an easily visible membrane-like structure, distinction between the abnormal amnion versus a large yolk sac may be difficult or impossible (Fig. 6-51). Nonetheless, abnormal development should be suspected in either case because the presence of a cystic structure larger than 6 mm in diameter without a living embryo is highly suggestive of pregnancy failure.

MATERNAL FACTORS

Maternal factors that may increase the risk of spontaneous miscarriage include age, smoking, structural uterine abnormalities, and a history of miscarriages.

Maternal age adversely affects outcome. Women older than 34 years are one and one half to five times more likely to miscarry than younger women.^{126,129,132,135,140,162} Until age 30, the incidence of miscarriage is approximately 12%; thereafter, the rate increases rapidly, exceeding 50% in women older than 45 years.¹⁶²

Both acquired and congenital structural uterine abnormalities are associated with increased risk of pregnancy loss. In addition to synechiae, acquired structural abnormalities that may affect outcome include fibroids. In women with fibroids, the pregnancy loss rate is almost twice that of women with a normal uterus, and in one study, the loss rate was statistically greater with multiple fibroids, but did not correlate with fibroid size or location.¹⁶³ Congenital structural malformations, which are typically of müllerian duct origin, primarily affect the rate of spontaneous abortion as opposed to the rate of conception. Septate uteri consistently have the strongest association with early miscarriage, presumably because of inadequate placental implantation on the poorly vascularized septum.¹⁶⁴ A less common congenital abnormality may be found in women whose mothers were exposed to diethylstilbestrol during pregnancy (daughters of women who took diethylstilbestrol [DES]).^{165,166} In these patients, developmental changes may cause cervical incompetence or a hypoplastic, T-shaped configuration of the endometrium, each of which contributes to an abnormally high miscarriage rate.

The prognosis for successful pregnancy in patients with structural uterine abnormalities relates to the specific abnormality and whether it is amenable to surgical correction. In comparison to lethal chromosomal embryonic mutations, these cases are relatively few in number.

The term *recurrent miscarriage* describes the situation of three or more consecutive first trimester spontaneous losses, which affects approximately 1% of couples.¹⁰⁹ Because the cause for this problem is multifactorial, evaluation of these patients requires a broad range of diagnostic tests that

FIGURE 6-48. Four different patients, each with what appears to be a prominent double bleb sign. *A.* This is a failed pregnancy, which by accurate dating was 7.8 weeks' gestational age (GA) (*arrow* points to amnion). *B.* This 7-week GA embryo had bradycardia (81 beats per minute) as well as an abnormally thick amnion (*arrow*). Follow-up scan confirmed demise. YS, yolk sac. *C.* These two closely opposed round structures represent two yolk sacs associated with monozygotic twinning. *D.* This case, which is virtually identical in appearance to *C*, is due to an umbilical cord cyst adjacent to the yolk sac; a living embryo is between these 2 structures (*arrow*). The pregnancy subsequently failed at 18 weeks.

FIGURE 6-47. In this 6-week intrauterine pregnancy, the diameter of the amniotic cavity (AC) was much too large relative to the embryonic crown-rump length (between calipers). In addition, the amnion (arrow) was too easily seen. Follow-up sonographic examination revealed demise.

FIGURE 6-49. In this transabdominal scan, the amnion is too easily seen and slightly irregular, and the amniotic cavity is no longer spherical. Despite these findings, follow-up ultrasound examination revealed a normally developing fetus.

FIGURE 6-48. Relationship of the diameter of the amniotic cavity (AC) to the crown-rump length (CRL) in normal (solid circles) and abnormal (gray circles) embryos. As evident from this graph, abnormal pregnancies have a large amniotic cavity diameter. (From Horrow MM: *Enlarged amniotic cavity: A new sonographic sign of early embryonic death.* AJR Am J Roentgenol 158:359, 1992.)

FIGURE 6-50. This transvaginal scan reveals an easily visible round structure with a mean diameter of 8 mm. The distinction between an abnormal amnion versus a large yolk sac is not always possible, but in this case, a small yolk sac is also present (arrow). Therefore, this appearance is consistent with a failed pregnancy.

evaluate anatomic, hormonal, genetic, and autoimmune factors. Readers interested in the clinical aspects of this topic should consult an up-to-date gynecologic textbook, such as *Danforth's Obstetrics and Gynecology*.¹⁰⁹

Sonographic findings in patients with recurrent spontaneous abortion depend on when the sonogram is done. Although

approximately three fourths of these patients will have a living embryo demonstrated at some point during the first trimester, follow-up confirms a four to five times greater likelihood of subsequent loss compared with women without a history of recurrent pregnancy loss.^{167,168} Because in most cases the pregnancy fails by approximately 8 weeks' GA,

FIGURE 6-51. A single, round structure (arrows) with a mean diameter of 9 mm is visible in this gestational sac. It could be either an abnormal amnion or a large yolk sac; in either case, the appearance is abnormal and consistent with a failed pregnancy.

it may be prudent to perform a vaginal sonographic examination at this time (as opposed to earlier) to provide realistic feedback to these patients.¹⁶⁹

USEFULNESS OF HCG LEVELS IN FIRST TRIMESTER PREGNANCY

There is no question that high-resolution ultrasound and the quantitative level of serum hCG are complementary and, when used together, optimize the evaluation of patients with threatened abortion. This is particularly true when the initial ultrasound findings are nondiagnostic. Because both gestational sac growth and hCG production relate to trophoblastic function, there is normally an excellent correlation between sac size and hCG level.¹⁷⁰

If a patient with a threatened abortion has a definitely abnormal gestational sac, a quantitative hCG level is not usually useful. In equivocal cases, or in women at risk for recurrent miscarriage, however, this assay can be extremely helpful for determining whether or not the pregnancy is progressing normally. In most patients with an abnormal IUP, the hCG level is disproportionately low relative to the sac size.¹⁷⁰⁻¹⁷³

Another indication for determining the quantitative hCG level is the presence of a small intrauterine fluid collection that lacks a DDS finding (transabdominal scan) or intra-decidual sign (transvaginal scan). In these cases, the level of hCG may be used to determine whether the intrauterine findings are due to a pseudogestational sac or an early IUP. Most often, ectopic pregnancies are associated with a disproportionately high level of hCG for the size of the fluid collection. Additionally, failure to detect an intrauterine

gestational sac when the hCG value exceeds the discriminatory level places the patient at risk for an ectopic pregnancy.^{169,174} Although the discriminatory hCG level for detecting an intrauterine sac varies somewhat from one ultrasound laboratory to another and also depends on the standard against which the hCG is calibrated, it is clear that combining the hCG level with the ultrasound findings significantly improves one's ability to interpret equivocal ultrasound findings and to diagnose ectopic pregnancy.^{174,175} Many ultrasound laboratories currently use between 1000 and 2000 mIU/mL (International Reference Preparation) as the hCG level above which an intrauterine gestational sac should normally be visible by transvaginal scanning.^{99,176-178}

ROLE OF DOPPLER IN PREDICTING PREGNANCY OUTCOME

Because energy levels associated with Doppler can be significantly greater than for imaging, and because the greatest potential for risk in ultrasound diagnosis is in fetal Doppler studies,¹²³ our ultrasound laboratory does not advocate routine use of Doppler in the first trimester. However, using controlled research protocols, several investigations have addressed Doppler applications in early pregnancy. With respect to an IUP (as opposed to ectopic pregnancy), the primary role of Doppler is to determine whether a first trimester pregnancy will have a normal outcome. To do this, attention has been focused on uteroplacental and corpus luteal flow patterns.

Uteroplacental flow can be evaluated by measuring flow velocity or a variety of indexes (systolic-diastolic ratio, resistive index [RI], pulsatility index) that characterize flow patterns within the main uterine artery or subchorionic vessels (spiral arteries). In a normal pregnancy, the indices within these vessels demonstrate a progressive decline from 6 to 12 weeks' gestation.^{21,36,179} Histo-morphometric anatomic correlation suggests that the basis for this progressive drop in resistance is the establishment of the intervillous circulation.²⁶ The usefulness of Doppler for predicting pregnancy outcome has not been established; some reports suggest that elevated resistance in the uterine or subchorionic vessels is associated with a high likelihood of spontaneous abortion,^{25,49,180} whereas others have found that Doppler analysis of these vessels is not predictive of outcome.^{179,181,182}

A second area of investigation is interrogation of corpus luteal blood flow during the first trimester.¹⁸³⁻¹⁸⁶ In these studies, conflicting results are also evident; one report suggested a relatively increased corpus luteal RI associated with threatened abortion,¹⁸⁴ whereas another found no significant difference in this measurement compared with that of the control population.¹⁸⁵ Interestingly, both of these studies agreed that the RI was abnormally increased in patients with missed abortion.^{184,185} Corpus luteal RIs have also been measured in an effort to predict pregnancy outcome; the results of this investigation show this parameter cannot be used successfully for this purpose.¹⁸⁶

Although Doppler has not proven useful for predicting a successful first trimester outcome, researchers have confirmed a correlation between first trimester uterine artery resistance and subsequent pregnancy complications. Most authors agree that as early as 11 weeks' GA, elevated uterine artery resistance can identify patients at risk for both intra-

FIGURE 6-52. Graphic representation noting the causes of human congenital anomalies. (From Moore KL, Persaud TVN: *The Developing Human: Clinically Oriented Embryology*, 7th ed. Philadelphia, WB Saunders, 2003, pp 158-186.)

FIGURE 6-53. Schematic illustration depicting the risk of developing a congenital anomaly relative to gestational age. (From Moore KL, Persaud TVN: *The Developing Human: Clinically Oriented Embryology*, 7th ed. Philadelphia, WB Saunders, 2003, pp 158-186.)

uterine growth restriction and pregnancy-induced hypertension.¹⁸⁷⁻¹⁸⁹ One explanation for this relationship is inadequate or incomplete trophoblastic invasion of the maternal vessels during the first trimester. Early identification of patients at risk for these complications could allow additional screening and possible intervention.

DETECTING FETAL ANOMALIES

Congenital fetal malformations can be the result of genetic or chromosomal, environmental, or combined factors. In more than 50% of cases, the origin is unknown; however, when a cause is identified, most are due to chromosomal aberrations (Fig. 6-52). Environmental causes, or teratogens,

are responsible for approximately 10% of anomalies. The timing of exposure of the embryo to a teratogen is critical to pregnancy outcome (Fig. 6-53). Very early exposures (up to 5 weeks' GA) typically have an all-or-none result: the embryo will either die or be unaffected. Exposure during organogenesis (5 to 10 weeks' GA) often affects organ development and results in severe congenital anomalies. Exposure during the fetal phase of development has a variable result.¹⁹⁰

With continued technologic improvements, imaging of the embryo has progressed far beyond identifying cardiac activity and measuring CRL. Although many congenital anomalies cannot be diagnosed with confidence until the second trimester, gross abnormalities such as large encephaloceles, holoprosencephaly, ventral wall defects, and

conjoined twins can often be detected in the latter part of the first trimester.^{4,191,192} Nonetheless, at this early stage of development, anomaly detection remains limited by the small size of the fetus.

DEVELOPMENTAL PITFALLS

As the embryo develops, several normal anatomic structures undergo developmental changes that can be misinterpreted as abnormal. One potentially confusing cystic space, readily visible in the posterior cranium between 7 and 9 weeks' GA, is the developing rhombencephalon (Fig. 6-54). This structure will ultimately contribute to the fourth ventricle, brain stem,

FIGURE 6-54. A well-defined cystic area in the posterior fossa (between calipers) represents the normally developing rhombencephalon in this 8.2-week embryo.

and cerebellum, and it should not be confused with a developing Dandy-Walker malformation or hydrocephalus.

Another potential source of confusion is prominence at the fetal umbilical cord insertion site. Beginning in the 8th week of gestation, physiologic herniation of fetal bowel into the base of the umbilical cord creates a focal mass. This mass can measure up to 7 mm in diameter and typically becomes most prominent at 9 to 10 weeks' GA, concurrent with a 90-degree counterclockwise rotation of the bowel around the base of the superior mesenteric artery (Fig. 6-55). The mass should not measure more than 7 mm, it should resolve by the end of the 11th week GA as the bowel returns to its intra-abdominal location, and it should no longer be seen once the CRL is 45 mm or greater.⁸³⁻⁸⁵

DIAGNOSING ANOMALIES (EXCLUDING NUCHAL TRANSLUCENCY)

By 10 weeks' GA, the fetal cranium, brain, neck, trunk, and extremities can be visualized, and gross anomalies can be detected in the first trimester.

Anencephaly is characterized by absence of development of the cranium with dystrophic brain tissue in the expected location of the fetal head. When this condition is visible during first trimester sonography, the fetal head has an irregular contour and is not contained by bone. The dystrophic brain tissue may extend beyond the usual location of the head, such as to either side of the face or

FIGURE 6-55. A. Ten-week embryo with a rounded mass protruding from the anterior abdominal wall, representing physiologic bowel herniated into the base of the umbilical cord (arrows). With continued normal development, the mass is typically no longer present by 12 weeks' gestational age. B. Three-dimensional image of a 10-week fetus with prominent physiologic bowel at the base of the umbilical cord (arrows).

A

B

FIGURE 6-56. Anencephaly. *A.* Twelve-week fetus with absent cranium and dystrophic brain tissue protruding above the face (*arrows*). The head size is smaller than normal. *B.* Eleven-week fetus (calipers) with anencephaly and dystrophic brain tissue extending anterior to the face (*arrows*).

anterior to the orbits, or the head may appear abnormally small (Fig. 6-56). No calcified cranium will be seen.^{193,194}

Large *encephaloceles*, defects in the cranium through which intracranial contents herniate outside the skull, can sometimes be identified (Fig. 6-57). With *holoprosencephaly*, a brain anomaly resulting from failure of cleavage of the prosencephalon into the cerebral hemispheres, the fetal head contains a large central cystic space and the falx and choroid plexus are absent (Fig. 6-58).¹⁹⁵ This devastating anomaly is often seen with trisomy 13 and, therefore, once detected, should prompt counseling for karyotype testing.

FIGURE 6-57. Fourteen-week fetus with an occipital defect (between calipers) and encephalocele (*arrows*) herniated outside the cranium.

FIGURE 6-58. Thirteen-week fetus with holoprosencephaly, demonstrating large single ventricle (*asterisk*) and absence of the falx due to failure of division of the prosencephalon or forebrain.

The presence of large cystic spaces behind the fetal head, neck, and trunk, like thickening of the nuchal translucency (see Chapter 3), are associated with abnormal chromosomes, particularly trisomies 13, 18, and 21 and Turner syndrome. These fluid collections are called *cystic hygromas* or *lymphangiectasia*.¹⁹⁶ The cystic spaces may extend down the trunk of the fetus, appearing as a halo around the fetus, or the spaces may be confined to the posterior fetal neck (Fig. 6-59).

FIGURE 6-59. Lymphangiectasia and cystic hygroma. *A.* Fourteen-week fetus encased by marked skin thickening and edema (between calipers) due to diffuse lymphangiectasia. *B.* Coronal image of fetal head and neck of a different fetus demonstrating focal cystic spaces around the neck (arrows) representing a cystic hygroma.

Large ventral wall defects, such as *omphalocele* and *gastroschisis*, can be differentiated from physiologic bowel herniation based on the size of the protruding anterior abdominal wall mass and persistence of the mass beyond 12 weeks' GA. If the size of the mass before 12 weeks' GA is more than 7 mm, a ventral wall defect should be suspected, and follow-up sonography should be performed after 12 weeks' GA to confirm the diagnosis. The protruding mass of an omphalocele typically has a smooth and rounded contour, because the extruded abdominal contents are contained by a peritoneal membrane (Fig. 6-60).¹⁹⁷ The contour of the gastroschisis is typically irregular, because bowel loops protruding through the defect are not contained by a membrane (Fig. 6-61).

Amniotic band syndrome is characterized by deformities of the fetus, including ventral wall defects, encephaloceles, and limb amputations. Severe cases of disruption of the fetus can sometimes be diagnosed in the first trimester (Fig. 6-62).^{197,198} Normally, by the end of the first trimester, the ventral wall should appear intact and all four extremities should be identified as present.

When monoamniotic twins are present during the early part of the first trimester, it is often difficult to tell whether

they are conjoined or separate but very close together. By the end of the first trimester, however, as the amniotic cavity enlarges, it is usually possible to differentiate true *conjoined twins* from individual monoamniotic twins, and the site of joining may be identified (Fig. 6-63).^{199,200}

CONCLUSION

Transvaginal ultrasound has changed the clinical approach for evaluating patients during the first trimester of pregnancy. In asymptomatic women, it can determine the number of gestational sacs and precisely date the pregnancy. In women who present with threatened abortion, ultrasound is often the first and frequently the only study required to sort out the many differential clinical considerations. In approximately 50% of these patients, the results reveal a normal IUP, and the pregnancy progresses without difficulty. In the remaining patients whose outcomes are abnormal, ultrasound can usually diagnose the specific problem, and expeditious and appropriate therapy can be undertaken. In the few remaining cases, a quantitative hCG determination may be indicated, or serial hCG and ultrasound examinations may be warranted.

Conclusions

INTRODUCTION

Ultrasound has become the essential tool of modern obstetric practice. With advances in technology and computer processing, what was once a mere curiosity has become crucial for the assessment of the placenta, membranes, fluid, and fetal anatomy, as is covered in the other portions of this text. The assignment of pregnancy age is the first task placed before the care provider, and ultrasound is the key modality used for this purpose. Additionally, ultrasound is far superior to the clinical examination for determining adequacy of interval fetal growth. With the development of Doppler technology, one can now assess fetal status to determine pathology earlier than as evidenced by abnormal fetal cardiotocography (CTG). As a result, Doppler ultrasound has become crucial for making management decisions in some high risk settings. The methods for dating a pregnancy, measuring growth, and assessing fetal status using Doppler technology are covered in this chapter.

DATING A PREGNANCY

Sonography provides an enormous amount of useful information to the practicing obstetrician. Arguably, the

single most useful piece of information that obstetric sonography provides is an accurate determination of menstrual age. It is difficult to imagine a clinical problem encountered during a pregnancy in which an accurate menstrual age is not highly desired before proceeding with an appropriate management plan.

It is important to establish from the outset what is meant by the term *menstrual age* and why it is so important in clinical obstetrics. *Fetal age* actually begins at conception, and an equivalent term is *conceptional age*. However, classically and by current convention, obstetricians date pregnancies in menstrual weeks, beginning from the 1st day of the last normal menstrual period. The appropriate term for this method of dating is *menstrual age*, and this term is used exclusively in this chapter when referring to the duration of a pregnancy.¹ Many obstetricians also use the term *gestational age (GA)*. Although *GA* should be equivalent to *conceptional age*, in clinical obstetric practice *GA* is used interchangeably with *menstrual age*. The term *conceptional age* should be reserved to describe pregnancies in which the actual date of conception is known; this is uncommon and is usually restricted to patients who have undergone assisted reproduction (e.g., in vitro fertilization, artificial insemination). Even if conceptional age is known, the menstrual age should be calculated from the conceptional age, based on the assumption of midcycle ovulation ($\text{menstrual age} = \text{conceptional age} + 14 \text{ days}$). Once this has been done, the menstrual age is established and should never be changed later in pregnancy. Subsequent fetal measurements then become an index of fetal growth rather than menstrual age.

*In December, 2005 the ultrasound community lost one of the pioneers in obstetric ultrasound, Dr. Frank P. Hadlock. Since the late 1970s Dr. Hadlock investigated the role of ultrasound in assigning gestational age (GA) and defining abnormal fetal growth patterns. He contributed to this chapter in previous editions. His formulae for weight prediction are still being used today in most ultrasound scanning equipment. He was a superb teacher and friend and will be dearly missed.

Table 7-1 Methods for Determining Menstrual Age

Clinical or Sonographic Parameter	Variability Estimate (+2 SD)
In vitro fertilization*	± 1 day
Ovulation induction*	± 3 days
Artificial insemination*	± 3 days
Single intercourse record*	± 3 days
Basal body temperature record*	± 4 days
First trimester physical examination	± 2 weeks
Second trimester physical examination	± 4 weeks
Third trimester physical examination	± 6 weeks
First trimester sonographic examination (crown rump ± 18% of the estimate length)	
Second trimester sonographic examination (head ± 18% of the estimate circumference, femur length)	
Third trimester sonographic examination (head ± 8% of the estimate circumference, femur length)	

SD, standard deviation.

*Those are indicators of conceptional age (menstrual age = conceptional age + 14 days)

Adapted from James D. Bowie, M.D., Duke University Medical Center.

Knowledge of menstrual age is important to the obstetrician because it affects clinical management in a number of important ways. First, knowledge of menstrual age is used in early pregnancy for the scheduling of invasive procedures such as chorionic villus sampling and genetic amniocentesis, and in the interpretation of biochemical tests such as expanded maternal serum biomarker screening (“quad-screen”) for risk assessment for neural tube defects and chromosomal anomalies (e.g., trisomy 21 and 18) in which the normal range of values changes over time. Second, knowledge of menstrual age allows the obstetrician to anticipate normal spontaneous delivery or to plan elective delivery within the time frame of a term pregnancy (37 to 42 weeks); this also allows the physician to institute measures that will optimize fetal outcome when labor ensues before 37 weeks or fails to ensue after 42 weeks. Third, knowledge of menstrual age is important in evaluating fetal growth because the normal range for the size of any fetal parameter changes with advancing age.¹ Thus, a fetal weight of 2000 g would be normal at 33 weeks but would indicate growth restriction at 36 weeks. When an anomaly is discovered sonographically, the mother’s choices are heavily influenced by menstrual age. Virtually all important clinical decisions require knowledge of the menstrual age.

Before the advent of sonography, menstrual age was established by the patient’s menstrual history, corroborated, preferably during early pregnancy, by physical examination of uterine size, and confirmed in the postnatal period by physical examination of the neonate.^{2,3} All three of these parameters alone or in combination were notoriously inaccurate (Table 7-1), but the menstrual history could be especially misleading for a number of reasons. First, many women may not accurately recall the 1st day of the last normal menstrual period (LMP), particularly if they are not trying to conceive. Also some women commonly misunderstand the question posed and report the last day instead of the 1st day of their last period. Moreover, for those who do remember their LMP, it may be unreliable or misleading

FIGURE 7-1. Length of the follicular phase of the menstrual cycle in a large number of patients studied by Matsumoto, Nogami, and Ohkuri.⁴ Note that the distribution is skewed to the right, with a higher number of patients ovulating late in the cycle (>day 21) than earlier in the cycle (<day 11). This corresponds to the findings in the study by Waldenström, Axelsson, and Nilsson,⁶ in which an early midtrimester ultrasound study agreed with the menstrual history in only about 80% of the cases. In 3%, the age by ultrasound evaluation was greater than expected from the optimal menstrual history (corresponding to early ovulation), and in about 17%, the age by ultrasound evaluation was less than expected from the optimal menstrual history (indicating late ovulation). (Adapted from Matsumoto S, Nogami Y, Ohkuri S: *Statistical studies on menstruation: A criticism on the definition of normal menstruation*. *Gumma J Med Sci* 11:294, 1962.)

because of oligomenorrhea, abnormal bleeding events, use of hormonal contraceptives, becoming pregnant in the first ovulatory cycle after a recent delivery, or ovulating very early (<day 11) or very late (>day 21) in the menstrual cycle. This latter point may be particularly important, because Matsumoto, Nogami, and Ohkuri⁴ reported that early or late ovulation occurs in approximately 20% of the population (Fig. 7-1). Indeed, many pregnancy dating formulae and calculator wheels are based on a 280-day gestation starting from the time of the LMP, which is, in turn, based upon a regular, 28-day menstrual cycle composed of 14 days in the follicular and luteal phases each. It is not surprising, then, that Campbell et al⁵ and Waldenström, Axelsson, and Nilsson⁶ found that, even in patients with optimal menstrual histories, a single second trimester biparietal diameter (BPD) measurement was more predictive of the estimated date of delivery (EDD) than the date of delivery calculated from the 1st day of the last normal menstrual period. One often hears the statements “This patient has good dates” or “That patient has bad dates.” What constitutes “good” as opposed to “bad” dates? Optimal menstrual histories are present when the patient has a certain last normal menstrual period (preferably recorded on a calendar), regular menses, no exposure to hormonal contraceptives, and no unusual bleeding. Thus, it should not be surprising that the most common indications for obstetric sonograms are related to uncertainty regarding the menstrual age.

Sonographic studies designed to evaluate the duration of pregnancy are based on measurements of the fetus, using size as an indirect indicator of menstrual age.^{1,7-32} These studies usually relied on cross-sectional evaluation of large numbers of patients with known dates of the beginning of the last normal menstrual period and no compounding variables in the menstrual history to question its validity. Rossavik and Fishburne³³ demonstrated that such populations

are equivalent to populations with known conception dates for studies of this type. Most studies also eliminated patients with multiple gestations and those with a history that might adversely affect fetal growth. In a properly designed cross-sectional analysis of any fetal biometric parameter, measurements are made in a large number of fetuses evenly distributed over the entire range of menstrual ages, with each fetus being measured only once in gestation; the latter point is important in avoiding bias in variability estimates. The data are then analyzed using regression analysis, with menstrual age as the dependent variable, and equations are generated that will predict menstrual age for any given measurement or set of measurements. Most of the published tables that provide predictions of menstrual age from sonographic measurements have been generated in this way.¹

The value of any given studied biometric parameter (e.g., BPD, head circumference [HC], femur length [FL], ear lobe length, nostril width) is based on ease of obtaining the measurement and the accuracy with which it predicts menstrual age. A measurement that is easily obtained but inaccurate for judging menstrual age is of little value. As well, a measurement that accurately predicts menstrual age but is very difficult to obtain is also usually not valuable. In inexperienced hands, a difficult measurement is often inaccurately obtained, thus nullifying its salutary effect on age prediction. The measurements currently recommended by the American Institute of Ultrasound in Medicine (BPD, HC, abdominal circumference [AC], and FL) are adequate for the purpose of estimating menstrual age; any additional measurement to predict menstrual age must improve current predictors, and thus far none has emerged.

Regardless of the number of sonographic measurements that one uses in predicting menstrual age, it is very important to remember that this is an inference of age from size, and to understand the variability that is associated with any such estimate. The variability, usually the result of measurement error or actual biologic variability in size, is expressed as ± 2 standard deviations, which should be applicable to 95% of the fetuses in a normal population. One must always keep in mind, however, that 5% of the time estimates will be outside this range. Inspection of the magnitude of the maximum errors observed in the original regression data will give a general idea about the largest mistake one could make prospectively predicting menstrual age in a clinical case setting.

Reporting a menstrual age estimate to one or two decimal places for a given fetal measurement or set of measurements may result in an unreasonable assumption regarding the degree of accuracy by the patient's primary clinician. Importantly, when reporting the menstrual age estimate, it is wise to avoid potential misunderstanding. Cardinal numbers (1, 2, 3, and so on) are used for counting. Ordinal numbers are used to express succession (first, second, third, and so on). Although often used interchangeably, they are not. A fetus in the 20th menstrual week of pregnancy is between the ages of 19 weeks 0 days and 19 weeks 6 days, whereas a fetus that is 20 menstrual weeks is 20 weeks 0 days. The cardinal number is more precise. Sonographic estimates of menstrual age should be reported in cardinal numbers.³⁴

As noted earlier, the BPD^{5,6} was more predictive of the EDD than the EDD calculated from the 1st day of the last normal menstrual period. Thus, the gold standard that was

used to test the validity of sonographic fetal biometry was less accurate than the sonographic measurement itself. The result is that the breadth of the variation about the mean for any sonographic measurement is in part due to the inaccuracy imposed by using the LMP to construct the axis of the curve defining the sonographic measurement. Understanding variation in measurements is very important. However, in practice, one should always choose the mean measurement for clinical case management. The principal reason to know the variation of a given measurement prediction is to gauge the potential danger to the patient if the mean estimate is very far from reality. During the remainder of this section, clues for gauging the potential for error will be provided.

FIRST TRIMESTER OF PREGNANCY (0 TO 13 WEEKS)

The earliest unequivocal sign of pregnancy using sonographic evaluation is the demonstration of the "gestational sac."³⁵⁻⁴¹ Interestingly, the term *gestational sac* is largely an invention of the early sonologists, who used the term to describe the ring-like structure they identified within the womb of women with positive pregnancy tests. The more precise term is *chorionic sac*. It is the developing chorionic villi that generate the bright echogenic ring noted near the endometrial cavity. The fluid contained therein is almost totally chorionic fluid during very early development. With early articulated-arm equipment (static imaging) and transabdominal real-time equipment the gestational sac could not be visualized until approximately 6 menstrual weeks, but with the new high-resolution real-time equipment, particularly those equipped with transvaginal probes, the gestational sac can usually be seen by 5 menstrual weeks. At this early stage in gestation, the average internal diameter of the gestational sac, calculated as the mean of the anteroposterior diameter, the transverse diameter and the longitudinal diameter (the so-called mean sac diameter [MSD]), can provide an estimation of menstrual age in a normally developing pregnancy (Table 7-2). Importantly, the measurement of the MSD is obtained from the interface of the chorionic villi and the chorionic fluid. Therefore, it represents an estimate of the mean internal diameter of the chorionic sac. The wall of the sac is not included.

There is some controversy in the literature regarding the precise age at which sonography can first detect a chorionic (gestational) sac; estimates range from 3 to 5 weeks.^{38,42,44} There is less controversy regarding the size of the gestational sac when it is first observed.⁴⁴ This is now thought to be approximately 2 to 3 mm MSD. Similarly, most observers agree that the MSD increases about 1 mm per day in early gestation.^{36,42,45,46} Controversy returns when one studies age estimates of MSD by various authors.^{38,42,43} Embryologic data and recent data gathered by de Crespigny, Cooper, and McKenna⁴⁴ leave little doubt that the MSD equals 2 to 3 mm at 4 weeks and 3 to 4 days.⁴¹ It is reasonably safe to assume that a gestational sac reaches 5 mm at 5 weeks.⁴³ Thus (until an MSD of 25 mm is reached), GA in days can be calculated by adding 30 to the MSD (i.e., MSD at 5 weeks or 35 days = 5 mm).^{36,46}

The early embryo cannot be seen at this time, but there are two features that differentiate the gestational sac from

Table 7-2 Relation Between Mean Sac Diameter, Menstrual Age, and Human Chorionic Gonadotropin Level

Mean Gestational Sac Diameter (mm)	Predicted Age Range (week) = 95% CI*	Predicted hCG (mIU/mL) Range = 95% CI†
2	5.0 (4.5–5.5)	1164 (629–2188)

CI, confidence interval; hCG, human chorionic gonadotropin.

FIGURE 7-2. The double decidua sign is a misnomer. This sonographic feature typical of early gestations simply should be called the double sac sign because of the origin of only one of the decidua. The origin of the inner of the double rings (the endometrial cavity [EC]) is less echogenic than the deeper layer (closer to the myometrium). It is the less echogenic superficial layer of the decidua vera (DV) that provides the “separation” between the more echogenic chorionic villi (C) and deeper decidua vera rings.

the pseudogestational sac of an ectopic gestation. One is the double sac sign, which is created by visualization of the deep layer of the decidua parietalis and the early villi separated by the less echogenic layer and more superficial layer of decidua parietalis (Fig. 7-2).^{18,50} Also of value is the intradecidual sign, wherein the developing sac, imbedded in the decidua,

deviates the endometrial cavity reflection (Fig. 7-3).⁴⁹ Visualization of an embryo or embryonic structure is a more reliable sign than either of the features just mentioned. The earliest embryonic structure detectable by sonography is the yolk sac. This can be seen using high-resolution vaginal probes during the 5th menstrual week (MSDs usually range from 6 to 12 mm when a yolk sac is seen in the absence of a concomitant embryo) (Fig. 7-4).

The MSD becomes progressively less reliable for predicting menstrual age as the first trimester of pregnancy advances. Once the embryo can be visualized, the measurement of choice for estimation of menstrual age becomes the crown rump length (CRL). The developing embryo can be consistently detected with transvaginal transducers when the CRL reaches 5 mm and can be detected when it is as small as 2 mm. If the embryo can be visualized and measured, then MSD is no longer used to predict age. The embryo achieves a CRL of 5 mm when the MSD equals approximately 14 mm. MSDs of 14 mm or less are very precise for predicting menstrual age in normal pregnancies. The accuracy of MSD measurements only deteriorates after this time. As a general principle, embryonic or fetal measurements are more precise than measurements of the gestational sac. In addition, the earlier the measurement, the more accurate it will be. Therefore, MSD measurements between 2 and 14 mm (i.e., before the embryo can be seen) are highly reliable because they represent the earliest possible sonographic measurement.

By the 6th menstrual week, one can usually identify the early embryo and usually cardiac activity, as well, in normally developing pregnancies (Fig. 7-5A). However, better visual-

FIGURE 7-3. Transvaginal sonogram demonstrating the "intradecidual sign." Note that the chorionic sac (CS) displaces the endometrial cavity (EC), indicating that the chorionic sac actually resides within the decidual vera and not within the endometrial cavity.

ization of the early embryo can be made between 7 and 13 menstrual weeks (see Fig. 7-5B). Warren et al⁴¹ demonstrated the developmental landmarks of the embryo during this time frame (Fig. 7-6). Although these anatomic features can provide clues to the age of the fetus, better estimates of menstrual age can be made by measurement of the CRL.^{23,29,31,39,51-60} Strictly speaking, investigators and clinical sonologists do not truly measure the CRL when determining the length of first trimester embryos and fetuses.⁶¹ The early embryo/fetus is curved (see Fig. 7-5B). The conventional measurement that is obtained is the maximal straight-line length of the fetus (see Fig. 7-5B).⁶¹ The true CRL is depicted in Figure 7-5C. An additional measurement that can be considered is the maximum axial length of the fetus depicted in Figure 7-5D. However, despite the minor inaccuracy of nomenclature, the maximal straight-line length as measured by virtually all practicing sonologists will be referred to in this chapter as the CRL. When using the CRL to predict menstrual age, one should use the average CRL measurement from three satisfactory images. Modern instruments compute the menstrual age from this measurement. Alternatively, one may refer to published tables for estimation of menstrual age (Table 7-3).

In general, there has been extreme uniformity in the CRL data from various centers dating back to the original studies of Robinson⁵¹ and Robinson and Fleming,⁵² and it

FIGURE 7-4. This high-resolution transvaginal real-time image demonstrates a yolk sac before the embryo is visible. Thus, a crown rump length cannot be measured at this stage of embryonic development. A-C. Instead, a mean diameter of the chorionic sac is determined, the "mean sac diameter." Three measurements—length (A), depth (B), and width (C) are obtained, summed, and then divided by three. The length and depth are measured on the same longitudinally oriented image, whereas the width is measured on a transversely oriented image. Note as well that the measurements are obtained from the interface of the chorionic fluid with the rim of chorionic villi; the "wall" is not included.

FIGURE 7-5. A. This high resolution transvaginal real-time image demonstrates the early embryo (E), which measures approximately 3 mm in this case, corresponding to a menstrual age of approximately 6 weeks \pm 8% (3 days). The yolk sac (YS) is identified immediately adjacent to the embryo because there is no yolk stalk at this stage of embryonic development. B. This high-resolution transvaginal real-time image demonstrates the typical measurement of the crown rump length. This measurement is the maximum straightline length and not a true crown rump length. C. Cursor position to measure the true crown rump length. D. Method of measuring the maximal axial length.

has been demonstrated that measurements made with static image equipment, transabdominal real-time equipment, and transvaginal real-time equipment demonstrate no significant differences. Additionally, Silva et al⁵⁹ evaluated patients with known dates of conception using high-resolution transvaginal probes, and their data correspond closely with those of the early investigators. The only difficulty with the older studies is that they do not provide data before 7 weeks. This posed a problem when estimating the menstrual age of embryos detected earlier than 7 weeks. In a comprehensive study of CRL, Hadlock et al²³ developed measurement tables establishing menstrual age for CRL as small as 2 mm and extended the range of CRL, data up to measurements as large as 12 cm (see Table 7-3). The majority of the early studies on CRL demonstrated that the accuracy of the method in predicting menstrual age was 3 to 5 days (\pm 2 standard deviations [SD]).⁵¹⁻⁵³

In a study by MacGregor et al,⁵⁶ however, the accuracy of the technique was demonstrated to decrease as pregnancy advanced into the late first trimester. Hadlock et al²³ concurred that accuracy decreases as the first trimester of pregnancy nears its end. Because MacGregor's study population had known dates of conception, this increase in variability with advancing pregnancy was believed to

represent early biologic variability in embryonic or fetal size. In an effort to simplify the reporting of variability estimates, Hadlock et al evaluated variability as a percentage of the predicted age and demonstrated that the variability is relatively uniform at 8% for CRL measurements between 2 mm and 12 cm. Thus, for a CRL menstrual age prediction of 8 weeks, the 95% confidence interval is 8 weeks \pm 8% = 8 weeks \pm 0.64 week. Similarly, for a CRL age estimation of 15 weeks, the variability would be 15 weeks \pm 8% = 15 weeks \pm 1.2 weeks. The optimal time for prediction of menstrual age from CRL measurements is between 6 and 9 weeks.

Benson and Doubilet⁸ recommended the following rules of thumb for visual estimates of early first trimester menstrual age. If a chorionic (gestational) sac with no yolk sac or embryo is seen, estimate the age at 5 menstrual weeks. If a chorionic (gestational) sac with a yolk sac but no embryo is seen, estimate the age at 5.5 menstrual weeks. If a chorionic (gestational) sac with a tiny embryo (<5 mm) adjacent to the yolk sac is seen, estimate the age at 6 menstrual weeks. Although these are simple visual estimates, their accuracy is uncanny.

Other measurements of the fetus can also be made in the first trimester of pregnancy. For example, Bovicelli et al⁵⁴ in 1981 evaluated the fetal BPD in comparison with the first

FIGURE 7-6. Sequential appearance of morphologic features as the chorionic sac, yolk sac, embryo, and fetus develop in the first trimester of pregnancy. Although used by the authors, "fetal pole" is an inexact term. Embryo and fetus are preferred terms. Note that the chorionic (gestational) sac is identified in all normal pregnancies beginning at 5 menstrual weeks. The yolk sac is seen in all normal pregnancies from 6 menstrual weeks onward, and the embryo is seen in all normal pregnancies from 7 menstrual weeks onward. Although of some interest scientifically, the appearance times of the cerebral "ventricle" (vesicle), falx, and midgut herniation are not of value in precise pregnancy dating. (From Warren WB, Timor-Tritsch I, Peisner DB, et al: Dating the early pregnancy by sequential appearance of embryonic structures. *Am J Obstet Gynecol* 161:747, 1989.)

*Measured in weeks.

[†]Measured in centimeters.

[‡]The 95% confidence interval is ± 8% of the predicted age.

From Hadlock FP, Shah YP, Kanan DJ, et al: Fetal crown-rump length: Reevaluation of relation to menstrual age (5-18 weeks) with high resolution real-time US. *Radiology* 182:501, 1992.

trimester CRL for predicting menstrual age between 7 and 13 weeks, and in 1982 Selbing³⁹ reported a similar study. Both groups demonstrated that the first trimester BPD is an accurate predictor of menstrual age but is not more accurate than the CRL and adds little, if anything, to the age estimate based on the CRL. Reece et al³¹ demonstrated similar results using early fetal "abdominal" (torso) circumference in the first trimester of pregnancy. Most recently, Sladkevicius et al⁶² compared 21 different CRL-based dating formulae to three different BPD-based dating formulae obtained at 12 to 14 weeks GA by abdominal ultrasound in 167 singleton pregnancies conceived following in vitro fertilization, and thus had definitively known pregnancy ages. Their findings showed that five of the CRL formulae generated very accurate pregnancy ages, and although the BPD formulae were also quite accurate, they had smaller random measurement errors than the CRL formulae. This led the authors to conclude that the BPD is a superior measurement than the CRL at 12 to 14 weeks for dating purposes. No measurements of the AC, HC, or FL were performed in this study, and thus, comments cannot be made about them in comparison to the CRL. In practice, the use of high-resolution vaginal probes allows very acceptable images of the head, abdomen, and femur for measurements of HC, BPD, AC, and FL from 10 weeks on. However, because these additional measurements are not necessarily more accurate than the CRL length in predicting age from 10 to 13 weeks and their use in conjunction with the CRL does not further improve age estimation, it is difficult to justify their use. Moreover, they are technically more difficult to obtain than the CRL measurement, and at least thus far their routine use is not warranted in the first trimester. The transition between first and second trimesters (13 to 14 weeks) is the appropriate time to make the transition from CRL to BPD, HC, AC, and FL.

In summary, the accuracy of first trimester fetal measurements in predicting menstrual age is well documented; there is very little biologic size variability during this time. This is in contrast to the third trimester of pregnancy, in which individual genetic expressions in fetal size can result in a very heterogeneous population. It is also well established that once menstrual age has been determined or corroborated by very early MSD (2 to 14 mm) or embryonic or fetal CRL in the first trimester of pregnancy, the menstrual age of the pregnancy is established and should *never* be changed based on biometric measurements made later in pregnancy.

Indeed, the same can be said of sonographic estimation of age at any time. An earlier measurement supersedes a later measurement, and sonographic estimates of age before 20 weeks gestation are highly reliable for pregnancy dating. In nearly all cases, sonographic estimates of age before 20 weeks gestation (except those with assisted conception and those maintaining basal body temperature charts) represent the most accurate scientific information establishing the menstrual age.

An important issue is the timing of the sonogram when the dates are uncertain. It has already been stated that the earlier the measurement is obtained, the more accurate is the estimate because biologic variability increases throughout gestation. Unfortunately, an age estimate at 7 menstrual weeks will be extremely accurate but provides little other useful information about the fetus, placenta, amniotic fluid volume, and cervix. An alternative is to wait until the second trimester

is under way before performing the sonogram to establish dates (15 to 18 weeks). Because dates are in question, the uterine size estimate is important in planning the timing of the early second trimester examination. If this second option is elected, dating accuracy will suffer. However, the accuracy at 15 to 18 weeks is still excellent and adequate for all clinical purposes. The value of waiting is that a large amount of additional information about the health of the pregnancy is obtained. Of course, there is also the possibility of obtaining both first trimester and second trimester sonograms, but this is associated with a significant increase in cost. The greatest accuracy per medical dollar spent is achieved in the first trimester. The greatest value per medical dollar spent is achieved in the early second trimester. If the dates of a pregnancy are clinically truly uncertain, the earliest possible ultrasound is advised to ensure the highest accuracy in assigning GA. This information may ultimately prove to be essential for the long-term management of the pregnancy, and therefore worth the additional expenditure up front.

SECOND AND THIRD TRIMESTERS OF PREGNANCY (14 TO 42 WEEKS)

In the second trimester of pregnancy, the fetus has grown sufficiently in size so that remarkable anatomic detail can be visualized (see Chapter 9). Many structures can be identified and measured during this time,^{22,23,33,63,64} but the basic fetal measurements used to estimate age are the BPD, HC, AC, and FL.¹ With training and practice, these measurements can be obtained with a high degree of consistency and accuracy. One must always remember, however, that the images and measurements must be made with great care in every case, and one must be certain to duplicate the technique of the investigator whose data one is using. Using measurements from poor images or images that depict fetal anomalies should be avoided.

Modern instrumentation computes the age estimate virtually in real time on the viewing screen because the cursors are fit to the structure being measured. The examiner should avoid the temptation to "massage" the endpoints of the measurement because the age computation on the viewing screen is smaller or larger than their preconceived notion of what the biometry should be. Instead, it is crucial to learn the rules for obtaining each measurement and to adhere to them rigorously; only then can the results be interpreted in a rational way.

BIOMETRY: FOLLOWING THE RULES

Crucial decisions may be made on the basis of fetal biometric measurements. Therefore, each clinical specialist must be well schooled in the proper techniques of obtaining these measurements. It is not necessary to repeat every erroneously taken measurement because correcting the measurement probably will not influence the interpretation of the case if the error is small. However, it is important that the interpreter can recognize the error and has a sense of both the magnitude and the direction of the error. For example, suppose that a BPD was erroneously measured in a fetus of 21 weeks menstrual age, known by early embryonic CRL. The erroneous measurement is 4.7 cm and

FIGURE 7-7. An accurate biparietal diameter can be obtained through any plane of section that intersects the third ventricle (TV) and thalami (T). The margins of the calvaria (C) must be symmetric. The first criterion ensures that the plane of section is taken at the proper craniocaudal plane. The second criterion ensures that the transducer is oriented perpendicular to the central axis of the head. Note the measurement is 74.6 mm.

FIGURE 7-8. Image of same fetus as in Figure 7-7 taken minutes apart. This biparietal diameter measurement meets the criterion of being taken through the third ventricle (TV) and thalami (T) but does not meet the criterion of demonstrating symmetric calvaria (C). The BPD measured from this plane (72.7 mm) is 2 mm smaller than the properly measured BPD of 74.6 mm (see Fig. 7-7). This degree of error is probably not clinically significant.

the predicted age by BPD is, therefore, 20.2 weeks. Analysis of the error leads one to recognize that the BPD was slightly undermeasured. One can recognize that a BPD predicting 20.2 weeks is within the normal range. Correcting the error would push the measurement toward the known menstrual age. Clearly, there is no reason to spend the time correcting the error. Note that this comment is only applicable for the occasional slight error in measurement and is not appropriate to systematic or large-scale errors that should be rectified expeditiously.

Potential errors in biometric measurements are numerous and can be engendered by equipment misregistration, aberrations of transducers, and type of transducer to name a few. It is important to ensure through the equipment manufacturer that the instrument is properly adjusted to make accurate linear measurements in every direction on the viewing screen, that biometric tables are accurately entered in the machine computation package, and finally, that subsequent computations are accurate. Although one does not have direct control over these adjustments, the wise sonologist never assumes that instrumentation is always accurate in this arena. *Aside from optimizing the image, one can only control two aspects of biometric measurement. One can choose the plane of section, and one can choose the endpoints of measurement (Figs. 7-7 to 7-12).*

The BPD can be appropriately measured through any plane of section that traverses the third ventricle and thalami (see Fig. 7-7).⁶⁵ Early in the history of BPD measurement, the BPD was defined as the widest distance between the parietal eminences. The “widest” BPD is not always obtained

though a plane of section that traverses the third ventricle and thalami. Occasionally, the “widest” BPD is obtained in a more cephalad location.⁶⁵ However, rather than dutifully searching for the widest diameter, it is now convention to measure all fetuses at the same anatomic plane in all centers across the country. The advantages of every practitioner obtaining the BPD in the same way are obvious. Searching for the widest BPD is likely to engender errors because there will be a tendency to accept an erroneous measurement wherein the error overestimates the measurement.

Any plane of section through a 360-degree arc that passes through the thalami and third ventricle is acceptable for measuring the BPD. This means that an accurate measurement can be obtained through an infinite number of planes (the significance of this point is made clear later). The rules for measuring the BPD are as follows. First, the correct plane of section is through the third ventricle and thalami, as noted. Second, the calvaria are smooth and symmetric bilaterally. Third, the cursors are consistently positioned in one of the three following ways: outer edge of near calvarial wall to inner edge of far calvarial wall, inner edge of near calvarial wall to outer edge of far calvarial wall, or middle of near calvarial wall to middle of far calvarial wall. Measuring from the outer edge of the near calvarial wall to the outer edge of the far calvarial wall is inappropriate. The first two criteria define the precise plane of section. Because there are two criteria that must be met to obtain a proper plane of section, the BPD measurement should be considered as a “two-dimensional” measurement. The third criterion describes the proper endpoints of measurement. Because the

FIGURE 7-9. Image of same fetus as in Figure 7-7 taken minutes apart. As with Figure 7-7, this plane of section fulfills the two criteria for measuring a biparietal diameter (BPD) (T, thalamic nucleus; TV, third ventricle). A. However, it also fulfills the third criterion necessary to measure a head circumference; the plane is properly oriented to the skull base. Demonstrating the cavum septi pellucidi (CSP) anteriorly and the tentorial hiatus posteriorly (Tm, tentorium) documents proper orientation of the plane of section to the skull base. Because this plane of section accurately meets all criteria for an HC measurement and because the ellipse is carefully fit to the calvarial margins, one may correctly assume that 263.6 mm is highly accurate. B. Note that the BPD measurement is 74.2 mm, only a 0.4-mm difference from that of Figure 7-7, demonstrating that any plane through the thalami and third ventricle with symmetric calvaria accurately measures the BPD.

FIGURE 7-10. Image of same fetus as in Figure 7-7 taken minutes apart. A. One reason for the development of the long linear transducer was to encompass the entire fetal calvaria in late pregnancy to measure both the biparietal and an occipitofrontal diameters necessary to compute a head circumference. Later, as measurement technology advanced, this requirement was also deemed necessary so that the computer-generated ellipse could be seen to "fit" the calvarial margin throughout. An error, however, was made during this measurement. The sonographer fit the ellipse to the scalp margin rather than the calvarial margin (C). B. With shorter linear transducers, the ellipse approximated a portion of the calvarial margin. This does not create a significant error. There is no need to purchase a long linear transducer solely for the purpose of demonstrating the entire perimeter of a third trimester fetal head.

calvaria are brightly echogenic and symmetric and the thalami are symmetric about the third ventricle, the BPD is a measurement that can be obtained with great consistency and accuracy. The symmetry makes it easy to see that the correct plane of section has been obtained. Common errors in BPD are illustrated in Figures 7-8 and 7-124.

Recall that the BPD can be obtained through an infinite number of planes. However, in the strictest sense, the HC is best obtained through a single plane of section. Thus, the HC is a more difficult measurement to obtain consistently correctly. The correct plane of section parallels the base of the skull. Therefore, the plane is more cephalad anteriorly

than it is posteriorly. Whereas when obtaining a properly measured BPD the transducer must be correctly oriented in two planes, the HC requires that the transducer be properly oriented in three planes. Because there are three criteria that must be met to obtain a proper plane of section, the HC measurement should be considered as a three-dimensional measurement. To measure the BPD the transducer must be (1) perpendicular to the parietal bones and (2) positioned at the correct cephalocaudal position to intersect the third ventricle and thalami. To measure the HC, the two criteria for the BPD must be fulfilled, and the transducer plane must be properly oriented to the skull base. Because the skull base

is very irregularly shaped, it is not used to orient the plane of the HC. Instead brain anatomy landmarks are used.

The rules for measuring the HC are as follows. The correct plane of section is through the third ventricle and thalami in the central portion of the brain (as with the BPD),

FIGURE 7-11. This is the same image as Figure 7-7 now used to measure the head circumference (HC). The plane of section meets all necessary criteria for biparietal diameter measurement but is not properly oriented to the skull base for HC measurement. Note that the cerebellum (Ce) rather than the tentorial hiatus is demonstrated posteriorly. The HC measured from this plane of section is 256.9 mm compared with 263.6 mm measured from the proper plane (compare with Fig. 7-9A).

but the cavum septi pellucidi must be visible in the anterior portion of the brain and the tentorial hiatus must be visible in the posterior portion of the brain. Some refer to this anatomy as an “arrow.” The cavum septi pellucidi and frontal horns are the “feathers.” The third ventricle and sylvian aqueduct are the “shaft.” The ambient and quadrigeminal cisterns and the tentorial hiatus are the “arrowhead.” The calvaria must be smooth and symmetric bilaterally. After the proper plane of section is obtained, the cursors are positioned at the outer edge of the near calvarial wall and the outer edge of the far calvarial wall. Most modern equipment then will allow a computer-generated ellipse to be fit to the calvarial margins (see Fig. 7-9A). The entire perimeter of the calvaria need not be demonstrated to accurately measure the HC.⁶⁶ The ellipse adequately estimates the head perimeter even when it is not entirely imaged (see Fig. 7-10).

Note several features. First, a properly measured BPD can be obtained on the same image as a properly oriented HC measurement (see Fig. 7-9B). The reverse is not necessarily true (see Figs. 7-11 and 7-12). Second, the proper position of the cursors to measure the HC is inappropriate for BPD measurements (compare Fig. 7-9A and B). Thus, if the BPD is measured first on the image, the cursors must then be moved before the computer-generated ellipse is fit to the calvarial margins for HC determination. Finally, it is important to be certain that the ellipse is fit to the calvaria and not the skin of the scalp (see Fig. 7-10A). Again, an analysis of an observed error should give the interpreter a sense of both the direction and magnitude of the error. If, for example, the sonographer fit the ellipse to the skin of the scalp and not to the calvaria, the error will increase the HC measurement (i.e., the “direction” of the error), and in a late, large fetus the error will be great (i.e., the “magnitude” of the error). In a young fetus the magnitude of the error will be small.

The FL measurement is technically the easiest of the common biometric measurements. This is due to the

FIGURE 7-12. Image of same fetus as in Figure 7-7 taken minutes apart. A. This biparietal diameter (BPD) measurement fulfills the criterion of symmetric calvaria but was not obtained through the thalami and third ventricles. It was obtained too near the vertex. The three “lines” seen in this image have been commonly displayed in the ultrasound literature. The central line is the interhemispheric fissure (IH). The lateral lines are composite reflections from the deep medullary veins (DMV) draining the periventricular white matter. Therefore, this plane is obtained cephalad to the lateral ventricular bodies, BPD measurement in this plane underestimates age. Compare this measurement of 71.9 mm with that obtained in the correct plane as illustrated in Figure 7-7 (74.6 mm). B. The head circumference (HC) measured in this plane also underestimates age. Compare the measurement of 250.7 mm with the correctly measured HC of 263.6 mm obtained in this fetus (compare with Fig. 7-9A).

essentially one-dimensional nature of the measurement. The transducer need only be aligned to the long axis of the bone to obtain a proper plane of section. No other transducer adjustment is necessary. However, that does not mean that errors in measurement or observational errors are rare.^{10,67,68} Quite the contrary is true.

The first feature to understand about the FL measurement is that one does not actually measure the entire femur. Only the ossified portions of the diaphysis and metaphysis are measured (Fig. 7-13).¹⁰ The cartilaginous ends of the femur are excluded. The ossified portion of the femur is more visible sonographically than the nonossified ends. Nonetheless, the cartilaginous ends of the femur are readily demonstrated (Fig. 7-14). Although the cartilaginous ends are excluded, they are the keys to accuracy and consistency in femoral length measurements. To obtain the measurement accurately, the transducer must be aligned to the long axis of the diaphysis. How does one know that the transducer is properly aligned? One method is to accept the longest femoral length as the most accurate measurement. This assumes that the only potential error is to undermeasure the bone because the transducer is improperly aligned to the bone. This is a false assumption.

FIGURE 7-13. Radiograph of the femur from a term neonatal autopsy specimen. Sonographic measurements of the “femur” include only the ossified portion of the diaphysis (D) and metaphysis (M). The cartilaginous femoral head (FH), greater trochanter (GT), and distal epiphysis (DE) are not included in the measurement. When it ossifies, the distal femoral epiphyseal (DFE) secondary ossification center is also not included in the measurement.

Proper alignment of the transducer to the long axis of the femur is ensured by demonstrating that both the femoral head or the greater trochanter and the femoral condyle are simultaneously in the plane of section (Fig. 7-15).¹⁰ If these two structures are seen, the plane is unambiguously through

FIGURE 7-15. This sonogram demonstrates the femur of a middle third trimester fetus. This is an ideal image from which to measure the femur. Because the greater trochanter (GT) and lateral condyle (LC) of the distal epiphysis are seen, one may be confident that the proper plane through the long axis of the femoral diaphysis has been obtained. The only remaining task is to position the endpoints of measurement properly (i.e., the electronic cursors). The proximal cursor is easily placed at the junction of bone and cartilage (*short arrow*). However, a choice must be made distally. Should the “point” (*long arrow*) along the lateral margin be included? Compare with Figure 7-13. No such ossified “point” exists. This structure, only seen sonographically, should not be included in the measurement and introduces a significant overestimate of femur size if included. The only way to choose properly the correct endpoint for placing the distal measurement cursor is to demonstrate clearly the junction of the distal epiphysis with the metaphysis (*short arrow*). As well, this image clearly depicts the ossification center (DFE) of the distal epiphysis.

FIGURE 7-14. A. Sonogram of the proximal fetal femur. Compare with Figure 7-13. The cartilaginous greater trochanter (GT) and femoral head (FH) are not included in the femoral measurement but are clearly seen. B. Sonogram of the distal femur (compare with Fig. 7-13). The cartilaginous distal epiphysis (DE) is also clearly seen but is not included in the femoral measurement. Although not included in the measurements, the cartilaginous ends of the femur are the keys to obtaining highly accurate and reproducible femoral measurements. See text.

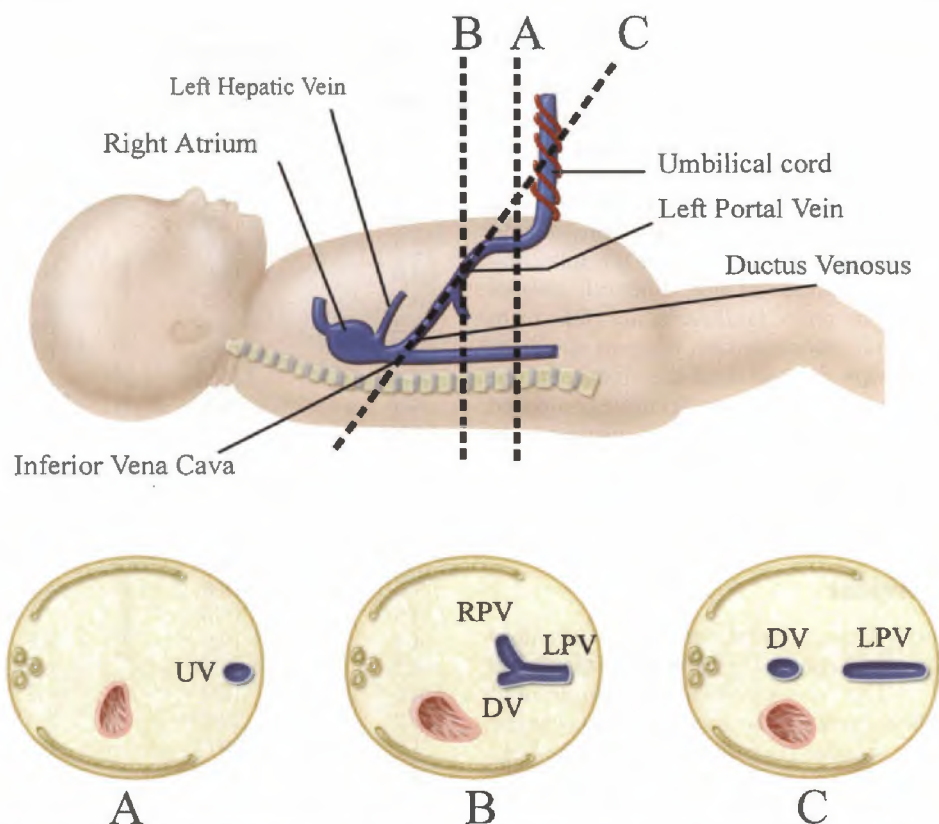

FIGURE 7-16. Umbilical venous circulation through the fetal liver. A. Plane of section depicting the umbilical vein (UV) in short axis (correlate with Fig. 7-17A). This plane is too caudal for abdominal circumference measurement. B. Plane of section through the junction of the left (LPV) and right (RPV) portal veins (correlate with Fig. 7-17B). This is the correct level for AC measurement (DV, ductus venosus). C. Plane of section aligned along the course of the LPV (correlate with Fig. 7-17C). Note that this plane is too inclined in a craniocaudal axis. (Illustration by James A. Cooper, MD, San Diego, CA.)

the femoral long axis. Thus, once can be confident that the proper plane of section to obtain an accurate measurement has been chosen. The only remaining task is to position the electronic cursors properly at the correct endpoints of measurement. Again, it is the cartilaginous ends that direct precise placement of the measurement cursors. The cursors are positioned at the junction of the bone with the cartilage (see Fig. 7-15). It is important not simply to choose the end of the brightest reflection as the endpoint of measurement because of an entity that has been called the “distal femoral point.” The distal femoral point is not part of the bony metaphysis.¹⁰ Including it significantly overmeasures the femur. Therefore, the rules for measurement of the femur are as follows. First, align the transducer to the femur and freeze the plane that shows both the cartilaginous femoral head and distal condyle. Then place the measurement cursors at the junction of the cartilage and bone, being careful to avoid the distal femoral point.

Finally, the AC is the most difficult of the four measurements that are ordinarily obtained. As with the HC, the AC is a three-dimensional measurement. Unfortunately, the abdominal anatomy is not symmetric like the brain anatomy. Further, there is no bright calvarial margin to check the perpendicularity of the planar axis and to provide easily seen endpoints of measurement.

The AC is measured in a location that estimates liver size. The liver is the largest organ in the fetal torso, and its size reflects aberrations of growth, both growth restriction and macrosomia. Therefore, one does not measure the circumference at the fetal “waist” (umbilicus) as one would in an adult. The fetal AC is measured at the position where the transverse-diameter of the liver is the greatest. This can be determined sonographically as the position where the right and left portal veins are continuous with one another (Fig. 7-16).⁶⁹ Some refer to this anatomic confluence of the intrahepatic portal veins as “the hockey stick.”

Therefore, the rules of measurement of the fetal AC are as follows. The correct cephalocaudal plane is the position where the right and left portal veins are continuous with one another. Second, the appearance of the lower ribs is symmetric. Finally, the shortest length of the umbilical segment of the left portal vein is depicted. If a long segment is seen, then the transducer is erroneously angled inferiorly instead of perpendicular to the midline (see Fig. 7-16C).⁶⁹ After this plane of section is frozen on the screen, the ellipse is fit to the skin edge. Note that this is distinctly different from the HC, where one specifically does not fit the ellipse to the skin edge but rather to the calvarial edge. Importantly, the skin margin may abut other soft tissue structures like the placenta or myometrium and be relatively inconspicuous.

Remember that the rib margin is easily seen, and one may mistakenly fit the ellipse margin to the rib instead of the skin. This will significantly undermeasure the AC. Although this error will have relatively little effect on the estimate of menstrual age, it will have a much greater effect on the weight estimate.

There will be many times when the landmarks for fetal AC measurement are less than optimally documented. In this circumstance, the reader should rely on the following rule: "round" covers a multitude of sins. This rule implies that, when the desired anatomic landmarks are difficult to demonstrate, the circumference estimate, wherein the transverse and anteroposterior diameters of the abdomen are equal or nearly so, is likely to be the more accurate compared with estimates wherein the diameters are disparate. In compliance with this concept, excessive pressure with the transducer should be avoided because it distorts the shape of the abdomen.

Biparietal Diameter

The BPD has received the greatest amount of attention in the literature as a means of establishing menstrual age.^{12,22,23,28,33,63,64,70} The measurement technique and pitfalls were described earlier. The menstrual age can be determined by using a standard reference table (Table 7-4). However, modern instruments immediately compute an age as the measurement is being obtained.

All reports on the BPD have demonstrated it to be an accurate predictor of menstrual age before 20 weeks. For example, Hadlock, Harrist, and Martinez-Poyer²² demonstrated the variability to be ± 1 week (2 SD) in a population of 1771 patients with optional menstrual histories seen between 14 and 20 weeks (Table 7-5). Persson and Weldner⁶⁴ and Rossavik and Fishburne³³ reported similar results in patients with known dates of conception, as did Crespigny and Speirs⁷⁰ in a large series of patients whose dates were confirmed by CRL in the first trimester of pregnancy. In addition, Campbell et al⁵ and Waldenström, Axelsson, and Nilsson,⁶ in independent studies, demonstrated that a BPD obtained between 14 and 20 menstrual weeks is a better predictor of the estimated date of confinement than an optimal menstrual history. Virtually all studies demonstrated a progressive increase in variability from 20 weeks to term, but the degree to which the variability increases in the late third trimester of pregnancy has been a subject of some disagreement in the literature.^{12,28,70,71} Most early authors concluded that the variability during this time frame is approximately $\pm 3\frac{1}{2}$ weeks (2 SD), but Kurtz et al²⁸ reported the variability to be ± 2 weeks during this time. This difference most likely is a statistical phenomenon, because the mathematical evaluation by Kurtz et al was performed on mean values from a number of different centers and does not directly include any of the raw data from the more than 25,000 patients who form the basis of their report. The variability they reported, then, represents the confidence interval of the mean and should not be comparable to the standard deviation reported by others.¹² In studies of patients with optimal menstrual histories, the variability of late third trimester BPD age predictions has been consistently demonstrated to be approximately $\pm 3\frac{1}{2}$ weeks. This has been confirmed in a large series of patients

Table 7-4

Predicted Menstrual Age for Biparietal Diameter (BPD) Measurements

BPD (cm)	Menstrual Age (week)	BPD (cm)	Menstrual Age (week)
2.6	13.9	6.2	25.3
2.7	14.2	6.3	25.7
2.8	14.5	6.4	26.1
2.9	14.7	6.5	26.4
3.0	15.0	6.6	26.8
3.1	15.3	6.7	27.2
3.2	15.6	6.8	27.6
3.3	15.9	6.9	28.0
3.4	16.2	7.0	28.3

in Australia in whom the menstrual ages were confirmed in early pregnancy by CRL.⁷⁰ Both of the later studies, however, eliminated patients with head shape abnormalities, multiple gestation, or diseases likely to adversely affect fetal growth. The large variability associated with third trimester use of the BPD has been confirmed in a study by Benson and Doubilet⁷ of patients whose menstrual histories had been established early in pregnancy by CRL; in this study, however, no attempt was made to eliminate multiple

gestations or patients with potential growth disturbances. These authors found that the variability in predicting menstrual age using BPD reached a peak of approximately 4.1 weeks (2 SD) in the late third trimester of pregnancy (Table 7-6).

In certain circumstances (e.g., ruptured membranes, breech presentations, multiple gestations), shape changes in the fetal head may lead to even greater errors than those mentioned here. If one suspects that the shape of the calvarium is other than typical, one should measure the cephalic index of the head to assess head shape (see Fig. 7-5). The cephalic index is calculated from the BPD and the fronto-occipital diameter (FOD) measured from the outer edge of the calvaria to the outer edge of the calvaria:

$$\text{Cephalic index} = \frac{\text{BPD}}{\text{FOD}} \times 100$$

Technically, manufacturers usually compute a cephalic index from the HC ellipse long and short axes. Because the short axis of the HC ellipse is not truly a BPD, a slight and clinically insignificant error is introduced into cephalic indexes computed in this way. In the first in utero study on this subject, Hadlock et al¹¹ evaluated 316 patients between 14 and 40 menstrual weeks and demonstrated that the cephalic index was essentially age independent over time, with a mean value of 78.3 and an SD of 4.4. They concluded that a cephalic index greater than 1 SD above or below the mean (<74, >83) may be associated with a significant

alteration in the BPD measurement expected for a given menstrual age and that the HC can be used effectively as an alternative means of establishing age in such cases. Gray et al⁷² found minimal changes in the mean value of age.

Doubilet and Greenes⁹ recommended an alternative approach to potential head shape variations by routinely calculating a shape-corrected BPD based on an idealized cephalic index of 78:

$$\text{Shape-corrected BPD} = \left(\frac{\text{BPD} \times \text{FOD}}{1.265} \right)$$

As expected, when this shape correction is performed, the BPD is equivalent to the HC in accuracy of menstrual age prediction because it has been rendered shape independent.^{7,9}

Head Circumference

The neonatal HC is an important measurement of neonatal head growth and has gained importance as an in utero ultrasound measurement because it is independent of head shape. The measurement is made as described earlier (see Fig. 7-9A). If an ultrasonic system does not have the computer-generated ellipse ability, reliable estimates of HC also can be calculated using the shortest and longest axes of the fetal head measured outer to outer (the same measurements used to calculate the cephalic index). Although ideally one should use the formula for the circumference of an ellipse for this calculation, adequate estimates of the HC can be made using the formula (D1 + D2) × 1.57. When the cephalic index indicates extreme dolicocephaly (value <70), the HC should not be calculated by this formula. The computer-generated ellipse should be used. The menstrual age can then be determined using a standard reference table (Table 7-7), although modern instruments compute the menstrual age from the HC as the measurement is being obtained.

Several authors demonstrated that HC is one of the most reliable individual parameters for estimation of menstrual age.^{14,73} This is due to its shape independence and the fact that it represents a balance between ease of measurement (and, therefore, measurement accuracy) and predictive validity for age. For example, in 1982, Law and MacRae⁷³ demonstrated in a series of 594 patients that the HC was superior to the BPD as a predictor of menstrual age. This has been a consistent finding in studies by Hadlock et al.^{18,21,22} Hill et al²⁷ and Benson and Doubilet⁷ also reported similar conclusions

Table 7-7 Predicted Menstrual Age for Head Circumference Measurements (8.5–36.0 cm)

in independent studies. As with the other individual parameters, however, the variability in age prediction from HC increases with advancing menstrual age (see Table 7-7). For example, Hadlock, Harrist, and Martinez-Poyer²² and Rossavik and Fishburne³³ demonstrated that this parameter can predict menstrual age to within ± 1 week (2 SD) before 20 weeks' gestation. Benson and Doubilet⁷ demonstrated that the variability in predicting age from HC increases progressively throughout pregnancy, reaching a peak of approximately ± 3.8 weeks (2 SD) in the late third trimester (see Tables 7-5 and 7-6).

Abdominal Circumference

The measurement of the fetal AC is made as described previously (Figs. 7-16 and 7-17). If the sonographic instrument is not equipped with a computer-generated ellipse measure-

ment capability, the circumference can be calculated using the transverse and anteroposterior diameters of the abdomen (measured from skin edge to skin edge) and the formula $(D1 + D2) \times 1.57$. The menstrual age can then be determined using a standard reference table (Table 7-8). However, as noted earlier, modern instruments immediately compute an age as the measurement is being obtained.

Of the four basic ultrasound measurements, the AC has generally had the largest reported variability.^{7,18,21,27} This is partly attributable to the fact that AC is more acutely affected by growth disturbances than the other basic parameters (see Tables 7-5 and 7-6). The observed variability is probably due more to measurement error than biologic variability (Fig. 7-18). Most authors have gone to extremes to exclude patients with growth disturbances from their study populations. Furthermore, of the four recommended measurements, AC measurements are the most difficult to obtain. The greatest differences in accuracy between AC and the other parameters in the study by Benson and Doubilet⁷ were observed in the second trimester of pregnancy, a point at which growth variations would be expected to be minimal (see Table 7-6).

In early pregnancy and in normally growing fetuses, the AC is only slightly less accurate on average than the other basic measurements if one strictly adheres to the rules of measurement. Similar results have been reported by Hill et al,²⁷ who demonstrated that the variability in predicting menstrual age (14 to 43 weeks) from AC in 265 normal weight fetuses was slightly less than that associated with the BPD. As with all other parameters, however, the variability in predicting menstrual age based on AC increases as pregnancy advances. For example, in a retrospective study of patients with menstrual dates corroborated by early CRL, Benson and Doubilet⁷ reported variability of $4\frac{1}{2}$ weeks (2 SD) in the late third trimester of pregnancy (see Table 7-6).

Femur Length

Because of its size, visibility, and ease of measurement the femur is generally preferred over the other long bones as a means of predicting menstrual age. The FL measurement was described in detail earlier (see Figs. 7-13 to 7-15). Although virtually all of the early work in femur biometry was done on white populations, it has been demonstrated that these measurements are not altered in any appreciable way in other races.^{21,30} Obviously, in any fetus suspected of having an osteochondral dysplasia, the FL should be excluded from calculation of menstrual age. Estimates of menstrual age can be obtained from standard reference tables (Table 7-9). However, as noted earlier, modern instruments immediately compute an age while the measurement is being obtained.

Most studies suggest that the FL is an accurate predictor of menstrual age in the early second trimester (2 SD = ± 1 week), but again variability increases as pregnancy advances. Furthermore, reported variability throughout the remainder of pregnancy from several laboratories has been inconsistent (see Tables 7-5 and 7-6).^{13,16,74,75} For example, Jeanty et al⁷⁴ reported a uniform variability for the FL age estimate of ± 2.1 weeks throughout the second and third trimesters of pregnancy, suggesting that the FL is just as accurate in predicting age at 40 weeks as it is at 14 weeks.

FIGURE 7-17. Abdominal circumference (AC) measurements correlated with Figure 7-16. Each measurement was obtained in the same fetus within minutes of one another. *A*. The abdominal circumference depicted here is obtained at the wrong craniocaudal plane. It is obtained in too caudal a position. This can be determined by two observations. First, the plane cuts through the short axis of the umbilical vein (UV) (correlate with Fig. 7-16A). Second, no ribs are visible laterally. Compare with the correct plane of section in *B* (GB, gallbladder). *B*. This is a properly oriented and measured AC. Note that it measures 176.9 mm. The ribs (R) are symmetric, and the junction of the right (RPV) and left (LPV) portal veins is seen. By contrast, the circumference measured in Figure 7-17A is only 168.3 mm. Note that the body of the fetal stomach (S) is nearly always visible in a well-performed AC measurement. In *A*, the gallbladder, a more caudal structure, is visible rather than the stomach. *C*. In this plane of section, a long length of the left portal vein (LPV) is seen rather than the junction of the right and left portals, as noted in Figures 7-16B and 7-17B. This indicates that the plane of section is inclined relative to the body axes. If the reader compares Figure 17B and C, one will note that in the latter the abdominal section is more elliptically shaped than in the former. The circumference is increased by this error (192.2 mm compared with 176.9 mm). It is because this latter error is very common that the rule “round covers a multitude of errors” applies.

Hadlock et al²⁵ believed that this is a statistical phenomenon resulting from the use of the wrong test of the variability estimate. Furthermore, although Hill et al²⁷ found FL to be the most accurate of all the individual parameters in predicting menstrual age, Ott⁷⁶ found it to be the least accurate. Hadlock et al¹⁸ and Benson and Doubilet⁷ found the FL to be roughly equivalent in accuracy to the other parameters in estimating menstrual age, reaching a peak variability of approximately ± 3.5 weeks in the late third trimester of pregnancy.

It is important to emphasize, as stated earlier, that variability of fetal head and femur measurements (BPD/HC/FL) is small early in gestation. Many tables list variability of these measurements as a grouped range, for example, 12 to 18 weeks = ± 1.3 weeks. Although the variability of slightly greater than one week is often acceptable and normal in most of the second trimester, one should be suspicious when this is found, early in the second trimester, for example, 12 to 14 weeks. A BPD, HC or FL 1 week less than the other measurements may be an early sign of microcephaly in the

case of a slightly smaller fetal head or trisomy 21 or a short limbed bony dysplasia in the case of a slightly smaller femur.

OTHER BIOMETRIC PARAMETERS

A number of other fetal structures can be imaged and measured with current high-resolution real-time ultrasound equipment. These measurements may rarely play a role when either the transverse axial image necessary for measurement of the BPD and HC or the proper plane for femur measurement is not obtainable. For example, when the head is in a direct occiput posterior position, the orbits are easily imaged, and several authors have published normal data for both the binocular distance and the interorbital and intraorbital diameters (see Appendix A-24).^{77,78} When the fetus is in a direct occiput anterior position, the posterior fossa is closer to the transducer, and the cerebellum can be seen to advantage. Hill et al²⁶ published normal data for the transverse diameter of the cerebellum (transverse cerebellar diameter), and some authors believe that it is preferable to other head

measurements for age prediction in cases in which fetal growth may be altered (Table 7-10).⁷⁹ Other notable measurements that may be used as substitute variables for predicting menstrual age include virtually all of the long bones of the arms and legs (see Appendices A-17 and A-18). In addition, normal data have been published for use of the fetal foot length (the growth of which appears to be spared in cases of intrauterine growth restriction) and fetal clavicle length measurements as predictors of menstrual age. The variability associated with age predictions based on these additional biometric parameters is outlined in Table 7-11. These measurements might be useful in certain circumstances, but in general, the basic fetal measurements previously mentioned serve as adequate indicators of menstrual age in most cases.

LATE PREGNANCY

Occasionally, an obstetrician is first confronted with a pregnant woman who is uncertain of her dates and has

FIGURE 7-18. In this plane of section, the acoustic beam enters the abdomen at a more caudal site and exits at a more cranial site. This is evident by two observations. First, no rib is seen on the "up" side of the abdomen and a length of rib (R) is seen on the "down" side. As well, the gallbladder (GB) is seen on the "up" side, whereas the body and fundus of the stomach (S) are seen on the "down" side (UV, umbilical vein). Note that the error introduced by this off-axis plane is less than that introduced by the off-axis plane depicted in Figure 7-17C. Importantly, recognizing the anatomic signals of error depicted in Figures 7-17A and C and 7-18 give the examiner both knowledge of the direction and magnitude of the error and suggest the change in transducer alignment needed to correct the error.

already reached the third trimester. Although the accuracy of first trimester ultrasound for predicting GA is ± 3 to 5 days, and ± 7 days for 12 to 18 weeks' GA,⁸⁰ biometric data are unreliable in the third trimester. This situation becomes clinically relevant when a determination for delivery may become necessary. Owing to the relatively slow maturation of the fetal pulmonary system in relation to all other organ systems, the risk of neonatal respiratory distress syndrome is non-negligibly high, even at near-term GA. This risk is essentially gone once a fetus has reliably achieved 39 weeks' menstrual age. Indeed, the American College of Obstetricians and Gynecologists (ACOG) stipulates strict criteria to ensure pulmonary maturity for the elective delivery of a fetus before 39 0/7 weeks' GA.⁸¹ If one of these criteria is successfully met, the obstetrician can reliably assume pulmonary maturity. These criteria include

- Fetal heart tones that have been documented for 20 weeks by non-electronic fetoscope or for 30 weeks by Doppler.
- The passage of 36 weeks since a serum or urine human chorionic gonadotropin pregnancy test was found to be positive by a reliable laboratory.
- Ultrasound measurement of a crown-rump length at 6 to 11 weeks' GA that supports a current GA equal to or greater than 39 weeks.
- Ultrasound measurement at 12 to 20 weeks of gestation that supports a clinically determined GA of 39 weeks or greater.

While there is no foolproof means of determining menstrual age in the circumstance of uncertain LMP and no early

ultrasound measurements, the fetal skeleton can provide some clues as to the duration of the pregnancy. Long bone ossification begins at the primary ossification center in the diaphysis starting at the end of the embryonic period. The secondary ossification centers appear later, with those of the heel and knee preceding all others. The bone growth occurring at these centers is referred to as the epiphysis.⁸² The distal femoral epiphysis, which is not included in the measurement of the femoral shaft, is not seen before 28 weeks' GA, but it is observed in 94% of fetuses at 34 weeks GA, and in an even greater proportion of older fetuses (see Figs. 7-15 and 7-19).^{82,83} These ossification centers appear earlier, on average, in female fetuses (Fig. 7-20).⁸⁴ The size of the distal femoral ossification center also cor-

relates with late GA (Fig. 7-21).⁸⁵ The proximal tibial epiphysis is not seen before 34 weeks' GA but does occur in 35% of 35-week-old fetuses, 80% of 37 week fetuses, and 100% of fetuses at or beyond 39 weeks GA.⁸² Thus, visualization of the distal femoral and proximal tibial epiphyseal ossification centers is helpful for confirming biometric data predicting menstrual age in late pregnancy (see Fig. 7-19).^{84,85}

FIGURE 7-19. Appearance time of the distal femoral (DFE) and proximal tibial (PTE) epiphyseal ossification centers in a mixed group of 61 fetuses that were well dated. (From Chinn DH, Bolding DB, Callen PW, et al: *Ultrasonographic identification of fetal lower extremity epiphyseal ossification centers. Radiology 147:815, 1983.*)

The appearance time of the epiphyseal ossification centers is insufficiently accurate to use as a sole arbiter of menstrual age in late pregnancy but can serve more as a confirmatory observation that the biometric data are accurate. For example if one encounters a fetus whose biometric measurements suggest a menstrual age of 36 weeks but in whom neither an ossified distal femoral or proximal tibial epiphyseal ossification center is visible, the possibility that the calculated menstrual age is erroneous is high. Potentially, such a fetus is macrosomic.

Additional GA markers exist. These include the transverse cerebellar diameter and foot length (the growth of both are spared in fetal growth restriction (see earlier as well as Tables 7-10 and 7-11), placental grading, small intestinal peristalsis, colonic echogenicity, and the presence or absence of colonic haustra.⁸² Placental grading is based on echogenicity attributed to increasing calcium and fibrous deposition with advancing age.^{82,86} On a grading system of 1 to 3, with 3 representing the most advanced or matured placenta, the distribution at term is 45% for grade 1, 55% for grade 2, and 5% to 10% for grade 3.⁸⁷ Although it is unusual to find a grade 1 placenta at or beyond 42 weeks' GA, grade 2 occurs 55% of the time, and grade 3, 45% of the time. Correlation between placental grading and pulmonic maturity is highly controversial, and various disorders have been shown to affect the sonographic appearance of the placenta (e.g., "premature" maturation with maternal chronic hypertension, and "delayed" maturation with diabetes mellitus and

FIGURE 7-20. Variation in the distal femoral epiphyseal ossification centers (DFE) appearance time and size in male and female fetuses. (From Mahony SB, Callen PW, Filly RA: *The distal femoral epiphyseal ossification center in the assessment of third trimester menstrual age: Sonographic identification and measurement. Radiology 155:201, 1985.*)

isoimmunization).^{82,88} Placental grading should *not* be used to determine fetal lung maturity.

With advancing GA, small-intestinal peristalsis "matures," developing into more vigorous and longer duration peristaltic waves. Just as with placental maturation, a grading system has been described for small intestinal peristalsis⁸²:

- Grade 0: Small intestinal peristalsis is absent.
- Grade 1: Few sporadic waves of small intestinal peristalsis in up to 3 discrete areas, present for durations of less than 3 seconds.
- Grade 2: Moderate waves of small intestinal peristalsis in more than 3 discrete areas, present for durations longer than 3 seconds.
- Grade 3: Active waves of small intestinal peristalsis that are seen throughout the observation interval.

Intestinal peristalsis can be seen as early as 18 weeks' GA. Grade 1 peristalsis can be observed in 88% of fetuses before 29 weeks' gestation, and grade 3 peristalsis in 80% of fetuses between 37 and 38 weeks' GA.⁸⁹

Colonic echogenicity is another sonographic marker that has been described. With advancing GA, there is an increase in luminal meconium content and a reduction in water leading to progressively increased echogenicity. When com-

FIGURE 7-21. Mean diameter of the distal femoral epiphyseal ossification centers (DFE) with increasing age of late third trimester fetuses. (From Mahony SB, Callen PW, Filly RA: The distal femoral epiphyseal ossification center in the assessment of third trimester menstrual age: Sonographic identification and measurement. *Radiology* 155:201, 1985.)

pared with the appearance of other intra-abdominal structures, this echogenicity can also be graded⁸²:

- Grade 0: The abdomen is uniform in appearance, and the colon is not identified.
- Grade 1: The colonic contents have an echo-free appearance. This is essentially identical to that of the bladder and the stomach; the colonic haustra can be identified.
- Grade 2: Intermediate. The colon appears more echodense than the bladder but less than the liver.
- Grade 3: The colonic contents have an echogenicity essentially equal to that of the liver

Grade 0 colonic echogenicity is present in 82% of fetuses less than 29 weeks' GA, but grade 3 is seen in 85% of fetuses older than 39 weeks' GA.⁸⁹ Finally, colonic haustra can be observed using ultrasound starting at 30 weeks' GA, and thus, can serve as an independent marker of a GA of at least 30 weeks.

Clearly, there is a point in pregnancy after which reliance on biometric parameters to date the pregnancy is invalid and serious errors can be made. After this point, it is no longer possible to "know" the menstrual age of the pregnancy. The use of secondary markers as described earlier can only provide a rough estimate of GA that is far too

imprecise to assign an exact date. Thus, the only information that can be reliably obtained from third trimester sonograms is the fetal weight and, by a follow-up study, whether interval growth is normal. Experts disagree regarding the point in pregnancy when sonographic estimates of age become too unreliable to use. However, all agree that the accuracy begins to deteriorate rapidly after the 20th week. The exact cutoff is debatable but lies somewhere in the range of 24 to 28 menstrual weeks.

CALCULATION OF MENSTRUAL AGE

The literature is replete with articles that focus on predicting menstrual age using ultrasound measurements of the fetus.^{5,32} A common theme among these articles is that the variability in predicting menstrual age increases as pregnancy advances for all fetal parameters (see Tables 7-5 and 7-6). The increase in variability is undoubtedly for the most part due to actual differences in fetal size, because it has been demonstrated consistently in populations with optimal menstrual histories, with known dates of conception, and in whom age was established early in pregnancy by use of the CRL measurement. For example, Hadlock, Harrist, and Martinez-Poyer²² studied 1771 patients with excellent menstrual histories and demonstrated that any of the individual parameters can provide accurate estimates of menstrual age (2 SD = ± 1 week) between 14 and 20 weeks. Persson and Weldner⁶⁴ and Rossavik and Fishburne³³ demonstrated similar results in patients with known dates of conception (see Table 7-5). In a large study of patients whose dates were confirmed by the gold standard of early CRL dating, Benson and Doubilet⁷ demonstrated that age estimates from individual parameters reach a maximum variability of approximately ± 4 weeks in the late third trimester of pregnancy (see Table 7-6). Thus, one should try to establish menstrual age as early in pregnancy as possible.

Which measurements should one use to predict age in a given case? Hadlock et al¹⁸ suggested that one should avoid the tendency to place excessive emphasis arbitrarily on any one measurement because, in a given case, any measurement could provide the best estimate of age. With this idea in mind, they postulated that multiple fetal measurements should be used in combination to provide a composite age estimate. The use of multiple measurements is especially important when one considers several points. (1) If one is using only one parameter and makes an imaging or measurement error, the magnitude of the error in age prediction could be significantly greater than the reported variability for that parameter. (2) It is not uncommon for normal fetuses to have measurements that are above or below the expected mean value at a given age and these differences are not always in the same direction. For example, a fetus may have a 75 percentile head size and a 25 percentile abdominal size. (3) The process of plane selection of the fetal head, abdomen, and femur allows a detailed look at important anatomic structure and, therefore, facilitates detection of abnormalities in these areas, including hydrocephalus, encephalocele, bowel obstruction, ascites, renal abnormalities, and dwarfism.

