ULTRASOUND EVALUATION OF THE FETAL THORAX

Juriy W. Wladimiroff, MD, PhD, Titia E. Cohen-Overbeek, MD, and Jacqueline A. M. Laudy, MD, PhD

The Fetal Lung

Normal Lung Development

Lung Hypoplasia

Congenital Cystic Adenomatoid Malformation

Bronchopulmonary Sequestration

Congenital High Airway Obstruction (Laryngeal Atresia)

Other Lung Abnormalities

The Fetal Diaphragm

Normal Development

Congenital Diaphragmatic Hernia

Congenital Hydrothorax

In this chapter, normal and abnormal development of fetal intrathoracic organs are discussed, with emphasis on the lungs and diaphragm. Each intrathoracic abnormality may not only have an impact on its own organ functioning but may also have an effect on neighboring organ systems such as diaphragmatic hernia resulting in lung hypoplasia. Diagnostic ultrasound and lately ultrafast magnetic resonance imaging (MRI) play a major role in the detection of fetal intrathoracic pathology. When additional imaging is required, the role of MRI and three-dimensional (3D) ultrasound in the elucidation of intrathoracic normal anatomy and pathologic conditions are discussed.

THE FETAL LUNG

The prenatal diagnosis of fetal abnormalities originating from the lung is dependent upon the sonographic appearance of intrathoracic space-occupying lesions.¹ The normal lung is of moderate echogenicity, which may vary in echogenicity from hypoechoic to isoechoic to hyperechoic when compared with the adjacent liver (Fig. 13-1).² Fetal lung lesions must be distinguished from extrapulmonic masses, such as a diaphragmatic hernia, in which intrathoracic stomach, intestine, and liver are present. Whereas fetal congenital cystic adenomatoid malformation (CCAM) is characterized by either a cystic or a solid hyperechoic mass, bronchopulmonary sequestration (BPS) appears as a well-defined uniformly hyperechoic solid mass mostly situated in the left basal lung.³ Based on the concept that each unit of embryonic lung includes a bronchial bud supplied by a systemic capillary plexus derived from the primitive aorta and containing a small branch of the pulmonary artery, Achiron et al⁴ attempted to group lung lesions according to (1) presence/absence of lung; (2) normal/abnormal lung; and (3) normal/abnormal vascular supply. This system would group congenital lung lesions into one of five groups of dysplasias. Although the concept is intriguing, it may also introduce confusion into an already complex topic.⁵ This chapter adheres to the more conventional systems of classification.

NORMAL LUNG DEVELOPMENT

Human lung development is divided into five stages: embryonic, pseudoglandular, canalicular, saccular, and alveolar (Fig. 13-2). The transition between stages occurs gradually, and there is considerable overlap from one stage to the next, and also between areas within the lung and between various gestational ages and individuals.⁶

During the embryonic stage, the lung arises as a diverticulum from the caudal end of the laryngotracheal groove of the foregut at the end of the fourth week. During the next few weeks, this diverticulum grows gradually caudally to form the primitive trachea. The end of the diverticulum divides into two sacs, the lung buds. By the end of the sixth week, all bronchopulmonary segments have been formed. During the pseudoglandular stage, conducting airways are formed by repeated dichotomous branching resulting in a tree of narrow, thick, epithelial-lined tubules. By the 16th week of gestation, the tracheobronchial tree has been formed. During the canalicular stage (16-28 weeks), the basic structure of the gas-exchanging portion of the lung is formed and vascularized. At the beginning of the saccular stage (28-36 weeks) airways terminate in large smooth-walled cylindrical structures and are subdivided by ridges called crests. The crests protrude into saccules. The end result of the saccular stage is a rapid increase in the gas exchange of the lung and rapid thinning of the interstitium. The alveolar stage (36 weeks-term) is characterized by further thinning of the blood-gas barrier, increase of surfactant production, and progressive branching of the respiratory airways.

Prenatal growth and development of the pulmonary blood vessels is closely linked to that of the bronchial tree. The sixth bronchial arches appear at about 5 weeks and develop into the main pulmonary arterial trunk with right and left branches during the next few weeks of the pseudoglandular period. By 7 weeks of gestation, the adult pattern of vessels connecting heart and lungs is established. The normal cardiac and pulmonary arterial and venous blood flow connections are illustrated in Figure 13-3. The pulmonary arteries and veins can be seen using color Doppler flow imaging (Fig. 13-4).

FIGURE 13-1. Slightly angled coronal sonographic plane of section in a late second trimester pregnancy demonstrating normal lungs (Lu) slightly more echogenic than the liver (Li). The hypoechoic muscular diaphragm (arrows) is seen on one side.

The in utero pulmonary vascular circuit is a high-resistance, high-pressure, low-flow system.⁷ In the fetus, normal gas exchange is placental in origin and pulmonary blood flow is low, merely supplying nutritional requirements for lung growth and some metabolic functions.⁸ In human fetuses, the total cardiac output supplying the lungs increases from 13% at 20 weeks to 25% at 30 weeks and remains constant during the remainder of pregnancy.⁹ This implies that pulmonary blood flow increases and pulmonary vascular resistance decreases with advancing gestation.

Fetal lung development incorporates a combination of two processes: lung growth and lung maturation, which are related, but appear to be separately controlled. A normal amount of amniotic fluid is important for fetal lung growth.¹⁰ Fetal intrapulmonary fluid is formed by active transport across pulmonary epithelium into the tracheobronchial lumen, where it establishes positive pressure within the developing lung. Lung-liquid volume and intratracheal pressure are maintained within very precise ranges by the larynx, which through unknown mechanisms regulates the efflux of lung liquid volume from the trachea to the amniotic space.¹⁰ Lung liquid contributes up to one third of amniotic fluid volume. Fetal breathing movements in humans can be recorded by ultrasonography from about 10 weeks of gestation. These respiratory movements produce significant changes in intrathoracic pressure, which may influence lung development.¹¹

LUNG HYPOPLASIA

Pulmonary hypoplasia is defined as the incomplete or defective development of the lung resulting in overall reduced size due to reduced numbers or size of acini.¹² With the incidence of lung hypoplasia being 1.1 per 1000 live births and a mortality rate of more than 50%, fetal lung hypoplasia poses a major diagnostic challenge.¹³ It is seen in greater than 10% of neonatal autopsies and occurs in association with other malformations, most commonly congenital diaphragmatic hernia, severe skeletal dysplasias and severe renal abnormalities.^{12,14} Early evaluation of the adequacy of fetal lung volumes used the subjective appearance of the bony thorax, measurements of the fetal thoracic circumference (TC) (Table 13-1), and the relationship of the thoracic circumference to the abdominal circumference (AC) (the thoracic circumference/abdominal circumference ratio) (Fig. 13-5).^{15,16} These measurements, of course, were only indirect assessments of fetal lung volume. Actual fetal lung size was initially estimated from two-dimensional (2D) ultrasound images. Measurements included lung area, lung circumference, and lung length/diameter.¹⁷⁻²¹ Lung length has been established in a plane through the long axis of the thorax from the superior end of the sternum to the level of the diaphragm or the inferior surface of the heart¹⁶ or from the apex to the base of the lung.¹⁹ Others studied the ratio of lung area to head circumference (LHR),²² lung length to thoracic circumference²³ and lung length multiplied by the width to head circumference,²⁴ particularly in cases of congenital diaphragmatic hernia (Fig. 13-6). From the data thus far, it appears that none of those biometric parameters is reliable enough to predict pulmonary hypoplasia with certainty. The introduction of 3D ultrasonography would allow for the assessment and correction of surface irregularities.²⁵ The more conventional 3D sonographic approach involves scrolling through one plane of the multiplanar display while delineating the lungs in a different plane. Alternatively, the VOCAL technique (Virtual Organ Computer-Aided Analysis, General Electric medical systems) allows volume calculations around a fixed axis through a number of sequential steps.²⁶ Whereas in an in vitro setting, rotational measurement of volume proved to be superior to the conventional technique,²⁵ in vivo study of fetal lung

volume demonstrated that the rotational method with VOCAL was less reproducible than the common multiplanar technique.²⁶ On the other hand, Moeglin et al²⁷ found no statistically significant difference between lung volume values obtained using the two 3D sonographic ultrasound modes. Not only different 3D ultrasound techniques but also different methods for measuring fetal lung volume have been reported. For the most part in earlier work, fetal lung volume was obtained by subtracting fetal heart volume from thoracic volume.²⁸ The disadvantage of this approach is the inclusion of mediastinal structures (thymus, trachea, esophagus, and great vessels) in the measurement of lung volume. Accuracy may be improved by direct determination of fetal lung volume, including separate measurement of the left and right lungs.^{29,30}

Most reports on direct lung volume measurement by 3D ultrasonography provide a definition of the upper and lower border, such as the level of the clavicle, and the dome of the diaphragm. This was the case in the study by Gerards²⁹ and was further highlighted by Peralta et al,³¹ who also emphasize the importance of defining the medial border of the lungs and distinction from the heart and mediastinal organs as well as the lateral border of the lungs and distinction from the thoracic cage.

*Measurements in centimeters.

From Chitkara U, Rosenberg J, Clivernek FA, et al: Prenatal sonographic assessment of the fetal thorax: Normal values. *Am J Obstet Gynecol* 156:1069, 1987.**FIGURE 13-5.** Coronal plane of section in a fetus with a severe skeletal dysplasia. Owing to marked shortening of the ribs and bony thorax, the lungs are markedly hypoplastic. The heart occupies much of the thorax (diaphragm, arrows).

In the past 6 to 7 years, there have been a number of interesting reports using MRI to image the lungs.³²⁻³⁴ The development of the single-shot rapid-acquisition with relaxation enhancement sequence, a rapid spin-echo-based T2-weighted sequence, has been a major step forward in fetal MRI.³² On MRI, the lungs are well depicted on T2-weighted images (Fig. 13-7).^{33,34} Fast-spin echo T2-weighted MR images of the fetal thorax provide a well-defined contrast between the fetal parenchyma and surrounding structures, which include the trachea, esophagus, diaphragm, and thoracic wall structures.³⁵ Moreover, the MR signal intensity of the fetal lung is a good indicator of fetal lung maturation.³⁶ MRI has been shown to be helpful in determining ipsilateral lung volume in cases of congenital diaphragmatic hernia (Fig. 13-8).³⁶

The question arises whether there is a preference for 3D ultrasonography or MRI for the determination of fetal lung volume development. 3D ultrasonography has the advantage of cost-effectiveness, ease and speed of use, and patient acceptability.³⁰ On the other hand, optimal 3D ultrasound resolution may not always be possible owing to fetal position, oligohydramnios, maternal obesity, fetal cardiac activity, and fetal (breathing) movements. The accurate delineation of the contour of the lung may be hampered because of reduced differentiation between fetal lung and liver.

The next question is whether these techniques will suffice in detecting lethal pulmonary hypoplasia. We know that prolonged and severe oligohydramnios, particularly during the canalicular phase of lung development, may cause a

$$\text{LHR} = \frac{A \times B \text{ (mm)}}{\text{HC (mm)}}$$

A Head Circumference

B

FIGURE 13-6. A. Diagrammatic illustration of the method for measuring the lung to head ratio (LHR) in a fetus with congenital diaphragmatic hernia. The measurement of the right lung (in the typical left congenital diaphragmatic hernia) uses a transverse axial plane of section of the fetal thorax at the level of the four-chamber view of the fetal heart. The plane of section should be symmetric so that a single rib is seen on each side. A measurement in millimeters (mm) is made from the thoracic aorta to the lateral inner chest wall (A). Another measurement, also in mm, is made in a plane perpendicular to the first measurement from the outer wall of the atrium to the inner aspect of the posterior chest wall (B). These two measurements are multiplied by one another and divided by the measurement of the head circumference also in mm. (From Roy A. Filly, MD, San Francisco, CA. Illustration by James A. Cooper, MD, San Diego, CA.) B. Transverse axial sonogram of a fetus with a left congenital diaphragmatic hernia. The two diameters (arrows) used in measuring the remaining area of the right lung are shown.

delay or even an arrest in pulmonary vascular development, resulting in reduced lung volume and raised pulmonary vascular resistance.³⁷ Doppler velocimetry of the fetal arterial lung circulation has shown that peak systolic velocity (PSV) in the proximal pulmonary artery flow velocity waveform is reduced in lethal lung hypoplasia (Fig. 13-9).³⁸

FIGURE 13-7. MRI obtained in 29-year-old pregnant woman at 30 weeks' gestation in whom detailed prenatal ultrasound depicted a normal fetal chest and fetal abdomen; MRI was performed because placenta accreta was suspected. Coronal single-shot rapid acquisition with relaxation enhancement (T2-weighted MR image 8/90, 4-mm section) of the fetal chest and fetal abdomen shows lungs (arrows) with high signal intensity. Use of this sequence facilitated easy identification of the lungs and planimetry. (From Williams G, Coakley FV, Qayyum A, et al: *Fetal relative lung volume: Quantification by using prenatal MR imaging lung volumetry*. *Radiology* 233:457, 2004.)

Nevertheless, as a single test it turned out not to be reliable enough for clinical application. A combination of clinical (onset, duration, degree of oligohydramnios), biometric (thoracic to abdominal ratio) and Doppler (PSV in proximal lung artery) parameters demonstrated a PPV of 100%, an overall accuracy of 93%, and a sensitivity of 71%.³⁹ Again, the clinical significance of this combined test is limited as a result of the restrictions in obtaining the necessary components of it and the low sensitivity of the combination. In another study, a raised pulsatility index (PI) in the arterial lung circulation was found in a substantial number of fetuses

FIGURE 13-8. Twenty-six-year-old woman at 24 weeks' gestation. Detailed prenatal ultrasound demonstrated a left CDH. A coronal single-shot RARE T2-weighted (TR/TE = 4/90 msec) 4 mm section of the fetal chest illustrates the technique of lung planimetry. The lung edge has been traced to calculate the lung volume for the section. The right lung cross-sectional area is being measured. The left lung is not visible, and the left hemithorax contains herniated bowel and stomach (asterisk). (From Coakley FV, Lopoo JB, Lu Y, et al: *Normal and hypoplastic fetal lungs: Volumetric assessment with prenatal single-shot rapid acquisition with relaxation enhancement MR imaging*. *Radiology* 216:107, 2000.)

FIGURE 13-9. Fetal proximal pulmonary artery flow velocity waveform during normal lung development (left) and in lung hypoplasia (right) at 34 weeks of gestation. Note the reduced velocity and two-pronged nature of the systolic component of the latter waveform. (From Laudy JA, Gaillard JLL, van der Anker JN, et al: *Doppler ultrasound imaging: A new technique to detect lung hypoplasia before birth? A case report*. *Ultrasound Obstet Gynecol* 7:189, 1996.)

that had developed lung hypoplasia.⁴⁰ Of interest is the nonreactivity of the flow pattern in the proximal pulmonary artery during exposure to maternal breathing, by mask, of 60% oxygenated air.⁴¹ This test, with a PPV of 79%, a sensitivity of 92%, and a specificity of 82%, seems quite promising. A different approach was taken by Fuke et al,⁴² who found the acceleration time/ejection time ratio in the fetal-pulmonary arterial flow velocity waveform to be reduced in the presence of lung hypoplasia. Whether 3D ultrasound, MRI, and Doppler ultrasound will ultimately produce a test that is clinically applicable and reliable, is as yet unclear.

CONGENITAL CYSTIC ADENOMATOID MALFORMATION

CCAM of the lung is a benign hamartomatous or dysplastic tumor characterized by overgrowth of terminal bronchioles with a reduction in number of alveoli.⁴³ These malformations are rare, with an incidence of 1 in 5000 live births.⁴⁴ CCAM develops during the pseudoglandular period (7–16 weeks), that is characterized by expansion of the conducting airways and peripheral lung tubules that branch and form buds resulting in acinar tubules. Vascularization of peripheral lung mesenchyme as well as closure of the pleural and peritoneal cavity takes place.⁴⁵ The cystic components of CCAM are lined by respiratory epithelium. There is usually communication with the normal tracheobronchial tree and vascularization from the pulmonary artery.⁴⁶ A possible gene interaction (*HOX B-5*; *FGF-7*; *PDGFB* gene) with CCAM has been suggested.^{47–49} CCAM is usually unilateral and lobar. In the late 1970s, Stocker et al¹² classified the more common types of CCAM into three categories: type 1, in which there is a large or predominant cyst (3 to 10 cm in diameter), compressing the normal parenchyma; type 2, composed of multiple cysts (0.5 to 2.0 cm in diameter) evenly distributed and blending with the adjacent normal parenchyma; and type 3, the small cystic or solid type. More recently, two additional subtypes of CCAM have been added to the classification; type 0, also known as acinar dysplasia, or agenesis with tissue that consists of bronchus-like structures and type IV consisting of a large peripheral cyst of the distal acinus lined predominantly with alveolar type cells. With this classification, Stocker¹² proposed that the designation of CCAM be changed to congenital pulmonary airway malformation (CPAM), owing to the fact that only three of the five types were cystic and only one type (type 3) adenomatoid. Adzick⁵⁰ proposed a prenatal classification of CCAM, based on ultrasound. In this classification, CCAM was either macrocystic or microcystic. Macrocystic lesions contain single or multiple cysts that are 5 mm or more in diameter and, therefore, are discernable on ultrasound; the prognosis is often more favorable (Fig. 13–10). Microcystic lesions appear as a solid hyperechogenic mass based on numerous acoustic interfaces (Fig. 13–11). Depending on the size of these lesions, esophageal compression may occur, resulting in reduced fetal swallowing and subsequent polyhydramnios. On prenatal MRI, microcystic lesions present as hyperintense and homogeneous T2-weighted images compared with normal lungs.⁵¹ Macrocysts can be demonstrated on MRI.⁵² Changes in thoracic position of other lung lobes, mediastinum, and cardiac structures must be identified.⁵³ Power Doppler son-

ography allows evaluation of the vascular supply of these lesions.⁴⁶ The natural history of CCAM is unpredictable in that it may grow or regress. The latter occurs in about 15% of cases and may be due to decompression into the tracheobronchial tree, outgrowth of blood supply or torsion around the vascular pedicle with infarction.^{54,55} On the other hand, development of fetal hydrops must be considered as a sign of impending fetal death (Fig. 13–12).

Quantification of CCAM can be achieved through measuring tumor volume and dividing this volume by head

FIGURE 13–10. Macrocystic CCAM. A. Macrocystic CCAM with small to moderate sized cysts. Surrounding hyperechogenic tissue characteristic of microcystic CCAM is also seen. B. Macrocystic CCAM with three large cysts adjacent to the heart (H).

FIGURE 13-11. Microcystic adenomatoid malformation of the fetal lungs at 30 weeks of gestation on a transverse (*left*) and longitudinal (*right*) cross-section.

circumference to standardize for gestational age.⁵⁶ Most cases of prenatally diagnosed CCAM have a good outcome.^{57,58} In cases of a large macrocystic CCAM that causes displacement of surrounding thoracic organs, prenatal treatment can be considered by means of cyst aspiration or thoraco-amniotic shunting.^{43,59} The latter will be more effective and prevent fluid accumulation. These procedures should be considered before 32 to 33 weeks of gestation, and delivery should be contemplated beyond this gestational age. Microcystic CCAM is not amenable to shunting, but in the presence of fetal hydrops has been treated by means of open fetal surgery providing there were no other abnormalities or abnormal karyotype.⁵⁰ Recently, it has been noted that prenatal steroids may help in the resolution of hydrops fetalis in fetuses with CCAM. The prognosis of the various forms of CCAM are often dictated more by the mass effect on adjacent structures (heart, great vessels) rather than the specific type. It should be noted that histological changes of

CCAM and BPS (see later in this chapter) can occur within the same lesion (sometimes referred to as a hybrid lesion). When CCAM is found within a BPS, it is most often histological Type 2.⁶⁰

CCAM should be differentiated from other lung lesions such as (1) congenital lobar emphysema characterised by lobar over-inflation without destruction of the alveolar septae⁶¹ and (2) bronchopulmonary sequestration.

BRONCHOPULMONARY SEQUESTRATION

BPS represents masses of nonfunctioning lung tissue that do not have a connection to the normal tracheobronchial tree and are supplied by an anomalous systemic artery and usually situated in the lower lobes.⁵⁰ Bronchopulmonary sequestrations are rare and are encountered in approximately 1.1% to 1.8% of all pulmonary resections.⁶² They are categorized as intralobar and extralobar. In both instances, arterial blood supply is from the systemic circulation (aortic branch) and venous drainage is either by means of the pulmonary veins (intralobar) or by means of the systemic veins (extralobar).⁴⁶ Intralobar BPS accounts for 75% of all pulmonary sequestrations.⁶³ The intralobar variety consists of an abnormal segment of lung tissue that shares the visceral pleural covering of the normal lung. Intralobar BPS has only rarely been reported prenatally. Extralobar BPS consists of a discrete accessory lobe of the lung with its own pleural covering.⁶³

They are typically found in the thorax and on the left side (65% to 90%) of cases.^{62,64-66} Extralobar BPS may also be found in the mediastinum or pericardium.⁶² Approximately 10% to 15% of extralobar sequestrations are found within or below the diaphragm.^{64,67} The arterial supply is systemic from an anomalous artery arising from the thoracic or abdominal aorta.⁶³ The venous drainage is usually systemic through the azygous, hemiazygous veins, or the superior vena cava.^{62,63} Extralobar sequestration occurs more frequently in males than females with a 4:1 ratio. Extralobar bronchopulmonary sequestration is associated with other fetal anomalies in approximately two thirds of cases, notably congenital diaphragmatic hernia, and foregut abnor-

FIGURE 13-13. Fetal bronchopulmonary sequestration (S) with supplying vessel (arrow) at 34 weeks' gestation. Pleural effusion (asterisk).

malities.^{64,68} The prognosis of BPS generally is good; pleural effusions and subsequently fetal hydrops may develop in a small percentage of affected fetuses.

On ultrasound examination BPS appears as a well-defined, solid, and triangular mass,⁵³ although cystic areas may be seen. Therefore, it is not surprising that BPS may mimic CCAM and vice versa. A diagnosis of BPS becomes more likely in the presence of a systemic vascular supply as established by 2D color or 2D power Doppler and/or unilateral pleural effusion (Fig. 13-13). As in CCAM, MRI has demonstrated to be helpful in the diagnosis of BPS. On T2-weighted images, there is a wedge-shaped area of very high and homogeneous signal intensity (Fig. 13-14).⁶⁹ In contrast to CCAM, a considerable number (approximately 68%) of BPS lesions regress dramatically before birth.⁵⁰ Obstetric management consists of careful monitoring in the majority of cases. Early delivery may be contemplated after 32 to 33 weeks of gestation. In earlier stages, intervention by means of thoracocentesis or thoracoamniotic shunting can be considered in the presence of associated pleural effusions and fetal hydrops. Subdiaphragmatic extralobar bronchopulmonary sequestrations may simulate adrenal or renal masses, from which they should be distinguished (Fig. 13-15).

CONGENITAL HIGH AIRWAY OBSTRUCTION (LARYNGEAL ATRESIA)

Congenital high airway obstruction syndrome (CHAOS) was defined by Hedrick et al⁷⁰ in 1994 as upper airway obstruction that is diagnosed in utero by ultrasound, with concomitant findings of large hyperechogenic lungs, flattened or inverted diaphragms, dilated airways distal to the obstruction, and fetal ascites or hydrops (Fig. 13-16).^{70,71}

Complete or near-complete obstruction of the upper airway in utero results in obstructed flow of fetal lung fluid and elevated intratracheal pressure, distension of the tracheobronchial tree, and lung expansion leading to tracheobronchomalacia, respiratory distress syndrome, and

FIGURE 13-14. Prenatal magnetic resonance imaging (MRI) appearances of typical extralobar sequestration in fetus at 22 weeks' gestation. Axial T2-weighted single-shot rapid acquisition with relaxation enhancement (RARE) MRI (TR/effective TE, infinite/100) of fetal chest. Sequestration (black asterisk) is visible as large left-sided triangular mass of increased signal intensity, relative to displaced and compressed normal lungs (arrows). Lungs and heart (white asterisk) are displaced to right. (From Dhingra R, Coakley FV, Albanese CT, et al: *Prenatal sonography and MR imaging of pulmonary sequestration*. *Am J Roentgenol* 180:433, 2003.)

capillary leak of unknown mechanism.⁷² The markedly enlarged lungs cause cardiac and caval compression and in utero heart failure as manifested by ascites, hydrops, and placentomegaly. The cause of CHAOS varies and is most commonly caused by laryngeal atresia, subglottic stenosis, or a laryngeal web.⁷²

Since 1989, when the first prenatal diagnosis was reported, upper airway obstruction has been reported with increasing frequency.^{73,74} It can be an isolated finding or can be present as part of Fraser syndrome, which includes tracheal or laryngeal atresia, renal agenesis, microphthalmia, cryptophthalmos and polydactyly, or syndactyly. The detection of this syndrome is important because it has autosomal-recessive inheritance.^{66,74,75}

The sonographic findings include bilateral and uniform hyperechogenicity of the fetal lungs, as well as ascites.⁷⁴ The hyperechogenicity is caused by the overdistention of the alveoli by lung fluid, whereas ascites is the result of the compression of the right atrium and great veins by hyperplastic lungs. It has been proposed that the overdistention of the air spaces with lung liquid promotes alveolar proliferation by redistribution of cells.⁷⁶ Although polyhydramnios represents a common additional finding, it is thought to be a late event during the natural history of the upper respiratory atresia.^{74,77}

Figure 13-17 summarizes the pathophysiologic mechanisms, as well as the ultrasonographic findings of upper respiratory atresia sequence.⁷⁴ The differential diagnosis includes bilateral CCAM, type 3.

FIGURE 13-15. Subdiaphragmatic extralobar bronchopulmonary sequestration. *A.* Longitudinal plane of section in fetus with a subdiaphragmatic mass (asterisk). This lesion is clearly separate from the adjacent adrenal gland (Ad) and the kidney (K) and proved to be a subdiaphragmatic extralobar bronchopulmonary sequestration. *B.* Color Doppler image from the same patient demonstrating the systemic arterial blood supply (arrow) to this lesion from the aorta.

OTHER LUNG ABNORMALITIES

Other lung lesions include congenital lobar inflation (congenital lobar emphysema), bronchogenic cysts, and neurenteric cysts. Congenital lobar emphysema is characterized by progressive hyperexpansion of the lung parenchyma in a segment or lobe of the lung owing to obstruction of the supplying bronchus.^{78,79} The right middle and upper lobes are most commonly affected.⁸⁰ Prenatally, congenital lobar emphysema has been described as a uniformly echogenic lesion with associated mass effect. A prenatal diagnosis has, however, been rare, probably owing to the fact that cellular and fluid composition of the affected lobe is very similar to normal lung upon ultrasound examination.⁸⁰

Bronchogenic cysts (Fig. 13-18) develop from abnormal budding of the ventricular diverticulum of the foregut

FIGURE 13-16. Coronal sonogram in a fetus with laryngeal atresia. Bilaterally enlarged hyperechogenic lungs are seen. Dilated fluid filled bronchi (arrows) and ascites (asterisks) are seen as well. Li, liver.

resulting in focal cystic duplication of the tracheobronchial tree.⁸⁰ They may present as single or, less commonly, as multiple lesions.⁸¹ The dimensions of bronchogenic cysts vary from a few millimeters to greater than 5 cm.⁸¹ The walls of the cysts contain fibrous tissue and small amounts of cartilage, and the content of the cysts may be watery or viscid.

Neurenteric cysts are posterior enteric remnants that result from incomplete separation of the notochord from the foregut in the third to fourth weeks of embryogenesis.⁸²⁻⁸⁴ The presumed cause of the incomplete separation is a persistent communication or adhesion between the ectoderm of the spinal cord and the endoderm of the foregut before neural tube closure. Approximately 90% of neurenteric cysts occur in the right posterior mediastinum, superior to the carina, and about 50% are associated with vertebral abnormalities such as scoliosis, hemivertebra, and butterfly vertebrae.^{82,84,85} These cysts may be unilocular, however, they often have an internal septation (Fig. 13-19). Mediastinal neurenteric cysts may displace and compress adjacent lungs, airways, the heart and great vessels, and those with coexistent intraspinal lesions may have signs and symptoms of central nervous system (CNS) abnormalities. The outcome depends mostly on the extent of displacement and functional impairment of the adjacent organs, and on the associated CNS defects. These cysts may cause pulmonary hypoplasia and severe postnatal respiratory distress requiring prolonged ventilatory support.^{85,86} The cyst size does not seem to be directly related to prognosis. The differential diagnosis for a large cyst within the thorax is predominantly a CCAM of the lung. Other possibilities include bronchopulmonary sequestration, bronchogenic cyst, congenital diaphragmatic hernia, and teratoma.⁸⁷ The association with vertebral abnormalities makes the diagnosis of a neurenteric cyst almost certain.

THE FETAL DIAPHRAGM

Normal Development

The diaphragm can be described as a dome-shaped musculo-tendinous septum between the thoracic and abdominal cavity consisting of a central aponeurotic segment and a peripheral muscular part. The embryologic development ends around the 8th week of conception. The development consists of the fusion of four different components, that is, ventrally from the septum transversum (mesoderm), which fuses with the pleuroperitoneal membranes, with the dorsal foregut mesentery, and laterally with muscular components of the thoracic wall. The normal diaphragm allows the

passage of organs, vessels, and nerves from the thoracic into the abdominal cavity. The normal diaphragm can be observed directly as a smooth hypoechoic line between the lungs and the liver or spleen.

CONGENITAL DIAPHRAGMATIC HERNIA

Congenital diaphragmatic hernia occurs in approximately 1 of 2200 live births and is associated with a high degree of morbidity and mortality.⁸⁸ Congenital diaphragmatic hernia is characterized by protrusion of abdominal viscera into the thoracic cavity through a diaphragmatic defect (Fig. 13-20). Consequently, lung development may be impaired and may

FIGURE 13-19. A. Transverse axial sonogram in a 28-week-gestation fetus with a neurenteric cyst. A septated cyst is seen in the right hemithorax. B. Abnormal thoracic vertebrae (arrow) are seen at the same site as the cyst.

even result in pulmonary hypoplasia. It is hypothesized that the cause of diaphragmatic hernia is a result of a primary diaphragmatic defect with secondary migration of abdominal organs into the thoracic cavity or a delayed fusion of the four diaphragmatic components. Almost all hernias occur through the posterolaterally located Bochdalek foramina, which characteristically involves the left side (75%). Foramen of Morgagni hernias occur in the anteromedial retrosternal part of the diaphragm as a result of maldevelopment of the septum transversum. In more than one half of the cases of congenital diaphragmatic hernia, associated structural or chromosomal abnormalities have been found.⁸⁹ Polyhydramnios, which is thought to result from gastrointestinal obstruction, is common and is frequently the indication for initial ultrasound examination.⁹⁰ The differential diagnosis of fetal diaphragmatic hernia includes cystic adenomatoid malformation of the lung, bronchogenic cysts, and bronchopulmonary sequestration. Congenital heart disease constitutes the majority of associated anomalies. The incidence of an

FIGURE 13-20. Postmortem photograph of a fetus with a left-sided congenital diaphragmatic hernia. The left lung (LL) is compressed by the large volume of herniated viscera, including the stomach (St) and intestine (Int). Note the compression of the right lung (RL) as well. In this fetus, the liver was not herniated into the chest. H, heart.

abnormal karyotype is approximately 10% but may rise to 20% when only fetuses with multiple anomalies were included. Polyhydramnios occurs in about 75%.⁹¹ A systematic review of 35 studies reporting data for congenital diaphragmatic hernia between 1985 and 1998 showed a median overall mortality rate of 58% for infants diagnosed in utero, 48% if born alive, and 33% postoperatively.⁹² The most significant cause of mortality in infants with congenital diaphragmatic hernia is not pulmonary hypertension but iatrogenic injury to their hypoplastic lungs.⁹³

The most typical sonographic features of a left congenital diaphragmatic hernia are absence of the fluid-filled stomach in its normal position in the abdomen, displacement of the heart across the mediastinum to the right side, and displacement of the liver in the left chest, inability to identify the left lung, and presence of the fluid filled stomach adjacent to the heart (Fig. 13-21). Most frequently, the left lobe of the liver herniates, to varying degrees, into the left hemithorax. The position of the stomach is often a clue to the degree of liver herniation. A more anteriorly positioned stomach often means there is little liver herniation, whereas a posteriorly positioned liver often means a large degree of liver herniation. The liver herniation can best be appreciated on coronal planes of section. The position of the portal vein and left hepatic veins make identification of the left lobe of the

FIGURE 13-21. Transverse axial sonogram in a fetus with a left congenital diaphragmatic hernia. The heart (H) is displaced to the right. The left lung was not visible, however, the compressed right lung (RL) was seen. Herniated liver (Li) is seen as a triangle of soft tissue anterior to the stomach (St) and adjacent to the heart. Bo, bowel.

liver more certain (Fig. 13-22). It should be remembered that a diaphragmatic hernia does not imply complete absence of the diaphragm. As such, a ridge of remaining left diaphragm may be seen on various planes of section (Fig. 13-23). Right-sided diaphragmatic hernias are less common and may be more difficult to diagnose. The echogenicity of the herniated liver may simulate the echogenicity of the normal lung. Observation of the fetal gallbladder or portal vessels will allow one to make the correct diagnosis.

Various biometric parameters have been proposed for the prediction of fetal outcome in the presence of diaphragmatic hernia such as fetal pulmonary artery size,⁶⁵ fetal lung diameter,²² and lung diameter/thoracic circumference ratio.²³ Currently, the most widely used method for the antenatal prediction of outcome is the LHR ratio (see Fig. 13-6).^{22,94} Recently, a significant association between LHR and lung volume was established, validating the use of LHR in the assessment of fetal lung growth.⁹⁵ In another study, however, the percentage of liver that herniated into the chest, and not fetal lung size, correlated with outcome in fetuses with congenital diaphragmatic.⁹⁶ A correlation has been found between lung volume as determined by MRI and ultrasound determined LHR in fetuses with isolated left congenital diaphragmatic hernia following adjustment for gestational age and birth weight.³⁶ MRI has been demonstrated to be more sensitive than ultrasound for detecting thoracic herniation (Fig. 13-24).⁹⁷ MRI appears to be most helpful in evaluation of right diaphragmatic hernia because it usually contains liver and bowel.⁵² Until recently, the only options available to couples with a fetus diagnosed with congenital diaphragmatic hernia was termination of pregnancy or to await outcome at the time of delivery.

An alternative approach was open surgery with the risk of premature labor and premature rupture of the membranes.⁹⁸ Lately, a novel approach of minimal access fetal surgery

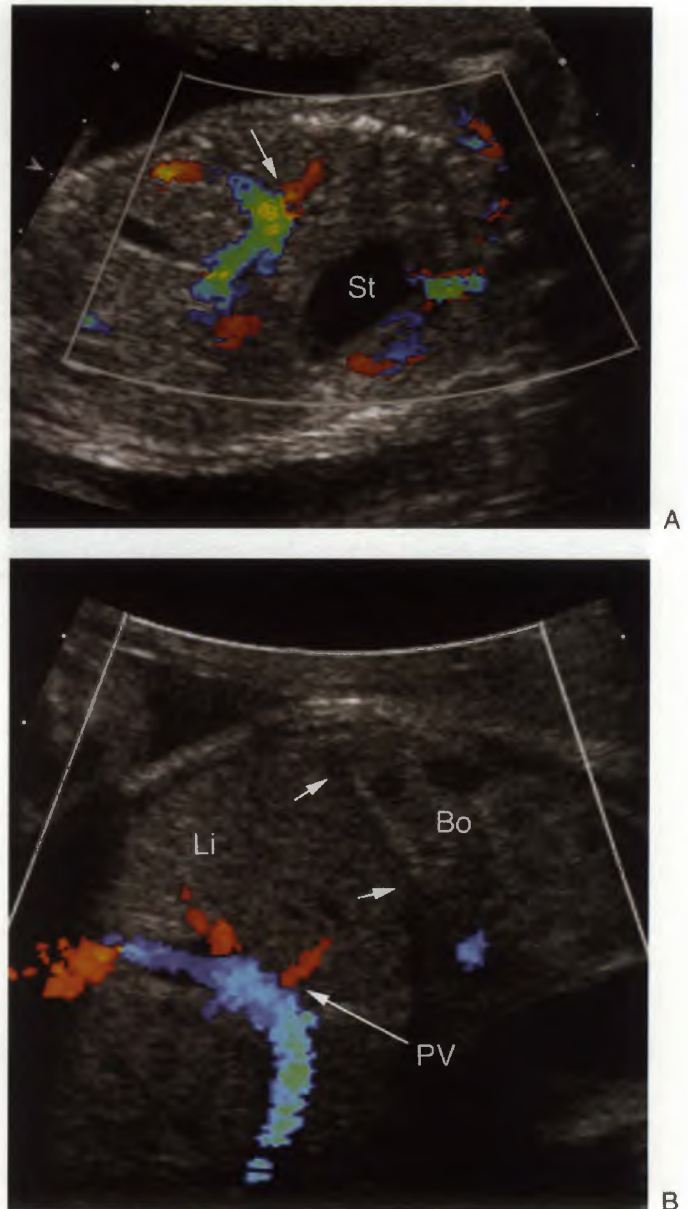

FIGURE 13-22. A. Left congenital diaphragmatic hernia with herniation of stomach (St) bowel and liver into the left hemithorax. Identification of the portal vein (arrow) extending into the thorax confirms that part of the liver has herniated. B. Left congenital diaphragmatic hernia in which only intestine (Bo) and stomach have herniated into the left chest. The normal position of the portal vein (arrow) below the diaphragm (arrows) confirms the absence of liver (Li) herniation.

is being explored. Using a fetoscope, videoscopic tracheal intubation is carried out. The current strategy is the placement of an intratracheal detachable balloon to facilitate tracheal occlusion with the objective to induce lung growth. The balloon can be removed in later gestation using a similar technique or by ultrasound guided puncture.^{71,95}

CONGENITAL HYDROTHORAX

Congenital fetal hydrothorax or pleural effusions may be associated with generalized edema and ascites or may occur

FIGURE 13-23. Left congenital diaphragmatic hernia with liver (Li) herniation into the left hemithorax. The liver can be seen extending superiorly above the ridge of remaining diaphragm (arrows). St, stomach.

FIGURE 13-24. Left congenital diaphragmatic hernia at 26 weeks' gestation, with partial upward herniation of liver into left hemithorax ("liver-up" congenital diaphragmatic hernia). Coronal T1-weighted spoiled gradient-echo magnetic resonance imaging scan (TR/TE, 140/4.2; flip angle, 700) shows upward herniation of left hepatic lobe (arrow). (From Leung JW, Coakley FV, Hricak H, et al: Prenatal MRI of congenital diaphragmatic hernia. *AJR Am J Roentgenol* 174:1607, 2000.)

FIGURE 13-25. Longitudinal cross-section of bilateral fetal hydrothorax at 36 weeks of gestation. Note the clear contour of the left and right fetal lung.

in isolation (Fig. 13-25). In both instances, fetal lung compression, and when prolonged, lung hypoplasia may develop, leading to severe respiratory problems in the neonatal period. The incidence of congenital fetal hydrothorax is estimated at approximately 1 in 15,000 pregnancies. Fluid accumulation can be unilateral or bilateral. Chylothorax is the most common cause of congenital hydrothorax. A mortality rate of more than 50% has been reported.⁹⁹ Lesions associated with pleural effusions include CCAM, BPS, congenital diaphragmatic hernia, congenital heart disease, cystic hygroma, and infection. Depending on the degree of fluid accumulation, mediastinal compression occurs with reduced fetal swallowing, resulting in polyhydramnios and risk of premature labor. Insertion of a thoracoamniotic shunt seems the most promising approach.^{100,101} It does not only aim at reversing fetal hydrothorax but may prevent development of lung hypoplasia and polyhydramnios. Shunting may also assist in differentiation between hydrothorax due to primary accumulation of pleural effusions and other causes of hydrothorax, notably infections. In the latter instance, drainage will not resolve the hydrothorax.¹⁰²

INTRODUCTION

Prenatal ultrasound for detection of fetal anomalies has become a routine part of the pregnancy management in most advanced countries. Fetal cardiac examination is an indispensable part of the prenatal ultrasound because of the following well-recognized reasons. First, congenital heart diseases (CHDs) are common congenital anomalies. The incidence of moderate to severe forms of CHD is about 6/1000 live births.¹ The incidence increases to 75/1000 live births if all mild lesions, such as bicuspid aortic valve and tiny muscular ventricular septal defects are included. The prenatal incidence of CHD is much higher with a tendency for an excess of complex lesions. Second, CHD is frequently associated with other noncardiac anomalies and chromosomal abnormalities.²⁻⁴ Extracardiac anomalies are found in 8% to 42% of patients with CHD. The incidence of chromosomal abnormalities ranges from 5% to 13% in live births with CHD^{2,3,5} and 15% to 50% in prenatal series.⁶⁻⁸ More than 50% of fetuses with abnormal chromosomes have cardiac anomalies. Nonchromosomal syndromes and associations comprise 1% to 5% of patients with CHD.³ Therefore, the presence of a congenital cardiac defect is an indication for chromosomal study and detailed ultrasound assessment of the extracardiac structures. Third, CHD is associated

with significant neonatal and childhood morbidity and mortality. Approximately one quarter of all infant deaths are due to congenital malformations and one third of these deaths are related to CHD.^{9,10} CHD is the leading cause of neonatal and childhood deaths, not only because of the complexity of the malformations but also due to its high incidence. Prenatal diagnosis of significant CHD has a positive impact on the postnatal management with reduced surgical delays, shorter intensive care unit stays, and avoidance of severe hemodynamic compromise. Some cardiac lesions, such as complete transposition of the great arteries, require delivery at a tertiary care center for urgent postnatal management. A few congenital cardiac abnormalities, such as atrial flutter, bradycardia with atrioventricular block, critical aortic stenosis, and critical pulmonary stenosis, require in utero medication or intervention.¹¹⁻¹⁴ Fourth, despite efforts to improve prenatal anomaly detection by introducing structured educational programs with basic ultrasound recommendations, cardiac anomalies continue to be overlooked and a huge variation in detection rates persists between geographic areas and centers.¹⁵⁻¹⁷

Fetal cardiac examination is performed either as a part of screening fetal sonography for a low-risk population or as a

Table 14-1 High-risk Groups for Congenital Heart Disease

Fetal Risk Factors	Maternal Risk Factors	Familial Risk Factors
Chromosomal abnormality	Maternal disease	Family history of congenital heart disease
Extracardiac anomaly	Congenital heart disease	Siblings
Omphalocele	Diabetes	Parents
Esophageal atresia	Collagen vascular disease	Family history of syndromes associated with congenital heart disease
Duodenal atresia	Anti-Ra/Lo antibody positive	Tuberous sclerosis
Diaphragmatic hernia	Phenylketonuria	Noonan syndrome
VACTERL association	Exposure to drugs, teratogens, or infections	Holt-Oram syndrome
Increased nuchal translucency	Alcohol	Chromosome 22q11 deletion
Nuchal fold thickening	Anticonvulsants	
Nonimmune hydrops	Lithium	
Polyhydramnios	Retinoic acid	
Oligohydramnios	Rubella, Coxsackie,	
Fetal cardiac dysrhythmia	Cytomegalovirus	
	Parvovirus B19	

VACTERL, Vertebral, Anal, Cardiac, TracheoEsophageal, Renal and Radial, and Limb abnormalities.

complete diagnostic test for groups at high risk for CHD (Table 14-1). The majority of the babies with CHD are born to parents with no identifiable risk factors. Therefore, the rate of detection of CHD depends largely on the sensitivity of the prenatal screening ultrasound. The earlier trials for fetal cardiac screening relied on a four-chamber view alone.^{18,19} However, this approach has proved inadequate for detection of abnormalities of visceral and atrial situs, the ventricular outflow tracts, and great arteries.^{20,21} Therefore, the screening examination should be extended to include the views for situs determination as well as the views for assessment of the ventricular outflow tracts and great arteries.²²⁻²⁴ Because the extended examination is rather extensive and complex, a well-standardized protocol should be set in order to reduce the examination time, while maintaining a high degree of diagnostic accuracy.

Fetal cardiac examination should be performed when adequate images can be obtained for diagnosis in the majority of routine patients. The ideal timing is a compromise between examining sufficiently late not to miss late-developing lesions, and yet offering the diagnosis as early as possible for patients to have additional testing, including chromosomal study and to consider the options, if any, applicable to their particular diagnosis.²⁵ The fetal heart can be visualized transvaginally as early as 9 weeks of gestation and abdominally by 11 weeks.²⁶ Fetal echocardiography, using both transvaginal and transabdominal approaches, at or before 16 weeks of gestation on fetuses at risk of CHD, allowed distinction between a normal and abnormal cardiac appearance in the majority of cases.^{27,28} However, the earlier scan is technically more difficult and less accurate than the second trimester scan, whereas some forms of cardiac malformations do not become evident in the early period of pregnancy. As a result, some of the late-developing lesions may go undetected during early evaluation.^{25,29,30} Therefore, fetal cardiac examination is usually performed at 18 to 22 weeks of gestation in the countries where the legal limit of termination of pregnancy is 24 weeks. The earlier scan is justifiably applicable for patients at increased risk of congenital anomalies.^{25,26}

Fetal cardiac examination requires a high-resolution ultrasound system with color and power Doppler, pulsed

and continuous wave spectral Doppler and M-mode capabilities. The transducer is chosen according to the gestational age, the size of the mother, and the amount of amniotic fluid. Usually a 5- to 7.5-MHz convex or sector transducer is adequate for the 15- to 30-week scans. A 3-MHz transducer can be required for an obese mother or when there is polyhydramnios. A 3-MHz transducer may also be required after the late second trimester. In general, it is preferable to use a transducer with the highest possible frequency. It is essential to record the real-time images on a digital storage system.

The major part of the screening fetal cardiac examination is real-time grey-scale imaging of the cardiac and major vascular structures with color Doppler interrogation of the ventricular inlets and outflow tracts, and great arteries. Identification and assessment of the vascular anatomy can be further facilitated by power Doppler technique.

Three-dimensional ultrasound has become available for fetal imaging. Its applications to fetal facial and musculoskeletal abnormalities have been well established. It has also been proven very useful for fetal cardiac examination (Fig. 14-1).³¹⁻³³ Following the acquisition of the volume dataset, the images are reconstructed offline in any desired planes. The image reconstruction enables the examiner to evaluate series of two-dimensional images in multiple views, evaluate intracardiac anatomy at different depth planes, and recreate casts of blood flow of the chambers and great vessels. This new technology not only enhances the ability of the examiner to identify normal and complex fetal heart anatomy but also facilitates routine image data acquisition by inexperienced personnel. Recent technology allows real-time three-dimensional or four-dimensional ultrasound for instantaneous acquisition of the volume data of the whole heart.

This chapter is divided into four parts according to the pathology and purposes of examinations: Part I, Congenital Heart Diseases; Part II, Cardiac Tumors; Part III, Cardiac Rhythm; Part IV, Cardiac Function.

Each part discusses the sonographic techniques, basic standard views and essential anatomy, the clues to the abnormalities, and the prenatal and postnatal treatment options and outcomes.

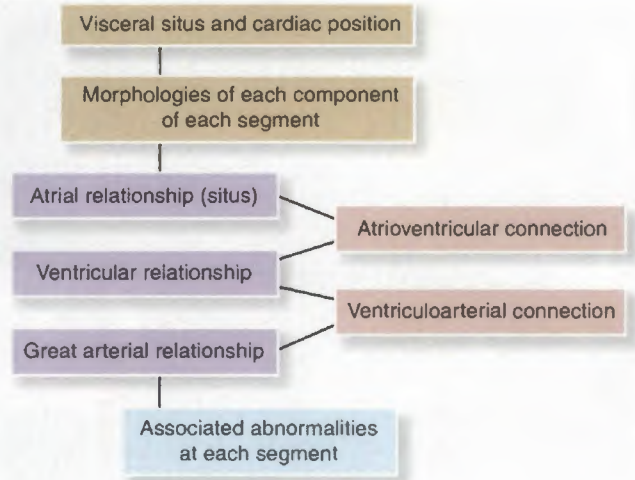

FIGURE 14-3. Steps of sequential segmental approach to congenital heart disease.

CONGENITAL HEART DISEASES

Sonographic Technique, Basic Standard Views, and Anatomy

For structural evaluation, the heart is assessed in a step-by-step fashion using sequential segmental analysis.^{34,35} In this approach, the heart is considered to consist of three segments: the *atria*, the *ventricles*, and the *great arteries*, and two connectors: the *atrioventricular (AV) junction* and the *ventriculoarterial junction* (Fig. 14-2). The key steps of the sequential segmental approach include (Fig. 14-3)

1. Determination of the visceral situs and position of the heart.
2. Identification of the morphologies of each component of each segment.
3. Assessment of the spatial relationships between the components of each segment.
 - a. Atrial relationship or situs
 - b. Ventricular relationship
 - c. Great arterial relationship
4. Determination of the connections between the segments at the AV and ventriculoarterial junctions.
 - a. AV connection
 - b. Ventriculoarterial connection
5. Evaluation of the associated malformation at each cardiac segment.

Sequential segmental approach can be achieved by continuous sweeping of the sonographic probe from the upper abdomen to the superior mediastinum in the orthogonal planes to the fetal body axis and along the long- and short-axis planes of the heart. In making a journey through the fetal heart and great vessels, the following landmark views should be obtained as the standard views for the complete anatomical assessment (Fig. 14-4)

1. Transverse view of the upper abdomen.
2. Four-chamber view.
3. Three-vessel view.
4. Left ventricular outflow tract view.
5. Right ventricular outflow tract view.
6. Basal short-axis view.
7. Aortic arch view.

Imaging Technique and Normal Anatomy

Fetal cardiac examination should begin with determination of the position and orientation of the fetus relative to the long axis of the mother and identification of the right and left sides of the fetus. This step can be quickly performed by sweeping the transducer in the transverse and longitudinal planes of the maternal body. It is essential not to determine the right and left sides of the fetus according to the position of the stomach because it can be on the wrong side. For the beginners, a doll can be positioned on the maternal abdomen to facilitate this step.

Once the right and left sides of the fetus are defined, the transverse view of the upper abdomen is obtained for the determination of the visceral situs, which is the first step of sequential segmental analysis (see Fig. 14-4).³⁴ It is strongly advised not to start the cardiac examination with the heart. The transverse view of the upper abdomen is the view that is used for the measurement of the abdominal circumference. In this view, the larger lobe of the liver and gallbladder are on the right, and the stomach on the left (Fig. 14-5). The cross-section of the abdominal aorta is at the left anterior corner of the spine, whereas the cross-section of the inferior vena cava is on the right. The inferior vena cava is an anterior structure compared with the aorta because it courses forward as it connects to the right atrium. In a well-taken image, a sickle-shaped spleen can be seen behind the stomach.

The transducer is then moved, along the long axis of the fetal body, toward the fetal head to obtain a four-chamber view (see Fig. 14-4).^{18,19} Because the transducer is swept from the upper abdomen to the four-chamber plane, it is important to follow the inferior vena cava connecting to the right atrium. In the four-chamber view, the heart occupies approximately one third of the thoracic area and the cardiac axis is directed 45 ± 20 degrees leftward from the coronal or sagittal plane (Fig. 14-6).^{36,37} In the first and second trimesters, the cardiac chambers seen in the four-chamber view are symmetric in size. The right atrium and ventricle become slightly larger than the left atrium and ventricle

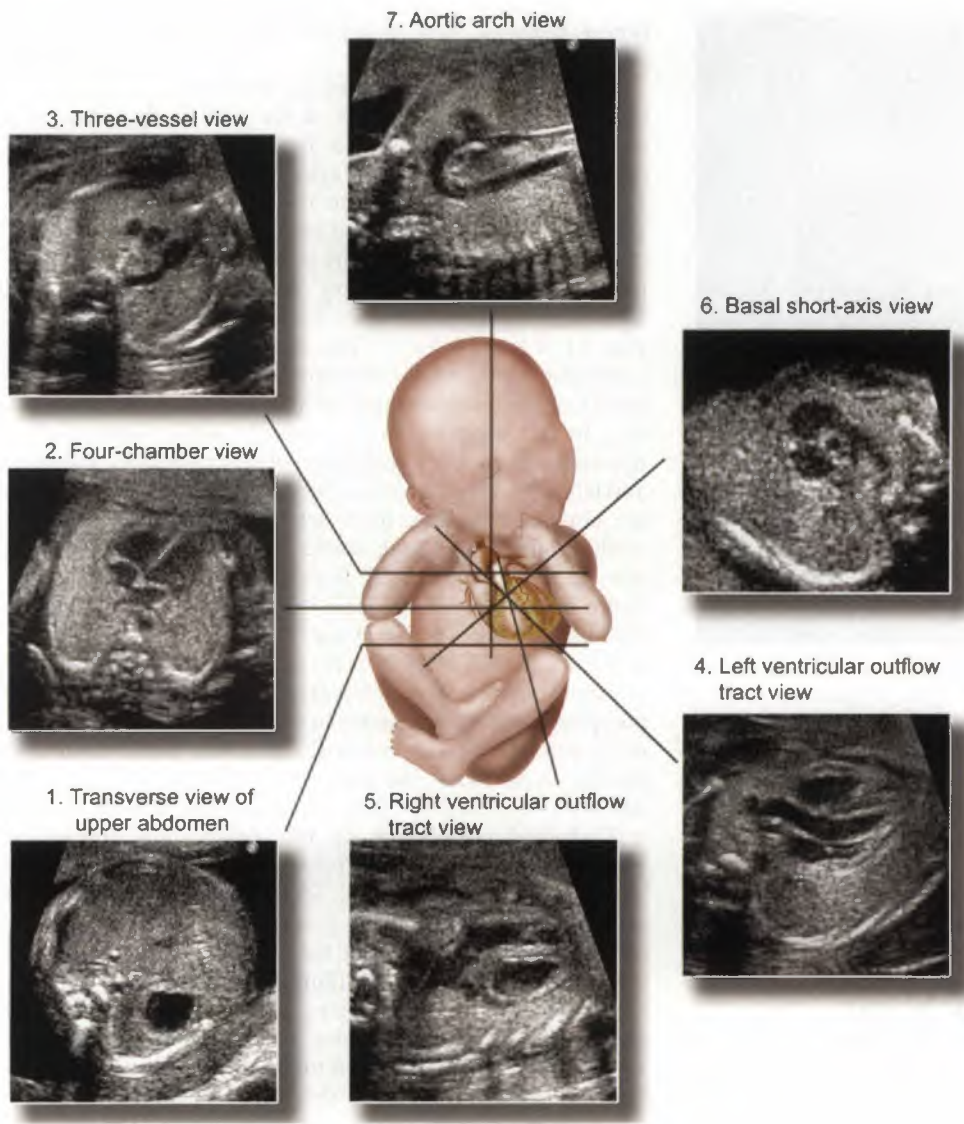

FIGURE 14-4. Basic sonographic views for fetal cardiac examination. (Illustration by Shi-Joon Yoo, MD, and James A. Cooper, MD.)

in the third trimester.^{38,39} The septum between the four chambers of the heart consists of three parts: atrial, AV, and ventricular (see Fig. 14-6B, C). The AV septum is present between the right atrium and left ventricle because the tricuspid valve has a more apical attachment to the septum than the mitral valve.⁴⁰ The central part of the atrial septum is the thin and mobile primum septum (see Fig. 14-6C). In the normal fetus, this part of the septum bulges toward the left atrium as the blood flows from the right atrium into the left atrium through the foramen ovale. The pulmonary veins are identifiable in the four-chamber view. Color and power Doppler techniques are helpful in identifying the pulmonary veins (see Fig. 14-6E). When color Doppler is used for identification of the pulmonary veins, the velocity setting should be set at less than 30 cm/second. Usually, the pulmonary veins that are seen in the four-chamber view are the lower veins, which course slightly forward as they connect to the left atrium. The upper pulmonary veins are more superior and anterior as compared with the lower veins and,

therefore, are not shown in the regular four-chamber view. The lowest section through the four chambers shows the coronary sinus as a small tubular structure between the left ventricle and the orifice of the inferior vena cava (see Fig. 14-6F).⁴¹ In the apical part of the right ventricle, a muscle bundle called 'the moderator band' crosses the cavity. It may be seen as a muscle bundle extending from the septum to the parietal wall (see Fig. 14-6B), but is more often seen as a muscle mass obliterating the apical part of the cavity (see Fig. 14-6A and C). The septal attachment of the AV valves and the presence of the moderator band are the two most important morphologic criteria for ventricular identification. On the other hand, differences in trabeculation pattern between the right and left ventricles are hardly recognizable on the fetal ultrasound examination. The function of the tricuspid and mitral valves should be assessed using color Doppler with a velocity set at 60 to 80 cm/second (see Fig. 14-6G). Trivial tricuspid regurgitation is not uncommon and is usually transient (see Fig. 14-6H).^{42,43}

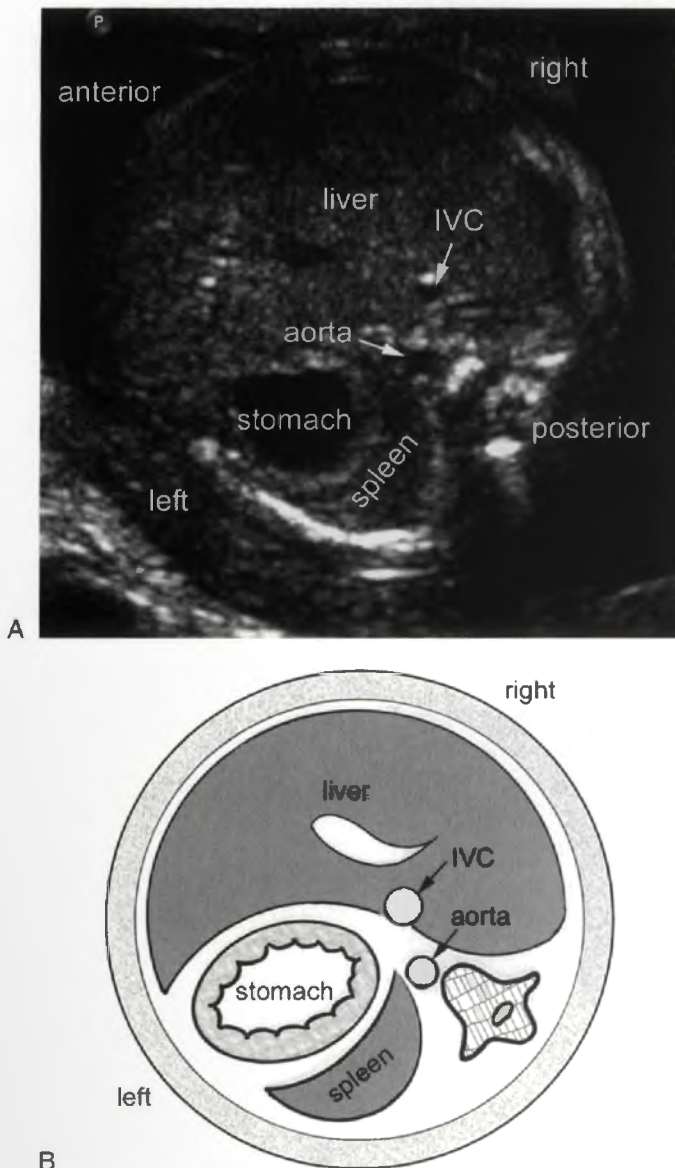

FIGURE 14-5. Transverse view of the upper abdomen (A) and corresponding diagram (B). The larger lobe of the liver is on the right, and the stomach on the left. The descending aorta (ao) is at the left anterior aspect of the spine. The inferior vena cava (IVC) is on the right side of the midline. Note that the inferior vena cava is located anteriorly at some distance from the spine as it courses forward to connect to the right atrium above this level.

A recent study using three-dimensional color Doppler technique showed mild-to-moderate tricuspid regurgitation in 83% of fetuses in the early second trimester.⁴³ However, substantial tricuspid regurgitation in the first trimester is frequently a marker of cardiac malformations or chromosomal defects in the absence of structural heart disease.⁴⁴⁻⁴⁶ The cross-section of the descending aorta is seen behind the heart at the left anterior aspect of the vertebral body. The cross-section of the esophagus can occasionally be seen as an echolucent structure adjacent to the aorta when the fetus swallows amniotic fluid. In contrast to the vascular structures, the esophagus barely demonstrates signal using color or

power Doppler, and disappears and reappears in a few seconds or minutes.

From the four-chamber plane, the transducer is moved upward along the long axis of the fetal body. The four-chamber view changes into a 'five-chamber view' in which the aortic valve is seen to arise from the left ventricular outflow tract in the center of the four chambers (see Fig. 14-6I). Further upward movement of the transducer creates a three-vessel view in which the oblique section of the main pulmonary artery and cross-sections of the ascending aorta and superior vena cava (SVC) are seen (see Figs. 14-4 and 14-7).^{47,48} The three vessels are arranged in a straight line from the left anterior to the right posterior aspect of the mediastinum with a decreasing order of the size. In the adjacent planes shown by slight downward or upward movement or angulation of the transducer, the right and left pulmonary arteries, and the ductal and aortic arches are visualized. In fact, there are three arches in the upper mediastinum; the ductal, aortic, and azygos venous arches (see Fig. 14-7C, F, and G). In addition, the trachea and the major bronchi are identifiable because they contain fluid in fetal life (see Fig. 14-7B, D, and G). Therefore, the position of the aortic arch relative to the trachea can be well defined. Normally, the aortic arch is a sausage-like structure coursing obliquely from right anterior to left posterior on the left side of the trachea. To emphasize the presence of the trachea in the three-vessel view, the term three vessels and trachea view has been suggested.^{49,50} The aortic and ductal arches make a V-shaped confluence at the descending aorta (see Fig. 14-7C and F). In the V-view, the ductal arch is slightly bigger than the aortic arch. After it arises from the main pulmonary artery, the right pulmonary artery takes a long horizontal course in front of the tracheal bifurcation before it reaches the right lung hilum (see Fig. 14-7). On the contrary, the left pulmonary artery courses obliquely backward and leftward to reach the left lung hilum. Also seen in the transverse view of the upper mediastinum at the level of the aortic arch is the innominate vein coursing horizontally in front of the ascending aorta. The identification of the various vascular structures in the upper mediastinum can be facilitated with color and power Doppler interrogation. However, the vessel sizes should not be measured by color or power Doppler as the vessels look significantly bigger because of the blooming effect. Anterior to the three vessels, the thymus is seen as an area of different echogenicity as compared with the lungs (see Fig. 14-7G).⁵¹⁻⁵³ Its echogenicity is similar to or slightly more than that of the adjacent lungs in the early second trimester and it becomes less echogenic in later pregnancy. It typically contains spindle-shaped echogenic spots that make its differentiation from the lungs possible. Its transverse diameter in millimeters is slightly smaller than the gestational age in weeks in the second trimester and becomes slightly larger as the pregnancy approaches the term.⁵⁴

The ventricular outflow tract views need special maneuvers (Fig. 14-8).^{23,55} The transducer is moved back to a four-chamber plane. Then the transducer is moved around the fetal thorax until the sonographic beam is positioned perpendicular to the ventricular septum. This procedure aligns the ventricular septum horizontally in the image. In this particular position, the left ventricular outflow tract view can be obtained simply by rotating the transducer 20 to

FIGURE 14-6. Four-chamber and five-chamber views (A–D). Three different four-chamber views and diagram (D). The right- and left-sided chambers are symmetric in size. The atrioventricular valves have offset attachments (dots in A–C) to the septum with the tricuspid valve having more apical attachment than the mitral valve. The apex of the right ventricle (RV) is obliterated in A and C by the moderator band (asterisk). The moderator band can also be seen as a distinct muscle bundle as shown in B. Right and left lower pulmonary veins (RLPV and LLPV) course obliquely forward as they connect to the left atrium (LA). The central part of the atrial septum is the septum primum (arrows in C). It is thin and mobile, and bulges into the left atrium. The descending aorta (ao) is seen at the left anterior corner of the spine. *Continued*

Both lower pulmonary veins course obliquely forward, whereas the right upper pulmonary vein courses obliquely backward as it connects to the left atrium. F. A lower section below the four-chamber view. The coronary sinus (CS) is seen as a tubular structure between the left ventricle (LV) and the inferior vena caval orifice (IVC). Note that its proximal part of the coronary sinus can be seen as a small round circle at the left atrioventricular junction in a regular four-chamber view as shown in B. G. Color Doppler image shows flow through the atrioventricular valves. H. Color Doppler image and Doppler spectrum show trivial tricuspid regurgitation (TR). E and A are the early and late diastolic peaks of the tricuspid inflow, respectively. I. Five-chamber view. A section slightly cranial to the regular four-chamber shows the left ventricular outflow tract (LVOT). RA, right atrium.

FIGURE 14-7. Three-vessel view and its vicinity. A–E. Serial transverse views of the upper mediastinum and a diagram (E) showing the anatomy of the three-vessel view. In its most basal cut (A), the main pulmonary artery (PA) branches into the right (R) and left (L) pulmonary arteries. Above this level (B), where the main pulmonary artery continues to the descending aorta (ao) through the ductus arteriosus, the following three vessels: the main pulmonary artery, the ascending aorta (Ao) and superior vena cava (svc) are aligned in a straight line from the left anterior aspect to the right posterior aspect of the thorax. The three vessels are sized in a decreasing order with the main pulmonary artery being the largest and the superior vena cava the smallest. The right and left bronchi, filled with fluid, are seen in the middle mediastinum. Immediately above this level (C), the aortic arch (aa) and ductus arteriosus form a V-shaped confluence at the descending aorta on the left side of the carina of the trachea. In the most cranial level of the three vessels (D), the sausage-shaped aortic arch is seen on the left side of the trachea. *Continued*

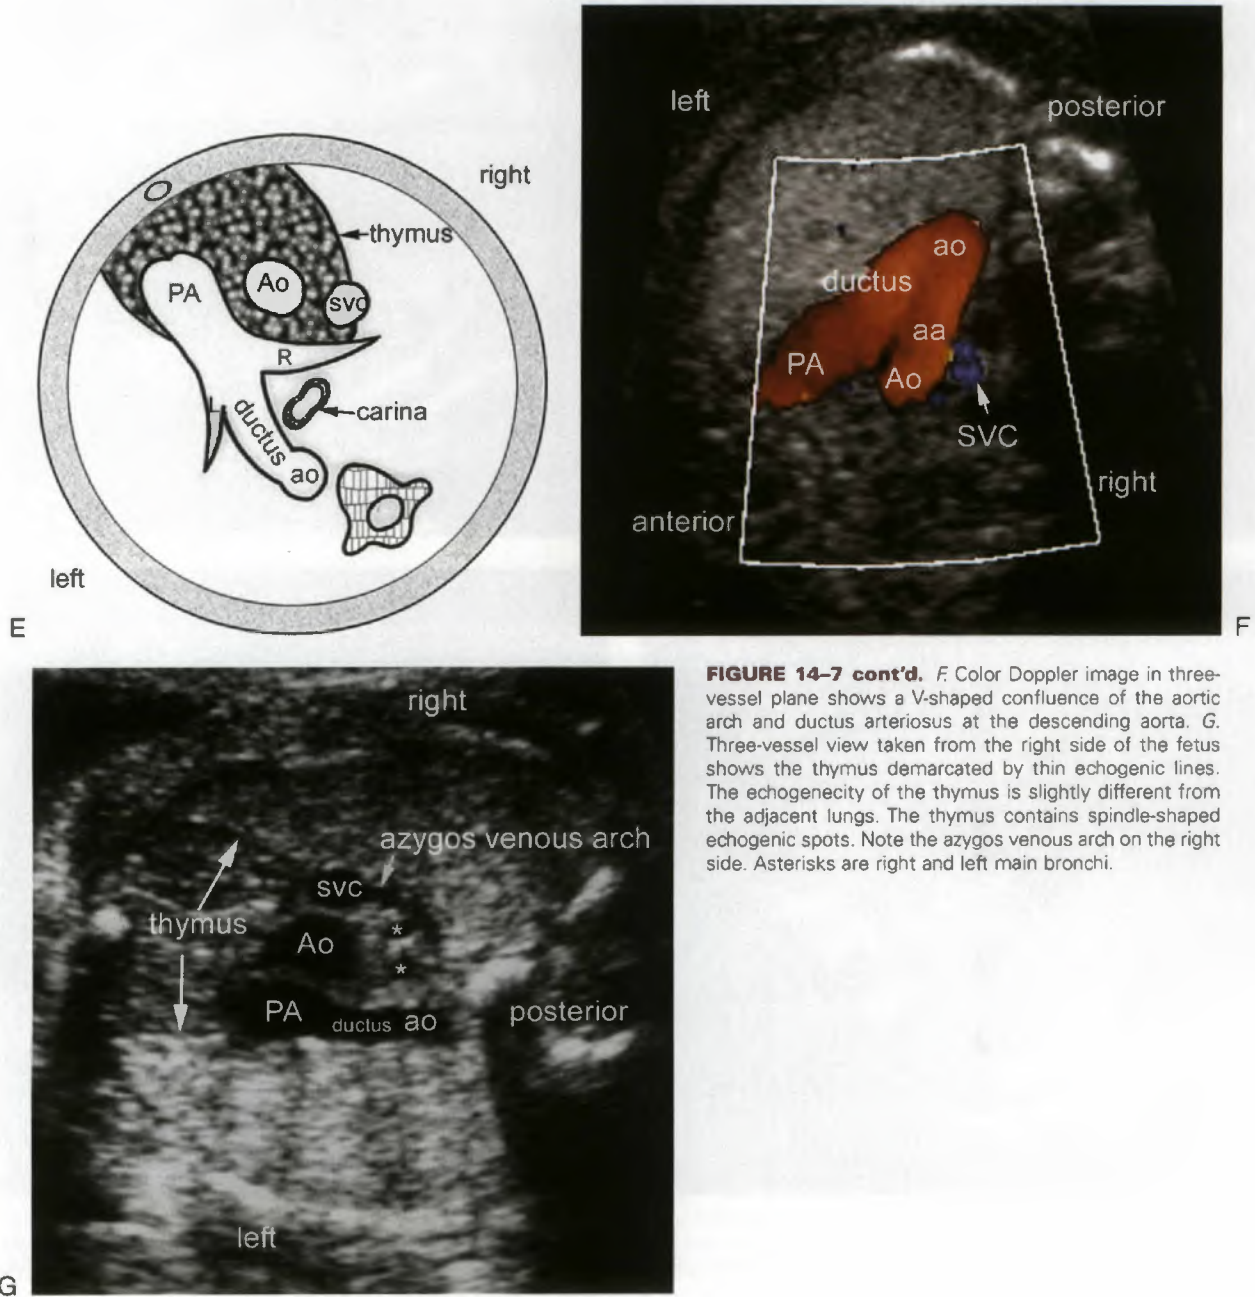

FIGURE 14-7 cont'd. *F* Color Doppler image in three-vessel plane shows a V-shaped confluence of the aortic arch and ductus arteriosus at the descending aorta. *G* Three-vessel view taken from the right side of the fetus shows the thymus demarcated by thin echogenic lines. The echogenicity of the thymus is slightly different from the adjacent lungs. The thymus contains spindle-shaped echogenic spots. Note the azygos venous arch on the right side. Asterisks are right and left main bronchi.

FIGURE 14-8. Left and right ventricular outflow tract views. A. Composite diagram showing how the ventricular outflow tract views are obtained in a fetus in supine cephalic presentation. The scan starts from any transducer position for a four-chamber view (*panel a*). In step I, the transducer is moved around the fetal chest until the ventricular septum is seen horizontally in the four-chamber view (*panel b*). In step II, the transducer is rotated 20 to 30 degrees (clockwise in this example with a fetus laying in supine cephalic presentation) towards the cardiac apex until the left ventricular outflow tract view (*panel c*) is shown. In step III, the transducer is moved upward towards the fetal head until the right ventricular outflow tract view (*panel d*) is shown. (Modified with permission from Yoo SJ, Lee YH, Kim ES, et al: *Tetralogy of Fallot in the fetus: Findings at targeted sonography. Ultrasound Obstet Gynecol 14:29, 1999.*) B–D. Left ventricular outflow tract views and diagram. Both the inlet and outlet of the left ventricle (LV) are seen. The anterior leaflet of the mitral valve is the anterior border of the left ventricular inlet in diastole, and the posterior border of the left ventricular outlet during systole. The aortic and mitral valves are in direct contact (*asterisk*). The left ventricular outflow tract courses upward and slightly forward. *Continued*

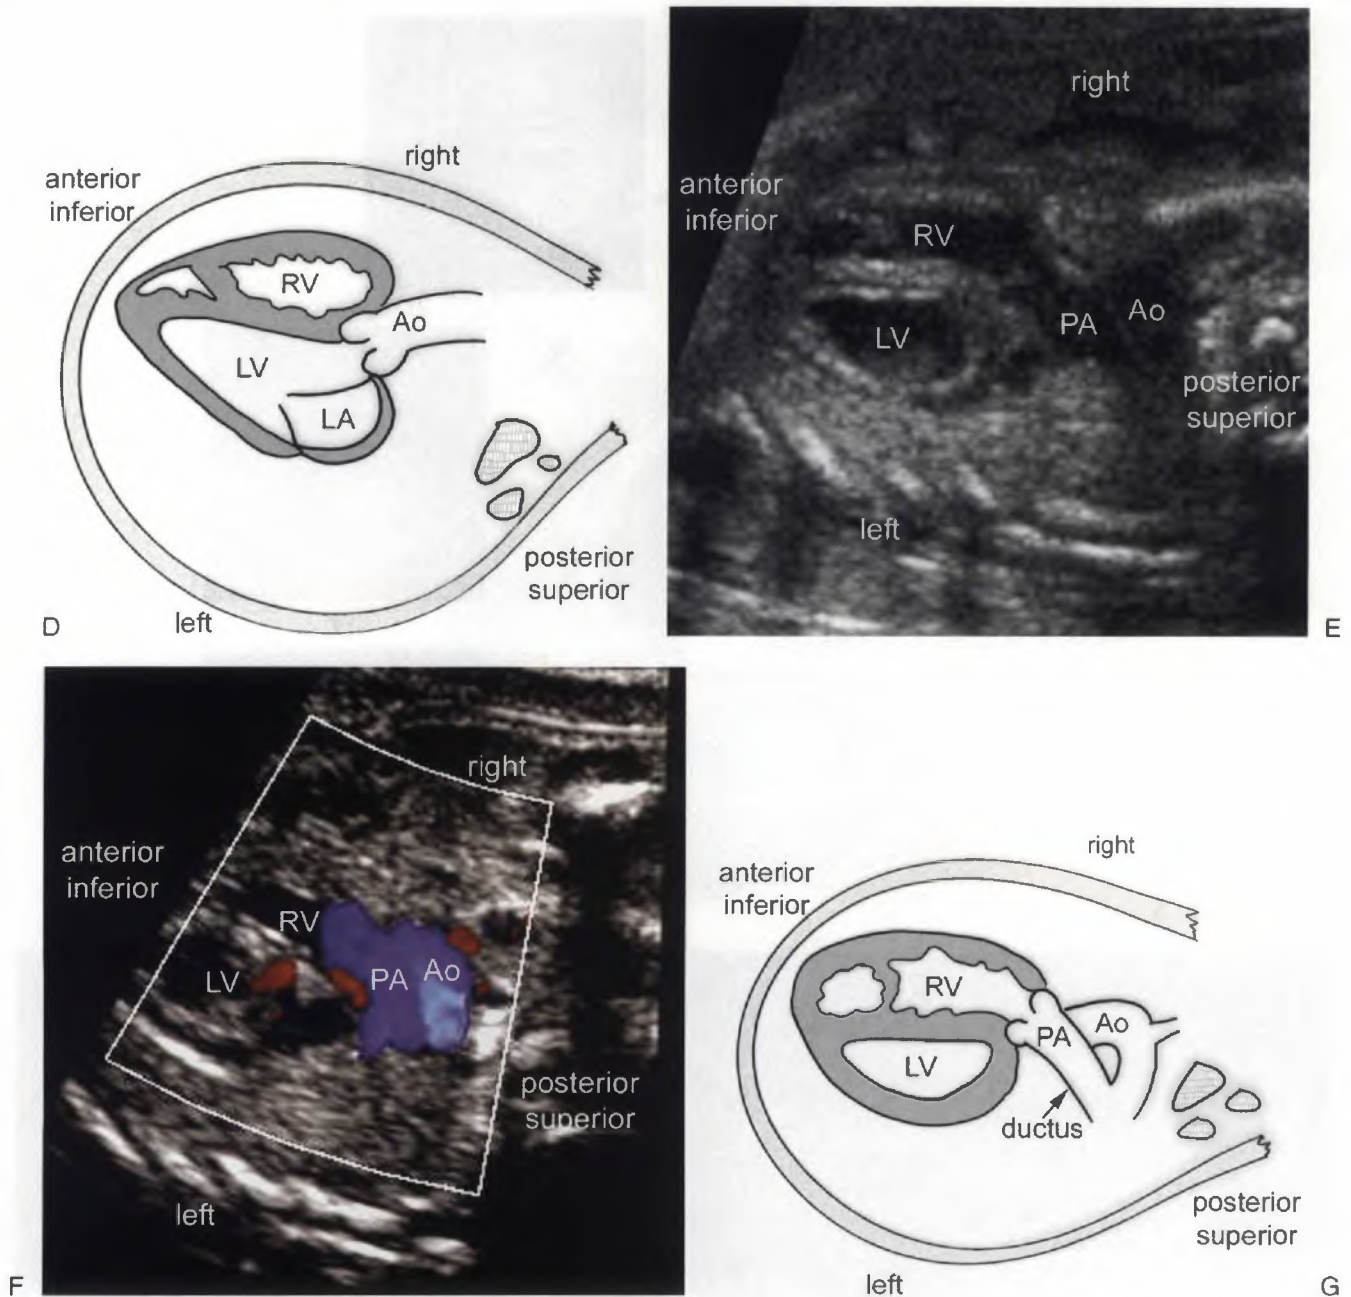

FIGURE 14-8 cont'd. E–G. Right ventricular outflow tract views and diagram. The right ventricular (RV) outflow tract leads to the main pulmonary artery (PA) upward and backward. Note the crossing nature of the ventricular outflow tracts to the arterial trunks by comparing the left and right ventricular outflow tract views. Ao, ascending aorta; ao, descending aorta; LA, left atrium; RA, right atrium.

30 degrees clockwise or counterclockwise toward the cardiac apex. By sliding the transducer upward toward the fetal head from this plane, the right ventricular outflow tract view can be obtained. By moving the transducer slightly up and down along the fetal thorax, the crossing nature of the ventricular outflow tracts can be clearly appreciated. Occasionally, the ventricular septum is hard to place perpendicular to the sonographic beam. In this situation, the transducer is positioned to the apex of the heart and then angled cranially toward the fetal head so that the sonographic beam is aligned parallel with the long axis of the

heart. This latter maneuver, however, is more difficult than the former. The left ventricular outflow tract view demonstrates not only the left ventricular outflow tract but also the left ventricular inlet, with the anterior leaflet of the mitral valve demarcating the two (see Fig. 14-8B to D). The aortic valve is in direct contact with the mitral valve, and therefore, the left ventricular outflow tract is not completely muscular. This is in contrast to the right ventricle, in which there is discontinuity between the pulmonary and tricuspid valves because of the presence of an intervening muscular crest that is called crista supraventricularis or ventriculoinfundibular

fold. Therefore, the right ventricular outflow tract is a completely muscular tunnel. The ventricular septum seen in the left ventricular outflow tract view is the more anterior part of the ventricular septum as compared with the septum seen in the four-chamber view. The part of the ventricular septum that abuts the aortic valve is the membranous septum, which is most commonly involved in ventricular septal defects. Commonly, this area of the septum normally appears defective because the septum has a curved configuration and the septum below the aortic valve is the thin membranous part, which makes the diagnosis of a small ventricular septal defect in this region very difficult. In the right ventricular outflow tract view, the right ventricular outflow tract leads to the main pulmonary artery upward and backward (see Fig. 14-8E to G). This is in contrast with the left ventricular outflow tract that courses upward and forward. In the left and right ventricular outflow tract views, the blood flow across the aortic and pulmonary valves should be assessed by using color Doppler with a velocity set at 80 to 100 cm/sec (see Fig. 14-8C and F).

The basal short-axis view is rather difficult to obtain. This view is an oblique view through the right lobe of the liver and the left shoulder (see Figs. 14-4 and 14-9). When an oblique section through these two structures is obtained, the transducer is angled up and down until the cross-sectioned aortic valve is encircled by the right atrium, right ventricle, main pulmonary artery, and right pulmonary artery. This view clearly shows the discontinuity between the tricuspid and pulmonary valves due to the crista supraventricularis or ventriculoinfundibular fold separating the two valves (*asterisks* in Fig. 14-9A). This view is best for assessing patency of the right ventricular outflow tract. As seen in the left ventricular outflow tract view, the part of the septum abutting the tricuspid valve is the membranous septum and, therefore, may appear defective. After the main pulmonary artery bifurcates into the right and left pulmonary arteries, the right pulmonary artery courses rightward along the posterior wall of the aortic valve, whereas the left pulmonary artery continues to the descending aorta through the ductus arteriosus. A different but equivalent anatomy can be seen in right anterior oblique long axis view of the right ventricle (see Fig. 14-9D). This view visualizes the three components of the right ventricle, namely the inlet, trabecular, and outlet parts. The three vessels are also visualized in their oblique or longitudinal sections.

The aortic arch view can be obtained from a three-vessel view. The transducer is moved around the fetal thorax until the sonographic beam is aligned with the cross-sections of the ascending and descending aorta (Fig. 14-10).^{55,56} The cross-sections of the ascending and descending aorta are then seen vertically in the three-vessel view. In this position, the transducer is rotated 90 degrees in either clockwise or counterclockwise direction and the aortic arch is shown as a candy cane configuration. The ductal arch view can be obtained in a similar manner. The transducer is moved around the fetal thorax until the oblique section of the main pulmonary artery and the cross-section of the ascending aorta are aligned vertically in the three-vessel view. Then, the transducer is rotated 90 degrees in either direction and a hockey stick view of the ductal arch is produced. In the aortic arch view, the ascending aorta arises from the center of the heart between the right and left atria and, therefore,

is some distance from the anterior chest wall. The aortic arch view shows the right innominate, left carotid, and left subclavian arteries arising from the greater curvature side of the arch. On the other hand, the ductal arch arises far anteriorly, immediately behind the anterior chest wall, as its proximal part is the main pulmonary artery. It takes a rather long course backward as it connects to the descending aorta through the ductus arteriosus. In contrast to the aortic arch, the ductal arch does not give rise to any branch to the head and neck. When the fetus is in either right or left lateral decubitus position, the candy cane and hockey stick views are not possible to obtain. Both arches are then assessed in transverse views (see Fig. 14-7B to F). In the later pregnancy, the ductus arteriosus may become tortuous and a faulty diagnosis of the aneurysm of the ductus arteriosus can be entertained (see Fig. 14-10F).

Normal measurement data for cardiac and major vascular dimensions are listed in the appendix.

Clues to the Abnormalities

Table 14-2 lists the key anatomic structures that should be investigated and the clues to the presence of CHD at each screening view.

Transverse View of the Upper Abdomen

The transverse view of the upper abdomen provides the main information regarding whether the visceral situs is normal or abnormal, and if it is abnormal, the pattern of situs most likely present. This is important because situs abnormalities are harbingers of CHD (Tables 14-3 and 14-4).^{34,57-60}

The term visceral situs refers to the pattern of arrangement of the body organs relative to the midline or sagittal plane. There are three types of visceral situs: namely, *situs solitus*, *situs inversus*, and *heterotaxy* (Fig. 14-11).^{58,61} The visceral situs can usually be determined by observing the location of the liver, stomach, abdominal aorta, and inferior vena cava as seen in the transverse view of the upper abdomen.

In situs solitus, the larger lobe of the liver and gall bladder are seen on the right and the stomach on the left (see Fig. 14-5). The spleen can be identified along the posterolateral wall of the stomach as a sickle-shaped structure. The abdominal aorta is located posteriorly at the left anterior aspect of the spine. The inferior vena cava is located more anteriorly on the right as it connects to the right-sided right atrium. In situs inversus, these right-left relationships are inverted (Fig. 14-12A). Situs inversus may escape detection if the right and left sides of the fetal body are not defined in the beginning of the fetal echocardiographic examination.

Heterotaxy (Greek, *heteros* [other than] + *taxis* [arrangement]) indicates an arrangement of the organs that is different from the orderly arrangement of either situs solitus or situs inversus (see Fig. 14-12B and C).⁶¹ Heterotaxy has often been called situs ambiguus, which means uncertain situs. However, 'situs ambiguus' is not an appropriate term, because the organ arrangement in heterotaxy is not uncertain but rather complex or hard to define.³⁴ Abdominal heterotaxy is characterized by jumbled-up arrangement of the nonpaired organs. Heterotaxy is almost always associated with asplenia or polysplenia.^{57,58,62-68} Heterotaxy with

FIGURE 14-9. Basal short-axis view and an alternative view. A–C. Basal-short axis views and diagram. The cross-section of the aortic valve (AV) or the ascending aortic root (Ao) is encircled by the right atrium (RA), right ventricle (RV), main pulmonary artery (PA) and right pulmonary artery (RPA). Note the discontinuity between the tricuspid and pulmonary valve annuli (*asterisks*). The right ventricular outflow tract is widely open. The main pulmonary artery connects to the descending aorta (ao) through the ductus arteriosus. (D) Right anterior oblique view of the right ventricle. This view is equivalent to the x-ray angiographic right anterior oblique view. The three components of the right ventricle, the inlet, apical trabecular, and outlet parts are well shown. The three vessels—the main pulmonary artery, the ascending aorta, and the superior vena cava (SVC)—are aligned as they are typically seen in the three-vessel view.

C

FIGURE 14-10. Aortic and ductal arch views. A. Composite diagram showing how the aortic and ductal arch views are obtained in a fetus in supine cephalic presentation. The scan starts from any transducer position for a three-vessel view (*panel a*). In step I, the transducer is moved around the fetal chest until the ascending aorta (Ao) and descending aorta (ao) are aligned vertically in the three-vessel view (*panel b*). In step II, the transducer is rotated 90 degrees either clockwise or counterclockwise until the aortic arch is seen as a candy cane-like structure (*panel c*). In step III, the transducer is moved back to a three-vessel view and moved around the fetal chest until the main pulmonary artery (PA) and the descending aorta (ao) are vertically aligned (*panel a*). In step IV, the transducer is rotated 90 degrees either clockwise or counterclockwise until the ductal arch is seen as a hockey stick-like structure (*panel d*). (Modified with permission from Yoo SJ, Lee YH, Kim ES, et al: Tetralogy of Fallot in the fetus: Findings at targeted sonography. *Ultrasound Obstet Gynecol* 14:29, 1999.) B and C. Aortic arch views and diagram. The aortic arch arises from the space between the right (RA) and left (LA) atria, and therefore, its origin is some distance away from the anterior chest wall. The aortic arch gives rise to the right innominate or brachiocephalic (RIA), left common carotid (LCA), and left subclavian (LSA) arteries. The cross-section of the innominate vein is seen in front of the right innominate artery. The cross-section of the right pulmonary artery (RPA) is seen immediately behind the ascending aorta. *Continued*

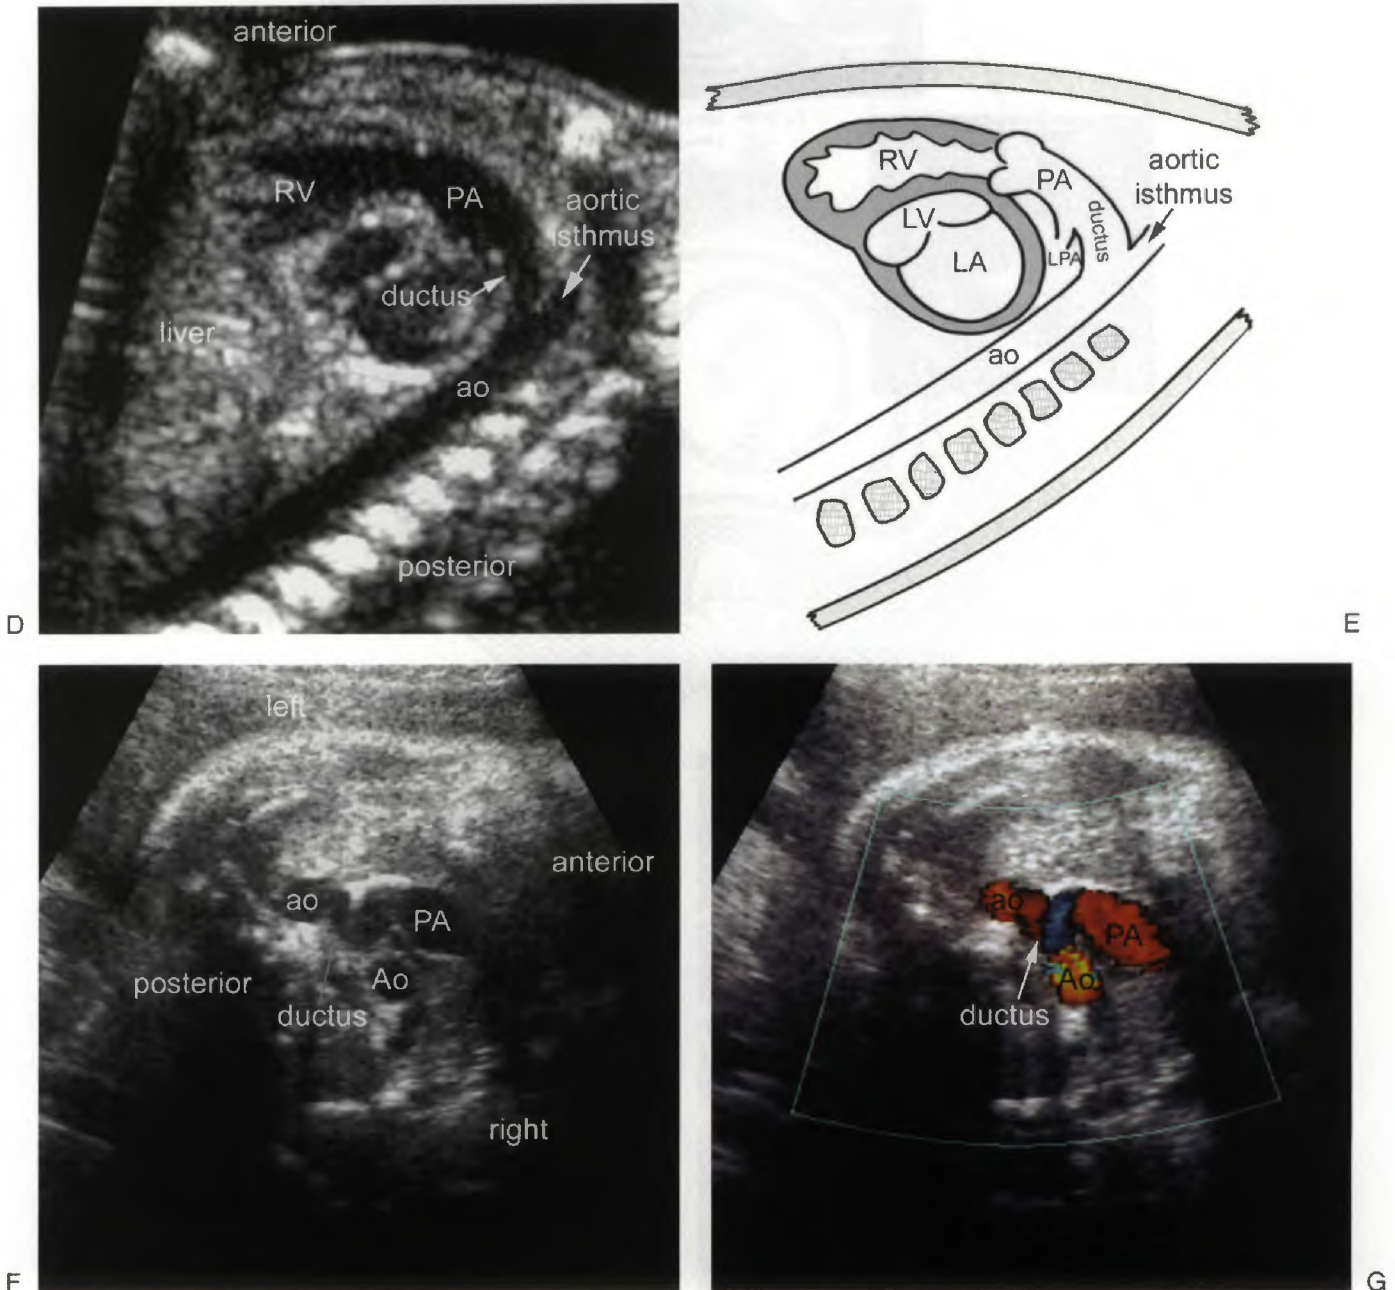

FIGURE 14-10 cont'd. *D* and *E*. Ductal arch views and diagram. The ductus arteriosus connects the main pulmonary artery to the descending aorta, thus forming a hockey stick-shaped arch. As its proximal part is the main pulmonary artery, its origin is immediately behind the anterior chest wall. In contrast to the aortic arch, it does not give rise to any head and neck branches. *F* and *G*. Tortuous ductus arteriosus in a fetus at 35 weeks of gestation. The ductus arteriosus tends to become tortuous in later pregnancy. It can be mistaken for an aneurysm of the ductus arteriosus. Color Doppler image (*G*) shows a U-loop of the ductus arteriosus with blue and red signals. LPA, left pulmonary artery.

Table 14-2 Clues to the Abnormality at Each Sonographic View

Sonographic View	Structures to Investigate	Clues to Abnormalities
Transverse view of upper abdomen	Larger lobe of the liver Stomach Abdominal aorta Inferior vena cava	Abnormal position of the stomach and liver Absent or multiple spleens Aorta and inferior vena cava on the same side of the spine Interruption of the inferior vena cava
Four-chamber view	Position, size and axis of the heart Size symmetry of cardiac chambers and great vessels Pulmonary veins Atrioventricular valve attachment and function Moderator band Septal integrity	Cardiac malposition Displaced heart Abnormal cardiac axis Abnormal atrioventricular connections; discordant connection, univentricular connection Cardiomegaly Asymmetric chamber and valve size Atrial, ventricular or atrioventricular septal defect Apical displacement of the septal leaflet of the tricuspid valve Abnormal pulmonary venous connections
Three-vessel view	Vessel number, alignment and size Position and size of aortic and ductal arches Trachea and bronchi Branch pulmonary arteries	Dilatation of the aorta, pulmonary trunk or superior vena cava Discrepancy in great arterial size Abnormal vessel alignment Abnormal vessel arrangement Aortapulmonary window Only two vessels Additional vessel Right descending aorta Abnormal origin or course of a pulmonary artery Ductal constriction or aneurysm Small or absent thymus
Left and right ventricular outflow tract views	Crossing nature of outflow tracts to arterial trunks Patency of outflow tracts and semilunar valves Septal integrity	Abnormal ventriculoarterial connections: transposition, double outlet right or left ventricle; and single arterial trunk Ventricular septal defect Overriding aorta or pulmonary trunk Abnormal dimension of the outflow tracts and/or arterial valves
Basal short-axis view	Crista supraventricularis Sub pulmonary outflow tract Size of aortic valve and left ventricular outflow tract	Ventricular septal defect in the outlet septum Right ventricular outflow tract narrowing Small size of the aortic valve
Aortic and ductal arch views	Position, contour and size of aortic and ductal arches Patency of the aortic arch Aortic arch branches	Ascending aorta smaller than descending aorta Focal or diffuse narrowing of the aortic arch Interruption of the aortic arch Right aortic arch Double aortic arch Ductal constriction or aneurysm Vessel behind the trachea

Table 14-3 Incidence of Congenital Heart Disease in Various Forms of Cardiac Malposition^{1, 57-60}

Visceral Situs and Heart Position	Incidence of Heart Defects
Situs solitus with levocardia (normal heart position)	<1%
Situs solitus with dextrocardia	>90%
Situs inversus with dextrocardia	10%–50%
Situs inversus with levocardia	>95%
Heterotaxy with right isomerism	~100%
Heterotaxy with left isomerism	Majority

asplenia is characterized by a symmetric liver extending from one side of the abdomen to the other with the stomach on either side (see Fig. 14-12B). In most cases of asplenia, the inferior vena cava and abdominal aorta are juxtaposed on the same side of the spine, with the former being located in front of the latter.^{62,64,67,69,70} Heterotaxy with polysplenia also shows an abnormally disposed liver with the stomach on either side (see Fig. 14-12C). In most cases of heterotaxy with polysplenia, the liver has an asymmetric contour with one side being larger than the other. In 75% to 90% of cases of polysplenia, the inferior vena cava shows interruption of its suprarenal-infrahepatic segment and connects instead to the azygos or hemiazygos vein to drain into the SVC.^{63-65,69,70} Interruption of the inferior vena cava is suspected when two, rather than one, vessels are seen in front of the spine in

Table 14-4 Abnormal Findings at Transverse View of the Upper Abdomen

Abnormal Finding	Significance
Stomach on the right side	The body situs is abnormal
Mirror-image arrangement of the liver, stomach, inferior vena cava, and abdominal aorta	The situs is inverted.
Transverse liver	Either right isomerism or left isomerism. Left isomerism tends to show some asymmetry of the hepatic configuration.
Piggy-backed abdominal aorta behind the inferior vena cava on the same side of the spine (so-called juxtaposition)	Highly suggestive of right isomerism. The dilated azygos vein receiving the interrupted inferior vena cava can occasionally be seen on the same side of the spine but the aorta is the anterior vessel.
Interruption of the inferior vena cava	Occurs in 75%–90% of left isomerism and rarely in other types of body situs.
Multiple spleens or lobulated single spleen	Means polysplenia and occurs in left isomerism with few exceptions.
No identifiable spleen	Can be due to technical limitation but is typically seen in right isomerism with few exceptions.

the transverse view of the upper abdomen and thorax (Figs. 14-12C and 14-13). The two vessels are usually of a similar size and aligned side by side or obliquely, with the azygos or hemiazygos vein located more posteriorly. This relationship can also be appreciated in the coronal plane. The splenic status can be assessed by scrutinizing the posterolateral aspect of the stomach. In asplenia, the hepatic tissue extends posteriorly along the greater curvature of the stomach. In polysplenia, a few small splenic masses can be identified along the greater curvature of the stomach (see Fig. 14-12C). In the thorax, heterotaxy is characterized by symmetry in the lung lobation, the bronchial and pulmonary arterial branching, and the shape of the atrial appendages. Most cases of heterotaxy and asplenia have both sides resembling the normal right side (right isomerism or bilateral right-sidedness), whereas most with heterotaxy and polysplenia have both sides resembling the normal left side (left isomerism or bilateral left sidedness). Investigation of the symmetry of these paired organs is a difficult task in the fetus, although it is not impossible, whereas symmetric arrangement per se is of little functional significance.^{34,71} It is very important, however, to thoroughly investigate the systemic and pulmonary venous drainage when the fetus shows abnormal visceral arrangement. CHD is exceedingly common in the presence of heterotaxy. Asplenia with right isomerism is almost always associated with severe CHD. Although left isomerism with polysplenia is also commonly associated with CHD, it is occasionally seen sporadically

and incidentally among patients receiving medical attention for purposes other than treatment for cardiac disease. Table 14-5 lists the CHDs and extracardiac defects that are commonly associated with the two forms of heterotaxy.

Four-Chamber View

The four-chamber view is an excellent screening view for detection of CHDs in the fetus. A four-chamber screening is able to detect 50% to 60% of cardiac malformations.^{20,21} It provides information about the position of the heart in the thorax, the overall heart size, the size of the individual chambers, the pulmonary venous connections to the atrial segment, the morphologic characteristics of the ventricles, the type of AV connection, and the integrity of the atrial, AV and ventricular septa (see Table 14-2).

The position of the heart is defined as levocardia, dextrocardia, or mesocardia according to where the main cardiac mass is located (Table 14-6 and Fig. 14-14). These terms are used only when the abnormal cardiac position is related primarily to the abnormality of the situs or the heart. When the heart is abnormally positioned secondary to the pulmonary, pleural, or diaphragmatic pathology, it is better to describe the side to which the heart is displaced. It is also preferable not to use the terms dextroversion, levoverion, dextroposition, and dextrorotation because they are defined differently among users and, therefore, confusing. Cardiac malposition is defined as any heart position other than levocardia in situs solitus.^{57,58,61} This definition of cardiac malposition refers not only to cardiac position but also to the appropriateness of the cardiac position in relation to the body situs. Therefore, levocardia in situs inversus is also an example of cardiac malposition. CHD is very common when there is cardiac malposition (see Table 14-3).

The displacement of the heart from extracardiac causes is often due to a mass effect from a primary lesion (see Table 14-6).^{59,60,72} These causes include diaphragmatic hernia or eventration, echogenic or cystic lung lesions such as cystic adenomatoid malformation, pulmonary sequestration, and bronchial atresia, lung tumor, and unilateral pleural effusion. The displacement of the heart can also be due to decreased volume of one lung, as in scimitar syndrome, unilateral absence of a branch pulmonary artery, and primary hypoplasia of a lung (see Fig. 14-14D).⁷³

As discussed earlier, the cardiac axis is approximately 45 degrees away from the sagittal and coronal planes.^{36,37} An abnormal base-apex axis of the heart is a clue to the diagnosis of a congenital malformation. The cardiac axis is directed more leftward in tetralogy of Fallot (see Fig. 14-14A) and truncus arteriosus, and when there is right chamber dilatation as in Ebstein anomaly, coarctation of aorta and hypoplastic left heart syndrome.^{36,37,55} On the contrary, the cardiac axis tends to be directed more forward or even to the right in congenitally corrected transposition of the great arteries or double inlet left ventricle with discordant ventriculoarterial connection (see Fig. 14-14C).^{60,74-78}

The AV connection and interventricular relationship are best defined in a four-chamber view.³⁴ To demonstrate this view, the ventricles should be identified according to their morphologic features. The septal attachment of the AV valves and the presence of the moderator band are the two most important morphologic criteria for ventricular identifi-

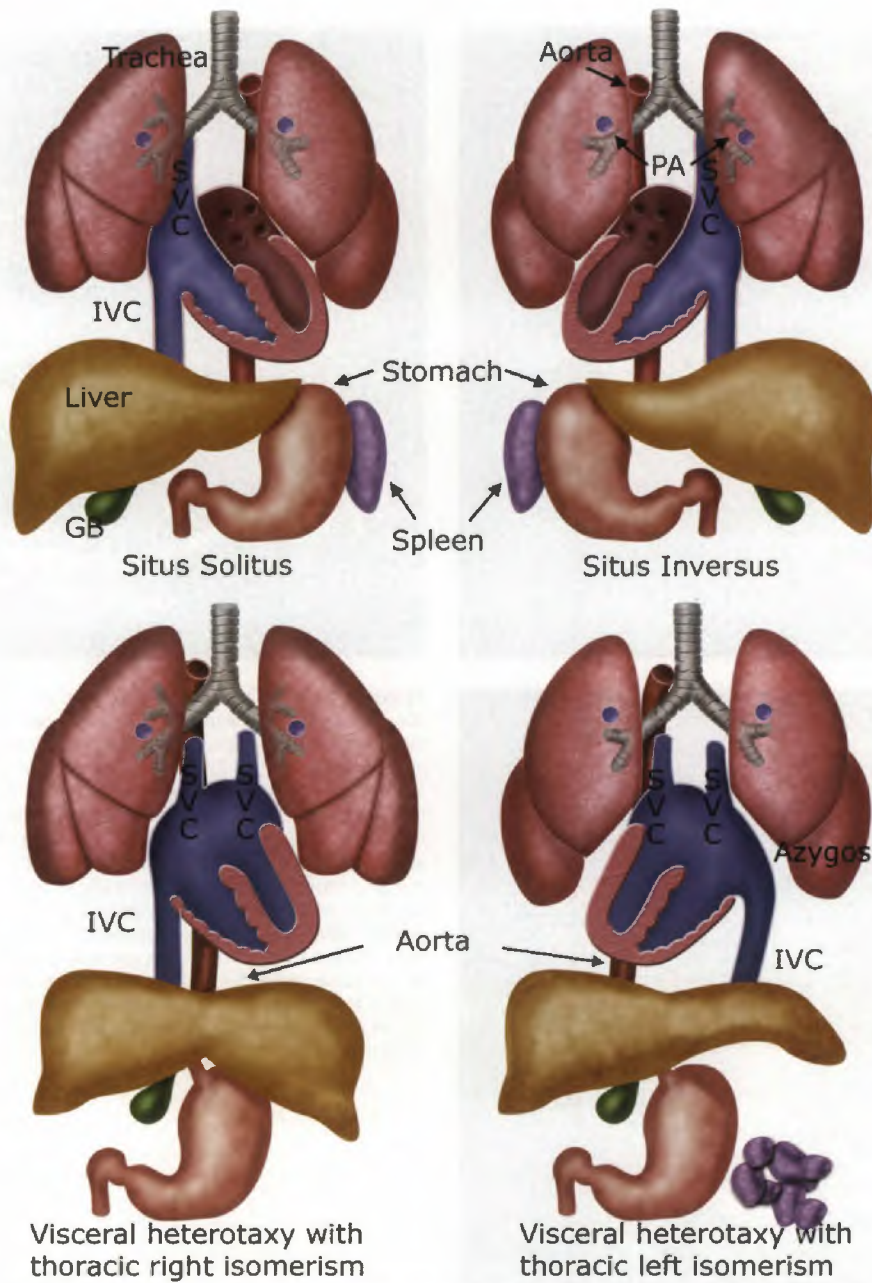

FIGURE 14-11. Types of visceral situs. GB, gallbladder; IVC, inferior vena cava; PA, branch pulmonary artery; SVC, superior vena cava. (Illustration by Shi-Joon Yoo, MD, and James A. Cooper, MD.)

FIGURE 14-12. Transverse view of the upper abdomen in situs inversus (A), heterotaxy with asplenia (B), and heterotaxy with polysplenia (C). Situs inversus is characterized by mirror-image arrangement of the abdominal organs. B. The abdominal aorta is piggy-backed behind the inferior vena cava (IVC) on the same side of the spine. This juxtaposed position of the inferior vena cava and abdominal aorta is seen in more than 90% of right isomerism. The liver extends from one side of the abdomen to the other. In C, two vessels are seen along the anterior margin of the spine. They are obliquely aligned in front of the spine. The posterior vessel is the dilated azygos vein that drains the interrupted inferior vena cava, which is associated with left isomerism in 75% to 90% of cases. The two vessels can also be aligned side-by-side in front of the spine. Note the multiple spleens (S) along the greater curvature side of the stomach. (C reprinted with permission from Yoo SJ, Lee YH, Cho KS, et al: *Sequential segmental approach to fetal congenital heart disease. Cardiol Young* 9:430, 1999.)

FIGURE 14-13. Left isomerism with interruption of the inferior vena cava. Two parallel large vessels are seen in front of the spine in both four-chamber (*A*) and oblique coronal (*B*) views. This is the characteristic feature of interrupted inferior vena cava with azygos or hemiazygos venous connection. L-A, left-sided atrium; LV, left ventricle; R-A, right-sided atrium; RV, right ventricle.

Table 14-5 Common Cardiac and Extracardiac Defects in Right and Left Isomerisms^{57, 58, 62-66}

	Right Isomerism	Left Isomerism
	Cardiac defects	
Bilateral superior venae cavae	45%	45%
Absence of coronary sinus	~100%	~60%
Interruption of the inferior vena cava	<2.5%	75%–90%
Juxtaposition of the aorta and inferior vena cava	>90%	Uncommon
Extracardiac type of total anomalous pulmonary venous connection	50%, with obstruction in 50%	Rare
Atrioventricular septal defect	90%	50%
Atrioventricular connection	Univentricular in 70%	Biventricular in ~75%
Ventriculoarterial connection	Concordant only in 4%	Concordant in ~70%
Pulmonary atresia or stenosis	80%	30%
Left-sided obstructive lesion	<5%	~30%
Heart block/bradycardia	Rare	Common
	Extracardiac defects	
Intestinal malrotation	Virtually all	Virtually all
Common extracardiac defects	Partial thoracic stomach (hiatal hernia) in ~25%	Biliary atresia and/or small or absent gallbladder in 20%, Urinary anomalies in 17%

cation (see Fig. 14-6). Once the morphologies of the ventricles are identified, the spatial relationship between the ventricles is defined. The ventricular relationship with the right ventricle on the right and the left ventricle on the left is called the d-loop ventricular relationship because it is the consequence of d-looping of the straight heart tube during embryogenesis (see Fig. 14-14A). The opposite relationship with the right ventricle on the left and the left ventricle on the right is called 'l-loop' ventricular relationship

(Fig. 14-14C). The pattern by which the atria are connected to the underlying ventricle or ventricles can be divided into biventricular and univentricular connections (Fig. 14-15).

Biventricular AV connections (see Fig. 14-15A) are either concordant or discordant when there is situs solitus or situs inversus. Discordant AV connection is almost always associated with discordant ventriculoarterial connection (Fig. 14-16). In this situation, the physiologic consequence of the discordant connection at the AV junction is cancelled

Table 14-6 Abnormal Position of the Heart

Category	Significance
Dextrocardia or mesocardia (without lung, pleural or bony pathology)	Means that there is a congenital heart disease except for few exceptions.
Rightward displacement of the heart due to right lung hypoplasia	Differential diagnoses include scimitar syndrome, agenesis of the right pulmonary artery and primary right lung hypoplasia.
Leftward displacement of the heart due to left lung hypoplasia	Differential diagnosis includes agenesis of the left pulmonary artery and left lung hypoplasia.
Anterior displacement of the heart	Bilateral diaphragmatic hernia

out by another discordant connection at the ventriculoarterial junction and, therefore, is rightfully called congenitally corrected transposition of the great arteries. When there is right or left isomerism, the AV connections are neither concordant nor discordant. Traditionally, these have been described as ambiguous connections. The AV connections in right or left isomerism, nonetheless, are not ambiguous. Instead, they need proper description.³⁴ Thus, they may be precisely described as right or left isomeric atria with biventricular connection to the ventricles exhibiting either a d-loop or l-loop ventricular relationship.

Univentricular AV connections (see Fig. 14-15*B*) are either in a form of double inlet connection or with absence of one AV connection, resulting in both atria connecting exclusively or mostly to one ventricle. Double inlet can lead to the main chamber of right or left ventricular morphology or to a solitary and indeterminate ventricle. Double inlet left ventricle is the most common type of double inlet in which the small right ventricle is usually located at the left upper aspect of the ventricular mass and there is discordant ventriculoarterial connection in the majority of cases (Fig. 14-17). Absent AV connections are seen involving more commonly the right AV junction than the left. The absent right AV connection is the key pathologic feature of tricuspid atresia (Fig. 14-18). The absent connection means that the atrium and the ventricle are apposed to each other but separated by the atrial and ventricular walls that are invaginated to the center of the heart.

Ventricular Disproportion

When there is univentricular connection, it is often difficult to precisely distinguish the morphologically right from the morphologically left ventricle by fetal ultrasound. In this setting, the morphology of the ventricles can be defined just by observing where the rudimentary chamber is located.³⁴ The presence of the rudimentary ventricular chamber at the anterior and superior aspect of the main ventricular chamber indicates that the main ventricular chamber is the morphologically left ventricle (see Figs. 14-17 and 14-18). On the contrary, the presence of the rudimentary ventricular chamber at the posterior and inferior corner of the main

chamber indicates that the main ventricular chamber is the morphologically right ventricle (Fig. 14-19).

In the setting of normal situs solitus and normal AV and ventriculoarterial connections, the four-chamber view frequently shows asymmetry in the cardiac chambers.^{38,39,79} Commonly, the asymmetry is due to dilated right atrium and right ventricle. Dilatation of the right atrium and ventricle means that there is increased blood flow volume through or valvar regurgitation on the right side of the heart, although it can also be due to right-sided heart failure (Table 14-7).

The most common causes of ventricular disproportion with right-sided dominance are the right-sided lesions. Significant tricuspid regurgitation is most often due to Ebstein malformation in which the septal and posterior leaflets of the tricuspid valve have their attachments downward into the right ventricle and are hypoplastic and dysplastic (Fig. 14-20).⁸⁰ As the displaced leaflets fail to align properly with the anterior leaflet, tricuspid regurgitation ensues during ventricular systole. Dilatation of the right atrium and right ventricle varies according to the severity of regurgitation. Uncommonly, the edges of the displaced septal and posterior leaflets are fused to the edge of the anterior leaflet, resulting in tricuspid stenosis with little regurgitation. In this stenotic form of Ebstein malformation, the right ventricle is not significantly dilated, whereas the right atrium is dilated. Tricuspid regurgitation can also be due to dysplastic valve leaflet without displaced attachments. Severe tricuspid regurgitation may be associated with progressive development of pulmonary stenosis or atresia and right-sided heart failure with hydrops fetalis.⁸⁰⁻⁸² A markedly dilated right atrium and right ventricle can be associated with atrial flutter. Severe cardiomegaly of any cause is complicated by significant lung hypoplasia that may further complicate the intrauterine and postnatal courses. A small pulmonary artery size in the presence of right atrial dilatation is suggestive of restricted flow through the pulmonary valve. This is typically seen with tricuspid regurgitation with or without pulmonary stenosis or atresia (Fig. 14-21).⁸⁰ In the majority of cases with pulmonary atresia or critical stenosis with intact ventricular septum, the right atrium is markedly dilated due to tricuspid regurgitation, whereas the right ventricle is markedly hypertrophied and its cavity shows a variable degree of hypoplasia.⁸³ Less commonly, pulmonary atresia is associated with a dilated right ventricle. This latter category has a much poorer prognosis, and the pulmonary atresia or severe stenosis is secondary to the tricuspid pathology. The sole source of blood supply to the pulmonary arteries in pulmonary atresia with intact ventricular septum is the ductus arteriosus. On color Doppler interrogation, one may recognize the forward flow in the right ventricle and retrograde flow in the main pulmonary artery kissing at the atretic pulmonary valve (see Fig. 14-21*C*). A small main pulmonary artery may not be obvious at fetal ultrasound.³⁷ Pulmonary atresia with a hypertrophied hypoplastic right ventricle is commonly associated with coronary arterial abnormalities that include dilatation with fistulous communication with the right ventricle, ostial stenosis and interruption of coronary arterial luminal patency.⁸⁴ Communications between the coronary arteries and hypoplastic hypertensive right ventricle can be demonstrated with color Doppler interrogation.⁸⁵

Trivial tricuspid regurgitation is not uncommon but it is rarely significant when it is seen in the 18- to 20-week scan

FIGURE 14-14. Normal and abnormal positions of the heart. *A.* Levocardia in a normal fetus. Approximately two thirds of the cardiac mass is located in the left thorax. The cardiac axis (*arrow*) is approximately 45 degrees off the coronal or sagittal plane and points in the left anterior direction. *B.* Levocardia with leftward rotation of the cardiac axis in a fetus with tetralogy of Fallot. The cardiac axis (*arrow*) lies in a coronal plane and is directed toward the left lateral chest wall. *C.* Dextrocardia in a fetus with corrected transposition of the great arteries. The major part of the cardiac mass is located in the right thorax. The cardiac axis (*arrow*) points in the right anterior direction. *D.* Rightward displacement of the heart due to right lung hypoplasia in a fetus with scimitar syndrome. The heart is located in the right thorax while its axis (*arrow*) pointing directly forward. When the heart is abnormally positioned secondary to extracardiac pathology, it is simply described as displaced. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

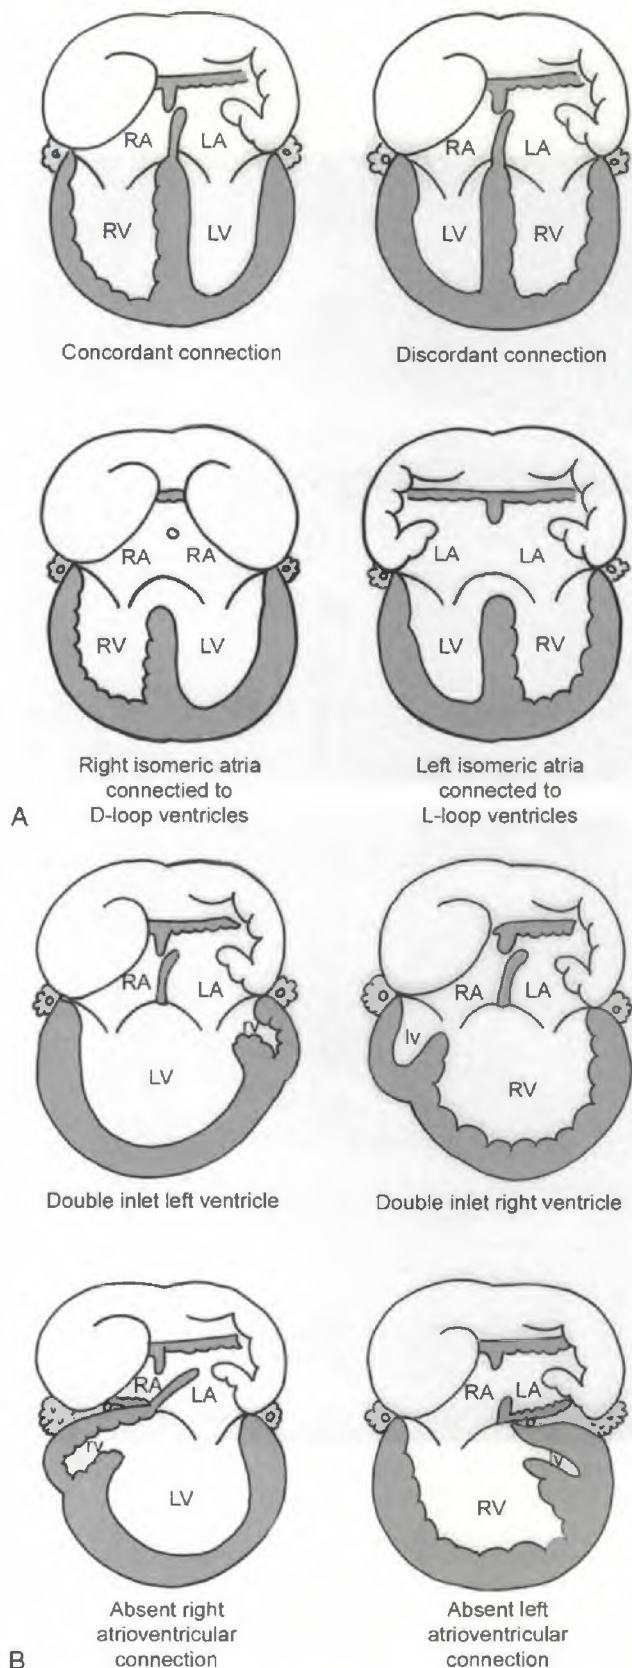

FIGURE 14-15. Biventricular (A) and univentricular atrioventricular connections (B). LA, left atrium; LV (lv), left ventricle; RA, right atrium; RV (rv), right ventricle.

and usually disappears in the later pregnancy or after birth (see Fig. 14-6H).^{42,43} However, tricuspid regurgitation in the first trimester is often associated with chromosomal abnormalities, especially when it is seen with abnormal nuchal translucency.⁴⁴⁻⁴⁶

Less common causes of ventricular disproportion with right-sided dominance are the left-sided obstructive lesions and anomalous pulmonary venous connections. Obstructive lesions of the left side of the heart, including various forms of mitral valve stenosis and left ventricular outflow tract obstruction, result in reduced flow into the left ventricle and, therefore, cause right-sided dominance with reduced right-to-left shunt or overt left-to-right shunt through the patent foramen ovale (Figs. 14-22 and 14-23). It has also been suggested that significant dilatation of the coronary sinus can contribute to left ventricular inflow obstruction.⁸⁶⁻⁸⁸ The diagnosis of left-sided obstructive lesions can be made by morphologic assessment and measurement of the mitral valve, aortic valve, and aortic arch, as well as color and spectral Doppler interrogation (see Figs. 14-22 and 14-23). Generalized smallness of the left side of the heart with various combinations of obstructive lesions is designated Shone syndrome. The more severe form of underdevelopment of the left-sided structures is the hypoplastic left heart syndrome, in which the degree of left ventricular hypoplasia precludes any form of biventricular repair (see Fig. 14-23).

Anomalous pulmonary venous connection is also a rare cause of ventricular and great arterial disproportion with right-sided dominance.⁸⁹⁻⁹¹ The disproportion is typically seen in total anomalous pulmonary venous connection (Fig. 14-24). In the presence of a large atrial septal defect or with infradiaphragmatic drainage, right-sided heart dilatation may not occur until late in pregnancy. Partial anomalous pulmonary venous return is unlikely to cause any significant disproportion of the chambers (Fig. 14-25). The diagnosis of anomalous pulmonary venous drainage can only be reliably excluded by direct examination of the routes of pulmonary venous drainage to the left atrium using color and power Doppler mapping (see Fig. 14-6E). It is important to know that the confluent pulmonary vein in anomalous pulmonary venous connection is very close to the posterior wall of the left atrium and, therefore, could be mistakenly considered to connect normally to the left atrium. Isolated dilatation of the SVC can be a clue to the diagnosis of anomalous drainage to the systemic vein.⁹²

Dilatation of the right ventricle in an otherwise normally structured heart without significant tricuspid regurgitation is described as ventricular discrepancy with right-sided dominance (Figs. 14-26 and 14-27). Earlier studies emphasized that right-sided dominance is highly predictive of coarctation or other forms of aortic arch obstruction.^{93,94} However, right-sided dominance is not a consistent fetal sonographic finding of coarctation, occurring in only 60% of infants with coarctation.⁹⁴ Furthermore, right-sided dominance does not distinguish between fetuses with coarctation and those without.^{95,96} Therefore, it is important to assess the size and configuration of the aortic arch when there is right-sided dominance. As a rule of thumb, right-sided dominance should be considered more significant when the ascending aorta is smaller than the SVC or descending aorta or when the aortic arch is significantly smaller than

FIGURE 14-16. Discordant atrioventricular and ventriculoarterial connections (congenitally corrected transposition of the great arteries). *A.* Four-chamber view shows levocardia and I-loop ventricular relationship with the morphologically right ventricle (RV) on the left and the morphologically left ventricle (LV) on the right. Note the more apical attachment of the left-sided atrioventricular valve to the septum (*asterisks*). *B.* Three-vessel view shows grossly abnormal great artery relationship with the ascending aorta (Ao) on the left anterior aspect of the main pulmonary artery (PA). This position is most commonly seen in and highly suggestive of corrected transposition of the great arteries in situs solitus. *C.* Right anterior oblique view shows superoinferior relationship of the parts of the ventricles and discordant ventriculoarterial connection. The subpulmonary outflow tract (*asterisk*) shows narrowing. *D.* Diagrammatic representation of the case. Ao, descending aorta; d, ventricular septal defect; L, left pulmonary artery; LA, left atrium; R, right pulmonary artery; RA, right atrium; SVC, superior vena cava.

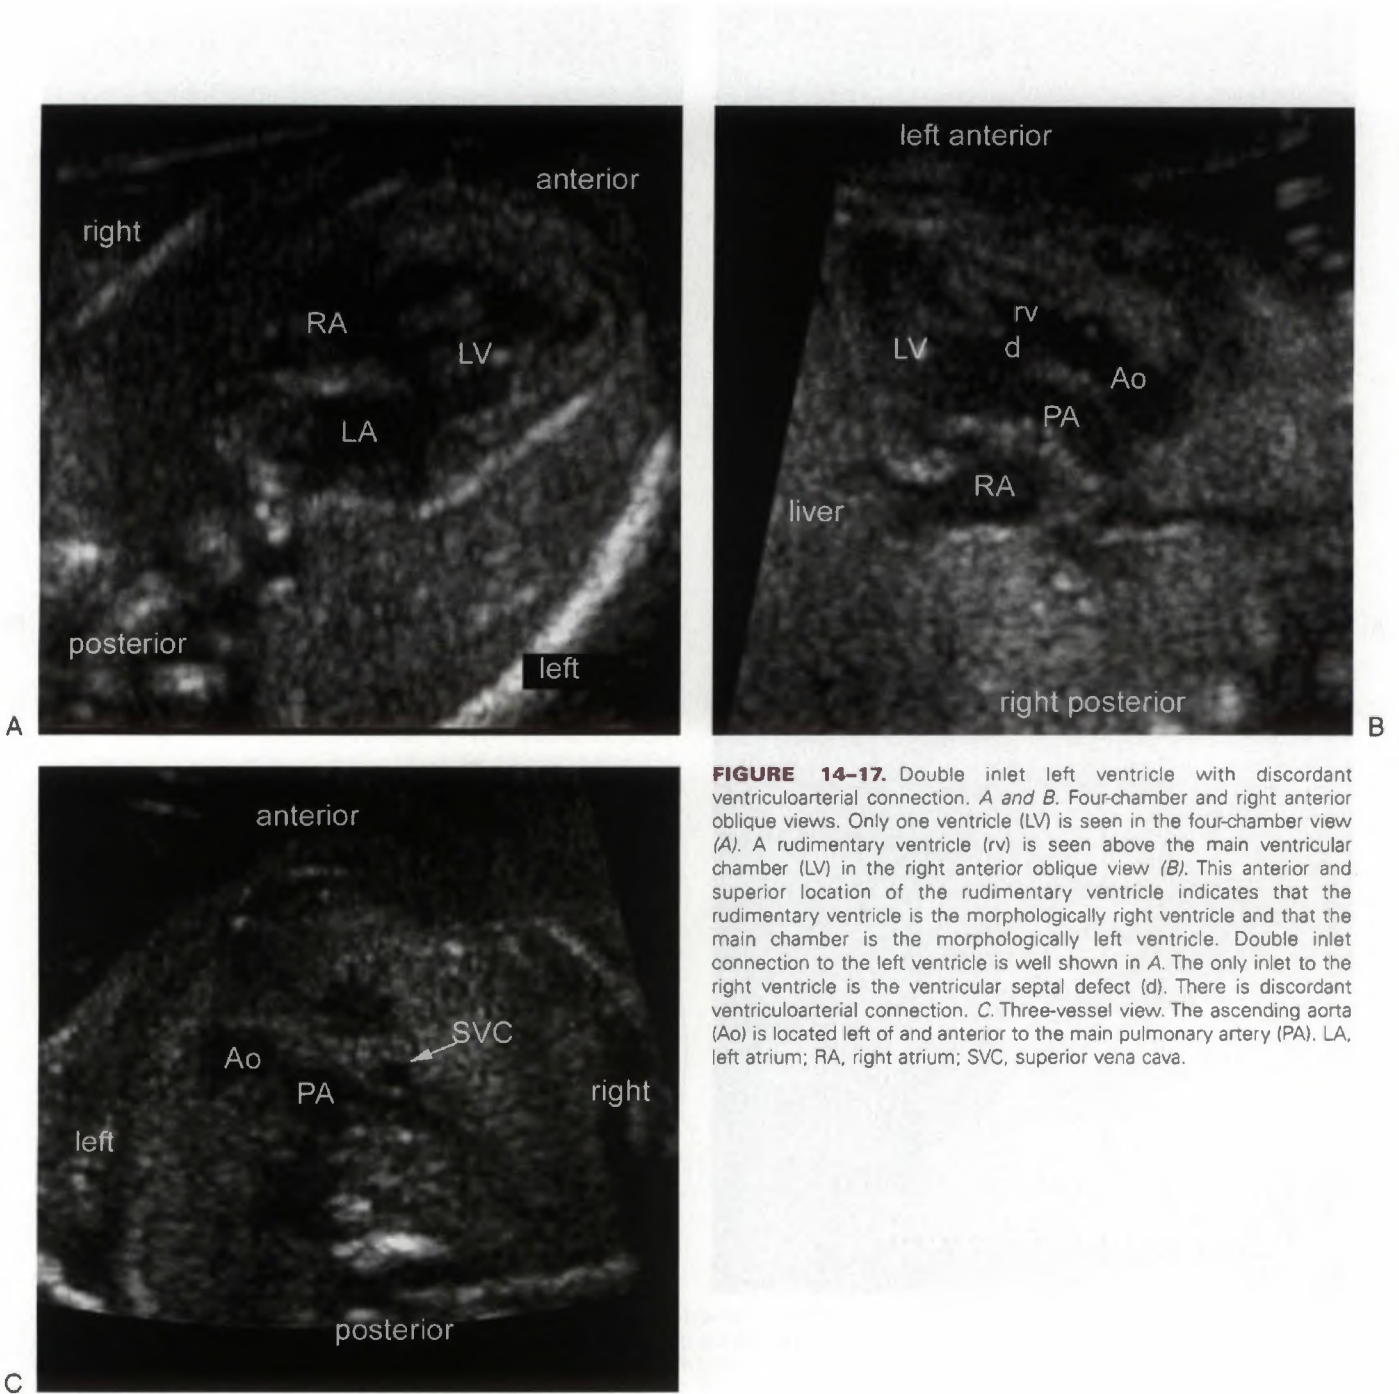

FIGURE 14-17. Double inlet left ventricle with discordant ventriculoarterial connection. *A and B.* Four-chamber and right anterior oblique views. Only one ventricle (LV) is seen in the four-chamber view (*A*). A rudimentary ventricle (rv) is seen above the main ventricular chamber (LV) in the right anterior oblique view (*B*). This anterior and superior location of the rudimentary ventricle indicates that the rudimentary ventricle is the morphologically right ventricle and that the main chamber is the morphologically left ventricle. Double inlet connection to the left ventricle is well shown in *A*. The only inlet to the right ventricle is the ventricular septal defect (d). There is discordant ventriculoarterial connection. *C.* Three-vessel view. The ascending aorta (Ao) is located left of and anterior to the main pulmonary artery (PA). LA, left atrium; RA, right atrium; SVC, superior vena cava.

FIGURE 14-18. Tricuspid atresia with normally related and connected great arteries. *A.* Four-chamber view shows that the muscular floor (*asterisks*) separates the right atrium (RA) from the underlying small right ventricle (rv). There is an unrestrictive ventricular septal defect (d) between the large left ventricle (LV) and the small right ventricle. *B.* Three-vessel view shows a normal relationship and size of the three vessels. *C.* Oblique sagittal view through the right ventricle shows the pulmonary artery (PA) arising from the right ventricle. *D.* Oblique sagittal view through the left ventricular outflow tract shows the aorta (Ao) arising from the left ventricle. ao, descending aorta; LA, left atrium; SVC, superior vena cava.

FIGURE 14-19. Univentricular connection to the morphologically right ventricle. Sagittal view shows the small rudimentary chamber (lv) at the posterior inferior aspect of the main chamber (RV). The rudimentary chamber can be regarded as the morphologically left ventricle because of its posterior and inferior location. Ao, ascending aorta. (Reprinted with permission from Yoo SJ, Lee YH, Cho KS, et al: *Sequential segmental approach to fetal congenital heart disease. Cardiol Young* 9:430, 1999.)

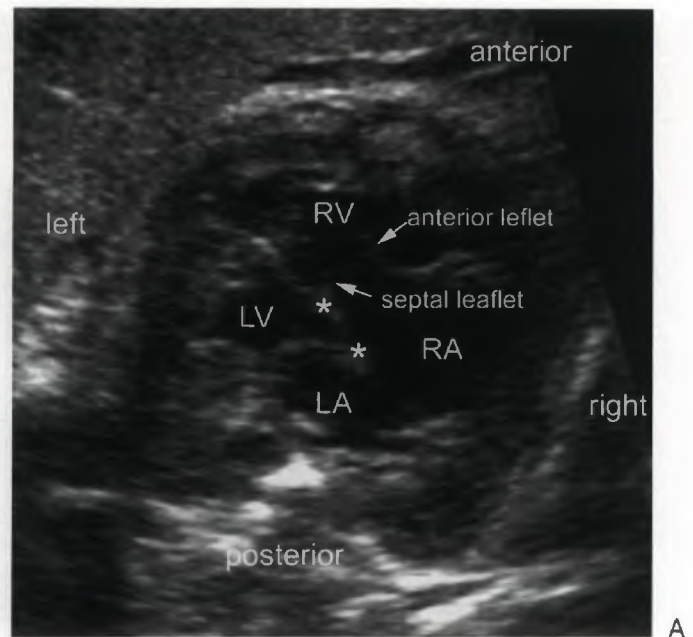

FIGURE 14-20. Ebstein's malformation. A. Four-chamber view shows a big heart with dilatation of the right atrium (RA) and right ventricle (RV). Note the displaced attachment of the septal leaflet of the tricuspid valve (upper asterisk). The anterior leaflet of the tricuspid valve has a normal insertion to the septum (lower asterisk). The anterior leaflet of the tricuspid valve is large, whereas the septal leaflet is small. B. Color Doppler image in the same view as A shows moderate tricuspid regurgitation. LA, left atrium; LV, left ventricle.

Table 14-7

Causes of Right-sided Dominance in the Four-Chamber View in the Presence of Normal Segmental Connections

With An Identifiable Cardiac Defect

Tricuspid regurgitation
Ebstein malformation
Dysplastic tricuspid valve
Unguarded tricuspid valve
Pulmonary atresia with intact ventricular septum
Left-sided obstructive lesion
Mitral stenosis: supra-valvar, valvar and subvalvar
Critical aortic stenosis
Hypoplastic left heart syndrome
Coarctation of the aorta
Anomalous pulmonary venous connection

Without An Identifiable Cardiac Defect

Coarctation of aorta
Constriction of ductus arteriosus

the ductal arch in the three-vessel view (see Figs. 14-26C and 14-27B). Reversed flow in the aortic arch is an important supportive sign of the obstructive lesion of the aortic arch.⁹⁷ Right-sided dominance is less predictive of the coarctation of aorta in later pregnancy because the right ventricle is normally bigger than the left ventricle as the pregnancy approaches the term.^{38,39,96} In fact, actual coarctation of the

aorta with a posterior shelf or waist lesion is uncommon in the fetus (see Fig. 14-27C). It is speculated that the aorta develops real narrowing with posterior shelf when the ductus arteriosus closes after birth in most isolated coarctations. Obvious coarctation of the aorta is usually a manifestation of a more complex form of aortic arch obstruction associated with other significant heart disease.

FIGURE 14-21. Pulmonary atresia with intact ventricular septum. *A.* Four-chamber view shows severe hypoplasia of the right ventricular cavity (rv) and markedly thickened right ventricular free wall. *B.* Three-vessel view shows that the ascending aorta (Ao) is more anteriorly located in relation to the main pulmonary artery (PA), causing a malaligned three-vessel view. The main pulmonary artery is slightly smaller than the ascending aorta. *C.* Ductal arch view with color Doppler shows left-to-right shunt across the ductus. The blood flow from the right ventricle (blue signal in right ventricular outflow tract [RVOT]) and the retrograde flow in the main pulmonary artery (red signal) collide at the atretic pulmonary valve. LA, left atrium; LV, left ventricle; RA, right atrium; SVC, superior vena cava.

FIGURE 14-22. Mitral stenosis. *A.* Four-chamber view shows that the left ventricle (LV) is smaller than the right ventricle (RV). The mitral valve leaflets are thickened. Note that the atrial septum is bowed toward the right atrium (RA). *B.* Color Doppler image in four-chamber view shows flow acceleration (arrows) through the mitral valve. LA, left atrium.

FIGURE 14-23. Hypoplastic left-sided heart syndrome. *A.* Four-chamber view shows that the left ventricle (LV) is very small. The cardiac apex (asterisk) is formed by the right ventricle (RV). The flap valve of the fossa ovalis is bowed toward the right atrium (RA) due to reversed shunt across the foramen ovale. Hyperechogenic endocardial surface of the left ventricle suggests endocardial fibroelastosis. *B and C.* *Continued*

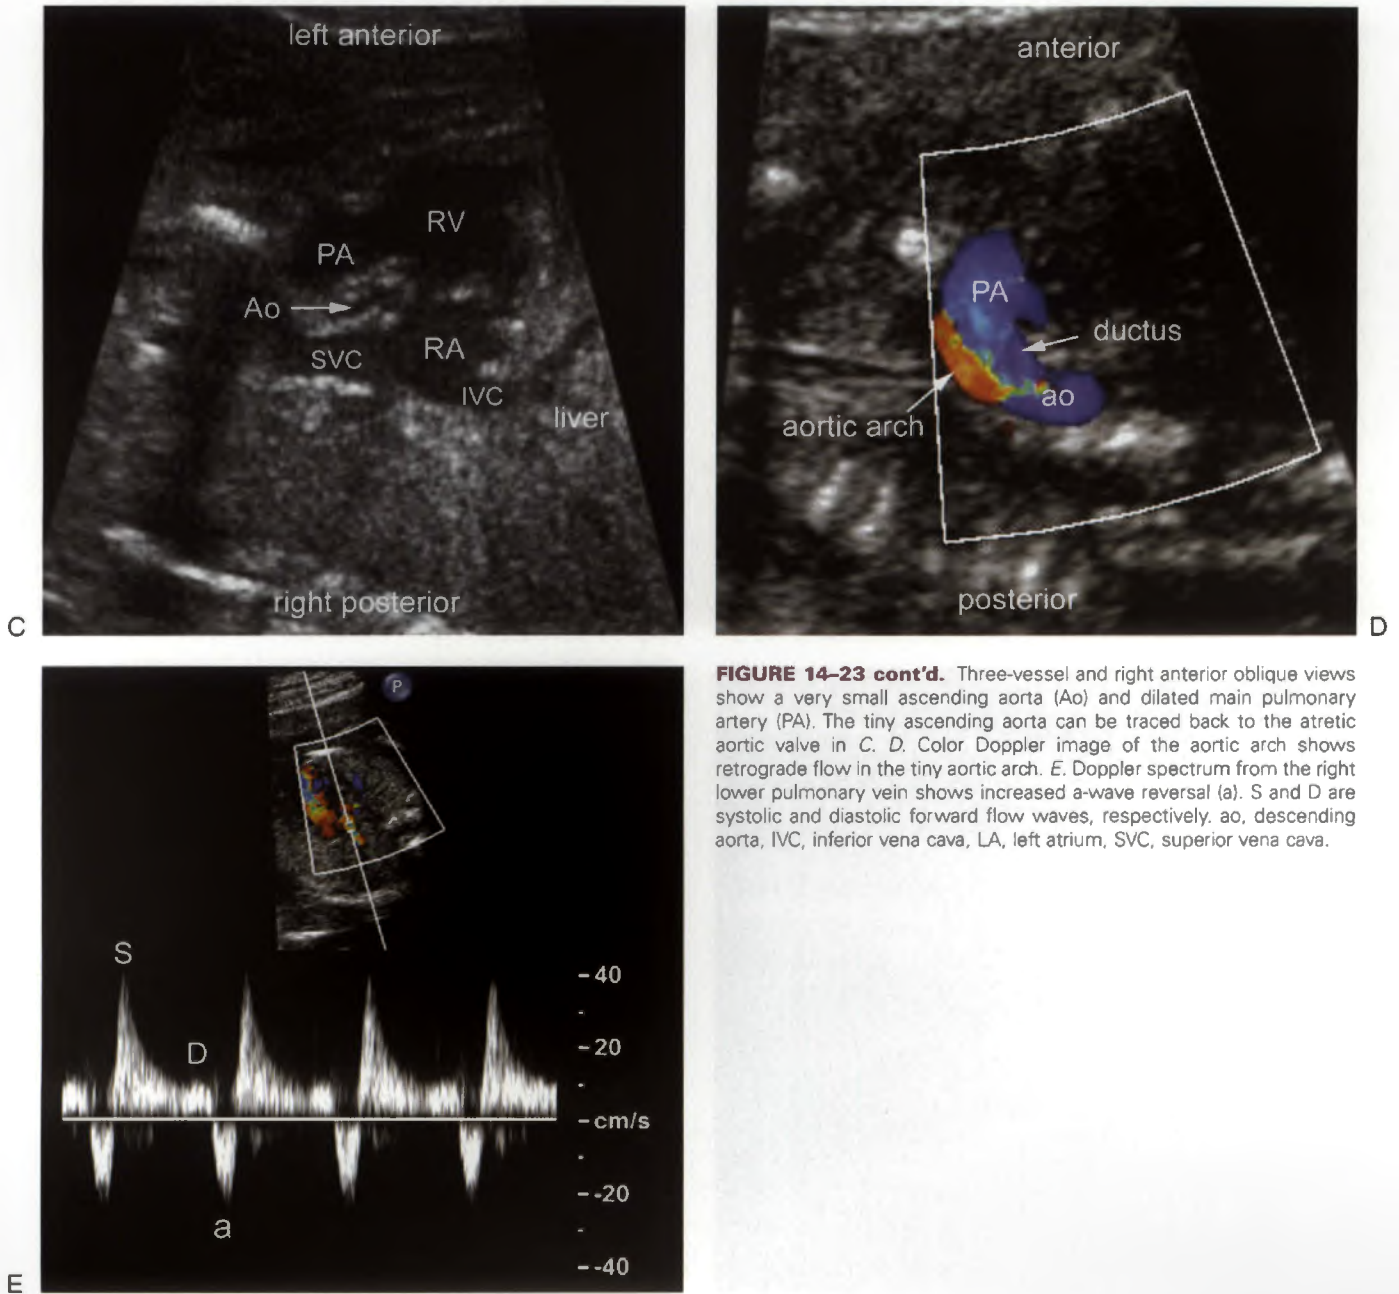

FIGURE 14-23 cont'd. Three-vessel and right anterior oblique views show a very small ascending aorta (Ao) and dilated main pulmonary artery (PA). The tiny ascending aorta can be traced back to the atretic aortic valve in *C*. *D*. Color Doppler image of the aortic arch shows retrograde flow in the tiny aortic arch. *E*. Doppler spectrum from the right lower pulmonary vein shows increased a-wave reversal (a). S and D are systolic and diastolic forward flow waves, respectively. ao, descending aorta, IVC, inferior vena cava, LA, left atrium, SVC, superior vena cava.

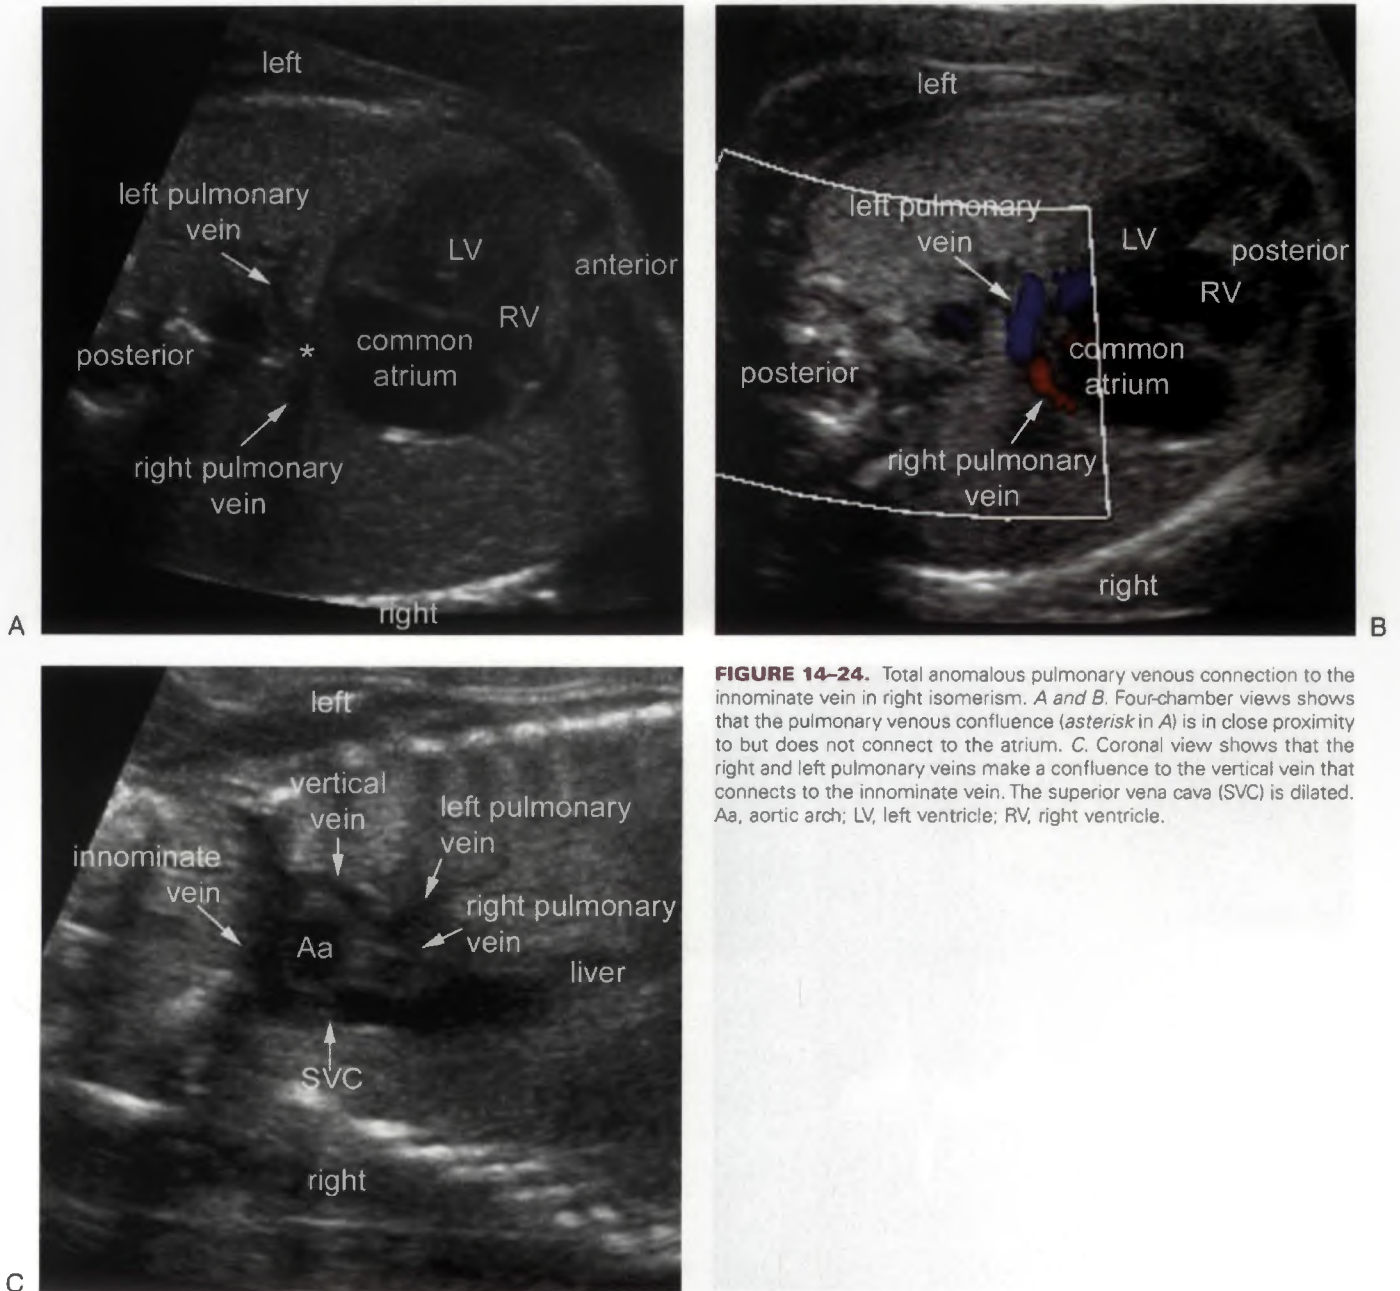

FIGURE 14-24. Total anomalous pulmonary venous connection to the innominate vein in right isomerism. *A and B.* Four-chamber views shows that the pulmonary venous confluence (*asterisk* in *A*) is in close proximity to but does not connect to the atrium. *C.* Coronal view shows that the right and left pulmonary veins make a confluence to the vertical vein that connects to the innominate vein. The superior vena cava (SVC) is dilated. Aa, aortic arch; LV, left ventricle; RV, right ventricle.

FIGURE 14-25. Partial anomalous pulmonary venous connection to the innominate vein. *A.* Four-chamber view shows the right lower pulmonary vein connecting to the left atrium (LA). Left pulmonary veins could not be traced back to the left atrium. There is no significant right-left discrepancy in chamber size. *B.* Three-vessel view shows an additional vessel (vertical vein) on the left-side of the main pulmonary artery (PA). The vertical vein collects the left pulmonary veins as shown in *C.* *C.* Oblique axial view shows the left pulmonary veins connecting to the innominate vein through the vertical vein. Ao, ascending aorta; ao, descending aorta; LV, left ventricle; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

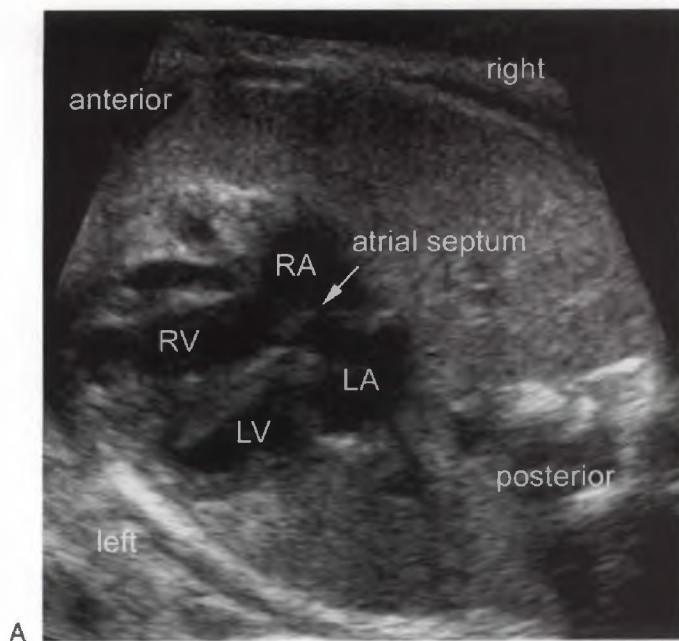

FIGURE 14-26. Isolated coarctation of the aorta. **A.** Four-chamber view shows right-sided dominance in chamber size. The flap valve of the fossa ovalis bulges toward the right atrium (RA). **B.** Color Doppler image in an identical view shows left-to-right shunt (*asterisk*) through the foramen ovale. **C.** Three-vessel view shows the ascending aorta (Ao) smaller than the superior vena cava (SVC). **D.** Three-vessel view at the aortic arch level shows hypoplastic left aortic arch. It is much smaller than the ductus arteriosus. **E.** Aortic arch view shows the small aortic arch and isthmus. ao, descending aorta; LA, left atrium; LV, left ventricle; PA, main pulmonary artery; RV, right ventricle.

FIGURE 14-27. Isolated coarctation of the aorta with posterior shelf. *A.* Four-chamber view shows the right-sided dominance in chamber size. *B.* Three-vessel view shows the large main pulmonary artery (PA) and small ascending aorta (Ao). *C.* Oblique axial view through the aortic and ductal arches shows the aortic arch to be much narrower than the ductus arteriosus. There is flow acceleration in the aortic arch. *D.* Aortic arch view shows diffuse narrowing of the aortic arch. There is an indentation (*arrow*) in the posterior wall of the aorta where the ductus arteriosus makes a confluence with the aortic arch. This is not a common finding of isolated coarctation in fetus. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

Ductal constriction is also associated with right-sided dominance (Fig. 14-28).⁹⁸⁻¹⁰⁰ Ductal constriction is classically seen with maternal administration of cyclo-oxygenase inhibitors such as indomethacin but are also seen without use of a triggering agent. When it is associated with cyclo-oxygenase inhibitor therapy, ductal constriction is reversible. Because delayed diagnosis of ductal constriction can lead to right heart failure with hydrops, intrauterine death and persistent pulmonary hypertension in newborns, its early

recognition is important. Ductal constriction is characterized by acute cardiomegaly with tricuspid regurgitation, right atrial and ventricular dilatation, and right ventricular hypertrophy and dyskinesia. Because of high right ventricular diastolic pressure, the tricuspid valve barely opens in diastole. The diagnosis is made by documenting flow acceleration through the narrow ductus arteriosus (see Fig. 14-28C). It has been suggested that the tortuous ductus arteriosus in later pregnancy also contributes to restricted

FIGURE 14-28. Constriction of the ductus arteriosus causing right-sided dominance. *A.* Four-chamber view shows marked dilatation of the right atrium (RA) and right ventricle (RV). The right ventricle is hypertrophied. *B.* Ductal arch view shows narrow ductus arteriosus. *C.* Pulsed-wave Doppler spectrum from the ductus shows continuous turbulent flow. ao, descending aorta; LA, left atrium; LV, left ventricle; PA, main pulmonary artery.

ductal flow, which needs yet to be proven based on a larger population study.¹⁰¹ One should be aware that the ductus arteriosus can be small, without physiologic constriction, when there is reduced blood flow from the right ventricle into the pulmonary artery as in tetralogy of Fallot and that the ductus arteriosus is absent in tetralogy of Fallot with absent pulmonary valve syndrome and pulmonary atresia with major aortopulmonary collateral arteries (MAPCA).^{55,100}

Extracardiac arteriovenous malformations with hyperdynamic circulation, such as a vein of Galen malformation and hepatic arteriovenous malformation, may also cause dilated right atrium and right ventricle. In fact, coarctation of the aorta is seen in approximately 40% of patients with a vein of Galen malformation (Fig. 14-29).¹⁰² It is considered

to be due to diminished blood flow through the aortic isthmus because of diversion of the blood flow into the vein of Galen malformation.

It is very important to know that right-sided dominance is also seen in some fetuses with intrauterine growth restriction as well as in those with tricuspid regurgitation or anomalous pulmonary venous connections.⁹⁴ In fact, mild to even moderate degree of right-sided dominance is not uncommon in the absence of a cardiovascular defect.

Doppler interrogation of flow through the patent foramen ovale is helpful in the differential diagnosis of the causes of dilatation of the right atrium and right ventricle. When there is left-to-right shunt through the patent foramen ovale, especially when the flap valve of the fossa ovalis

FIGURE 14-29. Vein of Galen malformation with coarctation of aorta. A. Transverse view of the brain shows an aneurysmally dilated vein of Galen and hydrocephalus. B. Four-chamber view shows cardiomegaly with right atrial (RA) and right ventricular (RV) dilatation. The right ventricle is also hypertrophied. C. Aortic arch view shows narrow aortic isthmus. D. Spectral Doppler tracing of the aortic isthmus shows systolic forward and diastolic retrograde flow. Ao, ascending aorta; ao, descending aorta; LA, left atrium; LV, left ventricle.

bulges into the right atrium, it is highly suggestive of a left-sided obstructive lesion that may have already developed or will develop later (see Figs. 14-22A, 14-23A and 14-26A).⁹⁶ When a severe left-side obstructive lesion is associated with a restrictive patent foramen ovale, pulmonary venous blood flow shows increased reversed flow with atrial contraction (see Fig. 14-23F).¹⁰³⁻¹⁰⁵ When there is right-to-left shunt through the patent foramen ovale, it is more likely a primary right-sided lesion such as tricuspid valve pathology with

or without right ventricular outflow tract obstruction, or anomalous pulmonary venous connection, or intrauterine growth retardation.

Left-sided dominance is much less common and usually seen with right ventricular hypoplasia, with or without right ventricular outflow tract obstruction. It can also be seen with tricuspid valve pathology causing reduction of the blood flow into the right ventricle, such as a straddling tricuspid valve. In the majority of cases of pulmonary atresia with

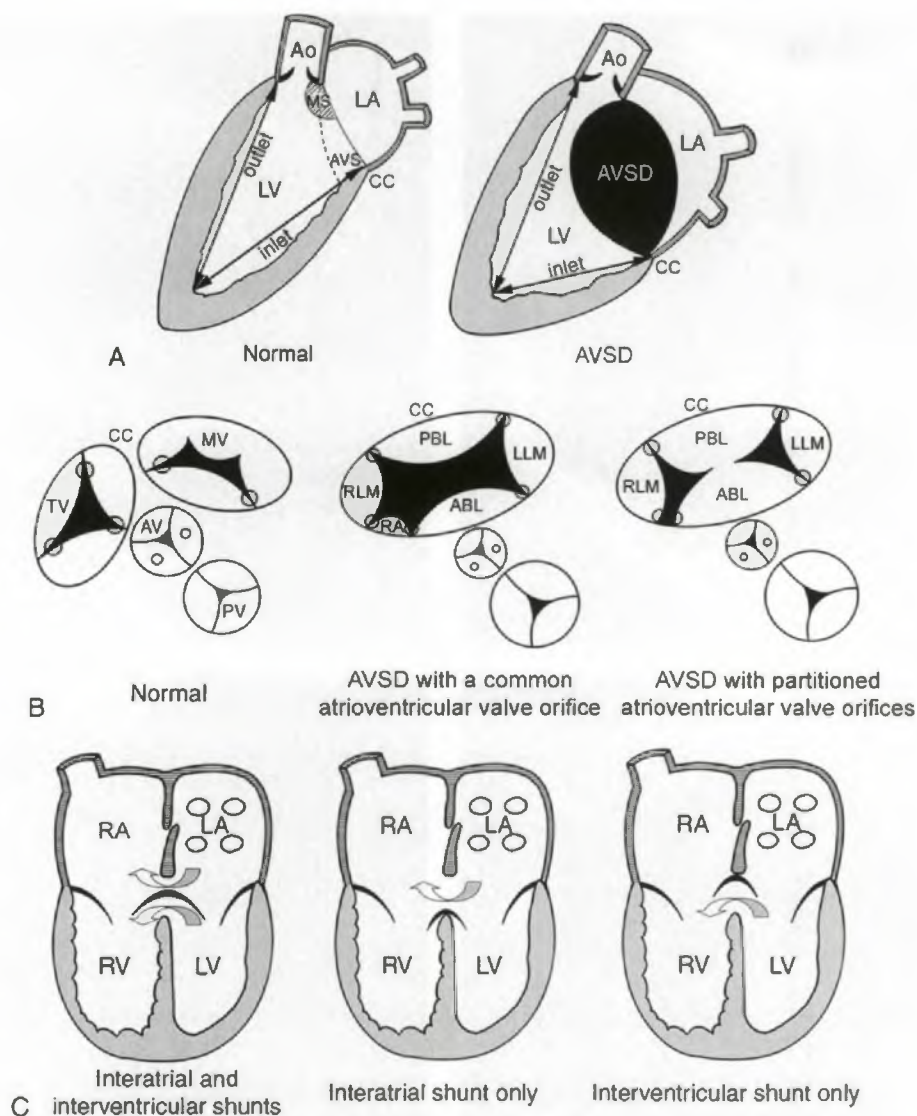

FIGURE 14-30. Diagrams showing characteristic features of atrioventricular septal defect (AVSD). **A.** Left ventricle seen from the left side showing inlet-outlet disproportion and increased distance between the aorta (Ao) and crux cordis (CC) in AVSD. **B.** Atrioventricular valves seen from above. Note the wedged position of the aortic valve (AV) between the tricuspid (TV) and mitral (MV) valves in the normal heart. The aortic valve has an unwedged position in AVSD with an increased distance between the aortic valve and crux cordis because of a common atrioventricular annulus. The five leaflets of AVSD are the anterior and posterior bridging leaflets (ABL and PBL), the left and right lateral leaflets (LLM and RLM), and the right anterior leaflet (RA). **C.** Level of shunts. The level of shunt across the AVSD is determined by the relationship of the bridging leaflets to the septal margins of the defect. AVS, atrioventricular septum; LA, left atrium; LV, left ventricle; MS, membranous septum; PV, pulmonary valve; RA, right atrium; RV, right ventricle.

intact ventricular septum, the right atrium is dilated but the right ventricle shows severe myocardial hypertrophy with hypoplastic cavity (see Fig. 14-21A).

Atrial, AV, and Ventricular Septal Defects

Atrial, AV, and ventricular septal defects can be seen in the four-chamber view. The so-called secundum atrial septal defect or fossa ovalis defect that involves the flap valve of the fossa ovalis cannot be diagnosed, unless it is very large because the flap valve of the fossa ovalis is a delicate membranous structure that shows floppy movement with flow across the patent foramen ovale. A defect involving the most posterior and superior part of the atrial septum is a superior sinus venosus defect and is almost always associated with

anomalous connection of the right upper pulmonary vein to the SVC. The defect involving the most posterior and inferior part of the atrial septum is an inferior sinus venosus defect and is associated with the inferior vena cava draining partially or totally into the left atrium. Both types of sinus venosus defects are rare.

The AV septal defect is characterized by a large septal defect in the center of the heart at the AV junction (Fig. 14-30). The AV septal defect is more than a simple septal defect. It is also characterized by a common AV annulus with abnormal arrangement of the valve leaflets, an unwedged position of the aortic valve, and a short dimension of the ventricular inlet with inlet-outlet disproportion of the left ventricle (see Fig. 14-30A). The AV valve consists of five leaflets: anterior and posterior bridging

FIGURE 14-31. Atrioventricular septal defect with both interatrial and interventricular shunts. *A.* A diastolic frame shows an atrioventricular septal defect (d). *B.* A systolic frame shows that the defect is divided into interatrial and interventricular components by the bridging leaflets. Note the shortened length of the ventricular inlet, which is only slightly longer than the atrial length. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

FIGURE 14-32. Atrioventricular septal defect with interatrial shunt only (primum atrial septal defect). *A.* A diastolic frame shows an atrioventricular septal defect (d). *B.* A systolic frame shows that the bridging leaflets are attached to the ventricular septal crest making the defect exclusively interatrial. Note that the length of the ventricle is almost equal to the length of the atrium, suggesting shortened ventricular inlet. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

leaflets, right and left lateral mural leaflets, and a right anterior leaflet between the right lateral mural and anterior bridging leaflets (see Fig. 14-30*B*). The right anterior leaflet can be vestigial. The valve orifice can be a common orifice for the right and left chambers. There can be partitioned right and left orifices when the anterior and posterior bridging leaflets are fused through a tongue of tissue. AV septal defects show different levels of shunts according to the relationship of the AV valve leaflets to the septum (see Fig. 14-30*C*). When the anterior and posterior bridging

leaflets do not attach to either the atrial or ventricular septal crest, there are two levels of shunting, interatrial and interventricular (Fig. 14-31). Less commonly, the bridging leaflets are attached to the ventricular septal crest, rendering the defect an exclusively interatrial communication (Fig. 14-32). This latter variant is also called primum atrial septal defect. Very rarely, the leaflets attach to the atrial septal crest, rendering the defect an exclusively interventricular communication. It is usually not difficult to make the diagnosis

FIGURE 14-33. Bilateral superior venae cavae. *A.* Axial view through the lower part of the four chambers shows the dilated coronary sinus (CS). Both the coronary sinus and inferior vena cava (IVC) open to the right atrium (RA). The dilated coronary sinus opening can be mistaken for an atrioventricular septal defect. *B.* True four-chamber view shows that the lower part of the atrial septum is intact. The dilated coronary sinus is seen at the left atrioventricular junction above the mitral valve annulus. *C.* Three-vessel view shows four vessels. The additional vessel is the left superior vena cava (LSVC) on the opposite side of the right superior vena cava (RSVC). A similar finding is also seen in partial or total anomalous pulmonary venous connection to the innominate vein. *D.* Oblique coronal view shows the dilated left superior vena cava and coronary sinus forming a J-shaped channel along the left atrium (LA). Ao, ascending aorta; LA, left atrium; LV, left ventricle; PA, main pulmonary artery; RV, right ventricle.

of AV septal defect by using a four-chamber view. The defect is seen as a large defect with the bridging leaflets free floating across the defect or attached to the ventricular septal crest (see Figs. 14-31 and 14-32). Also seen in AV septal defects is the shortening of the inlet. This feature can be appreciated by calculating the atrial-to-ventricular length ratio in the four-chamber view.^{106,107} In the normal heart, the atrial length is approximately half of the ventricular

length. In AV septal defects, the atrial length is more than two thirds of the ventricular length, with the ratio approaching almost 1:1 in many cases. This appearance will be helpful when the sonographic window is poor and does not allow proper visualization or when the defect needs to be differentiated from an inlet ventricular septal defect. The AV septal defect can be mimicked by a dilated coronary sinus in association with persistent left SVC (Fig. 14-33).¹⁰⁸

FIGURE 14-34. Atrioventricular septal defect with severe hypoplasia of the left ventricle. The ventricular septum is not aligned with the atrial septum. The ventricular septal crest and lower tip of the defective atrial septum are marked by asterisks. The left ventricle (LV) is very hypoplastic. The ventricular septum can be mistaken for a papillary muscle. LA, left atrium; RA, right atrium; RV, right ventricle.

FIGURE 14-35. Common atrium with a strand of remnant atrial septum in right isomerism. There is a large complete form of atrioventricular septal defect with a common atrial cavity. Only a thin strand of remnant atrial septum traverses the common atrial cavity. The strand is seen as a dot (arrow) in the center of the common atrium. This finding is highly suggestive of right isomerism. LV, left ventricle; RV, right ventricle.

According to the size of the ventricles, AV septal defects are classified into balanced, right-dominant, and left-dominant types (Fig. 14-34). The AV septal defect is often associated with obstruction of the left ventricular outflow tract and aortic arch. Left ventricular outflow tract narrowing can be due to the anterior bridging leaflet itself, abnormal accessory tissue from the AV valve, fibrous ridge, or prominent muscle bundle between the aortic and AV valves. However, it should be emphasized that the left ventricular outflow tract should be assessed during systolic phase. In diastole, the left ventricular outflow tract characteristically appears narrowed with the appearance of a goose-neck because the anterior bridging leaflet is displaced forward and downward. This goose-neck deformity of the left ventricular outflow tract should not be mistaken for an obstructive lesion. Most importantly, the AV septal defect is associated with a chromosomal abnormality in approximately 50% of cases.^{109,110} Interestingly, uncomplicated AV septal defects are more commonly associated with chromosomal abnormalities. AV septal defect is particularly common in visceral heterotaxy. It is seen in 90% of right isomerism and 50% of left isomerism (see Table 14-5). The type of AV septal defect is often characteristic of its association with right isomerism: the atria are a common chamber with only a strand of remnant atrial septal tissue in the center. The remnant atrial septal tissue is seen as a central dot in the common atrium in the four-chamber view (Fig. 14-35).

Inlet ventricular septal defects are not common. They are either perimembranous defects extending toward the ventricular inlet along the annulus of the septal leaflet of the tricuspid valve or muscular defects. The perimem-

branous inlet defect is bordered superiorly by the tricuspid and mitral valves, which appear to be continuous. Therefore, it is often difficult to differentiate it from the AV septal defect in the four-chamber view, in which situation the calculation of the atrial-to-ventricular length ratio can be helpful.^{106,107} The most important difference is the lower part of the atrial septum, which is intact in ventricular septal defect. It is interesting that both AV septal defects and perimembranous inlet ventricular septal defects are commonly associated with trisomy 21.¹¹¹

Pericardial fluid is also best seen in four-chamber view. The normal pericardial space contains a small amount of fluid that is seen as an echolucent stripe along the outer margin of the heart.¹¹² The fluid in the pericardial space moves toward the apex in systole and toward the base in diastole. This movement of the pericardial fluid can be appreciated with color Doppler. As the flowing fluid is seen as a linear structure in two-dimensional images, it can be mistaken for a coronary vessel. A pathologic amount of pericardial effusion may arise from or be associated with a variety of conditions including structural heart disease, impaired cardiac function, trisomy 21 and other chromosomal abnormalities, and infectious processes.^{113,114} A gross amount of pericardial effusion in an otherwise normal heart is an indication for fetal karyotyping.¹¹⁴

Three-Vessel View

The three-vessel view provides important clues to the diagnosis of almost all lesions involving the ventricular outflow tracts and great vessels (see Fig. 14-10).⁴⁷⁻⁵⁰ The abnormalities

Table 14-8 Abnormal Findings at Three-Vessel View⁴⁷

Abnormal Findings		Congenital Heart Diseases
Abnormal vessel size	Small ascending aorta and large main pulmonary artery	Coarctation of the aorta Interruption of the aortic arch Hypoplastic left heart syndrome Critical aortic stenosis
	Small main pulmonary artery and large ascending aorta	Tetralogy of Fallot Pulmonary atresia with ventricular septal defect Pulmonary atresia or critical stenosis with intact ventricular septal defect
	Dilated main pulmonary artery	Ebstein malformation Pulmonary valve stenosis Pulmonary regurgitation
	Dilated ascending aorta	Aortic valve stenosis Aortic regurgitation Marfan syndrome
	Dilated superior vena cava	Interruption of the inferior vena cava Supracardiac cardiac type of total or partial anomalous pulmonary venous connection Right-side heart failure Vein of Galen aneurysm
Abnormal vessel alignment	Anterior displacement of ascending aorta with small main pulmonary artery	Tetralogy of Fallot Double-outlet right ventricle with subpulmonary stenosis
	Posterior displacement of small ascending aorta	Hypoplastic left heart syndrome Interruption of the aortic arch
	Side-by-side relationship with same arterial size	Double-outlet right ventricle Some complete transposition of the great arteries
	Side-by-side relationship with ascending aorta	Double-outlet right ventricle with subaortic stenosis Complete transposition with subaortic stenosis
Abnormal vessel arrangement	Right anterior ascending aorta (triangular arrangement)	Complete transposition of the great arteries
	Left anterior ascending aorta	Some double-outlet right ventricle Corrected transposition of the great arteries
	Left-sided superior vena cava	Double-inlet left ventricle with transposition Absence of right superior vena cava
Abnormal vessel number	One artery	Truncus arteriosus Pulmonary atresia with ventricular septal defect and absent or hypoplastic main pulmonary artery
	Four vessels	Bilateral superior venae cavae Partial anomalous pulmonary venous connection

that can be seen in the three-vessel view include abnormal vessel size, alignment, arrangement, and number (Table 14-8).

The size of the great arterial trunks can easily be compared in the three-vessel view. Usually, the size of the vessel reflects the amount of blood flow passing through it. Therefore, there is a reciprocal relationship in size between the ascending aorta and the main pulmonary artery. A small ascending aorta and large pulmonary artery suggest diversion of the blood flow into the main pulmonary artery.⁴⁷⁻⁵⁰ When the ascending aorta is smaller than either the SVC or the descending aorta, it can safely be considered small (see Figs. 14-23B, 14-26C, 14-26D, 14-27B). In the presence of concordant AV and ventriculoarterial connections, preferential flow into the main pulmonary artery occurs when an obstructive lesion or lesions exist in the left side of the heart, as discussed in the previous section. These lesions are associated with variable degree of hypoplasia of

the left heart or the aortic arch, or both. Preferential flow to the right side of the heart also occurs with anomalous pulmonary venous connection, although it is not a constant finding.⁸⁹⁻⁹¹ Without preferential flow to it, a large main pulmonary artery can be due to poststenotic dilatation when there is pulmonary valve stenosis.^{47,48}

A small main pulmonary artery and a large ascending aorta suggest diversion of the blood flow into the ascending aorta. In the presence of normally related cardiac chambers and great arteries, preferential flow into the ascending aorta occurs most commonly with tricuspid valve regurgitation and/or obstructive right heart lesions such as tricuspid or pulmonary stenosis.

The main pulmonary artery is characteristically small in tetralogy of Fallot (Fig. 14-36).^{47,48,55} Morphologically, tetralogy of Fallot is characterized by leftward anterior and superior deviation of the outlet or infundibular septum

FIGURE 14-36. Tetralogy of Fallot. A. Three-vessel view shows malalignment of the three vessels with anterior displacement of the large ascending aorta (Ao) and mild posterior displacement of the small main pulmonary artery (PA). B. Left ventricular outflow tract view shows a large perimembranous ventricular septal defect (d). The aorta overrides the ventricular septum. C. Right anterior oblique view of the right ventricle (RV) shows narrowing of the right ventricular outflow tract (RVOT) due to leftward anterior deviation of the outlet septum (asterisk). The ventricular septal defect is seen posterior to the deviated outlet septum. D. Cartoon showing pathogenetic mechanism of tetralogy of Fallot. The essential feature of tetralogy is leftward, anterior and superior deviation of the outlet septum causing right ventricular outflow tract narrowing and malalignment type of ventricular septal defect. ao, descending aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; SVC, superior vena cava. (A reprinted with permission from Yoo SJ, Lee YH, Kim ES, et al: Tetralogy of Fallot in the fetus: Findings at targeted sonography. *Ultrasound Obstet Gynecol* 14:29, 1999.)

relative to the rest of the ventricular septum, causing a large malalignment type of ventricular septal defect, and subpulmonary and pulmonary stenosis (see Fig. 14-36C). The main pulmonary artery is invariably small and the ascending aorta dilated, which tends to be more obvious with advancing gestation.^{115,116} The only exception to this rule is when tetralogy is associated with absent pulmonary valve syndrome, which will be discussed later in this section. As

the ventricular septal defect in tetralogy involves the outlet part of the septum, it is not seen in the four-chamber view (see Fig. 14-14B) unless the defect extends to the inlet part of the septum or tetralogy is associated with an AV septal defect. As discussed earlier, the four-chamber view may show leftward deviation of the cardiac axis (see Fig. 14-14B).

Without preferential flow into it, a large ascending aorta can be due to poststenotic dilatation when there is aortic

FIGURE 14-37. Double outlet right ventricle. *A.* Three-vessel view shows a side-by-side relationship of the great arteries. *B.* Ventricular outflow tract view shows the aorta (Ao) arising from the right ventricle (RV). The ventricular septal defect (d) is below the aortic valve and is the only outlet of the right ventricle. *C.* More anterior cut of *B* shows that both aorta and pulmonary artery (PA) arise from the right ventricle. L, left pulmonary artery; LV, left ventricle; R, right pulmonary artery; SVC, superior vena cava. (A reprinted with permission from Yoo SJ, Lee YH, Cho KS: *Abnormal three-vessel view on sonography: A clue to the diagnosis of congenital heart disease in the fetus.* *Am J Roentgenol* 172:825, 1999.)

valve stenosis.⁴⁷ Marfan syndrome is a possible cause for an unexplained dilatation of the aorta.¹¹⁷

Dilatation of the SVC is seen in interruption of the inferior vena cava with azygos or hemiazygos venous continuation, arteriovenous malformations such as vein of Galen aneurysm, and right-sided heart failure.¹⁰² It is also dilated when there is anomalous pulmonary venous drainage into the innominate vein or directly into the SVC.⁹²

Abnormal vessel alignment refers to the three vessels not aligning in a straight line in spite of their left-right order being preserved. Most commonly, abnormal alignment is caused by anterior displacement of the ascending aorta with or without posterior displacement of the main pulmonary artery. This form of abnormal alignment is seen in most cases

of tetralogy of Fallot in which the dilated ascending aorta is displaced anteriorly and to the right, and the smaller main pulmonary artery is displaced posteriorly (see Fig. 14-36).^{47,48,55} It is also seen in double outlet right ventricle in which the great arteries are often located side by side (Fig. 14-37). Occasional cases of complete transposition of the great arteries may also show a similar arterial relationship.

Less commonly, abnormal alignment is caused by posterior displacement of the ascending aorta (see Fig. 14-23*B*). This form of abnormal alignment suggests severe obstructive lesions of the left side of the heart, such as hypoplastic left heart syndrome and interruption of the aortic arch.

Abnormal vessel arrangement refers to a gross distortion of the left-right order of the three vessels. The most common

FIGURE 14-38. Complete transposition of the great arteries. **A.** Three-vessel view shows triangular arrangement of the three vessels. The aorta (Ao) is located right and anterior to the main pulmonary artery (PA). **B.** Four-chamber view shows normal cardiac anatomy. The apex of the right ventricle (RV) is obliterated by the moderator band (*asterisks*). **C.** Ventricular outflow tract view shows discordant ventriculoarterial connection with parallel courses. **D.** Diagram shows the anatomy of complete transposition of the great arteries. ao, descending aorta; L, left pulmonary artery; LA, left atrium; LV, left ventricle; PA, main pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava. (C reprinted with permission from Yoo SJ, Lee YH, Cho KS, et al: *Sequential segmental approach to fetal congenital heart disease. Cardiol Young* 9:430, 1999.)

abnormal arrangement is a triangular arrangement (Fig. 14-38).^{34,47,48} The ascending aorta is located right anterior or directly anterior to the main pulmonary artery. This arrangement is seen in most cases of complete transposition of the great arteries and in some cases of double outlet right ventricle. Complete transposition is characterized by discordant ventriculoarterial connections in the presence of concordant AV connections. As a consequence, the systemic and pulmonary circulations have parallel circuits, which do not permit survival after birth if there is no mixing channel between the two circuits. In the majority of cases

with complete transposition, the ascending aorta is located right anteriorly to the main pulmonary artery, showing a triangular arrangement of the three vessels (see Fig. 14-38). However, there are significant variations in the great arterial relationship in complete transposition.

A less common form of abnormal arrangement is a reversed position of the great arterial trunks; that is, the ascending aorta being located to the left of and anterior to the main pulmonary artery (see Figs. 14-16B and 14-17C).^{34,47,48} This is typically seen in congenitally corrected transposition of the great arteries (see Fig. 14-16B).

As discussed earlier in this chapter, corrected transposition refers to a condition in which both AV and ventriculoarterial connections are discordant. A reversed great arterial position is also seen in double inlet left ventricle with discordant ventriculoarterial connection (see Fig. 14–17C). In all of these conditions, a significant discrepancy in size of the main pulmonary artery and ascending aorta suggests an obstructive lesion of the outflow that leads to the smaller of the two. Very rarely, the right SVC is not present and the systemic venous return from the upper body to the right atrium occurs through the left SVC by way of the coronary sinus.¹¹⁸

Presence of only two vessels in the three-vessel view is rare but suggests that one arterial trunk is missing or severely hypoplastic or that only one arterial trunk is present.^{47,48,55} It is most commonly seen in tetralogy of Fallot with pulmonary atresia (in other words, pulmonary atresia with ventricular septal defect) when the main pulmonary artery is not formed or severely hypoplastic. Only two vessels are typically seen in truncus arteriosus in which a single arterial trunk arises from the heart and gives rise to the ascending aorta, pulmonary arteries and coronary arteries (Fig. 14–39). At its most proximal plane of section, the common truncus is seen as a large arterial root. Immediately above this basal view through the truncal base, the pulmonary arteries arise from the posterior or right posterior wall of the truncus. The differentiation between common truncus and pulmonary atresia is clinically important. In pulmonary atresia, survival of the newborn depends on a patent ductus arteriosus or MAPCA as the sole vascular connection securing pulmonary artery perfusion (Fig. 14–40).^{55,120}

Four vessels in the three-vessel view are most commonly seen with bilateral superior venae cavae (see Fig. 14–33).^{47,48,121} The persistent left SVC is located at the left posterior aspect of the main pulmonary artery. Four vessels are also seen in partial or total anomalous pulmonary venous connection to the innominate vein in which the vertical vein connecting the anomalous vein to the innominate vein is an additional vessel (see Fig. 14–25).¹²²

An abnormal communication between the two arterial trunks characterizes the aortopulmonary window. The defect can involve the proximal or distal part or the entire length of the main pulmonary artery. The distal and total types can be associated with abnormal origin of the right pulmonary artery from the ascending aorta, and are frequently associated with interruption of the aortic arch. The diagnosis can be suspected when the three-vessel view shows a defect between the ascending aorta and main pulmonary artery in the presence of normal aortic and pulmonary valves in the ventricular outflow tract views.^{123,124}

A branch pulmonary artery can be absent or hypoplastic (Table 14–9). Unilateral absence of a branch pulmonary artery is characterized by agenesis of the proximal branch pulmonary artery with its distal part connected to the ipsilateral ductus arteriosus. The absent branch pulmonary artery is almost always on the opposite side of the aortic arch. After birth, the affected lung loses its major blood supply as the ductus arteriosus closes. The branch pulmonary arteries are small when there is severe obstruction of pulmonary outflow tract, as in tetralogy of Fallot with severe pulmonary stenosis or atresia. When tetralogy of Fallot with pulmonary atresia (that is, pulmonary atresia with

FIGURE 14–39. A and B. Truncus arteriosus. Three-vessel view shows only two vessels. The truncus gives rise to the right (R) and left (L) pulmonary arteries. SVC, superior vena cava.

ventricular septal defect) is associated with MAPCA, the branch pulmonary arteries can be hypoplastic or absent. Lung hypoplasia is associated with hypoplasia of the branch pulmonary artery. Hypoplasia of the right lung and right pulmonary artery is typically seen in scimitar syndrome. When a large part of a lung is supplied by an aberrant systemic artery, as in pulmonary sequestration, the ipsilateral branch pulmonary artery may be hypoplastic. Congenital diaphragmatic hernia is associated with variable degree of branch pulmonary artery hypoplasia. The antenatal branch pulmonary artery size correlates with lung weight and there-

fore with postnatal outcome.¹²⁴ The draining pulmonary veins of the lung having a small or absent pulmonary artery is small unless there is an alternative source of blood supply.⁷³

The left pulmonary artery can have a very distal origin from the main pulmonary artery and course leftward through the space between the trachea and esophagus, a condition called pulmonary artery sling. This condition is commonly associated with abnormal branching of the airway and severe stenosis of the distal trachea. A branch

Table 14-9		Abnormalities of Branch Pulmonary Arteries
Categories	Significances	
Absence	Unilateral absence of right or left pulmonary artery Unilateral or bilateral in pulmonary atresia with ventricular septal defect and major aortopulmonary collateral arteries

Dilatation	Constricted ductus arteriosus Absent pulmonary valve syndrome	
Abnormal course	Left pulmonary artery sling	
Abnormal origin	Anomalous origin of a branch pulmonary artery from the ascending aorta Proximal origin Distal origin	

pulmonary artery can have an abnormal origin from the proximal or distal ascending aorta (Fig. 14-41). This diagnosis can be facilitated by color or power Doppler interrogation.¹²⁵

As discussed elsewhere in this chapter, dilated branch pulmonary arteries are seen with a constricted ductus arteriosus (see Table 14-9).⁹⁸⁻¹⁰⁰ As the ductus arteriosus closes in the fetus, blood from the right side of the heart is totally directed through the high-resistance, fluid-filled lungs, resulting in dilatation of the branch pulmonary arteries and increased right ventricular afterload with right-sided heart dilatation and tricuspid regurgitation. Color and spectral Doppler interrogation of the constricting ductus shows turbulent flow with high velocity. A peak systolic velocity of greater than 1.5 m/second with increased diastolic flow velocity is suggestive of ductal constriction.

The branch pulmonary arteries are aneurysmally dilated when tetralogy of Fallot is associated with absent pulmonary valve syndrome (Fig. 14-42).^{55,126-128} This condition is usually associated with congenital absence of ductus arteriosus, suggesting that the pathogenetic mechanism of the dilatation of the branch pulmonary arteries is similar to that seen with premature closure of the ductus arteriosus. The ductus arteriosus can be aneurysmally dilated in later pregnancy (Fig. 14-43).¹²⁹⁻¹³¹

Ductus arteriosus aneurysms may be observed in patients with connective tissue abnormalities such as Marfan, Ehlers-Danlos, and Larsen syndromes. Spontaneous rupture, erosion, thromboembolism, infection, and compression of adjacent structures are some of the reported complications, although most regress spontaneously.^{117,131} The ductus arteriosus aneurysm is best seen in the three-vessel view.¹³⁰ It should be differentiated from the normal tortuous course

FIGURE 14-41. A, B. Origin of the right pulmonary artery from the aorta. Three-vessel views show anomalous origin of the right pulmonary artery (RPA) from the posterior wall of the ascending aorta (Ao). PA, main pulmonary artery; SVC, superior vena cava. of the ductus in late pregnancy (see Fig. 14-10F). Severely tortuous ductus, however, can be associated with physiologic ductal constriction with right-sided chamber enlargement.¹⁰¹

When there is a normal left aortic arch, the descending aorta is located at the left anterior aspect of the vertebral body. A right-sided descending aorta is strongly suggestive of a positional abnormality of the aortic arch, most commonly a right aortic arch and less commonly a double aortic arch (Figs. 14-44 and 14-45).^{133,134} In double aortic arch, the descending aorta seen in the three-vessel view can be on either side or even in the midline. Very rarely, the aortic arch is left sided relative to the trachea but crosses the midline behind the esophagus to descend on the right side. This rare condition is called circumflex retro-esophageal aortic arch. This condition also occurs with a right aortic arch having a left-sided descending aorta. Any vessel seen behind the trachea in the three-vessel or its adjacent view is an additional sign for an aortic arch anomaly (see Figs. 14-44 and 14-45).^{133,134} A retroesophageal vessel can be either an aberrant branch arising from the descending aorta or a part of the double or retroesophageal aortic arch. As mentioned earlier, the left pulmonary artery in pulmonary artery sling courses through the space between the distal trachea and esophagus.

Various syndromes related to chromosome 22q11 deletion are often associated with tetralogy of Fallot, truncus arteriosus, interruption of the aortic arch and aortic arch anomalies.^{134,135} Chromosome 22q11 deletion is usually associated with thymic hypoplasia or aplasia. Therefore, when a cardiac defect that has a high incidence of association with chromosome 22q11 deletion is found, the status of the thymus can be evaluated by using a three-vessel view.^{52,53} As mentioned, the transverse diameter of the thymus in millimeters is slightly smaller than the gestational

age in weeks in the second trimester and becomes slightly larger as the pregnancy approaches term.⁵⁴

Left and Right Ventricular Outflow Tract Views

Abnormalities of the ventricular outflow tracts are not only common but also relatively serious and complex. Ventricular outflow tract abnormalities can be categorized into two groups: those occurring as an isolated or complex lesion in the presence of normal ventriculoarterial connection, and those occurring as a complex malformation with abnormal ventriculoarterial connection.

The ventricular septal defect visualized in ventricular outflow tract views is most commonly a perimembranous defect with outlet extension (Fig. 14-46). These defects are seen below the aortic valve in the left ventricular outflow tract view. It is not unusual for the aortic valve to have a mildly overriding position relative to the ventricular septal crest in this view because the defect involves the curved part of the ventricular septum. One may imagine how a simple defect can be seen to override the ventricular septum by mentally removing the part of the septum below the aortic valve seen in a normal left ventricular outflow tract view. On the other hand, this part of the septum may be seen as falsely defective because of the partial volume effect of the oblique cut of the curved septum and the thinness of the membranous septum. Because shunting across a ventricular septal defect in an otherwise normal heart is minimal and for a brief period in the systolic phase, it is difficult to perceive the shunt flow by color Doppler interrogation.¹³⁵ Obviously, three-dimensional ultrasound is of significant help.¹³⁶ The ventricular septal defects of so-called malalignment type are more readily discernable. The malalignment involves the

FIGURE 14-42. Tetralogy of Fallot with absent pulmonary valve syndrome. **A.** Three-vessel view shows marked dilatation of the right and left pulmonary arteries (RPA and LPA). A constriction between the right ventricular outflow tract (RVOT) and main pulmonary artery (PA) is the small pulmonary valve annulus guarded by vestigial valve tissue. **B.** Color Doppler image in systolic phase shows turbulent flow across the small pulmonary valve annulus (*asterisk*). Note that both the right and left pulmonary arteries contain red and blue signals suggesting swirling of blood in the dilated lumen. **C.** Color Doppler image in the diastolic phase shows pulmonary regurgitation (*asterisk*). Note that the right and left pulmonary arteries are much smaller than they are in systole. Ao, ascending aorta; ao, descending aorta; RA, right atrium; SVC, superior vena cava.

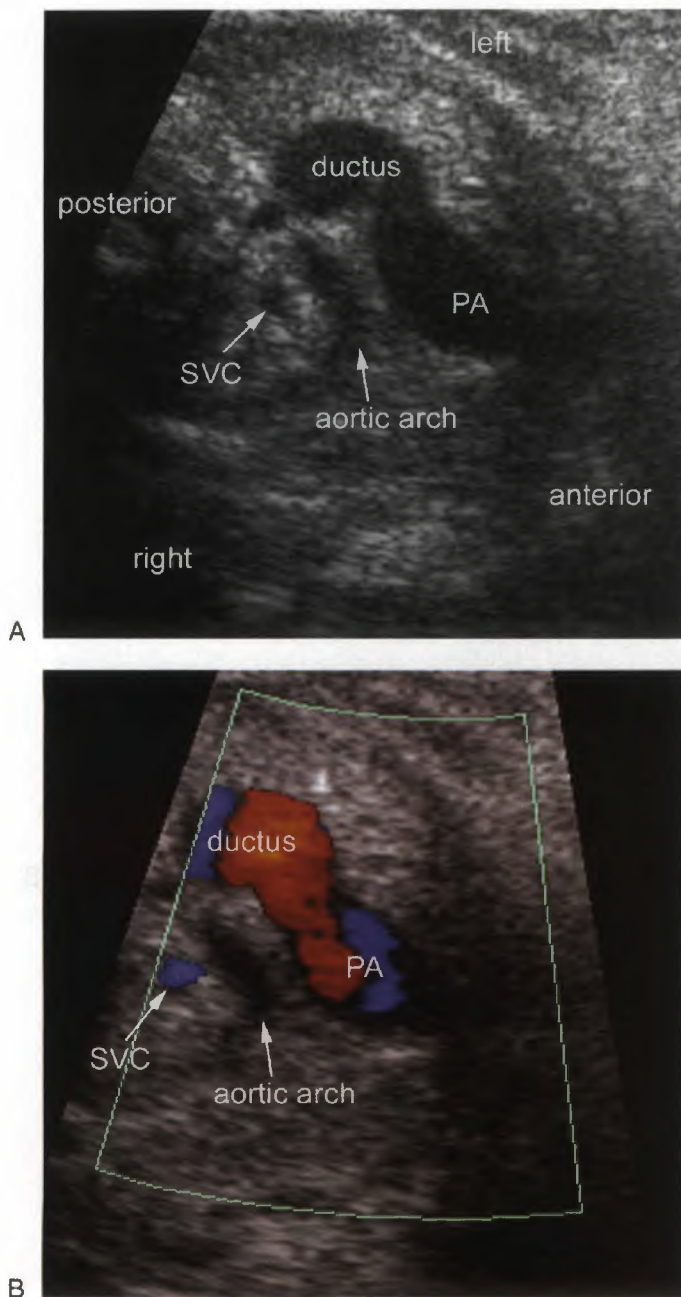

FIGURE 14-43. Aneurysm of the ductus arteriosus in a fetus at 34 weeks of gestation. *A.* Three-vessel view shows that the ductus arteriosus is markedly dilated at its aortic end. *B.* Color Doppler image in the same plane as *A* shows swirling blood flow within the dilated part of the ductus arteriosus. This condition should be differentiated from a normal tortuous ductus arteriosus seen in late gestation as shown in Fig. 14-10 *F* and *G*. PA, main pulmonary artery; SVC, superior vena cava.

outlet septum below the semilunar valves and is either forward or backward. The forward or anterior malalignment of the outlet septum encroaches on the right ventricular outflow tract and is typically seen in tetralogy of Fallot (see Fig. 14-36). It is often better appreciated in a short-axis or right anterior oblique view than in ventricular outflow tract views. The backward or posterior malalignment of the outlet septum encroaches on the left ventricular outflow tract and can be easily appreciated in a left ventricular outflow tract

view. The malaligned outlet septum is seen as a teardrop hanging from the aortic valve. When there is significant malalignment, interventricular shunt flow is readily visible with color Doppler. Significant posterior malalignment is associated with various forms of aortic arch obstruction including coarctation, tubular hypoplasia, or interruption. The doubly committed defects involving the most cranial part of the ventricular septum below the pulmonary valve may escape detection in this view.

The obstructive lesions of the left ventricular outflow tract include fibrous ridge, fibromuscular tunnel, accessory tissue arising from the mitral valve, and aortic valvar stenosis, all of which are difficult to identify during a fetal cardiac examination. Left ventricular outflow tract obstruction is often associated with the presence of muscle tissue between the aortic and mitral valves causing discontinuity between the two valves. This muscular crest is called the left ventriculoinfundibular fold. Turbulent flow with increased velocity during color and spectral Doppler examination supports the evidence for outflow tract obstruction. The obstructive lesion of the right ventricular outflow tract is characteristically seen in tetralogy of Fallot and best seen in a short-axis or right anterior oblique long axis view (see Fig. 14-36*C*). An aberrant muscle bundle can cross the right ventricular outflow tract causing progressive obstruction. Pulmonary valve stenosis is seldom evident in the second trimester scan, whereas it is not uncommon postnatally, suggesting that it is an evolving lesion.

The ventricular outflow tract views are the key planes for the assessment of the ventriculoarterial connections. The ventriculoarterial connections are classified as concordant, discordant, double outlet, and single outlet (Fig. 14-47). In defining the ventriculoarterial connections, a great artery is considered to be connected to a ventricle when more than half of its valve area is committed to that ventricle. Abnormal ventriculoarterial connections are characterized by loss of the normal crossing nature of the routes from the ventricular outflow tracts to the great arterial trunks.

Transposition of the Great Arteries

Discordant ventriculoarterial connection is found when the connection between the ventricles and great arterial trunks is reversed, that is, the right ventricle is connected to the aorta and the left ventricle to the pulmonary artery (see Fig. 14-47). Discordant ventriculoarterial connection is commonly called transposition of the great arteries when it is associated with either concordant or discordant AV connection. Discordant ventriculoarterial connection in the presence of concordant AV connection is the essential feature of complete transposition of the great arteries (see Fig. 14-38). Discordant ventriculoarterial connection in the presence of discordant AV connection is the essential feature of congenitally corrected transposition (see Fig. 14-16). In the classic forms of both complete and corrected transposition, the aorta is supported by a completely muscular infundibulum, whereas the pulmonary artery is not. In most cases of transposition, the ventricular outflow tracts are parallel to each other with the right ventricular outflow tract leading to the aorta positioned anterior to the left ventricular outflow tract leading to the pulmonary artery (see Figs. 14-16*C* and 14-38*C*). As discussed in the prior section

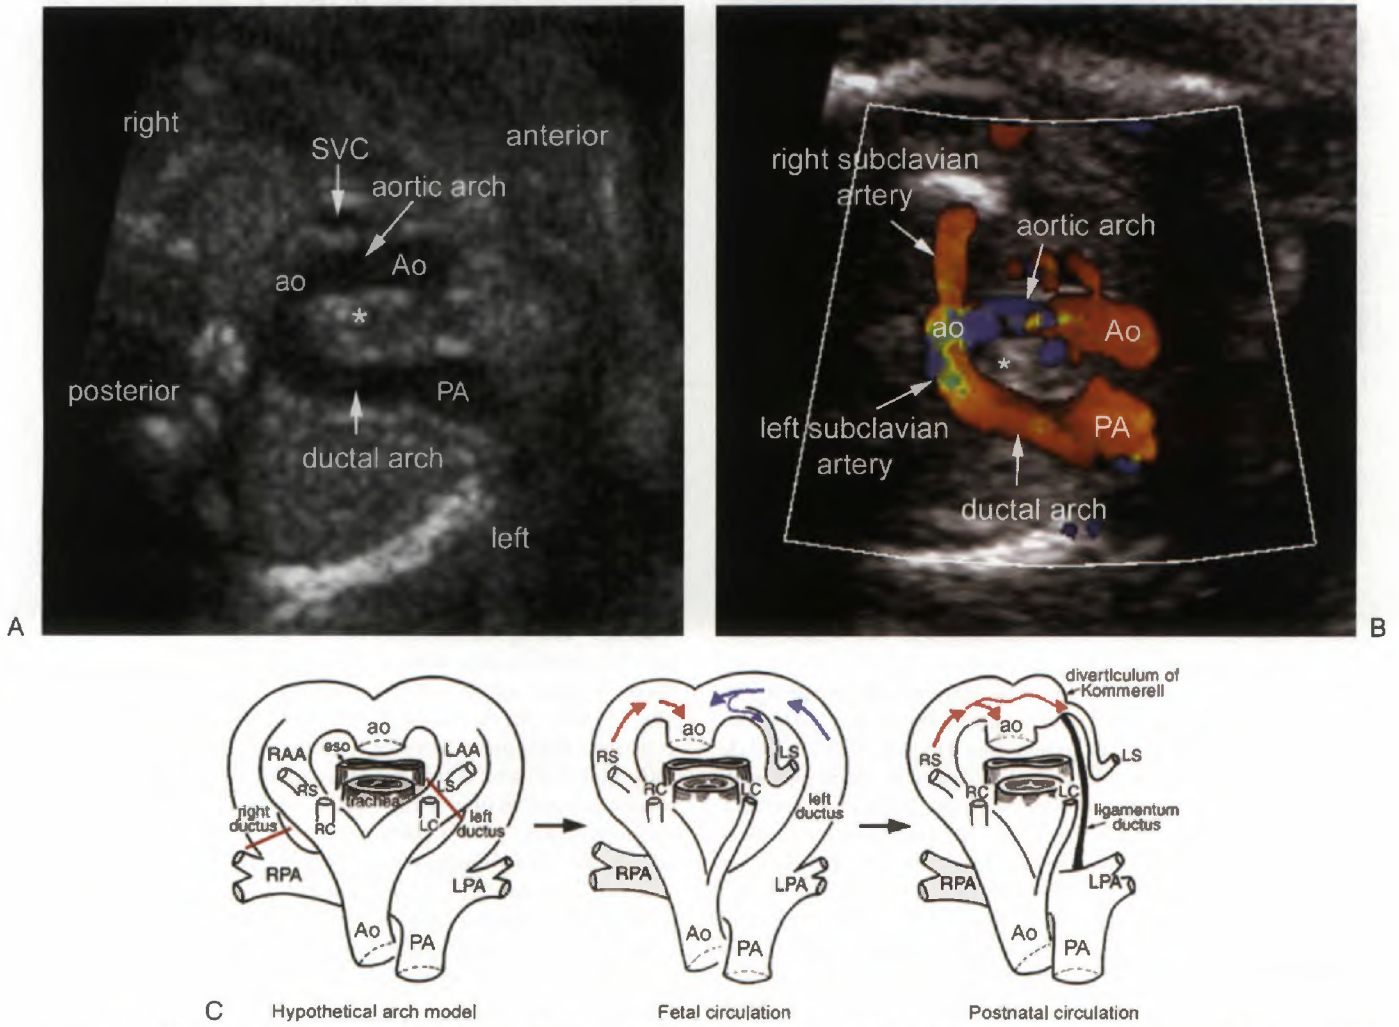

FIGURE 14-44. Right aortic arch with aberrant left subclavian artery. *A* and *B*. Three-vessel views show U-shaped vascular loop around the trachea (asterisk). The aortic arch is on the right side of the trachea, with the ductal arch on the left side. The proximal segment of the left subclavian artery connects the aortic and ductal arches, and the blood flow through this segment is reversed. After birth this segment persists as the aortic diverticulum of Kommerell. Note the wide gap between the ascending aorta (Ao) and main pulmonary artery (PA). *C*. Diagrams showing hypothetical morphogenesis. ao, descending aorta; eso, esophagus; LAA, left aortic arch; LC, left common carotid artery; LPA, left pulmonary artery; LS, left subclavian artery; RAA, right aortic arch; RC, right common carotid artery; RPA, right pulmonary artery; RS, right subclavian artery. about the three-vessel view, the majority of cases with complete transposition have the aorta right anterior to the pulmonary artery (see Fig. 14-38A), whereas the majority of the cases with corrected transposition have the aorta left anterior to the pulmonary artery (see Fig. 14-16B).^{34,47,48} A ventricular septal defect is found in approximately 40% of complete transpositions and in 60% to 70% of corrected transpositions. In both, left ventricular outflow tract obstruction is common. The obstruction can be due to posterior malalignment of the outlet septum relative to the rest of the septum, fibrous ridge, fibromuscular tunnel, accessory tissue from the mitral valve, or pulmonary valve stenosis. Right ventricular outflow tract obstruction is less common in both complete and corrected transposition. Size discrepancy of the great arterial trunks in the three-vessel view is a telltale sign of ventricular outflow tract obstruction. Corrected transposition is frequently associated with regurgitation of the left-sided tricuspid valve, either due to valve dysplasia or Ebstein malformation (Fig. 14-48).⁷⁴⁻⁷⁸ Also possible in corrected transposition is delayed or blocked AV conduction with arrhythmia, as will be discussed later.