The initial approach of Hadlock et al¹⁸ was to use a simple averaging technique in which the estimates of age are added and divided by the number of estimates made. For example,

consider the following measurements obtained in the early second trimester:

BPD	3.3 cm = 15.9 weeks
HC	12.4 cm = 16.2 weeks
AC	10.0 cm = 15.6 weeks
FL	2.2 cm = 16.3 weeks
Composite age	16.0 weeks \pm 1 week

However, these authors subsequently developed regression equations for use in predicting age from any single measurement or combination of measurements,¹⁸ and these equations have been validated prospectively.²¹ These regression equations have become routine in usage in clinical practice. However, if an ultrasonic system is not equipped with an appropriate computation software package, the simple averaging technique gives approximately equivalent results.

The development of this multiple parameter dating approach raises two questions immediately. The first is how many measurements of the fetus must one make to obtain the best estimate of menstrual age? Hadlock et al¹⁸ examined this issue over the entire 14- to 42-week age range and demonstrated that the use of the four basic measurements results in the greatest accuracy (lack of systematic bias), greatest precision (lowest range of variability), and smallest maximum observed errors. Although some authors questioned the validity of the method,⁷¹ Hill et al²⁷ validated the models in an independent study. Moreover, Hill et al demonstrated that the addition of a fifth parameter (radius length) does not add to the accuracy of the method. From a purely statistical point of view, both Hadlock et al¹⁶ and Hill et al²⁷ were unable to demonstrate significant improvement beyond the two-parameter model based on HC and FL. Persson and Weldner⁶⁴ reported similar results in a large study between 14 and 20 weeks (see Table 7-5). Although the variability of the two-parameter (HC, FL) model increases as pregnancy advances, it is relatively constant at 8% when expressed as a percentage of the estimate. For example, if the composite age estimate based on these two parameters is 20 weeks, then the variability associated with that estimate is 20 weeks \pm 1.6 weeks. In the late third trimester, a composite age estimate of 40 weeks would have a corresponding variability of 40 weeks \pm 3.2 weeks. Because the four-parameter method results in the lowest variability estimates, it is most commonly used in clinical practice.

The second important question that comes to mind using the multiple-parameter dating technique is how disparate the individual measurements can be and still be acceptable for incorporation into the composite age estimate. For example, if measurement of the fetal head (BPD or HC) gave an age estimate of 20 weeks and measurement of the FL gave an age estimate of 14 weeks, one would know empirically that the two cannot be averaged to provide a composite age. The fetus is almost certainly abnormal. To deal with this issue one can rely on fetal body ratio data as delineated in Tables 7-12 and 7-13. For example, if the BPD is to be used in the age estimate, one should first examine the cephalic index. If it indicates an abnormal head shape, the BPD should either be eliminated in favor of the HC or corrected for head shape.^{9,11,72} One can then measure the relationship between FL and HC. If this is normal, then both measurements can be used for the prediction of age.²⁰ If the FL:HC ratio is high, the head measurement should be deleted

Table 7-12 Normal Body Ratio Data (14–21 Weeks)

Menstrual Week	Cephalic Index (SD = 3.7) ⁷¹	Femur/BPD \times 100 (SD = 4.0) ²⁴	Femur/HC \times 100 (SD = 1.0) ²⁴	Femur/AC \times 100 (SD = 1.3) ²⁴

BPD, biparietal diameter; HC, head circumference; AC, abdominal circumference.

because of possible microcephaly; if this ratio is low, the FL age estimate should be deleted because of possible dwarfism.²⁰ These decisions are based on the assumption of normal anatomy of the head and long bones.

If AC is to be included in the age estimate, one must examine the relationship between FL and AC (FL/AC \times 100). If this ratio is low, one should avoid using the AC because of possible macrosomia; and if it is high, one should avoid using the AC because of possible intrauterine growth restriction.¹⁷ Because the AC may be affected by abnormal fetal growth, one can make a strong case for eliminating it from the age estimation procedure altogether, particularly in the third trimester of pregnancy.⁷ This case is even stronger in view of the inability to demonstrate a statistically significant improvement in the age estimation procedure by adding additional parameters to the combination of HC and FL.^{18,22}

The limiting factor in menstrual age estimates from fetal biometry is likely due to the genetic variation in actual fetal size as pregnancy advances and, to a lesser extent, the measurement errors associated with their use. Thus, it is unlikely that additional biometric parameters will add to the accuracy of the dating procedure using ultrasound evaluation. It is possible, and ever likely, that certain nonbiometric observations may prove helpful in narrowing the variability associated with ultrasound age estimates.¹ These observations include the degree of placental maturation,⁹⁶ amniotic fluid volume,⁹⁷ and maturation of the fetal bowel pattern (as explained above).^{96,98} The presence of a grade 3 placenta, low amniotic fluid volume (in the absence of ruptured membranes, fetal renal disease, or growth restriction), and a mature fetal bowel pattern would make one favor the higher end of the age estimate based on fetal biometry. For example, in the presence of the above-mentioned ancillary findings, if the biometric age estimate based on FL and head size was 34 weeks \pm 2.7 weeks, one would favor the high end of the estimate (36.7 weeks). These ancillary findings are useful and can be further supported by looking for epiphyseal ossification centers to correlate with late estimates of menstrual age.⁸⁵ Thus, in the case just described, the presence of the distal femoral and proximal tibial epiphyseal ossification centers would again favor the higher end of the age estimate, that is, 36.7 weeks (see earlier for more information on fetal maturation markers). Additional parameters for measurement, such as the fetal clavicle and foot, have also been looked at for estimation of age, and the latter appears to be immune to the effects of growth restriction.⁹⁹⁻¹⁰¹

The menstrual age based on the LMP dates should never be changed late in pregnancy based solely on ultrasound measurements. Great caution is mandatory when menstrual age based on the LMP differs from sonographic biometry late in pregnancy. All available clinical information must be carefully scrutinized before dates are "changed" in late pregnancy. Whenever this course of action is chosen, the potential for serious error must be forefront in the minds of the managing clinicians. More obvious, if dates have been established early in pregnancy by sonographic biometry, changing the dates based on later sonographic biometry is a formula for disaster.

ESTIMATION OF FETAL WEIGHT

Once biometric parameters have been measured, an estimate of fetal weight can be made. A number of techniques exist to perform this function. Formulas and nomograms for the estimation of fetal weight using combinations of BPD, HC, AC, and FL have been developed. Among the common fetal weight formulas are Shepard's and Hadlock's (see Appendix B).⁹⁰⁻⁹² These formulas have been validated, and, for example, the Shepard formula predicts fetal weight within 10% of the actual weight in 85% of cases.⁹⁰ The Hadlock formula improves upon this by the incorporation of three fetal parameters, reducing the random error by 15% to 25% less than with models utilizing two parameters.⁸² Most modern ultrasound equipment comes with computer packages that will automatically calculate an estimated fetal weight (EFW) based on one of these formulas. If such a function is not available, one can refer to 2 \times 2 nomogram tables that use two biometric parameters to provide an

estimate of fetal weight (e.g., BPD and AC, or AC and FL; see Appendix B-5).

One can compare the estimated fetal weight with established cross-sectional population-based growth curves. Lubchenco et al⁹³ in 1963 first described such a growth curve based on live-born birthweights of neonates born to white and Hispanic women in Denver, Colorado (5000 feet above sea level) from 24 to 42 weeks' GA. Brenner et al followed this up with a growth curve based upon white and black infants delivered in Cleveland and aborted fetuses from North Carolina.⁹¹ Differences exist among these population-based growth curves due to the inherent variation in populations studied based on numerous factors, including altitude, ethnicity, socioeconomic status, and time period. In an effort to overcome these limitations, Alexander et al⁹⁵ described 1991 United States national birthweight data from over three million live births from 20 to 44 weeks' GA. Nevertheless, all of these growth curves are based on birthweight, and not fetal weight. Because they are composite curves based on the endpoint of fetal growth at each successive GA, they are not true representations of the actual rate of fetal growth. Indeed, neonates born at earlier GAs are more likely to be born owing to other complications of pregnancy that may, in turn, result in inclusion of an abnormally high number of infants with intrauterine growth restriction (IUGR) at these time points, thereby possibly misrepresenting fetal weight at extremes of GA. This becomes quite relevant for clinical circumstances when one has a heightened suspicion for the potential development of growth restriction (see section on IUGR later). Despite these limitations, use of these growth curves has become commonplace because there currently does not exist a more superior method of determining fetal weight growth percentile (see later on individualized growth curves).

CLINICAL APPLICATION OF BIOMETRIC PARAMETERS

Intrauterine Growth Restriction

Definition

In any given population, there is a normal distribution of fetal size at each GA. Inherently, a fraction of fetuses will be small and large. Although fetuses at the extremes of size may be within the spectrum of normal and achieving their growth potential (see the section on individualized growth curves, later), it is more likely that the majority of these fetuses are growing abnormally, either underachieving or overachieving their potential. The terms small for gestational age (SGA) and IUGR have been confusingly used interchangeably. In 1967, Battaglia and Lubchenco¹⁰² defined SGA as birthweight being below the 10th percentile for GA. Whereas IUGR has been defined using a number of different criteria, including that for SGA, it is now generally a term reserved for the clinical circumstance of a fetus that is underachieving its growth potential. This is the way IUGR will be used in this chapter, while SGA will be a term reserved for constitutionally small fetuses that are meeting their growth potential as best as can be clinically determined.

A number of criteria have been used to capture a fetal population most at risk for abnormal growth. Among those

used to ascribe IUGR, the most common is a EFW less than the 10th percentile for GA. Alternative criteria include an EFW less than the 3rd, 5th, and 15th percentiles, as well as less than 2 standard deviations (SD) below the mean. The AC has also been used as a defining biometric parameter, because it is believed that among all fetal measures, pathologic growth affects hepatic size, and thus the AC first. An AC less than the 10th percentile, the 2.5th percentile, and 2 SDs below the mean for GA have all been used as defining criteria. Overly strict criteria may have very high positive predictive values, but may miss a sizable number of fetuses that also have pathologic growth. More specifically, although the 10th percentile will have a higher false-positive rate, it may detect the fetus genetically set to be at the 50th percentile but is pathologically small at the 9th percentile. As Dr. John Hobbins of the University of Colorado Health Sciences Center puts it rather eloquently: "The fetus genetically programmed to be in the 90th percentile who is born in the 20th percentile may be in more trouble than a baby born to a jockey and a gymnast who is in the 8th percentile." For the purpose of screening out a high-risk population, obstetric practitioners most commonly use a definition of less than the 10th percentile, and this will be the definition used in this chapter.

Etiologies

There are a number of causes of IUGR. A traditional method of distinguishing the etiologies of IUGR is symmetric versus asymmetric growth, in which the former is a situation when all biometric measurements are symmetrically lagging and the latter is when they are lagging asymmetrically (e.g., the BPD lags less than the AC that is expected for the GA at hand). Symmetric growth lag has been shown to occur from genetic disorders (e.g., trisomy 18), fetal infections (e.g., rubella and cytomegalovirus), congenital malformations, and a variety of syndromes (e.g., Cornelia de Lange).¹⁰³ Asymmetric growth lag tends to occur in situations of relative nutritional and oxygen deprivation. The basis of this distinction based upon patterns of symmetry comes from the thought that global insults to the fetus lead to a total restriction in fetal growth, whereas nutritional and oxygen deficiencies lead to an asymmetric growth pattern with preferential preservation of vital structures first such as the brain (thus, a head-to-body disproportion, or an AC lag relative to head parameters). This is of course prone to inaccuracy, because a late gestation fetus that has been exposed to a chronically nutritionally deficient or hypoxic environment through a major portion of pregnancy can also show growth lag of all fetal parts to a similar extent and, hence, may appear to be symmetrically restricted. Some forms of growth restriction may fall into either symmetric or asymmetric categories and, hence, do not easily lend themselves to classification. An example of this occurs in monochorionic twin gestations that are at risk for developing twin-twin transfusion syndrome, in which one twin (the donor) pumps a portion of its blood to the other twin (the recipient) through anomalous placental vascular anastomoses. The donor twin often develops significant anemia, growth restriction, and severe oligohydramnios, whereas the recipient twin becomes plethoric, congested, and edematous. The recipient twin is at profound risk for developing cardiac failure and subsequent hydrops

fetalis (please refer to other portions of this text for further information on this condition).

Pathologic growth that is the end result of inadequate nutrient and oxygen delivery to the fetus through the uteroplacental unit is attributed to uteroplacental insufficiency (UPI). Owing to the broad range of causes of IUGR, and because the major cause of IUGR is UPI, the remainder of this section will focus on IUGR of UPI etiology. It is important to remember that UPI is a terminal condition with a multifactorial etiology. A number of conditions can lead to UPI, and growth restriction as a result. These can be divided into placental and maternal disorders. Examples of placental causes include placental abruption of a chronic nature, placenta previa, mosaicism (e.g., localized placental trisomy 16), marginal or velamentous cord insertion, and primary placental disorders. Maternal etiologies can include behavioral states, such as smoking and cocaine abuse, and any chronic medical condition that affects systemic oxygenation or vasculature, and therefore also afflicts uteroplacental circulation and oxygen delivery: chronic lung disease (chronic obstructive pulmonary disease, emphysema), pre-existing diabetes mellitus, chronic hypertension, collagen vascular disorders (e.g., systemic lupus erythematosus), acquired thrombophilias (e.g., antiphospholipid antibody syndrome [APAS]), and inherited thrombophilias (e.g., Factor V Leiden or prothrombin 20210A mutation). The end result of all of these conditions is poor placentation, with a resultant reduction in placental blood flow or chronic hypoxemia.

Pathophysiology

The development of an adequate interface between the maternal and fetal circulations at the level of the placenta is vital to proper fetal growth, because a poor interface does not allow for adequate nutrient and oxygen delivery, nor for adequate removal of fetal metabolic wastes. As explained earlier, factors that affect any component of this interface can alter placental development, and thus fetal growth, in a detrimental fashion.

Placental development is an ongoing process throughout gestation, with key developments occurring in each trimester. The first trimester is marked by placental attachment, angiogenesis, cellular transport mechanisms for glucose, amino acids, and fatty acids, and the onset of fetal cardiac activity to facilitate distribution and disposal of various substances between the maternal-fetal circulations.¹⁰³ A number of maternal adaptations start in the first trimester, including postprandial hyperglycemia, intravascular volume expansion, and relative refractoriness to vasoactive substances. The second trimester is characterized by trophoblastic invasion into the uterine spiral arteries and vascular remodeling, resulting in the development of a low-resistance circuit, a massive increase in total villous surface area vastly improving capacity for maternal-fetal exchange, and a significant increase in fetal cardiac output. A resultant exponential increase in placental size is matched by an exponential fetal growth spurt. Finally, in the third trimester, the fetus prepares for an eventual extrauterine existence; longitudinal growth, along with establishment of fetal stores, especially body fat, is key to this goal.

IUGR is primarily the result of disturbances in placental vascular development.¹⁰³ In early pregnancy, miscarriage

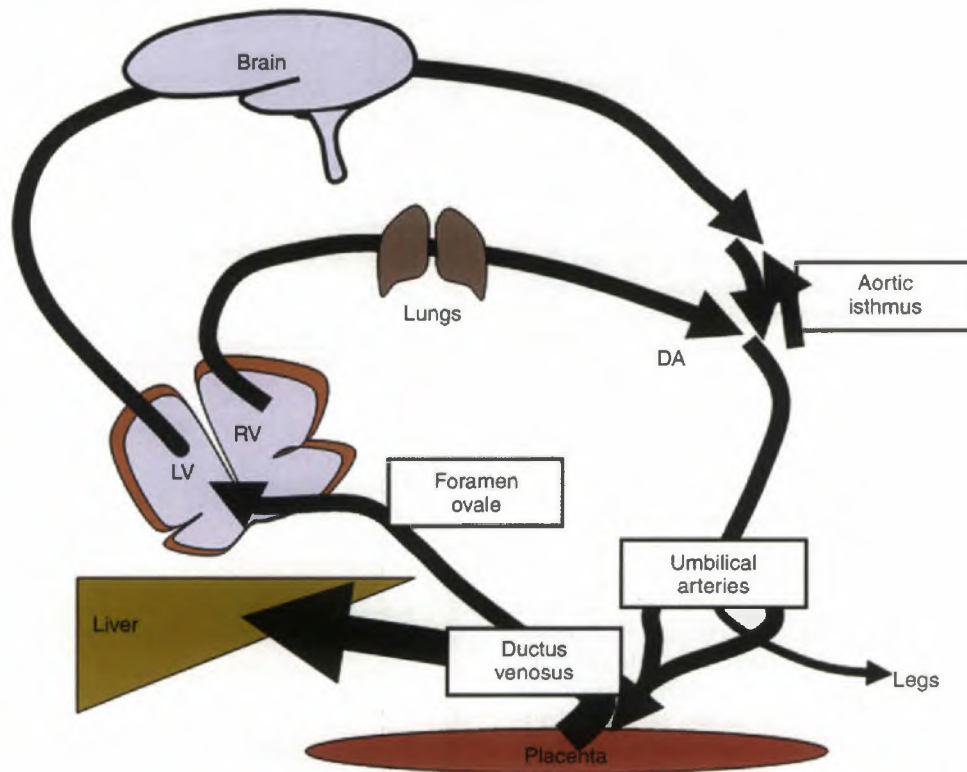

FIGURE 7-22. Fetoplacental blood flow. Note the presence of the ductus venosus, foramen ovale, and ductus arteriosus (DA) that are unique to the fetal circulation. LV, left ventricle; RV, right ventricle. (From Gabbe SG, Niebyl JR, Simpson JL: *Obstetrics: Normal and Problem Pregnancies*, 5th ed. Philadelphia, Churchill Livingstone, 2007.)

may result from inhibited angiogenesis and poor placental adherence. Later in gestation, inadequate trophoblastic invasion into the maternal spiral and radial arteries leads to the failure of establishment of a low-resistance circuit that is key to further fetal growth. As discussed earlier, a number of causes of IUGR exist. These conditions can affect the placenta directly, such as maternal placental floor infarcts and fetal villous obliteration, or may inhibit the maternal and fetal placental vascular flow, as in vaso-occlusive conditions (e.g., APAS). Stillbirth can occur in situations in which the insult is severe and early in onset, with inability for compensatory mechanisms to overcome the challenge. In cases in which compensation can initially occur and fetal survival is possible, one may yet encounter failure of adequate interval fetal growth in the second and third trimesters. In mild cases, only a relative reduction in fetal stores may be noticed at birth (i.e., a reduction in body fat and a reduction in the AC due to decreased hepatic glycogen stores), but in more severe cases, chronic hypoxia and metabolic acidosis may result, with possible profound implications for neonatal and later life.

The fetal response to UPI can be categorized into early and late cardiovascular adaptations that are relevant to sonographic assessment of fetal status (see later). Early adaptation is characterized by changes in blood flow to favor nutrient and oxygen distribution to essential organs, especially the brain (Fig. 7-22). Umbilical venous volume is reduced in early stages of UPI (persistent reduction in umbilical venous volume can lead to a diminished fetal blood volume, and hence reduced fetal renal perfusion; oligohydramnios can be

the end result).¹⁰⁴ This leads to greater diversion of the relatively nutrient- and oxygen-rich umbilical venous blood through the ductus venosus away from the liver and to the fetal heart; through the foramen ovale, this blood then enters the left side of the heart, and from there, moves on to the coronary and cerebral circulations.^{105,106} Facilitating this shunting is an elevation in right ventricular afterload owing to the high resistance of the pulmonary vasculature as well as the rising placental resistance seen in UPI; a reduction in left ventricular afterload occurs as well owing to a drop in cerebral vascular resistance.¹⁰⁷⁻¹¹¹ Thus, there is a relative increase in left ventricular cardiac output compared with the right.^{112,113} Late changes occur with progressive UPI and increasing placental resistance with development of oligohydramnios. Cardiac output declines owing to the rising afterload, resulting in reduced forward flow. As a result, the ability to handle preload is also significantly diminished, leading to an elevated central venous pressure and inhibition in forward venous flow.¹¹⁴⁻¹¹⁸ The final stage is global myocardial dysfunction and dilatation.¹¹⁹ At this juncture, fetal acidosis is an ominous clinical finding. Holosystolic tricuspid insufficiency and spontaneous fetal heart rate decelerations herald impending death.¹¹⁹

Short- and Long-Term Sequelae

As one might expect, fetuses with IUGR face a number of immediate challenges as neonates. When combined with prematurity, risks include increased mortality, necrotizing enterocolitis, and respiratory distress syndrome.¹²⁰ When

delivered at term, these neonates still face significant complications, including increased risk for mortality, transient tachypnea of the newborn, hypothermia (temperature $<36^{\circ}\text{C}$), hypoglycemia, polycythemia, hyperviscosity, hyperbilirubinemia, and impaired immune function.^{121–128} Although a significant number of moderately growth restricted fetuses go on to catch up in growth based on height and weight by 18 years of age, those fetuses that are below the 3rd percentile for birthweight have greater difficulty in doing so, and tend to have lower weight and shorter statures than their appropriate for GA (AGA) counterparts throughout childhood and adolescence.^{129,130} It is clear that growth-restricted, prematurely born infants are at increased risk for neurodevelopmental abnormalities and cognitive impairment.^{131,132} Term IUGR infants are also at risk for learning difficulties, behavioral problems, and worse school performance than term AGA children.^{130,131,133}

Interestingly, it has been hypothesized that growth-restricted infants may be prone to developing adult disorders. Known as the fetal origins of adult disease, or the Barker hypothesis, the supposition is that a poor in utero environment leads to fetal maladaptive changes that persist into infancy, childhood, and adulthood. Although useful for survival in a relatively hostile intrauterine environment, these changes, predominantly vascular in nature, become detrimental in the long term. Conditions that have been attributed to IUGR include hypertension, stroke, diabetes mellitus, atherosclerosis/hypercholesterolemia, and obesity.^{134–137} Although highly intriguing, definitive causality has not yet been established between IUGR and these conditions.

Assessment of Fetal Status

Fetal status fundamentally refers to the state of fetal oxygenation and acid-base equilibrium. A clinical circumstance of UPI jeopardizes oxygen and nutrient delivery to the fetus, necessitating an adaptive response, as explained in part earlier. Fetal compromise occurs when there is failure of such a response, or when these adaptive mechanisms are overcome with ongoing and worsening UPI. With timely intervention, a fetus can be saved from injury and even death. The often difficult challenge that confronts the obstetrician is the necessity to balance the risks of injury and intrauterine fetal demise with prolongation of pregnancy in the setting of IUGR against those associated with potential iatrogenic prematurity. Thus, evaluating fetal status is crucial to proper management of the IUGR fetus.

Once a fetus is identified to be at-risk by an ultrasound-derived weight estimate below the 10th percentile for GA, and it is clear that UPI is the primary pathologic culprit, the obstetrician should initiate fetal surveillance. Traditional methods have included nonstress testing (a particular form of cardiotocography, called CTG), amniotic fluid measurement, and biophysical profiling. It is now clear that abnormalities in findings using these modalities are relatively late in occurrence, with fetal acidosis often being already present by the time of evaluation (see below, and Fig. 7–23A and B).¹⁰³ Placental insufficiency can be detected noninvasively with ultrasound imaging, and with the relatively recent development of Doppler ultrasound, even fetal acid-base status can be inferred. Once acidosis sets in, intrauterine demise may soon follow. Thus, a method to identify a preacidotic state in

FIGURE 7-23. A. Timing of fetal responses to placental insufficiency. BPP, biophysical profile; DV, ductus venosus; IVC, inferior vena cava; MCA, middle cerebral artery; UAEDF/RF, umbilical artery end diastolic flow/reverse flow; UVP, umbilical venous pulsations. Note that numerous Doppler abnormalities occur before the onset of an abnormal BPP. B. Timing of fetal responses to placental insufficiency. Note that the timing of the loss of short-term variability on CTG correlates quite well with the onset of abnormal ductus venosus Doppler velocimetry. Thus, this is a direct link between a biophysical abnormality and abnormal ultrasound findings. Note also that worsening AFI (and therefore, development of, or worsening of, oligohydramnios) is a relatively late occurrence. AFI, amniotic fluid index; AO, aorta; DV, ductus venosus; IVC, inferior vena cava; MCA, middle cerebral artery; PI, pulsatility index; STV, short-term variability; UA, umbilical artery. an IUGR fetus becomes essential to have if one is to intervene in a timely fashion. The development of Doppler ultrasound has provided just such a tool.

Doppler Velocimetry

Doppler ultrasound is based on the principle of the Doppler effect, so named for Johann Christian Doppler, who identified this occurrence in 1842. Simply put, when energy is reflected from a moving boundary, the frequency of the reflected energy varies in relation to the velocity of the moving boundary. In sonographic terms, the Doppler phenomenon depends upon the ability of an ultrasound beam to be

FIGURE 7-24. Doppler effect. The Doppler phenomenon depends upon the ability of an ultrasound beam to be changed in frequency when encountering a moving object, and in this circumstance, red blood cells. (From Abuhamad A: Does Doppler U/S improve outcomes in growth-restricted fetuses? *Contemporary Ob/Gyn* 48:56, 2003.)

FIGURE 7-25. Umbilical artery Doppler waveform, shown as velocity (V) versus time (t). S, systolic; D, diastolic. Note that there is forward (positive) flow throughout the entire duration of the fetal cardiac cycle.

changed in frequency when encountering a moving object, and in this circumstance, red blood cells (Fig. 7-24) (see Chapter 22).

With interrogation of a blood vessel of interest, such as an umbilical artery, a characteristic waveform is generated (Fig. 7-25). In fact, as gestation advances and placental resistance declines in normal pregnancies, the umbilical artery Doppler waveform changes, reflecting a relatively greater and greater diastolic forward flow (Fig. 7-26). As one might surmise, in the setting of progressive UPI and elevated placental resistance, diastolic forward flow in the umbilical artery declines. Various Doppler indices exist to measure such placental resistance, and include S/D ratio, pulsatility index, and resistive index (Table 7-14). These measures are independent of the angle of insonation, because the generated waveform will reproduce both systolic and diastolic flows proportionately (Fig. 7-27A). Nonetheless, insonation of the vessel of interest as close to zero degrees as possible will yield a waveform with the most pronounced systolic and diastolic flows (Fig. 7-27B).

As explained earlier, UPI is associated with progressive worsening of placental resistance. This results in alterations in the maternal blood flow to the uteroplacental circuit, as well as fetal cardiovascular adaptive responses that can be

FIGURE 7-26. Normal umbilical artery Doppler waveform with advancing gestational age. Note the relative increase in diastolic forward flow with later gestational ages (and hence, a smaller S/D ratio with advancing age) as highlighted by the yellow circles. It is normal to have absent end-diastolic flow in the first and very early second trimesters.

detected by Doppler ultrasound of relevant vessels. Doppler interrogation of the fetal arterial system provides an indirect assessment of placental resistance, whereas the fetal venous system provides an assessment of the fetal cardiac function. By evaluating both fetal arterial and venous circulations, as well as the maternal uterine arteries, one can gauge the progression of UPI and IUGR well in advance of the development of oligohydramnios and fetal heart rate abnormalities.¹⁰³ Maternal evaluation can identify patients at risk for developing IUGR, pre-eclampsia, and placental abruption, whereas fetal evaluation can identify situations at risk for hypoxemia and acidosis based on the severity of Doppler findings.^{138,139}

The earliest stages of placental pathology can be detected by the presence of diastolic notching in the maternal uterine arteries at 12 to 14 weeks' gestation, and when this persists beyond 24 weeks, it is highly reflective of abnormal placental resistance (Fig. 7-28A and B).¹⁴⁰⁻¹⁴² This has been associated with adverse pregnancy outcomes such as IUGR, placental abruption, and pre-eclampsia.¹⁴³⁻¹⁴⁵ It has been observed by us that in circumstances of a lateralized placenta, a diastolic notch may appear only on the side ipsilateral to the placenta. On the fetal side, reduced umbilical artery end-diastolic velocity (EDV) can be seen when as little as 30% of the villous vessels are abnormal; with 70% abnormality, there can be complete absence (AEDV) or even reversal of umbilical artery end-diastolic velocity (REDV; Fig. 7-29).^{146,147} Thus, with progressive worsening of UPI, the umbilical artery S/D ratio will become increasingly larger until it can no longer be calculated when there is AEDV. As previously mentioned, in early stages of UPI, fetal adaptive

mechanisms lead to increased left ventricular output and decreased cerebral resistance. Cerebral arteries such as the middle cerebral artery (MCA) of the circle of Willis are part of a high impedance vascular bed with low end-diastolic flow velocities (Fig. 7-30). The MCA is a representative vessel that can be easily interrogated with Doppler ultrasound. In UPI, the MCA EDV is increased, and thus the MCA is characterized by a lower S/D ratio than normal (Fig. 7-31A to C).¹⁴⁸ This finding is often referred to as "brain-sparing."¹⁰³ These early changes in fetal blood flow, with elevated umbilical artery S/D ratio and a reduced MCA S/D ratio, are seen in fetuses that are at risk for developing hypoxemia but are typically not associated with acidosis.¹⁴⁹⁻¹⁵¹

As discussed earlier, in the situation of late fetal adaptation with advanced UPI, fetal cardiac function begins to fail and venous return begins to diminish. In this circumstance, Doppler assessment of the fetal venous circulation becomes necessary. Umbilical venous and portal circulations have waveforms that are steady and without pulsations. In contrast, central venous or precordial venous structures (ductus venosus, hepatic veins and the inferior vena cava [IVC]) have flow velocity waveforms that reflect central venous pressure changes characterized by triphasic wave-

forms (S, D, and *a* waves). The central venous waveforms are thus typically composed of systolic and diastolic peaks (S and D waves) that occur upon ventricular contraction and passive diastolic filling (Fig. 7-32).¹⁰³ A trough that occurs following the D wave, the *a* wave, is generated when there is a sudden increase in right atrial pressure due to the atrial contraction in late diastole and, as a result, an inhibition to venous return (see Fig. 7-32).¹⁰³ With severe right ventricular dysfunction, this atrial contraction can generate reverse flow along the venous system through the IVC, ductus venosus, and even into the umbilical vein in the most extreme circumstances in which the circulation is normally steady and without pulsations (Fig. 7-33A to C).¹⁰³ Venous back flow during atrial contraction (and hence a reversal in the *a* wave on Doppler interrogation) in the IVC and ductus venosus is most reflective of fetal metabolic acidemia as confirmed by percutaneous umbilical cord blood sampling (PUBS; see Fig. 7-33B).^{152,153} These findings precede the holosystolic tricuspid insufficiency and ominous spontaneous fetal heart rate decelerations that portend impending death as described earlier.

The clinical utility of Doppler ultrasound should be obvious. The scientific literature shows that this sonographic

FIGURE 7-27. A. Angle of insonation in Doppler ultrasound. The frequency shift is directly proportional to the speed with which the RBCs are moving within a particular vessel and it is also dependent on the cosine of the angle the ultrasound beam makes with the blood vessel (as shown in the equation with Fig. 7-24). Ideally one should obtain an angle as close as possible to 0 degrees. (Courtesy John Hobbins, MD, University of Colorado Health Sciences Center, Denver, CO.) B. Angle of insonation in Doppler ultrasound. Note the difference in waveforms generated depending upon the insonation angle. On the image on the right the beam is parallel to the vessel and on the image on the left the beam is almost perpendicular to the vessel.

modality, when appropriately used, reduces not only mortality, but also morbidity. The finding of AEDV or REDV marks a pregnancy that is at an 80-fold increased risk for perinatal mortality, and when intervention is appropriately timed, a roughly 40% reduction in mortality can be achieved.¹⁵⁴⁻¹⁵⁷ With the addition of venous Doppler assessment, the very preterm severely growth-restricted fetus can be better managed. Indeed, in 50% to 70% of cases, venous Doppler abnormalities occur before abnormal findings on fetal heart rate monitoring or biophysical profile (see Fig. 7-23A and B).¹⁵⁸ In circumstances in which there is a normal umbilical artery waveform and normal CTG testing, no fetuses have been shown to have hypoxemia/acidemia.¹⁵⁹ When there is abnormality in the umbilical artery waveform, and CTG remains normal, only 5% of fetuses have hypoxemia/acidemia. Finally, when there is

abnormality in both the umbilical artery Doppler velocimetry and CTG testing, 60% of fetuses can be found to have hypoxemia/acidemia by PUBS. Thus, the ideal time to deliver the IUGR fetus is before one sees abnormalities in the fetal heart rate tracing and only in the umbilical and venous circulations. A suggested algorithm for the management of the fetus with IUGR is shown in Figure 7-34.

ACCELERATED FETAL GROWTH

Accelerated fetal growth is generally referred to as macrosomia or large for GA (LGA). Although they are not mutually exclusive of one another, macrosomia and LGA are defined differently. LGA was originally defined by neonatologists as a way of defining newborns who had birthweights that were greater than 90th percentile for a given GA. Obstetricians

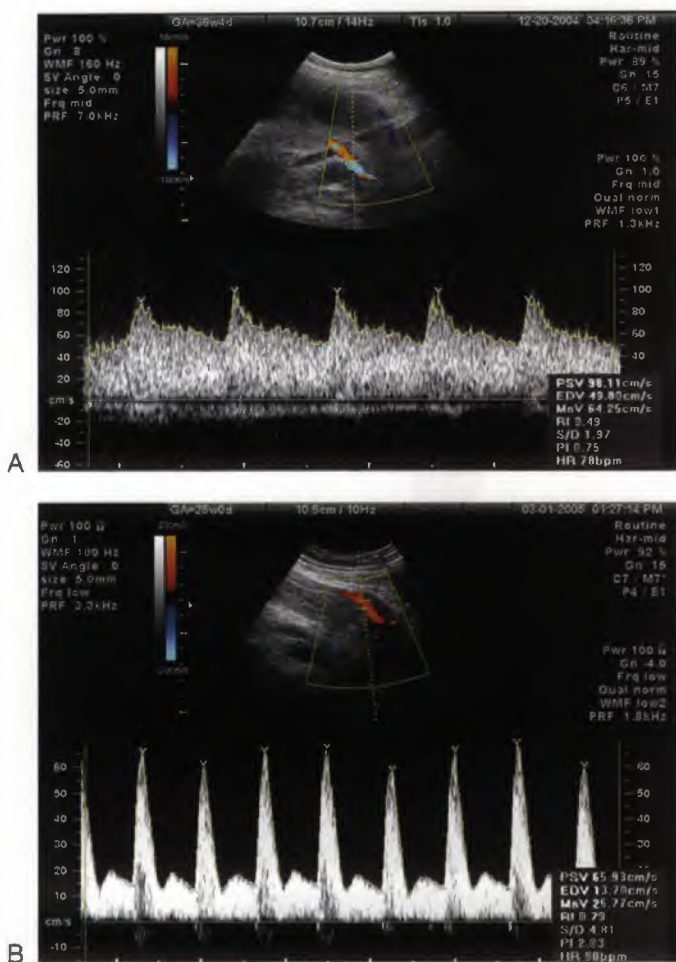

FIGURE 7-28. A. Normal uterine artery waveform. Note the lush flow during both maternal systole and diastole, and thus the low S/D ratio (< 2). B. Abnormal uterine artery waveform. Note the diastolic notch and the relative reduction in diastolic flow (and thus, an abnormally elevated S/D ratio). (A and B Courtesy Wayne Persutte, PhD, RDMS, Platte River Perinatal Clinic, University of Colorado Health Sciences Center, Denver, CO.)

and perinatologists subsequently moved the use of LGA back in time into the prenatal period to describe the fetus who had an EFW greater than 90th percentile for GA. In contrast, macrosomia, refers to fetal growth as depicted by EFW that has surpassed a specific weight (either 4000 g or 4500 g) regardless of the GA. Many obstetricians define macrosomia as an EFW greater than 4000 g because this identifies a group at greater risk for maternal and fetal injury than fetuses weighing less than 4000 g. Although the ACOG supports either definition, they also cite the particularly sharply increased incidence of maternal and fetal injury with fetal weights greater than 4500 g.¹⁶⁰ From a clinical viewpoint, the important issue is that a clinician be consistent with the definition used personally in practice. The associated factors or causes of LGA or macrosomia include maternal obesity, pregestational and gestational diabetes, erythroblastosis fetalis and other causes of hydrops fetalis, prior macrosomic infant, and postdates pregnancy (>42 weeks). There are also nonchromosomal genetic syndromes (e.g., Beckwith-Weidemann syndrome) that make up a very small percentage of macrosomic infants that are seen clinically.

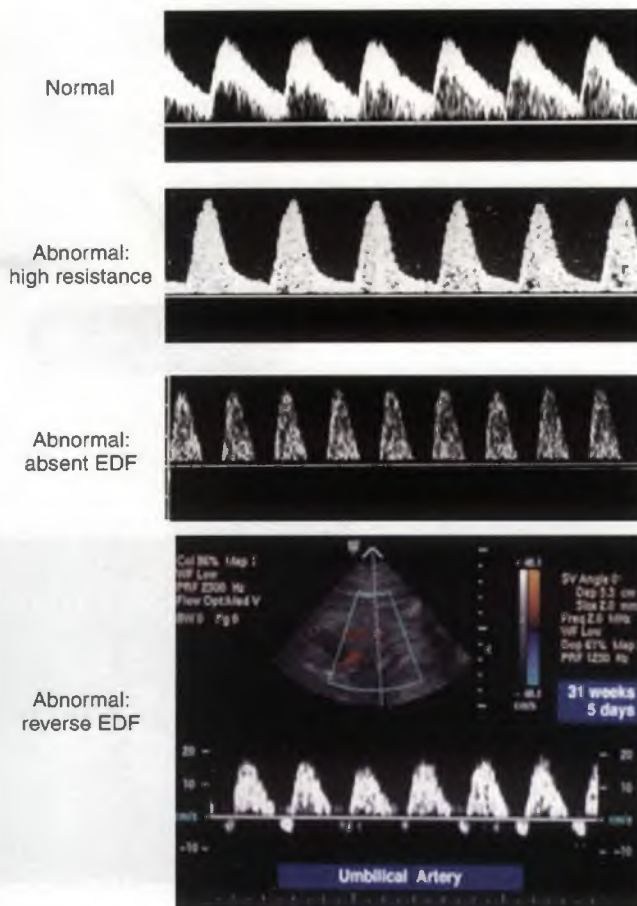

FIGURE 7-29. Appearance of umbilical artery waveform with progression of worsening uteroplacental insufficiency. This increase seen across gestation in diastolic flow is a result of the processes of branching angiogenesis at the end of the first trimester and beginning of the second, and nonbranching angiogenesis that starts at the end of the second trimester.

It is important to attempt to define the cause of a given LGA fetus antenatally, especially if the cause is gestational diabetes because intervention with either hypoglycemic agents or insulin can affect outcomes. However, the primary clinical concern with macrosomia is the risk of adverse events surrounding delivery, and this is particularly important clinically given that macrosomia complicates approximately 10% of all live births.¹⁶¹ Ten percent is a sizable number when one considers that there are nearly 4 million births per year in the United States alone. Table 7-15 shows recent birthweight percentiles from 3.8 million deliveries occurring in 1991. Maternal adverse events include increased risks of postpartum hemorrhage, sphincter and rectal lacerations, and a twofold increased risk of cesarean delivery.¹⁵⁶⁻¹⁶³ Although maternal injury is important, fetal injury associated with shoulder dystocia accounts for a significant percentage of obstetric litigation. Fetal trauma may result in brachial plexus injury (C5 and C6 injury—Erb-Duchenne palsy), clavicular fracture, humeral fracture, hypoxic-ischemic encephalopathy, and death.¹⁶⁴ Because cesarean section can obviate the adverse events associated with macrosomia,

FIGURE 7-30. Circle of Willis. The Circle of Willis is supplied by the internal carotid and the vertebral arteries. It is made up by communicating vessels between the posterior, middle and anterior cerebral arteries. The middle cerebral artery (MCA) carries 80% of cerebral blood flow. Of the cerebral vessels, the MCA is the most accessible to ultrasound. ACA, anterior cerebral artery; BA, basilar artery, IC, internal carotid artery; PCA, posterior cerebral artery; SCA, superior cerebellar artery. (From Veille JC, Hanson R, Tatum K, et al: *Longitudinal quantitation of MCA blood flow in normal human fetuses. AJOG* 169:1393, 1993.)

concerted efforts have been made to predict macrosomia antenatally in hopes of identifying at-risk pregnancies.

Available tools for diagnosing macrosomia antenatally include assessment of maternal risk factors, clinical examination of uterine size (fundal height), and ultrasound. However, prenatal diagnosis of macrosomia is often difficult even with the use of ultrasound given that 40% of these fetuses have no identifiable risk factors at birth.¹⁶⁵ The EFW is obtained from an equation that contains several fetal variables obtained from two-dimensional measurements with the AC, in general, being most heavily weighted in the formulas. Published studies to date have not been able to demonstrate the superiority of ultrasound based fetal weights over that of clinical estimates. One study comparing fetal weights derived by ultrasound, Leopold maneuvers, and maternal perception found no statistical differences between the three groups. Curiously, the maternal perception of fetal weight was closer to the actual weights than the other two methods.¹⁶⁷⁻¹⁶⁹ Although a variety of fetal biometric parameters, indices, and ratios have been reported in an attempt to identify the macrosomic fetus, the best endpoint to use for the diagnosis of fetal macrosomia is the EFW, for which the accuracy is at best marginal. In nondiabetic patients, ultrasound measurements used to diagnose macrosomia carry a sensitivity up to 50%, a specificity of 99%, a positive predictive value of up to 44%, and a negative predictive value of 60% to 99%.¹⁷⁰⁻¹⁷⁵ In spite of more than 45 published formulas for EFW, accurate diagnosis of macrosomia requires waiting until birth and

weighing the newborn. Benacerraf et al have shown that even when birthweight is greater than 4500 g, only half of these fetuses fell within 10% of the EFW by ultrasound. Furthermore, EFWs need to exceed 4800 g in order for 50% of the fetuses to reach the 4500 g macrosomic cutoff, or greater than 4700 g for 50% to be above 4000 g.^{170,176,177}

Increased amniotic fluid volume can be seen in the large for GA and macrosomic fetus. The prevalence of polyhydramnios is higher in pregnancies of nondiabetic mothers with a LGA fetus than with a non-LGA fetus.¹⁷⁸ When the EFW is above the 90th percentile, LGA can be diagnosed with greater confidence in the presence of polyhydramnios.

Although the incidence of shoulder dystocia in the general population has been reported to be up to 2.8%, the rate increases up to 9% in pregnancies complicated by gestational or preexisting diabetes.¹⁷⁹ The excess glycogen deposition that occurs in the diabetic pregnancy results in an overall larger torso with development of body to head disproportion. This leads to a larger than average shoulder girth with an increased risk for shoulder dystocia. The risk of shoulder dystocia is further increased when there is a macrosomic fetus in the diabetic patient. The rate of shoulder dystocia increases up to 23% with an EFW greater than 4000 g and up to 50% with an EFW greater than 4500 g. This has led obstetricians to perform elective cesarean sections for such patients to avoid shoulder dystocia. However, the risk of shoulder dystocia remains elevated in diabetic patients whose fetus may still be below 4000 g. This has led individuals to investigate the utility of formulas using ultrasound parameters in predicting shoulder dystocia.¹⁸⁰⁻¹⁸² In the study by Cohen et al., 415 diabetic patients with an EFW between 3800 and 4200 g resulted in the occurrence of 31 shoulder dystocias. Using the formula of abdominal diameter (calculated as AC divided by 3.14) minus the BPD, if the value obtained was greater than 2.6, then there was a 30% shoulder dystocia rate and if the value was less than 2.6, then there was a 0% rate of shoulder dystocia. As such, the negative predictive value appears most useful. However, it must be kept in mind that the overall number of patients in this study and in others trying to predict shoulder dystocia, remain small.

In summary, birthweight assessment remains the only accurate way to diagnose the macrosomic infant. It is unfortunate that ultrasound remains unreliable for the prenatal detection of macrosomia. However, there may be some promise with the use of formulas such as that by Cohen et al.¹⁸⁰ for predicting shoulder dystocia in the diabetic patient. With the advent of three-dimensional ultrasound, perhaps volumetric measures will provide greater diagnostic accuracy for the prenatal diagnosis of macrosomia.

INTERVAL FETAL GROWTH AND GROWTH POTENTIAL

Once fetal age has been firmly established, the determination of fetal growth becomes necessary in the high-risk pregnancy. As discussed earlier, various conditions and disorders predispose the fetus to poor or accelerated fetal growth. These conditions may be pre-existing in the mother (e.g., chronic hypertension, collagen vascular diseases, and APAS) or may be gestational (e.g., gestational diabetes, multiple pregnancy, and velamentous cord insertion), thereby marking

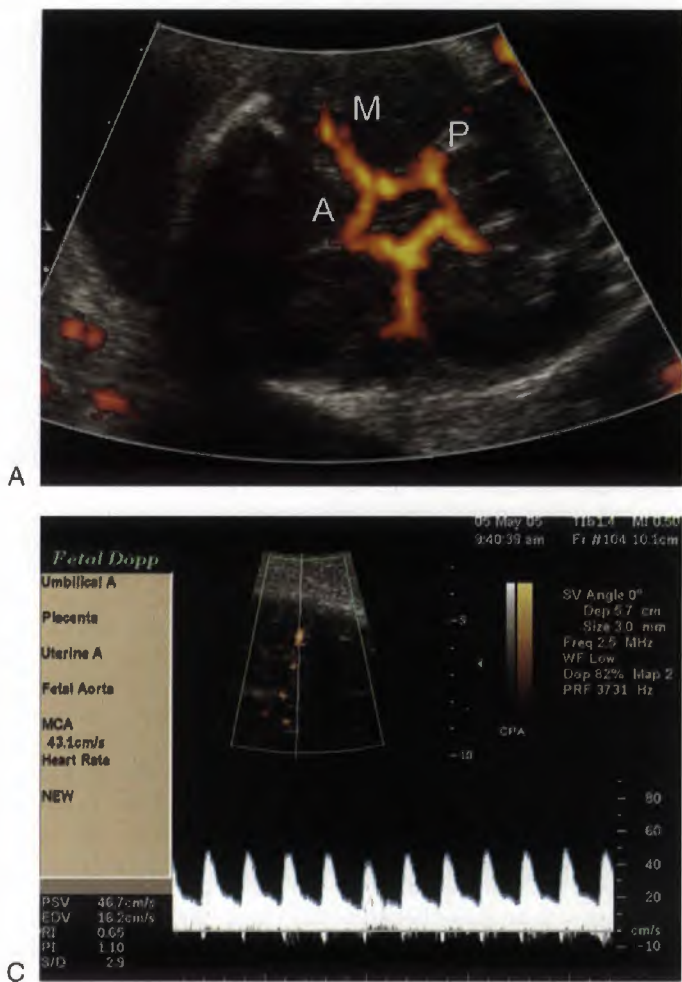

FIGURE 7-31. A. Middle cerebral artery Doppler ultrasound. A, Anterior cerebral artery (ACA); M, middle cerebral artery (MCA); P, posterior cerebral artery (PCA). B. Middle cerebral artery Doppler ultrasound. Normal. Note the relatively low end-diastolic velocity, yielding a high S/D ratio. C. Middle cerebral artery Doppler ultrasound. In uteroplacental insufficiency, the middle cerebral artery end diastolic velocity is increased, and thus the MCA is characterized by a lower S/D ratio than compared to normal. This finding is often referred to as “brain sparing.” (B and C Courtesy Wayne Persutte, PhD, RDMS, Platte River Perinatal Clinic, University of Colorado Health Sciences Center, Denver, CO.)

FIGURE 7-32. A typical and abnormal ductus venosus Doppler waveform. The central venous system has characteristic waveforms that reflect central venous pressure. These waveforms consist of 3 phases related to cardiac activity (refer to text). Note the reversed a wave in the abnormal waveform. S, systolic; D, diastolic; a, atrial kick. (From Hecher K, Campbell S: Characteristics of fetal venous blood flow under normal circumstances and during fetal demise. *Ultrasound Obstet Gynecol* 7:68, 1996.)

such a pregnancy as being “high risk.” In these circumstances, interval growth assessment becomes a necessary part of fetal surveillance. Inherent in determining interval growth is the necessity for at least two temporally spaced measurements of biometric parameters. Given that growth is continuous rather than sporadic, and that the identification of growth is limited by the technical capability of the ultrasound equipment used, the recommended interval between ultrasound evaluations of fetal growth is three weeks, because shorter intervals increase the likelihood of a false-positive diagnosis of abnormal growth.^{183,184}

Traditional methods of determining abnormal growth involve sequential measurements of interval growth and comparison of these biometric parameters to GA based population tables as described above (see Tables 7-4 and 7-7 to 7-9). One can also use these biometric parameters to estimate a fetal weight, and use this in comparison with population-based fetal weight for any particular GA (see earlier, and Table 7-15). Growth curve standards derived from cross-sectional data depend upon the assumption that the sample studied is composed of a single group of normally

growing fetuses having similar growth trajectories that show only random variation, and that the group is applicable to the clinical situation at hand. Using traditional cross-sectional methods, one assumes that a fetus initially measuring at the 15th percentile, that on remeasurement several weeks later, drops below the 10th percentile is a fetus at significant risk as opposed to one that remains at the 15th percentile, and

hence, is on its individual growth curve (Fig. 7-35). But what is one to do with the fetus that is determined to be anatomically and genetically normal but upon initial measurement is below the 10th percentile, for example, at the 8th percentile, and remains at the 8th percentile at several subsequent measurements performed at appropriate time intervals (Fig. 7-36)? If both parents are “small,” then one may assume that such a fetus is also constitutionally small, and the fact that the fetus maintains its growth percentile is reassuring. However, if the parents are both average or “large” in size, then even though such a fetus maintains its growth percentile, one may still have heightened concern for IUGR, and should initiate Doppler velocimetry assessment. One other circumstance to consider is the scenario in which, during fetal growth surveillance of a high risk pregnancy, one detects a fetus that is falling off its growth curve (i.e., crossing centiles) but remains above the 10th percentile at all times (e.g., goes from 50th percentile to 25th to the 15th percentile). Such a situation should also raise the level of concern, and such a fetus should heighten the frequency of surveillance, including the initiation of amniotic fluid assessment, regular CTG, and if appropriate, biophysical profiling. Doppler velocimetry has not been adequately

NORMAL RANGE OF FETAL WEIGHT

FIGURE 7-35. Fetal growth curve showing abnormal interval growth with crossing of centiles. Green line represents the mean, purple means 90th percentile, and blue means 10th percentile.

NORMAL RANGE OF FETAL WEIGHT

FIGURE 7-36. Fetal growth curve showing a constitutionally small fetus. The fetal weight at each gestational age is maintaining its own growth curve despite being less than the 10th percentile. Green line represents the mean, purple 90th percentile, and blue 10th percentile.

validated in fetuses that measure above the 10th percentile, and so may be used only with significant caution. In essence, a very small proportion of fetuses that measure above the 10th percentile for GA, and a sizable proportion of fetuses that measure below the 10th percentile, are truly pathologically growth-restricted (as a corollary, a similar case can

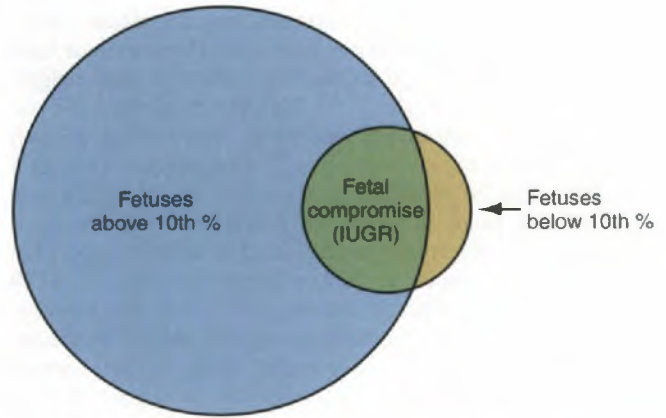

FIGURE 7-37. A very small proportion of fetuses that measure above the 10th percentile for gestational age, and a sizable proportion of fetuses that measure below the 10th percentile, are truly pathologically growth restricted (corresponding to the area demarcated "fetal compromise").

be made at the other end of the spectrum, when one is concerned with the large fetus). Figure 7-37 illustrates this graphically. Thus, the traditional method of identifying the potentially growth-restricted fetus may miss abnormally growing fetuses that are above the 10th percentile, and may falsely heighten concern regarding normally growing fetuses that happen to be below the 10th percentile.

Because of this limitation of population-based reference ranges to assess fetal growth, individualized growth models have been proposed by several investigators.¹⁸⁵⁻¹⁸⁷ By defining a growth curve specific to a particular fetus, the obvious limitations of population-based growth charts can be eliminated. Two different methods have been described to generate individualized growth curves (IGCs). The first was developed by Rossavik, and is based on the premise that in a normal fetus, normal growth before 28 weeks' GA predicts the subsequent normal growth pattern for that particular fetus; thus, each individual fetus acts as its own control. Two scans are obtained between 14 and 27 weeks' GA, separated by an interval of at least 5 weeks, and are sufficient to generate an IGC for that particular fetus. Growth curves can be generated for each ultrasound parameter (e.g., HC, AC, FL) and for EFW.^{186,188-192} A third and later scan is then necessary to determine whether the fetus is following its particular IGC. An extension of this method employing three-dimensional ultrasound has been proposed using fractional thigh volume measurements.¹⁹³ The premise of this technique is that human newborns have 15% body fat, which accounts for 46% of variance in birthweight. A significant correlation exists between fetal/neonatal limb volume and birthweight, so three-dimensional ultrasound scans of fractional thigh volume at at least two time points before 28 weeks' GA can be used to establish an individualized growth curve for a particular fetus. The Rossavik method has even been described for fetuses that are a part of a twin gestation.¹⁹³ The Rossavik method is limited by its dependency upon normal second trimester growth, and is useful in circumstances when a growth abnormality, if it is to occur, does so in the third trimester.

Because this approach is cumbersome in clinical practice by requiring three sets of scans, other models have been

developed that account for variables that contribute to the majority of the variance to newborn size. These include fetal gender, maternal weight at the first antenatal visit, height, ethnic group, and parity.^{187,194} Gardosi et al describe the generation of customized antenatal longitudinal growth charts based on these parameters.¹⁸⁷ The estimated size of a fetus can thus be projected at term and estimated for any specific time point in gestation. Deviation from this projected growth pattern can be identified by serial sonographic biometric measurements. In a retrospective study of 4179 pregnancies, with adjusted centiles, 28% of babies conventionally designated SGA (<10th percentile) and 22% of those designated LGA (>90th percentile) were within normal limits for the pregnancy.¹⁸⁷ Conversely, 24% and 26% of babies identified as small or large, respectively, with adjusted centiles were missed by conventional unadjusted centile assessment. Using these customized charts, babies designated as SGA had higher perinatal morbidity and mortality than normally grown babies and than those defined as SGA by traditional cross-sectional, population-based curves.^{195,196}

Although theoretically sound, the widespread use of individualized growth curves has not yet occurred, in part due to inadequate large-scale prospective evidence for improved perinatal outcomes and favorable cost-benefit ratios. Undoubtedly, such data will be forthcoming in the not-too-distant future. A number of questions remain with regard to IGCs. These questions will need to be thoroughly addressed before widespread adoption and replacement of traditional methods can become possible:

1. Should all fetuses undergo individualized or customized growth curve development?
2. How much of a deviation from an individualized growth curve is important for any given fetus?
3. When should Doppler ultrasound surveillance be initiated?
4. What of multiple gestations, especially those prone to non-UPI causes of IUGR, for example, monochorionic gestations?
5. Do there need to be gender- or ethnicity-specific modifications to the Rossavik formula for development of a more clinically relevant individualized growth curve (i.e., is there a need to integrate the Gardosi and Rossavik models)?

CONCLUSIONS

1. Biometric estimates of age infer age from size and are, therefore, less accurate as pregnancy progresses because of biologic variability in fetal size and associated measurement errors. This increase in variability is relatively constant at 8% when expressed as a percentage of the estimate.
2. If age is known unequivocally by conceptional data, the age is established (menstrual age = conceptional age + 14 days) and should usually not be changed based on ultrasound measurements.
3. If a patient's menstrual dates are in question or not known, the patient should be seen for biometric dating early in pregnancy. The highest accuracy is obtained in the first trimester by CRL (2 SD = 8% of the estimate). However, little is lost in dating accuracy if one waits until the uterine size suggests 18 weeks and a large amount of ancillary information is gained. For example, if a CRL obtained at 6 to 9 weeks' GA yields an EDD that is greater than 5 days off of that generated by conceptional dating (i.e., use of LMP), then one should defer assignment of the EDD and GA to the ultrasound. Subsequent ultrasound measurements become an index of growth rather than of age.
4. Beyond the first trimester of pregnancy, age estimates should be based on the multiple parameter technique, preferably before 20 weeks. The optimal combination of parameters is based on HC and FL. For example, in circumstances in which first trimester ultrasound dating is unavailable, and if biometric parameters that are measured before 20 weeks' GA yield an EDD that is greater than 7 days off of that generated by conceptional dating, then one should defer assignment of the EDD and GA to the ultrasound. Subsequent ultrasound measurements become an index of growth rather than of age.
5. There is a point in pregnancy after which sole reliance on biometric parameters to date the pregnancy is invalid. After that point, the only information that can be reliably obtained from sonograms is the fetal weight and, by a follow-up study, whether the interval growth is normal. In this setting, the appearance time of the epiphyseal ossification centers (as well as other discussed maturation markers) can be used as an internal check on the accuracy of the biometric estimate of menstrual age.
6. SGA and IUGR have been confusingly used interchangeably. Although IUGR has been defined using a number of different criteria, including that for SGA, it is now generally a term reserved for the clinical circumstance of a fetus that is underachieving its growth potential. A number of criteria have been used to capture a fetal population most at risk for abnormal growth. Among those used to ascribe IUGR, the most common is an EFW less than the 10th percentile for GA.
7. The fetal response to UPI insufficiency can be categorized into early and late cardiovascular adaptations that are relevant to sonographic assessment of fetal status. Early adaptation is characterized by changes in blood flow to favor nutrient and oxygen distribution to essential organs, especially the brain. Late changes occur with progressive UPI and increasing placental resistance with development of oligohydramnios. The final stage is global myocardial dysfunction and dilatation. At this juncture, fetal acidosis is an ominous clinical finding. Holosystolic tricuspid insufficiency and spontaneous fetal heart rate decelerations herald impending death.
8. Once a fetus is identified to be at-risk by an ultrasound-derived weight estimate below the 10th percentile for GA, and it is clear that UPI is the primary pathologic culprit, fetal surveillance should be initiated. Traditional methods have included non-stress testing, amniotic fluid measurement, and biophysical profiling. It is now clear that abnormalities in findings using these modalities are relatively late in occurrence, with fetal acidosis often being already present by the time of evaluation. Placental insufficiency can be detected noninvasively with Doppler ultrasound, allowing one to identify a preacidotic state in an IUGR fetus. This is essential to preventing adverse

fetal outcomes because once acidosis sets in, permanent fetal injury and intrauterine demise may soon follow.

9. Doppler interrogation of the fetal arterial system provides an indirect assessment of placental resistance, whereas the fetal venous system provides an assessment of the fetal cardiac function. By evaluating both fetal arterial and venous circulations, as well as the maternal uterine arteries, one can gauge the progression of UPI and IUGR well in advance of the development of oligohydramnios and fetal heart rate abnormalities.
10. The earliest stages of placental pathology can be detected by the presence of diastolic notching in the maternal uterine arteries at 12 to 14 weeks' gestation, and when this persists beyond 24 weeks, it is highly reflective of abnormal placental resistance. With progressive worsening of UPI, the umbilical artery S/D ratio will become increasingly larger until it can no longer be calculated when there is AEDV. Reduced umbilical artery EDV can be seen when as little as 30% of the villous vessels are abnormal; with 70% abnormality, there can be complete absence or even reversal of umbilical artery EDV.
11. In early stages of UPI, fetal adaptive mechanisms lead to increased left ventricular output and decreased cerebral resistance. In UPI, the MCA EDV is increased, and thus, the MCA is characterized by a lower S/D ratio than normal. This finding is often referred to as "brain sparing." These early changes in fetal blood flow, with elevated umbilical artery S/D ratio and a reduced MCA S/D ratio are seen in fetuses that are at risk for developing hypoxemia, but are typically not associated with acidosis.
12. When there is abnormality in the umbilical artery waveform, and CTG remains normal, only 5% of fetuses have hypoxemia/acidemia. When there is abnormality in both the umbilical artery Doppler velocimetry and CTG testing, 60% of fetuses can be found to have hypoxemia/acidemia by PUBS. Thus, the ideal time to deliver the IUGR fetus is before one sees abnormalities in the fetal heart rate tracing and only in the umbilical and venous circulations.
13. The scientific literature shows that Doppler ultrasound reduces not only mortality, but also morbidity in the setting of IUGR. The finding of AEDV or REDV marks a pregnancy that is at an 80-fold increased risk for perinatal mortality, and when intervention is appropriately timed, a roughly 40% reduction in mortality can be achieved. With the addition of venous Doppler assessment, the very preterm severely growth-restricted fetus can be better managed before permanent fetal injury or death occurs.
14. Macrosomia and LGA are defined differently. LGA describes the fetus that has an EFW greater than 90th percentile for GA. In contrast, macrosomia, refers to fetal growth as depicted by EFW that has surpassed a specific weight regardless of the GA. The ACOG supports either 4000 or 4500 g as the criterion for macrosomia, and the organization cites the particularly sharply increased incidence of maternal and fetal injury with fetal weights greater than 4500 g.
15. The primary clinical concern with macrosomia is the risk of adverse events surrounding delivery. This is particularly important clinically given that macrosomia complicates approximately 10% of all live births. Maternal adverse events include increased risks of postpartum hemorrhage, sphincter and rectal lacerations, and a 2-fold increased risk of cesarean delivery. Fetal trauma associated with shoulder dystocia may result in brachial plexus injury (C5 and C6 injury - Erb-Duchenne Palsy), clavicular fracture, humeral fracture, hypoxic-ischemic encephalopathy and death.
16. Inherent in determining interval growth is the necessity for at least two temporally spaced measurements of biometric parameters. Given that growth is continuous rather than sporadic, and that the identification of growth is limited by the technical capability of the ultrasound equipment used, the recommended interval between ultrasound evaluations of fetal growth is 3 weeks, because shorter intervals increase the likelihood of a false-positive diagnosis of abnormal growth.

Intrapartum Use of Ultrasound in Twin Gestations

Conclusion

INTRODUCTION

Ultrasound has revolutionized the care of women carrying twins. It begins with the diagnosis of twins and continues through the determination of chorionicity, cervical length measurement in predicting preterm delivery of twins, ultrasound screening for structural abnormalities and aneuploidy, management of complications unique to twins, and the intrapartum role of ultrasound in vaginal twin deliveries.¹⁻³ The problems found in twins are also seen in the increasing number of higher order multiples born in the United States and throughout the world.

Upon learning of a twin gestation, most parents are struck with joy and awe. The obstetrician and sonographic practitioner, however, are faced with numerous problems including prematurity, decreased survival, impaired growth, increased structural abnormalities, and aneuploidy.¹⁻⁶ Approximately 14% to 25% of twins are growth restricted and 25% require admission to neonatal intensive care units.^{7,8} The risk of cerebral palsy is four times greater for twins than singletons, and 17 times greater for triplets than singletons.^{9,10} The fetal death rate for twins of 15.5/1000 live births is almost four times higher than that of singletons, which is 4.3/1000 live births.¹¹ The likelihood of not surviving the first year of life is 7-fold greater for twins than for singletons.^{12,13} Twin-specific problems include twin-to-twin

transfusion syndrome (TTTS), monochorionic-monoamniotic twin placentation and variations of conjoined twins. Management decisions for one twin must consider the impact on the co-twin.^{14,15} Maternal complications such as preeclampsia and diabetes are two to three times more common in twin gestations than in singletons.^{16,17} Despite these risks, twins generally result in a successful pregnancy for both the parents and health care providers.

Twin gestations accounted for 3.2% of all live births in the United States in 2003.⁴ Multiple gestations have increased 1.33-fold in the United States over the past decade from 75,858 of 3,612,258 live births (1/48) in 1980 to 128,665 of 4,089,950 live births (1/31) in 2003. When considered as the proportion of pregnancies rather than live births (Fig. 8-1), twins comprised 1/94 pregnancies in 1980 and 1/62 in 2003. Figure 8-2 tracks the changes in the number of twin, triplet, and quadruplet live births in the United States from 1990 to 2003. All three categories of multiples increased from 1990 to 1998. From 1998 to 2003, however, the number of quadruplets declined, triplets leveled off, and the rate of increase in twins has slowed. Most multiple pregnancies are twins. They comprised 96.9% of all multiples in 1990, but this percentage decreased steadily to 95.7% in 2000 before increasing to 96% in 2001.

FIGURE 8-1. Twin and triplet pregnancies (expressed as 1/x) in the United States from 1990 to 2003. (From *Nativity Data Set: National Center for Health Statistics: Centers for Disease Control and Prevention, Atlanta CD-ROM 1997-2002; Series 21 11,12,14,15; and Yinon Y, Yagel S, Tepperberg-Dikawa M, et al: Prenatal diagnosis and outcome of congenital cytomegalovirus infection in twin pregnancies. Br J Obstet Gynaecol 113:295, 2006.*)

FIGURE 8-2. The number of twin, triplet, and quadruplet live births in the United States from 1990 to 2003.

ETIOLOGY OF TWINS

Twin embryology differs from that of singletons in that there are two embryos with one or two placentas. Twins are either monozygotic or dizygotic depending on the number of eggs fertilized at conception (Fig. 8-3).² Monozygotic twins, often called “identical” by nonmedical personnel, result from one egg being fertilized by one sperm that divides into two embryos within two to 14 days after fertilization. These twins have the same genetic makeup and are contemporaneous “clones” of one another. The rate of monozygotic twinning is constant throughout the world at approximately 1/250 pregnancies.² The timing of cleavage in monozygotic twinning determines the type of placentation and the like-

lihood of complications. Figure 8-4 is based on the classic report by Benirshke and Kim.² It depicts the first 17 days after ovulation in a monozygotic twin gestation and demonstrates three types of placentation: dichorionic-diamniotic (about 1/3, occurring on day 0-3), monochorionic-diamniotic (about 2/3, occurring on day 4-8), and monochorionic-monoamniotic (< 1%, occurring on day 9-12) that may result from this type of twinning (Table 8-1). Although the incidence of monozygotic twinning has been relatively constant throughout the world in spontaneous twin gestations (Table 8-2), it may be increased by assisted reproductive technologies, particularly those methods that alter the zona pellucida around the time of fertilization, or where there is

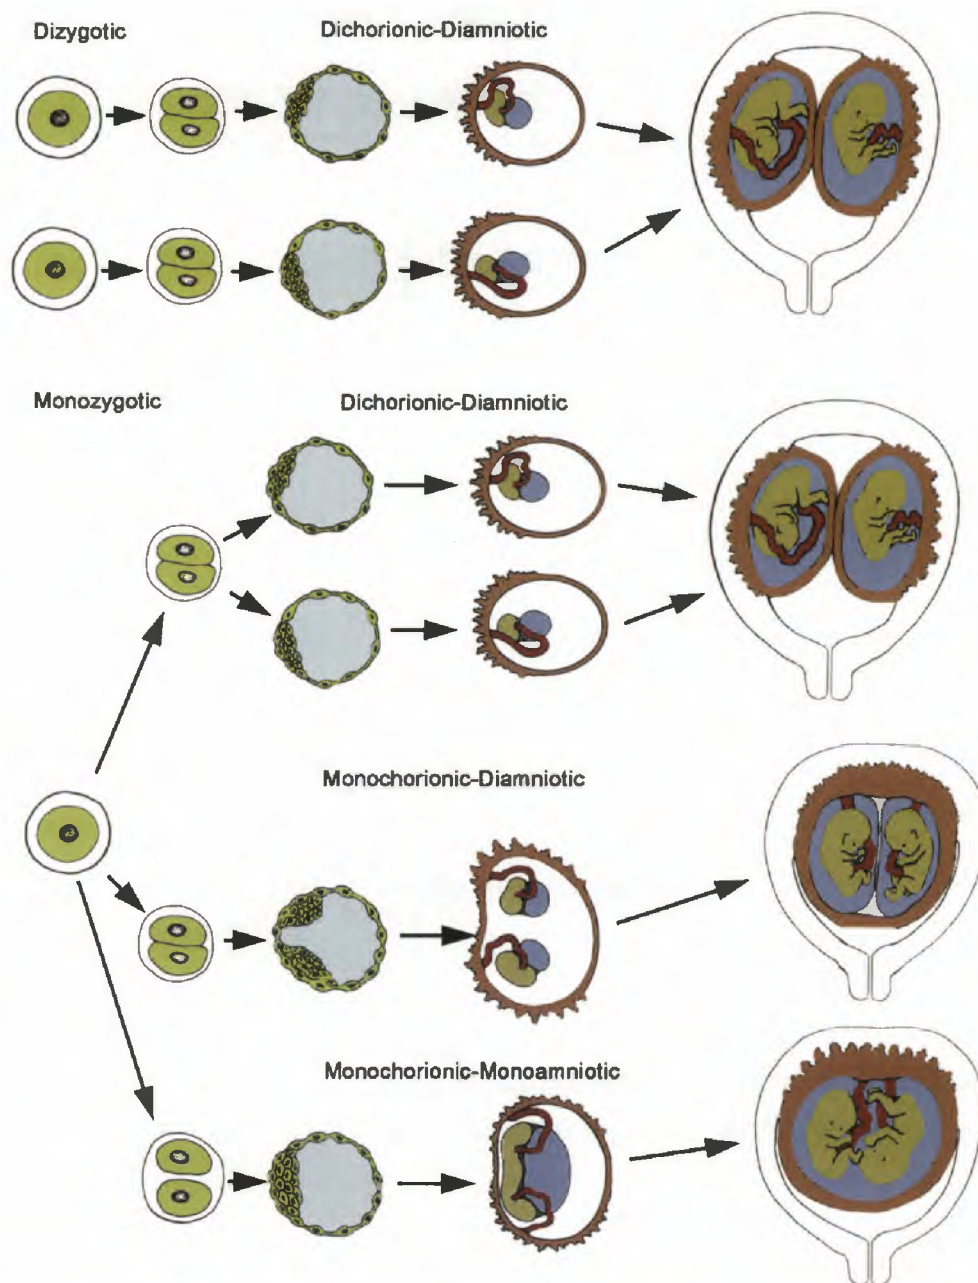

FIGURE 8-3. Diagram of the development and placentation of dizygotic and monozygotic twins. The degree to which monozygotic twins share placentas, chorions, and amnions depends on the stage of development at which splitting occurs. (Modified from Larsen WJ: *Human Embryology*, 2nd ed. New York, Churchill Livingstone, 1997.)

delayed blastocyst implantation.^{18,19} Dizygotic twinning varies by race, geographic area, maternal age, and the availability of assisted reproductive technologies.^{20,21} In the 1980s, the highest rate of dizygotic twinning was seen in an area of Nigeria, where it was 49/1000 live births. The lowest rate was found in Japan at 1.3/1000 live births (see Table 8-2).²² This increased rate in Nigerian women is due to a higher baseline level of follicle-stimulating hormone.²⁰ The maternal age peak for spontaneous multiples is 37 years of age.²¹

With the greater access to assisted reproductive technologies, the geographic differences in dizygotic twinning have

blurred in developed countries. To assess the impact of assisted reproductive technologies on multiple births, Bardis et al²³ reported on a survey of all deliveries for 1 week of 2003 in the United Kingdom. Of the 6913 deliveries, there were 100 twins (1.4%) and one triplet gestation (0.01%). Assisted reproductive technology was used to achieve 1.9% of all pregnancies delivered. The multiple pregnancy rate in the assisted reproductive technology group was 13.5% compared with 1.2% in spontaneous conceptions. Because of the greater morbidity and mortality seen with multiple gestations, fertility clinics have reduced the number of embryos trans-

MONOZYGOTIC TWINNING

FIGURE 8-4. The timing of monozygotic twinning demonstrating the impact of the day cleavage occurs on placentation and complications, that is, monochorionic monoamniotic placenta or conjoined twins. (From Benirschke K: *Multiple pregnancy (First of two parts)*. *N Engl J Med* 288:1276, 1973.)

Chorion	Amnion	Time to Division (Days)	Frequency
Dichorionic	Diamniotic	0-3	25%
Monochorionic	Diamniotic	4-8	75%
Monochorionic	Monoamniotic	9-12	~1%
Monochorionic	Monoamniotic (conjoined twins)	13-15	Rare

Geographic Area	Monozygotic	Dizygotic
Nigeria	5.0	49.0
United States		
Black	4.7	11.1
White	4.2	7.1
England and Wales	3.5	8.8
Japan	3.0	1.8

Adapted from MacGillivray I: Epidemiology of twin pregnancy. *Semin Perinatol* 10:4, 1986.

ferred for each cycle. This has decreased the rate of increase in the number of high order multiples. Figures 8-1 and 8-2 show a flattening of the curve for triplets in the United States from 1998 to 2003.⁴ Despite the lower number of embryos transferred in each cycle, the likelihood of a successful pregnancy has not decreased. Single embryo transfer is becoming more generally accepted. Crintini et al²⁴ reported on 107 infertility patients, of whom 41 had single embryo transfers and 66 had two blastocysts transferred. There was no difference in the implantation rate in 238 cycles in which one or two embryos were transferred (76% versus 66%, respectively) or in the pregnancy rate (76% versus 79%). Twinning rates, however, (3% versus 62%, respectively) differed dramatically.

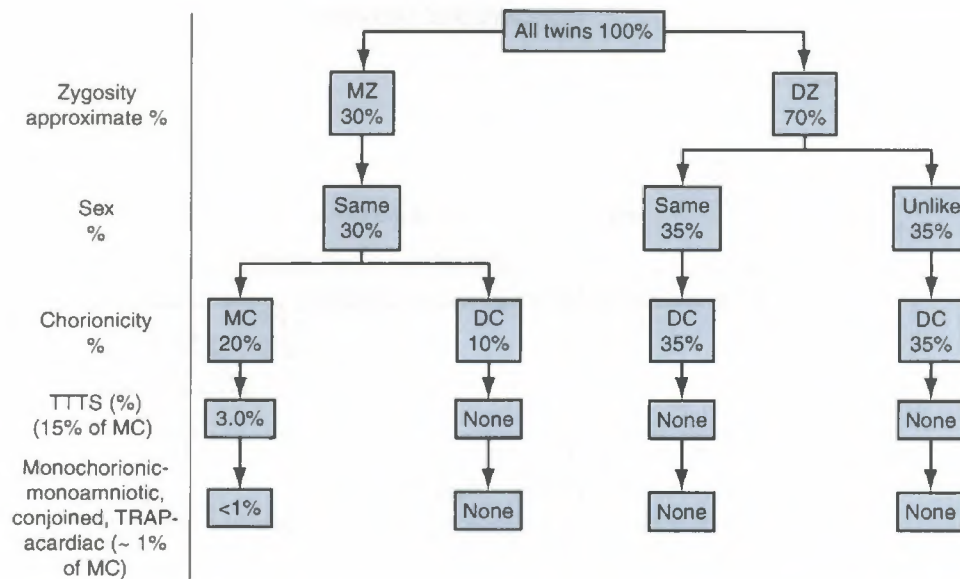

Dizygotic twins, often called "fraternal" by nonmedical personnel, result from the fertilization of two eggs by two sperm (see Figs. 8-3 and 8-5). The genetic makeup of these twins differs from one another. Dizygotic twinning varies by race, advancing maternal age, geography, season, ethnic origin, and increasing parity.^{21,25} The most dramatic increases have been seen with the use of assisted reproductive technologies.¹⁹ With very rare exceptions, dizygotic twins always have a dichorionic-diamniotic placenta, but monozygotic twins may have either a dichorionic-diamniotic or monochorionic-diamniotic placenta depending on the

timing of the twinning event (see Fig. 8-4).²⁶ The type of placentation is the most important predictor of the pregnancy-related complications in twin gestations. Chorionicity, not zygosity, determines the likelihood of many twin-related complications.^{27,28} A primary goal when performing an ultrasound in a patient with a multiple pregnancy, is to determine chorionicity.

DIAGNOSIS OF TWINS

Ultrasound is crucial for the diagnosis of twins. Before the availability of prenatal ultrasound, up to 50% of twin gestations were first discovered at the time of delivery. A clinical suspicion of multiple gestation should be raised when a patient has a larger than expected uterine size, if a patient's pregnancy associated symptoms, for example, hyperemesis gravidarum, seem excessive, or if she became pregnant using assisted reproductive technologies.^{29,30}

Every obstetric ultrasound should begin with a complete imaging sweep of the uterus. We always start in the suprapubic area and scan cephalad in a transverse axial plane until we reach the top of the uterine fundus. This sweep images the entire contents of the uterus and allows the sonographer to count the number of embryos or fetuses, determine their presentation and lie and document the situs,

MZ monozygous, DZ dizygous, MC monochorionic, DC dichorionic, TTTS twin to twin transfusion syndrome, TRAP twin reversed arterial perfusion.

FIGURE 8-5. Approximate distribution of monozygous and dizygous twinning with chorionicity and complications of monozygous twins as a percent of all twins. This represents the approximate distribution of twin gestations in the United States by zygosity and chorionicity. Both monochorionic and dichorionic twin gestations are at greater risk for maternal and fetal/neonatal complications (such as preeclampsia, diabetes, structural fetal abnormalities, aneuploidy, growth restriction) when compared with singleton gestations. Complications found only in monochorionic twin gestations include twin-to-twin transfusion (TTTS), monochorionic-monoamniotic twins, twin reversed arterial perfusion (TRAP) acardiac twins, conjoined twins, and fetus in fetu.

or left and right sides, of each fetus. This should be routinely done on every obstetric ultrasound so that multiple pregnancies and situs abnormalities are not missed.

Important sonographic details to note in the first trimester include the number of gestational sacs, the location of the placenta or placentas, the presence and characteristics of the dividing membrane or membranes, amniotic fluid status, the number of yolk sacs and the fetal heart rates.^{3,5,31} This information helps to determine chorionicity, which is essential for the provider when counseling patients regarding potential complications.³²

“VANISHING” TWINS

In 1986, Landy et al³³ reported on 1000 first trimester pregnancies with an incidence of twinning of just over 3%. They found approximately 20% of these twin gestations resulted in singleton live births, with or without vaginal bleeding. They called this the “vanishing twin” phenomenon. In a prospective series of 68 twin pregnancies diagnosed with two fetal heartbeats, dichorionic and monochorionic twins diagnosed earlier than 8 weeks were significantly more likely to result in a singleton pregnancy than those diagnosed after 8 weeks.³⁴ Dichorionic twins were more likely to result in one or two viable newborns when compared with similarly aged monochorionic-diamniotic twins (Fig. 8-6).

The prognosis for singletons resulting from a vanishing twin depends on the number of sacs seen initially and the timing of the loss of the co-twin. Dickey et al³⁵ found that 15% of singleton in vitro fertilization (IVF) births began as a higher order gestation. Schieve et al³⁶ noted that the greater

the number of fetal hearts seen on an early twin ultrasound examination the greater the subsequent risk of low birth weight for both singletons (such as “vanishing twins”) and twins. Pinborg et al³⁷ reported that of all IVF singletons born, 10.4% resulted from a twin gestation early in pregnancy. In their 624 IVF singletons, who were survivors of a vanishing co-twin identified by sonography in week 8, there was a higher incidence of preterm delivery and infant mortality when compared with 5237 singletons. These complications, however, were gestational age dependent. When they stratified the neonatal outcomes by the time of vanishing as early (< 8 weeks), intermediate (> 8 and < 22 weeks), and late (> 22 weeks), delivery at less than 32 weeks was 1.9%, 5.3%, and 21.4% respectively, and a neonatal intensive care unit stay of greater than 28 days was 8.7%, 15.7%, and 43.8% for early, intermediate, and late losses of a co-twin respectively. Neurodevelopmental disorders were also higher with a loss at a later gestational age with 3.3% early, 8.0% intermediate and 9.7% in the late “vanishing” group. In general, if a twin “vanished” at less than 8 weeks, the pregnancy outcomes were comparable with singletons from early singleton gestations. This highlights the importance of careful and repeated ultrasound examinations in the early stages of pregnancy to correctly diagnose and follow twins. We discuss the “appearing twin” later in this chapter.

PERINATAL LOSS IN TWIN GESTATIONS

Perinatal losses are greater in twin gestations than in singletons. Infant mortality rates in 1999 were more than five times higher at 32.9/1000 for live-born twins compared

FIGURE 8-6. The probability of delivering live-born twins, by chorionicity, when two fetal heartbeats were seen on a normal first trimester ultrasound.

FIGURE 8-7. Cumulative loss rate by chorionicity from 12 weeks to term in twin gestations.

with 6.2/1000 for live-born singletons in the United States.¹ Survival in twins depends on chorionicity, which determines the level of risk for anomalies, growth problems, and prematurity.³² Sebire et al³² reported that cumulative loss rate from 12 weeks to term was approximately 3% for dichorionic and almost 15% for mono chorionic twins (Fig. 8-7). The excess losses for mono chorionic twins relate to TTTS, prematurity, congenital abnormalities and monoamniotic-mono chorionic placentation. Because these losses are more likely to occur between 16 and 22 weeks (see Fig. 8-7), we suggest that ultrasound examinations be performed every 1 to 2 weeks during that time period for known mono chorionic-diamniotic twin gestations to screen for TTTS and, if necessary, to develop a management plan. Figure 8-8 shows an ultrasound of a 21-week twin gestation with a fetal demise of one twin. The head circumference and abdominal circumference of the twin with the demise are

much smaller than those of the living twin. Figure 8-9 is a photograph of a fetus papyraceus, or mummified remains of the lost twin found in the folds of the membranes of the placenta after delivery of the surviving twin at 38 weeks.

Although mono chorionic twins are at greater risk of complications than dichorionic twins, they represent only 20% of all twins (see Fig. 8-5). Most perinatal losses in twins are due to problems with prematurity, anomalies, or growth. Figure 8-10 compares the gestational age at delivery of the 121,346 twin versus 3,902,691 singleton live-born infants in the United States in 2002.⁴ At 28, 32, and 35 weeks' gestation, 0.8%, 2%, and 6.3% of singletons had delivered compared with 5.8%, 15.5%, and 41.9% of twins. This demonstrates a 6.7- to 8-fold higher risk of a preterm delivery at every week from 22 to 35 weeks for twins. Maternal and fetal complications including preeclampsia, gestational diabetes, and cerebral palsy are also increased.¹¹ Cerebral

FIGURE 8-8. Fetal demise of one twin with a surviving co-twin at 21 weeks' gestation. *A.* The collapsed cranium of the twin with the fetal demise compared with the surviving twin's cranium. *B.* The abdominal circumference of the fetal demise is compared with that of the surviving twin.

palsy rates increase with higher order multiples. They are 2.3/1000 in singleton live births, 12.6/1000 in twins, and 44.8/1000 in triplet gestations.³⁸

PLACENTATION

Chorionicity and Amnionicity

One of the most important, and sometimes overlooked roles a sonographic practitioner plays in the management of twins is the identification of chorionicity. This is generally a straightforward diagnosis for the sonographer/sonologist in the late first and early second trimester. Ultrasound is very useful in determining placentation, especially chorionicity and amnionicity, and these are very important in predicting

FIGURE 8-9. Fetus papyraceus resulting from a midtrimester fetal demise of a co-twin. This fetus was noted on inspection of the placenta and membranes following a term delivery of the surviving twin. (Pathology image courtesy of Melinda Sanders, MD, and Erika Walz, PA, University of Connecticut Health Center, Farmington, CT.)

twin pregnancy complications.^{3,5,32} Although ultrasound can almost always determine chorionicity, it only determines zygosity in a subset of twins (see Fig. 8-5).

First Trimester

First trimester evaluation is in the best time to determine chorionicity and amnionicity in multiple gestations. The diagnosis becomes more difficult as pregnancy progresses. First trimester diagnosis is based on the number of gestational sacs, amnions, and yolk sacs (Table 8-3 and Fig. 8-11). Transvaginal sonography is often used in the first trimester because these structures may be difficult to visualize transabdominally. Sonographers do almost as well as perinatologists in determining chorionicity. Weisz et al³⁹ compared the accuracy of sonographers and perinatologists in determining chorionicity in 172 twin cases before 14 weeks. The overall rate of agreement on the diagnosis of chorionicity was 90.1%. With dichorionic twins, they agreed on 118 of 119 (99.2%), whereas in monochorionic-diamniotic twins, there was agreement in 94.5%. Sonographers diagnosed 10 monochorionic-monoamniotic twins that were later diagnosed as monochorionic-diamniotic. This is a difficult diagnosis, however, that is often overcalled by both perinatologists and sonographers on the first or second scan. Because of this, we sometimes bring a woman back for two or three scans before diagnosing monochorionic-monoamniotic twins. Monteagudo⁴⁰ showed the use of first trimester vaginal sonography in correctly determining chorionicity and amnionicity in 43 twin pregnancies. The number of gestational sacs correlates with amnionicity; however, as discussed later, underestimation is possible.

Another diagnostic pitfall in the first trimester is the "appearing" twin. Doubilet and Benson⁴¹ have reported their experience with transvaginal ultrasound at 5.0 to 5.9 weeks' gestation and concluded that 30/220 (13.6%) twin pregnancies were diagnosed as singletons on initial evaluation. Monochorionic twins were more likely to be

FIGURE 8-10. The distribution of twin versus singleton live births delivered from 22 to 37 weeks in the United States in 2002. (From *Nativity Data Set: National Center for Health Statistics: Centers for Disease Control and Prevention, Atlanta CD-ROM 1997-2002; Series 21 11, 12, 14, 15.*)

Sonographic Determination of Chorionicity and Amnionicity in First Trimester Twin Gestations				
Placantation	Gestational Sacs	Yolk Sacs	Embryos/ Sac	Amniotic Cavities
DC, DA	2	2	1	2
MC, DA	1*	2	2*	2
MC, MA	1*	1 or partially divided*	2*	1

*Amnionicity cannot be determined by this finding. DC, dichorionic; DA, diamniotic; MC, monochorionic; MA, monoamniotic.

“appearing” twins. Of those initially diagnosed as singletons, 24/213 (11.3%) were dichorionic twin gestations, whereas 6/7 (85.7%) were monochorionic gestations. They reported that the pregnancy outcomes for the “appearing” twin gestations were comparable with other twin gestations.

The timing of the visualization of membranes and yolk sac depends on chorionicity and gestational age (see Fig. 8-4). Bromley and Benacerraf⁴² retrospectively reviewed the sonographic images of monochorionic twin pregnancies scanned between 6 and 9.5 weeks. This study included 20 diamniotic and two monoamniotic pregnancies. In diamniotic pregnancies less than 8 weeks, only yolk sacs and no dividing membranes were visualized. Two yolk sacs were noted in all but one case on scanning at a later gestational age (Fig. 8-12). In the monoamniotic cases, a single yolk sac was noted at 9 weeks with a single amnion around both embryos. A similar study correlating yolk sacs with amnionicity was performed by Shen et al⁴³ in 20 monochorionic-diamniotic pregnancies under 11 weeks’ gestation. In 85% (17/20) of monochorionic-diamniotic pregnancies, two yolk sacs were noted. In three, only one yolk sac was noted. To summarize, seeing two yolk

sacs is confirmation of diamniotic twins; however, a single yolk sac requires further confirmation before the diagnosis of monoamniotic twins should be made. The only criteria diagnostic of monochorionic-monoamniotic twins is the finding of a single amniotic cavity (see Table 8-3).

Second and Third Trimesters

The steps in determining placentation in the second and third trimesters include documentation of gender, placental masses, and characterization of the dividing membrane(s). If differing genders or two distinct placentas are noted, then dichorionic placentation has occurred.² If the same gender is present and there is one placenta, the type of placentation may be dichorionic-diamniotic, monochorionic-diamniotic, monochorionic-monoamniotic, or monochorionic with conjoined twins.⁴⁴ The intertwin dividing membrane ultrasound characteristics must then be evaluated to determine placentation.^{45,46}

Membrane Insertion, “Twin-Peak” Sign

Perhaps the most useful ultrasonographic marker for determining chorionicity is the appearance of the membrane at its insertion onto the chorionic plate or fetal surface of the placenta. Finberg⁴⁶ first reported the ultrasonographic appearance of the dividing membrane as it inserts onto the chorionic plate of the placenta. When the groove between the membranes at the insertion into the placenta appears thick, it is called the lambda or “twin-peak” sign, and a fused dichorionic-diamniotic placentation is likely (Figs. 8-13 and 8-14). If the insertion clearly joins the chorionic plate of the placenta as a thin, wispy membrane, it is called “T” sign, and a monochorionic-diamniotic placentation is likely (Fig. 8-15). Wood et al⁴⁷ reported the diagnostic utility of the twin-peak or lambda sign to determine chorionicity in a prospective series, with chorionicity confirmed by pathology

FIGURE 8-11. The first trimester is the best time to evaluate the chorionicity and amnionicity of twin gestations. *A.* Sonogram in a 10-week monochorionic-diamniotic gestation. A thin dividing membrane (arrow) from the two apposed amniotic sacs is seen. *B.* Sonogram from a 7-week dichorionic-diamniotic gestation. Both amnions (arrows) surrounding the developing embryos are well seen in this diamniotic twin pregnancy. Dichorionicity is confirmed by the thick intertwin membrane.

postdelivery. The twin-peak sign correctly predicted 34/36 dichorionic pregnancies, whereas its absence correctly predicted seven of eight monochorionic pregnancies. This yielded an overall positive-predictive value of 97%. Sepulveda et al⁴⁸ studied the impact of advancing gestational age on the twin-peak sign, comparing its sonographic presence at a 10- to 14-week scan with that at 16 and 20 weeks. Of the 101 twin pregnancies with a twin-peak sign at 10 to 14 weeks, 98 still had it at the 16-week scan. At the 20-week scan, however, only 87/101 pregnancies had the twin-peak sign. Therefore, advancing gestational age negatively affects the diagnosis of the twin-peak sign. Sepulveda also used a variation of the twin-peak sign to

FIGURE 8-12. Sonogram from a 6.5-week dichorionic-diamniotic twin pregnancy. Although the amniotic membranes are not well seen, both yolk sacs (arrows) in this diamniotic pregnancy are well seen.

assess chorionicity retrospectively and prospectively in triplet pregnancies. He called the junction of the three interfetal membranes the “epsilon zone” (Fig. 8-16).⁴⁹ In 19/20 triplet pregnancies prospectively studied, chorionicity was correctly diagnosed in the first trimester. There were 16 trichorionic pregnancies and four dichorionic pregnancies in this study.

The correct diagnosis of chorionicity and amnionicity in twin pregnancies is often straightforward early in gestation, when the division between the two gestational sacs are thick in dichorionic gestations (see Fig. 8-11*B*). If one is attempting to determine the chorionicity of twins in the second or third trimester and the diagnosis is equivocal, an attempt should be made to obtain and evaluate, early, first trimester scans if they were done previously, when the diagnosis can be more certain.

Membrane Thickness

A thicker dividing membrane is more likely to be seen in a dichorionic-diamniotic placenta. (see Figs. 8-13, 8-14, and 8-15). In a retrospective study of twin pregnancies, Hertzberg et al⁵⁰ determined that a thick dividing membrane (greater than 1 mm) indicated dichorionic-diamniotic twins in 38 of 42 cases. Townsend, Simpson, and Filly retrospectively reviewed 75 twin pregnancies to determine chorionicity based on membrane thickness. They found that a thick membrane predicted dichorionic-diamniotic placentation 83% of the time and was seen 89% of the time at the first sonogram.⁵¹ A thin membrane predicted 83% of monochorionic placentations but was seen only 54% of the time. A similar study from Winn et al⁵² used a membrane thickness of 2 mm or more as a cutoff. This accurately predicted monochorionic and dichorionic twins 82% and 95% of the time. Stagiannis et al⁵³ studied the reproducibility of membrane thickness to predict chorionicity. In their study, 27

FIGURE 8-13. “Twin-peak” sign with placental pathology of fetal membranes. *A.* Diagram of the “twin-peak” sign in dichorionic twin gestations. The chorion (C) and amnion (A) of each twin reflect away from the fused placenta to form the intertwin membrane. A potential space exists between the membranes, which are filled with the amniotic and chorionic mesoderm as seen in the pathology images of dichorionic membranes (*see inset*). *B.* In monochorionic-diamniotic twins the intertwin membrane is composed of only two amnions. A single chorion does not allow the chorionic mesoderm to access the potential space between the diamniotic membranes as seen in the pathology sample of monochorionic fetal membranes (*see inset*). (Pathology image courtesy of Melinda Sanders, MD, and Erika Walz, PA, University of Connecticut Health Center, Farmington, CT; from Finberg HJ: The “twin peak” sign: Reliable evidence of dichorionic twinning. *J Ultrasound Med* 11:571, 1992.)

FIGURE 8-14. *A.* The lambda, or “twin-peak” sign is demonstrated by the thicker placental membranes which widen (*arrow*) as they touch down on the chorionic plate indicating a fused dichorionic-diamniotic placenta. *B.* In cases where the placentas are on opposite sides and clearly separate, as in this case, observation of the twin-peak sign is not necessary to make the diagnosis of dichorionicity. One can still see the insinuation of the chorion (placental tissue) (*arrow*) into the dividing membrane.

twin pregnancies were scanned by two observers blinded to chorionicity on 52 occasions at five areas of the membranes. Membrane thickness measurements closest to the placenta were the most reproducible, but significant variation in membrane thickness does occur, particularly in the second and third trimesters.

Membrane Layers

D’Alton et al⁴⁵ prospectively studied 69 consecutive twin pregnancies to assess chorionicity by counting the number of layers in the dividing membrane visualized by ultrasound. If two layers were seen, a monochorionic pregnancy was diagnosed. If more than two were seen, a dichorionic pregnancy

FIGURE 8-15. T-sign as a thin wispy placental membrane joins the chorionic plate (arrow), indicating a mono chorionic, diamniotic placenta.

FIGURE 8-16. Trichorionic triplets imaged in the first trimester. Three separate gestational sacs meeting at the junction of the three interfetal membranes (the "epsilon zone" is identified).

was predicted. Confirmation was obtained after delivery by histopathology (see Fig. 8-13). Ultrasound counting of the membrane layers correctly predicted chorionicity in 68/69 twin pregnancies. There was 100% accuracy in predicting the 51 dichorionic pregnancies and 94.4% accuracy in predicting the 18 mono chorionic pregnancies. Vayssiere et al⁵⁴ performed a similar prospective study counting membrane layers and correctly predicted chorionicity in 60/63 twin pregnancies.

Multiple Sonographic Markers to Determine Chorionicity/Amnionicity

No single sonographic marker of chorionicity is completely reliable. The use of multiple markers enhances the accuracy of predicting chorionicity. Scardo et al⁵⁵ prospectively studied the accuracy of multiple sonographic markers to predict chorionicity and amnionicity in 100 consecutive twin pregnancies with postdelivery confirmation. They assessed placental number, fetal gender, membrane thickness, and presence of the twin-peak sign (see Figs. 8-14 and 8-15). They performed an average of 3.6 ultrasound examinations, starting at a mean gestational age of 22.6 weeks. Use of the composite sonographic markers had at least a 91% sensitivity and specificity for correctly determining chorionicity. The timing of these examinations was relatively late in gestation. With the greater acceptance of first trimester ultrasound, the accuracy of determining chorionicity should improve. Carroll et al⁵⁶ performed a similar study to predict chorionicity at 10 to 14 weeks' gestation using the number of placental sites, presence of a twin-peak sign, and intertwin membrane thickness. This study included 150 pregnancies with postnatal confirmation of chorionicity and included 116 dichorionic and 34 mono chorionic pregnancies. Prenatal ultrasound correctly predicted chorionicity in 139/150 pregnancies (93.3%). The most accurate predictors of dichorionic placentation were the twin-peak sign or separate placentas with a sensitivity and specificity of 97.4% and 100%, respectively.

Monoamniotic Twins

When the dividing membrane is not seen early in the ultrasound evaluation of a twin pregnancy, the diagnosis of mono chorionic-monoamniotic twins should be considered. This occurs in approximately 1% of all mono chorionic twins (see Figs. 8-3, 8-4, and 8-5). We require several examinations to search for the dividing membrane before making this diagnosis, because the membrane may not initially be apparent by ultrasound. Distinguishing mono chorionic-monoamniotic twins from a "stuck" twin in an oligo-hydramniotic sac can be difficult. Normal amniotic fluid volume and two free-floating twins with no visualized membrane separating them should clinch the diagnosis of mono chorionic-monoamniotic twins. Visualization of two cord insertions into the chorionic plate of the placenta in very close proximity to one another is also suggestive of mono chorionic-monoamniotic twins (Fig. 8-17).

Color and two-dimensional ultrasound readily show the umbilical cord entanglement that leads to the strikingly increased mortality for mono chorionic-monoamniotic twins (Fig. 8-18).^{2,57-59} Nyberg et al⁶⁰ first reported ultrasound evidence of cord entanglement as a sign of mono chorionic-monoamniotic twins. Townsend and Filly confirmed this finding in five sets of nonconjoined, mono chorionic-monoamniotic twin pregnancies (Fig. 8-19).⁶¹ Subsequent studies have supported this finding, which is characteristic of mono chorionic-monoamniotic twin pregnancies. Overton et al⁶² reported using color flow and pulsed wave Doppler to insonate a common cord mass to confirm mono chorionic-monoamniotic twins in the first trimester (Fig. 8-20). First trimester vaginal sonography using color Doppler has also

A

B

FIGURE 8-17. A. Cord insertions are seen in close proximity to one another in a monoamniotic-placenta by using color-flow Doppler. B. Placenta showing both umbilical cords close to one another with no intervening membranes. (Pathology image courtesy of Melinda Sanders, MD, and Erika Walz, PA, University of Connecticut Health Center, Farmington, CT.)

demonstrated cord entanglement.⁶³ Sonography may also be useful in the antenatal management of monoamniotic-monoamniotic twins. Belfort et al⁶⁴ reported extremely high blood flow velocities associated with umbilical vein compression by the entangled cords when following three monoamniotic-monoamniotic twin pregnancies (Fig. 8-21). Abuhamad et al⁶⁵ followed two monoamniotic-monoamniotic twin pregnancies with longitudinal Doppler flow velocities of the umbilical artery. Notching of the umbilical artery waveform was associated with increased narrowing of the umbilical vessels secondary to cord entanglement. Doppler interrogation of the aggregate cord mass may also demonstrate arterial flow, at differing heart rates in both fetuses, which is called a “galloping” Doppler pattern (Fig. 8-22). As with all multiple gestations, a velamentous insertion of the umbilical cord (that is, where the cord inserts into the mem-

FIGURE 8-18. Color-flow Doppler interrogation of adjacent abdominal cord insertions and tangled cords in monoamniotic twins.

FIGURE 8-19. A two-vessel umbilical cord wrapped around a three-vessel umbilical cord in monoamniotic twins.

branes rather than the chorionic plate) is more common in monoamniotic-monoamniotic placentas (Fig. 8-23).

Several different protocols have been proposed for the management of monoamniotic-monoamniotic twins. Because of the rarity of this condition, there are no randomized clinical trials. Rodis et al⁵⁷ showed that with daily antenatal surveillance after viability, the double survival rate for monoamniotic-monoamniotic twins was greater than 90%. They suggest serial sonograms, steroids to enhance fetal lung maturity, and daily nonstress tests starting at 24 to 26 weeks. They also recommended delivery by cesarean birth after documentation of fetal lung maturity at 33 to 34 weeks. Carr et al⁵⁸ reported that fetal mortality does not increase in monoamniotic twins after 30 weeks' gestation. A literature review by Roque et al⁵⁹ summarizing the outcomes of 133 monoamniotic-monoamniotic twin pregnancies, however,

reported a significant increase in perinatal loss after 32 weeks' gestation and recommended elective delivery at 32 weeks. An 11-center retrospective report on 96 monochorionic-monoamniotic twin pregnancies showed that intense inpatient fetal surveillance was superior to less intense outpatient fetal surveillance.⁶⁶ There was a 14.8% risk of intrauterine fetal loss in the 44 pregnancies managed as outpatients, although there were no fetal losses in the group admitted for monitoring. The protocols differed in the two arms of the study, however, and the results are therefore not comparable. The outpatient management consisted of electronic fetal monitoring one to three times per week compared with 1 hour, two to three times daily for the inpatient group. Thus, it is unclear if daily outpatient testing would accomplish similar results to those provided by the inpatient protocol. All studies on monochorionic-monoamniotic twins agree that they present the caregiver with a very high-risk clinical problem and require intense fetal surveillance beginning at viability and ending in a premature, often planned cesarean birth.

CONJOINED TWINS

The rare phenomenon of conjoined twins occurs in a monochorionic monoamniotic twin when the embryo divides at 13 to 15 days from conception (see Figs. 8-3, 8-4, and 8-5). The two fetal poles may be attached at varying sites (Table 8-4). The location of the shared sites provides the basis for the nomenclature describing conjoined twins. The most common conjoined twins are the omphalopagus or thoracopagus twins, which are joined at the abdomen or chest respectively (Fig. 8-24).⁶⁷

Ultrasound features of conjoined twins include visualizing the twins in the same relative positions in all views, direct opposition of the twins from each other, and extreme extension of the fetal spine.⁶⁸ Inseparable skin contours must

be persistent and at the same anatomic level to avoid a false diagnosis. An early ultrasound finding suggestive of conjoined twins is a bifid appearing fetal pole (Fig. 8-25).⁶⁹ Several pitfalls in the diagnosis have been described. Diamniotic twins in close proximity with a dividing membrane that is difficult to visualize may lead to a false-positive diagnosis. If the conjoined twins are very anomalous, a singleton fetus may be falsely diagnosed.⁷⁰ Finally, a discordant presentation (breech, vertex) may occur if the connection site is pliable.^{71,72}

Numerous variations in the types of conjoined twins may occur, and the prognosis for survival is generally very poor.⁷²

Table 8-4 Types of Conjoined Twins

Inferior conjunction: lower body in single or twins joined by some lower portion of body
Diprosopus: two faces with one head and body
Dicephalus: two heads with one body
Ischiopagus: joined by inferior sacrum and coccyx
Pygopagus: joined by posterolateral sacrum and coccyx
Superior conjunction: upper body is single or twins joined by some upper portion of body
Dipygus: single head, thorax, abdomen with two pelvis and four legs
Syncephalus: facial fusion with or without thoracic fusion
Craniopagus: joined at the head
Middle conjunction: fusion of midportion of the body, separate above and below
Thoracopagus: thoracic fusion
Omphalopagus (xiphopagus): joined from umbilicus to xiphoid cartilage
Thoraco-omphalopagus: thoracic and abdominal fusion
Rachipagus: vertebral fusion above sacrum

Adapted from Guttmacher AF, Nichols BC: Teratology of conjoined twins. *Birth Defects* 3:3, 1967.

FIGURE 8-24. Different types of conjoined twins. *Left*, Cases of limited fusions in which heads and limbs are separate and retain their identity. *A* to *C*, craniopagus; *D* to *G*, thoracopagus; *H* and *I*, pygopagus. *Right*, Cases of more extensive fusion. (From Patten BM: *Human Embryology*, 3rd ed. New York, McGraw Hill, 1968.)

When conjoined twins are diagnosed, there should be a systematic approach to define which major organs are present in each fetus, which are shared, and what vascular communications are present.⁷² Detailed scanning or fetal magnetic resonance imaging at 20 weeks or more provides a reliable picture of structural anomalies and of shared viscera. Fetal echocardiography is especially informative with thoracopagus conjoined twins (Fig. 8-26).⁷³ Spitz et al⁷⁴ reviewed the ultrasound diagnosis and prognosis of conjoined twins. Sharing of the cardiac and liver structures is not uncommon, and fetuses with a shared heart have a particularly bad prognosis.⁷⁴ The previously mentioned steps help determine

the prognosis for postnatal separation. A review of the experience at the Children's Hospital of Philadelphia, described 14 sets of conjoined twins.⁷⁵ Ten of the 14 were thoracoomphalopagus (Fig. 8-27). Associated anomalies included cardiac malformations in 11 of 14, congenital diaphragmatic hernia in four of 14 and abdominal wall defects in two of 14. Only 5/28 individual newborns survived after separation highlighting the grave prognosis.

The first trimester diagnosis of conjoined twins has also been described (see Fig. 8-25). In a review of the literature, Pajkrt and Jauniaux⁷⁶ reported that monochorionic-monoamniotic twins may be misdiagnosed as conjoined twins owing to limited fetal movement. They also reported that in pregnancies that continued after the diagnosis of conjoined twins, approximately one half died in utero and another 44% died during the neonatal period.

"STUCK" TWIN

An ominous ultrasound finding is the "stuck" twin. In this setting, one twin has normal or increased amniotic fluid and the other has severe oligohydramnios that makes that amniotic

FIGURE 8-25. Dicephalus-conjoined twins seen on an 11-week ultrasound. Two fetal heads (*arrows*) and a single thorax and abdomen are seen.

FIGURE 8-27. Newborn conjoined thoraco-omphalopagus twins.

FIGURE 8-26. Thoracopagus twins showing shared great vessels (*arrow*) using grayscale and color Doppler imaging.

FIGURE 8-28. Thin membrane (*arrow*) reflecting between the head and the back of the thorax in the oligohydramniotic sac of the "stuck" twin.

sac adhere to the sidewall of the uterus and confines the fetus to that area of the uterus. There are several causes of a stuck twin including bilateral, renal agenesis or other renal anomalies in the affected twin, severe growth restriction with oligohydramnios, or TTTS.⁷⁷ To diagnose a stuck twin, the sonographer/sonologist must perform a careful evaluation, looking for a dividing membrane. The fluid around the unaffected twin may be normal, but it is increased if TTTS is the cause.⁷⁸ The most informative areas around the fetus to find the dividing membrane are near the fetal neck, chin, or limbs. This is where a thin membrane may be seen bridging the gaps between fetal small parts (Fig. 8-28). The pregnant mother can be shifted from side to side to assure that the stuck twin does not move in the amniotic cavity. The diagnosis of a stuck twin is made when there is normal fluid or polyhydramnios around one twin, severe oligohydramnios around the stuck twin, and an adherent membrane is seen encasing this fetus and restricting fetal movement in the uterine cavity (Fig. 8-29). In some cases, the membranes around the stuck twin may form a "sling" (Fig. 8-30). The cause of the stuck twin must then be determined. A careful evaluation may reveal fetal anomalies to explain the oligohydramnios such as bilateral renal agenesis or multicystic dysplastic kidneys. These may be difficult to diagnose with the oligohydramnios but would be suggested by normal, rather than increased, amniotic fluid around the unaffected twin. Diagnostic amnioinfusion improves the prenatal diagnosis of fetal anomalies and may help to diagnose ruptured membranes in cases of oligohydramnios.^{79,80} The amnioinfusion of fluid around a stuck twin also improves the ability of the sonographer to perform a more informative anatomic survey. The instilled fluid can be aspirated for karyotype and infection studies.

FIGURE 8-29. "Stuck" twin. Note the position of the fetus stuck against the right anterior wall of the uterus. The fetal position persisted despite maternal position change. The membrane is not visible in this image.

TWIN-TO-TWIN TRANSFUSION SYNDROME

If the evaluation of the stuck twin has some, or all of the following features, the diagnosis of TTTS must be considered:

Monochorionic placentation

Same sex fetuses

Oligohydramnios (see Fig. 8-29) around one twin and polyhydramnios around the other

Velamentous cord insertion (see Fig. 8-23)

An enlarged bladder in the recipient twin, who has polyhydramnios (Fig. 8-31)

No bladder seen in the donor twin

Size discrepancy with the recipient twin significantly larger than the donor

Ultrasound is extremely helpful in establishing the diagnosis and improving the survival of infants with TTTS. There are numerous theories about the pathophysiology of TTTS including abnormal placentation, unbalanced vascular communications, and velamentous cord insertion. Vascular communications are found in up to 98% of monochorionic placentas. Therefore, unidirectional or unbalanced blood flow is necessary to explain the changes noted in TTTS.⁷⁷ These anastomoses may be arterial to venous (AVA) (Figs. 8-32 and 8-33), arterial to arterial (AAA), and venous to venous. AVA anastomoses are commonly present in monochorionic placentas. In fact, the majority of monochorionic-diamniotic placentas have AVA connections, often greater than one and often bidirectional. The presence of such a connection does not necessarily result in TTTS. Fichera et al⁸¹ evaluated the use of Doppler ultrasound to detect AAA in monochorionic-diamniotic twin pregnancies.

FIGURE 8-30. Twin-to-twin transfusion syndrome (TTTS) with a "sling" around the "stuck" twin. When there is little to no amniotic fluid in the amniotic sac of the donor "stuck" twin, the membrane appears as a sling around the fetus. In the absence of amniotic fluid in this sac, the fluid surrounding this twin may wrongly be assumed to be in its sac, when in fact it is the fluid in the adjacent recipient twin's sac with polyhydramnios. **A.** A pregnancy with TTTS in which the fetus on the right is enshrouded by its membrane in an oligohydramniotic sac. **B.** In this case of TTTS, the donor twin is in an anhydramniotic sac. The apposed membranes appear as a single membrane (*arrow*). The surrounding amniotic fluid (*asterisks*) is in the other twin's amniotic sac. **C.** A pregnancy with TTTS in which the fetus on the right is enshrouded by its membrane in an oligohydramniotic sac. Redundant amnion is seen projecting from the fetus and at times presents a confusing appearance. **D.** Scan of a donor fetus with severe oligohydramnios and redundant amnion (*arrow*) seen projecting into the amniotic fluid of the other fetus. (*A and C* courtesy of Vickie A. Feldstein, MD, University of California School of Medicine, San Francisco, CA.)

They are important because they appear to function as a compensatory mechanism for the other vascular imbalances. Superficial chorionic vessels between the cord insertions were identified by color, and the vessels were interrogated with pulsed wave Doppler.⁸² AAA were documented by the presence of bidirectional arterial flow in these vessels (see Fig. 8-33E). The presence of AAA was associated with a lower likelihood of TTTS. If TTTS did develop, it was generally not severe.⁸² Several studies have identified early ultrasound findings in monochorionic-diamniotic pregnancies that may predict TTTS, such as an increased nuchal translucency or alterations of flow in the fetal ductus venosus (Fig. 8-34).^{82,83} The in utero transfusion often leads to anemia in the donor and polycythemia in the recipient twin, which may be reflected in the placenta after delivery (Fig. 8-35).

Quintero et al⁸⁴ defined severe TTTS as the presence of polyhydramnios (maximum vertical pocket of amniotic fluid of > 8 cm) and oligohydramnios (maximum vertical pocket of amniotic fluid of < 2 cm). He proposed a staging system

FIGURE 8-31. Enlarged fetal bladder (arrow) noted in a recipient twin in twin-to-twin transfusion syndrome.

using visualization of the bladder in the donor twin, the presence or absence of hydrops in either twin, pulsed Doppler studies of the middle cerebral artery, umbilical artery and umbilical vein, and the demise of one or both twins (Fig. 8-36). In stage I, the bladder of the donor twin was still visible, whereas in stage II, the bladder was not visualized but the Doppler studies were normal. By stage III, there were Doppler abnormalities; in stage IV, hydrops was present; and in stage V, there was a demise of one or both twins (Table 8-5). Taylor et al⁸⁵ found that although this staging system was not useful for prediction of fetal outcome on initial evaluation, an increase in stage carried with it a higher risk of earlier perinatal loss. Thus, staging may be more useful in monitoring disease progression. Untreated TTTS that develops earlier than 26 weeks has a perinatal mortality rate of 90%.⁸⁶

A systematic approach should be used in the management of TTTS. We suggest documenting the maximum fluid pocket around the recipient twin, visualization of the fetal bladders, establishing growth curves for each, evaluating the cervical length, and performing pulsed wave Doppler of the umbilical arteries of each fetus. If the amniotic fluid volume becomes excessive around the recipient, the cervical length is becoming shorter, or Doppler interrogation reveals absent or reverse end-diastolic velocity, intervention should be considered (see Fig. 8-36). Hydrops in either the donor or recipient fetus can occur and therapy at this point should be directed at optimizing the outcome for the nonhydropic fetus.

There are several treatment protocols for TTTS, although evidence is mounting that the preferred therapy for severe TTTS is laser photocoagulation of the communicating vessels. Therapies include serial amnioreductions of the polyhydramnios around the recipient twin, needle hole septostomy of the intervening twin membrane, laser ablation of the communicating placental vessels, and cord ligation of one twin, usually the anomalous or hydropic fetus. Pregnancy termination may be considered in cases with very early onset and severe findings. The risks and

FIGURE 8-32. Illustrations of (A) normal-paired branch vessels from the umbilical cord and (B) arteriovenous anastomosis in monochorionic twin placenta. A, Normal paired branches of the umbilical artery (blue) and umbilical vein (red) are seen coursing together on the fetal surface of the placenta. Blood flows from the umbilical cord toward the placenta by way of the umbilical artery and returns by way of the umbilical vein. B, Unpaired vessels course on the fetal surface of the placenta. A branch of the donor umbilical artery (blue) meets a branch of the recipient umbilical vein (red) where they enter and exit the placental cotyledon by way of a common foramen. Note that the arteriovenous communication occurs deep within the placenta. (Courtesy of Vickie Feldstein, MD, University of California, San Francisco, School of Medicine, San Francisco, CA.)

Table 8-5 Staging of Twin-to-Twin Transfusion Syndrome⁸⁴

Stage	Amniotic Fluid	Fetal Bladder	MCA Doppler, Umbilical Artery or Vein	Hydrops	Fetal Demise
I	Donor—oligohydramnios Recipient—polyhydramnios	Normal	Normal	No	No
II	As above	Donor bladder not seen	Normal	No	No
III	As above	As above	Abnormal	No	No
IV	As above	As above	Abnormal	Yes, either twin	No
V	As above	As above	Abnormal	Yes, either twin	Yes, either twin

MCA, middle cerebral artery.

benefits of each therapy should be carefully discussed. In cases with hydrops of one fetus, cord ligation may be performed after consideration of the impact on the surviving co-twin. As the blood pressure of the dying fetus collapses, the vascular communications between the twins allow blood from the surviving twin to move down the pressure gradient to the dying twin. In this setting, a double fetal death or neurologic impairment of the survivor may occur.^{85,87} Sacrificing the hydropic fetus by cord ligation should prevent hypoperfusion of the surviving twin. When one twin has a coexisting major anomaly, cord ligation has been performed.⁸⁸

Therapeutic amniocentesis can be rapidly performed for TTTS as a primary treatment or as a temporizing measure before transfer to a center for laser photocoagulation. Two practical methods have been described. The wall suction method described by Elliott et al^{89,90} and the vacuum bottle method described by Dolinger et al.⁹¹ Both adequately remove the excessive amniotic fluid from the recipient twin's sac. We use an 18- or 20-gauge spinal needle and place the needle in the cavity away from the fundus of the uterus. By avoiding the fundus, the needle is less likely to pull out of the amniotic cavity as the uterine fundus shrinks from the decreasing in amniotic fluid volume. Removal of large quantities of amniotic fluid can be achieved safely.⁹⁰ A recommended endpoint is a maximum amniotic fluid depth around the recipient twin of 5 to 6 cm. Frequent assessment of fluid, fetal growth, and Doppler flow can be used to guide the timing of repeat procedures.

In some cases, only one therapeutic amniocentesis resolves the oligohydramnios-polyhydramnios seen in TTTS. This finding led to the hypothesis that an amniostomy may be used as a treatment for TTTS.⁹² By creating several needle holes in the dividing membrane, one allows free flow of fluid between the sacs, and equilibration of amniotic fluid in the two sacs may be achieved. A randomized trial of 73 pregnancies complicated by TTTS comparing amnioreduction with amniotic membrane septostomy has been performed.⁹³ The trial was stopped early when an interim analysis found no difference in the primary outcome of at least one twin surviving. In the amnioreduction group, at least one twin survived in 78% of cases compared with 80% in the septostomy group. The only potential advantage was that a single procedure was needed in 68% of the patients treated by septostomy compared with 46% of patients treated by amnioreduction. Concern exists, however, that septostomy may create monoamniotic twins with the potential for cord entanglement.⁹⁴ The dividing membrane may also rupture spontaneously leading to monoamniotic twins.^{95,96}

Laser surgery to separate the placental vascular communications between monochorionic twins in TTTS has been described.⁹⁷ Few centers exist for this technically challenging procedure. The vessels are sometimes difficult to visualize owing to placental location or previous amniocenteses, and preterm labor and rupture of membranes are known complications of the procedure (Fig. 8-37). A randomized trial of pregnancies with severe TTTS diagnosed before 26 weeks' gestation compared laser therapy with serial amnioreduction.⁹⁸ The trial was ended prematurely when laser separation study arm showed significantly better survival of at least one twin at 28 days and 6 months of newborn life compared with pregnancies treated by amnioreduction. A more important finding was that more infants were free of

FIGURE 8-37. A. Sonogram demonstrating laparoscope with laser (arrows) near an arteriovenous connection on the placental surface. B. Laser cautery of communicating placental vessels (arrow) using fetoscopy. (Courtesy of Julian E. De Lia, MD, St. Joseph Regional Medical Center, Milwaukee, WI.)

neurologic complications at 6 months of age in the laser treated group (52%) than in the amnioreduction group (31%). The interventional trials of TTTS highlight the fact that pregnancies complicated by severe TTTS are at very high risk for obstetric complications including the loss of one or both twins and have the potential for impaired neurologic outcomes in surviving twins despite current treatments.

ACARDIAC TWINS

An unusual and rare form of monochorionic twins is the acardiac twin. This may represent an extreme form of TTTS. One theory on the pathogenesis of acardiac twins was proposed by Driggers et al.⁹⁹ They described the ultrasound and postmortem evaluation of monochorionic twins with an early TTTS. The recipient twin had a severely hypoplastic heart and hydrops. They theorized that the

FIGURE 8-38. Acardiac twin with absence of formed cranium. Diffuse anasarca is seen with a focal cystic hygroma (arrow).

FIGURE 8-39. Color and pulsed Doppler imaging of an acardiac twin showing pulsatile flow from the donor twin.

FIGURE 8-40. Acardiac twin demonstrating the amorphous, vestigial structures cephalad and caudad as the distance from the umbilical cord arterial circulation increases. (Pathology images courtesy of Melinda Sanders, MD, and Erika Walz, PA, University of Connecticut Health Center, Farmington, CT.)

early TTTS led to cardiac dysfunction in the recipient twin followed by the twin reverse arterial perfusion (TRAP) of the recipient twin. This perfusion occurs through AAA on the placental surface carrying deoxygenated blood from the umbilical arterial circulation of the donor to the very abnormal recipient twin. The “rescue” of a dying fetus and evolution to an acardiac twin is called the TRAP sequence.¹⁰⁰ This perfusion with deoxygenated blood has been suggested as the mechanism leading to the typical ultrasound findings in acardiac twins. The recipient fetus is oxygenated through reverse flow in its umbilical arteries, which primarily nourish the structures in the lower trunk of the fetus. This preferential circulation to the caudal aspects of the recipient leads to the typical anatomic findings of an absent or vestigial head and heart. Early ultrasound detection of the TRAP sequence may be difficult. The acardiac twin may be mistaken for a fetal demise because no cardiac activity is present. Repeat studies document the acardiac twin. Early findings may also include cystic hygroma or increased long bone length, because the lower extremities of the acardiac twin are often preferentially perfused (Fig. 8-38). The acardiac twin typically has some recognizable fetal features such as limbs or bones, but there is no cardiac activity and major anomalies are the rule. Careful ultrasound examination of the placental surface of the acardiac twin can identify vascular connections to the donor twin through AAA.¹⁰¹ This leads to flow into the acardiac twin through its umbilical cord (Fig. 8-39).

Doppler ultrasound of the communicating vessels, the size of the recipient twin relative to the acardiac twin, and cardiac dysfunction/hydrops of the donor twin predict the outcome for the donor twin and help direct treatment during pregnancy.¹⁰² In 10 pregnancies, poor outcomes were

associated with a rapid growth of the acardiac twin or when the pulsatility index of the perfusing vessel was less than that of the donor twin.¹⁰³ Another study compared resistive indices and showed that a large difference (> 0.20) in the index between the donor and recipient twin was associated with improved outcomes.¹⁰² The decision to proceed to an ablative procedure requires serial ultrasonographic evaluations. Moore et al¹⁰⁴ reported the outcomes of 49 acardiac twin pregnancies. They found a significant correlation between the weight ratios of the twins. If the size of the acardiac twin exceeded 70% of donor twin’s estimated fetal weight, there was a significant increase in preterm birth, polyhydramnios, and heart failure of the pump twin (Fig. 8-40). The weight of the acardiac twin can be estimated in grams by the formula: $(1.2 \times \text{longest length}^2) - (1.7 \times \text{longest length})$.¹⁰⁴ Therefore, a relatively large weight of the acardiac twin may

be an indication for prenatal treatment. Other indications for therapy include polyhydramnios, cardiac dysfunction, and hydrops of the pump twin.

Tan and Sepulveda reviewed the literature for pregnancy outcomes after prenatal interruption of the vascular connections to the acardiac twin.^{105,106} Of the 71 cases treated by invasive procedures, 40 were treated by cord occlusion and 31 by intrafetal (acardiac twin) ablation of communicating vessels. The overall donor twin survival rate was 76%, with a median gestational age at delivery of 36 weeks. Intrafetal ablation of the umbilical vessels was superior to cord occlusion. It had an 87% success rate compared with 65% for cord occlusion and a mean gestational age at delivery of 37 weeks compared with 32 weeks for cord occlusion. The methods of intrafetal ablation of the communicating vessels included alcohol, monopolar diathermy, interstitial laser, and radiofrequency. Radiofrequency ablation appears to be the most efficacious. If the acardiac mass remains small compared with the donor fetus, complications are less likely.

ANEUPLOIDY SCREENING IN TWIN GESTATIONS

Advancing maternal age is a known risk factor for autosomal trisomies, the most common of which is Down syndrome. The average age of a woman delivering twins in the United States has increased from 27.8 years of age in 1991 to 29.3 in 2001.^{107,108} The average age for all mothers in the United States in 2001 was 27.4 years of age. The percent of all mothers 35 years of age or older giving birth has increased from 8.9% in 1990 to 13.7% in 2002. Of all women delivering multiple gestations, the percentage of women 35 years of age or older has increased from 11.4% in 1990 to 21% in 2001.⁴ Thus, mothers of twins are older and have an a priori increased risk for Down syndrome. Advances in reproductive technology have also played a major role in the increase in multiple gestations in the United States. Women using assisted reproductive technology are more likely to be older and in their later reproductive years.

The risk of Down syndrome in a twin pregnancy is greater than the age-specific risk in a singleton gestation. The precise difference, however, is difficult to determine. Rodis et al¹⁰⁹ calculated a theoretical maternal age-specific risk for Down syndrome in twin pregnancies. They assumed that the probability of Down syndrome was independent among the twins and that survivals were comparable with singletons. They stated that a risk of one, or the other, or both twins being affected was approximately 80% higher than the singleton maternal age-specific risk. This risk approximated the singleton risk of a woman 2 or 3 years older. Lee et al¹¹⁰ used a similar model but corrected for maternal race and zygosity. They concluded that the twin risk per pregnancy approached that of the singleton risk for a mother 3 or 4 years older. For example, a woman 32 years of age carrying twins would be quoted a Down syndrome risk for that pregnancy equal to that of a woman 35 or 36 years of age with a singleton pregnancy.

These theoretical estimates did not correspond to data on live-born twins. Wald et al¹¹¹ found a lower risk of Down syndrome in twins than the Rodis or Meyers studies postulated. In a meta-analysis of four cohort studies of 64

Down syndrome twins, the live birth prevalence of Down syndrome in twin pregnancies was only 18% higher than singletons. They concluded that the risk for a twin pregnancy resulting in a live-born with Down syndrome does not differ significantly from that of a singleton gestation. Doyle et al¹¹² in a study of 106 twin live births with Down syndrome found an even greater disparity from the theoretical estimates. He found that the prevalence was only 3% higher than singletons. This discrepancy between the estimated and the observed live-born twins may be explained by a higher intrauterine lethality for Down syndrome affected twins. Therefore, the prevalence of Down syndrome may be higher in the first and second trimester than at birth.³

Antenatal screening for Down syndrome in a twin gestation uses the same principles and methods generally applied to singletons, that is, maternal age, serum screening, and ultrasound. These modalities are employed to better estimate the specific risk of Down syndrome for that pregnancy. An antenatal diagnosis may be made by either chorionic villous sampling or amniocentesis. Both the screening and the diagnosis are complicated by the fact that the fetuses may be discordant for abnormal ultrasound findings and for aneuploidy, and that an invasive test, or fetal intervention, places both fetuses at risk.

Using live-birth data to assess Down syndrome risk in the second trimester requires a correction for fetal losses in both affected and unaffected pregnancies. With twin gestations, two corrections are necessary. The first is for the natural losses seen in the second and third trimesters for unaffected and Down syndrome fetuses, and the second is for the differential in twin losses based on chorionicity. Unaffected singletons have a loss rate of 1.46% from the midtrimester to term,¹¹³ whereas 15.7% of singleton Down syndrome fetuses are lost from 16 weeks to term. Estimates of loss for Down syndrome twins from the second trimester to term are not available. Using birth certificate data and observed-to-expected Down syndrome ratios, we estimated the live-born Down syndrome incidence in 1990 and the yearly incidence from 1995 to 2000.¹⁰⁷ There was a 1.8-fold increase in the contribution of multiples to Down syndrome live births from 2.6% in 1990 to 4.6% by the year 2000 (Table 8-6).³

This increase in Down syndrome fetuses in multiple gestations reinforces the need for Down syndrome screening. We have reviewed the lack of consensus on the age-related Down syndrome risks for twins. Maternal serum tests also use different norms (approximately twice the value used in singletons if the analyte is higher in Down syndrome pregnancies, or one half if the analyte is lower in Down syndrome) that factor in the contribution of both fetuses. Because fetuses can be discordant for aneuploidy, the individual contribution of each fetus to the serum analytes is not known. Therefore, the serum screen results are averaged for the pregnancy. Testing for Down syndrome in the first trimester uses serum screening with pregnancy associated plasma protein A (PAPP-A) and the free beta subunit of human chorionic gonadotropin (hCG). Spencer et al¹¹⁴ found that the normal PAPP-A in twins was 1.86 multiple of the median (MoM) greater than in singletons and the free beta was 2.099 MoM. Ultrasound screening requires that both fetuses are imaged and implies that structural markers or anomalies in twins carry with them similar implications for Down syndrome (likelihood ratios) and other aneuploidies.

Table 8-6 Contribution of Multiple Gestations to Down Syndrome Livebirth Prevalence³

Year	Total Live Births	Total Down Syndrome*	Down Syndrome from Multiple Gestations	% Down Syndrome from Multiple Gestations
1990	4,158,212	5900	152	2.6%
1995	3,899,589	6292	174	2.8%
1996	3,891,494	6498	231	3.6%
1997	3,880,894	6629	271	4.1%
1998	3,945,192	6850	294	4.3%
1999	3,963,465	6955	315	4.5%
2000	4,063,823	7264	334	4.6%

*Assuming no antenatal intervention.

FIGURE 8-41. Nuchal translucency in a twin gestation generally differs even in monochorionic-diamniotic twins.

First trimester ultrasound is performed to assess nuchal translucency (Fig. 8-41). Normative measures of nuchal translucency in unaffected and fetuses with Down syndrome are approximately the same in both singletons and twins. Maymon et al¹¹⁵ reported agreement of the mean nuchal translucency in singletons (1.5 mm/0.5) and in twins (1.5 mm/0.17). When evaluated using the mean MoM standard deviation (SD), the nuchal translucency MoM for singletons was 0.9 (0.5), whereas in twins, it was 0.9 (0.4). There was no statistically significant difference in either the actual values or the MoMs for nuchal translucency.

Spencer¹¹⁴ developed a theoretical first trimester twin Down syndrome detection model using a fixed 5% false-positive rate. Nuchal translucency and maternal age detected 75.2% of both discordant (that is, one twin positive and one twin negative) and concordant Down syndrome twins. Using free beta hCG, PAPP-A, and maternal age, there was a 51.5% detection rate if the twins were discordant for Down syndrome and 55.4% detection rate if they both had Down syndrome. When age, the serum screen, and ultrasound were combined in the first trimester (that is, nuchal translucency, free beta hCG, PAPP-A, and maternal age), there was a 79.7% detection rate in twins discordant for Down syndrome and an 81.3% detection rate if both had Down syndrome.

Although first trimester screening is becoming more popular, most Down syndrome screening in the United States is still done in the second trimester. A survey of maternal fetal medicine specialists in the United States in 2001 revealed that of the time they spent on antenatal diagnosis, 87.3% was devoted to second trimester screening and 12.7% to first trimester screening.¹¹⁶ Second trimester screening also uses maternal age, the serum screen, and ultrasound, or some combination of the three. The second trimester serum screen values for twins are also approximately twice (or one half) the level of singleton norms. Wald et al¹¹⁷ reported that the mean MoMs for twins were 2.23 for the maternal serum alpha-fetoprotein, 1.65 for estriol, 2.01 for hCG, and 1.99 for inhibin-A. Neveux et al¹¹⁸ estimated the second trimester serum screen values for Down syndrome twins depend on whether one or both of the fetuses are affected. If one twin was affected, the maternal serum alpha-fetoprotein was 1.89 MoMs, whereas if both were affected, it was 1.62 MoMs. The estriol was 1.47 MoM if one twin was affected and 1.22 MoM if both were affected, whereas the hCG was 3.26 MoM if one was affected and 4.51 MoM when both were affected. Maymon et al¹¹⁵ estimated the false-positive rates for second trimester serum screening and determined the amniocentesis rates in twins versus singletons. The false-positive rate for the triple test in twins was higher at 15% compared with 6% in singletons, and the amniocentesis rate was 18.3% in twins and 7.5% in singletons. The differences in both the false-positive and amniocentesis rates were statistically significant. A summary of the efficacy of antenatal Down syndrome screening in twins can be seen on Table 8-7.

Table 8-7 The Efficacy of Antenatal Down Syndrome Screening in Twins

Test	Sens. (%)	FPR (%)	LR
Maternal age ≥ 35 : U.S. 2000	50.2	13.4	3.7
First Trimester:			
Maternal age, hCG, PAPP-A ¹¹⁴	52	5	10.4
First Trimester:			
Maternal age, hCG, PAPP-A, NT ¹¹⁴	80.3	5	16.0
Second Trimester:			
Maternal age, triple screen ¹¹⁵	53	5	10.6

FPR, false positive rate; hCG, human chorionic gonadotropin; LR, likelihood ratio; NT, nuchal translucency; PAPP-A, pregnancy associated plasma protein A; Sens., sensitivity.

Table 8-8

The Estimated Down Syndrome Detection Rate in Twins by Chorionicity at a 5% False-Positive Rate Using Maternal Age, Ultrasound, and the Serum Screen¹¹⁹

Twin Pregnancy	Nuchal Translucency (mm) (%)	Combined test (%)*	Integrated test (%)**
Monochorionic	73	84	93
Dichorionic	68	70	78
All twins	69	72	80
Singletons	73	85	95

*NT, free beta-hCG, PAPP-A at 10-13 weeks with maternal age

**NT, PAPP-A at 10 to 13 weeks and AFP, estriol, and free beta-hCG, and inhibin A at 14 to 22 weeks with maternal age.

AFP, alpha fetoprotein; hCG, human chorionic gonadotropin; NT, nuchal translucency; PAPP-A, pregnancy associated plasma protein A

Both first and second trimester serum and ultrasound test results may be combined in the integrated test in singletons and twins. This includes nuchal translucency, PAPP-A, and free beta hCG or hCG in the first trimester and the quad screen in the second trimester. Wald estimated the Down syndrome detection rate in twins by chorionicity at a 5% FPR¹¹⁹ (Table 8-8).

A survey of maternal fetal medicine specialists in the United States in 2001 found that 97.6% of them used the serum screen for antenatal diagnosis and 91.5% used ultrasound.¹¹⁶ Those using ultrasound focused on anomalies (83.4%), biometry (77.9%), and the genetic sonogram (77.9%). Of the second trimester markers identified, those most commonly used were major anomalies, cardiac abnormalities, nuchal fold thickness, short femur or humerus, echogenic bowel, ventriculomegaly, and pyelectasis. Those used less than 50% of the time were echogenic intracardiac focus, choroid plexus cyst, two-vessel umbilical cord, clinodactyly, sandal gap deformity, and a wide pelvic angle. When these markers were identified, the Down syndrome risk was modified using likelihood ratios, or the ratio of the incidence of the marker in the exposed (that is, Down syndrome fetuses) over its incidence in the unexposed (that is, unaffected fetuses). This risk modification can be performed when these markers are isolated or when they are found in combination. Using maternal age and the genetic sonogram in singleton pregnancies, the sensitivities for Down syndrome range from 80.5% to 91.2% and the false-positive rates range from 4% to 14%. The extension of this methodology to twin gestations, although intuitively attractive, has not been critically evaluated.

INVASIVE TESTING IN TWIN GESTATIONS

Invasive testing using either chorionic villous sampling or amniocentesis carries a slightly greater risk than that found in singletons. Ghidini et al¹²⁰ reported on 101 twin pregnancies in which an amniocentesis was performed and 108 twins with no amniocentesis. The miscarriage rate for the twin gestations who had the amniocentesis was 3.5% and it was 3.2% without the amniocentesis, demonstrating a slightly higher miscarriage rate in the group with the

amniocentesis. Several other studies quote higher loss rates than singletons; however, most losses are not related to the procedure.¹²¹

CERVICAL LENGTH AND SPONTANEOUS PRETERM BIRTH

Twin gestations are at increased risk for preterm delivery (see Fig. 8-10). The mean age at delivery for live-born twins in the United States has decreased from 35.8 weeks' gestation in 1991 to 35.4 weeks' gestation in 2001.⁴ Despite the increase in dizygotic twinning from assisted reproductive technologies, and therefore, in dichorionic gestations, the percent of twins delivering at less than 37 weeks has increased from 65% in 1991 to 74.5% in 2001.¹ Cervical length is a predictor of term and preterm delivery in twins. A normal cervical length usually results in a near-term delivery. Imseis et al¹²² found that a cervical length of greater than 35 mm between 24 and 26 weeks' gestation indicated a low risk of delivery at less than 34 weeks' gestation in twins. A cervical length of greater than 35 mm had a 49% sensitivity, 94% specificity and 97% positive predictive value for a delivery greater than 34 weeks' gestation. Several studies suggest that a short cervical length at 20 to 28 weeks of gestation places a twin gestation at significant risk of a preterm delivery. Souka et al¹²³ found that a cervical length measurement of less than 25 mm at 23 weeks' gestation was strongly correlated with a spontaneous preterm delivery. Goldenberg et al¹²⁴ compared cervical length with other predictors of twin preterm delivery. Using a cervical length of less than 25 mm at 24 weeks' gestation, they found that it was a better predictor of preterm delivery at less than 32, 35, and 37 weeks' gestation than the presence of bacterial vaginosis, a positive fetal fibronectin, and other risk factors. In the 147 sets of twins, a cervical length of less than 25 mm at 24 weeks was associated with a delivery at less than 32 weeks' gestation in 26.9%. If the cervical length was less than 25 mm at 28 weeks however, only 13.2% delivered at less than 32 weeks' gestation. Guzman et al¹²⁵ used a slightly different cervical length cutoff and a different gestational age time frame but arrived at similar conclusions. If the cervical length was less than 2.0 mm between 15 and 24 weeks' gestation, there was a 50% delivery rate at less than 32 weeks' gestation. If the cervical length between 25 and 28 weeks was less than 2.0 mm, the rate of delivery at less than 32 weeks gestation was 16.1%. Table 8-9 summarizes the efficacy of a 23-week cervical length ultrasound to predict a spontaneous preterm delivery in twin gestations. As with almost every complication of twins chorionicity influences the rate of preterm deliveries for a given cervical length. Monochorionic-diamniotic twins have a preterm delivery rate of 9.1% at less than 28 weeks compared with 1.5% for dichorionic-diamniotic twins. Therefore, chorionicity alters the efficacy of cervical length as a screening tool to predict preterm delivery.¹²⁶ In general, a short cervix in a monochorionic-diamniotic twin is of more concern than a short cervix in a dichorionic-diamniotic twin.

Newman et al¹²⁷ investigated the impact of cervical cerclage on the obstetric outcome of twin gestations with a shortened cervical length in a nonrandomized prospective study. They followed 147 consecutive twin mothers who

underwent transvaginal ultrasonographic cervical length measurement between 18 and 26 weeks' gestation. As expected, the risk of preterm delivery increased with decreasing cervical length. Those with cervical lengths less than 25 mm were offered a cervical cerclage. Twenty-one of 128 twin gestations underwent cerclage, for a cervical length of less than 25 mm. When the twin pregnancies were stratified into cervical length quartiles, midtrimester cerclage did not alter the risks of preterm delivery when compared with restricted maternal activity.

MULTIFETAL PREGNANCY REDUCTION

Owing to the increased risk of prematurity and the concomitant long-term risks of neonatal morbidity associated with higher order multiple gestations, multifetal pregnancy reduction has evolved as a modality to decrease the number of fetuses in the index pregnancy. The early experience reported 85 first trimester reductions in which all but five were reduced from triplets or higher to twins.¹²⁸ Reductions were performed with transabdominal injection of intracardiac potassium chloride on dichorionic-diamniotic pregnancies because vascular anastomoses in monochorionic placentas would place the co-twin at risk. The mean gestational age at delivery was 35.7 weeks, but eight pregnancies lost all of the fetuses. A transvaginal approach for the potassium chloride delivery has also been tried.¹²⁹ A single center's series of 290 consecutive cases of multifetal pregnancy reduction compared the transabdominal with the transvaginal route. They found a higher total pregnancy loss rate for those performed transvaginally (16.7%) compared with those done transabdominally (2.7%).¹³⁰

Other factors affect the loss rate in multifetal pregnancy reduction. There is a learning curve for the procedure. The pregnancy loss rates for multifetal pregnancy reductions are inversely proportional to the operator's experience.¹³¹ Loss rates also vary by the number of fetuses at the start and at the conclusion of the procedure. In a report of a multicenter experience with 3513 completed reductions, the pregnancy loss rates were 15.4% for a starting number of six fetuses or more, 11.4% for a starting number of five fetuses, 7.3% for a starting number of four fetuses, and 4.5% for a starting number of three fetuses. Loss rates with a final number of

fetuses of three, two, or one were 18.4%, 6.0%, and 6.7%, respectively. In a single-center experience on 1000 consecutive multifetal pregnancy reductions, the overall complete pregnancy loss rate was 5.9%.¹³² The loss rate was lowest with a starting number of two fetuses (2.5%) and remained stable for reductions with starting numbers of three, four, or five fetuses but increased thereafter to 12.9% for six or more fetuses. Loss rates also increased as the finishing numbers increased. The rate of prematurity also rose with a higher finishing number. A final number of one, two, or three had a loss rate of 3.5% to 5.5% to 16.7% respectively. The mean gestational age at delivery for final singletons was 37.9 weeks; for twins, 35.3 weeks, and for triplets, 33.5 weeks. Note that these gestational ages are very similar to unreduced pregnancies with a similar number of fetuses. A comparison of reduced twins from triplets to nonreduced twins and triplets also confirmed that pregnancy losses and prematurity can be diminished with multifetal pregnancy reduction.¹³³ Given the potential impact for pregnancy loss and prematurity associated with a twin gestation, some practitioners now offer the reduction of twins to a singleton gestation.¹³⁴ Chorionic villous sampling has been used to guide multifetal pregnancy reduction.¹³⁴⁻¹³⁶

TWINS DISCORDANT FOR ANOMALIES

The finding of an anomalous fetus in a twin gestation is not uncommon.¹⁴ The background risk for major anomalies in all singleton pregnancies is 2% to 3%, and this is doubled for twins. There is a 3-fold increase in anomalies in monozygotic twins that may be related to the underlying cause of monozygotic twinning.¹³⁷ Structural cardiac abnormalities in monozygotic twins without TTTS are four times more common than the background risk.¹³⁸ The management of one anomalous fetus with a normal co-twin is problematic. The options for addressing this dichotomy depend on the severity of the anomaly, the gestational age at diagnosis, the health of the co-twin and the potential for the anomalous fetus to affect the long-term success of the pregnancy.

When an abnormality is found in one twin, selective reduction of that twin is possible. Evans et al¹³⁹ reported on selective reduction in 345 twin pregnancies. The total pregnancy loss at less than 24 weeks was 7% and after 24 weeks

FIGURE 8-42. Growth curves for twin gestations by chorionicity. Tenth-percentile growth curves of published nomograms of singletons reported by Brenner WE, Edelman DA, Hendricks CH (squares) and Zhang and Bowes (diamonds) and of monochorionic twins (closed circles) and dichorionic twins (open circles) reported by Ananth CV, et al. (Modified from Anath CV, Vintzileos AM, Shen-Schwartz S, et al: Standards of birthweight in twin gestations stratified by placental chorionicity. *Obstet Gynecol* 91:91, 1998. Reprinted with permission from the American College of Obstetricians and Gynecologists.)

was 0.9%. Of the twins delivering after 24 weeks, 12.4% delivered between 25 to 32 weeks and 79.8% delivered at greater than 32 weeks. For triplets, the loss rate was 12.8% before 24 weeks and for quadruplets it was 14.3% before 24 weeks.¹⁴⁰

METHOD USED FOR SELECTIVE REDUCTION OF THE ANOMALOUS FETUS

Selective termination in a dichorionic twin pregnancy uses transabdominal injection of potassium chloride into the fetal heart. Generally the needle is inserted into the left side of the fetal heart and remains in situ for several minutes to document fetal asystole. Rescanning is usually performed to confirm the fetal demise. Evans published the earliest experience in a multicenter study of 183 cases of selective fetocide.¹⁴¹ The fetal loss rate before 24 weeks was 8.3% with potassium chloride, and 41.7% with air embolization. A subsequent report of 402 cases using only potassium chloride injection found a 7.5% fetal loss rate before 24 weeks' gestation.¹³⁹

TWIN GROWTH

An important and easily obtained measure of fetal well-being in a multiple gestation is fetal growth. Growth discrepancy is calculated by subtracting the estimated fetal weight of the smaller fetus from the larger fetus and dividing by the weight of the larger fetus. Discordant birthweight is a diagnosis made on serial ultrasound examinations that can predict adverse pregnancy outcomes, especially for the smaller fetus.¹⁴²⁻¹⁴⁴ However, even in very discordant twins,

the size of the smaller fetus may frequently be appropriate for gestational age.¹⁴⁴ Yinon et al¹⁴⁵ has shown that in a small-for-gestational-age discordant twin, there is a much higher risk for adverse outcome than in an appropriate-for-gestational age discordant twin. Prospectively, therefore, pregnancy management should not be based on discordance alone. Additionally, there is controversy over the degree of discordance that can accurately be predicted by a single ultrasound examination.^{146,147} Serial biometry is a more accurate method to predict problematic discordant fetal growth.^{148,149} Twin growth is similar to that of singletons until 30 to 32 weeks' gestation and varies by chorionicity as seen in Figure 8-42.^{150,151} After 32 weeks, the placental reserve may limit fetal growth, leading to an asymmetric growth pattern (that is, lag in the abdominal circumference) seen in the third trimester. This asymmetric pattern typical of intrauterine growth restriction predicts the increased potential for adverse pregnancy outcomes.^{152,153}

Because twins are at greater risk for growth abnormalities, they are followed more frequently than singleton gestations. The minimum time between ultrasound examinations to determine that the weight difference, that is, from that found on the previous scan, is meaningful is two weeks.¹⁵⁴ Serial ultrasound examinations are usually performed in twin gestations at monthly intervals for normally growing twins and at 2-week intervals when growth abnormalities are documented or suspected. Monochorionic twins are at greater risk of growth disturbances, especially from 16 to 22 weeks and are followed at 1- to 2-week intervals during this time frame to screen for TTTS (see Fig. 8-7).³²

First trimester discordance in size can also be useful for predicting potential adverse outcomes. Kalish showed that a crown rump length (CRL) discordance greater than 10% among 159 twins between 11 and 14 weeks was associated

FIGURE 8-43. Vertex-vertex presentations in a twin gestation.

with nearly a 10-fold increased risk for fetal structural or chromosomal anomalies.¹⁵⁵ The same group showed that in 130 twin pregnancies, a greater than 3-day difference in CRL between 11 and 14 weeks predicted nearly a 6-fold increased risk for birthweight discordance greater than 20%.¹⁵⁶ Salomon et al¹⁵⁷ also found that when a CRL discrepancy was more than the 95th percentile, there was an increased risk of fetal aneuploidy.¹⁵⁷ Unlike almost everything else in twins, this was not influenced by chorionicity.

Intrapartum Use of Ultrasound in Twin Gestations

Multiple gestations pose numerous problems in the delivery room.^{158,159} There is a higher incidence of prematurity, abnormal fetal lie, abnormal placentation, cord accidents, and retained placentas. Because of this, we believe that ultrasound is an essential component in the intrapartum management of twins. Estimation of fetal weight, fetal lie, and presentation are best accomplished by ultrasound in twin pregnancies (Fig. 8-43). If the presenting fetus is in a transverse lie, ultrasound aids in the decision regarding the uterine incision. A transverse fetal lie with the fetal back down is generally delivered through a vertical uterine incision. If the fetal lie and estimated weights support a decision for a vaginal birth, ultrasound is very helpful in visualizing the position of the second twin during the second stage.¹⁵⁹ Ultrasound can ensure that no cord or fetal small parts are presenting. If the operator decides to perform a version of the second fetus, the ultrasound is often useful during the procedure. Even when a breech extraction is planned, ultrasound assists the clinician to correctly identify the fetal ankles aiding in the delivery process.

CONCLUSION

Multiple gestations pose interesting and exciting challenges to parents, obstetricians, and sonographers. We have reviewed the role of ultrasound in the diagnosis of twins, the determination of chorionicity, the management of complications unique to twins, the value of cervical length screening

to predict prematurity, the use of ultrasound in screening for aneuploidy in multiples, and the intrapartum role of ultrasound in twin gestations. Ultrasound is a valuable tool for the obstetrician and sonographer to improve the diagnosis of twins and higher order multiples to guide the care and management of complications relating to multiple gestations.

ULTRASOUND EVALUATION OF NORMAL FETAL ANATOMY

Roy A. Filly, MD and Vickie A. Feldstein, MD

Superficial Anatomy of the Fetus

Musculoskeletal System

Cardiovascular System

Gastrointestinal System

Respiratory System

Genitourinary System

Central Nervous System

Our understanding of normal fetal anatomy as seen on sonograms continues to be an area of considerable growth. Instrumentation has improved steadily, yielding both improved and more consistent image quality. Among the most significant advancements for fetal imaging has been the ability to choose the depth of the zone of best focus of the ultrasonic beam and to select frequency without changing transducers. With these capabilities, the area of anatomy being observed can be consistently inspected with the focused portion of the beam at an optimum frequency, both highly significant advantages. More recently, three-dimensional sonographic imaging has expanded our ability to evaluate the fetus in a near-infinite number of tomographic planes as well as with surface-rendered viewing.

Furthermore, sonologists have gradually improved their understanding of the anatomy portrayed on in utero sonograms. Unquestionably, clearer images have led the way to our improved understanding, but other factors have been involved. Not the least of these has been the surge in ultrasonic imaging of premature neonates.^{1,2} These tiny neonates are the equivalent of second trimester fetuses as early, at times, as 24 weeks. Visualization of their brain^{1,2} (Fig. 9-1) and abdominal (Fig. 9-2) anatomy in the more ideal ex utero environment, which permits the use of higher frequency transducers, a greater selection of planes of section, and comparison with other imaging modalities, has done much to improve our understanding of fetal anatomy. This information can be, to a large extent, extrapolated to younger fetuses. Also, magnetic resonance imaging continues to be a growth area in fetal imaging. Our ability to compare sonographic anatomy of the fetus with that portrayed on magnetic resonance imaging further enhances our understanding of fetal sonographic anatomy.³⁻⁷

The ability of sonography to detect intrafetal structures depends on a balance between spatial resolution and contrast.⁸ This balance, however, strongly favors contrast as the more important aspect of perception. For example, a large white dot on a white wall is difficult or impossible to see because no contrast differential exists even though the eye can spatially resolve easily a tiny black dot (high contrast)

on the same wall. Structures possessing high levels of subject contrast can be consistently detected at a smaller size (often equating to an earlier age) than those displaying poor contrast. Although sonographic contrast agents are available for imaging in adults and children, current agents do not cross the placenta in sufficient concentration to affect fetal organs.⁹ Therefore, sonologists possess no agents to alter contrast of fetal organs and thus are totally dependent on subject contrast (inherent contrast) for visualization of internal fetal morphologic details. Clearly, spatial resolution is also a critical feature in defining morphology but has not been the limiting factor in demonstrating fetal anatomy. Fortunately, sophisticated modern sonographic imaging systems have the ability to choose varying contrast settings, which enhance inherent tissue differences.

Another technology that has improved fetal imaging, particularly for earlier gestations, is the intracavitary (transvaginal) transducer.¹⁰⁻¹² Certain aspects of fetal, indeed embryonic, anatomy can be seen with amazing detail (Fig. 9-3). Although this methodology is crucial to modern imaging, we intend to concentrate our discussion on anatomy visualized by transabdominal transducers in fetuses beyond the 14th week. When examining later pregnancies, in the context of fetal anatomic imaging, we use transvaginal transducers predominantly to visualize the presenting part when transabdominal transducers fail to adequately image this region of the fetus's anatomy (i.e., distal sacrum in a fetus in breech presentation).

Other parameters, important in fetal imaging, also cannot be controlled. Sonography is a tomographic technique. Appropriate positioning for obtaining the best tomographic plane is always desirable. However, we are unable to control fetal position to attain this end. We also cannot control maternal body habitus or the amount of amniotic fluid, both of which may dramatically alter our ability to discern fetal anatomy. Despite these problems, a large number of fetal structures are consistently visible sonographically.

High-resolution, real-time scanners with their flexible approach to imaging are mandatory for modern fetal sonography.¹³⁻¹⁵ In the following sections, various aspects of fetal

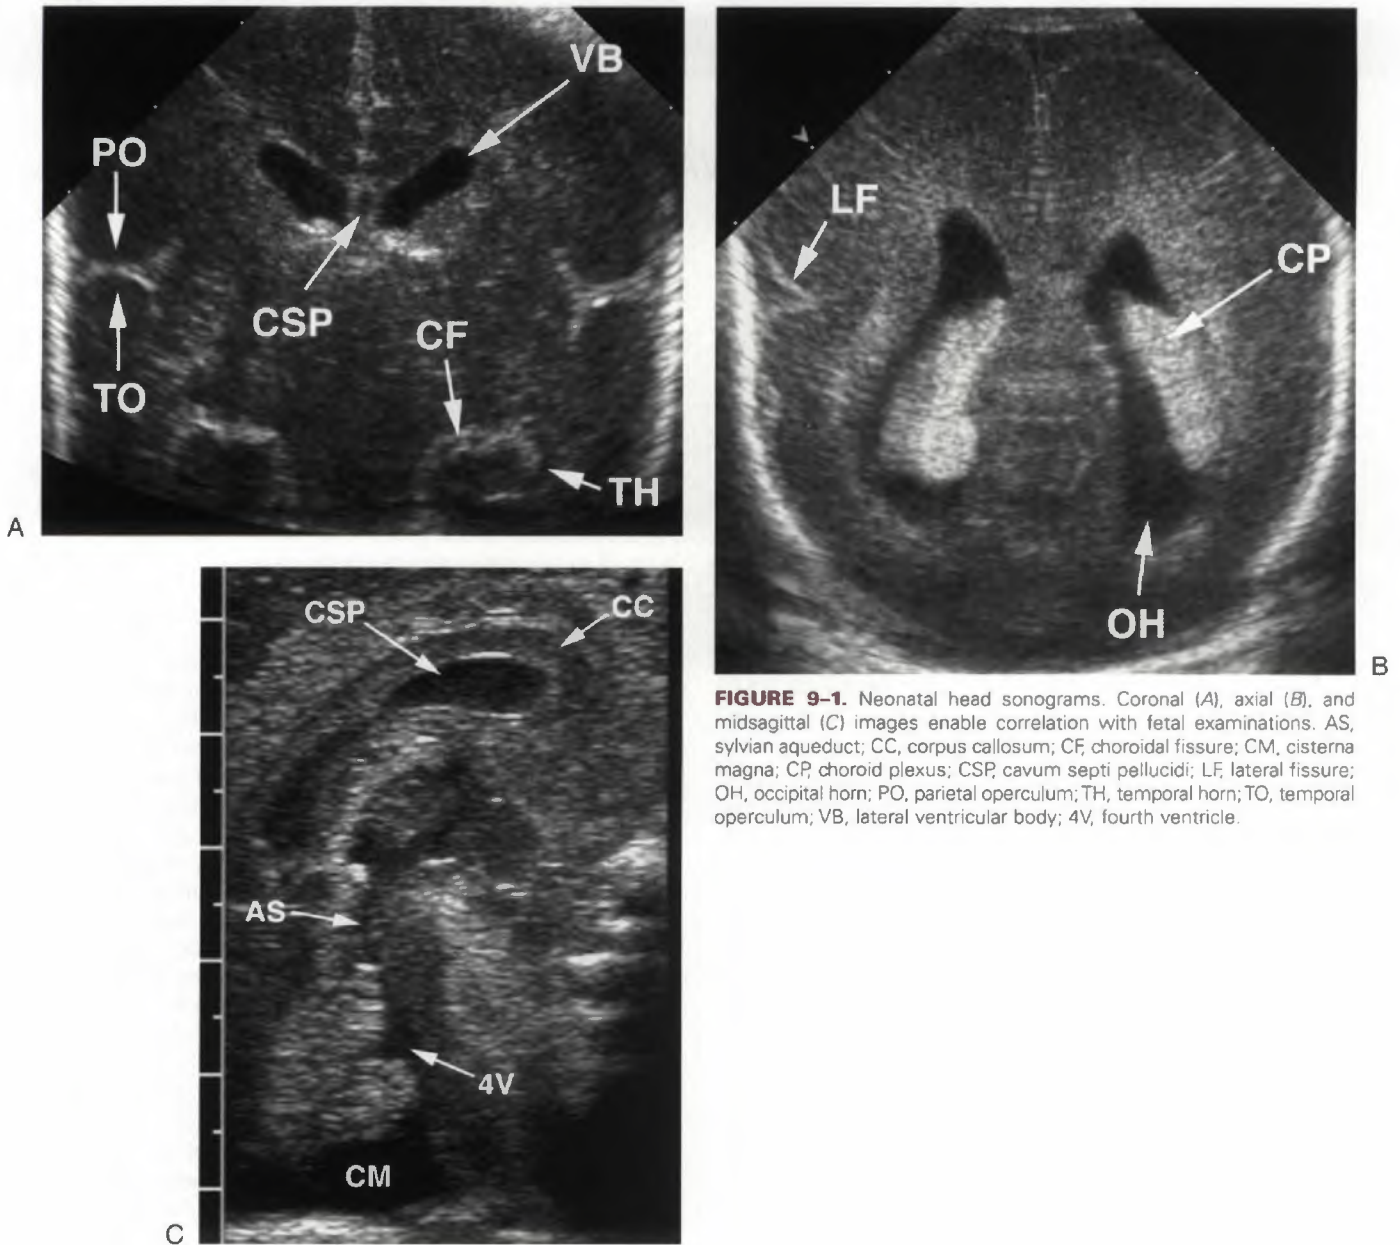

FIGURE 9-1. Neonatal head sonograms. Coronal (A), axial (B), and midsagittal (C) images enable correlation with fetal examinations. AS, sylvian aqueduct; CC, corpus callosum; CF, choroidal fissure; CM, cisterna magna; CP, choroid plexus; CSP, cavum septi pellucidi; LF, lateral fissure; OH, occipital horn; PO, parietal operculum; TH, temporal horn; TO, temporal operculum; VB, lateral ventricular body; 4V, fourth ventricle.

FIGURE 9-2. Neonatal abdominal sonograms. A. Transverse axial image. B. Parasagittal image. AG, adrenal gland, both cortex (thicker and darker) and medulla (thinner and brighter); CB, Bertin column; P, medullary pyramid of the kidney.

FIGURE 9-3. Transvaginal sonogram of a 17-mm embryo. This mid-sagittal view demonstrates the large early fourth ventricle formed by the folding of the rhombencephalon (R). A, amnion.

anatomy are detailed as seen on such instrumentation. An estimate is made of the ability of ultrasound instrumentation to consistently demonstrate the anatomic part under consideration as well as an attempt to estimate when the fetus has attained sufficient size such that the anatomic structure is large enough to be detected. It is important to recall that size and visualization may be relative at any given stage of development. For example, in a small fetus with a well-distended urinary bladder, identification of the bladder is relatively easy. Alternatively, identification of the bladder will be difficult in a term fetus that has recently voided. The urine, in this instance, provides the "contrast" that ordinarily makes the urinary bladder an easy structure to perceive. If this contrast agent drains away, the size of the fetus (and thus its bladder) will not rescue one from the loss of contrast. Important also is the concept that the human eye sees best in the "relative" rather than the "absolute" sense of size. Thus, in a young fetus, the cerebral ventricle is much more readily seen than in an older fetus because the relative size of the ventricle compared with overall brain size is larger early (even though the absolute size is larger later).

If the sonographer begins with a specific intent to image a particular fetal part, it is frequently possible to succeed.^{8,16} To accomplish this end, the sonographer must (1) assess the precise fetal position; (2) consider whether the anatomic part of interest is best visualized in planes perpendicular to the fetal long axis or parallel to the fetal long axis; and (3) adjust acoustic imaging parameters, particularly time-gain compensation, and transducer angulation to visualize the area to best advantage. Obviously, such rules are the same throughout all of sonography. The challenge of imaging intrafetal structures is to apply these rules when fetal position is

changing such that the current scanning plane is no longer applicable for the part one wishes to visualize.

The flexibility offered by real-time sonographic systems enables one to survey the fetus quickly to determine precise position. Second, the sonographic tomograms, which are rapidly generated (virtually "real-time" imaging), enable one to view a large volume of the fetus with closely spaced sections. Such a rapid look at many contiguous tomograms eliminates one of the basic flaws of tomographic imaging of a moving target. Finally, fetal movements are viewed directly, which enables one to quickly reorient the transducer to the optimal plane of section to image the structure of interest. As digital image storage and viewing continues to expand, cine clip technology has greatly improved the capture and viewing of many fetal parts, especially those that are in motion, such as the heart. Currently, three-dimensional imaging systems have reached a clinically relevant stage of development.¹⁷⁻¹⁹ These instruments depend on "volume imaging." That is, a volume of tissue (the fetus) is insonated and the data are gathered in the processing computer. From this "volume," three-dimensional images are generated. Of perhaps greater importance in the future, individual planes of section in virtually any orientation can be computed. When and if it becomes possible to generate equivalent planar images to those obtained with a hand-held transducer, the current method of "fluoroscopic" sonography, the entire nature of sonography will change. The technical challenges of sonography will be greatly reduced (Fig. 9-4). Three-dimensional imaging of fetal anatomy will be covered in a separate chapter.

Fetal parts of interest to the sonologist fall into three major categories of subject contrast that subsequently determine the relative ease with which the structure is sonographically visible: (1) structures that generate high-amplitude reflections (e.g., ossified bones, submucosa of fetal bowel); (2) structures that generate no internal echoes (e.g., fluid-containing viscera); and (3) those that generate midrange gray echoes (e.g., the parenchymal organs such as the lungs, brain, spleen, liver, kidneys, muscles). The categories are listed from most visible to least visible. Within the last category, one may anticipate seeing a spectrum of gray shades that will enable distinction between several parenchymal organs and intraorgan components. For example, the medullary portions of the fetal renal parenchyma generate lower amplitude internal echoes than do the surrounding cortical tissues and Bertin septa, thus enabling recognition of this separate component of renal tissue (Fig. 9-5).²⁰

A feature of critical importance for organ imaging is the fetal position. Clearly, a prone fetus is in an optimal position for imaging the kidneys, ordinarily difficult to perceive, but in a poor position to demonstrate the urinary bladder, which is usually easy to image. Determination of fetal position should be accomplished in all obstetric sonographic examinations from the second trimester onward. The fetal position should be determined as precisely as possible before an interpretation of fetal anatomy is begun, because the position of a structure will often influence our interpretation. The general fetal orientation is first assessed (i.e., longitudinal, oblique, or transverse). Once this is determined, the presentation (i.e., cephalic, breech) and location of the fetal spine are noted. If, for example, the fetal spine is on the maternal left side and the fetus is in a cephalic presentation,

FIGURE 9-4. Normal face in a 35-menstrual-week fetus. A. Multiplanar and volume-rendered images of the fetal face are displayed. Upper left, a coronal view through the nose and lips is seen. Upper right, a sagittal or profile view of the face is seen. Lower left, an axial plane through the anterior alveolar ridge of the primary palate is shown. Lower right, a volume-rendered image of the face using surface and light techniques is shown. A line is visible crossing the upper lip of the fetus, which identifies the level of the axial plane in the lower left box. Note two tooth buds in the anterior alveolar ridge (arrows). B. Images from multiple rotations of the fetal face are shown. Generally, a volume is rotated with a knob on the work panel to provide the impression of three-dimensionality. (From Pretorius DH, Nelson TR: *Three-dimensional ultrasound in gynecology and obstetrics*. *Ultrasound Q* 14:218, 1998.)

one can judge that the fetus is lying on its left side (Fig. 9-6). Conversely, if the fetus is breech, then it must be lying on its right side. The reverse is the case for breech and cephalic fetuses when the fetal spine lies on the maternal right side. In the transverse or oblique fetal positions, the same rules apply but with a different orientation.

Such an analysis of fetal position is vital for proper interpretation of abdominal and thoracic situs and for identification of abnormal fetal structures. For instance, a rounded, fluid-filled structure in the left posterior portion of the upper fetal abdomen may be assumed to represent the fundus of the fetal stomach. However, a structure of identical appearance but located on the right side of the upper fetal abdomen must be interpreted as a pathologic lesion or an abnormality of situs.

It is important to recall that pathologic structures are frequently more visible than their normal counterparts (e.g., dilated small bowel loops are easier to detect than normal small bowel loops). However, it is even more important to keep in mind that the most difficult pathologic observation is to recognize the absence of a structure that ordinarily

FIGURE 9-5. Sonogram of a fetal kidney in longitudinal axis (arrows). The medullary pyramids (darker, triangle-shaped areas) are distinguished from surrounding cortical tissues and septa of Bertin.

could be visualized (e.g., a missing portion of an extremity or the inability to see the stomach when esophageal atresia without tracheoesophageal fistula is present).

SUPERFICIAL ANATOMY OF THE FETUS

Routine sonography for obstetric indications rarely requires a survey of superficial fetal structures. However, when an anomaly is suspected, a careful look at superficial features of the fetus becomes important or even mandatory. Superficial anatomy considered in this section includes the face, ears, hair, and external genitalia. Importantly, technologic advancements in three-dimensional renderings of fetal sonograms have had a dramatic impact on visualization of superficial fetal anatomy.²¹⁻²³ Please refer to Chapter 24 for details.

The fetal face can be viewed with considerable clarity with two-dimensional sonography. Expectant mothers are often surprised to see their fetus so clearly (Figs. 9-7 to 9-9). The brow, cheeks, eyelids (and occasionally even eyelashes), nose, lips, and chin can be seen with consistency. The nose and lips are the more important to image in detail (to exclude clefting). The alae, column, and nares can be clearly depicted (Figs. 9-10 and 9-11). The upper lip is more important diagnostically than the lower lip and fortunately easier to see. Visualization is usually good enough to identify the philtrum. The cheeks are prominent, as expected, and the subcutaneous tissues of the cheek, because of the presence of a large fat pad, are brightly echogenic (Fig. 9-12). The profile is also readily demonstrated (see Fig. 9-9) and provides useful information about the brow (e.g., frontal bossing), chin (e.g., hypognathia), and nose (e.g., midface hypoplasia and the Down syndrome).

The ears can be visualized quite well and their progressive maturation noted.²⁴ The external auditory canal, helix (and

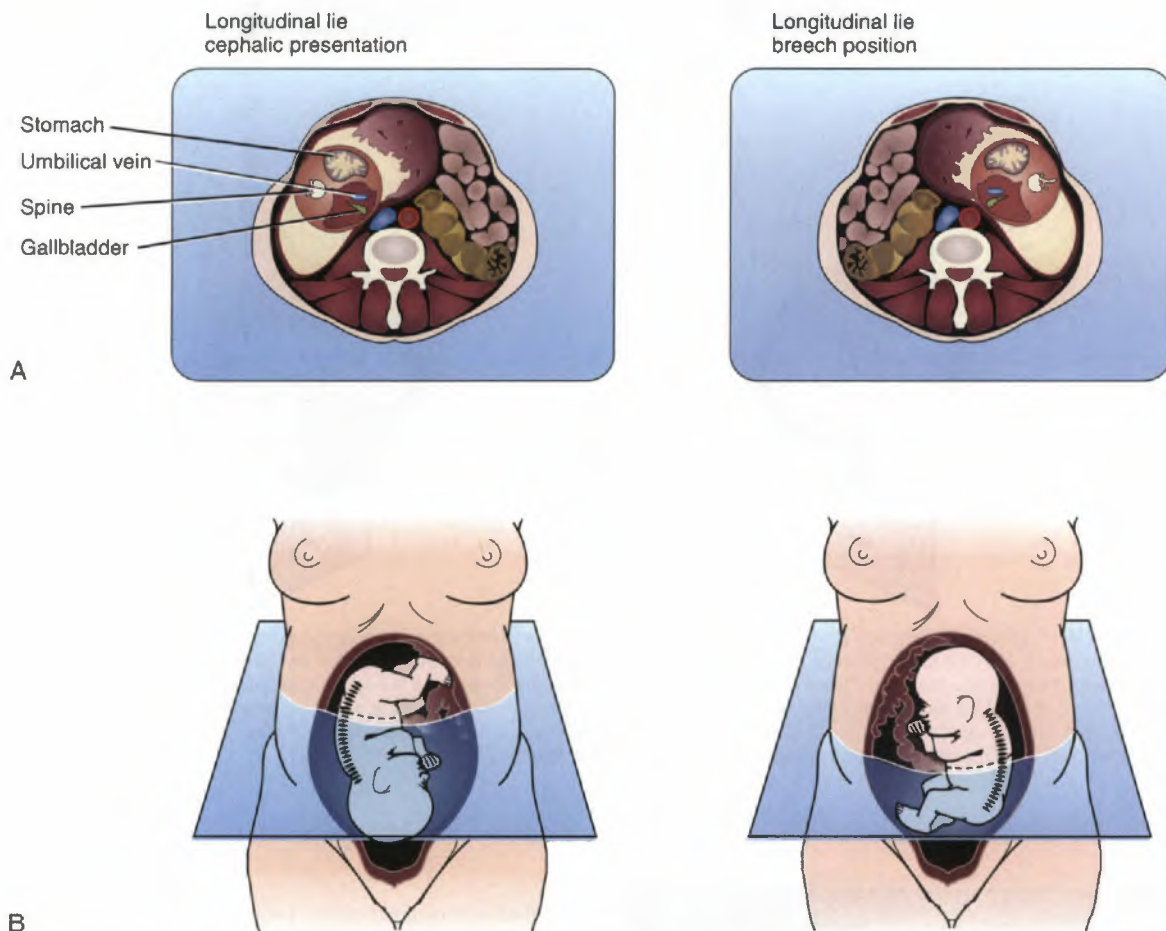

FIGURE 9-6. Knowledge of the plane of section across the maternal abdomen (longitudinal or transverse) as well as the position of the fetal spine and left-sided (stomach) and right-sided (gallbladder) structures can be used to determine fetal lie and presenting part. *A.* This transverse scan of the gravid uterus demonstrates the fetal spine on the maternal right with the fetus lying with its right side down (stomach anterior, gallbladder posterior). Because these images are viewed looking up from the patient's feet, the fetus must be in a longitudinal lie and in cephalic presentation. *B.* When the gravid uterus is scanned transversely and the fetal spine is on the maternal left, with the right side down, the fetus is in a longitudinal lie and in breech presentation. *Continued*

FIGURE 9-6 cont'd. C. When a longitudinal plane of section demonstrates the fetal body to be transected transversely and the fetal spine is nearest the lower uterine segment, with the fetal right side down, the fetus is in a transverse lie with the fetal head on the maternal left. D. When a longitudinal plane of section demonstrates the fetal body to be transected transversely and the fetal spine is nearest the uterine fundus with the fetal right side down, the fetus is in a transverse lie with the fetal head on the maternal right. Although real-time scanning of the gravid uterus quickly allows the observer to determine fetal lie and presentation, this maneuver of identifying specific right- and left-sided structures within the fetal body forces one to determine fetal position accurately and identify normal and pathologic fetal anatomy.

FIGURE 9-7. Coronal section of the fetal face that demonstrates the palpebral fissures (PF) particularly well. NB, nasal bone.

antihelix in older fetuses), lobule, and tragus can be depicted (Fig. 9-13), but the relative position of the ear (e.g., as in low-set ears) is difficult to judge—a task more readily accomplished with three-dimensional imaging. The ear may be protuberant and can be mistaken for an abnormality, especially an encephalocele.²⁵

Scalp hair is readily perceived in late fetuses (that have some). The bright linear echoes protruding from or paralleling the scalp and neck are quite conspicuous. Indeed, the only benefit of recognizing hair is not to be misled into mistaking long hair for a pathologic process, namely, an encephalocele or cystic hygroma, because longer hair, wet and matted by the amniotic fluid, may trap some of the fluid between it and the skin of the occiput or neck, creating the false impression of a cystic mass in this location (Fig. 9-14).

The external genitalia can be appreciated from early second trimester onward. Gender can be quite accurately assigned.²⁶⁻²⁸ Ordinarily, this is not of clinical consequence. However, in certain circumstances, gender should always be

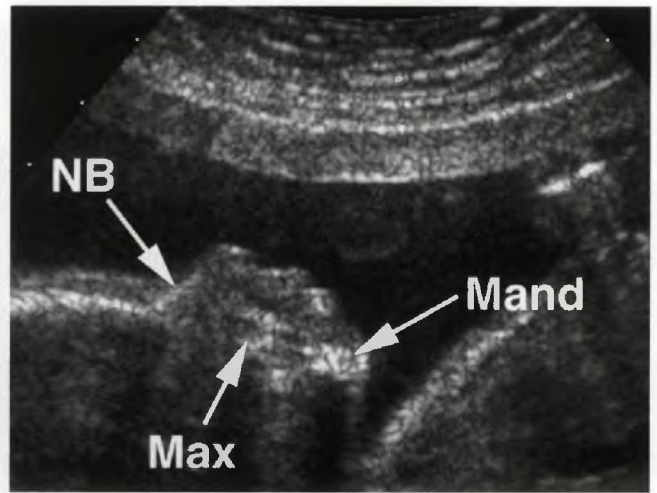

FIGURE 9-8. Sonogram of the fetal face. Even though this image is a tomogram with relatively little depth, facial features are seen well. Amniotic fluid surrounding the face provides the "contrast" for visualization. 1, brow; 2, eyelid; 3, cheek; 4, ala of nose; 5, nostril; 6, philtrum; 7, upper lip; 8, lower lip.

FIGURE 9-10. "Coronal" sonogram of the nose and mouth. Nasal structure is particularly well seen. 1, ala; 2, column; 3, nostril. The mouth displays less detail, although consistent and characteristic layering of echoes is seen. These layers are (presumably) the subcutaneous fat (5) and muscular tissue (6), the orbicularis oris muscle, and (7) the mucosal tissue.

determined. These include all living twins in which a single placental site is seen or when monozygotic twinning, other than for reasons of placentation, would be considered detrimental to pregnancy outcome.²⁹ All fetuses with suspected lower urinary tract obstruction should have gender determined because the differential diagnosis is different in boys and girls. Certain other circumstances would require gender determination if karyotyping were refused or impractical to perform. These include, but are not limited to, risk for X-linked disorders or when the Turner syndrome is suspected because of a dysmorphic feature (e.g., cystic hygroma).