Single and Double Outlet Ventricle

Double outlet can be from the right or left ventricle. Double-outlet right or left ventricle is a type of ventriculoarterial connection in which both great arteries arise exclusively or predominantly from the morphologically right or left ventricle. It is very important to understand that the term double-outlet ventricle is used only to describe how the great arteries arise from or connect to the underlying

ventricles. Therefore, tetralogy of Fallot with more than 50% override of the aortic valve over the ventricular septum has theoretically a double-outlet right ventricular connection. As with discordant ventriculoarterial connection, double-outlet ventricle can occur with any type of atrial situs and any type of AV connection. Double-outlet ventricle is associated with a ventricular septal defect in almost all cases. The ventricular septal defect is the sole outlet of the left ventricle when there is double-outlet right ventricle and the sole outlet of the right ventricle when there is double-outlet left ventricle. The location of the ventricular septal defect relative to the great arterial trunk dictates the hemodynamic consequence of double-outlet ventricle (Fig. 14-49), although the presence or absence of the aortic or pulmonary outflow tract obstruction is also an important contributing factor. Therefore, the ventricular septal defects in double-outlet ventricle are classified as subaortic, subpulmonary, doubly committed, and noncommitted. When double-outlet right ventricle is associated with a subaortic ventricular septal defect, the physiology is that of an isolated ventricular septal defect. When double-outlet right ventricle is associated with a subpulmonary defect, the physiology is that of complete transposition with a ventricular septal defect. When the defect is doubly committed or noncommitted, the physiology depends on the intracardiac streaming of the blood flow. The diagnosis of double outlet and the proximity of the great arterial trunks to the ventricular septal defect should be assessed by using the ventricular outflow tract views (see Fig. 14-37). Of note, the ventriculoarterial connection should be analyzed by a full sweep through the ventricular outflow tracts because appearance in a single view can be misleading. The great arteries tend to have a side-by-side, parallel relationship, with the aorta on the right side, when there is situs solitus and concordant AV connection (see Fig. 14-37C). In the majority of cases with double-outlet right ventricle, both great arteries are supported by a completely muscular infundibulum. Double-outlet right ventricle with subaortic ventricular septal defect is often associated with subpulmonary obstruction, whereas double-outlet right ventricle with subpulmonary defect is often associated with subaortic obstruction or an obstructive lesion of the aortic arch. Double-outlet left ventricle is extremely rare and shows wide morphological variation.

Single-outlet from the heart can be through a single arterial trunk or truncus arteriosus. Single arterial trunk is present when one arterial trunk is missing. It can be a form of pulmonary atresia when the main pulmonary arterial trunk is not formed or is atretic and the aorta is the sole outlet of the ventricle. On the other hand, aortic atresia is not associated with single arterial trunk because the ascending aorta is patent to the level of the aortic valve and gives rise to the coronary arteries. Truncus arteriosus or common arterial trunk is a condition in which one arterial trunk arises from the base of the ventricles by way of a single arterial valve to give rise to the systemic, coronary, and one or both pulmonary arteries (see Fig. 14-39). In almost all cases, there is a large ventricular septal defect immediately underneath the common arterial valve or truncal valve. The common arterial valve usually overrides the ventricular septum, but may have exclusive commitment to either the right or left ventricle. The truncal valve is often stenotic or regurgitant.¹¹⁹ The ventricular septal defect and the origin of

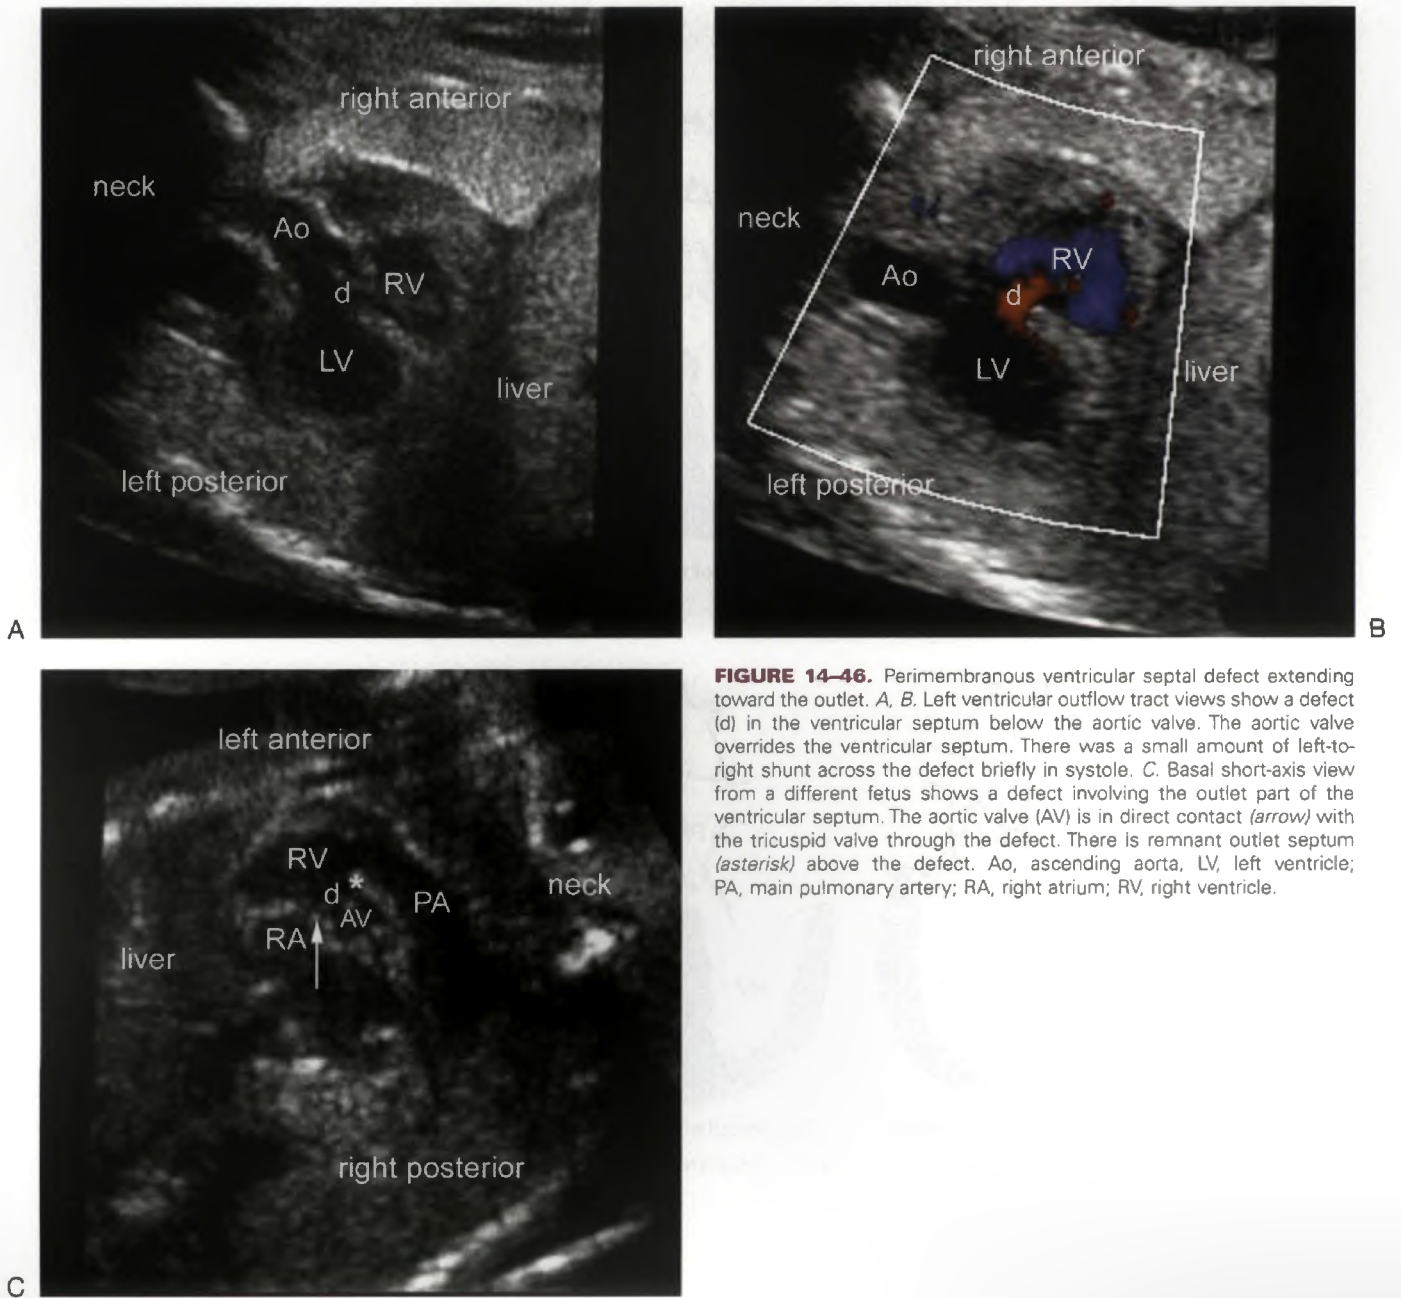

FIGURE 14-46. Perimembranous ventricular septal defect extending toward the outlet. *A, B.* Left ventricular outflow tract views show a defect (d) in the ventricular septum below the aortic valve. The aortic valve overrides the ventricular septum. There was a small amount of left-to-right shunt across the defect briefly in systole. *C.* Basal short-axis view from a different fetus shows a defect involving the outlet part of the ventricular septum. The aortic valve (AV) is in direct contact (arrow) with the tricuspid valve through the defect. There is remnant outlet septum (asterisk) above the defect. Ao, ascending aorta, LV, left ventricle; PA, main pulmonary artery; RA, right atrium; RV, right ventricle.

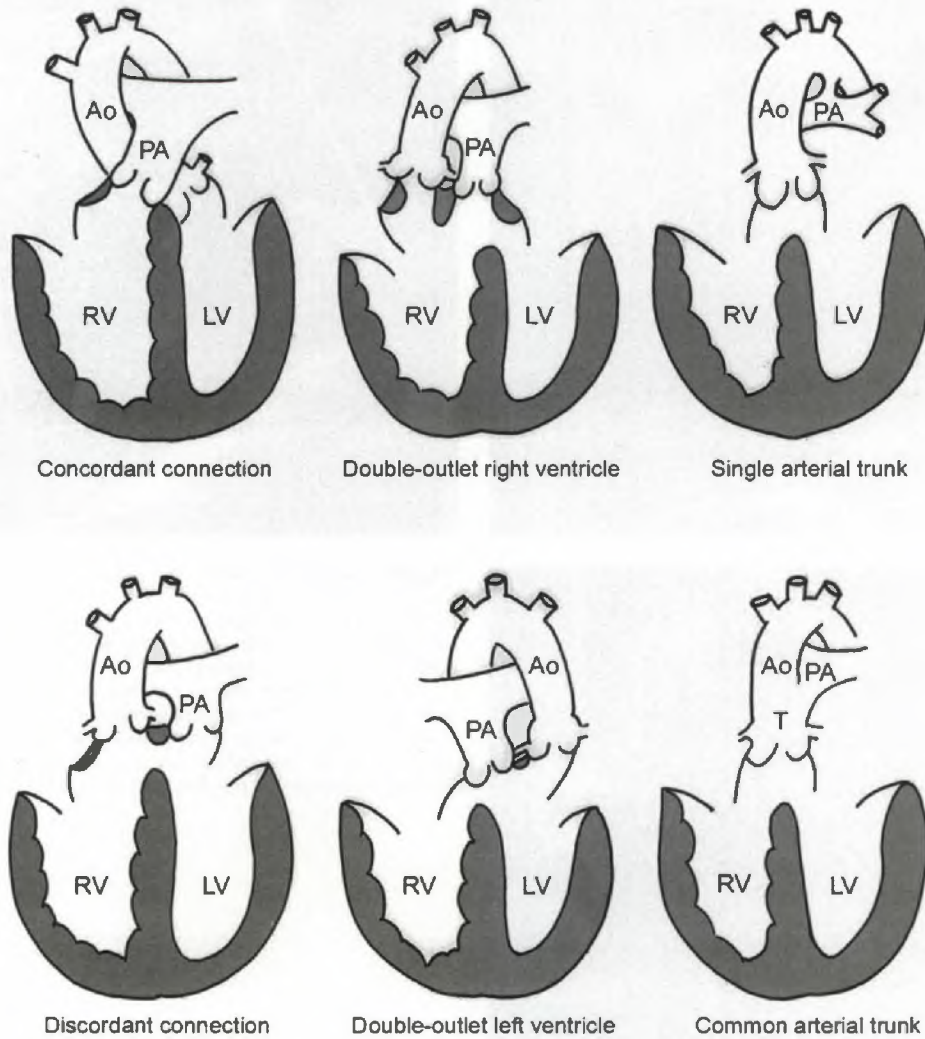

FIGURE 14-47. Types of ventriculoarterial connections. Ao, ascending aorta; LV, left ventricle; PA, main pulmonary artery; RV, right ventricle; T, truncus.

FIGURE 14-48. Corrected transposition of the great arteries with Ebstein malformation of the left-sided tricuspid valve. A moderator band (dots) is seen in the apical part of the left-sided right ventricle (RV). There is discordant atrioventricular connection. Septal attachment of the left-sided tricuspid valve is apically displaced. The anterior leaflet of the tricuspid valve is adherent to the septal leaflet, causing tricuspid stenosis. LA, left atrium; LV, left ventricle; RA, right atrium.

the common arterial trunk are best seen in the left ventricular outflow tract view, a finding that is very similar to that of tetralogy of Fallot. Only two vessels are seen in three-vessel view, but this finding is not specific for truncus and is also seen when the main pulmonary artery is not formed or is very small, as in tetralogy of Fallot with pulmonary atresia (in other words, pulmonary atresia with ventricular septal defect).^{47,48} To make the diagnosis of truncus arteriosus, one should visualize the origins of the pulmonary arteries from the proximal ascending aorta.^{137,138} Truncus arteriosus is occasionally associated with interruption of the aortic arch.

Basal Short-Axis View

The basal short-axis view is of particular value in the definitive diagnosis of tetralogy of Fallot (see Fig. 14-35C). The essence of tetralogy is the leftward, anterior, and superior deviation of the outlet septum, causing subpulmonary outlet tract narrowing and an outlet-type of ventricular septal defect. This single most important feature of tetralogy is best appreciated in the basal short-axis view or right anterior oblique view of the right ventricle. In addition, the enlarged aortic root can easily be contrasted to the diminutive pulmonary valve. The aberrant muscle bundle in the right ventricle can also be detected but the significance of its presence is often questionable.

Because this view visualizes the outlet septum extending from the tricuspid to the pulmonary valve, the ventricular septal defect involving this area can be identified and its type determined.⁵⁵ However, the intact membranous septum

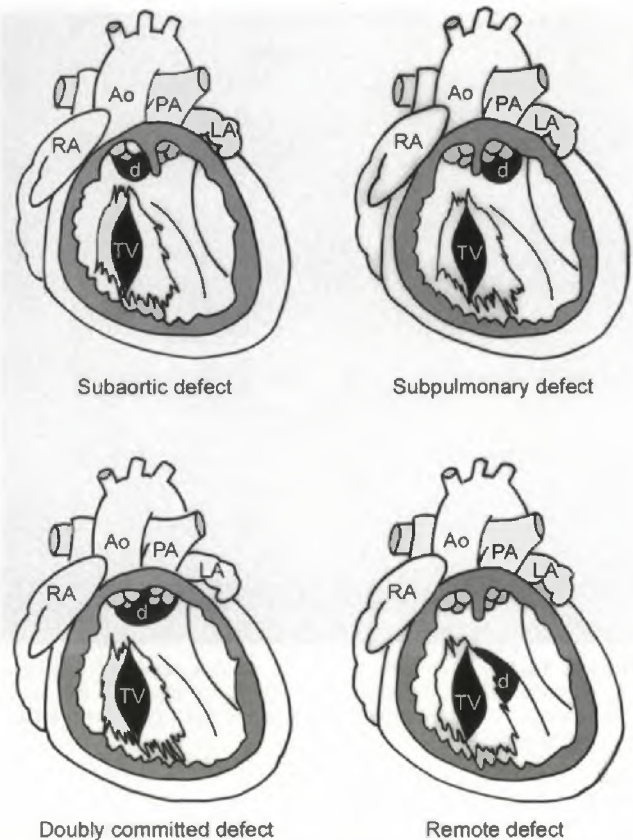

FIGURE 14-49. Types of ventricular septal defect in double outlet right ventricle. Ao, ascending aorta; d, ventricular septal defect; LA, left atrium; PA, main pulmonary artery; RA, right atrium; TV, tricuspid valve.

around the tricuspid valve insertion can be mistaken for a defect.

Aortic and Ductal Arch Views

The aortic arch view is useful in the diagnosis of an obstructive lesion of the aortic arch. As a rule-of-thumb, an obstructive lesion should be suspected when the ascending aorta is smaller than the descending aorta, which can also be appreciated in the three-vessel view (see Figs. 14-26 and 14-27). Discrete coarctation can be seen as a sharp indentation of the posterior wall of the descending aorta on the opposite side of the ductal confluence (see Fig. 14-27). Importantly, discrete coarctation is usually seen in association with an intracardiac left-sided obstructive lesion during fetal life. Isolated coarctation rarely shows overt indentation of the posterior wall of the descending aorta in fetal life. Posterior indentation or shelf lesion is considered to develop when the ductus closes after birth. As has been discussed earlier, fetuses having right-sided dominance of the ventricular and great arterial size are at risk of postnatal development of isolated coarctation.⁹³⁻⁹⁶ Obstructive lesions of the aortic arch can also be suspected from the so-called V- or Y-confluence view of the arches. When the aortic arch is significantly smaller than the ductal arch, tubular hypoplasia of the aortic arch must be suspected (see Fig. 14-26D). When there is interruption, the aorta courses straight to its last branch without forming an arch or an arc (Fig. 14-50).

FIGURE 14-50. Interrupted aortic arch. Oblique sagittal view shows the left common carotid artery (arrows), in this case, as the direct continuation of the ascending aorta (Ao). PA, main pulmonary artery; RV, right ventricle.

The positional abnormalities of the aortic arch can better be appreciated in the three-vessel view.

Prenatal and Postnatal Treatment Options and Outcomes of Congenital Heart Diseases

Indeed, fetal cardiac anomalies are recognizable by contemporary ultrasound imaging and often represent a more severe spectrum of cardiovascular disease than those seen after birth. A pediatric cardiologist should be involved in parental counseling as a key figure in detailed lesion diagnosis and in counseling parents about the prognosis of the lesion. Reported outcome data of specific cardiac lesions are useful in providing crude information about the overall prognosis. However, because the pathology spectrum of many defects is far from being uniform, counseling on prognosis and management should be adapted to the individual patient. The task of the fetal cardiologist is to help parents find the best solution for the family.

A timely and precise prenatal diagnosis allows appropriate counseling of the parents, and prenatal and postnatal management planning. It provides the opportunity for detailed ultrasound assessment of extracardiac malformations and chromosomal studies. Prenatal diagnosis enables stratification of cases into those that need in utero intervention, those that need delivery at a tertiary care center for an urgent postnatal management, and those that do not require urgent postnatal treatment. A timely diagnosis of a severe cardiac defect with poor prenatal and postnatal outcome also enables the parents to opt for termination of the pregnancy.

The course of an individual malformation in fetal life is often different from what would be expected postnatally. For instance, there is an increased incidence of spontaneous

Table 14-10 Ductus-Dependent Congenital Heart Disease

Ductus-Dependent Pulmonary Circulation	Ductus-Dependent Systemic Circulation
Pulmonary atresia or critical pulmonary stenosis with intact ventricular septum	Critical aortic stenosis
Tetralogy of Fallot with severe pulmonary stenosis or atresia	Hypoplastic left heart syndrome
Other forms of complex defect with severe pulmonary stenosis or atresia	Severe coarctation of aorta
Complete transposition of the great arteries	Interruption of the aortic arch
	Complete transposition of the great arteries

intrauterine demise in any fetus with chromosomal anomalies.^{6,7} Fetal loss is also common in cardiac anomalies that are associated with severe AV or semilunar valve regurgitation,^{128,139} in unbalanced AV septal defects with complete AV block,¹⁴⁰ and congestive heart failure.

In utero treatment includes drug therapy for fetal arrhythmias with heart failure, which is discussed in Part III of this chapter, and balloon dilatation of severe aortic or pulmonary valvar stenosis.¹¹⁻¹⁴ For most structural cardiac anomalies, however, antenatal treatment is neither warranted nor available.

The decision to transfer to a tertiary care center for planned delivery and immediate postnatal management depends on whether the systemic or pulmonary circulation will largely depend on the persistent patency of the ductus arteriosus after birth. Defects requiring persistent postnatal patency of the ductus arteriosus are called ductus-dependent CHDs (Table 14-10).^{97,141} They include severe obstructive lesions of either the right or left side of the heart and lesions that require mixing of the systemic and pulmonary circulation through the ductus for survival. Because transition of the circulation and closure of vital fetal shunts occur at the same time as in healthy newborns, babies with ductus-dependent circulation are often asymptomatic and may escape detection immediately after delivery. They become increasingly and rather rapidly cyanotic, tachypneic, and hypotensive as the ductus arteriosus progressively constricts between 1 and 2 days of age. Not surprisingly, there is reduced morbidity and mortality associated with the fetal diagnosis of ductus-dependent cardiac lesions and in utero transfer to centers providing optimal neonatal care.¹⁴²⁻¹⁴⁴

Neonatal treatment includes the immediate intravenous administration of prostaglandin E1 to maintain the patency of the ductus arteriosus until surgery. Often, interventional catheter procedures are required to improve blood flow mixing through the atrial septum (balloon atrioseptostomy in complete transposition of the great arteries) or to improve blood flow through obstructed valves (balloon dilatation of severe semilunar valve stenosis or atresia). A few specific congenital heart lesions that are not obviously ductus dependent but affect the lungs or airway may also require urgent postnatal care. These include Ebstein disease and tetralogy of Fallot with absent pulmonary valve.^{128,139}

Postnatal treatment options include surgical treatment, catheter intervention, medical follow-up for potential

Table 14–11 Functionally Single Ventricle

Hearts With Univentricular Atrioventricular Connection	Hearts With Biventricular Atrioventricular Connection, One Ventricle Being Too Small
Tricuspid atresia	Pulmonary atresia with intact ventricular septum
Mitral atresia	Hypoplastic left heart syndrome
Double inlet right ventricle	Severe form of critical aortic stenosis
Double inlet left ventricle	Unbalanced form of atrioventricular septal defect
Double inlet indeterminate ventricle	Double outlet right ventricle with an underdeveloped ventricle
Severe form of unbalanced atrioventricular connection	Severe straddling of tricuspid or mitral valve

spontaneous resolution, and compassionate care. When treatment is required, surgical management is the ultimate option in the majority of cases. In a few conditions such as aortic valve stenosis, pulmonary valve stenosis, and peripheral pulmonary artery stenosis, balloon dilatation by catheter intervention is the primary choice. In addition, many of the patent ductus arteriosi, secundum atrial septal defects, and ventricular septal defects can be closed by placing a device through an interventional procedure.

There are two distinct pathways of surgical treatment for CHD: biventricular and univentricular repairs, depending mostly on the size of the ventricles and the anatomy of the AV valves. Biventricular repair is an ideal option for any CHD. However, there are cases in which one ventricle is not large enough to support either the systemic or pulmonary circulation after a biventricular repair. Rarely, one ventricle is entirely absent. Such cases include hypoplastic left heart syndrome, unbalanced forms of AV septal defect, tricuspid atresia, and double inlet ventricles, and are collectively termed as functionally single ventricles or univentricular hearts (Table 14–11). The goal of the univentricular repair is to use the functionally single ventricle as the chamber to support the systemic circulation whereas the pulmonary circulation is maintained by the pressure gradient between the systemic and pulmonary venous systems without the aid of ventricular systole.

Biventricular repair is a single-stage operation in most cases, although some complicated defects require staged operations. The timing of surgery depends on whether the systemic or pulmonary circulation is ductus dependent. Most ductus-dependant lesions require surgical repair within a few days of life. Most nonductus-dependent defects are repaired between the ages of 3 months and a few years, according to the hemodynamic impact of the defect on the cardiac function and pulmonary vasculature. Univentricular repair usually consists of three staged operations. The first stage consists of either a systemic-to-pulmonary arterial shunt for cases with pulmonary stenosis or atresia and pulmonary arterial hypoplasia, or pulmonary arterial banding for those with no significant pulmonary stenosis. Systemic-to-pulmonary arterial shunt operation is usually performed in the first few days of life, whereas pulmonary artery banding is performed in a few weeks depending on the patient's

condition. Cases with mild pulmonary stenosis and good pulmonary arterial growth do not require a first stage operation. The second-stage operation is the bidirectional cavopulmonary connection (bidirectional Glenn) in which the SVC or caeve are connected, end-to-side, to the pulmonary artery on the same side. This operation is usually performed at the age of 6 to 9 months, although it can be performed earlier or later. The third stage operation is the modified Fontan operation in which the inferior vena cava is connected to the pulmonary artery by using an intracardiac tunnel or extracardiac conduit. It is also called the total cavopulmonary connection. This procedure is usually performed 12 to 24 months following the bidirectional cavopulmonary connection. Each stage of univentricular repair is associated with significant mortality and morbidity, which varies according to the underlying pathology. Prognosis tends to be better when the main ventricular chamber is the morphologically left ventricle rather than the morphologically right ventricle. The postoperative prognosis of major CHDs is summarized in Table 14–12.¹⁴⁵ However, this information should be used cautiously because the outcome is often influenced by other associated factors including institutional policies and standards. More detailed information is beyond the scope of this chapter.

CARDIAC TUMORS

Primary cardiac tumors are uncommon in the fetus and neonate.¹⁴⁶ However, cardiac tumors are seen more frequently in fetuses than in neonates, occurring in 0.1% to 0.2% of fetal echocardiographic series.^{147,148} This is due to the widespread use of ultrasound as a screening tool for all pregnancies. The majority of the fetal cardiac tumors are rhabdomyomas, with an incidence ranging from 50% to greater than 90%.^{147–150} Other less common fetal cardiac tumors include fibroma, teratoma, hemangioma, lipoma, and myxoma.

Rhabdomyomas are hamartomatous proliferative lesions that are associated with tuberous sclerosis in 50% to 80% of cases.^{147–152} More than 50% of cases with tuberous sclerosis have cardiac rhabdomyomas. Rhabdomyomas are characteristically multiple in nature. On fetal ultrasound, they are seen as homogeneously hyperechogenic, round masses (Fig. 14–51). Not uncommonly, a large predominant mass is seen with tiny satellite tumors. Small tumors may be associated with subtle changes in myocardial echogenicity without showing obvious masses. Even a single detectable tumor in the fetus does not exclude a rhabdomyoma. Although multiplicity of the tumor is sufficient to establish the diagnosis of rhabdomyomas, multifocal localized nodular hypertrophy of the myocardium is a rare cause of multiple masses on ultrasound.¹⁵³ Tumors tend to appear in early second trimester, increase in size until the early third trimester, and then regress during later pregnancy and in the first few years of life. Because brain tubers are difficult to detect sonographically, magnetic resonance imaging has been used.¹⁵⁴

Fibroma is second in frequency following rhabdomyoma.^{147–150,155} The ventricular septal myocardium is the most common site, followed by right and left ventricular free wall. Usually, fibromas are solitary, homogeneously echogenic mass but there may be associated areas of cystic degeneration.

Table 14–12 Risk Categories and Mortality Rates of Surgical Procedures

Risk Category (Mortality Rate)	Diseases or Procedures
1 (0.4%)	Secundum ASD, PAPVC, PDA > 30d, COA > 30d
2 (3.8%)	VSD, Primum ASD, Common atrium, ASD and VSD, LV-RA shunt, TAPVC > 30d, Coronary artery fistula, AP window, Pulmonary stenosis, TOF, Pulmonary artery stenosis, Pulmonary valve replacement, Aortic stenosis > 30d, Subaortic stenosis, COA ≤ 30d, Vascular rings, Bidirectional cavopulmonary anastomosis
3 (8.5%)	Complete AVSD, TOF with pulmonary atresia, DORV, Complete TGA (arterial switch operation), Cor triatriatum, COA with VSD, Mitral valvotomy, mitral valve replacement, Left ventricular outflow tract patch, Aortic valve replacement, Ross procedure, Tricuspid valvotomy, valvuloplasty or valve replacement, Ebstein anomaly > 30d, Reimplantation of anomalous pulmonary artery, Systemic-to-pulmonary artery shunt, RV-pulmonary artery conduit, Fontan procedure
4 (19.4%)	AS ≤ 30d, Konno procedure for complex LV outflow tract obstruction, Interrupted or hypoplastic aortic arch, Complete TGA with VSD (arterial switch with VSD closure), Complete TGA with VSD and subpulmonary stenosis (Rastelli), Corrected TGA (double switch operation), Truncus arteriosus, Unifocalization for TOF with pulmonary atresia, TAPVC ≤ 30d,
5 (NA)	Ebstein anomaly ≤ 30d, Truncus arteriosus with interrupted aortic arch
6 (47.7%)	Hypoplastic left heart syndrome (stage I Norwood operation), Damus-Kaye-Stansel operation

ASD, atrial septal defect; AVSD, atrioventricular septal defect; COA, coarctation of the aorta; DORV, double outlet right ventricle; LV, left ventricle; PAPVC, partial anomalous pulmonary venous connection; PDA, patent ductus arteriosus; RA, right atrium; TAPVC, total anomalous pulmonary venous connection; TGA, transposition of the great arteries; TOF, Tetralogy of Fallot. Modified from Jenkins, KJ, Gauvreau K, Newberger JW, et al: Consensus-based method for risk adjustment for surgery for congenital heart disease. *J Thorac Cardiovascul Surg* 129:110, 2002.

Fibromas may cause either inflow or outflow obstruction of the right or left or both ventricles, depending on their location and size. Fibromas arising from the ventricular septum may cause heart block and arrhythmias. Occasionally, cardiac fibromas are observed with extracardiac malformations or syndromes that include nevoid basal cell carcinoma (Gorlin) syndrome, cleft lip and palate, and Beckwith-Wiedemann syndrome. Spontaneous regression of fibroma is rare.

Teratoma is a rare tumor originating mainly from the pericardium and, less commonly, from the atrial or ventricular myocardium.^{147–150,156,157} Typically, intrapericardial teratomas are attached to the great arterial roots. The tumor is characterized by a mass of heterogeneous echogenicity with solid and cystic components. It is associated with pericardial effusion that contains echogenic debris in the majority of cases. The pericardial effusion is often massive, causing life-threatening tamponade that requires in

utero pericardiocentesis or fetal surgery. Similar to teratomas in other locations, the mass may contain calcifications or bones. However, one should be aware that calcification of the myocardium can result from dystrophic deposition of calcium in the areas of myocardial ischemia, necrosis, bleeding, fibrosis, or infection.¹⁵⁸ Calcific myocardial deposits are also reported in chromosomal abnormalities. Calcification of the tension apparatus of the mitral or tricuspid valve is not uncommon and known as an echogenic focus. The relationship between echogenic ventricular focus and chromosomal abnormalities is discussed elsewhere in this textbook.

Hemangioma is also a rare tumor originating from any location in the heart or pericardium, with the right atrium being the most common location (Fig. 14–52).^{147–150,159} Similar to teratoma, pericardial effusion is commonly associated and may need in utero pericardiocentesis. Cardiac hemangiomas may be associated with multiple hemangiomas

in the skin and elsewhere. Other forms of vascular tumors including lymphangiomas are also reported in the literature. Generally, vascular tumors are associated with a favorable outcome. Hemangiomas tend to regress spontaneously, having the best prognosis of all cardiac tumors.

The prognosis during fetal and postnatal life depends mainly on the location and size of the tumor or tumors.¹⁴⁷⁻¹⁵⁰

Poor prognostic factors include intracardiac flow obstruction, altered valve function with regurgitation, arrhythmias, large pericardial effusion, and fetal hydrops. Rarely, compression or involvement of the coronary artery by the tumor may result in fatal outcome. Postnatal prognosis also depends on spontaneous regression or growth of the tumor and associated malformations or syndromes. Surgical results are best for hemangiomas, followed by teratomas. Complete excision is often difficult in large fibromas and cardiac transplantation may be required.

CARDIAC RHYTHM

Normal Fetal Cardiac Rhythm

The cardiac conduction system is composed of highly specialized muscle tissue that is able to generate the cardiac impulse, transport it across the fibrous ring of the AV junction, and deliver it throughout the ventricles. After originating within the sinus node, the electrical impulse proceeds by way of atrial tissue to the AV node, the His-Purkinje system, and the ventricular myocardium. The electrical impulse is physiologically delayed within the compact AV node, which functions as a filter against the propagation of abnormally fast atrial rates or very premature atrial beats to the ventricles. The normal fetal cardiac rhythm is regular with a 1:1 AV relationship. The sequential mode of AV depolarization results in rhythmic contraction and relaxation of atrial and ventricular myocardium, allowing coordinated filling and emptying of the heart. The heart rate increases rapidly in early gestation until it reaches the peak rate of 175 + 20 beats per minute at approximately 8 weeks.^{160,161} Then, the heart rate gradually decreases to 140 + 20 beats per minute at

FIGURE 14-51. Rhabdomyomas. Four-chamber view shows multiple tumors (asterisks) involving both ventricles, interventricular septum and right atrium (RA). LA, left atrium; LV, left ventricle, RV, right ventricle.

FIGURE 14-52. Hemangioma. A. Four-chamber view at 32 weeks shows a round protruding mass (arrow) arising from the posterior wall of the right atrium (RA). B. Four-chamber view at 35 weeks shows growth of the mass and development of an echolucent cystic area. The removed mass showed histological features of hemangioma with central hemorrhage. LA, left atrium; LV, left ventricle; RV, right ventricle.

FIGURE 14-53. Normal M-mode tracing for cardiac rhythm assessment using four-chamber view. The M-mode beam is directed through the atrial and ventricular walls to demonstrate atrial and ventricular systolic wall motions simultaneously. Atrial contractions (a's) are followed by ventricular contractions (V's). LA, left atrium; LV, left ventricle; LVFW, left ventricular free wall; RA, right atrium; RAFW, right atrial free wall; RV, right ventricle.

20 weeks and 130 + 20 beats per minute toward term, as a result of increasing parasympathetic influence on the electrical conduction system after the first trimester.^{162,163}

Sonographic Techniques for Cardiac Rhythm Assessment

As in extrauterine life, the classification of fetal rhythm and conduction anomalies relies primarily on the chronology of atrial and ventricular electrophysiologic events. However, the assessment of the fetal cardiac rhythm is more challenging because a conventional real-time electrocardiogram cannot be obtained. M mode and pulsed wave Doppler echocardiography have been used as surrogates because they enable the study of atrial and ventricular electrical events indirectly by their respective mechanical consequences.^{164,165}

M Mode Echocardiography

Guided by real-time two-dimensional echocardiography, the M mode ultrasound beam is aligned simultaneously through the atrial and ventricular walls to record the sequence of their systolic wall motions. The preferred M mode beam direction is through the atrial and ventricular walls immediately above and below the AV junction because these parts show the most pronounced lateral excursion during a cardiac cycle (Fig. 14-53). A limitation of M mode tracings is that the onset and maximal timing of the atrial and ventricular systolic events are not well-defined and,

therefore, the precise measurement of the time interval between atrial and ventricular contractions (AV time-interval) is not possible.

Pulsed Wave Doppler

In comparison with M mode, Doppler flow waves that represent atrial and ventricular systolic events are more clearly delineated. By placing the Doppler cursor across the SVC and the ascending aorta, it is possible to record the flow velocity patterns from both vessels simultaneously (SVC/Aorta Doppler) (Fig. 14-54, upper panel). The beginning of the retrograde flow in the SVC reflects the onset of atrial systole, whereas the beginning of the aortic forward flow marks the beginning of ventricular systole. Alternatively, the blood flow through the mitral valve and left ventricular outflow tract can be sampled simultaneously by placing the cursor on the anterior leaflet of the mitral valve in the left ventricular outflow tract view (inflow/outflow Doppler) (see Fig. 14-54, lower panel). This technique makes use of the fact that the anterior leaflet is the anterior border of the left ventricular inlet in diastole and the posterior border of the outlet in systole. The beginning of the A-wave of the mitral valve flow is the onset of atrial systole, whereas the beginning of the flow through the left ventricular outflow tract marks the beginning of ventricular systole.

For simple determination of the fetal cardiac rhythm and rate, pulsed Doppler assessment of umbilical artery flow pattern is a convenient and rapid ultrasound method. M

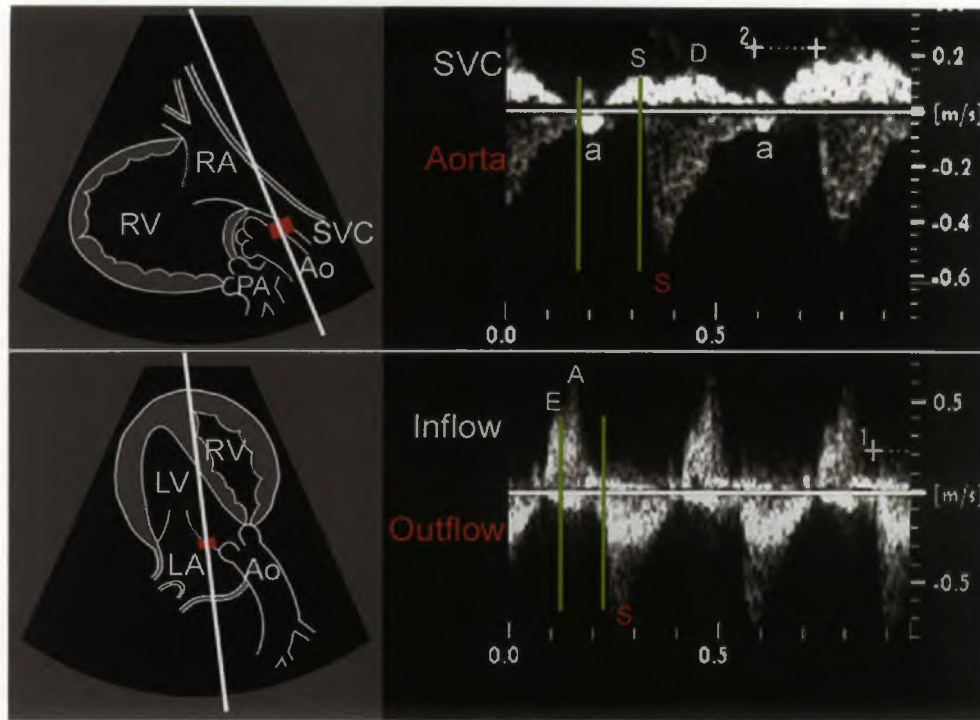

FIGURE 14-54. Pulsed Doppler flow curves showing normal atrioventricular relationship of cardiac rhythm. *Upper panel*, Simultaneous Doppler tracing from the superior vena cava (SVC) and ascending aorta (Ao). The superior vena caval flow curve consists of systolic (S) and diastolic (D) forward waves followed by small atrial reversed wave (a). The aortic flow curve consists of a single forward peak (S in red). The atrioventricular time interval is the time lapse between the onsets of the vena caval a-wave and aortic S-wave (between green lines). *Lower panel*, Simultaneous Doppler tracings from the left ventricular inflow and outflow tracts. The inflow flow curve consists of an E wave during early diastolic filling and A wave during atrial contraction. The outflow flow curve shows a single forward wave (S) in systole. The atrioventricular time interval is the time lapse between the onsets of the A and S waves (between green lines). LA, left atrium; LV, left ventricle; PA, main pulmonary artery; RA, right atrium; RV, right ventricle.

mode and spectral Doppler can be used to evaluate all types of fetal arrhythmia. Both pulsed Doppler methods are equally useful to evaluate the integrity of AV conduction during normal cardiac rhythm. Reference values of mechanical AV time intervals vary among different imaging modalities and gradually prolong as a result of increasing cardiac size and parasympathetic tone with advancing gestational age. Normal AV time-interval values are 190 ± 36 ms by M mode, 120 ± 11 ms by inflow/outflow Doppler, and 111 ± 17 ms by SVC/aorta Doppler.¹⁶⁵

Other Noninvasive Methods

Transabdominal fetal electrocardiography (ECG) and magnetocardiography have recently become commercially available.^{166,167} Fetal ECG is based on signal averaging of electrocardiographic complexes and does not allow beat-to-beat analysis. As a consequence, ECG is not helpful in the diagnosis of fetal rhythm and conduction abnormalities with irregular heart rates. Fetal magnetocardiogram provides better signal quality than ECG because of more favorable transmission properties of magnetic signals. Both magnetocardiograms and electrocardiograms may provide useful information on cardiac time intervals such as the QRS and QT duration. Assessment of myocardial movement by using tissue Doppler technique is an emerging tool for fetal cardiac rhythm disturbances and ventricular function (Fig. 14-55).¹⁶⁸

Abnormal Cardiac Rhythms

Fetal rhythm abnormalities affect at least 2% of pregnancies and are a common reason for referral to fetal cardiologists.¹⁶⁹⁻¹⁷¹ They may present (1) as an irregularity of the cardiac rhythm, (2) an abnormally slow or fast heart rate, or (3) a combination of abnormal rate and rhythm. Intermittent or sustained irregularity of the cardiac rhythm is usually caused by premature extracontractions and is by far the most common fetal rhythm abnormality (Table 14-13). Less common but potentially life threatening are intermittent or sustained episodes of excessively fast (tachycardia, > 180 beats per minute) or slow (bradycardia, < 100 beats per minute) heart rates. Sustained bradycardia is typically the result of complete AV block, sinus bradycardia, or atrial bigeminy. Supraventricular tachycardia, atrial flutter, and sinus tachycardia are the main causes of fetal tachycardia. Appropriate management depends on accurate diagnosis. Ultrasound is essential to determine the arrhythmia mechanism and the impact on cardiac function, to detect associated cardiac defects or tumors, and to survey the fetal heart rate and well-being for example, during antiarrhythmic treatment.

Irregular Cardiac Rhythm

Irregularity of the fetal cardiac rhythm with normal or near-normal average heart rates is most often related to premature beats that are generated by ectopic pacemaker

FIGURE 14-55. Sequential analysis of atrial (green) and ventricular (yellow) longitudinal wall motion by tissue Doppler. The typical Doppler curve (yellow) obtained from the base of the ventricles during sinus rhythm is composed of four waves. Two diastolic waves are produced by longitudinal tissue motion away from the apex, during early diastolic filling (Ea) and during atrial contraction (Aa). This is followed by two systolic waves towards the apex: the isovolumetric contraction (IVa) and the Sa wave. Atrioventricular time interval is the time lapse between the onsets of Aa and IVa waves.

Table 14-13 Fetal Arrhythmias: Mechanisms, Frequency, and Treatment Recommendations for Obstetricians^{169,171}

Arrhythmias	Frequency	Management Recommendation	Prognosis
Minor arrhythmias	90%		
Premature atrial contractions	Very common	Weekly monitoring of heart rate	Typically resolves SVT in 1%
Premature ventricular contractions	Rare	Weekly monitoring of heart rate	Usually resolves VT rare
Brief sinus tachy/bradycardia	Common	None	Excellent
Major arrhythmias	10%		
Complete atrioventricular block	35%	Urgent referral to tertiary care center	Irreversible Isolated: survival > 90% With LAI: survival < 10%
Supraventricular tachycardia	40%	Urgent referral to tertiary care center	Often resolves after birth No hydrops: survival > 96% Hydrops: survival 65-75%
Atrial flutter	10%-15%	Urgent referral to tertiary care center	Resolves after birth Survival > 90%
Ventricular tachycardia	Rare	Urgent referral to tertiary care center	Variable

LAI, left isomerism; SVT, supraventricular tachycardia; VT, ventricular tachycardia.

tissue usually located in the atria and rarely in the ventricles. The incidence of premature beats is not established in the healthy fetus, but ectopic atrial beats are quite common findings in healthy premature and term babies. *Premature atrial contractions (PACs)* can be observed at any gestational age but are most common in the last trimester in otherwise uneventful pregnancies.¹⁶⁹ PACs may be conducted to the ventricles or blocked within the AV node depending on the

degree of prematurity of the atrial event and thus present either as an extra beat or a missed beat on auscultation or ultrasound examination (Fig. 14-56). PACs are usually transient and benign findings. In the presence of an accessory AV conduction pathway, however, they may occasionally trigger reentrant supraventricular tachycardia. PACs have also been associated with structural heart disease (up to 2%), intracardiac tumors and redundancy of the

FIGURE 14-56. Premature atrial contractions. Simultaneous Doppler tracing of the superior vena cava (SVC) and ascending aorta showing isolated blocked (*upper panel*) and conducted (*lower panel*) premature atrial contractions (*arrows*). A, atrial contraction; S, ventricular contraction.

membrane of the foramen ovale. Multiple blocked PACs such as in atrial bigeminy may lower the fetal heart rate below 100 beats per minute and need to be differentiated from more serious causes of bradycardia. *Premature ventricular contractions (PVCs)* are rarely diagnosed antenatally. In general, they are equally well tolerated and benign but may occasionally be associated with intrinsic myocardial disease. The vast majority of fetuses with atrial and ventricular premature beats do not need any prenatal and postnatal treatment, and delivery should not be expedited based on these findings alone. However, because of the potential risk of progression to fetal tachyarrhythmias (see later), it appears prudent to monitor fetuses with frequent premature beats on a weekly or biweekly basis by auscultation or Doppler until the arrhythmia resolves.

Bradycardia

Brief episodes of sinus bradycardia of less than 1- to 2-minutes' duration are frequent and benign findings during the first and second trimester and do not require any treatment. Transient sinus bradycardia is not uncommon during fetal ultrasound examination when the fetal head is compressed by the probe. A more sustained decrease in average fetal heart rate may be observed during sinus bradycardia and atrial bigeminy with blocked premature atrial beats, whereas the bradycardia is always permanent in complete AV block. Because the ventricular rate is often regular and comparable among these rhythm anomalies, ultrasound imaging is essential for their diagnostic differentiation.

During *sinus bradycardia*, M mode and Doppler echocardiography reveal a regular atrial rate below 100 beats per minute with a normal 1:1 AV activation sequence. Sustained sinus bradycardia may be caused by a number of serious conditions including fetal hypoxia and acidosis, long QT

syndrome, and congenital sinus node dysfunction.¹⁷² Runs of ventricular tachycardia and 2:1 AV block are additional findings suggesting fetal long QT syndrome, which carries a guarded prognosis. Careful examination and, in the absence of a fetal magnetocardiogram, postnatal ECG are recommended in these children and their family members because early detection and treatment of long QT patients may be life-saving.

Sustained *atrial bigeminy* and trigeminy with blocked premature beats may lower the average heart rate of the fetus to 60 to 100 beats per minute and be confused with second- or third-degree AV block. Blocked premature beats and AV block are characterized by a higher atrial than ventricular rate. In AV block, however, the time intervals between consecutive atrial impulses hardly vary, whereas every second event occurs prematurely in atrial bigeminy (Fig. 14-57). This differentiation is important because bradycardia secondary to blocked premature beats resolves spontaneously without treatment, whereas complete AV block is an irreversible and potentially life-threatening disorder.

AV block refers to a delay of electrical conduction within the AV node, the bundle of His, or the bundle branches. First-degree AV block is characterized by a prolonged electrical AV conduction time but all impulses are conducted. Because 1:1 AV conduction is maintained, it is not possible to diagnose first-degree AV block without measurement of the AV time intervals. Second-degree AV block refers to a failure to conduct some, but not all atrial impulses to the ventricles. In 2:1 AV block every second atrial beat is conducted to the ventricles. In third degree or complete AV block (CAVB), the electrical AV communication is completely interrupted and atria and ventricles beat independently at their intrinsic rates. Typically, the ventricular rate in CAVB is between 40 and 80 beats per minute.¹⁴⁰ CAVB affects about 1 in 15,000 live-born babies

FIGURE 14-57. Atrial bigeminy. M-mode tracing through the atrial and ventricular walls shows that every second atrial beat (a's in red) occurs prematurely and is not conducted to the ventricle, resulting in ventricular bradycardia (V-V rate: 67 beats per minute). A, atrial contraction; LVFW, left ventricular free wall; RAFW, right atrial free wall; V, ventricular contraction.

FIGURE 14-58. Atrioventricular block. M-mode tracing of the atrial and ventricular walls (upper panel) and simultaneous Doppler tracing of the superior vena cava (SVC) and ascending aorta (lower panel) showing complete atrioventricular dissociation related to complete atrioventricular block. The atrial rate (a-a) is 140 beats per minute and the ventricular rate (V-V) is 54 beats per minute. LVFW, left ventricular free wall; RAFW, right atrial free wall.

but is definitely more frequent in utero, accounting for 30% to 40% of the major fetal arrhythmias. In approximately half of the cases, heart block is associated with structural cardiac lesions, most importantly left isomerism and congenitally corrected transposition (Fig. 14-58). The outcome of fetal CAVB with left isomerism is extremely poor.^{140,173} As an isolated disorder, CAVB is mainly associated with the transplacental passage of maternal autoantibodies to 48-kDa SSB/La, 52-kDa and/or 60-kDa SSA/Ro ribonucleoproteins.¹⁷⁴⁻¹⁷⁶ These antibodies are typically found in mothers with systemic lupus erythematosus or

Sjogren syndrome, but may be demonstrated in 1% to 2% of pregnant women with no clinical evidence of autoimmune disease.¹⁷⁴ The anti-Ro/La antibodies progressively enter the fetal circulation in the second trimester and may elicit an immune-mediated tissue injury resulting in progressive destruction of the AV node, myocardial inflammation, endocardial fibroelastosis, and dilated cardiomyopathy in the susceptible offspring.¹⁷⁵⁻¹⁷⁷ CAVB emerging after 20 weeks' gestation affects 1% to 2% of the cohort of antibody-positive mothers, whereas other cardiac manifestations are less common.^{174,178} The recurrence risk of immune-mediated CAVB in subsequent pregnancies is 8% to 18%.¹⁷⁵ There is a significant risk of demise, particularly in CAVB with fetal hydrops, poor ventricular function, heart rate of 55 beats or less per minute, and/or premature delivery.^{173,176,177,179} Numerous, often controversial, preventive and therapeutic approaches have been used to improve pregnancy outcome.¹¹ Theoretically, all pregnant women with anti-Ro/La antibodies, who are, therefore, at risk of delivering a child with CAVB, may be considered for preventive treatment. Indeed, this approach has been chosen for a small number of pregnancies that were treated with maternal plasma exchange, and administration of maternal immunoglobulin, steroid, or azathioprine.^{180,181} Considering the low fetal risk of less than 2% of developing CAVB, it is difficult to advocate preventive treatment for the entire cohort of mainly unaffected fetuses and mothers. The rationale to treat a fetus with CAVB is not to reverse the block to a normal rhythm because the complete block is an irreversible disease. The treatment is primarily to mitigate or prevent concomitant myocardial inflammation and to augment fetal heart rate. Fluorinated steroids (dexamethasone, betamethasone) are only minimally metabolized by the placenta and become useful when anti-inflammatory fetal treatment is desired. Maternal

FIGURE 14-59. Tachycardia with 1:1 atrioventricular relationship. Simultaneous Doppler tracing of the superior vena cava and ascending aorta showing fetal tachycardia of 182 beats per minute with normal 1:1 atrioventricular relationship and atrioventricular time intervals. This form of tachycardia may be caused by sinus tachycardia, permanent junctional reciprocating tachycardia (PJRT), and atrial ectopic tachycardia (AET). A, atrial contraction; V, ventricular contraction.

FIGURE 14-60. Supraventricular tachycardia. Simultaneous Doppler tracing of the superior vena cava and ascending aorta showing a fetal tachycardia of 222 beats per minute with an 1:1 atrioventricular relationship. The ventricular contraction (V) is closely followed by the atrial contraction (a) suggesting re-entrant SVT as the underlying arrhythmia mechanism.

dexamethasone administration has been shown to improve AV block, hydrops, and myocardial dysfunction.¹⁸² Beta-stimulation may be used to increase the fetal heart rate and myocardial contractility.^{11,183} Indeed, recent data suggest that the introduction of transplacental glucocorticoid and β -mimetic fetal therapy has a beneficial effect on outcome but without improving the AV block.¹¹ Most cases require permanent pacing for class I American Heart Association/American College of Cardiology indications during the first year of life.^{84,175}

Tachycardia

Disorders that lead to an intermittent or sustained increase in heart rate more than 180 beats per minute account for about two third of major fetal arrhythmias. According to the origin of the fast rhythm, tachycardias are classified into sinus tachycardia, supraventricular tachycardia, and ventricular tachycardia.^{160,185-189} Echocardiography is again the diagnostic cornerstone in establishing the arrhythmia mechanism and the hemodynamic consequences. The different mechanisms may be distinguished by analysis of the atrial and ventricular chronological relationship and by documentation of the AV and ventriculoatrial (VA) time-

intervals. All forms of tachyarrhythmias may be asymptomatic but, at the other end of the spectrum, may lead to congestive heart failure, dilated cardiomyopathy, neurologic lesions, and even death. Fetal hydrops has been associated with a mortality risk of up to 35%.¹⁸⁶

Sinus tachycardia is characterized by atrial rates of 180 to 200 beats per minute, normal 1:1 AV conduction and some variability of the fetal heart rate (Fig. 14-59). A variety of fetal and maternal conditions may be responsible for sustained sinus tachycardia including fetal distress, anemia, infections, maternal β -stimulation and fetal thyrotoxicosis secondary to thyroid-stimulating maternal autoantibodies. The importance of sinus tachycardia is recognizing and treating the underlying cause.

Supraventricular tachycardia (SVT) encompasses tachycardias with three different mechanisms that includes (1) AV reentrant tachycardia (AVRT) related to a fast retrograde conducting accessory pathway; (2) permanent junctional reciprocating tachycardia (PJRT) related to a slow retrograde conducting pathway; and (3) atrial ectopic tachycardia (AET) due to enhanced atrial focal automaticity. They may be differentiated based on their arrhythmia pattern and the AV and VA relationship. AVRT is by far the most common mechanism of fetal SVT 159 (Fig. 14-60). The onset and

FIGURE 14-61. Atrial flutter. M-mode tracing through the left ventricle (LV) and right atrium (RA) shows a fast atrial (A) rate (420 beats per minute) that is twice the ventricular (V) rate (210 beats per minute). The underlying arrhythmia is atrial flutter with 2:1 atrioventricular conduction. LVFW, left ventricular free wall; RAFW, right atrial free wall.

termination of reentrant SVT is sudden. Heart rates range between 180 and 300 beats per minute, and the arrhythmia pattern may be intermittent or incessant.

Atrial flutter is the result of an atrial electrical reentrant circuit and is mainly observed in the third trimester.^{187,188} Atrial rates range between 300 and 550 beats per minute, which is sufficiently fast that only every second or third atrial beat is conducted to the ventricles through the AV node. As a consequence, ventricular response rates are usually between 150 and 250 beats per minute (Fig. 14-61).

Ventricular tachycardia is extremely rare in the fetus. Intermittent runs of ventricular rates between 170 and 400 beats per minute exceed the atrial rate, and there is complete dissociation between atrial and ventricular events. Nevertheless, if the AV node is able to conduct retrograde to the atrium, a 1:1 AV relationship is possible and ventricular tachycardia becomes difficult to differentiate from reentrant SVT. Long QT syndrome should be suspected when there is bradycardia during sinus rhythm, intermittent or permanent complete heart block, or both.¹⁸⁹

Following the diagnosis of any major arrhythmia, imminent referral to a fetal tertiary care center with expertise in the surveillance and treatment of the mother and fetus is advised. In theory, three management options are available for fetal SVT and atrial flutter: (1) observation, (2) antiarrhythmic drug therapy, and (3) expedited delivery. Close pregnancy monitoring only is a valid option if the fetus presents with intermittent, brief runs of tachycardia in the absence of hemodynamic impairment. Prolonged or permanent episodes of tachycardia may significantly affect the fetal cardiovascular function and rapid and permanent conversion to sinus rhythm to prevent or resolve heart

failure is a primary goal. If a fetus presents with a major tachyarrhythmia after 35 weeks of gestation, expedited delivery followed by postnatal conversion is an option. At an earlier gestational age, the risks associated with premature delivery probably outweigh the potential hazards of fetal-maternal pharmacologic treatment. There is considerable experience in the transmaternal treatment of fetal tachyarrhythmias with a number of antiarrhythmic agents, including digoxin,^{164,186,190} procainamide (class Ia),¹⁹¹ flecainide (class Ic),¹⁸⁶ sotalol and amiodarone (class III).^{164,190,192} Direct fetal administration of adenosine, digoxin, and/or amiodarone, for example, into the umbilical vein, has been successfully used for the acute treatment of incessant, poorly tolerated SVT.^{193,194} Any antiarrhythmic treatment other than digoxin should be initiated in-hospital while monitoring the fetal and maternal cardiac rhythm. Permanent pharmacologic suppression of fetal tachyarrhythmia is achievable in most cases. Once the arrhythmia is under control, the successful antiarrhythmic treatment should be maintained until delivery with weekly controls of the fetal cardiac rhythm. Most newborns with fetal SVT require antiarrhythmic drug treatment for at least 6 to 12 months after birth. By contrast, once sinus rhythm has been established after birth, recurrence of atrial flutter is uncommon and no long-term drug treatment is usually required.

Examination for Pregnant Women With Anti-Ro/SSA and Anti-La/SSB Antibodies

About 1% to 2% of all pregnant women have anti-Ro/SSA and/or anti-La/SSB autoantibodies, most without any

antibody-related symptoms.¹⁷⁴ These antibodies increasingly enter the fetal circulation in midgestation and may induce a progressive destruction of the AV node in about 1% to 2% of anti-Ro/La antibody-positive pregnancies. As a result of this insult, the electrical AV conduction progressively prolongs to complete heart block after 20 weeks' gestation. Complete AV block may be preventable if the disease can be recognized and treated at an early stage of AV nodal damage, which is clinically characterized by a short-lived appearance of first or second degree AV block.¹⁹⁵ Doppler ultrasound allows simple and reproducible measurement of the mechanical AV time-intervals and thus represents a suitable tool in serially monitoring of the fetuses at risk of immune-mediated heart block. Normal AV time-intervals by SVC/aorta and inflow/outflow Doppler are in general below 140 ms independent of the fetal age. Transplacental fetal steroid treatment to prevent the progression to irreversible complete fetal AV block should be considered if there is significant lengthening of the AV time-intervals compatible with first or higher degree AV block in an anti-Ro/La antibody positive pregnancy between 20 and 24 weeks' gestation.

CARDIAC FUNCTION

Physiology of the Fetal Cardiovascular System

There are profound differences in the cardiovascular system before and after birth. The most important is that the placenta rather than the lungs is the major source of oxygenation in the fetus. The oxygenated blood from the placenta returns to the fetus through the umbilical venous system (Fig. 14–62). About 20% to 30% of the umbilical venous blood then bypasses the liver through a narrow, trumpet-shaped vessel, called the ductus venosus.¹⁹⁶ The narrowing of the ductus venosus transforms the continuous, low-velocity umbilical venous blood flow into a pulsatile high-velocity jet, reaching peak velocities up to 75 cm/sec. The flow acceleration gives the oxygenated blood enough momentum to preferentially stream across the foramen ovale into the left side of the heart, which supplies the upper extremities, the brain, and the coronary arteries; only a small proportion passes across the aortic isthmus into the descending aorta. In contrast, poorly oxygenated blood returning to the heart from the superior and inferior venae cavae is mainly directed into the right ventricle and then ejected into the pulmonary arterial trunk. A small proportion passes through the pulmonary circulation, but the majority is directed through the ductus arteriosus to the descending aorta, from which the blood flow is distributed to the abdominal organs, to tissues of the lower trunk and extremities, as well as to the placenta. Thus, in the fetal circulation both ventricles simultaneously eject blood into the systemic circulation. The combined ventricular output is about 450 ml/min/kg of fetal body weight, of which the right heart contributes 20% to 30% more than the left side.¹⁹⁷ Other major differences of fetal circulation as compared with postnatal circulation include a faster heart rate at 120 to 150 beats per minute, lower arterial blood pressure and peripheral resistance, and lower myocardial compliance and contractility. The latter is explained by an

increased constraint owing to fluid filled lungs, a higher proportion of non-contractile elements, and rigid type 1 collagen in the fetal myocardium, and a delay in calcium ion removal by the immature sarcoplasmic reticulum.^{198,199} Maturation changes such as an increase in myocardial adrenergic receptor density, a switch to more mature contractile protein isoforms, and better calcium ion handling result in a steady improvement of the myocardial function with advancing gestation.

CARDIAC CYCLE

Knowledge of fetal cardiac physiology is essential to understanding cardiovascular ultrasound findings. The cardiac cycle consists of five phases (Fig. 14–63). Three repetitive cardiac events are responsible for the antegrade delivery of blood during each cardiac cycle: ventricular contraction in systole, then active ventricular relaxation, and atrial contraction in diastole. With the onset of ventricular contraction, the AV valves close and the intraventricular pressure rises without ventricular shortening until it exceeds the pressure in the great arteries. Because the ventricular volumes do not change in this initial period of ventricular contraction, this period is called the isovolumetric contraction (IC) period. With further ventricular contraction, the ventricular pressure exceeds the pressures in the great arteries, the semilunar valves open, and the blood is ejected from the ventricles into the great arteries. Ventricular contraction during ejection of the stroke volume causes rapid descent of the AV valvar fibrous ring, allowing increased forward flow through the venae cavae, which is called an S-wave on Doppler tracing. As the ventricular pressure falls below the pressures of the great arteries, the semilunar valves close. The ventricular pressure then decreases with ventricular relaxation until the atrial pressures exceed the ventricular pressures. Because the ventricular volumes do not change in this initial period of active ventricular relaxation, the period is called isovolumetric relaxation (IR) period. With further relaxation, the ventricular pressures drop below the atrial pressures, and the AV valves open. This allows rapid inflow of blood into both ventricles during early diastole (E-wave), a fall in atrial pressures, and an increase in systemic venous forward flow (D-wave). As the pressure gradient across the AV valves diminishes, the atrial contraction contributes to ventricular filling in late diastole (A-wave). The rapid rise in atrial pressure during atrial systole is transmitted into the venous system, and results in reversed flow (a-wave) in the hepatic veins and venae cavae, and decreased antegrade flow in the ductus venosus and pulmonary veins.

Techniques for Cardiac Functional Assessment

Echocardiography is an excellent tool to indirectly assess fetal cardiac function and blood flow. A brief but global assessment of the fetal cardiac function should be incorporated in a basic ultrasound examination. This should include an eyeball assessment of the ventricular contractility (Do both ventricles become noticeably smaller in systole?), as well as Doppler assessment of ventricular inflow and ductus venosus flow. More detailed assessment of the

FIGURE 14-62. The fetal circulation. The colors indicate the oxygen saturation of the blood, and the arrows show the course of the blood from the placenta to the heart. Observe that three shunts permit most of the blood to bypass the liver and lungs: ductus venosus, foramen ovale, and ductus arteriosus. The poorly oxygenated blood returns to the placenta for oxygen and nutrients through the umbilical arteries. (From Moore K, Persaud TVN: *Before We Are Born: Essentials of Embryology and Birth Defects*, 6th ed. Philadelphia, WB Saunders, 2003.)

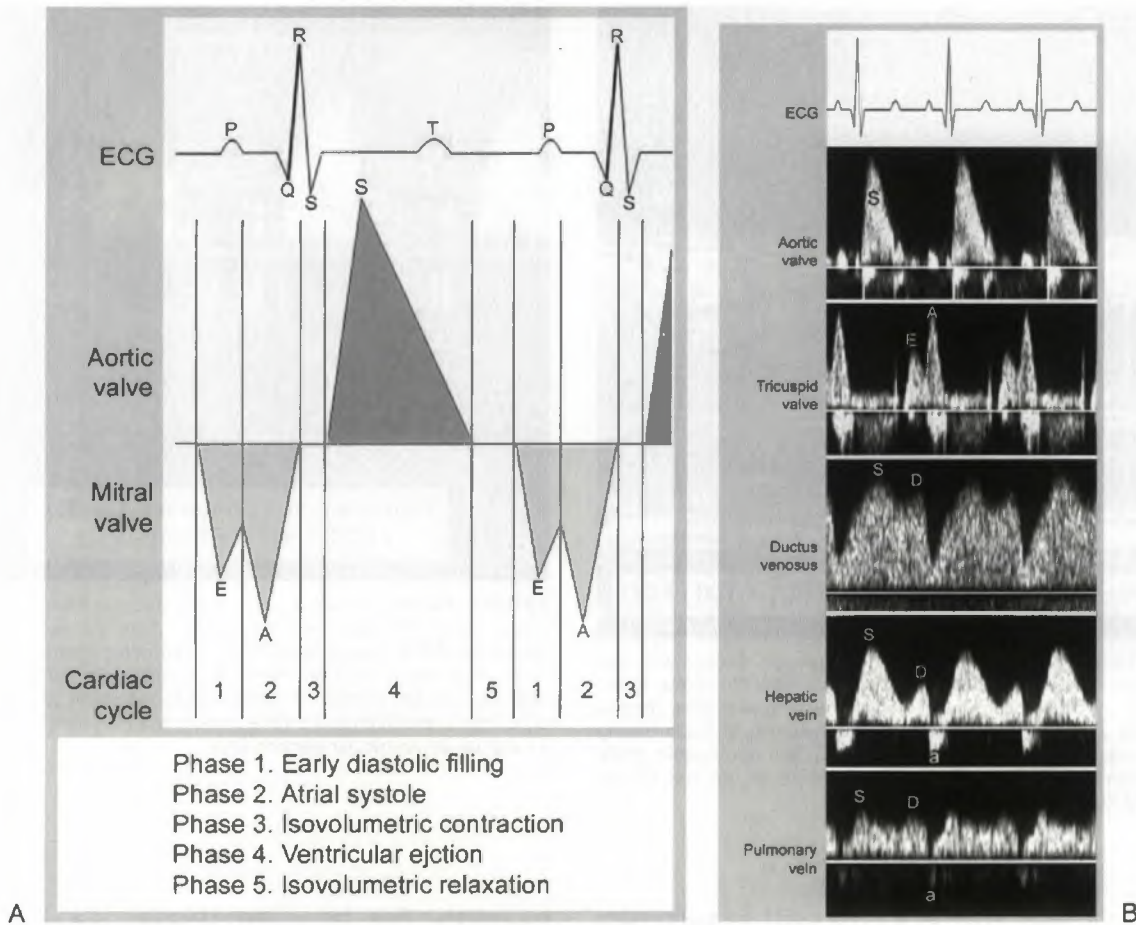

FIGURE 14-63. Correlation of cardiac phases (A) and Doppler tracings of normal venous, intracardiac and arterial blood flow (B). Electrical depolarization of the atria (P) and ventricles (QRS) precedes atrial (A) and ventricular (S) contractions, respectively. The largest proportion of ventricular filling occurs with atrial contraction in late diastole (A-wave in Phase 2). The rapid rise in atrial pressure is transmitted into the venous system (a-wave). With the onset of the ventricular contraction, atrioventricular valves close and the ventricular pressure rises without change in ventricular volume (isovolumetric contraction in Phase 3). When the ventricular pressure exceeds the pressure in the great arteries, the semilunar valves open, marking the onset of ventricular systole (arterial S-wave in Phase 4). Ventricular shortening during ejection of the stroke volume causes a rapid descent of the atrioventricular valve ring, allowing increased venous forward flow towards the atria (venous S-waves). When the ventricular pressure falls below the diastolic pressure in the great arteries, the semilunar valves close, marking the beginning of isovolumetric relaxation (Phase 5). When the ventricular pressure drops below the atrial pressure at the end of isovolumetric relaxation, the atrioventricular valves open. This is followed by a rapid inflow of blood into both ventricles during early diastole (E-wave in Phase 1), a fall in atrial pressure and an increase in systemic venous forward flow (D-wave).

cardiac and hemodynamic state is required in certain fetal (e.g., hydrops, growth restriction) and maternal (e.g., diabetes, multiple pregnancies) conditions.

Shortening Fraction

M mode ultrasound from a four-chamber view or, alternatively, a left ventricular short axis view is the simplest way to quantify changes in chamber and wall dimensions during the cardiac cycle.²⁰⁰ To accomplish this, the real-time-directed M mode cursor is placed perpendicular to the interventricular septal wall at the level of the chordae tendinae of the AV valves, and the M mode tracing is recorded (Fig. 14-64). This allows the examiner to measure the end-systolic (ESD) and end-diastolic (EDD) diameters as the respective maximal and minimal inward excursions of the ventricular wall. Shortening Fraction (SF) is then calculated using the equation: $SF = [(EDD - ESD) \times 100] / EDD$. SF of

both right and left ventricles is 28% to 40%. An abnormal shortening fraction is usually indicative of myocardial compromise or significant increase in ventricular workload.

Cardiac Output

Measurement of the cardiac output (CO) is useful in conditions that may lead to high output failure, such as agenesis of the ductus venosus, vascular tumors, and acardiac twins.^{201,202} The cardiac output is quantified by using the equation: $CO = A \times \text{Velocity time integral} \times HR$, where A is the cross-sectional area ($A = 2 \pi r^2$) of the valve, Velocity time integral is the area under the curve of the wave form, and HR is the heart rate. Pulsed Doppler signals should be obtained as parallel as possible to the blood flow direction, placing the sample volume immediately distal to the tips of the interrogated valve leaflet. The left CO can be estimated with reasonable accuracy at the mitral or aortic

FIGURE 14-64. M-mode tracing of ventricular dimensions and myocardial thickness. After obtaining a short axis view of the fetal heart, the M-mode cursor is positioned through the two ventricles, aligned perpendicular to the ventricular septum. The resulting M-mode tracing allows the measurement of end-diastolic (EDD) and end-systolic (ESD) ventricular dimensions for calculation of the shortening fraction. LV, left ventricle; RV, right ventricle.

valve and the right CO, at the tricuspid or pulmonary valve.^{203,204} The normal weight-corrected combined fetal CO is about 450 ml/min/kg, of which the right heart contributes 20% to 30% more than the left heart.¹⁹⁷

Diastolic Function

Useful information on ventricular filling characteristics is indirectly obtained by ventricular inflow characteristics; the duration of the left ventricular IR time; and the systemic and pulmonary venous Doppler flow patterns.^{205,206} *Ventricular filling* is examined by positioning the Doppler gate immediately distal to the respective AV valve. After about 10 weeks' gestation, the characteristic inflow waveform has a biphasic flow pattern representing early diastolic filling during ventricular relaxation (E-wave) and late diastolic filling during atrial contraction (A-wave), respectively (see Fig. 14-63). Peak A-wave velocity exceeds the peak E-wave velocity because ventricular filling of the fetus relies mainly on atrial contraction. Presumably due to improved ventricular relaxation, peak E-wave velocity increases in a linear fashion with advancing gestation, whereas there is little or no change in peak A.²⁰⁶ As a result, the average E/A ratios increase from approximately 0.6 at 20 weeks' gestation to 0.75 to 0.9 close to term.²⁰⁷ As diastolic inflow velocity profile relates primarily to changing pressure gradients between the atria and ventricles, it is influenced by numerous variables including intrinsic myocardial and valvar properties, loading conditions and heart rate. *Left ventricular IR time* (Fig. 14-65) can be determined from the interval between aortic valve closure and the onset of

FIGURE 14-65. Simultaneous Doppler tracing of the left ventricular inflow and outflow, and calculation of Tei index or myocardial performance index (MPI). The left ventricular isovolumetric contraction time (ICT) is the time interval between the mitral valve closure and the aortic valve opening. The left ventricular isovolumetric relaxation time (IRT) is the time interval between aortic valve closure and the onset of mitral inflow. ET stands for ventricular ejection time.

transmitral flow by pulsed Doppler. To allow precise measurement of this short time interval, tracings should be recorded at a sweep speed of greater than 200 mm/sec. The normal IR time is less than 60 ms.^{208,209} Prolonged relaxation time correlates with abnormal early diastolic filling. Pulsed Doppler examination of the inferior vena cava or hepatic vein, ductus venosus, and umbilical vessels is increasingly incorporated into the routine assessment of the fetus. The ultrasound beam for Doppler tracing should be aligned parallel to the blood flow direction for the assessment of velocity measurement, whereas the flow velocity ratios such as systolic/diastolic ratio, resistance index, and pulsatility index do not require parallel alignment of the ultrasound beam. The flow velocity of the inferior vena cava is primarily influenced by right atrial and ventricular pressure, whereas those of the ductus venosus and pulmonary veins more closely represent the left side of the heart. Venous flow waveforms are typically characterized by a biphasic forward flow during systole (S-wave) and early diastole (D-wave) and a short trough (a-wave) during atrial systole (see Fig. 14-63B). The degree of a-wave flow reversal varies considerably between individual veins. In the ductus venosus, blood flow remains antegrade also during atrial contraction, unlike in the venae cavae and hepatic veins. In the inferior vena cava, the ratio of peak reverse flow to peak systolic flow (preload index) is constant throughout gestation and lies between 0 and 0.37.²⁰⁹ The ratio of the duration of reverse flow during atrial contraction to systolic forward flow declines under normal conditions from around 25% to 5% between 12 weeks and term.²¹⁰ With abnormal diastolic filling of the heart, the venous D-wave diminishes or disappears altogether,

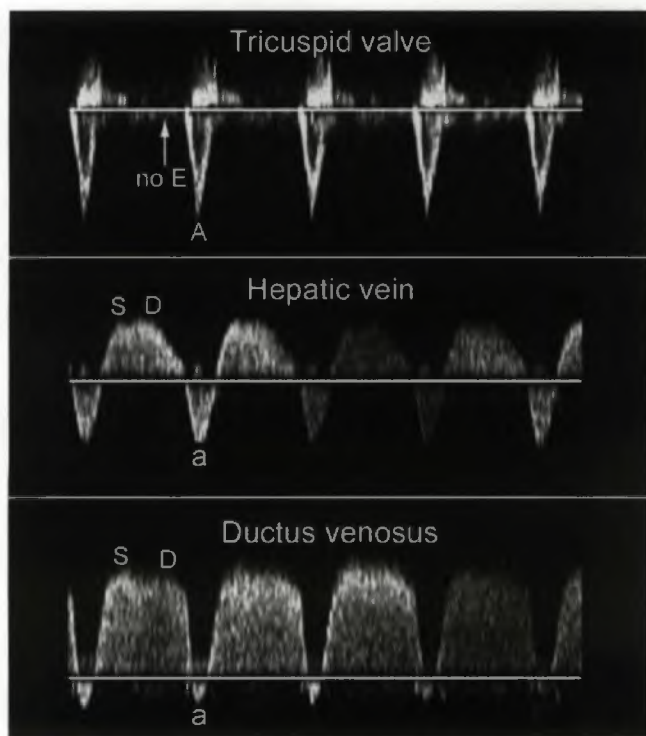

FIGURE 14-66. Abnormal diastolic function. Tricuspid inflow is abnormally short and occurs only in late diastole (A-wave). In addition there is increased reversal of blood flow during atrial contraction (a) in the hepatic vein and ductus venosus secondary to increase in end-diastolic ventricular pressure. S, systolic flow; D, early diastolic flow.

whereas the a-wave flow reversal secondary to atrial contraction increases. Abnormal early and late diastolic systemic venous flow may be observed in various conditions such as congestive heart failure and obstructive right-sided heart lesions. Transmission of venous pulsations into the portal and umbilical venous circulation correlates with increasing degrees of cardiac compromise. The end-stage finding of abnormal venous Doppler is atrial pulsations in the umbilical cord usually in association with fetal hydrops (Fig. 14-66).

Myocardial Performance Index

The Tei index or myocardial performance index is a Doppler index of combined systolic and diastolic function.^{208,211-213} The index is calculated by the sum of isovolumetric contraction and isovolumetric relaxation time-intervals divided by ejection time of the ventricle (see Fig. 14-65). Reference data for the mid- and late-gestational right and left-ventricular Tei indices differ between studies, ranging between 0.35 + 0.05 and 0.53 + 0.13.^{208,211,213} It has been used to assess the fetal cardiac status in normal and abnormal pregnancy conditions, including diabetes, twin-to-twin syndrome, fetal growth restriction, and congestive heart failure (see Fig. 14-66).

Abnormal Cardiac Function

Abnormal fetal cardiac function is usually associated with disorders of the heart muscles or abnormal ventricular

FIGURE 14-67. Diastolic dysfunction in cardiomyopathy. Simultaneous Doppler tracing of the left ventricular inflow and outflow shows prolonged isovolumetric relaxation (IRT; 88 ms) and increased myocardial performance index (MPI = 1). ET, ejection time; ICT, isovolumetric contraction time.

FIGURE 14-68. Severe global myocardial hypertrophy. Mid-ventricular short axis view and M-mode tracing shows marked myocardial hypertrophy. LV, left ventricle, LVFW, left ventricular free wall, RV, right ventricle, RVFW, right ventricular free wall.

loading conditions. Numerous reversible and irreversible conditions may influence the fetal myocardial performance including genetic disorders, viral infections, maternal autoimmune diseases, twin-to-twin transfusion syndrome (TTTS), arrhythmias, high output states, and placental failure.

Cardiomyopathies are not rare in fetus. The distinction between hypertrophic and dilated forms of cardiomyopathy may help in understanding and perhaps treating the underlying cause. Regardless of the cause, both may present with severe systolic and diastolic dysfunction, fetal hydrops, and even intrauterine demise. (Fig. 14-67)

Hypertrophic cardiomyopathy (HCM) is diagnosed when the ventricular wall thickness measures more than 2 standard deviations above the mean for gestational age (Fig. 14-68).²¹⁴ Increased wall stiffness may lead to poor diastolic filling of the heart and diminish the cardiac output. Intrinsic causes

include Noonan syndrome, familial HCM, α -thalassemia, and other rare disorders.²¹⁵ Maternal diabetes is the most common extrinsic cause. Insufficient maternal blood glucose control causes fetal hyperglycemia, which stimulates the fetal pancreatic insulin production and secretion. Hyperinsulinemia and hyperglycemia in turn causes generalized fetal macrosomia and organomegaly. HCM with disproportionate septal hypertrophy occurs in 30% of infants of diabetic mothers²¹⁶ and these morphologic changes are already detectable by echocardiography in mid gestation.²¹⁷ The septal hypertrophy seen in the setting of well-controlled maternal diabetes progresses from midtrimester to term without affecting cardiac filling and ejection and, moreover, spontaneously resolves during infancy.^{217,218} Contrary to the usually good prognosis of myocardial hypertrophy, severe HCM that is clinically indistinguishable from familial forms may occasionally be observed in association with maternal diabetes. Disproportionate ventricular septal hypertrophy may also cause obstruction of the left ventricular outflow. Thus, a careful examination of the fetal cardiac four-chamber and outflow tract views should be included in ultrasound assessment of diabetic pregnancies. TTTS complicates 10% to 15% of monochorionic multiple pregnancies.²¹⁹ Placental vascular anastomoses provide the basis for intertwin transfusion, resulting in unbalanced volume loading of the donor and recipient twins. The donor presents with chronic hypovolemia and oligohydramnios. Conversely, the recipient fetus is volume-overloaded with polyuria and polyhydramnios, and ventricular hypertrophy and hydrops may develop. Right ventricular outflow obstruction related to right ventricular muscle hypertrophy occurs in about 10% and may regress after successful intrauterine laser treatment or after birth.²²⁰

Dilated cardiomyopathy (DCM) presents with dilated, poorly contracting ventricles, AV regurgitation and often hydrops fetalis. DCM can be divided into two categories: myocardial damage due to inflammation and ischemia, and high output failure. Treatable high output failure may ensue when the cardiac output is massively increased for example, because of severe anemia, massive arteriovenous shunting, agenesis of ductus venosus, TTTS, or an acardiac twin. DCM may also be related to infection (parvovirus, cytomegalovirus, coxsackie B virus, adenovirus, toxoplasmosis), inflammation (maternal anti-Ro/La antibodies), and hereditary conditions (familial DCM).

A third form, *restrictive cardiomyopathy*, is unusual and mainly associated with endocardial fibroelastosis. Fibrosis of the endomyocardium should be suspected if the endocardium shows areas of persistently increased echogenicity on echocardiography. Endocardial fibroelastosis is commonly associated with maternal anti-Ro/La autoantibodies. Impaired diastolic filling decreases cardiac output of the affected fetus although the systolic function appears normal.

Acknowledgments

We are very grateful to Drs. Alessandra Bernasconi and Alexandra Jevremovic who informed us of the list of good cases, reviewed our draft manuscript so meticulously, and made valuable comments and corrections. We thank Ms. Jennifer Russell for reference management, Mrs. Eul Kyung Kim for making diagrams, and Ms. Harpal K. Gahunia for proofreading of the final manuscript.

Antenatal malformations of the gastrointestinal tract are being recognized with increasing frequency. This is due in part to improved technologic advances in sonographic imaging as well as a better understanding of the sonographic manifestations of gastrointestinal disease. As is discussed later in this chapter, often the initial sonographic clue to a gastrointestinal tract malformation is an indirect sonographic sign rather than observation of the abnormality itself; that is, polyhydramnios in cases of jejunal atresia and absence of a fluid-filled stomach in cases of esophageal atresia.

EMBRYOLOGY

The gastrointestinal tract begins its development early in the 3rd and 4th weeks. Longitudinal and lateral folding of the embryo results in incorporation of the dorsal part of the yolk sac.¹ Thus, the endoderm germ cell layer is incorporated into the embryo and forms the primordial (primitive) gut tube (Fig. 15-1).¹ This primitive gut is closed at the cranial end by the oropharyngeal membrane and at its caudal end by the cloacal membrane.² The endoderm of the primitive gut gives rise to most of the epithelium and glands of the digestive tract. The epithelium at the cranial and caudal ends of the tract are derived from the ectoderm of the stomodeum (primitive mouth) and proctodeum (anal pit), respectively. The muscular, connective tissue and other layers of the wall of the digestive tract are derived from the splanchnic mesenchyme surrounding the primitive gut.² In the anterior part of the embryo, the incorporation of the endoderm into the head fold results in the formation of the foregut, whereas in the posterior part of the embryo the hindgut forms.² The foregut is divided into a cranial and a caudal portion. The cranial portion develops in the head

and neck as the pharynx. In the middle region, the midgut forms, and initially this is in direct continuity with the yolk sac. In addition to the primitive gut tube, the endoderm layer also gives rise to the parenchyma of the two large glandular organs associated with the gastrointestinal duct, the liver and pancreas.¹

ESOPHAGUS

The esophagus runs from the pharynx to the stomach. It is usually collapsed and is visualized as two to four echogenic lines, representing the anterior and posterior esophageal walls. Occasionally, the esophagus may be filled with fluid and consequently depicted as a tiny tube.^{3,4}

Because of its nonlinearity, the esophagus is impossible to depict in its entirety and the cervical, thoracic, and abdominal portions are usually imaged separately. If at all feasible, the cervical section of the esophagus is best imaged in a sagittal plane; the thoracic section is best visualized behind and parallel to the trachea, and the distal abdominal section deviates from the spine and becomes visible upon its entrance into the stomach (Figs. 15-2 and 15-3).

Depiction of the esophagus (using transvaginal transducers) is easier in early pregnancy (12-16 weeks) than in late pregnancy, and as a general rule is best conducted in the late pregnancy with a high-resolution linear transducer.

Malinger et al⁴ were able to see three different patterns of esophageal motility between 19 and 25 weeks. The most frequent pattern was a simultaneous, synchronized opening of the esophageal lumen from the oropharynx to the lower esophageal sphincter, lasting 3 seconds on average, without any peristaltic waves. The second pattern consisted of a segmental opening of the esophageal lumen in conjunction

FIGURE 15-1. The gut tube in a 4-week embryo. (From Mitchell B, Sharma R: *Embryology: An Illustrated Colour Text*. Edinburgh, Elsevier/Churchill Livingstone, 2005, p. 39)

with peristaltic activity advancing from the pharynx through the mediastinum and into the stomach. The third pattern of motility was imaged in only one of 52 fetuses, in which the authors could see the passage of particulate contents as they moved upwards from the stomach into the pharynx.

Esophageal Atresia

Incidence

Esophageal atresia (EA) occurs with a prevalence between 1:5500 and 1:6000 births. More than 90% have an associated tracheoesophageal fistula (TEF).⁵⁻⁷ The main five types of this anomaly are presented in Figure 15-4. In the most common form (type A, 82%) the upper esophagus ends in a

blind pouch and the TEF is connected to the distal esophagus.

Associated Anomalies

Up to 64% of infants have associated anomalies,⁵⁻⁷ most often with VATER/VACTER (vertebral, anorectal, trachea, esophagus, cardiac, renal, and limb) association. Aneuploidy is also common and ranges between 5% to 10% in different series. The risk of Down syndrome is 30 times higher than expected in the general population.^{5,8,9}

The outcome of fetuses and infants with esophageal atresia is still unfavorable. Sparey et al⁶ reported a perinatal mortality of 21%, primarily as a result of associated anomalies. Long-term morbidity, mainly related to dysphagia, was present in 25% of infants older than 24 months old.

FIGURE 15-5. The pouch sign: *Left*, The pouch (arrow) is depicted on a sagittal section of the neck. *Right*, After a short time period, the pouch disappeared. (Courtesy of B. Vijayaraghavan: www.thefetus.net.)

Prenatal Diagnosis

The main sonographic markers of esophageal atresia are¹⁰⁻¹⁵:

1. A small or absent stomach.
2. Polyhydramnios.
3. Pouch sign of the esophageal blind end.

Because of the obstructed esophagus, less fluid is swallowed by the fetus and instead of arriving in the stomach it accumulates in the amniotic cavity. However, because a small or absent stomach and/or polyhydramnios may also be present in other anomalies, these sonographic features may only be regarded as indirect, inexplicit markers of esophageal atresia.

Stringer et al¹¹ noted that the predictive value for EA varies between 39% for a small stomach with polyhydramnios to 56% whenever polyhydramnios is present in the absence of the stomach. Isolated polyhydramnios occurs in 1:50 pregnancies in the general population. Considering the known incidence of esophageal atresia, it is estimated that isolated polyhydramnios will be the only marker of esophageal atresia in about 1% of cases. It is our experience that the presence of severe polyhydramnios and a non-visualized stomach over a prolonged time period with no upper gastrointestinal tract obstructive anomaly (for example, pressure from a goiter, et cetera) increases significantly the likelihood of EA.

In the last decade, several case reports have focused on the problematic detectability of the pouch sign, which represents the dilated blind end of the esophagus (Fig. 15-5).^{10,12-17} Its detection is not a simple task, because it fills and empties periodically, probably in correspondence with fetal swallowing. Furthermore, depending on the nature of the anomaly, the pouch may be located in the cervical region or mediastinum. Schulman et al¹⁴ noted that a detailed ultrasound examination may last up to 20 or 30 minutes because repeated scans of suspected regions are required.

They suggest the following sonographic views:

1. Coronal, through the fetal neck and chest, to visualize the upper airway; hypopharynx, larynx, and trachea.
2. Sagittal section of the fetus.
3. Two axial views: One at the level of the thyroid gland, and one at the level of the three great vessels and trachea.

The pouch sign has not been examined in large series, and, therefore, it is not yet possible to accurately define its sensitivity in detecting EA. Schulman et al¹⁴ found a pouch sign in all of their nine fetuses with EA whereas Langer et al¹³ detected the esophageal pouch in only one of six fetuses with EA. Of note, all current reports on the detection of the pouch sign are in fetuses in the second half of pregnancy.

A single umbilical artery is also a possible marker of esophageal atresia. Torfs et al⁵ noted that all types of esophageal atresia were significantly associated with a single umbilical artery. In our series of 450 fetuses with a single umbilical artery in early pregnancy there were three cases of esophageal atresia.

Because of the insufficient predictive value of ultrasound in the detection of esophageal atresia, several investigators examined the benefit of performing a magnetic resonance imaging (MRI) examination. MRI was found to increase the accuracy of diagnosis; however, the current data provided are mainly from case reports and large series are not yet available.^{13,18,19} Overall, the sensitivity of detecting EA/TEF is low; about 60% to 70% of cases are not detected in utero, mainly because polyhydramnios and small or nonvisualized stomachs are not apparent.

Timing of Diagnosis

There are currently no reports on the detection of a non-visualized stomach with polyhydramnios in fetuses with esophageal atresia before 18 weeks' gestation. The authors have seen three fetuses with esophageal atresia in which a normal-looking stomach and a normal amount of amniotic fluid were observed at 14 to 16 weeks' gestation. Polyhydramnios and nonvisualization of the stomach were noted only on a repeat scan at 20 weeks' gestation.

Therefore, it is possible that in many cases of esophageal atresia there is a tracheoesophageal fistula in early pregnancy. These fistulae probably start to narrow as pregnancy continues. If complete obliteration occurs, a small or nonvisualized stomach is expected. Occasionally the fistulous canal between the trachea and the distal portion of the esophagus is replaced by a ligamentous cord.²⁰ However, if the fistula does not obliterate completely, the stomach may be imaged.

FIGURE 15-6. Esophageal duplication cyst. *Left*, A transverse section, the stomach (S) and a cyst (c) in the posterior mediastinum. *Right*, A parasagittal section the cyst is located superiorly to the stomach (S) and the esophagus (E) is depicted. Caution: This is not the bubble of the duodenal atresia, which is expected to be located in the midabdomen and inferior to the stomach (*white circle*).

Esophageal and Duodenal Atresia or Pyloric Atresia

Esophageal atresia may occur in combination with other atresias in the gastrointestinal tract.^{21–23}

The association of esophageal and duodenal atresia without a tracheoesophageal fistula creates a closed loop of bowel involving the distal esophagus, stomach, and duodenum. Ultrasound will reveal a huge C-shaped fluid collection in the fetal abdomen, which may extend into the chest, or a cystic mass in the chest with dilation of stomach and first portion of the duodenum. The differential diagnosis in such cases includes diaphragmatic hernia, gastrointestinal obstruction, duplication cysts of the gastrointestinal tract, or a cystic anomaly of the lung.

Enteric Duplication Cysts

Enteric duplication cysts are rare congenital anomalies that may arise anywhere in the gastrointestinal tract. About one half of cases are in the midgut, one third in the foregut (esophagus stomach and proximal part of duodenum), and 13% occur in the colon. The duplication cysts form in parallel with the normal lumen of the gastrointestinal tract when two channels instead of one lumen develop between 6 and 8 weeks of fetal life. The walls of these cysts are composed of muscular and mucosal epithelium. Approximately one third of infants with enteric duplications have associated anomalies such as the split notochord syndrome, gastrointestinal malformations, and duplication of bladder, urethra, internal, and external genitalia. Children may suffer from various medical disorders such as peptic ulceration of the ectopic gastric tissue, hemoptysis in cases of fistula into a bronchus, infection of mediastinal cysts, and gastrointestinal obstructions. It is important to note that malignant transformations have been reported in some duplication cysts. Resection of duplication cysts is regarded as a standard of care because of the high incidence of associated disorders as well as the possibility of malignancy.^{24–28}

Esophageal duplication cysts account for about 10% of all mediastinal masses in children, with the majority occurring in the mid- to distal esophagus (Fig. 15–6). Their incidence

is about 1:8200 births, with a 2:1 male sex predominance.²⁶ Most esophageal duplications have a cystic form, whereas a tubular form is apparent in only 5% to 10% of cases.²⁴ The cystic form is sonographically imaged as a cyst or single viscous loop. The tubular form may represent as a hyper-echogenic mass adjacent to the normal gastrointestinal lumen (Fig. 15–7).

Laryngotracheoesophageal Cleft

A laryngotracheoesophageal cleft (LTEC) is an abnormality in the formation of the tracheoesophageal septum or a failure of the septum to reach the appropriate level. Several classifications of this anomaly have been suggested.^{29–32}

Associated anomalies are common; mainly gastrointestinal, cardiac, pulmonary, and genitourinary. LTEC also appears in three specific syndromes: Opitz-Frias, Pallister-Hall, and VACTER. Samuel et al,²⁹ who reported seven fetuses with LTEC, noted that all of them had a lung abnormality and esophageal atresia with a tracheoesophageal fistulae. Agastria was seen in four cases and microgastria in three cases. Infants suffer from repeated episodes of aspiration, chemical pneumonia, feeding problems, and a very high mortality rate.^{29–32}

The prenatal sonographic diagnosis should be suggested in cases of polyhydramnios, agastria or microgastria, and cystic anomalies in the lung.^{29,30} Because of the high incidence of associated anomalies, a detailed evaluation of all fetal organs is mandatory.

Split Notochord Syndrome and Neurenteric Cysts

Split notochord syndrome is a rare anomaly in which a cleft of the vertebral column is associated with gastrointestinal and central nervous system anomalies. Neurenteric cysts may also be present.^{33–35} Almog et al³⁴ reported on a fetus who had a stomach abnormally located in the right posterior mediastinum, with severe scoliosis and vertebral distortion. Agangi et al³⁵ reported on a fetus in which a cystic mass involving the lower part of the sacrum and an oblongated

FIGURE 15-7. Gastric duplication: *Left*, An hyperechogenic mass (M), which appears solid, is seen compressing the stomach (s) posteriorly; *Right*, Magnetic resonance scan clarifies that the mass (m) is actually a viscus behind the stomach (s). (From Levine D: *State of the art: Obstetric MR imaging. Radiology* 211:609, 1999.)

FIGURE 15-8. Split notochord syndrome. *Left*, A cystic mass observed on a transverse section of the chest. *Right*, In a lower transverse section a split vertebra (V) is connected to the cystic mass (arrow).

perineal structure closely resembling an intestinal loop were observed. The postnatal diagnosis was a protruding colon segment, imperforate anus, and lipomyelomeningocele. Sonographers should therefore be aware that prenatal findings of vertebral anomalies associated with intra-thoracic or intra-abdominal cystic masses may be suggestive of split notochord syndrome (Fig. 15-8). In many cases it is possible to image peristaltic movements inside the cystic mass. These peristaltic movements may be of help in the differential diagnosis of other cystic anomalies in the chest (bronchogenic cyst, cystic adenomatoid malformation, pulmonary sequestration) and in the abdomen (choledochal, omental, mesenteric, and ovarian cysts).

STOMACH

The fetal stomach first appears as a cystic structure in the upper left abdomen. It can be imaged in approximately 30% of fetuses at 8 weeks' gestation and should be observed in all fetuses at 11 weeks' gestation (Figs. 15-9 and 15-10).³⁶

FIGURE 15-9. A normal transverse/diagonal section of the fetal abdomen. GB, gallbladder; St, stomach; UV, umbilical vein.

FIGURE 15-10. Normal parasagittal section of chest and abdomen. S, stomach; K, kidney. The demarcation line of the diaphragm is marked by arrows.

Gastric Size

The dimensions of the stomach are defined as the largest area including the pyloric site on transverse or oblique scanning planes. The transverse section at the center of the gastric corpus is used for transverse and anteroposterior measurements. The gastric volume is calculated as a prolate ellipsoid. Several investigators have found a correlation among gastric area, gastric volume, and gestational age.³⁷⁻³⁹ However, the size of the stomach is influenced by the amount of amniotic fluid swallowed by the fetus, the amount of gastric secretions, and the rate of pyloric passage of gastric content. It seems, also, that gastric compliance normally varies between fetuses. Although in some fetuses a large stomach is always apparent, in others a small stomach is always depicted. Therefore, fluctuations in gastric size are expected and should be regarded as a physiologic phenomenon. Zimmer et al⁴⁰ performed serial measurements of the stomach 20 minutes apart in 146 fetuses between 14 and 41 weeks' gestation. The mean percentage change between each of the paired measurements was 16.6% to 43.1% for the different stomach dimensions.

In addition to the normal physiologic changes in the gastric size, sonographers should be aware that the stomach is an asymmetric organ and standardization of landmarks for its measurements is not always simple. Pathology in gastric size including nonvisualization should therefore be suggested only after several repeated scans. It should be remembered that a small amount of fluid in the stomach does not exclude the diagnosis of esophageal atresia. Either normal gastric secretions or aspiration and flow through a patent tracheoesophageal fistula may result in a small amount of gastric fluid.

Gastric Emptying Cycles

Cyclic changes in gastric size have been noted starting at 12 weeks' gestation. Sase et al^{41,42} performed continuous recordings of the stomach for 1 to 2 hours and sampled the gastric area ratio (gastric area divided by the area of the fetal abdominal transverse section) every minute. They found

that the gastric emptying cycles last 30 to 100 minutes before 24 weeks' gestation, about 40 minutes at 32 to 35 weeks' gestation and more than 80 minutes at term. The gastric volume near term is approximately 10 mL and the volume decrease with gastric emptying is about 60%. It was therefore estimated that gastric emptying accounts for a daily absorption of about 250 mL of swallowed amniotic fluid. Because the fetus swallows nearly 500 mL of amniotic fluid, it is suggested that the extra amount of fluid passes passively through the pylorus independent of the gastric emptying cycles.

Nonvisualization of the Stomach

Nonvisualization of the fetal stomach has been reported in 0.07% to 0.4% of pregnancies. The fetal outcome was abnormal in 48% to 100% of these cases.^{43,44}

Many of the fetuses had associated anomalies. The main disorders that should be suggested are

1. Mechanical obstruction of the esophagus.
 - a. Esophageal atresia.
 - b. Tumors of the pharynx, esophagus, or mediastinum.
 - c. Goiter.
 - d. Diaphragmatic hernia.
 - e. Intrathoracic masses such as large cystic adenomatoid malformations and tracheal atresia.
2. Anatomic disorders of the swallowing system, such as severe cleft palate.
3. Neurogenic disorders of the swallowing system.

The amount of amniotic fluid may be increased, decreased, or normal in cases of a nonvisualized stomach. Polyhydramnios is attributed to a decrease in the amount of amniotic fluid swallowed by the fetus. Oligohydromnios probably occurs in cases of a sick fetus with decreased production of amniotic fluid. In the authors' experience, *transient* nonvisualization of the stomach is not associated with an adverse outcome.

Congenital Microgastrica

Congenital microgastrica is an extremely rare anomaly that is believed to be a result of impairment of normal foregut development. Associated anomalies have been reported in many of these children, asplenia, Opitz syndrome, and laryngotracheoesophageal cleft being the most common anomalies.⁴⁵⁻⁴⁷

The sonographic diagnosis relies on the depiction of a very small stomach on repeated scans. The main differential diagnosis is a small stomach secondary to esophageal atresia. Of note, in congenital microgastrica the amniotic fluid volume may be normal,⁴⁵ whereas in esophageal atresia, polyhydramnios is a common finding. Postnatal surgical interventions such as gastric augmentation may be necessary in some cases because these children may be reluctant to feed normally and may suffer from malnutrition, growth restriction, and respiratory tract infections.^{46,47} However, in some cases, increased spitting up for several months is the only finding in infants who are otherwise healthy. The authors have seen two such cases; in one of the cases the mother reported that she also had increased spitting up during infancy. Therefore, it is important to tell parents that fetal microgastrica may in some cases have a favorable outcome.

FIGURE 15-11. A markedly dilated stomach at week 15.

Enlarged Stomach With Normal Amount of Amniotic Fluid. This is usually a normal anatomic variant with no adverse clinical outcome (Fig. 15-11).

Enlarged Stomach With Polyhydramnios. This anomaly is usually a result of a gastric outlet obstruction, that is, atresia of the pylorus, duodenum, or ileum and jejunum. Rarely, a very dilated C-shaped stomach may be observed in cases of both outlet (pylorus or duodenum) obstruction and inlet obstruction (esophageal atresia). In such cases reflux of fluid from the stomach into the esophagus is not possible.

Location of the Stomach

An abnormal location of the stomach is an important marker of other possible anomalies (Fig. 15-12):

1. Displacement in various directions
 - a. Diaphragmatic hernia
 - b. Subdiaphragmatic pulmonary sequestration
 - c. Adrenal masses
2. Complete situs inversus. Subjects with this anomaly may also suffer from the Kartagener syndrome.
3. Dextrogastrica or left-sided stomach with dextrocardia. These findings are common in the heterotaxy syndrome or polysplenia/asplenia syndrome.
4. Hypoplastic lung

Pyloric Atresia and Epidermolysis Bullosa

The incidence of pyloric atresia is approximately 1:100,000 live births. A familial occurrence has been reported and an autosomal, recessive transmission has been suggested. Associated anomalies have been reported in 30% to 44% of these fetuses.⁴⁸⁻⁵¹ The association with epidermolysis bullosa

FIGURE 15-12. Abnormal location of the stomach. Fetus with a left diaphragmatic hernia. The fluid-filled stomach is not seen in its normal location within the fetal abdomen. The stomach (St) is located within the thorax adjacent to the fetal heart (H). Lu, lung.

requires special attention. Epidermolysis bullosa is an inherited autosomal-recessive disease characterized by increased skin fragility, resulting in blisters and erosions after minor trauma. Mutations in 10 structural genes expressed in the cutaneous basement membrane zone have been reported. The association of epidermolysis bullosa and pyloric stenosis is highly lethal.

Prenatal Diagnosis

1. Dilated stomach and polyhydramnios.
2. Esophageal dilatation due to gastroesophageal reflux (Fig. 15-13).⁵²
3. Markers of skin denudation or blistering in Epidermolysis Bullosa.
 - a. Snowflake appearance of amniotic fluid.⁵³
 - b. External deformities and skin strikingly adhered to various organs.⁴⁸
4. High levels of maternal serum alpha-fetoprotein and acetylcholinesterase in epidermolysis bullosa.
5. DNA analysis and skin biopsy in epidermolysis bullosa.^{48,54}

Intraluminal Gastric Masses

Echogenic masses or debris are sometimes depicted within the fetal stomach (Fig. 15-14). Previously, this finding was mainly reported in fetuses after amniocentesis. It was suggested that these masses are the result of blood and cytogenetic material swallowed by the fetus.^{55,56} Improvement of ultrasound resolution has made it possible to see such masses in many cases in which no amniocentesis was performed. Therefore, it seems that this is a normal finding and any

FIGURE 15-13. Pyloric atresia: *Left*, A large stomach (S) on a transverse section. *Right*, In a sagittal section the severely dilated esophagus (E) is observed. (Courtesy of V. Suma: www.thefetus.net.)

FIGURE 15-14. Intragastric echoes (arrows). *Left*, sagittal section; *Right*, transverse section.

debris or sludge (skin cells, or defecated meconium, for instance) swallowed by the fetus may produce such an ultrasound image.

Gastric Duplication

Gastric duplication accounts for 8% of alimentary tract duplications. They may be either cystic or tubular, and usually appear along the greater curvature of the stomach. The female-to-male ratio is 2:1. In about one half of cases there are associated anomalies. Most common are duplications in other parts of the alimentary tract as well as vertebral anomalies.⁵⁷⁻⁵⁹

DUODENUM

The duodenum can be imaged on a transverse view of the fetal abdomen slightly caudal to the region of the pylorus. It is divided into four parts, with the head of the pancreas located inside the loop (Fig. 15-15). Usually two close echogenic lines are depicted representing the collapsed

duodenum. Levine et al⁶⁰ studied 123 low-risk pregnancies at 16 to 39 weeks' gestation and found a collapsed duodenum in all these cases. They therefore concluded that any distention of the duodenum raises the possibility of a pathologic disorder.

Using transvaginal scanning in early pregnancy, it is our experience that a short transient fluid-filled, almost cystic, dilatation of a part or the whole duodenum may be observed in normal fetuses likely representing a peristaltic wave (Fig. 15-16).

Duodenal Obstruction

Congenital duodenal obstruction has a reported incidence of 1:5000 to 10,000 live births and is the most common cause of fetal small bowel obstruction. The cause of duodenal atresia and stenosis is unknown. Failure of recanalization of the duodenal lumen, or intrauterine vascular ischemia during embryonic life are the most favored theories. The incidence of the anomaly is approximately equal in male and female fetuses and there is no racial predilection.^{61,62}

There are several mechanical factors that may also cause an obstruction of the duodenum.

1. Annular pancreas
2. Intestinal malrotation or volvulus
3. Superior mesenteric artery syndrome⁶³

Statistics

Nearly 70% of fetuses with duodenal obstruction have other structural anomalies, mainly anomalies of the gastrointestinal system and heart. Duodenal obstruction is also part of 23

different syndromes (OMIM, Online Mendelian Inheritance in Man).⁶⁴ One half of the children are born prematurely, and in 75% of cases, polyhydramnios is apparent.

Duodenal atresia is a classic marker of Down syndrome. The reported incidence of Down syndrome in these fetuses is 24% to 35%, with an overall risk ratio of 300.⁶⁵⁻⁶⁹ It is the authors' experience that in early pregnancy, most fetuses with Down syndrome have other associated anomalies, mainly increased nuchal edema. Therefore, in cases of normal biochemical markers and absence of nuchal edema, the risk of Down syndrome in fetuses with isolated duodenal atresia is significantly decreased to a risk ratio of nearly 30.

The outcome of patients with duodenal obstruction relies on the success rate of surgical procedures and severity of associated anomalies. A long-term follow-up over 30 years revealed a mortality rate of 9% and 12% of patients suffering from late complications.⁷⁰

Prenatal Diagnosis

The prenatal sonographic diagnosis of duodenal obstruction has been reported in 87% of cases.⁷¹ It mainly relies on the depiction of the double bubble sign.^{22,23,71-74} Polyhydramnios may also be observed in about 40% of cases mainly in the second half of pregnancy. In the double bubble sign, the dilated stomach and the first portion of the duodenum appear side by side across the midline of the upper fetal abdomen (Fig. 15-17). The double bubble sign has been observed as early as 12 weeks' gestation,^{22,72} however, in many cases, this sonographic sign has been observed only in the second half of pregnancy. The main reason for the late appearance of the double bubble sign is probably related to the hydrostatic pressure needed to dilate the duodenum and the degree of obstruction. In most cases, duodenal atresia occurs below the ampulla of Vater. In order to dilate the first portion of the duodenum above the ampulla of Vater, a large amount of swallowed amniotic fluid is needed in addition to a forward and backward obstruction which prevents the outflow into the intestine and backflow from the stomach to the esophagus. Another possible reason is that earlier in pregnancy, mild dilation of the duodenum is less than the resolution of the transabdominal scanning approach.

FIGURE 15-15. Duodenal distention in a case of jejunal atresia. All parts of the duodenum (1, 2, 3, 4) are distended and encircle the pancreas (P). S, stomach.

FIGURE 15-16. Duodenal peristalsis in early pregnancy. *Left*, A dilated segment of the duodenum (*arrow*) in continuity with the stomach (S). *Right*, After a few seconds the peristaltic wave disappeared.

FIGURE 15-17. The double bubble sign in duodenal atresia. *Left*, The dilated stomach (STO) and duodenum (DU). *Right*, During a peristaltic wave, the communication through the pylorus (p) is observed.

FIGURE 15-18. Transient dilation of the first part of the duodenum (D). S, stomach.

Transient Double Bubble Sign

Sonographic pitfalls in the diagnosis of duodenal obstruction are possible. Zimmer and Bronstein⁷³ reported on three fetuses at 15 weeks' gestation in which a double bubble sign was observed but disappeared on repeated scans after 10 to 15 minutes. All of these fetuses had a normal karyotype and were healthy at delivery. Since this publication, the authors have seen seven more cases of a transient double bubble sign in early pregnancy (Fig. 15-18). In one of these cases, trisomy 21 was detected and in another case the double bubble sign appeared again at 23 weeks' gestation and the fetus was found to have duodenal obstruction. In another case, the dilation of the duodenum remained until week 19 and then disappeared. The newborn was found to be healthy. Therefore, it seems that a transient double bubble sign in early pregnancy is not always an innocent finding and follow-up of these fetuses is mandatory.

FIGURE 15-19. Duodenal duplication cyst. The cystic structure (D) near the stomach (S) was believed to be a dilated duodenum. The correct diagnosis was found in the newborn. G, gallbladder, UV, umbilical vein.

A double bubble sign may also appear in other anomalies of the duodenum and stomach. Malon et al⁷⁵ noted a double bubble sign in a case of duodenal duplication. We also had a fetus with this finding (Fig. 15-19). Yoshizato et al⁷⁶ found a double bubble sign in a case of pyloric stenosis and a dilated gastric antrum (Box 15-1).

Midabdominal Cystic Mass—Differential Diagnosis

The most common disorders to be suggested in cases of an ultrasonic finding of a cystic mass at the midabdominal level are listed in Box 15-2.

In order to facilitate a proper diagnosis the following examinations are suggested:

1. Location of the cystic mass. A cystic finding above the level of the pylorus and posterior to it excludes the possibility of a duodenal anomaly.

BOX 15-1 Duodenal Dilatation: Etiology

1. Duodenal atresia or stenosis
2. Annular pancreas
3. Transient idiopathic dilation⁷³
4. Superior mesenteric artery syndrome⁶³
5. Segmental dilatation of duodenum⁷⁷

BOX 15-2 Midabdominal Cystic Mass: Differential Diagnosis

1. Choledochal cyst
2. Extrahepatic biliary atresia
3. Hepatic cyst
4. Peritoneal/omental cyst
5. Bronchogenic cyst
6. Neurenteric cyst
7. Cystic hygroma
8. Pyloric atresia
9. Pancreatic cyst
10. Intestinal duplication cyst especially those of the duodenum^{78,79}

2. Amniotic fluid level of digestive enzymes. A normal level of digestive enzymes excludes the possibility of extrahepatic biliary atresia. It usually also excludes a duodenal obstruction. A very low level or absence of enzymes is a marker of extrahepatic biliary atresia, whereas an increase in the level of digestive enzymes is expected in obstructions below the ampulla of Vater.
3. Search for associated structural anomalies. An anomaly of the vertebrae may be suggestive of a neurenteric cyst, whereas an anomaly of the diaphragm may serve as a clue to a bronchogenic cyst.
4. Amniotic fluid volume. An increase in amniotic fluid volume is common in obstruction of the gastrointestinal tract, whereas a normal amount of amniotic fluid decreases the probability of such an anomaly.

JEJUNUM AND ILEUM

The jejunum is located in the upper left side of the abdomen, and the ileum is located in the lower right side (Fig. 15-20). In early pregnancy, high-resolution ultrasonography portrays the small intestine as a sac of transparent “worms inside which small pieces of cotton wool move about.” The latter’s density/crowdedness and size differ between fetuses, and quite often within the fetus itself as well.

Up to 17 weeks’ gestation, peristalsis is obvious and full intestinal contents are seen (Fig. 15-21). After 18 weeks, peristaltic movements slow down and a gradual decrease in the intestinal content takes place, which makes the content appear as fluid or mucous. The intestine then remains nearly empty until close to term (Fig. 15-22). Of note, the sonographic features of the intestine rely highly on the resolution of the ultrasound machine used, transducer frequency, and the woman’s body habitus. The intestinal loops of a fetus in an obese woman, for instance, will be hardly depicted in a basic ultrasound scanner, presenting

FIGURE 15-20. The anatomic intra-abdominal location of jejunum and ileum.

FIGURE 15-21. Normal image of small intestine until week 17. It looks like transparent worms inside which small pieces of cotton wool move about.

only an image of “nonhomogenous clouds,” whereas a high-resolution scanner will increase the loops’ echogenicity.

Idiopathic Transient Early Intestinal Fluid Dilatation

Transient slight to moderate intestinal dilatation without intra-abdominal meconium or ascites is not rare in early pregnancy.⁸⁰ It occurs in about 1:400 fetuses at 14 to 17 weeks’ gestation and usually disappears at 18 to 22 weeks’ gestation. Maternal elevated temperature has been reported within 3 weeks of fetal findings in many of these cases. The authors

had more than 80 fetuses with this sonographic finding who had a favorable outcome (Fig. 15–23). Despite this reassuring data, it is suggested to search for possible cystic fibrosis, TORCH infection, and chromosomal anomalies. In addition, a sonographic follow-up until complete disappearance of intestinal dilatation is indicated.

FIGURE 15-22. Normal image of small intestine between weeks 20 and 22. The lumen of the intestine contains a small amount of mucous (arrows).

Jejunioleal Atresia

The jejunioleal atresia rate is 1.3 to 2.9 per 10,000 live births. An association with multiple pregnancies, the black race, vaginal bleeding during pregnancy and low birth weight has been noted.^{63,64,83–85} A hereditary form of intestinal atresia has also been observed.^{86,87} Chromosomal anomalies occur in less than 1% of cases. This is in contrast with duodenal atresia, in which chromosomal anomalies are very common.

An ischemic insult to the developing midgut during fetal development has been widely accepted as the underlying cause of jejunioleal atresia.⁸⁶ The presence of volvulus or intussusception has also been noted in many of these fetuses.⁸⁷ It is still unclear, however, whether these anomalies are the result or the cause of the intestinal atresia.

Jejunioleal atresias are classified as follows (Fig. 15–24):

Type I. This is a mucosal defect resulting in obstruction. The muscular wall is normal with an intact mesentery.

Type II. A fibrous cord connects two atretic bowel ends. The mesentery is intact.

Type IIIa. The two blind ends of the bowel are separated by a V-shaped defect in the mesentery.

Type IIIb. This type is also called “apple peel” or “Christmas tree” atresia. Two blind, completely separated ends of the bowel coiled around a mesenteric vessel.

Type IV. Multiple obstruction of any combination of types I to III.

Traditionally, jejunal and ileal atresia have been grouped together as intestinal atresia. However, there are data indicating that jejunal and ileal atresias may be considered as separate diseases. First, jejunal atresia is twice as common

FIGURE 15-23. Idiopathic transient dilatation of small bowel (arrows) in four different fetuses between weeks 14 and 16.

FIGURE 15-24. Graphic presentation of jejunoileal atresia: type 1 (A); type 2 (B); type 3a (C); type 3b (D); and type 4 (E). (From Donnelly LF, Jones BV, O'Hara SM, et al [eds]: *Diagnostic Imaging, Pediatrics*. 1st ed. Salt Lake City, Amirsys Inc., 2005, p. 18.)

FIGURE 15-25. Jejunol atresia. *Left*, Fetal stomach. *Middle*, Perigastric, very dilated bowel loops. *Right*, Autopsy demonstrating the abnormal loops. (Courtesy of F. Cuillier; www.thefetus.net.)

as ileal atresia. Second, Heij et al⁸⁸ and Sweeney et al⁸⁹ found that many cases of jejunal atresia were multiple atresias as opposed to an ileal atresia that had a single atresia in the vast majority of cases. Sweeney et al⁸⁹ noted an associated anomaly in only 1 of 45 patients with ileal atresia as opposed to 16 of 38 patients with jejunal atresia who had associated anomalies (cystic fibrosis, malrotation, congenital heart disease, Down syndrome, anorectal and vertebral anomalies, neural tube defect, and microcephaly). Third, antenatal perforation occurred rather frequently in ileal atresia but was significantly less common in jejunal atresia.⁸⁸

Prenatal Diagnosis

Sonographic features of intestinal atresia have been observed in 51% to 86% of fetuses in different series. The most common sonographic markers are hyperechogenic bowel, enlarged stomach, dilated bowel, intraperitoneal echogenic material, and polyhydramnios.⁹⁰⁻⁹³ However, it is of importance to note that there are differences between jejunal and ileal atresia. The jejunum has a higher compliance and therefore marked dilatation of the intestinal loops, enlarged stomach, and polyhydramnios are common (Fig. 15-25). In contrast, the compliance of the ileum is much lower and

Table 15-1 Sonographic Comparison Between Jejunal and Ileal Atresia in the Second Half of Pregnancy

	Intestinal Loops	Stomach	Peritoneal Calcification	Ascites	Associated Anomalies	Polyhydramnios
Jejunum	Marked dilation of loops, most of them on the left abdominal side. Enlargement of duodenum is common.	Large	Frequent	Very rare	Frequent	Frequent
Ileum	Usually only minor dilation of a few loops.	Normal	Frequent	Frequent	Rare	Rare

**FIGURE 15-26.** First clue of jejunal obstruction at week 15. An hyperechogenic rim is observed (arrows). Left, Transverse section. Right, Sagittal section. D, diaphragm.

most of the fluid passing in the intestine has already been absorbed. Therefore, perforation is more common, but dilation of the loops, changes in configuration of stomach and polyhydramnios are less common or even not observed.

Sonographers should be aware that in many cases of jejunoileal atresia the sonographic findings are noted only in the third trimester of pregnancy. In contrast, normal dilatation of intestinal loops in early pregnancy may actually occur during peristaltic movements. Repeated scans for several minutes are advocated in such cases to exclude the possibility of a false-positive diagnosis of intestinal obstruction (Table 15-1).

The following case presents the development of jejunal obstruction in early pregnancy; at 15 weeks' gestation, peritoneal calcifications were observed (Fig. 15-26). Amniocentesis for digestive enzymes revealed very high levels of liver enzymes suggesting an obstruction in the upper gastrointestinal tract. At 19 weeks' gestation ultrasound depicted marked dilation of the whole duodenum (but not of the jejunum) with a normal stomach and amniotic fluid volume (Fig. 15-27). The pregnancy was terminated and the post mortem examination revealed an apple peel atresia (Fig. 15-28). It seems therefore that in early pregnancy, dilation of the duodenum may precede the dilatation of the obstructed jejunum.

Meconium Ileus

Meconium ileus describes a condition in which a meconium plug obstructs the small intestine. Cystic fibrosis is the leading cause of meconium ileus. Although virtually all

**FIGURE 15-27.** Jejunal obstruction at week 19. The four dilated parts of the duodenum (1, 2, 3, and 4). The echogenic deposits are marked by arrows. S, stomach.

patients with meconium ileus will be shown to have cystic fibrosis, only approximately 15% to 20% of infants with cystic fibrosis present with intestinal obstruction related to meconium ileus.^{94,95} Other possible but less frequent reasons for meconium ileus are cytomegalovirus and syphilis.^{96,97}

Occasionally, no cause is determined and the disorder is regarded as idiopathic.

The main prenatal sonographic marker is hyperechogenic bowel with dilated loops containing meconium. Less specific markers are intraperitoneal echogenic material, ascites, dilated bowel loops, and meconium pseudocysts.^{94,95,98} In cases of cystic fibrosis, nonvisualization of the gallbladder may also be noted.⁹⁵ These sonographic findings may also present in cases of bowel perforation and an accurate differential diagnosis is therefore not always possible. A search for cystic fibrosis, TORCH, digestive enzymes, and fetal karyotype is therefore indicated.

BOWEL PERFORATION

Meconium Peritonitis

The incidence of intrauterine bowel perforation is 3.3 in 100,000 births.^{95,98} The underlying cause of perforation is unknown in the vast majority of cases. Possible causes are stenosis, atresia, volvulus, intussusception, cystic fibrosis,⁹⁵

and infections such as parvovirus B19, cytomegalovirus and hepatitis.⁹⁹⁻¹⁰¹

Traditionally, the term meconium peritonitis is used because it is believed that the leakage of meconium into the fetal abdomen leads to an aseptic chemical inflammation. In our experience in early pregnancy (52,000 examinations between weeks 14–16), the incidence of meconium spillage into the peritoneal cavity is 1:1000, and 20% of these occurrences are associated with gross structural anomalies.

Prenatal Diagnosis

The main sonographic markers reported in the literature are intraperitoneal calcifications, hyperechogenic dilated bowel loops, ascites, and polyhydramnios.^{98,102-105} It is our experience that the calcified meconium may present in several forms: as a continuous curvilinear form on the entire border of the peritoneum (“Sock-like” appearance) (Figs. 15–29 and 15–30); in a scattered form (Fig. 15–31); and as an isolated focus. The most frequent location of the focus is in the left upper abdominal quadrant behind the stomach (Fig. 15–32).

FIGURE 15-32. Perigastric calcification (arrows) projecting an acoustic shadow. S, stomach.

Meconium Cyst/Pseudocyst

Another sonographic appearance of bowel perforation is a meconium cyst or pseudocyst. It usually appears in early pregnancy as a cyst encircled by an hyperechogenic rim or bright spots with acoustic shadows behind them (Fig. 15-33). In some cases the cyst resolves later in pregnancy and the sonographic image resembles hyperechogenic bowel.

We recommend dividing cases of bowel perforation into two groups:

Primary or Idiopathic Perforation of Bowel Without Intestinal Obstruction. Primary or idiopathic perforation of bowel represents 96% of cases of bowel perforation. All of them appear in the first and early second trimester. The only sonographic finding is intraperitoneal calcifications. There is no evidence of ascites, polyhydramnios, or dilation of bowel loops. Intrauterine spontaneous sealing of the perforation occurs in most cases, and there are no clinical nor histologic findings of peritonitis in the fetus. The infants outcome is favorable and the only clue to an intrauterine episode of

bowel perforation is the postnatal radiographic finding of intra-abdominal calcifications.

Secondary Perforation of Bowel. Secondary perforation of bowel is a result of intestinal obstruction due to intestinal atresia, volvulus, cystic fibrosis, and so forth. It is uncommon and usually appears only in late pregnancy. The main sonographic findings are ascites, polyhydramnios, dilatation of bowel loops, and intraperitoneal calcifications.

Removal of debris and reduction of the intra-abdominal pressure may improve the mesenteric vascular supply for healing of the ruptured intestinal hole. It may also reduce lung compression and prevent pulmonary hypoplasia.¹⁰⁶ Postnatal surgery is mandatory in infants with clinical manifestation of bowel perforations or obstruction. The survival rate in most series is high (Box 15-3).^{98,102-105}

Meckel Diverticulum

Meckel diverticulum (Fig. 15-34) is apparent in 2% of the population and is regarded as the most common congenital anomaly of the gastrointestinal tract.^{107,108} The diverticulum that protrudes from the distal part of the ileum is a remnant of the embryonic yolk sac, which may also be referred to as the omphalomesenteric duct or vitelline duct. It usually contains all layers of the intestine but heterotopic tissue may also be present. Recently, Park et al¹⁰⁹ reviewed the records of 1476 patients in whom a Meckel diverticulum was found during surgery. Only 16% of cases were symptomatic. The most common clinical presentation in adults was bleeding and obstruction in children. Among the symptomatic patients, the male-to-female ratio was approximately 3:1. Being a common anomaly, it is of interest that only few cases have been detected in utero. It can therefore be suggested that the vast majority of these diverticulae are asymptomatic in the fetus and their sonographic features are similar to those of normal intestine.

Prenatal Diagnosis

Meckel diverticulum may be visualized only in cases of obstruction or intussusception. Even in these cases, the sonographic appearance is not characteristic and presents as

FIGURE 15-33. Shrinkage of a meconium cyst (arrow) throughout gestation.

BOX 15-3 Suggested Workup in Fetuses with Intra-abdominal Calcifications

1. Detailed scanning of all fetal organs including echocardiography
2. Search for cystic fibrosis

4. Fetal karyotype
5. Evaluation of digestive enzymes level in the amniotic fluid.

an intra-abdominal cyst or dilated bowel with various types of echogenicity and content, with or without peristalsis (Figs. 15-35 and 15-36).^{110,111}

Small Intestine Duplication

Duplications may occur along the entire length of the gastrointestinal tract but are most common in the small intestine, in particular the terminal ileum, which represents more than 70% of the small intestinal duplications. They usually lie on the mesenteric side of the bowel, and their size can be only a few millimeters or as long as the whole

intestine. The most common clinical findings in neonates and infants are vomiting, abdominal distention, volvulus, and intussusception.^{27,112}

The prenatal differential diagnosis is not always easy and includes other intra-abdominal cystic anomalies.^{28,113,114} The following factors may expedite a more definitive diagnosis of a duplication cyst:

1. Depiction of peristalsis in the cyst wall is highly suggestive of an intestinal origin
2. Early appearance (in the first and early second trimester)
3. Single loop dilatation

Congenital Intestinal Pseudo-Obstruction

Congenital intestinal pseudo-obstruction (CIPO) is a rare condition with an incidence of less than 1:100,000. It is characterized by recurrent episodes of intestinal paralytic obstruction with no causative mechanical factor. Visceral neuropathy or myopathy has been detected in many but not all cases. Associated urologic disorders are very common, mainly megacystis and in utero hydronephrosis. Parents should be informed that despite progress in treatment, the reported incidence of mortality is up to 25%.¹¹⁵⁻¹¹⁷

FIGURE 15-34. Meckel diverticulum: various morphologic forms. (From netterimages.com, with permission.)

The characteristic findings on prenatal ultrasound are moderately dilated intestinal fluid-filled loops with reduced or absent peristalsis (Fig. 15-37). Polyhydramnios and megacystis may be observed in many of the cases.¹¹⁵ Of note, there are no ascites or meconium in the peritoneum, which is of help in the differential diagnosis from jejunoileal atresia. Other differential diagnoses to be considered are Hirschsprung disease and congenital chloride diarrhea.

Congenital Chloride Diarrhea

Congenital chloride diarrhea is an autosomal-recessive disorder of chloride transport in the distal ileum and colon. It is characterized by life-long watery diarrhea of prenatal onset with high fecal chloride concentration. The anomaly is very rare. However, a high incidence of 1:3200 to 13,000

was reported in Kuwait and Finland.^{118,119} On ultrasound, polyhydramnios and slight-to-moderate distension of intestinal loops with peristalsis are observed (Fig. 15-38).

The differential diagnosis from CIPO relies on the presence of peristalsis as opposed to reduced or absent peristalsis in CIPO. The disorder should also be differentiated from jejunoileal atresia, in which intestinal loops distention is much more obvious and ascites and intraperitoneal meconium are apparent in many cases (Table 15-2).¹²⁰

COLON

It is difficult to sonographically differentiate between the small intestine and colon in the first half of pregnancy. The diagnosis is mainly based on the peripheral location of the colon. Later in pregnancy, the haustral folds may be

imaged. The rectosigmoid may be depicted by transvaginal ultrasound in the first trimester as an echogenic structure below the urinary bladder. Later its lumen becomes visible. Nomograms of the diameters of the descending colon and the rectum in the second half of pregnancy are currently available (Figs. 15-39, 15-40, and 15-41).¹²⁰ Normally, there is some sludgy content in the colon (Figs. 15-42 and 15-43), whereas the detection of increased fluid in the colon raises the possibility of a pathologic process.

Presently, there are very few and controversial reports on fetal colonic peristalsis. Although no colonic peristalsis was detected in a number of published studies,^{122,123} according to our experience, high resolution ultrasound is capable of revealing active peristalsis of the rectosigmoid as early as at 22 and 23 weeks of gestation.

FETAL DEFECACTION

Passage of meconium in utero is a frequent finding in the last weeks of pregnancy. Its incidence increases with advancing gestational age. A widely accepted concept suggests that fetuses do not normally defecate, and that the presence of

meconium-stained amniotic fluid implies fetal hypoxia.¹²⁴ However, there are some publications indicating that fetal defecation is a physiologic event. Animal models have demonstrated defecation to be independent of fetal distress.^{125,126} Ramon et al¹²⁷ observed fetal defecation throughout pregnancy in humans. They defined fetal defecation as the expulsion of rectal content through the anus into the amniotic fluid. The diameter and area of the anus were measured sonographically at times of maximum anal aperture in 240 fetuses between 15 and 41 weeks of gestation. One or more defecations were noted in all fetuses. The frequency of defecation was highest between weeks 28 and 34 of gestation. The expulsion of meconium has also been observed using color Doppler imaging (Fig. 15-44), and three- and four-dimensional ultrasonography.¹²⁸

Authors' opinion: We agree that fetal defecation is a physiologic process that occurs throughout pregnancy. The main issues strengthening this belief are related to the

following facts: In all early pregnancies, we see a variable amount of echogenic sludge in the amniotic fluid, using high frequency vaginal transducers (Fig. 15-45); the features and echogenicity of this sludge are similar to those of the meconium inside the fetal intestine; the echogenic debris which is sometimes detected in the fetal stomach also has an appearance similar to meconium (see Fig. 15-14). It is therefore possible that the fetus that is known to swallow its amniotic fluid also swallows its own meconium. In very rare occasions, it is possible to visualize the defecation process in the young fetus (Fig. 15-46). There is a correlation between the levels of intestinal and liver enzymes and normal or abnormal fetal defecation process in early and midpregnancy.¹²⁹

Hirschsprung Disease

Hirschsprung disease is caused by an abnormal innervation of the bowel beginning in the internal anal sphincter and

Week of gestation	Number	Descending colon diameter (mm)		Rectal diameter (mm)

extending proximally to involve a variable length of gut. It is the most common origin of intestinal obstruction in neonates with an incidence of 1:5000 live births. Male fetuses are affected more often than female fetuses (4:1). Associated anomalies are observed in 11% to 22% of cases, and trisomy 21 is detected in 3% to 10% of affected infants. Genetic factors appear to play a role in the disease with a familial history in about 5% of cases. The mortality rate of this pathology is 16% to 17%.^{130,131}

Prenatal Diagnosis

Only few reports on the prenatal sonographic diagnosis of the disease have been published.^{132,133} The main sonographic markers of this disorder are nonspecific, namely, bowel distention and polyhydramnios (Fig. 15-47). The correct diagnosis is usually made only in the first weeks of neonatal life.

FIGURE 15-47. Hirschsprung disease, third trimester. Multiple dilated loops. (Reproduced with permission from L.F. Goncalves, www.thefetus.net.)

FIGURE 15-48. Hirschsprung disease at week 16. The dilated descending colon is marked by arrows.

We have observed two cases in which dilated hyper-echogenic bowel was detected at 15 weeks' of gestation (Fig. 15-48); along with other sonographic structural anomalies. Amniocentesis revealed trisomy 21 in both cases, and an aganglionic colon was found on post-mortem examination after termination of pregnancy. Thus, the echogenic intestine depicted in some fetuses with Down syndrome may actually represent Hirschsprung disease.

ANAL ATRESIA

Anal atresia is the most frequent congenital anal anomaly, with an incidence of about 4:10,000 births. It may be subdivided into a high, low, and intermediate atresia according to the termination of the anal canal relatively to the levator ani muscle.^{134–136} Anal atresia has been described in more than 50 syndromes and malformative disorders, the most common being VATER and VACTER associations.^{64,134–136}

Out of 1425 cases of anal atresia observed in the EUROCAT survey,¹³⁵ 36% were isolated and 64% were accompanied with other malformations. High atresia was present in 10% of cases, whereas low atresia was present in 90% of cases. Forrester and Merz,¹³⁶ evaluating the data of 124 cases, found chromosomal anomalies in 8.1% and a family history in 2.4%. Stoll et al¹³⁴ reported that the recurrence risk for first degree relatives of probands was 3.7%, with the prevalence rate of nonanal atresia malformations being more than twice as high as that in controls.

FIGURE 15-49. Autopsy at week 17. The arrow points toward the anal membrane. (Courtesy Dr. Lisa L. Maroun.)

Prenatal Diagnosis

Because anal atresia may be present in cases of VATER/VACTER association, the demonstration of anomalies mainly in the vertebrae, heart, kidney, limbs, and esophagus should alert the sonographer to the possibility of anal atresia (Fig. 15-49). Currently, the prenatal detection rate of anal atresia is still low. Stoll et al⁹¹ reported a detection rate of only 8.2%.^{7,63} Most publications are actually case reports, and some of them are observations made in early pregnancy.

The main sonographic markers of anal atresia include^{137–143} dilated fetal intestinal loops with fluid inside the lumen (Fig. 15-50); a U- or V-shaped segment of distal bowel in the lower abdomen or pelvis, separated from the bladder with mild ascites; and intraluminal colonic calcifications, which probably represent enterolithiasis. The enterolithiasis is most likely the result of solidification and condensation of the stacked meconium (see Figs. 15-50 and 15-51).

The authors¹⁴⁴ have observed a fetus in which dilation of the bowel was noticed at 15 weeks of gestation. Although no intestinal anomaly could be detected on monthly follow-up scans, anal atresia was found in the newborn after delivery. Taipale et al¹⁴³ reported a fetus with an imperforate anus in which dilated bowel was first detected at 12 weeks of

FIGURE 15-51. Anal atresia at week 16. The enterolithiasis in the dilated descending colon is marked by arrows. S, stomach.

FIGURE 15-50. Anal atresia at week 15. Two sagittal sections of the same fetus. The dilated, fluid-filled rectosigmoid and descending colon is marked by white arrows. In the right figure, the enterolithiasis is marked by a black arrow.

gestation and then again in the third trimester. However, in the second trimester, the intestine appeared to be of normal size. It seems, therefore, that dilatation of the bowel in early pregnancy is a possible marker for anal atresia and the anomaly may be overlooked if only a midpregnancy ultrasound examination is performed. We believe that in the future, the studies of digestive enzymes in the amniotic fluid will be included in the work-up of fetuses with an intestinal dilation at early stages of pregnancy, as this examination has proved to be most helpful in the diagnosis of anal atresia.¹²⁹

HYPERCHOGENIC BOWEL

Sonographic Definition

The echogenicity of the intestine approaches that of surrounding bone (Fig. 15-52).

FIGURE 15-52. Hyperechogenic bowel (EB). The echogenicity of the bowel (*thin arrows*) is similar to that of the femur (F and *bold arrow*).

Prevalence is 0.2% to 1.8% in second trimester fetuses. The lack of a reliable objective method to evaluate bowel echogenicity leaves the diagnosis of this anomaly entirely in the hands of the subjective interpretation of the observer. The original description of increased bowel echogenicity used relatively low frequency transducers without newer harmonic imaging signal processing. Thus, one's own subjective assessment of bowel echogenicity and the artificial enhancement of transducer frequency, gain, and image processing may have an apparent impact on the interpreted echogenicity level of the bowel (Fig. 15-53).¹⁴⁵⁻¹⁴⁹ It is therefore critical that the diagnosis of hyperechogenic bowel is made only by experienced and highly skilled sonographers who use ultrasound machines with which they are familiar (Tables 15-3 and 15-4).

Summary

The diagnosis of hyperechogenic bowel should be made by experienced sonographers who are quite familiar with their ultrasound machines. In cases of hyperechogenic bowel, a search for structural anomalies, chromosomal disorders, infections, and cystic fibrosis should be performed. If these disorders are excluded and the maternal alpha-fetoprotein is normal, parents can be counselled that there is a very high probability of a favorable fetal outcome.

Volvulus

Volvulus is a condition in which bowel loops twist around the mesenteric artery or its branches. The ischemic necrosis may lead to intestinal atresia. It is, however, also possible that intestinal atresia develops first and is complicated by volvulus because of increased peristalsis in the dilated intestine proximal to the site of atresia. The incidence of fetal volvulus is difficult to determine because most data comes from case

FIGURE 15-53. The impact of ultrasound frequency on bowel echogenicity. *Left*, Echogenic bowel (*arrow*) depicted by high frequency transvaginal ultrasound. *Right*, Transabdominal scanning with lower frequency of the same fetus did not show bowel increased echogenicity.

reports. Of note however is the study of Komuro et al,⁸⁷ who found a volvulus in 14 of 48 newborns with jejunal atresia.

The characteristic sonographic marker of volvulus in fetuses and children is the whirlpool sign. The twisted bowel loop and its accompanying mesentery and mesenteric vessels exhibit a whirlpool-like configuration (Fig. 15-54).¹⁶²⁻¹⁶⁵ Color

Doppler imaging may facilitate the diagnosis by visualizing the twisted mesenteric vessels.^{162,163} Sonographers should be aware that the whirlpool sign is not depicted in all cases of fetal volvulus. In some instances the sonographic appearance is nonspecific, in which dilated loops of bowel, ascites, intra-abdominal cystic mass, and polyhydramnios are seen.^{166,167}

Table 15-3**Physical Causes for Increased Echogenicity of the Bowel**

1. Swallowed blood and/or meconium. Both of these matters will make the intestine seem hyperechogenic once they reach it. Prospective studies have shown that amniocentesis, chorionic villus sampling, and umbilical cord puncture during intrauterine transfusions are associated with an increase in bowel echogenicity up to 4 weeks following the procedure.^{150,151}
2. Thick meconium (constipation). Transient constipation is probably the most common reason for hyperechogenic bowel in normal fetuses. It is also a significant marker of cystic fibrosis.
3. Fluid inside or outside the intestine or in the intestinal wall. The echogenicity in such cases is the result of the different acoustic impedance of the adjacent media (that is, intestinal tissue versus fluid). The main clinical disorders are infection, obstruction with or without perforation, Hirschsprung disease, and intestinal ischemia.
4. Meconium between bowel loops. On ultrasound, meconium outside the intestine is more echogenic than meconium inside the intestinal lumen, and usually occurs in cases of obstruction or cystic fibrosis, although in many cases the reason for it is unknown.

FIGURE 15-54. Volvulus: Dilated bowel loop showing a whirlpool-like configuration, at week 34. (From Has R, Gunay S: 'Whirlpool' sign in the prenatal diagnosis of intestinal volvulus. *Ultrasound Obstet Gynecol* 20:307, 2002.)

Table 15-4**Clinical Causes of Hyperechogenic Bowel**

1. Transient, benign and idiopathic. We believe that the underlying cause of hyperechogenic bowel is transient constipation in the fetus with no clinical implications.
2. Chromosomal disorders. Chromosomal anomalies, especially trisomy 21, have been observed in fetus with an hyperechogenic bowel.¹⁵²⁻¹⁵⁷ It has been suggested that in aneuploid fetuses bowel motility is decreased, leading to increased water absorption from meconium and constipation. Actually, Hirschsprung disease is common in trisomy 21. The hyperechogenic bowel appears with other structural anomalies in many aneuploid fetuses. However, an isolated finding of hyperechogenic bowel is also associated with an increased risk of chromosomal anomalies.^{154,156}
3. Cystic fibrosis. The abnormal pancreatic enzymatic secretion and the thick viscous meconium may cause meconium ileus and even perforation. Cystic fibrosis has been reported in 0% to 13% of fetuses with hyperechogenic bowel.^{152-155,157} The differences between studies probably reflect the considerable ethnic variation of this disease. In the white population, the incidence is 1:2500 to 5000, whereas in Asian Americans, it is 1:35,000.¹⁵⁸ The risk of cystic fibrosis is much higher if the parents are carriers of the disease, although the absence of familial history does not preclude the possibility that the fetus is an index case.
4. Infection. Cytomegalovirus is the most common infection leading to paralytic ileus and perforation. However, hyperechogenic bowel has been reported in association with many other infections such as toxoplasma, rubella, varicella, and herpes simplex.^{155,157} Of note, despite these data there are recent large studies in which only very few or no infections at all were found in fetuses with hyperechogenic bowel.^{153,155}
5. Intrauterine growth restriction. Restriction of blood supply and bowel ischemia in these fetuses is probably the reason of the hyperechogenic appearance of the bowel.^{153,154,157,159} Doppler studies in intrauterine growth restriction fetuses with hyperechogenic bowel revealed a significant decrease in the pulsatility index in the superior mesenteric artery and celiac trunk.¹⁶⁰
6. Intrauterine fetal demise. Intrauterine fetal demise was reported in up to 5.8% of fetuses with an hyperechogenic bowel.¹⁵⁹ The echogenicity of the bowel is probably a result of hypoperfusion and bowel ischemia.
7. Thalassemia. Fetuses affected by homozygous alpha-thalassemia-1 are severely anemic and hypoxic. Hyperechogenic bowel has been observed in up to 31% of these cases.¹⁶¹ Therefore, it is recommended to examine high-risk populations with fetal hyperechogenic bowel for thalassemia.

Intrauterine Intussusception

Intrauterine intussusception is regarded as an uncommon clinical finding, accounting for only few cases of neonatal intestinal obstruction (Shimotake). Therefore, of interest is the report of Komuro et al⁸⁷ who found intussusception in 12/48 cases of neonatal jejunoileal atresia. The prenatal sonographic findings are usually nonspecific, namely ascites, dilated bowel loops, and features of meconium peritonitis.¹⁶⁸⁻¹⁷⁰ Shimotake et al¹⁶⁹ reported on a fetus in whom, in addition to the above-mentioned sonographic findings, they also detected a “target-like” appearance suggestive of intrauterine intussusception in the abdomen.

Malrotation

Malrotation of the intestine occurs as a result of failure of normal intestinal rotation and fixation, which usually is completed by the 12th week of gestation (Fig. 15-55). The reported incidence of the anomaly is as high as 2.86 per 10,000 live births and fetal deaths, and about 90% of symptomatic cases are discovered by the first year of life.¹⁷¹ The incidence of associated anomalies is very high reaching 94% in a large series.¹⁷¹ The most common anomalies are in the gastrointestinal tract mainly volvulus, diaphragmatic hernia, abdominal wall defects, heterotaxia syndrome, and situs inversus.¹⁷¹⁻¹⁷⁶ The prenatal sonographic diagnosis has been reported in few cases, relying on nonspecific markers such as dilation of bowel loops (Fig. 15-56), ascites, intra-abdominal cysts, situs inversus, and displacement of the fetal stomach.^{174,177-179}

Cloacal Dysgenesis Sequence

Cloacal dysgenesis sequence is a very rare anomaly defined as absence of anal, genital, and urinary orifices associated with smooth perineum. More than 80% of fetuses also have other major anomalies, mainly absent or dysplastic kidneys, hydroureters, megacystis, and pulmonary hypoplasia. Ultrasound may reveal a dilated fluid-filled colon with enterolithiasis, cystic structures in the pelvis, abnormalities of the genitalia and urinary tract, and oligohydramnios (Fig. 15-57).¹⁸⁰⁻¹⁸²

Suspected Pathology of the Gastrointestinal Tract: A Practical Approach (The 12 Commandments)

1. Intestinal dilatation. The most common associated problems are
 - a. Cystic fibrosis. In 75% of cases with this disease the fetal gallbladder will not be seen, and there is a low level of digestive enzymes.
 - b. Intrauterine infections—mainly TORCH
 - c. Structural anomalies. Detailed scanning of all fetal organs is mandatory. Special attention should be paid to the heart, genitalia, urinary tract, and umbilical cord.
 - d. Chromosomal anomalies.
2. Intestinal content
 - a. It should be remembered that in a dilated and obstructed intestine there is usually a problem with fluid absorption. Therefore, the presence of solid intestinal contents (excluding cases of cystic fibrosis) decreases significantly the probability of pathology.
 - b. The presence of enterolithiasis in a fluid-filled segment of the colon is suggestive of anal atresia or a fistula between the urinary system and colon.
3. Ascites
 - a. Ascites is the most significant marker of bowel perforation, especially if an increase in its amount is noted with progress of pregnancy. The ascites in such cases might be a solitary finding or present with bowel dilation and peritoneal calcifications.
 - b. Ascites may not present in perforation of the upper gastrointestinal tract, especially in early pregnancy.
4. The length and width of dilated bowel loops
 - a. An isolated dilation of a single loop, especially if depicted in early pregnancy, raises the possibility of a duplication cyst, particularly if debris is present within the cyst.
 - b. The more proximal the obstruction, the larger the diameter of the dilated loops. The largest dilations will be noted in those loops located on the left side of the fetus (the jejunum).^{29,31-33}
 - c. In cases of both proximal and distal obstruction of the stomach, a huge C-shape fluid filled stomach will appear.
 - d. After exclusion of cystic fibrosis, the presence of solid content in dilated loops (especially of the colon) usually has a good prognosis. In contrast, fluid-filled dilated loops are a marker of a pathologic process.
5. Anatomy and physiology
 - a. The presence of clear fluid in the colon and rectosigmoid (albeit a transient event) raises the possibility of anal atresia.
 - b. Dilation of the transverse colon in the second half of pregnancy is usually a normal physiologic finding as long as the small intestine seems normal.
 - c. Depiction of a distended duodenum around the pancreas is a marker of an obstruction.
 - d. It is currently impossible to know with certainty whether only one intestinal obstruction takes place, and unfeasible to pinpoint the precise location of the obstruction, and the length of the atretic intestine.
6. Peristalsis
 - a. Today no standardized method exists that quantitatively assesses peristaltic movements, and activity is assessed subjectively.
 - b. The presence or absence of peristalsis is a possible sonographic marker in many differential diagnoses. It serves as a definitive diagnostic finding only in cases of CIPO and congenital chloride diarrhea.
7. Intraperitoneal calcifications
 - a. In cases of an isolated finding of intraperitoneal calcification, a search for chromosomal anomalies, cystic fibrosis, infections, and digestive enzymes should be performed. Should all these tests prove normal, the probability of pathology in the newborn is very low.
8. Amniotic fluid volume
 - a. There might not be an increase in amniotic fluid volume in cases of gastrointestinal obstruction.

FIGURE 15-55. Process of physiologic herniation and reduction. At the beginning of the 8th menstrual week, a loop of midgut herniates into the proximal umbilical cord (A). The relationship to the superior mesenteric artery (SMA) to the bowel is illustrated in A1. At a later stage (B), the midgut begins to rotate 90 degrees counterclockwise (B1). At about the 12th menstrual week, the midgut returns to the abdomen (C and D), and at the same time progressive counterclockwise rotation occurs until the midgut has undergone a total of 270-degree rotation (C1 and D1). The final position of the cecum in the right lower quadrant is achieved later in the fetal period (E). (From Moore KL, Persaud TVN: *The Developing Human: Clinically Oriented Embryology*. Philadelphia, WB Saunders, 1998.)

- b. If there is an increase in amniotic fluid volume, it usually starts in the second half of pregnancy.
 - c. Upper gastrointestinal obstruction (esophagus, stomach, duodenum, and jejunum) are quite often associated with polyhydramnios. In contrast, polyhydramnios is much less common in low gastrointestinal obstructions (ileum, colon, rectum, and anus).
 - d. Polyhydramnios is common in congenital systemic diseases of the bowel (CIPO and congenital chloride diarrhea).
 - e. The presence of “snowflakes” in the fluid is suggestive of epidermolysis bullosa in cases of pyloric atresia.
9. Digestive enzymes in the amniotic fluid
- a. Digestive enzymes of the intestine and liver can be examined at 18 to 22 weeks' gestation.
 - b. A very low level of enzymes is suggestive of biliary atresia or cystic fibrosis.
 - c. A very high level of enzymes is suggestive of an obstruction of the duodenum or jejunum below the ampulla of Vater, and fetal vomiting.

- d. A normal level of enzymes reduces significantly the probability of biliary atresia or intestinal obstruction.
10. MRI
- There are at present no convincing studies that MRI is better than ultrasound in the detection of gastrointestinal obstruction. We believe that in the future, MRI will be of value in the differential diagnosis between tubular duplications of the gastrointestinal tract, and other intra-abdominal echogenic findings. It will probably also be of help in the diagnosis of intra-hepatic solid tumors and bleeding.
11. Ultrasound machines
- Sonographers are advised to make habitual use of the machines they have grown accustomed to, as transducer frequency and gain and image processing can artificially enhance the apparent level of echogenicity of the bowel, leading to misinterpretation of sonographic findings.
12. Parents consultation
- We are still in the process of becoming familiarized with the various anomalies of the digestive system. Because a large portion of them bear resemblance to each other and share the same sonographic markers, making precise diagnoses is sometimes unfeasible, and parents should be informed of all possible differential diagnoses including normal outcome.

FIGURE 15-56. Malrotation at week 28. An amorphous mass (AM) and dilated colon.

LIVER

The liver is an asymmetric structure. Its upper border is at the diaphragm. In a midclavicular parasagittal section of the right chest and abdomen the upper third is occupied by the lung, the middle third is occupied by the liver and the lower third is occupied by the intestine. In a midclavicular parasagittal section of the left chest and abdomen the upper third is occupied by the lung, about a quarter is occupied by the liver, and the remaining is occupied by the stomach and intestine. Sonographic differentiation between the fetal right and left lobes is not possible. An increase in the ultrasound attenuation coefficient of the liver as a function of gestational age has been observed. It has been suggested that this change is related to the increase in glycogen storage in the fetal liver.^{183,184}

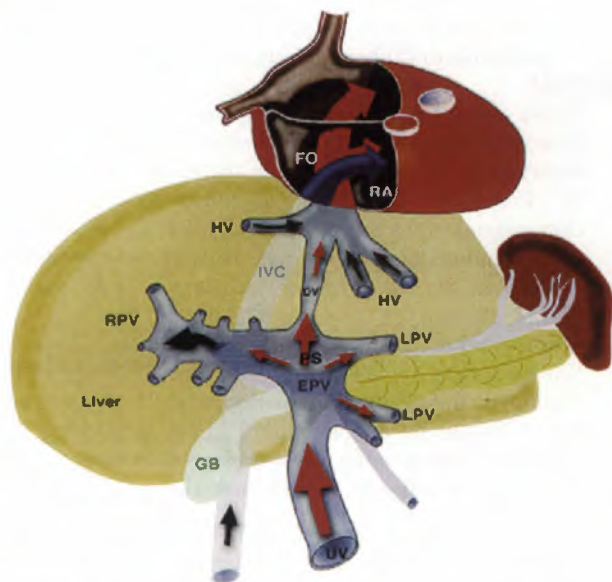

FIGURE 15-58. Schematic representation of the fetal umbilical, portal and hepatic venous circulations. The arrows indicate the direction of blood flow and the color, the degree of oxygen content (red, high; purple, medium; blue, low). The arrows indicate the direction of blood flow. DV, ductus venosus; EPV, extrahepatic portal vein; FO, foramen ovale; GB, gallbladder; HV, hepatic veins; IVC, inferior vena cava; LPV, left portal vein; PS, portal sinus; RA, right atrium; RPV, right portal vein; UV, umbilical vein. (From Mavrides E, Moscoso G, Carvacho JS, et al: *The anatomy of the umbilical, portal and hepatic venous systems in the human fetus at 14–19 weeks of gestation. Ultrasound Obstet Gynecol* 18:598, 2001.)

Hepatic Circulation

A schematic representation of the venous circulation is presented in Figure 15-58. There is an oblique insertion of the umbilical vein into the liver. Inside the liver there is a trifurcation—right and left portal veins, and the ductus venosus, which continues to the inferior vena cava (Fig. 15-59).

Hepatic Volume

The fetal hepatic volume may be estimated through measurements of hepatic length, circumference, and area using two- and three-dimensional ultrasound. Several studies have shown a high correlation among the liver volume, gestational age, and fetal weight in normal fetuses, whereas in small-for-gestational-age fetuses, the liver volume is decreased.¹⁸⁵⁻¹⁸⁸ Of note, because of the asymmetric configuration of the liver, accurate measurements of the liver dimensions is not a simple task in daily practice, and many sonographers assess the liver's size subjectively.

Hepatomegaly

Hepatomegaly, or hepatosplenomegaly, may be present in severe isoimmunization, congestive heart failure, infections, macrosomia, neoplasms, metabolic disorders such as Gaucher disease,¹⁸⁸ pyruvate kinase deficiency,¹⁹⁰ syphilis,¹⁹¹ and overgrowth disorders like Beckwith-Wiedemann syndrome. Hepatosplenomegaly with and without hydrops is a possible marker of Down syndrome. Several studies have shown that

FIGURE 15-59. Hepatic venous circulation in a transverse/diagonal section. DV, ductus venosus; LPV, left portal vein; RPV, right portal vein; S, stomach; UV, umbilical vein.

FIGURE 15-60. Hepatosplenomegaly in transient myelopoiesis and trisomy 21. Li, liver; Sp, spleen; S, stomach. (From Hamada H, Yamada N, Watanabe H, et al: *Hypoechoic hepatomegaly associated with transient abnormal myelopoiesis provides clues to trisomy 21 in the third-trimester fetus. Ultrasound Obstet Gynecol* 17:442, 2001.)

fetuses with trisomy 21 may have a transient myeloproliferative disorder in the second half of pregnancy (Fig. 15-60).¹⁹²⁻¹⁹⁷ The increased liver in these cases may have normal, hypoechoic, or hyperechogenic appearance. Fetal blood sampling will reveal leukocytosis with predominance of immature blast forms (Box 15-4).

Simple Transient Idiopathic Cysts in Early Pregnancy

In early pregnancy (14–16 weeks gestation), the authors have noted simple cysts in 1 in 2500 fetuses. These cysts are of various sizes ranging from very small ones to cysts of

10 mm. They may be located in different parts of the liver and disappear in the second half of pregnancy (Fig. 15-61). After labor the infant's liver functions tests are normal. Very rarely such cysts may also first present in the third trimester of pregnancy after a normal scan in the second trimester (Fig. 15-62).¹⁹⁸

Polycystic Liver Disease

There are several forms of polycystic liver disease. One of them is the Caroli disease, which is a rare autosomal recessive disorder, characterized by cystic dilatation of the intrahepatic bile ducts. Associated polycystic kidney disease is common. The main clinical manifestations are recurrent cholangitis, jaundice, cirrhosis, cholangiocarcinoma, and

renal impairment. The prenatal diagnosis has been reported in very few cases, presenting as a cluster of cystic lesions in the liver (Fig. 15-63).¹⁹⁹⁻²⁰² Polycystic kidneys may also be observed.

Hepatic Mesenchymal Hamartoma

Hepatic mesenchymal hamartoma is a rare benign tumor, usually presenting as a rapidly growing mass in the first two

BOX 15-4 Hepatic Cysts-Classification

A. Isolated Cyst (Location Everywhere, But Usually in the Periphery)

1. Simple transient idiopathic cysts
2. Lymphangioma

B. Polycystic Liver

1. Several forms with and without polycystic kidneys

C. Multiple Septated Cysts (Mesenchymal Hamartoma)

D. Hilar Cysts (Location in the Hilus of the Liver)

1. Choledochal cysts
2. Extrahepatic biliary atresia

FIGURE 15-62. A hepatic cyst that first appeared in the third trimester gradually disappeared after birth.

FIGURE 15-61. Simple transient idiopathic hepatic cysts (arrows) in three fetuses.

FIGURE 15-63. Caroli disease. A multicystic liver at week 30 (left) and in the newborn (right). (From Yuksel A, Has R, Isikoglu M, et al: Prenatal diagnosis of Caroli's disease. *Ultrasound Obstet Gynecol* 19:525, 2002.)

years of life. Because of its fast growth rate, it may cause hydrops, cardiac failure, and even fetal demise in utero. The sonographic appearance is of several cysts separated by thick septa. However, it may also present as a solid or mixed (solid and cystic) mass.²⁰³⁻²⁰⁷ Absence of atrioventricular malformations is of help in the differential diagnosis from large hemangiomas.

Nonimmune hydrops might be a sequela of mesenchymal hamartoma. An association between hepatic mesenchymal hamartoma and cystic changes in the placenta due to mesenchymal stem villous hyperplasia has been reported by several investigators.^{204,207} The underlying etiology of this association is not yet well understood. Resection of the tumor is the treatment of choice in cases of a large mass. In utero drainage of the cysts may be considered in premature fetuses, but its value is questionable because of the rapid reaccumulation of fluid in these cysts.²⁰⁴

HEPATIC MASSES

Hepatic Hemangioma

Hepatic hemangiomas are the most common benign tumors of the liver in the fetus and neonate. Synonyms used to describe this condition include hepatic arteriovenous malformation or hemangioendothelioma. They usually regress after an initial rapid growth, with complete involution by 12 to 18 months. Although benign, they can be life-threatening due to high output cardiac failure with and without hydrops, hemolytic anemia, severe thrombocytopenia, and disseminated intravascular coagulopathy (Kasabach-Merritt sequence).²⁰⁸⁻²¹² Corticosteroids are the treatment of choice in infancy, as they cause vasoconstriction of the rapidly proliferating endothelial cells that line the vascular channels. Morris et al²⁰⁸ have shown that maternal corticosteroid therapy was of value also in pregnancy, leading to a progressive decrease in the fetal hepatic mass.

The prenatal sonographic findings may vary depending on the tumor size (Fig. 15-64). Large tumors have a hypoechogenic appearance and atrioventricular malformations are noted. The feeding artery may show high velocity and low impedance blood flow, whereas the draining vein has an

FIGURE 15-64. Hemangioendothelioma presenting as a conglomerate of cystic and solid elements (white circle). (Reproduced with permission from G. Ochia, www.thefetus.net.)

antegrade blood flow pattern with low pulsatility.²⁰⁸⁻²¹⁰ Small tumors have a hyperechogenic appearance with no sonographic evidence of supplying or draining blood vessels.^{210,212} It is possible that these small masses actually present intra-uterine involution of the hemangioma. Because of possible fetal complications, cord blood sampling is advocated and infusion of blood products should be considered in premature fetuses with an obvious hematologic disorder.

Hepatoblastoma

Hepatoblastoma is the most common hepatic malignancy in young children. However, its incidence is very rare at approximately one per one million children younger than 15 years of age. The sonographic appearance is of a lobulated mass with an internal structure resembling spokes of a wheel²¹³ or a solid mass.²¹⁴

FIGURE 15-65. Liver calcifications (*arrows*) at week 18. The calcifications disappeared at week 32, and the outcome was favorable.

Liver Calcifications

The reported incidence of fetal liver calcifications is 1:1000 to 1:1750. In many cases, this is a transient idiopathic phenomenon without any consequences. In few cases an underlying pathology is detected, mainly infections (primarily cytomegalovirus), vascular pathologies such as hematoma, thromboemboli of hepatic and portal veins, tumors of the liver, and different chromosomal anomalies.²¹⁵⁻²¹⁸

Fetuses may have one, two, or more calcified foci (Fig. 15-65), or even diffuse calcification of the liver as well as peritoneal and intestinal calcifications. The incidence of associated anomalies varies in the different series. Bronshtein and Blazer²¹⁵ found associated anomalies in 21% of cases, whereas Simchen et al²¹⁸ found associated anomalies in 65% of fetuses. The presence of an isolated sonographic finding of calcification does not exclude the possibility of an infection or aneuploidy. It is therefore suggested to perform a detailed sonographic examination in these fetuses and consider a search for chromosomal anomalies and viral infections.

Gallbladder

Initially, the gallbladder is a solid mass at 4 weeks of embryonic life, and a definitive lumen develops by recanalization of the epithelium at the 7th week. Bile is formed by the liver at approximately 12 weeks' of gestation, entering the gallbladder and the intestinal system. When this fails to occur, the gallbladder remains atretic and does not develop. On ultrasound, the gallbladder appears at 7 to 14 weeks of gestation, as a teardrop of fluid with variable dimensions, and later gets a shape of a small club. It can be detected in 70% of fetuses at 13 weeks of gestation, and in 99% of cases at 15 weeks of gestation. In the second and third trimesters, the gallbladder is imaged as a small oval or rectangular cyst-like structure located to the right of the intrahepatic umbilical vein, at the lower border of the liver, close to the intestinal loops.

Gallbladder-Anatomic Variants

Different anatomic variants of the gallbladder can be observed, and no clinical implication has been noted in these different forms, as far as they are a solitary finding in the fetus.

Shape

The most common variants include duplication of gallbladder, huge gallbladder, L-shaped gallbladder, and transient septum (Fig. 15-66).

Location

Persistent Right Umbilical Vein

The gallbladder may be located to the left of the umbilical vein in cases of a persistent right umbilical vein (Fig. 15-67). Early in embryonic development there are two umbilical veins. The right umbilical vein atrophies and the left umbilical vein persists. Persistent right umbilical vein may result from failure of the right umbilical vein to regress resulting in a right umbilical vein that persists and coexists with the left umbilical vein. The right umbilical vein may replace the left umbilical vein, or the right umbilical vein may persist and bypass the liver draining aberrantly into the inferior vena cava or the right atrium. Sonographically, the umbilical vein drains into the right portal vein rather than the left portal vein, the intrahepatic umbilical vein is located lateral and not medial to the gallbladder and the portal vein (often described 'hockey stick') configuration curves toward the stomach rather than parallel or away from it to the right. According to the literature, as well as our experience with 98 fetuses, the frequency of this location is 2 to 4 in 1000 pregnancies. There is a low probability of additional structural anomalies; however, when this is a solitary finding it is regarded as a benign anatomical variant with a favorable outcome.²¹⁹⁻²²³ Other anatomic variants appear under the umbilical vein or floating and surrounded by the intestinal loops.

Nonvisualized Gallbladder

According to the authors' experience with more than 52,000 scans between 14 and 16 weeks' gestation, nonvisualization of the gallbladder is noted in 1:560 pregnancies. A nonvisualized gallbladder was defined as the inability to depict it on two targeted ultrasound examinations within a 1-week period. In about 25% of fetuses with a nonvisualized gallbladder, other structural and chromosomal anomalies are also observed. The main structural anomalies are Potter syndrome, abnormal kidneys, hydrops, diaphragmatic hernia, and mesomelia. The major chromosomal anomalies include triploidy (in 30% of cases), trisomy 9, 18, 20, and sex chromosome disorders.²²⁴

Nonvisualized Gallbladder as an Isolated Finding

The following disorders may be present:

1. Gallbladder agenesis. The incidence is about 13 to 65 in 100,000 in general population, including 1% of nonvisualized gallbladder (NVG) cases. Agenesis is an

FIGURE 15-66. Normal variability in size and shape of the gallbladder. *A.* A huge gallbladder (*arrows*) at week 15. *B.* A small gallbladder (*arrow*) at week 15. Stomach (*s*) and the umbilical vein (*UV*) are depicted. *C.* A septated gallbladder week 15. *D.* An L-shaped gallbladder at week 24.

anatomic variant that usually has no clinical sequela. Because of the familial tendency of this anomaly, ultrasound examination of the parents may be suggested in case of suspicion of such anomaly in the fetus.²²⁵

2. Cystic fibrosis. Less than 1% of fetuses with NVG will have cystic fibrosis, whereas the gallbladder is not detected in 75% of fetuses with cystic fibrosis. Cystic fibrosis is also associated with a low level of intestinal and liver enzymes in the amniotic fluid. This phenomenon might be of help in the prenatal diagnosis of the disease.⁹⁵
3. Extrahepatic biliary atresia. This rare anomaly is discussed later in the chapter.

In summary, in all cases of NVG a search for chromosomal anomalies, cystic fibrosis, and digestive enzymes should be performed.

Late-Onset Disappearance of Gallbladder

The authors observed four cases in which a gallbladder was depicted at 14 and 16 weeks' gestation but could not be seen later in pregnancy. In all these cases postnatal ultrasound revealed a normal gallbladder, and the infants had no medical disorders.

Fetal Gallstones (Sludge in Gallbladder)

There are several case reports of fetuses with sludge in the gallbladder appearing as a pear-shaped hyperechogenic structure. Usually, the gallbladder sludge mimics intrahepatic calcifications or hyperechogenic bowel. In most cases, this sonographic feature has been described in the second and third trimesters, and disappeared in the first postnatal month (Fig. 15-68).²²⁶⁻²²⁸ Brown et al²²⁶ reported on the presence of gallstones until the age of 4.5 years, with all of them being asymptomatic.

Extrahepatic Biliary Atresia

The prevalence of biliary atresia is 0.73 to 0.85 in 10,000 live births.^{229,230} Biliary atresia is the leading cause of extrahepatic obstructive jaundice in the newborn and is the single

most frequent indication for liver transplantation in childhood.²²⁹ It may be either isolated or associated with other malformations, mainly polysplenia, cardiac defects, and intra-abdominal anomalies. There are several variants of biliary atresia ranging from complete atresia to atresia of the choledochal duct. The French classification based on the anatomical pattern of the extrahepatic biliary tract remnants is most helpful for sonographers (Fig. 15-69).^{231,232}

Prenatal Diagnosis

There are few case reports on the detection of fetal biliary atresia.²³³⁻²³⁷ The diagnosis is mainly based on nonvisualization of the gallbladder, depiction of a cystic structure in the hepatic region or specifically in the hilum, and detection of low levels of liver enzymes in the amniotic fluid. The differentiation from a choledochal cyst is important.

Using the above-mentioned classification, the following work-up is proposed:

Types 1 and 3. The gallbladder exists in these cases. Hence, the diagnosis will be overlooked in the general low-risk population. In patients with a family history of biliary atresia it is suggested to evaluate amniotic fluid liver enzymes even when the fetal gallbladder is depicted.

Type 2. These cases may be identified by the presence of a cyst in the liver hilum, or nonvisualization of the gallbladder. A cyst in the liver hilum may also represent a choledochal cyst. Matsubara et al²³⁸ and Casaccia et al²³⁹ noted that the size of the choledochal cyst increased steadily as gestational age advanced, whereas the size of the cyst in congenital biliary atresia remained unchanged throughout pregnancy. However, these are only case reports, and patients should therefore be informed about the risk of biliary atresia in every case of a cyst in the liver hilum. We suggest examining liver enzymes in such pregnancies.

Type 4. In such cases, there is nonvisualization of the gallbladder. Evaluation of liver enzymes is recommended.

Choledochal Cyst

The incidence of choledochal cysts in Western countries is 1 per 100,000 live births. In Eastern countries such as Japan the incidence of this disorder is much higher. The female-to-male ratio is 3 to 4:1, and familial occurrences are scarce.

FIGURE 15-69. Anatomic patterns of the extrahepatic biliary remnant (French classification). (Courtesy of Dr. Christophe Chardot.)

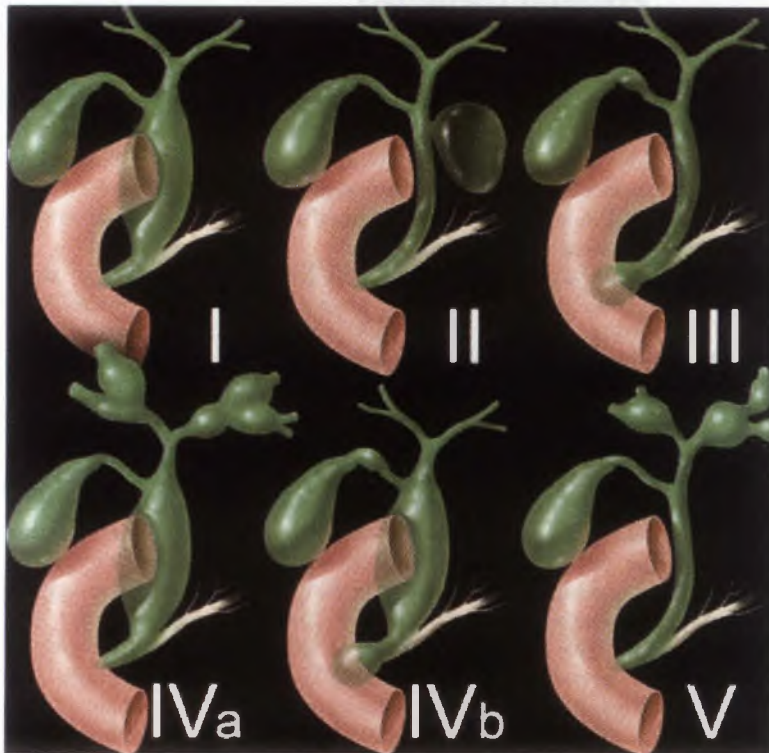

FIGURE 15-70. Graphic shows various types of choledochal malformation. Note the anomalous pancreatobiliary junction; pancreatic duct insert into common bile duct proximal to the sphincter of Oddi. (From Donnelly LF, Jones BV, O'Hara SM, et al [eds]: *Diagnostic Imaging: Pediatrics*, 1st ed. Salt Lake City, Amirsys Inc., 2005, p. 96.)

The cause of these cysts is still unclear. The two leading theories suggest²⁴⁰

1. Pancreatobiliary maljunction allowing pancreatic secretions to reflux into the biliary duct system.

There are five types of cystic anomalies of the choledochus (Todani classification) (Fig. 15-70).²⁴⁰

Excision of this cyst in infancy is advocated in order to prevent complications such as cholangitis and liver fibrosis. Of note, internal drainage procedures without cyst excision

FIGURE 15-71. Choledochal cyst: The elongated gallbladder (GB) and the round cyst (cyst) in the hepatic hilus resembles the exclamation mark. UV, umbilical vein.

avorable prognosis reported in the literature, we observed a fetus in which the choledochal cyst disappeared during pregnancy. In another case, the choledochal cyst diagnosed in utero, is currently asymptomatic and decreasing in size in the child.

Prenatal Diagnosis

The presence of a cystic structure in the hepatic hilus should always alert the physician to a possibility of a choledochal cyst.^{238,239} The authors noted that such cysts visualized in the same plane with the gallbladder provide an image of an exclamation mark (Fig. 15-71). The main differential diagnosis includes external biliary atresia and an isolated hepatic hilar cyst.

SPLEEN

Several investigators presented nomograms of the spleen showing a relationship between its size and gestational age.^{242,243} However, the spleen and liver have a similar echogenicity, and it is therefore difficult to precisely separate between these two organs while performing an ultrasound examination. The authors therefore believe that a reliable measurement of the normal spleen is not always accurate.

Splenomegaly

Because of the above-mentioned limitation, the sonographic diagnosis of splenomegaly mainly relies on the following three findings²⁴⁴:

1. The stomach is displaced anteriorly and to the midline by the enlarged spleen.
2. The spleen is very close to the anterior abdominal wall (Fig. 15-72).

FIGURE 15-72. Enlarged hyperechogenic spleen (arrows) in a case of cytomegalovirus infection. S, spine; UV, umbilical vein. (Courtesy of Dr. Ron Auslander.)

3. Color Doppler imaging depicts multiple ramifications of the splenic artery and vein.

Splenomegaly may present in various fetal disorders, the most common of which are

1. Rh isoimmunization and other forms of fetal anemia.^{245,246}
2. Infectious disorders such as cytomegalovirus.²⁴⁴
3. Metabolic disorders such as Gaucher disease, and pyruvate kinase deficiency.^{189,190}
4. Transient myeloproliferative disorder, which sometimes appears in fetuses with Down syndrome.¹⁹²⁻¹⁹⁷
5. Overgrowth disorders such as Beckwith-Wiedemann syndrome.

Splenic Cyst

Congenital splenic cysts are rare, of unknown origin, and usually present as an isolated finding. Spontaneous postnatal regression of these cysts has been described in many cases.²⁴⁷⁻²⁴⁹ Large cysts (larger than 40 mm) call for special attention because of possible acute complications such as rupture, hemorrhage, and infection during childhood. Surgery or aspiration of cysts and sclerosis are therefore the recommended treatment in large cysts.²⁴⁹ The sonographic differential diagnosis in the fetus includes cystic lesions in the upper left abdomen, mainly in the adrenal, kidney, mesentery, and gastrointestinal duplication cysts.

PANCREAS

It is very difficult to sonographically differentiate between a normal pancreas, intestinal loops, and retroperitoneal texture. Occasionally, the pancreas can be depicted in the space

FIGURE 15-73. Pancreas. The normal pancreas is marked by arrows. S, stomach; GB, gallbladder; KID, kidney; UV, umbilical vein.

between the stomach, gallbladder, umbilical vein, and kidney. This image is best attained in a transverse axial plane of section at the level of the kidney (Fig. 15-73). Hata et al²⁵⁰ were able to depict the pancreas in 80% of cases at 20 and 23 weeks' gestation, whereas at 36 and 39 weeks' gestation they could image the pancreas only in 38.4% of cases.

Annular Pancreas

The annular pancreas arises from persistence of the dorsal pancreatic bud, creating a constricting ring around the duodenum. The anomaly is rare and accounts for only 1% of neonatal intestinal obstruction. However, associated anomalies occur in 10% to 20% of these cases, mainly duodenal obstruction, intestinal malrotation, and Down syndrome.²⁵¹

An annular pancreas should therefore be suspected whenever the double bubble sign of duodenal obstruction is observed. There are a few reports of sonographic imaging of the annular pancreas, as an echogenic structure around the duodenum, immediately under the dilated segment.^{251,252}

In the authors' experience depiction of an annular pancreas is difficult, and in most cases of duodenal obstruction, only a double bubble sign is depicted.

Pancreatic Cyst

Congenital pancreatic cysts are rare and there is a female predominance. They arise from a developmental anomaly of the pancreatic ductal system. The cysts are either solitary or multiple and may even be so numerous to transform the pancreas into a cystic mass. The cysts are usually asymptomatic but may cause abdominal distension and pressure on adjacent viscera in the postnatal period. Excision of the cyst or internal drainage by cystoenterostomy is the treatment of choice in complicated cases.^{253,254} Associated anomalies

FIGURE 15-74. Polycystic pancreas at week 16 (Jeune syndrome). Two cysts (C) inside the demarcated pancreas. GB, gallbladder; KID, kidney; SS, spine; UV, umbilical vein.

have been observed in many of these fetuses. The most common are²⁵³⁻²⁵⁷

1. Polycystic disease of pancreas and kidney.
2. von Hippel-Lindau disease.
3. Asphyxiating thoracic dysplasia, short-limb dwarfism. (Jeune syndrome [Fig. 15-74]).
4. Hemihypertrophy.
5. Beckwith-Wiedemann syndrome.

The prenatal diagnosis of a pancreatic cyst should be suggested in cases of a sonographic findings of a cyst in the upper abdomen in the space between the stomach, gallbladder, umbilical vein, and kidney.^{253,255-257}

Pancreatoblastoma

Pancreatoblastoma is a rare tumor. The treatment of choice in childhood is chemotherapy and complete resection.^{258,259} The association with Beckwith-Wiedemann syndrome was observed in some cases.^{260,261} There are only very few reports on the antenatal findings in pancreatoblastoma. Cacciarì²⁶² observed an amorphous structure with some features resembling a kidney (Fig. 15-75), whereas Pelizzo et al²⁶⁰ found an isolated intra-abdominal cyst.

Idiopathic Intra-Abdominal Cysts

A unique type of fetal cystic mass of unknown origin has been observed by the authors in the first and early second trimesters of pregnancy. These cysts are usually located laterally, and may have an hyperechogenic rim. They may occupy up to 60% of the abdominal diameter (Fig. 15-76). A connection between these cysts and abdominal organs could not be identified. A gradual reduction in their size is noted with advancing gestation, and in some cases, the cyst disappears completely, whereas in other cases, a small

hyperechogenic mass remains with features resembling hyperechogenic bowel. It is therefore possible that some of these cysts may actually be meconium cysts. Fetal outcome in all these cases has been favorable. Because of the unknown origin of these cysts, fetuses should be followed by repeated scans to exclude other cystic pathologies. There is a high probability that the cysts will disappear and the fetus will be healthy.

ABDOMINAL WALL

Physiological Midgut Herniation

During normal embryonic life, a rapid elongation of the gut and its mesentery as well as simultaneous marked growth and expansion of the liver occurs. The abdominal cavity becomes too small to contain all the intestinal loops, and they enter the extra-embryonic coelom in the umbilical cord

(Figs. 15-55 and 15-77). This process of physiologic midgut herniation takes place during the 6th week of development. During the 10th week, the intestine returns into the abdominal cavity; this process referred to as reduction of the midgut hernia. Timor-Tritsch et al²⁶³ observed such normal herniation in 64% of fetuses at 8 weeks, in 100% during weeks 9 and 10, and in 25% of cases at 11 weeks of gestation. None of the fetuses studied at 12 weeks had a midgut herniation.

Omphalocele (Exomphalos)

An omphalocele is a defect in the ventral abdominal wall whereby the herniated intra-abdominal content is covered by a membrane consisting of peritoneum and amnion. The small bowel is the most common herniated viscera (Fig. 15-78). Less common are the liver, spleen, stomach, and large bowel. Although bowel is the most common herniated viscera, in moderate to large omphaloceles liver is

FIGURE 15-77. Physiologic midgut herniation (arrow) at week 10.

FIGURE 15-76. Idiopathic intra-abdominal cyst at week 16. *Left*, transverse; *Right*, sagittal. S, stomach; K, kidney.

FIGURE 15-78. Omphalocele. *Left*, Ultrasound at week 15 showing the intestinal content inside the umbilical cord (arrows). *Right*, The neonate.

invariably present. The prevalence of omphalocele varies considerably in the literature, ranging between 0.74 and 3.9 per 10,000 births.²⁶⁴⁻²⁶⁷

Associated Anomalies

Associated anomalies are observed in 67% to 88% of fetuses. Cardiac defects are present in 50% of cases, gastrointestinal anomalies in 40%, and chromosomal anomalies (mainly, trisomy 13, 18, and 21, and sex chromosome abnormalities) in 30% to 40% of cases.^{265,267-273} An association has been observed between the content of the omphalocele and chromosomal defects. Karyotype abnormalities are more common in omphaloceles containing only bowel, and are much less frequent in omphaloceles with liver herniation only.²⁷⁴⁻²⁷⁶ Currently, omphalocele is listed in 58 different syndromes.⁶⁴

Prognosis

The prognosis is related to the presence of associated structural and chromosomal anomalies. In a recent evaluation of 90 fetuses mainly with nonisolated omphalocele, the overall prognosis was generally poor.²⁷¹ However, review of the literature published between 1985 and 2003²⁷⁷ revealed that most children with an isolated omphalocele fully participate in normal activities and education without reduction in their quality of life.

Prenatal Diagnosis

The sonographic diagnosis of omphalocele is based on the presence of an abdominal wall defect with herniation of intestinal loops and liver (Fig. 15-79) as well as other abdominal organs into the omphalocele's sac. The umbilical cord is seen at the apex of the sac. It is the authors' experience that in most cases, it is possible to detect an edematous and cystic Wharton jelly around the trapped intestine. The cause and significance of these cysts are not clear (Fig. 15-80).

FIGURE 15-79. Omphalocele at week 13. The liver (L) inside the omphalocele sac (arrows).

Isolated Omphalocele—The Authors' Experience

In case of an omphalocele detected at 14 and 16 weeks' gestation, a meticulous detailed targeted sonographic survey of all fetal organs (including echocardiography) is performed. It is our experience that an isolated omphalocele is not associated with chromosomal anomalies. However, because the question of chromosomal anomalies in an isolated omphalocele has not been addressed in large series, we still offer fetal karyotyping in all cases of omphalocele detection.

We have also noticed that on occasion a small isolated omphalocele detected in early pregnancy (14–16 weeks) may

disappear later in pregnancy and the newborns are healthy at birth (Fig. 15–81). Usually these omphaloceles contain only one or few intestinal loops.²⁶⁹ The reason for a permanent or transient disappearance of an omphalocele is not yet clear, and very few reports on this phenomenon have been published.^{278,279} If no associated anomalies are detected and the karyotype is normal, there is still a need to perform follow-up scans in pregnancy in order to detect possible markers of the Beckwith-Wiedemann syndrome.

Omphalocele and Beckwith-Wiedemann Syndrome

Beckwith-Wiedemann syndrome has been reported in 10% to 22% of fetuses with isolated omphalocele.^{271,272} It should be emphasized that it is yet not clear at which gestational age the classic signs of Beckwith-Wiedemann syndrome, namely, macroglossia, organomegaly, cystic and enlarged pancreas and abnormal kidneys, are apparent on ultrasound

examination (Fig. 15–82). There are even reports of late manifestation of the characteristic findings of this syndrome after delivery.²⁸⁰ A careful ultrasound follow-up throughout gestation is therefore advocated in order to provide parents and caregivers with the maximum information for the ideal management of the pregnancy. Furthermore, it is worthwhile to follow up fetuses with omphalocele after birth (ultrasound of kidneys and adrenals) in order to exclude the possibility of Wilms' tumor and adrenal tumors, which may develop in the Beckwith-Wiedemann syndrome (Box 15–5).

Gastroschisis

Gastroschisis is a paraumbilical defect of the abdominal wall, that is almost always right sided, resulting in evisceration of the abdominal content into the amniotic cavity (Fig. 15–84). As opposed to omphalocele, the herniated content in gastroschisis is not covered by membranes. The term "gastroschisis minor" denotes a small defect in which only omentum protrudes through the abdominal wall.

Incidence and Etiology

The incidence of gastroschisis varies significantly between different geographic areas. For example, its rate is 4.4 per 10,000 births in southwest of England,²⁸¹ 3.01 per 10,000 births in Hawaii,²⁸² and 0.47 per 10,000 births in Japan.²⁶⁵ A remarkable increase in the incidence of the anomaly was observed over the two last decades in many countries. The underlying reason for this increase is not yet elucidated. Several causative factors, including exposure to drugs, chemicals and smoking, have been suggested but they remain unsubstantiated.²⁶⁵ Of interest, many studies have shown that gastroschisis is associated with a lower overall maternal age than omphalocele.^{264,265,267,270,283}

Associated Anomalies

The incidence of associated structural and chromosomal anomalies is lower than that in omphalocele. Chromosomal aberrations have been detected in 0% to 3%.^{265,267,270,272,273} The reported incidence of structural anomalies ranges between 5% in England and Wales,²⁸¹ 18.8% in Japan¹² and 51% in France.²⁶⁷ The most common disorder is intestinal

FIGURE 15–80. Omphalocele (oc) and Wharton jelly cyst (arrow) at week 16.

FIGURE 15–81. Transient omphalocele. Left, Omphalocele at week 15 (arrows). Right, Normal umbilical cord in the same fetus at week 20 (wide arrow).

FIGURE 15-82. Omphalocele with Beckwith-Wiedemann syndrome. *A.* An omphalocele with predominant liver herniation is seen. *B.* An enlarged fetal kidney is identified. *C.* Markedly enlarged pancreas (*arrows*). *D.* Macroglossia with a protruding tongue (*arrow*).

atresia (10%–20%), which in some cases also causes intussusception and volvulus.^{267,277,283–285} It has been suggested that the main reasons for the intestinal damage are exposure to the amniotic fluid and constriction at the abdominal wall defect resulting in ischemia.²⁸⁵

Mode of Delivery

There is currently a trend to deliver these fetuses by a cesarean section assuming that more damage may be caused to the herniated intestine during vaginal delivery. However, studies addressing this issue failed to show a difference in

fetal morbidity or mortality between vaginal and abdominal deliveries.^{285–289}

Prognosis

The survival rate is approximately 92% in fetuses with no other major anomalies.^{272,277,288,290,291} Long-term outcomes are mainly related to the gastrointestinal condition. Approximately 10% of patients will have hypoperistalsis syndrome.²⁷⁷ Other problems, including severe neurologic and developmental disorders, have also been reported in some cases.²⁷²

Prenatal Diagnosis

The characteristic sonographic finding is that of cauliflower-like intestinal loops floating freely in the amniotic fluid (Fig. 15–85). The diagnosis can be made in the first trimester.²⁹² Unlike cases of omphalocele, there is no membranous sac and the umbilical cord is usually normally inserted left of the abdominal wall defect. Evisceration of the liver or other abdominal organs is rare. Marked dilatation and thickening of herniated bowel may be a sign of intestinal damage; however, the accuracy of ultrasound in determining abnormal bowel in this condition has been disappointing. In the third trimester, the normal fluid-filled herniated colon should not be mistaken for abnormally dilated bowel.

BOX 15–5 Differential Diagnosis of Omphalocele

1. Gastroschisis is discussed later in the chapter.
2. Midline disruption sequence is discussed later in the chapter.
3. Physiological midgut herniation. Physiological midgut herniation may be large; Therefore, it may not be possible to differentiate it from an omphalocele containing solely intestinal loops in the first trimester. Only omphaloceles containing liver may definitely be diagnosed in the first trimester.
4. Umbilical cord. Cyst, edema, lymphangioma, or calcified Wharton jelly (Fig. 15–83).
5. Umbilical hernia

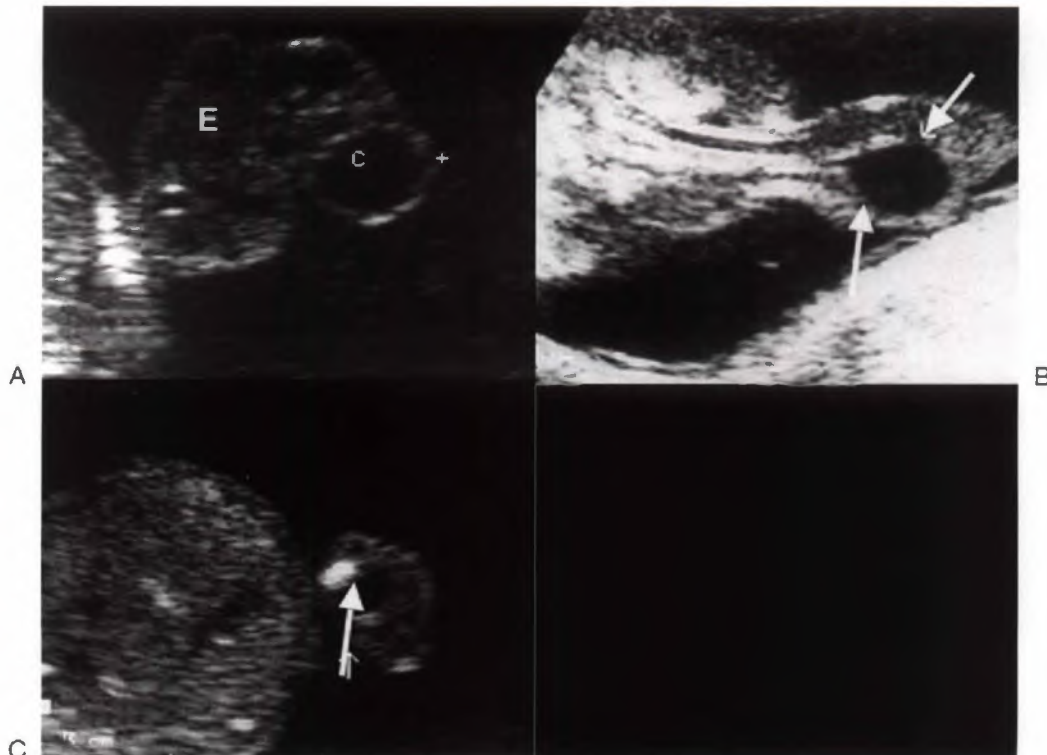

FIGURE 15–83. Differential diagnosis of omphalocele. *A.* An edematous cord (E) with a cyst (c). *B.* A medium size umbilical cyst (arrows). *C.* A small umbilical cyst and calcified focus (arrow).

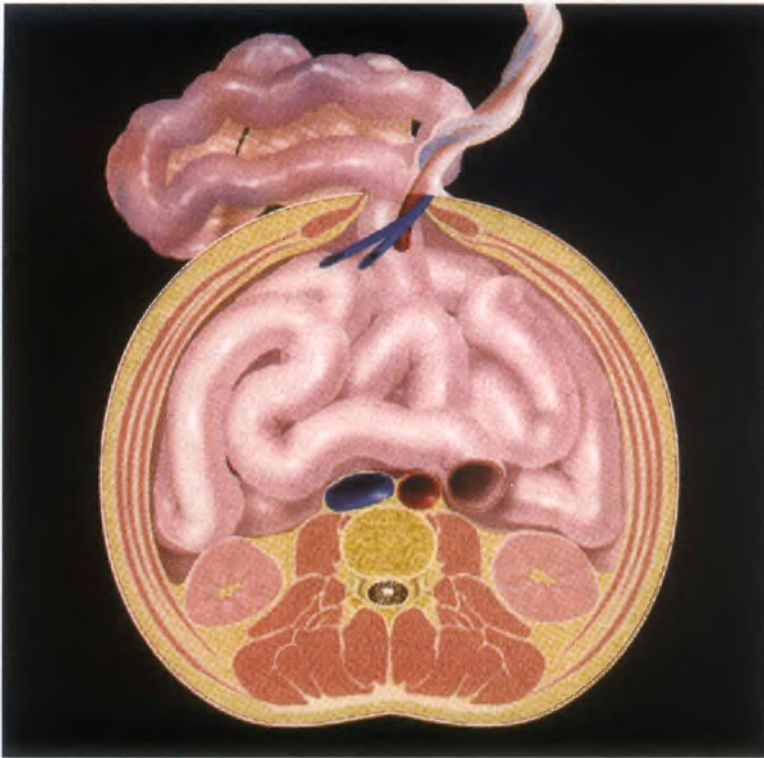

FIGURE 15-84. A. Graphic presentation of an abdominal wall defect with herniation of small bowel. The defect is to the right and adjacent to the normally inserted umbilical cord. (From Donnelly LF, Jones BV, O'Hara SM, et al [eds]: *Diagnostic Imaging: Pediatrics*, 1st ed. Salt Lake City, Amirsys Inc., 2005, p. 66.) B. Newborn with gastroschisis. Herniated bowel is seen to the right of the umbilical cord. In this case the bowel is thickened and matted. (From Clark DA, *Atlas of Neonatology: A companion to Avery's Diseases of the Newborn*. Philadelphia, WB Saunders Co., 2000.)

Additional differential diagnoses include

1. Midline disruption sequence.
2. Cloacal extrophy or bladder extrophy.
3. Cystic or edematous umbilical cord.

MIDLINE DISRUPTION SEQUENCE

During the 4th week of gestation, the embryo begins to undergo a process of folding that converts it from a flat germ disc into a three-dimensional structure. The cephalic, lateral, and caudal edges are brought together along the ventral midline, and the endodermal, mesodermal and ectodermal layers fuse to the corresponding layer on the opposite side. The fusion process of the amnion also starts at this stage and the amniotic sac encircles the fetus (Fig. 15-86). A defect in these embryologic processes results in fetal anomalies. The extent of malformation depends on the time of insult and size of damaged embryonic zone. As to the abdominal wall, if the damaged embryonic zone is large an evisceration of many abdominal organs is expected. In case of an improper closing of the amnion, part of the eviscerated organs will be located outside the amniotic sac (Fig. 15-87).²⁹³ In addition to the abdominal wall, malformations observed in other structures may involve the limbs, lower urinary system, cloaca, and external genitalia.

Many syndromes and variations of abdominal wall defects have been described. The spectrum of midline disruption

syndromes is wide and includes many anomalies. A careful review of the literature reveals that there is significant overlapping between these syndromes and that the differences are often hardly distinguishable. Furthermore, the terminology is not always clear and many synonyms are used to denote such syndromes.²⁹³⁻³⁰² The authors therefore assume that the different anomalies reported are actually variable forms of a large spectrum of midline disruption. Midline disruption anomalies are rare, and hence, it is difficult to determine their incidence. Among 52,000 pregnancies examined by the authors, there were seven fetuses with a midline disruption sequence. The earliest diagnosis was made at 8 weeks of gestation (Box 15-6).

CLOACAL EXSTROPY SEQUENCE

The best known variant of this anomaly is the OEIS complex characterized by omphalocele, extrophy of bladder, imperforate anus, and spinal anomalies. The main sonographic findings of cloacal extrophy are nonvisualization of the bladder, anterior abdominal wall defect, or a cystic mass protruding from the anterior abdominal wall, omphalocele, skeletal anomalies, and abnormal genitalia (Fig. 15-88).^{303,304}

Vesicoallantoic Cyst/Patent Urachus

When a cystic structure is seen adjacent to the lower anterior abdominal wall, the diagnosis of omphalocele is often

FIGURE 15-86. Illustration of serial embryonic development during the 4th week of development (6th menstrual week). A1-A3 is the beginning of the 4th week, B1-B3 at 22 days, C1-C3 at 26 days, D1-D3 at 28 days. B1, C1, and D1 are lateral views at the plane of section designated in A1, A2 to D2 are sagittal views, and A3 to D3 are transverse views at planes designated at A1 to D1. (From Moore KL, Persaud TVN: *The Developing Human: Clinically Oriented Embryology*. Philadelphia, WB Saunders, 1998.)

FIGURE 15-89. Vesico-allantoic cyst/patent urachus. A cyst (Cy) adjacent to the anterior abdominal wall is seen in continuity (asterisk) with the fetal urinary bladder (Bl).

suspected. When the cyst is seen to connect to the fetal urinary bladder (located normally within the fetal pelvis), the diagnosis of a vesico-allantoic cyst/patent urachus should be entertained (Fig. 15-89).

The allantois is an embryonic structure that develops as a diverticulum from the yolk sac. The allantois becomes incorporated into the embryo, connecting the ventral aspect of the urogenital sinus to the external portion of the umbilicus.³⁰⁵ The urachus is an embryologic remnant of the allantois. The lumen of the allantois eventually becomes obliterated and the urachus closes to form the median umbilical ligament.³⁰⁶

A patent urachus is rare, with an incidence of 1% to 2.5% per 100,000.³⁰⁷ As mentioned previously, whereas an omphalocele is often first suspected when a cystic mass is seen, the presence of a fluid-filled mass in direct communication with the fetal urinary bladder, as well as the absence of bowel contents, allows one to discriminate between the two. This is important because the prognosis is far different with few associated abnormalities when a patent urachus is seen.³⁰⁶

EMBRYOLOGY

Structurally and functionally, the urogenital system can be divided into two entirely different components—the urinary system and the genital system. Both of these develop from a common mesodermal ridge of tissue, the intermediate mesoderm, along the posterior wall of the abdominal cavity. Initially, the excretory ducts of both systems enter a common cavity, the cloaca.¹

Human embryos develop three sets of excretory organs or kidney systems during intrauterine life.^{1,3} The embryonic kidneys, which are formed in a cranial to caudal sequence, in order of appearance are the pronephros, the mesonephros, and the metanephros. The pronephros, analogous to the kidneys in primitive fishes and the mesonephros, which are well developed and analogous to the kidneys of amphibians, both regress in utero. The third set of kidneys, the metanephroi, become the permanent kidneys (Fig. 16-1).^{2,3}

The pronephros is seen in the 3rd week of development and completely degenerates by the start of the 5th week. The second kidney, the mesonephros, also regresses by the 4th month; however, it serves as an excretory organ for the

embryo while the definitive kidney begins its development. Certain elements of the mesonephros are retained in the mature urogenital system as part of the reproductive tract.³

The metanephros, or definitive kidney, forms in the sacral region as a pair of new structures called the metanephric diverticulum or ureteric bud. It emanates from the distal portion of the mesonephric duct and comes in contact with and penetrates the metanephric mesenchymal blastema (metanephric mesoderm) at approximately the 28th day.^{2,3}

The ureteric bud and metanephric mesoderm exert reciprocal inductive effects toward each other, and the proper differentiation of these structures depends on these inductive signals. The metanephric mesoderm induces the ureteric bud to branch, and in turn, the ureteric bud induces the metanephric mesoderm to condense and undergo mesenchymal-epithelial conversion. The nephron, which consists of the glomerulus, proximal tubule, loop of Henle, and distal tubule, is thought to derive from the metanephric mesoderm, whereas the collecting system, consisting of collecting ducts, calyces, pelvis, and ureter, is formed from the ureteric bud (see Fig. 16-1).³

New York, Churchill Livingstone, 1997.) (Illustration by James A. Cooper, MD, San Diego, CA.)

The division of the ureteric bud results in the eventual pelvicalyceal patterns and their corresponding renal lobules. The first few divisions of the ureteric bud give rise to the renal pelvis, major and minor calyces, and collecting tubules. Thereafter, the first generations of collecting ducts are formed. When the ureteric bud first invades the metanephric mesoderm, its expanded end forms an ampulla that will eventually give rise to the renal pelvis. By the 6th week, the ureteric bud has bifurcated at least four times, yielding 16 branches. These branches then coalesce to form two to four major calyces extending from the renal pelvis. By the 7th week, the next four generations of branches also fuse, forming the minor calyces. By the 32nd week, approximately 11 additional generations of bifurcation have resulted in approximately 1 to 3 million branches, which will become the collecting duct tubules. In humans, although renal maturation continues to take place postnatally, nephrogenesis is completed before birth.³

Bladder and Urethra

During the 4th to 7th weeks of development, the cloaca is divided by the urorectal septum into the urogenital sinus anteriorly and the anal canal posteriorly. The urogenital sinus is divided into three parts, of which the upper and largest part is the urinary bladder. Initially the bladder is continuous with the allantois, but when the lumen of the allantois is obliterated, a thick fibrous cord, the urachus, remains and connects the apex of the bladder with the umbilicus. The next part is a somewhat narrow canal, the pelvic part of the urogenital sinus, which in the male embryo, gives rise to the prostatic and membranous parts of the urethra and the entire urethra in female embryos. The caudal urogenital sinus forms the phallic urethra in the male embryo and the distal vaginal vestibule in the female embryo.^{1,2}

The Normal Urinary Tract

Bladder

Urine is first produced by the kidneys during the 9th week of embryonic life. At this stage, the urine in the bladder can be visualized as a fluid-filled structure within the fetal pelvis (Fig. 16-2).

During the second and third trimester, the bladder will empty and refill continuously every 25 to 30 minutes. This cycle can be monitored during the sonographic examination. The position of the fetal bladder can virtually always be identified, because it lies between the umbilical arteries within the fetal pelvis. These arteries are readily seen with the use of color Doppler imaging. At the end of the pregnancy, this cycle decreases, especially in female fetuses possibly due to hormonal influence on the fetal bladder neck. This may induce a pseudomegabladder (see later) (Figs. 16-3 and 16-4).^{4,5}

FIGURE 16-2. Fetal bladder in the first trimester at 12 weeks' gestational age. Sagittal scan of the fetus. The bladder is seen as a small cystic structure (*arrow*) in the fetal pelvis.

FIGURE 16-3. Fetal bladder in the second trimester (male fetus). A. Transverse scan through the fetal pelvis demonstrating the bladder (*thick arrow*) and the fetal sex (*thin arrow*). B. Color Doppler of the umbilical arteries at both sides of the bladder (*arrow*).

Kidneys

With the use of transvaginal probes, fetal anatomic structures can be visualized earlier than with transabdominal ultrasound (US). Therefore, the fetal kidneys can be demonstrated at approximately 11 weeks transvaginally and at 12 weeks using transabdominal probes. During the first trimester, the kidneys appear as hyperechoic oval structures at both sides of the spine (their hyperechogenicity can be compared to that of the liver or spleen) (Fig. 16-5). This echogenicity will progressively decrease, and during the third trimester, the cortical echogenicity will always be less than that of the liver or spleen. Simultaneous to the decreased echogenicity, corticomedullary (CMD) differentiation will appear at approximately 14 to 15 weeks. This should always be demonstrated in fetuses older than 18 weeks. Prominent pyramids should not be misinterpreted as calyceal dilatation (Fig. 16-6). The fetal kidneys' growth can be evaluated throughout pregnancy by measuring renal length and comparing it to normal charts. (As a simple rule, renal growth is 1.1 mm/gestational week.) During the second and

FIGURE 16-4. Sagittal scan through the fetal abdomen. Fetal bladder (arrow) in the third trimester.

third trimesters, the kidneys are easily identified by imaging the dorsolumbar spine and scanning on either side in parasagittal and transverse axial sections. Urine distending the renal pelvis may help in their identification. Under normal conditions, the fetal ureters are not visible.⁴⁻⁶

Evidence of a Normally Functioning Urinary Tract

In addition to the visualization of the bladder and normal kidneys, the assessment of the urinary tract (UT) should include an evaluation of the amniotic fluid volume. After 14 weeks, two thirds of the normal amniotic fluid is produced by fetal urination and one third from pulmonary fluid. A normal volume of amniotic fluid is mandatory for proper development of the fetal lung. A normal sized thorax can be confirmed by measuring thoracic diameters or thoracic circumference.⁷

The Abnormal Urinary Tract

The overall prevalence of renal tract anomalies is estimated at 5/1000 births. The percentage is likely higher when considering transient anomalies. Anomalies involving the UT are numerous and variable. They can be isolated or

FIGURE 16-5. Fetal kidney, first trimester. Parasagittal scan of a first trimester fetus. The kidney appears as a hyperechoic small oval mass (thick arrow). The adrenal above it is hypoechoic (thin arrow). H, fetal head.

FIGURE 16-6. Second and third trimester kidneys. A. Second trimester. Sagittal scan through a kidney (K) that appears hyperechoic but with corticomedullary differentiation. Ch, chest. B. Third trimester. The kidney is limited by the crosses. Corticomedullary differentiation is clearly visible.

The adrenal gland (*arrows*) on the same side as the absent kidney, is now elongated in what has been described as “the lying down adrenal sign.”

appear in association with another organ system’s anomalies. Therefore, the sonographic examination should be as meticulous as possible in order to visualize possible associated features. These additional findings will determine the prognosis.⁸⁻¹⁴

Abnormal Renal Number

Bilateral renal agenesis is incompatible with extrauterine life. This condition, at times referred to as Potter’s syndrome, results in pulmonary hypoplasia and musculoskeletal abnormalities. The diagnosis is based initially on anhydramnios after 15 weeks and on the nonvisualization of normal renal structures (Fig. 16-7). The bladder is empty (very rarely, a small fluid-filled structure can be observed in the fetal pelvis. It might correspond to retrograde filling of the bladder). Whenever there is a question as to whether the kidneys are present, fetal magnetic resonance imaging (MRI) may help

with the diagnosis. Enlarged, globular adrenals should not be misinterpreted as dysplastic kidneys.¹⁵⁻¹⁸

Unilateral agenesis occurs in 1/500 pregnancies. At the time of sonography, a normal kidney will not be identified in either lumbar area. When no other complication or malformation is present, the prognosis for postnatal life is excellent (Fig. 16-8). The ipsilateral adrenal gland is usually present, and appears globular and should not be mistaken for the kidney. Without the adjacent kidney, the adrenal gland may be elongated in appearance in what has been called “the lying down adrenal sign” (see Fig. 16-8*B*). In case of left renal agenesis, the left colonic flexure occupies the empty lumbar fossa and should not be confused with a cystic kidney or a dilated ureter. Whenever one or both lumbar fossas are empty, the kidneys should be searched for in an ectopic location (see later) (noteworthy, renal agenesis can theoretically result from the in utero regression of multicystic renal dysplasia).¹⁹⁻²¹

FIGURE 16-9. Uncomplicated renal duplication (second trimester). Parasagittal scan through one kidney. Some urine distends the two separated collecting systems (arrows).

FIGURE 16-10. Ectopic pelvic kidney, third trimester. Oblique view of the fetal abdomen. The pelvic kidney (K) lies above the bladder (B). Ab, fetal abdomen.

Renal Duplication

When no complication occurs, renal duplication is a benign condition and should be considered a normal variant (Fig. 16-9). If complicated, it should be included in the differential diagnosis of UT dilatation (see later).

Abnormal Kidney Location

There are various ectopic locations possible for the kidney. The ectopic kidney is recognizable thanks to its characteristic CMD. An ectopic kidney is usually smaller and may be malrotated. Complications such as dilatation or dysplasia

FIGURE 16-11. Horseshoe kidney, third trimester. Transverse scan through the middle fetal abdomen. The two kidneys fuse on the midline (arrows). Sp, spine.