Female gender should be assigned only by identification of the major and minor labia (Fig. 9-15). Assigning female gender because of an inability to see a penis will result in many diagnostic errors. Male genitalia are readily seen (Fig. 9-16). The penis and scrotum are most obvious. Testes may be seen in the scrotal sac, sometimes as early as the beginning of the third trimester (the testes are intraabdominal during most of gestation, but are often visualized in the presence of ascites). Details of the penis, including the glans,

urethra, and corpora cavernosa, may be appreciated (Fig. 9-17). Even the foreskin is visible in some cases.

MUSCULOSKELETAL SYSTEM

Real-time ultrasonography provides the most appropriate format for imaging fetal bones. The resolution and flexibility offered by such systems enable one to survey the fetal skeleton rapidly. Of all structures within the fetus, the ossified portions of the skeleton possess the highest level of subject contrast and thus are seen earlier and more consistently than any other organ system.^{13,30-33} Indeed, sonography surpasses all other imaging modalities in fetal

skeletal imaging. Although radiographs of abortuses demonstrate bony morphology more advantageously than would a sonogram,^{34,35} the reverse is true of fetuses in the womb, where overlying maternal soft tissues and bones, fetal movement, and inappropriate fetal position defeat radiographic techniques in visualization of the early fetal skeleton. With volume imaging (three-dimensional sonography) special processing can give a more global view of fetal skeletal structures than can be achieved with two-dimensional sonography.³⁶⁻³⁸ This enhances the image and diagnostic process for assessment of both normalcy and pathology.

Fetal position is extremely important. The posterior elements of the fetal spine may be clearly imaged with the fetus in a prone or decubitus position but are difficult to image when the fetus is supine.³⁹ Similarly, the extremities are imaged to excellent advantage when floating freely in the amniotic fluid. The same extremity tucked under the fetus will be quite difficult to image.

Despite these potential problems, fetal skeletal structures remain the earliest and most readily recognized fetal anatomic structures. Indeed, the earliest structures seen with consistency are the ossification centers of the maxilla, mandible, and clavicle, the first bones of the human body to ossify.¹³ The calvaria can be imaged from the late first trimester onward. The same is true of the long bones of the upper and lower extremity (Fig. 9-18). Visibility of bony detail rapidly increases, and by 15 to 16 menstrual weeks (sometimes earlier), even phalanges can be visualized. Bones of only 2 to 3 mm in size can be consistently imaged by sonography, provided that no unusual impediments to the scanning procedure exist (Fig. 9-19). Many specific bony structures can be depicted. Bones in both the appendicular and axial skeleton are well imaged.

It is important to clarify that sonography has the capacity to visualize not only the ossified portions of the fetal skeleton but also the cartilaginous portions.¹³ Cartilaginous ends of the long bones may be seen by the early second trimester. Indeed, bones entirely in cartilage can be seen sonographically (Fig. 9-20). It is equally important to recognize that the full thickness of the ossified diaphysis of long bones is not seen sonographically.⁴⁰ This is due to acoustic shadowing. The cartilaginous ends of long bones help us to recognize this aberration. By matching up the width of the epiphysis, the full thickness of which can be seen, with the apparent "width" of the bony diaphysis, it is clear that these are unequal (Figs. 9-21 and 9-22). This observation helps to correct some perceptual errors that can lead to erroneous diagnoses. For example, the inability to see the full thickness of the femoral diaphysis creates the impression that the fetal femur farther from the transducer is bowed (Fig. 9-23).⁴⁰ This error is caused by visualization of only the medial cortex of the femoral diaphysis (which is normally curved) (Fig. 9-24). However, the inability to "visually correct" this normal curvature by simultaneous observation of the "straight" lateral cortex causes the perceptual error.

The majority of the bones of the appendicular skeleton can be seen in early to middle second trimester, although phalanges may be difficult to perceive in some instances. It is a general rule of appendicular skeletal imaging that the more proximal a bone, the more readily it is identified. This rule in one sense is untrue of the hands and feet, in which the metacarpals and metatarsals are seen more readily and

earlier than either the carpal or tarsal bones (see Figs. 9-19 and 9-25). This is because the metacarpals and metatarsals are well ossified at 4 months, whereas the carpals and tarsals (except for the tarsal calcaneus and talus) remain cartilaginous throughout pregnancy. The tarsal calcaneus and talus ossify between the 5th and 6th months, whereas the remaining tarsals and carpals do not ossify until after birth (Figs. 9-26 and 9-27).

FIGURE 9-16. Nonerect fetal penis seen sonographically. FS, foreskin; S, shaft.

The scapula (Figs. 9-28 and 9-29), clavicle (Fig. 9-30), humerus (see Figs. 9-28 and 9-31), radius (Fig. 9-32), ulna (see Figs. 9-31 and 9-32), metacarpals (see Figs. 9-19 and 9-32), and phalanges (see Figs. 9-19 and 9-33) can be imaged in most cases. Interestingly, the clavicle may be difficult to see, presumably because of the flexed position of the fetal neck, which draws the calvaria into a position that obscures the clavicle. Nonetheless, if one desires to see the clavicle,

FIGURE 9-18. Sonogram of a 10½-week-old embryo demonstrates the tiny (approximately 1 mm) primary ossification center of the femur (arrow). (From Mahony BS, Filly RA: *High-resolution sonographic assessment of the fetal extremities*. *J Ultrasound Med* 3:489, 1984.)

FIGURE 9-19. Sonogram of a 20-week fetal forearm and wrist. CR, cartilaginous carpal bones; R, radial diaphysis (distal radial epiphysis is also cartilaginous).

this can nearly always be accomplished. Indeed, measurements exist for normal clavicular length at various gestational ages.⁴¹ Similarly, the femur (Figs. 9-34 to 9-37), tibia (Figs. 9-38 and 9-39), fibula (see Fig. 9-38), metatarsals (see Figs. 9-25 and 9-26), and phalanges (see Fig. 9-25) of the lower extremity can be appreciated well sonographically.

FIGURE 9-20. A. Midsagittal sonogram of the fetal knee. B. Axial sonogram (similar to the knee radiograph called the "sunrise view"). CL, posterior cruciate ligament; DFE, distal femoral epiphysis; P, patella (a bone that is entirely cartilaginous); PL, patellar ligament; PTE, proximal tibial epiphysis. Note the echogenic synovium located between the patella, patella ligament and the epiphyses.

The figures demonstrating the hip joint, femur, and knee (see Figs. 9-34 to 9-38) may be reviewed to appreciate the remarkably detailed anatomy that can be achieved with high-resolution sonography.

The simplest way to identify the types of long bones of the extremity viewed on the sonogram is to obtain planes of section that traverse the short axis of the limb. Sonograms obtained in such a plane through the forearm and calf will demonstrate two bones. In the lower leg, the more lateral bone is the fibula, and the medial bone is the tibia (see Fig. 9-38). This method works as well in the forearm but is less precise because pronation may cause the radius and ulna to "cross." In the normal fetus, the tibia and fibula and

FIGURE 9-21. A. Sonogram best demonstrating the femur farther from the transducer. Arrows mark the edges of the distal epiphysis. Arrowheads mark the apparent “edges” of the distal femoral diaphysis. The more medial edge of the diaphysis matches the edge of the medial condyle, but the lateral edges of “diaphysis” and lateral condyle are widely disparate. B. The same exercise can be performed on the nearer femur. Again, arrows mark the edges of the distal epiphysis and arrowheads mark the “edges” of the femoral diaphysis. Shadowing by the bone but not the cartilage causes this deceptive appearance.

FIGURE 9-22. Sector sonogram of the distal femur taken such that the lines of sight from the transducer intersect the inferior end of the femoral metaphysis at the epiphyseal plate (1). By this maneuver, the full thickness of the distal ossified femur is seen sonographically (compare with Fig. 9-21). Now, the thickness of the epiphysis (arrows) and ossified femoral shaft match perfectly. 2, patella; 3, secondary ossification center of the distal femoral epiphysis.

radius and ulna end at the same level distally (see Fig. 9-32). Proximally, of course, the ulna is longer than the radius (see Fig. 9-31) and the tibia is longer than the fibula. This allows both ready differentiation of the tibia and fibula in the lower extremity and of the radius from the ulna in the upper extremity. That both paired long bones of the upper and

lower extremity end at the same level distally is important in assessing possible limb reduction abnormalities.

The hand can be assessed more critically than the foot.⁴²⁻⁴⁴ With patience, one can usually discern all four fingers and the thumb. The hand is frequently clenched in a fist-like fashion, which can complicate the counting of fingers. However, even under this circumstance, one can frequently make the necessary observations. The toes, although smaller than the fingers, can be seen relatively well with modern equipment (see Figs. 9-25 and 9-27). If difficulty arises, it is usually the functionally less important fourth and fifth toes that are not seen.

It is possible in the late third trimester fetus to identify the distal femoral (see Figs. 9-22 and 9-40) and proximal tibial (see Fig. 9-40) epiphyseal ossification centers.^{45,46} Ossification of these epiphyses, as seen on radiographs, is known to be an indicator of fetal maturity. Identification of the epiphyseal ossification centers about the knee provides a different type of parameter that sonologists can use in the assessment of gestational age in the third trimester of pregnancy. In general, visualization of a distal femoral epiphyseal ossification center indicates a gestational age of at least 33 weeks (Figs. 9-41 to 9-43). Similarly, the same data suggest that demonstration of the proximal tibial epiphysis indicates a gestational age of at least 35 weeks. These ossification centers appear earlier, on average, in female fetuses (see Fig. 9-42).⁴⁶ The size of the distal femoral ossification center correlates with late gestational age (see Fig. 9-43).⁴⁶ The proximal humeral epiphyseal ossification center is usually the last to ossify of the secondary ossification centers.

As stated earlier, many bones of the fetal appendicular skeleton are entirely cartilaginous. Some of these still can be imaged sonographically. Indeed, the patella can be seen rather commonly (see Figs. 9-20 and 9-22). This bone does not begin to ossify until after birth. All of the carpal and most of the tarsal bones are entirely cartilaginous (see Figs. 9-19, 9-25, 9-26, and 9-32). The carpal bones cannot be seen discretely. Rather, they are perceived as a conglom-

FIGURE 9-23. The diaphysis of the femur nearer to the transducer appears straight (Fs). The full thickness of the diaphysis is not seen. The diaphysis of the femur farther from the transducer appears curved (Fc). Compare with Figure 9-24. This is a normal shape of the medial aspect of the bone. However, the straight lateral cortex seen in the radiograph but not the sonogram visually compensates the curvature because the full thickness of bone is not perceived.

FIGURE 9-24. Radiograph of a midtrimester fetal femur. Note that our eye compensates for the curvature of the medial diaphyseal cortex (curved arrows) by noting the straight lateral diaphyseal cortex (straight arrows). Compare with Figure 9-23.

erate hypoechoic band spanning the gap from the distal radius and ulna to the proximal metacarpal ossification centers (see Fig. 9-32). Of course, this gap also includes the cartilaginous epiphyses of the long bones as well. Conversely, some of the tarsal bones can be discretely identified from time to time (see Figs. 9-25 and 9-26). These include, most

notably, the early tarsal calcaneus and talus (before 24 weeks) and the tarsal navicular and cuboid throughout gestation.

Visualization of the cartilaginous ends of the long bones assists in their measurement in two ways. The measurement of fetal long bones is confined to the ossified portion. A potential error is to foreshorten the bone by failing to obtain the plane of section through the true long axis of the bone. To avoid underestimating length, this shortcoming is often compensated for by assuming the “longest” measurement obtained in several attempts to be the most accurate, an assumption that can lead to serious overestimates, as is discussed shortly. However, if both cartilaginous ends of the desired bone to be measured are seen, this guarantees that the plane of section has passed through the longest axis of the bone (Fig. 9-44). The only remaining task to minimize error is to accurately position measurement cursors at the ends of the bone.

Another common misconception in measurement of the femur is that no other tissue in proximity to the bony termination will yield an echo of equal brightness to the bone. Thus, one should always place measurement cursors from the edge of the distal brightest reflection to the edge of the proximal brightest reflection. This long-standing belief is unfortunately erroneous, especially in older fetuses, although younger fetuses are not exempt from this potentially significant error in femur length estimation.⁴⁷ Figure 9-45 demonstrates that a nonosseous, but nonetheless equally bright, reflection is returned from tissues distal to the epiphyseal plate but in immediate contiguity with the distal femoral metaphysis. This is called the distal femoral point for lack of a more precise anatomic term.⁴⁷ That this point is not part of the ossified femur can be determined by noting its relationship to the cartilaginous lateral condyle. The

FIGURE 9-29. A and B. Parasagittal sonograms of the scapula. 1, infraspinous fossa; 2, infraspinatus muscle; 3, scapular spine; 4, supraspinatus muscle; 5, supraspinous fossa; 6, subscapularis muscle; 7, ribs in short axis.

femoral metaphysis ends at the beginning of the distal femoral epiphysis and does not overlap the edge of the epiphysis. Compare the radiograph of the fetal femur in Figure 9-24 with the sonogram of the fetal femur in Figure 9-45. No such ossified femoral point exists.

Sonography, from time to time, demonstrates rather extraordinary features of the musculoskeletal system of the extremities. At present, no known diagnostic usefulness for this information has been established, nor is it possible to demonstrate such structures with the consistency necessary to use their visualization in diagnostic pursuits. However, several of these remarkable features are demonstrated in Figures 9-46 to 9-48.

Many bones or components of bones of the axial skeleton are also routinely visualized. In the skull region, one can perceive a number of bones individually or as a conglomerate. The greater wings of the sphenoid and petrous ridge are easily identified and define the anterior, middle, and posterior cranial fossae (Fig. 9-49). The orbits can be visualized without difficulty unless the more anteriorly positioned orbit severely shadows the more posteriorly positioned orbit (Fig. 9-50). Standards have been established for fetal interorbital distances to evaluate hypotelorism and

FIGURE 9-32. *A* and *B*. hypertelorism.⁴⁸ In older fetuses, surprising detail of the intraorbital contents can be appreciated, including the wall of the globe, lens, retrobulbar fat, optic nerve, and rectus muscles (Fig. 9-51). Portions of the maxilla and nearly the entire mandible can be identified, as can the bony nasal ridge (see Fig. 9-50). Similarly, the frontal, parietal, and squama of the temporal and occipital bones, the bones making up the calvaria, can be seen clearly. The cartilaginous

FIGURE 9-34. Coronal image of the fetal hip. 1, ischial ossification center; 2, cartilaginous acetabulum; 3, femoral head in cartilage; 4, greater trochanter in cartilage; 5, femoral diaphysis. Note the echogenic synovium between the cartilaginous acetabulum and the femoral head. Refer to Figure 9-20A.

zones of articulation of these bones, the coronal, sagittal, and lambdoid sutures, are commonly visible (Fig. 9-52). The fontanels may be seen as well (Fig. 9-53). These anatomic features are particularly well seen in three-dimensional reconstructions of the calvaria, as demonstrated in Chapter 24. Sutures and fontanels are the windows for brain imaging (Fig. 9-54). Although many individuals who perform sonography do not realize that they are employing sutures and fontanels to image the fetal brain, they visually ascertain that, as they move the transducer, “fuzzy” brain images suddenly become clearer. The reason, of course, is that as they move the transducer the beam inevitably passes through a suture or fontanel, enabling even the unsophisticated imager to take advantage of these gaps between the calvarial plates.

The ribs, spine, and pelvis are easily imaged and serve as excellent anatomic landmarks. In the pelvis, the iliac ossification centers are easily observed from early second trimester onward (ossified at 2.5 to 3 fetal months). Ischial ossification (see Fig. 9-34) is present at 4 months, but pubic ossification is not present until 6 months.

The spine is an extremely important structure in fetal diagnosis.^{39,49-51} With the advent of maternal serum alpha-fetoprotein screening, as well as the concurrent development of sophisticated high-resolution ultrasound imaging technology, the potential exists to diagnose nearly all lesions of spina bifida before the 20th week of pregnancy.³² These changes in obstetric care mandate that the morphology of the fetal spine be well understood by sonologists. The sequence of development of ossification centers in the fetal vertebral column has been extensively studied in the past with radiologic and histologic methods.^{34,35} Each vertebra usually has three primary ossification centers, one for the

FIGURE 9-35. A and B. Longitudinal (A) and transverse axial (B) sonograms of the fetal thigh. 1, posterior hip joint capsule; 2, greater trochanter; 3, femoral diaphysis; 4, lateral condyle; 5, medial condyle; QF, quadriceps femoris muscle; BF, biceps femoris muscle; F, femoral diaphysis.

FIGURE 9-36. A. Parasagittal sonogram of the fetal knee. The femoral condyle (1) articulates with the tibial plateau (proximal tibial epiphysis). B. Midsagittal sonogram of the fetal knee. Note the gap (3) between the distal femoral epiphysis (1) and the proximal tibial epiphysis (2). This is due to the intercondylar notch (see Fig. 9-37).

FIGURE 9-37. Axial sonogram of the knee in flexion. CL, cruciate ligaments; FM, femoral metaphysis; ICN, intercondylar notch [note the brightly echogenic synovium within the joint]; P, patella.

body (centrum) and one on each side of the posterior neural arch. The centra are ossified first in the lower thoracic and upper lumbar regions, followed by progressive ossification in both the cephalic and caudal directions. By contrast, and in general, the ossification centers for the posterior neural arch appear in a more standard cephalocaudal direction. The posterior neural arch first begins to ossify (sonographically recognizable high-amplitude reflections) at the base of the transverse process (Fig. 9-55). Ossification proceeds from this center to progressively include the laminae and pedicles. The progression of ossification of the laminae is more important for the diagnosis of neural tube defects because spina bifida is the most consistently demonstrable dysmorphic lesion in open spinal defects. This abnormality is recognized sonographically by an abnormal outward flaring of the posterior neural arch ossification centers.

Varying degrees of maturation of spinal ossification are present at differing levels of the spine when we are most frequently called on to assess normalcy of the fetal spine.³⁹ Although there are some exceptions as noted previously, ossification in the neural arch first appears at the base of the transverse process. Early posterior neural arch ossification then progresses anteriorly into the pedicles, also contributing a portion of the vertebral body, and posteriorly into the laminae. Additionally, craniocaudal extension into

FIGURE 9-38. A and B. Coronal sonograms of the knee (off axis). 1, proximal fibular epiphysis; 2, fibular diaphysis; 3, tibial diaphysis; 4, proximal tibial epiphysis; 5, patella; 6, femoral metaphysis; 7, lateral femoral condyle.

FIGURE 9-39. Axial sonogram of the distal tibia and a portion of the ankle joint. C, calcaneus; TM, tibial metaphysis; MM, medial malleolus; T, talus (a bone that is entirely cartilaginous).

the articular processes and lateral extension into the transverse processes occur. Because the critical observation in the diagnosis of open spinal neural tube defects is the demonstration of spina bifida (seen as an outward flaring of the posterior arch ossification centers), the ideal situation to confirm normalcy is to observe the antithesis of this pathologic state (e.g., inward angulation of the laminae). This indeed is the case when visible ossification is present in the normal laminae (Fig. 9-56). Unfortunately, there is insufficient ossification of the laminae to perceive inward angulation of the posterior neural arch ossification centers in the lower spine to confirm normalcy of the fetal spine during the crucial stage of gestation when this sonographic diagnosis must be made (18 to 22 menstrual weeks) (see Fig. 9-55).^{49,52} This is particularly important when considering the most

common location of such lesions (e.g., lumbar and sacral regions).⁴⁹ Easily identifiable ossification of the laminae is visible in the cervical region in all fetuses by 18 to 19 menstrual weeks, whereas thoracic ossification of the laminae is only partially visible during the 18- to 19-menstrual-week period.³⁹ There is no ossification of the laminae in the lumbar or sacral regions of fetuses examined before 19 menstrual weeks (see Fig. 9-55). The thoracic vertebrae consistently demonstrate partial ossification of the laminae in the range of 20 to 22 weeks; the lumbar region does not demonstrate a similar degree of ossification until 22 to 24 weeks (Fig. 9-57). The sacral spine reveals no evidence of ossification in the laminae before 22 weeks. Only after 25 weeks is there consistently recognizable ossification of the arch in the sacral region (Fig. 9-58). Fetal position (either prone or decubitus) does not appear to affect appreciably the ability to discern the degree of neural arch ossification, although the prone position usually results in the clearest images (Fig. 9-59). If the fetus is supine, a critical examination of the posterior neural arch cannot be carried out (Fig. 9-60).³⁹

The spine may be seen in both longitudinal and transverse axial planes. Although both planes are important, the transverse axial plane demonstrates the anatomy to best advantage. On longitudinal planes of section, the posterior elements are seen as “parallel” bands of echoes. In fact, they are not precisely parallel because they flare in the upper cervical region and converge in the sacrum. In addition, careful scanning usually discloses a slight widening of the lumbar area. It is important not to mistake this slight lumbar widening as a pathologic event. Because the fetal spine is normally kyphotic, usually one cannot visualize the entire spine in a single longitudinal coronal plane. For this reason, transverse axial planes of section are necessary to be certain that the entire spine has been imaged on a segment-by-segment basis. Caution must be exercised as well to ensure that the spine has been examined in its entirety on transverse planes. At the cephalic end, no problem arises because one encounters the calvaria. However, the caudal end is more difficult. One can successfully use the ischial ossification

FIGURE 9-40. A. Coronal sonogram of the distal thigh in a term fetus. DFE, ossification center of distal femoral epiphysis; PTE, ossification center of proximal tibial epiphysis. Note the large and similar sizes of the ossification centers, a virtually certain sign of a near-term fetus. B. Coronal sonogram through the proximal humerus shows an early secondary ossification center in the humeral head, another finding indicating a later gestation. PHE, ossification center of proximal humeral epiphysis.

centers as landmarks to ensure that the caudal end of the spine has been reached (Fig. 9-61). In older fetuses, both spinal and spinal canal anatomy can often be quite dramatically depicted (Fig. 9-62).

Cartilaginous structure in the axial skeleton is less conspicuous than in the appendicular skeleton but nonetheless is visible in virtually all fetuses. The sutures of the calvarial vault already have been noted. The cartilaginous neurocentral synchondrosis of the spine (the junction of the

FIGURE 9-45. View of the fetal femur, third trimester. A bright reflector (curved arrow) is seen in continuity with the lateral femoral metaphysis. This structure is not part of the ossified femur. Endpoints of femur measurement are marked by straight arrows. 1, greater trochanter; 2, femoral diaphysis; 3, lateral condyle; 4, ossification center of the distal epiphysis.

centrum and the posterior ossification centers) is visible in all fetuses from the end of the first trimester onward (see Figs. 9-55 to 9-59).³⁹ Similarly, the gaps between the vertebral body ossification centers are a composite of the nonossified margin of the adjoining vertebral bodies plus the intervertebral disk (see Fig. 9-60). The margin of cartilage in the vertebral body is best appreciated posteriorly, lying between the ossification center and the dura of the spinal canal (see Fig. 9-62C and D). As well, the spinous processes of the posterior neural arch are occasionally seen; these structures again are entirely composed of cartilage in fetal life (see Fig. 9-62C).

One feature that cannot be well judged on sonograms is the degree of ossification of the bones. Thus, increased ossification, as in osteopetrosis, is completely unrecognized on sonograms. Similarly, diminished ossification is poorly judged. Only in the most extremely osteopenic bone can one appreciate diminished ossification on sonograms. Examples are the nearly nonossified calvaria in fetuses with osteogenesis imperfecta lethalis or recessive hypophosphatasia,⁵³⁻⁵⁵ or the spine in fetuses with achondrogenesis.⁵⁶

Little space is devoted to the fetal muscular system, even though many muscles and muscle groups may be seen quite well (see Figs. 9-28 and 9-29). In general, normal muscles are quite hypoechoic, at times so much so that they simulate fluid collections. This is most notable of the abdominal wall musculature, which may simulate ascites (pseudoascites) (Fig. 9-63).³⁷ At present, high-resolution sonographic equipment decreases the propensity to “overcall” ascites caused by this artifactual situation because the layers of the abdominal wall can be seen quite clearly.⁵⁸

The abdominal wall muscles, the internal and external oblique and the transversus abdominis, are, at times, so clearly visible that the individual layers can be detected (Fig. 9-64). More commonly seen as a single layer of muscles, this tissue is easily recognized as lying within the abdominal wall by noting its position between the subcutaneous fat and the peritoneal fat. The latter is traced from the

paranephric fat as it curves onto the flank. Furthermore, the abdominal wall muscles “meet” the ends of the lower thoracic ribs, whereas ascites would pass “between” the ribs and the abdominal viscera.⁵⁸

CARDIOVASCULAR SYSTEM

The anatomy of the heart and great vessels is discussed in detail in Chapter 14. In this chapter, the focus is on those fetal vessels visible within the uterus and fetal corpus that are not covered elsewhere. Indeed, a surprisingly large number of individual fetal blood vessels can be seen. Color Doppler sonography has greatly added to our ability to consistently demonstrate fetal vessels.

The fetal circulation begins in the placenta. In virtually all second and third trimester fetuses, one can detect the surface (fetal) vessels of the placenta, and with color Doppler sonography, one can even appreciate that these vessels penetrate the placental substance. The surface vessels coalesce at the cord “insertion.” The identification of the advent of percutaneous umbilical (fetal) blood sampling for diagnosis and management (see Chapter 17).⁵⁹ The cord “insertion” is often easily seen, but if not, it is worthwhile to search for large placental surface vessels and trace these to the cord and to use color Doppler sonography.

The normal umbilical cord is composed of two arteries and a vein (Fig. 9-65). The cord is virtually always coiled and sometimes extremely so. This leads to a variety of appearances of the cord when viewed with tomographic sections as generated by sonography (Fig. 9-66). Indeed, the “simple” task of counting cord vessels can be made quite frustrating by the coils. To obtain the correct count of cord vessels consistently, one must rely on a true transverse axial section of the cord vessels. Longitudinal or oblique views can be misleading.

These vessels enter the fetus, by definition, at the umbilicus and there immediately diverge.⁶⁰ The umbilical vein proceeds cephalically (Fig. 9-67); the umbilical arteries egress from a caudal direction. The umbilical arteries proceed along the margin of the urinary bladder from their origin at the iliac arteries in their course toward the umbilicus (Fig. 9-68). As they course along the bladder margin, they should not be mistaken for dilated ureters, a distinction easily made by interrogating them with color Doppler sonography. Regardless of the degree of bladder distention, normal umbilical arteries *always* flank the bladder wall. Thus, this relationship can be employed both to detect the umbilical arteries or the urinary bladder, particularly when pathology has altered the expected appearance of the bladder. Although not representing certain evidence of a three-vessel cord, the identification of two umbilical arteries flanking the bladder lumen represents excellent evidence for a three-vessel cord and, employing color Doppler sonography, constitutes the easiest method of “confirming” a three-vessel cord.

The umbilical vein joins the fetal portal circulation. The fetal portal circulation is seen with a high degree of consistency on sonograms. Obviously, the larger the fetus, the more readily one will see the smaller elements of this system. Importantly, many of the illustrations seen in the literature incorrectly interpret the fetal umbilical and portal venous anatomy. Confusion has led not only to improper

nomenclature but also to use of inappropriate landmarks for obtaining important fetal measurements. With a clear understanding of fetal portal vein anatomy, one can avoid these pitfalls and better appreciate fetal and adult segmental hepatic anatomy.

The dynamics of fetal circulation determine the details of fetal hepatic portal venous and segmental anatomy.⁶¹ Because there are no blood-diverting branches of the umbilical vein, the volume of placental blood entering the left portal venous

system equals that in the umbilical vein. Thus, the umbilical vein and the portion (umbilical segment) of the left portal vein that it joins have the same diameter (see Fig. 9-67). Therefore, the left portal vein of the fetus is larger than the right, the reverse of the situation seen in the child and adult. From this point, blood may reach the right atrium through several avenues. A common misconception of the fetal circulation is that the bulk of umbilical venous blood bypasses the liver capillary bed through a large patent ductus

FIGURE 9-56. Lumbar vertebra, transverse axial sonogram. The laminae (L) demonstrate early ossification causing the appearance of "inward angulation" of the posterior arch. (From Filly RA, Simpson GF, Linkowski G: *Fetal spine morphology and maturation during the second trimester: Sonographic evaluation.* *J Ultrasound Med* 6:631, 1987)

venous. However, in utero, the ductus venosus averages only one seventh the diameter of the umbilical vein⁶² and even may be closed (see Fig. 9-67).⁶³ It should be remembered, however, that the peripheral resistance of the hepatic vascular bed is not present in the ductus venosus, enabling this smaller caliber vessel to carry a larger quantity of blood

than might be expected. Nonetheless, a significant portion of umbilical venous blood, which carries the highest concentration of nutrients and oxygen in the fetus, actually circulates through the left lobe of the fetal liver through branches supplying the medial and lateral segments before entering the systemic venous system through the left and middle hepatic veins (Fig. 9-69). Although the right lobe of the liver receives a small amount of umbilical venous blood from the left portal vein, the bulk of blood entering the right portal vein is derived from the main portal vein, which, in the fetus, contains low concentrations of both nutrients and oxygen.⁶³ The unequal distribution of nutrients to the fetal liver partially accounts for the relatively large size of the left lobe of the fetal liver. After closure of the umbilical vein at birth, the nutrient supply to the entire liver equalizes and the relative size of the left lobe decreases.

In the fetus, the umbilical vein courses cephalically in the free margin of the falciform ligament (see Fig. 9-67). As noted earlier, it joins the umbilical portion of the left portal vein near the caudal margin of the left intersegmental fissure of the liver.⁶⁴ After birth, the umbilical vein thromboses, collapses, and ultimately becomes the ligamentum teres hepatis, a classic marker of left intersegmental fissure (indeed, for a very long time this structure was considered the line of division of the left and right hepatic lobes). The precise line of division between the umbilical vein and the umbilical segment of the left portal vein is the point at which the most anterior of the medial and lateral segmental branches to the left hepatic lobe egress the left portal vein (the branches to segments 3 and 4). Remember, the umbilical vein has no blood diverting branches. Therefore, those two hepatic intraparenchymal vessels had to originate from the umbilical segment of the left portal vein.

The umbilical portion of the left portal vein has a predominantly posterior course but also courses superiorly in the left intersegmental fissure (see Fig. 9-67). As noted

FIGURE 9-59. Transverse axial sonograms, sacral spine, same fetus in prone (A) and decubitus (B) positions. The posterior arch (POC) anatomy is seen well in either position. (From Filly RA, Simpson GF, Linkowski G: *Fetal spine morphology and maturation during the second trimester: Sonographic evaluation.* *J Ultrasound Med* 6:631, 1987.)

earlier, its branches supply the medial and lateral segments of the left lobe of the liver.⁶⁵ The left portal vein then courses abruptly to the right, exits the left intersegmental fissure, and forms the transverse portion (pars transversa) of the left portal vein (see Figs. 9-69 and 9-70). The pars transversa joins imperceptibly with the right portal vein at the main

FIGURE 9-61. Axial sonogram of the pelvis demonstrating the early ossification centers of the pubis (P). Also seen is an ischial ossification (I).

lobar fissure. The ductus venosus originates from the pars transversa (but occasionally more rightward).⁶⁶ The ductus continues posteriorly but assumes a more cephalad course than the umbilical portion of the left portal vein (see Fig. 9-70). It continues as an unbranched structure to join the left or, less commonly, the middle hepatic vein (this distinction is somewhat artificial as the left hepatic vein, the middle hepatic vein and the ductus venosus most commonly form a confluence before entering the inferior vena cava). In this position, the ductus venosus lies in the superior extension of the gastrohepatic ligament, which separates the developing

caudate lobe posteriorly from the medial and lateral segments of the left hepatic lobe anteriorly (the gastrohepatic ligament, the dominant ligament of the lesser omentum, also separates the greater and lesser peritoneal cavities). After birth, the ductus venosus closes and becomes the fibrous ligamentum venosum.⁶⁴

Sonograms of the upper portion of the fetal abdomen clearly demonstrate the anatomy just described (see Figs. 9-67 to 9-70). Because the umbilical vein courses cephalically, transversely oriented planes of section intersect this vessel's short axis (see Fig. 9-64). Slight cephalad movement of the transducer demonstrates a position at which this venous structure abruptly courses posteriorly (see Figs. 9-69 and 9-70). This posteriorly coursing vein represents the umbilical portion of the left portal vein rather than the cephalic portion of the umbilical vein, as it is commonly mislabeled in the literature. That this vessel is indeed the left portal vein is easily observed as branches to the medial and lateral segments of the left lobe are noted to arise from this vein (see Figs. 9-69 and 9-70). When the umbilical portion of the left portal vein is seen throughout its entire course, one can be certain that some angulation has been introduced into the scan plane because this venous structure courses not only posterior but slightly cephalad (see Fig. 9-67). A variety of branches of the umbilical segment of the left portal vein are

occasionally imaged; these include the medial, superolateral, and inferolateral branches (see Fig. 9-69).

The right portal vein divides into anterior and posterior segmental branches, as in the adult (see Fig. 9-70). Each supplies a respective segment of the right hepatic lobe. The hepatic veins can be recognized by their relationship to portal veins⁶⁴ and can be seen to radiate toward the inferior vena cava, coalescing with this venous channel immediately before it enters the right atrium (Fig. 9-71). These veins divide the liver into lobes and segments. The hepatic veins are most easily sought near the level of the diaphragm, where their caliber is the largest.⁶⁷ Nonetheless, the middle and right hepatic veins are commonly seen in more inferior planes of section by noting their relative position compared with the right portal vein divisions (see Fig. 9-70). The right hepatic vein (anterior branch) passes between the anterior and posterior divisions of the right portal vein, whereas the middle hepatic vein always crosses anterior to the right portal vein (in the main lobar fissure). The aorta and inferior vena cava have a similar course in the lower abdomen but diverge in the upper abdomen, where the aorta penetrates the diaphragm posteriorly (in contact with the spine), whereas the inferior vena cava turns anteriorly to join the right atrium (Fig. 9-72).

The great vessels and heart are described in detail in Chapter 14. Briefly, a second or third trimester sonogram of

all pregnancies should include a four-chamber heart view (Fig. 9-73). Outlet views of the cardiac ventricles are recommended in the most recent guidelines.⁶⁸ Useful information about the position and size of the great vessels can be quickly gleaned from a transverse axial view of the upper medi-

astinum by simply moving the transducer cephalically from the four-chamber heart view. This section traverses the superior vena cava, the ascending and descending thoracic aorta, the pulmonary artery, and the ductus arteriosus (coursing from the pulmonary artery to the descending thoracic aorta) (Fig. 9-74).

The vessels arising from the transverse aorta are frequently visible and include the brachiocephalic, left common carotid, and left subclavian arteries (Fig. 9-75*A*). The common carotid arteries and jugular veins are also commonly seen in the neck of older fetuses. The brachial artery and vein are less frequently seen adjacent to the humerus but again can be found using color Doppler sonography.

Intracranial arterial structures are easily perceived using color Doppler sonography (Fig. 9-76). These include the vessels of the circle of Willis seen in the basilar cisterns surrounding the inferior portion of the third ventricle. Also, the middle cerebral artery can be identified coursing in the sylvian cistern, the posterior cerebral artery in the ambient cistern, the anterior cerebral arteries in the interhemispheric cistern (near the genu of the corpus callosum), and the basilar artery in the interpeduncular cistern. Also commonly seen is the pericallosal artery after the formation of the corpus callosum commences and proceeds to its body.

The abdominal aorta and inferior vena cava are easily identified, as are the common iliac arteries and veins (see Fig. 9-75*B* and *C*). Other branches of the abdominal aorta can be consistently visualized using color Doppler sonography. These include the celiac axis, the superior mesenteric artery, and the renal arteries. Similarly, the renal veins can be consistently seen.

In the leg, the superficial femoral artery and vein (Fig. 9-77) may be visualized in older fetuses. When the knee is extended, it is not difficult to trace these vessels to the level of the popliteal artery and vein, a virtually impossible task when the knee is flexed.

GASTROINTESTINAL SYSTEM

Many components of the gastrointestinal system can be seen sonographically, some as early as the end of the first trimester.⁶⁹ The largest parenchymal organ of the system and of the torso, the liver, is seen consistently from the second trimester onward, although its margins are often indistinct in the earlier phases of pregnancy. Conversely, the other major parenchymal organ of the gastrointestinal system, the pancreas, is much less commonly seen, even in third trimester fetuses. For lack of a better section in which to include it, the spleen is considered with the gastrointestinal tract. This organ is also visible consistently in the second trimester, but, like the liver, its margins are frequently indistinct. Conversely, those portions of the fetal gastrointestinal system that consistently contain fluid, the stomach (see Figs. 9-64, 9-69, and 9-70) and gallbladder (see Figs. 9-63 and 9-64), are among the earliest and most consistently seen of fetal structures.

The components within and about the oral cavity are seen relatively well on sonography.⁷⁰ The lips and cheeks have been described in the section on superficial anatomy (see Figs. 9-10 and 9-11). Also consistently seen is the tongue (Fig. 9-78). The tongue is seen to best advantage during swallowing movements. The gingival ridge with tooth buds is seen commonly in fetuses of 20 weeks or more (see Fig. 9-78A). The hard palate is difficult to define consistently but with practice can be detected. For this reason, cleft palate is more difficult to detect than cleft lip. Clefting of the soft palate is difficult to diagnosis sonographically because the soft palate cannot be recognized discretely. The

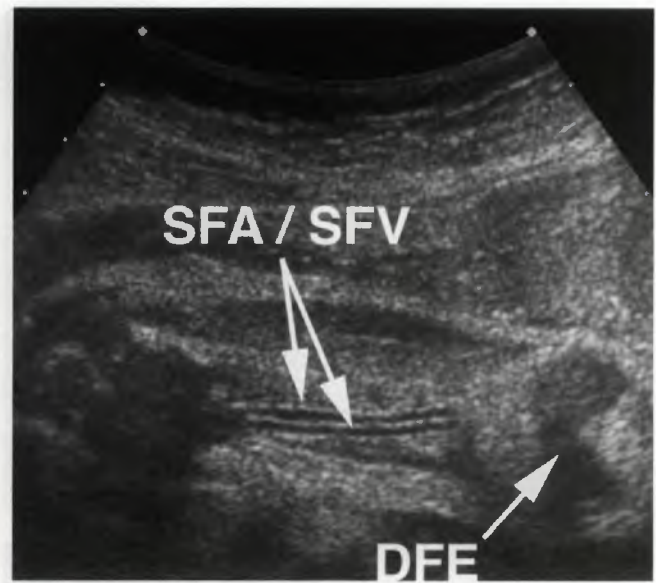

FIGURE 9-77. Superficial femoral artery and vein (SFA/SFV) seen side by side in the mid and distal thigh. DFE, distal femoral epiphysis.

oropharynx and laryngeal pharynx frequently contain fluid and thus are seen relatively often when sought (see Figs. 9-78 and 9-79). Transverse axial scans through the upper neck are quite successful for visualization of the pharynx, but longitudinal coronal images, more difficult to obtain, display the anatomy to greater advantage. In longitudinal coronal planes, the continuity of the pharyngeal zones can be appreciated as well as the larynx protruding into the pharynx (see Fig. 9-79). The piriform sinuses, valleculae, and glottis may be appreciated.

The mid- and distal esophagus may be seen surprisingly often when sought (Fig. 9-80).⁷⁰ The proximal esophagus is extraordinarily difficult, if not impossible, to visualize in the normal fetus. The mid- and distal esophagus may be seen, although inconsistently, in both longitudinal coronal and transverse axial images. The key to identification of this structure is the descending thoracic aorta, a structure easily seen. The mid- and distal portions of the esophagus lie immediately anterior to the descending thoracic aorta. The aorta is first visualized in a longitudinal coronal plane. The transducer is then slowly moved anteriorly. As the aorta disappears from view, the esophagus comes into view but is much more difficult to recognize. It is seen as five parallel linear echoes. The hyperechoic serosa and lumen and the hypoechoic muscular wall (Fig. 9-81) create these. Conceptually, one could apply a similar strategy to visualization of the upper third of the esophagus. In this instance, one would image the trachea (see the following section) in a longitudinal coronal plane and then slowly move the transducer posteriorly. As the trachea disappears, the esophagus should again come into view. Unfortunately, this concept, although anatomically correct, is practically unsuccessful.

The stomach and gallbladder are the only portions of the subdiaphragmatic fetal gastrointestinal system that consistently contain fluid (see Figs. 9-63, 9-64, 9-69, and 9-70).^{69,71,72}

FIGURE 9-78. Transverse axial sonograms of the (A), mandible; (B) maxilla, and (C) tongue. FM, facial musculature; FP, cheek fat pads (Bichat); H, hypopharynx; M, mandibular mentum; TB, tooth buds; T, tongue.

FIGURE 9-79. Coronal sonogram of the fetal hypopharynx. The fluid-filled oropharynx (OP) and laryngopharynx (LP) are well seen. Fluid slightly distends the piriform sinuses (PS). E, epiglottis.

Thus, any fluid-containing small bowel should be viewed with suspicion, although in late fetuses one not infrequently sees very small amounts of normal succus entericus in the small bowel lumen, usually made more obvious by accompanying peristalsis. Fluid contained within the normal fetal stomach is almost entirely imbibed. The fetus begins to swallow amniotic fluid at approximately 16 weeks.^{71,72} The volume that the fetus swallows increases dramatically throughout pregnancy and reaches 400 to 500 mL by term. There is a relative proportionality between the volume of urine produced and the amount of amniotic fluid imbibed by the fetus. In the absence of a patent esophagus, the stomach will be empty (invisible) except in two circumstances. First, and most common, is the concomitant presence of a tracheoesophageal fistula, enabling the fetus to “breathe” fluid into the esophagus and thence to the stomach.⁷³ More likely, the gastric fluid comes from the fluid produced by the lung that then drains through the fistula into the stomach rather than by “breathing” fluid into the trachea and thence through the fistula. This pathologic

FIGURE 9-80. A-C. Coronal sonograms depicting demonstration of the mid and distal esophagus. First (A), the descending aorta (AO) is localized. C, diaphragmatic crura; S, stomach. As the transducer is moved anteriorly (B and C), the esophagus (arrows) comes into view.

FIGURE 9-81. Coronal (A) and transverse axial (B) sonograms demonstrating the esophagus (E). The serosa and lumen appear hyper-echoic, and the muscular wall is hypoechoic. St, stomach; GB, gallbladder, Ao, aorta, SVC, superior vena cava. Distally, the esophagus lies anterior to the descending aorta (compare with Fig. 9-80). Proximally, it lies posterior to the transverse aorta (B) and medial to the ascending aorta (A).

event is commonly associated with polyhydramnios in late pregnancy but not always before 24 weeks. Second, the association of esophageal atresia without tracheoesophageal fistula but with a second proximal gastrointestinal tract atresia or obstruction will allow secretions from the stomach to accumulate within the gastric lumen.

The stomach varies considerably in size depending, presumably, on how much amniotic fluid has been recently imbibed by the fetus.^{71,72} A prominent stomach never should be taken as sole evidence of obstruction. When the stomach is well distended, its various parts (i.e., the fundus, body, and antrum) can be identified (Fig. 9-82). The fundus is most posterior, whereas the antrum is most anterior. The incisura angularis can be noted when the stomach is well distended. The incisura angularis is a notch of variable depth that is usually found along the lesser curvature between the body and antrum of the stomach.⁷⁴

Small bowel becomes progressively more visible through the second and third trimesters. Meconium begins accumulating in the small bowel during early and middle second trimester. This may impart the appearance of a “conglomerate” zone of increased echogenicity in the mid- and lower abdomen of the fetus. This should not be mistaken either for an abnormal mass (pseudomass of bowel)⁷⁵⁻⁷⁷ or of a bowel abnormality. With passage of time, and somewhat dependent on ease of imaging, discrete small bowel loops become visible (Fig. 9-83). With modern equipment, the bowel wall is seen to good advantage. The submucosa and serosa display greater echogenicity than the muscular layers, the thinner muscularis mucosa and thicker muscularis propria. Later in pregnancy, deposition of fat in the mesentery probably accentuates the separation of individual bowel loops and increases echogenicity in the region of the abdomen where the small bowel resides.

Importantly, “increased echogenicity” of the bowel has been implicated as a harbinger of several serious abnormalities of the fetus.^{78,79} Therefore, it is important to discriminate increased echogenicity of the bowel content (potentially indicating a problem) from echogenicity caused

FIGURE 9-82. A. Coronal image of the stomach demonstrating all portions of the stomach including the fundus (F), body (B), antrum (A), and pylorus (P). The duodenal bulb (D) (not containing fluid) lies adjacent to the gallbladder (GB). B. Axial sonogram of the fetal stomach showing the fundus (F) and body (B). A portion of the left lung (L) and spleen (Sp) are included. D, diaphragm.

FIGURE 9-83. A and B. Discrete small bowel (SB) loops are clearly visible on images through the fetal abdomen. The morphology of the bowel wall is well shown. The dominant feature of the small bowel wall is the submucosa (SM) which demonstrates bright echoes (not to be mistaken for "echogenic bowel"). The muscularis propria (MP) which demonstrates darker gray echoes lies "outside" of the submucosa and the muscularis mucosa (MM, also dark) lies "inside" of the submucosa. Note that the anterior abdominal wall musculature (AWM), like all musculature, demonstrates darker gray echoes. If one looks closely, one can appreciate the more echogenic small bowel mucosa "sandwiched" between the layers of muscularis mucosa. St, stomach.

by normal bowel structure, but perceived in conglomerate to represent "increased bowel echogenicity" (unlikely to indicate a problem). Examining to see if the echogenicity is due to well-visualized submucosa or mesenteric fat will avoid these issues. Generally, high-frequency transducers demonstrate the submucosa of the small bowel to much

greater advantage, thus giving the examiner the impression that the bowel is "echogenic".⁸⁰ When transducers with frequencies greater than 5 MHz are being employed, the probability that fetal bowel wall structure has resulted in an impression of "increased echogenicity" is great. Confirmation with lower frequency transducers should be done. By late

FIGURE 9-84. A, B, and C. Three sonograms of the fetal abdomen demonstrating, by position, the descending (D), transverse (T), and a markedly looped sigmoid (S) colon. Bl, bladder; St, stomach.

pregnancy, almost regardless of equipment quality, discrete small bowel containing small amounts of fluid (succus entericus) can be visualized in nearly all fetuses.⁸¹

The colon tends to become visible near the beginning of the third trimester and, again, is seen progressively better with increasing gestational age.^{81,82} The colon tends to be relatively hypoechoic (Figs. 9-84 and 9-85). As such, colon should not be mistaken for dilated small bowel. It is the characteristic course of the colon that most readily permits distinction from pathologically dilated small bowel. The ascending colon courses along the right flank (see Fig. 9-84A) in relation to the right kidney. As it approaches the liver, it bends leftward, in the hepatic flexure (see Fig. 9-84A). The transverse colon courses along the free edge of the liver (see Figs. 9-84A and 9-85A) and passes inferior to the stomach. At the splenic flexure, the colon turns posteriorly and again comes into intimate relationship with the kidney; of course, in this instance it is the left

kidney. Frequently, when imaging the kidneys, the colon is detected. Indeed, when a kidney is absent, the colon occupies the renal fossa and should not be misinterpreted as a normal or abnormal kidney. Finally, the sigmoid colon arcs over the urinary bladder to join the rectum (see Figs. 9-84B and 9-85B). Occasionally, haustral markings can be noted in the colon wall. A redundant sigmoid colon (see Fig. 9-85B) should not be mistaken for dilated small bowel.

The liver, as noted earlier, is proportionately larger in the fetus than in the child or adult.⁸³ Similarly, in the early second trimester, the liver constitutes 10% of the total fetal weight but only 5% of the total weight at term. The fetal liver, in addition, has a substantially larger left lobe. Indeed, the fetal liver spans the entire width of the abdomen throughout pregnancy, the left lobe always contacting the left abdominal wall. This would be unusual but possible in an adult.

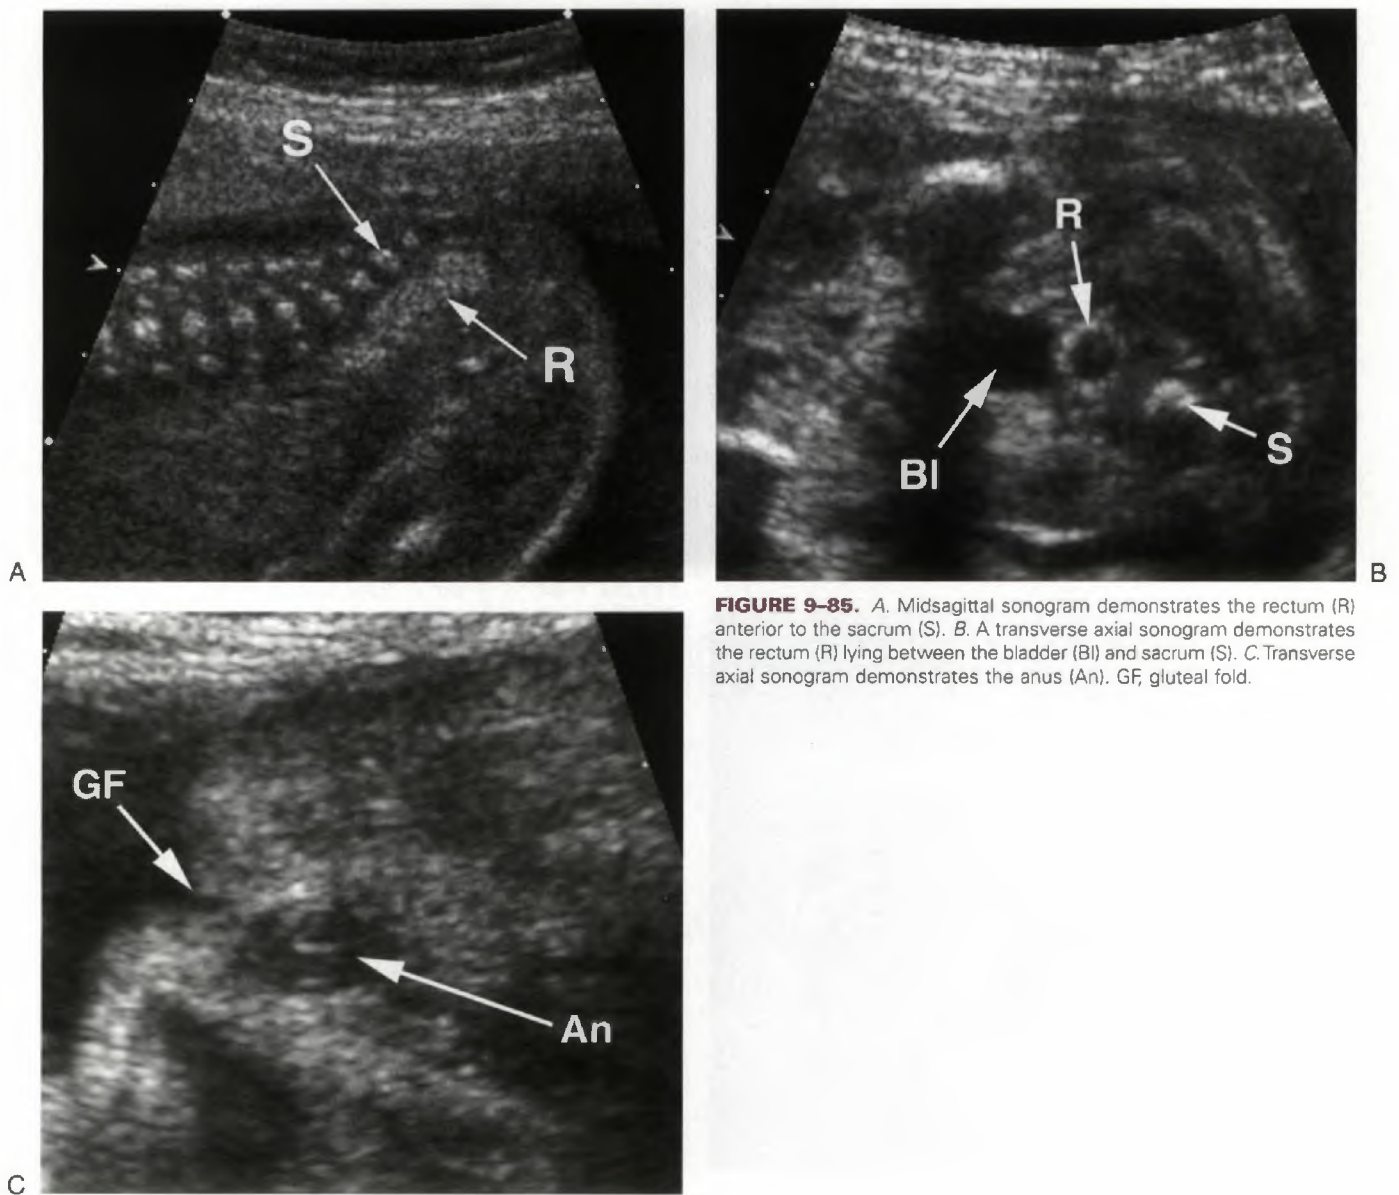

FIGURE 9-85. A. Midsagittal sonogram demonstrates the rectum (R) anterior to the sacrum (S). B. A transverse axial sonogram demonstrates the rectum (R) lying between the bladder (BI) and sacrum (S). C. Transverse axial sonogram demonstrates the anus (An). GF, gluteal fold.

The two major segments of each hepatic lobe can be seen in older fetuses (see Fig. 9-71) and to some extent even in early second trimester fetuses.^{61,64} The lateral segment of the left lobe extends to the left of the umbilical segment of the left portal vein (see Figs. 9-9 and 9-70). The medial segment of the left lobe is the tissue lying between the gallbladder (or middle hepatic vein more superiorly) and the umbilical segment of the left portal vein or the intersegmental fissure more caudally (Fig. 9-86). The right lobe is all of the hepatic tissue lying to the right of the gallbladder, middle hepatic vein, and inferior vena cava (see Figs. 9-64 and 9-70). These latter three structures all reside in the main lobar fissure. The left portal vein and left hepatic vein mark the left intersegmental fissure. Finally, the right intersegmental fissure is marked by the right hepatic vein cephalically and its anterior branch inferiorly.

As noted earlier, the pancreas is difficult to perceive at any gestational age. The pancreatic tissue lies posterior to the stomach, an area that can be visualized consistently in the fetus. However, discrete perception of the pancreas requires demonstration of the splenic vein and origin of the superior mesenteric artery in a transverse axial plane of section (Fig. 9-87). The pancreas then is the band of tissue between these vessels and the posterior gastric wall. Occasionally, the pancreas is slightly greater in echogenicity than the peripancreatic tissues and organs, making visualization easier.

The spleen is not truly a gastrointestinal organ (see Figs. 9-70 and 9-82B). The spleen is bounded by the diaphragm superiorly, the lower ribs laterally, the stomach medially, and the diaphragm and kidney posteriorly. It is only the inferior margin that is difficult to delimit. In the

FIGURE 9-86. Transverse axial sonogram of the fetal abdomen after an intraperitoneal transfusion for Rh isoimmunization enables recognition of many peritoneal spaces, including the right (RSP) and left (LSP) subphrenic spaces and the right anterior (RAS) and left subhepatic (LSH) spaces. Segmental anatomy of the fetal liver is also well seen, including the medial (MS) and lateral (LS) segments of the left hepatic lobe. GB, gallbladder; RL, right hepatic lobe; SB, small bowel; UV, umbilical vein.

FIGURE 9-87. A and B. The fetal pancreas is not commonly seen discretely but is well depicted in these examples. When sought, it can often be detected. Those who perform abdominal sonograms in adults and children will recognize the familiar landmarks. In example B the pancreas (P) is enlarged (Beckwith-Wiedemann syndrome). The pancreas lies between the splenic vein (SV) and the posterior stomach wall (S). PB, pancreatic body; PT, pancreatic tail; SMA, superior mesenteric artery; SMV, superior mesenteric vein.

fetus, the spleen echogenicity is similar to that of the liver. In the adult, the liver is slightly less echogenic than the spleen.⁸⁴⁻⁸⁷ The spleen grows progressively through fetal life, and nomograms of splenic size are available in the literature.⁸⁴

RESPIRATORY SYSTEM

The upper respiratory tract system is seen partially. The nose has been previously illustrated (see Figs. 9-10 and 9-11). The nasal cavity, septum, and palate can be detected with practice. As noted earlier, portions of the pharynx and hypopharynx are commonly visible because of the presence of fluid.⁷⁰ The piriform sinuses are seen when fluid filled (see Fig. 9-79). When relatively large amounts of fluid are present in the pharynx of an older fetus, the epiglottis may be seen protruding into the fluid (Fig. 9-88). The epiglottis is particularly visible during swallowing.

The larynx is virtually always visible when the hypopharynx is fluid filled (see Figs. 9-79 and 9-88). Details of laryngeal anatomy are not particularly evident, but the larynx itself is easily recognized as a superior constriction of the tracheal fluid column protruding into the hypopharynx and flanked by the piriform sinuses. If the head is markedly flexed, the overlying mandible frequently defeats efforts to visualize the larynx and hypopharynx.

The trachea is a relatively easy structure to visualize (Figs. 9-88 to 9-90).⁷⁰ Again, this is predominantly because it is consistently fluid filled. The lungs produce fluid that is

not only expelled into the trachea. Additionally, the trachea, along much of its length, is flanked by the conspicuous pulsations of the common carotid arteries. The trachea usually can be traced to its distal end, passing posterior to the aortic arch (see Fig. 9-89A), but the carina and bronchi are quite difficult to perceive. Because mainstem bronchi are usually invisible, smaller ramifications of the bronchi are, for all intents and purposes, universally invisible at this time in the development of fetal sonography.

The right and left pulmonary arteries and pulmonary veins (Figs. 9-91 and 9-92) are visible in a large percentage of second and third trimester fetuses. However, one

FIGURE 9-88. A and B. Coronal sections through the hypopharynx (H), epiglottis (E), larynx (L), and trachea (T). LC, laryngeal cartilage.

FIGURE 9-89. Relationships of mediastinal and neck structures. Three midsagittal (A) or parasagittal (B and C) sonograms demonstrate the trachea (T) down to the level of the aortic arch (A). D, diaphragm; L, liver; LA, left atrium; PV, left portal vein; V, inferior vena cava.

generally pursues visualization of these major vessels during examination of the heart rather than the lungs. Details of the pulmonary arterial and venous anatomy are found in Chapter 14.

The lung (at least lung tissue) can be seen from late first trimester onward. Early in pregnancy, definition of the lung is drawn more from the structures that surround it. These

heart (and to a lesser extent other mediastinal structures) medially. Inferiorly, the early lung blends imperceptibly with the liver. These two organs are equal in echogenicity throughout some of the second trimester. As pregnancy progresses, the lung becomes more echogenic than the liver (Fig. 9-93). The reason for this is unknown. It was speculated that this difference may signal pulmonary

of greater echogenicity than the liver can be seen earlier in pregnancy than lung maturity can possibly develop.^{88,89} Furthermore, the muscular portion of the diaphragm becomes progressively more visible with fetal growth and the hypertrophy of the diaphragmatic muscle that occurs as the fetus “breathes” against atelectatic, fluid-filled lungs

(Fig. 9-94). These markers of the inferior extent of the lung improve pulmonary tissue visibility with advancing gestational age. Discrete pulmonary lobes are not visible in the normal fetus, but when a pleural effusion is present, insinuation of fluid into the major fissures (and the minor fissure on the right) marks lobar boundaries.

FIGURE 9-93. Coronal sonogram (A) through the fetal chest. Echogenicity differences between lung (L) and liver (Li) and lung and thymus (T) are easily seen in this older fetus. B. Axial sonogram through the fetal chest. Again, the echogenicity differences between the lung and thymus (T) are easily seen. GENITOURINARY SYSTEM

Although the extreme variability of fetal positioning and the lack of subject contrast between kidney and the surrounding tissues do not permit consistent identification of both fetal kidneys, normal fetal kidneys are commonly identified in their paraspinous location as early as 15 menstrual weeks. Visualization typically becomes consistent by the 20th week.⁹⁰

In longitudinal section, fetal kidneys appear as bilateral elliptic structures, and in transverse section, they have a circular appearance adjacent to the lumbar spinal ossification centers bilaterally (Fig. 9-95). Later in pregnancy, hyperechogenic retroperitoneal fat, which surrounds the kidneys, assists in their sonographic visualization (see Figs. 9-95 and 9-96). The fetal renal pyramids can frequently be discriminated from the surrounding cortex and columns of Bertin in most fetuses and are arranged in an anterior and posterior row (see Fig. 9-95A) in a configuration corresponding to the calices that contact the apices of the pyramids (the papillae).²⁰ The echotexture of the normal fetal renal cortex, which usually approximates or may even be slightly greater than that of the surrounding tissues, highlights the relatively echopenic pyramids. The characteristic position of the pyramids avoids any potential confusion with renal parenchymal cysts. Confusion with dilated calices is avoided by noting the interspaced columns of Bertin and the lack of communication with dilated infundibula and pelvis. Within the renal sinus of fetuses, there is generally a paucity, or more commonly a frank absence, of fat. Intrarenal collecting structures, the pelvis and infundibula, are commonly seen in fetuses because they frequently contain fluid,^{91,92} a topic that is addressed in Chapter 16.

The fetal kidneys grow throughout gestation. Standards for renal length, width, thickness, volume, and circumference have been established as a function of menstrual age and correspond with measurements of renal size obtained on stillborn fetuses postnatally.⁹³⁻⁹⁵ Throughout pregnancy, the ratio of kidney circumference to abdominal circumference remains relatively constant at 0.27 to 0.30. Such measurements are more efficient for detecting enlarged kidneys than small kidneys. Diminution in renal size is more difficult to detect because the exact renal border, especially of small

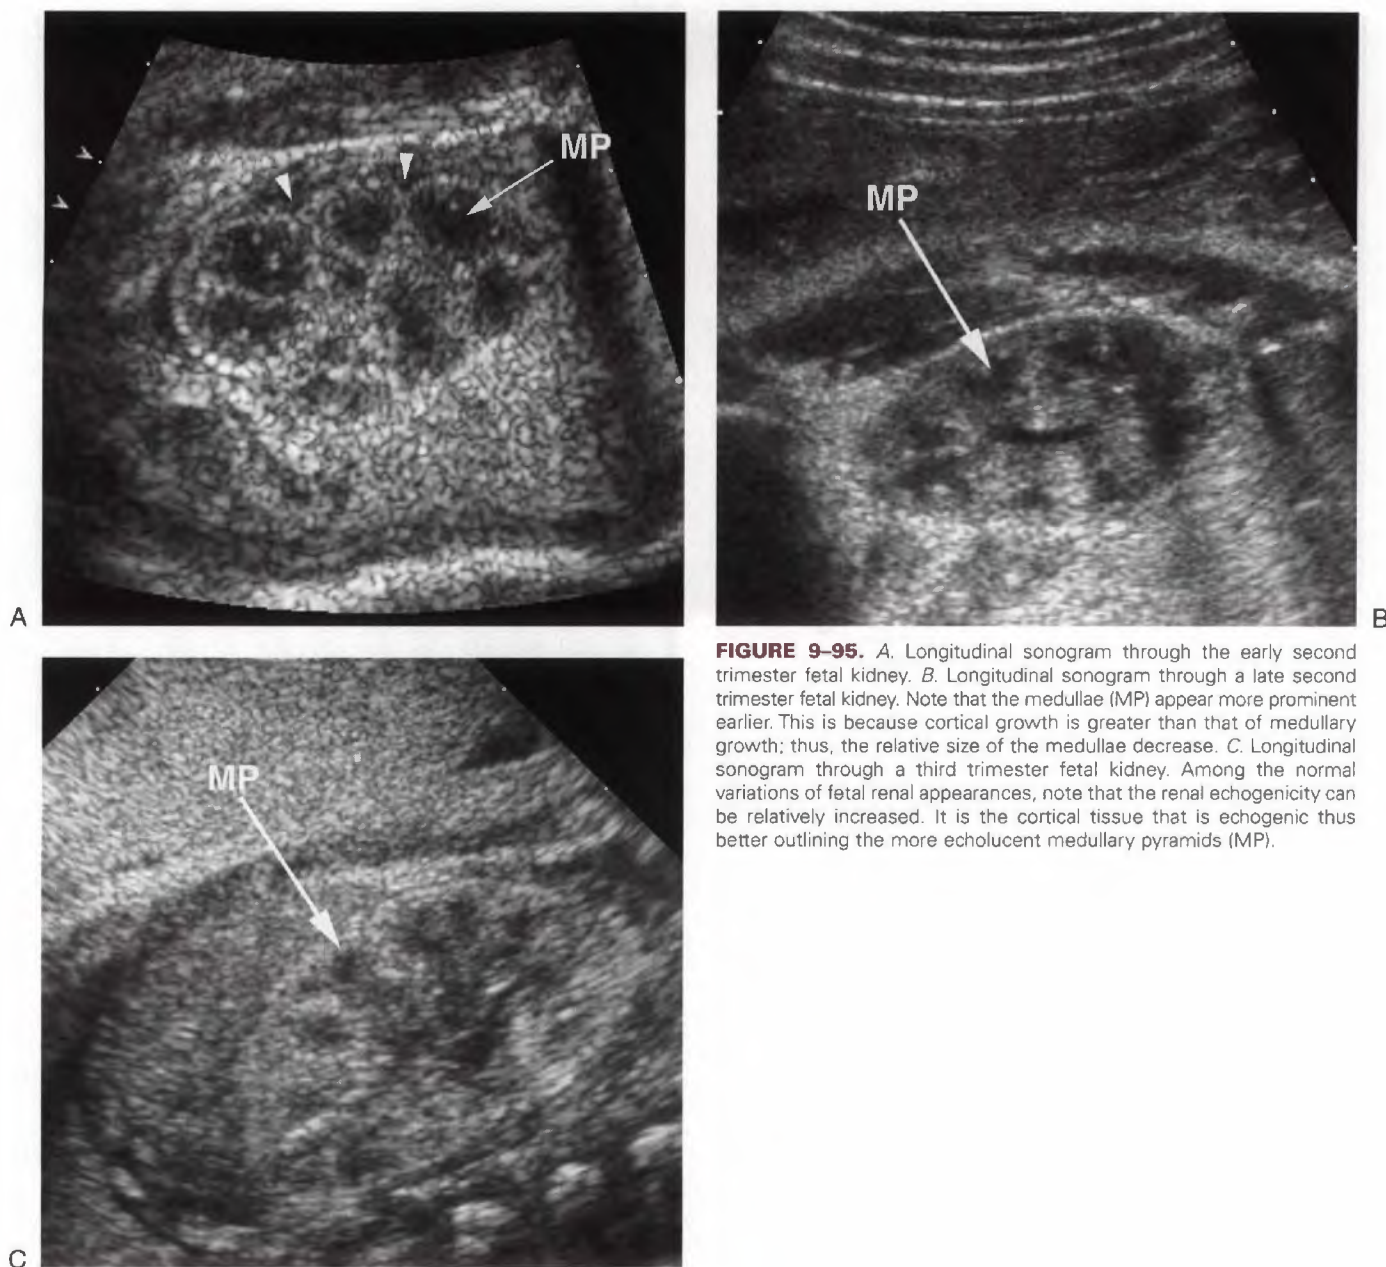

FIGURE 9-95. A. Longitudinal sonogram through the early second trimester fetal kidney. B. Longitudinal sonogram through a late second trimester fetal kidney. Note that the medullae (MP) appear more prominent earlier. This is because cortical growth is greater than that of medullary growth; thus, the relative size of the medullae decrease. C. Longitudinal sonogram through a third trimester fetal kidney. Among the normal variations of fetal renal appearances, note that the renal echogenicity can be relatively increased. It is the cortical tissue that is echogenic thus better outlining the more echolucent medullary pyramids (MP).

kidneys, may be partially obscured, because the plane of section may not be through the longest renal axis, and because of the wide standard deviation in renal size.⁹³⁻⁹⁵

The normal fetal ureter is, for all intents and purposes, not identifiable in fetuses. Uncommonly, one may see a normal ureter, but visualization of a fetal ureter should always suggest pathologic dilatation. However, as early as 15 menstrual weeks, the normal fetal urinary bladder can be identified (see Fig. 9-68). Only a few cubic centimeters of bladder urine would be needed to allow ready visualization in a young fetus. Because the fetus normally fills and empties the urinary bladder every 30 to 45 minutes, the bladder will frequently be seen to increase in size and to empty during the course of a sonographic examination.⁹⁶⁻⁹⁸ Similarly, fetuses in whom the urinary bladder is not visualized can be

examined at intervals for bladder filling. If the bladder cannot be seen in the presence of oligohydramnios, sequential imaging to test for bladder filling is mandatory.

At 32 weeks of gestation, the maximum fetal bladder volume measures 10 mL. By term, the normal fetal bladder volume quadruples. Similarly, fetal urine production, as calculated by determination of change in bladder volume with time, increases from 9.6 mL/h at 30 weeks to 27.3 mL/h at 40 weeks' menstrual age.^{96,97} Of course, term fetuses void; thus, the bladder may be empty.⁹⁸ Filling and emptying of the fetal urinary bladder confirms that the fetus produces urine but does not indicate the "quality" of urine produced. The normal fetal urinary bladder, the wall of which is very thin and virtually invisible when the bladder is well distended, occupies a midline position within the fetal pelvis (Fig. 9-97).

FIGURE 9-96. Transverse axial sonogram of a fetal kidney margined by perirenal fat (arrows). The brightly echogenic perirenal fat helps to sonographically outline the less echogenic renal parenchyma.

Changes in volume of the urinary bladder with time differentiate it from cystic pathologic pelvic structures. Recall that the umbilical arteries always flank the urinary bladder regardless of the degree of bladder distention. This anatomic relationship is extremely useful for identification of a persistently empty urinary bladder or the confirmation of a massively overdistended bladder.

The normal fetal urethra may be identified, from time to time, as an hyperechogenic line extending the length of an erect penis (see Fig. 9-17). In female and in male fetuses examined when the penis is flaccid, the normal urethra is difficult or impossible to identify. The uterus and ovaries cannot be visualized in normal female fetuses. The testes can be visualized in male fetuses only after they have descended into the scrotum. The prostate cannot be visualized. The external genitalia were discussed previously in the *Superficial Anatomy of the Fetus* section.

The fetal adrenal gland, although not part of the genitourinary system, is seen quite routinely when searching for the kidneys (see Figs. 9-96 and 9-98).^{99,100} Indeed, even in the presence of agenesis of one or both kidneys, the adrenal glands can be appreciated in their expected paraspinous locations. The fetal adrenal glands may often be imaged after 30 menstrual weeks. The adrenal glands have a specific size, shape, and echogenicity. The echo pattern is so characteristic that the cortex and medulla can be appreciated separately (see Figs. 9-63, 9-64, and 9-98). In the fetus, both adrenal glands cap the upper renal poles (in the adult the left adrenal gland most often lies anterior to the upper pole).¹⁰⁰ The right adrenal is seen more consistently. Its upper portion lies immediately posterior to the proximal inferior vena cava (see Fig. 9-98).

CENTRAL NERVOUS SYSTEM

The fetal brain was one of the first areas of investigational interest in the diagnosis of fetal anomalies.¹⁰¹ This was a

A

B

FIGURE 9-97. A. Transverse axial sonogram through the fetal pelvis. 1, urinary bladder; 2, rectum; 3, femoral head; 4, femoral diaphysis. B. Oblique axial sonogram through the fetal pelvis with nondirectional color Doppler. The umbilical arteries (UA) mark the lateral margins of the bladder (BL).

result of two factors: (1) the fetal head was imaged routinely to obtain a biparietal diameter for the determination of gestational age; and (2) central nervous system anomalies are among the most common birth defects. At first, only gross morphologic aberrations such as anencephaly or advanced hydrocephalus were discovered prenatally. Because instrumentation has improved to the present day, many malformations of the brain can be diagnosed with accuracy even before 20 weeks of development.¹⁰²⁻¹⁰⁷

The path to the diagnosis of anomalous development, as always, begins with a firm grasp of normal developmental anatomy. Initially, many errors were made when interpreting normal fetal intracranial anatomy as seen by sonography.¹⁰⁸⁻¹¹⁰ This was due to the unusual circumstance that “fluid” and

FIGURE 9-98. A. Transverse axial sonogram of the right adrenal gland (RA), although much anatomy can be seen on this image of the upper fetal abdomen. Note both limbs of the right adrenal gland immediately posterior to the inferior vena cava (V) and a portion of the left adrenal gland (unlabeled) to the left of the aorta (Ao). The abdominal wall, including the subcutaneous fat (S), muscle layers (M), and properitoneal fat (F), is well seen. St, stomach. B. Coronal sonogram of the adrenal (A) demonstrating its typical triangular "hat" appearance. K, opposite kidney.

FIGURE 9-99. A. Transverse axial scan at the level of the lateral ventricular atria in a 14-week-old fetus. The brain parenchyma (P) is very lucent. C, choroid plexus; IF, interhemispheric fissure. B. Slightly caudal scan demonstrates well-developed thalami (T) and midbrain (M). The frontal horns (F) are large and filled with cerebrospinal fluid.

FIGURE 9-100. A and B. Parasagittal sonograms in late first trimester demonstrate that, even this early in development, choroid plexus (C) fills the posterior and inferior portions of the ventricle. Specular reflectors demarcate the frontal horn (F) that is devoid of choroid plexus and thus seen as a “fluid-containing” portion of the ventricular system. The early temporal horn is seen (T). Note absence of an occipital horn. Choroid (C) fills the body, atrium, and early temporal horn. Note as well how remarkably thin the cerebral cortical (CC) tissue is.

“solid” areas of the brain did not behave in an anticipated manner. It was initially expected that the sonographic appearance of the lateral ventricles would be dominated by cerebrospinal fluid, which would render them echolucent. Instead, their appearance was dominated by highly echogenic choroid plexus (Figs. 9-99 to 9-102).^{111,112} Conversely, the bulk of neural tissue, the telencephalon, diencephalon, and mesencephalon, is quite echopenic compared with other solid tissues in the human body (see Fig. 9-99).^{111,113} The more recent entrant into the area of diagnostic sonography can well imagine the potential for misinterpretation among early researchers when the largest fluid-containing areas of the brain yielded the greatest amplitude echoes, whereas the solid tissue yielded the lowest. To further complicate matters, dramatic changes occur as brain development progresses, resulting in ever-changing positions of certain “landmarks.” These changes had never been observed *in vivo*, and post-mortem examination of the brain can be at variance with its appearance during life.

A series of key observations led to the clear delineation of normal developmental neuroanatomy as viewed sonographically. These observations included recognition of the fetal third ventricle, the brightly echogenic choroid plexus,¹¹¹ and pulsating vasculature in several cisterns.¹¹³ The first two identified the supratentorial ventricular system. The last enabled identification of the sylvian cistern (middle cerebral artery pulsation), interpeduncular cistern (basilar artery pulsation), and ambient cisterns (posterior cerebral artery pulsations) (see Fig. 9-76). The landmarks established by these observations provided a framework for subsequent identification of other specific neural structures.

Later in the course of the development of sonography, the neonatal brain came under study (see Figs. 9-1 and 9-103).^{1,2,112} Interestingly, this resulted in much greater understanding of the appearance of the *fetal* brain because examination of “newborn children” now begins commonly as early as 25 to 26 weeks of development in the preterm infant (essentially a second trimester fetus) (see Fig. 9-1). Investigators then began to apply neuroanatomy as learned from the neonatal brain, which was imaged with great clarity through the anterior fontanel, to the developing fetal brain. The following analysis of fetal intracranial anatomy is presented on the basis of these observations.

The fetal head can be clearly discriminated from the fetal torso when an embryo reaches a crown rump length of 10 to 15 mm. By the 10th to 11th weeks after the last normal menstrual period (see Fig. 9-3), one can already begin to appreciate anatomy inside the developing fetal head. At this point, the intracranial tissue components consist almost entirely of the thalamus and corpus striatum, which yield the symmetric appearance of the brain as these structures narrow the developing third ventricle into a midline specular reflector.

By the end of the first trimester, the thalamus, third ventricle, midbrain, brain stem, and cerebellar hemispheres have achieved an appearance that will remain largely unchanged, other than progressive enlargement, throughout the remaining period of sonographic observation of the fetus (see Fig. 9-99). Therefore, the vast majority of the changes that are observed—and they are substantial—relate to the growth and development of the telencephalon. As mentioned earlier, by the end of the first and beginning of the second

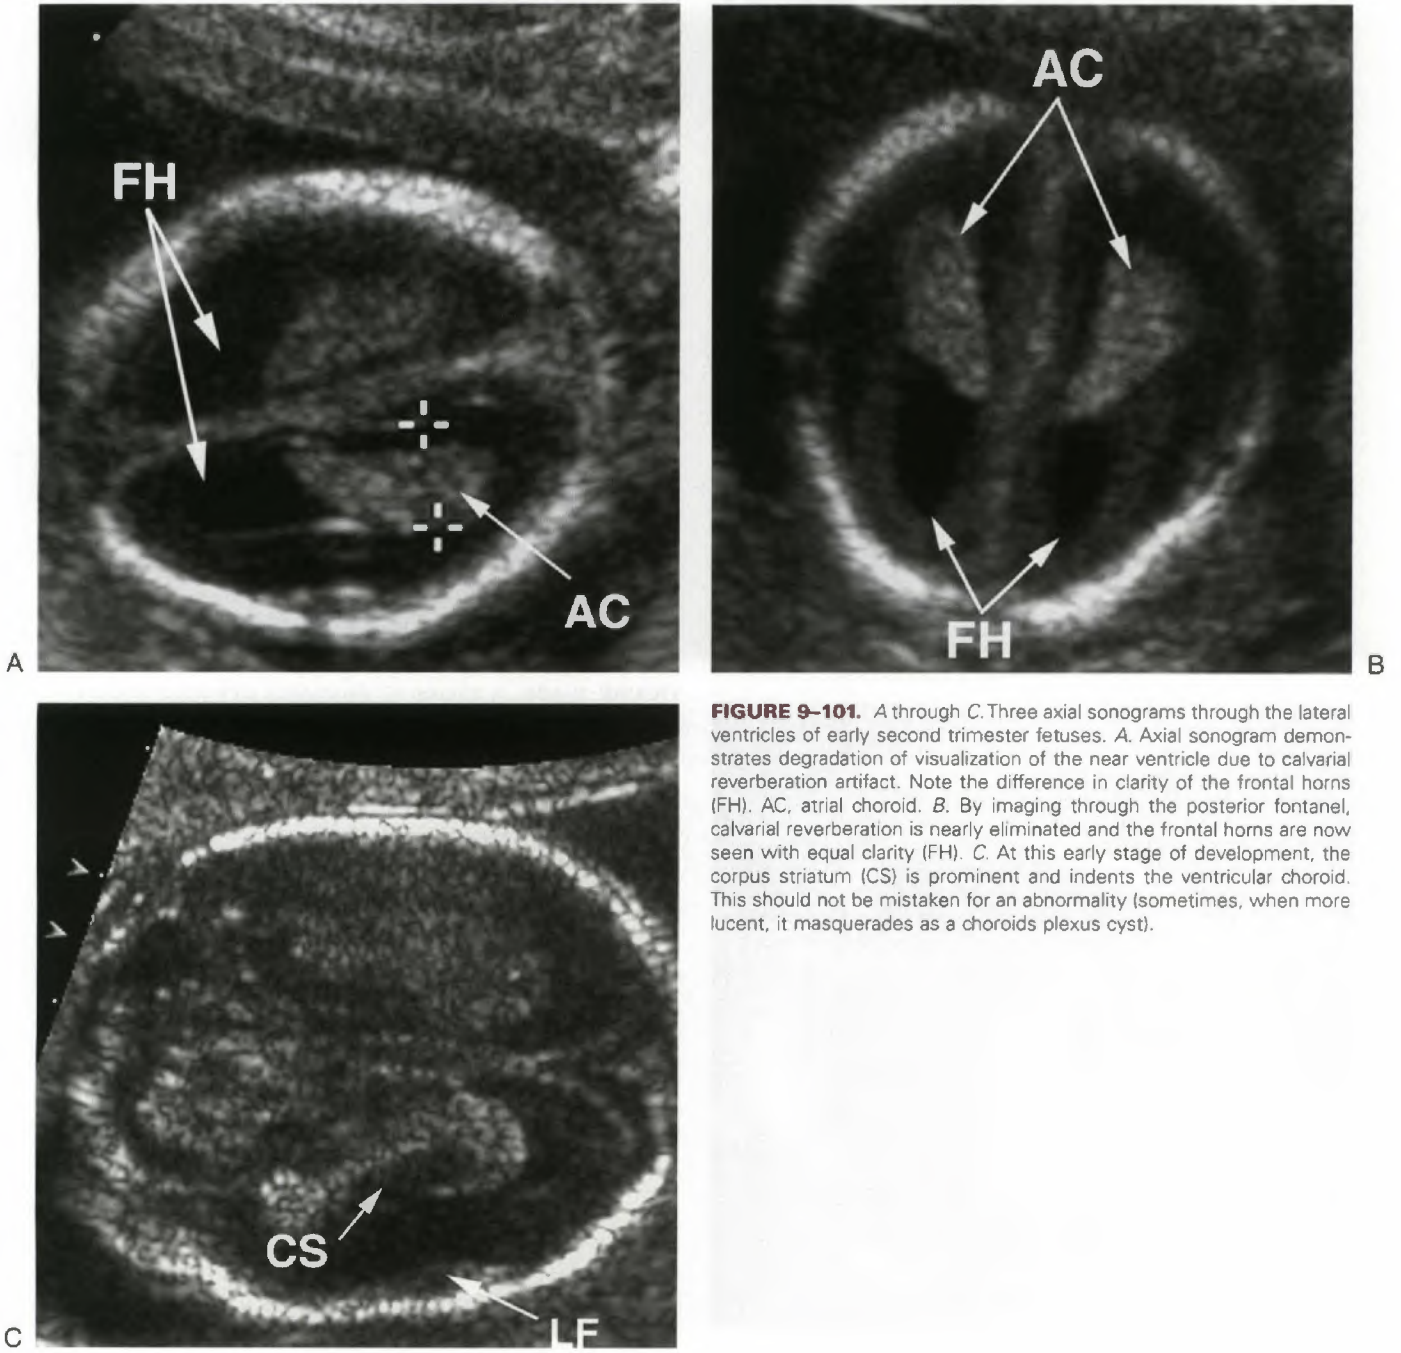

FIGURE 9-101. A through C. Three axial sonograms through the lateral ventricles of early second trimester fetuses. A. Axial sonogram demonstrates degradation of visualization of the near ventricle due to calvarial reverberation artifact. Note the difference in clarity of the frontal horns (FH). AC, atrial choroid. B. By imaging through the posterior fontanel, calvarial reverberation is nearly eliminated and the frontal horns are now seen with equal clarity (FH). C. At this early stage of development, the corpus striatum (CS) is prominent and indents the ventricular choroid. This should not be mistaken for an abnormality (sometimes, when more lucent, it masquerades as a choroids plexus cyst).

FIGURE 9-102. A through C. Parasagittal sonograms through the ventricle of 16- to 18-week-old fetuses. The choroid (C) defines the ventricular size and the position of the ventricular atrium. Note the substantial increase in cortical brain (CC) thickness compared with fetuses only a few weeks younger (see Fig. 9-100). Bright echoes marginate the edge of the telencephalon (*straight arrows*). The bright reflector represents surface leptomeninges (SL). Note the beginnings of an occipital horn (OH) in C and compare with the more developed occipital horn (OH) in C. Note, as well, that the frontal horn (FH) is much narrower in craniocaudal diameter because growth of the head of the caudate nucleus has reshaped this portion of the ventricle. B, ventricular body; TH, developing temporal horn.

FIGURE 9-103. Parasagittal sonogram of the brain of a 6-month-old child. Gyri (G) are well developed. Pia-arachnoid (PA) tissues cover the surface of the brain and make the sulci (S) highly conspicuous. Careful inspection of gyri shows that cortical "gray matter" is less echogenic than the "white matter" (this is almost certainly not a difference due to gray and white matter distinction but to the vessels coursing through the central gyrus). CH, caudate head; CP, choroid plexus; FH, frontal horn; T, thalamus.

trimesters, the lateral ventricles (see Figs. 9-99 and 9-100) dominate the sonographic appearance of the telencephalon. The brightly echogenic choroid plexus dominates in turn. By 12 to 13 weeks, the lateral ventricles can be clearly seen, appear ovoid, and are largely filled with choroid plexus. Only the frontal horns are devoid of choroid plexus as they are throughout life (see Figs. 9-99B, 9-100, and 9-101). At this stage of development, only the rudiment of a temporal horn (see Fig. 9-100B) and an occipital horn has yet to develop. The frontal horn, body of the ventricle, and atrium of the ventricle are large and easily detected. The choroid is the easiest structure to recognize because of its size and high-amplitude echogenicity. Conversely, the mantle of developing cerebral cortex surrounding the lateral ventricle is more difficult to delineate because of its low-amplitude echogenicity (Fig. 9-99A), but a demarcation between the lateral ventricle and the cerebral mantle can be appreciated from specular reflections arising from the walls of the lateral ventricle (see Figs. 9-99B and 9-100B). These, of course, are seen where the acoustic beam intersects the ventricular wall perpendicularly. By 16 to 18 weeks the mantle of developing cortical tissue has thickened appreciably (compare Figs. 9-100 and 9-102). As the occipital lobe has increased in volume, an occipital horn of the lateral ventricle has gradually appeared (see Figs. 9-100 through 9-102).