FIGURE 16-12. Crossed fused ectopia, third trimester. Transverse oblique view of the fetal abdomen (Ab) demonstrating the two fused kidneys (limited by the arrows). Sp, spine.

do occur. One or both kidneys can be ectopic. The pelvic location is the commonest location for ectopic kidneys to appear (Fig. 16-10). Other ectopic locations include horseshoe, crossed fused ectopia (both kidneys lie on the same side), and intrathoracic ectopia. In horseshoe kidneys, a bridge of renal tissue can be visualized in front of the spine (Fig. 16-11). Crossed ectopia should be differentiated from duplex kidneys. In crossed (fused) ectopia, there is an angulation between the two kidneys, whereas in duplication, the two renal moieties lie in the same continuous plane (Fig. 16-12).^{22,23}

Abnormal Kidney Size

The kidneys must be systematically measured whenever their echogenicity is abnormal or whenever the amniotic fluid volume is reduced.

Small kidneys (below -2 standard deviations [SDs]) are usually seen when hypoplasia or dysplasia (or both) resulting from an embryologic maldevelopment, secondary to reflux (reflux nephropathy), obstruction, or to an ischemic phenomenon is present. Small kidneys may also result from so-called tubular dysgenesis associated with the maternal ingestion of angiotensin II antagonists. The prognosis of small kidneys depends on the remaining renal function. Cases with oligohydramnios have the poorest prognosis.^{24,25}

Dysplastic renal parenchyma appears hyperechoic and is often associated with parenchymal cysts. Dysplastic and ischemic kidneys are part of the differential diagnosis of hyperechoic kidneys (see later). The differential diagnosis of hyperechoic kidneys (above +2 SDs) includes renal dilatation, cystic kidneys, syndromes with organomegaly (i.e., Beckwith-Wiedemann syndrome) and renal tumors (see later).

Urinary Tract Dilatation

Dilatation of the renal pelvis is a common finding on obstetric US. Its frequency is evaluated at approximately 1% to 4% of all pregnancies. Yet, all dilatations do not have the same clinical relevance; furthermore, their antenatal and postnatal evolution is variable. This has led to abundant and somewhat controversial literature about the best work-up and follow-up after birth.^{13,26,27}

Definition. Various criteria are used in order to objectively evaluate renal dilatation. In our experience, the best criterion is the measurement of the anteroposterior diameter of the renal pelvis on a transverse scan of the fetal abdomen (Fig. 16-13). Using this measurement, several threshold values have been applied in order to be able to predict the postnatal outcome, especially in cases with moderate dilatation (less than 15 mm). Many authors agree that the upper limit should be 4 mm during the second and 7 mm during the third trimester of the pregnancy (see Figs. 16-13 to 16-15). These limits are set in order to detect not only

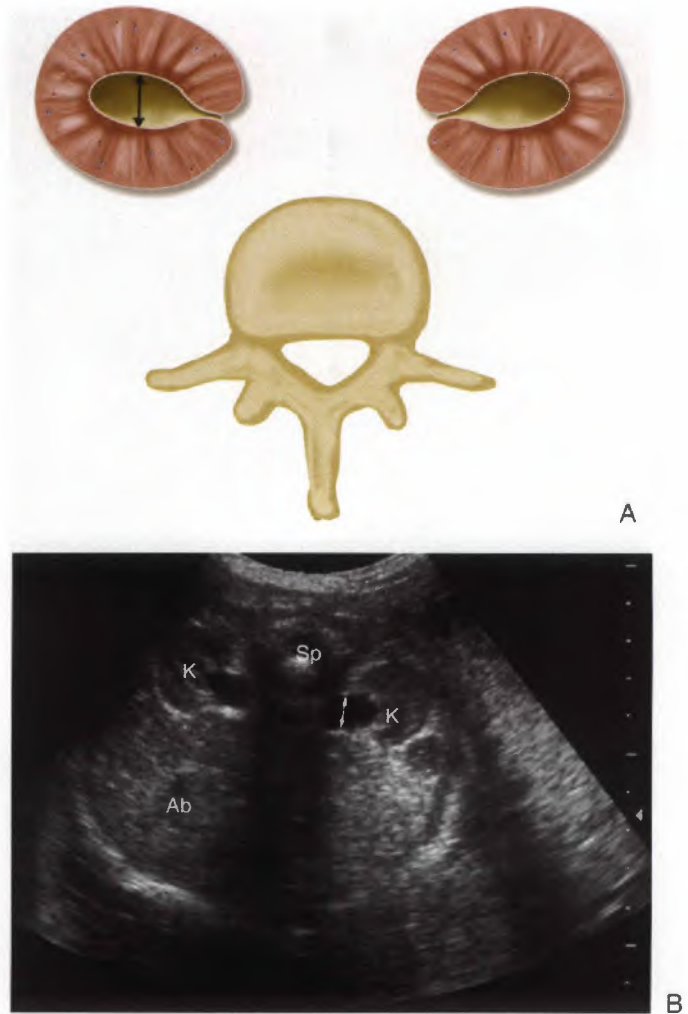

FIGURE 16-13. Bilateral mild dilatation. (A) Illustration demonstrating the method for measuring the degree of dilatation. A transverse axial plane of section of the fetal abdomen is obtained and an anteroposterior measurement of the renal pelvis is obtained. (Illustration by James A. Cooper, MD, San Diego, CA.) (B) Transverse sonographic scan through both kidneys (K) demonstrating a mildly distended renal pelvis and the method of measuring the renal pelvis (arrows). Ab, fetal abdomen; Sp, spine.

Sp, fetal spine. *B.* Sagittal scan through the dilated kidney measuring 72 mm between the calipers.

FIGURE 16-16. Ureteral dilatation (case of ureteropelvic obstruction). Transverse scan of the fetal abdomen demonstrating the dilated tortuous ureter (12 mm between the calipers). Ab, abdomen; B, bladder; Sp, spine.

FIGURE 16-17. Ureteral dilatation (case of vesicoureteric reflux). Coronal view of the fetal trunk showing bilateral pelvic and ureteral dilatation (arrows). Ch, chest.

patients that will need corrective surgery (in case of obstructive dilatation) but also the majority of fetuses and neonates presenting with vesicoureteric reflux. These patients are at risk for developing complications and eventually worsening renal function.²⁷⁻³⁵

Pyelectasis refers to a visible renal pelvis below the significant threshold. During the second trimester, there are reports of this feature as a minor sign of chromosomal anomaly.³² Other sonographic evidence of an abnormality of the UT includes the visibility of the fetal ureter during pregnancy (Figs. 16-16 and 16-17) and the demonstration of an enlarged bladder (more than 3 cm length during the second and 5 cm during the third trimester) (Fig. 16-18).^{34,36}

Findings During Obstetric Ultrasound. Abnormalities resulting in dilatation of the UT can be found at any time

FIGURE 16-18. Megacystis, early second trimester (case of urethral atresia). Frontal view through the fetal head and abdomen. The abdomen is filled by the distended urinary bladder (B). H, fetal head.

during pregnancy. The degree of dilatation may increase or decrease during each trimester. Therefore, in order to screen all potentially abnormal cases, some authors advocate performing one sonographic examination during each trimester.³³ This is controversial, because most abnormalities, particularly mild UT dilatation, do not change significantly during pregnancy and, therefore, are unlikely to alter pregnancy and fetal management.

Table 16-1 Causes of Urinary Tract Dilatation

UPJ obstruction
Nonobstructive dilatation
UVJ obstruction
VUR
Duplication
Megacalycosis
Infundibular stenosis
Bladder outlet obstruction
So-called megacystis-megaureter association
Megacystis microcolon-hypopertalsis syndrome

UPJ, ureteropelvic obstruction; UVJ, ureterovesical junction obstruction; VUR, vesicoureteric reflux.

Once dilatation of the collecting system has been detected in utero, the subsequent evaluation should answer three major questions: the origin of the dilatation, the coexistence of associated anomalies, and finally, the prognosis of the malformation. The most common cause for UT dilatation is ureteropelvic obstruction (UPJ). Other causes include ureterovesical junction obstruction (UVJ), vesicoureteric reflux (VUR), complicated duplex kidneys, and bladder outlet obstruction (BOO) (Table 16-1).

In cases of UPJ obstruction, the renal pelvis is dilated. As mentioned earlier, the threshold measurement on a transverse scan of the kidney is 7 mm for mild dilatation, between 7 and 15 mm for moderate dilatation, and more than 15 mm for marked dilatation. The more dilated the system, the more likely there is to be a decrease in renal function after birth. Furthermore, thinned, hyperechogenic renal cortices with cysts often correspond to obstructive dysplasia and impaired function (Fig. 16-19). Yet, unfortunately, there is often no direct correlation between the renal appearance and postnatal function (see Figs. 16-14 and 16-15).³⁴⁻³⁸

Noteworthy, obstruction may lead to leakage (rupture of a renal calyx or even bladder), and to urinary extravasation either as a perirenal urinoma or as ascites. The functional significance of the leakage is not straightforward. In some

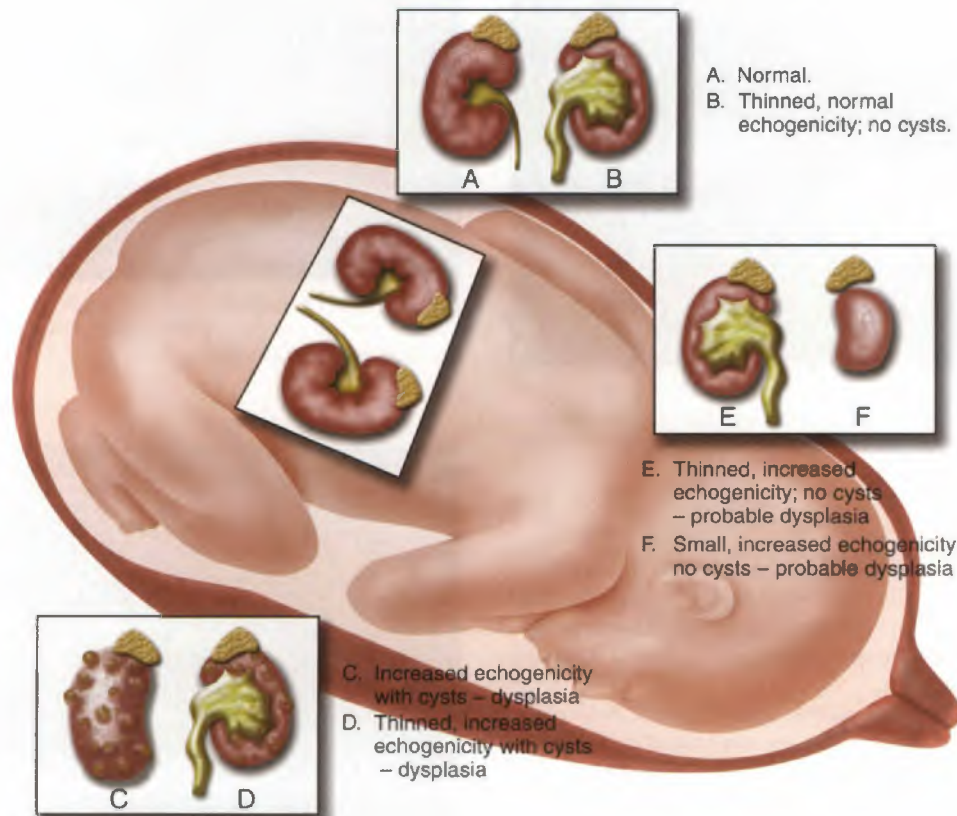

FIGURE 16-19. Urinary tract obstruction produces a varied response from the kidneys. A. The kidney may remain normal in distal obstruction, without reflux. B. Pelvocaliectasis may attenuate the parenchymal thickness. C. The kidney may suffer cystic dysplasia (parenchymal cysts), become fibrotic (increased echogenicity), and cease to function (lack of pelvocaliectasis). D. Alternatively, it may undergo cystic dysplasia with parenchymal cysts and increased echogenicity but continue to have pelvocaliectasis and a thinned parenchyma. If no cysts are visible but the parenchyma is of greatly increased echogenicity, either with (E) or without (F) pelvocaliectasis, dysplasia is probably, but not invariably present. (Illustration by James A. Cooper, M., San Diego, CA.)

FIGURE 16-20. Perirenal urinoma (secondary to a ureteropelvic obstruction), end second trimester. Rotated coronal scan demonstrating the dilated kidney (K) and perirenal urinoma (U). Ch, chest.

instances, it may protect the renal parenchyma, whereas in others renal growth is impaired (Fig. 16-20).^{24,39,40}

The main differential diagnosis of UPJ obstruction is *nonobstructive dilatation* (which is a postnatal diagnosis), multicystic dysplastic kidney (MDK) (part of cystic renal diseases, see below) and UVJ obstruction. Rarer differential diagnoses of UPJ obstruction are megacalycosis due to medullary hypoplasia (the calyces are more dilated than the renal pelvis) and infundibular stenosis (no medullary hypoplasia, but still calyceal dilatation).

The diagnosis of UVJ obstruction is based on the demonstration of a dilated ureter. Peristaltic waves modify the caliber of the ureter (see Fig. 16-16).^{12-14,36} The dilatation may increase in utero, but it usually decreases after birth. In most instances, it is not possible to differentiate between dilatation secondary to UVJ obstruction from that secondary to high-grade vesicoureteric reflux (see Fig. 16-17). A hint for a differential diagnosis is the variability of the diameter of the renal pelvis during one single examination. This would favor VUR.

Renal duplication is usually easy to demonstrate once dilatation has developed. Various complications may occur at the level of renal duplications; for instance, obstruction at the upper or lower moiety or MDK at the upper or lower moiety. Both can be associated with distal insertion of the ureter ending either as an ureterocele or into an ectopic extravascular insertion. The ureterocele is seen as a septum within the bladder. It may prolapse into the urethra and result in acute in utero obstruction. The parenchyma related to obstruction may be thinned and dysplastic. The ectopic extravascular insertion may be difficult to diagnose in utero (Figs. 16-21 and 16-22).⁴¹⁻⁴⁴

Finally, the level of UT obstruction can be located below the bladder. The most frequent cause in male fetuses is posterior urethral valves (PUVs). The condition may or not

induce dilatation of the upper UT. The dilatation can be unilateral or bilateral, and may be related to obstruction or to VUR.^{45,46} The degree of associated dysplasia is also variable. There seems to be a correlation between cortical echogenicity and the degree of obstructive dysplasia (Figs. 16-19 and 16-23).³⁷

In cases of obstruction, the bladder “reacts” in different ways: it can enlarge, its wall can thicken, or the bladder may rupture and urinary ascites appears; other protective decompressive mechanisms may develop through VUR, urinomas, extravasation, or recanalization of the urachus (Fig. 16-24).³⁹

Bladder enlargement due to obstruction secondary to PUV must be differentiated from other causes of BOO and from other causes of large bladder without obstruction (Table 16-2). Urethral atresia may result in megacystis detected during the first trimester and oligohydramnios (see Fig. 16-18); the condition often has a poor prognosis. A dilated penile urethra may be seen. Megacystis-megaureter association is related to massive VUR (Fig. 16-25). In such a case, the amniotic fluid volume is normal. Megacystis-microcolon-hypoperistalsis syndrome is a rare condition occurring in female fetuses with a poor postnatal prognosis (see later).⁴⁶⁻⁴⁹

Prognosis and In Utero Treatment. Whenever a renal anomaly (mainly dilatation) is detected, a complete survey of the fetal anatomy should be performed in order to detect associated malformations that would indicate the need for chromosomal analysis or the possibility of polymalformative syndromes; both worsen the prognosis.^{10,50,51}

In cases of dilatation, the prognosis will depend upon the type and extent of anomalies. Features of poor prognosis include early diagnosis, bilateral marked dilatation, persistently obstructed bladder, oligohydramnios, and secondary lung hypoplasia. Bilateral renal dilatation and BOO have an increased risk of associated chromosomal anomalies, and therefore, in such cases, an evaluation of fetal chromosomes may be warranted. The finding of associated hyperechogenic and cystic renal parenchyma is frequently but only partially informative (positive predictive value [PPV] = 59%, negative predictive value [NPV] = 56%) about renal function. Conversely, normal cortical echogenicity does not exclude dysplasia.

The role of measuring urinary electrolytes in the fetal urine obtained through transabdominal puncture is controversial. There are discrepancies in the predictive values of urine biochemistry owing to small sample size, variations in cutoff values, gestational age, and sampling frequency. Fetuses with renal damage show decreased urinary concentrating especially of sodium and calcium without clear convincing confirmation. Measurements of B₂-immunoglobulin on C cystatin in the fetal urines allow a better accuracy (Table 16-3). The outcome of vesicoamniotic shunting is also controversial. Although technically relatively easy, the long-term results have not been convincing.⁵²⁻⁵⁶

Management of Fetal Renal Pelvic Dilatation After Birth. It is of utmost importance that any information relevant for the proper postnatal management is correctly transmitted to the postnatal team that will be in charge of the newborn. A variety of findings may be seen in the neonate after birth that suggest an abnormality of the UT (Table 16-4). After birth, some conditions require an

FIGURE 16-21. Renal duplication - Obstructed upper pole and ectopic ureterocele (third trimester). *A.* Illustration demonstrating duplication of the collecting system. Typically the upper pole moiety is obstructed and the lower pole moiety often demonstrates reflux. The ureter from the upper pole moiety inserts more medial and caudal into the bladder than the ureter from the lower pole. This is referred to as the Meyer-Wiegert rule. Dilatation of the submucosal portion of the ureter results in a ureterocele. (*Illustration by James A. Cooper, M.D., San Diego, CA.*) *B.* Sagittal scan through the left kidney demonstrating the dilated upper pole (UP) and normal lower pole (LP). *C.* Sagittal scan through the bladder (B) displaying the ureterocele (arrow).

FIGURE 16-22. Complicated duplex system, third trimester. *A.* Sagittal scan of the left kidney. Both the upper (Up) and lower pole (Lp) are dilated. Sp, fetal spine. *B.* Transverse scan of the fetal abdomen demonstrating the dilated kidney (K), the dilated ureters (U; they should not be confused with dilated intestinal tract), and the urinary bladder (B).

FIGURE 16-23. Posterior urethral valves and obstructive dysplasia. *A.* Coronal scan demonstrates a distended bladder (BI), dilated ureters (U) and a dilated posterior urethra (PU). *B.* Bilateral hydronephrosis and hyperechogenic kidneys suggesting dysplasia. *C.* A sonogram slightly later of one of the kidneys confirms obstructive cystic dysplasia (arrows).

immediate confirmation and therapeutic maneuvers. For instance, obstructive PUVs or prolapsed ectopic ureterocele into the urethra leading to oligoanuria necessitate immediate treatment. In case of such suspicions, US and a voiding cystourethrogram (VCUG) should be performed immediately after birth in order to confirm the anomaly.⁵⁷

In all other cases, the work-up should be planned without emergency. There is controversy regarding the respective role of US and VCUG in the postnatal work-up. Some authors advocate the systematic use of a VCUG in every case of antenatal detection of UT dilatation; for others, only patients with persistent dilatation should undergo a VCUG.^{58,59} Whatever the choice, all patients are put under prophylactic antibiotic therapy until a final diagnosis and a final therapeutic decision is made.

Practically, we have applied an algorithm based on US examinations (Fig. 16-26). An US including the kidneys, bladder, and ureters should be performed during the first week of life in order to verify the UT abnormality. The sonographic analysis should be as detailed as possible, and any significant anomaly should lead one to perform a VCUG. If the examination is negative, a repeat sonographic examination should be performed at the age of 1 month. Again, if any abnormality is found, a VCUG should be

FIGURE 16-24. Posterior urethral valves and urinoma, third trimester. Transverse scan of the fetal abdomen. The bladder (B) is small and its wall thickened. At the level of the left kidney, a large urinoma (U) has developed. The right kidney (RK) is just moderately dilated. Sp, spine.

performed, but if no anomaly is demonstrated, no further evaluation is needed. At this stage, any prophylactic antibiotic therapy should be stopped.⁶⁰

The role of VCUG is clearly to detect vesicoureteric reflux that will render long-term follow-up and persistent prophylaxis necessary. This attitude is intended to reduce unnecessary complications that are associated with high grades of VUR. It will also demonstrate anomalies of the urethra and potentially abnormal ureteral endings. Follow-up studies include US (every 6 months for a period of 2 years) in order to verify renal growth, VCUG every year to monitor the reflux, and MAG3 isotopic studies in order to verify renal function.⁶¹⁻⁶³

If no reflux is present, complementary imaging is necessary in order to determine the origin of the dilatation. Renal function is assessed through isotopic studies; the morphology of complex or complicated UT malformations are best evaluated by MRI. The technique is particularly helpful for the assessment of the severely dilated UT and complicated duplex systems with dilatation of the upper and lower pole moieties. Also, the technique is able to provide information on the functional status of the kidney. It will help the surgeon in optimizing treatment.⁶⁴ After this evaluation and if a conservative attitude is elected, a sonographic

Thickening of the pelvic wall
Thickening of the ureteral wall
Ureteral dilatation above 3 mm
Enlarged bladder

FIGURE 16-25. Megacystis megaureter association, third trimester. Transverse scan (A and B) of the fetal abdomen showing variation in the dilatation of the renal pelvis at two different moments during the same examination. The bladder (B) is markedly enlarged. At birth there was bilateral grade V reflux. Sp, spine.

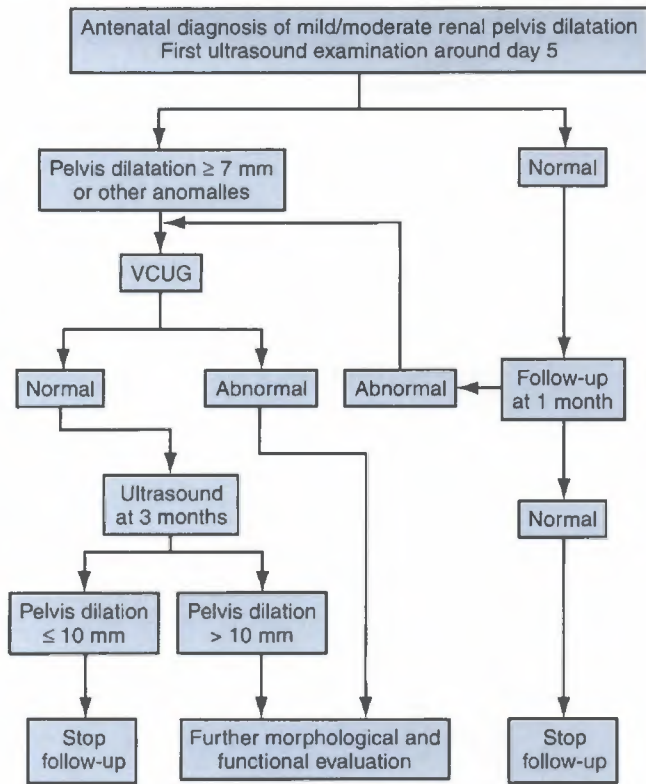

FIGURE 16-26. Postnatal imaging strategy in infants with mild to moderate fetal renal pelvic dilatation.

follow-up is advised in order to follow renal growth and dilatation. It has been shown that a large proportion of UT dilatation resolves spontaneously.⁶³

The length of follow-up must be adapted to the type of anomaly. If the dilatation of the renal pelvis measures less than 10 mm, a baseline US can be performed at 3 months; if no further dilatation occurs, the follow-up can be stopped because worsening rarely occurs. For dilatation greater than 10 mm or for ureteral dilatation, a longer follow-up is needed. During the period of follow-up (2 to 3 years), it is also important to exclude worsening of the renal function that would suggest the need for alternative treatment.⁶⁵⁻⁶⁷ Using this algorithm, very few abnormal cases escape the work up and the risk of complications is very low. Some centers use the grading system of the Society of Fetal Urology, although its value in management and prognosis is uncertain (Fig. 16-27).

Hyperechoic Kidneys

Hyperechogenicity of the fetal kidney is defined by comparison with the adjacent liver or spleen. This is difficult to assess in the first and second trimester because the kidney is “physiologically” hyperechoic (or isoechoic at the end of the second trimester) relative to the liver. It is easier to characterize after 28 weeks when the renal cortex should always be hypoechoic compared to the liver and spleen.

Hyperechogenicity of both fetal kidneys can result from various diseases (Table 16-5).

SOCIETY OF FETAL UROLOGY GRADING SYSTEM OF CONGENITAL HYDRONEPHROSIS

Grade	Central renal complex	Renal parenchymal thickness
0	Intact	Normal
I	Mild splitting of pelvis (dilatation)	Normal
II	Moderate splitting of pelvis and calyces, but complex, confined within renal border	Normal
III	Marked splitting, pelvis dilated outside renal borders and calyces dilated	Normal
IV	Further pelvicalyceal dilatation	Thinned

ADPKD, autosomal-dominant polycystic kidney disease; ARPKD, autosomal-recessive polycystic kidney disease; GCD, glomerulocystic disease; MCD, medullary cystic disease.

The main etiologies are obstructive dysplasia and cystic renal disease (see later). There are many other causes that include syndromes, acquired fetal renal diseases (renal vein thrombosis [RVT], infections, toxic agents), maternofetal disease, and congenital nephrotic syndromes. However, hyperechoic kidneys may also be seen as a normal variant. Therefore, the work-up of hyperechoic kidneys should include a detailed sonographic evaluation of the kidneys and UT; a detailed analysis of the family history and of the natural course of the disease (see Table 16-5 and Fig. 16-28).^{10,68-72}

The prognosis is defined by the suspected diagnosis, the associated malformations, and chromosomal anomalies. Again, oligohydramnios is associated with a poor prognosis.

Hyperechogenicity of one kidney: unilateral hyperechogenicity can be seen with unilateral multicystic dysplasia, unilateral obstructive dysplasia, a renal tumor, or unilateral RVT (see later) (Fig. 16-29).

Cystic Renal Diseases

Classification of Renal Cystic Diseases. Typically, renal cystic diseases are separated into diseases with or without hereditary transmission (Table 16-6). Parenchymal dysplasia is the most frequent cause of noninherited renal cysts. Autosomal-dominant polycystic kidney disease (ADPKD) is the most frequent cause of inherited cystic disease. Yet, with recent developments in genetics, this separation has become less clear. For instance, there are some rare cases of MDKs with familial transmission (the so-called "renal adysplasia").⁷³

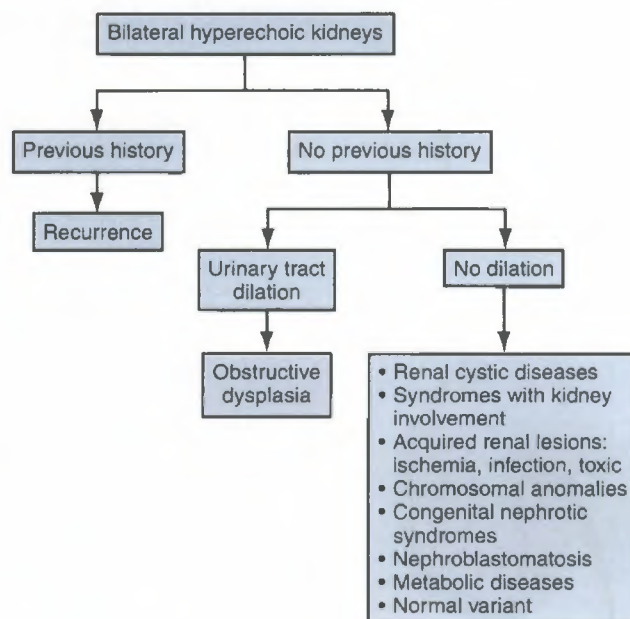

FIGURE 16-28. Etiologies of bilateral hyperechoic kidneys.

The group with clearly identifiable genetic transmission includes autosomal-recessive polycystic kidney disease (ARPKD) and ADPKD, medullary cystic disease (MCD), and certain cases of glomerulocystic diseases. The latter can be encountered as an isolated finding or, more often, as part

FIGURE 16-29. Unilateral hyperechoic kidney, case of (cystic) dysplasia, second trimester. Sagittal scan through the right kidney. The renal parenchyma is hyperechoic and contains a cyst in the upper pole (arrow). The lower pole is dilated (case of multicystic dysplastic kidney in the upper pole of a duplex system). Ch, chest.

of a syndrome in which inheritance may or may not be known (see later). Among the polymalformative syndromes, renal cystic disease can be the main and essential finding or just an accessory anomaly.^{10,74-77}

Sonographic Evaluation. The sonographic evaluation has to be as detailed as possible because some features are essential for the differential diagnosis. The kidneys have to be measured and compared with studies establishing “size versus gestational age” nomograms.⁶ The overall echogenicity must be appreciated by comparing the parenchymal echogenicity with that of the liver or spleen (especially in the third trimester). Noteworthy, evaluating hyperechogenicity is somewhat subjective and is also dependent on the equipment used and maternal obesity. The presence or absence of CMD is an important differentiating criterion. Normal CMD, that is, hypolucent medullae relative to cortex is present in the second trimester. Finally the detection of renal cysts, their size, and their location are useful in the differential diagnosis (see Table 16-5).

hepatic fibrosis develop in many babies who survive the perinatal period. Mutations in the *PKHD1* gene are usually demonstrated in this disease.⁷⁷ Yet, because some infants do survive the neonatal period with few or little symptoms, additional genes are probably involved.

The disease is characterized by marked elongation of the collecting tubules that expand into multiple small cysts. The cystic dilatation of the tubules is variable and predominates in the medulla. The outer cortex is spared because it contains no tubules. There is associated biliary dysgenesis. Hepatic fibrosis has been described on pathologic examination of affected fetuses.⁷⁸

The sonographic presentation varies according to the severity of involvement. The most typical presentation is that of markedly enlarged hyperechoic kidneys (+4 → +15 SD), without CMD (Fig. 16-30A and B). This appearance can be observed in the second trimester. The patterns may evolve, and the size of the kidneys may continuously increase during the third trimester. Other findings include oligohydramnios and lung hypoplasia, and therefore, the prognosis is usually poor. There are no other malformations associated with ARPKD. The list of differential diagnoses includes glomerulocystic disease and Bardet-Biedl syndrome (BBS) (see later).^{79,80} In these two diseases, the parenchyma is more homogenous than in ARPKD. When the kidneys are not as enlarged (+2 → +6 SD), the diagnosis may be more difficult to ascertain. A hypoechoic outer cortical rim that is usually present in the recessive type may help in suggesting the diagnosis (see Fig. 16-30C). Cysts (greater than 3 mm) may be already apparent in the fetus in the third trimester; they may appear unilateral, and their number varies. This finding occurs in one third of diagnosed fetal cases but is not specific.⁸¹

Another presentation of ARPKD can be reversed CMD with large (+2 → +4 SD) kidneys (Fig. 16-31). This finding is probably related to increased number of interfaces within the medullae, and to inspissated material within the dilated tubules. It is an important observation because there are very few other causes of reversed CMD. These patients have a better prognosis when the amniotic fluid volume is preserved. The differential diagnosis includes metabolic

They are still large and hyperechoic, but the peripheral cortex is somewhat hypoechoic (*arrows*) (cortical rim sign).

disorders and intrauterine growth restriction. The liver abnormalities, for example, hepatic fibrosis, are not demonstrated in utero.^{78,82-88}

Autosomal-Dominant Polycystic Kidney Disease

ADPKD is the most common form of polycystic kidneys disease in humans and occurs in 1 in 800 live births. ADPKD is an inherited condition that includes at least three phenotypically indistinguishable but genetically distinct

entities caused by mutations in three genes—*PKD1*, *PKD2*, and *PKD3*. The *PKD1* gene is located on chromosome arm 16p in 90% of patients and is related to spontaneous mutation in 10%. ADPKD is transmitted as an autosomal-dominant trait, with almost 100% penetrance if patients live long enough. Because of the variable expressivity and spontaneous mutation, a family history is not found in nearly one half of patients. Defective polycystins appear to contribute to cyst formation by affecting epithelial cell maturation, resulting in the development of cysts of varying sizes in the cortex and medulla.⁷⁷ There is likely one or more other

genes involved because some obvious cases have neither of these mutations.

The disease is characterized by the presence of multiple cysts that develop on the wall of collecting tubules and nephrons. The cysts are scattered within the cortex and medulla. These cysts enlarge progressively and are typically identified in early adulthood. Cysts may also develop in the liver, spleen and pancreas in adults.⁸⁹

In the fetus, a pattern highly suggestive of the disease has been recently described by Brun et al⁹⁰ and was encountered in more than 80% of affected patients in the third trimester. They found moderately enlarged kidneys (1-2 SD above the

mean) which have hyperechoic cortices and relatively hypoechoic medullae (Fig. 16-32). For the authors, the hyperechoic cortex is probably related to the presence of multiple microcysts that predominate at this stage in the cortex. In most cases, the amniotic fluid volume was normal.⁹⁰ Although the exact sensitivity of the pattern is unknown, its demonstration should prompt a familial inquiry including sonography of the parents and grandparents because 50% of cases with the dominant form are discovered following the sonographic detection. However, it is estimated that an unknown percentage of cases of ADPKD are the result of a new mutation. A list of differential diagnoses exists for this pattern and should be considered (Table 16-7 and Fig. 16-33). For some patients, only long-term follow-up will establish the final diagnosis.

As mentioned earlier, in ADPKD, cysts develop only later in adulthood, yet, exceptionally, cysts may be encountered in utero.^{90,91} Several other sonographic patterns may be

encountered and suggest ADPKD. First, the kidneys may have a normal appearance in utero; the percentage of cases with a completely normal pattern is unknown. In a few patients affected by autosomal-dominant polycystic kidneys, the kidneys may be diffusely hyperechoic and markedly enlarged (+4 → +8 SD) without CMD. Cysts may develop in utero or after birth in the subcapsular area. This pattern corresponds to the “glomerulocystic variant” of the disease (Fig. 16-34).^{80,92-94} The prognosis is still good unless oligohydramnios develops. In such case, hypertension and renal failure may develop rapidly after birth.

Interestingly, other UT malformations may be present in association with ADPKD. These include unilateral MDK, UPJ obstruction, duplex systems, and even congenital metabolic diseases.⁹⁰

After birth, as mentioned earlier, the cysts progressively develop; cystic renal involvement may be asymmetric in the infant and child, whereas in some cases, there is a reduction in renal size following birth.^{89-91,95-97}

Glomerulocystic Kidneys

On histopathology, glomerulocystic kidneys (GLC) are defined as kidneys that contain cysts that correspond to distended Bowman spaces. Five to 10 percent of the spaces must be affected in order to establish such a diagnosis. Glomerular cysts are not specific to a simple disorder. They can be present with other types of renal cystic diseases, both inherited and sporadic, in certain syndromes, and in dysplastic kidneys (Table 16-8).

On sonographic examination, the classic GLCs appear enlarged (+4 → +8 SD), hyperechoic, and without CMD (Fig. 16-35). The most suggestive feature is when subcapsular cortical cysts are present (see Figs. 16-34 and 16-35). They can develop in utero or after birth. When present, the diagnosis is straightforward. This finding may help to characterize various syndromes in association with GLC

FIGURE 16-34. Autosomal-dominant polycystic disease (ADPKD), glomerulocystic form in a neonate. Sagittal scan through the enlarged kidney, which appears hyperechoic with multiple tiny cysts, mostly peripheral. The father was affected by ADPKD.

when other malformations coexist. The prognosis will be based on associated findings and on the volume of amniotic fluid. The cysts may develop after birth only.^{80,92-94,98}

Medullary Cystic Dysplasia

MCD, in which cysts involve mainly the medullary tubules, is a feature of many syndromes. It may be associated with glomerulocystic changes as well (see Table 16-8). Tubulointerstitial fibrosis may develop progressively. The renal findings seen in MCD are the renal histologic changes

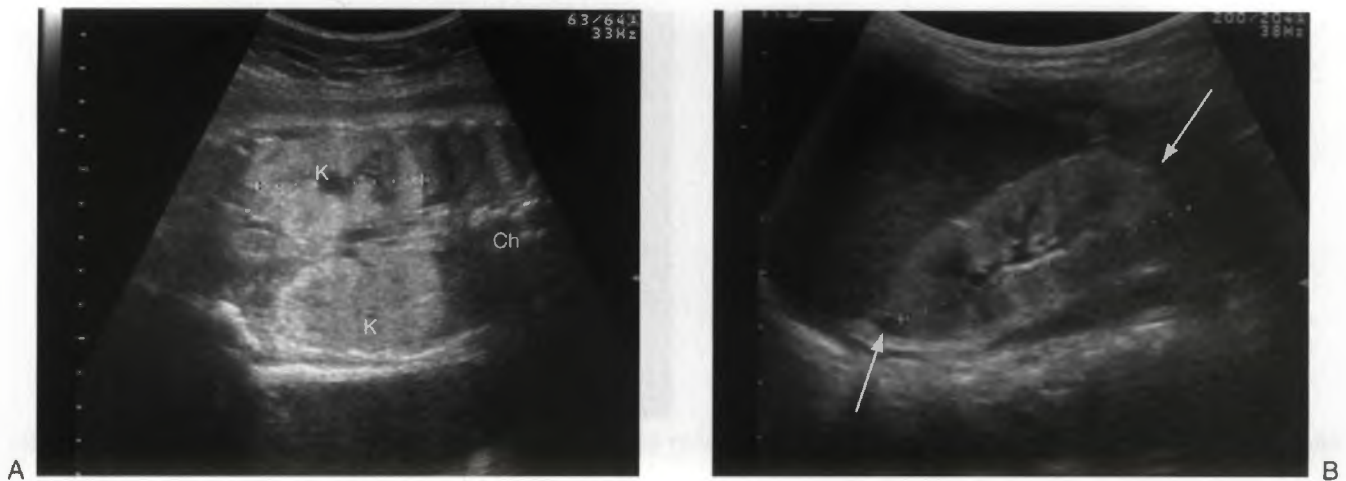

FIGURE 16-35. Glomerulocystic kidney in a “diabetes and renal cyst syndrome.” *A.* In utero, third trimester. Front view through both kidneys (K), which appear enlarged and hyperechoic without corticomedullary differentiation. Ch, chest. *B.* At birth, sagittal scan through the right kidney. Small peripheral cysts have now appeared (arrows).

FIGURE 16-36. Medullary cystic dysplasia, case of Meckel-Gruber syndrome. Transverse scan of the fetal abdomen. Both kidneys display an abnormal pattern: diffusely cystic changes involving the entire kidney. (An occipital encephalocele was also present, which is not shown.)

FIGURE 16-37. Bardet-Biedl syndrome, third trimester. Transverse scan of the fetal abdomen. Both kidneys (K) are enlarged without corticomedullary differentiation. (Polydactyly, which is not shown, was also present.) Sp, spine.

typically encountered in the Meckel-Gruber syndrome. The medullary cystic changes develop very early in the pregnancy and are obvious as early as the end of the first trimester. The demonstration of anomalies of the central nervous system and of the extremities (polydactyly) render the diagnosis even more certain. On sonography, the kidneys are enlarged, a pseudo-cortico-medullary differentiation is present already at the end of the first trimester and the medulla is very prominent. This pattern as demonstrated at this early stage is very typical⁹⁹ (Fig. 16-36).

Cystic dysplasia is also common in BBS. The renal lesions are not concentrated in the medullary areas but are more diffuse. The sonographic pattern is that of diffuse hyper-

echoic, slightly or markedly enlarged kidneys. Cysts may be present in utero or develop after birth. Polydactyly is a classic associated finding in utero. The other abnormalities of BBS develop later in childhood (Fig. 16-37).^{79,99-102}

Unclassified Cystic Diseases

Macrocysts may be encountered in cases of tuberous sclerosis. The cysts have specific histopathologic features that include eosinophilic epithelium. Other evidence of the disease, such as cardiac rhabdomyomas and intracerebral lesions, may be present in utero. Several other syndromes include microcysts or macrocysts (e.g., Ivemark syndrome) (Fig. 16-38).^{103,104}

FIGURE 16-38. Ivermark II syndrome, second trimester. *A.* Sagittal scan through the hyperechoic kidney, corticomedullary differentiation. *B.* Associated limb deformity: an angulated femur is visible (*arrow*).

Diseases Without Genetic Transmission

Multicystic Dysplastic Kidney

Among the group without hereditary transmission, MDK is one of the most common diseases (although as mentioned earlier, there is known to be an inheritable subgroup⁷³). The sonographic findings in patients with MDK are usually straightforward: unilateral involvement with noncommunicating cysts of variable size, variable amount of hyperechoic stroma, no normal cortex or medulla, irregular renal contours, and no identifiable collecting system (Figs. 16-39 and 16-40). The cysts can be large, presenting as a large fetal abdominal mass, or on the contrary, microcystic. MDK may also develop in the upper part of a duplex system (see Fig. 16-29) or be located in an ectopic position (Fig. 16-41). The size of the cysts may decrease in utero or after birth (see Fig. 16-40). Therefore, the entire MDK may “disappear” and give the appearance of renal agenesis. Unilateral involvement carries a good prognosis, although there may be an anomaly affecting the contralateral kidney (i.e., UPJ obstruction). The condition can be

FIGURE 16-39. Multicystic dysplastic kidney (MDK), third trimester. Transverse scan of the fetal abdomen. The MDK is limited by the calipers (47.9 mm). Sp, spine.

FIGURE 16-40. Multicystic dysplastic kidney (MDK), spontaneous involution. *A.* In utero transverse scan of the fetal abdomen. Typical MDK of the left kidney (K). L, liver, Sp, spine. *B.* At age 1 year, sagittal scan of the left flank. The size of the cysts have decreased and only two remained. S, spleen.

associated with other system's malformations (Fig. 16-42). When MDK is an isolated finding, there is no increased risk of chromosomal anomaly. Cases with bilateral involvement (1 out of 15 cases) are associated with severe oligohydramnios and pulmonary hypoplasia; they carry a poor prognosis (Fig. 16-43).^{21,105-107}

FIGURE 16-41. Multicystic dysplastic kidney (MDK) of an ectopic pelvic kidney (second trimester). Frontal view of the fetal abdomen. The hyperechoic MDK is visible (arrows) in the pelvis, to the right of the aorta and iliac artery.

Obstructive Dysplasia

Obstructive renal dysplasia is the other most common cause for nonhereditary fetal renal cystic disease and hyperechoic kidneys. In such cases, there is a dilatation of the upper and lower UT associated with hyperechogenicity of the renal parenchyma and ultimately cysts of variable sizes within the renal cortex. The renal function is usually impaired (Figs. 16-19 and 16-44).^{73,104,108}

Simple Renal Cyst

Simple renal cysts are uncommon in the fetus. They may disappear "spontaneously."^{109,110} The discovery of a cyst necessitates simple US follow-up in order to exclude the development of a more diffuse distribution and other cystic diseases (Fig. 16-45).

The Work-Up of Fetal Cystic Disease. The basis for the work-up must rely on the following:

- The sonographic patterns at presentation and on follow-up (see Tables 16-5, 16-7, and 16-9 to 16-12; and Fig. 16-28).
- Associated malformations.^{10,104}
- Family history.

The discovery of abnormal kidneys on obstetrical US in cases of a positive familial history signifies the likelihood of recurrence of the disease. In the absence of family history, the diagnosis will be based on the sonographic patterns at presentation and associated malformations. Complementary

examination such as MRI should be performed as required by the sonographic findings. Subsequently, once the most common or the most typical diagnoses are considered, other diagnoses should also be considered whenever the maternal history reveals specific symptoms (e.g., diabetes, some metabolic diseases).¹¹¹⁻¹¹⁷

Renal Tumors

More than half of all congenital abdominal masses found in the neonate originate in the kidney. In the fetus, the most common renal tumor is the mesoblastic nephroma (Fig. 16-46). It appears as a solid tumor that is sometimes difficult to delineate from the adjacent renal parenchyma. The tumor can appear partially cystic. In utero, polyhydramnios is typically associated and hypertension develops after birth. Cases of fetal renal Wilms' tumor have been reported as solid or partially cystic tumors. The prognosis is good. Bilateral involvement suggests nephroblastomatosis, which is a condition with multiple benign nodular lesions.

Patients with Beckwith-Wiedemann syndrome, congenital aniridia, and Perlman and Drash syndromes are at risk of developing renal tumors. The main differential diagnosis of a cystic renal tumor includes MDK.^{113,114,117-120} Solid masses adjacent to the kidney, such as neuroblastoma and subdiaphragmatic pulmonary sequestration, should be differentiated from true renal masses.

Acquired Renal Pathologies

Renal anomalies can occur during pregnancy because of a maternal disease or because of ischemic damage (or both). For instance, maternal diabetes and twin pregnancy increases the risk for RVT in the fetus. Sonographically, at

FIGURE 16-46. Mesoblastic nephroma, third trimester. Sagittal scan of the fetal trunk. A large round solid mass (M) has developed in the lower pole of the right kidney (RK). B, bladder; Ch, chest; LK, left kidney.

FIGURE 16-47. Subacute renal vein thrombosis, third trimester. Transverse scan of both kidneys. The left kidney (LK) is larger and more globular than the right one (RK). Some hyperechoic stripes are visible (arrows). Sp, spine. (Courtesy of P Sonigo MD, Paris, France.)

the acute stage of the thrombosis, the volume of the affected kidney and its echogenicity increase. In some cases, Doppler analysis may confirm the thrombosis. Rapidly, collateral vessels develop and the renal vascularization becomes almost normal. Some vascular calcifications in the interlobar areas may remain as sequelae (Fig. 16-47). A thrombus within the inferior vena cava and adrenal hemorrhage may be associated findings.¹¹⁹ Maternal deficit in neuropeptidase may induce an acute transient glomerulonephritis in the fetus that results in increased volume and echogenicity. Transient renal failure may occur at birth (Fig. 16-48).¹²² Maternofetal infection may involve the kidneys and present with increased echogenicity as demonstrated in some cases with cytomegalovirus.

Other Congenital Renal Disorders

Congenital Nephrotic Syndrome

Congenital nephrotic syndrome may rarely affect the fetus. The kidneys appear diffusely hyperechoic usually without CMD. The placenta is thick, and polyhydramnios is present. The proteinemia can be detected in the amniotic fluid. A particular association is the Drash syndrome that includes pseudohermaphroditism and a particular nephrotic syndrome (mesangial sclerosis). Patients affected by the syndrome carry an increased risk for Wilms' tumor (Fig. 16-49).^{12,123-126}

Bladder, Urethra, and Urachus

As mentioned earlier, the bladder is the first structure of the UT to be seen in the fetal pelvis at approximately 9 to 10 weeks that indicates urine is being produced. Its demonstration is an important part of the obstetric US assessment of normal fetal development. Anomalies of the UT can be suspected whenever the bladder is enlarged (more than 3 cm length in the second trimester, more than 6 cm in the third trimester of the pregnancy) or not visible during an entire examination.

Whenever an *enlarged bladder (megacystis)* is demonstrated, BOO should be suspected first. During the first and early second trimester, it could result from urethral atresia and prune-belly syndrome. The kidneys may appear hyperechoic owing to obstructive dysplasia. The prognosis is poor (see Figs. 16-18 and 16-23).^{127,128} In the second and third trimester in the male fetus, megacystis almost always results from PUV. The bladder wall may be thickened, and the upper UT may or may not be dilated with hyperechoic renal parenchyma corresponding to obstructive dysplasia. The condition can also be associated with perirenal urinoma due to extravasation.

The differential diagnosis of an enlarged bladder should include marked vesicoureteric reflux and megacystis-microcolon-hypperistalsis syndrome (see Table 16-2). The latter occurs virtually always in female fetuses. The short colon is difficult to assess by US and is easier to demonstrate by fetal MR imaging.¹⁸ Finally, one should not forget to

consider a pseudoenlarged bladder in the third trimester female fetus.^{46,127-129}

When the *bladder is not visible*, the amount of amniotic fluid helps to differentiate cases secondary to lack of urine production from bladder malformation. In case of oligohydramnios or anhydramnios, absent or nonfunctioning kidneys should be suspected (bilateral renal agenesis, bilateral MDKs). When the amount of amniotic fluid is just slightly reduced, intrauterine growth restriction and

FIGURE 16-49. Congenital nephrotic syndrome, third trimester. Frontal view of both kidneys (K), which appear enlarged and hyperechoic, with poor corticomedullary differentiation. Oligohydramnios was associated. Ch, chest.

FIGURE 16-48. Acute glomerulonephritis secondary to maternal deficit in neuropeptidase. Third trimester scan. A. Sagittal scan of the left kidney (LK) with a thick hyperechoic cortex (arrows). S, spleen; St, stomach. B. Transverse scan through both kidneys that display the same thick hyperechoic appearance. Sp, spine.

FIGURE 16-50. Bladder exstrophy, late second trimester. A. Transverse scan through the fetal pelvis. The bladder structure is recognized between the two umbilical arteries (arrows). B. Color Doppler confirms the absence of bladder structure.

maternofetal infection should be considered.¹³⁰ **One should never assume that the explanation for oligohydramnios or anhydramnios is due to rupture of the membranes until one has demonstrated a functioning UT by identification of the urinary bladder and/or the kidneys.**

If the amount of amniotic fluid is normal, a bladder malformation should be considered. In case of bladder exstrophy, no bladder is seen between the umbilical arteries (Fig. 16-50). Instead, a soft tissue mass is seen just below the umbilicus corresponding to the open bladder (mucosa). In the male fetus, the penis is shortened and widened, and the gender ambiguous. The condition has to be differentiated from the omphalocele-exstrophy-imperforate anus (OEIS) complex, in which an omphalocele is present as well.¹³⁰⁻¹³⁴

An abnormal bladder may also be observed in cases of cloacal malformation sequence (persistence of the urogenital sinus). In this condition, there is a single opening draining the bladder, the vagina, and eventually the colon. It may be difficult to differentiate between these different structures by US alone (Fig. 16-51).^{18,133,134}

In the male fetus, the main malformation involving the urethra is PUV (see earlier). This condition results in BOO at variable degrees. On US, the distended posterior urethra can sometimes be clearly demonstrated (see Fig. 16-23). The prognosis is also variable depending on the degree of obstruction and renal dysplasia. Anterior valves are very rarely demonstrated in utero. The main differential diagnosis is megalourethra (Fig. 16-52), in which is a deficient spongy tissue around the urethra, which is dilated to a variable extent.^{135,136}

Under normal conditions, the urachus is not seen in utero because this canal becomes fibrotic after the first trimester. Anomalies related to a (partially) patent urachus include patent distended urachus in association with a BOO or an urachal cyst that should always be included in the differential diagnosis of midabdominal cysts.^{49,137,138}

Another finding related to the embryo-fetal development of the allantoic-urachal complex is the discovery of a cyst

FIGURE 16-51. Persistence of urogenital sinus, end of first trimester. Sagittal scan of the fetus. At the level of the fetal pelvis, a cystic polylobulated mass (M) replaces the normal anatomy. No bladder is seen. H, head.

(allantoic cyst) connected to the bladder but developed within the umbilical cord. These cysts resolve or rupture spontaneously at birth; in some cases, the urachus has to be repaired surgically after birth (Fig. 16-53).

FETAL GENITAL TRACT

Normal Genitalia

The determination of fetal sex is possible during the obstetric sonographic examination. The improvement of high-resolution US and the use of transvaginal probes allow detailed visualization of the fetal genital anatomy often at the end of the first trimester.

Up to 11 weeks, the external genitalia are identical in both sexes. After 14 weeks, when a rapid growth of the penis occurs, the differences between both are evident. On the sagittal scan, the penis points upward, whereas the clitoris

FIGURE 16-52. Megabladder and megalourethra, second trimester. *A.* Coronal view of the fetus. The bladder (BI) occupies most of the fetal abdomen (urinary tract was bilaterally dilated as well). H, fetal head. *B.* Transverse axial view through the penis showing the dilated urethra (arrow) without spongious tissue around it.

FIGURE 16-53. Allantoic cyst, third trimester. A large cyst (C) located within the umbilical cord connects with the bladder (B) through a small channel (arrow). No other malformation is visible.

FIGURE 16-54. Male sex, first trimester. Sagittal sign. Sagittal scan of the fetus. The penis points upward (arrow).

points downward (Fig. 16-54). During the second trimester, the difference between both sexes becomes even more obvious because the labia or the scrotum and penis are more clearly visible.

The testes can be identified within the scrotum after 26 weeks (Fig. 16-55), and minor degrees of hydrocele is a normal finding. During the third trimester, the labia major and minor can be visualized. Under normal circumstances, the ovaries are usually not identified. On the contrary, during the (late) second and third trimester, the normal uterus can be visualized owing to its physiologic hypertrophy secondary to hormonal influence. The uterus appears as a round or oval mass within the fetal pelvis interposed between the rectum and fetal urinary bladder (Fig. 16-56). The normal endometrium appears hyperechoic.

The determination of the sex is important not only for the parents but also in the presence of specific familial diseases (i.e., hemophilia) or in case of various morphologic anomalies (ovarian cysts, BOO, and so on).¹³⁹⁻¹⁴²

Ambiguous Genitalia

Ambiguous genitalia is characterized by a difficulty to assign the fetal gender during the US examination in the second or

third trimester. The examiner is unable to differentiate between a short penis and a hypertrophied clitoris. Furthermore, a bifid scrotum can be misinterpreted as the labia major (Fig. 16-57). The condition can be isolated or part of various syndromes; therefore, and as usual, the sonogram examination should be as detailed as possible and chromosomal analysis should be obtained. Two classic associations should be underscored. Ambiguous genitalia can be part of a cloacal malformation in which there is a common opening of the bladder, vagina, and rectum. On the other hand, ambiguous genitalia can be associated and the clue to the diagnosis of an adrenogenital syndrome (AGS). In the female fetus affected by AGS, the clitoris is hypertrophied; the demonstration of enlarged wrinkled adrenals (see later) are typical for this diagnosis. A genitourethral fistula may exist as well but is difficult to demonstrate. In boys with AGS, the disease may develop unrecognized unless the adrenals hypertrophy.¹⁴³⁻¹⁴⁸

Male Genital Anomalies

Hypospadias/Epispadias

Hypospadias is a frequent malformation of the penis that appears shorter and broadened. During micturition, the jet

FIGURE 16-55. Normal scrotum, third trimester. The two testes are clearly identified (*arrows*).

FIGURE 16-57. Ambiguous genitalia, third trimester. Scan through the scrotum. The two hemiscrotum are separated by a penis that is too short (*arrow*) (split scrotum sign).

FIGURE 16-56. Normal female sex. *A.* Scan through the major and minor labia (*arrows*). *B.* Transverse scan through the pelvis of a female fetus. Note how the uterus (*arrows*) is interposed between the rectum and bladder (Bl) and indents the bladder. In a male fetus no soft tissue will be seen between the rectum and bladder.

FIGURE 16-58. Hypospadias, third trimester. Scan through the distal end of the penis (arrow), which appears somewhat shortened and broadened.

FIGURE 16-59. Bilateral ovarian cysts, third trimester. Frontal view of the fetal trunk demonstrating two cystic masses (M). In one of them, a smaller cyst is visible (daughter cyst sign) (arrow). Ch, chest; St, stomach.

Table 16-13

Differential Diagnosis of Peritoneal (Partially) Cystic Masses in the Female Fetus

Ovarian cyst
 Duplication cyst
 Urachal cyst (midline)
 Hydrocolpos (midline)
 Lymphangioma (cystic)
 Mesenteric cyst
 Teratoma (cystic)
 Meconium pseudocyst

is directed downward. It is usually an isolated finding but can be associated with numerous syndromes (Fig. 16-58). Epispadias is one end of a spectrum, and bladder exstrophy is at the other extreme. The urethral opening lies on the dorsal part of the penis. It is a difficult sonographic diagnosis.^{148,149}

Scrotum

As mentioned earlier, the testes can be visualized within the scrotum at approximately 26 weeks. An isolated undescended testis is not an abnormal finding in utero. A small amount of peritesticular fluid can also be considered as a normal variant. If the fluid collection is hyperechogenic, meconium peritonitis should be suspected. Scrotal intestinal hernia can also be observed in utero. It is important to note that the testis may undergo torsion in utero or in the neonatal period. At the acute stage, the testis is large and hypoechoic. At the chronic stage, the testis appears small and sometimes calcified.¹⁵⁰⁻¹⁵³

Female Genital Anomalies

Ovarian Cysts

The ovarian cyst is the commonest cause of cystic mass in the female fetus. Such cysts result from maternofetal hormonal influence and are equivalent to follicles. These cysts may be small or large (> 8 cm), unilateral or bilateral (rare), unique or multiple (rare). They are usually completely cystic; the presence of small cyst within the cyst is a useful diagnostic sign (so-called daughter cyst sign). Torsion and bleeding may occur in utero and result in various types of echogenicities within the cyst (completely echogenic, fluid/fluid level, septa, and so on). The differential diagnosis includes other causes of cystic or semicystic masses (Table 16-13 and Figs. 16-59 to 16-61). Spontaneous involution occurs in utero or after birth, but the cyst may also rupture. Treatment is controversial because some authors favor in utero puncture, whereas some favor postnatal surgery and others a conservative attitude. If a conservative attitude is elected, a close clinical and US follow-up with a monthly follow-up for 6 months should be considered.¹⁵⁵⁻¹⁶² It is important to note that bilateral ovarian cysts may be a symptom of hypothyroidism or associated with maternal diabetes.

Hydrocolpos—Vaginal Malformations

Vaginal malformations and atresia lead to hydrocolpos, which is visualized as a midline cystic mass (Fig. 16-62). A clue to the diagnosis is the demonstration of the uterine cervix at the superior aspect of the cystic mass. The condition can be part of a cloacal malformation, associated with renal agenesis/MDK or part of syndromes (i.e., Drash, BBS, and so on) (Fig. 16-63).¹⁶³⁻¹⁶⁶

FIGURE 16-80. Large ovarian cyst, third trimester. Very large cystic mass is seen within the pelvis and lower abdomen (*arrows*). Fibrinous strands are seen within the cyst characteristic of hemorrhage.

FIGURE 16-62. Hydrocolpos, third trimester. Echogenic mass (M) above the bladder (B) corresponding to a hydrocolpos filled with mucous.

FIGURE 16-61. Choledochal cyst, third trimester. Cystic mass (M) in the right flank connected to biliary ducts (*arrows*) and corresponding to a choledochal cyst. Sp, spine. Dist = 2.80cm

FIGURE 16-63. Cloacal malformation, third trimester. Transverse scan through the fetal pelvis. One single (cystic) cavity (M) is visible draining the bladder and vagina. It contains an echogenic material (mucous?).

FIGURE 16-64. Normal adrenals. A. Second trimester. Coronal view. The triangle-shaped adrenal is visible (*arrows*) above the kidney (*short arrow*). B. Third trimester. Transverse scan. The right adrenal is visible (*arrows*) with a cortico (hypoechoic)-medullary (hyperechoic) differentiation.

FETAL ADRENALS

Normal Adrenals

The fetal adrenals are easily demonstrated, especially using transvaginal probes at the end of the first trimester (see Fig. 16-5). They appear as pyramid-shaped hyperechoic structures at the superior aspect of the hyperechoic kidneys. At that stage, their size is approximately half that of the kidney. Progressively, during the second trimester, CMD “appears” (hyperechoic cortex, hyperechoic medulla). The shape is that of an inverted “V” on the superior aspect of the kidney. The size of the gland increases but relatively less than the kidney. During the third trimester, the appearance of the fetal adrenals is very similar to that of the neonatal adrenals (Y-shaped, hypoechoic cortex, hyperechoic medulla) (Fig. 16-64).

In cases of renal agenesis, the adrenal is usually present and more globular or may be elongated (the lying down adrenal sign) (see Fig. 16-8). It should not be misinterpreted as a dysplastic kidney.^{167,168}

Adrenogenital Syndrome

In case of AGS, the adrenals may enlarge as early as the second trimester. They may display the so-called cerebriform wrinkled pattern (Fig. 16-65). The condition is associated with ambiguous genitalia in the female fetus (see earlier). Several authors have proposed using maternal corticotherapy, once the condition has been ascertained, in order to reduce the virilization of the female fetus.^{167,169,170}

FIGURE 16-65. Adrenogenital syndrome, third trimester. Sagittal scan through the right flank demonstrating the hypertrophied adrenal (*arrows*). L, liver; Sp, spine.

Adrenal Masses

Whenever a mass is detected in the suprarenal area, a neuroblastoma should be suspected first regardless of the pattern of the mass. Neuroblastoma may present as a cystic, a solid or more complex appearance. Color Doppler imaging may demonstrate increasing vascularization of the hyperechoic regions of the mass. The prognosis of antenatal

FIGURE 16-66. Neuroblastoma. A. Transverse axial scan of the fetal abdomen in a second trimester fetus. A large paraspinal solid mass (arrows) with a single cystic component is seen. This was a neuroblastoma at birth. S, spine. B. Partially cystic mass (between calipers) corresponding to the neuroblastoma. Sp, spine.

neuroblastoma is excellent even when hepatic metastases are present. Furthermore, some cases of spontaneous involution have been reported (Fig. 16-66). The differential diagnosis should include adrenal hemorrhage, associated or not with RVT, and adrenal cysts (Fig. 16-67). Bilateral calcifications are unusual and may suggest Wolman syndrome (Fig. 16-68). Isolated, uncomplicated small cysts may be observed at the level of the adrenals (see Fig. 16-67). Their size is usually small and they disappear spontaneously. Large cysts develop in association with the Beckwith-Wiedemann syndrome. These cysts may bleed, and their appearance becomes more complex. Extra-adrenal causes, such as subdiaphragmatic pulmonary sequestration, should also be included in the differential diagnosis (Table 16-14).¹⁷¹⁻¹⁸⁵

DEFINITION OF HYDROPS

Hydrops fetalis is typically defined as the presence of extracellular fluid in at least two fetal body compartments. These fluid collections include scalp and body wall edema, pericardial effusion, pleural effusions, and ascites (Figs. 17-1 to 17-8). This definition is more than academic. As is discussed below, in general, the prognosis for fetal hydrops is poor. Therefore, this term should only be used when the above criteria are met. The presence of ascites is often used to diagnose hydrops. Ascites may result from a variety of conditions, many of which should not be categorized as hydrops. For example, ascites may result from a unilateral high-grade ureteropelvic junction obstruction in which fornical rupture into the retroperitoneal and ultimately peritoneal space occurs. Although the kidney may not ultimately fare well, the prognosis for the fetus is usually excellent. The same is also true for a small amount of ascites resulting from a small bowel perforation, which may ultimately heal in utero. Therefore, hydrops fetalis should not be used to describe these conditions. It should be noted, however, that in those fetal conditions in which hydrops is a known outcome of progressive disease, a single accumulation of fluid in a body cavity may be enough to warrant referring to the condition as early hydrops. High cardiac output resulting from vascular abnormalities such as fetal sacrococcygeal teratoma and chorioangioma are examples of this situation. Some authors include polyhydramnios due to increased urine output, as well as placentomegaly as additional criteria for the diagnosis of hydrops fetalis.¹

Classically, the disease has been divided into two main entities based on etiology: immune (related to fetal anemia secondary to maternal alloimmunization to red cell antigens)

and nonimmune (related to a variety of other causes). Clearly, the advent of the widespread use of Rhesus immune globulin for the prevention of RhD alloimmunization has resulted in a shift in favor of the non-immune variety. In 1970, McAfee et al² reported that 82% of cases of fetal hydrops were immune mediated whereas in one recent series, 95% of cases of hydrops were classified as nonimmune.³

FIGURE 17-1. Scalp edema noted (between arrows) at 32 weeks' gestation. Etiology: idiopathic. (Courtesy of Anthony Swartz, BS, RT(R), RDMS.)

FIGURE 17-2. Cross-sectional view of the fetal thoracic cavity at 19 weeks' gestation. Note pericardial effusion (arrow). Also note the cardiomegaly. Etiology: maternal RhD alloimmunization and resulting hemolytic disease of the fetus/newborn.

FIGURE 17-4. Predominantly left-sided pleural effusion (large arrow) at 30 weeks' gestation. Fetal heart (asterisk) is displaced to the right side of the chest. Large left-sided pulmonary sequestration is noted (small arrow). Note extreme polyhydramnios as well. Etiology: intrathoracic mass with deviation of mediastinum. (Courtesy of Sharon Pinette, RDMS.)

FIGURE 17-3. Bilateral pleural effusions (arrows) at 32 weeks' gestation. HT, midline fetal heart. Etiology: idiopathic. (Courtesy of Anthony Swartz, BS, RT(R), RDMS.)

FIGURE 17-5. Cross-sectional view of the fetal abdomen at 32 weeks' gestation. Note ascites (arrows). Etiology: fetal cytomegalovirus infection.

MATERNAL COMPLICATIONS OF FETAL HYDROPS

Fetal hydrops is often associated with polyhydramnios, leading to such maternal complications as supine hypotension syndrome, preterm labor, and preterm premature rupture of the membranes. If placental hydrops is significant, an additional life-threatening complication called Ballantyne syndrome (also known as mirror syndrome, triple edema, and psuedotoxemia) has been described.⁴ The mirror syndrome is so named because the mother mirrors the hydropic state of the fetus. Although first described in association with immune hydrops, many subsequent case descriptions have been described in the literature secondary to nonimmune

hydrops fetalis (NIHF) due to a variety of etiologies. In this syndrome, maternal edema, rapid weight gain, mild proteinuria, and hypertension are noted. Although the condition shares many of the same clinical features of preeclampsia, the maternal intravascular volume appears to be expanded as opposed to the typical hemoconcentration seen with preeclampsia. Maternal hematocrit and albumin are low

FIGURE 17-6. Cross-sectional view of the fetal abdomen at 19 weeks' gestation. Note ascites (arrow). Etiology: trisomy 22. (Courtesy of Sharon Pinette, RDMS.)

FIGURE 17-7. Longitudinal section of the fetal abdomen (fetal head on left) at 19 weeks' gestation - same fetus as illustrated in Figure 17-6. Note ascites (arrow). Etiology: trisomy 22. (Courtesy of Sharon Pinette, RDMS.)

with minimal or no loss of urinary protein. Although the pathophysiology is unknown, hyperplacentosis is thought to be central to the cause. Reversal of maternal symptoms has been reported with the resolution of fetal hydrops after in utero treatment.⁵ In other situations, the maternal condition worsens after correction of the hydropic fetal state owing to continued placentomegaly. In these cases, delivery is curative.

FIGURE 17-8. Longitudinal view of the fetal thorax and abdomen at 19 weeks' gestation (head on left of image). Note early ascites (arrows). Etiology: maternal RhD alloimmunization and resulting hemolytic disease of the fetus/newborn.

IMMUNE HYDROPS

Pathophysiology

The formation of maternal antibodies (red cell alloimmunization) to more than 40 different red cell antigens has been associated with severe fetal anemia (Table 17-1). The RhD (Rh₀[D]) antigen is considered the most immunogenic of the antigens found on the surface of the human red blood cell.⁶ In 1941, Levine, Katzin, and Burham⁷ demonstrated that antibodies to the RhD antigen in pregnant women caused hemolysis and anemia in their offspring. Although this condition was originally called erythroblastosis fetalis secondary to the finding of a large number of immature red cells in the neonatal circulation, today it is known as hemolytic disease of the fetus and newborn (HDFN).

When RhD-positive fetal cells enter the maternal circulation as a result of pregnancy-related events such as miscarriage or delivery, anti-D antibody can be formed (Fig. 17-9). The administration of RhD immune globulin in these instances is effective in preventing the formation of anti-D antibody in more than 99% of cases. However, in rare cases, because of the inadvertent omission of the administration of immune globulin or improper dosing, the patient may become sensitized to the RhD antigen. Although the fetus that causes this alloimmunization is usually unaffected, transplacental passage of maternal anti-D antibodies in a subsequent pregnancy allows for their attachment to RhD-positive fetal red cells, resulting in the sequestration and destruction of these cells in the fetal spleen. Without treatment, this condition may lead to progressive anemia, excessive fluid collection in extracellular spaces (hydrops fetalis), and eventually fetal death. In milder cases, neonates may be born with only a minor degree of anemia, but the ongoing destruction of red cells results in hyperbilirubinemia. Unconjugated bilirubin then has the potential to enter the cerebral compartment and produce kernicterus.

Extramedullary hematopoietic sites are incorporated in the liver and spleen, resulting in enlargement of these organs.

From Mari G, Deter RL, Carpenter RL, et al: Noninvasive diagnosis by Doppler ultrasonography of fetal anemia due to maternal red-cell alloimmunization. *N Engl J Med* 342:9, 2000.

Fetal hydrops does not occur until the fetal hemoglobin has fallen to below six standard deviations from the mean for gestational age.⁸ In general, a small pericardial effusion represents the first extracellular compartment to exhibit excess fluid accumulation. This is followed by the onset of ascites and pleural effusions; scalp edema is a late manifestation. The early second trimester fetus may be severely anemic without demonstrating overt hydrops; rarely is the third trimester fetus anemic without hydrops being easily seen by ultrasound. This may be related to the significant reduction in normal fetal lymph flow that occurs with advancing gestational age.⁹

The exact mechanism of hydrops fetalis secondary to fetal anemia has not been well elucidated. Primary mechanisms that have been proposed include hypoproteinemia, myocardial failure, and lymphatic obstruction.

Hypoproteinemia has been suggested to occur owing to hepatic dysfunction with decreased production of serum proteins or owing to extravasation of proteins from the intravascular compartment secondary to endothelial damage. Iron overload due to hemolysis may contribute to free radical formation and endothelial dysfunction in HDFN.¹⁰ De Groot et al¹¹ also noted decreased circulating levels of cGMP in fetuses with immune hydrops as compared to nonhydropic fetuses with only anemia. They proposed that this finding was related to endothelial cell damage in the hydropic fetuses. However, a study of 225 fetuses with HDFN noted that the serum albumin concentration was in the normal range in 71% of cases with hydrops.¹² The authors concluded that hypoalbuminemia is the unlikely cause of hydrops in immune-mediated cases. Moise et al¹³ studied umbilical venous pressure as a surrogate for fetal

FIGURE 17-9. A. Initial pregnancy in which the mother is Rh negative and is carrying a fetus that is Rh positive. B. At the time of delivery, the fetal Rh positive red blood cells enter the maternal circulation and initiate an antibody response. C. In a subsequent pregnancy, antibodies enter the fetal circulation, attaching to the red blood cells and resulting in the sequestration and destruction of these cells. (Illustration by James A. Cooper, MD, San Diego, CA.)

central venous pressure (CVP) in cases of hydrops fetalis related to maternal red cell alloimmunization. They also evaluated colloid osmotic pressure (COP) at the time of the cordocentesis before intrauterine transfusion (IUT). These two important Starling forces that would contribute to the movement of fluid from the intravascular compartment to the extravascular space were therefore evaluated. Although the CVP-COP gradient was decreased in hydropic fetuses, a high venous pressure was the predominant abnormality. This led the authors to speculate that a high venous pressure was secondary to high-output cardiac failure in the anemic fetus. Such an increase in the venous pressure would cause a functional lymphatic blockade at the confluence of the right and left lymphatic duct systems and the corresponding brachiocephalic veins. Animal studies have indicated that for each 1-mm increase in venous pressure, there is a 17% reduction in lymphatic flow.¹⁴ This theory is supported by the clinical observation that blood transfused into the peritoneal cavity of the hydropic fetus is not readily absorbed.¹⁵

Significance of Detection of Immune-Mediated Hydrops

The fetus with hydrops fetalis secondary to maternal red cell alloimmunization represents a true challenge in perinatal management. Often this situation is the result of late entry into prenatal care; less commonly, it is secondary to late referral to perinatal centers experienced with the early detection of fetal anemia. The hydropic fetus represents end-stage disease in HDFN and is associated with a worse prognosis than if hydrops is absent. In one series of 213 fetuses undergoing 599 IUTs, the absence of hydrops or the presence of only mild hydrops was associated with a 98% rate of perinatal survival.¹⁶ Severe hydrops was associated with a 55% survival rate. Clearly, the goal of optimal management of HDFN should be the early detection of fetal anemia before the advent of hydrops.

Evaluation of the Sensitized Pregnancy

Maternal Antibody Measurement

The typical fetus becomes at risk for anemia once a maternal antibody screen (indirect Coombs) is determined to be positive for a red cell antibody that has been associated with HDFN. Maternal indirect Coombs titers are used to assess the degree of risk for fetal disease. Maternal antibody determinations are usually repeated at 4-week intervals in the first and second trimester and every 2 weeks in the third trimester. A critical value is considered the threshold level of antibody associated with fetal hydrops. Most centers use a titer value between 8 and 32 (dilution: 1:8 and 1:32) for both anti-D and other antibodies that cause HDFN as their definition of a critical value. The one notable exception to this is anti-K (Kell, K1) antibody. This particular antibody causes fetal anemia through two different mechanisms; sequestration of sensitized fetal red cells in the spleen and bone marrow suppression.¹⁷ For this reason, a critical value of 8 (dilution 1:8) is often used for the Kell antibody. Once a patient is found to have a critical antibody titer, fetal testing is indicated.

Fetal Antigen Testing

Paternal evaluation is the next step in management. If the patient's partner is negative for the particular red cell antigen involved and paternity is assured, then further evaluation of the fetus is unnecessary. In other cases, paternal phenotype testing using serology will reveal a heterozygous state. With the advent of the cloning of many of the genes responsible for the blood group antigens associated with HDFN, amniocentesis can be performed to obtain fetal DNA. Polymerase chain reaction (PCR) primers can then be used to determine the blood type of the fetus. This approach is now available for the D, C/c, E/e, and Kell (K1)/cellano (K2),/JK,Fy/Fy, M/N, S/s antigens. Typically, a reference laboratory will require a sample of maternal blood as a negative control and paternal blood as a positive control. If the fetus is noted to be negative for the involved red cell antigen, then no further testing is necessary. If the fetus is found to be positive, serial evaluation is needed (see later). Results of PCR testing on amniotic fluid that indicate an antigen-negative fetus should be viewed with some degree of suspicion when paternity is not assured or the patient's partner is not available for testing. In rare cases, a paternal gene rearrangement could lead to an incorrect correlation between fetal serology (phenotype) and PCR (genotype) results on amniotic fluid. In one review of 500 cases of amniotic fluid typing for the fetal RhD antigen, this rate of error was reported to be 1.3%.¹⁸ Two fetuses died, one neonate required exchange transfusions, another neonate needed phototherapy in conjunction with a simple transfusion, and the remaining infant was lost to follow-up. Many laboratories have turned to the use of multiplex PCR in an effort to reduce this possibility for error. Another strategy that has been suggested when the fetus is determined to be antigen negative by PCR and paternity is in question is to repeat the maternal titer in 6 weeks. A rising maternal titer (more than a two-dilution increase) should make the fetal PCR typing suspect. Cordocentesis for direct acquisition of fetal blood for serologic typing should be considered in these cases.

Clearly, a noninvasive technique for determining the fetal red cell antigen status would negate the risk of fetal loss and enhanced maternal sensitization associated with amniocentesis. Lo et al¹⁹ were the first to describe the use of free fetal DNA found in maternal plasma for fetal RhD typing. Several large series have confirmed the accuracy of this test.^{20,21} Free DNA RhD typing is now routinely employed in clinical practice in the United Kingdom and Europe. Unfortunately, the test is not yet available for clinical use in the United States. Free DNA testing can currently only be used for fetal RhD typing. Assays for RhC and Kell typing are being developed.

Diagnosis of Fetal Anemia

Once the fetus is determined to be antigen positive in association with a critical maternal titer, there are two approaches that are used to predict fetal anemia. The more traditional approach has been to employ serial amniocenteses to measure the bilirubin in the amniotic fluid through the ΔOD_{450} assay. This approach has been virtually replaced by the use of serial assessments using Doppler ultrasound (discussed below).

FIGURE 17-10. Queenan curve for ΔOD_{450} between 14 and 40 weeks' gestation.

Amniocentesis

Amniotic fluid bilirubin has been used for more than four decades as an indirect measure of the degree of fetal hemolysis. Immune-mediated red cell destruction results in the release of free hemoglobin into the fetal circulation. This is then metabolized to bilirubin, which gains access to the amniotic cavity predominantly through the egress of tracheal fluid. Fluid is analyzed by spectrophotometry and a baseline measurement is established between 365 and 550 nm. The peak of the optical density reading at 450 nm is then subtracted from this baseline to calculate the ΔOD_{450} . This value is then plotted on a normative curve for gestations of greater than 27 weeks consisting of three zones known as the Liley curve.²² Values in zone one are indicative of minimal fetal hemolytic disease, whereas values in zone 3 indicate severe disease with the potential for fetal death without intervention. Confidence was lost in this method when Nicolaides et al²³ reported that “modified” Liley curves extrapolated to gestational ages of less than 27 weeks missed 70% of anemic fetuses between 18 and 25 weeks' gestation. Queenan et al²⁴ subsequently published normal ΔOD_{450} values between 14 and 40 weeks' gestation based on 520 unaffected pregnancies (Fig. 17-10). A recent study compared the Liley curve with that of Queenan and noted that the latter was associated with improved accuracy for the detection of severe fetal anemia.²⁵

Amniocentesis can be initiated as early as 18 weeks' gestation using the Queenan curve. Procedures are repeated at 1- to 2-week intervals based on the initial value of the ΔOD_{450} and subsequent trends. All attempts should be made to avoid a transplacental puncture so as to avert an anamnestic response and resultant worsening fetal hemolytic disease. Amniocenteses should be continued until fetal lung maturity is documented, at which time induction of labor would appear to be a more reasonable approach than continued amniocenteses. Cordocentesis should be undertaken with blood readied IUT when the ΔOD_{450} value reaches the upper portion of the *Rh-positive, affected* zone.

Middle Cerebral Artery Doppler

The peak systolic velocity of blood moving through various fetal vessels has been investigated as a method of determining when the fetus is developing anemia. This concept is based on animal data indicating that fetal blood velocities become elevated in response to an increase in cardiac output and a decline in blood viscosity when the fetus becomes anemic. Initial reports using such fetal vessels as the umbilical vein, descending thoracic aorta, and common carotid artery were disappointing in the prediction of fetal hematocrit.

Mari and coworkers²⁶ are credited with the first description of using the peak systolic velocity in the middle cerebral artery to detect fetal anemia. Because the normal peak systolic velocity in this vessel increases with advancing gestational age, the value in centimeters/second must be converted to multiples of the median (MoMs; Fig. 17-11 and Table 17-2). These authors established a normogram for fetal hemoglobin from 265 normal fetuses that had undergone cordocentesis for a variety of diagnostic indications. Mild anemia was defined as 0.84 to 0.65 MoM for gestational age, moderate anemia was 0.65 to 0.55 MoM, and severe anemia less than 0.55 MoM. One hundred eleven at-risk fetuses whose mothers were alloimmunized predominantly to RhD were then evaluated prospectively. An middle cerebral artery (MCA) velocity of greater than 1.50 MoMs detected all cases of moderate to severe anemia with a 10% false-positive rate. In a prospective study performed at 10 centers, Oepkes et al²⁵ followed 165 fetuses with both MCA Doppler and amniocentesis for ΔOD_{450} . MCA Doppler was determined to be more accurate than amniocentesis in detecting severe fetal anemia (sensitivity: 88%, specificity: 82%).

Fetal MCA velocity determinations can be initiated as early as 18 weeks' gestation once the fetus is at risk for the development of anemia. Doppler studies are repeated every 1 to 2 weeks based on the trend in the data. The false-positive rate for the prediction of fetal anemia increases after 35 weeks' gestation.²⁷ Color flow or power Doppler is used

FIGURE 17-11. Normogram for mild anemia (1.29 MoMs) and moderate-severe anemia (1.5 MoMs). Zone A values, mild anemia; zone B values, moderate to severe anemia. MoM, multiple of median.

Table 17-2

Expected Peak Velocity of Systolic Blood Flow in the Middle Cerebral Artery as a Function of Gestational Age

Week of Gestation	Multiples of the Median			
	1.00 (Median)	1.29	1.50	1.55
	Peak Velocity in cm/sec			
18	23.2	29.9	34.8	36.0
20	25.5	32.8	38.2	39.5
22	27.9	36.0	41.9	43.3
24	30.7	39.5	46.0	47.5
26	33.6	43.3	50.4	52.1
28	36.9	47.6	55.4	57.2

to locate the MCA over the anterior wing of the fetal sphenoid bone (Figs. 17-12 and 17-13). All attempts are made to place the Doppler gate in the proximal portion of the MCA just distal to its origin from the carotid siphon. The angle of insonation is kept as close to zero as possible (i.e., the Doppler beam is “end-on” with the vessel); angle correction using computerized software is not used. The MCA closest to the ultrasound transducer is usually used because it is easier to visualize. However, the MCA in the far field has been shown to give equivalent results when the angle of insonation is minimal.²⁸ Doppler measurements should be undertaken during a period of fetal apnea and absent fetal movement. A manual measurement of the peak velocity is preferred over real-time software-based assessment

of the velocity. A value of greater than 1.5 MoMs is indicative of fetal anemia and warrants further investigation with cordocentesis to determine the fetal hematocrit.

Choice of Surveillance Method

A growing body of evidence supports the use of serial MCA Doppler over amniocentesis for the detection of fetal anemia in the at-risk fetus. Previous experience has indicated that a significant learning curve exists for the accurate measurement of the MCA Doppler.²⁹ For this reason, referral centers should consider performing MCA Doppler scans in conjunction with serial amniocenteses for ΔOD_{450} until expertise has been achieved. In addition, referral to a distant perinatal

FIGURE 17-12. Anterior and middle cerebral artery (arrow) using color flow Doppler for localization. (Courtesy of Anthony Swartz, BS, RT(R), RDMS.)

center with experience in Doppler may not be practical for weekly testing. In such cases, serial amniocenteses may be a valid tool for following these pregnancies.⁶

Overall Management

First sensitized pregnancy or pregnancy with a history of a minimally affected neonate (a pregnancy that was monitored with serial maternal titers, MCAs or amniocenteses and the fetus and neonate did not require transfusions) (Fig. 17-14):

- Follow maternal titers every 4 weeks up to 24 weeks' gestation; repeat every 2 weeks thereafter.
- Once a critical value is reached (usually 32; 8 for anti-Kell), begin serial MCA Doppler scans as early as 18 weeks' gestation. Alternatively, initiate amniocentesis every 10 days to 2 weeks for ΔOD_{450} using the Queenan curve.
- In cases of a heterozygous paternal phenotype, perform amniocentesis by 24 weeks to determine the fetal antigen status. Send maternal and paternal blood samples with the amniotic fluid. If an antigen-negative fetus is found, no further testing is warranted.
- Begin antenatal testing at 32 weeks' gestation, with twice-weekly biophysical profiles.
- If the MCA Doppler is greater than 1.5 MoMs or the ΔOD_{450} value enters the upper portion of the *Rh positive (affected)* zone of Queenan curve, perform cordocentesis with blood readied for IUT for a fetal hematocrit of less than 30%.
- If repeat MCA velocities remain less than 1.5 MoMs, consider induction at 37 to 38 weeks' gestation. If the MCA velocity is greater than 1.5 MoMs at more than 35 weeks' gestation, perform amniocentesis for ΔOD_{450} and fetal lung maturity. If mature and the ΔOD_{450} value is not in the upper, *Rh positive (affected)* zone, induce delivery in 2 weeks. If the fetal lungs are noted to be immature and the ΔOD_{450} value is in the upper, *Rh positive (affected)*

FIGURE 17-13. Middle cerebral artery assessment at 19 weeks' gestation. Top image illustrates power Doppler localization of the proximal MCA vessel. Note Doppler gate location. Peak systolic velocity on lower image was measured at 52.42 cm/sec; 1.87 MoMs for this gestational age. (Courtesy of Anthony Swartz, BS, RT(R), RDMS.)

zone, consider administering 7 days of maternal phenobarbital (30 mg PO TID) to enhance fetal hepatic maturity.³⁰ Induce labor in 1 week. If fetal lung immaturity is noted and the ΔOD_{450} value is not in the upper, *Rh positive (affected)* zone, repeat the amniocentesis in 2 weeks.

- If using serial ΔOD_{450} values and these remain below the *Rh positive (affected)* zone, perform the last amniocentesis at 37 weeks. If mature and the ΔOD_{450} value is not in the upper, *Rh positive (affected)* zone, induce delivery in 1 to 2 weeks. If immature lungs and the ΔOD_{450} value is in the upper, *Rh positive (affected)* zone, consider administering 7 days of maternal phenobarbital (30 mg PO TID) to enhance fetal hepatic maturity.³⁰ Induce labor in 1 week.
- *Previously affected fetus or infant (fetus needed IUTs or neonate required exchange transfusions)* (Fig. 17-15):
- Maternal titers are *not* helpful in predicting the onset of fetal anemia after the first affected gestation.
- In cases of a heterozygous paternal phenotype, perform amniocentesis at 15 weeks' gestation to determine the fetal RhD status. If an RhD-negative fetus is found, no further testing is warranted.
- Begin serial MCA Doppler assessment or amniocenteses for ΔOD_{450} (Queenan curve) at 18 weeks' gestation. Repeat at 1- to 2-week intervals.
- Remainder of protocol is similar to the first affected pregnancy.

Intrauterine Transfusion

Method

The majority of IUTs are undertaken through ultrasound-directed needle puncture of the umbilical cord at its insertion into the placenta or by puncture of the intrahepatic portion of the umbilical vein. After an initial fetal blood sample is obtained to determine the hematocrit, an intravenous dose of a paralytic agent is administered to reduce

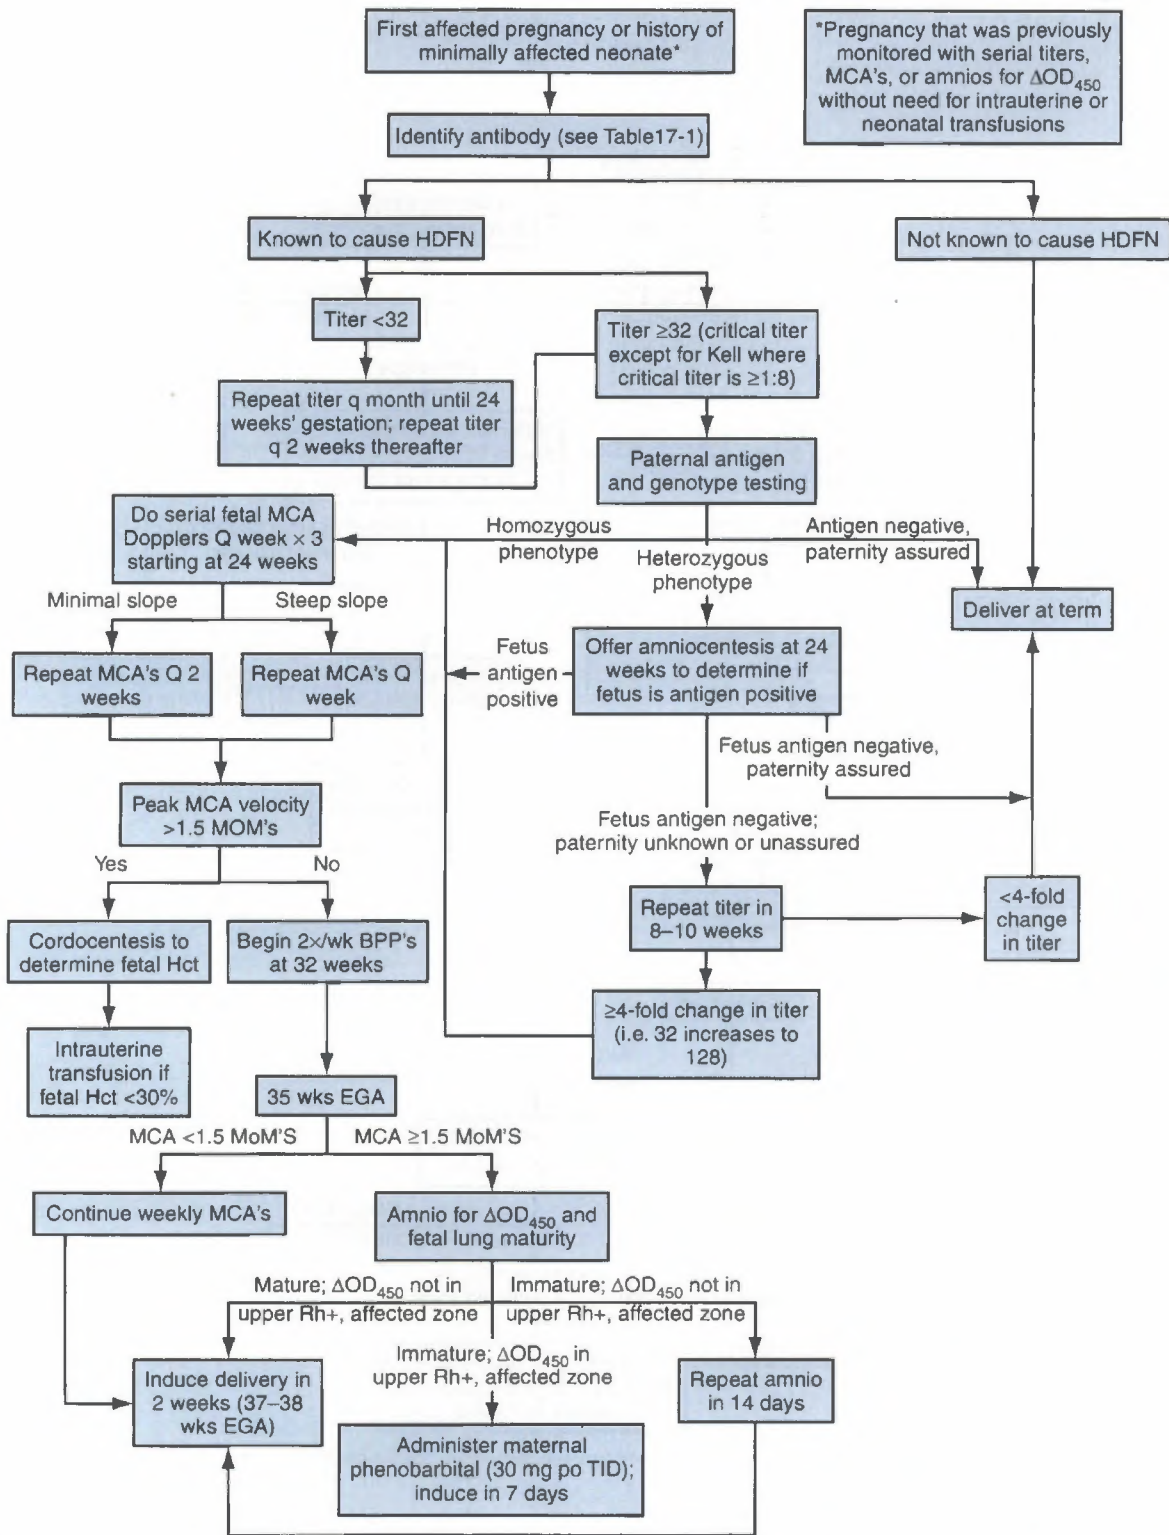

FIGURE 17-14. Algorithm for the management of the first affected pregnancy in a red blood cell alloimmunized patient. This algorithm can also be used in the patient with a previous alloimmunized pregnancy with a minimally affected neonate, that is, the pregnancy was followed with serial maternal antibody titers or serial amniocenteses for ΔOD_{450} or middle cerebral artery Doppler scans. The fetus and neonate should not have required transfusion therapy.

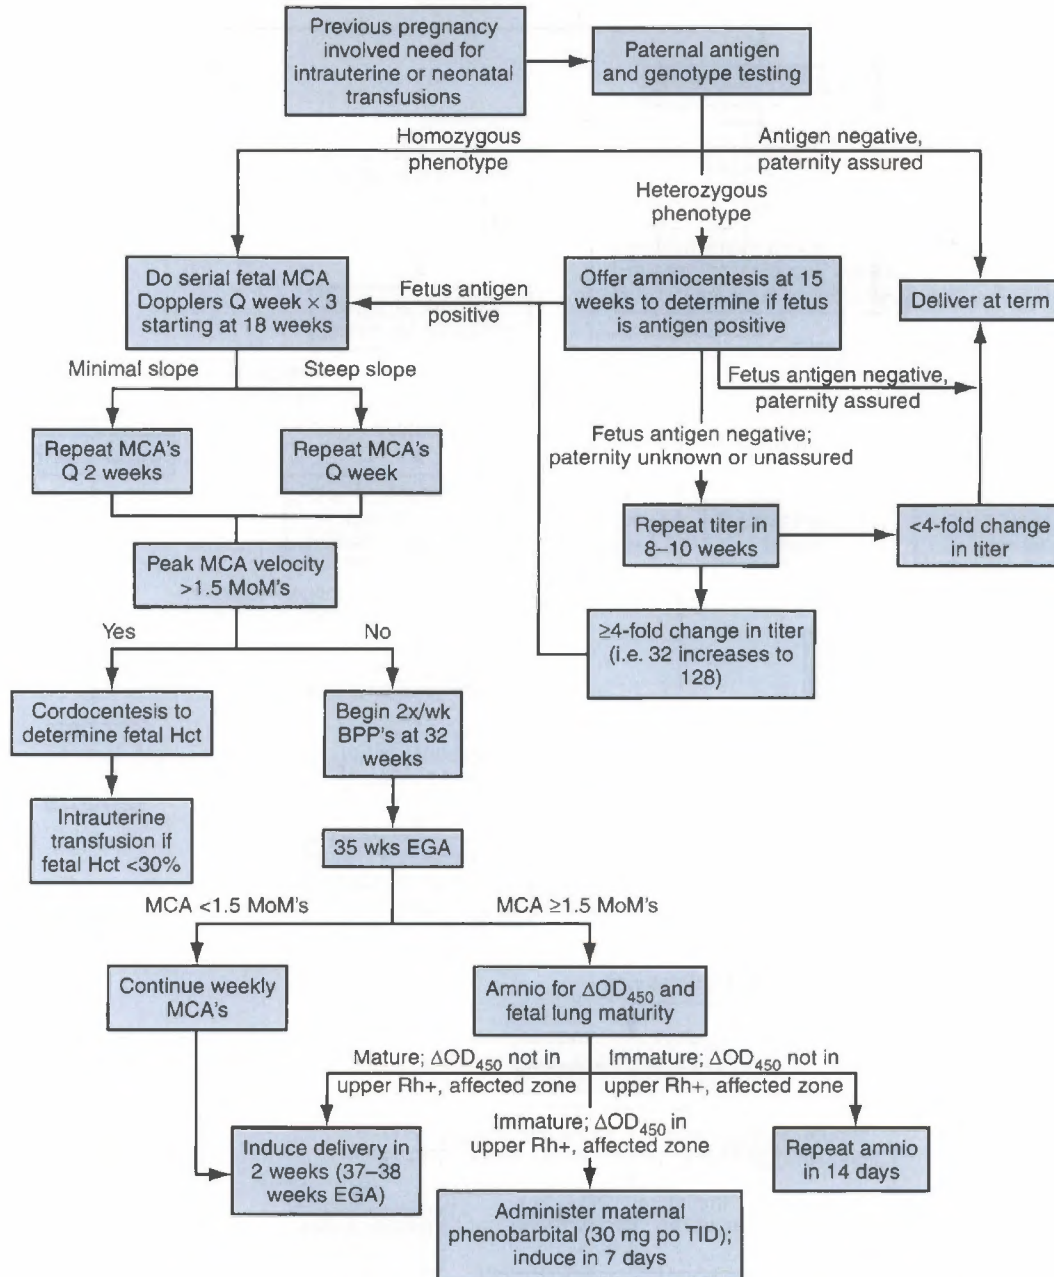

FIGURE 17-15. Algorithm for the management of a subsequent alloimmunized pregnancy when the previous fetus/infant required intrauterine and/or neonatal transfusions.

FIGURE 17-16. Packed red blood cells seen streaming in the fetal umbilical vein (*arrow*) at the time of an intravascular transfusion at 26 weeks' gestation. The cord insertion into the anterior placenta is located at the asterisk.

interference from fetal movement.³¹ Tightly packed donor red cells (hematocrit 78% to 80%) are then infused. Streaming of the dense cells down the umbilical vein can be seen with real-time ultrasound (Fig. 17-16). Various formulas based on fetal weight estimated by ultrasound can be used to determine the volume of red cells to infuse. A final sample of blood is then submitted for fetal hematocrit.

A decline in fetal hematocrit of approximately 1% per day can be expected between procedures. In an effort to allow for a reasonable interval between IUTs, many centers transfuse to a final hematocrit value of 50% to 65%. Other centers employ a combined approach of first performing an intravascular transfusion (IVT), followed by an intraperitoneal infusion (IPT) of red cells.³² The latter allows for slow absorption at a rate of approximately 10% per day and results in a more stable hematocrit between procedures. Subsequent IUTs are scheduled at 14-day intervals until suppression of fetal erythropoiesis is noted on Kleihauer-Betke stains. This usually occurs by the third IUT. Thereafter, the interval for repeat procedures can be determined based on the decline in hematocrit for the individual fetus, usually a 3- to 4-week interval.

When IPTs were used as the sole means of in utero therapy, fetuses were routinely delivered at 32 weeks' gestation. Hyaline membrane disease and the need for neonatal exchange transfusions for the treatment of hyperbilirubinemia were common. As experience with IVT became widespread, pregnancies were delivered at later gestational ages. It now appears reasonable to perform the final IUT as late as 35 weeks' gestation, with delivery anticipated at 37 to 38 weeks.³³ Maternal oral phenobarbital (30 mg TID) administered approximately 10 days before delivery can be given to enhance the neonate's ability to conjugate bilirubin and has negated the need for exchange transfusions after birth.³⁰

The transfusion of the hydropic fetus requires several special considerations. It is generally accepted that hydrops fetalis is associated with poor absorption of red blood cells from the peritoneal cavity.¹⁵ Harman et al³⁴ compared the experience at one referral center with IVT and IPT techniques for the treatment of the hydropic fetus using historic controls. Survival of the hydropic fetus was improved from 48% with IPT to 86% with IVT. Therefore, it would appear that IVT should be the primary modality for the management of the hydropic, anemic fetus. The severely anemic fetus in the early second trimester does not tolerate the acute correction of its hematocrit to normal values.³⁵ In these situations, the initial hematocrit should not be increased by more than fourfold at the time of the first procedure.³⁶ A repeat IVT is then performed within 48 hours to correct the fetal hematocrit into the normal range.

The Patient With Recurrent Immune Hydrops Fetalis

The patient who presents with recurrent immune hydrops fetalis at less than 20 weeks' gestation represents a true perinatal challenge. Technical limitations make umbilical cord puncture difficult. On occasion, an intraperitoneal transfusion can be attempted before the overt development of hydrops; however, formulas for calculating the correct volume for transfusion do not exist. Plasmapheresis has been suggested as a modality that may have a role in the treatment of severe HDFN. Although acute declines in maternal antibody titer are achieved, a rebound to even higher antibody levels usually occurs. Intravenous immune globulin (IVIG) is another treatment modality that has generated extreme interest for the treatment of severe fetal hemolytic disease. Several mechanisms of action have been postulated including decrease of maternal antibody levels through anti-idiotypic suppression, blockade of the placental Fc receptor sites, and fetal reticuloendothelial blockade. Voto and coworkers³⁷ compared the outcome of 30 patients receiving IVIG before 20 weeks' gestation followed by IUTs after 20 weeks to a group of 39 patients treated with only IUTs between 20 and 25 weeks' gestation. Hydrops fetalis was less frequent in the IVIG/IUT group as compared with the IUT-only group (27% versus 74%; relative risk [RR], 0.36). In addition, the incidence of fetal death was markedly decreased with the addition of IVIG (20% versus 51%; RR, 0.39). These data would suggest that both plasmapheresis and IVIG could play a role in the prolongation of pregnancy until IUT can be initiated. Ruma et al³⁸ used a combined treatment program of plasmapheresis and IVIG in patients with a history of recurrent early second trimester hydrops fetalis or an extremely elevated maternal anti-red cell titer. Patients underwent a single-volume plasmapheresis every other day for three procedures at 10 to 12 weeks' gestation. After the third procedure, the first half of a 2-g/kg loading dose of IVIG was administered. The following day, the second half of the loading dose (1g/kg) of IVIG was given. The patients were then maintained on a weekly infusion of 1 g/kg of IVIG until 20 weeks' gestation. IUTs were initiated when an elevation in the MCA velocity was detected. All nine pregnancies resulted in a live-born infant. The authors concluded that their combined immunomodulation was

effective in prolonging gestation until successful IUTs could be undertaken in these select pregnancies.

Prognosis

Serial intravascular IUTs inevitably result in fetal bone marrow suppression. Typically, these infants are born with a virtual absence of circulating reticulocytes with a red cell population consisting mainly of transfused red cells containing adult hemoglobin. Exchange neonatal transfusions for hyperbilirubinemia are rarely necessary allowing for significant maternal anti-red cell antibodies to remain in the neonatal circulation. Early neonatal reticulocytosis is therefore depressed and often by 4 to 6 weeks of age, these neonates require a "top-up" transfusion owing to symptoms associated with anemia. These infants should be followed with weekly hematocrits and reticulocyte counts. Most infants require only one transfusion, although the requirement for up to three transfusions has been reported.³⁹ Neonatal erythropoietin injections have met with mixed results because persistent maternal antibodies in the neonate probably are the major factor for the lack of circulating reticulocytes.⁴⁰ Supplemental iron is unnecessary because iron stores are elevated in these children as a result of in utero hemolysis and replacement of red cells with donor blood from serial IUTs.

Investigations regarding the long-term neurologic evaluation of infants that have been treated with IVTs are limited. Neurologic outcome in cases of hydrops fetalis is similar to that of the nonhydropic fetus.⁴¹ Cerebral palsy and developmental delay are more common in fetuses with HDFN when compared with unaffected infants, although a normal outcome can be expected in more than 90% of cases.⁴² A review of the cases of cerebral palsy reveals that the mean gestational age at delivery was 33.5 weeks; 80% of cases were delivered by emergency cesarean section. Sensorineural hearing loss is more frequent in infants affected by HDFN, probably because of their prolonged exposure to elevated levels of bilirubin and its toxic effect on the developing eighth cranial nerve.⁴¹

NONIMMUNE HYDROPS

Incidence

NIHF has been reported to occur in approximately 1 in 3000 pregnancies.⁴³

Etiology

More than 120 causes of NIHF have been reported (Table 17-3). In a review of almost 800 cases, Machin⁴³ noted that fetal cardiovascular disease was the leading cause of NIHF, accounting for one quarter of cases. This category included structural cardiac lesions, arrhythmias, and high-output failure related to large fetal tumors. The second highest category was chromosomal abnormalities (10% of cases), followed by thoracic lesions (9%), twin-to-twin transfusion (8%), nonimmune causes of fetal anemia (6%), and fetal infection (4%). A variety of other etiologies comprised the remaining 24% of cases; 22% of cases were considered idiopathic.

Pathophysiology

Because the etiology of NIHF is so diverse, few studies have addressed the pathophysiology of this condition. Weiner⁴⁴ has proposed that three possible mechanisms may play a role—inadequate cardiac output, structural lymphatic obstruction, and hypoproteinemia. Decreased cardiac output can be the result of regurgitant intracardiac flows owing to the abnormal structure of valves (example: Ebstein anomaly), obstruction to preload or afterload based on intrathoracic lesions (example: chylothorax), or poor myocardial contractility (adenovirus-induced myocarditis). Structural lymphatic obstruction can occur in Turner or Noonan syndrome. Various congenital infections may lead to endothelial damage (increased capillary permeability) and loss of intravascular proteins (example: cytomegalovirus).

In a series of 20 fetuses with NIHF, umbilical venous pressure was elevated at the time of cordocentesis in 65% of the cases.⁴⁴ Correction of some of the lesions resulted in normalization of the venous pressure on subsequent measurements, which were accompanied by resolution of the hydrops. These authors concluded that an elevated umbilical venous pressure signaled inadequate cardiac output as the cause of the NIHF. Normalization of the venous pressure after correction of the fetal condition invariably resulted in perinatal survival.

Evaluation

The initial diagnosis of hydrops fetalis is often made at the time of a routine ultrasound examination. Generalized skin edema is often the first feature of fetal hydrops revealed by ultrasound in early pregnancy.⁴⁵ Skin edema is best and most clearly observed at the level of the fetal head and more specifically at the back of the neck. This is the rationale for the measurement of the nuchal translucency. At other times, the patient complains of a decrease in fetal movement or a rapid increase in weight gain or abdominal girth, which are signs of significant polyhydramnios.

A comprehensive ultrasound examination should be undertaken. Special emphasis should be placed on evaluation of cardiac structures and rhythm. If necessary, a fetal echocardiogram should be undertaken. A decrease in cardiac output with right atrial overload is likely the primary cause in most cases of early hydrops fetalis. Inadequate cardiac output can be due to a major cardiac anomaly such as atrioventricular septal defect, fast ventricular rate with suboptimal filling of the ventricles, or cardiomyopathy.⁴⁵

The sonographic finding of pericardial fluid has been somewhat controversial. Initially, the finding of any pericardial fluid was believed to be abnormal.⁴⁶ Subsequently, numerous investigators have evaluated pregnancies prospectively for this finding.⁴⁷⁻⁴⁹ These investigators have determined that in the absence of cardiac structural or rhythm abnormalities, suspected anemia, viral infections, or suspected chromosomal abnormalities, the finding of 2 mm or less of pericardial fluid is a normal finding.

As was mentioned earlier, although ascites may be an early finding of hydrops in fetuses with conditions known to progress to hydrops (e.g., HDFN, sacrococcygeal teratoma, and so on), the finding of ascites in the presence of urinary and gastrointestinal tract abnormalities should not be considered an early sign of hydrops.

Table 17-3 Causes and Associations of Nonimmune Hydrops

Cause	Frequency*
<i>Focal Abnormalities</i>	
<i>Cranial</i>	
Fetal intracranial hemorrhage	Low
Vein of Galen aneurysm	Low
Cerebral tumor	Low
<i>Thorax</i>	
<i>Cardiac structural defects</i>	
AV septal defect, isolated or in association with Down syndrome	Low
AV septal defect in combination with heterotaxia syndrome (sinus ambiguous, left atrial isomerism, right atrial isomerism) and bradyarrhythmia	High
Tricuspid dysplasia and Ebstein's anomaly	Low
Severe obstruction of right ventricular outflow tract by pulmonary stenosis, pulmonary atresia, and premature obstruction of the ductus arteriosus (spontaneously or with indomethacin)	Low
Absent pulmonary valve syndrome (mostly combined with tetralogy of Fallot or agenesis of the ductus arteriosus)	Low
Truncus arteriosus communis with truncal valve insufficiency	Low
Premature closure of the foramen ovale	
Unknown	
Severe obstruction of left ventricular outflow tract by aortic stenosis and atresia leading to interatrial left-to-right shunt or premature closure of foramen ovale	Low

*Rate of the occurrence of hydrops if the fetus has the respective disease. In the vast majority of causes and associations, the incidence are too low for giving reliable information.

Reprinted with permission from Tercanli S, Gembruch U, Holzgreve W: Nonimmune hydrops fetalis: Diagnosis and management. In Callen PW (ed): *Ultrasonography in Obstetrics and Gynecology*, 4th ed. Philadelphia, W. B. Saunders, 2000, p 553.

FIGURE 17-17. Normal values for amniotic fluid mucopolysaccharides corrected for total protein. Xs represent 40 normal control patients; ◆ represent 71 cases of nonimmune hydrops fetalis. Noted two cases of fetal death were found to have elevated levels of MPS, although cultured amniocytes for 21 different lysosomal enzymes were normal. Three abnormal cases are depicted. (Reprinted with permission from Kooper AJ, Janssens PM, de Groot AN, et al: *Lysosomal storage diseases in non-immune hydrops fetalis pregnancies*. *Clin Chim Acta* 371:176, 2006.)

Doppler evaluation of the middle cerebral artery should also be performed in these patients. An elevated value of the peak systolic velocity of the MCA has been associated with fetal anemia even in cases of NIHF.⁵⁰

A careful maternal history should then be undertaken. This should include queries regarding exposure to children with *fifth disease* ("slapped cheek" disease) due to parvovirus B19. Maternal symptoms that would indicate subsequent infection include fever, arthralgia, and an exanthema on the upper body.⁵¹ Parvovirus B19 is a small single-stranded DNA virus.⁵¹ It is a potent inhibitor of hematopoiesis because it lytically infects erythroid precursor cells. The cellular receptor for parvovirus B19 is globoside, which is found on erythrocyte progenitor cells (erythroblasts and megakaryocytes) and also on erythrocytes, synovium, placental tissue, fetal myocardium and endothelial cells.⁵¹ This explains the etiology of the maternal and fetal signs and symptoms affecting maternal joints and fetal red blood cells, placenta, and myocardium. Infection with parvovirus B19 usually takes place through respiratory droplets, but it can also be transmitted by blood and blood-derived products, and may also be transmitted vertically from mother to fetus. Vertical transmission does not occur if the mother is immune at the time of exposure. When maternal infection does occur, viremia in the mother reaches its peak approximately 1 week after infection. Maternal symptoms start approximately 10 to 14 days after infection in approximately 50% of infected women.⁵¹ Parvovirus B19 IgM antibodies become detectable in maternal serum within 7 to 10 days after infection, peak at 10 to 14 days, and then decrease within 2 to 3 months. IgG antibodies rise more slowly and reach a plateau at 4 weeks after infection.⁵¹ A previous obstetric history of stillbirth or a hydropic fetus should lead the investigator to contemplate lysosomal storage diseases. Similarly, a consanguineous relationship would also lead one to consider autosomal-recessive diseases as the etiology.

The next step in the diagnostic evaluation usually entails maternal venipuncture. Tests should include an antibody screen for anti-red cell antibodies, rapid test for syphilis, and a Kleihauer-Betke test or fetal cell stain by flow cytometry. Maternal serologies for toxoplasmosis, cytomegalovirus, and parvovirus should be considered but may not be diagnostic particularly with acute onset of fetal hydrops.

Although cordocentesis to sample fetal blood to perform rapid assays was commonly used in the past for the initial assessment of NIHF, fluorescent in situ hybridization for major chromosomal abnormalities, and PCR testing for viral infections have decreased the role of this procedure. Amniocentesis is warranted to complete the acute investigation. Samples should be sent for fluorescent in situ hybridization, PCR for toxoplasmosis, cytomegalovirus, parvovirus, adenovirus, and enteroviruses. Kooper et al⁵² found that up to 8% of cases of NIHF may be related to lysosomal storage diseases. They recommend consideration of amniotic fluid analysis for mucopolysaccharides and neuraminic acid (Figs. 17-17 and 17-18). Cultured amniocytes should be analyzed for complete karyotype as well as enzymatic levels for the more common lysosomal disorders including β -glucuronidase, β -glucosidase, and β -galactosidase. Consideration for testing of other lysosomal diseases should be undertaken if warranted by maternal history. These would include Niemann-Pick types A and C, Wolman, Faber, Mucopolipidosis II, and multiple sulfatase deficiency.

Treatment

A limited number of cases of NIHF can be treated in utero; however, these cases are based on an accurate determination of the specific etiology (Fig. 17-19).

Parvovirus has been associated with profound fetal anemia and hydrops fetalis when maternal infection occurs before 20 weeks' gestation.⁵³ In one series of 1019 pregnant

FIGURE 17–18. Normal values for amniotic fluid bound and free neuraminic acid corrected for total protein. Xs represent 40 normal control patients; ♦ represent 71 cases of NIHF. Two abnormal cases are depicted. (Reprinted with permission from Kooper AJ, Janssens PM, de Groot AN, et al: *Lysosomal storage diseases in non-immune hydrops fetalis pregnancies. Clin Chim Acta* 371:176, 2006.)

women with seroconversion, the risk for fetal hydrops was 3.9%. The peak incidence of parvovirus associated hydrops fetalis is between 17 and 24 weeks of gestation.⁴⁷ The MCA Doppler can be used in an analogous fashion to immune hydrops to confirm the anemia when there is an elevated systolic velocity of more than 1.5 MoMs. Although maternal serology (positive IgM or new presence of an IgG antibody in a patient that was previously seronegative) can be used to confirm some cases, amniocentesis for PCR determination of parvovirus usually is diagnostic in 24 to 48 hours. In one large series, one third of cases of fetal hydrops spontaneously resolved within 5 weeks; half of these cases occurred before 23 weeks' gestation.⁵⁴ In another series, IUT of packed red cells was associated with survival in approximately 85% of cases, whereas those cases with hydrops that were observed were universally fatal.⁵³ IUTs have also proved successful in cases of fetal hydrops secondary to fetomaternal hemorrhage.⁵⁵ If a recurrent decline in fetal hematocrit is detected due to a persistent fetomaternal bleed, abandonment of additional transfusions may be warranted.

Other bacterial and viral infections are associated with NIHF including cytomegalovirus, adenovirus, toxoplasmosis, and syphilis. Fetal cytomegalovirus infection has been treated with maternal and direct fetal administration of hyperimmune globulin; however, the few reported cases of NIHF have not resolved with this therapy.⁵⁶ Adenovirus can cause fetal myocarditis with resulting hydrops.⁵⁷ Maternal administration of digoxin has been successful in increasing fetal myocardial function resulting in resolution of the hydrops. NIHF related to fetal toxoplasmosis has resolved after maternal administration of pyrimethamine, sulphadiazine, and folic acid with good short-term neurologic outcome.⁵⁸ Fetal infection with syphilis that results in NIHF can reverse with maternal treatment with penicillin however the overall prognosis due to cerebral complications remains high.⁵⁹

Both fetal bradyarrhythmias and tachyarrhythmias have been associated with fetal hydrops. Ventricular rates of less

than 50 bpm due to structural cardiac lesions or inflammation secondary to maternal anti-Ro antibodies are not amenable to therapy. The administration of maternal betamimetics has not been successful at increasing the fetal heart rate. Attempts at direct fetal pacing have also failed.⁶⁰ Both fetal atrial flutter and supraventricular tachycardia are associated with NIHF. Parenteral administration of digoxin followed by the addition of flecanide or sotalol is usually successful in converting these to a sinus rhythm.⁶¹

Solid lesions of the chest and sacrococcygeal teratomas in association with NIHF have been treated with open fetal surgery with mixed results.⁶² Referral to a center experienced in open fetal surgery should be considered if NIHF is noted before 26 weeks' gestation.

Unilateral pleural effusions or large, predominantly macrocystic cystic adenomatoid malformations of the fetal lung represent space-occupying lesions that can shift the mediastinum to the opposite side of the fetal chest. Therefore, these lesions can cause an obstruction to venous return as well as decreased cardiac output and subsequent development of NIHF. In the case of a large hydrothorax or macrocystic cystic adenomatoid malformation of the lung, thoracoamniotic shunt placement under ultrasound guidance has been successful in decreasing the size of the fluid or cyst resulting in a return of the mediastinum to its midline position.⁶³ Hydrops usually resolves within several weeks.

Twin-to-twin transfusion can present early in gestation with massive polyhydramnios in the "recipient" twin. Quintero⁶⁴ has proposed a staging system that describes various progressive ultrasound findings with stage IV disease defined as hydrops fetalis in one or both twins. Typically this occurs in the recipient of the twin pair. Untreated severe twin-to-twin transfusion at less than 24 to 26 weeks is associated with a 90% perinatal mortality.⁶⁵ Serial amnioreduction to remove the excess amniotic fluid or septostomy to allow for equilibration of the fluid between the amniotic compartments only marginally improves perinatal survival. In a large randomized trial, fetoscopic-directed laser ablation of

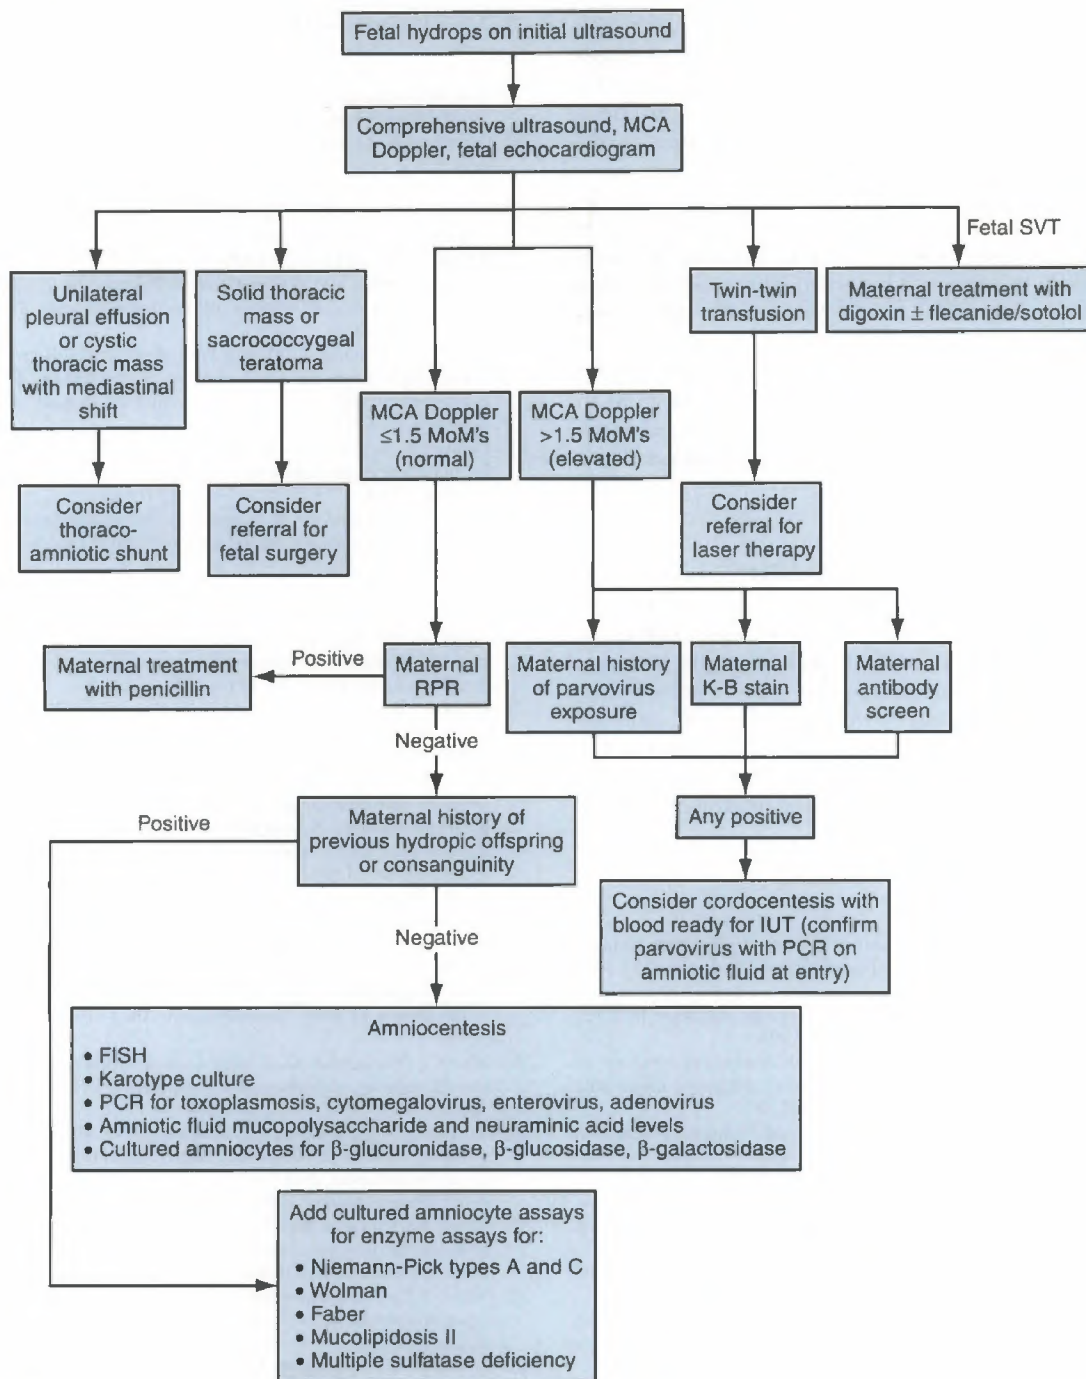

FIGURE 17-19. Algorithm for the management and treatment of nonimmune hydrops fetalis.

the anastomoses between the placental circulations of the twins resulted in an overall perinatal survival of 70%.⁶⁶ Laser therapy is now considered the standard of care in this condition.

Prognosis

Perinatal survival for NIHF has improved modestly with advances in perinatal/neonatal medicine. Clearly, the etiology of the hydrops defines the ultimate outcome. New therapies

such as IUT for fetal anemia secondary to parvovirus infection and laser therapy for twin-to-twin transfusion have markedly improved the prognosis in these specific conditions.

Mortality rates as high as 98% were reported in some series in the early 1980s; more recent data would suggest a survival rate between 30% and 40%.⁶⁷⁻⁶⁹ Several factors have been identified that predict a better prognosis. In one prospective series of 83 cases, the survival rate after exclusion of chromosomal abnormalities was 31% when NIHF was

detected before 24 weeks' gestation and 48% after this gestational age.³ In another series, no infant with an Apgar score at 5 minutes of less than 5 survived the neonatal period.⁶⁹ The presence of major pleural effusions has also been associated with poor perinatal survival. Nakayama et al⁶⁸ reported a survival rate of 25% when pleural effusions were present as compared with 61% when they were absent. In addition, fetuses who developed pleural effusions after 29 weeks' gestation and who delivered after 31 weeks' gestation were more likely to survive. This is thought to be related to extrinsic compression of the fetal lungs with subsequent development of pulmonary hypoplasia.

Few studies on long-term outcome in NIHF have been reported. In one small series of 19 infants that survived to 1 year of age, 15% had severe psychomotor delay, whereas an additional 10% exhibited mild mental retardation.⁶⁸

CONCLUSION

Both immune hydrops fetalis and NIHF are signs of significant fetal disease with a guarded prognosis. Advances in prophylaxis and prenatal treatment have markedly changed the outcome for the fetus with immune hydrops. Some inroads in prenatal therapy have been achieved in certain conditions associated with NIHF such as fetal tachyarrhythmias, fetal parvovirus infection, and twin-to-twin transfusion syndrome. The majority of cases remain problematic because there is no effective treatment and the perinatal mortality rate remains high.

ULTRASOUND EVALUATION OF THE CERVIX

Vincenzo Berghella, MD, and George Bega, MD

Introduction

Ultrasound of the Cervix—Techniques

- Transabdominal
- Translabial
- Transvaginal

Limitations and Pitfalls

- Full Bladder
- Too Much Pressure
- Contraction
- Underdeveloped Lower Uterine Segment

Clinical Applications

- Transvaginal Ultrasound Examination of the Cervix for Prediction of Preterm Birth

Screening Test

What to Measure

- Cervical Length
- Funneling
- Other Measurements

Dynamic Changes (Spontaneous or After Transfundal Pressure)

Normal Versus Abnormal

Best Gestational Age and Frequency of Examinations

Populations

- Singleton Low Risk

- Singleton High Risk

- Twins

- Triples

- Women With Cerclage

Three-Dimensional Transvaginal Ultrasound Examination of the Cervix

What Pathophysiologic Mechanisms Associate a Short Cervical Length With Preterm Birth?

Interventions for Preventing Preterm Birth if a Short Cervical Length is Identified in Asymptomatic Women

- Ultrasound-Indicated Cerclage

- Indomethacin

Predicting the Latency in Preterm Premature Rupture of the Membranes

Prediction of Start of Spontaneous Labor

Predicting the Success of Labor Induction and Mode of Delivery

Conclusions

INTRODUCTION

Ultrasound of the cervix during pregnancy has been the focus of much research during the past decade. Significant advances have been made in understanding the proper role of this sonographic screening test. In this chapter we will review the technique of transvaginal cervical assessment and discuss its role in clinical practice.

ULTRASOUND OF THE CERVIX—TECHNIQUES

Transabdominal

In the 1970s, the first attempts at evaluating the cervix used transabdominal ultrasound (TAU). Unfortunately, this technique does not have sufficient reliability or validity, because of the following shortcomings: (1) the bladder often needs to be adequately filled to obtain a good image, resulting in elongation of the cervix and masking of any

funneling of the internal os; (2) fetal parts can obscure the cervix, especially after 20 weeks; and (3) the distance from the probe to the cervix results in degraded image quality.¹ Therefore, TAU should not be used for assessment of the cervix, even as a screening test, since its sensitivity for prediction of disease (e.g., increased risk for preterm birth [PTB]) is unacceptably low (8%),² much lower than the two other techniques described later.

Translabial

Translabial (also known as transperineal) ultrasound (TLU) was first described in France in the early 1980s. This technique involves having the woman lie on table with the hips and knees flexed, while a gloved transducer in a sagittal orientation is positioned on the perineum between the labia majora (Fig. 18–1). Elevation of the woman's hips with a cushion can be used to improve visualization. Compared with TAU, this technique does not require bladder filling, is

FIGURE 18-1. Diagrams and translabial sonogram of the female pelvis showing the transducer placed at the vaginal introitus and oriented in the direction of the vagina. BI, bladder; EO, external os; FH, fetal head; IO, internal os; V, vagina. (Illustration by James A. Cooper, MD, San Diego, CA.)

FIGURE 18-2. A. Translabial sonogram revealing an apparent cervical length of 2.12 cm. The true cervical length is partially obscured by rectal gas (arrows). B. Transvaginal sonogram from the same patient. The true cervical length of 4.09 cm is now clearly seen.

not impaired by obstruction by fetal parts, with the transducer closer to the cervix, achieving close to 100% visualization. Other advantages of this technique are the transducer does not enter the vagina (so no pressure can be exerted on the cervix), it does not require an additional transducer, and it is well accepted by most women. The main drawback of TLU is that gas in the rectum frequently can impede visualization of the cervix, especially the external os (Fig. 18-2). This technique is also a lot more difficult to master than transvaginal ultrasound and, therefore, is an unsatisfactory alternative to transvaginal ultrasound.³

Transvaginal

The first studies of the human cervix using transvaginal ultrasound (TVU) are from the late 1980s. A clean transvaginal probe covered by a condom is inserted into the anterior fornix of the vagina (Fig. 18-3). The technique shares the advantages of translabial ultrasound; however, the probe is close to the cervix, without the problem of obscuring bowel gas. Thus, it has become the preferred gold standard method of evaluating the cervix in virtually all clinical settings (Fig. 18-4). Current recommendations for the performance of TVU of the cervix are shown in Table 18-1.¹

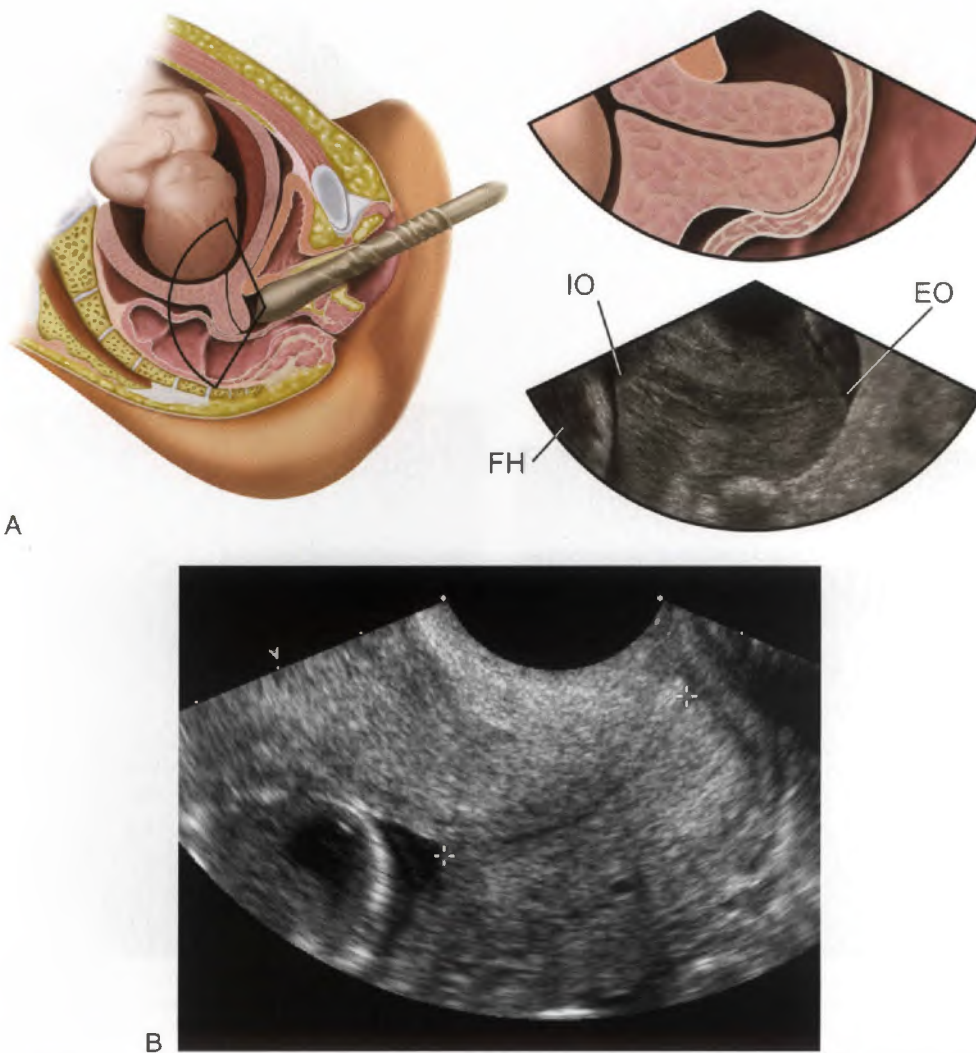

FIGURE 18-3. A. Diagrams and sonogram of the female pelvis demonstrating placement of the transvaginal transducer in the vagina. FH, fetal head; EO, external os; IO, internal os. (Illustration by James A. Cooper, M.D., San Diego, CA.) B. A two-dimensional ultrasound image of the cervix in its longest axis in the sagittal view. The internal and external os as well as the entire endocervical canal can be clearly seen, and the image is enlarged so that it occupies more than 75% of the screen.

FIGURE 18-4. Three methods of imaging the cervix. *A.* Transabdominal sonogram. The cervix, which is distant from the ultrasound transducer, is poorly seen and measures 1.62 cm. *B.* Translabial sonogram in the same patient. Although the cervix is seen somewhat better, shadowing from air in the rectum (*arrows*) obscures the true cervical length. *C.* Transvaginal sonogram. The true cervical length is now well seen and is virtually double the initial length measured.

The total time for a TVU of the cervix is approximately 5 minutes. For best results, the following criteria should be sought: the internal os should be either flat or at an isosceles angle with respect to the uterus, the whole length of the cervix should be visualized, a symmetric image of the external os should be obtained, the distance from the surface of the posterior lip to the cervical canal should be equal to the distance from the surface of the anterior lip to the cervical canal, and there should be no increased echogenicity in the cervix (a sign of excessive pressure).⁴

LIMITATIONS AND PITFALLS

Although TVU of the cervix is usually straightforward, there can be an anatomic or technical difficulty that may be encountered in approximately one fourth of patients.⁵

Full Bladder

A bladder that is not completely empty of urine can exert pressure on the cervix, and mask possible funneling or opening of the internal os.

Too Much Pressure

Excessive pressure by the examiner can also mask funneling and/or opening of the internal os, and elongate the cervix. It can be easily identified by excessive echogenicity of the cervix (Fig. 18-5).

Contraction

Uterine segment contractions may mimic the appearance of funneling of the internal cervical os. In such cases, there is

Table 18-1 Recommendations for the Technical Performance of Transvaginal Ultrasound Examination of the Cervix

1. Have the woman empty her bladder;
2. Prepare the clean probe covered by a condom;
3. Insert the probe (probe can be inserted by the woman for more comfort);
4. Guide the probe in the anterior fornix of the vagina (Fig. 18-3A)
5. Obtain a sagittal long-axis view of endocervical canal, along its entire length;
6. Withdraw the probe until the image is blurred, and reapply just enough pressure to restore the image (to avoid excessive pressure on the cervix, which can elongate it);
7. Enlarge the image so that the cervix occupies at least two thirds of the image, and both external and internal os are well seen (Fig. 18-3B)
8. Measure the cervical length from the internal to the external os along the endocervical canal;
9. Obtain at least three measurements, and record the shortest best measurement in millimeters;
10. Apply transfundal pressure for 15 seconds, and record cervical length again.

FIGURE 18-5. The ultrasound image on the left shows a cervix under excessive pressure from the vaginal probe. As a result, the anterior lip of the cervix is significantly thinner than the posterior lip of the cervix as shown by the double-headed arrows. The small triangular markers (*arrowheads*) show the increased echogenicity below the posterior lip of the cervix, a typical sign of excessive pressure. The image on the right shows that the anterior and posterior lips of the cervix are equal (as shown by the double-headed arrows) but still there is increased echogenicity below the posterior lip of the cervix. This demonstrates that there is still excessive pressure making the measurement of the cervix inadequate. The small short arrows in both images represent the vaginal mucosa that appears sonographically as a hyperechoic line. The vaginal mucosa is a reliable marker to identify the level where the external os should be seen (in difficult cases), and whether there is sliding between anterior and posterior lips of the cervix, which is another sign of excessive pressure.

rounded myometrium around the cervix, and a normal cervix distal to the contraction (Fig. 18-6).

Underdeveloped Lower Uterine Segment

Often, before 14 weeks, the lower uterine segment is difficult to distinguish from the endocervical canal, because the gestational sac has not reached a sufficient size to completely expand the lower part of the uterus. Therefore, the measurement of the true cervical length (CL) is very difficult before 14 weeks. At other times, especially between 14 and 18 weeks, the presence of a contraction can also close the lower uterine segment, and make the distinction between this structure and the true CL difficult.

As is similarly done with other sonographic measurement techniques, such as the nuchal translucency measurement, some have recommended that a sonographer be supervised for his or her first 50 TVUs of the cervix to acquire sufficient expertise and ensure accuracy and reproducibility.

CLINICAL APPLICATIONS

Transvaginal Ultrasound Examination of the Cervix for Prediction of Preterm Birth

Screening Test

TVU of the cervix is often used in obstetrics as a screening test for the prediction of PTB.¹ To be clinically beneficial, a screening test must fulfill specific criteria.⁶

Important and Prevalent Condition. First, it must screen for a clinically important and prevalent condition. PTB occurs in 12% of births in the United States, or approximately 500,000 pregnancies per year in this nation alone.⁷ It is the main cause of perinatal morbidity and mortality, and as such may be in fact the most important condition in obstetrics. In terms of years of life lost, PTB is one of the most important diseases in all of medicine.

FIGURE 18-8. A. The diagram on the left and the ultrasound image on the right show a cervix with significant lower uterine segment contractions (*asterisks*). Lower uterine segment contractions should be considered whenever the cervical length measures more than 50 mm, the cervical canal assumes an S shape, and the lower uterine segments (either anteriorly or posteriorly or both) are thickened and asymmetric. The lower uterine segment contraction severely distorts the landmarks of the cervix and makes the measurement of cervical length inadequate. B. Lower uterine segment contractions (*asterisks*) seen on a transabdominal sonogram. The pseudocervical length measures more than 7 cm. This measurement alone should make one suspect of contractions. C. Although the cervix is not adequately visualized on this transabdominal sonogram, problems with adequate measurement are compounded by lower uterine segment contractions (*asterisks*). The reflection (*arrow*) between the contractions may simulate and can be misinterpreted as the endocervical canal.

Technique Well Described. The technique is well described (see Table 18-1).

Safe and Acceptable. TVU of the cervix is very safe. There is no inoculation of bacteria with TVU.⁸ In a randomized trial comparing the use of TVU or the nonuse of TVU in the presence of premature preterm rupture of membranes (PPROM), there was no increased risk of infection for mother or fetus with TVU of the cervix compared with no TVU of the cervix.⁹ TVU is also well accepted by pregnant women. Pain and severe discomfort is experienced by less than 2% of women undergoing TVU, and more than 99% of women would agree to a similar procedure in the future.^{10,11}

Reliable/Reproducible. The interobserver and intraobserver variability of TVU are both less than 10%.^{12,13} This low variability between operators is achieved only with strict adherence to proper technique as described earlier and after adequate training with supervised scans.

Recognizable Early Asymptomatic Phase. The changes of the cervix that ultimately lead to preterm or term labor have been demonstrated by TVU. These changes include initial opening of the internal os, progressive cervical shortening and widening along the endocervical canal from the internal to the external os, and ultimate opening of the external os. The earliest changes at the internal os are almost always asymptomatic and can only be detected by TVU.

Valid (Accuracy of Prediction). Comparison With Manual Exam of the Cervix. Cervical assessment by manual (digital) examination was a traditional method for prediction of PTB. Digital and TVU examinations of CL every 2 weeks from 14 to 30 weeks' gestation (with examiners blinded to the results of the alternate technique)¹² both independently predict PTB, but TVU has a much stronger association with PTB than manual examination of the cervix. The mean sonographic CL of the PTB group was significantly shorter

FIGURE 18-7. Diagram illustrating the major landmarks of the cervix and its surroundings. A is cervical length, B is funnel length, C is funnel width, D is the distance from internal os to the level of cerclage, E is the distance from the level of cerclage to the external os. Typically the fetal head is the presenting part seen adjacent to the level of the internal os or funnel. The maternal bladder is seen anteriorly above the anterior lower uterine segment.

than that of the term delivery group, whereas there was no difference in manual cervical measurements between the two groups.¹²

The relative lack of success of the digital exam in predicting PTB is probably due to the fact that it is subjective (interobserver variability of 52%),¹⁴ not accurate for evaluating the internal os (the whole upper half of the cervix is not measurable by this method),¹⁵ and nonspecific (15% to 16% of primiparous women and 17% to 35% of multiparous women who are delivered at term have cervixes that are 1 to 2 cm dilated by manual examination in the late second trimester).¹⁶ Sonographic CL measurements are, on the average, 11 mm longer than manual estimations. The majority, about three fourths, of asymptomatic women with funneling of the internal os have a closed and at least 2-cm-long cervix on manual examination.¹³ These data show that TVU is clearly superior to manual examination for evaluation of the cervix and prediction of PTB.

WHAT TO MEASURE

Cervical Length

Different cervical parameters have been evaluated as predictors of PTB (Fig. 18-7). CL, as measured from the

internal to the external os along the endocervical canal, is the most reproducible and reliable measurement (Figs. 18-3*B* and 18-8*A* and *B*). If the cervical canal is curved, the CL can be measured either as the sum of two straight lines that essentially follow the curve (when the a deviation of the canal is > 5 mm), or by a straight line between internal and external os (Fig. 18-8*C*).¹⁷ A short CL is usually straight, and the presence of a curved cervix generally signifies a CL greater than 25 mm and, therefore, is a reassuring finding. If the cervical canal is closed, CL is probably the only parameter that needs to be measured.

Funneling

In about 10% of low-risk¹⁸ and 25% to 33% of high-risk women,^{12,13,17} the internal os is open (Fig. 18-9). In this case, the open portion of cervix (funnel length) and internal os diameter (funnel width) can be measured. Percent funneling is defined as funnel length divided by total CL. Total CL is equivalent to the sum of funnel length and functional CL. Functional CL in this case is the closed portion of the endocervical canal only. Functional CL is the sonographic CL used for calculations and predictions, and the term CL, if not otherwise specified, refers to the functional CL.

If funneling is present, the shape can be recorded. A continuous process of funneling has been described, going from a normal T shape, to Y, then V, and finally a U shape (Figs. 18-10 and 18-11).¹⁹ It appears that U-shaped funneling is more likely to be associated with PTB compared with a V-shaped funnel²⁰; however, these distinctions are somewhat subjective.

Careful evaluation of the apparent funneling with transvaginal ultrasound over several minutes (at least 5) should resolve any question of the morphology of the upper cervical canal. In some instances, the depth of a true funnel may be difficult to quantify, because the funneled portion may merge with the lower uterine segment and the characteristic shoulder that depicts the border between lower uterine segment and the true cervix may be flattened. Funneling has been reported to have higher interobserver variability among examiners and different centers than CL.¹⁸

In spite of these difficulties, funneling has been reported to have better or similar predictive accuracy for PTB than CL.^{12,13,18} In one high-risk population, minimal funneling (< 25%) noted between 14 and 22 weeks was not associated with a significant increase in PTB, whereas moderate (25% to 50%) and severe funneling (> 50%) were associated with a 50% or more probability of PTB.¹³ The fact that less than 25% funneling is not associated with an increased risk of PTB is important, because this is a common finding that should not raise alarm or result in intervention. Funneling has also been shown in all studies, not just high-risk ones, to predict PTB.^{12,13,17,18,21-26} Almost always, if funneling is present, the CL is short (<25 mm). In the presence of a short CL, the presence of funneling may^{18,22,25,26} or may not^{17,21,23,24} add to the prediction of PTB or adverse perinatal outcome. Compared with a CL less than 25 mm alone, adding funneling can increase the sensitivity for PTB (from 61% to 74%) without major changes in specificity, and positive and negative predictive values.²² Also, the risk of PTB is higher if both a short CL and funneling are detected, compared with a short CL without funneling.²⁶ On the contrary, the presence

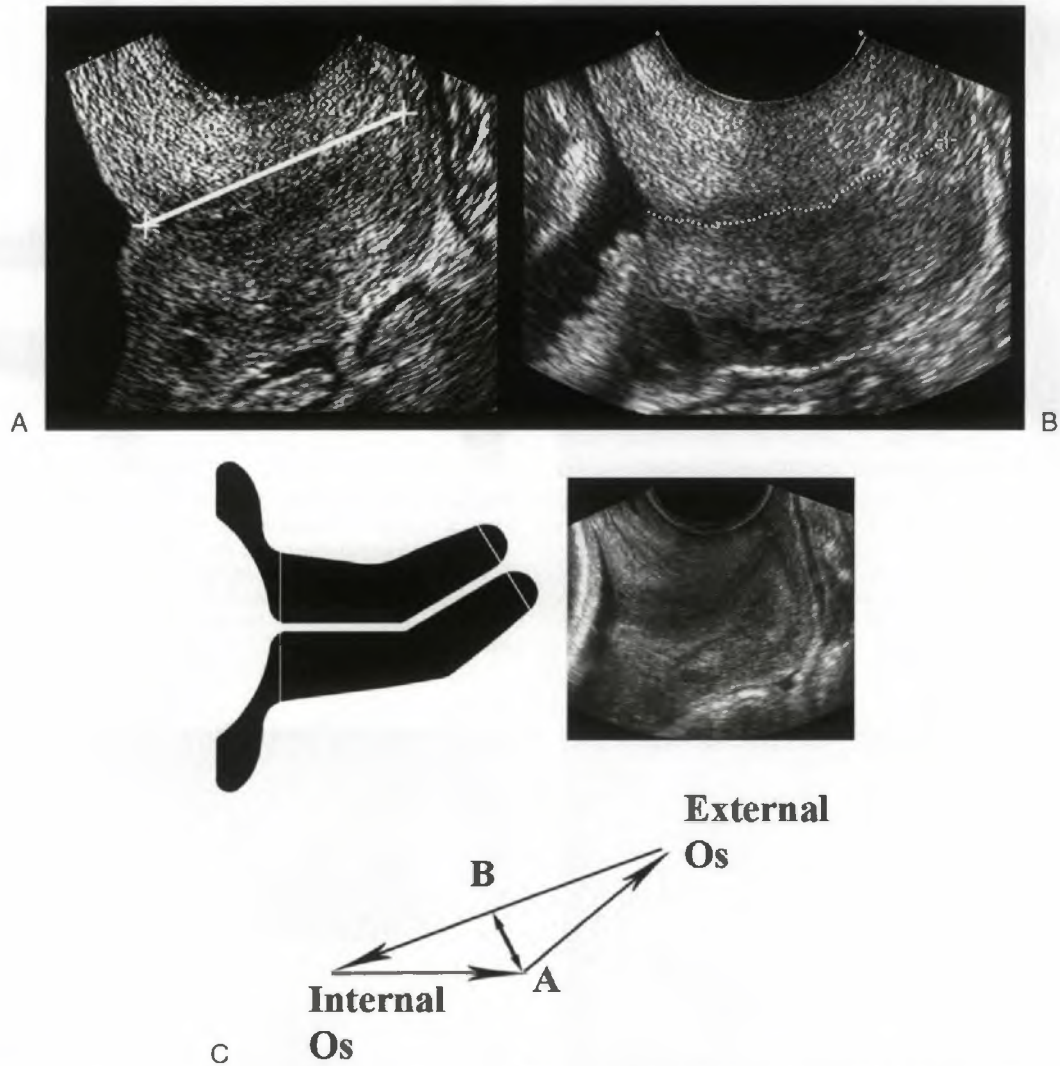

FIGURE 18-8. Measurement of the cervix using three techniques. *A.* The cervical length is measured in a straight fashion from the internal os to the external os because the cervical canal appears to be straight. *B.* The canal is measured with the manual draw feature of the equipment. As you can see, the draw feature will not properly draw the cervical canal and will overestimate the cervical length. *C.* The diagram and the ultrasound image illustrate the curved cervix and the decision-making process whether to measure the cervix in a straight line or in two steps. The curved cervix can be assessed by connecting the internal os to the level where the straight canal bends upward (A), then another line connects A to external os. The external os is connected with a line to the internal os. If the height of this triangle (distance A-B) is more than 5 mm, then the cervical canal should be measured in two steps.

of funneling in a woman with a normal (≥ 25 mm) CL does not seem to increase her risk of PTB²⁷ (funnel Y in Fig. 18-10).

Other Measurements

Many parameters other than CL and presence or absence of a funnel have been studied,²⁸ including funnel width, funnel

FIGURE 18-9. Sonogram in a patient with cervical funneling. Typically funnel width is measured by identifying the lower uterine segment notch (or genu) either anteriorly or posteriorly (or both), and a line perpendicular to the axis of the cervical canal connects to the opposite side. The funnel length is measured by connecting the middle of the funnel width with the tip of the funnel. Cervical length is measured from the tip of the funnel to external os.

FIGURE 18-10. These diagrams show the typical shapes of the cervical funnels. T represents a closed normal cervix. Y represents a small funnel, which if less than 25%, with a cervical length ≥ 25 mm, may not be clinically significant. V represents a more significant funnel, closer to the external os. U represents the funnel of most concern; this is the clinical situation in which more often the cervix can be dilated by manual examination.

FIGURE 18-11. These ultrasound images show the respective funnel shapes, as depicted in Figure 18-10.

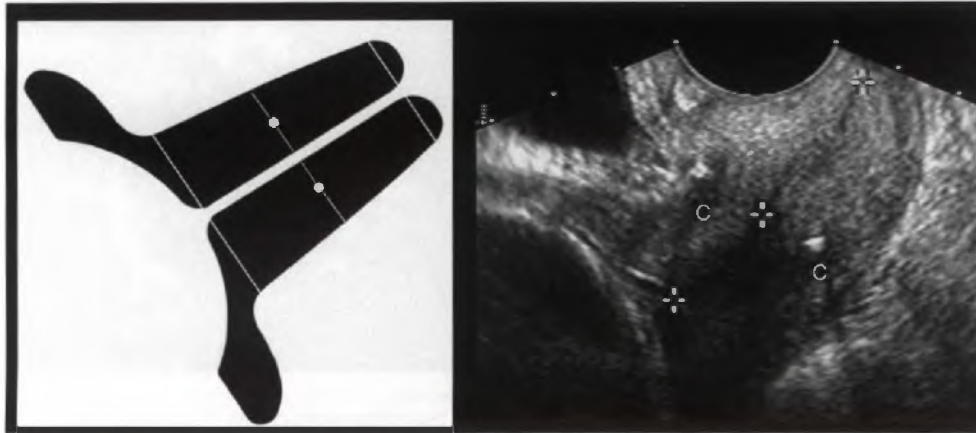

FIGURE 18-12. Diagram and an ultrasound image of a cervix with a cerclage in place. The cerclage (C) is seen as two bright spots seen in the anterior and posterior lips of the cervix. The measurement of the cervix in these cases is done from internal os to the level of cerclage, and from the level of cerclage to the external os. Note that the orientation of the cervix in this figure is not horizontal but vertical, a situation that usually makes the identification of the landmarks more difficult because the ultrasound beam does not hit the endocervical canal in a perpendicular fashion.

length, endocervical canal dilatation, cervical index (funnel length +1/functional length), anterior and posterior cervical width, cervical angle, cervical canal contour (straight versus curved), cervical position (horizontal versus vertical), lower uterine segment thickness, vascularity, visibility of chorion-amnion membranes at the internal os, presence of sludge,²⁹ cervical gland area,³⁰ quantitative tissue characterization,³¹ and others. None of these parameters has proved more reliable or predictive than CL. Additionally, there is insufficient evidence to assess if the addition of any of these parameters improves the predictive accuracy already provided by CL. Several other measurements may be taken in the presence of a cerclage (Figs. 18-7 and 18-12 to 18-15). Although these measurements are predictive of PTB, again CL alone can be used with good predictive accuracy even in women with a cerclage in place.

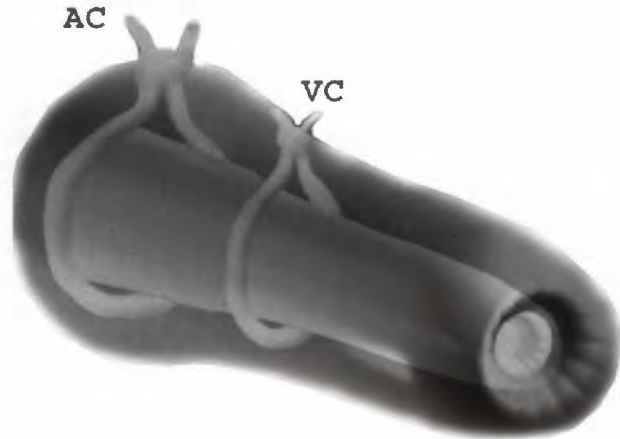

FIGURE 18-13. Three dimensional (3D) graphic of the cervix showing the usual locations of abdominal (AC) and vaginal (VC) cerclages. As seen in the image, the abdominal cerclage is high up and close to the level of the lower uterine segment, whereas the vaginal cerclage is placed usually somewhere in the middle of the cervical canal.

FIGURE 18-14. Three ultrasound images of vaginal cerclages. A. A two-dimensional ultrasound image of a cervix with a vaginal cerclage in which the cerclage sutures are seen only as two bright spots (arrows). B. A three-dimensional ultrasound derived image of a cervix with a vaginal cerclage in the axial plane in which the suture is depicted in its entirety (arrows). C. A three-dimensional ultrasound-derived image of a cervix with a vaginal cerclage (arrows) in the axial plane in which the suture has pulled through from the posterior lip of the cervix and can no longer be effective in preventing preterm birth.

FIGURE 18-15. Two ultrasound images of the cervix with an abdominal cerclage. *A.* A two-dimensional ultrasound image of a cervix with an abdominal cerclage in which the cerclage sutures (*arrows*) are seen only as two bright spots placed at the level of the internal os. *B.* A three-dimensional ultrasound-derived image of a cervix with an abdominal cerclage in the axial plane. Note the entire visualization of the suture (*arrows*).

DYNAMIC CHANGES (SPONTANEOUS OR AFTER TRANSFUNDAL PRESSURE)

In less than 5% of TVU, CL may change dynamically during the course of a 5- to 10-minute examination, and in some cases, funneling of the upper cervical canal may appear and resolve. This usually happens if the woman is having contractions. Similarly, the cervix may shorten in response to transfundal pressure (TFP) in approximately 5% of cases.³² When changes occur, the shortest CL should be recorded. In most of the cases in which the cervix shortens spontaneously or in response to TFP, it is already abnormal at baseline. There is conflicting evidence concerning whether TFP increases the screening potential of TVU. In one study, only one of nine patients with an initially normal cervix who had abnormalities after the application of TFP delivered preterm,¹² and adding response to TFP as a screening criteria for PTB did not significantly increase predictive accuracy. In contrast, in a larger study, dynamic changes, either spontaneous or after TFP, significantly improved the predictive accuracy of TVU for PTB.¹⁷ Dynamic changes may indeed improve predictive accuracy; use the shortest best CL.

NORMAL VERSUS ABNORMAL

A normal CL is 25 to 50 mm at 14 to approximately 30 weeks. Twenty-five millimeters is the 10% percentile for low-risk singletons¹⁸ and approximately the 25% percentile for high-risk singletons.^{12,17} A short CL is one less than 25 mm at these gestational ages, with the best prediction for PTB obtained at 16 to 24 weeks. **The shorter the CL, the higher the risk of PTB.**¹⁸ A short CL is a better predictor of early PTB than later PTB.³³ A CL greater than 50 mm is also normal but often reflects a measurement that includes the lower uterine segment, as often happens before 16 weeks.

BEST GESTATIONAL AGE AND FREQUENCY OF EXAMINATIONS

Almost all patients, even those at the highest risk, have a normal CL in the first and early second trimesters. Before 14 weeks, measuring CL may be predictive only in very high-risk women, such as those with a prior second trimester loss

or history of a large cervical cone biopsy. In a study of TVU of the cervix in high-risk women, only 5% had a CL greater than 25 mm between 10 and 14 weeks, and these women were indeed very high risk because of prior history.³⁴ Sensitivity for the prediction of PTB is very low in this time interval, because most women destined to deliver preterm have cervical shortening usually detected ≥ 16 weeks. An additional drawback of very early screening is that the lower uterine segment is difficult to distinguish from the true cervix in the late first and early second trimesters. After 30 weeks, the CL progressively shortens in preparation for term labor, so that a CL less than 25 mm, especially 15 to 24 mm, after 30 weeks can be physiologic and not associated with an increased risk of PTB in asymptomatic women. The most common gestational age when a short cervix or funneling develops is 18 to 22 weeks.^{12,13} Therefore, if a screening program is to include only one CL assessment, it should be done in this time interval. High-risk patients destined to deliver preterm may have earlier cervical changes. **The earlier the short CL is detected, the higher the risk of PTB.** A cervix of less than 25 mm had a positive predictive value of 70% when detected between 14 and 18 weeks, and of 40% when detected between 18 and 22 weeks, in high-risk women.¹² Therefore, it may be that women with the highest risk of PTB (e.g., patients with classical histories of cervical incompetence, prior second trimester losses, or early PTBs) may benefit from early (i.e., 14–18 weeks) ultrasound examination to determine their need for intervention.

The benefit of repeated TVU examinations and the ideal interval for repeating TVU has not been clearly established. If a screening program were employed in relatively low-risk women, one TVU of the cervix at approximately 18 to 22 weeks would likely be most effective. It appears that one normal TVU CL assessment between 14 and 18 weeks and another between 18 and 22 weeks is reassuring in most high-risk women.²² In women at very high risk for PTB, such as those with prior second trimester loss or very early spontaneous PTB, some have advocated TVU of the cervix every 2 weeks, at least between 14 and 24 weeks. The fact that TVU at 14 to 22 weeks is at least as predictive of PTB as TVU after 22 weeks is important, because interventions to

prevent PTB are most effective when changes leading to PTB are detected early in the process.

POPULATIONS

There have been numerous studies evaluating the predictive accuracy of TVU CL for PTB in many different populations.¹ The populations screened include asymptomatic women with singleton, twin, and triplet pregnancies, and symptomatic women with preterm labor (PTL) or PPRM, as well as low-risk women, high-risk populations, and patients with a cerclage in place. Although the TVU technique in these studies is similar, study population (in particular, the incidence of prior PTB), gestational age at which TVU was done, frequency of TVU, cervical parameters studied, and outcomes vary. In reviewing the available studies, it is important to use those with the best design, that is, those that describe proper technique, blinding of managing physicians to ultrasound results, and the inclusion of large numbers of patients. In most studies, the cervical parameter found to have the best predictive accuracy, as determined by receiver operating characteristic curves, is a CL less than 25 mm. The screening interval is early in the second trimester, usually between 16 and 24 weeks. The most common primary outcome is spontaneous PTB at less than 35 weeks' gestation (Table 18-2).^{17,18,35-40}

Singleton Low Risk

Numerous studies have reported nomograms for CL in nonselected pregnant women with singleton gestations.^{18,41,42}

In low-risk women, CL is a continuous variable, with a mean of 35 to 40 mm from 14 to 30 weeks, with the lower 10th percentile being 25 mm and the upper 10th (90th percentile) being 50 mm.^{18,42} A progressive and natural shortening of CL is noticed after 30 weeks, even in patients destined to deliver at term.⁴¹ There may be a very slight progressive linear reduction of CL even before 30 weeks.⁴³ There seems to be no difference in CL between nulliparous and multiparous women throughout pregnancy, whereas risk factors for PTB such as African origin, age younger than 20 years, low ponderal index, and prior miscarriage or PTB are associated with a shorter CL.⁴⁵

In asymptomatic singleton gestations, as in all other groups, the shorter the cervix, the higher the risk of PTB.¹ Using different cutoffs for CL from 15 to 34 mm, the positive predictive values ranged from 6% to 44%.¹ These relatively low values are likely due at least in part to the low prevalence of PTB in this population (0.8% to 15%). In one of the better-designed, larger studies,¹⁸ the sensitivity was only 37% and the positive predictive value only 18%. This means that the majority (63%) of the few such women without risk factors who delivered preterm were not identified by TVU screening, and that 82% of these low-risk patients who were found to have a short CL less than 25 mm at 24 weeks delivered at or after 35 weeks. Given this findings, routine screening with TVU CL is not recommended for all pregnant women.

Singleton High Risk

Risk factors for PTB are numerous. Several studies have assessed the predictive value of TVU CL in women with

some of the most important of these risk factors, including a prior PTB,¹⁷ cone biopsy,³⁵ two or more voluntary terminations,³⁷ or mullerian anomaly.³⁶ As Table 18-2 shows, TVU CL between 14 and 24 weeks is predictive of PTB in all of these high-risk populations. In fact, the worse the obstetric history, the shorter the cervix, because prematurity risk is a continuum.⁴⁴ A woman with clinical risk factors for PTB who has a normal (≥ 25 mm) TVU CL between 18 and 22 weeks has a risk of PTB of less than 10%, which represents a significant reduction in risk and can prevent unnecessary interventions in these women. On the contrary, the sensitivity of TVU CL to detect which high-risk women will deliver preterm is often higher than 60%, much higher than in low-risk women. The prevalence of PTB less than 35 weeks is often greater than 50% when the additional risk factor of TVU CL less than 25 mm is discovered at less than 24 weeks in these women with historic risk factors for PTB. These positive predictive values are also much higher than those in low-risk women (see Table 18-2). PTB within 4 weeks of TVU occurs in about 13% of asymptomatic women with short CL, and in none of the pregnancies without such change; so steroid therapy for fetal maturity is rarely indicated, even in asymptomatic women with a short CL.²² It is important to note that, at least in high-risk patients, PTB following the detection of a short CL is most often preceded by PPRM (48%–68%) instead of PTL.^{12,45} A CL less than 10 mm in these women is particularly predictive of PPRM.⁴⁶ TVU in women with a prior PTB less than 32 weeks demonstrated that the best predictive accuracy is achieved with serial TVUs, including the shortest cervix seen after spontaneous or TFP-elicited changes.¹⁷ The sensitivity and positive predictive value reached 69% and 55%, respectively. This was the only blinded multicenter study controlled for quality performed in women at high-risk for PTB and, therefore, contains the most reliable and valid predictive data in this population.¹⁷

Twins

Despite the significant contribution of PTB to perinatal morbidity and mortality in twin pregnancies, the prediction of PTB in twins using traditional clinical means is limited. A CL of 25 mm or less at 24 weeks' gestation is the best of all the predictors of PTB evaluated in twins, including fetal fibronectin and bacterial vaginosis³⁸ (see Table 18-2). Compared with singleton pregnancies, twin pregnancies that deliver at term have been shown to have a similar TVU CL at 14 to 19 weeks but have a progressively much shorter cervix starting after 20 weeks' gestation.⁴⁷ Because cervical shortening can occur after 20 weeks' gestation even in some twin pregnancies destined to deliver at term,⁴⁷ TVU of the cervix before 20 to 24 weeks may lead to better prediction of PTB, but unfortunately, the predictive value of sonographic CL determination in twins between 24 and 34 weeks' gestation is low.⁴⁸ As with high-risk singletons, a short cervix is a good predictor of PTB in twins. The shorter the CL and the more severe the funneling, the higher the risk of PTB. Importantly, only less than 10% of twin pregnancies with a sonographic CL of greater than 35 mm between 18 and 26 weeks deliver before 35 weeks.⁴⁹ This finding should allow obstetricians to avoid bed rest and other interventions commonly used in twin pregnancies. Unfortunately,

sensitivity of TVU CL to predict which twin gestations will deliver preterm is only 30%. This is probably because multiple gestations deliver preterm not because of cervical insufficiency but because of rapid uterine expansion leading to contractions, a process not well screened by TVU CL.¹

Triplets

Few studies have reported on TVU of the cervix and its prediction of PTB in triplet pregnancies. As shown in Table 18-2, sensitivity of TVU CL to predict which triplet gestations will deliver preterm is low, as in twin gestations, making this screening test not very effective in general in multiple gestations.³⁹

Women With Cerclage

TVU of the cervix has been evaluated in women with history-indicated, ultrasound-indicated, or physical examination-indicated cerclage in place. Most studies have shown that transvaginal cerclage is placed in the middle part of the cervix in the vast majority of cases (see Figs. 18-13 and 18-14).⁵⁰⁻⁵² Transabdominal cerclage is instead placed at the internal os (see Figs. 18-13 and 18-15). It would be reasonable to believe that the higher (closer to the internal os) the cerclage suture is placed, the most effective is the prevention of PTB. Evaluation of pre- and post-cerclage TVU CL has shown that CL usually increases post-cerclage, and that an increase in CL is associated with a higher rate of term delivery.^{53,54}

Studies that evaluated the accuracy of TVU for predicting PTB in patients with cerclage⁵⁰⁻⁵³ all show that TVU cervical parameters are predictive of PTB. CL less than 25 mm and upper cervix (the closed portion above the cerclage, see Fig. 18-12) less than 10 mm are probably the two best predictive parameters.

THREE-DIMENSIONAL TRANSVAGINAL ULTRASOUND EXAMINATION OF THE CERVIX

Recent developments in ultrasound technology make possible the acquisition of two-dimensional ultrasound data in a three-dimensional volume through dedicated ultrasound transducers. The three-dimensional volume data are presented in a variety of orthogonal multiplanar displays in which sagittal, axial, and coronal views of the cervix are shown simultaneously (Fig. 18-16). The multiplanar view makes possible visualization of anatomic planes that are simply impossible with two-dimensional ultrasound (i.e., planes that are perpendicular to the ultrasound beam such as the coronal plane of the cervix). In addition, the three-dimensional multiplanar display makes possible the visualization of the true midsagittal plane of the cervix by objectively selecting the midsagittal plane in the coronal view (Figs. 18-17 and 18-18). The coronal view of the cervix is a unique view that is obtained only with three-dimensional ultrasound and provides new information on the shape and dimensions of the endocervical canal. The visualization of the funnel is also improved by using three-dimensional ultrasound because the funnel can be evaluated in all three

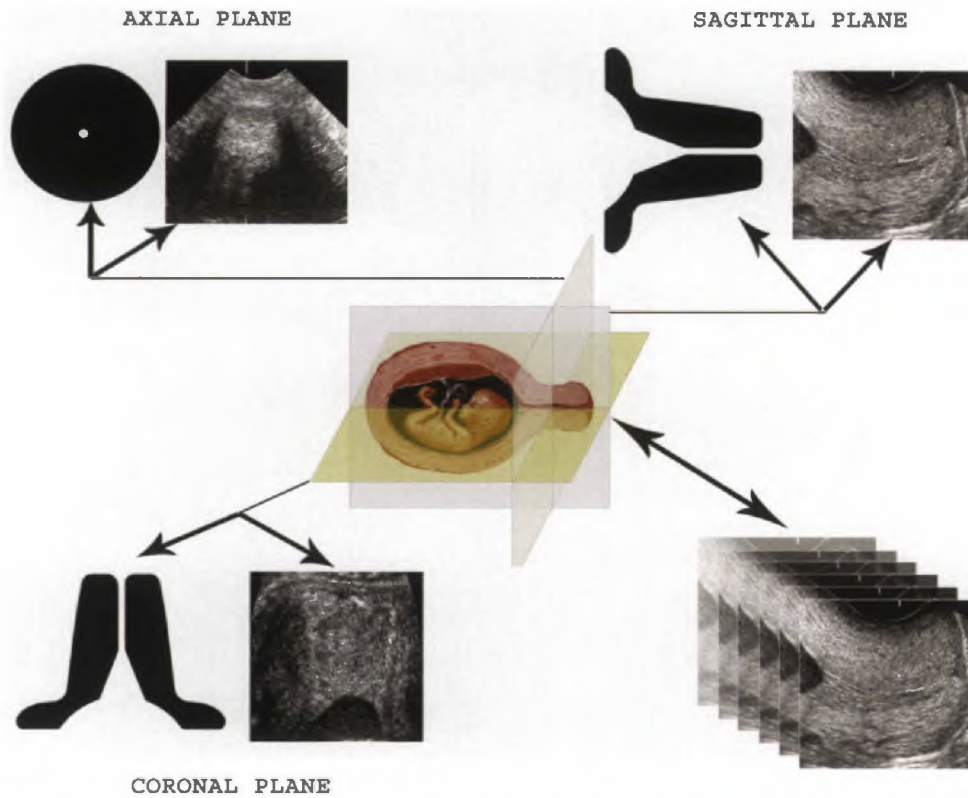

FIGURE 18-16. Diagram illustrating a three-dimensional volume acquisition of two-dimensional images of the cervix in the sagittal plane and the subsequent display of the cervix in three orthogonal planes (sagittal, axial, and coronal). Note that these three planes simultaneously shown (sagittal, axial, and coronal) are interactively linked to each other in a 90-degree (orthogonal) relationship. The evaluation of the cervix is not limited to the sagittal plane only but extends with the axial and coronal planes. Note that cervical length, and funnel length and width are shown both in sagittal and coronal planes. The coronal plane funnel width is the true funnel width, whereas what most people call funnel width in sagittal view is really the true funnel height.

FIGURE 18-17. These diagrams illustrate the relationship between the ultrasound beam and the midsagittal axis of the endocervical canal. In the left diagram, the ultrasound beam is precisely lined up in the midsagittal axis of the endocervical canal, which theoretically is the right plane to estimate the cervical length. The diagram in the middle shows that the ultrasound beam is cutting the endocervical canal obliquely, somewhat overestimating its length. The diagram on the right shows the ultrasound beam cutting only part of the endocervical canal, thus significantly underestimating the cervical length. As the operator tries to blindly line up the ultrasound beam with the midsagittal plane of the endocervical canal, he typically observes small differences (1–3 mm) in the values from one measurement to the other.

FIGURE 18-18. An ultrasound image of a normal cervix displayed in the multiplanar display. *A.* The sagittal plane of the cervix that corresponds to the acquisition plane of this volume. *B.* The computer-generated axial plane of the cervix cut precisely at the level of the cross-planar point (the orange dot) 90 degrees from the sagittal plane. *C.* The coronal plane of the cervix again precisely 90 degrees from the sagittal plane coronally. The green line in the coronal plane represents the true midsagittal plane of the cervical canal and is operator selectable. The green line illustrates the point the three-dimensional ultrasound objectively obtains the true midsagittal plane of the cervix. The red and yellow lines represent the parasagittal planes that commonly two-dimensional ultrasound operators take as they blindly try to line up the ultrasound beam to the midsagittal plane of the cervix.

planes: sagittal, axial, and coronal. The coronal funnel width is the true width of the funnel because the commonly known funnel width as seen with two-dimensional ultrasound represents the true funnel height (Fig. 18-19). The coronal funnel or endocervical canal widths are not necessarily the same value as their respective sagittal values and as such may provide additional, new and potentially useful information⁵⁵ (see Figs. 18-16 and 18-20 to 18-22). Three-dimensional ultrasound makes it possible to obtain an axial plane through the cervix at the level of the cerclage, demonstrating the entire stitch (see Figs. 18-14 and 18-15).⁵⁵ This view is not readily obtainable with conventional two-dimensional ultrasound. Whether three-dimensional ultrasound imaging will improve clinical management in patients with or without a cerclage in place is unknown. New display and acquisition methods enable the operator to view the cervix in multiple slices in operator-selectable distances such as computed tomography or magnetic resonance imaging-like displays or view the sagittal and coronal views of the cervix in real time such as with virtual contrast imaging (Figs. 18-23 to 18-25). Volume imaging methods of the cervix provide not only additional imaging views of the cervix but also assist in better standardizing the evaluation of the cervix by obtaining the important views of the cervix (i.e., the midsagittal view of the cervix) in a controlled fashion. Further research work is needed to evaluate whether this additional information has any impact in clinical management.

WHAT PATHOPHYSIOLOGIC MECHANISMS ASSOCIATE A SHORT CERVICAL LENGTH WITH PRETERM BIRTH?

There are three main mechanisms that have been associated with the development of an asymptomatic short CL. First, the most obvious hypothesis is that a short CL is caused by an intrinsic weakness of the cervix, or cervical insufficiency (this term is preferred rather than cervical incompetence).⁵⁶ This cervical insufficiency is due in most cases to traumatic or surgical damage, or much more rarely, a congenital disorder or a connective tissue disease. It is interesting to note that almost no women, even the most high-risk, have a short CL in the first trimester.³⁴ This is probably because the pressure the growing gestational sac exerts on the cervix will be unlikely to open up even the weakest of cervixes. Second, another hypothesis is that a short CL is due to an inflammatory or infectious process. There is a strong association between a short CL on TVU and infection. High amniotic fluid Interleukin-6 (IL-6), later development of chorioamnionitis,⁵⁷ and acute inflammatory lesions of the placenta⁵⁸ have all been associated with a short CL on TVU. Women with both a short CL and bacterial vaginosis have a higher incidence of PTB than matched women with just a short CL but no bacterial vaginosis.⁵⁹ A short CL leading to PTB is often associated with PPROM instead of PTL, providing

FIGURE 18-19. A multiplanar image of the cervix with minimal funneling (*yellow trace*) in the sagittal plane (*A*). In the axial plane (*B*) and the coronal plane (*C*), the funnel length and width are both seen significantly larger as compared with the sagittal plane.

FIGURE 18-20. A composite image of a cervix with funnel shown in a multiplanar display (*A, B, C*) and in "Niche" mode (*D*) that shows all three planes intersecting with each other to create a three-dimensional relationship between the planes.

FIGURE 18-21. The three-dimensional ultrasound-derived coronal planes of six different cervixes depicting the cervical canal shape. Note the different shapes of each of these cervixes in the coronal plane.

FIGURE 18-22. A multiplanar display of the cervix (*A* is sagittal, *B* is axial, and *C* is coronal) with a significant funnel with "sludge" in it seen in *A* and *C*. Note that the "sludge" is better visualized in the coronal plane (*C*). Also, note that coronal plane of the funnel is more than twice as wide as is the height of the funnel.

FIGURE 18-23. A relatively new way of presenting volume ultrasound data in a “CT and MRI like” display. The three-dimensional ultrasound volume of the cervix is shown here in multiple images of the cervix within the volume in the sagittal plane (the operator may select coronal and axial planes too) precisely 0.5 mm apart from each other. This display appears to be useful especially to understand volume ultrasound imaging of the cervix and better identify the image that represents the adequate plane to measure the cervical canal.

additional evidence for the role of infection in these women.⁴⁵ There is insufficient evidence thus far to discern if the infection causes the development of the short CL, or the association between infection and short CL occurs because the short CL allows ascending infection from the vagina. A short CL can provide easier access of potentially pathologic vaginal organisms into the intrauterine environment, leading to prolonged subclinical chorioamnionitis and subsequent PTB. Women with a normal CL have mechanical and immunologic protection against the ascent of lower vaginal organisms.

Third, recent studies have shown that the majority of asymptomatic women with CL less than 25 mm before 24 weeks have some contractions, more than controls with a normal cervix.^{60,61} It is unclear whether contractions cause the short CL, are a result of the short cervix, or whether these two factors work synergistically.

Most probably, these three, as well as other mechanisms, often act synergistically in certain women to contribute, in each individual in different ways, to the development of a short CL.

INTERVENTIONS FOR PREVENTING PRETERM BIRTH IF A SHORT CERVICAL LENGTH IS IDENTIFIED IN ASYMPTOMATIC WOMEN

Many investigators believe the high negative predictive value of TVU of the cervix is important because women with a normal CL can be reassured and interventions avoided. However, a high negative predictive value alone is not sufficient to validate that screening is beneficial. For TVU to be judged cost-effective, there must be an effective intervention to prevent PTB if the test is positive.

Ultrasound-Indicated Cerclage

Because cervical insufficiency is one of the leading hypotheses for short CL, cervical cerclage has been the first intervention postulated to be beneficial in this clinical situation. Randomized studies on history-indicated (previously called prophylactic, or elective) cerclage without the use of TVU have shown that this procedure does not prevent PTB in

FIGURE 18-24. A, B, C. A four-dimensional multiplanar image of the cervix with a vaginal cerclage with funneling present before fundal pressure. D. The coronal plane of the funnel after 15 seconds of fundal pressure. Note that the funnel width is widened in the coronal plane after the fundal pressure, something that we simply cannot observe with two-dimensional ultrasound.

FIGURE 18-25. Virtual contrast imaging (VCI) of the cervix otherwise known as thin volume imaging. On the left (A), there is a two-dimensional ultrasound image of the cervix displayed simultaneously with a VCI derived image of the cervix in the coronal plane (B). This dual view enables the operator to evaluate the cervix real time not only in the sagittal plane but also in the true coronal plane by properly placing the dotted green line in the preferred plane in the two-dimensional image, as seen on the left.

high-risk singleton gestations,^{62,63} except for the subgroup of women with three or more prior second trimester losses or PTBs,⁶⁴ and it is also not beneficial in twin gestations.⁶⁵ Given these disappointing results, researchers have hypothesized that a subgroup of women in whom a cerclage may be beneficial could be identified with TVU of the cervix. For asymptomatic women with a short CL, in fact the only intervention studied so far by randomized trials has been cervical cerclage. Cerclage was indeed devised more than 50 years ago for women with both a poor obstetric history

characterized by second trimester losses, and cervical changes in the current pregnancy.^{66,67} The four randomized trials⁶⁸⁻⁷¹ on the efficacy of ultrasound-indicated cerclage have been analyzed in a meta-analysis,⁷² which allowed not only larger numbers and more robust statistics but also careful analysis of different populations of women with a short CL. In fact, ultrasound-indicated cerclage has different effects in different populations (Table 18-3).^{72,73} In women with a singleton gestation and a prior PTB or a second trimester loss, performing a cerclage if the TVU CL becomes

Table 18-3 Efficacy of Ultrasound-Indicated Cerclage^{72,73}

Population	Effect of Cerclage on PTB <35 Weeks
Singleton gestations	
Low-risk for PTB (no other risk factor)	24% decrease (nonsignificant)
Prior PTB 16-36 weeks	39% decrease (significant)
Prior second trimester loss	43% decrease (significant)
Twin gestations	215% increase (significant)

PTB, preterm birth.

less than 25 mm prior to 24 weeks prevents recurrent PTB. In women with a singleton gestation and either no risk factors, ultrasound-indicated cerclage was neither beneficial nor detrimental, with more studies needed to assess its efficacy. In women with twin gestations, ultrasound-indicated cerclage was detrimental. This last finding is not surprising, given the fact that TVU is not a good screening method for PTB in this population, who probably has PTB because of contractions and not a weak cervix.⁷⁴ Interestingly, cerclage for a short CL is efficacious both before and after 20 weeks, and both at the 25 and 15 mm cutoffs. Interestingly, the placement of a reinforcement (also called rescue) cerclage once a first cerclage seems to be failing is not associated with benefit, and this procedure should be avoided.⁷⁵

Indomethacin

The only randomized trial⁶⁹ that showed benefit from cerclage also gave indomethacin to these women, and not to the controls, raising the possibility that indomethacin may have contributed significantly to the prevention of PTB in that study. Analysis of the effect of indomethacin indeed reveals that it can prevent PTB less than 24 weeks and PPROM in women with a short CL.⁷⁶ Given that women with a short CL are often found to be having contractions,^{60,61} it is possible that one of the most efficacious interventions is tocolytic therapy.

Antibiotics

A short CL has also been associated with infection. Analysis of the effect of antibiotics reveals no effect of this therapy on prevention of PTB in women with a short CL.⁷⁷ Unfortunately antibiotics have often failed to prevent PTB when used for other risk factors for PTB, such as just a prior PTB,⁷⁸ positive fetal fibronectin,⁷⁹ or symptomatic PTL.⁸⁰ Other interventions such as bed rest, progesterone therapy, and others have not yet been adequately studied.

ANOTHER BENEFIT OF TRANSVAGINAL ULTRASOUND SCREENING IN ASYMPTOMATIC WOMEN: AVOIDING CERCLAGE IF EXAMINATION IS NORMAL

There are at least two major benefits to TVU screening. First, it identifies women who may benefit from cerclage (i.e., women with a prior PTB or second trimester loss who develop a short CL in the subsequent pregnancy at 14 to 24 weeks). Second, it can be used to avoid performing unneeded

interventions (e.g., cerclage) in women whose TVU CL remains normal. One randomized study⁸¹ and three non-randomized studies⁸²⁻⁸⁴ have evaluated whether women with suspected cervical insufficiency can be safely followed with TVU, with placement of a cerclage only in those who develop a short CL, compared with universal history-indicated cerclage. At least 60% of these high-risk women maintain a normal CL until after 24 weeks and deliver at term, and can be spared any intervention. Only about 40% develop a short CL and are at true risk of PTB, and can be offered intervention. Management of women with risk factors for PTB with serial TVU of the cervix appears to be a safe alternative to traditional history-indicated cerclage, but this finding should be confirmed by larger randomized trials.

DIAGNOSIS AND MANAGEMENT OF WOMEN WITH SUSPECTED PRETERM LABOR

TVU of the cervix has been studied extensively as a predictor of PTB in women with symptoms of PTL (see Table 18-2). All studies have reported a statistically significant positive predictive accuracy of TVU CL for PTB.⁸⁵ The presence of sludge (see Fig. 18-22) in women with suspected PTL is associated with intramniotic infection and high risk for PTB.²⁹ TVU CL is indeed very helpful clinically in the management of women with suspected PTL. First, it helps in the diagnosis. The diagnosis of PTL was usually made between 20 and 36 weeks by regular contractions and documented cervical change by manual examination. Indeed, more than 70% of women with the diagnosis of PTL deliver at term, and would receive unnecessary interventions. Women with these findings but a TVU CL of ≥ 30 mm and negative fetal fibronectin, have less than a 1% chance of delivering within 1 week, and less than 10% chance of delivering before 35 weeks, and should not receive steroids for fetal maturity, tocolysis, or other interventions. The diagnosis of PTL should be confirmed by a TVU CL less than 20 mm and a positive fetal fibronectin, and only these women should receive interventions.⁸⁵ A randomized trial in our center is currently evaluating the benefit of such approach. Previously, a decrease in incidence of birth weight less than 2500 g was reported when TVU of the cervix was used to triage patients to bed rest and tocolysis only if the TVU CL was less than 30 mm compared with historic controls.⁸⁶ Using TVU in symptomatic women with suspected PTL for management has been shown to decrease the incidence of hospitalization and costs, but did not decrease PTB.^{87,88} The shorter the CL is in women with PTL, the higher is the risk of intra-

amniotic infection, and this is also related to gestational age at presentation.⁸⁹ Women in PTL with a CL less than 10 mm at less than 28 weeks have a $\geq 25\%$ incidence of intra-amniotic infection.

The possible utility of repeat measurement of CL after tocolysis for PTL predicts PTB, but not any better than the first measurement at presentation. The variation in CL between first and repeat CL seems not to be predictive of PTB, so that "to repeat ultrasonographic CL measurement after successful tocolysis [may be] useless."⁹⁰

PREDICTING THE LATENCY IN PRETERM PREMATURE RUPTURE OF THE MEMBRANES

Several studies have evaluated the utility of TVU of the cervix in women with PPROM. A randomized trial demonstrated the safety of performing TVU in this group, because women who had TVU had similar incidences of maternal and neonatal infections as controls who did not undergo TVU.⁹ The latency to delivery is directly correlated with CL, with women with shorter CLs having the shorter latencies.^{91,92} There are no studies to assess if this clinical knowledge affects outcomes.

PREDICTION OF START OF SPONTANEOUS LABOR

TVU of the cervix can be useful in predicting the onset of labor in term women.^{93,94} When the TVU CL is measured at 37 weeks, the mean of gestational age at delivery increased from 38 weeks for women with a CL of 10 mm to 41 weeks for women with a CL of 35 mm, with a 68% chance of delivering after 41 3/7 weeks if CL is greater than 40 mm (Fig. 18-26).⁹⁴

PREDICTING THE SUCCESS OF LABOR INDUCTION AND MODE OF DELIVERY

Several studies have evaluated the predictive accuracy of TVU of the cervix in term gravidas for length of induction and incidence of success (vaginal delivery). Short CL (<30 mm,⁹⁵ <28 mm,⁹⁶ <26 mm,⁹⁷ or wedging⁹⁸) is associated with a short duration of labor and a higher incidence of vaginal delivery compared with a longer cervix. Although some studies did not find that TVU of the cervix added significantly to the prediction obtained by dilatation of the cervix on manual examination,^{99,100} most did find that TVU CL was a better predictor than any Bishop score parameter.⁹⁴⁻⁹⁷ A recent randomized trial showed that the use of TVU CL instead of Bishop score for management of induction is associated with a decreased need for intracervical prostaglandin treatment without adverse effects on the success of the induction.¹⁰¹ Additionally, women in spontaneous labor with a TVU of less than 20 mm have just a 4% incidence of cesarean delivery, whereas women with a TVU CL greater than 40 mm have a 12% chance of cesarean delivery.⁹¹

CONCLUSIONS

TVU for cervical assessment is one of the best techniques for predicting PTB. The use of TVU of the cervix has been

FIGURE 18-26. Survival curve estimates of percentages of women not delivered at different gestational ages, according to sonographically measured cervical length at 37 weeks. (Redrawn with permission from Ramanathan G, Yu C, Osei E, et al: *Ultrasound examination at 37 weeks' gestation in the prediction of pregnancy outcome: the value of cervical assessment. Ultrasound Obstet Gynecol* 22:598, 2003.)

found to be safe and acceptable to patients. A CL of less than 25 mm between 16 and 24 weeks has been shown to be the most reliable threshold for an increased risk of PTB. The shorter the cervix, the higher is the risk of PTB, and the earlier in gestational age the shortening occurs, the higher is the risk. The role of TVU of the cervix has been studied in a wide variety of settings and with different patient populations, always showing good prediction of PTB. Screening frequency should depend on severity of obstetric history, with serial TVUs of the cervix having a better predictive accuracy than a single evaluation, especially in high-risk populations. Women with a prior PTB or a second trimester loss who then develop a TVU CL less than 25 mm at 16 to 23 6/7 weeks while carrying a singleton gestation may benefit from ultrasound-indicated cerclage. There is accumulating evidence that this technique can be used to safely avoid cerclage placement unless or until cervical change occurs, but this management also needs to be confirmed by appropriate prospective trials. There are still limited data concerning whether TVU of the cervix is clinically useful in caring for women being evaluated for PTL or who experience PPROM, or for prediction of success of labor induction. Future research on all these clinical applications of TVU of the cervix has the potential to significantly improve the health outcomes of pregnant women and their babies.

PLACENTA

The placenta is a fascinating but often ignored organ that provides primary support for the developing fetus. In *The Diseases and Deformities of the Foetus* (1892), JW Ballantyne wrote

*A diseased foetus without its placenta is an imperfect specimen, and a description of a foetal malady, unless accompanied by a notice of the placental condition, is incomplete. Deductions drawn from such a case cannot be considered as conclusive, for in the missing placenta or cord may have existed the cause of the disease and death. During intrauterine life the foetus, the membranes, the cord and the placenta form an organic whole, and disease of any part must react upon and affect the others.*²¹

The same could be said in reference to sonography and the value of sonographic assessment of the placenta. Those who perform obstetric ultrasound (US) are encouraged to study this interesting, crucial structure because significant placental pathology may be found, often before the fetus is affected. Recognition of frequent anatomic variants and clinically important lesions of the placenta is highly valuable for optimal performance and interpretation of prenatal US.

This chapter reviews normal placental and umbilical cord development and anatomy, and presents common abnormalities of the placenta (including maternal and fetal processes) and cord, as shown by US, highlighted with pathologic correlation.

Normal Development and Anatomy

The recently released ovum is normally fertilized in the fallopian tube and reaches the uterine cavity as the morula, which rapidly evolves into the blastocyst. The blastocyst, in turn, attaches to and implants in the endometrium on day 5 to 6 after fertilization.² The outer cell layer of the blastocyst, which will become the placenta, transforms to the trophoblastic cell mass that intermixes with endometrial cells (10th postovulatory day). The trophoblast shortly thereafter differentiates into the cytotrophoblast and syncytiotrophoblast. The latter cells erode into the endometrial glands and blood vessels.

Between 10 to 13 days after ovulation, lacunae or clefts appear among the rapidly proliferating trophoblastic cell mass. These spaces form the intervillous space, the wide channels where the transfer of gases and nutrients occurs between maternal and fetal circulations (Fig. 19-1). Early on, this proliferation of villi is characterized by a hyperechoic appearance on US, although a definitive placenta is only well seen after 10 to 12 weeks. Villi form from mesenchyme, and blood vessels that sprout into the primary villous stems, which then branch into secondary and tertiary villi. Around 8 weeks' gestation, the villi oriented toward the endometrium (now called the decidua) continue to divide and grow as the chorion frondosum. The villi toward the endometrial cavity atrophy and form a smooth surface, the chorion laeve. The chorion normally apposes with the amnion at approximately 12 to 16 weeks.

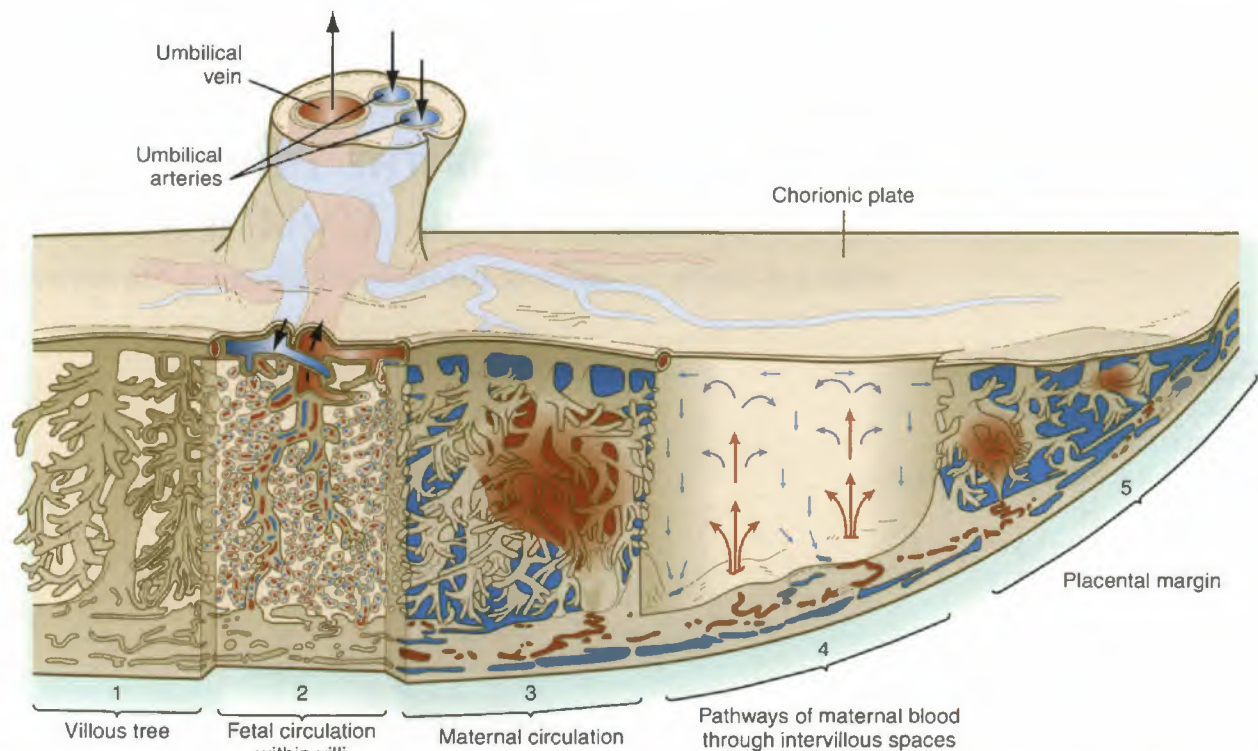

FIGURE 19-1. Schematic representation of placental structure delineating intervillous spaces, sites of exchange between maternal, and fetal circulations. (From Carlson BM (ed): *Human Embryology and Developmental Biology*. Philadelphia, Elsevier Ltd., 2004.)

True maternal blood flow is not established until 12 weeks of gestation; before then plasma (not blood) flow occurs in the intervillous space.^{2,3} Uteroplacental circulation occurs when uterine spiral arterioles, dislodging the trophoblastic plugs, are transformed into flaccid, dilated uteroplacental arterioles, creating low-pressure, low-impedance blood flow to the intervillous space, thereby establishing an adequate reservoir of oxygen and nutrients for support of the early fetus. Investigators have described normal and abnormal early placental/villous circulation at 8 to 12 weeks.⁴ Overall, there is a decrease in resistance to blood flow in the uterine circulation from early gestation to term in normal pregnancies.⁵

Sonographic evaluation of the placenta begins with localization. At US, the placenta may be visible as early as 10 weeks as a thickening of the hyperechoic rim of tissue around the gestational sac (Fig. 19-2). At 12 to 13 weeks, intervillous blood flow is easily demonstrable by color or power Doppler sonography. By 14 to 15 weeks, the placenta is well established and a prominent hypoechoic area, the retroplacental complex, composed of the decidua, myometrium, and uterine vessels, may be readily visualized (Fig. 19-3). At 16 to 18 weeks, small intraplacental arteries may be demonstrated with color or power Doppler US at low-flow settings. The third trimester placenta is a very vascular organ, and both retroplacental and intraplacental arteries are widely distributed and discernible at color or power Doppler imaging.

FIGURE 19-2. Transvaginal sonogram of first trimester pregnancy. At this stage, the placenta (PI) is recognized as focal thickening of hyperechoic tissue adjacent to the gestation sac.

Placental Size/Shape

US can be used to assess placental size, thickness, and echotexture. Because the placenta is primarily a fetal organ, its size is often a reflection of the health and size of the fetus. The normal term placenta measures 15 to 20 cm in diameter

FIGURE 19-3. Retroplacental complex, which includes prominent vessels (arrows) and is relatively hypoechoic compared with adjacent placenta (PI), is demonstrated on this transabdominal ultrasound view.

with a volume of 400 to 600 mL.² Although there is a broad range, normal placental thickness is approximately 1 mm per week of gestation.^{6,7} As a general rule, the placenta should be approximately equal in thickness (in millimeters) to the gestational age in weeks, \pm 10 mm. The term placenta should generally not be thicker than 45 mm, although some exceptions occur.⁶ Placental volume in the second trimester has been reported to be a predictor of abnormal fetal outcome, but the method of measurement is complex and not widely adopted.⁸⁻¹¹ A thin placenta may be a marker for a small-for-dates fetus or a sign of growth restriction. Marked polyhydramnios may cause thinning of the placenta (Fig. 19-4). In the presence of marked polyhydramnios, a normal size placenta may in fact be abnormally thickened.

Placentomegaly has many causes. A small area of attachment to the uterus may cause artifactual thickening of the placenta, but careful and complete scanning of the maternal surface and insertion site can make this apparent (Fig. 19-5). The causes of a truly thick placenta may generally be divided into two categories, based on sonographic morphology: homogeneous and heterogeneous echotexture. Common causes of homogeneous thickening are diabetes mellitus (DM; typically gestational-onset DM), anemia, hydrops, infection (villitis) and, rarely, aneuploidy (Fig. 19-6A and B). If multiple small cystic spaces are seen within a thickened placenta, the differential diagnosis would include: triploidy, placental hemorrhage, villitis, mesenchymal dysplasia,¹² and Beckwith-Wiedemann syndrome (Figs. 19-7 and 19-8).¹³ Heterogeneous thickening may be seen with intraplacental hemorrhage, which is further discussed in a later section.

Circumvallate Placenta and Succenturiate Lobe

Circumvallate placenta is an abnormality of placental shape whereby the membranes insert inward from the edge, toward the center of the placenta. The placenta is termed circummarginate if the fetal membrane insertion is flat. More often,

FIGURE 19-4. The anterior placenta (PI) is relatively thin in this third trimester pregnancy complicated by hydrops fetalis with polyhydramnios (amniotic fluid pocket measured by electronic calipers) and fetal pleural effusion.

FIGURE 19-5. Apparently thick placenta (PI) due to short site of attachment to uterus.

the transition where the fetal vessels of the chorionic plate terminate has a raised or rolled edge, termed circumvallate.^{13,14} Circumvallate placenta is characterized by thickened, rolled chorioamniotic membranes peripherally. This condition may be complete (involving 100%) or partial, when only a portion of the placental circumference is involved. In general,

FIGURE 19-6. A and B. Two sonograms of a homogenous thick placenta seen in a second trimester pregnancy complicated by hydrops. Note the smooth and homogeneous echotexture of the placenta.

circummarginate or partial circumvallate placentas are of no clinical (obstetric or fetal) significance. However, complete circumvallation has been associated with an increased risk of bleeding, low birth weight/intrauterine growth restriction (IUGR), oligohydramnios, preterm labor/delivery, placental abruption, and perinatal mortality. On US, an irregular placental edge with a heaped up appearance may be noted (Fig. 19-9).^{15,16} The thickened ridge of peripheral tissue, often found at pathologic inspection to be accompanied by chronic placental hemorrhage or infarction, merits consideration because of its unusual but fairly characteristic sonographic appearance (Fig. 19-10A and B). Of note, the classic US feature of a rolled-up placental edge can appear on some views as a linear structure protruding into the fluid-filled amniotic cavity, and thus can potentially be misinterpreted as a uterine synechia (Figs. 19-11A and B, and 19-12).¹⁷ It is possible to assess the degree of circumvallation sonographically by evaluating the entire placental edge over 360 degrees, with the transducer oriented radially to the placenta.

FIGURE 19-7. Thick heterogeneous placenta with small cystic areas demonstrated in a case of mesenchymal dysplasia.

FIGURE 19-8. Thick placenta with multiple cystic lesions shown by ultrasound. Images of the fetus revealed visceromegaly and macroglossia, with proven Beckwith-Wiedemann syndrome.

Succenturiate (or accessory) lobe of the placenta occurs in approximately 5% of pregnancies.¹⁴ This is recognized on US as a distinct, apparently separate mass of placental tissue, without recognizable bridging tissue.¹⁸ In these cases, there is a higher incidence of placental infarction and velamentous insertion of the umbilical cord. The most serious potential complication associated with this condition is when umbilical vessels supplying the succenturiate lobe cross the internal cervical os (vasa previa), to be covered in greater detail in a later section.

B

FIGURE 19-9. Characteristic appearance on ultrasound of circumvallate placenta. *A.* Curled peripheral edges (*arrows*) are seen in this anterior placenta. *B.* Curled peripheral edges (*arrows*) are shown in this pregnancy at 15 weeks' gestation. Note that at this stage, the amnion is not yet apposed to the chorion.

A

B

FIGURE 19-10. *A* and *B.* Two views of a complete circumvallate placenta in the second trimester with thick, curled peripheral ridge. This should not be confused with a uterine synechia.

Placental Calcifications

It is known that the placenta can mature and calcify (recognized as the sonographic sign of aging) at a fairly reproducible rate. A sonographic classification system for grading placentas in utero according to maturational changes was developed by Grannum et al.¹⁹ Extensive research attempted to correlate the placental maturity assessed by US with lung maturity in the 1970s and early 1980s.²⁰ Although early investigations were promising, it was later demonstrated that the US findings of placental maturation do not reliably predict fetal lung maturity. As a result, placental grading, which was in vogue for a time, is now rarely pursued because it is of little clinical value. Premature or accelerated placental calcification has been associated with several factors including chronic maternal hypertension, preeclampsia, IUGR, and maternal cigarette smoking (Fig. 19-13*A* and *B*).²¹

Focal Cystic/Hypoechoic Lesions

Cystic or hypoechoic lesions are frequent placental abnormalities, commonly noted after 25 weeks' gestation. Although they may represent a variety of entities, small hypoechoic areas are often of no clinical significance (Fig. 19-14). They are more concerning if they are seen early in gestation, are numerous or large.²² Although they represent a variety of pathologic entities, common etiologies for hypoechoic placental lesions include: intervillous thrombus, and decidual septal cysts. Intervillous thrombi (IVT) are usually 1 to 2 cm in diameter and consist of coagulated maternal blood in the intervillous space, often surrounded by compressed or infarcted villi (Fig. 19-15). They are very common, with reported incidence of 30% to 40%.²³ At times, IVT may appear as larger sonolucent lesions, which can cause some confusion and concern.

FIGURE 19-11. A. Linear structure shown protruding into fluid filled cavity (*arrow*) may be confused for other processes such as a uterine synechiae or amniotic band. B. An additional ultrasound view, perpendicular to the first, confirms that this represents the curled placental edge (*arrow*) of a circumvallate placenta.

Decidual septal cysts are usually less than 3 cm in diameter, with reported incidence of 20%. They usually occur near the subchorionic zone and result from degeneration of decidual cells within septa that extend from the decidual floor and support the placenta, resulting in cavities filled with homogeneous fibrinous fluid. Hemorrhage into the cavity may resemble IVT, and it is often difficult to distinguish these entities with US. Correct determination can be made at pathologic examination (Fig. 19-16).

Hypoechoic placental lesions may result from perivillous fibrin deposition, typically located at the periphery of the placenta, with macroscopically visible plaques occurring in 20% to 25% of uncomplicated pregnancies. Subchorionic fibrin deposition results in triangular or rectangular areas of

FIGURE 19-12. Gross pathologic specimen, viewed from the fetal surface, of a circumvallate placenta at term, with evidence of chronic hemorrhage peripherally.

fibrin deposited under the fetal surface of the placenta, with the base of the triangle along the chorion. At pathology, they are noted in approximately 20% of placentas. It has been observed that most placental surface cysts detected on sonography are related to cystic change in an area of subchorionic fibrin.²⁴ These entities are usually of no clinical significance because they are typically associated with normal pregnancy outcomes, and have no distinguishing sonographic appearance other than their characteristic locations.

The processes described likely account for the commonly reported sonographic finding of placental or venous lakes that appear as sonolucent intraplacental spaces. On US, swirling internal echoes can sometimes be observed and their shape may be modified with change in maternal position or uterine contractions.²⁵ Such hypoechoic cystic placental lesions, sometimes referred to as placental lakes, have variably been reported in association with maternal-fetal Rh incompatibility, elevated maternal serum alpha-fetoprotein levels, and edematous placentas (Fig. 19-17). They do not, however, appear to be of clinical concern because they have no proven effect on placental function or fetal health. Investigations into the clinical significance of these findings at routine obstetric US have revealed no associated risk of pregnancy complication or poor outcome.²⁶ In a report of placental lakes seen on US between 15 and 34 weeks' gestation in low-risk pregnancies, no significant difference in birth weight, gestational age at delivery, or adverse obstetric outcome was observed.²⁷

Vascular Abnormalities

Placental infarction is a localized area of ischemic villous necrosis, resulting from interruption in maternal blood supply, more common at the periphery of the placenta. Most are roughly triangular in appearance at pathology, with the base of the triangle along the basal plate (Fig. 19-18). These have been associated with post-term pregnancies, maternal hypertension, and anticardiolipin antibodies. Most are due to thrombotic occlusion of an uteroplacental artery, less often from retroplacental hematoma stripping the placenta

FIGURE 19-15. Transabdominal ultrasound image of an anterior placenta with hypoechoic lesions, which are nonspecific based on sonographic appearance and later proven to represent intervillous thrombi.

FIGURE 19-16. Gross pathologic specimen of a term placenta revealing a focus of coagulated blood within the intervillous space, called an intervillous thrombus.

away from its blood supply. Most placental infarction is not readily detectable by US because it is isoechoic with adjacent placental tissue,²⁸ unless there is associated hemorrhage in which case, the chronicity of the bleed will influence the echogenicity. In rare instances, acute placental infarction may be visible as a slightly hyperechoic region. Fortunately, most infarctions are small, affect less than 5% of the placenta, and are not clinically significant. When infarction occurs early, centrally or extensively (greater than 30% involvement of the placenta), it is strongly associated with pregnancy-induced hypertension, IUGR, preterm delivery and even fetal death.^{14,22} Power Doppler US is being investigated as a means to detect areas of placental ischemia or infarction manifest as areas of diminished blood flow.

A separate and distinct process, which is of clinical consequence and has been diagnosed by prenatal US is *maternal floor infarction*. This rare but important, clinically relevant condition is worth understanding and recognizing

FIGURE 19-17. Focal hypoechoic cystic placental lesion. No other placental lesion or fetal abnormality seen in this pregnancy with a history of elevated maternal serum alpha-fetoprotein and normal outcome.

FIGURE 19-19. Gross pathologic placental specimen, viewed from the maternal surface, revealing maternal floor infarction with yellowish material representing excess fibrin deposition.

FIGURE 19-18. Serial sections from a gross pathologic specimen of a term placenta with multiple small sites of infarction.

because it is associated with significant fetal risk and has been reported to recur in subsequent pregnancies. This type of infarction is characterized histologically by massive deposition of fibrin in the basal plate of the placenta, encasing the villi which become avascular and necrotic (Fig. 19-19). The resulting impaired perfusion of the intervillous space by maternal blood is associated with a high incidence of fetal morbidity and mortality. In one series, fetal death occurred in 40% of cases, preterm birth in 60%, and IUGR in 54% of live births.²⁹ This condition has been diagnosed by prenatal US with hyperechoic areas corresponding to infarction, predominantly along the maternal surface, but extending through much of the placental tissue (Fig. 19-20*A* and *B*). Interspersed hypoechoic areas of varying dimensions and marked placental thickening have been

noted as well (Fig. 19-21*A* and *B*).³⁰ One hallmark on sonography is the typical basal location near the decidua (maternal surface), which is relatively unique to maternal floor infarction.

Fetal artery thrombosis results in a triangular region of injury, with the base of the triangle fused with the basal plate of placenta, as seen at gross pathology. The reported incidence is 5% in normal placentas, increased in cases of maternal DM. There is an association with maternal coagulation disorders, and they may serve as a marker for thrombosis elsewhere in the fetal vascular system. However, these lesions are not detectable by prenatal US.

Hematomas

It is helpful to consider the location, etiology, sonographic appearance, and clinical impact when confronting blood collections related to the placenta (Fig. 19-22). Massive subchorionic thrombosis results from a large thrombus that strips the chorion away from villous tissue. This may result in a bulging protuberance that elevates and distorts the fetal surface of the placenta, sometimes referred to as a Breus mole (an unfortunate misnomer because this entity bears no relationship to a molar pregnancy or gestational trophoblastic disease). It is quite rare, with reported incidence of 0.05%. Its significance is controversial. In some cases, it may be associated with preterm delivery and spontaneous abortion, possibly due to venous compromise in the uteroplacental circulation.³¹ Sonographically, it appears as a hypoechoic or cystic area along the fetal surface of the placenta³² (Figs. 19-23*A* and *B*, and 19-24).

Subchorionic or marginal hematoma is a hematoma at the lateral margin of the placenta and has an incidence of 2% (Fig. 19-25). It occurs most often with placental implantation in the inferior uterus or lower uterine segment (LUS) and probably arises from rupture of uteroplacental veins. They can be associated with miscarriage and preterm labor but are generally of little significance. Rarely, prepla-

FIGURE 19-20. A. Transabdominal sonogram of an abnormally thick, heterogeneous placenta. B. Same patient demonstrated altered perfusion shown by color Doppler ultrasound. This was seen in association with intrauterine growth restriction and oligohydramnios. Maternal floor infarction was confirmed by pathologic inspection of the placenta postpartum.

central or subamniotic hematomas may be seen, although even large hematomas in this location tend to be of little consequence to the fetus. However, some data suggest that this lesion may be of significance in causing fetal growth restriction and fetomaternal hemorrhage in some cases.³³

Retroplacental hematomas, which can manifest as the clinical condition of placental abruption, are of greatest clinical consequence. They are likely due to rupture of a decidual arteriole with bleeding separating the basal plate of the placenta from the uterine wall. The reported incidence at pathology is 5% with threefold increased risk in patients with preeclampsia. This lesion often leads to basal plate necrosis and villous infarction. The reported associations

FIGURE 19-21. A and B. Another example of pathologically proven maternal floor infarction shown on grayscale and power Doppler ultrasound.

include maternal hypertension/preeclampsia, obstruction of venous drainage of the placenta, cocaine abuse, cigarette smoking, anticardiolipin antibodies, blunt trauma, and chorioamnionitis. The clinical significance of such bleeds is related to the gestational age at onset and to their size: as expected, smaller hematomas have a larger impact on early

FIGURE 19-23. A. (less than 20 wk) gestations, whereas large hematomas, which may cause significant infarction of villi, must strip more than 30% to 40% of placenta away from myometrium to have clinical implications.

When imaging the placenta, the retroplacental hypoechoic complex, composed of uteroplacental vessels (predominantly veins) and myometrium and measuring 1 to 2 cm in thickness (see Fig. 19-3), should be observed. When this region appears thicker, the possibility of retroplacental hemorrhage, focal myometrial contraction, or leiomyoma should be considered. Focal contractions are transient, typically changing in appearance during the examination and myomas are usually distinguishable by their round shape, attenuation and

FIGURE 19-25. Hypoechoic collection deep to the lateral margin of the placenta, representing a subchorionic, or marginal hematoma (arrow) shown by ultrasound.

internal vascularity on Doppler interrogation, not present within hematomas.

Placental Abruptio

Placental abruptio is characterized by spontaneous hemorrhage behind or within the placenta with premature separation of the normally implanted placenta from the uterus. The clinical condition (abruption) and the pathologic condition (hematoma) both refer to the abnormal accumulation of maternal blood within or beneath the placenta or membranes.^{34,35} The incidence of placental abruptio is 0.5% to 1%.^{36,37} It is one of the leading causes of perinatal mortality, accounting for 15% to 20% of all perinatal deaths.³⁸ If the bleeding is extensive, maternal cardiovascular shock and disseminated intravascular coagulopathy may develop. Associated maternal conditions linked with abruptio are hypertension, preeclampsia, abdominal trauma (especially

FIGURE 19-26. Hypoechoic collection (between calipers) deep to the placenta, near its lateral margin toward the maternal surface. This small retroplacental hematoma was of no clinical consequence.

anterior placentas), cocaine abuse, cigarette smoking (twofold increase), alcohol use and advanced maternal age.³⁹⁻⁴¹

Occasionally, retroplacental or intraplacental hematomas are small and clinically silent (Fig. 19-26). Large hematomas are typically apparent and present clinically with classic features of sudden abdominal pain/cramping, vaginal bleeding, uterine tenderness and often with onset of labor. However, this reported classic presentation occurs in a minority of cases. It is important to remember that not all cases of abruption are identifiable as hemorrhage on US. The sensitivity of US in visualizing hemorrhage is reported to be approximately 50%, but the lack of a gold standard [pathology] limits this evaluation.⁴² In one series, retroplacental blood clot was seen by US in only 15% of the cases.⁴¹ Sonography of abruption may be relatively normal, non-contributory and potentially misleading because US may not be reflective of the gravity of the clinical situation. Given that US cannot always reliably identify this condition, particularly in the emergent setting, it may be ill-advised to perform a US examination and potentially delay management when there is a high clinical suspicion of placental abruption and urgent intervention is indicated.

Still, sonography, given its wide and quick availability, is the only reasonably accurate and practical method of evaluating placental abruption, when clinical circumstances allow.^{43,44} Rarely, magnetic resonance imaging (MRI) may be used to show hemorrhage, particularly in cases of chronic abruption, but the expense and limited availability preclude its frequent use. If abnormal, US may show a hypoechoic, subchorionic thickened area at the margin of the placenta.⁴⁵ Doppler US can be useful in distinguishing acute hematoma from hypoechoic retroplacental uterine veins.

The most common site of separation is at the edge of the placenta, sometimes referred to as a marginal abruption or marginal hematoma, often with centrifugal extension away

FIGURE 19-27. Large retroplacental hematoma (arrows) shown by ultrasound with significant elevation and detachment of the posterior placenta from the uterine wall in a patient who presented with clinical features typical of abruption.

from the placenta. Rarely, this subchorionic hemorrhage may be difficult to differentiate from unapposed chorion and amnion, which may be normal up to 18 weeks of gestational age. The gravest prognosis is for gestations complicated by retroplacental hemorrhage, in which a significant (>30%–40%) placental detachment from the myometrium not uncommonly results in IUGR or fetal demise.^{22,46}

The extent of placental detachment and the volume (sonographic estimate = $L \times W \times H/2$) and location of the bleed are the best predictors of pregnancy outcome. It seems fairly well documented that if a hemorrhage is visible at sonography, the patient is at higher risk than if no hematoma is seen in patients with vaginal bleeding.⁴⁷ Ball et al found that the presence of a sonographically visible subchorionic hemorrhage increased the risk of placental abruption 11-fold and the risk of miscarriage or stillbirth two- to fourfold.^{48,49} In general, the worst outcomes are seen with retroplacental bleeds, hematomas larger than 50 mL, and greater than 50% placental detachment (Figs. 19-27 and 19-28).⁵⁰⁻⁵²

The sonographic appearance of retroplacental hemorrhage varies, depending on age and location of the bleed. Characteristically, hemorrhage may be acutely (0–48 h) hyperechoic, becoming isoechoic at 3 to 7 days, followed by hypoechoic echotexture at 1 to 2 weeks.⁴⁵ After 2 weeks, portions of the clot may become anechoic. Hematomas also tend to become smaller with age, although the rate of decrease is variable.

Placenta Previa

A frequent US finding is an early diagnosis of placenta previa that appears to move (“migrate”) away from the internal cervical os during the latter half of pregnancy (Fig. 19-29A and B). The term placental migration has been used, but it is somewhat misleading. Rather than moving, it is suggested that the placenta is carried toward the fundus, away from the os because of elongation of the uterus with differential growth primarily in the LUS, as gestation advances. Thus the majority of cases of potential previa

FIGURE 19-28. Gross pathologic specimen from a pregnancy complicated by abruption with large retroplacental hematomas, acute and subacute.

resolve before term (Fig. 19-30*A* and *B*). Although a fairly high incidence of apparent previas has been reported in the second trimester, few true previas persist at term.⁵³⁻⁵⁶

Placenta previa refers to a placenta that overlies or is proximate to the internal cervical os and is the most common cause of bleeding in the third trimester. The incidence of previa at term ranges from 0.5% to 1.0%, with greatly increased frequency in multiparous women, advanced maternal age, previous abortion, and prior cesarean section.^{13,39,57,58} It is theorized that the increased incidence in multiparous women results from the depletion of normal decidua by each subsequent pregnancy, leaving the scantier decidua in the LUS for implantation. And, the higher incidence with prior cesarean sections is attributable to scarring in the LUS that renders its growth/elongation impaired; hence, the placenta is unable to migrate away from the internal os. The rate of migration of the placental edge away from the cervical os, which may occur progressively throughout the third trimester, has been measured and may be useful in predicting the eventual route of delivery.⁵⁹

The terminology used to describe types of placenta previa is often confusing and variably understood (Fig. 19-31). Complete placenta previa, the condition in which a portion of the placenta completely covers the internal os, is straightforward and widely accepted (Fig. 19-32*A* and *B*). The term

FIGURE 19-29. *A.* On initial second trimester sonogram, the posterior placenta overlies the region of the cervix (*arrow*), as seen on transabdominal ultrasound views. *B.* On follow-up third trimester examination, the placenta appears to have "migrated" without residual evidence of previa.

central previa is used when the midportion of the placenta, not just the edge, completely covers the os. Partial previa is used when the placenta partially covers the internal os, a condition that, strictly speaking, can only be applied when the internal os is dilated to some degree. Marginal previa describes placental tissue that reaches the edge, but does not cover the internal os. Confusion arises when describing a placenta shown to encroach upon cervical stroma but not reach or cover the os. Such forms of previa may be difficult to delineate sonographically and to convey with current terminology (Fig. 19-33*A* and *B*). Many investigators have

FIGURE 19-30. A. Transvaginal sonogram in the second trimester shows the inferior placental edge overlying the internal cervical os (arrow). PI, placenta. B. Follow-up transabdominal sonogram with color Doppler in the third trimester of this pregnancy shows resolution without residual evidence of previa. Leading edge of the placenta (arrow).

chosen to use the term incomplete placenta previa and to report the measured distance from the placental edge to the internal os (Fig. 19-34A and B). Low-lying placenta refers to one that extends into the LUS, usually more than 2 cm from the internal os, and does not cover or reach it.

The problem of potential or possible previa is one that has stimulated much investigation. Placenta previa is eminently detectable with US. Complete previa, with placenta completely covering the internal os, is typically readily diagnosed sonographically. It is worth noting that an overly distended maternal bladder or a transient myometrial contraction of the LUS can potentially mimic a true placenta previa (Fig. 19-35A to C).⁶⁰ Awareness of these pitfalls can help avoid false-positive interpretations. The role and reliability of US in assessing previa has been particularly enhanced with the use of translabial and transvaginal techniques.³³ With translabial (also referred to as transperineal) imaging, the patient empties her bladder and assumes the

FIGURE 19-31. Illustration depicting different types of placenta previa. In cases of marginal previa and low-lying placenta, additional information regarding the distance from the leading edge of the placenta to the internal cervical os is often helpful. (Illustration by James A. Cooper, MD, San Diego, CA.)

lithotomy position. The sector transducer, with sterile cover and gel applied, is placed at the vaginal introitus affording a detailed, accurate, quick and well-tolerated view of the cervix to ascertain length and placental location relative to the internal os. The improved spatial and contrast resolution of transvaginal and translabial techniques compared with transabdominal US results from less interposed soft tissue and diminished acoustic attenuation (Fig. 19-36A and B). The safety and effectiveness of these approaches, which are now widely accepted and routinely used to assess the LUS, cervix, and placental location have been demonstrated.^{61,62} Translabial US has been shown to be superior to transabdominal views in both diagnosis and exclusion of previa. In one series comparing translabial US findings with placental location determined at delivery, the sensitivity was 100% and specificity 70% if a distance of less than 2 cm was recorded from placenta to internal os. For a threshold of 1 cm, the sensitivity decreased slightly to 90% but the specificity increased to 95%.⁶³ It should be noted that when performing translabial scanning, shadowing from air within the rectum may obscure the true cervical length.

As mentioned earlier, the majority of placentas located in the LUS in the second trimester are found to not be in the region of the cervix by the time of delivery (Fig. 19-37A and B). Persistence of previa to term can be predicted based on gestational age at US detection of previa and on whether the

A

B

placenta overlaps the internal os in the second trimester and to what extent.⁶⁴ It should be noted that the precise definition of the term overlap used in several reports is unclear. It is likely that the authors refer to the apparent crossing and attachment of the placenta across the cervical os due to a rounded bulging of the placenta near the cervix. If there were true attachment across the cervical os, then focal infarction of the placental edge would be the only likely explanation as to why a placenta previa resolved on

A

B

FIGURE 19-33. Transvaginal sonograms in the second trimester demonstrating different forms of placenta previa. A. The inferior placental edge (PI) is shown to completely cover the internal cervical os (arrow), indicating complete previa. B. In this case, the inferior placental edge (PI) is shown to encroach upon the posterior cervix but not reach or cover the internal cervical os (arrow).

subsequent sonographic scanning. It has been reported that the chance of a previa at term is 5% if the placenta extends more than 15 mm over the internal os at 12 to 16 weeks.⁶⁵ It is worthwhile to consider the corollary of this; 95% of such placentas will resolve without evidence of previa in the third trimester. Other investigators found that when the lower placental edge overlaps the internal cervical os by 23 mm, measured by transvaginal US at 11 to 14 weeks, the probability of placenta previa at term was 8% (sensitivity 83%, specificity 86%).⁶⁶ In another series using transvaginal US at 18 to 23 weeks, if the placental edge extended more than 15 mm over the os, the positive predictive value of previa at delivery was 19% with 100% sensitivity.⁶⁷ The advantage of

FIGURE 19-34. Additional examples of complete and incomplete previa demonstrated by transvaginal ultrasound. *A.* The thin inferior edge of the posterior placenta (PI) reaches and covers the internal os (arrow), extending onto anterior cervical tissue. *B.* In this case, the inferior placental edge (PI) extends onto the cervix posteriorly and is located approximately 1 cm from the internal cervical os (arrow).

determining placental position at 20 to 23 weeks is a lower false-positive rate of predicting previa compared with earlier stages of pregnancy (Fig. 19-38*A* to *C*). An overlap of the os by the placenta at this stage is associated with a high probability of previa at delivery, and in one series, no cases with measured overlap of more than 25 mm at this stage subsequently delivered vaginally.⁶⁸

Studies have also addressed the correlation between placental edge to internal os distance, as seen by transvaginal US in the late third trimester, and the mode of delivery. As expected, the likelihood of vaginal delivery rose significantly as the edge to os distance increased (Fig. 19-39*A* and *B*).⁶⁹

In summary, low-lying, incomplete or potential placenta previas are common in the second trimester, with only a small minority persisting into the late third trimester. If it is uncertain whether a placenta previa truly exists in the

second trimester examination, a translabial or transvaginal examination is suggested. Excluding a placenta previa early in gestation, rather than saying “cannot exclude placenta previa” will save the patient from unnecessary precautions that may be indicated in patients with true placenta previa. In cases in which a placenta previa is still suspected, follow-up third trimester US examinations to include targeted translabial or transvaginal imaging are suggested. These are safe, effective, well-tolerated means to avoid pitfalls, better image the region of the LUS, and are usually diagnostic. Also, in cases of incomplete placenta previa, measurement of the distance from internal cervical os to the placental edge, as seen by US, is a useful adjunct for predicting likelihood of safe vaginal delivery. Finding a placenta 2 cm or less from the internal os near term places the patient at risk and may require cesarean section for delivery.⁷⁰ It should also be remembered that many of these patients may also successfully deliver vaginally, with the fetal head tamponading the leading edge of the placenta at the time of delivery. Performing targeted translabial or transvaginal scans in patients at risk serves to precisely localize the placenta and aids in making the correct diagnosis of previa, which is essential for optimal obstetric management.

Vasa Previa

Vasa previa is a rare but clinically important condition related to placenta previa in which fetal blood vessels are positioned between the presenting fetal part and the cervix. Fetal vessels run through the membranes over the cervix and under the presenting fetal part, unprotected by placenta. The estimated incidence of vasa previa is approximately 1 in 2500 deliveries.⁷¹ Vasa previa occurs in the setting of either velamentous or membranous insertion of the cord (into the membranes rather than the placenta) or when umbilical vessels coursing between the placenta and a succenturiate lobe cross the internal os in the chorionic membranes (Fig. 19-40). The possible consequences of this condition, including hemorrhage and potential fetal exsanguination, are devastating. Reports of prenatal diagnosis of vasa previa by means of US with color Doppler techniques have been published.^{72,73}

The importance and clinical impact of prenatal diagnosis of vasa previa with US is significant.^{74,75} Improved outcomes depend on accurate prenatal diagnosis and delivery by cesarean section before rupture of membranes. In one retrospective study, when vasa previa was not recognized prenatally, it was associated with perinatal mortality of approximately 56%, whereas 97% of fetuses survived when the diagnosis was made prenatally (Fig. 19-41).⁷⁶

On US, vasa previa may appear as linear echolucent structures overlying the cervix, but this is not always appreciated on grayscale images (Fig. 19-42*A* to *C*). The importance of using color or power Doppler US techniques for the prenatal diagnosis of vasa previa has been emphasized.^{77,78} When these Doppler techniques are used, flow can be demonstrated within the vessels overlying the cervix and spectral Doppler may reveal fetal arterial waveforms (Fig. 19-43*A* to *E*). It is important to differentiate true vasa previa from a funic presentation, with umbilical cord positioned in front of the presenting fetal part, near the endocervical os. Funic presentation may temporarily simulate

FIGURE 19-35. Pseudo placenta previa due to transient myometrial contraction at the lower uterine segment (LUS). *A* and *B*. On initial transabdominal ultrasound views, the anterior placenta (PI) appears to completely cover the internal cervical os, suggesting complete previa. *Asterisks*, lower uterine segment contraction. *C*. Additional TA image obtained 15 minutes later, after focal LUS contraction has resolved, shows the normal appearing cervix (between calipers) without evidence of previa.

FIGURE 19-36. A. No evidence of previa was appreciated on this transabdominal (TA) view of the cervix in the third trimester. However, at this stage of gestation and with the fetus in cephalic presentation, the fetal head limits and often obscures the adequate visualization of the relationship of the cervix and placenta. B. Additional targeted transvaginal views were obtained revealing the presence of a complete previa. PI, placenta.

vasa previa but may be differentiated by re-examining the patient and observing moving vessels, a change in cord position, or a free-floating cord, falling away from the internal cervical os with change in maternal position. It may also be helpful to interrogate the placenta to demonstrate the site of umbilical cord insertion. Another point of clarification; vasa previa should be distinguished from the observation of a marginal vein or venous sinus at the inferior placental edge, near the internal cervical os, which is a form of placenta previa.

It has been shown that the majority of cases of vasa previa in asymptomatic women can be diagnosed with US by evaluating the cord insertion and by targeting the LUS, with transvaginal and color Doppler US, if the placental cord insertion cannot be identified or if there is a low-lying placenta or a suspected succenturiate lobe (Fig. 19-44A and B).⁷⁴ Most cases of vasa previa diagnosed by prenatal US are incidentally detected in women being evaluated for low-

FIGURE 19-37. Two transvaginal sonograms assessing the cervix and placental position. A. On the initial study in the mid-second trimester, the placenta is shown to overlie the cervix consistent with complete previa. B. Follow-up study performed 6 weeks later shows the inferior edge of the posterior placenta abutting the posterior margin of the cervix but no longer extending to or covering the os. PI, placenta.

lying placentas. It has been shown that a second trimester low-lying placenta or previa is a significant risk factor for vasa previa, even if the low-lying placenta or previa appears to have resolved in the third trimester. In one series, 69% of vasa previa at delivery had a second trimester placenta previa as documented by midtrimester US compared with 4% of controls.⁷⁹ Therefore, it is strongly suggested that a third trimester scan performed to follow-up a low-lying placenta include targeted evaluation with Doppler to assess for possible vasa previa, given the dramatic impact on outcome when this condition is diagnosed prenatally, prompting appropriate, potentially life-saving perinatal management.

Placenta Accreta

Placenta accreta refers to abnormal adherence of the placenta to the uterus with subsequent failure to separate

FIGURE 19-38. A. On the initial transvaginal sonogram performed at 16 weeks' gestation, the placenta (Pl) extends over and approximately 15 mm across the internal cervical os. B and C. Follow-up transabdominal and transvaginal views at 23 weeks' gestation demonstrate interval change. At this stage, the placental edge extends onto posterior cervix (Cx), but no longer overlies the internal os.

FIGURE 19-39. A. Second trimester transvaginal ultrasound reveals the inferior placental edge overlying posterior cervical tissue and extending to the internal os. The small amount of hypoechoic material within the upper cervical canal represents blood (arrow). B. On follow-up transvaginal ultrasound performed 1 month later, the os to inferior placental edge distance measures 2 cm. This patient subsequently delivered vaginally.

FIGURE 19-40. Illustration depicting abnormalities of umbilical cord insertion into the placenta. With a velamentous insertion of the umbilical cord into the membranes or with a succenturiate lobe, fetal vessels, within the chorionic membranes and unprotected by the placenta, may course across the cervix and result in a vasa previa. (Illustration by James A. Cooper, MD, San Diego, CA.)

after delivery of the fetus. Placental trophoblastic cells have tissue-invasive characteristics similar to malignant neoplastic cells. When trophoblastic villi burrow into an area of poorly developed or absent decidua, placenta accreta results (Fig. 19-45A and B). The type of accreta varies according to the depth of invasion. These abnormalities of placental attachment are defined as villi penetrate the decidua but not the myometrium (accreta); villi penetrate and invade into the myometrium but not the serosa (increta); villi penetrate through the myometrium and may perforate the serosa, sometimes into adjacent organs (percreta) (Fig. 19-46).⁸⁰ The prevalence is estimated to be 1 in 2500 pregnancies, but in women with placenta previa, the prevalence is nearly 10%. The incidence of placenta accreta (often used interchangeably as a general term to describe all of these conditions) is increasing. The most frequent predisposing conditions are previous cesarean section and placenta previa. It has been found that in the setting of anterior placenta previa, the risk of placenta accreta increases from 24% in women with 1 prior cesarean delivery to 67% in women with three or more prior cesareans.⁵⁷

Careful assessment of such at-risk pregnancies is warranted because this condition may lead to massive obstetric hemorrhage. Prenatal diagnosis allows effective delivery management planning to minimize morbidity. The diagnosis can be made by US, and the sonographic features of placenta accreta have been described. These include irregularly shaped placental lacunae (vascular spaces) with

FIGURE 19-41. Pathologic specimen with velamentous insertion of the umbilical cord and vasa previa, which was not recognized prenatally.

turbulent internal flow shown by Doppler, thinning of the myometrium overlying the placenta, loss of the retroplacental hypoechoic “clear” zone, absence of a decidual interface with normal placental echogenicity, interruption or increased vascularity of the uterine serosa–posterior bladder wall interface, and apparent bulging or protrusion of the placenta into the bladder (Fig. 19-47A and B). The prominent or multiple hypoechoic-anechoic irregular spaces (lacunae) in the placenta may result in a moth-eaten or Swiss cheese appearance of the placenta.⁸¹ It has been reported that the presence of placental lacunae is the most predictive sonographic sign of accreta with a sensitivity of 79% in the 15- to 20-week range and sensitivity of 93% in the 15- to 40-week range.⁸²

The appearance of the retroplacental hypoechoic space is of particular interest on US. The finding of obliteration of the retroplacental “clear space” is commonly thought to be associated with placenta accreta. In placenta accreta, this normally hypoechoic, 1- to 2-cm band is absent or markedly thinned (< 2 mm), and there may be loss of the normal decidual interface between the placenta and myometrium.^{83,84} This observation is incompletely sensitive, and it may not always be a reliable diagnostic sign because false-positive results do occur.⁸² Still, absence or thinning of this zone, particularly in a patient with a low-lying placenta or previa is suggestive and concerning. Doppler US techniques may be used to demonstrate turbulent flow within the placental lacunae. There may be marked periplacental vascularity on color Doppler.⁸⁵⁻⁸⁷ Rarely, placental villous tissue may be visualized invading the bladder.⁸⁶

The diagnosis of accreta should be carefully considered when a patient with risk factors (prior cesarean delivery or other uterine surgery, including myomectomy or hysterotomy) is shown by US to have placental implantation overlying the region of the uterine scar and manifests any of the described sonographic features associated with this condition. In addition to grayscale US findings, targeted Doppler assessment should be performed and, at times, MRI considered in this evaluation because it may provide additional diagnostic information in equivocal cases or when the placenta is

FIGURE 19-42. A. Transabdominal sonogram demonstrates tubular structures overlying the region of the cervix (*arrow*). B and C. On transabdominal and transvaginal views with color Doppler ultrasound, these are shown to represent vessels coursing between the anterior placenta and posterior succenturiate lobe, indicating vasa previa.

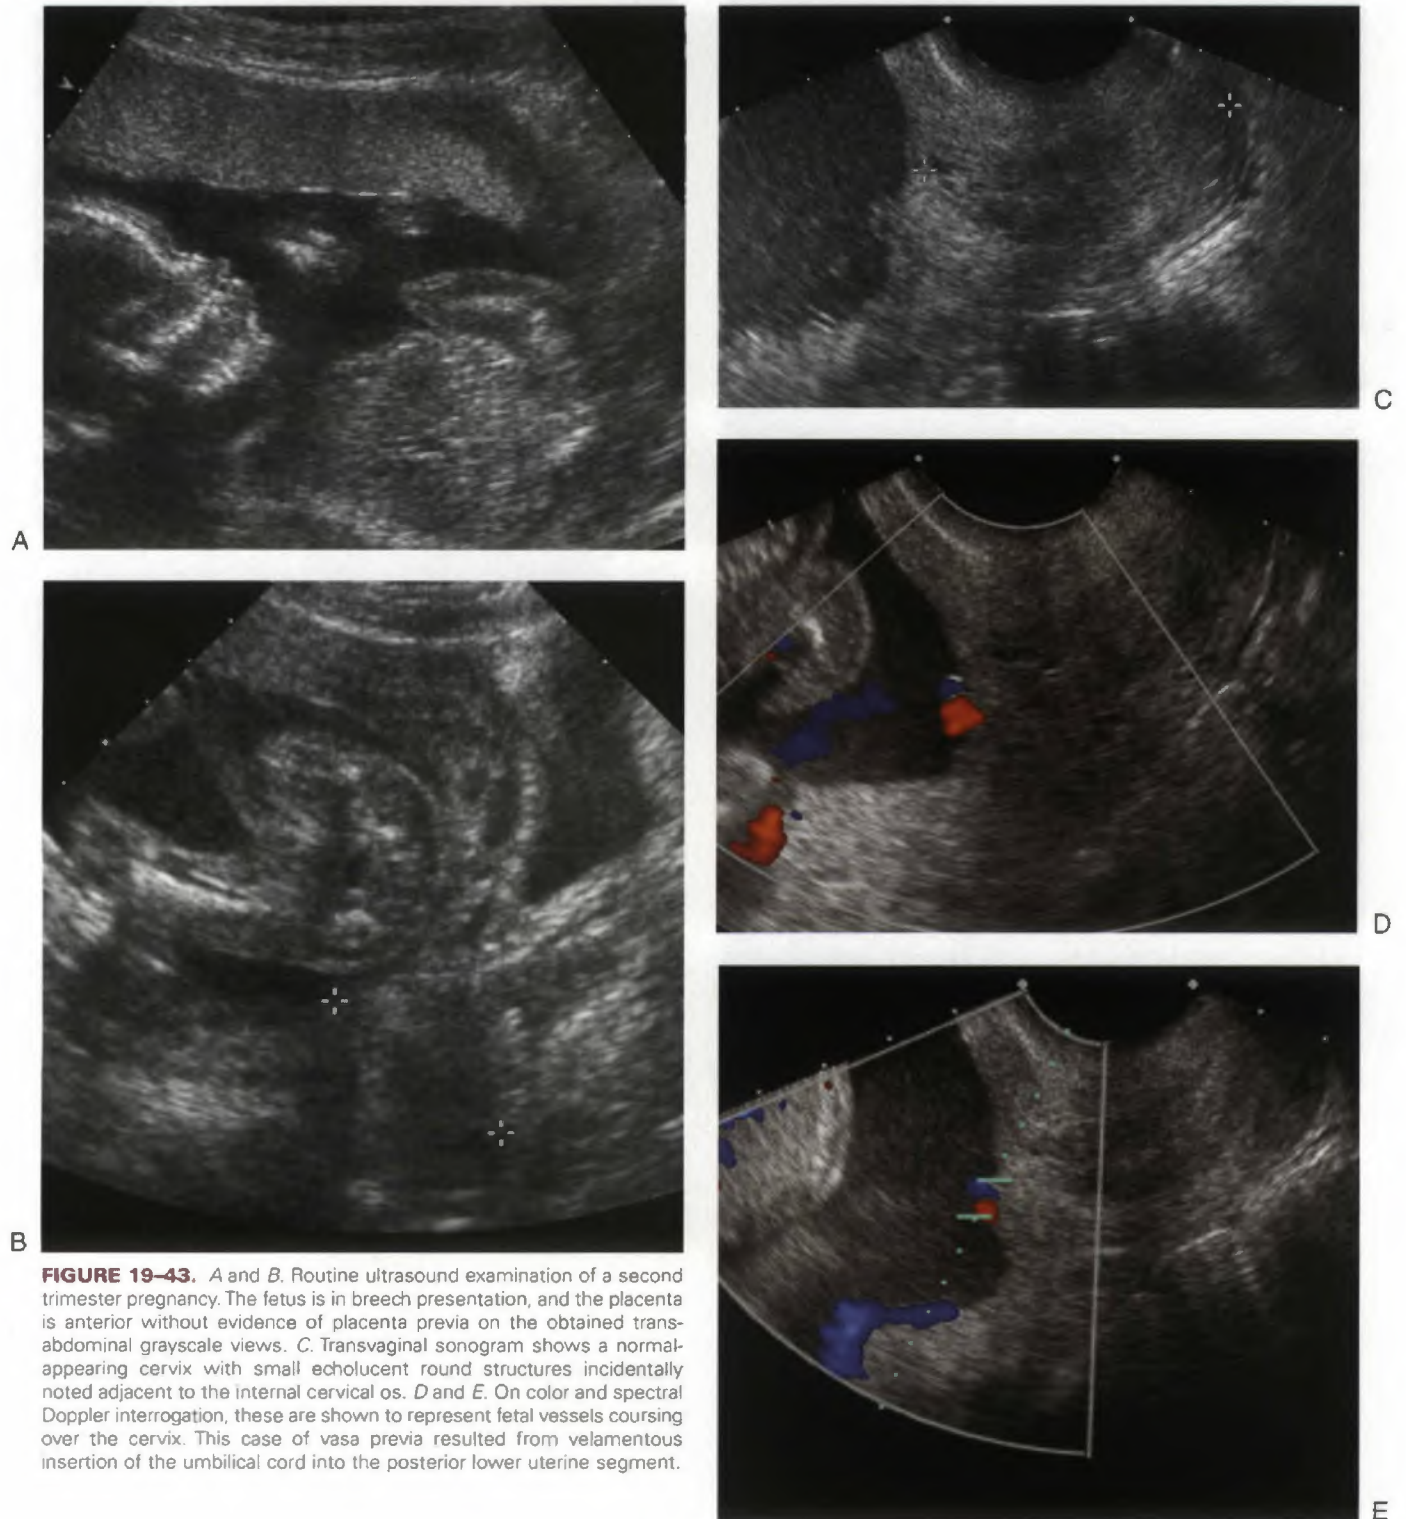

FIGURE 19-43. *A* and *B*. Routine ultrasound examination of a second trimester pregnancy. The fetus is in breech presentation, and the placenta is anterior without evidence of placenta previa on the obtained trans-abdominal grayscale views. *C*. Transvaginal sonogram shows a normal-appearing cervix with small echolucent round structures incidentally noted adjacent to the internal cervical os. *D* and *E*. On color and spectral Doppler interrogation, these are shown to represent fetal vessels coursing over the cervix. This case of vasa previa resulted from velamentous insertion of the umbilical cord into the posterior lower uterine segment.

FIGURE 19-44. A and B. Vasa previa shown by transvaginal sonograms with color and spectral Doppler techniques.

posterior in location (Fig. 19-48A and B).^{84,89,90} A two-stage imaging protocol to evaluate women at high risk for placenta accreta, using US first followed by MRI in cases with inconclusive US features, to optimize diagnostic accuracy has been proposed.⁹¹ These efforts are warranted because prenatal diagnosis of accreta triggers appropriate preoperative and perioperative procedures, and helps reduce fetal and maternal morbidity.

Nontrophoblastic Placental Tumors

Primary placental tumors are divided into trophoblastic and nontrophoblastic types. Trophoblastic disease is covered in detail elsewhere in this text (see Chapter 29). The majority of nontrophoblastic placental tumors are chorioangiomas.

FIGURE 19-45. A and B. Pathologic specimens, gross and microscopic, revealing placenta accreta with invasion of the decidua by trophoblastic villi.

FIGURE 19-46. Illustration of types of placenta accreta. (Illustration by James A. Cooper, MD, San Diego, CA.)

Chorioangiomas are the most common benign neoplasm of the placenta, consisting of a vascular mass arising from chorionic tissue, similar to a hemangioma, although a few authors prefer to classify it as a hamartoma. The reported incidence of chorioangiomas at pathology is 1% (Fig. 19-49). Most are small and have no clinical significance or sequelae.

FIGURE 19-47. Grayscale (*A*) and power Doppler (*B*) ultrasound of placenta accreta. Complete placenta previa was identified in this patient with three prior cesarean deliveries who presented in the late third trimester with vaginal bleeding. On these views targeting the anterior lower uterine segment, the placenta appears heterogeneous with prominent vascular spaces. There is also loss of the retroplacental hypoechoic zone. Placenta in creta was confirmed at cesarean hysterectomy.

FIGURE 19-48. *A* and *B*. T1- and T2-weighted sagittal magnetic resonance imaging scans (MRIs) of the patient shown in Figure 19-47. MRI was used to confirm the diagnosis of placenta previa and accreta, to assist in delivery planning, and operative management. Invasion of the myometrium at the anterior lower uterine segment by placental tissue is revealed.

Large chorioangiomas (> 5 cm) range in frequency from 1:500-1:16,000 live births.⁹² These lesions can be associated with fetal and maternal complications including polyhydramnios, hydrops, fetal cardiomegaly, thrombocytopenia, IUGR, preterm labor, preeclampsia, and elevated maternal serum alpha-fetoprotein.^{93,94}

On US, chorioangiomas appear as well-circumscribed, round, hypoechoic or mixed echogenic masses that usually occur near the umbilical cord insertion site on the fetal surface of the placenta (Fig. 19-50*A* and *B*). They measure from 1 to 5 cm in diameter and often demonstrate moderate vascularity with Doppler interrogation. In one series reviewing US and Doppler flow characteristics, these lesions all showed abundant blood flow or a large feeding vessel

(Fig. 19-51*A* and *B*).⁹³ The prominent blood flow in these benign tumors, which poses a risk to the fetus, may be helpful in distinguishing chorioangioma from other placental processes such as hematoma, subchorionic fibrin deposition, hydropic degeneration, adjacent degenerating leiomyoma, or placental teratoma.^{95,96} US can be used to assess and serially monitor the fetus in an effort to detect signs of volume overload with decompensation or hydrops. In utero

FIGURE 19-49. Gross pathologic specimen of a large chorioangioma, appearing as a smooth, round mass on the fetal surface of the placenta, located near the cord insertion site.

intervention with laser coagulation of placental chorioangioma blood supply has been described.⁹⁷

Placental teratoma is an exceedingly rare placental neoplasm.⁹⁸ Controversy exists over their origin as primary neoplasm or as abnormal fetus developing in a twin pregnancy. On US, they appear as cystic and solid masses with calcifications occurring in approximately 40%.

Placental Doppler

With the widespread application of spectral and color Doppler US imaging in the uteroplacental, umbilical, and fetal circulations, a potential extension is the interrogation of blood flow in the intraplacental arteries. There has been interest and investigation into the clinical significance and possible utility of Doppler measurements of placental perfusion. Use of placental Doppler in the first and early second trimester has not been generally successful or useful. One preliminary report characterized umbilical placental blood flow gradient during the early second trimester of normal pregnancy and established the presence of decreasing gradient.⁹⁹ Later in pregnancy, the use of intraplacental Doppler interrogation may be revealing.¹⁰⁰⁻¹⁰² However, this technique is still investigational and the role of intraplacental Doppler is not clearly established compared with uterine artery and other accepted and clinically applied Doppler measurement techniques, covered elsewhere in this text (see Chapter 22).

UMBILICAL CORD

Many umbilical cord abnormalities can be detected sonographically and have important prognostic implications for perinatal morbidity and mortality. Abnormalities of the cord may be associated with fetal anomalies, chromosomal abnormalities, and potential complications during pregnancy. Several cord lesions are reported in association with adverse perinatal outcomes. Knowledge of normal umbilical cord

A

B

FIGURE 19-50. A. Sonogram from a 25-week-old gestation showing an incidental solid, relatively hypoechoic mass (*arrow*) at the fetal surface of the placenta. B. Blood flow is shown within this lesion on color Doppler ultrasound. This chorioangioma did not result in fetal compromise and was confirmed postnatally.

development and anatomy, and awareness of common abnormalities of the cord is therefore important for accurate prenatal diagnosis and assessment.^{103,104}

Embryology

In the fourth menstrual week, the blastocyst implants into the endometrium. The blastocyst contains the embryonic disc that is composed of two cell layers: the ectoderm and endoderm. The ectoderm forms the amniotic sac and the endoderm forms the yolk sac.^{104,105} The embryonic disc, located between the two sacs, grows more rapidly along its dorsal than its ventral surface, causing the embryo to infold along its ventral surface in longitudinal and transverse directions. The dorsal surface flexes into and grows into the amniotic cavity. With infolding, the ventral surface engulfs a portion of the primary yolk sac and divides the yolk sac into

FIGURE 19-51. A and B. Transabdominal power Doppler images revealing prominent flow within this chorioangioma, noted along the fetal surface of the anterior placenta.

the intraembryonic portion, which becomes the primitive gut, and the extraembryonic portion, which becomes the omphalomesenteric duct. The proximal portion of the omphalomesenteric duct narrows and elongates, whereas the distal portion remains focally dilated and is known as the secondary yolk sac. The fetal end of the omphalomesenteric duct may persist as a Meckel diverticulum. The secondary yolk sac eventually disconnects from the omphalomesenteric duct and resides within the chorionic space. Sonographically, the secondary yolk sac may be seen at approximately 9 to 11 weeks, located between the unapposed amnion and chorion. At birth, the atrophic secondary yolk sac may be identified on the chorionic plate as a 3- to 5-mm disc.¹⁰⁴

FIGURE 19-52. Ultrasound of a normal three-vessel umbilical cord with both arteries and a single vein seen in long axis.

The amnion rapidly expands and eventually apposes the chorion, usually by 12 to 16 weeks. As the amnion expands, the embryo and connecting stalk become covered with amniotic epithelium. The connecting stalk develops blood vessels and fuses with the omphalomesenteric duct at approximately 7 to 8 weeks to become the umbilical cord.

Toward the caudal end of the embryo, the allantois or urachus develops as a second outpouching from the primitive gut and projects into the connecting stalk. The allantois is connected to the urinary bladder and may persist as a patent urachus or urachal cyst. The blood vessels of the allantois develop into the vessels of the umbilical cord, and therefore, the umbilical arteries that course lateral to the urinary bladder are continuous with the iliac arteries within the pelvis.^{104,106}

Anatomy

The umbilical cord is first visualized by US at 8 weeks as a straight, rather thick structure. At this point, the length of the umbilical cord is approximately equal to the crown rump length. Although it is not possible to directly measure by US, the umbilical cord usually continues to be the same length as the fetus throughout pregnancy. The diameter of the umbilical cord is normally less than 2 cm.¹⁰⁷ The umbilical cord develops up to 40 spiral turns as it elongates during gestation.¹⁰⁸ The umbilical cord twists toward the left more frequently than to the right. Coiling is thought to aid in protecting the cord by resisting compression of the vessels.¹⁰⁹ The development of cord length and twist are also dependent upon tensile forces placed upon the cord by fetal movements. Therefore, there must be adequate fluid space and fetal activity to ensure normal length and coiling of the umbilical cord.¹⁰⁴

Normally, the umbilical cord contains two arteries and one vein (Fig. 19-52). Although, early in development there

FIGURE 19-53. A. Color Doppler ultrasound showing two umbilical arteries flanking the fluid-filled fetal bladder (BI). B. In a separate case, a single umbilical artery is shown adjacent to the bladder.

are two umbilical veins, the right umbilical vein atrophies and the left umbilical vein persists. The umbilical vein carries oxygenated blood returning from the placenta and connects with the left portal vein in the liver. The umbilical arteries are continuous with the internal iliac arteries and carry deoxygenated blood from the fetus toward the placenta. The presence of two umbilical arteries may be confirmed by visualizing a short axis view of the umbilical cord and identifying two arteries and one vein or by visualizing vessels on each side, lateral to the fetal bladder on US (Fig. 19-53A and B). The vessels within the cord are surrounded by Wharton jelly, a gelatinous connective tissue that helps protect the umbilical vessels from compression.¹⁰⁴

Abnormalities of the Umbilical Cord

Single Umbilical Artery

The most common abnormality of the umbilical cord is a single umbilical artery (SUA) seen in approximately 1% of

FIGURE 19-54. A. Transverse view showing a normal three-vessel umbilical cord (two arteries and one vein). B. An example of a single umbilical artery (arrow) with a two-vessel cord seen on this ultrasound image.

pregnancies (Fig. 19-54A and B).²⁵ Absence of one umbilical artery may occur as aplasia or as the consequence of atrophy of one artery secondary to thrombosis.¹⁰⁴ The presence of a SUA should be confirmed at the fetal end of the cord because it may represent a normal variant due to fusion of the two umbilical arteries at the placental end of the cord (Fig. 19-55A and B).^{104,110} There has been great interest in the nature and significance of SUA regarding its association with fetal structural malformations, chromosomal abnormalities, and poor perinatal results.¹¹¹

Increased incidence of fetal morphologic anomalies, including cardiac and genitourinary defects, in the setting of a SUA has been reported.^{104,112-115} Currently, there is no definite correlation between SUA and any specific type or pattern of anomalies. SUA has been reported in association with malformations of all major organ systems and may also be seen with chromosomal abnormalities. In one series, 15%

FIGURE 19-55. Transverse views through different portions of the umbilical cord showing (A) three vessels and (B) two vessels.

of cases with SUA, found by US at 20 weeks, had other malformations and/or chromosomal abnormalities confirmed at birth. Importantly, *no* aneuploidy was found in fetuses *without* other associated findings by US and *all* serious congenital malformations accompanying the SUA were recognized prenatally.¹¹⁶ In another report, 72% of cases with antenatal diagnosis of SUA were isolated (no other anomalies identified by US). None of these fetuses had an abnormal echocardiogram. Of those fetuses with other anomalies, the four-chamber view of the heart accurately predicted all but one abnormal echocardiogram.¹¹⁷

Even in the absence of associated anomalies, there is an increased risk of IUGR in a fetus with SUA.^{118,119} It has been proposed that, most likely SUA is either part of a constellation of multiple anomalies (which are typically more notable on US than SUA), not its cause, or it develops during pregnancy by atrophy and then may be related to restricted fetal growth.¹⁰⁴

The discovery of a SUA on US warrants a meticulous search for any other associated detectable fetal malformation. In the absence of these, the risk of chromosomal abnormality or other major structural malformation is very low. Follow-

FIGURE 19-56. Pathologic specimen of a true knot of the umbilical cord, seen in a case of in utero fetal demise.

up US to assess fetal growth is also indicated when a SUA is observed. It should be remembered however that SUA is most often found in healthy, structurally normal fetuses.

The presence of more than one umbilical vein or more than two umbilical arteries is considered a multivessel cord. Multivessel cords are rare and have been reported in association with congenital anomalies and conjoined twins.¹²⁰

Length

Abnormally short umbilical cords can occur as a primary phenomenon secondary to failure of embryonic in-folding which is associated with limb body wall defects. Shortened umbilical cords can also occur secondarily when there is decreased fetal movement, as seen with underlying central nervous system or musculoskeletal abnormalities, or when there is limited space, as seen with oligohydramnios or multiple gestations.¹⁰⁴ Short cords have been reported in association with an increased incidence of congenital anomalies, in trisomy 21, oligohydramnios, and breech presentation. Shortened umbilical cords may lead to cord compression, placental abruption, or other difficulties associated with poor fetal descent during delivery.^{104,121,122} Although short cords have been associated with decreased fetal movement, the relationship between long cords and increased fetal movement is uncertain, and the etiology for elongated cords remains unclear. An abnormally long umbilical cord may predispose to cord knots, nuchal cord, and cord prolapse. These conditions may lead to cord compression and decreased perfusion secondary to obstruction of venous return.

Knots of the umbilical cord are classified as true and false. True knots occur in 1% of singleton pregnancies and can be a complication of monochorionic (MC) monoamniotic twin pregnancies (Fig. 19-56). They are rarely detected on prenatal US.¹²³ They may form as a result of torsion of the cord, forming a loop through which the fetus may slip, forming a knot.¹²⁴ The term false knots is a misnomer

FIGURE 19-57. Sonogram of a false knot of the umbilical cord, with focal redundancy of cord vessels.

because they represent a focal redundancy of the vessels that can appear sonographically as a vascular protuberance, simulating a knot (Fig. 19-57). The key feature is that the US appearance does not persist in all scanning planes.¹²⁵

Nuchal Cord

Nuchal cords, the term used to describe entanglement of the umbilical cord around the fetal neck, have been reported in approximately 25% of pregnancies, with an incidence ranging between 16% and 30%. They are frequently noted in many otherwise normal, uncomplicated pregnancies with uneventful deliveries in the vast majority of cases, and they are rarely associated with perinatal morbidity or mortality. But they have been considered worrisome for possible associated fetal injury, particularly when there are two or more tight loops around the fetal neck.^{104,126} In one report, nuchal cords were implicated in the intrauterine deaths of three term fetuses who had presented with decreased fetal movements but with normal amniotic fluid volume, fetal size and umbilical artery Doppler findings before delivery.¹²⁷

Nuchal cords may be recognized on prenatal US with many published reports of this observation.¹²⁸ They are recognized sonographically as two adjacent loops of cord in cross-section posterior to the neck on sagittal images and by visualizing cord circumferentially around the fetal neck on axial images, best appreciated with color Doppler interrogation (Fig. 19-58*A* and *B*).¹²⁹ A single loop of umbilical cord seen near the fetal neck is most often an incidental finding and not associated with fetal risk. Antenatal nuchal cords usually occur randomly, with increased frequency later in gestation.¹³⁰ It has been noted that nuchal cords seen by US early in pregnancy may spontaneously reduce during gestation.

The question of whether or not nuchal cords are associated with significantly increased adverse fetal outcome is rather controversial and remains unclear, despite many investigations. Furthermore, the question of whether the sonographic observation of a nuchal cord should be searched for at the time of an US examination and, if seen, should be reported has been debated.¹³¹ It has been suggested that the

A

B

FIGURE 19-58. *A* and *B*. Two examples of nuchal cords shown by color Doppler ultrasound. In each case, cord vessels are shown circumferentially around the fetal neck.

observation of a nuchal cord is of greater concern when seen in association with other findings, specifically decreased amniotic fluid volume, growth restriction, post-dates, and especially decreased fetal movements.¹³² These authors submit that nuchal cords should be sought for and reported, and their presence should, in some cases, prompt further evaluation with antenatal testing, close surveillance, and possible intervention (delivery).

Other investigators have found that antenatal nuchal cords found by US are rarely associated with perinatal complications.^{130,133} A study of the utility of US in assessing for nuchal cords in term or post-term pregnancies at the time of induction found that the sensitivity of US in their detection was low, and fetal outcome and clinical management was not significantly altered by the information, arguing against searching for or reporting this finding.¹³⁴ In one series, nuchal cord was present at 18% of deliveries. The sensitivity of US in the diagnosis of nuchal cords was only

37.5% before induction of labor at term. Nuchal cord was not associated with increased risk of cesarean section or poor neonatal outcome and did not alter or influence clinical management at time of delivery.¹³⁵

Coiling

US assessment of the umbilical cord can reveal the direction of cord twists (left helix seven times more common than right) and the frequency of twists of the vessels (referred to as the coiling index) (Fig. 19–59). The normal umbilical cord coiling index (UCI) is calculated as the number of complete coils divided by the length of the cord in centimeters. In a series of 122 uncomplicated pregnancies and in a literature review dating back to 1966, the mean (SD) UCI was 0.17 (+/- 0.009) coils/cm.^{136,137} Investigators have reported the

frequency of and clinical correlation with abnormally coiled cords (Fig. 19–60).¹³⁸ Abnormal cord coiling (UCI < 10th centile (< 0.07) or greater than 90th centile (> 0.30) has been associated with adverse pregnancy outcome.

Undercoiled (< 0.07 coils/cm) and overcoiled (> 0.30 coils/cm) cords have been seen at all gestational ages. In one report, hypocoiling of the cord was associated with increased incidence of fetal demise, intrapartum fetal heart rate decelerations, operative delivery for fetal distress, structural and chromosomal abnormalities, and chorioamnionitis (Fig. 19–61A and B). Hypercoiling of the cord was associated with increased incidence of fetal growth restriction, intrapartum fetal heart rate decelerations, vascular thrombosis, and cord stenosis (Fig. 19–62). Of note, it is not clear to the investigators whether abnormal coiling was actually a cause of the pathology, or one of the sequelae, or both.¹³⁷

Other reports describe abnormal cord coiling in association with fetal demise, fetal intolerance to labor, preterm delivery,

FIGURE 19–59. Power Doppler ultrasound of the umbilical cord with left helix (*arrow*). This direction of cord twists is much more common than right.

FIGURE 19–60. Pathologic specimens of 3 different umbilical cords with different degrees of coiling. The cord at the top is markedly overcoiled.

FIGURE 19–61. Undercoiled umbilical cord (*arrow*) demonstrated by (A) grayscale and (B) color Doppler ultrasound.

FIGURE 19-62. Sonogram of a markedly overcoiled cord.

FIGURE 19-63. Pathologic specimen of singleton term placenta and markedly overcoiled umbilical cord. Thrombosis of chorionic plate (fetal placental) vessels was observed in this case.

fetal structural and chromosomal abnormalities, velamentous cord insertion, SUA, IUGR, and chorioamnionitis. Abnormal cord overcoiling has also been associated with thrombosis of chorionic plate (fetal placental) vessels and of the umbilical vein (Fig. 19-63).^{109,139,140} Thus, it appears that abnormal cord coiling is a chronic state, established in early gestation, that may have chronic (growth restriction) and acute (fetal intolerance to labor and fetal demise) effects on the fetus. The underlying cause of abnormal cord coiling is not known, nor is it understood why the degree of coiling is of importance to fetal wellbeing.

Antenatal detection of abnormal cord coil index by US can be performed (Fig. 19-64).¹⁴¹ The antenatal UCI can be calculated by measuring the distance between two pairs of coils as seen on longitudinal US images of the umbilical

FIGURE 19-64. Sonogram used to measure the umbilical cord coiling index. The distance between coils is demarcated by the calipers.

FIGURE 19-65. Longitudinally cut umbilical cord specimens showing marked overcoiling (*top*) and undercoiling (*bottom*). Coiling index is calculated as the number of complete coils of the umbilical cord vessels divided by the length of cord (in centimeters).

cord. The sonographic evaluation of umbilical cord coiling in the second trimester was found to correlate with true UCI, obtained after birth (Fig. 19-65).¹⁴² In one series, abnormal cord coiling detected at second trimester US was associated with a higher prevalence of SGA neonates and nonreassuring fetal status in labor.¹⁴³ Such investigations are of interest, although the impact on clinical decision making and potential for decreasing risk of adverse perinatal outcome is not yet determined. The cord coil index, the reliability of its detection by US in utero, and the impact on clinical outcome warrants further study and is under investigation.

Insertion

Early in development, the embryo rotates such that the yolk sac and adjacent connecting stalk are positioned opposite

FIGURE 19-66. Normal central insertion of the umbilical cord into the anterior placenta, shown on color Doppler ultrasound.

the implantation site. This allows the umbilical cord to insert centrally within the placenta (Fig. 19-66). As the placenta develops, it is believed to grow preferentially in areas of optimal myometrial perfusion and atrophy in areas of suboptimal blood supply. As a result, the cord insertion may become somewhat eccentric despite its initial central attachment. This process is referred to as trophotropism.¹⁰¹

Marginal/Velamentous Insertion of the Cord. An exaggerated form of eccentric insertion occurs in 7% of pregnancies, with insertion of the cord at the margin of the placenta (Fig. 19-67A and B). This is known as a battledore placenta. In 1% of pregnancies, the cord inserts beyond the placental edge into the free membranes of the placenta. This is known as velamentous insertion of the cord and may be complicated by rupture and thrombosis of the umbilical vessels because they are not protected by Wharton jelly.¹⁰¹

Pregnancies with velamentous cord insertion are at risk for the development of fetal growth restriction, prematurity, congenital anomalies, fetal bleeding, retained placenta, and fetal demise. Vasa previa, discussed previously, results from velamentous insertion of the cord with umbilical vessels crossing the cervical os. Such variations in placental insertion of the umbilical cord, including marginal and velamentous insertions can be detected by US.¹⁴⁴⁻¹⁴⁶ In a study of the feasibility of identifying velamentous insertion of the cord using grayscale and color Doppler US, the placental cord insertion site was identified in 99% of cases and all cases of velamentous insertion confirmed after delivery were suspected by prenatal US (Fig. 19-68).¹⁴⁷ Assessment of placental cord insertion site on obstetric US potentially can identify pregnancies with velamentous insertion and, therefore, those at risk for obstetric complications including vasa previa. Velamentous insertion of the umbilical cord is also often seen in one fetus of a MC twin pregnancy.

A

B

FIGURE 19-67. Grayscale (A) and color Doppler (B) ultrasound views revealing marginal cord insertion into the placenta.

Anterior Abdominal Wall Defects

Body stalk anomaly, omphalocele, and gastroschisis are abnormalities of anterior abdominal wall development that are related to the development of the umbilical cord. Body stalk anomaly and omphalocele are likely due to a failure of embryonic infolding.^{121,148} Body stalk anomaly is far more severe than omphalocele because it involves longitudinal and lateral folds and is always fatal, whereas omphalocele results from abnormalities of transverse folds only. Failure of embryonic in-folding prevents normal development of the connecting stalk and therefore, the umbilical cord is absent or rudimentary.¹⁴⁹ Gastroschisis is an anterior abdominal wall defect that likely involves an abnormality of vascular

FIGURE 19-68. Color Doppler ultrasound of a velamentous cord insertion.

embryology rather than body wall folding.¹²⁹ It has been suggested that exaggeration of the normal regression of the right umbilical vein causes a defect in the anterior abdominal wall, through which fetal bowel segments protrude into the amniotic cavity. This defect is almost always seen to the right of an otherwise normal umbilical cord insertion.

Cord Cysts and Masses

Focal abnormalities within the umbilical cord may be seen incidentally during routine sonography. Certain US characteristics may be helpful in assessing focal lesions of the umbilical cord and in guiding management. The presence of an umbilical cord mass warrants evaluation of flow within the vessels, to assess for vascular compromise resulting from compression or thrombosis.

Single or multiple cysts of the umbilical cord can be seen at sonography (Fig. 19-69). An association between second and third trimester umbilical cord cysts with fetal anomalies and aneuploidy has been reported.^{107,150-152} Cysts of the umbilical cord seen in the first trimester more likely represent a normal finding.¹⁰⁷ True cysts of the umbilical cord are lined by epithelium and include remnants of the omphalomesenteric duct or allantoic duct. Amniotic inclusion cysts are lined by amniotic epithelium and develop when a portion of the amnion becomes entrapped in the formation of the umbilical cord. Omphalomesenteric and allantoic duct cysts are located toward the fetal end of the umbilical cord and may be seen in association with anomalies of the gastrointestinal and genitourinary tract, because they are developmentally related. Allantoic duct cysts have been reported in association with omphalocele, patent urachus, and possibly, obstructive uropathy.^{153,154}

Pseudocysts, which are not lined by epithelium, result from focal edema within or focal absence of Wharton jelly,

A

B

FIGURE 19-69. Two patients with umbilical cord cysts. A. Small cyst (arrow). B. Large cyst (arrow).

secondary to degenerative changes. They are more common than true cysts, and they have also been reported in association with omphalocele.¹⁵¹

Focal masses of the cord include tumors, hematomas, varices, and aneurysms. Hemangiomas, although rare, are the most common tumors of the umbilical cord and may appear as a hyperechogenic or multicystic lesion, usually located near the cord insertion at the placenta. Hematomas of the cord are usually focal and typically result from invasive procedures, such as cordocentesis. They most often appear hyperechoic, but the echogenicity may vary depending upon the age of the blood. Rarely, they may develop spontaneously, owing to venous bleeding related to umbilical cord knots or torsion, and may be detected serendipitously or with the

FIGURE 19-70. Pathologic specimen of a monochorionic placenta, seen from the fetal surface, following injection of colored dyes into the umbilical vessels. The cord insertion sites into the shared placenta are labeled. The arteries are blue for both twins. The veins are yellow for twin A and red for twin B.

onset of fetal distress.¹⁵⁵ Hematomas are associated with 50% risk of fetal loss and therefore, this diagnosis should prompt fetal monitoring and possible emergency delivery.¹⁵⁶

Umbilical vein varices may involve the intra-abdominal or extrafetal portion of the umbilical vein. Extrafetal varices can result in vascular compromise secondary to thrombosis. Cases of intra-abdominal umbilical vein varices associated with fetal anomalies and mortality have been reported; however, the significance of this finding remains uncertain.^{157,158} Umbilical artery aneurysms are very rare lesions that may be complicated by rupture, dissection, or clot, resulting in vascular compromise.

Multiple Pregnancies

Twin gestation is not the emphasis of this chapter and is covered in detail elsewhere in this text (see Chapter 8). It is worth noting here, however, that the high risks associated with some twin pregnancies is largely related to the placentas and umbilical cords, thus making the material covered in this chapter of particular relevance. Specifically, the risks associated with MC twin gestations are largely related to the shared placenta and its vascular anatomy. This anatomy has been carefully studied in postpartum placentas^{159,160} (Fig. 19-70). More recent work has addressed the in utero sonographic assessment of these pregnancies, revealing the value of focused attention to the shared placenta, cord insertion sites and intertwin vascular connections.

The number of chorions (placentas) and amnions in a monozygotic (fertilization of a single ovum) twin pregnancy depends on when the fertilized ovum divides relative to differentiation of the chorion and amnion. Division between 4 and 8 days after fertilization results in an MC, diamniotic (DA) gestation and occurs in approximately 75% of monozygotic twin pregnancies. Sonographic detection of a MC, DA twin pregnancy and its differentiation from a dichorionic DA twin pregnancy is most accurate in the first trimester (Fig. 19-71). In the third trimester, it may be more difficult to assess true membrane thickness and, thus, chori-

A

B

FIGURE 19-71. A. First trimester sonogram of monozygotic twins. A thin membrane (*arrow*) is seen separating the two embryos, A and B, thus a monozygotic diamniotic twin pregnancy. B. First trimester sonogram of dichorionic twins. In addition to two gestational sacs each with an embryo, a thick intervening membrane is seen (*arrow*), thus a dichorionic diamniotic pregnancy.

onicity. If early comparison sonograms are not available at the time of a second or third trimester examination, the patient should be questioned as to whether a first trimester sonogram was performed and that sonogram should be evaluated to determine chorionicity.

One fairly common complication in MC twins is birth-weight discordance, which may result from unequal placental sharing. Unequal placental sharing is an abnormality of placentation. In singleton placentas, the site of placental implantation is theorized to determine the eventual cord insertion site. Factors that alter placenta parenchymal function or affect the area of the placenta available to each MC twin for nutrient delivery, gas exchange, and waste removal may affect fetal growth. MC placentas are frequently shared unequally, and when this occurs, discordance in

FIGURE 19-72. Pathologic specimen of an unequally shared monochorionic placenta with one central (c) and one velamentous (v) umbilical cord insertion. Significant (20%) birth-weight discordance was observed in this twin pair, with the velamentous cord belonging to the smaller twin.

growth often results (Fig. 19-72).^{161,162} Other unique features of MC placental vascular architecture such as the number, type, and caliber of intertwin vascular anastomoses and the distance between umbilical cord insertions likely also contribute to growth and birth weight discrepancy and to the risk of developing twin-to-twin transfusion syndrome (TTTS).

Velamentous cord insertions have been reported to occur in 13% to 45% of twin gestations, and have been associated with twin growth disorders. Although in the past umbilical cord insertion sites were not routinely examined by obstetric US, as mentioned in a previous section, it is worthwhile doing so to detect velamentous and marginal cord insertions that can be identified by US in singleton and twin gestations in the second trimester. Peripheral cord insertion in one twin of a MC pair is associated with an increased risk for unequal placental sharing and birth-weight discordance. It is possible that identification of cord insertion locations by prenatal US in MC twin pairs may be used as a proxy for identifying unequal placental sharing and is likely to correlate with both postpartum placental pathologic examination findings and with risk of growth and birth weight discordance. Identification of MC twin pairs with at least one peripheral cord insertion should prompt close surveillance with serial USs to assess fetal weight and growth.¹⁶²

TTTS is the most common complication of MC twinning, reportedly occurring in approximately 10% to 20% of MC twin pregnancies. Through intertwin vascular connections on and within the placenta, blood is transfused from the donor (who can become growth-restricted and develop oligohydramnios, resulting in a “stuck” appearance) to the recipient, who can develop circulatory overload and respond with polyuria, resulting in polyhydramnios. There is significant variation in the manifestations of TTTS, including range in the gestational age and acuity of onset, probably reflecting the particular intertwin vascular anatomy (the number, size and character of connections) in the shared placenta, unique in each case.^{163,164} (Fig. 19-73).

FIGURE 19-73. Monochorionic twin placenta with velamentous (Ve) and central (C) cord insertion sites. The feeding arterial limb (A) and draining venous limb (V) of an intertwin arteriovenous anastomosis is shown, with direction of flow indicated (arrow).

Twins and Abnormalities in Amniotic Fluid Volume

The importance of amniotic fluid to fetal well-being cannot be overstated. Although once relegated to an afterthought during the sonographic examination, the evaluation of amniotic fluid is now considered an integral and important part of the sonographic evaluation of the gravid patient.

AMNIOTIC FLUID PHYSIOLOGY

Amniotic fluid serves a number of important functions in the normal development of the embryo and fetus: it cushions the fetus against physical trauma, allows for growth of the fetus free from restriction or distortion by adjacent structures, provides for a thermally stable environment, allows the respiratory and gastrointestinal tracts and musculoskeletal system to develop normally, helps to prevent infection, and may provide a short-term source of fluid and nutrients to the developing embryo.^{1,2}

A number of anatomic sites are involved in the regulation of amniotic fluid (Fig. 20-1). The volume of amniotic fluid at any moment represents a balance between those structures producing or allowing passage of fluid into the amniotic cavity: chorion frondosum and membranes, skin, urinary tract, and respiratory tract; and those involved in the removal of amniotic fluid: gastrointestinal tract, respiratory tract, and the amniotic-chorionic interface at the uterine wall.¹⁻¹⁰ Two additional pathways include the intramembranous and transmembranous routes. The more important intramembranous pathway includes transfers between amniotic fluid and fetal blood perfusing the fetal surface of the placenta, fetal skin, and umbilical cord. The transmembranous pathway involves exchange across the fetal mem-

branes between amniotic fluid and maternal blood within the wall of the uterus.¹ The importance of intra- and transmembranous pathways has been made clear, because the total amniotic fluid volume (AFV) cannot be accounted for on the basis of the fetal kidneys, lungs, and swallowing alone. Intramembranous flow reaches nearly 400 mL/day at term (Fig. 20-2).⁹

In early pregnancy, the chorioamnion acts almost as a molecular sieve, allowing for the free passage of water and solutes, electrolytes, creatinine, and urea. Little embryonic contribution to the amniotic fluid occurs at this time, as evidenced by the presence of chorioamniotic fluid both before and in the absence of a living embryo. In the mid-to-late first trimester, diffusion through the embryonic skin readily occurs because the skin is only four cell layers thick.¹¹ Diffusion across this permeable barrier continues until fetal keratinization at 24 to 26 weeks' gestation.^{2,11}

In the latter half of gestation, the two primary sources of amniotic fluid are the fetal kidneys and lungs. The primary sources of amniotic fluid removal are the gastrointestinal tract (swallowing) and absorption into the fetal blood perfusing the surface of the placenta.¹ In the second and third trimesters, fetal urination plays an important role in the production of amniotic fluid. The excretion of hypotonic urine by the fetal kidneys has been reported as early as 12 weeks.^{12,13} Confirmatory evidence of the kidneys' role in amniotic fluid production is based in part on the finding that, in the third trimester, concentrations of sodium and chloride in the fetal amniotic fluid and urine decrease, whereas the concentrations of urea and creatinine increase in both fluids.² Likewise, in the second trimester, sodium and potassium concentrations are significantly lower in amniotic

FIGURE 20-1. The major fetal and maternal amniotic structures involved in the formation and reabsorption of amniotic fluid. (From Wallenburg HCS: *The amniotic fluid. J Perinatal Med* 5:193, 1977.)

fluid compared with the maternal serum. This is in part due to small amounts of urine contributing to the amniotic fluid composition.^{7,14} At 18 weeks' gestation, fetal urine production has been estimated to be between 7 and 17 mL/day and increases steadily throughout pregnancy (see Fig. 20-2).¹⁵ It has been estimated that the volume of urine produced by the human fetus during the latter half of gestation is approximately 30% of body weight daily.^{1,16} At term it is approximately 800 mL/day (range, 600 to 1200 mL/day), which approximates the total AFV at this stage.^{2,17} The presence of normal AFV in the second and third trimesters implies that at least one functioning kidney must be present. A reduction in fetal renal arterial blood flow or an increase in renal tubular reabsorption from antidiuretic hormone (both a result of fetal hypoxemia) results in a diminution of AFV.

In addition to the fetal kidneys, the lungs also contribute to the total AFV (see Fig. 20-2). Although the exact amount of fluid secreted by the respiratory tract is not known, it is presumed to be in the range of 60 to 100 mL/kg/day of fetal weight near term.^{10,18} Most of the fetal lung fluid leaves the trachea during episodes of fetal breathing.^{10,19} According to Brace,¹ less than 1% of the secreted fluid is needed to expand the lungs with growth. Approximately half of the fluid that exits the trachea enters the amniotic fluid.²⁰ It has been wrongly assumed that the lungs provide a pathway for the absorption of fluid in the normal fetus. As Brace¹ stated, "only under conditions of fetal asphyxia or distress do the fetal lungs absorb fluid."

The removal of amniotic fluid throughout pregnancy is largely a result of fetal swallowing. Approximately one half of the daily urine produced is removed by fetal swallowing. Fetal swallowing has been estimated to be as low as 200 mL/day and as high as 1500 mL/day. Whereas at 20 weeks' gestation the percentage of AFV swallowed is small (approximately 5%), at term the fetus may swallow as much as 50% of the total AFV.²¹ In their model of AFV dynamics, Mann, Nijland, and Ross⁹ found that relatively low rates of swallowing in proportion to urine and lung fluid production account for the gradual increase in AFV in the first and second trimesters. They also found that increased swallowed AFV contributes to the reduction in AFV near term and possibly to the development of oligohydramnios in post-term patients. It is unlikely that fetal urination and swallowing can explain the total variation in AFV. As mentioned previously, intramembranous and, to a lesser degree, transmembranous flow between the amniotic space and mother and fetus are also likely to play a role in the fluctuations of AFV. Intramembranous flow reaches nearly 400 mL/day at term.⁹

A number of investigators calculated the volume of amniotic fluid throughout gestation. Weisman, Itskovitz-Eldor,

FIGURE 20-3. Amniotic fluid volume by gestational age. (From Weissman A, Itskovitz-Eldor J, Jakobi P: Sonographic measurement of amniotic fluid volume in the first trimester of pregnancy. *J Ultrasound Med* 15:772, 1996.)

and Jakobi²² calculated the volume of amniotic fluid in the first trimester (Fig. 20-3). They found that the quantity of amniotic fluid increased from approximately 1 mL at 7 weeks to 25 mL at 10 weeks and 60 mL at 12 weeks. These authors made the interesting point that if an early amniocentesis is performed, removing 1 mL per gestational week, at 9 weeks, 72% of the AFV will be removed, whereas at 17 to 18 weeks, less than 10% of the total volume is removed. Brace and Wolf⁶ found that the AFV progressively rises from 8 weeks' gestation, reaching its statistical maximum (variance analysis) at 22 weeks' gestation and remaining at this level (630 to 817 mL) through 39 weeks (Fig. 20-4). These authors calculated the mean changes in AFV on a weekly basis (based on a polynomial regression equation). At 8 weeks, the volume was increasing at 10 mL/week; at 13 weeks, it increased to 25 mL/week; and at 21 weeks, it reached a maximum of 60 mL/week. The weekly volume increment then decreased and reached zero at 33 weeks' gestation, at which point the mean volume reached its peak. After term, the AFV declines at a rate of approximately 8% per week. During the first half of pregnancy, AFV is closely correlated with fetal weight. The amniotic fluid–fetal volume ratio increases until about 30 weeks' gestation and then appears to decline. The late third trimester gestation fetus urinates and swallows a volume of amniotic fluid equal to 20% to 30% of its body weight per day, whereas an adult, in comparison, urinates and swallows approximately 2% to 3% of its body weight per day.

Although it has long been known that fetal metabolism and blood volume affect AFV, it is only in the last 2 decades that maternal effects, disease states, and hydration have been shown to affect fetal hydration, blood volume, and therefore, AFV.^{11,23} Goodlin, Anderson, and Gallagher²³ in 1983 demonstrated the relationships between elevated maternal intravascular volume and polyhydramnios and between decreased maternal intravascular volume and oligohydramnios. Maternal hydration may increase AFV by improving

FIGURE 20-4. Nomogram shows amniotic fluid volumes as a function of gestational age on a linear scale. Dots are means for each 2-week interval. Percentiles are calculated from polynomial regression equation and standard deviation of residuals. Shaded area covers 95% confidence interval. (From Brace RA, Wolf EJ: Normal amniotic fluid volume changes throughout pregnancy. *Am J Obstet Gynecol* 161:386, 1989.)

uteroplacental blood flow or by bulk transfer of water across the placenta.²⁴ In a study of patients with normal AFV, Kilpatrick and Safford²⁵ found that both maternal serum and urinary osmolality significantly decreased after the ingestion of 2 L of water, whereas AFV increased.

Echogenic Amniotic Fluid

In 1978, Bree²⁶ and subsequently Parulekar²⁷ in 1983, reported on the presence of echogenic 'particles' in amniotic fluid. Whereas initially this was believed to represent vernix, its appearance as early as 15 weeks makes this unlikely. Khaleghian²⁸ reported this finding and raised the possibility that these echoes were secondary to meconium. Whereas the cause of these echoes remains uncertain, they are unlikely to purely represent either meconium or vernix. More recently, Espinoza et al²⁹ have identified these echoes within the amniotic fluid near the cervix during transvaginal examinations and have termed these echoes *amniotic fluid sludge*. In their study, the prevalence of amniotic fluid sludge was 1% in patients with uncomplicated term pregnancies and 22.6% in those with preterm labor and intact membranes. Their conclusion was that "the presence of amniotic fluid 'sludge' in patients with preterm labor and intact membranes is a risk factor for microbial invasion of the amniotic cavity (MIAC), histological chorioamnionitis and impending preterm delivery." Another study by Mungen et al³⁰ found that in term patients, the presence of sonographically echogenic amniotic fluid was not associated with any adverse pregnancy outcome and "therefore should not alter routine pregnancy management."

ULTRASOUND AND AMNIOTIC FLUID ESTIMATION

The recognition of the importance of amniotic fluid in fetal development made it imperative to develop methods of assessing the AFV throughout pregnancy. Although ultra-

FIGURE 20-5. Longitudinal sonogram in a second trimester gestation with normal amniotic fluid. Subjective evaluation of normal amniotic fluid depends on the relationship between amniotic fluid and the space occupied by the fetus and placenta.

FIGURE 20-6. Sonogram of a fetus with renal agenesis. Virtually no amniotic fluid is seen. The fetus is "crowded" within the uterus. The only relatively anechoic space is occupied by the umbilical cord (*asterisk*).

sound has many advantages, not the least of which is its noninvasive nature, it also has inherent problems. The greatest difficulty relates to the tomographic nature of this modality. Sonographic scans across the gravid uterus are two-dimensional slices of the intrauterine contents. A decision about the amount of AFV requires that the examiner sum the individual pockets of amniotic fluid at the time of scanning or interpretation of the recorded films. Although most experienced sonologists are capable of making a subjective decision about the amount of fluid, the lack of objectivity is troublesome to some.

Although clinicians were readily able to recognize the development of an acute and severe excess of amniotic fluid in their patients, it was often difficult to recognize too little amniotic fluid. A noninvasive method of imaging marked reductions in AFV was needed. Sonography was, and is, well suited to this task. Sonographic assessment of oligohydramnios has been largely based in the past on the subjective judgment of the sonologist. The technique of subjective assessment of amniotic fluid involves comparing the echo-free fluid areas surrounding the fetus with the space occupied by the fetus and placenta (Fig. 20-5).³¹ When too little fluid is present, the fetus appears crowded within the uterus (Fig. 20-6). In an interesting study, Halperin et al³² evaluated inter- and intraobserver variability in the subjective assessment of AFV. In their study, experienced sonographers subjectively assigned patients to groups with normal, borderline-low, or reduced AFV. They found that more experienced sonographers had significantly higher intraobserver correlation scores ($\kappa = 0.94$ versus 0.63).³¹ In another study, Moore et al³¹ demonstrated that well-trained observers could subjectively identify patients with oligohydramnios with an intraclass correlation coefficient of 0.81 .³¹ Using a subjective assessment of AFV, Goldstein and Filly³³ reported intraobserver and interobserver agreements of 84% and 96%, respectively (Fig. 20-7).

FIGURE 20-7. Mean of transverse measurements of the largest amniotic fluid pocket versus subjectively judged amniotic fluid volume (AFV). There is a good correlation between AFV estimates judged with pocket measurements and estimates judged subjectively. 1.0, oligohydramnios (little to no amniotic fluid, virtually no pocket free of umbilical cord, crowding of small parts); 2.0, somewhat decreased amniotic fluid (not frank oligohydramnios but subjectively less than expected AFV for gestational age); 3.0, normal (good fluid-fetal interface, especially about small parts, with fetus filling the anteroposterior diameter of the uterus); 4.0, somewhat increased (more fluid than expected around small parts, slight interface of fluid between fetus and uterine wall); 5.0, frank polyhydramnios (fetus does not fill the uterine cavity in the anteroposterior dimension and much more than expected fluid around both the fetal trunk and small parts). (From Goldstein RB, Filly RA: Sonographic estimation of amniotic fluid volume. *J Ultrasound Med* 7:363, 1988.)

Even though experienced sonologists and sonographers are capable of making such judgments, it is impossible to disseminate criteria for use by less experienced examiners. Furthermore, there is no method of ensuring that even the most experienced examiners use the same visual cues when attempting to diagnose too little fluid. Manning, Hill, and Platt³⁴ made an excellent step forward in visual evaluation in their description of a simple measurement to judge oligohydramnios. Their technique involves scanning the uterus to select the single deepest amniotic fluid pocket free of umbilical cord and fetal parts (Fig. 20-8). The greatest vertical dimension of this pocket is then measured with the ultrasound transducer perpendicular to the floor. This meas-

FIGURE 20-8. Normal amniotic fluid volume assessed by measurement of the largest single pocket of fluid. In this 22-week gestation, the largest vertical pocket of amniotic fluid, devoid of umbilical cord, is 24 mm.

urement has also been referred to as the maximum vertical pocket (MVP). At the time of their original study, a diagnosis of oligohydramnios was made when the single deepest pocket was less than 1 cm. This measurement has come to be known as the 1-cm rule. Although devised to assess pregnancies in which growth restriction was suspected, it was also used in the evaluation of post-term patients and in the fetal biophysical profile. The 1-cm rule originally described in the early 1980s was modified a number of times by others to increase as well as decrease the maximum allowable amniotic fluid pocket to define oligohydramnios, including measurements of 2 cm, 3 cm, and 0.5 cm (Table 20-1).^{35,36} Unfortunately, this rule and others have subsequently proved too stringent to use. Bottoms et al³⁷ and others correctly noted that the absence of a fluid pocket at least 1 cm in depth was extremely rare and thus an insensitive marker for poor obstetric outcome.³¹

In 1987, Phelan et al³⁸ and subsequently Rutherford et al^{39,40} and Moore and Cayle⁴¹ developed a semiquantitative sonographic assessment of the AFV that has come to be known as the amniotic fluid index (AFI). This measurement is based on the division of the gravid uterus into four quadrants using the external maternal landmarks of the umbilicus and linea nigra (Fig. 20-9 and Table 20-2). The deepest amniotic fluid pocket in each quadrant, in a similar manner to the MVP, is measured. These four measurements are added together, and the sum is referred to as the AFI (Table 20-3). In a 1997 review, Hill¹¹ noted that Phelan et al's³⁸ original description of the AFI did not mention whether pockets of amniotic fluid containing umbilical cord should be included or excluded. Subsequently, Rutherford et al⁴⁰ stated that the umbilical cord or an extremity may traverse a pocket of measured amniotic fluid (Fig. 20-10).¹¹ However, when the pocket is almost entirely filled with either umbilical cord or extremities, it should not be included as one of the measured pockets (Fig. 20-11). It should be noted, however, that many sonologists include only pockets that are free of umbilical cord and extremities.¹¹

Investigators and practitioners have used a variety of thresholds to define abnormalities in AFV. Moore and

42	63	69	110	175	192	30

Amniotic fluid index values are obtained by measuring the vertical depth of the largest clear amniotic fluid pocket in each of four equal uterine quadrants. The values from each quadrant are measured in millimeters and added together.

From Moore TR, Cayle JE: The amniotic fluid index in normal human pregnancy. *Am J Obstet Gynecol* 162:1168, 1990.

Table 20-2 Amniotic Fluid Index Technique

Position patient supine.

A linear, curvilinear, or sector transducer can be used.

Divide the uterus into four quadrants using the maternal sagittal midline vertically, and arbitrary transverse line approximately halfway between the symphysis pubis and the upper edge of the uterine fundus.

The transducer must be kept parallel to the maternal sagittal plane and perpendicular to the maternal coronal plane throughout.

The deepest unobstructed and clear pocket of amniotic fluid is visualized, and the image frozen. The ultrasound calipers are manipulated to measure the pocket in a strictly vertical direction.

The process is repeated in each of four quadrants and the pocket measurements summed = AFI.

If the AFI is <8 cm, perform the four quadrant evaluation three times and average the values.

AFI, amniotic fluid index.

Adapted from Moore TR: Clinical assessment of amniotic fluid. *Clin Obstet Gynecol* 40:300, 1997.

Cayle⁴¹ defined oligohydramnios when the AFI was less than the fifth percentile, which corresponded to an AFI of less than 7 to 8 cm. Rutherford et al³⁹ used 5 cm as a threshold to define oligohydramnios, a number that would be slightly less than the first percentile. Although controversy still exists as to which threshold values to use, values greater than 5 cm and less than 18 to 20 cm are considered by most examiners to be normal. Thus, the 1-cm rule has been replaced by the 5-cm rule.

Many studies found that the AFI more closely relates to the AFV based on dye-dilution studies and, in many cases, is more accurate than measuring a single pocket; however, this has not been true in all investigations. In one study comparing the AFI with dye-dilution methods, Dildy et al⁴² found that the AFI overestimated the actual volume by as much as 88.7% at lower volumes and underestimated the actual volume by as much as 53.9% at higher volumes. In a dye-dilution study at the time of amniocentesis by Chauhan et al,⁴³ in which they correlated semiquantitative methods (AFI and two-diameter pocket measurements) with AFV, poor correlation was found. The authors concluded

FIGURE 20-10. Sonogram of a pocket of amniotic fluid in a patient with hydrops fetalis and polyhydramnios. Two small segments of umbilical cord (arrows) are seen traversing the measured pocket of amniotic fluid. The placenta (P), which appears normal to prominent in this case, is, in fact, abnormally thickened.

that “for any specific AFI or two-diameter amniotic fluid pocket the 95% confidence range is so wide that ultrasonographic assessment is simply not a reasonable reflection of actual AFV. At a given AFI or two-diameter pocket measurement the prediction limits may include both conditions of oligohydramnios and polyhydramnios (that is, an AFI of 11 cm at the 95% range will vary from 141 to 1565 mL). A 95% confidence level that the actual AFV exceeds 500 mL (not oligohydramnios) requires that the AFI be greater than 30 cm (a measurement consistent with polyhydramnios).” Moore and Cayle,⁴¹ in their original study, found the absolute error to be relatively constant at 10 mm regardless of the amount of fluid measured. However, they found that the percentage of error created during measurement of small volumes of amniotic fluid (less than 10 cm) was 20% or more. Likewise, although positive predictive accuracies are high for the group with AFI less than 5 cm, the sensitivities for the detection of oligohydramnios are poor: between 18% and 40%. A study by Baron, Morgan, and Garite⁴⁴ correlating the likelihood of abnormal fetal heart rate tracing and need for cesarean section for fetal distress found no difference in the group in which the AFI was between 5.1 and 8.0 and the group in which the AFI was between 8.0 cm and 20 cm.

Several groups tried to refine the results of the AFI to gain additional information. In one study, Myles and Strassner⁴⁵ examined the distribution of fluid between upper quadrants and lower quadrants. In two groups with the same AFI, those with greater fluid in the upper quadrants had a greater incidence of meconium staining, 1-minute Apgar scores less than 7, variable decelerations, late decelerations, cesarean section for fetal distress, and arterial pH less than 7.2 than did those in which the fluid in the lower quadrants

A

B

FIGURE 20-11. A. Apparent amniotic fluid pocket (asterisk) in a third trimester pregnancy. B. Color Doppler interrogation reveals that this pocket is entirely filled with umbilical cord.

was greater. The theory is that less fluid in the lower quadrants leads to head or umbilical cord compression during labor. In a similar 1998 study by Buckshee et al,⁴⁶ those with greater than 50% AFV distributed in the upper quadrants formed the “upper greater” group, whereas the rest of the patients constituted the “lower greater” group. The upper greater group had a higher incidence of cesarean section for nonreassuring fetal heart rate (40.74% versus 9.6%), persistent variable decelerations (14.8% versus 0%), and bradycardia (25.9% versus 4.1%). Interestingly, there was no statistically significant difference in the predictive value of perinatal outcome (Apgar, neonatal intensive care unit admissions). In another study, Sadovsky et al⁴⁷ evaluated additional cord containing amniotic fluid pockets in women in whom the AFI was less than 5 cm. In the subgroup in which the cord-containing pocket was greater than 5 cm (which would ordinarily be excluded), there was no evidence of an increase in poor outcome, normally seen in women with oligohydramnios. A 1998 report by Magann et al⁴⁸ found that using multiple assessments (that is, AFI plus deepest pocket) did not add to accuracy. In their report, the accuracy

of ultrasound estimates of abnormal AFV was relatively low (ranging from 12% to 53% correct).

PITFALLS IN AMNIOTIC FLUID VOLUME ESTIMATION

Normally, it is easy to reach a conclusion as to the total AFV whether one uses subjective or objective methods of assessment. Studies demonstrated that fetal movement does not impact negatively the assessment of AFV.⁴⁹ The choice of either curvilinear or sector transducers does not have an effect on estimated AFV.⁵⁰ Measurements of AFV do not appear to be influenced by maternal position.⁵¹ No difference in AFI measurement were noted when patients were in the supine or 45-degree elevated position. However, studies have shown that fetal position may influence amniotic fluid volume measurements. A study by Fok et al⁵² studied the effect of fetal position on two of the measurements of the AFV, AFI, and the single deepest pocket (SDP). The AFI was on average 4.35 cm higher for fetuses lying centrally within the uterus compared with fetuses lying laterally inside the uterus. There was no difference for SDP measurements of fetuses lying laterally or centrally or for different orientations of the fetal trunk. Their conclusion was that SDP may be a more consistent parameter for the estimation of amniotic fluid volume.

Excessive maternal abdominal transducer pressure impacts AFI measurements. Flack et al⁵³ found that high pressure on the maternal abdomen resulted in a 21% decrease in AFI. Four additional potential pitfalls exist. First, as stated earlier, an umbilical cord-filled amniotic fluid pocket should not be used in the assessment of AFV. Color Doppler flow imaging often assists in identifying the umbilical cord (see Fig. 20-11). Second, fat tends to scatter the ultrasound

beam and as such may introduce artifactual echoes into the amniotic fluid. Obese patients may seem to have significantly reduced fluid because of these artifactual echoes (Fig. 20-12). Using a lower frequency transducer may often assist one in correctly assessing AFV in these patients. Third, in the third trimester, free-floating particles, perhaps resulting from vernix, may make the true amniotic space less conspicuous (Fig. 20-13). Fourth, a single large pocket of

FIGURE 20-12. Sonogram in a moderately obese patient. Artifactual echoes within the amniotic fluid make the actual amniotic fluid less apparent.

FIGURE 20-13. Two images of the amniotic fluid in a third trimester gestation. Highly echogenic fluid is seen surrounding the umbilical cord.

FIGURE 20-14. A. Sonogram of the fundic portion of the uterus in a second trimester pregnancy. Although this single large amniotic fluid pocket simulates polyhydramnios, it was the only area of amniotic fluid. B. Sonogram of the same patient in the mid- to lower uterine segment. No amniotic fluid is seen in this scan. If amniotic fluid volume had to be assessed on the basis of this image alone, it would be interpreted as oligohydramnios.

amniotic fluid seen on a static hard copy image may not be representative of the AFV in its entirety (Fig. 20-14).

As stated previously, color Doppler may prove useful in identifying an umbilical cord-filled pocket of what appears to be amniotic fluid in the patient with oligohydramnios. However, in the patient with otherwise normal amniotic fluid volume, it may underestimate AFV and lead to the false-positive diagnosis of oligohydramnios. A study of the use of color Doppler in the ultrasound estimate of AFV found that the use of color Doppler imaging resulted in the diagnosis of oligohydramnios in 21% of women who had normal AFVs.⁵⁴ The extremes of AFV did not seem to be impaired by the concurrent use of color Doppler with AFI and subjective evaluation of AFV.

FIGURE 20-15. Sonogram of a second trimester pregnancy. Measurements of this amniotic fluid pocket might be made in a variety of locations by different examiners, and some examiners may choose not even to use this pocket for measurement.

COMMENTARY ON IMAGING ASSESSMENT OF AMNIOTIC FLUID VOLUME

Even though sonographic assessment of AFV has been attempted for more than 2 decades, there is still no consensus as to the best method to report the status of AFV in an individual patient. There is a tendency to favor the assignment of an objective number to represent the AFV rather than rely on subjective descriptions of amniotic fluid. Somehow intertwined in this decision to use objective descriptors is the notion that assessments that result in a numeric value will be more accurate than those based on subjective descriptors. The reliance on fetal biometry rather than on the patient's last menstrual period to estimate gestational age in a fetus with intrauterine growth restriction (IUGR) is a perfect example of the problems with this sentiment. Likewise, there is an implied but never-stated view that these semiquantitative measurements are easier to acquire and require a less experienced sonographer or sonologist to perform than subjective estimations. Virtually every review of the sonographic imaging of AFV seems to have a statement similar to this one from this excellent review of the subject: "Subjective methods seem adequate to recognize abnormal AFV, but well-trained and experienced sonographers are necessary for clinically useful results. A disadvantage of the subjective technique is the lack of a numeric result that can be used to compare patients and to follow trends in AFV over time. Semiquantitative criteria for sonographic assessment of AFV have been developed to circumvent this limitation."⁵⁵ Is not a well-trained and experienced sonographer necessary to make objective assessments of AFV (that is, SDP or AFI)? To gain more insight into this issue, the reader should perform the following experiment. Photograph a single image of an amniotic fluid pocket that contains a small amount of umbilical cord or extremity or both (Fig. 20-15). Show this photograph to four different sonographers or sonologists with experience in performing

quantitative estimations of AFV, and ask them to measure this quadrant. It is highly likely that not only will some of the measurements vary from examiner to examiner but some individuals will choose not to use such an image in their calculations. Having a single well-trained and experienced examiner perform AFV estimations is the ideal solution, regardless of the method that is chosen.

Perhaps my major problem with the use of objective numeric values applied to AFVs is how the information is used in management decisions regarding the patient. I have attended management conferences in many centers throughout the country, and have repeatedly heard a similar discussion: "the AFI is 4.2 cm; therefore, the patient will be delivered immediately, whereas the patient in the next bed with an AFI of 5.2 cm and otherwise similar clinical findings will be sent home and return for follow-up monitoring." (There is no statistical difference in the AFI measurements in these hypothetical patients.) Again, because a numeric value is assigned to an interpretation does not make it any more accurate or useful than subjective assessments. The AFI is probably the best of the semiquantitative methods available for AFV assessment, but it should not be considered to be without its own inherent limitations. If subjective assessments of AFV are to be made, the person responsible for interpreting the examination should ideally scan the patient and not rely entirely on static images, particularly when AFVs are marginally abnormal.

OLIGOHYDRAMNIOS

Oligohydramnios describes the condition in which the AFV is decreased relative to gestational age.⁵⁵ Quantitatively, oligohydramnios is defined as an AFV less than 300 to 500 mL after the midtrimester.^{5,55} Subjectively, oligohydramnios is described by an obvious lack of fluid, poor fluid-fetal interface, and marked crowding of fetal parts (see Fig. 20-6).⁵⁶ Semiquantitatively, it is described by an MVP less than 1 to 2 cm, a two-diameter pocket of less than 15 cm,² and an AFI less than 5 cm (see Table 20-1).^{31,35,40,55,57} As described previously, controversy exists as to the semiquantitative threshold that should be used to define oligohydramnios. Although most examiners use an AFI of 5 cm as the threshold, many use 5%. As Hill described, a single 3.2 × 2.2 cm pocket of amniotic fluid would be considered a normal AFV by Manning et al⁵⁸ but would be considered oligohydramnios by both Phelan et al⁵⁸ and Magann et al.^{11,57}

Oligohydramnios may be due to a variety of conditions, including urinary tract abnormalities such as renal agenesis, bilateral renal obstruction, bilateral renal dysplasia, and posterior urethral valves or atresia; and prenatal abnormalities, including uteroplacental insufficiency leading to IUGR, preterm premature rupture of the membranes (PROM), and post-term pregnancy. Regardless of the cause, many investigators have noted increased perinatal morbidity and occasionally fetal or neonatal death in the presence of oligohydramnios.^{34-36,44,56,59-66}

INTRAUTERINE GROWTH RESTRICTION

The earliest sonographic evaluations of the potentially growth-restricted patient recognized the important role of amniotic fluid. The first use of sonographic evaluation of

decreased amniotic fluid was in the diagnosis of the growth-restricted fetus. Manning and Platt⁶⁷ and others recognized the high incidence of oligohydramnios in these patients. In 1980, Manning, Platt, and Sipos⁶⁸ used the MVP assessment of AFV in the fetal biophysical profile score. This assessment was termed the qualitative AFV (qAFV). For the purposes of the biophysical profile score, patients with less than a 1 cm pocket in both vertical and transverse diameters are designated as having decreased AFV and given a score of 0. Those with a largest vertical and transverse pocket ≥ 1.0 cm, but ≤ 2.0 cm in vertical diameter, and ≥ 1.0 cm in transverse diameter are designated as having marginal qAFV. If qAFV is greater than 2.0 cm but less than 8.0 cm in vertical diameter and ≥ 1.0 cm in transverse diameter, the patient is reported as having normal qAFV. In 1984, Chamberlain et al⁵⁵ performed a retrospective analysis of the impact of abnormal AFV and perinatal morbidity and mortality in a high-risk population. The perinatal mortality rate was increased 13-fold more than normal when AFV was sonographically marginal and increased 47-fold (187.5/1000) if severe oligohydramnios was present. Initially, the finding of a single largest amniotic fluid pocket no larger than 1 cm was found to be predictive of IUGR. Unfortunately, this criterion was too stringent and not sensitive enough to allow it alone to detect these patients. Although Chamberlain et al⁵⁵ and Manning et al⁶⁸ found that a qAFV of less than 1 cm was associated with IUGR in 78.8% to 89.6% of patients referred with clinically suspected IUGR, when qAFV is used as the sole criterion in a screening test for IUGR, the sensitivity reported by other investigators ranged from 4% to 15.8%.^{56,69}

In theory, the hypoxemia resulting from poor placental perfusion results in a redistribution of cardiac output, so that the brain is protected with increased blood flow relative to the abdomen and kidneys. The decreased renal perfusion and increased antidiuretic hormone release from hypoxemia result in decreased urine output and oligohydramnios. In addition, in the presence of hypoxia, fetal lung resorption of fluid increases.¹ Opposing the diminution in AFV from uteroplacental insufficiency is the increased fluid that might result from hypoxic suppression of fetal swallowing.¹⁰ Decreased fluid in the amniotic space can result in pressure against the umbilical cord and further complicate the already decreased perfusion to the fetus. Assessment of the AFV is now an important part of antenatal evaluation, along with the nonstress test in the fetus with suspected growth restriction.

In 1983, Miyazaki and Taylor,⁷⁰ and subsequently others, demonstrated an improvement in fetal heart rate patterns of patients with oligohydramnios after saline amnioinfusion into the amniotic sac.⁷¹⁻⁷⁵ A technique often used is as follows: A bolus of room temperature saline is given (~600 mL) over a 1-hour period by infusion pump, followed by infusion of saline at 200 mL/hr until the AFI is greater than 5 cm or 8 cm.²⁴ An excellent review of the controlled trials of amnioinfusion studies appeared in a report by Kilpatrick (Table 20-4).²⁴ Although a number of investigators reported relief of variable decelerations, none of the studies demonstrated an improvement in neonatal outcome based on Apgar scores or clinically significant cord gas results.²⁴ Another less invasive technique is that of maternal hydration. A study by Kilpatrick et al⁷⁶ demonstrated an increase in the AFI of 30% when women with oligohydramnios were treated with hydration of 2 L of water.

POST-TERM PATIENTS

Post-term patients have increased morbidity with an increased risk of meconium aspiration, fetal postmaturity syndrome, and fetal death.^{65,77,78} Amniotic fluid begins to decline near term and may do so precipitously in the post-term patient. Although the relationship between decreased amniotic fluid and perinatal morbidity is not known for certain, several theories have been proposed to explain this relationship. Perhaps the most popular is that placental insufficiency in these patients results in a redistribution of cardiac blood flow such that renal perfusion is decreased, resulting in oligohydramnios, whereas cerebral blood flow is increased. A report by Bar-Hava et al⁷⁷ showed that this mechanism is unlikely to play a major role in the post-term patient and that increased reabsorption in the fetal kidneys may be more important. An interesting 1999 report by Sylvester and Divon⁷⁸ examined the relationship among gestational age, birthweight, and AFV in 758 consecutive nondiabetic post-term patients (≥ 41 weeks gestation). AFI was obtained within 3 days of delivery. The relationship between AFI and birthweight was best described as a linear equation, whereas that between AFI and gestational age was insignificant; regression analysis yielded a very wide scatterplot. In the small-for-gestational-age, appropriate-for-gestational-age, and large-for-gestational-age groups, the mean AFI (incidence of oligohydramnios) was 8.0 cm (28%), 10.5 cm (11%), and 11.8 cm (3%), respectively. In these same groups, the mean gestational age was 41.6 weeks, 41.6 weeks, and 41.5 weeks, respectively. The authors concluded that AFI is independent of gestational age and strongly dependent on birthweight. If confirmed, this would indicate that the progressive decrease in AFI seen in post-term patients is a pathologic rather than a physiologic process. Morris et al⁷⁹ evaluated the utility of the measurement of the amniotic fluid index and the single deepest pocket measurement in patients with prolonged pregnancy. They found that the

AFI is superior to a measure of the single deepest pocket as an assessment of the fetus at or after 40 weeks, but has a poor sensitivity for adverse pregnancy outcome. Their conclusion: "Routine use is likely to lead to increased obstetric intervention without improvement in perinatal outcomes."

PULMONARY HYPOPLASIA

Patients with prolonged oligohydramnios from any cause—whether renal, preterm PROM, and so on—are at increased risk for pulmonary hypoplasia, which is invariably fatal. It has long been known that amniotic fluid is an important factor in the normal development of the fetal lungs. What has been less clear is the manner in which oligohydramnios interferes with this normal developmental process. There are normally four stages of fetal lung development: embryonic, from conception to the 5th week; pseudoglandular, from the 5th to the 17th week; canalicular, from the 16th week to the 24th week; and terminal sac or alveolar period, from the 24th week to term and beyond. By the 16th week of gestation, all of the branches of the tracheobronchial tree up to the terminal bronchioles are established.⁸⁰ Oligohydramnios, resulting in pulmonary hypoplasia characterized by inadequate development of pulmonary acini and restricted vascularization, normally occurs during the canalicular stage of development. Several theories have been postulated in the past to explain pulmonary hypoplasia in patients with severe oligohydramnios: abnormal fetal breathing, increased pressure on the fetal thorax, and abnormal pulmonary fluid egress.⁸⁰ Abnormalities of fetal breathing are unlikely to be the cause because normal fetal breathing movements occur in animals as well as in humans with oligohydramnios-related pulmonary hypoplasia. Compression of the fetal thorax is also an unlikely cause because amniotic sac pressure in patients with oligohydramnios is low. Normally, the pressure in the amniotic space is between 1 and 14 mm Hg. When oligohydramnios is present and the membranes are intact, the intra-amniotic pressure is ≤ 1 mm Hg.^{11,81} It has been postulated that fetal lung fluid acts as an internal stent for the developing surrounding lung.⁸² Normally, the upper airways produce resistance to the egress of fluid out of the trachea. In the presence of oligohydramnios and low amniotic pressure, it is theorized that the pressure gradient results in the loss of this lung fluid.⁸¹ In addition, interesting work by Harding, Hooper, and Dickson⁸³ in sheep showed that the rise in pulmonary airway pressure relative to amniotic sac pressure may also be caused by increased spinal flexion and resulting increased abdominal and thoracic pressure in the fetus with oligohydramnios. In this 1996 study, Kilbride, Yeast, and Thibeault⁸⁴ evaluated patients who experienced PROM less than 29 weeks' gestation. Most patients did not experience a change in amniotic fluid status over time; however, as many as 20% of patients did. Although the prognosis was dismal and the likelihood of pulmonary hypoplasia was great in the group in which the amniotic fluid pockets were less than 1 cm, there was no association between patients with moderate oligohydramnios (1 to 2 cm pockets) and pulmonary hypoplasia. Thus, on the basis of this study, it is inappropriate to group all patients with an AFI less than 5 cm together in an attempt to prognosticate the development of pulmonary hypoplasia.

PREMATURE RUPTURE OF MEMBRANES

PROM is rupture of the amniotic sac before the onset of uterine contractions. This is reported to occur in approximately 10% of pregnancies at term and between 0.7% and 2.0% of pregnancies before 37 weeks.^{64,85} PROM occurring at term is usually managed by induction of labor; however, preterm PROM is often treated conservatively. Although most patients at term will begin labor soon after membrane rupture, the earlier in gestation that membrane rupture occurs, the more likely it is that the latency period will be long.⁶⁴ Patients who experience rupture early in pregnancy have the added risk of pulmonary hypoplasia. Pulmonary hypoplasia has been reported in patients with PROM, particularly when the rupture occurs before 26 weeks and when the duration of the rupture is at least 2 weeks and often greater than 5 weeks.⁸⁶ As mentioned, a critical amount of amniotic fluid is necessary for normal lung development to occur. Lack of fluid, as might occur with PROM, results in a lack of the normal internal stenting force in the developing fetal lungs. The likelihood of pulmonary hypoplasia is dependent as much on the time of membrane rupture as the amount of residual fluid and duration of oligohydramnios.

Patients with preterm PROM are at increased risk for chorioamnionitis (between 25% and 46%), fetal morbidity, and death (between 37% and 78%).⁸⁷ The likelihood of these complications is dependent on the timing of membrane rupture, amount of residual amniotic fluid, and duration of persistent oligohydramnios. Hadi, Hodson, and Strickland⁶³ reported an overall survival rate of 55%. When delivery occurred before 25 weeks of gestation, 6.7% survived. For the cases delivered between 26 and 34 weeks of gestation, the survival rate was 89.4%. Although the prognosis is often poor when membrane rupture occurs early, it is not universally grave for all patients. Several series reported resealing of the leak, with reaccumulation of fluid and normal outcomes.^{88,89} These events, although uncommon, must be considered at the time of counseling.

Aside from the issues of pulmonary hypoplasia, patients with PROM have a higher incidence of cesarean section for fetal distress than do patients with oligohydramnios from other causes. In Sarno, Ahn, and Phelan's⁹⁰ study, the cesarean section rate for fetal distress was 19% for PROM compared with less than 1% for other causes of oligohydramnios. Even when the evidence is overwhelming that PROM is the likely explanation for decreased fluid, the fetal urinary bladder should be identified to exclude renal agenesis as the primary cause.

INTRAPARTUM OLIGOHYDRAMNIOS IN HIGH-RISK PATIENTS

In the past decade, a number of studies reported that oligohydramnios (defined as an AFI \leq 5 cm) in laboring patients was associated with a poor peripartum outcome. As such, there are centers in which the results of the AFI are used to triage patients. However, an increasing number of reports have disputed the utility of a low AFI for predicting outcome. Chauhan et al⁹¹ in 1997 found that the sensitivity and positive predictive values of an AFI less than the fifth percentile for gestational age to predict a pH less than 7.00

were 0.8% and 22%, respectively, and for an AFI less than or equal to 5.0 cm, 0.5% and 11%, respectively. In this study, "receiver-operator characteristic curves indicated that an AFI between 0 and 20 cannot predict accurately which patients will have cesarean sections for distress or be delivered of a newborn with a low Apgar score at 5 minutes or a pH less than 7.10." The patients in this study were high risk, with either medical or obstetric complications. In two studies, patients having an intrapartum assessment of AFI were significantly more likely to have abdominal delivery for presumed fetal distress without improving perinatal outcome.^{61,92} In a randomized, controlled trial, Alfirevic et al⁹³ compared the impact of the AFI and maximum pool depth on the incidence of obstetric interventions in post-term pregnancies. Compared with maximum pool depth, the AFI led to more obstetric interventions without any impact on perinatal outcome. Recently, Ott⁹⁴ performed a study to assess the relationship of AFV and perinatal outcome. As he stated, "AFI is a weaker predictor of perinatal outcome than has been classically suggested. Although the AFI identification of polyhydramnios was helpful in identifying LGA fetuses and fetuses at risk for congenital abnormalities, oligohydramnios was a rather weak predictor of poor perinatal outcome. There was an increased risk of nonreassuring fetal heart rate patterns during labor for the oligohydramnios patient, but only in preterm patients." In his report, he summarized some of the studies showing similar findings. Garmel et al⁹⁵ studied 65 patients with oligohydramnios and found a higher incidence of premature delivery, but no increase in IUGR, perinatal death, or birth asphyxia. Kreiser et al⁹⁶ evaluated 150 low-risk patients and found no increase in poor perinatal outcome in cases of isolated oligohydramnios. Magann et al⁹⁷ studied 1001 high-risk patients and reported that oligohydramnios was a poor diagnostic test to predict poor outcome. Other investigators have found similar results.^{91,96,98-100} In a meta-analysis of the relationship between AFI and perinatal outcome, Chauhan et al¹⁰¹ came to the conclusion that there was an association between oligohydramnios and an increased incidence of cesarean delivery for nonreassuring fetal heart rate patterns and low Apgar score; however, insufficient data related it to neonatal acidosis, and called for further prospective studies with large enough numbers to properly evaluate the relationship. A large study by Morris et al⁷⁹ found that AFI has a poor sensitivity for adverse pregnancy outcome, and was likely to lead to increased obstetric intervention without improving outcome. To compound the controversy, a number of studies have compared AFI to actual AFV, determined by the dye-dilution technique, and found that the AFI was an unreliable technique for accurately estimating amniotic fluid.^{43,102}

FREQUENCY OF AMNIOTIC FLUID VOLUME ASSESSMENTS IN THE HIGH-RISK PATIENT

A final question that should be addressed is how frequently one should perform semiquantitative assessment of AFI during antepartum testing in the high-risk patient. Wing et al¹⁰³ and Lagrew et al¹⁰⁴ evaluated this issue. Wing et al concluded that, for patients at less than 41 weeks' of gestation undergoing antepartum testing, weekly assessment of AFI is

probably adequate if the initial measurement is in the normal range (≥ 8 cm) because the risk of having oligohydramnios within 4 days is only 1.7% and within 7 days only 2.2%. As they stated in their report, "for patients at less than 41 weeks of gestation whose initial amniotic fluid index measurement is in the low-normal range (5 to 8 cm), twice-weekly assessment is justified on the basis of a higher risk for an amniotic fluid index ≤ 5 cm within 4 days (12.3%). For all patients at ≥ 41 weeks of gestation, twice-weekly amniotic fluid index assessments are recommended regardless of the initial measurement." In 1992, Lagrew et al¹⁰⁴ addressed the issue of frequency for amniotic volume assessment. They concluded that there is a minimal risk ($< 0.5\%$) for oligohydramnios in the 4 days after a normal AFI; therefore, AFI measurements in patients less than 41 weeks of gestation should be performed weekly.

OTHER CONDITIONS ASSOCIATED WITH OR CAUSATIVE OF OLIGOHYDRAMNIOS

There have been reports of oligohydramnios complicating chorionic villus sampling procedures. In a 1991 series by Cheng et al,¹⁰⁵ oligohydramnios developed in 2.7% of chromosomally normal pregnancies versus 0% in the control amniocentesis group. They theorized that chorionic villus sampling may cause a placental or endometrial injury that may result in perigestational hemorrhage. This, in turn, may result in altered fetoplacental perfusion. In their series, none of the patients in whom oligohydramnios developed survived.

Bronshtein and Zimmer¹⁰⁶ reported an association between oligohydramnios in the early second trimester, chorioamniotic separation, and fetal malformations. Nine patients with oligohydramnios and chorioamniotic separation were identified among 7000 women who underwent a transvaginal ultrasound examination at 15 to 16 weeks' gestation before any invasive procedure. Oligohydramnios was defined as a reduced amount of amniotic fluid, a distance of more than 1 cm between the chorion and amnion, and a good turgor of the amnion without floating membranes or intrauterine sheets. Fetal malformations were observed in all nine patients. In four of six fetuses for which chromosomal analysis was available, an abnormal karyotype was found (three cases of trisomy 18, one case of trisomy 21). They hypothesized that in malformed fetuses the secretion of fluid across the skin was reduced or that fetal malformations are associated with some defects in the structure of the amniotic membrane, which may lead to a reduced compliance or decrease in the ability to produce amniotic fluid. Another potential explanation may be leakage of amniotic fluid through a small hole in the amnion and accumulation of the fluid in the extra-amniotic space.

Prostaglandin inhibitors such as indomethacin can cause a dramatic reduction in the volume of amniotic fluid, probably as a result of decreased fetal urine production. The fetal kidneys are sensitive to indomethacin as early as 21 weeks' gestation and may respond to the drug's effects as early as 5 hours after administration. The effect is usually reversed after discontinuation of the drug. This side effect of the medication is used at times in patients with polyhydramnios to decrease the amniotic fluid through maternal ingestion.

OLIGOHYDRAMNIOS AND ASSESSMENT OF FETAL WEIGHT AND MALFORMATIONS

Two other issues that should be discussed are the impact of oligohydramnios on estimation of fetal weight and the detection of congenital malformations. Barnhard, Bar-Hava, and Divon¹⁰⁷ reported clinical and sonographic intrapartum fetal weight estimates in singleton term patients with decreased amniotic fluid volume. In addition to standard biometry for estimation of gestational age and fetal weight, amniotic fluid was assessed. Oligohydramnios was defined as an AFI equal to 5 cm. The authors found that clinical and sonographic estimated fetal weights were significantly less accurate in patients with oligohydramnios than those derived from patients with normal amniotic fluid. The incidence of clinical and sonographic estimated fetal weights within $\pm 10\%$ of the actual birthweight was 70.1% and 68.4%, respectively.

Levine et al¹⁰⁸ studied the effect of oligohydramnios on the detection of fetal anomalies with sonography. They evaluated a group of patients with ruptured membranes to determine the effect of oligohydramnios on the detection of anomalies and compared the results with those of a control group. Although anomalies were missed in both groups, they were of the type known to be difficult to diagnose antenatally and frequently missed on sonography (hand abnormalities and cardiac anomalies). The authors concluded that most "serious" noncardiac anomalies are detected even in the presence of oligohydramnios.

POLYHYDRAMNIOS

Polyhydramnios is an excessive accumulation of amniotic fluid at some time during pregnancy. Its incidence varies from 0.2% to 3.3%¹⁰⁹⁻¹¹² and depends on how this abnormality is defined (described later). The author prefers the use of the term *polyhydramnios* rather than *hydramnios*, which may often be used to describe the same condition. Pathologically and clinically, it is defined as an excess of amniotic fluid, greater than 1500 to 2000 mL.^{5,113} Although a reasonably accurate assessment of excessive amniotic fluid can be made with dye-dilution studies, for many years the diagnosis was made and confirmed at delivery, a less than ideal way to estimate volume accurately. Before ultrasound, the diagnosis was made when the fundal height exceeded the patient's gestational age or there was difficulty in palpating fetal parts or auscultating the fetal heart.¹¹⁴ In the past 20 years, ultrasound has played a pivotal role in correctly making this diagnosis in the patient who presents "large for dates." The methodology used to arrive at this diagnosis varies tremendously and is controversial. Most clinicians agree that ultrasound is the appropriate tool to estimate AFV. More than two decades ago, one of the first sonographic techniques used for the diagnosis of polyhydramnios was the total intrauterine volume.^{115,116} The diagnosis of polyhydramnios was made if the total intrauterine volume exceeded 1 standard deviation above the mean volume for gestational age. This technique was cumbersome and was soon abandoned.¹¹⁴ It became apparent to many sonologists that a subjective estimate of amniotic fluid (defining polyhydramnios when a fetus in the mid- to late second or third

FIGURE 20-16. Sonogram of a patient with marked polyhydramnios. The fetus is surrounded and virtually floating in the amniotic fluid.

FIGURE 20-17. Sonogram of a fetus with polyhydramnios resulting from gastrointestinal tract obstruction. A pocket of amniotic fluid larger than 8 cm is seen.

trimester appears to float in the amniotic fluid, displaced away from the anterior uterine wall or placenta) could be readily obtained (Fig. 20-16). Other sonologists measure the single deepest AFV pocket (defining polyhydramnios when the deepest pocket is greater than 8 cm), and still others use the AFI (a summation of the deepest pocket in four cord and extremity-free quadrants in the gravid uterus; here, polyhydramnios exists when the AFI is greater than 24 cm) (Fig. 20-17).^{33,117,118} It is unlikely that any cases of true polyhydramnios escape detection when the AFV is analyzed subjectively by even a moderately experienced examiner. The greater problem is that too many false-positive diagnoses are likely when only subjective criteria are used. Many cases of normal pregnancies in the early second trimester may appear to have too much amniotic fluid. Care must be taken to avoid diagnosing polyhydramnios under this circumstance. Likewise, many cases of mild polyhydramnios occur in pregnancies with normal fetuses and normal pregnancy outcomes. For this reason, the author prefers to use the subjective assessment as a first line of screening and apply objective measurements such as the AFI when the amniotic fluid seems excessive.

An interesting study by Carlson et al¹¹⁹ attempted to compare the utility of subjective estimation of the severity of polyhydramnios (mild, moderate, and severe) versus the AFI value of greater than 24 cm and assessment of the single deepest amniotic fluid pocket. Using the description of severe polyhydramnios, they found only 11 of 24 anomalies versus 22 of 24 anomalies using an AFI of greater than 24 cm. In their study, not only did an AFI of greater than 24 cm predict 49 of 50 cases of true polyhydramnios confirmed at delivery, but this measurement also included 92% of all anomalies and 100% of all trisomies and fetal and neonatal deaths. These results include seven patients in whom the AFI was less than 24 cm but one pocket of fluid that was greater than 8 cm. None of these fetuses or neonates had fetal anomalies, aneuploidy, perinatal death, neonatal intensive

care unit admission, or a diagnosis of polyhydramnios at delivery.

Polyhydramnios can result from a variety of maternal and neonatal disorders, and it may either be acute or chronic. Acute polyhydramnios, which may appear within days and is uncommon, usually occurs in the second trimester.⁵⁵ Chronic polyhydramnios occurs gradually, usually in the third trimester, and is often asymptomatic. Polyhydramnios often resolves spontaneously, and when it does, the pregnancy is not associated with increased morbidity and mortality.^{120,121}

A variety of conditions, maternal and fetal, are known to be causative or associated with polyhydramnios (Table 20-5). Perhaps the most notable maternal disorder associated with polyhydramnios is diabetes mellitus. Most series mention diabetes mellitus as a common cause of increased amniotic fluid. These cases, under further examination, almost always involve patients with poor diabetic control and, as is discussed later, are associated with macrosomia. Erythroblastosis fetalis and associated hydrops may result in polyhydramnios. For that matter, fetal conditions resulting in hydrops often manifest polyhydramnios.

Fetal structural and chromosomal abnormalities are responsible for a significant number of polyhydramnios cases. The degree of polyhydramnios correlates with the probability that an anomaly will be detected. In Damato et al's¹²² study of patients with sonographically documented polyhydramnios, in the lowest ranked group (MVP depth, 8 to 9.5 cm), 50% of fetuses manifested an anomaly, whereas in the highest rank (MVP, 16.0 cm or greater) 88% had anomalies. Central nervous system (CNS) abnormalities were once the most common cause for polyhydramnios resulting from fetal structural abnormalities. This is no longer true, perhaps in part because of recognition of severe CNS abnormalities in the second trimester resulting in termination before the development of polyhydramnios. Gastrointestinal tract abnormalities are now perhaps the most common structural cause; atresia or obstruction (that is, duodenal atresia or

esophageal atresia) is the likely explanation (Fig. 20-18). These atresias, which are proximal to the distal large bowel and colon, interfere with the normal absorption of water and result in excessive amniotic fluid. Patients with these abnormalities may not manifest polyhydramnios either at all or not until the third trimester of pregnancy (absence of polyhydramnios should not exclude the diagnosis of gastrointestinal tract obstruction) (Fig. 20-19). In fetuses with esophageal atresia, polyhydramnios may develop in only 40% of cases.¹²³ In an animal study in which esophageal ligation was performed, Gilbert and Brace demonstrated that intramembranous absorption of amniotic fluid increased dramatically and thus may explain in part the failure for polyhydramnios to occur in those fetuses who are unable to swallow normally due to obstruction.¹²³⁻¹²⁵

Other fetal structural defects include cardiovascular, urinary tract abnormalities, and skeletal abnormalities. Two urinary tract abnormalities, congenital mesoblastic nephroma

FIGURE 20-18. Sonogram of a patient with esophageal atresia and polyhydramnios. Absence of the fetal stomach (arrow) and increased amniotic fluid (asterisk) are seen.

FIGURE 20-19. Sonogram of a patient with duodenal atresia detected in the second trimester. A dilated stomach and proximal duodenum are seen; however, the amniotic fluid volume is normal. D, duodenum; S, stomach.

and unilateral ureteropelvic junction obstruction, may be associated with polyhydramnios (Fig. 20-20).¹²⁶⁻¹²⁸ Although somewhat paradoxical, the polyhydramnios associated with ureteropelvic junction obstruction may be due to impairment of the concentrating ability of the kidney, resulting in high urine output. The association of lethal skeletal abnormalities with polyhydramnios is also interesting. Although no good explanation for this association has been presented,

FIGURE 20-20. Sonogram demonstrating polyhydramnios (asterisk) in a patient with unilateral ureteropelvic junction obstruction (arrow).

there is no question that this association exists. Twin pregnancy, particularly monochorionic, can be associated with marked polyhydramnios owing to twin-to-twin transfusion syndrome. Movement disorders, akinesia, and hypokinesia may be associated with polyhydramnios.¹²⁹ Aberrant fetal movements with associated polyhydramnios have been reported in cases of myotonic dystrophy and congenital myasthenia gravis.¹³⁰⁻¹³² Maternal symptoms may be lacking, and these cases may appear normal sonographically. Medications may be associated with polyhydramnios. The ingestion of lithium is thought to cause polyhydramnios by causing fetal diabetes insipidus as well as cardiac decompensation.^{114,133}

When no structural abnormalities are detected, polyhydramnios is said to be idiopathic. Before reaching this conclusion, two other entities should be considered: growth disturbances and chromosomal abnormalities. Studies comparing patients with normal AFV and those with polyhydramnios found a significantly higher incidence of fetuses with birth weights greater than 4000 g or greater than 90th percentile weight for gestational age in the polyhydramniotic group.¹³⁴ Benson, Coughlin, and Doubilet¹³⁵ evaluated the utility of AFV in the diagnosis of the large for gestational age fetus in nondiabetic patients. Polyhydramnios occurred more frequently in large for gestational age fetuses than in not large for gestational age fetuses (17% versus 8%) but had little effect on the positive predictive value of a fetal weight estimate above the 90th percentile. Of interest, the combination of oligohydramnios and a fetal weight estimate below

the 90th percentile virtually excluded the possibility of a large for gestational age fetus.

There is an increased incidence of chromosomal abnormalities when polyhydramnios is associated with morphologic fetal abnormalities. Brady et al,¹³⁶ Zahn, Hankin, and Yeomans,¹³⁷ Barnhard, Bar-Hava, and Divon,¹⁰⁹ and Sickler et al¹³⁸ demonstrated an increased incidence of karyotype abnormalities when polyhydramnios was present with either associated morphologic abnormalities or IUGR. In the absence of sonographically detected morphologic abnormalities, amniocentesis is not absolutely indicated.¹⁰⁹

POLYHYDRAMNIOS: MORBIDITY AND AMNIOREDUCTION

Aside from association with fetal and maternal abnormalities, polyhydramnios itself may result in perinatal morbidity. The reported prevalence of preterm births with polyhydramnios is between 11.1% and 29.4%.¹³⁹ In studies by Many et al,^{140,141} the prevalence of prematurity was highest among those with malformations (39%) followed by those with diabetes mellitus (22.2%). In addition, abdominal pain and premature uterine contractions may lead to PROM and preterm delivery. Rupture of the membranes with sudden decompression of the uterus may lead to abruptio placentae.

In patients with severe polyhydramnios and difficulties with pain and breathing, therapeutic amniocenteses are often performed. The sonographic endpoint in patients having a therapeutic amniocentesis is either an AFI less than 24 cm or a maximal deepest pocket less than 8 cm.¹⁴² Elliott et al¹⁴² evaluated large volume fluid removal in patients with polyhydramnios. Ninety-four patients had 200 therapeutic amniocenteses for the following indications: twin-to-twin transfusion syndrome, 36 (38%); idiopathic, 24 (26%); diabetes mellitus, 11 (12%); fetal anomalies, 11 (12%); chromosomal anomalies, 5 (5%); twins (not twin-to-twin transfusion syndrome), 4 (4%); and other, 3 (3%). The mean AFV removed at each therapeutic amniocentesis was 1666 mL. The mean rate of fluid removed was 54 mL/minute. Patients with twin-to-twin transfusion syndrome required more repeat therapeutic amniocenteses (3.4 per patient) than other diagnoses (1.4 per patient). The mean gestational age at the time of the first therapeutic amniocentesis was 29 weeks 6 days. Indications for amnioreduction included either symptoms or acute abdominal distension. An 18-gauge spinal needle was used, with the tip in a cephalic direction. This allowed the needle to move up to 180 degrees as the uterus became smaller with decompression. Suction was used (1000 mL over 20 minutes). Delivery was delayed to a median gestational age of 37 weeks. There were complications in three patients: ruptured membranes occurring in one patient (1 day after her seventh amniocentesis), chorioamnionitis 18 hours after amniocentesis, and placental abruption. Although 33% of patients were given tocolytic drugs, there were no deliveries within 7 days of a procedure for "unstoppable" preterm labor. Leung et al¹⁴³ followed prospectively all patients with polyhydramnios treated with rapid amniodrainage under continuous ultrasound guidance using a vacuum wounder-drainage system from 1995 to 2002 in a university teaching hospital. In the group of 70 patients with 130 procedures, there were four procedure-related complications representing a 3.1% complication rate.

FIGURE 20-21. Sonogram in a patient with marked polyhydramnios. The placenta (P) becomes thin as the uterus expands from the increased amniotic fluid volume.

Because fluid often tends to reaccumulate rapidly, other noninvasive pharmacologic treatments of polyhydramnios have been sought. Currently, maternally ingested prostaglandin synthetase inhibitors such as indomethacin are used to treat polyhydramnios.^{144,145} Indomethacin freely passes the placental barrier and can be detected in fetal blood within 15 minutes after administration. Its main mechanism of action is in the reduction of fetal urine output. Two potential ill effects of this treatment may be overtreatment with resultant oligohydramnios and premature closure of the ductus arteriosus. These may often reverse with cessation of treatment.

IMAGING CONSIDERATIONS IN POLYHYDRAMNIOS

Patients with polyhydramnios present several diagnostic imaging challenges to the sonologist. Because the fetus has a large volume of fluid surrounding it, excessive movement may make attempts at interrogation of an organ or structure difficult. Likewise, the fetus may be positioned deep within the uterus, far from the ultrasound transducer and beyond ideal imaging zone ranges for an individual transducer. Occasionally, having the patient turn on her side may make imaging easier momentarily. As the uterus expands because of excessive fluid, placental thickness tends to decrease. A placenta that measures 35 mm in an anteroposterior dimension at 34 to 35 weeks gestation in a patient with hydrops fetalis and severe polyhydramnios may in fact be abnormally thickened (see Figs. 20-10 and 20-21). This is similar to the patient with chronic obstructive pulmonary disease and cardiac failure who has a large barrel chest with what appears to be a normal-sized heart. The heart may

FIGURE 20-22. Sonogram from a patient with a diamniotic dichorionic twin pregnancy. Subjective evaluation revealed normal amniotic fluid in each gestational sac on either side of the amniotic membrane (arrow).

be abnormally enlarged but appear normal because of elongation and compression by overdistended lungs.

TWINS AND ABNORMALITIES IN AMNIOTIC FLUID VOLUME

Multiple gestations and twins in particular present a unique set of diagnostic difficulties with regard to amniotic fluid assessment. In the rare occurrence of monoamniotic twins, individual fluid compartments no longer exist; thus, standard subjective and semiquantitative assessments of AFV are more difficult. Although subjective evaluations of amniotic fluid in diamniotic pregnancies can be readily made, semiquantitative evaluation of AFV using the AFI can only be performed if modifications are made to the original protocol (Fig. 20-22). When a diamniotic twin pregnancy is evaluated sonographically, a question often asked is, "What is the normal expected amniotic fluid volume in each sac?" Magann et al¹⁴⁶ performed a dye-dilution study of 45 diamniotic twin pregnancies to determine the AFV. The AFV per amniotic sac ranged from 155 to 5430 mL, with a mean of 877 mL. This value is comparable to or slightly higher than the AFV reported for third trimester singletons. The AFV in individual amniotic cavities and the total of both cavities in the diamniotic twin pregnancies in their study were unchanged across the entire gestational age range (27 to 38 weeks). Several innovative semiquantitative methods have been attempted to assess AFV in twin gestations (that is, AFI of each sac or a modified AFI in which each sac is divided into two portions).¹⁴⁷ Watson et al¹⁴⁸ assessed AFI of the total volume of the uterus without regard for the amniotic membrane (Fig. 20-23). Magann et al¹⁴⁹ found that an additional method of performing a standard AFI measurement while disregarding the amniotic membrane is too inaccurate to be clinically useful.

In cases of monochorionic diamniotic twins, the ominous complication of twin-to-twin transfusion syndrome may

FIGURE 20-23. Amniotic fluid index values as a function of gestational age in 210 uncomplicated twin pregnancies (without regard for the intervening amniotic membrane). Dark squares indicate means, and bars indicate one standard deviation. (From Watson WJ, Harlass FE, Menard MK, et al: *Sonographic assessment of amniotic fluid in normal twin pregnancy*. *Am J Perinatol* 12:123, 1995.)

develop. This occurs as a result of transplacental communication with vascular anastomoses between the circulations of the twins. The twins are often discordant in size; the recipient, larger twin resides within a polyhydramniotic sac and the donor, smaller growth-restricted twin within an oligohydramniotic sac (Fig. 20-24). Because the oligohydramnios may be severe (virtually no amniotic fluid) in the donor twin sac one must be careful not to assume that the fluid surrounding the donor is in the donor sac (Fig. 20-25A). More often than not, the fluid adjacent to the donor twin in a case of severe twin-to-twin transfusion syndrome is that of the recipient's sac. One visual clue that may be helpful is that the fluid in the donor sac may have a different echogenicity (often increased) compared with the recipient (Fig. 20-25B). Because of the high mortality for one or both twins (70% to 100%), a number of innovative interventional procedures have been attempted to alleviate this condition, including amnioreduction of the polyhydramniotic sac, laser occlusion of placental vessels, and amniotic septostomy.^{150,151} Historically, the most widely used technique was serial amniocenteses of the polyhydramniotic sac. Numerous reports attested to the value of this technique in not only relieving excessive fluid but allowing a normalization of growth of both twins and a significant decrease in perinatal mortality.¹⁵¹⁻¹⁵³ In sites performing amnioreductions, real-time ultrasound guidance is used for entrance into the recipient's amniotic sac.¹⁵⁴ An effort is made to avoid the intertwin membrane and, thus, the gestational sac of the donor twin so as not to perform an unintentional septostomy. An 18-gauge needle is introduced into the amniotic cavity with polyhydramnios, and then connected to either wall suction or a syringe attached to extension tubing in an effort to actively drain the amniotic fluid, thereby reducing the total procedure time. Fluid is

FIGURE 20-24. Sonogram of a patient with a mono chorionic twin pregnancy with twin-to-twin transfusion syndrome. A. The donor fetus in the oligohydramniotic sac (arrow) is "stuck" to the anterior uterine wall. B. The recipient fetus is in a polyhydramniotic sac (asterisk). Often the dividing amniotic membrane cannot be identified.

removed until the deepest vertical pocket is less than or equal to 6 cm, or a total of 5 L is removed. Although the exact mechanism that improves this condition after amnioreduction is not known, it is likely due to relief of pressure on poorly supported vessels of a velamentous insertion or to improvement in blood flow of balanced vascular anastomoses.^{155,156} Inadvertent or purposeful amniotic septostomy may also allow a normalization of amniotic fluid in both amniotic sacs.¹⁵² This procedure is not without complications. Monoamniotic twins, umbilical cord entanglement, and fetal death have been reported after amniotic septostomy.¹⁵⁷

FIGURE 20-25. A. Sonogram of the fetal abdomen and surrounding amniotic fluid in a case of twin-to-twin transfusion syndrome. At first glance the fluid surrounding the donor abdomen appears to reside within its amniotic sac. In fact, there is only a small amount of hyperechogenic fluid (*arrow*) seen within the amniotic sac that enshrouds the fetus. B. Sonogram of the two amniotic sacs in a pregnancy with twin-to-twin transfusion syndrome. The amniotic fluid (*arrow*) surrounding the donor twin (Do) is more echogenic than the fluid in the recipient sac (Re).

Conclusion

In adult medicine, physical examination of the patient plays a crucial role in the assessment of health. The vital signs (heart rate, respiratory rate, temperature, urine output, state of alertness and activity) are universally used in the detection of health or disease. Similarly, the Apgar score for evaluation of the newborn assesses pulse rate, respiratory effort, appearance, tone, and responsiveness. The advent of real-time ultrasound has made it possible to perform a similar direct examination of the fetus in order to evaluate its state of health. In 1980, Manning and colleagues¹ introduced a biophysical profile (BPP) for evaluation of the fetus. This score consisted of five parameters: fetal breathing movements, gross fetal movements, fetal tone, fetal heart rate, and fetal urine output (amniotic fluid volume). This chapter reviews the role of the original BPP, and its modifications (Tables 21-1 and 21-2),^{1,2} in the evaluation of fetal health. Importantly, we review the basic physiology and pathophysiology of the various components of the fetal BPP, and the role of each component or combination of components in predicting fetal asphyxia, and discuss the clinical applications of the BPP in high-risk patients.

The main objectives of any fetal surveillance modality are twofold: first, to identify fetuses at risk of intra- or extrauterine death or severe morbidity, and second, to identify these potential threats early enough to allow interventions to prevent adverse outcomes. In order to understand how to best evaluate the state of health of the fetus, it is important to realize that fetal disease may arise from a number of different pathways, and that tests of fetal well-being should be appropriate for the specific pathologic

condition that is proposed to put the fetus at risk. Thus, we recently presented an argument for condition-specific antenatal testing, because a form of surveillance that is ideal for one condition may be totally inappropriate for another.³ Electronic fetal heart rate monitoring, in the form of the nonstress test (NST) is the most frequently used method for antepartum detection of fetal asphyxia. However, this method is limited because it relies solely on the fetal heart rate for determining the state of fetal health. And although a reactive NST is efficacious in determining that the fetus is not asphyxiated at the time of testing, it is associated with high false-positive rates (50%–75%).^{4–6} Thus, an unacceptably high proportion of tested fetuses will be judged to have a nonreassuring status following an NST and may be subjected to unnecessary intervention. The BPP gives a more complete evaluation of the state of fetal health, and overcomes the problem of the high false-positive rates of the NST by assessing other parameters of fetal well-being, giving it improved diagnostic accuracy in the detection of antepartum fetal acidemia.

TECHNIQUE FOR THE BIOPHYSICAL PROFILE

The first step in performing a BPP is performing a continuous fetal heart rate tracing, called an NST (Fig. 21-1). It is considered reactive, or reassuring, if there is a normal baseline of 110 to 160 beats per minute, and there are two or more accelerations over a period of 20 minutes. An acceleration is defined as an increase of the fetal heart rate

Table 21-1 Fetal Biophysical Profile Scoring

Variable	Score 2	Score 0
Fetal breathing movements	Presence of at least 30 seconds of sustained fetal breathing movements in 30 minutes of observation	Less than 30 seconds of fetal breathing movements in 30 minutes
Fetal movements	Three or more gross body movements in 30 minutes of observation. Simultaneous limb and trunk movements are counted as a single movement	Two or less gross body movements in 30 minutes of observation
Fetal tone	At least one episode of motion of a limb from a position of flexion to extension and a rapid return to flexion	Fetus in a position of semi- or full-limb extension with no return to flexion with movement; absence of fetal movement is counted as absent tone.
Fetal reactivity	Presence of two or more fetal heart rate accelerations of at least 15 beats per minute and lasting at least 15 seconds and associated with fetal movement in 40 minutes	No acceleration or less than two accelerations of the fetal heart rate in 40 minutes of observation
Qualitative amniotic fluid volume	A pocket of amniotic fluid that measures at least 1 cm in two perpendicular planes	Largest pocket of amniotic fluid measures less than 1 cm in two perpendicular planes
Maximal score	10	
Minimal score		0

From Manning FA, Platt LD, Sipos L: Antepartum fetal evaluation: Development of a fetal biophysical profile score. *Am J Obstet Gynecol* 136:787, 1980.

Table 21-2 Criteria for Scoring Biophysical Variables (Maximal Score 12, Minimal Score 0)

Score	Criteria
Nonstress Test	
2 (NST2)	Five or more fetal heart rate accelerations of at least 15 beats per minute in amplitude and at least 15 seconds duration associated with fetal movements in a 20-minute period
1 (NST1)	Two to four accelerations of at least 15 beats per minute in amplitude and at least 15 seconds duration associated with fetal movements in a 20-minute period
0 (NST0)	One or fewer accelerations in a 20-minute period
Fetal Movements	
2 (FM2)	At least three gross (trunk and limbs) episodes of fetal movements within 30 minutes; simultaneous limb and trunk movements were counted as a single movement
1 (FM1)	One or two fetal movements within 30 minutes
0 (FM0)	Absence of fetal movements within 30 minutes
Fetal Breathing Movements	
2 (FBM2)	At least one episode of fetal breathing of at least 60 seconds duration within a 30-minute observation period
1 (FBM1)	At least one episode of fetal breathing lasting 30 to 60 seconds within 30 minutes
0 (FBM0)	Absence of fetal breathing or breathing lasting less than 30 seconds within 30 minutes
Fetal Tone	
2 (FT2)	At least one episode of extension of extremities with return to position of flexion and also one episode of extension of spine with return to position of flexion
1 (FT1)	At least one episode of extension of extremities with return to position of flexion or one episode of extension of spine with return to flexion
0 (FT0)	Extremities in extension; fetal movements not followed by return to flexion; open hand
Amniotic Fluid Volume	
2 (AF2)	Fluid evident throughout the uterine cavity; a pocket that measures 2 cm or more in vertical diameter
1 (AF1)	A pocket that measures less than 2 cm but more than 1 cm in vertical diameter
0 (AF0)	Crowding of fetal small parts; largest pocket less than 1 cm in vertical diameter
Placental Grading	
2 (PL2)	Placental grading 0, 1, or 2
1 (PL1)	Placental posterior difficult to evaluate
0 (PL0)	Placental grading 3

From Vintzileos AM, Campbell WA, Ingardia CJ, et al: The fetal biophysical profile and its predictive value. *Obstet Gynecol* 62:271, 1983. Reprinted with permission from The American College of Obstetricians and Gynecologists.

FIGURE 21-1. A. Reactive nonstress test. Fetal heart rate accelerations (*curved arrows*) of at least 15 beats per minute lasting 15 seconds or longer are readily identified in this patient. B. Nonreactive nonstress test. Lack of fetal heart rate acceleration (*arrows*). This pattern could indicate the effect of fetal sleep, medications, or hypoxia.

over the baseline of at least 15 beats per minute, and lasting at least 15 seconds.⁷ Following the NST, real-time sonography is performed to evaluate the fetal biophysical activities (see Tables 21-1 and 21-2).^{1,2} It is important that the examiner has adequate skill and experience and that appropriate technique is applied.⁸ Amniotic fluid volume measurements should be performed only in cord loop-free pockets of amniotic fluid (Fig. 21-2).⁸ Fetal breathing movements should be considered present only if they are continuous for at least 30 seconds, with breath-to-breath intervals of less

than 6 seconds.⁸ The correct plane for assessing fetal breathing movements is shown in Figure 21-3. Similarly, gross fetal movements are only considered present if three or more rolling movements of the trunk are observed within 30 minutes.⁸ Isolated limb movements do not meet the criteria for a normal score for gross fetal movements on a BPP. The examination is completed when a normal biophysical score (of 8/8 in the Manning BPP scoring system¹ or 12/12 in the scoring system described by Vintzileos et al²) has been achieved, or after 30 minutes of continuous real-time

FIGURE 21-2. Sonogram demonstrating amniotic fluid measurement as part of the biophysical profile. The amniotic fluid pocket is measured in two perpendicular planes.

FIGURE 21-3. Longitudinal sonogram of a fetus demonstrating the recommended plane of section for evaluating fetal breathing movements. Downward movement of the fetal diaphragm (D) and abdomen and an inward, rocking motion of the fetal thorax (T) can be seen when fetal breathing is present. S, stomach.

sonographic examination (see Tables 21-1 and 21-2). More than 90% of tests that are normal are completed within the first 4 minutes, and the average testing time is less than 8 minutes.⁹ Some have suggested using fetal acoustic stimulation to shorten the period for testing. Pinette and colleagues¹⁰ used acoustic stimulation in 412 women if the biophysical score was not reassuring within 5 minutes of testing, and compared these with 458 control subjects in whom acoustic stimulation was not used. They found that the fetal acoustic stimulation group required less time for testing (3 minutes), had fewer nonreassuring tests (5%), and fewer tests with no fetal breathing movements.

The two scoring systems differ; in the original BPP described by Manning et al,¹ each of five parameters were either given a score of two when normal or zero, when abnormal, with no scores in between (see Table 21-1). As a result, a fetus who had some movements and tone, but did not meet the threshold for a score of two, was awarded a score of zero, the same score as a fetus demonstrating no movement or tone whatsoever. To deal with this limitation, Vintzileos et al² in 1983 proposed another scoring system (see Table 21-2), which gave intermediate scores, and also included placental grading as one of the biophysical variables. A normal biophysical score (of >8) is considered predictive of a nonacidotic fetus. The presence of oligohydramnios in either scoring system is considered abnormal, because reduced amniotic fluid puts the fetus at risk of cord compression, death, or adverse perinatal outcomes, regardless of the scores of the other biophysical parameters. The value of the BPP is not the overall score per se, because different components of the BPP have different clinical implications.^{8,11} This is discussed further in a later section.

The Biophysical Profile: Original Findings

Before the development of the BPP, it had been noted that sonographic assessment of fetal breathing movements was as accurate a predictor of fetal well-being as the reactive NST, and that the combination of the NST with an assessment of breathing movements led to a lower rate of false-positive results.¹² This raised the prospect of using other forms of surveillance to complement fetal heart rate. In the original BPP study by Manning and co-workers,¹ which included 216 women with high-risk pregnancies, the NST was performed just before the ultrasound examination.¹ The patients were managed according to their NST results, and the physicians were blinded to the results of the other components of the BPP; therefore, these results did not influence outcomes. Although the patients were evaluated at different intervals, only the last observation was used in the assessment for the study, and in all cases, this was within a week of delivery. Outcomes assessed were the 5-minute Apgar score, incidence of fetal distress (defined as an abnormal fetal heart rate tracing necessitating emergency delivery), and perinatal mortality. The investigators found an association between abnormal biophysical scores and low 5-minute Apgar scores. They found that the absence of fetal breathing movements was most predictive of fetal distress in labor, even more so than a nonreactive NST. Importantly, no perinatal deaths occurred in fetuses with a BPP score of 10/10. The fetal death rate after a single normal test ranged from 6.1/1000 for fetuses with normal fetal tone, to 12.8/1000 for fetuses with a reactive NST.¹ This was statistically nonsignificant, but the incidence of fetal death

after any single normal parameter was much lower than that in the general population. Conversely, fetuses with any abnormal parameter had a higher death rate than that in the general population, ranging from 58.8/1000 in fetuses with a nonreactive NST, to 142/1000 in the absence of fetal movements. A lack of fetal movements, therefore, was most predictive of fetal demise.

Vintzileos and colleagues² assessed 150 high-risk pregnancies using a modified BPP that included placental grading and assigned intermediate scores for fetuses that demonstrated some biophysical activity that was insufficient to meet the criteria used in the Manning study. These authors determined that this modification of the BPP was more accurate in the identification of the hypoxic fetus than any other alternative single method.

Thus, both the original and modified BPP, tested in observational studies, demonstrated an association between abnormal biophysical scores and adverse perinatal outcome. Conversely, it showed an inverse correlation between normal biophysical scores and adverse perinatal outcomes.

Validation of the Biophysical Profile: Correlation With Perinatal Death

In 1981, Manning and colleagues¹³ published the results of a prospective study of the BPP in 1184 high risk patients. Among these patients, six perinatal deaths occurred, giving a perinatal mortality rate of 5.06/1000. This was considerably less than the previously observed perinatal death rate of 65 per 1000 births observed in a similar high-risk population in the same region the previous year.

In 1984, Baskett and colleagues¹⁴ published their findings in using the BPP in the management of 2485 high-risk pregnancies. The overall perinatal mortality was 9.2/1000. However, among those pregnancies with a normal BPP, the perinatal mortality was 1/1000. In the same year, Manning and colleagues¹⁵ published the results of the first randomized controlled trial comparing the BPP (375 patients) with the NST (360 patients). They found that the BPP had higher prediction of low Apgar scores. Although the BPP had higher sensitivity, specificity, and accuracy than the NST, these differences were not statistically significant.

In a study of 29 fetuses with a biophysical score of 0/10, Manning and colleagues¹⁶ found that almost half (48.3%) had a perinatal death. This fetal demise occurred as early as 30 minutes and as long as 11 days after the biophysical score of 0 was obtained. Although there was extremely high morbidity among fetuses with a BPP of zero, some did survive. Thus, a grossly abnormal biophysical score of zero

is not necessarily incompatible with survival after delivery; therefore, inaction based on the assumption that the prognosis is dismal is not justified. Manning et al^{17,18} further explored the use of the fetal BPP in evaluating 12,620 high-risk patients. When the BPP score was 8 or more, the perinatal mortality was 0.652 per 1000 tests; and when the biophysical score was very abnormal (score 0), the perinatal mortality rose drastically to 187 per 1000 tests, demonstrating a direct correlation between the biophysical score and perinatal mortality. The corrected false-negative rate was 0.634 per 1000. A subsequent study by the same authors reporting 19,221 high-risk pregnancies¹⁸ found that the incidence of intrauterine death after a normal biophysical score (8 or more) was only 0.726 per 1000. Manning et al,¹⁹ in a study of 26,780 high-risk pregnancies, demonstrated a strong inverse linear correlation between the biophysical score and perinatal morbidity.

These studies, and several subsequent ones tested the BPP in fairly large groups of patients,^{20,21} and provided strong evidence of its clinical usefulness, so that today the BPP is widely used in clinical practice.

PHYSIOLOGIC BASIS FOR THE BIOPHYSICAL PROFILE

Aberrations of fetal health can be divided into those that are chronic and those of acute origin; the fetal BPP is designed to assess both of these. Fetal heart rate reactivity, breathing movements, gross movements, and tone evaluate the state of fetal well-being on an acute basis, whereas the amniotic fluid volume and placental grading evaluate chronic fetal threats to fetal health. For instance, impaired uteroplacental blood and placental dysfunction may lead to redistribution of the fetal cardiac output away from nonvital organs such as the kidney, resulting in decreased fetal urinary output with resultant oligohydramnios. Variable decelerations, on the other hand, most likely reflect acute cord compression.

The individual fetal biophysical activities are dependent on initiation and regulation by specific centers in the central nervous system (CNS) (Table 21-3).⁹ Thus, the presence of any given biophysical activity implies intactness of the CNS center that regulates that activity.⁹ These individual centers are sensitive to, and can be depressed by, varying degrees of fetal hypoxemia or acidemia.⁹ Both animal and human data have demonstrated that these centers cease activity when subjected to hypoxemia at different thresholds for different centers.²² These centers can also be depressed by medications, injury, or hemorrhage. In addition, biophysical activities are subject to physiologic periodicity, so the absence of a

biophysical activity may not necessarily reflect a state of altered health. At term or near term, the fetus has cycles of periodicity of about 20 minutes; this has been likened to the circadian or diurnal cycle in adults. Thus, the duration of testing should be at least 30 minutes.

Appearance of the Components of the Biophysical Profile Across Gestational Age

The CNS centers that control the individual biophysical activities start functioning at different times during gestation (see Tables 21-3 and 21-4).²³ For instance, tone, controlled by a center in the cortex-subcortical area, is the earliest biophysical activity to appear during intrauterine life, first being observed at a gestational age of approximately 8 weeks. The next biophysical activity to appear is fetal movement, regulated by a center in the cortex nuclei, appearing at about 9 weeks of gestation; thus, the sonographic observation of both fetal movements and tone are not affected by gestational age, as long as the sonogram is performed after the first trimester. Breathing movements are the next to appear at about 21 weeks. The fetal breathing center is located in the ventral surface of the fourth ventricle. The last of the fetal biophysical activities to appear is fetal heart rate reactivity; this appears late in the second trimester or early in the third trimester, and is regulated in the posterior hypothalamus and medulla. The variations in biophysical components throughout gestation have been described by

Vintzileos et al²³ (see Table 21-4). The frequency of reactive NSTs significantly increases after 32 weeks compared with earlier gestations. In later pregnancy, however, fetal breathing and amniotic fluid volume are decreased after 40 weeks compared with earlier gestations. Grade 3 placentas appear after 32 weeks.²³ In a large study of 11,012 BPPs in 5582 women with normal perinatal outcomes, Baskett and colleagues²⁴ found that NSTs and fetal breathing movements were likely to be abnormal at 26 to 33 weeks' gestation, compared to pregnancies at later gestations. Similarly, NSTs, amniotic fluid volumes, and fetal breathing movements and tone were more likely to be abnormal after 42 weeks compared with pregnancies at 37 to 41 weeks. Interestingly, Vintzileos et al²³ and Baskett and colleagues²⁴ found that the overall frequency of reassuring biophysical scores (8 or higher) was not altered by gestational age until 41 weeks, although many of the individual biophysical components changed across gestation.

The Biophysical Profile and Fetal Acid-Base Status

In order to define the relationship between the BPP and fetal acid-base status, Vintzileos and colleagues²⁵ performed fetal BPPs on 124 nonlaboring pregnant patients at gestational ages ranging from 26 to 43 weeks immediately before cesarean delivery (Figs. 21-4 through Fig. 21-9). In all cases, umbilical arterial samples were taken for pH at delivery. This methodology avoided the long interval between

FIGURE 21-4. Relationship between the fetal biophysical profile score and cord arterial pH. (From Vintzileos AM, Gaffney SE, Salinger LM, et al: *The relationship between fetal biophysical profile and cord pH in patients undergoing cesarean section before the onset of labor. Obstet Gynecol* 70:196, 1987. Reprinted with permission from The American College of Obstetricians and Gynecology.)

FIGURE 21-5. Relationship between cord artery pH and absent fetal biophysical activities. The pH tends to be lower in the absence of movements and/or tone compared with nonreactive nonstress testing or absence of breathing. Results are expressed in means (95% error bars). No FBM, absent fetal breathing; No FM, absent fetal movements; No FT, absent fetal tone; NR NST, nonreactive nonstress test. (From Vintzileos AM, Fleming AD, Scorza WE, et al: *Relationship between fetal biophysical activities and umbilical cord blood gases. Am J Obstet Gynecol* 165:707, 1991.)

FIGURE 21-7. Relationship between cord artery carbon dioxide partial pressure (PCO₂) and absent fetal biophysical activities. The PCO₂ tends to be higher in the absence of movements or tone compared with nonreactive nonstress testing and absence of breathing. Results are means expressed in millimeters of mercury (95% error bars). No FBM, absent fetal breathing; No FM, absent fetal movements; No FT, absent fetal tone; NR NST, nonreactive nonstress test. (From Vintzileos AM, Fleming AD, Scorza WE, et al: *Relationship between fetal biophysical activities and umbilical cord blood gases. Am J Obstet Gynecol* 165:707, 1991.)

FIGURE 21-6. Relationship between cord artery oxygen partial pressure (PO₂) and absent fetal biophysical activities. The PO₂ tends to be lower in the absence of movements or tone compared with nonreactive nonstress testing and absence of breathing. Results are means expressed in millimeters of mercury (95% error bars). No FBM, absent fetal breathing; No FM, absent fetal movements; No FT, absent fetal tone; NR NST, nonreactive nonstress test. (From Vintzileos AM, Fleming AD, Scorza WE, et al: *Relationship between fetal biophysical activities and umbilical cord blood gases. Am J Obstet Gynecol* 165:707, 1991.)

FIGURE 21-8. Relationship between cord artery bicarbonate level and absent fetal biophysical activities. The bicarbonate level tends to be lower in the absence of movements or tone compared with nonreactive nonstress testing and absence of breathing. Results are means expressed in millimoles per liter (95% error bars). No FBM, absent fetal breathing; No FM, absent fetal movements; No FT, absent fetal tone; NR NST, nonreactive nonstress test. (From Vintzileos AM, Fleming AD, Scorza WE, et al: *Relationship between fetal biophysical activities and umbilical cord blood gases. Am J Obstet Gynecol* 165:707, 1991.)

FIGURE 21-9. Relationship between cord artery base excess and absent fetal biophysical activities. The base excess tends to be lower in the absence of movements or tone compared with nonreactive nonstress testing and absence of breathing. Results are means expressed in millimoles per liter (95% error bars). No FBM, absent fetal breathing; No FM, absent fetal movements; No FT, absent fetal tone; NR NST, nonreactive nonstress test. (From Vintzileos AM, Fleming AD, Scorza WE, et al: Relationship between fetal biophysical activities and umbilical cord blood gases. *Am J Obstet Gynecol* 165:707, 1991.)

biophysical assessment and delivery observed in prior studies, eliminating the effect of labor and medications on neonatal status. These investigators found the sensitivity, specificity, and positive and negative predictive values of a BPP score of less than 8 for fetal acidemia (defined as an umbilical arterial pH of <7.2) to be 90%, 96%, 82%, and 98%, respectively.²⁵ Using a combination of only a nonreactive NST and absent fetal breathing movements, they found improved sensitivity, specificity, and positive and negative predictive values for fetal acidemia of 100%, 92%, 71%, and 100%, respectively.²⁵ When movements and tone were both absent (in seven fetuses), the mean cord pH was 6.95 ± 0.06 . As the neonatal umbilical arterial pH values became lower, fetal biophysical activities disappeared sequentially (see Fig. 21-5).

The Gradual Hypoxia Concept

Vintzileos and colleagues were the first to make the observation that the biophysical activities that appear first during fetal life are the last to disappear when there is fetal asphyxia or intra-amniotic infection.²⁵ They termed this the gradual hypoxia concept.^{8,25-27} The first biophysical activities to become compromised in the presence of fetal acidemia are fetal heart rate reactivity and fetal breathing movements; these are the last biophysical activities to appear in intrauterine development (see Fig. 21-5). As fetal acidemia progresses, fetal body movements and then fetal tone sequentially become absent (see Fig. 21-5).²⁷ In fetuses with normal movements and tone but a nonreactive NST and no breathing, the incidence of acidemia was 59%, whereas fetuses with a nonreactive NST, no breathing movements, and compromised body movements and tone had an incidence of acidemia of 75%. This suggests that fetuses with no breathing movements and a nonreactive NST were more likely to be acidemic when there were no fetal movements and absent fetal tone.²⁵ These findings provide further support for the gradual hypoxia concept. All fetuses with the absence of all four biophysical activities had umbilical cord arterial pH values in the acidemic range.²⁵

Thus, when the umbilical arterial pH drops below 7.20, fetal heart rate reactivity and fetal breathing movements are abolished (see Fig. 21-5). A pH value between 7.10 and 7.20 is associated with compromised fetal body movements and fetal tone, whereas pH values lower than 7.10 are associated with absent body movements and tone (see Fig. 21-5).²⁵ When, in addition to fetal heart rate nonreactivity and absence of fetal breathing, fetal body movements and tone were absent, perinatal mortality rose to 100%.² Thus, the presence of a given biophysical activity during sonography provides important information and implies absence of malfunction of the fetal CNS center that regulates that activity, thus indirectly ruling out fetal acidemia.

The Implications of the Gradual Hypoxia Concept on the Interpretation of the Biophysical Profile

The gradual hypoxia concept brings into question the arbitrary assignment of equal weights of the individual activities in predicting fetal asphyxia in the fetal BPP. Because the individual components become compromised at different levels of fetal acidemia, it has been proposed that the overall score is less important than the results of the individual components. For instance, the presence of fetal breathing movements rules out fetal acidemia (pH <7.2). The absence of fetal movements and tone, when there are absent fetal breathing movements, if periodicity or other causes have been ruled out, suggest profound fetal compromise, and carry an increased risk of mortality or morbidity.

Manning and colleagues²⁸ also questioned the use of an equal score for each biophysical component. Perinatal morbidity outcomes of 525 fetuses were studied and compared with the last total abnormal biophysical score, as well as examining the individual score composition.²⁸ These investigators found that the accuracy of the score in predicting outcome depended primarily on the combination of the individual biophysical components rather than the total score. They found, as we had, that fetal heart rate reactivity (NST), amniotic fluid volume, and fetal breathing movements were the most powerful indicators of perinatal outcome.²⁸

Several studies demonstrated a strong association between reduced amniotic fluid volume and an increased risk of adverse perinatal outcome in a dose-response fashion.^{1,2,29,30} Chamberlain et al²⁹ found that patients with normal amniotic fluid volume (largest vertical pocket between 2 and 8 cm) had a perinatal mortality rate of 1.97 per 1000, whereas patients with marginal amniotic fluid volume (largest pocket 1 to 2 cm) and severe oligohydramnios (largest pocket <1 cm) had perinatal mortality rates of 37.7 per 1000 and 109.4 per 1000, respectively. Grade 3 placentas have been associated with an increased incidence of abnormal fetal heart rate patterns (44.4%) and abruptio placentae (14.8%) during labor.² Thus, placental grading is considered a chronic marker of fetal well-being, and some have included it in modifications of the BPP.²

In interpreting the BPP, however, it is important first to exclude normal periodicity or administration of medications that have a depressant effect on biophysical activities as

being responsible for the abnormal results. Thus, the diagnosis of acidemia should only be made after exclusion of other causes for the abnormal test.

The Effect of Preterm Premature Rupture of the Membranes on the Biophysical Profile

Vintzileos et al²³ compared BPPs from 25 to 44 weeks between patients with intact membranes and patients with preterm premature rupture of the membranes (PPROM) of comparable gestational ages. Both groups had a similar frequency of reassuring biophysical scores (equal to 8) regardless of membrane status, suggesting that the same conclusions could be drawn from the BPP score regardless of whether or not the membranes were ruptured. However, as far as the individual BPP components were concerned, PPRM was associated with increased fetal heart rate reactivity when compared with gestations with intact membranes.²³ Conversely, gestations with PPRM had a decrease in fetal breathing movements, and amniotic fluid volume in comparison with those gestations without PPRM.²³ However, there was no significant difference in fetal body movements or fetal tone between the groups, nor was there any change in the overall biophysical score between both groups. It is important to be aware of these alterations in fetal biophysical activities in patients with PPRM to avoid inappropriate interpretation of BPP results and unnecessary interventions in these patients.

The Role of the Nonstress Test in the Biophysical Profile

Manning and co-workers carried out a study evaluating only the ultrasound-monitored components of the BPP without including the NST, using the NST only if one or more of the ultrasound components were abnormal.³¹ With this method, only 2.7% of 2712 tested patients required an NST, with no compromise in perinatal outcomes.³¹ The practice of omitting the NST was subsequently challenged by Eden et al,³² who found an increased incidence of abnormal perinatal outcome in fetuses with variable decelerations during NST testing despite normal ultrasound monitored biophysical components.³² Mills and colleagues³³ evaluated 500 high-risk pregnancies with 2038 BPPs, and concluded no biophysical assessment was necessary when fetal growth was normal, but recommended twice-weekly NSTs and ultrasound assessment of fetal growth every 2 weeks in cases in which there was abnormal fetal growth. They suggested that the fetal BPP should be reserved for cases with abnormal or equivocal NST results. It is our practice to perform the NST as an integral part of our BPP.

The Biophysical Profile in the Management of High-Risk Pregnancy

The BPP has been studied in the evaluation of several specific high-risk conditions including postdate pregnancy,³⁴ diabetes mellitus,³⁵ intrauterine growth restriction,^{36,37} twin pregnancy,³⁸ and PPRM.^{39,40} Johnson and colleagues³⁴ found, in a study of the BPP in 307 postdate patients, that a

normal biophysical score was associated with a higher rate of nonintervention and, therefore, increased rates of spontaneous onset of labor. This consequently resulted in a reduction in cesarean delivery rates (15% versus 42% for patients who underwent induction of labor).³⁴ In a later study of 238 diabetic pregnancies, the same group of investigators found that fetuses with abnormal BPP scores had higher rates of intensive care nursery admissions, cesarean section (50%), operative intervention, and neonatal morbidity.³⁵ Lodeiro et al,³⁸ evaluating high-risk twin pregnancies, found the sensitivity, specificity, and positive and negative predictive values of the biophysical score in predicting fetal distress to be 83.3%, 100%, and 97.7%, respectively. Data from Manning et al⁴¹ suggest the incidence of cerebral palsy is lower in populations tested with the BPP, compared with populations in which BPP testing was not instituted. Although encouraging, these patients were monitored with other measures in addition to the BPP; therefore, the question still remains as to whether the decreased cerebral palsy rate was due solely to biophysical score assessment.⁴¹

The BPP is also a powerful tool in the evaluation of the growth-restricted fetus. Odibo and colleagues³⁷ evaluated the fetal surveillance modalities available for antepartum surveillance of the growth-restricted fetus, and concluded that the BPP was the optimal test. Ribbert and colleagues^{42,43} examined the relationship between fetal BPP results and cord blood gases from cordocentesis. These investigators found that fetal heart rate reactivity was compromised when the difference between the expected and observed pH was below 2 standard deviations (SD). Fetal breathing movements were compromised at pH values below 3 SD, and fetal body movements and fetal tone were both absent at pH values at or below 5 SD. The authors also concluded that fetal acidemia in initial stages causes fetal heart rate nonreactivity and abolishes fetal breathing movements, whereas absence of body movements and tone are late manifestations of fetal asphyxia. These findings are consistent with the gradual hypoxia concept.

A Proposed Algorithm for Using the Biophysical Profile in Clinical Practice

We present a suggested algorithm for using the BPP based on the gradual hypoxia concept in Figure 21–10.

The modified BPP describes a testing scheme using the NST with an evaluation of the amniotic fluid. Thus, this modification assesses both the most sensitive acute marker (fetal heart rate tracing) and chronic marker (amniotic fluid volume) of fetal well-being. The perinatal morbidity and mortality of the modified BPP compares favorably with that of the complete BPP^{20,21} (see Fig. 21–10). Of course, depending on the specific clinical situation, Doppler studies, including those of the uterine, umbilical, middle cerebral arteries, and the ductus venosus can also be helpful. The specific criteria used to define normal versus abnormal biophysical activities are illustrated in Table 21–5. Because fetal acidemia is ruled out when the NST is reactive, fetal examination should always start with an NST and evaluation of amniotic fluid volume. If, however, the NST is nonreactive for 40 minutes, real-time ultrasonography is performed. Because fetal breathing movements lasting more than

30 seconds are as accurate as a reactive NST in excluding fetal acidemia, once fetal breathing movements lasting more than 30 seconds are detected, the examination is terminated. If during a 30-minute real-time observation, however, all biophysical activities are absent, delivery should take place promptly. When the NST is nonreactive and there are no detectable fetal breathing movements or breathing movements lasting less than 30 seconds, extended testing is performed to differentiate between fetal asphyxia and fetal sleep. The amniotic fluid volume is always evaluated regardless of

the NST results. Oligohydramnios in term or near-term gestations, as well as in pregnancies complicated by intrauterine growth restriction is considered abnormal, and it is prudent to deliver women with oligohydramnios to avoid cord accident and in utero death. In very preterm gestations with oligohydramnios, however, delivery may be associated with high perinatal mortality due to prematurity. At gestational ages less than 26 weeks, each day of prolongation of gestation may be associated with increase in survival of 2% to 3%. Therefore, it is desirable to delay delivery as long as safely possible. In these cases, close fetal surveillance is mandatory with BPPs and fetal heart rate monitoring at least once a day. Doppler velocimetry of the uteroplacental circulation should be used in the management of preterm high-risk fetuses, especially those with intrauterine growth restriction. However, many fetuses at risk (that is, fetuses of diabetic mothers or postdate fetuses) do not suffer from reduced blood flow but from gas exchange disturbances at the trophoblastic membrane level; in these cases, it is unlikely that fetal Doppler velocimetry will be helpful.

Miller et al²¹ evaluated the false-positive and false-negative rates of their antepartum testing results using the modified BPP. Over a 4-year period, they reported on 54,617 modified BPPs performed on 15,482 patients. The false-negative rate was 0.08%. The false-positive rate was 60%; however, intervention resulting from a false-positive test resulted in iatrogenic prematurity in only 1.5% of cases. Nageotte et al²⁰ compared the modified BPP with the contraction stress test. They evaluated the outcomes of high-risk patients who had a negative modified BPP with those whose last antepartum assessment was a negative contraction stress test. Patients managed by the modified BPP had a lower incidence of adverse perinatal outcomes after reassuring testing (5.1% versus 7.0%, $p < .05$). In our experience using the modified BPP, intrauterine deaths of structurally normal fetuses occurring after a reassuring assessment is a rarity. In addition, this protocol has decreased the testing time, increased the number of tested patients, and, therefore, improved the efficiency of our unit. Management on the basis of the total BPP score rather than the individual biophysical components can result in misuse of this testing method. The most

frequent errors in interpreting and applying fetal biophysical assessment data have been described in detail.⁸

The Role of the Fetal Biophysical Profile in Detecting Intra-Amniotic Infection in Patients With Preterm Premature Rupture of the Membranes

PPROM is a leading cause of preterm birth and perinatal mortality and morbidity. When there is extreme prematurity, attempts are generally made for conservative management, prolonging gestation, with the hope of improving perinatal outcomes. However, there is often intra-amniotic infection, which jeopardizes the health of the fetus and mother. Intra-amniotic infection is an indication for delivery; yet, the commonly used modalities are imprecise in diagnosing intra-amniotic infection. Vintzileos et al⁴⁴ were the first to publish an association between abnormal fetal biophysical assessment and intra-amniotic infection in this group of patients. The initial study was observational, and the results from the biophysical assessment were not used for management.⁴⁴ Patients with PPRM were monitored with frequent (every 1 to 3 days) BPPs. None of the patients had any clinical signs of infection or labor at the time of ultrasound examination. The last BPP before delivery was correlated with the development of clinical infection. In the cases in which the interval between the last biophysical assessment and delivery was less than 24 hours, an abnormal BPP was associated with an overall infection rate of 93.7%; in contrast, a normal BPP was associated with an overall infection rate of 2.7%.⁴⁴ This strong correlation between BPP score and infectious morbidity did not exist when the testing-delivery interval was greater than 24 hours.⁴⁴ An interesting observation was that the earliest manifestations of intra-amniotic infection included a nonreactive NST and absence of fetal breathing, whereas advanced infection (fetuses that subsequently developed neonatal sepsis) was associated with compromise of both fetal body movements and tone.⁴⁴ There were no cord pH differences between infected and noninfected cases; thus, the diminished biophysical activities were attributed to infection and not acidemia. Further

studies by Vintzileos and colleagues^{39,40} have demonstrated the use of the BPP in the management of PPRM.

At least 11 further studies, none of which were randomized or controlled, have evaluated the relationship between BPP assessment and infectious outcome in patients with PPRM.⁴⁵⁻⁵⁴ There are summarized in Table 21-6. Eight of the 12 studies demonstrated an association between abnormal biophysical assessment and infectious outcomes. It is important to note that testing was done on a daily basis in those studies that demonstrated a correlation.

Five studies failed to demonstrate an association between abnormal biophysical assessment and infectious outcome. Miller et al⁴⁵ evaluated 47 patients with PPRM and did not find an association between clinical chorioamnionitis and the BPP performed within 2 days of delivery. There were no cases of fetal or neonatal sepsis in their study, and testing was performed at a frequency of 24 to 48 hours. Although it may be that clinical chorioamnionitis alone is not associated with abnormal BPP assessment, the testing frequency in this study was not optimal. Del Valle et al⁴⁸ evaluated the association between BPP assessment with regard to maternal amnionitis and neonatal sepsis. However, in this study, the frequency of testing was 48 to 72 hours, and the overall infection rate was low. In the third study by Carroll et al,⁵³ intra-amniotic infection as diagnosed by amniocentesis and cordocentesis was used as the outcome measure. They found no correlation between positive cultures and biophysical assessment. However, the majority of positive cultures were with *Mycoplasma* species.

In summary, the data suggest that the correlation between abnormal BPP and infectious perinatal outcome depends on the BPP being performed within 24 hours of delivery. In addition, colonization of the amniotic cavity with the *Mycoplasma* is not necessarily associated with an abnormal BPP evaluation.

We carried out a prospective study of 73 patients with PPRM, in which the BPP results were used for management.⁴⁰ Their outcomes were compared with two other historic groups, one managed without any invasive or fetal evaluation (control group) and the other managed with amniocentesis alone. We found that the group managed based on their BPP results developed significantly fewer

Lippincott, 1998, p 793.*)

maternal and neonatal infections. Clinical amnionitis, possible neonatal sepsis, and neonatal sepsis occurred in 5.4%, 5.4%, and 1.4%, respectively, in the study group compared with 25.5%, 13.6%, and 9.5%, respectively, in the control group.⁴⁰ Neonatal sepsis was also less in the study group (1.3%) compared with the group managed by amniocentesis (12.3%). Figure 21-11 illustrates a protocol based on the individual biophysical components rather than on the total score for managing patients with PPRM. Again, the BPP or NST testing of these patients needs to be performed daily to predict infectious outcomes (see Fig. 21-11).

In a study of 53 patients with PPRM whose only indication for delivery was an abnormal biophysical assessment, only five of the 15 fetuses in whom neonatal sepsis subsequently developed were born acidemic.¹⁰ The remaining 10 septic neonates as well as all 17 with possible neonatal sepsis were born with normal cord blood pH values, suggesting that acidemia does not play a major role in diminishing the fetal biophysical activities in the setting of intra-amniotic infection. It has been postulated that increased prostaglandin production from phospholipase A₂-producing bacteria or cytokines such as interleukin or tumor necrosis factors may cause hemodynamic changes of the fetal placental unit through vasoconstriction of the umbilical and chorionic vessels.

The Effects of Medications on the Biophysical Profile

A variety of medications that are commonly used in obstetric practice have significant effects on the BPP (Tables 21-7 through 21-10). The corticosteroids (dexamethasone

Table 21-7 Studies on the Effects of Corticosteroids on Fetal Biophysical Activities

12/12 studies found decreased FHR reactivity (days 1 to 3)
 8/8 studies found decreased FBM (days 1 to 2)
 10/10 studies found decreased FM (days 1 to 2)
 3/3 studies found no change in FT
 1/4 studies found decreased BPP scores (days 1 to 3)
 4/4 studies found decreased BPP scores (days 1 to 3)
 BPP scores returned to baseline by day 4 (96 hours)
 Betamethasone had more pronounced fetal effects than dexamethasone

and betamethasone) are given in preterm gestations at risk of delivery, in order to promote fetal lung maturation. Reductions in fetal breathing, fetal heart rate reactivity/variability, and fetal movements are observed within 48 hours following steroid administration in at least one third of fetuses (see Tables 21-7 and 21-8).³⁵⁻³⁹ Interestingly, Jackson and colleagues⁵⁷ found a reduction in amniotic fluid volume within 72 hours of steroid administration and attributed this to decreased fetal breathing movements. Our group studied the effects of magnesium sulfate, the tocolytic used most commonly in the United States, on the BPP in 25 fetuses and found that this medication did not significantly

alter the BPP.⁶⁰ Similarly, both Carlan⁶¹ and Peaceman^{62,63} and their coworkers found that although magnesium sulfate decreased fetal heart reactivity and breathing movements, it had no effects on the other sonographically monitored BPP parameters (see Tables 21–9 and 21–10). Hallak and coworkers⁶³ studied the effects of terbutaline and indomethacin, two other widely used tocolytics, on the BPP in 30 low-risk patients between 26 and 32 weeks of gestation with no signs of preterm labor. They found an increase in breathing movements, but no change in body movements. Studies evaluating the effects of magnesium sulfate on the BPP are summarized in Table 21–10.

If one is not aware of the effects of medications on the BPP, inappropriate interpretation of the results may occur resulting in the possibility of iatrogenic and unnecessary premature delivery. Conversely, it will help prevent erroneously attributing an abnormal BPP to administration of medications that do not affect the BPP.

CONCLUSION

The BPP is a powerful tool in the evaluation of fetal well-being, and evaluates the intactness of the CNS centers responsible for the individual biophysical activities. The BPP assesses both acute and chronic markers of fetal well-being; understanding the pathophysiologic basis for the BPP, using proper technique in its performance, and correct interpretation and intervention based on the results are crucial to its accuracy in predicting fetal status and ensuring optimal perinatal outcomes. In the majority of cases, a modified BPP, assessing fetal heart rate reactivity, and amniotic fluid volume are adequate for assessment of the fetal status. The presence of fetal breathing movements essentially rules out fetal academia. Finally, it is not the absolute score per se but rather the individual components that determine outcomes.

Fetal Doppler and Intrauterine Growth Restriction

PHYSICAL PRINCIPLES

The Doppler effect, first reported by Christian Doppler in 1842,¹ describes the *apparent* variation in frequency of a light or a sound wave as the source of the wave approaches or moves away relative to an observer. The traditional example that is given to describe this physical phenomenon is the apparent change in sound level of a train as the train approaches and then departs a station. The sound seems higher in pitch as the train approaches the station and seems lower in pitch as the train departs the station. The actual sound of the train is constant, it is the apparent change in sound pitch to a stationary observer that describes the Doppler effect. This apparent change in sound pitch (Doppler effect), or what is also termed the frequency shift, is proportional to the speed of movement of the sound-emitting source. In clinical applications, when an ultrasound beam with a certain frequency is used to insonate a certain blood vessel, the reflected frequency or frequency shift is directly proportional to the speed with which the red blood cells are moving (blood flow velocity) within that particular vessel. This frequency shift of the returning signal is displayed in a graphic form as a time-dependent plot. In this display, the vertical axis represents the frequency shift and the horizontal axis represents the temporal change of this frequency shift as it relates to the events of the cardiac cycle (Fig. 22-1). This frequency shift is highest during systole, when the blood flow is at its fastest, and lowest during end-diastole, when the blood flow is at its slowest in the peripheral circulation. Given that the velocity of flow in a particular vascular bed is inversely proportional to the downstream impedance to flow, the frequency shift therefore derives information on the downstream impedance to flow of the vascular bed under study. The frequency shift is also dependent on the cosine of the angle that the ultrasound beam makes with the targeted blood vessel (see formula in Fig. 22-1). When the sound beam is parallel to the blood vessel of interest and thus

the moving red cells, the entire Doppler shift is measured. However, when an angle exists between the direction of flow and the sound beam, the measured velocity is less than the true velocity.² The degree to which the velocity is accurately measured depends on the angle of incidence (cosine Θ). At an angle of 0 degrees, the measured velocity is equal to the true velocity. When the sound beam is perpendicular to the direction of flow (90 degrees), the measured velocity is zero, because the cosine of 90 degrees is zero.² Thus, ideally, one wants to measure the velocity with as small an angle as possible.

FIGURE 22-1. The Doppler effect (f_d) is dependent on the initial frequency of the ultrasound transducer (f_0), the velocity of flow (V) of the blood within a vessel, and the cosine of the angle (A) that the ultrasound beam makes with the direction of blood flow. The frequency shift (f_d) is displayed as a time-dependent plot within a cardiac cycle.

FIGURE 22-2. Doppler indices commonly used in obstetrical imaging. D, diastole; M, mean; PI, pulsatility index; RI, resistance index; S, systole.

FIGURE 22-3. Doppler waveforms of the umbilical artery in a normal fetus in the third trimester of pregnancy. Note the increased end-diastolic velocity, consistent with a low impedance circulation.

Given that the insonating angle is difficult to measure in clinical practice, indices that rely on ratios of frequency shifts were developed to quantitate Doppler waveforms. By relying on ratios of frequency shifts, these Doppler indices are thus independent of the effects of the insonating angle of the ultrasound beam. Doppler indices that are commonly used in obstetric practice are shown in Figure 22-2.

FETAL ARTERIAL DOPPLER

Umbilical Artery

The umbilical arterial circulation is normally a low impedance circulation, with an increase in the amount of end-diastolic flow with advancing gestation.^{3,4}

Umbilical arterial Doppler waveforms reflect the status of the placental circulation, and the increase in end-diastolic flow that is seen with advancing gestation is a direct result of an increase in the number of tertiary stem villi that takes place with placental maturation (Fig. 22-3).^{5,6} Diseases that

FIGURE 22-4. Abnormal umbilical artery waveforms; decreased end-diastolic velocity (A), absent end-diastolic velocity (B), reversed end-diastolic velocity (C).

obliterate small muscular arteries in placental tertiary stem villi result in a progressive decrease in end-diastolic flow in the umbilical arterial Doppler waveforms until absent and then reverse flow during diastole is noted (Fig. 22-4).^{7,8} Reversed diastolic flow in the umbilical arterial circulation represents an advanced stage of placental compromise and is associated with more than 70% of placental arterial obliteration.⁹⁻¹² The notation of absent or reversed end-diastolic flow in the umbilical artery is commonly associated with severe intrauterine growth restriction (IUGR) and oligohydramnios.^{13,14}

Doppler waveforms of the umbilical arteries can be obtained from any segment along the umbilical cord. Waveforms obtained from the placental end of the cord show more end-diastolic flow, thus lower ratio values (RI, S/D) than waveforms obtained from the abdominal cord insertion.¹⁵ Differences in Doppler indices of arterial waveforms obtained from different anatomic locations of the same umbilical cord are generally minor and have no significance on clinical practice (Tables 22-1 to 22-3).^{3,4}

Middle Cerebral Artery

The middle cerebral artery is the most accessible cerebral vessel to ultrasound imaging in the fetus, and it carries more than 80% of cerebral blood flow.¹⁶ The cerebral circulation is normally a high-impedance circulation with continuous forward flow throughout the cardiac cycle.¹⁷ This is the reverse of flow within the umbilical cord toward the placenta. In the presence of fetal hypoxemia, central redistribution of blood flow occurs, resulting in an increased blood flow to the brain (Fig. 22-5), heart, and adrenals, and a reduction in flow to the peripheral and placental circulations. This blood flow redistribution is known as the brain-sparing reflex and plays a major role in fetal adaptation to oxygen deprivation.¹⁷⁻¹⁹

The right and left middle cerebral arteries represent major branches of the circle of Willis in the fetal brain. The circle of Willis, which is supplied by the internal carotids and vertebral arteries, can be imaged with color flow Doppler ultrasound in a transverse plane of the fetal head obtained at the base of the skull (Fig. 22-6). In this transverse plane, the proximal and distal middle cerebral arteries are seen in their long axis, with their course almost parallel to the ultrasound

beam. As such, the insonating beam, which is parallel to the vessel and thus has a cosine of 0 degrees, will result in a measured velocity that accurately reflects the true velocity of blood in this vessel. Middle cerebral artery Doppler waveforms, obtained from the proximal portion of the vessel, immediately after its origin from the circle of Willis, have shown the best reproducibility (Tables 22-4 and 22-5 and Fig. 22-7).¹⁹

Although middle cerebral artery Doppler evaluation is often used to assess fetal well-being in the fetus with suspected IUGR (see later), more recently, middle cerebral artery velocity has been used in assessing the degree of anemia in fetuses with hemolytic disease due to Rh isoimmunization and parvovirus B19 infection (see Chapter 17) (Table 22-6).

Uterine Artery

Pregnancy is associated with physiologic changes at the level of the uterine vasculature, resulting in a progressive decrease

in impedance with advancing gestation.²⁰ This maternal adaptation to pregnancy is thought to result from the trophoblastic invasion of the maternal spiral arterioles in the first half of pregnancy.²¹ The invaded maternal spiral arterioles are rendered maximally dilated and minimally responsive to the sympathetic and parasympathetic systems. This adaptation is intended to ensure a sustained increase in blood flow to the uterus during pregnancy.

The uterine circulation can be assessed by Doppler velocimetry of the uterine arteries. Each uterine vessel can be demonstrated by color Doppler as it crosses over the hypogastric artery and vein just before it enters the uterus at the uterine-cervical junction (Fig. 22-8). Pulsed Doppler velocimetry of the uterine artery should be obtained immediately after the vessel crosses the hypogastric artery and before it divides into the uterine and cervical branches. The presence of a notch in the waveform and an increase in the impedance index after 22 weeks of gestation characterizes an abnormal uterine circulation (Fig. 22-9 and Tables 22-7 and 22-8).²² A substantial risk of complication is noted in

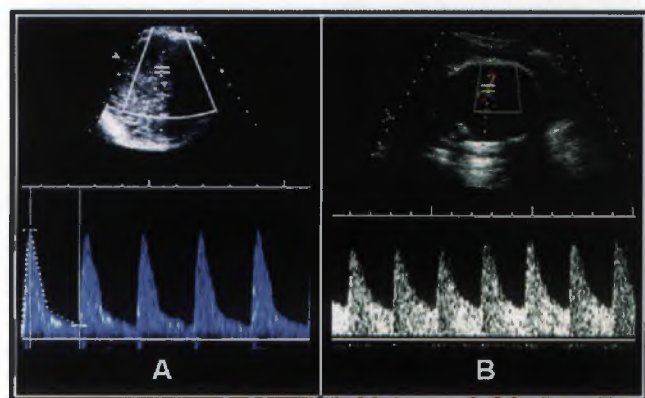

FIGURE 22-5. Doppler waveforms of the middle cerebral artery in a normal fetus (A) and in a hypoxemic fetus (B). Note the increase in end-diastolic velocity in fetus B resulting from a low impedance cerebral circulation as part of the brain-sparing reflex.

right ventricle. Specific information with regard to right ventricular preload, myocardial compliance, and right ventricular end-diastolic pressure can be derived from Doppler flow studies of the inferior vena cava and ductus venosus in the fetus.²⁵⁻³⁰

FIGURE 22-8. Color Doppler imaging in the lateral lower uterine segment showing the uterine artery (main) as it crosses over the hypogastric vessels (iliacs) before it enters the uterus and then divides into a uterine and a cervical branch.

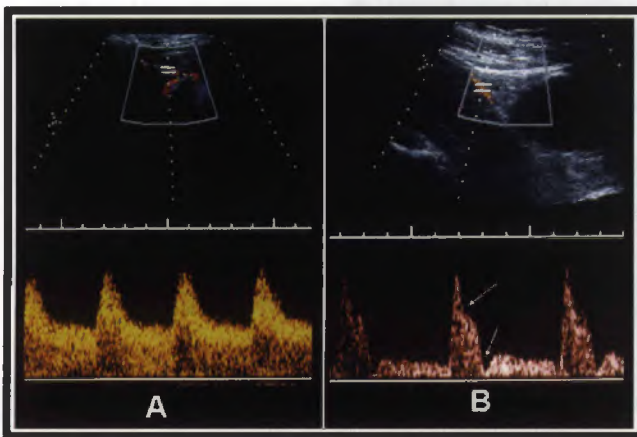

FIGURE 22-9. Doppler waveforms of the uterine artery obtained in the late second trimester of pregnancy showing a normal uterine circulation (A) with increased end-diastolic velocity implying a low impedance circulation and an abnormal uterine artery circulation (B) with a waveform notch and low end-diastolic velocity (high impedance).

Inferior vena cava Doppler waveforms can be obtained from a coronal plane of the chest and abdomen. In this view, the inferior vena cava can be imaged as it enters into the right atrium, joined by the ductus venosus and the left hepatic vein (Fig. 22-10). The inferior vena cava can be studied at two locations: at the inlet into the right atrium or in the segment between the entrance of the hepatic vein and the ductus venosus. A good correlation coefficient exists between these two measurement sites, and the location that provides the smallest angle of insonation with the blood flow should be chosen.²⁹ Inferior vena cava Doppler waveforms are triphasic in shape, with the first phase corresponding to ventricular systole, the second phase to early diastole, and the third phase to late diastole or the atrial kick (Fig. 22-11).

Ductus venosus Doppler waveforms can be easily obtained from a transverse view of the fetal abdomen at the same anatomic plane of the abdominal circumference (Fig. 22-12). By superimposing color flow Doppler to the grayscale image, the ductus venosus can be identified as it branches from the portal vein. High-velocity flow and

FIGURE 22-10. A. Three-dimensional B flow image from a 17-week-old fetus illustrating the relationships of the venous system, heart and aorta. B. Color Doppler ultrasound of a coronal plane of the fetal abdomen and chest showing the inferior vena cava (IVC), joined by the ductus venosus (DV) and the left hepatic vein (LHV) as it enters the right atrium (RA). (A from DeVore GR: *Pulsed Doppler examination of the fetal heart*. In Goldberg BB, McGahan JP [eds]: *Fetal Ductus Venosus in Atlas of Ultrasound Measurements*, 2nd ed. Philadelphia, Mosby Inc/Elsevier, 2006.)

turbulence is commonly seen within the ductus venosus given its narrow lumen. The presence of turbulence on color flow Doppler helps in identifying the ductus venosus in early gestations. Ductus venosus Doppler waveforms are biphasic in shape, with the first phase corresponding to ventricular systole, the second phase to early diastole, and the nadir of the second phase to late diastole or the atrial kick (Fig. 22-13 and Tables 22-9 to 22-12).

Blood flow through the umbilical vein carrying oxygenated blood to the fetus can be assessed either within its entrance into the fetal abdomen or adjacent to the fetus within the amniotic fluid (Table 22-13).

FETAL CARDIAC DOPPLER

Optimizing Your Image

Adequate imaging of the fetal heart is essential for accurate Doppler measurements. Several steps can improve ultrasound imaging when faced with suboptimal scanning conditions. Resort to the echocardiography settings on your

ultrasound equipment as the first step in optimizing your image. The echocardiography settings allow for enhanced image contrast, tissue characterization, and a faster frame rate which improve cardiac imaging. Other steps include minimizing the depth on the display monitor, insonating the heart through an angle that avoids shadowing by the fetal ribs and sternum, adjusting the focal zones to the area of interest, and most important, enlarging the area of interest (zoom), which allows visualization of details within the heart. These simple steps result in an adequate visualization of the fetal heart in most conditions. When adding color Doppler to your grayscale image, select high-velocity scales given that the velocity of cardiac blood flow is higher than the peripheral fetal circulation. By adjusting your filters to a high setting and by directing the angle of insonation of your ultrasound beam parallel to the direction of blood flow, the color Doppler image is optimized and wall motion artifact is significantly reduced.

Doppler indices in fetal echocardiography are quantitative parameters and, for the majority, are angle dependent. To obtain accurate Doppler indices in fetal echocardiography,

FIGURE 22-11. Doppler waveforms of the inferior vena cava in a normal fetus in the third trimester of pregnancy. Note the presence of reversed flow during the atrial contraction phase of diastole.

FIGURE 22-13. Doppler waveforms of the ductus venosus in a normal fetus in the third trimester of pregnancy. Note the presence of forward flow within the ductus venosus throughout the cardiac cycle.

FIGURE 22-12. Color Doppler ultrasound of a transverse plane of the fetal abdomen showing the umbilical vein (UV) and the ductus venosus (DV). Note the presence of turbulence on color Doppler in the ductus venosus.

the sample volume is placed distal to the respective valves, the insonating angle should be within 15 to 20 degrees of the direction of blood flow, Doppler waveforms should be obtained during fetal apnea, and multiple measurements should be made. Color Doppler is used to direct placement of the sample volume; placing the sample volume at the

brightest colors of the blood flow segment will ensure the best measurements. Figure 22–14 shows Doppler indices commonly used in fetal echocardiography.

The fetal circulation is different from the adult circulation in many aspects. The fetal circulation is in parallel rather than in series, and the right ventricular cardiac output is greater than the left ventricular cardiac output.^{31,32} The progressive development of organs during gestation influence blood distribution and vascular impedance.³¹ With advancing gestation, ventricular compliance is increased, total peripheral resistance is decreased, preload is increased, and combined cardiac output is increased.³¹ Compliance of the left side of the fetal heart increases more rapidly than compliance of the right side of the fetal heart with advancing gestation.³¹ The pulmonary vascular resistance is high in the fetus, and the pulmonary arterial pressure is almost systemic.^{33,34} Flow to the pulmonary vascular bed is maintained at a low rate, with a noted increase toward the end of gestation.^{32,33} Cardiac output in the fetus is mainly affected by preload and ventricular compliance.³¹ The presence of right-to-left shunts at the level of the foramen ovale and ductus arteriosus have a significant impact on cardiac flow patterns and affect the distribution of blood and oxygen to various organs. Flow across the foramen ovale contributes to the majority of blood entering the left ventricle, and more than two thirds of right ventricular output is directed to the ductus arteriosus.^{32,35} This shunting mechanism ensures the delivery of blood with high oxygen content to the coronary and cerebral circulations.

FIGURE 22-14. Doppler indices that are commonly used in fetal echocardiography. Peak-systolic velocity (A), time-velocity integral (B), and time-to-peak velocity (C).

Doppler waveforms across the atrioventricular valves are bicuspid in shape (Fig. 22-15). The first peak (E wave), corresponds to early ventricular filling of diastole, and the second peak (A wave) corresponds to atrial systole or the atrial kick. Unlike in postnatal life, the velocity of the A wave is higher than that of the E wave in the fetus.^{31,36} This highlights the importance of the role that atrial systole plays in cardiac filling in the fetus. The E/A ratio increases with advancing gestation and reflects ventricular diastolic function.^{31,36} E and A velocity peaks are higher in the right ventricle, and this right ventricular dominance is noted from the first trimester.^{31,36,37} Shifting to left ventricular dominance starts in utero toward the end of gestation.³¹ The E/A ratio is an index of ventricular preload and compliance (Table 22-14).³¹

Doppler waveforms across the semilunar valves are uniphasic in shape (Fig. 22-16). Indices most commonly used for the semilunar Doppler waveforms include the peak systolic velocity (PSV) and the time to peak velocity (TPV).

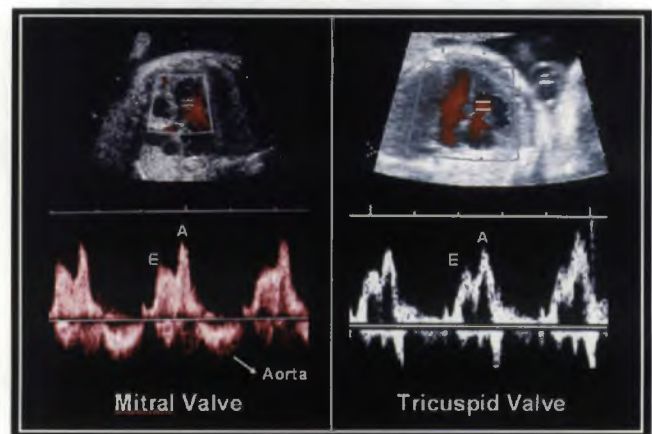

FIGURE 22-15. Doppler waveforms obtained across the mitral and tricuspid valves. Owing to the proximity of the mitral and aortic valves, a portion of the aortic outflow is noted during systole (arrow, aorta).

FIGURE 22-16. Doppler waveforms obtained across the aortic valve.

PSV and TPV increase with advancing gestation across the semilunar valves.^{31,35,38-41} PSV is higher across the aorta than across the pulmonary artery owing to a decreased afterload and a smaller diameter across the aorta.^{31,35,38-41} These Doppler indices reflect ventricular contractility, arterial pressures, and afterloads (Table 22-15).

FETAL DOPPLER AND INTRAUTERINE GROWTH RESTRICTION

Arterial Doppler abnormalities, at the level of the umbilical and middle cerebral arteries (brain sparing reflex), confirm the presence of hypoxemia in the growth-restricted fetus and present early warning signs (see Table 22-5).⁴²⁻⁴⁵ Once arterial centralization occurs, however, no clear trend is noted in the observational period, and thus, arterial redistribution may not be helpful for the timing of the delivery.⁴² On the other hand, the presence of reversed end-diastolic flow in the umbilical arteries is a sign of advanced fetal compromise, and strong consideration should be given for delivery except for extreme prematurity. Cesarean delivery should be given preference in this setting because labor may cause further fetal compromise.

The current literature suggest that venous Doppler abnormalities in the inferior vena cava and ductus venosus and abnormal fetal heart rate monitoring, even in its computerized version, follow arterial Doppler abnormalities and are thus associated with a more advanced stage of fetal compromise.⁴²⁻⁴⁶

Furthermore, in the majority of severely growth-restricted fetuses, sequential deterioration of arterial and

From DeVore GR: Pulsed Doppler examination of the fetal heart. In Goldberg BB, McGahan JP (eds): Atlas of Ultrasound Measurements, 2nd ed. Philadelphia, Mosby Inc/Elsevier, 2006.

venous Doppler precedes biophysical profile score deterioration.⁴³ At least one third of fetuses show early signs of circulatory deregulation 1 week before biophysical profile deterioration, and in most cases, Doppler deterioration preceded biophysical profile deterioration by 1 day.⁴³

The occurrence of such abnormal late stage changes of vascular adaptation by the fetus IUGR appears to be the best predictor of perinatal death, independent of gestational age and weight.⁴⁵ In a longitudinal study on Doppler and IUGR fetuses, all intrauterine deaths and all neonatal deaths, with the exception of one case, had late Doppler changes at the time of delivery, whereas only a few of the surviving fetuses showed such changes.⁴⁵

This sequential deterioration of the hypoxic, growth-restricted fetus is rarely seen at gestations beyond 34 weeks.^{47,48} Indeed, normal umbilical artery Doppler is common in growth-restricted fetuses in late gestations, and cerebroplacental ratios have poor correlation with outcome of IUGR fetuses at greater than 34 weeks of gestation.⁴⁹ Therefore, caution should be exercised when Doppler is used in the clinical management of fetuses with IUGR beyond 34 weeks of gestation.

The pathophysiology of fetal growth restriction has not been fully described because recent studies have highlighted the presence of significant variation in fetal adaptation to hypoxemia. The pattern of incremental deterioration of arterial Doppler abnormalities, followed by venous Doppler abnormalities, then followed by abnormal fetal heart tracings and biophysical profile abnormalities is not seen in approximately 20% of preterm fetuses.⁴² Furthermore, only 70% of fetuses with IUGR show significant deterioration of all vascular beds by the time they were delivered and about 10% showed no significant circulatory change by delivery

time.⁴³ In a prospective, observational study, more than 50% of fetuses with IUGR delivered because of abnormal fetal heart rate tracings did not have venous Doppler abnormalities.⁴⁵ In view of these findings, the universal introduction of venous Doppler in the clinical management of the growth-restricted fetus should await the results of randomized trials on this subject.

IUGR is associated with several changes at the level of the fetal heart involving preload, afterload, ventricular compliance, and myocardial contractility. An increase in afterload is seen at the level of the right ventricle owing to increased placental impedance.⁵⁰ A decrease in afterload is noted at the level of the left ventricle owing to decreased cerebral impedance associated with the brain-sparing reflex.⁵⁰ These changes in afterload result in a redistribution of the cardiac output from right to left ventricle.⁵⁰ Preload is reduced at both atrioventricular valves owing to hypovolemia and decreased filling associated with IUGR.^{39,47,51,52} This decrease in preload is reflected by a decrease in the E/A ratio, decreased atrial peak, and decreased time velocity integral at the mitral and tricuspid valves.^{39,51,52}

Evidence of reduced myocardial contractility in the presence of severe IUGR has also been reported. Ventricular ejection force, an index of ventricular systolic function that is independent of preload and afterload is decreased at the level of the right and left ventricle in fetal growth restriction.⁵³ IUGR fetuses with reduced ventricular ejection force have a shorter time to delivery, a higher incidence of nonreassuring fetal heart rate tracing, and a lower pH at birth when compared with controls.⁵³ A significant correlation between the severity of fetal acidosis at cordocentesis and ventricular ejection force values validates the association of this index and the severity of fetal compromise.⁵³

Myocardial cell damage, demonstrated by elevated levels of cardiac troponin T, is seen in some fetuses with severe growth restriction.⁵⁰ This advanced stage of fetal compromise is associated with signs of increased systemic venous pressure, a change in the distribution of cardiac output, a rise in right ventricle afterload, and a high incidence of tricuspid regurgitation.⁵⁰ These findings suggest that Doppler abnormalities in the proximal venous system of the growth-restricted fetus suggest fetal myocardial cell damage and increased systemic venous pressure.⁵⁰

The fetal heart plays a central role in the adaptive mechanisms for hypoxemia and placental insufficiency. As discussed in this chapter, longitudinal data on the hemodynamic sequence of the natural history of fetal growth restriction show that the umbilical artery and middle cerebral artery are the first variables to become abnormal.⁵⁴ These arterial Doppler abnormalities are followed by abnormalities in the right cardiac diastolic indices, followed by the right cardiac systolic indices, and finally, by both left diastolic and systolic cardiac indices.⁵⁴ Preserving the left systolic function as the last variable to become abnormal ensures an adequate left ventricular output, which supplies the cerebral and coronary circulations.

Several of the Doppler changes seen in association with fetal IUGR in the peripheral circulation are directly related to the adaptation of the fetal heart. The current management of IUGR involves Doppler at the peripheral arterial circulation (middle cerebral and umbilical arteries), central venous vessels (ductus venosus and inferior vena cava), and cardiotocography. Adding cardiac Doppler may improve management of the fetus with IUGR, but studies are lacking on the prospective clinical evaluation of the IUGR fetus with cardiac Doppler. However, it is becoming more obvious that those changes in the central venous circulation reflect an advanced stage of fetal compromise, commonly associated with myocardial dysfunction and damage.

Conclusion

Ultrasonography is the primary screening modality for obstetric imaging. When additional information is needed to care for pregnant patients, magnetic resonance imaging (MRI) can be used. This modality allows for visualization of maternal and fetal anatomy when sonography is insufficient to provide an adequate diagnosis. Because of radiation exposure, use of computed tomography (CT) is generally limited to evaluation of the acute maternal abdomen, when MRI is not available for this indication.

Because MRI provides superior contrast resolution compared with CT, uses no ionizing radiation, and permits imaging in more than one plane, it has been used in fetomaternal imaging. Traditionally, pelvic MRI has been used during pregnancy to evaluate maternal anatomy and abnormalities such as adnexal masses, which required further characterization beyond that available with ultrasound. Although adnexal structures can be visualized with conventional MRI techniques, fetal anatomy typically cannot be adequately assessed with conventional sequences because of degradation of image quality by fetal motion during the relatively long acquisition times.¹⁻³ Fast-scan techniques allow for imaging without maternal or fetal sedation and have markedly increased enthusiasm for use of this imaging tool to evaluate the obstetric patient and fetus. In this chapter, I address the use of CT and fast MRI in the evaluation of the pregnant patient and the fetus.

SAFETY ISSUES

Safety of Computed Tomography in Pregnancy

In general, because of the potential effects of radiation on the developing conceptus, we try to avoid the use of CT during pregnancy. The dose to the uterus from an abdominal CT is typically about 10 mGy (1 rad), and the dose to the uterus from an abdominal and pelvic CT is about 30 mGy (3 rads).⁴ In the first trimester, this dose is sufficient to be associated with spontaneous abortion and growth restriction. In the second and third trimesters, these risks are decreased. However, there is a slight increased risk of childhood cancer with fetal irradiation.^{5,6} The National Council on Radiation Protection and Measurements states that the risk of an abnormality caused by diagnostic radiation is considered to be negligible at 5 rads or less compared with the other risks of pregnancy.⁷ Therefore, when the benefit of diagnosis supercedes the theoretic risk of radiation exposure to the fetus, it is worthwhile to perform diagnostic imaging with CT.

To minimize these risks, when performing a CT scan in a pregnant patient, it is important to have the scanner controls set in a manner to minimize radiation dose. Scans for evaluation of abdominopelvic disease should be performed with intravenous contrast to maximize the diagnostic

information obtained, and to limit the need for repeating the study if a noncontrast scan is insufficient for diagnosis.

Safety of Magnetic Resonance Imaging in Pregnancy

There are no known biologic risks associated with MRI. No delayed sequelae from MRI examination have been encountered, and it is expected that the potential risk for any delayed sequelae is extremely small or nonexistent. The MRI procedure is not believed to be hazardous to the fetus.⁸⁻¹² In a survey of female MRI workers, no substantial increase in adverse pregnancy outcomes was found.⁹ According to the Safety Committee of the Society for Magnetic Resonance Imaging,¹³ MRI procedures are indicated for use in pregnant women if other nonionizing forms of diagnostic imaging are inadequate or if the examination provides important information that would otherwise require exposure to ionizing radiation (e.g., x-ray CT). It is required that pregnant patients be informed that, to date, although there is no indication that the use of clinical MRI procedures during pregnancy produces deleterious effects, according to the Food and Drug Administration,¹² the safety of MRI procedures during pregnancy has not been definitively proven. Also, it is well known that dividing cells, as in the case of the developing embryo during the first trimester, are susceptible to injury from a variety of physical agents. Because of limited data, we avoid MRI in the first trimester when feasible. However, if the MRI is being ordered for assessment of right lower quadrant pain, and the alternative imaging modality is CT (if MRI is not performed) then the risk of radiation exposure with CT must be weighed against the theoretic risk of MRI exposure. Because MRI is believed to be safe in pregnancy, the recent recommendation of Shellock and Crues is that "in cases where the referring physician and attending radiologist can defend that the findings of the MR procedure have the potential to affect the care of the mother or fetus... the MR procedure may be performed... regardless of the trimester."¹⁴ Note that this discussion regarding safety of MR in pregnancy is for imaging at 1.5 T or lower field strengths. Imaging at higher field strengths has not yet been proven safe in pregnancy.

Gadolinium is not recommended for use in pregnancy. Gadolinium has been shown to cross the placenta and appear within the fetal bladder only moments after intravenous administration.¹⁵ From the fetal bladder, the contrast is excreted into the amniotic fluid, where it is then swallowed and potentially reabsorbed from the gastrointestinal tract. Because of this reabsorption, the half-life of gadolinium in the fetal circulation is not known.¹⁵ Gadopentate dimeglumine has been shown to retard development slightly in rats when given in doses 2.5 times the human dose.¹⁶ It is considered a pregnancy category C drug (meaning that it should be given only if potential benefit outweighs the risk) because animal studies revealed adverse effects, but no controlled studies have been performed in humans.¹⁶

Fast Magnetic Resonance Imaging

Most of the MRI scans in this chapter from Beth Israel Deaconess Medical Center were obtained with a 1.5 T

superconducting system with four- or eight-element phased-array surface coils. The minimum gradient rise time is 600 microseconds (for a 25-mT peak gradient amplitude). The whole body specific absorption rate is less than 3.0 W/kg. Patients are positioned supine and feet first in the magnet to minimize claustrophobia. Images are acquired in axial, coronal, and sagittal planes of the fetus or orthogonal to the maternal pelvis depending on the indication for the examination. If patients are claustrophobic, sedation can be given with sublingual benzodiazepines. If the patient is uncomfortable lying supine, she can be imaged in the lateral decubitus position.

T2-Weighted Imaging

Half Fourier single-shot RARE (*Rapid Acquisition with Relaxation Enhancement*) technique is used to obtain T2-weighted images. This is a turbo-spin echo technique in which the echo train length is approximately one half as long as a typical RARE sequence. The missing data are artificially created by computer to shorten acquisition time. A typical sequence for fetal imaging uses an echo spacing of 4.2 milliseconds, a TE of 60 milliseconds, an echo train length of 72, 1 acquisition, 4-mm section thickness, 24 × 24 cm field of view, and 192 × 256 acquisition matrix. A 130- to 150-degree refocusing pulse is used to minimize the amount of radio-frequency power deposition.

The acquisition time per image ranges from 400 to 800 milliseconds, depending on the imaging parameters. A 1-second delay between image acquisitions minimizes the specific absorption rate. Thus, the scan time for 13 slices acquired in a single sequence is 17 seconds. The highly T2-weighted RARE sequences provide excellent contrast resolution of the fetal tissues.¹⁷⁻²¹ When using RARE imaging for evaluation of the fetus, it may be desirable to have contiguous sections because the fetus may move between sequences. However, for a better signal-noise ratio in fetuses for which motion is less of an issue, the acquisitions can be interleaved with an interslice gap equal to that of the slice thickness to minimize inadvertent radiofrequency excitation of adjacent sections.