The relative echogenicity of structures, which will be viewed throughout the remainder of gestation, is largely established at this time. Two types of tissue are brightly echogenic and, therefore, most easily seen during the examination of the fetal brain. These tissues are the choroid plexus, as noted earlier, and the brain coverings: the dura (pachymeninx) and pia-arachnoid (leptomeninges). Interestingly, the choroid develops from the vascular pia. The leptomeninges demarcate the edges of the brain with a brightly reflective

margin of echoes (see Figs. 9-102 through 9-104). Peripheral to this brightly echogenic margin are the subarachnoid spaces that contain cerebrospinal fluid (Figs. 9-103 through 9-105). A feature that confounds the inexperienced sonologist is the relative lack of change in echogenicity between the peripheral (i.e., cortical brain) tissue and the cerebrospinal fluid space as seen across the brightly reflecting marginal echo from the pia-arachnoid (indeed, the cerebrospinal fluid-containing space may be more echogenic) (see Figs. 9-104 and 9-105). This perceptual problem originates from the anticipation that the subarachnoid spaces should be anechoic, whereas the brain parenchyma should be brightly echogenic. This reasonable assumption is untrue in many instances. Recall that these spaces have both cerebrospinal fluid and pia-arachnoid tissue within them. It is the relative amount of these two components that determines the sonographic appearance of the subarachnoid spaces. Small subarachnoid cisterns (such as the basal and perimesencephalic cisterns) have an appearance dominated by pia-arachnoid and thus are seen as brightly echogenic spaces (Fig. 9-106). This is not to say that these cisterns are devoid of cerebrospinal fluid, but the fluid does not significantly influence their sonographic appearance. Conversely, larger subarachnoid spaces, such as those over the convexities of the hemispheres (see Fig. 9-103 and 9-104) and the cisterna magna (Fig. 9-107), have an appearance dominated by cerebrospinal fluid. Thus, they behave, in the sonographic sense, as one would anticipate for a fluid-containing cavity. Intermediate-sized subarachnoid spaces will have both anechoic zones from visible cerebrospinal fluid and brightly echogenic zones from visible pia-arachnoid tissues (see Figs. 9-104 through 9-106). The bright margination provided by the leptomeninges enable one to visualize, for example, the midbrain quite elegantly (see Fig. 9-106). Without these margin echoes, our perception of the midbrain would be greatly hindered.

As noted earlier, brightly reflecting structures dominate the appearance of the fetal brain as seen by the sonologist. The choroid plexus and brain coverings (pia-arachnoid and dura) are the two major components within the developing calvaria that produce bright reflections. The important dural structures from the perspective of sonographic fetal brain anatomy are the falx cerebri and the tentorium (see Figs. 9-104 through 9-108). Occasionally, neural structure generates high-amplitude reflections. This is particularly true of the basal ganglia, especially the lenticular nuclei (see Fig. 9-107). The cerebellar vermis and the surface tissues of the cerebellar hemispheres also appear very bright (Figs. 9-109 and 9-110), but this appearance is again secondary to leptomeninges. The cerebellar folia "drag" meninges below the "surface" of the hemisphere, making the surface tissues appear bright (Fig. 9-109B). The cerebellar vermis has the greatest number of folia and intertwined meninges. Thus, it often appears strikingly hyperechogenic (Fig. 9-110B).

Also important as high-amplitude echoing structures are specular reflections from the walls of the ventricular system (see Figs. 9-99B, 9-100B, 9-101A and 9-102C). Such reflections occur when the ultrasonic beam strikes the smooth ventricular wall perpendicularly or nearly so. Thus, one would assume that points and lines of brightness so produced might vary from moment to moment depending on the direction in which the transducer was pointed. This,

FIGURE 9-104. A through D. Sequence of sonogram obtained through fontanels and sutures. This technique enables one to see symmetrical brain anatomy. The surface leptomeninges (SL) are crucial to discriminating the edge of the brain tissue and the adjacent cisterns. BV, bridging veins; CC, convexity cistern; CCa, corpus callosum; CF, calcarine fissure; ChF, choroidal fissure; DMV, deep medullary veins; FC, falx cerebri; LF, lateral fissure; OH, occipital horn; OL, occipital lobe; SSS, superior sagittal sinus; SV, septal vein; TH, temporal horn.

however, is not the case for two reasons. First, fetal brain images are predominantly produced in transverse axial planes (appropriate for both biparietal diameter and head circumference measurements) (see Figs. 9-99B and 9-101A) and less commonly coronal or parasagittal (see Fig. 9-102C) planes. In these planes, the beam tends to intersect the ventricular system perpendicularly at the same interfaces. Second, the curvature of the bony calvaria limits the number of axial, coronal, and parasagittal planes that can be achieved as a result of significant beam divergence when the beam intersects curved portions of calvaria. Thus, the specular reflections from the ventricular walls tend to be seen in stable locations and can be used as important and reproducible anatomic landmarks.

Additionally, within the substance of the brain, most notably in the region of the cerebral white matter tracks, other bright reflections are noted (see Figs. 9-104 to 9-106, and 9-111). Earlier, these reflectors were mistaken for the lateral ventricular walls, with which they are contiguous (see Figs. 9-105 and 9-108).^{110,113,114} The origins of these reflections are blood vessels draining the deeper white matter regions (see Figs. 9-104D, 9-105, 9-108, and 9-111).¹¹⁵ Interestingly, pia accompanies these vessels as they course through the brain substance. Therefore, again it is the

leptomeninges that account for bright echoes in the fetal brain. Thus, the brightly echoing structures of the fetal brain, including the surface echoes, cisterns, draining veins of the deep white matter, and choroid plexus, are all tied to the pia mater. As Dr. James Bowie observed one day regarding the *grand unifying theory of bright echoes in the brain*, "it's all pia" (personal communication, 1991).

The sonographic "skeleton" of the developing fetal brain originates from the brightly reflective structures just considered. Using these structures as the framework, numerous discrete neural tissue areas are discernible sonographically (see Figs. 9-106, 9-107 and 9-112).^{1,2} As the brain develops, multiple areas of the telencephalon, diencephalon, midbrain, pons, and cerebellum become anatomically identifiable. These are recognized by variations in the echogenicity of specific nuclei and tracts that pass through these zones (see Figs. 9-105, 9-107, 9-109B, 9-110, 9-111A, and 9-112). Several brain nuclei, as well as some other areas of neural tissue, demonstrate a moderate increase in echo amplitude compared with surrounding brain elements (see Figs. 9-105, 9-107, 9-112 and 9-113). These nuclei demonstrate lower amplitude signals than choroid or leptomeninges. Among these structures are the caudate and lenticular nuclei, separated by the internal capsule. Less commonly, the

FIGURE 9-105. Coronal section through the heads of the caudate nuclei (CN). The frontal horn (FH), which is not well seen, drapes over the caudate. Extending between the ventricular margin and the edge of the brain are linear echogenic structures previously mistaken for ventricles (arrows). Also seen are bridging strands of pia-arachnoid through the cistern (C) over the convexities (probably bridging veins covered with pia-arachnoid). F, falx; LF, lateral fissure.

claustrum, margined by the extreme and external capsules, is visible. Similarly, the substantia nigra (Fig. 9-106B) in the midbrain and dentate nuclei of the cerebellum (Fig. 9-107A, not labeled) are discernible. Also the pars ventralis (belly) of the pons is seen as a zone of moderate echogenicity as opposed to the pars dorsalis (tegmentum), which returns low-amplitude echoes (Fig. 9-114).¹

It is important for sonologists to be familiar with the appearance of the lateral ventricles as they change throughout growth and development of the fetal brain. By 18 to 20 weeks, easily recognizable occipital horns and temporal horns are visible (see Fig. 9-102). The lateral ventricles have achieved their adult components. From this point onward, the lateral ventricles change in shape and proportion as influenced by neural tissues growing adjacent to their walls. For example, the growth of the caudate nucleus markedly reshapes the frontal horn of the lateral ventricles (see Fig. 9-102).¹¹⁶ However, throughout the period of observation of fetal lateral ventricles (from 13 to 40 weeks), the size of the atria remains largely unchanged. The transverse diameter of the ventricular atrium at the level of the glomus of the choroid plexus shows an average dimension of approximately 7 mm and an upper limit of 10 mm throughout the second and third trimesters.¹¹⁷ This is the most convenient area to recognize fetal ventricular enlargement, as is discussed in detail in the section on ventriculomegaly in Chapter 10.^{111,112,117} It is important to note that the frontal (anterior) and occipital (posterior) horns of the lateral ventricles do not possess choroid plexus (see Figs. 9-100 through 9-102). Between 24 weeks and term, the telencephalon undergoes little structural change other

FIGURE 9-106. A and B. Sonogram demonstrating the midbrain. The midbrain is seen well because of the sharp outline provided by the brightly echogenic perimesencephalic cisterns (the leptomeninges provide the bright line of demarcation). AC, ambient cistern; CC, crural cistern; IPC, interpeduncular cistern; QPC, quadrigeminal plate cistern. These marginate the cerebral peduncles (CP) and the quadrigeminal plate (QP). AS, aqueduct of Sylvius; SN, substantia nigra.

FIGURE 9-107. A and B. Transverse axial sonograms demonstrating many discrete neural structures. Note the varying echogenicities of the cisterns. Large cisterns (1, cistern magna) have an appearance dominated by cerebrospinal fluid. Small cisterns (7, basal cisterns) are dominated by pia-arachnoid. 2, cerebellar hemisphere; 3, quadrigeminal cistern; 4, ambient cistern; 5, crural cistern; 6, interpeduncular cistern (note walls of basilar artery centrally in this cistern); 8, hypothalamus; 9, inferior recess of third ventricle; 10, sylvian aqueduct; 11, head of caudate; 12, lentiform nuclei; 13, lateral fissure; 14, frontal horn; 15, atrial choroid; 16, posterior limb of internal capsule; 17, thalamus; 18, tentorial hiatus; 19, falx cerebri.

FIGURE 9-108. A. Transverse axial sonogram near the vertex. Bright linear echoes (arrows) often mistaken for lateral ventricles are clearly seen. Note that these echoes extend to the brain edge. C, convexity cistern with cerebrospinal and hair-like bridging veins covered by brightly echogenic pia-arachnoid; F, falx; PF, parieto-occipital fissure. B. Off-axis scan through both the lateral ventricle and the linear echo (arrow) seen in A. The occipital horn (OH) is now well seen. Note again that the linear echo extends to the brain edge, whereas the occipital horn is entirely margined by brain tissue. CA, calcar avis; CP, choroid.

FIGURE 9-109. A. Posterior fossa view (transverse axial) demonstrating cerebellar folia (CF). AC, ambient cistern; LF, lateral fissure; MB, midbrain. B. Parasagittal sonogram of the posterior fossa. Cerebellar white matter tracts (T) are well seen. The bright margin of the cerebellum is “artificial” in that it is due to reflections from leptomeninges drawn into the cerebellum by folia formation (gray matter is hypoechoic).

than increased cortical growth and the consequent increase in convolutions (and thus sulcal markings), which can be recognized adjacent to the convexities (Figs. 9-115A and 9-116A).¹¹⁸ The increase in brain volume causes the lateral ventricles, which are growing more slowly, to become progressively less conspicuous.

As opposed to sulci, which are narrow and develop later as gyri form, fissures are broader, present earlier in development, and can be seen before 20 weeks.¹¹⁹ Of the two that

are commonly seen, the parieto-occipital fissure, an indentation medially adjacent to the interhemispheric cistern, is smaller (see Figs. 9-108A, 9-111B and 9-115A). The lateral fissure (insula and sylvian fossa/fissure) is a deep groove in the lateral margin of the developing telencephalon.^{117,120,121} The groove is seen as a smooth depression as early as 14 weeks (Fig. 9-101C).¹¹⁹ Subsequently, its appearance gradually changes as the fronto-parietal and temporal opercula develop (see Figs. 9-105, 9-107, 9-109, 9-112, and 9-116).¹¹⁹ This important fissure results in frequent confusion because it causes a portion of the brain surface to be invaginated deeply into the hemisphere (see Figs. 9-105, 9-107, 9-109, and 9-112). The pia-arachnoid on the surface of the insula, the tissue at the base of the lateral fissure, generates a curvilinear reflection that appears to lie within the brain substance rather than at its “edge.” This echo is often mistaken for a specular reflection from the lateral wall of the lateral ventricle, an error leading to misdiagnoses of hydrocephalus. With progressive growth of the temporal and parietal lobes, this fissure progressively closes, burying the previously exposed insular cortex behind the developing temporal and parietal opercula (see Figs. 9-116 and 9-117). By term (38 to 42 weeks), the lateral fissure closes and ultimately becomes the sylvian cistern complex.

Other fissures and sulci become visible at predictable times during fetal brain development. This developmental sequence, or the failure thereof, enables one to diagnose or exclude certain brain malformations associated with migrational abnormalities. Among these are either the absence of formation of fissures and sulci (lissencephalic anomalies) or the appearance of fissures and sulci in aberrant locations (dysplastic brain).^{119,122} The calcarine fissure (sulcus) (Fig. 9-104A) is associated with the parieto-occipital fissure. The calcarine fissure angles caudally from the mid portion of the parieto-occipital fissure, creating a prominent fold in the medial occipital lobe (the two fissures form a “Y” lying on its side). The calcarine fissure’s greatest importance is that, as it grows, it indents the medial aspect of the occipital horn, thereby actually changing the shape of the ventricle at the junction of the atrium and occipital horn (the other piece of developing brain that greatly reshapes ventricular configuration is the caudate nucleus). The folded tissue is called the “calcar avis” (translated meaning the “bird’s heel,” which it somewhat resembles [at least to the anatomist who described it—I would have called it the “bird’s beak”]) (see Figs. 9-108B and 9-116B). The calcarine fissure is easily seen on coronal sections of the posterior brain (see Fig. 9-104A). In the coronal plane, one would think that it is the parieto-occipital fissure except that the coronal plane favors visualization of the calcarine fissure, whereas the axial plane favors visualization of the parieto-occipital fissure (see Fig. 9-115B). The calcarine fissure (sulcus) becomes visible by the 24th week.¹¹⁹ The cingulate sulcus, the sulcus that parallels the superior surface of the corpus callosum (see Fig. 9-114), also becomes visible at approximately the same time as the calcarine sulcus.¹¹⁹ The cingulate sulcus is important in that it does not form when there is complete agenesis of the corpus callosum. Thus, the formation of the corpus callosum is the “causative” element determining sulcation of the medial frontoparietal cortex. Because the cingulate sulcus is the first of the medial sulci to develop, its presence is helpful in excluding complete callosal agenesis.

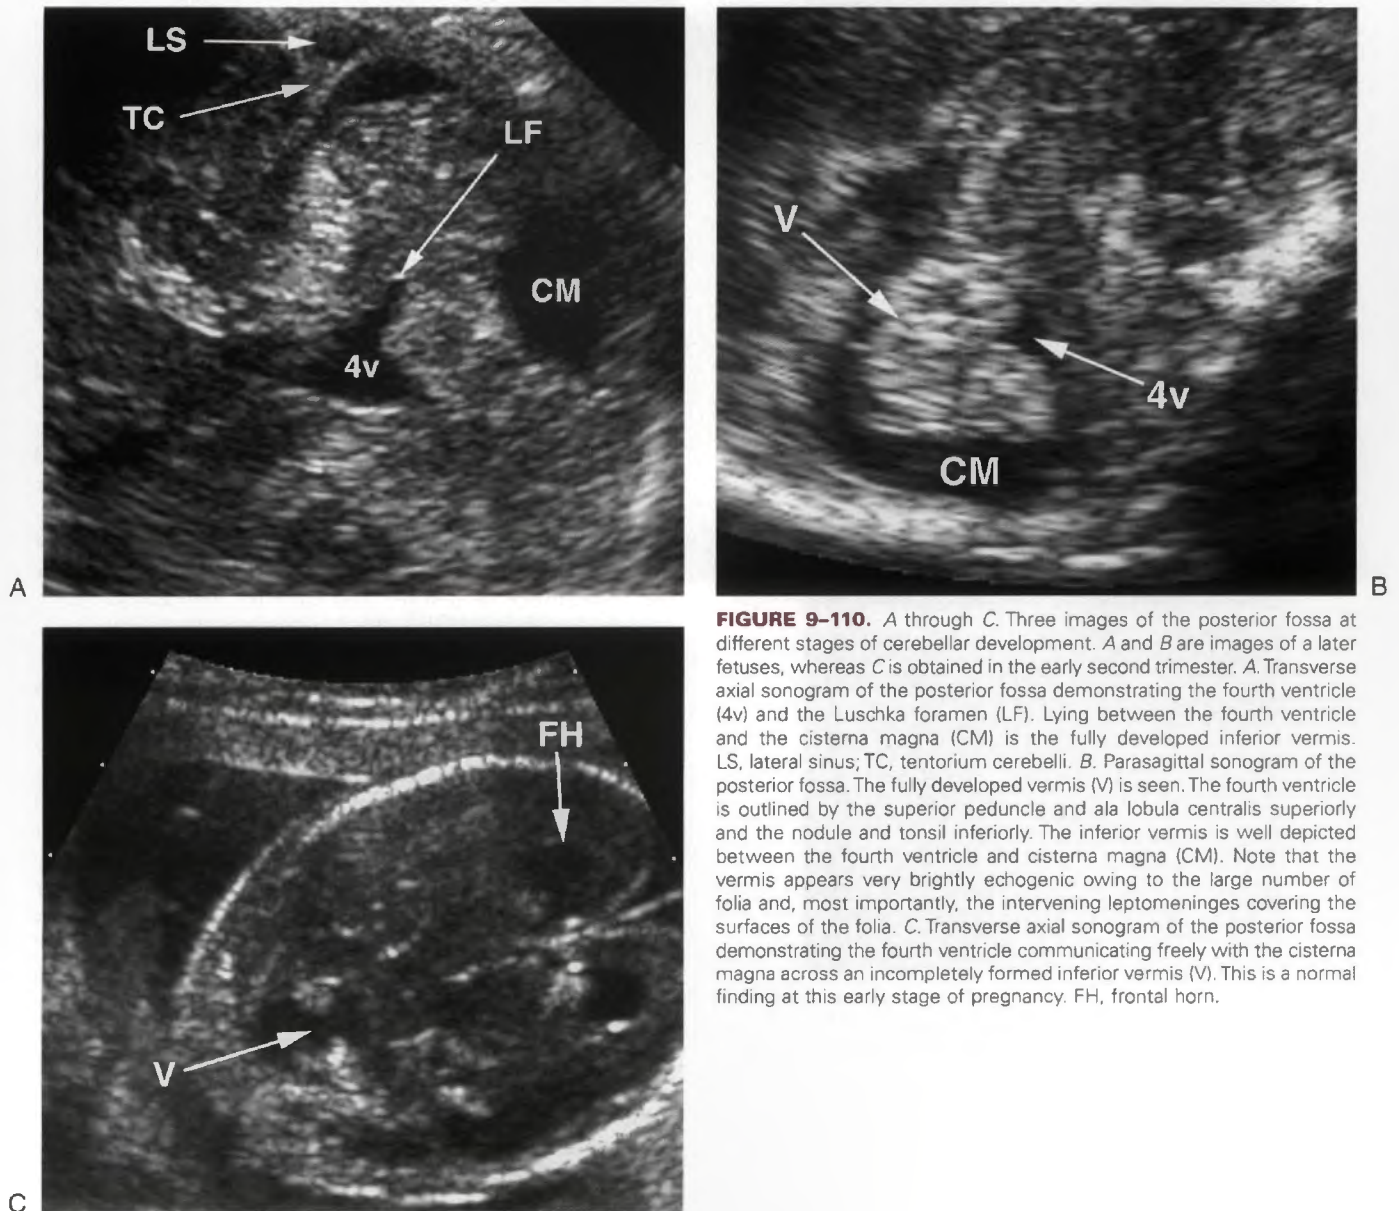

FIGURE 9-110. A through C. Three images of the posterior fossa at different stages of cerebellar development. A and B are images of a later fetuses, whereas C is obtained in the early second trimester. A. Transverse axial sonogram of the posterior fossa demonstrating the fourth ventricle (4v) and the Luschka foramen (LF). Lying between the fourth ventricle and the cisterna magna (CM) is the fully developed inferior vermis. LS, lateral sinus; TC, tentorium cerebelli. B. Parasagittal sonogram of the posterior fossa. The fully developed vermis (V) is seen. The fourth ventricle is outlined by the superior peduncle and ala lobula centralis superiorly and the nodule and tonsil inferiorly. The inferior vermis is well depicted between the fourth ventricle and cisterna magna (CM). Note that the vermis appears very brightly echogenic owing to the large number of folia and, most importantly, the intervening leptomeninges covering the surfaces of the folia. C. Transverse axial sonogram of the posterior fossa demonstrating the fourth ventricle communicating freely with the cisterna magna across an incompletely formed inferior vermis (V). This is a normal finding at this early stage of pregnancy. FH, frontal horn.

FIGURE 9-111. A. Coronal plane. B. Parasagittal plane. The deep medullary veins (DMV) and the bridging veins (BV) are invested with pia mater and thus are brightly reflective. Brightly reflective surface leptomeninges (SL) demarcate the brain surface and help to discreetly detect fissures and sulci such as the parieto-occipital fissure (POF). CC, corpus callosum; CF, columns of the fornix; CN, caudate nucleus; FH, frontal horn.

FIGURE 9-112. Transverse axial sonogram. 1, falx; 2, frontal horn; 3, caudate head; 4, anterior limb of internal capsule; 5, lentiform nuclei; 6, lateral sulcus; 7, thalamus; 8, third ventricle; 9, quadrigeminal bodies.

Finally, the sulci over the convexities gradually become increasingly visible from the beginning of the third trimester onward.¹¹⁹ Among other recognizable sulci are sulci on the inferior frontal lobe that help define the gyrus rectus (see Figs. 9-116 and 9-117).

A structure of great importance in fetal neuroanatomy is the corpus callosum (Fig. 9-118). The corpus callosum begins its development between the 10th and 11th weeks of

gestation. It has achieved its adult configuration by the end of the 17th week. The development starts at the genu and proceeds posteriorly to the splenium. However, the rostrum (the most anterior part of the corpus callosum) forms last. The rostrum is not usually seen on prenatal sonograms. Sonographic imaging of the corpus callosum for the detection of abnormal formation should not be attempted in earnest until after 17 weeks (see Fig. 9-118D). The best views of the corpus callosum are obtained in the midsagittal plane (see Figs. 9-114B and 9-118B). However information about the corpus callosum can be obtained in other planes of section. The body and genu can be seen in coronal and axial planes (see Figs. 9-111A, 9-113A, and 9-118A). Unfortunately, when partial agenesis (dysgenesis) of the corpus callosum is present, it is typically the splenium and distal body that are missing. Importantly, the splenium can be imaged in axial planes of section, although with some difficulty, because the plane of section must approach from the occipital region (see Fig. 9-118C). Occipital ossification and the smaller posterior fontanel make this approach difficult at times. An extremely helpful structure, both in terms of visualization of the corpus callosum and for excluding complete agenesis of the corpus callosum, is the cavum septi pellucidi/cavum vergae complex (see Fig. 9-113). The cavum septi pellucidi is the median cleft between the two laminae of the septum pellucidum. Sometimes called the fifth ventricle, it is not. It is not lined by ependyma. The cavum vergae (described by the Italian anatomist, Verga) is the posterior extension of the cavum septi pellucidi (see Fig. 9-113C). The actual line of division is the fornix, but as the fornix is not visible in a midsagittal plane, I use the Monroe foramen to demarcate the end of one cavum and the beginning of the other (see Fig. 9-113C). The corpus callosum is the roof of the cavae, and the roof of the third ventricle is the floor of the cava. Fortunately, we

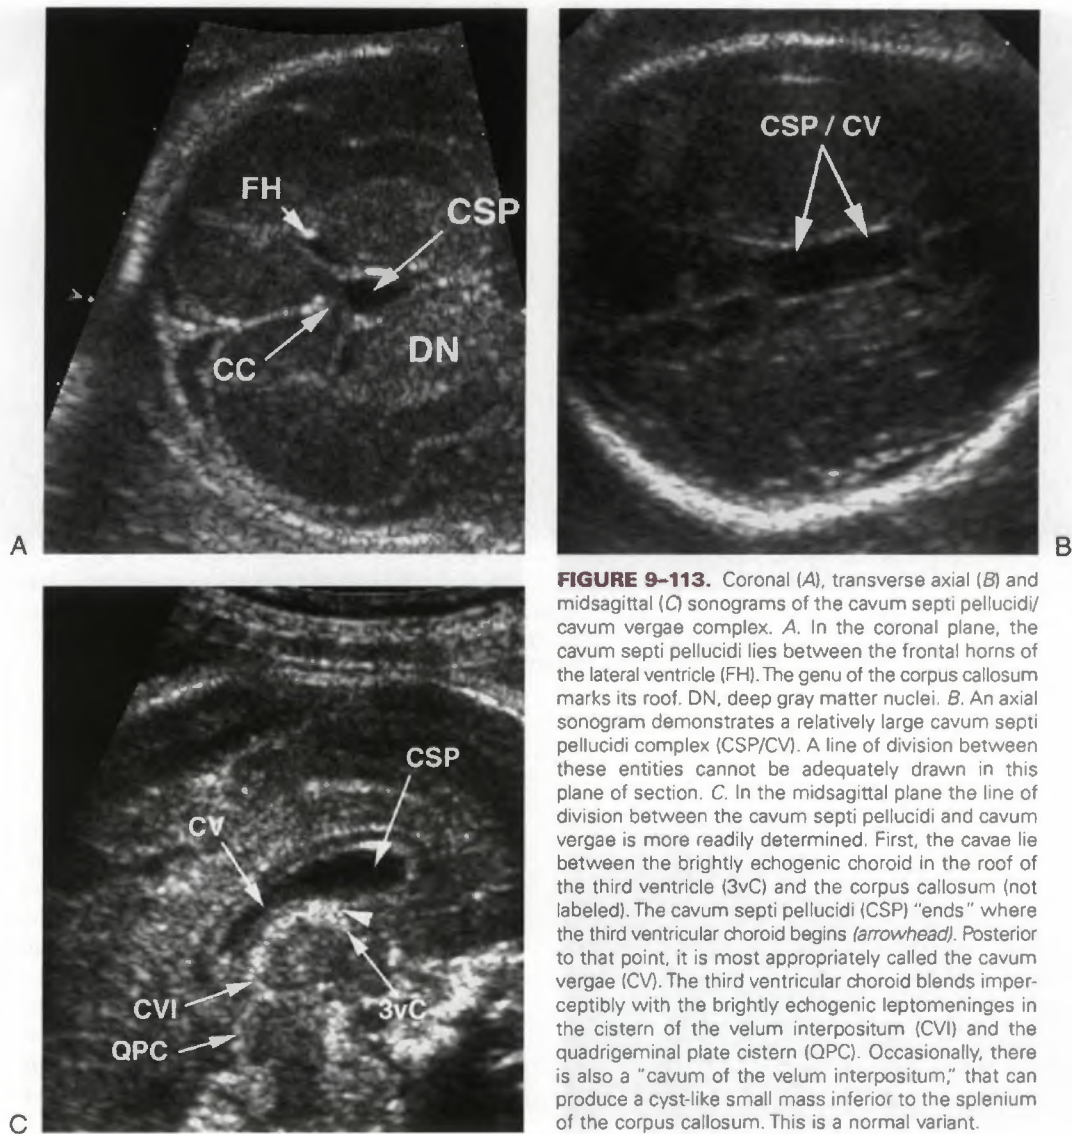

FIGURE 9-113. Coronal (A), transverse axial (B) and midsagittal (C) sonograms of the cavum septi pellucidi/cavum vergae complex. A. In the coronal plane, the cavum septi pellucidi lies between the frontal horns of the lateral ventricle (FH). The genu of the corpus callosum marks its roof. DN, deep gray matter nuclei. B. An axial sonogram demonstrates a relatively large cavum septi pellucidi complex (CSP/CV). A line of division between these entities cannot be adequately drawn in this plane of section. C. In the midsagittal plane the line of division between the cavum septi pellucidi and cavum vergae is more readily determined. First, the cavae lie between the brightly echogenic choroid in the roof of the third ventricle (3vC) and the corpus callosum (not labeled). The cavum septi pellucidi (CSP) "ends" where the third ventricular choroid begins (arrowhead). Posterior to that point, it is most appropriately called the cavum vergae (CV). The third ventricular choroid blends imperceptibly with the brightly echogenic leptomeninges in the cistern of the velum interpositum (CVI) and the quadrigeminal plate cistern (QPC). Occasionally, there is also a "cavum of the velum interpositum," that can produce a cyst-like small mass inferior to the splenium of the corpus callosum. This is a normal variant.

have an excellent marker of the roof of the third ventricle. This is because the third ventricular choroid recurves along the roof (see Figs. 9-113C and 9-118B). The most anterior extent of the third ventricular choroids (see Fig. 9-113C) marks the position of the Monroe foramen and thus is a very reasonable dividing line between the cavum septi pellucidi and the cavum vergae. In axial planes of section, a reasonable line of division cannot be drawn (see Fig. 9-113B). A final aspect of callosal development is that formation of the cingulate gyrus (and thus the cingulate sulcus) is dependent on the formation of the corpus callosum (see Fig. 9-114).

The cerebellar vermis, like the corpus callosum, is also a late structure to develop (see Fig. 9-110). Indeed, of the major parts of the fetal brain to develop, the cerebellar vermis is last in line. The cerebellum is well imaged throughout the second and third trimesters (except near term when occipital ossification is sufficiently great to thwart passage of the acoustic beam) (see Figs. 9-109, 9-110, 9-114, and

9-118B). Like the corpus callosum, the cerebellar vermis develops from "front to back." Thus, the inferior portion of the vermis does not complete its formation until relatively late (in the range of the 18th gestational week). Sonographically, one detects the inferior vermis lying between the fourth ventricle and the cisterna magna (see Figs. 9-110A, 9-110B, and 9-114A). In midsagittal planes, the fourth ventricle is outlined by the superior peduncle and ala lobula centralis superiorly and the nodule and tonsil inferiorly. The inferior vermis is well depicted between the fourth ventricle and cisterna magna. Note that the vermis appears very brightly echogenic owing to its large number of folia (see Fig. 9-110B) and, most importantly, the intervening leptomeninges covering the surfaces of the folia. By contrast, in a 16- to 17-week-old fetus, a transverse axial sonogram of the posterior fossa typically demonstrates the fourth ventricle communicating freely with the cisterna magna across an incompletely formed inferior vermis (see Fig. 9-110C). This

FIGURE 9-114. Midsagittal sonograms of a younger (A) and older (B) fetus. The cingulate sulcus (CS) is readily seen. The cingulate gyrus (not labeled) lies between the cingulate sulcus and the corpus callosum (CC). In the older fetus, more visible sulci along the medial frontal and parietal lobes are visible (B). 4v, fourth ventricle; CM cisterna magna; CV, cerebellar vermis; IPC, interpeduncular cistern; Pb, belly of pons; QPC, quadrigeminal plate cistern.

FIGURE 9-115. A. Younger fetus. B. Older fetus. Sonograms concentrating on the brain surface. In the younger fetus, the brain surface is relatively smooth, although some of the major developing fissures are visible. POF, parieto-occipital fissure; LF, lateral fissure. In the older fetus, numerous sulci and gyri are visible (arrowheads). CC, convexity cistern; FC, falx cerebri; IHC, interhemispheric cistern.

FIGURE 9-116. A and B. Transverse axial sonograms of a fetus with little calcification of the calvaria (recessive osteogenesis imperfecta). A. Note the lack of near calvarial reverberation artifact enabling visualization of the near temporal lobe with greater clarity than the far temporal lobe (*short arrows*). AC, ambient cistern; GR, gyrus rectus; T, thalamus. B. Note the clarity with which the near ventricle is visualized. 1, occipital horn; 2, calcar avis; 3, atrial choroid; 4, corpus callosum [it is very unusual to see so much of the corpus callosum in an axial plane]; 5, frontal horn; 6, veins in the deep white matter; 7, sulci; 8, falx cerebri.

FIGURE 9-117. Coronal sonogram, anteriorly. CG, cingulate gyrus; CN, caudate nucleus; F, falx; FG, frontal gyri; FH, frontal horn; LS, lateral sulcus; PO, parietal operculum; TO, temporal operculum.

is a normal finding at this early stage of pregnancy. The cerebellar hemispheres are outlined by the fluid in the cisterna magna (see Fig. 9-110). The fourth ventricle can be depicted throughout the second and third trimesters unless technical imaging problems confound its visualization (indeed, the “fourth ventricle” is even seen in the first trimester [see Fig. 9-3]).

One of the difficulties in mastering the sonographic anatomy of intracranial structures is the usual inability to see both hemispheres of the brain symmetrically.¹²³ The hemisphere nearest to the transducer is virtually always “clouded” over by reverberation artifacts generated as the acoustic beam passes through the near calvarial wall. Calvarial ossification appears to be at the root of this artifact because the artifact is markedly reduced in fetuses with recessive osteogenesis imperfecta or other bone dysplasias wherein calvarial ossification is nearly absent (see Fig. 9-116). Unfortunately, essentially all other fetuses possess calvarial ossification. The following rule should always be applied: The sonologist must assume that the intracranial anatomy of the fetus is symmetric, whether normal or abnormal, unless images document an asymmetry. Visualization of the near hemisphere requires that we use bone-free windows in the near calvaria. The “windows” are the anterolateral and posterolateral fontanels in axial approach or the anterior and posterior fontanels in coronal imaging. Because the anterolateral and posterolateral fontanels are nearer to the base of the brain than to the vertex, using the anterolateral

FIGURE 9-118. A. Coronal section through the body (B) of the corpus callosum. B. Midsagittal sonograms show the corpus callosum to best advantage. B, body; G, genu; S, splenium. C. Axial view "aimed" at the occiput demonstrates the splenium (S), the most crucial portion of the corpus callosum to demonstrate. In an "occiput up" fetus, a midsagittal sonogram of the corpus callosum would be nearly impossible to obtain. D. Nineteen-week-old fetus with corpus callosum well demonstrated. 3VC, choroid plexus in the roof of the third ventricle; AC, atrial choroids; CeV, vermis of the cerebellum; CSP, cavum septi pellucidum; CV, cavum vergae; FH, frontal horn; QPC, quadrigeminal plate cistern; SSS, superior sagittal sinus.

FIGURE 9-119. Longitudinal sonogram at the craniocervical junction demonstrating the cervical cord (CC). P, posterior arch ossification centers; PA, pia-arachnoid; V, vertebral body ossification centers; arrow, dura.

and posterolateral fontanelles results in images of the near hemisphere that are off axis to the axial plane (at least in most images). Therefore, caution must be exercised in the interpretation of the off axis planes, particularly when judging the size of the near ventricular atrium.

As noted earlier, the fetal spine is seen well from 15 to 16 weeks onward. However, we often delay evaluation for suspected myelomeningocele until 18 to 20 weeks of gestation. This is due to significant and favorable maturational changes in the spine that occur during this period. The posterior ossification centers begin at the base of the transverse processes (see Figs. 9-55 to 9-60). As ossification progresses, the laminae become visible (see Figs. 9-56 to 9-58 and 9-62). The inward angulation of the normal laminae is the opposite of the outward splaying of the laminae seen in spina bifida, an optimal situation for detecting this anomaly. Spina bifida, of course, is the bony anomaly seen in all myelomeningoceles. The spinal cord neural tissue, like that of most brain tissue, is echogenic (see Fig. 9-62). The conus medullaris (see Fig. 9-62D) and the craniocervical junction (Fig. 9-119) can be seen, albeit inconsistently, in nearly all fetuses by 18 to 20 menstrual weeks. The tissues surrounding the cord (leptomeninges) are brightly echogenic, as are those that surround the brain, and the dura is usually also seen discretely as a linear bright reflector (see Fig. 9-62C and D, and 9-63). In fetuses with myelomeningoceles, determination of the most cephalic spinal level of the lesion is an important factor in prognosis. This level can be determined by counting up from the last ossified vertebral segment (assumed to be S-4 in the second trimester and S-5 in the third trimester) (Fig. 9-120).

Intracranial Cysts

Conclusions

Central nervous system (CNS) malformations are some of the most common of all congenital abnormalities. Neural tube defects are the CNS malformations most frequently encountered at birth and amount to approximately 1 to 2 cases per 1000 births. The incidence of intracranial abnormalities with an intact neural tube is uncertain because it is likely that most of these escape detection at birth and only become manifest in later life. Long-term follow-up studies suggest that the incidence may be as high as one in 100 births.¹

Ultrasound has been used for nearly 30 years as the main modality to help diagnose fetal CNS anomalies. In recent years, fetal magnetic resonance imaging (MRI) has emerged as a promising new technique that may add, in selected cases, important information,^{2,3} although the real advantage over ultrasound remains debated.^{4,5} In this chapter, the investigation of the fetal brain and the identification of CNS anomalies are reviewed.

NORMAL SONOGRAPHIC ANATOMY OF THE FETAL CENTRAL NERVOUS SYSTEM

The fetal cerebrum undergoes major developmental changes throughout the entire gestation. High resolution transvaginal probes have allowed detailed investigation of the human embryo in vivo in the very first part of pregnancy (Figs. 10-1 and 10-2). Starting from 7 weeks' gestation, the primary cerebral vesicles can be identified as fluid-filled areas with transvaginal sonography. From 11 weeks' gestation, the brightly echogenic choroid plexuses filling the large lateral ventricles are the most prominent intracranial structures (see Fig. 10-1). In the second trimester, a detailed sonographic examination of the already well-developed cerebral structures, allowing the detection of most anomalies, is feasible. How-

ever, the results of an obstetric sonogram greatly depend upon the level of expertise of the sonographer and the time dedicated to the scan. In evaluating the fetal brain, a distinction must be made between a basic examination (frequently referred to as a level one, routine, or standard scan) and a fetal neurosonogram (or level two examination). The basic scan is fundamentally a screening examination for low-risk patients, and there is a general consensus that it is conveniently carried out by two transverse axial views of the head, demonstrating the lateral ventricles, basal ganglia, cavum septum pellucidum, and posterior fossa (Fig. 10-3).⁶ Measurement of the biparietal diameter, head circumference and internal diameter of the atrium is recommended. Some advocate also measurement of the transverse cerebellar diameter and/or cisterna magna depth.⁷

A fetal neurosonogram is a diagnostic examination, usually performed in a patient at increased risk of fetal anomalies and may include coronal and sagittal views of the head that are more difficult to obtain but that have the advantage of delineating more clearly, subtle details of intracranial anatomy, particularly by using a vaginal probe in fetuses in cephalic presentation (Fig. 10-4). Three-dimensional ultrasound is a useful adjunct to the bidimensional examination in that it allows visualization of scanning planes difficult or impossible to obtain directly (Fig. 10-5).⁸

The examination of the fetal spine requires expertise and meticulous scanning, and the results are heavily dependent on the fetal position. Sonography demonstrates the ossification centers of the vertebrae (one inside the body, one at the junction of the lamina and pedicle on each side) that appear brightly echogenic. Three types of scanning planes can be used to evaluate the integrity of the spine. In *transverse planes*, the vertebrae have different anatomic configurations dependent upon the spinal level imaged (Fig. 10-6). Fetal

FIGURE 10-1. Sonography of the embryonic and early fetal brain as demonstrated by sagittal sections (*upper row*) and axial sections (*lower row*). At *7 weeks' gestation* (transvaginal scan), the rhombencephalic vesicle, that will give rise to the fourth ventricle (4v) is usually the only demonstrable structure: at *8 weeks* (transvaginal scan) the remaining two primary vesicles of the brain can be demonstrated: the mesencephalic vesicle, which will give rise to the aqueduct of Sylvius (AS), and the prosencephalic vesicle, which will develop into the third ventricle; at *13 weeks*, the intracranial anatomy is dominated by the prominent choroid plexuses of the lateral ventricles. The midline can also be clearly visualized at this time in gestation.

FIGURE 10-2. Multiplanar sonography of the primary cerebral vesicles at 8 weeks + 4 days' gestation with a 10 MHz transvaginal transducer. The *rhombencephalic vesicle* (4v), the *mesencephalic vesicle* (A), the *prosencephalic vesicle* (3v), and the tiny cavities of the *telencephalic vesicles* (LV) can be readily appreciated. The labeled lines on figure (A) represent the planes of section shown on the other images (B), (C), and (D).

FIGURE 10-3. The transventricular (A) and transcerebellar (B) views in a normal midtrimester fetus. The cavum septum pellucidum, atrium of the lateral ventricle, and the cisterna magna are all well seen.

FIGURE 10-4. Sagittal (A) and coronal sections (B, C) of a normal midtrimester fetus. CSP, cavum septi pellucidum; 3v, third ventricle; 4v, fourth ventricle.

FIGURE 10-5. Multiplanar imaging of the fetal brain using three-dimensional sonography. The data volume has been obtained with the probe aligned along the axial plane (A). Two orthogonal sections have been reconstructed demonstrating simultaneously the coronal (B) and midsagittal planes (C). There is an excellent correlation between the midsagittal plane reconstructed from the ultrasound volume and (D) the corresponding plane obtained with standard two-dimensional ultrasound. CSP, cavum septum pellucidum.

FIGURE 10-6. Transverse views of the fetal spine in the cervical (A), thoracic (B), lumbar (C), and sacral area (D) vertebral bodies and lamina/pedicles (arrows).

FIGURE 10-7. Sagittal view of the fetal spine.

thoracic and lumbar vertebrae have a triangular shape, with the ossification centers surrounding the neural canal. The first cervical vertebrae are quadrangular in shape, and the sacral vertebrae are flat. Examination of the spine is a dynamic process. While using the axial approach, the ultrasound transducer is swept along the entire length of the spine. In *sagittal planes* the ossification centers of the vertebral body and posterior arches form two parallel lines that converge in the sacrum. When the fetus is prone, a true sagittal section can also be obtained, directing the ultrasound beam across the unossified spinous process. This allows visualization of the neural tube and of the spinal cord within it. In the second and third trimester of gestation, the conus medullaris is usually found at the level of L2–L3 (Fig. 10-7).⁹ In *coronal planes*, one, two, or three parallel lines are visualized, depending on the orientation of the sound beam (Fig. 10-8).

Integrity of the neural canal is inferred by the regular disposition of the ossification centers of the spine and the presence of soft tissue covering the spine. If a true sagittal section can be obtained, visualizing the conus medullaris in its normal location further strengthens the diagnosis of normalcy.

In the basic examination, a longitudinal view of the spine should always be demonstrated. However, detailed evaluation is complex, and usually requires an expert, or level 2, scan.¹⁰

MAGNETIC RESONANCE IMAGING OF THE FETAL BRAIN

MRI has been used in obstetric patients for diagnosis of fetal cerebral anomalies. The MRI procedure is not believed to be hazardous to the fetus, and new equipment allows fast scanning at a reasonable level of resolution. In general, the anatomy is well depicted in fetuses older than 20 weeks' gestation. Compared with ultrasound, MRI has a lower spatial resolution but is particularly valuable because of greater contrast resolution (Fig. 10-9). It has been found to be particularly valuable in the assessment of migrational disorders, intracranial hemorrhage (ICH), and complex cerebral anomalies. Furthermore, it is not influenced by fetal position, skull calcification, and oligohydramnios. There is a controversy in the current literature whether MRI provides additional diagnostic information to the sonographic examination when the sonogram is performed by an expert.^{4,5} Nevertheless, the use of MRI in obstetric patients is becoming widespread.² It should be stressed, however, that often with current technology, this technique gives the best results only after fetal viability, when termination of pregnancy is no longer possible in most countries.

VENTRICULOMEGALY

Enlargement of the lateral cerebral ventricles (Fig. 10-10) can be regarded as a nonspecific marker of abnormal brain development and is encountered with many different cerebral anomalies. Therefore, evaluation of the integrity of the cerebral lateral ventricles is of particular importance while screening for fetal cerebral anomalies. Although many different approaches to the evaluation of the integrity of lateral ventricles have been proposed, measurement of the internal width of the atrium of the lateral ventricle at the level of the glomus of the choroid plexus is currently favored.¹¹ Under normal conditions, the measurement is less than 10 mm, whereas a value of more than 15 mm indicates *severe ventriculomegaly* and is often associated with an intracranial malformation at birth. The outcome of these fetuses is variable and depends largely on the underlying etiology of the ventricular dilatation. The available studies suggest that fetuses with isolated severe ventriculomegaly have an increased risk of perinatal death and a probability of severe neurologic sequelae in the range of 50% of survivors.¹² An

FIGURE 10-8. Three-dimensional coronal views of the fetal spine obtained reslicing an ultrasound volume. Depending on the orientation and thickness of the ultrasound beam, (A) the bodies of the vertebrae, (B) the transverse processes, or (C) both can be demonstrated.

FIGURE 10-9. Magnetic resonance image of the fetal brain in the second (A) and third trimester (B,C).

FIGURE 10-10. Normal transventricular scan (A) demonstrating an atrium of lateral ventricle of normal size, (B) mild ventriculomegaly, and (C) severe ventriculomegaly.

FIGURE 10-11. Bilateral (A) and unilateral (B) mild ventriculomegaly.

intermediate value of the atrial width, 10 to 15 mm, is commonly referred to as *mild ventriculomegaly*. It is associated with an increased probability of cerebral and extracerebral malformations, aneuploidies, and infections and, therefore, these patients should be carefully evaluated in a referral center. Fetuses with *isolated* mild ventriculomegaly usually have a good outcome, and in most instances, the ventricles stabilize or return to normal size throughout gestation. However, these fetuses run an increased risk of neurologic compromise and, in some cases, develop severe cerebral anomalies, including hydrocephalus, white matter injury, and cortical plate abnormalities, in the last part of the gestation or after birth.¹³ The risk is particularly increased when the atrial width is greater than 12 mm, when the dilatation affects both lateral ventricles and in female fetuses (Fig. 10-11).¹³ It has been suggested that the term mild ventriculomegaly should be limited only to cases with atrial measurements of 10 to 12 mm, whereas values of 12.1 to 15 mm should be referred to as *moderate* ventriculomegaly, because they tend to have in general a worse outcome.¹⁴

Congenital hydrocephalus has genetic implications. It should be stressed that the experience thus far indicates that antenatal ultrasound is unreliable for predicting the recurrence of isolated ventriculomegaly, and particularly of the X-linked variety, because in many cases, enlargement of the lateral ventricles develops only late in gestation or after birth. DNA analysis for the X-linked variety is now available and should be considered, although the exact sensitivity remains uncertain.¹⁵⁻¹⁷

When the diagnosis of severe ventriculomegaly is made before viability, many parents would probably request termination of pregnancy. In continuing pregnancies, no modifications of standard obstetric management are required. A cesarean section is recommended only in those cases with associated macrocrania. Cephalocentesis to reduce cranial size is associated with significant morbidity and is indicated only in cases with a presumption of a severe prognosis.¹⁸

Table 10-1

Incidence of Neural Tube Defects in Various Geographic Areas

	Spina Bifida Incidence per 1000 Births	Anencephaly Incidence per 1000 Births
South Wales	4.1	3.5
Southampton	3.2	1.9
Birmingham, UK	2.8	2.0
Charleston		
White	1.5	1.2
Black	0.6	0.2
Alexandria	.0	3.6
Japan	0.3	0.6

Modified from Brocklehurst G. In Vinken PJ, Bruyn GW (eds): *Handbook of Clinical Neurology* vol 32. Amsterdam, Elsevier/North Holland Biomedical Press, 1978. pp 519-578.

NEURAL TUBE DEFECTS

The average incidence of neural tube defects, is 1 to 2 in 1000 births, with a peak of 7 in 1000 in South Wales (Table 10-1).¹ The multifactorial etiology of these anomalies is well established (Tables 10-2 and 10-3).

Anencephaly

Anencephaly is characterized by the absence of the cranial vault and telencephalon. Necrotic remnants of the brain stem and rhombencephalic structures are covered by a vascular membrane. Associated malformations are common and include spina bifida, cleft lip/palate, clubfoot, and omphalocele. Polyhydramnios is frequently found. The diagnosis is easy in the second and third trimester, and relies on the demonstration of the absence of the cranial vault

Table 10-2 Recognized Causes of Neural Tube Defects

Multifactorial inheritance
Anencephaly, meningomyelocele, meningocele, and encephalocele
Single mutant genes
Meckel syndrome, autosomal recessive (phenotype includes occipital encephalocele and rarely anencephaly)
Median-cleft face syndrome, possibly autosomal dominant (phenotype includes anterior encephalocele)
Robert syndrome, autosomal-recessive inheritance (phenotype includes anterior encephalocele)
Syndrome of anterior sacral meningomyelocele and anal stenosis—ominant, either autosomal or X-linked
Jarco-Levin syndrome, autosomal-recessive inheritance (phenotype includes meningomyelocele)
HARDE syndrome autosomal-recessive inheritance (phenotype includes encephalocele)
Chromosome abnormalities
13 trisomy
18 trisomy
Triploidy
Other abnormalities, such as unbalanced translocation and ring chromosome
Probably hereditary, but mode of transmission not established
Syndrome of occipital encephalocele, myopia, and retinal dysplasia
Anterior encephalocele among Bantus and Thais
Teratogens
Valproic acid (phenotype includes spina bifida)
Aminopterin/amethopterin (phenotype includes anencephaly and encephalocele)
Thalidomide (phenotype includes, rarely, anencephaly and meningomyelocele)
Maternal predisposing factors
Diabetes mellitus (anencephaly more frequent than spina bifida)
Specific phenotypes, but without known cause
Syndrome of craniofacial and limb defects secondary to aberrant tissue bands (phenotype includes multiple encephaloceles)
Cloacal exstrophy (phenotype includes myelocystocele)
Sacroccygeal teratoma (phenotype includes meningomyelocele)

Modified from Main DM, Mennuti MT: Neural tube defects: Issues in prenatal diagnosis and counseling. *Obstet Gynecol* 67; 1, 1986.

(Fig. 10-12). Anencephaly is considered to be the final stage of acrania, as a consequence of disruption of abnormal brain tissue unprotected by the calvarium.¹⁹ Although the term acrania is often used in conjunction with anencephaly, the term implies absence of the entire skull, including the skull base, which is not true in anencephaly.^{20,21} The skull base is present in anencephaly and the calvarium is absent (acalvaria). Although the fetal head can be positively

Table 10-3 Estimated Incidence of Neural Tube Defects (NTD) Based on Specific Risk Factors in the United States

Population	Incidence per 1000 Live Births
Mother as reference	
General incidence	1.4-1.6
Women undergoing amniocentesis for Advanced maternal age	1.5-3.0
Women with diabetes mellitus	20
Women on valproic acid in first trimester	10-20
Fetus as reference	
One sibling with NTD	15-30
Two siblings with NTD*	57
Parent with NTD	11
Half sibling with NTD	8
First cousin (mother's sister's child)	10
Other first cousins	3
Sibling with severe scoliosis secondary to multiple vertebral defects	15-30
Sibling with occult spina dysraphism	15-30
Sibling with sacroccygeal teratoma or hamartoma	~15-30

*Risk is higher in British studies. Risk increases further for three or more siblings or combinations of other close relatives.
Modified from Main DM, Mennuti MT: Neural tube defects: Issues in prenatal diagnosis and counseling. *Obstet Gynecol* 67:1, 1986.

identified by vaginal sonography as early as the 7th week of gestation, the diagnosis may be difficult in the first trimester. Absent calvarial mineralization before 10 to 12 weeks' gestation makes the differentiation of normal and abnormal brain difficult. Therefore, a cephalic pole, albeit overtly abnormal, is usually present in early gestation, and may be difficult to identify and differentiate from the normal brain before 11 weeks' gestation (see Fig. 10-12).²²

Spina Bifida

The term *spina bifida* refers to incomplete closure of the bony elements of the spine (lamina and spinous processes) posteriorly.²³⁻²⁵ Spina bifida is commonly subdivided into open and closed forms.²⁶ Open spina bifida is predominant at birth and is a full-thickness defect of the skin, underlying soft tissues and vertebral arches exposing the neural canal. The defect may be covered by a thin meningeal membrane, an extension of dura and arachnoid *without neural tissue* through the posterior spina bifida (meningocele). In the presence of neural tissue inside the sac, the lesion is defined as a myelomeningocele, a term often used to indicate all cases of spina bifida aperta. The defect may vary considerably in size. The lumbar, thoracolumbar, or sacrolumbar areas are most frequently affected. Leakage of cerebrospinal fluid through the defect causes an increased concentration of alpha-fetoprotein (AFP) in the amniotic fluid and maternal serum.¹⁰ Closed spina bifida is characterized by a vertebral schisis covered by skin. The skin is usually pigmented,

FIGURE 10-12. Anencephaly in the third (A) and second trimester (B,C). (A. Courtesy of Renato Ximenes, Sao Paulo, Brazil.)

dimpled, or composed of areas with hypertrichosis. A subcutaneous mass, a meningocele or lipoma, may be present. Maternal serum and amniotic fluid AFP are usually within normal limits.²⁷

Developmentally, there is a localized failure of closure of the neural folds (neural tube) in patients with myelomeningoceles. As a result, the neural tube remains open and the neural folds remain in continuity with the cutaneous ectoderm at the skin surface.²³ The spinal cord, which is open at the skin surface, is referred to as the *neural placode*.²³ Failure of separation of the neural placode and cutaneous ectoderm prevents the tissue destined to form the pedicles and lamina to migrate properly relative to the neural ectoderm.²³ As a result, the pedicles and lamina are everted, facing posterolaterally instead of posteromedially, and the spinal canal undergoes fusiform enlargement in the area of the spina bifida (Fig. 10-13).²³

Open spina bifida can be identified sonographically by demonstrating the defect of the neural tube that is constantly associated with separation of the posterior processes of the vertebrae, absence of posterior soft tissues, and (frequently) with the cyst formed by the myelomeningocele (see Fig. 10-13). Prenatal recognition has been reported as early as the first trimester.²⁸ However, in everyday practice, the diagnosis remains difficult even at midgestation and always requires meticulous scanning. The experience of the operator, the quality of the equipment and the amount of time dedicated to the scan continue to represent critical factors. The accuracy of referral centers is close to 100%.¹⁰ The sensitivity of routine nontargeted examinations at midgestation is extremely variable in different studies, and it is probably about 40% when ultrasound is the only method and about 80% when ultrasound is used in conjunction with maternal serum AFP screening.²⁹⁻³² Examination of the fetal head can assist the sonologist, because open spina bifida is consistently associated with easily recognizable cranial abnormalities.^{33,34} Leakage of cerebrospinal fluid leads to displacement of the cerebellar vermis, fourth ventricle, and medulla oblongata through the foramen magnum inside the upper cervical canal (Chiari type II or Arnold-Chiari malformation). Sonographically, this results in small head measurement at midgestation, obliteration of the cisterna magna, small size and abnormal shape of the cerebellum that is impacted deep into the posterior fossa (banana sign),

and frontal concavity (lemon sign) (Fig. 10-14). The observation of a normal appearance of the cerebellum and a normal cisterna magna virtually excludes a myelomeningocele. Hydrocephalus of variable degree is present in virtually all cases of spina bifida aperta at birth but in less than 70% of cases in the midtrimester.^{33,34} It should be noted that other intracranial abnormalities are often seen in association with a myelomeningocele and Chiari II malformation (Table 10-4).²³ In particular, abnormalities of the corpus callosum are seen in 70% to 90% of affected patients.²³ These abnormalities consist of hypoplasia or absence of the splenium and rostrum of the corpus callosum.²³

Closed spina bifida is associated with normal intracranial anatomy and normal AFP, and therefore, is often difficult to diagnose, with the possible exception of cases associated with large subcutaneous lesions, such as meningoceles or, more frequently, lipomas (Fig. 10-15).²⁷

Although anencephaly is invariably fatal, the outcome for infants with open spina bifida is dictated by the site and extension of the lesion. The mortality rate remains high in the long term and many of the survivors suffer from significant disabilities such as lower limb paralysis or dysfunction and incontinence.³⁵ Sagittal views are most useful in assessing the severity and location of the lesion. The top or the most cephalic extent of the bone malformation in spina bifida is often referred to as "the level of the lesion." This level can be determined by counting up from the last ossified vertebral segment (assumed to be S-4 in the second trimester and S-5 in the third trimester). If it is technically difficult to assess the lower spine, one can assume that the last rib indicates T-12 and the top of the iliac wing indicates L-5 to S-1 (see Fig. 10-13B).³⁶ Recently, attempts have been made at intrauterine repair of spina bifida and it has been suggested that these operations may reduce the morbidity of the affected infants. Although preliminary evidence suggests an improvement in the posterior fossa abnormality, the final analysis of improvement in outcome will have to await large multicenter studies. It has been suggested that elective caesarean section may be beneficial to the infants in reducing the rate of neurologic complications and particularly the level of motor paralysis.³⁷ However, these results remain a matter of debate.³⁷⁻³⁹

The outcome of closed spina bifida is difficult to predict in utero. These infants usually do not develop Arnold-Chiari

FIGURE 10-13. Myelomeningocele in a midtrimester fetus. *A.* The posterior elements of the spine (*arrows*) are splayed outward. The myelomeningocele is flat in this plane of section. *B.* Although the defect in the spine cannot be recognized in this view, the fluid-filled myelomeningocele is well seen. The last ossified spinal segment in this second trimester fetus is S4, and thus, counting upward, the top of the lesion is at the L2-L3 level (*arrow*). *C.* Coronal plane of section demonstrating fusiform enlargement of the spinal canal (*arrows*) in the area of the spina bifida.

malformation and hydrocephalus. However, particularly those with subcutaneous masses may suffer from neurologic sequelae of variable entity.⁴⁰

Cephalocele

The term *cephalocele* indicates a protrusion of intracranial contents through a bony defect of the skull. In most cases, the lesion arises from the midline. They are the most

FIGURE 10-14. The cranial signs associated with open spina bifida. *A.* The lemon sign from the frontal concavity (*arrows*). *B.* The banana sign of the compressed cerebellar hemispheres (*arrows*).

common in the occipital area in the white populations in Europe and North America, accounting for approximately 80% of cephaloceles in that group.⁴¹ In southeast Asia, the most common location for cephaloceles is the fronto-ethmoidal region.⁴¹⁻⁴³ Parietal cephaloceles are the least common and often associated with significant underlying brain abnormalities.^{41,43} Encephaloceles are characterized by the presence of brain tissue inside the lesion. When only meninges protrude, the term cranial meningocele should be

used. Cephaloceles often cause impaired cerebrospinal fluid circulation and hydrocephalus. Massive encephaloceles may be associated with microcephaly. Cephaloceles are frequently associated with other anomalies or are part of a syndrome (Table 10-5).

Fetal cephaloceles should be suspected when a paracranial mass is seen on sonography (Fig. 10-16). The diagnosis of encephalocoeles is easy, because the presence of brain tissue inside the sac is striking on ultrasound.^{44,45} Differentiation of a cranial meningocele from soft tissue edema or a cystic hygroma of the neck may be difficult. Demonstration of the bony defect in the skull would allow a proper diagnosis but cranial meningoceles are often associated with extremely small (few millimeters) defects that are not amenable to antenatal sonographic recognition. Indirect clues can assist the diagnosis. Cranial cephaloceles are very often associated with ventriculomegaly. The major differential diagnostic consideration is that of cystic hygromas. Cystic

hygromas arise from the region of the neck, have multiple internal septations and a thick wall, and are often associated with generalized soft tissue edema and hydrops.

The pediatric literature suggests that the outcome of cephaloceles is mainly related to the presence or absence of brain tissue inside the lesion. However, the largest available antenatal series reports a dismal prognosis for both varieties.^{44,45}

Table 10-4

Frequency of Brain and Spine Anomalies in Patients With Chiari II Malformations

Anomaly	Frequency
Myelomeningocele	Always
Hydrocephalus	Almost always
Dysplastic tentorium	Almost always
Small posterior fossa	Almost always
Luckenschädel	Almost always
Caudal Displacement of brainstem	Usually
Cervicomedullary kink	Usually
Upward Cerebellar Herniation	Usually
Large massa intermedia	Usually
Elongated cranial nerves	Usually
Tectal beak	Usually
Callosal hypogenesis	Usually
Syringohydromyelia	~50%
Malformations of cortical development	Occasionally
Aqueductal stenosis	Occasionally

MIDLINE ANOMALIES

Midline cerebral anomalies include a group of brain defects that encompass a wide spectrum of severity and are typically associated with craniofacial malformations.

The *holoprosencephalies* are complex abnormalities of the forebrain that share in common an incomplete separation of the cerebral hemispheres and formation of diencephalic structures.⁴⁶ The most widely accepted classification of these disorders (Fig. 10-17) recognizes four major varieties: the alobar, semilobar, and lobar types, plus the more recently described middle interhemispheric variant. In the *alobar* variety, the most pronounced one, the interhemispheric fissure, falx cerebri, and corpus callosum are totally absent; there is a single primitive ventricle (holoventricle); the thalami are fused in the midline; and there is absence of the third ventricle, neurohypophysis, and olfactory bulbs and tracts. In *semilobar* holoprosencephaly, the two cerebral hemispheres are partially separated posteriorly but there is still a single

ventricular cavity. In both the alobar and semilobar forms, the roof of the ventricular cavity, the *tela choroidea*, normally enfolded within the brain, may balloon out between the cerebral convexity and the skull to form a cyst of variable size, called the *dorsal sac*. Alobar and semilobar holoprosencephaly are often associated with microcephaly, less frequently with macrocephaly, which is invariably due to a dorsal cyst and or internal obstructive hydrocephalus. In the lobar variety, the interhemispheric fissure is well developed posteriorly and anteriorly, but there is still a variable degree of fusion of the cingulate gyrus and of the lateral ventricles, and absence of the septum pellucidum. In the middle interhemispheric variant of holoprosencephaly, fusion occurs mostly at the level of the bodies of lateral ventricles, whereas

FIGURE 10-18. Multiplanar sonography of alobar holoprosencephaly in the midtrimester. *A.* Median plane demonstrating the single ventricular cavity, which has a rim of cortex anteriorly and amply communicates posteriorly with a dorsal sac. *B.* Axial scan at the level of the thalami, demonstrating the crescent shaped single ventricle and the absence of the midline in the anterior cortex. *C.* In a slightly craniad axial plane than the previous one, the communication between the ventricular cavity and the dorsal sac is demonstrated.

FIGURE 10-19. Different varieties of alobar holoprosencephaly (*A*) pancake type: only a thin rim of cortex is present, and the ventricular cavity continues anteriorly and posteriorly with a large dorsal sac; (*B*) cup variety: the cortex is partially enfolded over the ventricular cavity with a better delineation of the transition between the ventricle and the dorsal sac; (*C*) ball variety: the cortex is completely enfolded over the ventricular cavity, and there is no dorsal sac. All varieties share in common a very similar bulb-like appearance of the thalami (arrows).

the frontal horns and posterior horns are relatively well developed.⁴⁷ In patients with semilobar holoprosencephaly the splenium of the corpus callosum is present without the genu or body of the corpus callosum.^{41,48,49} As Barkovich states:

Holoprosencephaly is the only brain anomaly described in which the posterior corpus callosum forms in the absence of anterior callosal formation.^{41 (p 367)}

Alobar and semilobar holoprosencephaly are typically and almost constantly associated with facial anomalies that can be regarded as the consequence of hypoplasia of the midfacial structures. The malformations span between cyclopia and severe hypotelorism with median cleft lip/palate. The nose may be absent, replaced by a proboscis, or extremely flattened.⁴⁶ Conversely, facial anomalies are rarely encountered in the lobar form and middle interhemispheric variant.

Holoprosencephaly at birth is exceedingly rare. This anomaly has a high intrauterine fatality rate and is not infrequently encountered in prenatal studies. The etiology is heterogeneous. In most cases, the anomaly is isolated and

sporadic. In other cases, chromosomal abnormalities have been found (trisomy 13 and polyploidy) and anatomic abnormalities are found.

Prenatal diagnosis of alobar holoprosencephaly depends on the demonstration of a single rudimentary cerebral ventricle, that may protrude posteriorly through the incompletely enfolded cortex to form a dorsal sac (Fig. 10-18). According to the degree of enfoldment of the cortex over the ventricular cavity and the presence or absence of a dorsal sac, three varieties of alobar holoprosencephaly are commonly distinguished: the pancake, the cup, and the ball type (Fig. 10-19). Additional findings include the presence of typical facial anomalies. Similar findings are expected with the semilobar type. The middle interhemispheric variant of alobar holoprosencephaly is featured by relatively well-formed frontal horns that are fused in the midline without the intervening septum pellucidum and communicate posteriorly with a single rudimentary cavity (Fig. 10-20). Recognition of the lobar variety has also been reported, although the differentiation from other cerebral anomalies such as the simple agenesis of the septum pellucidum is always difficult. Although this condition may be suspected in

FIGURE 10-20. Middle interhemispheric variant of holoprosencephaly in the axial (A), anterior coronal (B), and midcoronal plane (C). The frontal horns are well developed and there is a partial formation of the interhemispheric fissure. However the midcoronal plane reveals a common ventricular cavity with hypoplastic undivided thalami.

FIGURE 10-21. Lobar holoprosencephaly. (A, B) Postnatal magnetic resonance image; (C) prenatal ultrasound study. The frontal horns are fused centrally, as well as the fornices (arrow), which form a thick fascicle running in the floor of the cavity.

FIGURE 10-22. A. Color Doppler demonstration of anterior cerebral artery (ACA) branching in a normal fetus and giving rise to the pericallosal artery. B. Lobar holoprosencephaly: the interhemispheric fissure is shallow and the arteries branching from the anterior cerebral artery run on the surface of the brain (serpent crawling). C. In agenesis of the corpus callosum, the arteries ascend vertically without forming a loop. 3v, third ventricle.

axial scans, mainly because of the concomitance of absence of the septum pellucidum and ventriculomegaly, the coronal scan is more informative in that it demonstrates the flat squared roof of the frontal horns as well as the ample inferior communication with the inferior third ventricle. The presence of the fused fornices, which appear as a linear structure running within the third ventricle from the anterior to the posterior commissure, is a frequent and very specific finding with this condition (Fig. 10-21).^{50,51} As in

lobar holoprosencephaly, the interhemispheric fissure is shallow anteriorly owing to the fusion of the frontal lobes and the branches of the anterior cerebral artery run along the surface of the brain giving rise on color Doppler imaging to a typical sign that has been referred to as the serpent crawling under the skull (Fig. 10-22).⁵²

The invariably poor prognosis for infants affected by alobar and semilobar holoprosencephaly is well established. Thus far, cases diagnosed in utero with lobar holopros-

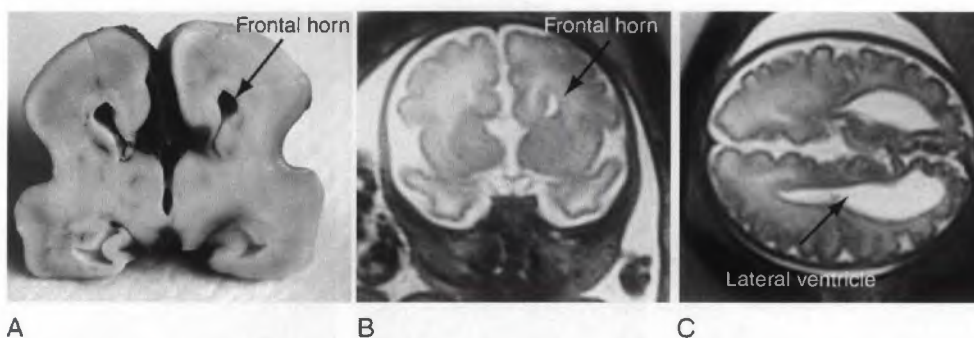

FIGURE 10-23. Complete agenesis of the corpus callosum: (A) pathology in a midtrimester fetus; (B, C) magnetic resonance at 32 weeks. Apart from the absence of the corpus callosum, a number of abnormal findings can be appreciated including the increased separation of the hemispheres, the comma-shaped frontal horns, and the teardrop shape of the lateral ventricles in the axial plane, referred to as colpocephaly.

FIGURE 10-24. Sonography of fetal agenesis of the corpus callosum. A. In the axial plane, the interhemispheric fissure (IHF) appears wider than usual without evidence of the cavum septi pellucidi. B. In the coronal and (C) sagittal plane, no corpus callosum or cavum septi pellucidi can be seen above the third ventricle (3v).

encephaly have also had extremely poor neurologic development.^{50,52}

Agenesis of the Corpus Callosum

Agenesis of the corpus callosum (ACC) is an anomaly of uncertain prevalence and clinical significance. Estimates of 0.3% to 0.7% in the general population and 2% to 3% in the developmentally disabled are usually quoted.^{53,54} The etiology is heterogeneous. Genetic factors are probably predominant. The high frequency of associated malformations and chromosomal aberrations suggest that ACC is often a part of a widespread developmental disturbance.

ACC may be either complete or partial. In the latter case, also referred to as dysgenesis of the corpus callosum, the caudal portion (splenium and body) is missing to varying degrees.

The diagnosis of ACC is possible from midgestation onward⁵⁵ but is a challenge even for expert sonologists.⁵⁶ The anatomic elements useful for the diagnosis are summarized in Figure 10-23. With complete ACC, there is no septum pellucidum, the two hemispheres tend to be more separated than usual in the central part of the brain, and

there are typical modifications in the morphology of the lateral ventricle. In the coronal section, the frontal horns are separated more than usual and have a comma-like shape, whereas in the transverse axial plane, the lateral ventricles have a teardrop-like shape that is due to the combination of the posterior enlargement of the atria and occipital horn with frontal horns that have a normal size but are more separated than usual. This finding is referred to as colpocephaly. The third ventricle may be rostrally displaced. In routine examinations, an increased atrial width with a typical teardrop configuration of the lateral ventricles and failure to visualize the cavum septum pellucidum should alert the physician to the possibility of fetal ACC. Once a suspicion has been formulated, a direct diagnosis is possible by demonstrating the absence of the corpus callosum on coronal and sagittal scans (Fig. 10-24). These views are at times difficult to obtain, in particular in fetuses in vertex presentation. However, vaginal sonography is of great advantage in such cases. Abnormal branching of the anterior cerebral artery can also be demonstrated with the use of color Doppler ultrasound (see Fig. 10-22).

Diagnosis of partial ACC has also been reported, but the sonographic findings are even more elusive than with the

FIGURE 10-25. Partial agenesis of the corpus callosum. *A.* In this fetus at 21 weeks' gestation, the corpus callosum/cavum septi pellucidi complex is much smaller than normal; in fact it does not entirely cover the third ventricle, but only reaches about midway. *B.* The corpus callosum appears thin and barely discernible with gray scale imaging and can be positively identified only when highlighted by the course of the pericallosal artery.

complete form (Fig. 10-25).^{55,57} The cavum septi pellucidi is usually present, and the axial sections may be completely unremarkable. Identification of partial ACC requires a median section demonstrating that the posterior portion of the corpus callosum is absent. This results in the corpus callosum forming an incomplete arch over the area of the third ventricle. The incomplete corpus callosum tends also to be thinner and on top forms an angle that is more open posteriorly than usual.

Midline interhemispheric cysts may be seen in association with ACC. Barkovich et al⁴¹ divide ACC with interhemispheric cysts into two major groups: Type 1, in which the interhemispheric cyst is a diverticulum of the ventricular system and thus communicates with the ventricles and type 2, in which multiple cysts are present that do not communicate with the ventricles. Type 2 ACC with interhemispheric cyst is often associated with subcortical heterotopia. Of note, as with all types of cysts, the cysts associated with callosal agenesis may not develop or become apparent on imaging until late in gestation.^{41,58,59} These cysts can be associated with macrocephaly or frank hydrocephalus at birth.^{41,58,59}

ACC, be it complete or partial, is frequently a part of syndromes or multiple malformations (Table 10-6). The most common mentioned is Aicardi syndrome, an X-linked dominant disorder consisting of infantile spasms, callosal agenesis or hypogenesis, chorioretinopathy, severe global developmental delay, and medically refractory epilepsy.^{41,60,61} Imaging may demonstrate: callosal agenesis or hypogenesis, heterotopias, cortical dysplasia, posterior fossa cysts, cerebellar hypoplasia, choroid plexus papillomas, and microphthalmia. When ACC is an isolated finding it is associated with a normal to borderline intellectual development in most cases.^{55,62} However, long-term studies indicate a progressive decrease in intellectual capacity throughout the years, and most infants tend to have significant difficulties in school.⁶³ ACC has also been linked to psychosis.⁶⁴

Absence of the septum pellucidum is the rule with holoprosencephaly and ACC. It may also occur with other intracranial anomalies, such as deMorsier syndrome, or septo-optic dysplasia, cortical abnormalities, and schizencephaly, and it may also be present as an isolated finding (Fig. 10-26).^{47,65-67}

The differential diagnosis is frequently difficult. However, pediatric data suggest that the prognosis is usually severe, with more than 90% of cases demonstrating mental retardation or severe neurologic abnormalities when associated with other anomalies and 66% demonstrating motor defects or mental delay when isolated.⁶⁷

Dandy-Walker Malformation

The term *Dandy-Walker syndrome or malformation* was originally described in 1914 by Dandy and Blackfan in which a rare malformation of the posterior fossa consisting of marked cystic dilatation of the fourth ventricle with anterior and superior displacement of a vermis with complete or partial agenesis was seen.⁶⁸ Three additional cases and a review of the literature were reported by Taggart and Walker in 1942.⁶⁹ In an additional report and review of the malformation in 1954, Benda labeled this abnormality as the Dandy-Walker malformation.⁷⁰ Since the original description, a number of other abnormalities of the posterior fossa with similarities to the Dandy-Walker malformation have been described including the Dandy-Walker variant (partial agenesis of the vermis without a large dilated cystic fourth ventricle), megacisterna magna and Blake's pouch cyst. Some investigators have suggested that all of these entities be grouped and referred to as the Dandy-Walker complex.⁴⁹ The difficulty in using one term to describe these entities is that the prognosis for each can be different. Strictly described, the Dandy-Walker malformation should be used to describe (1) marked cystic dilatation of the fourth ventricle, which may fill much of the posterior fossa; (2) hypogenesis or agenesis of the cerebellar vermis; and (3) superior displacement of the tentorium and lateral sinuses. The cisterna magna is compressed and reduced to a virtual space between the dilated fourth ventricle and the dura mater.⁷¹ The cerebellar hemispheres are often anterolaterally displaced. Hydrocephalus, although frequently seen in cases of Dandy-Walker malformation, is not necessary for the diagnosis.

Sonographically, the median plane is the most important one for the diagnosis. The cystic fourth ventricle extends superiorly, displacing the cerebellar vermis (which is frequently

hypoplastic) and elevates the *tentorium cerebelli* and the *torcular Herophili* above its normal position (Fig. 10-27). Dandy-Walker malformation is frequently associated with other neural defects, mostly with other midline anomalies, such as ACC and holoprosencephaly. Other deformities include encephaloceles, polycystic kidneys, cardiovascular defects, and facial

clefing. Table 10-7 lists the most frequent associations. Even if isolated, it has been generally considered to have a poor prognosis. However, recent experience with MRI in infants suggests that those cases in which the vermis appears hypoplastic have a subnormal intelligence in 85% of cases versus only 15% of those in which the vermis appears to be intact.^{72,73} In a study by Boddaert et al, the cerebellar vermis was considered normal with MRI if it was possible to document three main anatomic landmarks in the median plane: the fastigium point that corresponds to the posterior apex of the fourth ventricle and the two main fissures.⁷² A similar approach has also been suggested for antenatal studies. Both MRI and multiplanar, possibly, transvaginal ultrasound can be used. However, it is expected that the small size of the vermis and the difficulty in obtaining an exact median plane will, at times, represent major limiting factors, particularly in early gestation.

Dandy-Walker malformation is exceedingly rare, with an estimated incidence of about 1:30,000 births, and is found in 4% to 12% of all cases of infantile hydrocephalus. However, minor variations of this condition are frequently encountered, attested by an increasing number of reports, both in the prenatal and pediatric literature. The term *Dandy-Walker complex* (or *continuum*) is used to indicate the spectrum of abnormal findings that share in common an enlargement of the posterior fossa (fourth ventricle or cisterna magna) and the impression of a V-shaped cleft in the cerebellar vermis in the axial plane (Fig. 10-28).^{72,74,75} When other anomalies are excluded, however, careful evaluation of the posterior fossa anatomy may help determine the specific abnormality and prognosis (Fig. 10-29).

Enlargement of the cisterna magna, referred to as a *megacisterna magna*, was a diagnosis introduced by Gonsette et al^{76,77} to describe a series of adult patients with markedly enlarged posterior fossa cisterns due to cerebellar atrophy. Since the original description, the term has been "loosely applied" to describe an enlarged retrocerebellar space (cisterna magna) and a normal and intact vermis and normal cerebellar hemispheres.⁷⁷ In prenatal sonograms, if the cisterna magna depth is greater than 10 mm and the cerebellar vermis appears intact and in its normal position, the condition is usually referred to as *megacisterna magna*. Although this is a risk factor for associated malformations including aneuploidies (trisomy 18 in particular),^{78,79} most isolated cases are of no consequence.^{8,40,74,80} If there is the impression of a V-shaped cleft in the cerebellum in the axial plane and the median plane reveals a vermis that is intact with a cyst in the posterior fossa the diagnosis is most likely a *Blake's pouch cyst*, and the prognosis is usually good.^{40,81} A *Blake's pouch cyst* represents herniation of the inferior aspect of the fourth ventricle through the foramen of Magendie into the valleculla and retovermian cistern.⁴⁰

In 1976 Harwood-Nash introduced the term *Dandy-Walker variant* to describe "an outpouching of an ependymal lined cyst from the fourth ventricle" associated with dysplasia of the vermis.^{77,82} A hypoplastic superiorly rotated vermis is the landmark of *vermian hypoplasia* previously referred to as Dandy-Walker variant, a condition that is frequently associated with other intracranial anomalies and carries a very high risk of abnormal neurodevelopment.⁷²⁻⁷⁴ Distinction between an intact and an hypoplastic vermis is far from simple. From approximately midgestation, under normal

FIGURE 10-26. Absence of the septum pellucidum (arrow) in axial and coronal (A, B) sonograms and (C) intrauterine magnetic resonance imaging.

FIGURE 10-27. Dandy-Walker malformation. In the axial plane (A) a large fourth ventricle with a V-shaped defect in the cerebellum is seen (arrow); (B) in the sagittal plane, the cisterna magna appears large (in fact, the cystic fourth ventricle) (arrow) and the cerebellar vermis is displaced superiorly and rotated. Comparing this image with the normal appearance of this section (C), it can also be observed that the cerebellar vermis is small and shapeless, and that the fourth ventricle expands superiorly, from which a superior dislocation of the tentorium and torcular herophilii can be inferred (arrows). 3v, third ventricle.

conditions, it is usually possible with either sonography or MRI to demonstrate the fastigium of the fourth ventricle and the two main fissures in the median plane.⁷²⁻⁷⁴ With hypoplasia of the vermis, these landmarks cannot be identified. Nomograms of the normal size of the vermis throughout gestation are also available (Table 10-8).⁸³

In our own experience, isolated megacisterna magna and Blake's pouch cyst represent the bulk of the posterior fossa anomalies that are diagnosed antenatally.⁸ Although the data thus far are limited and the neurologic risk cannot be predicted precisely, it would seem that in the majority of these cases, the prognosis is good. It should be noted that there are some authors who believe that both conditions (megacisterna magna and Dandy-Walker variant) may represent a Blake's pouch cyst.⁷⁷

The greatest diagnostic challenge is probably represented by *Joubert syndrome*, an anomaly with autosomal-recessive transmission that is featured by absence or hypoplasia of the vermis, which is not rotated. In a pregnancy at specific risk, the condition can be suspected when a communication is seen between the fourth ventricle and a cisterna magna of normal size in the transverse plane (Fig. 10-30).⁸⁴ In the absence of the vermis, the two hemispheres impinge on the midline, and therefore, the median plane is of little use. However, at times, it may demonstrate a fourth ventricle of slightly irregular shape.⁸⁴ In the absence of a positive familial history, however, this finding has a very low predictive value and most cases we have seen were found to be normal at birth.

Caution is warranted while making the diagnosis of a minor variety of the Dandy-Walker continuum, the Dandy-Walker variant, or inferior vermian agenesis. Development of the cerebellar vermis is incomplete before 20 weeks' gestation, and thus a defect and abnormality of the vermis may be suspected if imaged too early.⁸⁵ Even in cases diagnosed after 20 weeks, there is evidence that isolated inferior vermian hypoplasia is overdiagnosed prenatally, even with the use of MRI. Thus, postnatal confirmation is warranted.⁸⁶ In a study correlating the Dandy-Walker malformation complex and postmortem pathology, Phillips et al⁸⁷ found that two sonographic variables in the transverse axial plane correlated well with the pathologic diagnosis: the severity of the vermian defect and the shape of the gap between the hemispheres in transverse cerebellar images. A trapezoidal gap, with a broad dorsal base and relatively straight sides, corresponded to hypoplasia of aplasia of the vermis at autopsy (see Fig. 10-27A). However, a keyhole-shaped gap with convex sides was not associated with macroscopic or microscopic cerebellar pathology⁸⁷ (Fig. 10-28C).

In general, meticulous scanning with a multiplanar approach is recommended in cases with a suspicion of a posterior fossa anomaly. The poor correlation that has been demonstrated in several studies between antenatal diagnosis and autopsy findings is probably related to the use of only axial planes, which can be extremely misleading. In the axial plane, entities that are clinically different, such as Dandy-Walker malformation, vermian hypoplasia, and Blake's pouch cyst may be difficult to distinguish from one

another. Because the diagnosis of midline anomalies depends on section planes of the fetal head that are sometimes difficult to obtain, we have found that three-dimensional ultrasound is frequently of considerable help. Multiplanar slicing of a volume obtained from axial scans usually provide images of diagnostic quality.⁸

DESTRUCTIVE CEREBRAL LESIONS

Many congenital anomalies of the brain are not the consequence of an embryogenetic malformative process but are due to a destructive process. The pathophysiology is frequently unclear and the condition remains idiopathic. However, a link with obstetric complications of different nature is frequently found.

Intracranial hemorrhage (ICH) is usually found at the level of the lateral ventricles, although it can occur in other anatomic locations. It is a frequent complication in premature infants, although rarely, it may occur antenatally, as a consequence of coagulopathy or trauma, or other yet unexplained factors. The sonographic appearance of an ICH is extremely variable depending on the severity and the time since it occurred (Fig. 10-31).⁸⁸ When imaging the fetal head in an axial plane of section, the imaging plane needs to be symmetric without any angulation. The normal choroid plexus on one side may simulate a germinal matrix hemorrhage when the imaging plane is asymmetric. Blood that accumulates into the ventricles appears initially as a hyperechogenic collection. With time, the blood clot retracts and demonstrates an anechoic core, and is frequently associated with ventricular dilatation (grade 3 hemorrhage). Large hemorrhagic collections may be complicated by infarcts and destruction of the surrounding white matter. (grade 4 hemorrhage). The prognosis in these cases is severe. In a review of the literature, perinatal death occurred in about 50% of cases and 50% of survivors had neurologic compromise at long-term follow-up. There was a correlation between the outcome and the grade of the hemorrhage. The prognosis was more favorable with grade 1 and 2 hemorrhages (hemorrhage limited to the germinal matrix or lateral ventricles without ventriculomegaly), that at times may even resolve in utero, and was usually severe with grade 3 and 4 lesions (intraventricular hemorrhage associated with severe ventriculomegaly and white matter destruction respectively).⁸⁸

Congenital *porencephaly* is defined as the presence of cystic cavities within the brain matter (Fig. 10-32). The cavities

usually communicate with the ventricular system, the subarachnoid space, or both.⁸⁹ Loss of cerebral tissue may derive from a morphogenetic disorder (true porencephaly or *schizencephaly*). More frequently, it is the consequence of an intrauterine disruption (pseudoporencephaly or encephaloclastic porencephaly). The developmental form is typically bilateral and symmetric, and is frequently associated with microcephaly. In *pseudoporencephaly* a unilateral lesion is usually found. In both cases, there is a wide variability in the size of the lesion.⁸⁹ Cerebrospinal fluid turnover is often impaired and hydrocephalus is present. *Hydranencephaly* can be regarded as an extreme form of pseudoporencephaly. Most of the cerebral hemispheres are replaced by fluid. The brain stem and rhomboencephalic structures are usually spared. The head may be small, of normal size, or extremely enlarged. The etiology is heterogeneous. Congenital infections including toxoplasmosis and cytomegalovirus (CMV), and intrauterine narrowing or occlusion of the internal carotid arteries have been reported. Accurate antenatal diagnosis of both schizencephaly and porencephaly has been reported. However, it should be stressed that porencephaly is a disruption that usually occurs only in the third trimester.

The outcome of infants with a congenital destructive process of the brain is dictated by the size and location of the lesion. Extensive porencephaly, particularly if associated with hydrocephalus or microcephaly, and hydranencephaly have a uniformly poor outcome.⁸⁹

Periventricular leukomalacia is a degenerative disorder of the white matter that is most frequently encountered in premature infants and is frequently associated with a poor prognosis. The cystic variety of this condition has been described recently in the fetus. The diagnosis is made by demonstrating multiple small cysts close to the upper corner of the lateral ventricles (see Fig. 10-32C).⁹⁰

Intrauterine infection in general is one of the major causes of congenital brain lesions, and CMV in particular is one of the leading causes of brain damage in children. Fetuses with CMV infection affecting the brain may present with a wide range of intracranial abnormalities. The most frequent findings in our experience include echogenic bowel and abnormal intracranial anatomy. The cerebral findings are pleomorphic and include periventricular and intraparenchymal echogenicity, ventriculomegaly, cerebellar hypoplasia, microcephaly and cortical abnormalities.⁹¹

Although the experience thus far is scanty, it would seem that ultrasound plays a limited role in the prenatal diagnosis

of CMV infection. In our experience, while examining a pregnant patient with recent infection, the positive predictive value of abnormal sonographic findings in the prediction of symptomatic neonatal infection is in the range of 80%, but the sensitivity is only 20%.

DISORDERS OF NERVE CELL PROLIFERATION

The association between decreased head size and reduction of both brain mass and total cell number in *microcephalic infants* is well established. However, the threshold of abnormality is uncertain. Some authors suggest employing a head circumference below 2 standard deviations (SDs) from the mean as diagnostic criterion. Others prefer to consider head circumference below 3 SDs as abnormal (Table 10-9). The

incidence of microcephaly obviously varies in different surveys, depending on the definition used to identify the lesion.

Microcephaly should not be considered as a single clinical entity but rather as a symptom of many etiologic disturbances, including both environmental and genetic factors (Table 10–10). Microcephaly is featured by a typical disproportion in size between the skull and the face. The forehead is sloping. The brain is small, with the cerebral hemispheres affected to a greater extent than the diencephalic and rhomboencephalic structures. Abnormal convoluted patterns, including macrogyria, microgyria, and agyria, are frequently found. The ventricles may be enlarged. Microcephaly is frequently found in cases of porencephaly, lissencephaly, and holoprosencephaly.

Many difficulties arise in attempting to identify fetal microcephaly. The utility of head measurements alone may be hampered by incorrect dating or intrauterine growth restriction. Furthermore, the natural history of fetal microcephaly is largely unknown. A progressive development of the lesion interfering with early recognition has been described. A comparison of biometric parameters such as the head circumference–abdominal circumference ratio and the femur length–biparietal diameter ratio has been suggested. Nevertheless, both false-positive and false-negative diagnoses occur frequently.⁹² It is clear that the predictive value of ultrasound biometry has significant limitations. A qualitative evaluation of the intracranial structures is a very useful adjunct to biometry because many cases of microcephaly are associated with morphologic derangement, particularly with ventriculomegaly, schizencephaly, and disorders of ventral induction. Demonstration of a sloping forehead also increases the index of suspicion (Fig. 10–33).⁹³

The final outcome of microcephaly is uncertain. Infants with a small head have a significantly increased risk of neurologic compromise, and there is a correlation with the size of the head. When the head circumference is extremely small (e.g., 4 SDs or more below the mean) and there are associated abnormalities, the prognosis tends to be severe.

Megalencephaly, that is, an abnormally large brain, is usually found in individuals of normal and even superior intelligence, but it may be associated with mental retardation and neurologic impairment.⁹⁴ Megalencephaly is also a part of congenital anomalies and syndromes such as Beckwith-Wiedemann syndrome, achondroplasia, neurofibromatosis, and tuberous sclerosis (Table 10–11). Obstetric and pediatric sonographers are frequently challenged by the problem of megalencephaly, a condition that should be suspected in the presence of abnormally large head measurements without evidence of hydrocephalus or intracranial masses. In such cases, examination of the parents may be of help, because asymptomatic megalencephaly is frequently familial.

Intracranial Tumors

Fetal *intracranial tumors* are rare. The incidence has been estimated at 0.34 per million live births. There are several classifications of congenital brain tumors (Table 10–12). In a review of 48 cases diagnosed antenatally,⁹⁵ teratomas accounted for 62% of cases. Neuroepithelial tumors were present in 15%, lipomas in 10%, and craniopharyngiomas in 6%. The origin of tumors diagnosed in utero is frequently difficult to ascertain, given the large dimensions of the mass.

Neurofibromatosis (autosomal dominant)
Fragile X syndrome (X-linked recessive)

However, most of the lesions are supratentorial, in contrast to the more frequent infratentorial location of brain tumors occurring in older children.

Fetal intracranial tumors are frequently associated with macrocephaly, ventricular enlargement, intracranial calcifications, and hemorrhage. Ventriculomegaly is most frequently the cause of obstruction to cerebrospinal fluid circulation. However, overproduction of fluid may occur with teratomas and choroid plexus papillomas. Polyhydramnios is present in 40% of cases. In most cases, the mechanism is probably related to failure of swallowing, whether this is neurologically induced or is the consequence of mechanical obstruction to the pharynx. Hydrops has also been reported, most frequently as a consequence of arteriovenous shunting within the large tumoral mass, causing high-output cardiac failure. Facial dysmorphism is frequent with large tumors. There is well-established association between interhemispheric lipomas and ACC. There is no established association between fetal and neonatal tumors and chromosomal aberrations.

A brain tumor is suspected when mass-occupying lesions, cystic areas, or solid areas are seen within the fetal head (Fig. 10-34). Ultrasound does not allow a specific diagnosis of the histologic variety. Fetal teratomas, astrocytomas and

FIGURE 10-34. Fetal intracranial tumors: *A* and *B*. Intracranial teratoma (arrows). *C* and *D*. Multiple lipomas (arrows) in a fetus with associated agenesis of the corpus callosum.

craniopharyngiomas have a similar appearance, that is, a complex mass distorting the brain architecture, possibly associated with macrocephaly, ventriculomegaly and intracranial calcifications. Intracranial lipomas are well-defined hyperechogenic areas, usually located in the midline, in the position normally occupied by the corpus callosum, and within the bodies of lateral ventricles. Eventually, choroid plexus papillomas appear as large choroid plexuses, most frequently in association with ventriculomegaly and subarachnoid space enlargement.⁹⁵

The natural history of fetal brain tumors is uncertain. However, the available data suggest that even very severe lesions may develop rapidly in late gestation. In fact, several cases have been reported in which midtrimester sonograms were unremarkable. Teratomas may be associated with increased maternal serum and amniotic fluid AFP.

The differential diagnosis of brain tumors include other space-occupying intracranial lesions. At times, it may be particularly challenging to distinguish between a tumor and a fresh intraparenchymal hemorrhage. Cerebral hemorrhage usually lacks the mass effect that is found with tumors. In these cases, serial sonograms (in 2 to 3 weeks) most severe ICHs are expected to result in cavitation, ventriculomegaly, and blood clot formation) or antenatal MRI will usually solve the problem.

The prognosis of congenital tumors is poor. In a review of 48 cases, the overall mortality rate was 77%.⁹⁵ No clear data are available with regard to the degree of neurologic impairment in survivors, but this is expected to be high as well. The histologic type of the tumor is certainly a major factor. In a postnatal series, the 1-year survival rate of teratomas was only 7%, compared with rates of 44% in patients with astrocytomas and 50% in patients with choroid plexus papillomas. There are many limitations to the antenatal diagnosis of the specific types of tumor. However, large complex masses distorting intracranial anatomy (usually teratomas, astrocytomas, or craniopharyngiomas) were found to have an overall survival rate of only 14%. On the other hand, intracranial lipomas, with a specific ultrasound appearance, were associated with a survival rate of 100% and no developmental handicap.⁹⁵

ANOMALIES OF NEURONAL MIGRATION

The neuronal cells that form the gray matter originate internally to the brain, on the surface of the lateral ventricles, and only later migrate along radially aligned glial cells to the surface of the brain. The migration occurs in different waves that last for several weeks. Most of the process takes place between 8 weeks' and 16 weeks' gestation but continues up to 25 weeks. Once the neuronal cells have reached their destination on the surface of the brain, they undergo a process of maturation and differentiation, grow axons and dendrites, and develop synapses with other neurons, giving rise to a well-ordered, six-layer cortex. Migration abnormalities are characterized by the incomplete formation of the cortical layers, with abnormal locations of neurons that have failed to reach their final destination. In general, the cortex is thickened by a large, disorganized layer of neurons. Conversely, the white matter underneath the cortex is thinned by failure of production of axons by the disorganized neuronal cells. Macroscopically, the main finding is an alteration in the convolutional pattern of the brain, which may be associated with modifications in brain mass and size of the ventricles.

Failure of neuron migration includes a broad spectrum of anomalies: absence to severe reduction of convolutions (*lissencephaly*), increased number of small convolutions (*polymicrogyria*), *unilateral megalencephaly*, *schizencephaly*, and *gray matter heterotopias*. The migrational process may be arrested by environmental factors (ischemia, teratogens), but a genetic predisposition is clearly present at least for some anomalies.

Postnatally, the technique of choice for the diagnosis of this condition is MRI, which allows a clear discrimination between white and gray matter. However, sonographic detection of typical macroscopic abnormalities of brain anatomy (clefts in the cortex, gyral anomalies, and so on) has led us to suspect and even diagnose these conditions antenatally, although usually only in late gestation (Fig. 10-35).⁹⁶ In the past, it was assumed that abnormalities of sulcal development such as lissencephaly, could not be diagnosed until 27 to 28 weeks.⁹⁷ A recent study by Toi et al⁹⁸ documented the appearance time of the parieto-occipital fissure, calcarine fissure, cingulate, and some convexity sulci. In their

FIGURE 10-35. Fetal cortical abnormalities demonstrated by sonography and magnetic resonance imaging. *A* and *B*. Abnormal convolution associated with unusual shape of the cortex (*arrows*) and underlying lateral ventricle. *C* and *D*. This fetus at 34 weeks' gestation has a very smooth brain and an unusual echogenicity of the cortex.

FIGURE 10-36. Complex arteriovenous malformation with dilatation of the vein of Galen in a third trimester fetus. *A*. Axial view of the head demonstrating increased echogenicity of the cortex with poor delineation of anatomic details and a fluid-filled midline tortuous lesion (*arrow*) in the posterior third of the brain, at the level of the vein of Galen cistern. *B*. Color Doppler demonstrates blood flow within the fluid-filled lesion and typically dilated venous sinuses. *C*. Spectral Doppler demonstrating high velocity pulsatile venous blood flow in the enlarged vein of Galen.

study, they noted the youngest age at which a specific sulcus was first visible in any fetus and also the age after which the sulcus was visible in all fetuses. Sulci could be seen by transabdominal ultrasound as early as 18.5 weeks. Medial hemispheric sulci and the insula were visible earlier and more confidently than convexity sulci. The earliest gestational ages at which specific sulci could be seen in any fetus were as follows: parieto-occipital fissure, 18.5 weeks; calcarine sulcus, 18.5 weeks; cingulate sulcus, 23.2 weeks; and convexity sulci, 23.2 weeks. In their series, the gestational ages at which these sulci were always visible were: parieto-occipital fissure, greater than 20.5 weeks; calcarine sulcus, greater than 21.9 weeks; cingulate sulcus, greater than 24.3 weeks; and convexity sulci, greater than 27.9 weeks. Failure of sulcation beyond these stated gestational ages may allow one to suspect lissencephaly.

VASCULAR ABNORMALITIES

Vascular anomalies of the fetal brain are rare, and only a handful of cases have been described thus far. The majority of reports concentrate upon the vein of Galen vascular malformations. More recently, thrombosis of the dural sinuses has been described.

The term aneurysm of the vein of Galen indicates a spectrum of arteriovenous malformations, ranging from a

single large aneurysmal dilatation of the vein of Galen to multiple communications between the vein and the carotid and vertebrobasilar systems.⁹⁹ Three types are described: (1) arteriovenous fistula, (2) arteriovenous malformation with ectasia of the vein of Galen, and (3) varix of the vein of Galen. The arteriovenous fistula is frequently manifest in the fetal or neonatal period with high-output heart failure due to cardiac overload. Both the ectasia and the varix tend to present later in life with bleeding episodes and are not associated with cardiac failure. Arteriovenous fistulae associated with a varix are not part of the definition when they are located elsewhere in the brain.

Prenatally, the typical finding is an elongated anechoic area at the level of the cistern of the vein of Galen, with color and pulsed Doppler evidence of turbulent venous and blood arterial flow (Fig. 10-36).¹⁰⁰ The cerebral architecture may be intact, or it may be distorted because of the concomitance of ventriculomegaly, porencephaly, and brain edema, which is inferred by increased echogenicity of the cortex. The dural sinuses and neck vessels are frequently enlarged, and signs of cardiac overload may be present, including cardiomegaly, hepatosplenomegaly, soft tissue edema, polyhydramnios and hydrops. Color Doppler may help in identifying the origin of the vessels feeding the lesion, an observation that may have practical implications for assessing the prognosis. MRI has also been used in these cases.

FIGURE 10-37. Congenital thrombosis of the dural sinuses. *A.* A large fluid collection is seen posteriorly to the brain (*long arrow*), corresponding to the dilated superior sagittal sinus. *B.* Within the greatly enlarged sinus, a thrombus is seen as an echogenic mass. *C.* Color Doppler ultrasound demonstrates stop of blood flow (*arrow*) within the enlarged portion of the superior sagittal sinus.

Although vein of Galen aneurysms may become symptomatic in the elderly, they are more frequently seen in the neonatal period. The common clinical features in the neonate are cardiomegaly with congestive heart failure and increased intracranial pressure with hydrocephaly or cranial bruit. Focal neurologic deficit, seizure, and hemorrhages are less common findings. The available experience with prenatal diagnosis suggests a mortality rate in the range of 50%, and normal development in about 50% of survivors.^{89,100,101}

The outcome was strongly dependent on the antenatal evidence of other intracranial abnormalities (hydrocephalus, brain edema, porencephaly) and hydrops. When any of these abnormalities was found, the prognosis was always poor. In general, cases with a normal postnatal development had isolated vascular lesions, without cerebral or cardiovascular compromise in utero and were treated after birth with angiographic embolization.¹⁰¹

Dural sinus thrombosis is a well-known entity in the neonatal period that has been documented in utero as well. The etiology includes trauma; systemic conditions such as sepsis, meningitis, and dehydration; and hypercoagulopathy caused by polycythemia or deficiency of physiologic anticoagulants (antithrombin, protein C or protein S, factor V Leiden mutation). Prematurity and perinatal asphyxia are considered predisposing factors. A possible role of maternal pre-eclampsia has also been suggested. However, in up to 40% of cases, the condition is idiopathic.¹⁰²

In the cases thus far diagnosed in utero, ultrasound revealed a dilated superior sagittal sinus containing a thrombus. Color Doppler has documented the interruption of blood flow at the level of the dilated sinuses (Fig. 10-37).¹⁰² MRI and MRJ angiography are the techniques of choice for the diagnosis after birth and have been used antenatally as well.

The clinical presentation of thrombosis of the dural sinuses in newborn infants is variable. Symptoms include seizures, unexplained irritability, macrocephaly, or a bulging fontanel. Postnatal studies reveal that in general thrombosis of the cerebral venous circulation is an important and under-recognized cause of seizures in term infants. The natural history is variable. In the absence of perinatal asphyxia, normal neurodevelopmental outcome is likely and the risk of seizure recurrence is low. A poor outcome should be expected especially in preterm neonates, and in cases of secondary cerebral sinus thrombosis. Associated imaging

signs such as infarction or ventricular hemorrhage are correlated with poor prognosis. Sequelae may also depend on the location of the thrombus. In a recent study, all patients with permanent neurologic disability had thrombosis of the deep veins with an associated deep cerebral infarction; in contrast, all patients with thrombosis without infarction or with superficial cortical venous infarction had uniformly a good outcome.¹⁰³

INTRACRANIAL CYSTS

Intracranial arachnoid cysts are accumulations of clear cerebrospinal-like fluid between the dura and the brain substance. The histologic diagnosis is not always available, and the term is frequently used to indicate any intracranial cyst located in the subarachnoid space.

Arachnoid cysts have been found anywhere in the central nervous system including the spinal canal. The most frequent locations are the surface of the cerebral hemispheres in the sites of the major fissures (sylvian, rolandic, and inter-hemispheric), the region of sella turcica, the anterior fossa, and the middle fossa. Less frequently, they are seen in the posterior fossa. Most of the cases diagnosed antenatally involve supratentorial cysts, in the midline, sylvian fissure, and ambient cistern. Arachnoid cysts may be primary (congenital) or secondary (acquired). Congenital types are believed to be formed by maldevelopment of the leptomeninges and do not freely communicate with the subarachnoid space. Acquired types are formed as the result of hemorrhage, trauma, and infection, and often communicate with the subarachnoid space. Arachnoid cysts have the potential to grow as the result of either some communication with the subarachnoid space from a ball-valve mechanism or cerebrospinal fluid production by a choroid plexus-like tissue contained within the cyst wall. Large arachnoid cysts can cause obstructive ventriculomegaly by compressing the foramen of Monro or the aqueduct posteriorly, or by blocking the basal cisterns. Hydrocephalus and macrocephaly are the most common presentations in the neonatal period. Arachnoid cysts have been reported very rarely in association with other anomalies. The list includes trisomy 18, tetralogy of Fallot, sacroccygeal tumor, and neurofibromatosis.

Ultrasound examination of arachnoid cysts demonstrates a well-defined anechoic lesion with adjacent mass effect,

FIGURE 10-38. Sonograms of fetuses with arachnoid cysts. A. A small cyst (arrow) in the ambient cistern. B. A midline bilocular cyst (arrows). C. A very large cyst (arrow) arising from the sylvian fissure.

FIGURE 10-39. Choroid plexus cyst (arrow). A. Single and small (arrow). B. Large bilateral (arrows). C. Multiple (arrows).

occasionally associated with hydrocephalus (Fig. 10-38). The overall majority of arachnoid cysts diagnosed in utero thus far have been recognized only in the third trimester. In a few cases, unremarkable sonograms had been obtained in the midtrimester. Therefore, it is likely that most of these lesions develop only in late gestation. Differentiating fetal arachnoid cysts from other intracranial fluid collections may be difficult at times. However, in the largest available series, multiplanar brain imaging and vaginal sonography of vertex fetuses were found to be extremely effective.⁸⁹ Porencephalic cysts are located inside the brain substance, whereas arachnoid cysts lie between the skull and brain surface. Furthermore, the majority of congenital porencephalic cysts communicate with the lateral ventricles. In schizencephaly, the fluid-filled collection connects the lateral ventricles to the subarachnoid space.

A posterior fossa arachnoid cyst is distinguished from the Dandy-Walker complex by demonstrating the integrity of the cerebellar vermis. Another useful clue is the demonstration that arachnoid cysts tend to be laterally positioned and result in an asymmetric posterior fossa.

In many cases, arachnoid cysts are asymptomatic, but they may cause epilepsy, mild motor or sensory abnormalities, or hydrocephalus. Hydrocephalus and macrocephaly are the most common presentations in the neonatal period.

Neurosurgical series in general suggest a good prognosis, with absence of symptoms in more than 70% of cases. The location of the cyst has influence on the final outcome. In one series, temporal cysts were found to have the best outcome, with more than 90% of patients recovering completely

or with only slight deficits, and there were no deaths. The other locations were associated with a significantly poorer outcomes. In particular, posterior fossa arachnoid cysts had the worst outcomes.^{104,105}

Gliopendymal cysts are thought to derive from displaced neuroectodermal tissue and have the same ultrasound appearance of arachnoid cysts.¹⁰⁶ Differentiation between these two entities is usually possible only on the basis of histologic examination. However, the diagnosis of a gliopendymal cyst should be favored when the cyst is in the midline and is associated with ACC (see earlier). The distinction may not be clinically relevant, because it is uncertain whether the prognostic implications are different.

Choroid plexus cysts appear as round sonolucent areas in the substance of the choroid plexus of the lateral ventricles (Fig. 10-39). They have been described with increasing frequency over the last decade. Surveys of low-risk pregnant patients indicate that the frequency of this finding in the midtrimester is in the range of 1%. However, the real incidence is probably dependent on the resolution of the ultrasound equipment, the attention of the operator, and the definition of the choroid plexus cyst that is employed. Although on average, the incidence in most studies is in the range of 1%, figures as high as 3.6% have been reported.^{107,108}

Choroid plexus cysts may be unilateral or bilateral, and occasionally are multiple. They are typically found at the level of the atrium of lateral ventricles, less frequently within the bodies. When examined with high-resolution ultrasound equipment, the choroid plexus of the lateral ventricle often appears slightly heterogeneous. To be called a choroid plexus

cyst, the lesion should measure at least 2 mm in diameter. Large cysts up to 14 mm may be seen, and usually contain internal septations.

The diagnosis of a choroid plexus cyst is readily made in the majority of cases by noting the typical location within the atria of lateral ventricles, with a normal appearance of the surrounding fetal brain. The only problem that can be encountered at times is differentiating a large choroid plexus cyst slightly distending the cavity of a ventricle from primary ventriculomegaly. In such cases, the most important clue is the demonstration that choroid plexus cysts have a thick echogenic wall and tend to have internal septations. In dubious cases, a follow-up scan may be useful as most choroid plexus cysts usually rapidly decrease in size and may even disappear with advancing gestation. A localized intraventricular bleed may result in a blood clot resembling an abnormality of the choroid plexus. However, the clot is less regular than a choroid plexus cysts and the surrounding ventricle is usually enlarged.

However, fetal choroid plexus cysts are benign findings that are at times associated with an increased likelihood of trisomy 18. The available data do not indicate an association with other chromosomal aberrations, including trisomy 21.^{109,110} In 80% to 90% of fetuses with trisomy 18, anatomic deformities are detected by ultrasound.⁷⁹ On the basis of these data, a prudent approach is to perform a thorough sonographic examination of the fetus when a choroid plexus cyst is identified. This examination should include evaluation of the hands and feet, and a thorough examination of the fetal heart. If an additional ultrasound abnormality is identified, chromosomal analysis should be offered to the patient. There is debate as to how the patient with an isolated choroid plexus cyst should be counseled. Some investigators believe that when the cyst is isolated and a thorough ultrasound evaluation reveals no other abnormalities that the cyst may be considered a normal variant.¹¹¹ Snijders and co-workers¹¹⁰ have reported that in the presence of a choroid plexus cyst, the risk of trisomy 18 is increased 1.5 times over the baseline. Additional reassurance can be obtained by correlating ultrasound findings with serum biochemical markers.

From time to time, suggestions have been made that the risk of aneuploidy is related to the size of the cyst, whether it is unilateral or bilateral, and whether it is persistent or disappears. From the available literature, no evidence supports any of these suggestions. Small cysts, unilateral cysts, and transient cysts have been documented in association with aneuploidies.

Isolated choroid plexus cysts do not modify standard obstetric management. Because no deleterious effect on the fetus has been thus far reported with this finding, there is no need in our opinion for follow-up scans. A handful of very large cysts of the choroid plexuses causing intracranial hypertension have been described in the neurosurgical literature, but these cysts represent probably a separate clinical entity.¹¹²

CONCLUSIONS

Modern ultrasound equipment yields a unique potential for the evaluation of the normal and abnormal fetal central nervous system. A large number of congenital anomalies can be consistently recognized. Transvaginal sonography is

extending antenatal diagnosis to very early gestation MRI can be used to improve the accuracy of the diagnosis in selected cases.

Nevertheless, there are many limits to the prenatal diagnosis of CNS anomalies. Some studies of low-risk patients undergoing basic examinations have reported sensitivities in excess of 80%.^{31,113} However, these results probably far overestimate the diagnostic potential of the technique. These surveys had invariably very short follow-up and almost only included open neural tube defects, whose recognition was probably facilitated by systematic screening with maternal serum AFP. Pitfalls of prenatal ultrasound are well documented and occur for a number of reasons. One of the most important limitations is related to continuing brain development in the second half of gestation and into the neonatal period that limits the detection of anomalies such as microcephaly and cortical malformations. Furthermore, some cerebral lesions are not due to faulty embryologic development but represent the consequence of acquired prenatal, perinatal, and postnatal insults. Even in expert hands, some types of anomalies may be difficult or impossible to diagnose in utero, in a proportion that is yet impossible to determine with precision.¹¹⁴

On the other hand, when an anomaly is identified, counseling the parents and deciding a sensible obstetric management is frequently difficult. Some cerebral anomalies have outcomes that can be predicted with reasonable precision. This is certainly the case with catastrophic lesions such as anencephaly and severe holoprosencephaly, as well as with anomalies that are invariably detected at birth, such as spina bifida. However, there is a large number of conditions that can be accurately identified in utero and yet have an unclear natural history. ACC, mild ventriculomegaly, and minor variations of the Dandy-Walker continuum are remarkable examples with this regard.

Conclusions

CRANIOFACIAL ANOMALIES

Craniofacial anomalies include a wide spectrum of malformations. Accurate sonographic diagnosis is possible from early gestation onward and has been described in many publications.¹⁻⁵ However, a meticulous scanning technique is required that may be difficult to apply in all examinations. Part of the problem is the reconstruction from tomographic planes of the complex tridimensional anatomy of the face. Furthermore, the face is frequently difficult or impossible to access owing to the position of the fetus. Most national guidelines for the standard examination of fetal anatomy include only a few views of the fetal face, mostly demonstration of orbits and eyes, but do not consider feasible an examination of nose, lips, and chin. The accuracy of referral centers in the investigation of high-risk patients is universally reported to be very high.²⁻⁶ Conversely, the sensitivity of standard examinations in a low-risk group of patients is extremely variable, but tends to be low, in the range of 20% to 40%, with a general tendency to recognize facial malformations associated with other anomalies and to miss the isolated ones.⁷⁻¹⁰

Craniofacial malformations may be clinically relevant when seen in isolation, and they may also be associated with other congenital anomalies or be a part of a syndrome. Evaluation of the face is indeed an important part of the clinical genetic examination that is performed postnatally. Therefore, any time a fetal anomaly is identified, the diagnostic workup should include a detailed examination of the fetal face. Apart from obvious malformations, such examinations may also identify subtle dysmorphism that may be crucial for a definitive diagnosis.

Normal Sonographic Anatomy of the Fetal Face

With two-dimensional (2D) ultrasound, a combination of planes must be used to assess facial anomalies (Fig. 11-1).^{1,3,4,6} The following discussion applies mostly to the midtrimester fetus. However, many details of facial anatomy can be identified as early as 11 weeks, particularly by using transvaginal sonography. In the third trimester of gestation, the examination frequently fails because of intrauterine crowding and unfavorable fetal position. Necessary prerequisites of sonography of the fetal face are that it is accessible and there is a pocket of amniotic fluid in front of it, particularly for three-dimensional scanning.

The midsagittal plane is one of the most useful images in that it allows visualization of the profile, which is also one of the most easily recognizable sonographic images of the fetus for the parents. The forehead, nose, and jaw are readily appreciated in this view, which is important to assess the integrity of these structures as well (Table 11-1).

Although the fetal profile is an extremely important view, axial or coronal planes must be obtained to assess the integrity of eyes and lips. A transverse axial scan slightly caudal to the one commonly used for the determination of the biparietal diameter easily reveals orbits and eyes (Table 11-2). The lens and extraocular structures such as muscles, retro-orbital fat, and optic nerve may be visualized. Movements of the eyes are frequently seen during fetal life. It should be remembered that they are usually not synchronous and conjugated. Nomograms for binocular distance, interocular distance, and ocular diameter are available (Table 11-3). By moving the transducer caudally, the superior lip and palate can be visualized. Further caudal movements display the tongue inside the oral cavity and the mandible.

FIGURE 11-1. Sagittal (A), axial (B, C), and coronal (D) views of the fetal head demonstrating the relevant details of facial anatomy.

Table 11-1 Normal Appearance of Fetal Facial Features on Ultrasound in the Midsagittal Section Plane

Structure	Normal Appearance
Forehead	Almost linear immediately above the articulation between the nasal bones and the frontal bone, followed by a smooth backwards bend. This view allows measurement of the thickness of the frontal skin (at the level of the middle of the frontal bend).
Nasal bones	Oblique along a frontocaudal direction. This view allows measurement of the length of the nasal bones and of the superior facial angle (angle between the vertical section of the frontal bone and the nasal bones).
Nasal soft tissues	The columella is oblique or horizontal but should not be vertical.
Upper lip	The philtrum is linear, and should present no bulging. This view allows measurement of the length of the philtrum.
Secondary palate	Thick echoic line, beginning at the alveolar level, and extending horizontally backward. Its middle is marked by a notch, present on both the superior and inferior edges, and corresponds to the transverse palatal suture. ³² The notch is mostly visible on the superior edge.
Oral cavity	The tongue is slightly oblique upward (10–15°). Its tip lies immediately behind the alveolar ridge.
Inferior lip	Rests edge to edge with the upper lip. Both lips are arranged along the same axis; there should be no anteroposterior shift between them.
Chin	At the level of the vertical line traced on the prefrontal skin (esthetic vertical line of the face).

Table 11-2 Normal Appearance of Fetal Facial Features on Ultrasound in the Axial Section Planes

Structure	Normal Appearance
Orbits	The interorbital axis is perpendicular to the strict sagittal axis. This view allows measurement of the inner and outer interorbital lengths.
Nasal septum, molar	The nasal septum is perpendicular to the axial plane. The two malar arches are symmetric with regard arches to the nasal septum
Upper lip, maxilla	There is no lack of continuity of the upper lip. The maxilla appears as a regular, U-shaped echoic alveolus, secondary plate bend. The alveolus and tooth buds appear as hypoechoic spots regularly layered along the alveolar ridge. There is no shift between adjacent alveoli. The hard palate appears as an echoic structure, with a complex shape. The anterior part is semicircular and lies immediately posterior to the alveolar ridge. The posterior part presents as a rectangle-shaped figure, with a notch on its distal side. This view allows measurement of the size of the maxilla.
Oral cavity	The tongue occupies the totality of the oral cavity, and is glued to the alveolar ridge. Posteriorly, the tongue ends at the oropharynx level. This view allows measurement of the width and length of the tongue.
Mandible	Appears as a regular V-shaped echoic image. Both hemimandibles are almost rectilinear. The symphysis menti is clearly visible. The alveoli appear as regularly layered phypoechoic spots. This view allows measurement of the size of the mandible (for example, mandible width and computation of mandible width/maxilla width ratio).

From Rotten D, Levailant JM: Two- and three-dimensional sonographic assessment of the fetal face. 1. A systematic analysis of the normal face. *Ultrasound Obstet Gynecol* 23:224, 2004.

From Romero R, Pitu G, Jeanty P, et al: Prenatal Diagnosis of Congenital Anomalies. Norwalk, CT, Appleton & Lange, 1988, p 83.

Coronal planes provide similar information to the axial ones (Table 11-4). However, a section tangential to the anterior face and demonstrating the tip of the nose, nostrils, and upper lip is probably the most useful one in assessing the integrity of the upper lip. The nostrils typically appear as two small anechoic areas. In this scanning plane, demonstrating that the hyperechogenic upper lip separates the anechoic nostrils from the oral rim virtually excludes the presence of cleft lip (CL).

The principles of three-dimensional (3D) ultrasound are described in detail elsewhere in this text (see Chapter 24). Diagnosis of craniofacial anomalies is one of the most important areas of application of this technique in obstetric sonography. The advantages over standard 2D ultrasound include the visualization of scanning planes that are physically impossible or very difficult to obtain; the demonstration of the surface of the face; and the possibility to have panoramic views of the entire face (Fig. 11-2). The limitations of the technique are the same as that for 2D sonograms. If the fetal face is not accessible or there is not a pocket of amniotic fluid separating the face from the surrounding structures, a 3D view will be of little help. However, in expert hands, a satisfying examination is possible in

Table 11-4

Normal Appearance of the Fetal Facial Features on Ultrasound in the Coronal Section Planes

Structure	Normal Appearance
Nose-mouth view	The nostrils are symmetric. The columella is visualized as an intact line.
Alveolus, nasal septum	The alveolar ridge is regular and appears as an echoic band where tooth buds appear as hypoechoic holes. The nasal septum is perpendicular to the alveolar ridge lining.
Hard palate	Bow-shaped, with a symmetric bend. On each side, it is in continuity with the malar bone.
Retropalatal region	The vomer bone appears as a medial echoic spot isolated in an empty space, with no visible supporting structure acquisition

From Rotten D, Levallant JM: Two- and three-dimensional sonographic assessment of the fetal face. 1. A systematic analysis of the normal face. *Ultrasound Obstet Gynecol* 23:224, 2004.

FIGURE 11-2. Three-dimensional ultrasound: multiplanar analysis demonstrating simultaneously sagittal (A), axial (B), and coronal views (C) of the fetal face.

FIGURE 11-3. Three-dimensional ultrasound: surface rendering of the fetal face at 11 weeks (A), 19 weeks (B), and 37 weeks (C).

the majority of cases in the second to early third trimester. The relative value of 2D over 3D ultrasound has been debated.^{6,11} In expert hands, 2D ultrasound is extremely precise in the identification and categorization of craniofacial malformations and we have not found any significant diagnostic advantage from the use of 3D.⁶ It has been suggested that 3D ultrasound of fetal craniofacial anomalies has other potential benefits, such as offering the parents a realistic and understandable image of the fetal anomaly, and allowing better communication with the specialists involved in the management of the infant. Most of the experience with 3D ultrasound has been derived from referral centers. The impact of this technique in standard examinations has yet to be assessed. In general, 3D ultrasound is complex and probably beyond the scope of a basic evaluation of fetal anatomy in low-risk pregnancies. However, it is possible that four-dimensional ultrasound, which allows a rapid and accurate

visualization of the external surface of the fetus, could prove useful for assessment of facial anatomy in such settings.

Once an ultrasound volume has been acquired, it can be studied with a variety of approaches. Thus far, three modes have been reported to be useful in the diagnosis of craniofacial anomalies. The multiplanar mode consists in the simultaneous demonstration of three orthogonal planes whose direction is chosen by the operator. Typically, the volume is obtained from the profile view of the fetus, which is displayed on the upper left corner of the screen, while the two perpendicular planes are demonstrated in the upper right and lower quadrants (see Fig. 11-2). The advantage is that it may be difficult at times to obtain the exact plane in a moving fetus. The surface mode allows one to visualize the external surface of the fetal face when it is surrounded by fluid (Fig. 11-3). Eventually, the maximum or transparent mode allows one to demonstrate the brightest echoes

FIGURE 11-4. Three-dimensional ultrasound: the skeleton of the face and skull is clearly demonstrated with the maximum or transparent mode. The different sutures and fontanel are depicted in the coronal (A), superior (B), and lateral view (C) of the skull: 1. bregmatic fontanel; 2. frontal or metopic suture; 3. coronal suture; 4. parietal suture; 5. sphenoid fontanel; 6. mastoid suture.

FIGURE 11-5. Three-dimensional ultrasound: anterior (A) and reverse view (B) of the fetal face. The same ultrasound volume is used, and only the point of view is changed. The reverse view provides an image of the anterior palate and nasal fossa.

within the volume and it can be used to visualize the skull (Fig. 11-4).

One limitation of 2D ultrasound is the difficulty in visualizing clearly the posterior portion of the palate, owing to shadowing artifacts arising from the anterior palate. 3D sonography often overcomes this difficulty. One approach

is the so-called reverse view of the face, that is, once the volume has been acquired, the face is viewed in surface mode from the back instead from the front (Fig. 11-5).^{11,12} Another approach consists in insinating the face at an angle that demonstrates the palate (Figs. 11-6 and 11-7).¹³

FIGURE 11-6. Three-dimensional ultrasound: angled approach to visualize the fetal palate. A. To overcome acoustic shadowing from the alveolar ridge, a midsagittal view of the fetal face is obtained and the transducer is angled to insonate the secondary palate with a angle of about 45 degrees. B. A static three-dimensional volume is obtained and rotated to bring the secondary palate in a vertical position. C. Reslicing the volume in multiplanar mode, an axial view displaying both the alveolar ridge and secondary palate is obtained. The soft palate can be appreciated in the sagittal section. However, it lies at an angle to the secondary palate and is not demonstrated in the axial view.

FIGURE 11-7. Three-dimensional ultrasound: TUI (multiple slices) of the fetal palate visualized with an angled approach. Comparing the reference midsagittal view with the coronal slices, the entire secondary palate is clearly demonstrated.

Magnetic resonance imaging has also been used in the diagnostic workup of craniofacial anomalies and may be helpful particularly in the assessment of facial clefts.^{14,15}

Typical Facial Clefts

Facial clefts are the most frequent craniofacial anomalies and the second most common congenital malformation, accounting for 13% of all anomalies. The incidence is approximately 1.4 cases per 1000 births.^{7,16} Clefts can occur in any part of the face but typically involve the line running between each nostril and the central part of the posterior

palate. Atypical types of facial clefts differ in the etiology, clinical implications, and in the diagnostic approach used to manage them, and therefore, they are discussed separately.

Typical facial clefts are commonly referred to as cleft lip (CL) and cleft palate (CP). CL may be associated with CP (CL-CP). CP refers to a defect of the posterior portion of the palate in the presence of a normal upper lip and anterior palate. The anatomy and pathogenesis of these defects can be better understood in light of the embryologic development. The fetal splanchnocranium derives from outgrowths of mesenchyme that surround the primitive oral cavity or stomodeum (Fig. 11-8). These outgrowths (frontonasal

FIGURE 11-8. Frontal views of the heads of human embryos from 4 to 8 weeks of age. (From Carlson BM [ed]: *Human Embryology and Developmental Biology*, 3rd ed. Philadelphia, Mosby/Elsevier, 2004, p 322.)

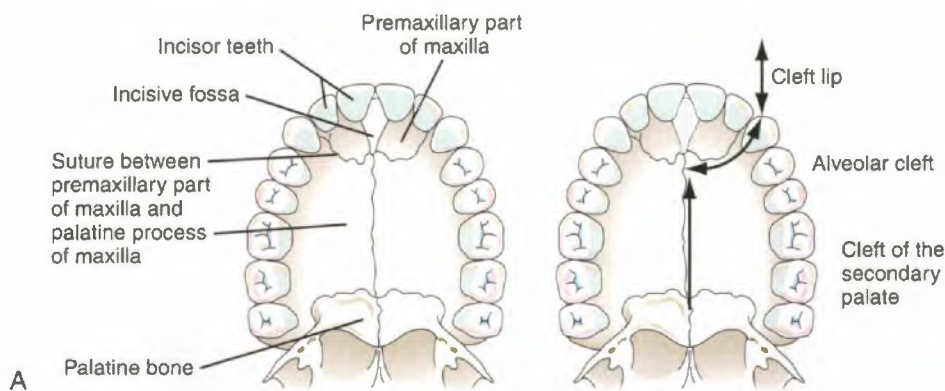

FIGURE 11-9. A. Drawing of the human palate in the axial plane highlights the anatomy of the premaxillary part of the maxilla and the lateral palatine processes of the secondary palate. Their points of fusion are indicated by the black lines between them. The four incisor teeth arise from the premaxillary portion of the primary palate, and the remaining teeth, from the canines posteriorly, arise from the lateral palatine processes of the secondary palate. (Adapted and reprinted from Moore KL: *The Developing Human: Clinically Oriented Embryology*, 6th ed. Philadelphia, WB Saunders, 1998, p 245.) B. Schematic representation of the various cleft constituents of the palate. (From Rotten D, Levaillant JM: *Two and three-dimensional sonographic assessment of the fetal face. 2. Analysis of cleft lip, alveolus and palate. Ultrasound Obstet Gynecol* 24:402, 2004.)

prominence, maxillary prominence, and mandibular prominence) are separated by grooves that eventually undergo fusion and obliteration. The palate originates from the fusion of three palatine processes. The median palatal process originates from the medial nasal prominences, and the two lateral ones originate from the maxillary processes. The palatine processes fuse also with the nasal septum, which divides the nasal cavities. The palate is commonly divided in three parts: the anterior or primary palate, the posterior or secondary palate, and the soft palate (Fig. 11-9). Typical facial clefts derive presumably from failure of fusion of the different bony structures and overlying soft tissues, with persistence of the embryologic grooves (Fig. 11-10).

CL-CP and isolated CP are two different anomalies. With exceedingly rare exceptions, recurrences are type specific. If the index case has CL-CP, there is no increased risk for isolated CP, and vice versa. Roughly, of all cases with typical facial clefts, 25% have CL, 50% have CL-CP, and 25% have CP.

In the vast majority of cases, typical facial clefts have a multifactorial etiology. The empiric risks of recurrence for these cases are reported in Table 11-5. In some cases, however, facial clefts are a part of well-established genetic and nongenetic syndromes. The claimed risk associated with intake of diazepam and steroidal agents has not been confirmed in carefully controlled studies. Chromosomal abnormalities are rare in postnatal series but rather frequent in the prenatal ones.^{2,6,17,18} The discrepancy may be due to a high rate of intrauterine selection of aneuploid fetuses, as well as to the inclusion of an excess of atypical clefts.

Facial clefts encompass a broad spectrum of severity. The typical CL appears as a linear defect extending from one side of the lip into the nostril (Table 11-6). CL-CP may extend through the alveolar ridge and hard palate, reaching the floor of the nasal cavity or even the floor of the orbit (Table 11-7). CP may include defects of the hard palate, the soft palate, or both or the submucosal tissue (see Table 11-8 and Fig. 11-10)

Associated anomalies are found in 50% of patients with isolated CP and in only 13% of those with CL-CP. An

incidence of 60% has been found in embryos and fetuses with facial clefting. In the majority of patients, the associated anomalies do not conform to an established syndrome. In cases of either isolated CL or CP, the most frequent anomaly is clubfoot, whereas in cases of CL-CP, it is polydactyly. Of particular importance is the association with congenital heart disease. No specific pattern could be identified. Specific associations with well-described syndromes are shown in Table 11-9.

The sonographic diagnosis of CL in the fetus depends on demonstration of a groove extending from one of the nostrils inside the lip and possibly the alveolar ridge. With standard 2D ultrasound, facial clefts can be recognized and categorized by a combination of coronal and axial scans. In our experience, CL is best visualized in an anterior coronal plane, demonstrating a linear defect extending from one nostril to the oral rim, usually associated with distortion of both upper lip and nose (Fig. 11-11). Extension of the defect into the palate is better demonstrated in an axial scan of the maxilla (Fig. 11-12). By angling the transducer, it is usually possible to evaluate the degree of extension of the defect, that is to identify whether the lesion is limited to the most anterior part of the palate or the alveolar ridge, or it continues into the posterior palate (see Fig. 11-12). Indirect sonographic findings can also be noted that correlate with the type of defect. In all typical clefts with bilateral CL-CP, the axial and sagittal views demonstrate a protrusion of the central portion of the palate and lip that is commonly referred to as the premaxillary pseudomass (Fig. 11-13). With bilateral CL-CP there is a major distortion of facial anatomy, and the pseudomass is a more obvious and reliable finding than the visualization of the clefts itself.¹⁹ Conversely, with unilateral CL-CP or bilateral CL, the profile view is always unremarkable. The diagnosis of CL-CP, mostly of the bilateral type, has been described even in early gestation, at 11 to 14 weeks, predominantly because of the demonstration of a premaxillary pseudomass.

If a satisfying ultrasound volume can be acquired, the diagnosis of cleft lip is easy. The transparent mode can be used to demonstrate whether the palate is involved or not

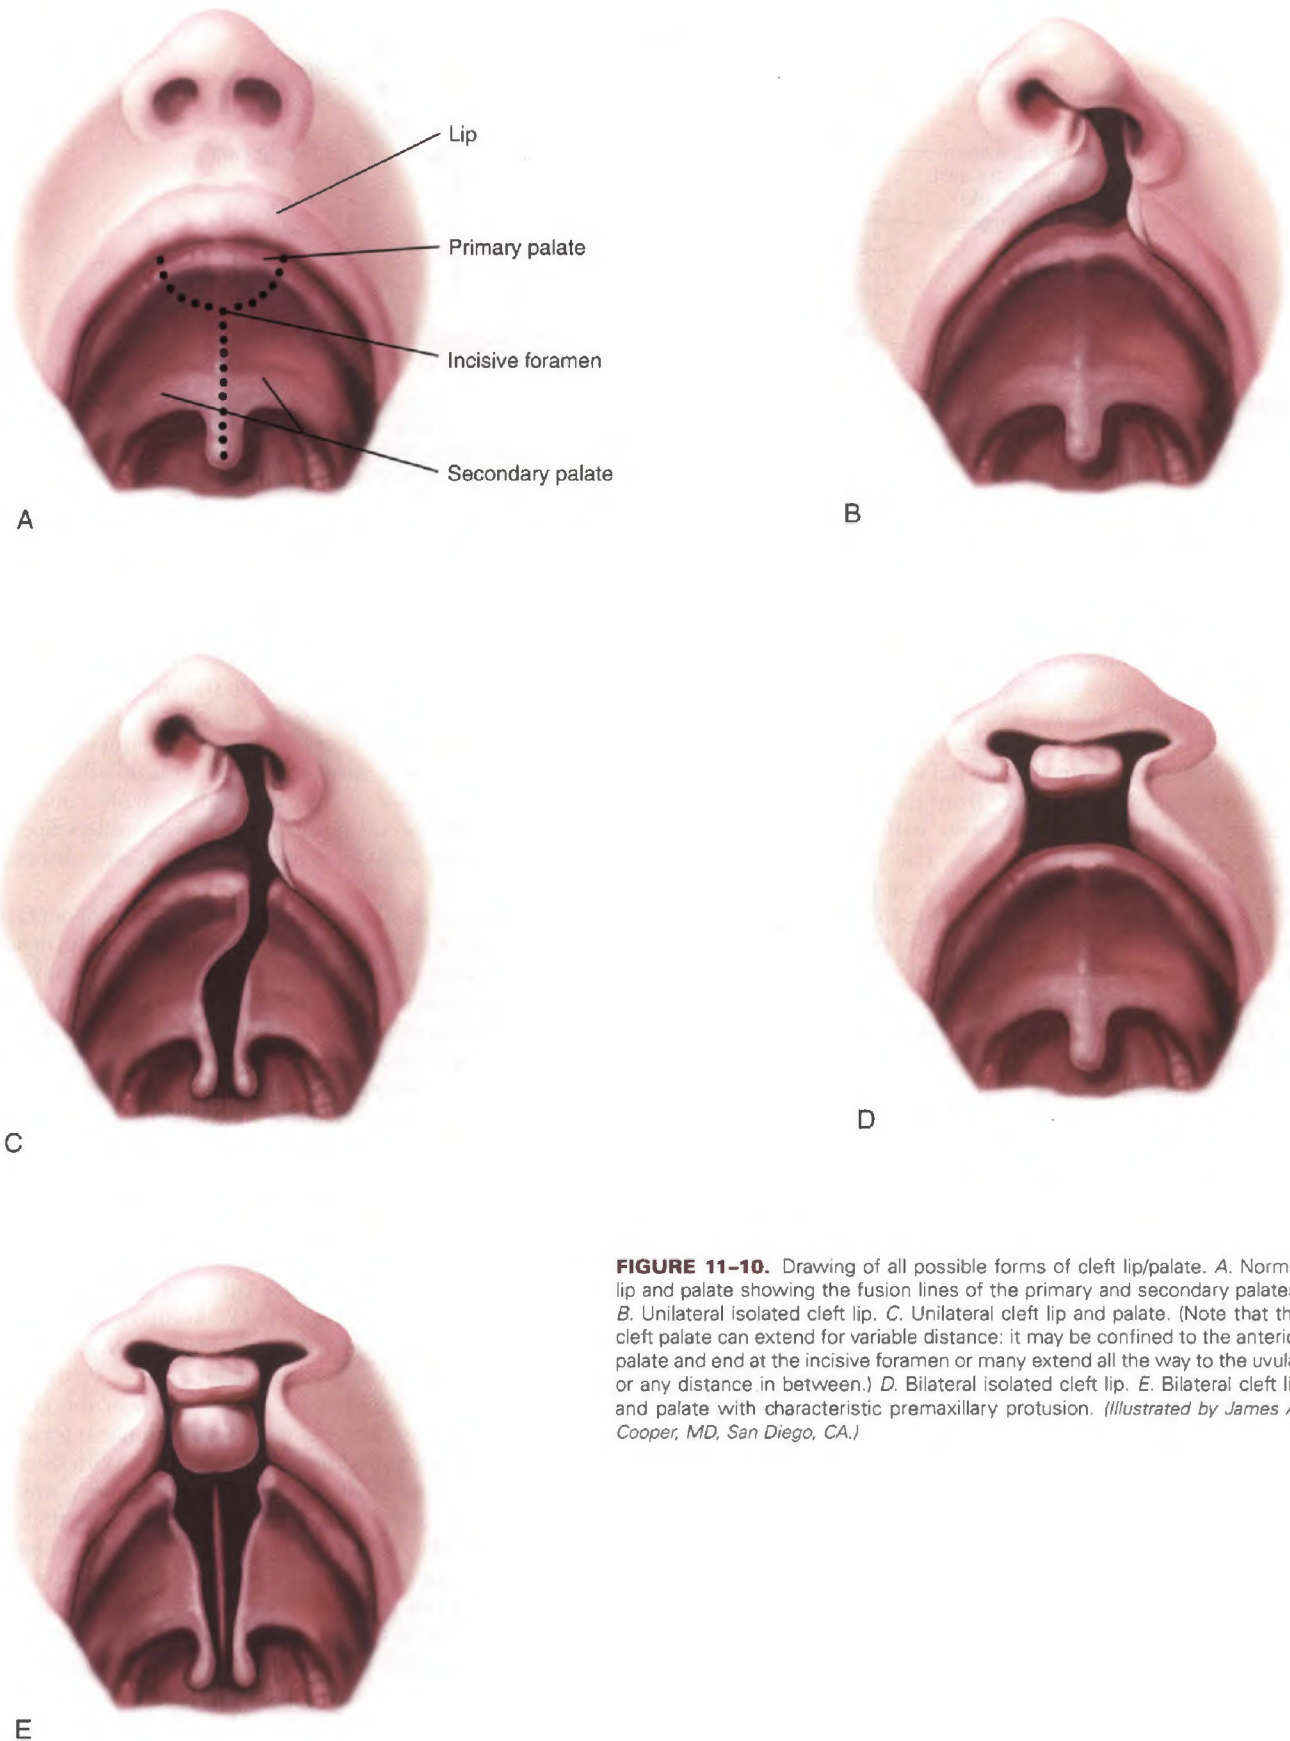

FIGURE 11-10. Drawing of all possible forms of cleft lip/palate. *A.* Normal lip and palate showing the fusion lines of the primary and secondary palates. *B.* Unilateral isolated cleft lip. *C.* Unilateral cleft lip and palate. (Note that the cleft palate can extend for variable distance: it may be confined to the anterior palate and end at the incisive foramen or many extend all the way to the uvula, or any distance in between.) *D.* Bilateral isolated cleft lip. *E.* Bilateral cleft lip and palate with characteristic premaxillary protusion. Table 11-5 Risk of Recurrent Cleft Lip/Cleft Palate in Subsequent Offspring

Variable	Cleft Lip/Palate (%)
Unaffected parent	
No affected offspring	0.1
No affected offspring plus 1 affected first cousin	0.4
One affected offspring	4.0
Two affected offspring	9.0
One affected offspring plus one affected relative	4.0
Affected parents	
One parent plus no affected offspring	4.0
One parent plus one affected offspring	10-17
Two parents plus one affected offspring	60.0

(Fig. 11-14). If the palate is insonated at an angle, the degree of internal extension of the cleft can be appreciated (Fig. 11-15). Magnetic resonance imaging may also be used in selected cases, as it is effective for evaluating the involvement of the palate (Fig. 11-16) and may also allow the diagnosis of CP, which is difficult if not impossible with ultrasound.

The prognosis of facial clefts depends primarily on the presence and type of associated anomalies. Mild clefts, such as lineal indentations of the lips or submucosal cleft of the soft palate, may not require surgical correction. Larger defects cause cosmetic, swallowing, and respiratory problems. Recent advances in surgical technique have produced good cosmetic and functional results. Cases that are associated with a defect in the posterior palate represent the greatest challenge for surgical correction, as the soft palate is involved in the process of swallowing and vocalizing. Furthermore, auditory tubal disorders may lead in time to acoustic problems and deafness.

Table 11-6 Sonographic Characteristics of Unilateral or Bilateral Cleft Lip

Section Plane	Unilateral Cleft	Bilateral Cleft
Sagittal and parasagittal	The midsagittal view is usually normal. The parasagittal views show the cleft of the upper lip as a defect between two thickened zones, with visible asymmetry between both sides of the defect. The narinal bridge is always complete, but there is a flattened narinal bend.	The normal image of the lip is replaced by the protruding premaxillary prolabium. The prolabium is stuck to the nose, which is consequently flattened. The columella cannot be analyzed.
Axial	The loss of continuity of the labial arc is clearly apparent. The nostrils are asymmetric and distorted, but the nasal aisles are always present, constituting a bridge over the cleft.	On each side, the protruding premaxillary prolabium is separated from the remaining upper lip extremities by the clefts. Both nostrils are flattened but complete.
Coronal	The loss of lip continuity is clearly apparent.	The defects in lip continuity are clearly apparent.

From Rotten D, Levallant JM: Two- and three-dimensional sonographic assessment of the fetal face. 2. Analysis of cleft lip, alveolus and palate. *Ultrasound Obstet Gynecol* 24:402, 2004

Table 11-7 Sonographic Characteristics of Unilateral or Bilateral Cleft Alveolus

Section Plane	Unilateral Cleft	Bilateral Cleft
Axial	The alveolar defect ranges from a simple slant to a cleft involving the alveolus and pre-maxilla. Clefts involving the alveolus present as a defect in alveolar continuity: - a simple irregularity in the alveolar lining signals an alveolar slant; - a defect in alveolar regularity with anteroposterior shift between the two hemimaxillae signals a cleft involving the alveolus and pre-maxilla.	The pre-maxilla is protruded together with the prolabium. The premaxillary mass is analyzed (size, soft tissue and bone content). The external parts of both alveoli are symmetrical.
Coronal	There is a defect in alveolar continuity, with missing buds.	There is a median defect in alveolar continuity. This contrasts with an intact hard palate.

From Rotten D, Levallant JM: Two- and three-dimensional sonographic assessment of the fetal face. 2. Analysis of cleft lip, alveolus and palate. *Ultrasound Obstet Gynecol* 24:402, 2004.

Table 11-8 Sonographic Characteristics of Unilateral or Bilateral Secondary Palate Cleft

Section Plane	Secondary Palate Cleft With a Unilateral CLA	Secondary Palate Cleft With a Bilateral CLA
Midsagittal and parasagittal	The successive views show a defect in hard palate continuity. This defect is asymmetric. It is not strictly median, but lateralized, usually towards the same side as the CLA cleft.	An hyperechoic midline image is present in the midsagittal view. Care must be taken: although a median line is present it is not the palate, but the vomer bone. On each side of the sagittal view, the parasagittal views show the hard palate defects
Axial	When looking for the palate caudally to the alveolus (remember that the alveoli are separated by a defect and a shift), one does not find it. The only apparent image is that of an oblique vomer bone (10–5°)	The anteroposterior hyperechoic line corresponding to the vomer bone is present Anteriorly, it extends onto the premaxillary prolabium On each side of this median structure, the cleft is readily apparent.
Coronal	Medially, the palatal arch is interrupted by a defect. Actually, this defect is not symmetric, but lateralized on the same side as the CLA cleft. Thus, the two half arches are not symmetrical. The wider half is on the non-pathologic side. The vomer bone is deflected toward the half arch situated on the pathologic side, and rests on it.	The hard palate cannot be imaged. The vomer appears as a suspended midline line, with no supportive structure to rest on. The palatal arch is reduced to two small lateral structures.

From Rotten D, Levallant JM: Two- and three-dimensional sonographic assessment of the fetal face. 2. Analysis of cleft lip, alveolus and palate. *Ultrasound Obstet Gynecol* 24:402, 2004

Atypical Facial Clefts

Approximately 3% of clefts occur in portions of the face different from the line joining the nostrils to the posterior palate. The prevalence is much higher in prenatal studies due to both the high intrauterine fatality rate that is associated with some of these conditions and probably the higher detection rate due to the frequency of associated malformations.

The atypical cleft that has been reported most frequently in prenatal diagnosis series is the median cleft or Tessier cleft number 0. This is a quadrangular defect in the central portion of the upper lip and palate, usually associated with a flattened nose. It accounts for less than 1% all cases of cleft lip. It is considered to represent the consequence of underdevelopment of the frontonasal prominence, which normally joins the two maxillary prominences. Development of the midface is induced by the prechordal mesenchyme, which is also responsible for the differentiation of the midline structures of the brain. This explains the frequent association of median clefts with alobar or semilobar holoprosencephaly.^{20,21} The typical combination of findings in these cases include hypotelorism, flat nose, and median CL (Fig. 11-17).

Median CL may also occur in association with hypertelorism (increased orbital distance), a combination that is pathognomonic of the “median cleft face syndrome” or “frontonasal dysplasia.”²² The pathogenesis is much different in these cases. The premaxilla is present, as well as the nose that is usually bifid, and the brain is normal in most cases. The diagnosis relies on the demonstration of a wide central defect involving both the upper lip and the palate in axial or coronal scans.

The prognosis of a median cleft depends entirely on the association with other anomalies. Median cleft face syndrome is usually associated with normal intelligence. Radical cosmetic surgery may be required. Alobar and semilobar holoprosencephaly associated with median clefts and hypotelorism both have a extremely poor prognosis. Severe holoprosencephaly is also associated with other craniofacial anomalies due to underdevelopment of the midface that include a combination of hypotelorism/cyclopia, absence of a nose, and presence of a proboscis (Fig. 11-18).^{20,21}

Bilateral CL-CP is usually associated with anterior displacement of the premaxilla. In a minority of cases, it may occur without protrusion and a flat facial profile.² This is a different and more extreme anomaly than typical CL-CP, which is probably pathophysiologically connected to median CL, and usually associated with multiple anomalies and chromosomal aberrations, trisomy 18 in particular (Fig. 11-19).

The most common atypical cleft found at birth is the lateral one (or Tessier number 7), which has an estimated incidence of one in 3000 to 5600 live births and may be either unilateral (more frequently on the left side) or bilateral.^{23,24} It is probably due to defective development of the branchial arches and is characterized by a variable degree of widening of the oral commissure (macrostomia) associated with hypoplasia of the lateral skeleton of the face (maxilla, zygomatic bone, ascending branch of the mandible) and external ear. A handful of cases have been diagnosed antenatally. Sonographic findings include unusual deepening of the corners of the mouth and asymmetry between the two sides of the face. 3D ultrasound is particularly valuable for recognizing lateral clefts (Fig. 11-20). central portion of the face, nose, lips and alveolar ridge are well visualized with a standard 2D scan. However, the lateral part of the fetal face is not equally accessible. A panoramic view of the entire face in surface mode is certainly the best approach for this diagnosis.²⁴ Atypical facial clefts probably can also occur also with a disruptive mechanisms, as it is attested by cases of amniotic band syndrome.²

Lateral clefts of the face are usually isolated malformations. Surgical correction is possible but is extremely challenging owing to the association with underlying skeletal abnormalities involving the mandible. Ear abnormalities are also frequent.

FIGURE 11-11. Anterior coronal plane of the fetal face demonstrating unilateral cleft lip.

FIGURE 11-12. Axial planes of the maxilla in fetuses with facial clefts: *A.* Isolated cleft lip (arrow): the alveolar ridge is intact albeit irregular in shape as it frequently happens in these cases. *B.* Unilateral cleft lip and palate: the defect only extends to the alveolar ridge (arrow); note that one toothbud is missing but that the secondary palate does look intact; this defect is frequently referred to as cleft alveolus. *C.* Unilateral cleft lip and palate; the defect is seen extending to the secondary palate (arrow). *D.* Bilateral cleft lip and palate (arrows); the anterior protrusion of the central portion of the maxilla (or premaxilla) indicates that the defect extends posteriorly to the secondary palate.

Orbital and Ocular Defects

In early development, the eyes are placed laterally in the primitive face in a fashion similar to that of lower animals with panoramic vision. As gestation progresses, they migrate toward the midline, creating favorable conditions for the development of stereoscopic vision. Hypertelorism is an increased interorbital distance, and this can be either an isolated finding or associated with many clinical syndromes or malformations. Mild hypertelorism is a common variant. However, there is a high likelihood of mental retardation when either associated anomalies or an extreme degree of hypertelorism is found. The most common anomalies with hypertelorism are the median cleft face syndrome; craniosynostoses such as Apert, Crouzon, and Pfeiffer syndromes; agenesis of the corpus callosum; and anterior encephaloceles. Hypertelorism per se results only in cosmetic problems and possible impairment of stereoscopic binocular vision. For severe cases, a number of operative procedures, such as

canthoplasty, orbitoplasty, surgical positioning of the eyebrows, and rhinoplasty, have been proposed.

Hypotelorism (decreased interorbital distance) is almost always found in association with other severe anomalies, almost invariably with holoprosencephaly. The prognosis, which depends on the associated anomalies, is usually very poor.^{2,3,20,21}

Microphthalmia is defined as a decreased size of the eyeball, and anophthalmia refers to the absence of the eye; however, the term anophthalmia should be reserved for the pathologist, who must demonstrate not only absence of the eye but also of optic nerves, chiasma, and tracts. Microphthalmia/anophthalmia, which is either unilateral or bilateral, is usually associated with many genetic syndromes. Prenatal diagnosis of microphthalmia is based on the demonstration of decreased ocular diameters (Fig. 11-21) and careful examination of the intraorbital anatomy is indicated to identify lens, pupil, and optic nerve.²⁵ Congenital microphthalmia is frequently associated with visual disorders and

FIGURE 11-21. Ocular anomalies: (A, B) bilateral and unilateral microphthalmia (arrows); (C) cataract (arrows).

with other anomalies. Goldenhar syndrome (found in about 1 per 5000 births) is associated with hypoplasia of one half of the face (hemifacial microsomia) that often includes unilateral anophthalmia, and ear, dental, and facial abnormalities (Fig. 11-21).²⁶ It has been reported that at least in some cases, microphthalmia may develop throughout gestation and early prenatal diagnosis may be impossible.²⁵

A cataract is a clouding of the lens in the eye that affects vision. Most cataracts are related to aging. Cataracts are very common in older people. Rarely, this is found at birth, and in these cases the disease is usually bilateral. Sonographically, cataract is associated with an echogenic lens²⁵ (see Fig. 11-21). In the majority of cases, cataracts are a part of multiple anomalies and syndromes, or are associated with congenital infections. Congenital cataract can be treated by removal of the lens. The prognosis however depends largely on the associated anomalies.

Congenital obstruction of the nasolacrimal duct results in cystic dilatation of the proximal part of the duct. Dacryocystocele has been identified prenatally as an anechoic mass medial and slightly inferior to the eye²⁷ (Fig. 11-22). Although the differential diagnosis includes an anterior encephalocele, hemangioma, and a dermoid cyst, the sonographic appearance is typical. Postnatally, dacryocystoceles resolve spontaneously in about 90% of cases within the first 6 months of life.

Micrognathia, Retrognathia, and Macroglossia

The mandible forms the floor of the oral cavity and contains the tongue. If the mandible is severely hypoplastic (micrognathia) or posteriorly displaced (retrognathia), a typical malformative sequence occurs: the tongue is displaced superiorly and posteriorly, leading to both abnormal closure of the palatine process, which results in either a cleft palate or a high arched palate, and glossoptosis that may cause suffocation at birth. This sequence is frequently referred to as the Robin anomalad. It may be a sporadic isolated finding (in about 40% of cases), or it may be associated with other anomalies or with recognized genetic and nongenetic syndromes including Treacher Collins, Robin and Robert syndromes, chromosomal abnormalities (mainly trisomy 18 and triploidy), and teratogen exposure. Otocephaly is a rare, lethal, sporadic abnormality characterized by severe hypo-

FIGURE 11-22. Bilateral dacryocystoceles (D) in a second trimester fetus. Orbits are indicated by arrows.

plasia of the mandible (agnathia) and severe midline defects, including holoprosencephaly, anterior encephalocele, cyclopia, aglossia, microstomia, and midfacial location of the ears (so-called ear-head).

Micrognathia/retrognathia encompass a wide spectrum of severity, and probably most mild cases can not be recognized in utero. Conversely, severe forms can be identified since early gestation²⁸ and different approaches have been suggested from time to time. Probably, the simplest one is the profile view to demonstrate that the midportion of the mandible is not aligned with the maxilla (Fig. 11-23).^{3,29} In this view, the upper lip is usually very prominent and the chin is receding. However, this is a subjective observation and, at times, is associated with many uncertainties. The index of suspicion increases when the tongue appears to be displaced posteriorly and superiorly.³⁰ Measurement of the

FIGURE 11-23. Severe micrognathia (arrows) in a fetus with dysmorphic facies and multiple anomalies: (A) sagittal view of the fetal face demonstrating protruding upper lip and small chin; (B) three-dimensional ultrasound, surface mode, demonstrating abnormal face with small chin and hypertelorism; (C) three-dimensional ultrasound, maximum mode demonstrating the small mandible; (D) postnatal radiograph.

mandible has also been proposed.^{5,31,32} Distinguishing micrognathia from retrognathia is not simple, and the two conditions frequently coexist.⁵ Intrauterine development of micrognathia, limiting early prenatal diagnosis, has been suggested as contributing to the difficulty of diagnosis.²⁹ With 3D ultrasound in transparent mode, the entire mandible can be visualized and this may increase diagnostic precision³³ (see Fig. 11-23).

Severe micrognathia can be a neonatal emergency due to airway obstruction by the tongue in the small oral cavity. If prenatal diagnosis is made, a pediatrician should be present in the delivery room and be prepared to intubate the infant.^{29,34} However, the prognosis depends mostly on the presence of associated anomalies.^{34,35} Probably, only the most severe cases and those with associated malformations are detected in utero, and this may explain the poor outcome of most neonatal series.

The fetal tongue can be identified as early as 14 weeks' gestation.³⁶ Malformations of the tongue include microglossia and macroglossia.³⁶ Macroglossia is defined as a resting tongue that protrudes beyond the teeth or alveolar ridge.^{36,37} Sonography has demonstrated macroglossia in patients with trisomy 21 and Beckwith-Weidemann syndrome (Fig. 11-24). However, macroglossia may also be seen in patients with hypothyroidism, storage diseases, and other genetic syndromes.^{36,38}

Tumors of the Face

Epignathus is a very rare teratoma arising from the oral cavity or pharynx. Most cases of epignathus arise from the sphenoid bone. Some arise from the hard and soft palate, the pharynx, the tongue, and jaw. From their sites of origin, the tumors grow into the oral or nasal cavity or intracranially. The tumors, which are usually benign, consist of tissues derived from any of the three germinal layers; most of them contain adipose tissue, cartilage, bone, and nervous

FIGURE 11-24. Beckwith-Weidemann in a second trimester fetus. A protruding tongue is well seen (arrow) in the profile view.

tissue. Prenatal diagnosis is suggested by the demonstration of a solid tumor arising from the oral cavity (Fig. 11-25); calcifications and cystic components may also be present.^{39,40} A careful examination of the brain is important because the tumor may grow intracranially. The outlook depends on the size of the lesion and the involvement of vital structures. Lesions detected antenatally have been very large. Polyhydramnios has been associated with poor prognosis. The major cause of neonatal death is asphyxia due to airway obstruction. Surgical resection and normal postoperative course are possible.

FIGURE 11-25. Epignathus. A. Antenatal sonogram demonstrating a large mass (asterisk). B, C. Postnatal images in a similar case. (B, C. courtesy of Frank Chervenak, MD, New York, NY and www.thefetus.net).

Myoblastoma is a very rare benign tumor, which usually arises from the oral cavity. The tumor occurs in females exclusively, and it may be the consequence of excessive production of estrogens by the fetal ovaries under human chorionic gonadotropin stimulation. The ultrasound features are those of a large solid mass protruding from the fetal mouth. Vascular connections between the tumor and the floor of the oral cavity may be demonstrated using color Doppler ultrasound. Polyhydramnios (due to pharyngeal compression) is common.

Intracranial teratomas may grow outside the skull and protrude from the orbits (Fig. 11-26).

Facial Dysmorphism

Modern high-resolution ultrasound allows detailed evaluation of the fetal face, and an expert sonologist can perform on a living fetus in early gestation an anatomic examination that in many ways is similar to the clinical evaluation that can be performed on a live infant. Facial dysmorphism is now amenable to antenatal detection, and 3D sonography is certainly valuable in these settings (Fig. 11-27). The detection of even subtle facial findings has been useful to diagnose or corroborate the diagnosis of syndromes in pregnancies at increased risk.^{6,26,29,32,33,41-51} However, some caution is necessary because facial features may demonstrate extreme variations in normal individuals.

Among the facial dysmorphisms that can be reliably identified, Binder syndrome or maxillonasal dysplasia is characterized by the association of an extremely small and flat nose, a convex upper lip, and malocclusion. Antenatally, the profile view is particularly striking, with an extremely small and flat nose that does not form an angle with the forehead^{42,43} (Fig. 11-28). This condition does not seem to affect neurologic development, and surgical treatment is available.⁵² However, an association with chondrodysplasia punctata has been described.

FIGURE 11-26. Orbital teratoma. Large cystic and solid mass (arrow) projecting beyond the orbit.

CRANIOSYNOSTOSIS

Premature ossification and closure of the cranial sutures results in the abnormal shape and size of the skull. In severe cases, this condition can also cause compression on cranial nerves and increased pressure on the growing brain. The final result depends upon the sutures that are involved and the time the closure takes place. Craniosynostosis (or cranio-stenosis) occurs in about 1 of 2500 births. In most cases, only one suture is affected and the condition is isolated and

FIGURE 11-27. This fetus had increased nuchal translucency in the late first trimester, and a thick nuchal fold and polyhydramnios in the second trimester. Although the bidimensional examination of the fetal face (*A, B, C*) is negative, the surface mode (*D*) reveals unusual facies with antimongoloid slanting of the eyelids. Noonan syndrome was diagnosed after birth.

FIGURE 11-28. Binder syndrome: (*A*) sagittal view of the face; (*B*) fetal profile in three-dimensional surface mode ultrasound; (*C*) postnatal image. Note the small and flat nose with absence of any angle between forehead and nose.

sporadic. However, in a minority of cases, closure of multiple sutures is possible and associated anomalies are present. Craniosynostosis is a part of many genetic syndromes. The genetic defect underlying some of these has been identified. Most frequently this is a mutation in the genes encoding the fibroblast growth factor receptors 1, 2, and 3.

The most frequent craniosynostosis is due to closure of the sagittal suture, which is responsible for about half of the cases, resulting in an elongated head (scaphocephaly). The second most frequent type is due to closure of the coronal suture that results in a very flat, recessed forehead (brachycephaly).

Crouzon and Apert syndromes are the most common of the craniosynostosis syndromes. The main findings include premature closure of the coronal suture, hypoplasia of the midface, exophthalmos, and polydactyly/syndactyly of the hands and feet. Crouzon syndrome occurs in approximately 1 in 25,000 births. It may be transmitted as an autosomal-dominant genetic condition or appear as a fresh mutation. The appearance of an infant with Crouzon syndrome can vary in severity from a mild presentation with subtle midface characteristics to severe forms with multiple cranial sutures fused and marked midface and ocular problems. The incidence of Apert syndrome is approximately 1 in 100,000

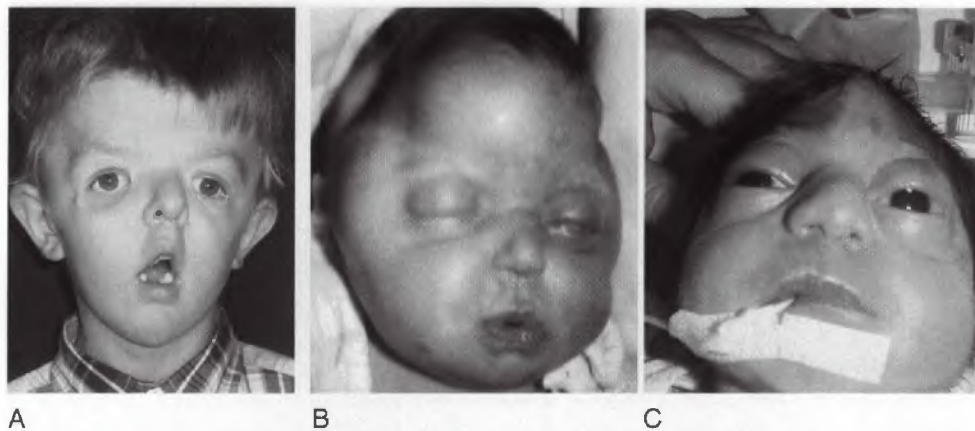

FIGURE 11-29. Craniosynostosis syndromes: (A) Apert syndrome; (B) Pfeiffer syndrome, lethal variety (cloverleaf skull); (C) trigonocephaly.

FIGURE 11-30. Antenatal sonogram from the case demonstrated in Figure 11-25B: (A, B) sagittal and axial sonograms demonstrating the cloverleaf skull (arrows); (C) exophthalmos and hypertelorism.

births and most cases are fresh mutations. The general features of a child with Apert syndrome are similar to those in a child with Crouzon syndrome (Fig. 11-29). However, there is not as much variability between cases and the degree of presentation is more severe. Other types of craniosynostosis syndromes that have been diagnosed in utero include Pfeiffer syndrome, which is characterized by closure of all sutures with cloverleaf skull, and trigonocephaly, which is due to closure of the metopic suture that results in a triangular forehead (see Fig. 11-29). Type II thanatophoric dysplasia is also associated with craniosynostosis.

The experience with prenatal diagnosis of craniosynostosis is limited and consists mostly of case reports and small series of severe types.^{6,45,46,48,53-60} Most likely, the majority of cases are missed antenatally. We are aware of many infants that were diagnosed after birth with craniosynostosis and had completely unremarkable prenatal sonograms. Dolicocephaly due to compression is a frequent finding during fetal life, and we expect that differentiation from the most frequent type of craniosynostosis, closure of the sagittal suture, would be impossible in most cases. Even severe forms may be associated only with subtle findings, particularly in early gestation. Craniosynostosis should be suspected in the presence of an

abnormal skull shape⁵⁴ (Fig. 11-30). Failure to visualize the sutures, which are normally seen as linear interruptions of the echogenic calvarium, increase the index of suspicion.⁵⁴ Recently, reports on 3D ultrasound suggest that this technique may be valuable in the diagnosis of craniosynostosis.^{6,53,55} Apart from the demonstration of panoramic views of the cranium using the standard surface mode (Fig. 11-31), the transparent or maximum mode allows one to better visualize the sutures, which is particularly useful for demonstrating the abnormal compensatory opening of the patent sutures that occurs when there is craniosynostosis. With premature closure of the coronal sutures, for example, there is a typical enlargement of the metopic one^{56,61} (Fig. 11-32).

ANOMALIES OF THE NECK

Current ultrasound equipment allows the visualization of the main anatomic structures of the neck: upper airways and esophagus, vessels, and spine. A detailed investigation of the cervical structures is usually possible as early as the 18th week of gestation. However, flexion of the head and an unfavorable position of the fetus can make the examination difficult. Views of the fetal neck at 25 weeks of gestation are

FIGURE 11-31. Pfeiffer syndrome, lethal variety: (A, B) three-dimensional surface mode (C) compared with a postnatal image.

FIGURE 11-32. The metopic suture (arrow) in a normal fetus (A) and in two fetuses with craniosynostosis and multiple anomalies (B, C). Note the presence of a wormian bone in (C).

FIGURE 11-33. The fetal neck structures at 25 weeks' gestation.

provided in Figure 11-33. Most anatomic components of this area are demonstrated in these sonograms. The tongue is seen filling the oral cavity. Shadowing from the facial bones obscures the hard palate, but its position can be inferred by the curvature of the tongue and by the soft palate. Real-time examination greatly enhances the under-

standing of these structures, because movement of both the tongue and the soft palate is frequently seen. Behind the soft palate and below a high-level echo complex presumably arising from the sphenoid, the fluid-filled pharyngeal cavity is seen and can be followed until it bifurcates into the larynx and hypopharynx. With high-resolution ultrasound, the

esophagus may be seen, as a multilayered structure. The serosa and the mucosa appear as echogenic lines, interposed within the hypoechogenic muscular walls. With slight angulation of the transducer, the main neck vessels, the common carotid artery, and the jugular veins are demonstrated, and the identification is facilitated by the use of color Doppler. At closer inspection, minute details, such as the vocal cords, may be appreciated. On real-time ultrasound examination, it is frequently possible to demonstrate the contractions of the vestibulum of the larynx.

Nuchal Cystic Hygroma

The term hygroma means moist tumor. Cystic hygromas are anomalies of the lymphatic system characterized by single or multiple cysts within the soft tissues. In the fetus, they usually occur in the nuchal region, much less frequently in the axillary region or anterior neck region. Nuchal cystic hygroma is associated in the majority of cases with generalized lymphatic obstruction, and the term lymphatic obstruction sequence has been proposed. In the embryo, the lymphatic system drains into the jugular lymphatic sac. A communication between this primitive structure and the jugular vein is formed at 40 days of gestation (conceptional age). Failure of development of this communication results

in lymphatic stasis. Dilatation of the jugular lymphatic sac leads to the formation of cystic structures in the cervical region. If a connection between the lymphatic and the venous system does not occur at this point, a progressive peripheral lymphedema and nonimmune hydrops will develop, leading to early intrauterine death⁶² (Fig. 11–34). If the connection is formed, the sequence is interrupted, and the fluid collections are resorbed. The redundant skin will give rise to webbed neck (pterygium colli), which is a typical manifestation of many genetic and nongenetic conditions. Uplifting and anterior rotation of the ears and an abnormal hair pattern are other consequences of overdistention of the jugular lymphatic sac. Distention of the tributary lymphatics may result in peripheral lymphedema, which, in turn, may give rise to redundancy of the skin of the face and puffy hands and feet, with deep-set narrow nails. It has also been suggested that transitory ascites may result in laxity of the anterior abdominal wall and prune-belly syndrome.⁶²

Sonographically, overdistention of the jugular lymphatic sacs that are located in both sides of the neck results in the formation of a cystic structure that is usually partitioned by a thick fibrous band corresponding to the nuchal ligament. Within the cystic structure, thinner septa are seen and probably represent fibrous structures of the neck or deposits of fibrin, giving to the lesion a typical honeycomb appearance (Fig. 11–35). Most cases seen in the second trimester have decreased amounts of amniotic fluid, and a few have either normal fluid or polyhydramnios. The size of the lesions may vary greatly from small collections of fluid to enormous cysts that may be larger than the fetus. In cases of generalized hydrops, pleural effusions, ascites, and severe skin edema are present.

There is a correlation between increased nuchal translucency and cystic hygroma. Cystic hygroma can be regarded as the most severe end of the spectrum of increased nuchal translucency. Typically, when nuchal translucency is in excess of 4 mm, septa are seen within it. The prevalence of nuchal cystic hygroma depends upon gestational age. Nuchal cystic hygromas have a high rate of intrauterine selection, and they are exceedingly rare at birth. Conversely, they are found in 1:250 fetuses at 11 to 14 weeks.⁶³

Nuchal cystic hygromas are frequently found in association with chromosomal aberrations and, consequently, with a wide variety of anatomic defects. In the first trimester, autosomal trisomies and trisomy 21 in particular are more

FIGURE 11-34. Cystic nuchal hygroma with lymphatic obstruction sequence.

FIGURE 11-35. Nuchal cystic hygroma: (A) small hygroma in a second trimester fetus: two separate fluid accumulations are seen on each side of the neck (arrows); (B) large cystic hygroma (arrow) in a fetus at 14 weeks' gestation; (C) three-dimensional ultrasound in surface mode in a fetus with a cystic hygroma (arrow).

FIGURE 11-36. Although the antenatal diagnosis was cervical teratoma, this fetus was found at birth to have a cavernous lymphangioma infiltrating the neck tissues. *A, B.* Two-dimensional sonograms demonstrating the large neck mass. *C.* Surface rendered 3D sonogram demonstrating the mass.

FIGURE 11-37. Large cervical teratoma.

frequent.⁶³ In the midtrimester, Turner syndrome is predominant.⁶² Nuchal cystic hygroma with normal karyotype can be inherited as an autosomal recessive trait.⁶⁴ Webbed necks or redundant skin are found in genetic and nongenetic syndromes, such as Noonan syndrome, familial pterygium colli, and fetal alcohol syndrome.

The prognosis depends upon the gestational age and the association with hydrops or other anomalies. Of cases diagnosed at 11 to 14 weeks' gestation, only 17% will have an intact survival. The mortality rate of cases seen at mid-gestation is close to 100%.⁶³

Other Neck Masses

Lymphangiomas and hemangiomas have overlapping histopathologic and sonographic findings, and are the most frequent neck tumors in infancy. Associated anomalies and hydrops are rarely seen, and very frequently the lesion is only diagnosed in late gestation. Sonographically, they appear as a complex mass of variable dimensions, usually infiltrating the surrounding tissues (Fig. 11-36).^{65,66} The prognosis is usually severe. These tumors can cause polyhydramnios and dystocia, as well as airway obstruction or swallowing difficulties after birth.⁶⁷ Surgical resection is

usually required but is associated with many complications (facial nerve palsy, mandibular maldevelopment, malocclusion, abnormal tooth eruption, and speech difficulties). Infiltration of the surrounding tissues frequently requires multiple operations.

Cervical teratomas are rare tumors that vary in size and generally consist of a mixture of cystic and solid components, frequently with internal calcifications^{68,69} (Fig. 11-37). Obstruction of the airways and esophagus leads frequently to polyhydramnios and acute respiratory failure in the newborn period. With large masses, the prognosis is poor with a high risk of perinatal death. In infants, surviving surgical correction is difficult because these tumors tend to be large, and extensive neck dissection and multiple additional procedures are necessary to achieve complete resection of the tumor with acceptable functional and cosmetic results.⁶⁹

Fetal goiter (enlargement of the thyroid gland) can be associated with hyperthyroidism, hypothyroidism or an euthyroid state. Congenital hypothyroidism occurs in about 1 in 4000 live births. However most hypothyroid infants have primary thyroid dysgenesis (absent or hypoplastic thyroid gland), secondary (pituitary) or tertiary (hypothalamic) hypothyroidism, which are associated with a normal or

FIGURE 11-38. Fetal goiter (arrow) that was found to be associated with hypothyroidism as a consequence of excessive maternal propylthiouracil assumption.

small thyroid gland. Only a minority have thyroid dysmorphogenesis or hypothyroidism secondary to intrauterine exposure to antithyroid medications, which are associated with goiter in the newborn period. The two drugs primarily responsible for the latter are iodide preparations and propylthiouracil. Iodide preparations are administered as expectorant medications, and radiopaque dyes are used in amniography. Maternal ingestion of as little as 12 mg/day may result in congenital hypothyroidism. About 1% of mothers exposed to propylthiouracil have hypothyroid infants.

Ultrasound diagnosis of goiter is based on the demonstration of a solid, anteriorly located symmetric mass, which may result in hyperextension of the fetal head⁷⁰⁻⁷³ (Fig. 11-38). Polyhydramnios is common due to mechanical obstruction of the esophagus. The prognosis depends on the basic cause of the goiter. Fetal blood sampling can aid in determining fetal thyroid status, especially in women suffering from Graves' disease in which either transplacental transfer of drugs or thyroid-stimulating antibodies may result in fetal goiter.^{70,71} Maternal therapy usually corrects fetal hyperthyroidism. Direct fetal therapy in cases of fetal hypothyroidism can be undertaken by amniocentesis, and this can result in resolution of the fetal goiter.^{70,71}

The differential diagnosis of neck masses is frequently difficult. The ultrasound findings of anterior hygroma/hemangioma and cervical teratoma overlap.⁶⁷ In general, cervical teratomas are mostly solid, may contain calcifications, and are well demarcated from surrounding tissues. Conversely, hygromas/hemangiomas tend to have significant

fluid components and to infiltrate the tissues of the neck and face. Goiter has always a solid appearance, is well demarcated from the surrounding tissues, is relatively small compared with the previous lesions, and when it is large, it is bilobed.

In general, any mass growing in the anterior neck region of the fetus particularly if large and associated with polyhydramnios may be associated with a potentially lethal airway obstruction at birth. In these cases, delivery of the fetus in a tertiary care center is always recommended. An ex utero intrapartum treatment (EXIT) procedure may also be considered. This process involves a cesarean section in which only the head of the fetus is delivered at first to allow pediatricians to ensure airway access by either intubation or tracheotomy while the fetus is still attached to the umbilical cord and placenta.⁷⁴⁻⁷⁶

CONCLUSIONS

Facial clefts are frequent malformations. However, evaluation of the fetal face is difficult with standard sonographic techniques and these anomalies are frequently missed. Other facial anomalies, such as micrognathia, ocular anomalies, and craniosynostosis are rare, and even in expert hands, they may be difficult to recognize. Nuchal cystic hygroma is one of the most frequent anomalies diagnosed antenatally. Large masses occurring in the anterior neck be associated with respiratory insufficiency and require individualized treatment in tertiary care centers.

DEVELOPMENT OF THE FETAL SKELETON

The skeleton is composed of two tissues (bone and cartilage), three cell types (osteoblasts, osteoclasts, and chondrocytes), and more than 200 skeletal elements spread throughout the body.^{1,2} Skeletal tissues derive from three embryonic cell lineages: (1) cranial neural crest cells, which originate the craniofacial skeleton, including the calvarium, midface, mandible and teeth; (2) paraxial mesoderm cells or somites, which are the embryologic precursors of the axial skeleton; and (3) the lateral plate mesoderm, which is responsible for limb formation.^{1,3-6} Embryologically, limb buds begin to develop during the 4th week of embryonic life (6th menstrual week) as clusters of mesenchymal cells covered by a layer of ectoderm.¹⁻³ Mesenchymal models of bone (anlagen) form around the 5th week of embryonic life (7th menstrual week) (Fig. 12-1).³ Development of the upper limbs antecedes that of the lower limbs in bud appearance, differentiation, and establishment of final relative limb size. Limbs develop in a proximodistal sequence, with the anlagen of the humerus and femur forming first, followed by the radius and the ulna, the tibia and the fibula, the metacarpal and the metatarsal bones, and, finally, the phalanges.^{1,2,7}

Skeletogenesis (Genetics and Embryology)

Skeletogenesis involves four steps: patterning, organogenesis, growth, and homeostasis.⁶ Patterning is the process by which the final size, shape, number and arrangement of bones are determined.^{2,6} This process takes place long before skeletogenesis, and three signaling regions have been identified: (1)

an apical ectodermal ridge; (2) an area consisting of ectoderm covering the sides of the bud; and (3) a zone of polarizing activity.³ The apical ectodermal ridge consists of densely packed ectodermal cells located at the tip of the limb bud, which express several fibroblast growth factors (FGFs) that initiate and control limb outgrowth.^{5,8,9} The ectoderm covering the sides of the bud regulates dorsoventral patterning.⁵ The zone of polarizing activity is located on the posterior limb bud margin. It is responsible for antero-posterior patterning and, thus, the formation of digits.^{9,10} Besides FGFs, several other genes are involved in the control of limb patterning, including Sonic hedgehog (Shh), GLI-Kruppel family member GLI3 (Gli3), sal-like 1 (Sall1), Hoxd13, Hoxa13, bone morphogenetic/cartilage-derived morphogenetic protein (CDMP), growth differentiation factors (GDFs), noggin (Nog), t-box family 4 and 5 (Tbx-4 and Tbx-5), Wnt7-a, radical fringe (Rfng), engrailed (en), and LIM homeobox transcription factor 1 beta (Lmx1b).¹

Bone and cartilage are formed during the organogenesis period, which consists of three phases: condensation, cell differentiation, and histogenesis. Condensation is pivotal in skeletal development, because the templates for the future bones (anlagen) are defined at this stage.⁴ Condensation initiation, boundary set, proliferation, adhesion, and growth are regulated by complex interactions between extracellular matrix molecules, cell surface receptors, cell adhesion molecules (e.g., fibronectin, tenascin, Noggin, syndecan, and N-CAM), homeobox genes (e.g., Hoxa-2, Hoxa-13, Hoxd-11, and Hoxd-11-13), transcription factors (e.g. runt related transcription factor 2 [RUNX2], winged-helix transcription factor [CFKH-1], mesenchyme forkhead 1 [MFH-1], paired box transcription factors 1 and 9 [PAX-1, PAX-9], periaxin 1 and 2 [PRX-1 and PRX-2], scleraxis, and mammalian

FIGURE 12-1. Diagram of the mesenchymal precartilage primordia of the axial and appendicular skeletons at 5 weeks' embryonic age (7 weeks' menstrual age). These develop further and eventually ossify to form skeletal structures as designated. Several central nervous system structures are also designated. FIGURE 12-2. Endochondral bone formation. *A.* Mesenchymal cells condense. *B.* Cells of condensations become chondrocytes (c). *C.* Chondrocytes at the center of condensation stop proliferating and become hypertrophic (h). *D.* Perichondrial cells adjacent to hypertrophic chondrocytes become osteoblasts, forming bone collar (bc). Hypertrophic chondrocytes direct the formation of mineralized matrix, attract blood vessels, and undergo apoptosis. *E.* Osteoblasts of primary spongiosa accompany vascular invasion, forming the primary spongiosa (ps). *F.* Chondrocytes continue to proliferate, lengthening the bone. Osteoblasts of primary spongiosa are precursors of eventual trabecular bone; osteoblasts of bone collar become cortical bone. *G.* At the end of the bone, the secondary ossification center (soc) forms through cycles of chondrocyte hypertrophy, vascular invasion, and osteoblast activity. The growth plate below the secondary center of ossification forms orderly columns of proliferating chondrocytes (col). Hematopoietic marrow (hm) expands in marrow space along with stromal cells. (From Kronenberg HM: *Developmental regulation of the growth plate.* *Nature* 423:332, 2003.)