Because the RARE sequence is a single-slice acquisition technique,^{18,21} it limits artifacts related to maternal and fetal motion^{18,21}; only the slice in which the motion occurred will be affected. This will generally lead to nonvisualization of a portion of the fetal anatomy but may lead to repeated visualization of a fetal part.²¹ For example, if the hand moves in plane with the sequence, it may be visualized more than once during the scan. Because fetal motion generally occurs throughout the examination, we have each acquisition serve as the scout for the subsequent acquisition when evaluating fetal anatomy.

T1-Weighted Imaging

T1-weighted imaging of the fetus is more difficult than T2-weighted imaging, because there is less inherent soft tissue contrast. In addition, because most T1-weighted sequences are not single shot, the images are degraded by motion that occurs during the breath-hold. Our current favored technique is a TurboFLASH with repetition time (TR)/TE = 15.4/4.2, 6 mm slice thickness, 35 cm field of

FIGURE 23-1. Axial noncontrast computed tomography (CT) images in a pregnant patient with appendicitis. A. A normal terminal ileum is present (*curved arrow*). B and C. Just below the image in A, a 13-mm tubular structure (*straight arrows*) arises from the cecum, causing mass effect on the cecum (c), consistent with an inflamed appendix.

view, and matrix of 160×256 . T1-weighted images are useful for evaluating the maternal pelvis, confirming hemorrhage or fat in a lesion, and assessing the liver position in cases of congenital diaphragmatic hernia.

Maternal Imaging

Abdominal Pain. Typically, evaluation of abdominal pain in a pregnant patient can be performed without a radiologic examination. The classic case necessitating a CT examination is a pregnant patient with right-sided pain in whom the diagnosis of appendicitis is uncertain, and for whom MRI for appendicitis is either contraindicated or not available (Fig. 23-1). Because, in pregnancy, the appendix is lifted out of the pelvis by the growing uterus, the clinical diagnosis of appendicitis is difficult. If the appendix is not visualized sonographically, it is reasonable to obtain additional imaging in patients in whom appendicitis is of concern. Pregnant patients have an increased incidence of perforation compared with nonpregnant patients with appendicitis. Similar to the nonpregnant patient, a mass may be seen focally indenting the cecum. Occasionally, CT may be performed for bowel obstruction or left-sided pain. These

cases should be interpreted in a manner similar to that of the nonpregnant patient.

MRI can be useful in the evaluation of abdominal pain in the pregnant patient without the need for ionizing radiation. Examples include evaluation for suspected appendicitis^{22,23} (Fig. 23-2, Table 23-1), abdominal pregnancies,²⁴⁻²⁶ uterine rupture,²⁷ pelvic vein thrombosis,²⁸ biliary disease (Fig. 23-3A), and small bowel obstruction complicating pregnancy (Fig. 23-4).

Hydronephrosis. MRI also can be used in the evaluation of the maternal urinary tract. Physiologic hydronephrosis is the most common cause of dilatation of the urinary tract in pregnancy (Fig. 23-3B). However, renal colic also can occur secondary to stones in .03% to .24% of pregnant patients.²⁹⁻³¹ In physiologic hydroureteronephrosis, the dilatation extends to the sacral promontory, with tapering of the lower part of the dilated ureter. In obstruction caused by stones, an intrinsic ureteral mass is present. The traditional screening method for evaluating the pregnant patient with renal colic is ultrasound. Intravenous urography is performed in occasional cases. Some now advocate CT urograms because they are more sensitive for small stones. However, in CT urography the radiation dose to the uterus is about 3 rads. With the

FIGURE 23-2. Mild acute appendicitis at 13 weeks' gestation. Coronal magnetic resonance image shows an enlarged fluid-filled appendix (*arrow*) measuring up to 9 mm in diameter. Note the increased signal intensity (*arrowheads*) in the mesoappendix consistent with inflammatory changes. Surgery and pathology confirmed the diagnosis. (From Eyvazzadeh A: MR imaging of right lower quadrant pain in pregnancy. *AJR Am J Roentgenol* 183:908, 2004.)

advent of MR urography, it is no longer necessary to expose the pregnant patient to the radiation and iodinated contrast media risks. Roy et al³² showed that in 15 cases of hydro-ureteronephrosis in pregnancy, MR urography correctly identified 10 cases of physiologic dilatation, 4 cases of stones, and 1 case of ureteropelvic junction obstruction. Scans can be performed both with a thick slab heavily T2-weighted image and with thin slices in the maternal axial plane to assess for small filling defects.

Adnexal Masses. It is well established that MRI is useful in the pregnant patient for the evaluation of adnexal masses that cannot be fully characterized by ultrasound. As Weinreb et al³³ and Kier et al³⁴ found, in 7 of 16 (43%) patients and 8 of 17 (47%) patients studied respectively, MRI added additional information beyond that afforded by ultrasound (Fig. 23-5). Fast MRI techniques provide exquisite characterization of masses (Fig. 23-6) and should be considered when designing a protocol for these examinations. We have found MR to be particularly helpful in patients who have hyperstimulated ovaries, and in whom ovarian torsion is of concern due to pelvic pain. In these cases, torsion can be present, even with normal flow on Doppler examination. MRI can show edematous ovarian

stroma, associated with intermittent or partial torsion (see Fig. 23-6).

Pelvimetry

Although pelvimetry is no longer commonly performed, it is beneficial in patients who desire a trial of labor when the fetus is in breech presentation.³⁵⁻³⁷ When pelvimetry is requested, MRI offers the benefit of accurate measurement of the bony structures in the pelvis without ionizing radiation. When MRI is not available, CT pelvimetry has been shown to be as reliable as conventional radiographic pelvimetry.

Using the protocol for CT pelvimetry as described by Federle et al,³⁸ the radiation exposure is much less than that using conventional x-ray pelvimetry. Dose estimates using low-exposure (40 mA) technique demonstrate a maximal dose to the fetus of 0.23 rad. In this protocol, anteroposterior (AP) and lateral scout digital views are obtained, and one transverse axial section is obtained through the fovea of the femoral heads (Fig. 23-7). The AP pelvic inlet diameter (from the sacral promontory to the posterosuperior margin of the pubic symphysis) and transverse pelvic inlet diameter (between the arcuate lines of the iliac bones) are measured directly on scout views, using electronic calipers. The interspinous diameter is measured between the ischial spines on the axial image.

For MRI pelvimetry, gradient-echo techniques are used, with scan times of less than 5 minutes.^{36,39} A midline sagittal view is obtained for assessment of the fetal presentation and for measurement of the anteroposterior pelvic inlet diameter (see Fig. 23-7D). Oblique coronal views (parallel to the AP pelvic inlet) are obtained for measurement of the pelvic inlet (maximum distance between the arcuate lines of the iliac bones on either side) and bispinous diameter.³⁶

Using acceptable values of greater than 11.0 cm for the anteroposterior pelvic inlet, greater than 9.5 cm for the transverse midpelvic distance (interspinous distance), and greater than 11.0 cm for the pelvic outlet, van Loon et al³⁶ showed that, although use of MRI pelvimetry in breech presentation at term did not reduce the overall cesarean section rate, it allowed better selection of the delivery route with a significantly lower emergency cesarean section rate.

Placental Evaluation

In patients with suspected placenta previa, a sagittal MRI sequence oriented in the plane of the cervix is used to assess the placental margin.^{3,40,41} Given widespread use of transvaginal and translabial ultrasound, this is unlikely to be a common indication for an MRI examination. However, the placental edge is easily identified with fast-scan techniques (Fig. 23-8). Unusual placental abnormalities, such as succenturiate lobe, are readily assessed with MRI.¹ MRI also has been advocated in the evaluation of placental masses such as chorioangioma.⁴²

A number of case reports recommended MRI for the evaluation of placenta accreta.⁴³⁻⁴⁶ Placenta accreta, including its variants placenta increta and percreta, is a disorder that results in significant intrapartum morbidity and mortality. Uncontrollable bleeding frequently leads to hysterectomy. Abnormalities of placental attachment may

FIGURE 23-5. Ovarian neoplasm identified during pregnancy. A. Transvaginal sonogram showing an early intrauterine gestation with an identifiable embryo (arrow). Lobulated soft tissue mass (*) and fluid are seen within the cul-de-sac. B. Sagittal T2-weighted image. The full extent of the large solid and cystic mass (*), posterior to the gravid uterus and embryo (arrow), is clearly evident. There is evidence of invasion of the sigmoid colon (open arrow) and ascites (A). The appearance on magnetic resonance imaging is indicative of an ovarian malignancy. (Case courtesy of V. A. Feldstein, MD, San Francisco, CA.)

FIGURE 23-6. Ovarian edema in a 28-year-old woman with twins (reduced from quadruplets) at 14 weeks' gestation who had undergone ovulation induction and had an enlarging solid left ovarian mass by ultrasound. **A.** Sagittal turbo-spin echo (TR/TE = 5139/90, 2 acquisition, matrix = 140×256 , ETL = 7, slice thickness = 5 mm, FOV = 26×35 cm, acquisition time = 3 minutes, 3 seconds) image of the gravid uterus (U) and enlarged left ovary ($14 \times 9 \times 8$ cm) with small peripheral follicles (arrows). The follicles have low signal intensity, likely resulting from hemorrhage. The enlarged left ovary was histologically shown to be due to massive ovarian edema. Because of the relatively long scan time, fetal structures cannot be identified. **B.** Single-shot RARE image in the coronal plane demonstrates the gravid uterus (U) with body of one fetus (arrow), hyperstimulated right ovary (open arrow), and the edematous left ovary (O). **C.** Coronal RARE image slightly more anteriorly shows fetuses in three gestational sacs. Two fetuses were alive and one was dead (arrow). (From Levine D: *State of the art: Obstetric MR imaging. Radiology* 211:609, 1999.)

result in the placenta attaching directly onto the myometrium (placenta accreta), extending more deeply into the myometrium (placenta increta), or invading through the uterine serosa (placenta percreta). These conditions occur in 5% of patients with placenta previa, in up to 10% of patients after four or more cesarean sections, and in 67% of patients who have both placenta previa and four or more cesarean sections.⁴⁷

A study from our laboratory⁴⁸ found that transvaginal ultrasound with a partially full bladder was most beneficial in the evaluation of placenta accreta occurring in the lower uterine segment. However, in 1 of 17 cases, the placenta

accreta was identified only by the MRI examination because of a posterior placenta occurring over a region of a previous myomectomy (Fig. 23-9). We recommend that transvaginal ultrasound with a partially full bladder be the method of choice for the evaluation of placenta accreta. For patients with a history of myomectomy and posterior placenta, MRI should be considered.

Computed Tomographic Amniography

In rare cases in which ultrasound is not sufficient to diagnose monoamniotic twins, amniography may be used.⁴⁹⁻⁵¹ For

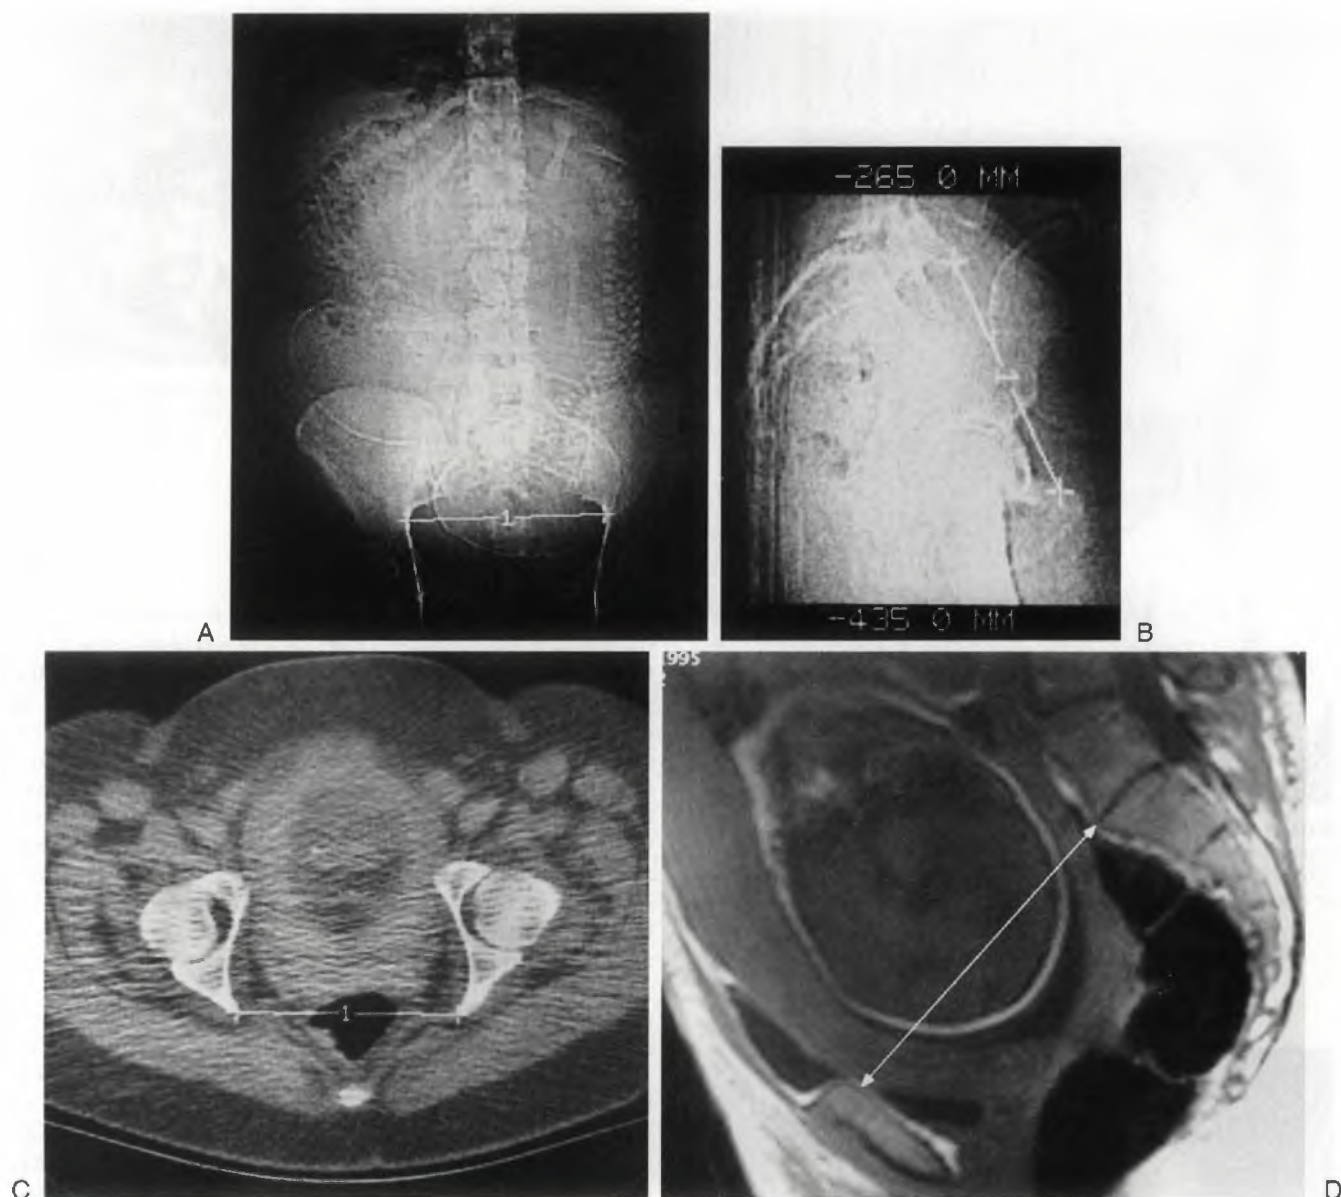

FIGURE 23-7. Computed tomography (CT) (A-C) and magnetic resonance imaging (MRI) (D) pelvimetry. A. Anteroposterior scout view demonstrating the transverse pelvic inlet, measured with electronic cursors. B. Lateral scout view demonstrating the obstetric conjugate measurement of the anteroposterior pelvic inlet. C. Transverse CT section through the ischial spines demonstrating the bispinous or transverse diameter. D. MRI pelvimetry. T1-weighted sagittal view of the pelvis demonstrates the pelvic inlet (arrows). This view is used as a scout for subsequent sequences.

CT amniography, sonography is used to select a transverse plane of section and this location is marked. A single transverse axial precontrast CT may be obtained at this level. Using sonographic guidance, the amniotic sac is punctured and water-soluble iodinated contrast material is instilled. When a contrast agent with a concentration of 300 mg of iodine per millimeter of solution is used, 1 mL per 100 mL of anticipated amniotic fluid volume provides adequate opacification. Typically, 8 to 10 mL of contrast agent is used in a third trimester twin pregnancy with normal amniotic fluid volume. A postcontrast transverse CT scan is obtained (Fig. 23-10). Monoamnicity is indicated by the presence of contrast material completely surrounding each twin, although rarely this appearance may be mimicked by a

diamniotic pregnancy with a stuck twin. Finberg and Clewell⁵⁰ reported that the presence of contrast material within the gastrointestinal tract of both twins, after a delay of approximately 4 hours, is a reliable, unambiguous sign of monoamnicity.

Fetal Imaging

Early studies using MRI in the evaluation of fetal morphology were hindered by fetal motion. Recommendations were made to limit imaging to late pregnancy or to cases of oligohydramnios because fetal motion is lessened in these situations.^{35,52} Garden et al⁵³ described gradient-echo images for the evaluation of fetal anatomy. Images were

FIGURE 23-8. Partial placenta previa in a 29-week pregnancy. Sagittal magnetic resonance imaging of the cervix shows placenta tip (arrow) partially covering the internal os of the cervix. (From Levine D: *State of the art: Obstetric MR imaging*. *Radiology* 211:609, 1999.)

FIGURE 23-9. Placenta accreta diagnosed with magnetic resonance imaging (MRI) in a patient with a previous posterior myomectomy. Coronal RARE MRI shows an absent myometrial-placental interface in a posterolateral location (arrowhead) surrounded by normal myometrial-placental interface (small white arrows). This region was not well evaluated with ultrasound. A fibroid (F) is present in the right lateral aspect of the uterus. (From Levine D: *Placenta accreta: Evaluation with color Doppler, power Doppler and fast MRI*. *Radiology* 205:773, 1997.)

FIGURE 23-10. Computed tomography (CT) amniogram. Transverse CT section obtained after contrast instillation showing opacified amniotic fluid (arrows) completely surrounding both fetuses, confirming monoamnicity.

obtained in 3 to 14 seconds that reduced artifact from fetal motion but were compromised by low signal-to-noise ratio. Other investigators used benzodiazepines to sedate the pregnant patient or curarization by direct fetal injection to decrease fetal motion.^{1,3,54-58} Subsequently, echo planar imaging was advocated for obstetric MRI because its short (100 milliseconds) scan time makes fetal paralysis unnecessary.^{6,59} However, echo planar imaging has several disadvantages, including susceptibility artifacts, chemical shift artifacts, and limited availability as a result of special hardware requirements.⁶⁰ Despite these limitations, fetal MRI has been suggested as an important technique to evaluate anomalous fetuses.⁶¹⁻⁶³

Fast MRI sequences with subsecond image acquisitions, such as single-shot RARE MRI, allow for excellent visualization of fetal anatomy.²¹ In fetuses less than 20 weeks' gestational age, obtaining images with respect to fetal anatomy is important. In older gestational age groups, this is less of an issue. For ease of image interpretation, we attempt to align our acquisition planes orthogonal to fetal anatomy. However, if the fetus moves and the planes are slightly nonorthogonal, the acquisitions are not repeated, unless a particular question cannot be answered with the acquired images.

Real-Time Imaging

We have recently begun using real-time imaging for improved assessment of specific areas of fetal anatomy. Using this technique, single images are repeated until they are obtained in the appropriate fetal orientation in order to best display the fetal anatomy.^{64,65} We have found this to be particularly helpful to illustrate the normal fetal corpus callosum and to demonstrate the secondary palate in fetuses at risk for cleft palate (Fig. 23-11).^{66,67}

Fetal Central Nervous System Anomalies

One area in which MRI has proven to be especially beneficial is in the evaluation of the fetal central nervous system (CNS). Sonographic evaluation of the fetal CNS is limited by the nonspecific appearance of some anomalies; by

FIGURE 23-11. Fetus with micrognathia at 35 weeks, with soft palate defect seen on midline MR image obtained with real-time sequences. Real-time was helpful in obtaining images during fetal swallowing that allowed for outlining of the palate abnormality. Image shows an intact anterior palate (arrow), however the tongue (T) rides above the palatal shelf posteriorly, consistent with a cleft soft palate. Postnatal diagnosis was cleft soft palate with Robin sequence. The neonate required a tongue-lip adhesion to control his airway and permit feeding.

technical factors that limit resolution of the side of the brain near the transducer; by ossification, which obscures visualization of posterior fossa structures; and by subtle parenchymal abnormalities, which frequently cannot be visualized with ultrasound.⁶⁸ Multiplanar views can be difficult to obtain with sonography because of fetal position or advanced gestational age. MRI can be used to obtain multiplanar views. In addition, MRI allows for direct visualization of the brain parenchyma and, thus, detailed evaluation of the CNS anatomy in a manner not possible with sonography.⁶⁹ Many case reports and series reports detail the potential of MRI to improve on the sonographic diagnosis of CNS anomalies.^{63,70-81}

Results from our study demonstrated that of 124 fetuses with CNS anomalies confirmed at our institution, there were 86 changes in counseling, 49 major changes in diagnosis, and 27 clear changes in management.⁸¹ MRI findings not visualized by ultrasound include porencephaly (Fig. 23-12), dysgenesis of the corpus callosum, cortical gyral abnormalities (Fig. 23-13), tethered cord, cortical clefts, midbrain abnormalities (Fig. 23-14), dysgenesis of the septi pellucidi, holoprosencephaly, cerebellar hypoplasia, subependymal (Fig. 23-15) and cortical tubers, vascular malformation, subdural and intratentorial hemorrhage (Fig. 23-16), and vermian cysts. Abnormalities better defined by MRI than ultrasound include encephaloceles (Fig. 23-17), arteriovenous malformations, distal neural tube defects, and the mass effect of arachnoid cysts (Fig. 23-18).^{69,81,82} We found that MRI was least helpful in patients with a normal confirmatory sonogram and myelomeningocele.

The information provided by MRI allows for improved patient counseling, which may be used to assist patients in the decision to continue or discontinue a pregnancy, or to facilitate planning the mode of delivery and perinatal care. The types of management changes were correlated with gestational age, with decisions to terminate/continue a pregnancy at early gestational ages, and decisions regarding mode of delivery, location of delivery, and perinatal care made late in gestation.⁸¹ At times, MRI in the third trimester can obviate the need for postnatal MRI (which may require neonatal sedation and its associated risks).

We have found MRI to be especially useful in fetuses with ventriculomegaly (see Figs. 23-12 and 23-14). The degree of ventriculomegaly, the cause of ventriculomegaly, and any associated findings are important in providing a management plan and prognosis for the fetus.⁸³⁻⁸⁶ MRI has been beneficial in establishing the presence of a normal corpus callosum in fetuses with suspected callosal agenesis,⁷⁹ and it has been helpful in diagnosing callosal dysgenesis in fetuses when sonography shows only ventriculomegaly.^{69,87}

MRI has aided our understanding of rare CNS anomalies such as an intratentorial hematoma (see Fig. 23-16). These lesions differ from arachnoid cysts in that they are adjacent to bone instead of adjacent to the brain. Other areas of hemorrhage can be seen. These lesions may regress and not be evident at birth.⁸⁸

Evaluation of neural tube defects can also be performed with MRI. MRI examination is very helpful in visualizing caudal neural tube defects that may be difficult to visualize with sonography. MRI is also useful in visualizing posterior fossa structures in cases of Chiari type II malformation, and this information is helpful in pre- and postoperative assessment of patients undergoing in utero therapy of spinal neural tube defect.^{89,90} However, for the majority of sonographically well-visualized spinal neural tube defects in which fetal surgery is not being performed, MRI has limited potential to influence care.⁹²

We have also evaluated fetal cerebral cortical development in relation to gestational age compared with norms based on anatomic specimens.⁹¹ We found that cortical development by MRI follows a predictable course and lags slightly compared with that described in anatomic specimens. Cortical development is often further delayed in fetuses with mild ventriculomegaly or other CNS abnormalities. The time course of the appearance of normal cortical landmarks is important in screening for fetuses with suspected migrational disorders such as lissencephaly. In addition, if the cortical development is markedly delayed compared with the gestational age and the fetus has an otherwise normal-appearing brain, these neonates may benefit from early intervention postnatally.

The Fetal Surgery Patient

A rapidly expanding area for MRI is in the evaluation of fetuses that potentially will undergo in utero surgery and in fetuses being assessed for potential ex utero intrapartum treatment (EXIT) procedure. In the EXIT procedure, the fetus is partially delivered, and while still attached to the umbilical circulation, diagnostic and therapeutic maneuvers are undertaken to ensure that the baby will be able to breathe and adequately oxygenate once the cord is clamped

FIGURE 23-12. Mild ventriculomegaly with multifocal hemorrhage and cortical destruction in 16-week gestational age fetus. *A.* Coronal sonogram demonstrated mild ventriculomegaly with slightly irregular margins of one of the ventricles. *B* and *C.* Coronal RARE images show destruction of brain tissue in right frontal lobe (arrows on *B*) and focal area of low signal intensity (open arrow on *C*). *D.* Axial fast T1-weighted magnetic resonance imaging reveals extra-axial high and low signal intensity (curved arrow) consistent with blood products. This image was acquired in 15 seconds. Note the degradation in image quality due to fetal motion during image acquisition. This illustrates the inherent problem of fetal motion in obstetric imaging when sequences longer than 1 second are used. (From Levine D: *Fetal CNS anomalies depicted with ultrafast MR imaging.* *AJR Am J Roentgenol* 172:813, 1999.)

FIGURE 23-13. Fetus at 22 weeks' gestational age with agenesis of the corpus callosum and migrational abnormality. *A.* Axial image shows non-dilated ventricles with colpocephaly appearance with slit-like frontal horns. The hemispheres are splayed apart by an interhemispheric cyst that was better visualized sonographically (not shown). A region of abnormal gyral pattern is marked with an arrow. *B.* Sagittal image again shows the abnormal parenchyma with abnormality of both the cortical gyral pattern and the signal intensity of the white matter (*arrows*). This parenchymal abnormality was not evident sonographically. This type of information is important when counseling patients because the associated abnormalities help predict prognosis in fetuses with callosal dysgenesis.

FIGURE 23-14. Ventriculomegaly at 19 weeks' gestational age by ultrasound with kinked midbrain by MRI. Sagittal T2-weighted MR shows marked ventriculomegaly and an abnormal configuration of the brainstem with a posterior kink (*arrowhead*) at the pontomesencephalic junction and an anterior kink (*arrow*) at the level of the fourth ventricle. The cerebellar vermis is hypoplastic. This type of abnormality is important because it indicates an early severe insult to the brain.

FIGURE 23-15. Fetus at 35 weeks' gestational age at risk for tuberous sclerosis due to sonographic findings of cardiac rhabdomyomas. Sagittal magnetic resonance image shows subependymal tubers (*arrows*), which were not visible sonographically. This allows for improved counseling of the patients at risk for tuberous sclerosis.

FIGURE 23-16. Intratentorial hematoma. *A.* Axial sonogram at 22 weeks' gestation shows a fluid collection in the posterior fossa with an hyperechogenic area (*arrow*) in a dependent location, suggesting focal calcification. A mass effect is shown as a slight flattened appearance to the cerebellar hemispheres. *B.* Sagittal MR shows a fluid collection adjacent to bone (*asterisk*), of intermediate signal intensity, lower than surrounding cerebrospinal and amniotic fluid, suggesting blood products. The fluid collection deviates the cerebellum anteriorly (*arrowhead*). The area that was hyperechogenic on ultrasound is of low signal on MR (*arrow*). This should be distinguished from an arachnoid cyst that would be adjacent to brain rather than conforming to bone. At 30 weeks, a similar appearance (not shown) was seen. At birth, a head ultrasound was normal. (Case courtesy of Robert Barr, MD, North Carolina).

(or to place the fetus on extracorporeal membrane oxygenation before clamping the cord).

For the fetal surgery patient, MRI is very helpful to ensure that unexpected anomalies are not present before undertaking the morbidity of fetal surgery.^{92,93} In addition, MRI is helpful in the documentation of liver position in fetuses with congenital diaphragmatic hernia (CDH,

Fig. 23-19).^{93,94} The liver position is important for prognosis because in cases of isolated CDH, the presence or absence of liver in the fetal chest is associated with respective mortalities of 57% and 7%.^{95,96} This difference in mortality is believed in part to be due to the size of the hernia and the associated pulmonary hypoplasia. MRI is also helpful in fetuses with CDH in the assessment of the amount of normal-appearing lung remaining because the lung is poorly visualized with sonography but is well depicted on MRI.⁹⁴ In patients undergoing surgery for neural tube defects, MRI is helpful in characterizing the Chiari malformation, because the amount of cerebellar herniation is easily followed on serial MRI examinations.

In patients being evaluated for fetal procedures, MR is helpful for visualizing the potential airway obstruction (Figs. 23-20 and 23-21) and in planning for intervention at the time of delivery.^{97,98}

Fetal Non-Central Nervous System Anomalies

In the fetal lung, MRI has been shown to be helpful in accurately depicting the type of lung mass.⁹⁹ MR volumetry is also being established as an accurate method for measuring lung volume, to predict pulmonary hypoplasia.^{100,101}

MRI contributes to the definition of fetal abdominal and pelvic masses^{97,102} (Figs. 23-22 and 23-23). In a case from our series, fetal ultrasound showed an hyperechogenic abdominal mass suggestive of a meconium pseudocyst. MRI showed that the mass was more likely to be a gastric duplication cyst, which was confirmed with postnatal imaging (see Fig. 23-22). We demonstrated other anomalies by MRI, including omphalocele, gastroschisis, and cloacal malformation (see Fig. 23-23). Further studies are needed to assess how additional information from MRI affects patient management and outcome.

Screening for Anomalies

MRI also has the potential to aid in genetic counseling and screening for disease processes for which limited prenatal diagnosis is available. Examples of this are tuberous sclerosis (see Fig. 23-15) in which subependymal tubers have been visualized with MR as early as 21 weeks' gestational age,¹⁰³ hemochromatosis,⁹³ and polymicrogyria or lissencephaly.⁸² The sensitivity and specificity of prenatal MR for evaluation of these anomalies remains to be determined.

Potential Pitfalls in Fetal Evaluation Using Fast Magnetic Resonance Imaging

As for all patients, there are absolute contraindications to MRI in pregnant patients (e.g., a ferromagnetic cerebral aneurysm clip), and some patients are too claustrophobic to undergo the examination. Use of short-bore magnets makes claustrophobia less of a concern, but if a patient is shorter than 5 feet 4 inches in height, her head will likely be within the magnet bore, even using a short bore magnet. An additional problem is that pregnant patients may have difficulty lying on their backs, especially in the third trimester. If a patient cannot lie on her back, she can be scanned in the decubitus position.

FIGURE 23-17. Posterior encephalocele in a fetus at 20 weeks' (A and B) and 32 weeks' gestational age (C). A. Axial sonogram shows a posterior encephalocele. A small amount of tissue is seen within the sac (arrow). B. Axial magnetic resonance image shows that the structures of the posterior fossa appear normal. A portion of the encephalocele is seen posteriorly (arrowheads). The information that the majority of the brain appeared normal was helpful to the patient in deciding to continue the pregnancy. C. In the same fetus at 32 weeks' gestational age, a sagittal image demonstrates that only a small portion of posterior cortex (arrow) is tented toward the encephalocele (E). At surgery, the encephalocele was removed and a small portion of cortex was pushed back into the cranial vault without difficulty. Postnatally, a meningocele sac was excised and the neural content returned to the posterior fossa. The infant is doing well at 1 year of age. (A and B from Levine D: *State of the art: Obstetric MR imaging*. *Radiology* 211:609, 1999. C from Levine D: *Fetal CNS anomalies depicted with ultrafast MR imaging*. *AJR Am J Roentgenol* 172:813, 1999.)

FIGURE 23-18. Arachnoid cyst in a 27-week gestational age fetus. A. Axial sonogram demonstrates an extra-axial collection (C), but it is difficult to assess involvement of the ventricular system. Coronal (B) and sagittal (C) magnetic resonance images clearly demonstrate the extra-axial nature of this extensive arachnoid cyst with mass effect on the surrounding structures. (From Levine D: *State of the art: Obstetric MR imaging*. *Radiology* 211:609, 1999.)

FIGURE 23-19. Sonogram and magnetic resonance imaging (MRI) of fetal congenital diaphragmatic hernia (CDH) in a 32-year-old woman at 25 weeks gestation. *A.* Transverse axial sonogram demonstrates herniated bowel and liver within the fetal thorax (*asterisk*). Distinction between fetal bowel and liver is not possible on this image. The heart (H) is displaced to the right by the herniated contents. *B.* Single-shot fast-spin echo T2-weighted (TE of 100 milliseconds) coronal section through the fetal thorax, demonstrating multiple bowel loops (*arrow*) in the left side of the chest. This confirms the presence of a left-sided CDH. The compressed right lung is visible. The left lung is not seen. *C.* Spoiled gradient-echo T1-weighted (flip angle of 70 degrees, and TR/TE of 120/4.2 milliseconds) coronal section through the fetal thorax, at a level more anterior to the section in *B.* The liver is of relatively high signal on this sequence, facilitating identification of hepatic position. Herniation of the left hepatic lobe (*arrow*) into the left side of the chest is seen. (MRI courtesy of Fergus Coakley, MD, University of California at San Francisco.)

FIGURE 23-20. MR in planning for EXIT procedure. Sagittal MRI of fetus with neck mass. The MR showed the heterogeneous neck mass (M). Sequential images showed the trachea (arrowhead) to be patent but narrowed and deviated in the region of the mass. Because of concerns regarding ability to intubate at delivery, an EXIT procedure was performed. After partial delivery, while still attached to the umbilical cord, the fetus was intubated. After the intubation the umbilical cord was ligated.

Although artifacts from fetal motion are minimized using fast-scan techniques, if the fetus moves continuously during a sequence, reduced image quality is inevitable. This movement can be accommodated by repeated sequence acquisition if the anatomy has not been well visualized, or with use of real-time imaging, which allows for specific image slices to be obtained, until the pertinent anatomy is documented. In some cases when MR is undertaken for fetal indications, fetal movement that occurs after the scout acquisitions are obtained or between imaging sequences makes it difficult to obtain specific image planes. This is especially true in the evaluation of the distal extremities. When motion is not a problem, sequential images allow for assessment of the hands and feet. However, even small amounts of motion limit viewing of the extremities in their entirety. When the entire fetus moves, the region of interest may not be in the image plane at all. Because of signal-to-noise limitations, small fetal structures may be difficult to identify and evaluate. Thin structures surrounded by fluid can be difficult to visualize as a result of partial volume averaging occurring over the thickness of the slice. Examples include the membranous sac of a neural tube defect, the wall of an arachnoid cyst, and the forming corpus callosum in the second trimester.

IMAGING BEYOND ANATOMY

MRI has the potential to give a wealth of information beyond anatomic images. Diffusion-weighted imaging, MR spectroscopy, and oxygenation imaging are all examples of the type of additional information that can be provided by MRI. In addition, MR volumetry can be used to potentially affect care of the pregnant patient.

Diffusion-Weighted Imaging

Echo-planar diffusion-weighted imaging is being increasingly performed to assess for early brain damage.^{104,105} Use of this technique can demonstrate hypoxic ischemic injury before anatomic abnormalities are seen on the more standard T1- and T2-weighted images. The apparent diffusion coefficient decreases with an acute injury.¹⁰⁶ Restricted diffusion can also be seen in areas of increased cellularity and advanced myelination,¹⁰⁷ and can be used to assess normal and abnormal myelination patterns. Diffusion-weighted imaging also can be performed to characterize cystic lesions in utero and distinguish them from the bulky mobile amniotic fluid.¹⁰⁸ It is also possible that diffusion measurements may be useful in assessing lung maturation.¹⁰⁹

Magnetic Resonance Spectroscopy

MR spectroscopy has the potential to show changes in composition of tissues and fluids in the fetus, potentially allowing for assessment of phospholipids in amniotic fluid¹¹⁰ and normal development^{111,112} and ischemia of the brain in the third trimester.¹⁰⁴ However, this tool is still being developed for use clinically in the fetus. Problems with use of MR spectroscopy are the relatively long scan times that allow for fetal motion to occur and the potential for partial volume averaging of small structures.

Oxygenation Imaging

Placental oxygenation imaging may allow for early detection of growth restriction.¹¹³ In a sheep study, Wedegartner et al¹¹⁴ described the use of blood oxygen level-dependent MRI to provide assessment of fetal brain, liver, heart, lung, and placental oxygenation in sheep with hypoxia, and showed the strongest changes in T2* values in the liver and heart (both organs with high blood flow in utero), with smaller changes in the brain, placenta, and lungs. It is anticipated that use of functional imaging studies like this will allow for improved distinction between the normal but small for gestational age fetus from a growth-restricted fetus.

Magnetic Resonance Volumetry

Three-dimensional volumetry is easily performed on fetal MRI. Potential applications include (1) assessment of lung volumes in cases of chest masses and hernias; (2) better assessment of fetal weight (for example in diabetics with macrosomia, potentially allowing for decreased cesarean section rate or, in differentiating between the growth-restricted fetus from the normal but small for gestational age fetus); and (3) cerebral parenchymal volumes in cases of ventriculomegaly to better predict outcomes.

FIGURE 23-21. Sonograms and magnetic resonance imaging from a fetus with laryngeal atresia. *A.* Coronal plane of section demonstrates markedly enlarged and hyperechogenic lungs bilaterally (*asterisks*). *B.* Single-shot fast-spin echo (effective TE 100 milliseconds) demonstrates enlarged fetal lung (*arrow*). Marked ascites is also seen (*asterisk*). *C.* Coronal plane of section sonogram demonstrates the dilated fluid filled trachea (*arrows*) in this fetus. *D.* Single-shot fast-spin echo (effective TE 100 milliseconds) demonstrates the trachea (*arrow*) as a high intensity structure. (MRI courtesy of Fergus Coakley, MD, University of California at San Francisco.)

FIGURE 23-22. Gastric duplication cyst in a 28-week gestational age fetus. *A.* Oblique coronal ultrasound shows an hyperechogenic mass in the abdomen (calipers), suggestive of a meconium pseudocyst. *B.* Sagittal RARE image demonstrates the mass (m) impressing on the stomach (s). The mass is of slightly lower signal intensity than the stomach on this T2-weighted image. *C.* Axial RARE image shows similar findings to *B.* *D.* Axial T1-weighted image (TR/TE = 126/4; flip angle = 80 degrees; FOV = 24 × 32 cm; matrix = 96 × 256; 5-mm slice thickness; one signal acquired; section thickness, 5 mm) shows that the mass (m) has slightly higher signal than adjacent stomach. The appearance of the mass suggests a duplication cyst, which was confirmed postnatally. (From Levine D: *State of the art: Obstetric MR imaging. Radiology* 211:609, 1999.)

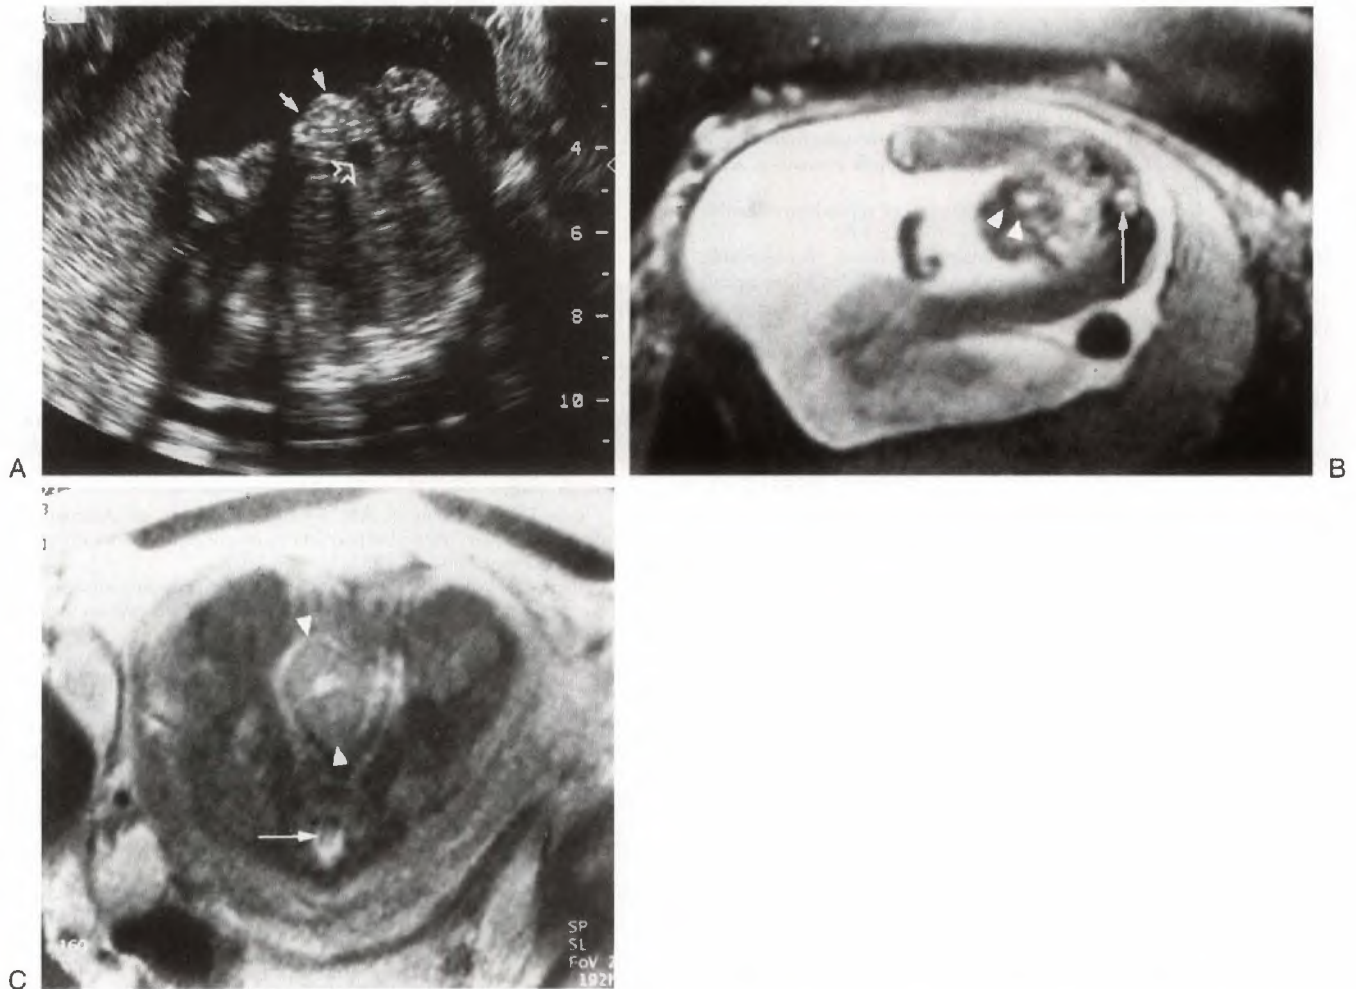

FIGURE 23-23. Cloacal exstrophy in a 20-week gestational age fetus. *A.* Sagittal ultrasound image demonstrates a low anterior abdominal wall defect (*arrows*). A fluid collection is seen in the pelvis suggestive of a deformed bladder (*open arrow*); however, a bladder should not be seen in a case of exstrophy. The kidneys were not visualized. *B.* Axial magnetic resonance image (MRI) at 20 weeks shows a pelvic kidney (*arrowheads*) in the region of the fluid collection seen by ultrasound. The spinal cord is seen at this level (*thin white arrow*) consistent with a tethered cord. *C.* Axial MRI at 38 weeks again shows the pelvic kidney (*arrowheads*) and tethered cord (*arrow*). These diagnoses were made prospectively after discussion with specialists in pediatric surgery and pediatric radiology. One of the benefits of fetal MRI is that specialists who are not accustomed to obstetric sonography may be better able to understand MRI with which they are more familiar. (From Levine D: *State of the art: Obstetric MR imaging. Radiology* 211:609, 1999.)

CONCLUSION

Ultrasound continues to be the screening modality of choice in the evaluation of the maternal pelvis and fetus because of its relatively low cost and real-time capability. However, there are many cases in which alternative imaging is useful as an adjunct to ultrasound. The use of CT is typically limited to patients with abdominal pain at risk for appendicitis, but MRI use is increasing. Indications for fetal MRI include evaluation of adnexal masses, hydroureteronephrosis of pregnancy, and fetal anomalies. As our experience with fast MRI techniques increases, we will continue to identify patients in whom MRI contributes to patient evaluation.

Conclusion

Two-dimensional (2D) ultrasound has been the mainstay of sonography for the past 30 years. Although technologic advances have improved image resolution, the technique of taking one 2D image at a time while spending extended periods of time one-on-one with a patient did not change until recently. As three-dimensional (3D) ultrasound emerges, the ability to acquire an entire volume of ultrasound information and then display any plane within the volume after the patient has left the premises opens a huge number of display possibilities that ultrasound had never enjoyed.

3D volume imaging is not new. Computed tomography (CT) and magnetic resonance imaging (MRI) have used 3D volume acquisition, followed by 2D reconstruction of many different types, surpassing ultrasound in these imaging display capabilities. Now that ultrasound has acquired this ability to obtain 3D volumes and display them in numerous new ways, many more opportunities have been opened in sonography. These opportunities are explored in this chapter.

The ability to think in three dimensions while scanning in two dimensions has always distinguished ultrasound practitioners from members of other disciplines. The ability now to display these 3D images digitally, heretofore available only in the mind's eye, represents an enormous advance in the field of ultrasound in obstetrics and gynecology.

BASIC PRINCIPLES

There are two basic methods for producing a 3D volume data set. One of these methods involves free-hand acquisition, manually sweeping a 2D ultrasound transducer across the patient to produce a volume ultimately digitally saved. Although the addition of a position-sensing device to the transducer may standardize the sweep, the free-hand sweep still has the inherent limitations of the differences in individual operators' sweep techniques and speed. This manual acquisition technique has been largely abandoned.

The more current method of acquiring volumes involves an automated acquisition, still done with a 2D sweep, now housed within a mechanical volume probe. This allows the volume to be acquired at a constant speed, resulting in a reproducible volume that permits measuring in all planes. In the future, nonmechanical matrix-array transducers will likely allow for far more rapid volume acquisitions, resulting in real-time volume imaging. Four-dimensional (4D) ultrasound is defined as 3D ultrasound that is displayed over time, or real-time 3D (the fourth dimension being the time dimension).

Once the volume is acquired in a standardized fashion using an automated acquisition transducer, there are many important displays available to the sonologist to demonstrate the anatomy within the volume. The following five types of displays represent the most common and most useful methods of obtaining anatomic images from a volume acquisition.¹⁻⁹

1. Multiplanar reconstruction allows viewing of three simultaneous orthogonal planes, with a single dot representing the point of intersection of all three planes. Using the tools provided by the manufacturer, we can navigate through this volume by moving either the dot or the individual planes to display any tomographic plane as well as the corresponding images that are perpendicular to that plane of section. This kind of manipulation gives us complete control over the volume and enables us to display any plane in any orientation from within the volume. Of the three displayed perpendicular planes (A, B, and C), the C plane is the one that can never be acquired by scanning the patient directly (Figs. 24-1 and 24-2). Although planes A and B are perpendicular to each other, and can be acquired from the patient using 2D ultrasound, the ability to reconstruct the C plane is what makes this technique unique.^{4,6,8}

FIGURE 24-1. A. Multiplanar reconstruction of a fetal face showing the A plane as a profile, the B plane as transverse view through the orbits, and the C plane as a coronal view through the face. Also shown in the right lower quadrant of the image is a surface reconstruction emphasizing the midface. B. Close-up of the surface rendering on the same case, emphasizing the region of the maxilla, nose and nasal septum, and lips.

FIGURE 24-2. A. Multiplanar reconstruction of the fetal head in a fetus who has agenesis of the corpus callosum as well as an interhemispheric cyst. Note that the reconstructed plane (plane C) in the left lower quadrant of the image shows this plane akin to a CT plane of section. B. Plane C view shows the parallel orientation of the lateral ventricles and the cyst (*arrow*).

FIGURE 24-3. This figure shows three sets of images taken at right angles to each other, displaying parallel slices through the volume in each of the three orthogonal planes. Note that this fetus, who has mild ventriculomegaly, can be viewed in any reconstructed plane, regardless of the way the image was obtained. All of these images were obtained from a single volume acquisition. *A.* Coronal planes of section displayed from a sagittally obtained plane. *B.* Sagittal planes of section displayed from a coronally obtained plane. *Continued*

2. The volume can also be displayed in 8 to 10 parallel tomographic slices, similar to the displays used by CT and MRI. We can choose the distance between the individual slices and the number of slices displayed. These multiple parallel slices can be demonstrated in any of the three orthogonal planes chosen, thus showing the parallel slices in either plane A, plane B, or plane C

(Fig. 24-3). Without having to actively navigate throughout the volume, one can interrogate the entire volume in multiple slices and multiple planes.¹⁰

3. The surface-rendering mode is the display method that has been publicized in the lay press, often showing baby faces in utero (Fig. 24-4). This rendering requires a fluid interface in front of the area being imaged.^{5,11,12} We can

FIGURE 24-3, cont'd. C. Transverse axial planes of section displayed from a coronally obtained plane.

FIGURE 24-4. A and B. Surface rendering of the fetal face of two different fetuses in the third trimester. Note the detail of the facial features of these two fetuses.

FIGURE 24-5. A. A fetal face using the soft tissue rendering technique showing the surface of the face, nose, lips, and chin. B. The same fetus imaged using a bony window and in profile, demonstrating that the maxilla is more echogenic than the surrounding soft tissues of the nose and lips. These two images were obtained from the same volume but displayed with different post-processing settings.

turn the object around, looking at various aspects of its surface, as well as slice through the object and looking at cut surfaces of the volume.

One can then select one of the many postprocessing techniques to display either the soft tissue surface or the skeleton of the fetus (Figs. 24-5 to 24-7). There is also a transparent mode, which allows the color Doppler display to shine through a transparent fetal body^{13,14} (Fig. 24-8). Finally, one can further evaluate the anatomy by using an electronic scalpel to cut away parts of the image, eliminating areas that are not part of the anatomy being sought, hence accentuating the area of interest (Fig. 24-9). The electronic scalpel has been shown to be very important in the evaluation of fetal malformations.¹⁵

4. The inverse mode is a rendering technique of the entire volume in which all of the cystic areas within the volume become digitally opaque and all of the solid areas become transparent (Figs. 24-10 to 24-12). This technique allows us to visualize all of the cystic areas that are otherwise hidden inside the volume. Surface rendering techniques do not permit us to visualize the cystic areas contained within a volume, and the multislice and the three orthogonal planes techniques allow us to see a only thin slice of the cystic areas at one time. The inverse mode is the only way to see, in a bird's eye view, all of the cystic areas otherwise hidden within the volume. We then can use our electronic scalpel to further slice the volume in order to concentrate on a particular area within it.¹⁶⁻¹⁹

5. Because mechanical sweeps are too slow to render adequate real-time images of the heart, an alternate method is often used called spatiotemporal image correlation (STIC). This is a cardiac gating technique that interrogates an entire cardiac cycle and plays it back, allowing us to see the anatomy of the heart in real time.²⁰⁻²³ One then can display this real-time volume in three orthogonal views, in inverse mode, or any other type of display necessary. Such volumes can be manipulated to display the four chambers of the heart, the great vessels, or any other portion of the cardiac anatomy within the sample volume (Fig. 24-13).

The most important benefit of using volume imaging, however, is the ability to save entire volumes, containing all of the patient's sonographic information. Volumes can then be manipulated, reinterrogated, and reconstructed into different displays, either in 3D or 2D display modes, well after the patient has left the examining area. This allows the ultrasound examination to be far less operator dependent, because it no longer is completely reliant on the skill and eyes of the sonographer or sonologist holding the probe. If an image was not taken at the time of the original scan, or if the fetus was not in a perfect position, these additional images can be reconstructed and viewed after the patient has finished her examination.²⁴⁻²⁶ Measurements also can be made within the volume—measurements that were perhaps inadvertently omitted at the time of the scan or measurements

FIGURE 24-6. *A*, A distal limb abnormality of the upper extremity with a transverse limb defect involving the wrist and hand is shown. The hand appears to be missing on this surface rendering view using soft tissue settings. *B*, The same volume is shown with a bone window, demonstrating that there are two digits (*arrow*) within the distal portion of the amputated wrist. The ability to see the bones or the soft tissue settings using the same volume is an advantage of 3D, which enables the practitioner to evaluate different aspects of the abnormality without having to return to the patient.

FIGURE 24-7. The bony window is used to demonstrate the fetal face. Note that the maxilla is particularly well seen using this maximum intensity window.

that can only be achieved in reconstructed planes. Last, one can transmit the entire data to other centers for review and virtual rescan for tertiary consultations or merely as an educational tool.^{26,27} These capabilities make 3D volume imaging incredibly powerful in the field of sonography.

APPLICATIONS OF THREE-DIMENSIONAL ULTRASOUND

The applications of 3D sonography are multifaceted and include the ability to perform the entire scan using a few rapidly obtained 3D volumes. This technique could replace the tedious 2D image acquisition, allowing the entire scan to be reconstructed virtually from a few volumes that contain an infinite number of image slices.^{24,25} 3D sonography is also helpful in evaluating further those malformations seen in 2D that can be more extensively examined using surface rendering or multiple reconstructed planes. There are also many applications for imaging the heart and the face, performing volumetric measurements of many fetal organs, evaluating the first trimester fetus, and looking at the fetus using Doppler within the 3D displays. All of these are discussed in detail later in the chapter.

First, the overall importance of using volume imaging relates to the ability to save all of the sonographic information in a few volumes, to display any view or any plane long after the patient has left. This was first presented by Nelson et al,²⁶ who evaluated the feasibility of performing 3D ultrasound studies and transmitting them to another center across the country, for offline review at this remote location. This study showed that 3D sonography could produce images of diagnostic quality, which could be transmitted and reconstructed to produce images similar to the original images obtained during the patient's 2D scan. Although the quality of the reconstructed images was inferior to the original 2D images obtained directly from the

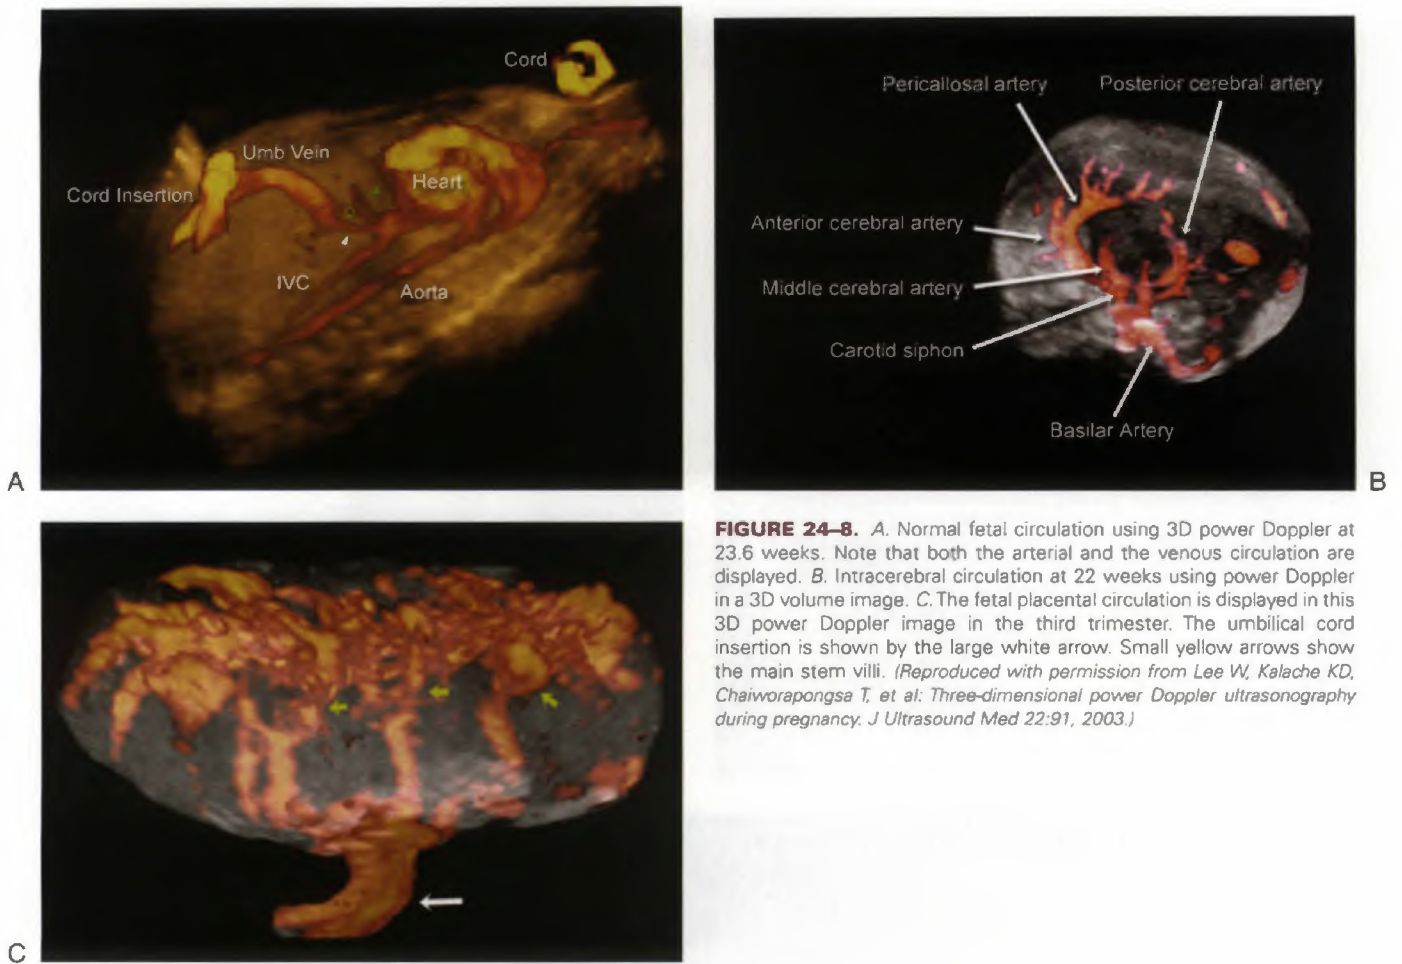

FIGURE 24-8. A. Normal fetal circulation using 3D power Doppler at 23.6 weeks. Note that both the arterial and the venous circulation are displayed. B. Intracerebral circulation at 22 weeks using power Doppler in a 3D volume image. C. The fetal placental circulation is displayed in this 3D power Doppler image in the third trimester. The umbilical cord insertion is shown by the large white arrow. Small yellow arrows show the main stem villi. FIGURE 24-9. A. Bilateral hydroceles as well as bilateral inguinal hernias (arrows) extending into the scrotum. B. The two testicles within the scrotum surrounded by fluid using the surface-rendering technique. This was achieved by cutting away part of the image using an electronic scalpel to demonstrate the surface of the testes inside of the scrotum. Note that one of the hernia sacs is also visualized on this surface view.

FIGURE 24-10. A. A coronal view through the fetal frontal horns in a fetus with mild ventriculomegaly. Note the presence of the cavum septum pellucidum (*arrow*) in between the frontal horns. B. Multiplanar reconstruction of the same fetus, demonstrating the presence of an intact corpus callosum (*arrow*). The third plane in the left lower corner of the image shows a transverse section through the atria of the lateral ventricles in a completely reconstructed view not obtainable in conventional 2D scanning. C. The inverse mode of the same case, showing a cast of the lateral ventricles and cavum septum pellucidum between the two frontal horns.

FIGURE 24-11. A. A reconstructed transverse view through the fetal head of a fetus with hydrocephalus and round cystic areas associated with the frontal horns. B. The inverse mode is shown, demonstrating a cast of the dilated lateral ventricles and frontal cystic areas.

patient, this study showed that it was clinically feasible to acquire 3D volume data at one site and display the data at another with reasonable clinical quality.²⁶

IMPROVING THE EFFICIENCY OF ULTRASOUND PRACTICE WITH THREE-DIMENSIONAL ULTRASOUND

There is no doubt that 3D volume imaging can be used to display all of the information that normally is obtained using 2D ultrasound, plus much more, in a very short time frame (Fig. 24-14).

In a pilot study of 25 cases, we first investigated the concept that five 3D volume sweeps could be used to produce all of the images necessary for a complete second trimester sonographic fetal survey. We demonstrated that the five volume data sets, designed to encompass all of the fetal anatomy (focused on the head, face, chest, abdomen, and lower extremities), could be saved and reviewed virtually on a review station, to produce the complete fetal survey, displaying fetal anatomy, as well as the biparietal diameter and femur-length measurements.²⁴ A complete structural survey was accomplished in 20 of the 25 fetuses, with most of the incomplete surveys due to the lack of complete visualization of a hand. Most importantly, however, the five volume acquisitions were accomplished in 1 minute and the review of the five volumes was done offline in only 5 minutes, resulting in a total scan time of 6 minutes compared with approximately 14 minutes per scan for performing the same examination in standard 2D imaging. This volume data set approach to the screening second trimester structural

surveys could markedly improve efficiency in ultrasound departments, because the scan could be performed in less than half the time spent performing a standard 2D fetal sonogram.

This study was expanded further using 50 patients, comparing the ability of three independent physicians to review the volumes.²⁵ The traditional 2D scan time was 19.6 minutes per scan, compared with 1.8 minutes for the acquisition of the five volumes by the sonographer. The review of the volumes, including the offline measurement of the biparietal diameter and femur, varied between 4.79 and 5.53 minutes for the three interpreting physicians. At least 90% of all anatomic landmarks were identified successfully on virtual 3D reconstruction, compared with 2D. All three physicians were equally successful at reconstructing the images as well as identifying the fetuses with abnormalities. This also indicates a marked time savings in performing the standard fetal anatomic survey, which was performed in less than 2 minutes of actual scanning time.²⁵ This application of 3D ultrasound is likely to become important in our attempt to improve the efficiency of our ultrasound departments.

The review and rescan of sonographic volumes is also crucial in allowing ultrasound to gain some of the standardization and flexibility enjoyed by CT and MRI. This application of volume sonography is likely to decrease operator dependency, which has plagued ultrasound for so long. The 3D virtual examination also is well suited for echocardiography, in which volumes can be obtained and sent to centers that can further evaluate the entire cardiac data set. This concept of volume scanning with offline interpretation would be particularly helpful for patients scanned

FIGURE 24-12. Lobar holoprosencephaly demonstrating absence of the cavum septum pellucidum and fusion of the frontal horns across the midline. *A.* A coronal view of the region of the frontal horns showing absence of the cavum septum pellucidum and connecting frontal horns. *B.* Multiplanar reconstruction of the three orthogonal planes. The defect is shown by the dot (top right, bottom left), which is located in the region where the cavum septum pellucidum should be. Also note that the inverse mode is shown in the lower right quadrant box, demonstrating a cast of the ventricles. *C.* A rendered image of the inside of the lateral ventricles right at the fusion between the lateral ventricles. *Continued*

in remote locations where tertiary care expertise may not be easily obtainable. In particular, in areas where fetal heart expertise may not be available, practitioners would have the option to obtain assistance by forwarding these data sets to cardiac centers.^{28,29}

EVALUATION OF CONGENITAL ABNORMALITIES WITH THREE-DIMENSIONAL ULTRASOUND

Investigators have compared the use of 3D and 2D ultrasound in the assessment of fetal malformations identified originally by 2D ultrasound.³⁰⁻³⁷ Much of this research has shown that volume imaging can add value to the standard 2D ultrasound in evaluating fetuses with malformations.^{32,34,35,37} The largest studies were reported by Merz and his group,³⁷ who studied 906 anomalous fetuses and demonstrated that 3D sonography proved advantageous, providing additional information in 60.8% of cases when compared with 2D ultrasound alone. This additional information was derived from tomographic multiplanar reconstruction in most cases, although in some patients, the surface-rendering mode best displayed the malformation. Dyson et al³⁴ studied 63 patients with 103 anomalies using both 2D and 3D ultrasound. The investigators found that 3D images provided additional information in 51% of the anomalies, was equivalent in 45% of anomalies, and disadvantageous in 4% when compared with 2D ultrasound alone. Although half of the patients benefited from 3D ultrasound, there was only one patient whose management was actually affected by the 3D information. The type of anomalies in which 3-D imaging was helpful included facial defects, limb abnormalities, and neural tube defects. The additional benefit of 3D ultrasound was derived largely from the ability to reconstruct multiplanar slices from the 3D ultrasound volume data sets. These authors, as did Mertz et al, concluded that 3D

ultrasound should be used as an adjunct to 2D imaging for providing comprehensive evaluation of congenital fetal abnormalities.^{34,37}

Other investigators, however, found that 3D ultrasound imaging did not provide significant additional information compared with what could be accomplished using 2D ultrasound. Although some of the malformations may be better visualized using 3D reconstruction, these authors believed that 3D ultrasound did not provide significant additional information that would change management in these anomalous cases.³⁵

The Fetal Face

Evaluation of the fetal face with 3-D ultrasound has received much attention in the literature as a complimentary technique to 2D sonography, once a fetal malformation is identified. A volume acquisition of the fetal face can be reoriented such that a true midline sagittal plane can be derived from a fetus who is not in a favorable position (Fig. 24-15). If a fetus is not in an ideal position to evaluate the profile, the true midsagittal plane can be reconstructed from a volume of a fetal face, thus optimizing the detection of fetal facial anomalies such as micrognathia.³⁸ Surface rendering views also can be helpful to evaluate the fetal lip and chin, and multiplanar views can be used to evaluate the fetal palate in cases of suspected cleft palate (Figs. 24-15 to 24-21).³⁹⁻⁴³

3D reconstruction of the fetal facial surface is one of the first applications made popular in the lay press, owing to the exquisite and life-like appearance of the fetal face this technology produces (see Fig. 24-4). A volume acquisition of the fetal face can allow the operator to reconstruct any plane throughout the entire volume, not only in three orthogonal planes but also in parallel tomographic slices as well as surface rendering.^{39-42,44} This concept has led many investigators to study the addition of 3D ultrasound imaging to the

FIGURE 24-13. A. Multiplanar reconstruction of a normal second trimester heart. The four-chamber view is in the left upper quadrant, and the reconstructed view of the pulmonary artery is shown in the right upper quadrant of the image (plane B). B. The pulmonary outflow tract indicated by the dot (*arrow*) in the acquisition plane (plane A). The pulmonary artery is also seen in the reconstructed view on the other two planes and the dot (*arrow*) indicates a single point in space that represents the pulmonary outflow tract. *Continued*

standard 2D ultrasound study, to determine the additional benefit of using 3D imaging in facial anomalies.

Many studies have suggested that the evaluation of the fetal face using the multiple displays available from a volume have improved diagnostic accuracy for the detection of cleft lip and palate, and micrognathia, as well as orbital abnormalities and nasal bone dysplasia.^{38,41,42,45} Goncalves et al³⁰ have shown, in an elegant review of the literature, that among 11 studies that evaluated the addition of 3D to 2D ultrasound for the evaluation of the fetal face, seven concluded that there was additional information provided.^{38,46-51} Four suggested that no additional useful information was provided.⁵²⁻⁵⁵

Several investigators, including Pretorius et al^{41,52} and Mertz et al,³⁸ have suggested that 3D ultrasound confirmed facial abnormalities more frequently than did 2D ultrasound, and Mertz et al found an additional anomaly in a 3D ultrasound examination that had not been identified previously in 2D examination.

The main area of interest has been evaluating the fetal palate, which remains elusive using 2D ultrasound alone (see Fig. 24-18). Campbell et al^{56,57} found that the most accurate imaging of the palate could be accomplished by using a 3D reverse-face view, in which the 3D rendering surface is adjusted to optimize the face from the inside of the skull. This image is obtained by performing a 3D surface rendering of the fetal face with a frontal-view display, and then rotating the volume 180 degrees along the Y or vertical axis, such that the back of the face is visible, showing the palate area, nasal cavity, and orbits from the back. The window of the surface-rendering area then is placed from

back to front, and the inside of the maxilla is demonstrated in this 3D reverse-face view. According to Campbell et al, this improves the visualization of the palate area (Fig. 24-22).

Chmait et al⁴³ studied more than 50 patients and also found that 3D ultrasound was better than 2D in evaluating clefts of the palate in particular. Mittermayer et al⁵⁴ found a greater accuracy of 3D ultrasound for the detection of cleft palate. A larger study, however, by Rotten and Levailant,^{58,59} looked at combining 2D and 3D ultrasound examinations for the best diagnosis of facial clefts. They studied 96 fetuses with facial clefting at a mean gestational age of 28 weeks and found that the anatomic defect was correctly identified in 97.5% of their affected cases. In 8.3% of cases, the facial clefts were missed or underestimated, and in 4.1% of cases, the facial clefts were overestimated as having a palatal component. Hata et al⁴⁷ studied 94 healthy fetuses and showed that both 2D and 3D ultrasound showed normal anatomy with equal accuracy.

Looking at other aspects of the fetal face, Lee et al⁶⁰ showed that 3D multiplanar imaging has a very high likelihood of producing a true midline sagittal view of the fetal profile, which is very useful for detecting micrognathia regardless of the fetal position. Mertz et al³⁸ evaluated 618 patients and found that the true midsagittal profile was obtainable using 2D in only 69% of cases. 3D reconstruction allowed for the evaluation of the profile in all cases. Among the 25 cases of facial abnormalities, five cases had additional features identified using 3D ultrasound. Mangione⁵⁵ evaluated the use of 3D ultrasound to detect facial dysmorphism in a study of 41 patients. He found that 3D imaging performed better than 2D ultrasound in 20 cases, and that 2D imaging was more accurate in two cases, with the remaining cases having no detectable difference between the information derived from 2D and 3D ultrasound. It is important to note, however, that in seven cases, the 3D images could not be technically obtained, indicating some technical limitations of 3D ultrasound. These authors concluded that the evaluation of craniofacial dysmorphism, particularly the study of the fetal ears, was helpful in their patients (Figs. 24-23 and 24-24).

Others have evaluated fetal cranial sutures and fontanels using 3D ultrasound, and surface rendering of the fetal volume has been particularly helpful in this set of patients.⁶¹⁻⁶⁴ Although gestational age influenced the visibility of the sutures and fontanels, 3D ultrasound was a reliable technique for viewing most of the fetal sutures and fontanels during the second half of pregnancy (Fig. 24-25). This has an impact when evaluating fetuses for cranial synostosis and related syndromes.⁶⁵

Another benefit of 3D ultrasound evaluation of the face is the ability to demonstrate to the patient and the plastic surgeon the extent of the lesion. Although practitioners who are trained in ultrasound can mentally reconstruct the extent of the abnormality based on standard 2D images, our non-scanning colleagues and the patients benefit greatly from seeing the face displayed in a traditional and less abstract way.⁶⁶

The imaging of the fetal brain is one of the areas in which 3D multiplanar imaging has been studied in great detail and is most helpful. Imaging the brain through the fetal fontanel allows us to obtain an excellent volume of the entire brain, which subsequently can be reconstructed in any plane.⁶⁷⁻⁶⁹

FIGURE 24-14. A. Tomographic imaging display of a normal second trimester fetal head, demonstrating that one can obtain views of the lateral ventricles, choroid plexus, posterior fossa and nuchal fold using the same single volume displayed in this way. B. A similar tomographic display through the fetal chest. Note that the entire heart is well displayed, demonstrating both the aorta and the pulmonary artery, as well as the fetal stomach underneath the heart using these multiple parallel slices. *Continued*

FIGURE 24-16. A and B. Two views of a fetus in the second trimester with a cleft lip and palate demonstrating the surface rendering of the defect.

This allows the visualization of the corpus callosum, which is not usually seen in the standard 2D fetal imaging planes (Fig. 24-26).^{70,71} Monteagudo et al⁶⁹ have shown the versatility of 3D volume imaging in demonstrating many views and a multitude of planes of the fetal brain. A rapid sweep of the entire neuroanatomy of the brain can be accomplished within seconds and demonstrated using all of the different display modalities offline (Figs. 24-27 and 24-28). This is similar to what can be achieved with CT and MR. Monteagudo et al⁶⁹ have demonstrated that the practitioner can navigate through the volume using the marker dot showing the exact location of structures throughout the brain in many orientations different from the usual scanning

planes. For example, one can evaluate the brain using the three-horned view, which depicts the anterior, posterior, and inferior horns on the same image.⁷² Fetal brain volume also can be measured by 3D ultrasound and correlated to fetal growth.⁷³ The use of Doppler flow imaging for assessing fetal brain flow can be done using power Doppler within a 3D volume⁷⁴ (see Fig. 24-8). Mueller et al⁵³ found 3D ultrasound beneficial in evaluating fetal central nervous system abnormalities: Among 11 fetuses, one case of spina bifida was recognized by 3D ultrasound and not by 2D, and one case of encephalocele was more accurately depicted using 3D ultrasound (Fig. 24-29). The benefit of 3D imaging in the brain, however, resides in the better visualization of the intracranial midline, in particular, the corpus callosum (see Fig. 24-26).

The remainder of the neural tube, particularly in cases of spina bifida, has also been studied using 3D (Fig. 24-30). The spine can be laid out using the maximum mode skeletal settings to evaluate one vertebra and one level at a time (Figs. 24-31 and 24-32).⁷⁵⁻⁷⁹ Lee et al⁷⁶ studied nine fetuses with both 2D and 3D ultrasound and found that 2D ultrasound agreed with the postnatal vertebral segment level of the defect in six of nine cases of spina bifida. Using 3D ultrasound in the same cases resulted in agreement to within one level of spinal segment in eight out of nine infants, and the meningeal sac could be rendered in five out of nine cases. These authors concluded that the 3D approach improved the characterization of spina bifida by adding important diagnostic information to what already was accomplished with 2D ultrasound.⁷⁶

The Fetal Skeleton and Extremities

Nelson and Pretorius⁸⁰ first showed that 3D imaging could be applied to the skeleton, with good visualization of the bones and vertebral bodies. Using the maximum intensity mode (skeletal setting), the skeleton becomes more echogenic and easier to evaluate (see Figs. 24-5, 24-6, and 24-33). 3D volume imaging has demonstrated several skeletal dysplasias, including thanatophoric dysplasia, achondrogenesis, achondroplasia, chondrodysplasia punctata, and Apert syndrome.⁸¹⁻⁸⁸ Generally, the correct diagnosis is made using 2D imaging; however, according to Krakow et al,⁸⁹ 3D imaging confirms the diagnosis and can provide improved visualization of the abnormalities. Multiple case reports and short case series in the literature emphasize the specific features that 3D ultrasound can identify better than 2D ultrasound can. These include additional facial anomalies such as micrognathia and dysmorphic low-set ears, as well as the scapular anomaly in campomelic dysplasia, depressed nasal bridge and frontal bossing in thanatophoric dysplasia, abnormal vertebral bodies and absence of ribs in Jarcho-Levin syndrome, and low-set ears and midface hypoplasia in Larsen's syndrome, just to name a few.^{73,86-88,90-95} Ruano et al⁹¹ evaluated the contribution of 3D volume imaging in the depiction of skeletal dysplasias in six cases. Among three cases of achondroplasia, two cases of osteogenesis imperfecta and one case of chondrodysplasia punctata, 2D ultrasound was used to make the correct diagnosis in four cases, whereas 3D ultrasound achieved the correct diagnosis in all six. These authors indicated that 3D ultrasound had an advantage over 2D ultrasound in that the entire fetus could be imaged within a volume, as opposed to only one portion of the fetus using single, 2D ultrasound slices. Therefore, 3D ultrasound seemed to be a complimentary method to 2D

ultrasound in providing the exact skeletal diagnosis. Opinions that 3D volume imaging provides valuable diagnostic information above and beyond 2D ultrasound remain restricted to relatively small case studies (Figs. 24-34 to 24-36).

There have been several attempts to use 3D ultrasound to aid in the detection of fetuses with Down syndrome (Fig. 24-37). Lee et al⁹⁴ studied the ability of 3D to provide fetal iliac angle measurements and showed that a standardized iliac angle could be acquired more easily from a volume of the fetal pelvis than from the 2D single-slice technique. These authors demonstrated a significantly

narrower fetal iliac angle (79 degrees) in normal fetuses, compared with those with Down syndrome (87.7 degrees), $P < 0.001$. The multiplanar view made it easy for different examiners to obtain reliable measurements, making the interobserver and intraobserver reliability of this angle measurement acceptable. For a false-positive rate of 5%, the iliac angle threshold of 87 degrees correctly identified 56% of fetuses with Down syndrome.

Several investigators have also studied the nasal bone in fetuses with Down syndrome in the second and third trimesters, using 3D imaging.⁹⁵⁻⁹⁷ Lee et al⁹⁵ studied 40

FIGURE 24-28. A. Intracranial hemorrhage in the third trimester shown in multiplanar reconstruction. fetuses, including 20 with Down syndrome, and found that there was substantial agreement between two independent examiners in determining whether the fetal nasal bone was ossified. This study demonstrated that 3D ultrasound could be used to evaluate the nasal bone with good interobserver agreement. These investigators reported that nonvisualization of the nasal bone identified up to 45% of fetuses with Down syndrome. Several studies evaluated the use of 3D ultrasound to assess the fetal nasal bone ossification,⁹⁷ including Peralta et al,⁹⁸ who examined 450 fetuses using 3D ultrasound immediately after 2D evaluation of the nasal bone in screening for chromosomal abnormalities between 11 and 14 weeks. In 93.6% of cases, they found that the nasal bone was visualized using 2D ultrasound; 29 fetuses (6.4%) had apparent absence of the nasal bone. Assessing these 29 fetuses with 3D ultrasound in more detail, there was absence

FIGURE 24–30. Surface rendering of a neural tube defect (arrow) in the lumbosacral region of a second trimester fetus.

of both nasal bones in 25 of the 29 cases (86.2%) and absence of just one nasal bone in four of 29 (13.8%) of the cases. There was absence of one or both nasal bones in 0.7% of the chromosomally normal fetuses in this study, 61.3% of fetuses with trisomy 21, and 46.7% of those with other chromosomal abnormalities. 3D ultrasound in this study showed that there is a gap between the two nasal bones in about 20% of fetuses, which may lead to an erroneous diagnosis of absent nasal bone in the perfect midsagittal plane.⁹⁸ Benoit et al⁹⁷ demonstrated that the best way to evaluate the nasal bone in the early fetus is to use the maximum mode rendering to evaluate the skeleton in the frontal view of the rendered image, to evaluate the presence of one or both nasal bones. This differs from the sagittal views used by other practitioners. It must be stressed, however, that when obtaining a volume for the purpose of evaluating nasal bone ossification, the ultrasound beam must be at the proper angle with respect to the fetus. With an angle of 30 to 60 degrees, a good volume of the fetal profile will provide visualization of the nasal bone area with good quality on reconstructed images. The quality of the volume obtained will determine the final quality of the image rendered.⁹⁹

The First Trimester of Pregnancy

3D ultrasound in the first trimester is a very exciting area of active research. Using a high frequency transvaginal transducer, Blaas displayed images of the primitive brain, revealing that adequate images of very small structures could be demonstrated and accurately reconstructed using 3D volume imaging (sonoembryology) (Figs. 24–38 and 24–39).^{100–103}

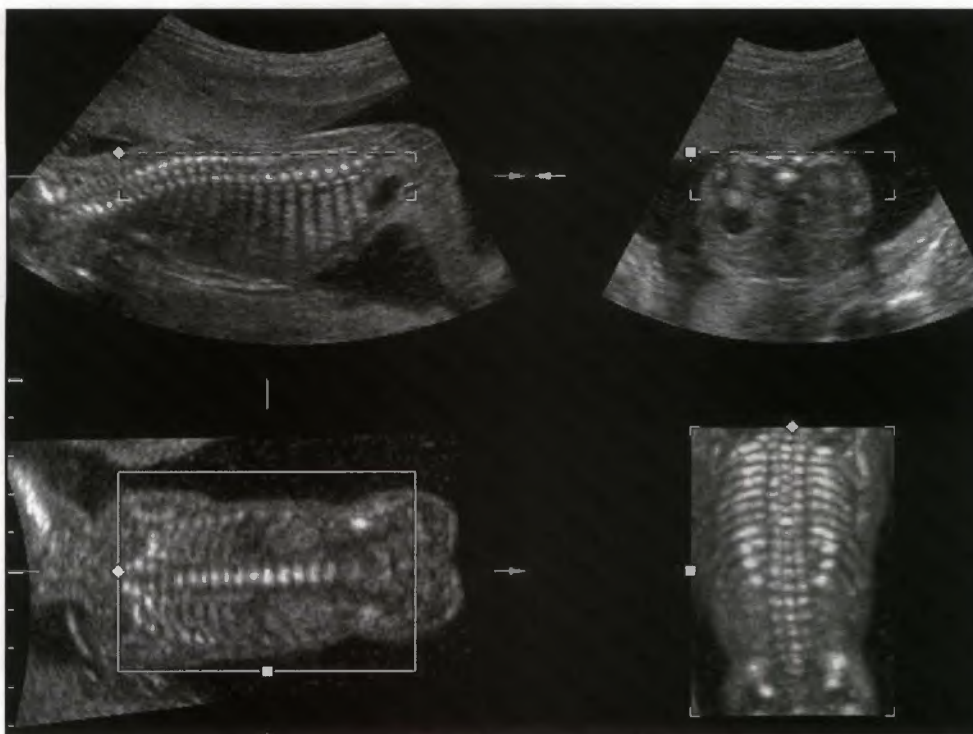

FIGURE 24-31. Multiplanar reconstruction of the normal fetal spine in the second trimester, using a bone window to enhance the appearance of the skeleton.

FIGURE 24-32. Close-up of an early third trimester fetal lumbar spine using the bone window. Note the detail of the vertebral bodies and the posterior aspect of the lower ribs.

It also is possible to use 3D imaging multiplanar reconstruction techniques to evaluate the nuchal translucency in fetuses who are not in an adequate position for the standard 2D measurement. Several studies have shown that there is excellent agreement between the standard 2D nuchal translucency measurements and the sagittal images obtained from volumes of the same fetuses by reslicing the sagittal 3D volumes.¹⁰⁴⁻¹¹⁰ Paul et al¹⁰⁹ demonstrated that if the 3D acquisition was performed with the fetus in an appropriate position for the nuchal translucency measurement, clear visualization of the nuchal membrane was achieved in 38 out of 40 fetuses, compared with 24 out of 40 when the fetus was in a random position when the acquisition was taken. Clearly, the agreement between the standard 2D nuchal translucency measurement and the 3D reconstructed measurement was far worse for volumes acquired randomly. Other practitioners have found that there was overestimation of the nuchal translucency measurements by transabdominal and transvaginal 3D reconstruction techniques when the nuchal translucency was less than 3 mm; when it was greater than 3 mm, the nuchal translucency was underestimated by 3D reconstruction.¹¹⁰ Therefore, because of these widely differing opinions, nuchal translucency measurements on reconstructed planes have not been adopted fully at this time.

Other approaches to 3D evaluation of the first trimester of pregnancy include anatomic imaging of the fetus such as evaluation of the heart, brain, and extremities, as well as the placenta, and yolk sac. Success rates for evaluating overall fetal anatomy were higher using 3D ultrasound compared

A

B

FIGURE 24-33. A second trimester fetus with a vertebral body abnormality at the level of T11. Note the scoliosis produced by the vertebral body abnormality seen on the standard 2D image. *B.* The 3D reconstruction of this fetal skeleton using the bone window. This view demonstrates that there is unilateral absence of a rib at T10 (arrow), with a normal rib on the opposite side. The rib abnormality was not appreciated on the initial 2D scan, but was first seen on the 3D reconstruction.

with 2D (78.8% versus 47.5%), including better rates of visualization of the cerebral ventricles, choroid plexus, stomach, and so on.¹¹¹⁻¹¹³ In the study by Hull, it was also noted that the scanning time was significantly shorter when using 3D volume imaging compared with 2D ultrasound in first trimester scans. In that study, the nuchal translucency thickness was measured successfully in 96.6% of fetuses using 3D, compared with 37.5% of fetuses using 2D ultrasound.¹¹¹

Another area of interest as an application of 3D imaging is the measurement of the gestational sac, placenta, and fetal volumes in the first trimester, and the relationship of these volumes to the presence of major chromosomal abnormalities.¹¹³⁻¹¹⁹ In a study by Falcon et al¹¹⁷ on 417 normal

FIGURE 24-34. Third trimester fetus with a unilateral clubfoot shown in surface-rendering mode.

FIGURE 24-35. Second trimester fetus with arthrogryposis, showing bilateral clenched hands with overlapping index fingers seen with surface rendering.

pregnancies and 83 pregnancies with major chromosomal abnormalities, the mean gestational sac volume was smaller in fetuses with trisomy 13 and triploidy, and the placental volumes were smaller in pregnancies with trisomies 13 and 18. The degree of fetal growth restriction may be more

FIGURE 24-36. Second trimester fetus with arthrogryposis, showing the contractures of both lower and upper extremities. Note the unusual posture of this fetus, indicating fixed positioning of the limbs. An advantage to 3D reconstruction is the wide field of view available to see the overall positioning of the fetus in utero.

accurately measured using volume imaging as opposed to standard 2D ultrasound.

The Fetal Heart

There is much research activity concerning the 3D and 4D evaluations of the fetal heart.¹²⁰⁻¹³³ Goncalves et al³⁰ presents an excellent summary of the studies that have occurred to date. In general, when comparing 2D and 3D imaging, 2D imaging has a better success rate in identifying the four chambers and the great vessels of the heart.³⁰ Unfortunately, owing to the fast movement of the heart, the 4D and 3D images produced are blurred by the cardiac cycle motion. The resultant lack of resolution has limited the ability of volume ultrasound to have clear enough imaging to compete. This is likely to change when matrix transducers become generally available for fetal imaging.

Some practitioners have used volume imaging to transmit data to another site, and such remote visualization of the heart has been relatively successful in some of these settings. One study reports a complete heart evaluation in 76% of cases in which the data set was transmitted to observers who were not involved in the image acquisition.¹³⁷

More recently, the STIC acquisition technique, using current slow frame rates, has been proposed to try to improve the resolution of standard 4D imaging of the heart. This technique is a method by which the complete cardiac cycle is displayed in motion using a 3D cine loop.^{21-23,28,138-140} This cine loop sequence is the result of a slow single sweep

C

FIGURE 24-39. A. Nine-week-old fetus showing surface rendering detail of the fetal face, the presence of the fetal ear, the limb buds and cord insertion. B. A later first trimester fetus (11 weeks) imaged from the back, demonstrating the location of the fetal ear as well as detail of the extremities and back. C. The fetal ears again are noted at 13 weeks on a reconstructed surface image, which also shows details of the fetal face and insertion of the cord on the placenta.

recording of an entire 3D data set, from which the information regarding cardiac activity is averaged into one cycle. The fetus must remain motionless during the entire acquisition for this technique to be successful. This results in a higher resolution of the cardiac anatomy compared with standard 4D imaging, which is blurred owing to the fast cardiac activity. Vinals et al¹⁴⁰ studied 50 patients and uploaded acquired volume data sets using the Internet. The data sets were acquired by two sonographers with limited experience in cardiac imaging and received by an experienced cardiac investigator, who reviewed the cardiac cycles and achieved a complete cardiac examination in 86% and 95% of these cases sent by the two respective sonographers. In another study, four reviewers studied a single cardiac volume from each of 18 fetuses, seven of which had congenital heart disease. Ninety-three percent of the cases of congenital heart disease were correctly identified, with only one case missed by two of the four observers.¹⁴¹ There were a few cases, however, in which adequate imaging was not possible, and therefore, the specificity for identifying congenital heart disease was only 45%, owing to the many artifacts and inadequate views. Using the STIC technique, Goncalves et al¹²² studied 69 fetuses, half of whom were normal and half of whom had abnormalities. They demonstrated that volumes could be manipulated interactively, and the anomalies could be displayed in 4D to show the extents of the defects.

Several other types of settings have been used to better visualize the cardiac structures. These include several different postprocessing programs, such as the minimum projection mode, which emphasizes the cystic areas within the volume, as well as a free-hand acquisition of 3D volume.^{142,143} Chaoui et al¹⁴⁴ have used color in the STIC technique. Three planes could be demonstrated in 24 of 27 fetuses with congenital heart disease, and in 31 of 35 fetuses with normal hearts. In the four normal fetuses with inadequate visualization using color Doppler STIC, the region of interest was at right angles to the ultrasound beam. Although this is a promising technique, there remain limitations to this type of imaging and artifacts to be overcome. DeVore et al¹²⁴ demonstrated the spin technique, in which the volume can be displayed in three-orthogonal planes of the heart, allowing the practitioner to spin around the dot in plane A using simple techniques of rotating around the X and Y axes to obtain standard cardiac views (see Fig. 24-13). Much work is being done to take this concept even further and automate the ability to find the various cardiac views from inside a volume using standardization of volume imaging. This would require that the volume be obtained and then standardized in the three orthogonal planes such that the four-chamber view would be located in the A plane.^{145,146} A preset algorithm then could be applied to the volume to enable the automatic display of the great vessels and arches.

Yet another attempt to visualize the fetal heart uses the inverse mode, such that an echogenic cast is made of the heart, similar to an angiogram¹⁴⁷ (see Fig. 24-13). The solid areas usually seen by ultrasound as hyperechogenic fade away and become transparent, so that the cast of the fetal heart can be seen in its entirety. This also can be done using the STIC technique, so that the cast is seen to pulsate. There is no doubt that in the future, the matrix probe will result in

FIGURE 24-40. A. Normal fetal heart showing the normal great vessel crossover seen with power Doppler in a rendered image. B. Similar view of the great vessels of a fetus with transposition of the great arteries. Note the parallel course of the vessels in this rendered power Doppler volume image. (Reproduced with permission from Goncalves LF, Espinoza J, Romero R, et al: A systematic approach to prenatal diagnosis of transposition of the great arteries using 4-dimensional ultrasonography with spatiotemporal image correlation. *J Ultrasound Med* 23:1225, 2004.)

much higher frame rates enabling true real-time 4D ultrasound of the heart rather than a cine loop of one reconstructed cycle. Such probes already exist for adult and pediatric cardiac work; however, these have not yet been fully adapted for fetal imaging. Although there still are limitations to the image quality produced by the matrix array transducers today, it is likely that these probes will be sufficiently improved to allow a true real-time cardiac examination using volume technology.

The evaluation of the vascular system of the fetus has been studied using 3D power Doppler (Fig. 24-40). This involves not only the evaluation of the heart using Doppler, but also the study of the blood vessels throughout the fetal body and the placenta (see Fig. 24-8). Chaoui et al¹²³ have shown images of the fetal vascular system, stressing the importance of optimizing the power Doppler image before the 3D application. The reconstruction of satisfactory images, however, was possible in only 64% of pregnancies with abnormal vascular anatomy. The problems this group encountered included difficult fetal position, fetal movement, and overlapping signals from neighboring vessels. Specific areas of study using power Doppler in 3D imaging includes assessment of fetal renal blood flow, as well as normal fetal liver blood flow, showing the normal liver vascularization and changes in flow with advancing gestational age.¹⁴⁸⁻¹⁵⁰ In a prospective study, Kalache et al¹⁵⁰ examined 390 fetuses, of whom eight had vascular anomalies including an absent ductus venosus, direct connection between the umbilical vein and the right atrium, and direct connection between the umbilical vein and the inferior vena cava. They found that 3D power Doppler was very helpful in mapping the course of the umbilical vein and the portal systemic circulation, as well as the ductus venosus, in these patients. 3D power Doppler was also used to evaluate the vasculature in

a case of pulmonary sequestration, adequately demonstrating the abnormal blood supply.¹⁵¹

EVALUATION OF VOLUME MEASUREMENTS

An important clinical application of 3D volume imaging is the ability to measure volumes more easily and accurately, compared with using 2D imaging. Several practitioners have demonstrated that 3D sonographic methods provide a more accurate volume measurement than the usual multiple 2D images, regardless of the shape and regularity of objects.¹⁵²⁻¹⁵⁵ Specific areas that have been studied include the fetal lung and the prenatal diagnosis of pulmonary hypoplasia, particularly in cases of diaphragmatic hernia.¹⁵³⁻¹⁶⁵ There also have been volume measurements reported of the kidneys, liver, spine, thigh, and other extremities, as well as fetal weight.¹⁶⁹⁻¹⁸⁵ Fetal brain volumes have been calculated using 3D volume imaging, with excellent success and good intraobserver and interobserver variability.^{73,185} 3D fractional limb volumes have been investigated as a way to predict birth weight and overall fetal growth and nutrition during gestation.¹⁷⁴⁻¹⁸⁰ Lee et al¹⁸⁰ have studied fractional limb volume, including both the upper arm and the thigh, in 100 fetuses at a mean of 39 weeks' menstrual age. The best prediction, which included abdominal circumference and fractional thigh volume, deviated by only -0.025% $\pm 7.8\%$ from actual birth weight. Thirty additional fetuses were tested prospectively, and the 3D method predicted 20 of 30 fetal weights to within 5% of the true birth weight, compared with the traditional 2D method, which predicted only six of 30 weights with the same accuracy. Other investigators also have studied thigh volume and have found that this measurement has promise as a useful reference in evaluating fetal growth and nutritional status in utero.^{177,179,180} Song et al¹⁷⁹ also found that 3D ultrasound thigh volume measurements were simple to perform and were more accurate than 2D ultrasound methods for predicting estimated weight during the third trimester.

Several investigators have studied the volume and appearance of the placenta in an attempt to quantify fetal growth and well-being.^{187,188} The volume measurement of the placenta, however, was not an accurate technique for predicting growth-restricted fetuses.¹⁸⁷

Volumetric evaluation of the fetal lungs also has spurred a large amount of study using the 3D technique called virtual organ computer-aided analysis (VOCAL, GE Healthcare).¹⁵³⁻¹⁶⁵ Kalache et al^{161,162} also studied 32 fetuses at risk for pulmonary hypoplasia and found that both 3D multiplanar reconstruction and 3D VOCAL methods could be used to obtain accurate measurements of fetal lung volumes. VOCAL does have the advantage of being able to trace out irregular areas of lung parenchymas, such as in cases of diaphragmatic hernia compressing the lung. Volume sweeps are best performed with the fetus in transverse section. The ability to measure lung volume with 3D ultrasound has resulted in new nomograms for the normal fetal lung volume at different gestational ages. This method could be an alternative to MRI in imaging the fetal lungs. Sabogal et al¹⁶⁸ studied 75 patients at 20 to 30 weeks with 182 volumes, showing that 3D sonography-derived measurements were reliable and reproducible within that

window of gestational age. 3D assessment of fetal lungs was also studied as a prognostic factor for isolated diaphragmatic hernia. The observed-to-expected fetal lung-volume ratio was significantly lower in the group of fetuses with congenital diaphragmatic hernia, compared with the control group.¹⁶⁴ The distribution of this ratio was particularly low in patients with congenital diaphragmatic hernia who did not survive compared with those who survived.

ARTIFACTS

The artifacts that occur as a result of volume imaging can be different from those that are familiar in 2D ultrasound.¹⁸⁹⁻¹⁹¹ The usual artifacts, such as shadowing and through-transmission, are present in any kind of ultrasound examination, but there also are new artifacts inherent to 3D reconstruction of images (Figs. 24-41 to 24-44). These include motion artifacts, such as fetal movement and cardiac motion. It also is important to recognize acoustic shadowing, because it is unlikely to be in the expected location in a reconstructed image. Shadowing is understandable based on the acquisition image, but as different planes are reconstructed, the shadow may no longer make sense and may be misinterpreted for pathology. Acoustic enhancement behind a cystic structure is also a finding that is an obvious part of a standard ultrasound image but that can be practically unrecognizable in a reconstructed image. The cystic area that has generated the through transmission is unlikely to be located in the usual proximity to the enhanced area in a reconstructed image and may not even appear in the image at all. Other artifacts can be produced, such as apparent limb or facial defects, based on the position of the acquiring data box within the image. It is important to learn about the appearances of these new artifacts in order to recognize them when they occur.

PARENTAL-FETAL BONDING

Seeing the fetus in such a real-life form as 3D surface rendering may arouse many emotions from the mother and father, and family members (Figs. 24-45 and 24-46). This type of parental-fetal bonding can sometimes lead to altered behaviors of lifestyle, such as cessation of smoking or cessation of alcohol usage by the mother. There are several studies that compare the effects of 2D ultrasound with 3D and 4D ultrasound scanning on maternal emotional status and bonding.¹⁹²⁻¹⁹⁴ Rustico et al¹⁹³ studied 52 women randomly assigned to 2D or 2D followed by 4D imaging. The patients who were examined with 4D ultrasound were more likely to see facial expressions of their fetuses, and hand-to-mouth movements compared with patients who were examined with 2D ultrasound. However, in this randomized study, the addition of 4D ultrasound did not change the antenatal emotional attachment of the mother, compared with patients undergoing conventional 2D ultrasound alone. On the other hand, Ji et al¹⁹² studied 50 mothers who received 3D ultrasound and 50 who received standard 2D ultrasound scans. The 3D ultrasound patients appeared more positively influenced and showed their ultrasound images to greater numbers of people within their family and friends compared with those who had 2D ultrasounds alone. This study suggested that 3D ultrasound

FIGURE 24-41. Multiplanar reconstruction of a third trimester fetal face showing an artifact due to fetal movement. There is an indentation in the nose on one side best seen in multiplanar plane B (*arrow*) and transmitted to the surface rendering as an elongated nose on one side (*arrow*). This is an artifact due to fetal movement during the acquisition and appears on all reconstructed views.

FIGURE 24-42. Third trimester fetal face showing the shadow from the digits of the hand that is located in front of the face. The hand itself is not seen owing to the position of the surface-rendering window, but the shadow of the digits is visualized as an artifact on the face.

may have a greater impact on the maternal-fetal bonding process. As we can see, there is controversy concerning whether the addition of 3D and 4D ultrasound increases the maternal or parental bonding to the fetus. At present, there are a number of organizations in business that provide entertainment ultrasound, which is mostly 3D imaging that

FIGURE 24-43. First trimester pregnancy at 6 weeks showing a gestational sac with a yolk sac. Note the shape of an intrauterine device (IUD) (*arrow*) located below the level of the gestational sac. This is actually the shadow of the IUD, which is located in a different plane. Such a shadow is an artifact, which is reconstructed in a plane different from the location of the IUD itself.

FIGURE 24-44. Multiplanar reconstruction and surface rendering of a late first trimester fetus showing that the entire fetus is located within the rendering box. Note that the rendered image shows the entire fetus, complete with extremities. *A.* Example of what happens if the fetus is moved partly out of the render box. *B.* Both the skull and the lower extremities are moved out, resulting in the rendered image that appears to have the fetal lower leg cut (*arrow*) off just above the knee. This is an artifact, which is dependent on the placement of the render box.

FIGURE 24-45. Late first trimester fetus showing upper extremities and face in a very life-like position.

FIGURE 24-46. Third trimester fetus yawning, which is easily recognizable by family members viewing the scan.

is done in many cases by nonmedical personnel. The ultrasound community and the major national ultrasound societies have condemned these nonmedical facilities.

CONCLUSION

3D ultrasound is in its infancy and is one of the most exciting advances in sonography in the last decade. It started out as a problem-solving tool as an adjunct to 2D imaging in selected circumstances, but it has become increasingly a part of sonography in obstetrics and gynecology. One of the most important features of volume ultrasound is the ability to save an entire volume data set of sonographic information, which can be displayed and rescanned in ways similar to those used in CT and MRI. Such displays provide ultrasound with an opportunity to be as efficient, versatile, and standardized as these other cross-sectional imaging techniques. As the resolution of reconstructed volume sonographic images improves, and as the frame rate of real-time or 4D ultrasound increases, the potential of volume imaging in ultrasound will be far-reaching and may well reshape the way that ultrasound is practiced today.

Fetal Cardiac Interventions

INTRODUCTION

The potential for the field of fetal surgery would never even have been considered without the existence of prenatal ultrasound diagnosis. This makes the discussion of these interventions particularly pertinent to a textbook dedicated to ultrasound in obstetrics and gynecology.

Most malformations considered for fetal surgery may be initially detected as abnormal on routine screening but may not be accurately identified until a targeted examination is performed. It is self-evident that an accurate diagnosis is critical to determining the appropriateness of a fetal surgical intervention. Fetal malformations that are not isolated or are associated with aneuploidy or a syndrome have always been excluded as candidates for intervention. This is because the risk-benefit ratio, given that all procedures involve some maternal risk, is not acceptable. Therefore, great effort should be made to confirm both the accurate diagnosis of a malformation and the fact that it is truly isolated. Ancillary techniques to ensure full and accurate assessment include fetal echocardiography, magnetic resonance imaging (MRI), and karyotyping, depending on what additional problems the fetus is most at risk. Regardless, one must always counsel patients regarding the fallibility of the process and that abnormalities initially that are believed to be isolated may not ultimately prove to be so in the final analysis.

The indications for fetal surgical interventions have expanded, as has the total number of procedures performed, the sites at which they are performed, and the number of physicians performing them. However, overall these procedures remain very limited when compared with the number of pregnancies and even the number of fetuses with malformations. One of the responsibilities of physicians with an

interest in prenatal diagnosis and intervention, in the future, is to determine training needs and oversight for operators and centers involved in this field. It is unclear how many centers would be needed given the rarity of malformations and the even smaller proportion of those with a malformation that may need fetal intervention. A decision will need to be made if ease of accessibility is a substitute for volume of procedures performed. Certainly with access to the World Wide Web, patients in our experience have become savvy consumers who are readily able to establish contact and provide information necessary to make a preliminary assessment regarding their fetus's diagnosis. This, together with the increasing ease of large volume electronic transfer of information, has made geographic proximity less important.

Over the past decade technologic advances have allowed a transition toward less invasive procedures. Initial fetal surgical procedures at the University of California, San Francisco (UCSF) involved maternal laparotomy and hysterotomy. This approach evolved into laparotomy and uterine endoscopy, and most recently, into percutaneous procedures using laparoscopic devices with diameters at times of 3 mm or less. Our experience suggests that the less invasive approaches are associated with a less complicated post-operative recovery for the mothers but does not entirely eliminate morbidity¹ (Table 25-1). Each one of these approaches is discussed in detail.

HYSTEROTOMY

The feasibility of performing a hysterotomy and subsequent closure of the gravid human uterus was tested in the primate

Table 25-1**Maternal Morbidity and Mortality for 178 Interventions at UCSF With Postoperative Continuing Pregnancy and Divided into Operative Subgroups**

Operative Technique	Open Hysterotomy	Endoscopy FETENDO/ Lap-FETENDO	Percutaneous FIGS/ Lap-FIGS	All Interventions
Patients with postop continuing pregnancy	79	68	31	178
Gestational age at surgery [wk]	25.1	24.5	21.1	24.2
Range [wk]	17.6–30.4	17.9–32.1	17.0–26.6	17.0–32.1
Gestational age at delivery [wk]	30.1	30.4	32.7	30.7
Range [wk]	21.6–36.7	19.6–39.3	21.7–40.4	19.6–40.4
Interval surgery to delivery [wk]	4.9	6.0	11.6	6.5
Range [wk]	0–16	0–19	0.3–21.4	0–21.4
Pulmonary edema	22/79 (27.8%)	17/68 (25.0%)	0/31 (0%)	39/178 (21.9%)
Bleeding requiring blood transfusion	11/87 (12.6%)	2/69 (2.9%)	0/31 (0%)	13/187 (7.0%)
PTL leading to delivery	26/79 (32.9%)	18/68 (26.5%)	4/31 (12.9%)	48/178 (27.0%)
Preterm premature rupture of membranes (PPROM)	41/79 (51.9%)	30/68 (44.1%)	8/31 (25.8%)	79/178 (44.4%)
Chorioamnionitis	7/79 (8.9%)	1/68 (1.5%)	0/31 (0%)	8/178 (4.5%)

FIGURE 25-1. Photograph of operative laparotomy and hysterotomy in a Rhesus monkey. This early work paved the way for the ability to perform such procedures safely in the mother carrying a fetus with a variety of malformations.

(Fig. 25-1). The reason for using the primate model is that other gravid large animal models such as the sheep, are much more forgiving. The sheep uterus is more thin walled and has a multicotyledonary placenta. Closure is more straightforward, and preterm labor is rarely a significant problem. The safety profile in this series of primate fetal surgeries was reassuring, including subsequent fertility.² The human experience is now extensive, both from UCSF and others,^{1,3,4} primarily associated with the large numbers of fetal spina bifida repairs. We currently reserve maternal laparotomy/hysterotomy procedures for repair of spina bifida, resection of sacrococcygeal teratoma and other tumors, and lobectomy for congenital cystic adenomatoid malformation (CCAM) of the lung.

Risks

We have recently reviewed our experience at UCSF with maternal hysterotomy¹ (see Table 25-1). Eighty-seven hysterotomies were performed between 1989 and 2003. There were significant immediate postoperative complications. In the early experience, pulmonary edema related to multiple tocolytic use, particularly nitroglycerin, and aggressive fluid management was a significant problem.⁵ Thirteen percent required transfusion for intraoperative blood loss. Pregnancy outcomes were also significantly affected by a preterm premature rupture of membrane (PPROM) rate of 52%, and 33% having preterm labor refractory to maximal tocolytic management leading to delivery. The mean time from hysterotomy to delivery was 4.9 weeks (range 0 to 16 weeks). The mean gestational age at the time of delivery was 30.1 weeks (range 21.6 to 36.7 weeks). Others^{6,7} have similar experiences with respect to an increased risk of preterm delivery following hysterotomy. Most of the morbidity associated with hysterotomy has decreased with experience. Significant pulmonary edema or blood loss is rare, and the mean gestational age at the time of delivery for repair of myelomeningocele (MMC) is now around 34 weeks.

Procedure

The practical aspects of hysterotomy and postoperative management have evolved since the initial years of experience. The following is a description of our current approach. Lengthy discussions regarding the risks, benefits, and alternatives of the procedure are important, including the experimental nature of the surgery. We generally differentiate the risks to the mother, the fetus, and the pregnancy in our counseling. The risks to the mother are similar to any major abdominal surgery, although in this case, there is no direct physical benefit to her. In addition there are the risks associated with aggressive tocolytic therapy and bed rest in

a hypercoagulable state. The risks to the fetus are primarily vascular instability and hypoperfusion intraoperatively leading to organ injury or death, and prematurity due to postoperative complications. The risks to the pregnancy are primarily preterm labor and premature rupture of membranes and preterm delivery. Infectious complications are rare, except when premature rupture leads to prolonged latency. An important additional discussion point is that all subsequent deliveries, including the index pregnancy, must be by cesarean section. Data regarding future fertility are reassuring, with no increased incidence of infertility in the UCSF experience in those patients attempting pregnancy.⁸ Experience from Children's Hospital of Pennsylvania (CHOP) suggests a concerning risk for uterine rupture/dehiscence in subsequent pregnancies that may be as high as 6% to 12%,⁹ which would be considerably higher than the risk after previous low transverse cesarean section (1% or less)¹⁰ or classic cesarean section (5% to 10%).¹¹ Another potential risk in subsequent pregnancies is placenta accreta. The reason for this risk is that the site of a hysterotomy performed in the second trimester is never in the same area as a cesarean section entry. There is an increased risk of placenta accreta in any case in which implantation is in an area of uterine scarring. Multiple incisions increase the likelihood of implantation in such an area. To our knowledge, there has not been a case of accreta in a fetal surgical patient of ours in a subsequent pregnancy.

Ultrasound is used for guidance before the hysterotomy procedure. Once the patient has had general anesthesia and intubation initiated, and the sterile field is established, ultrasound is used to establish fetal lie, its location within the uterus, and the position of the placenta. Transabdominal manipulation with ultrasound guidance is used to position the fetus such that the fetal surgical site is near the fundus. Depending on the maternal body habitus and fetal size and position, this may be challenging. Laparotomy is then performed, and the ultrasound transducer, covered in a sterile sleeve, is placed directly on the surface of the uterus. The edge of the placenta is identified, because this information is critical in deciding where to perform the uterine entry. Generally, one wants to make the uterine incision centered as far from the placental edge as possible. The reason for this is that once the incision is made, and the amniotic fluid leaves the confines of the uterus, the uterus shrinks. One is generally surprised at how close the incision is to the edge of the placenta regardless of one's efforts. The reason proximity to the placental edge is so critical is because of the risk of bleeding and abruption, which cannot readily be controlled and, if significant, will usually necessitate immediate delivery for maternal safety.

Ultrasound is also used to identify the specific position of the fetus within the uterus. Generally the incision in the uterus will have been made so as to have optimal access to the fetal part to be surgically addressed. Ultrasound is also used for transuterine monitoring of the fetal heart during the procedure. Following completion of the fetal intervention, the membranes and myometrium are closed with several layers of suture. A catheter is left in the uterine cavity to allow lactated Ringer's solution to be infused together with antibiotics. Ultrasound determines the volume of "amniotic" fluid, which is generally at a low-normal level to minimize stress on the suture line.

Post-operative management generally involves 24 hours of intravenous tocolysis with magnesium sulfate as well as maintenance with oral indomethacin for a total of 48 hours. Long-term tocolytic maintenance with nifedipine is continued basically until delivery. Antibiotic "prophylaxis" is continued for 24 hours. Ultrasound monitoring to evaluate fetal health, amniotic fluid volume, cervical length, and ductal patency is performed at least daily. Hospital discharge generally occurs 4 to 5 days after surgery. If all goes well, long-term monitoring with ultrasound continues at a weekly frequency.

FETOSCOPY

The growing popularity of videoendoscopic surgery in the 1990s, combined with earlier experience with fetoscopy, paved the way for the concept of endoscopic fetal surgery. The rationale was that a tiny puncture of the amniotic cavity would overcome some of the limiting steps in fetal surgery: (1) preterm labor, which was believed to be triggered by the large uterine incision of open fetal surgery; and (2) significant maternal morbidity associated with a large laparotomy. The ultimate hope was that fetoscopic interventions would be possible by a percutaneous approach. Animal models were developed to test the new instruments and techniques. The ovine model is very resistant to postoperative preterm contractions, as mentioned earlier, and therefore not ideal to study the hypothesis that endoscopic access to the uterine cavity was associated with less uterine activity than after hysterotomy. We studied that aspect in midtrimester Rhesus monkeys (*Macaca mulatta*) who underwent triple cannulation of the amniotic cavity during 60 minutes. No significant postoperative premature contractions could be demonstrated, in contrast to uterine irritability following hysterotomy.¹² Use of this higher species is limited by ethical and financial constraints, but today, the model is still in use for study on healing of the fetal membranes after fetoscopic cannulation.

Risks

The risks of fetoscopy are associated with the uterine puncture as well as the specific procedure that is being treated. In some cases, adverse outcomes may be inherent to the severity of the disease being treated, such as in twin-to-twin transfusion syndrome (TTTS). In the UCSF experience,¹ the morbidities were in some cases similar to the more invasive procedure of hysterotomy and in some cases much more akin to the pattern seen in the so-called fetal image-guided surgery (FIGS). One reason for this is that the initial UCSF approach was "macroinvasive" endoscopy including laparotomy, uterine exteriorization and general anesthesia. Current risk profiles with a percutaneous approach and smaller instruments demonstrate less morbidity.¹³ This includes a much lower rate of preterm labor and even PPRM. Length of hospitalization and time of return to normal maternal activity are also much improved.

Procedure

Patients are generally premedicated with a tocolytic agent, often indomethacin, and given prophylactic intravenous

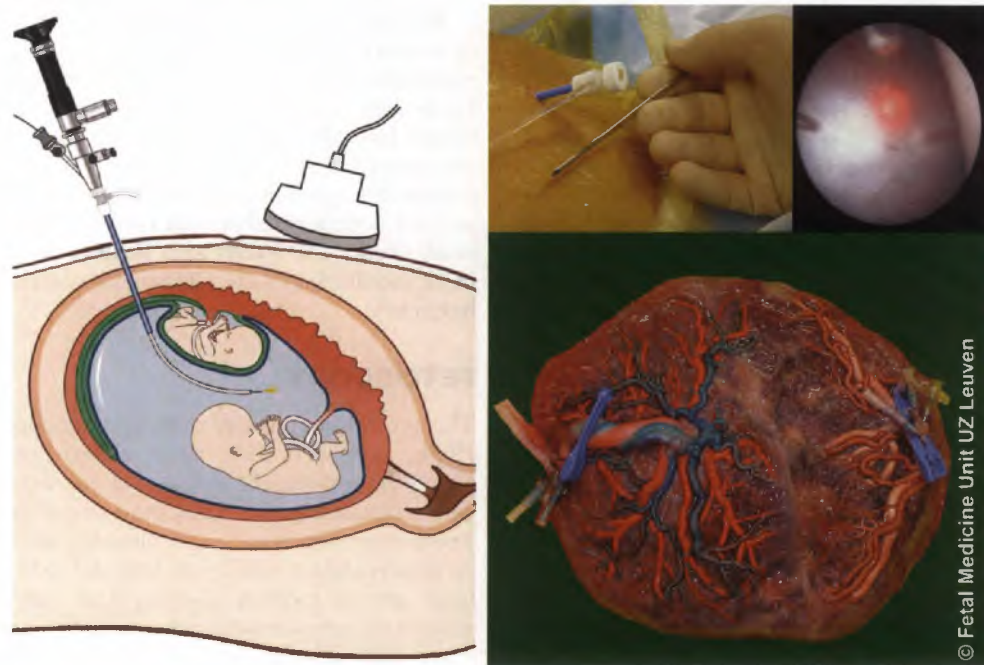

FIGURE 25-2. Schematic drawing of a percutaneous fetoscopic laser coagulation procedure for TTTS. (Reprinted with permission from Group TE: *The Eurofoetus Group*. Bottom: injected placenta after procedure, demonstrating ablated vessels.

(IV) antibiotics. The procedures are performed under local or regional anesthesia. Depending on the gestational age and the tradition of the center, the surgery may be performed in the surgical operating rooms, labor and delivery, or the ultrasound suite. Cannulas, instruments, and particularly, endoscopes have undergone a tremendous evolution in the past 10 years, based on prototypes developed in animal models. Operative fetoscopy is a sonoendoscopic enterprise that has evolved so that the surgical team can see the ultrasound and fetoscopic images simultaneously. Purpose-designed embryo- or fetoscopes typically have remote eyepieces, to reduce weight and facilitate precise movements. Nearly all are bendable fiber-endoscopes rather than conventional rod lens scopes, and as the number of pixels increases over time, image quality improves. Typical diameters are between 1.0 and 2.0 mm. Thin-walled semiflexible plastic cannulas (10f Check-flo introducers, Cook Medical, Bloomington, IN) are used to create amniotic access, so that instrument changes are possible. Sharp trocars have been developed to accommodate the wide range of diameters used for different operations (Karl Storz, Germany). Alternatively, one introduces the endoscope sheath loaded with a sharp obturator (Fig. 25–2). Specifics can be reviewed in several texts.^{14,15} Basically, however, ultrasound is used to identify an appropriate entry point and then is used to direct the trochar into the amniotic cavity, avoiding the placenta and the fetus, and obviously maternal organs such as bowel and bladder. One group has documented the safety, in their hands, of a transplacental approach.¹⁶ Despite this experience, most operators still attempt to avoid the placenta. The trochar is then replaced by the fetoscope. Ultrasound is still used to direct the scope within the uterus, because its field

and depth of view can be relatively limited. These procedures are “sono-endoscopic.” For cases of TTTS, the endoscope is in the sac of the recipient twin, the one with the polyhydramnios. The entry point is determined by the factors noted earlier, but also to allow good visualization of the vascular equator of the twins. The whole equator is then explored, and any unpaired vessels consistent with abnormal communications are ablated using the laser fiber that is advanced through the operating channel of the endoscope sleeve. After successful ablation, the endoscope is withdrawn and the polyhydramnios drained through the cannula under ultrasound guidance. Once the fluid has reached a normal level (deepest vertical pocket of around 5 to 6 cm) the cannula is removed. This amnioreduction reduces the risk of port-site leaking and amniotic fluid irritation of the peritoneal cavity, which may be painful. It may also improve placental perfusion, but regardless, makes the patient more comfortable. In many cases, little or no tocolytic medication is needed, and patients are generally discharged within 24 hours or less of the procedure.

SHUNTS AND RADIOFREQUENCY ABLATION

Shunts are used for chronic drainage of fluid-filled fetal cavities, organs, and cysts. The first shunt was developed by Harrison at UCSF in the early 1980s.¹⁷ This is basically a double pigtail shunt that is introduced through a 14-gauge introducer (Cook Medical, Bloomington, IN). The Rodeck shunt was developed during a similar time period in the United Kingdom. It is also a double pigtail shunt but is longer and has a greater diameter (Rocket Medical, UK).

Obviously it uses a larger diameter introducer.¹⁸ These catheters are used for draining obstructed bladders, pleural effusions, and large macrocystic CCAMs.

Radiofrequency ablation (RFA) is most commonly used in the nonobstetric patient for the destruction of tumor tissue in solid organs such as the liver. The group at the UCSF Fetal Treatment Center was first to use it for the application of localized cautery of vascular communications. Initially, it was used for ablating the feeding vessels to the anomalous fetus in twin-reversed-arterial perfusion (TRAP).¹⁹ Since that time, we have used it for selective reduction in monochorionic twin gestations discordant for severe anomalies and in patients with severe TTTS without hope for salvage of one of the twins.

Risks

The risks of complication of shunt placement and RFA are lower than for the more invasive fetal surgical interventions such as hysterotomy. Obviously by definition, all invasive procedures involve a risk of hemorrhage and infection. However, in our experience, these adverse events occur at a much lower frequency (see Table 25-1).¹ The triggering of preterm delivery by these procedures is also quite unusual, although the risk of PPROM remains. There is also the risk of fetal injury, which in cases of monochorionic twins, generally is related to hypotension from acute hypovolemia in the normal co-twin secondary to exsanguination into the placental vascular bed and the other fetus.

Procedure

As we have become more comfortable with these procedures, the length of hospitalization, complexity of perioperative management, and type of anesthesia have changed. In many cases, they can be performed as an outpatient procedure. Tocolytic prophylaxis is given as a single dose of indomethacin. Routine preoperative antibiotic prophylaxis is given. These procedures are performed completely under ultrasound guidance (FIGS). We perform these procedures using either spinal or local anesthesia. For shunts, a small incision is made in the maternal skin, and then the introducer with the trochar in place is advanced into the amniotic cavity. Care is used to evaluate the myometrium that will be traversed, with a high frequency transducer and color flow Doppler with low flow settings, to avoid large veins. We generally avoid a transplacental approach as well. The trochar and introducer are then advanced into the area where the shunt will be placed. Once in position, the trochar is removed and care taken to not allow the fluid to be drained and escape by placing one's finger over the end. The shunt is then loaded into the introducer and advanced using an internal pushing device. These pushers either are of a certain length or have marks on them to advance just the internal coil of the catheter stent out of the introducer. It is critical to image this with ultrasound as well. Once the inner coils of the catheter stent are appropriately positioned, the introducer is carefully withdrawn, while at the same time advancing the shunt further, so that the outer coil is positioned on the skin of the fetus, within the amniotic cavity. Care must be taken to have enough of a fluid gap between the fetus and the wall of the uterus to minimize the risk of

the outer end of the shunt being stuck in the myometrium or maternal abdominal wall, with the risk of an amnioperitoneal shunt. Given the ready access to these shunts, and the fact that physicians feel capable of performing the procedure because of their comfort with image-guided procedures such as amniocentesis, this may be the most frequently and widely performed fetal surgical intervention. Unfortunately, this experience and associated outcomes are not documented in the scientific literature.

Postoperative management involves maternal and fetal monitoring. Further tocolytic management is tailored based on contraction activity. Frequently, no further medication is necessary. Maternal vital signs should be followed carefully because direct observation of the uterine puncture is not possible to determine hemostasis because of the percutaneous approach. One benefit of not needing tocolysis is that the hemostatic mechanism of the uterus in response to a puncture is a localized contraction. Ultrasound is obviously critical to fetal follow-up.

The RFA device that we currently use at UCSF includes a 17-g needle device (RITA Medical, Fremont, CA). The perioperative management is identical to that discussed earlier with shunts, except that local anesthesia alone is generally used. In the case of TRAP, the instrument is guided into the tissue of the acardiac twin at the level of the cord insertion. The prongs are deployed, and energy transmission to the device initiated. Because of the heat generation, there is outgassing that is readily visible with ultrasound. The procedure is considered completed when there is no evidence of flow in the acardiac twin or the cord leading to it on color and pulsed Doppler imaging. The prongs are then retracted and the device withdrawn. Postoperative monitoring is similar to shunt placement, and further tocolytic management is rarely necessary. The patients can generally be discharged within hours of the procedure.

DISEASE ENTITIES

Monochorionic Twin Problems

Twin-Twin Transfusion Syndrome

In an estimated 15% of monochorionic (MC) twins, there is a chronic imbalance in the net flow of blood across the vascular anastomoses, resulting in TTTS. The condition is usually explained by the combination of transfusion from the donor, leading to hypovolemia, oliguria, and oligohydramnios in the donor twin (so-called stuck twin) and hypervolemia, polyuria, and polyhydramnios in the recipient twin. The recipient twin often develops circulatory volume overload and hydrops. The condition coincides with specific patterns of vascular anastomoses. This forms the basis for the surgical approach to this condition. Fetal vessels run on the surface of the placenta, where they can be documented by fetoscopic inspection, and ablated (see Fig. 25-2). Although several types of anastomoses exist, knowledge about their nature (either by Doppler studies or by fetoscopy) does not play a role in TTTS: all intertwin anastomoses should be ablated as to functionally "bichorionize" the placenta (see Fig. 25-2).

The diagnosis of TTTS is based on ultrasound documentation of very specifically discrepant amniotic fluid levels.

Table 25-2 Staging of Twin to Twin Transfusion Syndrome

Stage	Polyhydramnios/Oligohydramnios*	Persistently Empty Bladder in Donor	Abnormal Doppler†	Hydrops	Demise
I	X				
II	X	X			
III	X	X	X		
IV				X	
V					X

*Polyhydramnios = deepest vertical pocket ≥ 8 cm, Oligohydramnios = deepest vertical pocket < 2 cm

†At least one of the following: 1) umbilical artery absent/reserved end diastolic flow, 2) absent/reversed end diastolic flow in the ductus venosus, and 3) pulsatile umbilical venous flow

Modified from Quintero RA, Morales WJ, Allen MH, et al: Staging of twin-twin transfusion syndrome. *J Perinatol* 19:550, 1999; and Taylor MJO, Jolly M, Wee L, et al: Validation of the Quintero staging system for twin-twin transfusion syndrome. *Obstet Gynecol* 100:1257, 2002.

It requires the presence of oligouric oligohydramnios (deepest vertical pool [DVP] < 2 cm), together with polyuric polyhydramnios (8 cm DVP < 20 weeks; ≥ 10 cm ≥ 20 weeks; criteria based on the Eurofoetus trial). Intrauterine growth restriction may be part of the clinical picture but is *not* a criterion for establishing the diagnosis or an indication for therapy. The natural history of TTTS is not clearly defined yet, but in a number of cases, it may be progressive, with development of abnormal Doppler patterns in the umbilical artery of the donor fetus or abnormal venous Doppler patterns in the recipient, and ultimately fetal hydrops or fetal death. The latter signs form the basis of the ultrasound-based Quintero stages²⁰ (Table 25-2). However, cases may occasionally progress acutely from having discrepant fluids (stage I or II) directly to the stage of fetal death (stage V). This staging also does not necessarily determine management based on currently available data.

If left untreated, perinatal loss is more than 80% in severe TTTS; therefore, therapy is mandatory and fetoscopic laser has the best pathophysiologic basis. In addition, the Eurofoetus randomized trial demonstrated better outcomes after fetoscopic laser than after serial amnioreduction.²¹ The median gestational age at delivery was significantly higher in the laser-treated group compared with the amnioreduction group. Survival of at least one twin to 6 months was higher following laser therapy. Amnioreduction more often leads to demise of both twins. Survival chances were similar for donors and recipients. It is important to stress that laser coagulation is more effective than amnioreduction for a given stage. It is true that survival decreases according to stage; however, even for stage IV, survival of the hydropic recipient is 50%.²² Therefore, this does not justify promoting selective fetocide based purely on the stage of the disease at presentation. Preoperative measurement of the cervix can assess the risk for premature delivery.²³ With a cervix less than 30 mm, the risk for delivery before 34 weeks is about 74%. If the cervix is less than 20 mm, the vast majority of patients miscarry. The risk for PPRM is estimated to be around 10% or less; the risk for abruption is 1% to 2% but relates to the amnioreduction part of the procedure. Other uncommon complications are chorioamnionitis and hemorrhage. Post-laser fetal anemia and recurrent or persistent TTTS should be screened for and may suggest incomplete division of the placenta. Recent injection studies have demonstrated that this might be more often the case than expected, and that it does not always lead to clinical

problems.²⁴ Cardiac abnormalities can develop as well and require postnatal follow-up by a pediatric cardiologist. Therefore, it should be clear that compulsive postoperative ultrasound follow-up by experienced fetal medicine specialists is a critical component of successful therapy.

In the Eurofoetus trial,²¹ a higher percentage of infants were alive without major neurologic morbidity at age 6 months or greater in the laser group (Table 25-3). The long-term follow-up of these patients is now pending. Until that time, counseling can be based on the detailed follow-up studies of Hecher's group,²⁵ with a 6% rate of severe handicap compared with 20% to 25%, which is the rate commonly associated with amnioreduction.

As noted earlier, TTTS predisposes to right ventricular outlet tract obstruction (pulmonary stenosis) in 8% of ex-recipients. Of these patients, half needed balloon dilatation.²⁶ Other pre-laser in utero signs of cardiac decompensation resolved and were undetectable postnatally. Normal renal function was also documented in former donors.²⁷

Fetoscopic laser coagulation is the most frequently performed obstetric endoscopic procedure, with more than 1500 procedures performed by the Eurofoetus centers alone. Single center series reported better results than in the randomized trial. Experience, case selection, and probably closer postoperative management may play a role in this difference. Additional centers have started offering this operation with comparable results. The benefits and disadvantages of the growing number of centers, and the potential dilution of experience is a point of healthy discussion.

Discordant Monochorionic Twins

Most MC twins are indeed very similar in appearance, but major discordances in structural and even in chromosomal anomalies can occur. Abnormalities associated with twins include those of the neural tube, brain, face, gastrointestinal tract, anterior abdominal wall and heart, with more than 80% being discordant. MC twins can also be discordant for aneuploidy (trisomy 13 or 21, monosomy 45,X). Counseling issues may be very challenging in heterokaryotypic twins, because it is not possible to exclude hidden but phenotypically important mosaicism and microchimerism in the twin with normal karyotype.²⁸ Options for MC twin pregnancies discordant for structural and chromosomal anomalies are essentially expectant management, selective fetocide, or

Table 25-3 Randomized Controlled Trial of Fetoscopic Laser Surgery Versus Serial Amniodrainage

	Laser n=72	Amnioreduction n=70	P value
Gestation age at randomization (weeks)	20.6 (2.4)	20.9 (2.5)	ns
Quintero stage at randomization

AFV, amniotic fluid volume; ns, not significant.

Baseline characteristics according to group, results reported as number of pregnancies (n(percent)), means (SD).

*Two patients had 2 laser procedures.

[†]With number of fetuses as denominator (P value adjusted for clustering).

[‡]Severe intraventricular hemorrhage was defined as ventricular bleeding with dilatation of the cerebral ventricles (grade III) or parenchymal hemorrhage (grade IV).

[§]Cystic periventricular leukomalacia was defined as periventricular densities evolving into extensive cystic lesions (grade III) or extending into the deep white matter evolving into cystic lesions (grade IV).

termination of the entire pregnancy. There is no ethical dilemma as to selective fetocide when there is a nonviable co-twin, for example, in TRAP sequence (see later), or even in complicated TTTS with associated severe irreversible anomalies. Also, when there is a high risk of fetal demise of one twin in the previable period, fetocide may prevent complications to the co-twin at the moment of demise. In other situations, the ethical dilemma is more complex. In the rare event of discordant chromosomal, or more commonly, structural or acquired anomalies, there is no immediate, or in some cases, even remote risk of demise of the anomalous fetus, and therefore no serious threat to the co-twin. In such situations, the poor quality of life for the abnormal twin may not be acceptable to the parents. In those situations, selective fetocide may be a more appropriate option than termination of the entire pregnancy. The situation becomes even more complex when some of these anomalies are diagnosed very early in pregnancy, at a time when it is difficult to reliably predict the natural history of the disease.

Conventional fetocide by intracardiac potassium chloride injection cannot be used because it could affect the co-twin

through the anastomoses, or post-mortem fetofetal haemorrhage might occur. Therefore, it is recommended to arrest both arterial and venous flow in the cord of the target fetus. Initially this was achieved by fetoscopic cord ligation, but today, most use bipolar cord coagulation.²⁹ Alternative minimally invasive techniques include the use of (interstitial as well as noncontact) laser, monopolar, or radiofrequency energy. It is difficult to compare results with different energy modalities because they may include patients with different conditions, gestational age at treatment, and experience of the operators.

There are two studies in the current literature reporting a significant case series experience. One is from the group of Robyr et al.³⁰ We published a prospective follow-up study on 80 consecutive cord occlusions (87 fetuses), mainly with bipolar coagulation.³¹ The survival rate was 83%. Half of the in utero losses were in the immediate postoperative period, potentially related to incomplete occlusion (which was more likely after laser coagulation). The other losses were thought to be due to cord complications, raising the possibility that intertwin septostomy during the procedure

should be avoided. PPRM is the most common complication and is responsible for all perinatal deaths. Ninety-three percent of survivors were neurodevelopmentally normal at 1 year or older. Those with neurodevelopmental abnormalities generally delivered prematurely often after PPRM. There was a clear effect of experience, with a dramatic decrease in PPRM and intact survival in the first versus subsequent 40 procedures. Therefore, we recommend that the procedures are performed by an experienced operator and whenever possible late in gestation so as to minimize the consequences of PPRM. However, this may not be an option because of legal and/or ethical constraints (Table 25-4).

Twin-Reversed-Arterial-Perfusion or Acardiac Twinning

The TRAP sequence is a very rare occurrence, affecting 1% of monozygotic twin pregnancies, or 1 in 35,000 pregnancies. The pathophysiology is based on a vascular communication on the surface of the placenta between the cord insertion of a normal fetus, known as the “pump twin” and the cord insertion of an acardiac twin. The acardiac twin can develop to a varying degree with skeletal development of the lower extremities, and pelvis and abdomen. In some cases, there is development of a cranium. As the name suggests, a pumping heart in this twin is exceedingly rare. The mass can be large because of cystic hygromas or lymphatic distension of the integument. The perfusion of this mass/fetus is in a reversed fashion, driven by the heart of the normal pump twin. The blood flow is toward the acardiac in the artery or arteries (acardiac fetuses often have single umbilical arteries) and returns through the vein. This was documented initially with Doppler ultrasound by Benson et al.³² The acardiac twin is obviously nonviable; however, the normal pump twin can be adversely affected by the increased cardiac output required to perfuse the additional tissue. In addition, the blood returning to the pump twin will be “twice used,” which may have an adverse effect. The natural history of this sequence includes

development of polyhydramnios in the sac of the pump twin related to increased cardiac output and renal perfusion and urine output. This predisposes to preterm labor and delivery. In addition, if the condition is progressive, the high output state can lead to hydrops and death. The perinatal mortality in one large series was 55%.³³ In some cases, fetal demise can precede hydrops possibly related to a predisposition to arrhythmia or embolism, related to the sluggish circulation through the acardiac twin. Moore et al.³⁵ correlated the relative size of the acardiac twin with adverse outcome. If the acardiac twin was 70% or more of the calculated weight of the normal twin, the rate of preterm delivery was 90%; polyhydramnios, 40%; and congestive heart failure, 30%. This compares with rates of 75%, 30%, and 10%, respectively, if the weight ratio was less than 70%. Dashe et al.³⁴ correlated diastolic flow in the cord to the acardiac twin to flow toward the placenta and found that a larger discrepancy in resistive index was associated with a better outcome in their six cases.

As the morbidity and mortality for the pump twin appear directly related to the degree of perfusion of the acardiac twin, it seems evident that any decrease or interruption of blood flow to this tissue will have a beneficial therapeutic effect. A variety of techniques have been used to achieve this with varying success. These techniques include fetoscopic laser ablation of the vessels in the cord to the acardiac twin,³⁵ fetoscopic cord ligation,³⁶ intravascular alcohol injection to sclerose the vessel,³⁷ hysterotomy to remove the acardiac twin,³⁸ bipolar cord coagulation,³⁹ and RFA.¹⁹ The therapies most commonly used currently are laser, bipolar coagulation, and RFA. A recent series of the former two techniques⁴⁰ in 60 patients resulted in an 80% survival rate, with two thirds of the patients delivering after 36 weeks. The procedures were performed at a median gestational age of 18 weeks. The most recent experience with RFA⁴¹ recorded a survival of 92%, with a mean delivery gestational age of 35.6 weeks. The results in monoamniotic gestations were not comparable, with only one of four surviving. It is possible that this is related to the length of cord from the placenta to the acardiac twin in monoamniotic gestations complicated by TRAP. In the three cases of nonsurvivors, the umbilical cord was short compared with the one that had a longer cord, which is more similar to that seen in diamniotic gestations. This may predispose the pump twin either to clot propagation in a retrograde fashion into its circulation, or secondary hemorrhage into the acardiac twin.

Congenital Diaphragmatic Hernia

The natural history of babies with isolated congenital diaphragmatic hernia (CDH) is determined by the degree of lung development at delivery. CDH babies have smaller and less compliant lungs with fewer airway branches and abnormal pulmonary vessels than normal neonates. Hypoplasia is lethal in 30% to 40% of prenatally diagnosed and live-born cases.⁴²⁻⁴⁴ Initially, a variety of indirect measures were used to assess the prognosis of fetuses with left CDH. More recently, with left-sided lesions, in addition to herniation of liver into the thorax, the area of the remaining right lung and its relationship to the head circumference, the lung-to-head ratio (LHR) has been assessed to determine prognosis in these patients (Fig. 25-3). The presence of herniation of part

FIGURE 25-3. Two somewhat different measuring techniques for assessing the lung-to-head ratio (LHR) have been used. **A.** Illustration of the method for measuring the LHR in a fetus with congenital diaphragmatic hernia. The measurement of the right lung (in the typical left congenital diaphragmatic hernia) uses a transverse axial plane of section of the fetal thorax at the level of the four-chamber view of the fetal heart. The plane of section should be symmetric so that a single rib is seen on each side. A measurement in millimeters is made from the thoracic aorta to the lateral inner chest wall (A). Another measurement, also in millimeters, is made in a plane perpendicular to the first measurement from the outer wall of the atrium to the inner aspect of the posterior chest wall (B). These two measurements are multiplied by one another and divided by the measurement of the head circumference also in mm. Method of Roy A. Filly, MD, San Francisco. (Illustration by James A. Cooper, MD, San Diego, CA.) **B.** Measurement of the LHR: A transverse section of the chest is taken at the level of the four-chamber view. The contralateral lung is measured: The longest axis is measured and multiplied by the longest measurement perpendicular to it. This is shown on a drawing (top left) and ultrasound image (right). This is placed over the head circumference, which is measured at the standard biparietal view, typically showing two equal hemispheres, the septum cavum pellucidum, one third of the way from the front to the back, and the posterior horns of the lateral ventricles (schematic drawing at bottom left). (From Deprest J, Jania J, Van Schoubroecka D, et al: Current consequences of prenatal diagnosis of congenital diaphragmatic hernia. *J Pediatr Surg* 41:423, 2006.)

FETO, fetal endoscopic tracheal occlusion; LHR, lung-to-head ratio; N, number, n.a., not applicable.

From Jani J, Keller RL, Benachi A, et al: Prenatal prediction of survival in isolated left-sided diaphragmatic hernia. *Ultrasound Obstet Gynecol* 27:18, 2006.

of the liver into the thorax and a low LHR during midgestation are validated indicators of poor outcome^{45,46} (Table 25-5). In a multicenter study of 86 fetuses with left-sided CDH and liver herniation, that were managed expectantly and live born after 30 weeks of gestation, survival increased from 0% for those with an LHR of 0.4 to 0.7 to about 15% for an LHR of 0.8 to 0.9, 65% for an LHR of 1.0 to 1.5, and 83% for an LHR higher than 1.5. In other words, in the subgroup with an LHR of less than 1.0 and liver herniation, approximately 90% will succumb to the consequences of severe pulmonary hypoplasia. Because this problem cannot be solved by any currently available postnatal therapy, it makes sense to consider interventions in these pregnancies that stimulate lung growth prenatally.⁴⁷ Initially, surgeons emulated postnatal interventions for CDH, that is, *anatomic* repair of the diaphragm. The procedure was shown to be feasible, except when the liver was herniated. Acute reduction of the liver into the abdomen causes kinking of the ductus venosus, thereby blocking venous blood from the umbilical vein. Therefore, fetuses with the liver up, that is, those that are the target group, cannot benefit from in utero anatomic repair.

As an alternative, the use of fetal tracheal occlusion (TO) was explored. The concept for this treatment came after recognition of the pathophysiology of fetuses with congenital high airway obstruction, in which lung overgrowth was virtually always present. TO prevents egress of lung liquid, leading to increased pulmonary stretch and accelerated growth of airways and pulmonary vessels. The timing and duration of the occlusion are crucial for the quality and response of airways and pulmonary vessels and the subject of intense debate.⁴⁸ Sustained TO leads to a decreased number of type II alveolar cells, the surfactant producing cell in the lung. In sheep, TO in the late *canalicular* phase of lung development with prenatal *reversal* (plug-unplug sequence or *temporary* TO) is associated with in utero recovery of the type II alveolar cell population.⁴⁹ Clinically, occlusion by tracheal clipping was first performed through hysterotomy and later through laparotomy and multiple uterine ports.⁵⁰ However, fetoscopic tracheal dissection caused frequent local complications.^{51,52} In the early surgical treatment of fetuses with CDH in which tracheal occlusion by ligature or clipping was used, fetuses were delivered with maintenance of the placental-umbilical circulation while

FIGURE 25-4. Photograph of a neonate status post reversal of tracheal occlusion procedure during intubation, while the placental umbilical circulation is still maintained.

the tracheal occlusion was reversed, the so-called ex utero intrapartum treatment (EXIT) procedure (Fig. 25-4).

Today it seems that TO can be best achieved by (1) percutaneous (rather than via laparotomy) access and (2) by tracheoscopic balloon occlusion (rather than external clipping)⁵³ (Fig. 25-5). This makes fetal surgery more acceptable to the mother and avoids the risks of neck dissection in the fetus. Occlusion with an expandable balloon accommodates the needs of tracheal growth. It also makes the occlusion more easily reversible, which presently is done at the transition of the sacular to alveolar phase of lung development. In utero restoration of the airways makes vaginal delivery possible in the referring tertiary center, rather than forcing patients to stay at a fetal surgery center far from home in addition to the benefit for lung development.⁵⁴

The fetal endoscopic tracheal occlusion (FETO) task group (Leuven, London and Barcelona) has gathered considerable experience with the following protocol. Singleton pregnancies complicated by CDH in an otherwise anatomically and chromosomally normal fetus are eligible

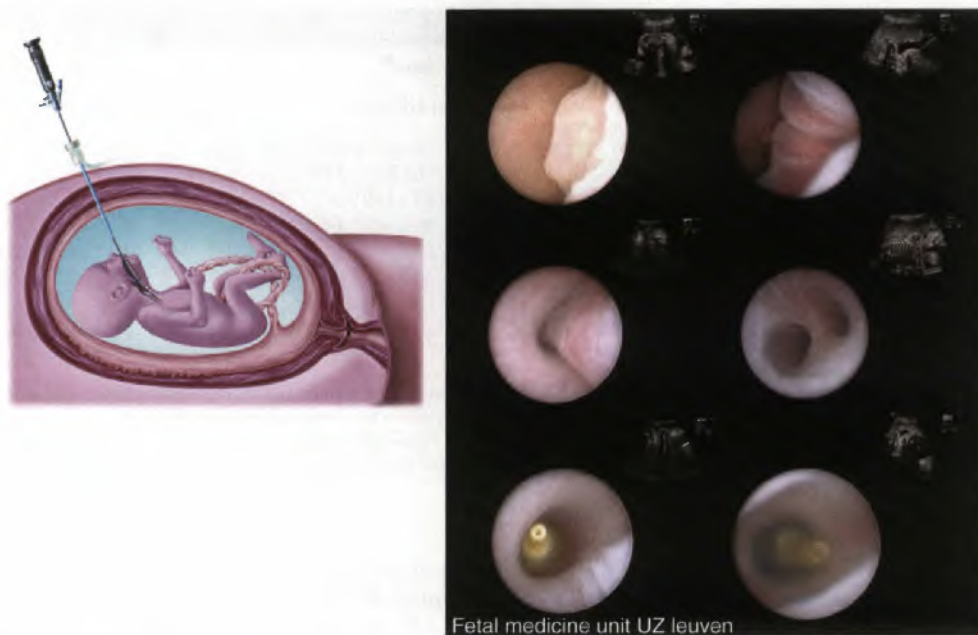

FIGURE 25-5. Schematic drawing of percutaneous FETO and fetoscopic images of landmarks during percutaneous FETO. (Reprinted with permission from ISUOG, John Wiley & Sons, Ltd and the authors.) From top left to right bottom: epiglottis, vocal cords, trachea, carina, inflated and detached balloon, vocal cords about to close over the balloon. Not all images are from the same patient. (Reprinted with permission from Nelson S, Cameron A, Deprest J: Fetoscopic surgery for in utero management of congenital diaphragmatic hernia. *Fetal Matern Med Rev* 17:69, 2006.)

for fetal therapy if there is intrathoracic herniation of the liver and the LHR is less than 1.0. Although these criteria are actually only truly validated for left-sided cases, the same ones are used for right-sided CDH. FETO is performed at 26 to 28 weeks, and whenever possible, removal of the balloon is performed at 34 weeks. Essentially, a 1.2-mm endoscope within a 3.0-mm sheath (Karl Storz, Tuttlingen, Germany) is introduced into the trachea to position, and later, retrieve a detachable balloon between the carina and vocal cords. FETO as well as fetoscopic removal are typically performed after prophylactic tocolytics, epidural maternal anesthesia, and fetal analgesia and paralysis have been administered. Patients are routinely admitted for 2 postoperative days. Ultrasound examination is performed every 1 to 2 weeks to confirm the endotracheal presence of the inflated balloon and to monitor lung growth (Fig. 25-6). Whenever preterm delivery is anticipated, active tocolysis is attempted unless contraindicated and a course of corticosteroids is administered when time allows.

In a report on 35 cases occluded at 26 to 28 weeks, mean operation time was 22 minutes. The survival rate was 55%, compared with 8% in contemporary controls treated by postnatal therapy. Pulmonary morbidity is lower than expected for severe cases, and survivors are not neurologically impaired at the age of 1 year. The limiting factor of the procedure is PPRM before 32 weeks, which still occurs in 35% of cases and leads to preterm delivery in 30% (<37 weeks). This compares favorably with the randomized trial from UCSF, in which the procedure was done through laparotomy and 5-mm transuterine ports (Table 25-6).

The growing experience yields some important trends. First, the rate as well as the consequences of iatrogenic

FIGURE 25-6. Sonogram of a fetus after placement of a tracheal occluding balloon. The balloon is seen between the calipers and arrows, distending and occluding the trachea.

PPROM have been improving. The incidence decreases with increasing experience.⁵⁵ The rate of delivery at less than 32 weeks is now 11% in our entire experience. For instance, in our last 20 cases, the mean gestation at delivery following FETO with in utero reversal at 34 weeks is now 37 weeks compared to 34 weeks initially. Survival rates are greater than 50% in a homogenous group of 43 consecutive left-sided CDH cases.⁴⁸ Prenatal balloon removal improves survival (33% without versus 66% with prenatal removal).⁵⁴

Table 25-6 Comparison of Recent Series of Fetoscopic Tracheal Occlusion

Criteria (left sided)	RCT Harrison ⁵²		Deprest ⁵³
	Liver up and LHR<1.4		Liver up and LHR<1.0
	Standard neonatal care - n=13	Fetoscopic clip (n=2) or balloon (n=9)	FETO n=20
PPROM	3 (23%)	11 (100%)	
<32 wk		Not specified	7 (35%) <32 wk
<34 wk		11 (100%) < 34 wk	10 (50%) <34 wk
Gestational age at delivery (range; wk)	37.0±1.5 (34.0-39.0)	30.8±2.0 (28.0-34.0)	33.2 (27.0-38.5)
Birthweight (kg)	3.03±0.48	1.49±0.36	2.12±0.66
Survival n (%)	8/11 (73%) at 90 d	10/13 (77%) at 90 d	10/20 (50%) at discharge

FETO, fetal endoscopic tracheal occlusion; LHR, lung-to-head ratio; PPROM, preterm premature rupture of the membranes; RCT, randomized controlled trial. Data from Harrison MR, Sydorak RM, Farrell JA, et al: Fetoscopic temporary tracheal occlusion for congenital diaphragmatic hernia: prelude to a randomized, controlled trial. *J Pediatr Surg* 38:1012, 2003; and Deprest J, Gratacos E, Nicolaides KH: Fetoscopic tracheal occlusion (FETO) for severe congenital diaphragmatic hernia: evolution of a technique and preliminary results. *Ultrasound Obstet Gynecol* 24:121, 2004.

Survival after FETO is highly dependent on the LHR measured at the end of second trimester (see Table 25-5 and Fig. 25-3). It increased from 17% for an LHR of 0.4 to 0.5 to 62% for an LHR of 0.6 to 0.7 and 78% for an LHR of 0.8 to 0.9. This has prompted the proposal to classify cases and stratify prenatal therapy for cases with isolated (left-sided) CDH and liver up, based on LHR in this fashion:

1. Fetuses with an LHR that is greater or equal to 0.6 and less than 1.0 are considered to have *severe hypoplasia*. They have a predicted survival rate of greater than 60% following and less than 15% without FETO, respectively. A randomized study of FETO at 26 to 28 weeks with in utero reversal at greater than 34 weeks versus standard postnatal care is proposed.
2. Fetuses with an LHR of less than 0.6 have extreme hypoplasia because their predicted survival rate is 0% and this can be increased to only 17% with FETO at 26 to 28 weeks. An alternative approach to consider is very early (<24 weeks) occlusion.
3. Fetuses with intermediate lung hypoplasia (an LHR greater or equal to 1.0 and less than 1.3) thus far have not been considered to be candidates for fetal surgery. However, in Europe, they have an anticipated survival of about 60%. This is considerably lower than the greater than 90% survival rate observed in fetuses with an LHR less than or equal to 0.8 and less than 1.0 treated by FETO. These fetuses have a larger lung surface area and, as a consequence, a larger lung liquid production. Therefore, a good response to TO can be anticipated. They might be the patients who would benefit from the greater growth rate later in pregnancy, and thus, FETO could be carried out later (e.g., in the sacular phase), reducing the consequences of iatrogenic PPROM, when that might occur.⁴⁸ Again, in this group, a randomized study comparing late TO versus expectant management is proposed.

Congenital Cystic Adenomatoid Malformation

CCAM is a lung hamartoma that consists of abnormal proliferation of terminal bronchioles. Pathologically, these

are classified based on the postnatal experience into types I through III. Type I are unilocular large cysts of varying size, type II are a mixture of macrocystic and microcystic lesions, and type III are microcystic lesions. The vast majority of CCAMs are clinically benign prenatally and postnatally, although they are generally resected at some point owing to the risk of infection and a very low risk of malignant transformation. Management consists of appropriate counseling and ensuring that the relevant specialists are involved in the postnatal evaluation and treatment.

In contrast, some CCAMs, generally type III, are large enough and cause a degree of mediastinal shift, leading to hydrops secondary to cardiac compression and compromise to venous return, or secondary to raised intrathoracic pressure and lymphatic obstruction. In cases of fetal hydrops, typically presenting as fetal ascites, pleuropericardial effusions and subcutaneous edema, intervention is needed to prevent in utero fetal demise. If the hydrops is severe enough, the mother may also be at risk, from "mirror" or Ballantyne syndrome, particularly in the presence of placentomegaly. This manifests itself as a severe preeclampsia-like situation. In an attempt to be able to predict which patients with CCAM are at risk of developing hydrops, the use of the proportion of the mass of the lesion divided by the head circumference (CCAM Volume Ratio [CVR]) has been proposed.⁵⁶ When the CVR is higher than 1.6, there is a 80% risk for fetal hydrops. Hydropic fetuses greater than 32 weeks' gestational age should be delivered. When hydrops is found earlier than 32 weeks in utero, intervention can be life saving. In type III CCAMs with hydrops, administration of a course of betamethasone, identical to that used for acceleration of lung maturity, has been associated with resolution of the hydrops and survival.⁵⁷ Short case series have also described different surgical interventions. In some cases, percutaneous puncture and thoracoamniotic shunting of type I macrocystic masses may be successful.⁵⁸ Others have proposed to use this approach more liberally. Laser and RFA coagulation of the masses have been attempted, but these methods can cause thermal damage to surrounding structures. They can also worsen fetal hydrops, leading to in utero death.

The most successful radical intervention is excision of the diseased lobes (Fig. 25-7). Fetal lobectomy is done using

FIGURE 25-7. Photograph of in utero resection of congenital cystic adenomatoid malformation (CCAM) of the lung. The instrument on the right is on top of the affected part of the lung.

open fetal surgery with quite high survival rates in cases in which hydrops resolves postsurgically. In a series of 22 cases operated on between 21 and 31 weeks, there were 11 long-term survivors who were developmentally normal (up to 12 years of age).⁵⁹

Hydrops resolved in 1 to 2 weeks, followed by reversal of mediastinal shift. Causes of fetal death despite fetal surgery were termination of pregnancy for “mirror” syndrome (n=1), preterm labor or chorioamnionitis (n=2), and fetal hemodynamic compromise leading to intraoperative death in six fetuses and postoperative death in another two cases. To reduce the risk of intraoperative deaths due to hypovolemia and hypotension, means of resuscitation, including direct access to the fetal circulation and appropriate fetal monitoring techniques, are now part of these open procedures.

Sacroccocygeal Teratoma

Sacroccocygeal teratomas (SCTs) are exophytic cystic and solid tumors arising from the area of the coccyx. The cases of SCT that are relevant to the discussion of fetal surgery are giant, solid and highly vascularized. The amount of blood flow through SCTs can lead to high-output cardiac overload, hydrops, and death. Attempts have been made to either perform a definitive resection or simply devascularize the tumor in hopes of allowing cardiac recovery.⁶⁰ In the largest reported series from Children’s Hospital of Philadelphia (CHOP), even in the most experienced hands, the outcomes are poor. In the small group that advanced to fetal resection, the survival was encouraging (3/4), however the morbidity was significant (Fig. 25-8). These included one maternal and one fetal transfusion, and a fetal cardiac arrest with successful resuscitation. In addition, these fetuses delivered very preterm (mean 29 weeks) and remained in the hospital for up to 34 weeks’ gestation. Postnatally, there was one neonatal death, one embolic event leading to loss of one kidney and bowel injury, and one case of chronic lung disease. The long-term maternal sequelae of a hysterotomy have been discussed previously. Clearly, attempts at a less invasive approach to tackling this problem are important,

FIGURE 25-8. Photograph of in utero surgery before resection of a large sacroccocygeal teratoma.

although overall, the cases that truly need fetal rather than neonatal intervention are exceedingly rare.

Myelomeningocele

The premise of fetal surgery for spina bifida is the “two-hit” hypothesis (correcting abnormalities of the brain and spine). The suggestion is that although the lack of closure of the neural tube leads to neurologic deficit, this is worsened by the ongoing injury to the placode from exposure to the amniotic fluid and trauma from impact with the uterine wall.⁶¹ Additional work with animal models suggested that the cerebellar herniation associated with Arnold-Chiari II malformation was caused secondarily by the open neural tube, and might be reversible.⁶¹ Preliminary experience at Vanderbilt and CHOP did show that intrauterine microsurgical closure of myelomeningocele improves outcome.^{4,62} Both studies showed a decreased shunting rate for hydrocephalus, in part due to reversal of cerebellar herniation, which is a component of the Arnold-Chiari II malformation. Shunt status affects cognitive functioning in later life and therefore is a surrogate marker for long-term sequelae. Another important co-determinant of long-term outcome is the upper level of the lesion.⁶³ The higher the vertebral level, the higher the likelihood of needing a shunt. The gestational age at repair is also important: The shunt rate drops significantly from 71% to 39% when fetal surgery is done before 25 weeks. These findings were taken into account when designing the Management of Myelomeningocele Study (MOMS). This is a multicenter National Institute of Health (NIH)-funded randomized trial comparing maternal-fetal surgery to routine postnatal management of spina bifida (www.spinabifidamoms.com). Inclusion criteria for this trial are a gestational age of less than 26 weeks at the time of randomization, a normal karyotype, no additional fetal malformations, and the willingness to relocate to one of the study sites (e.g., UCSF, Vanderbilt, or CHOP) until after delivery, if randomized to prenatal surgery, or to return there for delivery if randomized to postnatal management.

The myelomeningocele repair is done with techniques similar to those used postnatally (Fig. 25-9). In the United States, no fetal surgery for spina bifida is available outside the trial. From an obstetric viewpoint, Table 25-7 summarizes some important outcome variables from published experience. Open fetal surgery today has a definite but acceptable maternal risk. Pulmonary edema has been an issue, but may be reduced by refining tocolytic regimens. Transfusions are rare (2.2% in the Vanderbilt experience), and bowel obstruction happened in a single case. Preterm labor leading to preterm delivery at less than 30 weeks occurs in about 10% to 15%. Oligohydramnios is not uncommon but usually is without significant clinical consequences. An occasional case of lethal lung hypoplasia has been observed, however. This raises the critical issue of fetal risk, that is, an inherent iatrogenic risk of perinatal death (at the time of surgery or preterm delivery), which in these studies, was 3% to 6%. This is a risk the fetus would not be exposed to with routine management for a problem that is not life-threatening in utero. With fetal surgery for spina bifida, this is the first time that such radical surgery has been used to decrease long-term morbidity rather than prenatal/neonatal mortality. This alters the risk-benefit equation significantly.

Lower Urinary Tract Obstruction

The sequelae of lower urinary tract obstruction (LUTO) have been documented in several animal models.⁶⁴⁻⁶⁶ This closely mirrors the natural history as it is observed in the human fetus, with obstruction due to posterior urethral valves or less commonly urethral atresia. Complete obstruction leads to progressively severe oligohydramnios and then anhydramnios. Depending on the gestational age that this occurs, pulmonary hypoplasia results. In addition, the reflux and elevated back pressure on the renal parenchyma leads to cystic dysplasia and renal failure. In these studies, this led to shunting of the obstructed distended bladders, allowing

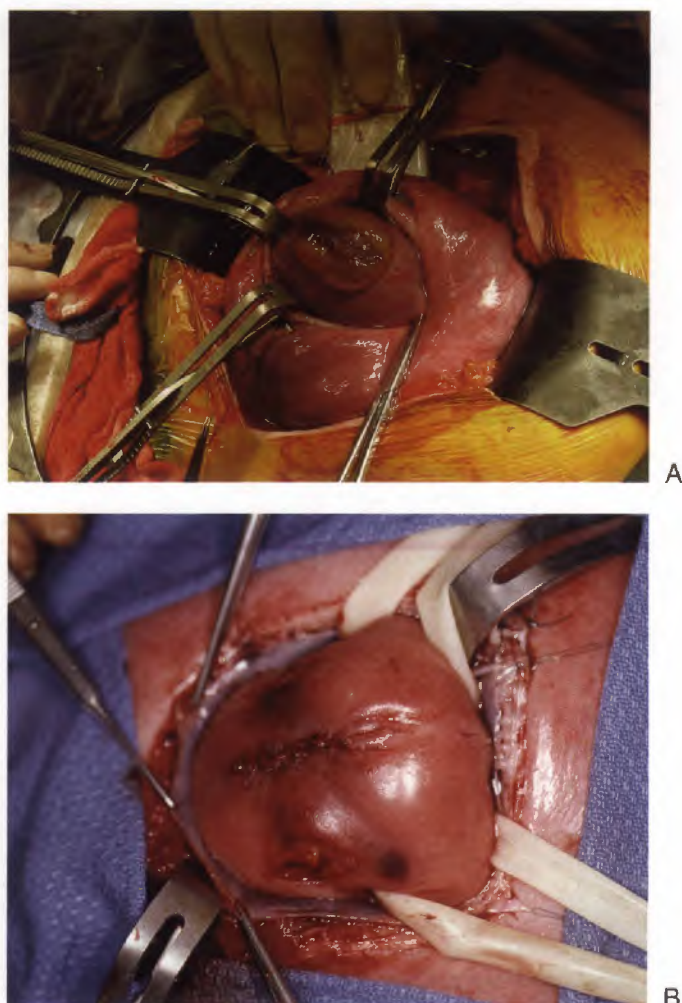

FIGURE 25-9. Photograph of a lumbar myelomeningocele before (A) and after (B) in utero repair.

Table 25-7 Obstetric and Short-Term Outcomes in the CHOP and VUMC Series on MMC Repair

	CHOP (Johnson ⁴ ; n=51)	VUMC (Bruner ⁶³ ; n=178)
Gestation at surgery (wks)	23+0 (20+0-25+4)	(19-30); later <26 wks
Gestation at delivery (wks)	34+4 (25+4-37)*	33+5 (25-38)
Chiari malformation		
Before (moderate/severe)	14%/86%	
After	100%/0%	7%/0%
Postnatal shunt (postnatal age)	46% (21 wks)	46% (12 wks)
Perinatal losses	3/51 (prematurity)	5/178 (2.8%) (not specified)
Length of hospital stay	4 days	3.3 days (3-7)
Oligohydramnios		25% early on 30% readmission rate
Delivery <30 wks	5/47 (10.6%) [†]	11.8%
Delivery >32 wks	(40/47) 85% [†]	(not specified)
Maternal complications	None reported, including dehiscence or rupture; one amniotic fluid leak through hysterotomy	9(5.1%) mild pulmonary edema 1 bowel obstruction 4(2.2%) dehiscence, asymptomatic in three

FIGURE 25-10. Placement of a fetal bladder shunt depicted schematically. The double pigtail catheter is pushed off the needle so that one end is in the bladder and the other end is in the amniotic space. (From Adzick NS, Flake AW, Harrison MR: *Recent advances in prenatal diagnosis and treatment. Pediatric Clin North Am* 32:1103, 1985.)

Table 25-8 Fetal Urine Prognostic Thresholds*

	Good Prognosis	Poor Prognosis
Sodium	<90 mmol/L	>100 mmol/L
Chloride	<90 mmol/L	>100 mmol/L
Osmolality	<180 mOsm/L	>200 mOsm/L
Total protein	<20 mg/dL	>40 mg/dL
Beta-2 microglobulin	<6 mg/L	>10 mg/L

*Thresholds are based on urine obtained between 18–24 weeks' estimated gestational age. Values that fall between good and poor prognosis are considered 'gray zone', with expectation for moderate or greater postnatal renal impairment, but potential for postnatal pulmonary survival. (Johnson MP, personal communication.)

reaccumulation of amniotic fluid⁶⁷ (Fig. 25-10). As experience increased, it became clear that case selection was critical. In some cases with irreversible renal damage, pulmonary growth could be salvaged, but the terrible morbidity of neonatal renal failure and anticipation of long-term dialysis with later transplantation had to be confronted. This led to attempts to be able to predict fetal and thus neonatal renal function to avoid the above-mentioned scenario. It made sense that the best evaluation of renal function would be to sample fetal urine and analyze urinary electrolytes and other analytes. Evaluation of urinary electrolytes remains the most predictive when two sequential vesicocenteses are performed several days apart, in cases in which there is refilling of the bladder and sonographically normal-appearing renal parenchyma⁶⁸ (Table 25-8). Following this management algorithm, a recent series has documented variable success. Although the children that had follow-up at around 5 years of age were neurodevelopmentally normal, many were lagging in growth and had persistent pulmonary issues. In the 18 survivors, six had acceptable renal function, four mild insufficiency and six required dialysis and transplantation.⁶⁹ Similar experience

is mirrored by other centers,^{70,71} with chronic renal insufficiency in half to two thirds of survivors, despite all having favorable fetal urine profiles as a prerequisite for in utero intervention.

Therefore, the approach to obstructive uropathy may need to be changed to lead to improved outcomes. This is critical because the long-term morbidity of neonatal renal impairment is so high. One newer approach is to perform fetal cystoscopy. The endoscopes available now are the same size as some of the trochars used to place the bladder shunts. Therefore, fetal and maternal postoperative complications should be similar. With cystoscopy, there is a potential to correct the obstructive problem completely and allow normal bladder cycling for the remainder of the pregnancy. The results are not consistent, but in those with success, the outcomes are remarkably promising, suggesting that this is an avenue worth pursuing.^{72,73}

Pleural Effusions

Fetal pleural effusions are rare; however, when they are large and cause a severe mediastinal shift, they can secondarily lead to hydrops and stillbirth. They are almost always lymphatic in origin. There is a significant association with aneuploidy and fetal karyotyping should be considered.⁷⁴ When bilateral pleural effusions of similar size are identified, the diagnosis of diffuse congenital pulmonary lymphangiectasia needs to be considered.⁷⁵ The significance of this is that even with successful drainage, there is generally neonatal respiratory failure because of abnormal lymphatics affecting gas exchange in the alveoli. This needs to be taken into account when counseling patients about possible interventions. The option of shunt drainage of pleural effusions is considered when progression to hydrops is documented. This is particularly the case when fetal echocardiography documents abnormal ventricular filling.⁷⁶ Recent series of cases with shunting document technical success. However, a residual risk of prematurity and neonatal mortality, potentially

FIGURE 25-11. In utero repair of aortic stenosis. After needle puncture of the left ventricle (LV), a balloon catheter (arrow) is advanced into the aorta and the balloon is inflated to dilate the aorta.

related to the underlying pathology rather than the pleural effusion itself, remains.^{58,77}

Fetal Cardiac Interventions

One of the most exciting fields in the field of minimally invasive fetal therapy is the treatment of congenital heart defects (CHDs). Some defects are structurally simple, but because of the dynamic situation during fetal life, a progressively abnormal development of the great vessels and ventricles ensues. This then results in a poorly functioning heart after birth. An example of this is progressive critical aortic stenosis that may progress to hypoplastic left-sided heart syndrome (HLHS). It has been speculated that in utero reversal of the stenosis can reverse progression to ventricular hypoplasia. At present, the standard postnatal treatment for a single-ventricle heart (HLHS) is a staged palliative surgery (Norwood operation, followed by a Fontan procedure). The same principle may apply to critical pulmonary stenosis with intact ventricular septum, which leads to hypoplasia of the right side of the heart.

There is increasing experience with ultrasound-guided fetal heart catheterization and valvular balloon dilatation. In many cases, this can be done by a percutaneous approach (Fig. 25-11). The largest experience by far resides with the group at Boston Children's/Brigham and Women's Hospital.⁷⁸ In more than 50% of cases, the valvular dilatation is successful, but in about 20% of these, progression to hypoplasia cannot be reversed. Experience with HLHS with restrictive or intact atrial septum is more limited, as is that with pulmonary atresia or stenosis with intact ventricular septum. However, further research will determine optimal patient selection, timing, and technique for the different types of correctable heart defects. As noted earlier, these procedures can be percutaneous and involve needles that are smaller than fetoscopes or shunt trochars. Therefore, the

maternal and pregnancy risk profile is relatively low. This should allow a lower threshold for innovative intervention and may expand the indications, even if the success rate is variable.

Transrectal Scanning

High-resolution transvaginal sonography (TVS) has been widely available since the mid-1980s and has gained acceptance as an integral part of gynecologic and early obstetric sonographic examinations.¹ In many ultrasound laboratories, the standard examination of the female pelvis is composed of the traditional transvesical/transabdominal approach (TAS) combined with TVS and, in some cases, transvaginal color flow Doppler (TVCFD).^{2,3}

TAS is performed through the full urinary bladder and provides a wider field of view than the transvaginal approach. The transvesical approach provides better visualization of superficial structures and structures remote from the vagina than the transvaginal approach. The transvaginal approach bypasses attenuating tissue and allows a high frequency probe to be placed close to the "target organs." TVS demonstrates anatomic detail of the uterus, ovaries, and adnexa, which cannot be duplicated by TAS. The normal sonographic anatomy described in this chapter reflects a combined transvesical and transvaginal approach and is weighted, as in clinical practice, to use the positive attributes of both TVS and TAS.

As with all ultrasound applications, it is standard practice to use the highest possible transducer frequency, which allows visualization of the target organs. Using TAS, visualization of the pelvic organs is limited by body habitus owing to sonic attenuation of the intervening anterior abdominal wall, subcutaneous and properitoneal fat, and fat in the mesentery and omentum. As a result of this attenuation and the distance of the area of interest from the anterior abdominal wall, it is often not possible to use high frequency transducers and benefit from their inherent enhanced axial and lateral resolution. Differences in sonic attenuation among patients results in the need to use different transducers and different transducer frequencies in multifrequency broad-

band probes. It should be noted, however, that even with careful scanning technique in the optimal patient, 5- and 6-MHz transvaginal transducers may not provide resolution adequate for use in early pregnancy. Before applying data from the literature, it is advisable to confirm its reproducibility in one's own laboratory.⁴

TRANSVAGINAL SONOGRAPHY

Indications

As noted earlier, TVS provides diagnostic information that cannot be obtained with TAS. TVS should be incorporated into the examination in all situations in which it will provide additional clinically useful diagnostic information. Indications for TVS include

- Gynecologic sonography.
- Early first trimester obstetric sonography.
- Obstetric applications later in pregnancy when enhanced visualization of structures adjacent to the cervix is necessary based on TAS findings, including placenta previa, evaluation of the fetal lumbosacral spine in breech fetuses, evaluation of the fetal intracranial contents in cephalic fetuses, and evaluation of the fetal nuchal region before 14 weeks' gestation.
- Suspected ectopic pregnancy.
- Patients with suspected lower abdominal disease in whom a diagnosis has not been made with TAS (e.g., suspected diverticulitis).
- Follicle monitoring.
- Monitoring for assisted reproductive techniques.

In general, TAS is performed first, and then TVS is performed after the patient empties the urinary bladder. In urgent or

emergent situations when the patient arrives with an empty or incompletely filled urinary bladder, after a quick survey to assess the degree of bladder distention and the presence of obvious, large pelvic masses, a transvaginal examination is performed. In patients with significant free intraperitoneal fluid demonstrated with TVS, the hepatorenal space (Morrison's pouch) and paracolic gutters are examined with TAS for a volumetric estimate of free fluid.⁵ Patients who are being assessed on a serial basis for specific targeted examinations such as follicle monitoring are usually examined with TVS only.

The diagnostic information available from TAS and TVS is often complementary. Although TVS provides enhanced resolution, and may visualize the ovaries and adnexal structures when they are obscured on TAS by acoustic shadowing from bowel gas,⁶ TAS may visualize high or laterally positioned ovaries or pelvic masses not seen with TVS.⁷ TAS may show the size and location of a mass, which can then be better characterized with TVS.

There are clearly situations in which TVS cannot or should not be performed. Contraindications include

- Premenarchal or virginal patients.
- Any patient who does not willingly consent to vaginal examination.

Patients with a narrow introitus or vagina may experience discomfort at the time of attempted probe insertion, which should result in immediate termination of the transvaginal portion of the examination. In general, TVS should be considered in any patient in whom bimanual examination is appropriate. In fact, it is our experience that in the older patient population and in patients with severe vaginal or pelvic pain, TVS is more easily accepted than the bimanual examination.⁶

Patient Preparation

There is no specific preparation for TVS, except that the patient should void before the examination so that the urinary bladder is empty or almost completely empty. As with any other ultrasound examination, the sonologist or sonographer should obtain pertinent historic information from the patient before the examination. An adequate explanation of the procedure is essential, and consent must be obtained before the examination. In our practice, verbal consent is considered to be adequate.

Many patients are apprehensive at any mention of an "internal" examination, and most patients equate a TVS scan with a bimanual internal examination until the procedure is adequately explained. In the explanation, it is important to note why it is necessary to perform the TVS and to stress that the examination is a simple, usually painless procedure and that only part of the probe is inserted. In our institution, the majority of the transvaginal examinations are performed by sonographers. If a male examiner (sonologist or sonographer) is to perform the examination, a female staff member (an aide, nurse, or other staff member) is brought into the room for the entire transvaginal examination to act as a chaperone.

In any diagnostic examination, it is important to introduce all staff members who are in the examination room to the patient. This is even more critical in TVS. To maintain

patient dignity, the patient is appropriately covered with a sheet and placed in the supine position with the knees bent and the feet flat on the table, approximately shoulder width apart. The head and shoulders are slightly elevated with a pillow and, if possible, the patient is placed in a slightly reversed Trendelenburg position so that free intraperitoneal fluid can gravitate to the posterior cul-de-sac.

When only TVS examinations are performed or when TVS is being used to guide an invasive procedure, it is often desirable to use an examination table with leg supports so that the probe can be moved freely in all directions and the examiner is in a position to insert and remove instrumentation without constraint. When using an examination bed, it is sometimes not possible to angle the probe anteriorly because that handle of the probe is obstructed by the bed. Under those circumstances, one can place a foam wedge or a few folded towels behind the patient's hips. If anterior structures are still out of the field of view, it may be necessary to ask the patient to flex her hips and bring her knees up toward her chest.

Probe Preparation

Probe preparation before TVS must take into consideration the following potential adverse effects:

1. Spread of infectious disease
2. Chemical irritation of the vagina
3. Latex allergy
4. Deleterious effect of the lubricant on sperm motility

To prevent the spread of infectious disease, the probe should be soaked in disinfectant between uses and a disposable cover, usually a latex condom, should be placed over the probe for the examination. If the patient has an allergy to latex, an alternate nonlatex cover should be used, which is often available from the probe manufacturer.

Many types of disinfectants are available. Most are glutaraldehyde based. We currently use Metricide (Metric Research Corp, Parker, CO) in our laboratory. Other brands include Sporidicin (Sporidicin International, Rockville, MD) and Cidex (Surgikos, Arlington, TX). The probe manufacturers usually recommend brands for their instruments and may also specify a limit to the maximum time that a probe may be immersed in disinfectant without damaging the probe or voiding the warranty. It is advisable to contact the probe manufacturer if information regarding the type of disinfectant and immersion time limit is not provided in the manual.

As indicated on the product label, disinfectants are toxic and caustic chemicals and should be treated with caution to safeguard the patient and staff members. Follow the instructions on the product label. Staff members must wear gloves when using a disinfectant or when touching a probe that has been immersed in disinfectant. Some manufacturers recommend the use of safety goggles. Emergency eyewash stations should be available on site. Care should be taken to rinse the probe with water or alcohol before covering the probe with a disposable cover. A wide range of probe covers are available, ranging from commercially available covers designed specifically for ultrasound probes to latex condoms. Having stated the need to follow the necessary precautions, we have used disinfectants for many years without incident.

Between examinations, we keep the probe immersed for 20 minutes in disinfectant in a reservoir inside a ductless fume system (PCimedical, Deep River, CT) on a cart situated beside the scanner. This cart also holds the other paraphernalia needed on an ongoing basis by the sonographer. If the condom breaks or tears, then more complete probe sterilization is necessary before reusing the probe. All ultrasound probes that come in contact with blood or body fluids should be covered, cleaned, and disinfected appropriately.

Once the probe has been disinfected and wiped clean, a small amount of transducer coupling gel is placed inside the tip of the condom (or other probe cover), and the condom is pulled over the shaft of the probe. The coupling gel should eliminate any air from the beam path. If there are air bubbles over the transducer face, the condom or probe cover should be readjusted. The final step in the process of probe preparation is to lubricate the tip of the covered probe with a sterile lubricant such as Muko (Ingram & Bell Medical, Don Mills, Ontario, Canada) to facilitate probe insertion. If the procedure is being performed as part of an infertility study, it is recommended that water or saline be used as a lubricant because some of the more commonly used lubricants may have an adverse effect on sperm motility.⁸ The sonographer must wear gloves while preparing the probe and performing the examination.

Examination Technique

Once the patient and transducer have been prepared, an 8- to 10-cm depth of field is selected to ensure that the transducer's position can be monitored during insertion. Once the probe has been inserted into the introitus, the operator should watch the screen and monitor the position of the probe continuously. This is critical to patient safety and to prevent inadvertent positioning of the probe in the posterior vaginal fornix, where the operator will see only bowel if the uterus is anteverted and will be unable to identify any anatomic landmarks. The probe is inserted into the vagina, and the scan generally performed through the anterior vaginal wall, anterior vaginal fornix, or lateral fornices. Probe position is determined by the site of optimal visualization of specific pelvic viscera.

The orientation of the probe is controlled by probe rotation and angulation. Three basic scanning maneuvers are performed to achieve appropriate orientation:

1. The probe can be rotated from 0 to 90 degrees about its long axis to obtain any plane of scan from sagittal to coronal (Figs. 26-1 and 26-2).
2. The probe can be angled or pointed in any direction (within the limitations of vaginal discomfort) to direct the plane of section (see Fig. 26-2C).
3. The probe can be advanced or withdrawn, which will move adjacent pelvic viscera and displace bowel, and allow structures to be placed in the focal zone of the transducer or out of regions of near-field artifact.

During insertion of the probe, the orientation of the transducer can be assessed by noting the position of the urinary bladder, which usually contains a small residual amount of urine. The normally consistent position of the angle of the bladder relative to the more variable positions of the uterus and ovaries makes it a good landmark to use when initially

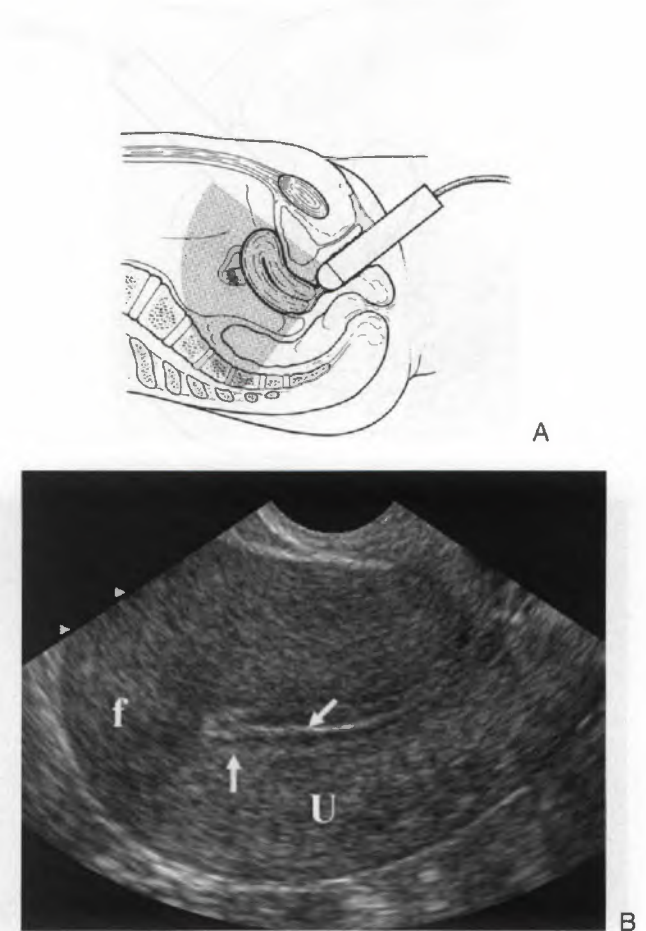

FIGURE 26-1. A. Diagram of sagittal transvaginal scan plane. (From Lyons EA, Gratton D, Harrington C: *Transvaginal sonography of normal pelvic anatomy*. *Radiol Clin North Am* 30:663, 1992.) B. Transvaginal sonogram in the sagittal plane showing the corpus (U) and fundus (f) of the uterus. Endometrial canal (vertical arrow) basal layer of the endometrium (oblique arrow).

assessing transducer position and orientation. Rotating the probe 90 degrees into the coronal plane permits visualization of both the uterus and adnexa. Before recording any images, a complete pelvic survey should be performed. This survey is performed by slowly sweeping the beam in a sagittal plane from the midline through both adnexa to the lateral pelvic side walls. The probe is then rotated to the coronal plane, and the beam swept from the cervix to the fundus of the uterus. The survey quickly ascertains the relative positions of the uterus and ovaries and identify any obvious masses.

After the survey, standard views are obtained. In our institution these include

Sagittal plane: (1) cervix, endocervical canal, posterior cul-de-sac, (2) uterus and endometrium, (3) right ovary and adnexa, and (4) left ovary and adnexa.

Coronal plane: (1) vagina, (2) cervix and posterior cul-de-sac, (3) uterine corpus and endometrium, (4) uterine fundus and endometrium, (5) right ovary and adnexa, and (6) left ovary and adnexa.

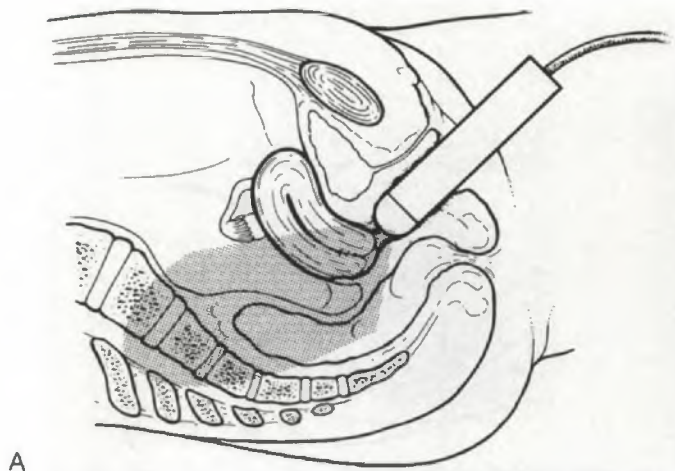

FIGURE 26-2. A. Diagram of coronal transvaginal scan plane. (From Lyons EA, Gratton D, Harrington C: *Transvaginal sonography of normal pelvic anatomy*. *Radiol Clin North Am* 30:663, 1992.) B. Transvaginal sonogram in the coronal plane through the corpus (U) of the uterus. Endometrium (open arrow). Serosal surface of the uterus (arrows). C. Transvaginal sonogram in the coronal oblique plane angled toward the left ovary demonstrating the left ovary (o), the external iliac vein (Ve), and the internal iliac artery (A) and vein (V). C, cyst.

Although these standard images are obtained, they are by no means the complete examination. Obtaining these images indicates that the entire organ or region imaged has been carefully assessed at real time in two orthogonal planes. Any pathology or variant of normal must be assessed and appropriate images recorded. Color flow Doppler, power Doppler, and pulsed Doppler are added to the examination depending on the clinical situation and pathology demonstrated on grayscale imaging.

Using three-dimensional ultrasound, a true coronal view of the uterus can be obtained that displays the entire endometrial canal in a view not otherwise available.

As noted previously, the angle of the bladder is a relatively constant landmark. It is noted later (see "The Uterus and Vagina") that the cervix is bound to the angle of the bladder by the parametrium. By locating the cervix, the position and location of the uterus can then be determined. Visualization of the ovaries may be more difficult and often requires significant angulation of the probe.

When the uterus is anteverted, a helpful technique for locating the ovary is to first obtain a coronal image of the uterine fundus and then to angle the probe out to the cornua and broad ligament. Once this region is identified, the ovary can usually be identified by slowly sweeping the beam anteriorly and posteriorly. If the ovary is positioned high in the pelvis or if the uterus is markedly anteverted, raising or flexing the patient's hips may help visualize the ovary. Another more common maneuver for the "high ovary" is to apply pressure of the anterior abdominal wall laterally by flexing the fingers, indenting the wall and drawing the mobile ovary or a mass down into the field of view of the transvaginal probe.

The capability to use the probe tip to assess pelvic structures for tenderness is an added advantage of TVS. By applying gentle pressure with the transducer tip to pelvic structures, it is possible to localize a region of tenderness with greater specificity than with TAS or bimanual examination. Moreover, a region of tenderness that has been

identified on bimanual examination can be investigated with TVS to determine which pelvic structure produces the same response.

In response to gentle pressure with the transvaginal probe, pelvic organs should normally slide over one another. Zimmer, Timor-Tritsch, and Rottem⁹ described this effect, which is referred to as the sliding organ sign. A restriction to normal motion may indicate the presence of adhesions. Sometimes the organ of origin of a mass may not be obvious from grayscale and color Doppler findings. Motion of the mass with probe pressure may help to determine the organ of origin.

Safety

The American Institute of Ultrasound in Medicine (AIUM) Bioeffects Committee identified an ultrasound intensity (free-field spatial peak, temporal average [SPTA]) of 100 mW/cm² as the intensity below which no significant biologic effects in mammalian tissues exposed *in vivo* have been confirmed.^{10,11} The Food and Drug Administration set the acoustic output limit (SPTA) for fetal imaging at 94 mW/cm². Manufacturers now have the option to market systems that exceed the previously allowed application-specific intensity levels provided that the exposure levels are displayed on screen so that the level can be monitored by the operator. In 1992, the National Electrical Manufacturer's Association and the AIUM agreed on voluntary output display standards, which consist of the thermal index (TI) and mechanical index (MI). These indexes provide a more accurate estimate of biologic exposure than do intensity levels, allowing operators to apply the ALARA principle for ultrasound exposure (as low as reasonably achievable). The AIUM guidelines conclude that no independently confirmed experimental evidence indicates damage in animal models below certain prescribed levels (TI < 2, and MI < 0.3).¹¹ The AIUM further states and reaffirmed as of March 26, 1997 that "There are no confirmed biological effects on patients or instrument operators caused by exposures from present diagnostic ultrasound instruments. Although the possibility exists that such biological effects may be identified in the future, current data indicate that the benefits to patients of the prudent use of diagnostic ultrasound outweigh the risks, if any, that may be present."¹² Because TVS is often used in early pregnancy during organogenesis, prudent use of the technology dictates that the transducer output be kept at the lowest level necessary to obtain appropriate diagnostic information. The operator should apply the ALARA principle in ultrasound scanning and, moreover, should keep the TI and MI at safe levels. In particular, sonographers and sonologists should be cognizant that ultrasound exposure levels with pulsed Doppler may frequently exceed the prescribed levels and pay close attention to the TI and MI. Pulsed Doppler should be used for as brief a period as possible to obtain necessary, clinically relevant information.

TRUE AND FALSE PELVES

The pelvis is arbitrarily divided into two structurally continuous compartments: the true and false pelves. The division is defined by the sacral promontory and the linea terminalis. The linea terminalis is the arcuate line of the

ilium, the iliopectineal line, and the crest of the pubis. The false pelvis is bounded by the flanged portions of the iliac bones, the base of the sacrum posteriorly, and the abdominal wall anteriorly and laterally. The true pelvis is bounded anteriorly by the pubis and pubic rami, posteriorly by the sacrum and coccyx, laterally by the fused ilium and ischium, and inferiorly by the muscles of the pelvic floor.

In the absence of masses in the nongravid patient, the uterus, ovaries, and adnexa are situated in the true pelvis. The urinary bladder and loops of small bowel are situated anterior to the uterus and adnexal structures in the true pelvis. As the urinary bladder fills, the dome of the bladder extends into the false pelvis and displaces the loops of small bowel, providing a sonic window (Fig. 26-3) for TAS.⁵ Intracavitary probes (transvaginal and transrectal) allow visualization of pelvic viscera from within the true pelvis. Translabial sonography views the true pelvis from the pelvic floor.¹³

The disadvantages of TVS compared with TAS include a limited field of view and an inability to examine the false pelvis adequately. The full urinary bladder in TAS provides a window to examine the true pelvis by displacement of bowel but may also inadvertently displace pathologic structures into the false pelvis. A quick scan of the true and false pelves at the end of the study after the patient has voided is part of a routine examination. It will allow one to detect large masses that have been displaced by the full bladder and masses that mimic a full bladder (Figs. 26-4 and 26-5). On the postvoid examination, it is often necessary to use compression to displace gas in loops of small bowel and colon, especially when searching for a small mass in the false pelvis.

When TVS is used, free fluid is often demonstrated in the posterior cul-de-sac in normal patients (Figs. 26-6 and 26-7). The presence of fluid in the anterior cul-de-sac or lateral pelvic recesses or a large amount of fluid in the posterior cul-de-sac suggests a large intraperitoneal fluid collection (Figs. 26-8 and 26-9). The volume of fluid may be estimated by examining the hepatorenal space (Morrison's pouch) (see Fig. 26-9B).

PELVIC MUSCULATURE, FASCIAL PLANES, LIGAMENTOUS ATTACHMENTS

The superficial or subcutaneous fascia is areolar in texture and contains varying amounts of fat. The subcutaneous fascia is continuous with the superficial fascia of the thigh, labia majora, and perineum. The anterior and lateral walls of the false pelvis are the anterior and lateral muscles of the abdominal wall. Laterally, these muscles include the external and internal obliques and the transversus abdominis, which is the inner muscle layer^{14,15} (Fig. 26-10). The rectus abdominis muscles are paired paramedian muscles oriented longitudinally on either side of the linea alba (see Figs. 26-10 and 26-11). The pelvic attachment of the rectus abdominis muscles is the crest of the pubis. The aponeuroses of the external and internal obliques and transversus muscles fuse with the anterior rectus abdominis fascia to form the linea alba in the midline. It should be noted that the anatomy of the rectus sheath is different above and below the arcuate

FIGURE 26-5. Ovarian cyst mistaken for the urinary bladder. A. Longitudinal midline scan. At the time of the examination, a large ovarian cyst (c) was missed because it was interpreted to be the urinary bladder. B. The bladder (b) was identified only when the transducer was angled caudad. C. Longitudinal midline scan of the cyst being aspirated. The tip of the needle is seen in the middle of the cyst (arrow). The bladder (b) is filling and is now better visualized. D. After 300 mL of clear serous fluid was aspirated, only the bladder lies anterior to the uterus. Note that scans A and D look identical.

line.¹⁴ Below the arcuate line, a rectus sheath hematoma may extend across the midline and displace the bladder posteriorly.¹⁶ Above the arcuate line, however, a hematoma will be confined and not cross the midline. Without careful evaluation of the abdominal wall and the epicenter of the mass, a hematoma of the rectus sheath may be mistaken for a mass of pelvic origin.

Masses in the space of Retzius (also known as the prevesical or retropubic space) may also be confused with

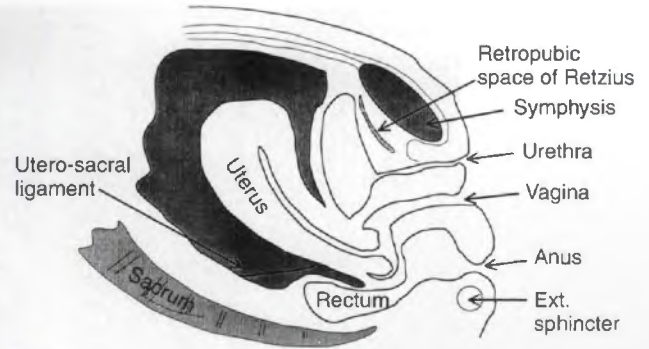

FIGURE 26-6. Diagram of a midline sagittal section through the pelvis showing the peritoneal reflections including the anterior cul-de-sac (vesicouterine recess) and the posterior cul-de-sac (rectouterine recess). The posterior cul-de-sac is closely related to the posterior fornix of the vagina.

FIGURE 26-7. Free fluid in the posterior cul-de-sac. Transvaginal sonogram in the sagittal plane demonstrating a small amount of free fluid in the posterior cul-de-sac (horizontal arrow). The endometrium is in the late proliferative phase. The functional zone of the endometrium (f) is hypoechoic compared with the echogenic basal layer (oblique arrows).

FIGURE 26-8. Ectopic pregnancy with blood in the posterior cul-de-sac. Debris-filled fluid (ff) is present in the posterior cul-de-sac in this patient with a ruptured ectopic pregnancy. The posterior cul-de-sac extends to the inferior aspect of the posterior lip of the cervix (c) and is in contact with the posterior vaginal fornix. Endocervical canal (oblique arrow); decidual cast (curved arrow). b, bowel; bl, partially full bladder.

masses arising from the pelvic viscera. The space of Retzius is situated between the transversalis fascia and the extraperitoneal fascia^{14,15} (see Figs. 26-6 and 26-10). The transversalis fascia is a thin layer of connective tissue separating the transversus abdominis from the extraperitoneal fascia (see Fig. 26-10). Below the umbilicus, the extraperitoneal fascia presents two well-defined layers. The umbilical vesical fascia is the deeper of the two and is continuous with the vesical fascia. The umbilical prevesical fascia lies between the transversalis and umbilical vesical fasciae and is fused to the latter. It is also fused to the transversalis fascia along the medial umbilical ligaments and at the umbilicus. The

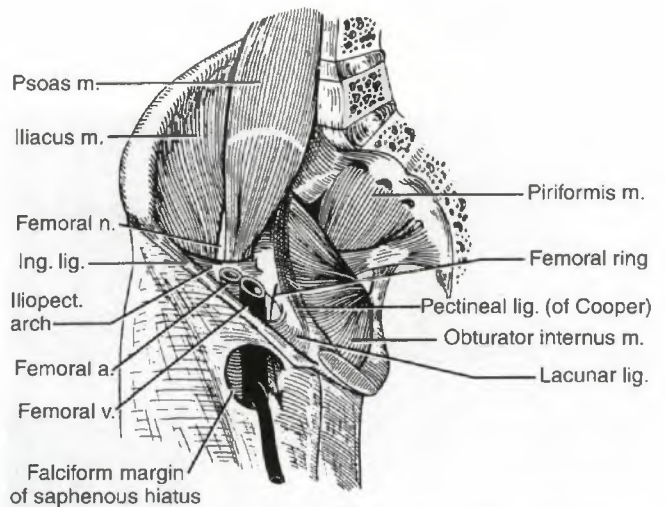

FIGURE 26-12. Diagram of the pelvic musculature. (From Pansky B: *Review of Gross Anatomy, 5th ed.* New York, Macmillan, 1987.)

resultant space between the transversalis fascia and the umbilical prevesical fascia is the space of Retzius. Sonographically, masses in the space of Retzius (usually hematomas or abscesses) displace the bladder posteriorly.¹⁷ Posterior displacement of the urinary bladder is a characteristic feature of masses in the space of Retzius, which allows differentiation from pelvic or abdominal masses that displace the bladder inferiorly or anteriorly.

Muscles of the pelvis include those of the lower limb (psoas major, iliacus, piriformis, obturator internus) and the pelvic diaphragm (levator ani, coccygeus).^{15,18} The psoas major is a large triangular muscle that arises from the lumbar transverse processes and the vertebral bodies and the disks of T-12 to L-2. It descends through the false pelvis on the pelvic side wall anteriorly and exits posterior to the inguinal ligament (Fig. 26-12). It converges with the iliacus to form a tendon that inserts on the lesser trochanter of the femur. The iliacus arises from the concavity of the upper two thirds

FIGURE 26-13. Transverse sonogram through the right iliac fossa, using the gravid uterus (U) as a sonic window, showing the relative positions of the iliacus (I) and psoas major (P) muscles separated by a fascial plane (F) in the false pelvis. The iliac vessels are medial to the psoas. EIA, external iliac artery; EIV, external iliac vein; IIA, internal iliac artery; IIV, internal iliac vein; IW, iliac wing; VB, vertebral body.

FIGURE 26-14. Transverse sonogram through the pelvic side wall angled to the right to visualize the psoas major (P), the iliacus muscle (I), and the psoas tendon (Pt). The external iliac artery (EIA) and vein (V) are anterior to the iliopsoas muscle bundle.

of the iliac fossa, the ventral surface of the sacroiliac and iliolumbar ligaments, and the lateral aspect of the upper part of the sacrum.¹⁸

Sonographically, the psoas is seen in the lower abdomen in a paravertebral position. In a transverse sonogram of the lower abdomen, the psoas is rounded and hypoechoic. Because the transducer is angled inferiorly, the psoas muscles diverge laterally and, in the false pelvis, assume a position medial and slightly anterior to the iliacus muscle (see Figs. 26-12 and 26-13). In the false pelvis, the iliac wings are identified as brightly echogenic linear structures with loss of distal sonic information (see Fig. 26-13). More inferiorly, within the true pelvis the iliacus/psoas muscle is seen as a hypoechoic, discretely marginated muscle; its two component muscles are separated by a brightly echogenic line, which represents interposed fascia continuous with the psoas tendon (Fig. 26-14). The psoas may be demonstrated in its long axis by scanning in a longitudinal oblique plane (Fig. 26-15). In thin patients, the fasciculi of the psoas muscle may be identified (see Fig. 26-15). Movement of the normal psoas muscle may be seen with flexion of the hip.

The piriformis muscle arises from the sacrum between the pelvic sacral foramina and from the gluteal surface of the ilium^{14,15} (Fig. 26-16). On pelvic sonography, the piriformis can be identified posteriorly within the pelvis until it passes through the greater sciatic notch (Fig. 26-17) to insert onto the greater trochanter of the femur. The obturator internus muscle arises from the anterolateral pelvic wall surrounding the obturator foramen and passes through the lesser sciatic foramen to insert on the greater trochanter of the femur (Fig. 26-18).

The pelvic diaphragm is formed by the levator ani and coccygeus muscles. This is the most caudal structure of the pelvic cavity and can be routinely identified on TAS when

FIGURE 26-15. Coronal sonogram through the distended urinary bladder (B), with the transducer situated medially and angled laterally to visualize the psoas major (P) and the iliacus muscles (I) in their long axes. EIV, external iliac vein; F, iliopsoas fascial plane; Pt, psoas tendon.

the transducer is angled inferiorly (Fig. 26-19). The perineal body is situated between the anus and vagina. It is formed by the median raphe of the levator ani and the central tendon of the perineum on which converge the bulbocavernosus and superficial transverse perineal muscles and the external anal sphincter.¹⁴ The perineal body provides much of the support for the perineum.¹⁹ The right and left broad ligaments are folds of peritoneum, which extend from the

lateral aspects of the uterus to the lateral pelvic side walls (Fig. 26-20) and divide the pelvic cavity into anterior and posterior compartments. The free border of the broad ligament contains the uterine (fallopian) tube.^{15,20}

The broad ligaments may be identified sonographically when they are outlined by free intraperitoneal fluid (Fig. 26-21) or when the uterus is retroverted. The ovary is

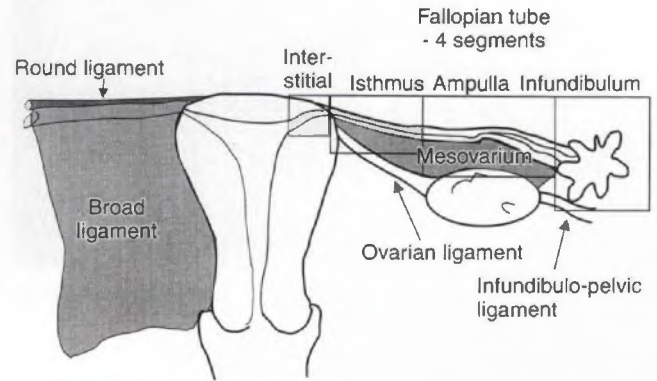

FIGURE 26-20. Diagram of the ovary, uterus, and adjacent peritoneal reflection and ligaments.

attached to the posterior layer of the broad ligament by reflections of peritoneum referred to as the mesovarium (Fig. 26-22). The superior margin of the portion of the broad ligament containing the fallopian tube is referred to as the mesosalpinx. The superior margin of the broad ligament lateral to the fimbriated end of the fallopian tube is the suspensory ligament of the ovary (infundibulopelvic ligament) through which course the ovarian vessels and nerves²⁰ (see Fig. 26-22).

The round ligaments arise in the uterine cornua, anterior to the fallopian tubes in the broad ligaments, and extend anterolaterally to run beneath the inguinal ligament and insert into the fascia of the labia majora.²⁰ The ovarian (uteroovarian) ligaments arise from the uterine cornua posterior to the uterine tubes and attach to the inferior extremity of the ovary. In the absence of free intraperitoneal fluid, the mesovarium, mesosalpinx, ovarian, and round ligaments are not identified sonographically. The suspensory ligament of the ovary is usually not seen. The ovarian artery within the suspensory ligament of the ovary, however, is often identified with TAS or TVS. According to Kurjak and Zalud,²¹ the ovarian artery can be identified within the suspensory ligament in approximately 21% of women in the reproductive age group and in 4% of postmenopausal women.

The base of the lateral margin of the broad ligament is continuous with dense connective tissue of the pelvic floor, which is united with the supravaginal portion of the cervix. The lower medial margin of the broad ligament is widely attached to the connective tissues adjacent to the cervix known as the parametrium.¹⁹ The uterosacral ligaments (see Figs. 26-3 and 26-22) extend posterolaterally from the supravaginal cervix, encircle the rectum, and insert into the fascia over the sacrum. The uterosacral ligaments form the lateral boundaries of the rectouterine pouch.

VASCULAR ANATOMY

The common iliac arteries course anteriorly and medially to the psoas muscles (see Fig. 26-22).^{22,23} The right common iliac vein ascends posteriorly and then laterally to the right common iliac artery. The left common iliac vein ascends medially and then posteriorly to the left common iliac artery. The common iliac arteries bifurcate to form the external and internal iliac arteries. The external iliac arteries supply most of the lower limbs. The internal iliac arteries supply the pelvic viscera, walls of the pelvis, perineum, and gluteal regions (Fig. 26-23).

The external iliac arteries course through the false pelvis without entering the true pelvis. In the nongravid state, the caliber of the external iliac arteries is greater than that of the internal iliac arteries. The external iliac arteries assume a course adjacent to the medial psoas border and exit the pelvis through the femoral canals at the level of the inguinal ligaments (see Figs. 26-12, 26-13, and 26-22). The right external iliac vein ascends medially and then posteriorly to the right external iliac artery. The left external iliac vein is medial to the left external iliac artery.

The internal iliac arteries arise at the bifurcation of the common iliac arteries at the level of the L-5/S-1 disk immediately anterior to the sacroiliac joints and course approximately 4 cm posteriorly to the superior margin of the greater sciatic foramen. The internal iliac arteries then divide into anterior and posterior trunks, which pass posteriorly into the greater sciatic foramina. The anterior division divides into the following branches: (1) umbilical and superior vesicle; (2) inferior vesicle; (3) uterine; (4) vaginal; (5) middle rectal; (6) obturator; (7) internal pudendal; and (8) inferior gluteal. The posterior division divides into the iliolumbar, lateral sacral, and superior gluteal (see Fig. 26-23). High-velocity, high-impedance flow is the characteristic Doppler signal of the internal and external iliac arteries (Fig. 26-24). Anterior to the internal iliac arteries are the ureters, ovaries, and fimbriated ends of the fallopian tubes (see Fig. 26-22). The internal iliac veins are posterior to their respective arteries.

In patients in the reproductive age group, TVCFD can demonstrate the internal iliac arteries (Fig. 26-25) in 99% of patients and the external iliac arteries in 95% of patients.²⁴ In postmenopausal patients, the internal and external iliac arteries are demonstrated in 82% and 78% of patients, respectively. Occasionally, the division of the internal iliac artery into the anterior and posterior branches can be seen on TVS.

The uterine artery runs medially on the levator ani to the cervix. Approximately 2 cm from the cervix, it crosses superior and anterior to the ureter (Fig. 26-26). The uterine artery ascends in a tortuous course lateral to the uterus in the broad ligament to the junction of the fallopian tubes and the uterus. From the cornua of the uterus, the uterine artery courses laterally to reach the hilum of the ovary, and it ends by joining with the ovarian artery. The uterine artery supplies the cervix. Branches of the cervical branch of the uterine artery anastomose with branches of the vaginal artery to form the azygos arteries of the vagina, one of which is anterior to and the other posterior to the vagina.^{15,22} The uterine arteries provide the main arterial supply to the uterus. Although the uterine arteries anastomose with the ovarian and vaginal arteries, the predominance of uterine blood supply from the uterine arteries is underscored by the fact

FIGURE 26-22. Diagram of the female pelvis (superior view). (Copyright 1954 Novartis. From Netter FH: *The CIBA Collection of Medical Illustrations*, Volume 2, *Reproductive System*. Section VI, Plate 7. Summit, NJ, CIBA-Geigy Co, 1954. All rights reserved.)

that the uterine arteries undergo marked hypertrophy in pregnancy, whereas the other vessels do not.¹⁹ As they ascend lateral to the uterus, the uterine arteries produce multiple branches that pierce the uterine wall and then divide into the anterior and posterior arcuate arteries, which anastomose extensively with each other across the midline between the middle and outer layers of the myometrium²⁰ (see Figs. 26–22 and 26–27). The radial arteries arise as multiple branches from the arcuate arteries and travel centrally to supply the rich capillary network in the deeper layers of the myometrium and the endometrium (Fig. 26–28). Before entering the endometrium, the radial arteries give rise to the straight and spiral arteries of the endometrium. The straight arteries supply the basal layer of the endometrium. The muscular spiral arteries supply the superficial two thirds of the endometrium and become longer and more tortuous in the secretory phase of the menstrual cycle.