SRY box 9 [SOX-9]), and growth factors (e.g. bone morphogenetic proteins, fibroblast growth factor-2 [FGF-2], transforming growth factor β).¹¹

Cell differentiation and histogenesis (osteogenesis) initiate during the 7th week of embryonic development (9th menstrual week), with bones developing by either endochondral or membranous ossification.⁶

Endochondral Ossification

The axial and appendicular skeletons are formed by endochondral ossification (Fig. 12-2). Cartilaginous models of the future bones differentiate within mesenchymal condensations during the 6th week of development (8th menstrual week), with primary ossification centers developing in the middle of the anlagen between the 7th and 12th week of development (9th to 14th menstrual weeks).³ SOX9 plays an important role in chondrogenesis and, indeed, mutations in this gene cause campomelic dysplasia, a severe skeletal disorder characterized by congenital bowing and angulation of the long bones (especially of the tibia), hypoplastic scapulae, sex reversal in male fetuses, and a high lethality rate due to respiratory distress.¹ Another gene involved in chondro-

genesis is procollagen type II alpha 1 (COL2A1), which encodes collagen type II.^{1,12}

Within primary ossification centers, hypertrophic cartilage matrix is degraded, chondrocytes undergo apoptosis, osteoblasts replace the disappearing cartilage with trabecular bone, and bone marrow is formed.¹ Simultaneously, osteoblasts in the perichondrium begin to deposit a collar of compact bone matrix along the diaphysis.^{1,12} Osteoblast differentiation is controlled by RUNX2¹³ and Osterix,¹⁴ whereas proliferation is controlled by the low-density lipoprotein receptor-related protein 5 (LPR5) signaling pathway.² Eventually, cartilage in the center of the anlagen degrades, mineralizes, and is removed by osteoclasts.^{3,4} Vascular ingrowth is stimulated by vascular endothelial growth factor, with the influx of osteoprogenitor cells occurring at the same time that the bone matrix is deposited along the periosteum of the mid-shaft.^{3,4,15} Some of these invading cells differentiate into hematopoietic stem cells, whereas others differentiate into osteoclasts or osteoblasts.⁶

Secondary ossification centers begin to appear at the extremities of bones (epiphysis) later in pregnancy.³ The portion of cartilage trapped between the expanding primary and secondary ossification centers is known as the growth plate or physis.³ This structure is responsible for the longitudinal growth of long bones until definitive fusion between epiphyses and diaphyses occurs at the end of puberty.^{3,4,12} Longitudinal growth is coordinated by Indian hedgehog (Ihh), a stimulator of chondrocyte proliferation at the growth plate.¹ Bone mass, shape, and strength are maintained throughout development and adult life by balancing bone destruction and formation. Homeostasis is the process that controls the continuing remodeling of bones.⁶

It is important to realize that when a long bone is imaged by ultrasound, only the diaphyses are measured, because the epiphyses usually are not clearly visualized. With favorable conditions, good images of the epiphysis can be obtained, especially when high frequency transducers are used (Fig. 12-3). Secondary ossification centers may often be visualized by ultrasound in the third trimester. The distal femoral ossification center may be seen at approximately 32 to 33 weeks of gestation, the proximal tibial epiphyseal center at 34 to 35 weeks, and the proximal humeral epiphyseal ossification center at 37 to 38 weeks of gestation (Fig. 12-4A and B). When all three centers are identified, it is likely that the fetus is at least 37 weeks. These ossification centers may be seen slightly earlier in female fetuses than in male fetuses. The timeline for the radiographic and histologic appearance of primary and secondary ossification centers is illustrated in Figure 12-4C.

The axial skeleton (e.g., vertebrae and the dorsal part of the ribs) originates from the somites. Formation of new somites and detachment of these structures from the paraxial mesoderm occur in the craniocaudal direction in a highly organized fashion.⁵ A molecular clock produced by oscillations of cycling genes (e.g. c-hairy-1, lunatic fringe [l-fng], and naked cuticle 1 [nkd1]) stimulates Notch receptor signaling waves that sweep through the paraxial mesoderm.¹⁶⁻¹⁹ Spatial coordination is provided by a decreasing gradient of FGF8 from the posterior to the anterior pole of the embryo.^{5,18,20} Differential expression of delta-like (Dll) proteins determines the size and polarity of the somites,⁵ which mature as they move rostrally and differentiate into

FIGURE 12-3. A. Proximal humeral epiphysis imaged with a high-frequency linear transducer (10 MHz) in a fetus at 29 weeks' gestation. B. Measurement of the femur in a third trimester patient. The femur should be measured along the ossified bone (between the Xs). The specular reflection from the surface of the femoral epiphysis (arrow) should not be measured.

dermatomyotomes and sclerotomes.^{5,18} Dermatomyotomes give rise to the appendicular and axial musculatures, as well as the dorsal epithelium. The sclerotome is the precursor of the axial skeleton, and its formation is initiated and controlled by Sonic hedgehog.^{5,21,22}

Intramembranous Ossification

The craniofacial skeleton and clavicles develop by intramembranous ossification.¹ This process differs from endochondral ossification by the direct differentiation of mesenchymal cells into osteoblasts, which produce a bone matrix rich in type I collagen.^{1-3,12,15} Bone remodeling is accomplished by the continuous and concerted action of osteoblasts (cells that produce bone matrix) and osteoclasts (cells that remove bone).

SKELETAL DYSPLASIAS

Abnormal development, growth, or maintenance of cartilage and bone tissues result in skeletal dysplasias. Skeletal dysplasias are a heterogeneous group of disorders affecting

the development of chondro-osseous tissues and resulting in abnormalities in the size and shape of various segments of the skeleton. Despite recent advances in imaging and molecular genetics,²³⁻²⁵ accurate prenatal diagnosis of skeletal dysplasias remains a clinical challenge.²⁶ Although 253 osteochondrodysplasias and 45 genetically determined dysostoses have been included in the most recent revision of the International Nosology and Classification of Constitutional Disorders of Bone²⁷ (and more will probably be identified as distinct entities), the number that can be recognized with the use of sonography in the antepartum period is considerably smaller. In subsequent sections of this chapter, we review the birth prevalence, classification, and molecular genetics of skeletal dysplasias that are identifiable at birth.

Birth Prevalence and Contribution to Perinatal Mortality

In a large multicenter study conducted in Italy, the birth prevalence of skeletal dysplasias recognizable in the neonatal period, excluding limb amputations, was estimated as 2.4/10,000 births.²⁸ Twenty-three percent of the affected

FIGURE 12-4. A. Sonogram of the lower extremity at the knee in a fetus at 35 weeks' gestation. Increased echogenicity from the secondary ossification centers of distal femoral (DFE) and proximal tibial (PTE) epiphyses are seen. B. Sonogram of the proximal humerus in a fetus at 38 weeks' gestation. Ossification of the proximal humeral epiphysal ossification center (PHE) is well seen. *Continued*

FIGURE 12-4 cont'd. C. Diagram of the skeleton of a full-term newborn. The times that the ossification centers appear are designated in embryologic weeks (add 2 weeks for menstrual age). These times are somewhat different than those using ultrasound because ultrasound is more sensitive for detection of ossification than radiographic methods. All refer to the primary ossification centers unless otherwise designated. Only at birth are the lower extremities the same lengths as the upper extremities; subsequently, the lower extremities grow to become longer than the upper extremities. Table 12-1**Birth Prevalence of Skeletal Dysplasias (per 10,000 total births)**

	Birth Prevalence (per 10,000)	Frequency Among Perinatal Deaths
Thanatophoric dysplasia	0.69	1:246
Achondroplasia	0.37	—
Achondrogenesis	0.23	1:639
Osteogenesis imperfecta type II	0.18	1:799
Osteogenesis imperfecta (other types)	0.18	—
Asphyxiating thoracic dysplasia	0.14	1:3,196
Chondrodysplasia punctata	0.09	—
Campomelic dysplasia	0.05	1:3,196
Chondroectodermal dysplasia	0.05	1:3,196
Larsen's syndrome	0.05	—
Mesomelic dysplasia (Larger's type)	0.05	—
Others	0.46	1:800

From Camera G, Mastroiacovo P: Birth prevalence of skeletal dysplasias in the Italian multicentric monitoring system for birth defects. In Papadatos CJ, Bartsocas CS (eds): *Skeletal Dysplasias*. New York, Alan R. Liss, 1982, p 441.

infants were stillborn, whereas 32% died during the first week of life. The overall frequency of skeletal dysplasias among perinatal deaths was 9.1 per 1000. This study also reported on the birth prevalence of the different skeletal dysplasias and their relative frequency among perinatal deaths (Table 12-1). The four most common skeletal dysplasias were thanatophoric dysplasia, achondroplasia, osteogenesis imperfecta (OI), and achondrogenesis. Thanatophoric dysplasia and achondrogenesis accounted for 62% of all lethal skeletal dysplasias, and the most common nonlethal skeletal dysplasia was achondroplasia.²⁸ In another large series performed in western Scotland, the prevalence of skeletal dysplasias at birth was 1.1 per 10,000 births. The most frequent conditions were thanatophoric dysplasia (1/42,000), OI (1/56,000), chondrodysplasia punctata (1/84,000), campomelic syndrome (1/112,000), and achondrogenesis (1/112,000).²⁹ Rasmussen et al³⁰ reported a prevalence of 2.14/10,000 deliveries in a longitudinal study, which included elective pregnancy termination, stillborn infants at more than 20 weeks of gestation, and live-born infants diagnosed by the 5th day of life. The rate of lethal cases in this latter study was 0.95/10,000 deliveries.³⁰ Other studies reporting on the prevalence of skeletal dysplasias are summarized in Table 12-2.²⁸⁻³⁹ Of interest, the study reporting the highest prevalence of skeletal dysplasias at birth (9.5/10,000 births) was conducted in a population with a high rate of consanguineous unions.³⁹

Classification of Skeletal Dysplasias

International Nosology and Classification of Constitutional Disorders of Bone

Over the past 30 years, the classification of skeletal dysplasias has evolved from one based on clinical/

Table 12-2**Overall Birth Prevalence of Osteochondrodysplasias – Summary of 12 Studies**

Reference	Rate per 10,000	Comment
Gustavson and Jorulf ³¹	4.7	In newborns

radiologic/pathologic descriptions to one that also includes the underlying molecular abnormality for those conditions for which the defect is known.⁴⁰

The first uniform classification, proposed in 1977, was called International Nomenclature for Skeletal Dysplasias. The classification was based purely on descriptive findings of either clinical or radiologic nature.⁴¹ Since its initial publication, the classification has undergone three revisions. In 1992,⁴²⁻⁴⁴ it was reoriented based on radiologic diagnosis and morphologic criteria, and similar conditions were grouped into families, depending on the presumed pathogenetic similarities. Five years later, the classification was reorganized to take into account information regarding genes or protein defects underlying the families of disorders.^{45,46} Thus, those disorders for which a genetic defect was well documented were regrouped into distinct families based on specific mutations. These included, for example, the "achondroplasia group" of disorders with mutations in the fibroblast growth factor receptor 3 gene, the "diastrophic dysplasia group" of disorders with mutations in the diastrophic dysplasia sulfate transporter gene, the type II collagenopathies with mutations in the type II collagen gene, and the type XI collagenopathies with mutations in the cartilage oligomeric protein gene. Several new groups were added, including the lethal skeletal dysplasias group, the fragmented bones group, and the miscellaneous neonatal severe dysplasia group. The classification was last revised during the 5th Meeting of the International Skeletal Dysplasia Society, which took place in Oxford, England in

2001; it is now called the International Nosology and Classification of Constitutional Disorders of Bones (2001).²⁷ Although this classification remains a combination of morphologic and molecular groupings of disorders, genetically determined dysostoses were added to skeletal dysplasias (or osteochondrodysplasias), because these two groups overlap in clinical practice. Dysostoses are skeletal malformations that occur during the first 8 weeks of embryonic life and for which the phenotype is static, that is, the phenotype does not evolve throughout life.²⁷ In contrast, skeletal dysplasias, which often present after the embryonic period, are characterized by a more general involvement of the skeleton, and the phenotype continues to evolve throughout life.²⁷ Genetically determined dysostoses have been divided into three groups: those with predominant cranial and facial involvement (e.g., Crouzon syndrome), those with predominant axial involvement (e.g., spondylocostal dysostoses), and those with predominant involvement of the extremities (e.g., Fanconi syndrome). The full version of the International Nosology and Classification of Constitutional Disorders of Bones²⁷ can be downloaded from the International Skeletal Dysplasia Society website (<http://www.isds.ch/ISDSframes.html>).

Molecular-Pathogenetic Classification of Skeletal Dysplasias

As acknowledged earlier, at least in part, by the above-mentioned nosology classification, evolving knowledge regarding the molecular basis of skeletal dysplasias indicates that a spectrum of phenotypes share a similar genetic basis.^{24,25,47-51} For example, disorders that originate during patterning are generally caused by Hox or Pax genes.⁶ In contrast, growth defects are frequently caused by mutations in genes that encode for extracellular matrix products or for regulatory signal peptides.⁶ Therefore, a parallel molecular classification based on the structure and function of implicated genes and proteins has been developed to help further understand the pathogenesis of individual disorders. The Molecular-Pathogenetic Classification of Genetic Disorders of the Skeleton is presented in Table 12-3,²⁴ and complements the International Nosology and Classification of Constitutional Disorders of Bone.²⁷ Skeletal disorders with a well-documented genetic and biochemical basis have been assigned to one of seven groups: (1) defects in extracellular structural proteins; (2) defects in metabolic pathways (including enzymes, ion channels and transporters); (3) defects in folding and degradation of macromolecules; (4) defects in hormones and signal transduction mechanisms; (5) defects in nuclear proteins and transcription factors; (6) defects in oncogenes and tumor suppressor genes; and (7) defects in RNA and DNA processing and metabolism.

The reader is reminded that only approximately one third of bone dysplasias have had their molecular basis elucidated, and that new genes involved in skeletal dysplasias are continually being discovered.²⁵ We review the mutations associated with specific skeletal dysplasias in subsequent sections of this chapter.

Lethal Skeletal Dysplasias

Of special interest to perinatologists are the group of lethal osteochondrodysplasias, which were classified by Spranger

and Maroteaux⁵² into 11 subgroups based on radioanatomic manifestations (Table 12-4). The purpose of this classification was to facilitate differential diagnosis, and the groups do not necessarily constitute pathogenetic families.

Terminology Frequently Used to Describe Bone Dysplasias

Shortening of the extremities can involve the entire limb (micromelia), the proximal segment (rhizomelia), the intermediate segment (mesomelia), or the distal segment (acromelia) (Fig. 12-5). The diagnosis of rhizomelia or mesomelia requires comparing the dimensions of the bones of the legs and forearm with those of the thighs and arms. Figures 12-6 and 12-7 display the relationships between the humerus and ulna, as well as the femur and tibia, which can be used for the objective assessment of rhizomelia and mesomelia. Table 12-5 presents a list of skeletal dysplasias characterized by rhizomelia, mesomelia, and micromelia.

Several skeletal dysplasias feature alterations of the hands and feet. The term polydactyly refers to the presence of more than five digits. It is classified as postaxial if the extra digits are on the ulnar or fibular side, and preaxial if they are located on the radial or tibial side. Syndactyly refers to soft tissue or bony fusion of adjacent digits. Clinodactyly consists of deviation of a finger (or fingers).

The most common spinal abnormality seen in skeletal dysplasias is platyspondyly, which consists of the flattening of the vertebrae (Fig. 12-8).⁵³⁻⁵⁹ Kyphosis and scoliosis can also be identified in utero (Figs. 12-9 and 12-10).⁶⁰⁻⁶⁴ Prenatal diagnosis of hemivertebra (Fig. 12-11)^{60,65,66} and coronal clefting of vertebral bodies have been made.^{63,67}

Biometry of the Fetal Skeleton in the Diagnosis of Bone Dysplasias

Long bone biometry has been used extensively for the prediction of gestational age. Nomograms for this purpose make use of the long bone as the independent variable and the estimated fetal age as the dependent variable. However, the type of nomogram required to assess the normality of bone dimensions uses gestational age as the independent variable and long bone length as the dependent variable. For the proper use of these nomograms, the clinician must know the accurate gestational age of the fetus. Therefore, patients at risk for skeletal dysplasias are advised to seek prenatal care at an early gestational age in order to assess all clinical estimators of gestational age. Tables 12-6 and 12-7 present nomograms for the measurement of limb biometry for the upper and lower extremities, respectively. Comparisons between limb dimensions and the head circumference can be used for patients presenting with uncertain gestational age (Figs. 12-12 and 12-13). Although some investigators have employed the biparietal diameter for this purpose, the head circumference has the advantage of being shape independent. A limitation of this approach is that it assumes that the cranium is not involved in the dysplastic process, and this may not be the case in some skeletal dysplasias.

The nomograms and figures in this chapter provide the mean, the 5th, and the 95th percentiles of limb biometric parameters. The reader should be aware that 5% of the general population would fall outside these boundaries.

Ideally, a more stringent criterion, such as the 1st percentile of limb growth for gestational age, should be used for diagnosis. Unfortunately, none of the currently available nomograms have been based on a sufficient number of patients to provide an accurate discrimination between the 5th and the 1st percentiles. However, most skeletal dysplasias diagnosed in utero or at birth are associated with dramatic long bone shortening, and under these circumstances, the precise boundary used (1st or 5th percentile) is not critical. An exception to this is achondroplasia, in which limb biometry is mildly affected until the third trimester, when abnormal growth can be detected by examining the slope of growth of the femur length.⁶⁸ In a study including 127 cases of 17 skeletal dysplasias, Gonçalves and Jeanty⁶⁹ concluded, with the use of discriminant analysis, that the degree of shortening of the femur length can be used as the initial step in distinguishing among the five most common disorders: thanatophoric dysplasia, OI type II, achondrogenesis, achondroplasia, and hypochondroplasia. Gabrielli et al.⁷⁰ evaluated the possibility of an early diagnosis of skeletal dysplasias in high-risk patients. A total of 149 consecutive,

uncomplicated singleton pregnancies at 9 to 13 weeks after amenorrhea were scanned by transvaginal ultrasound. Eight additional patients with previous pregnancies affected with skeletal dysplasias were evaluated with serial examinations every 2 weeks from 10 to 11 weeks of gestation onward. Significant correlations between femur length and both crown rump length and biparietal diameter were found. Of the five cases with skeletal dysplasias, two (one with recurrent OI, the other with recurrent achondrogenesis) were diagnosed in the first trimester. The results of this study suggest that an early evaluation of the fetus and the correlation of femur length with crown rump length and of femur length with biparietal diameter might be helpful in the early diagnosis of severe skeletal dysplasias. In less severe cases, however, biometric evaluation appeared to be of limited value. Nomograms for long bone measurements according to crown rump length in a large population of normal fetuses examined between 11 and 14 weeks of gestation have been recently published and their role in the early assessment of pregnancies at risk for skeletal dysplasias remains to be determined.⁷¹

Clinical Presentation

The challenge of antenatal diagnosis of skeletal dysplasias generally presents itself in one of two ways: (1) a patient who has delivered an infant with a skeletal dysplasia and desires antenatal assessment in a subsequent pregnancy; or (2) the incidental finding of a shortened, bowed, or anomalous extremity during a routine sonographic examination. In

FIGURE 12-7. Relationship between the lengths of the tibia and femur.

Table 12-5 Skeletal Dysplasias Characterized by Rhizomelia, Mesomelia, and Micromelia

Rhizomelia

- Thanatophoric dysplasia
- Atelosteogenesis
- Chondrodysplasia punctata (rhizomelic type)
- Congenital short femur
- Achondroplasia
- Hypochondroplasia

Mesomelia

- Mesomelic dysplasia (Langer, Reinhardt, and Robinow types)
- Ellis-van Creveld syndrome (chondroectodermal dysplasia)

Acromesomelia

- Ellis-van Creveld syndrome (chondroectodermal dysplasia)

Micromelia

- Achondrogenesis
- Atelosteogenesis
- Short-rib-polydactyly syndrome
- Diastrophic dysplasia
- Fibrochondrogenesis
- Osteogenesis imperfecta (type II)
- Kniest dysplasia
- Dyssegmental dysplasia
- Roberts syndrome

patients at risk, the examination is easier when the particular phenotype is known. The inability to obtain reliable information about skeletal mineralization and the involvement of other systems (e.g., skin) with sonography is a limiting factor in the establishment of an accurate diagnosis after the identification of an incidental finding. Another limitation is the paucity of information about the in utero natural history of these disorders.

Despite these difficulties and limitations, good medical reasons justify attempting an accurate prenatal diagnosis of skeletal dysplasias. A number of these disorders are uniformly lethal (see Table 12-4), whereas others are associ-

Note the markedly flattened vertebrae.

ated with mental retardation.⁷² In addition, there is a group of disorders associated with thrombocytopenia for which vaginal delivery may expose the infants to the risk of intracranial hemorrhage. Accurate diagnosis of skeletal dysplasias is therefore important for prenatal counseling.

FIGURE 12-9. Coronal scan of the fetal spine by two-dimensional ultrasound showing scoliosis.

Diagnostic Imaging and the Prenatal Diagnosis of Skeletal Dysplasias

Despite the increasing availability of molecular testing, a comprehensive molecular diagnostic search for all skeletal dysplasias is not possible at this time. Indeed, as mentioned in a previous section of this chapter, only about one third of skeletal dysplasias have had their molecular basis defined.²⁵ Therefore, the role of diagnostic imaging in the prenatal investigation of skeletal dysplasias are (1) to narrow the

differential diagnosis of skeletal dysplasias so that appropriate confirmatory molecular tests can be selected, (2) to predict lethality; and (3) to identify the fetus with a skeletal dysplasia early enough in pregnancy so that the diagnostic workup can be completed before the limit of fetal viability.⁷³⁻⁷⁷

Ultrasound is the primary imaging modality used for the initial diagnostic evaluation of an affected fetus, and several studies have explored the role of ultrasound in the detection

FIGURE 12-11. Coronal scan of the fetal spine showing lateral hemivertebra (arrow) in the thoracic segment.

of skeletal dysplasias.^{53,68,78-88} The first was a prospective analysis of a high-risk population (15 women, 16 cases) carrying a genetic risk for skeletal dysplasias conducted by Kurtz et al.⁶⁸ Based on second trimester findings, five abnormal fetuses among 16 fetuses at risk were correctly diagnosed. Weldner et al.⁹² screened 12,453 patients in the second and third trimesters, and estimated the prevalence of skeletal dysplasias detectable by prenatal ultrasound as 7.5/10,000. Sharony et al.⁸⁴ studied fetuses and stillbirths referred from other centers for suspected skeletal dysplasia. Most of the cases were sporadic, and the most common final diagnoses were OI (16%) and thanatophoric dysplasia (14%). Table 12-8 summarizes the diagnostic accuracy of two-dimensional ultrasound (2DUS) for prenatal diagnosis of skeletal dysplasias.^{26,38,88-91}

Several investigators have proposed that three-dimensional ultrasonography (3DUS) may improve the diagnostic accuracy for prenatal diagnosis of skeletal dysplasia.⁹²⁻¹⁰⁴ The rationale for this expectation is that the availability of rendering algorithms to reconstruct the fetal skeleton may allow the observation of phenotypic features not detectable by 2DUS. For example, Garjian et al.⁹⁵ and Krakow et al.¹⁰² reported on the diagnosis of additional facial^{95,102} and scapular anomalies,⁹⁵ as well as abnormal calcification patterns¹⁰² in fetuses with skeletal dysplasias. Moeglin and Benoit,⁹⁸ on the other hand, used the multiplanar visualization method to demonstrate the pointed appearance of the

upper femoral diaphysis in achondroplasia. Three-dimensional reconstruction of the fetal bones is best performed using the maximum intensity projection mode, a rendering algorithm that prioritizes the display of voxels with the highest gray levels contained within a region of interest selected by the user^{95,98} (Fig. 12-14). If the fetus is

examined early enough in the pregnancy, the entire skeleton can be included within the region of interest, and therefore, panoramic visualization can be achieved.⁹⁵ However, the diagnosis may still be missed, because the phenotypic characteristics of some skeletal dysplasias do not manifest until later in pregnancy. Case reports and small series of skeletal

dysplasias have been published describing phenotypic characteristics or skeletal features for which 3DUS may provide additional information (Table 12–9).^{93,95–98,100–103,105}

Three-dimensional helical computerized tomography (3DHCT) has recently been proposed as an adjunctive imaging modality for the prenatal diagnosis of skeletal dysplasias (Fig. 12–15).¹⁰⁶ Like 3DUS, postprocessing techniques such as maximum intensity projection, surface rendering, and volume rendering can be used for three-dimensional reconstruction.^{107–109} Long bone measurements obtained by postmortem helical CT studies have been compared with those obtained within 24 hours of delivery by ultrasound, and a significant correlation between the two methods was observed.¹¹⁰ Excellent panoramic images of the fetal skeleton can be obtained by 3DHCT without superimposition of the maternal skeleton (which occurs with radiography). Ruano et al¹⁰⁶ compared the phenotypic characteristics of three skeletal dysplasias [achondroplasia (n=3), OI (n=2), and chondrodysplasia punctata (n=1)] visualized by prenatal 3DHCT, 3DUS, and 2DUS. Deformation of the fetal pelvis and an increase in the intervertebral space of the lumbar vertebrae were diagnosed more often using 3DHCT than 2DUS and 3DUS. In

contrast, some phenotypic characteristics of fetuses with skeletal dysplasias were demonstrated only by ultrasound: phalangeal hypoplasia, point-calcified epiphysis (both by 2DUS and 3DUS), and facial dysmorphism (by 3DUS only). Although the overall count of correct phenotypic characteristics detected prenatally favored 3DHCT over 3DUS (94.3% [33/35] versus 77.1% [27/35], $p=0.03$, McNemar's test for correlated samples), the diagnostic performance of 3DHCT was not superior to that of 3DUS, because the correct prenatal diagnosis was established by both modalities in all cases. Provided that the two diagnostic methods have comparable diagnostic accuracy, 3DUS has two important advantages over 3DHCT, namely the lack of radiation exposure and wider availability in the clinical setting. It is also noteworthy that the overall experience with 3DUS for the diagnosis of skeletal dysplasias is still limited.^{92–105,111–116} Nevertheless, even in this study, 3DUS performed better than 2DUS, both in the identification of phenotypic characteristics (77.1% [27/35] versus 51.4% [18/35], $p=0.004$, McNemar's test for correlated samples) and in establishing an accurate diagnosis.

Approach to the Diagnosis of Skeletal Dysplasias

A proposed systematic approach to the prenatal diagnosis of skeletal dysplasias is summarized in Table 12–10 and described in greater detail in the following section.

Evaluation of the Long Bones

Measurements. All long bones should be measured in all extremities. Comparisons with other segments should be performed to establish whether the limb shortening is predominantly rhizomelic, mesomelic, or acromelic, or whether it involves all segments (see Figs. 12–5, 12–6, 12–7, and 12–14). A detailed examination of each bone is necessary

Table 12–8

Accuracy of Prenatal Ultrasound for Diagnosis of Skeletal Dysplasias

Author	Year	Number of Cases	Correct Diagnosis (%)
Gordienko et al ³⁸	1996	26	73 (9)
Caffney et al ⁸⁸	1998	35	31 (11)
Tretter et al ⁹⁰	1998	27	48 (13)
Hersh et al ⁹¹	1998	23	48 (11)
Doray et al ⁸⁹	2000	47	60 (28)
Parilla et al ²⁶	2003	31	65 (20)

FIGURE 12–14. Comparison between the surface rendering mode (A) and the maximum intensity projection mode (B), for the visualization of the fetal leg of a fetus with mesomelic shortening of the long bones. With the surface rendering mode, the external surface of the leg is visualized. By switching the rendering algorithm to maximum intensity projection, only the voxels with the highest intensity are displayed, with clear depiction of the mesomelic shortening of the long bones (the tibia and fibula are proportionately shorter than the femur).

Table 12-9 Additional Phenotypic Findings and Improved Visualization in Cases of Skeletal Dysplasias by Prenatal 3DUS as Compared to 2DUS in Published Reports

Skeletal Dysplasia	Phenotypic Characteristics Identified Better by 3DUS than 2DUS
Platyospondylic lethal chondrodysplasia ⁹³ Campomelic dysplasia ^{95,109,116}	Enhanced visualization of femoral and tibial bowing; Better characterization of the facial soft tissues with surface rendering Micrognathia; Flat face; Hypoplastic scapulae; Bifid foot; Fan-like position of the toes
Thanatophoric dysplasia ^{95-97,102}	Improved characterization of frontal bossing and depressed nasal bridge; Demonstration of redundant skin folds; Low-set dysmorphic ears
Achondroplasia ^{98,102}	Improved characterization of frontal bossing and depressed nasal bridge; Superior evaluation of the epiphyses and metaphyses of the long bones, with demonstration of a vertical metaphyseal slope; Caudal narrowing of the interpedicular distance; Clear visualization of trident hand;
Chondrodysplasia punctata, rhizomelic form ¹⁰²	Better visualization of disproportion between limb segments Improved characterization of the Binder facies (depressed nasal bridge, mid-face hypoplasia, small nose with upturned alae);
Achondrogenesis ¹⁰²	Identification of laryngeal stippling Panoramic demonstration of short neck and severe shortening of all segments of the limbs
Jarcho-Levin syndrome ¹⁰¹	Vertebral defects with absence of ribs and transverse process
Spondylocostal dysostosis ¹¹¹	Fan-like rib cage with rib fusion
Larsen syndrome ¹⁰⁵	Genu recurvatum, midface hypoplasia, low set ears
Cleidocranial dysplasia ¹¹⁵	Widened cranial sutures, poor mineralization of the occipital bones, pseudoarthrosis of the clavicle
Apert syndrome ^{113,114}	Coronal craniosynostosis

2DUS, two-dimensional ultrasound; 3DUS, three-dimensional ultrasound.

Phenotypic characteristics of osteogenesis imperfecta,⁹⁵ short rib–polydactyly syndrome,¹⁰⁰ and Apert's syndrome¹⁰² have also been described using 3DUS, although no additional findings to 2DUS were observed.

to exclude the absence or hypoplasia of individual bones (fibula, tibia, ulna, radius, clavicles, and scapulae).^{85,117-120}

Degree of Mineralization. An attempt should be made to characterize the degree of mineralization. This can be assessed by examining the acoustic shadow behind the bone and the echogenicity of the bone itself. Signs of demineralization include the visualization of an unusually prominent falx and the absence or decreased echogenicity of the spine. It should be stressed that there are limitations for the sonographic evaluation of mineralization of long bones and that other structures, such as the skull, may be better suited for this assessment (Fig. 12-16).

Degree of Long Bone Curvature. At present, there is no objective means of assessing long bone curvature, and experience is the only tool assisting the operator in discerning the boundary between normality and abnormality. Campomelia (excessive bowing, Fig. 12-17) is characteristic of certain disorders (e.g., campomelic dysplasia).

Metaphyseal Flaring. Metaphyseal flaring denotes widening at the level of the metaphyseal growth plate. It can be observed in many conditions, including achondroplasia, hypochondroplasia, hypochondrogenesis, asphyxiating thoracic dysplasia, chondrodysplasia punctata, diastrophic dysplasia, hypophosphatasia, Kniest dysplasia, kyphomelic dysplasia, metatropic dysplasia, and OI.¹²¹

Fractures. The possibility of fractures should be considered, because they can be present in some conditions

(e.g., OI, Fig. 12-18). The fractures may be extremely subtle, or may lead to angulation and separation of the segments of the affected bone (Fig. 12-19).

Prediction of Pulmonary Hypoplasia

Several skeletal dysplasias are associated with a hypoplastic thorax. This is extremely important because chest restriction leads to pulmonary hypoplasia, a frequent cause of death in these conditions (see Table 12-4). When a severe skeletal dysplasia is diagnosed, the presence of marked thoracic involvement and pulmonary hypoplasia will allow the clinician to counsel the parents regarding prognosis despite the fact that the specific type of dysplasia may not be known. A number of ultrasonographic parameters have been investigated for the prediction of pulmonary hypoplasia. These include measurements of the thorax and lungs, ratios between thoracic measurements and other biometric parameters, Doppler velocimetry of the pulmonary arteries, Doppler evaluation of tracheal fluid flow, and more recently, three-dimensional volumetric measurements of the fetal lungs by either ultrasound or magnetic resonance imaging (MRI).

Evaluation of Thoracic and Lung Dimensions by Two-Dimensional Ultrasound. Thoracic and lung biometry have been extensively studied to identify fetuses at high risk for pulmonary hypoplasia.¹²²⁻¹³³ Table 12-11 lists skeletal

FIGURE 12-15. Comparison of phenotypic features of osteogenesis imperfecta by three-dimensional helical computer tomography (3DHCT), three-dimensional ultrasound (3DUS), two-dimensional ultrasound (2DUS), and postmortem radiographs. Prenatal diagnosis of osteogenesis imperfecta at 33 weeks of gestation by 2D-US, 3D-US, and 3-HCT. *A.* 2DUS: transverse section of fetal head with a skull fracture (f) deformed due to the transducer pressure. *B.* 2DUS: coronal section of fetal thorax showing irregular ribs (arrow). *C.* 2DUS: sagittal section of the right arm showing a short and bowed arm (f). *D.* 2DUS: sagittal section of fetal femur with a fracture (f). *E.* 3DUS: three-dimensional rendered bone mode image showing lateral view of fetal skull with a fracture (f) that could be differentiated from a normal coronal suture (CS) by the location and the deforming aspect depending on the transducer pressure; this was confirmed at postmortem examination. *F.* 3DUS: rendered bone mode demonstrating posterior view of fetal thorax showing fractured and irregular ribs (f). *G.* 3DUS: rendered bone mode image showing short and bowing radius and cubitus (f). *H.* 3DUS: rendered bone mode image showing a fractured femur (f). *I.* 3DHCT: posterior view of entire fetus confirming fractures of ribs and femur (f) as well as decreased mineralization of the skull. *J.* Postmortem radiologic examination, confirming shortening, bowing and fracture of long bones. (From Ruano R, Molho M, Roume J, et al: Prenatal diagnosis of fetal skeletal dysplasias by combining two-dimensional and three-dimensional ultrasound and intrauterine three-dimensional helical computer tomography. *Ultrasound Obstet Gynecol* 24:134, 2004.)

dysplasias associated with altered thoracic dimensions, whereas Figures 12-20 and 12-21 illustrate features associated with a hypoplastic thorax.

Methods used to measure the bony thorax, chest, lungs, and heart by 2DUS are illustrated in Figure 12-22. Thoracic dimensions in fetuses with known gestational age can be evaluated by the nomograms reproduced in Tables 12-12 and 12-13. When gestational age is uncertain, age-independent ratios, such as the thoracic-to-abdominal circumference ratio (normal value: 0.77 to 1.01) and the thoracic-to-head circumference ratio (normal value: 0.56 to 1.04) can be used.¹²³

A summary of the diagnostic accuracy of biometric parameters for the diagnosis of pulmonary hypoplasia is presented in Table 12-14.^{124-130,133-139} Of particular interest are the measurements of the right lung diameter or the ratio between right lung diameter/bony thoracic circumference proposed by Merz et al.¹³¹ In a study of 32 fetuses with a postnatal diagnosis of pulmonary hypoplasia (skeletal dysplasias [n = 7], renal agenesis [n = 11], diaphragmatic hernia [n = 7], and hydrothorax [n = 2]), all had a right lung diameter below the 5th percentile for age, regardless of the primary disorder.¹³⁶ In a subsequent study of 19 fetuses with

congenital diaphragmatic hernia, Bahlmann et al¹³⁷ demonstrated that the ratio of right lung diameter/bony thoracic circumference detected all fetuses with pulmonary hypoplasia with 100% sensitivity and 100% specificity.

Short Femur Length and Prediction of Lethality in Skeletal Dysplasias. Rahemtullah et al¹⁴⁰ studied 18 cases of skeletal dysplasias, and all lethal cases were associated with a femur length/abdominal circumference ratio of 0.16. Although the test detected lethal cases with 100% sensitivity, two cases of achondroplasia were erroneously identified as lethal with this method. A less pragmatic approach has been proposed by Hersh et al,⁹¹ who were able to predict lethality in 23 out of 25 cases of skeletal dysplasias with a femur length below the first percentile for age, after combining this information with other sonographic findings (i.e., bell-shaped thorax, decreased bone echogenicity, or both).

Lung Volumetry by Three-Dimensional Ultrasound
Fetal lung volumetry by 3DUS has been performed using two techniques: multiplanar¹⁴¹⁻¹⁴⁶ (Fig. 12-23) and VOCAL (Virtual Organ Computer-Aided AnaLysis, GE Medical Systems, Milwaukee, Wisconsin) (Fig. 12-24).¹⁴⁷⁻¹⁵⁴ Nomograms for lung volumetry by 3DUS have been proposed by several investigators.^{141-143,149,152,153,155,156}

Table 12-10

Steps for Examination of the Fetus With a Suspected Skeletal Dysplasia by Two-Dimensional and Three-Dimensional Ultrasound

1. Measure all long bones
2. Compare with other segments and classify the limb shortening as:
 - a. Rhizomelia
 - b. Mesomelia
 - c. Acromelia
 - d. Severe micromelia
3. Qualitative assessment of long bones:
 - a. Demineralization
 - b. Fractures
 - c. Bowing
 - d. Metaphyseal flaring
 - e. Absence of bones
4. Measure chest dimensions to determine risk of pulmonary hypoplasia
5. Evaluation of hands and feet
 - a. Digits (polydactyly/syndactyly)
 - b. Positional deformities
6. Evaluation of the cranium
 - a. Macrocrania
 - b. Frontal bossing
 - c. Cloverleaf skull
 - d. Hypertelorism/Hypotelorism
7. Facial clefts
8. Examination of the spine
 - a. Platyspondyly
 - b. Demineralization
 - c. Hemi vertebrae
 - d. Coronal clefts
 - e. Vertebral disorganization
9. Evaluation of internal organs, including echocardiography
10. Fetal motion
11. Amniotic fluid volume

FIGURE 12-16. Demineralization of the skull in a case of osteogenesis imperfecta. The lateral ventricle and choroid plexus in the near field are well seen due to lack of normal mineralization of the calvarium. Normally reverberation artifact from the calvarium would obscure these structures.

Kalache et al¹⁴⁷ demonstrated that both the 3D multiplanar and 3D VOCAL modes can be used to measure pulmonary volumes in fetuses, an observation that was subsequently confirmed by Moeglin et al.¹⁵² A potential advantage of the VOCAL technique is the possibility of obtaining fine contours of the lungs, which may be particularly valuable when the outline of the organ in question is irregular, such as in cases of congenital diaphragmatic hernia. In contrast, lung volume measurements obtained by the 3D multiplanar technique are faster, taking usually less than 5 minutes to perform.¹⁵² Volumes are best estimated when datasets are acquired using a transverse view of the fetal thorax.^{143,153} Ruano et al¹⁵⁴ compared volumetric measurements of the fetal lungs obtained using the VOCAL method and the actual volume at autopsy in eight cases of congenital diaphragmatic hernia and 25 controls without pulmonary malformations. The mean relative error of 3DUS to estimate the actual lung volume was -7.19% (range: -42.70% to +18.11%) in cases of congenital diaphragmatic

FIGURE 12-18. A. Three-dimensional ultrasonography in a case of osteogenesis imperfecta type II. The volume dataset was rendered using the maximum intensity (skeletal) mode. Multiple fractures in the ribs are present. Note the severe bowing and shortening of the left femur (F) and humerus (H). (B) Sonogram of a fetus with osteogenesis imperfecta type II. The femur is markedly shortened (arrow) with multiple fractures.

FIGURE 12-19. In utero fracture in a case of osteogenesis imperfecta. The arrows indicate the hypoechoic fracture line.

Table 12-11

Skeletal Dysplasias Associated With Altered Thoracic Dimensions

Long, narrow thorax
Asphyxiating thoracic dysplasia (Jeune)
Chondroectodermal dysplasia (Ellis-van Creveld)
Metatropic dysplasia
Fibrochondrogenesis
Atelosteogenesis
Camptomelic dysplasia
Jarcho-Levin syndrome
Achondrogenesis
Osteogenesis imperfecta congenital
Hypophosphatasia
Dyssegmental dysplasia
Cleidocranial dysplasia
Short thorax
Osteogenesis imperfecta (type II)
Kniest's dysplasia (metatropic dysplasia type II)
Pena-Shokeir syndrome
Hypoplastic thorax
Short rib-polydactyly syndrome (type I, type II)
Thanatophoric dysplasia
Cerebrocostomandibular syndrome
Cleidocranial dysplasia syndrome
Homozygous achondroplasia
Melnik-Needles syndrome (osteodysplasty)
Fibrochondrogenesis
Otopalatodigital syndrome type II

hernia and -0.72% (range: -30.25% to +19.22%) in normal fetuses.

We have recently compared the diagnostic efficiency of lung volume measurements by 3DUS with that of biometric parameters measured by 2DUS in the identification of lethal pulmonary hypoplasia in 41 fetuses with musculoskeletal disorders (see Table 12-14). Lethal pulmonary hypoplasia was diagnosed in 34.1% of cases (14/41). Ninety-three

percent (13/14) of the fetuses with pulmonary hypoplasia had lung volumes below the 5th percentile for gestational age; however, because the number of false-positive diagnoses was too high (48.1% [13/27]), the test is unlikely to be clinically useful. The parameters with the highest diagnostic efficiency to predict lethal pulmonary hypoplasia in this population were (1) the right lung diameter (sensitivity 71.4% [10/14], specificity 92.6% [25/27], positive-predictive value

FIGURE 12-20. Longitudinal section of a fetus with thanatophoric dysplasia. Note the significant disproportion between the chest and abdomen.

FIGURE 12-21. Extremely short ribs in a fetus with short rib-polydactyly syndrome.

83.3% [10/12], negative predictive value 86.2% [25/29], and diagnostic efficiency 85.4% [35/41]); (2) thoracic circumference/abdominal circumference ratio (sensitivity 85.7% [12/14], specificity 85.2% [23/27], positive-predictive value 75.0% [12/16], negative predictive value 92.0% [23/25], and diagnostic efficiency 85.4% [35/41]); and (3) the femur length/abdominal circumference ratio (sensitivity 85.7% [12/14]), specificity 85.2% [23/27], positive-predictive value 75.0% [12/16], negative predictive value 92.0% [23/25], and diagnostic efficiency 85.4% [35/41]).

Evaluation of Lung Volume or Signal Intensity by Magnetic Resonance Imaging. Parameters proposed to evaluate lung volume by MRI include the relative lung volume (ratio of observed over expected lung volume), lung volume over estimated fetal weight ratio (LV/EFW), and the lung over spinal fluid signal intensity ratio (L/SF).¹⁵⁷⁻¹⁶⁴

FIGURE 12-22. A to F Illustration of the various methods to measure thoracic, lung, and heart dimensions.

Rypens et al¹⁵⁷ determined normal lung volume biometry across gestational age in 336 fetuses with normal lungs. Normal fetal lung volume increased with gestational age. There was, however, a constant ratio between the volume of the left and right lung volumes, with right lung volume accounting for 56% of the total fetal lung volume. MRI volumes corresponded to 90% of the volumes measured by pathologic examination.

Williams et al¹⁶⁰ calculated relative lung volume in a group of 91 fetuses with sonographically normal lungs and compared the measurements to 28 fetuses at risk for pulmonary hypoplasia. The mean relative lung volume was significantly smaller in the group of fetuses at risk for pulmonary hypoplasia ($34\% \pm 15\%$ versus $102\% \pm 17\%$, $p < 0.001$). Tanigaki et al¹⁶¹ compared the diagnostic performance of LV/EFW determined by MRI to three ultrasonographic parameters commonly used to assess the risk of pulmonary hypoplasia at birth. In a population of 17 fetuses at risk for pulmonary hypoplasia, a FLV/EFW below the 5th percentile for age was the most accurate diagnostic parameter.

Signal intensity ratios to predict lung hypoplasia have also been evaluated.¹⁶²⁻¹⁶⁴ Kuwashima et al.¹⁶² proposed that the lungs of fetuses with pulmonary hypoplasia would have low intensity signals, as opposed to fetuses with normal lung development. Osada et al¹⁶³ compared LV/EFW between 58 normal fetuses and 29 fetuses at risk for pulmonary hypoplasia. In addition to LV/EFW, the authors also evaluated lung signal intensities expressed as a proportion of the spinal fluid signal intensity lung/spinal fluid (L/SF). Although diagnostic indices were not reported in this study, ROC analysis showed that simultaneous

*All fetuses had pulmonary hypoplasia

[†]Case-control study; all fetuses in the column "Fetuses at risk" had pulmonary hypoplasia; 30 gestational age-matched control fetuses were studied.

[‡]Only papers for which data to calculate at least the sensitivity were included.

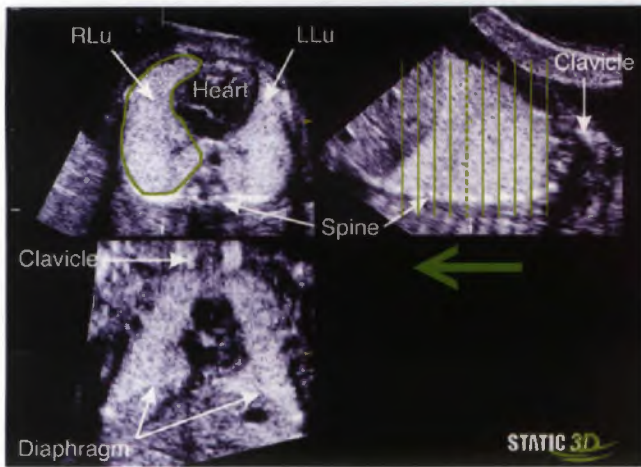

FIGURE 12-23. Three-dimensional fetal lung measurements using the multiplanar technique. Illustration of the image sequences (green vertical lines) used to obtain transverse views of the lung. The right lung (RLu) is outlined. Fetal lung volume is obtained by scrolling through the transverse plane (green arrow). LLu, left lung. (From Kalache KD, Espinoza J, Chaiworapongsa T, et al: Three-dimensional ultrasound fetal lung volume measurement: a systematic study comparing the multiplanar method with the rotational (VOCAL) technique. *Ultrasound Obstet Gynecol* 21:111, 2003.)

measurement of fetal lung volume and signal intensity by MRI had an area under the curve of 0.990 to predict lung hypoplasia, compared with 0.930 and 0.955 for lung volume or L/SF ratio alone. Keller et al¹⁶⁴ evaluated signal intensities of lung/liver, lung/amniotic fluid, lung/muscle, liver/fluid, and liver/muscle for the prediction of lung hypoplasia. In contrast to the study of Osada et al,¹⁶³ these signal intensity ratios did not differ significantly from those in the normal population.

Doppler Assessment of Tracheal Fluid Flow. Kalache et al¹⁶⁵ have proposed that the volume of lung fluid displaced in the trachea could be useful for the analysis of fetal lung function. The investigators tested this hypothesis in a case-control study that included six cases of congenital diaphragmatic hernia diagnosed prenatally and a control group of five healthy fetuses matched for gestational age to each case. Parameters analyzed included (1) the length of the inspiratory phase; (2) the length of the expiratory phase; (3) the peak velocities during inspiration and expiration; and (4) the volume estimation of the displaced fluid in the trachea during breathing (calculated as volume = velocity time integral [VTI] $\times \pi \times [d \times 0.5]^2$). The estimated breathing-related tracheal volume flow in uncomplicated pregnancies increased with gestational age (from 0.21 ± 0.10 ml/ breath at 26 weeks to 1.37 ± 0.48 ml/ breath at 36 weeks of gestation), and was significantly lower in fetuses with diaphragmatic hernia who died of pulmonary hypoplasia. Tracheal volume flow in survivors was comparable to controls.

Doppler Velocimetry of the Pulmonary Arteries. Underdevelopment and structural changes of the pulmonary vascular bed in cases of pulmonary hypoplasia may result in increased pulmonary vascular resistance and reduced pulmonary arterial compliance.¹⁶⁶ Therefore, several investigators have attempted to use Doppler measurements of the pulmonary arteries and of its branches in an attempt to

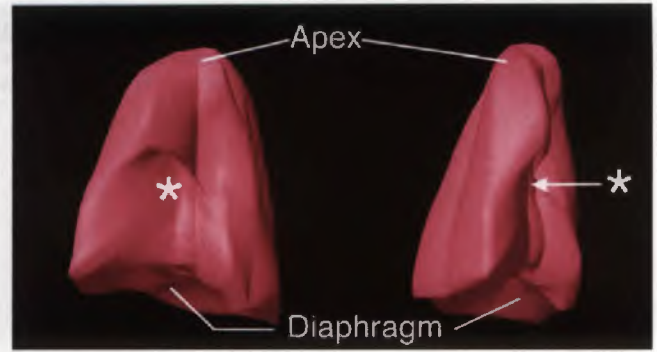

FIGURE 12-24. Three-dimensional model of the right lung volume obtained using VOCAL. Note the indentation of the fetal heart (asterisk). The frontal view is shown on the left and the lateral view on the right. (From Kalache KD, Espinoza J, Chaiworapongsa T, et al: Three-dimensional ultrasound fetal lung volume measurement: a systematic study comparing the multiplanar method with the rotational (VOCAL) technique. *Ultrasound Obstet Gynecol* 21:111, 2003.)

identify fetuses at risk for pulmonary hypoplasia.^{139,167-171} Mitchell et al¹⁶⁷ evaluated the resistance index of the peripheral pulmonary arteries for the prediction of pulmonary hypoplasia in 10 fetuses with bilateral multicystic dysplastic kidneys. The resistance index of the peripheral pulmonary arteries was above the 95th percentile for gestational age in 80% of the cases with pulmonary hypoplasia.

Subsequent studies have yielded contradictory results. Achiron et al¹⁶⁸ found that the pulsatility index of the peripheral pulmonary arteries were within normal limits in four fetuses with proven pulmonary hypoplasia, suggesting that the PI of the lung circulation would be a poor test to predict lung hypoplasia. Chaoui et al¹⁶⁹ reported that only six of nine fetuses with lung hypoplasia had an elevated pulsatility index in the main branches of the left and right pulmonary arteries. Similarly, Laudy et al¹³⁹ studied 40 fetuses at risk for pulmonary hypoplasia and found that Doppler velocimetry indices of the proximal and middle pulmonary branches were not better than chest biometry to predict pulmonary hypoplasia.

In contrast, Yoshimura et al¹⁷⁰ reported low peak systolic velocities in four out of five fetuses, and increased pulsatility index in five out of five fetuses with confirmed pulmonary hypoplasia (thanatophoric dysplasia [n = 2], nonimmune hydrops [n = 2] and bilateral renal agenesis [n = 1]). Rizzo et al,¹⁷¹ in a population of 20 fetuses with prolonged preterm premature rupture of the membranes, found that an elevated pulsatility index in a peripheral pulmonary artery observed 2 weeks after membrane rupture detected the subsequent development of pulmonary hypoplasia with a sensitivity of 62.5%, specificity of 94.6%, positive predictive value of 83.3%, and negative predictive value of 78.5%. Finally, Fuke et al¹⁷² proposed the use of acceleration time/ejection time at the main branches of the pulmonary arteries to identify fetuses at risk for pulmonary hypoplasia. The normal ratio is 0.17 ± 0.04 for the right and 0.15 ± 0.04 for the left pulmonary arteries, and this ratio does not change with gestational age. The test correctly identified five of six fetuses with pulmonary hypoplasia among the 17 fetuses at risk. All 11 normal fetuses had a normal acceleration time/ejection time of the pulmonary arteries.

FIGURE 12-25. Three-dimensional rendered volume using the maximum intensity (skeletal) mode showing postaxial polydactyly (arrow).

Evaluation of Hands and Feet

Hands and feet should be examined to exclude polydactyly (Fig. 12-25), brachydactyly, and extreme postural deformities such as those seen in diastrophic dysplasia. Table 12-15 shows a nomogram of the fetal foot size throughout gestation. Table 12-16 displays disorders associated with hand and foot deformities. Disproportion between hands and feet and the other parts of the extremity may also be a sign of a skeletal dysplasia. Figure 12-26 illustrates the relationship between femur and foot length. The femur length/foot length ratio is nearly constant from 14 to 40 weeks of gestation, with a mean value of 0.99 ± 0.06 (standard deviation). A ratio below 0.87 is considered abnormal.¹⁷³ Although fetuses with skeletal dysplasias have been reported to have abnormally low ratios, more experience is required to establish the diagnostic value of this method.¹⁷⁴ It is expected that a small proportion of normal fetuses may have an abnormal ratio. As in the case of other limb biometric parameters, large deviations from the lower limit of normal are likely to be significant.

Evaluation of the Fetal Cranium

Several skeletal dysplasias are associated with defects of membranous ossification and, therefore, affect skull bones. Examination of the skull bones may reveal poor ossification (see Fig. 12-16), frontal bossing (Fig. 12-27), or cloverleaf deformity (Fig. 12-28). Table 12-17 presents abnormalities of the skull and face in the different skeletal dysplasias.

Evaluation of the Fetal Face

Sonographic examination of facial features is of major importance in the assessment and diagnosis of fetuses with skeletal dysplasias, because many of these disorders are

FIGURE 12-27. Frontal bossing in a sagittal scan in a fetus with achondroplasia.

associated with typical abnormalities.¹⁷⁵ Sonographic evaluation of the fetal face is easily performed in a high percentage of patients from 16 to 20 weeks of gestation onward. The single most reliable view in detecting facial abnormalities is the sagittal view, because it permits determination of mid-face hypoplasia, which occurs in several skeletal dysplasias, such as thanatophoric dysplasia, achondroplasia, campomelic dysplasia, OI type I, and spondyloepiphyseal dysplasia congenita.^{81,176}

In median clefting, the central portion of the upper lip is absent, and on the midline sagittal view, no upper lip will be demonstrated. In bilateral cleft lip, the midline view will have variable appearance, depending on the amount of residual premaxillary tissue present in the midline. In unilateral cleft lip, the midline sagittal scan may be relatively normal but the parasagittal view will reveal the cleft. Clefts should subsequently be confirmed by imaging the lips in the coronal plane.

Cleft palate occurs in 66% of patients with cleft lip. Isolated cleft palate is more difficult to diagnose with ultrasound because of shadowing of facial bones. 3DUS has been

FIGURE 12-28. Cloverleaf skull in a patient with thanatophoric dysplasia.

shown to be superior to 2DUS for the prenatal diagnosis of cleft lip and palate.¹⁷⁷⁻¹⁷⁹ Potential advantages of 3DUS over 2DUS include (1) a true coronal view of the lips can be displayed, even when the original scanning plane was obtained from a different orientation; (2) 3D standardized multiplanar imaging makes it easier to successfully demonstrate the maxillary tooth-bearing alveolar ridge in suspected cases; and (3) the maxillary tooth-bearing alveolar ridge can be more accurately localized by multiplanar technique because this region can be easily mistaken for the mandibular ridge.^{180,181} Rendered views of the cleft lip/palate have been described as being particularly useful for patient counseling.^{180,182,183} A novel technique for visualization of the fetal palate, called the 3D reverse face view, has recently been proposed for the antenatal characterization of facial clefting, in particular clefting of the hard palate.¹⁸⁴ This technique consists of rotating the volume dataset 180 degrees around the vertical axis in order to examine the secondary palate. Campbell et al¹⁸⁵ reported preliminary results of this technique in eight cases of suspected orofacial clefting. A cleft in the soft palate was missed in only one case.

Micrognathia is also frequently observed in cases of skeletal dysplasia (Table 12-18).¹⁸⁶⁻¹⁸⁸ In an attempt to provide an objective tool to diagnose micrognathia prenatally, Palladini et al¹⁸⁹ proposed the jaw index, which is computed as the ratio between the anteroposterior mandibular diameter and the biparietal diameter. In a population of 198 malformed fetuses, 11 of which had micrognathia at necropsy or at birth, a jaw index below 23 correctly identified all cases of micrognathia with a false-positive rate of 2%. Rotten et al¹⁹⁰ proposed two parameters to differentiate between retrognathia and micrognathia: the inferior facial

FIGURE 12-29. Inferior facial angle. The inferior facial angle is defined as the angle between two lines traced on a sagittal profile view of the fetal face: (1) a reference line, orthogonal to the vertical part of the forehead, at the level of the synostosis of the nasal bones; and (2) the profile line, joining the tip of the mentum to the anterior border of the more protruding lip.

angle (Fig. 12-29), and the mandible width (MD/MX) ratio (Fig. 12-30). The inferior facial angle is used to diagnose retrognathia. It is defined as the angle between two lines traced on a sagittal profile view of the fetal face: (1) a reference line, orthogonal to the vertical part of the forehead, at the level of the synostosis of the nasal bones; and (2) the profile line, joining the tip of the mentum to the anterior border of the more protruding lip. In a population of fetuses at high risk for facial anomalies, an inferior facial angle less than 50 degrees identified retrognathia with a sensitivity of 100% and a specificity of 98.9%. The MD/MX ratio is computed using transverse sections of the mandible and maxilla, with the actual measurements performed 10 mm posteriorly to the anterior osseous border. An MD/MX ratio less than 0.785 between 18 and 28 weeks of gestation correctly identified micrognathia in three cases of Treacher Collins syndrome.

Intraorbital and interorbital diameters should also be measured, because hypertelorism may occur in cases of skeletal dysplasia (Table 12-19).

Evaluation of the Fetal Spine

Sonographic assessment of the fetal spine is another component of the examination of fetuses with suspected skeletal dysplasias. The following parameters should be assessed:

Vertebral Bodies. Fetal vertebral bodies are composed of three ossification centers representing the vertebral body and two laminae.¹⁹¹⁻¹⁹⁴ Abnormalities of the ossification centers of the fetal vertebral body may result in bony defects, such as hemivertebrae (see Fig. 12-11), butterfly vertebrae, or block vertebrae causing congenital scoliosis (see Figs. 12-9 and 12-10). A study of the associated anomalies

FIGURE 12-30. Mandible/maxilla (MD/MX) ratio. The MD/MX ratio is calculated using transverse sections of the mandible (B) and maxilla (A), with measurements performed 10 mm posteriorly to the anterior osseous border.

in 27 cases of prenatally detected hemivertebrae noted that, although 11 fetuses had no other abnormal findings, 16 had additional associated anomalies.¹⁹¹ These included cardiac, gastrointestinal, renal, facial, extremity, and cranial anomalies. Seven fetuses had bilateral renal agenesis (Potter sequence). Only five of the fetuses with additional anomalies survived. Usually these anomalies are not a risk factor for aneuploidy. Rib defects are often associated with thoracic vertebral body anomalies.

Platyspondyly may be diagnosed with current high-resolution sonography (see Fig. 12-8).¹⁹⁵ Objective evaluation may be performed by computing a ratio between measurements of the vertebral interspace to vertebral body height.⁵³

Clefting of the vertebrae may be complete or incomplete, or coronal or sagittal.⁶³ Coronal vertebral clefts are a result of missed fusion between the anterior and posterior primary ossification centers beyond 16 weeks of gestation, and can be observed by sonography in utero.^{196,197} Sagittal clefts in the vertebral bodies are believed to represent localized splitting of the notochord due to adhesions between ectoderm and endoderm during the embryonic period. The role of vertebral clefting in the diagnosis of skeletal dysplasias was assessed by searching the database at the International Skeletal Dysplasia Registry in a study conducted by Westvik and Lachman.¹⁹⁷ Coronal and sagittal clefts were present in 40 different conditions. Coronal clefts were more common than sagittal clefts and were mainly located in the thoracolumbar region. Clefts were most frequently observed in

atelosteogenesis (88%), followed by chondrodysplasia punctata (79%), dyssegmental dysplasia (73%), Kniest dysplasia (63%), and short rib-polydactyly syndrome (SRPS) (53%).¹⁹⁷ The authors concluded that vertebral clefts are of major diagnostic value in these groups of skeletal dysplasias.

Spinal Curvature. The most common osseous anomaly causing scoliosis is unilateral unsegmented bar with contralateral hemivertebrae.^{191,198-201} Spinal dysraphism may occur with congenital scoliosis, and this possibility should be examined carefully. An apparent etiologic relationship exists between neural tube defects and other vertebral anomalies. Siblings of infants with congenital scoliosis have a 4% risk of neural tube defects.²⁰² This increased risk is present in siblings of children with a single hemivertebrae, as well as multiple vertebral anomalies (with or without neural arch defects). The differential diagnosis of fetal scoliosis includes neural tube defects, large abdominal wall defects, amniotic band syndrome, caudal regression, and hemivertebrae. Nonossification of the lumbar vertebral bodies has been detected in achondrogenesis and other diseases.²⁰³⁻²⁰⁵

Evaluation of the Internal Organs

A detailed examination of the cardiovascular, genitourinary, gastrointestinal, and central nervous system (CNS) organs should be performed in all fetuses with skeletal anomalies. Some syndromes present with specific abnormalities of the internal organs, thus helping in the differential diagnoses of these entities. For example, congenital heart disease is a prominent feature of Ellis-van Creveld syndrome²⁰⁶ and Holt-Oram syndrome.²⁰⁷

Newborn Evaluation

Even when all efforts have been made to establish an accurate prenatal diagnosis, a careful study of the newborn is always required.⁸⁷ The evaluation should include a detailed physical examination performed by a geneticist or an individual with experience in the field of skeletal dysplasias and radiographs of the skeleton. The radiographs should include anterior, posterior, lateral, and Towne views of the skull, as well as anteroposterior views of the spine, extremities, and scapula,²⁰⁸ with separate films of hands and

feet. Examination of the skeletal radiographs will permit precise diagnoses in a large proportion of cases, because the classification of skeletal dysplasias is largely based on radiographic findings. In lethal skeletal dysplasias, histologic examination of the chondro-osseous tissue should be performed, because this information may help the physician reach a specific diagnosis. Chromosomal studies should be included, because there is a specific group of constitutional bone disorders associated with cytogenetic abnormalities. Biochemical studies are helpful in some cases (e.g., hypophosphatasia). DNA restriction and enzymatic activity assays should be considered if the phenotype suggests a metabolic disorder (e.g. mucopolysaccharidosis). Molecular diagnosis can be performed for disorders in which a specific genetic mutation has been identified, and it is recommended that DNA be saved in all cases.^{24,25,209}

Increased Nuchal Translucency and Skeletal Dysplasia

In chromosomally normal pregnancies, nuchal translucency (NT) thickness is associated with an increased risk of major anomalies,²¹⁰⁻²¹³ including skeletal dysplasias.^{101,213-217} For example, in the multicenter screening project for trisomy 21 using the combination of maternal age and NT, 100,000 pregnancies were included, and an association between nuchal translucency and a wide range of skeletal dysplasias was found among these patients.²¹⁰ In addition, several case reports and small series have also suggested that in chromosomally normal fetuses an association may exist between increased NT thickness and skeletal anomalies. Table 12-20 summarizes these data.

OSTEOCHONDRODYSPLASIAS

A growing number of skeletal dysplasias have been recognized in utero, and a complete account of each disorder is

beyond the scope of this chapter. The following discussion presents only a few of the most common disorders relevant to prenatal diagnosis.

Achondroplasia, Thanatophoric Dysplasia, and Hypochondroplasia

Achondroplasia, thanatophoric dysplasia, and hypochondroplasia are discussed in the same section, because these disorders are caused by different mutations in the fibroblast growth factor receptor-3 (*FGFR3*) gene.²¹⁸⁻²²⁵ Mutations in *FGFR3* are gain-of-function mutations that produce a constitutively active protein capable of initiating intracellular signal pathways in the absence of ligand binding.^{226,227} This activation leads to premature maturation of the bone.²²⁷ The critical clinical difference between thanatophoric dysplasia and achondroplasia/hypochondroplasia is severe shortening of the ribs in thanatophoric dysplasia, resulting in restricted lung volumes, respiratory insufficiency, and death within hours or days.²²⁸

Achondroplasia

The most common nonlethal skeletal dysplasia is achondroplasia, an autosomal-dominant condition with complete penetrance and an estimated prevalence ranging from 1:10,000 to 1:50,000 births.²²⁹⁻²³¹ It is clinically characterized by rhizomelic shortening of the limbs and mild limb bowing, exaggerated lumbar lordosis, and an enlarged head.²³² The bones of the hands and feet are short (brachydactyly). The head is large (macrocephaly), with frontal bossing, midface hypoplasia, a flattened nasal bridge, and a broad mandible. The problems in the prenatal diagnosis of this condition have been discussed in detail by Kurtz and colleagues.²³³ Moreover, Modaff et al²³⁴ provided data about the frequency of prenatal misdiagnosis of achondroplasia and illustrated the difficulty of making this diagnosis.

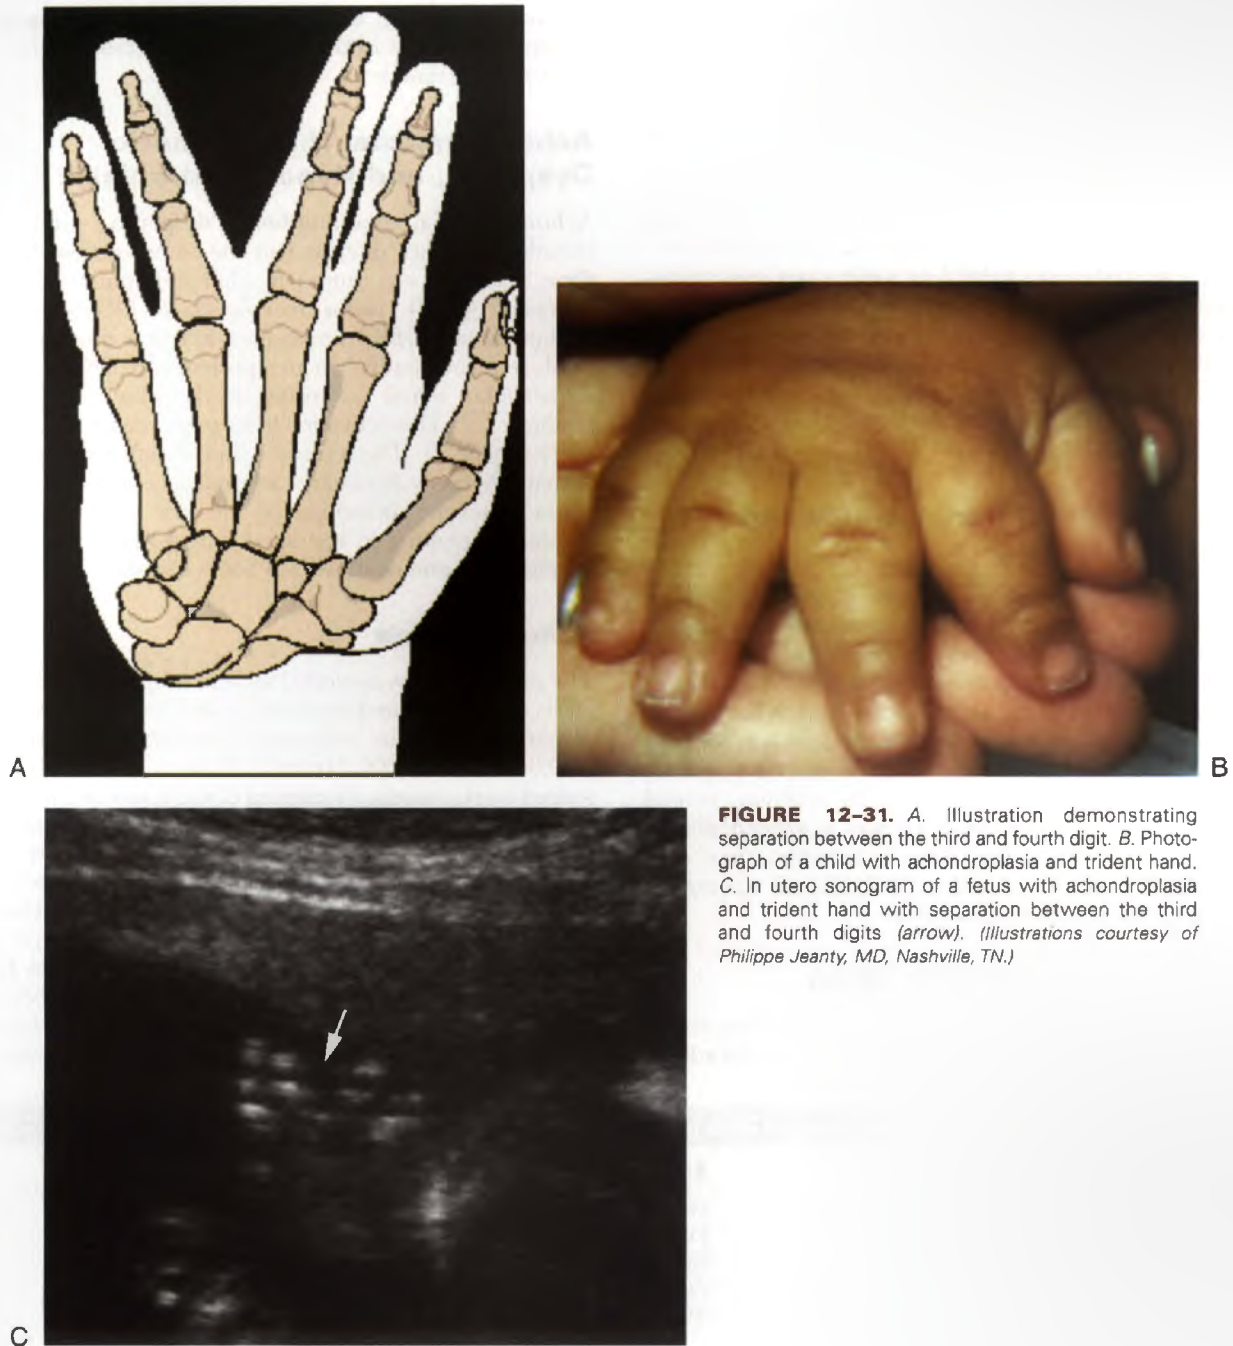

FIGURE 12-31. A. Illustration demonstrating separation between the third and fourth digit. B. Photograph of a child with achondroplasia and trident hand. C. In utero sonogram of a fetus with achondroplasia and trident hand with separation between the third and fourth digits (arrow). (Illustrations courtesy of Philippe Jeanty, MD, Nashville, TN.)

They retrospectively collected data from 37 consecutive referrals of infants with achondroplasia in whom ultrasound was performed prenatally. Nine of the 37 (24%) infants had a positive family history of achondroplasia; all nine were correctly diagnosed prenatally. Of the 28 infants with no family history of achondroplasia, 16 (57%) were recognized to have abnormalities on ultrasound, although none were diagnosed with certainty. Five received an appropriate diagnosis of “most likely” achondroplasia and four others were given a nonspecific (but appropriate) diagnosis of some skeletal dysplasia, not otherwise specified. In seven instances (25%), an incorrect diagnosis of a lethal or very severe disorder was assigned.

The major difficulty in the antenatal diagnosis is that the long bone growth in this disease is not recognized in most cases until the third trimester of pregnancy.^{69,233} However, prenatal diagnosis of achondroplasia is possible and has been reported.²³⁵⁻²³⁸ For example, the trident hand (an increased interspace between the third and fourth digit) is a specific finding for achondroplasia^{239,240} (Fig. 12-31). A distinct difference in the femoral length growth curves of homozygous, heterozygous, and unaffected children of achondroplastic parents was described by Patel et al²⁴¹ Fetuses with homozygous achondroplasia demonstrated early shortening of the femurs less than 3rd percentile at 14.0 to 16.5 weeks, biparietal diameter age (mean 15.6 weeks), whereas the fetuses

with heterozygous achondroplasia were affected later in pregnancy with femoral shortening less than 3rd percentile at 18.2 to 26.2 weeks biparietal diameter age (mean 21.5 weeks).²⁴¹ Recently, Tonni et al²³¹ reported the association of first trimester increased nuchal translucency in a fetus with achondroplasia, and Karadimas et al²⁴² reported a fetus with achondroplasia and multiple craniosynostoses.

More than 99% of the individuals with achondroplasia have one of two mutations in the *FGFR3* gene, which is located on the short arm of chromosome 4 at the 16.3 locus.²⁴³⁻²⁴⁵ The most common mutation is a guanine-to-adenine (G-to-A) transition at nucleotide 1138 in the amino acid 380. About 1% of affected individuals have a guanine-to-cytosine (G-to-C) transversion at the same nucleotide.^{218,246} A point mutation is called transition when a pyrimidine replaces a pyrimidine or a purine replaces a purine, and transversion when a pyrimidine replaces a purine or vice versa.²⁰⁹ The G380R mutation has been shown to result in constitutive activation of the *FGFR3* gene, which inhibits the chondrocyte proliferation and differentiation, and is responsible for the shortness of the long bones. Prenatal diagnosis in pregnancies in which one or both parents have achondroplasia is possible by molecular diagnosis, using chorionic villus sampling (CVS) or amniocentesis.^{238,247,248} Molecular analysis can also identify mutations in fetuses suspected to have achondroplasia based on ultrasound findings, making prenatal diagnosis more effective.

Heterozygous achondroplasia is compatible with a normal life and intellectual development. However, cervicomedullary junction abnormalities, which may lead to compression, put the infant with achondroplasia at risk for lethal sequelae.²⁴⁹ Cervicomedullary decompressive surgery can be life saving by decreasing neurologic complications associated with damage of the spinal cord, and may eliminate the profound central apnea that can cause sudden death.²⁵⁰ In the homozygous state (which occurs in 25% of the offspring of two parents with achondroplasia), the disease is usually lethal during the first 2 years of life.²²⁹ However, a case of survival for 37 months has been reported.²⁵¹ The radiologic characteristics of homozygous achondroplasia lie between those of thanatophoric dysplasia and heterozygous achondroplasia.

Administration of growth hormone (GH) has been proposed for the treatment of achondroplasia.²⁵² With the aim of determining the effectiveness of GH treatment on the short stature of individuals with achondroplasia, Tanaka et al²⁵³ conducted a long-term treatment study in 42 children (16 boys and 26 girls, aged 3 to 14 years) with achondroplasia. After evaluation of the hypothalamic-pituitary function and point mutation analysis, children were treated with GH for over 2 years. Post-treatment growth velocity and body proportion parameters were determined. The annual height gain during GH therapy was significantly greater than that before therapy (3.9 ± 1.0 cm/year before treatment vs 6.5 ± 1.8 cm/year for the first year, and 4.6 ± 1.6 cm/year for the second year of treatment) and body disproportion was not aggravated.²⁵³ However, individual variability in response to GH treatment was observed.²⁵⁴ Other innovative therapeutic approaches have been considered, including down-regulation of the tyrosine kinase activity of the *FGFR3* by selective chemical inhibitors,²³⁰ blocking antibodies to interfere with the binding of FGF ligands to *FGFR3*,²³⁰ and targeted overexpression of C-type natriuretic peptide.²⁵⁵

SADDAN (Severe Achondroplasia With Developmental Delay and Acanthosis Nigricans) Tavormina et al²⁵⁶ identified a *FGFR3* missense mutation in four unrelated individuals with skeletal dysplasias approaching the severity observed in thanatophoric dysplasia type I. Three of the four individuals developed extensive areas of acanthosis nigricans beginning in early childhood, suffered from severe neurologic impairments, and survived past infancy without prolonged life support measures. The *FGFR3* mutation (A1949T:Lys650Met) occurs at the nucleotide adjacent to the thanatophoric dysplasia type II mutation (A1948G:Lys650Glu) and results in a different amino acid substitution. The authors of the study referred to the phenotype caused by the Lys650Met mutation as "severe achondroplasia with developmental delay and acanthosis nigricans" (SADDAN) because it differs significantly from the phenotypes of other known *FGFR3* mutations. SADDAN is also associated with unusual bone deformities, such as femoral bowing with reverse (i.e., posterior apex) tibial and fibular bowing, and so-called ram's horn bowing of the clavicle. This condition has not been associated with cloverleaf skull or craniosynostosis.²⁵⁷

Thanatophoric Dysplasia

Thanatophoric dysplasia is the most common lethal skeletal dysplasia.²⁸ It is characterized by severe rhizomelia, normal trunk length with narrow thorax, and a large head with prominent forehead. It occurs in 0.24 to 0.69 of 10,000 births.^{29,30,220,258} Two subtypes (I and II) have been identified, which are phenotypically differentiated by the skull shape and femur morphology. Type I typically presents with bowed "telephone receiver" femurs²⁵⁹ (Fig. 12-32) and no cloverleaf skull, whereas the type II phenotype is characterized by a severe cloverleaf skull (see Fig. 12-28) and short, straight long bones.^{43,260} Mild cloverleaf skull has been described in patients with the type I subtype.^{259,261,262} Cloverleaf skull may result from premature closure of the coronal and lambdoid sutures, defective development of the cranial base with secondary synostosis, or a primary developmental disorder of the brain with secondary deformation of the skull. The differential diagnosis between the two types depends on the radiographic findings and histology. Both types of thanatophoric dysplasia are inherited in an autosomal-dominant manner. The majority of cases of thanatophoric dysplasia (all type I and most cases of type II) are sporadic. Some familial cases of type II have been reported.²⁶³⁻²⁶⁸

Distinct mutations in the *FGFR3* gene cause each one of the two types of thanatophoric dysplasia.^{229,263,266,269} Three common mutations (R248C, Y373C, and S249C) are found in approximately 90% of the patients with thanatophoric dysplasia type I.^{226,270,271} One mutation, K650E, is found in almost all cases of thanatophoric dysplasia type II.²⁷²⁻²⁷⁴ Camera et al²⁷⁵ reported an individual with the common thanatophoric dysplasia type I mutation and the clinical phenotype of achondroplasia. Although mosaicism was considered as a possible explanation for the milder phenotype, no trace of mosaicism was found in buccal mucosal cells or blood.

Prenatal sonographic findings depend on the specific type of thanatophoric dysplasia.¹⁹⁶ The association between cloverleaf skull and micromelia is specific to thanatophoric

dysplasia. Although campomelic syndrome may be also associated with cloverleaf skull, micromelia is not a feature of that condition. Ventriculomegaly, macrocranium, and polyhydramnios are frequently seen. Cerebellar hypoplasia is observed in approximately 37% of the cases in postnatal series.²²⁸ There is a relatively large calvarium with a prominent forehead (Fig. 12-33), a saddle nose, and hypertelorism. Additional findings include short ribs, platyspondyly (see Fig. 12-8), and short and broad tubular bones in the hands and feet.

Thanatophoric dysplasia is associated with a specific pattern of brain malformations, characterized by megalencephaly (100%), hippocampal dysplasia (100%), rudimentary dentate gyrus (100%), polymicrogyria (97%), enlarged temporal lobes (93%), abnormal deep transverse sulci across

FIGURE 12-33. Prominent forehead (frontal bossing) in a fetus with thanatophoric dysplasia.

the inferomedial temporal lobe (88%), subependymal neuronal heterotopia (81%), and subarachnoid neuroglial heterotopia (79%).²²⁸ This pattern of brain anomalies has been extensively described in the neuropathology literature and has been observed with similar frequency in thanatophoric dysplasia types I and II.²²⁸ Research conducted in mouse models for thanatophoric dysplasia suggests that the cortical malformations observed in thanatophoric dysplasia result from compound disturbances in cortical patterning, proliferation, and apoptosis. The result is gyral pattern abnormalities, regional dysplasia, and altered surface area (especially temporal lobe hyperplasia and premature sulcation).^{228,276,277} Macroscopic gyral abnormalities and enlargement of the temporal lobe probably occur in all cases of thanatophoric dysplasia, and are already present at mid gestation by the time that obstetric ultrasonography is performed.^{228,278}

The differential diagnoses of thanatophoric dysplasia include SRPS, homozygous achondroplasia (in which both parents are typically affected), and asphyxiating thoracic dysplasia (differentiated by slight shortening of the long bones and normal vertebrae). On a review of the radiologic findings of several cases of thanatophoric dysplasia, Horton and colleagues²⁷⁹ were able to discern a group of distinct entities characterized by severe platyspondyly. These disorders include the Torrance, San Diego, Lutton, and Shiraz types of platyspondylic lethal osteochondrodysplasias. Differential diagnosis among these entities is based on histologic and radiologic characteristics. Individuals with platyspondylic lethal skeletal dysplasia-San Diego type have *FGFR3* mutations that have been previously reported in association with thanatophoric dysplasia type I.²⁸⁰

Thanatophoric dysplasia is a uniformly lethal disorder, although survival for several months has been reported in isolated cases.^{268,279,281-284} Prenatal sonographic diagnosis has been documented,^{97,204,285-302} including a case in a triplet pregnancy.¹⁹² Prenatal diagnosis by CVS or amniocentesis is available.^{96,303-305}

Hypochondroplasia

Hypochondroplasia is an autosomal-dominant disorder that resembles achondroplasia,³⁰⁶ although the clinical symptoms and radiologic features in the hypochondroplasia are generally milder than those seen in the achondroplasia. Hypochondroplasia can result from a mutation in the *FGFR3* gene,^{307,308} even though genetic heterogeneity has been suspected.³⁰⁹ The incidence and prevalence of this disorder have not been determined, at least in part because of lack of agreement on a definitive set of diagnostic criteria, which makes it difficult to review data from the many studies reported in the literature. Most cases occur sporadically as a result of a new mutation.³¹⁰

Two *FGFR3* mutations (C1620A and C1620G) result in a lysine for asparagine substitution at codon 540 (N540K) and have been shown to cause hypochondroplasia.^{219,311} Several other *FGFR3* mutations have been proposed to cause a small number of cases of hypochondroplasia. In addition, the IGF-1 gene has been proposed to be linked to hypochondroplasia in a subset of cases, although no pathogenetic mutations have been identified.³⁰⁹

The differential diagnosis between this condition and achondroplasia is based on the spacing of the head and the lack of tibial bowing in hypochondroplasia.^{306,312-316} However, it is noteworthy that medial temporal lobe dysgenesis, similar to that observed in patients with thanatophoric dysplasia, has been recently described in three patients with a C1620A mutation in the *FGFR3* gene.^{317,318} Although this condition is generally first detected during childhood, prenatal diagnosis has been reported in fetuses at risk.^{236,313} Deviation of the fetal growth curve for femur length from the normal values and a normal growth curve for biparietal diameter has been suggested as a potential ultrasonographic marker for the prenatal diagnosis of hypochondroplasia.³¹⁹ DNA-based diagnosis through CVS or amniocentesis may be possible. It has been recommended that molecular analysis should include both the achondroplasia and hypochondroplasia mutations.³²⁰

Fibrochondrogenesis, Atelosteogenesis

Fibrochondrogenesis and atelosteogenesis have a clinical presentation similar to that of thanatophoric dysplasia. The differential diagnosis between these disorders in utero is difficult. Fibrochondrogenesis and atelosteogenesis are extremely rare, and only a few cases of each have been reported.^{63,321-328}

Fibrochondrogenesis

Fibrochondrogenesis is a very rare lethal chondrodysplasia, with only 15 cases reported until now.³²⁹ The first case was described in 1978 by Lazzaroni-Fossati et al.³³⁰ This disorder is inherited in an autosomal-recessive fashion and characterized by micromelia with significant metaphyseal flaring, normal head size, flat face, flattened nasal bridge with anteverted nostrils, prominent eyes, undermineralized skull, platyspondyly, clefting of the vertebral bodies, and a narrow and bell-shaped thorax.^{329,331-333} Metaphyseal flaring is not a feature of thanatophoric dysplasia.^{321,330,334,335} This condition has been described in four consanguineous families.^{322,330,333,336} Other conditions to be considered in the

differential diagnosis include metatropic dysplasia and Kniest dysplasia. Histologic examination is characterized by chondrocytes with fibroblastic appearance and poor endochondral ossification.^{323,333} Prenatal diagnosis of fibrochondrogenesis by ultrasound has been reported as early as 17 weeks of gestation.³²¹⁻³²³ The recurrence risk for fibrochondrogenesis is 25%, which emphasizes the importance of genetic counseling.³²³ At present, the molecular defect involved in fibrochondrogenesis is not known.³³⁷

Atelosteogenesis

Atelosteogenesis includes a heterogeneous group of disorders with overlapping phenotypic features. It is a lethal chondrodysplasia characterized by severe micromelia (with hypoplasia of the distal segments of the humerus and femur), bowing of long bones, flat nasal bridge, cleft palate, micrognathia, narrow chest with short ribs, coronal and sagittal vertebral clefts,⁶³ and dislocation at the level of the elbow and knee. Clubfoot deformities may also be present.³³⁸ Three subtypes of atelosteogenesis have been described based on radiologic and pathologic findings.³³⁹⁻³⁴² Sillence et al³⁴² retrospectively collected data from 17 referrals of fetuses and newborns with atelosteogenesis during a 20-year period. Clinically, all cases had marked limb shortening. Micrognathia, a flattened nasal bridge, and cleft palate were more common in atelosteogenesis type II, as was pulmonary hypoplasia. Talipes was present in 80% of the cases of atelosteogenesis type I. Radiographic findings of atelosteogenesis type I (five cases) showed distal hypoplasia of the femur; the humerus was absent or segment shaped; the radius, ulna, and tibia were bowed; there was absence of the fibula; and all cases had coronal clefts in the lumbar vertebra. In atelosteogenesis type II (11 cases), the femora were shortened with expanded club-like ends and not distally tapered, and the humeri presented with distal hypoplasia and pointing. The forearm was shorter due to distal hypoplasia of the ulnae and proximal hypoplasia of the radii. In the lower limbs, the tibiae were short and bowed, and the fibulae had proximal or distal hypoplasia and pointing. The sacrum was horizontal. All cases had an S-shaped cervical spine. Only one case of atelosteogenesis type III was reported, with distal tapering of the femur and humerus, absence of ossification of the fibula, and an S-shaped cervical spine.³⁴²

Atelosteogenesis types I and III are sporadic and caused by missense mutations in the gene encoding filamin B, a protein that has a role in vertebral segmentation, joint formation, and endochondral ossification.³⁴³ Atelosteogenesis type II is inherited with an autosomal-recessive pattern, and it is caused by a mutation in the diastrophic dysplasia sulfate transporter (DTDST) gene (*SLC26A2*).³⁴⁴⁻³⁴⁷ It overlaps phenotypically and genetically with diastrophic dysplasia and achondrogenesis type IB.^{342,348,349}

Differential diagnoses include diastrophic dysplasia and de la Chapelle dysplasia.^{350,351} Three cases of a lethal dysplasia termed boomerang dysplasia (so-called boomerang-like tibia) may actually represent the same disorder as atelosteogenesis type I.³⁵²

Achondrogenesis

Achondrogenesis, also known as anosteogenesis, is a lethal chondrodysplasia characterized by extreme micromelia, a

short trunk, and macrocrania. The birth prevalence ranges from 0.09 to 0.23 in 10,000 births.^{29,30,84,88,90} Traditionally, this disorder has been classified into two types: the more severe form, which is type I achondrogenesis (Parenti-Fraccaro), and type II achondrogenesis (Langer-Saldino), the less severe form. In 1998, type I was subdivided into two types: type IA (Houston-Harris) and type IB (Fraccaro).^{353,354} And although hypochondrogenesis had been considered a separate disorder from achondrogenesis, evidence now suggests that hypochondrogenesis and achondrogenesis type II are phenotypic variants of the same disorder.³⁵⁵⁻³⁵⁷ Indeed, clinically and radiologically, achondrogenesis type II, hypochondrogenesis, and neonatal spondyloepiphyseal dysplasia congenita form a continuous spectrum of disease.³⁵⁸ The fundamental biochemical disorder seems to be allelic mutations of the gene coding for type II procollagen.³⁵⁹ Whitley and Gorlin proposed a different classification dividing achondrogenesis into four types,³⁵⁹ but their proposal has not gained widespread acceptance.