Sonographic visualization of pelvic vascular structures with TAS and TVCFD depends on the sensitivity of the equipment, and will change as equipment improves and new technical developments are introduced. The following discussion of flow in pelvic vasculature is based on the current literature but may become dated as newer data become available.

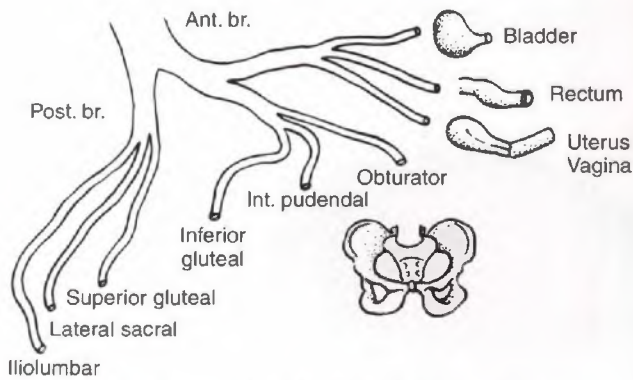

FIGURE 26–23. Branches of the internal iliac arteries and the pelvic viscera that they supply.

The resistive index (RI) and the pulsatility index (PI) are commonly used as Doppler indexes of vascular impedance. To prevent confusion, only RI values have been presented in this review. Much of the infertility literature, however, uses the PI as a predictor of vascular impedance. Readers are referred to reference articles in the literature for PI values.^{25–30} In addition, peak systolic velocities and RI values vary from one study to another. These numbers are provided only as a rough guide and should not be used as absolutes.

Using color flow Doppler (TVS or TAS), the uterine arteries can be identified lateral to the cervix at the level of the cervicocorporeal junction in virtually all patients in the reproductive age group and in 80% of postmenopausal

patients.²⁴ The uterine artery can be visualized with color flow Doppler as it ascends lateral to the uterus in the broad ligament to the junction of the fallopian tubes and the uterus. The pulsed Doppler waveform of the uterine artery demonstrates moderate- to high-velocity/high-resistance flow. The RI of the uterine arteries varies, possibly in part because of increased uterine flow associated with estrogen. Postmenopausal women have a statistically higher RI (0.89 ± 0.06) than women in the reproductive age group (0.86 ± 0.04). Kurjak and Kupesic³¹ demonstrated that the RI of the uterine arteries of postmenopausal women increases with years after menopause. In patients in the reproductive age group, the RI is statistically higher in the proliferative phase of the menstrual cycle (0.88 ± 0.05) than in the luteal phase (0.84 ± 0.06).^{24,31,32} During the proliferative phase, the RI decreases 1 to 2 days before ovulation and then increases 24 hours before ovulation.^{1,24} There is generally no significant difference in RI between the right and left uterine arteries irrespective of the side of ovulation.²⁴ The uterine artery RI decreases significantly in pregnancy.²⁴

In the radial arteries, the mean peak systolic flow velocity is approximately 23 cm/second (range, 9 to 44 cm/second), with a mean RI of 0.74 in the follicular phase dropping to 0.68 in the luteal phase.³¹⁻³³ The range of radial artery RI is

approximately 0.59 to 0.86.³³ Visualization of the radial arteries becomes more difficult with advancing years after menopause. In Kurjak and Kupesic's study,³¹ only 33% of women more than 16 years postmenopause had sonographically demonstrable radial arteries.

Visualization of endometrial (spiral artery) blood flow (Fig. 26-29) is generally possible in the periovulatory period, occurring as early as day 8 of the menstrual cycle.³¹⁻³⁷ Using TVCFD, the spiral arteries can be visualized in the functional zone of the endometrium during this period.³⁷ The RI of the spiral arteries decreases from approximately 0.64 in the follicular phase to 0.50 in the luteal phase.³¹ In women 1 to 5 years postmenopause, Kurjak and Kupesic³¹ demonstrated a mean RI in the spiral arteries of 0.72. They were able to demonstrate the spiral arteries in only 30% of women 1 to 5 years postmenopause and in no women who were more than 5 years postmenopause. Failure to visualize the spiral arteries in the subendometrial region and within the functional zone may be associated with infertility and may be predictive of outcome in in vitro fertilization.³⁸

Uterine venous channels follow a course similar to that of the arteries.²⁰ The arcuate venous plexus accompanies the arcuate arteries, passing circumferentially within the myometrium (Figs. 26-30 and 26-31). The venous plexus is

larger than the associated arterial channels and is frequently identified sonographically by both the transabdominal and transvaginal approaches.

The ovarian arteries arise from the lateral margin of the aorta at a level slightly inferior to the renal arteries. At the pelvic brim, they cross the external iliac artery and vein and course medially within the suspensory (infundibulopelvic) ligament of the ovary (see Figs. 26-21 and 26-32). The ovarian artery passes posteriorly in the mesovarium and breaks up into branches.

Ovarian arterial blood flow varies according to the stage of the menstrual cycle. Before formation of the dominant

FIGURE 26-32. Ovarian artery. A. Transabdominal sagittal oblique sonogram through the right ovary (Ov) demonstrating the right ovarian artery. B. Similar scan plane with pulsed Doppler showing a peak systolic velocity of 100 cms/sec.

follicle, flow is often low velocity and high resistance. Diastolic flow is low or absent,¹⁻³ and the mean RI is approximately 0.92 ± 0.08 ,³¹ with a peak velocity in the 10 to 40 cm/second range.³⁹ The peak systolic velocity remains relatively constant in the ovarian arteries bilaterally irrespective of the side of ovulation.³⁹ The impedance drops dramatically in the ovarian artery on the side with the dominant follicle in the periovulatory period and luteal phase. The RI of the ovarian artery on the side with the dominant follicle drops in the late follicular phase (days 12 to 14) to a mean RI of 0.86 ± 0.04 and by the early luteal phase flow is low resistance,¹⁻³ most obvious by day 21, when the mean RI is approximately 0.83 ± 0.04 .³¹ The RI rises during the late luteal phase.³ The changes in RI are thought to be due to hormone-mediated changes in vessel wall compliance, allowing increased blood flow to the ovary in the late follicular and early luteal phases.³ The nondominant ovary does not show cyclic changes, and the waveform remains high resistance throughout the cycle.

In postmenopausal women, the mean ovarian arterial RI is approximately 0.94 in the first 5 years postmenopause. In women 11 years or greater postmenopause, there is absent diastolic flow corresponding to an RI of 1.0.³¹

Intrafollicular (flow in the wall of the follicle) arterial flow velocity increases approximately 29 hours before follicle rupture, and the rise continues until approximately 72 hours after the formation of the corpus hemorrhagicum⁴⁰ (Fig. 26-33). The RI in the late follicular phase is approximately 0.54 ± 0.04 .⁴¹ The corpus luteum becomes highly vascularized within a few days after ovulation to provide a conduit for the delivery of luteal steroids to the general circulation.³⁹ The waveform of the corpus luteum is low resistance, with an RI in the early luteal phase of approximately 0.44 ± 0.4 , rising in the late luteal phase to approximately 0.50 ± 0.04 .⁴¹

Intraovarian arterial flow can be visualized within the stroma of the ovary using TVCFD and power Doppler⁴²

(Fig. 26-34). Visualization of intraovarian flow can be observed more frequently in the luteal phase than in the early follicular or periovulatory phases.²⁷ In Kurjak and Kupesic's series,³¹ it was not possible to detect intraovarian flow in postmenopausal patients.

Veins emerge from the hilum of the ovary forming the pampiniform plexus. These veins join together to form the ovarian vein, which ascends out of the pelvis adjacent to the ovarian artery.²⁰ The right ovarian vein empties into the inferior vena cava just below the renal vein. The left ovarian vein empties into the left renal vein. The ovarian veins, unlike the ovarian arteries, may become enlarged in pregnancy.²⁰

The lymph nodes and lymphatic channels are not normally visualized by sonography. However, knowledge of the location of the major lymph node groups is important to recognize them when they are pathologically enlarged. The main groups are (1) the common iliac lymph nodes that accompany the common iliac artery; (2) the external iliac lymph nodes that are situated in the false pelvis and pelvic side wall lateral to the bladder and are associated with the external iliac artery and vein; and (3) the internal iliac lymph nodes that surround the internal iliac vessels. Outlying groups include the sacral and obturator nodes.

The lymphatic drainage of the pelvic viscera is variable. The following is a general guideline to drainage of specific viscera, which is important in assessing nodal spread in neoplasia:

1. Ovaries: the lymphatic channels ascend along the ovarian arteries to the lateral aortic and periaortic nodes at the level of the renal hila.
2. Cervix: the lymphatic channels course lateral in the parametrium to the external iliac nodes, posterolateral to the internal iliac nodes, and posterior to the rectal or sacral nodes.

FIGURE 26-33. Intrafollicular flow. *A.* Transvaginal coronal oblique sonogram through the right ovary (OV) demonstrating a follicle measuring approximately 1.8 cm in maximal diameter. *B.* The cumulus oophorus (*arrow*) within the follicle. *C.* Power Doppler image demonstrating flow (*arrow*) in the wall of the follicle.

3. Uterus, lower corpus: the lymphatics course lateral to the external iliacs through the parametrium.
4. Uterus, lower corpus, fundus, and tube: the lymphatics accompany the ovarian channels.
5. Vagina: the lymphatics of the upper vagina accompany the uterine artery to the internal and external iliac lymph nodes, whereas those of the midvagina accompany the vaginal artery to the internal iliac lymph nodes. The vagina external to the hymen drains to the superficial inguinal nodes. This reflects the embryologic origin of the vagina, in which the fibromuscular wall of the upper two thirds of the vagina arises from the paramesonephric (müllerian) duct, which also gives rise to the uterus and fallopian tubes. The lower one third of the vagina arises from the urogenital sinus and, therefore, shares the lymphatic drainage with the external genitalia.

THE UTERUS AND VAGINA

The uterus is located in the true pelvis between the urinary bladder anteriorly and the rectosigmoid posteriorly. The anterior surface of the uterus is covered with peritoneum to the level of the junction between the uterine corpus and cervix. The peritoneal space anterior to the uterus is the vesicouterine pouch or anterior cul-de-sac (see Figs. 26-3 and 26-6 to 26-9). This space is usually empty but may contain loops of small bowel. Posteriorly, the peritoneal reflection extends to the posterior fornix of the vagina (Fig. 26-35), forming the posterior cul-de-sac. Laterally, the peritoneal reflection forms the broad ligaments.

The uterus consists of two major parts: the body, or corpus, and the cervix, which is the lower cylindrical portion that projects into the vagina (Fig. 26-36). The isthmus is a narrow portion of the uterus that corresponds to the

FIGURE 26-34. Intraovarian arterial flow. Transvaginal sonogram in the coronal oblique plane through the right ovary demonstrating arterial flow.

FIGURE 26-35. Posterior cul-de-sac/posterior vaginal fornix. Transvaginal sonogram in the sagittal plane through the uterine cervix with bowel (B) in the posterior cul-de-sac. The posterior wall of the vagina (arrows) is seen merging with the posterior lip of the cervix (P). The posterior fornix is demonstrated by a thin echogenic line (curved arrow). The external cervical os is seen at the end of the echogenic endocervical canal (short arrow).

approximate position of the internal os and is the separation between the corpus and cervix.⁴³ The anterior surface of the corpus is almost flat, whereas the posterior surface is convex. The uterine fallopian tubes emerge from the cone-shaped cornua of the uterus, which are situated at the junction between the superior and lateral uterine margins. The fundus of the uterus is the superior portion of the uterus between the insertion of the uterine fallopian tubes.^{19,43} The

ratio of the length of the body and fundus varies with age. Before menarche, the corpus is approximately one half the length of the cervix; in nulliparous women, the corpus and cervix are of approximately equal length; and in multiparous women, the corpus is about twice the length of the cervix.^{19,43} The corpus is predominantly muscular, whereas the cervix is composed predominantly of collagenous and elastic tissue; the proportion of smooth muscle is only about 10%.^{19,43}

The size of the uterus is variable. In adults of reproductive age, the uterus measures approximately 6 to 8.5 cm in length in nulliparous women and 8 to 10.5 cm in length in multiparous women.^{19,44-46} The width of the corpus measures approximately 3 to 5 cm in nulliparous women and 4 to 6 cm in multiparas. The anteroposterior (AP) diameter is 2 to 4 cm in nulliparas and 3 to 5 cm in multiparas.⁴⁶

After menopause, the uterus atrophies. In women who are more than 5 years postmenopause, the uterus measures 3.5 to 7.5 cm in length,^{45,46} 2 to 4 cm in width, and 1.7 to 3.3 cm in AP dimension.⁴⁶

The prepubertal uterus measures approximately 2.0 to 4.4 cm in length.^{47,48} Uterine length in neonates is similar, but the endometrium is thicker and more echogenic than in the prepubertal uterus, likely on the basis of high maternal estrogen levels resulting from placental estrogen production.⁴⁸ Uterine growth begins at approximately age 7 to 8 years, accelerates during puberty, and continues until approximately 20 years of age.⁴⁹

Uterine position is highly variable and changes with varying degrees of bladder and rectal distention. The cervix can be identified sonographically in the sagittal plane as that portion of the uterus immediately posterior to the angle of

FIGURE 26-36. A. Transvaginal sonogram in the sagittal plane demonstrating the corpus of the uterus. bo, bowel. B. Inferior angulation of the probe demonstrates the cervix (cx) and the endocervical canal (arrows). C. This two-image set is a typical two-dimensional sagittal image of the uterus (on the left) with the three-dimensional rendered image in the coronal plane (on the right). D. The three-dimensional coronal view has been rotated showing the triangular shaped echogenic endometrial canal (e). The fallopian tubes and ovaries are not seen in this case. E. A postoperative specimen of the uterus, tubes, and ovaries from a different patient showing an appearance comparable to the coronal image in D.

the bladder (see Fig. 26-3). The cervix is anchored at the angle of the bladder by the parametrium and is less freely movable than the corpus and fundus. The cervix and the vagina form a 90-degree angle, a condition referred to as anteversion (Fig. 26-37). The more movable corpus is usually flexed anteriorly on the cervix (anteflexed). Filling of the bladder usually straightens out the uterus so that on TAS the uterus does not appear anteflexed (see Fig. 26-3B) and the angle between the cervix and vagina is greater than 90 degrees. Retroversion (see Fig. 26-28), retroflexion (Fig. 26-38), and tilting of the uterus to the right or the left are considered to be normal variants in position unless the uterus is displaced by pelvic pathology.⁴⁵ Retroversion of the uterus can result in poor visualization of the endometrial canal on TAS and widening of the adnexa because of

visualization of the broad ligaments. In addition, as a result of attenuation of sound by the uterus, the fundus of a retroverted uterus may be “echo poor” in appearance. This “dropout” phenomenon may simulate the appearance of a fundal fibroid. The differentiation between the fundal fibroid and dropout of sound may be made by the lack of displacement of the endometrial canal and the lack of a contour abnormality of the latter. Alternatively, dropout in the fundus of a retroverted uterus is usually not a problem in TVS. The transvaginal approach is used to better assess the myometrium and endometrial canal and to detect the presence of a fibroid or other myometrial pathology. The retroverted uterus may also be difficult to assess with the TAS because the endometrial canal may be parallel to the sound beam and not be resolved (Fig. 26-39). When the

FIGURE 26-37. Anteflexed uterus. *A.* Transabdominal sonogram in the midline sagittal plane through the uterus. The bladder (*b*) is almost completely empty. *v*, vagina. *B.* Transvaginal midsagittal scan of an anteflexed uterus. *C.* Transvaginal scan of the cervix and lower uterine segment. The bladder (*b*) is almost empty. The endocervical canal (*ec*) and endometrial canals (*e*) form an angle of approximately 90 degrees in all three images.

FIGURE 26-38. Retroflexed uterus. Transabdominal (*A*) and transvaginal (*B*) sonograms in the midline sagittal plane through the uterus demonstrating a retroflexed uterus. Endometrial and endocervical canals (*arrows*). *b*, bladder; *c*, cervix.

uterus is retroflexed, the cervix may be interposed between the probe and the body of the uterus, making assessment of the myometrium difficult (Fig. 26-39*B*). To improve uterine visualization with the transvaginal probe, one must move the probe around the cervix. In this situation, move it posteriorly so that the probe now lies immediately adjacent to the body and fundus of the uterus (Fig. 26-39*C*). In this position, the person scanning can also use the probe to “palpate” the uterus and detect the presence of tenderness, which is seen in adenomyosis and endometritis.

The muscular layer of the uterus (myometrium) is composed of three distinct layers that can be differentiated sonographically.⁶ The outer layer of the myometrium consists of longitudinally oriented fibers that course over the fundus and converge at the cervix and cornua. The outer layer is separated from the intermediate layer by the arcuate vessels and is hypoechoic compared with the intermediate layer (Fig. 26-40). The intermediate layer is the thickest of the three layers. The muscle fibers consist of spiral bands extending from cornua to cervix, which interdigitate in the

midsagittal plane. The intermediate layer is considerably more echogenic than the inner layer and slightly more echogenic than the outer layer (see Fig. 26-40). The inner layer consists of longitudinal and circular fibers. The sonographic appearance is that of a thin hypoechoic halo surrounding the endometrium (see Fig. 26-40).

Contraction waves of the myometrium can be demonstrated sonographically. These waves are most apparent on videotapes or cine loops of real-time images played back at five times regular speed. The myometrial contractions result in a transmitted stripping motion of the endometrium typically beginning at the cervix and extending to the uterine fundus. The contractions increase in frequency in the periovulatory phase and are reversed in the menstrual phase.⁵⁰

Contraction waves of the inner layer of the myometrium may play a role in sperm transport, implantation, and

maintenance of pregnancy. Disordered and reversed contractions may be seen in some infertile patients. Waves arising from the cervix and extending to the fundus are seen less frequently in patients on oral contraceptives than in a matched control group.

The endometrium is a thin echogenic strip composed of a superficial layer (zona functionalis) and a deep basal layer. The thickness and sonographic appearance of the endometrium change cyclically with the menstrual cycle. In the menstrual phase, the endometrium is thin and brightly echogenic as the superficial layer is shed. During the early proliferative phase (days 5 to 9), the endometrium is a thin, brightly echogenic line (see Figs. 26-30 and 26-31). In the late proliferative phase (days 10 to 14), the functional zone of the endometrium increases in thickness under the influence of estrogen. During the late proliferative phase, the functional zone is thick and hypoechoic compared with the basal layer (see Figs. 26-7, 26-28, and 26-40). During the secretory phase (days 15 to 28), the functional layer becomes thickened, soft, and edematous under the influence of progesterone (Fig. 26-41). A glycogen-rich fluid is secreted by

FIGURE 26-39. A. Longitudinal transvesical sonogram of a retroverted uterus. The endometrial canal (arrow) in the body is not seen as it lies parallel to the ultrasound beam. b, bladder. B. Transvaginal sonogram in the sagittal plane of a retroverted uterus. The cervix (c) is interposed between the transvaginal probe and the body of the uterus. This gives suboptimal visualization of the myometrium and endometrial canal. C. Transvaginal sonogram of the body and fundus with the probe situated immediately adjacent to the uterus. There is better visualization of the endometrium (arrow).

FIGURE 26-41. Secretory endometrium. Transvaginal sonogram in the sagittal plane on day 19 of the menstrual cycle. The functional zone of the endometrium (f) has become isoechoic with the basal layer (b).

FIGURE 26-40. Myometrial layers. Transvaginal sonogram in the (A) sagittal and (B) coronal planes demonstrating the inner (i), middle (m), and outer (o) layers of myometrium.

FIGURE 26-42. Nabothian cyst. Transvaginal sonogram in the (A) sagittal and (B) coronal planes through the uterine cervix demonstrating a nabothian cyst (arrow).

the glandular epithelium, and the spiral arteries become tortuous. The resultant effect is that the functional layer increases in echogenicity to become isoechoic to the basal layer.⁶

Measurement of the endometrial thickness should be performed in the sagittal plane of the uterus and should include both the anterior and posterior portions of the endometrium (i.e., the endometrial layers anterior and posterior to the endometrial canal). This is often referred to as the “double-layer” thickness. The hypoechoic halo (inner layer of the myometrium) should not be included in the measurement.

The endometrial thickness is normally 4 to 8 mm in the proliferative phase, 6 to 10 mm in the periovulatory period, and 7 to 14 mm in the secretory phase.⁶ In postmenopausal women, the endometrium should measure less than 8 mm.⁵¹ Eighty-one percent of postmenopausal women have an endometrial thickness of less than 8 mm. It should be remembered that this measurement is for normal asymptomatic patients. Patients with postmenopausal bleeding and an endometrial double-layer thickness of 5 mm or more should have further evaluation. Patients receiving hormone replacement therapy have a wider range of endometrial thickness than those receiving no exogenous hormones.⁵¹

The endometrial canal is best visualized with three-dimensional sonography using the rendered coronal image (see Fig. 26-36). The triangular shaped canal is seen on the coronal view with the upper angles being the cornual portions of the canal (c). They will be contiguous with the intramural portion of the fallopian tube (see Fig. 26-36B). This view is also the best, if not the only view that one can use to confidently diagnose a congenital uterine anomaly. In particular are the anomalies resulting from a lack of fusion of the two müllerian or paramesonephric ducts of the primitive uterus. Complete failure of fusion results in two fallopian tubes, two uteri, and even two vaginas. Partial failure will give a bicornuate uterus, which is difficult to differentiate with conventional scans from a uterine septum. This differentiation is important because there is a different treatment for each condition.

The cervix is best visualized transvaginally, with the tip of the probe about 2 to 3 cm from it, depending on the focal zone of the transducer. The endocervical canal is a continuation of the endometrial canal, appearing as a thin, echogenic stripe (see Fig. 26-36B). Fluid is sometimes seen in the endocervical canal, particularly in the preovulatory period. Occasionally, air can be seen in the vaginal fornices surrounding the cervix.

Numerous cervical glands extend from the endocervical mucosa into the adjacent connective tissue of the cervix. Occlusion of the cervical glands results in the formation of retention cysts, known as nabothian cysts¹⁹ (Fig. 26-42).

The vagina is seen as a hypoechoic tubular structure with an echogenic lumen that curves inferiorly over the muscular perineal body at the introitus^{19,20} (see Fig. 26-37). The bladder, trigone, and urethra are anterior to the vagina, and the rectum is posterior. The distal ureters are lateral to the upper vagina and pass anteriorly to enter the bladder. The cervix projects through the anterior vaginal wall, separating the vagina into the anterior, posterior, and two lateral fornices. The posterior fornix of the vagina is closely related to the rectouterine recess of the peritoneal cavity (posterior cul-de-sac) and is separated by the thickness of the vaginal wall and peritoneal membrane²⁰ (see Fig. 26-35).

THE OVARIES

The ovaries are ellipsoid; the long axis is usually oriented vertically when the bladder is empty. Ovarian location is variable, especially in women who have been pregnant. In the nulliparous female, the ovaries are situated in the ovarian fossa (also known as the fossa of Waldeyer)²⁰ (see Fig. 26-2C). The ovarian fossa is situated on the lateral pelvic wall and is bounded by the obliterated umbilical artery anteriorly, the ureter and internal iliac artery posteriorly, and the external iliac vein superiorly.²⁰ One of the finger-like mucosal folds or fimbria, at the end of the fallopian tube is longer than the rest and is referred to as the ovarian fimbria. The ovarian fimbria and the suspensory (infundibulopelvic) ligament of the ovary are attached on the superior surface of

FIGURE 26-43. Three sectional views of the right ovary with multiple small follicles in a 34-year-old woman early in a normal menstrual cycle. A volume data set is collected and presented in three orthogonal views: transverse (A), sagittal (B), and coronal (C). The dimensions of the ovary are recorded using the electronic calipers, and the results are displayed in the image.

the ovary (see Fig. 26-20). The suspensory ligament of the ovary is a fold of peritoneum that arises from the pelvic side wall and contains the ovarian vessels and nerves. The inferior extremity of the ovary is slightly smaller than the superior (tubal) extremity. The inferior extremity is bound to the uterine cornua by the ovarian ligament, which lies within the broad ligament.²⁰ The lateral surface of the ovary is in contact with the parietal peritoneum lining the ovarian fossa, and most of the medial surface is covered by the uterine fallopian tube. The anterior border of the ovary is attached to the mesovarium. The hilus of the ovary, through which the vascular channels and nerves pass, is situated on the anterior border.^{15,20}

Ovarian size varies depending on age, menstrual status, pregnancy status, body habitus, and phase of the menstrual cycle.⁵² Cohen, Tice, and Mandel⁵³ measured ovarian volumes in premenarchal, menstruating, and postmenopausal subjects. In menstruating subjects, the mean ovarian volume was 9.8 mL, with 5% and 95% confidence intervals of 2.5 and 21.9 mL. For premenarchal girls, the mean was 3.0 mL, with 5% and 95% confidence intervals of 0.2 and 9.1 mL, and for postmenopausal patients 5.8 mL, with confidence intervals of 1.2 and 14.9 mL. Minor cyclic changes in volume were also identified, with highest volumes in the preovulatory phase and lowest volumes in the luteal phase.

Recruitment of follicles begins before the onset of menses. As fluid accumulates in the follicular antrum, the follicles increase in size and become sonographically visible. By the time the follicular size is 1 to 2 mm, they can be visualized with TVS. By day 5 to 7, multiple follicles are visible within the ovary⁵⁴ (Fig. 26-43). By day 8 to 12, one or more dominant follicles can be recognized (Fig. 26-44). Approximately 5% to 10% of patients have two dominant follicles. Up to 80% of patients have a second nondominant follicle that becomes almost as large as the dominant follicle. Nondominant follicles are usually smaller than 14 mm mean diameter.⁵⁴ For 4 to 5 days before ovulation, the dominant follicle grows

FIGURE 26-44. Dominant follicle. Transvaginal sonogram in the coronal oblique plane through the right ovary demonstrating a dominant follicle (arrow). ov, right ovary; U, uterus.

at a rate of 2 to 3 mm/day to reach a maximum mean diameter of approximately 20 mm (range, 16 to 28 mm).⁵⁴ Approximately 24 hours before ovulation, the granulosa layer separates from the theca layer, resulting in a hypoechoic ring. The cumulus oophorus (see Fig. 26-33) may occasionally be seen at this time.

Bleeding occurs into the follicle at the time of ovulation (corpus hemorrhagicum). The follicle decreases in size and may become echogenic or filled with echogenic debris or may be sonolucent if no internal bleeding has occurred. The corpus luteum may retain fluid over the next 4 to 5 days and increase in size to 2 to 3 cm⁵⁴ (Fig. 26-45). If pregnancy does not occur, the corpus luteum gradually involutes and atrophies to become the corpus albicans, which is not sonographically identifiable.

THE UTERINE (FALLOPIAN) TUBE

The uterine fallopian tubes are variable in length, measuring approximately 7 to 12 cm.⁴³ Each tube is situated in the superior free margin of the broad ligament and is covered by peritoneum. The uterine fallopian tube is narrowest in the interstitial or intramural portion, which is contained within the muscular wall of the uterus. The interstitial portion of the uterine fallopian tube measures approximately 1 cm in length and can be visualized with TVS in the superior right and left lateral corpus of the uterus. The sonographic appearance is that of a fine, echogenic line arising from the endometrial canal and extending through the uterine wall (Fig. 26-46). Using three-dimensional ultrasound, one can obtain a superior image with the coronal view of the endometrial canal and interstitial portion of the fallopian tube (see Fig. 26-46C).

The isthmus is the narrow segment of the tube adjacent to the uterine wall. It is round and cord-like. The tube widens laterally, forming the ampullary and infundibular regions (see Fig. 26-20). The infundibulum is funnel shaped, terminates as the fimbriated end of the tube, and opens into the peritoneal cavity.⁴³ The peritoneal ostium of the uterine tube is approximately 3 mm in diameter. The isthmus,

On three-dimensional ultrasound, this portion of the tube appears thicker than its true size.

ampulla, and infundibulum are usually not demonstrated with TAS or TVS unless there is tubal pathology or free fluid in the lateral pelvic recesses.

The vascular supply of the uterine tube comes from the vascular arch formed by the anastomosis of the uterine and ovarian arteries. Branches from this arch pass through the mesosalpinx to reach the uterine tube.⁴³

VESTIGIAL STRUCTURES

Part of the cranial end of the paramesonephric duct (which normally forms the uterus, uterine fallopian tube, and fibromuscular wall of the vagina) may persist as a vesicular appendage to the uterine fallopian tube referred to as a hydatid of Morgagni.⁵⁵ Hydatids of Morgagni may be visualized sonographically in the presence of free fluid (Fig. 26-47). Sonographically, they appear as small, unilocular, spheric, thin-walled cysts surrounded by the free intraperitoneal fluid.

The mesonephric ducts form the efferent ductules, epididymis, ductus deferens, seminal vesicles, and ejaculatory ducts in male fetuses. In female fetuses, the mesonephric ducts may persist as rudimentary, blind tubules in the parovarium, which is loose connective tissue in the mesosalpinx. Closer to the uterus, the mesonephric duct may persist as the duct of Gartner, which lies along the lateral wall of the uterus and vagina superior to the hymen.^{19,56} Mesonephric duct remnants may persist as parovarian and Gartner duct cysts.

THE URETERS

The ureters⁵⁷ are muscular tubes that measure 25 to 30 cm in length in the adult. In the pelvis, the ureters course within the extraperitoneal areolar tissue. In the true pelvis, the ureter begins anterior to the internal iliac artery and posterior to the ovary (Fig. 26-48). From there, it courses

FIGURE 26-47. Hydatid of Morgagni. Transvaginal sonogram in the coronal plane demonstrating a hydatid of Morgagni (*arrow*) surrounded by free fluid (*f*) in the left lateral pelvic recess. *ov*, left ovary; *U*, uterus.

anteriorly and medially to lie within the inferior medial portion of the broad ligament, where it is in close proximity to the uterine artery. The ureter then runs anterior, situated in front of the lateral fornices of the vagina, about 2 cm lateral to the supravaginal cervix, and then passes medially to enter the trigone of the bladder anterior to the vagina (Fig. 26-49). The relationships of the ureter to the ovary, cervix, uterine artery, and vagina are of clinical importance because pelvic pathology may result in secondary hydronephrosis resulting from ureteric obstruction (Fig. 26-50). As a result, if a pelvic mass is present, we evaluate the kidneys after the postvoid examination during gynecologic sonography. This is done to confirm the presence

FIGURE 26-48. Longitudinal transabdominal sonogram of the right ovary (O) with a dilated ureter (U) demonstrated immediately posterior. B, bladder.

FIGURE 26-52. A. Longitudinal transvaginal scan of the urethra and bladder (b) outlet. The hypoechoic tubular structure (arrow) is the smooth muscle portion of the urethra. The central faint echogenic line is the collapsed urethral lumen the muscle is thickest anteriorly and in the mid portion of the urethra. B. Transverse transvaginal scan of the proximal portion of the urethra showing the hypoechoic smooth muscle portion (arrow). The walls of the urethra are collapsed. The urinary bladder (b) in this patient is almost empty.

of two kidneys, assess their position, and identify any degree of obstructive uropathy.

THE URINARY BLADDER

The bladder is a distensible reservoir for urine. Its shape depends on the degree of distention of itself and neighboring viscera. The bladder is fixed inferiorly at the urethral orifice, base, and angle; and as it fills, the remainder of the walls displace movable viscera and conform to the space available within the confines of the true pelvis.⁵⁷ A transverse scan through the bladder superiorly gives it a rounded appearance. More inferiorly, the pelvic musculature and bones cause the bladder to appear square in the transverse plane (Fig. 26-51). The bladder wall is echogenic and should be of uniform thickness.

Transvaginal scanning enables better visualization of the trigone, posterior wall, and urethra. The ureteric and urethral orifices are visualized at the base and neck of the bladder, respectively.

The urethra can be seen throughout its length by translabial or better still, by transvaginal scanning (Fig. 26-52). The probe is placed at the introitus or just partially inserted into the vagina and directed upward. Around the inner layer of mucosa, there is a layer of smooth muscle and then an outer sheath of striated muscle. The longitudinally oriented smooth muscle is sonographically hypoechoic and is thicker on the anterior wall in the middle third of the urethra. The paraurethral glands of Skene lie posterior to the urethra near the urethrovaginal junction and empty through the paraurethral duct near the external urethral orifice. Urethral diverticula are distended urethral

FIGURE 26-53. A. A longitudinal transvaginal scan of the urethra (*open arrow*) and bladder (*b*). The solid echogenic neoplasm is seen between the arrows at the base of the urethra posteriorly. B. Transvaginal scan with color Doppler shows some internal vascularity to the solid mass (between the arrows).

FIGURE 26-54. A. This transverse transvaginal scan through a section of normal sigmoid colon to the right of the midline. The overall thickness is 0.71 mm (calipers 2) compared with the abnormal segment in B. B. A scan in a similar plane but to the left of the midline showing a thick walled loop of bowel. The overall thickness is 1.7 cm. The muscularis layer (hypoechoic) and the submucosa (echogenic) is thicker in the abnormal, inflamed segment than in the normal segment. The inflamed segment was also focally tender when depressed with the transvaginal probe.

mucous glands and are found posterior and lateral to the urethra anywhere along its length. They may be a source of pelvic pain and recurrent urinary tract infection, and should be looked for in the appropriate clinical situation. Infected debris within a diverticulum may be seen as layering out of echogenic material within the cystic diverticular sac.

A neoplasm of the Skene gland may also be seen posterior to the urethra as a solid mass (Fig. 26-53).

THE RECTOSIGMOID COLON

The sigmoid colon begins at the inlet of the true pelvis and is extremely variable in length. It has a mesentery, and its

course is variable, looping either to the left or right before ascending on the left to join the descending colon. The rectum begins at the third sacral vertebra and is fixed in position.¹⁵ The rectosigmoid colon usually contains gas and fecal material that cast an acoustic shadow and may make identification or differentiation from pelvic masses difficult. Often, the differentiation between a pelvic mass and the rectosigmoid colon can be made by real-time imaging if peristalsis can be visualized or if the characteristic appearance of bowel wall can be identified (Fig. 26-54). Differentiation between bowel contents and a mass is not usually a problem if the transvaginal approach is used (see Figs. 26-8 and 26-36A). The sigmoid is best imaged with the

FIGURE 26-55. Longitudinal transrectal scan of an (A) anteverted and (B) retroverted uterus. The bladder (b) is almost empty. The endometrium is thin (arrow). c, cervix.

transvaginal probe that is directed posterior to the adnexa and gently pushed deeper into the pelvis. The sigmoid should be examined in each patient if the patient's symptoms cannot be explained by examination of the rest of the pelvic organs.

Transrectal Scanning

Patients in whom a transvaginal scan is not possible can be scanned through the rectum. Using a conventional transvaginal probe, one can obtain superior images of the uterus, ovaries, and adnexa compared with the transvesical approach (Fig. 26-55). This is not commonly used but should be considered in the appropriate patient and with appropriate verbal consent and adequate lubrication. The study is not uncomfortable because the only discomfort is felt when the probe passes through the anal canal.

Ultrasound Evaluation of the Postpartum and Postabortive Uterus

Ultrasound is clearly the modality of choice for imaging the female pelvis, including the uterus and adnexal structures such as the ovaries and fallopian tubes. The endometrium, likewise, can be readily evaluated in the pre- and postmenopausal patient. In our clinical laboratory, a combination of transabdominal (transvesical) scanning as well as transvaginal examination are performed in most patients. This allows the examiner to evaluate the true pelvis in its entirety with a wide field of view, as well as using high-resolution interrogation of specific structures. Primary imaging with ultrasound in conjunction with clinical information guides optimal further imaging. When ultrasound fails to provide adequate information or does not answer the clinical question, further evaluation with magnetic resonance imaging (MRI) can be performed. This is discussed in detail in the chapter dedicated to the MRI of the uterus.

In this chapter, we discuss ultrasound evaluation of the normal uterus, anatomic variants, and its benign and malignant conditions. A discussion of the normal and abnormal endometrium in the patient that presents with abnormal uterine bleeding is presented in the following chapter.

IMAGING

The American Institute of Ultrasound in Medicine (AIUM) guidelines for imaging of the uterus have been developed to assist sonologists in performing sonographic studies of the female pelvis.¹ Knowing the potential but also the limitations of ultrasound helps us to maximize the probability of detecting most significant abnormalities. As with any clinical test, ultrasound of the pelvis should be performed only if there is a valid clinical reason. Following the AIUM guidelines, the indications for pelvic sonography include, but are not limited to

1. Pelvic pain
2. Dysmmenorrhea (painful menses)
3. Menorrhagia (excessive menstrual bleeding)

4. Metrorrhagia (irregular uterine bleeding)
5. Menometrorrhagia (excessive bleeding irregularly)
6. Follow-up on previously detected abnormality (that is, hemorrhagic cyst)
7. Evaluation or monitoring of infertile patients
8. Delayed menses or precocious puberty
9. Postmenopausal bleeding
10. Abnormal pelvic examination
11. Evaluation of congenital anomalies
12. Localization of intrauterine contraceptive device
13. Screening for malignancy in patients with an increased risk¹

Techniques

All relevant anatomic structures in the pelvis should be identified first by transabdominal technique, and then, more detailed evaluation of the deep pelvic structures should be performed by transvaginal technique. In specific situations in which transvaginal evaluation cannot be performed or tolerated, transrectal or transperineal evaluation can be very useful.

The transducer should be selected to operate at the highest clinically appropriate frequency that will allow adequate visualization of deep pelvic structures. For transabdominal evaluation, a 3.5-MHz or higher transducer is employed. Curved linear array, as well as sector, transducers with a smaller footprint are often employed. For transabdominal evaluation, the bladder should be adequately distended to displace bowel superiorly out of the true pelvis and provide an acoustic window to visualize the uterus and adnexa (Fig. 27-1).

For transvaginal evaluation, the urinary bladder should be emptied and the patient in comfortable position but with her pelvis tilted either with the use of stirrups or with an elevation under the hips. The patient or the sonographer, depending on the patient's preference, may introduce the vaginal transducer with real-time monitoring. For transvaginal

FIGURE 27-1. A. Sagittal-transabdominal view of the normal uterus. B. Transverse-transabdominal view of the normal uterus. Notice the acoustic window provided by the distended urinary bladder.

evaluation, the AIUM recommends using probes of 5 MHz or higher (Fig. 27-2). If a male sonologist is performing the examination, a female member of the staff should be present as a chaperone.

The vagina, uterus, and the urinary bladder are used as reference points for identification of the remaining normal and abnormal pelvic structures. The uterine size, shape, and orientation should be identified and documented in sagittal and transverse axial planes. The endometrium, myometrium, and cervix should be carefully evaluated, and their appearance documented. The uterine length is measured in long

FIGURE 27-2. A. Sagittal-transvaginal view of the normal uterus. B. Transverse-transvaginal view of the normal uterus.

axis from the fundus to the cervix, and the anteroposterior dimension is measured on the same image perpendicular to the length. The width is to be measured on a separate image on either a transaxial or coronal plane of section. If the volume of the uterine corpus is assessed the cervical component should be excluded.¹

Assessment of the endometrium is performed in a sagittal plane. Variations of the appearance of the endometrium with different phases of the menstrual cycle and with hormonal supplementation should be considered (Fig. 27-3). Myometrial masses and contour abnormalities should be recorded in two different planes and their locations recorded.¹ Doppler evaluation of the uterus and endometrium can be of added value.

Saline infused sonography (SIS) or, as it is often referred to, sonohysterography, is an innovative technique to evaluate a variety of endometrial and myometrial processes, which involve the endometrial canal. The most common indications for SIS are abnormal uterine bleeding in both pre- and postmenopausal women. Other indications include

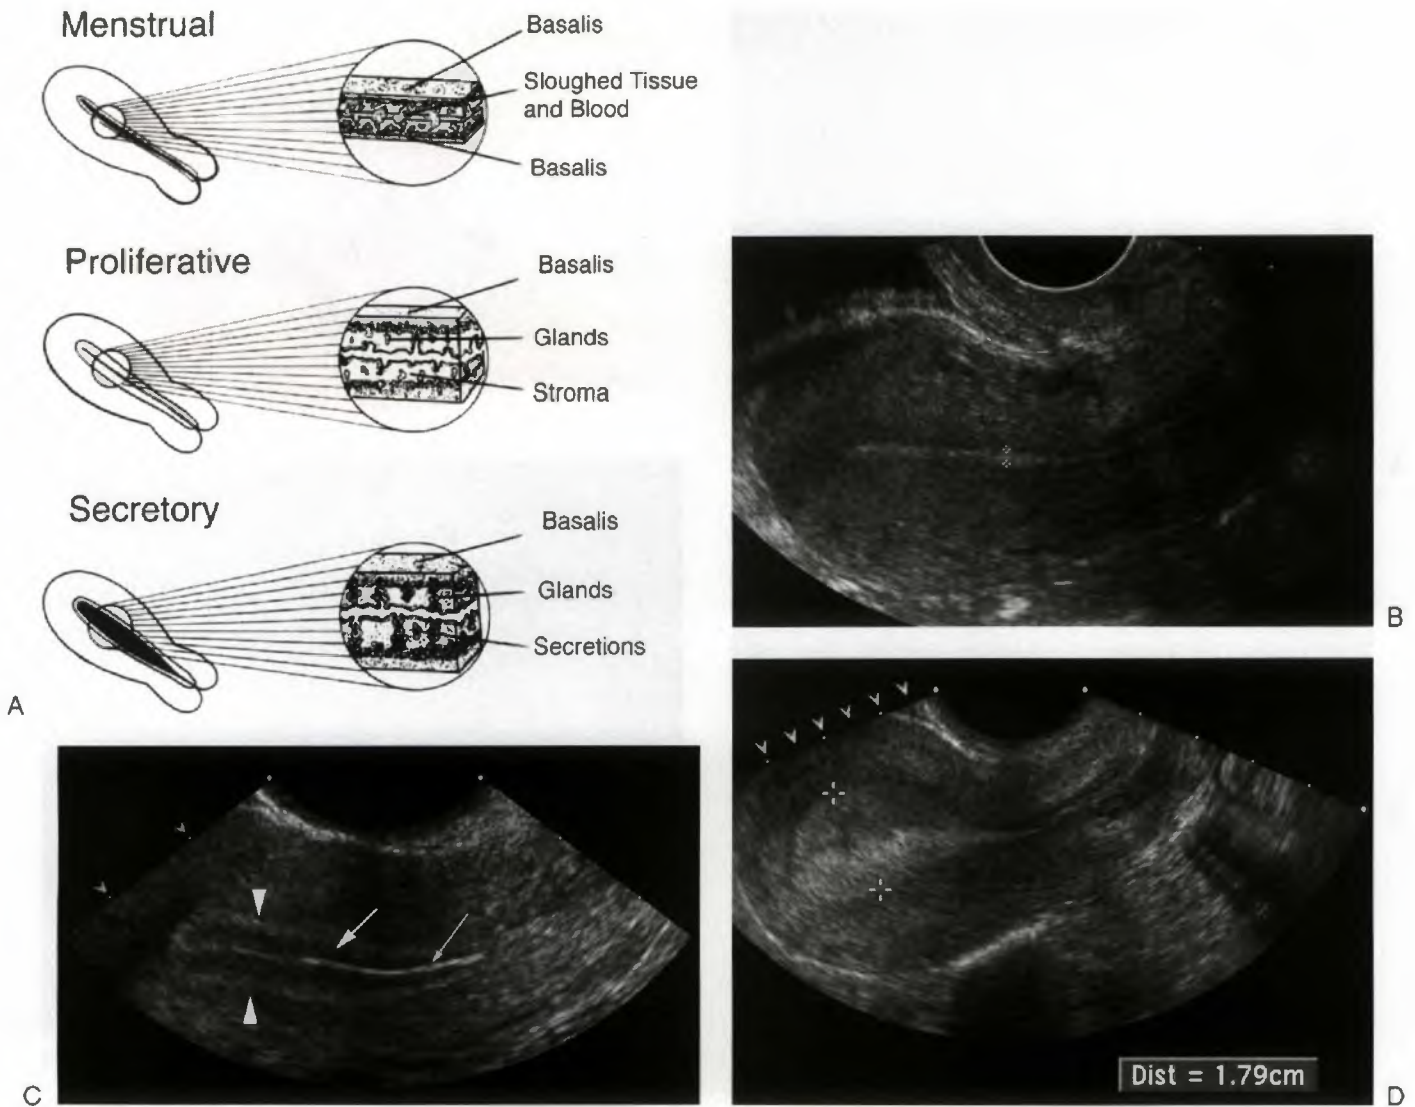

FIGURE 27-3. A. Diagram showing development of the endometrium during the menstrual, proliferative, and secretory phases. In the menstrual phase, the endometrium appears as a thin, irregular interface. The central echogenicity probably arises from sloughed tissue and blood. In the proliferative phase, the endometrium is relatively hypochoic, likely a reflection of the straight and orderly arrangement of the glandular elements. The central thin, echogenic line is likely a specular reflection from the endometrial surfaces. In the secretory phase, the endometrium achieves its maximum thickness and echogenicity. This appearance is from the distended and tortuous glands, which contain secretions. (From Fleischer AC, Kalemeris GC, Entman SS: *Sonographic depiction of the endometrium during normal cycles. Ultrasound Med Biol* 12:271, 1986, Pergamon Journals Ltd. Reprinted by permission of Elsevier Science. Copyright 1986 by World Federation of Ultrasound in Medicine and Biology.) B. Postmenstrual, early proliferative endometrium. C. Periovulatory endometrium. A three-layered endometrium is seen: the collapsed endometrial lumen is demonstrated by the central echogenic line (thin arrow). A hypochoic layer representing the edematous endometrium functionalis (thick arrow) and an outer hyperechoic layer representing the endometrium basalis (arrowheads) is seen. D. Secretory endometrium.

1. Infertility and habitual abortion
2. Congenital abnormalities or anatomic variants of uterine cavity.
3. Preoperative and postoperative evaluation of uterine cavity, especially with regard to uterine myomas, polyps, and cysts
4. Suspected uterine cavity synechiae
5. Further evaluation of suspected abnormalities as seen on transvaginal sonography, including focal or diffuse endometrial thickening or debris
6. Inadequate imaging of endometrium by transvaginal sonography

SIS is contraindicated in women who could be pregnant or have an active infection. Because the normal secretory endometrium may be thick and simulate endometrial disease, the examination should be scheduled in the follicular phase of the cycle, after menstrual flow has ceased but prior to ovulation, no later than the 10th day of the menstrual cycle. Active vaginal bleeding is not generally a contraindication but can make imaging challenging or even nondiagnostic.²

At our institution, we perform a preliminary transabdominal and transvaginal sonogram before SIS. After the procedure is explained to the patient, the external os is cleansed before catheterization of the cervical canal using

FIGURE 27-4. A. Sagittal-transvaginal image of balloon positioning in the cervix. B. Sagittal-transvaginal image after saline infusion. The normal thin endometrium is well seen.

aseptic technique. A sonohysterography catheter (flushed with saline to remove any air bubbles) is then advanced into the endometrial canal. Once in the endometrial canal, the balloon is inflated so that the catheter does not become dislodged. The speculum is removed, and the transvaginal probe is reinserted adjacent to the catheter. Under ultrasound guidance, the balloon is gently retracted to occlude the internal os. Sterile saline should be administered under real-time sonography. The amount of saline one introduces is variable, often between 5 and 30 mL. Normal anatomy and abnormal findings should be documented in two separate planes using the high-frequency transvaginal (TV) probe extending from one cornua to the other (Fig. 27-4).

ANATOMY

The uterus is a hollow organ in which the myometrium is firmly adherent to a thin internal layer of endometrium. Externally the uterus is imbedded between the two layers of the broad ligament. Anatomically, the uterus lies between the bladder anteriorly and the rectosigmoid colon posteriorly. The uterus is divided into two major parts, the body and cervix. The most superior aspect of the uterus is referred to as the fundus, and the entrance of the fallopian tubes into the uterus are referred to as the cornua. Anterior to the origin of the fallopian tubes are the round ligaments, one on each side, which extend anterolaterally, coursing through

FIGURE 27-5. A. Illustration demonstrating an anteverted, anteфлекed normal uterus. (Illustration by James A. Cooper, MD, San Diego, CA.) B. Midline sagittal sonogram demonstrating anteversion (cervix [Cx] to the vagina [V]) and anteфлекion (fundus [F] to cervix). A distended urinary bladder slightly displaces the fundus posteriorly.

the inguinal canals and inserting onto the fascia of the labia majora. The uterus has a dual blood supply. The majority of blood supply is from the uterine arteries arising from the internal iliac arteries and a minor blood supply is from the ovarian arteries.

The uterus is physiologically most often anteverted and anteфлекed (Fig. 27-5) but may also be retroфлекed (Fig. 27-6) or retroverted (Fig. 27-7). The cervix of the uterus is fixed in the midline but the body of the uterus can be mobile, and may change with varying degrees of bladder and rectal distention. Descriptions of flexion refer to the relationship of the body of the uterus to the cervix (usually the angle is about 270 degrees), whereas version refers to the cervical relationship to the vagina.

Retroversion and retroфлекion are not infrequent in the nongravid state. In these cases the fundus of the uterus is positioned in the sacral hollow. During pregnancy, by the 14th to 16th week of gestation, the uterus enlarges and physiologically undergoes reduction. The fundus and uterus

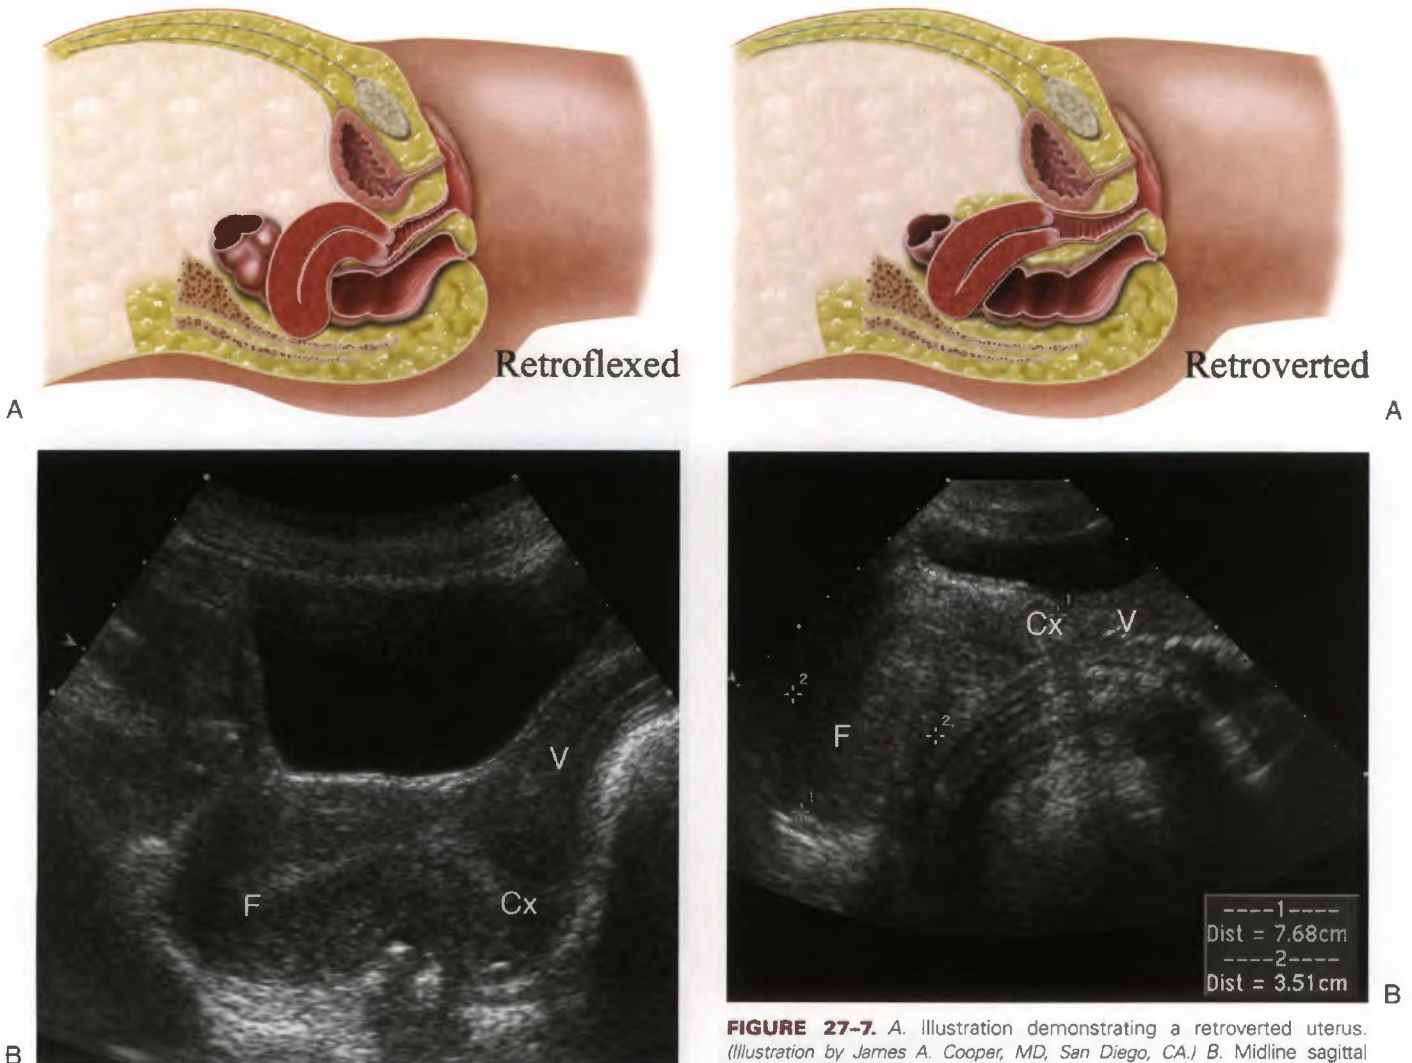

FIGURE 27-6. A. Illustration demonstrating an anteverted, retroflexed uterus. (Illustration by James A. Cooper, MD, San Diego, CA.) B. Midline sagittal sonogram demonstrating uterine retroflexion. The relationship of the cervix (Cx) to the vagina (V) is normal, but the fundus (F) is angled posteriorly.

FIGURE 27-7. A. Illustration demonstrating a retroverted uterus. (Illustration by James A. Cooper, MD, San Diego, CA.) B. Midline sagittal sonogram demonstrating retroversion. The cervix (Cx) is almost parallel to the vagina (V). There is often mild concomitant retroflexion as well. F, fundus.

then rise into the false pelvis. If this fails to happen, the uterus becomes “trapped” in the sacral hollow, often referred to as “incarcerated.” As the gestation evolves, the cervix is drawn upward either against or above the symphysis pubis, resulting in distortion of bladder and urethra. The posteriorly positioned fundus can cause pressure on the rectum. Usually, patients present between 13th to 17th week of pregnancy with symptoms of bladder outlet obstruction. A history of multiple trips to the emergency room for bladder outlet obstruction should raise suspicion. A constellation of three findings on sonography is diagnostic of an incarcerated uterus. First, the pregnancy is deep within the cul-de-sac. Second, the maternal urinary bladder lies anteriorly rather than inferiorly to the uterus and marked bladder distention is noted. Third, a soft tissue structure (the cervix) is seen between the bladder and pregnancy. This appearance can be misconstrued as an empty uterus associated with an

ectopic or abdominal pregnancy. Failure to recognize an incarcerated uterus can result in compromise of the uterine circulation, leading to spontaneous abortion or even uterine rupture. If recognized early, manual uterine repositioning usually is accomplished (Fig. 27-8).

The shape and size of the uterus varies throughout life, affected mostly by hormonal status. The mean measurement of a prepubertal uterus is 2.8 cm in length and 0.8 cm in maximum anteroposterior dimensions, with the cervix accounting for two thirds of the total length and contributing to the pear-shaped appearance (Fig. 27-9).³ It is important to remember that in the immediate postdelivery state, the neonatal uterus can be slightly larger owing to the effects of residual maternal hormones. For the same reason, the echogenic endometrium is well seen and a small amount of fluid can be present in the endometrial cavity.

From birth until 4 years of age, the uterus decreases in size. At approximately 8 years of age the uterus starts to grow preferentially in the fundus. The uterus continues to

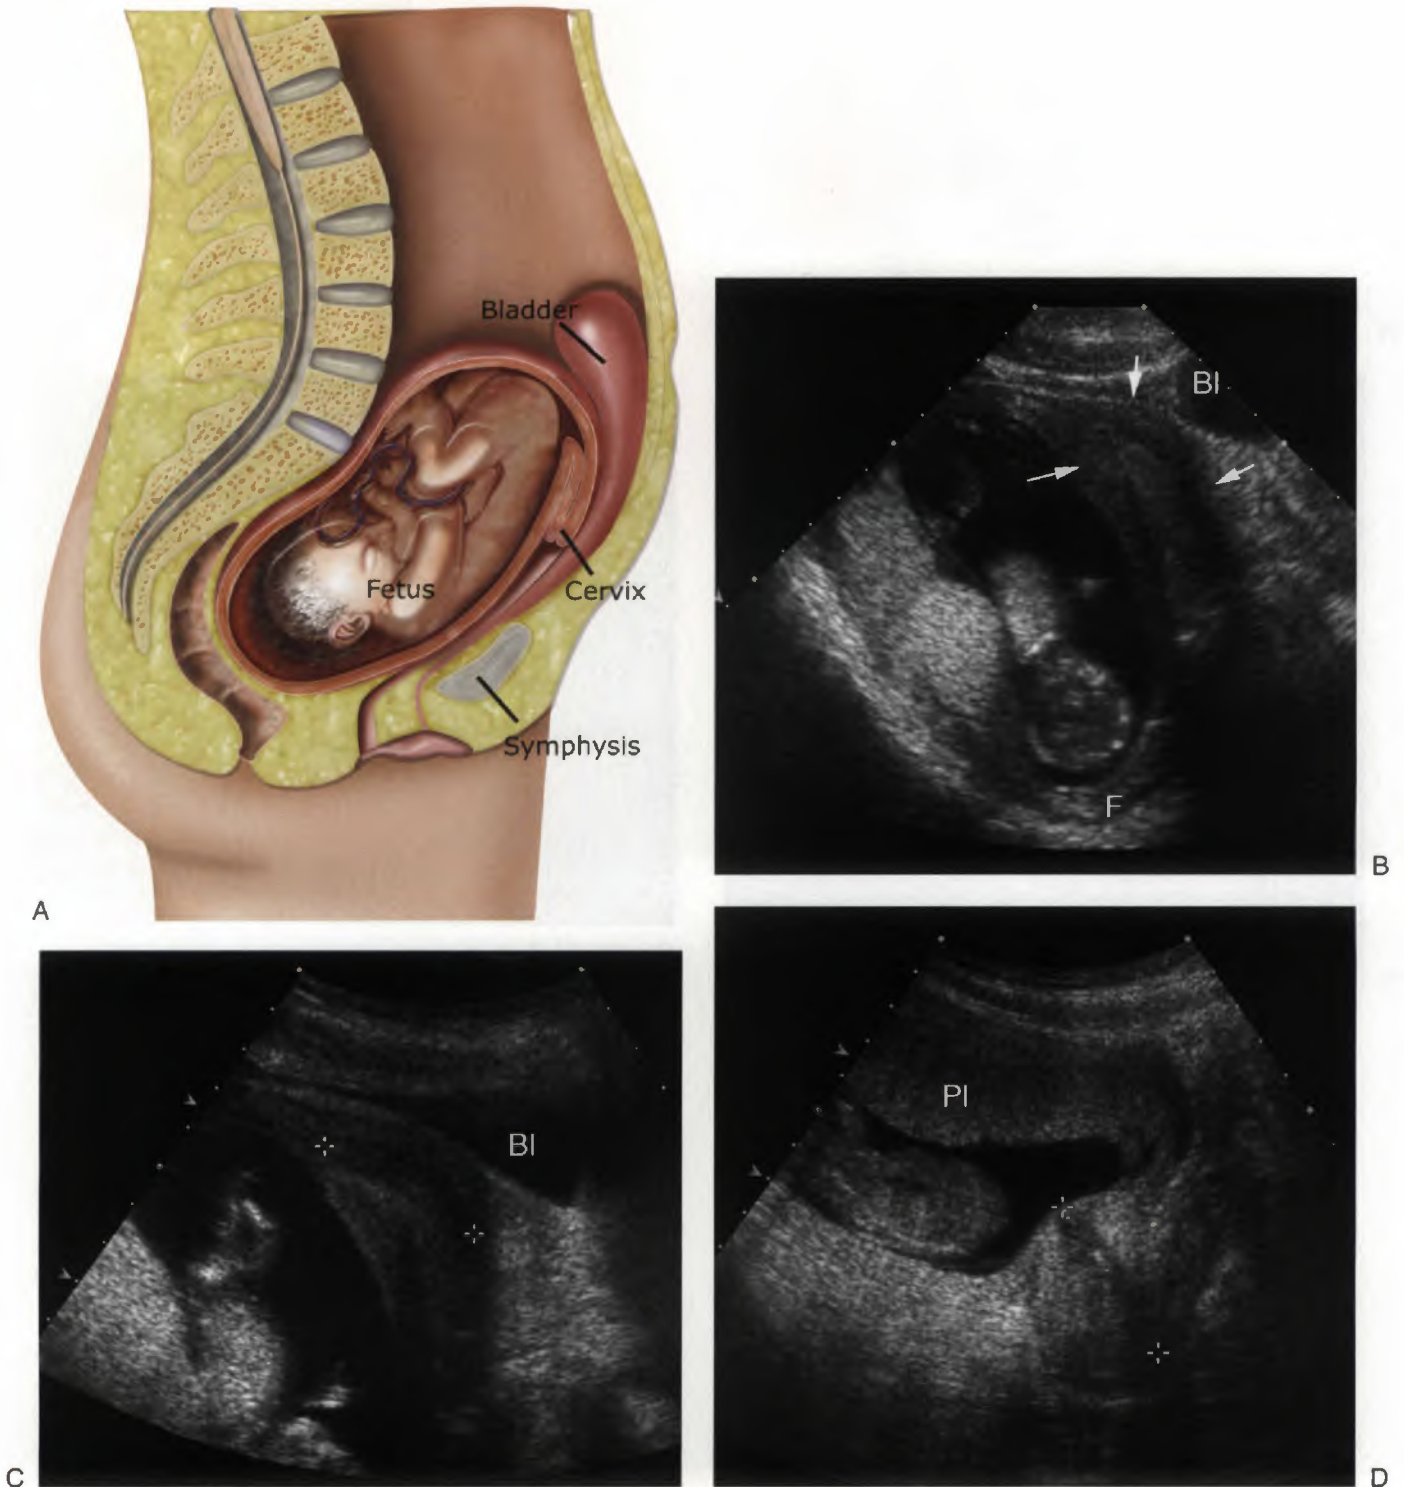

FIGURE 27-8. A. Incarcerated uterus. (Illustration by James A. Cooper, MD, San Diego, CA.) B. Sonogram of 14-week-old gestation. Patient presented with inability to empty urinary bladder. Sagittal-transabdominal images of an incarcerated uterus. The uterine fundus (F) is trapped in the sacral hollow. The cervix (arrows) is drawn anteriorly and superiorly, and can be misconstrued as an empty uterus with an ectopic or transabdominal pregnancy. C. Sagittal view of the same patient demonstrating the degree to which the bladder (BI) is drawn superiorly. D. Postmanual reduction view demonstrates physiologic relationship of the uterus and cervix (calipers). Note the normal anteriorly positioned placenta (PI) that appeared posterior when the uterus was incarcerated.

grow for several years after menarche until it reaches the mean dimensions of a reproductive age uterus, which are approximately 7 cm long and 4 cm wide.

Parity increases the size of the uterus, with a multiparous uterus measuring approximately 8.5 cm by 5.5 cm.⁴

The postmenopausal uterus is often small. The decrease in size is related to years passed after menopause,⁴ although

the reduction in size is believed to be most rapid during the first decade after menopause. The range can be from 3.5 to 6.5 cm in length and 1.2 to 1.8 cm in anteroposterior dimensions.⁵

The normal myometrium is composed of three layers. The innermost layer is the thinnest, relatively hypovascular and hypoechoic when compared with the adjacent echogenic endometrium. This appearance is often referred to as the subendometrial halo. The next layer is the intermediate layer, which is the thickest layer and demonstrates uniform echotexture in a normal uterus. The outer layer is thin again and slightly less echogenic. The arcuate vessels separate the outer layer from the intermediate layer. The arcuate arteries branch into radial arteries that penetrate the intermediate layer and reach the level of inner layer. The arcuate vessels (particularly the veins) can be prominent and mimic cystic changes. This potential misinterpretation can easily be clarified by using color Doppler imaging (Fig. 27-10).

The arcuate arteries can calcify in postmenopausal women; this process can be seen earlier in diabetic patients. This is considered part of normal aging process (Fig. 27-11). Sometimes, small hyperechoic foci are seen in inner myometrium (usually a few millimeters and nonshadowing in appearance), which are thought to represent dystrophic calcifications due to previous intrauterine instrumentation and have no clinical significance.

FIGURE 27-9. Sagittal-transabdominal view of the normal prepubertal uterus. Notice that the cervix (Cx) is significantly more prominent than the body or fundus (F). Bl, bladder.

Congenital Malformations

The incidence of congenital müllerian duct anomalies is estimated to be approximately 0.5%. They are often diagnosed during workup for infertility, frequent miscarriages, or menstrual disorders. As one might remember from the embryology, the two paired müllerian ducts ultimately develop into fallopian tubes, uterus, cervix, and the upper two thirds of the vagina. The lower two thirds of the vagina and the ovaries have a separate origin. Uterine malformations

FIGURE 27-10. Sagittal (A) and transverse sonograms (B) of the uterus with prominent arcuate vessels (arrows) that can mimic cystic changes. C. These cystic appearing spaces are confirmed to be arcuate vessels by applying color Doppler.

arise from three different causes: arrested development of müllerian ducts, failure of fusion of the müllerian ducts, or failure of resorption of the median septum.

The arrested development of the müllerian ducts causes uterine agenesis or hypoplasia. This may present as vaginal, cervical, fundal, tubal, or combined agenesis or hypoplasia (Fig. 27-12).

Agenesis of a unilateral müllerian duct leads to a unicornuate uterus with a single fallopian tube.⁶ In some cases, a rudimentary horn on the opposite side can be seen. This rudimentary horn may not communicate with the

normal side, which leads to retrograde menstruation and endometriosis, and makes resection necessary.

The poorest fetal survival among all uterine anomalies has been reported with a unicornuate uterus. Spontaneous abortion and preterm labor may occur.⁶ The unicornuate uterus seems to be most difficult to confidently diagnose on sonography, because it can be confused as a small uterus. Looking for the contralateral rudimentary horn, which can be filled with blood, can sometimes help. The rudimentary horn may have a distended and dystrophic appearance, and should not be mistaken for an adnexal mass. MRI is the study of choice in resolving these complicated situations.

Complete failure of fusion of the müllerian ducts leads to uterus didelphys, which is two uteri each with its own cervix. A sagittal vaginal septum is usually but not always present. This anomaly is associated with a successful pregnancy.⁶ The two uterine cavities and separate cervixes can be identified on ultrasound, but the vaginal septum is better evaluated on physical examination and with computed tomography and/or MRI (Fig. 27-13).

Partial fusion of the two müllerian ducts leads to formation of a bicornuate uterus and a single cervix. The fundal portion is concave and horns divergent (MRI criteria based on this appearance: intercornual distance > 4 cm, cleft depth at least 1 cm).⁶ Sonographically, in a bicornuate uterus, the cavities are widely separated, and a deep indentation in the fundal contour is obvious. This should be distinguished from a uterus didelphys, and a single cervix should be confirmed in the bicornuate uterus (Fig. 27-14).

Failure of resorption of the septum after complete fusion of the müllerian ducts leads to formation of septate uterus (MRI is best at separating this from a bicornuate uterus, although this can be diagnosed with ultrasound). The fundal contour is flat or indented less than 1 cm. Many patients with septate uterus experience repeated abortions. Confirming this type of anomaly is clinically important because metroplasty is reported to improve fetal survival.^{6,7} On sonography,

FIGURE 27-11. Sagittal-transvaginal view of the uterus demonstrates arcuate artery calcifications (arrows).

FIGURE 27-12. The more commonly diagnosed uterine anomalies. (Illustration by James A. Cooper, MD, San Diego, CA.)

FIGURE 27-13. A. Coronal transvaginal view of a didelphys uterus with completely separate right and left cavities. B. Computed tomography scan of the same patient demonstrating a uterine didelphys.

the smooth fundal contour is diagnostic, with close endometrial cavities separated by a very thin septum (Fig. 27-15).

Arcuate uterus is a normal variant with a thickened fundal portion of the uterus slightly indenting the endometrial canal (Fig. 27-16). The external contour of the uterus is normal. There is a single uterine cavity, and as such, there is no associated pregnancy loss.

Diethylstilbesterol, used in 1940 to 1970, has been reported to result in uterine anomalies in the female fetus, specifically a T-shaped uterus. Patients with this anomaly have increased risk for spontaneous abortions, preterm deliveries, and ectopic pregnancies.⁶ Sonography can reveal a small uterus with an irregular T-shaped appearance to the uterine cavity. Three-dimensional sonography with multiplanar capabilities can be of assistance in evaluation of the internal and external contours in these cases. Transvaginal sonography remains the primary imaging modality, although MRI is used as a problem-solving technique in more challenging cases.⁸

BENIGN UTERINE CONDITIONS

Adenomyosis

Adenomyosis is a common condition, although it is often overlooked. It is found in 70% of hysterectomy specimens. Adenomyosis is characterized by migration of endometrial

FIGURE 27-16. Transvaginal view of arcuate uterus with a small indentation in the fundal endometrium (*large arrow*). The outer contour of the uterus is smooth and normal appearing (*small arrows*).

glands from the stratum basale into the myometrium. This often occurs with reactive hyperplasia of the smooth muscle. The ectopic glands tend to be at least 2 to 3 mm below the endometrial-myometrial junction. Two widely accepted theories for the cause of adenomyosis are that it results from a defect or absence of the basement membrane at the endometrial-myometrial junction, or that it is related to endometrial migration by lymphatic or vascular channels. Possible risk factors include uterine trauma such as childbirth, uterine instrumentation, chronic endometritis, and hyperestrogenism.^{3,4,9,10}

Adenomyosis is most prevalent among mature reproductive age patients and is much less commonly seen in nulliparous or postmenopausal patients. Presenting symptoms are usually uterine tenderness, dysmenorrhea, menorrhagia, and uterine enlargement. These symptoms are very similar to the symptoms seen in patients with uterine fibroids, pelvic congestion syndrome, endometriosis, endometrial polyps, and endometrial carcinoma. Given the differences in clinical treatment, the imaging diagnosis is important. These symptoms can be extremely debilitating, and misdiagnosis can prolong appropriate care. Specific therapy such as gonadotropin-releasing hormone inhibitors, oral contraceptives, nonsteroidal anti-inflammatory drugs, oral contraceptives, and endometrial ablation are available.^{3,4,9,10}

One of the recently emerging therapies for adenomyosis is uterine artery embolization, but results for this treatment are controversial at this time. The only definitive treatment at this time is hysterectomy.¹¹

Sonography and MRI play an important role in the diagnosis and proper management of these patients. Imaging is also used to evaluate response to treatment, and progression of the disease. For optimal diagnosis, transvaginal ultrasound should be performed at high frequencies, between 5 to 10 MHz. The reported sensitivity and specificity of

transvaginal ultrasound for identifying adenomyosis ranges from 53% to 89% and 67% to 98%, respectively, and overall accuracy of 68% to 86%. MRI sensitivity ranges from 78% to 88% and specificity 67% to 93%.^{4,10} Although MRI and sonography are reported to have similar accuracy in diagnosing this condition, ultrasound is most often the first imaging study obtained in patients with the above-described symptoms.^{3,4,9} MRI is considered to have better accuracy in women with associated disorders.¹² It is also important to know that oftentimes leiomyomas and adenomyosis coexist (> 60%).

The imaging appearance of adenomyosis is based on ectopic glands that are surrounded by a stromal reaction of densely packed smooth muscle cells. This process often leads to the globular appearance of the uterus, which is defined as rounded enlargement of the uterus without a discrete mass or contour deformity. Although a focal adenomyoma can be seen, they are unlikely to cause a contour abnormality, as leiomyomas often do.

Transvaginal ultrasound can demonstrate the zonal anatomy, which is often altered with adenomyosis. Abnormal heterogeneous myometrium is observed with areas of increased or decreased echogenicity. Hypoechoic striations usually radiate throughout the involved parenchyma, believed to be edge shadows due to extreme smooth muscle hypertrophy. Even though this is very similar to shadowing caused by leiomyomas, the lack of distinct margins and mass effect make this finding more characteristic of adenomyosis. Sonographically, anechoic/cystic areas are seen, which on pathology, correspond to dilated glands. Hyperechoic foci representing endometrial tissue can also be seen (Fig. 27-17). Poor definition of the endometrial-myometrial junction with pseudo-widening of the endometrial echo is caused by heterotopic endometrial tissue extending from stratum basale.

Color Doppler examination has been helpful to differentiate adenomyosis from fibroid change. In adenomyosis there is often diffuse hypervascularity throughout the lesions when compared to the typical peripheral flow noted with fibroids.

Focal adenomyosis presents with a more atypical appearance (see Fig. 27-17). It is defined as focal mass with poorly defined margins in contrast with leiomyomas with distinct margins. Again, it is important to differentiate between those two. Surgically, leiomyomas can often be easily separated and removed from the adjacent endometrium, whereas adenomyomas are not often easily separated from the surrounding myometrium. When difficulties arise in sonographic diagnosis, MRI can be very helpful in achieving a more definitive diagnosis. Focal adenomyomas may be difficult to differentiate with both imaging modalities.^{4,10}

Sonography has reported sensitivity of 80% to 87% and specificity of 94% to 98% in differentiating between these two entities. The exceptions would be those rare occasions when an adenomyoma is protruding into the endometrial cavity and has an appearance identical to an intracavitary polyp versus leiomyoma. Some authors consider polypoid adenomyomas a separate entity from adenomyosis.¹³

Endometrial abnormalities such as hyperplasia and carcinoma are reported to occur more often in patients with adenomyosis.^{3,9} An adenocarcinoma has reported to rarely arise from adenomyosis. This would be very difficult to distinguish from typical adenomyosis without malignancy

FIGURE 27-17. Adenomyosis: spectrum of appearances. **A.** Enlarged uterus with typical features of adenomyosis. Multiple bright echogenic foci are seen throughout the myometrium (*small arrows*) in addition to numerous subendometrial and myometrial cysts (*large arrows*). **B.** Longitudinal sonogram demonstrating numerous hypoechoic, 'venetian blind' striations in the posterior myometrium. Although these striations may be seen in myomatous disease, the absence of a focal myoma and the presence of other features make this more characteristic of adenomyosis. **C.** Transvaginal sonogram in a patient with a focal adenomyoma (*arrows*). **D.** Color Doppler image of the same patient in **C**, demonstrating increased vascularity within the adenomyoma. **E.** Another patient with an adenomyoma. In this case the adenomyoma is hyperechoic (*arrow*) and indenting but separate from the endometrium.

A focal vascular adenomyoma (arrows) is seen in the background of diffuse adenomyosis. A large cystic and solid mass (asterisk) is seen, which was thought to be of ovarian origin. G. MRI axial T2 image demonstrates better the extent of adenomyosis, and a more focal adenomyoma (arrows). A small subtle area of serosal breakthrough is noted (black arrow), which represents “expelling” of the adenosarcoma, high T2-signal heterogeneous mass noted anteriorly (asterisk). H. Sagittal postcontrast image demonstrates tumor extension from the uterine wall into the anterior pelvis (arrows). The final pathology demonstrated, endometrial stromal sarcoma with heterogeneous differentiation, FIGO: III.

(see Fig. 27-17). A more common scenario would be an endometrial carcinoma extending into foci of adenomyosis. In cases in which the adenomyosis coexist with endometrial cancer, it is very difficult to distinguish whether the cancer is insinuating into preexisting areas of adenomyosis or areas of true myometrial cancer invasion are present. Differentiation is crucial because myometrial invasion is an important prognostic indicator. This kind of differentiation is not achieved on imaging and can be even very difficult on histopathology (Table 27-1).¹⁴

Leiomyoma (Fibroids)

Leiomyomas (fibroids) are the most common neoplasms of the uterus and are reported to occur in 20% to 30% of women older than 30 years of age. These tumors are usually

Table 27-1 Features of Adenomyosis	
Diffusely globular uterus but smooth external uterine contour	
Asymmetric globularity	
Myometrial cystic areas/echogenic foci	
Pseudothickening of the endometrium	
Diffuse increased internal vascularity	
Striated edge shadows/“Venetian blinds” without a discrete mass	
Focal ill-defined mass	
Features that help to differentiate from leiomyomas	
Smooth external contour	
Minimal mass effect on serosa/endometrium relative to the size of the lesion	
Lack of calcification	

FIGURE 27-18. Common locations of leiomyomas. (Illustration by James A. Cooper, MD, San Diego, CA.)

multiple, causing enlargement of the uterus and surface lobularity unlike adenomyosis, which causes globular but smooth-contoured uterine enlargement. Leiomyomas most commonly present as palpable pelvic masses, uterine enlargement, or as causes for pelvic pain and dysfunctional uterine bleeding. Leiomyomas can be intra-transmural, submucosal, subserosal, intracavitary, or exophytic or pedunculated (Fig. 27-18). On rare occasions, the exophytic fibroids can project into the broad ligament (intraligamentous). In these instances, the fibroid may clinically and radiologically simulate an ovarian mass (Fig. 27-19). They can be located in the cervix rather than in myometrium. An unusual form of a fibroid is the parasitic leiomyoma, a pedunculated subserosal myoma, which, if it is in close contact with an adjacent structure, can parasitize the blood supply and even become detached from the uterus. This classification of leiomyomas is relevant because symptoms and treatment vary according to their location and subtype.¹⁵

The growth of fibroids is dependent on estrogen levels. Rapid growth may occur during pregnancy but only in about 50% of patients (Fig. 27-20). Leiomyomas are associated with increased risk of early pregnancy failure, especially with multiple gestations.¹⁶ Cervical and lower uterine segment fibroids can interfere with delivery and should be monitored during pregnancy. As the estrogen level declines, the leiomyomas may regress and thus are rarely symptomatic in postmenopausal patients.¹⁵

FIGURE 27-19. Transverse abdominal sonogram. A left adnexal solid mass (asterisk) is seen. Although the location would make one think of an ovarian mass, it was in fact a broad ligament myoma. Ut, uterus.

Histologically, leiomyomas are composed of smooth muscle with varying amounts of fibrous connective tissue. The surrounding myometrium can become compressed and form a pseudocapsule, which can be readily identified on ultrasound and MRI imaging (Fig. 27-21). When rapidly

FIGURE 27-20. Longitudinal sonogram in a pregnant patient at 18 weeks' gestational age. An anterior lower uterine segment fibroid (arrows) is seen. It does not obstruct the cervix (demarcated by calipers). Bl, bladder.

FIGURE 27-21. Large uterine myoma demarcated by the calipers. A pseudocapsule can be seen from surrounding compressed myometrium (arrows).

growing, the leiomyomas can outgrow their blood supply, resulting in degeneration.¹⁵

Leiomyomas are usually readily recognized on sonography, often with a variable appearance. The uterus may be heterogeneous and globular in contour, which overlaps with the appearance of adenomyosis. Focal leiomyomas are usually heterogeneous but mostly hypoechoic when compared with the surrounding myometrium. The heterogeneity increases as the leiomyomas evolve through various changes such as growth, increased fibrosis, degeneration, and calcification (Fig. 27-22).

As leiomyomas increase in size, they tend to outgrow their blood supply, which leads to degeneration: hyaline, myxoid, calcification, cystic, and hemorrhagic (Fig. 27-23). This can give a more atypical appearance on sonography and on MRI (Fig. 27-24).^{15,16} Many leiomyomas demonstrate areas of characteristic acoustic attenuation. This may not always be secondary to calcification. This attenuation is believed to be caused by the transitional zone between apposed tissues such as fibrous tissue and smooth muscle, the margins of the leiomyoma with adjacent normal myometrium, and the edges of whorls and bundles of smooth muscle.¹⁷ This characteristic shadowing is very helpful in differentiating an exophytic leiomyoma from an adnexal/ovarian mass. Whereas this finding used to be very characteristic and specific of fibroids, it is currently recognized that adenomyosis with smooth muscle hypertrophy may produce a similar appearance (Fig. 27-25). Dystrophic calcification occurs predominantly in postmenopausal patients. The calcifications are curvilinear, with dense shadowing. Degeneration may produce cystic change, or edema with small multiple cystic spaces.

Submucosal fibroids may have varying degrees of intracavitary extension. The degree to which the fibroid projects into the endometrial cavity will help determine the

likelihood of hysteroscopic resection. Until recently, sonohysterography has been the best modality to determine the degree of intracavitary extension of the fibroid (Fig. 27-26). More recently, three-dimensional ultrasound has proved useful as well (Fig. 27-27). Transvaginal imaging may be limited if the fibroids are large. In this situation, transabdominal imaging may improve visualization. MRI is a valuable modality to evaluate large or atypical fibroids. The multiplanar capability and larger field of view is of great assistance.

Lipomatous Uterine Tumors

Lipomatous tumors of the uterus are rare benign conditions but are readily recognized on ultrasound. Sonographically, the characteristic appearance is a highly echogenic mass within the myometrium without any demonstrable Doppler flow. They are usually asymptomatic and do not require surgery. The histology can reveal a spectrum including pure lipomas, lipoleiomyomas, fibrolipomas, and myolipomas (Fig. 27-28).¹⁸

MALIGNANT CONDITIONS

Sarcomas

Although leiomyomas are benign, rapid growth in peri- and postmenopausal patients raises the possibility of sarcomatous change. Most leiomyosarcomas arise independently rather than from a preexisting leiomyoma although it does occur.¹⁹ It is commonly accepted that uterine sarcomas are extremely aggressive with poor prognosis. Early diagnosis can improve the survival rates, and therefore, attention to imaging clues is crucial. Usually there is no significant sonographic difference from rapidly growing or degenerating myoma

FIGURE 27-22. Variable appearance of uterine fibroids. *A.* Small intramural fibroid appearing as a round hypoechoic mass (*arrows*). *B.* Longitudinal sonogram in a patient with multiple uterine fibroids. The normal morphology of the uterus is markedly distorted. The endometrium could not be identified. An anterior subserosal fibroid (*arrow*) is projecting into the urinary bladder. *C.* Sonogram of a fibroid demonstrating peripheral calcification.

FIGURE 27-23. Marked cystic degeneration (*asterisk*) of a large intramural fibroid.

FIGURE 27-25. Large fibroid demonstrating areas of cystic change as well as shadowing (*venetian blind shadowing*). Both of these features are quite similar to the changes seen in adenomyosis.

FIGURE 27-24. Sagittal T2 MRI image demonstrating various different but common appearances of fibroids: Small submucosal fibroid impressing the endometrial canal with typical low T2 signal (*small arrows*), large anterior fibroid with internal edema and/or degeneration (*large arrow*), anterior lower uterine segment fibroid with very low T2 signal consistent with internal blood products/hemosiderin from “red degeneration” (*asterisk*).

and a sarcoma. In instances of degenerating myomas there can be change in the internal architecture and, an increase in solid components rather than progressive degeneration. The increased solid components can be appreciated if previous studies are available for comparison. MRI can be obtained to confirm the avid enhancement of those solid components. If there are no baseline or previous studies, it is very difficult to determine if solid portions of the

degenerated myoma are residual viable leiomyoma versus new developing leiomyosarcoma. The other signs of leiomyosarcoma include local invasion and distant metastases, which are detected on MRI or computed tomography (Fig. 27-29).

OTHER IATROGENIC PROCESSES

Arteriovenous Malformations

Arteriovenous malformations (AVMs) are multiple communications between the arterial and venous system without an intervening capillary network. These lesions can be congenital or more often iatrogenic due to intrauterine instrumentation. Acquired AVMs are more like multiple small arteriovenous fistulas. They can be secondary to trauma, malignancy, or infection. Specific etiologies include miscarriage, therapeutic abortion, dilation and curettage, cesarean delivery, carcinoma of the cervix or endometrium, uterine infection, trophoblastic disease, fibroids, endometriosis, and uterine surgery.²⁰ Sonography is often the first imaging study performed when the patient presents with a history of dysfunctional uterine bleeding. Color and duplex Doppler sonography have very characteristic findings. Serpiginous cystic areas and a vascular tangle of blood vessels can be seen in grayscale,

which fills with avid flow on color Doppler and demonstrate high-velocity, low-resistance flow on duplex Doppler (Fig. 27-30).^{21,22} The Doppler characteristics may be similar to cases of gestational trophoblastic disease. Therefore, when these imaging findings are seen, gestational trophoblastic disease should always be excluded by serum β -human chorionic gonadotropin levels, which would be negative in the cases of AVM.

Pseudoaneurysms are also reported to occur as a complication after intrauterine procedures. These can be distinguished from AVMs by color and duplex Doppler imaging. Pseudoaneurysms appear as a blood-filled cystic structure with swirling arterial blood flow.²¹

Knowing that uterine curettage or surgical trauma can cause uterine vascular abnormalities such as arteriovenous fistulas, pseudoaneurysms, and arteriovenous fistulas is useful when imaging patients with such clinical history and bleeding. Recognizing these lesions on imaging is important because treatment is quite different than for other causes of dysfunctional uterine bleeding. These abnormalities can be treated safely with transcatheter arterial embolization and may be worsened by uterine curettage. Acquired arteriovenous fistulas are reported to be much easier to treat than the congenital lesions because they only have single or bilateral feeding arteries, and typically are not fed by extrauterine vessels and lack a nidus, unlike congenital lesions.²¹

Intrauterine Contraceptive Devices

Contemporary intrauterine contraceptive devices (IUCDs), are easily visualized with transabdominal and transvaginal sonography. The brightly echogenic device with intense sound beam attenuation is well seen. Transvaginal sonography is commonly used to evaluate placement: Location and complications such as migration into the myometrium.²³ Three-dimensional ultrasound has been used with great success to improve visibility in technically challenging situations, as well as in confirming the specific type of the IUCD (Fig. 27-31).²⁴

If an IUCD is not seen on sonography and history confirms placement, a plain radiograph should be obtained to exclude a perforation and expulsion into the peritoneal cavity. Blood products as well as products of conception can obscure the visualization of the IUCD. There are occasions when an intrauterine contraceptive device is seen associated with an intrauterine pregnancy. Although IUCDs can be easily identified during the first trimester, they are rarely visualized in the second or third trimester of pregnancy. If removal is being considered, the relationship of the IUCD to the gestational sac becomes important (superior or inferior to the sac).

Ultrasound Evaluation of the Postpartum and Postabortive Uterus

Not infrequently, the sonologist is asked to evaluate the patient who has bleeding or pain after delivery or therapeutic abortion. The question most commonly asked is whether there are retained products of conception (RPOC) or a large hematoma within the uterine cavity. A basic knowledge of the normal postpartum uterus is necessary to accurately diagnose pathologic conditions.

FIGURE 27-28. Spectrum of lipomatous uterine tumors. A. Sonogram in which a 1.5-cm focal hyperechogenic mass is seen in the uterus (*arrows*). This was a lipoleiomyoma. B. Transabdominal sonogram demonstrating a large 5-cm lipoleiomyoma. C. Transvaginal sonogram of a very large 7-cm hyperechogenic mass (*asterisk*). This was also a lipoleiomyoma.

Tissue and fluid (arrows) representing retained products of conception are seen within the uterus. B. Doppler imaging of the same patient demonstrates markedly increased vascularity within the tissue.

FIGURE 27-33. Longitudinal sonogram in a patient 1 week after cesarean section. Residual air (arrow) is seen within the uterine cavity. The endometrium was thin and normal.

The normally enlarged gravid uterus begins to decrease in size several days after delivery.²⁵ The uterus rapidly decreases in size during the first 1 to 2 postpartum weeks and is usually back to its nongravid size by 6 to 8 weeks' postpartum.²⁵⁻²⁷ The endometrium returns to its pregravid state by 3 to 6 weeks' postpartum.²⁵ Small amounts of fluid and echogenic material (likely representing blood clot) may be seen in the normal postpartum uterus (Fig. 27-32).^{25,28} Bright hyperechogenic foci, likely secondary to air, can also be seen within the endometrial cavity and persist for several weeks postpartum (Fig. 27-33).^{25,29}

The thickness of the postpartum endometrium is variable, ranging in one study from a mean value of 15.8 mm on day 1 to a mean of 5.5 mm on day 28.³⁰

Several studies have evaluated the endometrial thickness as a sign of RPOC.^{25,31-38} Although there does not appear to be a cutoff value above which RPOC are certain, if the endometrium is extremely thin it is unlikely that there are RPOC. One study found that in the absence of an endometrial mass or when the endometrial thickness was less than 10 mm, RPOC was extremely unlikely.^{25,38} Thus, ultrasound appears to be more useful to exclude the diagnosis than to accurately make the correct diagnosis. A focal echogenic mass is suggestive of RPOC (Fig. 27-34).^{25,31,39} This, however, is not a specific or reliable sign, because a hematoma may have a similar appearance.²⁵ Doppler ultrasound has proved useful in some cases to assist in the diagnosis of RPOC.^{25,40} Whereas flow within a focal intracavitary mass is suggestive

FIGURE 27-35. A. A patient presented with bleeding 1 week postpartum. Tissue (arrows) was seen within the endometrial cavity. B. Doppler imaging demonstrated no evidence of blood flow within the tissue (arrows). This represented blood clots without retained products of conception.

of RPOC, the absence of flow does not exclude the diagnosis.^{25,38} Placental tissue may persist for months after delivery and be a source of persistent hemorrhage (Fig. 27-35).

In all cases of vaginal bleeding, in the postgravida state, in which tissue is seen within the uterine cavity, the diagnoses of gestational trophoblastic disease and ectopic pregnancy should be considered (Fig. 27-36). Clinical correlation as well as correlation with β -human chorionic gonadotrophic levels is often helpful in excluding these conditions.

Summary

Abnormal uterine bleeding accounts for up to 20% of gynecologic visits.¹ Obviously, any pregnancy event must first be excluded. Cheap, rapid, and monoclonal antibody urine β -human chorionic gonadotropin tests, now even readily available over the counter to our patients, make this a relatively simple maneuver. If a pregnancy event has been excluded, then the most likely cause of bleeding is dysfunctional anovulatory bleeding; what we often tell patients is hormone imbalance. However, as women get older, organic pathology such as polyps, submucous myomas, hyperplasias, and even frank carcinoma become more likely. The Surveillance Epidemiology and End Results (SEER) database² reports that the incidence of endometrial carcinoma in women 30 to 34 years of age is 2.3/100,000, and it increases to 6.1/100,000 between 35 to 40 years of age, and then rises dramatically to 36.2/100,000 in women 40 to 49 years of age. In postmenopausal women on no hormonal replacement therapy any bleeding is considered cancer until proven otherwise, although the incidence of malignancy in such patients ranges from 2% to 10%, depending on risk factors.³

The role of the clinician in a patient who presents with bleeding is twofold: first, in women over 40 years of age, it is to exclude endometrial carcinoma,⁴ and second, to identify the source of bleeding so it can be stopped or managed.

The vast majority of patients with abnormal bleeding will have dysfunctional uterine bleeding in association with episodes of anovulation that can best be managed hormonally or expectantly with reassurance (premenopausal), or endometrial atrophy (postmenopausal). The value of an approach to distinguish such patients from those with organic pathologic conditions in a safe, painless, and convenient manner is obvious.

EVOLUTION OF ENDOMETRIAL ASSESSMENT

Initially, curettage was the gold standard. First described in 1843,⁵ its performance in the hospital became the most common operation performed on women in the world. As early as the 1950s, a review of 6907 curettage procedures⁶ found the technique missed endometrial lesions in 10% of cases; of these, 80% were polyps.

In the 1970s, vacuum-suction curettage devices allowed sampling without anesthesia in an office setting. The most popular was the Vabra aspirator (Berkeley Medevices, Berkeley, CA). This was found to be 86% accurate in the diagnosis of cancer.⁷ Subsequently, cheaper, smaller, and less painful plastic catheters with their own internal pistons to generate suction became popular. One of these, the Pipelle device (Unimar, Wilton, CT), was found to have similar efficacy but better patient acceptance when compared with the Vabra.⁸

A number of studies have evaluated the efficacy of endometrial sampling with the Pipelle catheter. Rodriguez et al⁹ did a pathologic study of 25 hysterectomy specimens. The percentage of endometrial surface sampled by the Pipelle device was 4% versus 41% for the Vabra aspirator. In one widely publicized study,¹⁰ the Pipelle had a 97.5% sensitivity to detect endometrial cancer in 40 patients undergoing hysterectomy. The shortcoming of that study was that the diagnosis of malignancy was known before the performance of the specimen collection. Finally, in yet another study, Guido et al¹¹ also studied the Pipelle biopsy in patients with known carcinoma undergoing hysterectomy. Among 65 patients, a Pipelle biopsy provided tissue adequate for

analysis in 63 (97%). Malignancy was detected in only 54 patients (83%). Of the 11 with false-negative results, five (8%) had disease confined to endometrial polyps, and three (5%) had tumor localized to less than 5% of the surface area of the cavity. The surface area of the endometrial involvement in that study was less than or equal to 5% of the cavity in three of 65 (5%); 5% to 25% of the cavity in 12 of 65 (18%), of which the Pipelle missed four; 26% to 50% of the cavity in 20 of 65 (31%), of which the Pipelle missed four; and greater than 50% of the cavity in 30 of 65 patients (46%), of which the Pipelle missed none. These results provide great insight about the way endometrial carcinoma can be distributed over the endometrial surface or confined to a polyp. Because tumors localized in a polyp or a small area of endometrium may go undetected, the authors in that study concluded that the "Pipelle is excellent for detecting global processes in the endometrium."

From these data it seems that undirected sampling, whether through curettage or various types of suction aspiration, is often fraught with error, especially in cases in which the abnormality is not global but focal (polyps, focal hyperplasia, or carcinoma involving small areas of the uterine cavity).

Transvaginal Ultrasound

Introduced in the mid 1980s, the vaginal probe uses high frequency transducers in close proximity to the structure being studied. It yields a degree of image magnification that has been dubbed sonomicroscopy.¹² In the early 1990s it was used in women with postmenopausal bleeding to see if it could predict which patients lacked significant tissue and could avoid dilatation and curettage or endometrial biopsy and its discomfort, expense, and risk.^{13,14} Consistently, the finding of a thin distinct endometrial echo less than 4 to 5 mm has been shown to effectively exclude significant tissue in women with bleeding. Thus, the value and contribution of ultrasound in this setting lies in its high-negative predictive value, which is its ability to tell us who lacks significant tissue and can reliably avoid any endometrial sampling. If some physicians thought this was only possible in the hands of luminaries, the endometrial surveillance arm of the Postmenopausal Estrogen/Progestin Interventions (PEPI) Study¹⁵ went a long way to show that, in a multicentered trial with various investigators, visualization of a thin, distinct, endometrial echo had tremendous reliability. In that study an endometrial echo less than 5 mm had a 99% negative predictive value to exclude cancer (Fig. 28-1). Still, realizing that saying an endometrial echo 5 mm or less has a 99% negative predictive value is not remotely the same as saying that an endometrial echo greater than 5 mm is pathologic. In that study, the positive predictive value for disease of an endometrial echo greater than 5 mm was 9%, and if restricted to serious disease (cancer or atypical hyperplasia), the positive predictive value was merely 4%! In addition, that was a surveillance study; that is, the scans were not being performed for clinical history of bleeding. In my experience, many clinicians have inappropriately used a thick endometrial echo on ultrasound as an indicator of pathology. Such inappropriate application of transvaginal ultrasound is especially worrisome in patients with no bleeding in whom the finding is incidental.

FIGURE 28-1. Long axis transvaginal ultrasound image of a postmenopausal patient with uterine bleeding. A thin linear distinct endometrial echo here has a negative predictive value of 99%.

FIGURE 28-2. Long axis transvaginal ultrasound of a postmenopausal patient with an endometrial fluid collection. Note that the endometrium surrounding the fluid is thin. This picture is typical of inactive atrophic endometrium. Presumably the fluid collection is transudate and secondary to cervical stenosis in such a patient.

Endometrial thickness should be measured on a sagittal (long axis) image of the uterus and the measurement should be performed on the thickest portion of the endometrium, excluding the hypoechoic inner myometrium. It is a double thickness measurement from basalis to basalis. If fluid is present it is usually associated with cervical stenosis and atrophy (Fig. 28-2).¹⁶ In these cases, the endometrial layers are measured separately and should be symmetric (Fig. 28-3). Remember that the endometrial cavity is a three-dimensional structure and attempts must be made to image the entire cavity. Recognizing the potentially pivotal role of transvaginal ultrasound in diagnostic evaluation, a statement should be included in the report regarding the technical adequacy of the scan. A well-defined endometrial echo should be seen emanating from the endocervical canal. The endometrial echo should be distinct. Often fibroids, previous surgery, marked obesity, or a tipped uterus may make visualization suboptimal. If so, it is perfectly acceptable, and in fact appropriate, to conclude endometrial echo is not well visualized.

FIGURE 28-3. Long axis transvaginal ultrasound of a postmenopausal patient with endometrial fluid collection. The tissue surrounding the fluid is thick and irregular measuring 6.2 and 7.7 mm respectively (calipers). Histopathology in this patient revealed endometrial hyperplasia with atypia.

In these cases, ultrasound cannot be relied upon to exclude disease. The next step for such patients with bleeding should be either hysteroscopy or saline infusion sonohysterography, depending on the skill set and preference of the physician and patient.

Saline Infusion Sonohysterography

Although the use of fluid enhancement was described with abdominal ultrasound both for uterine and tubal observations,¹⁷ the use of fluid to better evaluate the endometrium never gained widespread use. The introduction of the vaginal probe has changed that considerably.^{18,19} The use of fluid instillation into the uterus coupled with such high-resolution transvaginal probes allows tremendous diagnostic enhancement with an inexpensive, simple, and well-tolerated office procedure.

Technique

A palpatory bimanual examination is performed. As with any type of uterine instrumentation, absolute knowledge of whether the uterus is anteverted or retroverted and, if so, how sharply, only serves to enhance one's success and safety. Often, uterine version can be appreciated by the skilled sonographer. The clinician in obstetrics and gynecology should also be concerned about the presence of uterine tenderness or decreased mobility. The speculum is inserted. The cervix is cleansed with an antiseptic solution (10% iodine based solution). A catheter is inserted into the cervix. This is done by grasping it with a ring forceps and gently feeding it through the cervical os. Sterile saline has been flushed through the catheter to rid it of small amounts of air, which when first injected will cause a very echogenic artifactual appearance (Fig. 28-4). The speculum is removed carefully so as not to dislodge the catheter. The vaginal probe is then reinserted. A 10 mL syringe (being careful to rid it of any air bubble) is attached to the catheter. Scanning

FIGURE 28-4. Saline infusion sonohysterogram in which air has been allowed to enter the uterine cavity. Notice the echogenicity (arrow) and acoustic shadowing that results. This artifact can be avoided by flushing air out of the catheter and being sure there is no air bubble in the syringe.

in a long axis projection, fluid is instilled while watching the video monitor. In that long axis projection, the transducer is moved from side to side (that is, from cornua to cornua). The amount of fluid instilled is variable and depends on the image that one is producing on the ultrasound screen. When the uterus has been completely surveyed from cornua to cornua in a long axis projection, the transducer is then rotated 90 degrees into a coronal plane and further fluid is instilled while fanning down toward the endocervical canal and up toward the uterine fundus.

Saline Infusion Sonohysterography—Technical Considerations

Timing of the Procedure

The uterus is an organ that has often had multiple procedures in many women including dilatation and curettages, childbirth, myomectomy, Cesarean sections, abortion, and so forth. As the endometrium proliferates it is not always a smooth homogeneous layer. Sonohysterography is best performed as soon as possible after the bleeding cycle has ended when the endometrium is as thin as it is going to be all month long. Otherwise, focal irregularities in the contour of the endometrium may be mistaken for small polyps or focal areas of endometrial hyperplasia (Fig. 28-5). This was supported in a prospective blinded study by Wolman et al²⁰ in which there was a 27% false positive rate in sonohysterography performed from day 16 to 28, whereas there were none when the procedure was performed before day 10.

Sometimes, the patient has such irregular bleeding that she cannot tell what is an actual menses. It may be helpful in such cases to use an empiric course of a progestogen such as medroxyprogesterone acetate 10 mg daily for 10 days as a medical curettage and then time the ultrasound evaluation to the withdrawal bleed.

FIGURE 28-5. Transvaginal pelvic scan of a patient 19 days since her last episode of bleeding. The endometrial surface is irregular. They measure 3.8 and 4.0 mm respectively. The irregular surface is not unusual especially in patients who have had previous dilatation and curettages, myomectomies, childbirth, and so forth. The irregular surface to the endometrium here identified as moguls can be misleading. Performing the procedure this long after the last bleeding episode can be fraught with error and should be avoided.

Difficulty Threading the Catheter

Occasionally, there will be difficulty in threading the catheter into its desired position. Using the other hand to change the position of the speculum will often modify the angle of the cervix with the fundus sufficiently to allow successful completion. Use of a tenaculum is a last resort. A cervical stabilizer will be less painful, less traumatic, and does not cause bleeding from the cervix.

Anesthesia/Analgesia

Anesthesia or analgesia is not required. In more than 1000 cases, I have seen three cases of a vasovagal response reminiscent of those occasionally seen with a plastic intrauterine device insertion in a nulliparous patient. The sonohysterography catheter is 1.8 mm in diameter and is remarkably painless in its insertion. The procedure is extremely well tolerated with no pain in the overwhelming majority of patients and minimal cramping in a very few.

Risk of Infection

Sonohysterography should be handled similarly to traditional hysterosalpinography. Thus, the decision about whether to obtain gonorrhea or chlamydia cultures as well as whether to use antibiotics depends very much on the patient population with which the physician normally deals. In my experience, I have not routinely obtained cultures for sexually-transmitted diseases nor have prophylactic antibiotics been used. In more than 1000 cases, I have not experienced any infectious morbidity. Of 1153 procedures performed²¹ the incidence of infectious complications that require surgical resolution was 0.7%, which is similar to diagnostic hysteroscopy²² but less than hysterosalpinography.²³

Concern About Spreading Adenocarcinoma into the Peritoneal Cavity

Concern about spreading adenocarcinoma is a question of the benefit outweighing any theoretical risk. It is no longer standard practice to tie the fallopian tubes with silk before a total abdominal hysterectomy and bilateral salpingo-oophorectomy for endometrial carcinoma. Furthermore, hysteroscopy with saline or other distending media would have the same theoretical concern. Survival rates of patients with endometrial carcinoma who underwent standard hysterosalpinography were not different between patients who demonstrated intraperitoneal spill of the contrast medium and those who did not.²⁴ Alcazar²⁵ performed sonohysterography on 14 consecutive patients with stage I adenocarcinoma of the endometrium. It was done at the time of laparotomy, just when the abdomen was opened but before the start of the surgical procedure. All 14 readily spilled saline from the fallopian tubes. The fluid was analyzed as were cell washings. Only one patient (7%) had malignant cells in the spilled fluid causing the authors to conclude that the risk of malignant cell dissemination exists but is small.

Inadequate Distension of the Cavity

In some patients, a patulous cervix results in a great deal of fluid running out transcervically. Other patients will have fluid going out through fallopian tubes even with slow injection and minimal pressure. As in hysteroscopy, some cavities are more difficult to distend than others. The position of the catheter should be checked, looking for its acoustic shadow in its entirety to the uterine fundus. However, unlike hysteroscopy (which requires distension for visualization), this procedure requires very little fluid to outline the cavity. Even a small ribbon of fluid acts as a sufficient interface to distinguish anterior and posterior endometrial surfaces and outline endometrial pathology.

Saline Infusion Sonohysterography-Pathology

In a prospective pilot study, saline infusion sonohysterography was performed in 21 women with abnormal perimenopausal uterine bleeding.²⁶ Of the 21 patients, eight had obvious polypoid lesions (Fig. 28-6) and were triaged for operative hysteroscopic removal. The pathology report confirmed benign polyps in all eight patients. Three patients had submucous myomas. Two had wire loop resectoscopic excision (Fig. 28-7A and B). The third, with a submucous myoma that extended to the serosal edge of the uterus, received expectant management. Nine patients had no obvious anatomic lesion, and the endometrial thickness of either the anterior or posterior wall was a maximum of 3.2 mm. The studies were purposely performed on days 4 to 6 of the bleeding cycle when early proliferative change would be expected if, in fact, no anatomic abnormality existed. Biopsy in all nine of these patients revealed early proliferative endometrium. Thus, these patients had dysfunctional (that is, anovulatory) uterine bleeding and were successfully treated with progestational agents. One

FIGURE 28-6. Saline infusion sonohysterogram of a patient with abnormal uterine bleeding. In this coronal view of the uterus, a polyp measuring 8.2×12.3 mm (calipers) is seen emanating from the posterior wall.

patient had an endometrial thickness along the anterior wall of 7.6 mm, although the posterior wall was thin (2.3 mm). Curettage with hysteroscopy revealed simple hyperplasia without atypia, and this patient was also treated with progestational agents. Thus, the conclusion was that endometrial fluid instillation (sonohysterogram) to enhance vaginal ultrasonography in perimenopausal women could reliably distinguish between patients with minimal tissue (3 mm or less single-layer measurements) whose bleeding is anovulatory and best treated hormonally from those patients with significant tissue (3 mm or more single-layer thickness) in need of formal curettage and hysteroscopy. Furthermore, polyps can be distinguished from submucous myomas. This allows appropriate triage for *operative* hysteroscopy in terms of skill required and length of time and equipment needed. Furthermore, this eliminates the need for diagnostic hysteroscopy in patients whose bleeding is dysfunctional.

As determined in this pilot study, the addition of saline infusion sonohysterography can reliably distinguish perimenopausal patients with dysfunctional abnormal bleeding (no anatomic abnormality) from those with globally thickened endometria or those with focal abnormalities.

Abnormal Uterine Bleeding—An Algorithm

A clinical algorithm was proposed and studied in a large prospective trial of perimenopausal women with abnormal bleeding, using unenhanced transvaginal ultrasonography, followed by saline infusion sonohysterography for selected patients, and then either no endometrial sampling, undirected endometrial sampling, or visually directed endometrial sampling, depending on whether the ultrasonographically-based triage revealed no anatomic abnormality, globally thickened endometrium, or focal abnormalities, respectively (Fig. 28-8).²⁷ In that study, 280 patients (65%) displayed a thin, distinct, and symmetric endometrial echo less than 5 mm on day 4 to 6, and dysfunctional uterine bleeding was

FIGURE 28-7. A. Long axis view of a patient with abnormal uterine bleeding. There is a central thickened uterine echo which measures 20.6×29.8 mm. B. Saline infusion sonohysterogram of the patient shown in A. The endoluminal mass (24.9×24.7 mm) outlined by calipers represents an intraluminal myoma. Note the acoustic shadowing emanating from the myoma. Furthermore, note the endometrial cavity itself is lined with thin endometrium compatible with the early proliferative phase in this perimenopausal patient.

diagnosed. One hundred fifty-three (35%) had saline infusion sonohysterography. Of these procedures, 44 (29%) were performed because of the inability to adequately characterize and measure the endometrium (Fig. 28-9A and B), and 109 (71%) were done for endometrial measurement greater than 5 mm. 61 of those patients then had both anterior and posterior endometrial thickness that was symmetric and less than 3 mm, compatible with dysfunctional uterine bleeding. Fifty-eight patients (13%) had focal polypoid masses

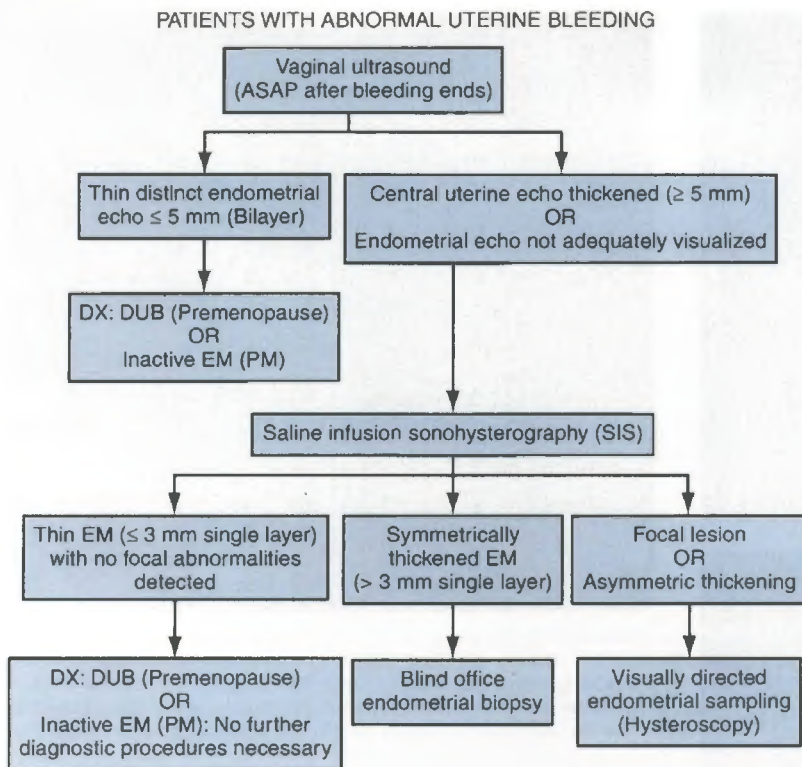

FIGURE 28-8. Clinical algorithm for patients with abnormal uterine bleeding. DUB, dysfunctional uterine bleeding.

FIGURE 28-9. A. Transvaginal scan in a long axis view of a perimenopausal patient with abnormal uterine bleeding. The endometrial echo is not sufficiently seen along its entirety to make an accurate diagnosis. B. Same patient as scanned in Figure 9A. Saline infusion sonohysterography reveals a lack of any endoluminal mass. The anterior and posterior endometrium measure 1.5 and 2.0 mm (calipers) respectively.

(Fig. 28-10A and B) that were removed hysteroscopically and confirmed pathologically. Twenty-two patients (5%) had submucous myomas, although 148 patients (34%) had clinical and ultrasonographic evidence of fibroids. Ten patients had symmetrical single-layer measurements of endometrium at saline infusion sonohysterography greater than 3 mm (range 3 mm–9 mm). Of these, the histologic type was proliferative endometrium in 5 patients and hyperplastic endometrium in 5 patients. Saline infusion

sonohysterography was technically inadequate in 2 patients who then underwent hysteroscopy with curettage. Undirected office biopsy alone without imaging potentially would have missed the diagnosis of focal lesions such as polyps, submucous myomas, and focal hyperplasia in up to 80 patients (18%).

Based on these results, it seems apparent that any blind endometrial sampling should be preceded by a fluid instillation sonohysterogram. A process must be shown to be

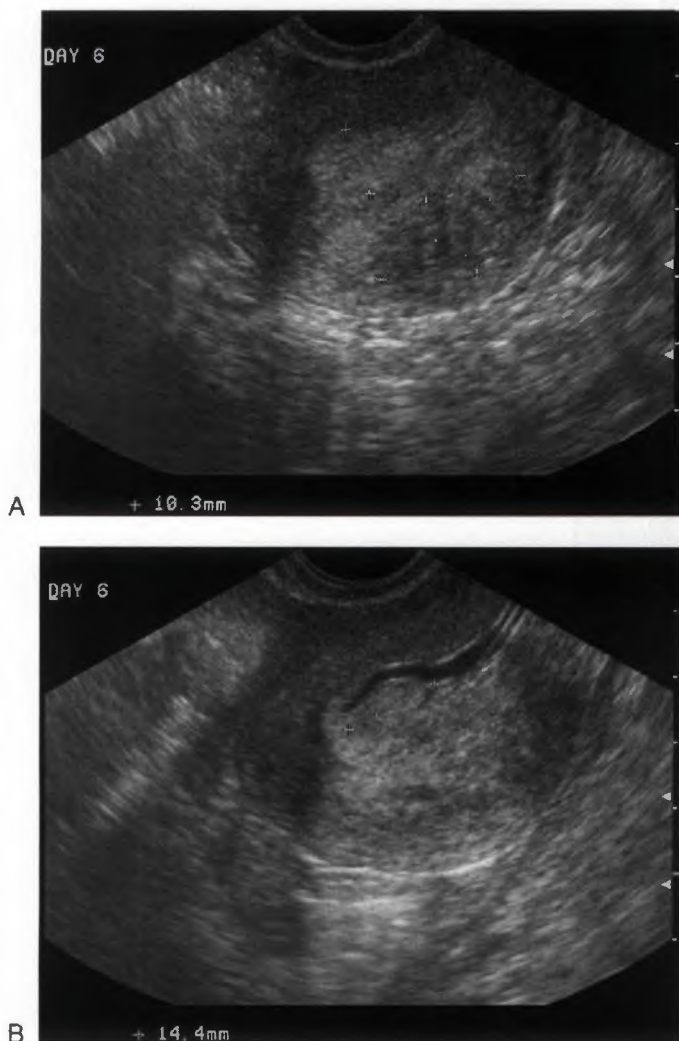

FIGURE 28-10. A. Long axis transvaginal ultrasound view of a perimenopausal patient with abnormal uterine bleeding. This is taken on day 6 just as the bleeding cycle has ended. The central uterine echoes are thickened and measure 10.3 mm. B. Saline infusion sonohysterogram of the patient shown in A. Note the presence of the catheter in the lower uterine segment. A polypoid lesion is seen extending from the fundal region. This measures 14.4 mm in its longest dimension. At the time of dilatation and curettage and hysteroscopy, a polyp was identified that was confirmed by pathology.

symmetrically “pan uterine” or global to justify a blind procedure. When changes are focal (that is, polyps, some hyperplasias, or some carcinomas), they can be appreciated as such with fluid instillation sonohysterography, and then directed biopsies must be carried out.

In the pilot study,²⁶ although nine of 21 patients had obvious sonographic and clinical evidence of fibroids, only three had a submucous component. Six of 21 had intramural-subserosal myomas coexisting with dysfunctional uterine bleeding. This was also true in the large prospective study,²⁷ when although 148/433 women had myomas only 22 had a submucous component.

Usually polyps are clearly discernable, as are submucous myomas. However, sometimes a broad-based polyp is difficult

FIGURE 28-11. Long axis view of the uterus in a patient with abnormal uterine bleeding. Saline infusion reveals a polypoid lesion emanating from the fundus. Color flow Doppler clearly identifies a central feeder vessel. Presence of such a feeder vessel can be used to make the diagnosis of a polyp even in the absence of saline infusion.

to distinguish from a submucosal myoma. This may be important for preoperative triage, in that a truly pedunculated submucous myoma will behave more like a polyp in terms of skill and equipment required for its removal in the operating room whereas a broad-based polyp may behave more like a myoma and require resectoscopic capability.

A reliable assessment with ultrasonography requires that the endometrial echo be homogeneous, surrounded by an intact hypoechoic junctional zone, and that the operator constantly remembers that the endometrial cavity is a three-dimensional structure. This may account for why Dijkhuizen et al²⁸ had 4 cases that supposedly measured less than 10 mm (some as little as 2 mm), and yet at hysteroscopy displayed polyps. Such cases underscore the importance of the three-dimensional character of the endometrial cavity and the occasional propensity of the ultrasonographic operator to obtain a limited number of two-dimensional views and assume that these represent the entire endometrial cavity. Any one frozen ultrasonographic image is nothing more than a two-dimensional snapshot, and failure to meticulously recreate three-dimensional anatomy will result in error. New three-dimensional ultrasound equipment will eliminate errors that may occur if the operator does not pay meticulous attention to mentally recreating three-dimensional anatomy.

Furthermore, the use of color flow or power Doppler to identify the central feeder vessel pathognomonic of an endometrial polyp is an alternative to sonohysterography in the diagnosis of polyps (Fig. 28-11). This had a positive predictive value of 81.3% in the study by Timmerman et al.²⁹

FIGURE 28-12. Saline infusion sonohysterogram in a patient who had been taking tamoxifen for 1 and one half years. A polypoid mass with multiple microcysts is seen in the uterine cavity.

Selective Estrogen Receptor Modulators—Tamoxifen

Tamoxifen, the first clinically available selective estrogen receptor modulator, was developed in 1966 and approved by the United States Food and Drug Administration in 1978.³⁰ It is the most prescribed antineoplastic drug in the world, with approximately 10 million women-use-years of experience. Tamoxifen has proved efficacious in all settings of breast cancer. However, in the mid-to-late 1980s, a series of letters to the editor and case reports announced an association between tamoxifen therapy in women with breast cancer and the development of endometrial carcinoma.³¹⁻³⁵ The published data demonstrating an association between tamoxifen and the development of benign as well as malignant endometrial lesions appeared to suggest a need for routine screening for endometrial neoplasms in women taking this drug.

Controversy existed about the extent of uterine surveillance, if any, that women on tamoxifen therapy require. We employed a regimen of transvaginal ultrasound and saline infusion sonohysterography when the image generated by an initial transvaginal ultrasound is of poor, indistinct quality, or suggestive of thickening of the endometrial wall. With the introduction of saline infusion sonohysterography³⁶ came the first reports of microcystic changes on ultrasound. Such changes represent glandular cystic atrophy and can be present in the basalis of the endometrium, in the proximal myometrium, or even within polyps (Fig. 28-12). Recent data seem to point to a high- and a low-risk group that can be identified before treatment with tamoxifen by screening with transvaginal ultrasound. Patients with no uterine abnormalities on transvaginal ultrasound appear to be at very low risk of developing atypical hyperplasia. However, patients with any lesions on the initial screen (although most are usually benign polyps) appear to have an 18-fold increased risk and, even if asymptomatic, may be appropriate candidates for ongoing surveillance, whereas low risk patients may be left alone unless they experience bleeding.

SUMMARY

Abnormal uterine bleeding, whether in perimenopausal or postmenopausal patients, is an important clinical concern and accounts for much medical intervention. When bleeding occurs in women over 40 years of age as well as any postmenopausal women, endometrial assessment is mandatory. In the past and present, many clinicians prefer to begin such assessment with blind endometrial sampling. This chapter has presented an ultrasound-based approach to such patients. When present, a thin distinct endometrial echo excludes significant pathology, assuming it is performed at an appropriate time if the patient is, in fact, cycling. When a thin distinct endometrial echo is not visualized (inadequate visualization or presence of thickened echo) then saline infusion sonohysterography can help to triage patients to no anatomic pathology, globally thickened anatomic pathology that may then be evaluated with blind endometrial sampling, and focal abnormalities that must be evaluated under direct vision. Such an ultrasound-based approach will not only help to exclude endometrial carcinoma, but also to identify the source of any bleeding for better clinical management.

INTRODUCTION

The term gestational trophoblastic neoplasia (GTN) encompasses a range of entities including the more common complete (CHM) and partial (PHM) hydatidiform mole, invasive mole (IM), coexistent complete mole and live fetus, and the rarer malignant entities choriocarcinoma (CC) and placental site trophoblastic tumor (PSTT). The major clinical significance of the diagnosis of CHM or PHM is the associated increased risk of development of subsequent persistent gestational trophoblastic neoplasia (pGTN), in the form of any of the other subtypes¹ (Fig. 29-1). However, in many cases in clinical practice, the strict distinction between these entities is often artificial. Following a suspected or proven diagnosis of a molar pregnancy, surveillance is usually instituted with serum and urine human chorionic gonadotropin (hCG) measurements and patients in whom the hCG levels either rise or fail to return to normal are considered as having pGTN and may be treated with chemotherapy without a further specific histologic tissue diagnosis having been made. The management of complications of GTN is most often performed in specialist tertiary referral centers. The aim of this chapter is not to provide a thorough dissertation on all aspects of GTN, but rather to discuss an overview of the important issues and to specifically highlight the use of ultrasound examination in the diagnosis and management of these conditions. For purposes of simplicity, the chapter is broadly divided into two sections, focusing on hydatidiform mole (HM) in the first instance and then pGTD and gestational trophoblastic tumors.

HYDATIDIFORM MOLAR PREGNANCY

Hydatidiform moles essentially represent an abnormality of placental development as a consequence of overexpression of paternally derived genes and are therefore examples of

abnormalities of imprinting. They are associated with structural placental abnormalities and fetal developmental defects, and are characterized pathologically from nonmolar pregnancies by the presence of abnormal trophoblast hyperplasia. They are simply divided into two major subtypes, CHM and PHM according to pathologic and genetic features.²

CHMs are almost always diploid, but in most cases, all genetic material is of paternal origin, either as a consequence of genomic endoreduplication following monospermic fertilization of an anucleate oocyte or, more rarely, dispermic fertilization of an anucleate oocyte (Fig. 29-2). In rare cases, it has now been recognized that an unusual genetic variant of CHM, termed biparental CHM exists, in which the karyotype appears to be normal diploid with compliments from both parents, but the phenotype is identical to classic CHM, the defect appearing to be a result of abnormalities of imprinting with subsequent overexpression of the paternal genome.³

Partial hydatidiform moles are almost always triploid, with the additional set of genetic material also being paternally derived, almost always due to dispermic fertilization of an apparently normal oocyte. In PHM, the presence of a maternal genome is associated with less trophoblastic hyperplasia and a greater degree of fetal development. Thus, overexpression of paternally transcribed genes is likely to play a role in the development of PHM, whereas CHMs reflect both overexpression of paternally transcribed and loss of maternally transcribed genes. All HM are associated with increased risk of development of pGTN, which is about 15% post CHM and 0.5% post PHM.⁴

Classically, these entities are clinically, as well as genetically, distinct, with PHM being associated with the presence of a fetus and coexistent patchy hydatidiform change of the placenta, whereas CHMs are not associated

SPECTRUM OF GESTATIONAL TROPHOBLASTIC NEOPLASIA

FIGURE 29-1. Illustration demonstrating the various subtypes of gestational trophoblastic disease and persistent gestational trophoblastic disease. Complete hydatidiform mole in which numerous vesicles, representing hydropic chorionic villi, are seen filling the uterus. Partial hydatidiform mole in which a fetus is seen associated with patchy cystic, hydatidiform change of the placenta. Dichorionic twin pregnancy with a normal fetus and coexisting complete hydatidiform mole. In these cases, the sonogram demonstrates a normal-appearing placenta associated with the fetus, as well as tissue that has the characteristic appearance of a complete hydatidiform mole. Invasive mole in which penetration of molar villi, usually from a complete hydatidiform mole, occurs in the myometrium. Choriocarcinoma in which trophoblastic invasion, in the absence of chorionic villus structures, may extend into and beyond the myometrium, with the potential of metastases (in this case, the lung). PSTT in which the myometrium is infiltrated by trophoblastic cells, which may extend beyond the uterus. (Illustration by James A. Cooper, MD, San Diego, CA.)

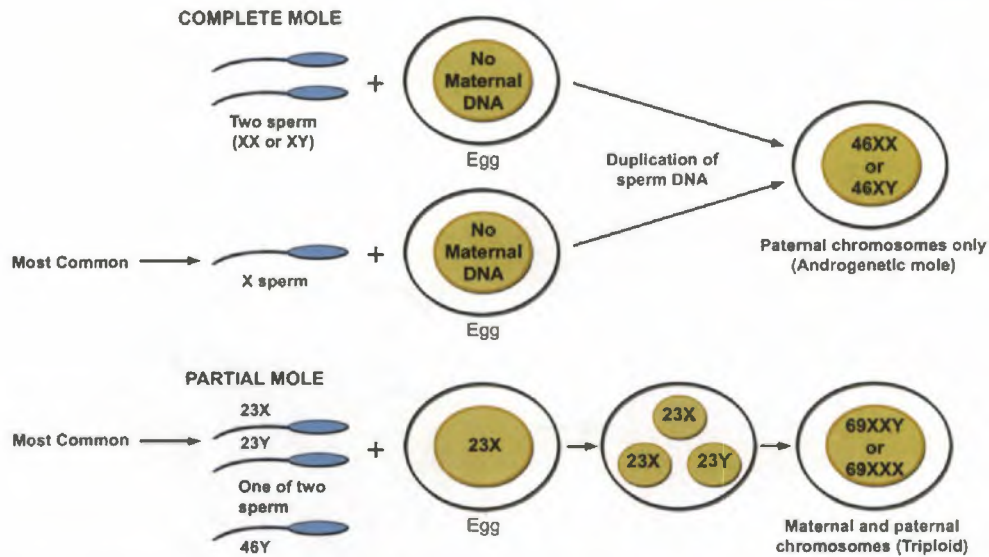

FIGURE 29-2. Patterns of fertilization to account for chromosomal origin of complete (46, XX) and triploid partial moles (XXY). In a complete mole, one or two sperm fertilize an egg that has lost its chromosomes. Partial moles are due to fertilization of an egg by one diploid, or two haploid sperm, depicted in this example as one 23,X and one 23,Y. Rarely, biparental complete moles are described, which are thought to be related to an imprinting defect. (Modified with permission from Crum CP: *The female genital tract*. with fetal development and demonstrate diffuse placental change (see Fig. 29-1). However, with increasing understanding of these pathologies, in combination with changes in the management of early pregnancy complications, such simplistic distinctions are no longer correct, because it is now recognized that histologic evidence of early fetal-type development can sometimes be identified in cases of CHM,⁵ whereas the majority of cases of PHM are associated with early pregnancy failure in the absence of an identifiable fetus.⁶ Therefore, it is important to emphasize that the classic clinical, sonographic and histopathologic descriptions of these conditions are now outdated in the era of current gynecologic management, and revised and updated criteria for their diagnosis are required.

The gold standard for the definitive diagnosis, and subtyping, of HM is histopathologic examination by a specialist pathologist, because both CHM and PHM have distinctive histologic characteristics even in the first trimester.⁷⁻⁹ In the normal placenta, cytotrophoblast, syncytiotrophoblast, and intermediate trophoblast are present during placental development. Villus trophoblast covers chorionic villi and consists predominantly of cytotrophoblast and syncytiotrophoblast, cytotrophoblast being the proliferating component while syncytiotrophoblast differentiates from fusion of cytotrophoblast, composed of multinucleated cells with abundant dense cytoplasm and secretion of hCG. The diagnostic pathologic features of molar pregnancies are essentially characterized by abnormal proliferation of villus trophoblast. (Fig. 29-3). Intermediate trophoblast, of various subtypes, is also present, and although of prime importance in implantation and placental site trophoblastic tumors, is not a major component of the diagnostic criteria for molar pregnancies.

In the classic, although now rarely seen, second trimester CHM, there is marked villus hydrops with extensive

circumferential villus trophoblast hyperplasia and central villus cistern formation (Figs. 29-3 and 29-4). However, in the first trimester, such features are not yet developed, the diagnostic features being abnormally distributed villus trophoblast hyperplasia, relative lack of villus hydrops, sheets of pleomorphic extravillous trophoblast, collapsed villus blood vessels and marked stromal karyorrhectic debris in association with characteristic abnormal budding villus architecture. In addition, extravillous trophoblast invasion may be abnormal in CHM, with absence of normal controlled endovascular trophoblast plugging of decidual vessels, instead showing florid interstitial trophoblast invasion, sometimes resulting in interstitial hemorrhage.⁷⁻¹⁰

PHMs also exhibit nonpolar trophoblast hyperplasia, but in first trimester PHMs, this may be patchy and mild. Other features include patchy mild villus hydrops with focal cistern formation, numerous villus vessels containing nucleated fetal red cells, angiomatoid change, abnormally shaped scalloped or dentate villi, with trophoblastic pseudoinclusions and villus stromal fibrosis. Fetal tissue may also be present. The main diagnostic histopathologic features of CM, PM, and non-molar hydropic abortion (HA) in products of conception evacuated in the first trimester are summarized in Table 29-1 (see Fig. 29-3).

It should be noted that although in most cases histopathologic diagnosis is easy, in some cases, a definite diagnosis may not be possible, particularly in cases with only limited material submitted for examination, and conceptions affected by other aneuploidies that may appear histologically similar to PHM. In such cases, ancillary diagnostic techniques may be required, including p57^{KIP2} immunohistochemistry^{11,12} (absent staining in CHM, positive nuclear staining in other diagnoses), assessment of ploidy using in situ hybridization or flow cytometry,¹³ and microsatellite polymorphism analysis.¹⁴

Changes in the Epidemiology of the Diagnosis of Hydatidiform Mole

Classically, patients with singleton CHM present with vaginal bleeding, uterine enlargement greater than expected for gestational age, and abnormally high levels of serum hCG levels with passage of vesicles per vagina (see Figs. 29–3 and

FIGURE 29–4. Pathologic specimen of the vesicles in a patient with a complete hydatidiform mole. (Courtesy of Jonathan Carter, MD, The University of Sydney, Sydney, Australia.)

29–4). Medical complications include pregnancy-induced hypertension, hyperthyroidism, hyperemesis, anemia, and development of ovarian theca-lutein cysts, which may even occasionally lead to ovarian torsion or cyst rupture¹⁵ (Fig. 29–5). This classic presentation now is highly unusual,¹⁶ because the majority of uncomplicated pregnancies, and all those presenting with first-trimester vaginal bleeding, now undergo routine ultrasound examination, at which time either molar change or missed abortion is diagnosed, both of which lead to evacuation of the uterus. This has resulted in

FIGURE 29–5. Intraoperative photograph of bilateral theca lutein cysts in a patient with gestational trophoblastic disease. (Courtesy of C. Michael Peterson, MD, Department of Obstetrics & Gynecology, University of Utah Health Sciences Center.)

Table 29–1 Diagnostic Histopathologic Features of Complete Mole (CHM), Partial Mole (PHM), and Nonmolar Hypopic Abortion (HA), in Products of Conception Evacuated in the First Trimester

	CHM	PHM	HA
Villous size	Moderate variation	Marked variation	Uniform
Villous outline	Budding	Irregular	Smooth*
Villous stroma	Mucoid/myxoid	Fibrotic	Hypocellular
Villous hydrops	Varied	Varied	Uniform
Cistern formation	Varied	Varied	Scanty
Stromal karyorrhectic debris	Present	Absent	Absent
Villous vessels	Absent/collapsed	Present	Absent/collapsed
Nucleated red blood cells	Very rare	Present	Present
Trophoblast pseudoinclusions	Present	Present	Rare*
Trophoblast hyperplasia	Present, moderate	Present, mild [†]	Absent
Extravillous trophoblast	Pleomorphic	Present	Absent
Implantation site	Florid [‡]	Normal	Normal
Fetal parts/amnion	Absent	Present	Present

*Cases of nonmolar fetal aneuploidy may demonstrate irregular, hypoxic villi with pseudoinclusions but no abnormal trophoblast hyperplasia is present.
[†]Abnormal trophoblast hyperplasia may be focal and demonstrate a lace-like pattern around the villus.
[‡]Extravillous interstitial trophoblast invasion may appear florid, but there is reduced normal endovascular trophoblast plugging and interstitial hemorrhage may be seen.

a marked reduction in the number of molar pregnancies presenting with the symptoms and signs of overgrowth of trophoblast and excessive hCG secretion, and most cases are now evacuated in the late first trimester, the average gestation at diagnosis in the United Kingdom now being approximately 10 weeks.¹⁷ It should be noted at this point, that ultrasound examination leads to earlier uterine evacuation in most cases following diagnosis of a failed pregnancy rather than identification of molar change (see later). In one recent study of patients with CHM, 40% were asymptomatic, the condition detected by routine sonographic examination, while 60% presented with vaginal bleeding; only 2% reported hyperemesis, and none had any other systemic manifestations.¹⁸

Ultrasound in the Detection of Hydatidiform Mole

HMs have been recognized by ultrasound examination for many years, but much of the literature refers to ongoing pregnancies with second trimester moles. The typical features reported include a uterine cavity filled with central heterogeneous mass with anechoic spaces of varying size and shape, a snowstorm-like appearance in the early days of ultrasound, without associated fetal development (see Figs. 29-1 and 29-6).^{19,20} In addition, theca lutein cysts secondary to the high hCG levels were reported, producing either soap-bubble or spoke-wheel appearance of the ovaries, which are enlarged (see Figs. 29-5 and 29-7). Doppler

ultrasound examination in this scenario almost always demonstrates high velocities and low resistance to flow in the uterine arterial circulation and low resistance flow from trophoblastic tissue (Fig. 29-8). In cases of invasive mole, in addition to the central uterine lesion, myometrial invasion is present, with choriocarcinoma (CC) appearing as a mass enlarging the uterus, with a heterogeneity corresponding to areas of necrosis and hemorrhage²¹ (Fig. 29-9).

However, in an analogous manner to the changing clinical aspects, such sonographic presentations are also now only rarely encountered, with most cases being evacuated in the first trimester, when ultrasound demonstration of hydatidiform changes is much less readily apparent.

Several studies have now reported on the use of ultrasonography for detection of HM in early pregnancy^{22,23} (Fig. 29-10). Fine et al²⁴ reported on the sonographic features of 22 PHMs compared with nonmolar abortions and suggested that cystic changes and increased placental echogenicity may be useful diagnostic features. Lazarus et al²⁵ examined 21 CHMs in the first and second trimester (4-18 weeks) and reported that correct pre-evacuation

diagnosis of HM could be made in about half; in no cases were theca lutein cysts present (Fig. 29-11). More recently, Benson et al²⁶ described 24 CHMs examined sonographically in a specialist center and reported that molar pregnancy was suspected by ultrasound in almost 80%, suggesting, as with all sonographic techniques, that experienced operators may achieve a higher rate of diagnostic accuracy. Jauniaux et al²⁷ reported that 10 of 11 pregnancies with sonographic features suggestive of HM at 10 to 14 weeks of gestation were pathologically proven HMs, indicating that specificity of sonographic diagnosis is high, but allowing no comment on sensitivity. Furthermore, Lindholm et al²⁸ reported that, on the basis of sonography and macroscopic examination of products of conception for molar change, about 80% of complete moles and 30% of partial moles could be detected, but it was noted that in several cases, macroscopic examination following uterine evacuation rather than the sonogram

FIGURE 29-8. Doppler spectral analysis from trophoblastic tissue in a patient with an invasive mole demonstrating flow velocity waveforms with low resistance.

FIGURE 29-10. Sagittal sonogram from a patient with a first trimester hydatidiform mole. In this case, an echogenic mass (large arrows) is seen filling the uterine cavity. Except for one small cyst (small arrow), there are virtually none of the cystic spaces that are characteristically seen in more advanced molar pregnancies. BI, bladder; M, myometrium.

FIGURE 29-9. A and B. Extension of an invasive mole (arrows) into the myometrium in two patients with markedly elevated hCG levels. BI, bladder.

FIGURE 29-11. Three patients presented with vaginal bleeding and positive pregnancy tests. *A.* This patient has a hyperechogenic mass (arrows) filling the uterine cavity. The appearance is similar to that of a first trimester hydatidiform mole (compare with Fig. 29-10). This was a nonviable pregnancy (missed abortion). *B.* Sonogram in a patient with early pregnancy and vaginal bleeding. This pregnancy was nonviable. A small cystic area, likely representing hydropic change (arrow), is seen. Am, amnion. *C.* In this patient, an irregular fluid collection (arrow) was seen in the uterine cavity. This has the appearance of a nonviable gestation. At pathologic evaluation, there was evidence of trophoblastic proliferation consistent with a first trimester hydatidiform mole. Bl, bladder.

raised the first clue to the diagnosis (Fig. 29-12). In most cases of both PHM and CHM reported in which the diagnosis was not suspected before evacuation, the initial sonographic diagnosis was that of missed miscarriage/anembryonic pregnancy.²⁹ Two larger, recent studies have reported that correct pre-evacuation identification of molar pregnancy by ultrasound in the first and early second trimester is achieved in around 40% to 60% of cases.^{17,30} The largest study by far to specifically address this issue examined the accuracy of routine ultrasound examination in 1,053 consecutive patients referred to a UK Regional trophoblastic disease unit for histologic review for possible or probable HM¹⁷; because all cases of GTN, suspected clinically, sonographically, or on the basis of histopathologic findings, are registered at the center, this allowed the highest possible ascertainment. The median gestational age in this study was only 10 weeks (range 5–27 weeks; Fig. 29-13). The final review diagnosis was HM in 859 (82%) cases, including 253 (29%) CHM and 606 (71%) PHM. Nonmolar hydropic miscarriage was diagnosed following histologic review in 194 (18%). Overall, around 40% of HM cases had a pre-evacuation ultrasound diagnosis suggesting molar pregnancy, including about 80% of CHM and 30% of PHM, the remainder of cases appearing sonographically simply as a missed miscarriage (Fig. 29-14).

FIGURE 29-12. Sonogram of a patient with a partial hydatidiform mole. Multiple cystic spaces are seen within the placenta. Triploidy was confirmed at pathologic examination. Embryo (arrow).

FIGURE 29-13. Gestational age distribution at evacuation of products of conception referred with suspected diagnosis of complete or partial hydatidiform mole to a regional center in 2004. The median gestational age at evacuation is 10 weeks (range: 5–27 weeks).¹⁷

FIGURE 29-14. Pre-evacuation detection rates of complete (CM) and partial (PM) hydatidiform molar pregnancies following routine sonographic examination. Less than half of all hydatidiform moles (overall) in whom an ultrasound examination had been carried out were identified as molar pre-evacuation, the detection of complete moles being significantly better than for partial moles.

FIGURE 29-15. Pre-evacuation detection rates of hydatidiform molar pregnancies by gestational age. There is no significant difference in detection rates across the age range, but there is a clear trend toward improved detection rates at 14 weeks' gestation and beyond.

There was a trend toward increasing ultrasound detection rate with increasing gestational age; sonographic features of HM were reported in 35% of cases before 14 weeks of gestation compared with around 60% after this time (Fig. 29-15). It should also be noted that more than 10% of the cases identified as molar on ultrasound examination were in fact nonmolar hydropic miscarriage on histologic review. The sensitivity, specificity, positive and negative predictive values for routine pre-evacuation ultrasound examination for HM therefore are 44%, 74%, 88%, and 23%, respectively. These data compare favorably with a similar, smaller, study reporting on cases from 5 years previously in which the overall pre-evacuation ultrasound detection rate was approximately 30%.⁶ This improvement is presumably as a consequence of increasing specialization of obstetric sonographers, increasing experience in the recognition of such pregnancies, and improved ultrasound technologies. It is likely that some further improvements will occur, but there are pathophysiologic reasons limiting the proportion of HM, especially PHM, that will demonstrate sonographically detectable features in the first trimester.^{8,9}

Therefore, with current gynecologic care, the majority of HMs present both clinically and sonographically as early pregnancy failure. Improved pre-evacuation detection of HM has potential important consequences for provision of medical care, because it could result in reduced numbers of products of conception undergoing histologic review and a reduced number of women undergoing follow-up for equivocal histologic findings, and would allow a safe increase in the proportion of nonmolar miscarriages that could be appropriately managed medically rather than with surgical evacuation of the uterus. In the United Kingdom, current Royal College of Obstetrics and Gynecology guidelines state that medical management of miscarriage is acceptable but medical methods of uterine evacuation are not recommended for suspected HM.^{1,31} Because medical management of miscarriage does not usually result in tissue being submitted for histologic examination, such cases need to be accurately preselected to minimize the risk of missing an undiagnosed HM, which may present later with pGTN. There are convincing data, based on cases of GTN following terminations

of pregnancy, that women presenting with clinical pGTN have significantly more complications, morbidity, and requirements for radical surgery and combination chemotherapy compared with women identified by hCG surveillance protocols.³²

Preliminary data suggest that the combination of ultrasound examination and maternal serum hCG measurement may provide a significantly improved method of pre-evacuation risk assessment for GTN, especially in those presenting with early pregnancy failure, although at present, no large scale studies of this combination have been performed. In molar pregnancies, maternal hCG concentrations are usually raised with associated low maternal serum alpha-fetoprotein (MSAFP) concentrations.³³ An hCG level more than two standard deviations above the mean, in combination with sonography, has been suggested as a way to identify up to 90% of cases,³⁴ and with the use of appropriate normal ranges for failed pregnancies, rather than ongoing pregnancies, this is likely to improve. In one recent study of 46 HMs examined at an early pregnancy assessment unit, in 33, HM was suspected sonographically, and in 15 cases for whom hCG results were available, nine were greater than two multiples of the median.³⁰ Further research in this area is likely to lead to significantly improved detection rates in the first trimester.

Management of Hydatidiform Mole

In many cases (see earlier), the diagnosis of HM is not suspected until a uterine curettage has been performed and the products of conception examined by the pathologist. In cases suspected sonographically, uterine evacuation is also required as the initial management because the pregnancy will not be continued. This should be carried out by suction evacuation rather than sharp curettage to minimize the risk of uterine perforation. Generally, repeated evacuations should not be carried out because there is an increased risk of uterine perforation, and if persistent molar tissue is present, it may be deeply invasive and will likely require chemotherapy.³⁵ Ultrasound examination, either real-time grayscale imaging or combined with color Doppler flow assessment is useful to ensure completeness of uterine evacuation and identify residual trophoblastic tissue.³⁶⁻⁴¹

Following uterine evacuation and histologic confirmation of the diagnosis, all patients should be followed up with serial hCG measurements for the early detection of pGTN, ideally by a centralized or regional service. The precise protocol of surveillance varies from country to country, but essentially women should be followed up until their hCG levels have been normal for at least 6 months. In addition, patients should be counseled that once they have had a molar pregnancy, there is increased risk of both a subsequent HM and pGTN development following any future pregnancy, even if it is nonmolar, owing to reactivation of latent trophoblast. Therefore, hCG levels must also be checked 6 and 10 weeks following any future pregnancies, regardless of its outcome. During the initial follow-up period, use of contraception is suggested because a subsequent pregnancy complicates the interpretation of a rising hCG level in this setting and because the hormonal effects of pregnancy may reactivate latent trophoblastic disease. There is controversy regarding the use of the combined oral

Table 29-2 International Federation of Gynecology and Obstetrics (FIGO) Staging System for Gestational Trophoblastic Neoplasia (GTN)⁴⁴

Stage	Criteria
Stage I	Disease confined to the uterus
Stage II	GTN extends outside the uterus but is limited to the genital structures (adnexa, vagina, broad ligament)
Stage III	GTN extends to the lungs with or without genital tract involvement
Stage IV	All other metastatic sites

contraceptive pill (OCP) in this setting, but it appears that OCP use has no adverse effect in those women in whom there is spontaneous fall of hCG levels to normal within 8 weeks of evacuation, whereas cases in which the hCG remains slightly raised may represent a subpopulation in whom there may be a risk of stimulating GTN growth by administered exogenous hormones. Therefore, most centers would at least recommend avoidance of the OCP until hCG levels have clearly returned to normal.³⁵

Persistent Gestational Trophoblastic Neoplasia

A subgroup of women following a molar pregnancy, and some patients following a nonmolar pregnancy, develop pGTN. This condition may be associated either with symptoms due to localized or metastatic disease or, because the majority follow HM, it may be detected by hCG surveillance. pGTN complicates about 15% of CHMs and about 0.5% PHMs, and is rare, although well reported, following nonmolar gestations.⁴

The criteria for diagnosing pGTN are slightly different between countries, with the United Kingdom, for example, having a more conservative approach. Nevertheless, the principles remain the same. pGTN either presents with clinically apparent disease (uncommon) or on hCG surveillance (common), when it is manifest as either plateauing or rising hCG concentrations. Following the identification of pGTN, further investigations are required to stage the disease, including uterine and liver ultrasound, and additional staging investigations such as chest radiograph, computed tomography, or magnetic resonance imaging as indicated. The results of these studies are used to determine the stage and prognosis score in order to assign patients to high-risk or low-risk groups.⁴²

There are many historical staging systems for GTN,⁴³ but now a more unified worldwide system has been agreed to allow comparison of outcome and treatment data across centers, the International Federation of Gynecology & Obstetrics (FIGO) 2000 Staging and Risk Factor Scoring System for GTN⁴⁴ (Tables 29-2 and 29-3). According to this system, the criteria for the diagnosis of post-HM pGTN are

1. Plateauing hCG for four measurements over a 3-week period or longer.

Table 29-3 International Federation of Gynecology and Obstetrics (FIGO) Risk Scoring System for Gestational Trophoblastic Neoplasia (GTN)⁴⁴

FIGO SCORE	0	1	2	4
<i>Criteria</i>				
Age	<40	≥40	–	–
Antecedent pregnancy	Mole	Miscarriage	Term	–
Interval from index pregnancy (months)	<4	4–<7	7–<13	≥13
Pretreatment serum hCG (IU/L)	<10 ³	10 ³ –<10 ⁴	10 ⁴ –<10 ⁵	≥10 ⁵
Largest tumor size (cm)	<3	3–<5	≥5	–
Site of metastases	Lung	Spleen, kidney	Gastro-intestinal	Liver, brain
Number of metastases	–	1–4	5–8	>8
Previous failed chemotherapy	–	–	Single agent	Multi agent

hCG, human chorionic gonadotropin.

For individual patients, a score is assigned for each variable and the scores summed to provide an overall score. The final result is expressed as the stage (roman numeral), then the score (Arabic numeral). An overall score of 6 or less equals low risk and 7 or higher equals high risk.

2. Rising hCG on three consecutive weekly measurements over a period of 2 weeks or longer.
3. Histologic evidence of choriocarcinoma.
4. hCG level remaining elevated for 6 months or more after evacuation.

Therefore, imaging techniques, including ultrasound, play an integral role in the initial assessment of a patient with pGTN. However, although genital tract lesions may be identified by sonography, this is most commonly in those cases with relatively high hCG levels; in those with lower hCG levels, although chemotherapy remains indicated, the uterine lesion, especially if intramyometrial, may not be visualized sonographically and, conversely, myometrial abnormalities may persist even after the tumor resolves.⁴⁵ In one series of more than 350 cases of GTN of varying types, initial sonography demonstrated molar tissue confined to the endometrial cavity in all cases of CHM, whereas in cases of IM and CC, myometrial invasion was correctly identified.⁴⁶ Doppler studies of the uterine vasculature in HM usually demonstrate significantly increased flow and reduced flow resistance, which, following evacuation, returns to normal in parallel with the serum hCG concentration, with a correlation between hCG levels and Doppler indices throughout.⁴⁷ Some data suggest that uterine artery resistance may be lower at presentation in cases of GTN subsequently requiring chemotherapy, compared with those requiring uterine evacuation alone and, hence, may provide additional risk stratification at presentation.^{46,48}

Treatment of Persistent Gestational Trophoblastic Neoplasia

Treatment of low-risk patients is with single-agent chemotherapy usually methotrexate with folinic acid. With such treatment, the overall survival in these patients is essentially now 100%, of which around 70% are cured with methotrexate alone, the remainder being resistant and requiring additional second agent or multiagent chemotherapy. In patients with high-risk pGTN, multidrug chemotherapy is administered, usually now based around weekly EMA-CO protocols (etoposide + methotrexate + dactinomycin and vincristine + cyclophosphamide).⁴² The overall survival rate in this group remains optimistic at around 90%, and the majority of deaths are in fact due to late presentation with advanced disease rather than true treatment failure. In relapsed disease, cisplatin-based agents are added to the protocol. Surgery usually plays little role in the initial management of most cases of pGTN but a major role in the management of PSTT (see below), because this is a less chemosensitive tumor and surgery may be curative. There are also specific modified protocols for specific clinical scenarios, such as central nervous system disease, which is not covered here. Following successful treatment, patients are followed up with hCG measurements until they have been normal for at least 12 months.⁴²

There are now numerous publications reporting on the use of sonographic examination, usually including color Doppler assessment of uterine blood flow, for both prediction and surveillance of response to chemotherapy in pGTN. Most of these reports describe similar features of GTN being associated with increased blood flow and reduced flow resistance, and there being a crude correlation between the Doppler indices and serum hCG levels.^{46,49-75} It should be noted that abnormal hCG levels in association with normal uterine sonography may indicate the presence of new or residual extrauterine disease. In clinical practice, however, although ultrasound examination, including Doppler studies, may provide some information regarding disease extent and response, the fact that serum hCG is such a sensitive and specific marker in this context means that serum hCG levels provide the most sensitive and simplest measure of disease extent. Therefore, this is the most important clinical parameter used to monitor disease response.⁷⁶

Occasionally there may be residual uterine vascular malformations following pGTN treatment, which may require embolization or even hysterectomy to control bleeding. Doppler studies may be useful to plan treatment and assess response but do not seem to predict success of embolization.^{77,78}

COEXISTENT HYDATIDIFORM MOLE AND NORMAL FETUS

This is a clinical scenario that may cause much confusion regarding the underlying pathology and appropriate management. The setting is usually that of a routine ultrasound examination demonstrating the presence of a morphologically normal fetus in association with apparent molar change of the placenta, often in the second or early third trimester. There are several possible explanations for this finding.

Partial Hydatidiform Mole

A theoretical possibility is that the pregnancy simply represents a PHM, but this is in reality highly unlikely, because triploid PHMs rarely progress through pregnancy and the fetus is almost never structurally normal. Potentially, the exceedingly uncommon mosaic PHM could result in such a clinical presentation and is associated with patchy diffuse placental molar change.⁷⁹

Dichorionic Twin Pregnancy With Normal Fetus and Coexisting Complete Hydatidiform Mole

A dichorionic twin pregnancy with a CHM and a normal co-twin, is well-reported, usually presenting on ultrasound examination as an apparently structurally normal fetus with a corresponding sonographically normal placenta, adjacent to which is a mass of placental tissue demonstrating molar change (Fig. 29-16). Initial small studies and case reports suggested that such pregnancies may be associated with increased risk of maternal complications and pGTN. Recently, the outcome of pregnancies with a histologically confirmed CHM and a normal co-twin has been examined in a series of 77 well-described cases from a tertiary center. In this large series, the risk of pGTN was no greater than that reported following a singleton CHM, and furthermore, the risk of pGTN was not increased by continuing the pregnancy. However, in cases in which pregnancy continuation was attempted, several complications may develop. About half will result in spontaneous fetal loss before 24 weeks' gestation, and of those that reach potential viability, 25% end in intrauterine death and 40% deliver severely preterm at less than 32 weeks' gestation. In this the largest series, severe pre-eclampsia was an unusual complication (<10%). Therefore, patients can be counseled that the overall take-home-baby rate in those opting for continuation is around 30%, with a 15% to 20% chance of pGTN development and an increased risk of pregnancy complications requiring intense obstetric surveillance.⁸⁰

Placental Mosaicism for Complete Hydatidiform Mole

A single well-documented, genetically proven, case of mosaicism for CHM has now been reported presenting with an apparently normal fetus at midgestation in association with patchy but diffuse molar change of the placenta. The pregnancy resulted in the live birth of a karyotypically and phenotypically normal infant with the placenta demonstrating admixed areas of CHM and normal villi, both confirmed to be derived from the same sperm by microsatellite typing.⁸¹

Placental Mesenchymal Dysplasia

Diffuse cystic molar changes of the placenta in association with an apparently normal fetus in the third trimester is usually due to placental mesenchymal dysplasia (PMD) rather than any type of GTN. Cases now recognized as PMD have previously been reported under a variety of names including placental vascular anomaly with diffuse

FIGURE 29-16. Coexistent mole and live fetus. *A.* Sonogram of the gravid uterus during the second trimester. Numerous cystic spaces are seen, apparently within the placenta. The presence of a living fetus virtually excludes the diagnosis of a complete hydatidiform mole. *B.* A slightly more lateral plane of section from the same patient reveals that in addition to the molar tissue (*asterisk*), a normal-appearing placenta (PI) is seen. In fact, this is a twin pregnancy, with a normal pregnancy and placenta, and a twin abnormal molar pregnancy.

FIGURE 29-17. Placental mesenchymal dysplasia. *A.* Ultrasound at 22 weeks' gestation demonstrating multiple cysts resembling molar tissue, involving the entire placenta. *B.* Photograph of the placenta in the same case. A close-up view of one of the numerous cyst-like villi, seen on and beneath the maternal surface of the placenta. (Reproduced with permission from Cohen MC, Roper EC, Sebire NJ, et al: Placental mesenchymal dysplasia associated with fetal aneuploidy. *Prenat Diagn* 25:187, 2005.)

stem villous hyperplasia,⁸² placentomegaly with massive hydrops of placental stem villi,^{83,84} angiomatous malformation of placental chorionic stem vessels,⁸⁵ placental vascular malformation with mesenchymal hyperplasia and a localized chorioangioma,⁸⁶ diffuse cystic placental change⁸⁷ and pseudopartial mole.^{85,88} There have now been around 70 well-documented cases of PMD reported,⁸²⁻¹⁰⁰ the prevalence appearing to be around 1 in 4,000 to 5,000 pregnancies.⁹²

PMD appears as diffuse molar change sonographically and often has a characteristic macroscopic appearance of the delivered placenta, which is enlarged with multiple cystic structures affecting the parenchyma and prominent, dilated

and tortuous chorionic vessels^{82,85} (Fig. 29-17). Histologic findings are diagnostic, demonstrating normal terminal villi mixed with hydropic stem villi, without trophoblast hyperplasia.^{82,83,85,88,91,93}

In addition to the sonographic identification of cystic placental changes, maternal serum levels of hCG are raised in about 40% and MSAFP is raised in all cases in which it has been recorded.^{93,99} Pregnancy complications are common, including preterm delivery in 75%, intrauterine growth restriction in 20% and intrauterine fetal death in 30%. In addition, approximately 20% of reported cases of PMD are associated with fetal Beckwith-Wiedemann syndrome with a

marked predominance (80%) of female fetuses suggesting a possible defect in imprinting.⁹⁹ Recent data suggest that placental tissue-specific androgenetic-biparental mosaicism may be the underlying cause of the condition.¹⁰⁰

INVASIVE HYDATIDIFORM MOLE

An invasive mole is defined as the penetration of molar villi from a CHM or PHM (although in practice almost always a CHM), into the myometrium or the uterine vasculature. Rarely, such molar tissue can penetrate the full thickness of the myometrium (percreta), leading to uterine perforation or local pelvic extension. In contrast to choriocarcinoma, invasive mole contains distinct molar chorionic villi, and usually becomes clinically apparent as pGTN following initial evacuation of a molar pregnancy, with persistent heavy vaginal bleeding and elevated hCG levels (see Figs. 29-1,

29-3, 29-9, and 29-18). The tumor appears sonographically as focal areas of increased echogenicity within the myometrium,¹⁰¹ which may appear similar to those of PSTT but occur concurrently or soon after a proven molar gestation. The lesion is usually heterogeneous, containing small fluid-filled cavities, and Doppler color flow mapping of the abnormal area can be used to evaluate the extent of the lesion and its subsequent response to chemotherapy.¹⁰²⁻¹⁰⁴ Treatment is usually with standard chemotherapy protocols or surgery, but adjunctive local ultrasound-guided injection of methotrexate has also been described.¹⁰⁵

Ectopic Hydatidiform Mole

Primary molar pregnancies outside of the uterine cavity, most often in a fallopian tube, may occur but are very rare.¹⁰⁶⁻¹⁰⁸ There is a tendency for nonspecialist pathologists to over diagnose tubal moles following salpingectomy because nonmolar early gestation sac specimens demonstrate abundant polar and extravillous trophoblast around the trophoblastic shell.¹⁰⁹ Criteria for diagnosis of CHMs or PHMs are identical to HMs present within the uterine cavity. Such patients present sonographically with a tubal ectopic pregnancy.

CHORIOCARCINOMA

This is a malignant neoplasm in which differentiation toward villous cytotrophoblast and syncytiotrophoblast is seen in the absence of chorionic villus structures. It can occur after CHM, PHM, normal pregnancy, stillbirth, miscarriage or ectopic pregnancy, but the incidence after CHM is about 1,000-fold greater than following a nonmolar pregnancy. CC either presents as pGTN in patients on hCG surveillance or as clinically apparent, often metastatic, disease in other patients. Uterine CC appears as a hemorrhagic nodule, which may be in communication with the uterine cavity or may be within the myometrium (see Figs. 29-1, 29-3, and 29-19). Microscopically, viable tumor

FIGURE 29-18. Invasive mole. Macroscopic photograph of a hysterectomy specimen containing an invasive mole. The uterine cavity is filled with vesicles (*thin arrow*), with multifocal myometrial invasion (*one area highlighted with thick arrow*).

is usually seen only at the periphery of the nodule and within vascular spaces in adjacent myometrium. In most patients, a bilaminar appearance can be identified, but some, especially post-treatment cases, may be predominantly composed of mainly mononuclear cytotrophoblast. CC metastasizes early and secondary nodules may be present in the cervix or vagina, or distant sites, at presentation. Unexplained intracerebral hemorrhage or acute cor pulmonale in a woman of childbearing age should always raise suspicion of CC. CC following a normal term pregnancy is presumably the result of metastatic intraplacental choriocarcinoma, such primary tumors being well reported but often microscopic and so they are not detected sonographically or at the time of delivery.^{110,111}

PLACENTAL SITE TROPHOBLASTIC TUMOR

This is a subtype of malignant GTN in which the predominant differentiation is toward intermediate extravillous, rather than villus, trophoblast. PSTTs usually present with amenorrhea or irregular vaginal bleeding many months or even years after the last known pregnancy, and their origin from both HM and nonmolar pregnancies have been demonstrated.^{112,113} The average interval from the last pregnancy is 3 to 4 years, in contrast to weeks or months for other types of pGTN. The uterus in PSTT is usually enlarged, and the hCG level is only mildly elevated. Diagnosis is usually made on the basis of curettage, which demonstrates myometrium infiltrated by trophoblastic cells with eosinophilic cytoplasm- and nuclear pleomorphism-forming clusters, which infiltrate between muscle fibers. PSTT can infiltrate relentlessly and extend into adjacent organs such as the ovary, parametrium, rectum or bladder, and distant metastases can occur, although much less commonly than for CC¹¹⁰ (see Figs. 29-1, 29-3, and 29-20).

PSTT has a lesser metastasizing potential, making it treatable with surgery. However, it is much more resistant to chemotherapy; therefore, hysterectomy is usually the treatment of choice, with chemotherapy indicated for patients

with metastases or residual disease. The mortality rate is approximately 20% and appears to be associated with the presence of lung metastases and presentation greater than 4 years from the previous pregnancy.¹¹⁴ Sonographically, there are no specific features to reliably distinguish diagnose PSTT, but in conjunction with the history, an irregular, usually localized, uterine mass lesion may be identified.

EPITHELIOD TROPHOBLASTIC TUMOR

This is the most recently described and rarest subtype of trophoblastic tumor, and it is essentially a variant of PSTT. It is also composed of trophoblast with an intermediate phenotype that often presents with a longer interval from the last pregnancy, around 6 to 7 years. Microscopically, it demonstrates a characteristic nodular, expansive growth pattern positive immunostaining with placental alkaline phosphatase. Behavior and treatment appears similar to PSTT.¹¹⁵

Breus Mole

This is an antiquated and misleading term, which should no longer be used, to describe a large subchorionic thrombus that lies between the chorionic plate and the underlying villous tissue. There is no relationship with any type of hydatidiform mole. Such lesions are usually lobulated and elevate the fetal surface of the placenta, bulging into the amniotic cavity; prenatal ultrasonic diagnosis is well reported¹¹⁶⁻¹²¹ (Fig. 29-21). Pathologically, the lesion consists solely of laminated thrombus. It was initially thought to be associated with miscarriage,¹²² but such massive subchorial thrombi have been demonstrated in placentas from live-born infants. It is probable that lesions of this type are due to sudden, marked slowing of blood flow in the intervillous space. The causes of this condition remain uncertain, but cases have now been reported following thrombolytic therapy in pregnant patients with prosthetic heart valves¹²³ and in women with thrombophilic conditions.¹²⁴

FIGURE 29-21. A and B. Breus mole. Two patients scanned in the second trimester of pregnancy with a subchorionic thrombohematoma. A hypoechoic area (asterisk) beneath the amniotic side of the placenta is seen in both patients. Although this lesion was initially thought to carry a poor prognosis, both fetuses delivered at term and were normal at birth.

Ovarian Masses in the Pregnant Patient

Ultrasound in the Diagnosis of Adnexal Torsion

Summary

Practice Points

Before the ultrasound era, any persistent palpable adnexal mass had to be removed surgically, because that was the only way of excluding malignancy. Today, we can make a fairly confident diagnosis of a pelvic mass on the basis of its ultrasound image.¹⁻¹³ This possibility allows us to offer individual and, it is hoped, optimal treatment of women with a palpable pelvic mass. Some masses are almost certainly best treated expectantly, certainly if they are not causing any symptoms (e.g., functional cysts, hydrosalpinx, and uterine myomas), others might be best treated by cyst puncture (e.g., peritoneal inclusion cysts),^{14,15} and yet others by surgery (e.g., borderline tumors and invasive malignancies). If surgery is judged to be the best treatment, then the ultrasound diagnosis may be important when choosing the optimal time and method of surgery: Many benign tumors can be removed laparoscopically by a gynecologist,¹⁶ whereas malignant masses require open surgery by an oncologic surgeon. No doubt, transvaginal ultrasound examination is an excellent tool for solving clinical problems in women with symptoms suggesting the presence of an adnexal mass. However, today's liberal use of transvaginal ultrasound also presents many problems to the clinicians. Many adnexal masses that would almost certainly have remained undetected before the

ultrasound era are now found incidentally at transvaginal ultrasound examination of women without symptoms of an adnexal tumor. The natural history of incidentally detected pelvic masses with benign ultrasound morphology is not known. We do not know how often such tumors will cause problems in the future (e.g., torsion, pain, infertility). We do not know if there is a risk of some of them becoming malignant or the magnitude of any such a risk. In one study, 86 asymptomatic women (72 premenopausal and 14 postmenopausal) with an adnexal mass with sonographic morphology compatible with a mature cystic teratoma (dermoid cyst) not larger than 6 cm, were managed expectantly. The women were followed up for a mean of 3 years. Torsion or other complications did not occur. Twenty-eight women who desired pregnancy became pregnant and had one or more uncomplicated pregnancies during follow-up. Growth rate of the mature cystic teratomas was very low.¹⁷ Hundreds of postmenopausal women with adnexal cysts—most of the cysts being simple cysts ≤ 5 cm in diameter—have been managed expectantly for up to 9 years without any adverse effects being noted.¹⁸⁻²⁵ It is by no means obvious that adnexal masses with benign ultrasound morphology incidentally detected at ultrasound examination should be surgically removed. Surgery is associated with risks. In published studies, the intraoperative and postoperative complication rate associated with adnexal surgery varies between 0.3% and 8%.²⁶⁻³¹ The mortality rate associated with adnexal surgery is difficult to estimate, but the mortality rate associated with gynecologic laparoscopic procedures may be 1 per 25,000.³² Long-term complications after gynecologic surgery include adhesion formation.³³

These adhesions, in turn, may cause infertility or bowel obstruction.³³⁻³⁵ I have found no published information on the incidence of small bowel obstruction after adnexal surgery, but one may expect one death due to postoperative small bowel obstruction per 625 hysterectomies (my own calculations made on the basis of information from references 33 and 36). To determine if surgical removal of adnexal masses with benign ultrasound morphology incidentally detected at ultrasound examination in asymptomatic women is beneficial, it would be necessary to conduct a randomized controlled trial comparing surgery with expectant management. However, it would probably be difficult to conduct such a trial. Experts in gynecologic ultrasound would have to perform all ultrasound examinations, because confusion of benign and malignant tumors resulting in inclusion of malignancies in the trial would be unacceptable. Moreover, the primary endpoint of such a trial is not obvious, follow-up time would need to be very long, the trial would need to be large, and individual preferences of women might make it difficult to recruit patients. My personal opinion is that one should not examine asymptomatic women with ultrasound (or with gynecological palpation), because there is no evidence that detection of pelvic masses that do not cause symptoms is beneficial. This is true even of malignant masses. We have to await the results of ongoing randomized trials evaluating ultrasound screening for ovarian cancer before we will know if detection of ovarian cancer at an asymptomatic stage improves the prognosis.³⁷

ULTRASOUND MORPHOLOGY FOR DISCRIMINATION BETWEEN BENIGN AND MALIGNANT EXTRAUTERINE PELVIC MASSES

Subjective evaluation of the grayscale ultrasound image, that is, pattern recognition, for discrimination between benign and malignant tumors can almost certainly be learned by anyone performing gynecologic ultrasound examinations on a regular basis, but diagnostic accuracy increases with increasing experience.³ An experienced ultrasound examiner can very confidently discriminate between benign and malignant pelvic tumors in the adnexal region using pattern recognition, the reported sensitivity of pattern recognition varying between 88% and 100% and the reported specificity between 62% and 96%.^{2,38-44} Pattern recognition has been shown to be superior to all other ultrasound methods (e.g., simple classification systems, scoring systems, mathematical models for calculating the risk of malignancy) for discrimination between benign and malignant extrauterine pelvic masses.^{2,43} Adding Doppler ultrasound examination to subjective evaluation of the grayscale ultrasound image does not seem to yield much improvement in diagnostic precision,^{2,38,39,42} but it may increase the confidence with which a correct diagnosis of benignity or malignancy is made^{2,38} (see later).

My personal experience is that absence of solid components and absence of irregularities in an adnexal mass at ultrasound examination suggests benignity, whereas any irregularity—be it in the outline, the cyst wall, or in the echogenicity of a tumor—suggests malignancy. I consider unilocular and multilocular cysts without solid components

to be benign, even though some cysts with an extremely large number of locules may be borderline mucinous cystadenomas of intestinal type,⁴⁵ even in the absence of irregularities or unequivocal solid components. In cystic tumors with solid components, the larger and more irregular the solid components are, the greater the risk of malignancy. In solid tumors, the more irregular the outline and echogenicity of the tumor, the greater the risk of malignancy. Using these simple rules, my detection rate (sensitivity) of malignant tumors including borderline tumors was 88% (21/24), with a specificity of 96% (143/149) in one series of patients undergoing preoperative ultrasound examination.² In a later series they were 83% (30/36) and 91% (91/100).⁴³ In these two series, all but two of the nine malignancies that were misdiagnosed as more likely to be benign than malignant were borderline tumors, the other two being a tubal cancer and a dysgerminoma.

Papillary projections—for example, a solid projection into a cyst cavity from the cyst wall of more than 3 mm in height⁴⁶—are a strong sign of malignancy.⁴⁷⁻⁵² In one of my own series, they seemed to be more common in borderline ovarian tumors (5/12, 42%) than in benign ovarian tumors (20/100, 20%) and primary invasive ovarian tumors (3/12, 25%) (unpublished data from reference 43). This has been confirmed by Romanini and coworkers.⁵³ Papillary projections seem to be particularly common in ovarian adenofibromas (5/7, 70%), but they are also often seen in serous cystadenomas (4/11, 37%) and mucinous cystadenomas (3/14, 21%) (unpublished data from reference 43). Papillary projections in benign tumors explain many false-positive ultrasound diagnoses of malignancy. Many false-positive and false-negative diagnoses with regard to malignancy are also explained by mucinous cystadenomas/mucinous borderline tumors because of their overlapping ultrasound morphology.

Ultrasound images representative of benign and malignant extrauterine pelvic tumors are shown in Figure 30-1. The difficulty of correctly classifying tumors with papillary projections is illustrated in Figure 30-2, and the overlapping ultrasound morphology of mucinous cystadenomas and mucinous borderline tumors (of intestinal type) is shown in Figure 30-3.

THE ROLE OF DOPPLER ULTRASOUND FOR DISCRIMINATION BETWEEN BENIGN AND MALIGNANT MASSES

Based on the results of prospective studies, there is little to support an important role of Doppler examination in the differential diagnosis of adnexal masses.^{1,2,38,39,42} In most cases, a correct diagnosis can be made on the basis of the grayscale ultrasound image alone. A comprehensive description of the use of (color) Doppler ultrasound examination in the diagnosis of adnexal masses is given in reference 54. In summary, pulsatility index and resistance index seem to be the *least suitable* Doppler variables for discrimination between benign and malignant adnexal masses. They have been claimed to be lower in malignant than in benign adnexal tumors, but there is substantial overlap in results between the two categories. Subjective evaluation of the color content of the tumor scan or measurement of time-averaged

FIGURE 30-1. Benign unilocular cyst (A) and multilocular cyst characterized by absence of solid components and absence of irregularities (B). (C) Malignant tumor characterized by presence of solid components and presence of irregularities.

maximum velocity in tumor vessels are probably better; a high level of color content in the tumor scan and high blood flow velocity in tumor vessels support the presence of malignancy. If measurement of blood flow velocity is to be used, it is the highest time-averaged maximum velocity recorded from tumor vessels that should be used to characterize the tumor. However, the color content of the tumor scan probably reflects tumor vascularity better than any other Doppler variable. It might be said to give an overall impression of tumor vascularization in that it probably reflects both the number and size of tumor vessels and their functional capacity. The international ovarian tumor analysis group have suggested the use of a color score (color score 1, no detectable vascularization; color score 2, minimal vascularization; color score 3, moderate vascularization; color score 4, abundant vascularization).⁴⁶ Despite evaluation of the color Doppler image being entirely subjective, results have been shown to be reproducible enough for clinical use.⁵⁵

ULTRASOUND MORPHOLOGY FOR MAKING A SPECIFIC DIAGNOSIS IN AN EXTRAUTERINE PELVIC MASS

Some types of tumor (e.g., endometriomas, mature cystic teratomas (dermoid cysts), hydro- pyo- and hemato-salpinx, peritoneal pseudocysts, paraovarian cysts, hemorrhagic corpus luteum cysts, myomas, abscesses and ovarian fibromas, thecomas, and Brenner tumours) may manifest a characteristic appearance at grayscale imaging.^{1,9,10,36-67} Therefore, an experienced ultrasound examiner can often make a correct specific diagnosis based on the grayscale ultrasound image by pattern recognition.^{1,38,39,63,64} In some cases, however, diagnosis may be confusing. For example, ovarian endometrioma may be difficult to distinguish from tubo-ovarian abscess, mature cystic teratoma (dermoid cyst), mucinous cystadenoma, and hemorrhagic cyst,⁵ as may pedunculated uterine leiomyoma from ovarian fibroma.⁵⁸ Doppler ultrasound examination does not contribute much to a correct specific diagnosis of an adnexal mass.¹

Table 30-1 Sensitivity and Specificity of Subjective Evaluation of the Grayscale Ultrasound Image ('Pattern Recognition') for Discrimination Between Benign and Malignant Pelvic Masses and for Making a Specific Diagnosis

Diagnosis	My Own Series ¹		Other Series ^{6-13, 38-42, 113}	
	Sensitivity	Specificity	Sensitivity	Specificity
Malignancy	88 (21/24) ^a	96 (143/149)	77-100	62-95
Dermoid cyst	90 (18/20) ^b	98 (150/153)	53-100	94-100
Endometrioma	92 (24/26)	97 (143/147)	43-84	89-100
Corpus luteum cyst	-	-	Not reported	Not reported
Hydro-, pyo-, or haemato-salpinx	100 (8/8)	100 (165/165)	83, 93	73, 90
Paraovarian or paratubal cyst	83 (5/6) ^c	99 (166/167)	10-97	Not reported
Peritoneal pseudocyst	100 (3/3)	99 (169/170)	Not reported	Not reported
Ovarian fibroma or fibrothecoma	56 (5/9)	100 (164/164)	Not reported	Not reported
Myoma	86 (6/7)	99 (165/166)	93	98

^aAll malignancies missed were borderline tumors.

^bNo specific diagnosis was suggested in the two cases missed (false-negative results). The two cysts were seen to contain sonolucent fluid, a few septae, and minor solid components not resembling fat or hair.

^cNo specific diagnosis was suggested in the case missed (false-negative).

From Valentin L: Use of morphology to characterize and manage common adnexal masses. *Best Pract Res Clin Obstet Gynaecol* 18:71, 2004

The sensitivity and specificity of pattern recognition in the diagnosis of some common specific diagnoses are shown in Table 30-1. It is important to emphasize that the ability to make a correct specific diagnosis in a series of pelvic tumors is highly dependent on the types of tumor in the tumor series studied. My own series¹ consists of a consecutive series of pelvic tumors removed at surgery. It contains a mixture of different types of tumor that in all likelihood is fairly representative of the types of pelvic tumor currently considered appropriate to operate.

ULTRASOUND CHARACTERISTICS OF MATURE CYSTIC TERATOMAS (DERMOID CYSTS)

Germ cell tumors constitute the second largest group of ovarian neoplasms (approximately 20%). Ovarian teratomas are the most common germ cell tumor and are derived from several histologic types, all of which contain mature or immature tissues of germ cell (pluripotential) origin.⁶⁸ These include the mature cystic teratoma (dermoid cyst); the monodermal teratoma, that is, a teratoma composed predominantly of one tissue element, the most common being mature thyroid tissue (struma ovarii) and immature teratoma.

Mature cystic teratoma or ovarian cystic teratoma are more appropriate terms than the more commonly used term dermoid cysts. These cystic tumors are the most common of the ovarian teratomas. They typically contain mature tissues of ectodermal (skin, brain), mesodermal (muscle, fat), and endodermal (mucinous or ciliated epithelium) origin.⁶⁸ They affect a younger age group (mean patient age, 30 years) than epithelial ovarian neoplasms⁶⁹ and are the most common ovarian masses in children.⁷⁰ Most mature cystic teratomas are asymptomatic.⁶⁸

Owing to the slow growth rate of mature cystic teratomas, with an average rate of 1.8 mm each year, some investigators advocate nonsurgical management of smaller (<6 cm)

tumors.⁷¹ Mature cystic teratomas requiring removal can be treated with simple cystectomy. The tumors are bilateral in about 10% of cases.^{68,72}

On gross pathologic examination, mature cystic teratomas are often (about 90%) unilocular and filled with sebaceous material, which is liquid at body temperature and semisolid at room temperature.^{68,72} Squamous epithelium lines the wall of the cyst, and compressed, often hyalinized, ovarian stroma covers the external surface.^{73,74} Hair follicles, skin glands, muscle, and other tissues are found within the wall. There is usually a raised protuberance projecting into the cyst cavity known as the Rokitansky nodule. Most of the hair typically arises from this protuberance,⁶⁸ as do bone or teeth when they are present.⁷⁵ Ectodermal tissue (skin derivatives and neural tissue) is invariably present.^{72,73,75} Mesodermal tissue (fat, bone, cartilage, muscle) is present in more than 90% of cases, and endodermal tissue (e.g., gastrointestinal and bronchial epithelium, thyroid tissue) is seen in most cases.⁷² Adipose tissue is present in 67% to 75% of cases, and teeth are seen in 31%.^{68,72,73,75}

Most mature cystic teratomas are easily recognized at grayscale imaging because of their fat and hair content.^{61,65} However, as many as 9% (1/11)¹¹ or even 18% (7/89)⁶⁵ of mature cystic teratomas may manifest a predominantly cystic echo pattern indistinguishable from other cystic masses. The most characteristic ultrasound features of a mature cystic teratoma are the presence of (1) a white ball (corresponding to hair and sebum), sometimes occupying the entire cystic tumor (Fig. 30-4A), (2) long, echogenic (white) lines and prominent echogenic dots in cyst fluid (corresponding to hair floating freely in non fatty fluid; see Fig. 30-4B), and (3) shadowing^{61,65,76} (see Fig. 30-4C). Shadowing often makes it difficult or impossible to correctly measure the size of mature cystic teratomas. The Rokitansky nodule or dermoid plug is hyperechogenic with shadowing due to adipose tissue, hair, or calcifications (see Fig. 30-4D). Mature teratomas may be small and not deform the shape of the ovary (see Fig. 30-4E). Intracystic nondependent spheres of lipid material can

FIGURE 30-4. Mature cystic teratoma with (A) typical white (hyperechoic) ball; (B) typical long hyperechoic lines and bright prominent spots representing hair in fluid; (C) typical shadowing, making it difficult to determine the true boundaries of the teratoma; (D) Rokitansky nodule or dermoid plug (arrow) with posterior acoustic shadowing; (E) small mature teratoma within the ovary (arrow); (F) intracystic nondependent spheres in a patient with a mature cystic teratoma.

occasionally be identified in mature cystic teratomas, producing a dramatic appearance (see Fig. 30-4F).

Some mature cystic teratomas are impossible to detect, even when they are clearly palpable, because their echogenicity is similar to surrounding bowel (personal experience). Confusion of mature cystic teratomas with endometriomas, mucinous cystadenomas, struma ovarii, serous cystadenomas, cystadenofibromas, and Brenner tumors have been reported.^{1,5,9,11,13,60,61}

ULTRASOUND CHARACTERISTICS OF BENIGN, HEMORRHAGIC AND INFLAMMATORY CYSTS

Ultrasound Characteristics of Endometriomas

Endometriomas are known to manifest typical ground glass appearance at gray scale imaging^{9,56,60,77} (Fig. 30-5A). Quite often, one or more solid masses are seen to protrude from the cyst wall into the cyst lumen (see Fig. 30-5B). According to Patel and co-workers, such protrusions (wall nodularity) are seen in 20% of endometriomas.⁷⁷ By definition, these protruding masses should be classified as solid papillary projections, but they probably represent blood clots or fibrin (my own speculation). Patel and colleagues⁷⁷ reported that hyperechoic wall foci were much more common in endometriomas than in other types of adnexal pathology (35% versus 6%), a finding that has not been reported by others (see Fig. 30-5C). Endometriomas may be unilateral or bilateral and may have slightly different echogenicity of the internal content, if bilateral (see Fig. 30-5D). At grayscale imaging, endometriomas may be confused with mature teratomas (dermoid cysts), abscesses, ovarian adenofibromas, ovarian fibromas, unspecified benign ovarian cysts, mucinous and serous cystadenomas, and hemorrhagic cysts.^{1,5,9,11,12,13,77}

Ultrasound Characteristics of Hemorrhagic Corpus Luteum Cysts

A hemorrhagic corpus luteum cyst is a cyst that typically contains spiderweb-like material.^{56,77} Bizarre blood clots may also be seen^{56,77} (Fig. 30-6A and B). Even an experienced ultrasound examiner may confuse such clots with papillary projections or solid components (see Fig. 30-6C). This explains why there is a risk of misclassifying corpus luteum cysts as malignant tumors. Doppler ultrasound examination may help to discriminate between a clot (no Doppler signals detectable) and a solid component (Doppler signals detectable) (personal experience). When in doubt, follow up with ultrasound after 6 to 12 weeks. However, some hemorrhagic cysts may take up to 4 months to regress (personal experience).

Ultrasound Characteristics of Pelvic Inflammatory Disease (Hydro-Pyo-Hemato-Salpinx)

Pelvic inflammatory disease (PID) usually occurs as a result of ascending spread of microorganisms from the vagina and cervix through the endometrial cavity, through the endometrium into the fallopian tubes.⁷⁸ The clinical

presentation often includes fever, pelvic pain, and a purulent vaginal discharge; however, a substantial amount of PID goes unrecognized because it is atypical or silent. The commonest causative organisms are *Chlamydia trachomatis* (which may run an indolent course) and *Neisseria gonorrhoeae*. Ultrasound is the imaging modality of choice in women with suspected pelvic inflammatory disease.

The normal fallopian tube is 10 cm long and is rarely visible on transvaginal sonography.⁷⁸ In most cases, a fluid-filled diseased tube is easily distinguishable from other types of adnexal masses at grayscale ultrasound examination (Fig. 30-7A). The most characteristic ultrasound features are (1) a fluid-filled sausage-shaped cystic structure, (2) the presence of incomplete septa, that is, septa that are not seen to reach the opposite wall of the cystic structure (see Fig. 30-7B), (3) on a transverse section of a fluid-filled tube, mucosal folds are seen to protrude into the lumen, resulting in cogwheel appearance (see Fig. 30-7C) if the tube is swollen and in beads-on-a-string appearance (see Fig. 30-7D) if it is not.^{4,79} When the acutely inflamed tube has a lumen filled with hyperechoic material corresponding to pus it is called a pyosalpinx. The acute process may resolve spontaneously or with antibiotic therapy. However, it may progress to the development of a tubo-ovarian complex in which the tube and ovary are seen distinctly but are not separable with the transvaginal probe. This may progress to a tubo-ovarian abscess with the loss of architectural definition between one or both of the adnexa with the formation of a conglomerate in which neither the ovary nor the tube can be separately recognized as such (see Fig. 30-7E). If the tube becomes blocked at the fimbrial or cornual end, it becomes convoluted and incomplete septa are visible, thus assuming a retort-shape. This is called a hydrosalpinx (see Fig. 30-7B). The process may lead to a chronic phase with fluid accumulation in the blocked tube and distention of the wall, which is rendered thin. The endosalpingeal folds disappear or are flattened; in the transverse plane, the tubal wall is thin, with echogenic remnants of the endosalpingeal folds (usually 2 to 3 mm), and is described as the beads-on-a-string appearance (see Fig. 30-7D).

The ultrasound morphology of a tubo-ovarian abscess may be that of a unilocular cystic structure, or that of complex multicystic structure with thick walls and thick septae, filled with homogeneously echogenic material (ground glass appearance). Given the complex and varied echogenicity of tubo-ovarian abscesses, it is not surprising that they may be confused with a variety of other conditions, such as endometriomas or malignancies.^{1,4,80,81} It is not always possible to distinguish a tubo-ovarian abscess from a pelvic abscess of another origin, such as a periappendiceal or diverticular abscess.⁴ Knowledge of the patient's history and clinical findings is a prerequisite for making a correct diagnosis. For a detailed description of the ultrasound morphology of different types of pelvic inflammatory disease, the reader is referred to references 79, 82, and 83.

Ultrasound Characteristics of Paraovarian Cysts

Paraovarian cysts may arise from embryonic ducts and are usually located between the tube and the ovary.⁵³ They may be of mesothelial, mesonephric, or paramesonephric

FIGURE 30-5. A. Endometrioma with homogeneously echogenic cyst fluid representing old blood. Ut, uterus. B. Wall nodularity (*arrow*), which likely represents blood clot. C. Endometrioma with calcification (*arrows*) in the wall. D. Bilateral endometriomas. U, uterus.

FIGURE 30-6. A. Hemorrhagic corpus luteum with spiderweb-like contents. B. Hemorrhagic cyst with blood clot. C. Hemorrhagic cyst with unusual appearance simulating a neoplasm.

origin.^{84,85} At ultrasound examination, a paraovarian cyst may be seen as a cyst clearly separate from a normal ovary (Fig. 30-8A). Sometimes it is difficult to distinguish an ovarian cyst from a paraovarian cyst,⁵⁶ and if no ovary is seen separately from the cyst, it may be impossible (see Fig. 30-8B). The cyst fluid may be anechoic or echogenic.⁵⁶ Papillary projections and septa may be present.⁸⁶ Malignancy may develop in a paraovarian cyst, border-line tumors probably being more common than invasive cancers, with malignancy being found most often in paraovarian cysts larger than 5 cm with papillary projections.^{56,84,87,88}

Ultrasound Characteristics of Peritoneal Pseudocysts

Peritoneal pseudocysts are fluid collections among adhesions occurring after an inflammatory process in the peritoneal cavity or after an operation. The typical ultrasound

morphology of a peritoneal pseudocyst is that of a cystic mass following the contours of the pelvis (even though pseudocysts may also be oval or round), with a deformed ovary suspended amongst adhesions centrally or peripherally in the cyst (Fig. 30-9). The cyst fluid may be anechoic or echogenic, and the cyst may contain both septa and papillary projections.^{15,56,89-91}

Ultrasound Characteristics of Ovarian Fibromas, Fibrothecomas, Thecofibromas, Thecomas, Brenner Tumors, and Other Benign Solid Ovarian Tumors

Fibromas and fibrothecomas usually yield an echo pattern indistinguishable from that of pedunculated myomas, that is, they are solid, round, or oval tumors with a smooth outline and a regular striped echogenicity. Different types of solid

FIGURE 30-7. *A.* Hydrosalpinx with a markedly dilated fluid-filled tube. *B.* Hydrosalpinx with a dilated convoluted fluid-filled tube. The folding over of the tube simulates the appearance of an incomplete septation (arrow). *C.* Dilated fallopian tube with thickened endosalpingeal folds (arrows) creating a cogwheel appearance. This appearance is seen more often in acute disease. *D.* Hydrosalpinx with dilated fluid-filled thin-walled fallopian tube with minimal thickening of the folds resembling beads on string. This is seen most often in chronic disease. *E.* Sagittal transvaginal image of a bilateral tubo-ovarian abscess. In the cul-de-sac, there has been complete breakdown in architecture; neither the ovary nor the tube is discernable.

FIGURE 30-8. Paraovarian cyst. *A.* The cyst is separate from a normal ovary (Ov) and uterus (Ut). *B.* In this case, it is difficult to discriminate between a paraovarian cyst and an superficial ovarian cyst. O, ovary.

FIGURE 30-10. A benign solid ovarian tumor may be confused with a uterine myoma if no connection is seen between the myoma and the uterus (e.g., in case of a pedunculated myoma). *A.* Ovarian fibroma. *B.* Exophytic uterine leiomyoma (arrow). Ut, uterus.

benign ovarian tumors, such as fibroma, thecoma, fibrothecoma, and Brenner tumor, may manifest similar echogenicity at grayscale sonography.^{56,59,66,67} However, it is my impression that the echogenicity of fibromas does differ from that of other benign solid ovarian tumors, such as thecomas and thecofibromas. I find the echogenicity of fibromas to be virtually identical to that of myomas, whereas thecomas and thecofibromas often manifest more lobular contours and slightly more irregular echogenicity (Fig. 30-10*A* and *B*). However, these diagnostic criteria did not perform well when tested prospectively.¹ On the other hand, it is probably sufficient from a clinical point of view to merely suggest a diagnosis of benign solid ovarian tumor, and to refrain from attempting to suggest a more specific diagnosis. Guerriero and coworkers⁹ reported confusion of ovarian endometrioma and fibroma at grayscale sonography, and such confusion also occurred in one of my own series.¹

Ultrasound Characteristics of Ovarian Serous Cystadenomas, Mucinous Cystadenomas, and Adenofibromas

In my experience the grayscale ultrasound images of serous cyst (aden)oma, mucinous cyst(aden)oma, and adenofibroma manifest overlapping characteristics. Therefore, I virtually never suggest any of these specific diagnoses on the basis of an ultrasound image. Overlapping characteristics have also found by others.⁵⁹ However, Fleischer and co-workers,⁷ Buy and colleagues,⁶³ and Guerriero and colleagues⁸ did find it possible to diagnose serous and mucinous cyst (aden)omas with grayscale sonography. Buy and co-workers⁶³ considered the characteristic features of a serous cystadenoma to be "a unilocular or bilocular cystic mass with homogenous water echogenicity, thin regular wall, thin regular septum (when present) and no vegetations," and those of a mucinous cystadenoma to be "a multilocular cyst containing fluid of different echogenicities, with regular wall and septa, and no vegetations." Using these criteria, they diagnosed serous cystadenomas with a sensitivity of 70% and a specificity of 98%, and mucinous cystadenomas with a sensitivity of 50% and a specificity of 96%. Fleischer and colleagues⁷ and Guerriero and co-workers⁸ found the sensitivity of grayscale imaging for diagnosing serous cystadenoma to be 75% and 78%, respectively, and the specificity to be 75% and 96%, respectively. The sensitivity and specificity of grayscale imaging for diagnosing mucinous cystadenomas were reported by Fleischer and co-workers to be 95% and 99%, respectively.⁷

The overlapping ultrasound features of serous and mucinous cystadenomas are shown in Figure 30-11.

Ovarian Masses in the Pregnant Patient

As a result of the widespread use of diagnostic ultrasound in the pregnant patient, adnexal masses are being recognized with increasing frequency. An excellent recent review analyzed the scope of the problem when ovarian masses are detected, as well as management issues.⁹² Before the routine use of obstetric ultrasound, adnexal masses were most often recognized either during a physical examination or when they became symptomatic. The prevalence of adnexal masses in the pregnant patient is reported to be between 1% and 2%.⁹³⁻⁹⁵

Of the adnexal masses detected, functional cysts are the most common in pregnancy.⁹² The relative frequency of all other nonfunctional ovarian tumors is most often a reflection of the patient's age.⁹² In descending order, the most common ovarian tumors found during pregnancy include functional ovarian cysts (follicular, corpus luteum, and theca-lutein), benign mature cystic teratomas, serous cystadenomas, paraovarian cysts, mucinous cystadenomas, endometriomas, and malignant tumors^{92,93,95-99} (Table 30-2 and Fig. 30-12). The timing of detection of an adnexal mass during pregnancy influences the likely etiology of the mass. Cystic adnexal masses less than 5 cm that are detected in the first 16 weeks are usually functional and almost always resolve spontaneously.⁹⁴ However, ovarian tumors that persist beyond 16 weeks are more likely to be neoplastic and, therefore, are more likely to result in surgical intervention.⁹² Ovarian malignancy is estimated to occur in approximately

2% to 3% of the masses identified during pregnancy,^{93,95-98,100,101} but the frequency reported varies substantially between studies.⁹² Ovarian tumors of low malignant potential (LMP) or borderline ovarian tumors are usually included in the category of ovarian malignancies.⁹²

Leiserowitz et al¹⁰² recently investigated the frequency of ovarian masses during pregnancy combining several California databases and analyzed the risk of ovarian malignancy during pregnancy. The California statistics suggested an occurrence of one malignancy for every 54,644 deliveries. Notably, the majority of the ovarian malignancies were actually LMP tumors. Ninety-five percent of the LMP tumors and 83.8% of the ovarian invasive malignancies were stage I. Nearly 40% of the ovarian invasive malignancies were germ cell tumors, which is typical for women in their reproductive years.^{92,102} The finding that most ovarian malignancies are low stage and low grade is consistent with previous reports.^{103,104} Most germ cell tumors are dysgerminomas, which are predominantly low stage.^{93,103} Consequently, the overall prognosis of pregnant patients with either an LMP tumor or an invasive ovarian malignancy is highly favorable. These findings should strongly influence the management of adnexal masses during pregnancy.⁹²

Zanetta et al¹⁰⁵ used US criteria to develop the following categories: simple cyst, endometriosis, or corpus luteum-like, dermoid-like, complex benign, borderline-like, and suspicious. They used their system to triage pregnant patients with adnexal masses into those who warranted surgical intervention (suspicious masses) versus those who were candidates for expectant management (all the other categories). In the limited number of patients who had adnexal surgery either antepartum or postpartum, the final pathology generally matched well with their US diagnoses. Magnetic resonance imaging can add additional diagnostic information in certain situations, particularly when the ultrasound examination is equivocal.¹⁰⁶

ULTRASOUND IN THE DIAGNOSIS OF ADNEXAL TORSION

Adnexal torsion is a serious condition that may be painful to varying degrees. It is the fifth most common gynecologic surgical emergency, with a prevalence of 2.7%.¹⁰⁷ Torsion may involve twisting of the ovary, fallopian tube, or both structures (Fig. 30-13A). Torsion usually occurs in the adnexa containing a lesion, for example, an ovarian cyst or a hydrosalpinx, but it may also occur in normal adnexa, especially in prepubertal girls.¹⁰⁸ Although there are some ultrasound findings suggestive of adnexal torsion, adnexal torsion can neither be 100% confirmed nor 100% excluded by ultrasound examination, not even using Doppler evaluation. Indeed, ultrasound findings are sometimes inconspicuous (Fig. 30-13A and B). In adnexal torsion, various degrees of arterial, venous, and lymphatic occlusion occur. This causes massive congestion and edema. Later hemorrhagic infarction may occur. This pathophysiology explains the ultrasound findings in cases of adnexal torsion. If a normal ovary is involved in the torsion, the edema causes enlargement of the ovary, and the ovary usually loses its oval shape and becomes round or globular. Another feature reported to be typical of ovarian torsion, especially in adolescent girls, is the

FIGURE 30-11. Grayscale ultrasound images of serous cyst(aden)oma and mucinous cyst(aden)oma manifest overlapping characteristics. *A, B,* and *C.* Serous cystadenomas. *D, E,* and *F.* Mucinous cystadenomas.

Table 30-2**Etiology of Ovarian Tumors During Pregnancy**

Benign Tumors	Malignant Tumors
Functional cysts	Borderline ovarian tumors
Follicular cysts	Malignant epithelial tumors
Corpus luteum cysts	Malignant germ cell tumors
Theca-lutein cysts	Sex cord/stromal tumors
Hemorrhagic cysts	Granulosa cell tumor
Paraovarian cysts	Cancer metastatic to the ovary
Benign cystic teratomas	Krukenberg tumors
Serous cystadenoma	Pseudomyxoma peritonei
Mucinous cystadenoma	
Endometriomas	

From Leiserowitz GS: Managing ovarian masses during pregnancy. CME Review Article. *Obstet Gynecol Surv* 16:463, 2006.

presence of several round small cysts up to 25 mm in diameter at the periphery of the enlarged ovary.¹⁰⁹ Thus, torsion of a normal ovary in an adolescent girl is characterized by unilateral ovarian enlargement with peripheral, dilated cysts¹⁰⁹ (see Fig. 30-13D). If torsion occurs in a hyperstimulated ovary after ovulation induction, the main ultrasound characteristic is a very swollen ovarian parenchyma, which makes the diseased ovary look distinctly different from the contralateral one.¹⁰⁹ If torsion occurs in an ovarian cyst or a hydrosalpinx, the wall, mucosal folds, and septa of the cyst look swollen at ultrasound examination¹⁰⁹⁻¹¹¹ (see Fig. 30-13A). If hemorrhagic infarction has occurred, echogenic fluid may be seen in cystic spaces in the tumor. Some fluid, often hyperechogenic and corresponding to blood, in the pouch of Douglas is also a common finding.¹⁰⁹ It may be difficult to detect ultrasound signs of torsion in an ovary containing a mature cystic teratoma, because of the shadowing typical of these tumors. Doppler ultrasound examination does not seem to play a decisive role in the diagnosis of adnexal torsion. Color Doppler signals can be detected either peripherally or centrally in a substantial proportion of twisted adnexa¹¹² (see Fig. 30-13C). Doppler findings probably parallel the vascular changes. Persistent arterial flow is compatible with less complete stages of torsion. Therefore, detection of flow using the Doppler technique does not exclude adnexal torsion.

SUMMARY

Pattern recognition is superior to all other ultrasound methods (e.g., simple classification systems, scoring systems, mathematical models for calculating the risk of malignancy) for discrimination between benign and malignant extrauterine pelvic masses. Pattern recognition for discrimination between benign and malignant tumors can almost certainly be learned by anyone performing gynaecologic ultrasound examinations on a regular basis, but diagnostic accuracy increases with increasing experience. Using pattern recognition a fairly confident specific diagnosis can be made of mature cystic teratoma, endometrioma, haemorrhagic corpus luteum cyst, hydrosalpinx, paraovarian cyst, and peritoneal pseudocyst. However, based on pattern recognition, pelvic abscesses are often confused with a variety of other

FIGURE 30-12. Second trimester pregnancy with left adnexal mass. An ovarian mature cystic teratoma (Ov) is seen adjacent to the uterus (U). F, fetal foot.

conditions. It is usually not possible to confidently discriminate between a solid benign ovarian tumor and a pedunculated uterine leiomyoma, or among ovarian fibroma, fibrothecoma, thecofibroma, and thecoma. Doppler ultrasound examination contributes little to a correct diagnosis of an adnexal mass, because in most cases, the grayscale ultrasound image contains sufficient diagnostic information. Ultrasound examination plays an important role when deciding how to treat extrauterine pelvic masses that cause symptoms: expectantly (e.g., hemorrhagic corpus luteum cysts), with puncture (e.g., peritoneal pseudocysts), or with surgery. Moreover, it allows choice of optimal time and method of operation (e.g., choice of laparoscopic surgery for benign lesions), if surgery is judged to be necessary. Optimal management of incidentally detected extrauterine pelvic masses with benign ultrasound morphology is unknown.

PRACTICE POINTS

The most characteristic ultrasound features of

- benign tumors: absence of solid components and no irregularity.
- malignant tumors: presence of solid components and irregularity.
- mature cystic teratoma (dermoid cyst): white ball, long, echogenic (white) lines, and prominent echogenic dots in cyst fluid, shadowing.
- endometrioma: ground glass appearance of cyst contents, wall nodularities.
- haemorrhagic corpus luteum cyst: spiderweb-like contents, bizarre blood clots.
- hydro-pyo-hematosalpinx: fluid-filled sausage-shaped cystic structure, incomplete septa, cogwheel appearance, beads-on-a-string appearance.
- paraovarian cyst: cyst clearly separate from a normal ovary.

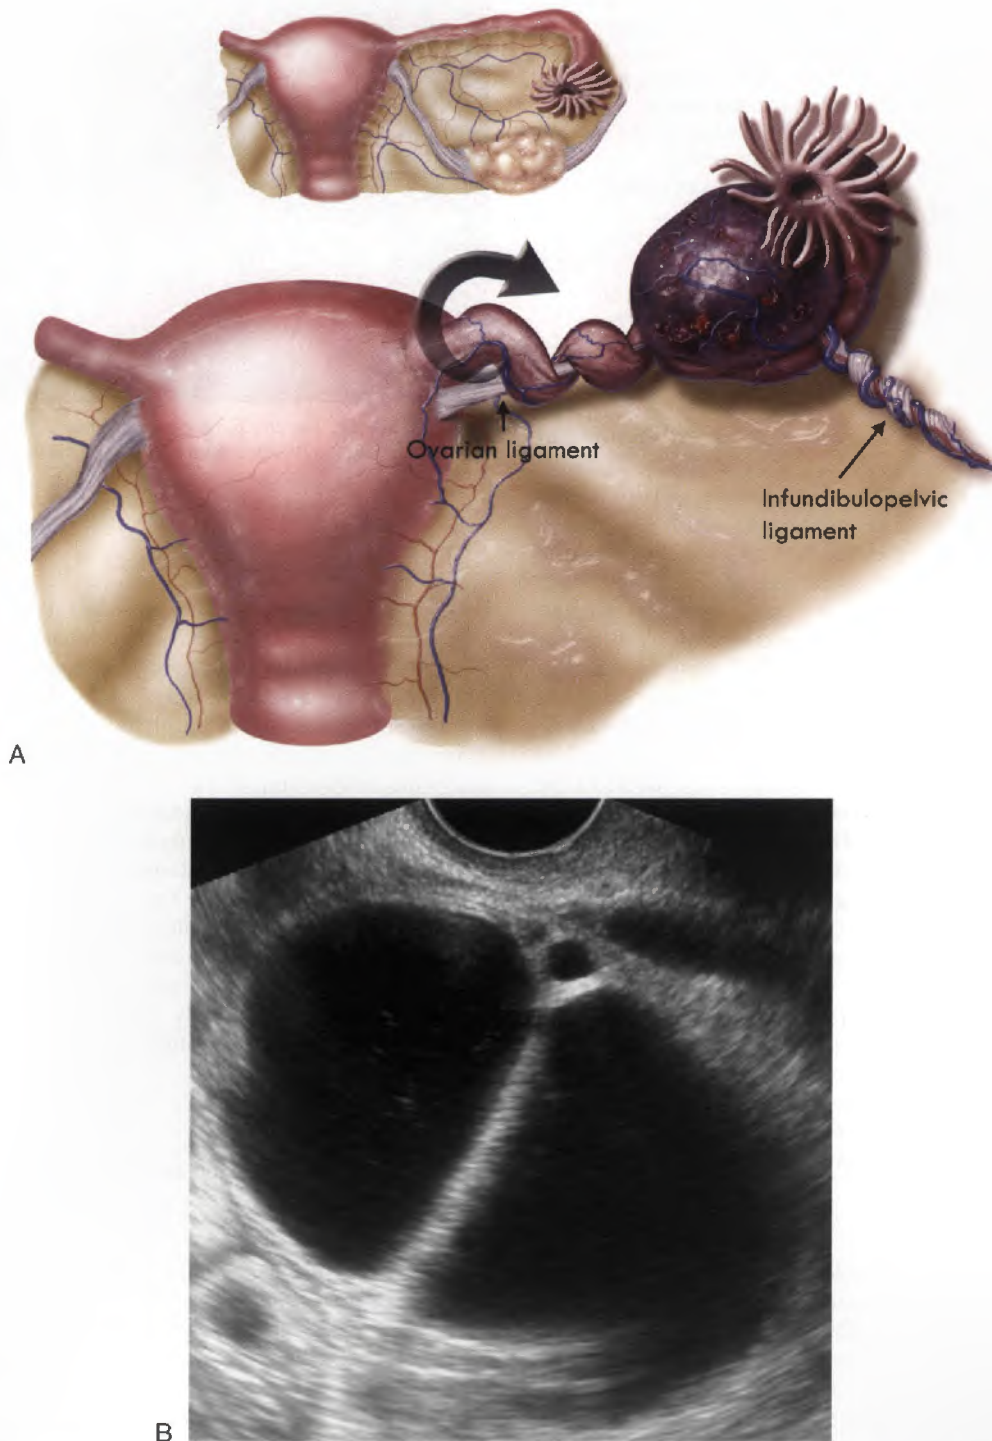

FIGURE 30-13. Ultrasound images of adnexal torsion. *A.* Illustration demonstrating adnexal torsion. Ovarian torsion results in twisting of suspensory ligaments and vascular pedicles resulting in venous occlusion and congestion. *B.* Twisted benign cyst; the only ultrasound feature suggesting torsion is the swollen cyst walls. (Illustration by James A. Cooper, MD, San Diego, CA.) *Continued*

FIGURE 30-13, cont'd C. Twisted ovarian cyst with vascularization detectable at Doppler ultrasound examination. Despite ovarian torsion, arterial flow is still visible. D. Ovarian torsion in a prepubertal girl. The ovary is more round than normal and has multiple peripheral cysts.

- peritoneal pseudocyst: cystic mass following the contours of the pelvis and with an ovary, often deformed, suspended amongst adhesions centrally or peripherally in the cyst.
- fibroma, fibrothecoma: echo pattern indistinguishable from that of a pedunculated myoma, that is, a solid, round, lobular, or oval tumor with a smooth outline and a regular stripy echogenicity.
- tubo-ovarian abscess; unilocular cystic structure, or complex multicystic structure with thick walls and thick septae, filled with homogeneously echogenic material (ground glass appearance).
- adnexal torsion; the walls and any septa of the twisted lesion may look swollen at ultrasound examination; there may be fluid in the pouch of Douglas; the presence of color and spectral Doppler signals in the lesion does not exclude torsion.

Concluding Remarks

Infertility is a medical condition revolving around a couple's inability to conceive after 1 year of unprotected intercourse. It is also an area of medicine that is overly imbued with emotion and misinformation. Our goal in this chapter is to provide medical practitioners with a broad overview of the role of ultrasonography in the diagnosis of root causes of infertility in women and describe its role in increasing the quality of care provided in the assisted reproductive technologies aimed at ameliorating infertility.

In North America, approximately 8% to 15% of couples in which the female partner is 15 to 45 years of age experience some form of infertility,^{1,2} that is, they have not conceived after 12 months of unprotected sexual intercourse.³ Normal fertility is considered to be between 20% to 22% per cycle, and approximately 50% after three cycles. Therefore, in a normal population, approximately 60% of women will become pregnant within 6 months, 80% within 12 months, and 90% within 18 months. In a "fertility-focused intercourse" study pregnancy was achieved in 76%, 90%, and 98% of cases by the first, third, and sixth cycles, respectively.⁴ The age of the female partner is of paramount importance in making decisions about when to begin investigations.⁵ In couples in which the woman is younger than 35 years of age,

it is generally accepted that infertility investigations be initiated after 12 to 18 months of unprotected intercourse. However, if the female partner is older than 35 years of age, has menstrual abnormalities, a history of pelvic disease or surgery, earlier initiation of the infertility work-up may be considered. It is important to remember that infertility is a couple's issue, and each couple will present with a different level of desire to pursue infertility investigations and therapy. Evaluation and management of infertility diagnosis and therapy will typically involve several members of a multidisciplinary team. Consensus documents outlining the optimal work-up of couples who present with infertility and optimal evaluation of the infertile female are available from the Canadian Fertility and Andrology Society and the American Society for Reproductive Medicine.^{6,7} These guidelines should be consulted for best practices in determining the sequence of diagnostic investigation and therapeutic intervention.

Ultrasonography is an integral and essential part of both the diagnostic and therapeutic steps in ameliorating infertility. Although the causes of infertility may have only female factors, only male factors, a combination of issues from each partner, or are idiopathic in nature, the steps taken toward

resolution of the couple's inability to conceive are shared. Each step in the diagnostic or therapeutic process should entail clear communication and involve education and counseling so that the couple understands the reasons for each test, is involved in each decision at each stage of therapy, and has realistic expectations of the therapeutic interventions. An ultrasound examination may be routinely included in the physical examination during the initial infertility consultation in clinics where ultrasonography is an integral part of clinical practice. There is a tremendous amount of information to be gained using ultrasonography early in infertility investigations. We believe that imaging has become the de facto standard for obtaining information once thought to be the purview of more conventional tests and should now be considered as a standard in infertility studies. Uterine and ovarian abnormalities such as cysts, tumors, fibroids, endometriomas, hydrosalpinx, and congenital abnormalities may be instantly visualized and appropriate action taken.⁸ In addition, a conceptus may be visualized very early in gestation.⁹⁻¹¹

The overall goal of imaging in infertility is to assist clinicians in accurate, timely diagnoses of the causes underlying a couple's inability to conceive and to play a role in the delivery of safe, effective treatment that will lead to a high probability of conception. It is sound clinical technical skill in creating and interpreting the images and timely, accurate decision-making following acquisition of the knowledge made possible by the images, and visualization of our tools during treatment procedures that allows ultrasonography to shine as a truly indispensable tool. Each member of the team providing clinical care has a role to play in the provision of the treatment plan and must also be able to respond to the emotional needs of the infertile couple regardless of the pregnancy outcome. Much of the reward that we receive as providers of reproductive health care comes from helping to establish a healthy pregnancy and monitoring the early development of the new life. Noninvasive imaging has provided the eyes that have facilitated the incredible increase in our knowledge of basic human reproductive processes. This new knowledge has, in turn, allowed us to increase our knowledge of the conditions that underlie reproductive failure and design safer, more effective treatments.

DIAGNOSTIC USE OF ULTRASONOGRAPHY IN INFERTILITY

Ovary

Assessment of Ovarian Follicular Development

Our notions of human folliculogenesis have been radically altered in the recent past.^{12,13} For the past 50 years, it has become generally accepted that a cohort of follicles is recruited to grow in the late luteal phase of the menstrual cycle, a single follicle is selected for preferential growth in the mid-follicular phase, with ovulation at mid-cycle and limited follicle development during luteal phase.¹⁴⁻¹⁷ It has been generally accepted that a single follicle grew by chance during a hormonally privileged period of the cycle in women referred to as the "Propitious Moment Theory."¹⁸ According

FIGURE 31-1. Normal ovary during a natural menstrual cycle demonstrating normal follicle population and distribution on day 12 after menstruation. A dominant follicle is visualized in the central portion of the image, and several subordinate follicles are observed in the left lateral aspect of the ovary.

to the theory, antral follicles were recruited and grew continuously until conditions were right for a gonadotropin surge, which stimulated ovulation of the follicles that just happened to be mature at exactly the right point in the cycle¹⁹⁻²¹ (Fig. 31-1).

A Wave Model for Ovarian Folliculogenesis

High-resolution transvaginal ultrasonographic evaluation of the numbers and diameters of antral follicles during the menstrual cycle resulted in the documentation of ovarian follicular waves in normal healthy women of reproductive age. Follicle waves are defined as the synchronous growth of a group of follicles that occur at regular intervals during the ovarian cycle.¹² Emergence of follicle waves occurs at regular intervals throughout the estrous cycle and is preceded by a rise in follicle-stimulating hormone (FSH) regardless of the species.^{12,19,20,22,23} The dominant follicle appears to be identifiable on the basis of size at approximately day 7 postmenstruation and grows at a rate of approximately 2 mm per day.^{13,24,25} The final wave of the human ovarian cycle was ovulatory, although all previous waves were anovulatory.^{12,13} Major waves were defined as those in which a dominant follicle was selected for preferential growth over subordinate follicles, and minor waves were those in which dominance was not manifest. Sixty-eight percent of 50 women evaluated exhibited two waves of follicle development during their ovarian cycles, whereas 32% exhibited three waves.¹³ Of the women with two follicle waves, 85% exhibited a minor wave-major wave pattern and the remaining 15% exhibited a major-major pattern. In the women with three follicle waves, 63% exhibited a minor-minor-major wave pattern, 19% exhibited a minor-major-major pattern, and the remaining 19% exhibited a major-major-major wave pattern.¹²

Waves of follicular development in women occur in association with changes in circulating concentrations of reproductively active hormones during the menstrual cycle. Regardless of when during the cycle the wave starts, all waves are preceded by a rise in serum FSH,^{12,22,23} as documented in domestic animals.^{19,20,22,23,26,27} The dominant ovulatory follicle in women with two versus three follicle waves emerges earlier and is associated with an earlier rise in serum estradiol levels in the mid-late follicular phase, earlier preovulatory surges in estradiol, luteinizing hormone (LH) and FSH, and a shorter interovulatory interval (IOI).¹²

Late antral follicle development in the luteal phase of normal menstrual cycles was not believed to occur in women owing to an inhibitory effect of luteal progesterone, estradiol, and inhibin on FSH and LH secretion.²⁸⁻³⁴ However, in the early 1950s, two periods of increased follicular growth were described during the sexual cycle.³⁵ The first wave of development occurred early in the cycle under the influence of FSH. From this wave, an ovulatory follicle developed. The second wave of development occurred in the early luteal phase. Follicles that grew more than 5 mm within the second wave in the mid-late luteal phase were believed to be atretic. More follicles were seen to grow during the postovulatory phase; however, follicles grew to a larger diameter in the preovulatory phase. Similarly, two waves of follicular development were reported in two women with 30- to 35-day cycles in the early days of ultrasound.³⁶ The follicular phase was reportedly long (>19 days), the luteal phase was short (<10 days), and follicular growth was associated with a rise in estradiol. An increase in the number of ultrasonographically detected follicles in both the early follicular and luteal phases was reported during the menstrual cycle.³⁷ A biphasic pattern of reproductively active hormones was also documented.³⁸ LH pulse frequency rose in the early luteal phase (~20 pulses per day) and early follicular phase (~20 pulses per day), compared with the mid-luteal phase (~5 pulses per day).³⁸ It is interesting that biphasic patterns of follicle growth and endocrine levels supported the notion of the development of ovarian follicular waves in women; however, the development of ovarian follicles during the luteal phase was considered to be an abnormal physiologic event in the early literature and up until the recent ultrasound based discoveries.

Preovulatory Follicles

A successful ovarian follicle is one that escapes the overwhelming odds of atresia and ovulates, releasing its oocyte into an environment where it has the potential to be fertilized. In natural cycles, the follicle destined to ovulate is physiologically selected for preferential development and eventual ovulation, whereas other follicles in its cohort are condemned to atresia by a mechanism that we are only beginning to understand^{39,40} (Fig. 31-2*A* and *B*). The current concepts regarding physiologic selection of the dominant follicle in women and nonhuman primates have been critically evaluated, and it has been determined that physiologic selection is completed only during the ovarian cycle in which the individual ovulation occurs.^{21,40-42} This notion is reinforced by our current best practices in ovarian stimulation in which the selection mechanism is overwhelmed and multiple follicles develop before oocyte collection.

FIGURE 31-2. Imminently preovulatory follicles recorded during natural menstrual cycles (*A*, *B*). Note the stigma development on the right aspects of the follicles as the time follicular rupture approaches. The stigma (*asterisk*) is the portion of the follicle that protrudes from the surface of the ovary and its apex represents the location of impending follicular rupture.

Preovulatory follicles physiologically differ from subordinate follicles in their cohort in that they have a more extensive and permeable capillary network.⁴³⁻⁴⁵ The vascular development surrounding the dominant follicle presumably facilitates accumulation of more circulating gonadotropins and achieves preferential development, whereas other follicles in the cohort are committed to atresia (Fig. 31-3*A* and *B*). The patterns and changes in blood flow around preovulatory follicles and, during ovulation, have been demonstrated by color flow Doppler ultrasonography in natural cycles and assisted reproductive technology (ART) cycles.⁴⁶⁻⁴⁸ Follicles imaged after the LH surge and before ovulation showed pronounced changes in their peripheral vascular flow. There was increased flow at the base of the follicles and concomitant flow at the apex of the follicles, consistent with histologic and ultrasonographic studies of preovulatory follicles.^{44,49} It appears that there is a very gradual decrease in impedance to blood flow in the vessels

FIGURE 31-3. Color flow and power Doppler images demonstrating perifollicular vascularity in imminently preovulatory follicles (A,B). Visualization of full vascular flow around the follicle is challenging owing to the tortuous path of the vascular supply to the dominant follicle.

immediately surrounding the follicle as the interval to ovulation decreases. Immediately before ovulation, the perifollicular vessels are easily identified and spectral Doppler flow wave forms may be generated. It remains unclear whether the enhanced vascularity in dominant follicles is a cause or reflection of selection or has any utility in predicting the quality of the oocyte it may contain in humans. It has been proposed that Doppler investigation of individual follicles may provide a direct indication of the health of the follicle and developmental competence of the oocyte.⁵⁰ In addition, there is a preliminary indication in an animal model that computer-assisted image analysis may be useful in assessing the probability of a follicle containing a competent oocyte.⁵¹ Assessment of perifollicular vascularity is beginning to be used in clinical ART settings.^{50,52} The clinical utility of assessing perifollicular vascularity appears to be controversial at present. Some studies have demonstrated a relationship between perifollicular vascularity and pregnancy rates;

however, others have not found a positive indication for incorporating this endpoint into assessment of the follicles in clinical ART at present.^{52,53} Similarly, there were no differences found in perifollicular vascularity of poor responders versus normal responders to ovarian stimulation in clinical IVF cycles.⁵⁴ New three-dimensional power Doppler imaging is able to generate outstanding images of the follicles before oocyte retrieval; however, their interpretation and clinical utility remain elusive.

Clinically, serial ultrasonography and assessment of circulating estrogen levels have potential in the isolation and identification of the root causes of follicular phase defects. Follicles may develop, and circulating estradiol concentrations appear to be within clinically normal limits for the follicular phase of the cycle; however, ultrasound examination may reveal the absence of a dominant follicle of preovulatory diameter. Alternatively, ultrasound examination during the late follicular phase of a spontaneous menstrual cycle may reveal a follicle of preovulatory diameter (e.g., 22 mm), yet the patient may exhibit clinically low estradiol concentrations. Follicles with this pattern of growth and regression have an thin, atretic appearance of the follicle wall, seem flaccid, fail to ovulate and subsequently regress⁵⁵ (Fig. 31-4A). When combined with our new knowledge of follicle wave patterns in women, serial ultrasonography and assessment of circulating hormone levels might be used to identify subtle defects in follicular recruitment, development, physiologic selection, final maturation, and ovulation. It seems reasonable that disturbances in the continuum of folliculogenesis may be responsible for much infertility previously classified as idiopathic.

Ovarian Endometriomas

Endometriosis is probably the most common benign gynecologic disease and has been estimated to be present in 10% to 25% of women with gynecologic disease and is detected in approximately 40% of women presenting with infertility.⁵⁶ Endometriosis is broadly defined as the presence of functional endometrial tissue outside the uterine cavity. There are several types of deposits, including plaques, implants, nodules and endometriomas. An endometrioma is a cystic structure that is lined with endometrial epithelium. Although most types of diffuse endometriosis may not be identified with ultrasonography, endometriomas are easily identified structures associated with infertility. Endometriomas are typically hypoechoic, multiple or single, cystic-appearing lesions that vary in size and have a low amplitude uniform echotexture in the cavity of the cyst. They appear to compromise normal ovarian function by disrupting folliculogenesis, ovulation, and normal ovulation (see Fig. 31-4B and C).

Ultrasonography is now being used as a part of therapy to ameliorate the effects of endometriomas when they are diagnosed. The technique involves ultrasound guided drainage of the endometriomas followed by treatment with a recombinant interleukin-2 under chronic administration of gonadotropin-releasing hormone (GnRH) analogs to suppress the response of endometrial tissue.⁵⁷ Results of this new therapeutic intervention appear promising.

Dermoid cysts (ovarian cystic teratomas) are the most common ovarian pathology in young women of reproductive age.⁵⁸⁻⁶⁰ The ultrasound appearance is broad; however,

FIGURE 31-4. A. Atriotic follicle of preovulatory diameter. Note the thin follicle walls and acute fluid-follicle wall transition. The follicle is impinged on by small peripheral follicles. B and C. Ovarian endometriomas demonstrating hypoechoic cystic structures with low amplitude uniformly distributed echotexture in the cavity of the cyst. D. Image of a small intraovarian dermoid cyst. The cyst is completely imbedded in the ovary and is surrounded by hyperechoic foci. Small follicles are observed in the surrounding stroma. Folliculogenesis and ovulation were impaired in this ovary. The contralateral ovary demonstrated compensatory hypertrophy. E. Image from a women in premature ovarian failure. Only the stroma of the ovary is identified. Some follicles smaller than 1 mm in diameter may be observed on the inferior aspect of the ovary.

most have evidence of hyperechoic tissues in a loosely organized mass.⁵⁹⁻⁶¹ In many cases, the dermoid mass may be completely imbedded in the ovary and not be detectable on laparoscopy (see Fig. 31-4D). Doppler flow characteristics of dermoid cysts are interesting in that vascular flow was detected in only approximately 24% of women in which they had been diagnosed.⁶²

Assessing Ovarian Reserve

Changes in demographic trends in the age at first pregnancy in our society have combined to yield more and more women wishing to conceive when they are older and less fertile.⁶³⁻⁶⁶ Numerous studies in recent years have demonstrated that fertility declines progressively as age advances. In ART, the main focus in determining the starting dose of gonadotropin for ovarian stimulation and prediction of the ovarian response is an assessment of what is termed the ovarian reserve. Ultrasonography is now being used to investigate follicular dynamics in aging women, as are detailed endocrine based tests.⁶⁷⁻⁷⁰ One focal point currently rests on day 3 antral follicle counts and FSH levels; however, the notion of day 3 follicle counts may need to be reconsidered in light of our new understanding of normal folliculogenesis.^{9,13} Decreased ovarian reserve, or number of follicles capable of being stimulated, is a primary reason for poor response to ovarian stimulation.⁷¹ The role of decreased numbers of antral follicles as women age relative to the capacity of the oocyte to be fertilized remains unclear.⁷⁰⁻⁷² The ovarian response to exogenous gonadotropin stimulation does decrease with age, but the range of individual variation is wide and age is only one part of the rough estimate of ovarian reserve and ovarian stimulation response.^{68,70-73}

There are several tests of "ovarian reserve" that include clomiphene citrate challenge and the GnRH agonist stimulation tests.^{67-70,74,75} Ovarian biopsy is also an option, although its use remains controversial.^{69,76} The endocrine tests offer prognostic information valuable in the counselling of aging infertile women.⁷⁰ However, there is accumulating evidence to suggest that ultrasonography may be used to estimate the number of antral follicles at specific times of the menstrual cycle and provide additional useful information of clinical relevance.^{67,77-79} Ultrasound assessments take place using antral follicle counts or measurement of ovarian volume. Antral follicle counts, typically done on days 3 to 7 after menstruation, may be used to predict the number of follicles likely to develop during ovarian stimulation.⁷⁹⁻⁸³ Women having fewer than five follicles smaller than 10 mm in diameter before ovarian stimulation have a greater chance of a poor ovarian response.⁸² The extent to which antral follicle counts correlate with endocrinologic measures of ovarian reserve (e.g., cycle day 3 FSH and estradiol concentrations) remains to be widely confirmed.^{67,68,73,78,84}

Ovarian volume assessments are based on the presumption that there is a significant correlation between the population of primordial follicles remaining in the ovary and the volume of the ovary, measured using either 2- or 3-dimensional ultrasonography.^{68,73,77,80} A very clear relationship between decreased ovarian volume and antral follicle counts and advancing age combined with increased FSH has been demonstrated.^{70,78} The ovaries in women with premature

ovarian failure have the characteristic appearance of women in menopause. The ovaries are small and show no evidence of follicular activity other than what might be perceived as follicles smaller than 1 mm around the periphery of the cortex (see Fig. 31-4E).

Although ultrasonography remains an important aspect of ovarian reserve estimation, understanding folliculogenesis in older women and attempts to predict the probability of a successful ovarian stimulation cycle, it is important to note that a recent study did not support the routine clinical use of any of the current ovarian reserve tests.^{68,72,73,82,84,85}

Determining Optimal Timing for Insemination

Ultrasound monitoring of dominant follicular development is being used to more precisely define the time of ovulation and estimate the optimum time to schedule intercourse or perform IUI, when indicated, in both spontaneous and stimulated cycles. Ultrasonography is far superior to simple monitoring of basal body temperature (BBT) or urinary LH excretion. Our ability to estimate the interval to ovulation is based upon detailed ultrasound based studies of preovulatory follicle growth from different diameters and detailed knowledge of follicle growth rates.^{12,25,86,87} During natural menstrual cycles, preovulatory follicles grow at approximately 1.6 mm per day and the mean diameter on the day before ovulation is 21.7 mm. In ovarian stimulation cycles, follicles grow slightly faster 1.8 mm per day, but the diameter on the day before ovulation is similar.²⁴ Given the relatively brief interval for which sperm remain functionally viable after IUI and the considerable costs involved, including ovarian ultrasonography is helpful in maximizing the effectiveness and efficiency of even the less invasive ART treatments. Definitive studies in humans have apparently not been done; however, in the equine animal model, ultrasonography is highly effective in estimating the interval to ovulation. Taken together, the data from detailed human studies and evidence from experimental animals would presume that accurate estimates may be easily calculated.^{13,23-25,88}

Ovarian Vascular Flow

The ovarian vessels may be visualized as they enter the ovarian hilus, and the intraovarian vascular supply also may be visualized. The ovary bearing the preovulatory follicle or corpus luteum exhibits lower resistance to blood flow than the vessels of the contralateral ovary based on spectral Doppler studies. The lowest impedance to blood flow occurs on the day of the LH peak while highest resistance to blood flow was observed on day 1 of menses.⁸⁹ However, a clear relationship between estradiol, progesterone, and other circulating hormones and the vascular indices of the ovarian and uterine arteries was not identified in a subsequent study.⁹⁰ Research is just beginning on the assessment of echotextural characteristics and vascular patterns of individual preovulatory follicles to evaluate the probability of ovulation or containing biologically competent oocytes.^{50,51,91}

Color flow and power flow Doppler ultrasonography in two and three dimensions has been used to evaluate ovarian blood flow during ovarian stimulation before oocyte

FIGURE 31-5. Sequence of images of ovulation. This ovulation occurred over 11 minutes and 30 seconds from the first detected fluid leakage to complete apposition of the follicle walls. Images range from 1 minute before the onset of ovulation to complete follicular evacuation. Time-code values are shown in the lower left corner of each image displaying hours, minutes, seconds, and frame number. (Reprinted with permission from Hanna MD, Chizen DR, Pierson RA: Characteristics of follicular evacuation during human ovulation. *J Ultrasound Obstet Gynaecol* 4:488, 1994.)

retrieval for in vitro fertilization (IVF) and an attempt has been made to associate ovarian vascular indices with IVF outcomes.^{50,92-95} In an initial study, peak velocity measurements and resistive indices decreased as the diameter of the follicles increased, consistent with the idea that the vascularity of the follicles increases as the interval to ovulation decreases. However, the ovarian vascular indices were not useful for predicting the outcome of IVF cycles.⁹³ Later studies reached the conclusion that there is indeed a physiologic relationship between follicular vascular indices and the clinical outcomes of assisted reproduction cycles.^{50,94,95} A strong correlation has been observed between oocyte recovery rates and the level of follicular vascularity, and it has been proposed that perifollicular blood flow may be indicative of the appropriate time for human chorionic gonadotropin (hCG) administration for optimal recovery rates.^{48,95-97}

Ovulation

Ovulation occurs on approximately day 14 after menstruation in a classically described textbook 28-day menstrual

cycle.^{21,44,98,99} The first uses of ultrasound scanning in gynecology revolved around trying to understand ovarian function and ovulation.³⁶ Transabdominal ultrasound scanning has been used for many years to detect ovulation in women. Visualization of follicle rupture and evacuation of the follicular fluid and cumulus/oocyte complex has only recently been demonstrated by ultrasonography^{100,101} (Fig. 31-5). The time required for ovulation appeared to vary from less than 1 minute to more than 20 minutes from the time that the first fluid leakage was observed until the walls of the former follicle were completely apposed. On average, follicular evacuation appeared to take approximately 10 minutes. However, the site of follicular evacuation/new corpus luteum was immediately detectable. The point of follicular rupture from the surface of the ovary was recognized for up to a week and the corpus luteum typically remains identifiable until the subsequent ovulatory cycle.^{100,102}

Following ovulation in normal cycles, the corpus luteum develops. Evaluation of the ovulations and period of early luteogenesis in normative control patients and patients referred for idiopathic infertility is revealing previously

unknown information regarding normal luteal function and undescribed flaws in the ovulation and luteogenesis.^{100,102-105}

Ovulation Failure

Failure of ovulation most probably occurs by one of two mechanisms, although several more mechanisms probably exist. The luteinized, unruptured follicle syndrome (LUF) has been debated; however, transvaginal ultrasound has been used for detailed descriptions.^{46,49,106} In ovulatory failure, dominant follicles attain preovulatory diameter and fail to rupture and extrude oocyte/cumulus complex. The oocyte/cumulus complex appears to remain within the lumen, the walls of the follicle thicken and acquire image attributes suggestive of luteal tissue (Fig. 31-6). The follicle wall-follicle fluid acquires hazy, indistinct borders. The LUF remains identifiable for the duration of the menstrual cycle and regresses typically by the subsequent menses. Basal body temperature charts and mid-cycle progesterone concentrations are typically within low clinically normal limits. Menses may be normal or somewhat lighter than normal for individual patients.

Alternative mechanisms for ovulatory failure involve the growth of the dominant follicle to a larger-than-usual diameter without ovulation.¹⁰⁶ In some cases, the capillaries in the follicle wall appear to fenestrate and extravasate blood into the follicular lumen. This is referred to as a hemorrhagic anovulatory follicle (HAF) (Fig. 31-7A and B). The follicular fluid of other anovulatory follicles remains clear and the fluid-follicle interface becomes acute (see Fig. 31-7C). There apparently is no luteinization of the follicular wall, which appears thin and highly echoic. In some cases, the granulosa cells around the interior of the follicles delaminate and float in the follicular lumen as the follicle regresses (see Fig. 31-7D and E). Mid-cycle progesterone values are below clinically normal. These types of anovulatory follicles typically remain static for one to several days and then begin to regress. The rates of follicular regression are to be highly variable. Menstrual periods following this type of ovulatory failure typically occur within a normal cycle length, although the amount of flow appears variable.

The use of ultrasonography to monitor follicular growth and confirm the occurrence of ovulation or ovulatory failure is becoming clinically useful. When considered along with well-timed circulating hormone levels, ultrasound offers answers to subtle problems in ovulatory dysfunction by the practicing clinician.

Corpus Luteum

The corpus luteum (CL) is a dynamic endocrine gland within the ovary that plays an integral role in regulation of the menstrual cycle and early pregnancy. The CL forms from cells of the ovarian follicle wall just before, during, and after ovulation. The precise origin of the cells that comprise the luteal gland remains controversial. However, it is believed that luteal cells originate from the theca and granulosa cells following breakdown of the basal lamina immediately before follicle rupture.¹⁰⁷ The CL undergoes profound neoangiogenesis during its development, is dependent on vascular flow for normal function, and exhibits degradation of the vascular supply during regression if the woman does not

conceive or during the late stages of gestation in pregnant women.^{107,108} The cyclic and temporary nature of the CL, its profound vascularity and its critical physiologic role regulating folliculogenesis, and the establishment and maintenance of pregnancy all make the luteal gland a primary target for assessment in infertility investigations.¹⁰⁴

The human CL was first studied in the 1950s using histologic evaluation of ovaries following hysterectomy and salpingo-oophorectomy.¹⁰⁹ Ultrasonography has since become an invaluable tool for evaluating the CL in vivo. It has been reported that the CL grows to a maximum diameter of 25 to 40 mm during the luteal phase, as determined by transabdominal ultrasonography.^{110,111} Some CL were reported to exhibit a "cystic cavity," whereas others did not.¹¹⁰⁻¹¹² Histologic evaluation of the CL revealed that there was fresh bleeding into the central cavity following follicle rupture.¹⁰⁹ The blood-filled CL is referred to as the 'corpus hemorrhagicum.' Growth of the CL is associated with an increase in luteal blood flow and serum progesterone concentrations.¹¹²⁻¹¹⁵ Peak luteal vascularity appears to occur 7 days after ovulation, the approximate day of maximal progesterone secretion.¹¹⁵

Ultrasonographic detection of the CL following ovulation has been reported to occur in only 50% to 80% of natural menstrual cycles in the earliest studies.^{110,112,116} However, later studies designed to visualize ovulation and study folliculogenesis have shown that the CL may be detected on the day of ovulation and throughout the luteal phase^{13,100,102,117} (Fig. 31-8). Immediately following follicular evacuation, the walls of the former follicle become highly vascularized in the first 48 to 72 hours. Blood and lymphatic vessels colonize the developing CL, and there is typically a pronounced ring of vascularity, which appears to follow the path of the vascular supply surrounding the former preovulatory follicle. The vascular ring becomes more apparent as the corpus luteum matures and is visually spectacular color or power flow Doppler interrogation (Fig. 31-9). The grayscale values for the CL follow the vascular perfusion of the gland.^{102,114,118} The luteal tissues are dark during luteogenesis and become progressively lighter shades of gray during luteal regression. Resistance to vascular flow is usually low as would be expected of an active endocrine tissue during the period of active progesterone secretion during the estrous cycle and during early pregnancy.

Two morphologic types of luteal glands were observed following ovulation: those with, and those without, a central fluid-filled cavity.¹⁰² Most CLs contained a fluid-filled cavity at some time during their life span. Central fluid-filled cavities were attributed to the leakage of blood into the follicular lumen following follicle rupture. The cavities were most likely to be observed immediately following ovulation and then subsequently declined. Therefore, the detection of a fluid-filled cavity in the CL was interpreted to be a normal physiologic event during the menstrual cycle resulting either from vascular leakage into the developing CL or extravasation of blood during luteogenesis. The corpus albicans may typically be visualized following luteal regression at least until the time of subsequent ovulation.¹⁰² Several corpora albicantia from previous cycles may occasionally be observed in the ovaries; however, visualization of these small structures may be dependent on the location of small follicles surrounding the regressing structures (Fig. 31-10).

FIGURE 31-6. A to F Sequence of images of luteinized unruptured follicle (LUF) development. The woman was participating in a study of ovulation and its relationship to the LH surge. Images here were recorded at 19 hours, 32 hours, 39 hours, 43 hours, 62 hours, and 96 hours after the LH surge, respectively.

FIGURE 31-7. *A* and *B.* Images from two women who developed hemorrhagic anovulatory follicles during a study of natural cycle folliculogenesis and ovulation. There is evidence of extravasated blood in the lumen of the structures, and the walls did not develop any visual evidence of luteinization. Progesterone levels were less than those accepted as clinically normal. *C.* Failure of ovulation and development of "cystic" follicle. Thin follicle walls are observed and small flecks of particulate matter are frequently seen in the lumen. *D* and *E.* In some cases of ovulatory failure, the granulosa cell layer delaminates and floats within the follicular lumen. Different types of cellular debris and epithelial sheets are frequently observed.

FIGURE 31-8. A and B. Color flow and power Doppler images of luteal glands visualized on the day of ovulation.

FIGURE 31-9. A to D. Color flow (A) and power Doppler images of new corpus luteum CL (B) and mature, mid-cycle luteal glands (C, D). Note the convolutions of the luteal wall in the power Doppler image of the developing CL.

FIGURE 31-10. A and B. Images of corpora albicantia (CA) from previous cycles. CA are visualized as hyperechoic structures (arrows) within the ovary.

Limited information on the serial characterization and correlation of luteal morphology and endocrinologic function during spontaneous menstrual cycles is available; however, luteal area, progesterone concentration, and estradiol concentration increased for approximately the first 6 days following ovulation, followed by a subsequent decline.^{102,103,114} The period of peak indicators was well correlated with the approximate time of maternal recognition of pregnancy. The vascular flow characteristics follow the decrease in luteal area and volume and decreasing progesterone levels as luteal regression ensues. The color flow mapping patterns become much less pronounced, and increased resistance to flow is observed. Definitive studies of the vascular dynamics within the corpus luteum have apparently not yet been performed; however, this is a promising research area with profound ramifications to infertility assessments, maternal recognition of pregnancy and etiology of early embryonic loss.^{103,104,114,118-122}

Color Doppler imaging combined with high-resolution grayscale ultrasonography in two and three dimensions now

allows evaluation of the functional development of luteal gland,^{102,104,111,115} Doppler imaging lends us the ability to visualize blood flow in very small vessels and assess the resistance to flow as an indicator of physiologic function.^{114,115}

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is a broad-spectrum metabolic disorder that commonly results in oligomenorrhea and anovulation.¹²³ In many women, it is also a cause of infertility.¹²⁴⁻¹²⁶ Many of the women present with hyperandrogenism and menstrual disorders, and it is interesting to note that many women do not appear to have a diagnosis of PCOS until they are referred to a reproductive endocrinologist for infertility; however, the disorder has many personal health consequences that should be addressed well in advance of an infertility referral.¹²⁵⁻¹³² Ovarian function in women with PCOS is poorly understood.¹³³ The patterns of follicular turnover, initiation of follicular growth, and physiologic selection of a dominant follicle differ markedly from women with normal folliculogenesis and menstrual function.¹²⁹

The diagnosis of PCOS is traditionally made on clinical history and endocrine assessment, and there is now an ongoing discussion on the merits of classifying women with the disorder on the basis of endocrine and metabolic criteria versus ovarian ultrasound based criteria.^{124,126,134,135} The classic “string-of-pearls” ultrasonographic appearance of the ovaries of a PCOS patient strongly supports the clinical diagnosis. In many cases, PCOS may be identified solely on the ultrasonographic morphology of the ovaries; however, the metabolic disorder may be present in a woman with normal-appearing ovaries, and women with ovaries profoundly suggestive of PCOS on ultrasound examination may appear to be phenotypically normal.^{125,134}

The ultrasonographic morphology of PCOS ovaries has been described and the attributes of PCOS morphology are being constantly updated as subtle differences in endocrine profiles are elucidated.^{124-126,129,134} (Fig. 31-11). PCOS is emerging as one of the most active areas of research in reproductive endocrinology, and the literature is literally exploding as research and clinical experience with the condition increase.¹³⁶ Ultrasonography is considered the gold standard for the detection of polycystic ovaries, but there is considerable challenge in developing a standardized definition of the ovarian appearance of PCOS ovaries.¹³³ Several definitions for the ultrasound definition of PCOS were considered before 2002.^{134,137} Increased stromal echogenicity appeared to be the most consistent finding among polycystic ovaries; however, evolving definitions have primarily focused on ovarian volume and follicle numbers, which are considered less subjective than stromal echogenicity in their appraisal.

Definition of Polycystic Ovary Syndrome Morphology by Ultrasonography

A clear, working definition of PCOS ovarian morphology has emerged from a series of studies leading to a consensus definition. A set of diagnostic criteria was developed in 2000 which was somewhat more intermediate than that previously reported.¹³⁴ The criteria included an ovarian volume greater

FIGURE 31-11. A to F. Images from women with differing expressions of the metabolic syndrome associated with polycystic ovary syndrome (PCOS). There are differing ultrasonographic appearances in the size and distribution of follicles within PCOS ovaries.

than 9 cm³, more than 10 follicles between 2 and 8 mm, and increased stromal echogenicity. Subsequently, a new set of criteria were developed that have become widely accepted.¹³⁸ This definition of the PCOS ovary includes increased ovarian stroma of greater than 5.5 cm² or a volume greater than 11 cm³ and detection of more than 12 follicles between 2 and 9 mm in diameter (mean of both ovaries). At present, the Rotterdam consensus workshop on PCOS definitions represents our best means of defining PCOS on ultrasound examination.¹³⁹ The consensus committee has abbreviated the 2003 definition of PCOS ovaries to having 12 or more follicles measuring 2 to 9 mm and an ovarian volume greater than 10 cm³.¹³⁹

Ovulation Induction in Women With Polycystic Ovary Syndrome

Ovulation induction in women with PCOS is challenging owing to the range of metabolic disorders with which patients present. Some women attain menstrual regularity and ovulatory function with the administration of metformin, an insulin-sensitizing drug, but others are nonresponsive (Fig. 31-12A and B). Restoration of menstrual cyclicity and ovulation induction strategies must be designed with the particular phenotype in mind.^{125,126,144,147,148} Ovulation induction with mild or more potent ovulation inducing agents, such as clomiphene citrate or recombinant follicle-stimulating hormone, respectively, are typically used and may or may not be followed by administration of low-dose recombinant human chorionic gonadotropin (rhCG) to initiate ovulation.^{147,149,150} GnRH agonists also may be used to help ameliorate the possibility of ovarian hyperstimulation syndrome (OHSS).¹⁵¹ The ovarian response varies as widely as the metabolic disorder.¹⁴⁷ Some women with PCOS are refractory to clomiphene citrate, and others exhibit an exaggerated response to even the smallest doses of rFSH.^{129,147,152} Regardless of the ovulation induction strategy employed, serial transvaginal ultrasonography is an extremely important adjunct in assessment of the ovarian response to the pharmaceutical agents used in ovulation induction of women with PCOS due to the heightened risk of OHSS.¹⁴⁷

Oviduct (Fallopian Tube)

The oviduct is difficult to visualize under normal circumstances because of the surrounding bowel and the similarities in tissue characteristics. However, it is possible to identify the oviduct from the uterine cornu, through the broad ligament, to the infundibulum in most patients (Fig. 31-13). The entire length of the oviduct is identifiable following hysterosalpingography (HSG) in women with patent oviducts. Similarly, visualization of the fimbria is more easily done following ovulation when collections of free fluid in the cul-de-sac help to outline the delicate fimbrial ends floating in the fluid (Fig. 31-14). Women with severely retroverted uteri or distended bowel present the most difficulty in imaging of the oviduct. The physical location of the uterus in the pelvis or having the oviduct surrounded by bowel containing gas pockets may render it nearly impossible to visualize. It is important to be able to develop the skill to visualize the entire oviduct from the uterus to the fimbria adjacent to the ovary consistently because transvaginal ultrasonography is

FIGURE 31-12. A and B. Images from patients with PCOS demonstrating recent corpus lutea. The patients' ovulatory and menstrual functions were restored with the administration of metformin.

the standard technique used to search for and evaluate early ectopic pregnancies.

Oviductal Pathology

Hydrosalpinx is easily diagnosed using transvaginal ultrasound.¹⁵³ Fluid accumulation in the oviduct appears as anechoic areas within the defined contours of the oviduct (Fig. 31-15). If hydrosalpinx is diagnosed, there are really only two treatment options available for the patient. Surgical repair of the distal oviduct is a delicate operation and is appropriate only for patients whose mucosa remains intact. IVF appears to be the option of choice; however, the rates of implantation and clinical pregnancy are generally lower in patients with ultrasonographically visible hydrosalpinges undergoing IVF and embryo transfer. Such patients may be appropriately treated before undergoing ART. In a randomized controlled clinical trial, patients who had prophylactic salpingectomy before IVF had significantly increased pregnancy and live birth rates.^{154,155} Typically, the dilated infundibulum and ampulla, apparently contiguous with the ovary, are seen. Small, nonpathologic aggregates of fluid

FIGURE 31-13. *A.* Image of the oviduct from the uterine cornu to the fimbria. *B.* The ampulla, infundibulum, and very fine interfaces representing the fimbria may be appreciated on the superior aspects of the ovaries (outline).

FIGURE 31-14. *A* and *B.* The fimbriated ends of the oviduct (arrow) are clearly visualized in free fluid surrounding the ovary following ovulation or hysterosalpingography.

may also be identified in the oviduct immediately following ovulation, intrauterine insemination, or saline-enhanced ultrasound examination.

If sufficient free fluid is present in the cul-de-sac, peritubal and periovarian adhesions may be visualized as hyperechoic foci or filmy strands when outlined by the fluid. Tubal lesions may be appreciated as irregularities, or swellings, on the otherwise smooth surface of the oviduct. In one case report, an oviductal torsion was identified preoperatively and followed allowing an appreciation of the ultrasound features associated with this rare condition.¹⁵⁶

Uterus

The endometrium undergoes dramatic morphologic changes mirroring the changes in ovarian follicular development and

luteal function in the ovaries during normal menstrual cycles. The endometrial detail that may be appreciated with high-resolution transvaginal ultrasonography is striking. The inner and outer strata of the endometrium may be clearly identified. The changes in echotexture of the stratum spongiosum during the follicular and luteal phases of the menstrual cycle are directly related to the circulating concentrations of estrogen and progesterone, and may be used as a bioassay from which to infer ovarian function¹⁵⁷⁻¹⁶¹ (Fig. 31-16).

The endometrium appears ultrasonographically as a thin, simple hyperechoic single stripe immediately following menses (A pattern). The stratum functionalis and basalis layers can be visually differentiated as the endometrium develops during the mid-late follicular phase (B pattern). A pronounced triple-line echotextural pattern, reflective of the

FIGURE 31-15. A and B. Hydrosalpinx is usually easily diagnosed as well-constrained fluid accumulation in the adnexae. In some cases, adhesions between the oviduct and ovary are visualized.

separation of the stratum basalis and functionalis layers, is observed in the periovulatory period in association with rising estradiol levels (C pattern). The triple-line pattern disappears after ovulation. After ovulation, the endometrium becomes progressively thicker and increases in echogenicity and a more homogeneous hyperechoic endometrium is observed as endometrial glands branch and expand under the influence of luteal progesterone in the secretory phase (D pattern). Visualization of active menstrual flow is indicative of menses (M pattern).^{157,161,162} The changes in echotexture of the endometrium are well correlated to the plasma estradiol levels and defined morphologic criteria, providing an instant bioassay of its functionality.

The degree of synchronicity between the ovaries and uterus may be indicative of subtle defects in reproductive hormone production or action.^{161,162} The presence of dominant follicles of preovulatory diameter combined with a thin, hyperechoic uterus would indicate potentially low levels of circulating estradiol. Similarly, endometrial hypertrophy in the absence of appropriate ovarian structures may be indicative of other clinical problems. The accuracy of ultrasonographic staging of the endometrium is 76% to 93% when compared with classic histologic dating.¹⁶² It is important to remember to integrate the findings of the ovarian and uterine examinations; full luteal function is expected when the endometrium is at least 11 mm in thickness during the mid-luteal phase.

Measuring the Endometrium

One highly variable endpoint in measuring the thickness of the endometrium appears to be the locations at which the measurement were taken and clear knowledge of exactly which layers to be measured. To clarify this issue, endometrial measurements should be taken using a line drawn from the endometrial-myometrial interface, on the superior to inferior aspects of the endometrial cavity, within 5 to 10 mm of the fundal aspect of the endometrium.¹⁶¹

Using this clearly defined location, endometrial thickness changes for the menstrual cycle in clinically normal women are demonstrable and are clearly responsive to the circulating levels of reproductively active hormones.^{161,163,164}

Myometrium

The myometrium apparently does not exhibit easily identifiable changes during the menstrual cycle. The echotexture appears homogenous throughout the body of the uterus. The vasculature of the uterus is distinct, especially at the interface with the broad ligament. Blood vessels in women who have previously been pregnant are demonstrably larger than those of nulligravida women and should be noted in women experiencing secondary infertility.

Uterine Abnormalities

The American Society for Reproductive Medicine has a standardized classification scheme for müllerian anomalies that serves as the starting point for characterizing the broad spectrum of anomalies seen in clinical practice (Fig. 31-17). Congenital abnormalities in the uterine cavity may be diagnosed using high-resolution transvaginal ultrasonography and may contribute to infertility by repeated early pregnancy loss.^{165,166} Although HSG is the usual infertility investigation dedicated to the diagnosis of uterine cavity abnormalities, it is possible to screen for anomalies such as an arcuate, unicornuate, bicornuate, or septate uterus using transvaginal ultrasonography at the time of initial referral¹⁶⁵⁻¹⁶⁹ (Fig. 31-18). Differentiation between a septate and bicornuate uterus is challenging in two-dimensional ultrasonography. However, it is important to establish the exact nature of the anomaly because the septate and bicornuate uteri are able to be repaired; however, they require two different surgical approaches^{170,171} (Fig. 31-19). Uterus didelphys may also be visualized as complete separation of the uterus and oviducts.¹⁷⁰

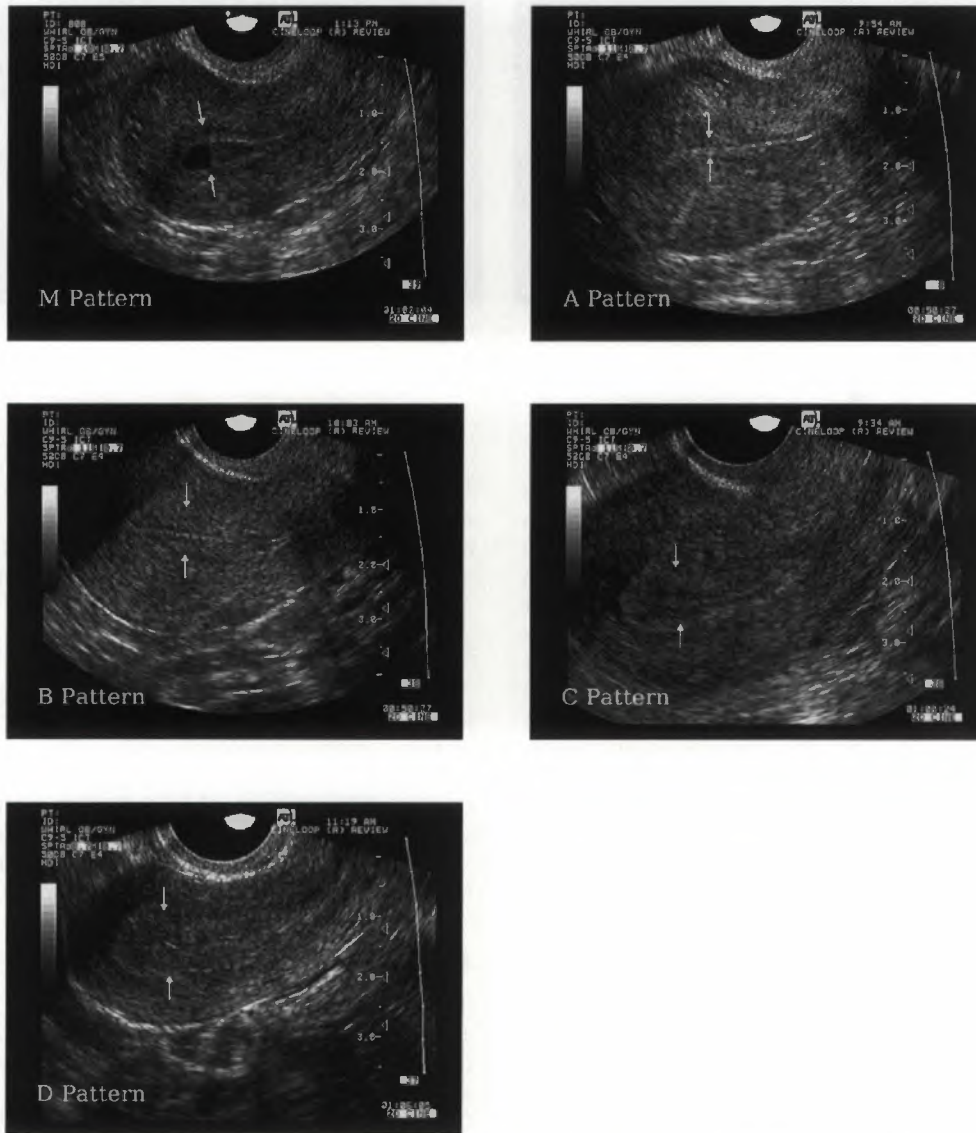

FIGURE 31-16. Ultrasound images of the uterus taken in the mid-sagittal plane showing the five primary patterns of endometrial development (M, A to D). For orientation, the cervix is located just out of the image to the right of the image and the fundus is seen to the left of the image. Evidence of active menstrual bleeding is observed within the uterine lumen (M). A thin, simple hyperechoic single stripe seen immediately following menstruation (A). Early follicular phase triple-line pattern indicative of increasing estradiol levels (B). Late follicular phase pronounced triple-line pattern with distinct separation of the stratum basalis and stratum functionalis observed with the high estradiol levels associated with the periovulatory period (C). Postovulation heterogenous, fully secretory endometrial pattern indicative of luteinization and exposure of the endometrial tissues to progesterone (D). Arrows identify the stratum basalis–myometrium interface. FIGURE 31-20. Saline enhanced ultrasonographic image of a bicornuate uterus in transverse plane.

FIGURE 31-19. Profound bicornuate uterus with a pregnancy established in the right uterine horn. Indentation of the serosal surface is clearly visualized.

If an anomaly is suspected following ultrasonographic examination, definitive HSG or MRI may be performed. The advantages of this approach are that ultrasonography is noninvasive, is performed without contrast dye or ionizing radiation, and reduces the potential chance of infection. MRI may subsequently be used to add anatomic detail that is not currently possible with ultrasonography (Fig. 31-20). Saline-enhanced ultrasonography or hysterosalpingo-contrast sonography may provide additional diagnostic information regarding intrauterine morphology and recognition of abnormalities such as septae, polyps, synechia, adhesions, or submucous myomas. In addition, a color flow Doppler investigation may be used to identify the vascular supply to various portions of the uterus, and it may be valuable to map vascular areas of a septum before resection.

FIGURE 31-21. A to D. Intramural leiomyomata are frequently visualized. Examples of fibroids that compromise the contours of the endometrial cavity are shown.

Fibroids (Leiomyomata)

Imaging uterine lesions has been greatly enhanced with the use of transvaginal ultrasonography.^{165,169,172} Leiomyomata are frequently diagnosed in the myometrium, and their location and size may be mapped. The location of each fibroid and its relationship to the endometrial cavity are important considerations in infertility investigation (Fig. 31-21). Leiomyomata located in the cornu may exert pressure and effectively occlude the intramural portion of the oviduct. Similarly, fibroids that significantly alter the contour of the uterine cavity may affect the ability of an embryo to implant. Changes in the diameter and echotexture of leiomyomata in consecutive examinations may be assessed following surgical removal or GnRHa analog therapy to reduce their size. Although correlations between the presence of leiomyomata with infertility or repeated embryo loss are not clear, ultrasonography may help in elucidating putative mechanisms for the root causes of reproductive failure. It would also appear to be useful to establish a uterine map for localization of leiomyomata, especially concentrating on color flow Doppler evaluation of the vascular supply before

surgical excision. Similarly, it seems reasonable to use ultrasonographic evaluation in the decision-making process when medical treatment for size reduction is used prior to surgical removal.

Adenomyosis

Tremendous strides have been made using ultrasound in the diagnosis of adenomyosis, although definitive diagnosis probably still remains within the MRI realm.¹⁷³⁻¹⁷⁷ A combined approach of HSG and transabdominal ultrasonography has not been successful; however, adenomyosis has been successfully evaluated using transvaginal ultrasonography.^{172,178} Uteri that demonstrate marked heterogeneity that used to be considered myomatous are now often noted to demonstrate the typical findings of adenomyosis, including small cystic change as well as hyperechogenic areas and “venetian blind” shadowing in the myometrium. Color flow mapping with transvaginal ultrasonography may be useful in the assessment of adenomyosis in some specialized centers, although it remains out of the realm of routine evaluation.¹⁷⁹⁻¹⁸⁴

Gartner Duct Cysts

Gartner duct cysts range from 2 mm to 10 cm and are typically remnants of the embryologic wolffian duct system. Segmental failure of complete resolution of the mesonephric ducts during gestation may present in adults in the broad ligament as pockets of well circumscribed fluid along the cervix at the level of the vaginal wall. The ultrasound appearance is typically single or multiple roughly spheric hypochoic structures along the lateral margins of the cervix and uterus.

Nabothian Cysts

Nabothian cysts of various diameters are frequently noted at the external cervical os. The presence of these cysts is probably not noteworthy; however, the correlation of these small cystic structures with any aspects of infertility is not known.

Hysterosalpingosonography

Assessment of tubal patency and evaluation of the uterine cavity are a basic part of an optimal infertility assessment.⁷ Implantation failure, spontaneous abortion, or complications in the third trimester of pregnancy such as preterm labor, premature rupture of membranes, or malpresentation all may be caused by structural abnormalities or anatomic distortion of the uterus and endometrial cavity.¹⁸⁵ One estimate is that up to 10% of infertility may be related to uterine abnormalities and up to a 32% incidence has been reported in women with secondary infertility.^{186,187} The increased incidence most likely arises from acquired uterine abnormalities following first trimester abortion or operative delivery.

It is likely that hysterosalpingosonography will replace standard HSG in the evaluation of infertility for initial assessment of the uterine cavity and tubal patency. The accuracy of sonohysterography (SHSG) versus standard HSG for uterine cavity assessment has been evaluated in several studies.^{188,189} It is also now more frequently used in women being evaluated for abnormal uterine bleeding and recurrent pregnancy loss.¹⁹⁰ Overall, the sensitivity of SHSG is superior to that of HSG for diagnosing intrauterine abnormalities.¹⁹¹

Sonohysterographic Technique

SHSG is performed by instillation of physiologic saline into the uterine cavity through a catheter such as a specially designed SHSG catheter, pediatric feeding tube, or pediatric Foley catheter and visualization of the uterus with concurrent transvaginal ultrasonography.^{192,193} A pediatric Foley catheter is considerably less expensive but is less rigid than the SHSG catheter. SHSG performed with the Foley catheter usually requires the use of a tenaculum on the anterior cervix to ease transcervical catheter insertion. Catheters designed for SHSG can usually be inserted without using a tenaculum, which is typically more comfortable for the patient. An experienced transvaginal ultrasonographer is also an important component of a successful SHSG.

Saline is a negative (hypochoic) contrast medium and is used to distend the cavity and outline the endometrial lumen

while the cavity is evaluated. SHSG is best performed in the follicular phase of the menstrual cycle, after menstruation, but before ovulation.¹⁹⁴ Scheduling SHSG at this time obviates the possibility of dislodging an early pregnancy and reduces false-positive results due to endometrial sloughing or blood clots that may occur in the late luteal phase of the cycle.

SHSG is best performed with the patient in a semi-upright lithotomy position. A speculum is first inserted into the vagina, and the cervix is visualized and washed with an antiseptic solution. The SHSG catheter is inserted approximately 3 to 4 cm beyond the distal aspect of the insufflation balloon, which is generally adequate to ensure that the balloon is just beyond the internal cervical os. The balloon is inflated with approximately 1 mL of normal saline to stabilize the catheter and prevent leakage of fluid back through the cervix. Care should be taken at this step to ensure that air is not introduced into the balloon. Air will create significant reflection artifacts in the image. The speculum is then removed, and the catheter left in place.

The transvaginal ultrasound probe is then gently inserted into the vagina, and the catheter balloon placement confirmed just above the internal cervical os in a sagittal plane. Normal saline (processed for intravenous use) is slowly instilled while the cavity is examined in both sagittal and transverse planes (Fig. 31–22). Documentation of findings is done either by print images or electronic acquisition and storage of digital images.

Tubal distention with normal saline and flow from the fimbriated end should be observed directly in women with patent oviducts.^{192,195} Fluid collection in the cul-de-sac is also indicative of at least one tube being patent. Agitation of the saline before infusion can enhance visualization; the bubbles in the fluid makes it appear hyperechoic.¹⁹⁶ Saline agitation should only be done after the uterine cavity has been assessed because the reflectivity caused by the bubbles will make imaging detail much more difficult to visualize. Color flow Doppler in two- or three-dimensions may be added to the scanning protocol to assist in visualization of the movement of fluid through, and its exit from, the oviduct.^{197,198}

One of the advantages of SHSG is that it allows evaluation of the size, shape, and contour of the uterine cavity in both the sagittal and transverse planes, and concurrent examination of the ovaries and other pelvic anatomy. This allows both identification and localization of filling defects such as polyps, fibroids, and adhesions (Fig. 31–23). The ability to evaluate the exterior uterine surface with concurrent ultrasonography helps to differentiate between septate and bicornuate uteri, two of the most commonly identified abnormalities.¹⁷¹ The thickness of the septum and its relationship to the fundal myometrium can be measured when uterine septae are identified. The application of color flow or power Doppler interrogation helps assess the relative vascularity of the septum before resection. SHSG appears to be fully capable of replacing HSG for assessment of the uterine cavity, and a normal SHSG finding is almost as reliable as a diagnostic hysteroscopy.^{186,191,192,199,200} Endometrial polyps or adhesions measuring less than 2mm may be difficult to identify on SHSG; however, these are likely clinically insignificant.²⁰¹ Three-dimensional SHSG is also an option with the new generation of ultrasound

FIGURE 31-22. A to C. Images recorded during hysterosalpingosonography. Mid-sagittal image of the uterus showing optimal placement of the catheter and the saline-filled insufflation balloon (A). Sagittal and transverse images of a normal uterine cavity. The fluid-endometrium interface is smooth and symmetric.

instruments and add the ability to reinterrogate the volumetric data in many planes.²⁰² Coronal planes appeared to provide the most useful information in identifying relationships between lesions and the uterine cavity.

Contrast-Enhanced Hysterosalpingosonography

If tubal assessment with saline alone is unsatisfactory, a contrast medium such as Echovist can be used.²⁰³ Echovist is a positive contrast media that consists of a stabilized mixture of microbubbles mixed with microparticles of galactose that are highly echogenic. The purpose of contrast agents is to increase the delineation and identification of anatomic structures in the ultrasonographic image by enhancing visualization of the fluid that is used.¹⁶⁸ Contrast agents also enhance the visualization of flow from the fimbrial end of the oviduct because perturbation of the contrast media creates easily visualized swirls on the ultrasound image as it exits the oviduct.

ULTRASONOGRAPHY IN ASSISTED REPRODUCTIVE TECHNOLOGY THERAPY

Monitoring the Course of Ovarian Stimulation

Ovarian stimulation protocols vary tremendously and have evolved from fairly simplistic administration of exogenous hormones derived from urinary sources to quite sophisticated blends of GnRH analogs, recombinant FSH, and LH and other compounds. Ultrasonography is used to determine the direct effects of the stimulatory drugs on the ovaries in all ovarian stimulation protocols. Ovarian stimulation protocols are changing constantly as new knowledge is incorporated into clinical practice; however, the goal of each is to override the physiologic mechanism of selection of a single dominant follicle and facilitate the development of many follicles so that properly matured oocytes may be retrieved for use in the ART. Ultrasonography is essential in determining the

FIGURE 31-23. A to D. Images of endometrial polyps and adhesions recorded during hysterosalpingosonography. Sonohysterography is very helpful in identifying small and large lesions that are difficult to appreciate on unenhanced ultrasonography.

numbers and fates of individual follicles stimulated by exogenous gonadotropin at each step. It is essential to tailor the ovarian response of each woman to the stimulation protocol and the number of oocytes desired and balanced against clinical assessment of the risk of ovarian hyperstimulation. The daily doses of gonadotropins may be increased or decreased depending on the patient's response. The relationships between circulating estradiol concentrations and follicular diameter that we may infer from natural cycle studies often do not exist during ovarian stimulation. We understand that not all follicles probably contribute equally to estradiol concentrations in the systemic circulation and that not all follicles will give rise to physiologically competent oocytes.

In all of the ART ovarian stimulation protocols, regardless of their technical complexity in the laboratory, the timing of hCG or recombinant LH administration is critical to establish a time for oocyte retrieval which will yield the highest quality of oocytes in the proper stage of development with the highest probability of fertilization. Although transabdominal ultrasonography has been used historically,

transvaginal ultrasonography is now the standard that we have for monitoring the course of follicular growth and development.²⁰⁴ With ultrasonography, we have a rapid, noninvasive, and highly visual approach to following the fates of individual follicles and cohorts of follicles. When we combine our knowledge of natural ovarian physiology with concomitant assessment of circulating estradiol concentrations and oocyte development, we use this information to predict optimal timing for induction of the final stages of folliculogenesis and oogenesis and oocyte retrieval^{50,52,205-207} (Fig. 31-24A and B).

The final phases of follicular maturation before oocyte retrieval are typically triggered using hCG in its native or a recombinant form when the largest follicle attains a predetermined diameter (e.g., 18 to 20 mm). The timing of hCG administrations varies based upon the attending physician's feel for the patient's stimulation cycle and the logistics imposed by the embryology laboratory. A dose of 10,000 IU of hCG is most commonly administered, and oocyte retrieval is scheduled 30 to 34 hours thereafter. In centers that do ovarian stimulations followed by ovulation

FIGURE 31-24. *A* and *B*. Images recorded at the end of ovarian stimulation protocols. Four large follicles may be identified within the ovary; however, only one follicle is observed in its largest dimension (*A*). The other follicles are seen only in glancing section. Expanded cumulus-oocyte complexes are observed still attached to the follicle wall (*B*). *C*. Multiple ovulation sites may be visualized following ovarian stimulation and ovulation induction. In this image, four distinct sites of follicular rupture are visualized.

induction and intrauterine insemination, the fates of the follicles should be determined. The number of ovulations and ovulation failures are important to document in each stimulation cycle (Fig. 31-24C). Many programs use only ultrasonographic monitoring to determine the course of ovarian stimulation, and it has been demonstrated that including estradiol monitoring during the stimulation protocol seldom changed the timing of hCG administration and did not affect pregnancy rates or the risks of ovarian hyperstimulation syndrome (OHSS).²⁰⁸ Volumetric ultrasound has been employed to help identify patients at risk for OHSS based on new developments in three-dimensional ultrasonography. There was a significant correlation between three-dimensional volume of the ovary on the first day of ovarian stimulation and the subsequent occurrence of OHSS.²⁰⁹

The relationships between follicle size and oocyte maturity remain mysterious. Follicle size remains the best way to estimate oocyte maturity, and oocyte maturity is clearly an

influence on the probability of conception and the ability of an embryo to develop into a successful pregnancy.^{48,50,52,210-213} Although we know that mature oocytes yield the highest fertilization rates, through recent developments in the embryo laboratory, we know that in vitro maturation (IVM) and fertilization are viable ideas in ART practice.^{214,215} The role of ultrasonography in IVM-IVF protocols will very definitely revolve around the optimal timing of oocyte retrieval for optimal fertilization and cleavage rates.²¹⁵⁻²¹⁸ Ovulation has been reported from follicles as small as 14 mm, and oocytes collected from small follicles are certainly capable of being fertilized. In a recent study, oocytes from follicles less than 10 mm in diameter and IVM were used to increase the number of transferable embryos.²¹⁹

Power Doppler ultrasonography assessments of perifollicular vascularity are beginning to show promise in the prediction of ART cycle outcomes.^{48,50,52} When combined with knowledge obtained through research in animal models, we know that there is a correlation between computer-

assisted ultrasound image attributes of follicles and the ability of the oocyte to fertilize; however, similar studies in humans have apparently not yet been completed.⁵¹

Examination of growth rates for individual follicles may be useful in predicting the number of follicles that may develop as a result of ovarian stimulation. This information is equally important when assessing the risks of OHSS.^{220,221} In the past, follicular growth rates during induced cycles were observed to be faster than those of natural cycles.²²² Growth rates of follicles in spontaneous cycles were similar to those recruited by hMG therapy in a report based on a mathematical equation developed to equate follicular growth rate to follicular age.²²³ Reduced follicle growth rates were observed in cycles in which a pregnancy was established and it was concluded that growth rate was a more useful characteristic for prediction of ovulation than follicular diameter.²²⁴ Follow-up work does not appear to have been done.

It will be logistically challenging to combine daily detailed ultrasound measurements of individually mapped follicles with per follicle fertilization and conception outcomes from the embryo laboratory and final pregnancy outcomes. However, the rationale that follicular growth rates may be more accurate in predicting the actual maturity of the ova is intriguing. Recent detailed studies on follicular growth have shown that follicles grow at approximately 1.5 mm per day regardless of whether they developed during natural menstrual cycles, oral contraceptive cycles, or during ovarian stimulation.^{24,25} These data fit well with a new mathematical model developed to predict the response to ovarian stimulation based on daily data on follicular growth rates.^{12,24,25,91,225}

Ovarian Hyperstimulation Syndrome

OHSS is a potentially serious complication of ovarian stimulation that is primarily iatrogenic, although spontaneous OHSS is possible.^{220,226–229} Ultrasonography in women with OHSS typically shows grossly enlarged ovaries containing numerous large follicular cysts with thin, highly echogenic borders, and dramatically increased local blood flow⁵⁵ (Fig. 31–25). The ovaries may enlarge to diameters in excess of 10 cm, and echotexture interpreted as intrafollicular hemorrhage in some of the large cysts frequently may be observed. If a pregnancy is established, OHSS is exacerbated.^{221,226,227} Extreme cases may require abdominal paracentesis and result in drainage of several liters of ascitic fluid.

Serial ultrasound examinations during ovarian stimulation cycles and careful tailoring of the dose of exogenous gonadotrophins has helped to limit the risk of OHSS.^{55,208,209,230,231} Clinicians may take an active role in the prevention of OHSS by aborting the treatment cycle altogether, or “coasting” the final days of the treatment cycle.^{209,232–234} Coasting refers to continuing to allow follicular development but withholding administration of additional gonadotropins and performing oocyte aspiration after 1 to 3 days of unstimulated development.^{233–235} If oocyte aspiration is performed when excessive numbers of pre-ovulatory follicles develop in association with markedly elevated serum estradiol concentrations and the risk of OHSS is high, single-embryo transfer may be done, or all embryos may be cryopreserved and single embryos replaced

FIGURE 31–25. Transvaginal ultrasound image of a woman with moderate ovarian hyperstimulation syndrome. Both ovaries are observed in the posterior cul-de-sac. The ovaries are in close contact and displace the uterus anteriorly. Both ovaries contain several large unruptured follicles.

in a subsequent cycle when the danger of establishing a pregnancy has passed.^{230–232,234,236,237} If OHSS occurs, transvaginal ultrasound-guided aspiration of the ascitic fluid may be performed.^{221,236} If torsion of an enlarged OHSS ovary is suspected, color flow Doppler imaging can help to establish an early and accurate diagnosis.^{221–233,235,238–240}

Ultrasound-Guided Oocyte Retrieval

The most visible use of ultrasound imaging in IVF has been the tremendous advance facilitated by transvaginal retrieval of oocytes.^{241–251} Oocyte retrieval was a procedure-limiting step when IVF was first done. Retrievals were done laparoscopically or using ultrasound guidance from transurethral, transvesicular, or transabdominal approaches.^{244,247,251–254} The advent of transvaginal transducers and concerted efforts to develop effective, accurate tracking of the needles used for follicle aspiration was probably the single most important step in making IVF as safe and effective as it is today.^{241,249–251,255–259}

Retrieval of oocytes in IVF cycles is now routinely performed under ultrasound guidance.²⁴⁵ An aspiration needle introduced through a guide attached to a transvaginal probe is inserted into first one ovary, then the other, through the vaginal fornices (Fig. 31–26). Almost all aspiration needles now in common use have a small band of highly reflective surface near the tip of the needle. The needle tip can be observed directly as it is guided into the ovaries and maneuvered into each follicle. The follicular fluid containing the oocyte/cumulus complex is then aspirated by application of gentle suction. The walls of the follicle collapse as the fluid is aspirated and the needle moved within the follicle to ensure that all of the follicular fluid is withdrawn. The path of the needle also may be estimated accurately by biopsy guide lines imposed on the ultrasound screen.

FIGURE 31-26. A and B. Ultrasound-guided oocyte retrieval. In both images, the oocyte collection needle may be visualized entering into a large follicle (arrow). The hyperechoic ring around the tip of the needle enhances its visualization. Image A is presented in the standard medical imaging orientation. Many assisted reproductive technology clinicians prefer the more gynecologically oriented image, as presented in B. (Images courtesy of Roger Stronell, MD.)

There are two main types of aspiration needles used for oocyte retrieval, single- and double-lumen needles. Single-lumen needles typically have a smaller diameter and tend to cause less discomfort.²⁴⁵ The double-lumen needles were developed for a technique involving constant infusion of oocyte collection media into the follicle at the same time as the follicular fluid is being removed. The double-lumen flushing technique is thought to increase the turbulence within the follicle, assist in dislodging the oocyte-cumulus complex from the follicle wall, and increase the chances of oocyte collection. In many, if not most, IVF centers, follicle aspirations are performed using single-lumen needles and no follicle flushing. All of the follicular fluid is first aspirated from the follicle then the follicle is then refilled with collection medium and reaspirated. A gentle back-and-forth motion on the plunger of the infusion syringe may be used to increase the turbulence of flow, which helps to increase the rate of oocyte retrieval. Swirling of the medium within the follicle may be easily visualized on the ultrasound screen. A prospective, randomized trial and a retrospective examination of 2378 cases comparing flushing techniques with no flushing demonstrated no significant differences in the number of oocytes retrieved; however, the overall time required for retrieval in women whose follicles were flushed was increased.^{245,260,261} The complication rates of oocyte retrieval are reportedly extremely low and almost all procedures are performed under conscious sedation on an outpatient basis.^{248,256,257,262-267}

Unsuccessful oocyte retrieval following apparently normal ovarian stimulation reportedly occurs in 1% to 7% of cycles—the so-called “empty follicle syndrome.” The etiology appears to be multifactorial and may involve both technical and biological mechanisms.^{245,268} Technical aspects of failure to retrieve oocytes include errors in administration of the hCG used to trigger the final phases of follicular maturation or difficulties with the quality of hCG used. In other patients, unsuccessful oocyte retrieval may be due to ovarian dysfunction underlying the root cause of the infertility.²⁶⁸

Endometrial Assessment at the Time of Embryo Transfer

Correlation of the probability of implantation with the thickness of the endometrium when fertilized ova are transferred into the uterus following IVF has been addressed in several studies.²⁶⁹ Ultrasonographic evaluation of the endometrium may have predictive value for the outcome of treatments to ameliorate infertility; however, the literature is diverse and, in many cases, contradictory. Definitive studies allowing us to draw decisive conclusions are required before we can apply predictive analysis of the endometrium to routine clinical care of infertile women.

Spectral Doppler and Color Flow Doppler Ultrasonography

Doppler ultrasonography of the uterine arteries has had a confusing history in the literature at least partially because of lack of differentiation between spectral Doppler and color flow Doppler imaging. Early studies tended to be based upon spectral Doppler examinations, that may be used to evaluate the resistance to blood flow by measuring the pulsatility index (PI), resistance index (RI), V_{max} , or the systolic to diastolic ratio (S/D ratio).²⁷⁰ Color flow Doppler imaging detects directional motion of blood flow either toward or away from the transducer (Fig. 31-27). Power Doppler imaging is used to turn motion in any direction into a visually discernable color overlay on the two- or three-dimensional ultrasound image.^{270,271}

Initial attempts to determine if evaluation of blood flow in the uterine arteries could be useful were based on RI calculations to look for differences in uterine receptivity. In a small study, no differences were found between women who conceived and those who did not.²⁷² Grouping data into low, medium, and high categories of PI of the uterine arteries was not useful in distinguishing between conception and nonconception cycles; however, no pregnancies were established in the women with high PI values.²⁷³ Elevated

FIGURE 31-27. Combined color flow and spectral Doppler image demonstrating placement of the Doppler gate directly into the path of the uterine artery. The spectral Doppler trace is represented by the waveform just below it. Vascular indices representing resistance to flow are calculated automatically and displayed on the lower left aspect of the image.

PI, as a measure of impedance to vascular flow in the uterine artery, was associated with a significantly lower pregnancy rate.²⁷⁴ Assessing the uterine artery RI was inconclusive, except that absent or low diastolic flow was associated with failure to conceive and PI in women undergoing cryopreserved embryo transfer cycles were lower in women who became pregnant than those who did not conceive.²⁷⁵ Uterine artery vascular impedance measured by RI was not found to be useful for predicting the probability of pregnancy, but if the PI was greater than 0.79 before hCG administration, poor uterine vascular perfusion was assumed.²⁷⁶ No further reports on this speculation were found. PI and RI in the uterine arteries were reported to be lower in conception cycles, although there was overlap in the confidence intervals. It was suggested that a PI greater than 3.3 and an RI greater than 0.95 before embryo transfer were associated with a low probability of conception.²⁷⁷ However, these conditions were met in only 9% of the cycles in the study.²⁷⁷ Furthermore, a study of women undergoing cycles to produce embryos using intracytoplasmic sperm, reported no differences in the PI on the day of embryo transfer between conception and nonconception cycles.²⁷⁸

In a critical review of the literature prior to 1996, some ultrasonographically detectable criteria were associated with negative pregnancy outcomes, although no prognostic value was observed in any measurement of vascular perfusion.²⁷⁹ A more recent study seems to confirm the results that women who conceived exhibited lower PI than those who did not.²⁸⁰

Endometrial perfusion studies on the day of hCG administration consistently reported that values for PI and V_{max} were not different regardless of whether or not conception occurred. However, when only the color flow data were examined, absence of detectable subendometrial vascular flow, indicative of poor vascular penetration, was associated with failure of implantation.²⁸¹ Subendometrial

or intraendometrial vascular flow on the day of embryo transfer appears to be an indicator for maintaining a pregnancy.^{282,283} Intraendometrial flow estimates in a study using power Doppler imaging to examine only women with an endometrial thickness greater than 10 mm demonstrated that women with color areas less than 5 mm², based upon calculation of the maximal area that showed evidence of motion, to be associated with a lower pregnancy rate.²⁸³ More recently, spiral arterial flow and uterine artery flow were not demonstrably different between pregnant and nonpregnant women; however, if spiral arterial flow could not be detected, conception did not occur.²⁸⁴

Imaging-Based Uterine Scoring System

An imaging-based scoring system to predict uterine sensitivity was proposed in the mid 1990s, which appears to have been based upon an earlier uterine biophysical profile system.^{285,286} The scoring system was designed by assigning “points” for various criteria and then adding the cumulative columns. Comparisons of uterine scores in women who conceived and those who did not were not different in any of the criteria evaluated, including endometrial thickness, endometrial pattern, PI, RI, color Doppler, and other vascular indices. Development of the scoring system appears to have ceased.

Three-Dimensional Imaging of the Endometrium

Three-dimensional ultrasonography first became available in the late 1990s, and it is now a part of almost all high-end imaging systems. There are several methods used to provide three-dimensional information, and there do not appear to be any studies comparing the same endpoints with different imaging systems or different three-dimensional imaging techniques.²⁸⁷ Prediction of the probability of implantation in ART programs has now extended into three-dimensional exploration of endometrial receptivity.²⁸⁸ Conclusive indicators have not been determined.

Pregnancy and implantation rates were significantly lower in women with endometrial volumes of less than 2 mL when compared among women who conceived and those who did not. Yet, no pregnancies were established when endometrial volumes were less than 1 mL. No relationship between three-dimensional volume of the endometrium and conception was found in a contemporary study.^{288,289} Similarly, no correlation was found among estradiol levels, endometrial thickness, or endometrial volume, leading to the conclusion that there was no predictive value in assessing endometrial volume. Endometrial thickness and endometrial volumes were not correlated with probability of pregnancy; however, three-dimensional power flow Doppler indices used to measure endometrial perfusion may have some predictive value.^{271,284,290,291} Spiral artery blood flow measurements in three dimensions had positive predictive value when performed on the first day of ovarian stimulation, whereas women who became pregnant had lower RI and a higher three-dimensional flow index than those who did not.^{271,284} Taken together, these observations provide a rationale for further investigation, although it is clear that a predictive index is beyond the limits of our current understanding.

FIGURE 31-28. A to C. Motion analysis graph demonstrating endometrial contractility over time. Each image represents 1.5 minutes. Women with slow (A; three contractions per minute), medium (B; five contractions per minute), and fast (C; seven to eight contractions per minute) uterine contractions are shown. The amplitude and frequency of the contractions may be easily visualized and measured.

Motion Analysis

Direct measurement of subendometrial contractions is a method of assessing endometrial function based on the observation that the uterus and endometrium are in constant motion.²⁹²⁻²⁹⁹ Objective assessment of subendometrial contractions applied to ART cycles for prediction of successful pregnancy has yielded some interesting results.³⁰⁰⁻³⁰² To conduct motion analysis, a computer is interfaced with the ultrasound scanner, digital image frames are acquired, and the pixels comprising the area of interest on the endometrial image along a single line are isolated. A line is serially acquired from images taken one or two times per second over a 5- to 10-minute period, the pixel data from the line are concatenated and the result is displayed as a graph of the velocity and amplitude of endometrial contractions (Fig. 31-28). Conceptually, this technique is similar to a high resolution version of M-mode ultrasound.

Assessment of subendometrial contractions may have a predictive effect on the probability of pregnancy.^{296,301} Women with a higher frequency of uterine contractions had lower pregnancy rates.³⁰¹ However, contradictory evidence has been reported.³⁰³ Exogenous progesterone administration on the day of embryo transfer reduced uterine contractility, and it has been hypothesized that progesterone supplementation before embryo transfer may improve the probability of pregnancy by reducing the possibility that the contractions may expel the embryos.^{302,304,305} The biologic effects of progesterone on uterine contractions were demonstrated by the observation that higher progesterone concentrations correlated with lower amplitude and frequency uterine contractions.^{297,305} It has been suggested that progesterone could be administered prophylactically to reduce the frequency and amplitude of endometrial contractions. Progesterone intervention may have a positive impact on pregnancy rates, although this hypothesis does not appear to have been critically tested.³⁰⁶ Endometrial contractions at the time of blastocyst transfer were lower and reached a nadir 7 days after hCG administration in IVF cycles. The slightly later time of blastocyst transfer was

FIGURE 31-29. Embryo transfer is enhanced by the use of ultrasound guidance to place the embryos at the optimal uterine location. Small hyperechoic areas (arrows) represent microbubbles of air expelled from the transfer pipette and serve to visualize embryo placement. (Image courtesy of Roger Stronell, MD.)

hypothesized to coincide with lower amplitude and frequency of contractions, thus facilitating implantation.³⁰⁶

Ultrasound-Guided Embryo Transfer

Optimal embryo placement in the uterine cavity is increasingly important in enhancing the probability of a successful pregnancy.³⁰⁷⁻³¹⁷ Ultrasonography is now routinely used to guide placement of the embryo transfer catheter to increase pregnancy rates (Fig. 31-29). Transabdominal ultrasound guidance is a more common means of directing embryo transfer catheter placement; however, transvaginal scanning may also be used.^{314,318} Ultrasound guidance of embryo replacement does not prevent the establishment of an ectopic gestation.³¹⁹ This observation may be interpreted to mean that the early human embryo may be mobile within the uterus before attachment and nidation. Three-dimensional

ultrasonography has opened new inquiries into the three-dimensional guidance of the embryo transfer catheter.^{316,320} Three-dimensional imaging may prove to be an advantage in identifying the optimal site for embryo placement.

Clinical and laboratory preparations for embryo transfer are the same, regardless of whether the transfer is to be ultrasound guided or not. Patients are placed in a lithotomy position, and a bivalve speculum is used to visualize the cervix. After mucus and secretions are removed by cleansing with culture media, the tip of the transfer catheter is introduced into the cervix. A 3- to 4-MHz large aperture transabdominal transducer is placed on the lower abdomen and pelvis in a sagittal plane, and the uterus and cervix are imaged through a full bladder window.^{313,321,322} Most embryo transfer catheters are easily visualized as a pair of highly echogenic lines within the endocervical canal. A transfer catheter system has been developed to increase the ease of imaging if the clinician has difficulty visualizing the standard catheters.³²³ Once the catheter has been identified, the tip is carefully guided through the uterine lumen using real-time imaging. Once the clinician attains the optimal place within the uterus, the embryos are gently expelled.³²⁴ The fluid droplet containing the embryos is visualized as a very small hypoechoic reflection deposited at the tip of the transfer catheter. Transvaginal ultrasound guidance is done similarly, except that a probe designed for intracavitary use is introduced through the speculum and placed into contact with the anterior vaginal fornix.^{314,318} The transfer catheter is visualized, and the tip is guided to the uterine location selected by the clinician. There is varied opinion on exactly what optimal embryo placement means.³²⁵⁻³²⁸

The usefulness of ultrasonographic guidance during embryo transfer versus nonvisually guided clinical touch remains controversial.^{311,317,321,327,329-334} Some clinicians prefer to rely on ultrasound guidance for mock transfers in cycles before IVF and embryo transfer and clinical touch in the actual procedure. Other practitioners use ultrasound guidance for all procedures, and still others make a decision regarding its use based on whether or not the transfer is likely to be classified as easy or difficult.^{317,322,335} Two recent meta-analyses and a subsequent randomized controlled trial were interpreted to mean that transabdominal ultrasound guidance versus clinical touch for embryo transfer significantly increased pregnancy rates although the rates of miscarriage, ectopic pregnancy and multiple pregnancy were not affected.^{333,336-338}

CONCLUDING REMARKS

Ultrasonography has critical roles in our ability to increase our understanding of normal reproductive processes, diagnose the root causes of many different aspects of infertility, and act as our eyes in administering therapy to ameliorate the inability to conceive. It is difficult to imagine where our knowledge of how to best help couples suffering from infertility would be without the diagnostic information and ability to intervene in a world in which ultrasonography did not exist. The techniques for understanding changes in the reproductive organs over time have allowed us unprecedented depth in understanding folliculogenesis, ovulation, luteal function, endometrial response, conception, and implantation. We believe that ultrasonography is the most profound tool

that we have yet acquired to understand human reproduction and that advanced imaging technology, as it continues to evolve, will be indispensable in exploring the deepest reaches of our reproductive biology.

Fertility After Ectopic Pregnancy

Conclusion

INTRODUCTION

In the United States, ectopic pregnancy is the leading cause of pregnancy-related deaths during the first trimester.¹ In 1992 ectopic pregnancies accounted for approximately 2% of reported pregnancies, and ectopic pregnancy-related deaths accounted for 9% of all pregnancy-related deaths.² The incidence of ectopic pregnancy has been increasing since the 1970s (Fig. 32-1).³ This increase in ectopic pregnancy diagnosis is multifactorial, owing to both a true increase in the disease, related to increased numbers of patients at risk for the disease (Table 32-1), and earlier diagnosis of cases that otherwise would have spontaneously resolved.

Before sensitive pregnancy tests and sonography, ectopic pregnancy was frequently a life-threatening diagnosis. In 1970 Breen⁴ reviewed 654 cases of ectopic pregnancy and found that in 49% of cases, the patients were admitted in shock. Because of this, surgery was performed as soon as the diagnosis was made. Today more sensitive tests for human chorionic gonadotropin (hCG) and the use of high-resolution ultrasonography allow earlier diagnosis of previously unsuspected cases. This has led to a shift from inpatient surgical therapy of ectopic pregnancy to selective outpatient management.³

In addition to earlier diagnosis of cases, several factors have led to an increased incidence of ectopic pregnancy:

1. The treatment of salpingitis has improved, leading to an increased number of patients with scarred but patent fallopian tubes.
2. Patients with scarred tubes who undergo tuboplasty are now able to get pregnant.
3. Expectant management is thought to increase the number of women who had ectopic pregnancies who are now able to conceive again.^{5,6}
4. Increased numbers of women are undergoing ovulation induction and other assisted reproduction techniques; the techniques themselves increase the incidence of ectopic pregnancy.

Currently, sonography and, more specifically, transvaginal sonography is used not only to diagnose ectopic pregnancy in symptomatic patients but to screen women at high risk; to guide decisions as to the most appropriate mode of therapy; and to monitor patients diagnosed with ectopic pregnancy who can be managed without surgery (either expectantly or with methotrexate). Thus, ultrasonography plays a role not only in the early diagnosis but also in our understanding of the natural history of ectopic pregnancy. This chapter illustrates the role of ultrasonography in the diagnosis and management of ectopic pregnancy.

Table 32-1 Risk Factors for Ectopic Pregnancy

Risk Factor	Odds Ratio*
High Risk	
Tubal surgery	21.0
Sterilization	9.3
Previous ectopic pregnancy	8.3
In utero exposure to diethylstilbestrol	5.6
Use of intrauterine device	4.2–45.0
Documented tubal disease	3.8–21.0
Moderate Risk	
Infertility	2.5–21.0
Previous genital infections	2.5–3.7
Multiple sexual partners	2.1
Slight Risk	
Previous pelvic/abdominal surgery	0.9–3.8
Cigarette smoking	2.3–2.5
Vaginal douching	1.1–3.1
Early age at first intercourse (<18 years)	1.6

*Single values, common odds ratio from homogeneous studies; point estimates, range of values from heterogeneous studies from Mol et al.⁹ and Ankum et al.¹²⁶

CLINICAL PRESENTATION OF ECTOPIC PREGNANCY

Clinical suspicion of ectopic pregnancy is raised when a patient has a positive pregnancy test, pain, bleeding, and an adnexal mass. However, the clinical triad of pain, bleeding, and adnexal mass is present in only 45% of patients.⁷ Further complicating matters is that this clinical triad is not specific

for ectopic pregnancy. In a study by Schwartz and DiPietro,⁷ only 14% of patients with clinically suspected ectopic pregnancy actually had this as their final diagnosis. Other diagnoses were symptomatic ovarian cysts (27%), pelvic inflammatory disease (PID) (15%), dysfunctional uterine bleeding (4%), and spontaneous abortions (5%). Obviously, this breakdown of patients will vary with individual hCG levels and risk factors (see Table 32-1).

Neither type of pain nor location of pain is specific for establishing the location of an ectopic pregnancy. In Breen's⁴ 1970 study, the location of the pain varied as follows: shoulder (11%, all of whom had ruptured ectopic pregnancies), generalized abdominal (13%), lower abdominal (74%), lower quadrant ipsilateral to ectopic (51%), lower quadrant contralateral to ectopic (9%, perhaps secondary to contralateral corpus luteum cyst), back (6%), and vaginal (0.9%).⁴

Patients typically present at approximately 5 to 6 weeks' gestational age. However, because menstrual dates are often inaccurate, an early gestational age by dates should not influence the diligence with which one seeks an ectopic pregnancy.

RISK FACTORS FOR ECTOPIC PREGNANCY

Patients with a history of ectopic pregnancy have a 12.6% chance of having a repeat ectopic pregnancy because risk factors contributing to the first episode are still present, along with further scarring of the fallopian tube as a result of the prior ectopic pregnancy. For patients with a history of PID and ectopic pregnancy, this risk is as high as 27%.⁸ Other important risk factors are tubal ligation and use of an intrauterine contraceptive device. Both of these methods of contraception effectively prevent pregnancy. However, if pregnancy does occur, an ectopic location should be strongly suspected (Fig. 32-2).⁹ A risk factor that is increasing in prevalence is that of women undergoing in vitro fertilization.

FIGURE 32-2. Ectopic pregnancy in a patient with intrauterine device (IUD). The patient presented with positive human chorionic gonadotropin (hCG) and abdominal pain. **A.** Transvaginal sagittal view of the uterus shows the IUD in appropriate position. No intrauterine pregnancy is visualized. **B.** Transvaginal transverse view shows the IUD in the uterine cavity and normal left ovary (*calipers*) with two cysts. **C.** Transvaginal sagittal view of the adnexa shows a tubal ring (*arrows*) with yolk sac. Because IUDs prevent implantation in the uterus, patients who become pregnant with an IUD in place have a high likelihood of ectopic pregnancy. The patient was treated surgically. (From Dialani V, Levine D: *Ectopic pregnancy: A review. Ultrasound Q 20:105, 2004.*)

The incidence of tubal pregnancy after oocyte retrieval/embryo transfer is as high as 4.5% (Fig. 32-3).¹⁰ This increased rate is the result of risk factors for ectopic pregnancy overlapping those for infertility, use of superovulating agents, which may alter tubal motility, and embryo transfer with retrograde embryo migration into diseased tubes.^{11,12} Even though identification of women at increased risk for ectopic pregnancy is helpful, because ectopic pregnancy is so common, it should be remembered that “a woman who is capable of conceiving is capable of having a pregnancy in a location other than the uterine cavity.”¹⁴

PREGNANCY TESTING

The role of quantification of serum beta-hCG correlation with the clinical scenario and sonographic findings cannot be overemphasized in the diagnosis of ectopic pregnancy. A negative hCG essentially excludes the diagnosis of a live pregnancy, although a chronic ectopic pregnancy may be present. Sensitive radioimmunoassays are widely available, which become positive at approximately 23 menstrual days (9 days after conception). This is before the first missed menstrual period and before a gestational sac can be seen with transvaginal sonography.

When reviewing the literature or evaluating guidelines in clinical practice, it is important to know which standard of hCG is being used in the referring clinician’s laboratory. In the 1960s, the Second International Standard (IS) was introduced. Later, a purer standard, the International Reference Preparation (IRP) was introduced and is the main standard in use today. Correlation between the second IS and IRP can be performed by multiplying by a factor of 1.8 (second IS \times 1.8 = IRP). Throughout the rest of this chapter, the hCG levels are corrected to IRP.

Early studies on gestational sac visualization evaluated normal early pregnancy and documented the presence of a sac when the hCG was 1000 to 2000 mIU/mL (IRP).¹³⁻¹⁹ It must be emphasized that the majority of these studies evaluated normal early pregnancies and described an intrauterine gestational sac as any collection of fluid in the endometrial cavity. Small fluid collections of 2 mm (without a decidual reaction) were considered sufficient to describe an early gestational sac. As discussed later in this chapter, this type of fluid collection can be due to the pseudogestational sac of an ectopic pregnancy or a decidual cyst and may not represent an intrauterine pregnancy (IUP). Therefore, a fluid collection without a surrounding hyperechogenic rim is not sufficient to exclude the diagnosis of an ectopic pregnancy. However,

FIGURE 32-3. Transabdominal sonogram in a patient after ovarian hyperstimulation. *A.* Transabdominal scan shows an enlarged (11 cm) hyperstimulated ovary (*calipers*) with large cysts. *B.* Transabdominal image shows the uterus (UT) with a ring-like mass in the left adnexa (*arrow*). *C.* Transvaginal scan shows the relationship between the ectopic pregnancy (*arrow*) with yolk sac and the ovary (O).

these values of hCG are helpful in triaging patients. When hCG is below the discriminatory zone (2000 mIU/mL, IRP) and no intrauterine gestation is visualized, the diagnosis could be an early IUP, a miscarriage, or an ectopic pregnancy, and therefore, close follow-up is indicated, rather than treatment.²⁰ When the hCG value is above the discriminatory zone, one can expect to see an intrauterine gestational sac; however, even without visualization of a sac, there could still be a very early normal IUP.

In a study by Mehta,²⁰ 676 patients with symptoms suggestive of ectopic pregnancy were evaluated. Of 128 patients without a definite IUP on sonography, 51 had hCG values of greater than 2000, and 17 of these (33%) had an IUP on follow-up. Technical quality, presence of fibroids, intrauterine contraceptive devices, large hemorrhage, and multiple gestations have been described as factors in non-visualization of an early gestational sac with respect to a discriminatory level of hCG.^{14,18,20} However, in Mehta's²⁰ study, none of these factors could be identified in 9 of 17 cases. The rate of indeterminate scans in this study (19%) was similar to that seen by Braffman et al,¹⁵ who used an hCG threshold of 1500 mIU/mL. Braffman et al found fluid collections without an intradecidual sign in 40 of 90 patients. This emphasizes that if an hCG level of 2000 is used to treat

patients for ectopic pregnancy, then it is possible those women with early intrauterine pregnancies will be inappropriately treated and will lose an otherwise normal pregnancy. Therefore, it is recommended that if a patient presents with any symptoms suggestive of ectopic pregnancy, for example, bleeding, pain, and a pelvic sonogram that appears normal (without a fluid collection or gestational sac) the report should indicate that "although the pelvic sonogram appears normal, an ectopic pregnancy or a normal IUP too early to be seen sonographically cannot be excluded."

In the past, most patients suspected to have ectopic pregnancy were treated with laparotomy or laparoscopy. Currently, watchful waiting or treatment with methotrexate can be used for stable patients. However, it should be noted that, in many of these patients, the diagnosis of ectopic pregnancy is not confirmed. If patients are treated merely because of a single elevated hCG value, it is possible that normal early pregnancies will be improperly treated. In clinical practice, the discriminatory zone level of hCG should be taken as a guideline rather than an absolute. This raises the issue of whether the "discriminatory zone" for diagnosis of ectopic pregnancy should be raised. This is problematic in that any increase in the discriminatory zone, while increasing sensitivity for normal early pregnancy, will

decrease the already low sensitivity for early ectopic pregnancy. An hCG of 2000 is the level at which a sac will be seen in most, but not all, normal early pregnancies.

The important concept to understand is that there is a gray zone of hCG levels in which sonography is frequently indeterminate. When a patient is in an indeterminate group and is stable and reliable, we recommend serial hCG levels or repeat sonography, or both. Unstable patients should be treated as clinically indicated.

A normal IUP demonstrates an hCG doubling time of 2 days (range, 1.2 to 2.2 days).²¹ In ectopic pregnancy, this doubling time is increased. If the hCG levels are rising abnormally (<60% increase over at least 48 hours and not steadily declining), the patient is presumed to have an ectopic pregnancy. Even small gestational sacs should grow 0.8 mm per day; therefore, a repeat exam in 2 to 3 days will show a definite change.

It should be recognized that 21% of ectopic pregnancies have an hCG rise that mimics an IUP.²²

Several studies demonstrated that ectopic and abnormal IUPs have a lower mean level of serum progesterone compared with normal pregnancies.^{23–28} A low progesterone level of less than 5 ng/mL can exclude a normal pregnancy with 99.8% accuracy.²² It has been suggested that this test is most helpful in patients who have an hCG below a discriminatory threshold when sonographic findings are nonspecific.²³ However, a prospective study by Condous et al²⁹ showed that a single visit strategy with ultrasound and progesterone is not sufficient to exclude ectopic pregnancy.

DIAGNOSIS OF ECTOPIC PREGNANCY

Diagnostic laparoscopy is considered the gold standard for the diagnosis of ectopic pregnancy, although this invasive approach has a false-negative rate of 3% to 4% and a false-positive rate of 5%.³⁰ The combined use of serum hCG testing and transvaginal sonography is the current non-invasive approach. Because of more sensitive laboratory tests and improved resolution with ultrasound, we are now able to detect ectopic pregnancies at an earlier stage compared with that possible in the 1970s.³⁰ It is, therefore, possible to have a more elective approach to management in stable patients. In addition, early diagnosis of ectopic pregnancy allows for screening of high-risk patients. Cacciatore, Stenman, and Ylostalo³¹ in 1994 screened 225 women with risk factors of prior ectopic pregnancy and PID and found that 24% had ectopic pregnancies, 84% of which were diagnosed at first screening (37 days of gestation). They suggested that such early diagnosis prevents tubal rupture, substantial hemorrhage, and the need for emergent care.

If a firm diagnosis is not established at the time of initial scanning, follow-up sonography is important. As mentioned previously, gestational sacs grow at a rate of 0.8 mm per day; therefore, follow-up sonography in 2 to 3 days will demonstrate growth in normal pregnancy. Ectopic pregnancies also grow and hemorrhage, and therefore may become more apparent on follow-up. Among patients diagnosed to have ectopic pregnancy, 5% to 18% are detected or confidently diagnosed only at a repeat ultrasound.³¹

SONOGRAPHY OF NORMAL EARLY INTRAUTERINE PREGNANCY VERSUS ECTOPIC PREGNANCY

In the work-up of ectopic pregnancy, the visualization of a normal early pregnancy dramatically reduces the likelihood of an ectopic pregnancy. Quoted risks for heterotopic pregnancies (concurrent pregnancies located both within the uterus and in an ectopic location) range from 1/30,000 to 1/2100 (Fig. 32–4).^{32–35} The 1/30,000 figure was obtained by multiplying the incidence of ectopic pregnancy and dizygotic twinning.³⁴ However, the incidence of heterotopic pregnancies is increasing, especially in women undergoing ovulation induction, in whom the risk for heterotopic pregnancy is as high as 2.9%. This high incidence results from the high prevalence of tubal damage among in vitro fertilization patients and the use of superovulation and multiple embryo transfer, which predispose patients to the condition.

However, in general, the finding of an IUP excludes the diagnosis of ectopic pregnancy, except for patients at high risk. Therefore, attention to the uterine contents and understanding of normal early pregnancy are important in the management of patients at risk for ectopic pregnancy. Because transvaginal sonography allows for earlier diagnosis of an IUP than does transabdominal scanning, it is the preferred modality for evaluation of patients at risk for ectopic pregnancy. However, transabdominal views are important to screen for hemoperitoneum (Fig. 32–5) and to visualize ectopic pregnancies beyond the range of the vaginal probe.

Early Intrauterine Pregnancy

The earliest sign of IUP is a small fluid collection in the endometrium. Sacs as small as 2 mm can be visualized with transvaginal sonography. However, because of the overlap with the decidual cysts and pseudogestational sacs of ectopic pregnancy, specificity for early IUP can be increased if a thin rim of echogenic material around the sac is visualized (Fig. 32–6). The sac should be eccentric to the endometrial cavity. This intradecidual sign was described by Yeh et al³⁶ in 1986 and appears at 4.5 menstrual weeks (2.5 weeks after conception). However, even among experienced radiologists, the accuracy of this finding is as low as 38%.^{37,38} Laing et al³⁸ found that the intradecidual sac sign has a sensitivity and specificity of 48% and 66%, respectively. In a study by Bateman et al,¹⁴ when sacs were less than 5 mm, only one third had a well-defined echogenic rim. This low sensitivity was due to the large number of indeterminate scans. However, in a study by Chiang et al³⁹ sensitivity and specificity of the intradecidual sign was found to be 60% to 68%, and 97% to 100%, respectively. In this study, Chiang and colleagues showed the importance of seeing the echogenic rim around the sac in more than one plane and assessing for lack of change in the appearance (Fig. 32–7). Owing to the possibility that a decidual cyst could be mistaken for a very early IUP, the prudent course is to follow up symptomatic patients with either hCG or sonography, or both.

The double decidual sac (DSS) sign (Fig. 32–8) is a more reliable indicator of an IUP,⁴⁰ but it is present slightly later than the intradecidual sign. The DSS sign is caused by the inner rim of chorionic villi surrounded by a thin crescent of fluid in the endometrial cavity, which, in turn, is surrounded

FIGURE 32-4. Transvaginal sonograms of patient with simultaneous intrauterine and extrauterine gestations. A. Sagittal view of the uterus demonstrates an intrauterine gestational sac with embryo (*calipers*). B. Transverse view toward the left shows intrauterine gestational sac (UT SAC) and left adnexal sac (L AD SAC). C. Magnified view of the left adnexa shows the extrauterine gestational sac with embryo (*calipers*) and yolk sac. Both embryos demonstrated cardiac activity. Heterotopic pregnancies are becoming more common with the use of ovulation induction agents. In patients with a history of ovulation induction, increased attention should be paid to the adnexa, even after an intrauterine pregnancy has been identified. This patient was not taking ovulation induction agents; this is a rare case of spontaneous heterotopic pregnancy.

by the outer echogenic rim of the decidua vera. This sign is highly reliable for the diagnosis of an intrauterine gestational sac. However, the DSS sign does not absolutely exclude a pseudogestational sac.⁴¹ The presence of the yolk sac (Fig. 32-9) and the embryo (Fig. 32-10) further increase confidence in the diagnosis of an early IUP.

As mentioned earlier, although the finding of an IUP markedly decreases the risk of ectopic pregnancy, all patients should have evaluation of the adnexa. The importance of this evaluation is emphasized in women who have undergone in vitro fertilization. In these women, even visualization of one ectopic pregnancy should not decrease vigilance to identify other gestations, because a patient with twin ectopic pregnancies with simultaneous live triplet intrauterine pregnancies has been reported.⁴²

Abnormal Intrauterine Pregnancy

One of the difficult tasks in evaluating for ectopic pregnancy is distinguishing an abnormal IUP from the pseudogestational sac of ectopic pregnancy. This frequently is not possible. The diagnostic criteria for abnormal IUP are discussed in detail in Chapter 6. If an intrauterine sac is seen with a diameter exceeding that at which a yolk sac should be seen (i.e., mean sac diameter greater than 10 mm without visualization of a yolk sac) (Fig. 32-11) and the patient's history is suggestive of ectopic pregnancy, a dilatation and curettage can be performed. If this documents the presence of villi, then a nonviable gestation is present, and the patient's risk for an extrauterine gestation is effectively eliminated. If villi are not detected, the patient is still at risk for ectopic

FIGURE 32-5. Tubal ring and hemoperitoneum in patient with abdominal pain, vaginal bleeding, and positive pregnancy test. *A.* Transabdominal sagittal view showing an empty endometrial cavity (*arrow*) within the uterus (UT). The uterus is surrounded by heterogenous hypoechoic material consistent with hemoperitoneum (H). bl, bladder. *B.* Transabdominal transverse view shows a tubal ring (*arrows*). No definite yolk sac or embryo is seen within the ring. The right ovary was seen separately (not shown). *C.* Transabdominal sagittal view, showing free fluid (FF) in the hepatorenal fossa. This shows the importance of transabdominal scanning.

FIGURE 32-6. Transvaginal sonogram of very early intrauterine pregnancies. *A.* Sagittal sonogram demonstrates intradecidual sign, with an echogenic ring formed by chorionic villi (C) located eccentric to the endometrial cavity (EC). *B.* Transvaginal transverse view of a very early intrauterine pregnancy. A 2-mm sac is present. Although there is the suggestion of a decidual reaction (*arrows*) because of the echogenic surrounding endometrium, it is not sufficient to represent definitely an early intrauterine pregnancy. For this patient, a follow-up sonogram or serial human chorionic gonadotropin levels (hCGs) should be obtained to guide clinical management if an ectopic pregnancy is suspected.

FIGURE 32-7. Pitfall in use of intradecidual sign. Transverse transvaginal scan in a patient suspected of harboring an ectopic pregnancy. *A.* Initial image demonstrates a 2-mm sac with mildly echogenic rim (arrows), eccentric to the endometrial stripe (curved arrows) suggestive of an intradecidual sign of normal early pregnancy. *B.* Image obtained 15 seconds after that in Figure 32-7A shows that the configuration of the fluid collection (arrow) has changed and the echogenic rim is no longer present. Small fluid collections in the endometrial cavity may show such changes. This change in appearance is consistent with blood in the endometrial cavity rather than an intrauterine gestational sac.

pregnancy. If the patient is stable, interval change in hCG levels can be monitored.

SCANNING TECHNIQUE

Transabdominal Scan

The sonographic evaluation of ectopic pregnancy should begin with a transabdominal scan to assess for any masses that might be out of the plane of the vaginal transducer. If the bladder is empty at the time of the initial examination, the examination can begin with transvaginal study; however, it must be emphasized that if the adnexal regions are not well evaluated, a transabdominal study through a full bladder should be performed. Cases have been reported of ectopic pregnancies visualized transabdominally that were

FIGURE 32-8. Transvaginal sonogram of an early pregnancy. This sonogram demonstrates the double decidual sac sign. The gestational sac is measured with calipers. The inner ring is formed by the echogenic chorionic villi. The outer ring is the deeper layer of decidua vera (D). The separating lucent zone is the more superficial decidua vera.

FIGURE 32-9. Sagittal transvaginal sonogram demonstrates the double decidual sac sign but also the more reliable feature of a yolk sac.

missed on vaginal scanning alone,^{43,44} especially in patients with pelvic masses such as fibroids.⁴⁴ In some cases in which only vaginal scanning is used, either the ectopic pregnancy will not be identified or the ectopic pregnancy will be misinterpreted as intrauterine. The renal regions are evaluated for free fluid in the abdomen (see Fig. 32-5).

Transvaginal Scan

Transvaginal sonography should then be performed. Multiple studies have shown that vaginal sonography provides additional clinically useful information above that available with transabdominal sonography for patients with suspected ectopic pregnancy.^{43,45-49} The uterine contents are closely evaluated for signs of early IUP. As mentioned earlier, the documentation of an IUP greatly diminishes the likelihood of ectopic pregnancy.

FIGURE 32-10. A. Sagittal transvaginal sonogram demonstrates an intrauterine gestational sac with an early embryo (*calipers*) with a crown rump length of 6 mm. B. Transverse view of the left adnexa shows the intrauterine gestational sac (gs) and a thick-walled left adnexal cyst (c). Although adnexal cysts in patients with intrauterine pregnancy should be examined to exclude ectopic pregnancy, once an intrauterine pregnancy is visualized, a cyst such as this most likely represents a corpus luteum.

FIGURE 32-11. Transvaginal scan in a pregnant patient with bleeding. Sagittal view of the uterus shows an irregular fluid (F) collection in the uterus. No double decidual sac sign, yolk sac, or embryo is seen; therefore, an intrauterine pregnancy cannot be diagnosed. The mean sac diameter is 29 mm. Because of the large sac size, it can be concluded that if this is an intrauterine pregnancy, it is not viable (see Chapter 6). Therefore, the uterus can be safely evacuated and the products examined for chorionic villi. If chorionic villi are found, an abnormal intrauterine pregnancy is established and the patient's risk for extrauterine gestation is effectively eliminated.

Assessment of the Adnexa

As shown in Figure 32-12, common locations of ectopic pregnancies are 75% to 80% in the ampullary portion of the fallopian tube, 10% in the isthmic portion, 5% in the fimbrial end, 2% to 4% in the interstitial end (sometimes called cornual ectopic), and 0.5% in the ovary.⁴ Abdominal and cervical pregnancies are very rare.

Because the tube is the most common location for ectopic pregnancies, it is important to scan above and below the ovaries and between the uterus and ovaries to exclude an adnexal mass (see Figs. 32-3 and 32-13 to 32-15). The location of the corpus luteum is not helpful in directing the examination because contralateral implantation occurs in up to one third of cases (Fig. 32-16).⁵⁰ When an adnexal mass is visualized, it should be examined for yolk sac, embryo, and heartbeat (Figs. 32-17 to 32-19). If a heartbeat is visualized, this likely will influence the mode of treatment, because methotrexate has a lower success rate in cases of ectopic pregnancy with cardiac activity. However, finding cardiac activity in an ectopic pregnancy occurs only about 10% of the time. A hyperechogenic ring is a fairly specific finding for ectopic pregnancy; but this is easily confused with a normal corpus luteum cyst (see Figs. 32-16, 32-20, and 32-21).

An anechoic cyst is unlikely to be an ectopic pregnancy. Even a complex cyst in the ovary is much more likely to be the corpus luteum than an ectopic pregnancy because ovarian ectopics represent less than 1% of all ectopic pregnancies.⁴ If a thick-walled cyst is seen, care should be taken to distinguish whether this is intraovarian (and, therefore, most likely the corpus luteum) or extraovarian (and, therefore, most likely an ectopic pregnancy) (see Figs. 32-16, and 32-20 to 32-22). If it is difficult to distinguish the corpus luteum cyst from a tubal mass, it may be helpful to palpate the abdomen over the region of the mass to determine whether it is tubal (moves separately from the ovary) or ovarian (moves with the ovary).⁵¹

Assessment of the Cul-De-Sac

The cul-de-sac should be examined for free fluid. Fluid, when present, should be characterized as simple or complex. Complex fluid is suggestive of blood and, therefore, ectopic pregnancy (see Figs. 32-5 and 32-23). When echogenic fluid

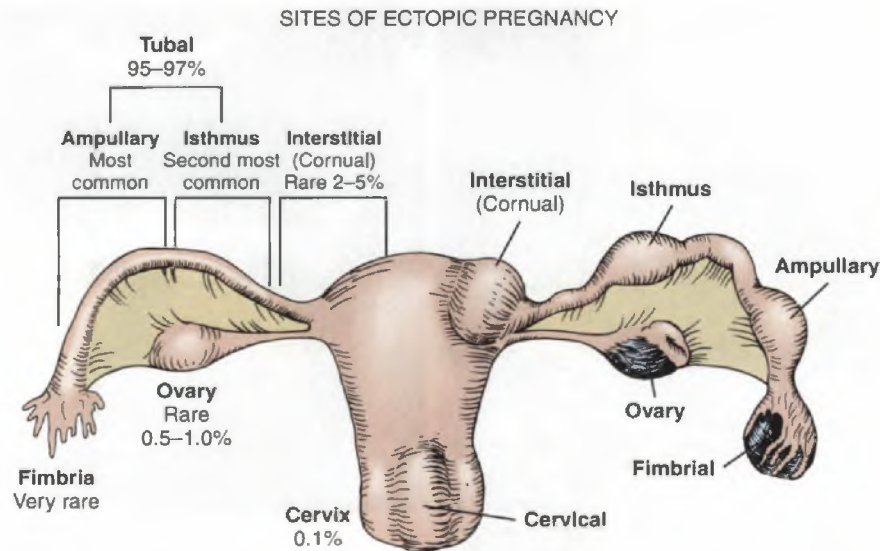

FIGURE 32-12. Common locations of ectopic pregnancy. Note that 95% to 97% of ectopic pregnancies occur somewhere along the course of the fallopian tube. (Modified from Benson RC: *Handbook of Obstetrics & Gynecology*, 8th ed. Los Altos, CA, Lange Medical Publications, 1983; and Schoenbaum S, Rosendorf L, Kappelman N, et al: *Gray-scale ultrasound in tubal pregnancy*. *Radiology* 127:757, 1978.)

FIGURE 32-13. Transvaginal sonogram of a patient suspected of harboring an ectopic pregnancy. Transverse view of the left adnexa shows a hypoechoic mass (*calipers*) adjacent to the left ovary (O). No intrauterine pregnancy was visualized. A patient who fails to demonstrate an intrauterine pregnancy and also demonstrates a mass separate from the ovary is worrisome for ectopic pregnancy. A mass of this type generally represents a hematosalpinx.

FIGURE 32-14. Tubal ring in a patient suspected of harboring an ectopic pregnancy. Transverse transvaginal scan shows a left tubal ring (*arrowheads*) adjacent to the ovary (*arrow*) with a corpus luteum cyst. Note the trace free fluid (f) adjacent to the ovary. These findings are consistent with ectopic pregnancy.

is visualized in a patient with positive hCG results this has a positive predictive value (86% to 93%) in the diagnosis of ectopic pregnancy,⁵² and may be the only transvaginal sonographic finding.⁵³ When free fluid is documented in the pelvis, it is helpful to obtain images of the kidneys in order to assess whether a large amount of hemoperitoneum is present (see Fig. 32-5).

SONOGRAPHIC FINDINGS IN ECTOPIC PREGNANCY

Adnexal Mass

Criteria for diagnosis of ectopic pregnancy are listed in Table 32-2. The most specific finding is of an extrauterine live embryo (see Figs. 32-18 and 32-19). Because of a lack

FIGURE 32-15. Transvaginal scan in a patient suspected of harboring an ectopic pregnancy. *A.* Sagittal view of the uterus shows a small amount of fluid in the endometrial cavity (EC). No pregnancy is seen. *B.* Transverse view of the cul-de-sac reveals complex fluid (F) consistent with blood. *C.* Transverse view of the left adnexa shows an echogenic tubal ring (*calipers*) medial to the left ovary (O). The combination of moderate fluid, a ring-like mass, and absence of an intrauterine pregnancy virtually confirms the presence of an ectopic pregnancy.

of sensitivity of this finding, most physicians use the criterion of an extraovarian adnexal mass. This finding has a specificity of up to 100% depending on the patient population selected (i.e., the discriminatory level of hCG for inclusion into the study). Most of the enlargement of the fallopian tube is caused by bleeding into the wall and lumen rather than from the products of conception.

As previously mentioned, it is important to distinguish between a tubal mass and an ovarian cyst. Sonographic findings that can help distinguish the corpus luteum from the adnexal ring of an ectopic pregnancy include a corpus luteum wall that is less echogenic compared with the wall of the tubal ring associated with the ectopic, and a corpus luteum wall that is less echogenic than the endometrium.^{54,55} If the diagnosis of an adherent ectopic pregnancy or exophytic ovarian cyst cannot be confirmed and the patient is stable, a follow-up examination can be performed (see Fig. 32-20). The rapid change in the appearance of the ovarian cyst frequently allows differentiation of the two conditions.⁵¹

Endometrial Findings

The endometrium may have a pseudogestational sac in ectopic pregnancy (see Figs. 32-16 and 32-24). The hormonal changes associated with ectopic pregnancy can cause fluid collections in the endometrial cavity, which mimic a gestational sac. In addition, blood products from an ectopic pregnancy can collect in the endometrium, leading to the appearance of a gestational sac. A pseudogestational sac is visualized in approximately 20% of patients with ectopic pregnancy.⁵⁶ This pseudogestational sac must be distinguished from the gestational sac of normal early IUP. Differentiating features are listed in Table 32-3.

There are no classic endometrial findings in ectopic pregnancy. The endometrial thickness in ectopic pregnancy varies from a thin to thick endometrium (Fig. 32-25).⁵⁷ Thin-walled, simple-appearing decidual cysts, usually at the junction of the endometrium and myometrium, are associated with ectopic pregnancy.⁵⁸ However, as mentioned earlier, decidual cysts are also seen with normal IUP and in

FIGURE 32-16. Transabdominal and transvaginal scans in a patient suspected of harboring an ectopic pregnancy. *A.* Transabdominal scan shows fluid centrally located within the endometrial cavity. *B.* Transvaginal sagittal image of the right ovary shows a thick-walled corpus luteal cyst. *C.* Transvaginal transverse image of the left adnexa shows the tubal ring (*arrow*) inferior to the left ovary. This case illustrates many features of ectopic pregnancy. A pseudosac can simulate a gestational sac. The corpus luteum can be contralateral to the ectopic pregnancy. The ring of the ectopic pregnancy is more echogenic than the ring around the corpus luteum. The ring of the ectopic pregnancy is adjacent to the ovary and not located within the ovary.

FIGURE 32-17. Transverse transvaginal sonogram of the left adnexa in a patient with an ectopic pregnancy. There is an adnexal ring containing a yolk sac (*arrowhead*) adjacent to the ovary (O). Just as a yolk sac within an intraendometrial fluid collection confirms an intrauterine pregnancy, a yolk sac within an adnexal mass confirms an extrauterine pregnancy.

FIGURE 32-18. Transverse transvaginal scan of the right adnexa in a patient with an ectopic pregnancy reveals an echogenic ring with embryo. M-mode demonstrates cardiac activity. Only about 10% of ectopic pregnancies will demonstrate a heartbeat at the time of diagnosis.

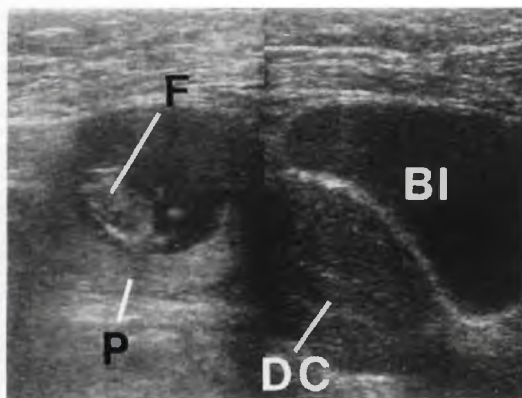

FIGURE 32-19. Composite linear array transabdominal sonogram of a patient suspected of harboring an ectopic pregnancy. A large ectopic gestation is located superior to the fundus of the uterus. A fetus (F) whose biparietal diameter was easily measured can be identified. Additionally, there is a well-developed placenta (p). Only a decidual cast (DC) is seen within the uterus. Although large and easily seen, such ectopic pregnancies may be misdiagnosed as intrauterine if the sonologist fails to observe the line of demarcation between the ectopic gestation and the uterine fundus. When this separation is not noted, the ectopic gestation is mistakenly incorporated into the uterine fundus. This error can be devastating to the patient. Bl, bladder.

nonpregnant patients (Fig. 32-26).^{58,59} These decidual cysts differ from a pseudogestational sac in that they are removed from the endometrial cavity. Decidual cysts are distinguished from the intradecidual sign of normal early pregnancy in that they do not have an echogenic rim.

When a patient is seen with an indeterminate fluid collection in the endometrium, clinical judgment influences patient care. In stable patients at risk for ectopic pregnancy in whom no adnexal mass is demonstrable, it is prudent to perform a follow-up ultrasound.

Free Fluid

Free fluid is a nonspecific finding, although a large amount of fluid is suggestive of an ectopic pregnancy (see Fig. 32-5). Complex fluid is consistent with hemoperitoneum (see Figs. 32-5 and 32-23). This is associated with ectopic pregnancy but does not necessarily signify tubal rupture, because a ruptured hemorrhagic corpus luteum cyst can also result in hemoperitoneum.^{60,61} A small amount of fluid can be seen in both normal and abnormal pregnancies. However, large amounts of fluid or complex fluid increase the likelihood of ectopic pregnancy.⁵³ If the patient is clinically unstable, differentiating between a ruptured ectopic and a ruptured hemorrhagic corpus luteum is unimportant, because in either case, a laparotomy is indicated. In unstable patients with demonstration of hemoperitoneum, the sonographic examination can be terminated without demonstrating an ectopic pregnancy. In the clinically stable patient, it is more important to carefully examine the adnexa to determine if an ectopic pregnancy is present. Transvaginal sonography has been shown to be more sensitive than culdocentesis for the detection of hemoperitoneum and has a higher negative predictive value.⁶² Therefore, vaginal sonography has almost completely replaced culdocentesis in the evaluation of ectopic pregnancy.

FIGURE 32-20. Transvaginal scan in a patient suspected of harboring an ectopic pregnancy. A. Sagittal transvaginal color Doppler image of a 2-cm thick-walled hemorrhagic cyst. Note the central fibrin strand mimicking a yolk sac (arrow). Note the ring of fire appearance to the cyst. B. Transverse, transvaginal image shows that the mass (arrows) is located within the ovary (arrowheads). Additional images (not shown) demonstrated an intrauterine gestational sac with yolk sac. Even in a patient with no visualized intrauterine pregnancy, an ovarian mass is more likely to represent a hemorrhagic corpus luteum cyst than an ovarian ectopic. In this case, the hemorrhagic cyst resolved on follow-up. (From Swire MN, Castro-Aragon I, Levine D: Various sonographic appearances of the hemorrhagic corpus luteum cyst. *Ultrasound Q* 20:49, 2004.)

The Normal Sonogram

When a patient is pregnant and has no identifiable intrauterine gestational sac, one of three possibilities exists: an early IUP that is too small for definite identification, a recent spontaneous abortion, or an ectopic pregnancy. Because 15% to 35% of ectopic pregnancies will not demonstrate an identifiable extrauterine mass on transvaginal sonography,^{52,53,61} an ectopic pregnancy cannot be excluded when no mass is seen. In up to 26% of patients with ectopic pregnancy, the sonogram may be completely normal (see

FIGURE 32-21. Transvaginal scans in a patient 6 weeks pregnant with bleeding and pain. *A.* Sagittal view of the uterus shows an intrauterine gestational sac (GS) with mean sac diameter of 12 mm. No yolk sac or embryo was identified. *B.* Sagittal view to the left shows a normal left ovary. *C.* Just lateral to the image in Figure 32-21*B*, adjacent to the left ovary (O), is a thick-walled cyst (*calipers*). The patient likely had a spontaneous abortion and an exophytic corpus luteum cyst. Because of atypical appearance of the adnexa, follow-up with human chorionic gonadotropin (hCG) and sonograms were obtained. The hCG levels declined normally. Within 4 weeks, the pelvic ultrasound was normal. This mass was believed to represent a hemorrhagic corpus luteum cyst.

FIGURE 32-22. Transvaginal scan in a patient with exophytic fibroid and corpus luteum cyst ipsilateral to an ectopic pregnancy. *A.* Transverse view of the right ovary shows a 2 cm cyst with strands of internal hemorrhage consistent with a hemorrhagic corpus luteum cyst. *B.* Transverse view of the right pelvis shows a pedunculated fibroid to the right of the uterus and an echogenic ring representing the ectopic pregnancy (EP) between the fibroid, uterus (UT), and ovary (OV). Fibroids can make the examination for ectopic pregnancy difficult, but as demonstrated in this case, ectopic gestational sacs can still be visualized in these complicated cases.

FIGURE 32-23. Transvaginal sonogram in a patient with ectopic pregnancy. *A.* Sagittal view of the uterus shows complex fluid in endometrial cavity (EC). *B.* Transverse view of the right adnexa shows 4-cm mass (*calipers*). *C.* Transverse view in the cul-de-sac shows echogenic fluid (F). Any free fluid seen in a patient without a demonstrable intrauterine pregnancy is worrisome for ectopic pregnancy. However, echogenic fluid is even more suggestive. In this patient with an adnexal mass and echogenic fluid, the diagnosis is almost certain.

Table 32-2 Criteria for Diagnosis of Ectopic Pregnancy

Criteria*	Sensitivity (%)	Specificity (%)
Extrauterine gestational sac with yolk sac or embryo (with or without heartbeat)	8-34	100
Adnexal ring	40-68	100
Complex adnexal mass separate from ovary	89-100	92-99
Any fluid	46-75	69-83
Moderate to large amount of free fluid	29-63	21-96
Echogenic fluid	56	96
Decidual cyst	21	92

*In patients with positive pregnancy test and no intrauterine pregnancy.

Data compiled from Cacciatore¹⁷; Bateman et al¹⁴; Nyberg et al¹⁹; Braffman et al¹⁵; Cacciatore, Stenman, and Ylostalo³¹; Dashefsky et al¹⁶; Thorsen et al¹⁸; Cacciatore, Stenman, and Ylostalo⁴⁵; Kivikoski, Martin, and Smeltzer⁴⁷; Nyberg et al⁵⁵; Frates et al⁶¹; Russell, Filly, and Damato⁵²; Ackerman et al⁵⁸; Fleischer et al⁷¹; Ari et al¹⁰⁵; Brown and Doubilet¹²⁸; Nyberg et al¹²⁹; DiMarchi, Kosasa, and Hale¹⁵⁰; Stiller, Haynes de Regt, and Blair¹⁵¹; Pennell et al¹³²; Filly¹³⁵; Cacciatore, Stenman, and Ylostalo¹⁵⁴; Rempfen¹⁵⁵; Timor-Trisch.¹⁵⁶

FIGURE 32-24. Pseudosac (PS) of ectopic pregnancy. Transvaginal sagittal view of the uterus shows a fluid collection centrally located in the endometrial cavity in a patient with an ectopic pregnancy.

Table 32-3

Differentiating Features of the Pseudogestational Sac of Ectopic Pregnancy and Normal Early Intrauterine Pregnancy (IUP)

Classic Sonographic Features	Early IUP	Pseudosac
Shape	Round	Ovoid
Location with respect to endometrial cavity	Eccentric	Central
Margins	Well defined	Poorly defined
Decidual reaction	Well defined	Absent
Single or double sac	May show double decidual sac sign	Single decidual layer

FIGURE 32-25. Normal pelvic sonogram in a patient suspected of harboring an ectopic pregnancy. *A*. Transvaginal transverse view of the uterus shows no intrauterine pregnancy. *B* and *C*. Transverse views of the adnexa are normal. Both ovaries are clearly identified. At real time, no abnormal masses were visualized. There is no free fluid in the cul-de-sac. Despite the normal appearance of this pelvis, there is an ectopic pregnancy. It is essential to remember that a normal pelvic sonogram does not exclude an ectopic pregnancy. Because of abnormally rising human chorionic gonadotropin levels (hCGs), the patient was treated with methotrexate (see Fig. 32-36).

FIGURE 32-26. Decidual cyst in a patient with an ectopic pregnancy. Transvaginal sagittal view of the uterus in a patient with ectopic pregnancy. A decidual cyst (*arrow*) is typically located at the endometrial-myometrial junction. These small cysts are associated with ectopic pregnancy but also can be present in a patient with an intrauterine pregnancy.

Fig. 32-25).⁵² Therefore, it is important to obtain clinical follow-up with repeat sonography if hCG continues to rise.

Mimics of Ectopic Pregnancy

False-positive findings of hematosalpinx can be due to an exophytic or ruptured corpus luteum cyst, pedunculated fibroids, ovarian torsion, retrograde flow of blood from a spontaneous abortion, a tuboovarian abscess, tubal cysts, or adjacent bowel (Fig. 32-27).⁵¹

Role of Doppler Sonography

Color and pulsed Doppler have been advocated to improve the diagnosis of ectopic pregnancy.⁶³⁻⁶⁵ Normal intrauterine pregnancies have low-impedance, high-diastolic flow at the placental implantation site. Because of low resistance, the area of color flow will appear continuous or nearly continuous during real-time examination. This is visualized in normal intrauterine pregnancies but not in the pseudogestational sac of an ectopic pregnancy.^{41,63,66} When an indeterminate intrauterine sac is visualized, color Doppler can be helpful in showing a color flash beneath the implantation site. However, the effects of Doppler's high-energy output focused on the small developing normal pregnancy should be considered. Therefore, use of this technique should be limited to cases in which the results of a color study will potentially affect management.

Similar to intrauterine pregnancies, ectopic pregnancies can have low-impedance and high-diastolic flow (Fig. 32-28). Color Doppler is most helpful when an extraovarian mass has not yet been found, because use of Doppler may allow for detection of an ectopic surrounded by loops of bowel. In a study by Pellerito et al,⁶⁵ 1 of 65 cases of ectopic pregnancy was identified by color Doppler when no mass was

FIGURE 32-27. Bowel mimicking ectopic pregnancy. Transvaginal image shows an echogenic ring-like mass adjacent to the ovary. During the scan, this mass was noted to peristaltic, showing that it was bowel, and not an ectopic pregnancy.

visualized by grayscale. However, the normal corpus luteum also has low-impedance flow. Care should be taken to ensure that a mass is extraovarian before analyzing the color flow. Resistive index has also been advocated to distinguish between ectopic pregnancy and corpus luteum cysts. However, there is considerable overlap between the resistive index of ectopic pregnancy and corpus luteum.^{30,65}

Although the presence of abnormal flow may indicate an ectopic pregnancy, the absence of color Doppler signal cannot be used to exclude ectopic pregnancy because early and dead ectopics can have absent flow.⁶⁵

One possible use of color Doppler is to identify tissue that is nonviable, which would then be more apt to respond to nonsurgical or expectant management^{30,67} or to monitor response to treatment.⁶⁷

RARE FORMS OF ECTOPIC PREGNANCY

As discussed earlier, approximately 95% of ectopic pregnancies occur in the ampullary or isthmic portion of the fallopian tube. The next most common site is in the interstitium of the tube (2% to 4%, Figs. 32-29 and 32-30), where it traverses the wall of the uterus to enter into the endometrial cavity. Ovarian, cervical (Figs. 32-31 and 32-32), and abdominal pregnancies are rare. Even less common are pregnancies occurring in a uterine scar (Fig. 32-33).⁶⁸ It is also important to assess for heterotopic pregnancy. When a pregnant patient presents with pelvic pain, and an IUP is visualized, care should still be taken to carefully assess the adnexa for additional gestational sacs.

Interstitial Pregnancy

Interstitial pregnancies (often called cornual) represent 2% to 4% of all ectopic pregnancies⁶⁹ but have a higher rate of morbidity and mortality because of later presentation and massive hemorrhage.⁷⁰ In this location, myometrium surrounds a portion of the expanding gestational sac, allowing it to enlarge painlessly for a relatively long time. The diagnosis is suggested when an IUP is visualized high in the fundus

FIGURE 32-28. Color Doppler of ectopic pregnancy. *A.* Transvaginal sonogram of a highly suspicious tubal ring shows peritrophoblastic flow. *B.* Pulsed Doppler shows low-impedance, high-diastolic flow. Arrows point to end diastole. *C.* In another patient, increased vascularity is seen around a corpus luteum cyst. Visualization of flow around an adnexal mass is frequently misleading because corpus luteum cysts show low-impedance, high-diastolic flow. Care should be taken to verify that a mass is extraovarian to raise the suspicion of ectopic pregnancy.

that is not surrounded in all planes by 5 mm of myometrium (see Fig. 32-29).⁷¹ The specificity of this 5-mm threshold has not been investigated. It should be remembered that the diagnosis of interstitial ectopic pregnancy can be difficult sonographically. It may be difficult to differentiate an eccentric normal IUP from an interstitial pregnancy (see Fig. 32-30*D*). True cornual pregnancies are those located in the horn of a bicornuate uterus. Previously therapy was by laparotomy. New therapies include systemic methotrexate⁷² or transvaginal sonographically guided injection of potassium chloride.⁷³

Cervical Pregnancy

Cervical pregnancies represent less than 1% of all ectopic pregnancies.^{74,75} Risk factors include multiparity, prior abortion, or instrumentation of the cervix or endometrial cavity. The sonographic diagnosis is made when a gestational sac with peritrophoblastic flow or a live embryo is identified

within the cervix. When a gestational sac with a yolk sac and embryo is seen within the cervix without a heartbeat, the differential diagnosis includes spontaneous abortion and cervical ectopic (see Figs. 32-31 and 32-32). In cases of spontaneous abortion, the sac shape and location should change on serial imaging. In cases of cervical ectopic pregnancy, the sac will be more round or hourglass shaped and should have trophoblastic flow on color Doppler.⁷⁶ However, increased flow in the cervix also can be seen around a spontaneous abortion.⁷⁷

Because the cervix is composed predominantly of fibrous tissue, patients may bleed profusely. In the past, as a result of life-threatening hemorrhage, the diagnosis of a cervical ectopic pregnancy frequently led to hysterectomy. At present, conservative treatments are possible with the hope of preserving future reproductive potential, including sonographically guided local potassium chloride injection,^{78,79} systemic or local methotrexate,^{76,78,80,81} or preoperative uterine artery embolization^{78,82} before dilatation and evacuation.

FIGURE 32-29. Live interstitial ectopic pregnancy. *A.* Transvaginal sagittal midline view of the uterus in a patient suspected of harboring an ectopic pregnancy shows no gestational sac in the endometrial cavity (*white arrows*). *B.* Transvaginal oblique transverse view shows a gestational sac high in the fundal region with an embryo (*E*). The crown rump length was consistent with 10 weeks. There is a paucity of myometrium laterally (*black arrows*). *C.* Magnified view shows no myometrium around the lateral aspect of the gestational sac (*black arrows*). *D.* M-mode demonstrates cardiac activity. It is common for interstitial ectopic pregnancies to present at a more advanced gestational age than ectopic pregnancies in other portions of the tube because the interstitial region dilates relatively painlessly.

Scar Pregnancy

Once an extremely rare entity, cesarean section scar pregnancy is being increasingly reported.⁸³ The hypothesis is that the conceptus enters the myometrium through a microscopic dehiscence tract or defect in the cesarean section scar.⁸⁴ There is complete embedding of the gestational sac in the myometrium. The myometrium between the bladder and the sac becomes thinner or disappears owing to distention of the sac. Only the thin, serosal layer is apparent. Criteria used for diagnosis are an empty uterus, empty cervical canal, development of the sac in the anterior part of the lower uterine segment, and an absence of healthy myometrium between the bladder wall and the gestational sac (see Fig. 32-33).⁸⁵ Current non- and minimally invasive treatments include sonographically guided methotrexate or potassium chloride injection,^{73,86} or intramuscular methotrexate.⁸⁷ Definitive treatment of a cesarean scar

pregnancy is by laparotomy and hysterotomy, with repair of the accompanying uterine scar dehiscence.⁸⁴ Other procedures that scar the uterus put the patient at increased risk for scar pregnancy. For example, a pregnancy can implant in a myomectomy scar.⁸⁸

Abdominal Pregnancy

Abdominal pregnancies are rare. The pregnancy typically develops in the ligaments of the ovary, usually the broad ligament. It can then obtain blood supply from the omentum and abdominal organs. Sonographically the pregnancy is seen separate from the uterus, adnexa, and ovaries (Fig. 32-34). Treatment is by laparotomy or laparoscopy.⁸⁹ Although abdominal pregnancy can result in a life-threatening emergency if diagnosed late, a viable pregnancy can result.

FIGURE 32-30. Pitfalls in the diagnosis of interstitial pregnancy. *A.* Transabdominal view of a patient suspected of having an ectopic pregnancy. A large partially necrotic fibroid is seen in the midline. *B.* Transverse transvaginal view shows the fibroid (F) in the midline with a gestational sac (gs) located to the far left of the uterus. *C.* Magnified view of the gestational sac shows a thick band of myometrium (arrows) around the gestational sac (gs), between the sac and the adjacent ovary (O). This is a normal intrauterine pregnancy in a sac deviated by a large fibroid. *D.* In another patient who presented with pelvic pain and a positive pregnancy test, a coronal transvaginal sonogram demonstrates a markedly eccentric gestational sac (arrow) on the right side of the uterus, suggesting the presence of an interstitial pregnancy. Follow-up sonograms demonstrated a more central location of the intrauterine gestational sac and a normally developing pregnancy.

Heterotopic Pregnancy

The occurrence of heterotopic pregnancies is increasing owing to ovulation induction, in vitro fertilization, embryo transfer, previous pelvic surgery, and history of previous ectopic pregnancy managed conservatively and by salpingostomy.⁹⁰ In such high-risk patients, the presence of an intrauterine gestation sac should not negate the need for careful evaluation of the adnexa and follow-up sonography in symptomatic patients (see Figs. 32-4 and 32-35).⁹¹ Hyperstimulated ovaries may make visualization of an ectopic pregnancy difficult.⁹² In these cases, transabdominal scanning often shows the ectopic pregnancy, which may not be in the range of the transvaginal probe owing to a large ovarian size. A greater level of suspicion may allow early laparoscopic intervention before life-threatening intra-abdominal bleeding occurs.⁹²

ROLE OF MAGNETIC RESONANCE IMAGING IN THE DIAGNOSIS OF ECTOPIC PREGNANCY

Ultrasound is the method of choice for imaging pregnant patients. However, magnetic resonance imaging (MRI) is being increasingly used in complicated patients in whom the diagnosis is unclear. MRI is helpful in known abdominal pregnancy in order to plan the surgical approach (see Fig. 32-34).⁹³ MRI can be used to diagnose tubal ectopic pregnancy in cases in which the sonogram is equivocal.^{94,95}

MANAGEMENT

Because ectopic pregnancy is now being diagnosed earlier and more frequently than in prior decades, management has shifted from emergency laparotomy to laparoscopy to even

FIGURE 32-31. Cervical ectopic pregnancy versus inevitable abortion. **A.** Sagittal transabdominal scan in a pregnant patient shows a sac in the lower uterine segment and cervix. The placenta is present in the cervical area and lower uterine segment (*arrows*). A yolk sac is present within the cervical portion of the gestational sac. **B.** Pulsed Doppler examination shows low-impedance flow. Flow around a gestational sac in the cervical region (or embryonic cardiac activity) differentiates a cervical ectopic from a spontaneous inevitable abortion. **C.** In another patient, a gestational sac (S) or sacs are seen within the cervix. The dilated endocervical canal is indicated with *arrows*. Color Doppler (not shown) demonstrated no flow around the cervical sac, which is consistent with an aborting gestation.

FIGURE 32-32. **A.** Transvaginal sagittal view of the uterus in a patient with cervical ectopic pregnancy. No gestational sac is present within the endometrial cavity (*straight arrows*), and an intact gestational sac (*curved arrows*) containing a yolk sac is present in the cervix. Gestational age is 6.2 weeks. A gestational sac with yolk sac is present in the cervix. **B.** Magnified view of the gestational sac shows an embryonic pole with cardiac activity, documented with M-mode tracing. Arrowheads mark the fetal pole. (From Frates M, Benson CB, Doubilet PM, et al: Cervical ectopic pregnancy: Results of conservative treatment. *Radiology* 191:773, 1994.)

FIGURE 32-33. Cesarean section scar pregnancy in patient after in vitro fertilization. *A.* Transabdominal image shows a retroflexed uterus with gestational sacs (A, B) in the lower uterine segment, clearly not in the body of the uterus. *B.* Transvaginal image shows the two sacs (arrows) located in the anterior lower uterine segment, in the expected location of a cesarean section scar. *C.* Transvaginal image shows yolk sac and embryo.

FIGURE 32-34. Abdominal ectopic pregnancy. *A.* Sagittal transvaginal image shows the fetal head (h) in the cul-de-sac, posterior to the uterus (U). *B.* Coronal gadolinium-enhanced image shows blood flow to the ectopic pregnancy (arrows). Note that gadolinium is not typically used during pregnancy but was in this case for surgical planning, because it was known that the pregnancy was nonviable.

FIGURE 32-35. Transabdominal images of twin heterotopic pregnancy in a patient after in vitro fertilization at 15 weeks' gestational age. A. Transverse image shows two gestational sacs (RT, LT). At first glance, these appear to each lie within a uterine horn; however, as shown in images B and C. The sac on the left does not have surrounding myometrium (arrows) consistent with a heterotopic pregnancy. At surgery, this was found to be an abdominal heterotopic pregnancy.

more conservative management in select cases. Benefits of noninvasive approaches include preservation of fertility with decreased morbidity and decreased cost.⁹⁶

Surgery

When a patient is unstable, has a live ectopic pregnancy (meaning cardiac activity is visualized), a relatively large adnexal mass (> 4 cm), or desires sterilization, surgery is the treatment of choice. Surgery is also performed when criteria are not met for expectant management or methotrexate therapy or if the patient may not be followed adequately after treatment.⁹⁷

Methotrexate

Methotrexate, a folate antagonist, is usually used for the treatment of ectopic pregnancy. This may be given as 50 mg/m² intramuscular (single dose regimen, without leucovorin, can be repeated on day 7 if hCG value did not decline 15% between days 4 and 7); or as 1 mg/kg intramuscular

(up to four doses with 0.1 mg/kg of leucovorin, with monitoring of hCG levels on alternate days until it declines 15% from previous value).^{98,99} Criteria for medical treatment vary between institutions. Relative contraindications according to the American College of Obstetricians and Gynecologists are a gestational sac of 3.5 cm or greater and embryonic cardiac motion.¹⁰⁰ Medical treatment is the preferred option if the patient has already undergone previous surgeries, has extensive pelvic adhesions, has a contraindication for general anesthesia, and after failure of conservative laparoscopic treatment.⁹⁷ Methotrexate is successful in 70% to 97% of cases and has demonstrated that fertility is preserved equally well compared with laparoscopy.^{81,101,102} Although most studies excluded ectopic pregnancies with cardiac activity, a 1998 report by Lipscomb et al¹⁰³ showed that 35 of 44 (79.5%) ectopic pregnancies of less than 3.5 cm in diameter with cardiac activity were successfully treated with methotrexate.

The most important predictor of treatment success with methotrexate is the hCG value. Tawfiq et al¹⁰⁴ found that only 7.5% of patients failed single-dose treatment when the

FIGURE 32-36. Two patients with tubal masses after treatment with methotrexate. *A.* Transverse transabdominal scan in a patient 10 days after treatment with methotrexate shows a complex cystic mass surrounding the uterus (U). This is a hematosalpinx, which had increased in size compared with that seen on scans before treatment. *B.* In another patient (see Fig. 32-25) in whom no ectopic pregnancy was seen sonographically but whose human chorionic gonadotropin levels (hCGs) were rising, a complex mass is seen in the region of the left tube. Both of these cases show the worrisome appearance of ectopic pregnancies after treatment with methotrexate. However, the hemorrhage into the tube with resulting enlarging mass does not indicate failure of treatment.

hCG level was less than 4000 IU/L compared to 65% when the level was greater than 4000 IU/L

Ultrasonography after methotrexate is indicated only in cases in which rupture is suspected. Sonography of patients treated with methotrexate is complicated because most patients show a worsening appearance, with increased hemorrhage around the ectopic (Fig. 32-36). There may be an initial increase in size of the tubal mass after methotrexate treatment (see Fig. 32-36), and an adnexal mass may be visible up to 3 months after treatment.^{105,106} The increase in tubal size and vascularity, in spite of the falling hCG level, represents a healing process and should not cause concern unless the patient is clinically unstable or has persistent symptoms.¹⁰⁵

Sonographically Guided Percutaneous Treatment

Sonographically guided intra-amniotic injection of potassium chloride or methotrexate are newer methods of treating ectopic pregnancy, especially unusual ectopic pregnancies.^{73,107,108} This is less frequently a choice in tubal pregnancies, in which intramuscular methotrexate is an effective and less invasive alternative. However intra-amniotic injection is the method of choice in cervical, interstitial, heterotopic, and cesarean scar pregnancies.⁷³ One mg/kg of methotrexate,¹⁰⁹ or 1 to 3 mL of potassium chloride at a concentration of 2 mEq/mL is injected directly into the gestational sac or the embryo, if the embryo is greater than 5 mm in length.⁷³ The advantages of this procedure are they ablate the ectopic pregnancy, permit normal continuation of a concomitant pregnancy, and preserve the uterus for subsequent pregnancies.

Expectant Management

One risk with methotrexate treatment in patients with unproven ectopic pregnancy is that some patients with

either early spontaneous abortion or very early IUP will be needlessly treated. In addition, many small ectopic pregnancies that previously went undiagnosed are now known to resolve spontaneously. These issues have led to increased interest in expectant management of ectopic pregnancy.

Lund¹¹⁰ reported expectant management as early as 1955. Multiple studies of minimally symptomatic women with declining or stable hCG levels and small adnexal masses (less than 4 cm) can be safely monitored without treatment.¹¹¹⁻¹¹³ Patients must be willing to undergo close monitoring. About 25% of patients diagnosed with ectopic pregnancy fit this description.^{111,114} In a study by Cacciatore et al,^{114,115} no further treatment was needed in 69% of patients, however 31% of patients required laparoscopy at an average of 9 days after diagnosis owing to worsening clinical symptoms.

Fernandez et al¹¹² monitored spontaneous resolution of laproscopically confirmed ectopic pregnancies managed conservatively in 14 patients and concluded that there is a high probability of spontaneous resolution of the pregnancy when the serum hCG level at diagnosis is less than 1000 mIU/mL. In a study by Korhonen, Stenman, and Ylostalo,¹¹⁶ the success rate for spontaneous resolution of ectopic pregnancy was 88% when the initial hCG level was less than 200 IU/L but only 25% at levels greater than 2,000 IU/L. In the 77 patients with a spontaneous resolution, the initial median hCG concentration was 374 IU/L (range, 20 to 10,762 IU/L), and it decreased to normal in 4 to 67 days (mean, 20 days). In this study, laparoscopy was performed in two thirds of the patients with a serum hCG level greater than 64% of the initial value after 7 days of follow-up.

In a different study by Korhonen, Stenman, and Ylostalo,¹¹⁷ low-dose oral methotrexate was compared with placebo in patients with an ectopic pregnancy smaller than 4 cm in greatest diameter, no signs of bleeding, and an hCG increase less than 50% in 2 days and found no difference in the groups. In each group, 77% of patients required no further treatment.

In a study by Elson,¹¹⁸ expectant management was 96% successful if the hCG was less than 175 IU/L, 66% successful if the hCG was 175 to 1500 IU/L, and 21% successful if hCG was greater than 1500 IU/L. There was 0% success rate if hCG was less than 1500 and the patient was more than 42 days pregnant.

In monitoring ectopic pregnancies, Atri et al^{105,111} demonstrated that patients receiving methotrexate and expectant management could have increased size or increased vascularity on follow-up. The long resolution time of the ectopic pregnancy is a drawback of medical treatment. In the series by Atri et al,¹⁰⁵ the tubal mass took up to 147 days to resolve completely.

Thus, the mass of the ectopic pregnancy can persist long after the hCG levels normalize. The benefit of expectant management is the avoidance of surgery or drugs. Disadvantages of expectant management include cost of serial hCG measurements and transvaginal sonograms, anxiety associated with waiting to decide whether other treatment is necessary, and the possibility of emergent laparotomy. It is possible that falling hCG levels can occur followed by rupture of the ectopic.^{119,120}

Tubal rupture, historically treated surgically, is an important issue with the trend toward nonsurgical management. Some investigators suggested that sonography can be used to determine whether the tubes are intact. The appearance of the adnexal mass,¹⁷ and the type and amount of intraperitoneal fluid⁷¹ have been suggested as predictors of tubal rupture. Although one report suggested that a tubal ring is associated with an intact tube,¹⁷ this has not been substantiated in more recent reports.^{37,52,60,61} Therefore, sonography should not be considered accurate in the characterization of fallopian tube status.

FERTILITY AFTER ECTOPIC PREGNANCY

Approximately 60% of surgically treated patients subsequently experience term pregnancy. A randomized study by Hajenius et al¹²¹ showed similar rates of tubal patency in patients treated with methotrexate compared with those treated with salpingostomy. Other studies showed ipsilateral tubal patency rates of 53% to 84%,^{113,122–125} with subsequent pregnancy rates of 27% to 80%.^{122,124,125} Although patient numbers are smaller in the follow-up of patients treated expectantly, subsequent pregnancy has been found in 86% of these patients.

CONCLUSION

Sonography and serum hCG guide the diagnosis and management of patients with ectopic pregnancy. An intrauterine gestational sac is typically seen when the hCG value is greater than 2000 mIU/mL (IRP). Knowledge of the variety of appearances of ectopic pregnancy will aid in diagnosis. Expectant medical and percutaneous management have decreased the number of patients needing laparoscopy/laparotomy. With these conservative treatments, there is an increased role for sonography in the appropriate triage and follow-up of patients with ectopic pregnancy. An algorithm for the work-up of ectopic pregnancy is presented (Fig. 32–37).

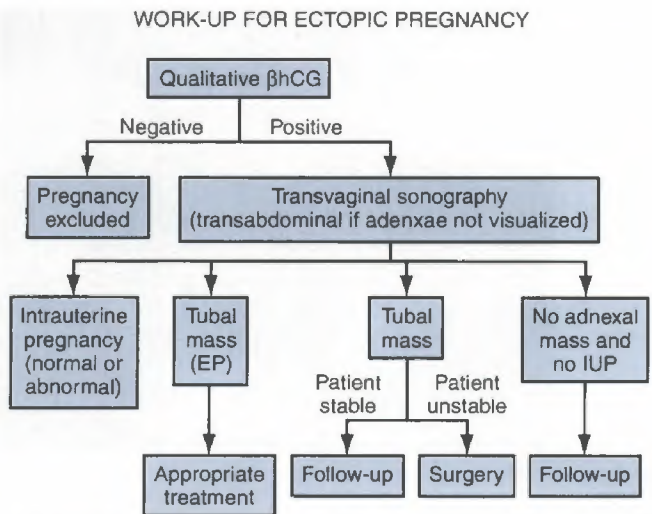

FIGURE 32-37. Algorithm for work-up of ectopic pregnancy. (Modified from Mehta TS, Levine D, Beckwith B: Treatment of ectopic pregnancy: is a human chorionic gonadotropin level of 2,000 mIU/mL a reasonable threshold? *Radiology* 205:569-573, 1997.)

Preoperative Staging

This chapter describes the main indications of magnetic resonance imaging (MRI) for the evaluation of nonobstetric gynecologic diseases. In the first two sections, the normal anatomy of the female pelvis and common congenital anomalies are discussed. In subsequent sections, the use of MRI in the setting of common benign pathologies, namely leiomyomas, adenomyosis, and endometriosis is outlined, and finally, the role of MRI in patients with malignant neoplasms of the reproductive organs is discussed. The main clinical and epidemiologic aspects are presented, in addition to imaging features in order to emphasize a practical clinical approach to the diagnostic question.

IMAGING TECHNIQUES

A detailed discussion of imaging techniques and protocols used in MRI is beyond the scope of this chapter. There are,

however, a few basic concepts with regard to imaging techniques that may make the images easier to understand to those not familiar with MRI.

T2-weighted images are the mainstream of MRI of the female pelvis. These images are used for evaluation of the normal anatomy and detection of most uterine and adnexal abnormalities. T1-weighted images, especially when used in conjunction with fat suppression, are helpful in characterizing the content of adnexal lesions, namely blood and fat. When used after the administration of intravenous gadolinium, T1-weighted images assist in the characterization of some benign and malignant tumors. As a general rule, on T1-weighted images, fat-containing lesions are bright. Water, such as the urine in the bladder, is dark. However, water is bright on T2-weighted images. Therefore, tissues with higher amounts of water, such as tumors and cysts, have high signal intensity on T2-weighted images. Gadolinium is

the main component of the most commonly used intravenous contrast media in MRI. Tissues that are impregnated by gadolinium show an increase in signal intensity on T1-weighted images when compared with images acquired before its administration. It is used to increase the contrast between normal and abnormal tissues in the body. For instance, many neoplastic processes enhance more avidly than the adjacent tissues and become more easily visible. In addition, it is used to improve visualization of vascular structures.

ANATOMY AND PHYSIOLOGY

Although it is not within the scope of this chapter to discuss the anatomy of the female pelvis, a few words on specific features of MRI are important. A basic concept that must be kept in mind is that the patient's hormonal status affect imaging features of the female gynecologic organs, irrespective of the imaging modality.¹⁻³

Uterus

The uterus typically measures from 6 to 9 cm in length in women of reproductive age, the cervix accounting for approximately 30% to 50% of the total, being proportionally larger in size before the menarche. Its anatomic features are best visualized using T2-weighted images, usually acquired in the axial and sagittal planes. T2-weighted sequences clearly depict the uterine zonal anatomy, which may be described considering two separate regions, the cervix and the uterine body.

The cervical anatomy is divided in three zones on T2-weighted sequences: the endocervical mucosa, which demonstrates high-signal intensity due to the presence of mucus glands; the cervical stroma, which demonstrates low signal intensity owing to the presence of fibrous connective tissue; and the peripherally located smooth muscle, which demonstrates intermediate signal intensity (Fig. 33-1). Varying amounts of mucus may be seen within the endocervical canal, which has a very high signal intensity similar to fluid.²⁻⁴

The zonal anatomy of the body of the uterus also consists of three distinct regions on T2-weighted sequences: centrally, the endometrium demonstrates a very high signal intensity; adjacent to the endometrium, the junctional zone (inner myometrial layer) demonstrates low signal intensity; and the outer myometrium, which demonstrates intermediate signal intensity (Fig. 33-2). At its inferior aspect, the junctional zone is continuous with the low signal intensity cervical stroma.⁴⁻⁶

Identification of the junctional zone is extremely important when evaluating the uterine magnetic resonance zonal anatomy. Studies have shown that the appearance of the zonal anatomy, in particular the ability to distinguish the junctional zone, is influenced by female hormones.¹⁻³ Normally, the junctional zone should not measure more than 11 mm in thickness in women of reproductive age. In postmenopausal women, women taking oral contraceptives, or in girls before menarche, the zonal anatomy is frequently indistinct and the junctional zone may be very thin.⁴

The MRI appearance of the endometrium is also hormonally influenced and varies with the menstrual cycle.

FIGURE 33-1. Normal cervix. Axial (A) and sagittal (B) T2-weighted image demonstrate the normal zonal anatomy of the cervix, composed of an external rim of smooth muscle (short arrow on A and B) with intermediate signal intensity, a dark ring of fibrous stroma (long arrow on A and B), and the endocervical mucosa (asterisk on A).

FIGURE 33-2. Normal uterus. Sagittal T2-weighted image demonstrates the high signal intensity of the endometrium (asterisk) and zonal anatomy of the uterus, characterized by a dark transitional zone (arrow) and intermediate signal intensity of the outer myometrium (arrowhead).

FIGURE 33-3. Apparent endometrial thickening. Sagittal T2-weighted (A) and enhanced T1-weighted (B) images. Apparent thickening of the endometrium is seen on the T2-weighted image (arrowheads); however, after enhancement of the endometrium, fluid within the cavity becomes evident (arrow).

The endometrium becomes progressively thicker between the early follicular (proliferative) phase and ovulation, measuring from 1 or 3 mm to an average of 8 or 9 mm. The endometrium should not measure more than 15 mm in thickness in women of menstrual age, and typically measures 11 mm or less in postmenopausal women who are not on hormonal replacement therapy.^{7,8} The endometrium has its highest signal intensity during the luteal (secretory) phase.^{1,3,4} It is imperative to remember that the use of T2-weighted images for evaluation of the thickness of the endometrium using may result in overestimation, because fluid within the endometrial cavity also has high signal intensity (Fig. 33-3).

Unlike the uterine corpus, the cervical zonal anatomy does not demonstrate significant changes during the menstrual cycle. In addition, because the cervix is composed largely of fibrous elastic tissue, the enhancement of the cervix is different from the uterine corpus. The uterine body is a very vascular structure when compared with the cervix and enhances more avidly and earlier than the cervix

FIGURE 33-4. Normal uterus. Gadolinium-enhanced sagittal T1-weighted image demonstrate the normal difference between the enhancement of the myometrium (asterisk) and cervical stroma (arrow).

(Fig. 33-4). This is important because the difference in enhancement may give the appearance of a pseudomass and lead to a misdiagnosis of cervical cancer in the unwary.

Ovaries

Normal ovaries have homogeneous intermediate T1 signal intensity; however, they are characterized by an outer high-signal-intensity cortex and a hypointense central medulla when imaged using T2-weighted sequences.⁹⁻¹² The ovaries measure approximately 2 cm × 2 cm × 3 cm; however, their size fluctuates according to the hormonal status, especially because of follicle production and enlargement. The ovaries are most readily identified in women of reproductive age by the presence of such follicles, which are seen as small cysts of high signal intensity on T2-weighted sequences and low signal intensity on T1-weighted sequences (Fig. 33-5). Primordial follicles are usually smaller, measuring up to 9 mm in diameter, whereas stimulated graafian follicles may reach up to 3 cm or 5 cm.⁹ Other features of these physiologic cysts seen on T2-weighted sequences include imperceptible or thin walls (less than 3 mm), and an absence of mural nodules (see Fig. 33-5).⁹⁻¹² Ovarian follicles are seen in only about 22% to 40% of postmenopausal patients.¹⁰ Ovarian stroma enhances after intravenous contrast administration and the use of fat-suppressed sequences help with the identification of ovaries when follicles are not visible.⁹

The normal fallopian tubes are not visualized on MRIs.^{11,12}

CONGENITAL ANOMALIES

MRI is the method of choice for evaluation of congenital anomalies. Advantages of the method include its noninvasiveness, lack of ionizing radiation, multiplanar capability enabling interrogation of the fundal contour of the uterus, and excellent soft tissue characterization. The use of MRI may reduce the number of invasive procedures and related costs by guiding management decisions.^{13,14}

FIGURE 33-5. Normal ovaries. Axial T2-weighted image demonstrates the presence of multiple hyperintense follicles in both ovaries (arrows), one of which represents the dominant follicle (asterisk).

Müllerian Duct Anomalies

Müllerian ducts are paired embryologic structures that normally fuse between the 6th and 11th weeks of gestation, forming the uterus, fallopian tubes, cervix, and most of the upper vagina.¹⁵ However, in 0.1% to 10.0% of the general population, either fusion fails to occur or the ducts do not have normal development, resulting in one of multiple anomalies.^{9,16-19} Although müllerian duct anomalies may be asymptomatic, they are more often associated with primary amenorrhea, infertility, obstetric complications, and endometriosis.^{15,17,20,21} It is estimated that about 15% of women who present with recurrent miscarriages have müllerian duct anomalies.²² In addition, 30% to 50% of these women have concurrent renal anomalies, which include agenesis, ectopia, fusion, malrotation, and duplication.^{9,15,20} Patients suspected of having müllerian duct anomalies are often initially investigated with transvaginal ultrasound, because it is widely available and has a relatively low cost. Although multiple studies have demonstrated the usefulness of MRI for the evaluation of müllerian ducts anomalies,²³⁻²⁹ it is frequently reserved for indeterminate cases or cases in which further information is needed. T2-weighted sequences are the most useful because zonal anatomy identification is necessary. In addition, the study must include an oblique coronal and axial plane to ensure adequate visualization of the contour of the uterine fundus.

There are many different classifications of müllerian duct anomalies, the American Society for Reproductive Medicine classification perhaps being the most used and well-known (Fig. 33-6).³⁰

Agenesis/Hypoplasia

The anomalies within this group result from bilateral nondevelopment or arrested development of the müllerian ducts. Agenesis of the upper vagina and uterus is the most

FIGURE 33-6. Graphic representation of multiple müllerian duct anomalies. American Society for Reproductive Medicine classification.

FIGURE 33-7. Uterus didelphys. Axial T2-weighted images of the pelvis (*A* and *B*) and coronal T1-weighted image of the abdomen (*C*) demonstrate two separate uteri (asterisks on *A* and arrows on *C*) and cervixes (black arrow on *A*), as well as two separate vaginas (white arrows on *B*). The right kidney was congenitally absent (*C*).

common anomaly in this group and part of the spectrum of the Mayer-Rokitansky-Küster-Hauser syndrome. Patients with this syndrome may present with an atrophic uterus, however, and vaginal abnormalities can range from hypoplasia to agenesis. Urinary system malformations are sometimes associated with Mayer-Rokitansky-Küster-Hauser syndrome. The second most common anomaly in this class is segmental vaginal agenesis. Isolated agenesis or hypoplasia of the uterus is very rare. In complete uterine agenesis, MRI demonstrates a short blind-ending vagina only, whereas in cases of uterine hypoplasia, the uterus is small and the intercornual diameter of the endometrial cavity is reduced, measuring less than 2.0 cm.

Unicornuate Uterus

A unicornuate uterus is the consequence of complete arrest or partial development of one müllerian duct. In 90% of cases, there is partial development of the duct, resulting in a rudimentary horn, which may contain functioning endometrium. The rudimentary horn may be obstructed or communicate with the main uterine cavity. Clinical associations include a very high rate of spontaneous

miscarriage, obstetric complications, and endometriosis. A unicornuate uterus has normal zonal anatomy and a characteristic banana-shaped configuration. A rudimentary horn can be seen as a soft tissue mass of similar signal intensity as the myometrium; and if obstructed, it may be distended with blood products, resulting in high signal intensity on T1-weighted sequences.

Uterus Didelphys

The uterus didelphys results from nonfusion of the müllerian ducts and is characterized by the presence of two separate uteri and cervixes, with a vertical septum in the upper vagina. Very rarely, two completely separated vaginas and vaginal orifices may be seen. Patients are usually asymptomatic, but hematometocolpos may occur if an obstructing transverse hemivaginal septum is present. Clinical complications are similar to those associated with a unicornuate uterus. MRI demonstrates two widely separated fusiform uterine horns and two cervixes (Fig. 33-7). The zonal anatomy is preserved. Vaginal septa may not be detected with MRI and physical examination may be necessary for confirmation and distinction from a bicornuate bicollis uterus.

FIGURE 33-8. Bicornuate unicollis uterus. Axial T2-weighted image demonstrates a clefted fundus (*white double-headed arrow*) and single cervix (*black arrow*).

Bicornuate Uterus

This anomaly is the result of partial failure of fusion of the müllerian ducts. It is characterized by an increased intercornual distance, typically measuring larger than 4 cm; a concave external contour of the fundus, measuring more than 1 cm in depth; and a fibrous-muscular septa separating the endometrial cavity in two. The septa may be incomplete, partially dividing the uterine cavity (bicornuate unicollis [Fig. 33-8]), or complete, extending all the way to the external cervical os (bicornuate bicollis). The vagina has normal development. Images obtained in the oblique coronal plane, along the long axis of the uterus, are useful in assessing the fundal contour. The dividing septum often exhibits signal characteristics of myometrium, but may be of low signal intensity inferiorly when fibrous tissue is present.

Septated Uterus

This is the most common müllerian duct anomaly and the result of failure of resorption of a fibrous septum in later stages of development.¹⁵ The resultant divided endometrial cavity may be small, and the septum may be partial or extend to the external cervical os. Reproductive complications are greatest in this class of müllerian duct anomaly. MRI features (Fig. 33-9), which distinguish a septated uterus from a bicornuate uterus, include a nonclefted fundal contour; a normal intercornual distance of less than 4 cm; and a thin, dividing, often fibrous septum of low T1- and T2-signal intensity.

Arcuate Uterus

This anomaly consists of mild indentation affecting only the fundal aspect of the endometrium because of minimally incomplete resorption of the uterovaginal septum. It is classified separately because it is a benign variant without clinical significance. On MRI, the arcuate uterus has a single endometrial cavity associated a small fundal cleft measuring less than 1.0 cm in depth.

FIGURE 33-9. Septated uterus. Axial T2-weighted image demonstrates a partial septum dividing the endometrial cavity (*arrow*) and a nonclefted uterine fundus (*arrowhead*).

Diethylstilbestrol Exposure

Diethylstilbestrol is a synthetic estrogen that was used in the past, up to 1971, to prevent miscarriages. It is estimated that approximately two thirds of the patients who were exposed to it in utero have uterine anomalies. The most common of these anomalies is the classic hypoplastic T-shaped uterus, but other deformities of the uterine horns and endometrial cavity may be identified.

Vaginal Anomalies

The lower third of the vagina originates from the urogenital sinus. Developmental failure of the urogenital sinus results either in the absence of the distal vagina or the presence of a transverse membrane, mimicking an imperforated hymen. In both cases, obstruction results in fluid distention of the vagina and uterus. The upper vagina presents with very thin walls, whereas the uterus may have thin or thick myometrium (Fig. 33-10). Hematometocolpos is identified as a heterogeneous collection with high T1- and T2-signal intensity.

Ovarian Anomalies

The ovaries are derived from primitive germ cells, which migrate to the embryonic gonadal ridge and subsequently descend into the pelvis. Congenital anomalies of the ovaries are habitually associated with chromosomal disease and represent gonadal dysgenesis. Turner syndrome (45X0 karyotype) and Turner syndrome mosaic (45X0/46XX karyotype) are common causes. The ovaries of patients with gonadal dysgenesis are absent or seen as fibrous streaks. The fat-suppressed T2-weighted and gadolinium-enhanced T1-weighted sequences are most helpful in the identification of ovaries.

FIGURE 33-10. Vaginal agenesis. Sagittal T2-weighted (A) and axial T2-weighted (B) images demonstrate mild distension of the uterine cavity (asterisk on A) and thickening of the myometrium (arrows on A), as well as absence of the vagina between the normal urethra (arrow on B) and rectum (asterisk on B).

LEIOMYOMAS

Definition and Epidemiology

Leiomyomas are benign tumors arising from uterine smooth muscle cells with a prevalence ranging from 25% to up to 77%.³¹ Leiomyomas are more often seen in women older than 30 to 35 years of age, and are 2 to 3 times more common in black women.^{32–34} Leiomyomas have a significant impact on public health, accounting for at least one third of the 600,000 hysterectomies performed each year in the United States.³⁵

Clinical Aspects

Most patients with leiomyomas are asymptomatic.³¹ Clinical symptoms associated with leiomyomas include dysfunctional

uterine bleeding, pelvic pressure, and pelvic pain. In addition, there is an association with impaired reproductive function, which may be related to impaired implantation, tubal obstruction, increased miscarriage, and preterm labor.^{36,37}

Symptoms are largely related to the location of the leiomyoma. Approximately 90% occur in the uterus, but about 5% to 10% are cervical in location. In pregnant patients, these may grow and cause dystocia.^{42,43} A minority of leiomyomas are seen in the round and broad ligaments (Fig. 33–11) or adnexa.

Uterine leiomyomas are classified as submucosal, intramural, or subserosal (Fig. 33–12). Approximately 5% of leiomyomas are submucosal in location (Fig. 33–13),⁴³ and typically present with menorrhagia. Clinically, the submucosal location is considered to be a cause of infertility, and can be treated with hysteroscopic resection. Submucosal leiomyomas are distinguished from large intramural leiomyomas by an endometrial location of the core or center of the lesion; and adjacent myometrium encircling the lesion by less than 180 degrees.

Subserosal leiomyomas account for approximately 10% to 20% of uterine leiomyomas, are located just under the uterine serosa, and may be pedunculated or sessile (see Figs. 32–13 and 33–14). Symptoms are associated with a large size or torsion of a pedunculated lesion. The bridging vascular sign (vascular vessels originating from the uterus and feeding a pelvic mass) is seen in approximately 77% of exophytic leiomyomas and is helpful in the differentiation from adnexal masses.⁴⁴ Another feature on imaging that may be useful to make the distinction between a subserosal leiomyoma and an ovarian mass is the identification of an ovarian vascular pedicle. The ovarian vascular pedicle is characterized by drainage of a pelvic mass by a gonadal vein. This pedicle is seen in 92% of the ovarian masses and 13% of pedunculated subserosal leiomyomas.⁴⁵

Pathophysiology

The pathophysiology of leiomyomas is unknown; however, genetic predisposition and hormonal status are involved in tumor development and growth.³¹ Because these tumors respond to hormonal stimulation, frequently they are noted to enlarge during pregnancy and involute after menopause. They may undergo various types of degeneration, the most frequent types being hyaline (seen in at least 60% of leiomyomas), cystic, myxoid, fatty, and hemorrhagic (Fig. 33–15).³⁸ In most cases, the distinction of different kinds of degeneration is not possible solely based on imaging findings; however, there are some features that may suggest one or another type. Degeneration may make the diagnosis difficult with ultrasound, and MRI characteristics may be used to identify a degenerating leiomyoma.^{39,40}

In addition, leiomyomas may present in unusual ways, such as metastasizing leiomyomas, intravenous leiomyomas, diffuse leiomyomatosis, and peritoneal disseminated leiomyomatosis. Although these uncommon presentations may seem to suggest a malignant behavior, they are essentially a variation in the growth pattern of this benign lesion.³⁸ Uterine leiomyosarcomas have been reported to

FIGURE 33-11. Round ligament leiomyoma. Axial T1-weighted (A) and T2-weighted (B) images demonstrate a round mass with the typical appearance of a degenerating leiomyoma (arrows), but separate from the uterus and herniated into the left inguinal canal. This was surgically proven to be a leiomyoma of the round ligament.

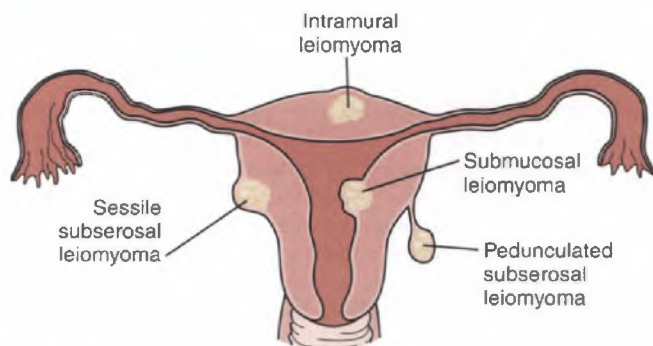

FIGURE 33-12. Graphical representation of a sessile subserosal leiomyoma (S), a pedunculated subserosal leiomyoma (P), an intramural leiomyoma (I), and a submucosal leiomyoma (M).

occur in association with leiomyomas,⁴¹ however, genetic studies suggest that these are two different entities arising from separate pathways.³¹ Sometimes, the distinction between a leiomyoma and a leiomyosarcoma cannot be reliably made based on MRI characteristics of the primary lesion; however, rapid growth, evidence of extrauterine

extension, lymphadenopathy, and metastases indicate malignancy (Fig. 33-16).

Treatment

The treatment of choice of a leiomyoma depends on its size and location, as well as on the clinical presentation. The most common options are hysterectomy, myomectomy (transabdominal, laparoscopic, and hysteroscopic), myolysis, and uterine artery embolization.^{31,37} Hysterectomy is usually performed in women who have completed childbearing and do not wish to preserve the uterus. Myomectomy is usually the choice of treatment for those patients who wish to preserve the uterus. In these cases, an abdominal approach is used for multiple large leiomyomas; the laparoscopic approach is appropriate for the resection of subserosal and pedunculated lesions, whereas the hysteroscopic technique is preferred for patients who have submucosal tumors. Uterine fibroid embolization is a safe and effective technique with the potential to become the first choice for treatment of symptomatic uterine fibroids.⁴⁶ Most patients are candidates for uterine embolization, as long as contraindications, such as active pelvic infection, renal insufficiency, and contrast allergy, are excluded. The main advantage of uterine fibroid embolization is the decreased morbidity when compared with other treatment options.

FIGURE 33-13. Myomatous uterus. Sagittal T2-weighted image demonstrates a small submucosal leiomyoma (*white arrow*) and distention of the endometrial cavity, which was due to blood (*asterisk*). Amongst others, a subserosal leiomyoma is identified in the fundus of the uterus (*black arrow*).

Diagnosis

The purpose of imaging these patients is to determine size and location of leiomyomas, as well as the presence of necrosis or hemorrhage; all of these factors are essential for selection of appropriate management. The diagnosis of a leiomyoma is typically confirmed and monitored by transvaginal ultrasound. Nonetheless, ultrasound evaluation may be limited when the uterus is retroverted or retroflexed, enlarged to an extent that prevents its complete visualization, in the presence of a pedunculated subserosal leiomyoma (when differentiation from an adnexal mass may be difficult), and when lesions present atypical imaging features. MRI is a problem-solving tool reserved for these cases, as well as for those in which conservative treatment is being contemplated. Although overall MRI and ultrasound have similar sensitivity (99% and 99%, respectively) and specificity (86% and 91%, respectively) to establish the presence of uterine leiomyomas, MRI is better to identify and determine the total number of lesions.⁴⁷ The advantages of MRI over ultrasound are likely related to its large field of view and multiplanar capabilities.⁴⁷ An additional benefit of MRI is the ability to distinguish leiomyomas from focal adenomyosis, which is

FIGURE 33-14. Leiomyoma and adenomyosis. Axial T2-weighted image demonstrates a small subserosal leiomyoma anteriorly (*asterisk*). The junctional zone is thickened and has indistinct margins. Multiple punctate foci with high signal intensity (*starry sky appearance*) (*arrowhead*), characteristic of adenomyosis, are seen.

clinically important because the treatment of these two entities may differ significantly if uterine preservation is necessary.^{48,49} Finally, MRI also has a role in predicting and monitoring treatment response, especially uterine artery embolization.⁵⁰⁻⁵² Factors reported to predict good response to treatment are a submucosal location, smaller baseline size, and high T2-signal intensity before embolization. On the other hand, the presence of hemorrhagic degeneration before embolization often predicts a poor response. Successful uterine artery embolization results in a reduction in size of both uterus and leiomyomas, and development of hemorrhagic infarction.^{50,51,53}

Imaging Characteristics

On MRI, a simple nondegenerating leiomyoma is seen as a well-circumscribed, round nodule or mass with low signal intensity on both T1- and T2-weighted sequences (see Fig. 33-15).⁴³ Intramural leiomyomas may demonstrate a high-signal-intensity pseudocapsule on T2-weighted sequences, which is thought to represent edema and vascular congestion of the surrounding myometrium (Fig. 33-17).⁵⁴ Calcifications may be seen as signal void areas, but may not be well visualized with MRI. Leiomyomas typically show marked enhancement after gadolinium administration, but the use of contrast material is only necessary to evaluate vascularity when embolization is being considered (see Fig. 33-15).

As mentioned previously, imaging characteristics of degeneration are nonspecific, but some magnetic resonance features may suggest specific types. Leiomyomas with cystic degeneration present with very high signal intensity on T2-weighted sequences (Fig. 33-18).⁴³ Low T2-signal intensity and a cobblestone appearance in a leiomyoma is usually due to hyaline degeneration.^{38,43} Hemorrhagic degeneration of leiomyomata are usually the result of rapid enlargement, as seen during pregnancy or after uterine artery embolization. Hemorrhagic degeneration characteristically has high signal intensity on T1-weighted sequences due to the high

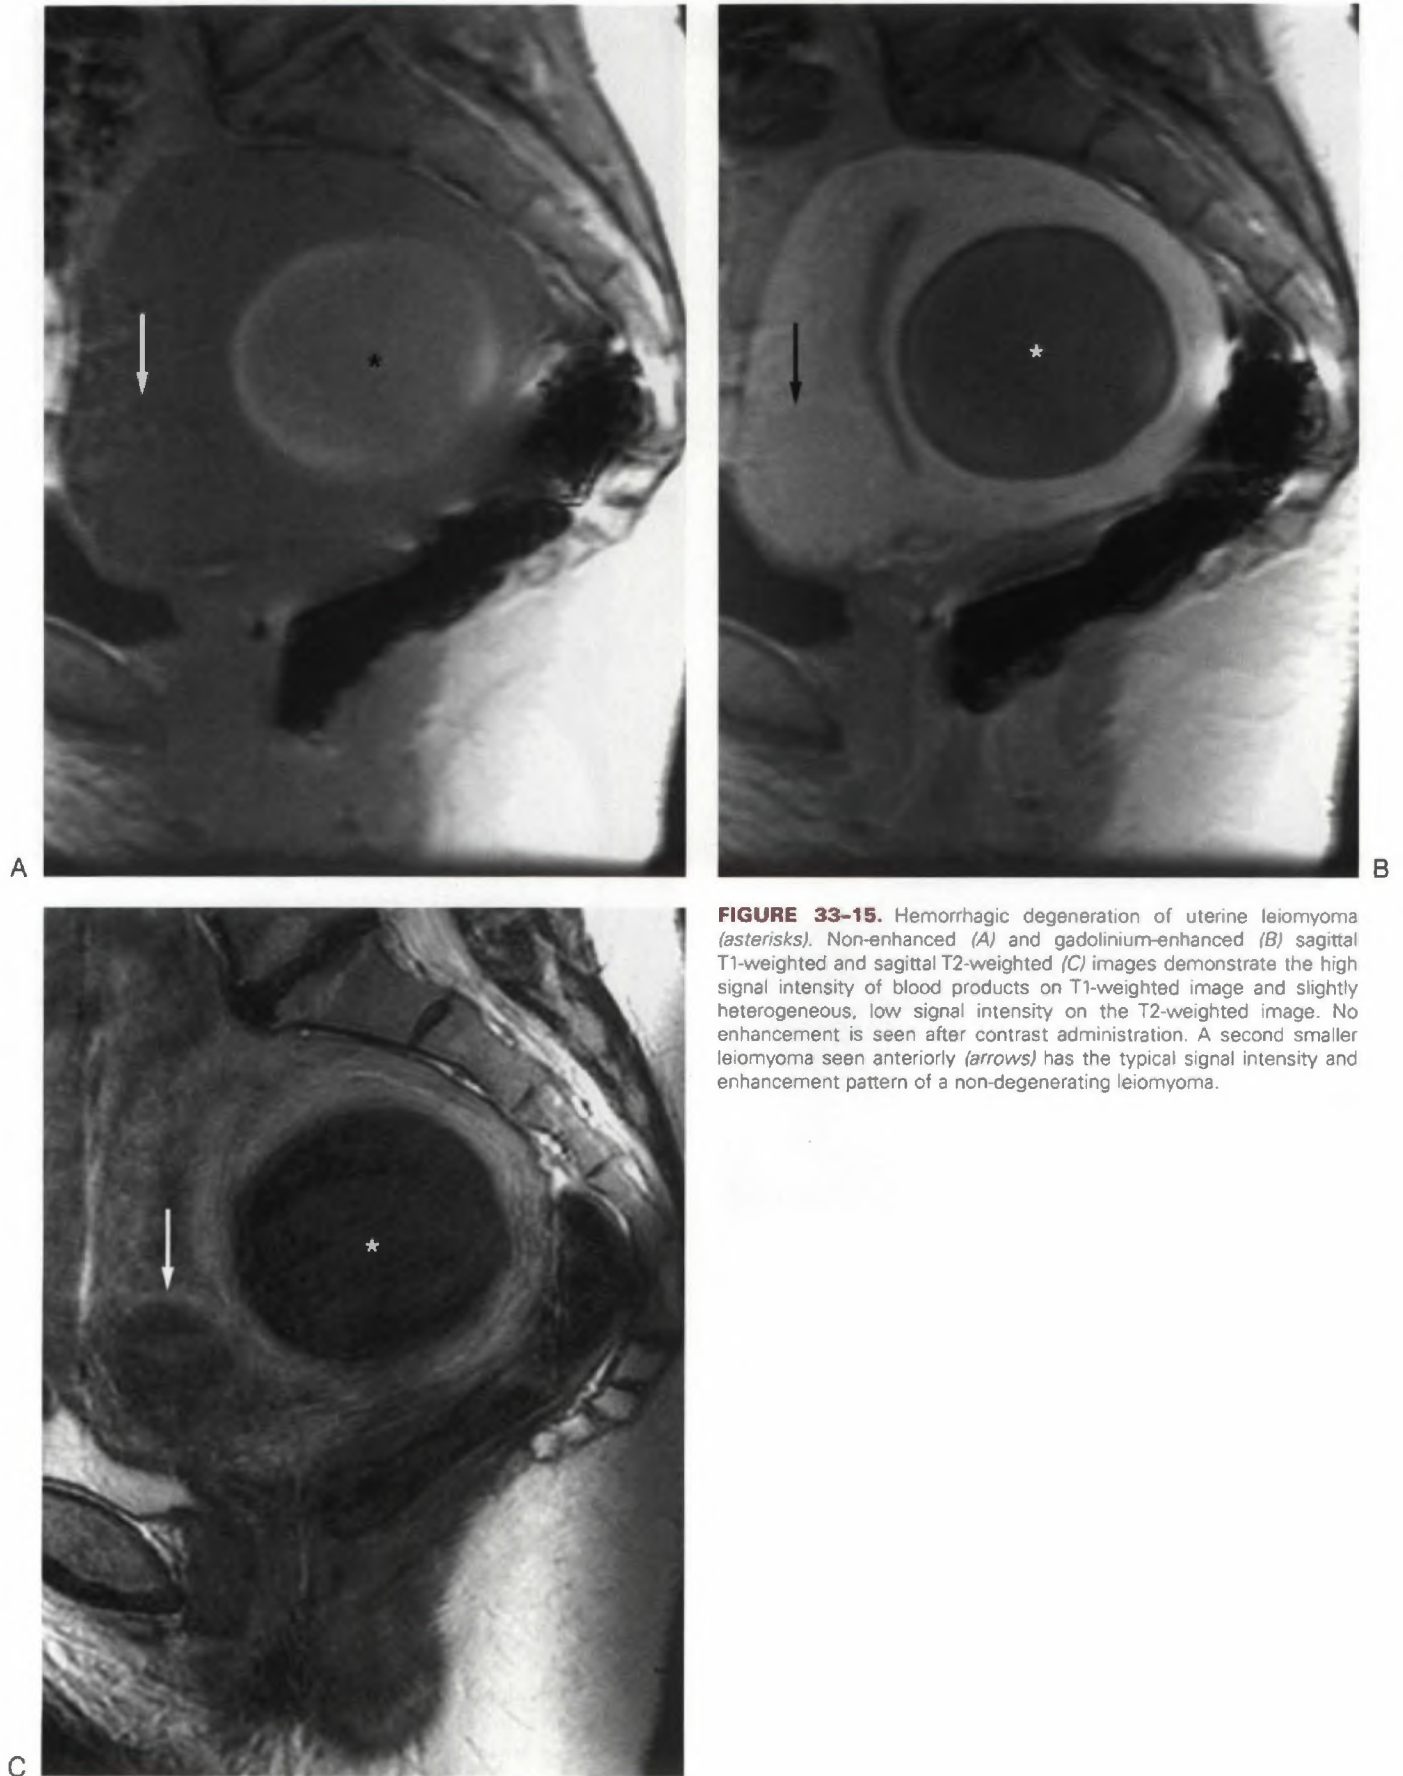

FIGURE 33-15. Hemorrhagic degeneration of uterine leiomyoma (*asterisks*). Non-enhanced (*A*) and gadolinium-enhanced (*B*) sagittal T1-weighted and sagittal T2-weighted (*C*) images demonstrate the high signal intensity of blood products on T1-weighted image and slightly heterogeneous, low signal intensity on the T2-weighted image. No enhancement is seen after contrast administration. A second smaller leiomyoma seen anteriorly (*arrows*) has the typical signal intensity and enhancement pattern of a non-degenerating leiomyoma.

FIGURE 33-16. Uterine sarcoma. Axial T2-weighted image. The endometrial cavity (*asterisk*) is displaced by a large cystic mass that contains mural nodules (*arrows*), a pathologically proven uterine sarcoma.

A

FIGURE 33-17. Leiomyomas and adenomyosis. Sagittal T2-weighted image demonstrate a diagnostic pseudocapsule of high signal intensity around a well-delimited leiomyoma (*arrow*). The junctional zone is diffusely thickened and has the characteristic starry sky appearance of adenomyosis (*arrowheads*). *Asterisk*, Nabothian cyst.

B

FIGURE 33-18. Cystic degeneration of uterine leiomyoma (*asterisks*). Axial T1-weighted (*A*) and sagittal T2-weighted (*B*) images demonstrate a well-circumscribed mass arising from the uterus. The lesion has cystic signal intensity characteristics (low and high T1-weighted and T2-weighted signal intensity, respectively). A few thin septations are seen. This was pathologically proven to be cystic degeneration of a leiomyoma.

proteinaceous content of blood or the presence of methemoglobin (see Fig. 33-15).^{38,43} The lesion may exhibit a rim of low signal intensity on T2 and high signal intensity on T1-weighted sequences, which represents obstructed veins around the lesion.⁴³ Myxoid degeneration is usually characterized by the presence of multiple areas of cystic change and very high T2-signal intensity.^{38,43}

ADENOMYOSIS

Definition and Epidemiology

Adenomyosis refers to the presence of intramyometrial endometrial mucosa (glands and stroma) surrounded by

hypertrophic myometrium. It is a common disorder; however, its exact prevalence is difficult to determine. The reported prevalence varies in both autopsy (20% to 67%)⁵⁵ and clinical studies (10% to 88%)⁵⁶⁻⁵⁹; this is likely the reflection of several factors, including inconsistent pathological definition of adenomyosis, different uterine specimen

processing, and varied patient inclusion criteria. Typically, adenomyosis is diagnosed in a multiparous woman in the 4th or 5th decade of life.

Clinical Aspects

The classic clinical scenario is that of a patient who presents with menorrhagia, dysmenorrhea, and metrorrhagia accompanied by an enlarged, soft uterus that is tender on examination. However, one third of patients with adenomyosis are asymptomatic. It is important to note that the frequency and severity of symptoms appear to correlate with the extent and depth of adenomyosis.^{55,60,61}

Pathophysiology

Adenomyosis causes globular and cystic enlargement of the uterus with some cysts filled with degraded red blood cells. It may be described as focal, diffuse, or both, depending on its distribution in the myometrium. Irrespective of presentation and unlike leiomyomas, the lesions have poorly defined margins.⁵⁵

There are three hypotheses that attempt to explain the development of adenomyosis.⁵⁵ Two of the hypotheses suggest a process of invagination of the basalis layer of the endometrial mucosa, either in between muscle fibers or along the intramyometrial lymphatic system. The third theory suggests adenomyosis develops as a result of metaplasia from de novo ectopic intramyometrial endometrial tissue.

In up to 80% of the cases, there is an additional uterine pathology, most commonly leiomyomas, but also endometrial polyps, endometrial hyperplasia, and endometrial adenocarcinoma.⁵⁵

Diagnosis

Although the typical clinical presentation may strongly suggest adenomyosis, the clinical diagnosis is not accurate and imaging is often used prior to treatment selection.

Imaging Characteristics

Transvaginal ultrasound is probably the first choice of imaging modality in patients with adenomyosis. It is widely available, and has low cost and good accuracy, similar to that reported to MRI. Its sensitivity ranges from 57% to 89% and the specificity from 65% to 98%.⁶²⁻⁶⁷ However, it is a technique that is operator dependent, and the best results are obtained with experienced examiners. In addition, the accuracy of the method decreases in patients who present with large uteri and associated leiomyomas. The reported sensitivity and specificity of MRI range from 70% to 86% and 86% to 93%, respectively,⁶²⁻⁶⁴ and MRI is generally used if ultrasound results are equivocal or when additional information is needed, especially for treatment planning.

The diagnosis of adenomyosis on MRI is made based on findings identified on T2-weighted sequences. Typical adenomyosis is characterized by the presence of focal or diffuse widening of the junctional zone (inner myometrium), or an ill-defined, hypointense, myometrial mass (see Figs. 33-14 and 33-17). The normal junctional zone in

FIGURE 33-19. Focal adenomyosis. Sagittal T2-weighted image demonstrate a region of thickened junctional zone (arrow) with indistinct margins.

premenopausal women appears as a band of low signal intensity between the endometrium and outer myometrium. Based on the study of Reinhold et al,⁶² identification of a junctional zone with 12 mm or more is diagnostic of adenomyosis, whereas a width of 8 mm or less reliably excludes the disease. For patients that fall in the indeterminate category (junctional zone measuring between 9 mm and 11 mm), secondary findings may help to establish the diagnosis. Such secondary findings include hyperintense punctate foci on T2-weighted images; hyperintense parallel lines radiating out from the endometrium, also on T2-weighted images; and ill-defined margins (see Fig. 33-14).^{49,63,68} The high-signal punctate foci are thought to be dilated endometrial glands, whereas the striations may represent endometrial invasion into the myometrium.⁶⁸ One of the greatest challenges for both ultrasound and MRI can be the differentiation between focal adenomyosis and a leiomyoma, the main differential diagnosis on MRI, because both lesions have low signal intensity on T2-weighted sequences and are concomitantly seen in 35% to 55% of the subjects.⁵⁵ The distinction is important because leiomyomas are often treated conservatively, whereas adenomyosis may require hysterectomy. Imaging features that suggest the diagnosis of focal adenomyosis are an ovoid rather than round shape; indistinct margins without a pseudocapsule; minimal mass effect; and continuation with the junctional zone (Fig. 33-19).^{68,69} Although small hyperintense areas

of hemorrhage are occasionally identified on T1-weighted sequences,⁶⁸ the T1-weighted images, with or without contrast enhancement, are not generally helpful in the diagnosis. It should be remembered, however, that focal adenomyosis or adenomyoma may not always be differentiated from a leiomyoma based on imaging findings.^{62,64}

ENDOMETRIOSIS

Definition and Epidemiology

Endometriosis refers to ectopic functional endometrial tissue, which may proliferate in response to hormonal secretion. White women between 25 and 40 years of age are more commonly affected by this process.⁷⁰ Endometriosis is identified in 5% to 15% of all premenopausal women, but in up to 50% of infertile patients.^{70–72} The overall incidence of endometriosis is 298/100,000 person-years; however, the incidence is five times greater if there is a history of infertility, especially if due to Müllerian duct anomalies.⁷⁰

Etiology

The etiology of endometriosis remains unclear; however, proposed theories include peritoneal seeding from retrograde transport of endometrial cells through the fallopian tubes, development from müllerian remnants, and peritoneal epithelium metaplasia. The suggested etiologic mechanisms may be complementary, although at present, the theory of retrograde transport of cells seems favored.⁷³

Clinicopathologic Aspects

Typical symptoms of endometriosis include dysmenorrhea, dyspareunia, chronic pelvic pain, and infertility. Although most frequently identified within the pelvis, endometriosis has been described in multiple locations, including the lungs, abdominal wall, and central nervous system.^{74–76} Within the pelvis, the sites of involvement in order of decreasing frequency are the ovaries (endometriomas), uterine ligaments, pouch of Douglas, and pelvic peritoneal surfaces. Ovarian involvement is bilateral in 30% to 50% cases.⁷⁷

Endometriomas are one of the most common blood-containing ovarian lesions and are usually seen in association with more extensive endometriosis. The ovarian tissue may be partially or completely replaced by the ectopic endometrial tissue, with glands and stroma seen lining the wall of the lesion. A thick and dense fibrous capsule is almost always present around the endometrioma. Although the endometrioma usually contains old degraded blood, fresh hemorrhage and clots are also identified. Adhesions to surrounding structures and internal septations are common and may lead to the misdiagnosis of an ovarian malignancy at ultrasound.

Imaging

MRI is usually reserved for cases in which ultrasound is inconclusive or when there is failure of regression of an ovarian mass seen in the context of endometriosis. Although there are MRI features that suggest the diagnosis of endometrioma, differentiation from a hemorrhagic cyst is

not always possible based on imaging criteria alone however, patients have typically undergone multiple ultrasound examinations before MRI and the persistence of a hemorrhagic adnexal mass favors the diagnosis of endometriosis.⁷⁸

The main advantage MRI has over ultrasound is its ability to confirm the presence of blood within the mass. Blood products demonstrate high signal intensity on T1-weighted images, which is characteristically persists with the application of fat suppression (Fig. 33–20).⁷⁹ On T2-weighted sequences, the contents of an endometrioma typically demonstrate low or intermediate signal intensity, depending on the concentration of methemoglobin and other iron products.⁸⁰ Layering of these low-signal-intensity blood products within the cyst is a frequently identified sign of endometriomas called T2-shading (Fig. 33–21).⁸¹ A black rim surrounding the lesion is another feature that has been described; however, it is not specific of endometriomas (see Fig. 33–21).⁷⁸ This rim is caused by the presence of iron within the mass, secondary to blood degradation. The fibrous wall of endometriomas typically has low signal intensity on both T1- and T2-weighted sequences and may show contrast enhancement.⁸² Although uncommon, cancer has been reported in association with endometriosis and should be suspected in the presence of an enhancing solid nodule or mass within the lesion (Fig. 33–22).⁸³ In a study by Brinton et al,⁴¹ patients with a long-standing history of ovarian endometriosis had increased risk of ovarian cancer (standardized incidence ratio of 4.2, ranging from 2.0 to 7.7).

In some instances, ultrasound may fail to correctly identify an obstructed, blood-filled, and dilated fallopian tube, which often occurs in endometriosis. The diagnostic dilemma may be resolved with MRI, owing to its large field-of-view and multiplanar capabilities. Endometrial implants are usually hyperintense on both T1- and T2-weighted images (Fig. 33–23); however, small endometrial implants ranging from 2 to 3 mm in diameter are often not detected by any imaging modality. MRI does appear to be fairly accurate for the detection of lesions greater than 1 cm in diameter, and the use of fat-suppressed T1 images reportedly increases the detection of smaller implants.^{84,85} Stratton et al⁸⁶ reported a reported a sensitivity and specificity of 69% and 75%, respectively for MRI detection of endometriosis using laparoscopy as a standard of reference. Another study reported similar results comparing MRI to laparoscopy; MRI had a diagnostic accuracy of approximately 77%. In addition, statistical analysis demonstrated excellent agreement between disease stages attributed by the two methods ($\kappa = 0.916$, $p < 0.001$).⁸⁶ MRI appears to be especially useful for the evaluation of deep pelvic endometriosis and cul-de-sac obliteration with sensitivities and specificities ranging from 68% to 94% and 76% to 100%, respectively.^{87–89}

CERVICAL CANCER

Epidemiology and Clinical Presentation

Cervical carcinoma represents the third most common gynecologic malignancy in the United States. It is diagnosed in one in every 135 American women over their lifetime, with approximately 9710 new cases and 3700 deaths estimated to occur in 2006.⁹⁰ Patients typically present

A

B

C

FIGURE 33-20. Ovarian endometrioma. Axial T1-weighted images, without (A) and with (B) fat saturation, and axial T2-weighted image (C) demonstrate a right ovarian mass (asterisks) of high signal intensity on T1-weighted images, which persists after fat-saturation, consistent with the presence of blood products.

FIGURE 33-21. Ovarian endometrioma. Axial T2-weighted image demonstrating layering of low-signal-intensity blood products within the endometrioma, also known as T2-shading sign (*arrow*). Another common finding is a very dark peripheral rim (*arrowhead*), due to hemosiderin deposition, which is also the result of blood degradation.

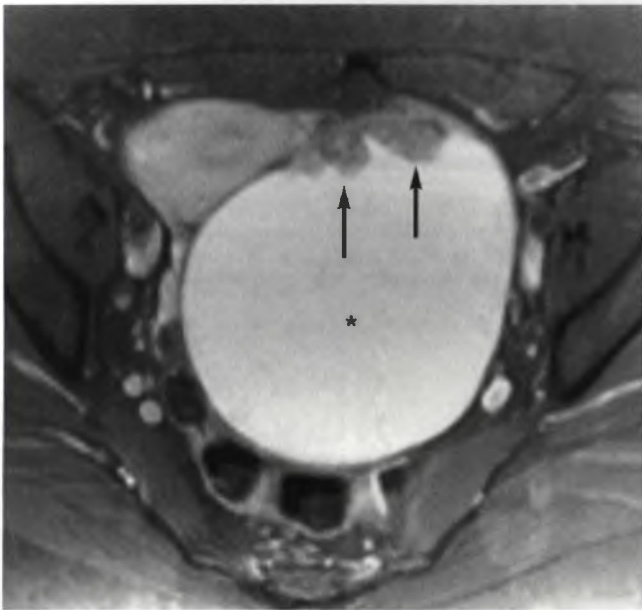

FIGURE 33-22. Clear cell carcinoma. Gadolinium-enhanced T1-weighted image with fat-saturation. A large cystic mass that contains fluid with high signal intensity after fat-saturation (*asterisk*), consistent with blood, is seen within the pelvis. Mural nodules (*arrows*) are suggestive of malignancy and the lesion was pathologically proven to be a clear cell carcinoma within an endometrioma.

between the third and fourth decades. Most noninvasive cervical cancers are asymptomatic and detected only by the Papanicolaou's (Pap) smear. Patients with invasive cancer in general have a history of intermenstrual or postcoital bleeding but may also be asymptomatic.

The most significant risk factor for development of cervical cancer is infection by human papilloma virus (HPV),

FIGURE 33-23. Endometriosis. Axial fat-saturated T1-weighted image demonstrates multiple masses of high signal intensity (*asterisks*), consistent with endometriosis.

especially types 16 and 18, among another 13 types also classified as high-risk viruses. More than a risk factor, it is likely that infection by HPV has causal effect. Several other risk factors have been reported, including an early sexual life, multiplicity of sexual partners, low socioeconomic status, smoking, and use of oral contraceptives; however, it is unclear if they represent independent factors or are directly or indirectly related to HPV infection.⁹¹

Histopathology

The vast majority are squamous cell carcinomas arising from foci of dysplasia and atypia at the squamocolumnar junction. The remaining 10% to 15% are adenocarcinomas that originate in the endocervical glands.^{92,93} Adenoma malignum is a very rare subtype of cervical adenocarcinoma (3%). It is a multicystic lesion associated with copious watery vaginal discharge and is diagnosed only with deep biopsies of the cervix. Although histologically, it is a well-differentiated lesion, in reality, it has very poor prognosis and response to therapy. The MRI appearance of adenoma malignum may be indistinguishable from a nabothian cyst. It is important to remember that this cancer is exceedingly uncommon and should not be diagnosed based on imaging findings alone.⁹⁴ A few other rare tumors, such as villoglandular tumors, may be seen in the uterine cervix.⁹⁵

There are three patterns of spread of squamous cell carcinoma of the cervix: direct invasion of adjacent organs, the most common; lymphatic dissemination to pelvic and para-aortic lymphnodes; and rarely, hematogenous spread to the lungs and bones.⁹⁶

Table 33-1

Carcinoma of the Uterine Cervix—Federation of Gynecology and Obstetrics Staging

Stage	Description	5-year Survival
0	Carcinoma in situ	
I	Confined to the uterus	
IA	Microscopically invasive	> 93%
IB1	Clinically visible < 4 cm	90%
IB2	Clinically visible > 4 cm	80%–95%
II A/B	Beyond the uterus, to the upper vagina (A) or parametrial invasion (B)	75%–78%
III A/B	Extension to lower vagina (A) or to pelvic sidewall and/or hydronephrosis (B)	47%–50%
IV A/B	Bladder/rectum invasion (A) or distant metastasis (B)	20%–30%

Diagnosis

Imaging has no role in the diagnosis of cervical cancer. In the majority of cases, the cancer is detected through Pap smear, or exfoliative cytology. The effective use of screening has caused a decline in incidence and mortality from invasive squamous cell carcinomas but a relative increase in incidence of adenocarcinomas.^{97–99}

Treatment

Treatment of cervical cancer largely depends on the stage of disease.^{92,100} Patients with microinvasive (stage IA) and early macroinvasive disease (stage IB1, IIA < 4 cm) are usually offered curative surgery—total hysterectomy, with or without lymphadenectomy. If fertility is desired, patients with microinvasive cervical cancer can be treated with cone biopsy. Primary radiotherapy is another alternative for early macroinvasive disease. For more advanced cases, treatment is usually a combination of surgery, radiotherapy, and chemotherapy.

Clinical Staging

Staging of cervical cancer aims at assessing tumor resectability and is currently based on the International Federation of Gynecology and Obstetrics (FIGO) classification system (Table 33-1). The FIGO classification is a clinical approach based on findings from physical examination, which may be performed under anesthesia. Nonetheless, staging is usually complemented by a combination of colposcopy, biopsy, chest radiography, intravenous excretory urography, barium enema, cystoscopy, or proctosigmoidoscopy. Although some studies have already shown the value of cross-sectional imaging,^{103–107} it has not yet been included in the FIGO staging system.^{101,102}

The FIGO staging system is used as a predictor of patient survival^{101,102} but has limitations. Studies have shown a

poor correlation between the clinical stage and surgical-pathologic findings. Errors in staging have been reported to reach 30% for stage I tumors, 50% for stage II, and 75% for stage III.^{93,108,109} These limitations relate particularly to a failure in the accurate estimation of tumor size, and the detection of parametrial, pelvic sidewall, bladder and rectal wall invasion, as well as metastases to distant organs.⁹³ In addition, nodal status, known to be one of the most important prognostic factors, is not included in the staging system.^{93,96,108,110}

Accurate staging influences clinical management. Current FIGO and International Gynecologic Cancer Society⁹⁶ guidelines suggest surgical treatment or radiotherapy alone for patients with early disease, stages IA, IB1, and IIA with tumor size less than or equal to 4 cm. Patients who have more extensive early disease, stages IB2 and IIA with tumor size greater than 4 cm, may require radiation and/or chemotherapy. Furthermore, stage IIB (limited extrauterine extension to the parametrium) disease or greater precludes curative surgical treatment.

Imaging

MRI is highly accurate for staging cervical cancer, surpassing clinical staging when only stage IIA or greater are considered (53% versus 73%–81%). The T2-weighted sequences are most valuable in the evaluation of cervical cancer. It is identified as a mass of intermediate signal intensity disrupting the normally low-signal-intensity cervical stroma.^{42,93} Dynamic gadolinium-enhanced T1-weighted imaging has been shown to improve detection of cervical cancer and may be especially useful for the evaluation of depth of stromal invasion, parametrial involvement, and bladder wall invasion.^{93,107,111} However, the use of single-phase contrast enhanced T1-weighted images may result in overestimation of disease.^{93,106}

Early Stage Disease

Microinvasive carcinoma (stage IA) cannot be detected by MRI; however, macroinvasive disease (stage IB) can be detected, with an accuracy of 91%.^{42,93} In addition, MRI may be used to determine the depth of stromal invasion.¹⁰⁷ In stage IB disease the cervical stromal ring completely surrounds the tumor (Fig. 33-24).^{42,93} Stage II disease is characterized by local extension of tumor beyond the uterus. Stage IIA indicates invasion of the upper two-thirds of the vagina and stage IIB indicates parametrial extension. Vaginal wall extension is best evaluated in the sagittal plane on MRI. Invasion of the vagina should only be diagnosed in the presence of vaginal wall thickening and an increase in the signal intensity of the normally low-signal-intensity vaginal wall on T2-weighted sequences.^{42,93}

Parametrial Extension

Axial T2-weighted images are used to determine parametrial invasion. Parametrial extension (stage IIB disease) is diagnosed in the presence of partial or complete disruption of the dark ring of cervical stroma, associated with an irregular interface between the cervix and adjacent fat (Fig. 33-25). The presence of a definite bulge of asymmetric

FIGURE 33-24. Stage IB cervical cancer. Axial T2-weighted image. A large hyperintense cervical cancer (*asterisk*) expands the cervix but does not extend beyond the low signal intensity ring of cervical stroma (*arrows*).

FIGURE 33-25. Stage IIB cervical cancer. Axial T2-weighted image. There is interruption (*arrows*) of the hypointense ring of cervical stroma by a large hyperintense cervical mass (*asterisk*) that bulges into the adjacent fat.

FIGURE 33-26. Stage IIIB cervical cancer. Axial T2-weighted image demonstrates a large cervical cancer extending to the pelvic sidewalls (*arrowheads*). A dilated left ureter (*arrow*) is present.

high signal tissue is a more specific finding of parametrial invasion. Occasionally, encasement of parametrial vessels may also be seen. Parametrial invasion is demonstrated with an accuracy of 68% to 96% on MRI.^{93,105,109} More important, MRI has a high negative predictive value for parametrial invasion—ranging from 79% to 100%.^{93,109,110,112} The positive predictive value of MRI for parametrial invasion is low, because MRI cannot accurately differentiate benign reactive changes seen adjacent to the cervix from actual tumor invasion.