Type IA achondrogenesis (Houston-Harris) is characterized by micromelia, lack of ossification of vertebral bodies but ossification of the pedicles in the cervical, and an upper thoracic region, and short ribs with multiple fractures. The calvarium is demineralized. Type IB (Fraccaro), which is a recessively inherited chondrodysplasia, is caused by a mutation in the *DTDS* gene³⁶⁰⁻³⁶² and is similar to type IA. The calvarium, however, is ossified, and fractured ribs cannot be seen. Although vertebral bodies are minimally ossified or not at all, the pedicles show some degree of ossification. Type II achondrogenesis is characterized by micromelia, a lack of mineralization of all or many of the vertebral bodies, sacrum, and ischium, an enlarged calvarium with normal ossification, variable shortening of the ribs, and an absence of fractures (Fig. 12-34).³⁶³ Table 12-21 illustrates the characteristics of the different types of achondrogenesis.^{364,365}

Prenatal diagnosis should be suspected on the basis of micromelia, lack of vertebral ossification, and a large head with various degrees of ossification of the calvarium.^{203,363-376} Polyhydramnios and hydrops have been associated with achondrogenesis. However, sonographic examinations of affected fetuses do not demonstrate fluid accumulation in body cavities. The hydropic appearance of these fetuses and neonates is probably attributable to redundancy of soft tissue mass over a limited skeletal frame. An association between cystic hygromas and achondrogenesis has been reported in a fetus with normal chromosomal constitution.^{363,365,377}

Achondrogenesis types IA and IB are inherited in an autosomal-recessive pattern, whereas most cases of achondrogenesis type II and hypochondrogenesis have been sporadic (new autosomal-dominant mutations). Some severe cases of type II achondrogenesis follow an autosomal-recessive pattern.³⁷⁸

The primary defect in achondrogenesis type IA is unknown. The only gene known to be associated with achondrogenesis type IB is *SLC26A2* (*DTDST*), which encodes a sulfate transporter protein.³⁷⁹ Because the basic defect in achondrogenesis type IB has been identified, diagnosis by molecular study is possible. The distinction between achondrogenesis type IB (which has a recurrence risk of 25%), and the more frequent autosomal dominant achondrogenesis type II, which has a lower recurrence risk, is important for genetic counseling. A couple at risk of

FIGURE 12-34. A. Frontal and lateral views in a case of achondrogenesis type II. There is no mineralization of the spine and ischial bones. The thorax is bell shaped, with short and straight ribs and no fractures. Long bones are short, with metaphyseal flaring and cupping. B. Transverse axial sonogram in a fetus with achondrogenesis. The lack of ossification of the spine (*arrow*) makes determination of anterior and posterior aspects of the fetus difficult in this view.

having a child with achondrogenesis type IB may take advantage of the possibility of molecular prenatal diagnosis by CVS or amniocentesis.^{344,348,360} Achondrogenesis type II/hypochondrogenesis results from mutations in the *COL2A1* gene.³⁸⁰ Prenatal diagnosis by molecular analysis of the *COL2A1* gene is available.

Osteogenesis Imperfecta and Hypophosphatasia

OI and hypophosphatasia are discussed together because they are characterized by skeletal demineralization.

Table 12-21 Radiologic Differences Between Achondrogenesis Type I (A-B), Type II, and Hypochondrogenesis

	Type IA (Houston-Harris)	Type IB (Fraccaro)	Type II (Langer-Saldino)	Hypochondrogenesis
Skull	Membranous calvarium	All parts of ossified skull well seen	Normal ossification	Normal ossification
Long bones	Extremely shortened with metaphyseal cupping and spurs Rectangular bones	Arms and legs shorter than with type IA with minimal ossification; abundant metaphyseal spiking or spurring on lower leg bones Square or stellate bones	Short and bowed with metaphyseal flaring and cupping Mushroom stem bones	Less bowed and shortened with irregular or smooth metaphyses
Spine	Vertebral bodies unossified, with partly ossified pedicles	Vertebral bodies minimally or not ossified, pedicles ossified	Variable pattern of ossified or unossified vertebral bodies and pedicles	Thoracic and upper lumbar vertebral bodies ossified but still platyspondylic Cervical and lower lumbar bodies unossified
Pelvis	Poorly formed and ossified, with crenated iliac bones Ischial bones poorly ossified, pubic bones unossified	Iliac bones same aspect as in type IA Ischial and pubic bones unossified	Halberd-like iliac bones with unossified ischial and pubic bones	Near normally developed iliac bones with partial ossification of ischial bones and unossified pubic bones
Thorax	Short and barrel-shaped Short ribs with cupped metaphyses and multiple fractures	Same as in type IA with unfractured ribs	Short and barrel or bell shaped with short unfractured ribs	Near normal but shallow cage with short unfractured ribs

From Spranger J: Pattern recognition in bone dysplasias. In Papadatos CJ, Bartsocas CS (eds): *Endocrine Genetics and Genetics of Growth*. New York, Alan R. Liss, 1985, p 315.

Osteogenesis Imperfecta

The term OI was introduced over a century ago to describe a newborn with extremely brittle bones (see Figs. 12-16, 12-18, and 12-19). At present, the term refers to a heterogeneous group of disorders caused, in most cases, by mutations in one or two structural genes for type I procollagen.³⁸¹⁻³⁸⁷ Extraskelatal malformations are variably associated with the disorder and include blue sclera, dentinogenesis imperfecta, hyperlaxity of ligaments and skin, hearing impairment, and presence of wormian bones on skull radiographs.³⁸⁷ Advanced paternal age is considered a risk factor for OI.³⁸⁸ The prevalence of OI is 0.18 per 10,000 births.^{29,30}

The most popular classification is that proposed by Silience and colleagues.³⁸⁹ A modification of this classification has been recently put forward by Rauch and Glorieux,³⁸⁷ and includes three additional types (V, VI, and VII [Table 12-22]). Clinically, the most relevant characteristic of OI is bone fragility, with severity increasing in the following order: (1) type I; (2) types IV, V, VI and VII; (3) type III; and (4) type II.³⁸⁷

In type I (autosomal dominant), there are no prenatal deformities. After birth, patients suffer from bone fragility, blue sclera (all ages), and hearing loss. There is osteoporosis, a normal calvarium, and no dentinogenesis imperfecta. Fractures may range from none to multiple, especially vertebral fractures that can lead to mild scoliosis.³⁸⁷ Mutations resulting in OI type I cause premature termination codons that lead to decreased production of type I procollagen.³⁸⁴

Type II is an autosomal-dominant condition.³⁹⁰ It is also known as the perinatal variety and is uniformly lethal. Other features are almost no ossification of the skull; beaded ribs; shortened, crumpled long bones; and multiple fractures in utero (see Fig. 12-18). The thorax is short but not narrow. Type II is subclassified into three subtypes (IIA, IIB, and IIC) according to radiologic criteria: subtype A has short, broad, crumpled long bones, angulation of tibias, and continuously beaded ribs; subtype B has short, broad, crumpled femurs, angulation of tibias but normal ribs or ribs with incomplete beading; and subtype C has long, thin, inadequately modeled long bones with multiple fractures and thin beaded ribs.³⁹¹

Type III (autosomal recessive and rare) is a nonlethal variety characterized by blue sclera and multiple fractures present at birth. The sclera becomes white with time. The membranous skull is severely deossified, and the long bones are mildly shortened but with marked angulations. Type IIB and type III OI are difficult to distinguish and may represent different degrees of severity of the same disorder.³⁹²

In type IV (autosomal dominant), the long bones and sclera are normal. There is mild to moderate osseous fragility, and 25% of the newborns have fractures. There is significant heterogeneity in the expression of the disease, even within the same family.³⁹³ From this heterogeneous group, Rauch and Glorieux have recently identified three separate clinical entities based on distinct clinical and bone histological features. These disorders have been classified as OI types V, VI, and VII (see Table 12-22).^{387,393-396} Type V

Table 12-22 Expanded Sillence Classification of Osteogenesis Imperfecta

Type	Clinical Severity	Typical Features	Typically Associated Mutations
I	Mild non-deforming osteogenesis imperfecta	Normal height or mild short stature; blue sclera; no dentinogenesis imperfecta	Premature stop codon in <i>COL1A1</i>
II	Perinatal lethal	Multiple rib and long bone fractures at birth; pronounced deformities; broad long bones; low density of skull bones on radiographs; dark sclera	Glycine substitutions in <i>COL1A1</i> or <i>COL1A2</i>
III	Severely deforming	Very short; triangular face; severe scoliosis; grayish sclera; dentinogenesis imperfecta	Glycine substitutions in <i>COL1A1</i> or <i>COL1A2</i>
IV	Moderately deforming	Moderately short; mild to moderate scoliosis; grayish or white sclera; dentinogenesis imperfecta	Glycine substitutions in <i>COL1A1</i> or <i>COL1A2</i>
V	Moderately deforming	Mild to moderate short stature; dislocation of radial head; mineralized interosseous membrane; hyperplastic callus; white sclera; no dentinogenesis imperfecta	Unknown
VI	Moderately to severely deforming	Moderately short; scoliosis; accumulation of osteoid in bone tissue, fish scale pattern of bone lamellation; white sclera; no dentinogenesis imperfecta	Unknown
VII	Moderately deforming	Mild short stature; short humeri and femora; coxa vara; white sclera; no dentinogenesis imperfecta	Unknown

From Rauch F, Glorieux PF: Osteogenesis imperfecta. *Lancet* 363:1377, 2004.

is characterized by moderate to severe bone fragility, calcification of the interosseous membrane at the forearm that severely limits movements of the hand, and predisposition to develop hyperplastic calluses. The characterization of type VI is based on bone histology showing an increased amount of osteoid and an abnormal pattern of lamellation. OI type VII is a recessive disorder with bone fragility, rhizomelia, and coxa vara. This type has been described only in a community of Native Americans in northern Quebec.³⁸⁷

OI type I is caused by a premature stop codon in *COL1A1*.³⁸² Types II, III and IV typically result from mutations that lead to substitutions for glycine within the triple helical domain of the pro-alpha chain, disrupting the normal folding of the molecule and initiating the production of abnormal collagen.^{397,398} Approximately 90% of the patients with a clinical diagnosis of OI have a mutation in either the *COL1A1* or *COL1A2* gene, resulting in abnormal molecular constitution of procollagen type I.^{387,398-401} Gene mutations associated with types V, VI, and VII have not been identified.³⁸⁷

The natural history of OI in utero is variable. Prenatal diagnosis of OI type II has been reported numerous times,^{95,402-423} even as early as 12 weeks of gestation by either 2DUS or 3DUS.⁴²⁴⁻⁴²⁷ It is important to note, however, that in some cases, fractures and limb shortening may not be observed until the second or even the third trimesters.⁴²⁸⁻⁴³⁰ A typical sonographic finding associated with OI type II is the improved visualization of intracranial structures. Prenatal diagnosis of OI types I, III, and IV have also been reported using either ultrasound, biochemistry or molecular techniques.⁴³¹⁻⁴³⁵ The differential diagnosis should consider other skeletal disorders such as hypophosphatasia, achondrogenesis, and campomelic dysplasia.

Hypophosphatasia

Hypophosphatasia is a rare autosomal-recessive inherited disorder with an estimated incidence of 1:100,000.⁴³⁶ It is characterized by demineralization of bones and low alkaline phosphatase (ALP) in serum and other tissues.⁴³⁷ The severity of the disease is inversely related to serum levels of ALP activity.⁴³⁸ ALP acts on pyrophosphate and other phosphate esters, leading to the accumulation of inorganic phosphates that are critical for the formation of bone crystals. Bone fragility is thought to be the result of deficient generation of bone crystals.⁴³⁹

Hypophosphatasia is a condition that has been subdivided into six clinical types according to the age of onset: (1) perinatal (lethal), (2) infantile, (3) childhood, (4) adult, (5) odontohypophosphatasia, and (6) pseudohypophosphatasia.⁴⁴⁰ The perinatal form is associated with stillbirth or early neonatal death due to either intracranial hemorrhage or respiratory insufficiency secondary to poorly developed ribs and reduced thoracic cavity volume.^{441,442} The infantile variant may cause craniosynostosis and nephrocalcinosis from hypercalcemia and hypercalciuria during the first year of life, and is often fatal. Premature loss of deciduous teeth and rickets are the cardinal clinical features of childhood hypophosphatasia. In the adult form, recurrent metatarsal stress fractures and pseudofractures in long bones can be the hallmark. Odontohypophosphatasia refers to especially mildly affected individuals who have dental, but no skeletal, manifestations. The teeth are predisposed to cavities and may be lost prematurely. Pseudohypophosphatasia is an extremely rare variant characterized by typical clinical, radiologic, and biochemical findings of infantile hypophosphatasia with the exception that the total serum ALP concentrations are normal or increased.⁴⁴⁰ The perinatal

and infantile varieties have an autosomal recessive pattern of inheritance, whereas the childhood, adult, and odontohypophosphatasia forms can be transmitted as either an autosomal-dominant or autosomal-recessive trait.⁴⁴³

Fetuses with congenital hypophosphatasia have generalized demineralization of the skeleton, with shortening and bowing of tubular bones. Multiple fractures are present. The generalized and marked demineralization of the cranial vault results in deformation of the skull after external compression. This sonographic sign is also present in some cases of OI type II and achondrogenesis type IA. Prenatal diagnosis of this condition has been reported with ultrasound^{444–454} and by assaying ALP in tissue obtained by CVS^{437,455,456} or amniotic fluid culture. ALP measurement in amniotic fluid is not a reliable means of making a diagnosis of hypophosphatasia because most of the ALP in amniotic fluid is of intestinal origin.^{457,458} The involved enzymes in hypophosphatasia are bone and liver ALPs, and these isoenzymes contribute only 16% of the total amniotic fluid enzymatic activity.⁴⁵⁹ Therefore, although prenatal diagnosis by DNA analysis is possible,⁴⁶⁰ this requires sequencing the entire gene, which increases the complexity of the process.

Hypophosphatasia has been shown to be caused by mutations in the ALP liver (*ALPL*) gene, also called the tissue non-specific alkaline phosphatase (*TNSALP*) gene, located on chromosome 1 p36.1-p34.^{461,462} A large spectrum of mutations is observed in the white population.^{463,464} At present, 178 mutations have been reported and a list is maintained in a recently updated database (<http://www.sesep.uvsq.fr/Data base.html>) and about 80% of all mutations are missense.⁴⁶⁸ Missense mutations in the gene lead to variable residual enzymatic activity and the extremely high phenotypic heterogeneity observed in hypophosphatasia.^{221,465}

Diastrophic Dysplasia

Diastrophic dysplasia is an autosomal-recessive disease with low frequency in most populations, but the condition is highly prevalent in Finland, with a carrier frequency of 1% to 2%.⁴⁶⁶ It is characterized by micromelia, clubfoot, hand deformities, multiple joint flexion contractures, and scoliosis.⁴⁶⁷ The diagnosis may be difficult at birth because of phenotypic variability, and milder cases are often diagnosed at a later age.⁴⁶⁸ The clinical features include rhizomelic-type micromelia, joint contractures, hand deformities with an abducted position of the thumbs (so-called hitchhiker thumb [Figs. 12–35 and 12–36]), spine disorders (e.g., scoliosis, kyphosis, spina bifida ocuta, spinal stenosis, lumbar lordosis) and severe talipes equinovarus. The head is normal, but micrognathia and cleft palate may be associated with this disease. Diastrophic dysplasia is a generalized disorder of cartilage leading to destruction of the cartilage matrix, formation of fibrous scar tissue and subsequent ossification. The latter process is responsible for the contractures. Mutations in the *DTDST* gene (*SLC26A2*), located on chromosome 5q32-q33.1,^{469,470} are associated with reduced sulfate transport in chondrocytes, resulting in undersulfation of proteoglycans, leading to abnormal cartilage formation.^{470–473} Five common *SLC26A2* mutations (R279W, IVS1+2T->C, DELV340, R178X, and C653S) account for approximately 65% of disease alleles.⁴⁷⁰ Sequence

FIGURE 12–35. Three-dimensional rendered volume of a fetus with diastrophic dysplasia showing a hitchhiker thumb.

FIGURE 12–36. Hitchhiker thumb in diastrophic dysplasia.

analysis of the coding region can detect mutations in greater than 90% of alleles in individuals with typical clinical, radiologic, and histologic features.⁴⁷⁰

Prenatal diagnosis of diastrophic dysplasia has been made in patients at risk,^{62,64,468,474–477} based on severe shortening and bowing of all long bones. Sepulveda et al⁴⁷⁸ reported

clearer visualization of the limbs and face deformities by 3DUS. Prenatal diagnosis in at-risk pregnancies in which the familial mutations have been identified can be accomplished by DNA analysis of fetal cells obtained by CVS or amniocentesis.⁴⁷⁹ Biochemical studies of fibroblasts and/or chondrocytes are available and may be useful for cases in which molecular genetic tests fail to identify *SLC26A2* mutations.⁴⁸⁰ This disorder has a wide spectrum, and some cases may not be diagnosable in utero.

Diastrophic dysplasia is not universally lethal. Intelligence and sexual development are unaffected. However, joint contractures and painful osteoarthritis are associated with severe physical handicaps that require corrective orthopedic surgery.⁴⁶⁶ There is an increased mortality rate in the neonatal period and infancy due to upper airway obstruction secondary to tracheobronchomalacia and medullary compression caused by severe cervical kyphosis.^{466,481}

Differential diagnoses include arthrogryposis multiplex congenita, atelosteogenesis type II, and pseudodiastrophic dysplasia. Pseudodiastrophic dysplasia has a similar presentation as diastrophic dysplasia⁴⁸² and is inherited in an autosomal recessive pattern.³⁰ Histologic examination is required for differential diagnosis, since the distinctive morphologic abnormalities of the growth plate noted in diastrophic dysplasia have not been observed in pseudodiastrophic dysplasia. Cetta et al⁴⁸³ demonstrated that a patient with pseudodiastrophic dysplasia had no defect in the *DTDS* gene and that both sulfate uptake by skin fibroblasts as well as sulfation of proteoglycans were normal.

Kniest-Like Disorders

The term Kniest-like disorders is used in reference to a group of conditions that share histologic and radiologic characteristics with Kniest syndrome but differ in terms of clinical presentation and inheritance.⁴⁸⁴

Kniest Syndrome

In 1952, Dr. Wilhelm Kniest⁴⁸⁵ published the case of a 3.5-year-old girl with "skeletal changes showing a certain relationship to classical chondrodystrophy but differing in many of its manifestations." His publication clarified the phenotypic differences between this condition and other forms of chondrodystrophies. Kniest syndrome is one of the type II collagenopathies, which are disorders that not only impair fetal growth, but are also characterized by ocular and otolaryngological abnormalities.⁴⁸⁶⁻⁴⁸⁹ The pattern of inheritance is autosomal dominant,²⁶⁵ and these diseases are caused by usually de novo mutations in the *COL2A1* gene.^{487,489,490} Other type II collagenopathies include spondyloepiphyseal dysplasia and Stickler dysplasia type I.⁴⁹¹

Phenotypic features of Kniest syndrome include rhizomelic shortening of the long bones with widened metaphyses and prominent joints. Spinal involvement is common and characterized by platyspondyly and coronal clefts. The thorax is broad and short. Other manifestations, which may be detected during prenatal life, include micrognathia and cleft palate.⁴⁹² However, Kniest syndrome may be difficult to recognize during the second trimester because long bone biometry does not become remarkably abnormal until the third trimester of pregnancy.⁴⁹² The prognosis varies widely,

ranging from long-term survival with short stature, kyphoscoliosis, and craniofacial anomalies, to lethality in the neonatal period secondary to tracheomalacia and respiratory distress.⁴⁹³ Other long-term disabilities include feeding difficulties, hearing impairment, and blindness.⁴⁹²

Dyssegmental Dysplasia

Dyssegmental dysplasia is a disorder characterized by anarchic ossification of the vertebral bodies (anyspondyly), metaphyseal flaring, and severe bowing of the long bones.^{494,495} Two distinct types have been recognized: the mild Rolland-Desbuquois and the lethal Silverman-Handmaker.^{494,497-499} Encephaloceles are frequently present in the Silverman-Handmaker type,⁴⁹⁶ and prenatal diagnosis has been established in patients at risk.^{497,500-502} The Silverman-Handmaker type is caused by a functional null mutation in the gene encoding Perlecan (*HSPG2*).⁵⁰³ The Rolland-Desbuquois type has milder radiographic features resembling Kniest dysplasia and, although long-term survival is possible, a substantial proportion of affected individuals die during the first year of life.^{263,493} Decreased levels of matrix metalloproteinase-2 and the tissue inhibitor of metalloproteinase-1 have been reported in cases of the Rolland-Desbuquois type of dyssegmental dysplasia.⁵⁰⁴ The inheritance of both conditions is autosomal recessive.^{264,495} Other disorders associated with vertebral disorganization include Jarcho-Levin syndrome and mesomelic dysplasia.

Campomelic Dysplasia

Campomelic dysplasia is a rare lethal disorder first described by Maroteaux in 1971.⁵⁰⁶ The prevalence varies between 0.05 and 1.6/10,000.^{506,507} The disorder is characterized by bowing of the long bones of the lower extremities, an enlarged and elongated skull with a peculiarly small face, hypoplastic scapulae, and several associated anomalies such as micrognathia, cleft palate, talipes equinovarus, congenital dislocation of the hip, macrocephaly, hydrocephalus, hydronephrosis, and congenital heart defects.³⁹⁰ The most important and significant features are bowing of the femur and tibia; other tubular bones are normal in length (see Fig. 12-17B). The thorax is narrow, can be bell shaped, and 11 pairs of ribs are usually present. Cervical vertebrae are hypoplastic and poorly ossified.⁵⁰⁸ In the largest clinical and genetic study conducted to date, which included 36 patients with CMD, Mansour et al⁵⁰⁶ concluded that campomelic dysplasia is a sporadic autosomal-dominant condition.

There are two short-bone varieties of campomelic dysplasia, representing distinct syndromes: (1) the normocephalic form, known as kyphomelic dysplasia, and (2) the craniostenotic type, which appears to be identical to Antley-Bixler syndrome. Antenatal diagnosis of campomelic dysplasia has been reported several times,^{90,116,196,509-516} and the differential diagnoses include OI, thanatophoric dysplasia, and hypophosphatasia.

A unique aspect of campomelic dysplasia is that 75% of affected infants with a male karyotype present with sex reversal syndrome and have female or ambiguous genitalia.^{517,518} The histology of the gonads varies from gonads with testicular differentiation to dysgenetic gonads with primary follicles. Indeed, mutations in the *SOX-9* gene,

Table 12–23 Disorders With Thoracic Dysplasia and Polydactyly

	Asphyxiating Thoracic Dysplasia (Jeune)	Chondroectodermal Dysplasia (Ellis–van Creveld)	Short-Rib Polydactyly Syndrome Type I (Saldino–Noonan)	Short-Rib Polydactyly Syndrome Type II (Majewski)	Short Rib Syndrome Type III (Naumoff)	Short Rib Syndrome Type IV (Beamer–Langer)

which is also a fundamental testis-differentiation gene common to all vertebrates,⁵¹⁹ have been reported in several patients with this disorder.^{517,518,520–523} These mutations interfere with DNA binding by *SOX-9* or truncate the C-terminal transactivation domain and thereby impede the ability of *SOX-9* to activate target genes during organ development.⁵²² Chromosomal translocations involving 17q have also been observed in several affected individuals.^{524–529}

Campomelic dysplasia is frequently lethal in infancy, although some cases of survivors have been reported.^{509,530–534} The cause of death is respiratory distress due to tracheomalacia.

Skeletal Dysplasias Characterized by a Hypoplastic Thorax

The dysplastic process involves the ribs and other bones of the rib cage in many skeletal dysplasias. A reduction in thoracic dimensions leads to restriction of lung growth and, consequently, pulmonary hypoplasia. Lung hypoplasia is the main cause of death in lethal skeletal dysplasias. There are specific groups of dysplasias in which thoracic hypoplasia is a cardinal feature. These include asphyxiating thoracic

dysplasia, Ellis–van Creveld syndrome, SRPS, and campomelic syndrome. Table 12–23 illustrates the criteria for the differential diagnoses of the first three of these conditions. Other disorders presenting with altered thoracic dimensions are thanatophoric dysplasia, atelosteogenesis, fibrochondrogenesis, achondrogenesis, and Jarcho-Levin syndrome (Fig. 12–37).⁵³⁵

Asphyxiating Thoracic Dysplasia (Jeune Syndrome)

Asphyxiating thoracic dysplasia, or Jeune syndrome,⁵³⁶ is a rare autosomal-recessive condition, with an estimated prevalence of 0.14/10,000 births.^{537–539} Asphyxiating thoracic dysplasia is characterized by a combination of a small thorax, varying degrees of brachymelia, polydactyly, pelvic abnormalities, and renal involvement.⁵⁴⁰ Phenotypic expression is wide and includes lethal,⁵⁴¹ mild,^{538,542} and latent⁵³⁹ forms. In severe cases, thoracic narrowing is responsible for pulmonary hypoplasia, respiratory failure, and early infancy death.⁵⁴³ Conversely, the presence and the degree of renal involvement^{544–556} constitute the main prognostic factor in the milder forms.^{542,553,557} Individuals

FIGURE 12-37. Jarcho-Levin syndrome. There is dramatic spinal shortening with disorganization of the vertebral bodies, a characteristic chest deformity (crab-like appearance with posterior fusion and anterior flaring of the ribs), and unaffected long bones.

surviving childhood are likely to have a clinical course complicated by respiratory distress, recurrent pulmonary infections,⁵⁴⁴ hepatic,^{547,554,556-563} and pancreatic involvement.^{564,565} Ocular/retinal manifestations have been sporadically described in association with Jeune syndrome.^{547,566-568}

Skeletal Findings. The thorax is described as narrow and bell shaped, and the ribs are short, broad and horizontally oriented.^{545,569} Brachymelia, if present, is predominantly of the rhizomelic type.^{566,570,571} Long bones may be bowed^{569,571} and have visible proximal ossification centers at birth in two thirds of the cases.⁵⁷¹ Postaxial polydactyly is not a constant finding, with both the upper and lower limbs variably affected.^{557,569,570,572,573} Pelvic findings include small-squared iliac wings, a trident pelvis (shortened ilia with a downward hook of the greater sciatic notches), and horizontal acetabular roofs with spur-shaped projections.^{540,570,571,573} A handlebar-like conformation of clavicles has been reported.^{540,571} Cleft lip and palate can also occur.

Renal Findings. The degree of renal involvement is the main prognostic factor for individuals surviving the neonatal period.^{542,545,547,552,557} Renal failure can occur during childhood^{545,547,551,553} and may require renal transplantation.^{544,546,549} Cystic or scleroatrophic changes, partly indistinguishable from those associated with juvenile

nephronophthisis, are the two characteristic histologic patterns of renal involvement.^{545,548,552} Cystinuria has also been described in patients with Jeune syndrome.^{550,575}

Hepatic Findings. Liver involvement ranges from subclinical to biliary cirrhosis and progressive portal hypertension^{558,560,576} requiring transplantation during childhood.⁵⁵⁸ Intralobular bile ducts loss, portal tract periphery bile duct proliferation and fibrosis are the most frequent histologic findings.^{547,554,558} Because liver involvement at early stages can be subclinical and manifest as early as in the neonatal period,^{561,563} early diagnostic work-up and close follow-up of hepatic function has been proposed.⁵⁶⁰

Other Findings. Ophthalmologic evaluation of long-term survivors has revealed a wide spectrum of retinal anomalies. Pigmentation, dystrophy, degeneration, and aplasia have been reported among long-term survivors.^{547,567,568,577} Visual loss and night blindness have been sporadically reported as the initial manifestation of mild forms of the Jeune syndrome.⁵⁶⁸ Other associated anomalies include Dandy Walker malformation,^{561,578} agenesis of the corpus callosum,⁵⁶¹ situs inversus,⁵⁷⁹ neuroectodermal tumor in the soft tissue of the chest wall,⁵⁴⁹ Hirschsprung disease,⁵⁸⁰ and asplenia.⁵⁷⁹

Prenatal Diagnosis. Prenatal sonographic diagnosis of Jeune syndrome^{540,557,569-572,574,581-586} has been reported several times in the literature. A positive familial history contributes to second trimester recognition of recurrent forms,^{569-571,581} whereas diagnosis in low-risk pregnancies is more challenging and has been reported in the third trimester.⁵⁴⁰

Although the locus for asphyxiating thoracic dystrophy maps to chromosome 15q13, mutation analysis of two candidate genes (*GREMLIN* and *FORMIN*) did not reveal pathogenic mutations.⁵⁸⁷ Thus, molecular diagnosis for this condition is not available clinically at the time of this writing.⁵⁸⁸

Surgical Management for Respiratory Distress. Lateral thoracic expansion, a surgical procedure that attempts to enlarge the thoracic cage by separating ribs from their periosteum and plating them together with titanium struts, has been performed in a handful of patients with asphyxiating thoracic dysplasia, resulting in improvement in respiratory function and/or eliminating the need for external ventilators.⁵⁸⁹⁻⁵⁹²

Short Rib-Polydactyly Syndromes

SRPSs are an heterogeneous group of disorders inherited as an autosomal-recessive trait.^{45,593} Traditionally, four major types of short rib-polydactyly syndromes have been described: type I (Saldino-Noonan),⁵⁹⁴ type II (Majewski),⁵⁹⁵ type III (Verma-Naumoff),⁵⁹⁶ and type IV (Beemer-Langer).⁵⁹⁷ These conditions are classified within the family short rib dysplasia with or without polydactyly group, which also includes asphyxiating thoracic dysplasia (Jeune syndrome) and chondroectodermal dysplasia (Ellis-van Creveld dysplasia).²⁷ Because SRPSs I through IV are lethal in the newborn period because of the severe pulmonary hypoplasia and associated anomalies and, conversely, Ellis-van Creveld and Jeune syndromes are not uniformly lethal,⁵⁹⁸ accurate prenatal diagnosis is important in order to provide adequate counseling.

FIGURE 12-38. Short rib–polydactyly syndrome. There is severe shortening of all long bones, very short and horizontal ribs, and postaxial polydactyly in all four extremities. Note the angulation of the bones in the forearm.

SRPSs I through IV are characterized by short limbs/micromelic dwarfism, constricted thorax, usually polydactyly, and multiple anomalies of major organs (Fig. 12–38).^{599–603} Spranger and Maroteaux have indicated that the absence of polydactyly does not exclude the diagnosis of this entity.^{52,604–606} In fact, although polydactyly is a constant feature in SRPS type II (Majewski) and is commonly found in types I and III (Saldino-Noonan and Verma-Naumoff),⁶⁰⁷ patients with SRPS type IV (Beemer) seldom have polydactyly.^{597,608,609}

Differential Diagnosis. SRPSs have been identified prenatally by 2DUS^{579,604,605,610–629} and 3DUS,^{100,630} as well as by fetoscopy.⁶³¹ Table 12–23 illustrates the differential diagnosis and features of the disorders characterized by polydactyly and a narrow thorax. Differential diagnosis is often a challenging task, especially before birth, because a high degree of overlap exists in clinical and radiologic features. Indeed, there is debate as to whether the various forms of SRPSs are related to different genes, to different mutations on the same gene, or due to variability of expression of the same mutant gene.^{602,603,632–637}

Molecular Diagnosis. The molecular basis of the SRPSs has not been elucidated. Urioste⁶³⁸ recognized a balanced pericentric inversion of chromosome 4 in a proband with clinical and radiologic manifestations of SRPS and proposed that the disorder could be due to disruption of a gene in the 4p16 region (the same region where the gene for

FIGURE 12-39. Postaxial polydactyly in a fetus with Ellis–van Creveld syndrome.

Ellis–van Creveld syndrome maps). However, this association has been subsequently excluded both in a family with SRPS III,⁶³⁹ as well as in 10 unrelated cases of SRPS III by sequence analysis.⁶⁴⁰

Chondroectodermal Dysplasia

Chondroectodermal dysplasia, also known as Ellis–van Creveld syndrome, is a rare autosomal-recessive condition with an estimated birth prevalence of 1/60,000 in the general population and 5/1,000 among the Amish community of Lancaster County, Pennsylvania.^{641–643} Ellis–van Creveld syndrome is defined by the tetrad of chondrodysplasia, ectodermal dysplasia, polydactyly, and congenital heart disease.⁶⁴⁴ The combination and severity of each of these features is extremely variable, and as a consequence, the clinical course and prognosis range from death in the neonatal period because of cardiopulmonary complications^{645–647} to long-term survival.⁶⁴⁸

Skeletal Findings. In Ellis–van Creveld syndrome, the long bones most commonly present mesomelic^{206,649–653} or acromesomelic shortening.^{644,650,654–660} The presence and severity of rib cage dysplasia is an important factor in determining prognosis. A narrow thorax with short and horizontal ribs is frequently associated with pulmonary hypoplasia, early respiratory failure, and recurrent pulmonary infections.^{645–647,650,661,662}

Postaxial polydactyly (Figs. 12–39 and 12–40) can involve the hands and feet in several combinations: only hands bilaterally,^{206,600,644,649–651,653,655,659,662–666} both hands and both feet,^{646–650,652,657,667–673} or both hands and one foot.^{654,671,674,675} Clinodactyly^{644,648,666} and syndactyly^{646,650,659,662,663,673,676–680} have also been reported. Bowing of the long bones,^{600,644,650,654,655,658,659,673} genu valgus,^{643,644,648,652,656,664,669–671,676,677} and pelvic radiologic anomalies (including broad, squared and vertically short ilia, trident configuration of the acetabula, spur-like projections at the acetabular roof)^{643,646,649,653,662,663,666,672,673,679} are additional phenotypic features. The vertebrae and skull have a normal appearance.^{649,672}

FIGURE 12-40. Sonographic image of the hand shown in Figure 12-39. Note the abnormal angulation of the extra digit on the ulnar side of the forearm (arrow).

Cardiac Defects. Congenital heart disease occurs in up to 60% of affected individuals,^{680,681} and its presence and severity are strongly correlated to mortality rate.⁶⁴⁹ The most common cardiac anomalies are those characterized by defects of the endocardial cushion closure, such as atrial septal defects,^{206,647,649,651,661,664,667,671,673,674,677} ventricular septal defects,^{653,659,662} atrioventricular septal defects,⁶⁸⁴ atrioventricular canal,^{643,660,669,671,679,683} and single atrium.^{646,649,652,657,660,663,665,667,678,684-687} Mitral clefts,^{648,657,660} complex cardiac malformations,^{660,663,679} and complete situs inversus⁶⁵⁶ have also been reported in Ellis-van Creveld syndrome.

Ectodermal Dysplasia. Clinical manifestations of ectodermal dysplasia are present in 70% of cases.⁶⁶⁹ The most frequent are dystrophic changes of the fingernails, thin and sparse hair, and oral and dental abnormalities.^{644,649,661} Short upper lip, multiple and hyperplastic frenula, and fusion of the upper lip to the gingival margin are common in patients with Ellis-van Creveld syndrome.^{657,670,676} Dental anomalies include dysmorphic cone-shaped and microdontic teeth, taurodontism, delay in eruption or anodontia,^{206,644,649,650,653-656,666,670,671,677,678,683,686,687} natal, and neonatal teeth.^{645,663,665,676,690,691} Sporadic cases of micrognathia^{672,678,688,690} and mandibular malocclusion⁶⁹⁰ have been reported. This variety of oral manifestations requires multidisciplinary dental treatment, with special attention to the high incidence of cardiac defects in these patients⁶⁷⁶

Other Manifestations. CNS anomalies can occasionally occur in association with Ellis-van Creveld syndrome, including ventriculomegaly,⁶⁶³ Arnold Chiari malformation,⁶⁶² Dandy Walker anomaly,⁶⁴³ and spina bifida occulta.⁶⁵⁶ The kidneys are rarely involved, although there are sporadic reports of renal agenesis, congenital megaureter,⁶⁷⁸ renal medullary dysplasia,⁶⁹¹ and nephronophthisis.⁶⁷¹ An association between Ellis-van Creveld syndrome and bile duct dysplasia requiring liver transplantation has been reported.^{655,691} Thymic hypoplasia,⁶⁸⁴ Hodgkin's disease, nodular sclerosing at young age,⁶⁹² and retinal dystrophy⁶⁶⁸ are other less common associations.

Prenatal Diagnosis. Prenatal diagnosis by ultrasound has been reported during second^{648,649,653,669,677,681,695-700} and third trimesters,^{600,646,647,651,662,667,675,679,693-698} as well as in the first trimester.⁶⁵¹ Fetoscopy has been performed in selected cases.^{667,693,695}

Differential Diagnosis. Differentiating between Ellis-van Creveld and Jeune syndrome can be challenging⁶⁹⁹ because there is a great degree of overlap in the phenotypic features of these two conditions.^{671,700} McKusick-Kaufman syndrome shares with Ellis-van Creveld postaxial polydactyly and heart defects,⁷⁰¹ but differentiating characteristics include absence of chondrodysplasia and ectodermodyplasia, as well as the presence of hydrometrocolpos.⁷⁰² Weyers acrofacial dysostosis, an autosomal-dominant condition, shares with Ellis-van Creveld the mild short stature, postaxial polydactyly, dental and nail dystrophy. On the other hand, thoracic dysplasia and congenital heart disease are not typical features in Weyers acrofacial dysostosis. Linkage and haplotype analysis raised the possibility that Weyers acrofacial dysostosis is the heterozygous expression of a mutation that, in the homozygous form, causes Ellis-van Creveld syndrome.^{703,704}

Genetics and Molecular Diagnosis. Mutations on two nonhomologous genes named *EVC1*^{703,705} and *EVC2*,^{706,707} both mapping to the short arm of chromosome 4 (4p16) in a head-to-head configuration, are candidates for Ellis-van Creveld syndrome. However, it has been recently reported that mutations in either the *EVC1* or *EVC2* gene are not uniformly found in all subjects with a phenotypic diagnosis of Ellis-van Creveld syndrome.⁷⁰⁸ Typing of microsatellite markers flanking the EVC locus has been reported for first trimester diagnosis of Ellis-van Creveld syndrome in a family with a previously affected child.⁶⁷⁵ There is debate about the possibility of partial manifestations in heterozygous carriers.^{648,666,674,686,703}

Skeletal Dysplasias With Predominant Membranous Bone Involvement

A group of skeletal dysplasias is characterized by disruption in the process of intramembranous bone ossification. These include cleidocranial dysplasia, Yunis-Varom syndrome, and isolated parietal foramina. Among these disorders, cleidocranial dysplasia is the one that has been more often diagnosed prenatally.

Cleidocranial Dysplasia

Cleidocranial dysplasia is an autosomal-dominant condition characterized by clavicular aplasia or hypoplasia,

FIGURE 12-41. A. Three-dimensional rendering of the fetal skull at 18 3/7 weeks of gestation using the maximum intensity projection mode demonstrates widening of the coronal suture, absence of the squamous portion of the temporal bone, and absence of the nasal bones in a fetus with cleidocranial dysplasia. B. Labeled three-dimensional image of a normal fetal skull at 18 3/7 weeks (control). (From Soto E, Richani K, Goncalves LF, et al: *Three-dimensional ultrasound in the prenatal diagnosis of cleidocranial dysplasia associated with B-cell immunodeficiency*. *Ultrasound Obstet Gynecol* 27:574, 2006.)

brachycephaly, midface hypoplasia, patent or delayed closure of fontanels (Fig. 12-41), delayed eruption of permanent teeth, and relatively short stature.⁷⁰⁹⁻⁷¹² The incidence of cleidocranial dysplasia is estimated to be 0.5/100,000 live births.⁷¹³ Cleidocranial dysplasia is caused by mutations in the human osteoblast-specific transcription factor gene (*RUNX2*),⁷¹⁴⁻⁷¹⁷ formerly known as *CBFA1* (core-binding factor a-1),⁷¹⁸ located in chromosome 6p21.⁷¹⁹⁻⁷²¹ The *RUNX2* gene is essential for osteoblast differentiation and, thus, affects both membranous and endochondral bone formation.^{722,723} *RUNX2* induces and regulates the expression of genes involved in bone matrix formation and remodeling by modification of chromatin or interaction with co-regulatory proteins.^{724,725}

Prenatal diagnosis of cleidocranial dysplasia by ultrasound has been reported as early as 14 weeks of gestation.⁷²⁶ The most common finding is the detection of unilateral and bilateral hypoplastic and hypomineralized clavicles, although pseudoarthrosis (fracture) of the clavicle (Fig. 12-42) has also been reported.¹¹⁵ Other features include hypomineralization/poor ossification of the cranial bones and/or pelvis, large fontanels with wide sutures, obvious corpus callosum, brachycephaly, fronto-parietal-occipital bossing, low nasal bridge, and long bones below the fifth percentile.⁷²⁷⁻⁷³³ Molecular prenatal diagnosis for *RUNX2* mutations can be accomplished by analysis of fetal tissue, or obtained by CVS or amniocentesis.⁷³⁴

The differential diagnosis includes disorders characterized by poor mineralization of the calvarium, such as hypophosphatasia, as well as disorders that have fracture/pseudoarthrosis of the clavicle as one of the characteristic phenotypic features (e.g., congenital pseudoarthrosis of the clavicle and Yunis-Varon syndrome). Congenital pseudoarthrosis defines a spontaneous fracture that progresses to nonunion and is associated with abnormal movement at the site. The mechanisms proposed for this clavicular defect include an

FIGURE 12-42. Three-dimensional rendering of the fetal shoulders using the maximum intensity projection mode in a fetus with cleidocranial dysplasia. The arrow points to a site of pseudoarthrosis (fracture) of the clavicle. (From Soto E, Richani K, Goncalves LF, et al: *Three-dimensional ultrasound in the prenatal diagnosis of cleidocranial dysplasia associated with B-cell immunodeficiency*. *Ultrasound Obstet Gynecol* 27:574, 2006.)

abnormal elevation of the first rib and right subclavian artery^{735,736} or a failure of fusion of the two ossification centers (congenital pseudoarthrosis).⁷³⁵ Yunis-Varon syndrome is described in the next section.

Yunis-Varon Syndrome

Yunis-Varon syndrome is an autosomal-recessive disorder that shares characteristics with cleidocranial dysplasia but, in addition, includes micrognathia, bilateral absence of the thumbs and distal phalanges of the fingers, as well as hypoplasia of the great toes.⁷³⁷ This condition has not been diagnosed prenatally.

Table 12-24 Congenital Amputations

Absent limbs only
Single absent limb
Multiple absent limbs
Absent limbs with rings
Congenital ring constriction syndrome
Absent limbs and face anomaly
Aglossia-adactylia syndromes
Möebius syndrome

Limb Deficiency or Congenital Amputations

On occasion, the only identifiable anomaly is the absence of an extremity (limb deficiency) or a segment of an extremity (congenital amputation) (Table 12-24).⁷³⁸ These disorders differ from osteochondrodysplasias, and the terms usually used to refer to limb reduction abnormalities include⁷³⁹:

- Amelia: absence of a limb or limbs
- Hemimelia: absence of a longitudinal segment of a limb (e.g. radial aplasia, radial hypoplasia)
- Phocomelia: hypoplasia of the limbs, with hands and feet attached to the shoulder and hips
- Acheira: absence of the hands
- Apodia: absence of a foot or feet
- Acheiropodia: absence of hands and feet.

The overall incidence of congenital limb reduction deformities ranges from 0.49 to 3.5 per 10,000 births (Table 12-25).^{740,741} It has been estimated that approximately 50% of these limb reduction defects are simple transverse reduction deficiencies

Table 12-25

Prevalence of Different Types of Limb Reduction Malformations in Hungary, 1975-1977

Type	Total	Population Prevalence (per 1000 Births)
Terminal transverse	79	0.14
Radial	13	0.09
Ulnar	41	0.11
Split hand and/or foot	20	0.04
Ring constriction	62	0.49
Total	274	0.49

From Bod M, Czeizel A, Lenz W: Incidence at birth of different types of limb reduction abnormalities in Hungary 1975-1977. *Hum Genet* 65:27, 1983.

FIGURE 12-43. Sonogram of a fetus with radial aplasia. The hand deviates toward the side of the absent bone (radius).

of one forearm or hand without associated anomalies.^{740,741} The remainder consist of multiple reduction deficiencies, with an approximate 23% incidence of additional anomalies of the internal organs or craniofacial structures.⁷³⁸

Limb deficiencies can present alone or as part of a specific syndrome. An isolated limb deficiency of the upper extremity (e.g., distal segment of an arm) is generally an isolated anomaly. The hand often deviates in the direction of the absent bone (Fig. 12-43). In contrast, congenital amputation of the leg generally occurs within the context of a syndrome, as do bilateral amputations or reduction of all limbs.⁷⁴²

Isolated amputation of an extremity can be due to amniotic band syndrome, exposure to a teratogen, or a vascular accident. In most cases, the anomaly is sporadic, and the risk of recurrence is negligible. Sonographic findings related to these conditions have been reviewed in depth by Bromley and Benacerraf.⁷⁴³

In the largest study conducted to date, which included a population of 709,030 births from 20 malformation registries in 12 European countries, the overall prenatal detection rate for limb reduction defects was 35.6% (89/250), with a higher detection rate observed among cases with associated malformations (49.1% [55/112]). The frequency of chromosomal anomalies in the presence of associated malformations was 14.3% (16/112), with eight cases of trisomy 18, two cases of trisomy 21, and one case each of triple X, Klinefelter syndrome, deletion 7q, + isochromosome 12p, deletion 3q and unbalanced translocation t(5;14)(p13;q13). Among fetuses with a normal karyotype and associated anomalies, 33.9% (38/112) had syndromic disorders or associations, including amniotic bands, VATER association, Poland syndrome, Hanhart syndrome, Brachmann-De Lange syndrome, thrombocytopenia-radial aplasia (TAR) syndrome, limb bodywall complex, caudal regression syndrome, Fanconi anaemia, ulnar mammary syndrome, Holt-Oram syndrome, Roberts syndrome, femur-fibula-ulna syndrome, Aarskog syndrome, Adams-Oliver syndrome, Oto-facio-digital type 2 syndrome, Robinow syndrome, Carey-Fineman-Ziter syndrome, and twin-reversed arterial perfusion sequence.

The following section reviews syndromes in which a limb amputation or deficiency is associated with other anomalies. We follow the classification proposed by Goldberg (see Table 12-24).⁷³⁸

Syndromes With Absent Limbs and Facial Anomalies

Aglossia-Adactylia Syndrome

Aglossia-adactylia syndrome consists of transverse amputations of the limbs and malformations of the mouth, including micrognathia, vestigial tongue (hypoglossia), dental abnormalities, and ankylosis of the tongue to the hard palate, the floor of the mouth, or the lips (glossopalatine ankylosis). The spectrum of anomalies of the extremities is variable, ranging from absent digits to severe deficiencies of all four extremities. Intelligence is generally normal. The condition is sporadic and has been attributed to a vascular accident.^{744,745} It includes the Moebius sequence, Hanhart syndrome, glossopalatine ankylosis syndrome, limb deficiency-splenogonadal fusion syndrome, and Charlie M syndrome.⁷⁴⁶⁻⁷⁵¹ There is confusion in the classification of these patients because of the associated anomalies and the frequency of overlapping features. Although some authors have considered Hanhart syndrome and glossopalatine ankylosis syndrome as distinct entities, differential diagnosis is extremely difficult.⁷⁵²

Moebius Sequence

The Moebius sequence consists of a number of facial anomalies attributed to paralysis of the sixth and seventh cranial nerves.⁷⁵³ Limited jaw mobility and micrognathia are present.^{754,755} Ptosis is also a common feature. The Moebius sequence is generally sporadic, but autosomal-dominant, autosomal-recessive, and X-linked recessive forms have been described.⁷⁵⁶⁻⁷⁵⁸ A large study conducted in Brazil documented the association between exposure to misoprostol during early pregnancy and vascular disruption defects,

including Moebius sequence and transverse limb reduction defects.⁷⁵⁹ The associated limb reduction anomalies (25% of cases) are generally present in the upper extremities and range from transverse deficiencies to absent digits. Mental retardation occurs in 10% of the cases.⁷⁵⁶ The Moebius, Poland, and Klippel-Feil syndromes have been considered subclavian artery supply disruption sequences, based on the hypothesis that interruption of the early embryonic blood supply to the subclavian artery, vertebral artery, and their branches may lead to these conditions.^{757,760-766}

Limb Reduction Defects Associated With Other Anomalies

Congenital Hemidysplasia With Ichthyosiform Erythroderma and Limb Defects

Congenital hemidysplasia with ichthyosiform erythroderma and limb defects (CHILD syndrome) is a defect characterized by strict demarcation of the lesions to one side of the midline.⁷⁶⁷⁻⁷⁶⁹ The presence of unilateral defects of long bones is an important feature of the syndrome.⁷⁷⁰ Limb deficiencies may vary from hypoplasia of phalanges or metacarpals to complete absence of an extremity. The calvarium, scapulae, or ribs may also be involved. Zellweger syndrome, chondrodysplasia punctata, and warfarin embryopathy may present with similar findings. Visceral anomalies include congenital heart disease,^{770,771} unilateral hydronephrosis, hydroureter, and unilateral absence of the kidney, fallopian tube, ovaries, adrenal gland, and thyroid. CHILD syndrome predominantly affects females (by a ratio of 19:1)^{772,773} and is caused by mutations in the NSDHL gene (NAD[P]H steroid dehydrogenase-like protein), located at Xq28 and encoding a β -hydroxysteroid dehydrogenase involved in the cholesterol biosynthetic pathway.⁷⁷⁴⁻⁷⁷⁶

Fibula Aplasia Complex Brachydactyly (Du Pan Syndrome)

Fibula aplasia complex brachydactyly (Du Pan syndrome) is an extremely rare condition characterized by bilateral agenesis of the fibula with abnormalities of the metacarpals and proximal phalanges. Limb reduction defects can involve the lower extremities.⁷⁷⁷ An autosomal-recessive pattern of inheritance has been suggested.⁷⁷⁸ Faiyaz-Ul-Haque et al⁷⁷⁹ have examined genomic DNA from a family with Du Pan syndrome for mutations in the *CDMP1* gene. Affected individuals were homozygous for a missense mutation, *T1322C*, in the coding region of the *CDMP1* gene. Homozygous *CDMP1* mutations also cause Hunter-Thompson and Grebe syndromes.⁷⁸⁰

Splenogonadal Fusion Syndrome

Splenogonadal fusion syndrome is characterized by limb reduction defects and splenogonadal fusion.^{781,782} Most reported cases have occurred in boys.⁷⁸³ Typically, there is a mass in the scrotum, and an ectopic spleen is identified during surgery.⁷⁸⁴ There is a continuous type in which the normally located spleen is connected to the gonad by bands or cords of splenic tissue.⁷⁸⁵ A review of 14 reported cases indicates that there is some overlap between this syndrome

and the aglossia-adactylia syndrome or Hanhart syndrome.⁷⁸⁶

Adams-Oliver Syndrome

Adams-Oliver syndrome is a group of disorders characterized by the association of limb reduction defects and scalp anomalies (aplasia cutis and deficiency of bony calvarium).⁷⁸⁷ Sporadic and familial cases have been reported.⁷⁸⁸ Other organ systems may be involved, and there are reports of associated cardiovascular, brain, pulmonary and renal anomalies.⁷⁸⁹⁻⁷⁹⁵ Becker et al⁷⁹⁶ reported prenatal diagnosis by ultrasound of two cases of Adams-Oliver syndrome in the same family, the first at 13 weeks and the second at 23 weeks of gestation. Both cases showed limb reduction defects and, in the second case, the scalp defect was diagnosed as an echo-free space between the scalp and bone.

Phocomelia

In phocomelia, the extremities resemble those of a seal. Typically, the hands and feet are present, but the intervening arms and legs are absent. Hands and feet may be normal or abnormal. Three syndromes must be considered in the differential diagnosis of phocomelia: Roberts syndrome, some varieties of the TAR syndrome, and Grebe syndrome. Phocomelia also can be caused by exposure to thalidomide.⁷⁹⁷ Prenatal diagnosis of phocomelia has been reported by 3DUS.⁷⁹⁸

Roberts Syndrome and SC Phocomelia Syndrome

Roberts syndrome is an autosomal-recessive disorder characterized by the association of tetraphocomelia and craniofacial dysmorphism, including macrocephaly, hypertelorism, shallow orbits, facial clefting defects, and hypoplastic nasal alae.⁷⁹⁹⁻⁸⁰² The upper extremities are generally more severely affected than the lower extremities. Polyhydramnios has been noted, and other anomalies associated with the syndrome include horseshoe kidney, ventriculomegaly, cephalocele, and spina bifida.⁸⁰³ Roberts syndrome is caused by mutations in the *ESCO2* gene (establishment of cohesion 1 homolog 2).⁸⁰⁴

SC phocomelia syndrome is an allelic disorder caused by mutations in the *ESCO2* gene⁸⁰² with a similar, but milder phenotype than Roberts syndrome. SC phocomelia (named after the first descriptions in two families with surnames beginning with S and C, respectively)⁸⁰⁵ is characterized by (1) nearly symmetric reductive malformations of the limbs, resembling phocomelia; (2) flexion contractures of various joints; (3) minor anomalies, including capillary hemangioma of the face, forehead and ears, hypoplastic cartilages of the ears and nose, micrognathia, scanty silvery-blond hair, and cloudy corneas; (4) growth restriction; and (5) mental retardation.²⁶⁴ Mental retardation may be mild and survival into adulthood is common.⁸⁰²

Differentiation between the two conditions is based on phenotypic characteristics only, as the phenotype cannot be predicted by the genotype. Prenatal diagnosis for both conditions has been reported.^{26,803,806-817}

Grebe Syndrome

Grebe syndrome (Grebe-Quelle-Salgado chondrodystrophy) is an autosomal-recessive nonlethal acromesomelic skeletal disorder. It was first described in two girls by Grebe,⁸¹⁸ and subsequently in 47 Brazilian individuals by Quelle-Salgado.⁸¹⁹ The prevalence at birth has been estimated as 5:1,000,000.⁸²⁰ Affected individuals have normal head, neck, and trunk skeleton, relatively normal humeri and femora, short and deformed radii, ulnae, tibiae, and fibulae, and severe abnormalities of hands and feet. Polydactyly is frequent. Digits are very small and have been variously described bulbous,⁸²¹ bud-like,⁸²² mere knobs,⁸²³ globular appendages,⁸²⁴ or stubby toe-like fingers.⁸²⁵ The proximal and middle phalanges of the fingers and toes are invariably absent, while the distal phalanges are present.⁸²⁴ Radiographic documentation has provided information on subtle clinical characteristics for obligate heterozygotes: polydactyly, brachydactyly, hallux valgus, and metatarsus adductus.⁸²⁴⁻⁸²⁷ The disease is caused by a missense mutation in the gene encoding cartilage-derived morphogenetic protein-1 (CDMP-1).⁸²⁸ Survivors have normal intelligence and develop normal secondary sexual characteristics. Prenatal diagnosis of Grebe syndrome has been made based on the phenotypic features of the disease (acromesomelic dysplasia and dysmorphic distal appendages with normal craniofacial and axial skeletal development),^{821,829,830} as well as by the identification of mutations in the CDMP-1 gene.⁸³⁰

Thrombocytopenia With Absent Radius Syndrome

TAR syndrome is discussed in detail in the section on radial clubhand deformities.

Congenital Short Femur (Proximal Femoral Focal Deficiency)

Proximal femoral focal deficiency, or congenital short femur, refers to a group of disorders encompassing a wide range of congenital developmental anomalies of the femur. The disorder has been classified into five groups: type I, simple hypoplasia of the femur; type II, short femur with angulated shaft; type III, short femur with coxa vara (most common); type IV, absent or defective proximal femur; and type V, absent or rudimentary femur^{831,832} (Fig. 12-44). One or both femora can be affected, although the right femur is more frequently involved. Anomalies of the upper limbs can also be present and do not exclude the diagnosis.²⁹ Proximal femoral focal deficiency syndrome may be associated with umbilical or inguinal hernias. If both femora are affected, it is important to examine the face carefully, because the disorder may be bilateral femoral hypoplasia and unusual facies syndrome,^{833,834} which consists of bilateral femoral hypoplasia and facial anomalies, including short nose with broad tip, long philtrum, micrognathia, and cleft palate. Long bone abnormalities can extend to other segments of the lower extremities (absent fibula) and to the upper extremities. Femoral focal deficiency syndrome is considered a sporadic condition, but a familial form has been described. Except in bilateral proximal focal deficiency, the diagnosis is usually suspected when there is unilateral short femur, in the absence of other anomalies.⁸³⁴⁻⁸³⁸

FIGURE 12-44. Second trimester sonogram in a fetus with proximal femoral focal deficiency. The right femur (arrow) is significantly shorter than the left.

If the defect is unilateral, it may correspond to the femur-fibula-ulnar or femur-tibia-radius complex. These two syndromes have different implications for genetic counseling: the former is nonfamilial, whereas the second has a strong genetic component.⁸³⁹

SPLIT HAND AND FOOT DEFORMITIES

The term split-hand-and-foot syndrome is used to refer to a group of disorders characterized by splitting of the hand and foot into two parts. Other terms include lobster-claw deformity, ectrodactyly, and aborted fingers.^{774,840} The conditions are classified into typical and atypical varieties.⁸⁴¹ The typical form consists of absence of both the finger and the metacarpal bone, resulting in a deep V-shaped central defect that clearly divides the hand into an ulnar and a radial part. It occurs in 1 per 90,000 live births and has a familial tendency (usually inherited in an autosomal dominant fashion).⁸⁴² The atypical variety is characterized by a much wider cleft formed by a defect of the metacarpals and the middle fingers. As a consequence, the cleft is U shaped and wide, with only thumb and small finger remaining. The atypical variety occurs in 1 per 150,000 live births.⁸⁴³

Although a complex system for the classification of these disorders, based on the distribution of remaining fingers, has been proposed,⁸⁴⁴ it is not helpful in differential diagnosis and syndrome classification. Split-hand-and-foot deformities can occur as isolated anomalies or as part of a more complex syndrome. The syndromic types are more frequently encountered.

The split-hand-and-foot and absent-long-bones syndromes include two conditions in which there is split hand and aplasia of the tibia or split foot with aplasia of the ulna. However, skeletal anomalies are not limited to these bones; the clavicle, femur, and fibula can also be affected. The pattern of inheritance of these disorders has not been clearly

determined. Autosomal-dominant, recessive, and X-linked recessive patterns have been proposed.⁸⁴⁵

ECTRODACTYLY ECTODERMAL DYSPLASIA-CLEFT LIP/PALATE SYNDROME

Ectrodactyly ectodermal dysplasia-cleft lip/palate syndrome is an autosomal-dominant condition characterized by the triad of ectrodactyly, ectodermal dysplasia, and facial clefting.⁸⁴⁶ Ectrodactyly generally involves the four extremities, with more severe deformities of the hands.^{847,848} The spectrum of ectodermal defects is wide and includes hypopigmentation, dry skin, sparse hair, and dental defects.⁸⁴⁹⁻⁸⁵² Tear duct anomalies and decreased lacrimal secretions lead to chronic keratoconjunctivitis and severe loss of visual acuity.^{853,854} Cleft lip is generally bilateral. Obstructive uropathy often occurs in this condition.⁸⁵⁵ Intelligence is generally normal.⁸⁵⁸ Mutations in the *P63* gene account for most cases of ectodermal dysplasia-cleft lip/palate syndrome.^{846,857}

A different group of syndromes involves associations of the split-hand-and-foot deformity with other anomalies. These entities include split foot and triphalangeal thumb, split foot and hand and central polydactyly, Karsch-Neugebauer syndrome (split hand and foot with congenital nystagmus), and mandibulofacial dysostosis (Fontaine syndrome).⁸⁵⁸

CLUBHANDS

Clubhand deformities are classified into two main categories: radial and ulnar. Radial clubhand includes a wide spectrum of disorders that encompass absent thumb, thumb hypoplasia, thin first metacarpal, and absent radius (Table 12-26). Ulnar clubhand is much less frequent than radial clubhand and ranges from mild deviations of the hand on the ulnar side of the forearm to complete absence of the ulna. Although radial clubhand is frequently syndromic, ulnar clubhand is usually an isolated anomaly.⁸⁵⁹⁻⁸⁶² Table 12-27 displays conditions that present with ulnar ray defects.

Whenever a clubhand is identified, it is important to conduct a thorough examination of the fetus and newborn to delineate associated anomalies that may suggest a syndrome. Fetal blood-sampling procedures and fetal echocardiography are recommended. A complete blood cell count, including platelets, is important to establish the diagnosis of Fanconi pancytopenia, TAR syndrome, and Aase syndrome. A fetal karyotype is indicated because several chromosomal abnormalities (e.g., trisomy 18, trisomy 21, and other structural aberrations) have been reported in association with clubhand deformities. Congenital heart disease is an important feature of the Holt-Oram syndrome, the Lewis upper limb-cardiovascular syndrome, and some cases of TAR syndrome.

Radial Clubhand

The term isolated radial clubhand indicates that the clubhand is not part of a recognized syndrome.^{862,863} However, this does not exclude that other anomalies may be

Table 12–26 Radial Ray Defects: A Differential Diagnosis of Congenital Deficiency of the Radius and Radial Ray

I.	Isolated: nonsyndromatic
II.	Syndromes with blood dyscrasias
	A. Fanconi anemia
	B. Thrombocytopenia with absent radii syndrome
	C. Aase syndrome: congenital anemia, nonopposable triphalangeal thumb, scaphoid and distal radius hypoplasia, radioulnar synostosis, short stature with narrow shoulders, autosomal recessive (see Diamond-Blackfan syndrome for a similar, perhaps identical, syndrome)
III.	Syndromes with congenital heart disease
	A. Holt-Oram syndrome
	B. Lewis upper limb–cardiovascular syndrome: more extensive arm malformations and more complex heart anomalies than with Holt-Oram but probably not a separate syndrome, autosomal dominant
IV.	Syndromes with craniofacial abnormalities
	A. Nager acrofacial dysostosis
	B. Radial clubhand and cleft lip and/or cleft palate: sporadic
	C. Juberg-Hayward syndrome: cleft lip and palate, hypoplastic thumbs, short radius, radial head subluxation, autosomal recessive
	D. Baller-Gerold syndrome: craniosynostosis, bilateral radial clubhand, absent/hypoplastic thumb, autosomal recessive
	E. Rothmund-Thomson syndrome: prematurely aged skin changes, juvenile cataract, sparse gray hair, absent thumbs, radial clubhands, occasional knee dysplasia (see Progeria syndromes)
	F. Duane-radial dysplasia syndrome: abnormal ocular movements: inability to abduct and eyeball retraction with adduction, radius and radial ray hypoplasia, vertebral anomalies, renal malformation, autosomal dominant (see Klippel-Feil variants)
	G. The IVIC syndrome (Instituto Venezolano de Investigaciones Cientificas): radial ray deficiency, hypoplastic or absent thumbs and radial clubhands, impaired hearing, abnormal movements of extraocular muscles with strabismus, autosomal dominant
	H. LARD syndrome (lacrimo-auriculo-radial-dental; Levy-Hollister): absent lacrimal structures, protuberant ears, thumb and radial hypoplasia, abnormal teeth, autosomal dominant
	I. Radial defects with ear anomalies and cranial nerve 7 dysfunction
	J. Radial hypoplasia, triphalangeal thumb, hypospadias, diastema or maxillary central incisors, autosomal dominant
V.	Syndromes with congenital scoliosis
	A. VATER association
	B. Goldenhar syndrome (oculoauriculovertebral dysplasia)
	C. Klippel-Feil syndrome
VI.	Radial aplasia and chromosome aberrations
VII.	Syndromes with mental retardation
	A. Seckel's syndrome (bird-headed dwarfism): microcephaly, beaklike protrusion of nose, mental retardation, absent/hypoplastic thumbs, bilateral dislocated hips
VIII.	Thalidomide embryopathy (of historical interest, but some 60% had radial clubhand)

Reproduced with permission from Goldberg MD: *The Dysmorphic Child: An Orthopedic Perspective*. New York, Raven Press, 1987.

present (e.g., scoliosis and congenital heart disease). Isolated nonsyndromic radial clubhand is generally a sporadic disorder.^{859–862} A detailed list of conditions associated with radial clubhands is presented in Table 12–26.

Radial Clubhand and Hematologic Disorders

Radial clubhand may be part of the three syndromes characterized by hematologic abnormalities: Fanconi pancytopenia, TAR syndrome, and Aase syndrome.

Fanconi Anemia

Fanconi anemia (pancytopenia) is an autosomal-recessive disease characterized by the association of bone marrow failure (anemia, leukopenia, and thrombocytopenia)⁸⁶⁴ and skeletal anomalies, including radial clubhand with absent thumbs, radial hypoplasia, and a high frequency of chromosomal instability (demonstrated in amniotic fluid cells or fetal lymphocytes as a high frequency of chromosomal

breakage after incubation with diepoxy-butane).^{865–868} Approximately 25% of affected individuals do not have limb reduction anomalies. Associated findings include microcephaly, congenital dislocation of the hips, scoliosis, as well as cardiac, pulmonary, and gastrointestinal anomalies.^{869–871} Intrauterine growth restriction is common. Up to 25% of the patients will show some degree of mental deficiency. It is assumed that the basic defect is related to the inability to repair DNA damage, in particular that of so-called DNA cross-links. At present, at least 11 complementation groups (A, B, C D1/BRCA2, D2, E, F, G, I, J, and L)⁸⁷² and eight associated genes have been identified: *FANCA*, *FANCC*, *FANCD2*, *FANCE*, *FANCF*, *FANCG/XRCC9*, *FANCL* and *FANCD1 (BRCA2)*.^{873–880} About 200 mutations have been described, and among these, mutations in the gene for complementation group FA-A (*FANCA*) account for approximately 65% of the cases.⁸⁷² Prenatal diagnosis has been reported many times.^{837,881–891} Molecular genetic testing is currently available for mutation analysis of the common Ashkenazi Jewish *FANCC* mutation and sequence analysis for *FANCA*, *FANCC*, *FANCF*, and *FANCG*.⁸⁹² For those cases

Table 12-27 Ulnar Ray Defects: A Differential Diagnosis of Congenital Deficiency of the Ulna and Ulnar Ray

- I. Isolated: nonsyndromic absent ulna
- II. Ulna hypoplasia and skeletal deficiency elsewhere
 - A. Ulna aplasia with lobster claw deformity of hand and/or foot, autosomal dominant
 - B. Femur-fibula-ulna complex
- III. Syndromes with ulna deficiency
 - A. Cornelia de Lange's syndrome
 - B. Miller syndrome (postaxial acrofacial dysostosis): absent ulna and ulnar rays and absent fourth and fifth toes; Treacher-Collins mandibulofacial hypoplasia, autosomal recessive; distinguish from Nagai preaxial acrofacial dysostosis
 - C. Pallister ulnar-mammary syndrome: hypoplasia of ulna and ulnar rays; hypoplasia of the breast and absence of apocrine sweat glands, autosomal dominant
 - D. Pillay syndrome (ophthalmomandibulomelic dysplasia): absent distal third of ulna, absent olecranon, hypoplastic trochlea and proximal radius, fusion of interphalangeal joints in ulnar fingers, knee dysplasia; corneal opacities, fusion of temporomandibular joint, autosomal dominant
 - E. Weyers' oligodactyly syndrome: deficiency of ulna and ulnar rays, antecubital webbing, short sternum, malformed kidney and spleen, cleft lip and palate, sporadic
 - F. Schnizel's syndrome: absent/hypoplastic fourth, fifth metacarpals and phalanges, hypogenitalism, anal atresia, autosomal dominant
 - G. Mesomelic dwarfism, Reinhardt-Pfeiffer type (ulno-fibula dysplasia): a generalized bone dysplasia but with a disproportionate hypoplasia of the ulna and fibula, autosomal dominant
 - H. Mesomelic dwarfism, Langer's type: a generalized bone dysplasia, but with aplasia of the distal ulna and proximal fibula and hypoplasia of the mandible

Reproduced with permission from Goldberg MD: *The Dysmorphic Child: An Orthopedic Perspective*. New York, Raven Press, 1987.

in which the affected gene and parental mutations are not known (e.g., in case of radial ray abnormalities identified by ultrasound but negative family history), chromosome breakage studies after exposure to DNA cross-linking agents,⁸⁸⁵⁻⁸⁸⁷ or single-cell parameter flow cytometry of amniotic fluid cell cultures, or bivariate flow cytometry of umbilical cord cell cultures⁸⁹³ have been used for prenatal diagnosis. The rationale for the use flow cytometry to test for Fanconi anemia is the hypersensitivity Fanconi anemia cells to alkylating agents leading to elevated G2-phase cell fractions in positive cases.⁸⁹³

Thrombocytopenia With Absent Radius Syndrome

TAR syndrome is an autosomal recessive disorder characterized by thrombocytopenia (platelet count of less than 100,000/mm³) and bilateral absence of the radius.⁸⁹⁵⁻⁸⁹⁸ Thumbs and metacarpals are always present. The ulna and humerus may be absent, and clubfoot deformities may occur. Congenital heart disease is present in 33% of the cases (e.g., tetralogy of Fallot and septal defects). Delivery by cesarean section is recommended, because these fetuses are at risk for intracranial hemorrhage.^{899,900} TAR has been successfully diagnosed in utero many times.⁸⁹⁹⁻⁹¹⁴

Aase Syndrome

Aase syndrome is an autosomal-recessive condition characterized by congenital hypoplastic anemia and a radial clubhand with bilateral triphalangeal thumb and a hypoplastic distal radius.⁹¹⁵⁻⁹¹⁸ Cardiac defects (ventricular septal defects and coarctation of the aorta) may be present.⁹¹⁹ Triphalangeal thumbs are a feature of several

bone dysostoses and malformation syndromes. They may also occur in random association with other defects, and as isolated, often familial, anomalies.⁹²⁰ The differential diagnosis of this condition includes Holt-Oram syndrome, Diamond-Blackfan syndrome,^{921,922} chromosomal abnormalities, and fetal hydantoin syndrome.

Holt-Oram Syndrome

Holt-Oram syndrome is an autosomal-dominant disorder characterized by congenital heart disease (mainly atrial septal defects, secundum type, and ventricular septal defects),^{207,921,923-926} aplasia or hypoplasia of the radius, and triphalangeal or absent thumbs.^{927,928} Limb defects are often asymmetric, with the left side being more affected than the right side. There is no correlation between the severity of the limb defects and cardiac anomalies.^{929,930} Indeed, some individuals have only a skeletal anomaly.⁹³² Other findings include hypertelorism, chest wall, and vertebral anomalies.⁹³¹⁻⁹³⁴ This condition has been diagnosed prenatally by 2DUS and 3DUS.^{931,935-939} Holt-Oram syndrome is caused by mutations in the *TBX5* gene,^{939,940} and pre-implantation diagnosis of this condition has been reported.⁹⁴¹ The upper limb-cardiovascular syndrome described by Lewis and colleagues is probably not a separate entity from Holt-Oram syndrome.⁹⁴²

Radial Clubhand and Scoliosis

Radial clubhand may also be associated with congenital scoliosis. The three syndromes that should be considered part of the differential diagnosis include VATER association, some cases of the Goldenhar syndrome, and the Klippel-Feil syndrome.⁹⁴³

VATER Association

VATER association is the result of a defective mesodermal development during embryogenesis before the 35th day of gestation.⁹⁴⁴⁻⁹⁴⁷ The typical findings are vertebral segmentation defects (70%), anal atresia (80%), tracheoesophageal fistula (70%), esophageal atresia, and radial and renal defects (65% and 53%, respectively).^{948,949} Other anomalies include a single umbilical artery (35%) and congenital heart disease, occurring in nearly 50% of the patients.⁹⁵⁰⁻⁹⁵⁵ VATER association occurs sporadically, although recurrence within a sibship has been reported.⁹⁵³ Prenatal diagnosis by sonography has been reported.^{66,955-965}

Goldenhar Syndrome

Goldenhar syndrome is characterized by hemifacial microsomia, vertebral anomalies, and radial defects.⁹⁶⁶⁻⁹⁷⁰ Alterations in the morphogenesis of the first and second brachial arches result in hypoplasia of the malar, maxillary, or mandibular region; microtia; and ocular and oropharyngeal anomalies.⁹⁷⁰⁻⁹⁷⁵ Prenatal diagnosis has been reported.^{972,977-979}

Klippel-Feil Syndrome

Klippel-Feil syndrome is characterized by fusion of any two of the cervical vertebrae, resulting in short neck, low posterior hair line, and restricted mobility of the upper spine. Several associated anomalies may be present, including spina bifida, cleft palate, rib abnormalities, lung disorders, congenital heart disease, and limb anomalies.⁹⁸⁰ Klippel-Feil syndrome has not been diagnosed prenatally.

Other Conditions Associated With Radial Clubhand

Radial clubhand has also been reported in association with several chromosomal anomalies, including trisomies 18 and 21, deletion of the long arm of 13, and ring formation of chromosome 4.^{868,981,982}

Some disorders present with craniofacial abnormalities and radial clubhand deformities. These conditions are sporadic and have common features that make a prenatal differential diagnosis difficult. The most common craniofacial anomaly is cleft lip and palate. Uuspaa's study of 3225 cases with orofacial cleft showed a 2.8% association with upper extremity deformities.⁹⁸³

Ulnar Clubhand

Ulnar clubhand usually occurs as an isolated, nonsyndromic anomaly. Syndromes that may have ulnar clubhand as part of their phenotype (e.g., Poland syndrome) are described in Table 12-27.⁹⁸⁴

Polydactyly

Polydactyly is the presence of an additional digit (see Fig. 12-25).^{985,986} The extra digit may range from a fleshy nubbin to a complete digit with controlled flexion and extension (see Figs. 12-39 and 12-40). Polydactyly can be

FIGURE 12-45. Femoral hypoplasia–unusual facies syndrome. Note the absence of the left femur and only a tiny portion of ossified bone on the right side. There is partial fusion of the tibia and fibula. Of interest is the presence of preaxial polydactyly (arrows) in both feet.

classified as postaxial (the most common form), preaxial, and central (see Table 12-16). Postaxial polydactyly occurs on the ulnar side of the hand and fibular side of the foot.⁹⁸⁷⁻⁹⁸⁹ Preaxial polydactyly is present on the radial side of the hand and the tibial side of the foot (Fig. 12-45).⁹⁹⁰ Central polydactyly consists of an extra digit that is usually hidden between the long and the ring finger.⁹⁹¹⁻⁹⁹⁴

Evidence from mouse models suggests that many types of polydactyly involve the hedgehog pathway, either directly or indirectly. Specifically, mutations in the downstream effector of Shh, *GLI3*, give rise to several polydactyly phenotypes, the mildest of which are postaxial polydactyly type I and preaxial polydactyly type IV (or Creig cephalopolysyndactyly).⁵ Postaxial polydactyly type I is about 10 times more frequent in blacks than in whites, and is characterized by an extra digit that is well developed and articulates with the fifth digit or an extra metacarpal/metatarsal.²⁶⁴ Creig cephalopolysyndactyly is characterized by pre- or postaxial polysyndactyly of variable degrees, frontal bossing, and hypertelorism.⁵ The most severe malformations are found in Pallister-Hall syndrome, which is characterized by hypothalamic hamartomas, craniofacial anomalies, polysyndactyly, and anal defects.⁹⁹⁴

Although the majority of cases of polydactyly are isolated and inherited as an autosomal-dominant trait, polydactyly is

Table 12-28 Disorders of the Developing Motor System on All Levels, Leading to Immobilization

Disorders of the developing neuromuscular system
Loss of anterior horn cells
Radicular disease with collagen proliferation
Peripheral neuropathy with neurofibromatosis
Congenital myasthenia
Neonatal myasthenia (maternal myasthenia gravis)
Amyoplasia congenital
Congenital muscular dystrophy
Central core disease
Congenital myotonic dystrophy
Glycogen accumulation myopathy
Disorders of developing connective tissue or connective tissue disease
Muscular and articular connective tissue dystrophy
Articular defects by mesenchymal dysplasia
Increased collagen synthesis
Disorders of developing medulla or medullar disease
Congenital spinal epidural hemorrhage
Congenital duplication of the spinal canal
Disorders of brain development (e.g., porencephaly or brain disease)
Congenital encephalopathy

a phenotypic trait in 119 disorders (97 syndromic and 22 nonsyndromic), 39 of which are caused by mutations in known genes and 16 are mapped to a locus in the genome.⁹⁹⁵ Central polydactyly is often bilateral and may be associated with other hand and foot malformations.⁹⁹¹⁻⁹⁹³ Preaxial polydactyly, however, especially when a triphalangeal thumb is present, is more likely to be part of a syndrome.

Arthrogryposis

The term arthrogryposis multiplex congenita (AMC) refers to multiple joint contractures present at birth in an intact skeleton.⁹⁹⁶⁻⁹⁹⁹ The condition is present in 3 per 10,000 live births.^{999,1000}

Normal fetal movement between 7 and 8 weeks of gestation onward is important for the development of the joints; limitation of the fetal joint motion leads to the development of contractures and AMC.^{1001,1002} This has been confirmed in animal models,¹⁰⁰³ including chick and rat embryos injected with tubocurarin and botulism toxins,^{1004,1005} viral myopathy induced by coxsackie A viruses,¹⁰⁰⁶ and cross-section of the spinal cord.¹⁰⁰⁷ Therefore, AMC is a syndrome, not a specific disorder. The incidence of the different underlying causes of AMC is variable in the literature. Neurologic, muscular, connective tissue, skeletal abnormalities, and intrauterine crowding can lead to impaired fetal motion and AMC.^{1001,1002} Table 12-28 shows a list of motor disorders that can lead to AMC. In a series of 74 children, Banker¹⁰⁰⁹ found that the most common causes of AMC were neurogenic disorders, followed by myopathic disorders. Similarly, in an autopsy series of 75 fetuses and newborns, Swinyard¹⁰⁰⁹ reported CNS disorders as a cause of AMC in 75% of the cases, followed by muscular disorders in 10% to 15%. In contrast, Quinn et al¹⁰¹⁰ reported that only 5 of 21 cases of lethal AMC were of neurogenic etiology, whereas 11 were myogenic and 5 were of uncertain pathology.

The etiology of AMC may derive from hereditary conditions,¹⁰¹²⁻¹⁰¹⁸ infectious agents, drugs, toxins and fetal alcohol syndrome.^{1003,1004,1021} Maternal hyperthermia has also been associated with AMC.¹⁰²⁰ Maternal antibodies specific for a fetal acetylcholine receptor have been reported to cause fetal AMC without evidence of maternal myasthenia gravis.^{1021,1023} In addition, plasma from human mothers of fetuses with AMC, when injected into pregnant mice, causes deformities in the offspring.¹⁰²³ The pattern of inheritance depends on the specific cause of AMC.¹⁰²⁴ In a series of 350 cases, Hall¹⁰²⁵ found that 46% of them corresponded to a syndrome with no recurrence risk, 23% corresponded to disorders inherited with a Mendelian pattern (autosomal dominant, autosomal recessive, or X-linked), 20% were unknown conditions, 6% were associated with environmental disorders, 3% were chromosomal, and 2% were multifactorial in origin.

The recurrence risk varies depending on the underlying cause. Hall and Reed¹⁰²⁰ found that in 20% of 350 patients, no diagnosis was made. They concluded that, in this situation, the risk for recurrence would be 4.7% if only the limbs were affected, 7% if the CNS was involved, and 1.4% if the limbs and another area were involved.

In most cases of AMC, deformities are usually symmetric and involve the four limbs (Fig. 12-46). Anomalies of the lower extremities only, or bimeric involvement, can also occur. The severity of the deformities increases distally in the involved limb, with the hands and feet typically being the most affected.

Cardinal findings on prenatal ultrasonography include absence of fetal movement on real-time examination and severe flexion deformities.¹⁰²⁶⁻¹⁰⁴¹ Four-dimensional ultrasonography may help to better characterize the phenotype prenatally.¹⁰⁴³ Zelop and Benacerraf¹⁰³³ evaluated the clinical significance and outcome of postural deformities and contractures of the upper extremities detected prenatally. Among 52 fetuses with sonographically detected abnormalities

FIGURE 12-46. Arthrogryposis multiplex congenita. There is flexion of the upper limbs with hyperextension of the lower limbs.

of the upper extremities, 26 (59%) had aneuploidies, mostly trisomy 18 (88% [23/26]). Fetuses with a normal karyotype presented with a variety of syndromic conditions, including three cases of arthrogryposis multiplex congenita, and one case each of Pierre-Robin sequence, Freeman-Sheldon, and Whistler syndrome requiring gastroscopy-tube placement, and bilateral syndactyly requiring multiple corrective surgical procedures. The survival rate was 5% (8/52), and only one of the survivors was phenotypically normal after birth.

Many congenital anomalies are associated with AMC. The most frequent are cleft palate, Klippel-Feil syndrome, meningomyelocele, and congenital heart disease. Ten percent of patients with AMC have associated anomalies of the CNS.⁹⁹⁷

The prognosis of AMC depends on the specific cause. Although some cases are uniformly lethal, others are associated with mild to moderate handicap. In a retrospective study of 828 cases of AMC, Fahy and Hall¹⁰⁴³ found that polyhydramnios is a poor prognostic sign.

CLUBFOOT

Clubfoot (talipes equinovarus) is a congenital malformation of the bones of the ankle and foot resulting in the adduction of the forefoot, inversion of the heel, and plantar flexion of the forefoot and ankle.¹¹⁴¹ There is subluxation of the

FIGURE 12-47. Sonogram of the lower extremity in a fetus with unilateral clubfoot. Normally, when the tibia and fibula are seen, only a portion of the foot is seen in the same plane. The abnormal medial deviation of the foot results in all structures being seen en face.

talo-calcaneo-navicular joint. As a result of this malformation, the dorsal aspect of the foot is often rotated medially, which assumes a clublike appearance.¹¹⁴² The sonographic diagnosis is made when the metatarsals and phalanges of the foot are seen in the same plane as the tibia and fibula^{1142,1144} (Fig. 12-47).

The severity of the clubfoot deformity varies from a postural deformity often requiring no treatment; an isolated clubfoot deformity, needing casting and possible surgery, often with a favorable outcome; or a complex clubfoot abnormality associated with other chromosomal, neuromuscular, or structural abnormalities. Clubfoot may also result from restriction of movement in utero as in severe oligohydramnios.¹¹⁴² The prevalence is often stated as one per 1000 live births, with a 2:1 male-to-female predisposition.¹¹⁴⁵ Several series have demonstrated that an initially diagnosed isolated clubfoot abnormality was noted to be complex and associated with other abnormalities either later in pregnancy or in the neonatal period.^{1142,1146} False-positive diagnoses are more prevalent when unilateral clubfoot is suspected than when bilateral clubfoot was suspected or diagnosed.¹¹⁴² The association of an isolated clubfoot abnormality with aneuploidy is controversial. Shipp and Benacerraf found that 5.9% of 87 fetuses with isolated clubfoot had an abnormal karyotype and concluded that amniocentesis is indicated after that diagnosis.¹¹⁴⁹ Other investigators came to the opposite conclusion.^{1142,1143,1148} In the series by Malone et al,¹¹⁴¹ there were no cases of aneuploidy on karyotype when the clubfoot was isolated.