Stage III Disease

Invasion of the lower third of the vagina (IIIA) and pelvic sidewall invasion (IIIB) characterizes stage III disease. Pelvic sidewall invasion (stage IIIB) is demonstrated by the loss of fat planes between the tumor and iliac blood vessels and muscles of the pelvic sidewall.⁹³ The increased signal intensity of these muscles may also be observed on T2-weighted sequences.⁹³ An important indicator of pelvic sidewall invasion is the presence of hydronephrosis; therefore, MRI evaluation must include imaging of the upper abdomen, more specifically the kidneys, for assessment of hydronephrosis.^{42,93} MRI has an accuracy of approximately 95% to characterize stage III disease (Fig. 33-26).¹¹²

Stage IV Disease

Bladder and rectal invasion are also characterized by loss of fat planes between the organs and the tumor, as well as by increased T2 signal intensity, enhancement, thickening and

FIGURE 33-27. Stage IVA cervical cancer. Gadolinium-enhanced sagittal T1-weighted image. An enhancing mass (arrow) is seen in the posterior bladder wall representing bladder invasion by the large cervical cancer (asterisk).

irregularity of the bladder and rectum walls (Fig. 33-27).^{42,93} MRI is 96% accurate in making the diagnosis of bladder and rectal invasion, respectively.¹¹²

Tumor Size Assessment

Tumor size has been shown to be a significant prognostic factor and several studies have demonstrated that MRI is an accurate technique for assessing tumor size.^{93,103,108,110,112} MRI measurements are within 0.5 cm of the surgical in 70% to 90% of the cases.⁹³

Lymph Node Assessment

The FIGO staging of cervical cancer does not include the evaluation of lymph nodes, although it has been shown that lymph node metastases carry significant prognostic information. For instance, in patients undergoing surgery for stage IB and IIA disease, survival decreases from 85% to 90% and to 50% to 55% if lymph nodes are positive. MRI determination of lymph node involvement is largely dependent on size criteria in current practice. A threshold of 1 cm diameter in the short-axis is generally accepted as indicative of metastatic involvement.¹¹³⁻¹¹⁵ However, enlarged lymph nodes may represent reactive, hyperplastic change in patients with malignancy, and small nodes may

contain microscopic foci of metastatic disease. An exciting new development in the detection of metastatic lymph node disease is the use of ultra-small superparamagnetic iron oxide-enhanced MRI. Initial studies have consistently reported excellent results for detection of pelvic lymph nodes in a variety of cancers.¹¹³⁻¹¹⁵ The reported specificities and negative predictive values range from 80% to 99% and 98% to 100%, respectively. The sensitivity of the method was shown to range widely, from 25% to 100%.

ENDOMETRIAL CANCER

Epidemiology and Clinical Presentation

Endometrial carcinoma is the fourth most common cancer in women, and the most common of the gynecologic malignancies. In 2006, 41,200 new cases and 7350 deaths are expected to occur.⁹⁰ Despite the high incidence of cases as compared with other gynecologic malignancies, endometrial cancer is associated with the best prognosis, and most patients with newly diagnosed disease are cured by surgery alone or in combination with adjuvant radiation therapy.¹¹⁶ Endometrial cancer occurs more frequently in whites and typically presents during the 6th and 7th decades with painless postmenopausal bleeding.^{117,118} Many risk factors have been described, most directly or indirectly related to estrogen exposure, including early menarche, late menopause, nulliparity, Stein-Leventhal syndrome (polycystic ovary syndrome), diabetes, and obesity. In addition, a higher incidence of endometrial cancer is associated with adenomatous polyps, breast cancer and the use of unopposed estrogen therapy.¹¹⁷⁻¹²⁰

Histopathology

More than 80% of endometrial cancers are of the endometrioid type, which refers to the presence of endometrial type glands of varying differentiation. These are subdivided into two groups, type 1 (low grade) and type 2 (high grade). Type 1 endometrial cancers are related to long-term unopposed estrogen therapy; they originate from endometrial hyperplasia and have a more favorable prognosis. Type 2 cancers represent 10% of endometrial cancers; they are most often seen in association with atrophic endometrium, and have a poorer prognosis. Other histologic types include serous and clear cell carcinomas. Approximately 8% of patients with endometrial cancer present with a synchronous ovarian carcinoma of the same histology.¹¹⁷

Endometrial carcinoma may present as a localized endometrial lesion, mimicking a polyp, or as diffuse thickening of the endometrium. Tumor spread initially occurs by direct myometrial or cervical extension. Lymphatic invasion is usually limited to the pelvis but may extend to periaortic and aortocaval nodes.¹¹⁷ Transtubal peritoneal seeding and hematogenous dissemination to the lungs or other sites may occur.^{121,122}

Diagnosis

The diagnosis of endometrial cancer is based on histologic evaluation of endometrial biopsy specimens, which is highly

accurate, especially in symptomatic postmenopausal women. The two most common diagnostic pathways are biopsy or transvaginal ultrasound, followed by biopsy.¹¹⁷ An estimation of the risk of cancer following ultrasound in a postmenopausal woman depends on the presence or absence of vaginal bleeding and on the thickness of the endometrial stripe. In patients with vaginal bleeding, an endometrium measuring more than 4 to 5 mm translates to a risk of approximately 7.3%, whereas in the absence of bleeding, a similar risk (6.7%) is seen if the endometrium measures 11 mm or more in thickness.⁸ In these two situations, biopsy is warranted. MRI has no role in diagnosing the disease and is usually reserved as an aid for pretreatment planning.

Treatment

The primary treatment modality of endometrial cancer is total hysterectomy with bilateral salpingo-oophorectomy, and peritoneal fluid aspiration and washings. In selected cases, omentectomy and retroperitoneal lymph node dissection are performed.¹¹⁷ Radiation therapy is generally prescribed as an adjuvant treatment, targeting microscopic lymphadenopathy. In patients who are medically inoperable, it may be used with curative purposes. Systemic adjuvant chemotherapy seems to have results similar to those obtained with radiation therapy but with greater toxicity. In patients with more advanced disease, its use is palliative.¹¹⁷

Staging

Patients with endometrial cancer are staged surgically, usually using the system proposed by FIGO (Table 33-2)¹²³ or the American Joint Committee on Cancer.¹²⁴ Staging provides prognostic information, but it is also important for making treatment selection.

A poorer prognosis is expected in patients who present with deep myometrial invasion (> 50%, stage IC), cervical extension (stage II), and nodal involvement (stage IIIC). Other important prognostic factors are positive peritoneal

cytology, poorly differentiated cancer, serous papillary tumor, and clear cell tumors.

Depth of myometrial invasion was found to be the single most important predictor of survival at 5 and 10 years, in a series of 1566 women with endometrial carcinoma.¹²⁶ Women with superficial myometrial invasion (less than 50% of myometrial wall thickness) have a 3% to 9% incidence of lymph node metastases and a survival rate of 85% at 5 years. Deep myometrial invasion (> 50% of myometrial wall thickness) is associated with a 20% to 40% risk of nodal disease and a survival rate of 63% at 5 years.¹²⁶ Besides providing prognostic information, staging is also important for treatment selection. For instance, there is evidence that radiation therapy is not indicated in low or intermediate risk stage I disease (stage IA and IB), but may be beneficial for patients with more advanced disease and higher risk.¹²³ Similarly, surgical treatment is dictated by staging, and patients with stage IA or IB disease do not require radical lymphadenectomy.¹²³

MRI is an accurate tool for endometrial cancer staging, with an overall staging accuracy of approximately 85%.^{106,127} The use of gadolinium is an important part of the study. It has been shown to increase the accuracy of the method.^{106,128-130} Many studies have demonstrated that MRI is particularly accurate for assessment of myometrial invasion. Reported accuracy for the identification of deep myometrial invasion varies from 74% to 95%,¹²⁷⁻¹³⁷ compared with 68% to 73% for transvaginal ultrasonography.^{128,138} However, MRI can overestimate myometrial invasion, especially when bulky disease stretches and thins the myometrium.^{134,135} Finally, MRI can also assess cervical extension of tumor (stage II) and extrauterine disease (stages III and IV).

Although the evaluation of nodal metastasis with imaging modalities typically has not been as good as the surgical approach due to the limited accuracy of the size criteria used, results of studies applying ultra-small particles of iron oxide or ultra-small superparamagnetic iron oxide (unavailable in the United States, as its use is not yet approved by the Food and Drug Administration) have been promising. Rockall¹¹⁴ reported excellent sensitivity and specificity for the detection of nodal metastasis on analysis performed per node and per patient, ranging from 82% to 100% and 87% to 97%. The negative predictive value varied between 96% and 100%.

Imaging

As mentioned previously, MRI is not used for the diagnosis of endometrial carcinoma, but it is an established part of patient evaluation when locally extensive disease is suspected or when physical examination is limited.

Endometrial carcinoma is usually seen as an endometrial mass, which is iso- or hypointense to normal endometrium on T1-weighted sequences, and slightly hyperintense or heterogeneous on T2-weighted sequences. After contrast administration, tumor enhancement is variable, depending on histologic type and temporal resolution. Endometrial carcinoma is usually hypointense to the myometrium on early phase images. The administration of gadolinium allows tumors to be distinguished from debris or fluid in the endometrial and endocervical cavities. In addition, as the

Table 33-2 Carcinoma of the Endometrium—Federation of Gynecology and Obstetrics Staging

Stage	Description	5-year Survival
0	Carcinoma in situ

FIGURE 33-28. Stage IB endometrial cancer. Gadolinium-enhanced sagittal T1-weighted image demonstrating expansion of the endometrial cavity by an enhancing mass (*asterisk*) and associated focal superficial invasion of the myometrium anteriorly (*arrow*).

zonal anatomy may not be clearly defined in postmenopausal women, dynamic gadolinium enhancement facilitates the visualization of the junctional zone and the tumor-myometrium interface.

Superficial myometrial invasion (stage IB) is suspected in the presence of interruption of the dark junctional zone on T2-weighted sequences or subendometrial band of enhancement after contrast administration (Fig. 33-28).^{127,128,137} Deep myometrial invasion (stage IC) is characterized if tumor is seen extending into more than 50% of the myometrial thickness, with an intact outer rim (Fig. 33-29).

Cervical extension of tumor (stage II) is best evaluated using sagittal T2-weighted or contrast-enhanced images and may appear as a mass expanding the cervical canal. Stage III disease is characterized by extension of tumor beyond the serosa, to the adnexa and parametrium, positive peritoneal cytology, invasion of the vagina, and metastatic pelvic and para-aortic lymph nodes (Fig. 33-30). Stage IV is defined as bladder or rectal invasion and distant metastases. Invasion of the bladder and rectum is suggested by the loss of normal tissue planes, especially fat planes, associated with an increase in signal intensity and thickness of bladder or rectal walls on T2-weighted images. Contrast administration is also useful to make this diagnosis.

FIGURE 33-29. Stage IC endometrial cancer. Sagittal T2-weighted image demonstrating a large hyperintense mass (*asterisk*) invading more than 50% of the myometrium in the anterior uterine wall (*arrow*).

ADNEXAL MASSES

Epidemiology and Clinical Significance

Every woman, pre- and post-menopausal, develops an adnexal mass in her lifetime. In the vast majority of cases these are functional cysts that are involute and remain undiagnosed; however, about 1.5% of women develop a malignant ovarian tumor.¹ For the year 2006, 20,180 new cases of ovarian cancer and 15,310 deaths are expected to occur.⁹⁰ Adnexal masses, irrespective of the diagnosis and aggressiveness status, represent a major indication for gynecologic surgery. Approximately 5% to 10% of women in the United States undergo surgery because of a suspected ovarian mass. Imaging plays an important role in staging patients and planning treatment.¹³⁹

Many factors must be taken into account when imaging work-up is being considered. These include the patient's age and menopausal status, cancer antigen 125 levels, and clinical history. A precise diagnosis of a benign lesion is crucial, as further unnecessary work-up is then avoided, resulting in reduction of overall costs, morbidity, and patient's anxiety. Conversely, if resection of a benign lesion is warranted, less invasive approaches, such as laparoscopic surgery, may be used. Furthermore, patients who have malignant lesions should be referred to a gynecologic oncologist, as specialized management has been shown to result in improved survival.¹⁴⁰

Imaging Diagnosis and the Role of Magnetic Resonance Imaging

The primary imaging modality for the evaluation of an adnexal mass is ultrasound. It has a sensitivity and specificity for differentiating benign from malignant adnexal masses

FIGURE 33-30. Stage IIIA endometrial cancer. Sagittal T2-weighted (A) and gadolinium-enhanced axial T1-weighted (B) images. The sagittal image demonstrates extension of the endometrial tumor to the cervix (*asterisk*) and bilateral solid and cystic ovarian masses that represent metastases (*arrows*). The axial T1-weighted gadolinium-enhanced image shows enhancement of the tumor invading the ovaries and bilateral enhancing solid and cystic ovarian masses that represent metastases (*arrows*). A small amount of free fluid is seen in the cul-de-sac (*arrowheads*).

that range from 50% to 100% and 46% to 100%, and is particularly useful in distinguishing simple cysts from complex cystic or solid lesions. MRI is sometimes an option, especially for women who have sonographically indeterminate lesions and a low risk for malignancy. Advantages of MRI over ultrasound relate to its ability to better depict information on the composition of soft tissue masses, using differences in tissue relaxation times. MRI typically is not a first-line modality because it is expensive and ultrasound more often than not provides all additional information necessary to guide management. However, it is a good tool to differentiate a benign from a malignant lesion, with an accuracy of 88% to 93%.¹⁴¹⁻¹⁴⁴ The Radiology Diagnostic Oncology Group study showed that MRI was the most accurate technique in the preoperative assessment of adnexal masses for possible ovarian malignancy, whereas there was no significant difference between ultrasound and computed tomography.¹⁴⁴ The authors also noted that malignancies were seldom subtle and peritoneal spread was often present at the time of imaging.

Differentiation of Benign and Malignant Lesions

As a general rule, benign masses are cystic and have thin walls and septa (less than 3 mm); however, there are exceptions to this rule, as shown subsequently.

Malignant adnexal masses are classically said to have internal complexity, a somewhat indeterminate term to describe the presence of mural nodules, thick septa, solid components, and necrosis. Another feature that also favors malignancy is bilateralism.⁸² Malignant tumors are rarely subtle lesions, and frequently, peritoneal spread is identified at the time of imaging.¹⁴⁴ Although lesion size has been reported to be a useful attribute to differentiate a benign from a malignant lesion,^{145,146} it is important to remember that even very large tumors are more often benign.

Although a solid adnexal mass is suggestive of malignancy, especially metastasis, not all solid tumors are malignant,¹⁴⁷ and MRI can diagnose some benign entities with enough accuracy to avoid further work-up.

A good diagnostic approach is to categorize the adnexal masses into one of the following groups: lesions with distinctive features (fat, blood, and fibrous tissue) and a specific diagnosis; cystic, benign-appearing lesions; cystic, malignant appearing lesions; and predominantly solid lesions.

Specific Diagnosis Based on Magnetic Resonance Imaging Findings

Adnexal Masses With Distinctive Imaging Features (Fat, Blood, and Fibrous Tissue)

Dermoid cysts, also known as benign mature teratoma, are hamartomas composed of hair, teeth, fat, and mural nodules.^{82,142,148,149} Usually identified during the first three decades of life, these lesions are not uncommon but may be missed in up to 27% of cases on ultrasound examination.¹⁴⁸ A possible explanation for this is that the echogenicity of fat in the dermoid cyst on ultrasound may simulate surrounding normal structures. In contrast, because of fat, these tumors are identified on MRI without difficulty, because the high signal intensity of fat on T1-weighted images is lost after fat suppression techniques are applied (Fig. 33–31).^{82,142}

The two most common adnexal lesions that contain blood are hemorrhagic cysts and endometriomas. Endometriomas have been extensively discussed earlier in this chapter. Imaging of hemorrhagic cyst with MRI is not as common, as these usually resolve after one or two menstrual cycles and follow-up is completed with ultrasound only. Herein, it suffices to say that if MRI confirms blood within an endometrial cyst, no further diagnostic tests are unnecessary.

Fibromas are the most common sex cord tumors and represent 4% of all ovarian neoplasms. Because of their solid appearance, they can be misdiagnosed as a malignant lesion at ultrasound; however, on MRI fibromas have a very characteristic appearance. Fibromas are composed of bundles of spindle cells resembling fibroblasts, collagen, and hyalinized fibrous tissue and demonstrate low signal intensity on both T2- and T1-weighted sequences and only slight enhancement after gadolinium administration (Fig. 33–32). Ascites may be present in up to 40% of cases, more often when the lesion is large. Meig syndrome refers to its association with pleural effusions.^{82,142,150,151} Its malignant potential is reported to be less than one percent. Two other lesions that characteristically present with foci of low signal intensity on both T2- and T1-weighted sequences are the fibrothecoma and the cystadenofibroma. The fibrothecoma is a variant of the fibroma that has a small population of thecal cells containing intracellular lipid. It is similar in appearance on MRI but may be hormonally active or be associated with endometrial polyps and hyperplasia.^{82,142,150,151} The cystadenofibroma is a variant of a serous cystadenoma with very low malignant potential. In most cases it presents as a multiseptated mass.^{82,142}

Cystic, Benign-Appearing Lesions

This group is composed of various entities, the most frequently identified ones being physiologic cysts, including follicular and corpus luteum cysts; theca-lutein cysts;

paraovarian cysts; hydrosalpinx; peritoneal inclusion cysts; and cystadenomas. In the vast majority of patients, ultrasound correctly diagnoses and classifies the cysts as benign. However, MRI may provide additional diagnostic information in an occasional case complicated by infection or hemorrhage.

Cystic, Malignant-Appearing Lesions

Epithelial tumors represent the most common primary ovarian cancers^{82,152}; therefore, they are the most common malignant appearing cystic adnexal masses. Histologically, these tumors are classified as serous, mucinous, endometrioid, and mesonephroid (clear cell). Typically they are cystadenocarcinomas or borderline tumors. Distinguishing these two entities can be difficult, because both present with similar imaging features, namely, thick walls or septations and some solid component (Figs. 33–33 and 33–34).⁸² The absence of invasion or metastatic disease favors the diagnosis of a borderline tumor. Ascites is frequently considered a sign of more aggressive disease. In addition, extensive calcifications usually indicate malignancy, especially in the case of serous tumors. The T1 and T2 signal intensity of the cystic areas of a mucinous tumor is variable, owing to different amounts of mucin within locules.⁸²

Predominantly Solid Lesions

Predominantly solid lesions of the adnexa may represent primary ovarian lesions, leiomyomas, and nonovarian tumors, such as metastases and lymphoma.

The ovaries are the most common sites of metastasis to the female genital tract. Primary tumors commonly spreading to the ovaries are the endometrial, cervical, gastric, colorectal, and breast cancers.¹⁵³ Ovarian metastases have no specific appearance, but are commonly bilateral and strongly enhancing masses. They can be predominantly cystic and with necrotic areas (see Fig. 32–30). The primary tumor is usually clinically overt.^{153–156} Although exceptionally rare, ovarian lymphoma may be suspected in the presence of extensive lymphadenopathy associated with nonobstructive vessel encasement.¹⁵⁷

Primary ovarian tumors can also present as predominantly solid masses; examples are the dysgerminomas, granulosa cell tumors, and Sertoli-Leydig tumors, also known as androblastomas and arrhenoblastomas. All three types are uncommon tumors without specific imaging features and all may present with associated cystic areas (Fig. 33–35). They are most frequently diagnosed in patients younger than 30 years of age, although granulosa cell tumors also have a peak incidence in postmenopausal women. Dysgerminomas are responsible for one third of all ovarian tumors during pregnancy and disproportionate amount of adenopathy, relative to the size and appearance of the ovarian lesion, is sometimes noted.⁹⁶ Granulosa cell tumors and Sertoli-Leydig cell tumors are hormonally active, the former producing estrogen and the latter androgen.^{150,158,159} Hormonal secretion helps building up a clinical differential diagnosis.

A pedunculated leiomyoma, or a leiomyoma of the broad ligament and adnexa may be misdiagnosed as solid ovarian lesion at ultrasound, especially because the origin of the lesion is hard to determine. In this situation, MRI may

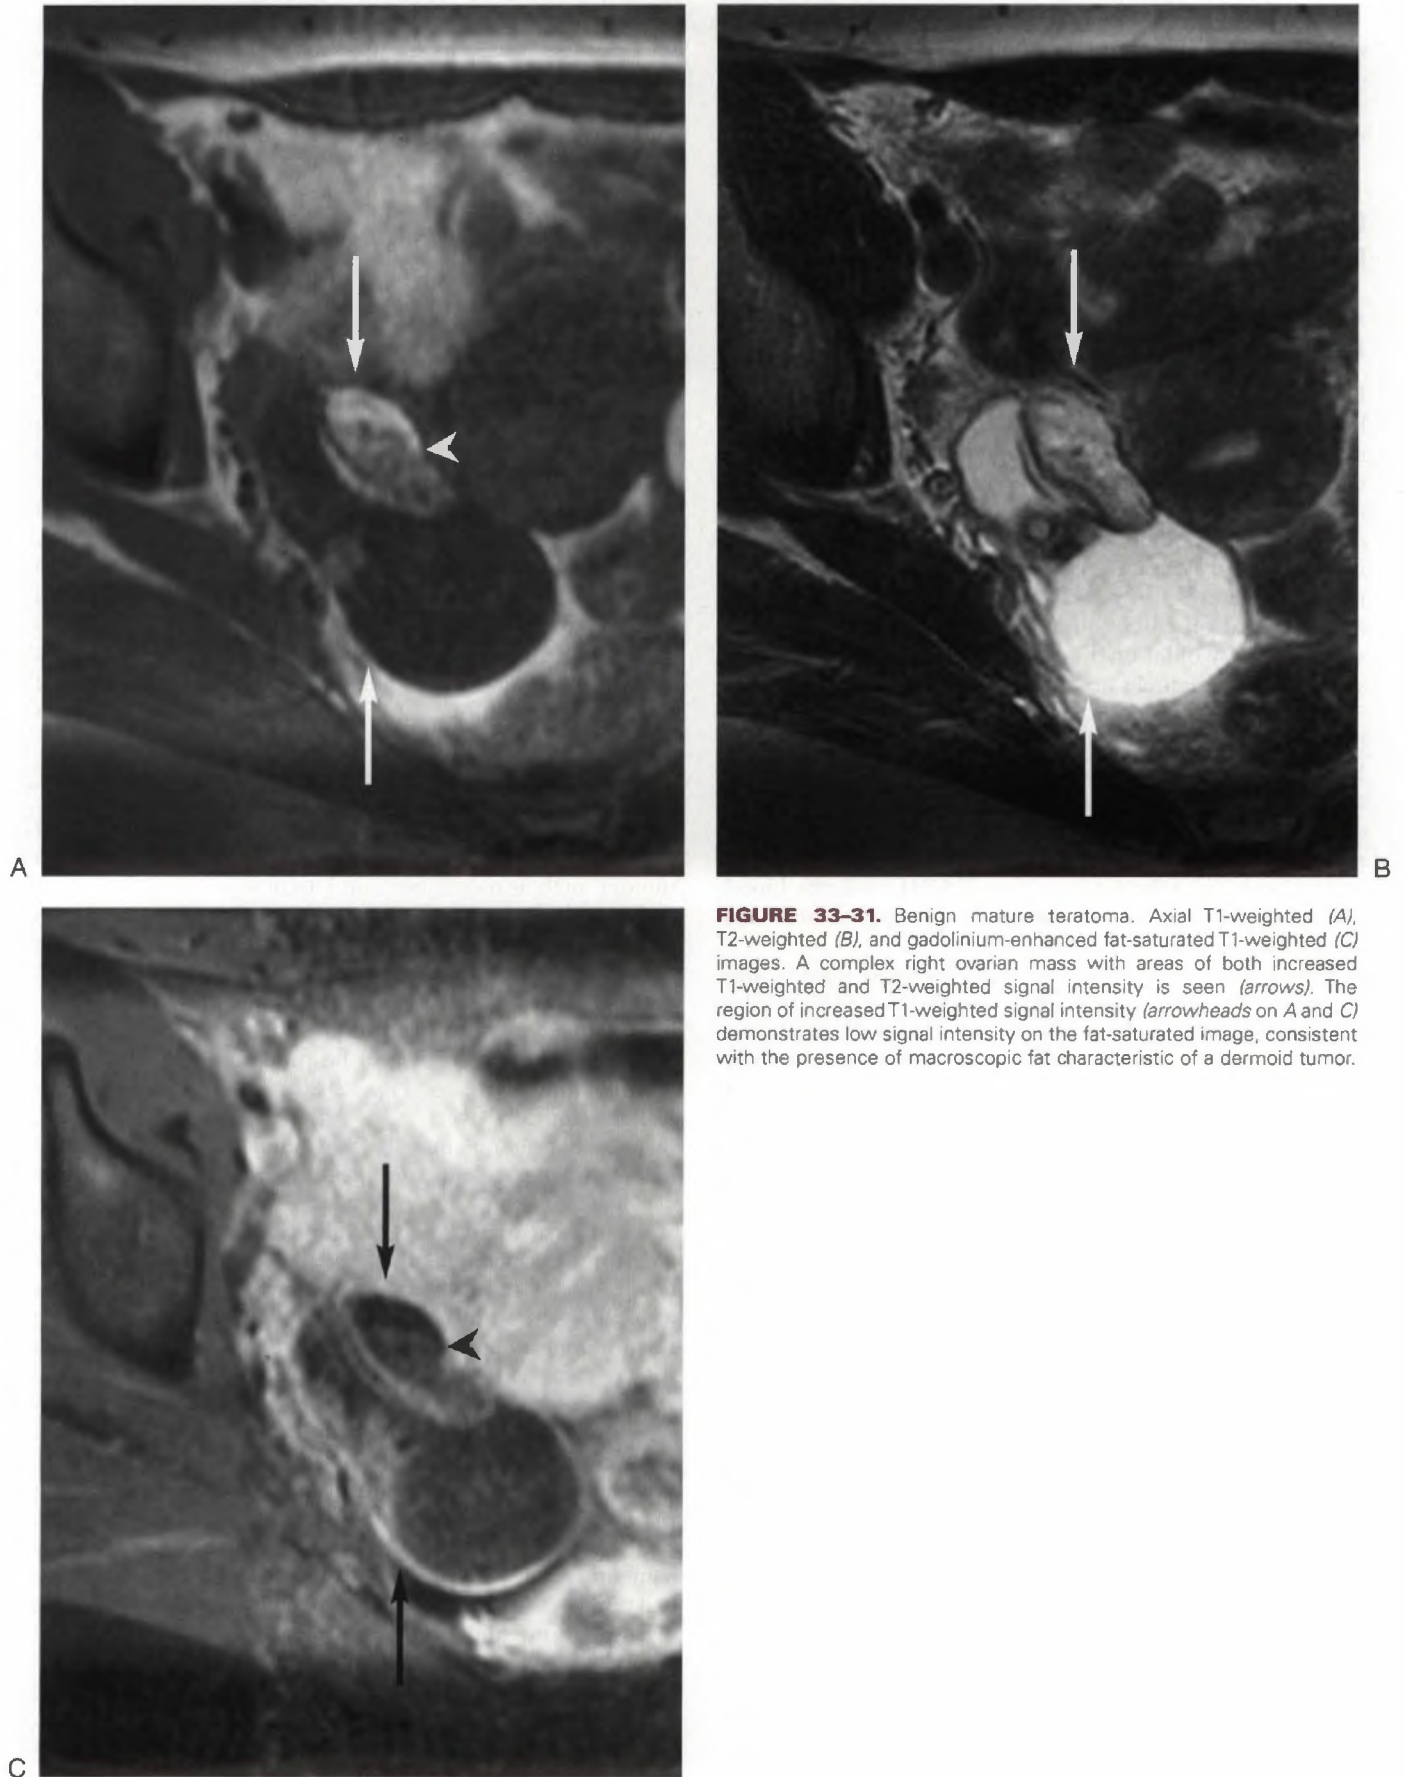

FIGURE 33-31. Benign mature teratoma. Axial T1-weighted (A), T2-weighted (B), and gadolinium-enhanced fat-saturated T1-weighted (C) images. A complex right ovarian mass with areas of both increased T1-weighted and T2-weighted signal intensity is seen (arrows). The region of increased T1-weighted signal intensity (arrowheads on A and C) demonstrates low signal intensity on the fat-saturated image, consistent with the presence of macroscopic fat characteristic of a dermoid tumor.

FIGURE 33-32. Ovarian fibroma. Axial T1-weighted (A), T2-weighted (B), and gadolinium-enhanced T1-weighted (C) images demonstrate a hypointense mass in the right ovary (asterisks). This mass has low signal intensity on both T1 (A) and T2-weighted images (B) and demonstrates only slight enhancement after intravenous gadolinium administration (C), typical for an ovarian fibroma.

A

B

FIGURE 33-33. Borderline epithelial ovarian tumor. Axial T1-weighted (A) and T2-weighted (B) images demonstrate a large ovarian mass with solid (arrows) and cystic (asterisks) components. The findings are consistent with a malignant neoplasm, but not specific for any particular histology. Histopathologic analysis diagnosed a borderline ovarian cancer.

prove to be very helpful making the correct diagnosis. As mentioned previously, leiomyomas have very typical appearance on MRI.^{38,43,54}

Preoperative Staging

Ovarian cancers most often present at an advanced stage with widespread intraperitoneal metastases. The disease is

FIGURE 33-34. Ovarian serous cystadenocarcinoma. Sagittal T2-weighted image demonstrate a large ovarian mass with solid (arrow) and cystic (asterisk) components. The findings are consistent with a malignant neoplasm, but not specific for any particular histology. This tumor is indistinguishable from a borderline tumor (see Fig. 32-33) based on radiologic findings in the absence of metastatic disease. Histopathologic analysis diagnosed a serous adenocarcinoma.

surgically and pathologically staged; the surgical procedure characterized by a laparotomy including total abdominal hysterectomy, bilateral salpingo-oophorectomy, and omentectomy. In addition, biopsy of multiple frequently involved sites is recommended, including the mesentery, diaphragm, peritoneal surfaces, pelvic nodes, and para-aortic nodes.

Although final staging usually results from postoperative histologic findings, this may be modified after imaging analysis. Besides detecting and characterizing adnexal masses as likely malignant, imaging is used to demonstrate metastases, thus preventing understaging. CT and MRI can often detect specific sites of disease that may be unresectable. As such, neoadjuvant chemotherapy with interval debulking rather than primary debulking with adjuvant chemotherapy may be utilized.¹⁶⁰ Qayyum et al¹⁶¹ found that preoperative computed tomography and MRI were equally accurate in the detection of inoperable tumor and prediction of suboptimal debulking in newly diagnosed epithelial ovarian cancer. Imaging sensitivity, specificity, positive predictive value, and negative predictive value were 76%, 99%, 94%, and 96%, respectively.

FIGURE 33-35. Granulosa cell tumor. Axial T2-weighted (A) and gadolinium-enhanced T1-weighted (B) images. The small enhancing solid mass (B) with low T2 signal (A) (arrows) was proven to be a granulosa cell tumor on histopathologic analysis.

Both computed tomography and MRI have been shown to accurately identify foci of small peritoneal implants, with sensitivities of 95% and 92%, respectively.¹⁶² Similar results were obtained by the Radiology Diagnostic Oncology Group, investigating and comparing the use of Doppler and conventional ultrasound, computed tomography, and MRI for staging of ovarian cancer. In this study, for differentiating nonadvanced disease (benign lesions, stage I and II cancers) from advanced malignancy (stage III and IV cancers), the specificity of MRI was 88% and the sensitivity 98%. Ultrasound had the highest specificity (96%), but the lowest sensitivity (75%); whereas computed tomography results were similar to MRI (specificity equal to 89% and sensitivity equal to 92%).¹⁴⁴

Summary and Conclusions

INTRODUCTION

Major advances in breast ultrasound (US) have occurred in the last decade in diagnostic breast imaging services. For many years, technical inadequacies, focus on mammography, and inexperience with US may have prevented broadening of the accepted indications for breast US and limited some of its potential uses for problem solving from being realized. US analysis of masses was allowed only for cyst versus solid characterization and not for differentiation of benign from malignant solid masses.¹ More recently, transducer developments, systems improvements, and user experience have advanced US depiction of masses sufficiently to attempt classifying solid masses into categories defined by likelihood of malignancy.²⁻⁶ Currently, the US evaluation of palpable breast masses and those seen on mammograms has become standard of care in the United States. Although x-ray mammography is the only imaging technique for breast cancer screening established by randomized controlled trials to reduce mortality, the contributions of other imaging methods in the completion of the problem-solving process have been recognized. Among the other methods for imaging breast tissue, US is second to mammography because of its use for many years, its accessibility and relatively low cost, and the unique opportunity it affords for real-time guidance of needle biopsy and other interventional procedures.

Equipment and Technique

Compared with mammography, a summative modality, breast US performed with high-resolution handheld probes is a tomographic imaging technique with synthesis during real-time scanning of the very thin slices within a small rectangular or square field of view (FOV) of 4 to 5 cm

dimensions. Real-time scanning enables tracing of ductal anatomy, perception of architectural distortion, and differentiation of a mass from normal anatomic components.

Important technical progress has been made. High frequency linear broad bandwidth transducers enable scanning to be performed with high resolution in superficial tissues and without compromise of penetration deeper in the FOV, up to 5 cm. These transducers are available for use with all high-end systems as well as more modestly priced US scanners designed primarily for breast imaging and US-guided interventional procedures. Typical bandwidth ranges of these linear transducers are 5 to 10 MHz, 5 to 12 MHz, 8 to 15 MHz, and more recently, 5 to 17 MHz and 8 to 17 MHz. Center frequencies are equal to or greater than 8 MHz, and the footprints vary from 38 mm to more than 50 mm, enabling efficient survey scanning. Linear transducers are excellent for real-time guidance of the needle in breast interventional procedures. However, transducer footprints greater than 60 mm are too large for use on the average size breast, with loss of contact likely to occur at either end of the transducer face.

Several manufacturers have developed spatial compounding.⁷⁻⁸ Spatial compounding is produced by the intersection of three to nine angulated beams within tissue. This mode diminishes acoustic speckle to enable clear and confident perception of marginal detail when a mass is centered within the FOV. The greatest smoothing occurs with the intersection of nine beams, but the tradeoff is reduction in frame rate, which may become too slow for scanning in real time. The use of spatial compounding with three intersecting beams achieves image improvement with an adequate frame rate. Because of the angulated beams, posterior acoustic features—shadowing or enhancement—of a mass centered

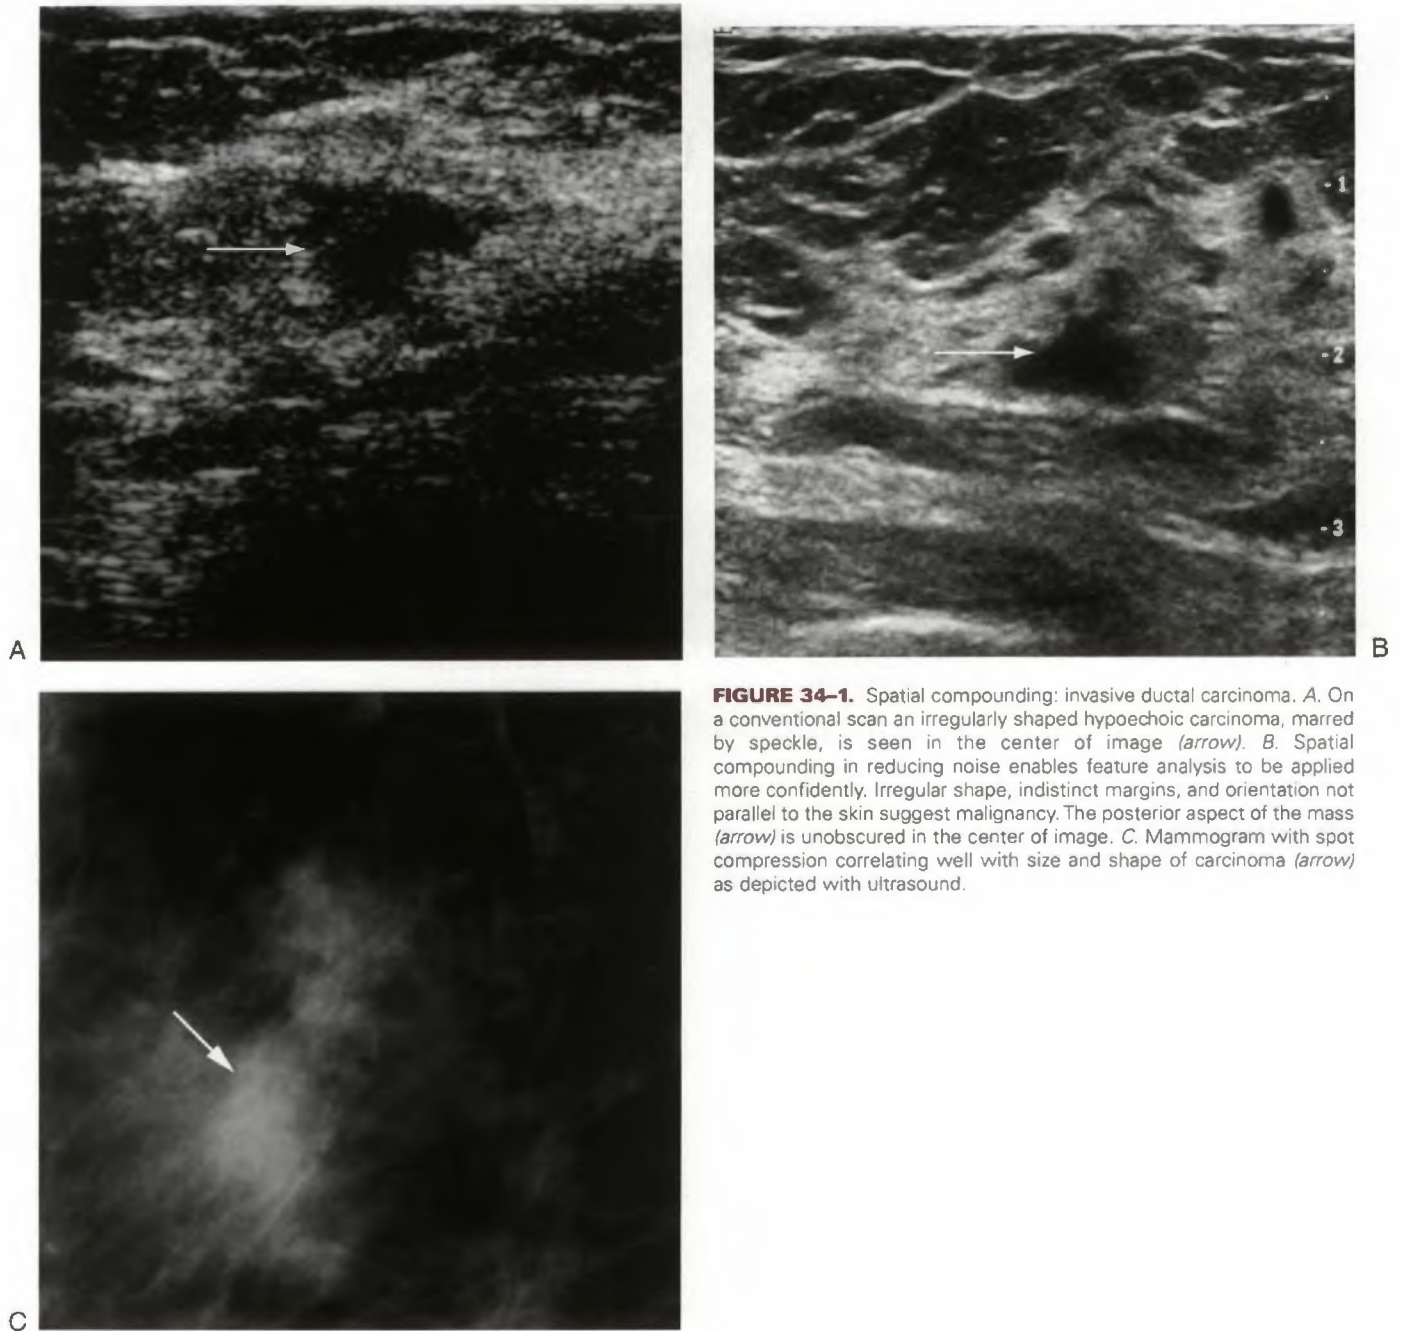

FIGURE 34-1. Spatial compounding: invasive ductal carcinoma. *A.* On a conventional scan an irregularly shaped hypoechoic carcinoma, marred by speckle, is seen in the center of image (*arrow*). *B.* Spatial compounding in reducing noise enables feature analysis to be applied more confidently. Irregular shape, indistinct margins, and orientation not parallel to the skin suggest malignancy. The posterior aspect of the mass (*arrow*) is unobscured in the center of image. *C.* Mammogram with spot compression correlating well with size and shape of carcinoma (*arrow*) as depicted with ultrasound.

within the FOV may be less apparent or appear triangular with the apex of the triangle facing the deepest part of the image. In my view, the opportunity afforded by spatial compounding for better perception of marginal features and better depiction of the posterior aspect of a mass, which may be obscured by intense shadowing, is sufficient compensation for diminishing imaging of posterior features. These are less significant than shape, margin, and orientation in assessing likelihood of malignancy of the mass (Fig. 34-1).

Newer US systems have broad dynamic ranges that, at the high end, can be used to optimize the grayscale for breast imaging—different types of tissues should be represented in shades of gray rather than two-toned in black and white.

The older contrast settings may have been responsible in part for serious misinterpretation of a cancer as a cyst (Fig. 34-2). The dynamic range and image presets should not eliminate contrast to achieve a broad grayscale. If the image is adjusted in this way, it will appear washed out, and differences between structures of similar echogenicity, such as fat lobules and some fibroadenomas, may not be perceptible.

Intraoperative curved linear or straight linear probes with short footprints of approximately 18 mm ranging from 15 to 17 (or higher) MHz at the high end of their bandwidths are beneficial in breast imaging. These high-resolution, small “hockey stick” transducers are often useful for scanning the skin and very superficial subcutaneous tissues to identify and

FIGURE 34-2. High contrast versus broad grayscale: invasive ductal carcinoma. *A.* This sonographic image is bright black and white which impairs ability to perceive echoes in the mass or its indistinct anterior margin. Strong enhancement and near-anechogenicity suggest erroneously that the mass is a simple cyst. *B.* Sonographic image of a mass in a different patient with the same diagnosis, poorly differentiated invasive ductal carcinoma, is easier to interpret. Its broad grayscale enables recognition of marginal detail and differences in the echogenicity of normal tissues and abnormalities. The cancer is just anterior to the pectoral muscle layer. US is unreliable in determining involvement; pectoral muscle enhancement on MRI is more reliable. Deep to the pectoral muscle, a portion of rib (*arrowhead*) can be seen.

characterize lesions located in the skin, such as sebaceous or epidermal inclusion cysts. A thin offset pad or mound of gel must still be used to bring the skin into focus. The tissue posterior to the nipple-areolar complex may also be difficult to image because of shadowing from the crevices of the nipple. The small-footprint probes can be angulated into this area and depict the ducts and fibroglandular tissue without artifact.

Other developments suited for breast imaging may include tissue harmonic imaging that heightens contrast and may aid in distinguishing similar-appearing hypoechoic structures from one another, such as fat lobules and fibroadenomas (Fig. 34-3).^{9,10}

Although elastography has been studied for more than a decade, several manufacturers have recently begun to market transducers adapted for clinical use. The principle of elastography is that tissue compression produces strain (displacement) within the tissue, and the strain is smaller in harder tissue than in softer tissue. Thus, by measuring the tissue strain produced by compression, one can estimate tissue hardness, which could be useful in diagnosing breast cancer.¹¹ Through color-coding, brightness-darkness, and lesion size on compression, the degree of compressibility of malignant and benign masses can be used as another feature along with morphologic characteristics in differentiating benign from malignant masses.¹¹⁻¹³ Results of research in the usefulness of elasticity imaging and ways to measure mass compressibility will be forthcoming in the next few years.

Except for some niche applications, color and power Doppler imaging have not significantly increased the specificity of mass characterization above and beyond that of morphologic assessment. For circumscribed hypoechoic masses thought possibly to be cysts, power Doppler can

FIGURE 34-3. Spatial compounding and tissue harmonic imaging. *A.* Biopsy-proven hypoechoic fibroadenoma (*arrow*) is in an interlocking pattern with surrounding fat lobules. The mass could be mistaken for a fat lobule. Spatial compounding reduces speckle. *B.* With tissue harmonic imaging added to spatial compounding, the heightened contrast increases conspicuity of the fibroadenoma. The fibroadenoma (*arrow*) lies at the junction of the hypoechoic zone of fat lobules and the more echogenic fibroglandular tissue. Hypoechoic ducts of normal caliber, some branching, can be seen within the fibroglandular tissue.

excite motion of particles within thick fluid. Color Doppler can be used to show absence of internal flow with demonstration of some vascularity at the rim or tissue surrounding the lesion. For Doppler imaging, scanning pressure should be very light, enough only to maintain contact so that the blood vessels are not occluded by compression of the tissue. Although research using intravenous contrast materials has been performed in Europe, the United States Food and Drug Administration has not yet approved contrast medium for breast US.

The Breast Ultrasound Examination

For optimal, high-resolution scanning of the breast with high frequency probes, a basic principle is to minimize the thickness of tissue to be traversed by the acoustic beam. The breast is a cooperative organ in its mobility: For the outer breast, a patient can be positioned obliquely to her opposite side with a bolster or wedge to support her back and shoulder. The breast tissue falls contralaterally and the thickness of the outer half reduced compared with a fully supine or upright position. For most women, the preponderance of fibroglandular tissue is in the upper outer quadrant. Most of the pathology resides there as well. Similarly, for the medial breast, the bulk of the breast tissue falls laterally when the patient is fully supine, decreasing the skin-to-pectoral muscle distance in the inner half of the breast.

Mammography, US, and the clinical picture should be brought together and US adapted to answer the questions raised in an individual case. As an example, if the patient best feels a mass in her breast when she is seated or standing, the sonogram can be performed with her in the position she best feels the mass. For each patient and for each breast lesion being studied with US, the focal zones and gain settings should be adjusted and image presets selected to ensure both an adequate grayscale as well as sufficient contrast to identify a mass of slightly different echogenicity compared with adjacent normal tissue. For establishing the location of a mass on or within the skin, a thin offset pad or mound of gel should be used to place the superficial mass within the focal zones of the transducer.

The images should be labelled with the patient's name and an identifying number (medical record number, birth date, and so forth), name and location of the facility, initials or other identifier of the person performing the study, breast laterality (right or left), clock-face notation, distance from the nipple in centimeters, and view, such as transverse, longitudinal or sagittal, oblique, radial (as in hands of a clock rotating 360° around the nipple), and the orthogonal, antiradial projection.

For survey breast US, quadrant-by-quadrant systematic scanning in overlapping views in two projections, including the retroareolar area and axillary regions will result in complete evaluations. The recording of images is controversial, and there is no consensus; some breast imagers record a radial view of each quadrant if no abnormality is present, and others will record only patient demographics for documentation that a scan had been performed.

If a mass or other abnormality is found on either targeted or survey scanning, images should be recorded in two projections, the first being the longest dimension found and the second a view perpendicular to the first. The naming of

FIGURE 34-4. Staging carcinomas: measurement of size. Invasive ductal carcinoma is predominantly hypoechoic, but the mass is indistinctly separated from the echogenic halo (arrow) that surrounds it. The halo may or may not contain tumor cells, but two measurements, one of the hypoechoic area alone and a second, the diameter of the hypoechoic component plus the echogenic rim, could be reported.

these projections should reflect the position of the transducer against the breast in the recorded images. Although some masses may develop along planes defined by the ductal segments, such as radial, many masses do not. Scars, abscesses, and many cancers are not oriented radially, and transducer orientation might accurately be labelled oblique.

Measuring masses can be problematic. The longest axis of a mass should be located, recorded, and measured at its boundary. When the mass is circumscribed, the edge of the mass is easy to recognize. When the borders of a mass are indistinct and there is no abrupt transition between the mass and the tissue surrounding it, as is the case in many carcinomas, it is more difficult to know where to place the calipers. Remember that the size of a cancer is important in its staging. Perhaps the best recommendation is to measure the hypoechoic portion in three dimensions and then to measure the hypoechoic portion along with the echogenic halo surrounding the lesion (Fig. 34-4). The halo may or may not contain tumor cells or just reflect desmoplastic response or compression of the fibroglandular parenchyma.

Anatomy

The breast is a modified sweat gland located between two layers of superficial pectoral fascia on the anterior thorax between the second and sixth ribs. The posterior layer of pectoral fascia lies anterior to the pectoral muscle and the anterior layer of this fascia lies just beneath the skin. Portions of the anterior layer are sometimes seen on sonograms as curved echogenic lines just posterior to the deeper of the two layers of skin (Fig. 34-5). Cooper ligaments, the connective tissue suspensory ligaments supporting the breast, straddle

FIGURE 34-5. Skin. Normal skin of the breast is a 2-mm complex (arrow) composed of two echogenic lines with a thin hypoechoic layer sandwiched between. The complex can have slight increased thickness at the areola and in the lower breast. An offset pad or mound of gel is needed to bring the skin into focus.

the two fascial layers and can also be identified on both mammograms and sonograms.

With considerable individual variation, 12 to 20 duct segments comprise the breast, along with fat and stroma. The duct segments end in puncta at the nipple, a contractile protuberance surrounded by the pigmented areola, widely variable in its width. In the areola are sebaceous glands of Montgomery, some of which may communicate with lactiferous ducts. Normal ducts vary in caliber ranging from less than 1 mm in diameter in the central breast to more than 5 to 8 mm near the nipple. As the ducts arborize, they become smaller and smaller, eventually ending in lobules, similar to leaves emanating from twigs. The lobules are approximately 3 mm in greatest dimension. The significant anatomic structure in the breast is the terminal duct-lobular unit, where cancers arise as well as cysts and fibroadenomas. Acini within the lobules may distend with fluid, forming microcysts (Fig. 34-6). Lobules are not present in the vestigial male breast, and unless a man has been receiving estrogenic therapy for prostate carcinoma or if he has an XXY chromosome (Klinefelter syndrome), one would not expect a breast mass to be either a fibroadenoma or cyst. In many women, a cone of fibroglandular parenchyma, flanked on either side by subcutaneous fat can be seen, with ducts passing through it on their way to the nipple (Fig. 34-7).

A premammary layer of subcutaneous fat is identifiable on US images. The fat lobules that comprise this layer are larger than those in the posterior fat layer that is found anterior to the pectoral muscle. These fat lobules often are oval in one view and outlined by a thin, echogenic layer of connective tissue (Fig. 34-8). Fat, hypoechoic in the breast compared with elsewhere in the body, is the reference tissue for echogenicity, not fibroglandular tissue, which is more echogenic. The fat-fibroglandular-fat layers can be homogeneous within their layers, or the breast composition can be heterogeneous with an admixture of fat and fibroglandular tissue throughout.

The arterial blood supply to the breast is axillary artery to thoracoacromial, lateral thoracic, and subscapular arteries, as well as subclavian to internal mammary artery. A venous plexus lies beneath the nipple with drainage to intercostal, axillary, and internal thoracic veins.

FIGURE 34-6. Microcysts are fluid-containing dilated lobular acini, and these contain milk of calcium layering in the dependent portion of the tiny cysts (arrows). Groups of microcysts can be considered probably benign (Breast Imaging Reporting and Data System category 3, for short interval follow-up, most commonly 6 months) but must be scanned carefully to exclude a solid component. Biopsy is advised for microcysts seen in conjunction with a solid mass or tissue focus.

FIGURE 34-7. Retroareolar anatomy. In scanning this region of the breast, a central cone of echogenicity through which ducts converge toward the nipple is flanked by hypoechoic fat. Angling the probe from the side of the nipple about 45 degrees accomplishes visualization without shadowing artifact from the uneven surfaces of the nipple. Other techniques include moving the nipple-areolar complex to one side and scanning directly as well as using a small-footprint, high-frequency linear probe.

More than 90% of the lymphatic drainage of the breast is to the ipsilateral axilla, including lymphatics from the subareolar lymphatic plexus and medial lymphatics. A small percentage of lymphatics drain to the contralateral axilla, accounting for crossover metastases, or into the internal mammary chain. Lymph nodes resembling miniature kidneys on US can be identified within the breast and provide the identity of a mammographically-visible nodule when its radiolucent hilus is obscured (Fig. 34-9). Intramammary lymph nodes are usually seen in the upper, posterior two

FIGURE 34-8. A. Fat lobules in the breast are discrete, may mimic fibroadenomas, and are bound by thin connective tissue capsules. B. Orthogonal view can demonstrate elongation and interconnection of the fat lobules (arrow), excluding a mass.

FIGURE 34-9. Normal intramammary lymph node resembles a miniature kidney in the center of the image (arrow). The cortex should measure less than 3 mm and be hypoechoic compared with fat. Fat in the hilus of the node is isoechoic with fibroglandular tissue and far more echogenic than breast fat lobules. Rib (R), fat lobule (F), fibroglandular tissue (asterisk).

thirds of the breast, but are found also, but less commonly, in medial locations.

Normal axillary lymph nodes can range in size from less than a centimeter to several centimeters if the node is dominated by fat and has only a very thin cortical rim. To determine whether or not the axilla will be dissected, most breast surgeons currently perform sentinel node imaging at the time of lumpectomy or mastectomy. Injected isosulfan blue dye, technetium sulfur colloid, or both are used, and the affected node or nodes, hot or blue, that appear to drain the tumor are removed. If no metastatic tumor is found within the node, the axilla is spared surgical exploration. If an abnormal lymph node with a cortical bulge containing a focal area of increased or decreased echogenicity, or an abnormally large, dense, rounded node is found on mammography, US can be used to direct sampling of the abnormal-appearing portion of the lymph either with fine

needle or core biopsy (Figs. 34-10 and 34-11). If metastatic involvement is confirmed, the sentinel node procedure is unnecessary and the surgeon will remove axillary nodes.

An US probe angled between the second and fifth ribs from a parasternal vantage point can be used to identify internal mammary lymph nodes, but many breast oncologic surgeons do not harvest these nodes. Unless there is some action attendant upon identification of internal mammary nodes, it is unnecessary to look for them.

The skin of the breast is thin, and with US, seen as a complex of two echogenic lines separated by a narrow hypoechoic band, that measures 2 mm or less, except at the areola and in the lower posterior breast near the inframammary fold.

Lesion Feature Analysis and Interpretation

Just as systematization of descriptors for mammography has provided a framework for assessment, management, and reporting, a set of feature categories for US and a lexicon of descriptors within these categories formalizes pattern recognition and makes possible the consistent classification of breast lesions.^{2,4-6} No one feature alone can be relied upon for diagnosis, and using combinations of features to analyze a mass, breast imagers can be more confident in classifying solid masses seen on US as benign, indeterminate, or malignant (Table 34-1, American College of Radiology Breast Imaging Reporting and Data System [BI-RADS] Lexicon). Final assessment categories similar to those used for mammography can be applied to US and multimodality breast imaging assessments. The phrases accompanying the final assessment categories are required by Federal law (the Mammography Quality Standards Act of 1992) to be given in any diagnostic mammography report unless additional imaging (category 0 or Incomplete) is recommended. In the last edition of BI-RADS, integrated reporting of

FIGURE 34-10. Abnormal lymph nodes: tuberculosis. *A.* Mediolateral oblique mammogram shows dense, enlarged lymph node in the left axilla (*arrow*) of a woman 32 years of age. No abnormality is seen in the breast. *B.* Sonogram of axillary nodes shows cortex to be markedly thickened to 1 cm and containing hypoechoic foci. Biopsy is required to differentiate between metastatic and benign reactive lymph nodes. *C.* Ultrasound-guided core biopsy performed with ultrasound guidance demonstrating the needle directed into one of the hypoechoic areas in nodal cortex. Pathology revealed caseating granulomas with culture of acid-fast bacilli consistent with tuberculosis.

FIGURE 34-11. Abnormal lymph nodes. **A.** Metastatic breast cancer in lymph node. A woman 57 years of age with invasive ductal carcinoma. Lymph node was detected during survey scan performed to evaluate extent of disease. Although the node is only slightly enlarged, the upper anterior cortex (*asterisk*) is thickened, lobulated, and hyperechoic. Presence of hilar fat is not a reliable sign of benign etiology, and biopsy is indicated. **B.** Chronic lymphocytic leukemia. Mediolateral oblique mammograms show massive bilateral lymph nodal enlargement, a hallmark of chronic lymphocytic leukemia. Note enlargement also of low axillary or intramammary lymph node (*arrow*), right breast. **C.** Chronic lymphocytic leukemia ultrasound (US) of right axilla shows group of bulky lymph nodes correlating with mammographic findings. The border between the hilar fat and cortex of these nodes is blurred, and the cortex is extremely thick. Similar findings were present in US examination of the left axilla. **D.** Color Doppler sonogram of right axillary lymph nodes in a patient with chronic lymphocytic leukemia showing flow in hilus of node. US can be used to guide the needle's path toward the thick area of cortex and away from the vascular hilus.

Table 34-1**ACR BI-RADS-Ultrasound Lexicon Classification Form**

A. Masses: A **mass** occupies space and should be seen in two different projections.

<i>Shape</i>	<i>Posterior Acoustic Features</i>
Oval	None
Round	Enhancement
Irregular	Shadowing
	Combined pattern
<i>Orientation</i>	<i>Surrounding Tissue</i>
Parallel	Identifiable effect
Not parallel	Duct changes
<i>Margin</i>	<i>Cooper ligament changes</i>
Circumscribed	
Not circumscribed	<i>Edema</i>
Indistinct	Architectural distortion
Angular	Skin thickening
Microlobulated	Skin reaction/irregularity
Spiculated	
<i>Lesion Boundary</i>	
Abrupt interface	
Echogenic halo	
<i>Echo Pattern</i>	
Anechoic	
Hyperechoic	
Complex	
Hypoechoic	
Isoechoic	

B. Calcifications: Calcifications are poorly characterized with ultrasound but can be recognized particularly in a mass.

Macrocalcifications
Microcalcifications out of mass
Microcalcifications in mass

C. Special Cases: Special cases are those with a unique diagnosis or finding.

Clustered microcysts
Complicated cysts
Mass in or on skin
Foreign body
Lymph nodes – intramammary
Lymph nodes – axillary

D. Vascularity

Not present or not assessed
Present in lesion
Present immediately adjacent to lesion
Diffusely increased vascularity in surrounding tissue

Assessment Category

Category 0 – Incomplete

Final Assessment

Category 1 – Negative

Category 2 – Benign finding

Category 3 – Probably benign finding

Category 4 – Suspicious abnormality

Category 5 – Highly suggestive of malignancy

Category 6 – Known cancer

mammography and US is recommended and, if magnetic resonance imaging (MRI) was performed, inclusion also of its findings.^{3,4} Although the equivalent US criteria for probably benign mammographic lesions (BI-RADS category 3, less than 2% likelihood of malignancy), remain to be validated by multicenter data, the fibroadenoma, an oval or macrolobulated, circumscribed, hypoechoic mass with orientation parallel to the skin (Fig. 34-12) has become the prototype of the probably benign mass through common use.^{2,4,14,15} It is hoped that analysis of breast lesions reported in the American College of Radiology Imaging Network (ACRIN 6666, www.acrin.org) research study of US for breast cancer screening in women of high risk with mammographically dense breasts will provide additional support.

INDICATIONS FOR BREAST ULTRASOUND

The indications listed in the American College of Radiology practice guideline for the performance of the breast US examination summarize most of the ways that US is currently used to solve diagnostic problems and include the following list.¹⁶ Breast cancer screening, the province of mammography, is not among the indications.

1. Identification and characterization of palpable and nonpalpable abnormalities and the further evaluation of clinical and mammographic findings.
2. Guidance of interventional procedures.
3. Evaluating problems associated with breast implants.
4. The postsurgical breast including treatment planning for radiation therapy.
5. Initial imaging technique for young (younger than 30 years of age), lactating, and pregnant women.

Palpable and Nonpalpable Abnormalities

Density of Breast Tissue

When a patient complains of a mass or thickening of the breast, or is referred for evaluation of a palpable finding on clinical examination, in general, mammography is the initial examination if the patient is older than 30 to 35 years of age. The usefulness of US in problem solving depends in part on the overall mammographic breast density.^{17,18} In women with heterogeneously or extremely dense breasts, because of lack of contrast between the mass and the breast tissue around it, a mass that might explain the physical finding can be overlooked or imperceptible (white on white) on a mammogram (Fig. 34-13).

US is indicated for evaluating a palpable mass or one suspected in, or partially obscured by, dense fibroglandular tissue. The mammographic evaluation may include a view tangential to the mass or thickening, on which a small, radiopaque skin marker should be placed. This view may allow the convex anterior border of a mass to be silhouetted in the subcutaneous fat (Fig. 34-14). A well-exposed mammogram in dense breast tissue can depict calcifications in or near the mass, and the standard of care would be violated if mammography were not performed, but an endless number

FIGURE 34-12. Fibroadenomas. A. Typical fibroadenoma, prototype of the Breast Imaging Reporting and Data System 3 category; probably benign finding. Noteworthy features are oval shape, circumscribed margin, and parallel to the skin. Mass is more hypoechoic than adjacent fat lobules. B. Grouping of fibroadenomas. The micro- and macrolobulation of this aggregate of masses may make it reasonable to biopsy, as in this case.

of additional views that contribute only to the radiation dose without profiling the mass should be avoided. US has the triple function of lesion identification, characterization, and guidance for biopsy, if indicated.

Calcifications

Additionally, if US is directed to an area of calcifications, an associated mass may be seen (Fig. 34-15). The mass may increase the likelihood of invasive disease, although rarely ductal carcinoma in situ can present as a mass,¹⁸ and US can be used as the imaging guide for tissue sampling (with radiography of the cores to confirm calcifications within the specimens). This application of US is becoming common in current practice.

Inflammatory Processes Including Inflammatory Carcinoma

When the pathologic process itself contributes to overall breast density significantly enough to limit mammography, US is indicated. An example is an inflammatory process, such as mastitis. In this case, US can be used to identify and guide drainage of an underlying abscess. When inflammatory carcinoma is suspected, tumor masses that are hidden in

dense, edematous breast tissue may be found with ultrasound or MRI (Fig. 34-16).

Fatty Breast: Need for Ultrasound?

Less clear is the need for US in a site of clinical concern when the mammogram in two views shows the area to be fatty. Although US may not be indicated in these cases and the standard of care does not require it, in the author's experience, US has at times provided specific answers when mammography has been negative but unhelpful, the tissue fatty, and a mass distinctly palpable.

Negative Predictive Value of Ultrasound and Mammography

In their evaluation of palpable masses, Soo et al¹⁹ studied 420 patients with 455 palpable masses and found that when mammography is negative and targeted US is also negative, the negative predictive value for cancer is high (99.8%). A 99.9% negative predictive value of a negative clinical examination, mammography, and US was also reported for 3516 patients studied by investigators from The Netherlands.²⁰ If US is performed to confirm or to characterize a mass suspected on mammograms, and if no mass is found, the

FIGURE 34-13. Decreased sensitivity of mammography in dense fibroglandular tissue: role of ultrasound. *A.* Mediolateral oblique mammogram of heterogeneously dense breast. Mass palpable in lower breast (●), is invisible in a background of dense, white fibroglandular tissue on the mammogram. *B.* Ultrasound unmasks a hypoechoic, irregularly shaped, spiculated mass. *C.* On subsequent ultrasound survey, a second abnormal area was identified on the sonogram.

FIGURE 34-14. A. Spot compression mammographic view with x-ray beam tangential to mass (♦) frames anterior border of mass in subcutaneous fat. B. Ultrasound shows mass just anterior to pectoral muscle (PM) to be solid, irregularly shaped, and indistinctly margined. As in this case, posterior acoustic enhancement, rather than shadowing, is associated with many poorly differentiated invasive ductal carcinomas.

parenchymal focus that might explain the mammographic findings can be correlated with the shape, size, and anatomic arrangement of fat and fibroglandular tissue on US, accounting also for changes in a patient's position (upright in mammography and supine or supine oblique in US). This correlation supports US exclusion of an abnormality and should be helpful to the referring clinician, but to direct patient management, particularly if a mass or thickening is palpated, a biopsy may be performed if warranted by clinical suspicion.

When mammography is negative but US confirms a mass as the cause of a palpable finding, BI-RADS feature analysis is applied to assess its likelihood of malignancy. Currently, when sonography determines that a palpable mass is solid, many breast imagers and clinicians will recommend or perform biopsy, although the imaging assessment of the mass is benign or probably benign. There have been a few studies reporting on the safety of basing management recommendations on sonographic features of palpable masses.^{19,21,22} Each of these methods substantiates the safety of short-term follow-up, commonly in 6 months, if the palpable mass has not been imaged previously. This management protocol is for masses that have benign sonographic features, such as a fibroadenoma: oval shape, circumscribed margin, and orientation parallel to the skin. When a mass has these features but is hyperechoic to fat and isoechoic to fibroglandular tissue, such as a lipoma, its assessment is benign (Fig. 34-17). The follow-up recommendation is for 1 year, and biopsy is unnecessary.² The difficulty in arriving at

management recommendations is accentuated when the mass is new or newly palpated, and there is no history of weight loss (accounting for new palpability of a mass that may or may not have been present previously) or change in physician. If the mass is new and not definitively benign by mammographic or sonographic criteria, as lipomas and hamartomas would be, the standard of care would require biopsy, preferably image-guided percutaneous large-needle biopsy for histology rather than an open surgical procedure.

A second scenario in evolving management strategies concerns the use of survey US examinations, unilateral or bilateral, when the patient complains of one palpable mass and US depicts several in one or both breasts. If these masses all look alike and have no sonographic features that are associated with malignancy, why biopsy the palpable one or the largest one? Logic would call for all or none to be biopsied, although many breast imagers defend biopsy of the largest mass or one that is palpable. The dilemma arises commonly when young women with palpable masses are sent by their physicians for breast evaluation, and the palpable mass identifiable with US as a probable fibroadenoma and others may be seen if survey scanning is performed.

Ultrasound Guidance of Interventional Procedures

Of all of the imaging techniques used to evaluate breast abnormalities and guide interventions for tissue sampling or surgical excision, US is the only one to be performed in real

FIGURE 34-15. Recurrent carcinoma. *A.* Invasive and intraductal carcinoma. A woman 59 years of age had been treated for high-grade ductal carcinoma in situ with lumpectomy and radiation therapy 4 years earlier. Mammographic view with magnification shows new microcalcifications at lumpectomy site (*arrow*). Linear marker placed on skin denotes surgical incision site for the lumpectomy. *B* and *C.* Ultrasound images show hypoechoic mass containing microcalcifications (*arrows*) in a background of postsurgical architectural distortion correlating with the mammographic finding. Tiny, echogenic foci, the microcalcifications, which measure 0.1 to 0.5 mm in diameter, will not cause posterior acoustic shadowing. The uneven, concentrated distribution of these particles allows differentiation from speckle.

FIGURE 34-16. Breast edema: inflammatory breast cancer. *A.* Underlying cause of the edema and pronounced skin thickening, greater than 1 cm (*arrow*), is inflammatory breast cancer. Breast edema is seen with ultrasound as an interstitial network of angular, hypoechoic fluid collections different from the radial pattern of ducts. Often, a mass or masses can be seen with ultrasound. The most common histology is invasive ductal carcinoma. Other causes of edema include congestive heart failure, renal failure, radiation therapy, mastitis, and abscess. *B.* Sonogram shows architectural distortion and tissue heterogeneity in area of pain and redness one month after delivery in lactating patient. *C.* Abscess, about to discharge spontaneously through the skin, develops 2 months later despite antibiotic treatment. Ultrasound-guided drainage was successful.

time. Patients and physicians prefer US guidance for its rapidity, comfort (the patient is supine or supine-oblique rather than prone as she would be for stereotactically or MRI-guided biopsies), reliability, and accuracy. US is the choice for biopsy of solid masses with either spring-activated devices using 12- or 14-gauge needles or with vacuum-assisted devices that yield larger specimens obtained with needles ranging from 8 to 12 gauge, as well as biopsy devices using other mechanisms. If US rather than stereotactic guidance is elected for a mass containing microcalcifications or for microcalcifications identified with US that are not associated with a mass, specimen radiography should be performed to confirm microcalcifications in the biopsy specimens. US is also an excellent imaging guide for pre-surgical localization as well as for aspiration of cysts and drainage of abscesses.

The management recommendations for BI-RADS assessments 4 (suspicious for malignancy) and 5 (highly suggestive of malignancy) are tissue sampling, and image-guided percutaneous biopsies are replacing surgical biopsies in current practice. Probably benign lesions, such as fibroadenomas, are often biopsied as well if requested by the patient or her referring physician, but short-interval follow-up is the suggested management.

In the past, category 5 lesions—those for which cancer is the diagnosis in more than 95%—went directly to surgical excision, frozen section (not reliable for microcalcifications) providing the histologic documentation. It was thought unnecessary to perform needle biopsies before surgical excision. Currently, sentinel node imaging and biopsy are nearing standard of care, and histologic diagnosis of invasive tumor is required beforehand. Image-guided core biopsy

FIGURE 34-17. Lipoma. *A.* Spot compression mammographic view tangential to palpable mass, which is marked by metallic BB on skin. Area of fat density lies beneath the marker, arrows outlining its posterior aspect. *B.* Ultrasound image shows encapsulated subcutaneous mass, more echogenic than the fat lobules surrounding it. This represents a lipoma (*asterisk*), correlating with the benign mammographic assessment but providing a specific diagnosis.

specimens can also be used to determine the estrogen and progesterone receptor status, along with other prognostic factors. Most patients with masses and calcifications thought possibly to be malignant are biopsied with imaging guidance before surgery, using US wherever possible.

The biopsy technique calls for written informed consent, sterile draping of the cleansed area of the breast to be biopsied, preparation according to the manufacturer's recommendations of the same high-resolution linear broadband width probe used for scanning (Cidex or glutaraldehyde followed by a sterile water rinse are two ways to prepare the probe), and the entire procedure performed with direct US visualization. The area is anesthetized with 10 mL or more of 1% lidocaine (with epinephrine for hemostasis if vacuum assisted devices are used with 8- to 11-gauge needles), a small incision—a few millimeters—is made in the skin, and approximately five passes are made into the lesion if a spring-activated device and 14-gauge needle are used. The needle is advanced into tissue in alignment with the middle of the short end of the transducer and passes along the long axis of the probe, parallel to the face of the transducer and perpendicular to the expected path of the beam. The more horizontal the entry, the better the entire needle shaft is seen. Most devices that fire will have throws between 2 and 2.3 cm. If the mass is small, less than a centimeter in greatest dimension, to prevent overshooting the target, one should stop short of the targeted lesion by about 1 cm and fire. Specimens are placed in formalin jars, but the needle should never be immersed in formalin and then re-enter the breast.

At the conclusion of the procedure, for small masses that may be obscured by the biopsy procedure itself or large malignant-appearing masses that may be treated with several cycles of neoadjuvant chemotherapy prior to surgery,

tiny marker clips should be placed within or adjacent to the biopsied lesion. The marker clips of titanium, stainless steel, or ceramic are preloaded into needles and once the biopsy location has been verified with US, the clips can be deployed. Lateral and craniocaudal mammographic views should be taken after clip placement for correlation of mammographic and sonographic findings as well as to document the proximity of the clip to the lesion or biopsy site (Fig. 34-18).

If image-guided biopsy services are provided for patients, it is the responsibility of the breast imager who has performed the biopsy to receive the histopathology interpretation, make certain that it is concordant with the prebiopsy assessment, and notify the patient or referring physician with the biopsy results and a management recommendation.

With increasingly frequent use of contrast-enhanced MRI for evaluation of the extent of disease in newly diagnosed breast cancer patients as well as for screening of high-risk women, especially those who have breast cancer (BRCA) 1 and 2 genetic abnormalities, second-look US is commonly performed to locate a mass that correlates with an enhancing lesion seen on MRI. Biopsy can then be guided with US and accomplished more rapidly, in real time, and more comfortably for the patient than an MRI-guided biopsy, in which the patient is prone and requires intravenous administration of gadolinium for lesion visualization, breast compression for lesion targeting, and several MRI sequences to confirm accuracy.

Evaluating Problems With Breast Implants

Indications for breast US in women with augmented breasts are the same as those for women without breast prostheses, with the additional application of US to determine the

FIGURE 34-18. Marker clip. *A.* Small indistinctly margined mass (*asterisk*) before ultrasound-guided core needle biopsy. *B.* After biopsy, with ultrasound guidance, a small marker clip (*short arrow*) was placed within the mass. Microcalcifications are present adjacent to the mass (*large arrow*). After marker clip placement, it is important to obtain lateral and craniocaudal mammograms that can be used later to guide presurgical localization and to detect clip migration should it have occurred. *C.* Mediolateral oblique mammogram confirms clip placement within a small, low-density mass, a mixed invasive ductal and lobular carcinoma. Clip can be used as target for needle-wire placement for presurgical localization before excision.

FIGURE 34-19. Silicone implant rupture. *A.* A woman 47 years of age with rupture of 20-year-old silicone implants and replacement with saline breast prostheses. Visible through the implant is residual silicone in the breast tissue. *B.* Snowstorm pattern (*asterisk*) of free silicone in tissue with gradual decrease in posterior echoes; the pattern is also called echogenic noise. The silicone obscures the implant shell, a portion of which remains visible (*arrow*). *C.* Hypoechoic, cuboidal silicone granulomas (*arrow*) occur with long-standing extracapsular rupture of silicone implants; as the signature of free silicone, the snowstorm pattern is more common.

nature of palpable masses as either originating in the breast, as a breast lesion, free silicone or silicone granuloma, or related to the implant as a wrinkle, fold, or shell irregularity. Although MRI has been found to be more sensitive and specific in identifying intracapsular and extracapsular rupture of silicone implants, the “snowstorm” or “echogenic noise” US signature of extravasated silicone is characteristic (Fig. 34-19).²⁴⁻²⁷ US can also suggest intracapsular rupture, whatever its clinical significance, by depicting shreds of implant shell floating within the silicone gel and producing a stepladder of echogenic lines or wavy echogenic bands. For evaluating a palpable mass, before recommending MRI, US should be used as a lower cost, more rapid, reliable method of making the important distinction of the origin of a mass

within the breast rather than as related to the implant. At the same time, if the mass is of breast origin, it can be characterized as cystic or solid, and its features analyzed using BI-RADS to assign a level of suspicion of malignancy. For saline implants, the use of either MRI or US is unnecessary to confirm rupture of clinically apparent deflation.

The Postsurgical Breast and Treatment Planning for Radiation Therapy

After the surgical excision of a breast malignancy, a seroma nearly always develops at the lumpectomy site. Septa or clumps of echogenic material may be present within the

FIGURE 34-20. Postsurgical fluid collection after lumpectomy for carcinoma. Nearly all lumpectomy patients have seromas that may last for weeks or months after the surgical procedures. The collections are not drained unless there are clinical signs of abscess formation. The skin is focally thickened at the incision site, and fluid collects within the tract made by the scalpel. As the fluid is gradually resorbed, scarring develops at the lumpectomy site, the circumscribed margins of the fluid collection replaced by spiculation as a manifestation of scarring. Sequential studies that track these changes over time can help exclude recurrence.

fluid collection, but unless the patient shows signs of abscess, the fluid collection should not be aspirated (Fig. 34-20). Abscess formation is unusual, and the gradual resorption of fluid over a period of months is thought to promote cosmesis by preserving the normal contours of the breast rather than creating a crater in the breast by draining the fluid collection. Unless significant mass remains in the breast after lumpectomy, neither mammography nor US can be relied upon to show the residual tumor; here, contrast-enhanced MRI may show clumped enhancement at the involved tumor margin.

After 6 to 12 months have elapsed, the seroma will have been resorbed gradually and replaced by scarring with imaging features similar to those of malignancy. The margins of the scar are spiculated and indistinct, and posterior acoustic shadowing replaces the seroma's enhancement. Knowledge of the marginal status at excision, sequential studies, and the ability to follow the path of the scalpel from the skin, where there is focal thickening in a V pattern, down to the tumor bed helps in excluding recurrence (Fig. 34-21). As with mammography, a new mass or other interval change at or near the lumpectomy site can signal recurrence. The average time to local recurrence after lumpectomy and radiation therapy is 3 years, and between 3 and 7 years, recurrent tumor is most likely to be found within a few centimeters of the lumpectomy site.²⁷⁻²⁹

There are various methods of demarcating a lumpectomy site for radiation therapy. Computed tomography (CT) can be used, and some surgeons mark the boundaries of the lumpectomy site with surgical clips to facilitate radiation treatment planning. US can provide the shortest distance from the skin to a carcinoma for presurgical needle-wire

A

B

FIGURE 34-21. Changes after breast conserving therapy. *A.* Scar after lumpectomy and radiation therapy. Tangential mammographic view shows focally thickened skin 5 years after breast conservation for carcinoma. The focal thickening does not resolve, and wisps of scar around the tumor bed are expected findings. *B.* US shows findings similar to those seen on the mammogram: a "V" at the skin incision site, with focal thickening, and intense scarring along the scalpel tract extending from the skin to the tumor bed just anterior to the pectoral muscle. Recurrence, not present, would be evident as a new mass or microcalcifications adjacent to the scar or a bulbous enlargement within the tumor bed after the site has been stable for a year or more. Average time to local recurrence is 3 years.

localization of a nonpalpable mass, once the excision has been performed. Likewise, the target area for radiation therapy can be mapped with US more directly using its real-time capabilities, although radiation oncologists more commonly use CT simulation for treatment planning.^{27,28} For whole breast irradiation with a boost, the depth of the tumor bed from the skin surface can be shown, the dimensions and shape of the fluid collection can be depicted on orthogonal views, and its volume calculated from dimensions in these views.

More recently, another application of US in radiation treatment planning for breast cancer has been identified. Partial breast irradiation, a brachytherapy procedure with radioactive seeds (Iridium 192) delivered to the lumpectomy

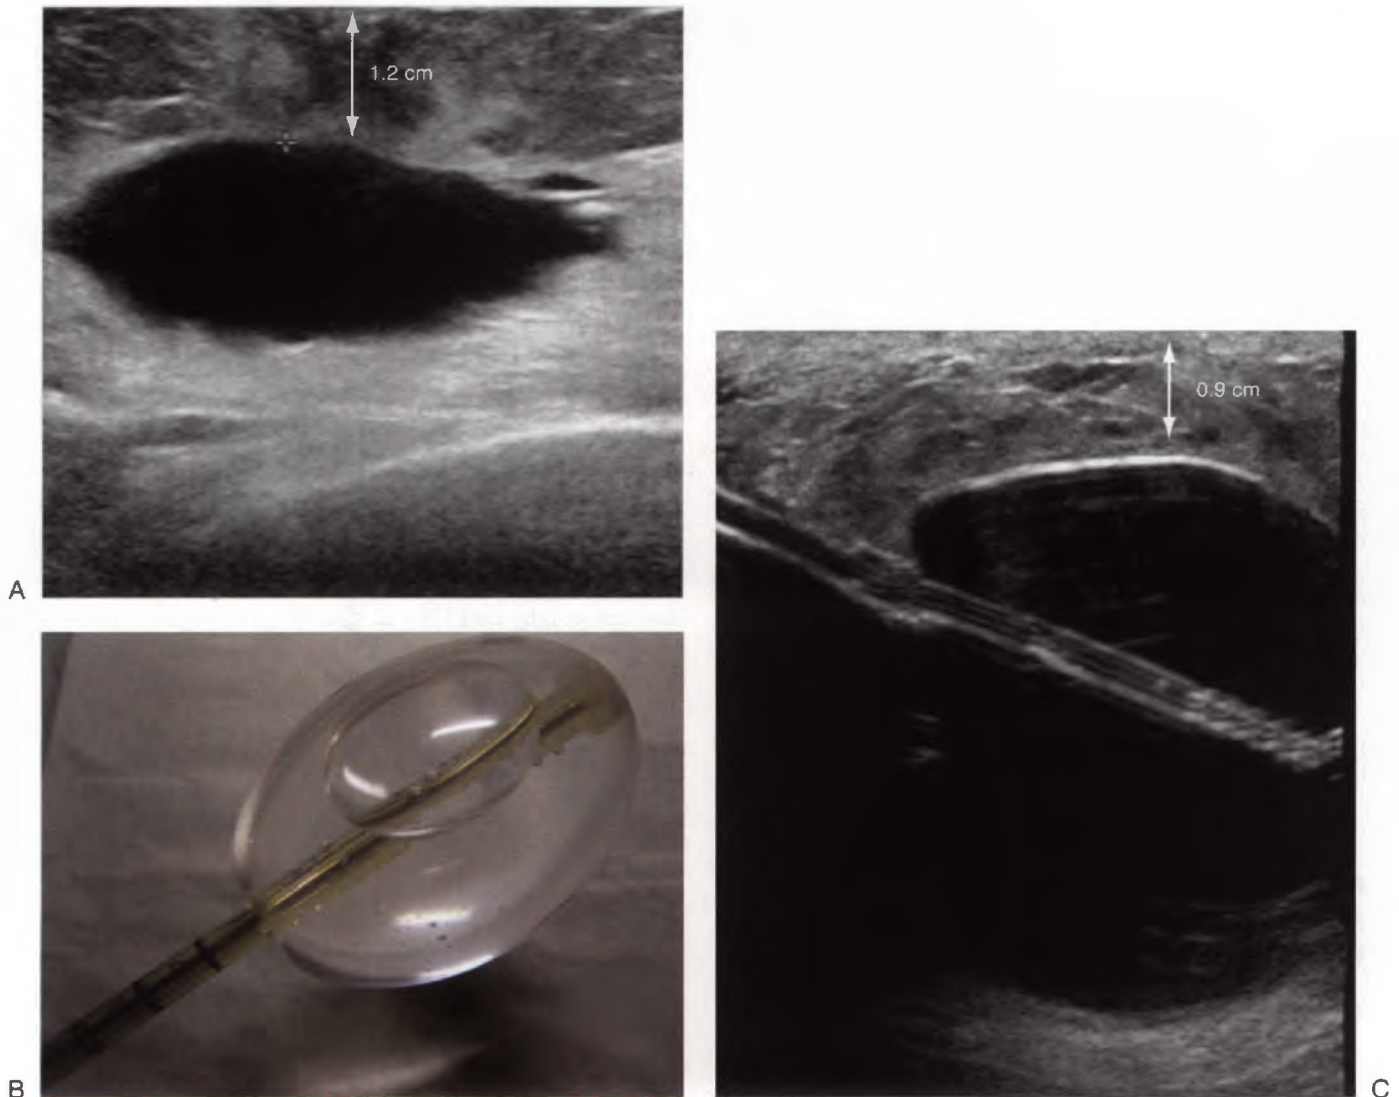

FIGURE 34-22. Ultrasound guidance for device for partial breast irradiation. *A.* Ultrasound scan confirms eligibility: seroma is ample and tissue thickness between skin and top of seroma, which must be at least 0.6 cm, is 1.2 cm. *B.* The fully inflated balloon shown filled with saline during preplacement testing. *C.* Balloon catheter placement is successful. The fully inflated balloon occupies the entire lumpectomy cavity, and the remeasured skin-to-balloon surface distance remains acceptable.

site through a balloon catheter (MammoSite, Cytyc Corporation, Marlborough, MA) or several other techniques, has become an option for some women with small invasive or in situ tumors. High-dose radiotherapy is delivered twice a day through these catheters, which can be placed either surgically at time of lumpectomy or percutaneously with US guidance. Some protocols, such as National Surgical Adjuvant Breast and Bowel Project B-39 (A Randomized Phase III Study of Conventional Whole Breast Irradiation Versus Partial Breast Irradiation for Women with Stage 0, I, or II Breast Cancer), call for histologically free margins of resection, which may take 24 hours or more to establish. If the device is to be placed with US guidance within the first weeks following surgical excision of the tumor, US is used to determine eligibility. The seroma should be oval or round, and at least 3 cm in one of its dimensions. The key measurement is the distance from the skin to the top of the seroma, a tissue thickness of at least 0.6 cm to prevent injury to the

skin and ensure even and equal radiation throughout the field (Fig. 34-22).^{28,29} Although many surgeons are learning the use of US to place these catheters into the lumpectomy site, breast radiologists experienced in image-guided interventions may be preferred for safe, percutaneous insertion of these relatively large devices into the tumor bed with direct US visualization.

YOUNG, PREGNANT, AND LACTATING PATIENTS

The American College of Radiology Practice Guideline for the Performance of the Breast Ultrasound Examination (2002) suggests that US be the initial imaging technique for women 30 years of age and younger.¹⁶ Most women younger than 30 years of age have come to clinical attention because of palpable masses, pain, or signs of mastitis and abscess. Exceptions to this include women at high risk of breast

cancer such as those who have breast cancer 1 or 2 genetic abnormalities or strong familial breast cancer patterns for whom mammographic screening is recommended to commence approximately 10 years before the age at which the first-degree relative (mother, sister, daughter) was diagnosed. If the US findings suggest malignancy, bilateral mammography is indicated for assessing extent of disease before any intervention.^{22,23} For example, mammography might reveal microcalcifications not seen or suspected at US or an area of architectural distortion not appreciated sonographically. In addition, if US demonstrates no abnormality, bilateral mammography or bilateral mediolateral oblique mammographic views may help to exclude pathology.²²

Fear of radiation exposure is unjustified; radiation exposure to a fetus or to the nongravid pelvic organs from mammography, a highly collimated examination, is near zero.³⁰ When mammography might show significant abnormalities not seen at US, the benefits of mammography outweigh any perceived negatives of an x-ray study.

When US of a palpable mass in a young patient, most commonly a fibroadenoma, shows a solid lesion with typical benign features, such as oval shape, circumscribed margins, and orientation parallel to the skin, mammography may be unnecessary.^{31,32} Management of the mass may include clinical or US follow-up; tissue sampling if the patient or physician requests it; or excision of the mass for abatement of pain. In general, there is no consensus concerning the need for mammography in a patient younger than 30 years of age when an initial US examination is negative.

Controversial or Evolving Applications of Breast Ultrasound in Problem Solving

Characterizing Multiple Masses

A rule of multiplicity is often invoked in evaluating and managing multiple masses.³³ This dictum states that multiple masses with similar, mammographically benign features need not be characterized with US; the recommendation is for annual mammographic follow-up.³³ Others believe that the capability for increasing interpretive accuracy is promoted with a supplemental US examination.³⁴ Additionally and anecdotally, many breast imagers will relate, and some have reported their experiences in finding an unsuspected cancer adjacent to cysts or benign solid masses as they scan to characterize masses observed on mammograms. US is time consuming, and its acknowledged operator dependence arouses skepticism in using US to follow-up masses after their initial characterization. The use of US in continued patient follow-up of multiple masses is variable, although improvement in interpretive consistency has been noted recently.³⁵ There is no established standard to suggest follow-up intervals or guide patient management in these cases. Most management recommendations are extrapolated from those applicable to mammography.

If the breasts are fatty, soft tissue density masses are more conspicuous against the gray background of fat. Once a mass has been diagnosed with US as a simple cyst, it is not difficult to follow its increase or decrease mammographically. If breast tissue is heterogeneously or extremely dense, confident mammographic follow-up may be more difficult and,

in this scenario, US may be used. Recognition of similar pattern of anatomy surrounding the mass compared with a previous study will aid in comparability of size and appearance. Any new mass that is either palpable or evident on the mammograms should be characterized with US.^{16,34}

For Extent of Disease Bilaterally, Including Axillary Evaluation, in Breast Cancer Patients

When establishing a candidate's eligibility for breast conservation when the breast tissue is dense and the index carcinoma was seen best with US, there has been increasing use of US to survey the entire affected breast and the contralateral breast for additional foci.³⁵⁻³⁹ Although these independent reports have suggested efficacy, the effectiveness of this approach, however, may be substantiated by additional data from the ACRIN 6666 multicenter trial, screening breast ultrasound in high-risk women, currently closed to accrual, and whose third follow-up round of mammography and US will also offer participants contrast-enhanced MRI at some sites.

The US assessment of extent of disease should include the axillae, or at least the axilla of the affected breast. In scanning the axilla, if lymph nodes are seen to have cortical contour bulges or masses (see Fig. 34-11), US-guided percutaneous core or fine-needle biopsy can confirm metastatic involvement, obviating the need for a sentinel node procedure.⁴⁰

Staging

Establishment of multicentricity can alter treatment decisions, as is becoming recognized with increasing incorporation of MRI in the evaluations of breast cancer patients. With detection of additional cancers in breast quadrants other than that in which the cancer was originally found, plans for conservation have been changed to mastectomy. Both US and MRI are being used, sometimes competitively, in this way for assessing extent of disease in newly diagnosed breast cancer patients. Hlawatsch et al⁴¹ found that a combination of mammography and whole breast US was adequate in most cases and certainly less costly. Berg³⁹ reported 93% accuracy of mammography, physical examination, and US compared with the accuracy of MRI, mammography, and physical examination at 99%. Data are accumulating in support of the efficacy of MRI to assess extent of disease, and MRI bested clinical examination, mammography, and US in breast cancer detection in those very high-risk women with breast cancer 1 and 2.⁴² If CE-MRI is planned for evaluating a newly diagnosed breast cancer patient, it would be unnecessary to start out with bilateral survey US. Handheld small FOV screening breast US is time consuming, and completeness of the study is difficult to ensure. Anticipating increasing need, automated scanners, older versions of which became extinct in the early 1990s, are in development by several of the manufacturers of US equipment. Some of these automated systems are designed to acquire images using mammographic-like positioning for greater certainty in correlating with findings on mammography. These systems, whose efficacy remains to be

validated, could offer answers to the challenges of follow-up of solid masses, interobserver inconsistency and other operator dependence issues. Determining the order of and most cost-effective imaging methods for judging extent of cancer involvement is an area of active research.

SUMMARY AND CONCLUSIONS

In recent years, technical advances, increasing familiarity with breast anatomy as depicted sonographically, and a standardized approach to interpretation have broadened the clinical applications of breast US. With mammography and physical examination, breast US makes important contributions to problem solving. The accepted indications for using US to examine the breasts include evaluation of palpable and mammographic masses; guiding interventional procedures, evaluating implant problems; the postsurgical breast and radiation treatment planning; and as the initial imaging technique in young (30 years of age and younger), pregnant, and lactating patients.¹⁶ Newer or controversial applications are also discussed, including use of US to look for an associated mass in an area of microcalcifications seen on mammograms; initial evaluation and follow-up of patients with multiple similar, benign-appearing masses; and survey US for extent of disease and treatment planning for patients with at least one established focus of breast cancer. Although much progress has been made in breast US, it should be kept in mind that US is to be used *with* mammography and not as a substitute for mammographic screening.

Breast Ultrasound

The End'

When I began my involvement with diagnostic ultrasonography three decades ago, this chapter would have been considered ludicrous. Virtually all of ultrasonography was considered to be either an artifact or a pitfall. Clinicians did not take this modality seriously, and few critical decisions were ever based on the results of the ultrasound examination alone. With time, improvements in both technology and our understanding of normal and abnormal findings made this a useful clinical diagnostic modality. It did not take long for important clinical decisions to be based solely on the results of the ultrasound examination, for example, surgery, early delivery of the fetus, or even termination of the pregnancy. This evolution, although welcomed by many, has placed a large responsibility on the sonographer. The phrase "primum non nocere," or first do no harm, has never proven more true.

This chapter is not an attempt to explain the physical principles of ultrasound or artifact production. It is also unlikely that such a chapter could ever be all-inclusive. I have attempted to find examples of pitfalls, the diagnostic dilemmas that have the potential to lead us to the wrong diagnosis. I have tried to cover both basic potential pitfalls and some of the more esoteric normal variants. Undoubtedly, some readers will find examples here that are so basic as to seem almost insulting. I apologize in advance and will only respond that this chapter is meant to appeal to a wide audience of beginners and "well-seasoned" experts. I also do not attempt to give an overly detailed explanation for each example but try to offer what is theorized at the time.

If I am able to avoid one false-positive diagnosis and prevent unnecessary surgery, termination of a pregnancy, or even 20 weeks of an emotional roller coaster for the parents, I have fulfilled my goal.

PELVIS, GRAVID, AND NONGRAVID UTERUS

FIGURE 35-1. Longitudinal sonograms demonstrating the maternal urinary bladder and the gravid uterus. A. An apparent soft tissue mass is seen in the urinary bladder (arrow). B. In fact, this is the stream of urine entering the bladder through the ureteral orifice.

FIGURE 35-2. A. What appears to be a large pelvic cyst is seen in this patient (arrow). BI, bladder. B. Although the connection to the bladder was not seen in A, this bladder diverticulum (D) is clearly seen in another plane of section.

FIGURE 35-3. Bowel within the pelvis can masquerade as ovarian cysts. A. In this patient, bowel gas and its shadowing create the appearance of a mass (asterisk). BI, bladder. B. The strong reflection adjacent to the urinary bladder (BI) or the "squared" appearance (arrows) to the "cyst" should make one suspicious that bowel gas artifact is causing this appearance. C. In a different patient, a true ovarian cyst (cursors) has borders on nearly every side and has enhanced through-sound transmission and internal echoes. BI, bladder. D. In another patient, two different planes of section demonstrate what appears to be a large pelvic cyst (?C). In fact, this was due to bowel gas artifact. UB, bladder. E. Because this appearance was virtually indistinguishable from a pelvic cyst, a computed tomographic scan was performed immediately after the sonogram, confirming the artifactual nature of this "cyst." The scans were normal without evidence of a pelvic mass.

FIGURE 35-4. Dilated fallopian tubes simulating ovarian cysts. *A.* A transverse sonogram in this patient demonstrates what appear to be two ovarian cysts (*arrows*) posterior to the uterus (*cursors*). *B.* A longitudinal sonogram displays the elongated tubular nature of this fluid collection (*arrow*), which is more compatible with a dilated fallopian tube. U, uterus. *C.* In another patient, two large, rounded fluid collections are seen (*arrows*) simulating ovarian cysts. *D.* A longitudinal plane of section through one of these collections demonstrates the tubular (T) retort nature of these dilated fallopian tubes.

FIGURE 35-5. A 19-year-old woman presented with severe pelvic pain. She had been in an emergency room 1 month earlier with the same symptoms. A pelvic sonogram demonstrates an enlarged ovary with arterial and venous blood flow. Three hours later, an avascular necrotic ovary from ovarian torsion was removed at surgery. Do not be reassured by an apparently normal sonogram when ovarian torsion is suspected.

FIGURE 35-7. Two round and oval structures are seen in the right adnexa. Although they might be mistaken for abnormal ovaries or paraovarian masses they represent normal prominent bowel. Typical hypoechoic muscularis (*arrows*) is seen.

FIGURE 35-6. Bowel simulating an ovarian cystic teratoma (dermoid). *A.* A large shadowing mass (*asterisk*) is seen adjacent to or possibly emanating from the ovary (Ov). *B.* Minutes later the normal ovary and adnexal structures are well seen. The bowel, which was the cause of the shadowing, was not seen.

FIGURE 35-8. Pregnancy with coexistent ovarian carcinoma. Unfortunately, just because a patient is pregnant does not mean that she cannot have a concomitant ovarian cancer. A multilocular cystic mass (arrows) with solid components is seen adjacent to the gravid uterus.

FIGURE 35-10. Longitudinal scan through the cervix of a gravid uterus. Multiple nabothian cysts are seen in the cervix. These retention cysts are common and should not be confused with low-implanted gestational sacs or other pathology.

FIGURE 35-9. A. Transverse axial sonogram of the pelvis in a non gravid patient. There appears to be either a duplication of the uterus or the uterus and an adjacent mass (C, F). Rt, right. B. A sagittal scan demonstrates that what was seen in the transverse scan was the cervix (C) and fundus (F) of an anteverted uterus. The dashed line represents the plane of section in A. H, head.

FIGURE 35-11. In this patient, the uterus is markedly enlarged and lobular with numerous small cystic areas (*arrows*) throughout. Although this has an appearance similar to a hydatidiform mole, in fact, the serum hCG was zero and the mass was due to myomatous disease. Bl, bladder.

FIGURE 35-13. Sonogram of a gravid uterus in the second trimester demonstrating a circumvallate placenta (*arrow*). The infolding of the edge of the placenta should not be confused with a uterine synechia.

FIGURE 35-12. Transverse scan through the gravid uterus demonstrates a uterine synechia (*arrow*) crossing the uterine cavity from the anterior to the posterior wall. The fetus moved freely around the synechia. This should not be confused with an amniotic band.

FIGURE 35-14. Transverse scan of the pelvis demonstrating a left adnexal solid mass (*asterisk*). Although the anatomic position might suggest an ovarian lesion, the solid nature of the mass should suggest the possibility of a broad ligament myoma, which was ultimately demonstrated on a magnetic resonance imaging scan. U, uterus; R, right.

FIGURE 35-15. A myometrial contraction (M) is common in first and second trimester sonograms. This should not be confused with a myoma. Two features help make this distinction: First, in general, myometrial contractions tend to bulge inwardly without affecting the outer contour of the uterus. Uterine fibroids tend to bulge inward and outward. Second, myometrial contractions may resolve during the time of scanning.

FIGURE 35-17. Marked overdistention of the urinary bladder results in the appearance of a markedly elongated cervix (*between calipers*). One is visualizing not only the cervix but the apposed anterior and posterior walls of the lower uterine segment.

FIGURE 35-16. A myometrial contraction (M) in this second trimester pregnancy simulates a myoma. This should not be confused with a succenturiate lobe of the placenta. P, placenta.

FIGURE 35-18. A distended urinary bladder has caused the anterior and posterior walls of the lower uterine segment (*arrows*) to come near one another. The trapped amniotic fluid gives the appearance of an incompetent cervix. The cervix was normal in this case.

FIGURE 35-19. Myometrial contractions of the lower uterine segment are common and may often touch one another. *A.* In this case the contractions (*asterisks*) of the lower uterine segment simulate an open and incompetent cervix. *B.* The normal-appearing cervix, in fact, is well seen (*calipers*) caudal to this contraction.

FIGURE 35-20. Myometrial contractions of the lower uterine segment may often touch one another (*asterisks*). These have been referred to as “kissing contractions.” Bl, bladder.

FIGURE 35-21. A. "Kissing contractions" of the lower uterine segment (*asterisks*). The caudal end of the placenta rests at the junction of these contractions. These contractions should not be confused with the cervix and mistakenly called a placenta previa. P, placenta. B. With time, there was resolution of the anterior contraction, so that the internal cervical os could be identified (*arrow*).

FIGURE 35-22. Artfactual short cervix. A. Transperineal scan demonstrates a short cervix (*between calipers*) measuring 1.8 cm. Shadowing (*arrows*) from the rectum obscures the remainder of the cervix. B. A transvaginal scan in the same patient demonstrates a normal length to the cervix (*between calipers*) of 3.43 cm.

FIGURE 35-23. Dynamic changes of cervix. Three transvaginal scans of the cervix (A to C) taken minutes apart, demonstrate progressive dilatation of the cervix with fluid entering the endocervical canal. This finding should be reported to the referring obstetrician and the residual shortened closed length of the cervix should be reported, as well as the total cervical length.

FIGURE 35-24. A. A slightly oblique longitudinal scan through the uterus. A small area of placental tissue (*asterisk*) is separate from the major portion of the placenta (P). This appears to be a succenturiate lobe of the placenta. B. When the scan plane is aligned along the major long axis of the placenta, the area in A can be seen to be continuous with the remainder of the placenta.

FIGURE 35-25. In some patients, the surface area over which the placenta implants may be small. This short insertion site may create the false appearance of a thickened hydropic placenta (P).

FIGURE 35-26. Changing placenta previa. A. A transvaginal scan in a patient at 17 weeks demonstrates a complete placenta previa. The leading edge (*arrow*) of the posterior placenta (P) extends across the internal cervical os. B. Six weeks later at 23 weeks, the leading edge of the placenta extends to but not beyond the internal cervical os.

FIGURE 35-27. A. Veins present in the decidua basalis and myometrium contribute to a hypoechoic region beneath the placenta (*arrows*). This should not be misinterpreted as an abruption. B. Doppler interrogation of this region will often confirm the venous nature of this area. C. In this case, the veins (*arrows*) deep to the placenta (P) are clearly seen.

FIGURE 35-28. A hypoechoic area (*asterisk*) behind the placenta (P) simulates a placental abruption. It is in fact a myometrial contraction that resolved during the examination.

FIGURE 35-30. Transverse scan of the gravid uterus demonstrates the fetal head (H). A calcified structure (*arrows*) is seen adjacent to the fetal head. At first glance, this appears to be another fetus but in fact represents a calcified myoma.

FIGURE 35-29. Prominent vessels (*arrows*) at the periphery of the uterus. These are common in the uterus and should not be mistaken as a precursor to an abruption or as trophoblastic disease. *A.* In this patient, the arcuate vessels (*arrows*) at the periphery of the uterus are quite prominent. *B.* With color Doppler flow imaging, the vascular nature of these structures is well seen.

FIGURE 35-31. Incarcerated uterus. A persistently retroflexed or retroverted uterus may become 'trapped' within the sacral hollow. *A.* Longitudinal scan demonstrating an incarcerated uterus in the early second trimester. What appears to be the lower uterine segment is in fact the fundus (F) that is stuck within the sacral hollow. The cervix (C) is drawn anteriorly and superiorly. The urethra often becomes obstructed, and these patients are often seen in the emergency room with urinary obstruction. P, placenta. *B.* After manual reduction, the cervix (C) and uterus now have a more normal appearance. The placenta (P), which appeared to be posterior in the prerelief scan, is now seen anteriorly.

FIGURE 35-32. *A.* A transvaginal sonogram demonstrates an embryo and yolk sac (arrow) centrally positioned in what appears to be the uterus. *B.* A transabdominal sonogram of the same patient demonstrates that the pregnancy was in the fallopian tube (TUBE). A small fluid collection representing fluid within the endometrial cavity (decidual cast) of the uterus (UT) is seen. The patient had an ectopic pregnancy.

FIGURE 35-33. A. A transvaginal sonogram demonstrates an ill-defined soft tissue mass (*arrow*) in a cystic fluid collection within the ovary. The uniformly thick wall of the cyst simulates a decidual reaction. This has the appearance of a disorganized embryo within a gestational sac. B. An additional scan of the same adnexa demonstrates a more characteristic "fishnet" appearance of hemorrhage within an ovarian cyst.

FIGURE 35-34. A vascular ring (*arrow*) is seen around a cyst within the adnexa. Although this "ring of fire" was once thought to be characteristic of an ectopic pregnancy, it is recognized that a corpus luteum cyst, as in this case, may produce a similar appearance.

THE FIRST TRIMESTER

FIGURE 35-35. *A.* Small gestational sac, seen too early to characterize, is seen within the decidualized endometrium. A normal intrauterine pregnancy resulted. *B.* Small cystic structure (*arrow*) is seen in the periphery of the endometrium. Although the structure is similar to a small gestational sac as seen in *A*, this was a decidual cyst of an ectopic pregnancy.

FIGURE 35-36. Transverse scan of an early gravid uterus. Although there appears to be two gestational sacs (*arrows*), in fact, there was only one. Moving the transducer slightly over to one side demonstrated the single gestational sac. This effect is believed to be due to the refraction of sound at the interface between the abdominal musculature and fat.

A

B

FIGURE 35-37. A. A sonogram of the gravid uterus in the first trimester demonstrates what appears to be two gestational sacs divided by a thick intertwin membrane (*arrow*). B. With slight angulation one can see that the structure dividing the gestational sac was a uterine synechia (*arrow*). E, embryo.

FIGURE 35-38. Transvaginal sonogram of an early intrauterine pregnancy and intrauterine device (IUD). The linear structure (*arrow*) seen in the lower uterine segment is an IUD. The relationship of the IUD and the gestational sac should be reported.

FIGURE 35-39. The yolk sac (*arrow*) is commonly identified in first trimester pregnancies. This should not be included in the measurement of the embryonic crown rump length or mistakenly called a twin gestation.

FIGURE 35-40. A. Longitudinal section through the uterus of a patient presenting with vaginal bleeding during early pregnancy. A yolk sac (Y) is seen in addition to what appears to be an abnormal embryo (*arrow*). B. A transverse scan reveals that no embryo is present and that the tissue seen in A was due to partial volume through the developing placenta (*line*). This was a case of early pregnancy failure. C. Sonogram of another patient with a first trimester pregnancy at 6 weeks and 2 days. A soft tissue area is seen apparently within the gestational sac simulating a nonviable embryo (*arrow*). D. On the opposite side of the gestational sac, a yolk sac and embryo are seen (*arrow*). The patient's pregnancy was subsequently uneventful, and she delivered a normal infant. The structure seen in (C) was a lobular portion of the placenta referred to recently as the "chorionic bump." (See Harris RD, Couto C, Karpovsky C, et al. *The chorionic bump: A first-trimester pregnancy sonographic finding associated with a guarded prognosis.* *J Ultrasound Med* 25:757, 2006.)

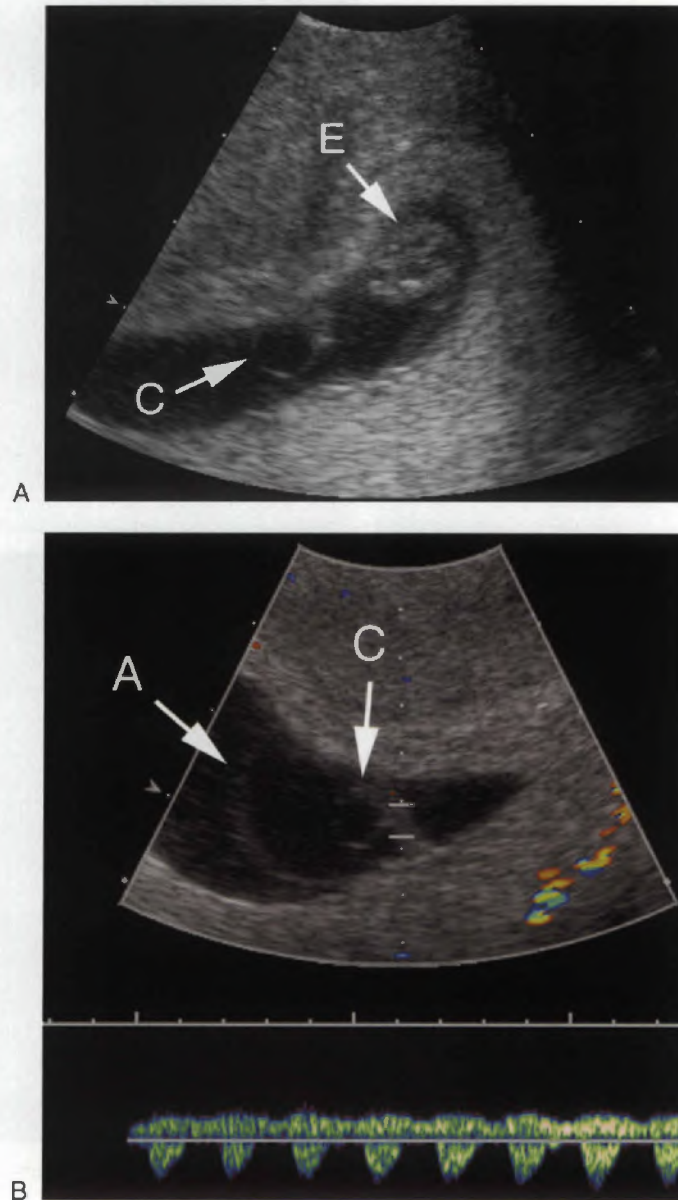

FIGURE 35-41. A. An umbilical cord cyst (C) is seen in this first trimester pregnancy separate from the embryo (E). B. Doppler interrogation of the umbilical cord demonstrates that the cyst (C) is associated with the umbilical cord. A, amnion.

FIGURE 35-42. A. Sonogram of an embryo demonstrates normal herniation of bowel (*arrow*) into the umbilical cord adjacent to the anterior abdominal wall. B. Sonogram of another embryo demonstrates an even larger but normal appearance to the herniated bowel (*arrow*). C. A follow-up scan of the patient in B demonstrates a normal anterior abdominal wall without evidence of an anterior abdominal wall defect. If there is any question, a follow-up scan, as was done in this case, should be performed.

FIGURE 35-43. The amnion (*arrow*) is frequently identified in first trimester gestations. It apposes the chorion between 12 and 16 weeks' gestation. It should not be mistaken for amniotic band syndrome.

FIGURE 35-44. A prominent fluid-filled intracranial area (*arrow*) can be seen in the cranium of the embryo particularly with transvaginal sonography. This represents the developing rhombencephalon and should not be mistaken for either hydrocephalus or holoprosencephaly.

A

B

FIGURE 35-45. A. A transabdominal sonogram of the gravid uterus demonstrated what appeared to be a normal embryo. B. A transvaginal sonogram of the same patient done at the time of chorionic villus sampling demonstrates a large monoventricular cavity (*arrows*) consistent with holoprosencephaly. Trisomy 13 was detected.

A

B

FIGURE 35-46. Although the diagnosis of anencephaly is certainly possible in the first trimester, the likelihood of a false-negative diagnosis is high. The angiomatic stroma (A, *arrow*) in a case of anencephaly simulates the normal brain in another case (B, *arrow*).

FIGURE 35-47. A. Normal integument (nuchal translucency) (*arrow*) in an early second trimester fetus. B. Normally, the nuchal translucency is measured to determine if it is abnormally increased in thickness. In this fetus, the large rounded configuration to the nuchal translucency (*arrow*) can readily be determined to be abnormal subjectively.

FIGURE 35-48. *A.* In this case of an abnormally increased nuchal translucency, there is the potential to misinterpret the outermost reflection of integument (*arrow*) as representing amnion. *B.* In another plane of section, the amnion (*A*) can be seen distinct from the integumentary edema (*arrows*). *C.* In this fetus, the abnormally increased nuchal translucency can be readily distinguished from the adjacent amnion (*arrow*).

THE FETAL HEAD AND NECK

FIGURE 35-49. A. Sonogram of a third trimester fetus demonstrates what appears to be scalp thickening (arrow). B. In a slightly wider field of view, it can be clearly seen that what appeared to be fetal scalp was in fact the wall of the maternal urinary bladder. Bl, bladder.

FIGURE 35-50. Pseudocleft of the face. The space (arrow) between the fetal nose (N) and cheek (C) should not be misinterpreted as a cleft. E, eye.

FIGURE 35-51. Pseudocleft lip. *A.* An angled “oblique” view of the face demonstrates what appears to be a gap in the lip (*arrow*). *B.* Normal-appearing lip (*arrow*) obtained on a slightly different plane of section.

FIGURE 35-52. *A.* Coronal plane of section of the fetal face. Because of a slight compression of the fetal face, the upper lip creates the appearance of a mass (*arrow*). *B.* As the mouth opens wider, the upper lip (*arrow*) appears normal.

FIGURE 35-53. A. A steep oblique transverse plane of section of the fetal head demonstrates what appears to be marked nuchal thickening (*arrow*). B. A longitudinal plane of section demonstrates that the nuchal integument (*arrow*) is prominent as a result of extension of the fetal head on the neck. As expected, the neonate was normal.

FIGURE 35-54. Normal fetal hair (*arrows*) may be seen commonly in third trimester fetuses. This should not be mistaken for a calvarial mass or scalp edema.

FIGURE 35-55. Sonogram of the fetal head commonly used for measurement of the biparietal diameter and head circumference. This case has a common variation referred to as dolichocephaly. The importance is that measurement of the biparietal diameter in such fetuses will tend to underestimate gestational age. Dolichocephaly may also be seen in cases of breech presentation, oligohydramnios, and fetuses with myelomeningocele.

FIGURE 35-56. Interaction of the sound beam with the curved surface of the calvarium produces troubling appearances. This fetus appears to have overlapping sutures (*arrow*). In fact, this was an artifact related to refraction of the sound beam. The fetal calvarium was normal when the transducer angle was changed.

FIGURE 35-58. A transverse axial plane of section demonstrates an echogenic mass (*arrow*), which appears to be within the fetal brain. This is due to a slightly oblique scan in which projection of the petrous ridge at the same level of the normal brain on the opposite side is seen.

FIGURE 35-57. Frontal concave scalloping (*arrows*), the so-called lemon sign, has been described in patients with a myelomeningocele. This may also be a normal finding, as it was in this case.

FIGURE 35-59. Projections from the fetal cranium can often be disturbing. In cases of polyhydramnios, the fetal ear (E) can be seen perpendicular to the fetal skull and may simulate an encephalocele, which would be uncommon in this location.

FIGURE 35-60. Amniotic fluid (*arrow*) is "trapped" between the posterior fetal neck and the myometrium. This may simulate such pathology as a cystic hygroma. Identification of structures within the fluid, such as umbilical cord, as in this case, or displacing the fetus away from the uterine wall will often reveal this to be "artifactual." H, head.

FIGURE 35-62. The cisterna magna (*arrows*) may be normally prominent. Controversy exists regarding the significance of a prominent cisterna magna in the absence of ventricular dilation. It is my belief that if the cisterna magna is prominent, the cerebellar vermis (*v*) is normal, the ventricles are normal, and no other malformations are detected, then the overwhelming likelihood is that this is a normal variant.

A

B

FIGURE 35-61. A and B. Two slightly angled transverse axial scans of the fetal head at 14 weeks' gestation demonstrate what appears to be vermian agenesis (*arrow*). It should be remembered that development of the posterior fossa anatomy is usually not complete until the middle of the second trimester. This fetus developed normally.

FIGURE 35-63. Steep transverse scan through the posterior fossa may contribute to a pitfall. The normal space (arrow) between the cerebellar hemispheres (vallecula) may appear overly prominent and simulate vermian agenesis.

FIGURE 35-64. Linear echoes (arrows) seen in the region of the cisterna magna should not be mistaken for either an arachnoid cyst or a dilated sinus. The exact etiology is controversial, although a recent hypothesis is that these may represent the vestigial remnants of Blake's pouch. (From Robinson AJ, Goldstein R: The cisterna magna septa: Vestigial remnants of Blake's pouch and a potential new marker for normal development of the rhombencephalon. *J Ultrasound Med* 26:83, 2007)

FIGURE 35-65. A and B. The choroid plexus cyst (arrow) is a normal variant that has been the subject of much controversy during the past several years. Although most cases are simply normal variants that will resolve by 24 to 26 weeks' gestation, some cases may be associated with other anomalies and trisomy 18.

FIGURE 35-66. *A.* This patient has what appears to be a choroid plexus cyst (*arrow*) on this somewhat oblique scan of the fetal head. *B.* On a more conventional transverse axial plane of section, this “pseudocyst” elongates (*arrows*), proving to indent rather than be within the substance of the choroid plexus. Although the exact cause of this is uncertain, it may represent the corpus striatum.

FIGURE 35-67. Heterogeneous choroid plexus bilaterally. No defined cysts were seen. The fetus and neonate developed normally.

FIGURE 35-68. The cavum septi pellucidum is normally seen in scans of the second trimester fetal brain. At times, a prominent but normal posterior continuation, referred to as the cavum vergae, can be seen. *A* and *B*. Portions of the cavum (*arrows*) may simulate either an arachnoid cyst or a dilated third ventricle. *C*. The normal third ventricle (*arrow*) is easily identified in this case.

FIGURE 35-69. *A*. Transverse axial sonogram of the fetal head. In the expected position of the cavum septum pellucidum, a trilinear structure is seen (*arrow*). This represents the columns of the fornix and should not be mistaken for the cavum septum pellucidum, which is at a slightly more rostral level. *B*. At a slightly more rostral level, the normal cavum septum pellucidum is seen (*arrow*). The normal cavum is filled with fluid and has a box-like appearance.

FIGURE 35-70. The normal fetal brain is sonolucent (*asterisks*) and may simulate cerebrospinal fluid. This may incorrectly lead to the diagnosis of hydrocephalus. Identification of the lateral ventricular walls (*arrows*) and the choroid plexus within will help resolve this confusion.

FIGURE 35-71. *A.* Transverse axial scan in which both choroids plexi are seen (*asterisks*). *B.* In this angulated scan, the choroid plexi (*arrows*) simulate bilateral subependymal hemorrhages. This fetus was normal on subsequent scans and on neurosonograms at birth.

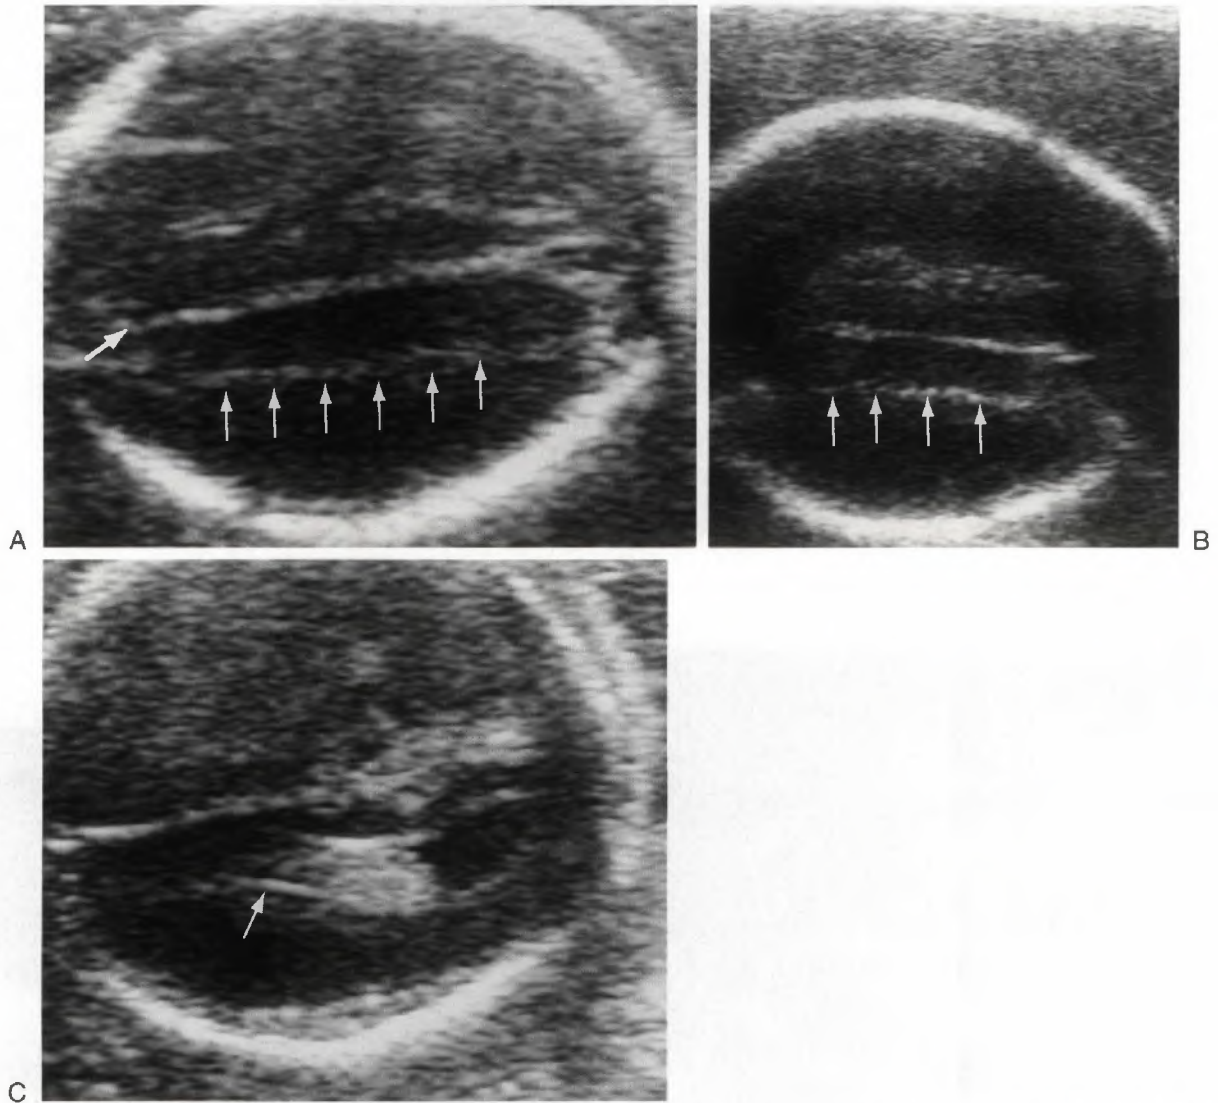

FIGURE 35-72. A and B. Transverse axial plane of section in two normal patients. The paramedian lines (*small arrows*) (paralleling the midline interhemispheric fissure echo [*large arrow*]) are due to deep cerebral medullary white matter veins and not the lateral wall of the lateral ventricle. C. The lateral wall of the lateral ventricle (*arrow*) is seen at a slightly more basal level and angling laterally away from the midline.

FIGURE 35-73. Shadowing (*arrow*) from the iliac wing (*curved arrow*) may simulate a gap or fluid-filled cystic space (i.e., myelomeningocele) of the lumbar spine.

FIGURE 35-75. The hyaloid artery (*arrow*) and a branch of the ophthalmic artery can be seen in this sonogram. This vessel often degenerates during the third trimester.

FIGURE 35-74. A. A sac-like structure is seen just posterior and adjacent to the lumbosacral spine (*arrow*). This has the appearance of a myelomeningocele sac. B. Color Doppler imaging demonstrates that this structure is the umbilical cord.

THE FETAL THORAX

FIGURE 35-76. The fetal hypopharynx (*arrow*) may be prominent. It may be seen to fill and empty with fluid during the examination. This should not be mistaken as representing esophageal obstruction.

FIGURE 35-77. The echogenicity of the fetal lung (Lu) may often be misleading. The lung in this oblique coronal scan appears brightly echogenic compared with the liver (Li); however, this fetus neither is mature nor has lung pathology.

FIGURE 35-78. *A.* Angled transverse axial plane of section at the level of the fetal heart (H). The fetal stomach (S) is seen at the same level as the heart, raising the possibility of a diaphragmatic hernia. *B.* This sagittal plane of section from the same patient reminds us that the diaphragms (*arrow*) are curved, and a slightly angled transverse plane of section will portray what appears to be a diaphragmatic hernia, although the stomach (S) is, in fact, below the diaphragm.

FIGURE 35-79. Pseudoskin thickening and pseudoascites. *A.* The sonolucent region (*arrows*) at the level of the thorax does not represent integumentary edema but rather the normal thoracic musculature. *B.* At a slightly lower plane of section, the same appearance is seen (*arrows*) simulating ascites. *C.* In another patient, this appearance is also noted at the region of the scapula (*arrows*), where it is often most prominent.

FIGURE 35-80. A high-amplitude echo (*short arrow*) with shadowing is seen possibly involving the pericardium. This is the normal rib seen along its short axis. The contralateral rib (*long arrow*) is somewhat more elongated.

FIGURE 35-81. Soft tissue seen within the ventricle is always worrisome for either thrombus or neoplasm. In this patient, the normal but prominent moderator band of the right ventricle (*M*) is seen. *RV*, right ventricle; *LV*, left ventricle.

FIGURE 35-82. A. An apparent defect in the ventricular septum (*arrow*) is seen. This may be due to the origin of the aortic root and the thin membranous septum. B. Slight change of the transducer position demonstrates a normal-appearing septum.

FIGURE 35-83. A. The poorly echogenic myocardium (*arrows*) may simulate pericardial fluid. The observation that this area blends imperceptibly with the intraventricular septum should alert one that this is a normal cardiac structure and not pericardial fluid. B. The case in A should be contrasted with real pericardial fluid (*arrow*), which contains no echoes.

FIGURE 35-84. Echogenic intracardiac focus. *A.* A high-amplitude echo (*arrow*) is seen in the left ventricle in this patient. This appearance is believed to be due to reflection from calcification in the papillary muscle. In this case, the echogenic structure was fairly large. The significance of this finding is controversial; in some cases, it is associated with karyotype abnormalities. *B.* A smaller echogenic intracardiac focus (*arrow*) is seen in another patient. *C.* In this patient, a reflection (*arrow*) from the atrioventricular valve is seen. It appears similar to an echogenic intracardiac focus. *D.* The reflection from the surface of the valve (*arrow*) is better seen in another plane of section.

THE FETAL ABDOMEN

FIGURE 35-85. Pseudo-omphalocele in two patients. *A* and *C*. Excessive pressure with the linear array transducer causes deformation of the abdominal wall, simulating an abdominal wall defect. Identification of the normal skin covering this protuberance (*arrows*) and less pressure on the maternal abdomen will usually resolve the confusion. *B* and *D*. Same patients demonstrating normal anterior abdominal wall with light pressure on the maternal abdomen. *S*, stomach.

FIGURE 35-86. Pseudogastroschisis caused by an extremity (E) adjacent to the umbilical cord insertion site (*arrow*).

FIGURE 35-87. Gastroschisis in a second trimester pregnancy. Multiple loops of bowel are seen adjacent to the fetal abdomen within the amniotic fluid. What appears to be dilated bowel is normal colon (*arrow*), which may appear to be prominent although nondilated.

FIGURE 35-88. A. Pseudoascites resulting from the poorly echogenic appearance of the normal integument (*arrows*). B and C. A small amount of real ascites is identified in this patient. Notice that the fluid invaginates between the viscera on the right side (*arrows*).

FIGURE 35-89. Debris within the fetal stomach (*arrow*). Although occasionally the cause may be known (i.e., swallowed blood from an intrauterine transfusion), most often it is unknown. This is almost always an innocuous finding.

FIGURE 35-90. Hyperechogenicity within the fetal abdomen (*arrows*). This finding has received recent attention in the literature as a possible clue to the diagnosis of either cystic fibrosis or aneuploidy. The problem is in differentiating normal from abnormal. *A* and *B*. Normal chromosomes and no evidence of cystic fibrosis. *bl*, bladder. *C*. A case of meconium ileus and cystic fibrosis at birth (*arrows*). To be called “echogenic bowel” the echogenicity of the bowel should be similar to adjacent bone.

FIGURE 35-91. Pseudohyperechoic fetal bowel. *A.* Sonogram of the fetal abdomen obtained with an 8-MHz frequency transducer demonstrates hyperechoic fetal bowel (*arrows*). The bowel wall is accentuated at this frequency. *B.* Sonogram of the same patient obtained with a 5-MHz frequency transducer appears more normal in appearance. This is a common phenomenon, and the sonologist should be aware of the effect of transducer frequency on bowel echogenicity before declaring the bowel echogenicity abnormal and proceeding to invasive testing.

FIGURE 35-92. *A* and *B.* Fetal gallstones (*arrows*) seen in two third trimester fetuses. In both cases, the fetus was otherwise normal. This finding does not indicate biliary pathology and may resolve before birth.

FIGURE 35-93. Pseudo-double bubble sign. The double bubble may be seen in cases of duodenal obstruction and has been associated with trisomy 21. *A.* In this case, the fluid-filled structure adjacent to the stomach (S) is the gallbladder (*arrow*) and not the duodenum. *B.* A sonogram of the fetal abdomen in the third trimester demonstrates a prominent segment of colon (*arrow*) adjacent to the fetal stomach (S) and should not be misinterpreted as dilated duodenum.

FIGURE 35-94. The fetal intestine (*arrow*) may simulate other nonintestinal structures such as a dilated ureter. This is especially true in the second trimester, when the meconium-filled distal small bowel and colon are sonolucent. K, kidney.

FIGURE 35-95. *A* and *B*. The fetal colon may be prominent in the third trimester fetus. Normal colon in two fetuses in the third trimester. The colon (*arrows*) is prominent but normal in both of these patients.

FIGURE 35-96. The normal rectum (*arrow*) can occasionally be seen in the second and third trimester fetus. This should not be mistaken for a myelomeningocele or other intrapelvic pathology. B, bladder.

FIGURE 35-97. In the presence of fetal ascites (*A*), fluid may enter the lesser sac and result in outlining of the greater omentum (*arrow*). This should not be mistaken for a dilated loop of intestine. L, liver.

FIGURE 35-98. The normal fetal renal pyramids may be sonolucent (*arrows*) and simulate hydronephrosis. This appearance is normal and should be seen as a normal and expected finding. Failure to identify a dilated medial renal pelvis should reassure the interpreter.

FIGURE 35-100. The normal poorly echogenic pararenal musculature (quadratus lumborum and psoas) (*arrows*) may simulate fluid around the kidney (K). Sp, spine.

FIGURE 35-99. The non-fluid-filled colon (*arrows*) is seen adjacent to the kidney (K) in this patient. This should not be misinterpreted as a renal mass.

FIGURE 35-101. An oval paraspinous soft tissue structure is seen simulating the fetal kidney (*arrow*). This structure is the normal adrenal gland, which often is quite prominent in the fetus. The hyperechoic medulla and hypoechoic cortex are well seen.

A

B

FIGURE 35-102. Persistent right umbilical vein. *A.* In this transverse axial scan, the portal vein (*arrow*) is curving toward, rather than away from the stomach (*s*). This is a case of persistent right umbilical vein. No other anomalies were detected. *B.* In another case of persistent right umbilical vein, the umbilical vein (*arrow*) is to the right rather than the left of the gallbladder (*GB*).

A

B

FIGURE 35-103. Umbilical vein varix. Initially it was thought that the prognosis in cases of umbilical vein varix was uniformly poor. If there are no associated abnormalities, most cases do well. *A.* Umbilical vein varix (*arrow*) seen adjacent to the anterior abdominal wall and the urinary bladder (*Bl*). *B.* Color Doppler imaging of an umbilical vein varix (*arrow*). In neither case was there associated abnormalities, and the outcome was normal in both cases.

FIGURE 35-104. A short-axis view of the umbilical cord should always be obtained when attempting to identify the number of vessels. In this case, the long-axis view (*open arrow*) appears to show two umbilical arteries (A) and one vein (V). In the short-axis view (*curved arrow*), the correct interpretation of a single umbilical artery in a two-vessel cord can be made.

AMNIOTIC FLUID AND MEMBRANES

A

B

FIGURE 35-105. When amniotic fluid volume is assessed, the “pocket” of fluid should be free of umbilical cord. A. In this patient, there appears to be a 3-cm pocket of amniotic fluid (*calipers*). B. Doppler evaluation of this area revealed that this “pocket” was not amniotic fluid but all umbilical cord.

FIGURE 35-106. *A.* In this scan of a second trimester pregnancy, a large amniotic fluid pocket is seen, suggesting polyhydramnios. *B.* Little amniotic fluid is seen in a scan near the lower portion of the uterus. The total volume of amniotic fluid was normal. Thus, single views of the gravid uterus may be misleading as to the correct volume of amniotic fluid.

FIGURE 35-107. *A.* Large fluid collection (*asterisk*) appears to be amniotic fluid; however, it represents a markedly dilated urinary bladder in a patient with posterior urethral valves. In fact, there was virtually no amniotic fluid. *B.* Another sonogram in the same case demonstrates a dilated posterior urethra (*U*) and dilated ureters (*arrow*) in addition to the dilated urinary bladder.

FIGURE 35-108. In this early second trimester fetus, the amnion (*arrows*) is seen slightly separated from the chorion. This is normal until the 12th to 14th week of gestation, at which time the two membranes appose one another.

FIGURE 35-109. Pseudochoorioamniotic separation. *A.* Apparent chorioamniotic separation is seen with an unapposed amniotic membrane (*arrows*). *B.* Color Doppler imaging reveals that the structure thought to represent membrane was, in fact, umbilical cord.

FIGURE 35-110. *A.* A linear structure (*arrow*) is seen anteriorly adjacent to the fetal head and placenta. It has the appearance of a free-floating amniotic membrane. *B.* With a larger field of view, the membrane is seen to represent the surface of the placenta, under which is a hypoechoic area (*asterisk*) likely representing a subchorionic plate hematoma.

THE FETAL SKELETON

FIGURE 35-111. A. The normal fetal femur has a medial curve to the metadiaphyseal region. This is seen in the femur farthest from the transducer (*arrow*). The femur closest to the transducer (*cursors*) will demonstrate a straight appearance because the lateral aspect is reflecting the sound and the medial aspect is within its shadow. B. Radiograph of a normal neonatal femur demonstrating the normal curved appearance of its medial aspect (*arrow*).

FIGURE 35-112. Scans of the fetal femur often demonstrate a linear projection from the distal end. A. This projection (*arrow*) is a specular reflection from the distal epiphyseal cartilage (*asterisk*). B. The measurement of the femur should not include this reflection (*arrow*). C. The measurement should include only the calcified bone. Inclusion of this reflection would have overestimated the gestational age by as much as 3 weeks.

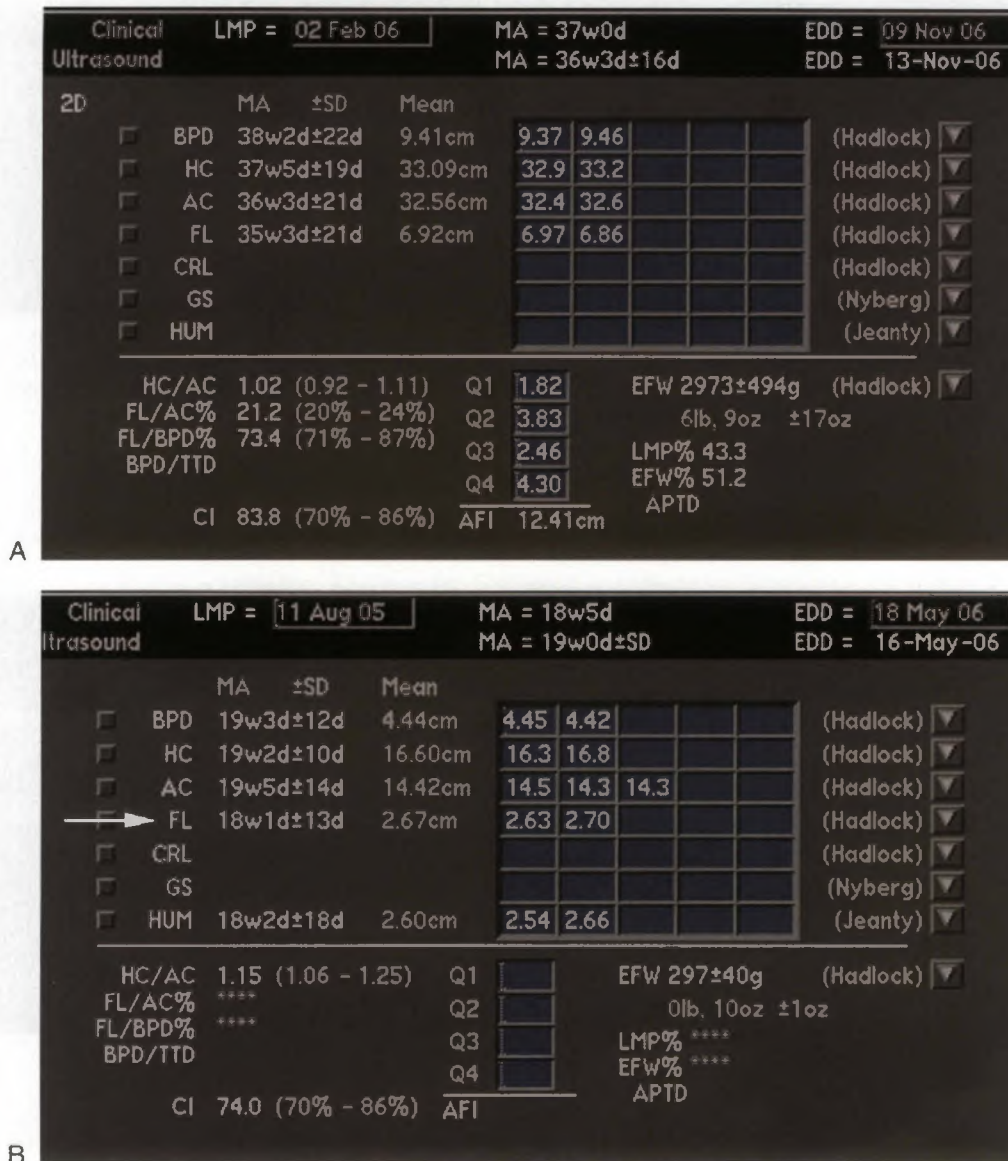

FIGURE 35-113. Significance of short femoral length. **A.** In the mid to late third trimester, it is not unusual for the femur to be significantly shorter than the other measurements used to estimate gestational age. In this case, the femur is approximately 2 weeks less than the head circumference and menstrual age. The etiology of this is uncertain, and is often attributed to biologic variation and or ethnicity. If the bones appear normal morphologically and no anomalies are seen, it is likely a normal variant. This fetus was from white parents of normal height and middle socioeconomic status. **B.** Although the femur can be smaller than other measurements in the third trimester, it is not acceptable for it to be greater than one week less than the other measurements in the late first and early to mid second trimester, as it was in this case (*arrow*). Although this may be nothing more than a temporary growth lag or normal variation at this stage, it may also be a sign of trisomy 21 or an early manifestation of a short-limb skeletal dysplasia. This was a case of trisomy 21. One should not take comfort in comparing the femur measurement to the estimated gestational age by ultrasound. Remember, that unless excluded, the femur measurement is included in the sonographic estimation of gestational age.

FIGURE 35-114. Pseudolimb reduction. *A.* Pronation and supination of the forearm may create the appearance that the radius (R) or the ulna (U) is abnormally short (limb reduction abnormality). When both bones are "short" at opposite ends in the same scan, one should be suspicious that this is a technical rather than a real abnormality. *B.* Partial volume of the proximal forearm makes it appear as though the radius and ulna are hypoplastic. *C.* Slight change in transducer angulation reveals that both bones of the forearm are present and normal. *D.* Again, a tomographic plane of section demonstrating only part of the fibula. Both bones of the leg were present and normal.

FIGURE 35-115. The appearance of the epiphyseal ossification centers is helpful in assessing gestational age. A. The synovial tissue is echogenic (*arrow*) and may simulate the appearance of one of these centers, as in this case. The real epiphyseal center would be slightly more proximal. B. Synovial tissue (S) is well seen in the same case, without evidence of calcification within the epiphyseal center (*arrow*).

FIGURE 35-116. In this case, both hands of the fetus are adjacent to one another. The fingers (*arrows*) from one hand and the fingers (*open arrow*) from the other simulate the appearance of polydactyly.

FIGURE 35-117. *A.* Separation of the first and second toe (*arrow*) referred to as a sandal gap deformity. This abnormality has been described in some fetuses and neonates with trisomy 21; however, it may also be a positional abnormality and normal variant. *B.* A scan performed later demonstrated normal appearance of the foot. No other abnormalities were seen, and the neonate was normal at birth.

MULTIPLE GESTATIONS

FIGURE 35-118. Although ideally multiple gestation pregnancies should never be missed, it is my experience that when cases are missed, it is usually in the first trimester, even with transvaginal scanning. *A.* A transvaginal sonogram done for vaginal bleeding revealed a yolk sac (*arrow*), with cardiac activity noted at the edge of the yolk sac. *B.* Because of continued spotting, the patient returned the following week. At this time, two yolk sacs (*arrows*) were identified in this monochorionic pregnancy.

FIGURE 35-119. The false-negative diagnosis of twins is unusual in the second trimester. If this occurs, it likely results from not “connecting” the fetal head to its body during routine scanning. *A.* In this patient, the fetal head (*straight arrow*) and body (*curved arrow*) are seen in this longitudinal plane of section. Unfortunately, these structures are from different fetuses in this twin pregnancy. *B.* The only way to be absolutely sure of the relation of the head (H) to the body is to demonstrate both structures on the same scan connected to one another through the neck (N) (T, thorax). *C.* The dividing membrane (*arrow*) is seen on another plane of section clearly dividing the two fetuses.

FIGURE 35-120. Membrane thickness is often useful in differentiating between monozygotic twins (thin membrane) and dizygotic twins (thick membrane). This method is not always successful, however. *A.* In this twin pregnancy, a scan at 14 weeks' gestation demonstrates a thin membrane (*arrow*) dividing the two gestational sacs. This implies monozygosity. *B.* A longitudinal plane of section at the same time reveals both an anterior placenta (*asterisk*) and a posterior placenta (*double asterisks*).

FIGURE 35-121. In this twin gestation, one of the twins was noted to be fixed to the anterior uterine wall. It was initially assumed that this was a monoamniotic twin gestation. Careful inspection reveals that the membrane (*arrow*) dividing the twins can be seen. The anterior fetus is in an oligohydramniotic sac and is smaller than the other twin. This was a case of twin-to-twin transfusion syndrome.

A

B

C

FIGURE 35-122. A. Monozygotic diamniotic twin pregnancy with twin-to-twin transfusion syndrome. Although it appears as if there is a large amount of fluid (*asterisk*) surrounding the donor twin (D), in fact only a small amount of fluid is seen within the surrounding membrane (*arrows*). B. Monozygotic diamniotic twin pregnancy with twin-to-twin transfusion syndrome. Membrane surrounds the donor twin in an oligohydramniotic sac. The membrane has a free edge (*arrow*) projecting into the amniotic fluid surrounding the recipient twin. C. Drawing demonstrating the collapsed membrane surrounding the donor twin in an oligohydramniotic sac, similar to what is seen in B.

ARTIFACTS

FIGURE 35-123. Side lobe (gradient) artifact can occur with even the most sophisticated ultrasound scanning equipment. In this case, a side lobe artifact is seen overlying the fetal head (*arrows*). The artifactual nature of these echoes can be confirmed by noting that these echoes are not confined to the head but extend beyond its confines. In addition, changing the scan plane orientation will show the region to be normal.

FIGURE 35-124. *A* and *C*. Two cases of artifact (*arrow*) appear in the fetal stomach and duodenum. *B* and *D*. If one changes the scanning plane, these echoes will disappear from the area of concern.

FIGURE 35-125. The differentiation of real from artifactual echoes is often problematic during sonographic scanning. A common misconception is that changing to a lower frequency transducer and decreasing the overall system gain or just reducing the system gain will only cause the artifactual echoes alone to disappear. Although it is true that artifactual echoes will not be displayed with these maneuvers, it should be remembered that the real echoes will not be displayed either. *A.* In this patient, numerous low-level echoes (*arrows*) were seen swirling in the amniotic fluid during real-time scanning. Although the origin of the echoes is not known, they may represent shed fetal epithelial cells. *B.* When the system gain was decreased, these real echoes virtually disappeared. Although the hard copy images do not resolve this dilemma, the echoes were clearly seen to be moving and real when the sonologist was performing the scan.

BREAST ULTRASOUND

FIGURE 35-126. Cancer or artifact? *A.* Is small, hypoechoic suspicious mass or refraction at edges of curved surfaces (*arrow*) cause of the shadowing? *B.* Slight change in patient position, probe angulation, or amount of compression applied by transducer can often provide resolution. (*Images courtesy of E. Mendelson, MD.*)

FIGURE 35-127. Orthogonal imaging. A. Hypoechoic mass with posterior acoustic shadowing is recommended for ultrasound-guided biopsy. B. The "mass" is a rib sitting in normal location behind muscle. Orthogonal imaging and knowledge of US breast anatomy are essential to avoid misdiagnosis. (Images courtesy of E. Mendelson, MD.)

FIGURE 35-128. Fat lobules in the breast, as in this case, are discrete and may mimic fibroadenomas, and are bound by thin connective tissue capsules. (Image courtesy of E. Mendelson, MD.)

'THE END'

A **FIGURE 35-129.** After viewing so many artifacts, pitfalls, and normal variants, you wonder whether: *A.* The umbilical cord is smiling back at you. *B.* The fetus is blowing bubbles.

APPENDIX A

Measurements Frequently Used to Estimate Gestational Age and Fetal Biometry

Table A-1 Methods for Determining Menstrual Age

Clinical or Sonographic Parameter	Variability Estimate (2 SD)
In vitro fertilization*	±1 day
Ovulation induction*	±3 days
Artificial insemination*	±3 days
Single intercourse record*	±3 days
Basal body temperature record*	±4 days
First trimester physical examination	±2 weeks
Second trimester physical examination	±4 weeks
Third trimester physical examination	±6 weeks
First trimester sonographic examination (CRL)	±8% of the estimate
Second trimester sonographic examination (HC, FL)	±8% of the estimate
Third trimester sonographic examination (HC, FL)	±8% of the estimate

CRL, crown rump length; FL, femur length; HC, head circumference.

*These are indicators of conceptual age (menstrual age = conceptual age + 14 days).

Adapted from Frank P. Hadlock, MD, and James D. Bowie, MD.

Table A-2 Variability in Predicting Menstrual Age from Sonographic Measurements (14–20 Weeks)

Parameter	Variability (2 SD)			
	<i>Hadlock et al</i> [*]	<i>Rossavik and Fishburne</i> [†]	<i>Persson and Weldner</i> [‡]	<i>Benson and Doubilet</i> [§]
BPD	0.94 wk	1.02 wk	0.92 wk	1.40 wk
HC	0.84 wk	0.92 wk	ND	1.20 wk
AC	1.04 wk	1.12 wk	ND	2.10 wk
FL	0.96 wk	ND	0.98 wk	1.40 wk
BPD, FL	0.80 wk	ND	0.78 wk	ND
HC, FL	0.76 wk	ND	ND	ND

AC, abdominal circumference; BPD, biparietal diameter; FL, femur length; HC, head circumference; ND, no data.

Measurements Used in Assessing Fetal Weight, Growth, and Body Proportions

Table B-1 Equations for the Estimation of Fetal Weight

Source	Year	Equation
AC equations		
Campbell and Wilkin*	1975	$\text{Ln EFW} = -4.564 + 0.282 (\text{AC}) - 0.00331 (\text{AC})^2$
Hadlock et al	1984	$\text{Ln EFW} = 2.695 + 0.253 (\text{AC}) - 0.00275 (\text{AC})^2$
Jordaan	1983	$\text{Log}_{10} \text{EFW} = 0.6328 + 0.1881 (\text{AC}) - 0.0043 (\text{AC})^2 + 0.000036239 (\text{AC})^3$
Warsof et al*	1977	$\text{Log}_{10} \text{EFW} = -1.8367 + 0.092 (\text{AC}) - 0.000019 (\text{AC})^3$
Higginbottom et al	1975	$\text{EFW} = 0.0816 (\text{AC})^3$
FL equation		
Warsof et al	1986	$\text{Ln EFW} = 4.6914 + 0.151 (\text{FL})^2 - 0.0119 (\text{FL})^3$
AC/FL equations		
Hadlock et al	1985	$\text{Log}_{10} \text{EFW} = 1.304 + 0.05281 (\text{AC}) + 0.1938 (\text{FL}) - 0.004 (\text{AC})(\text{FL})$
Warsof et al	1986	$\text{Ln EFW} = 2.792 + 1.08 (\text{FL}) + 0.0036 (\text{AC})^2 - 0.027 (\text{FL})(\text{AC})$
Woo et al	1985	$\text{Log}_{10} \text{EFW} = 0.59 + 0.08 (\text{AC}) + 0.28 (\text{FL}) - 0.00716 (\text{AC})(\text{FL})$
AC/BPD equations		
Warsof et al*	1977	$\text{Log}_{10} \text{EFW} = 1.599 + 0.144 (\text{BPD}) + 0.032 (\text{AC}) - 0.000111 (\text{BPD})^2 (\text{AC})$
Hadlock et al	1984	$\text{Log}_{10} \text{EFW} = 1.1134 + 0.05845 (\text{AC}) - 0.000604 (\text{AC})^2 - 0.007365 (\text{BPD})^2 + 0.000595 (\text{BPD})(\text{AC}) + 0.1694 (\text{BPD})$
Jordaan*	1983	$\text{Log}_{10} \text{EFW} = -1.1683 + 0.0377 (\text{AC}) + 0.0950 (\text{BPD}) - 0.0015 (\text{BPD})(\text{AC})$
Hsieh et al	1987	$\text{Log}_{10} \text{EFW} = 2.1315 + 0.0056541 (\text{AC})(\text{BPD}) - 0.00015515 (\text{BPD})(\text{AC})^2 + 0.000019782 (\text{AC})^3 + 0.052594 (\text{BPD})$
Woo et al	1985	$\text{Log}_{10} \text{EFW} = 1.63 + 0.16 (\text{BPD}) + 0.00111 (\text{AC})^2 - 0.0000859 (\text{BPD})(\text{AC})^2$
Vintzileos et al	1987	$\text{Log}_{10} \text{EFW} = 1.879 + 0.084 (\text{BPD}) + 0.026 (\text{AC})$
Shepard et al*	1982	$\text{Log}_{10} \text{EFW} = -1.7492 + 0.166 (\text{BPD}) + 0.046 (\text{AC}) - 0.002546 (\text{BPD})$
AC/BPD/FL equations		
Woo et al	1985	$\text{Log}_{10} \text{EFW} = 1.54 + 0.15 (\text{BPD}) + 0.00111 (\text{AC})^2 - 0.0000764 (\text{BPD})(\text{AC})^2 + 0.05 (\text{FL}) - 0.000992 (\text{FL})(\text{AC})$
Shinozuka et al†	1987	$\text{EFW} = 0.23966 (\text{AC})^2 (\text{FL}) + 1.6230 (\text{BPD})^3$
Hadlock et al	1985	$\text{Log}_{10} \text{EFW} = 1.335 - 0.0034 (\text{AC})(\text{FL}) + 0.0316 (\text{BPD}) + 0.0457 (\text{AC}) + 0.1623 (\text{FL})$
Hsieh et al	1987	$\text{Log}_{10} \text{EFW} = 2.7193 + 0.0094962 (\text{AC})(\text{BPD}) - 0.1432 (\text{FL}) - 0.00076742 (\text{AC})(\text{BPD})^2 + 0.001745 (\text{FL})(\text{BPD})^2$

Continued

Table B-1 Equations for the Estimation of Fetal Weight—Continued

Source	Year	Equation
AC/HC/FL equations		
Hadlock et al	1984	$\text{Log}_{10} \text{EFW} = 1.326 - 0.00326 (\text{AC}) (\text{FL}) + 0.0107 (\text{HC}) + 0.0438 (\text{AC}) + 0.158 (\text{FL})$
Ott et al ^a	1986	$\text{Log}_{10} \text{EFW} = 2.0661 + 0.04355 (\text{HC}) + 0.05394 (\text{AC}) - 0.0008582 (\text{HC}) (\text{AC}) + 1.2594 (\text{FL}/\text{AC})$
Combs et al	1993	$\text{EFW} - 0.23718 (\text{AC})^2 (\text{FL}) + 0.03312 (\text{HC})^5$
AC/HC/BPD/± FL equations		
Jordaan	1983	$\text{Log}_{10} \text{EFW} = 2.3231 + 0.02904 (\text{AC}) + 0.0079 (\text{HC}) - 0.0058 (\text{BPD})$
Hadlock et al	1985	$\text{Log}_{10} \text{EFW} = 1.3596 + 0.0064 (\text{HC}) + 0.0424 (\text{AC}) + 0.174 (\text{FL}) + 0.00061 (\text{BPD}) (\text{AC}) - 0.00386 (\text{AC}) (\text{FL})$
Maternal characteristics equation		
Nahum et al [†]	2002	$\text{EFW} = \text{Gestational age (d)}^\mu (9.38 + 0.264^\mu \text{ fetal sex}^\delta + 0.000233 \times \text{maternal height [cm]} \times \text{maternal weight at 26.0 wks [kg]} + 4.62 \times \text{third-trimester maternal weight gain rate [kg/d]} \times [\text{parity} + 1])^\parallel$

Ln, Natural logarithm; EFW, estimated fetal weight (expressed in grams).

AC, FL, BPD, and HC are expressed in centimeters.

^aThe estimated fetal weight for these six algorithms is expressed in kilograms rather than grams.

[†]The equation of Shinozuka et al has been modified from its original form to include the fetal AC instead of the fetal transverse and anteroposterior abdominal diameters, as were described in the original equation. (Shinozuka N, Okai T, Kohzuma S, et al: Formulas for fetal weight estimation by ultrasound measurements based on neonatal specific gravities and volumes. *J Obstet Gynecol* 157:1140, 1987 and Combs CA, Jackle RK, Rosenn B, et al: Sonographic estimation of fetal weight based on a model of fetal volume. *Obstet Gynecol* 82:365, 1993).

[‡]This equation applies only to healthy white mothers who carry term singleton pregnancies. Fetal weight estimates that use this equation should be adjusted systematically for (1) black maternal race (decrement by 161 g), (2) East Asian maternal race (decrement by 291 g), (3) chronic hypertension (decrement by 161 g), (4) pregnancy-induced hypertension/preeclampsia (decrement by 105 g), (5) maternal cigarette smoking (decrement by 17 g per cigarette smoked per day), and (6) high altitude (decrement by 102 g for every 1000 meters in altitude above sea level).

[§]Fetal sex independently explains approximately 1% of the variance in term fetal weight. It is a significant predictor of birth weight (*F* test, *P* < 0.001), but it has little overall impact in birth weight predictions. When 0 is entered for fetal sex so that sex is ignored, the mean absolute prediction error does not change, and the median absolute prediction error increases only slightly by 10 g (0.2%). Thus fetal sex, although potentially useful if available, is nonessential for use of the maternal characteristics equation.

^{||}Where fetal sex = +1 for male, -1 for female, and 0 when sex is not known; gestational age = days since the onset of the last normal period = the conception age (in days) + 14. (Wahum GC, Stanislaw H: Ultrasonographic prediction of term birth weight: How accurate is it? *Am J Obstet Gynecol* 188:566, 2003.)

From Hill LM: Fetal weight. In Goldberg BB, McGahan JP (eds): *Atlas of Ultrasound Measurements*, 2nd ed. Philadelphia, Mosby Inc/Elsevier, 2006.

From Hadlock FP, Harrist RB, Carpenter RJ, et al: Sonographic estimation of fetal weight. Radiology 150:535, 1984.

Table B-6 Normal Body Ratio Data (14 to 21 Wk)

Menstrual Week	Cephalic Index (SD = 3.7)*	Femur/BPD × 100 (SD = 4.0) [†]	Femur/HC × 100 (SD = 1.0) [‡]	Femur/AC × 100 (SD = 1.3) [‡]
14	81.5	58.0	15.0	19.0
15	81.0	59.0	15.7	19.3
16	80.5	61.0	16.4	19.8
17	80.1	63.0	16.9	20.3
18	79.7	65.0	17.5	20.8
19	79.4	67.0	18.1	21.0
20	79.1	69.0	18.4	21.3
21	78.8	70.0	18.6	21.5

AC, abdominal circumference; BPD, biparietal diameter; HC, head circumference; SD, standard deviation.

*Data from Gray DL, Songster GS, Parvin CA, et al: Cephalic index: A gestational age-dependent biometric parameter. *Obstet Gynecol* 74:600, 1989.

[†]Data from Hadlock FP, Harrist RB, Martínez-Poyer J: Fetal body ratios in second trimester: A useful tool for identifying chromosomal abnormalities? *J Ultrasound Med* 11:81, 1992.

Table B-7 Normal Fetal Body Ratios (22 to 40 Wk)

Menstrual Week	Cephalic Index (SD = 4.4)*	Femur/BPD × 100 (SD = 5.0) [†]	Femur/HC × 100 (SD = 1.1) [‡]	Femur/AC × 100 (SD = 1.3) [‡]
22	78.3	77.4	18.6	21.6
23	78.3	77.6	18.8	21.7
24	78.3	77.8	19.0	21.7
25	78.3	78.0	19.2	21.8
26	78.3	78.2	19.4	21.8
27	78.3	78.4	19.6	21.9
28	78.3	78.6	19.8	21.9
29	78.3	78.8	20.0	21.9
30	78.3	79.0	20.3	22.0
31	78.3	79.2	20.5	22.0
32	78.3	79.4	20.7	22.1
33	78.3	79.6	20.9	22.1
34	78.3	79.8	21.1	22.2
35	78.3	80.0	21.4	22.2
36	78.3	80.2	21.6	22.2
37	78.3	80.4	21.8	22.3
38	78.3	80.6	22.0	22.3
39	78.3	80.8	22.2	22.3
40	78.3	81.0	22.4	22.4

AC, abdominal circumference; BPD, biparietal diameter; HC, head circumference; SD, standard deviation.

*Data from Hadlock FP, Deter RL, Carpenter RJ, et al: The effect of head shape on the accuracy of BPD in estimating fetal gestational age. *AJR* 137:83, 1981.

[†]Data from Hohler CW, Quetel TA: The relationship between fetal femur length and biparietal diameter in the last half of pregnancy. *Am J Obstet Gynecol* 141:759, 1981.

[‡]Data from Hadlock FP, Harrist RB, Shah YP, et al: The use of femur length/head circumference relation in obstetrical sonography. *J Ultrasound Med* 3:439, 1984.

[§]Data from Hadlock FP, Deter RL, Harrist RB, et al: A date-independent predictor of intrauterine growth retardation: Femur length/abdominal circumference ratio. *AJR* 141:979, 1983.

Table B-8 Comparison of Fetal Parameters in LGA and AGA Fetuses

Parameter	AGA Group (mean \pm SD)	LGA Group (mean \pm SD)	p Value
BPD (cm)	9.2 \pm 0.4	9.6 \pm 0.4	<.0001
HC (cm)	33.7 \pm 1.1	35.2 \pm 1.3	<.0001
AC (cm)	33.6 \pm 1.6	37.4 \pm 1.3	<.0001
FL (cm)	7.4 \pm 0.4	7.6 \pm 0.3	<.0001
HC/AC	1.0 \pm 0.05	0.94 \pm 0.04	<.0001
FL/AC*	22.0 \pm 1.0	20.5 \pm 1.0	<.0001

AC, abdominal circumference; AGA, appropriate for gestational age; BPD, biparietal diameter; FL, femur length; HC, head circumference; LGA, large for gestational age.

*FL/AC expressed as FL/AC \times 100.

From Hadlock FP, Harrist RB, Fearnleyhough TC, et al: Use of femur length/abdominal circumference ratio in detecting the macrosomic fetus. *Radiology* 154:503, 1985.

Table B-9 Conventional Sonographic Criteria for IUGR: Performance Characteristics

Criterion	Predictive Values (%) ^{*†}			
	Sensitivity (%) [*]	Specificity (%) [*]	Positive	Negative
Advanced placental grade	62	64	16	94
Elevated FL/AC	34-49	78-83	18-20	92-93
Low TIUV	57-80	72-76	21-24	92-97
Small BPD	24-88	62-94	21-44	92-98
Small BPD and advanced placental grade	59	86	32	95
Slow rate of BPD growth	75	84	35	97
Low EFW	89	88	45	99
Decreased AFV	24	98	55	92
Elevated HC/AC	82	94	62	98

AFV, amniotic fluid volume; BPD, biparietal diameter; EFW, estimated fetal weight; FL/AC, femur length/abdominal circumference ratio; HC/AC, head circumference/abdominal circumference ratio; IUGR, intrauterine growth restriction; TIUV, total intrauterine volume.

^{*}A range of values is given for a criterion when difference studies apply that criterion in two or more ways.

[†]Computed using Bayes' theorem and assuming an IUGR prevalence rate of 10%.

From Benson CB, Doubilet PM, Saltzman DH: Intrauterine growth retardation: Predictive value of US criteria for antenatal diagnosis. *Radiology* 160:415, 1986.

APPENDIX C

Measurements for Amniotic Fluid Assessment

Table C-1

Amniotic Fluid Index Values in Normal Pregnancy

Week	Amniotic Fluid Index Percentile Values (mm)				
	3rd	5th	50th	95th	97th
16	73	79	121	185	201
17	77	83	127	194	211

40	1.285	2.115	2.945

From Baschat AA: Relationship between placental blood flow resistance and precordial venous Doppler indices. *Ultrasound Obstet Gynecol* 22:561, 2003.

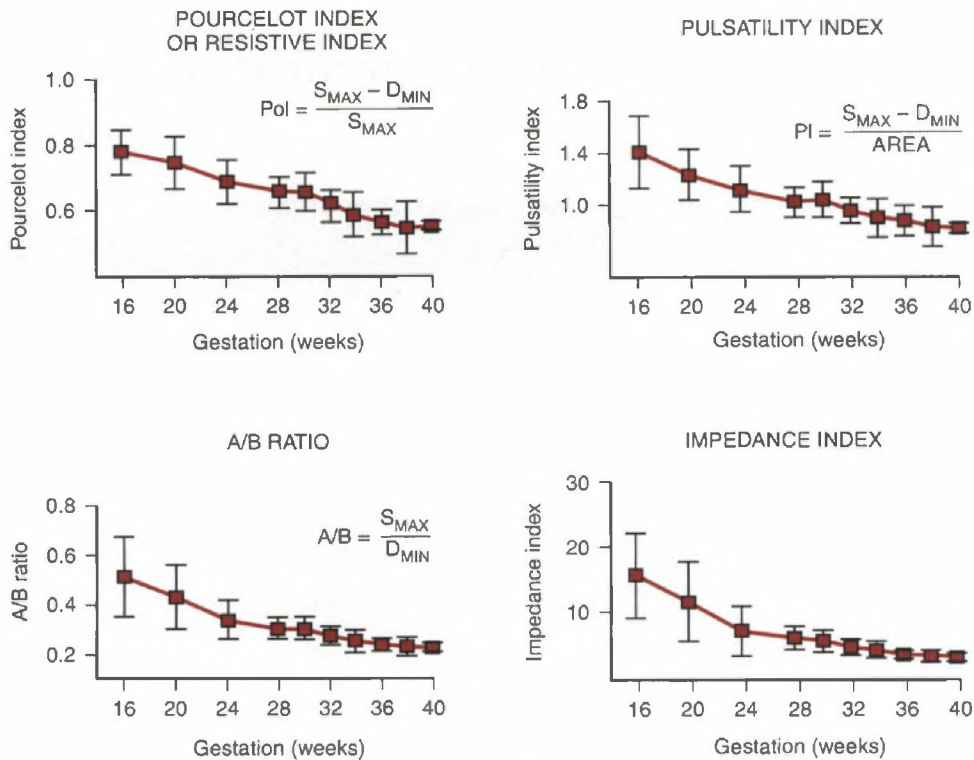

FIGURE D-1. Doppler waveform analysis of the fetal umbilical artery. With advancing gestation and increasing compliance of the placenta, there is a progressive decrease in the systolic/diastolic ratio, Pourcelot index (PoI), and pulsatility index (PI) of the umbilical artery that is a result of increased placental flow owing to decreased resistance. (Modified from Erskine RLA, Ritchie JWK: Umbilical artery blood flow characteristics in normal and growth retarded fetuses. *Br J Obstet Gynecol* 92:605, 1985.)

FIGURE D-2. Middle cerebral artery Doppler systolic/diastolic ratios. (Modified from Woo JSK, Liang ST, Lo RL, Chan FY: Middle cerebral artery Doppler flow velocity waveforms. *Obstet Gynecol* 70:613, 1987. Reprinted with permission from the American College of Obstetricians and Gynecologists.)

Doppler of the Middle Cerebral Artery to Assess Fetal Anemia

Table E-1

Threshold of Peak Velocity of Systolic Blood Flow in the Middle Cerebral Artery Above Which Mild, Moderate, and Severe Anemia Occurs

Gestation (wk)	Threshold of the Peak Velocity of the Middle Cerebral Artery (cm/sec) Above Which Degree of Anemia is Classified			
	1.00 (Median)	Mild Anemia (1.29 MoM)	Moderate Anemia (1.50 MoM)	Severe Anemia (1.55 MoM)
18	23.2	29.9	34.8	36.0
20	25.5	32.8	38.2	39.5
22	27.9	36.0	41.9	43.3
24	30.7	39.5	46.0	47.5
26	33.6	43.3	50.4	52.1
28	36.9	47.6	55.4	57.2
30	40.5	52.2	60.7	62.8
32	44.4	57.3	66.6	68.9
34	48.7	62.9	73.1	75.6
36	53.5	69.0	80.2	82.9
38	58.7	75.7	88.0	91.0
40	64.4	83.0	96.6	99.8

MoM, multiple of median.

From Kessler J, Rasmussen S, Hanson M, et al: Longitudinal reference ranges for ductus venosus flow velocities and waveform indices. *Ultrasound Obstet Gynecol* 28:890, 2006.

FIGURE F-1. Left ventricular (LV) and right ventricular (RV) dimensions and LV/RV ratio. Measurements should be taken from a diastolic four-chamber view. (Modified with permission from Shapiro I, Degani S, Leibovitz Z, et al: Fetal cardiac measurements derived by transvaginal and transabdominal cross-sectional echocardiography from 14 weeks of gestation to term. *Ultrasound Obstet Gynecol* 12:404, 1998.) (Figure by Shi-Joon Yoo, MD, Toronto, Canada.)

Diastole

FIGURE F-2. Thicknesses of the right ventricular wall, interventricular septum and left ventricular wall. Measurements should be taken from a diastolic four-chamber view. (Modified with permission from Firpo C, Hoffman JL, Silverman NH: Evaluation of fetal heart dimensions from 12 weeks to term. *Am J Cardiol* 87:594, 2001.) (Figure by Shi-Joon Yoo, MD, Toronto, Canada.)

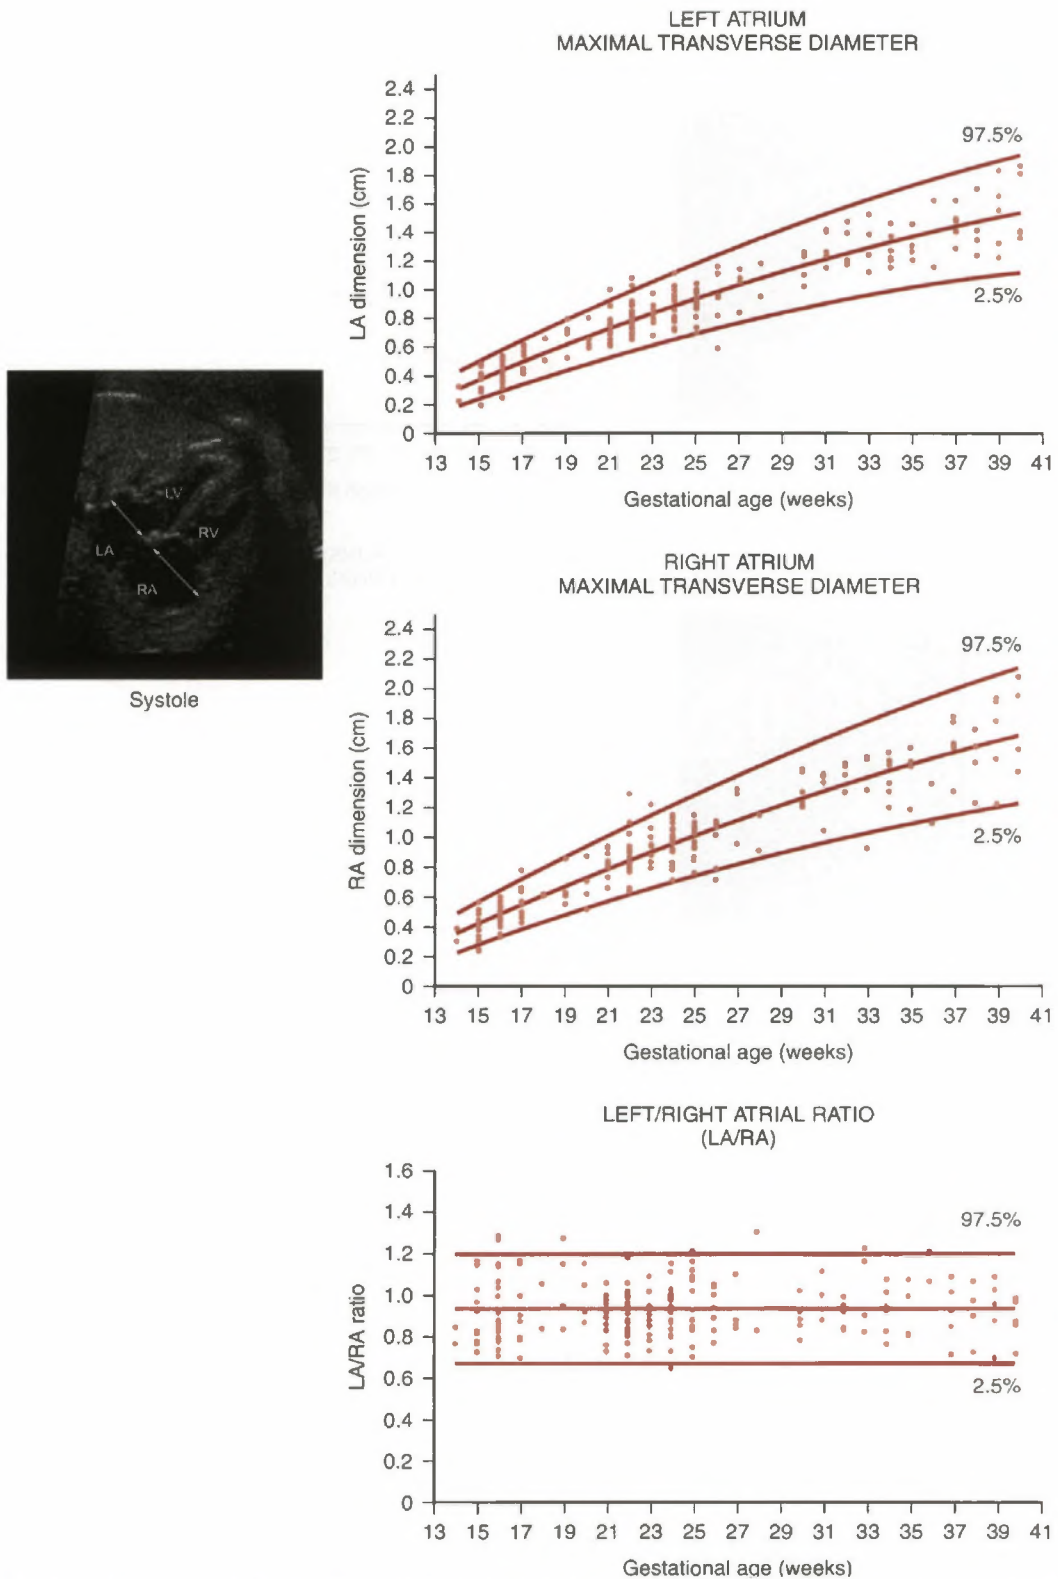

FIGURE F-3. Left atrial (LA) and right atrial (RA) dimensions and LA/RA ratio. Measurements should be taken from a systolic four-chamber view. (Modified with permission from Shapiro I, Degani S, Leibovitz Z, et al: Fetal cardiac measurements derived by transvaginal and transabdominal cross-sectional echocardiography from 14 weeks of gestation to term. *Ultrasound Obstet Gynecol* 12:404, 1998.) (Figure by Shi-Joon Yoo, MD, Toronto, Canada.)

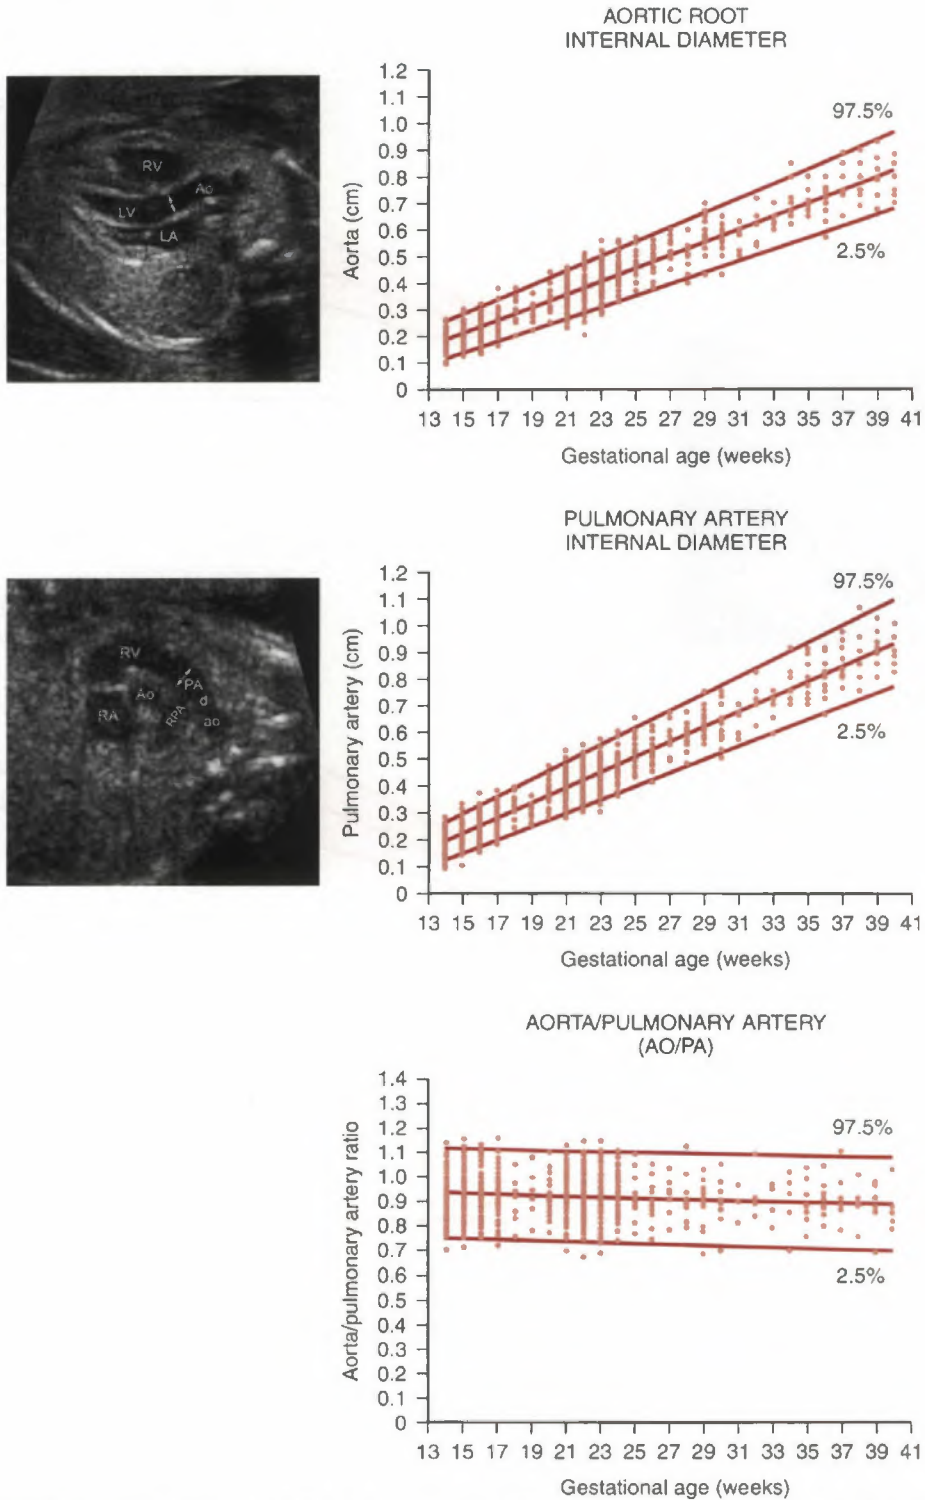

FIGURE F-4. Diameters of the ascending aorta (Ao) and main pulmonary trunk (PA) and aorta/pulmonary artery ratio. ao, descending aorta; d, ductus arteriosus; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle. (Modified with permission from Shapiro I, Degani S, Leibovitz Z, et al: *Fetal cardiac measurements derived by transvaginal and transabdominal cross-sectional echocardiography from 14 weeks of gestation to term. Ultrasound Obstet Gynecol* 12:404, 1998.) (Figure by Shi-Joon Yoo, MD, Toronto, Canada.)

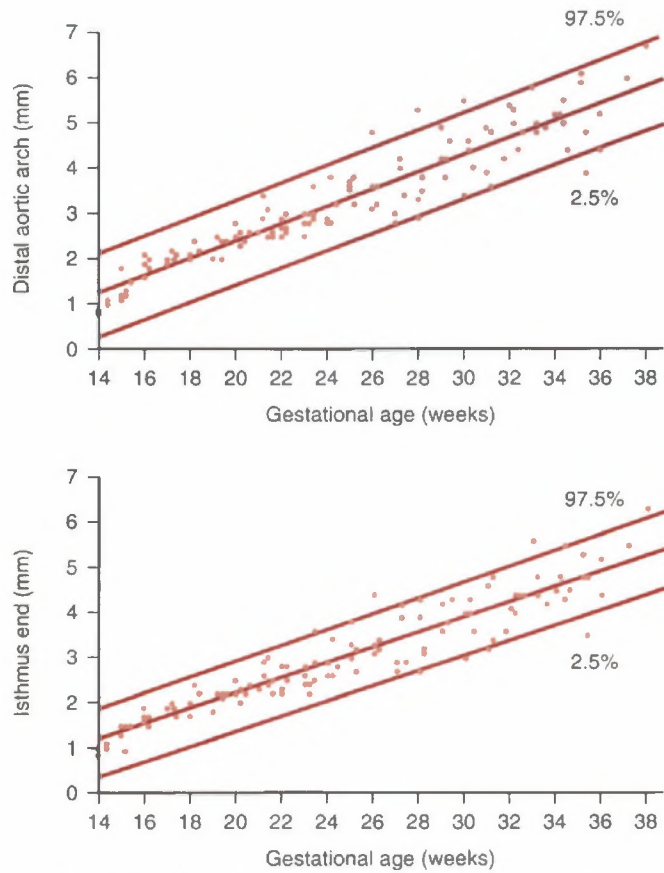

FIGURE F-5. Diameters of the distal aortic arch (upper double headed arrow) and distal end of the aortic isthmus (lower double headed arrow). LCCA, left common carotid artery; LSA, left subclavian artery; RIA, right innominate artery. (Modified with permission from Achiron R, Zimand S, Hegesh J, et al: Fetal aortic arch measurements between 14 and 38 weeks' gestation: in-utero ultrasonographic study. *Ultrasound Obstet Gynecol* 15:226, 2000.) (Figure by Shi-Joon Yoo, MD, Toronto, Canada.)

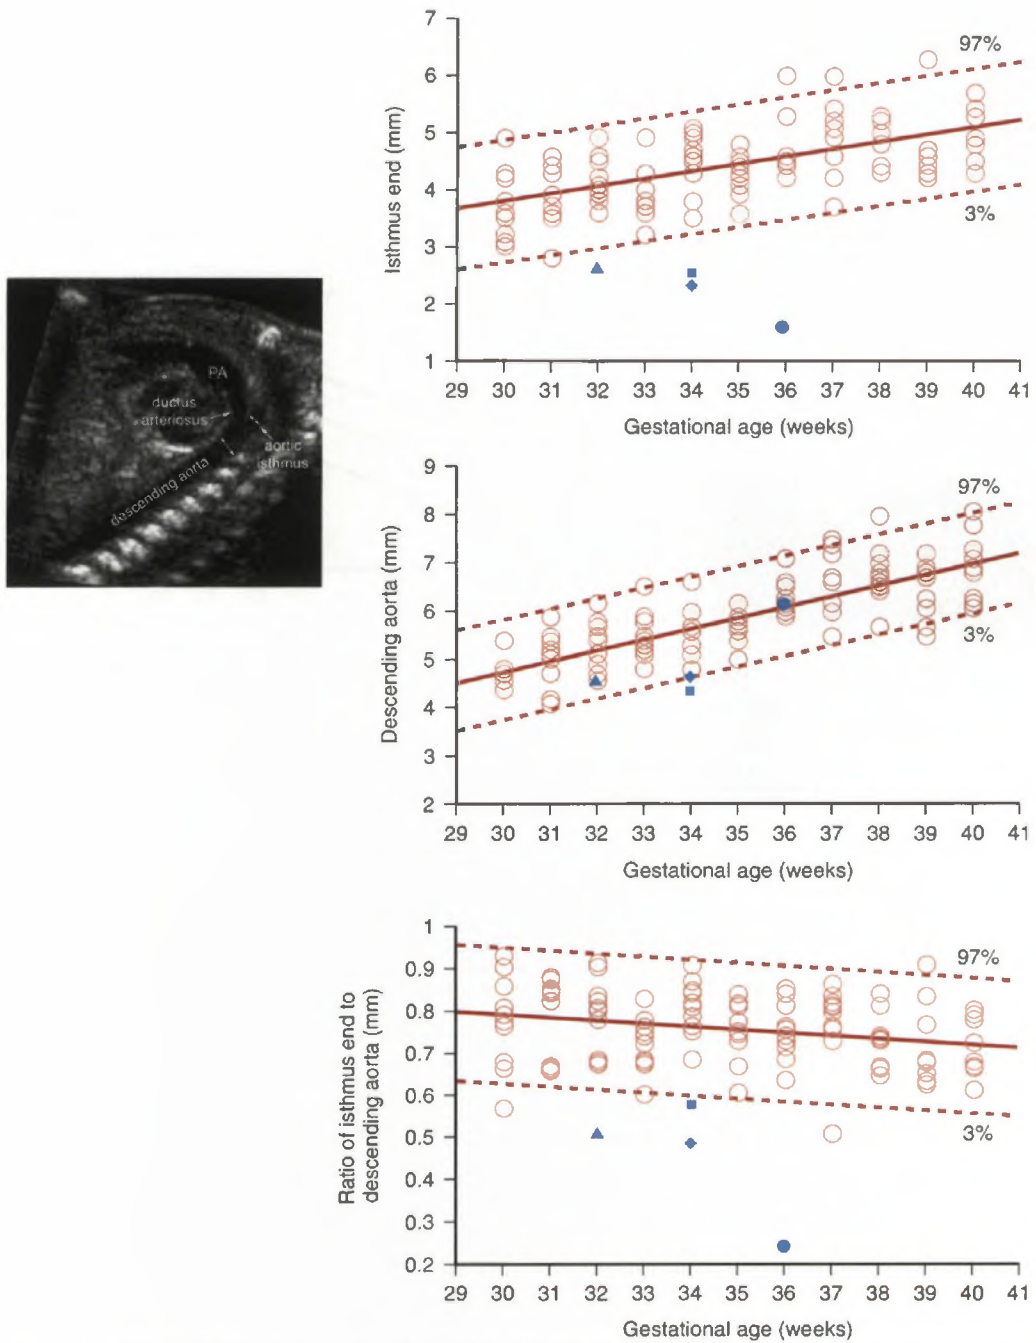

FIGURE F-6. Diameters of the distal end of the aortic isthmus and proximal descending aorta and isthmus/descending aorta ratio. PA, main pulmonary artery. (Modified with permission from Nomiya M, Ueda Y, Toyota Y, Kawano H: Fetal aortic isthmus growth and morphology in late gestation. *Ultrasound Obstet Gynecol* 19:153, 2002.) (Figure by Shi-Joon Yoo, MD, Toronto, Canada.)

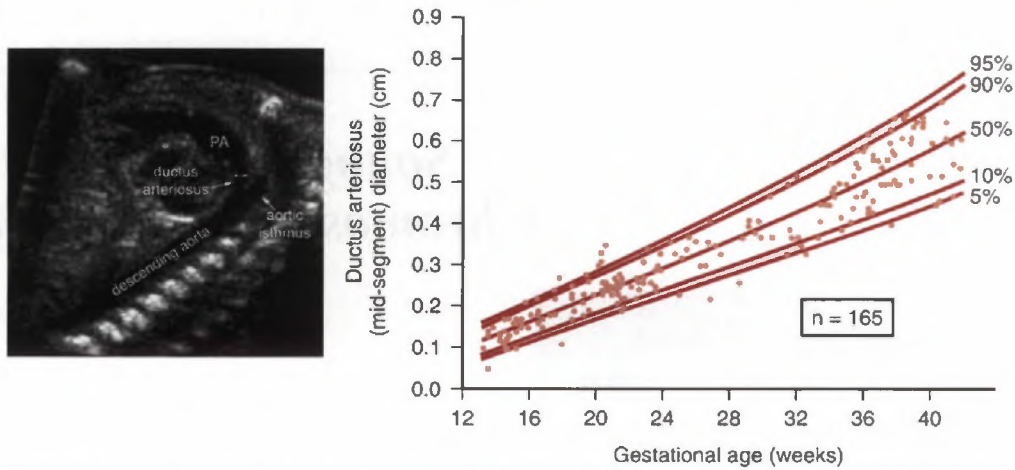

FIGURE F-7. Diameter of the mid-segment of the ductus arteriosus. PA, main pulmonary artery. (Modified with permission from Mielke G, Benda N: Reference ranges for two-dimensional echocardiographic examination of the fetal ductus arteriosus. *Ultrasound Obstet Gynecol* 15:219, 2000.) (Figure by Shi-Joon Yoo, MD, Toronto, Canada.)

FIGURE F-8. Diameters of the right and left pulmonary arteries (RPA and LPA respectively). Ao, ascending aorta; ao, descending aorta; PA, main pulmonary artery; SVC, superior vena cava. (Modified with permission from Firpo C, Hoffman JL, Silverman NH: Evaluation of fetal heart dimensions from 12 weeks to term. *Am J Cardiol* 87:594, 2001.) (Figure by Shi-Joon Yoo, MD, Toronto, Canada.)

Sonographic Detection of Chromosomal Abnormalities

APPENDIX H

Normal Measurements of the Uterus and Ovaries

Table H-1 Ovarian Volume by Decade of Life

Decade	Mean Volume (cm ³)	Standard Deviation	No. of Ovaries	95% Confidence Interval (cm ³)*
1	1.7	1.4	19	0.2-4.9
2	7.8	4.4	83	1.7-18.5
3	10.2	6.2	308	2.6-23.1
4	9.5	5.4	358	2.6-20.7
5	9.0	5.8	206	2.1-20.9
6	6.2	3.6	57	1.6-14.2
7	6.0	3.8	44	1.0-15.0

*Calculated on the basis of cube root values, then transformed back to cubic centimeters.

From Cohen HL, Tice HM, Mandel FS: Ovarian volumes measured by US: Bigger than we think. *Radiology* 177:189, 1990.

Table H-2 Ovarian Volume by Menstrual Status

Group	Mean Volume (cm ³)	Standard Deviation	95% No. of Ovaries	Confidence Interval (cm ³)*
Premenarchal	3.0	2.3	32	0.2-9.1
Menstruating	9.8	5.8	866	2.5-21.9
Postmenopausal	5.8	3.6	100	1.2-14.1

*Calculated on the basis of cube root values, then transformed back to cubic centimeters.

From Cohen HL, Tice HM, Mandel FS: Ovarian volumes measured by US: Bigger than we think. *Radiology* 177:189, 1990.

Table H-3 Normal Uterine Diameters and Volume*

Age (y)	No. of Patients	Uterine Diameters (mm)				Uterine Volume (cm ³)	
		TUL	COAP	CEAP	COAP/CEAP	By Chronologic Age	By Bone Age
		Mean SD	Mean SD	Mean SD	Mean SD	Mean SD	Mean SD

CEAP, anteroposterior diameter of the cervix; COAP, anteroposterior diameter of the corpus; SD, standard deviation; TUL, total uterine length.

*As determined by ultrasonography in 114 girls from age 2 to 13.

From Orsini LF: Pelvic organs in premenarcheal girls: Real-time ultrasonography. *Radiology* 153:113, 1984.

Medications and Reported Associated Malformations

Table I-1 Selected Medications and Reported Associated Malformations*

Drug	Malformation
Acetazolamide	Sacrococcygeal teratoma
Acyclovir	CDH, neural tube defect, cleft lip, clubfoot, transposition
Alprazolam	Umbilical hernia, clubfoot
Albuterol	Cleft palate, cranioschisis, cardiovascular defect, spina bifida, polydactyly, fetal tachycardia
Amantadine	Cardiac defects
Aminopterin	Neural tube defects, hydrocephalus, limb shortening, cleft lip/palate, clubfoot
<i>p</i> -Aminosalicylic acid	Ear deformity, limb deformity, hypospadias
Amiodarone	IUGR, ventricular septal defect, micrognathia
Amitriptyline	Limb reduction, micrognathia, hypospadias, cleft palate, thanatophoric dysplasia
Ampicillin	Transposition of the great vessels
Amobarbital	Anencephaly, cardiac defects, limb deformity, cleft lip/palate, polydactyly, genitourinary defects, clubfoot
Amphetamine	Cerebral injury in neonates
Aspirin	Intracranial hemorrhage, IUGR
Atenolol	Hypospadias, cardiovascular defects
Atropine	Polydactyly, limb reduction
Azatadine	Oral cleft, limb reduction
Baclofen	Spina bifida
Belladonna	Eye/ear malformations, hypospadias
Benztropine	Cardiovascular defects
Bromides	Polydactyly, gastrointestinal anomalies, clubfoot, IUGR
Busulfan	IUGR, cleft palate, neural tube defects
Captopril	Second-trimester hypocalvaria, oligohydramnios, renal dysfunction
Carbamazepine	Neural tube defects, cardiac defects
Carisoprodol	Oral clefts
Cephalexin	Cardiovascular defects, oral clefts
Cephradine	Cardiovascular defects
Chlorambucil	Renal agenesis, cardiac defects
Chlordiazepoxide	Microcephaly, duodenal atresia, cardiac defects
Chloroquine	Wilms tumor, hemihypertrophy, tetralogy of Fallot
Chlorothiazide	Fetal bradycardia
Chlorpheniramine	Polydactyly, gastrointestinal defects, hydrocephalus
Chlorpromazine	Microcephaly, syndactyly
Chlorpropamide	Microcephaly, hand anomalies
Ciprofloxacin	Hypospadias, cerebellar hypoplasia, cardiovascular defect, femoral aplasia
Clarithromycin	Craniofacial abnormalities, absent clavicles, spina bifida, cleft lip, pulmonary hypoplasia, coloboma, heart anomaly, choanal atresia, retardation (mental and somatic), genital and ear anomalies (CHARGE) association
Clomiphene	Microcephaly, neural tube defects, cleft lip/palate, cardiac defects, syndactyly, clubfoot, hypospadias
Clonazepam	Cardiovascular defects
Clorazepate	Bifid foot, absent scrotum, short femur, absent fibula, absent metacarpal bones, renal agenesis
Cloxacillin	Cardiovascular defects
Cocaine	Spontaneous abortion, placental abruption, cardiac defects, urinary tract and limb abnormalities, bowel atresias, IUGR
Codeine	Pulmonary and genitourinary defects, hydrocephalus, cleft lip/palate
Colchicine	Cardiac malformation, syndactyly, cleft palate
Cortisone	Cataracts, cyclopia, VSD, coarctation of the aorta, clubfoot, cleft lip, gastroschisis
Coumarin derivatives	Spontaneous abortion, IUGR, neural tube defects (open and closed) (dorsal midline dysplasia), cardiac defects, scoliosis, limb hypoplasia, cleft palate
Cyclophosphamide	Cleft palate, hand abnormalities, cardiac defects, IUGR
Cyclosporine	Limb hypoplasia, agenesis of the corpus callosum, anencephaly, IUGR

Continued

Table 1-1 Selected Medications and Reported Associated Malformations*—Continued

Drug	Malformation
Cyproheptadine	Cleft lip/palate, hypospadias
Cytarabine	Hand abnormalities (lobster claw deformity), lower limb defects, neural tube defects, cardiac defects
Dacarbazine	Limb reduction defects, cleft palate, encephalocele
Danazol	Ambiguous genitalia
Daunorubicin	IUGR
Dexfenfluramine	Hand malformation, anencephaly, vertebral abnormality
Diazepam	Cleft lip/palate, cardiac defects
Dicyclomine	Polydactyly
Dilantin	Microcephaly, hypertelorism, cleft lip/palate, hypoplasia of distal phalanges, short neck, broad nasal ridge
Diltiazem	Cardiovascular defects
Dimenhydrinate	Cardiovascular defects
Diphenhydramine	Cleft lip/palate, genitourinary defects, clubfoot, cardiac defects
Disulfiram	Clubfoot, vertebral defects, anal atresia, cardiac anomalies, tracheoesophageal fistula with esophageal atresia, renal anomalies, limb anomalies (VACTERL) syndrome, phocomelia
Doxepin	Oral clefts, polydactyly
Droperidol	Hydrocephalus, cerebral hypoplasia
Enalapril	Hypocalvaria, renal defects
Ephedrine	Clubfoot
Ethanol (alcohol)	IUGR, microphthalmia, micrognathia, microcephaly, hypoplastic maxilla, cardiac defects, genitourinary defects, radioulnar synostosis, Klippel-Fell anomaly, diaphragmatic hernia
Ethoheptazine	Umbilical hernia, hip dislocation
Ethotoin	Cleft lip/palate, patent ductus arteriosus
Ethosuximide	Cleft lip/palate, hydrocephalus, patent ductus arteriosus, spontaneous hemorrhage in the neonate
Etretinate	Neural tube defects, facial dysmorphia, multiple synostoses, syndactylies, limb reduction
Fluconazole	Craniosynostosis, cleft palate, limb shortening
Fluorouracil	Radial aplasia, pulmonary hypoplasia, esophageal and duodenal atresia, cloacal malformation
Fluphenazine	Ocular hypertelorism, cleft lip/palate, imperforate anus
Furosemide	Hypospadias
Griseofulvin	Conjoined twins
Haloperidol	Limb reduction, aortic valve defect
Heparin	Cardiovascular defects
Heroin	IUGR, multiple and varied congenital malformations
Hydroxyprogesterone	Spina bifida, anencephaly, tetralogy of Fallot, truncus arteriosus, VSD
Hydroxyzine	Oral clefts
Hyoscyamine	Polydactyly, limb reduction
Ibuprofen	Oligohydramnios, premature closure of patent ductus arteriosus
Imipramine	Diaphragmatic hernia, cleft palate, exencephaly, renal cystic dysplasia, amelia
Indomethacin	Oligohydramnios, premature closure of patent ductus arteriosus, phocomelia, penile agenesis
Isoetharine	Clubfoot
Isotretinoin	Hydrocephalus, neural tube defects, microphthalmia, microcephaly, cardiac defects, limb abnormalities, cleft palate
Itraconazole	Limb defect
Ketoconazole	Limb defect
Ketolac	Constriction of the ductus arteriosus, fetal renal impairment
Levothyroxine	Cardiac defects, polydactyly
Lindane	Hypospadias
Lisinopril	Hypocalvaria, polydactyly, oligohydramnios
Lithium	Cardiac defects (Ebstein anomaly, VSD, coarctation, mitral atresia), neural tube defects
Lovastatin	Aortic hypoplasia, VSD, anal atresia, renal dysplasia, radial aplasia
Lysergic acid diethylamide	IUGR, limb reduction, neural tube defects, cardiac defects
Marijuana	IUGR, facial anomalies
Mechlorethamine	IUGR, oligodactyly, malformed kidneys
Medroxyprogesterone	Cardiovascular defect
Meclizine	Eye and ear defects, hypoplastic heart, respiratory defects
Mefenamic acid	Constriction of the ductus arteriosus
Melphalan	IUGR
Meprobamate	Cardiac defects, omphalocele, joint abnormalities
Mercaptopurine	Cleft palate, microphthalmia, IUGR
Metaproterenol	Polydactyly

Continued

Table 1-1 Selected Medications and Reported Associated Malformations*—Continued

Drug	Malformation
Methimazole	Patent urachus
Methotrexate	IUGR, hypertelorism, dextroposition of the heart, absent digits, absence of frontal bone
Methotrimeprazine	Hydrocephalus, cardiac defects
Metronidazole	Spontaneous abortion, limb, cardiac, urinary, and facial abnormalities
Mifepristone	Sirenomelia, caudal regression syndrome
Minoxidil	Omphalocele, clinodactyly, cardiac defects (VSD and transposition)
Misoprostol	Limb defects, hypocalvaria, cleft lip, clubfoot, gastroschisis
Norethindrone	Neural tube defects, hydrocephalus
Norethynodrel	Cardiac defects, hypospadias
Nortriptyline	Limb reduction
Ofloxacin	Myelomeningocele, hydrocephalus, hypospadias
Omeprazole	Anencephaly, hydranencephaly, clubfoot
Oxazepam	Neural tube defects, IUGR
Paramethadione	Spontaneous abortions, IUGR, cardiac defects
Penicillamine	Hydrocephalus, flexion deformities, perforated bowel
Pentoxifylline	Cardiac defects
Phenacetin	Craniosynostosis and atresia, musculoskeletal and urinary tract defects
Phenobarbital	Cardiovascular defects
Phensuximide	Ambiguous genitalia
Phenylephrine	Eye and ear abnormalities, syndactyly, clubfoot, musculoskeletal defects
Phenylpropanolamine	Eye and ear abnormalities, polydactyly, hypospadias
Phenytoin	Microcephaly, hypertelorism, cleft lip/palate, hypoplasia of distal phalanges, short neck, broad nasal ridge
Podophyllum	Limb reduction
Procarbazine	IUGR, cardiac defects, oligodactyly, malformed kidneys
Prochlorperazine	Cleft palate/micrognathia, cardiac defects, skeletal defects
Propoxyphene	Limb abnormalities, omphalocele, micrognathia, clubfoot, microcephaly
Quinacrine	Renal agenesis, neural tube defects
Quinine	Neural tube defects, hydrocephalus, limb defects, facial defects, cardiac defects, urogenital abnormalities, vertebral abnormality, gastrointestinal anomaly
Reserpine	Microcephaly, hydronephrosis
Retinoic acid	Hydrocephalus, neural tube defects, microphthalmia, microcephaly, cardiac defects, limb abnormalities, cleft palate
Rifampin	Anencephaly, hydrocephalus, limb malformation
Sodium iodide	Ablation of fetal thyroid gland
Sulfasalazine	Cleft lip/palate, hydrocephalus, cardiac defects, urinary tract abnormalities
Sulfonamides	Limb hypoplasia, urinary tract abnormalities
Sumatriptan	Phocomelia, tibial aplasia, clubfoot, cleft palate
Tamoxifen	Ambiguous genitalia
Tazarotene	Reduced skeletal ossification, hydrocephaly, spina bifida, cardiac defects
Temazepam	Oral clefts
Terfenadine	Polydactyly
Tetracycline	Hypospadias, limb hypoplasia
Thioguanine	Absent digits
Tolbutamide	Syndactyly, cardiac defects, clubfoot
Trifluoperazine	Phocomelia, transposition of the great vessels
Trimethadione	IUGR, microcephaly, cleft lip/palate, cardiac defects, malformed hand, clubfoot, ambiguous genitalia, esophageal atresia, tracheoesophageal fistula
Trimethoprim	Cardiovascular defects
Valproic acid	Neural tube defects, cardiac defects, facial dysmorphism, hypertelorism, protruding eyes, micrognathia, hydrocephalus, cleft lip/palate, microcephaly, limb reduction, scoliosis, renal hypoplasia, duodenal atresia, hand deformity
Zidovudine	Renal agenesis, microphthalmus, polydactyly, cleft lip/palate, clubfoot, VSD

CDH, congenital diaphragmatic hernia; IUGR, intrauterine growth restriction; VSD, ventricular septal defect.

*This list represents selected medications and their possible associations with fetal structural abnormalities. Many of the listed associations are based on isolated case reports that have appeared in the medical literature for which the association is unproven or in animal studies where the dosage of medication far exceeded the normal clinical amount normally used. It is likely that in many cases the reported association was coincidental to, rather than resultant from, the medication.

This list is not intended for patient counseling regarding the likelihood of fetal malformations or abnormalities. The table should be used by the sonologist/sonographer as a guide for evaluating specific organ systems in addition to a thorough sonographic examination. In all cases of suspected teratogenic effects, a reproductive geneticist or teratologist and the drug manufacturer should be consulted.

Modified from Briggs GG, Freeman RK, Yaffe SJ: *Drugs in Pregnancy and Lactation*, 7th ed. Philadelphia, Lippincott Williams & Wilkins, 2005.

APPENDIX J

Estimated Radiation Exposure to the Fetus during Radiographic Examinations

Table J-1 Estimated Fetal Dose for Single Radiographic Image of Abdomen or Pelvis With Fetus in Field of View

Patient Body Thickness (cm)	Estimated Dose			
	Anteroposterior		Lateral	
	mSv	mrem	mSv	mrem
14-15	1.0	100	0.7	70
16-19	1.5	150	1.0	100
20-23	2.1	210	1.5	150
24-26	3.1	310	2.0	200
27-30	4.3	430	3.0	300
31-34	5.6	560	4.0	400

Note.—Fluoroscopy fetal dose = $0.15 \times$ entrance skin dose; mSv = millisievert, mrem = millirem (roentgen equivalent man).

Table J-2 Estimated Fetal Dose for CT of the Abdomen or Pelvis With Fetus in Field of View

Multidetector CT (Four-Slice Scanner)				Single-Detector Helical CT			
Technique		Dose		Technique		Dose	
mAs	pitch	mSv	rem	mAs	pitch	mSv	rem
300	4.5	35	3.5	300	1.0	35	3.5
300	6.5	25	2.5	300	1.5	25	2.5
200	4.5	23	2.3	200	1.0	23	2.3
200	6.5	15	1.5	200	1.5	15	1.5
150	4.5	17.5	1.75	150	1.0	17.5	1.75
150	6.5	12.5	1.25	150	1.5	12.5	1.25

Note.—Calculations are based on 120 kVp and a slice thickness of ≥ 5 mm. Slice thickness is an acquisition parameter that refers to the width of the detector element along the long axis of the patient. The nominal beam width for a four-slice multidetector CT (MDCT) scanner with an acquisition slice thickness of 5 mm is 20 mm. Below 5 mm on MDCT systems, the penumbra of the X-ray beam results in increased dose. The increase for 3-mm slices is 10–20%, the increase for 1-mm slices is 30–40%, and the increase for 0.5-mm slices is 50–150% depending on manufacturer. mAs = milliamperere-second, mSv = millisievert, rem = roentgen equivalent man.

From El-Khoury CY, Madsen MT, Blake ME, Yankowitz J: A new pregnancy policy for a new era. *Am J Roentgenol* 181:335, 2003.
